Publication Information and Contributors

Introduction

Corrosion: Fundamentals, Testing, and Protection was published in 2003 as Volume 13A of the *ASM Handbook*. The Volume was prepared under the direction of the ASM Handbook Committee.

Volume Editors

The Volume Editors were Stephen D. Cramer and Bernard S. Covino, Jr.

Foreword

ASM International is pleased to publish *ASM Handbook,* Volume 13A, *Corrosion: Fundamentals, Testing, and Protection,* the first book in a two-volume revision of the landmark 1987 *Metals Handbook,* 9th Edition volume on corrosion. *ASM Handbook,* Volume 13A has been completely revised and updated to address the needs of ASM International members and the global technical community for current and comprehensive information on

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

corrosion principles, evaluation techniques, and protection methods. Advances in material science and corrosion technologies since the 1987 *Corrosion* volume was published have lessened some of the costs and degradation caused by corrosion. However, the systems that society relies on have increased in complexity during this time, so corrosion can have more far-reaching effects. Corrosion remains a multibillion-dollar problem that confronts nearly every engineer in every industry.

ASM International is indebted to the Co-Chairs and Editors of this Handbook, Stephen D. Cramer and Bernard S. Covino, Jr., who had the vision and the drive to undertake the huge effort to update and revise the 1987 *Corrosion* volume. *ASM Handbook,* Volume 13A is the first fruit of their efforts; they are also leading the project to complete *ASM Handbook,* Volume 13B, *Corrosion: Materials, Environments, and Industries,* scheduled to publish in 2005. The Editors have done an outstanding job in organizing the project, in recruiting renowned experts to oversee sections and to write or revise articles, and in reviewing every manuscript. We are pleased with their vision to recruit authors from Canada, Mexico, France, Germany, United Kingdom, Poland, Japan, India, and Australia, as well as from the United States. This diverse community of volunteers, sharing their knowledge and experience, make this Volume truly an *international* effort.

We thank the authors and reviewers of the 1987 *Corrosion* volume, which at the time was the largest, most comprehensive volume on a single topic ever published by ASM. This new edition builds upon that groundbreaking project. Thanks also go to the ASM Handbook Committee for their oversight and involvement, and to the ASM editorial staff for their tireless efforts.

We are especially grateful to the nearly 200 authors and reviewers listed in the next several pages. Their willingness to invest their time and effort and to share their knowledge and experience by writing, rewriting, and reviewing articles has made this Handbook an outstanding source of information.

Donald R. Muzyka, President, ASM International

Stanley C. Theobald, Managing Director, ASM International

Preface

The direct cost of corrosion in the United States was estimated to be $276 billion annually for 1998, or 3.1% of the 1998 U.S. gross domestic product of $8.79 trillion Ref 1. Of the industry sectors analyzed, utilities and transportation experienced the largest costs. The largest investment in corrosion control and protection strategies was in protective organic coatings. Indirect costs of corrosion, including lost productivity and corrosion-related overhead and taxes, when averaged over industry sectors, were roughly equal to or greater than the direct costs. In some cases they were substantially greater. For example, indirect corrosion costs related to the U.S. bridge infrastructure were estimated to be more than 10 times the $8.3 billion direct cost from bridge corrosion damage. Additional information is available in the article “Direct Costs of Corrosion in the United States” in this Volume.

ASM Handbook, Volume 13A, *Corrosion: Fundamentals, Testing, and Protection,* is the first volume in a two-volume update, revision, and expansion of *Corrosion,* Volume 13 of the ninth edition *Metals Handbook,* published in 1987. The second volume—*ASM Handbook,* Volume 13B, *Corrosion: Materials, Environments, and Industries*—is to be published in 2005. The purpose of these two volumes is to represent the current state of knowledge in the field of corrosion and to provide a perspective on future trends in the field. Metals remain the major focus of the Handbook, but nonmetallic materials occupy a more prominent position that reflects their wide and effective use to solve problems of corrosion. Wet or aqueous corrosion remains the major focus, but dry or gaseous corrosion is discussed more fully, reflecting the increased importance of processes at elevated and high temperatures.

ASM Handbook, Volume 13A recognizes the global nature of corrosion research and practice and the international level of corrosion activities and interactions required to provide cost-effective, safe, and environmentally sound solutions to materials problems in chemically aggressive environments. Twenty percent of the articles in Volume 13A did not appear in the 1987 Handbook. Authors from more than ten countries have contributed to Volume 13A. The table of contents has been translated into Spanish, French, Russian, Japanese, and Chinese to make the Handbook accessible to a diverse audience. Extensive references provide a road map to the corrosion literature and are augmented by Selected References that are a source of additional information.

Information technology has changed dramatically since 1987, and the most significant occurrence has been the development of the Internet as an information resource. In response, ASM International has made the contents of this Handbook and others in the *ASM Handbook* series available on the Web. This Handbook also provides a

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

list, current at the time of publication, of significant data sources and of major national, international, academic, and government corrosion organizations and institutions that are accessible on the Web.

Corrosion is described by well-known laws of thermodynamics, kinetics, and electrochemistry. The many variables that influence the behavior of a material in its environment can lead to a wide and complex range of performance, from the benign to the catastrophic. Understanding and avoiding detrimental corrosion is an interdisciplinary effort requiring knowledge of chemistry, electrochemistry, materials, engineering, and structures. All applications of engineered materials pivot on the fulcrum between environmental degradation, of which corrosion is a major element, and service or service life, with cost determining the point of balance. Costs are determined not in the spare confines of a material and its environment but in a complex landscape defined by technical, economic, social, environmental, health, safety, legal, and consumer constraints. This is illustrated by the experience of a Portland, OR Water Bureau engineer working to make way for a new light rail line along city streets Ref 2:

…Construction conflicts are anticipated…, but day-to-day construction also alters the original design and corrosion control scheme of existing installations. As development occurs and utilities weave and cross, coatings are damaged, pipes are shorted, wires are cut, and test stations always seem to disappear…Work had to be sequenced and paced to minimize traffic interference… Environmental regulators were classifying the pavement as an engineered cap for brownfield and other contaminated areas…Utilities responded by characterizing the roadway as a constantly opening and closing zipper because we continually construct there… Corrosion control methods for urban areas must be designed for installation and operation in a congested environment that is constantly changing.

This Handbook is organized into six major sections addressing corrosion fundamentals, testing, and protection.

The first Section, “Fundamentals of Corrosion,” covers the theory of aqueous and gaseous corrosion from the thermodynamic and kinetic perspectives. It presents the principles of electrochemistry, the mechanisms of corrosion processes, and the methods for measuring corrosion rates in aqueous, molten salt, liquid metals, and gaseous environments. It introduces geochemical modeling as a means for characterizing and understanding corrosion in complex environments. While corrosion is usually associated with the environmental degradation of a material, this Section also describes ways in which corrosion is used for constructive or beneficial purposes.

The second Section, “Forms of Corrosion,” describes how to recognize the different types of corrosion and the forces that influence them. It addresses uniform corrosion, localized corrosion, metallurgically influenced corrosion, mechanically assisted corrosion, environmentally induced cracking, and microbiologically influenced corrosion. The Section introduces the complex processes of wear-corrosion interactions that accelerate material deterioration at rates greater than those resulting from wear processes or corrosion processes alone.

The third Section, “Corrosion Testing and Evaluation,” describes the planning of corrosion tests, evaluation of test results, laboratory corrosion testing, simulated service testing, and in-service techniques for damage detection and monitoring. It concludes by describing standard methods and practices for evaluating the various forms of corrosion.

The fourth Section, “Methods of Corrosion Protection,” begins by discussing as a baseline the corrosion resistance of bulk materials. The Section continues with methods of corrosion protection, including surface treatments and conversion coatings, ceramic, glass and oxide coatings, metal coatings, coatings and linings, electrochemical corrosion control methods, and corrosion inhibitors.

The fifth Section, “Designing for Corrosion Control and Prevention,” continues the theme of the fourth Section from the perspective of materials selection and equipment design. Corrosion control is an economic process as well as a technical process, and this Section discusses corrosion economic calculations, predictive modeling for structure service life, and a review of corrosion costs in the United States.

The sixth Section, “Tools for the Corrosionist,” covers topics that are complementary to corrosion fundamentals, testing, and protection. It is a new addition to the Handbook. The topics include conventions and definitions in corrosion and oxidation, applications of modern analytical instruments in corrosion, materials science, statistics, and information sources and databases.

Other useful Handbook contents include the “Glossary of Terms,” containing definitions of corrosion, electrochemistry, and materials terms common to corrosion and defined in the literature of ISO, ASTM, and NACE International. The “Corrosion Rate Conversion” Section includes conversions in both nomograph and tabular form. The metric conversion guide features conversion factors for common units and includes SI

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

prefixes. Finally, “Abbreviations and Symbols” provides a key to common acronyms, abbreviations, and symbols.

The six Sections in the Handbook are divided into several subsections. These subsections were organized and written under the leadership of the following individuals (listed in alphabetical order):

Chairperson	Subsection Title
Vinod S. Agarwala	In-Service Techniques for Damage Detection and Monitoring
Rudolph G. Buchheit	Surface Treatments and Conversion Coatings
Bernard S. Covino, Jr.	Laboratory Corrosion Testing
Bruce D. Craig	Environmentally Induced Cracking
Stephen D. Cramer	Simulated Service Testing Metal Coatings Corrosion Inhibitors Tools for the Corrosionist
Marek Danielewski	Fundamentals of Gaseous Corrosion
Stephen C. Dexter	Microbiologically Influenced Corrosion
Peter Elliott	Designing for Corrosion Control and Protection
Gerald Frankel	Metallurgically Influenced Corrosion
William A. Glaeser	Mechanically Assisted Degradation
Russell D. Kane	Uniform Corrosion
Carl E. Locke, Jr.	Electrochemical Corrosion Control Methods
Philippe Marcus	Fundamentals of Corrosion Thermodynamics
Paul M. Natishan	Corrosion Resistance of Bulk Materials
Bopinder S. Phull	Evaluating Forms of Corrosion
Vilupanur A. Ravi	Ceramic, Glass, and Oxide Coatings
Pierre R. Roberge	Planning Corrosion Tests and Evaluating Results
John R. Scully	Fundamentals of Aqueous Corrosion Kinetics
Susan Smialowska	Localized Corrosion
Kenneth B. Tator	Coatings and Linings
Peter F. Tortorelli	Fundamentals Applied to Specific Environments
Ian Wright	Mechanically Assisted Degradation
Margaret Ziomek-Moroz	Fundamentals of Corrosion for Constructive Purposes

These talented and dedicated individuals generously devoted considerable time to the preparation of this Handbook. They were joined in this effort by more than 120 authors who contributed their expertise and creativity in a collaborative venture to write or revise the articles and by more than 200 reviewers and 5 translators. These volunteers built on the contributions of earlier Handbook authors and reviewers who provided the solid foundation on which the present Handbook rests.

For articles revised from the previous edition, the contribution of these authors is acknowledged at the end of articles. This location in no way diminishes their contribution or our gratitude. Those responsible for the current revision are named after the title. The variation in the amount of revision is broad. The many completely new articles presented no challenge for attribution, but assigning fair credit for revised articles was more problematic. The choice of presenting authors' names without comment or with the qualifier “Revised by” is solely the responsibility of the ASM staff.

We thank ASM International and the ASM staff for their skilled support and valued expertise in the production of this Handbook. In particular, we thank Charles Moosbrugger, Gayle Anton, and Scott Henry for their encouragement, tactful diplomacy, and many discussions, plus, we should add, their wistful forbearance as deadlines came and went. The Albany Research Center, U.S. Department of Energy, gave us support and flexibility in our assignments to participate in this project and we are most grateful. In particular, we thank our supervisors Jeffrey A. Hawk and Cynthia P. Doğan, who were most gracious and generous with their encouragement throughout the project.

مرجع مهندسی مواد و متالورژی

We close with these thoughtful words from T.R.B. (Tom) Watson, president of NACE International, 1964–65, author of *Why Metals Corrode,* and corrosion leader. (Ref 3)
Mighty ships upon the ocean, suffer from severe corrosion.
Even those that stay at dockside, are rapidly becoming oxide.
Alas, that piling in the sea is mostly Fe_2O_3.
And where the ocean meets the shore, you'll find there's Fe_3O_4.
'Cause when the wind is salt and gusty, things are getting awfully rusty.
We can measure it, we can test it, we can halt it or arrest it;
We can scrape it and weigh it; we can coat it or spray it;
We can examine and dissect it; we can cathodically protect it.
We can pick it up and drop it, but heaven knows we'll never stop it.
So here's to rust, no doubt about it; most of us would starve without it.
That said, given the thermodynamic, kinetic, and economic principles at work in our world, corrosion will not stop. This Handbook helps show us how to live with it.
Stephen D. Cramer
Bernard S. Covino, Jr.
U.S. Department of Energy, Albany Research Center

Staff

ASM International staff who contributed to the development of the Volume included Charles Moosbrugger, Project Editor; Bonnie R. Sanders, Manager of Production; Gayle J. Anton, Editorial Assitant; Nancy Hrivnak, Jill Kinson, and Carol Polakowski, Production Editors; and Kathryn Muldoon, Production Assistant. Editorial Assistance was provided by Elizabeth Marquard, Heather Lampman, Mary Jane Riddlebaugh, and Beverly Musgrove. The Volume was prepared under the direction of Scott D. Henry, Assistant Director of Technical Publications and William W. Scott, Jr., Director of Technical Publications.

Preparation of Online Volume

ASM Handbook, Volume 13A, *Corrosion: Fundatmentals, Testing, and Protection*, was converted to electronic files in 2004. The conversion was based on the First printing (2003). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed. ASM International staff who oversaw the conversion of the Volume to electronic files were Sally Fahrenholz-Mann, Sue Hess, and Susan Cheek. The electronic version was prepared under the direction of Stanley Theobald, Managing Director.

P. Marcus, Introduction to the Fundamentals of Corrosion, *Corrosion: Fundamentals, Testing, and Protection,* Vol 13A, *ASM Handbook*, ASM International, 2003, p 3-4

Introduction to the Fundamentals of Corrosion

Philippe Marcus, Ecole Nationale Supérieure de Chimie de Paris, Université Pierre et Marie Curie

Introduction

THE SIGNIFICANT TECHNICAL CHALLENGES and the high cost directly related to corrosion provide strong incentives for engineers and other technical personnel to develop a firm grasp on the fundamental bases of corrosion. Understanding the fundamentals of corrosion is necessary not only for identifying corrosion mechanisms (a significant achievement by itself), but also for preventing corrosion by appropriate corrosion protection means and for predicting the corrosion behavior of metallic materials in service conditions. Understanding the mechanisms of corrosion is the key to the development of a knowledge-based design of corrosion resistant alloys and to the prediction of the long-term behavior of metallic materials in corrosive environments.

Two major areas are usually distinguished in the corrosion of metals and alloys. The first area is where the metal or alloy is exposed to a liquid electrolyte, usually water, and thus typically called aqueous corrosion. The second area is where corrosion takes place in a gaseous environment, often called oxidation, high- temperature oxidation, or high-temperature corrosion, and called gaseous corrosion here. These two areas have been (and still are sometimes) referred to as wet corrosion and dry corrosion. This distinction finds its origin (and its justification) in some fundamental differences in the mechanisms, in particular the electrochemical nature of reactions occurring in aqueous solution (or in a nonaqueous electrolyte), as compared to the formation of thick oxide layers in air or other oxidizing atmospheres, at high temperature with fast transport processes by solid-state diffusion through a growing oxide. The separation between the two areas, however, should not be overemphasized, because there are also similarities and analogies, for example:

- The initial stages of reaction involve the adsorption of chemical species on the metal surface that can be described by the Gibbs equation for both liquid and gaseous environments.
- The nucleation and growth phenomena of oxide layers and other compounds
- The use of surface analytical techniques

The fundamental aspects of aqueous and gaseous corrosion are addressed in this first Section of the Handbook. Corrosion of metallic materials is generally detrimental and must be prevented, but if it is well understood and controlled, it can also be used in a powerful and constructive manner for electrochemical production of fine patterns on metal as well as on semiconductor surfaces. These constructive purposes also include electrochemical machining (down to the micro- or even the nanoscale), electrochemical and chemical-mechanical polishing, and anodes for batteries and fuel cells. These topics are also addressed in this Section.

Thermodynamics

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The thermodynamic aspects of corrosion, whether for aqueous corrosion or gaseous corrosion, are discussed first. This approach is logical because the object of thermodynamics is to examine the driving force for corrosion. Thermodynamics sets the framework of what is possible and what is not. It predicts the direction in which the changes of the system can occur. The only reactions that can take place spontaneously are those that will lower the energy of the system. If thermodynamic calculations predict that a reaction cannot occur, the reaction will indeed not occur. However, thermodynamics does not provide any information on the rate at which a reaction will occur; that is the area of kinetics.

Corrosion in aqueous solution is an electrochemical process where the corroding metal is an electrode in contact with an electrolyte. The processes taking place at the metal surface are thus electrode processes, and such processes must be defined. There is also a need to define electrode potentials and the way they can be measured with reference electrodes. These points are covered in three articles in this Section: "Electrode Processes," "Electrode Potentials," and "Potential Measurements with Reference Electrodes."

With these basic notions defined, it is possible to explain the principle of potential-pH (*E*-pH) diagrams in the article "Potential versus pH (Pourbaix) Diagrams." These diagrams allow us to visualize in a practical and easy way the domains of stability of chemical species (solid phases and dissolved species) and to know at a glance what corrosion reactions can occur in a given metal-solution system. In the article on potential-pH diagrams, the diagrams for high temperature water are also presented, as well as an extension of the concept to species adsorbed on metal surfaces. The more specific topic of thermodynamics of corrosion in molten salts is treated in a separate article, "Molten Salt Corrosion Thermodynamics." The interesting contribution of geochemistry in modeling of stable chemical states in complex chemical environments is considered in the last article, "Geochemical Modeling," in this group of articles on corrosion thermodynamics.

It is not superfluous to reemphasize the fact that thermodynamics can only be a first step in the investigation of the corrosion behavior of a given metal/aqueous solution system. Thermodynamics provides the road map. Using it, the possible destinations are clearly known.

Kinetics

Once thermodynamics are understood, it becomes necessary to undertake another task, namely to examine which reactions, among those reactions allowed by thermodynamics, will occur and at what rate. This subject is addressed by a group of articles on the fundamentals of aqueous corrosion kinetics.

The first article, "Kinetics of Aqueous Corrosion," examines the relations between the current and the potential associated with each of the two or more electrochemical reactions constituting the mixed system characteristic of corrosion. The current-potential (*I-E*) curves, the corrosion potential, and the corrosion current form the basis of the kinetic approach. Here activation energies of the reactions come into play. The concept of mixed potential is essential. Corrosion occurs if both an anodic and a cathodic reaction take place, each reaction involving chemical species that correspond to a different oxidation-reduction system. Because of this, the corrosion potential is not an equilibrium potential but rather is considered a mixed potential.

On this ground, and without forgetting the framework set by thermodynamics, the mechanisms of corrosion in aqueous solution are discussed in the article "Aqueous Corrosion Reaction Mechanisms." The latest advances in this area, achieved by an intense effort in research worldwide, are reviewed. Inevitably, areas in which the mechanisms are not yet fully elucidated still exist and justify present and future research.

Passivation of metals and alloys, a phenomenon in which a thin protective layer of oxide or oxihydroxide is formed on the surface, is a major aspect of corrosion from the scientific as well as the engineering point of view. This phenomenon—discussed in the article "Passivity" in this Section—is also an area in which huge

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

progress has been made in recent years. The mechanisms of oxide film growth, the chemical composition and the chemical states, the crystallographic structure, and the semiconductor properties of passive films are now better understood. The acquired knowledge allows more accurate prediction of the long-term behavior of passive films and design of passive layers that are increasingly resistant to corrosion. It is an area where the contribution of surface chemical and structural analysis has been overwhelming.

It is interesting to note that passivity is a good example of a case where potential-pH diagrams must be used with caution. Indeed, whereas the *E*-pH diagrams predict well the formation of passive oxides on copper, they predict the absence of passive film in acid solution on metals such as nickel, iron, and chromium, which are in fact well passivated. This is due to the very low dissolution rate of the oxides of these metals at low pH. Thanks to the formation of passive films rich in chromium oxide, passivation of alloys containing chromium, whether they are nickel-base or iron-base alloys (stainless steels), is a major feature of highly corrosion-resistant alloys.

Finally, to define critical reaction paths, the appropriate experimental methods must be available to measure corrosion rates. These methods are presented in the last article, "Methods for Determining Aqueous Corrosion Reaction Rates," in the group of articles on fundamentals of corrosion kinetics.

Gaseous Corrosion

The next group of articles, on fundamentals of gaseous corrosion (often called oxidation in a broad sense, rather than the strict sense of the formation of an oxide), is organized in a similar manner to the group on aqueous corrosion. The group of articles starts with the "Introduction to the Fundamentals of Corrosion in Gases," followed by a review of thermodynamics in the article "Thermodynamics of Gaseous Corrosion." Here the environment is not conductive, and the ionic processes take place only on the metal surface and in or on the corrosion products. Thermodynamics defines and quantifies the driving force of the oxidation reaction; that is, the lowering of the energy level of the metal. The chemical equilibrium between gas phase (e.g., oxygen, water vapor, hydrogen sulfide) and compounds formed on the metal surface (oxide or sulfide in the examples cited earlier) can be represented by diagrams of the partial pressure of formation versus temperature. Such diagrams, called Ellingham diagrams, allow us to quickly visualize the domains of stability of different oxides. Similar diagrams have also been calculated for sulfides.

The kinetics of gaseous corrosion of metals and alloys and the oxidation mechanisms are examined in two articles: "Kinetics of Gaseous Corrosion Processes" and "Gaseous Corrosion Mechanisms." The different oxidation laws (i.e., the mass increase as a function of time) are presented in detail. The oxide layers developed at high temperature are quite thick (up to several micrometers) compared to the layers formed at room temperature because of kinetic limitations associated with diffusion in the solid state. The diffusion mechanisms, in which defects such as cation and anion vacancies play a key role, are discussed. The effect of impurities is also considered. The differences between the lattice constants of the substrate and the oxide lead to the existence of stresses at the interface and in the oxide. Such stresses play a major role in the properties of the oxide layers, and it is important to understand how they are generated. The role of dislocations is also an important aspect in high temperature oxidation.

In some industrial applications, the corrosive environment is complex, and the corrosion products are not protective oxides. The phenomena related to corrosion by hot gases and combustion products are considered in the article "Gaseous Corrosion Mechanisms."

Appropriate experimental methods must be used to measure the kinetics of dry oxidation. Such methods are described in the last article, "Methods for Measuring Gaseous Corrosion Rates," in this group of articles on the fundamentals of gaseous corrosion.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Corrosion in more specific environments— molten salts (the thermodynamics of which has been addressed in a previous article) and liquid metals—is considered in the next group of articles. Molten salts are addressed in two articles, “Corrosion by Molten Salts” and “Corrosion by Molten Nitrates, Nitrites, and Fluorides.” Under certain conditions, which are described in the article “Corrosion by Liquid Metals,” the liquid metal can penetrate into the grain boundaries of the metallic material at rates that are sometimes spectacular. A dangerous consequence is embrittlement of the metal.

At this point, the reader has been provided with all the fundamental bases of thermodynamics and kinetics necessary to understand the mechanisms of corrosion of metals in aqueous solution and the mechanisms of oxidation at high temperature, including the relevant experimental methods.

P. Marcus, Introduction to the Fundamentals of Corrosion, *Corrosion: Fundamentals, Testing, and Protection,* Vol 13A, *ASM Handbook*, ASM International, 2003, p 3-4

Constructive Uses of Corrosion

The fundamental electrochemical reactions of corrosion, in particular anodic dissolution, can be, if they are well understood and controlled, used in a very powerful way to design and fabricate patterns on metal surfaces. The article “Electrochemical Machining” describes the use of such reactions to produce surface architectures at scales down to the micrometer and now approaching the nanometer scale. The article “Electropolishing” reviews another use of corrosion for constructive purpose, where electrochemical reactions are used to produce finely polished metallic surfaces by controlled dissolution in an appropriate electrolyte. Chemical- mechanical polishing, often called chemical- mechanical planarization (CMP) is rapidly developing under the impetus of important applications in the microelectronic industry; these advances are described in the article “Chemical-Mechanical Planarization for Semiconductors” in this Section. The combination of mechanical abrasion with dissolution of the surface allows the fast planarization of complex structures (e.g., with narrow copper interconnects). For this process to be efficient and industrially applicable, very good control of the attack taking place in the corrosive bath is necessary and requires a detailed understanding of the mechanisms of dissolution and passivation of the metal surfaces subjected to CMP.

There are other areas of importance in classical and modern technologies that rely, from the mechanistic point of view, on controlled corrosion. These are described in the articles “Electrochemical Refining,” “Anodes for Batteries,” and “Fuel Cells,” which are the final articles in this Section of the Handbook.

Introduction to the Fundamentals of Corrosion

Philippe Marcus, Ecole Nationale Supérieure de Chimie de Paris, Université Pierre et Marie Curie

Conclusions

The fundamental aspects of corrosion, discussed in this Section, are indispensable, not only to understand the mechanisms, but also to control corrosion, to design appropriate means of corrosion protection, and to be able to predict the long-term corrosion behavior of metallic materials. The articles of this Section have been written

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

by leading scientists from the academic and industrial research world, and this Section represents a major review of the fundamentals of corrosion. It opens the way to the articles of the following Sections on the different forms of corrosion, including uniform corrosion, localized corrosion, and stress-corrosion cracking, on corrosion testing and evaluation, and finally on the methods of corrosion protection.

Introduction to Fundamentals of Corrosion Thermodynamics

Philippe Marcus, Ecole Nationale Supérieure de Chimie de Paris, Université Pierre et Marie Curie

Introduction

THE DRIVING FORCE of corrosion is the lowering of energy associated with the oxidation of a metal. Thermodynamics examines and quantifies this driving force. It predicts if reactions can or cannot occur (i.e., if the metal will corrode or be stable). It does not predict at what rate these changes can or will occur: this is the area of kinetics. However, knowing from thermodynamics what reactions are possible is a necessary step in the attempt to understand, predict, and control corrosion.

Electrochemical Reactions

Corrosion of metals and alloys in aqueous environments or other ionically conducting liquids is almost always electrochemical in nature. It occurs when two or more electrochemical reactions take place on a metal surface. One of these reactions results in the change of the metal or some elements in the metal alloy from a metallic state into a nonmetallic state. The products of corrosion may be dissolved species or solid corrosion products. Because electrochemical reactions are at the origin of corrosion, the corroding metal surface is considered an electrode. The ionically conducting liquid is the electrolyte in which the reactions take place. Different aspects of these reactions are considered in the articles “Electrode Processes,” “Electrode Potentials,” and “Potential Measurements with Reference Electrodes” in this Section:

- *The structure of the electrode/electrolyte interface:* There is a separation of charges between electrons in the metal and ions in the electrolyte, creating an electrically charged double layer. The ions in the solution interact with water molecules. Adsorption of ions on the electrode surface may also occur.
- *Transport of chemical species:* This takes place through the double layer and in the electrolyte by diffusion.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- *The potential difference across the electrode/ electrolyte interface:* Electrode potentials need to be measured to evaluate the corrosion behavior of a metal (this is true for both the thermodynamics and the kinetics of corrosion). Potential measurements require the use of reference electrodes.
- *The processes governing corrosion:* These are electrode processes, involving oxidation and reduction reactions (or anodic or cathodic reactions). The corroding system does not produce any net charge and, thus, the electrons produced by the electrochemical oxidation of the metal (the anodic reaction) must be consumed by an electrochemical reduction reaction (the cathodic reaction).

Potential-pH (*E*-pH) diagrams (Pourbaix diagrams), based on equilibrium thermodynamics for metal-water systems, show at a glance the regions of stability of the various phases that can exist in the system. Their principle and their construction are presented in the article "Potential versus pH (Pourbaix) Diagrams" for binary metal-water systems and for ternary metal-additive-water systems. Their applications as well as their limitations are also discussed. The *E*-pH diagrams are very useful as a thermodynamic framework for kinetic interpretation, but they do not provide information on corrosion rates.

The prediction of the corrosion behavior of metals in aqueous solutions at high temperatures is also of considerable importance for different technologies (including power generation systems in general and nuclear power systems in particular). Potential pH diagrams for metals in high temperature water are presented.

The principle of *E*-pH diagrams has been extended to the case of adsorbed species on metal surfaces in water. Whereas the solid compounds treated in the classical diagrams are three-dimensional (bulk) compounds (e.g., oxides, hydroxides, sulfides), the formation of more stable two-dimensional adsorbed phases has been considered only recently. Due to the large energy of adsorption, adsorbed layers may form under *E*- pH conditions in which the usual solid compounds are thermodynamically unstable, and these adsorbed layers can induce marked changes in the corrosion behavior of metals. The method of calculation of the equilibrium potentials of species adsorbed on an electrode surface in water is presented, together with examples of applications, in a section on *E*-pH diagrams for adsorbed species.

P. Marcus, Introduction to Fundamentals of Corrosion Thermodynamics, *Corrosion: Fundamentals, Testing, and Protection,* Vol 13A, *ASM Handbook*, ASM International, 2003, p 5

Philippe Marcus, Ecole Nationale Supérieure de Chimie de Paris, Université Pierre et Marie Curie

Molten Salt Corrosion Thermodynamics

Molten salts constitute a special environment of importance in a number of technologies. There is no solvent analogous to water in molten salts. A specific potential scale must be established for each medium, as described in the article "Molten Salt Corrosion Thermodynamics" in this Section. Equilibrium diagrams, analogous to the *E*-pH diagrams for aqueous solutions, have been constructed. In these diagrams, the equilibrium potential, *E*, is plotted as a function of the activity of oxide in the melt, expressed as $pO^{2-} = -\log O^{2-}$. The thermodynamics of molten salt electrochemical cells is treated here.

Geochemical Modeling

The article “Geochemical Modeling” discusses modeling software that has been developed by geochemists to describe the chemical state of local environments, with interesting and important applications in corrosion. These include nuclear waste storage, atmospheric corrosion involving environmental effects on corrosion product stability, and corrosion in elevated and high-temperature aqueous systems.

Electrode Processes

Revised by E. Protopopoff and P. Marcus, Laboratoire de Physico-Chimie des Surfaces, CNRS, Ecole Nationale Supérieure de Chimie de Paris, Université Pierre et Marie Curie

Introduction

ELECTROCHEMICAL, OR ELECTRODE, REACTIONS are reactions that occur with charge transfer between neutral or ionic reactants and a conducting material, called the electrode, acting as an electron source or an electron sink (Ref 1). Electrochemical reactions involve change in valence; that is, oxidation or reduction of the reacting elements. Oxidation and reduction are commonly defined as follows. Oxidation is the removal of electrons from atoms or groups of atoms, resulting in an increase in valence, and reduction is the addition of electrons to atoms or groups of atoms, resulting in a decrease in valence (Ref 2).

Electrode Processes

Revised by E. Protopopoff and P. Marcus, Laboratoire de Physico-Chimie des Surfaces, CNRS, Ecole Nationale Supérieure de Chimie de Paris, Université Pierre et Marie Curie

Electrode Reactions

Because electrochemical reactions occur in an electrochemical cell with oxidation reactions occurring at one electrode and reduction reactions occurring at the other electrode, they are often further defined as either cathodic reactions or anodic reactions. By definition, cathodic reactions are those types of reactions that result in reduction, such as:

$$M^{2+}(aq) + 2e^- \rightarrow M(s) \quad \text{(Eq 1)}$$

Anodic reactions are those types of reactions that result in oxidation, such as:

$$M(s) \rightarrow M^{2+}(aq) + 2e^- \quad \text{(Eq 2)}$$

Because of the production of electrons during oxidation and the consumption of electrons during reduction, oxidation and reduction are coupled events. If the ability to store large amounts of electrons does not exist,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

equivalent processes of oxidation and reduction will occur together during the course of normal electrochemical reactions. The oxidized species provide the electrons for the reduced species.

The Electric Field near the Electrode

The examples stated earlier, like many aqueous corrosion situations, involve the reaction of aqueous metal species at a metal electrode surface. The metal-aqueous solution interface is complex, as is the mechanism by which the reactions take place across the interface. Because the reduction-oxidation reactions involve ionic species in the electrolyte reacting at or near the metal surface, the electrode surface is charged relative to the solution and the reactions are associated with specific electrode potentials.

The charged interface results in an electric field that extends into the solution and has a dramatic effect. A solution that contains water as the primary solvent is affected by the electric field near the metal because of its structure. Water is polar and can be visualized as dipolar molecules that have a positive side (hydrogen atoms) and a negative side (oxygen atoms). In the electric field caused by the charged interface, the water molecules act as small dipoles and align themselves in the direction of the electric field.

Electrode Processes

Revised by E. Protopopoff and P. Marcus, Laboratoire de Physico-Chimie des Surfaces, CNRS, Ecole Nationale Supérieure de Chimie de Paris, Université Pierre et Marie Curie

Solvation of Ions

Ions that are present in the solution are charged because of the loss or gain of electrons. The positive charged ions (cations) and negative charged ions (anions) also have an electric field associated with them. The solvent (water) molecules act as small dipoles; therefore, they are also attracted to the charged ions and align themselves in the electric field established by the charge of the ion. Because the electric field is strongest close to the ion, some water molecules reside very close to an ionic species in solution. The attraction is great enough that these water molecules travel with the ion as it moves through the solvent. The tightly bound water molecules are referred to as the primary water sheath of the ion. The electric field is weaker at distances outside the primary water sheath, but it still disturbs the polar water molecules as the ion passes through the solution. The water molecules that are disturbed as the ion passes, but do not move with the ion, are usually referred to as the secondary water sheath. Figure 1 shows a representation of the primary and secondary solvent molecules for a cation in water. Because of their smaller size relative to anions, cations have a stronger electric field close to the ion and more water molecules are associated in their primary water sheath. Anions have few, if any, primary water molecules. A detailed description of the hydration of ions in solution is given in Ref 1.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

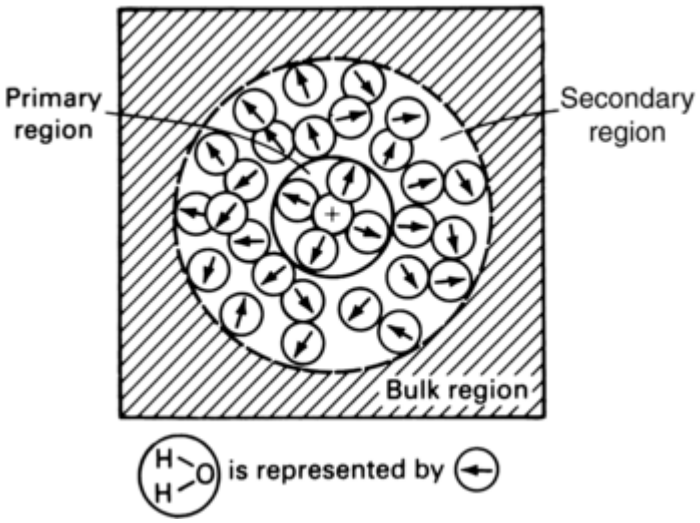

Fig. 1 Schematic of the primary and secondary solvent molecules around a cation in water

Ions and polar water molecules are attracted to the metal-aqueous solution interface of an electrode because of the strong electric field in this region. Water molecules form a first row at the metal surface. This row of water molecules limits the distance to which hydrated ions can approach the interface. Figure 2 shows a schematic diagram of a charged interface and the locations of cations at the surface. Also, the primary water molecules associated with the ionic species limit the distance the cations can approach. The plane of positive charge containing the cations closest to a negatively charged surface is thus at a fixed distance from the metal. This plane of charge is referred to as the outer- Helmholtz plane (OHP).

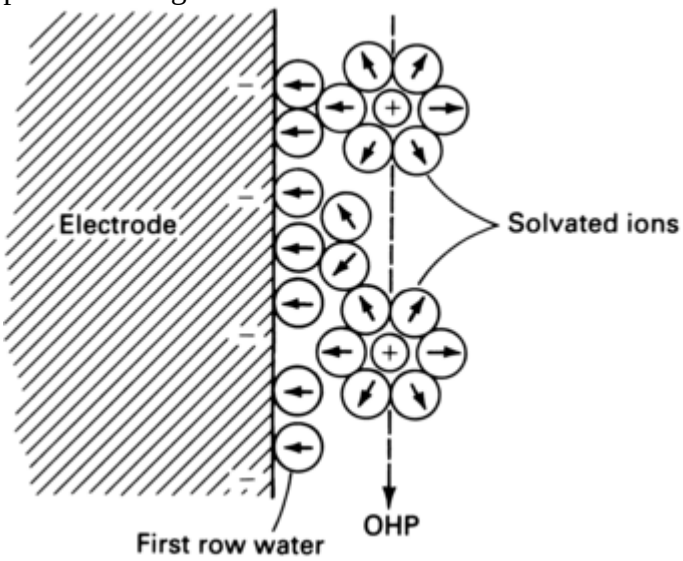

Fig. 2 Schematic of a charged interface and of the locations of cations at the electrode surface. OHP, outer-Helmholtz plane

The region of the interface with charge separation (Fig. 3) is called the electric double layer and can be represented as a charged capacitor (Ref 1). The potential drop across the interface is also often simplified as a linear change in potential from the metal surface to the OHP.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

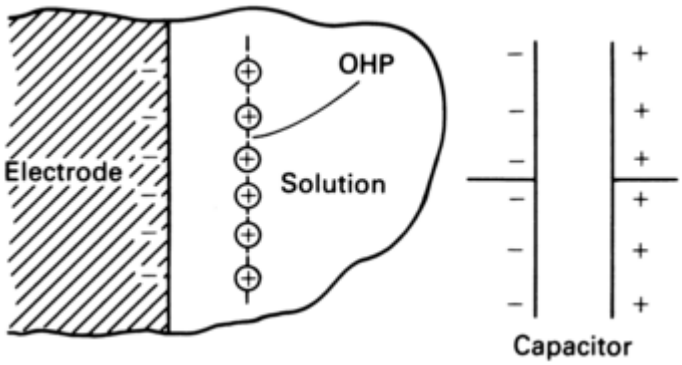

Fig. 3 The simplified electric double layer at a metal-aqueous solution interface and equivalent capacitor. OHP, outer-Helmholtz plane

The electric equivalent of a metal-aqueous solution interface where no reactions with electron transfer occur over a large range of potentials is a simple capacitor (Fig. 3). The electrode is then ideally polarizable. This is the case of mercury in poorly reactive electrolytes (Ref 1). Noble metals like platinum or gold behave as ideal polarizable electrodes within a limited range of potential.

However, on most metals, especially the corrodible ones, reactions with electron transfer across the interface (electrochemical reactions) occur, leading to charge transfer currents, or faradic current. The interface is a barrier to the transfer of electrons from or to the metal; this can be represented by a resistance called the charge-transfer resistance. This resistance is not a simple ohmic resistance, because it varies with the electrode potential. It is constant only in a limited potential range. The electrical circuit equivalent to a metal-electrolyte interface with charge transfer is thus a parallel combination of a double-layer capacitance (C_{DL}) and a charge transfer resistance (R_{CT}) (Fig. 4) (Ref 1). It must be noted that this is the electrical equivalent of a very simple interface; for example, the circuit equivalent to an electrode covered by an oxide film is more complicated (Ref 1).

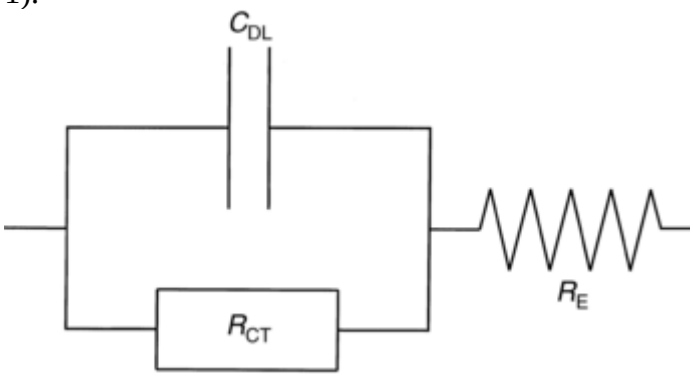

Fig. 4 Electric circuit equivalent to a metal-electrolyte interface showing the double-layer capacitance (C_{DL}) in parallel with the charge transfer resistance (R_{CT}). R_E is the ohmic resistance of the electrolyte (Ref 1).

If there were no difficulty in the transfer of electrons across the interface, the only resistance to the electron flow would be the diffusion of aqueous species to and from the electrode. The electrode would then be ideally nonpolarizable, and its potential would not change until the solution was deficient in electron acceptors and/or donors. This property is sought after for reference electrodes (see the article in this Section, “Potential Measurements with Reference Electrodes”).

However, when dealing with the kinetics of electrochemical reactions (see the article “Kinetics of Aqueous Corrosion” in this Volume), the metal-electrolyte interface represents an energy barrier that must be overcome. Thus, reactions at the interface are often dominated by activated processes, and control of activation by polarization plays a significant role in electrochemical kinetics. A key in controlling corrosion consists in minimizing the kinetics of the anodic reaction, that is, dissolution of the metal, or the kinetics of the cathodic reactions.

Introduction

ONE OF THE IMPORTANT FEATURES of the electrified interface between the electrode and the electrolyte in the aqueous corrosion of metals is the existence of a potential difference across the double layer, which leads to the definition of the electrode potential. The electrode potential is one of the most important parameters in both the thermodynamics and the kinetics of corrosion. The fundamentals of electrode potentials are discussed in this article. Examples of the calculations of the potential at equilibrium are given in the article “Potential versus pH (Pourbaix) Diagrams” in this Section of the Volume.

Thermodynamics of Chemical Equilibria

The object of chemical thermodynamics is to develop a mathematical treatment of the chemical equilibria and the driving forces behind chemical reactions. The desire is to catalog quantitative data concerning known equilibria that later can be used to predict other equilibria.

The driving force for chemical reactions at constant pressure is the Gibbs free energy change, which has been expressed in thermodynamic treatments as the balance between the effects of energy (enthalpy) change and entropy change. The entropy of a system is related to the number of ways in which microscopic particles can be distributed among states accessible to them. The enthalpy (*H*), the entropy (*S*), and the free energy (*G*) are thermodynamic state functions (Ref 1, 2).

Free Energy and Chemical Potential. The Gibbs free energy (*G*) is the result of its enthalpy (*H*) and its entropic factor (*TS*): $G = H - TS$, where T is the absolute temperature (in Kelvin) (Ref 2). The partial molar free energy for a substance A is equal to $(\partial G/\partial n_A)_{n_i \neq n_A, T, P}$, where n_A and n_i are the number of moles of A and any other constituent i and P is the pressure. It is usually called chemical potential (μ_A) and depends not only on the chemical formula of the species involved but also on its activity (a_A) (corrected concentration—see end of this section):

$$(\partial G/\partial n_A)_{n_i \neq n_A, T, P} = \mu_A = \mu_A^0 + RT \ln a_A \qquad \text{(Eq 1)}$$

where R is the gas constant (8.3143 J/K · mol), and μ_A^0 is the standard chemical potential of A; that is, the chemical potential of A in an arbitrarily selected state. If A is a pure condensed substance, a_A is equal to unity; if A is a species in solution, a_A is equal to the product of the concentration of A (usually molality m_A in number of moles of A per kilogram of solvent) by an activity coefficient (γ_A) representing the deviation from ideal behavior.

The standard state for a gaseous substance is the substance under a pressure such that its fugacity is 1 bar (0.1 MPa), for most gases a pressure of ~1 atm. The standard state for a condensed substance is the pure substance at the given temperature (T) and under pressure (P). The standard state for a dissolved species is the hypothetical ideal solution of the species with unit molality (mol/kg) at T and P. The μ_A^0 is dependent on the temperature and, for a condensed substance, also on the pressure (this dependence is small and usually neglected for pressures not too far from 1 bar). The usual convention is to assign the value 0 to the chemical potentials of the elements in their stable form and standard state at 25 °C (77 °F), for example, pure gaseous H_2 and O_2 at fugacity equal to 1 bar, solvated protons at activity unity. Hence, the standard chemical potential of a substance is equal to its standard Gibbs free energy of formation from its elements at 25 °C (77 °F) under 1 bar pressure.

Law of Chemical Equilibria. Consider the following chemical reaction:

$$\Sigma \nu_R R \leftrightarrow \Sigma \nu_P P \qquad \text{(Eq 2)}$$

where R and P designate the reactants and products, respectively, and ν_R and ν_P are the associated stoichiometric coefficients.

The molar Gibbs free energy change for this reaction is:

$$\Delta_r G = \Sigma \nu_P \mu_P - \Sigma \nu_R \mu_R \qquad \text{(Eq 3)}$$

where μ_P and μ_R are the chemical potentials of the products and reactants, respectively. If the chemical potentials are expressed as in Eq 1, one obtains:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\Delta_r G = \left(\Sigma \nu_P \mu_P^0 - \Sigma \nu_R \mu_R^0\right) + RT\left(\Sigma \nu_P \ln a_P - \Sigma \nu_R \ln a_R\right) = \Delta_r G^0 + RT \ln\left(\frac{\Pi a_P^{\nu P}}{\Pi a_R^{\nu R}}\right) \quad \text{(Eq 4)}$$

where R is the gas constant, Π is the symbol for multiplying a series of terms, a_P and a_R are the activities of the products and reactants, respectively, and $\Delta_r G^0$ is the standard free energy change for the reaction:

$$\Delta_r G^0 = \Sigma \nu_P \mu_P^0 - \Sigma \nu_R \mu_R^0 \quad \text{(Eq 5)}$$

When the reaction is in thermodynamic equilibrium (there is no tendency for the reaction to proceed either forward or backward), it has been shown that its molar Gibbs free energy change ($\Delta_r G$) is equal to zero (Ref 2). Then, from Eq. 4 the classic equilibrium law is obtained:

$$\frac{\Pi a^{\nu P}}{\Pi a^{\nu R}} = K_{eq} \quad \text{(Eq 6)}$$

where K_{eq} is the equilibrium constant for the reaction at the temperature T:

$$K_{eq} = \exp\left(-\frac{\Delta_r G^0}{RT}\right) \quad \text{(Eq 7)}$$

The standard chemical potentials, or free energies of formation, of an extensive number of compounds have been cataloged for various temperatures. Typical data sources are listed as the Selected References. This allows the prediction of standard free energy changes and equilibrium constants for reactions over a wide range of conditions.

Reactions in Aqueous Solution

Galvanic Cell Reactions. If a strip of metal is placed in water, some metal atoms will be oxidized into hydrated (solvated) ions. Because of the electrons remaining in the metal (called an *electrode*), the positively charged metallic ions will remain very close to the negatively charged metal strip in a double layer, where a very high potential gradient exists, as described in the article “Electrode Processes” in this Volume. Thus, a potential difference will exist between the metal and the solution. This potential difference is not measurable, but it is possible to measure the potential difference between this system and another metal-ion system. If a zinc electrode placed in a solution of zinc ions is linked through an electric circuit including a voltmeter to a copper electrode placed in a solution of copper ions (Fig. 1), a positive potential difference will be measured between the copper electrode and the zinc electrode. This is evidence that copper is a more noble metal than zinc and has

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

less tendency to oxidize. This can be checked directly by the chemical reaction in Eq 8; if zinc is put into a solution containing copper ions, zinc will dissolve, while copper will deposit from its ions on to the zinc. This metal-displacement reaction is due to the oxidation-reduction reaction between zinc metal and copper ions:

$$Zn(s) + Cu^{2+}(aq) \rightarrow Zn^{2+}(aq) + Cu(s) \qquad \text{(Eq 8)}$$

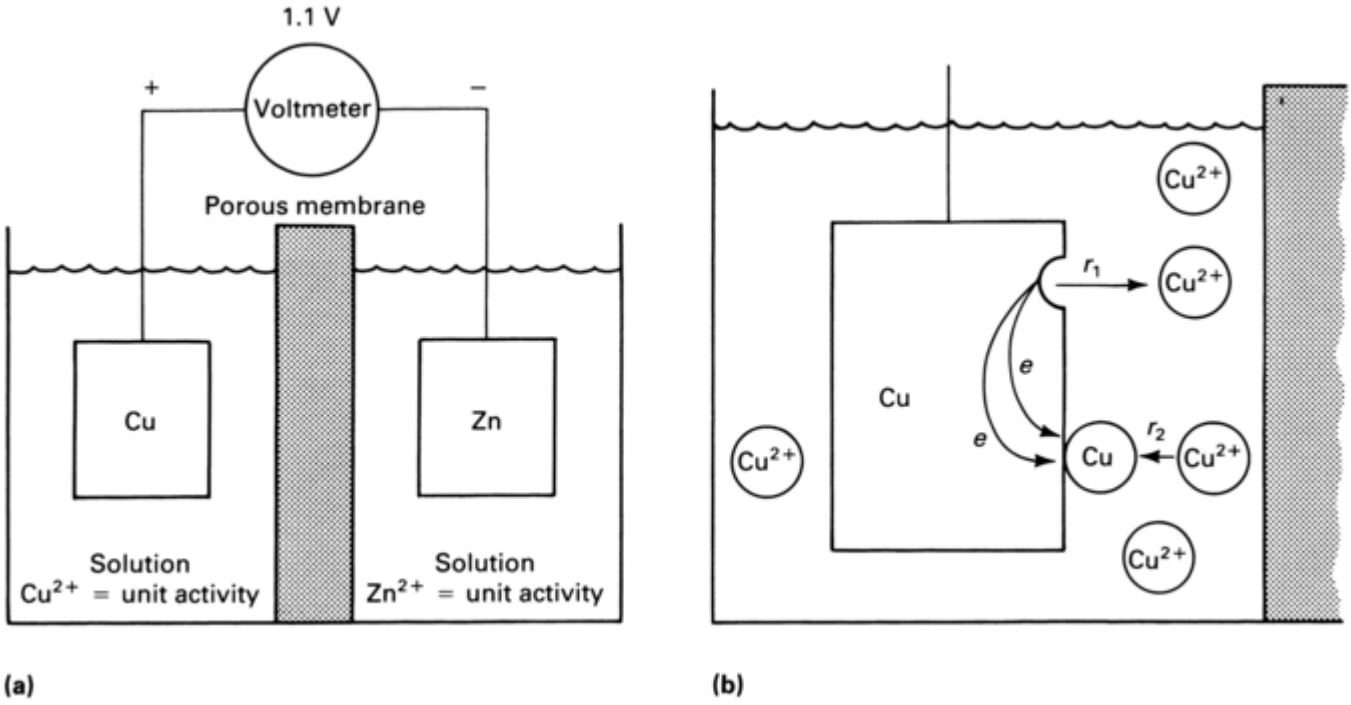

Fig. 1 Typical electrochemical cell (a) used to study the free energy change that accompanies electrochemical or corrosion reactions. In this example, the cell contains copper and zinc electrodes in equilibrium, with their ions separated by a porous membrane to mitigate mixing. For purposes of simplicity, the concentration of metal ions is maintained at unit activity; that is, each solution contains approximately 1 mole of metal ion per liter. The reactions for copper and zinc electrodes in each half-cell are given in Eq 9 and 10. However, at equilibrium, metal dissolution and deposition occur at each electrode at equal rates ($r_1 = r_2$), as shown in (b), which illustrates copper atoms being oxidized to cupric ions and, at other areas, cupric ions being reduced to metallic copper. Source: Ref 3

This reaction takes place spontaneously, because the standard free energy change associated with it ($\Delta_r G^0 = \mu^0_{Zn^{2+}} + \mu^0_{Cu} - \mu^0_{Zn} - \mu^0_{Cu^{2+}}$) is negative. Zinc metal will react with copper ions almost to completion; the reaction will stop only when the concentration of copper ions is very small and such that equilibrium is reached, with $\Delta_r G = \Delta_r G^0 + RT \ln a_{Zn^{2+}} / a_{Cu^{2+}} = 0$. If the reverse procedure is tried, that is, copper metal placed in a solution containing zinc ions, because it is associated with a strongly positive standard free energy change, the reaction will occur to only a very small extent, with the reaction stopping when a certain very small concentration of copper ions has been produced, such that equilibrium is reached.

The same reaction may be studied in an electrochemical cell, such as the one shown and described in Fig. 1(a). An electric circuit links a copper electrode in a solution of copper sulfate to a zinc electrode in a solution of zinc sulfate. If the external conduction path is closed, the oxidation-reduction reaction in Eq 8 will take place but under the form of two spatially separated electron-transfer reactions occurring each at one electrode, which are:

- An oxidation-dissolution reaction involving the extraction of electrons from outer metal atoms to form metallic ions at the zinc electrode, called the anode:

$$Zn(s) \rightarrow Zn^{2+}(aq) + 2e^- \qquad \text{(Eq 9)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- A reduction-deposition reaction involving the addition of electrons to the metallic ions to form metal atoms deposited at the copper electrode, called the cathode:

$$Cu^{2+}(aq) + 2e^- \rightarrow Cu(s) \qquad \text{(Eq 10)}$$

Electrons will flow from the zinc anode where they are produced to the copper cathode where they are consumed; the two half-reactions in Eq 9 and 10 naturally combine in the electrochemical cell to form the oxidation-reduction reaction of Eq 8, termed the *chemical cell reaction.* They are referred to as *electrochemical, electrode,* or *half-cell reactions.* The requirement for writing the equation of the overall reaction by combination of the oxidation and reduction half-cell reactions is that the same number of electrons should be produced or consumed at each electrode. At equilibrium, $\Delta_r G = 0$, the electron flow stops, and oxidation and reduction reactions occur at each electrode with equal rates, as shown schematically in Fig. 1(b) for the case of copper dissolution and deposition.

Electrochemical cells in which the electrode reactions take place spontaneously and give rise to an electron flow are called galvanic cells. The chemical energy produced by the cell reaction during the transformation of reactants with high overall free energy into products with low overall free energy can be converted through the electron flow into electrical energy. This principle is used in batteries and fuel cells. The external circuit can be replaced with a direct current (dc) power supply, which will force electrons to go in a direction opposite to the one they tend to go naturally and make the cell reaction proceed in the backward direction to create chemical substances with high overall free energy. This process thus converts electrical into chemical energy and is used in electrolytic cells or battery charging.

Corrosion Reactions. The two types of cell processes described previously are of interest when dealing with corrosion. Corrosion reactions are similar to galvanic cells, with the two electrodes being different parts of the metal. Anodic dissolution takes place on certain zones of the surface of a metal and is coupled to cathodic reactions taking place on other zones. The short circuit provided by the conducting metal leads to a continuous metal dissolution. However, application of external potentials, as in electrolytic cells, can be used to protect metals (see the article “Cathodic Protection” in this Volume).

While the anodic dissolution involves only the metallic phase, the reduction reaction (cathodic reaction) involves the environment. Several different cathodic reactions (consuming electrons) are encountered in metallic corrosion in aqueous systems. The most common are:

- Proton reduction (in acid media):

$$2H^+(aq) + 2e^- \rightarrow H_2$$

- Water reduction (in neutral or basic media):

$$2H_2O(l) + 2e^- \rightarrow H_2 + 2OH^-(aq)$$

- Reduction of dissolved oxygen:

$$O_2 + 4H^+(aq) + 4e^- \rightarrow 2H_2O(l) \quad \text{(in acid media)}$$
$$O_2 + 2H_2O(l) + 4e^- \rightarrow 4OH^-(aq)$$
$$\text{(in neutral or basic media)}$$

- Metal ion reduction:

$$M^{3+}(aq) + e^- \rightarrow M^{2+}(aq)$$

- Metal deposition:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$M^{2+}(aq) + 2e^- \rightarrow M$$

Proton reduction in acidic media is very common, and oxygen reduction is also often encountered, because aqueous solutions in contact with air contain significant amounts of dissolved oxygen. Metallic ion reduction and metal deposition are less common and are encountered most often in chemical process streams (Ref 4).

Thermodynamics of Electrochemical Equilibria

The Electromotive Force of Galvanic Cells. Consider the following two simple half-cell reactions: oxidation at electrode 1:

$$c_1R_1 \rightarrow b_1O_1 + ne^- \qquad \text{(Eq 11)}$$

and reduction at electrode 2:

$$b_2O_2 + ne^- \rightarrow c_2R_2 \qquad \text{(Eq 12)}$$

where R_i represents a reduced species; O_i is an oxidized species; and b_i, c_i are stoichiometric coefficients, and n is an integer.

It is assumed that the spontaneous galvanic cell reaction is the following:

$$b_2O_2 + c_1R_1 \rightarrow b_1O_1 + c_2R_2 \qquad \text{(Eq 13)}$$

If the resistance between the electrodes of the galvanic cell is made very high, so that very little current flows, the extent of reaction being small enough not to change the activities of reactants and products, the potential difference between the two electrodes remains constant and is the maximum cell voltage, called the electromotive force (emf) of the cell. The electrical energy produced is then maximum and equal for the transformation of 1 mole of reactants to the absolute value of the molar free energy of the cell chemical reaction:

$$|\Delta_r G| \approx \text{Charge passed} \times \text{Potential difference}$$

Conversely, if the cell reaction is driven by an outside source of electric power to go against its spontaneous tendency (as in an electrolytic or charging cell), $|\Delta_r G|$ is the minimum energy required to drive the backward reaction. Under ideal thermodynamically reversible conditions, where infinitesimal currents are allowed to flow in one or another direction, the cell reaction is at equilibrium, and the perfect equality holds. A noteworthy property is that, whatever the direction of the cell reaction, the polarity of each electrode remains unchanged (see Fig. 1a, Ref 5). If the cell reaction as written in Eq 13 proceeds spontaneously, the electrons flow into an external circuit from electrode 1 where electrons are produced (Eq 11) to electrode 2 where electrons are consumed (Eq 12). Electrode 2 is a cathode, and its polarity is positive. Electrode 1 is an anode, and its polarity is negative. Conversely, if the cell reaction is driven backward by an outside electric power source, the electrons are forced to flow in the opposite direction (from electrode 2 to 1), and half-reactions 1 and 2 are reversed, so electrode 1 becomes a cathode, and electrode 2 becomes an anode, but the polarities of the two

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

electrodes are left unchanged. Hence, the magnitude and the sign of the cell voltage at equilibrium (emf) depend only on the couple of half-reactions involved. From the thermodynamic convention, the free energy change of a spontaneous cell reaction, which liberates energy, is negative. If the emf is the potential of electrode 2 minus the potential of electrode 1 ($\Delta E = E_2 - E_1$), and if $\Delta_r G$ designates the free energy of the cell reaction written in the sense of Eq 13, that is, reduction at electrode 2 (Eq 12) and oxidation at electrode 1 (Eq 11), the relation between $\Delta_r G$ and ΔE is:

$$\Delta_r G = -nF\Delta E \qquad \text{(Eq 14)}$$

where n is the number of electrons exchanged in both half-reactions, and F is the Faraday constant (96,487 coulombs) equal to the charge of 1 mole of electrons.
Using Eq 3 and 4, Eq 14 may be rewritten as:

$$\Sigma \nu_P \mu_P - \Sigma \nu_R \mu_R = \left(\Sigma \nu_P \mu_P^0 - \Sigma \nu_R \mu_R^0\right) + RT \ln\left(\frac{\Pi a_P^{\nu P}}{\Pi a_R^{\nu R}}\right) = -nF\Delta E \qquad \text{(Eq 15)}$$

Compared to a chemical equilibrium where, at a given temperature, the ratio $\left(\Pi a_P^{\nu P} / \Pi a_R^{\nu R}\right)$ is equal to a constant K_{eq} (Eq 6), the electrochemical cell at equilibrium is a system with one more degree of freedom, because either the ratio of activities or the cell emf can impose on it.
If the cell reaction occurs under conditions in which the reactants and products are in their standard states, the equation becomes:

$$\Delta_r G^0 = \Sigma \nu_P \mu_P^0 - \Sigma \nu_R \mu_R^0 = -nF\Delta E^0 \qquad \text{(Eq 16)}$$

where ΔE^0 is the standard cell emf.
The Hydrogen Potential Scale. The absolute potential of an electrode, or even the potential difference between a metal electrode and the surrounding solution, cannot be determined experimentally. It is only possible to measure the voltage across an electrochemical cell, that is, the difference of potential between two identical wires connected to two electrodes. A potential scale may be defined by measuring all electrode potentials with respect to an electrode of constant potential, called the reference electrode. The reference electrode arbitrarily chosen to establish a universal potential scale is the standard hydrogen electrode (SHE). It consists of a platinized platinum electrode (wire or sheet) immersed in an aqueous solution of unit activity of protons, saturated with hydrogen gas at a fugacity of 1 bar. The half-cell reaction is the equilibrium:

$$H^+(aq) + e^- \rightleftharpoons \frac{1}{2}H_2(g) \qquad \text{(Eq 17)}$$

The SHE possesses the advantages of achieving its equilibrium potential quickly and reproducibly and maintaining it very stable with time (see comparison with other reference electrodes in the article “Potential Measurements with Reference Electrodes” in this Volume). From the convention, the SHE potential is taken as zero. The potential of any electrode can then be determined with respect to this zero reference and is called the potential of the electrode on the standard hydrogen scale, denoted $E_{(SHE)}$.
The Potential Sign Convention (Reduction Convention). Before establishing tables of standard potentials for various electrodes on the standard hydrogen scale, it is necessary to fix the convention for the sign of a standard potential value (E^0). The potential of any electrode is expressed with respect to the SHE by building (really or virtually) a cell in which the other electrode is a SHE. Consider a typical half-cell reaction with an oxidation-reduction (O/R) couple, where O represents the oxidized species and R the reduced species. The cell is represented as:

$$Pt, H_2(g)(f = 1 \text{ bar})|H^+(aq)(a = 1) \,||\, O/R \qquad \text{(Eq 18)}$$

Depending on the position of the O/R electrode on the hydrogen scale, the spontaneous single electrode or half-cell reaction will proceed in one direction or the other: R oxidation: $cR \rightarrow bO + ne^-$ combined with proton reduction: $H^+(aq) + e^- \rightarrow \frac{1}{2}H_2(g)$; or, O reduction: $bO + ne^- \rightarrow cR$ combined with hydrogen oxidation: $\frac{1}{2}H_2(g) \rightarrow H^+(aq) + e^-$.
For example, the coupling of the oxidation/ reduction couple Fe^{2+}/Fe with the H^+/H_2 couple brings about the spontaneous oxidation of iron (the free energy of the cell reaction ΔG_{ox}^{Fe} is negative, the Fe^{2+}/Fe electrode is negative). The situation is entirely different with a Cu^{2+}/Cu system. If coupled with the H^+/H_2 couple, the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

reduction of copper ions is spontaneous (ΔG^{Cu}_{red}, negative; ΔG^{Cu}_{ox}, positive, the polarity of the Cu^{2+}/Cu electrode is positive). The difference between these two metal couples in the direction of the spontaneous reaction with respect to the hydrogen couple must be represented by a sign. This sign will allow cataloging cell potentials from single electrode values and hence compute cell emfs. It was shown previously that the polarity of each electrode in an electrochemical cell is invariant, irrespective of whether the electrode reactions proceed in the spontaneous or the reverse direction. The most meaningful convention is to assign to the potential of the O/R electrode the same sign as its experimentally observed polarity in the cell connecting this electrode to the SHE (Eq 18). The potential of the O/R couple on the standard hydrogen scale, in volts, denoted $E_{O/R(SHE)}$, is thus equal to the cell voltage measured as the potential of the O/R electrode minus the potential of the SHE (zero by convention). When the O/R electrode is in equilibrium, the whole cell is also in equilibrium, and the equilibrium electrode potential versus SHE may be obtained by applying Eq 14 to this particular cell:

$$\Delta G_{red} = -nFE_{O/R(SHE)} \qquad \text{(Eq 19)}$$

where ΔG_{red} is the molar free energy change of the balanced reaction of reduction of the oxidized species O by $H_2(g)$:

$$bO + \frac{n}{2}H_2(g) \leftrightarrow cR + nH^+(aq) \qquad \text{(Eq 20)}$$

Then:

$$E_{O/R(SHE)} = -\frac{\Delta G_{red}}{nF} = +\frac{\Delta G_{ox}}{nF} = \frac{b\mu_O - c\mu_R + \frac{n}{2}\mu^0_{H_2}(g) - n\mu^0_{H^+}(aq)}{nF} \qquad \text{(Eq 21)}$$

This *equilibrium potential,* called the *reversible potential,* is the electrode potential measured under zero current (rest potential) when the electrochemical equilibrium between O and R occurs at the electrode-electrolyte interface.

At the International Union of Pure and Applied Chemistry (IUPAC) meeting held in Stockholm in 1953, it was decided that the half-cell reactions should be conventionally written in the reduction direction:

$$bO + ne^- \leftrightarrow cR \qquad \text{(Eq 22)}$$

and the corresponding equilibrium potentials referred to the SHE obtained from the relation in Eq 21. The reaction as written in Eq 22 stands implicitly for the overall chemical reaction in Eq 20; the electrode equilibrium potential is conveniently written as:

$$E_{O/R(SHE)} = \frac{\left(b\mu_O + n\mu^0_{e^-} - c\mu_R\right)}{nF} \qquad \text{(Eq 23)}$$

where μ^0_e–is the standard chemical potential or Gibbs free energy of a conventional electron, equal to $\mu^0_{H_2}(g) - \mu^0_{H_+}(aq)$. It may be checked that:

$$E^0_{H^+/H_2(SHE)} = \mu^0_{H^+}(aq) + \mu^0_{e^-} - \tfrac{1}{2}\mu^0_{H_2}(g) = 0 \qquad \text{(Eq 24)}$$

The IUPAC convention selects the reduction as the conventional direction for writing electrochemical reactions. This is, of course, not necessarily the spontaneous direction of a reaction, so the corresponding Gibbs free energy change may be positive and the potential negative. As a result of this reduction convention, the potential of the Fe^{2+}/Fe electrode has a negative sign and the one of Cu^{2+}/Cu a positive sign. A negative sign indicates a trend toward corrosion in the presence of H^+ ions; that is, the metallic cations have a greater tendency to exist in aqueous solution than the protons. A positive sign indicates, on the contrary, that the proton is more stable than the metallic cations. It is to be noted that there was another convention, called the American convention, where the equation $\Delta G = -nFE$ is applied to the reactions written in the oxidation direction. This leads to opposite signs for all oxidation/reduction couples. The advantage of the IUPAC convention, now used worldwide, is that the electrode potential signs correspond to the real polarities measured when the electrode of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

interest is connected to the standard H^+/H_2 electrode and hence are fixed for a given O/R couple, whether reduction or oxidation is considered.

The Nernst Equation. If the chemical potentials in Eq 23 are developed using Eq 1, the following expression of the equilibrium or reversible potential for half-cell reaction, known as the Nernst equation, is obtained:

$$E_{O/R} = E^0_{O/R} + \frac{RT}{nF} \ln \frac{(a_O)^b}{(a_R)^c} \qquad \text{(Eq 25)}$$

where a_O and a_R are the activities of the oxidized and reduced species, respectively, and $E^0_{O/R}$ is the standard electrode potential referred to the SHE, corresponding to unit activity of both species:

$$E^0_{O/R} = -\frac{\Delta G^0_{red}}{nF} = +\frac{\Delta G^0_{ox}}{nF} = \frac{\left(b\mu^0_O + n\mu^0_{e^-} - c\mu^0_R\right)}{nF} \qquad \text{(Eq 26)}$$

Equation 25 shows that the equilibrium potential increases with the ratio of the activities of the oxidized form to the reduced form.

$K^{+} + e^- \rightarrow K$	-2.93
$Li^{+} + e^- \rightarrow Li$	-3.05

For example, the standard electrode potential for zinc—the accepted value for which is -0.763 V/SHE (Table 1)—is obtained by measuring the emf of a cell made of a SHE and a zinc electrode in a zinc salt solution of unit activity (Fig. 2). As described previously, the emf is a measurement of the maximum potential that exists in the galvanic cell when zero current is flowing between the electrode and the SHE.

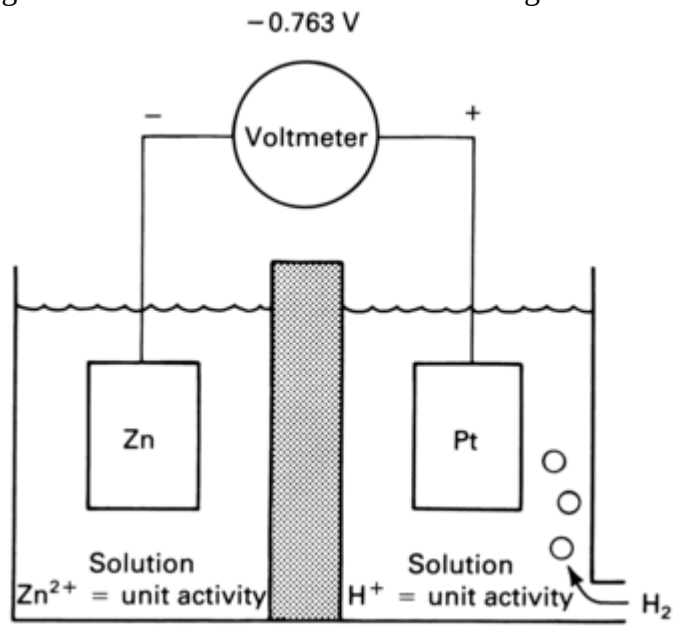

Fig. 2 Electrochemical cell containing a standard zinc electrode and a standard hydrogen electrode (SHE) (H_2 fugacity = 1 bar). The measurement of the cell voltage gives the standard equilibrium potential of the Zn^{2+}/Zn couple versus SHE.

This procedure can be repeated by exchanging the zinc electrode with any other metal, and the surrounding electrolyte by a solution of metal ion, in order to obtain the series of standard half- cell potentials listed in Table 1. The position of a particular metal in the emf series gives an indication of the tendency of the metal to be oxidized. The higher the metal is on the potential scale, the more noble it is and resistant to oxidation; the lower

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

on the scale it is, the more easily oxidized it is. The metals listed in Table 1 below the H^+/H_2 couple (SHE) are easily oxidized and reduce protons into $H_2(g)$, while the metals listed above the SHE have their metal ions reduced into metal by $H_2(g)$. However, care should be taken when predicting the behavior of a metal from the data in Table 1, because they are given for standard conditions, usually not close to the real corrosion conditions. Changes in concentration (i.e., activity) or temperature will change the electrode potentials according to Eq 25. The comparison between the standard potentials of half-cells from Table 1 is used to predict the abilities of metals to reduce other metal ions from solution. For example, consider the Daniell cell, constituted as follows:

$$Zn \,|\, Zn^{2+},\ SO_4^{2-} \,\|\, Cu^{2+},\ SO_4^{2-} \,|\, Cu \qquad \text{(Eq 27)}$$

The potential of the Cu^{2+}/Cu couple is higher than the potential of the Zn^{2+}/Zn couple. If the electrodes are coupled together in a galvanic cell, electrons will flow from the zinc electrode, which produces electrons via the oxidation reaction, through the external circuit to the copper electrode, which consumes electrons via the reduction reaction. The calculated standard emf for this cell is $\Delta E^0 = E^0(Cu^{+2}/Cu) - E^0(Zn^{+2}/Zn) = +0.337 - (-0.763) = +1.100$ V/SHE. Then, the standard free energy for the cell reaction is (Eq 16) $\Delta_r G^0 = -2F\Delta E^0 = -212.3$ kJ/mol. Its sign indicates that there is a natural tendency for zinc atoms to reduce cupric ions and be oxidized into Zn^{2+} (Eq 8).

It is important to note that the calculated equilibrium potentials are for a very specific condition (standard state) and may not apply to a specific corrosion environment; also, there are thermodynamic quantities that do not take into account the factors that may limit a reaction, such as slow kinetics or protection by corrosion product layers. More complete emf series (Ref 6, 7) and potentials in other environments (Ref 8) are available.

Introduction

ELECTRODE POTENTIAL MEASUREMENT is an important aspect of corrosion studies and corrosion prevention. It is included in any determination of the corrosion rate of metals and alloys in various environments and in the control of the potential in cathodic and anodic protection. The potential of an electrode can be determined only by measuring the voltage in an electrochemical cell between this electrode and an electrode of constant potential, called the reference electrode. Many errors and problems can be avoided by careful selection of the best reference electrode for a specific case and by knowledge of the electrochemical principles that control the potential measurements in order to obtain meaningful measurements. A reference electrode, once selected, must be properly used, taking into account the stability of its potential and the problem of ohmic (*IR*) drop. Many different reference electrodes are available, and others can be designed by the users themselves for particular situations. Each electrode has its characteristic rest potential value, which is used to convert potential values measured with respect to this reference into values expressed with respect to other references. In particular, the conversion of the potentials from or to the hydrogen scale is frequently required for use of potential- pH diagrams, which are discussed in the article “Potential versus pH (Pourbaix) Diagrams” in this Section of the volume.

The Three-Electrode Device

When a system is at rest and no significant current is flowing, the use of only one other electrode as a reference is sufficient to measure the test (or working) electrode potential versus the reference potential. When a current is flowing spontaneously in a galvanic cell or is imposed on an electrolytic cell, reactions at both electrodes are not at equilibrium, and there is consequently an overpotential on each of them. The potential difference measured between the two electrodes then includes the value of the two overpotentials, and it is not possible to determine the potential of the test electrode. To obtain this value, a third electrode, the auxiliary or counterelectrode, must be used (Fig. 1). In this arrangement, current flows only between the test and the auxiliary electrodes. A high-impedance voltmeter placed between the test and the reference electrodes prevents any significant current flow through the reference electrode, which then shows a negligible overpotential and remains very close to its rest potential. Most reference electrodes can be damaged by current flow. The test electrode potential and its changes under electric current flow can then be measured with respect to a fixed reference potential. The three- electrode system is widely used in laboratory and field potential measurement.

Electrode Selection Characteristics

A good reference electrode must reach its potential quickly, be reproducible, and remain stable with time. It must have a practically nonpolarizable metal-solution interface; that is, its potential must not depart significantly from the equilibrium value on the passage of a small current across the interface. The potential of the junction between the electrolytes of the reference and test electrodes must be minimized. These criteria are detailed subsequently.

Stable and Reproducible Potential. Electrodes used as references should rapidly achieve a stable and reproducible potential that is free of significant fluctuations. To obtain these characteristics, it is advantageous, whenever possible, to use reversible electrodes, which can easily be made.

The reference electrode arbitrarily chosen to establish a universal potential scale is the standard hydrogen electrode (SHE). It consists of a platinized or black platinum wire or sheet immersed in an aqueous solution of unit activity of protons saturated with hydrogen gas at a fugacity of one bar (14.5 psia). The half-cell reaction is $H^+(aq) + e^- \leftrightarrow \frac{1}{2}H_2(g)$. Any non-standard reversible hydrogen electrode with well-controlled H^+ activity and H_2 fugacity can also be used as a reference. The equilibrium potential (E_{eq}) of a nonstandard reversible hydrogen electrode versus the SHE is, from the Nernst equation (Eq 25 of the article “Electrode Potentials” in this Section of the volume):

$$E_{eq(H^+/H_2)} = E^\circ_{(H^+/H_2)} + \frac{RT}{F}\ln\frac{a_{H^+}}{\sqrt{f_{H_2}}} \qquad \text{(Eq 1)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

where R is the gas constant, T is the absolute temperature, F is the Faraday constant, a_{H^+} is the proton activity in solution, and f_{H_2} is the H_2 fugacity near the electrode; the SHE potential, $E^o_{(H^+/H_2)}$, is, by convention, equal to zero.

Platinization of a smooth platinum electrode is achieved by electrodeposition from a solution of H_2PtCl_6 of a black platinum layer having a very rough surface and hence a very high specific area. The electrolyte is made up of a mineral acid (HCl or H_2SO_4) with a well-defined activity of H^+. Hydrogen gas is bubbled on the black platinum.

While the hydrogen electrode is the fundamental reference, it has certain disadvantages in real conditions: the electrolyte must be prepared with an accurately known proton activity; the hydrogen gas must be purified, particularly from oxygen; furthermore, the platinum electrode must be frequently replatinized, because it easily gets "poisoned" by the adsorption of impurities present in the solution, which prevents the establishment of the equilibrium potential. For these reasons, practical corrosion measurements are usually not performed with the SHE but with secondary reference electrodes that are easier to construct and handle, less sensitive to impurities, and whose potential is very stable and well- known with respect to the SHE (Ref 1).

The simpler reference electrodes are metal-ion (M^{z+}/M) electrodes, also called metallic electrodes of the first kind. The copper-copper sulfate ($CuSO_4/Cu$) electrode is an excellent example of a good reversible electrode and it is widely used as a reference electrode in the corrosion field. It can easily be made by immersing a copper wire in a glass tube filled with a $CuSO_4$ aqueous solution and terminated by a porous plug (to allow ionic conduction with the cell electrolyte), as shown in Fig. 2.

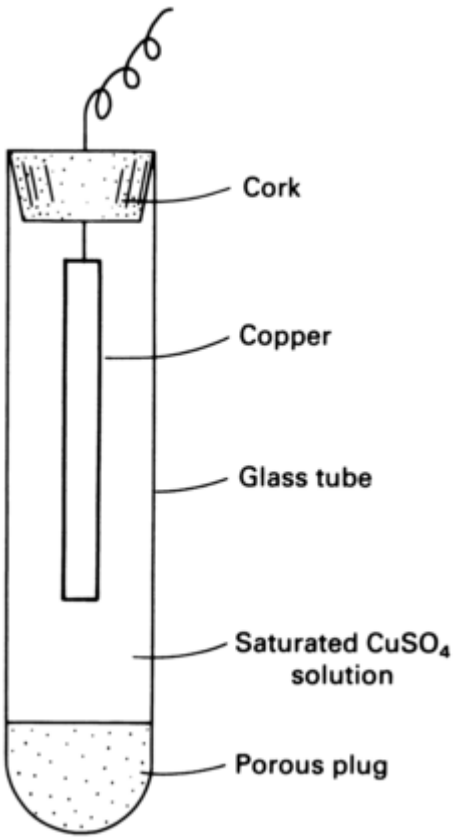

Fig. 2 Schematic of a copper/copper sulfate reference electrode

This electrode is reversible, because a small cathodic current produces the reduction reaction ($Cu^{2+} + 2e^- \rightarrow Cu$), while an anodic current brings about the oxidation reaction ($Cu \rightarrow Cu^{2+} + 2e^-$). Copper is a semi-noble metal and does not dissolve anodically in a solution of protons. In the case of the $CuSO_4/Cu$ electrode, the rest potential is equal to the equilibrium potential that can be computed from the Nernst equation:

$$E_{eq(Cu^{2+}/Cu)} = E^0_{(Cu^{2+}/Cu)} + \frac{RT}{2F} \ln a^{2+}_{Cu} \qquad \text{(Eq 2)}$$

where the standard potential $E^o_{(Cu^{2+}/Cu)} = +0.337$ V versus SHE (see Table 1 in the article "Electrode Potentials" in this Volume), and $a_{Cu^{2+}}$ is the activity of Cu^{2+} in the aqueous solution. If a copper solution of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

concentration 1.00 mol/L is used (where $a_{Cu^{2+}} < 1$), the equilibrium potential of the $CuSO_4/Cu$ electrode takes the value +0.310 V versus SHE at 25 °C (77 °F). This well-defined reversible electrode is reliable and easy to build.

Another common metal-ion electrode is the silver electrode (Ag^+/Ag). The Nernst equation applied to the half-cell reaction $Ag^+ + e^- \leftrightarrow Ag$ gives:

$$E_{eq(Ag^+/Ag)} = E^{\circ}_{(Ag^+/Ag)} + \frac{RT}{F} \ln a_{Ag^+} \qquad \text{(Eq 3)}$$

where the standard potential $E^{o}_{(Ag+/Ag)} = 0.800$ V versus SHE.

Metallic electrodes of the second kind (also called secondary reference electrodes) are similar electrodes where the potential-determining activity of the metallic ion, $a_{M^{z+}}$, in solution is controlled by putting the metal M in contact with a sparingly soluble M compound (salt, oxide, hydroxide), itself in contact with the solution. Then, $a_{M^{z+}}$ is determined by the solubility product of the salt and the activity of the anion.

For example, if silver chloride (AgCl), only slightly soluble in water, is present on the silver surface, then the following equilibrium holds:

$$AgCl \leftrightarrow Ag^+ + Cl^- \qquad \text{(Eq 4)}$$

The equilibrium mass law gives the solubility product as $a_{Ag+} \cdot a_{Cl-} = K_{s(AgCl)}$. Expressing a_{Ag+} from this relation and placing it in Eq 3 leads to the following expression of the equilibrium potential of the Ag^+, Cl^-/AgCl/Ag half-cell:

$$\begin{aligned} E_{(Ag^+,Cl^-/AgCl/Ag)} &= E^{0}_{(Ag^+/Ag)} + \frac{RT}{F} \ln K_{s(AgCl)} \\ &\quad - \frac{RT}{F} \ln a_{Cl^-} \qquad \text{(Eq 5)} \\ &= E_{(Ag^+,Cl^-/AgCl/Ag)} - \frac{RT}{F} \ln a_{Cl^-} \end{aligned}$$

corresponding to the global electrode equilibrium:

$$AgCl + e^- \leftrightarrow Ag + Cl^- \qquad \text{(Eq 6)}$$

The standard potential of this reversible silver-silver chloride (Ag/Cl) electrode is $E^{o}_{(Ag+,Cl-/AgCl/Ag)} = E^{o}_{(Ag+/Ag)} + \ln K_{s(AgCl)}$. At 25 °C, (77 °F), because $E^{o}_{Ag+/Ag} = 0.800$ V/SHE and $K_{s(AgCl)} = 1.78 \cdot 10^{-10}$, $E^{o}_{(Ag+,Cl-/AgCl/Ag)} = +0.222$ V/SHE (Ref 2). From Eq 5, the potential of this type of reference electrode depends on the activity of the anion in solution (Cl^- here), and this activity is controlled by the addition of a soluble salt of this anion (KCl). If a KCl solution of concentration 1.00 mol/L is used (where $a_{Cl-} < 1$), the equilibrium potential of the AgCl/Ag electrode takes the value +0.237 V/ SHE at 25 °C (77 °F). In a saturated KCl solution (where $a_{Cl-} > 1$), it is +0.198 V/SHE (Ref 2).

Figure 3 shows a typical Ag-AgCl electrode. The AgCl coating is made by anodization of the silver wire in a chloride-containing solution. This electrode is easily assembled and can be placed directly into the electrochemical cell. Quite similar are the $Pb/PbSO_4$ and the $Ag-Ag_2O$ (Ref 1, 2).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

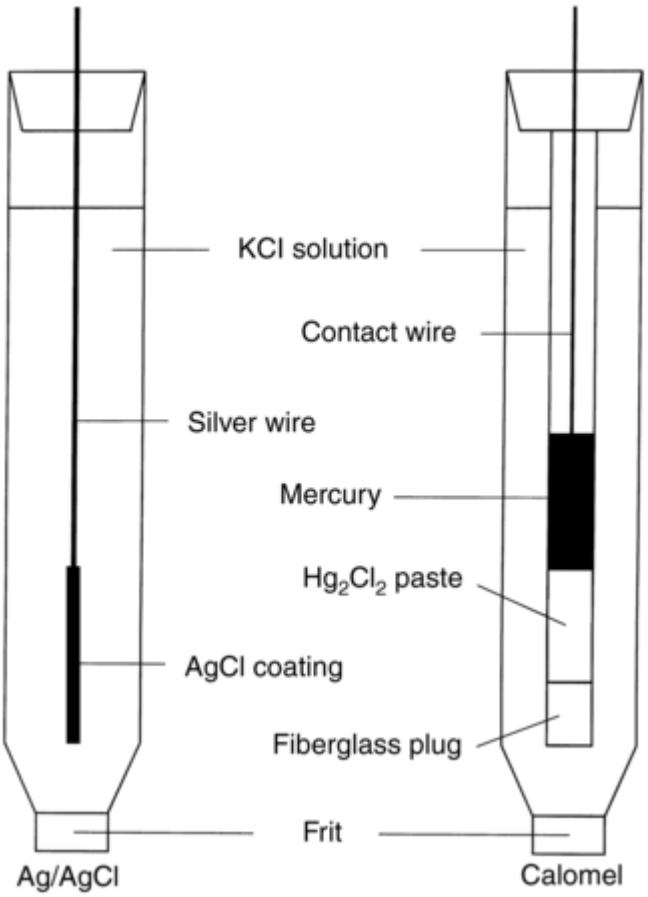

Fig. 3 Schematic of silver-silver chloride and calomel reference electrodes. Source: Ref 12

The most used secondary reference electrode is the calomel electrode (Hg-Hg_2Cl_2). The sparingly soluble salt is, in this case, calomel (Hg_2Cl_2) which floats as a paste on the top of a liquid mercury drop and which, in contact with a KCl solution, dissociates slightly into Hg_2^{2+} and Cl^- ions. Using the same method as for the Ag-AgCl electrode, the following relation is obtained:

$$E_{\left(Hg_2^{2+},Cl^-/Hg_2Cl_2/Hg\right)} = E^\circ_{Hg_2^{2+}/Hg} + \frac{RT}{2F}\ln K_{s(Hg_2Cl_2)} - \frac{RT}{F}\ln a_{Cl^-} = E^\circ_{\left(Hg_2^{2+},Cl^-/Hg_2Cl_2/Hg\right)} - \frac{RT}{F}\ln a_{Cl^-} \quad \text{(Eq 7)}$$

corresponding to the global electrode equilibrium:

$$Hg_2Cl_2 + 2e^- \leftrightarrow 2Hg + 2Cl^- \quad \text{(Eq 8)}$$

Figure 3 shows a typical calomel electrode. A platinum wire connects the electrode to the rest of the circuit. The most usual calomel electrodes are prepared with KCl solutions at a unit molarity of Cl^- (normal calomel electrode or NCE) or saturated calomel electrode or (SCE). At 25 °C (77 °F), $E Hg_2^{2+}, Cl^-/Hg_2Cl_2/Hg$ = 0.268 V/SHE, E_{NCE} = 0.281 V, and E_{SCE} = 0.242 V/SHE (Ref 2). The SCE has the advantage of being the easiest to prepare. However, due to the high temperature dependence of the KCl solubility, its potential varies markedly with temperature (~1 mV/°C as compared to 0.1 mV/°C for the NCE) (Ref 2), so its use makes mandatory the accurate monitoring of the temperature of experiment. Moreover, one must be careful when using a calomel electrode that only very low currents pass through the interface, because HgO may form, which irreversibly spoils the electrode.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Similar reference electrodes for measurements in aqueous solutions are the mercurous sulfate electrode (Hg_2^{2+}, $SO_4^{2-}/Hg_2SO_4/Hg$) in a solution of potassium sulfate, and the mercuric oxide electrode (Hg^{2+}, OH^-/HgO/Hg) in a solution of sodium hydroxide. Their potentials at 25 °C (77 °F) may be found in the literature (Ref 1, 2).

All of these secondary reference electrodes are reversible. In some practical cases, nonreversible electrodes such as graphite are used. Although not as good, their potential stability in a particular environment is considered sufficient for certain applications. In the selection of reference electrodes, their durability and price must also be considered.

Low Polarizability. A good reference electrode must have a practically nonpolarizable metal-solution interface; that is, its potential must not depart significantly from the equilibrium value on the passage across it of a small current (even minimized in the three-electrode device, Fig. 1), because the electrode polarization introduces an error in the potential measurement. The potential versus current density response of a good reference electrode, called a polarization curve, should be as flat as possible.

Consider that the electrode equilibrium is $bO + ne^- = cR$, where O is the oxidized species; R is the reduced species; and n is an integer. The net current density across the interface is proportional to the difference between the anodic and the cathodic rates. If the electrode reaction rate is limited by the electron transfer across the metal-solution interface (electron transfer is slow compared to mass transport of O and R between the bulk solution and the interface), the net current density is simply related to the overpotential $\eta = E - E_{eq}$, where E is the potential, and E_{eq} is the equilibrium potential, by (Ref 3):

$$i = i_0 \exp\left(\frac{-\alpha nF}{RT}\eta\right) - i_0 \exp\left(-\frac{(1-\alpha)nF\eta}{RT}\right) \qquad \text{(Eq 9)}$$

where i_0 is the exchange current density of the electrode reaction; and α is the charge transfer coefficient for the anodic reaction ($0 < \alpha < 1$), whose value is close to 0.5 for a single-step reaction ($n = 1$). (More detailed information on polarization curves can be found in the articles “Kinetics of Aqueous Corrosion” and “Electrochemical Methods of Corrosion Testing” in this Volume).

For potentials close to the equilibrium potential, such as $\eta < RT/F$ (26 mV at room temperature), the relation (Eq 9) can be approximated by a linear i versus η dependence:

$$i = i_0\left(\frac{nF}{RT}\right)\eta \qquad \text{(Eq 10)}$$

or

$$\eta = \left(\frac{RT}{nFi_0}\right)i \qquad \text{(Eq 11)}$$

The term $RT/nFi_0 = (d\eta/di)_0$ is called the polarization resistance, R_p. A good reference electrode should have a low polarization resistance, which implies high exchange current density. This happens for high rate constants for the anodic and cathodic reactions and high concentrations of reacting species O and R. With regard to this criterion, the SHE that has $i_0 > 10^{-3}$ A/ geometric cm^2 is a particularly good reference electrode (Ref 3).

It is a question of judgment how polarizable the reference electrode can be. The answer depends on the precision required and the impedance of the voltmeter used. A high-impedance voltmeter (10^{12} ohms) may provide acceptable results with a relatively polarizable electrode.

The Liquid Junction Potential. Reference electrodes are usually made of a metal immersed in a well-defined electrolyte. In the case of the $CuSO_4$/Cu electrode, the electrolyte is a saturated $CuSO_4$ aqueous solution; for the SCE, it is a saturated KCl solution. This electrolyte that characterizes the reference electrode must come into contact with the liquid environment of the test electrode to complete the measuring circuit (Fig. 4). There is direct contact between different aqueous media. The difference in chemical composition of the two solutions produces a phenomenon of interdiffusion. In this process, except for a few electrolytes such as KCl, the cations and anions move at different speeds. As an example, in hydrogen chloride (HCl) solution in contact with another medium, the H^+ ions move faster than the Cl^- ions. As a result, a charge separation appears at the limit between the two liquids, the liquid junction. This produces a potential difference called the liquid junction potential, which is included in the measured voltage, V, as expressed in:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$V = V_T - V_R + V_{LJP} \quad \text{(Eq 12)}$$

where V_T is the test potential to be measured, V_R is the reference electrode potential, and V_{LJP} is the unknown liquid junction potential.

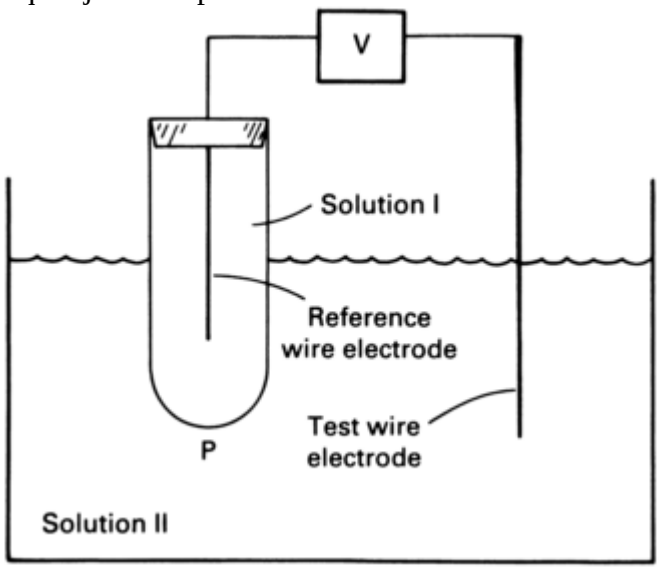

Fig. 4 Schematic of an electrochemical cell with liquid junction potential. P, interface; V, voltmeter

In order to determine V_T, the liquid junction potential must be eliminated or minimized. The best way, when possible, is to design a reference electrode using an electrolyte identical to the solution in which the test electrode is immersed (Fig. 4). However, in most cases this is not possible, and the best approach is to minimize the liquid junction potential by using a reference electrolyte with a chemical composition as close as possible to the corrosion environment. The use of a solution of KCl (such as in the calomel electrode) offers a partial answer. The diffusion rates of potassium (K^+) and chloride (Cl^-) ions are similar. In contact with another electrolyte, a KCl solution does not produce much charge separation and, consequently, no significant liquid junction potential. The ions present in the other solution, however, also diffuse, and they may do so at different rates, thus producing some separation of charge at the interface (P in Fig. 4).

The remaining liquid junction potential, after minimization, constitutes an error that is frequently accepted in electrode potential measurements, especially when compared with results determined under similar experimental conditions. While liquid junction potentials must be minimized as much as possible, there is no general solution for this; each individual case must be well thought out.

Operating Conditions for Reference Electrodes

When a reference electrode has been selected for a particular application, its proper use requires caution and specific measurement conditions. When measuring the potential of a polarized test electrode versus a reference electrode, it is important not to polarize or damage the latter by applying a significant current density. Also, the ohmic (*IR*) drop must be minimized.

Very Low Current Density. It is important to use a reference electrode that operates at its known open-circuit potential and thus avoid applying any significant overpotential to it. This is achieved by using a high-impedance voltmeter that has a negligible input current and, for test electrode polarization measurements, by using an auxiliary electrode in a three-electrode system (Fig. 1).

The value tolerated for the maximum overpotential on the reference electrode, at the condition that it stays under the limit over which the electrode suffers irreversible damages (like the calomel electrode), is a matter of judgment that depends on the accepted magnitude of error in the particular case under investigation. The use of an electrometer or a high-impedance voltmeter (10^{12} ohms) fulfills the usual requirements. When a lower impedance instrument is used, an unacceptable overpotential could result if the electrode is too polarizable.

The *IR* Drop and Its Mitigation. The *IR* drop is an ohmic voltage that results from electric current flow in ionic solutions. Electrolytes have an ohmic resistance; when a current passes through them, an *IR* voltage can be observed between two distinct points. When the reference electrode is immersed at some distance from a working or test electrode, it is in the electric field somewhere along the current path. An electrolyte resistance exists along the path between the test and the reference electrodes. As current flows through that path, an *IR* voltage appears in the potential measurement according to:

$$V = V_T - V_R + IR \qquad \text{(Eq 13)}$$

where V_T is the test potential to be measured, V_R is the reference electrode potential, and *IR* is the ohmic drop. In this case, the liquid junction potential has been neglected. The *IR* drop constitutes a second unknown value in a single equation. It must be eliminated or minimized.

The Luggin capillary is a tube, usually made of glass, that has been narrowed by elongation at one end. The narrow end is placed as close as possible to the test electrode surface (Fig. 1), and the other end of the tube goes to the reference electrode compartment. The Luggin capillary is filled with cell electrolyte, which provides an electric link between the reference and the test electrode. The use of a high-impedance voltmeter prevents significant current flow into the reference electrode and into the capillary tube between the test electrode and the reference electrode compartment (Fig. 1). This absence of current eliminates the *IR* drop, and the measurement of V_T is then possible. A residual *IR* drop may, however, exist between the tip of the Luggin capillary and the test electrode. This is usually negligible, however, especially in high-conductivity media.

The remote electrode technique can be used only for measurement in an electrolyte with very low resistivity, usually in the laboratory. It is applicable, for example, in a molten salt solution, in which the ohmic resistance *R* is very small. In such a case, the reference electrode can be placed a few centimeters away from the test electrode, because the *IR* drop remains negligible. In other electrolytes (for example, in measurements in soils), the ohmic resistance is rather large, and the *IR* drop cannot be eliminated in this manner.

The Current Interruption Technique. In this case, when the current is flowing, the *IR* drop is included in the measurement. A recording of the potential is shown in Fig. 5. At time t_1, the current is interrupted so that $I = 0$ and $IR = 0$.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

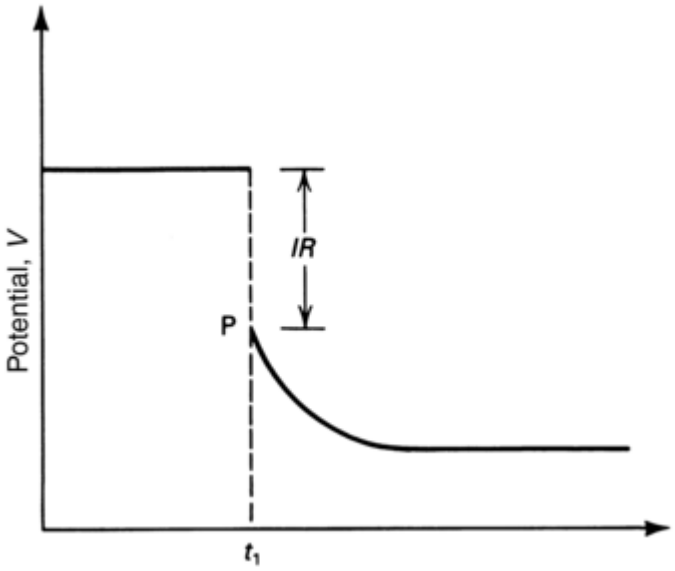

Fig. 5 The potential decay at current interruption. *IR* is the potential drop due to the electrolyte ohmic resistance.

At the moment of the interruption, however, the electrode is still polarized, as can be seen at point P in Fig. 5. The progressive capacitance discharge and depolarization of the test electrode take some time. The potential measured at the instant of interruption then represents the test electrode potential corrected for the *IR* drop. Precise measurements of this potential are obtained with an oscilloscope.

Potential Conversion Between Reference Electrodes. Due to the number of different reference electrodes used, each potential measurement must be accompanied by a clear statement of the reference used. It is often needed to express electrode potentials versus a particular reference, regardless of the actual reference used in the measurement. The procedure is illustrated in the following example. The electrode potential of a buried steel pipe is measured with respect to a $CuSO_4$/Cu electrode, and the value is -650 mV for a pH 4 environment. If that value is mistakenly placed in the iron *E*-pH (Pourbaix) diagram (Fig. 1 in the article "Potential versus pH (Pourbaix) Diagrams" in this Volume), it could be concluded that corrosion will not occur. This conclusion, however, would be incorrect, because the *E*-pH (Pourbaix) diagrams are always computed with respect to the SHE. It is then necessary to express the measured electrode potential with respect to the SHE before consulting the *E*-pH (Pourbaix) diagram. The $CuSO_4$/Cu electrode potential is +310 mV versus SHE, so this value must be added to the measured potential: E_{SHE} = -650 + 310 = -340 mV. The principle of this conversion is illustrated in the electrode potential conversion diagram of Fig. 6.

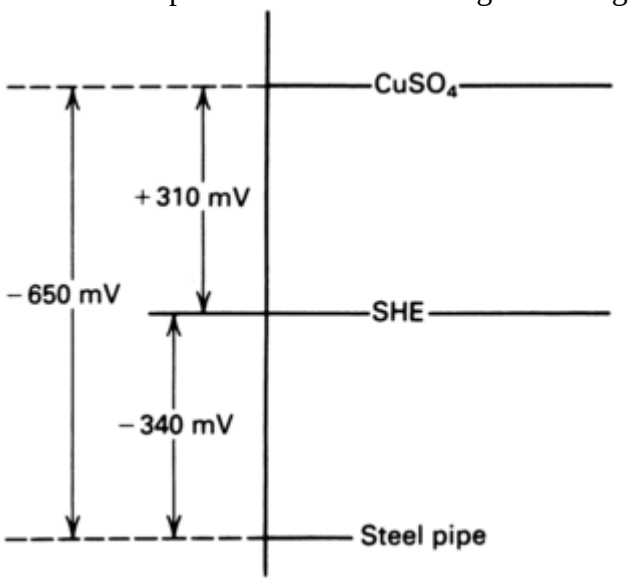

Fig. 6 Diagram of potential conversion between reference electrodes. SHE, standard hydrogen electrode; $CuSO_4$, copper-copper sulfate electrode. SHE, standard hydrogen electrode

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The value of -340 mV placed in the *E*-pH Pourbaix diagram at a pH 4 clearly lies in the corrosion region for iron. It would then be definitely necessary to consider the cost benefit of a protection system for the steel pipe.

Potential versus pH (Pourbaix) Diagrams

E. Protopopoff and P. Marcus, CNRS, Ecole Nationale Supérieure de Chimie de Paris, Université Pierre et Marie Curie

Introduction

THE PRINCIPLE OF POTENTIAL-pH DIAGRAMS was established in the 1940s in Belgium by Marcel Pourbaix (Ref 1, 2, 3, 4). A potential- pH diagram is a graphical representation of the relations, derived from the Nernst equation, between the pH and the equilibrium potentials (*E*) of the most probable electrochemical reactions occurring in a solution containing a specific element. The standard equilibrium potentials are computed from thermodynamic data (standard chemical potentials, or Gibbs free energies of formation). The equilibrium relations drawn for a given concentration of the element or for a given ratio of activities of two dissolved species of the element give *E*-pH lines. The representation of the equilibrium pHs for acid-base reactions (independent of the potential) gives vertical lines. All those lines delimit *E*-pH domains of stability for the various species of the element, metal, ions, oxides, and hydroxides. Potential- pH diagrams synthesize many important types of information that are useful in corrosion and in other fields. They make it possible to discern at a glance the stable species for specific conditions of potential and pH (Ref 1, 2, 3, 4).

The principle of *E*-pH diagrams may be simply understood with the case of iron in water. Corrosion in deaerated water is expressed by the electrochemical reaction $Fe \rightarrow Fe^{2+} + 2e^-$. The equilibrium potential for the Fe^{2+}/Fe couple can be calculated using the Nernst equation:

$$E_{Fe^{2+}/Fe} = E^{\circ}_{Fe^{2+}/Fe} + \frac{RT}{2F} \ln a_{Fe^{2+}} \qquad \text{(Eq 1)}$$

where $E^{o}_{Fe^{2+}/Fe}$ is the standard potential value for the couple, *R* is the gas constant, *T* is the absolute temperature, *F* is the Faraday constant, and $a_{Fe^{2+}}$ is activity for the ferrous ion in solution.

For a given temperature and Fe^{2+} concentration (activity $a_{Fe^{2+}}$), the equilibrium potential is constant and is represented as a horizontal line in a *E*-pH diagram (Fig. 1). This line indicates the potential at which Fe and Fe^{2+} at a given concentration are in equilibrium and can coexist with no net tendency for one to transform into the other. At potentials above the line, iron metal is not stable and tends to dissolve as Fe^{2+}, hence the Fe^{2+} concentration increases until a new equilibrium is reached; this is a domain of stability for Fe^{2+}. At potentials below the equilibrium line, the stability of the metallic iron increases, Fe^{2+} tends to be reduced, and thus its concentration decreases; this is the domain of stability for the metal (Fig. 1).

مرجع مهندسی مواد و متالورژی

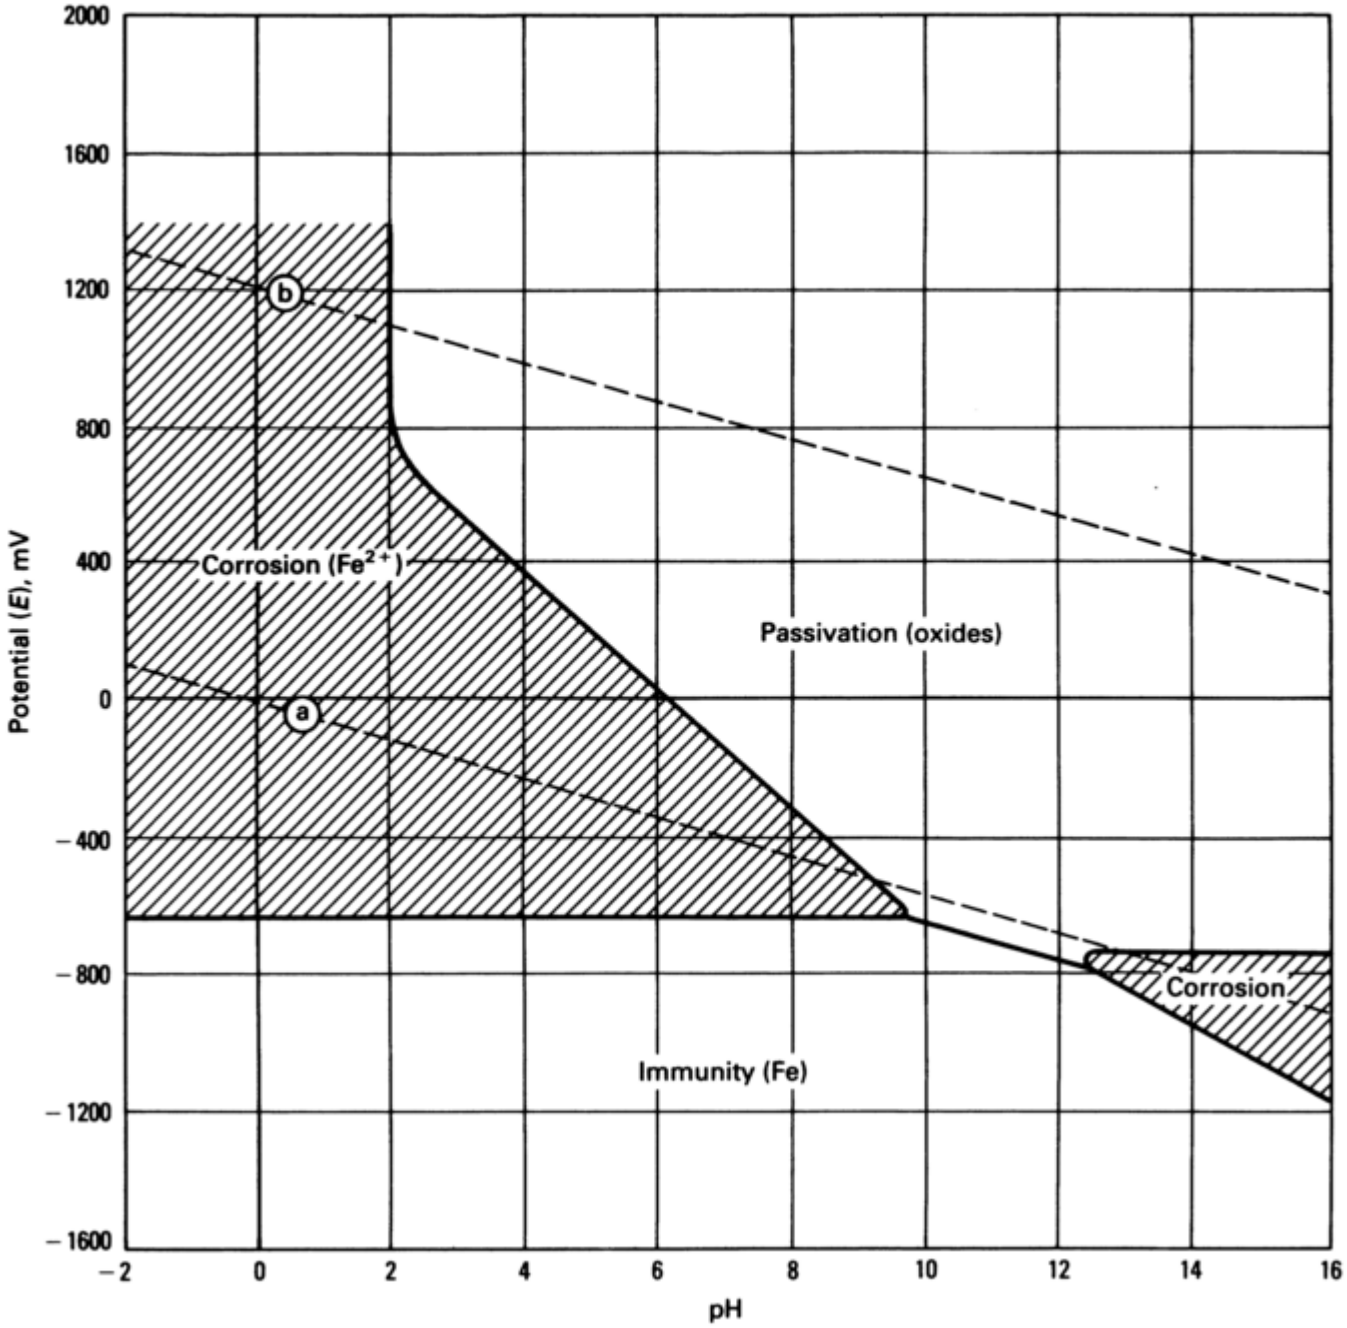

Fig. 1 Iron *E*-pH diagram. Dashed lines a and b are explained in Fig. 7 and in the corresponding text.

The diagrams of all metal-water systems have the same common features; the lower *E*-pH lines give the limit between the domain of stability of the metal and the domain of stability of either the first metallic ion or the first metallic oxide.

For *E*-pH conditions below these lines, the metal is stable, and corrosion cannot take place. This is the immunity region (Fig. 1).

For *E*-pH conditions above the line for the equilibrium between the metal and the first metallic ion, the metal is not stable, and it tends to be oxidized and dissolved into ions. The system is then in the corrosion or activity region of the diagram. Besides the main corrosion region in the stability domains of the metallic ions at low pH (acid corrosion), there is generally also a smaller domain of stability of oxygenated metallic ions at high pHs, leading to alkaline corrosion (Fig. 1).

When the reaction of the metal with water produces an oxide (or hydroxide) that forms a protective layer, the metal is said to be passivated. For *E*-pH conditions above the lines for the metal-oxide and ion-oxide equilibria, the system is in the passivation region (Fig. 1).

Diagrams such as Fig. 1, (Ref 1, 2, 3, 4), have proved to be useful in corrosion as well as in many other fields, such as industrial electrolysis, plating, electrowinning and electrorefining of metals, primary and secondary

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

electric cells, water treatment, and hydrometallurgy. It is important to emphasize that these diagrams are based on thermodynamic calculations for a number of selected chemical species and the possible equilibria between them. It is possible to predict from a *E*-pH diagram if a metal will tend to corrode or not. It is not possible, however, to determine from these diagrams alone how long a metal will resist corrosion. Pourbaix diagrams offer a framework for kinetic interpretation, but they do not provide information on corrosion rates (Ref 3). They are not a substitute for kinetic studies. Each *E*-pH diagram is computed for selected chemical species corresponding to the possible forms of the element considered in the solution under study. The addition of one or more elements, for example, carbon, sulfur, or chlorine, to a system will introduce new equilibria. Their representation in the *E*-pH diagram will produce a new diagram more complex than the previous one.

Calculation and Construction of *E*-pH Diagrams

Potential-pH diagrams are based on thermodynamic calculations. The equilibrium lines that set the limits between the various stability domains are calculated for the various electrochemical or chemical equilibria between the chemical species considered. There are three types of reactions to be considered:

- Electrochemical reactions of pure charge (electron) transfer
- Electrochemical reactions involving both electron and solvated proton (H^+) transfer
- Acid-base reactions of pure H^+ transfer (no electrons involved)

Pure Charge Transfer Reactions. These electrochemical reactions involve only a reduced species on one side and an oxidized species and electrons on the other side. They have no solvated protons (H^+) as reacting particles; consequently, they are not influenced by pH. An example of a reaction of this type is the oxidation/reduction of Ni/Ni^{2+}: $Ni \rightleftharpoons Ni^{2+} + 2e^-$. From the Nernst equation (Eq 1), the equilibrium potential for the couple Ni^{2+}/Ni can be written:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$E_{Ni^{2+}/Ni} = E^{\circ}_{Ni^{2+}/Ni} + \frac{RT}{2F}\ln a_{Ni^{2+}}$$
$$= E^{\circ}_{Ni^{2+}/Ni} + \frac{RT}{2F}\ln 10 \log a_{Ni^{2+}} \qquad \text{(Eq 2)}$$
$$= E^{\circ}_{Ni^{2+}/Ni} + 2.303\frac{RT}{2F}\log a_{Ni^{2+}}$$

where $E^{o}_{(Ni^{2+}/Ni)}$ is the standard potential for the couple and $a_{Ni^{2+}}$ is the activity of Ni^{2+} in the solution; *R*, *T*, and *F* are defined in Eq 1; at a temperature of 25 °C (298.15 K), $RT \ln 10/F \approx 0.059$ V.

The potential depends on the Ni^{2+} activity but not on H^{+} ions. It is then independent of the pH. For a given value of $a_{Ni^{2+}}$, it is represented by a horizontal line in a *E*-pH diagram.

The standard potential, E^{o}, is:

$$E^{\circ}_{Ni^{2+}/Ni} = \frac{\mu^{0}_{Ni^{2+}} + \mu^{0}_{e^-} - \mu^{0}_{Ni}}{2F} \qquad \text{(Eq 3)}$$

By convention, at 25 °C (298.15 K), the standard chemical potentials of a species under elemental form and of the conventional electron are equal to 0. This gives $\mu^{0}_{Ni} = \mu^{0}_{e^-} = 0$ and simplifies the previous equation:

$$E^{\circ}_{Ni^{2+}/Ni}(298.15\ \text{K}) = \frac{\mu^{0}_{Ni^{2+}}}{2F}(298.15\ \text{K}) \qquad \text{(Eq 4)}$$

The values of the standard chemical potentials at 25 °C are found in the *Atlas of Electrochemical Equilibria* (Ref 4) or listed as standard Gibbs free energies of formation in tables of chemical thermodynamic properties (Ref 5) or in specialized papers. They are given for the formation of the substance from its elements in their standard states. The standard state for the dissolved species is the hypothetical ideal solution of the substance at unit molality (number of moles of the species per kilogram of water). At 25 °C, the numerical value of the molality may be approximated by the value of the molarity in number of moles per liter of water.

If the value of $\mu^{0}_{Ni^{2+}}$ at 25 °C is −48.2 kJ/mol (Ref 4), the standard potential is:

$$E^{\circ}_{Ni^{2+}/Ni}(298.15\ \text{K}) = \frac{-48,200}{2\times 96,487} = -0.25\ \text{V} \qquad \text{(Eq 5)}$$

This result can be introduced into Eq 2 to give the equilibrium potential for the couple Ni^{2+}/Ni at 25 °C:

$$E_{Ni^{2+}/Ni}(298.15\ \text{K}) = -0.25 + 0.030\log a_{Ni^{2+}} \qquad \text{(Eq 6)}$$

As previously stated, this potential depends only on the activity of Ni^{2+}, not on the pH. It is usually assumed in *E*-pH diagrams that the solution behaves ideally; that is, the activity coefficient of each dissolved species is unity, so the activity of the species is simply equal to the numerical value of its molality (or molarity at 25 °C). This assumption is reasonably accurate for molalities of less than 10^{-3} mol/kg in the pH range 2 to 12. Outside these limits, the Pourbaix diagram is valid only for activities, and molalities must be corrected.

It is customary to select four molalities (molarities at 25 °C): 1 or 10^{0}, 10^{-2}, 10^{-4}, and 10^{-6} mol/kg (mol/L) to show the effect of ion concentration. This will provide four horizontal lines, as shown in Fig. 2:

- At an activity of 10^{o}, $E_{Ni^{2+}/Ni} = E^{o}_{Ni^{2+}/Ni} = -0.25$ V
- With 10^{-2}, $E_{Ni^{2+}/Ni} = -0.25 + 0.030 \log 10^{-2} = -0.31$ V
- With 10^{-4}, $E_{Ni^{2+}/Ni} = -0.37$ V
- With 10^{-6}, $E_{Ni^{2+}/Ni} = -0.43$ V

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

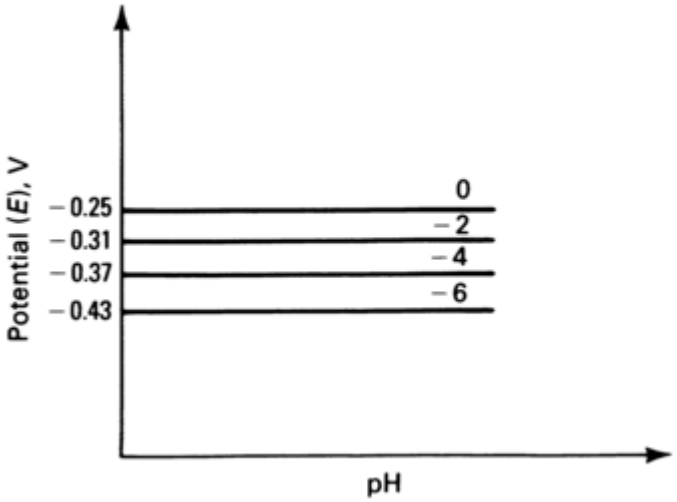

Fig. 2 Partial *E*-pH diagram for the equilibrium $Ni^{2+} + 2e^- = Ni$ for various values of log $a_{Ni^{2+}}$

For any activity of Ni^{2+} in the solution, a horizontal line represents the potential at which nickel ions at the given activity and nickel metal are in equilibrium. Above the line is the region of stability of Ni^{2+} ions at a higher activity; nickel metal at these potentials will tend to corrode (dissolve) and produce Ni^{2+}, the stable species. Below the line, Ni^{2+} ions will tend to be reduced into metallic nickel, and nickel in this condition is stable and will not corrode (dissolve). It is immune to corrosion.

Reactions Involving Both Electron and Proton Transfer. Consider a typical electrochemical reaction with proton transfer in an aqueous electrolyte:

$$bO + mH^+ + ne^- \rightleftharpoons cR + dH_2O \qquad \text{(Eq 7)}$$

where O and R are the oxidized and the reduced form of the considered element, respectively; *b*, *m*, *c*, and *d* are stoichiometric coefficients; and *n* is an integer.

From the Nernst equation, the equilibrium potential is equal to:

$$E_{eq(O/R)} = \frac{\Delta G_{ox}}{nF} = \frac{\Delta G^\circ_{ox}}{nF} + \frac{RT}{nF} \ln \frac{(a_O)^b (a_{H^+})}{(a_R)^c (a_{H_2O})} \qquad \text{(Eq 8)}$$

with Δ_{ox} $E^o_{(O/R)} = -\Delta G^0_{red}/nF = (b\mu^0_O + m\mu^0_{H^+} + n\mu^0_{e^-} - c\mu^0_R - d\mu^0_{H_2O})/nF$; where ΔG^0_{red} is the standard Gibbs free energy charge of reduction. The activity of water can be taken equal to unity in not too concentrated aqueous solutions. If O or R is a pure solid phase (oxide, hydroxide, or metal), a_O or a_R is equal to unity. The pH of the solution is pH = -log aH^+. Hence:

$$E_{eq(O/R)} = E^\circ_{eq(O/R)} + 2.303 \frac{RT}{nF} \log \frac{(a_O)^b}{(a_R)^c} - 2.303 \frac{mRT}{nF} pH \qquad \text{(Eq 9)}$$

This equation shows that the equilibrium potential corresponding to a given ratio $r = (a_O)^b / (a_R)^c$ is a linear function of pH (decreasing if *m* is positive).

As an example, nickel can react with water to form an oxide, according to the electrochemical reaction:

$$Ni + H_2O \rightleftharpoons NiO + 2H^+ + 2e^- \qquad \text{(Eq 10)}$$

The Nernst equation can be written as follows:

$$E_{NiO/Ni^{2+}} = E^\circ + 2.303 \frac{RT}{zF} \log \frac{a_{NiO}}{a_{Ni}} - 2.303 \frac{RT}{F} pH \qquad \text{(Eq 11)}$$

where the standard potential E^o is given by:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$E^\circ = \frac{\left(\mu^0_{NiO} + 2\mu^0_{H^+} + 2\mu^0_{e^-} - \mu^0_{Ni} - \mu^0_{H_2O}\right)}{2F}$$

From the data in Ref 4:

$$E^\circ\,(298.15\ \text{K}) = \frac{\left(-215{,}940 + 0 + 0 - 0 - \left(-237{,}190\right)\right)}{\left(2 \times 96{,}487\right)}$$

$$= +0.11\ \text{V}$$

The NiO and Ni are solid phases, and they are considered to be pure; their activity is therefore 1. Equation 11 can then be simplified, and the equilibrium potential at 25 °C becomes:

$E_{eq(NiO/Ni)}(298.15\ \text{K}) = +0.11 - 0.059\ \text{pH}$ (Eq 12)

In this case, the equilibrium potential decreases with an increase in pH, as represented in the partial *E*-pH diagram of Fig. 3. The diagonal line gives the value of the equilibrium potential of the NiO/Ni couple at all pH values. Above the line, NiO is stable, and below it, nickel metal is stable.

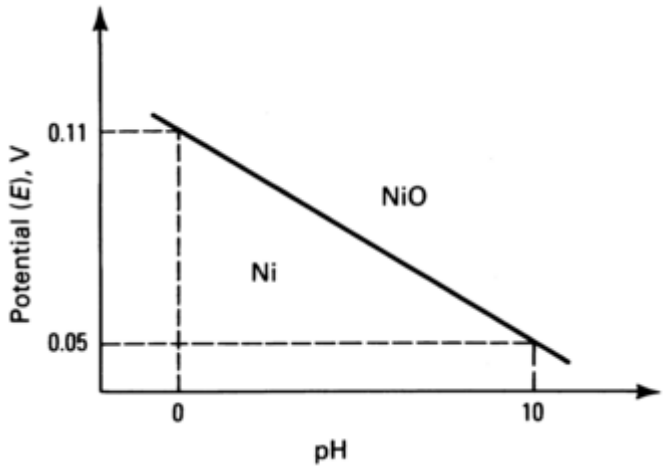

Fig. 3 Partial *E*-pH diagram for the equilibrium Ni + H_2O = NiO + $2H^+$ + $2e^-$

Potential-pH diagrams are very general and can also be applied to electrochemical reactions involving nonmetallic elements. An example involving the reduction of nitrite ion (NO_2^-) to ammonium ion (NH_4^+) is given here. In this case, the metal of the electrode supports the reaction by giving or taking away electrons, as follows:

$$NO_2^- + 8H^+ + 6e^- \rightleftharpoons NH_4^+ + 2H_2O$$

The Nernst equation gives:

$$E = E^\circ + 2.303\left(\frac{RT}{6F}\right)\log\frac{a_{NO_2^-}}{a_{NH_4^+}} - 2.303\frac{8RT}{6F}\text{pH} \qquad \text{(Eq 13)}$$

where the standard potential is expressed as:

$$E^\circ = \frac{\left(\mu^0_{NO_2^-} + 8\mu^0_{H^+} + 6\mu^0_{e^-} - \mu^0_{NH_4^+} - 2\mu^0_{H_2O}\right)}{6F}$$

From the data in Ref 4:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$E^\circ(298.15\ \mathrm{K}) = \frac{(-34{,}520 + 0 + 0 - (-79{,}500) - 2(-237{,}190))}{(6 \times 96{,}487)}$$
$$= +0.90\ \mathrm{V}$$

The equilibrium potential at 25 °C is then given by:

$$E(298.15\ \mathrm{K}) = 0.90 + 0.010 \log \frac{a_{NO_2^-}}{a_{NH_4^+}} - 0.079\ \mathrm{pH} \qquad \text{(Eq 14)}$$

This *E*-pH relation is represented for equal activity in NO_2^- and NH_4^+ by the line drawn in Fig. 4.

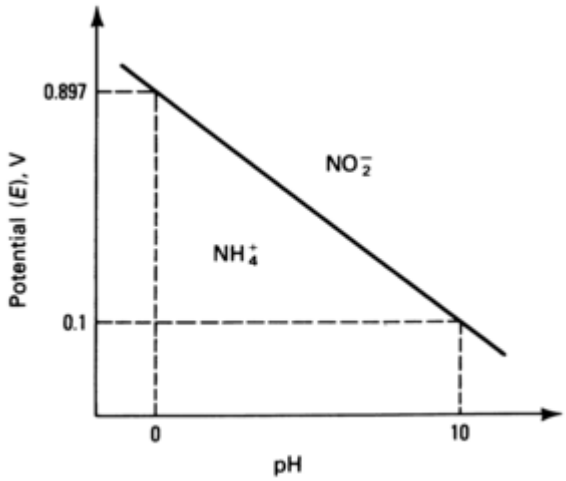

Fig. 4 Partial *E*-pH diagram for the equilibrium NO_2^- + 8H$^+$ + 6*e*$^-$ = NH_4^+ + 2H$_2$O

Above the line, the ratio (a_{NO-2}/a_{NH+4}) is higher than unity, so this is a region where NO_2- is predominantly stable. Below the line, the ratio (a_{NO-2}/a_{NH+4}) is lower than unity, so this is a region where NH_4+ is predominantly stable.

Acid-Base Reactions. Consider a typical acid-base chemical reaction in aqueous solution, between the acid form C and the basic form B:

$$c\mathrm{C} + d\mathrm{H_2O} = b\mathrm{B} + m\mathrm{H^+} \qquad \text{(Eq 15)}$$

When the reaction is in thermodynamic equilibrium:

$$\Delta_r G^0 = b\mu_B^0 + m\mu_{H^+}^0 - c\mu_C^0 - d\mu_{H_2O}^0$$
$$= -2.303RT \log \mathrm{K_{eq}}$$

where $\Delta_r G^0$ is the standard Gibbs free energy change, μ^0 represents the standard chemical potentials of the different substances, and K_{eq} is the equilibrium constant for the reaction: $K_{eq} = (a_B)^b(a_{H+})^m/(a_C)^c(a_{H_2O})^d$.

The activity of water may be taken equal to unity in not too concentrated aqueous solutions. If B or C is a pure solid phase (metal, oxide, or hydroxide), a_B or a_C is equal to unity. Using pH = $-\log a_{H+}$, the previous equation may be rearranged as:

$$\log \mathrm{K_{eq}} = \log \frac{(a_B)^b}{(a_C)^c} - m\mathrm{pH} = \frac{-\Delta_r G^0}{2.303RT} \qquad \text{(Eq 16)}$$

This equation shows that the ratio of the activities of the basic form to the acid form increases with pH. The pH at equilibrium corresponding to a given ratio $r = (a_B)^b/(a_C)^c$ can be determined from:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$pH_{eq} = \frac{pK_{eq}}{m} + \frac{(\log r)}{m} \qquad \text{(Eq 17)}$$

with $pK_{eq} = -\log K_{eq} = \Delta_r G^0/2.303\,RT$.

This equilibrium pH does not depend on the potential and will be represented on the *E*-pH diagram by a vertical line. As an example, in the case of cobalt, Co^{2+} and CoO are involved in an acid-base reaction:

$$Co^{2+} + H_2O \rightleftharpoons CoO + 2H^+ \qquad \text{(Eq 18)}$$

CoO and H_2O both have activities of 1, so the application of Eq 17 gives:

$$pH_{eq} = \frac{pK_{eq}}{2} - \frac{(\log a_{Co^{2+}})}{2} \qquad \text{(Eq 19)}$$

with:

$$pK_{eq} = (\mu^0_{CoO} + 2\mu^0_{H^+} - \mu^0_{Co^{2+}} - \mu^0_{H_2O})/2.303RT.$$

By replacing the standard chemical potentials by their values given in the *Atlas of Electrochemical Equilibria* (Ref 4):

$$pK_{eq}(298.15\ K) = \frac{(-218{,}860 + 0 - (-53{,}560) - (-237{,}190))}{(8.3143 \times 298.15 \times 2.303)} = 12.6$$

and finally:

$$pH_{eq}(298.15\ K) = 6.3 - \frac{(\log a_{Co^{2+}})}{2}$$

Thus, for an activity unity for Co^{2+}, pH_{eq} = 6.3. This value can also be obtained by the intersection of two equilibrium *E*-pH lines. As shown previously for nickel, there are electrochemical equilibria between the metal and its first ion (Co^{2+}) and between the metal and its first oxide (CoO). It is possible to determine the equilibrium *E*-pH lines for the couples Co^{2+}/Co and CoO/Co, as shown in Fig. 5. The two lines intersect at point P, and above them are the domains of stability for Co^{2+} and CoO. The boundary between these two domains is a vertical line containing point P and located at pH 6.3 for $a_{Co^{2+}} = 1$ (Fig. 5).

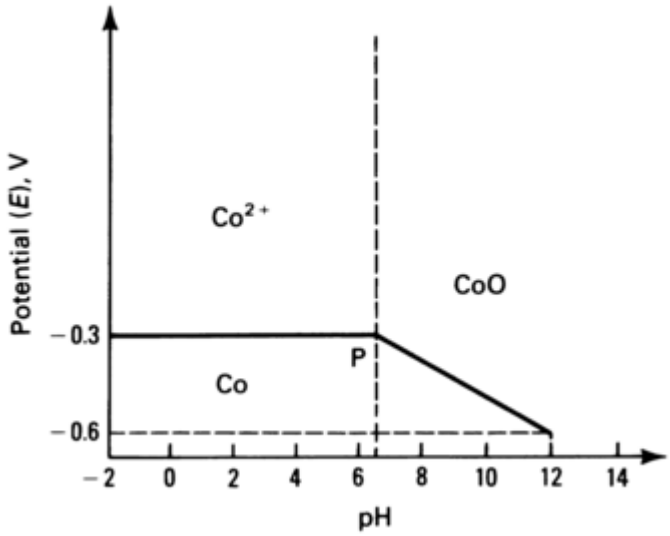

Fig. 5 Partial *E*-pH diagram for the Co^{2+}/Co and CoO/Co couples for $a_{Co^{2+}} = 1$

Figure 6(a) shows a partial *E*-pH diagram for different values of $\log a_{Co^{2+}}$ in which only three chemical species—Co, Co^{2+}, and CoO (or the hydroxide $Co(OH)_2$)—are considered. There are, however, other possible

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

chemical species, dissolved or solid, that must be considered. This introduces new equilibria that modify the diagram to give Fig. 6(b).

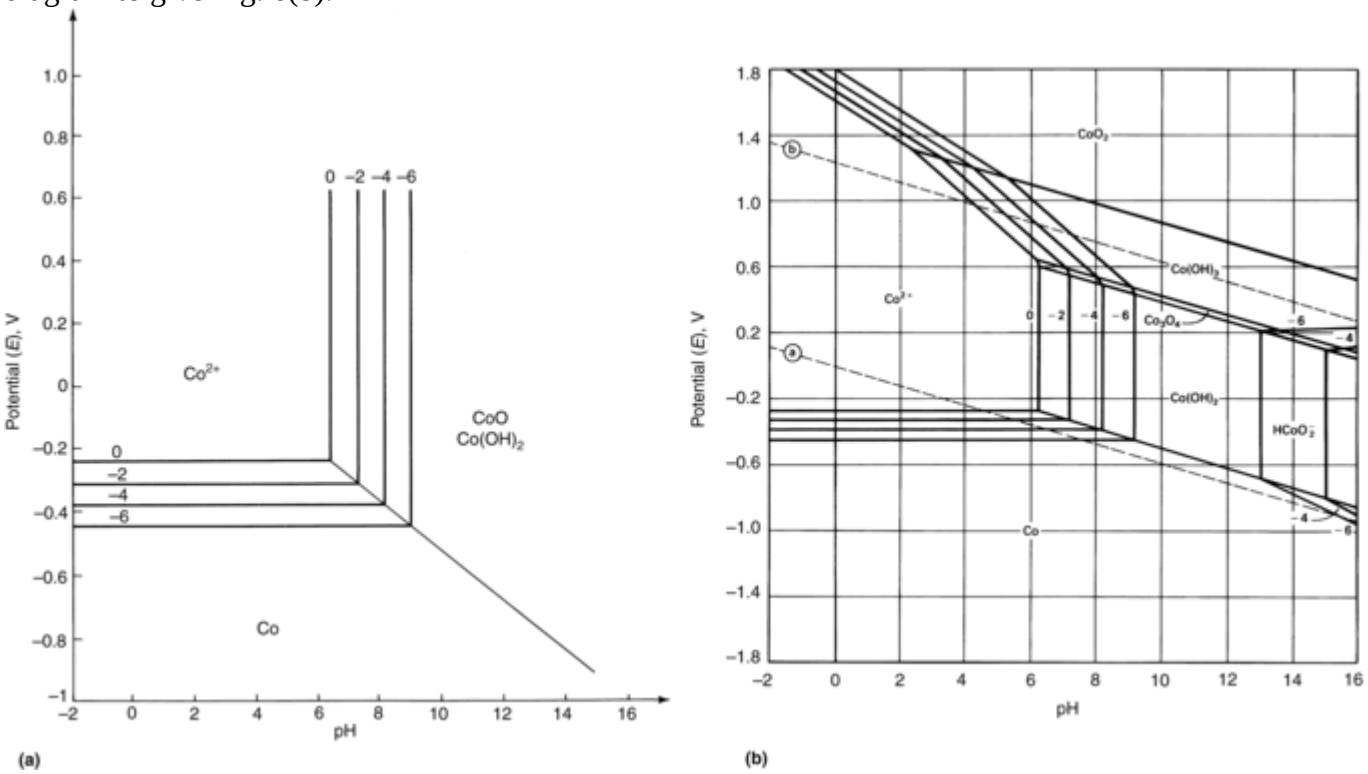

Fig. 6 *E*-pH diagram for the cobalt-water system for various values of log $a_{Co^{2+}}$. (a) Partial *E*-pH diagram. (b) Complete *E*-pH diagram

The Water *E*-pH Diagram. Pourbaix diagrams are traced for equilibrium reactions taking place in water; consequently, the water system must always be considered at the same time as the system under investigation in any *E*-pH diagram. Water can be decomposed into oxygen and hydrogen, according to the following electrode reactions:

$$2H_2O_{(l)} + 2e^- \rightleftharpoons H_{2(g)} + 2OH^-_{(aq)} \qquad \text{(Eq 20)}$$

and

$$H_2O_{(l)} \rightleftharpoons \tfrac{1}{2}O_{2(g)} + 2H^+_{(aq)} + 2e^-$$

Considering the equilibrium of water dissociation/ionization into solvated protons and hydroxide ions:

$$H_2O_{(l)} \rightleftharpoons H^+_{(aq)} + OH^+_{(aq)}$$

equilibria (Eq 20) may also be written as:

$$2H^+_{(aq)} + 2e^- \rightleftharpoons H_{2(g)}$$

and

$$2OH_{(aq)} \rightleftharpoons \tfrac{1}{2}O_{2(g)} + H_2O_{(l)} + 2e^-$$

The equilibrium potentials of these two electrochemical reactions can be determined by using the Nernst equation. For the water/hydrogen or proton/hydrogen couple:

$$E_{H^+/H_2} = E^\circ_{H^+/H_2} - \frac{2.303\,RT}{2F}\log f_{H_2} - \frac{2.303\,RT}{F}\,\mathrm{pH} \qquad \text{(Eq 21)}$$

where f_{H_2} is the fugacity or pressure of hydrogen near the electrode (in fact, dimensionless fugacity is equal to the numerical value of the fugacity expressed in bar). At 25 °C (298.15 K), because, by definition, $E^\circ_{H^+/H_2} = 0$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

V/SHE (see the article “Electrode Potentials” in this Section of the Volume), the previous equation can be rewritten as:

$$E_{H^+/H_2}(298.15\ \text{K}) = -0.030 \log f_{H_2} - 0.059\ \text{pH} \qquad \text{(Eq 22)}$$

This relation for $f_{H_2} = 1 (p_{H_2} = 1\ \text{bar})$ Fig. 6(b) and 7 by line **a**, which decreases with increasing pH.

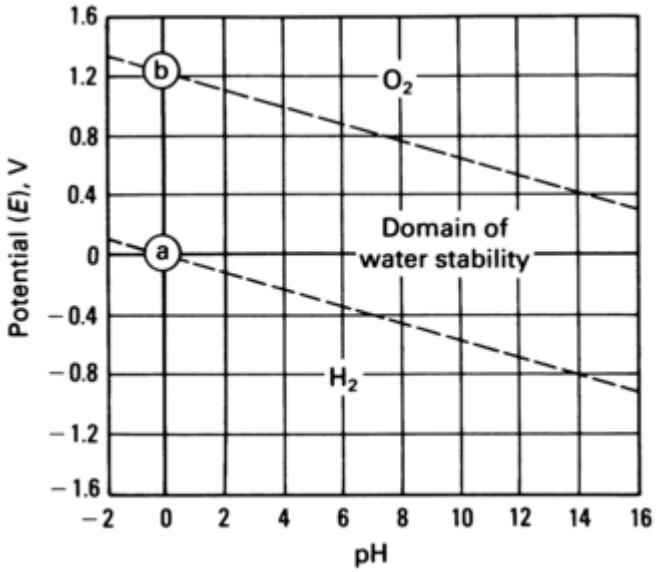

Fig. 7 The water *E*-pH diagram at 25 °C (298.15 K) and 1 bar

For the oxygen/water or oxygen/hydroxide couple:

$$E_{O_2/H_2O} = E^\circ_{O_2/H_2O} + 2.303\frac{RT}{4F}\log f_{O_2} - 2.303\frac{RT}{F}\text{pH} \qquad \text{(Eq 23)}$$

where f_{O_2} is the fugacity of O_2 near the electrode. The water activity is, as usual, assumed to be 1. At 25 °C (298.15 K), the standard potential for O_2/H_2O is 1.23 V SHE (Ref 4), so the equation can be rewritten as:

$$E_{O_2/H_2O}(298.15\ \text{K}) = 1.23 + 0.015\log f_{O_2} - 0.059\ \text{pH} \qquad \text{(Eq 24)}$$

This relation for $f_{O_2} = 1 (p_{O_2} = 1\ \text{bar})$ is represented by line **b** in Fig. 6(b) and 7.

It is interesting to note that the pressures of hydrogen and oxygen in the vicinity of the electrode are usually identical and nearly equal to the pressure that exists in the electrochemical cell. To be rigorous, the water vapor pressure should be taken into account, but it is frequently neglected as not being very significant at 25 °C (298.15 K). When the pressure increases, line **b** in Fig. 7 is displaced upward in the diagram, and line **a** is lowered. The result is that the domain of water stability increases with increasing pressure.

The water system is very important for a good understanding of the corrosion behavior of metals; it is represented (usually by dashed lines) in all Pourbaix diagrams (Ref 4).

Conventions for *E*-pH Diagram Construction. In the construction of diagrams for binary (metal-water) systems, the authors follow the original Pourbaix format (Ref 4) and delineate regions within which condensed phases are stable by solid lines, whereas coexistence lines separating the predominance areas for dissolved species are drawn dashed, even in the regions where the condensed species are stable (Fig. 8). Also, it is common to draw the lines of separation between solid compounds and dissolved species for a number of different activities of the latter. The large number of lines may render the diagram difficult to read (Fig. 8). Moreover, the amount of the chemical element considered, when summed over all dissolved species containing this element, should be constant over the diagram. On diagrams calculated on this principle of constant total element concentration, as the activities in the ideal solution model are taken equal to the numerical values of the concentrations

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

(molalities), the lines corresponding to the limits of the stability domain of a solid species are rounded where two solution species coexist (e.g., the boundaries between domains of Fe^{2+}, Fe^{3+}, and Fe_2O_3 in Fig. 8).

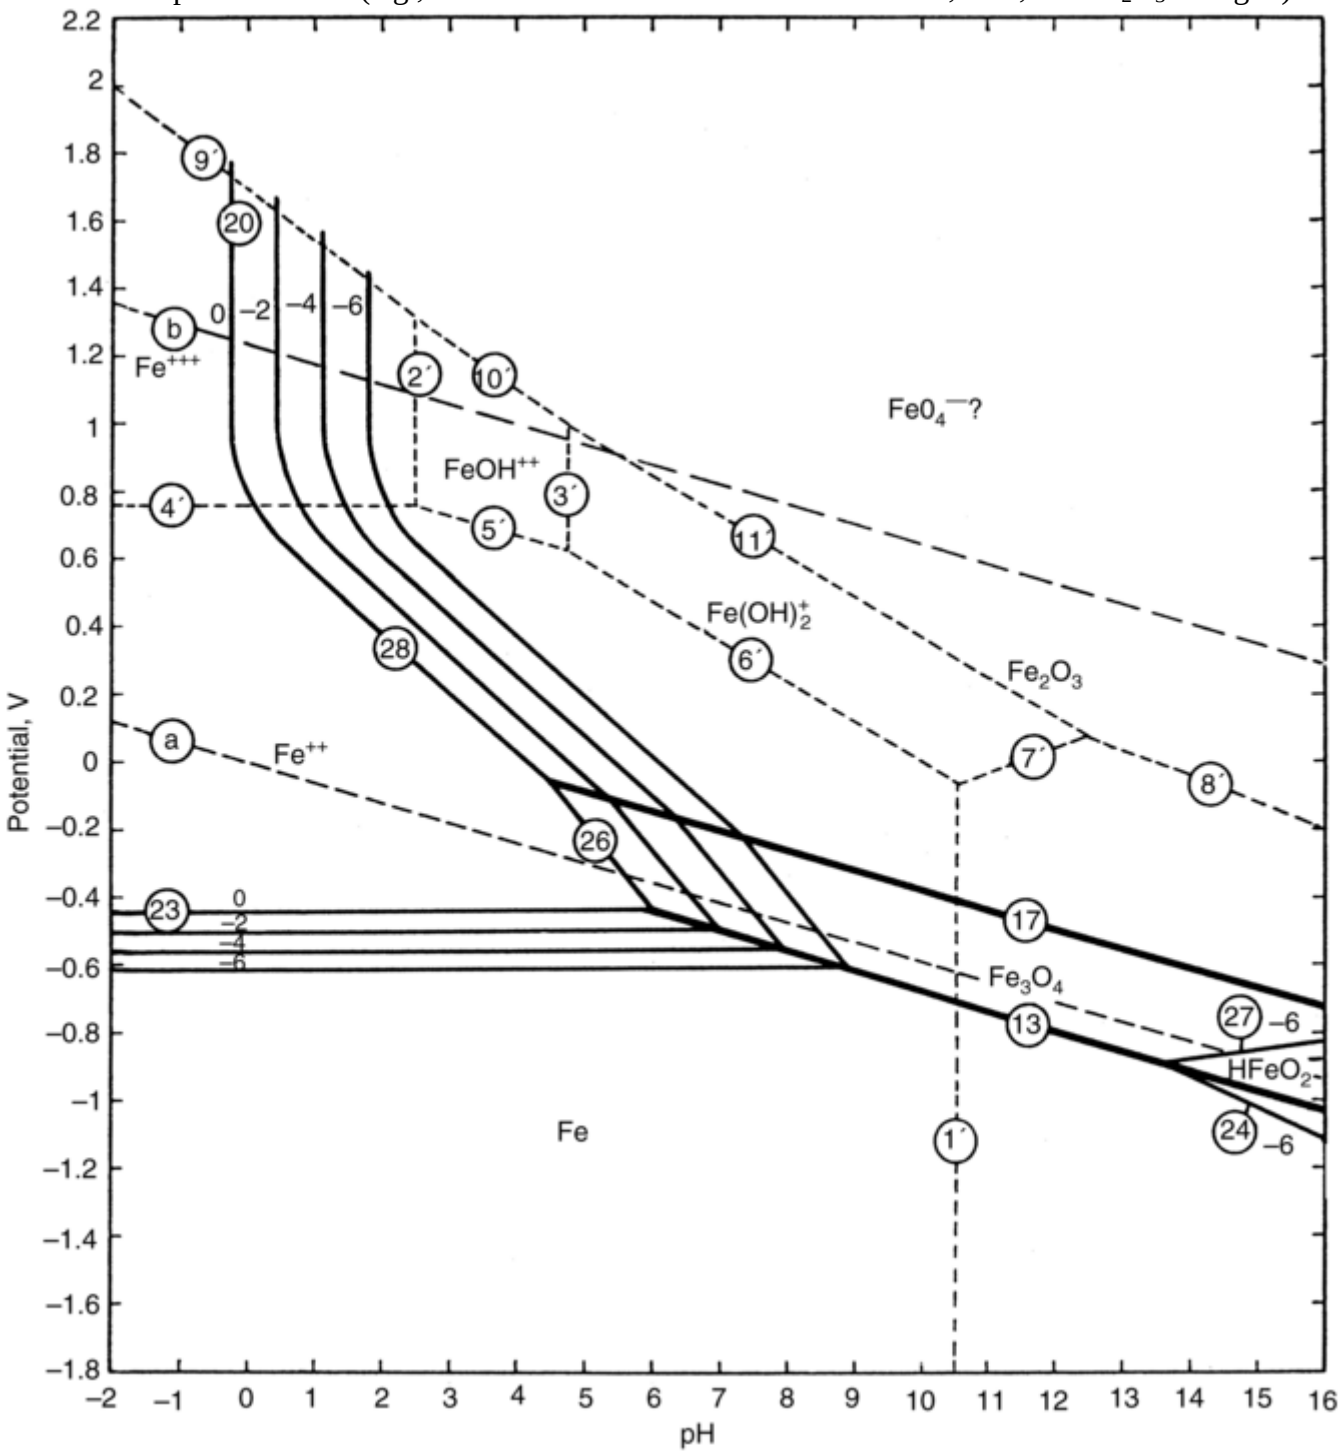

Fig. 8 Original Pourbaix diagram for the iron-water system at 25 °C (298.15 K) (oxides are considered; hydroxides are not). Source: Ref 4

When this principle is adopted rigorously, the diagrams are tedious to compute. Therefore widely adopted convention in calculating the *E*- pH line for the equilibrium between a solid species and a dissolved species is that the dissolved species has simply an activity equal to the molality equal to that it would have if it were the only form present, that is, the selected molality of the element in solution, divided by the number of atoms of the element in a molecule of the species. The effect of this simplifying assumption is that all lines on the diagrams are straight. Figure 9 shows a diagram simplified with respect to the original Pourbaix format (Fig. 8). The diagram (Fig. 9) is further simplified by limiting the pH range from 0 to 14.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

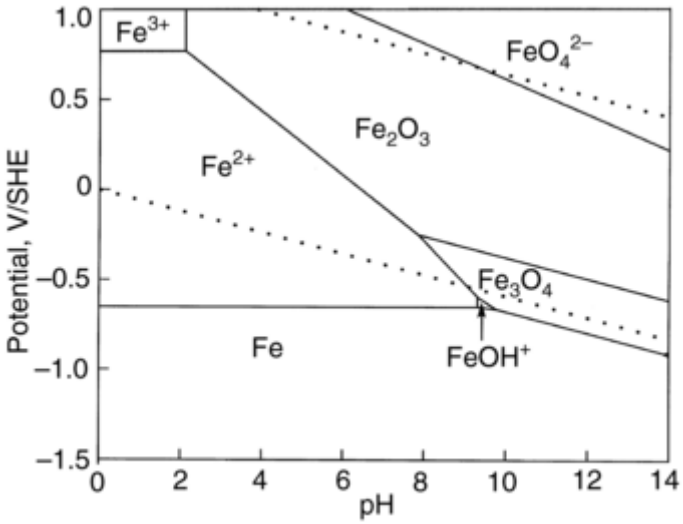

Fig. 9 Simplified *E*-pH diagram for the iron-water system at 25 °C for a molality of dissolved iron equal to 10^{-6} mol/kg. Pressure of hydrogen and oxygen, 1 atm

Consider the consequences of choosing a convention on the element concentration when constructing a diagram. For an equilibrium between two dissolved forms, R and O, of an element. The *E*-pH line calculated for equal concentration of the two forms separates the domains of relative predominance of R and O is calculated from the Nernst equation for equal concentrations of the element under the two forms. When the chemical formulae of the two forms contain the same number of atoms of the element, the concentrations of the two forms are equal, so the logarithmic term with the ratio of activities in the Nernst equation is equal to 0. In this case, the equation of the separation line does not depend on the total concentration of the element (Ref 4, 6, 41). For example, for the reaction:

$$SO_4^{2-} + 10H^+ + 8e^- \rightleftharpoons H_2S_{(aq)} + 4H_2O \qquad \text{(Eq 25)}$$

the equilibrium equation is:

$$E = E^\circ + 2.303\left(\frac{RT}{8F}\right)\log\frac{a_{SO_4^{2-}}}{a_{H_2S}} - 2.303\frac{5RT}{4F}\,\text{pH} \qquad \text{(Eq 26)}$$

The equation of the limit between the areas of relative predominance of SO_4^{2-} and H_2S(aq) simplifies to:

$$E = E^\circ - 2.303\frac{5RT}{4F}\,\text{pH} \qquad \text{(Eq 27)}$$

This is not true when the formula of the two dissolved forms do not contain the same number of atoms of the element. For example, for the reaction:

$$S_2O_3^{2-} + 10H^+ + 8e^- \rightleftharpoons 2H_2S + 3H_2O \qquad \text{(Eq 28)}$$

the equilibrium equation is:

$$E = E^\circ + 2.303\frac{RT}{8F}\log\frac{a_{S_2O_3^{2-}}}{\left(a_{H_2S}\right)^2} - 2.303\frac{5RT}{4F}\,\text{pH} \qquad \text{(Eq 29)}$$

In this case, the equation of the separation line depends on the total concentration of sulfur (molality m_S). If it were considered that the total element amount is constant, the equation of the limit of the areas of relative predominance would correspond to the case where half of sulfur is as H_2S(aq) and the other half as $S_2O_3^{2-}$.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

This would be obtained by taking the concentration $m_S/2$ for $H_2S(aq)$ and $m_S/4$ for $S_2O_3^{2-}$ (Ref 4, 6, 41). The equation of the separation line would then be:

$$E = E^\circ + 2.303\frac{RT}{8F}\log\left[\frac{m_S/4}{(m_S/2)^2}\right] - 2.303\frac{5RT}{4F}\text{pH}$$

or

$$E = E^\circ - 2.303\frac{RT}{8F}\log m_S - 2.303\frac{5RT}{4F}\text{pH} \qquad \text{(Eq 30)}$$

If the simplifying convention described previously is chosen, the *E*-pH line for equilibrium between two dissolved species is calculated considering that each dissolved species is the only form of the element present in solution; for example, taking the concentration m_S for $H_2S(aq)$ and $m_S/2$ for $S_2O_3^{2-}$. Then, the equation of the separation line is:

$$E = E^\circ + 2.303\left(\frac{RT}{8F}\right)\log\frac{(m_S/2)}{(m_S)^2} - 2.303\frac{5RT}{4F}\text{pH}$$

or

$$E = E^\circ - 2.303\left(\frac{RT}{8F}\right)\log 2 - 2.303\left(\frac{RT}{8F}\right)\log m_S - 2.303\frac{5RT}{4F}\text{pH} \qquad \text{(Eq 31)}$$

The simplification with respect to the classic Pourbaix presentation of the diagrams allows a gain of clarity and makes easier the construction of the more complex diagrams for multicomponent systems.

Diagrams for Metastable Species. It is to be noted that the species present in solution in real conditions are not necessarily the more stable ones but may be metastable species that are less stable thermodynamically but, for kinetic reasons, are the ones effectively present in solution for a finite time. A classic example is the sulfur-water system where the oxidized forms of sulfur present in solution are not necessarily the thermodynamically stable species elemental solid sulfur, hydrogenosulfate, HSO_4^-, and sulfate, SO_4^{2-}, ions but can be the metastable dithionates $S_2O_6^{2-}$, hydrosulfites ($HS_2O_4^-$, $S_2O_4^{2-}$) sulfites (H_2SO_3, HSO_3^-, and SO_3^{2-}), tetrathionates ($S_4O_6^{2-}$), or thiosulfates ($HS_2O_3^-$, $S_2O_3^{2-}$) (Ref 4, 6, 7, 41). Possible reactions between the metal and sulfur metastable species are of interest for prediction of corrosion in industrial systems. The *E*-pH diagram for the sulfur-water system showing the thermodynamically stable species is given in Fig. 10 for a sulfur activity (molarity) of 10^{-4} mol/kg. It exhibits a small stability domain of solid sulfur from acid to neutral pHs. The same diagram shows the *E*-pH lines for the case where the thiosulfate species are considered as the only oxidized forms of sulfur (dashed lines). According to the construction conventions, the activity of the dissolved sulfides containing one sulfur atom per molecule or ion is taken as 10^{-4} and the activity of thiosulfate species containing two sulfur atoms per ion as 0.5×10^{-4}.

Practical Use of *E*-pH Diagrams

The *E*-pH diagram is an important tool for understanding electrochemical phenomena. It provides useful thermodynamic information in a simple figure. Two cases are presented here to illustrate its practical use in corrosion prediction.

Corrosion of Nickel. A rod of nickel is immersed in an aqueous deaerated acid solution that contains 10^{-4} mol/L of Ni^{2+} ions. The system is at 25 °C (77 °F) under 1 atm pressure. The *E*-pH diagram corresponding to these conditions is shown in Fig. 11.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

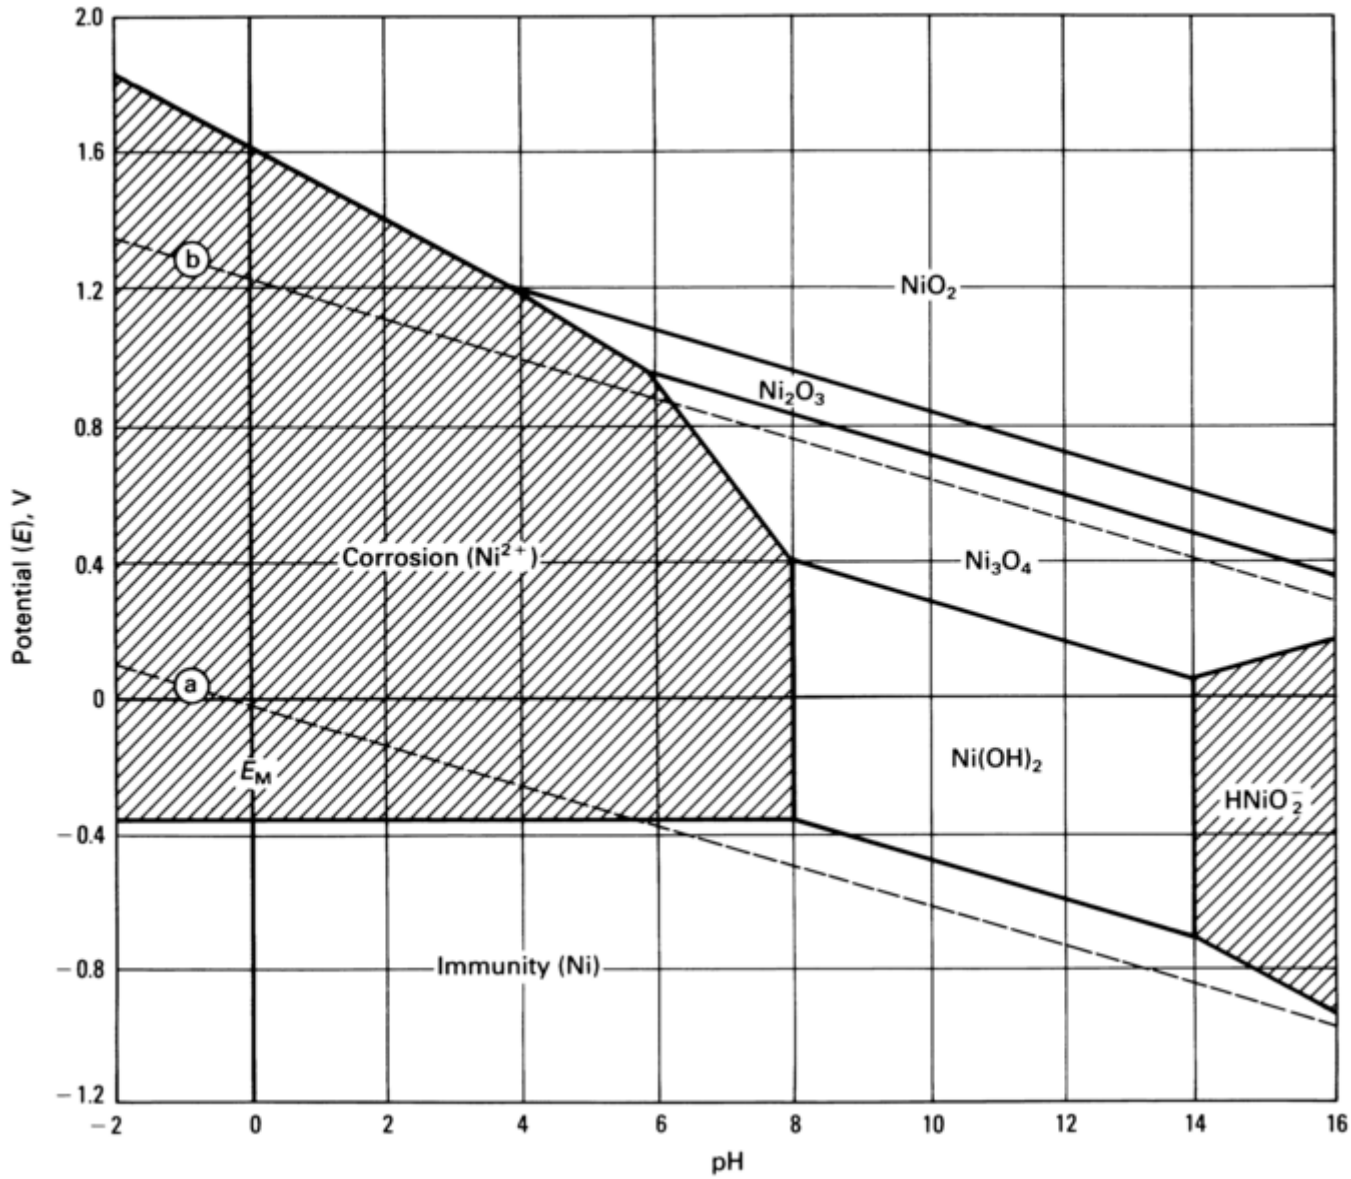

Fig. 11 *E*-pH diagram for nickel for $a_{Ni^{2+}} = 10^{-4}$

At the metal-water interface, two electrochemical reactions are possible:

$$Ni \rightleftharpoons Ni^{2+} + 2e^- \qquad \text{(Eq 32)}$$

and

$$2H^+ + 2e^- \rightleftharpoons H_2 \qquad \text{(Eq 33)}$$

The equilibrium potentials of the Ni^{2+}/Ni and the H^+/H_2 electrodes can be computed. From Eq 6, $E_{Ni^{2+}/Ni} = -0.25 + 0.030 \log a_{Ni^{2+}}$, which, for $a_{Ni^{2+}} = 10^{-4}$, gives $E_{Ni^{2+}/Ni} \approx -0.37$ V (Fig. 2). From Eq 22, $E_{H^+/H_2} = -0.059$ pH, which, at pH = 1, for example, gives $E_{H^+/H_2} \approx -0.06$ V. $E_{Ni^{2+}/Ni} < E_{H^+/H_2}$ up to a pH of approximately 6 (Fig. 11). Thus, when connected via an electrical circuit, electrons tend to flow from the more negative nickel electrode, where they are produced by the oxidation reaction, to the less negative hydrogen electrode, where they are consumed by the reduction reaction. In this case, the two electrodes are formed on the surface of the conducting nickel rod. The two reactions will proceed under a common electrode potential or mixed potential, with a value somewhere between the nickel and hydrogen equilibrium potentials. Up to pH ≈ 6, the mixed potential, E_M, is located above the Ni^{2+}/Ni equilibrium potential in the region of Ni^{2+} stability and below the H^+/H_2 equilibrium potential in the region of H_2 stability (Fig. 11). Hence, nickel is not stable at low pH in water, and it tends to oxidize (corrode) into Ni^{2+}, while H^+ is reduced into hydrogen gas (hydrogen evolution).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Thus, the Pourbaix diagram explains the tendency for nickel to corrode in acid solutions. It does not indicate the rate of corrosion, however. This important information has to be obtained from a kinetic experiment, for example, from the recording of current versus potential curve around the corrosion potential.

The Pourbaix diagram also shows that when the pH increases to approximately 6, the difference between the nickel and the hydrogen equilibrium potential decreases in magnitude, and consequently, the corrosion tendency diminishes. For pHs between 6 and 8 (limit of stability of Ni^{2+}), Fig. 11 shows that the hydrogen electrode potential becomes lower than the nickel one. Under these conditions, H^+ can no longer accept the electrons from nickel. The mixed potential of the system is, in this case, below the equilibrium potential of Ni^{2+}/Ni, in the region of metal immunity. Hence, in water at room temperature, nickel does not corrode for pH 6 to 8. No such pH range exists for the iron-water system, where the Fe^{2+}/Fe electrode potential is always lower than the H^+/H_2 electrode potential (Fig. 1, 8, 9). Therefore, iron will always corrode to ferrous ions with evolution of H_2 in acid and neutral solutions. In contrast, the behavior of nickel makes this metal slightly noble (in the small pH range of 6 to 8), and, from the diagram, it is expected to resist corrosion better than iron. Moreover, an increase in hydrogen pressure, according to Eq 22, lowers the equilibrium line of H^+/H_2 while it does not change the equilibrium line of Ni^{2+}/Ni. As a result, an increase in pressure leads to greater corrosion resistance for nickel. For pHs higher than 8, films of NiO (or the hydrated form $Ni(OH)_2$) and Ni_3O_4 can form at the surface at anodic potentials, as can be seen in Fig. 11. These oxides may, in some cases, protect the metal by forming a protective layer that prevents or mitigates further corrosion. This phenomenon is called passivation. It also occurs on iron with the formation of magnetite (Fe_3O_4) or hematite (Fe_2O_3) at anodic potentials (Fig. 8, 9). The presence of species such as chlorine ions may increase the corrosion tendency of metals, because these species may attack the protective layer and then favor corrosion. Figures 1, 8, and 11 illustrate that iron or nickel may corrode (dissolve) in very strong alkaline solutions as $HFeO_2^-$ or $HNiO_2^-$, respectively, or, more likely, as the hydrated forms $Fe(OH)_3^-$ or $Ni(OH)_3^-$.

Corrosion of Copper. Observation of the copper *E*-pH diagram in Fig. 12 immediately reveals that the corrosion of copper immersed in deaerated acid water is not likely to occur. The H^+/H_2 equilibrium potential represented by line **a** is always *lower* than the Cu^{2+}/Cu equilibrium potential. The H^+ ions are stable in contact with copper metal, which cannot corrode (is immune) in water solutions free from oxidizing agents.

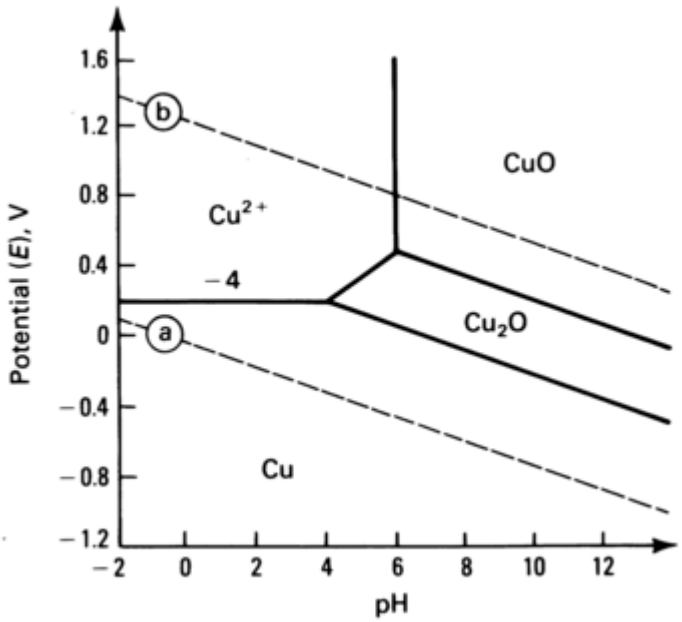

Fig. 12 Partial *E*-pH diagram for copper for $a_{Cu^{2+}} = 10^{-4}$

The presence of dissolved oxygen in nondeaerated solutions introduces another possible reaction: O_2 reduction into H_2O, with an equilibrium potential higher than that of Cu^{2+}/Cu. The O_2/H_2O couple is then a good acceptor for the electrons produced by copper oxidation. The two electrochemical reactions:

$$Cu \rightarrow Cu^{2+} + 2e^- \qquad \text{(Eq 34)}$$

and

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O$ (Eq 35)

take place spontaneously in acid solutions at the surface of an immersed piece of copper at a common (mixed) potential. In neutral or alkaline solutions, O_2 reduction will be coupled with copper oxidation into Cu_2O.

E-pH Diagrams for Ternary Systems

The *E*-pH diagrams for corrosion protection give valuable information if all the substances present in the actual system under investigation (metal or metalloid in aqueous solution) are taken into account when the diagrams are constructed. The previous discussion assumed that the solution did not contain chlorine, sulfur, or other species capable of forming solid compounds or soluble complexes with the metal. In the presence of such elements, other diagrams must be considered that may reveal different metal corrosion behavior. Hence, diagrams for binary metal-water (M-H_2O) systems are of limited usefulness, and diagrams for multicomponent systems must be calculated. For example, the simple diagram of gold in water (Au-H_2O system) does not show any solubility for that metal. The addition of cyanide (CN) ions to the system, however, leads to the formation of a gold complex soluble in water. Hence, gold, which does not corrode in pure water can dissolve in the presence of cyanide. This property is the basis of gold plating and of the hydrometallurgy of that metal. Diagrams for the ternary system Au- CN^--H_2O must then be constructed to show the conditions of stability for the gold complex. A general bibliography of *E*-pH diagrams for multicomponent systems in aqueous solutions is given in Ref 8.

Diagrams for ternary metal-additive-water (M-A-H_2O) systems are frequently used. In most cases, the amount of one element in the dissolved form is substantially greater than that of the other. If so, the reactions involving only the major element will be practically independent of the reactions involving the minor element. Thus, the diagram of the major element alone, drawn with dashed lines, will serve as a background for the diagram for the combined system, drawn with solid lines. The behavior of the minor element may be or may not be independent of that of the major element. It will be independent if the minor element forms no stable solid compound or dissolved complex with the major element; in this case the diagram for the ternary system will just be the diagram of the minor element alone superimposed on the diagram of the major element alone. Otherwise the diagram for the ternary system may be drastically different. Again, the convention is that in the regions of stability of a dissolved species, the latter is considered as the only element form present. When the minor element forms a dissolved complex with the major element, this solution species is considered as a species of the minor element, and hence its concentration is the one of the minor element.

Consider the case where the concentration of additive in the dissolved form is much higher than the tolerated concentration of dissolved metal. First, the *E*-pH diagram for the A-H_2O system must be calculated to determine the areas of predominance for the various species of A. Then, in each area delineated with dashed lines, the *E*-pH equilibria lines for the various reactions between the metal and the predominant A species to form metal compounds or complexes are calculated. A metal-additive dissolved complex is considered as a metal species.

As an example of calculations for a ternary system involving metal-additive solid compounds, consider the following reactions for the iron-sulfur-water system:

- FeS_2/Fe^{2+} equilibrium in sulfide media:

$$FeS_2 + 4H^+ + 2e^- \rightleftharpoons Fe^{2+} + 2H_2S(aq) \quad \text{(Eq 36)}$$

- or

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$FeS_2 + 2H^+ + 2e^- \rightleftharpoons Fe^{2+} + 2HS^-$$ (Eq 37)

- Fe^{2+}/FeS_2 equilibrium in thiosulfate media:

$$Fe^{2+} + HS_2O_3^- + 5H^+ + 6e^- \rightleftharpoons FeS_2 + 3H_2O$$ (Eq 38)

- or

$$Fe^{2+} + S_2O_3^{2-} + 6H^+ + 6e^- \rightleftharpoons FeS_2 + 3H_2O$$ (Eq 39)

- Fe_2O_3/FeS_2 equilibrium in thiosulfate media:

$$Fe_2O_3 + 2S_2O_3^{2-} + 18H^+ + 14e^- \rightleftharpoons 2FeS_2 + 9H_2O$$ (Eq 40)

At 25 °C (77 °F), the equations for the previously mentioned equilibria are, respectively, if m_S and m_{Fe} are the molalities of sulfur and iron in solution:

$$E = E^\circ - 0.059 \log\left(\frac{m_S}{2}\right) - \frac{0.059}{2}\log m_{Fe} - 2 \times 0.059\ pH$$ (Eq 41)

or

$$E = E^\circ - 0.059 \log\left(\frac{m_S}{2}\right) - \frac{0.059}{2}\log m_{Fe} - 0.059\ pH$$ (Eq 42)

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$E = E^\circ + \frac{0.059}{6}\log\left(\frac{m_S}{2}\right) + \frac{0.059}{6}\log m_{Fe} - \tfrac{5}{6}\times 0.059\ \text{pH} \qquad \text{(Eq 43)}$$

or

$$E = E^\circ + \frac{0.059}{6}\log\left(\frac{m_S}{2}\right) + \frac{0.059}{6}\log m_{Fe} - 0.059\ \text{pH} \qquad \text{(Eq 44)}$$

$$E = E^\circ + \frac{0.059}{7}\log\left(\frac{m_S}{2}\right) - \tfrac{6}{7}\times 0.059\ \text{pH} \qquad \text{(Eq 45)}$$

Metals may form compounds in dissolved form with sulfur (e.g., $FeSO_4$(aq), $FeSO_4^+$, $CuSO_3^-$). Consider the $Cu^{2+}/CuSO_3^-$ equilibrium in sulfite media in a case where $m_{Cu} \ll m_S$:

$$Cu^{2+} + SO_3^{2-} + e^- \rightleftharpoons CuSO_3^- \qquad \text{(Eq 46)}$$

$$E = E^\circ + 0.059\log a_{SO_3^{2-}} + 0.059\log\left(\frac{a_{Cu^{2+}}}{a_{CuSO_3^-}}\right) \qquad \text{(Eq 47)}$$

The equation of the boundary line between the domains of relative predominance of Cu^{2+} and $CuSO_3^-$ would be obtained (if the latter were stable) for $a_{Cu^{2+}} = a_{CuSO_3^-} (= m_{Cu})$:

$$E = E^o + 0.059\ \log m_S \qquad \text{(Eq 48)}$$

An illustration is given for the system iron- sulfur-water in water containing thiosulfates. This case is of technological importance, because thiosulfates dissolved in aqueous solution are known to be detrimental to the corrosion resistance of stainless steels (Ref 9, 10, 11, 12, 13, 14, 15, 16). The concentration of the dissolved sulfur impurity expressed in molality is usually approximately 10^{-4} mol/kg, and the molality of dissolved iron is considered to be 10^{-6} mol/kg. Such a small value allows conservative predictions of corrosion, because it is generally agreed that there is no corrosion when the concentration of metal that can be dissolved in a solution initially free from it is lower or equal to 10^{-6} mol/kg. Thus, the major element here is sulfur, and the binary diagram used as a background is the one of the metastable sulfur-water system (compare with Fig. 10), showing the thermodynamically stable sulfides (H_2S(aq) and HS^-) as reduced forms of sulfur and the metastable thiosulfates ($HS_2O_3^-$ and $S_2O_3^{2-}$) as the only oxidized forms. The ternary diagram for the iron-sulfur-water system is plotted in Fig. 13.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

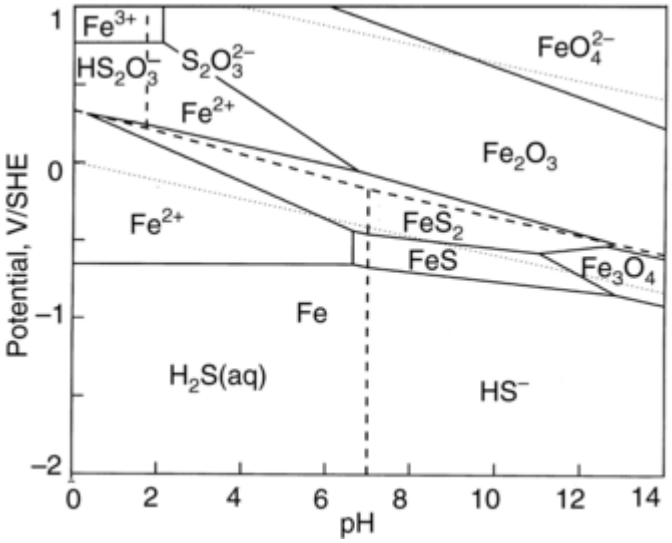

Fig. 13 *E*-pH diagram for the iron-sulfur-water system at 25 °C (298.15 K) in the case where the metastable thiosulfates are the only oxidized forms of sulfur. The stability domains are limited by the dotted lines for the water system, dashed lines for the sulfur-water system, and solid lines for the iron-sulfur-water system. $m_S = 10^{-4}$ mol/kg. $m_{Fe} = 10^{-6}$ mol/kg

A comparison with the diagram of the binary iron-water system (Fig. 8, 9) shows that iron interacts with sulfides or thiosulfates in the mid- pH region to form iron sufides (FeS and FeS_2), replacing Fe^{2+} in acid solutions and magnetite (Fe_3O_4) in neutral and alkaline solutions. Because metal sulfides are good ionic conductors, they offer little protection against corrosion. Although the diagram predicts Fe_2O_3 could be formed on the surface under anodic (strongly oxidizing) conditions over a large pH range and protect iron from corrosion, the incompatibility between FeS_2 and Fe_2O_3 actually prevents growth of an adhesive Fe_2O_3 layer (Ref 17). Hence, the diagram predicts that iron passivation will not occur in the presence of sulfides or thiosulfates in solution.

The diagram for the chromium-sulfur-water system is plotted in Fig. 14. There is no range of stability of chromium sulfides (at least for $m_S \leq 10^{-4}$ mol/kg), so the diagram is identical to the binary diagram for the chromium-water system. It shows that chromium sulfides are less stable than the chromic oxide (Cr_2O_3) or hydroxide ($Cr(OH)_3$), which provide the exceptional corrosion resistance of chromium.

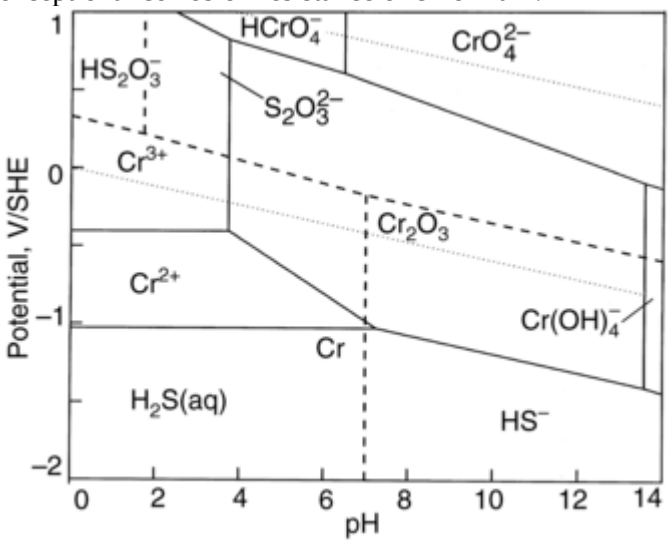

Fig. 14 *E*-pH diagram for the chromium-sulfur-water system at 25 °C (298.15 K) in the case where the thiosulfates are the only oxidized forms of sulfur. The stability domains are limited by the dotted lines for the water system, dashed lines for the sulfur-water system, and solid lines for the chromium-sulfur-water system. $m_S = 10^{-4}$ mol/kg and $m_{Cr} = 10^{-6}$ mol/kg

E-pH Diagrams for High- Temperature Aqueous Solutions

Prediction of the corrosion behavior of metals in aqueous solutions at high temperatures is of considerable technological interest. Such a situation is steel vessels in contact with pressurized water at 300 °C (573.15 K) in nuclear power reactors. It was necessary to extend the *E*-pH equilibrium diagrams originally established at 25 °C (Ref 4) to higher temperatures. The main problem is that there are few thermodynamic data available for chemical species dissolved in water above 60 °C (333.15 K). The increase in water vapor pressure with temperature in closed cells leads to high pressures. This makes it necessary to carry out experiments in autoclaves, high- strength vessels with special seals (Ref 18). Often, thermodynamic-state functions data at high temperatures are obtained by extrapolation from the data at 25 °C using empirical hypotheses on the influence of temperature on molar heat capacities. In particular, entropy correspondence principles have been established that make possible the calculation of entropies and heat capacities of ions at temperatures up to 300 °C from the entropy values at 25 °C (Ref 19, 20). An alternate treatment of the problem is the calculation of temperature coefficients of standard equilibrium potentials of electrochemical reactions from thermodynamic data at 25 °C (Ref 21). A review of these different methods of estimation is given in Ref 8.

High-temperature Pourbaix diagrams are, by nature, less accurate than those at 25 °C that are based on experimental data, because they are based on estimates. The effects of pressure on the equilibria can be ignored up to 300 °C because the magnitude of the errors introduced is within the uncertainty of the data (Ref 18, 19).

At high temperature, the molar scale for activities must not be used, because, due to water volume changes, the molarity for a given solute quantity (number of moles of solute per liter of water) varies with temperature. One can only use the molality (number of moles of solute per kilogram of water), which is equal to the molarity at 25 °C (77 °F) but is invariant with temperature. The standard state for each dissolved species is the hypothetical ideal solution of the substance at unit molality.

Thermodynamic Conventions for High Temperature. High-temperature thermodynamic calculations for aqueous solutions require one to specify additional conventions, and one must be careful about which convention applies when using a set of high temperature data.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Standard chemical potentials, or Gibbs free energies of formation at a temperature *T*, may be given for the formation of the substance from its elements in their standard states at *T* or at 25 °C (77 °F). Thus, in the first convention, the standard values of elements or diatomic gases are zero at any temperature, whereas, in the second one, they are zero only at 25 °C (77 °F). Using the second convention, values are given in Table 1 for hydrospecies and sulfur species at 25 and 300 °C. Table 2 lists the values for iron and its compounds.

(a) Values after correction of the difference in convention for the free energy of formation of H^+(aq) at 300 °C (573.15 K) between this text and Ref 17

Two conventions exist for the potential scale: the “universal” convention and the “alternate” convention. In the universal convention, the electrode potentials are referred to the potential of the standard hydrogen electrode (SHE) at the temperature considered; that is, the potential of the SHE $(p_{H_2} = 1\text{bar}, a_{H^+} = 1)$ is taken equal to 0 V at all temperatures. Hence, the chemical potential (Gibbs free energy) of the conventional electron used in the writing of electrode (half- cell) reactions is, at all temperatures:

$$\left(\mu^0_{e^-}\right)_1(T) = \tfrac{1}{2}\mu^0_{H_2}(T) - \mu^0_{H^+}(T) \qquad \text{(Eq 49)}$$

With this convention, the *E*-pH line for the H^+(aq)/H_2(g) couple passes by the point (*E* = 0, pH = 0) at any *T* (Fig. 13).

In the alternate convention, the potentials are referred to the potential of the SHE at 25 °C (77 °F). Here, the chemical potential of the conventional electron is the same at all temperatures:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\left(\mu^0_{e^-}\right)_2 = \tfrac{1}{2}\mu^0_{H_2}(298.15\ \mathrm{K}) - \mu^0_{H^+}(298.15\ \mathrm{K}) = 0 \qquad \text{(Eq 50)}$$

In this convention, the potential of the SHE depends on temperature, and the *E*-pH line for the $H^+(aq)/H_2(g)$ couple intersects the vertical axis for pH = 0 above 0 V for $T > 25$ °C (Fig. 15). The two conventions become identical at 25 °C: $(\mu^0_{e^-})_1(298.15\ \mathrm{K}) = (\mu^0_{e^-})_2 = 0$.

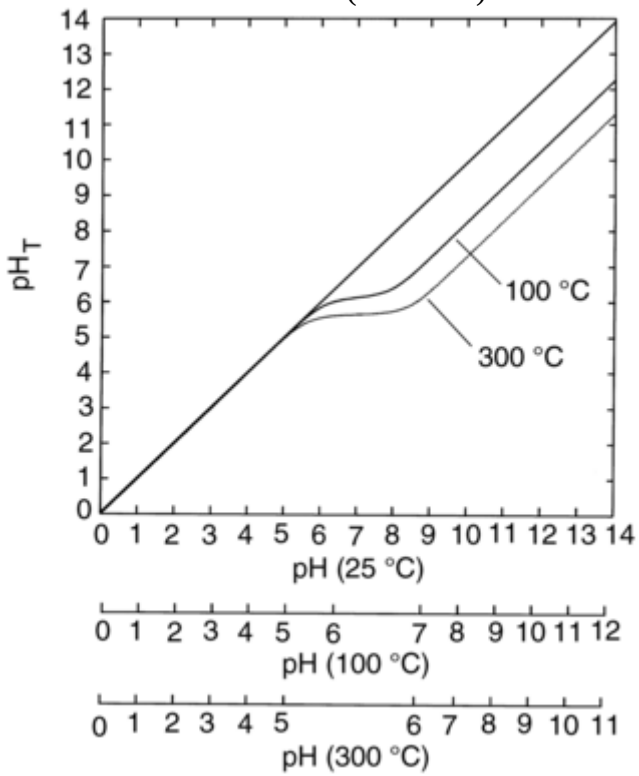

Fig. 15 pH at 100 and 300 °C (373.15 and 573.15 K) versus pH at 25 °C (298.15 K) in an unbuffered solution ($pH_{200} = pH_{300}$). Also, the correspondence between the pH scales at the different temperatures is shown.

Solvated H^+ ($H^+(aq)$) is often considered as a reference substance whose standard chemical potential, or Gibbs free energy of formation, is taken to be zero at all temperatures. Use of the universal convention produces the simple relation $(\mu^0_{e^-})_1(T) = \mu^0_{H_2}(T)$.

Variation of pH with Temperature. For a correct interpretation of the high-temperature *E*- pH diagrams, the change of pH of the solution with the temperature must be taken into account. The pH of an aqueous solution is determined by:

- The equilibrium constant for water dissociation into solvated protons and hydroxide ions, $H_2O(l) = H^+(aq) + OH^-(aq)$, also called the ionic product of water, $(K_w)_T = a_{H^+} \cdot a_{OH^-}$, which increases with temperature
- The concentrations and dissociation constants of the other constituents of the solution

Because the temperature dependence of dissociation constants is not the same for all acids and bases, it is not possible to calculate the pH scale for a given temperature in a manner that would apply to all aqueous solutions. At least, the temperature effect can be visualized on the *E*-pH diagram at a given temperature by marking by vertical lines the position of three important pH values (Ref 24):

- $pH = -\log_{10}(K_w)_T = 0$, which corresponds to a 1 molal solution of a strong (completely dissociated) acid
- $pH = -\log_{10}(K_w)_T = (pK_w)_T$, which corresponds to a 1 molal solution of a strong base
- $pH = \frac{1}{2}(pK_w)_T$, which corresponds to neutral water. Indeed, in neutral aqueous solutions:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\left(a_{H^+}\right)_n = \left(a_{OH^-}\right)_n = \sqrt{\left(K_w\right)_T}$$

Hence, the neutral pH is $pH_n = -\log_{10}\left(a_{H+}\right)_n = -\frac{1}{2}(\log_{10}(K_w)_T) = \frac{1}{2}(pK_w)_T$.

The pK_w decreases from 14.00 at 25 °C to 12.27 at 100 °C (373.15 K) and 11.30 at 200 and 300 (473.15 and 573.15 K) (Ref 22). Accordingly, the pH of a neutral aqueous solution is 7.00 at 25 °C, whereas it is 6.13 at 100 °C and 5.65 at 200 and 300 °C.

In an unbuffered solution (with completely dissociated acid or base), the proton activity is fixed only by the water ionic product (from here simply denoted K_T), which increases with *T*. Thus, a solution that has a certain pH at 25 °C will have a lower pH at a higher temperature. In this simple case, the change in pH can be calculated in the following way (Ref 23). Consider the general case of a solution of a certain pH at 25 °C: From the definition of the water ionic product $K_{25} = a^{25}_{H+} \cdot a^{25}_{OH-}$, hence $pK_{25} = pH_{25} + pOH_{25}$. As the temperature is raised, the equilibrium of dissociation of water will be shifted, and equivalent amounts of additional H^+ and OH^- will be generated in solution. Thus:

$$K_T = a^T_{H^+} + a^T_{OH^-} = \left(a^{25}_{H^+} + x\right)\left(a^{25}_{OH^-} + x\right) \qquad \text{(Eq 51)}$$

where *x* is the increase in ion activity as a result of the temperature change from 25 °C to *T*. This is a quadratic equation in *x*: $x^2 + \left(a^{25}_{H+} + a^{25}_{OH-}\right)x + (K_{25} - K_T) = 0$, whose physically meaningful solution is:

$$x^+ = \frac{-\left(a^{25}_{H^+} + a^{25}_{OH^-}\right) + \sqrt{\left(a^{25}_{H^+} + a^{25}_{OH^-}\right)^2 + 4\left(K_T - K_{25}\right)}}{2} \qquad \text{(Eq 52)}$$

The pH at *T* is $pH_T = -\log_{10}\left(a^{25}_{H+} + x^+\right)$. It takes limiting values:

- $$\text{For low pHs: } pH_{25} < pK_T/2 < 7$$
$$\Rightarrow a^{25}_{H^+} \gg \sqrt{K_T} > \sqrt{K_{25}} \gg a^{25}_{OH^-}$$
$$\Rightarrow x^+ \approx \left(K_T - K_{25}\right)/a^{25}_{H^+} \ll a_{H^+_T} \approx a^{25}_{H^+}$$
$$\Rightarrow pH_T \approx pH_{25}$$

- $$\text{For high pHs: } pH_{25} > \left(14 - pK_T/2\right) > 7$$
$$\Rightarrow a^{25}_{H^+} \ll \sqrt{K_{25}} < \sqrt{K_T} \ll a^{25}_{OH^-}$$
$$\Rightarrow x^+ \approx \left(K_T - K_{25}\right)\Big/\left(a^{25}_{OH^-}\right)^2 \ll 1 \rightarrow a_{OH^-_T} \approx a^{25}_{OH^-}$$
$$\Rightarrow a_{H^+_T} \approx K_T/a^{25}_{OH^-} = a^{25}_{H^+}\, K_T/K_{25}$$
$$\Rightarrow pH_T \approx pH_{25} + pK_T \approx pK_{25}$$

-

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

For neutral pHs: $pH_{25} \approx 7$

$$\Rightarrow a^{25}_{H^+} \approx a^{25}_{OH^-} \approx \sqrt{K_{25}} \rightarrow K_T$$

$$\approx \left(a^{25}_{H^+} + x^+\right)^2 = \left(a^{T}_{H^+}\right)^2$$

$$\Rightarrow a^{T}_{H^+} \approx \sqrt{K_T}$$

$$\Rightarrow pH_T \approx pK_T/2$$

The pH values at 100 and 300 °C are plotted versus the pH at 25 °C 15 in Fig. 15. Also, the correspondence between the pH scales at different temperatures is plotted. (The pH at 200 °C is equal to the pH at 300 °C, because pK_w is practically the same at these two temperatures [Ref 22].) To compare the behavior of an electrode in an unbuffered solution of given pH at 25 °C with the one in the same solution at *T*, the corrected pH must be employed when using the *E*-pH diagram at *T*.

It must be noted that, in a buffered solution, the pH is fixed by the equilibrium of an acid- base couple, and it is the variation of the acid dissociation constant with temperature that is predominant in fixing the pH variation.

Temperature Effects on the *E*-pH Diagrams for Binary Systems. The diagram for the iron- water system at 300 °C is plotted in Fig. 16. Even after correction of the temperature effect on pH, the net effect of increase of temperature is to shift the diagram to lower values of pH (Ref 17, 23, 24, 25). Comparison of higher-temperature diagrams to the diagram at 25 °C (Fig. 8) gives the following trends for the influence of temperature:

- The domains of stability of the Fe^{2+} and Fe^{3+} cations are contracted to the benefit of condensed species Fe, Fe_3O_4, and Fe_2O_3; that is, the solubility of the latter species in acid solutions is lower at 300 °C than at 25 °C.
- There is an expansion below pH 14 of the domain of stability of the dihypoferrite ion $HFeO_2^-$ (or $Fe(OH)_3^-$) at the expense of Fe, Fe_3O_4, and Fe_2O_3; that is, the solubility of the condensed species in alkaline solutions is substantially greater at 300 °C.

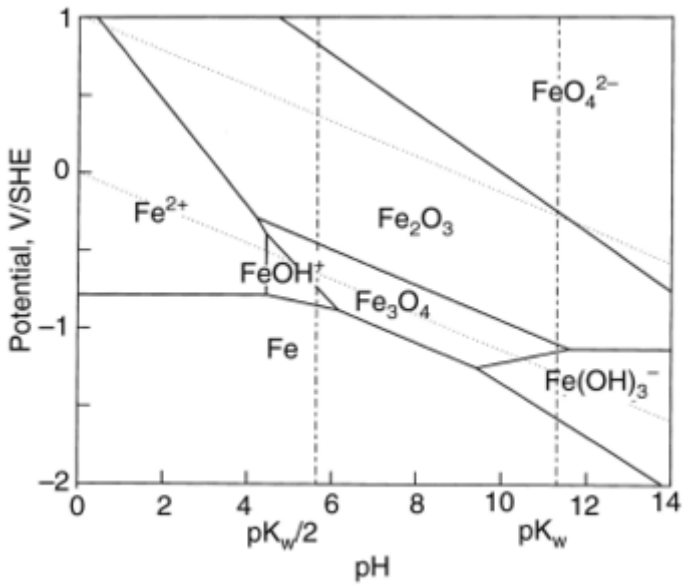

Fig. 16 *E*-pH diagram for the iron-water system at 300 °C (573.15 K). $m_{Fe} = 10^{-6}$ mol/kg

The diagram for the chromium-water system at 300 °C (573.15 K) is plotted in Fig. 17. Compared to the diagram at 25 °C (Fig. 14), $CrOH^{2+}$ replaces Cr^{3+} as the trivalent species at low pH and anodic potentials. Effects of temperature similar to those described for the iron-water system are observed. The Cr_2O_3 (or $Cr(OH)_3$) becomes less soluble (more stable) in acid solution and more soluble (less stable) in alkaline solutions, where CrO_2^- ($Cr(OH)_4^-$) is the stable ion (Ref 17, 26, 27, 28).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

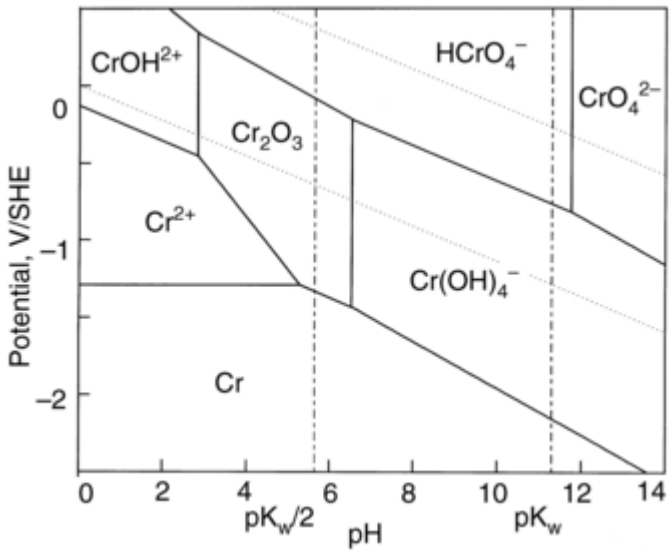

Fig. 17 *E*-pH diagram for the chromium-water system at 300 °C (573.15 K). $m_{Cr} = 10^{-6}$ mol/kg

Similar effects are also predicted for various other metals (Ref 17, 18, 26, 27). Thus, the most significant effect of the increase of temperature is an expansion of the domain of corrosion in strong alkaline environment, which was confirmed experimentally (Ref 8, 23).

Temperature Effects on *E*-pH Diagrams for Ternary Systems. Diagrams for multi-component systems in high-temperature aqueous solutions are obviously of great interest for predicting corrosion behavior in numerous industrial conditions. A general bibliography of *E*-pH diagrams for multicomponent systems in high-temperature aqueous solutions is given in Ref 8. As an example, the diagram for the ternary system iron-sulfur-water with thiosulfates at 300 °C (573.15 K), for $a_S = 10^{-4}$ and $a_{Fe} = 10^{-6}$, is shown in Fig. 18. It may be compared to the diagram at 25 °C, presented previously (Fig. 13), to visualize the effects of increasing temperature. Concerning the sulfur-water system, there is an increased stability of the acid forms of dissolved sulfur, $H_2S(aq)$ and $HS_2O_3^-$, at the expense of HS^- and $S_2O_3^{2-}$. At 300 °C, the diagram for the iron-sulfur-water system is identical to the one for the iron-water system (Fig. 16). Besides the effects described previously for the iron-water system (contraction of the domains of stability of Fe^{2+} and Fe^{3+} and expansion of the domain of $Fe(OH)_3^-$), the main effect of temperature rise is that the range of stability of the sulphides FeS and FeS_2 is drastically reduced (Ref 17, 29) and even suppressed for the sulfur activity of the diagram ($a_S = 10^{-4}$).

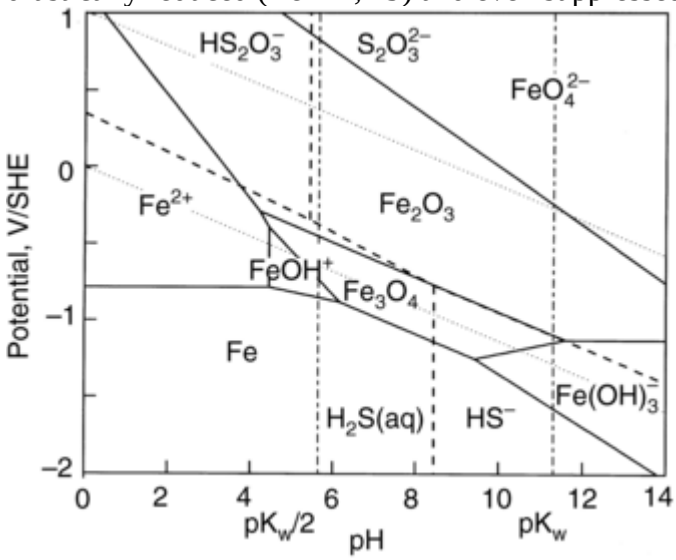

Fig. 18 *E*-pH diagram for the iron-sulfur-water system at 300 °C (573.15 K) in the case where the thiosulfates are the only oxidized forms of sulfur. $m_S = 10^{-4}$ mol/kg, $m_{Fe} = 10^{-6}$ mol/kg

Similarly, the diagram for the chromium-sulfur-water system at 300 °C (572 °F) is identical to the diagram for the chromium-water system shown in Fig. 17, because it shows no chromium sulfides.

High-temperature *E*-pH diagrams for various metal-chlorine-water systems, which are very important for the interpretation and prediction of corrosion phenomena in high-salinity brines, can be found in Ref 30. Also, the *E*-pH diagrams for the quaternary system Fe-Cl-S-H_2O up to 250 °C (523.15 K) are of direct interest in the phenomenon of stress cracking in sulfide-containing brines (Ref 31).

E-pH Diagrams for Adsorbed Species

The principle of *E*-pH diagrams can be extended to the case of bidimensional layers of species adsorbed on metal surfaces. The solid compounds treated in the usual diagrams are three-dimensional (bulk) compounds (oxides, hydroxides, sulfides, etc.). However, the formation of a three-dimensional solid compound M_xA_y (A may be O, OH, S …) by reaction of gaseous or dissolved forms of A with a metal, M, is often preceded by the formation of a two- dimensional phase of A adsorbed on the metal surface. This surface phase is more stable than the bulk compound (Ref 32). When there is creation of a true chemical bond between A atoms and metal surface atoms (bond energies larger than 200 kJ/mol, at least at low coverage), the adsorption is also called *chemisorption.* Adsorbed (chemisorbed) monolayers may form under *E*-pH conditions where the bulk compounds are thermodynamically unstable, and a classic diagram would predict only the existence of the bare metal. Chemisorption must not be neglected, because the presence of a chemisorbed monolayer can induce marked changes in the reactivity of the metal. For example, it has been shown that a monolayer of sulfur adsorbed on nickel or nickel-iron alloys enhances the anodic dissolution and hinders the formation of the passive film, drastically affecting the corrosion resistance of the metallic material (Ref 33, 34). Therefore, *E*-pH diagrams for adsorbed species are of interest for predicting corrosion risk (Ref 34). The method of calculation of the equilibrium potentials of oxidation-reduction couples involving a species adsorbed on an electrode surface is presented subsequently.

Principle of *E*-pH Diagrams for Adsorbed Species. Consider the case where a species A (which may be an element, H, O, S or a molecular species, OH or H_2O) is adsorbed from solution on a metal surface M in the form of a neutral monolayer [denoted $A_{ads}(M)$]. The adsorption of A from a dissolved species in aqueous solution may result from an electrooxidation or an electroreduction reaction, depending on the valence state of A in the dissolved species (it may then be called electroadsorption). The adsorption of an atom or molecule on a metal surface in water involves the replacement of adsorbed water molecules and a competition with the adsorption of oxygen species (atomic oxygen O or hydroxyl OH) produced by electrooxidation of water or hydroxide (OH^-) ions present in the electrolyte. For simplicity, a Langmuir model for adsorption is taken in which it is assumed that the two-dimensional (surface) phase is an ideal substitutional solution where species adsorb competitively on the same sites without lateral interactions between adsorbed species.

Under these conditions, the chemical potential of each adsorbed species $A_{ads}(M)$ in the surface phase of a metal M can be expressed as follows:

$$\mu_{A_{ads}(M)} = \mu^0_{A_{ads}(M)} + RT \ln \theta_A \qquad \text{(Eq 53)}$$

where θ_A is the relative coverage by adsorbed A ($0 \leq \theta_A \leq 1$; $\theta_A = 1$ for a complete monolayer of A); $\mu^0_{A_{ads}}(M)$ is the standard chemical potential of A, corresponding to the saturation of the surface by $A_{ads}(M)$. The total coverage on the surface is equal to unity; the coverage by water is $\theta_{H_2O} = (1 - \sum\theta_{Ai})$, where θ_{Ai} is the coverage by any other adsorbed species.

As an example of the method of calculation of the *E*-pH relations, consider the adsorption of hydroxyl on a metal surface from adsorbed water:

$$H_2O_{ads}(M) \rightleftharpoons OH_{ads}(M) + H^+ + e^- \qquad \text{(Eq 54)}$$

The equilibrium potential of this half-cell reaction is obtained by applying the Nernst equation, using the expression of the chemical potentials of adsorbed hydroxyl and water, as given in Eq 53:

www.iran–mavad.com

مرجع مهندسی مواد و متالورژی

$$E = E^\circ + 2.303\left(\frac{RT}{F}\right)\log\left[\frac{\theta_{OH}}{\theta_{H_2O}}\right] - 2.303\left(\frac{RT}{F}\right)pH \quad \text{(Eq 55)}$$

where θ_{OH} and θ_{H_2O} are the relative coverages by adsorbed hydroxyl and water on the M surface.
The standard potential E^o on the SHE scale is given by:

$$E^\circ_{(SHE)} = \frac{\left(\mu^0_{OH_{ads}(M)} + \mu^0_{H^+} + \mu^0_{e^-} - \mu^0_{H_2O_{ads}(M)}\right)}{F} \quad \text{(Eq 56)}$$

The standard chemical potentials, or Gibbs free energies of formation, for adsorbed sulfur oxygen, or hydroxyl are derived from literature thermodynamic data on the reversible chemisorption of these species at the metal-water interface or, if not available, at the metal-gas interface (Ref 35, 36, 37, 38, 39). Adsorbed water is weakly adsorbed on most transition metals, compared to chemisorbed species. In the absence of accurate thermodynamic data, the standard Gibbs free energy of adsorption of water from the liquid state may be neglected; that is, the standard Gibbs free energy of adsorbed water is approximated by the free energy of liquid water. This value and the values for sulfur and oxygen adsorbed on iron, calculated for the formation of the chemisorbed species from S and O_2 in their standard state at 25 °C, are listed in Table 3.

Table 3 Standard Gibbs free energies of formation (chemical potentials) for water, oxygen, and sulfur adsorbed on iron surfaces at 25 and 300 °C

E-pH Equations for Oxygen and Sulfur Adsorbed on Iron. As an example, presented here are the *E*-pH relations for the equilibria between oxygen and sulfur adsorbed on iron and dissolved species in water containing sulfides (H_2S or HS^-) or thiosulfates ($HS_2O_3^-$ or $S_2O_3^{2-}$). It is considered that the ratio of the area of electrode to the volume of solution is small enough so that the activity (molality m_S) of each dissolved sulfur species is independent of the sulfur surface coverage, θ_S. The uncertainty on these equations is relatively high because of the lack of accuracy of the thermodynamic measurements presently available for chemisorbed sulfur and oxygen:

$$S_{ads}(Fe) + H_2O(l) \rightleftharpoons O_{ads}(Fe) + H_2S(aq) \quad \text{(Eq 57)}$$

At 25 °C:

$$\log(\theta_O/\theta_S) = -18.8 - \log m_S \quad \text{(Eq 58)}$$

At 300 °C:

$$\log(\theta_O/\theta_S) = -7.9 - \log m_S \quad \text{(Eq 59)}$$

where θ_O and θ_S are the relative coverages by the adsorbed oxygen and sulfur on the Fe surface.

$$S_{ads}(Fe) + H_2O(l) \rightleftharpoons O_{ads}(Fe) + HS^- + H^+ \quad \text{(Eq 60)}$$

At 25 °C:

$$\log(\theta_O/\theta_S) = pH - 25.8 - \log m_S \quad \text{(Eq 61)}$$

At 300 °C:

$$\log(\theta_O/\theta_S) = pH - 16.4 - \log m_S \quad \text{(Eq 62)}$$

$$H_2O_{ads}(Fe) \rightleftharpoons O_{ads}(Fe) + 2H^+ + 2e^- \quad \text{(Eq 63)}$$

مرجع مهندسی مواد و متالورژی

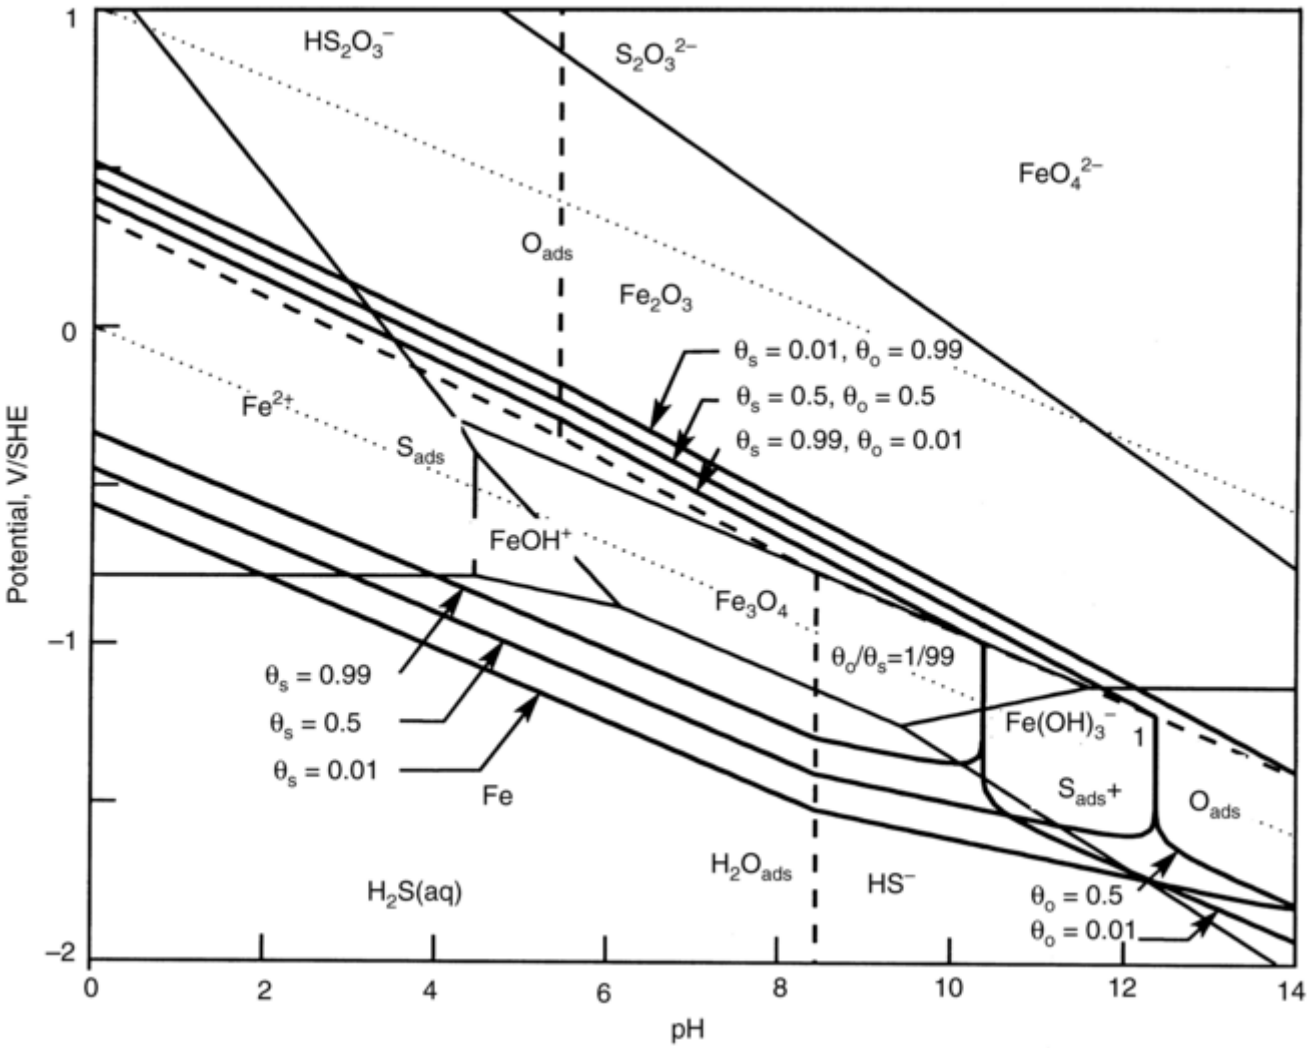

Fig. 20 *E*-pH diagram for the system of sulfur, oxygen, and water adsorbed on iron at 300 °C (573.15 K) in the case where the thiosulfates are the only oxidized forms of sulfur. The stability domains are limited by the dotted lines for the water system, dashed lines for the sulfur-water system, and thin solid lines for the iron-sulfur-water system and thick solid lines for the adsorbed species system. θ_S and θ_O are the relative surface coverages of adsorbed sulfur and oxygen, respectively. $m_S = 10^{-4}$ mol/kg, $m_{Fe} = 10^{-6}$ mol/kg

The domains of stability of adsorbed species are limited by lines corresponding to significant values of the surface coverage: θ = 0.01; 0.5; 0.99. For $\theta_S > 0.5$ and a ratio $\theta_O/\theta_S < 0.01$, sulfur is considered as the only adsorbed species in the domain, and θ_O may be neglected in Eq 51, Eq 52, Eq 52, Eq 52, Eq 52. Similarly, for $\theta_O > 0.5$ and a ratio $\theta_O/\theta_S > 100$, oxygen is considered as the only adsorbed species, and θ_S may be neglected in Eq 64 and 65. For $0.01 < \theta_O/\theta_S < 100$, the adsorbed phase is a mixture of coadsorbed sulfur and oxygen, and both terms θ_S and θ_O must be taken into account in the equations.

In the stability domain of H_2S(aq), the ratio θ_O/θ_S is constant (Eq 58, 59). It is negligible at 25 and 300 °C (for $m_S = 10^{-4}$ mol/kg), hence, θ_O can be neglected in Eq 67 and 68, and only sulfur is adsorbed by replacement of water. For a given value of θ_S, the ratio θ_S/θ_{H_2O}($\theta_{H_2O} = 1 - \theta_S - \theta_O$) is fixed, and the *E*-pH relation for sulfur adsorption from H_2S(aq) by replacement of water (Eq 67, 68) gives a straight line (Fig. 19, 20).

In the stability domain of HS^-, the ratio θ_O/θ_S increases with pH, according to Eq 61 and 62. At 25 °C, this ratio is infinitesimal up to pH 14. At 300 °C for $m_S = 10^{-4}$ mol/kg, it becomes significant (>0.01) for a pH value below 14. The pH values corresponding to $\theta_O/\theta_S = 0.01$ (pH = 10.4) and $\theta_O/\theta_S = 1$ (pH = 12.4) are represented by vertical lines in the diagram (Fig. 20). The first vertical line is the left boundary of a domain, where sulfur and oxygen are coadsorbed. In this domain, as the ratio θ_O/θ_S varies with pH, the ratios $\theta_S/(1 - \theta_S - \theta_O)$ and $\theta_O(1 - \theta_S - \theta_O)$ depend both on θ_S (or θ_O) and pH. Therefore, the *E*-pH relations calculated for sulfur adsorption from HS^- (Eq 70, 71) and oxygen adsorption from water (Eq 64, 65), for given values of θ_S and θ_O, give nonstraight

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

lines (Fig. 20). These lines become vertical at the pH values where the water coverage becomes infinitesimal, that is, the coverage $\theta_S + \theta_O$ reaches unity (full monolayer of coadsorbed sulfur and oxygen). At these pHs, the line for a given sulfur coverage, θ_S, meets the line for the complementary oxygen coverage $\theta_O = 1 - \theta_S$, and they merge with the vertical line plotted for the corresponding ratio θ_O/θ_S (Fig. 20).

In the stability domains of thiosulfates, the *E*- pH relations for the replacement reaction between adsorbed sulfur and oxygen give straight lines for a fixed ratio θ_O/θ_S (Eq 73, 74, 76, 77). A simplification occurs here, because the water coverage $\theta_{H_2O} = 1 - \theta_O - \theta_S$ is negligible in the domain of thiosulfates (that can be checked by associating Eq 58 and 59 or 61 and 62 with 64 and 65 and calculating θ_{H_2O} at the anodic limit of the sulfides domains), so θ_O in Eq 73, 74, 76, and 77 can be approximated by $1 - \theta_S$. Then, straight lines are obtained for given values of θ_S, which delimit the respective stability domains of adsorbed sulfur and oxygen (Fig. 19, 20).

The diagrams (Fig. 19, 20) allow the prediction of the *E*-pH conditions in which sulfur is adsorbed on an iron surface from sulfides or from thiosulfates dissolved in water (Ref 40). The main features are the following: when the potential is increased, adsorbed water molecules are replaced by sulfur atoms adsorbed by electrooxidation of sulfides. Similarly, when the potential is decreased, adsorbed oxygen atoms (or hydroxyl groups) are replaced, totally or partially, by sulfur atoms adsorbed by electroreduction of thiosulfates. The replacement takes place within a very narrow range of potential (~0.06 V at 25 °C; ~0.11 V at 300 °C). At 300 °C, the stability domain of adsorbed sulfur alone is limited at high pH by the domain of coadsorption S_{ads} - O_{ads} (Ref 40).

The two-dimensional reactions involving oxygen (hydroxyl) and sulfur adsorbed on bare iron surfaces are of a different nature than the reactions involving the three-dimensional (bulk) Fe- O(OH) or iron-sulfur compounds. Hence, the diagrams developed here (Fig. 19, 20) are different from the classic *E*-pH diagrams of the iron-sulfur-water system (Fig. 13, 18). However, superimposition of the two types of diagrams is useful to discuss in more detail the possible effects of an adsorbed sulfur layer on the corrosion behavior of iron. At room temperature, the domain of stability of the adsorbed sulfur monolayer includes the stability domains of the bulk metal sulfides and Fe_3O_4 and overlaps the domains of metallic iron (immunity domain) of Fe^{2+} (activity domain), and Fe_2O_3 (Fig. 19). Sulfur adsorption is then expected for *E*-pH conditions where iron sulfides are not thermodynamically stable, which reflects the excess of stability of the two- dimensional chemisorbed species with respect to the three-dimensional compounds. At 300 °C, whereas no region of stability of iron sulfide exists for $m_S = 10^{-4}$ mol/kg, adsorbed sulfur is stable in a large domain, which includes the domain of Fe_3O_4 and overlaps the domains of iron, Fe^{2+}, Fe_2O_3, and $Fe(OH)_3^-$ (Fig. 20).

The prediction of domains of thermodynamic stability of adsorbed sulfur on iron in thiosulfate solutions supports the experimental observation of sulfur adsorption by thiosulfate reduction on iron-chromium alloys, which was invoked to explain the detrimental effect of dissolved thiosulfates on the corrosion resistance of ferritic stainless steels (Ref 16). The diagrams indicate stability of S_{ads} in a large part of the passivity domain. The chemisorption of sulfur on bare iron is a process in competition with the formation of Fe_3O_4 (and Fe_2O_3 in a limited *E*-pH region). The equilibrium *E*-pH diagrams are constructed on a thermodynamic basis and do not indicate which species actually form on a bare iron electrode polarized in the passive domain: the two-dimensional (surface) species $S_{ads}(Fe)$ or a three-dimensional (bulk) oxide. If the kinetics of adsorption of sulfur on bare iron is more rapid than the kinetics of formation of oxide layers on iron, a sulfur monolayer may form on iron and prevent or delay passivation of the iron. Detrimental effects of sulfur on the corrosion resistance of iron are then expected, even under *E*- pH conditions where a classic diagram predicts passivity. The diagrams (Fig. 19, 20) also predict that sulfur is likely to adsorb in part of the domain of anodic dissolution of iron; this is important because dissolution enhanced by adsorbed sulfur is experimentally observed in the activity domains of nickel- and iron-base alloys (Ref 33, 34). Even if the metal is not thermodynamically stable and dissolves, a sulfur monolayer may adsorb on the fresh surface, which is continuously produced, and increase the kinetics of dissolution.

Thus, the *E*-pH diagrams presented here showing the domains of thermodynamic stability of adsorbed layers on metals, provide a basis for assessing the risk of corrosion of metals or alloys induced by species adsorbed from aqueous solutions.

Molten Salt Corrosion Thermodynamics

Kurt H. Stern, Naval Research Laboratory

Introduction

MOLTEN SALTS—in contrast to aqueous solutions in which an electrolyte (acid, base, salt) is dissolved in a molecular solvent—are essentially completely ionic. Thus the terms *solute* and *solvent* can be defined only in quantitative terms. For example, the terms lose their meaning in a NaCl-AgCl melt where composition can vary continuously from pure NaCl to pure AgCl. This is true even when the electrodes immersed in the melt are reversible only to some of the ions in the melt. For example, in the cell:

$$Ag|AgCl|1NaCl|Cl_2 \qquad \text{(Eq 1)}$$

the chlorine electrode is reversible to Cl^- and the silver electrode is reversible to Ag^+. When this cell is used to obtain thermodynamic data, it is assumed that the cell is stable; that is, its composition does not change with time. However, when the concentration of AgCl is very low, this will not be the case, since the silver electrode will react spontaneously with the melt:

$$Ag + NaCl = AgCl + Na \qquad \text{(Eq 2)}$$

Thus the concentration of AgCl will spontaneously increase in the melt, and the electromotive forces (emf) measured for the preceding cell will not be stable but will change in the direction indicating increasing Ag concentration. The point at which this happens depends on the system.

Molten Salt Corrosion Thermodynamics

Kurt H. Stern, Naval Research Laboratory

Thermodynamics of Cells

One major use of electrochemical cells is to obtain thermodynamic data for salts. The basic thermodynamics applicable to galvanic cells for aqueous solutions is discussed elsewhere in this Volume. Only those aspects that are different for molten salts are emphasized in this article. Thus, for the cell given in Eq 1, the cell reactions are:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$Ag = Ag^+ + e^-$ $\frac{1}{2}Cl_2 + e^- = Cl^-$ (Eq 3)

and the result is:

$Ag + \frac{1}{2}Cl_2 = AgCl(a)$ (Eq 4)

where a is the activity of AgCl and the cell emf is

$$E = E^\circ - \frac{RT}{F}\ln a \quad \text{(Eq 5)}$$

It is assumed that when Cl_2 is in its standard state of unit fugacity (nearly equal to unit pressure) and silver is in its standard state (pure metal), E^o is the cell emf for:

$Ag(a = 1) + \frac{1}{2}Cl_2(f = 1) = AgCl(a = 1)$ (Eq 6)

and the only variable in Eq 5 is the activity of AgCl. (It should be emphasized that in any thermodynamic treatment, only neutral components; that is, AgCl, rather than Ag^+ or Cl^-, can appear.) In contrast to aqueous solutions, the activity, a, is usually defined on the mole fraction scale. The emf is E for the cell reaction shown previously, where:

$\Delta G = -nFE$ (Eq 7)

and

$$\Delta G = \Delta G^\circ + \frac{RT}{F}\ln a \quad \text{(Eq 8)}$$

The superscript ^{o}(ΔG^o, E^o) refers to the standard state, which in this case is the pure material; that is, AgCl. An activity coefficient, γ, is defined in terms of the activity, a, and the mole fraction, X:

$$\gamma = a/X$$

Note that γ may be less, equal, or greater than unity. This definition is based on Raoult's law standard state:

$\gamma = 1$ when $a = X$ (Eq 9)

In the case of an electrochemical cell, using Eq 1 as an example, where the cell emf is directly related to the activity of AgCl, the activity of the second component, NaCl, can then be calculated by the Gibbs-Duhem equation, which at constant temperature and pressure is:

$\sum X_i \, d \ln a_i = 0$ (Eq 10)

For the AgCl-NaCl system, the activity of AgCl(a_1) is known from experimental data (Eq 5), and the activity of NaCl(a_2) can then be calculated from Eq 10. The procedure for doing this is discussed in thermodynamic texts such as Ref 1. It generally requires a graphical integration as discussed in standard thermodynamics texts as well as standard free energies of formation (ΔG^o) of the pure components, which can be obtained from reference works like Ref 2. This equation shows that if the composition varies, the chemical potentials of the components do not change independently but instead in a related way.

In contrast to aqueous solutions where the potential of the hydrogen electrode ($\frac{1}{2}H_2 = H^+ + e^-$) is commonly assigned the value “zero” when reactants and products are in their standard states, no such condition exists for molten salts, because there is no solvent analogous to water in molten salts. Thus it is necessary to establish a specific scale for each medium; for example, $\frac{1}{2}Cl_2 + e^- = Cl^-$. It should be noted that while metal electrodes, Ag in the previous example, can be directly immersed in the melt, gas electrodes, like the chlorine electrode, require a solid surface on which the equilibrium $\frac{1}{2}Cl_2 + e^- = Cl^-$ can take place. Graphite has frequently been used for chlorine; platinum is often chosen for other gases, such as oxygen.

Electrodes for Molten Salts

The classification of electrodes is similar to that used for aqueous media. There are reference electrodes that maintain a constant potential independent of the melt concentration, and indicator electrodes that are reversible to some ion in the melt and can therefore be used to measure its activity.

Reference Electrodes. Historically, the oldest reference electrodes are those that use a liquid junction (LJ) between the electrode compartment and the melt under study. The Ag/AgCl electrode is of this type, and its half-cell is:

$$\mathrm{Ag/AgCl,\ NaCl(reference\ melt)} \times \mathrm{LJ\,|(melt\ under\ study)} \qquad \text{(Eq 11)}$$

The melt under study contains the same ions as the reference melt, but its concentration is variable. If the concentrations of the two melts are not too far apart, the LJ potential is probably negligible. One way of forming the junction is to insert an asbestos fiber into a small hole between the compartments. It may also be formed inside a material that is porous and thus can be saturated with the melt but that prevents bulk mixing. Jenkins, Mamantov, and Manning (Ref 3) described a reference for use in molten fluorides based on the Ni/Ni(II) couple, which uses boron nitride as the separator. The boron nitride becomes saturated by the melt and thus serves as an LJ that isolates the reference melt. Porous glass can also be used as a separator, but obviously not in fluoride melts.

Another reference electrode useful in melts that contain oxide ion, usually as Na_2O, was developed by Liang, Bowen, and Elliott (Ref 4). This electrode is:

$$\frac{\mathrm{W, Na_2S, WS_2}}{\mathrm{11Al_2O_3\,(beta\ alumina)}} \qquad \text{(Eq 12)}$$

and operates at an oxide activity fixed by the reaction:

$$\tfrac{1}{2}\mathrm{W(s) + Na_2S + \tfrac{1}{2}O_2 = \tfrac{1}{2}WS(s) + Na_2O} \qquad \text{(Eq 13)}$$

inside a beta alumina membrane, where S is solid. Alternatively, mullite, a ceramic that is also a sodium ion conductor, can also be used as a separator that isolates the reference electrode from the melt under study. This is particularly useful because mullite closed-end tubes are readily available, and the reference electrode and its associated melt are then simply inserted into the tube.

For melts containing dissolved oxides, the oxygen electrode inside a zirconia membrane is a useful reference. The actual electrode is platinum bathed in an environment of O_2 at a fixed partial pressure. Air is usually used as the source of oxygen. The platinum is forced into a zirconia tube stabilized with a divalent oxide, such as CaO, MgO, or Y_2O_3, which acts as an oxide ion conductor. The electrode reaction is:

$$\tfrac{1}{2}O_2 + 2e = O^{2-} \qquad \text{(Eq 14)}$$

Indicator Electrodes. The chief characteristic of indicator electrodes is that their potential varies with the activity of an ionic component, usually in a Nernstian way. The performance of molten salt indicator electrodes does not differ substantially from the performance of other electrodes. For example, the Ag electrode in the melt under study changes its potential with changes in melt composition (Eq 5). However, because of the

technical problems in maintaining an LJ, such as corrosion, most indicator electrodes use solid-state materials that are ionic conductors: stabilized zirconia, which is an oxide-ion conductor; beta-alumina, a sodium-ion conductor; and sulfide-ion conductors, such as Cu_2S. For an example of how the silver reference electrode can be combined with other electrodes to measure oxide ion activity, see Ref 5.

In selecting these materials, the range of temperatures and gas phase composition over which the material is an ionic conductor must be considered. If a substantial fraction of the conductivity is electronic, the response of the electrode will not be Nernstian, and emf measurements will give inaccurate results. For each material there is a diagram that separates the ionic conductivity from the electronic (*n*-type and *p*-type) as a function of pressure and temperature (Ref 6), and it is obviously desirable that most of the conductivity is ionic if the material is to be useful.

Materials based on stabilized zirconia are particularly useful, because they are oxide ion conductors. The electrical properties of these materials have been described in detail (Ref 7). The uses of these materials fall into two categories: equilibrium methods and nonequilibrium methods. Examples of equilibrium methods include:

- Measurement of the O_2 partial pressure in gases (Ref 7)
- Measurement of the O_2 solubility in metals (Ref 7)
- Measurement of the dissociation pressure of solid oxides (Ref 7)
- Measurement of the oxide activity in molten salts (Ref 8, 9, 10) and in glasses (Ref 11)

Nonequilibrium methods include:

- Operation of an oxygen fuel cell (Ref 4)
- Changing the O_2 content of gases (Ref 12, 13)
- Measurement of the diffusivity of O_2 in metals (Ref 14)
- Titration of O_2 into and out of metals (Ref 14) and molten salts (Ref 15)

Molten Salt Corrosion Thermodynamics

Kurt H. Stern, Naval Research Laboratory

Thermodynamics of Molten Salt Corrosion

Corrosion of metals in aqueous solution has been studied for many years, and the thermodynamic principles have been discussed by Pourbaix (Ref 16, 17). The applicable principles are commonly summarized in Pourbaix diagrams, which contain a great deal of data in a convenient arrangement that allows the prediction of what reactions will occur in a particular system.

A corresponding system for molten salt corrosion has been explicitly described for molten chlorides (Ref 18, 19). In contrast to aqueous solutions where corrosion is always accompanied by oxidation, corrosion in molten salts can be caused by the solubility of the metal in the salt, particularly if the metal dissolves in its own chloride. The more usual case is one in which the metal is oxidized.

Littlewood has used the convention that the free energy of formation of the halide ion from the halogen gas at one atmosphere pressure and unit halide activity is zero at all temperatures. Gibbs energies (ΔG) are converted to potentials by the usual relation $E = -\Delta G/nF$. In Pourbaix diagrams, equilibrium potentials are plotted against pH with a resulting schematic division into regions of stability of different solid phases. For molten salts, Littlewood chose the activity of oxide in the melt, expressed as pO^{2-}(p = -log), and the appropriate diagram is then E versus pO^{2-}. Such diagrams can be constructed for any metal and melt, and Littlewood has described several cases (Ref 20), including those in which there is more than one stable oxide, such as titanium. These diagrams should be as useful for molten salts as Pourbaix diagrams are for aqueous solutions. However, although this work was published about 30 years ago, it does not seem to have been widely used.

Such a diagram that plots potential as a function of pO^{2-} is given in Fig. 1 for the Ti-NaCl system at 800 °C and Fig. 2 for the Ti-$MgCl_2$ system. Note that O^{2-} is the concentration on the mole fraction scale and pO^{2-} is its negative logarithm. On both diagrams, the outer scale, labeled log O_2, refers to the pressure of oxygen gas in each system.

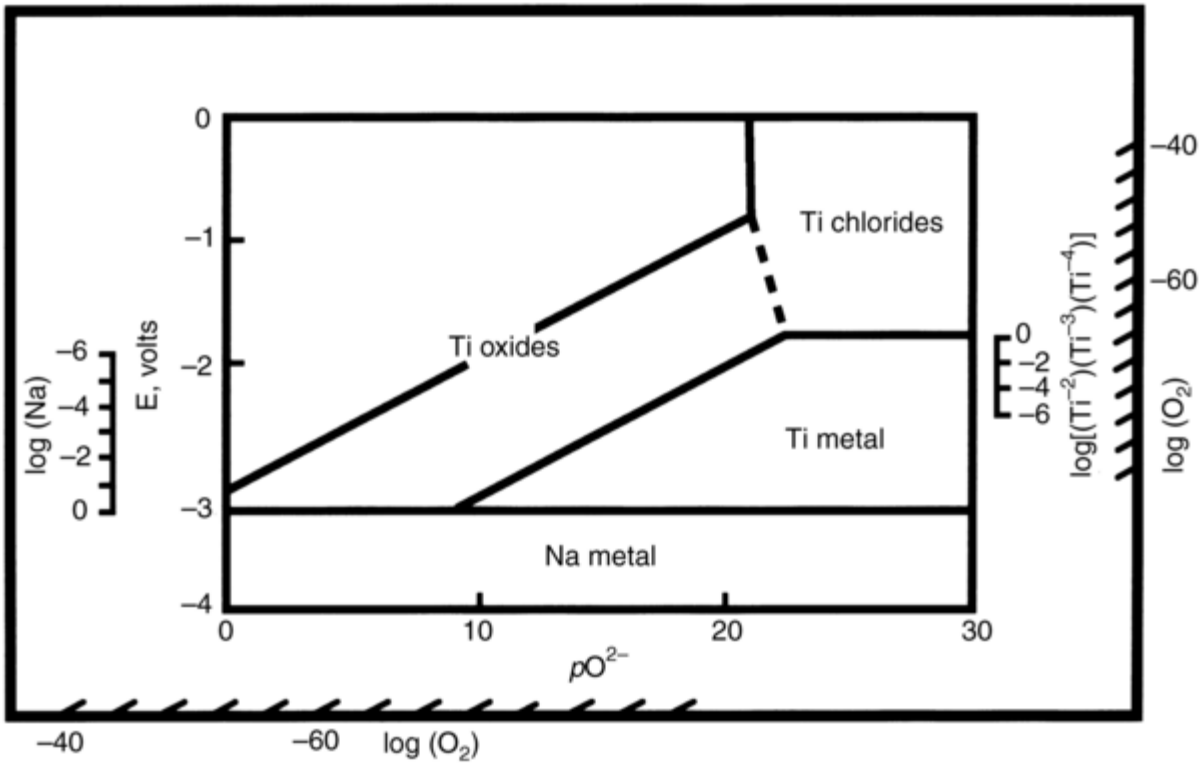

Fig. 1 E-pO^{2-} diagram for Ti-NaCl system at 800 °C (approximate). Source: Ref 20

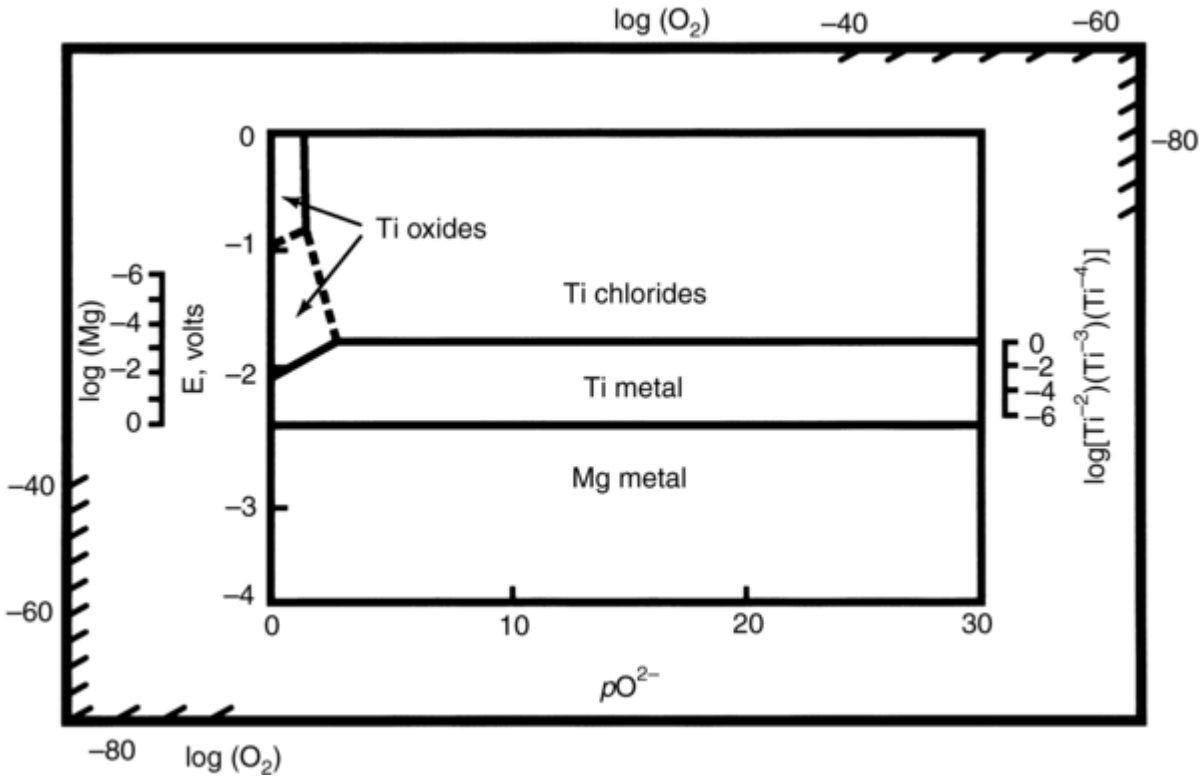

Fig. 2 E-pO^{2-} diagram for Ti-$MgCl_2$ system at 800 °C (approximate). Source: Ref 20

The corrosion of titanium is affected by three factors: the titanium chloride content of the $MgCl_2$ melt, Mg or Na content, and oxygen content of the product. The interplay of the three factors can be readily investigated by a detailed comparison of Fig. 1 and 2. Comparison of the diagrams shows that for a given value of pO^{2-}, the oxygen activity in the titanium metal product would be much lower for magnesium reduction than for sodium reduction. The equilibrium potentials after the reaction has gone to completion will be -3.20V for sodium and -2.47V for magnesium. Suppose, for example, the oxide contamination present in the two cases is sufficient to produce a pO^{2-} value of 20 in the slag and that excess reductant has been used. Figure 1 shows that under these

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

conditions, the oxygen activity in the titanium metal produced by sodium reduction would be about 10^{-62}, while that produced by magnesium reduction (Fig. 2) would be about 10^{-86}.

Geochemical Modeling

Steven A. Matthes, U.S. Department of Energy, Albany Research Center

Introduction

CORROSION SCIENTISTS AND ENGINEERS frequently need to describe the chemical state of local environments, including mass distribution of aqueous species, and the interaction of these aqueous species with metal surfaces, corrosion films, and gases. In high temperature corrosion, metals may be corroded by nonaqueous fluids or by solids such as slags. These types of interactions are geochemical in nature; that is, the reactions are the same as those found in natural aqueous, high-temperature, or magmatic systems. When

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

chemical systems are simple with few possible reactions likely to occur, the geochemistry of a local environment may be described through experience and some (usually tedious) hand calculation.

When the geochemistry of an environment is more complex, however, quantitative models of aqueous or solid phase chemistry that are beyond the predictive power of experience and hand calculation are required. The need for a consistent way to evaluate complex geochemical systems has led to a rapid increase in the field of *geochemical modeling.* The rapid growth roughly parallels the rise in power and reduction in cost of computers needed to evaluate the complicated quantitative models of solution chemistry. Geochemical modeling is now being used to understand and predict scaling, susceptibility to corrosion, atmospheric corrosion rates, acid rain, corrosion film solubility, and environmental impacts of aqueous species in runoff.

Geochemical modeling software (GMS) is widely used by scientists and engineers to solve a variety of materials and energy-balance problems. The predictive ability of GMS allows the user to model real situations and to ascertain how materials should behave when subjected to different environments. The advent of inexpensive and powerful desktop computers and a wide variety of both commercial and freeware software tools make this predictive power available to almost every scientist and engineer. As an example, the freeware program PHREEQC is capable of simulating a wide range of aqueous geochemical reactions including the mixing of waters, addition of net irreversible reactions to solution, dissolving and precipitating phases to achieve equilibrium with the aqueous phase, and the effects of changing temperature. The PHREEQC program and commercial software packages such as AquaChem (Fig. 1) now have sophisticated graphical user interfaces for performing geochemical modeling.

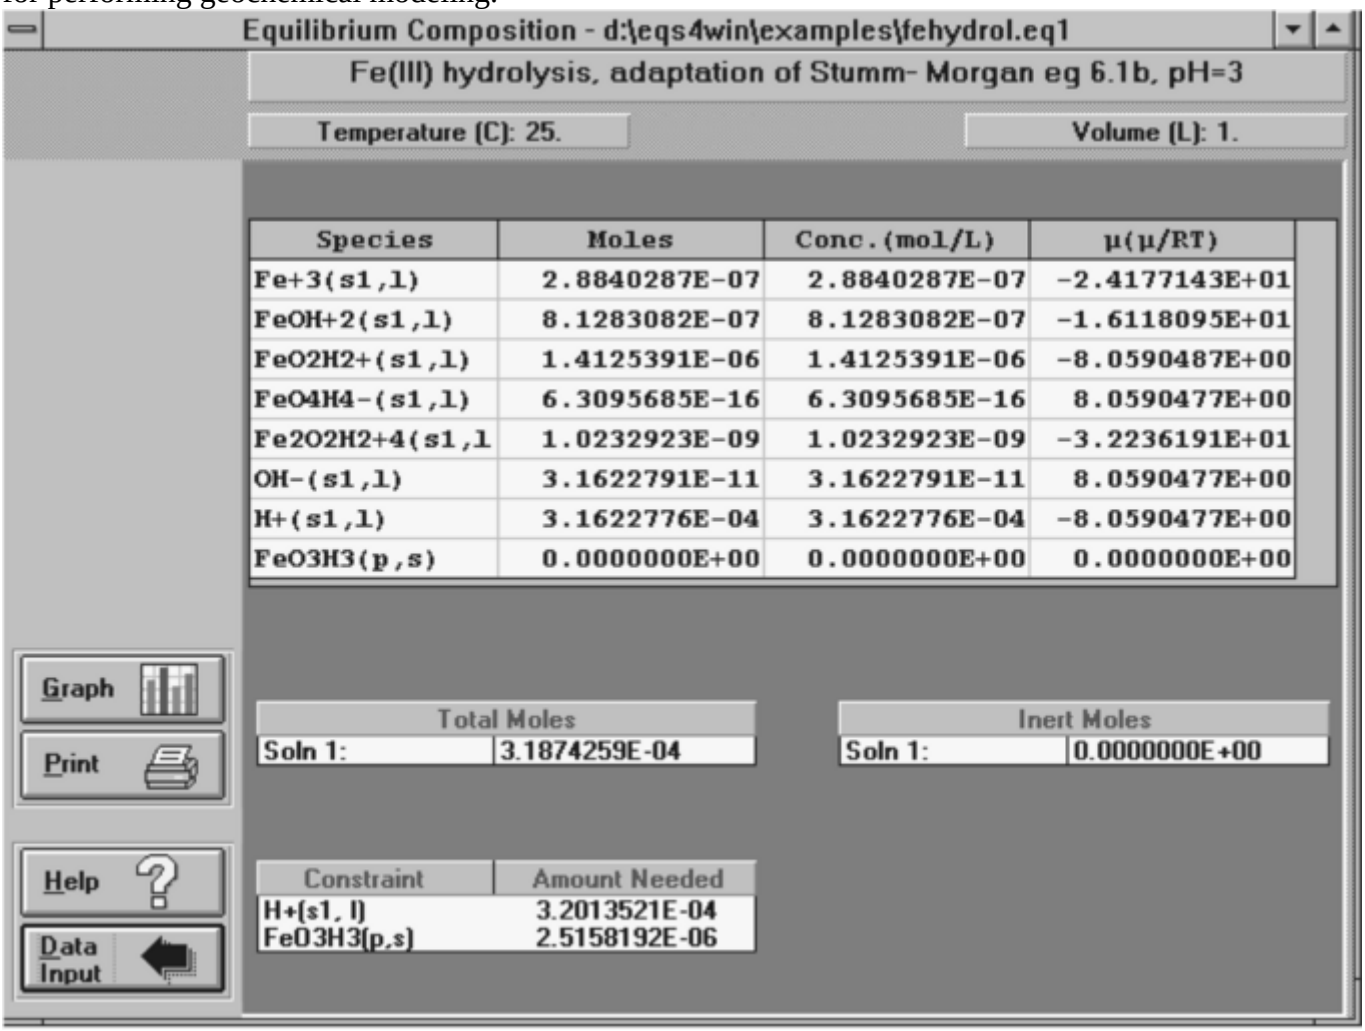

Fig. 1 Determination of equilibrium composition using the geochemical modeling software (GMS) AquaChem

Concentrations of elements, molarities and activities of aqueous species, pH, saturation indices, and the electrochemical oxidation state of the system are calculated with this type of software. Mole transfers of phases to achieve equilibrium can also be calculated as a function of specific reversible and irreversible reactions, provided the necessary thermodynamic data are available.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The electrochemical oxidation state of aqueous systems is usually given as the negative log of the electron activity (*pe*) or the electrochemical oxidation potential (E_H) in geochemical modeling. Just as pH is useful in describing the equilibrium position of all acid/base pairs in a system:

$$(\text{Acid/base}) \qquad HB = H^+ + B^-$$

$$K = \{H^+\}\{B^+\}/\{HB\} \qquad pH = -\log\{H^+\}$$

pe expresses the equilibrium position of all redox pairs in a system. For example, for the Fe^{+3}/ Fe^{+2} redox couple,

$$(\text{Redox}) \qquad Fe^{+3} + e^- = Fe^{+2}$$

$$K = \{Fe^{+2}\}/(\{Fe^{+3}\}\{e^-\}) \qquad pe = -\log\{e^-\}$$

Just as pH may be considered the *controlling variable* for the acid/base system, *pe* is the controlling variable for the redox system. Treating the electron like other reactants and products in a system allows redox reactions such as the previous one to be combined directly with other reactions leading to the determination of equilibrium constants for the combined reactions of interest in a system. Although E_H is usually thought of as the measured potential of an aqueous system, it is also related to the *pe* by the equation:

$$E_H = (2.303RT_k/F)pe$$

where R is the gas constant, F is the Faraday constant, and T_k is the absolute temperature.

The environments that GMS best describes, aqueous systems that are open or closed to the atmosphere and that have interactions with one or more solid phases, are precisely the same environments that concern corrosion engineers. Software systems such as The Geochemist's Workbench can easily model aqueous systems in contact with several mineral phases (Fig. 2). Ironically, GMS systems are seldom used by corrosion scientists and engineers, even though geochemical modeling may provide greater insight into the causes and results of corrosion reactions and processes.

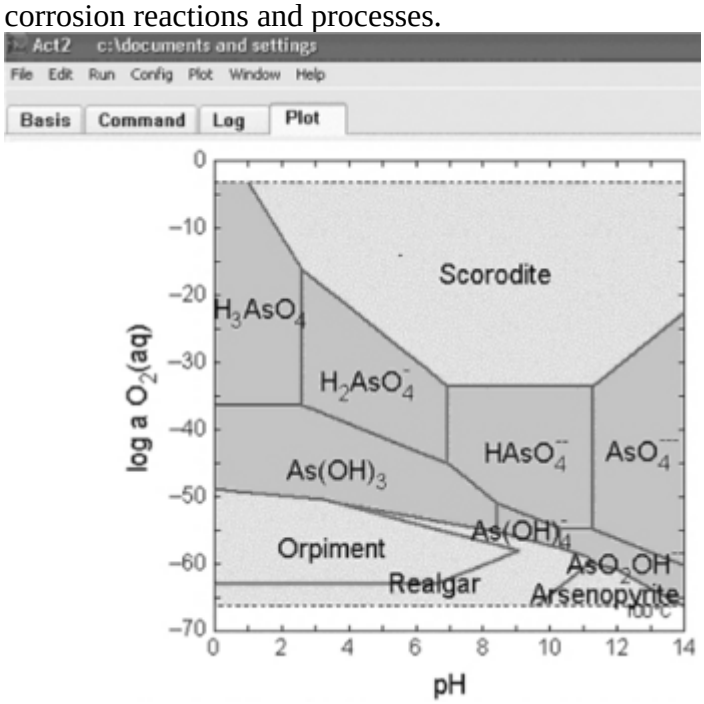

Fig. 2 A plot of log of oxygen activity (log a O_2 (aqueous) versus pH) for arsenic minerals using The Geochemist's Workbench. Log a O_2 is log of oxidation potential.

Geochemical Modeling

Steven A. Matthes, U.S. Department of Energy, Albany Research Center

History of Geochemical Modeling

In 1947, an algorithm for the numerical solution of equilibrium states in a multicomponent system was published (Ref 1). Although intended for a desk calculator, the method was quickly adopted for use with digital computers. The algorithm was based on the evaluation of equations for equilibrium constants.

Garrels and Thompson (Ref 2) calculated (by hand) the composition of seawater in terms of dissociated ions (Na^+, Ca^{++}, HCO_3^-, etc.). This calculation gave rise to a type of geochemical model that predicts species distributions, saturation indices, and gas fugacities from chemical analyses. Equilibrium models of this type have become widely used, largely because of the availability of software such as SOLMNEQ (Ref 3), WATEQ (Ref 4), and MINEQL (Ref 5).

Another type of geochemical model, the reaction path model, was introduced in 1967 (Ref 6) and was used to model the effects of evaporation (gradually increasing concentration) on species distribution. This model extended geochemical modeling from the evaluation of a fixed system to having the ability to simulate a process.

Hegelson (Ref 7) built on previous work by coding the general equations for species distribution and mass transfer into a computer program. The program Path1 (Ref 8) was the first general computer method for modeling reaction paths such as weathering, evaporation, ore deposition, and hydrothermal alteration.

One way of modeling reaction paths is by repeatedly solving for the system equilibrium state algebraically. Karpov and Kaz'min (Ref 9) and Karpov et al. (Ref 10) applied this idea to GMS, allowing an algebraic solution to systems varying in temperature and composition. In 1979, EQ3/EQ6 (Ref 11) was introduced as the first geochemical model to be documented and distributed based on algebraic equations. This greatly simplified the computer code and separated mass and heat transfer calculations from the chemical equilibrium calculations. Parkhurst et al. introduced PHREEQE (Ref 12) (a precursor to PHREEQC) a year later, and most GMS developed since then uses the algebraic method for determination of equilibrium states. A more comprehensive history of GMS can be found in Ref 13.

Today, a large number of sophisticated GMS are available (Table 1) based on the pioneering work conducted in the 1960s and 1970s. These programs owe their existence to the compilation of thermodynamic data on which all geochemical modeling depends (Ref 14). An excellent compilation of thermodynamic and kinetic databases may be found at http://www.nea.fr/html/ science/docs/1996/nsc-doc96-27.html.

Geochemical Modeling

Steven A. Matthes, U.S. Department of Energy, Albany Research Center

---

Principles of Geochemical Modeling

A *model* is a predictive tool for describing reality in a simplified way. For a model to be successful, it must adequately describe a real system but be simple enough that it can be easily evaluated. The *system* is that portion of the environment one wishes to study. A *closed system* has fixed composition; an *open system* can involve mass transfer into or out of the system. A system has boundaries (extent) that may be as small as a raindrop or as large as an ocean. A general discussion of models can be found in the article "Modeling Corrosion Processes" in this Volume.

Geochemical models are normally based on the equilibrium system containing a liquid and one or more mineral phases with an initial known composition and temperature. This allows the equilibrium state of a system to be determined. In a closed system at known temperature, the model can predict the distribution of mass between mineral phases and aqueous species as well as the species activities, the fugacities of gases that may exist in the system, and the saturation state of the minerals. The constituents of the system remain in chemical equilibrium throughout the calculation. Transfer of mass into or out of the system and variation in temperature drive the system to a series of new equilibria over the course of the reaction path. The composition of a system may be buffered by equilibrium with an external gas reservoir such as the atmosphere (Fig. 3).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

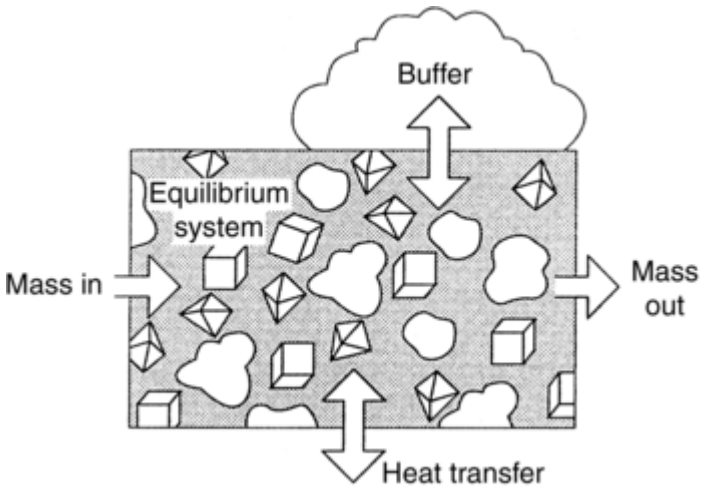

Fig. 3 Schematic diagram of a reaction model. Source: Ref 13

In complicated models, system composition and/or temperature may vary, and so the model must be able to account for transport of mass or heat into or out of the system. The initial equilibrium state is then the starting point for the reaction path to follow.

Because geochemical models deal with equilibrium systems, it is useful to define *equilibrium.* In general a system is in equilibrium when no spontaneous change occurs within the defined boundaries of the system. In this case the system can be said to be in *complete equilibrium,* and all possible chemical reactions are in equilibrium. If one or more possible reactions tend toward equilibrium at an extremely slow rate, the system is in *metastable equilibrium.* In *partial equilibrium,* the liquid phase (fluid) may be in equilibrium but not in equilibrium with one or more mineral phases in contact with it. If a small portion of a system is chosen, this subsystem may be in *local equilibrium.*

A successful geochemical model must at least define:

- Initial conditions of the system (composition and temperature)
- Type of equilibrium to be maintained
- Mass or temperature change occurring in the system during the reaction process to be modeled

The initial system contains by convention 1 kg (2.2 lb) of water, an amount that may be altered by the modeler. Mineral phases may also be included with each mineral in equilibrium with the fluid. In general, the system will be constrained by defining the initial conditions:

- Solvent water mass (1 kg by default)
- Amounts of mineral phases
- Fugacities of any gases at known partial pressure
- Fluid chemistry, amounts of dissolved components as determined by chemical analysis
- Activities of a species such as H^+, HCO_3^-, CO_3^{2-}

Once the initial conditions of a system have been so defined, the modeler can introduce a reactant (*titration model*) to the equilibrium system. The reactant dissolves irreversibly, which may cause mineral phases in the system to dissolve (i.e., the reactant is an acid) or the precipitation of one or more mineral phases that become saturated in relation to the fluid phase. The reaction proceeds until the reactant is exhausted or saturated in the system. In most geochemical systems, the solubility of minerals is very small, so the fluid is likely to reach saturation after only a small amount of mineral has dissolved.

Many corrosion processes occur in liquids in contact with a gaseous phase. The gas (usually the atmosphere in geochemical models) acts to buffer the system chemistry by allowing the fluid to maintain equilibrium with the gas phase. Models of this type are called *fixed-fugacity reaction paths.* Models where the fugacities may vary during the reaction, usually because of a reaction causing the evolution of a gas, are called *sliding-fugacity reaction paths.*

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Systems where the activities of the aqueous species may vary during the course of a reaction are called *sliding-activity* models and *fixed-activity* models when the activities remain the same.
In *flow-through reaction path* models, the change in a fluid can be followed as it flows over or through various mineral phases, which may react with the fluid. This type of model may also be used to study changes in equilibrium in a fluid undergoing evaporation.

Limitations in Geochemical Modeling

A geochemical model is only as good as the completeness and accuracy with which the initial system conditions are defined. Usually this requires a chemical analysis, the pH, and/or the oxidation state (the dissolved oxygen content) of liquid samples. The accuracy of pH in particular can be problematic in geochemical systems, as the usually low total dissolved ion content in natural systems makes pH determination difficult. In such cases the use of field pH measurements or isolation of the system from atmospheric CO_2 in transport to the lab is paramount. Accuracy may also be improved by the use of low ionic strength pH standards. Chemical analysis will usually require both atomic spectroscopy for metal cations and ion chromatography or chemometric methods for anions. Liquid samples should not be stabilized by acidification unless the fluid is filtered to remove sediment and/or colloidal solids before acidification.
A model can be successful only if the thermodynamic dataset contains the mineral phases and aqueous species required for the system. Many datasets have limited ranges of pH, and so a dataset that does not contain solubility data for a species above pH 10 will be inadequate for systems at pH greater than 10. In addition, all thermodynamic datasets have errors related to chemical analysis and extrapolation. Many equilibrium constants have been determined for narrow temperature ranges, usually around room temperature, and datasets may contain extrapolated data for temperatures beyond this range.
Accuracy of calculated activity coefficients is another limitation to the model. For solutions of 1 molal or less ionic strength, models that use the Debye-Huckel method are fairly accurate. At higher ionic strengths, however, a model may require “Pitzer equations” to calculate activity coefficients in brines. The program PHREEQPITZ is a GMS designed specifically for systems of this type.
Most importantly, the modeler must make correct assumptions about the kind of equilibrium studied and develop an accurate perception of the reaction process. Does the system defined by the modeler accurately depict the real system? Are the mineral phases the correct ones? Are all the phases present necessary to describe the system? Is the system open or closed?

Geochemical Modeling

Steven A. Matthes, U.S. Department of Energy, Albany Research Center

Describing Equilibrium

A geochemical system for a given bulk composition can be described as the sum total of one or more phases present in the system. *Phases* are separable, distinct, homogeneous regions of space within the system. They are separated from each other by *surfaces*, which are characterized by gross changes in composition and properties between the separated phases.

In most geochemical models, a system will always contain an aqueous phase containing water and dissolved species, and it may also contact mineral and gas phases. If the system has only a fluid phase, it is called *homogeneous.* It is called *heterogeneous* if it contains solid and/or gaseous phases as well. Species are the subcomponents of the phases. A gas phase may contain the species CO_2 or O_2, while the fluid phase may contain the species H^+, Ca^{++}, NO_3^-, HCO_3^-, CO_3^+, or Cl^-.

Equilibrium is calculated by determining that state (at fixed temperature and pressure) at which the phases, surfaces, and species within the system have reached the minimum value for the Gibb's free energy function. The minimum is determined by evaluating the sum of the chemical potential functions (thermodynamic components) for each of the species in the system being modeled. The problem then becomes how to choose the thermodynamic components that best describe the system.

In a system to be modeled containing (a) water, (b) aqueous species, (c) minerals, and (d) gases, it is first necessary to determine all the possible independent chemical reactions possible between the species. Second, the sum total of the species present must balance the known mass of the system (i.e., if the system starts with 3 millimoles of sodium, it must have 3 millimoles of sodium at the calculated equilibrium). Third, the principle of electroneutrality requires that the ionic species in the fluid remain charge balanced.

Once the distribution of the species in the fluid phase has been determined, satisfying the previously mentioned criteria, the degree of undersaturation or supersaturation of each aqueous species with respect to the mineral phases of the system can be calculated. The *saturation index* is the calculated saturation of a fluid with respect to a mineral phase. Undersaturated minerals have negative saturation indexes. A positive saturation index indicates the mineral is supersaturated and the system is in metastable equilibrium while the system precipitates the supersaturated mineral.

The fugacity of the gases present in the system can also be calculated analogous to the saturation indices. The fugacities calculated are for a gas phase in equilibrium with the system.

Finally, *pe* and E_H, the electrochemical oxidation state of the equilibrium, may be determined. Many natural systems, especially at low temperatures, are not in equilibrium. The calculated values for *pe* and E_H can help ascertain the disequilibrium of a system.

All of the previously described calculations in the geochemical model are subject to Gibb's phase rule, better known as the degrees of freedom of the system. In most geochemical systems the degrees of freedom, or the number of pieces of information needed to describe the state, equals the sum of the number of phases in the system plus the number of aqueous species in the fluid. The number of phases equals each mineral phase plus each gas plus one for the fluid phase in which the aqueous species reside. This supplies the number of independent variables required by thermodynamics to solve each equation of the geochemical model.

Geochemical modeling must also account for changes in the system during the reaction that is modeled. A good example would be the disappearance of a mineral phase that has completely dissolved in the course of the reaction. If such a change to the system takes place, the degrees of freedom for the system change. Also, a mineral surface has been eliminated, the chemical reactions in the system have changed, and the equilibrium constants have altered. The modeling software must be able to compensate for all these changes.

The geochemical model describing a system consists of a set of equations with the principle unknowns typically being the mass of the water, the amount of the mineral phases, and the concentration of the aqueous species.

مرجع مهندسی مواد و متالورژی

Although most of the equations in the model are linear, some equations are nonlinear and use the Newton-Raphson iteration method for solving the equations.

Geochemical Modeling

Steven A. Matthes, U.S. Department of Energy, Albany Research Center

Applications of Geochemical Modeling to Corrosion

As is true with all geochemical reactions in nature, corrosion is a spontaneous phenomenon. For example, iron is a common component in the crust of the earth. Being a fairly reactive metal, iron is usually found not in the elemental state but as sulfides and oxides. Structures of iron and steel exposed to nature will tend to revert to the compounds (sulfides and oxides) from which the iron was extracted. Like iron, most other metals will corrode to a greater or lesser extent when exposed to air and water in the environment. Geochemical modeling software such as Outokumpu's HSC Chemistry can provide important information on the conditions required for corrosion to occur and ways to limit or prevent corrosion.

One of the earliest applications of GMS to the study of corrosion was in the computer-calculated construction of potential-pH plots, frequently referred to as Pourbaix diagrams (Ref 15). Pourbaix diagrams are a diagnostic tool to thermodynamically determine if a metal will corrode, form a passive film, or remain immune to corrosion when exposed to an aqueous environment (Fig. 4). The Pourbaix diagram consists of a plot of electrochemical potential (E_H) of metallic species in water (for example Fe_3O_4, Fe^{++}, Fe, etc.), versus pH (i.e. the acidity or basicity of water). The plots are constructed by considering which phase is thermodynamically most stable at a given pH, potential, and temperature.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

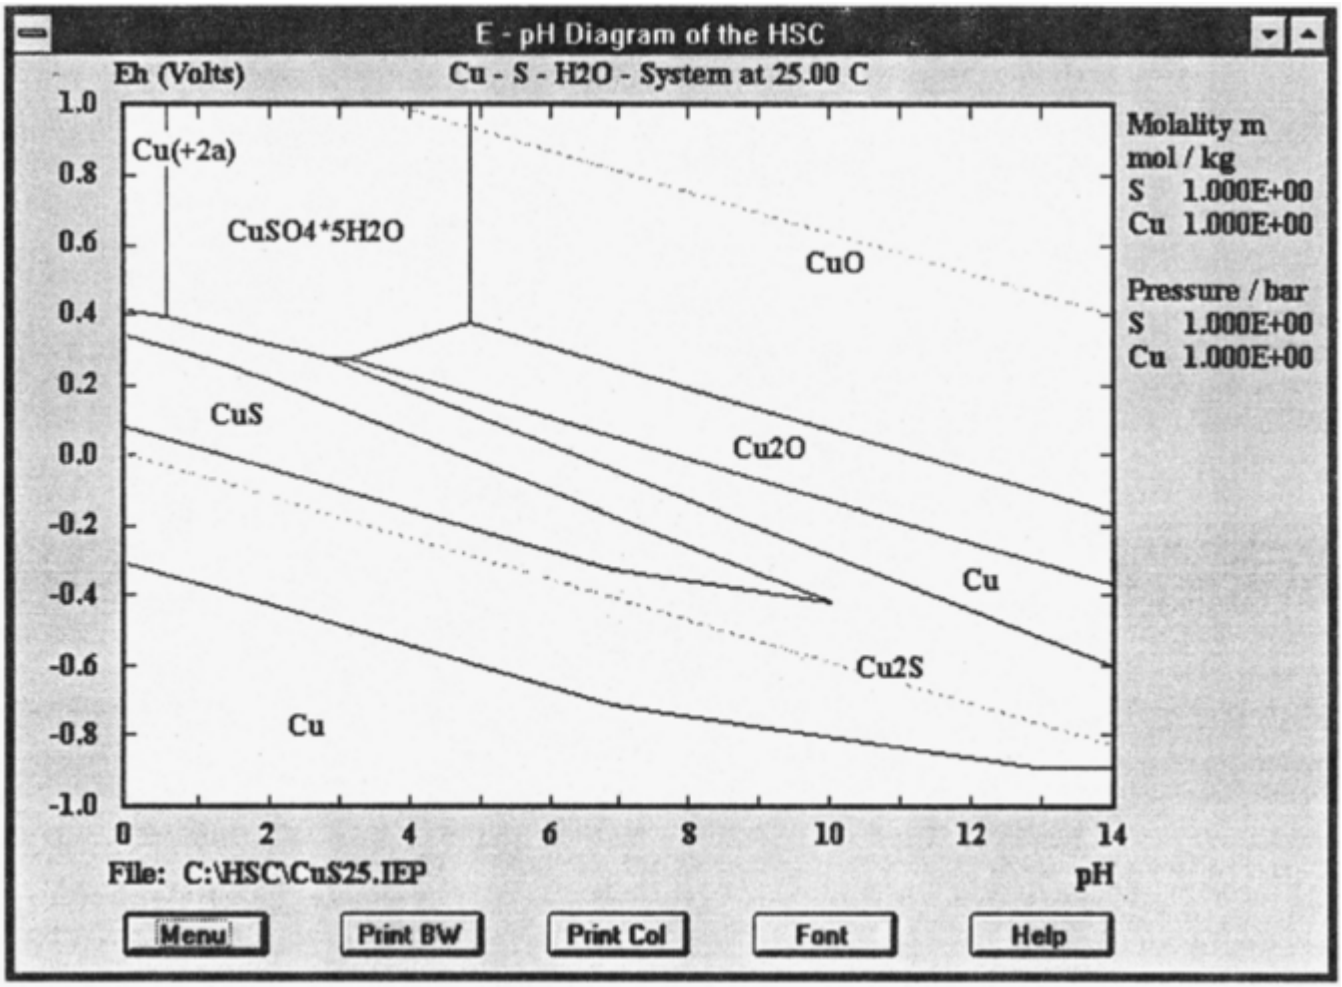

Fig. 4 A Pourbaix diagram (potential versus pH at 25 °C) for the copper, sulfur, water system derived using HSC Chemistry

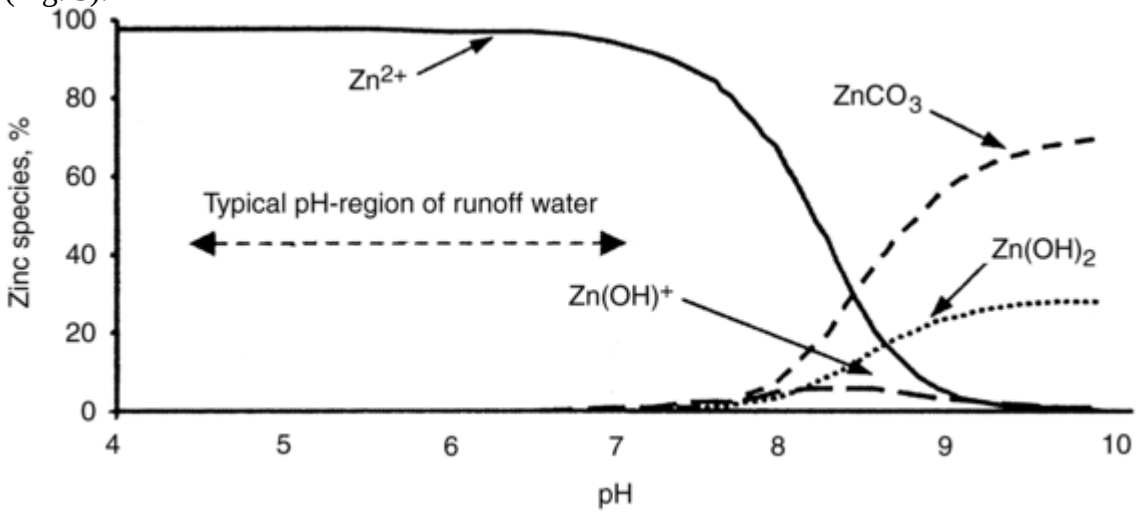
Using software called POT-pH-TEMP, the Electric Power Research Institute (EPRI) (Ref 16) calculated and published a large number of Pourbaix diagrams for a series of two and three component systems from 25 to 300 °C (75 to 570 °F). Elements studied were, S, Fe, Ni, Cr, C, B, N, Cu, Ti, and Zr. The diagrams were originally applied to corrosion problems in the nuclear power industry but were of such general nature that they have been used on a wide range of corrosion problems. Much GMS will generate the data for producing Pourbaix diagrams or will generate the diagrams themselves (Fig. 4).

One of the more useful features of geochemical modeling software is the ability to predict chemical speciation. In a study on the environmental effects on zinc atmospheric corrosion, Wallinder and Leygraf (Ref 17) were able to model the concentration of zinc species as a function of pH in the runoff water from zinc corrosion films (Fig. 5).



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 5 Chemical speciation of zinc in precipitation runoff as a function of pH predicted by the computer models MINTEQA2 and WHAM. The data are representative of the situation immediately after the runoff is released from zinc sample surfaces exposed in the Stockholm area.

Geochemical modeling software is frequently used in nuclear waste management. A number of articles have been written concerning corrosion of steel canisters and concrete containers or barriers holding nuclear waste. Atkinson et al. (Ref 18) used PHREEQE with additional data on nuclides to model corrosion of iron components and soluble species in concrete. A study of corrosion of metal canisters in a cementitious environment (high pH) using CHEQMATE and PHREEQE was done (Ref 19). The programs EQ3NR and PHREEQE were used to model the solubilities of actinide corrosion products in groundwaters (Ref 20, 21, 22). Interactions between groundwater and cement were studied to assess long-term performance of nuclear waste containment designs. The effect of the corrosion of concrete barriers and the subsequent alkaline plume that resulted were also studied (Ref 23), and others investigated corrosion of cemented waste in salt brines (Ref 24). Sharland et al. (Ref 25) used CHEQMATE and PHREEQE to study changes in E_H of the pore water and the removal of oxygen by the corrosion of metal canisters at a model nuclear repository. The PHREEQE software was also used to calculate variations in E_H in geochemical repositories (Ref 26). The computer model BLT-EC was developed for simulating the release and geochemical transport of contaminants from a subsurface nuclear disposal facility (Ref 27). The leaching behavior of uranium oxide subjected to groundwater corrosion and the resultant speciation was studied (Ref 28). In a later article, a thermodynamic model of the corrosion of uranium dioxide in granitic groundwater was described (Ref 29). The speciation of uranium phases in the weathering zone of the Bangombé U-Deposit using The Geochemist's Workbench (Fig. 6) was also studied (Ref 30).

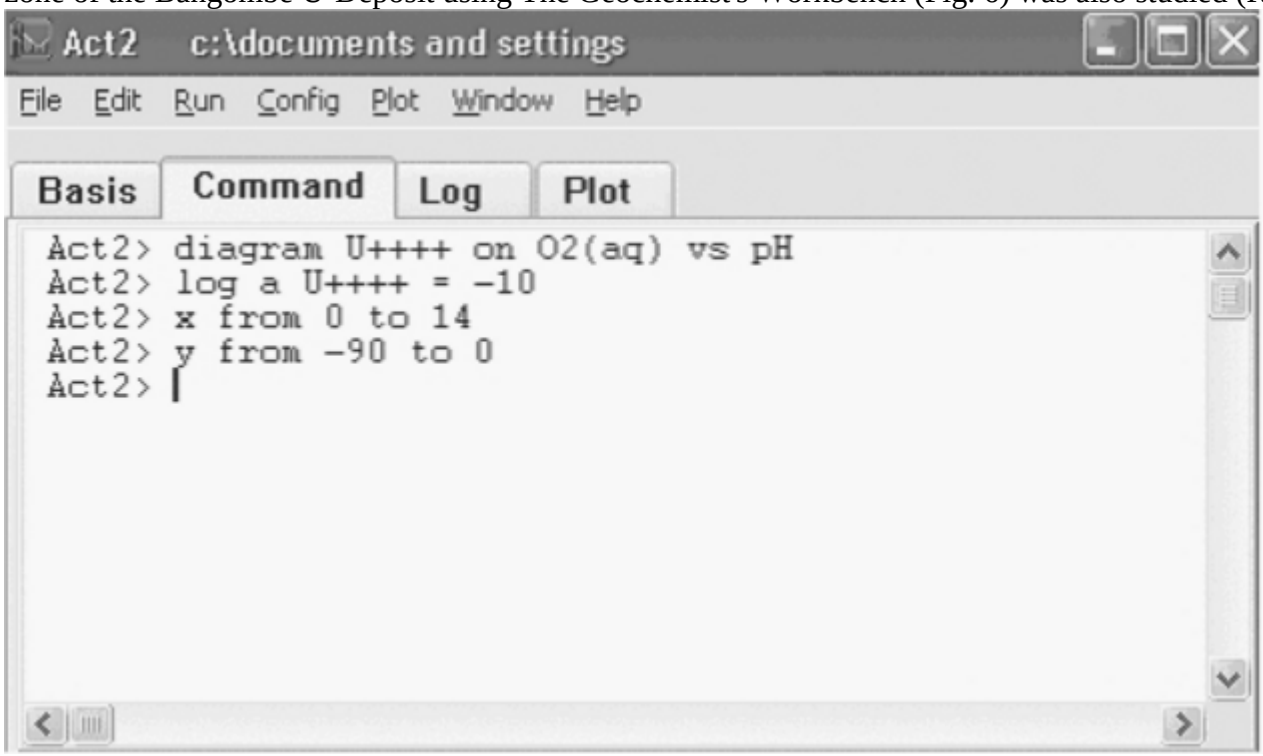


Fig. 6 Programming a U^{4+} stability diagram (log O_2 (aq) versus pH) using The Geochemist's Workbench.

A number of articles have concerned geochemical modeling of the corrosion of vitrified nuclear waste or glass. The programs PHREEQE and GLASSOL were used to examine corrosion of powdered simulated high-level waste glass (Ref 31). The program CONDIMENT was used to model the fluxes of radionuclides released from the corrosion of vitrified waste into the geosphere (Ref 32). Glass corrosion in brines has been investigated using Pitzer equations (Ref 33), and the corrosion of French nuclear glass reference material R717 has also been studied (Ref 34, 35). Lolivier et al. investigated the interaction of the corrosion of R717 with boom clay (Ref 36). Diffusion of radionuclides in compacted bentonite caused by glass corrosion was modeled using PHREEQE (Ref 37). The same program was also used to model the corrosion behavior of powdered glass with or without the presence of oxygen (Ref 38). Aertens and Ghaleb looked at new methods for modeling glass corrosion and investigated two classes of methods for doing this type of modeling. (Ref 39).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In another study, geochemical modeling was used to investigate the effect of sulfate and carbonate mineral-bearing reservoirs on scaling and corrosion damage of production tubing (Ref 40). The software H2OTREAT and MINTEQ were used to evaluate water treatment requirements for aquifer thermal energy storage (Ref 41). The saturation index of calcium carbonate calculated by WATEQ was used to predict corrosion and scaling in water pipe (Ref 42). Geochemical modeling was used for contamination mapping including that caused by secondary pollution from corrosion in another report (Ref 43).

The PHREEQC package has been used to calculate the contributions of acid rain, dry deposition of acid gases, and dissolved CO_2 (Ref 44, 45) to the dissolution of corrosion films from zinc and copper surfaces (Fig. 7). In the same studies and in one by Matthes et al. (Ref 46), PHREEQC was used to calculate solubility curves for a number of known minerals in zinc, copper, and lead corrosion films. The effect of water quality on copper corrosion using MINEQL+ was also studied (Ref 47).

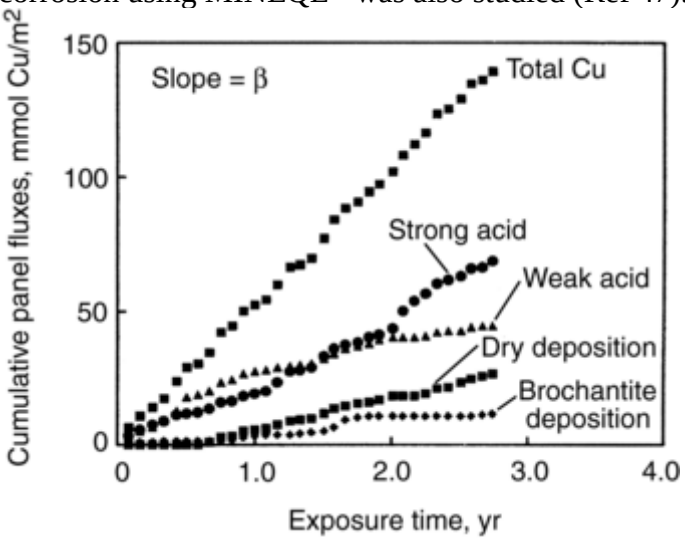

Fig. 7 The contributions of strong acid (acid rain), weak acid (dissolved atmospheric CO_2), and dry deposition (conversion of corrosion film minerals to more soluble species by reaction with acidic gases, SO_2 and HNO_3) to runoff from a copper corrosion film calculated using PHREEQC. The formation of the corrosion film mineral brochantite is also modeled.

Geochemical Modeling Features

Geochemical modeling can perform many useful tasks for the corrosion scientist:

- Construction of E_H vs pH (Pourbaix) diagrams
- Speciation in aqueous and nonaqueous solutions (Fig. 8)
- Construction of solubility curves
- Equilibrium in high-temperature corrosion systems
- Metals complexing
- Calculation of equilibrium concentrations
- Reaction path calculations
- Gas-liquid-solid phase calculations (Fig. 9)
- Surface complexation
- Inverse modeling
- Automatic reaction balancing
- Modeling irreversible reactions

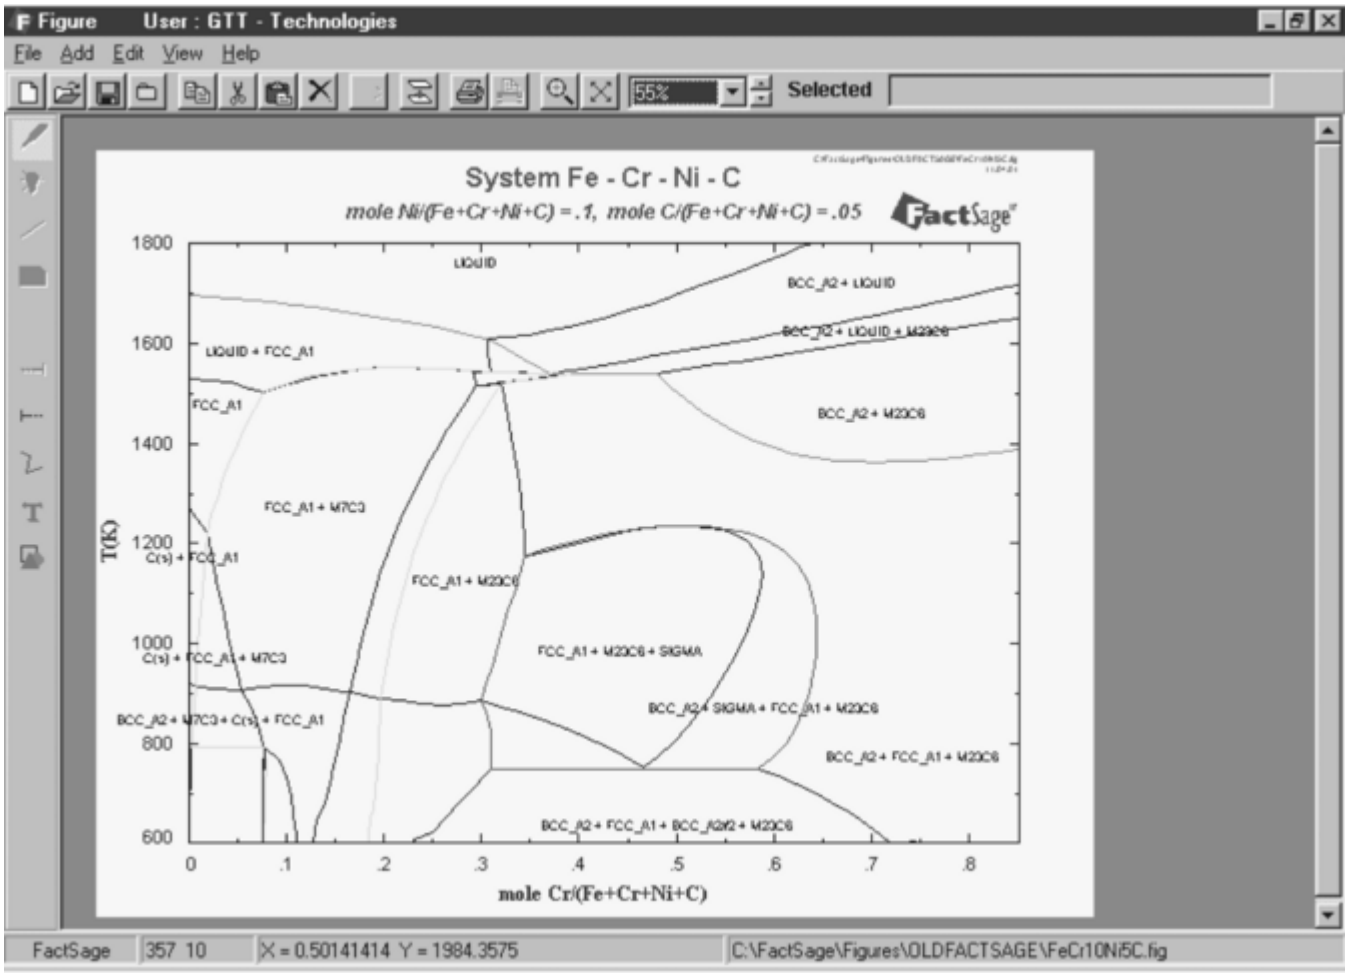

Fig. 9 High-temperature phase diagram for the Fe-Cr-Ni-C system using FactSage (GTT Technologies) geochemical modeling software

These calculations are performed by the use of thermodynamics equations and large databases of thermodynamic data. A number of geochemical modeling software packages that can do these calculations are available, both as commercial and freeware products. Some of these programs are quite complex and have a steep learning curve. Some may require additional user training.

Kinetics of Aqueous Corrosion

D.W. Shoesmith, University of Western Ontario

Introduction

THIS ARTICLE gives a general introduction to the kinetics of aqueous corrosion, with an emphasis on electrochemical principles. The concept of a corrosion process as a combination of electrochemical reactions is important, because, for aqueous corrosion processes, electrochemical techniques are the predominant methods used in their study to measure rates as well as in the development of on-line sensors. The primary goal of this article is to introduce the electrochemical concepts. Readers interested in more fundamental details of electrochemistry, electrochemical methods, and their application to corrosion processes will find Ref 1, 2, 3, 4 useful.

Kinetics of Aqueous Corrosion

D.W. Shoesmith, University of Western Ontario

Basis of Corrosion Reactions

Aqueous corrosion is an electrochemical process occurring at the interface between a material (commonly, but not exclusively, a metal) and an aqueous solution. For corrosion to occur, an oxidation reaction (generally, metal dissolution and/or metal oxide formation) and a reduction reaction (commonly, proton, water, or dissolved oxygen reduction) must occur simultaneously. In electrochemical terms, an anodic (oxidation, or Ox) reaction:

$$M \rightarrow M^{n+} + ne^- \quad \text{(Eq 1)}$$

where M denotes a metal and M^{n+} a dissolved metal cation, is coupled to a cathodic (reduction, or R) reaction:

$$Ox + ne^- \rightarrow Red \quad \text{(Eq 2)}$$

where Ox denotes a soluble oxidant and Red the reduced form of the oxidant that may or may not be a soluble species. An example of a cathodic reagent that produces a soluble product is oxygen reduction:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad \text{(Eq 3)}$$

An example of a cathodic reaction producing a gaseous product is proton reduction:

$$2H^+ + 2e^- \rightarrow H_2 \quad \text{(Eq 4)}$$

The sum of two electrochemical half-reactions, one anodic (such as Eq 1) and one cathodic (such as Eq 2), is the overall corrosion reaction:

$$M + Ox \rightarrow M^{n+} + Red \quad \text{(Eq 5)}$$

An example is the dissolution of iron in an aerated solution:

$$2Fe + O_2 + 2H_2O \rightarrow 2Fe^{2+} + 4OH^- \quad \text{(Eq 6)}$$

Thus, corrosion is the coupling together of two electrochemical reactions on the same surface. This coupling occurs at a single potential, known as the corrosion potential (E_{corr}). This potential will depend on the relative rates of the coupled anodic and cathodic reactions (see subsequent information), and the oxidation state of the dissolved metal cation may change as E_{corr} changes. Thus, an oxidant capable of driving the corrosion potential to a more positive value could produce a higher oxidation state of the metal (e.g., Fe^{3+} rather than Fe^{2+}). The corroding material-solution combination can be considered a short-circuited galvanic cell in which the energy is dissipated by the consumption of cathodic reagent (oxidant). This situation is illustrated schematically in Fig. 1(a).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

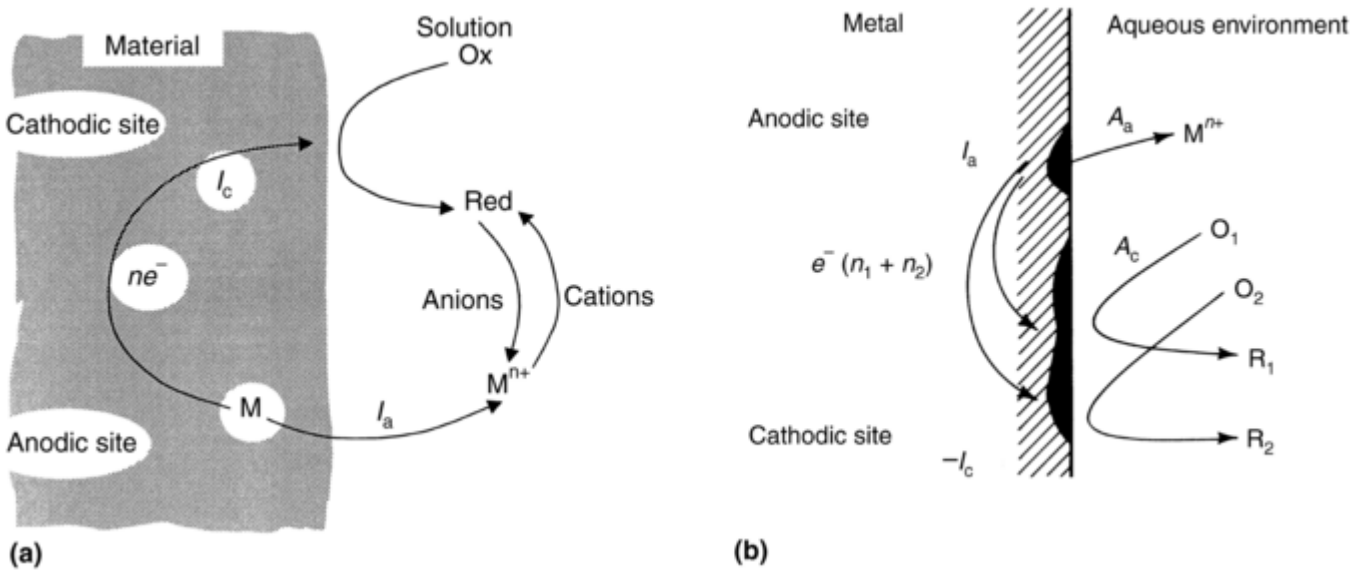

Fig. 1 Galvanic cells. (a) Schematic illustrating the short-circuit galvanic cell that exists during corrosion. (b) The coupling of an anodic reaction with two distinct cathodic reactions. The relative anodic (A_a) and cathodic (A_c) areas of the corroding surface are also illustrated.

To maintain a balance, the amount of cathodic reagent (Ox) consumed must be equal to the amount of corrosion product (M^{n+}) formed. Because electrons are liberated by the anodic reaction and consumed by the cathodic reaction, corrosion can be expressed in terms of an electrochemical current (I). Furthermore, the requirement for mass balance requires that the current flowing into the cathodic reaction must be equal to the current flowing out of the anodic reaction. Clearly, by inspection of Fig. 1(a), these currents are opposite in sign.
By definition, under open-circuit or freely corroding conditions:

$$I_a = |I_c| = I_{corr} \quad \text{(Eq 7)}$$

where I_a is the anodic current, I_c is the cathodic current, and I_{corr} is the corrosion current. The short-circuited nature of the overall corrosion process means that I_{corr} cannot be directly measured on open circuit. Techniques for its measurement are discussed elsewhere in this Volume. The value of I_{corr} is a measure of the rate of the corrosion process and therefore of the rate of material degradation. The current and the amount of material corroded are related by Faraday's law:

$$I_{corr}t = \frac{nFw}{M} \quad \text{(Eq 8)}$$

where I_{corr} is expressed in amps; t is the time of exposure to the corrosive environment (seconds); nF is the number of coulombs (C) required to convert 1 mol of material to corrosion product; n is the number of electrons transferred or liberated in the oxidation reaction; F is the Faraday constant (96,480 C/mol); M is the molecular weight of the material in grams (g); and w is the mass of corroded material (g).
It is possible for the anodic reaction to be supported by more than one cathodic reaction (Fig. 1b). For example, in oxygenated acidic solutions, the generic corrosion reaction (Eq 1) could be driven by both proton reduction (Eq 4) and oxygen reduction (Eq 3). When complex alloys are involved, the anodic corrosion reaction may also be the sum of more than one dissolution reaction; that is, the congruent dissolution of a Ni-Cr-Mo alloy would involve the dissolution of each alloy component with partial anodic currents proportional to the atomic fraction of each component in the alloy. The corrosion current (I_{corr}) then equals the sum of the component partial currents:

$$I_{corr} = \sum I_a = -\sum I_c \quad \text{(Eq 9)}$$

Additionally, the area and location of the anodic and cathodic sites (A_a and A_c, Fig. 1b) may be different. As a consequence, although the total anodic and cathodic currents must be equal, the respective current densities need not be:

$$I_a = -I_c;\ A_a \neq A_c \quad \text{(Eq 10)}$$

And, therefore:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\frac{I_a}{A_a} \neq -\frac{I_c}{A_c} \qquad \text{(Eq 11)}$$

The term *I/A* is a current density and will be designated *i*.

This inequality in current densities can have serious implications. For a smooth, single-component metal surface, the anodic and cathodic sites will be separated, at any one instant, by only a few nanometers. In general terms, the anodic and cathodic sites will shift with time, so that the surface reacts evenly as it undergoes general corrosion. At the atomic scale, however, the surface is not necessarily smooth and is usually considered to comprise surface terraces, ledges, and kinks, as illustrated in Fig. 2. Also, surface defects such as ad-atoms, vacancies, and emergent defects may also exist. Because the coordination number (*N*) of atoms in these various locations differs, that is:

$$N_{\text{terrace}} > N_{\text{ledge}} > N_{\text{kink}} \qquad \text{(Eq 12)}$$

there will be a difference in strength of surface bonding, and atoms will be preferentially removed in the order kink, then ledge, then terrace; that is, surface defects represent potential anodic sites.

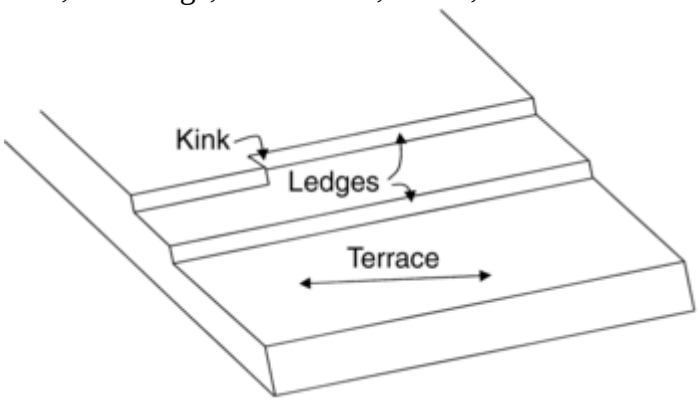

Fig. 2 A metal surface on the atomic scale showing the existence of kinks, ledges, and terraces

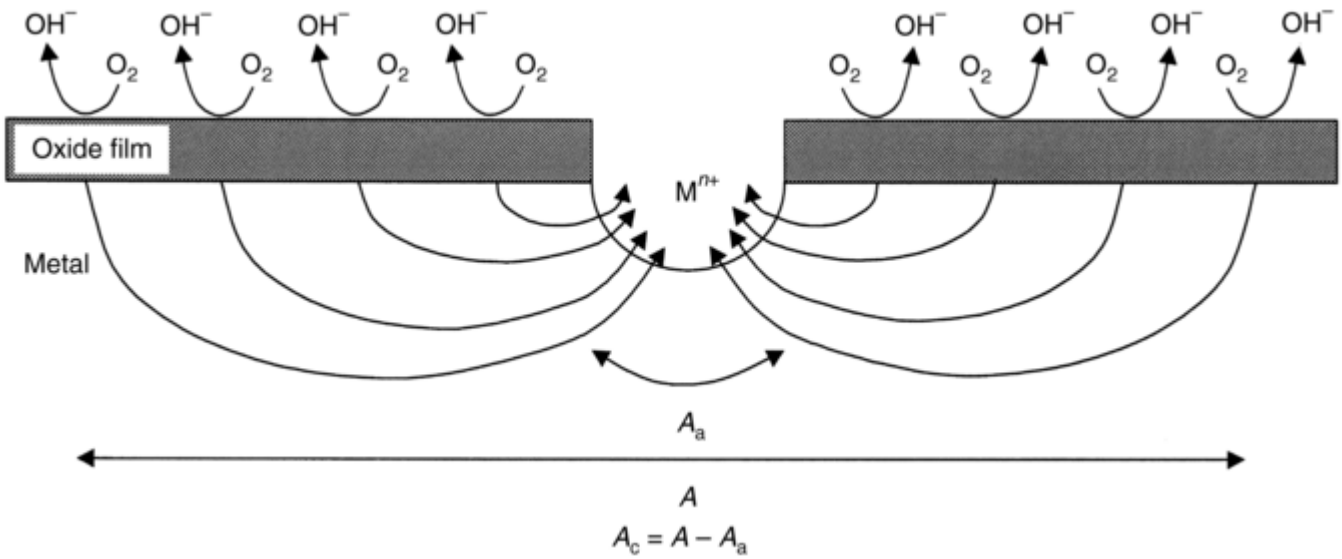
The separation of anodes and cathodes induced by these atomic defects is, however, minor compared to the separations induced by other surface features, such as surface asperity, alloy phases, grain boundaries, impurity inclusions, residual stresses due to processes such as cold working, and high-resistance surface oxide films. These features can often lead to the stabilization of discrete anodic and cathodic sites. The specific combination of a small anode area and a large cathode area can lead to large discrepancies in anodic and cathodic current densities, that is, to large anodic current densities at a small number of discrete sites. Such a situation is particularly dangerous when the majority of a metal surface is oxide covered (acting as a cathode) and only a small number of bare metal sites (acting as anodes) are exposed to the solution environment. Such a situation exists during pitting, crevice corrosion, and stress-corrosion cracking, as illustrated for pitting in Fig. 3.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 3 A small anode/large cathode situation that can exist at a local corrosion site. A_a and A_c are the available anode and cathode areas; M^{n+} is the corrosion product

Thus, it is clear that aqueous corrosion is a complicated process that can occur in a wide variety of forms and is affected by many chemical, electrochemical, and metallurgical variables, including:

- The composition and metallurgical properties of the metal or alloy
- The chemical composition and physical properties of the environment, such as temperature and conductivity
- The presence or absence of surface films
- The properties of the surface films, such as resistivity, thickness, nature of defects, and coherence

Kinetics of Aqueous Corrosion

D.W. Shoesmith, University of Western Ontario

Thermodynamic Basis for Corrosion

The thermodynamic feasibility of a particular corrosion reaction is determined by the relative values of the equilibrium potentials, E_e, of the electrochemical reactions involved. These potentials can be determined from the Nernst equation, which, for the two half-reactions, Eq 1 and Eq 2, can be written:

$$(E_e)_{M/M^{n+}} = (E^0)_{M/M^{n+}} + 2.303\frac{RT}{nF}\log\{a_{M^{n+}}\} \quad \text{(Eq 13)}$$

where the activity of the solid, M, is taken as 1, and:

$$(E_e)_{Ox/Red} = (E^0)_{Ox/Red} - 2.303\frac{RT}{nF}\log\left\{\frac{a_{Red}}{a_{Ox}}\right\} \quad \text{(Eq 14)}$$

to yield for the overall corrosion reaction:

$$E_e = \Delta E^0 - \frac{2.303RT\log}{nF}\left\{\frac{a_{M^{n+}}a_{Red}}{a_{Ox}a_M}\right\} \quad \text{(Eq 15)}$$

where ΔE^0 is the difference in standard potentials for the anodic (Eq 1) and cathodic (Eq 2) reactions (available from a table of standard potentials), R is the gas constant equal to 8.314 J/ mol · K, T is absolute temperature, n and F are as defined in Eq 8, and a_i represents the activities of the various species involved. Because the activity of a solid is 1, a_M is eliminated from Eq 15, and it is more common to write the equation in terms of concentration (c):

$$E_e = \Delta E^0 - 2.303\frac{RT\log}{nF}\left\{\frac{c_{M^{n+}}c_{Red}}{c_{Ox}}\right\} \quad \text{(Eq 16)}$$

The thermodynamics of a particular metal- aqueous system can be summarized in a potential-pH, or Pourbaix diagram, as described elsewhere in this Volume. The key feature in determining whether or not a particular corrosion reaction can proceed is the difference in equilibrium potentials (E_e) for the two component electrochemical half-reactions, as illustrated in Fig. 4. That is:

$$(E_e)_{M/M^{n+}} < (E_e)_{Ox/Red} \quad \text{(Eq 17)}$$

Thus, the thermodynamic driving force (ΔE_{therm}) for corrosion is given by:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$\Delta E_{\text{therm}} = (E_e)_{\text{Ox/Red}} - (E_e)_{\text{M/M}^{n+}} \quad \text{(Eq 18)}$$

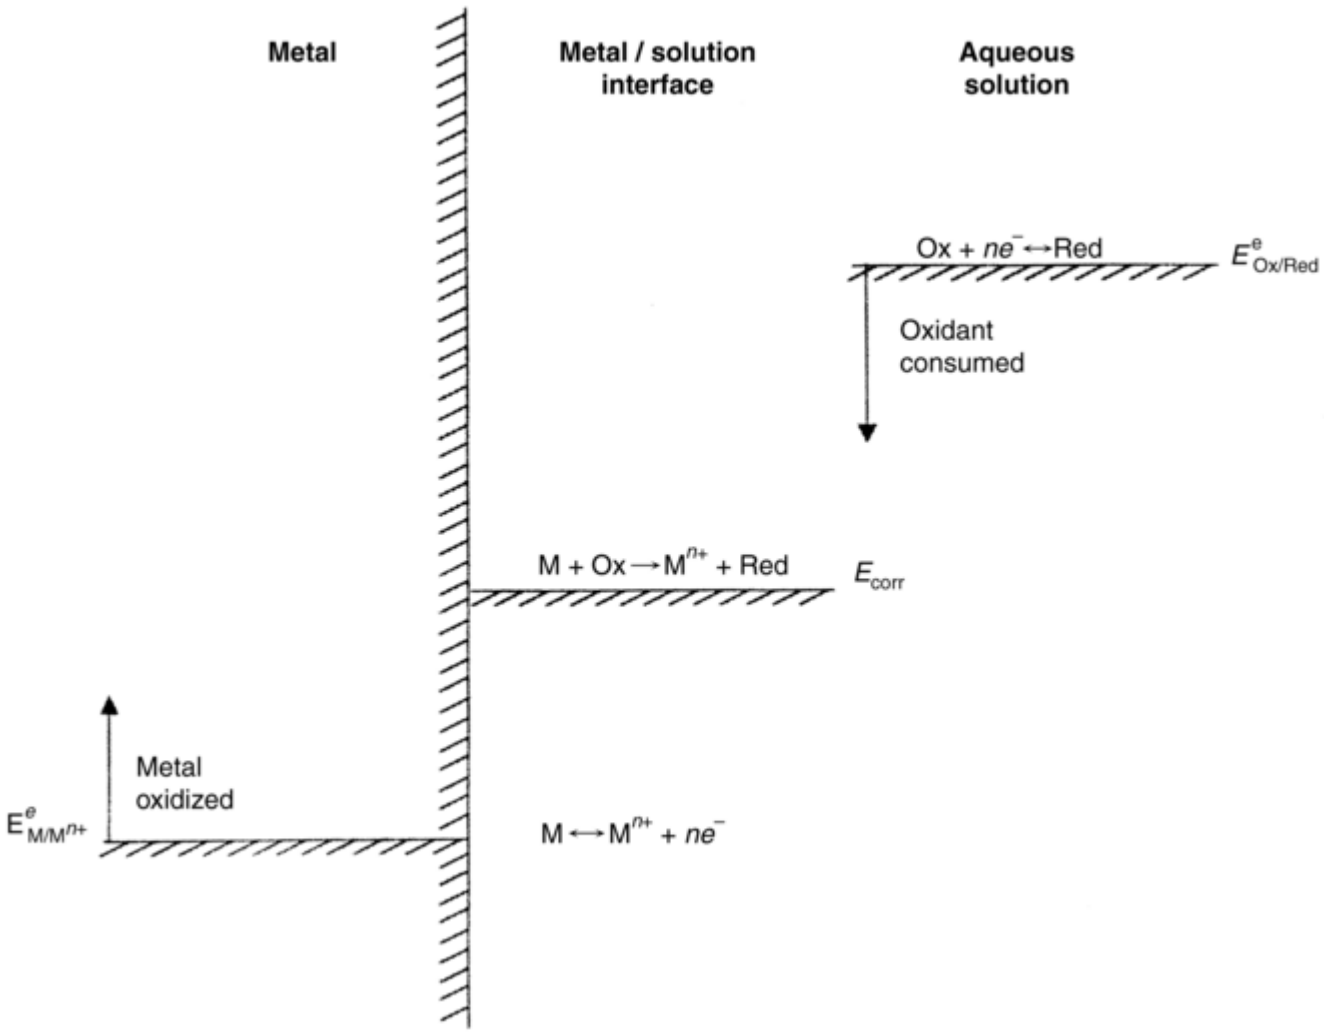

Fig. 4 The thermodynamic driving force for corrosion across a metal/aqueous solution interface in the presence of a soluble oxidant, Ox. The values of the equilibrium potentials are shown schematically.

It is possible that this driving force could increase or decrease with time if either the concentration of available oxidant, c_{Ox}, or the concentration of soluble corrosion product, $C_{M^{n+}}$, change with time, as illustrated in Fig. 4 and discernible by inspection of Eq 16. However, the most important questions for the corrosion engineer are: How fast does the corrosion reaction occur, and can it be prevented or at least slowed to an acceptable rate? To answer these questions and to determine a course of action, it is essential to have some knowledge of the steps involved in the overall corrosion process.

Kinetics of Aqueous Corrosion

D.W. Shoesmith, University of Western Ontario

Kinetics of Aqueous Corrosion Processes

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The overall process can be controlled by any one or combination of several reactions depicted in Fig. 5. The interfacial kinetics of either the anodic (step 1) or cathodic (step 2) reactions could be rate controlling. Alternatively, if these reactions are fast and the concentration of cathodic reagent (c_{Ox}) is low, then the rate of transport of the oxidant (Ox) to the cathodic site (step 3 → 2) could be rate limiting. This situation is quite common for corrosion driven by dissolved oxygen that has limited solubility. If the metal dissolution reaction (step 1) is reversible, that is, the reverse metal deposition ($M^{n+} + ne^- \rightarrow M$) can also occur, then the rate of transport of M^{n+} away from the anodic site (step 4) could be rate determining.

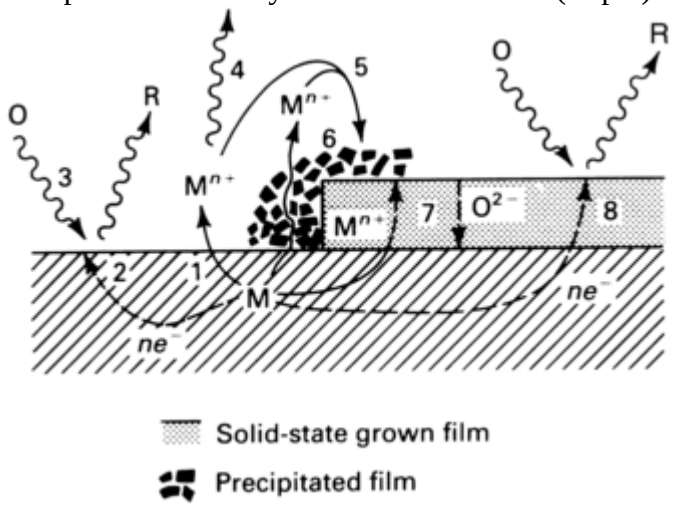

Fig. 5 Various possible reaction steps on a corroding metal surface. Reactions 1 to 8 are defined in the text.

The presence of corrosion films can add many additional complications. If the anodic reaction (step 1) is fast and the transport step (step 4) is slow, then local supersaturation with dissolved corrosion product at the corroding surface:

$$\left(c_{M^{n+}}\right) > \left(c_{M^{n+}}\right)_{sat} \qquad \text{(Eq 19)}$$

could lead to the deposition of corrosion product deposits such as oxides, hydroxides, or metal salts. These deposition processes could be accelerated or prevented by local pH changes due to the cathodic reaction (Eq 3) or metal cation hydrolysis equilibria:

$$M^{n+} + yOH^- \leftrightarrow M(OH)_y^{(n-y)^-} + 2yH^+ \qquad \text{(Eq 20)}$$

The local situation at the corroding surface becomes complicated, and the primary parameter governing whether or not corrosion product deposits form, aside from the balance between interfacial kinetics and solution transport, is the deposit solubility and how it varies with pH (Fig. 6). As shown, the solubility tends to be at a minimum at approximately neutral pH and to increase at high and, especially, low pH. At high pH, solubility is increased by the stabilization of hydrolyzed metal cations (i.e., the equilibrium the reaction in Eq 20 is pushed to the right), whereas in acidic solutions, the oxide/hydroxide is destabilized by the increased proton concentration (i.e., the equilibrium in Eq 20 is pushed to the left). This is a very simplified description of oxide/hydroxide solubility, and the reader is referred to Ref. 5 for a more detailed discussion.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

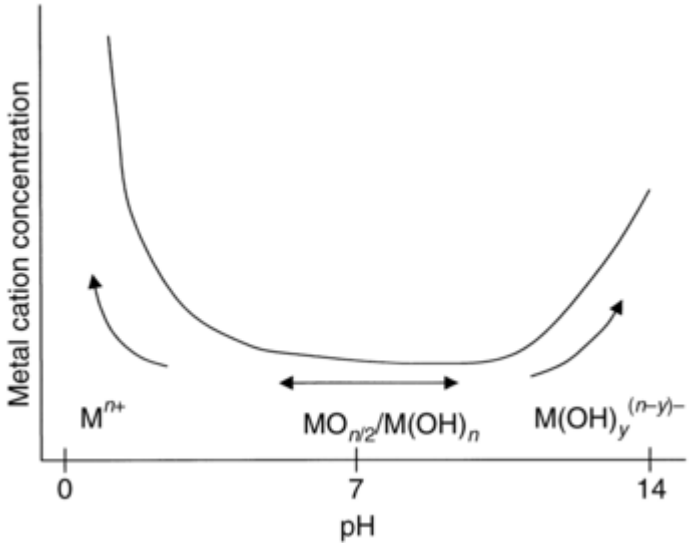

Fig. 6 Solubility of a metal cation as a function of solution pH

Precipitation reactions of this type are likely to produce porous deposits, and corrosion could then become controlled by the transport of M^{n+} or Ox (step 6 in Fig. 5) through these porous deposits. By contrast, when coherent, nonporous oxide films (passive films) form spontaneously on the metal surface by solid state as opposed to precipitation reactions, then ionic or defect transport processes through the oxide (step 7 in Fig. 5) would ensure extremely low corrosion rates. This represents the condition of passivity. The presence of defects in the passive film in the form of pores, grain boundaries, or fractures can lead to localized corrosion. Finally, it is possible for the corrosion process to be controlled by the electronic conductivity of passive films (step 8 in Fig. 5) when the cathodic reaction occurs on the surface of the film. Using this range of possibilities, the remainder of this article discusses some of these processes and the laws that govern them.

Activation Control of Corrosion

Activation control is the term used to describe control of the corrosion process by the electrochemical half-reactions (Eq 1, 2) and step 1 and 2 in Fig. 5 The overall anodic reaction is the transfer of a metal atom from the metal surface to the aqueous solution as the cation M^{n+} or as some hydrolyzed $\left(M(OH)_y^{(ny)+}\right)$ or anion-complexed $\left(MA_y^{(nyx)+}\right)$ form, where complexation is with the anion A^{x-}:

$$M_{surface} \rightarrow M^{+}_{surface} \rightarrow M^{n+}_{surface} \rightarrow M^{n+}_{solution} \qquad \text{(Eq 21)}$$

As indicated in Eq 21, various surface intermediates may be involved in the overall anodic dissolution process, although these intermediates may only be detectable in a detailed electrochemical investigation. Thus, the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

simplest proposed mechanism for the anodic dissolution of iron under acidic conditions proceeds via the following steps:

$$Fe + H_2O \leftrightarrow Fe(OH)_{ads} + H^+ + e \quad \text{(Eq 22)}$$

$$Fe(OH)_{ads} \leftrightarrow FeOH^+ + e^- \quad \text{(Eq 23)}$$

$$FeOH^+ + H^+ \leftrightarrow Fe^{2+} + H_2O \quad \text{(Eq 24)}$$

Similarly, the cathodic reaction, for example, O_2 reduction, proceeds via a sequence of reaction steps involving intermediates such as hydrogen peroxide:

$$O_2 + 2H^+ + 2e^- \rightarrow H_2O_2 \quad \text{(Eq 25)}$$

$$H_2O_2 + 2H^+ + 2e^- \rightarrow 2H_2O \quad \text{(Eq 26)}$$

Either the anodic or cathodic reaction can control the overall rate of the corrosion reaction. Electrochemical methods (Ref 6) can be used to disturb these reactions from their equilibrium potentials and hence to determine the relationship between current and potential. An example of the form of this relationship, demonstrating a metal dissolution/deposition reaction, is shown in Fig. 7. This curve follows the Butler-Volmer equation:

$$I = I_0\left\{\exp\left(\frac{\alpha F}{RT}\eta\right) - \exp(1-\alpha)\frac{F}{RT}\eta\right\} \quad \text{(Eq 27)}$$

where I is the current; I_0 is the exchange current; F is the Faraday constant; R is the gas constant; T the absolute temperature; and α is the transfer or symmetry coefficient, generally taken to be 0.5. The term η is the overpotential, defined by:

$$\eta = E - (E_e)_{M/M^{n+}} \quad \text{(Eq 28)}$$

where E is the experimentally applied potential, and E_e is given by the Nernst equation (Eq 16), with $\Delta E^0 = E^0_{M/M^{n+}}$. The overpotential is a measure of how far the reaction is from equilibrium.

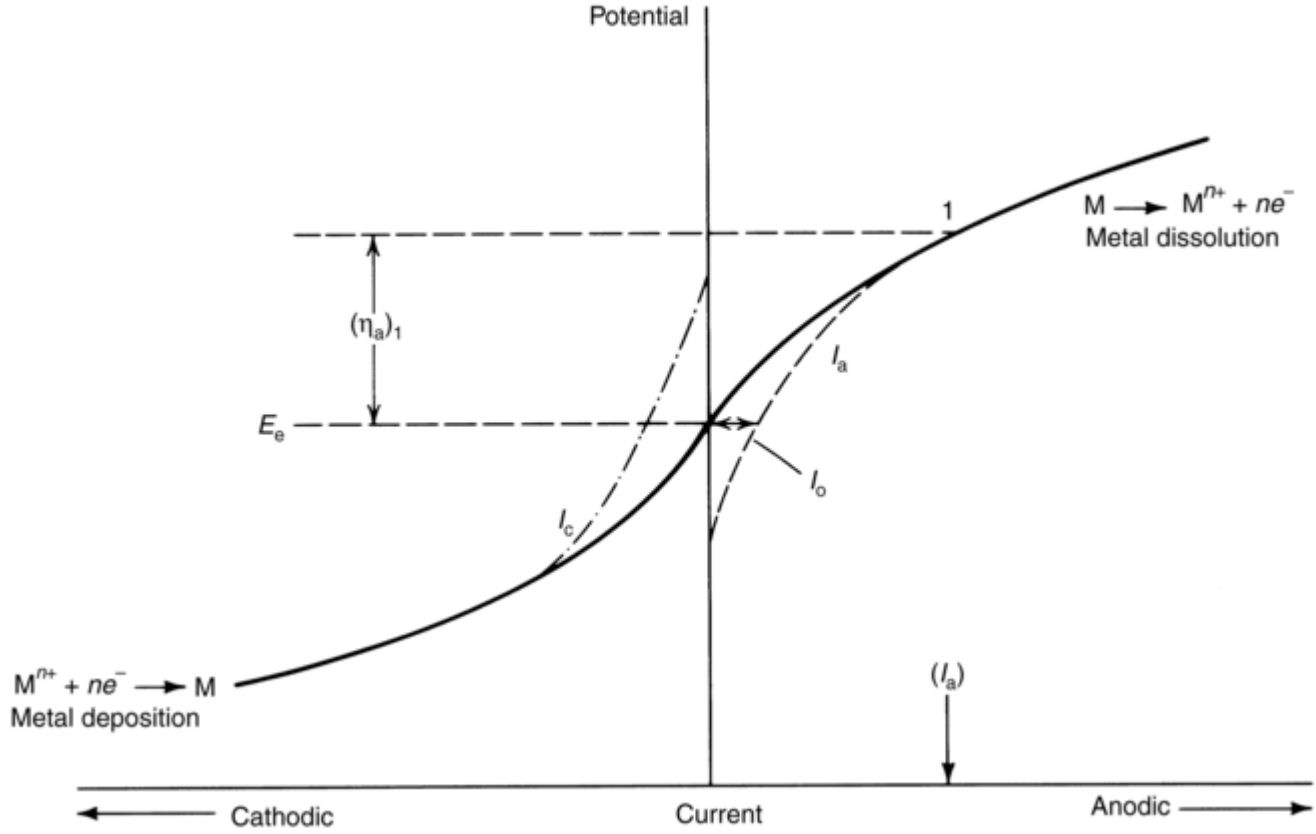

Fig. 7 Current-potential (Butler-Volmer) relationship for a metal dissolution/deposition reaction. The solid line shows the measurable current; the dashed lines (I_a, I_c) show the partial dissolution/deposition

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

currents; I_o is the exchange current at E_e; (η_a) is the anodic overpotential that would exist if the potential were held at point 1.

At equilibrium ($\eta = 0$; $E = E_e$), no measurable current flows, but the equilibrium is dynamic, with the rate of metal dissolution ($M \rightarrow M^{n+} + ne^-$) ($I_a$) equal to the rate of metal cation deposition ($M^{n+} + ne^- \rightarrow M$) ($-I_c$):

$$I_a = -I_c = I_o \qquad \text{(Eq 29)}$$

where I_o is termed the exchange current for this electrochemical reaction. The exchange current is the equivalent of an electrochemical rate constant and is therefore a direct measure of the kinetics of the reaction. The dynamic nature of the reaction at $E = E_e$ can be appreciated by consideration of the partial anodic and cathodic currents, plotted as dashed lines in Fig. 7. If the potential is made more positive than the equilibrium potential, then $I_a > |I_c|$ (i.e., the first exponential term in Eq 27 increases in value, and the second one decreases), and the metal dissolution reaction will proceed. Similarly, if E is made more negative than the equilibrium potential, $I_a > |I_c|$, then metal cation deposition proceeds. Over a short potential range, the two reactions oppose each other, but for sufficiently large overpotentials (η_a, anodic; or η_c, cathodic), one reaction occurs at a negligible rate; that is, one or the other of the exponential terms in the Butler-Volmer equation (Eq 27) becomes negligible. In this condition, the overpotential is in the Tafel region (as indicated by point 1 in Fig. 7), and for this positive polarization, the metal dissolution current is given by:

$$I_a = I_o \exp\left\{\frac{\alpha F}{RT}\eta_a\right\} \qquad \text{(Eq 30)}$$

or

$$\log I_a = \log I_o + 2.303\frac{\alpha F}{RT}\eta_a \qquad \text{(Eq 31)}$$

and a plot of log I_a versus η_a will yield an intercept from which I_o can be obtained and will have a slope with a Tafel coefficient, β_a, given by:

$$\beta_a = 2.303\frac{RT}{\alpha F} \qquad \text{(Eq 32)}$$

A similar procedure could be applied for a sufficiently large cathodic overpotential (η_c) to yield an equal value of I_o as well as a value for the cathodic Tafel coefficient, β_c. The values of β_a and β_c contain much information on the mechanism of the dissolution/deposition reaction steps but are commonly used as empirical coefficients in corrosion engineering studies. A similar analysis could be performed for a potential cathodic reaction (Eq 2), and Fig. 8 shows the two current-potential curves on the same plot.

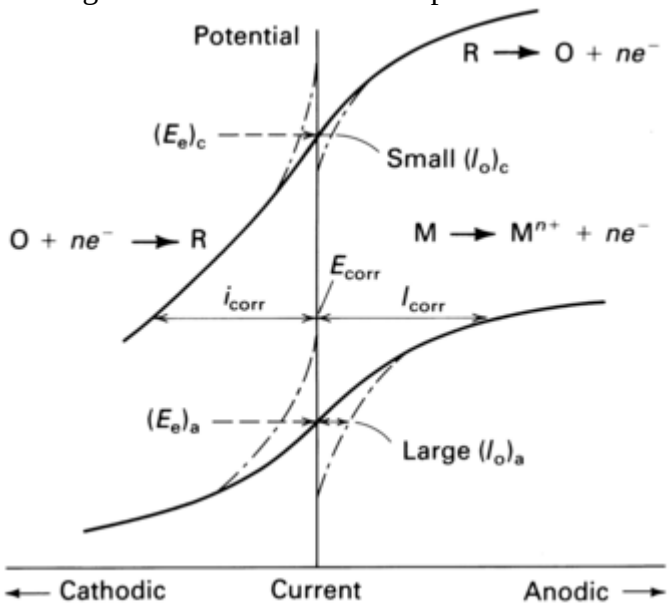

Fig. 8 Current-potential relationships for a metal dissolution/deposition process ($M \leftrightarrow M^{n+} + e^-$) and an oxidant/reductant reaction ($O + ne^- \leftrightarrow R$) showing the coupling together of the anodic component of one

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

reaction to the cathodic component of the other to yield a corrosion reaction proceeding at the corrosion potential, E_{corr}

The establishment of a corrosion reaction involves the coupling together of the anodic half of one reaction to the cathodic half of another. Which reaction provides which half is determined by the relative values of the equilibrium potentials, that is, condition (Eq 17), as illustrated in Fig. 4. This coupling of half-reactions produces an equation relating the measured current to the corrosion current, which is similar in form to the Butler-Volmer equation (Eq 27):

$$i = i_{corr}\left\{\exp\left(\frac{\alpha_a F\eta}{RT}\right) - \exp\left(\frac{-\alpha_c F\eta}{RT}\right)\right\} \qquad \text{(Eq 33)}$$

where i and i_{corr} represent current densities (current/surface area), $\alpha_a \neq \alpha_c$, and there is no reason why $\alpha_a + \alpha_c = 1$, as was the case with the Butler-Volmer equation. Note: From this point on, current densities (i) rather than currents (I) will be used.

Because this coupling of half-reactions produces a short-circuited corrosion reaction on the surface of the metal, the anodic current due to metal dissolution must be equal and opposite in sign to the cathodic current due to oxidant reduction:

$$i_a = -i_c = i_{corr} \qquad \text{(Eq 34)}$$

where i_a is given by the first term in Eq 33 and i_c by the second. This coupling together to produce equal anodic and cathodic currents can only occur at a single potential, designated the corrosion potential, E_{corr}, which must lie between the two equilibrium potentials (Fig. 8), thus satisfying the condition in Eq 15:

$$(E_e)_a < E_{corr} < (E_e)_c \qquad \text{(Eq 35)}$$

where $(E_e)_a$ is equivalent to $(E_e)_{M/M^{n+}}$ and $(E_e)_c$ to $(E_e)_{Ox/Red}$.

The metal dissolution (anodic) reaction is driven by an anodic activation overpotential:

$$\eta_a^A = E_{corr} - (E_e)_a \qquad \text{(Eq 36)}$$

and the oxidant reduction (cathodic) reaction by a cathodic activation overpotential:

$$\eta_c^A = E_{corr} - (E_e)_c \qquad \text{(Eq 37)}$$

Obviously, from Eq 18:

$$\Delta E = \eta_a^A + |\eta_c^A| \qquad \text{(Eq 38)}$$

Two additional observations can be made with regard to Fig. 8. First, ΔE is sufficiently large that E_{corr} is in the Tafel regions for both the anodic and cathodic half-reaction. This is not necessarily always the case, as discussed subsequently. Second, the two current-potential curves are not necessarily symmetrical and seldom have an identical shape. The shape and symmetry of the curves are determined by the differences in i_o for the coupled anodic and cathodic reactions and the values of the Tafel coefficients, β_a and β_c. In Fig. 8, the metal dissolution/deposition reaction is shown to have a larger i_o than the oxidant/reductant reaction, and the anodic and cathodic branches are shown close to symmetrical (i.e., $\beta_a \sim \beta_c$). The consequence of the large i_o is that the current-potential curve is steep, and only small values of η_a^A are required to achieve large currents. By contrast, the current-potential relationship for the cathodic reaction is shallow, because i_o is small, and the anodic and cathodic branches are not symmetrical (i.e., $\beta_a \neq \beta_c$).

Because both reactions are occurring on different sites on the same surface,Fig. 1, i_{corr} cannot be measured by coupling the metal to an ammeter. However, E_{corr} can be measured against a suitable reference electrode by using a voltmeter with an input impedance high enough to draw insignificant current in the measuring circuit. Figure 8 shows that the value of E_{corr} is determined by the shape of the current-potential relationships for the two reactions; that is, it is a parameter with kinetic but not thermodynamic significance. Because its value is determined by the properties of more than one reaction, the corrosion potential is often termed a mixed potential.

In the literature, diagrams such as the one in Fig. 8 are often plotted in the form log i versus E, and the algebraic sign of the cathodic current is neglected, so that the anodic and cathodic currents can be plotted in the same quadrant (Fig. 9). Such diagrams are termed Evans diagrams. The two linear portions in an Evans diagram are

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

the Tafel regions, with slopes given by Eq 30 and the equivalent plot for the cathodic reaction. Sometimes, the nonlinearity close to the equilibrium potentials is ignored, and the curves are plotted as totally linear. This approximation acknowledges that, commonly, the two i_o values are orders of magnitude lower than i_{corr} and therefore have a negligible effect on the scale of the Evans diagram. It should be noted that the currents plotted in an Evans diagram are the partial currents for the anodic and cathodic reactions, and that the measurable current is the sum of these two partial currents (taking into account that they are opposite in sign). The value of such diagrams is in their use to illustrate the influence of various parameters on the corrosion process.

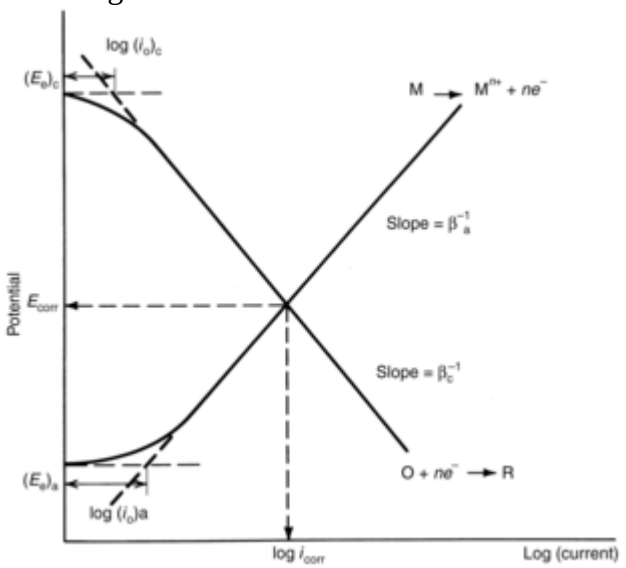

Fig. 9 The current-potential relationships of Fig. 8 plotted in the form of an Evans diagram. Note: The solid lines are partial anodic and cathodic currents, not measurable currents.

Figure 10(a) shows an Evans diagram for the same anodic dissolution process coupled to two different cathodic reactions. Recalling the definition of ΔE_{therm} from Eq 18, the following can be written:

$$\Delta E'_{therm} < \Delta E''_{therm} \qquad \text{(Eq 39)}$$

leading to:

$$i'_{corr} < i''_{corr} \qquad \text{(Eq 40)}$$

that is, the bigger the difference in equilibrium potentials, the larger the corrosion current. The anodic activation overpotential for the first reaction ($\eta_a^A = E_{corr} - (E_e)_a$) is less than that for the second:

$$\left(\eta_a^A\right)'' > \left(\eta_a^A\right)' \qquad \text{(Eq 41)}$$

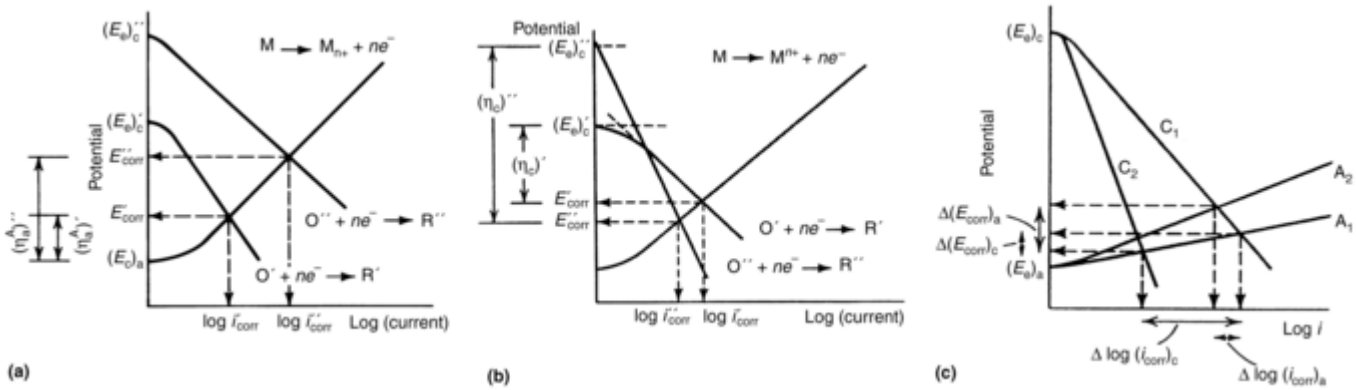

Fig. 10 Evans diagram for one anodic dissolution reaction coupled (separately) to one of two different oxidant reduction reactions. (a) The two oxidant reduction reactions have similar kinetic characteristics (i.e., similar current-potential shapes). (b) The two oxidant reduction reactions have very different kinetic characteristics (i.e., very different current-potential shapes). (c) An anodic dissolution reaction

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

with a large $(i_{corr})_a$ coupled to an oxidant reduction reaction with a small $(i_{corr})_c$. The currents labeled C_1 and C_2 show the effect on log (i_{corr}) and E_{corr} of changing the concentration of available oxidant.

The value of ΔE_{therm} is not the only parameter controlling the corrosion rate. Figure 10(b) shows the same situation as in Fig. 10(a) , except that the two cathodic reactions possess very different polarization characteristics (i.e., relationships between current and potential). Despite the fact that $(E_e)_c > (E_e)'_c$, the activation overpotential $(\eta_a^A) < (\eta_a^A)'$, and the corrosion couple with the largest thermodynamic driving force produces the lowest corrosion current. Inspection of Fig. 10(b) shows this can be attributed to the differences in exchange currents, i_o, and slopes, hence different Tafel coefficients, β_c, for the two cathodic reactions. This situation is common for active metals in acidic or neutral aerated solutions. Even though the thermodynamic driving force for corrosion is greater in neutral solutions containing dissolved oxygen, corrosion proceeds more rapidly in deaerated acidic solutions. This is due to the slowness of the kinetics for oxygen reduction and can be appreciated by comparing the kinetic characteristics for the two processes on iron. Thus, $(i_o)_{H^+/H_2} = 10^{-3}$ to 10^{-2} A/m^2, and $(\beta_c)_{H^+/H_2} \cong 120$ mV/decade. By comparison, $(i_o)_{O_2/H_2O} \cong 10^{-10}$ A/m^2, and $(\beta_c)_{O_2/H_2O} > 120$ mV/decade.

Rate Control by the Anodic or Cathodic Reaction. The overall rate of corrosion will be controlled by the kinetically slowest reaction, that is, the one with the smallest exchange current and/or largest Tafel coefficient. This can be appreciated from Fig. 10(c) in which $(i_o)_a > (i_o)_c$ and $\beta_a < \beta_c$. This leads to a large difference in activation overpotentials, with:

$$\eta_a^A \ll \eta_a^C \qquad \text{(Eq 42)}$$

This means the cathodic reaction is strongly polarized and must be driven significantly to achieve the corrosion current. By contrast, the anodic reaction remains close to equilibrium, requiring only a small overpotential (anodic) to achieve the same corrosion current.

Under these conditions, the corrosion potential, E_{corr}, lies close to the equilibrium potential for the kinetically fastest reaction. If the cathodic reaction was the fastest, then $E_{corr} \rightarrow (E_e)_C$, and the anodic metal dissolution reaction would be rate controlling. If the kinetics of the two half- reactions were similar (i.e., $(i_o)_a \cong (i_o)_c$ and $\beta_a \cong \beta_c$), then E_{corr} would be approximately equidistant between the two equilibrium potentials, and the corrosion reaction would be under mixed anodic/cathodic control. This is the situation illustrated in Fig. 9. The corrosion of iron in aerated neutral solution can be used to illustrate the point. For the metal dissolution reaction, $(i_o)_{Fe/Fe^{2+}} \cong 10^{-4}$ to 10^{-5} A/m^2 and $(\beta_a)_{Fe/Fe^{2+}} \cong 50$ to 80 mV/decade, whereas for O_2 reduction, $(i_o)_{O_2/H_2O} \cong 10^{-10}$ A/m^2 and $(\beta_c)_{O_2/H_2O} > 120$ mV/decade. Consequently, O_2 reduction should be rate controlling, and E_{corr} would lie close to the equilibrium potential for iron dissolution.

Figure 10(c) also shows the effects of changing the kinetics of the two reactions. Such changes could be caused by increasing the available concentration of cathodic reagent or by increasing the surface area of available metal. Changing the reagent concentration would also lead to a change in $(E_e)_c$, but this is ignored in Fig. 10(c) for the sake of clarity. Changes in the kinetics of the fast anodic reaction are reflected in changes in the value of E_{corr} ($\Delta(E_{corr})_a$ large) but have little effect on i_{corr} ($\Delta\log(i_{corr})_a$ small). However, changes in the kinetics of the slow cathodic reaction have little effect on E_{corr} ($\Delta(E_{corr})_c$ small) but a significant influence on i_{corr} ($\Delta\log(i_{corr})_c$ large). Thus, in this example, the cathodic reaction is the rate-controlling reaction, and the anodic reaction is said to be potential determining. Such changes in E_{corr} can sometimes be used as diagnostic tests for ascertaining the rate-determining step, and the maximum benefit in slowing corrosion can be gained by attending to the rate-determining step. Additionally, a measurement of E_{corr} and its evolution with time provides a simple but only qualitative way of tracking the evolution of a corrosion process with time.

Mass Transport Control

The relationships between current and potential described previously are valid when the overall corrosion process is under activation control, that is, controlled by the interfacial rate of one or the other of the half-reactions (step 1 or 2 in Fig. 5). However, if the cathodic reagent at the corrosion site is in short supply, then mass transport of this reagent could become rate controlling (Eq 3, Fig. 5). Under these conditions, the cathodic charge-transfer process is fast enough to reduce the concentration of the cathodic reagent at the corrosion site to a value less than that in the bulk solution. Because the rate of the cathodic reaction is proportional to the surface concentration of reagent, the reaction rate will be limited (polarized) by this drop in concentration. For a sufficiently fast charge transfer, the surface concentration will fall to 0, and the corrosion process will be totally controlled by flux of oxidant to the corroding surface. In the case of one-dimensional transport, this flux (J) can be calculated from the solution of Fick's first law:

$$J = -D\left(\frac{\partial c_{Ox}}{\partial x}\right)_{x=0} \qquad \text{(Eq 43)}$$

at the corroding site ($x = 0$), where D is the diffusion coefficient, and c_O is the reagent concentration at point x. Diffusion gradients evolve with time, according to Fick's second law:

$$\frac{\partial c_O}{\partial t} = D\left(\frac{\partial^2 c}{\partial x^2}\right)_{x,t} \qquad \text{(Eq 44)}$$

and, for non-steady-state conditions (i.e., $\partial c/\partial x$ at x varies with time), conditions are complicated.

General corrosion processes, however, generally occur under steady-state conditions, because convective flow of the environment occurs (e.g., flow down a pipe). For this situation, a simple analysis can be achieved by linearizing the concentration-distance profile according to the Nernst diffusion layer treatment (Fig. 11). This linearization yields a demarcation line at a distance, δ, from the surface such that, for $x > \delta$, the bulk concentration is maintained by convection. For $x < \delta$, the oxidant is assumed to be transported to the surface by diffusion only. This solution layer is termed the diffusion layer, and its thickness is determined by the local geometry at the site and the solution velocity (degree of convection). Of course, this is an approximation, because the transition from convective flow to diffusive transport is more gradual and not so strictly demarcated.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

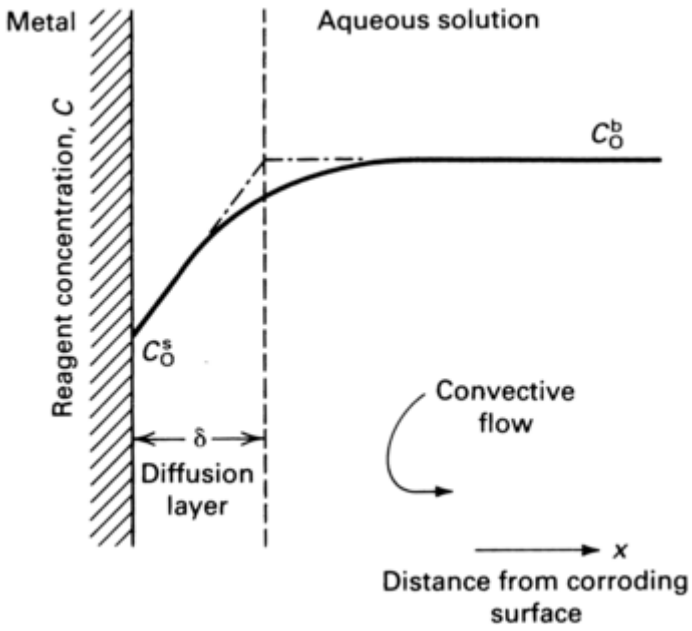

Fig. 11 Illustration showing the concentration-distance profile for oxidant O involved in a corrosion process with a metal in which the overall process is partially controlled by convective-diffusive transport of the oxidant to the corroding surface. The dashed-dotted lines show the concentration profile assumed in the Nernst diffusion layer treatment.

Using this simplified treatment, Eq 43 can be written:

$$J = -\frac{D}{\delta}\left(c_{Ox}^{s} - c_{Ox}^{b}\right) \qquad \text{(Eq 45)}$$

where c_{Ox}^{s} is the oxidant concentration at the corroding surface ($x = 0$), and c_{O}^{b} is the concentration for $x \geq \delta$. For steady-state conditions, all the oxidant transported down the concentration gradient to the corroding surface must react electrochemically. If it did not, then the concentration at the corroding surface would adjust until it did.

This condition of mass balance means that the cathodic current (expressed in A/cm^2) must be directly proportional to the flux (expressed in mol/cm^2/s). The proportionality constant is given by Faraday's law (Eq 8) and can be written:

$$i_{corr} = i_c = -\frac{nFD_O}{\delta}\left(c_{Ox}^{s} - c_{Ox}^{b}\right) \qquad \text{(Eq 46)}$$

The corrosion current is equal to the cathodic current, because the overall corrosion reaction is controlled by the transport of oxidant to the surface; that is, corrosion can only progress at the rate that oxidant becomes available. Under limiting conditions, $c_{O}^{s} \rightarrow 0$, and a maximum transport-controlled corrosion current is obtained:

$$\left(i_c\right)_{lim} = \left(i_{corr}\right)_{max} = \frac{nFD_{Ox}}{\delta} c_{Ox}^{b} \qquad \text{(Eq 47)}$$

When corrosion is occurring at this limiting rate, the rate can only be increased or decreased by varying either the bulk concentration of oxidant, c_{Ox}^{b}, or the thickness of the diffusion layer, δ.

This limitation on corrosion rate is termed concentration polarization and is illustrated in the Evans diagram in Fig. 12. For a small shift of the potential away from the equilibrium potential (point 1), $c_{Ox}^{s} = c_{Ox}^{b}$, and there is no limitation on reagent supply. The current remains in the Tafel region; that is, charge transfer is still rate controlling, and the overpotential is purely an activation overpotential (η_c^A). For a larger shift of potential from $(E_e)_c$, $c_{Ox}^{s} < c_{Ox}^{b}$ (point 2), and the current is less than expected on the basis of activation control; that is, the current follows the solid line as opposed to the dashed-dotted line. Under these conditions, the current is partly

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

activation and partly transport controlled, and the total overpotential (η_T) is the sum of an activation (η^A) and a concentration (η^C) overpotential:

$$\eta_T = \eta^A + \eta^C \qquad \text{(Eq 48)}$$

For a sufficiently large polarization from equilibrium, $c^s_{Ox} \rightarrow 0$, the current becomes independent of potential, and the cathodic current is now at the maximum given by Eq 47.

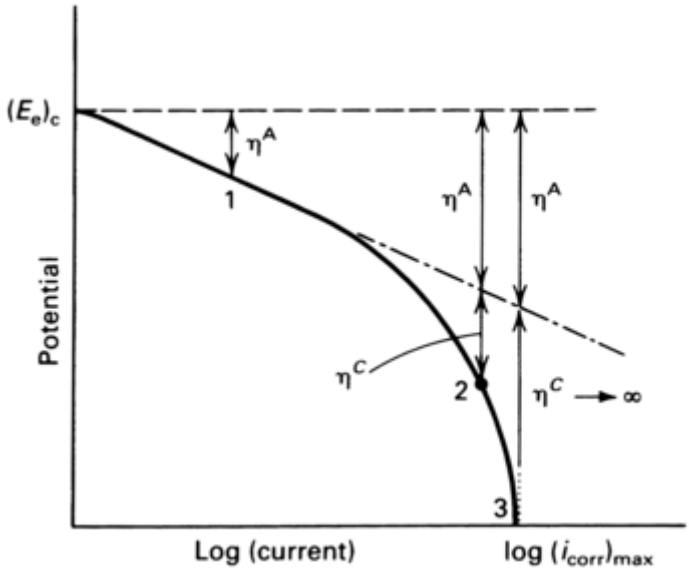

Fig. 12 Partial Evans diagram (i.e., showing only the partial current for the oxidant reduction reaction) for mixed activation-concentration polarization

The effect of a number of corrosion parameters for a corrosion process proceeding under various degrees of activation/mass transport control can be assessed using an Evans diagram, as shown in Fig. 13. Three situations are considered. For cathodic curve 1, corrosion occurs with the anodic reaction totally activation controlled ($\eta_a^T = \eta_a^A$) and the cathodic reaction totally mass transport controlled ($\eta_c^T = \eta_c^C$), that is, $c^s_{Ox} = 0$. If the solution is now made to flow, the thickness of the diffusion layer (δ) will decrease, $(i_c)_{lim}$ (Eq 47) will increase and hence so will the corrosion current. The figure shows that E_{corr} shifts to a more positive value, and:

$$\eta_c^T = (E_e)_c - E_{corr} = \eta_c^A + \eta_c^C \qquad \text{(Eq 49)}$$

decreases due to a decrease in η_c^C. For more vigorous stirring, η_c^C reaches 0, because the flux of oxidant to the corroding surface is now sufficiently large to maintain $c^s_{Ox} = c^b_{Ox}$. Again, E_{corr} shifts to a more positive value to reflect this decrease in η_c^T because $\eta_c^C = 0$. The cathodic reaction is now fully activation controlled ($\eta_c^T = \eta_c^A$), and further increases in fluid velocity will not affect the corrosion rate. Such changes in E_{corr} and i_{corr} with the degree of convection can be used to indicate whether mass transport control is operative. If the anodic, as opposed to the cathodic, reaction was mass transport controlled, then a similar analysis would apply, but E_{corr} would shift to more negative values with increasing degree of convection.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

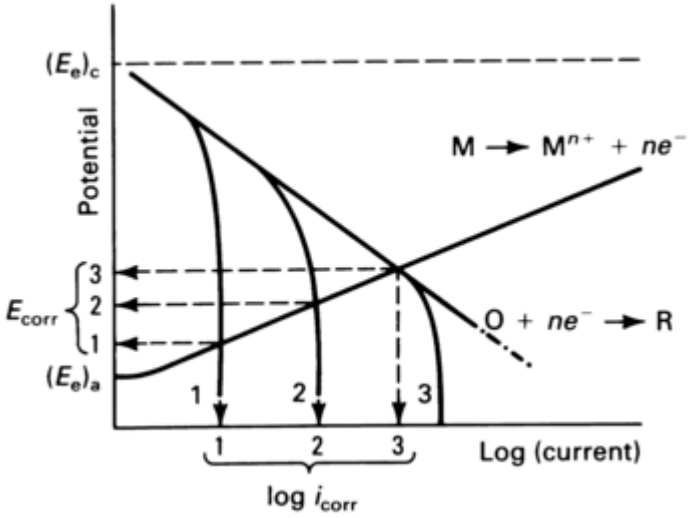

Fig. 13 Evans diagram showing the influence on E_{corr} and log (i_{corr}) of changing the transport rate of oxidant O to the corroding surface

More generally, the term D_O/δ is termed the mass transport coefficient (m_c), and Eq 46 is written in the form:

$$\frac{i_{corr}}{nF} = m_c\left(c_{Ox}^{b} - c_{Ox}^{s}\right) \qquad \text{(Eq 50)}$$

An equation for the corrosion rate under activation control can also be written in the simplified form:

$$\frac{i_{corr}}{nF} = k_c c_{Ox}^{s} \qquad \text{(Eq 51)}$$

where k_c can be considered a potential-dependent rate constant for the cathodic reaction.

Equation 51 could be considered a restatement of the Butler-Volmer equation, and the reader is referred to standard electrochemical text books for more detailed descriptions (Ref 6). Combining Eq 50 and 51 and eliminating c_{Ox}^{s} yields:

$$i_{corr} = nFc_{Ox}^{b}\left\{\frac{m_c k_c}{(m_c + k_c)}\right\} \qquad \text{(Eq 52)}$$

where k_c can be considered the activation control parameter and m_c the mass transport control parameter.

Whether activation or mass transport kinetics determine the corrosion rate is straight forwardly appreciated by considering the relative values of m_c and k_c in Eq 52. For $m_c \gg k_c$, the bracketed term reduces to k_c, and the corrosion current is activation controlled. For $m_c \ll k_c$, the term reduces to m_c, and corrosion would be mass transport controlled.

While Eq 52 may define the relative importance of activation and mass transport control, it does not contain any information on the factors that control mass transport and hence determine the value of m_c. The dependence of m_c on solution flow rate can be determined experimentally, and its form varies, depending on the geometry of the system. In general, this dependence takes the form:

$$i_{corr} \propto f^{n} \qquad \text{(Eq 53)}$$

where f is the flow rate, and n is a constant that depends primarily on the geometry of the system. For flow over a flat plate, n is 0.33 for laminar flow (smooth, $Re < 2200$), where Re is the Reynold's number (defined subsequently).

The variation of m_c depends not only on flow rate but also on properties such as the kinematic viscosity of the fluid (ν), the diffusion coefficient of the species (D), as well as the geometry of the system. These effects can be specified using dimensionless parameters such as the Reynold's; Re; and Schmidt, Sc, numbers given by:

$$Re = f\frac{L}{\nu} \qquad \text{(Eq 54)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$Sc = \frac{\nu}{D} \qquad \text{(Eq 55)}$$

The Reynolds number is a measure of the ratio of convective to viscous forces in the fluid, and, for laminar flow down a pipe, L is a characteristic length. The Schmidt number quantifies the relationship between hydrodynamic and diffusion boundary layers at the corroding surface. Thus, it can be shown that for flow over a smooth, flat, corroding surface:

$$(i_{corr})_{max} = 0.62nFD_O c_O^b (Re)^{\alpha} (Sc)^{\beta} \qquad \text{(Eq 56)}$$

where α and β are numerical constants that depend on the geometry of the system and the convective flow conditions.

Smooth, laminar flow can only be achieved up to a certain Reynold's number or flow rate, f, if L and ν are constant, beyond which the flow becomes turbulent, and the dependence of i_{corr} on flow rate increases. For still higher rates, activation control can be achieved ($m_c \gg k_c$), and the corrosion rate becomes independent of flow rate. This behavior is illustrated in Fig. 14. The solid line shows the effect of flow rate when the corrosion reaction is fast (k_c large), and a large flow rate is required to achieve activation control ($m_c \gg k_c$). The dotted line shows the behavior expected for a slow corrosion reaction (k_c small), when only a small flow rate is required to achieve activation control.

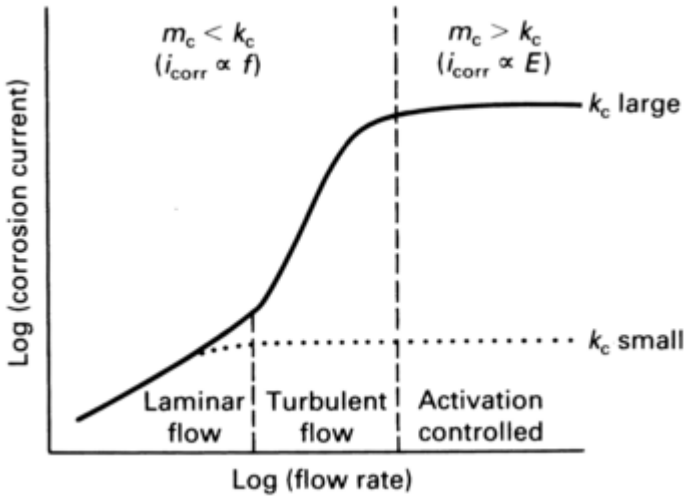

Fig. 14 The influence of solution flow rate on the corrosion rate (expressed as a current) showing the response in different flow regimes

Influence of Corrosion Product Deposits

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Thus far in the discussion of transport effects, only the transport of the cathodic reagent (step 3 in Fig. 5) has been considered. The transport of the anodic (metal) dissolution product (step 4 in Fig. 5) also affects the corrosion rate but in a different way. If dissolved metal ions are allowed to build up at the corroding surface, supersaturation of solid oxides/hydroxides can occur, leading to film formation reactions (step 5 in Fig. 5). These corrosion product deposits will form at a rate determined by the rate of the corrosion process and the solubility of the metal cations in the particular exposure environment. Determining their influence on the corrosion rate is not simple. A key feature is the porosity of the deposit (ε), because this determines the area of metal left exposed and also reduces the diffusion coefficient of both the anodic dissolution product and the cathodic reagent by a factor directly proportional to the porosity. The pores are also likely to be nonlinear, and their effective length will be greater than the thickness of the deposit. The diffusion coefficient will, therefore, also be attenuated by a tortuosity (τ) factor. The effective diffusion coefficient (D_{eff}) will be given by:

$$D_{eff} = \varepsilon\tau D_{Ox} \qquad \text{(Eq 57)}$$

This situation is illustrated schematically in Fig. 15, and Eq 45 for the corrosion rate could be rewritten to yield:

$$i_{corr} = \frac{nF\varepsilon\tau D_{Ox}}{l}\left(c_{Ox}^{s} - c_{Ox}^{b}\right) \qquad \text{(Eq 58)}$$

where corrosion is only occurring on a fraction (εA) of the original exposed metal area, A, and l is the thickness of the corrosion product deposit. It should be noted that this represents a very simplified discussion of what could be a much more complicated process.

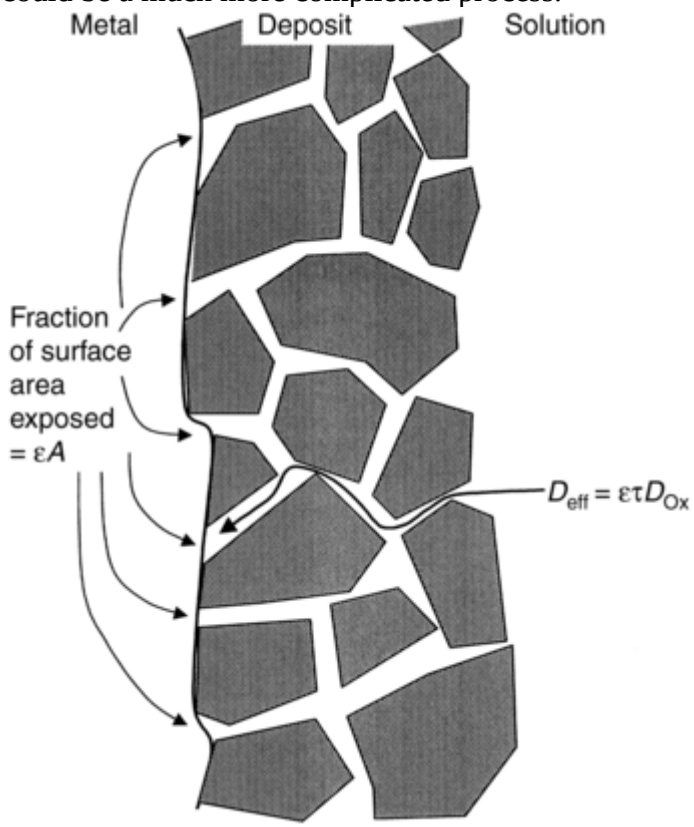

Fig. 15 Schematic illustrating how the presence of a corrosion product deposit influences the corrosion of an underlying metal by limiting both the area of exposed metal and the diffusion of oxidant to the corroding surface. D, diffusion coefficient; ε, porosity; τ, tortuosity factor; *A*, area

Kinetics of Corrosion of Passive Metals

The formation of a passive film (step 7 in Fig. 5) can have a large influence on the corrosion rate. Passivation becomes thermodynamically possible when the corrosion potential exceeds (becomes more positive than) the potential corresponding to the equilibrium between the metal and one of its oxides/hydroxides:

$$E_{corr} > (E_e)_{M/MO} \quad \text{(Eq 59)}$$

Inspection of the Pourbaix diagram for the metal/ metal oxide/aqueous solution system shows that this condition moves E_{corr} into the oxide stability region, as illustrated in Fig. 16 for the iron/iron oxide/water system. For point 1, $E_{corr} < (E_e)_{M/MO}$, and corrosion of the bare metal is expected, while, for point 2, $E_{corr} > (E_e)_{M/MO}$, and the metal should be oxide covered and passive. It should be noted that experimentally measured primary passive potentials inevitably do not correspond directly with these thermodynamically determined potentials, because kinetic as well as thermodynamic effects are involved in oxide film formation.

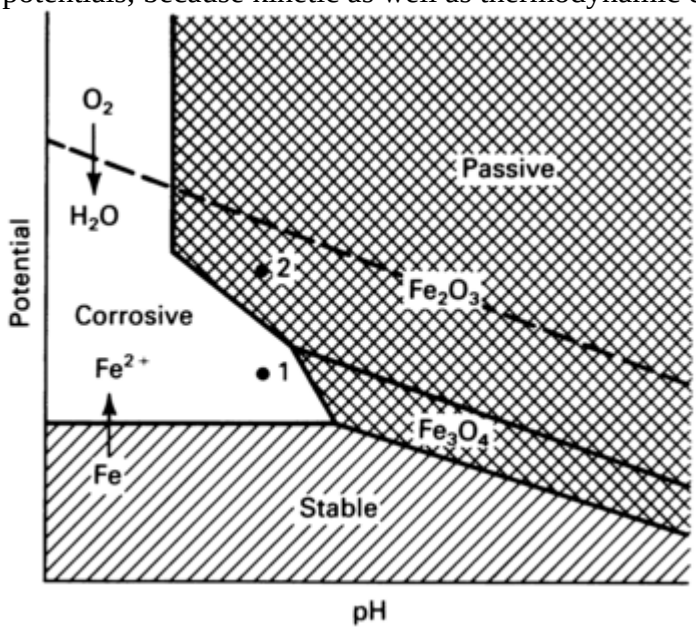

Fig. 16 Simplified Pourbaix (equilibrium potential-pH) diagram for the iron-water system. The upper dashed line shows the potential for H_2O in equilibrium with O_2.

The current-potential or polarization curve for the anodic process is shown in Fig. 17 and can be divided into a number of regions. In region AB, the active region, metal dissolution is unimpeded, because no passive film is present. Because such polarization curves are usually recorded under activation control conditions, local supersaturation leading to the deposition of corrosion products (discussed previously) is generally assumed not to influence the active dissolution of the metal. However, for real corrosion conditions, and especially for reactive metals such as iron, the current in this region could be suppressed by corrosion product deposits, as discussed previously. For the purposes of the present discussion, it is assumed that this does not occur. For active dissolution, therefore, the current should conform to the Tafel relationship (Eq 30), and its extrapolation back to $(E_e)_a$ would yield a value of $(i_o)_a$.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

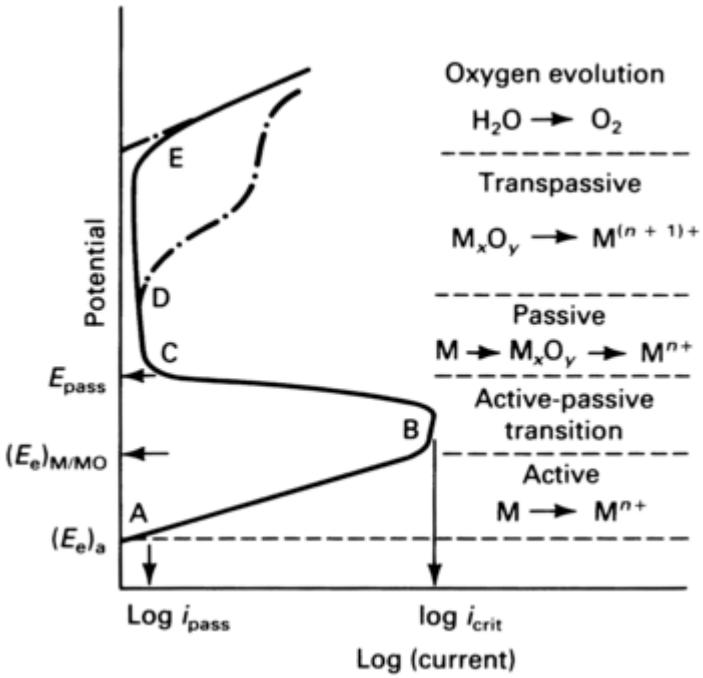

Fig. 17 Polarization curve for a metal that undergoes active-to-passive and passive-to-transpassive transitions

At a potential B, shown in Fig. 17 to coincide with $(E_e)_{M/MO}$ (although, as noted previously, this is rarely the case experimentally), there is a departure from the Tafel relationship, leading eventually to a decrease in current to a low value. The electrode is said to have undergone an active-to-passive transition and, by point C, has become passive. The potential at point B may or may not correspond to the potential $(E_e)_{M/MO}$. Thermodynamics demands only that the condition in Eq 59 be satisfied. The maximum current achieved immediately before the transition is termed the critical passivating current (i_{crit}). The potential at which the current falls to the passive value is called the passivation potential (E_{pass}), and it corresponds to the onset of full passivity. For gold, silver, and platinum, the passivation potential is close to $(E_e)_{M/MO}$, but for most other metals, it is much more positive than this equilibrium value.

For $E > E_{pass}$, the metal is said to be in the passive state, and the current is very low. A comparison of critical currents to passive currents puts the industrial importance of passivity into perspective. Critical passivating currents (expressed as current densities) can be as high as tens of mA/cm^2, while passive currents can be as low as nA/cm^2. Consequently, from the industrial corrosion perspective, the establishment of passivity is an important feature.

A detailed discussion of the properties of passive films is beyond the scope of this article (see the article “Passivity” in this Volume). A number of theories exist to explain the growth kinetics and properties of oxide films, but the discussion of one of them, the point defect model (Ref 7), serves to illustrate the critical features of the current-potential behavior in the passive region. The essential features of this model are shown schematically in Fig. 18. The film is assumed to be composed of an inner barrier layer, whose insulating properties provide the essential corrosion protection, and an outer recrystallized layer that confers little extra corrosion protection and is composed of hydrated metal species. This outer layer may not exist in acidic solutions in which the metal cations are highly soluble (Fig. 6). Considerable experimental evidence exists to support this structure.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

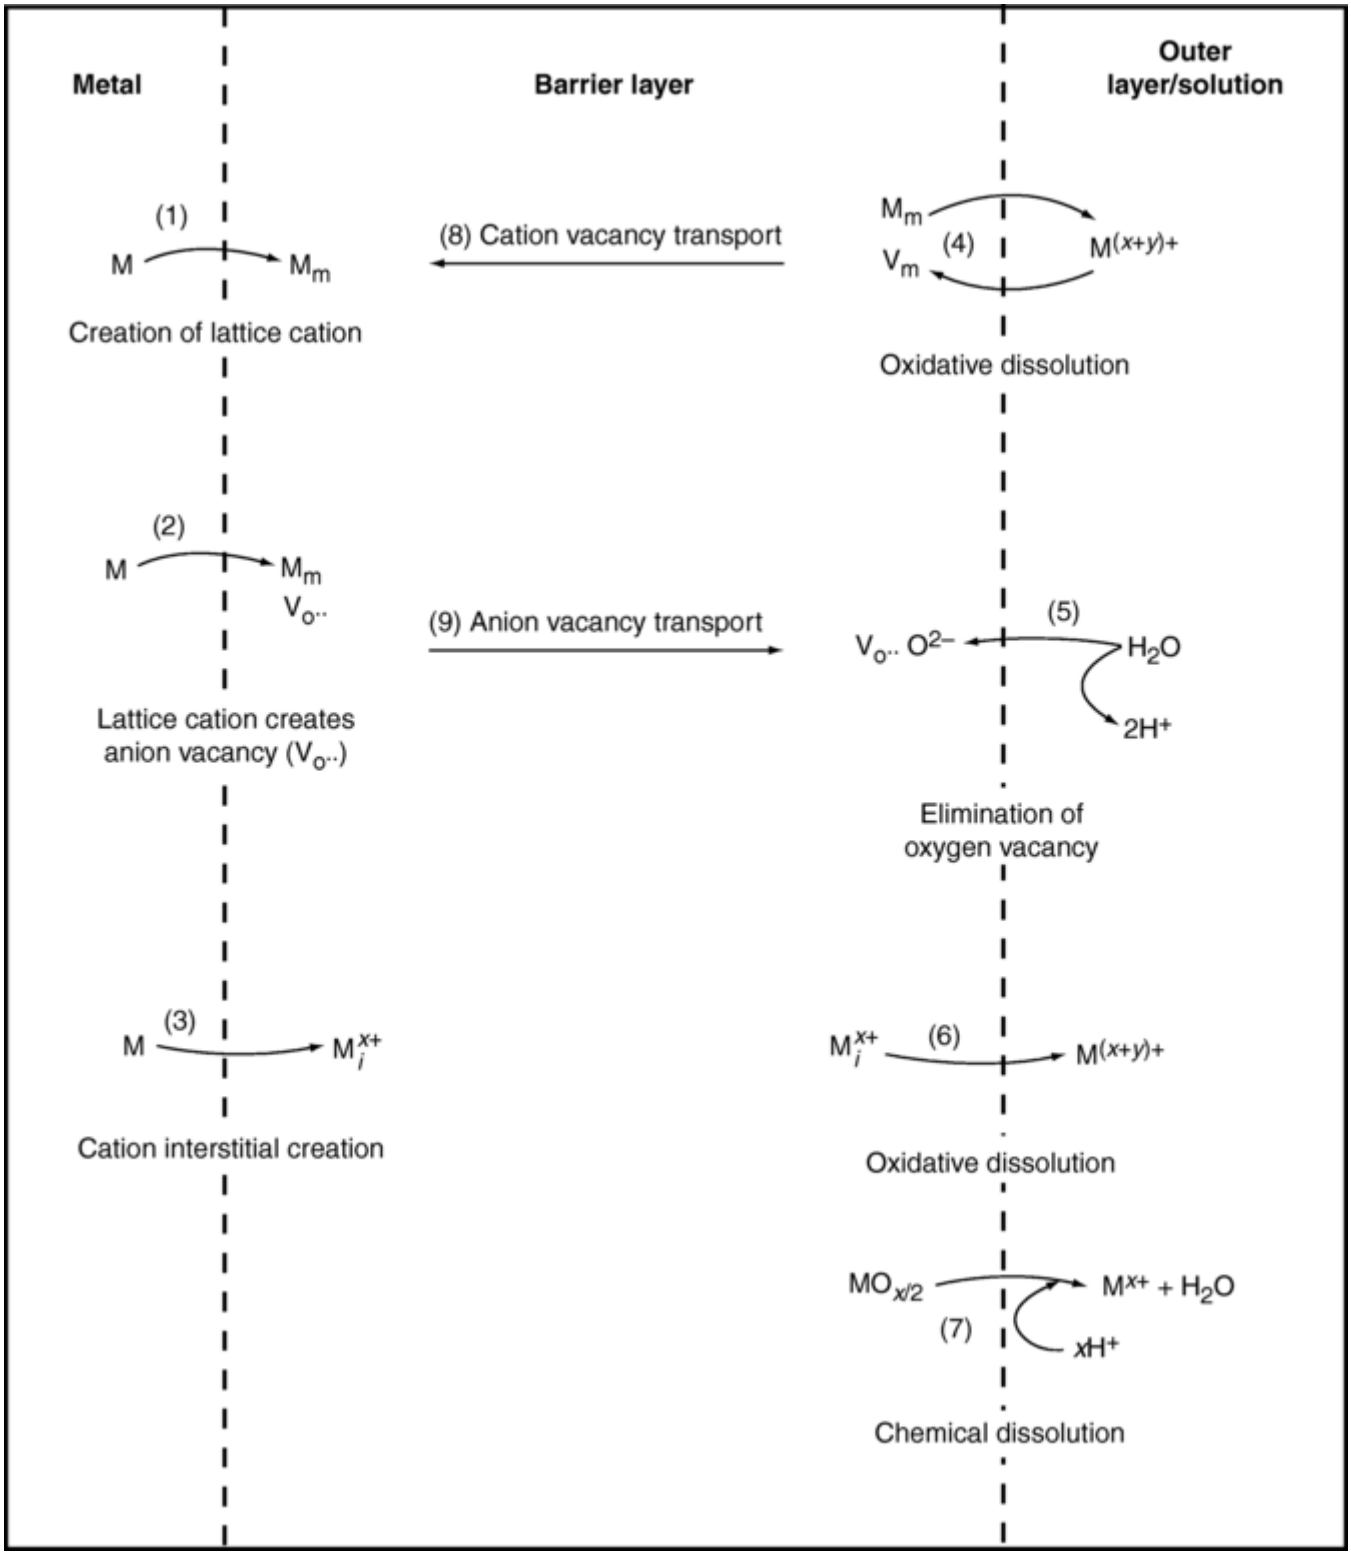

Fig. 18 Schematic description of the point defect model for the growth of a passive oxide film

Oxide growth is assumed to occur by the transport of defects through the film under the influence of the electric field that exists within the oxide. The nature of the defect depends on the metal/alloy and the nature of the growing oxide. However, the key vacancies are anion vacancies (V_{o}^{--})created at the metal-oxide interface, cation vacancies (V_m) created at the oxide- solution interface, and cation interstitials created at the metal-oxide interface. The general observation that the current in the passive region is independent of potential can be interpreted in terms of this model. As the potential is increased through the passive region, a progressive thickening of the oxide occurs, such that the electric field within the oxide remains constant. Thus, the steady-state current at each potential is a balance between oxide formation at the metal-oxide interface and

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

dissolution/recrystallization (to the outer hydrated layer) at the oxide-solution interface. Reference 7 provides more extensive discussions.

For high anodic potentials, the observed behavior depends on the nature of the metal and the properties of the oxide film. For metals that form insulating oxides (e.g., aluminum, titanium, zirconium), the films continue to thicken with increasing potential, and low passive currents are maintained. For other metals, for example, iron, chromium, nickel, and materials such as stainless steels and nickel-chromium alloys, oxygen evolution can occur on the outside of the passive film once the potential exceeds point E (Fig. 17):

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \qquad \text{(Eq 60)}$$

For this reaction to occur, the film must be electronically conducting. This is possible because the passive films formed are thin (nanometers) and possess semiconducting properties. The dashed-dotted line in Fig. 17, in the potential region D to E, corresponds to the phenomenon of transpassivity. In this region, the oxide film begins to dissolve oxidatively, generally as a hydrolyzed cation in a higher oxidation state than that which exists in the film. An example would be the dissolution of chromium, present in the passive film on stainless steels as Cr^{III}, as Cr^{VI} in the form of CrO_4^{2-}. While transpassive dissolution, starting at point D, and O_2 evolution, starting at point E, are shown as clearly separated in Fig. 17, they often occur together, and a distinct transpassive region cannot be observed.

When coupled to a cathodic reaction in a corrosion process, a number of criteria must be satisfied if the metal is to be in the passive region and, on normal industrial time scales, free of corrosion:

- The equilibrium potential for the cathodic reaction ($(E_e)_c$) must be greater than the passivation potential (E_{pass}).
- The cathodic reaction must be capable of driving the anodic reaction to a current in excess of the critical passivation current, i_{crit}, in Fig. 17.

Three possible situations are shown in the Evans diagram in Fig. 19. The solid line shows the anodic polarization curve, and lines 1, 2, and 3 show the cathodic polarization curves for three different cathodic half-reactions ($O_n + ne^- \rightarrow R_n$).

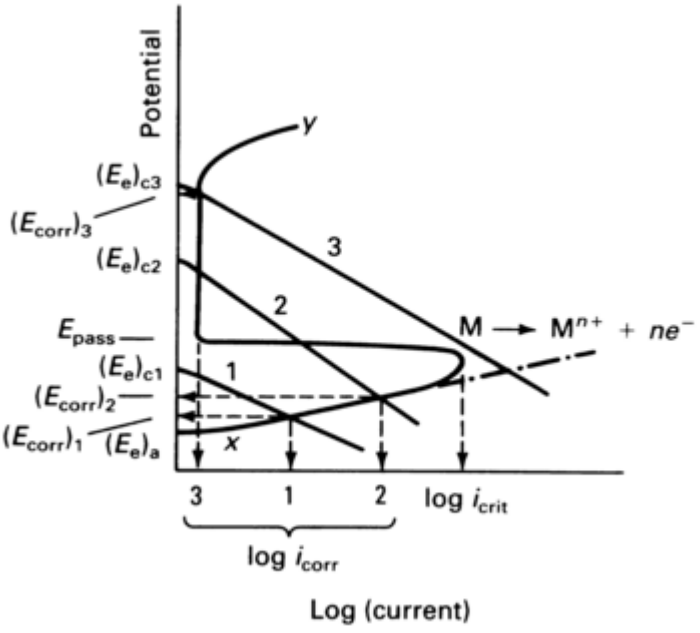

Fig. 19 Effect of various cathodic reactions on the corrosion current and potential for a metal capable of undergoing an active-passive transition

For cathodic reaction 1 (Fig. 19), $(E_e)_{c1} < E_{pass}$. Because the corrosion potential must lie between $(E_e)_a$ and $(E_e)_{c1}$ for the two reactions to form a corrosion couple, the required condition for passivation, $E_{corr} > E_{pass}$, cannot be achieved. Therefore, E_{corr} remains in the active region, and the metal will actively corrode.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

For cathodic reaction 2 (Fig. 19), the condition $(E_e)_{c2} > E_{pass}$ is met, but the two polarization curves intersect at an anodic current $<i_{crit}$. Again, $E_{corr} < E_{pass}$, and the metal corrodes in the active region at an even higher current than for cathodic reaction 1.

For cathodic reaction 3 (Fig. 19), the conditions $(E_e)_{c3} > E_{pass}$ and $i > i_{crit}$ are both met. As a consequence, $E_{corr} > E_{pass}$, and the metal passivates, with the corrosion current equal to the passive dissolution current.

It is clear from this discussion that mild oxidizing agents ($\Delta E_{therm} = (E_e)_c - (E_e)_a$ small) could leave the material susceptible to corrosion, and strong oxidizing agents (ΔE_{therm} large) are required to ensure the metal will be in the passive region. However, in the presence of extremely strong oxidizing agents, it is possible for E_{corr} to become sufficiently positive that physical instabilities in the oxide become feasible. These minor film breakdown events can lead to many forms of localized corrosion if allowed to stabilize. A discussion of these processes is beyond the scope of this article, but the danger in fracturing the passive film can be appreciated from a consideration of the extrapolation of the anodic active region, shown by the dashed-dotted line in Fig. 19. If the oxide did not form, then this extrapolation shows that currents at positive potentials would be very large. Thus, breakdown of the passive film at a local site within the passive region would lead to an extremely high local current density and the possibility of deep localized corrosion of the metal.

Introduction

CORROSION OF METALLIC MATERIALS is governed by electrochemical kinetics, so that the general concepts developed for studying electrochemical reaction mechanisms may be applied to corrosion. The processes of charge transfer taking place at the electrode interface within the double layer and of mass transport at the vicinity of the electrode surface are introduced first. Then, the corrosion processes, which involve anodic and cathodic reactions at specific electrode sites, are described briefly. Some reaction mechanisms for cathodic and anodic processes are presented to illustrate the great variety of reaction mechanisms occurring at the electrode interface. Some experimental methods for devising a reliable reaction model are also described. The presentations given here are limited to a survey of each item; readers wishing more detailed information are invited to consult the many books devoted to electrode kinetics and corrosion processes (Ref 1, 2, 3, 4).

Fundamental Aspects of Electrode Kinetics

Electrochemical reactions may be considered as physical and chemical processes of electric charge transfer between two phases containing different charge carriers: electrons in the metallic phase and ions in the electrolyte. This charge transfer induces an electric current flow and chemical transformations at the interface.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

A thorough investigation of an electrochemical process involves the identification of reactants, the separation of elementary interfacial reactions, and the establishment of a reaction mechanism. Analytical methods are generally applied to identify the initial, final, and, sometimes, intermediate species, while kinetic methods are used to identify the links between the elementary reaction steps and assess their rate constant. Kinetic methods differ from other methods by the following points:

- Reactions are localized at the interface so that they concern a tiny volume and a small number of identifiable entities.
- Most in situ surface analytical techniques cannot be applied because of the presence of electrolyte.
- The kinetics are easily characterized by electric signals (the current flowing across the interface and the electrode potential) with more and more sophisticated methods.

The rate of charge transfer reactions governed only by the activation energy is derived first. Then, the case in which mass transport modifies the concentration gradient of the species at the interface and, therefore, changes the overall reaction rate is discussed.

Charge-Transfer Process

Charge transfer may take place as a single step determined by the activation energy or as a multistep transfer involving intermediate species in the reaction.
Single-Step Charge Transfer Reaction Rate. Different macroscopic descriptions allowed the absolute reaction rate, k, to be associated with the change in activation energy (Gibbs free energy, or $\Delta G^{\ddagger}$), through the Arrhenius equation:

$$k = C \exp\left(-\frac{\Delta G^{\ddagger}}{RT}\right) \qquad \text{(Eq 1)}$$

where C is a constant, T is the absolute temperature (in K), and R is the gas constant (8.31 J/mol · K). The activation energy change $\Delta G^{\ddagger}$, in electrochemical reactions is not the difference in free energy, ΔG, between the initial and final states of the reactants; it takes into account the height of the energy barrier, as will be explained, and depends on the cell potential E. For a reaction involving the forward and backward single-step transfer of z electrons per molecule of the species considered, the simplest situation, which leads to the empirical Tafel law between the current density and the electrode potential, consists in postulating that a change in potential (ΔE) induces a change in free energy, $\Delta G^{\ddagger}$, according to the following relationship. For the anodic (oxidation) reaction:

$$\Delta G_{a}^{\ddagger} = \Delta G_{0,a}^{\ddagger} - \alpha z F \Delta E \qquad \text{(Eq 2)}$$

For the cathodic (reduction) reaction:

$$\Delta G_{c}^{\ddagger} = \Delta G_{0,c}^{\ddagger} + (1-\alpha) z F \Delta E \qquad \text{(Eq 3)}$$

where F is the Faraday constant (96,485 C/mol), α is the charge-transfer coefficient ($0 \le \alpha \le 1$). The subscript 0 indicates that all reactants are in a standard state (constant temperature, pressure, potential, activity, etc.). Equations 2 and 3 indicate how the electric energy shift $zF\Delta E$ of the z moles of electrons induced by the electrode potential change (ΔE) is shared between the two partial reactions. This may be illustrated in Fig. 1 that shows the free energy evolution during both the reduction (from left to right) and oxidation reactions (from right to left). The solid lines correspond to the standard conditions for both reactions; in that case (ΔE = 0), $\Delta G_{0,c}^{\ddagger}$ represents the energy required by one mole of oxidized species to reach the activated state, A, from the initial stable state (minimum energy), and be reduced. $\Delta G_{0,a}^{\ddagger}$ represents the energy required by one mole of reduced species to reach the activated state, A, from the initial stable state (minimum energy) and be oxidized. The dashed line corresponds to the activation energy of one mole of oxidized species and z moles of electrons during the reduction reaction after a potential change ΔE. The anodic curve was arbitrarily kept unchanged.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

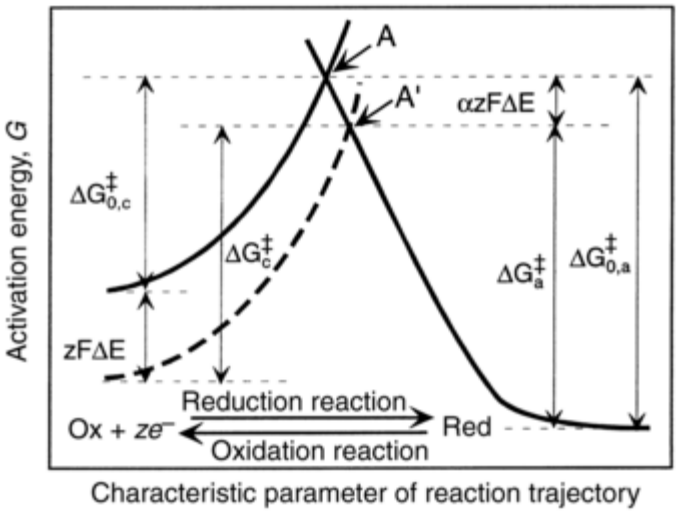

Fig. 1 Schematic representation of the influence of a potential change on the activation energy during charge transfer in an oxidation-reduction reaction

It can be seen graphically that if α represents the fraction of the electric energy $zF\Delta E$ devoted to the activation energy of the oxidation reaction, the height of the energy barrier is decreased by a factor $\alpha zF\Delta E$ for the oxidation reaction (Eq 2) while it is increased by a factor $\Delta G_c^{\ddagger} - \Delta G_{0,c}^{\ddagger} = zF\Delta E - \alpha zF\Delta E$ for the reduction reaction (Eq 3). The dependence of the anodic and cathodic rate constants, k_a and k_c, on the electrode potential is obtained as a consequence of Eq 1, Eq 2, Eq 3:

$$k_a = k_{0,a} \exp\left(\frac{\alpha zF}{RT}\Delta E\right) \quad \text{and}$$

$$k_c = k_{0,c} \exp\left(\frac{-(1-\alpha)zF}{RT}\Delta E\right) \qquad \text{(Eq 4)}$$

Current-Potential Relationship. The current provided by the oxidation-reduction reaction is proportional to the net production rate of the oxidized species:

$$i = zF\left\{k_{0,a} C_{red}^{i} \exp\left(\frac{\alpha zF}{RT}\Delta E\right) - k_{0,c} C_{ox}^{i} \exp\left(\frac{-(1-\alpha)zF}{RT}\Delta E\right)\right\} \qquad \text{(Eq 5)}$$

where i is the current density, and C_{ox}^{i}, C_{red}^{i}(in mol/cm^3) are the concentrations of the oxidized and reduced species at the electrode interface. For a purely charge-transfer controlled reaction, the mass-transport processes are fast so that the concentrations at the interface are equal to the concentrations in the electrolyte bulk and do not depend on the electrode potential. It is convenient to introduce the standard equilibrium potential, E_0, which corresponds to $i = 0$ for identical concentrations of the oxidized and reduced species in the solution. In that case, since the reaction rates $k_{0,a}$ and $k_{0,c}$ are equal (= k_0, termed *exchange rate constant* of the reaction, in cm/s), i can be expressed as:

$$i = zFk_0\left\{C_{red}^{i} \exp\left(\frac{\alpha zF}{RT}(E-E_0)\right) - C_{ox}^{i} \exp\left(\frac{-(1-\alpha)zF}{RT}(E-E_0)\right)\right\} \qquad \text{(Eq 6)}$$

This equation gives the expression (Nernst law) of the equilibrium potential (E_{eq}) in the solution considered ($C_{ox}^{i} \neq C_{red}^{i}$):

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$E_{eq} = E_0 + \frac{RT}{zF} \ln\left(\frac{C^i_{ox}}{C^i_{red}}\right) \qquad \text{(Eq 7)}$$

from which the overpotential, $\eta = E - E_{eq}$, is defined. Equation 6 gives the Butler-Volmer equation, which is the basis of the electrochemical kinetics (Ref 5, 6):

$$i = i_0\left[\exp\left(\frac{\alpha z F}{RT}\eta\right) - \exp\left(\frac{-(1-\alpha)zF}{RT}\eta\right)\right] \qquad \text{(Eq 8)}$$

where the exchange current density (i_0) is defined as:

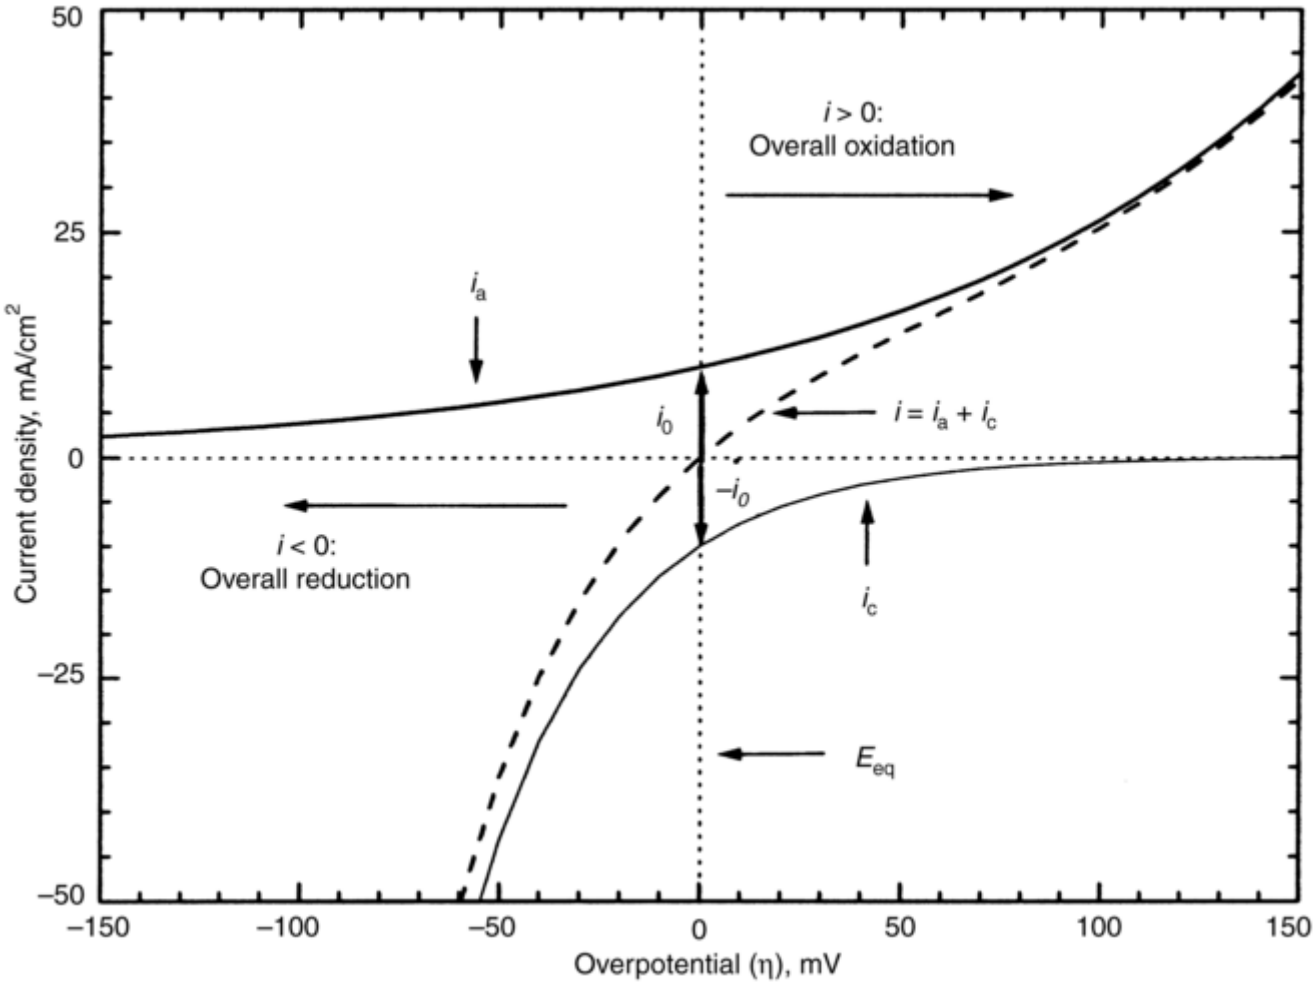
$$i_0 = zFk_0\left(C^i_{red}\right)^{1-\alpha}\left(C^i_{ox}\right)^{\alpha} \qquad \text{(Eq 9)}$$

gives information on the degree of reversibility of the reaction. The Butler-Volmer equation gives the partial anodic and cathodic currents. At sufficiently high anodic overpotentials, the cathodic process becomes negligible. At sufficiently high cathodic overpotentials, the anodic process becomes negligible. The anodic i_a and cathodic i_c current densities are then:

$$i_a = i_0 \exp\left(\frac{\alpha z F}{RT}\eta\right) \quad \text{and}$$

$$i_c = -i_0 \exp\left(\frac{-(1-\alpha)zF}{RT}\eta\right) \qquad \text{(Eq 10)}$$

According to the International Union of Pure and Applied Chemistry (IUPAC) recommendation, the cathodic current and its Tafel coefficient, -(1 - α)zF/RT, are expressed by negative values. In these equations (Tafel laws), the logarithm of the current density (in absolute value) is a linear function of the electrode potential. Figure 2 summarizes the current behavior given by Eq 8 and 10.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 2 Butler-Volmer electrode kinetics. i_0 = 10 mA/cm^2, charge transfer coefficient, α = 0.75, charge number, z = 1, T = 298 K

Multistep Charge Transfer. In the single-step charge transfer, z electrons are exchanged simultaneously. However, this requires a much higher activation energy than consecutive elementary reaction steps involving only one electron transfer. As a simple example, consider the situation where two electrons are transferred (z = 2) via two irreversible reactions involving an adsorbed intermediate species, B_{ad}.

$$M + A_{sol} \xrightarrow{k_1} B_{ad} + e^- \qquad \text{(Eq 11)}$$

$$B_{ad} \xrightarrow{k_2} C_{sol} + A_{sol} + e^- \qquad \text{(Eq 12)}$$

M is the metal and A_{sol} and C_{sol} are species in solution. For example, the dissolution of iron in sulfuric acid at low current may be modeled by these reactions with M, A_{sol}, B_{ad}, and C_{sol} representing, respectively, Fe, OH^-, $(FeOH)_{ad}$, and Fe^{2+} in solution (Ref 7). B_{ad} covers a fraction (θ) of the electrode surface area ($0 < \theta < 1$) so that the reaction in Eq 11 takes place only at the fractional area of 1 - θ. If a Langmuir-type adsorption isotherm can be assumed, the superficial concentration (in mol/cm^2) (C_B) of B_{ad} is equal to $\beta\theta$, where β is the maximum concentration of B_{ad} (in mol/cm^2), while the concentration C_M of atoms M available for the reaction shown in Eq 11 is $\beta(1 - \theta)$. For first-order kinetic reactions, the mass and charge balances can be expressed, respectively, as follows when the concentration of C_{sol} at the interface can be assumed to be constant:

$$\frac{dC_B}{dt} = \beta\frac{d\theta}{dt} = k_1 C_M - k_2 C_B = k_{0,1}\exp(b_1 E)\beta(1-\theta) - k_{0,2}\exp(b_2 E)\beta\theta \qquad \text{(Eq 13)}$$

$$i = F(k_1 C_M + k_2 C_B) = F\left(k_{0,1}\exp(b_1 E)\beta(1-\theta) + k_{0,2}\exp(b_2 E)\beta\theta\right) \qquad \text{(Eq 14)}$$

where b_1 and b_2 are the Tafel coefficients and $k_{0,1}$ and $k_{0,2}$ are the reaction rates, expressed in s^{-1} at the potential E = 0 V, defined with an arbitrary potential reference. In the literature, reaction rates $k'_{0,i} = k_{0,i}\beta$ in mol/cm^2 per s are frequently introduced so that the parameter β appears in Eq 13 only. Often, β values of about 2 to 5 × 10^{-9} mol/cm^2 are used; they correspond to one adsorbed molecule per one surface atom for an electrode with a certain surface roughness. At the steady state (subscript s), there is no time change in the potential, current, and surface coverage; the righthand side of Eq 13 is then equal to zero, which gives the steady-state value of θ:

$$\theta_s = \frac{k'_{0,1}\exp(b_1 E_s)}{\left\{k'_{0,1}\exp(b_1 E_s) + k'_{0,2}\exp(b_2 E_s)\right\}} \qquad \text{(Eq 15)}$$

The equation of the steady-state polarization curve follows, from Eq 14:

$$i = \frac{2F\left\{k'_{0,1}\exp(b_1 E_s)k'_{0,2}\exp(b_2 E_s)\right\}}{\left\{k'_{0,1}\exp(b_1 E_s) + k'_{0,2}\exp(b_2 E_s)\right\}} \qquad \text{(Eq 16)}$$

If $b_1 > b_2$, the current density is determined by the reaction in Eq 11 at low potentials ($k_1 \ll k_2$) and by the reaction in Eq 12 at high potentials ($k_1 \gg k_2$) leading to a Tafel plot [log(i) - E] with two different slopes, b_1 at low potentials and b_2 at high potentials. The surface concentration of the adsorbed intermediate species $\beta \cdot \theta$ or its potential dependence cannot in general be observed experimentally by steady-state methods. In contrast, the impedance technique or other time or frequency resolved methods can track the relaxation of θ induced by a potential change.

Mass Transport Process and Mixed Kinetics

The Butler-Volmer equation is valid for systems under pure charge transfer control; the mass transport is much faster than the charge transfer and ensures the constant supply of reactants at the interface. This is not the case

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

for fast charge- transfer reactions and differences in the concentration of the reacting species, C_{ox}^{i} and C_{red}^{i}, at the interface, and C_{ox} and C_{red}, in the bulk of the electrolyte appear. Equation 8 is then rewritten as:

$$i = i_0\left[\frac{C_{red}^{i}}{C_{red}}\exp\left(\frac{\alpha z F}{RT}\eta\right) - \frac{C_{ox}^{i}}{C_{ox}}\exp\left(\frac{-(1-\alpha)zF}{RT}\eta\right)\right] \qquad \text{(Eq 17)}$$

In this situation, the current density is determined by both the diffusion and activation processes (mixed kinetics). Under the assumption of linear concentrations in the Nernst diffusion layer of thickness δ, the mixed current density (i_{mix}) is:

$$i_{mix} = \frac{zFD_{red}\left(C_{red} - C_{red}^{i}\right)}{\delta} \qquad \text{(Eq 18)}$$

where D_{red} is the diffusion coefficient (cm^2/s) of the reduced species, since the flux of these species consumed in the reaction is balanced by the flux arriving by diffusion. C_{red}^{i} can be calculated with Fick's law, which gives the full expression of i_{mix}:

$$i_{mix} = i_{act}\frac{D_{red}D_{ox}}{D_{red}D_{ox} + \delta\left(k_c D_{red} + k_a D_{ox}\right)} \qquad \text{(Eq 19)}$$

where the pure activation current density (i_{act}) is given by Eq 6:

$$i_{act} = zF(k_a C_{red} - k_c C_{ox}) \qquad \text{(Eq 20)}$$

Mass transport of both oxidized and reduced species is supposed here to be controlled by diffusion; if the reaction rate is controlled by diffusion of only one species, the diffusion coefficient of the other species is taken to be infinite.

If the reaction rate is fast enough, the concentration of the species consumed at the interface tends to be zero. The overall reaction is under mass-transport control, and i_{mix} tends to be the diffusion limiting current density (i_{lim}) (given by Eq 18 with $C_{red}^{i} = 0$), which is independent of the potential. For slower kinetics, the current densities i_{mix}, i_{act}, and i_{lim} are related by the following equation when the reverse reaction is negligible:

$$\frac{1}{i_{mix}} = \frac{1}{i_{lim}} + \frac{1}{i_{act}} \qquad \text{(Eq 21)}$$

Figure 3 presents the polarization curves when the overall reaction rate is influenced by the diffusion process. The kinetic constants determining the pure activation current density i_{act} are those used in Fig. 2, while the diffusion limiting current densities are set to 25 mA/cm^2 for both anodic and cathodic reactions. The deviation between the current-density curves ($i_{mix,a}$ and $i_{mix,c}$) for the mixed kinetics and $i_{act,a}$ and $i_{act,c}$ for the pure activation-controlled kinetics can be noted. It should be emphasized that the diffusion effects are already present at the equilibrium potential since the exchange current density (i'_0) is lower in Fig. 3 than i_0 in Fig. 2.

Electrode Kinetics near the Corrosion Potential

The specifics of electrode kinetics near the zero-overall current are described with respect to the reversible process presented earlier. It is shown that these kinetics may be advantageously analyzed by dynamic techniques such as electrochemical impedance spectroscopy.

Coupling of Anodic and Cathodic Processes. Though corrosion is basically an electrochemical process, no overall current flow is observed during the free corrosion of a metal (M) at the open-circuit potential, because the anodic process that produces electrons and the cathodic process that consumes electrons, which can be written formally:

$$\text{Anodic reaction} \quad M \rightarrow M^{z_a^+} + z_a e^- \qquad \text{(Eq 22)}$$

$$\text{Cathodic reaction} \quad Ox + z_c e^- \rightarrow \text{Red} \qquad \text{(Eq 23)}$$

are taking place simultaneously and at the same rate. A more detailed description of these processes is shown later in this article.

The reactions in Eq 22 and 23 are not the forward and backward branches of the same reversible reaction, so that they cannot be referred to the same equilibrium potential. The simplest way to describe the kinetics of both processes is to consider that each reaction obeys the Tafel law (Eq 10), which is often experimentally verified because of the large difference in the equilibrium potentials of the anodic and cathodic processes. The potential must be expressed with respect to the same arbitrarily chosen reference electrode, which gives for the anodic and cathodic current density, respectively, from Eq 6:

$$i_a = z_a F C_M k_{0,a} \exp\left(b_a \left(E - E_{ref}\right)\right) \quad \text{and}$$
$$i_c = -z_c F C_{ox}^i k_{0,c} \exp\left(b_c \left(E - E_{ref}\right)\right) \qquad \text{(Eq 24)}$$

As stated earlier, free corrosion of metals provides a zero overall current, so that the following relationship at the corrosion potential (E_{corr}) allows the corrosion rate i_{corr} to be derived:

$$i_{corr} = z_a F C_M k_{0,a} \exp\left(b_a \left(E_{corr} - E_{ref}\right)\right)$$
$$= z_c F C_{ox}^i k_{0,c} \exp\left(b_c \left(E_{corr} - E_{ref}\right)\right) \qquad \text{(Eq 25)}$$

The current density near the corrosion potential is then:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$i = i_a + i_c = i_{corr}\left\{\exp\left(b_a\left(E - E_{corr}\right)\right) - \exp\left(b_c\left(E - E_{corr}\right)\right)\right\} \quad \text{(Eq 26)}$$

This equation is very similar to Eq. 8, except that the Tafel coefficients b_a and b_c are no longer mutually related by the charge-transfer coefficients (α and 1 - α), and that E_{corr} is a mixed potential and *not* a thermodynamic equilibrium potential. Differentiation of Eq. 26 yields the slope of the polarization curve at the corrosion potential, which is the reciprocal of the polarization resistance (R_p):

$$\frac{di}{dE} = \frac{1}{R_p} = i_{corr}\left(b_a - b_c\right) = 2.303 i_{corr}\frac{\beta_a + \beta_c}{\beta_a \beta_c} \quad \text{(Eq 27)}$$

In this equation, known as the Stern-Geary equation, R_p is given as a function of the Tafel coefficients $b_a(>0)$ and $b_c(<0)$, expressed in V^{-1}, and as a function of the Tafel slopes $\beta_a = 2.303/ b_a$ and $\beta_c = 2.303/|b_c|$, expressed in V/current decade, which are often used in practice. Equation 27 implicitly assumes several hypotheses, namely:

- Both anodic and cathodic processes obey the Tafel law; that is, both reactions are under pure activation control.
- The anodic and cathodic currents are additive but kinetically independent; that is, without any interaction between them.

Since the work of Wagner and Traud in 1938 (Ref 8), it is known that the electrode surface is actually divided into local cells with the particularity that in each cell the anodic and cathodic processes do not simultaneously take place. The spatial distribution of the cathodic and anodic regions is due to local differences in the electrode microstructure, grain boundaries, presence of inclusions, and so forth. If the anodic reaction obeys the Tafel law on the fraction of surface area θ_a where it takes place and if the cathodic reaction obeys the Tafel law on the fraction of surface area θ_c where it takes place, the overall current density can be written:

$$i = i_a + i_c = i_{0,a}\theta_a \exp\left(b_a\left(E - E_{corr}\right)\right) - i_{0,c}\theta_c \exp\left(b_c\left(E - E_{corr}\right)\right) \quad \text{(Eq 28)}$$

where $i_{0,a}$ and $i_{0,c}$ are the mean current densities on the anodic and cathodic regions, respectively, at the corrosion potential. The derivation of Eq 28 at E_{corr} leads to a new expression of the polarization resistance:

$$\frac{1}{R_p} = \frac{di}{dE} = i_{corr}\left(b_a - b_c\right) + i_{0,a}\frac{d\theta_a}{dE} - i_{0,c}\frac{d\theta_c}{dE} \quad \text{(Eq 29)}$$

Comparison of Equations 27 and 29 clearly demonstrates that the Stern-Geary equation is valid only if the fractional surface areas are independent of the potential around E_{corr}. It is important to note that dissolution preferably occurs at crystallographic defects, which are more reactive sites. Moreover, surface coverage is a dynamic feature related to the balance between adsorption/desorption processes. This suggests that changes in the electrode potential are likely to induce changes in the surface coverage of the adsorbed species, which will affect the value of the polarization resistance (Eq 29). Electrochemical impedance spectroscopy (EIS) allows the terms $d\theta_a/dE$ and $d\theta_c/dE$ to be separated from di/ dE and, therefore, allows the Stern-Geary equation to be generalized, as shown in the next paragraph.

Brief Review of Electrochemical Impedance Spectroscopy. The current density flowing through the electrode interface may be expressed as a function of the potential (E) and of different parameters (p) of the electrode kinetics, like the surface coverage of adsorbed species, the interfacial concentration of reactants, and so forth:

$$i = f(E, p_1, p_2, p_3 \ldots) \quad \text{(Eq 30)}$$

For simplification, only one parameter (p), which typically may be the surface coverage (θ) by an adsorbed species, is considered in the following. The Taylor expansion of Eq 30 is:

$$di = \left.\frac{\partial i}{\partial E}\right|_p dE + \left.\frac{\partial i}{\partial p}\right|_E dp \quad \text{(Eq 31)}$$

A variation (dE) of potential thus yields a direct change in the current density i (first term in the righthand side of Eq 31) for a constant value of p, and an indirect change (second term) through the variation dp of p. The

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

change in p generally implies the variation of surface coverage of some species and, therefore, requires a certain time period to occur. Figure 4 schematically presents the i and p changes induced by a small potential jump (ΔE). For simple systems, these changes follow an exponential-like function with the same time constant (τ) that conveys information about the kinetics of the reaction: fast electrochemical systems will show short time constants and slow electrochemical systems will show long time constants.

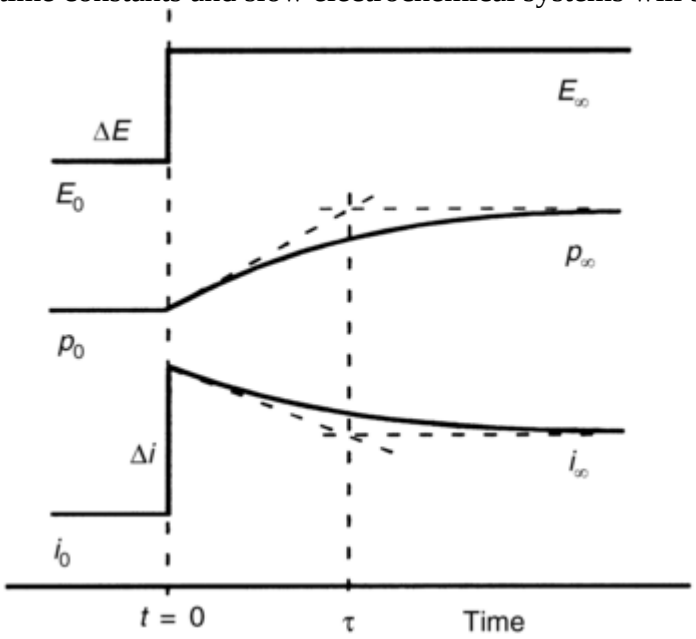

Fig. 4 Schematic representation of a parameter, *p*, and current density, *i*, changes following a potential jump at time *t* = 0

In practice, most electrochemical systems depend on several parameters (p) that have different time constants so that the time behavior of i after a small potential jump ΔE is complex and difficult to interpret. In contrast, valuable kinetic information may be obtained in the frequency domain with EIS, using a small amplitude alternating current (ac) perturbing signal. In the simple case of a single parameter (p) representing the surface coverage (θ) of an intermediate species, Eq 31 gives:

$$\frac{1}{Z_F} = \frac{di}{dE} = \frac{1}{R_t} + \left.\frac{\partial i}{\partial \theta}\right|_E \frac{d\theta}{dE} = \frac{1}{R_t} + \left.\frac{\partial i}{\partial \theta}\right|_E \frac{C}{1 + j\omega\tau} \qquad \text{(Eq 32)}$$

where Z_F denotes the faradaic impedance, R_t is the charge-transfer resistance, $\omega = 2\pi f$ is the pulsation and f the frequency (in Hz) of the perturbation signal, and C is constant for a given potential. C is positive if θ increases with increasing E, which corresponds to an adsorption effect for an anodic reaction. C is negative if θ decreases with increasing E, which corresponds to a desorption effect for an anodic reaction. The term $\partial i/\partial\theta|_E$ characterizes the effect of the adsorbed species on the current: i increases if the effect is catalytic while it decreases if the species is an inhibitor or a passivating agent. According to the sign of the last term in Eq 32, an inductive loop ($ImZ_F > 0$) or a capacitive loop ($ImZ_F < 0$) appears in the Nyquist plot of Z_F in the complex plane (ReZ, $-ImZ$) as summarized as follows:

$\partial i/\partial\theta > 0$ **(catalyzer)**	$d\theta/dE > 0$ **(adsorption)**	$d\theta/dE < 0$ **(desorption)**
	Inductive loop	Capacitive loop
$\partial i/\partial\theta < 0$ (inhibitor/passivating species)	Capacitive loop	Inductive loop

Thus, the adsorption of a catalyzer on the electrode surface and, alternatively, the desorption of an inhibitor lead to an inductive loop in the faradaic impedance. Conversely, the passivation process induces a capacitive behavior.

Equation 32 shows that Z_F is reduced to the charge-transfer resistance (R_t) at high frequency since the term ($1 + j\omega\tau$) tends to infinity. Moreover, from Eq 29, it can be seen that $1/R_t = i_{corr}(b_a - b_c)$ since $d\theta_a/dE$ and $d\theta_c/dE$ vanish at high frequency where di/dE is the inverse of the charge-transfer resistance. In other words, R_t fulfills the Stern-Geary equation when the electrode surface is divided into numerous anodic and cathodic local cells with potential-dependent fractional area, while R_p does not. Thus:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$i_{corr} = \frac{B}{R_t} \quad \text{with} \quad B = \frac{1}{b_a - b_c} = \frac{1}{2.303} \frac{\beta_a \beta_c}{\beta_a + \beta_c} \qquad \text{(Eq 33)}$$

More generally, if several parameters (p) with different associated time constants are involved in the reaction process, several capacitive and/or inductive loops will appear in the impedance diagram. It is worth remembering that the diffusion impedance cannot be represented by a well-defined time constant (τ) as that presented in Eq 32; it shows a more complicated behavior. However, Eq 33 remains valid even when the electrochemical system is partly or completely limited by mass transport (Ref 9).

It is also important to note that Z_F cannot be directly measured. Indeed, the impedance of the metal-electrolyte interface, which is accessible to measure, contains the contributions of the electrolyte (solution) resistance (R_e) and that of the interface capacitance (double-layer capacitance) C_d, in addition to the faradaic component (Z_F). Figure 5(a) presents the electric equivalent circuit of the interface and Fig. 5(b) represents the schematic Nyquist diagram of Z when the product of $\partial i/\partial\theta|_E$ and C in Eq 32 is negative, which gives the capacitive behavior of Z_F.

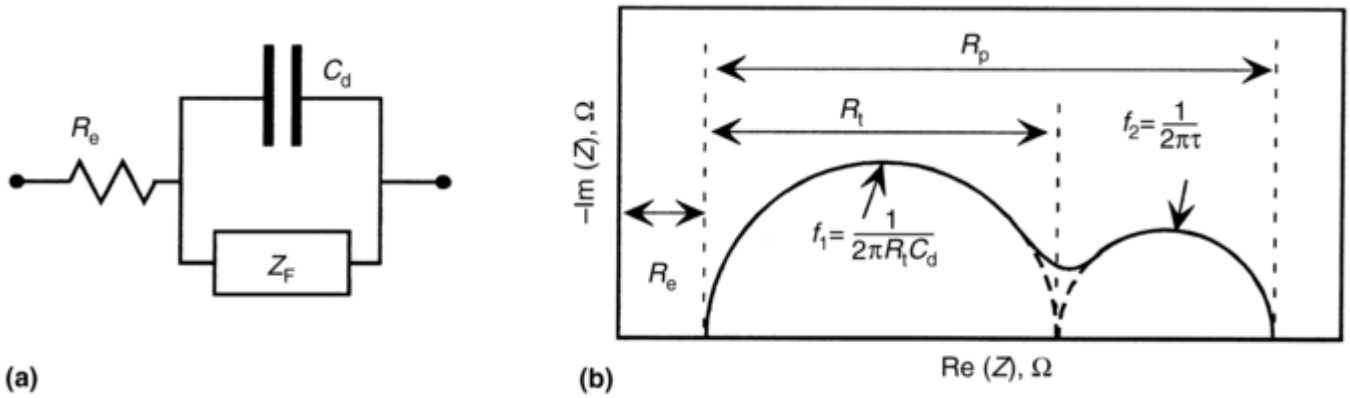

Fig. 5 Impedance models. (a) Equivalent electrical circuit of the interface; (b) Nyquist diagram of Z for a negative product of $\partial i/\partial\theta|_E$ and C in Eq 32

Mechanisms of Cathodic Processes

Cathodic processes are half-cell reactions necessary to allow corrosion reactions to take place. Indeed, the metal-dissolving anodic reaction is forcibly coupled to a cathodic counterpart that consumes the electrons produced by the anodic reaction, so that the overall electronic flux is zero for any free-corroding electrode. In principle, any reduction reaction involving species present in the electrolyte and an equilibrium potential which is higher than that of the metal dissolution can act as the cathodic branch of the overall corrosion reaction (see

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Pourbaix, Ref 10, and Evans, Ref 11, diagrams for thermodynamic and kinetic information, respectively). In the case of corrosion in an aqueous medium, the main cathodic processes, which are summarized in the following paragraphs, are easy to identify because of the ubiquitous presence of protons and dissolved oxygen that are active charge acceptors.

Proton Reduction

The main cathodic process in acidic media is proton reduction, or, more precisely, hydronium ion reduction, according to the overall reaction:

$$2H^+ + 2e^- \rightarrow H_2 \qquad \text{(Eq 34)}$$

The final reaction product is dissolved molecular hydrogen that can lead to H_2-bubble evolution over the metallic surface. The reaction in Eq 34 is the overall representation of a multistep reaction mechanism usually referred as the Volmer-Tafel-Heyrovsky route (Ref 5). The first step (Volmer reaction) is the proton discharge at the interface that yields an adsorbed hydrogen atom, H_{ad}, at the metallic surface:

$$H^+ + e^- \rightarrow H_{ad} \qquad \text{(Eq 35)}$$

Then, H_{ad} desorbs in the form of dissolved molecular gas according to two possible pathways. In the Volmer-Heyrovsky route, the hydrogen desorption is an electrochemical reaction involving one proton and one adsorbed H_{ad}:

$$H^+ + H_{ad} + e^- \rightarrow H_2 \qquad \text{(Eq 36)}$$

In contrast, the Volmer-Tafel route is the chemical recombination of two atomic adsorbates without electron transfer:

$$H_{ad} + H_{ad} \rightarrow H_2 \qquad \text{(Eq 37)}$$

The reactions in Eqs 35, 36, 37 are the typical cathodic processes in acidic solutions for most metals (Fe, Zn, Al, etc.) and alloys. Nevertheless, on the basis of the thermodynamic equilibrium analysis (Pourbaix diagram), noble metals, as well as copper, are not expected to corrode with hydrogen evolution, since their dissolution equilibrium potential is higher than that of the proton reduction. However, the presence of complexing agents (for instance, chloride) may act as a reaction catalyst and give rise to copper corrosion with hydrogen evolution.

Oxygen Reduction

Aqueous solutions in contact with air contain different amounts of dissolved oxygen depending on various parameters, such as temperature and electrolyte composition. In practice, most corrosion processes take place in such aerated environments so that dissolved oxygen is almost always available for reduction according to the following overall reactions:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad \text{(neutral and alkaline media)} \qquad \text{(Eq 38)}$$

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \quad \text{(acidic media)} \qquad \text{(Eq 39)}$$

Reactions 38 and 39 represent generic rough simplifications of several possible complex multistep mechanisms that depend on the metal nature and many other parameters. Whatever the specific mechanism, however, aqueous corrosion reactions are often controlled cathodically, which means that the higher the availability of dissolved oxygen in the electrolyte, the higher the corrosion rate. This is why metallic structures in contact with stirred electrolytes or in partially immersed conditions are more prone to severe corrosion attack.

Water Reduction

In some cases, when the electrolyte does not have an excess of protons or dissolved oxygen; that is, in neutral or alkaline deaerated media, the cathodic branch of the corrosion reaction may be the reduction of water itself. The overall reaction is:

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \qquad \text{(Eq 40)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

which can be split into at least two consecutive steps: water dissociation in H^+ and OH^- that precedes proton reduction (Eq 34). The reactions in Eqs 34 and 40 are alternative descriptions of the same reaction, which is the obvious consequence of the fact that water is a permanent source of protons. In other words, the most adequate description depends on the pH of the solution. From a thermodynamic point of view, the reaction in Eq 40, as well as the reaction in Eq 34, is not supposed to take place as the cathodic counterpart of the corrosion of metal (M) if the dissolution equilibrium potential of $M/M^{z+}{}_{\alpha}$ is higher than that of the H^+/H reaction. For these reasons, copper is not expected to corrode in acidic media or in deaerated media.

Mechanisms of Anodic Processes

Mechanisms of metal dissolution have been widely investigated in the literature and recently reviewed by Keddam (Ref 12). Examples are given below for pure metals (iron, copper) and a binary alloy (Fe-17Cr) corroding in acidic solutions. The emphasis of these examples is on the necessity of coupling the classical experimental techniques (polarization curve, electrochemical impedance) with more advanced techniques (ring-disk electrode, electrochemical quartz-crystal microbalance) in order to collect a large amount of kinetic information to make the proposed reaction mechanism as reliable as possible (Ref 13).

Fe Dissolution in H_2SO_4

The two main dissolution mechanisms reported in the literature, the *catalytic mechanism* by Heusler (Ref 14) and the *consecutive mechanism* by Bockris and others (Ref 15) are summarized first. Then, the effect of an organic inhibitor on the dissolution mechanism of iron in an acidic medium is investigated.

Catalytic Mechanism. In acidic media, iron atoms dissolve and produce ferrous ions in solution (indicated by the subscript sol) according to the overall dissolution reaction:

$$Fe \rightarrow (Fe^{2+})_{sol} + 2e^- \quad \text{(Eq 41)}$$

Heusler proposed the following mechanism for the overall reaction:

$$Fe + OH^- \rightleftarrows Fe(OH)_{ad} + e^- \quad \text{(Eq 42)}$$

$$Fe + Fe(OH)_{ad} \rightarrow Fe(OH)_{ad} + (Fe^{2+})_{sol} + 2e^- \quad \text{(Eq 43)}$$

The adsorbed $Fe(OH)_{ad}$ species formed by the reaction in Eq 42 acts as a catalyzer in the reaction in Eq 43 since it is not consumed. At the steady state, under the assumption that the reaction in Eq 42 is fast (quasi-equilibrium hypothesis), the model predicts a Tafel slope of $(1 + 2\alpha_2)F/RT$ in the polarization curve, where α_2 stands for the

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

charge-transfer coefficient in the reaction in Eq 43. Heusler postulated a value of 0.5 for α_2; thus this reaction mechanism should exhibit a Tafel slope of 30 mV per decade.

This mechanism is often associated with the presence of crystallographic defects on the electrode surface: for example, $Fe(OH)_{ad}$ would be formed at the kink sites, and $(OH)_{ad}$ would move to its neighbor atom when the reaction in Eq 43 proceeds, because the departure of a kink atom creates a new kink.

Consecutive Mechanism. According to Bockris and others, the dissolution mechanism differs from the previous one on the second step only. The reaction represented by Eq 43 is replaced by:

$$Fe(OH)_{ad} \rightarrow Fe(OH)^{+}_{sol} + e^{-} \qquad \text{(Eq 44)}$$

$$Fe(OH)^{+}_{sol} \rightleftarrows (Fe^{2+})_{sol} + OH^{-} \qquad \text{(Eq 45)}$$

$Fe(OH)_{ad}$ plays the role of a reaction intermediate that is consumed. On the basis of similar hypotheses, the reaction in Eq 42 is fast, and the Tafel coefficient of Eq 44 is equal to $\alpha_2 = 0.5$. The Tafel slope $(1 + \alpha_2)F/RT$ of the polarization curve is 40 mV per decade for this mechanism. Hence, under these highly restrictive hypotheses, the mechanism of iron dissolution can be identified by measuring the Tafel slope of the polarization curve.

Later, on the basis of EIS data, Keddam and others pointed out that the hypothesis of fast reversible reaction given in Eq 42 was in contradiction with experimental data (Ref 7). They proposed a reaction mechanism similar to that proposed by Bockris and others but in which the reactions given in Eqs 42 and 44 are irreversible. Good agreement was found between the experimental and theoretical time constants of the relaxation of the surface coverage by $Fe(OH)_{ad}$. The charge-transfer resistance was also in good agreement with that calculated from the Tafel slopes of Eq 42 and 44.

These models with a single intermediate species are able to describe the steady state around the corrosion potential. The nonstationary behavior, however, needs more complex models that take into account three or four species such as those proposed later by Keddam and others (Ref 16).

Effect of Propargylic Alcohol on the Corrosion Mechanism. Propargylic alcohol (PA) is the simplest molecule in the acetylene group and constitutes one of the main compounds for inhibiting corrosion of iron or carbon steel in acidic medium. The inhibiting effect has been examined by Benzekri and others (Ref 17), who coupled EIS and rotating ring-disk electrode (RRDE) experiments, and revisited by Itagaki and others (Ref 18), who used a channel-flow cell described schematically in Fig. 6. The electrolyte flows from the working electrode (WE) to the detector electrode (DE), which are embedded in an insulating material.

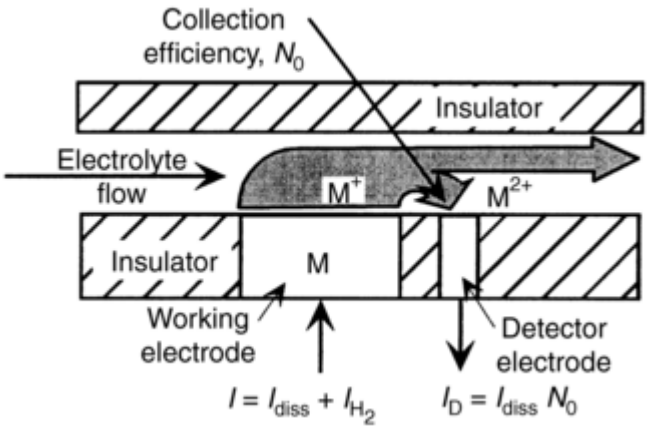

Fig. 6 Schematic representation of the channel-flow cell. Source: Ref 18

At the WE, metal dissolution takes place in parallel with, for instance, hydrogen evolution so that the overall current measured (I) is:

$$I = I_{diss} + I_{H_2} \qquad \text{(Eq 46)}$$

where I_{diss} is the dissolution current and I_{H_2} the hydrogen current. A fraction of the metallic ions produced at the WE is oxidized or reduced on the DE, located downstream, according to the potential applied on the DE that is adequately chosen to avoid oxidizing the dissolved hydrogen produced at the WE. The ratio N_0 of the fluxes of ions captured at the DE and produced at the WE, often named *collection efficiency*, is controlled only

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

by the cell geometry. It can be determined either by calibration experiments or by theoretical calculations. From the currents measured, I on the WE and I_D on the DE, the dissolution current $I_{diss} = I_D/N_0$ and the hydrogen current $I_{H_2} = I - I_D/N_0$ on the WE can be evaluated.

Figure 7 presents the results obtained by Itagaki and others (Ref 18) for an iron WE in sulfuric acid with or without the presence of PA. A DE in gold was used to make the influence of dissolved hydrogen oxidation negligible. The potential of the WE was measured against a saturated (mercurous) sulfate electrode (SSE). Figure 7(a) shows that, up to approximately 10 mA/ cm^2, i_{diss} in presence of inhibitor is higher than in its absence. However, this result is not conclusive for the corrosion current since the potential of the electrode was shifted toward more cathodic potentials in the presence of PA that acts essentially to diminish the reduction of hydronium ions. Indeed, weight-loss and impedance measurements have shown that the inhibiting effect of PA essentially decreases the cathodic current at a given potential, so that the overall corrosion process is inhibited (Ref 9).

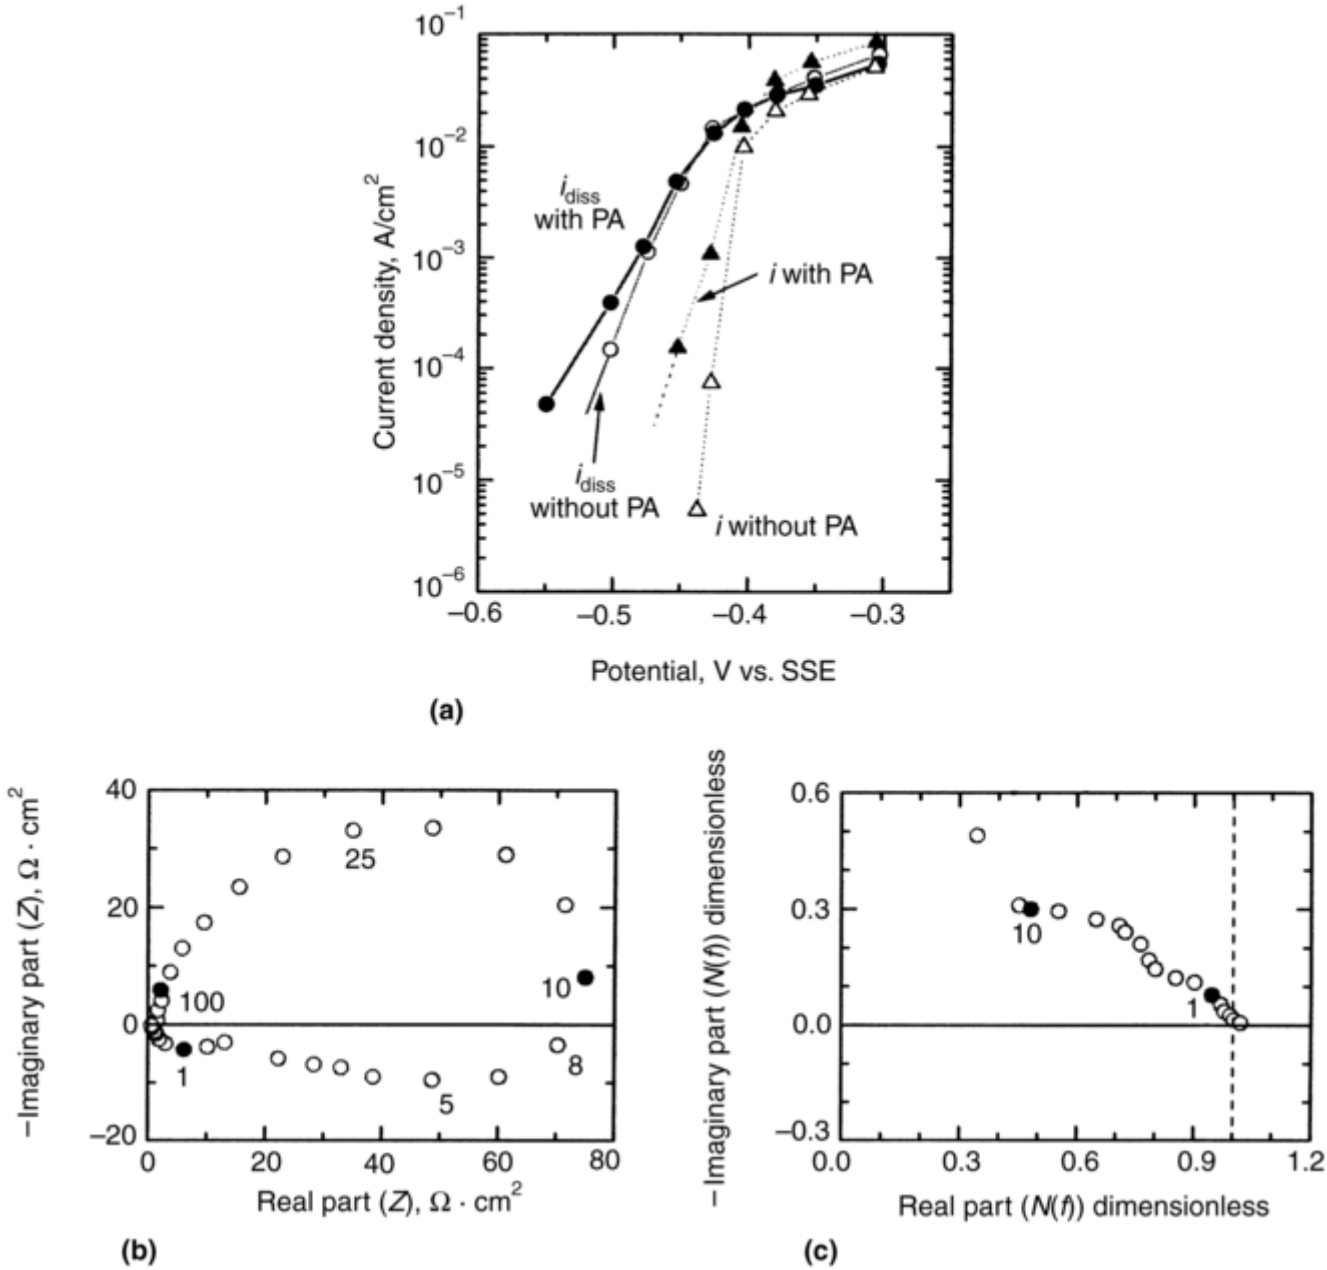

Fig. 7 Dissolution of Fe in Na_2SO_4 + H_2SO_4 (0.5 M SO_4^{2-}, pH 1), with or without addition of 50 mM propargylic alcohol (PA). www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

According to the dissolution models proposed by Heusler and Bockris and others, the reaction mechanism can be determined from the slope of the polarization curve: 30 mV/decade for the catalytic mechanism (Ref 14) and 40 mV per decade for the consecutive dissolution model (Ref 15). However, the slope of the log(i)-E curve in Fig. 7(a) changed from 11 to 25 mV per decade and that of the log(i_{diss})-E curve changed from 32 to 48 mV per decade when the inhibitor was added to the solution. None of these slopes correspond to the reaction mechanisms predicted by Heusler (Ref 14) or Bockris and others (Ref 15). The change in Tafel slope would also suggest that the PA was at the origin of the change in dissolution mechanism whereas it acted mainly on the cathodic reaction, as mentioned previously.

Figure 7(b) presents the electrochemical impedance measured at the overall current density of 0.5 mA/cm^2 in the presence of PA. It is important to mention that the polarization curves in Fig. 7(a) were obtained by a potential sweep method; thus the dynamic behavior investigated in steady-state conditions with the impedance technique was markedly different. The high-frequency capacitive loop, the apex of which was measured at 25 Hz, corresponds to the double- layer capacitance, approximately 80 μF/cm^2, in parallel with the charge-transfer resistance, approximately 80 Ω · cm^2. Two inductive loops can be seen in the low-frequency range (f < 8 Hz). They were attributed to the relaxation of the surface coverages by a dissolution intermediate species (loop around 5 Hz) and by the adsorbed inhibitor (loop around 1 Hz). The impedance spectra at frequencies higher than 2 Hz and the fact that the product R_tI was close to 40 mV suggest that the iron dissolution occurred via the consecutive mechanism proposed by Keddam and others (Ref 7).

The fraction of current consumed to form the dissolving species (here Fe^{2+}) is defined at any frequency (f) by the ratio $N(f) = \Delta I_{diss}/\Delta I$ derived from the ratio $\Delta I_D/\Delta I$, measured under ac regime, divided by the dynamic collection efficiency. Figure 7(c) shows that $N(f)$ was smaller than 1 above 1 Hz, which indicates that a large part of the ac current was not consumed by the dissolution itself but was used in the formation of adsorbed intermediate species. In contrast, the low-frequency limit of $N(f)$ is close to unity, as expected from the Faraday law.

The coupling of advanced experimental techniques offers deeper insight into the reaction mechanism of iron dissolution and also explains how the PA inhibits the corrosion process by decreasing the hydrogen-evolution reaction rate.

Dissolution of Copper in Hydrochloric Acid

Copper and copper alloys are widely used in industrial applications because of their high electrical and thermal conductivity and, also, good corrosion resistance in various media. However, the latter decreases significantly in the presence of chloride ions that lead to copper dissolution as cuprous ions at low anodic potentials and cupric ions at higher potentials (Ref 19). Figure 8 presents results of EIS, ring-disk electrode (RDE), and electrochemical quartz crystal microbalance (EQCM) experiments carried out simultaneously on an electrodeposited copper EQCM electrode surrounded by a thin platinum ring (Ref 20). Since the EQCM electrode could not rotate, an impinging jet cell was employed instead of a RRDE to control the hydrodynamic conditions.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

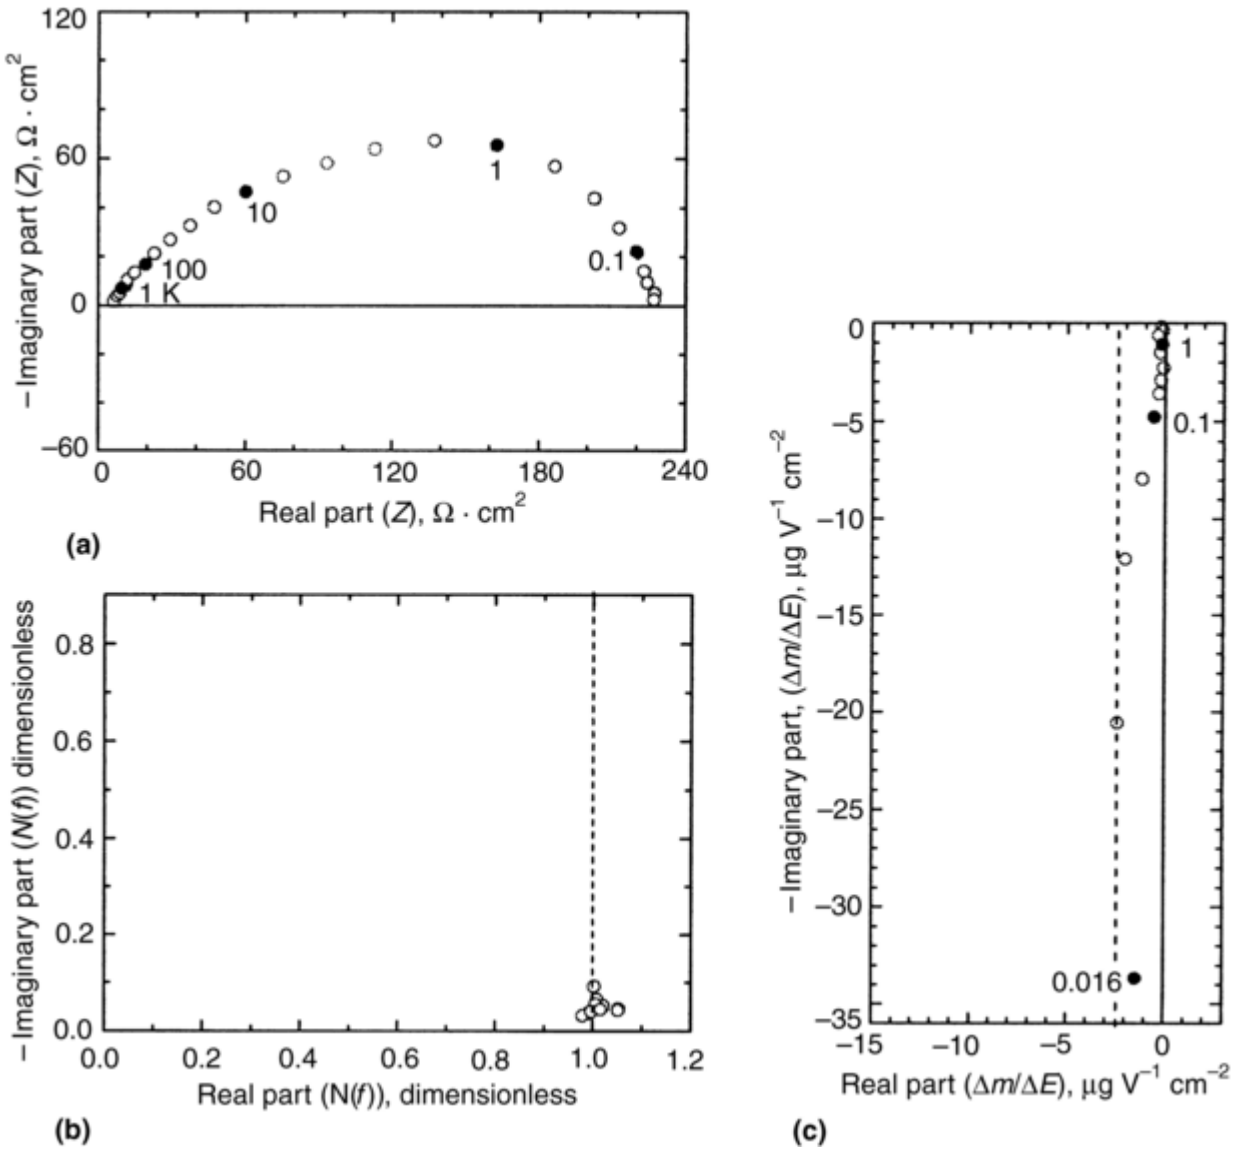

Fig. 8 Dissolution of Cu in 1 *M* NaCl + 0.05 *M* Na_2CO_3, pH 8, *i* = 0.1 mA/cm^2. (a) Impedance diagram; (b) $N(f) = \Delta I_{diss}/\Delta I$; (c) $\Delta m/\Delta E$. Source: Ref 20

The impedance diagram (Fig. 8a) shows two badly separated capacitive loops. The capacitance associated with the high-frequency loop is equal to 50 μF/cm^2 and, therefore, can be attributed to the double-layer capacitance in parallel with the charge-transfer resistance. The low-frequency loop is then related to the faradaic impedance due to the relaxation of the surface coverage by a dissolution intermediate. In contrast with the case of iron presented above, Fig. 8(b) shows an emission efficiency $N(f) = \Delta I_{diss}/\Delta I$ of 1 regardless of the perturbation frequency, indicating that there is no charge transfer in the formation of adsorbed intermediate species; that is, the reaction is purely chemical. The change in mass (Δm) induced by a perturbation in potential ΔE at frequency f gives a ratio $\Delta m/\Delta E$ parallel to the imaginary axis in the Nyquist plane (Fig. 8c) at low frequency, with a negative real part, which corresponds actually to electrode dissolution. By coupling EQCM and EIS data, the gram-equivalent (A), which represents the change in mass per mole of electrons exchanged ($\Delta Q/F$), can be evaluated as follows:

$$A(\omega) = \frac{\Delta m}{\Delta Q/F} = j\omega F \frac{\Delta m}{\Delta I} = j\omega F \frac{\Delta m}{\Delta E}\frac{\Delta E}{\Delta I}$$
$$= j\omega F \frac{\Delta m}{\Delta E}(\omega) Z(\omega) \qquad \text{(Eq 47)}$$

since $\Delta I = j\omega \Delta Q$ and $Z = \Delta E/\Delta I$. The low- frequency limit of $A(\omega)$, $-2\pi f_0 F \mathrm{Im}(\Delta m/\Delta E) R_p$, can be obtained from the imaginary part of $\Delta m/\Delta E = -33.5 \times 10^{-6}$ μg/(V · cm^2) at frequency f_0 = 16 mHz. A value of 73.8 g

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

equivalent, close to the atomic mass of copper (63.5 g) when considering the experimental accuracy, was found, which confirms that copper actually dissolves as a monovalent ion in chloride medium at low anodic potential. The most probable dissolution mechanism consistent with the results of the EIS, RDE, and EQCM techniques is then the following:

$$Cu + Cl^- \rightarrow Cu(Cl^-)_{ad} \quad \text{(Eq 48)}$$

$$Cu(Cl^-)_{ad} \rightarrow (CuCl) + e^- \quad \text{(Eq 49)}$$

The intermediate species, which is likely $Cu(Cl^-)_{ad}$, is adsorbed through a chemical reaction (no charge transfer), as suggested earlier. The subsequent electrochemical desorption of this species is potential dependent and generates the low-frequency capacitive loop in the impedance diagram. These combined EIS, RDE, and EQCM experiments allowed the electric state of the reaction intermediate to be demonstrated unambiguously. This is an important advancement in the understanding of the reaction mechanism.

Anodic Dissolution of a Binary Alloy: Iron-Chromium

Iron-chromium (Fe-Cr) binary alloys constitute a model material for investigating corrosion of stainless steels. This is the reason why the dissolution and passivation mechanisms of iron- chromium alloys have been extensively studied in the literature. The mechanism of Fe-17Cr dissolution in 1*M* H_2SO_4 devised from EIS and RDE experiments (Ref 21) is discussed subsequently. Typical results are presented in Fig. 9. The polarization curve shows that this alloy becomes passive above -0.8 V versus SSE. At the critical potential of approximately -0.88 V versus SSE, the current density was about 3 mA/ cm^2, several orders of magnitude lower than that measured with an iron electrode, indicating that chromium promotes the passivation process substantially.

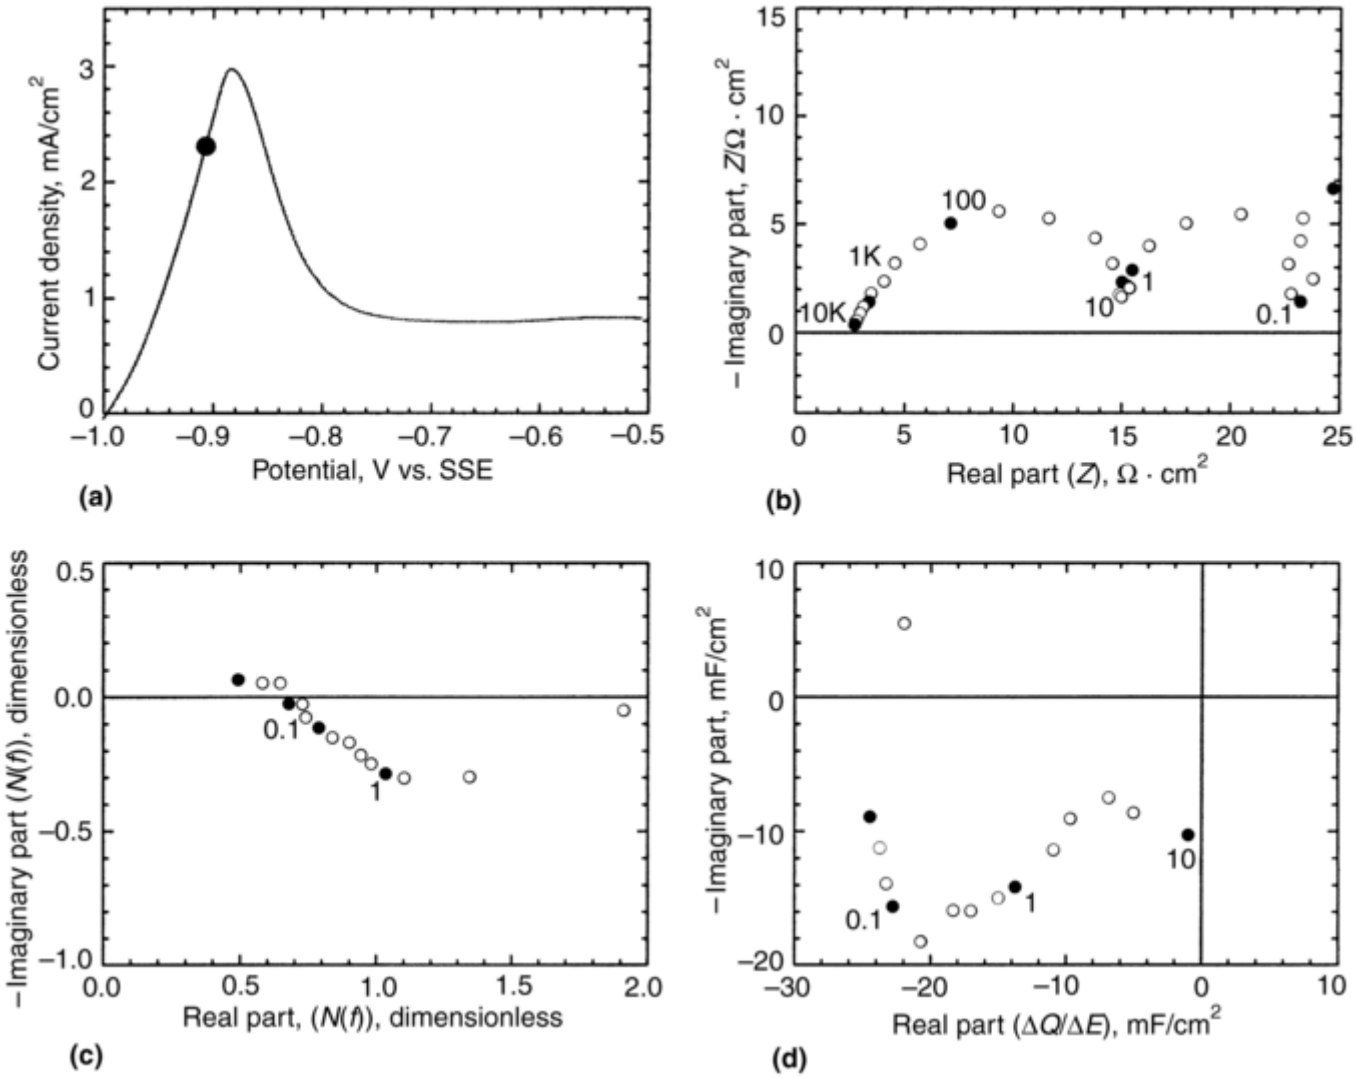

Fig. 9 Dissolution of Fe-17Cr in 1 *M* H_2SO_4. (a) Polarization curve. (b) Impedance diagram at point A. (c) *N*(*f*) at point A. (d) Δ*Q*/Δ*E* at point A calculated from *N*(*f*) and *Z* data. Source: Ref 22

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The impedance diagram, measured at point A of the polarization curve, exhibits four time constants, in addition to the high-frequency time constant related to the charge-transfer resistance in parallel with the double-layer capacitance. The four time constants correspond to the relaxation of the surface coverage by four intermediate species. Figure 9(c) presents the ratio $N(f) = i_{diss}/i$ where i_{diss} is the current density relative to the dissolution of the Fe^{2+} ions collected at the ring and i is the overall current density. Both current densities are the responses to an ac potential perturbation at frequency f. It should be noted that i contains the contribution of both chromium and iron dissolution. A remarkable result is that the modulus of $N(f)$ was greater than unity at frequencies above 1 Hz; that is, the faradaic efficiency of the iron dissolution was surprisingly greater than 100%, indicating that a surplus of charge was supplied to the iron dissolution, as explained later in this article. The ratio $\Delta Q/\Delta E$, where Q denotes the charge stored at the electrode surface calculated according to the algorithm developed for the dissolution of an iron electrode (Ref 17), is given in Fig. 9(d).

To explain the main features of the aforementioned results and of those obtained in the passivation domain for alloys of various Cr content, the simplified reaction mechanism presented in Fig. 10 was devised. Only three reaction intermediates ($Fe(I)_{ad}$, $Fe(II)_{ad}$, and $Cr(III)_{ad}$) were used to avoid a more intricate model that would be difficult to handle. The reactions relative to Cr contained the dissolution in $Cr(II)_{sol}$ species and the formation of a passive species $Cr(III)_{ad}$. The Cr dissolution step is necessary to model the uniformity of the electrode dissolution, which gives a molar ratio of Fe and Cr dissolved in the solution equal to that of the metallic matrix. Otherwise, selective dissolution of iron would give rise to a macroporosity that was not observed experimentally. The effect of the $Cr(III)_{ad}$ passive species was to slow down the iron dissolution rate markedly, as proposed by Frankenthal (Ref 23). The mechanism of Fe dissolution contains the catalytic step (Eq B in Fig. 10) introduced by Heusler, but only two adsorbed species have been considered here instead of four in the mechanism proposed by Keddam and others (Ref 7). This model contains no Fe passivation reaction; the passive behavior observed experimentally was simulated by the Cr passivation that slows down the alloy dissolution by virtue of the uniform dissolution conditions.

Fig. 10 Schematic representation of the activation-passivation transition mechanism of Fe-Cr alloy in an acidic medium

From the charge and mass balances for the reactions in Fig. 10, the polarization curve, the impedance diagrams, the dynamic emission coefficient $N(f)$ of Fe^{2+}, and the ratio $\Delta Q/\Delta E$ were calculated. Figure 11 presents the results at point A of the polarization curve in Fig. 9(a). The impedance diagram was suitably reproduced except for the low-frequency behavior. This discrepancy is due to the simplifications in the model. The decrease in $N(f)$ with decreasing frequency in Fig. 11(b) was also simulated, but the maximum value was significantly smaller than that obtained experimentally. The extra charge necessary to dissolve the iron beyond the Faraday law, mentioned earlier, was supplied by the surface relaxation of $Cr(III)_{ad}$ species. The $\Delta Q/\Delta E$ curve was also correctly reproduced with two time constants and a negative real part, but the time constant in the simulated high-frequency loop was significantly smaller than the experimental one.

The coupling of steady-state polarization, EIS, and RRDE experiments allowed a more reliable model of the reaction mechanism to be proposed. This is a very appropriate method to select the adequate model among all those devised from the single measurement of polarization curves.

Passivity

Jerome Kruger, Johns Hopkins University

Introduction

ALL METALS AND ALLOYS, with the exception of gold, have a thin protective corrosion product film present on their surface resulting from reaction with the environment. If such a film did not exist on metallic materials exposed to the environment, they would revert back to the thermodynamically stable condition of their origin—the ores used to produce them. Some of these films—the passive films—on some, but not all, metals and alloys have special characteristics that enable them to provide superior corrosion- resistant metal surfaces. These protective "passive" films are responsible for the phenomenon of passivity.

The first metal found to exhibit the phenomenon of passivity was iron. Uhlig (Ref 1) has written a review of the history of passivity that lists three 18th century scientists—the Russian Lomonosov in 1738, the German Wenzel in 1782, and the Briton Keir in 1790—who observed that the highly reactive surface of iron became unexpectedly unreactive after immersion in concentrated nitric acid. This effect was first called *passivity* by Schönbein.

This unexpected phenomenon of passivity occupies a central position in controlling corrosion processes, enabling the use of metallic materials in the many technologies of the 21st century. Moreover, it is the breakdown of the passive film that leads to the inability of metals and alloys to perform their assigned functions because of localized corrosion failure modes such as stress corrosion, pitting, crevice corrosion, and corrosion fatigue. Its importance to materials technology transcends, however, corrosion science and corrosion engineering. For example, one of the main reasons silicon replaced germanium in semiconductor device technology was that silicon forms effective passive films and germanium does not (Ref 2).

Early work in the area of passivity that had an enormous impact on providing technology with improved engineering materials is, of course, the development of the stainless steels. This has promoted the continual development of a large number of alloys that exhibit corrosion resistance because of the protection provided by the passive film.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

An improved understanding of the role that alloying constituents play in determining the properties of this passive film will lead to guidelines that can be used to develop engineering alloys with improved corrosion resistance. The scope of this article limits the discussion of all of the details on the subject of passivity. Moreover, the passivation behavior of all of the various metals and semiconductors that exhibit passivity is not given. Instead, this article discusses the classic passive metal iron and its alloys as illustrative examples of metals exhibiting passivity. References 3, 4, 5, 6, 7 provide a more extensive treatment of the subject of passivity in general and passivity of other metals and semiconductors in addition to iron.

General Aspects

Importance of Passivity to Corrosion-Control Technology. If the passive film did not exist, most of the technologies that depend on the use of metals could not exist because the phenomenon of passivity is a critical element in controlling corrosion processes. Therefore, the destruction of passivity at local breakdowns leads to a large part of the corrosion failures of metal and alloy structures—localized attack such as pitting, crevice corrosion, stress corrosion, and corrosion fatigue.

The development of the stainless steels in the 1920s is regarded as a major application of the phenomenon of passivity. This development has contributed significantly to modern technology by providing the design engineer with engineering materials such as the large number of iron and nickel-base alloys as well as many other alloy systems that exhibit superior corrosion resistance—this effort continues today.

Types of Passivity. There are two types of passivity:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- *Type 1.* A metal active in the electromotive force (emf) series is passive when its electrochemical behavior in a given environment becomes that of a metal noble in the emf series (low corrosion rate, noble potential).
- *Type 2.* A metal is passive while, still from the standpoint of thermodynamics at an active potential in a given environment, it exhibits a low corrosion rate (low corrosion rate, active potential). This type of passivity can be termed "practical passivity."

Only type 1 passivity is considered here. Examples of metals or alloys exhibiting such passivity are nickel, chromium, titanium, iron in oxidizing environments, stainless steels, and many others. Examples of type 2 passivity are lead in sulfuric acid and iron in an inhibited pickling acid.

A major characteristic of a type 1 passive system is the existence of a polarization curve (*i*, current density, or rate, versus *E*, potential, or driving force), of the sort shown in Fig. 1. It illustrates well a restatement of the definition of type 1 passivity as first proposed by Wagner (Ref 8). He suggested that a metal becomes passive when, upon increasing its potential in the positive or anodic (oxidizing) direction, a potential is reached where the current (rate of anodic dissolution) sharply decreases to a value less than that observed at a less anodic potential. This decrease in anodic dissolution rate, in spite of the fact that the driving force for dissolution is brought to a higher value, is the result of the formation of a passive film.

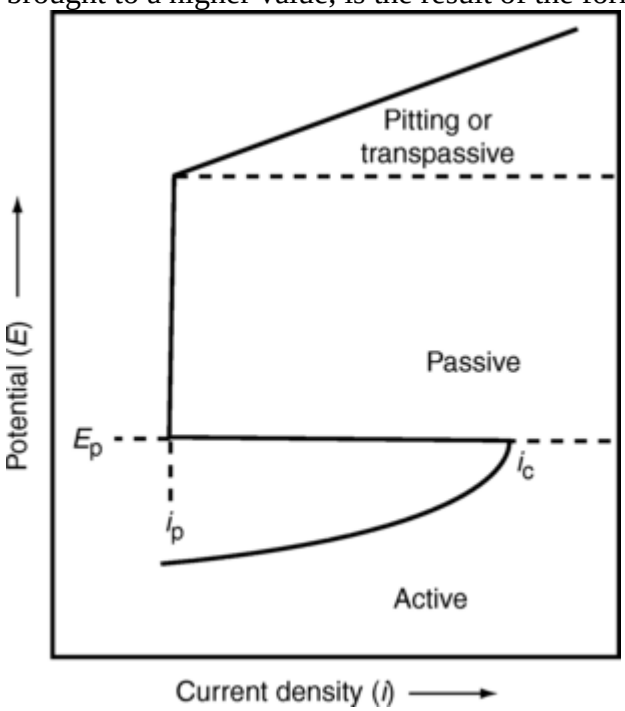

Fig. 1 The idealized anodic polarization curve for an iron-water system exhibiting passivity. Three different potential regions are shown; the active, passive, and pitting or transpassive regions. E_p is potential above which the system becomes passive and exhibits the passive current density i_p. The critical current density for passivation is i_c.

Another more practical definition has been provided by an ASTM standard: "passive—the state of metal surface characterized by low corrosion rates in a potential region that is strongly oxidizing for the metal" (Ref 9).

Employing Passivity to Control Corrosion. Passivity can be used to control corrosion by using methods that bring the potential of the surface to be protected to a value in the passive region. This can be accomplished by the following tactics:

- Using a device called a potentiostat, a current can be applied to the metal to be protected that will set and control the potential at a value greater than the passivating potential, E_p. This method of producing passivity is called anodic protection (Fig. 1).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- For environments containing damaging species such as chloride ions that cause pitting, the potentiostat or other devices that control the potential can be used as in the item above to set the potential to a value in the passive region below the critical potential for pitting, E_{pit}.
- Alloys or metals that spontaneously form a passive film, for example, stainless steels, nickel, or titanium alloys, can be used in applications that require resistance to corrosion. Usually a pretreatment such as that described below is desirable.
- A surface pretreatment can be carried out on an alloy capable of being passivated. The use of such a pretreatment has been a standard practice for stainless steels for many years. The passivating procedure involves immersion of thoroughly degreased stainless steel parts in a nitric acid solution followed by a thorough rinsing in clean, hot water. The most popular solution and conditions of operation for passivating stainless steel is a 30 min immersion in a 20 vol% nitric acid solution at 49 °C (120 °F). However, other solutions and treatments may be used, depending on the type of stainless steel being treated (Ref 10).
- The environment can be modified to produce a passive surface. Oxidizing agents such as chromate and concentrated nitric acid are examples of passivating solutions that maintain a passive state on some metals and alloys.

Thermodynamics of Passivity

Thermodynamics provide a guide to the conditions under which passivation becomes possible. A valuable guide to thermodynamics is the potential-pH diagram, the Pourbaix diagram. Pourbaix's *Atlas of Electrochemical Equilibria in Aqueous Solutions* (Ref 11) describes applications of these potential-pH equilibrium diagrams to corrosion science and engineering. One major application is the establishment of the theoretical domains or conditions for corrosion, immunity, and passivation.

Figure 2 shows a simplified diagram for the iron-water system. The three theoretical domains show on a thermodynamic basis the potential- pH conditions where no corrosion is possible (immunity), where a corrosion-product film forms that may confer protection against corrosion (passivation), and where corrosion is expected (corrosion). (Pourbaix designates the immunity domain as that of “thermodynamic nobility” and the total of the passivation and immunity domains as that of “practical nobility.”) Whether the film is passive (protective) or not is a kinetic consideration and not a thermodynamic one (see the section “Nature of the Passive Film” in this article). Such Pourbaix diagrams can identify metals capable of forming films that, depending on their properties, may or may not be protective, and conditions can be determined where there is a transition from passivation to activation. One could call the equilibrium diagrams a “road map of the possible.”

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

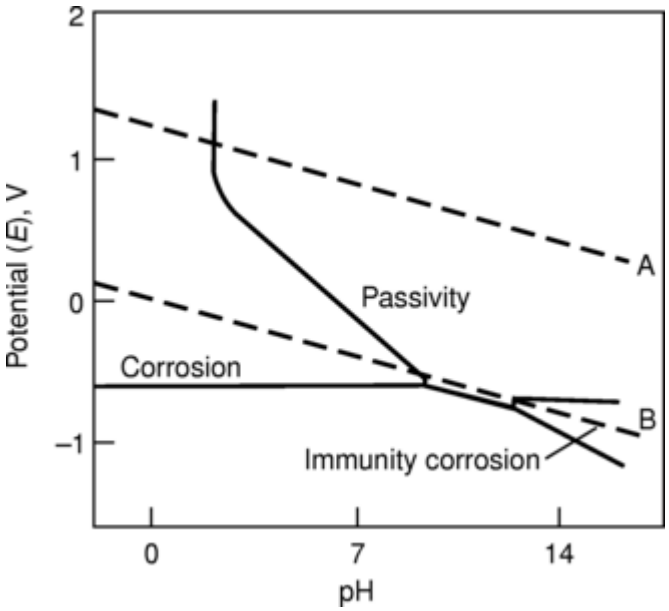

Fig. 2 Simplified potential-pH equilibrium diagram (Pourbaix diagram) for the iron-water system. Above equilibrium line A oxygen is evolved, and below equilibrium line B hydrogen is evolved. Source: Ref 11

The diagrams can, therefore, be used as a basis for identifying the active, passive, and transpassive regions of active-passive polarization curves (see Fig. 1). Thus, potentials above the oxygen-evolution line (the line marked A in Fig. 2) are in the transpassive region. Also, the diagrams can be used to interpret the reasons for loss of the protective nature of the passive film in the transpassive region. For example, the protective layer on stainless steels that contain chromium involves Cr(III); at higher potentials Cr(III) is oxidized to Cr(VI), and the protective Cr_2O_3 becomes the soluble chromate ion, resulting in the loss of corrosion resistance. Usually, the passive regions of the polarization curves correspond to potentials in the equilibrium diagrams where protective solid compounds are stable. However, even though the active regions of the polarization curves usually lie in regions labeled as “corrosion” on the potential-pH diagrams, this is not always the case. For example, iron can passivate in sulfuric acid solutions under conditions where the diagrams would predict corrosion and, hence, an active condition, but the rate of passive-film dissolution is so extremely slow that the film is metastable and thereby prevents metal dissolution.

Kinetics of Passivity

From the standpoint of the kinetics, passivity can be characterized as the conditions existing on a metal surface because of the presence of a protective film that markedly lowers the rate of corrosion, even though from thermodynamic (corrosion tendency) considerations one would expect active corrosion. Figure 1, which depicts

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

an idealized anodic polarization curve for a metal surface, can serve as a basis for describing in a general way the kinetics of passivation. Anodic polarization curves obtained from a real system under practical conditions (Ref 12) are shown in Fig. 3. They still include the general features of the ideal curve (Fig. 3). Figure 3 shows a comparison of iron and 304L stainless steel in H_2SO_4. In Fig. 1, where the anodic polarization curve is that of a metal that exhibits an ability to become passive, the current initially increases with an increase in potential, but when the potential reaches the value of the passivating potential, E_p, the critical current density for passivation, i_c, is reached, and a marked drop in current density (corrosion rate) is observed. This is the onset of passivity, and the current density remains low at i_p as the potential is increased to higher values. If the potential is increased to sufficiently high values, the current density begins to rise, and either pitting results or the transpassive region is entered. In the transpassive region, oxygen evolution and possibly increased corrosion takes place.

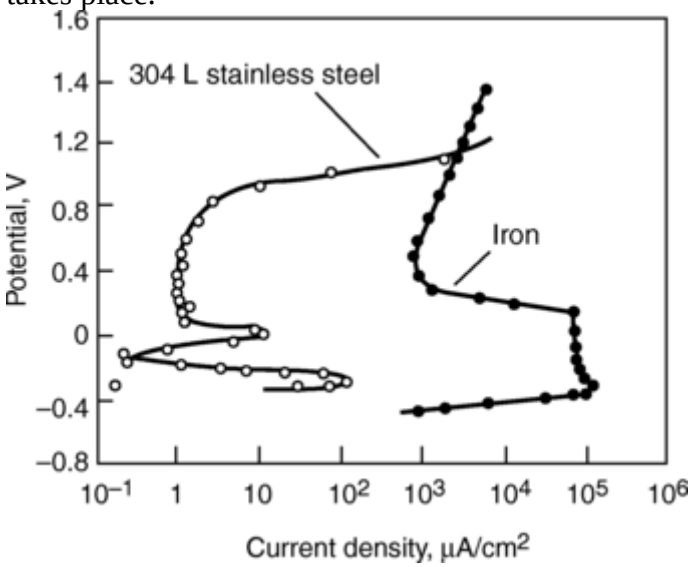

Fig. 3 Comparison of anodic polarization curves for iron and 304L stainless steel in 1 *N* H_2SO_4. Adapted from Ref 12

The corrosion potential of a metal surface is controlled by the intersection of the anodic (potential increases in the positive direction) and cathodic (potential increases in the negative direction) polarization curves where the anodic and cathodic reaction rates are equal. Therefore, even though a metal may be capable of exhibiting passivity, its corrosion rate will depend on where the cathodic polarization curve intersects the passive metal anodic curve of the type shown in Fig. 1. Figure 4 shows three possible cases. If the cathodic reaction produces a polarization curve such as A, which is indicative of oxidizing conditions, the corrosion potential will be located in the passive region, and the system can exhibit a low corrosion rate. If the cathodic reaction produces curve C, which is indicative of reducing conditions, the corrosion potential will be in the active region, and the corrosion rate can be high. Curve B represents an intermediate case where passivity, if it exists at all, will be unstable, and the surface will oscillate between active and passive states.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

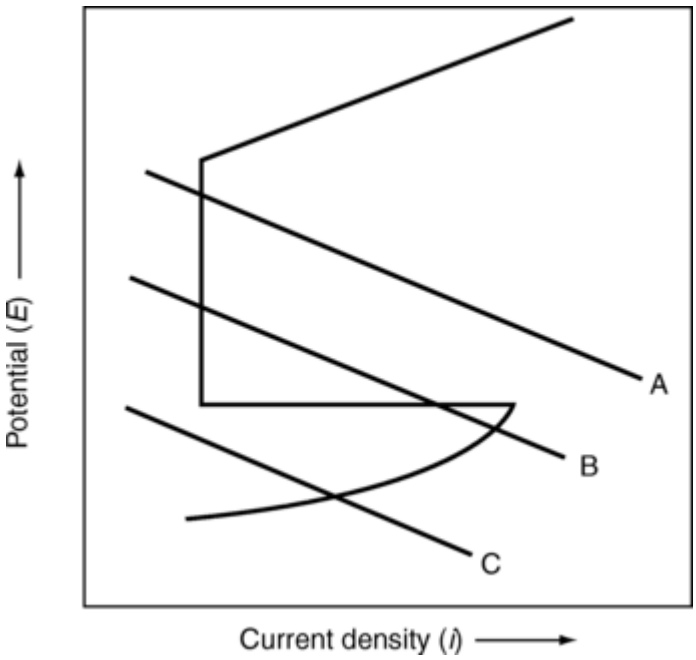

Fig. 4 Intersections of three possible cathodic polarization curves (straight lines A, B, C) with an anodic polarization curve for a system capable of exhibiting passivity. The corrosion rate depends on the current density at the intersection. Curve A produces a passive system, curve C an active system, and curve B an unstable system.

Nature of the Passive Film

It is now widely believed that a film is responsible for the condition of passivity—one of the major accomplishments of past research. The understanding of the nature of passive films has been greatly enhanced in recent years, resulting in the development of many models of the passive film by the application of a whole array of in situ and ex situ techniques developed over the past 25 to 30 years. Two examples of collections of such models (Fig. 5) have been given by Sato (Ref 13) and Cohen (Ref 14). This section discusses five of the properties of passive films: the thickness, the composition, the structure, and the electronic and mechanical properties. These five aspects are discussed using, for the purpose of illustration, the films on iron and iron alloys. Since all of the properties that determine the nature of the passive film are interrelated, the discussion of each is artificially limited.

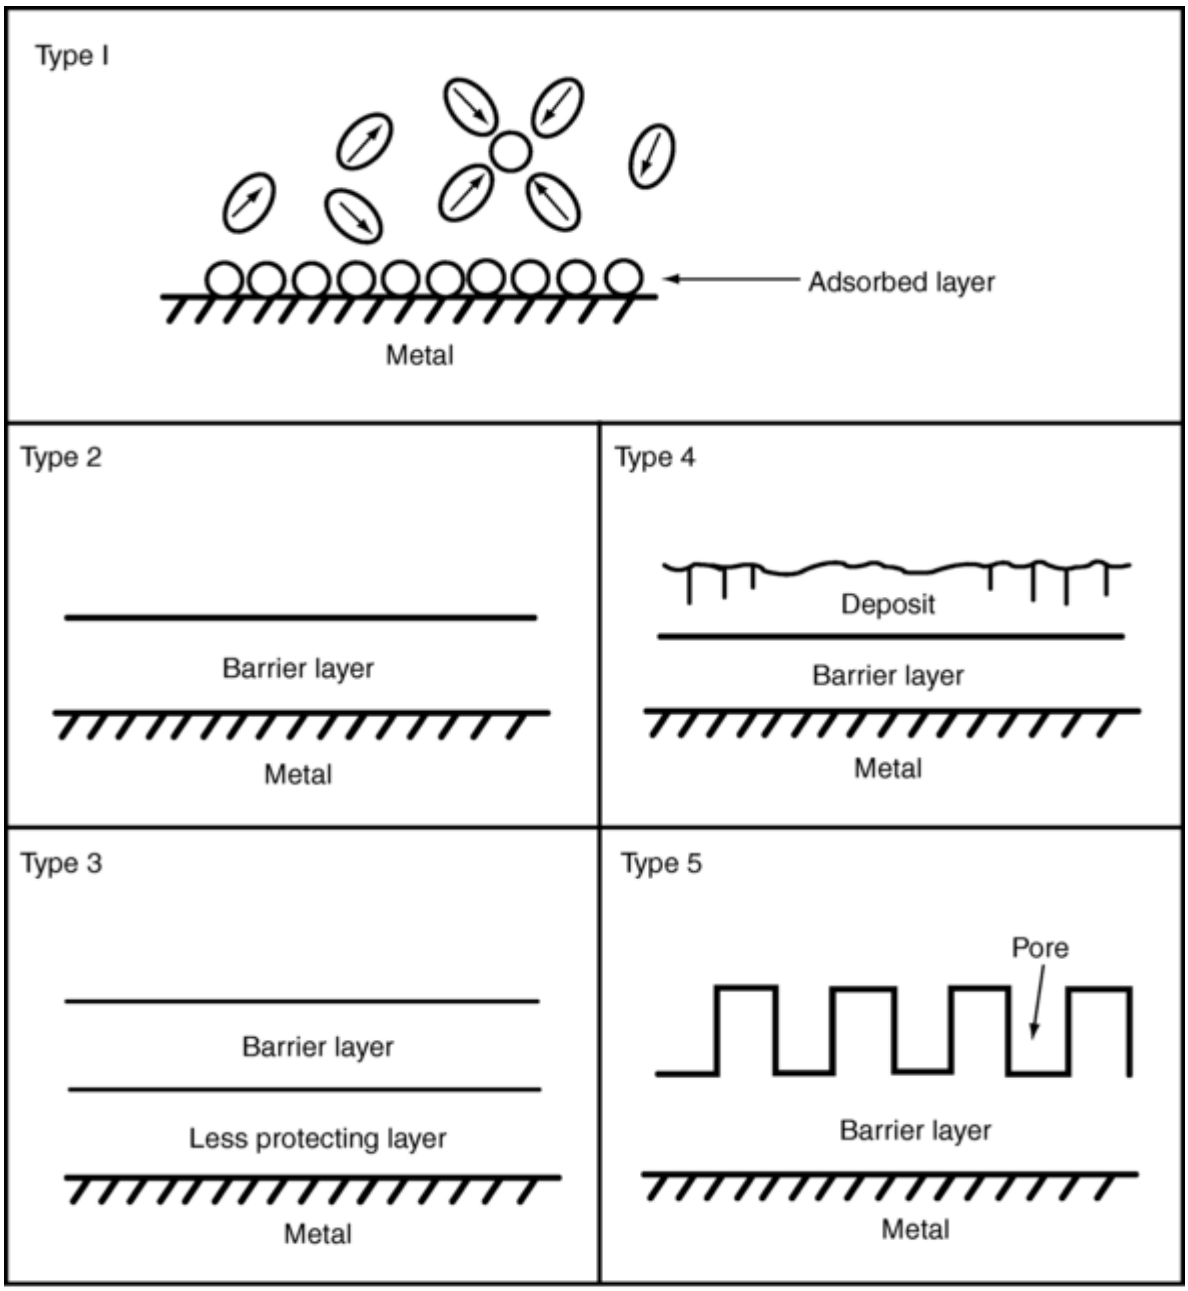
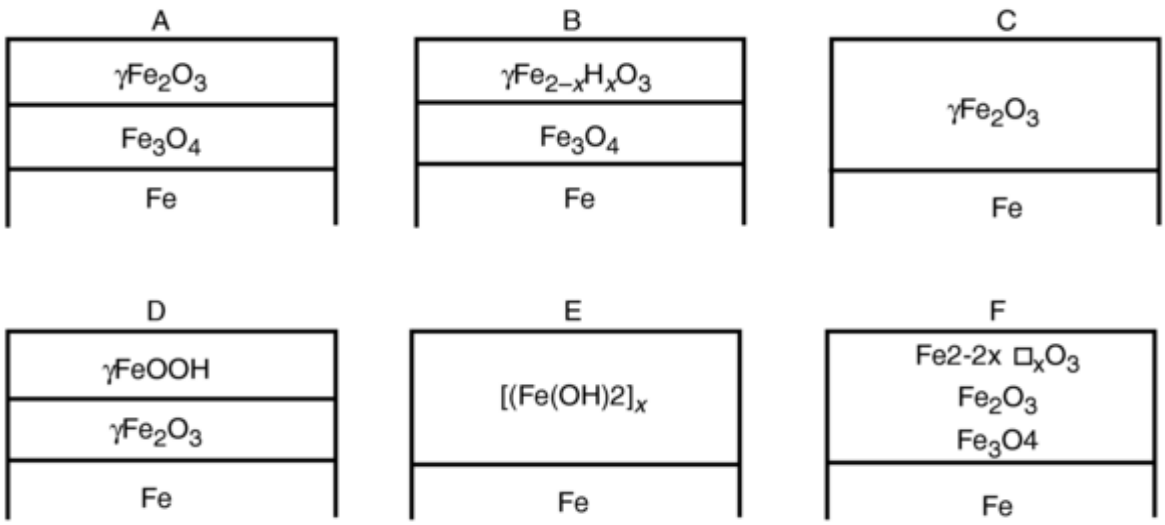
مرجع مهندسی مواد و متالورژی



(a)



(b)

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 5 Proposed models of the passive film. (a) General models include monolayers and multiple layers. Source: Ref 13. (b) Detailed proposed models for iron having single or double layers containing combinations of oxides, hydroxides, and oxyhydroxides. Source: Ref 14

Thickness. Ever since passivity was discovered, the thickness of the passive film has been a source of great controversy between those who proposed a two-dimensional film (Ref 15), in which an adsorbed monolayer or less than a monolayer of oxygen retards surface reaction rates, and those who proposed a three-dimensional film (Ref 16), in which a phase oxide that had a thickness greater than one unit cell could serve as a barrier to the diffusion of metal cations into the solution. The application of numerous techniques appear to have resolved this issue because, depending on conditions, it has been shown by a number of studies that the passive film can be either two- or three-dimensional.
Some of these studies establishing the three- dimensional picture (thickness > monolayer) have been:

- In situ ellipsometric (Ref 17, 18) measurements of the thickness of the passive film as it formed
- Cathodic reduction (coulometric) measurements of thickness (Ref 19, 20)

For confirming passive-film thicknesses of less than a monolayer, coulometric electrochemical techniques have been employed (Ref 21, 22, 23). One of these studies by Frankenthal (Ref 22) have actually provided a link between two- and three-dimensional films. He found that at low potentials in the passive region (-0.4 to -0.1 V(SHE)) for iron in a nearly neutral borate-buffer solution, the film measured was less than a unit cell for Fe_3O_4 or γFe_2O_3 (around 0.84 nm). This film may be considered to be adsorbed oxygen. Above these potentials, he measured thicknesses greater than the unit cell for the phase oxide with Fe(III), for example, γFe_2O_3. Ellipsometric studies (Ref 24) on easily passivated metals such as chromium also show a quite wide potential region (as much as 1000 mV wide) where passive films exhibit thicknesses less than one unit cell of a phase oxide both in neutral and acidic solutions.
Chemical composition is, perhaps, the major property controlling the nature of passive films. For the passive film on iron, many studies have resulted in a confusing array of chemical compositions.
A good summary of some of the ideas that have come out of these investigations is the collection of some of the proposed models shown in Fig. 5(b) (Ref 14). These models involve either single or double layers that contain different combinations and arrangements of the following oxides, hydroxides, or oxyhydroxides: Fe_3O_4, γFe_2O_3, FeOOH, a polymeric layered $Fe(OH)_2$ (Ref 25), a nonstoichiometric cation-deficient γFe_2O_3 containing varying amounts of protons ($Fe_{2-x}H_xO_3$) (Ref 26), and a cation-deficient Fe_2O_3 ($Fe_{2-2x}G_xO_3$) (Ref 14). In addition to this list from the two models shown in Fig. 5(b) is a later model from Cahan and Chen (Ref 27), who characterize the chemical composition loosely as “a highly protonated, trivalent iron oxyhydroxide capable of existing over a relatively wide range of stoichiometry.”
The models for iron shown in Fig. 5(b) have led to a number of issues concerning the chemical compositions of passive films:

- The number of layers in a passive film (Ref 20, 25, 26, 28, 29, 30, 31, 32, 33)
- The presence of hydrogen in some passive films (Ref 30, 34, 35, 36, 37, 38, 39, 40) (where in situ techniques are necessary)
- The existence, nature, and binding states of alloying elements with oxygen in the passive films on alloys (Ref 31, 33, 41, 42, 43)

Structure. Because chemical composition determines structure, these two aspects of the nature of the passive film are tied closely together, making much of the discussion on chemical composition relevant to structure. A major emphasis of many of the structural investigations of the structure of the passive film has been on the issue of crystallinity. Depending on the metal or alloy bearing the passive layer, ex situ studies (Ref 29, 32, 44, 45)—some researchers have found (Ref 32, 34) that structural changes may take place upon the transfer of a passivated specimen from an aqueous solution to the vacuum used in an ex situ technique—and in situ studies (Ref 30, 34, 39, 45, 46) found passive films with either crystalline or noncrystalline structures.
Some studies (Ref 47, 48, 49, 50) have contended that for some systems, for example, high-chromium stainless steels or passive films formed on iron by passivation in chromate solutions, the film is noncrystalline and that this noncrystallinity is promoted by certain alloying elements such as chromium and by the presence of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

hydrogen in the structure of the film (Ref 2). There is also a large body of literature suggesting that the crystallization of the oxide layers on titanium alloys adversely affects the properties that enhance the passivity of the film (Ref 51, 52, 53, 54). Other studies (Ref 55, 56) have, however, found that superior passive films are crystalline and become more so upon aging (Ref 57).

Electronic Properties. This aspect of the nature of the passive film is an important factor in controlling the mechanisms of film formation, breakdown, and the rate of metal dissolution. This is so because dissolution, film formation, and breakdown all involve the movement of electrons and ions from the metal surface through the passive film or from the solution into the film. Moreover, electron-transfer reactions that occur on surfaces with passive films depend strongly on the electronic properties of such films.

Iron—like other metals exhibiting type 1 passivity but unlike electronic valve metals such as aluminum, titanium, and tantalum—forms a very thin, passive layer (less than 10 nm). The valve metals, however, whose films are good insulators, can support large electric fields and by so doing form quite thick films (hundreds of nanometers). Oxygen cannot be evolved from valve metals. Iron, when high potentials are applied, evolves oxygen instead of continuing to grow a thicker film. It is for this reason that many workers have suggested that the passive film on iron is a good electronic conductor, or at least a semiconductor (Ref 58). Many ideas on the role of electronic properties of electron-transfer reactions at the passive-film surface have suggested films with different electronic characteristics, namely a semiconducting film (Ref 58, 59, 60, 61, 62, 63) or a film with low electronic conductivity that is an insulator or partially an insulator to support the large fields required if the proposed mechanism of film growth is field-assisted ionic migration (Ref 19, 50, 64, 65).

Cahan and Chen (Ref 27) attempted to reconcile these opposing findings, proposing that the passive film on iron is neither a semiconductor nor an insulator, but a combination of both, that is, a “chemi-conductor,” which they define as “a material whose stoichiometry can be varied by oxidative and/or reductive valency state changes. This nonstoichiometry can then modify the local electronic (and/or ionic) conductivity of the film.”

The mechanical properties of passive films can be an important factor in the breakdown of passivity. Even though the determination of the mechanical properties of passive films is difficult, a few attempts have been made to measure these properties for a number of metals (Ref 66, 67, 68). These studies have shown that applied potentials (Ref 68) and alloying (Ref 66, 67) can control the ductility of some passive layers. It has been suggested (Ref 2) that the effect of alloying may be a consequence of the passive film, for example, on a chromium alloy being more noncrystalline than that on iron. An ex situ study of the passive layers formed in nitric acid solutions on stainless steels (Ref 52) found these films to be crystalline, epitaxial, and composite. This suggested that the mechanical properties of such films may be anisotropic and brittle with a high degree of adherence stress at the metal/film interface.

Passivity

Jerome Kruger, Johns Hopkins University

Passive-Film Formation and Dissolution

Processes. Passivity results from bringing a metal surface into the passivity region of a system exhibiting a passive polarization curve (Fig. 1) and thereby forming "the passive film." Sato and Okamoto (Ref 69) have pointed out that there are three possible processes that can produce passive films. The three passivation processes defined below describe possible ways in which the imposition of an electrochemical current can result in the formation of a passive film.

Direct film formation involves the reaction of a metal surface with an aqueous solution to form either a chemisorbed oxygen film or a compact three-dimensional (more than one atomic layer) film, usually an oxide or oxyhydroxide represented by:

$$M + H_2O = MO_{ads} + 2H^+ + 2e^- \quad \text{(Eq 1)}$$

or

$$M + H_2O = MO(\text{oxide}) + 2H^+ + 2e^- \quad \text{(Eq 2)}$$

Dissolution precipitation produces a passive layer by the formation of an oxide, oxyhydroxide, or hydroxide film by the precipitation of dissolved metal ions as described by the two-step process:

$$M = M^{z+} + ze^- \quad \text{(Eq 3)}$$

$$M^{z+} + zH_2O = M(OH)_z + zH^+ \quad \text{(Eq 4)}$$

The anodic oxidation of metal ions in solution forms an oxide film containing the metal ion in a higher oxidation state as shown by:

$$M = M^{z+} + ze^- \quad \text{(Eq 5)}$$

$$2M^{z+} + (z + x)H_2O = M_2O_{(z+x)} + 2(z + x)H^+ + 2xe^- \quad \text{(Eq 6)}$$

Rate Laws of Passive-Film Formation. As a result of the passivation processes described previously, it is possible to develop various expressions for the rate of passive-film formation by applying either of two electrochemical methods to form the passive film; these methods are described below.

Galvanostatic anodic oxidation or passivation applies a constant current and measures the change in potential as a function of time. When the potential for that surface, with respect to a reference electrode, is observed as a function of time, it is found that the potential rises initially during an induction time, τ_p, until it reaches a relatively constant value, E_p, the passivation potential, as shown in Fig. 1. The relationship between τ_p and the critical current density for passivation, i_c, is given by Sato and Okamoto (Ref 69) as $\tau_p = k(i - i_c)^n$, where k and n are constants with n having been found to be -1 for iron by Frank (Ref 70).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Potentiostatic anodic oxidation or passivation sets the potential of the metallic surface at a constant value and observes the variation of the current with time. It has been proposed (Ref 71) that potentiostatic passivation involves a competition between metal dissolution and film formation with the total current density, which is the reaction rate for the passivation process given by the expression $i = (i_{diss} + i_{film})(1 - \theta)$, where i_{diss} is the current density for film dissolution, i_{film} is the current density for film formation, and θ is the fraction of the surface covered by the passive film.

Mechanism of Formation. A review of the mechanisms of passive-film formation has been given by Fromhold (Ref 72). He has pointed out that it has been shown experimentally that the relationship between the electric field *E* across the passive film (potential difference across the film divided by the film thickness, usually several millions volts per centimeter) and the current density, *i*, can be given by:

$$E - E^{o} = A \log i \qquad \text{(Eq 7)}$$

where E^{o} and *A* are constants. A number of the proposed mechanisms for the growth of the passive film in the limiting thickness region (where film growth levels off) are some form of a field- assisted ion conduction mechanism based on the oxidation theory developed by Cabrera and Mott (Ref 73) such as the hopping (Ref 74), induced space charge (Ref 75), and point defect (Ref 76) mechanisms. A major problem in deciding which of the field-assisted ion conduction mechanisms is operative for iron in neutral solutions is that the kinetics of passive-film growth follow equally well either inverse logarithmic or direct logarithmic rate laws. Figure 6 shows the extent of this problem for iron in a neutral borate buffer solution. The inverse logarithmic law indicates a field-assisted ion conduction mechanism; the direct logarithmic law can be expected from a place-exchange mechanism. In addition, there are the models that do not depend on field-assisted ion conduction. These include the chemisorption of oxygen model (Ref 15, 77), the place-exchange mechanism (Ref 78), and the bipolar fixed charge induced passivity mechanism (Ref 79). Fromhold (Ref 72) has found that no mechanism can adequately explain all aspects of the film-formation process.

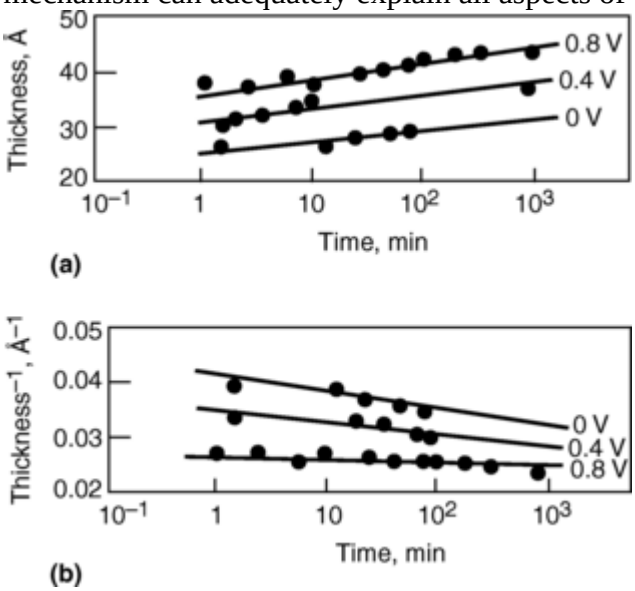

Fig. 6 Logarithmic plots of the growth of passive film on iron by potentiostatic anodic polarization at different potentials in pH 8.4 borate-buffer solution (a) Direct. (b) Inverse. Source: Ref 70

Dissolution. The process of passive-film dissolution is as important as that of film formation in controlling corrosion. Attention has mainly been placed on the dissolution of passive films in acid solutions (Ref 80) that involve either galvanostatic or steady-state open circuit conditions (Ref 58). An important aspect of passive-film dissolution is the existence of a potential, the Flade potential, that delineates the transition from the passive to the active state. It was first observed by Flade (Ref 81) when he found that the open-circuit potential of a passive metal surface decreased continuously and then ceased to change momentarily and arrested, before decaying to more active values that signaled the onset of the active state. Uhlig and King (Ref 82) have given a number of examples of this transition through the Flade potential during the decay of passivity. Other studies (Ref 33, 42, 83, 84) focused on the examination of the reduction and dissolution of individual species in passive films in mildly acidic and basic solutions. Finally, an investigation (Ref 85) that studied passive-film

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

dissolution in nearly neutral solutions was able to distinguish between the field and chemical effects that result in passive-film thinning.

Breakdown of the Passive Film

When a fourth cathodic curve is added above line A in Fig. 4, a line that intersects the anodic passive curve at a point where the current density is increasing sharply, breakdown of the passive film results, leading to the most damaging kinds of corrosion—the localized forms of corrosion, pitting, crevice corrosion, intergranular attack, and stress corrosion. A number of reviews of breakdown or pitting that deal with breakdown as the initiation step of pitting exist (Ref 86, 87, 88, 89, 90).

Mechanisms. Many theories or models have been proposed to describe the events leading to pitting or crevice-corrosion initiation. Successful models must, of course, explain the phenomenology of breakdown. The following phenomena are usually considered to be associated with chemical breakdown that leads to localized attack (Ref 86):

- A certain critical potential for breakdown must be exceeded.
- Damaging species (examples are chloride ions or the higher atomic weight halides) are needed to initiate and propagate breakdown.
- An induction time exists that starts with the initiation of the breakdown process by the introduction of conditions conducive to breakdown and ends with the completion of the process when breakdown commences.
- Highly localized sites exist at which breakdown occurs.

In order to develop a better understanding of breakdowns that can lead to an improved resistance to localized corrosion, three groups of models for passive-film breakdown have been proposed; these groups are described below.

Adsorbed Ion Displacement Model (Ref 91, 92). The passive film is considered by this model to be an adsorbed oxygen film (probably a monolayer). Breakdown occurs when a more strongly adsorbing damaging anion, for example, a chloride ion, displaces the oxygen forming the passive film. After the chloride ion is adsorbed on the surface, the breakdown process is initiated because the bonding of the metal ions to the metal lattice is weakened.

In ion migration or penetration models, damaging anions move through the passive film; the breakdown process is complete when an anion reaches the metal/film interface. All of these models consider the passive film to be three dimensional. They differ widely in their proposed mode of penetration. At one extreme is a model assuming the existence of pores in the passive film (Ref 93, 94). The other type of penetration models are those involving migration of the damaging anion through a lattice, via defects or via some sort of ion-exchange process. Ion migration in a lattice can occur in a variety of ways (Ref 95, 96, 97, 98). Some of these models postulate that the penetrating chloride ions occupy sites in the lattice, and recent x-ray absorption spectroscopic studies find that evidence for the existence of chloride in the lattice of the passive film (Ref 99, 100).

Breakdown repair or film-tearing models involve many dynamic breakdown-repassivation events during which chemically or electrochemically induced mechanical disruption of the passive film is followed by repair of the break. This dynamic process will then lead to the breakdown of passivity (Ref 101, 102). More recent studies (Ref 99, 103) have shown that metastable pitting events—breakdown-repair processes that occur below the critical potential for breakdown, E_{crit}—may be involved in breakdown. One of these studies (Ref 99) proposes a mechanism that describes the events of metastable pitting that lead to stable pit growth as follows:

- Anion (e.g., chloride-ion) movement through the passive film at local sites under an electric field
- Formation of metal chloride at discrete sites at the passive-film/metal interface

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- Initiation of pitting upon rupture of the film at metal-chloride sites
- Pit growth at exposed sites sustained when chloride ions under diffusion control can prevent repassivation

It has been pointed out (Ref 91), however, that stable pitting (occurs above E_{crit}), rather than metastable pitting (observed below E_{crit}), is from an engineering standpoint the real corrosion risk.

Effect of Alloy Composition and Structure. Alloy composition has been found to affect breakdown phenomenologically by shifting E_{crit} in the noble direction (Ref 104). This shift has been explained by the production of a passive film that is more difficult to penetrate because it provides fewer diffusion paths (Ref 47, 105), by alloying elements affecting repassivation kinetics (Ref 106), or by the formation of complexes with, for example, molybdenum, an alloy component that increases resistance to pitting by reducing the flux of cation vacancies in the passive film toward the film/metal interface and thereby increasing the induction time for breakdown (Ref 107). Another example has been found for amorphous and partially nanocrystalline alloys of aluminum that exhibit increased pit-growth potentials, reduced pit-propagation rates, and increased repassivation rates when compared to polycrystalline high-purity aluminum (Ref 108). This is an effect of both adding alloy elements and changing the alloy structure.

Alloy structure determines the sites on a surface where the breakdown of the passive film is initiated. These sites have been shown to be related to the defect structure of the underlying metal (Ref 90, 91), with the density of sites in many instances depending on the crystallographic orientation of a particular grain (Ref 109). Another important factor leading to the production of breakdown sites is the presence of nonmetallic inclusions, especially the manganese sulfide inclusions found in stainless steels (Ref 90, 91). Finally, intermetallic phase particles acting as local cathodes (Ref 110, 111) as, for example, the $FeAl_3$ in iron-contaminated aluminum alloys, raise the pH of the local environment and cause alkaline dissolution (Ref 91) of the matrix at its boundary with the particle and thereby initiate breakdown.

Methods for Determining Aqueous Corrosion Reaction Rates

John R. Scully and Robert G. Kelly, University of Virginia

Introduction

CORROSION OF MATERIALS IN AQUEOUS SOLUTIONS is often thermodynamically possible but kinetically limited. Therefore, it is important to determine the rates of corrosion processes. Corrosion rate determination can serve many engineering and scientific purposes. For example, it can be used to:

- Screen available materials to find the most resistant material for a given application.
- Determine operating conditions where corrosion rates are low versus those where rates are high, by varying conditions.
- Determine probable service lifetimes of materials forming components, equipment, and processes.
- Evaluate new alloys or treatments or existing alloys in new environments.
- Evaluate lots, heats, or treatments of materials to ensure that specified quality is achieved before release, shipment, or acceptance.
- Evaluate environmental conditions such as new chemical species, inhibitors, or plant- operation conditions such as temperature excursions.
- Determine the most economical means of reducing corrosion through use of inhibitors, pretreatments, coatings, or cathodic protection.
- Determine the relative corrosivity of one environment compared to another.
- Study corrosion mechanisms.

Methods for determination of corrosion rates can be differentiated between those that measure the cumulative results of corrosion over some period of time and those that provide instantaneous rate information. Corrosion rates do not often increase monotonically with environmental conditions but exhibit sharp thresholds that distinguish regions of low corrosion rates from other regions where corrosion rates are dangerously high. It is sometimes of greater interest to define these thresholds than it is to determine the rates in the regions where corrosion rates are high. Examples of the latter are pitting or crevice corrosion where passive films are broken down and local corrosion rates can be extremely high. This article addresses electrochemical methods for instantaneous rate determination and threshold determination as well as nonelectrochemical methods that can determine incremental or cumulative rates of corrosion.

Electrochemical Methods

Several textbooks and symposia proceedings cover the application of electrochemical methods that can be used for corrosion testing (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16). This article highlights many of the commonly used laboratory methods used to determine instantaneous corrosion rates as well as methods that characterize corrosion thresholds that signal conditions for high rates of corrosion. Techniques discussed include Tafel extrapolation, polarization resistance, electrochemical impedance spectroscopy, electrochemical noise resistance, use of rotating disks and cylinders to study aspects of corrosion affected by solution flow, polarization methods for assessing susceptibility to localized corrosion, scratch repassivation, potential-step repassivation, electrochemical noise applied to pitting, potentiodynamic repassivation techniques for assessing sensitization, and methods for determining underpaint corrosion rates associated with corrosion under organic coatings on metals.

Electrode Reaction Thermodynamics and Kinetics in Corrosion

Metallic corrosion is usually an electrochemical process. Electrochemical processes require anodes and cathodes in electrical contact as well as an ionic conduction path through an electrolyte. The electron flow between the anodic and cathodic areas quantifies the rates of the oxidation and reduction reactions. When anodes are physically separated from cathodes, the current can be readily measured by replacing direct electrical contact with a zero-resistance ammeter (ZRA), The conversion of the reaction rate per unit area, J, from units of mol/cm^2 · s to electrical current density, (A/cm^2), is accomplished with Faraday's constant, F, and knowledge of the number of electrons, n, transferred to complete the electrochemical reaction a single time:

$$i = I/A = nFJ \qquad \text{(Eq 1)}$$

where I is the current resulting from an electrochemical reaction over a known electrode surface area, n is the number of electrons transferred (equivalents/mol), F is Faraday's constant (96,484.6 Coulombs/equivalent), and A is the electrode surface area.

Monitoring this current provides the means for assessing the kinetics of the corrosion process, not just the thermodynamic tendencies for corrosion or merely the mass of metal loss registered after the test.

Typical corrosion processes occurring under freely corroding conditions involve at least one cathodic and one anodic reaction. The thermodynamics discussed previously dictate the circumstances where these reactions will proceed spontaneously. The current measured during a polarization experiment, i_{app}, involving a single- charge-transfer-controlled oxidation reaction and single charge-transfer-controlled reduction reaction is:

$$i_{app} = i_{corr}\left[\exp\left(\frac{\alpha_a F(E - E_{corr})}{RT}\right) - \exp\left(-\frac{\alpha_c F(E - E_{corr})}{RT}\right)\right] \qquad \text{(Eq 2)}$$

where i_{corr} is the corrosion current density, E is the applied potential, R is the ideal gas constant, T is the temperature, and α is the transfer coefficient.

The corrosion potential, E_{corr}, is a kinetically and thermodynamically determined “mixed” potential given by the interception of the lines describing the total anodic and cathodic reaction rates. At E_{corr}, $i_{ox} = i_{red}$ and i_{corr} is described by the magnitude of i_{ox} at E_{corr} as shown in Fig. 1. Either reaction rate may become mass-transport limited under certain circumstances, in which case Eq. 2 does not apply.

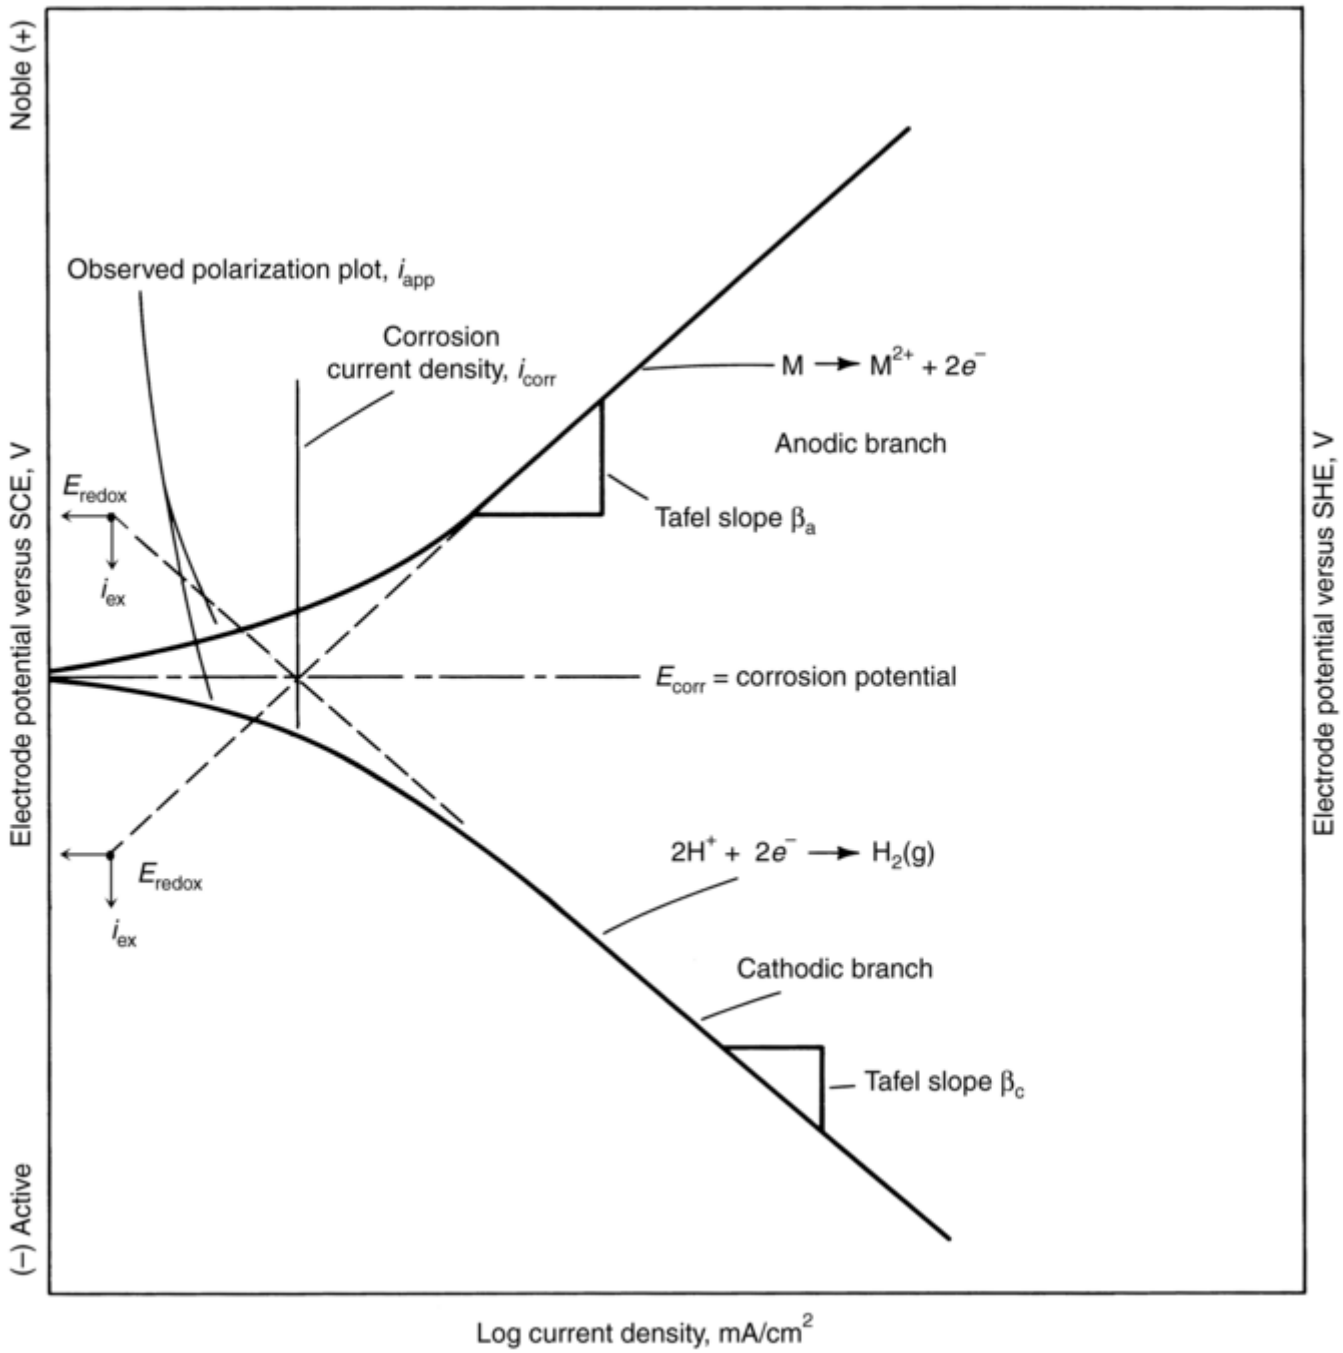

Fig. 1 Application of mixed-potential theory showing the electrochemical potential-current relationship for a corroding system consisting of a single charge-transfer-controlled cathodic reaction and charge-transfer-controlled anodic electrochemical reaction. β_c and β_a are Tafel slopes. Source: Ref 17

Obtaining Corrosion Rates from Electrochemical Kinetic Data. According to mixed- potential theory, any overall electrochemical reaction can be algebraically divided into half-cell oxidation and reduction reactions in which there can be no net electrical charge accumulation (Ref 17). For open-circuit corrosion in the absence of an applied potential, the oxidation of the metal and the reduction of some specie in solution occur simultaneously at the metal/electrolyte interface as described by Eq 2. Under these circumstances, the net measurable current density, i_{app}, is zero. However, a finite rate of corrosion defined by i_{corr} occurs at local anodic sites on the metal surface as indicated in Fig. 1. When the corrosion potential, E_{corr}, is located at a potential that is distinctly different from the reversible electrode potentials (E_{redox}) of either the corroding metal or the species in solution that is cathodically reduced, the oxidation of cathodic reactants or the reduction of any metallic ions in solution becomes negligible. Because the magnitude of i_{ox} at E_{corr} is the quantity of interest in the corroding system, this parameter must be determined independently of the oxidation reaction rates of other adsorbed or dissolved reactants.

مرجع مهندسی مواد و متالورژی

The information obtained in a polarization experiment is i_{app} as a function of the potential, E, as shown by the thick solid line in Fig. 1, where $i_{app} = i_{ox} - i_{red}$. To obtain i_{app} as a function of E, the applied potential between the reference electrode and working electrode is controlled and scanned at constant rate (potentiodynamic), instantaneously increased a fixed amount, or stepped at various times (potentiostaircase) (Ref 18). The applied current, I_{app}, is measured and normalized with respect to the surface area (i.e., $i_{app} = I_{app}/A$). Conversely, i_{app} can be supplied between the working and counterelectrodes under galvanostatic or galvanostaircase control, and the resulting potential between the working and reference electrodes is monitored. Several ASTM standards discuss methods for performing these experiments (Ref 19, Ref 20, 21). Several approaches are available to determine i_{corr} from such experimental information. These methods are discussed in the sections that follow.

Conversion of Corrosion Rates to Mass Loss and Penetration Rate. Determination of I_{ox} at open-circuit potential or other potential of interest, where $I_{ox} = i_{ox} \times$ area, over a known period of time leads to direct determination of the mass loss:

$$M = \frac{I_{ox} t (AW)}{nF} \qquad \text{(Eq 3)}$$

where M is the mass loss (g), $I_{ox}t$ is the product of current and time (coulombs), and AW is the atomic weight of the electroactive species (g/ mol).

This relation is known as Faraday's First Law. Rearrangement of Eq 3 leads to a straightforward determination of the corrosion penetration rate (applicable only when i_{ox}, μA/cm^2, is uniformly distributed over the entire wetted surface area or where the localized actively corroding area, A, is known), as follows:

$$CR = \frac{K_1 i_{ox} (EW)}{\rho} \qquad \text{(Eq 4)}$$

where CR is the corrosion penetration rate (in mm/yr, EW is the equivalent weight (considered dimensionless in this calculation because the units of equivalents/mol are included in K_1), and ρ is the metal or alloy density, g/cm^3.

The constant $K_1 = 3.27 \times 10^{-3}$ when i_{ox} is expressed as μA/cm^2. K_1 has units of mm · g/ μA · cm · yr when CR is desired in mm/yr. ASTM G 102 gives other values for this constant when CR is expressed in other units (Ref 22). Expressions are also available to calculate mass- loss rate per unit area, MR, from knowledge of electrochemical corrosion rate. For instance:

$$MR = K_2 i_{ox} (EW) \qquad \text{(Eq 5)}$$

where $K_2 = 8.954 \times 10^{-3}$ g · cm^2/μA · m^2 · d when MR is expressed as g/m^2 · day. For alloys, the equivalent weight EW should be calculated as outlined in ASTM G 102 (Ref 22):

$$EW = \frac{1}{\sum \left(\frac{n_i f_i}{AW_i} \right)} \qquad \text{(Eq 6)}$$

where f_i is the mass fraction of the ith component of the alloy (-), AW_i is the atomic weight of the ith component element (g/mol), n_i is the number of electrons transferred or lost when oxidizing the ith component element under the conditions of the corrosion process (equivalents/mol), and i is the number of component elements in the alloy.

n is usually equal to the stable valence of the elements oxidized from the metallic state or must be determined from either a Pourbaix (potential- pH) diagram or experimentally from an analysis of the corroding solution. This expression assumes that all the component elements oxidize when the alloy corrodes and that they are all oxidizing at essentially a uniform rate. In some situations, these assumptions are not valid; in these cases, the calculated corrosion rate will be in error. For example, if an alloy is composed of two or more phases and one phase preferentially corrodes, the calculation must take this into consideration.

Electrochemical Methods for the Study of Uniform Corrosion: Polarization Methods

One method for examining the corrosion behavior of a metal is to determine the E-i_{app} relationship by conducting a polarization experiment. The following E-i_{app} relationship is often experimentally observed between applied current and potential. The expression is applicable to charge-transfer-controlled corrosion processes regardless of the exact number of charge-transfer-controlled reactions or reaction steps. It provides the basis for the electrochemical polarization technique (Ref 1, 2, 17, 18, 23):

$$i_{app} = i_{corr}\left[\left(\exp\left\{\frac{2.303(E-E_{corr})}{\beta_a}\right\}\right) - \exp\left\{-\frac{2.303(E-E_{corr})}{\beta_C}\right\}\right] + C\frac{\partial E}{\partial t} \qquad \text{(Eq 7)}$$

where C is the interfacial capacitance associated with the electrochemical double layer (Ref 1, 2), and β_a and β_c are the apparent anodic and cathodic Tafel slopes $(\partial E/\partial \log i_{app}) = 2.303RT/\alpha F$ given by the slopes of the polarization curves in the anodic and cathodic Tafel regimes, respectively, and $\partial E/\partial t$ is the time rate of change in applied potential; that is, the voltage scan rate.

The second term of the expression ($C\partial E/\partial t$) approaches 0 at low voltage scan rates dE/dt. This is desirable since the goal is to obtain i_{corr} at E_{corr}. Note that i_{app} becomes approximately equal to either i_{ox} or i_{red} at large η, where $\eta = (E - E_{corr})$. At very large anodic or cathodic overpotentials, Eq 7 can be rearranged in the form of the Tafel expression (Ref 1, 2, 3, 5, 7, 19, 23):

$$\eta_a = \beta_a \log\left(\frac{i_{app}}{i_{corr}}\right) \qquad \text{(Eq 8a)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$\eta_c = -\beta_c \log\left(\frac{i_{app}}{i_{corr}}\right) \quad \text{(Eq 8b)}$$

where η_a and η_c are the anodic and cathodic overpotentials, respectively.

Equations 8a and (b) are only strictly valid for a single anodic or cathodic reaction, respectively, although approximately linear behavior can be observed despite several reactions. The linear portion of the solid line describing E-i_{app} in Fig. 1 above the E_{corr} describes a single anodic reaction that can be described by Eq 8a.

Tafel Extrapolation to Determine Corrosion Rate. In cases where Eq 8a and (b) are valid, η can be plotted versus log(i_{app}) over a sufficient range to obtain a linear relationship between the logarithm of current density and potential (Ref 1, 5, 7, 23), i_{corr} is determined from extrapolation of i_{app} from either the anodic or the cathodic Tafel region to the open-circuit or corrosion potential (i.e., zero overpotential). Figure 1 illustrates this method. The method is potentially damaging to the corroding metal since a large overpotential must be applied. This is particularly true in the case of anodic polarization, in which the surface is changing because of corrosion and/or passivation of the metal. No ASTM standard currently exists for this method.

Complications with the Polarization Method Involving Solution Resistance. Tafel extrapolation as well as other polarization techniques can be complicated by several factors. One such factor, ohmic resistance, arises from the resistivity of the solution, cell geometry, location of the reference electrode, and magnitude of applied current (Ref 2, 6). Ohmic resistance can contribute a voltage error to the measured potential. This error is summed algebraically with the true interfacial overpotential across the electrochemical interface (the potential usually sought in electrochemical measurements) measured with respect to a reference electrode. Placement of the reference electrode near the working electrode with a Luggin-Haber capillary is used to minimize the solution resistance error, which can be estimated from the product of the applied current density, the solution resistivity, and the perpendicular distance from the Luggin probe to the specimen surface in a planar electrode geometry. The error contributes to the measured overpotential:

$$\eta_{app} = \eta_{true\ interfacial} + i_{app}R_s \quad \text{(Eq 9)}$$

$R_s(\Omega \cdot cm^2)$ is the uncompensated solution resistance between the working electrode and the position where the reference electrode senses the potential in solution (at the tip of the Luggin- Haber capillary). Thus, $\eta_{app} > \eta_{true}$ at a high anodic or cathodic applied current density, $E_{app} > E_{true}$ and the Tafel slope desired from a fit of Eq 7 or 8a to E versus i_{app} data is not obtained. When the dominant term in Eq 9 is the second term, a linear relationship between η and i_{app} is obtained instead of the semilogarithmic relationship discussed previously. The true scan rate in the potentiodynamic technique may also be altered by ohmic resistance since the applied potential that contains the ohmic component is controlled during the scan, not the true overpotential. Several excellent reviews are available on the subject of the voltage error introduced from solution resistance (Ref 24, 25, 26, 27).

Complications Involving Concentration Polarization Effects. The Tafel relationship established through Eq 7 and 8a is dependent on pure activation control, or charge-transfer control. An additional consideration involves the concept of concentration polarization. In this case, the reaction rate is fast enough that the reacting specie is depleted (reduction reaction) or concentrated (oxidation) at the reacting surface. In order to maintain the reaction rate, diffusion through the electrolyte becomes the kinetic limitation. The reaction becomes diffusion controlled at the limiting current density, i_L. The deviation from activation control in the case of a cathodic reaction can result in an additional overpotential known as a mass-transport overpotential, η_{conc}. This overpotential is described by (Ref 4, 5):

$$\eta_{conc} = \left[\frac{2.303RT}{nF}\right]\log\left[1 - \frac{i_{app}}{i_L}\right] \quad \text{(Eq 10)}$$

where i_L is the mass transfer limiting current density defined by Fick's first law at steady state.

As i_{app} approaches i_L, the concentration overpotential, η_{conc}, becomes very large. The cathodic reaction may be under mixed charge-transfer/mass-transport or mass-transport control for many corrosion situations, particularly if the cathodic reaction is O_2 reduction (Ref 5). The cathodic polarization behavior associated with "mixed" charge-transfer/mass-transfer control can be described mathematically by the algebraic sum of Eq 8a and 10. Tafel extrapolation of cathodic data becomes difficult under these conditions because the Tafel region is not extensive.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

For a completely mass-transport-limited corrosion process, the concentration of the cathodic reacting specie C_b approaches 0 at the electrode interface and $i_{corr} = i_L$ (Fig. 2) (Ref 2). The diffusional boundary layer thickness, δ, is decreased by increasing solution stirring or rotation rate, Ω(rad/s), in the case of a rotating cylinder or disk electrode (Ref 1). The limiting current density i_L is a linear function of concentration gradient (Ref 15). The concentration gradient (C_b/δ) increases as a function of $\Omega^{0.5}$ or $\Omega^{0.7}$ for the rotating disk and cylinder, respectively (Ref 2, 15). For a mass-transport-controlled cathodic reaction, i_{corr} is increased with flow as shown in Fig. 2. The governing equation for the rotating cylinder electrode is (Ref 15):

$$i_L = 0.079nFC_bD^{0.64}\nu^{-0.34}\Omega^{0.7}r^{0.4} \quad \text{(Eq 11)}$$

and for the rotating-disk electrode is (Ref 2, 15):

$$i_L = 0.621nFC_bD^{0.67}\nu^{-0.167}\Omega^{0.5} \quad \text{(Eq 12)}$$

where C_b is the reacting species concentration in the bulk solution (moles/cm^3), D is the diffusion coefficient for the reacting specie (cm^2/s), ν is the kinematic viscosity of the solution (cm^2/s), and r is the cylinder or disk radius (cm).

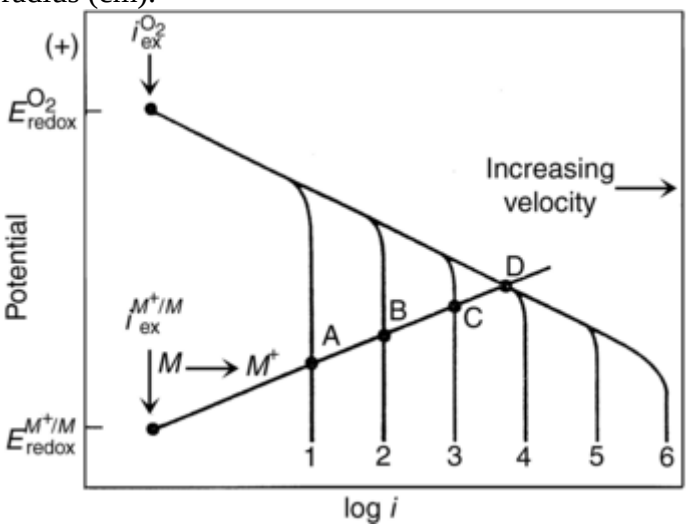

Fig. 2 Application of mixed-potential theory showing the electrochemical potential-current relationship for a corroding system consisting of a mass-transport-controlled cathodic reaction and a charge-transfer-controlled anodic reaction. As the fluid velocity increases from 1 to 4, the corrosion rate increases from A to D.

Corrosion engineers often favor the rotating cylinder to simulate flow in turbulent piping systems since this flow regime is readily obtained (Ref 15). In contrast, the rotating-disk electrode operates in the laminar flow regime even at high rotation rates and does not accurately represent many corrosion situations (Ref 15). No ASTM methods currently exist to examine mass-transport-controlled corrosion kinetics.

Polarization Resistance Methods

Stern and Geary simplified the kinetic expression describing charge-transfer-controlled reaction kinetics (Eq 7) for the case of small overpotentials with respect to E_{corr} (Ref 28, 29). Equation 7 can be linearized when $\eta/\beta < 0.1$. This simplified relationship has the following form if the second term describing the capacitive current, $C(\partial E/\partial t)$, is negligible:

$$i_{corr} = \left(\frac{\Delta i_{app}}{2.3\Delta E}\right)\left(\frac{\beta_a\beta_c}{(\beta_a + \beta_c)}\right) \qquad \text{(Eq 13)}$$

rearranging:

$$i_{corr} = \left(\frac{1}{2.3R_p}\right)\left(\frac{\beta_a\beta_c}{(\beta_a + \beta_c)}\right) \qquad \text{(Eq 14)}$$

where R_p is the polarization resistance ($\Omega \cdot cm^2$) given by $\partial E/\partial i$ at $t = \infty$ and $\Delta E = 0$.
i_{app} is often approximately linear with potential within ±5 to 10 mV of E_{corr} as shown for AISI 430 stainless steel in H_2SO_4 (Fig. 3). The slope of this plot, $\Delta E/\Delta i$, when determined at E_{corr} as shown in Fig. 3 defines the polarization resistance, which is inversely proportional to corrosion rate (Ref 30, 31). The surface area of the working electrode must be known. Knowledge of R_p, β_a, and β_c permit direct determination of the corrosion rate

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

at any instant in time using Eq 14 (Ref 28, 29, 31, 32). The ASTM standards G 59 (Ref 21) and G 96 (Ref 33) describe standard procedures for conducting polarization resistance measurements.

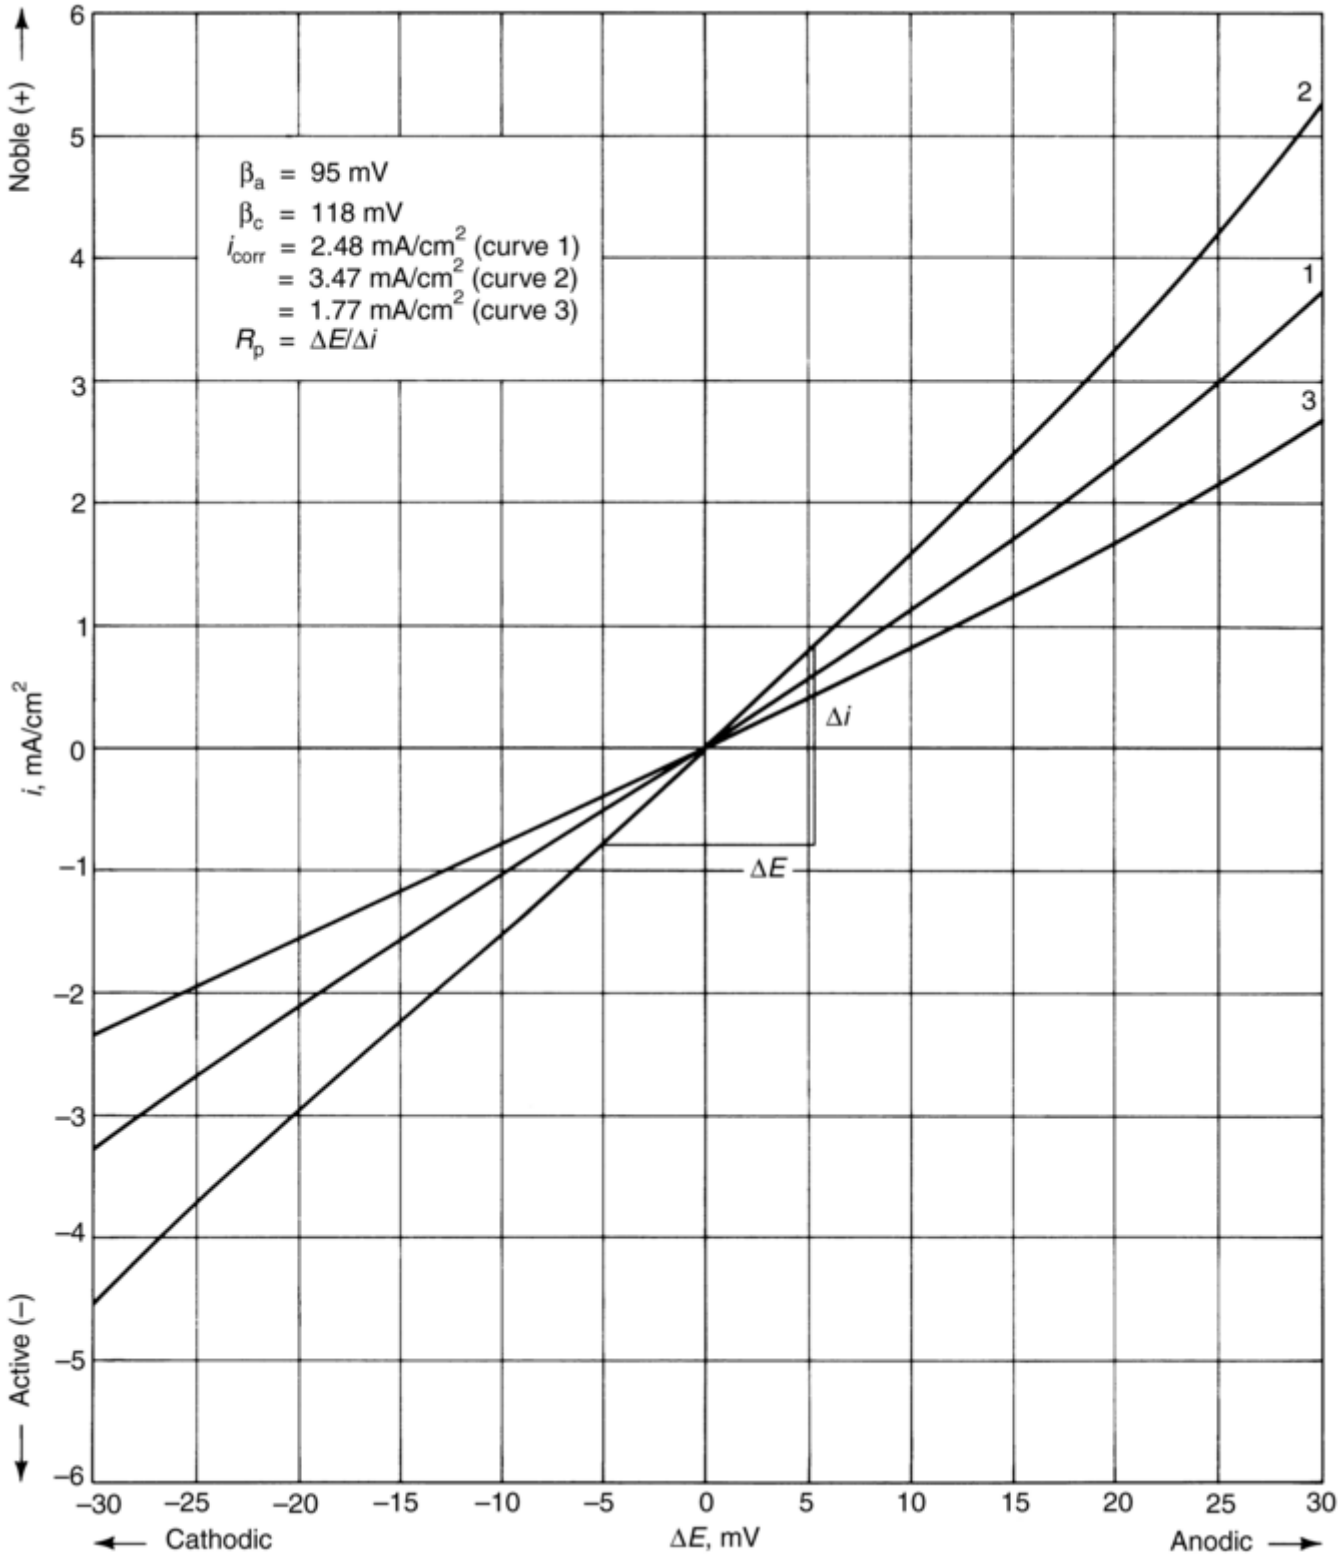

Fig. 3 ASTM G 59 polarization curves for polarization resistance measurements based on the results from eight independent laboratories for type 430 stainless steel in 1 *N* H_2SO_4. Curve 1 is the mean result, with curves 2 and 3 showing the 95% confidence limits. Source: Ref 21

This review focuses on corroding systems with different cathodic and anodic half-cell reactions. However, the concept of polarization resistance applies equally well to reduction-oxidation systems involving a single half-cell reaction. Here, the exchange current density, i_0, may be calculated from the polarization resistance, where R is the ideal gas constant, F is Faraday's constant, T is the temperature, and α_a and α_c are the anodic and cathodic multistep electron-transfer coefficients, respectively, for the reduction-oxidation process.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$R_n\left(\Omega \cdot \mathrm{cm}^2\right) = \left[\frac{\Delta E}{\Delta i}\right]_{(E - E_{rev}) \to 0} = \left(\frac{RT}{i_0 F\left(\alpha_a + \alpha_c\right)}\right)$$

Other techniques exploit nonlinearity at larger overpotentials that invalidate the approximation given by Eq 13 (Ref 34). The Oldham-Mansfeld method calculates i_{corr} from nonlinear E versus i_{app} data obtained usually within ±30 mV of E_{corr} using tangent slopes and intercepts to calculate corrosion rate without high overpotential determination of β_a and β_c (Ref 35). Computerized curve fitting can exploit nonlinearity to calculate β_a, and β_c from low overpotential data, avoiding the destructive nature of large overpotentials. The Mansfeld technique substitutes Eq 14 into Eq 7 eliminating i_{corr} (Ref 36). β_a and β_c are determined from the best fit of the resulting expression containing β_a and β_c as unknowns to a nonlinear plot of η versus $2.3 i_{app} R_p$. η versus i_{app} data are obtained within ±30 mV of E_{corr}. R_p is determined from the linear slope of E versus i_{app} within ±5 mV of E_{corr}. i_{corr} is subsequently determined from Eq 13 using the computed values of R_p, β_a, and β_c.

Complications with polarization resistance measurements, and possible remedies are reported in the literature (Ref 34, 35, 36, 37, 38, 39, 40). Three of the most common errors involve: (a) invalidation of the results through oxidation of some other electroactive species besides the corroding metal in question, (b) a change in the open-circuit or corrosion potential during the time taken to perform the measurement, and (c) use of a large η, invalidating the assumption of a linear relationship between i_{app} and E required by Eq 13 and 14.

Another source of error involves cases in which both the anodic and cathodic reactions are not charge-transfer-controlled processes, as required for the derivation of Eq 13. Modifications to Eq 7 exist for cases in which pure activation control is not maintained, such as in the case of partial diffusion control or passivation (Ref 41). Other researchers have attempted to calibrate the polarization resistance method with gravimetrically determined mass loss (Ref 42). In fact, polarization resistance data for a number of alloy- electrolyte systems have been compared to the observed average corrosion currents determined from mass loss via Faraday's law (Ref 32). A linear correspondence was obtained over six orders of magnitude in corrosion rates.

Two other frequently encountered complications are the need to correct polarization data for errors that arise from the contribution of solution resistance, R_s, and the addition of capacitive current, CdE/dt, which occurs with increasing scan rate (Ref 16). Capacitive current gives rise to hysteresis in current-potential plots (Ref 43). Solution resistance contributes to a voltage error as discussed previously, as well as a scan-rate error. Since the applied potential is increased by an ohmic voltage component, an apparent value of polarization resistance R'_P is obtained that overestimates R_p by an amount equal to R_s. Consequently, the corrosion rate is underestimated. Hysteresis in the current density-applied potential plot is brought about for combinations of high voltage scan rate and large interfacial capacitances as well as large polarization resistances. Attempting to determine R_p at too fast of a scan rate underestimates its true value, leading to an overestimation of corrosion rate. This error can be minimized by determining the polarization resistance at a slow scan rate or by extrapolating the results at several slow scan rates to zero scan rate. Alternatively, one may take two or more current-density measurements from potentiostatic data after long time periods near E_{corr} to minimize fast-scan-rate effects. These complications and others have been reviewed elsewhere (Ref 44).

Many treatments of this subject have used an electrical equivalent circuit model to simulate the corroding metal/electrolyte interface (Ref 1, 44, 45). The simplest form of such a model is shown in Fig. 4. The three parameters discussed previously (R_p, R_s, and C) that approximate a corroding electrochemical interface are shown. The algebraic sum of R_s and R_p is measured when a direct-current measurement is performed. The impedance associated with a capacitor approaches infinity as the voltage scan rate approaches 0, and parallel circuit elements are always dominated by the element with the smallest impedance. Therefore, the sum of R_s and R_p is measured. The true corrosion rate will be underestimated when R_s is appreciable. Conversely, any experiment conducted at a fast voltage scan rate causes the algebraic sum of the ohmic resistance and the resultant impedance of the parallel resistive-capacitive network to be measured. This value will be lower than the sum of R_p and R_s determined at an infinitely slow scan rate, as current leaks through the parallel capacitive element at higher scan rate due to its low impedance at high frequency. This will usually result in an overestimation of the true corrosion rate. These complications can be overcome by using the electrochemical impedance method.

Electrochemical Impedance Methods

One approach for determining the polarization resistance of a metal involves the electrochemical impedance (sometimes known as alternating current, or ac, impedance) method (Ref 2, 43, 44, 45, 46, 47). ASTM G 106, "Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements," contains an appendix reviewing the technique. In this technique, typically a small-amplitude sinusoidal potential perturbation is applied to the working electrode at a number of discrete frequencies, ω. ω is the angular velocity in rad/s, $\omega = 2\pi f$, where f is frequency in Hz. At each one of the discrete frequencies, the resulting current waveform will exhibit a sinusoidal response that is out of phase with the applied potential signal by a certain amount (Φ) and has a current amplitude that is inversely proportional to the impedance of the interface. The electrochemical impedance, $Z(\omega)$, is the frequency-dependent proportionality factor that acts as a transfer function by establishing a relationship between the excitation voltage signal and the current response of the system:

$$Z(\omega) = V(\omega)/i(\omega) \qquad \text{(Eq 15)}$$

where V is the time varying voltage across the circuit [$V = V_0 \sin(\omega t)$], i is the time varying current density through the circuit [$i = i_0 \sin(\omega t + \Phi)$], $Z(\omega)$ is the impedance ($\Omega \cdot cm^2$), and t is time (s),
$Z(\omega)$ is a complex-valued vector quantity with real and imaginary components whose values are frequency-dependent:

$$Z(\omega) = Z'(\omega) + jZ''(\omega) \qquad \text{(Eq 16)}$$

where $Z'(\omega)$ is the real component of impedance [$Z'(\omega) = |Z(\omega)| \cos(\Phi)$], $Z''(\omega)$ is the imaginary component of impedance [$Z''(\omega) = |Z(\omega)| \sin(\Phi)$], j is the imaginary number $\sqrt{-1}$, $|Z(\omega)|$ is the impedance magnitude, where $|Z(\omega)| = (Z'(\omega)^2 + Z''(\omega)^2)^{1/2}$.
The electrochemical impedance is a fundamental characteristic of the electrochemical system it describes. Knowledge of the frequency dependence of impedance for a corroding system allows a determination of an appropriate equivalent electrical circuit describing that system. Table 1 shows the transfer functions for resistors, capacitors, and inductors.

مرجع مهندسی مواد و متالورژی

Table 1 Linear circuit elements commonly used in electrochemical impedance

Circuit element	Impedance[(a)]
Resistor	$Z(\omega) = R$
Capacitor	$Z(\omega) = -j/\omega C$
Inductor	$Z(\omega) = j\omega L$

(a) ω is the frequency; $j = \sqrt{-1}$

Figure 4 illustrates the equivalent electrical circuit model for a simple case of an actively corroding metal. The impedance for that system can be described by:

$$Z(\omega) = R_s + \frac{R_p}{1+\omega^2 R_p^2 C^2} - \frac{j\omega C R_p^2}{1+\omega^2 R_p^2 C^2} \qquad \text{(Eq 17)}$$

where ω is the frequency of the applied signal where ω = 2π*f*(rad/s), *f* is the frequency of the applied signal [Hz(cycles/s)], *C* is the interfacial capacitance (F/cm^2). R_s is the solution resistance, and R_p is the polarization resistance.

The Bode magnitude and phase information of Fig. 5 and Eq 17 show that at very low frequencies:

$$Z_{\omega\to 0}(\omega) = R_s + R_p \qquad \text{(Eq 18)}$$

while at very high frequencies:

$$Z_{\omega\to \infty}(\omega) = R_s \qquad \text{(Eq 19)}$$

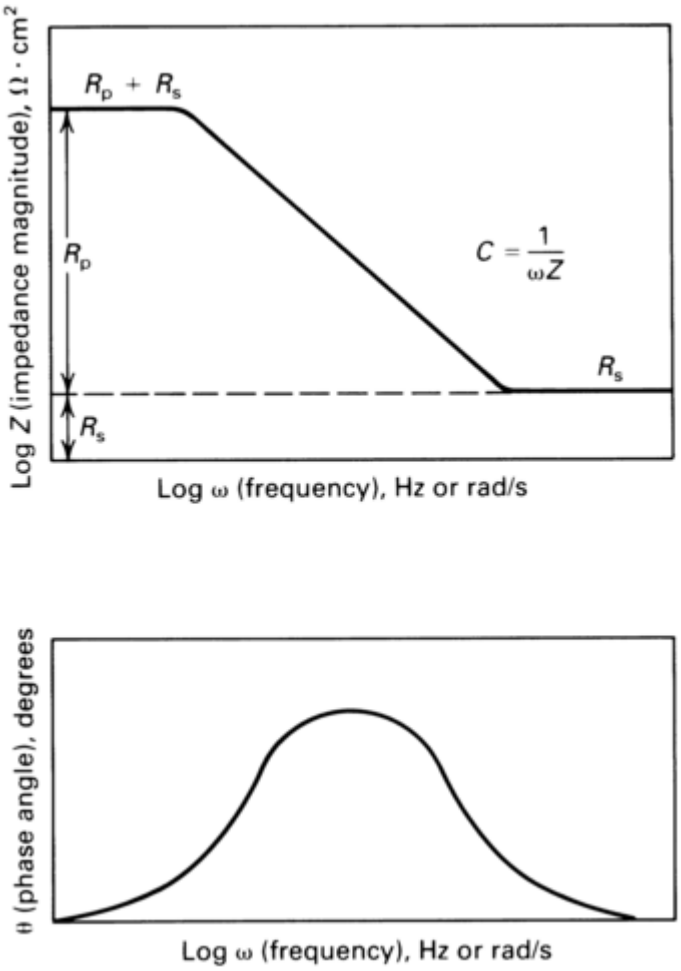

Fig. 5 Bode phase angle and magnitude plots demonstrating the frequency dependence of electrochemical impedance for the circuit model shown in Fig. 4

Determination of R_p is attainable in media of high resistivity because R_p can be mathematically separated from R_s by taking the difference between $Z(\omega)$ obtained at low and high ω($R_p = Z(\omega) \to 0 - Z(\omega) \to \infty$).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Determination of the corrosion rate using Eq 13 also requires knowledge of β_a, β_c and electrode area, A, which are not obtained in the impedance experiment (Ref 48). The minimum applied frequency required to obtain $R_s + R_p$ can be approximated by:

$$f_{min} < f_{bp} = \frac{1}{2\pi C\left(R_s + R_p\right)} \qquad \text{(Eq 20)}$$

where f_{bp} is the lower breakpoint frequency (Hz) is approximated by the point on the $\log|Z(\omega)|$ versus $\log f$ plot where the low-frequency plateau dominated by $R_s + R_p$ and the slope -1 region dominated by capacitance produce equal values of $Z(\omega)$, and f_{min} is the minimum test frequency (Hz) required according to Eq 20.

Since the magnitudes of C, R_s, and R_p are not known explicitly a priori, prudence dictates that f_{min} be selected as 0.1 to 0.5 of the estimated f_{bp}. Thus, large values of C, R_s, or R_p dictate that a low f_{min} is required to accurately obtain $R_p + R_s$ at $Z(\omega) \rightarrow 0$. One mHz is typically chosen as a reasonable initial choice of f_{min}, but it is obvious from Eq 20 that either a lower frequency may be required or a higher frequency permitted, depending on circumstances.

Either the anodic or cathodic half-cell reaction can become mass-transport limited and restrict the rate of corrosion at E_{corr}. The presence of diffusion-controlled corrosion processes does not invalidate the electrochemical impedance method but does require extra precaution and a modification to the circuit model of Fig. 4. In this case, the finite diffusional impedance is added in series with the usual charge-transfer parallel resistance shown in Fig. 4. The transfer function for the frequency-dependent finite diffusional impedance, $Z_D(\omega)$, has been described (Ref 49):

$$Z_D(\omega) = R_D\left[\frac{\tanh\sqrt{(j\omega s)}}{\sqrt{(j\omega s)}}\right] \qquad \text{(Eq 21)}$$

where $s = l_{eff}^2 / D$ where l_{eff} is the actual finite diffusion length and D is the diffusivity of the diffusing species that limits the interfacial reaction. The value of $Z_D(\omega)$ approaches the real component of diffusional resistance, R_D, as $\omega \rightarrow 0$. The frequency required to obtain R_D depends on the value of s. The larger the value of s, such as when l_{eff} is large or D is small, the lower the frequency required. R_p, defined as $[\partial E/\partial i_{app}]$ as $\omega \rightarrow 0$, is the sum of the charge-transfer-controlled, R_{ct} and diffusion-controlled, R_D, contributions to the polarization resistance assuming that $R_D + R_{ct} \gg R_s$; that is:

$$R_p = R_{ct} + R_D \qquad \text{(Eq 22)}$$

A very low frequency or scan rate may be required to obtain R_p defined by Eq 22 under circumstances where reactions are mass-transport limited as indicated by Eq 21. For instance, in the case where $l_{eff} = 0.1$ cm and $D = 10^{-5}$ cm^2/ s a frequency below 0.1 mHz is required to obtain R_p from $|Z(\omega)|$ at the zero-frequency limit. Hence, a common experimental problem in the case of diffusion-controlled electrochemical reactions is that extremely low frequencies (or scan rates) are required to complete the measurement of R_p. In the case where R_p is dominated by contributions from mass transport such that Eq 22 applies, the Stern approximation of Eq 13 and 14 must be modified to account for a Tafel slope for either the anodic or cathodic reaction under diffusion-controlled conditions (i.e., β_a or $\beta_c = \infty$). In fact, Eq 7 becomes invalid.

Similarly, a frequency above f_{max} must be applied to obtain R_s:

$$f > f_{max} = \frac{1}{2\pi C R_s} \qquad \text{(Eq 23)}$$

where f_{max} is the frequency required such that $Z(\omega)$ is dominated by R_s.

Typically, f must be in the kHz range to determine R_s. These issues equally plague time as well as frequency domain methods for obtaining R_p since in the time domain measurement, the triangle waveform is simply the Fourier synthesis of a series of sinusoidal signal functions.

The capacitance is also determined from the impedance technique. In many corroding systems, an interfacial capacitance associated with the electrified double-layer scales linearly with the true electrochemical surface area. An electrochemically based estimate of the surface area may be obtained if the area-specific capacitance is known or determined from a plot of C versus surface area (Ref 48).

A common issue in the use of impedance-derived capacitance concerns the use of constant- phase elements (CPE). The impedance associated with a CPE has been given by (Ref 50):

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$Z_{CPE}(\omega) = \left(\frac{1}{Y_0 (j\omega)^n} \right) \qquad \text{(Eq 24)}$$

Y_0 is the constant-phase-element parameter. (In the case of the impedance due to capacitance, the value of the capacitance C, is the parameter used; that is, $Y_0 = C$, in this expression, and $n = 1$). Y_0 and n are usually assumed to be frequency- independent parameters. The units for Y_0 are $s^n/\ \Omega$, while those for capacitance (C) are s/Ω. Hence, in the case of an ideal capacitor or resistor then $n = 1$ or 0, respectively, and either the magnitude of Y_0 equals the magnitude of C with the dimensions s/Ω or $1/Y_0 = R(\Omega)$. In the case of $n = 0.5$, an infinite diffusional impedance best describes the constant-phase element. At issue is the task of extracting physically meaningful parameters conveyed by the capacitance in the case of impedance data that are best represented in an electrical circuit model by a constant-phase element. Examples of such parameters extracted from ideal interfacial capacitance include electrode area in the case of a double- layer capacitance, surface coverage in the case of an adsorption pseudocapacitance, and dielectric constant or dielectric layer thickness in the case of a coating or oxide with dielectric properties. Other parameters may be extracted from capacitance associated with solid-state impedance experiments, but these are beyond the scope of this article. In the case where $n = 0.8$ to 0.99, the CPE is often treated as a nonideal capacitance value and attempts are made to extract physically meaningful parameters from the CPE data. One equation proposed to convert Y_0 into C is (Ref 51):

$$C = Y_0 \left(\omega''_{max} \right)^{n-1} \qquad \text{(Eq 25)}$$

where ω_{max} is the frequency where the imaginary component of impedance, Z'', is maximized. This frequency is independent of n. In an earlier approach, $C = Y_0(\omega)^{n-1}/\sin(n\pi/2)$ was suggested as a method for extracting capacitance, C, from Y_0 where ω was taken as the frequency where the phase angle was maximized (Ref 52). This method has the disadvantage that the exact value of ω associated with the phase angle maximum changes with the value of n.

Methods for Determining Aqueous Corrosion Reaction Rates

John R. Scully and Robert G. Kelly, University of Virginia

Frequency Modulation Methods

Both harmonic and electrochemical frequency modulation (EFM) methods take advantage of nonlinearity in the voltage-current (*E-I*) response of electrochemical interfaces to determine corrosion rate (Ref 53, 54, 55, 56). A special application of harmonic methods involves harmonic impedance spectroscopy (Ref 57). The EFM method uses one or more ac voltage perturbations in order to extract corrosion rate. The electrochemical frequency modulation method has recently been reviewed (Ref 58). In the most often used EFM method, a potential perturbation by two sine waves of different frequencies is applied across a corroding metal interface. The *E-I* behavior of corroding interfaces is typically nonlinear such that a potential perturbation in the form of a sine wave at one or more frequencies can result in a current response at the same and at other frequencies. The result of such a potential perturbation is various ac current responses at various frequencies such as zero, harmonic, and intermodulation. The magnitude of these current responses can be used to extract information on the corrosion rate of the electrochemical interface or conversely the reduction-oxidation rate of an interface dominated by redox reactions as well as the Tafel parameters. This is an advantage over linear polarization resistance and EIS methods, which can provide the $Z(\omega)$ and the polarization resistance of the corroding interface at $\omega = 0$, but do not uniquely determine Tafel parameters in the same set of data. Separate experiments must be used to define Tafel parameters. A special extension of the method involves harmonic impedance spectroscopy where the harmonic currents are converted to harmonic impedance values at various frequencies through knowledge of the magnitude of the ac perturbation.

In the EFM method, an ac voltage perturbation is applied at two frequencies, ω_1 and ω_2. As an example the voltage perturbation could be given as:

$$\eta = V_0[\sin(\omega_1 t) + \sin(\omega_2 t)] \qquad \text{(Eq 26)}$$

where $\eta = E - E_{corr}$ and V_0 is the magnitude of the voltage amplitude applied.

Harmonic current responses occur at ω_1, $2\omega_1$, $3\omega_1$, as well as at ω_2, $2\omega_2$, and $3\omega_2$, and so forth. Additionally, a current response can be seen at various intermodulation frequencies such as $2\omega_1 \pm \omega_2$ and $2\omega_2 \pm \omega_1$. Consider the application of this method to a charge-transfer-controlled corrosion process with an *E-I* response that behaves according to Eq 7. Under the assumption that $\omega_2 > \omega_1$ and $\beta_a < \beta_c$, the corrosion current density, i_{corr}, and Tafel parameters, b_a (where $b_a = \beta_a/\ln 10$) and b_c, can be determined from the equations summarized in Table 2. The current components at the angular frequency ω_1 or ω_2 can be measured at ω_1 or ω_2. The intermodulation components $\omega_1 \pm \omega_2$ can be determined from the signal response at $\omega_1 + \omega_2$ or $\omega_1 - \omega_2$ and so forth. The method is one of the few that enable extraction of corrosion rate and Tafel parameters directly from a single measurement (also see Ref 34 and 35). Currently, there are no ASTM standards for this technique.

Table 2 Governing equations for extraction of i_{corr}, as well as b_a and b_c from harmonic and intermodulation frequency data

Reaction type	Governing equation	Determination of i_{corr}	Determination of Tafel parameters
Charge-transfer-controlled Tafel behavior	$i_{app} = i_{corr}\left[\left(\exp\left\{\frac{2.303(E-E_{corr})}{\beta_a}\right\}\right) - \exp\left\{-\frac{2.303(E-E_{corr})}{\beta_c}\right\}\right]$	$i_{corr} = \frac{i_{\omega_1\omega_2}^{\ 2}}{2\sqrt{8i_{\omega_1\omega_2}i_{2\omega_2\pm\omega_1} - 3i_{\omega_2\pm\omega_1}^2}}$	$b_a = \frac{i_{\omega_1\omega_2}V_0}{i_{\omega_2\pm\omega_1} + \sqrt{8i_{\omega_1\omega_2}i_{2\omega_2\pm\omega_1} - 3i_{\omega_2\pm\omega_1}^2}}$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Passive or anodic mass-transport control	$i = i_{corr}\left[1 - \exp\left(\frac{-\eta}{b_c}\right)\right]$	$i_{corr} = \frac{i_{\omega_1,\omega_2}{}^2}{2i_{\omega_2 \pm \omega_1}}$	$b_c = \frac{i_{\omega_1,\omega_2}}{2i_{\omega_2 \pm \omega_1}} V_0$
Cathodic mass-transport control	$i = i_{corr}\left[\exp\left(\frac{\eta}{b_a}\right) - 1\right]$	$i_{corr} = \frac{i_{\omega_1,\omega_2}{}^2}{2i_{\omega_2 \pm \omega_1}}$	$b_a = \frac{i_{\omega_1,\omega_2}}{2i_{\omega_2 \pm \omega_1}} V_0$

Note that $b_a = \beta_a/\ln 10$, and $b_c = \beta_c/\ln 10$. Also, $i_{2\omega'_1\omega'_2}$ can be evaluated at $i_{2\omega'_1+\omega'_2}$ or $i_{2\omega'_1-\omega'_2}$; $i_{\omega'_1\omega'_2}$ can be evaluated at $i_{\omega'_1+\omega'_2}$ or $i_{\omega'_1-\omega'_2}$; $i_{\omega'_1}$, and $i_{\omega'_2}$ can be evaluated at $i_{\omega'_2}$ or $i_{\omega'_2}$. Electrochemical Noise Resistance

Electrochemical noise analysis can provide a parameter called the electrochemical noise resistance, R_n (Ref 59, 60, 61, 62, 63, 64, 65). This parameter should be used in a manner analogous to polarization resistance. One electrode configuration that enables such a measurement involves connecting a zero-resistance ammeter (ZRA) between two nominally identical corroding electrodes immersed in the same solution. A third, nominally identical electrode can be immersed in solution and connected to the first two using a high-impedance voltmeter. This electrode serves as a "noisy" pseudoreference electrode. This approach is attractive in field applications due to the more rugged nature of the metallic electrode compared to laboratory electrodes but complicates the analysis because two uncorrelated potential sources (i.e., from the couple and the

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

pseudoreference) are measured in the collection of potential noise, V_n. Since $V_{n(meas)} = (V^2_{n(couple)} + V^2_{n(pseudoref)})^{1/2}$, $V_{n(meas)}$ must be divided by $\sqrt{2}$(Ref 66), to yield $V_{n(couple)}$. Another alternative is a four-electrode arrangement where the first pair is coupled through a zero-resistance ammeter to monitor current and the second pair is connected with a high-impedance voltmeter to sample an uncorrelated $V_{n(couple)}$. Alternatively, a less noisy, conventional reference electrode may be utilized in the three-electrode arrangement. In this case, $V_{n(meas)}$ and $I_{n(meas)}$ are correlated. The reference electrode noise can be separately defined as the electrochemical voltage noise between two nominally identical reference electrodes (Ref 67). If the reference electrode noise is low, then the $\sqrt{2}$correction factor is not needed. In either case, the third electrode (reference electrode) is connected to the first two via a high-impedance voltmeter.

These arrangements enable simultaneous recording of the galvanic current with time and the galvanic couple potential versus time. The standard deviation of the voltage noise divided by the standard deviation of the current noise has been proposed to yield a statistical parameter called the noise resistance R_n (Ref 59, 60, 61, 62, 63, 64, 65, 66, 68). Analysis of simulated noise data has led to the conclusion that the ratio of the standard deviations of the current and voltage noises measured between two identical electrodes can be normalized by surface area by multiplying by $\sqrt{A_v A_i}$(Ref 65):

$$R_n\left(\text{ohm}\cdot\text{cm}^2\right) = \left[\frac{\sigma_{V(meas)}}{\sigma_{I(meas)}}\right]\sqrt{A_V A_I} \qquad \text{(Eq 27)}$$

where $\sigma_{V(meas)}$ is the standard deviation of the voltage noise, $\sigma_{I(meas)}$ is the standard deviation of the current noise, and A_v and A_I are the surface areas of the corroding electrodes used for voltage and current measurement, respectively. Correlations between this parameter and conventionally determined polarization resistance as well as mass-loss-based corrosion rates have been obtained (Ref 60, 66). Unfortunately, experimental confirmation of the area normalization factor has not been extensively performed. Recall that in the case of a polarization resistance determined from E-i_{app} data or EIS data at the zero-frequency limit, measured resistance can be multiplied by electrode area and will yield the same area-normalized polarization resistance over a broad range of electrode areas.

Moreover, the correlation has lacked a rigorous fundamental foundation for correlating R_n with corrosion rate despite the intuitive connection between σ_V and σ_I given by the proportionality factor R_n. The surface of one freely corroding electrode could be divided into area patches that experience fluctuations in interfacial resistance that produce changes in anodic and cathodic half-cell reaction rates in any one. The electrode potential must then change in each patch to drive the half-cell reactions such that the sum of all the anodic half-cell currents from all patches equals the sum of all cathodic half-cell currents, regardless of whether the source of cathodic half-cell current is from capacitive discharge or electrochemical reaction (Ref 64). Some global change in potential also occurs on the electrode. If the first electrode is now connected to a second electrode whose interfacial properties and global electrode potential do not change on their own at the same instant in time and by the same degree as on the first electrode, then a galvanic cell is momentarily created that induces a further difference in anodic and cathodic half-cell currents on the first electrode. Current now flows between the first and second electrode such that the sum of anodic and cathodic half-cell currents over all patches on both electrodes is equal. When the interfacial resistances return to normal values over all patches, the potential difference between the two electrodes is eliminated and so is the measurable current between the two electrodes. Bertocci argued that the external current fluctuation measured between two identical electrodes is identical to the fluctuation in one electrode (Ref 64, 65). Others have argued using concepts of mixed-potential theory that, at worst, the current sampled is only one-half of the total for equal-size electrodes.

Theoretical relationships establishing the connection between R_n and R_p have been sought by several researchers (Ref 65, 69, 70, 71, 72), but their validity has been questioned. A great concern has been that the largest current peaks would occur during the most rapid voltage fluctuations since the electrode interface contains a capacitance through which current can be shorted (Ref 64, 65). Thus, when voltage fluctuations are rapid, the measured noise current will be shorted through the interfacial capacitance assuming a simple electrical equivalent circuit model consisting of two parallel resistor-capacitor networks describing the interface for each electrode connected in series through R_s. This situation would lead to the lowest impedance between the two electrodes during the most rapid voltage fluctuations that, in turn, produce the greatest current fluctuations. The theoretical maximum measured current would be given by the voltage fluctuation divided by

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

R_s. The outcome would be a statistical noise-resistance parameter that is proportional to, or heavily influenced by, higher- frequency data. Indeed, R_n was found to equal an absolute impedance at some frequency that depended on the frequency of the voltage fluctuations and the RC time constant of the electrode interface in one study of simulated noise (Ref 64). Unfortunately, a R_n value obtained at high frequency would be smaller in magnitude than the R_p obtained at the zero-frequency limit. Hence, it would not represent the desired zero-frequency limit interfacial resistance, R_p. Indeed, such underestimations in the true value of R_p have been observed experimentally (Ref 66, 68).

Recently, a more rigorous theoretical and experimental analysis has been made comparing the spectral noise resistance obtained at each frequency with both the polarization resistance obtained from the zero-frequency limit of impedance magnitude data, $|Z(\omega = 0)|$, as well as the frequency-dependent impedance of two electrodes (Ref 73, 74, 75, 76, 77). The spectral noise resistance $R_{sn}(\omega)$ was determined by taking the square root of power spectral density of the voltage noise $(V^2/Hz)^{1/2}$ and dividing it by the square root of power spectral density of the current noise $(A^2/\ Hz)^{1/2}$ at each frequency using the same two- electrode arrangement as discussed previously (Ref 76, 77):

$$R_{sn}(\omega) = \frac{\sqrt{(V_{PSD})}}{\sqrt{(I_{PSD})}} \qquad \text{(Eq 28)}$$

$R_{sn}(\omega)$ is proportional to the magnitude of the cell impedance, $|Z(\omega)|$ in the two-electrode arrangement (Ref 76, 77). The proportionality factor is unity in the case of identically sized electrodes in a two-electrode cell with identical impedances and a noiseless reference electrode (Ref 76, 77). Therefore, the spectral noise resistance at the zero-frequency limit could equal the interfacial impedance at the zero-frequency limit $|Z(\omega = 0)|$ in the theoretical case of identical electrode impedances with negligible R_s. Figure 6 gives data for identical iron electrodes in 1 *M* Na_2SO_4 with an iron reference electrode. Here $R_{sn}(\omega) = \sqrt{3}|Z(\omega)|$ due to the noisy reference electrode. Thus $2|Z(\omega)|$ and $R_{sn}(\omega)$ appear to be similar. It is well known that in many instances $|Z(\omega = 0)|$ equals R_p. Even R_n may equal $R_{sn}(\omega = 0) = |Z(\omega = 0)| = R_p$ if $|Z(\omega)|$ equals R_p in the frequency regime dominating the R_n value. The frequency range dominating the R_n value is determined by several factors, but this statement is more likely to be true if $|Z(\omega)|$ and $R_{sn}(\omega)$ both exhibit long low-frequency plateaus over a broad frequency range that encompasses the f_{min} and f_s utilized in the R_n measurement. Here f_{min} is given by the total sampling time, T, where $f_{min} = 1/T$ and f_s equals the data sampling rate. R_n typically varies with f_s and underestimates $|Z(\omega = 0)|$. Unfortunately, $R_{sn}(\omega \rightarrow 0)$ does not equal R_p in the zero-frequency limit under many other conditions, such as when $\log (R_s/R_p) > 0$ or in the case of very noisy reference electrodes (Ref 76, 77). Moreover, $R_{sn}(\omega)$ can be dominated by the properties of the high-impedance electrode in the case of dissimilar electrode impedances that are equally noisy, but this is not always the case. For instance, the low-impedance electrode in a two- electrode cell with a third reference electrode can be sensed by $R_{sn}(\omega)$ if the higher impedance electrode is much noisier than the low-impedance electrode (Ref 76, 77). Recent attempts have been made to address circumstances where $R_{sn}(\omega)$ lies in between $|Z(\omega)|_1$ and $|Z(\omega)|_2$ representing the high- and low-impedance electrodes. Methods have been suggested for sensing the current fluctuations on both electrodes (Ref 72). The reader is referred to these articles for more information.

Methods for Determining Aqueous Corrosion Reaction Rates

John R. Scully and Robert G. Kelly, University of Virginia

Electrochemical Methods for the Study of Galvanic Corrosion Rates

Methods Based on Mixed-Potential Theory. The thermodynamic tendency for galvanic corrosion may be determined from the electromotive series (Ref 4, 5) or from the construction of a galvanic series (Ref 79), as discussed in ASTM G 82, "Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance." Galvanic corrosion rates can also be determined from mixed-potential theory as shown in Fig. 7. In the case of bimetal or multimetal galvanic attack in which two or more metals are electrically in contact with one another, there is in theory a minimum of two cathodic and two anodic reactions. One of each of these reactions is occurring on each metal. In this case, the more noble of the two metals is cathodically polarized, and its anodic reaction rate will thus be suppressed. Conversely, the less noble or anodic material is anodically polarized, and the anodic reaction rate is accelerated. The mixed potential (the galvanic couple potential, E_{couple}) of the galvanic couple and the resulting galvanic current can be uniquely determined from the sums of all of the individual anodic and cathodic currents obtained for each material at each potential when:

$$\Sigma i_a A_a = \Sigma i_c A_c \text{ at } E_{couple} \qquad \text{(Eq 29)}$$

where i_a and i_c are the anodic and cathodic current densities ($\mu A/cm^2$), respectively, and A_a and A_c are the anodic and cathodic areas (cm^2).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

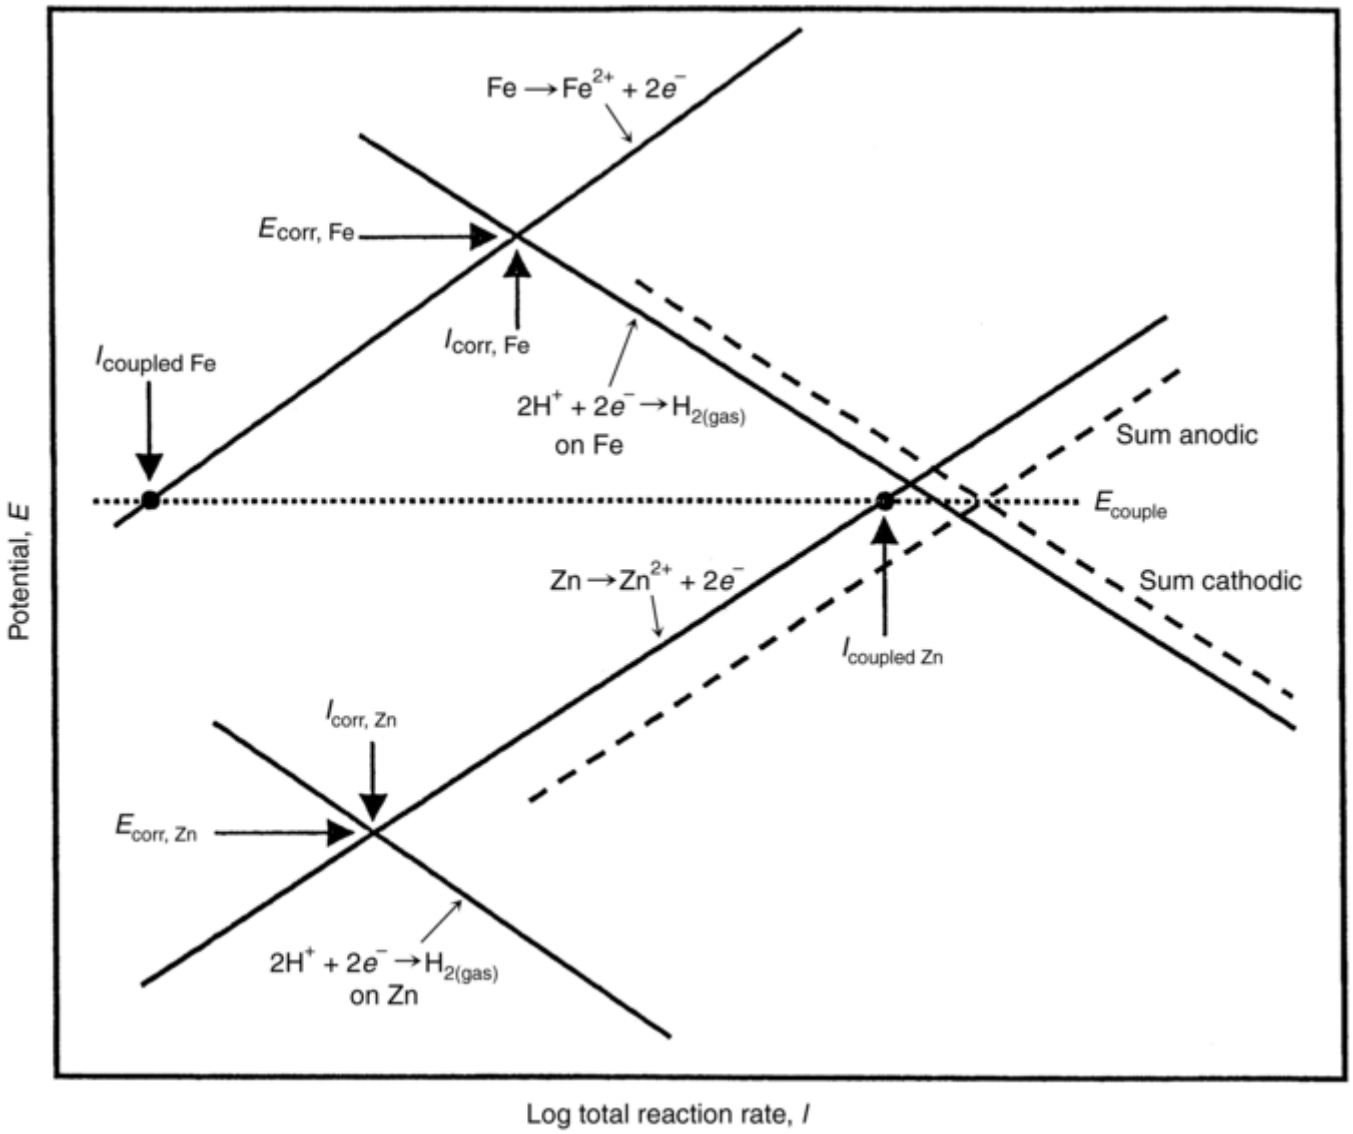

Fig. 7 Potential-current relationships for the case of a galvanic couple between two corroding metals. Iron is the more noble metal; zinc is less noble metal.

The galvanic couple potential is defined by the potential where the sum of the anodic currents equals the sum of the cathodic currents for all of the reactions on all of the metals in the couple. The galvanic couple potential can be determined either by direct measurement with a reference electrode or from polarization data if: (1) polarization data are available for each material in the galvanic couple, (2) the area of each metal is known, and (3) the current distribution is uniform. Once E_{couple} is determined, the galvanic corrosion rate may be estimated for the metal of interest in the couple if a relationship such as given in Eq 7 is known for that metal. In simple bimetal cases, direct superposition of polarization data (corrected for wetted surface area) yields E_{couple} and the galvanic corrosion rate (Ref 79). However, because applied currents instead of true anodic or cathodic currents are measured in any polarization experiment, the E-log(I) superposition technique will introduce the least error when the cathodic reduction reaction rate on the anode is negligible and the anodic oxidation reaction rate on the cathode is negligible at the galvanic couple potential. Obviously, when the open circuit potential OCPs of the anode and cathode are similar, error is more likely. Fortunately, galvanic corrosion may be less significant in these cases. In addition, special care must be taken in the procedures used to develop the polarization data (Ref 79), especially if time effects are to be taken into consideration when evaluating long-term galvanic corrosion behavior.

Direct Measurement of Galvanic Corrosion Rates. A more straightforward procedure involves immersing the two dissimilar metals in an electrolyte and electrically connecting the materials together using a zero-resistance ammeter to measure the additional galvanic current (Ref 9, 80, 81). In this method, the galvanic current is directly determined as a function of time. The galvanic corrosion rate so determined is the additional corrosion

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

created with the couple and will not equal the true corrosion rate. This is given by the sum of the galvanic corrosion rate and the corrosion rate under freely corroding conditions unless the latter is negligible. Recall that the corrosion rate of the uncoupled anode is undetermined by this method since an equal cathodic reaction rate is occurring on the same surface. A reference electrode connected to the galvanic couple can be used to determine the galvanic couple potential. ASTM standards do not exist for direct, mixed-potential theory, or scanning potential probe methods.

Potential probe methods may be used to determine and map the local ionic currents associated with galvanic corrosion cells between dissimilar metals or heterogeneities on complex alloy surfaces (Ref 82, 83, 84, 85). In the most straightforward application, the local potential is mapped over a planar electrode oriented in the *x-y* plane to give an indication of local current. The basic concept is that the ionic current density in three dimensions can be mapped by either scanning an array of reference electrodes or by vibrating a single electrode. The orthogonal ionic current flow can be expressed in terms of solution conductivity and the gradient in potential in the solution above the galvanic couple:

$$i = -\kappa(\nabla E) \qquad \text{(Eq 30)}$$

where κ is the solution conductivity and $\nabla E = \delta_1 dE/dx + \delta_2 dE/dy + \delta_3 dE/dz$ where *x*, *y*, and *z* define axes in a coordinate system and δ_1, δ_2, and δ_3 are unity vectors. The advantage of the vibrating technique is that minor differences between the reference potential of separate electrodes is eliminated by using a single vibrating reference electrode. The ionic current density so recorded is the component of current density flowing perpendicular to isopotential lines in solution established due to the galvanic couple and the established potential gradient. Therefore, a map of local current can be constructed by scanning over a planar electrode in the *x-y* plane, where *z* is the vertical distance in the solution above the electrode. Locations of high local current imply significant galvanic interactions.

Methods for Determining Aqueous Corrosion Reaction Rates

John R. Scully and Robert G. Kelly, University of Virginia

Electrochemical Methods for the Definition of Conditions Where Corrosion Rates Are High

Pitting and crevice corrosion are associated with the local breakdown of passivity, often in halide-containing solutions (Ref 86). Passive corrosion rates are often very low and are not discussed further. Localized corrosion occurs at rates an order of magnitude greater than the rates during passive dissolution. Therefore, it is often of great interest to determine the conditions under which localized corrosion occur instead of the exact propagation rates, which are usually intolerable. Electrochemical tests for evaluating the susceptibility of a material to pitting and to crevice corrosion include potentiodynamic, potentiostatic, scratch potentiostatic, potentiostaircase, tribo-ellipsometric methods, pit-propagation rate curves, galvanostatic, and electrochemical noise measurements (Ref 87, 88). These methods identify critical potential, temperature, and environmental conditions associated with the thresholds between low rates (e.g., passive dissolution at 1 $\mu A/cm^2$ or less than 1 mpy depending on alloy) and high rates of corrosion (e.g., locally as high as 1 A/cm^2). Two critical potentials of significant importance are the breakdown (E_{bd}) and protection (E_{prot}) or repassivation potential. The former is the potential at which pits or crevices develop or become stabilized. The latter is often defined as the least noble potentials at which pits, once formed, will propagate. Below this potential, pits repassivate. A simple potential-based criterion for local corrosion is the comparison of E_{corr} with such a threshold potential associated with breakdown of passive films. A useful concept for safety against the transition to local corrosion is that $E_{corr} \ll E_{bd}$ and E_{prot} where E_{bd} is often associated with stabilization of local corrosion and E_{prot} is associated with repassivation. When this situation exists, the chance of local high-rate corrosion processes is often low. Therefore, it is important to determine these two potentials.

Cyclic Potentiodynamic Polarization Methods to Determine E_{bd} and E_{prot}. ASTM G 61 (Ref 89) describes a procedure for conducting cyclic potentiodynamic polarization measurements to determine relative susceptibility to localized corrosion. The method is designed for use with iron- or nickel-base alloys in chloride environments. In this test, a cyclic anodic polarization scan is performed at a fixed voltage scan rate. Figure 8(a) shows the cyclic potentiodynamic method. Particular attention is focused on two features of cyclic polarization behavior (Fig. 8a). The first is the potential at which the anodic current increases significantly with applied potential (the breakdown potential, E_{bd}). In general, the more noble this potential, obtained at a fixed scan rate in this test, the less susceptible the alloy is to the initiation of localized attack. The second feature of great interest is the potential at which the hysteresis loop is completed during reverse polarization scan after localized corrosion propagation. This potential is often taken as the repassivation potential or protection potential, E_{prot}. In general, once initiated, localized corrosion sites can propagate only at some potential more positive than the potential at which the hysteresis loop is completed (when determined at a fixed scan rate). In other words, repassivation will occur at more negative potentials even after localized corrosion initiation. Therefore, the more positive the potential at which the hysteresis loop is completed, the less likely that localized corrosion will propagate. ASTM G 61 (Ref 89) discusses cyclic polarization behavior for Hastelloy C-276 and 304 stainless steel in 3.5% sodium chloride solution. Based on this criterion, it is evident that Hastelloy C-276 is more resistant to localized corrosion in this environment than AISI 304 stainless steel.

(c) Potentiostatic current-time curve for a previously passivated surface which pits at $E_1 < E_{BD} < E_2$. (d) Potentiostatic current-time curve for active surface. The protection potential is found as $E_3 < E_{prot} < E_2$. Source: Ref 86

Complications with Cyclic Potentiodynamic Polarization Methods. Although the cyclic method is a reasonable method for screening variations in alloy composition and environments for pitting susceptibility, the cyclic potentiodynamic polarization method has been found to have a number of shortcomings (Ref 87, 88, 89, 90, 91, 92). One major problem concerns the effect of the potential scan rate. The values of both E_{bd} and E_{prot} are a strong function of the manner in which the tests are performed, particularly the potential scan rate employed. Experimental values of E_{bd} are linked to the induction time required for pitting. Another complication arises from allowing too much pitting propagation to occur before reversing the scan direction. This either alters the localized chemistry in pits, affects pit depth, or both. Pit depth alters the diffusion length associated with the dilution of pit chemistry necessary for repassivation. This factor affects the polarization behavior after the reversal in the direction of scanning and influences E_{prot}. From an engineering standpoint, metal surfaces held at potentials below the repassivation potential of the deepest pits should be safe against stable pit propagation.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

That is to say, stable pits should not propagate. It has been found that E_{bd} observed after potentiostatic holds or the slowest scan rates approaches the protection potential found after minimal pit growth (Ref 92). This suggests the existence of a single critical potential for pit growth in the absence of crevices or other occluded sites (Ref 92).

Potentiostatic and Galvanostatic Methods for Localized Corrosion. The shortcomings of the cyclic potentiodynamic polarization method have become the basis for several other electrochemical techniques. Other methods are shown in Fig. 8. In the galvanostatic or galvanostaircase technique (Fig. 8b), potential is measured versus time at various constant applied currents that are incrementally increased in steps, then reversed, and decreased. In the case of passive materials, a potential rise during galvanostatic testing indicates passive film growth, while a decline indicates breakdown and growth of local corrosion sites. In the galvanostaircase technique, the current is step increased. Potential measurements are made until the time rate of change in potential approaches 0. These forward and reverse potential-current density data are extrapolated to the zero current density to obtain E_{bd} and E_{prot}. The technique is described by ASTM G 100 "Standard Test Method for Conducting Cyclic Galvanostaircase Polarization Tests" (Ref 93) as a test method for aluminum alloys. Potentiostatic methods can overcome the inherent problems involving scan rate. A more conservative estimate of E_{bd} can be obtained by polarizing individual samples for long periods of time at potentials above and below the values of E_{prot} and E_{bd} previously determined from the potentiodynamic method (Fig. 8c). Eventual initiation is indicated by a current increase. In another approach (Fig. 8d), initiation of pits is intentionally induced by applying a "stimulation" potential well above E_{bd} and then quickly shifting to a preselected potential below that value. If this second applied potential is above E_{prot}, propagation of the existing pits will continue and the current will increase. However, at potentials less than E_{prot} the pits will eventually repassivate and the current will subsequently decrease with time. The critical potential for pitting is defined as the most noble potential at which pits repassivate after the stimulation step. This approach is covered in ASTM F 746 "Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials" (Ref 94).

Determination of E_{prot} by Potential Step- Down or Scan-Down Methods. As stated previously, E_{bd} and E_{prot} often depend strongly on the method by which they are determined and, therefore, do not uniquely define intrinsic material properties. The E_{prot} values determined from the scanning method can be complicated by scan rate, pit size or depth, vertex potential/ current, polarization curve shape, and specimen geometry (Ref 95, 96). Some investigators have found more consistent E_{prot} values after a critical charge has passed, while others report a single critical potential (Ref 92). Often this potential is difficult to determine and has been taken at various points of the polarization curve (Ref 98).

What is needed is a method for determination of E_{prot} that defines a conservative value of this potential that likely reflects a true pit or crevice repassivation potential. Tsujikawa has developed a method for determination of E_{prot} from previously grown pits and crevices (Ref 99, 100). This method and its variations have been successfully used by several research groups and associates the critical potential for repassivation E_{prot} with the need to grow local corrosion sites to a critical minimum size (Ref 101). The method is an enhancement of the determination of E_{prot} from potentiodynamic *E-I* scans that involve scan reversal to the point where pits are repassivated. In the potential step-down method, the potential is first set at a high enough value to induce and grow stable pits to the specified size. The potential can then be stepped down or scanned downward while the pit propagation current is recorded. Subsequently, the potential may be held after initiating a pit in order to determine the time until repassivation (Ref 102). Moreover, long potential holds at selected applied potentials enables confirmation of a true repassivation potential often indicated by an abrupt decrease in current density at the time when the chemical conditions favoring pit stability (often expressed as some fraction of the salt-saturation concentration) are no longer maintained. Abrupt transitions in finite repassivation time toward infinity with increasing hold potential may indicate that conditions favorable to pit growth are sustained. Another benefit of determining E_{prot} from controlled growth of pits and crevices is that the repassivation potential can be determined from pits of preselected sizes that can be controlled by the duration of the potential holds. The method has been successfully applied to nickel-base alloys, stainless steels, and aluminum-base alloys. This method is being standardized by the committee for Japanese Industrial Standards. When a one-dimensional pit or pencil electrode is tested, the pit propagation kinetics can be recorded from a single pit (Ref 103). Whether pit growth is ohmic, mass transport, or charge-transfer controlled may also be determined. Moreover, the effects of various material and solution parameters (e.g., flow rate, conductivity, and solution composition) on pit propagation can be determined.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The Scratch-Repassivation Method for Localized Corrosion. One additional potentiostatic technique to be mentioned in the area of localized corrosion involves the scratch method (Ref 96). In this method, the alloy surface is scratched at a constant potential and the current is measured as a function of time. The potential dependencies of the induction time and the repassivation time are determined by monitoring the current change over a range of different potentials. This is shown in Fig. 9. From this information the critical pitting potential, thought to be less than E_{bd} determined by potentiodynamic scan, can be found. Other methods of studying localized corrosion are also available (Ref 86).

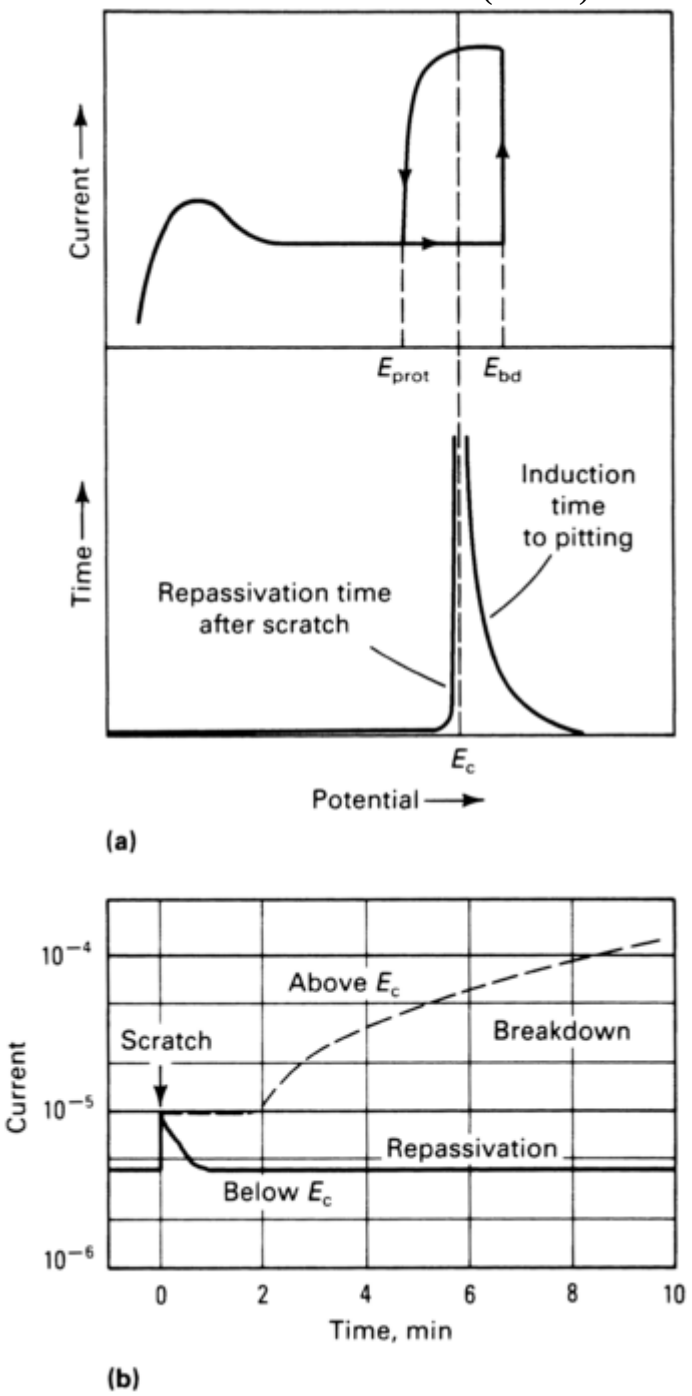

Fig. 9 Potential versus time plot of scratch test illustrating a possible location of the critical potential, E_c, as it relates to the induction time and the repassivation time. Source: Ref 86

Statistical Distributions in Critical Potentials. E_{bd} is typically observed to be a significantly "statistically distributed" property compared to the repassivation potential. This is often observed when critical potentials are determined by potentiodynamic scanning, but can be observed during potentiostatic tests where the pit incubation time and subsequent survival probabilities are also seen to be distributed. E_{prot} distributions are often attributed to distributions in pit size. However, E_{prot} is not distributed when pits are uniformly large (Ref 97)

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

and may not depend on the depth of corrosion damage at all during crevice corrosion when a crevice former controls mass transport (Ref 104). Statistical distributions in pitting potentials have been observed for AISI 304 (Ref 105), Fe-Cr-*X* (where *X* = niobium, molybdenum, or titanium) alloys (Ref 106), AISI 316 (Ref 107), titanium (Ref 108), high-purity aluminum (Ref 109), 2024-T3 (Ref 110), and amorphous aluminum-base alloys (Ref 111). This means that significant variations are seen when a number of specimens are tested under identical conditions. These distributions have been attributed to the stochastic nature of pitting (Ref 107), distributions in oxide-film cation vacancy transport properties (Ref 112), the effects of potential on the nature of the eligible sites for the metastable pit nucleation process (Ref 105), and the population of fatal flaws or pit initiating defects on an electrode surface (Ref 113). The possibility that oxide defects at densities exceeding millions of sites/cm^3 produces specimen-to-specimen variations appears unlikely for specimens with surface areas of the order of a few cm^2. It appears to be more reasonable to expect that sample-to-sample variations are, instead, associated with distributions in the population of micrometer-scale defects such as sulfide inclusions in stainless steel (Ref 114) and constituent particles in aluminum alloys (Ref 112) that control pit nucleation intensity and produce micropit-to-micropit variations in growth rates and transport characteristics (e.g., D_{eff}, pit shape) for a large population of metastable pits grown at a single potential. A statistical distribution of peak I_{pit}/r_{pit} ratios (where I_{pit} is the peak pit current and r_{pit} is pit radius) was observed for a large population of pits at a fixed potential in high-purity aluminum (Ref 109). Although not rigorously proven, it is reasonable to argue that a slightly lower D_{eff} or slightly larger I_{pit}/r_{pit} ratio for a given pit might lead to pit stabilization at differing applied potentials on an electrode with its own unique population of metastable pits. Moreover, such behavior is likely controlled by micrometer- scale defects spaced at tens of micrometer lateral separation distances across planar electrode surfaces. Investigators who seek information on critical potentials for engineering use should consider appropriate specimen sizes relative to critical defect densities and spacings. There are no ASTM standards that address these issues. However, the size of test specimens recommended in many ASTM standards is conservatively large, leading to conservative values of E_{bd}.

Electrochemical noise (EN) methods are used increasingly as a nondestructive tool for evaluating susceptibility to localized corrosion as well as stress-corrosion cracking (SCC), particularly in field or process plant applications (Ref 115, 116, 117, 118, 119, 120). Electrochemical noise methods are appealing because they may be conducted at open circuit without perturbing the corroding system. However, no consensus currently exists as to the most appropriate test procedure or analysis method, or how well results correlate with coupon exposures. The transient development of bare metal at newly formed pit or cracking sites as a result of temporary propagation and repassivation can result in potential noise (open-circuit EN), current noise (potentiostatic EN), or both. In the latter case, the current noise is measured with a zero-resistance ammeter (ZRA) used to monitor a galvanic couple consisting of two identical electrodes while the potential noise comes from the reference electrode (or third metallic electrode) monitoring the couple potential. The noise signal, hereafter referred to as a potential or current time record, is caused by the galvanic couple formed between the very small anode sites corroding at current densities approaching 10 A/cm^2 in pitting corrosion and the much larger remaining cathode surface operating at lower cathodic current densities (e.g., 10 μA/ cm^2). Regarding pitting phenomena, a negative shift in measured potential is observed (OCP and galvanic couple EN), an increase in current is observed for potentiostatic EN, and current fluctuations of either polarity are observed for galvanic couple EN.

Several analysis methods exist including electrochemical (Ref 121), statistical (Ref 119, 120), spectral (Ref 115, 116, 117, 118, 119, 120, 121), and autocorrelation (Ref 117). Some of the approaches for determination of spectral noise resistance during uniform corrosion are discussed in the section on polarization resistance. Electrochemical analysis may also enable the determination of pit sizes from the charge associated with each pitting event (Ref 109) or from attempting to determine pit current densities. Statistical analyses include determining the root mean square (rms), variance, and standard deviations of the EN voltage or current time records, as well as a noise resistance, R_{EN}, taken as the ratio of the rms or standard deviation of the potential and current time records acquired over various periods of time (Ref 105). Spectral analysis consists of Fourier transformation of EN data acquired in the time domain to create a power spectral density plot (Ref 117, 118, 120, 122). Qualitative assessment of the benefits of inhibitors or the effects of process stream variations are made possible by comparing statistical or spectral results. Quantitative analysis and predictive capability still require further development.

Use of Shot Noise Methods During Pitting. In the prepitting stage, multiple subcritical pitting events are often observed. The current time record shows exponential decaying or rising transients associated with discrete

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

pitting events. In many systems, these prepitting events occur at potentials far more negative than E_{bd} and sometimes E_{prot}. Numerous investigators have proposed that the ratio of peak pit current to pit radius during metastable pitting or product of pit current density times pit radius (I_{pit}/r_{pit} or $i_{pit} \cdot r_{pit}$) provides an insightful parameter that can be used to characterize the risk of stable pit propagation based on the critical acidified chemistry theory of Galvele (Ref 123).

When anodic current is monitored near the pitting potential, multiple overlapping metastable pitting events are often detected as current spikes at potentials just below E_{bd}. Electrochemical noise analysis provides one method for extracting information on pitting from such complicated current time records. That is, the power spectrum for a population of spikes of similar amplitude and duration is the sum of the spectra for each spike and should have the same shape as an individual spike. It has been proposed to use shot noise analysis to calculate the pit charge from power spectral density (PSD) obtained from a current-time record (Ref 124, 125, 126). According to this approach, pit charge, q_{pit}, and through Faraday's Law the pit radius, r_{pit}, for the pit events that dominate the current time record, can be determined from the PSD of a pitting current noise spectrum. The PSD of current fluctuations for the case of randomly occurring, exponentially decaying current spikes associated with metastable pitting events during the prepitting stage can be described by (Ref 123):

$$\frac{I^2}{\Delta f} = \left[\frac{2 q_{pit} I_{mean}}{1 + (2\pi f \tau)^2} \right] \qquad \text{(Eq 31)}$$

where f is the spectrum frequency, Δf is the frequency resolution given by the data acquisition frequency divided by the number of data points collected, q_{pit} is the pit charge, I_{mean} is the mean current from a *I-t* record containing multiple current fluctuations associated with pit events after subtraction of any background passive current, I is the amplitude of pit current fluctuations, and τ is the time constant for individual exponentially decaying current transients that comprise the current fluctuations. Hence, the low-frequency limit of a log $I^2/\Delta f$ versus log f plot provides information on q_{pit} for known I_{mean}. The frequency of the intercept (or breakpoint frequency) of the sloping part of the high- frequency PSD with the low-frequency plateau, f_{bpt}, provides information on the time constant for exponentially decaying pitting events, τ; $f_{bpt} = \frac{1}{2}\pi\tau$. Therefore, q_{pit} and τ_{pit} may be extracted from current PSD plots constructed from current-time data containing many overlapping metastable pitting events. This has been successfully done for aluminum alloys (Ref 127, 128). Unfortunately, the approach has its shortcomings. The parameters recovered are heavily biased toward smaller, more numerous pitting events that dominate the current time record. The biggest and/or fastest growing pits that might readily form stable propagating pits may not be detected. However, the method does enable determination of pit sizes at various potentials and allows the comparison of one environment, temperature, or set of plant conditions to another. No ASTM standard currently exists on this topic.

Methods for Determining Aqueous Corrosion Reaction Rates

John R. Scully and Robert G. Kelly, University of Virginia

Evaluation of Intergranular Corrosion Rates

Most methods of evaluating intergranular corrosion test for susceptibility as opposed to intergranular corrosion rate. There are many acid-exposure-type tests that rely on visual and metallographic examination to evaluate susceptibility. One example of an electrochemical test that examines susceptibility is described in this section. Stainless steel alloys that exhibit susceptibility can be expected to experience high rates of intergranular corrosion in certain service environments.

Evaluation of Alloy Sensitization. Measurement of the coulombs generated during the electrochemical polarization of a material from the passive range to the active corrosion potential can be used to quantify the susceptibility to intergranular attack associated with the precipitation of chromium carbides and chromium

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

nitrides at grain boundaries (Ref 129, 130, 131). The method is described by ASTM G 108 (Ref 132). A modification of this procedure, called the double-loop electrokinetic repassivation test (Ref 133, 134), involves a potentiodynamic polarization of the metal surface initially from the open-circuit potential in the active region to a potential in the passive range. This is immediately followed by a reverse polarization in the opposite direction back to the open-circuit potential. The second method is less dependent on surface finish and precise knowledge of the grain size. Both variations of the method are shown in Fig. 10. In the latter method, the degree of sensitization is determined by the ratio, (I_r/I_a), of the maximum current generated in the reactivation, I_r, or reverse scan compared to that generated in the initial anodic scan, I_a. The procedure is contingent on the presence of anodic current during the reactivation scan that results mainly from incomplete passivation of the zone adjacent to the grain boundaries that is depleted of chromium due to carbide precipitation at grain boundaries. For nonsensitized material, the passive film remains essentially intact during the reverse scan and the magnitude of the reactivation polarization peak remains small. For the same reasons, the charge Q (obtained from integration of current versus potential for a known voltage scan rate) in the single-loop method is small for nonsensitized material. As a refinement to the method the charge is normalized by the grain- boundary area (GBA) because this is the area from which most of the current arises in the single reactivation scan (Ref 131):

$$P = Q/GBA \quad \text{(Eq 32)}$$

$$GBA = A_s\left[5.09544 \times 10^{-3} \times \exp\left(0.34696 \times GS\right)\right] \quad \text{(Eq 33)}$$

where P is the reaction charge density associated with the sensitized area (coulombs/cm^2), A_s is the wetted specimen surface area, GBA is the grain-boundary area, and GS is the ASTM grain size in accordance with ASTM E 112, “Test Methods for Determining the Average Grain Size.”

www.iran–mavad.com
مرجع مهندسی مواد و متالورژی

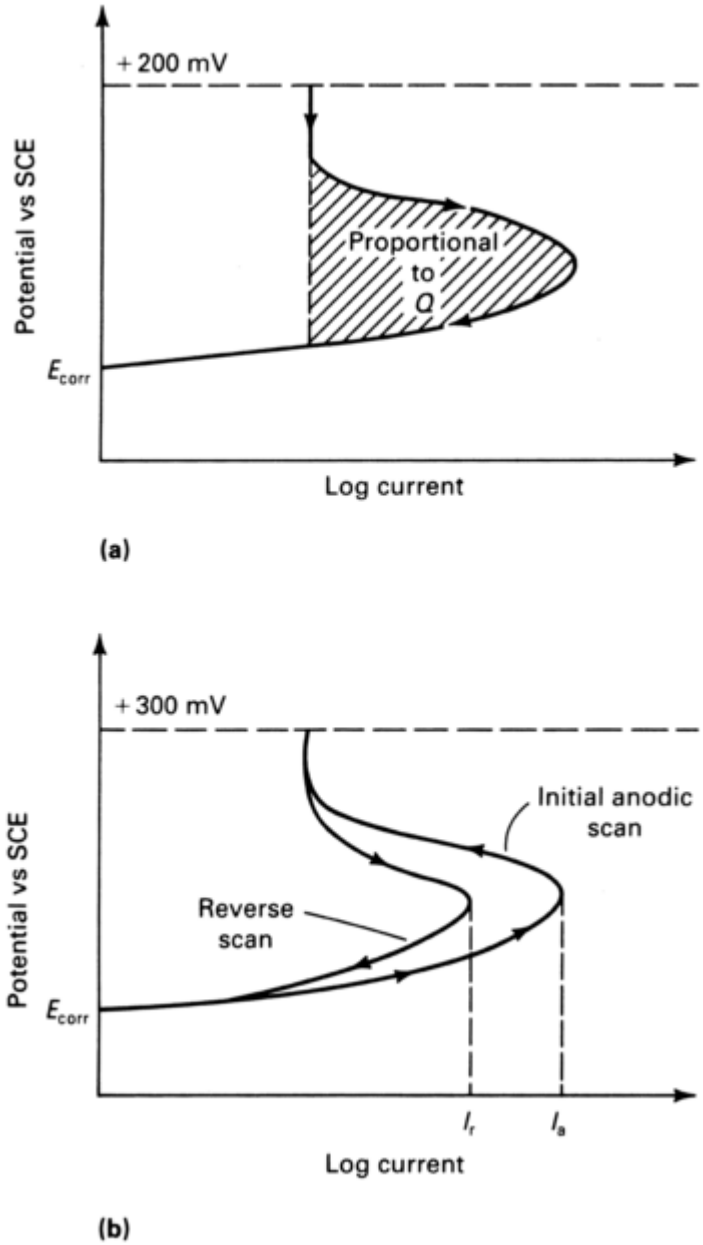

Fig. 10 Two procedures for anodic reactivation polarization testing. (a) Clarke method. (b) Akashi method. Source: Ref 133, 134

The same procedure can be used to normalize the ratio I_r/I_a (Ref 134). The current peak, I_r, for the reactivation scan is normalized for the grain- boundary area, while the initial anodic current peak remains normalized to A_s.

$$\frac{i_r}{i_a} = \left[\frac{I_r}{I_a \times \left[5.09544 \times 10^{-3} \exp\left(0.34696 \times GS\right)\right]}\right] \quad \text{(Eq 34)}$$

i_r/i_a ratios approaching 1 imply sensitization. A number of investigators have correlated this electrochemically derived ratio with optical metallographic evaluations of the degree of material sensitization such as those outlined in ASTM A 262 (Ref 135). This has been accomplished for several different Fe-Ni-Cr alloys (Ref 136, 137, 138). The technique is nondestructive to the underlying metal and can be applied in the field.

Few methods exist for determination of intergranular corrosion rates. Serial metallographic sectioning and the foil-penetration method are the most prominent. In the foil-penetration rate, intergranular penetration is sensed using a foil held at open circuit or under potentiostatic control. The method can be repeated at several foil

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

thicknesses to determine whether rates are linear or not. In this way, the rate of penetration on the fastest intergranular path can be determined (Ref 139, 140).

Electrochemical Methods for Evaluation of Corrosion Rates under Paints

Electrochemical impedance spectroscopy (EIS) techniques offer an advanced method of evaluating the performance of metallic-based coatings (passive film forming and/or conversion coatings) and the barrier properties of organic coatings and corrosion rates under paints (Ref 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151). The method does not accelerate the corrosion reaction and is nondestructive. The technique is quite sensitive to changes in the resistive-capacitive nature of coatings as well as the electrochemical interface. It is possible to monitor the polarization resistance of the corroding interface with this technique. In this respect,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

the electrochemical impedance technique offers several advantages over direct current (dc) electrochemical techniques in that resistances related to the corrosion rate can be separated from the high dc resistance of the dielectric coating. This is not possible with the dc methods. Because a large frequency bandwidth is used for the applied signal (usually from the mHz range to the kHz range), the electrochemical impedance technique is "spectroscopic" and surpasses the capabilities of single-frequency impedance methods. The reason for this lies in the capability of the electrochemical impedance technique to discriminate between the resistive properties of the coating because of its ionic and/or electronic conductivity, the capacitive nature of the coating due to its dielectric constant, area, and thickness and the RC time constant of the electrified interface. Although impedance circuit models for coatings (Fig. 11) contain more elements than the model shown in Fig. 4, frequency regimes in which impedance information is primarily due to the coating capacitance or coating resistance can be separated from one another and analyzed independently by using a broad frequency bandwidth. The barrier properties of the coating can be followed as a function of exposure time. Large decreases signify permeation of ionic species through the coating or the presence of defects in the coating (Ref 148, 149). However, this is not the main focus of this article, which addresses methods to determine corrosion rates. The polarization resistance may be determined from the low-frequency time constant as shown in Fig. 11. However, recall that conversion of R_p to corrosion rate requires that the area specific polarization resistance be known as discussed previously. Thus, a major problem is knowledge of the corroding area.

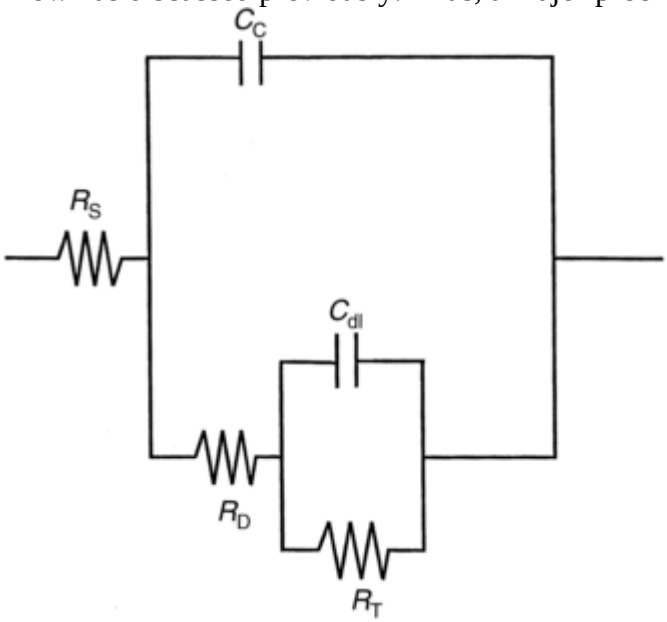

Fig. 11 Electrical equivalent circuit to simulate a coated steel panel with a defect. R_D is the coating defect resistance, R_T is a charge-transfer resistance (similar to R_p) at the metal interface where water has penetrated. C_{dl} is the double-layer capacitance; C_c is the coating capacitance. Source: Ref 144, 145, 147

There are at least two situations that need to be discussed. These are cases where the coating is defect free but acts as an electrolyte allowing underpaint corrosion and the case where there are discrete defects and corrosion only occurs at these sites. Consider the case of an excellent barrier coating with isolated defects. One of the key difficulties in determining the rates of corrosion under paints is assessment of the defect area that is actively corroding. There are several ways to determine active area. Extraction of capacitance from EIS data is possible from equivalent circuit model fitting for sufficiently degraded defective coatings, as shown in Fig. 12. However, conversion of capacitance to area requires knowledge of the area-specific capacitance at the interface between electrolyte and metal. Such area-specific capacitance values have been developed for only a few corroding situations (Ref 48). For instance, area-specific capacitance has been developed for steel in soil, but has not been developed for coatings (Ref 48). The breakpoint frequency is a useful method for estimating the area fraction of physical defects in an organic coating (Ref 147, 148, 149, 150). The dependency between the high-frequency breakpoint frequency and defect area can be described by:

$$f_{bpt} = \left(\frac{1}{2\pi\varepsilon\varepsilon_0\rho}\right)\left(\frac{A_d}{A}\right) \qquad \text{(Eq 35)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

where A_d is the defect area where electrochemical reactions operate, A is the total painted surface area, and ρ is the resistivity of the coating at the defect.

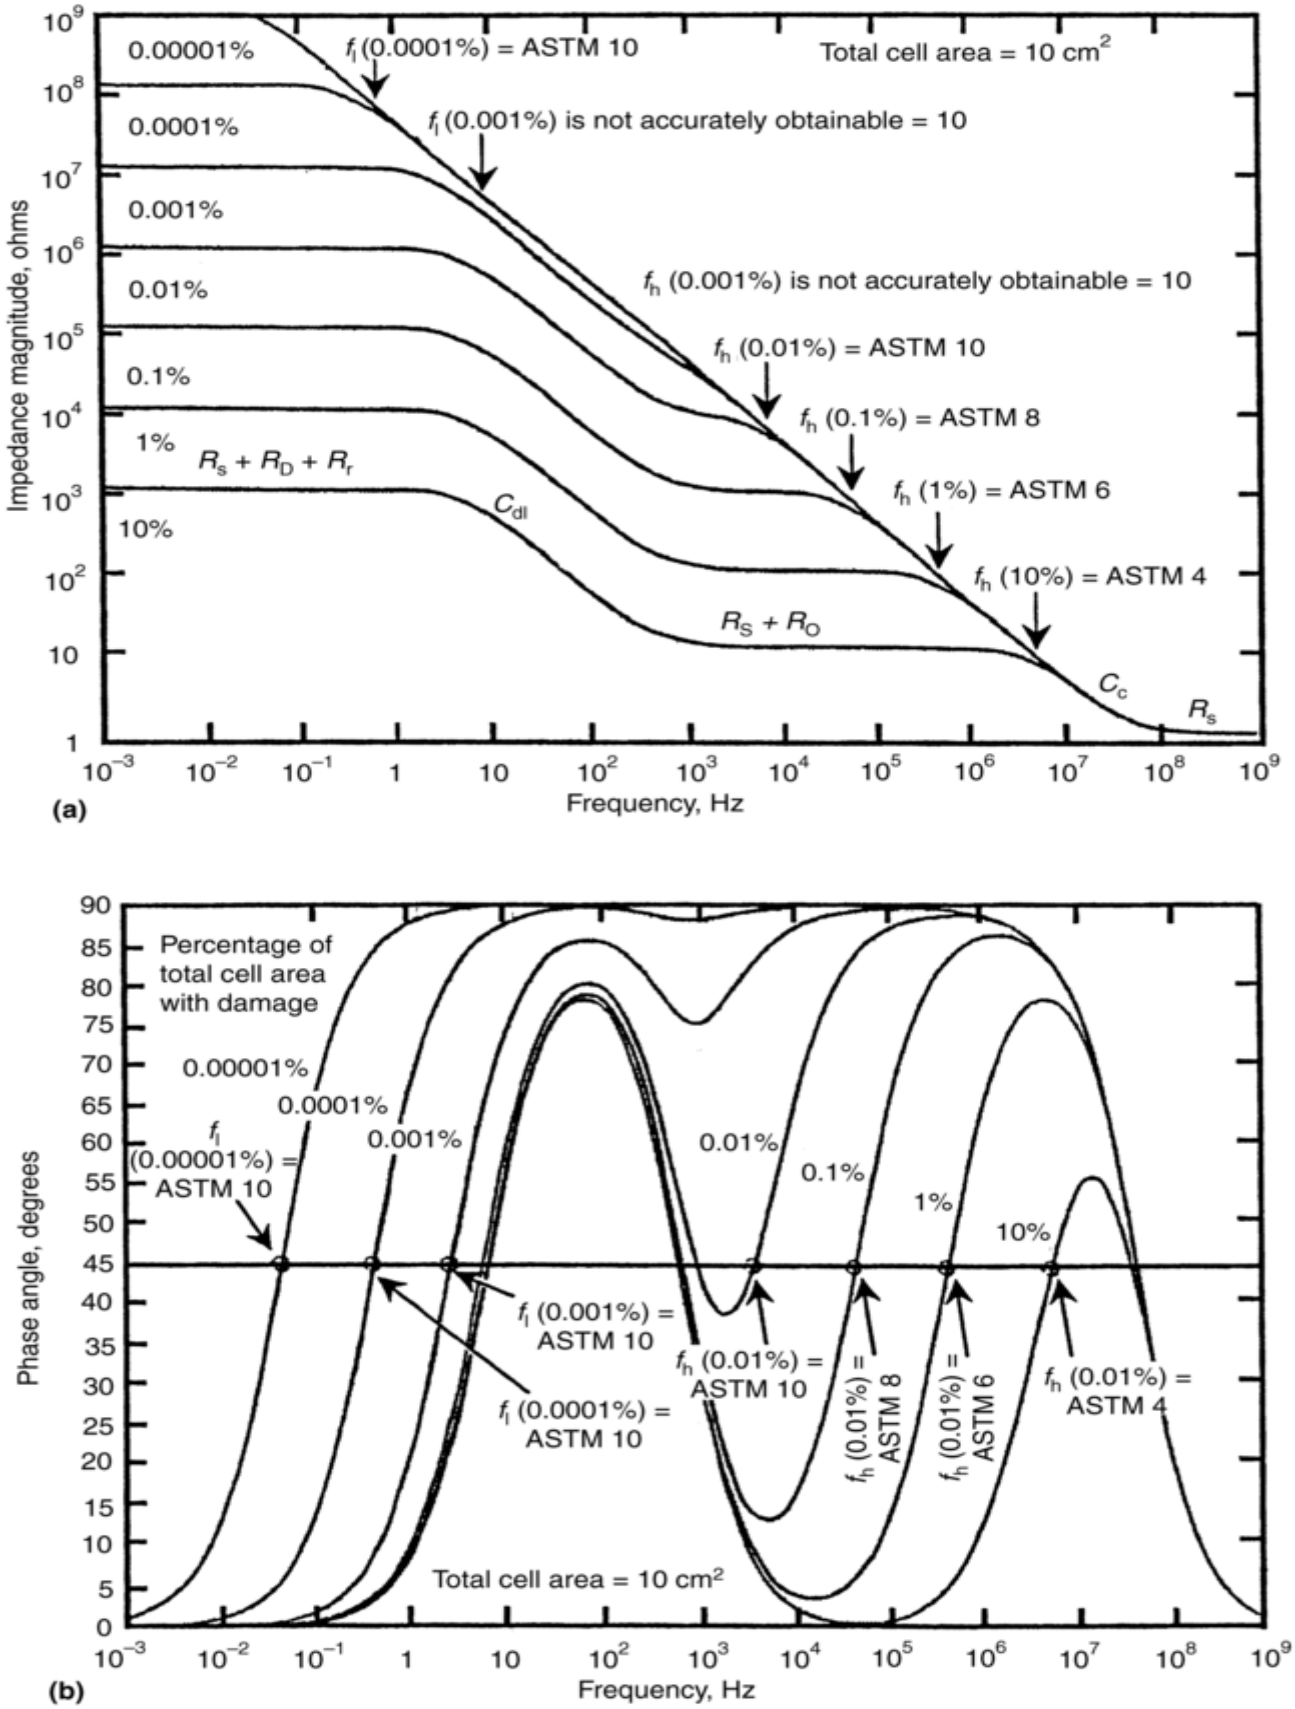

Fig. 12 Theoretical Bode magnitude and phase-angle plots for various known electrochemically active defect areas for a coating containing a cylindrical defect penetrating the metal substrate and no delaminated regions. (a) Bode magnitude. (b) Bode phase angle. ASTM visual ratings according to standards D 610 and D 714 are included for comparison. Source: Ref 150

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Equation 35 provides a rough measure of the estimated change in defect area. Increases in f_{bpt} occur mainly as a function of the increases in the defective area. However, circumstances may exist where small increases in ε and very large decreases in ρ occur simultaneously so that f_{bpt} does not relate linearly to defect area. Moreover, bare metal under delaminated coating regions may not be detected under all circumstances especially if the coating resistivity over the delaminated area and dielectric constant are identical to those in regions where the coating is not delaminated. The hypothetical relationship between f_{bpt} and open defect area over a range of pore dimensions is shown in Fig. 12 (Ref 150). From knowledge of defect area, the corrosion rate could be determined at the pore sites.

Electrochemical Noise Methods for Organic Coating Evaluation. Electrochemical noise methods have also been explored as a method to analyze the degradation of polymer- coated metals (Ref 151, 152, 153, 154). A variety of methods have been used. A common method involves the use of a cell with two identical working electrodes connected through a ZRA. The entire galvanic couple is coupled through a high-impedance voltmeter to an ideally noiseless reference electrode. Two samples often experience drastically different behavior; for instance, if one electrode has a coating defect and the other does not then asymmetrical electrode behavior results. The spectral noise impedance obtained is equivalent to the geometric mean of the moduli of individual electrode impedances. Instrument noise should be carefully considered when this approach is used to analyze high-resistance coatings. In principle, a noise-resistance value equivalent to the polarization resistance can be obtained. Knowledge of the corroding area enables calculation of the corrosion rate in the areas where corrosion occurs. Methods have not been developed and consensus has not been reached on approaches for determining corrosion rates under paints using EN methods.

Methods for Determining Aqueous Corrosion Reaction Rates

John R. Scully and Robert G. Kelly, University of Virginia

Nonelectrochemical Methods That Determine Cumulative Mass Loss

Corrosion Rate Determination through Gravimetric Determination of Mass Loss. Corrosion rates are often determined from gravimetric measurement of mass loss in the laboratory either under conditions that mimic those in the field or under conditions that are accelerated. The latter is often achieved by raising the temperature or concentrating corrodents in the aqueous solutions used for testing. Field exposure is also simulated by various lab cabinet methods such as salt spray, prohesion, and Q-fog methods that introduce various weathering cycles including full immersion. The typical wisdom is that the accelerated test protocol produces the same form of corrosion, accelerates the mechanism of corrosion that is operative in the field, and correlates in some manner with field lifetimes or rates. Often the latter is not achieved in accelerated lab tests. In these cases, a relative ranking of materials or treatments is gained from corrosion rate determination by mass loss. It is desired that the same ranking is obtained in field testing. Mass-loss methods can be attractive for use in weathering-type environments that involve wetting and drying. Under these conditions, electrochemical methods may not be suitable.

ASTM standards cover many important procedural factors such as surface finish, and postexposure cleaning required for successful determination of mass loss. For instance, postcleaning exposure can introduce errors if cleaning methods remove additional metal besides the corrosion products. Conversely, nonremoval corrosion products or other deposits can produce mass gain that either partially or completely offsets small mass losses. Ideally, posttest cleaning methods rapidly remove corrosion products, but corrode underlying metal only a negligible amount. It follows that it can be difficult to determine the corrosion rates of passive metals by mass-loss methods because only very small mass changes occur over substantial time periods. In order to obtain measurable mass loss after exposure of a specimen, a rule used is that the exposure period must equal or exceed the ratio 2000/mpy = the number of exposure hours necessary (Ref 4).

Instantaneous corrosion rate determination is not possible from mass loss because the time period of corrosion is uncertain and may not equal the exposure time period. Consequently, corrosion rate determination from a single mass-loss measurement represents an average over the period of exposure. The average corrosion rate can be obtained simply from standard relationships based on Faraday's law given a known mass loss measured after specimen cleaning (Ref 4, 155):

$$\text{Average corrosion rate} = \left(\frac{KW}{ATρ}\right) \qquad \text{(Eq 36)}$$

where K is a constant (see Table 3), T is the time of exposure (hours), A is the area (cm^2), W is mass loss (grams), and ρ is material density in g/cm^3.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Table 3 Constants *K* used in Eq 36 for desired penetration law units and mass-loss rate units

Corrosion rate units desired	Constant *K* in corrosion rate equation
Mils per year (mpy)	3.45×10^6
Inches per year (ipy)	3.45×10^3
Inches per month (ipm)	2.87×10^2
Millimeters per year (mm/yr)	8.76×10^4
Micrometers per year (μm/yr)	8.76×10^7
Picometers per second (pm/s)	2.78×10^6
Grams per square meter per hour (g/m^2 · h)	$1.00 \times 10^4 \times \rho$
Milligrams per square decimeter per day (mdd)	$2.40 \times 10^6 \times \rho$
Micrograms per square meter per second (μg/m^2 · s)	$2.78 \times 10^6 \times \rho$

Note: ρ is the density in g/cm^3. Source: Ref 155

Many different units are used to express corrosion rates. Using various values of *K*, mass- loss rate in different units can be produced (Ref 155). Appropriate modification of Eq 36 can be used to produce mass-loss rates per unit area (Table 3).

Corrosion usually does not occur at a constant rate during the entire period of exposure. Procedures exist to ascertain whether or not the corrosion rate is increasing, decreasing, or constant with time. Removal at unit time periods in the beginning or end of a total exposure period or at prescribed time intervals can be used to ascertain this information (Ref 4, 5). Periodic determination of mass loss can be converted to mass-loss rate and penetration rate, assuming uniform attack. Mass-loss information can be obtained from full immersion in aqueous environments, alternate immersion, splash and spray, or gaseous corrosion exposure. Moreover, mass-loss methods may be useful in extremely low conductivity environments where electrochemical methods find difficulty. Corrosion rate determination by mass-loss methods can be misleading when corrosion occurs in a highly localized manner. In these cases, a depth gage, calipers, microscopic methods, and metallographic cross sections are preferred.

Corrosion Rate Determination via Electrical-Resistance Methods. The electrical-resistance test method operates on the principle that the electrical resistance of the corrosion measuring element depends on the electrical resistance of the metallic cross section. Resistance is given by:

$$R = (\rho)\left(\frac{l}{A}\right) \qquad \text{(Eq 37)}$$

where *R* is resistance of sensing element, ρ is resistivity of sensing element (temperature-dependent material property), l is length of sensing element, and *A* is cross-sectional area.

The resistance of the sensing element increases as the cross-sectional area of the sensing element decreases. Thus, the resistance increase is proportional to the reduction in cross-sectional area of the resistance-sensing element and corrosion can be detected (Ref 156, 157). Clearly, this method is only suitable in cases of uniform corrosion since high aspect ratio pits may not decrease the resistance of the sensing element in proportion to locally high corrosion rates. In practice, a resistance-measuring element constructed of the same material as the material of interest is exposed in the test environment. One shortcoming is when the component of interest cannot be matched exactly in the choice of sensing element. Often a second sensing element protected from the corrosive environment is measured simultaneously. The ratio of the resistances changes is determined. This compensates for any effects of exposure temperature on resistivity. The measurement taken gives the cumulative metal loss at the time of the measurement. The first derivative of measurements taken over time can be used to determine the rate of change of cross-sectional area *A* and, consequently, mass-loss rate. In other words, the slope of the mass-loss curve versus time can yield the mass loss per unit area per unit time. The slope at any time gives the corrosion rate at that time. The method can be used in atmospheric, gaseous, nonaqueous, or other environments where electrochemical methods may be compromised.

Corrosion Rate Determination Using Magnetic Methods. A magnetic field is created by current flow through a wire coil. The magnetic induction whose magnitude is the magnetic flux density can be enhanced by placing a ferromagnetic material in the center of such a wire coil. The saturation flux or magnetic induction reaches a saturation value upon application of a sufficient magnetic field. This saturation flux is proportional to the mass of the ferromagnetic material and its relative permeability. Mass loss by uniform corrosion can be detected by a

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

decrease in the saturation value upon application of a magnetic field strength that saturates after corrosion has occurred and mass has been lost.

Thus, the change in magnetic saturation induction of a ferromagnetic material can be used to determine the loss in mass of the test object. As in the case of the electrical-resistance methods, localized corrosion will not provide a change in magnetic field strength proportional to very localized depth of attack. A series of measurements on a single electrode provides a means to determine the rate of mass loss and corrosion rate. This method has been applied to coated metals and is capable of determining corrosion rates under painted cobalt (Ref 158, 159).

An additional means of using magnetic effects to measure corrosion rates has been pursued using superconducting quantum interference devices (SQUIDs) to measure the electrical currents within metals resulting from corrosion activity on the metal surface. Magnetic fields are generated perpendicular to the metal surface with an intensity that scales with the corrosion rate. The SQUID acts as a sort of noninvasive ammeter, measuring the electron movement associated with corrosion activity. Early work by Bellingham, et al. (Ref 160, 161) demonstrated that corrosion activity did cause detectable magnetic signals. More recently, Abedi (Ref 162) has shown that a correlation exists between the temporal summation of the spatially integrated magnetic activity (referred to as TSSIMA) and the mass loss due to uniform corrosion for aluminum alloy 7075-T6 (UNS A97075-T6) in 0.1 *M* NaOH. More recent work has shown a correlation between corrosion activity and TSSIMA for crevice corrosion as shown in Fig. 13. The spatial distribution of the damage on surface (Fig. 13) corresponds to the distribution of magnetic activity observed over the 190 h of exposure.

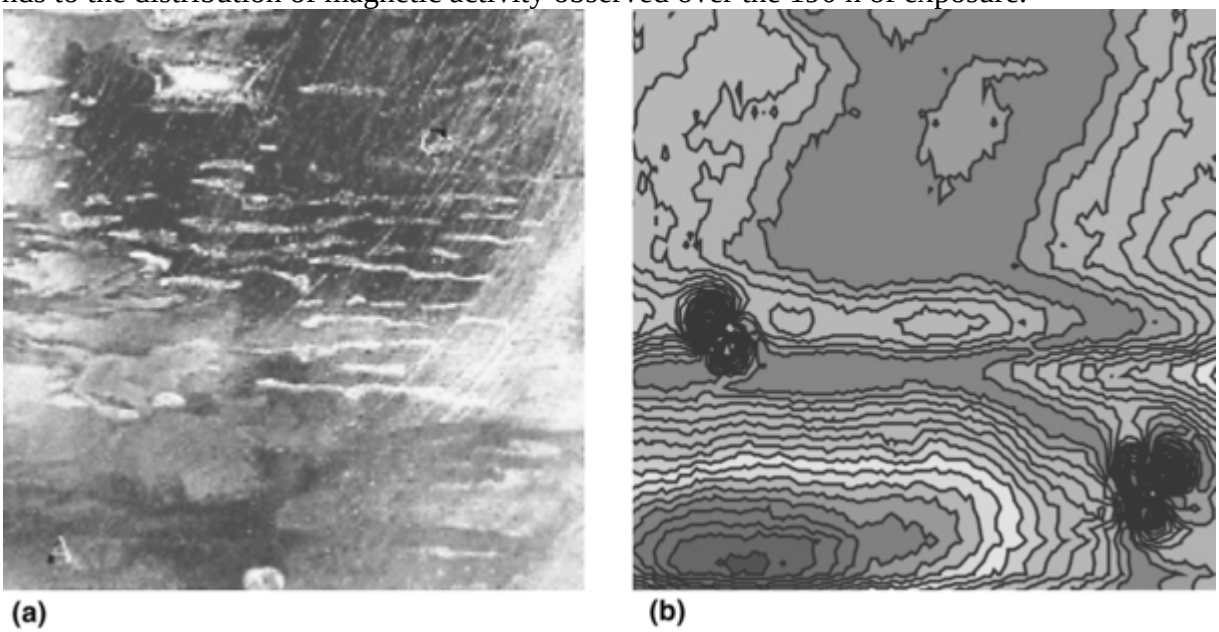

Fig. 13 Noninvasive detection of hidden corrosion. (a) Micrograph of the lower (hidden) surface on a planar 2024-T3 sample that was exposed to a corrosive solution typical of an aircraft lap joint. The dark gray area in the upper center of the image corresponds to noncorroded aluminum. (b) The cumulative magnetic activity of the sample showing the more active regions in white and less active ones in dark gray. Source: Ref 163

The potential advantages of SQUID measurements include their high sensitivity, their noninvasive nature, and thus their ability to probe corrosion activity within occluded regions for which direct electrochemical measurements are not possible (Ref 164). Quantitative interpretation of the signals in terms of metal dissolution still requires development of a stronger theoretical underpinning. In the absence of such, the measurement of corrosion rate requires extensive calibration studies and a control of specimen geometry and corrosion mode.

Corrosion Rate Determination Using the Quartz Crystal Microbalance. The quartz crystal microbalance offers a method for determining the mass loss or gain on an electrode material (m) (Ref 45, 165). In this case, the electrode material must first be deposited on a substrate with piezoelectric properties such as a slice of quartz crystal. Hence, the corrosion rate of the material deposited can be determined. The quartz crystal will oscillate at a frequency, f_0, given by its geometry when a sinusoidal electrical signal is applied at this frequency. The

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

frequency of oscillation is sensitive to the mass change on the crystal surface as expressed by the Sauerbrey equation (Ref 165):

$$\Delta f = \left(\frac{-2 f_0^2 mn}{(\rho\mu)^{1/2}} \right) = -C_f m \qquad \text{(Eq 38)}$$

where Δf is the frequency change given by the addition or subtraction of mass per unit area of quartz crystal, n is the harmonic number of oscillation, μ is the shear modulus of quartz, and ρ is the density of quartz. When these constants are considered together, a single constant known as the sensitivity factor, C_f, is produced such that the mass change is directly proportional to the frequency change. This method can be used to determine mass loss or gain over time in gas- phase, thin-layer, or solution-phase corrosion.

Unfortunately, the behavior of the crystal depends on the medium in which a crystal is operating. Therefore, a coating, film, and/or aqueous solution change the values of f_0 and C_f because such a medium effectively couples to the crystal surface and creates additional resistance to the shear-wave oscillation used to detect a mass change. The method is quite sensitive to mass change. For instance, almost 0.01 $\mu g/cm^2$ mass change can be detected by a 1 Hz change in frequency.

The measurement taken gives the cumulative metal loss at the time of the measurement. The first derivative of many measurements taken over time can be used to determine the rate of change of mass and, consequently, the corrosion rate over a known area. This method has been used in several corrosion studies (Ref 166, 167). The method has the advantage of being useful for corrosion-rate determination in the gas phase, in nonaqueous environments, or when other electrochemical reactions may occur at equal or greater rates as the metal dissolution rate. However, the method has the disadvantage of being unable to detect and properly ascertain the rate of localized corrosion when only highly localized changes in mass occur. The resulting frequency change will not reflect the locally high amounts of mass loss.

Solution Analysis Methods. Another nonelectrochemical means of assessing corrosion rate is the analysis of solution composition (Ref 168). As a metallic material corrodes, the metal cations are released into solution. If they can be quantitatively captured and accurately analyzed, the total dissolution of the material can be calculated directly. The challenge in such measurements is related to distribution of the metal-dissolution products. To the extent that cations precipitate as corrosion products, the measured solution concentration will be lowered. However, recent work using solution analysis methods to monitor corrosivity of secondary waters in a nuclear power plant toward the steel piping (Ref 169) has demonstrated that measurement of highly soluble alloying elements may provide an alternative approach. The concentration of soluble manganese was monitored online by ion chromatography and shown to correlate to the amount of solid iron corrosion products collected. Although the manganese was present at substantially less than 1 wt% in the steel, its high solubility in the near-neutral pH of the secondary water allowed it to be monitored whereas the iron precipitated.

Metrological methods, to some degree, represent the most direct approach to measuring corrosion rate. Establishing the extent of material thinning can be done using several approaches including x-ray measurements of thickness, optical measurements of surface topography, and scanning probe microscopies. X-ray radiography measures the material density as a function of position. Calibration standards allow the radiograph to be converted to a thickness map. In the case of optical metrology measurements, a number of commercial methods allow high-resolution measurements of surface topography. Confocal laser scanning microscopy (CLSM), white light interferometry, and scanning laser profilometry systems all have advantages and disadvantages with respect to speed, lateral and depth resolution, field of view, dynamic range, and cost (Ref 170, 171, 172). The scanning probe microscopies (STM, AFM, and NSOM) have been used to measure extremely low corrosion rates (Ref 173).

Assuming the availability of a datum, that is, a position of known thickness (or a calibration curve in the case of radiography), these methods allow quantitative measurements of the material lost due to corrosion. It must be noted that with the exception of painstaking serial, cross-sectional metallography, all metrology methods are line-of-sight for the radiation used. This situation leads to the need to assume that all damage intersects the surface. Undercutting attack, as seen in some pitting systems, can go undetected so the corrosion rate is underestimated. However, corrosion under organic paint can be observed since thin paint layers are transparent to laser radiation (Ref 174).

Thin-layer activation involves the production of a radioactive layer of material on the surface of the structure of interest. Typically, this layer is made via the exposure of a small section to a beam of high-energy charged

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

particles. Gamma radiation is emitted from the sample as the isotope decays and is detected. As the surface corrodes, less radiation is emitted as the total mass is decreased. In this way, the corrosion rate of the structure can be monitored. The levels of radiation emitted are very small, but the existence of high-sensitivity radiation detectors makes this method highly sensitive. Low corrosion rates can be monitored in situ, and the effects of corrective actions determined quickly (Ref 175).

Introduction to Fundamentals of Corrosion in Gases

Revised by Marek Danielewski, AGH University of Science and Technology, Cracow, Poland

---

Introduction

ENGINEERING MATERIALS are subject to deterioration when exposed to high-temperature environments. Whether they survive or not in technological applications depends on how fast they react. The rate of corrosion varies widely; some intermetallics (β-NiAl) react extremely slowly. Some metals (Fe) oxidize very rapidly, whereas other metals (Cr, Co) react relatively slowly. From the chemical point of view, the gas- metal reactions represent a broad class of heterogeneous reactions. The composition and structure of the scales produced on metals are a key factor in their behavior in technical applications.

Historically, corrosion in gases has been primarily a problem in combustion systems. Thus, the gas-metal reactions are usually referred to as oxidation in its broad chemical sense, whether the reaction is with pure oxygen, water, sulfur dioxide (SO_2), or whatever the gas might be. The corrosion product (oxide layer) is termed *scale.* Being the corrosion product, the protective properties of scale decrease the reaction rate. The concepts and methods developed to understand gas-metal reactions can be used to describe any arbitrary gas-

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

solid reaction at high temperature; for example, oxidation of the silicone carbide. The high temperature corrosion is a highly technical challenge; the reason for this is that the efficiency of thermal processes and engines increases with operating temperature. Such high- temperature service is especially damaging to most metals because of the exponential increase of reaction rate with temperature. In most cases, corrosion resistance at high temperatures does not accompany the good mechanical properties of structural materials; therefore, protective coatings must be applied.

Electrochemical principles are insufficient to understand the mechanism of oxidation. For gaseous reactions, a basic understanding of the diffusion processes is much more profitable. The first results of a high-temperature corrosion study (not yet defined as corrosion and even diffusion) were published in 1684 by Boyle in *Experiments and Considerations about the Porosity of Bodies in Two Essays.* In studying reactive diffusion in the Cu-S system, Boyle reported the observation of interaction between copper and sulfur through examination of metallographic cross sections. Electrochemistry and aqueous corrosion principles were developed at the beginning of the 19th century. In 1855 Fick formulated the basic principles of diffusion in solids. The systematic study of high-temperature oxidation began in the 1920s. In 1933 Wagner published his pioneering paper on gas corrosion of metals. The first journal devoted to corrosion in gases, *Oxidation of Metals,* was published in the 1960s.

The following articles introduce the subject of gas corrosion to professional engineers and students. A brief summary of thermodynamic concepts is followed by an explanation of the defect structure of solid oxides and the effect of these defects on the rate of mass transport. Commonly observed kinetics of oxidation are described and related to the observed corrosion mechanisms, as illustrated in Fig. 1 of the next article, “Thermodynamics of Gaseous Corrosion.”

In high temperature gaseous corrosion, the oxidant first adsorbs on the metal surface in molecular (physical adsorption) and ionic form (chemical adsorption), and it may also dissolve in metal. Oxide nucleates at favorable sites and most commonly grows laterally, due to surface diffusion, to form a complete thin film (scale). As the scale thickens, it provides a protective barrier to shield the metal from the gas. For scale growth, electrons must move through the film to reach the oxidant atoms adsorbed on the surface, and oxidant ions and/or metal ions must move through the scale barrier. Diffusion of the oxidant into the metal may result in internal oxidation.

Growth and thermal stresses in the oxide scale may create microcracks and/or delaminate scale from the underlying metal. Stresses affect the diffusion process and modify the oxidation mechanism and very often cause scale spallation. Improved oxidation resistance can be achieved by developing better alloys, by applying protective coatings, and by altering the composition of the gas phase.

Fundamental Data

Essential to an understanding of gaseous corrosion are the crystal structure and the density (molar volume) of the oxide and of the metal on which the oxide builds. Both may affect growth stresses in the oxide. For high-temperature service, the melting points of the oxide and metal, their structure, and thermal expansion coefficients, which affect oxide adherence during heating and cooling, are all important to know. These data for pure metals can be found in Table 1 here and in Table 1 of next article, “Thermodynamics of Gaseous Corrosion.” Likewise, data for oxides are shown in Table 2 and in Table 2 of the next article.

Thermodynamics of Gaseous Corrosion

Zbigniew Grzesik, University of Mining and Metallurgy (Krakow, Poland)

Introduction

METALS can react chemically when exposed to air or to other more aggressive gases. The reaction rate of some metals is so slow that they are virtually unattacked, but for others, the reaction can be violent. As with most chemical processes, elevated-temperature service is more severe because of the exponential increase in reaction rate with temperature.

The most common reactant is oxygen in the air; therefore, all gas-metal reactions are usually referred to as oxidation, using the term in its broad chemical sense whether the reaction is with oxygen, water vapor, hydrogen sulfide (H_2S), or whatever the gas might be. Throughout this article, the process is called oxidation, and the corrosion product is termed an oxide.

Corrosion in gases differs from aqueous corrosion in that electrochemical principles do not help greatly in understanding the mechanism of oxidation. For gaseous reactions, a fundamental knowledge of the diffusion processes involved is much more useful. The principles of high-temperature oxidation began to be understood in the 1920s, whereas electrochemistry and aqueous corrosion principles were developed approximately 100 years earlier. The first journal devoted to corrosion in gases, *Oxidation of Metals*, began publication in 1970. This article addresses thermodynamic concepts; the commonly observed kinetics of oxidation are described in the article “Kinetics of Gaseous Corrosion Processes” in this Volume.

The mechanisms of oxidation are shown schematically in Fig. 1. The gas is first adsorbed on the metal surface as atomic oxygen. Oxide nucleates at favorable sites and most commonly grows laterally to form a complete thin film. As the layer thickens, it provides a protective scale barrier to shield the metal from the gas. For scale growth, electrons must move through the oxide to reach the oxygen atoms adsorbed on the surface, and oxygen ions, metal ions, or both must move through the oxide barrier. Oxygen may also diffuse into the metal.

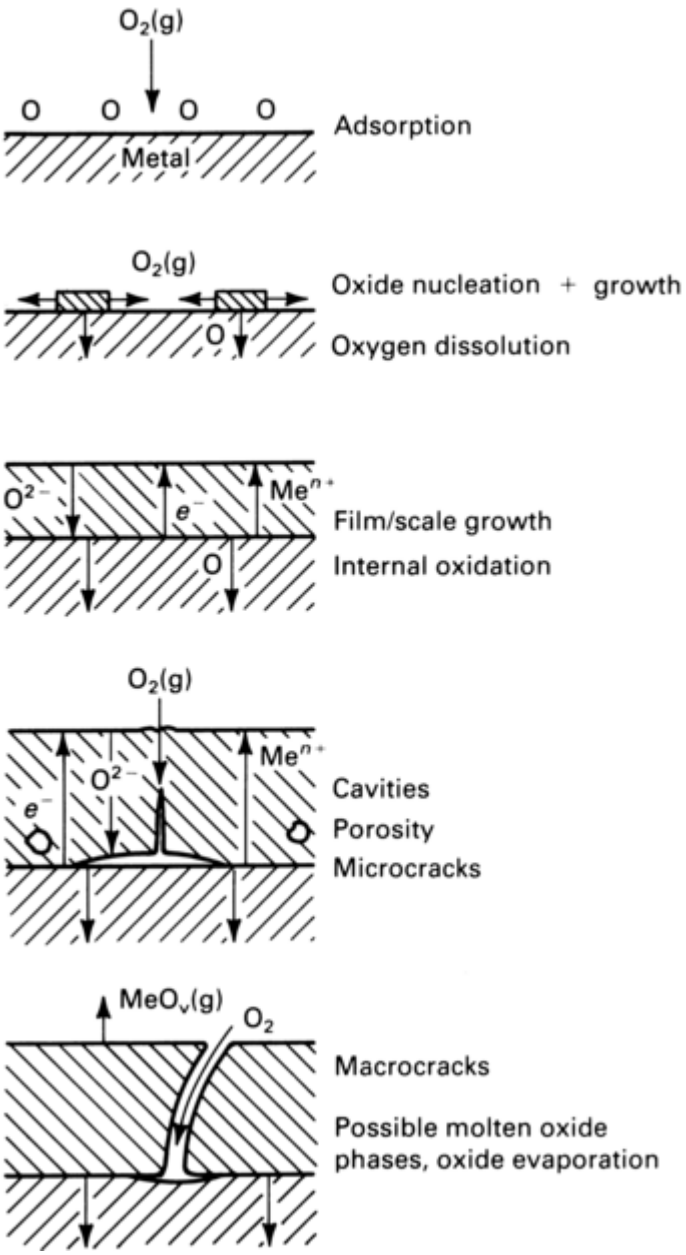

Fig. 1 Schematic of the principal phenomena taking place during the reaction of metals with oxygen. Source: Ref 1

Growth stresses in the scale may create cavities and microcracks in the scale, modifying the oxidation mechanism or even causing the oxide to fail to protect the metal from the gas. Improved oxidation resistance can be achieved by selection of suitable alloys for the given environment and by application of protective coatings.

Fundamental Data

Essential to an understanding of the gaseous corrosion of a metal are the crystal structure and the molar volume of the metal on which the oxide builds, both of which may affect growth stresses in the oxide. For high-temperature service, the melting point of the metal and the structural changes that take place during heating and cooling, which affect oxide adherence, must be known. These data are presented in Table 1 for pure metals. For the oxides, structures, melting and boiling points, molar volume, and oxide/ metal volume ratio (Pilling-Bedworth ratio) are shown in Table 2.

Table 1 Structures and thermal properties of pure metals

Thermodynamics plays a very important role in studying the gaseous corrosion of metallic materials. It is possible to determine several critical parameters of the oxidation reaction on the basis of thermodynamic data, namely, the temperature and oxidizing gas pressure in which particular chemical compounds can be formed, the phase sequence in the multilayered scale growing on metal, the equilibrium composition of the gas mixture, and partial pressures of volatile oxidation products. In spite of its name, thermodynamics does not inform on the reaction rate; it does not describe “the dynamics” of the systems. Thermodynamics determines the equilibrium state. The Gibbs energy change, which is the driving force of any chemical reaction, is not related to the reaction rate. Reaction rate is a kinetic problem and depends on the mechanism of the slowest step of the overall reaction process. On the other hand, the thermodynamic considerations of metal-oxidant equilibria and phase diagrams are invaluable tools for the interpretation of the oxidation mechanisms and processes. Some typical examples of such considerations are described in the following section of this article.

Free Energy of Reaction

The chemical reaction describing the oxidation process of a pure divalent metal, M, by an oxidizing gas, X_2 (oxygen, sulfur, and others), may be written as:

$$aM + \frac{b}{2}X_2 = M_aX_b \qquad \text{(Eq 1)}$$

where M_aX_b is the reaction product (oxide, sulfide, etc.). The fundamental criterion, which allows for the evaluation of whether, at a given temperature and oxidant gas pressure, the oxidation process of a determined metal may occur, is the sign of the Gibbs energy change, ΔG (Ref 4, 5). The Second Law of Thermodynamics describes ΔG as:

$$\Delta G = \Delta H - T\Delta S \qquad \text{(Eq 2)}$$

where ΔH denotes the enthalpy of reaction, T is the absolute temperature, and ΔS is the entropy change. For a spontaneous reaction at constant pressure and temperature, ΔG is negative ($\Delta G < 0$). In the case of nonspontaneous reactions, ΔG is positive ($\Delta G > 0$), and if $\Delta G = 0$, the system is at equilibrium. The Gibbs energy change of the chemical reaction given by Eq 1 equals the sum of the chemical potentials, μ, of all components present in the system (M, X_2, M_aX_b):

$$\Delta G = \mu_{M_aX_b} - a\mu_M - \frac{b}{2}\mu_{X_2} \qquad \text{(Eq 3)}$$

The chemical potential, μ_i, and the activity, a_i, of a given i-component are interrelated, as follows:

$$\mu_i = \mu_i^0 + RT \ln a_i \qquad \text{(Eq 4)}$$

where R is the gas constant, and μ_i^0 is the chemical potential of a given i-component in the standard state. Generally, the activities of pure solid components (such as metals and oxides) are equal to unity, and therefore $\mu_M = \mu_M^0$ and $\mu_{M_aX_b} = \mu_{M_aX_b}^0$. The activity of gaseous component X_2 can be approximated by its pressure:

$$\mu_{X_2} = \mu_{X_2}^0 + RT \ln p_{X_2} \qquad \text{(Eq 5)}$$

Thus, Eq 3 may be presented in the following form:

$$\Delta G = \mu_{M_aX_b}^0 - a\mu_M^0 - \frac{b}{2}\mu_{X_2}^0 - \frac{b}{2}RT \ln p_{X_2} \qquad \text{(Eq 6)}$$

Because the sum of the standard chemical potentials is the standard Gibbs energy change, ΔG^0, then the previous equation may be written as:

$$\Delta G = \Delta G^0 - \frac{b}{2}RT \ln p_{X_2} \qquad \text{(Eq 7)}$$

At equilibrium, where $\Delta G = 0$, Eq 7 can be presented in the form:

$$\Delta G^0 = \frac{b}{2}RT \ln p_{X_2}^{eq} \qquad \text{(Eq 8)}$$

In the previous equation, $p_{X_2}^{eq}$ denotes the dissociation pressure of the M_aX_b compound and may be calculated from the following relation:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$p_{X_2}^{eq} = \exp\left(\frac{2\Delta G^0}{bRT}\right) \qquad \text{(Eq 9)}$$

Thermodynamically, if the oxidant pressure is lower than the calculated value of the equilibrium dissociation pressure of the M_aX_b compound, then the metal, M, is not oxidized. In the opposite case, the spontaneous oxidation reaction may occur. It should be emphasized that the calculated value of dissociation pressure of a given compound is related to the equilibrium state. In practice, thermodynamically unstable oxides can be formed during high-temperature oxidation of metals by gases. An example of such unstable oxides is Wustite (FeO), which is unstable in air unless the temperature is higher than 570 °C (1060 °F). In fact, Wustite is a major component of the scale formed on steel beyond this temperature, and after rapid cooling to room temperature, it remains in the scale as a result of the extremely slow decomposition kinetics of FeO. See the Fe-O binary phase diagram (Fig. 2); the diagram shows that other scale components are Fe_2O_3 and Fe_3O_4.

Richardson-Jeffes Diagrams

The determination of the standard Gibbs energy change of formation of oxides as well as the corresponding dissociation pressures of the oxides as a function of temperature—without any calculations—is very convenient when using Richardson-Jeffes diagrams (Gibbs energy-temperature diagrams) (Ref 6). Such a diagram, Fig. 3, is a plot of the standard Gibbs energies of formation of the oxides per mole of oxygen, O_2 (e.g., $2Ni + O_2 = 2NiO$, or $\frac{4}{3}Al + O_2 = \frac{2}{3}Al_2O_3$), versus temperature. Auxiliary outer scales in the upper, right, and bottom part of the plot are used for determination of conditions in which a given metal is oxidized by pure oxygen gas or oxidizing gas mixtures, CO/CO_2 and H_2/ H_2O. The standard Gibbs energy change of formation of any oxide at a given temperature can be read directly on the ΔG^0 scale, for example, the Gibbs energy of formation of SiO_2 at 1200 °C (2190 °F) equals approximately -600 kJ for one mole of SiO_2

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

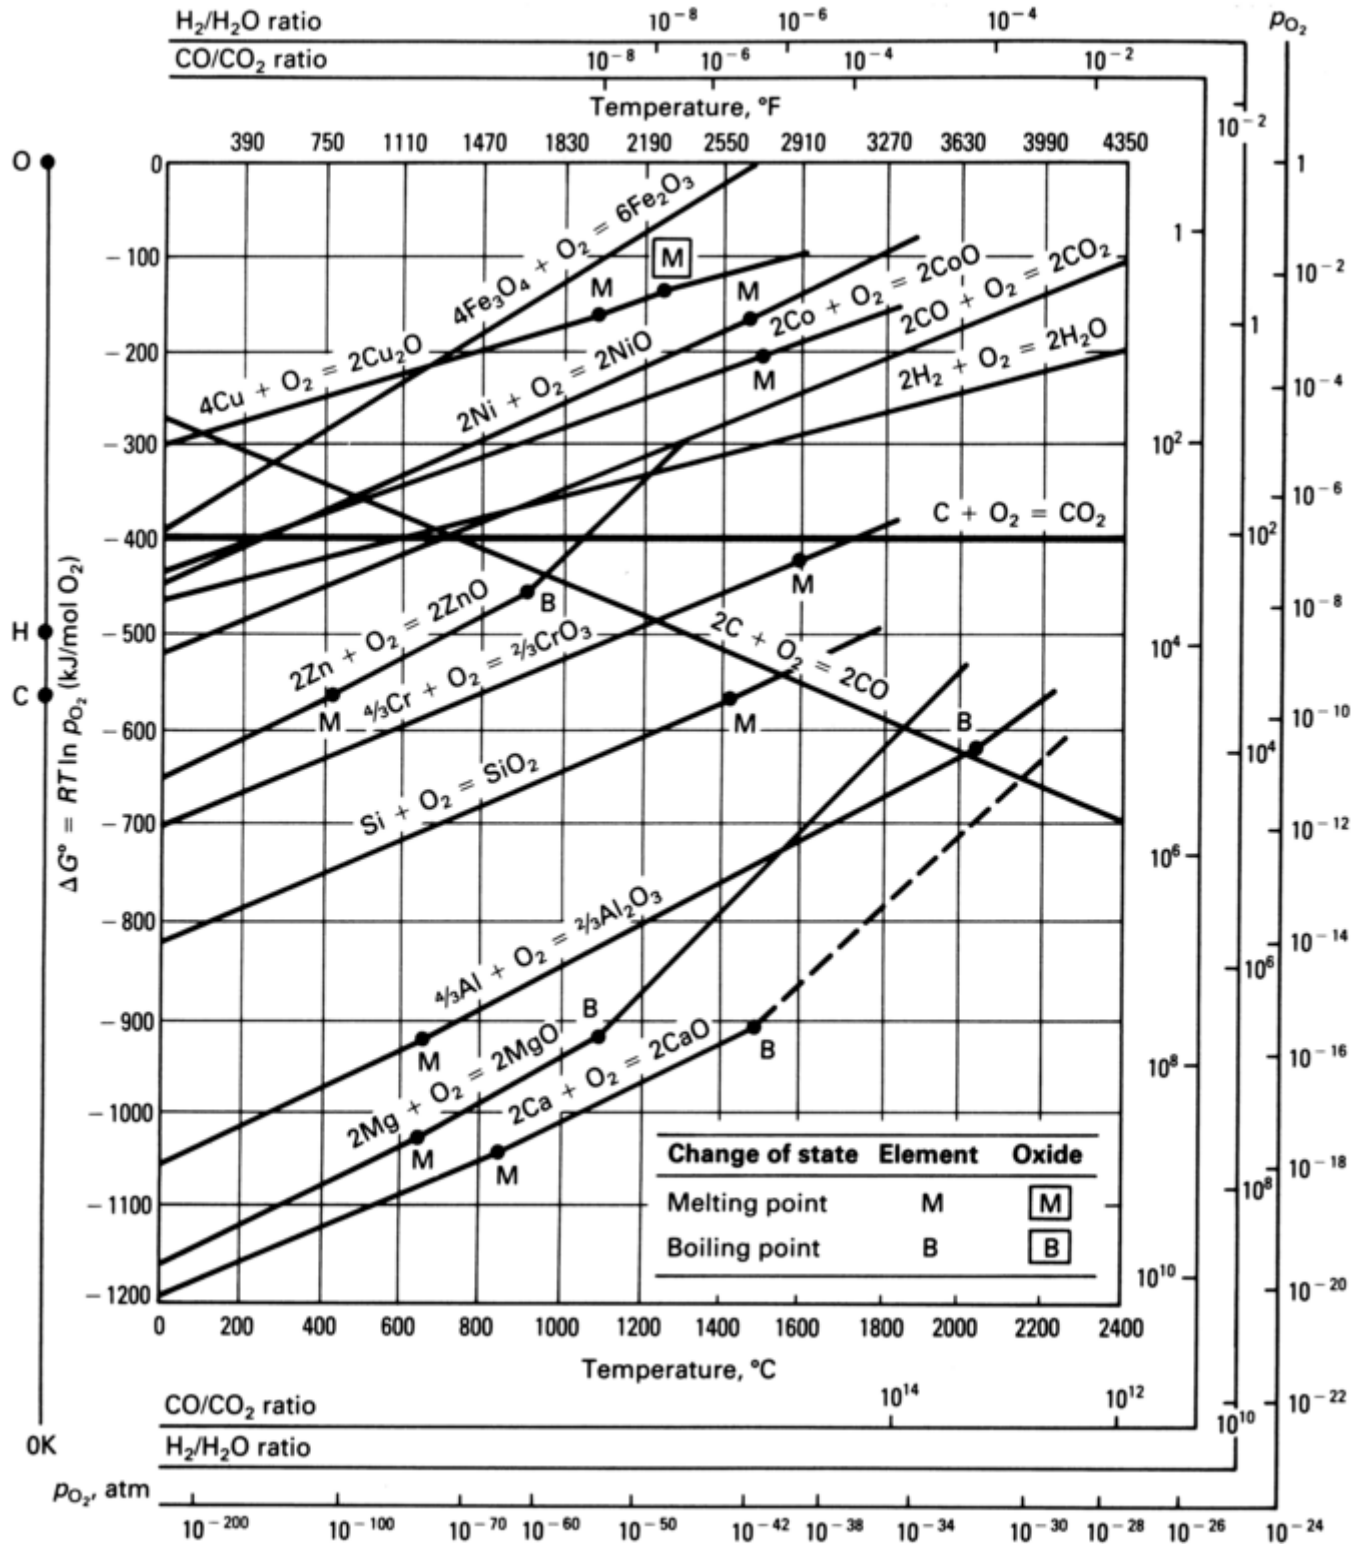

Fig. 3 Richardson-Jeffes diagram showing standard Gibbs free energy of formation as a function of temperature for metal oxide systems. Source: Ref 7

The dissociation pressure of a given oxide at constant temperature can be read on the partial pressure of oxygen, p_{O_2}, scale from the intersection of this scale with a straight line, drawn from index point labeled “O” at the upper left corner of the diagram through the appropriate temperature point on the line, related to the formation of a corresponding oxide. By way of example, the dissociation pressure of SiO_2 is approximately 10^{-20} atm O_2 at 1200 °C (2190 °F). Thus, silicon is not oxidized to SiO_2 at partial pressures lower than 10^{-20} atm at this temperature. On the other hand, from a thermodynamical point of view, SiO_2 can be formed from silicon at any pressure of oxygen greater than 10^{-20} atm at 1200 °C (2190 °F). The determination of the dissociation pressures of oxides is of considerable practical consequence in predicting which metallic materials are oxidized

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

at given conditions and, as a consequence, how a low partial pressure of oxygen should be used to prevent oxidation. However, very low partial pressures of oxygen in ambient gases ($p_{O_2} < 10^{-6}$ atm) are, in practice, seldom realized by means of vacuum systems or by oxygen-purified noble gases (such as argon or helium). Generally, to obtain very low partial pressure of oxygen, oxidizing gas mixtures are used in which oxygen is one of the components, for example, CO_2-CO-O_2 or H_2O-H_2-O_2. The essential chemical reactions for these gas mixtures can be written as follows:

$$CO_2 = CO + \frac{1}{2}O_2 \qquad \text{(Eq 10)}$$

$$H_2O = H_2 + \frac{1}{2}O_2 \qquad \text{(Eq 11)}$$

The corresponding equilibrium partial pressures of oxygen, p_{O_2}, established at equilibrium state may be expressed as:

$$p_{O_2} = \left(\frac{p_{CO_2}}{p_{CO}}\right)^2 \exp\left(-\frac{2\Delta G^0_{10}}{RT}\right) \qquad \text{(Eq 12)}$$

$$p_{O_2} = \left(\frac{p_{H_2O}}{p_{H_2}}\right)^2 \exp\left(-\frac{2\Delta G^0_{11}}{RT}\right) \qquad \text{(Eq 13)}$$

where ΔG^0_{10} and ΔG^0_{11} are the standard Gibbs energy changes of the reactions in Eq 10 and 11, respectively. As can be seen from Eq 12 and 13, for constant ratios of p_{CO}/p_{CO_2} or p_{H_2}/p_{H_2O}, the partial pressure of oxygen is also constant and does not depend significantly on the total pressure of the system. In other words, at a given temperature, p_{O_2} can be easily controlled by controlling the ratio of p_{CO}/p_{CO_2} or p_{H_2}/p_{H_2O}. Consequently, it is possible to choose such a ratio of corresponding gases that the partial pressure of oxygen reaches the value of the dissociation pressure of a given oxide. Such an equilibrium ratio can be read off the Richardson-Jeffes diagrams. For instance, to find a p_{CO}/p_{CO_2} ratio for which the Si-SiO_2-O_2 system is at equilibrium at 1000 °C (1830 °F), a straight line should be drawn from the index point labeled “C” at the left-hand scale through the 1000 °C (1830 °F) point on the line related to the formation of SiO_2. The equilibrium p_{CO}/p_{CO_2} ratio can be read from the intersection of this line with the p_{CO}/p_{CO_2} scale and equals 10^6. In the same way, appropriate equilibrium ratios of p_{H_2}/p_{H_2O} can be read using the index point labeled “H” on the left- hand scale and the p_{H_2}/p_{H_2O} scale.

The Richardson-Jeffes diagrams, although very convenient, cannot be used to obtain more precise values of dissociation pressures. In such cases, rather detailed thermodynamic calculations, described at the beginning of this section, should be performed. Diagrams similar to Fig. 3 are available for formation of sulfides, nitrides, carbides, and halides (Ref 8).

Phase Sequence in the Multilayered Scale

Thermodynamic data can be used to predict the local equilibria in the sequence of phases for multilayered oxide scales. In general, if a metal can form several oxides, the sequence of oxides in the scale growing on this metal can be predicted, with the most oxygen-deficient oxide contacting the metal and the most oxygen-rich oxide next to the gas phase. However, not all oxides are stable at a given temperature and so may not be present in the scale. This is the reason why thermodynamic analysis should be used to determine the phase sequence in the multilayered scale. As an example, referring to the Fe-O phase diagram (Fig. 2) and the oxide layer sequence in the scale growing on iron, the following chemical reactions should be considered:

$$Fe + \frac{1}{2}O_2 = FeO \quad \text{(Eq 14)}$$

$$3Fe + 2O_2 = Fe_3O_4 \quad \text{(Eq 15)}$$

$$2Fe + \frac{3}{2}O_2 = Fe_2O_3 \quad \text{(Eq 16)}$$

For the previous chemical reactions, the dissociation pressure of each oxide can be calculated according to the detailed description given in the first part of this article. At a given temperature, the oxide whose oxygen dissociation pressure is the lowest will form on iron, for example, FeO above 570 °C (1060 °F). To determine whether Fe_3O_4 or Fe_2O_3 forms on FeO, the following reaction and corresponding thermodynamic equilibria should be considered:

$$3FeO + \frac{1}{2}O_2 = Fe_3O_4 \quad \text{(Eq 17)}$$

$$2FeO + \frac{1}{2}O_2 = Fe_2O_3 \quad \text{(Eq 18)}$$

The FeO remains at equilibrium with the oxide whose dissociation pressure is lower (Fe_3O_4). As a consequence, during oxidation by oxygen at temperatures higher than 570 °C (1060 °F), the following phase sequence can be expected on the iron substrate: FeO-Fe_3O_4-Fe_2O_3 (Ref 9).

Kellogg Diagrams

To show a stability range in more complicated multioxidant systems, it is convenient to fix the temperature and plot the other variables, such as gas pressure or alloy composition. These diagrams are called isothermal stability diagrams and show the stability range of particular phases of the system. For the situation of one pure metal and several oxidants, the thermodynamic phase stabilities are shown on log-log plots of the two principal gaseous components, as shown in Fig. 4 for an Fe-O-S system at 727 °C (1341 °F). Such diagrams are constructed on the basis of the chemical potentials of all elements and their compounds that are present in the system. These plots assume that the gas phase is in internal equilibrium with respect to every gaseous species. To plot such a diagram, the equilibria between particular phases of a system should be considered by drawing boundaries, which represent equilibrium between specific oxides or sulfides.

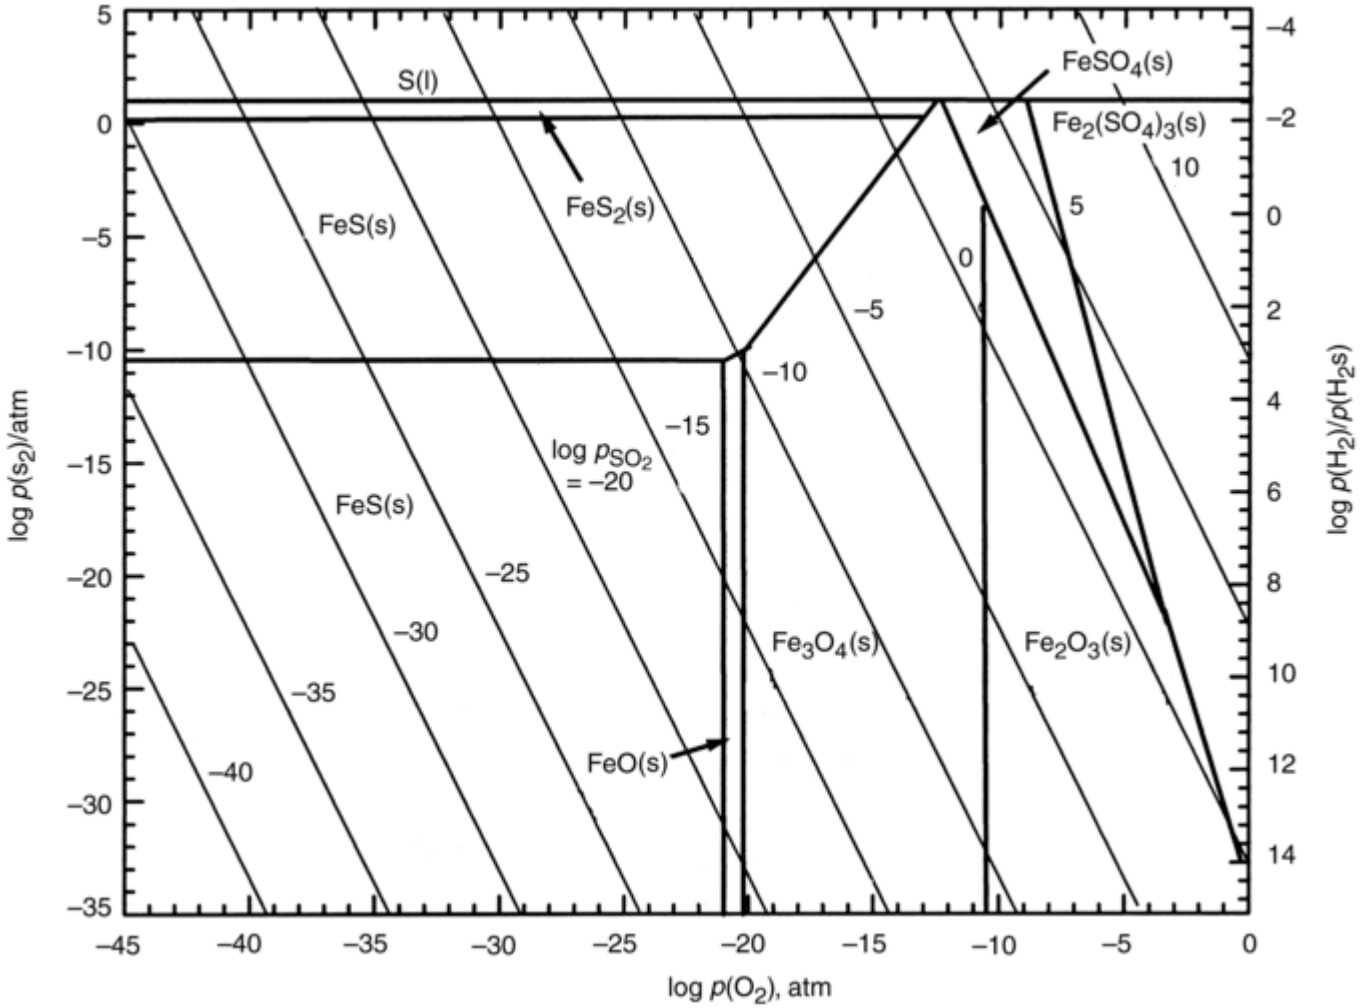

Fig. 4 The thermodynamic phase stabilities in the Fe-O-S system at 727 °C (1341 °F). s, solid; l, liquid

For example, the boundary between Fe(s) and FeO(s) phase (Fig. 4) represents the following equilibrium:

$$Fe + \frac{1}{2}O_2 = FeO \qquad \text{(Eq 19)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The dissociation pressure of FeO equals 2.3×10^{-22} atm at 727 °C (1341 °F). Next, the boundary between the appropriate oxide (FeO) and sulfide phase (FeS) is constructed from the following equilibrium:

$$FeO + \frac{1}{2}S_2 = FeS + \frac{1}{2}O_2 \quad \text{(Eq 20)}$$

Z. Grzesik, Thermodynamics of Gaseous Corrosion, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 90–96

Thermodynamics of Gaseous Corrosion

Zbigniew Grzesik, University of Mining and Metallurgy (Krakow, Poland)

Determination of Partial Pressures of Gas Mixtures

Because the corrosive action of oxygen, hydrogen, or sulfur and their compounds is very common in many essential branches of modern industry, Kellogg diagrams often present auxiliary scales for $p_{SO_2}, p_{H_2}/p_{H_2S}, p_{H_2O}/p_{H_2}$, and so on. However, the composition of a given gas mixture (e.g., SO_2 and O_2) is a function of temperature. For example, if an iron sample is placed into a container of a SO_2-O_2 gas mixture with defined composition at room temperature, and then the container is heated to a higher temperature, the values of initial partial pressures of SO_2 and O_2 cannot be used to determine the presence of oxidation products on iron. If a composition of a gas mixture is known at a given temperature, it is possible to calculate the partial pressures of particular gases at any temperature. To determine the composition of a gas mixture containing S_2 and O_2 at high temperature, the following equilibria should be considered:

$$S_2 + \frac{1}{2}O_2 = S_2O \quad \text{(Eq 21)}$$

$$S_2O + \frac{1}{2}O_2 = 2SO \quad \text{(Eq 22)}$$

$$SO + \frac{1}{2}O_2 = SO_2 \quad \text{(Eq 23)}$$

$$SO_2 + \frac{1}{2}O_2 = SO_3 \quad \text{(Eq 24)}$$

For the previous chemical reactions, the corresponding oxygen partial pressures can be calculated:

$$p_{O_2} = \left(\frac{p_{S_2O}}{p_{S_2}}\right)^2 \exp\left(\frac{2\Delta G^0_{21}}{RT}\right) \quad \text{(Eq 25)}$$

$$p_{O_2} = \left(\frac{p^2_{SO}}{p_{S_2O}}\right)^2 \exp\left(\frac{2\Delta G^0_{22}}{RT}\right) \quad \text{(Eq 26)}$$

$$p_{O_2} = \left(\frac{p_{SO_2}}{p_{SO}}\right)^2 \exp\left(\frac{2\Delta G^0_{23}}{RT}\right) \quad \text{(Eq 27)}$$

$$p_{O_2} = \left(\frac{p_{SO_3}}{p_{SO_2}}\right)^2 \exp\left(\frac{2\Delta G^0_{24}}{RT}\right) \quad \text{(Eq 28)}$$

Additionally, a mass balance for oxygen and sulfur should be considered:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$N_S = 2n_{S_2} + 2n_{S_2O} + n_{SO} + n_{SO_2} + n_{SO_3} \quad \text{(Eq 29)}$$

$$N_{O_2} = \frac{1}{2}n_{S_2O} + \frac{1}{2}n_{SO} + n_{SO_2} + \frac{3}{2}n_{SO_3} + n_{O_2} \quad \text{(Eq 30)}$$

where N_S and N_{O_2} denote total amounts of sulfur and oxygen presented in the system (in moles), and $n_{S_2}, n_{S_2O}, n_{SO}, n_{SO_2}, n_{SO_3}$, and n_{O_2} denote the number of moles of a particular gas present at equilibrium in the system at specified temperature. The partial pressure of any gaseous species, p_i, can be written as:

$$p_i = \frac{n_i}{\sum_{i=1}^{m} n_i} p_{tot} \quad \text{(Eq 31)}$$

where n_i is a number of moles of the *i*-gaseous species, *m* is the total number of species in the gas mixture, and p_{tot} denotes the total gas pressure (total gas pressure is usually known). Equations 25, 26, 27, 28, 29, 30, 31 can be solved numerically, and the partial pressures of particular gases in the gas mixture can be determined.

Z. Grzesik, Thermodynamics of Gaseous Corrosion, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 90–96

Thermodynamics of Gaseous Corrosion

Zbigniew Grzesik, University of Mining and Metallurgy (Krakow, Poland)

Partial Pressures of Volatile Oxidation Products

The oxidation reaction product of a given metal may be volatile, liquid, or solid. Even the solid or liquid product could have a high total vapor pressure involving several species. If the oxidation product is volatile, it is useful to determine its partial vapor pressure as a function of oxygen pressure at a given temperature. In the chromium-oxygen system, three volatile oxides can be formed—CrO(g), CrO_2(g), CrO_3(g)—in which solid chromium, Cr(s), can also sublime to form gaseous chromium, Cr(g). The only stable oxide in the chromium-oxygen system is Cr_2O_3(s). The partial pressures of particular volatile species in the chromium-oxygen system for oxygen pressure less than the dissociation pressure of Cr_2O_3 can be determined from the following equilibria:

$$Cr(s) + \frac{1}{2}O_2 = CrO(g) \quad \text{(Eq 32)}$$

$$Cr(s) + O_2 = CrO_2(g) \quad \text{(Eq 33)}$$

$$Cr(s) + \frac{3}{2}O_2 = CrO_3(g) \quad \text{(Eq 34)}$$

$$Cr(s) = Cr(g) \quad \text{(Eq 35)}$$

In the case of oxygen partial pressure higher than the dissociation pressure of Cr_2O_3, the partial pressures of the volatile oxides and gaseous chromium can be determined from the appropriate chemical reaction:

$$Cr_2O_3(s) = 2CrO(g) + \frac{1}{2}O_2 \quad \text{(Eq 36)}$$

$$Cr_2O_3(s) = 2CrO_2(g) - \frac{1}{2}O_2 \quad \text{(Eq 37)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$Cr_2O_3(s) = 2CrO_3(g) - \frac{3}{2}O_2 \quad \text{(Eq 38)}$$

$$Cr_2O_3(s) = 2Cr(g) + \frac{3}{2}O_2 \quad \text{(Eq 39)}$$

The results of such calculations are presented in Fig. 5. From a practical point of view, it is very important that the partial pressures of volatile CrO_2 and CrO_3 increase with increasing oxygen pressure and temperature. At temperatures higher than 1000 °C (1830 °F), the weight loss of pure chromium- or chromia (Cr_2O_3)-forming alloys in air, due to the loss of the volatile CrO_2 and CrO_3, can be significant. The Cr_2O_3 layer loses its good protective properties. The reaction kinetics are described by a scaling evaporation mechanism provided in Ref 10.

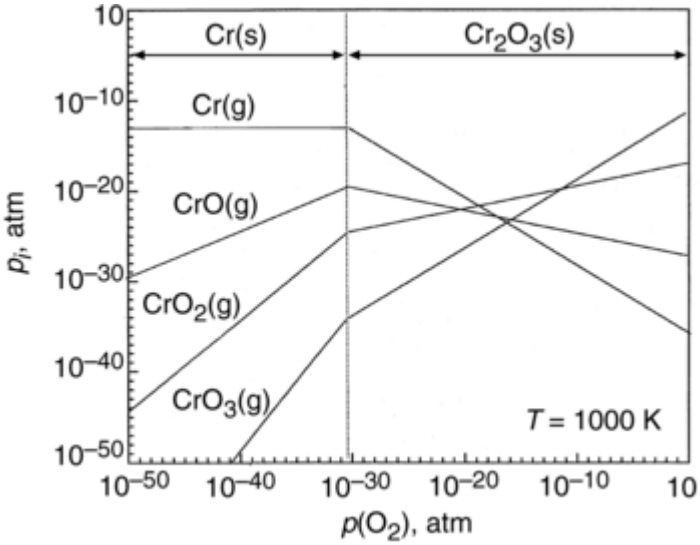

Fig. 5 The diagram of partial pressures of volatile species in the chromium-oxygen system as a function of oxygen pressure at 727 °C (1341 °F). s, solid; g, gas

Theoretical considerations presented in this chapter show that thermodynamics has a fundamental significance in studying the processes occurring in the high-temperature corrosion of metallic materials. Rather simple calculations made on the basis of thermodynamic data determine conditions of temperature, composition, and pressure of reacting gas mixture in which particular reaction products can be formed. As a consequence, thermodynamic considerations may help to optimize the composition of reacting atmosphere and/or alloy and are often the first step in the development of the corrosion resistant materials.

Introduction

IN 1923, N.B. Pilling and R.E. Bedworth classified metals into two groups: those that form protective oxide scales and those that do not (Ref 1). They suggested that unprotective scales are formed if the volume of the oxide layer is less than the volume of metal reacted. For example, in the oxidation of aluminum:

$$2Al + \frac{3}{2}O_2 = Al_2O_3 \quad \text{(Eq 1)}$$

the Pilling-Bedworth molar volume ratio is:

$$\frac{\text{Volume of 1 mol of } Al_2O_3}{\text{Volume of 2 mol of Al}} = 1.287 \quad \text{(Eq 2)}$$

where the volumes are calculated from molecular and atomic weights and the densities of the phases.
If the ratio is less than 1, the oxide scales are usually nonprotective. Scales on metals such as magnesium, potassium, sodium, and calcium are porous or crack due to tensile stresses and provide no efficient barrier to penetration of the gas to the metal surface. If the ratio is more than 1, the protective scale may develop and protect the metal or alloy from the gas so that oxidation can proceed only by solid-state diffusion, which is slow even at high temperatures (iron, nickel, cobalt, chromium, silicon, and aluminum and their alloys). If the ratio is over 2, as is the case with tungsten and niobium, during the scale growth large compressive stresses often develop in the oxide that may cause the scale to crack and/or spall off, leaving the metal unprotected.
Exceptions to the Pilling-Bedworth classification are numerous. The assumption that metal oxides grow by diffusion of oxygen inward through the oxide layer to the metal is seldom valid. The texture, the direction(s) of scale growth, and the possibility of plastic flow by the oxide or metal were not considered. Nevertheless, historically, Pilling and Bedworth took the first step in understanding of the processes by which metals react with gases. Although there may be exceptions, the volume ratio, as a rough rule-of-thumb, is usually correct. The Pilling- Bedworth volume ratios for many common oxides are listed in Table 2 of the article “Thermodynamics of Gaseous Corrosion” in this Volume.

Defect Structure of Oxides

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The basic defect structures of solids were first published by Frenkel (in metals and oxides), Schottky (simple oxides), and Wagner (spinels). Schottky and Wagner started the new discipline, which is now called solid-state chemistry. Point- defect chemistry is the part of it that deals with defect reactions and their equilibria in solids. Such reactions can be written according to Krö ger-Vink notation and must obey the usual rules of electrochemical equations (mass and charge conservancy). The key difference is an additional conservation law, the "rule of the lattice conservancy," which states that only a stoichiometric number of the cationic and anionic lattice elements can be formed/consumed as a result of a reaction. The meaning of symbols used in the chemistry of point defects can be found in general textbooks or monographs on high-temperature corrosion (Ref 2, 3, 4).

Ionic compounds can have appreciable quantities of intrinsic defects (giving rise to ionic conductivity at stoichiometric composition) due to Schottky and/or Frenkel defects (Fig. 1). Schottky defects are combinations of cation vacancies, anion vacancies, and electronic defects:

$$O = V_X + V_{Me} \qquad \text{(Eq 3)}$$

where V_X and V_{Me} denote the vacancy in anionic sublattice and cationic sublattice, respectively (Fig. 1a). Schottky defects are formed and annihilate at interfaces, and they seldom dominate in oxides that provide protective scales. At high temperatures, ionic defects are ionized and electronic defects are formed in the proper ratio necessary to maintain electrical neutrality: $0 = e^- + h^\cdot$ where e^- denotes the electron (free or localized) and $h^\cdot$ is the electron hole. During oxidation, when the metal is protected by a layer of oxide, electrons migrate from the metal, through the oxide, to adsorbed oxygen at the oxide/gas interface and accelerate the rate of reaction.

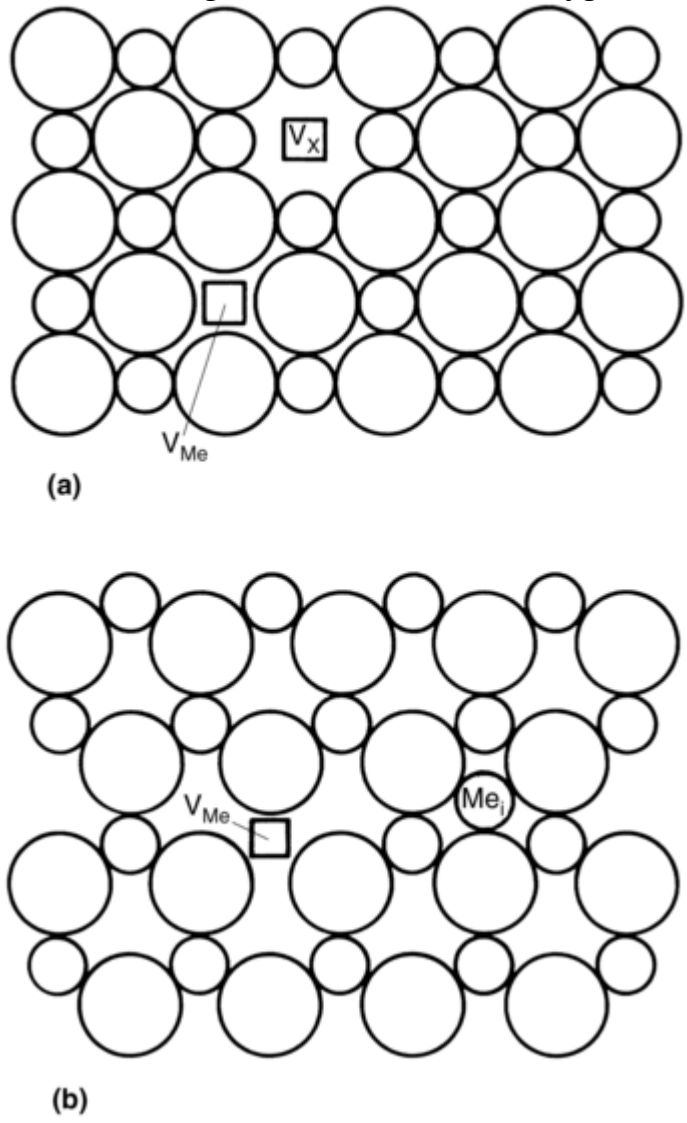

Fig. 1 Defects in ionic crystals. (a) Schottky defect. (b) Frenkel defect. Vacancies (V_X, V_{Me}) are indicated by open squares. Interstitial ion (Me_i) is shown as shaded circle.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Frenkel defects are combinations of cation vacancies, interstitial cations, and electronic defects. The reaction of their formation can be written in the form $Me_{Me} = Me_i + V_{Me}$ (Fig. 1b). Frenkel defects are formed/annihilated within the oxide, are the result of "inner sublimation," and are present in the majority of oxides that protect steels and alloys. Metal cations are generally much smaller than an oxygen anion. Consequently interstitial cations are mobile, showing high diffusivity (mobility). Ionic electrical conductivity is possible in such crystals by the diffusion of interstitial cations and by the diffusion of vacancies. Metallic oxides may have a stoichiometric composition only at specific temperature and pressure conditions. Some oxides always show a certain degree of nonstoichiometry, such as wustite ($Fe_{1-y}O$). This nonstoichiometry usually implies higher concentrations of defects. The higher-defect concentration leads to the formation of a less-protective scale. A typical example is iron, which can be used at temperatures below 570 °C (1060 °F). At T > 570 °C, the highly defected wustite is formed ($Fe_{1-y}O$ where ~0.05 < y < 0.18), accelerating the oxidation rate by two orders of magnitude.

An example of oxides grown to provide protective scales are electronic semiconductors that allow mass transport of ions through the scale layer. They may be categorized as *p*-type, *n*-type, and amphoteric semiconductors (Table 1). They always have the other minority defects that contribute to the diffusivity (ionic conductivity).

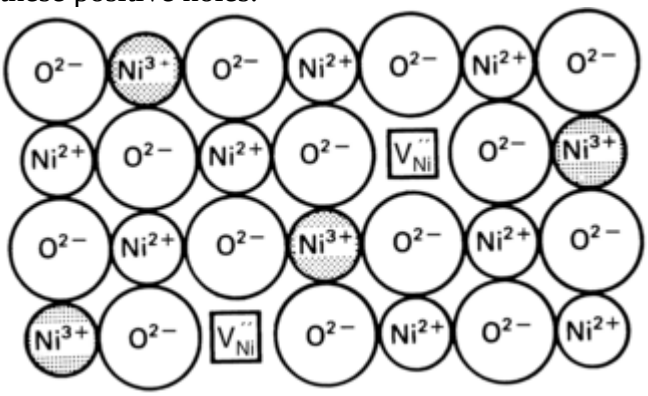
Table 1 Classification of electrical conductors: oxides, sulfides, and nitrides

Metallic conductors are in parentheses.

Metal-excess semiconductors (*n*-type)
BeO, MgO, CaO, SrO, BaO, BaS, ScN, CeO_2, ThO_2, UO_3, U_3O_8, TiO_2, TiS_2, (Ti_2S_3), TiN, ZrO_2, V_2O_5, (V_2S_3), VN, Nb_2O_5, Ta_2O_5, Cu_2O, Cr_2S_3, MoO_3, WO_3, WS_2, MnO_2, Fe_2O_3, $MgFe_2O_4$, $NiFe_2O_4$, $ZnFe_2O_4$, $ZnCo_2O_4$, ($CuFeS_2$), ZnO, CdO, CdS, HgS(red), Al_2O_3, $MgAl_2O_4$, $ZnAl_2O_4$, Tl_2O_3, (In_2O_3), SiO_2, SnO_2, PbO_2, and at low oxidant pressures Cr_2O_3, PbS, and MnS
Metal-deficit semiconductors (*p*-type)
UO_2, (VS), (CrS), Cr_2O_3, (<1250 °C, or 2280 °F), $MgCr_2O_4$, $FeCr_2O_4$, $CoCr_2O_4$, $ZnCr_2O_4$, (WO_2), MoS_2, MnO, Mn_3O_4, Mn_2O_3, ReS_2, FeO, FeS, NiO, NiS, CoO, (Co_3O_4), PdO, Cu_2O, Cu_2S, Ag_2O, $CoAl_2O_4$, $NiAl_2O_4$, (Tl_2O), Tl_2S, (GeO), SnS, (PbO), (Sb_2S_3), (Bi_2S_3), and at high oxidant pressures only: Cr_2O_3, PbS, and MnS
Amphoteric conductors
(TiO), (Ti_2O_3), (VO), Cr_2O_3 (>1250 °C, or 2280 °F), MoO_2, FeS_2, (OsS_2), (IrO_2), RuO_2, Cr_2O_3, PbS, and MnS

Source: Ref 5

The *p*-type metal-deficit oxides are nonstoichiometric compounds with cation vacancies being the dominating defects. A typical example is $Ni_{1-y}O$ (Fig. 2), a cation-deficient oxide that provides the additional electrons needed for ionic bonding and electrical neutrality by donating electrons from the 3*d* subshells of a fraction of the nickel ions (i.e., forms electron holes as electronic defects). The reaction of defects in NiO can be written as $\frac{1}{2}O_2(g) = O_O + V_{Ni}'' + 2h^{\cdot}$. In this way, for every cation vacancy present in the oxide, two nickelic ions (Ni^{3+}) will be present. Each Ni^{3+} has a low-energy positively charged electron hole that electrons from other nickelous ions (Ni^{2+}) can easily move into. The positive or *p*-type semiconductors carry most of their current by means of these positive holes.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 2 Ionic arrangement in *p*-type NiO scale. Cation vacancies are indicated as open squares. The Ni^{3+} cations (i.e., the electron holes, h) are shaded, the Ni^{2+} cations are nickel ions in their lattice positions, Ni_{Ni}. Vacancies are open squares.

Cations diffuse through the scale from the Ni/ NiO interface where the nickel atoms enter the oxide: Ni(metallic) + V_{Ni}= Ni_{Ni} + $2e^-$. They diffuse by cation vacancies ($J_c = -J_V$) to the NiO/gas interface where they react with adsorbed oxygen: $Ni_{Ni} + O^{2-} = V_{Ni} + Ni_{Ni} + O_O$ or traditionally $Ni_{2+} + O^{2-} = NiO$. Electrons migrate from the metal surface, by electron holes, to the adsorbed oxygen atoms, which then become chemisorbed oxygen anions: O(adsorbed) + $2e^- = O^{2-}$. In this way, while cations and electrons move outward through the scale toward the gas, cation vacancies, and electron holes move inward toward the metal. Consequently, as the scale thickens, the cation vacancies may accumulate to form voids at the Ni/ NiO interface and "destroy" an otherwise compact scale.

The *n*-type semiconductor oxides have free electrons as the major charge carriers. They may be either cation excess ($Me_{a+y}X_b$) or anion deficient (Me_aX_{b-y}). Beryllium oxide ($Be_{1+y}O$), a cation-excess oxide, is shown in Fig. 3. Oxygen in the gas adsorbs on the $Be_{1+y}O$ surface and picks up free electrons from the oxide to become chemisorbed O^{2-} ions, which then react with excess metal cations at BeO external interface: $Be_i^{\cdot\cdot}$ + O^{2-} = Be_{Be} + O_O (or $Be^{2+} + O^{2-}$ = BeO). The cations diffuse interstitially from the underlying beryllium metal. The free electrons migrate from the metal surface where the beryllium enters the oxide and ionizes: Be(metallic) = $Be_i^{\cdot\cdot}$ + $2e^-$. As with *p*-type oxides, the cation-excess *n*-type oxides grow at the oxide/gas interface.

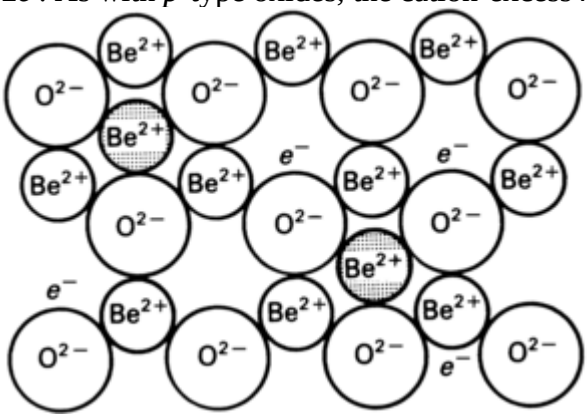


Fig. 3 Ionic arrangement in *n*-type cation-excess BeO. Interstitial cations Be_i are shaded; free electrons are indicated as e^-.

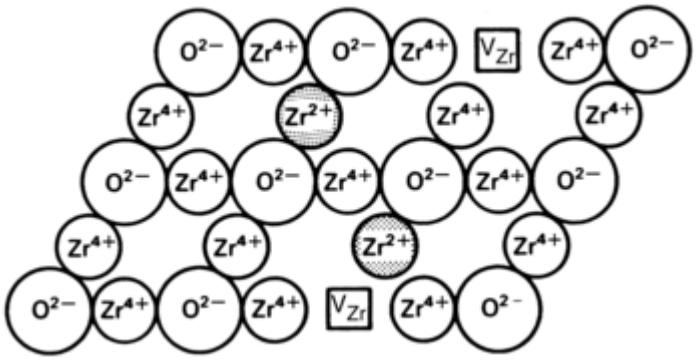
Another group of *n*-type semiconductors oxides is anion deficient, as exemplified by zirconium dioxide (ZrO_{2-y}). In this case, although most of the cations contribute four electrons to the ionic bonding, a small fraction of the zirconium cations contribute only two electrons to become the zirconium ion Zr^{2+}. Therefore, to maintain electrical neutrality, an equal number of anion vacancies must be present in the oxide. This arrangement is shown in Fig. 4. The oxide grows at the metal/oxide interface by inward diffusion of O^{2-} through the anion vacancies in the oxide:

$J_O = -J_V$ (Eq 4)



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 4 Ionic arrangement in *n*-type anion-deficient ZrO_2. Anion vacancies, V_{Zr} are indicated as open squares; Zr^{2+} ions are shaded.

Amphoteric Oxides. A number of compounds show nonstoichiometry with either a deficiency of cations or a deficiency of anions. An important example is chromia ($Cr_{2\pm y}O_3$) (Ref 3) and lead sulfide ($Pb_{1\pm y}S$). Both compounds have a minimum in electrical conductivity at the stoichiometric composition and are metal deficient (*p*-type semiconductors) at the high-oxidant activities and metal excess (*n*-type) at low pressures.

Chromium oxide is a cation-excess oxide at low oxygen pressures and a cation-deficient oxide at high oxygen activities. The mechanism of mass transport in the growing chromia scale depends on the oxygen activity. The oxygen pressure may be low enough to keep the whole chromia layer below the stoichiometric composition (in the *n*-type range). In such a case, the chromia scale grows in a manner already discussed for *n*-type semiconductor oxides. At higher oxygen activities the mechanism of diffusion is more complex. Somewhere within the scale there is a transition layer (near-stoichiometric chromia) dividing the oxide into the two "parts," the *n*-type semiconductor (from the chromium/chromia interface to near-stoichiometric chromia) and the *p*-type semiconductor (from the near-stoichiometric chromia to the chromia/gas interface). The mechanism of diffusion and reactions at interfaces depends on the type of oxide that stays in contact with this interface. Oxygen in the gas adsorbs on the chromia surface and picks up free electrons from the chromia to become a chemisorbed O^{2-} ion: O(adsorbed) + $2e^-$ = O^{2-}. At low oxygen partial pressures, this oxygen ion reacts with chromium interstitial ions that are diffusing interstitially from the chromium metal: $2Cr_i^{\cdot\cdot\cdot} + 3O^{2-} = 2Cr_{Cr} + 3O_O$ (or $2Cr^{3+} + 3O^{2-} = Cr_2O_3$). The free electrons come from the metal surface as the chromium enters chromia and ionizes (Cr(metallic) = $Cr_i^{\cdot\cdot\cdot}$) + $3e^-$). They can travel through vacant high-energy levels, that is, diffuse by the counterflow of the electron holes: $J_e = -J_h$. As with *p*-type oxides, the cation-excess *n*-type chromia grows at the oxide/gas interface as cations diffuse outward through the scale. At high oxygen pressures, chromia in contact with gaseous oxygen is a *p*-type oxide. Thus, the reaction at the external interface is: $2Cr_{Cr} + 3O^{2-} = 2V_{Cr}^{'''} + 2Cr_{Cr} + 3O_O$ (or $2Cr^{3+} + 3O^{2-} = Cr_2O_3$). Somewhere within the growing chromia there is an intermediate layer where the properties of this oxide change from *n*-type to *p*-type. Consequently, outward flow of the interstitial cations converts to the inward vacancy flow (note that this transition of the dominating defects does not affect the direction of the cation flow). Mass transport in amphoteric oxides is not well known; the transition processes may generate stresses and other effects. Grain boundaries and dislocations affect the rate of the transport process.

Solid-State Diffusion

Diffusion processes in solids play a key role in the oxidation of metals. As already stated, the oxidation reaction may be the result of the outward diffusion of metal ions from the metal surface through the oxide layer to the adsorbed oxygen anions at the oxide/gas interface (e.g., *p*-type NiO), the result of the diffusion of anions inward through the oxide to the metal (e.g., *p*- type ZrO_2) or the result of both processes. The diffusion of atomic oxygen into the metal from the oxide (e.g., into titanium) can also be involved.

Within an alloy, interdiffusion plays a key role, for example, the outward diffusion of the reacting metal atoms during their selective oxidation forces the simultaneous inward diffusion of all other alloy elements.

Diffusion Mechanisms. Atoms or ions move (diffuse) through solids by many mechanisms. The most common is the vacancy mechanism of diffusion. An atom or ion oscillating (“sitting”) on a regular lattice site can move to a vacant site nearby (diffuse by jumping) (Fig. 5a). In many metal systems, vacancies are the dominating defects, while ionic oxides often show a more complex defect structure. They contain Schottky and Frenkel defects that also involve vacancies and electronic defects. For metal atoms, this is relatively easy because the jump distances are short. For ionic crystals, the jump distances are much longer because cation sites are surrounded by anion sites, and vice versa.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

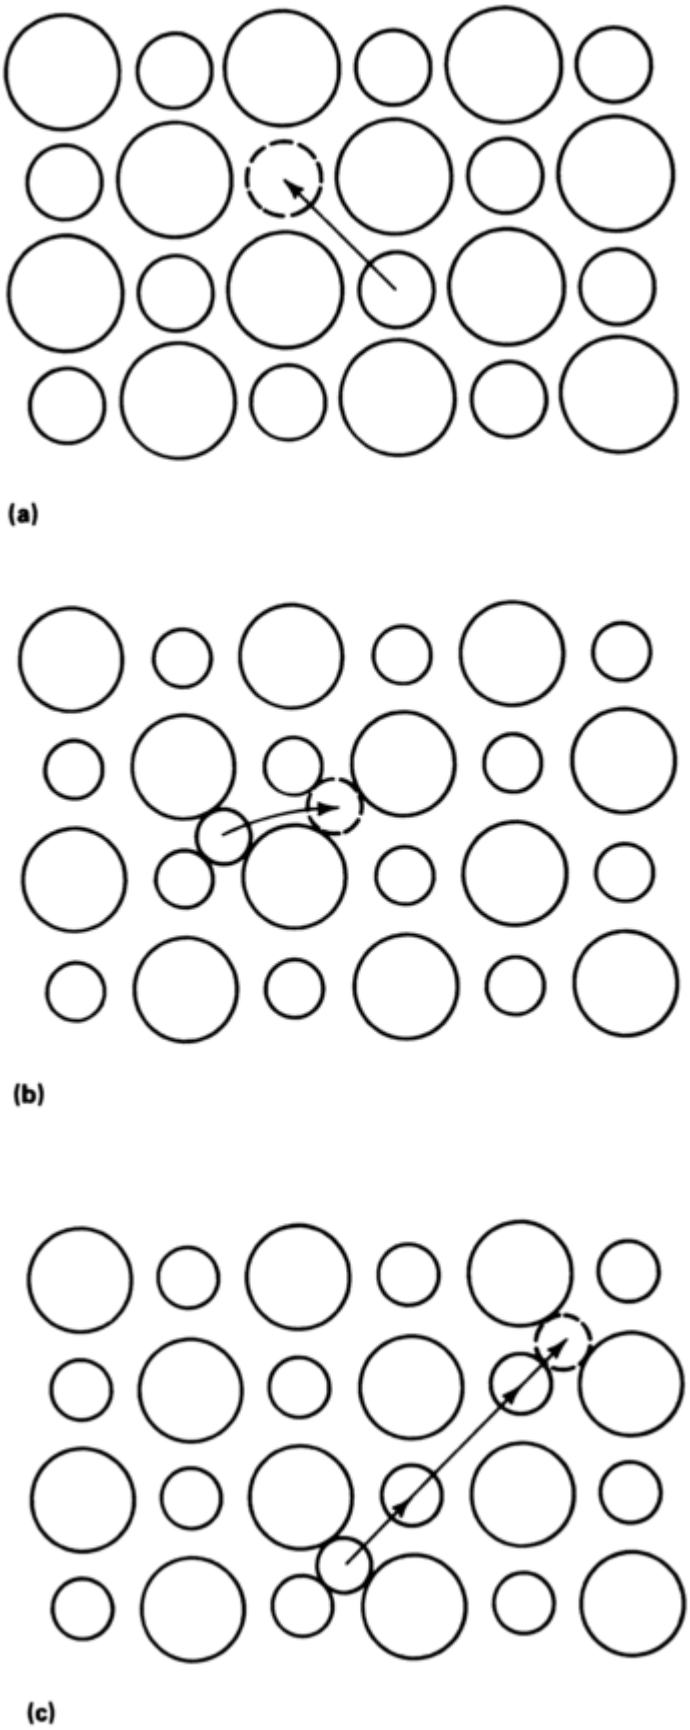

Fig. 5 Diffusion mechanisms. (a) Vacancy diffusion. (b) Interstitial diffusion. (c) Interstitial diffusion with displacement

Small interstitial atoms diffuse readily from one interstitial position to another. In ionic oxides, the cations may diffuse interstitially (Fig. 5b), but anions are usually not small enough to do so. In ionic crystals, an interstitial ion often moves into a regular lattice site, knocking another ion into a different interstitial position or to the next

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

lattice site. This chain effect may extend for several atomic spacings in a line or in different direction. Figure 5(c) shows such interstitial diffusion with displacement.

Fick's Law. In 1855, Fick formulated his two laws of diffusion for the simplest sort of diffusion system: a binary system at constant temperature and pressure, with net movement of atoms in only one direction. This is the basic situation for diffusion through an oxide growing on a pure metal.

Fick's first law states that the rate of mass transfer is proportional to the concentration gradient of the diffusing element:

$$\mathbf{J}_i = -D_i \nabla C_i \qquad \text{(Eq 5)}$$

where $\mathbf{J}_i$ is the flux of the i-th specie (i.e., net mass transported per second through a unit surface area perpendicular to the direction of flow), ∇C_i is the concentration gradient (in one-dimensional, planar systems it becomes:) $\nabla C_i = \mathbf{i}(\partial C_i / \partial x)$, and D_i is the proper diffusion coefficient, cm^2/s.

The term “proper” means the necessity of the careful examination of the process (experiment) and model of mass transport before using diffusivity data. To model the oxidation processes (i.e., the reactive diffusion), the chemical diffusion coefficients and/or self-diffusion coefficients are useful. To analyze the interdiffusion, the intrinsic and/or self-diffusion coefficients must be known. The ideal Fickian diffusion (Eq 5) is a tracer diffusion, such as an iron isotope in iron.

Diffusivity (D) is proportional to effective jump frequency (number of jumps per second when an atom changes position, f) and the square of the jump distance (λ) $D = \frac{1}{6} f \lambda^2$. More precisely, it depends on the type of diffusing atoms, the chemical bonding, the crystallographic structure of the alloy or oxide, the temperature, and many other factors. When gas oxidation is analyzed in solids, the diffusivities change many orders of magnitude, $D \in$ (10^{-18} to 10^{-6}, cm^2/s). Other flux formula were proposed by Nernst- Planck, Onsager, Darken, and others.

The Nernst-Planck flux formula is common in electrochemistry and was used by Wagner to analyze the mass transport during the oxidation of the pure metal:

$$\mathbf{J}_i = -B_i C_i \mathbf{F} \qquad \text{(Eq 6)}$$

where B_i is the mobility and $\mathbf{F}$ is the local force acting on the ith element.

The Darken flux formula is common in interdiffusion studies. It was used by Wagner to analyze the reaction of the selective oxidation of the alloy:

$$\mathbf{J}_i = -\mathbf{J}_i^{\text{diff}} + C_i v \qquad \text{(Eq 7)}$$

where J_i^{diff} denotes the diffusion flux (given, e.g., by Eq 5 or 6) and v is the drift or convection velocity.

Conservation of Mass. The governing law of diffusion, and the mass transport in general, is the law of mass conservation. Its general form is accepted in all instances of mass transport:

$$\frac{\partial c_i}{\partial t} = -\nabla \mathbf{J}_i + A_i \qquad \text{(Eq 8)}$$

where the terms on the right-hand side are the local divergence ∇ of the flux of the ith element; A_i is the local source/sink of mass, for example, as a result of chemical reactions. This equation reads: the local change of concentration is the effect of the difference between the local inflow and outflow of mass and a result of chemical reactions. The chemical reactions, the last term, can usually be neglected in solids.

In most cases, planar (one-dimensional) systems are analyzed. Thus, the law of mass conservation (or the continuity equation) is:

$$\frac{\partial c_i}{\partial t} = -\frac{\partial \mathbf{J}}{\partial x} \qquad \text{(Eq 9)}$$

When the mass transport is due to the diffusion only, Fick's first law is the proper flux formula, and the diffusivity does not depend on concentration, then Eq 8 reduces to the Fick's 1855 formula. The equation of mass conservation (Eq 9) reduces to Fick's second law:

$$\frac{\partial c_i}{\partial t} = -D_i \frac{\partial^2 C_i}{\partial x^2} \qquad \text{(Eq 10)}$$

As an example of the Fickian diffusion, the diffusion of oxygen into a metal can be analyzed. When internal oxidation does not occur, the concentration of oxygen changes with time according to the Fick's second law (Eq

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

10). Solution of the problem depends on the initial and the boundary conditions. When oxygen atoms diffuse inwardly from the surface of an infinite plate, with a constant diffusivity D and at the constant interfacial concentration C', the solution has a relatively simple form. The concentration of oxygen is a function of distance from the metal surface and of the time [$C = C(t, x)$]. It is expressed by:

$$\frac{C' - C}{C' - C^0} = \text{erf}\left(\frac{x}{2\sqrt{Dt}}\right) \qquad \text{(Eq 11)}$$

where C_0 is a constant, the initial (t = 0) concentration of the oxygen in the plate. The error function, erf, is tabulated in books on diffusion and probability.

Figure 6 shows the oxygen concentration as a function of distance from external interface for an arbitrary time (t > 0). During the whole diffusion process, C^0 and C' are constant. One may now ask how fast an arbitrary concentration of oxygen (C'' = constant < C') changes its "position," that is, how fast the oxygen penetrates the plate. For the fixed value of oxygen concentration, C'', Eq 11 reduces to:

$$x(C'') \propto \sqrt{Dt} \qquad \text{(Eq 12)}$$

This means the penetration rate is a parabolic function of time.

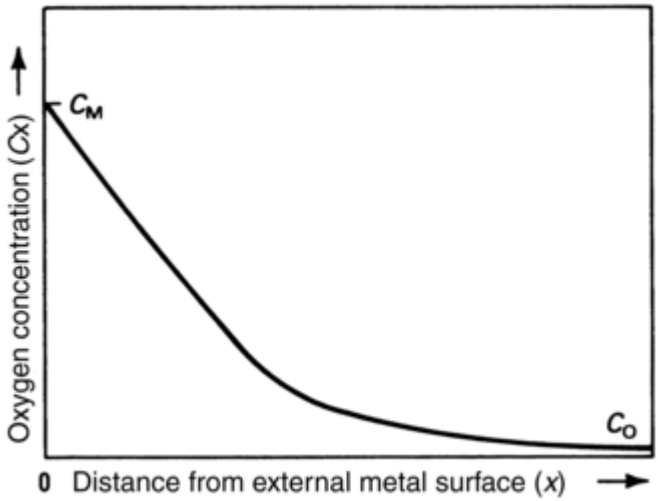

Fig. 6 Non-steady-state diffusion. Oxygen distribution during its diffusion into the semi-infinite plate. C_M, concentration at metal/oxide interface; C_0, initial concentration

The Diffusion Coefficient. Diffusivity is proportional to the defect concentration. All defects in a given sublattice contribute to mass transport; for example, the self-diffusion coefficient of metal, D^*_{Me}, in an oxide is given by:

$$D^*_{\text{Me}} = \sum_{i=1}^{n} N_i D_i^* \qquad \text{(Eq 13)}$$

where D_i^* denotes the self-diffusion coefficient of the i-th defect and N_i is the molar ratio of defects in Me sublattice.

The diffusion coefficient may also depend on crystal orientation (in hexagonal crystals). It implies anisotropic transport properties, and in such a case diffusivity cannot be expressed as a scalar quantity. For oxides that grow epitaxially and/or have a preferred orientation, the diffusivity can differ by orders of magnitude from that of a random polycrystalline oxide.

Temperature has a major effect on the diffusion coefficient. In the temperature range where a single mechanism of diffusion dominates and where this mechanism is a thermally activated process, the well-known Arrhenius relation holds. According to the Arrhenius equation, diffusivity increases exponentially with temperature:

$$D = D_0 \exp\left(\frac{-Q_a}{RT}\right) \qquad \text{(Eq 14)}$$

where D_0 is a constant that depends on frequency of effective jumps, Q_a denotes activation energy for diffusion, R is the gas constant, and T the absolute temperature.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Activation energies for interstitial diffusion are lower than those for vacancy diffusion. The activation energy has a major impact on the temperature dependence of a diffusion process. High values of Q_a mean that the diffusion proceeds much more rapidly at high temperatures, but might be much slower at low temperatures. If the diffusivity D is plotted on a natural logarithm scale as a function of $1/T$, the slope of the resulting straight line is $-Q_a/R$. If the graph shows two intersecting lines, it indicates that the diffusion mechanism that dominates at low temperatures—for example, the grain-boundary diffusion—differs from the one operating at high temperatures (the volume diffusion). Typical values of D_0 and Q_a for diffusion in oxides are listed in Table 2, (Ref 6).

Table 2 Selected diffusion data in metal oxides

Metal oxide	Temperature		Frequency factor (D_0), cm^2/s	Activation energy for diffusion (Q_a)	
	°C	**°F**		**kJ/mol**	**BTU/mol**
Copper in Cu_2O	800–1050	1470–1920	0.12	151.0	143
Nickel in NiO	740–1400	1365–2550	0.017	234	222
Oxygen in Fe_2O_3	1150–1250	2100–2280	10^{11}	610	578
Iron in Fe_3O_4	750–1000	1380–1830	5.2	230	218
Iron in $Fe_{0.92}O$	690–1010	1275–1850	0.014	126.4	120
Chromium in Cr_2O_3	1000–1350	1830–2460	4000	420	398
Oxygen in UO_2	450–600	840–1110	2.6×10^{-5}	124	118
Magnesium in MgO	1400–1600	2550–2910	0.25	330	313

Source: Ref 6

Effect of Impurities. All oxides contain certain substitutional cations (impurities) from the oxidized alloy (present before the oxidation) and/or from the gas phase during oxidation. Although the solubility limit for foreign ions is low, they can have a great effect on the oxide transport properties, and consequently on the oxidation rate.

In *p*-type oxides, such as NiO, the substitutional cations have a valence greater than the Ni^{2+} ions that are replaced, increasing the concentration of cation vacancies. Two aluminum ions (Al^{3+}) replacing two Ni^{2+} ions in the cationic sublattice supply two extra free electrons. Consequently, to maintain the local electrical neutrality condition, an additional cation vacancy must be formed. The increase of concentration of cation vacancies in NiO increases the nickel diffusivity in this oxide. On the other side, substitutional cations with a valence lower than +2 reduce diffusion in NiO by reducing the number of cation vacancies. Divalent cations have little effect on diffusion when substituting for Ni^{2+} ions. For *n*-type oxides, the effect is reversed; if Al^{3+} substitutes some titanium ions (Ti^{4+}) in titanium dioxide (TiO_2), more anion vacancies will be formed in the oxide. Diffusivity of oxygen then increases because of the increase in anion vacancy concentration. Higher- valence impurity ions would decrease oxygen diffusion in *n*-type oxides. The impurity effect is especially important for diffusion at low temperatures at which the native defect concentration is low, and the activation energy is associated with the movement of ions only. At high temperatures, the activation energy increases because it involves formation of defects as well as their motion.

Fast Diffusion Paths. The activation energies for diffusion along line and surface defects in solids are much lower than those for volume diffusion. Dislocations, grain boundaries, porosity networks, and interfaces form rapid diffusion paths. At low temperatures, below the Tammann temperature ($T_T \cong \frac{2}{3}T_m$, where T_m is the melting temperature), volume diffusion is virtually stopped in oxides. In metals, diffusion along dislocations is more important than volume diffusion below about one-half of the absolute melting point, T_m. Above the Tammann temperature, the volume diffusion predominates in both metals and oxides.

Oxide Texture

Amorphous Oxides. In the very early stages of oxidation and especially at low and intermediate temperatures ($T < T_T$), some oxides appear to grow with an amorphous structure. In general, the oxides in which the molar ratio of oxygen to metal is higher than one form glasses. They contain more oxygen than metal in their formulas so that oxygen triangles or tetrahedra are formed around each of the metal ions. The random network ring structures that result allow large anions or molecular oxygen to move through them more readily than the smaller cations do. Amorphous oxides tend to crystallize as they age. Examples are silicon dioxide (SiO_2), tantalum pentoxide (Ta_2O_5), and niobium pentoxide (Nb_2O_5). In contrast, oxides with M_2O and MO formulas have structures in which the small cations can move readily. They are apparently always crystalline. Examples are NiO, cuprous oxide (Cu_2O), and zinc oxide (ZnO).

In general the amorphous and nanostructure form of oxides increases mobility and is desirable in coatings and alloys that form protective scale as a result of selective oxidation. In such a case, the stability of the oxide layer depends on continuous supply of oxidized metal; that is, it depends on the interdiffusion rate within an alloy.

Epitaxy. As a crystalline oxide grows on a metal surface, it often aligns its crystal structure to be compatible with the structure of the metal substrate. This epitaxial growth results in the best fit between the two different crystal structures. For example, either (111) or (001) planes of Cu_2O grow parallel to the Cu (001) plane with the • 110• directions of Cu_2O parallel to the • 110• of copper (Ref 7).

Stress develops in an epitaxial oxide layer as it grows because of the slight misfit between the oxide and metal crystals. Such stress is likely to produce dislocation arrays within the oxide that eventually become fast diffusion paths and accelerate mass transport through the film. A mosaic structure may develop in the oxide because of the growth stresses. The mosaic structure consists of small crystallites with orientations very slightly tilted or twisted with respect to each other. The boundaries between the crystallites are dislocation arrays that again serve as fast diffusion paths.

Stresses in epitaxial layers increase as the films grow thicker until a point is reached when the bulk scale tends to become polycrystalline and epitaxy is gradually lost. Epitaxy may last up to about 50 nm in many cases, but it seldom exceeds 100 nm.

Preferred Orientation. Above the Tammann temperature the oxide grain size (diameter) increases with the scale thickness. Crystals that are favorably oriented can grow at the expense of their neighboring grains until the oxide surface consists of a few large grains with similar orientation. Below the Tammann temperature, fine-grained scales are formed. The variation in growth rate of different oxide grains produces roughening of the scale surface and is commonly observed (Ref 2, 3, 4).

Oxidation Kinetics

Linear Oxidation Reaction Rates. If the metal surface is not protected by an oxide barrier layer, then the oxidation rate usually remains constant with time. In such a case, the surface processes and/or reactions are the rate-controlling steps. This situation occurs in many cases:

- The Pilling-Bedworth ratio is less than one.
- The oxide is volatile.
- Oxide forms molten eutectic with the underlying metal.
- The scale spalls off or cracks due to internal stresses.
- A porous, unprotective oxide forms on the metals.

The linear oxidation rate is:

$$\frac{dX}{dt} = k_L \qquad \text{(Eq 15)}$$

where X is the mass (or thickness) of the oxide formed, t is the time of oxidation, and k_L is the linear rate constant. Upon integration and when the initial (at $t = 0$) scale thickness equals 0, the linear oxidation equation is:

$$X = k_L t \qquad \text{(Eq 16)}$$

The oxidation never slows down; after a short time at high temperature, the metal will be completely destroyed. Figure 7 shows the relationship between oxide mass and time for linear oxidation.

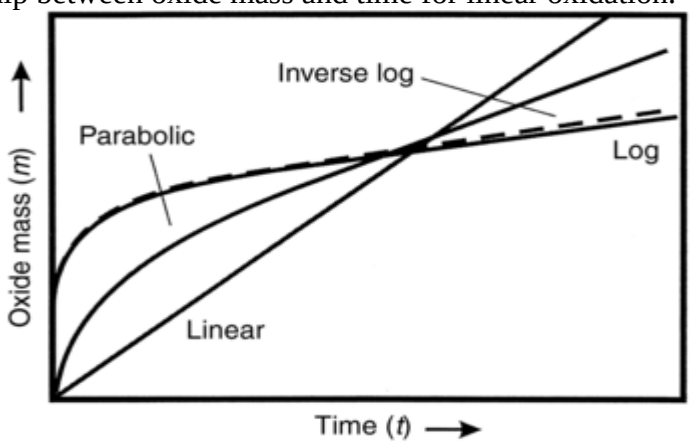

Fig. 7 Types of the oxidation kinetics: linear, logarithmic, inverse logarithmic, and parabolic oxidation kinetics

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Logarithmic and Inverse Logarithmic Reaction Rates. At low temperatures when only a thin film of oxide is formed (for example, under 100 nm), the oxidation is usually observed to follow either logarithmic or inverse logarithmic kinetics. Transport processes across the film are rate controlling, with the driving force being electric fields across the film. The logarithmic equation is:

$$X = k_e \log(at + 1) \quad \text{(Eq 17)}$$

where k_e and a are constants.
The inverse logarithmic equation is:

$$\frac{1}{X} = b - k_i \log t \quad \text{(Eq 18)}$$

where b and k_i are constants. Under the difficult experimental conditions involved in making measurements in the thin-film range, it is difficult to distinguish between logarithmic and inverse logarithmic oxidation. Both Eq 17 and 18 have two constants that can be adjusted to fit the data quite well. Metals oxidizing with logarithmic or inverse log kinetics reach a limiting film thickness at which oxidation apparently stops. Figure 7 shows the curves for both logarithmic and inverse logarithmic kinetics.
Parabolic Kinetics. When the rate-controlling step in the oxidation process is the diffusion of ions through a compact barrier layer of oxide, with the chemical potential gradient as the driving force, the parabolic rate law is usually observed. As the oxide grows thicker, the diffusion distance increases and the oxidation rate slows down. The rate is inversely proportional to the oxide thickness:

$$\frac{dX}{dt} = \frac{k'}{X} \quad \text{(Eq 19)}$$

where k' is the parabolic rate constant. Upon separating the variables and integrating Eq 19 with the initial condition that at time $t = 0$ the oxide thickness $X = 0$, the integral form of the parabolic equation results:

$$X^2 = k't \quad \text{(Eq 20)}$$

Figure 7 shows the parabolic oxidation curve.
Other Reaction Rate Equations. A number of other kinetics equations have been fitted to the experimental data, but it is believed that they describe a combination of the mechanisms described previously, rather than any new basic process. A cubic relationship:

$$X^3 = k't \quad \text{(Eq 21)}$$

has been reported for very long oxidation periods (t > 10,000 h). It can be shown mathematically to be an intermediate stage between logarithmic and parabolic kinetics.
Initial Oxidation Processes: Adsorption and Nucleation. To begin oxidation, oxygen gas is chemisorbed on the metal surface until a complete two-dimensional oxygen layer is formed. Some atomic oxygen also dissolves into the metal at the same time. After the monolayer forms, discrete nuclei of three-dimensional oxide appear on the surface and begin expanding laterally at an ever-increasing rate. The nuclei may originate at structural defects, such as grain boundaries, impurity particles, and dislocations. The concentration of nuclei depends primarily on the crystal orientation of the metal, with more nuclei forming at high pressures and low temperatures.
These oxide islands grow outward rapidly by surface diffusion of adsorbed oxygen until a complete film three or four monolayers thick covers the metal. The oxidation rate then drops abruptly. If chemisorption were still the rate-controlling (slow) step in oxidation after the thin film is completed, a logarithmic rate law should be observed. The logarithmic rate law is the result of a strong electric field across the film that affects the oxidation rate.

Thin-Film Mechanisms

Many theories have been proposed to explain the oxidation mechanism at low temperatures or in the early stages of high-temperature oxidation where logarithmic kinetics are commonly observed. None of the theories are completely accepted yet, and perhaps none is completely correct, but they have common threads of agreement that indicate reasonably well what is happening. Some of the most important theories are briefly described in this Section.

The Cabrera-Mott theory, probably the best established theory of thin-film oxidation, applies to films up to about 10 nm thick (Ref 8). It proposes that electrons from the metal easily pass through the thin film by tunneling to reach adsorbed oxygen at the oxide/gas surface and form oxygen anions. A potential of approximately 1 V is set up between the external oxide surface and the metal. For a film 1 nm thick, the field strength would be 10^7 V/cm, powerful enough to pull cations from the metal and through the film. The rate-controlling step is the transfer of cations (or anions) into the oxide or the movement of the ions through the oxide. The electric field reduces this barrier. The structure of the oxide determines whether cations or anions migrate through the oxide. As the film grows thicker, the field strength decreases until it has so little effect on the ions that the rate-controlling mechanism changes.

Cabrera and Mott developed an inverse logarithmic kinetic equation to describe the mechanism. A logarithmic equation is more commonly observed, but it can be derived from the Cabrera- Mott mechanism if the activation energy for ionic migration is a function of film thickness. Such a situation would exist if the oxide film were initially amorphous and became more crystalline with aging, giving a constant field strength through the film instead of a constant voltage.

The Hauffe-Ilschner theory, a modification of Mott's original concept of a space charge developed across the oxide film, proposes that quantum-mechanical tunneling of electrons is the rate-controlling step (Ref 9). After the film thickness reaches about 10 nm, tunneling becomes increasingly difficult, and the observed reaction rate decreases greatly. For film thickness up to perhaps 20 nm, a logarithmic equation results. For films from 20 to 200 nm thick, the inverse logarithmic relationship holds. Potentials across thin films have been measured; a change in sign of the potential is interpreted as a change from electronic transport control to ionic transport control.

The Grimley-Trapnell theory (Ref 10). Grimley and Trapnell used the Cabrera-Mott model, but assumed a constant electric field instead of a constant potential. They assumed that the adsorbed oxygen layer would always be complete, even at high temperatures and low pressure. The adsorbed oxygen would take electrons from cations in the oxide, not from the metal, so that a space charge would develop at the MO/O-ads interface (O-ads being the adsorbed oxygen layer) and be independent of the oxide thickness. If the rate-controlling step is diffusion of cations through vacancies, logarithmic kinetics should be observed. If some other process is rate controlling, linear kinetics is most likely.

The Uhlig theory, developed by Uhlig and extended by Fromhold, also predicts logarithmic kinetics at temperatures up to 600 K (Ref 11). The rate-controlling step is the thermal emission of electrons from the metal into the oxide (or electron holes from the adsorbed oxygen ions to the oxide) under the combined effects of induced potential and applied field. The field is created by the diffusing ions. Because growth of the film depends on the electronic work function of the metal, the theory explains oxidation rate changes at crystal and magnetic transformations; most other theories do not.

The Wagner Theory of Oxidation. During the oxidation process the two reactants are separated by an oxide layer. Thus, it is necessary to postulate that mass transport (volume diffusion in simple cases) occurs through such growing oxide scale. Before presenting Wagner's derivation of the parabolic rate equation for scale growth

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

on a metal in which diffusion of ions or electrons is rate-controlling step, a simplified treatment is given to emphasize the main features of diffusion-controlled oxidation.

One can assume that a pure metal reacts with an oxidant and the growth of a dense, planar and single-phase oxide occurs. Moreover, the following conditions regarding this phase are necessary for which the theory is valid:

- One type of defect dominates in the oxide.
- The thermodynamic equilibria are established on both Me/scale and scale/oxidant interfaces.
- The oxide scale shows small deviation from stoichiometry.
- The oxidant solubility in the metal, the oxide evaporation, and any other processes at interfaces are negligible.
- The scale is thick compared with distances over which space charge effects occur (electrical double layer).

From the assumption of low nonstoichiometry it follows that the metal and oxidant concentrations in the growing scale do not depend on position and are constant. Consequently, when the metal (e.g., interstitial cations Me_i) diffusion dominates, Fick's second law (Eq 10) reduces to:

$$\frac{\partial}{\partial x}\mathbf{J}_{\mathrm{Me_i}} = 0 \qquad \text{(Eq 22)}$$

from which it follows that the flux of metal does not depend on position in the scale and depends on time only. The rate of growth of the oxide scale, dX/dt, is then proportional to the flux of metal ions $\mathbf{J}_{\mathrm{Me}}$ by Fick's first law (Eq 5):

$$\mathbf{J}_{\mathrm{Me}} = \mathbf{J}_{\mathrm{Me_i}} = -D_{\mathrm{Me_i}}\frac{\partial C_{\mathrm{Me_i}}}{\partial x} \qquad \text{(Eq 23)}$$

When the diffusion coefficient does not depend on defect concentration, then from Eq 22 and 23 it follows that the gradient of metal concentration in the growing scale is constant. It allows further simplification of the flux formulas:

$$\mathbf{J}_{\mathrm{Me}} = -D_{\mathrm{Me_i}}\frac{\Delta C_{\mathrm{Me_i}}}{X} \qquad \text{(Eq 24)}$$

where both flux and the scale thickness, X, are unknown. The last necessary equation relates the flux of metal at the external interface to the rate of scale formation. It is the mass balance at the scale/oxidant interface and is often called the Stefan condition:

$$\mathbf{J}_{\mathrm{Me}} = C_{\mathrm{Me}}\frac{dX}{dt} \qquad \text{(Eq 25)}$$

On combining Eq 24 and 25, the differential form of the parabolic rate law follows:

$$\frac{dX}{dt} = \left(D_{\mathrm{Me_i}}\frac{\Delta C_{\mathrm{Me_i}}}{C_{\mathrm{Me}}}\right)\frac{1}{X} = \frac{k'}{X} \qquad \text{(Eq 26)}$$

where the parabolic rate constant (term in the brackets) depends on diffusivity of defects and their concentrations. Integrating with the limit that at time $t = 0$ the oxide thickness $X = 0$, the integral form of the parabolic equation is:

$$X^2 = k't \qquad \text{(Eq 27)}$$

The Wagner Derivation. Figure 8 gives the reaction scheme for which the theory is valid. Two additional assumptions form the foundation of Wagner's theory of metal oxidation: (1) the migration (diffusion) of ions and electrons across the scale is the rate-controlling process, and (2) it is postulated that thermodynamic equilibrium is established locally through the growing scale. From the first postulate it follows that the more general Nernst-Planck flux formula must be used (instead of Fick's first law), which states that the flow of ions and electrons through a growing oxide layer depends on their concentration, mobility, and the driving force for migration (diffusion):

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\mathbf{J}_i = C_i B_i \mathbf{F} \qquad \text{(Eq 28)}$$

where B_i denotes the mobility of diffusing specie i and **F** is the sum of all forces acting on it.

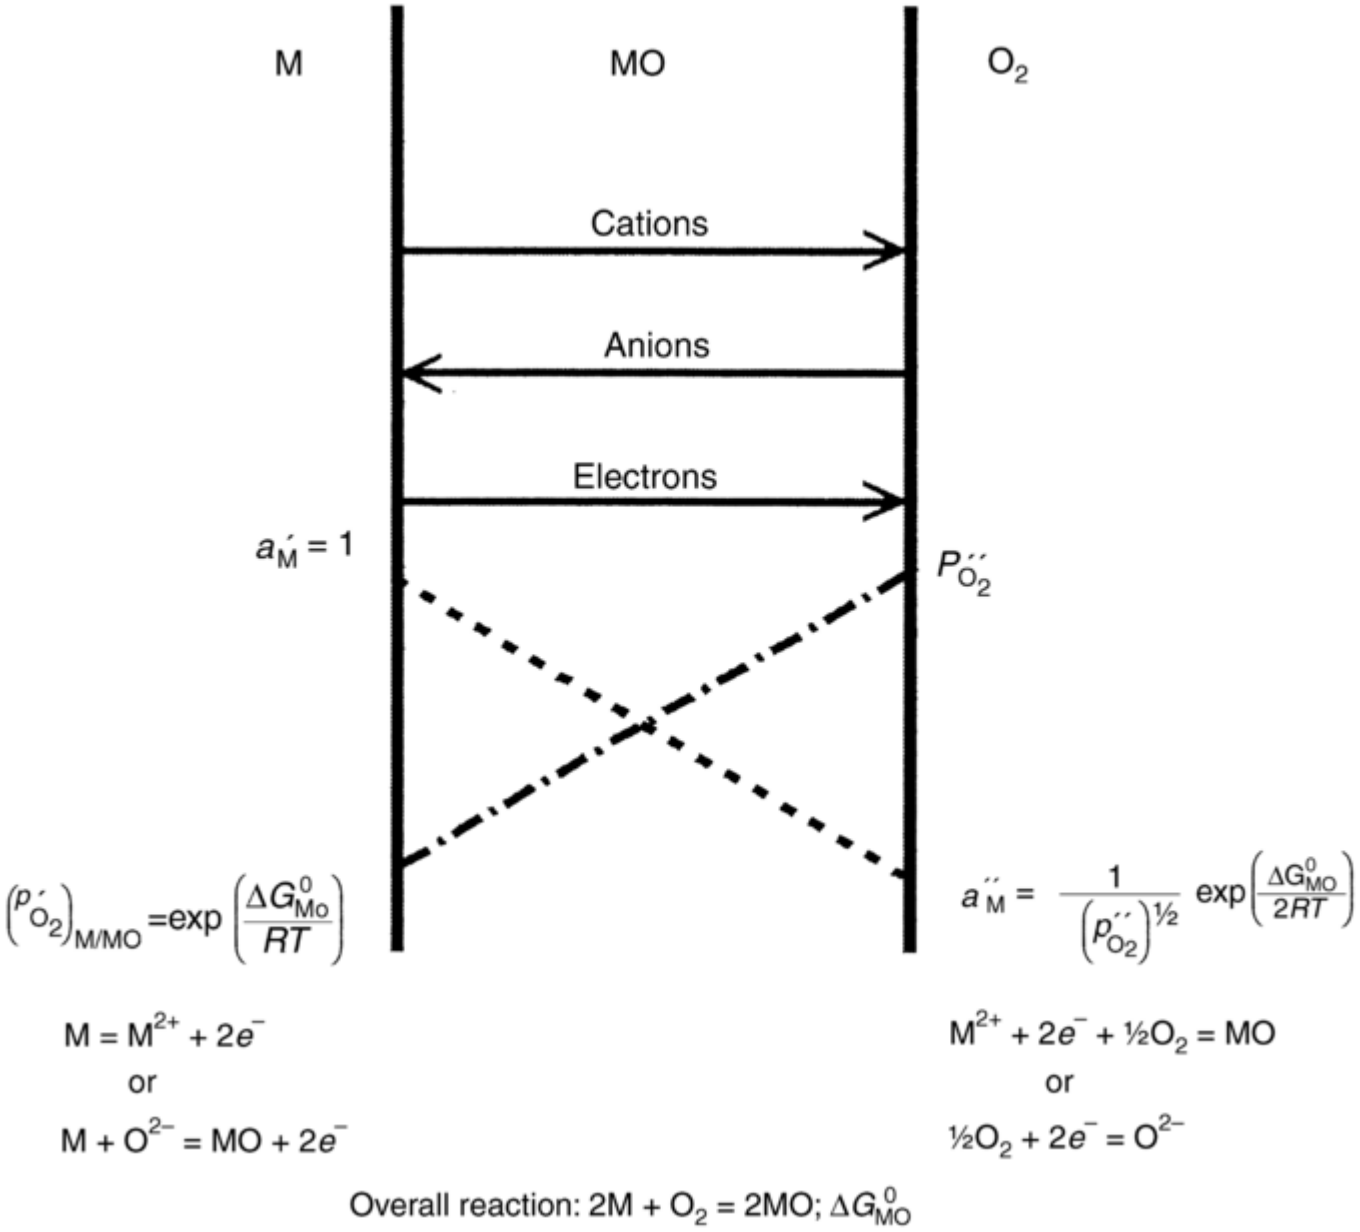

Fig. 8 Diagram of the scale formation according to the Wagner's model

A charged ion (valence z_i) moving through the oxide is acted upon by two forces: the chemical force (chemical potential gradient, $\partial\mu_i/\partial x$) and an electric potential gradient, $\partial\varphi/\partial x$. The flux is then:

$$\mathbf{J}_i = -C_i B_i \frac{1}{N_a}\left(\frac{\partial \mu_i}{\partial x} + z_i \mathbf{F}\frac{\partial \phi}{\partial x}\right) \qquad \text{(Eq 29)}$$

where N_a is Avogadro's number, φ an electrical potential, and **F** is Faraday's constant. The mobility and self-diffusion coefficients are related by the Nernst-Einstein relation: $D_i = B_i kT$. Thus, all of the fluxes in Eq 29 can be written as:

$$\mathbf{J}_c = -C_c D_c \frac{1}{RT}\left(\frac{\partial \mu_c}{\partial x} + z_c \mathbf{F}\frac{\partial \phi}{\partial x}\right) \qquad \text{(Eq 30)}$$

$$\mathbf{J}_a = -C_a D_a \frac{1}{RT}\left(\frac{\partial \mu_a}{\partial x} + z_a \mathbf{F}\frac{\partial \phi}{\partial x}\right) \qquad \text{(Eq 31)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\mathbf{J}_e = -C_e D_e \frac{1}{RT}\left(\frac{\partial \mu_e}{\partial x} + \mathbf{F}\frac{\partial \phi}{\partial x}\right) \quad \text{(Eq 32)}$$

where R is the gas constant, $N_a k = R$. These flux expressions introduce a new unknown variable. Consequently, an additional equation is necessary. As the oxide forms, the flow of ions through the scale must be balanced by the flow of electrons to maintain a local charge balance:

$$z_c\mathbf{J}_c + z_a\mathbf{J}_a - \mathbf{J}_e = 0 \quad \text{(Eq 33)}$$

where the subscripts a, c, and e refer to anions, cations, and electrons, respectively. Substituting Eq 30, Eq 31, and 32 into 33 yields:

$$\frac{\partial \phi}{\partial x} = \frac{1}{F}\frac{-C_c D_c z_c \frac{\partial \mu_c}{\partial x} - C_a D_a z_a \frac{\partial \mu_a}{\partial x} + C_e D_e \frac{\partial \mu_e}{\partial x}}{z_c^2 C_c D_c + z_a^2 C_a D_a + C_e D_e} \quad \text{(Eq 34)}$$

The postulate of the local thermodynamical equilibrium allows the assumption that everywhere through the oxide, the equilibria:

$$\mathrm{Me} = \mathrm{Me}^{z_c+} + z_c e \quad \text{(Eq 35)}$$

$$X = X^{z_a+} - |z_a| e \quad \text{(Eq 36)}$$

are established during the whole process and it follows that:

$$\mu_{Me} = \mu_c + z_c\mu_e \quad \text{(Eq 37)}$$

$$\mu_X = \mu_a - |z_a|\mu_e \quad \text{(Eq 38)}$$

Moreover, for such isothermal and isobaric process the Gibbs-Duhem relation holds:

$$N_{Me} d\mu_{Me} + N_X d\mu_X = 0 \quad \text{(Eq 39)}$$

Upon taking into account that oxides have near- stoichiometric composition, the ratio of molar concentrations may be expressed as:

$$\frac{N_{Me}}{N_X} = \frac{|z_a|}{z_c} \quad \text{(Eq 40)}$$

and Eq 39 becomes

$$|z_a| d\mu_{Me} + z_c d\mu_X = 0 \quad \text{(Eq 41)}$$

From Eq 37, Eq 38, Eq 39, the electrical potential gradient can be expressed by:

$$\frac{\partial \phi}{\partial x} = \frac{1}{z_c \mathbf{F}} \times\left(-\frac{\partial \mu_c}{\partial x} + \frac{C_e D_e}{z_c^2 C_c D + z_a^2 C_a D_a + C_e D_e}\frac{\partial \mu_{Me}}{\partial x}\right) \quad \text{(Eq 42)}$$

Eq 42 reduces to a simple relation:

$$\frac{\partial \phi}{\partial x} = \frac{1}{z_c \mathbf{F}}\left(-\frac{\partial \mu_c}{\partial x} + \frac{\partial \mu_{Me}}{\partial x}\right) = \frac{1}{\mathbf{F}}\frac{\partial \mu_e}{\partial x} \quad \text{(Eq 43)}$$

Introducing Eq 43 into the flux formulas (Eq 30 and 31) and taking into account relations Eq 37 and 38:

$$J_c = -C_c D_c \frac{1}{RT}\frac{\partial \mu_{Me}}{\partial x} \quad \text{(Eq 44)}$$

$$J_a = -C_a D_a \frac{1}{RT}\frac{\partial \mu_X}{\partial x} \quad \text{(Eq 45)}$$

The scale growth is a result of cation and anion fluxes, $dX = dX_c + dX_a$. Thus, from the mass balances at both interfaces (Eq 35):

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\frac{dX}{dt} = \frac{dX_c}{dt} - \frac{dX_a}{dt} = \frac{J_{Me}}{C_{Me}} - \frac{J_X}{C_X} \qquad \text{(Eq 46)}$$

Introducing Eq 44 and 45, and the Gibbs-Duhem relation (Eq 41), one gets:

$$\frac{dX}{dt} = -\frac{1}{RT}\left(\frac{|z_a|}{z_c}\frac{C_a D_a}{C_X} + \frac{C_c D_c}{C_{Me}}\right)\frac{\partial \mu_{Me}}{\partial x} \qquad \text{(Eq 47)}$$

The defect diffusion coefficient and self-diffusion coefficients are related through:

$$D^*_{Me} = N_c D_c \qquad \text{(Eq 48)}$$

Thus, Eq 47 becomes:

$$\frac{dX}{dt} = -\frac{1}{RT}\left(\frac{|z_a|}{z_c} D^*_a + D^*_c\right)\frac{\partial \mu_{Me}}{\partial x} \qquad \text{(Eq 49)}$$

The arguments (compare Eq 22, Eq 23, Eq 24, Eq 25, Eq 26 and Eq 49) are valid in the Wagner model. Thus, one can express the right-hand side of Eq 49 using average values. Upon integrating Eq 49 over the entire scale thickness X, from the inner surface (metal/oxide interface), at which the metal chemical potential is μ'_{Me}, to μ_{Me}at the outer (oxide/gas interface) Eq 49 becomes:

$$\frac{dX}{dt} = -\frac{1}{X}\frac{1}{RT}\int_{\mu'_{Me}}^{\tilde{\mu}_{Me}}\left(\frac{|z_a|}{z_c} D^*_a + D^*_c\right) d\mu_{Me} \qquad \text{(Eq 50)}$$

where

$$k'_p = \frac{1}{RT}\int_{\tilde{\mu}_{Me}}^{\mu'_{Me}}\left(\frac{|z_a|}{z_c} D^*_a + D^*_c\right) d\mu_{Me} \qquad \text{(Eq 51)}$$

is called the parabolic rate constant. Substituting the Gibbs-Duhem equation:

$$d\mu_{Me} = -\frac{z_c}{|z_a|} d\mu_X = -\frac{1}{2}\frac{z_c}{|z_a|} RT d\ln p_{O_2} \qquad \text{(Eq 52)}$$

the result is:

$$k'_p = \frac{1}{RT}\int_{p'_{O_2}}^{\tilde{p}_{O_2}}\left(D^*_a + \frac{z_c}{|z_a|} D^*_c\right) d\ln p_{O_2} \qquad \text{(Eq 53)}$$

The good agreement between parabolic rate constants calculated from conductivity or diffusivity data and the rate constants measured in oxidation experiments indicates that Wagner's assumptions are generally valid (Ref 2, 3). If the Wagner's principal assumptions about the scale are valid:

- The oxide scale is completely compact and adherent.
- The migration of ions through the scale is the rate-controlling process.
- Thermodynamic equilibrium exists at both the metal/oxide and oxide/gas interfaces.
- Thermodynamic equilibrium exists locally throughout the scale.
- The oxide deviates only slightly from stoichiometry.

Then, the Wagner model allows one to understand or use the model as a starting point for more complex reactions, such as the oxidation of alloys.

Effects of Temperature and Pressure. When kinetics of the oxidation are controlled by diffusion in the growing scale, the parabolic oxidation rate constant (Eq 19) increases exponentially with temperature, following the Arrhenius equation:

$$k'_p = k_0 \exp\left(-\frac{Q_a}{RT}\right) \qquad \text{(Eq 54)}$$

where k_0 is a constant dependent on the oxide composition and the gas pressure. According to Wagner's theory, for cation-deficient or cation- excess oxides where $D_c \gg D_a$, the activation energy Q_a for oxide growth is the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

same as the activation energy for diffusion of cations in the oxide. For anion-deficient oxides, such as ZrO_2, where $D_a \gg D_c$, the activation energy for oxide growth is the same as that for anion diffusion, verifying that ionic diffusion is the rate-controlling process.

To calculate the effect of pressure on the oxidation rate, Eq 53 can be used. For a cation- deficient *p*-type oxide, such as $Ni_{1-y}O$, growth occurs at the oxide/gas interface where:

$$\frac{1}{2}O_2(g) + Ni = NiO$$

Using the Kröger-Vink notation, the formation of the nondefect oxide ($NiO = Ni_{Ni} + O_o$) is given by $\frac{1}{2}O_2(g) + Ni = O_o + Ni_{Ni}$ where Ni_{Ni} and O_o indicate that Ni and O occupy the regular positions in the cationic and ionic sublattice. The formation of defects in this notation can be written as:

$$\tfrac{1}{2}O_2(g) = O_o + V''_{Ni} + 2h^{\cdot} \qquad \text{(Eq 55)}$$

where symbol V_{Ni} stands for a doubly charged cation vacancy, and $h^{\cdot}$ represents an electron hole. Thermodynamic equilibrium is established at the $Ni/O_2(g)$ interface so that at any time the equilibrium constant *K* for the reaction of the oxide formation (Eq 55) is:

$$K = \left[V''_{Ni}\right]\left[h^{\cdot}\right]^2 p_{O_2}^{-1/2} \qquad \text{(Eq 56)}$$

where p_{O_2} is the oxygen partial pressure and the brackets indicate the concentration of the species enclosed; for example, $[V_{Ni}]$ denotes the concentration of cation vacancies. The oxygen concentration at both interfaces is constant. Thus, the local thermodynamic equilibrium conditions imply that locally there must be two electron holes for every cation vacancy, or $[h^{\cdot}] = 2[V_{Ni}]$, then:

$$\left[V''_{Ni}\right] = (K/4)^{1/3} p_{O_2}^{1/6} \qquad \text{(Eq 57)}$$

The nickel diffusivity is proportional to the vacancy concentration (Eq 13), so that:

$$D^*_{Ni} = D_0 p_{O_2}^{1/6} \qquad \text{(Eq 58)}$$

where D_0 denotes here the cation diffusivity for oxygen pressure equal one.

It may be shown that for an oxide with simple defect structure (where only one type of defect dominates in a cationic or anionic sublattice) Eq 58 takes the form:

$$D^*_{Ni} = D_0 p_{O_2}^{\pm 1/n} \qquad \text{(Eq 59)}$$

where, theoretically, both the sign and *n* (generally a number between 2 and 8) depend on the type of dominating defect.

Substituting Eq 58 into Eq 53, the oxidation rate is:

$$k'_p = \frac{1}{2} D_0 \int_{p'_{O_2}}^{p''_{O_2}} \left(p_{O_2}^{1/6}\right) d \ln p_{O_2} \qquad \text{(Eq 60)}$$

which upon integration becomes:

$$k'_p = 3D_0 \left[\left(p''_{O_2}\right)^{1/6} - \left(p'_{O_2}\right)^{1/6}\right] \qquad \text{(Eq 61)}$$

In most cases, the ambient oxygen pressure p_{O_2} is much greater than the nickel oxide dissociation pressure p'_{O_2} so that:

$$k'_p = 3D_0 \left(p''_{O_2}\right)^{1/6} \qquad \text{(Eq 62)}$$

Equation 62 explains both the Arrhenius-type temperature dependence and the pressure dependence of the oxidation rate. For an oxide with a simple defect structure and where the concentration of defects at the $Me/O_2(g)$ interface is higher than at the oxide/Me interface, Eq 62 has the form:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$k_p' = \frac{n}{2} D_0 \left(p''_{O_2} \right)^{\pm 1/n} \qquad \text{(Eq 63)}$$

For oxides with a simple defect structure and when the concentration of defects at the Me/ $O_2(g)$ interface is lower than at oxide/Me interface—for example, Cu_2O—the oxidation rate is practically independent of the ambient oxygen pressure.

Gaseous Corrosion Mechanisms

Revised by Marek Danielewski, AGH University of Science and Technology, Cracow, Poland

Introduction

THE CHARACTERISTICS AND BEHAVIOR of scale produced by various types of oxidation are examined in this article. The basic models, concepts, processes and open questions for high-temperature gaseous corrosion are presented.

Gaseous Corrosion Mechanisms

Revised by Marek Danielewski, AGH University of Science and Technology, Cracow, Poland

Properties of Scales

Multiple Scale Layers. A pure metal that can be oxidized to more than one valence state can form a series of oxides in the form of separate layers. For example, iron forms highly defected wustite (FeO), magnetite (Fe_3O_4), and (at high oxygen pressure) hematite (Fe_2O_3) scale layers. The layers will be arranged with the most metal- rich oxide next to the metal and the most oxygen-rich layer on the outside. At temperatures above 583

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

°C (1081 °F), wustite is stable, and the sequence of oxides in the scale shows the following pattern: $Fe|FeO|Fe_3O_4|Fe_2O_3|O_2(g)$.

At temperatures below 583 °C (1081 °F), rapidly growing wustite is not stable, and consequently, iron shows satisfactory resistance to oxidation. The corrosion-resistant scale formed below 583 °C (1081 °F) on iron consists of magnetite and hematite: $Fe|Fe_3O_4|Fe_2O_3|O_2(g)$. A concentration gradient exists within each layer, with higher metal ion concentration closest to the metal. Another example is the copper-oxygen system, which may form the following sequence of oxides: $Cu|Cu_2O|CuO|O_2(g)$.

If the oxygen partial pressure in the gas is below the dissociation pressures of the outer oxygen-rich oxides, then only the thermodynamically stable, inner oxide(s) will form. In general, the lowest valence, inner oxide will usually show the defects in a cationic sublattice only (vacancies in wustite: $Fe_{1-y}O$, but interstitial cations in $Cr_{2+y}O_3$ and $Cu_{2+y}O$). The highest-valence oxide will usually show the vacancies in cationic and/or defects in anionic sublattices. The nonstoichiometry of such oxides (e.g., Fe_2O_3) is very low and often nonmeasurable. Consequently, the defect structure and transport properties of many technically important oxides are not very well known (e.g., Al_2O_3). A scale consisting of an inner layer with cations diffusing outward and an outer layer with anions diffusing inward will grow at the oxide-oxide interface.

Relative Thickness. When diffusion is the rate-controlling process and no porosity develops in the oxide layers, their relative thickness is proportional to the relative diffusion rates. For compact layers growing by a single diffusion mechanism, the ratio of thicknesses should be related to the ratio of the parabolic rate constants by:

$$\frac{X_1}{X_2} = \left(\frac{k'_{p1}}{k'_{p2}}\right)^{1/2} \qquad \text{(Eq 1)}$$

where subscripts 1 and 2 refer to layers 1 and 2. The thickness ratio, consequently, is a constant and does not change with time. Because the ions diffusing through the various layers are likely to be different, and because the crystal structures of the layers are certainly different, the thickness ratio is commonly found to be quite far from unity. One layer is usually much thicker than the others.

When diffusion controls the growth of each layer, the entire scale will appear to follow the parabolic oxidation equation, with an effective parabolic rate constant k'_p. However, this effective parabolic rate constant does not need to follow the Arrhenius equation (Eq. 54 in the article “Kinetics of Gaseous Corrosion Processes” in this Volume) unless the thickness ratios remain far from unity throughout the temperature range, that is, unless one layer predominates in the analyzed temperature range. If an inner scale predominates, its growth is independent of oxygen pressure, but if the outermost scale is the major part of the scale, the rate constant will vary with oxygen pressure.

Paralinear Oxidation. With some metals, the oxidation growth is parabolic at the beginning, but the protective scale gradually changes (as a whole layer or only partially) to a nonprotective layer. If the inner protective layer remains at a constant thickness, then the diffusion through this layer results in a linear rate of oxidation. The outer layer may become nonprotective by sublimation, transformation to a porous layer, fracture, and so on. This type of oxidation behavior that is initially parabolic and gradually transforms to linear is termed paralinear oxidation (Fig. 1).

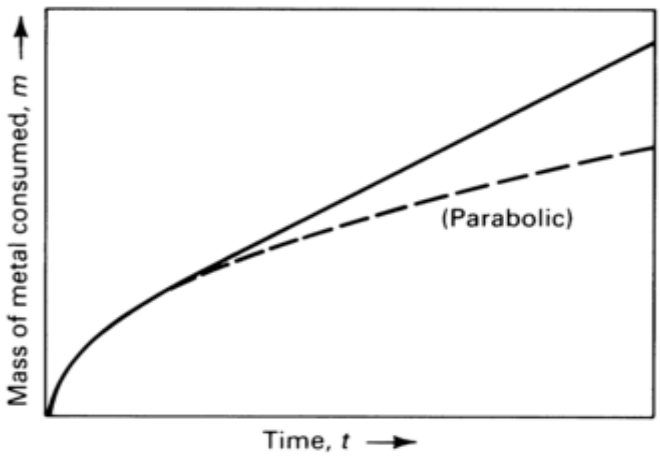

Fig. 1 Paralinear oxidation. Scale growth (mass) is initially parabolic and becomes linear with time.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Oxide Evaporation. At high temperatures, the evaporation of a protective oxide may limit its protective qualities or remove the oxide entirely, because the evaporation rate increases exponentially with temperature. Platinum alloys and refractory metals in particular tend to have volatile oxides. Suboxides and unusual valences are also often found at high temperatures; chromium, for example, forms only one stable solid oxide, Cr_2O_3, but vaporizes as CrO_3 at temperatures above 1173 K (1652 °F). Reactive evaporation in the chromium-oxygen system was measured experimentally and explained theoretically (Ref 1).

Evaporation may be much more intense in gases containing water or halide vapor if volatile hydroxides (hydrated oxides) or oxyhalides form. Theoretically, at low pressures when evaporating molecules do not return to the surface (do not resublimate), the evaporation rate is directly proportional to the sublimation vapor pressure of the oxide. In practical conditions, the total pressure often exceeds 1 atm, while the low oxygen partial pressure creates conditions for oxide evaporation. In such conditions at gas pressures above 10^{-3} to 10^{-4} atm and when the velocity of gas is low (laminar flow), a gaseous stagnant boundary layer slows the escape of the evaporated oxide molecules (stimulates resublimation). The boundary layer becomes thinner at higher gas velocities, leading to higher evaporation losses.

Reactive diffusion provides parabolic oxide growth. The rate of the scale growth decreases (Eq. 53 in the article "Kinetics of Gaseous Corrosion Processes" in this Volume), while the evaporation removes material from the oxide layer at a constant rate (time-independent process). The rate of diffusion through the oxide decreases until the two rates finally become equal. The oxide thickness then remains constant, and the metal oxidizes linearly; that is, the metal consumption shows linear time dependence. If more than one oxide layer protects the metal, the higher-valent, outermost oxide usually has the higher vapor pressure and is more volatile. A detailed analysis of evaporation processes and their impact on oxidation is presented in Ref 2.

Gaseous Corrosion Mechanisms

Revised by Marek Danielewski, AGH University of Science and Technology, Cracow, Poland

---

Stresses in Scales

Stress development is inherently coupled with scale growth processes and is often the key factor limiting the protective properties of the scale. During scale growth, recrystallization may occur in either the alloy or the oxide, altering the stresses radically. Changes in temperature usually have a great effect on the stress state for metals in such service. Numerous analyses of practical damage cases have shown that the failure of components is often initiated by stresses resulting from either the oxidation process itself or from operation of the oxidized element. In the past, stress development and relief were often neglected in laboratory investigations; today, the role of stress is well recognized (Ref 2, 3, 4).

There are generally three types of stress that have to be considered:

- External stresses, σ_{ext}, resulting from operation
- Thermally induced stresses, σ_{therm}, due to temperature changes of the system
- Growth stresses, σ_{ox}, resulting from the oxidation/corrosion process itself

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The sum of all stresses determines mechanical scale failure. If the sum reaches or exceeds a certain critical value, σ_c, cracking or spalling of the protective oxide follows:

$$\sigma_{tot} = \sigma_{ext} + \sigma_{therm} + \sigma_{ox} \geq \sigma_c \qquad \text{(Eq 2)}$$

Stresses can be measured by different experimental techniques and also predicted from model calculations to assess whether scale failure is likely (Ref 4).

Growth Stresses. The Pilling-Bedworth ratio, first published in 1925, was considered as a major factor for determining the magnitude of growth stress. The Pilling-Bedworth ratio is the ratio of the oxide volume per mole of the metal in the oxide to the metal volume per mole of metal in the metal or alloy. Numerous observations have shown that each step of the scale growth process can generate stress:

- Sometimes crystalline oxides grow on a metal substrate with an epitaxial relationship. As a result of the different lattice parameters, the stresses that develop often limit the epitaxy to several nanometers of scale.
- Polycrystalline oxides develop stresses along their grain boundaries as a consequence of growth of grains in the direction perpendicular to or different from the direction of the scale growth.
- Grain-boundary diffusion, diffusion along oxide grain boundaries, may lead to oxide formation within the growing scale at the boundaries and create compressive stresses.
- Any second phases or foreign inclusions in a metal may oxidize at a rate different from that of the parent metal and create high stresses within the oxide.
- Local changes in composition of the growing scale (due to large deviations from stoichiometry) may result in tensile stress; wustite is an important example, varying from $Fe_{0.95}O$ in equilibrium with the metal to as little as $Fe_{0.84}O$ in equilibrium with Fe_3O_4 at 1370 °C (2500 °F).
- Interdiffusion in a reacting alloy can generate stresses (i.e., Kirkendall effect) when alloy components have different mobilities.
- Diffusion of oxygen into the metal from the oxide creates compressive stresses in the metal, such as in the titanium-oxygen system.
- Surface geometry contributes an additional effect to the growth stresses in an adherent oxide, depending on the surface profile.

Figure 2 shows the four possibilities for changes in stress state in an oxide scale as it grows, assuming that the original growth stresses are compressive (Ref 5).

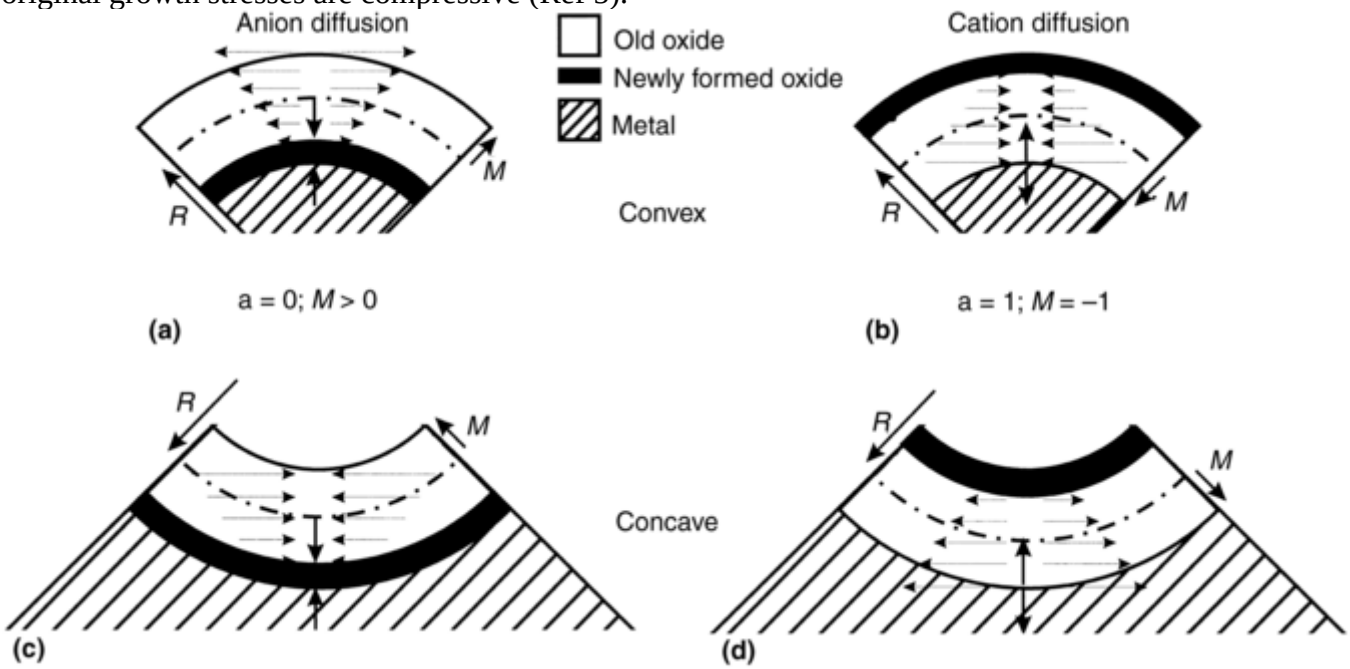

Fig. 2 The development of geometrically induced growth stresses (horizontal arrows) in oxide scales for four combinations of curved surfaces (convex and concave), and growth by anion (left) and by cation (right) diffusion. *R*, radius of curvature; *M*, oxide displacement vector; *a*, volume fraction of oxide formed at the interface. Details of (a) to (d) can be found in the text. Source: Ref 5

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

For a convex surface on which oxide grows at the oxide-gas interface by cation diffusion outward through the scale (Fig. 2b), the metal surface (M) will gradually recede, increasing the compressive stresses at the metal-oxide interface as long as adhesion is maintained. Figure 2(a) shows oxidation of a convex surface on which the oxide grows at the metal-oxide interface by anion diffusion inward and generates compressive stresses at the metal-oxide interface.

For concave surfaces (Fig. 2d), oxide grows at the oxide-gas interface by outward diffusion of cations. As the metal surface recedes, the compressive growth stresses are reduced and may eventually even become tensile if oxidation continues long enough. Figure 2(c) shows growth on a concave surface by anion diffusion inward for reaction at the metal-oxide interface. Very high compressive stresses develop during growth, until they exceed the cohesive strength of the oxide.

Two major types of growth stresses are distinguished. The first type is the geometrically induced growth stresses that are due to the surface curvature or components (Fig. 2), and the second type is the intrinsic growth stresses. As can often be seen in oxidation experiments on flat samples, the oxide scales crack at the edges of the specimens, for example, during tungsten oxidation. This type of growth stress has been analyzed (Ref 6).

With the help of models, the tangential and radial stresses can be calculated for the ideal case of curved surfaces with a constant radius of curvature. The oxidation increases the strain in the circumferential direction (tangential strain, ϵ^{t}_{ox}) at the rate:

$$\frac{d\varepsilon'_{ox}}{dt} = \frac{M}{R_s}\frac{dh}{dt} = \frac{M}{R_s R_{PB}}\frac{dX}{dt} \qquad \text{(Eq 3)}$$

where R_s denotes the radius of curvature of the surface (concave, $R_s < 0$; convex, $R_s > 0$), h is the metal recession, X denotes scale thickness, and R_{PB} is the Pilling-Bedworth ratio. The oxide displacement vector, M, can be calculated from the following expression:

$$M = R_{PB}(1 - a) - (1 - V) \qquad \text{(Eq 4)}$$

where a is the volume fraction of oxide formed at the oxide-gas interface and $(1 - a)$ at the metal-oxide interface, and V and $(1 - V)$ denote, respectively, the volume fraction of the metal consumed as a result of the injection of vacancies into the oxidized metal and its volume fraction consumed during oxide formation at the metal-oxide interface.

The scale thickness and metal recession are related:

$$X = R_{PB}h \qquad \text{(Eq 5)}$$

Equation 3 allows one to calculate the tangential stresses, σ^{t}_{ox}, when linear elastic behavior can be assumed. The magnitude of the maximum radial stresses, σ^{r}_{ox}, is given by:

$$\sigma^{r}_{ox} = \frac{R_{PB}h}{R_s}\sigma^{t}_{ox} \qquad \text{(Eq 6)}$$

The signs of the tangential and radial strains and stresses in the scale and at the metal-oxide interface are given by:

$$\text{sign}\varepsilon^{t}_{ox} = \text{sign}\left(-\varepsilon^{r}_{ox}R_s\right) \qquad \text{(Eq 7)}$$

$$\text{sign}\sigma^{t}_{ox} = \text{sign}\left(-\sigma^{r}_{ox}R_s\right) \qquad \text{(Eq 8)}$$

where "+" and "-" denote tensile and compressive stresses, respectively, and R_s is "+" if convex and "-" if concave.

At present, a relatively limited understanding of the mechanisms leading to intrinsic growth stresses has been achieved. The growth stresses were computed for alumina formers (FeCrAl and FeCrAlY alloys) and chromia formers (chromium, NiCr, and FeNiCr stainless steel); oxidation of pure nickel cannot be accurately predicted using model calculations (Ref 4).

Mechanical scale failure takes place when a critical stress level, σ_c, reached. This critical stress level can be converted into a critical strain, ε_c, by dividing the stress by the oxide Young's modulus, E_{ox}, if it is assumed that elastic behavior dominates in scale failure. Strain values are more easily accessible than stress values, because they can be determined by experiments.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Generally, two modes of failure dominate, depending on the stress distribution in the scale: the failure due to tensile stresses and the failure due to compressive stresses. For tensile failure, a mechanical model has been developed describing the critical strain, ε_c:

$$\varepsilon_c = \frac{K_{Ic}}{fE_{ox}\sqrt{\pi c}} \qquad \text{(Eq 9)}$$

where K_{Ic} denotes the fracture toughness of the scale, f is a geometrical factor, and c denotes the radius of the defect (pore, crack, precipitate, etc.). Applying this equation, a researcher computed the critical strains for some common oxides (Ref 4).

Transformation Stresses. Preferential oxidation of one component in an alloy may alter the alloy composition to the point that a crystallographic phase transformation occurs. A change in temperature could also cause crystallographic transformation of either the metal or the oxide. The volume change accompanying a transformation creates severe stresses in both the metal and the oxide. Some oxides initially form an amorphous/nanocrystalline structure and gradually crystallize as the film grows thicker. The tensile stress created by volume contraction may partially counteract the compressive growth stresses usually present.

Thermal Stresses. A common cause of failure of oxide protective scales is the stress created by cooling from the reaction temperature. The stress generated in the oxide is directly proportional to the difference in coefficients of linear expansion between the oxide and the metal. Coefficients are listed in Table 1 for a few important metal-oxide systems. In most cases, the thermal expansion of the oxide is less than that of the metal; therefore, compressive stress develops in the oxide during cooling. Multilayered scales will develop additional stresses at the oxide-oxide interface.

Table 1 Coefficients of linear thermal expansion (CTE) of metals and oxides

System	Oxide coefficient		Metal coefficient		Temperature range	
	10^{-6}/K	**10^{-6}/°F**	**10^{-6}/K**	**10^{-6}/°F**	**°C**	**°F**
Fe/FeO	12.2	6.78	15.3	8.50	100–900	212–1650
Fe/Fe_2O_3	14.9	8.28	15.3	8.50	20–900	70–1650
Ni/NiO	17.1	9.50	17.6	9.78	20–1000	70–1830
Co/CoO	15.0	8.3	14.0	7.8	25–350	75–660
Cr/Cr_2O_3	7.3	4.1	9.5	5.3	100–1000	212–1830
Cu/Cu_2O	4.3	2.4	18.6	10.3	20–750	70–1380

Gaseous Corrosion Mechanisms

Revised by Marek Danielewski, AGH University of Science and Technology, Cracow, Poland

Stress Relief

The oxide may develop porosity as it grows and relieves stress. If temperatures are high, the stress may reach the yield strength of either the metal or the oxide, so that plastic deformation relieves the stress. A brittle oxide may crack. A strong oxide may remain intact until the internal stresses exceed the adhesive forces between metal and oxide, so that the oxide pulls loose from the metal. These ways in which stresses can be relieved are discussed subsequently.

Porosity. For oxides that grow by cation diffusion outward through cation vacancies (*p*-type oxides, such as NiO), vacancies are created at the oxide-gas interface and diffuse inward through the scale as they exchange places with an equal number of outward-diffusing cations. The vacancies are annihilated within the oxide, at the metal-oxide interface, or within the metal, depending on the system. In some oxides, the vacancies collect together within the oxide to form approximately spherical cavities. The preferred sites for cavity formation are along paths of rapid diffusion, such as grain boundaries and dislocation lines.

Vacancies that are annihilated at the metal-oxide interface may cause detachment of the scale, because voids that form there reduce adhesion of oxide to metal. If detachment is only partial, the oxidation rate slows down, because the cross- sectional area available for diffusion decreases.

Plastic Flow of Oxide. Dislocations are formed in the oxide as it grows epitaxially on the metal because of the crystallographic lattice mismatch between oxide and metal. As the growth continues, these glissile slip dislocations move out into the oxide by the process of glide. Once out in the oxide, they become sessile growth dislocations.

Although dislocations are present in the oxide, slip is not an important process in relieving growth stress (Ref 8). Plastic deformation of the oxide occurs only at high temperatures, at which creep mechanisms become operative. The three important creep mechanisms in oxides are grain- boundary sliding, Herring-Nabarro creep, and climb. Grain-boundary sliding allows relative motion along the inherently weak boundaries. Herring-Nabarro creep allows grain elongation by diffusion of ions away from grain-boundary areas in compression over to boundaries in tension. Within the grains, dislocation climb is controlled by diffusion of the slower-moving ions. The creep rate increases with the amount of porosity in the oxide.

Cracking of Oxide. Tensile cracks relieve growth stresses in the oxide scale. As shown in Fig. 2, tensile stresses may eventually develop in an oxide growing on curved surfaces and cause fracture. In the case of anion diffusion inward on convex surfaces, if oxygen diffuses into the metal, the tensile stresses near the oxide-gas interface develop much more quickly.

Shear cracks can form in an oxide having high compressive stresses near the metal surface, if the scale cohesion is weak and adhesion to the metal is strong. If the metal-oxide interface is planar, a shear crack initiating at the interface can extend rapidly across the surface. However, if the interface is rough because oxidation has concentrated at the grain boundaries of the metal and keyed the oxide into the metal, rapid crack extension may be prevented and scale adherence may be improved.

Periodic cracking of a protective oxide results in the parabolic oxidation being interrupted by a sudden increase in rate when the gas can react directly with the bare metal surface. As oxide begins to cover the metal surface again, parabolic oxidation is resumed. A typical oxidation curve for this repeated process is shown in Fig. 3(a). The time periods between successive parabolic steps are sometimes fairly uniform, because a critical scale thickness is reached that causes cracks to be initiated. The overall oxidation of the metal approaches a slow linear process.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

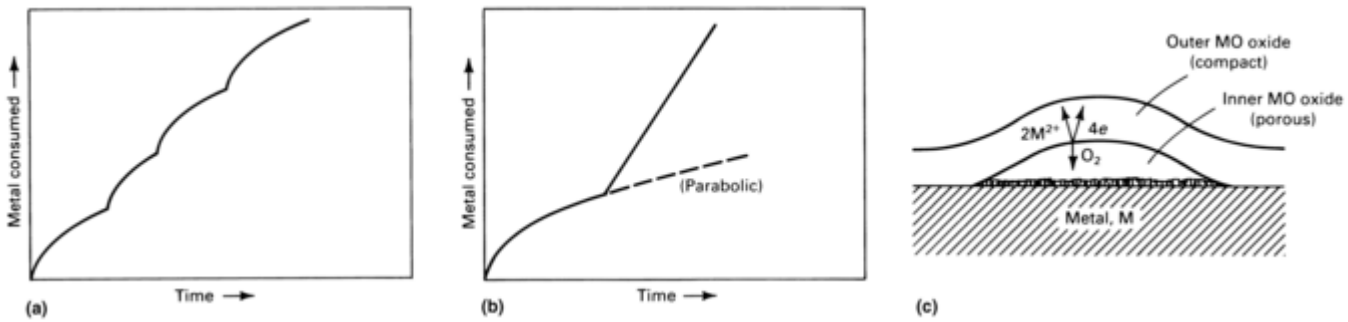

Fig. 3 Cracking of oxide. (a) Periodic cracking of the scale. (b) Breakaway oxidation. (c) Morphology of the single-phase double-layer scale

Occasionally, a metal oxidizes parabolically until the scale cracks or spalls off, and from that time on, the oxidation is linear. The oxide, originally protective, completely loses its protective properties. The breakaway oxidation commonly occurs if many cracks form continuously and extend quickly through the oxide. It can also occur for alloys that have had one component selectively oxidized. When the protective scale spalls off, the metal surface is so depleted in the component that the same protective scale cannot re- form. Breakaway oxidation (Fig. 3b) leaves bare metal continually exposed, unlike paralinear oxidation (Fig. 1), in which an inner protective scale always remains.

Decohesion and Double-Layer Formation. For scale growth by cation diffusion, a protective scale may eventually reach a thickness at which it can no longer deform plastically to conform to the receding metal surface. At this point, decohesion begins at some places along the metal- oxide interface. However, oxidation continues at the oxide-gas interface because cations continue to diffuse outward through the detached scale, driven by the chemical potential gradient across the scale.

At the inner scale surface, the cation concentration decreases, thus locally increasing the oxygen chemical potential. The increased chemical potential results in an increased pressure of O_2 gas that will form in the space between the scale and the metal. The O_2 is then transported to the metal surface by means of surface diffusion and/ or gas phase migration. Because its pressure is greater than the dissociation pressure of oxide in equilibrium with metal, an inner layer of oxide begins to form on the metal. This mechanism is called the dissociation mechanism of the scale growth (Ref 9).

The inner oxide layer forms a porous, fine- grained structure and has essentially the same composition as the compact outer layer. Initially, it starts forming at the nucleation sites of bare metal. The diffusion of O_2 from the outer layer to the inner layer is rate controlling, so that the inner layer grows mainly at its high points and forms a porous scale (Ref 9). Figure 3(c) shows the mechanism of the double-layer scale growth.

For the oxidation of pure chromium, it has been found that at temperatures above 1000 °C (1800 °F), the scale cracks periodically when the intrinsic growth stresses exceed a critical value (Ref 1). Several parabolic partial steps exist in the kinetics curve, which are due to cracking after each of these steps and exposure of the bare metal surface under a detached and cracked oxide scale to the surrounding atmosphere. Thus, the fast, initial oxidation period starts again, leading to a new parabolic partial oxidation curve if the temperature is increased to 1200 °C (2200 °F); the intervals for cracking become so short that they can no longer be resolved in the curve, and a fast, linear curve results. This shows that permanent cracking of the scale by intrinsic growth stresses allows no protection, and therefore, the initial surface oxidation steps are always rate determining. The buckling and cracking of oxide scales due to intrinsic growth stresses can be suppressed by the addition of active-elements to the alloy. There are several possible explanations for the active-element effect, which helps to improve adhesion of the scale and which has been proven for a number of different materials. The major mechanisms are changes of the transport properties in the scale; that is, metal cation diffusion in the outward direction can be suppressed by the presence of certain active elements so that only oxygen-inward transport occurs, leading to scale formation solely at the metal interface and reducing the growth stresses. Numerous mechanisms to explain the reactive- element effect were proposed (Ref 10):

- A change in the transport properties of the oxide; for example, suppression of cation diffusion results in a decreased oxidation rate, and the oxygen-inward diffusion becomes the dominating mode of transport

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

in the growing scale. As a result of the oxide formation at the metal-oxide interface, the growth stresses are reduced.

- An increase of the density of the nucleation sites at the metal surface results in fine- grained scale, leading to a more plastic scale.
- Highly reactive elements react with sulfur impurities in the metal substrate, thus impeding the segregation of sulfur to the metal-oxide interface, which would otherwise reduce the adhesion of the scale.
- The formation of oxide pegs in the metal (at the metal-oxide interface, for example, at the metal grain boundaries) leads to the keying of the oxide to the metal.
- Reducing the number of physical defects, such as pores in the oxide, decreases the susceptibility of the scale to cracking or detachment.
- The precipitation of oxides containing reactive elements reduces the fast diffusion along the grain boundaries.

Advanced materials and coatings used at temperatures near 1000 °C (1800 °F) benefit from the effect of active-element additions. The active element plays the key role in providing long- term oxidation protection of the protective coatings on gas turbine materials. The most common active elements are yttrium, cerium, rhenium, hafnium, and zirconium.

Deformation of Metal. Foils and thin-wall tubes are often observed to deform during oxidation, thus relieving the oxide growth stresses. At high temperatures, slip and creep mechanisms can be operative in metals while the temperature is still too low for plastic deformation of the oxide. The deformation processes are facilitated by accumulation of porosity in the metal, which is caused by outward cation diffusion (e.g., accumulation/injection of vacancies) and by the selective oxidation of one component of an alloy (e.g., Kirkendall effect in the alloy near the metal-oxide interface).

Catastrophic Oxidation. Although many oxidation failures can be described as catastrophes, the term *catastrophic oxidation* was originally reserved for the special situation in which a liquid phase is formed in the oxidation process. This can occur either when the metal is exposed to the vapors of a low-melting oxide or during oxidation of an alloy having a component that forms a low-melting oxide or sulfide (see Table 2 in the article “Thermodynamics of Gaseous Corrosion” in this Volume). The mechanisms of catastrophic oxidation vary, but the evidence shows that it occurs at the metal-oxide interface. A liquid phase seems to be essential. The liquid usually forms at the oxide-gas surface and penetrates the scale along grain boundaries or pores to reach the metal. The penetration paths can also serve as paths for rapid diffusion of reacting ions. Once at the metal-oxide interface, the liquid spreads out by capillary action, destroying adherence of the solid scale. In the case of alloys, the liquid can penetrate along the grain boundaries and cause intergranular corrosion. When diffusion and/or flow of the oxidant in the gas phase is the rate-limiting process, then oxidation in the absence of a protective scale proceeds linearly. In a case of fast reactions, the metal and corrosion products heat up from the exothermic reaction, and the oxidation process can be even more rapid.

Internal Oxidation/Sulfidation. Internal oxidation (sulfidation) is the term used to describe the formation of fine oxide or sulfide precipitates within an alloy. The oxidant dissolves in the alloy at the metal-oxide interface or at the bare metal surface if the gas pressure is below the dissociation pressure of the metal oxides. Subsequently, it diffuses into the metal and forms the most stable oxide that it can. This is usually the oxide of the most reactive component of the alloy. Internal oxides can form if the reactive element diffuses outward more slowly than the oxygen diffuses inward; otherwise, the surface scale would form. The transport (diffusion) of internally oxidized metal is controlled by the interdiffusion in the alloy. Oxygen transport in an alloy can be treated as Fickian diffusion (Eq 5 and 8 in the article “Kinetics of Gaseous Corrosion Processes” in this Volume). Because the diffusion coefficients of oxidized metal and oxidant vary exponentially with temperature, and because their activation energies are different, it is possible that internal oxidation will occur in an alloy only in a certain temperature range. Because diffusion of oxygen is usually the rate-controlling process in internal oxidation, parabolic behavior is often observed. Based on the assumption that interdiffusion of reactive metal B atoms is negligible and that oxygen has a very low solubility limit in the alloy, the simple quasi- stationary model of the process was formulated. A simple parabolic equation was derived that allows an estimation of the rate of the process (Ref 11):

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$X = \left(\frac{2N_o^S D_o t}{\nu N_B^i} \right)^{1/2} = k_p t^{1/2} \qquad \text{(Eq 10)}$$

where N_o^S is the mole fraction of oxygen in the alloy at its surface, N_B^i is the initial mole fraction of reactive metal B in the alloy, D_o is the diffusion coefficient of oxygen in the alloy, ν is the ratio of oxygen atoms to metal atoms in the reaction product, and X is the thickness of the internal oxidation zone (i.e., the subscale).

The real processes encountered in practice are more complex. In a binary alloy, a mixed (A,B)O oxide may form as the internal oxide. This will occur if AO and BO have considerable mutual solubility so that the free energy of the system is lowered by precipitation of the mixed oxide. For example, the internal oxide that forms in unalloyed steels is (Fe,Mn)O (Ref 12).

When a cast 25Cr-20Ni-Fe alloy with silicon added is oxidized at 1000 °C (1800 °F), the chromia protective layer is formed on the metal, with the most external layer being a manganese- iron spinel, $(MnFe)Cr_2O_4$. The silica is thermodynamically more stable than chromia. Moreover, the chromia dissociation pressure at the alloy-Cr_2O_3 interface is higher than the Cr-Cr_2O_4 equilibrium. Thus, the amount of oxygen dissolved in the alloy subsurface zone is sufficient to form an internal oxidation subscale (silica precipitation zone).

Internal oxidation of chromium often affects the mechanical properties of alloys; for example, it results in a carbide-free zone. It is a result of the chromium consumption during internal oxidation and of the decomposition of less stable chromium carbides, $Cr_{23}C_6$ (Ref 13). In practice, the protective scales often have cracks, open porosity, or other macrodefects. Moreover, an oxidizing atmosphere can be complex, containing oxygen and sulfur compounds. The cracks are fast diffusion paths for inward transport of oxidant into the underlying steel alloy, and in such a case, the internal sulfidation by the sulfur-bearing molecules is often observed (Ref 14).

Alloy Oxidation: The Doping Principle (Ref 2, 3, 4). For oxides that form according to the mechanism outlined in Ref 12 and that contain impurity cations that are soluble in the oxide, the impurities alter the defect concentration of the scale. Consequently, the oxide growth rate may also be altered by the alloy impurities. Whether the oxidation rate increases or decreases depends on the relative valences of the cations and on the type of oxide.

In a *p*-type semiconducting oxide (NiO, CoO, MnS), the oxidation rate is controlled by cation diffusion through cation vacancies. If the number of cation vacancies can be decreased, the oxidation is slowed. If a few cations with a higher valence are substituted for the regular cations in an oxide, the vacancy concentration is increased. Adding lower-valent cations, such as lithium ions (Li^+), to NiO will reduce the cation vacancy concentration. Substituting ions with the same valence as the rest of the cations in the oxide does not result in a doping effect.

The *n*-type semiconducting oxides behave opposite to the *p*-type oxides. For the oxides that grow by anion diffusion through anion vacancies (typified by ZrO_2), the anion vacancies exist because some cations have a lower-than-normal valence and contribute fewer electrons to the oxygen than required by the structural arrangement. Consequently, anion vacancies are present. If additional low-valent cations replace the regular higher-valent cations, the oxidation rate increases.

The doping principle is not very helpful in developing oxidation-resistant alloys, because the concentration of foreign cations that can be put into solid solution in the oxide is restricted by solubility limits, and the number of foreign ions that could be used is extremely limited by their valence. Moreover, many technically important oxides, nitrides, or sulfides are ionic conductors.

Selective Oxidation. An alloy is selectively oxidized if one component, usually the most reactive one, is preferentially oxidized. Otherwise, when two or more alloy elements react, the process is called concurrent oxidation. The simplest case would be a binary alloy with a uniform scale composed entirely of only the oxide that one of the components can form. An obvious example of selective oxidation would be scale formation on alloy A-B, where A is so noble that AO is not thermodynamically stable at the environmental pressure and temperature. That is, the oxygen partial pressure in the gas is less than the equilibrium (dissociation) pressure of AO oxide. Only BO scale can form.

For situations in which both A and B can react with oxygen at the temperature and gas pressure involved, but A is somewhat more noble than B, the alloy composition determines which oxide forms. The scheme of selective oxidation of a binary alloy is shown in Fig. 4. The *x*-axis is position and the *y*-axis is the concentration. Alloying element A becomes depleted as it reacts at the metal-oxide interface. This creates a concentration gradient of A, causing A to diffuse from the interior of the alloy toward the surface. At the same time, depleting

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

A near the metal surface increases the concentration of B so that B should diffuse inward. If the diffusivities (*J*) of A and B in the alloy are similar to the diffusivity of A in the oxide, the element A will not be seriously depleted at the metal-oxide interface, and AO continues to form. However, the diffusion through the alloy is usually much slower than through the oxide; consequently, the concentration of B will increase at the alloy surface until it reaches N_B^*, the critical concentration at which formation of BO is thermodynamically favorable. At that time, BO will form along with AO.

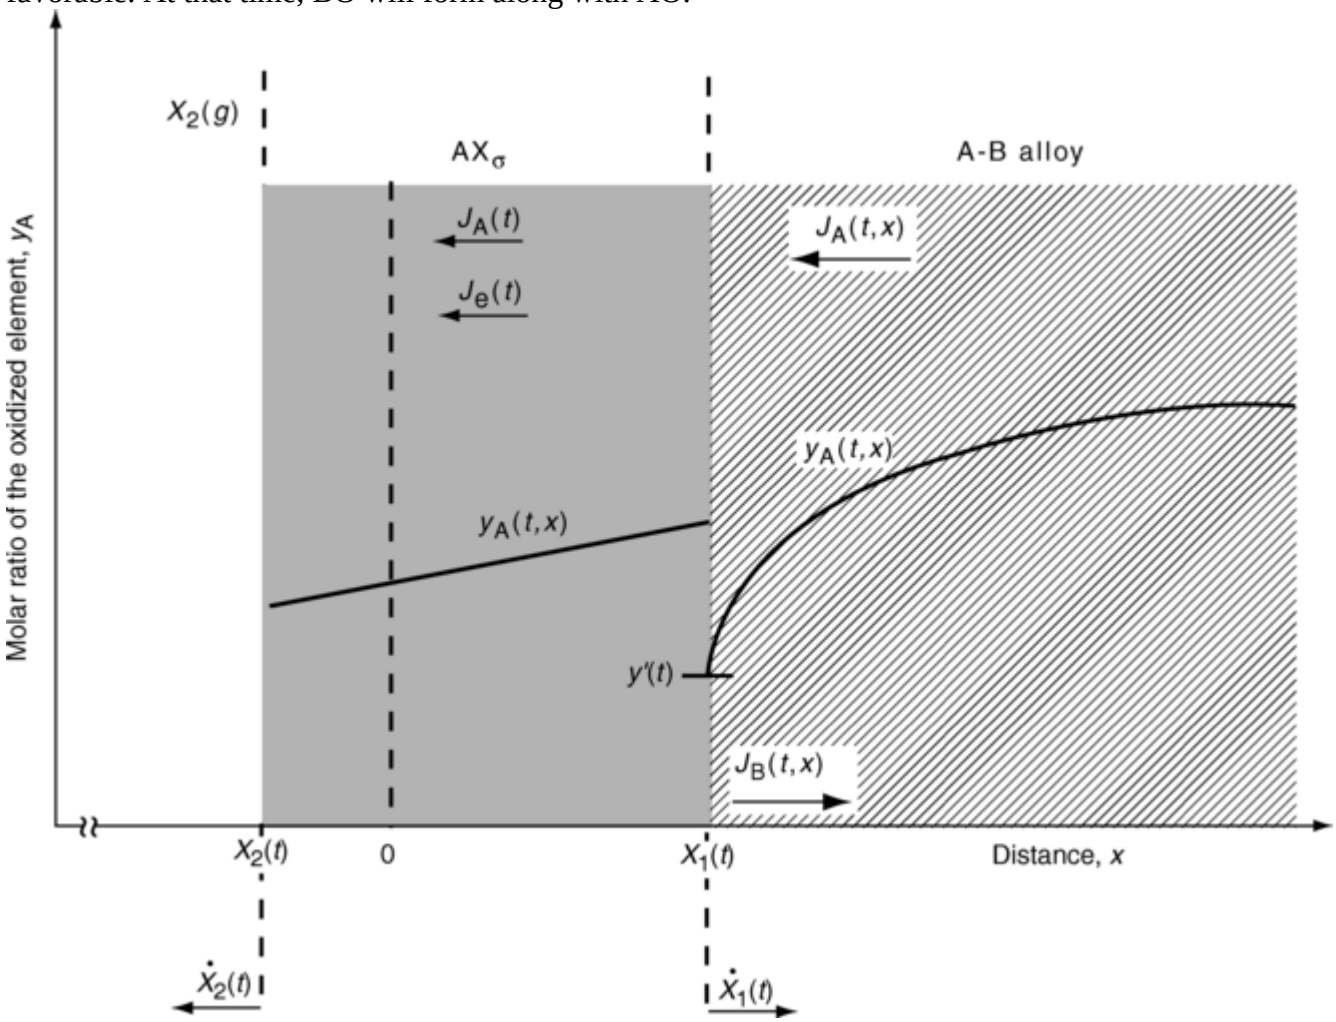

Fig. 4 Schematic showing the mass flow and scale growth during the selective oxidation of a binary alloy. Location is plotted on *x*-axis and the concentration of component A(y_A) is plotted on *y*-axis. The initial surface of A-B alloy (at $t = 0$) is at $x = 0$. $X_1(t)$ and $X_2(t)$ are the positions of the oxide/alloy and oxidant/oxide interface, respectively. $\dot{X}_1(t)$ and $\dot{X}_2(t)$ are their velocities. *J* is the diffusivity flux.

Reducing Oxidation Rates. The oxidation rate of a reactive metal cannot be markedly reduced by alloying it with a noble metal. If the concentration of the reactive element is far greater than the critical concentration needed to form an external scale, that is, if $N_B \gg N_B^*$, alloying with a noble metal will have very little effect on the oxidation rate.

The model of parabolic, selective oxidation of a binary A-B alloy was proposed by Wagner for a binary nickel-platinum alloy (Ref 15). Wagner combined his theory of metal oxidation with the Darken model of interdiffusion in binary alloys (Ref 16), and obtained an analytical solution for the kinetics of oxidation of nickel-platinum-type alloys. His theory later became a starting point for examination of interdiffusion in *p*-type oxide solid solutions for non-steady-state conditions (Ref 17, 18). During selective oxidation of a binary nickel-platinum alloy, the following reaction takes place at the alloy-oxide interface:

$$Ni(alloy) + \frac{1}{2}O_2(g) = NiO(s) \qquad \text{(Eq 11)}$$

When diffusivity of the oxidant in the oxide is negligible and a single type of defect dominates in the metal sublattice, then the parabolic rate constant for nickel oxidation is expressed by:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$k'_p(t) = 3D_o\left[\left(p''_{O_2}\right)^{1/6} - \left(p'_{O_2}(t)\right)^{1/6}\right] \quad \text{(Eq 12)}$$

where p_{O_2} and $p'_{O_2}(t)$ denote the equilibrium oxygen partial pressure in gas atmosphere and at the NiO-alloy interface.

As a result of nickel depletion at the NiO-Ni interface, the nickel concentration in the alloy decreases. Consequently, the dissociation pressure of NiO in equilibrium with the alloy increases. Thus, $p'_{O_2}(t)$ is an unknown variable depending on time, and the parabolic rate is not a constant but depends on time. When the alloy is an ideal solid solution, that is, $a_{Ni} = y_{Ni}$, the dissociation pressure of NiO for reaction (Eq 11) can be written in the form:

$$p'_{O_2}(t) = K^{-1/2} a_{Ni}(t)^{-1/2} \approx K^{-1/2} y_{Ni}(t)^{1/2} \quad \text{(Eq 13)}$$

One can relate the parabolic rate constant to the flux (J) of reacting nickel at (Ni-Pt)|NiO interface (compare Table 2 and Fig. 4). The resulting mass balance at this interface (Stefan condition) takes the form:

$$-J_{Ni}\left(t, X_1(t)\right) = D_{NiPt}\left.\frac{\partial y_{Ni}}{\partial x}\right|_{x=X_1(t)} = c\frac{dX_1(t)}{dt} \quad \text{(Eq 14)}$$

where D_{NiPt} is the interdiffusion coefficient in the alloy at the (Ni-Pt)|NiO interface.

Table 2 Basic assumptions by different authors for modeling selective oxidation of alloys

interface depends on time, is allowed.

On applying Eq 11, Eq 12, Eq 13, Eq 14, one can express the flux at the Ni|NiO interface as a function of the concentration of the diffusing nickel at this interface. Wagner has shown both theoretically and experimentally that alloying nickel with a small amount of platinum will have very little effect on the oxidation. Oxide growth will be markedly slower only when enough platinum is added to make nickel an extremely low concentration of the alloy. The oxidation rate is then no longer controlled by diffusion of nickel through the oxide but rather by interdiffusion of both nickel and platinum in the alloy.

The practical importance of a model of selective oxidation is that it predict the ability of an alloy and/or coating to support formation of a protective scale.

Composite External Scales. Wagner has shown that for an A-B alloy that is forming both AO and BO oxides, the mole fraction of B at the alloy surface must not exceed:

$$N_B^i \le \left(1 - N_A^*\right) = \frac{V}{z_B M_O}\left(\frac{\pi k_p'}{D_B}\right)^{1/2} \qquad \text{(Eq 15)}$$

where N_A^* is the minimum concentration of A necessary to form AO, V is the molar volume of the alloy, z_B is the valence of B, M_O is the atomic weight of oxygen, k_p' is the parabolic rate constant for growth of BO, and D_B is the diffusion coefficient of B in the alloy. The previous formula does not take into account any complications, such as porosity and internal oxidation. If the concentration of B lies anywhere between N_B^* and $(1 - N_A^*)$, thermodynamics predicts that both AO and BO are formed.

Concurrent Oxidation. When oxides of both metals form, their relative positions and distribution depend on the thermodynamic properties of the oxides and the alloy, the diffusion processes, and the reaction mechanisms. There are two common situations: both metals in a binary alloy oxidize to form two separate oxide phases, or mixed oxides, such as spinels, form.

The first situation involves immiscible oxides, with the more stable oxide growing slowly. With both AO and BO stable but with rapid growth of AO and slow growth of BO, the more stable BO may nucleate first but gradually becomes overwhelmed and surrounded by fast-growing AO (Fig. 5a, b). If diffusion in the alloy is rapid, the oxidation proceeds to form an AO scale with BO islands scattered through it. However, if diffusion in the alloy is slow, the metal becomes depleted of A near the metal-oxide interface, while the growth of BO continues until it forms a complete layer, undercutting the AO (Fig. 5c). Pockets of AO at the metal-oxide interface will gradually be eliminated by the displacement reaction, $AO + B_{(alloy)} \rightarrow BO + A_{(alloy)}$. Because BO is thermodynamically more stable than AO, this reaction will not go in the opposite direction. Such displacement reaction continues even if the oxygen supply is cut off.

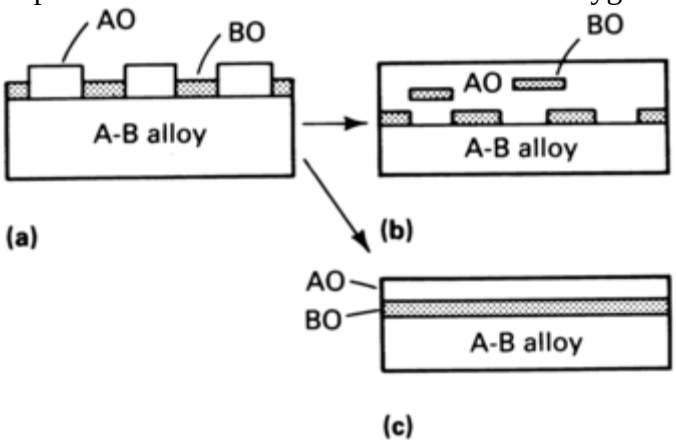

Fig. 5 Simultaneous growth of competing oxides. BO is more stable, but AO grows faster. (a) Early stage with nucleation of both oxides. (b) Later stage if diffusion in alloy is rapid. (c) Final stage if diffusion in alloy is slow

The second situation involves two oxides that are partially miscible. For alloys rich in A, an AO scale will form, with some B ions dissolved substitutionally in the AO structure. If the solubility limit is exceeded when B ions continue to diffuse into the scale, BO precipitates as small islands throughout the AO layer. Even if the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

solubility limit is not reached, the more stable BO may nucleate within the AO scale and precipitate. For alloys rich in B, a BO layer first forms. If B ions diffuse through the scale faster than A ions do, the concentration of A ultimately builds up in the scale close to the metal-oxide interface. An AO layer then forms underneath the BO.

Double Oxides. A great deal of research has been directed toward developing alloys that form slow-growing complex oxides. The silicates are particularly important because they can form glassy structures that severely limit diffusion of ions. Therefore, silicide coatings on metals have been successfully used at high temperatures.

Spinels often have extremely low diffusion rates. Spinels are double oxides of a metal with +2 valence and a metal with +3 valence, having the general formula $MO \cdot Me_2O_3$ and also having the crystal structure of the mineral spinel ($MgO \cdot Al_2O_3$). The iron oxide, Fe_3O_4, has an inverse spinel structure. For iron-chromium alloys, the spinel phase can be either stoichiometric $FeO \cdot Cr_2O_3$ or the solid solution $Fe_{3-x}Cr_xO_4$. Although many ternary oxides tend to be brittle, much research has been devoted to minor alloy additions to improve the high-temperature mechanical properties of those ternary scales that are extremely protective.

Corrosion in Complex Atmospheres. High- temperature corrosion has a wide potential for research and development, because new technologies and new materials have led to new challenges with regard to high-temperature corrosion performance. Higher operation temperatures are desired, because they result in higher efficiencies of engines and process plants. The need to operate within more aggressive environments results from the growing demand to dispose of municipal and industrial wastes and residues.

Sulfidation

In distillation and gasification processes, high amounts of sulfur may be present in the form of H_2S, while, at the same time, the oxygen partial pressures are extremely low. As a result, on conventional materials, sulfide scales are formed instead of oxides. Due to their high defect concentration, the sulfide scales show extremely high growth rates on these materials (Fig. 6), which is contrary to the protective effect that most of the oxide scales exhibit on these materials (Ref 19). For this reason, the use of conventional steels is basically limited to temperatures of 450 to 550 °C (840 to 1020 °F) when sulfidation occurs. To find materials solutions, intensive studies have been performed with a large number of conventional materials and with new groups of materials, such as the aluminides and the silicides. The application of coatings based on these compounds on the low-cost conventional steels seems to be feasible. The highest resistance under these conditions was by $MoSi_2$. However, $MoSi_2$ failed as a coating due to spalling attributed to the difference in thermal expansion of $MoSi_2$ and conventional steels. Iron aluminides are attractive on the basis of cost. However, again, their coefficients of thermal expansion do not match that of low-alloy, high-temperature steels, and they are sensitive to hydrogen embrittlement. Titanium aluminide (TiAl), which is applied as plasma spray coating by different techniques or in the form of a diffusion coating by codiffusion, is used for operating temperatures to 700 °C (1300 °F) in sulfidizing atmospheres.

Metal Dusting

Metal dusting occurs in atmospheres with very low oxygen partial pressures and carbon activities greater than 1. The mechanisms of this process are well understood (Ref 20). During metal dusting, the material disintegrates into a powder of nanosize metal particles and graphite (graphite wool). This process is a catastrophic form of high-temperature corrosion. The incubation period for metal dusting attack in the case of high-alloy materials may last up to more than 10,000 h. The depletion of chromium in the metal subsurface zone of these materials may play a significant role in the initiation of dusting attack. In this case, the use of protective coatings is a solution. These protective coatings could contain a much higher level of the scale-forming elements. Commercial coatings are based on enriching the subsurface of steels by the diffusion of aluminum. Recent investigations show that TiAl coatings and SiAl coatings can further improve the resistance of steels under such conditions (Ref 21).

Chlorine Corrosion

A chlorine corrosion knowledge base was created in the 1950s. The mechanisms are well understood, but the use of the metals is still limited up to 650 °C (1200 °F) for environments with low oxygen partial pressures and up to 800 °C (1470 °F) for conventional materials in oxidizing environments. The main problem when chlorine corrosion occurs is the formation of volatile metal chlorides. These metal chlorides develop partial pressures above the critical value of ~10^{-4} atm. Thermodynamic analysis shows that the resistant base alloy should consist of nickel with high amounts of chromium and molybdenum, because their evaporation rates would be low. However, such alloy compositions are sensitive to the presence of oxygen, because highly volatile chromium oxychlorides and molybdenum oxychlorides will be formed. Thus, the development of new materials is an important target for such environments. The existing database on the corrosion resistance under oxidizing/chloridizing environments shows that a high aluminum reservoir in the metal subsurface zone seems to be the only way to offer sufficient corrosion protection at high operating temperatures.

Summary Outline of Alloy Oxidation

A schematic diagram has been constructed to show the complexity of morphologies of scale growth on binary alloys (Ref 22) (Fig. 7). The diagram illustrates some types of structures that are known to form; it does not pretend to present those that would be theoretically possible.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

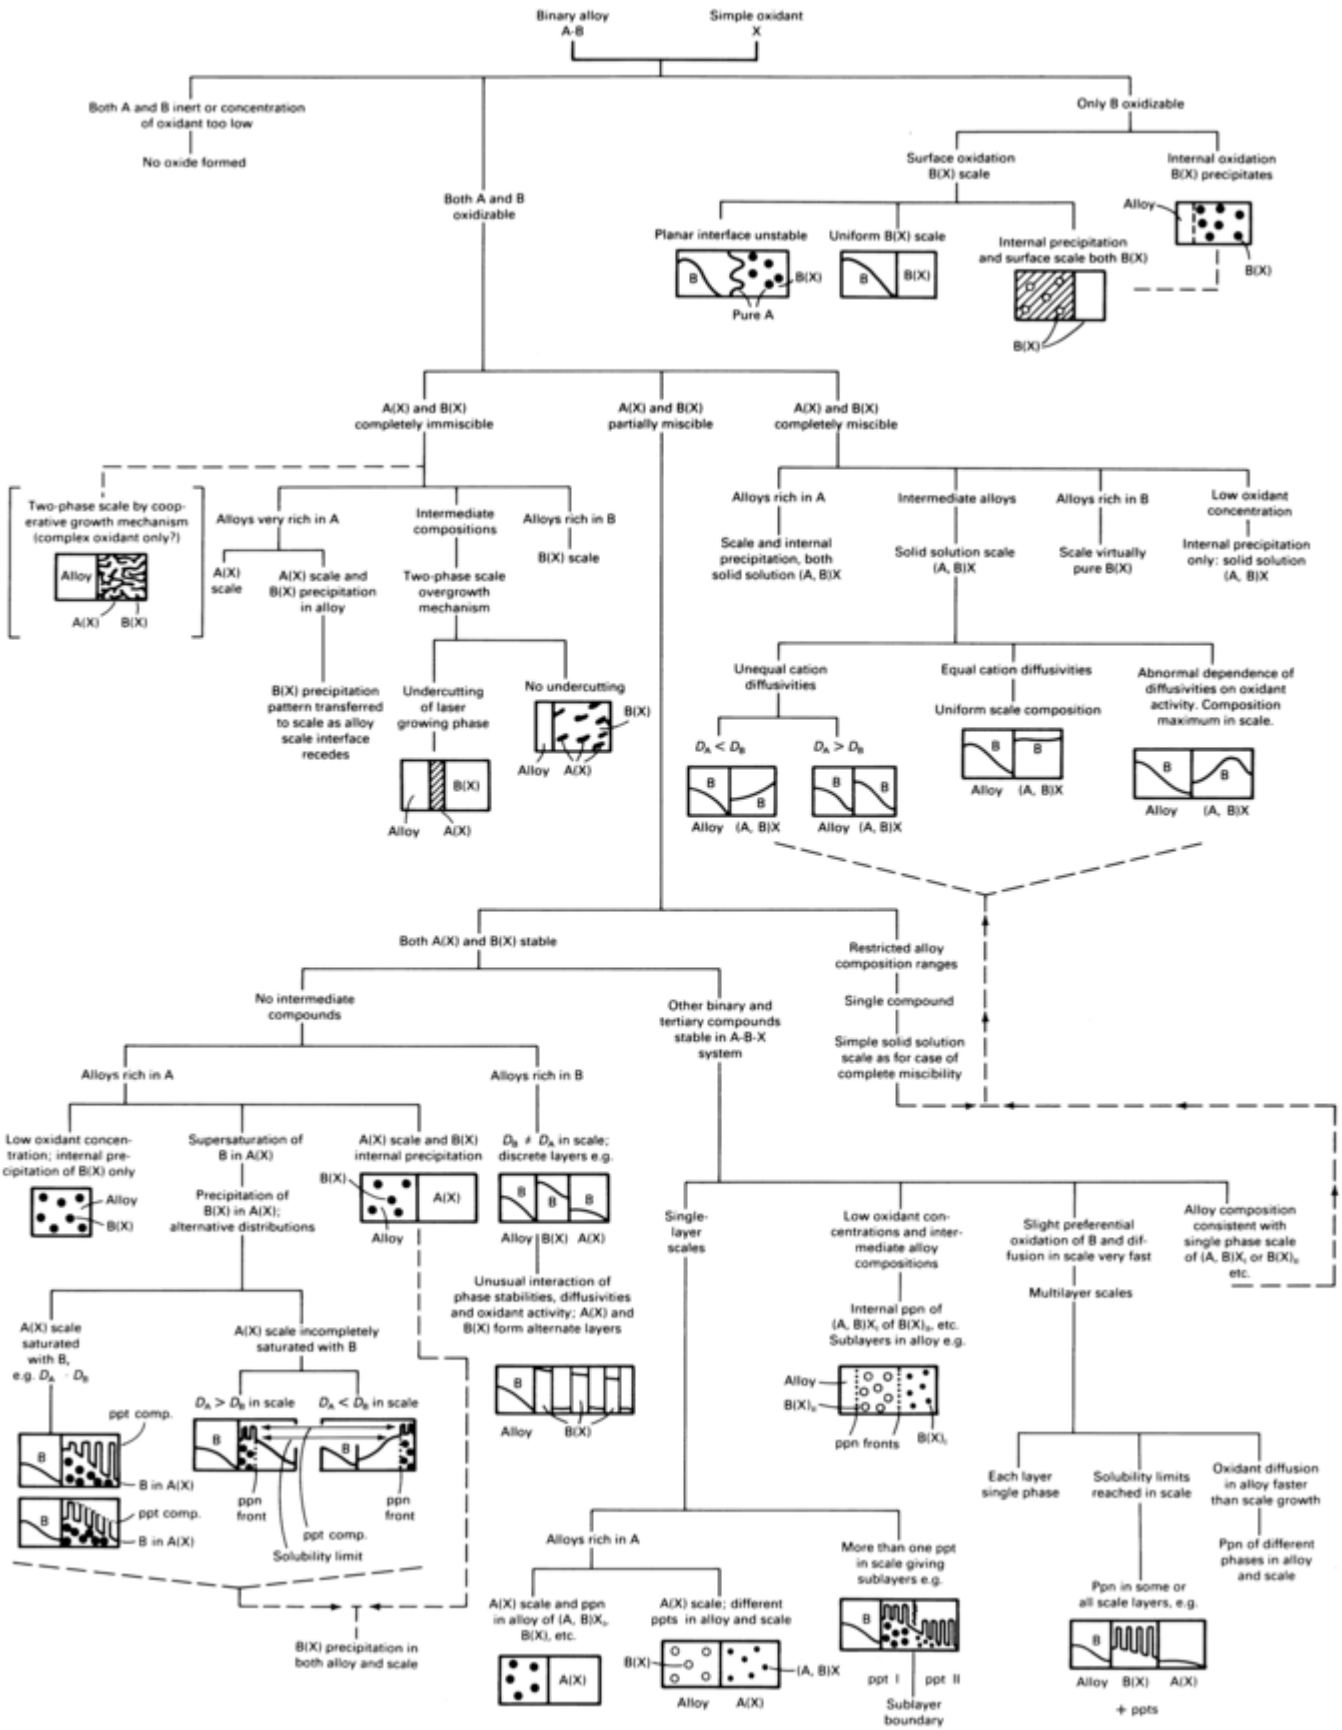

Fig. 7 Schematic showing the relationships between scale morphologies on binary alloys. ppn, precipitation; ppt, precipitate. Source: Ref 22

The demand for an increase in process temperatures requires new structural materials and coatings. There is still a significant potential for theoretical studies. The progress in fundamental studies may significantly speed the development of the new materials and coatings.

Introduction

CORROSION RATES of metal alloy test specimens having identical masses but different shapes (e.g., flat circular, cylindrical, or spherical), or identical shapes but different sizes, are not necessarily the same. It has been shown that the best reproducibility of results is obtained with flat samples (Ref 1). Therefore, corrosion studies usually use rectangular- or circular- shaped flat specimens, with thicknesses not exceeding 1 mm (0.04 in.) and total surface area of a few square centimeters (approximately 1 $in.^2$). To eliminate the effect of edges and corners on the corrosion process, these sample parts can be rounded. The corrosion process is additionally

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

influenced by surface finish (grinding, mechanical or electrolytic polishing, etc.). It is advised to use 600-grit emery paper and ultrasound cleaning when preparing test specimens (Ref 2).

Discontinuous Methods

Most metals react with oxidizing gases (oxygen, nitrogen, sulfur, chlorine) to yield solid products such as scale. These scales are generally adherent to the metallic substrate in a wide temperature range. In such cases, any direct and continuous records of weight losses are impossible. The corrosion rate data can be obtained indirectly by measuring:

- Scale thickness
- Scale weight per unit surface area
- Loss of metal thickness
- Loss of material weight per unit surface area
- Weight change of oxidant bonded in the scale per unit surface area as a function of time

Thickness or weight of the scale or the uncorroded material can be measured in a discontinuous manner at room temperature. Specimens with identical starting dimensions can be exposed to a controlled environment and then removed and measured at differing exposure times. This series of experiments and samples provides the time dependence of the corrosion process.

Scale thickness is measured on the metallographic cross sections. The procedure is simple when the scale is homogeneous, has the same composition on the whole surface, and when internal oxidation does not occur in the metallic core. The dependence of scale thickness on time can be used for the determination of a kinetic law for the oxidation rate. In the case when the rate-controlling step in the oxidation process is the diffusion of ions through a compact barrier layer of oxide with the chemical potential gradient as the driving force, the parabolic rate law is usually observed. As the oxide grows thicker, the diffusion distance increases, and the oxidation rate slows down. The rate (dx/dt) is inversely proportional to the oxide thickness (x) or:

$$\frac{dx}{dt} = \frac{k_p}{x}$$

On integration, the parabolic equation is obtained:

$$x^2 = 2k_p t$$

and the parabolic rate constant, k_p, can be determined from the experiment in units of cm^2/s or similar length squared per time units.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

To measure the weight of the scale or the uncorroded metal, it is necessary to remove the corrosion product, which is a rather troublesome task. There are standard practices for removing these corrosion products, however (Ref 3). The discontinuous methods for examining uncorroded base metals are rarely used in studying high-temperature corrosion. However, it should be stressed that the discontinuous methods have certain advantages. Discontinuous methods allow for examination of specimens after different lapse times, so it is possible to follow changes in scale and alloy structure at different stages of the corrosion process.

Continuous Methods

Direct measurements of weight or thickness loss during the corrosion process are possible only in the case when the corrosion product is volatile. Metals that form volatile oxides are not numerous. For example, tungsten, molybdenum, and platinum belong to this group. In such cases, the rate of corrosion can be determined continuously on the basis of thickness or weight changes in time. Thickness can be measured during the corrosion experiment by means of a cathetometer.

The weight of an oxidant bonded by a unit surface area, $\Delta m/A$, in units of g/cm^2, can be measured continuously, and in such a case, oxidation of a single sample provides information for determining the rate of corrosion. Again, if the kinetic law of this process is parabolic, the weight-based parabolic rate constant, k_p, can be calculated in units of $g^2/cm^4 \cdot s$. The three principal methods are volumetric, manometric, and thermogravimetric.

The volumetric method is based on measuring the volume of gaseous oxidant consumed by the corroding material under isobaric conditions (Ref 4). This method is highly sensitive but has some limitations. Oxidation cannot be performed in gas mixtures, and gaseous products cannot be formed, because they would disable accurate measurements of oxidant volume.

The manometric method consists of measuring the pressure variations in the reaction zone brought about by the oxidation process (Ref 5). The manometric method is as sensitive as the volumetric one and has similar limitations. An additional problem is that it does not allow maintaining strictly isobaric conditions during the oxidation test.

Thermogravimetric Analysis (TGA). This method is most frequently used in oxidation rate measurements. It is experimentally simple and does not impose any limitations as far as the gas phase composition is concerned. Thermogravimetry consists of measuring the weight changes of the oxidized sample placed in the reaction zone (Fig. 1a). The precision of new thermobalances is such that mass changes as low as 0.1 μg can be measured. This enables determining very small parabolic rate constants, on the order of 10^{-14} $g^2/cm^4 \cdot s$. Gaseous reaction products do not affect the accuracy of measurements, although the rate of reaction calculated from experimental curves may differ from the "real" rate.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

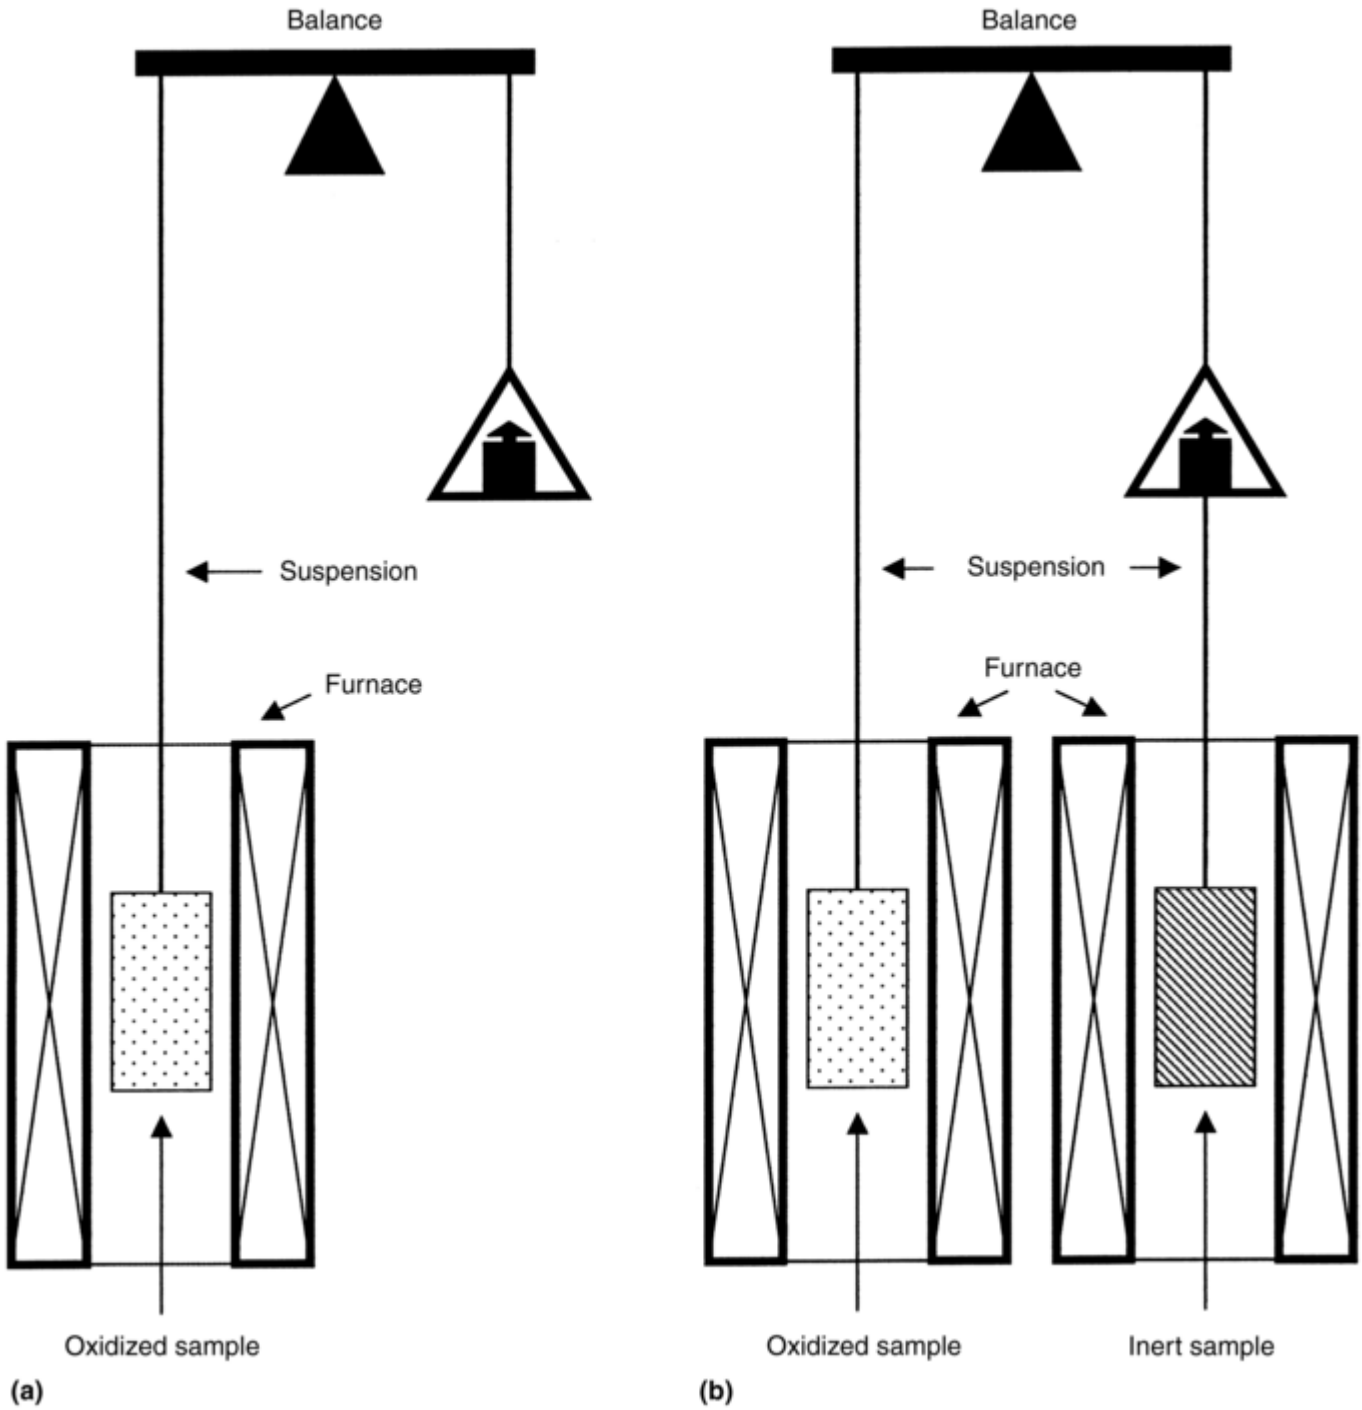

Fig. 1 Schematic drawing of thermobalances for thermogravimetric analysis. (a) Tube furnace and microbalance without compensation for hydrostatic lift. (b) With compensation for hydrostatic lift

The gaseous components may appear as a result of direct reaction between metal and oxidant, but they may also appear as products of secondary reaction between the primary product and the oxidant. In both cases, the weight change taken from the TGA measurement, $\Delta m(t)$, is a difference between the weight of the oxidant taking part in the reaction with the metal, $\Delta m_{ox}(t)$, and the weight of a volatile component of the corrosion product, $\Delta m_{vol}(t)$:

$$\Delta m(t) = \Delta m_{ox}(t) - \Delta m_{vol}(t)$$

The real corrosion rate in such a case is higher than that resulting from the analysis of the TGA curve. This situation arises in chromia formers when the oxidation temperature exceeds approximately 900 °C (1650 °F). Chromium (III) oxide, Cr_2O_3, oxidizes to a volatile CrO_3, and in the presence of water vapor, other volatile compounds are formed, such as $CrO_2(OH)_2$ (Ref 6).

An important source of measuring errors in the TGA method, especially when the weight gains are small, may come from the weight changes of the fixture that supports the sample. The suspensions are usually made of thin

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

platinum or platinum-rhodium wires, quartz fibers, or preoxidized Fe-Cr-Al wires covered with a protective film of alumina. High temperatures (over 1000 °C, or 1830 °F) and at high partial pressures of oxygen combined with prolonged test times (thousands of hours) would cause a volatile PtO_2 to form. Platinum wires should be avoided. At low partial pressures of oxygen and high temperatures, using quartz suspensions is not recommended because of possible formation of a volatile oxide, SiO. However, by weighing the suspension fixture before and after the experiment, it can be checked whether or not the weight change of the fixture due to corrosion is negligible.

In TGA measurements of oxidation rate, it should be realized that the measured weight of the sample also includes that of gases that are dissolved in the metallic phase without taking part in the oxidation process. One metal with high solubility for oxygen is titanium. Its high- temperature variety, α-Ti, can dissolve as much as 30 at.% oxygen. In the TiAl alloys under the protective alumina scale, there appears a *Z*- phase, $Ti_5Al_3O_2$ (Ref 7), which may bond similar amounts of oxygen as the protective scale. The interpretation of thermogravimetric curves is easier when scale morphologies and cross sections are also examined. This is particularly important when the scale has varying composition on the metal surface and when the internal oxidation zone appears in the metal substrate.

When the specimen is inserted from room temperature into the hot zone of the furnace, it should be realized that its weight slightly increases as a result of hydrostatic lift. The density of gas is inversely proportional to temperature. The hydrostatic lift should be taken into consideration in a situation when the total weight gain of the sample is expected to be small. The effect can be eliminated by means of a thermobalance where the second arm is loaded with a sample having the same dimensions as the investigated one but made of an inert material, for example, Al_2O_3 (Fig. 1b). Both samples are heated to the same temperature. Thermogravimetric curves obtained for the same material in different laboratories exhibit a significant scatter caused by differences in measuring instrument design and experimental conditions. The discrepancies may be due to different gas flow rates in the reaction zone of the furnace, variations in the atmospheric pressure, different air humidity in the case of open systems, or slight differences in temperature or temperature fluctuations in the furnace.

Because of simplicity and high accuracy of measurements, the TGA method is the one most often encountered in corrosion studies. However, other methods can also be used successfully to suit some cases. The thickness of very thin, transparent oxide films is determined by measuring the light interference or polarization changes. It is also possible to determine the rate of corrosion on the basis of measured electrical conductivity of the corrosion product.

Corrosion by Molten Salts

Robert A. Rapp, The Ohio State University

Introduction

THE OPERATION of high-temperature engineering systems, despite their associated materials problems, is inherent to advanced technologies that strive to gain an advantage in thermodynamic driving force or in reaction kinetics or both. Certain high-temperature systems involve the contact of materials with a large quantity, or significant depth, of a salt solution above its liquidus temperature. Such systems include the molten carbonate fuel cell (MCFC), molten chloride baths to melt used aluminum beverage cans, the Hall-Heroult aluminum electrowinning cell with a fluoride (cryolite)-base electrolyte, nitrate/nitrite heat-exchange salts, and fused salt descaling or heat treatment baths. In other important engineering systems, the accelerated corrosion of materials results from the contact of materials with thin films of deposited fused salts. This important corrosion mode, analogous in certain aspects to aqueous atmospheric corrosion near room temperature, is called *hot corrosion.*

Gas turbines, steam generators, incinerators, and various petrochemical process vessels operate at high temperatures (600 to 1100 °C, or 1100 to 2000 °F) and involve metallic or ceramic materials in contact with combustion product gases containing inorganic impurities. As these gases are cooled below their dewpoint, fused alkali sulfate-base salt films may condense on the hardware to generate an aggressive hot corrosion condition. Sometimes, the salt is deposited directly as liquid droplets from the gas stream, sometimes as solid salt particles shed from an upstream filter or compressor for a marine gas turbine. Both in understanding and testing for corrosion by molten salts at high temperatures, the relevant salt depth and the gaseous atmosphere must be respected.

The chemistry and corrosion have been studied for many fused salt systems: chlorides, fluorides, carbonates, sulfates, hydroxides, oxides, and nitrate/nitrite. In analog to aqueous solutions, each of these melts is a dominant ionic conductor of electricity (an electrolyte), and each melt exhibits both an oxidation potential and an acid/base character, which depend on the salt composition and its surrounding environment. Because of their high thermodynamic stability, fused alkali sulfates are frequently formed from the combustion of fossil fuels,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

because impurities from both the fuel and the combustion air (perhaps containing a sea salt aerosol) react to form a product based on fused sodium sulfate. Besides its specific engineering significance, fundamental studies of the sodium sulfate system are available in the greatest depth, so this system is chosen to illustrate the important aspects of fused salt corrosion in this article. However, comments pointing out particular aspects of other salt systems are also made. Reference 1 provides a description of further engineering aspects of fused salt corrosion.

Phase Stability and Salt Chemistry

In many respects, the corrosion of materials by fused salts at high temperature has many common aspects with aqueous corrosion near room temperature. Because of its high thermodynamic stability, fused sodium sulfate is frequently the aggressive salt film in combustion product gases that causes hot corrosion. At 1200 K (1700 °F) for the equilibrium:

$Na_2SO_4 = Na_2O + SO_3(g)$ (Eq 1)

$$\log a_{Na_2O} + \log P_{SO_3} = -16.7 (\text{at } 1200\ \text{K}) \quad \text{(Eq 2)}$$

where a_{Na_2O} is the thermodynamic activity for Na_2O, and P is the partial pressure of SO_3. According to Ref 2, one can define the basicity of a sodium-sulfate-base melt as log a_{Na_2O} and its acidity as log P_{SO_3}.

In analog to the Pourbaix approach to the study of aqueous corrosion, Fig. 1 presents a phase stability diagram for the Na-S-O system at 1173 K (1652 °F), where the ordinate is the oxidizing potential and the abscissa is a quantitative measure of the melt basicity/acidity (Ref 3). Figure 1 is calculated from known values of the standard Gibbs formation energies for the phases indicated, and the dotted lines partition the field of Na_2SO_4 stability according to the dominant minority solute species in the Na_2SO_4 solvent. In contrast to aqueous solutions, molecular oxygen has a very low solubility in fused Na_2SO_4, and dissolved SO_3 $(S_2O_7^{2-})$ is the primary oxidizing solute (Ref 4). Oxygen molecules are also almost insoluble in other fused salts. Therefore, in contrast to aqueous solutions, the hydrogen ion has little presence or importance in most fused salts; instead, the electrochemical reduction of oxyanion species is usually important, and the alkali oxide activity is the key indication of melt basicity.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

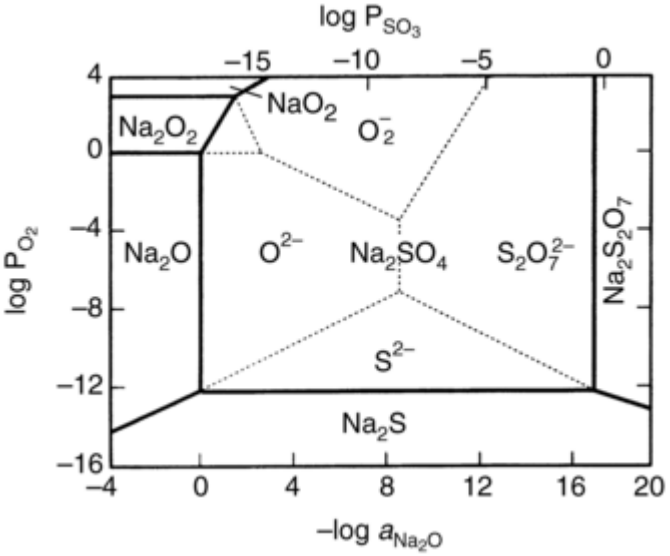

Fig. 1 Na-S-O phase stability diagram for 1173 K (1652 °F). Source: Ref 3

Following the early authors of fused salt stability diagrams, the abscissa for Fig. 1 increases to the right with increasing melt acidity, the opposite to the Pourbaix formalism for aqueous solutions. The basicity and acidity, respectively, of other fused salt systems can be described analogously, so long as only one cation is involved: Na_2CO_3 (log a_{Na_2O}, log P_{CO_2}); NaOH (log a_{Na_2O}, log P_{H_2O}); and $NaNO_3$ (log a_{Na_2O}, log P_{NO_2}). Similar Pourbaix-style phase stability diagrams can be calculated for the other salt systems; today, readily available software will provide such plots.

Electrochemical probes have been developed for the individual measurement of the thermodynamic activities of oxygen and sodium in fused sodium-sulfate-base melts (Fig. 2). These probes involve Na^+- and O^{2-}-conducting solid electrolytes in combination with reference electrodes of known, fixed activities for sodium and oxygen (Ref 3, 5, 6). By the combined use of these two sensors, the thermodynamic activity of Na_2O can be determined, providing a quantitative measure of the melt basicity (abscissa scale in Fig. 1) equivalent to the use of the pH electrode for aqueous solutions. The oxygen sensor alone provides the measurement of the oxygen potential, corresponding to the redox ordinate scale of Fig. 1. When only sodium cations are involved, with sulfate or several other anions, these probes can accurately provide a measure of melt basicity defined as log $a_{Na_2O}$and the oxidation potential (log P_{O_2}). Analogous sensors have been used with fused carbonate melts, fused chloride melts, and for oxyfluoride melts (Ref 7), and they could be developed for other fused salt systems.

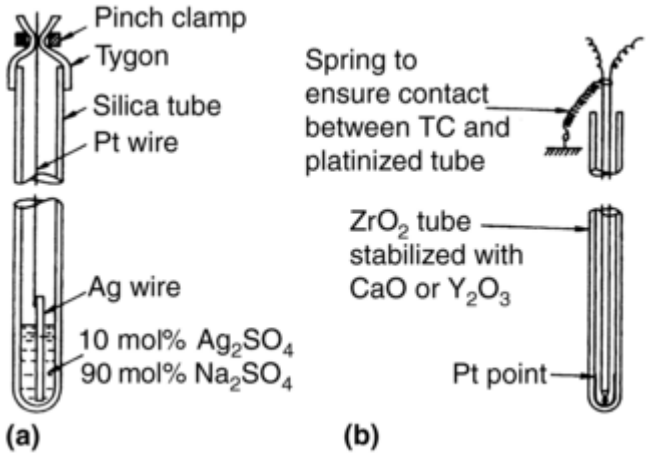

Fig. 2 Experimental electrochemical reference electrodes to simultaneously measure sodium and oxygen activities and thereby, melt basicity. (a) Ag/Ag^+ electrode. (b) ZrO_2 electrode. Source: Ref 3, 5, 6

Because of the high temperatures involved, the usual highly oxidized state of the aggressive fused salts, and the thermodynamic incompatibility of the oxidizing salt and the reducing metal, the hope for corrosion immunity

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

for materials cannot be realized. Rather, to achieve passivity, the stability and solubility of a protective oxide in contact with the corrosive medium are of great importance, as is the consequence of a localized failure/penetration of the protective oxide. In this context, a protective oxide refers to one obeying diffusion-limited growth kinetics. Thus, the engineer must choose materials and modify processes or environments to achieve an adherent protective oxide with minimal solubility in the fused salt.

Following the Pourbaix approach, the solubility of a (protective) oxide in a (corrosive) solvent is understood by the superposition of a phase stability diagram for that oxide over that for the solvent, for example, Fig. 1 for the Na_2SO_4 salt. Thus, quaternary phase stability diagrams have been generated for many M-Na-S-O systems for the metals of interest, as illustrated by the Cr- Na-S-O stability diagram of Fig. 3 (Ref 8). As for aqueous Pourbaix diagrams, within the field of Cr_2O_3 stability, dashed lines indicate the calculated concentrations for each solute (assuming an ideal solution). The ratio between the actual measured solubilities and the calculated solubilities provides a value for the activity coefficient for the particular solute. Implicit to Fig. 3 is the absence of any field for the stability of chromium metal, either pure or in an alloy. Thus, anytime the fused Na_2SO_4 salt would contact chromium or an alloy containing chromium, a reaction must be expected, most usually to form a sulfide product phase. This behavior is also common to the other important base-metal components, iron, nickel, cobalt, aluminum, and so on (Ref 6). The most important aspect of alloy protection is to prevent contact of the alloy and the salt, for example, by an adherent protective oxide with minimal solubility.

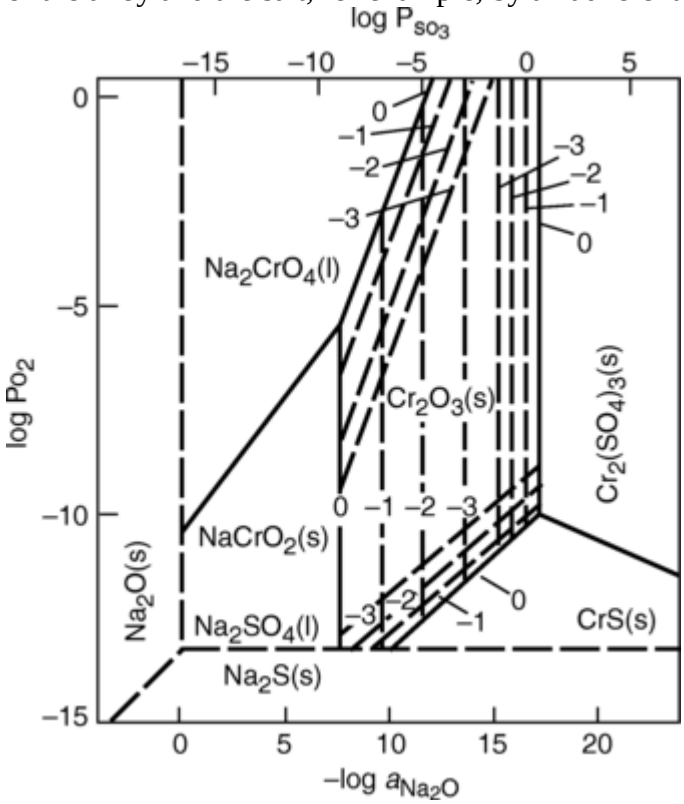

Fig. 3 Na-Cr-S-O phase stability diagram for 1200 K (1700 °F). Source: Ref 8

The Cr-Na-S-O system of Fig. 3 is rather complicated, because Cr_2O_3 can form two acidic ($Cr_2(SO_4)_3$ and CrS) and two basic (Na_2CrO_4 and $NaCrO_2$) solutes. The experimentally measured Cr_2O_3 solubility at 1200 K (1700 °F) and 1 atm O_2 and the relevant dissolution reactions with the predicted slopes are presented in Fig. 4 (Ref 8). In this range of dilute solutions, the expected dependencies for each of the three solutes are closely followed, consistent with Fig. 3. Additional experiments at lower P_{O_2}showed that $NaCrO_2$ becomes the dominant basic solute instead of Na_2CrO_4. Whenever a given cation from an oxide changes its valence on dissolution, for example, forming CrO_4^{2+} from Cr_2O_3 dissolution, the resulting solubility depends on both the basicity and the oxygen activity. In this instance, the solubility of Cr_2O_3 is higher at high oxygen activity and lower at low oxygen activity, for a given basicity. The experimental results of Fig. 4 are in complete agreement with those expected by the Pourbaix thermodynamic approach of Fig. 3, except that at such a high temperature, the oxide solubility can actually be measured and applied to a corrosion model.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

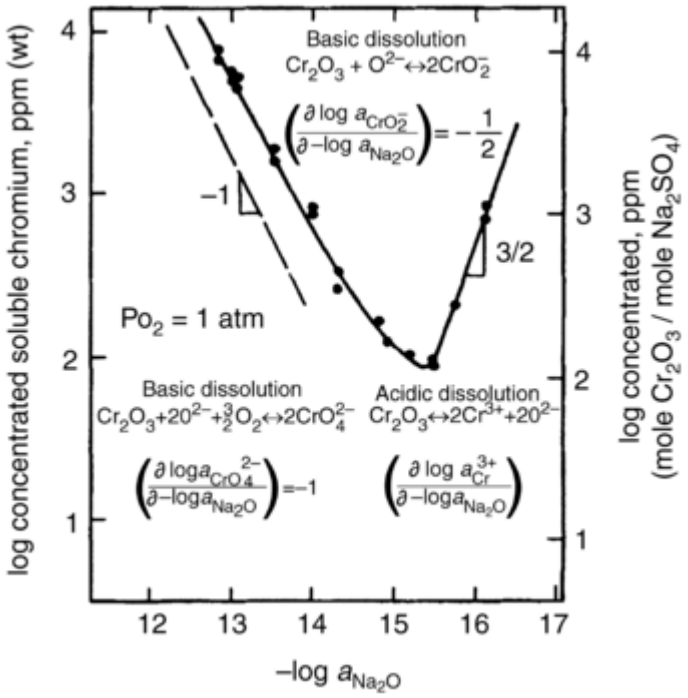

Fig. 4 Experimentally measured solubilities for chromium oxide in fused Na_2SO_4 at 1200 K (1700 °F) and 1 atm oxygen. Source: Ref 8

Figure 5 presents a compilation of such experimentally established solubility plots for 1200 K (1700 °F) and 1 atm O_2 (Ref 5, 6). From these plots, the oxides for nickel and cobalt are the most basic, and the oxides of chromium and aluminum are the most acidic, with approximately six decades of basicity separating their respective solubility minima. For every oxide except SiO_2, the solubility curves comprise the individual contributions from simple (uncomplexed) acidic and basic solutes, with readily predicted slopes. Each plot (except SiO_2) then is comprised of a leg plotting the basic solubility (left side) and another leg plotting the acidic solubility (right side). For basic solubility:

$$\mathrm{MO}_x + \mathrm{O}^{2-} = \mathrm{MO}_{x+1}^{2-}$$
$$d\log\left[\mathrm{MO}_{x+1}^{2-}\right] \Big/ d\left(-\log a_{\mathrm{Na_2O}}\right) = -1 \qquad \text{(Eq 3)}$$

for acidic solubility:

$$\mathrm{MO}_x = \mathrm{M}^{2x+} + x\mathrm{O}^{2-}$$
$$d\log\left[\mathrm{M}^{2x+}\right] \Big/ d\left(-\log a_{\mathrm{Na_2O}}\right) = +x \qquad \text{(Eq 4)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

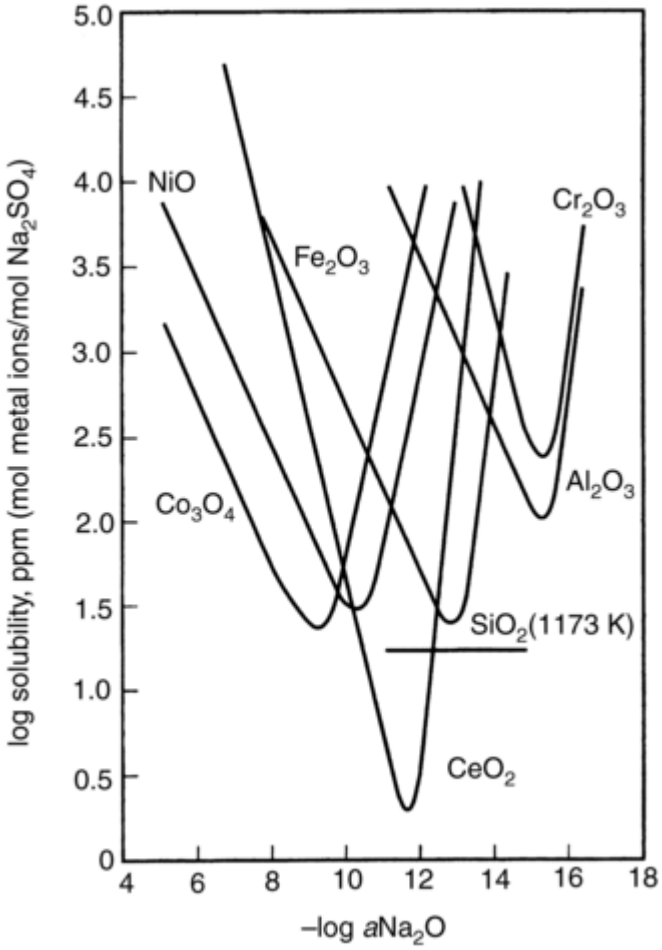

Fig. 5 Compilation of measured solubilities for several oxides in fused pure Na_2SO_4 at 1200 K (1700 °F). Source: Ref 5, 6

Silica, in the indicated (acidic) experimental range, produces only a molecular (no ionic) solute, so no basicity dependence was found. (However, a basic solute does form for silica in more basic solutions.)

The solubility plots of Fig. 5 offer some insight concerning the selection of materials for specific applications. As the first cut, one should choose a material whose slow-growing, adherent oxide scale is close to its solubility minimum for the local conditions in an application, as determined by calculation or measurement. Accordingly, a silica protective film is known to be very resistant to acidic salts, for example, on SiC or Si_3N_4 materials in high-sulfur coal environments (Ref 9). In contact with a quite basic salt, for example, alkali carbonate, silica is readily attacked to form a soluble Na_2SiO_3 product. So, perhaps counter to intuition, combustion product gases in a high-sulfur (acidic) coal-burning facility are less corrosive to a silica-protected material than in an environment with low sulfur but high alkali content. In gas turbine practice, coatings based on Cr_2O_3 and Al_2O_3 have proven effective, because the very acid service condition resulting from sulfur in the fuel and sulfate from seawater corresponds to the minima for their solubility plots. While these protective oxides are the best for this application, any penetration of the oxide provides the condition needed to form sulfides for all of the superalloy components. For this reason, the trace reactive-element additions, such as yttrium, cerium, and lanthanum, which are added to high-temperature alloys to improve scale adherence, also contribute to protection from hot corrosion.

Corrosion by Molten Salts

Robert A. Rapp, The Ohio State University

Electrochemistry and Fused Salt Corrosion

The electrochemical tests that have proven so important to understanding aqueous corrosion, as reviewed elsewhere in this Volume, also apply directly to corrosion by fused salts. However, fused salt experimentation is probably made more difficult and complicated by the myriad salts of interest. Again, it is important to differentiate between a deep melt and a surface film, because certain important differences in mechanistic interpretation apply. Likewise, because the acid/base and oxidizing potential of a fused salt may be decided by an equilibrium with an ambient gas phase, it is important to match the experimental environment with the service conditions, to the extent possible. For this reason, sulfur-free air should not be substituted in the laboratory testing of hot corrosion for sulfur- laden combustion product gases. Relative to the laboratory electrochemical methods, all the traditional and more advanced techniques can be used for deep melts (crucible tests), for example, three-electrode polarization scanning to establish the kinetics for cathodic and anodic half-cell reactions, chronopotentiometric and chronoamperometric scans, cyclic voltammetry, impedance spectroscopy, electrochemical noise analysis, and so on. Likewise, potentiometric monitoring of the corrosion potential can be done, even for thin fused salt films. Details for such methodologies are beyond the scope of this article, but example studies that establish the electrochemical reactions are available for pure Na_2SO_4 (Ref 3, 10, 11). The Cr-Na-S-O system (Ref 12) and the Mo-Na-S-O system (Ref 13) have been studied in detail.

The mechanistic information that can be gleaned for these electrochemical studies, at least for fused sulfate corrosion of metals, points out the special importance of the cathodic reduction reaction. As shown in Fig. 6, on deep cathodic polarization for a platinum working electrode in fused Na_2SO_4, the reduction of the dissolved oxidant $S_2O_7^{2-}$ (in an acidic melt) becomes quickly limited by diffusion of the ion to the cathode. A resulting sharp drop in the oxidizing potential of the platinum then causes the reduction of the sulfate ion (Ref 3):

$$SO_4^{2-} + 8e^- = S^{2-} + 4O^{2-} \qquad \text{(Eq 5)}$$

although this reaction probably occurs over several intermediate steps. Potentiometric reference electrodes, as shown in Fig. 2, have established that when the oxidizing potential dropped rapidly, sulfide ions were formed, and the melt in contact with this cathode greatly shifted in a basic direction.

مرجع مهندسی مواد و متالورژی

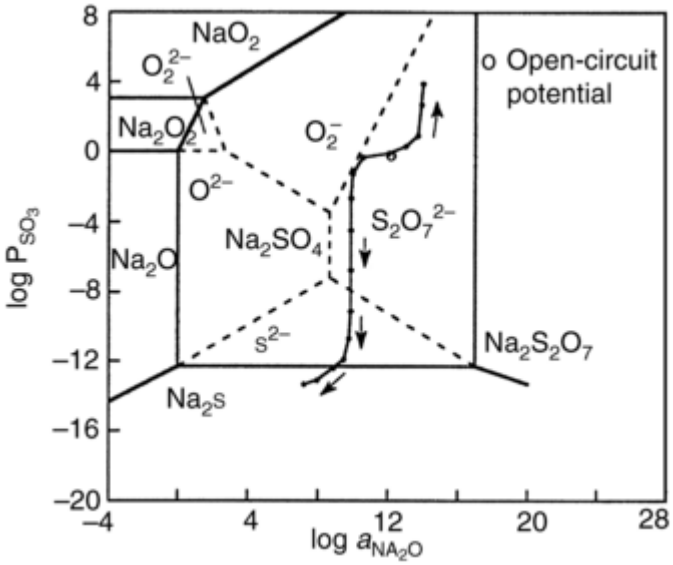

Fig. 6 Trace of basicity and oxygen activity measured on polarization of a platinum working electrode in 0.1% SO_2-O_2 gas at 900 °C (1650 °F). Scan rate, 0.1 mV/s. Source: Ref 3

The relevance of this laboratory experiment on platinum to the corrosive attack of a base metal is apparent. A bare engineering alloy (Fe- Ni-Cr-Al) at high temperatures constitutes a highly reducing condition, equivalent to a deep cathodic polarization driven electrically at the platinum working electrode. If the reactive salt should come into contact with the bare alloy, then immediate sulfidation must be expected, and the salt would locally become very basic. With eutectic temperature in the nickel-sulfur system at 645 °C (1195 °F), perhaps a liquid sulfide product would be formed. This is known to wet and progress along grain boundaries of the alloy. In contact with fused Na_2SO_4, because both chromium and aluminum form thermodynamically more stable sulfides than nickel or iron, these more reactive alloying elements could be removed from the alloy by precipitation of internal sulfides. However, because chromium and aluminum are usually intended to grow and maintain the protective oxide scale, their reaction to form sulfides would eliminate this protection.

Because fused salts are known to readily wet surfaces and interfaces, local ingress of the salt through flaws in the protective scale may also lead to detachment of the scale. Finally, the site of such local sulfide formation would become much more basic than the bulk melt (or salt film), and thus, a gradient in the solubility for the protective oxide in the salt should be established. The significance of the local basicity shift is detailed later.

The extreme consequences of a sulfate melt contacting the bare alloy suggests some important aspects for experimental corrosion testing. First, one can never simply immerse a bare base-metal specimen into a bath of hot sulfate salt. An immediate reaction must occur (the metal and the salt are thermodynamically incompatible), so no eventual protection can be expected. Both in experimentation and in engineering applications, some intentionally formed protective oxide should be provided by some preoxidation (in the absence of sulfur). The resistance to fused salt corrosion would then be measured by the initiation time required for the salt to selectively attack some chemical or physical flaw in the protective scale, which would lead to the salt contacting the alloy substrate. For many salt and alloy combinations, rapid attack leading to a failure must be expected after the initiation time.

Of course, different salts pose different types and levels of attack. Consider a nickel-base containment vessel for a fused nitrate/nitrite or carbonate salt. Because nickel does not form a stable nitride or carbide corrosion product, a severe reaction equivalent to sulfide formation in sulfate corrosion is not experienced. However, metal-salt contact would still provide an electrochemical reduction of the oxidizing salt, with a corresponding increase in local melt basicity. If instead, a nickel-chromium or iron-chromium alloy were involved, a nitride or carbide of chromium could result on salt-metal contact. When chloride salts, or complex salts containing chloride, contact a metal, having breached the protective oxide, volatile species are often formed and lost from the alloy. The alloy components iron and chromium often suffer evaporation attack via loss of volatile chlorides, which requires a porous scale in order for the vapors to escape. Sometimes, after volatile species have left the alloy reaction site, the metal component of the vapor species may be reoxidized away from this interface, reforming chlorine (or HCl) vapor to return the substrate to repeat the reaction and continue the cycle.

Scale Fluxing: A Hot Corrosion Mechanism

Such a detailed knowledge of oxide solubilities in fused Na_2SO_4, as shown in Fig. 5, leads to the idea that sustained fused salt corrosion could result upon dissolution of the protective oxide and reprecipitation of that solute elsewhere in the salt at a site of lower solubility. The dissolution attack of a protective oxide would reduce its thickness and ultimately lead to its localized attack and scale penetration. A reprecipitation of the solute to form separate oxide particles in the salt would not contribute to any protection. This scale fluxing mechanism is consistent with observed corroded microstructures (porous oxide in a salt matrix) and is applicable to either a deep salt melt or a thin salt film hot corrosion. This scale fluxing mechanism is illustrated for a thin salt film in Fig. 7 (Ref 15) and is denoted as the negative solubility gradient criterion. The decrease in solubility for the oxide across the salt film could be maintained by a combination of gradients in the local salt basicity and its oxygen activity. Probably, such gradients would be more extreme for a salt film (hot corrosion) than for a deep melt. (Remember that the oxidant that is soluble in fused sodium sulfate is dissolved SO_3 [$S_2O_7^{2-}$ ions] and not molecular O_2, as for aqueous solutions.)

مرجع مهندسی مواد و متالورژی

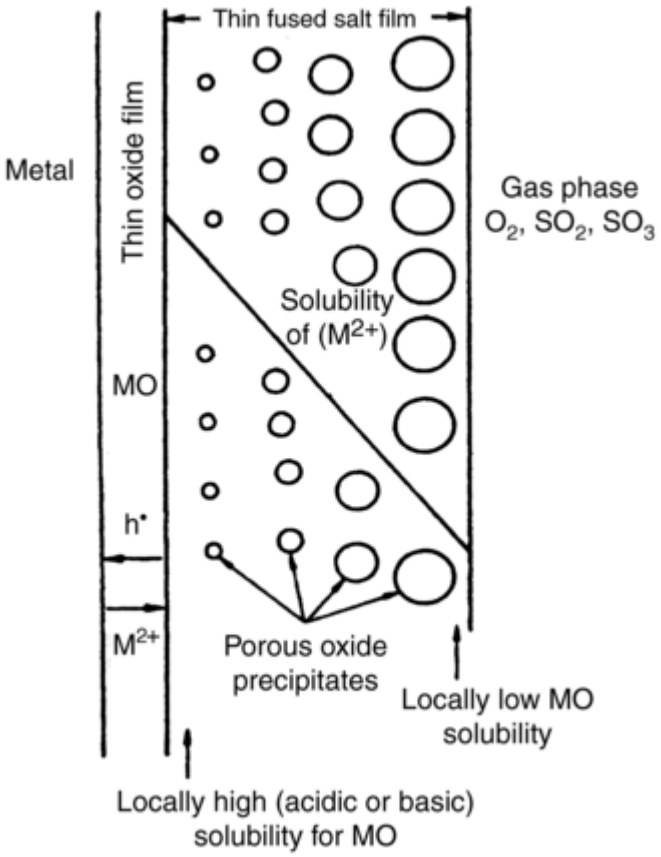

Fig. 7 Reprecipitation of porous MO oxide supported by a negative solubility gradient in the fused salt film. Source: Ref 15

Figure 8 illustrates several conditions leading to a negative solubility gradient on the basis of an idealized solubility curve for the protective oxide (Ref 15). In case A, sustained basic fluxing and reprecipitation is favored, because a dominant basic solute has a higher solubility at the oxide-salt interface than at the salt-gas interface. In case C, an acidic solute satisfies these conditions. In case B, a negative solubility gradient is realized whenever the local conditions cause the corresponding interfacial solubilities to straddle a minimum. Other factors leading to concentration (and solubility) gradients in the salt film include preferential evaporation of some component from the salt-gas interface, such as oxide or oxychloride vapors of refractory metals: vanadium, molybdenum, tungsten, and so on. Reactions, for example, sulfidation, between the salt and the metal lead to high basicity at the metal- salt interface. Likewise, the basicity at the site of the electrochemical reduction reaction is always increased. However, as detailed in Ref 5 and 15, the cathodic reduction reaction might occur at either side of the salt film, depending on several factors, for example, the presence of multivalent transition metal ions in solution. A temperature gradient in the salt at the interface would also contribute to a solubility gradient. Certainly, the solubility of any oxide in any salt would decrease with decreasing temperature. The several sorts of reactions and a thermal gradient all generally lead to some gradient in the solubility of the protective oxide scale. The magnitude of the problem would be greater for a thin salt film than for a deep melt. Accordingly, laboratory studies to test or clarify hot corrosion should not be conducted in a deep melt. The most representative, but expensive, testing for hot corrosion is provided by burner rigs supporting salt injection, where the fuel has the representative sulfur content.

مرجع مهندسی مواد و متالورژی

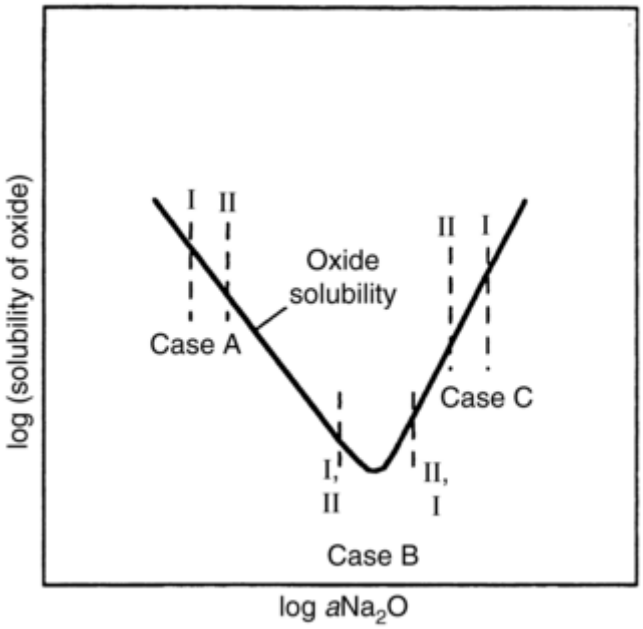

Fig. 8 Types of sustained hot corrosion of a pure metal. Site I is the oxide-salt interface, and site II is the salt-gas interface. Source: Ref 15

Historically, it has been demonstrated (Ref 16) that a condensed fused salt film is required for severe hot corrosion attack, and that Na_2SO_4 vapor in air is innocuous. Researchers (Ref 17, 18, 19) showed that the attack does not necessarily depend on an alloy sulfidation-oxidation sequence but rather on a destructive dissolution (fluxing) of the normally protective oxide in dependence on the presence of Na_2O in the fused salt film. Thin coatings of Na_2CO_3 and $NaNO_3$ on the alloys produced accelerated attack similar to Na_2SO_4, although sulfur was absent from the system. Finally, while pure nickel reacts rapidly with Na_2SO_4, because a sulfide phase is formed, a Na_2CO_3 film does not produce such rapid attack of nickel, because no carbide is formed. In total, these studies illustrated qualitatively that salt-alloy reactions can (but might not) shift the acid/base character of a fused salt film, thereby effecting a fluxing of the protective scale.

During nominally the same time period, researchers (Ref 20) studied the attack of pure nickel and nickel-base alloys beneath a fused Na_2SO_4 film at 1000 °C (1830 °F) and suggested a scale fluxing mechanism consistent with Fig. 7. A basic fluxing of the protective NiO scale and subsequent oxide reprecipitation resulted from the following reaction:

$$4Ni + Na_2SO_4 = Na_2O + 3NiO + NiS \qquad \text{(Eq 6)}$$

According to this reaction, nickel metal reacts with fused Na_2SO_4 (not a gas phase reactant) to form NiO and thereby reduces the oxygen activity until the sulfur activity of the salt contacting the metal is sufficient to form liquid nickel sulfide. As sulfur is removed from the salt by reaction with nickel, the local salt basicity (sodium oxide activity) increases, such that the normally protective NiO scale is dissolved/fluxed to form a basic solute, proposed to be nickelate ions. As part of the characteristic morphology for a corroded nickel specimen, nickel sulfide was seen in the metal, and nonprotective NiO particles were found precipitated within the external salt film. These results supported what is today known as a basic fluxing reaction, that is, corrosive attack by forming a basic solute of the protective scale.

Researchers (Ref 21) showed that Al_2O_3- forming nickel-base alloys containing the refractory elements molybdenum, tungsten, or vanadium can suffer Na_2SO_4-induced catastrophic attack, with the formation of stable solute ions involving oxide ions (MoO_4^{2-}, WO_4^{2-}, or VO_3^- ions, respectively). Again, the precipitation of a nonprotective oxide (Al_2O_3) in the salt film correlated to a local reduction in the Al_2O_3 solubility as MoO_3 and WO_3 evaporation occurred at the salt-gas interface. Later, researchers (Ref 22) showed that the acidic solubility of any oxide (except SiO_2) would be increased by the presence of strongly acidic components in the salt. This type of accelerated attack associated with refractory metal oxide solutes has become known as acidic fluxing. Researchers (Ref 23) also demonstrated acidic fluxing in the attack of superalloys containing refractory-metal elements.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Besides the designations of basic and acidic scale fluxing, the subject of hot corrosion is otherwise classified into type I high-temperature hot corrosion (HTHC) and type II low-temperature hot corrosion (LTHC). For type I HTHC, the salt film is considered to be the relatively pure solvent, and the temperature must nominally exceed its melting point. For type II LTHC, the liquidus temperature for the salt film could be significantly lower than the melting point for the pure solvent because of a significant dissolution of some corrosion product. The dissolution reactions previously discussed here generally refer to type I HTHC. Researchers (Ref 24) showed that the corrosion kinetics of Na_2SO_4-coated coupons of Ni-30Cr and Co-30Cr alloys suffered maximum rates at approximately 650 and 750 °C (1200 and 1380 °F), respectively, that is, well below the 884 °C (1623 °F) melting point for the pure Na_2SO_4 The reaction product morphologies were characterized by a nonuniform attack in the form of pits, with only minor sulfide formation and little depletion of chromium or aluminum in the alloy substrate. On correlation of the experimentally determined compositions of the final salt films to the calculated phase stability diagrams, the researchers showed that these contaminated salt films were indeed above their liquidus temperatures. Type II hot corrosion was treated in greater detail (Ref 25, 26). Although the details of attack for LTHC differ from those for HTHC, the mechanism for LTCH can also be rationalized in terms of a scale fluxing driven by a negative solubility gradient, as illustrated in Fig. 7.

Corrosion by Molten Salts

Robert A. Rapp, The Ohio State University

Consequences of Salt Chemistry on Corrosion

With the understanding that oxide solubilities in fused salts take on the general behavior exhibited in Fig. 5, that is, at least when simple uncomplexed solutes are involved, a number of concepts helpful to controlling corrosion by fused salts can be understood. In general, the analyses that follow apply to both corrosion in deep melts as well as thin films, although, as stated previously, steeper gradients are expected for hot corrosion involving thin salt films.

Negative Solubility Gradient Criterion. Regarding the model for continuing scale dissolution and reprecipitation presented by Fig. 7 and 8, one can inquire whether specific experimental evidence has supported this mechanism. In fact, during the hot corrosion of preoxidized nickel by a fused film of Na_2SO_4, researchers (Ref 27) used potentiometric probes to trace the local changes in P_{O_2} and log a_{Na_2O} as a function of corrosion time. The experiments were done to respond to a question raised (Ref 28) as to how a NiO scale could be subject to sulfidation and basic fluxing when the typical gas turbine combustion product gases are far to the acid side of the NiO solubility minimum shown in Fig. 5. In equilibrium with an acidic gas, a positive solubility gradient should not lead to NiO dissolution/reprecipitation. The researchers found that for certain (inadequate) preoxidation conditions, the NiO oxide was rapidly attacked by the salt film. Consistent with the model for basic fluxing of Eq 6, the penetration of the salt through the NiO scale to contact the nickel substrate led to a large decrease in local P_{O_2}. Simultaneously, sulfidation of the nickel occurred with such a significant increase in the salt film basicity that the negative solubility gradient criterion was indeed satisfied, even for a quite acidic surrounding gas phase. Similar experiments for improved preoxidation conditions (higher nickel purity or thicker scale) showed that the NiO scale was not penetrated, sulfidation and a large shift in basicity did not occur, and the coupon therefore suffered little corrosion attack. These experiments showed the severe consequences of direct salt- metal contact, which causes the local chemistry of the salt film to differ greatly from that in equilibrium with the gas phase. In general, one can conclude that unless the metal is well passivated by a protective oxide, the salt chemistry will be dominated by the reaction at the metal-salt interface.

Synergistic Corrosion. On examining the solubility plots for various oxides in Fig. 5, the great displacement in solubilities for the various oxides is apparent. The common base metals for engineering alloys, nickel, cobalt, and iron, form the most basic oxides (subject to acidic dissolution), while the most common protective oxides, chromia and Al_2O_3, are the most acidic oxides, (subject to basic dissolution). Because the oxidation of an alloy, for example, an iron-chromium alloy (or nickel-chromium, cobalt-chromium, and so on, also involving aluminum) should lead to the presence of both basic and acidic oxides in the protective scale, this situation represents a potential hazard in the presence of a fused salt with a local basicity value between the solubility minima for the two oxides. Therefore, the potential for synergistic dissolution of the protective scale on an iron-chromium alloy was studied (Ref 29) according to the following coupled reactions:

$$Fe_2O_3 = 2Fe^{3+} + 3O^{2-} \quad \text{(acidic dissolution of } Fe_2O_3\text{)} \qquad \text{(Eq 7)}$$

$$Cr_2O_3 + 2O^{2-} + \tfrac{3}{2}O_2(g) = 2CrO_4^{2-} \quad \text{(basic dissolution of } Cr_2O_3\text{)} \qquad \text{(Eq 8)}$$

According to these equations, the product O^{2-} ions for the acidic dissolution of Fe_2O_3 should serve as a reactant for the basic dissolution of Cr_2O_3. For fused Na_2SO_4 salt with a basicity of approximately -13.9 pH (between the relevant minima in Fig. 5), the kinetics of dissolution were measured for powders of Fe_2O_3 and Cr_2O_3, both individually and in the presence of the second oxide. In each case, the mixed oxides dissolved very much faster

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

than the single oxides. These results show that a mixed oxide protective scale may be subject to accelerated attack by a fused salt. Accordingly, researchers (Ref 24, 25, 26) showed the beneficial effect of high chromium content in nickel-chromium and cobalt-chromium alloys in excluding the oxidation of nickel and cobalt, thereby minimizing type II LTHC. Researchers (Ref 30) showed that cobalt-chromium coatings with more than 37.5% Cr and a small reactive-element addition provide excellent LTHC resistance.

Strongly Acidic Oxides. High-temperature engineering alloys frequently contain the alloying elements chromium, tungsten, and molybdenum, while vanadium is often an impurity in low-grade fuels. The oxides of these elements have the tendency to complex with oxide ions in solutions to form chromate, tungstate, molybdate, and vanadate anions. All of these compounds contribute to a reduction in the liquidus temperature in their solutions with sodium sulfate. A lower liquidus temperature means that the potential for hot corrosion by a thin fused salt film is extended to lower temperatures or farther downstream in a combustion system. In addition, the complexing behavior of these oxides introduces an important influence on the acid/base chemistry of the salt and thereby on the scale fluxing mechanism. A phase stability diagram describing the stable vanadate solutes for a sodium sulfate/vanadate solution containing 30 mol% V species at 1173 K (1652 °F) is presented in Fig. 9(a) (Ref 31). Because of their common axes, Fig. 9(a) for the Na-V-S-O system represents a superposition of the Na-V-O phase stabilities onto Fig. 1 for Na_2SO_4, as was also done in Fig. 3 for the Na-Cr-S-O system. The fields of dominance for the solutes Na_3VO_4 (orthovanadate), $NaVO_3$ (metavanadate), and V_2O_5 (vanadium pentoxide) are apparent in Fig. 9(a), and, under the assumption of an ideal solution, the concentrations of these solutes are plotted in Fig. 9(b) for a sodium sulfate/vanadate solution containing 30 mol% V.

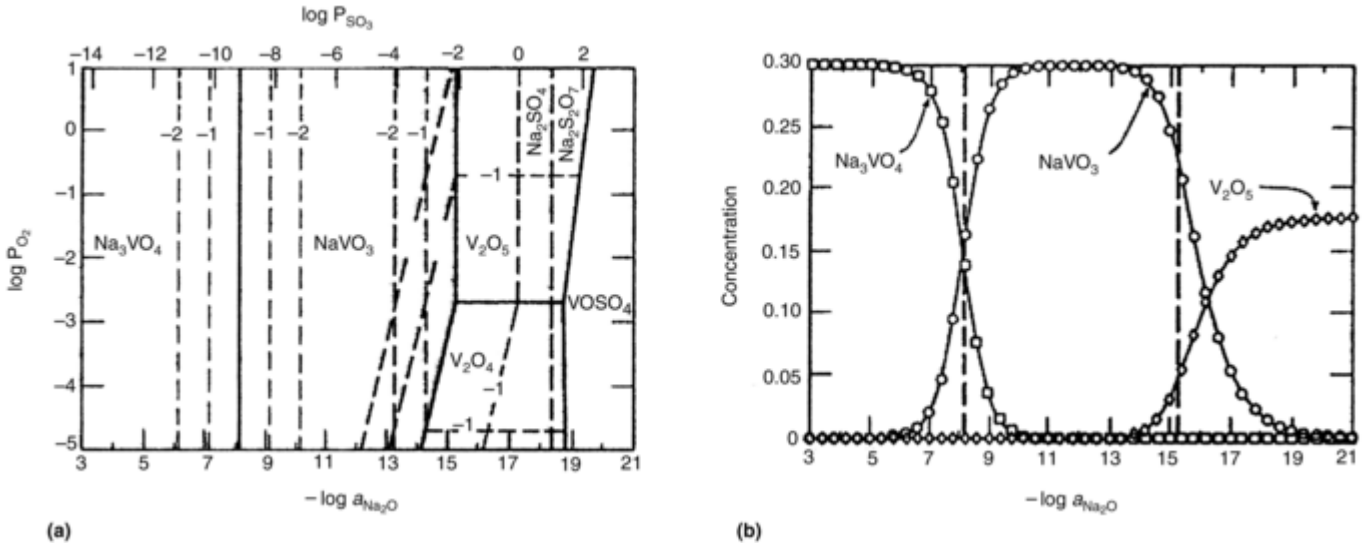

Fig. 9 The Na-V-S-O system. (a) Phase stability diagram at 1173 K (1652 °F). (b) Equilibrium concentrations for Na_3VO_4, $NaVO_3$, and V_2O_5 in a sodium sulfate/vanadate solution containing 30 mol% V at 1173 K (1652 °F)

The solubilities of the oxides CeO_2, HfO_2, and Y_2O_3 were measured as a function of salt basicity at 1173K (1652 °F) and 1 atm O_2 (Ref 22). The results were initially very surprising, because the magnitudes for their solubilities were quite high (approximately 100 ppm at their minima), and the solubility curves seem to be shifted toward a relatively basic value. To clarify these apparent discrepancies, the solubility of CeO_2 in pure Na_2SO_4 was measured for comparison. The plot of Fig. 10 shows that the presence of the vanadate component led to a very large increase in the acidic solubility for CeO_2, which, accordingly, shifted the solubility minimum to a more basic value (Ref 22). The slopes for the acidic dissolution of CeO_2 are in perfect agreement with the reactions:

$$CeO_2 + 2Na_2SO_4 = Ce(SO_4)_2 + 2Na_2O \quad (\text{in pure } Na_2SO_4) \qquad \text{(Eq 9)}$$

$$3CeO_2 + 4NaVO_3 = Ce_3(VO_4)_4 \quad (\text{in } NaVO_3\text{-}Na_2SO_4 \text{ solution}) \qquad \text{(Eq 10)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Because the oxide CeO_2 has no special properties, the effect of the strong acid $NaVO_3$, and even more so V_2O_5, in increasing the acidic solubility and thereby shifting the melt chemistry must be considered a general occurrence expected for all oxides. The magnitudes of these changes would significantly affect the attack of a metal or alloy through the negative solubility gradient mechanism. Other strongly acidic salts would similarly tend to complex with oxide ions to form, for example, molybdate, tungstate, and chromate ions. The salt AlF_3 is also strongly acidic and complexes with oxide ions, for example, in fused chloride or fluoride solutions, to form three different oxyfluoride complexes.

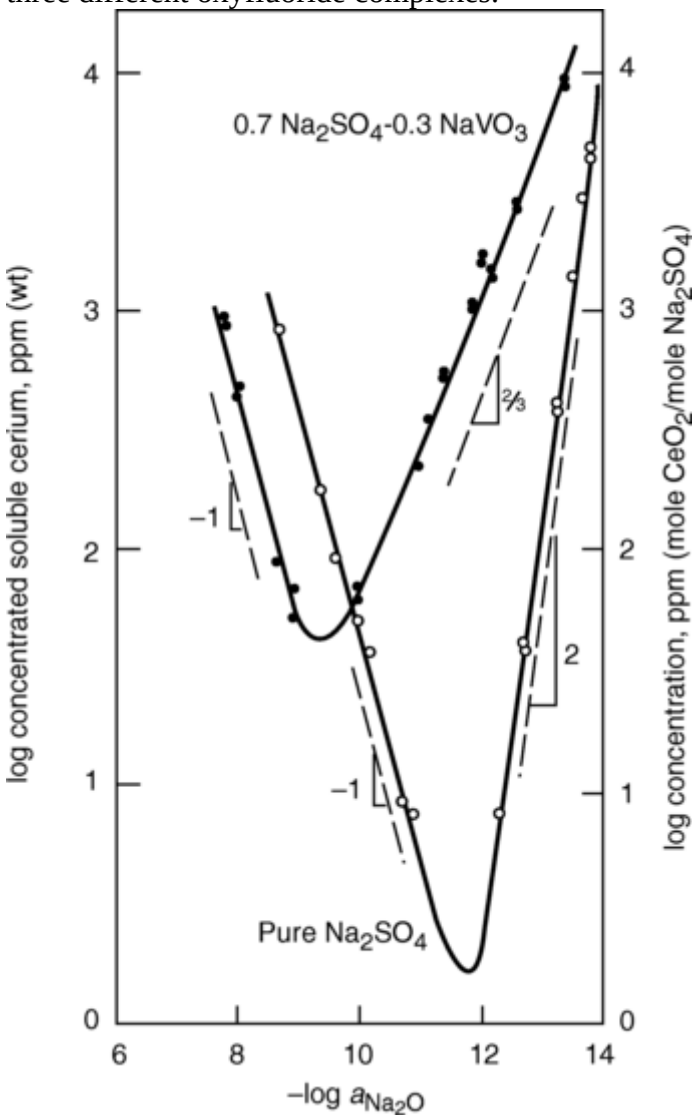

Fig. 10 Measured solubilities of CeO_2 in pure Na_2SO_4 and in 0.7 Na_2SO_4-0.3$NaVO_3$ at 1173 K (1652 °F) and 1 atm O_2

Protective Behavior of Chromium. Finally, one needs to understand why chromium is the most effective alloying element to combat corrosion by sodium sulfate. As illustrated in Fig. 11, the answer seems to lie in the oxygen pressure dependence for the basic dissolution of Cr_2O_3 (Ref 27). Because the valence of chromium is increased from +3 to +6 on Cr_2O_3 dissolution to form CrO_4^{2-} ions, the basic solubility of Cr_2O_3:

$$Cr_2O_3 + 2Na_2O + \tfrac{3}{2}O_2\,(g) = 2Na_2CrO_4$$

$$\left(\frac{d\log[Na_2CrO_4]}{d\log P_{O_2}}\right) = +\tfrac{3}{4} \qquad \text{(Eq 11)}$$

increases with increasing oxygen activity. Figure 11 illustrates the hot corrosion of a Cr_2O_3-protected alloy threatened by penetration of the salt at some grain boundaries or other defect. Because any thin salt film will be more reducing at the oxide-salt interface (certainly at a metal-salt interface) than farther away from this interface (toward the oxidizing gas), the chromate solute will experience a positive solubility gradient, and

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

therefore, consumptive reprecipitation of oxide in the salt film will not occur. Rather, the chromate ion will reprecipitate the oxide, satisfying a reduction in its solubility, at the most reduced sites, for example, the flaws or grain boundaries of the scale. In this way, the chromium serves as a protective component to plug flaws in the scale. In aqueous solutions, where chromatic inhibitors have been popular (but are now avoided for environmental reasons), the protective mechanism is believed to be the same.

Conclusions

In this article, the importance of the acid/base and oxidizing character of a fused salt to the corrosion mechanism has been emphasized. In many regards, corrosion by a fused salt shares common characteristics with aqueous corrosion. Corrosion by fused sodium sulfate, also including additions of vanadates, has been emphasized for two reasons: this salt system probably has the greatest practical importance, because it relates to corrosion in combustion product gases; and the fundamental data and models have been better developed for this salt system. For many combinations of fused salt contacting an alloy or other material, the condition leading to failure may be represented by penetration of the salt to contact the reducing substrate, because the salt and the substrate are often thermodynamically incompatible. Consequently, the best protection from fused salt corrosion is then the formation and retention of a dense, adherent protective oxide scale. Because of possible synergistic dissolution, a pure, one-phase protective oxide is preferred. Because of the special solubility dependence for Cr_2O_3 on oxygen activity, chromium serves as the best protective alloy component to resist attack by an acidic salt. In general, where such knowledge is available, a protective scale should be chosen, such that the minimum in its solubility matches the relevant salt condition. In corrosion testing, care should be given so that the salt and gas compositions and the relevant salt thickness are chosen to match the problem. Provision of an initial protective scale by preoxidation is also useful.

Corrosion by Molten Nitrates, Nitrites, and Fluorides, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 124–128

Corrosion by Molten Nitrates, Nitrites, and Fluorides

Introduction

MOLTEN SALTS, often called fused salts, are used in many engineering systems. They can cause corrosion by the solution of constituents of the container material, selective attack, pitting, electrochemical reactions, mass transport due to thermal gradients, reaction of constituents of the molten salt with the container material, reaction of impurities in the molten salt with the container material, and reaction of impurities in the molten salt with the alloy. Many hundreds of molten salt/metal corrosion studies have been documented, yet predictions of corrosion are difficult if not impossible.

The most prevalent molten salts in use are nitrates and halides. Other molten salts that have been extensively studied but are not widely used include carbonates, sulfates, hydroxides, and oxides.

Corrosion by Molten Nitrates, Nitrites, and Fluorides, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 124–128

Corrosion by Molten Nitrates, Nitrites, and Fluorides

Test Methods

A number of kinetic and thermodynamic studies of corrosion by molten salts have been carried out in capsule-type containers. These studies can determine the nature of the corroding species and the corrosion products under static isothermal conditions and do provide some much- needed information. However, to provide the information needed for an actual flowing system, corrosion studies must be conducted in thermal convection loops or forced convection loops, which will include the effects of thermal gradients, flow, chemistry changes, and surface area. These loops can also include electrochemical probes and gas monitors. An example of the types of information gained from thermal convection loops during an intensive study of the corrosion of various alloys by molten salts is given subsequently. A thermal convection loop is shown in Fig. 1.

Purification

Molten salts, whether used for experimental purposes or in actual systems, must be kept free of contaminants. Maintaining purity, which involves initial makeup, transfer, and operation, is specific for each type of molten salt. For example, even though the constituents of the molten fluoride salts used in the Oak Ridge molten salt reactor experiment were available in very pure grades, purification by a hydrogen/hydrogen fluoride (H_2/HF) gas purge for 20 h was necessary (Ref 1). For nitrates with a melting point of approximately 220 °C (430 °F), purging with argon flowing above and through the salt at 250 to 300 °C (480 to 570 °F) removes significant amounts of water vapor (Ref 2). Another purification method used for this same type of salt consisted of bubbling pure dry oxygen gas through the 350 °C (660 °F) melt for 2 h and then bubbling pure dry nitrogen for 30 min to remove the oxygen (Ref 3). All metals that contact the molten salt during purification must be carefully selected to avoid contamination from transfer tubes, thermocouple wells, the makeup vessel, and the container itself. This selection process may be an experiment in itself.

Corrosion by Molten Nitrates, Nitrites, and Fluorides

Nitrates/Nitrites

Nitrate mixtures have probably been studied and used more than any other molten salt group. This is perhaps because of the low operating temperatures possible (200 to 400 °C, or 390 to 750 °F). Steels of varying types are generally chosen to contain these systems, because, in general, the basicity of the melt prevents iron corrosion. Protection by passive films is less reliable, because oxide ion discharge may break down the passive film.

Electropolished iron spontaneously passivates in molten sodium nitrate/potassium nitrite ($NaNO_3$-KNO_2) in the temperature range of 230 to 310 °C (445 to 590 °F) at certain potentials (Ref 4). A magnetite (Fe_3O_4) film is formed, along with a reduction of nitrite or any trace of oxygen gas dissolved in the melt. At higher potentials, all reactions occur on the passivated iron. Above the passivation potentials, dissolution occurs, with ferric ion dissolving in the melt. At even higher potentials, nitrogen oxides are evolved, and nitrate ions dissolve in the nitrite melt. At higher currents, hematite (Fe_2O_3) is formed as a suspension, and NO_2 is detected. Carbon steel in molten sodium nitrate/potassium nitrate ($NaNO_3$-KNO_3) at temperatures ranging from 250 to 450 °C (480 to 840 °F) forms a passivating film consisting mainly of Fe_3O_4 (Ref 3).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Iron anodes in molten alkali nitrates and nitrites at temperatures ranging from 240 to 320 °C (465 to 610 °F) acquire a passive state in both melts. In nitrate melts, the protective Fe_3O_4 oxidizes to Fe_2O_3 and the gaseous products differ for each melt (Ref 5).

An interesting study was conducted on the corrosion characteristics of several eutectic molten salt mixtures on such materials as carbon steel, stainless steel, and Inconel in the temperature range of 250 to 400 °C (480 to 750 °F) in a nonflowing system (Ref 6). The salt mixtures and corrosion rates for carbon steel and stainless steel are given in Table 1. As expected, the corrosion rate was much higher for carbon steel than for stainless steel in the same mixture. Low corrosion rates were found for both steels in mixtures containing large amounts of alkaline nitrate. The nitrate ions had a passivating effect.

Table 1 Corrosion rates of iron-base alloys in eutectic molten salt mixtures

Salt mixture	Corrosion rate			
	Carbon steel		**Stainless steel**	
	μm/yr	**mils/yr**	**μm/yr**	**mils/yr**
$NaNO_3$-NaCl-Na_2SO_4 (86.3,8.4,5.3 mol%, respectively)	15	0.6	1	0.03
KNO_3-KCl (94.6 mol%, respectively)	23	0.9	7.5	0.3
LiCl-KCl (58.42 mol%, respectively)	63	2.5	20	0.8

Electrochemical studies showed high resistance to corrosion by Inconel. Again, the sulfate- containing mixture caused less corrosion because of the passivating property of the nitrate as well as the preferential adsorption of sulfate ions.

Surface analysis by Auger electron spectroscopy indicated varying thicknesses of iron oxide, nickel, and chromium layers. The Auger analysis showed that an annealed and air-cooled stainless steel specimen exposed to molten lithium chloride (LiCl)/potassium chloride (KCl) salt had corrosion to a depth five times greater than that of an unannealed stainless steel specimen. Chromium carbide precipitation developed during slow cooling and was responsible for the increased corrosion. The mechanism of corrosion of iron and steel by these molten eutectic salts can be described by the following reactions:

$$Fe \leftrightarrow Fe^{2+} + 2e^- \quad \text{(Eq 1)}$$

$$LiCl + H_2O \leftrightarrow LiOH + HCl \quad \text{(Eq 2)}$$

$$H^+e^- \leftrightarrow \tfrac{1}{2}H_2,\ H_2O + 2e^- \leftrightharpoons O^{2-} + H_2 \quad \text{(Eq 3)}$$

$$\tfrac{1}{2}O_2 + 2e^- \leftrightarrow O^{2-} \quad \text{(Eq 4)}$$

$$Fe^{3+} + e \leftrightarrow Fe^{2+} \quad \text{(Eq 5)}$$

$$Fe^{2+} + O^{2-} \leftrightarrow FeO \quad \text{(Eq 6)}$$

$$3FeO + O^{2-} \leftrightarrow Fe_3O_4 + 2e^- \quad \text{(Eq 7)}$$

$$2Fe_3O_4 + O^{2-} \leftrightarrow 3Fe_2O_3 + 2e^- \quad \text{(Eq 8)}$$

Carbon or chromium-molybdenum steels have been used in an actual flowing and operating system of KNO_3-NaO_2-NaO_3 (53, 40, and 7 mol%, respectively) at temperatures to 450 °C (840 °F) (Ref 7). For higher temperatures and longer times, nickel or austenitic stainless steels are used. Weld joints are still a problem in both cases.

Alloy 800 (UNS N08800) and types 304 (UNS S30400), 304L (UNS S30403), and 316 (UNS S31600) stainless steels were exposed to thermally convective $NaNO_3$-KNO_3 salt (draw salt) under argon at 375 to 600 °C (705 to 1110 °F) for more than 4500 h (Ref 2). The exposure resulted in the growth of thin oxide films on all alloys and the dissolution of chromium by the salt. The weight change data for the alloys indicated that the metal in the oxide film constituted most of the metal loss, that the corrosion rate, in general, increased with temperature, and that, although the greatest metal loss corresponded to a penetration rate of 25 μm/yr (1 mil/ yr), the rate was less than 13 μm/yr (0.5 mil/yr) in most cases. These latter rates are somewhat smaller than those reported for similar loops operated with the salt exposed to the atmosphere (Ref 8, 9) but are within a factor of 2 to 5. Spalling had a significant effect on metal loss at intermediate temperatures in the type 304L stainless steel loop.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Metallographic examinations showed no evidence of intergranular attack or of significant cold-leg deposits. Weight change data further confirmed the absence of thermal gradient mass transport processes in these draw salt systems.
Raising the maximum temperature of the type 316 stainless steel loop from 595 to 620 °C (1105 to 1150 °F) dramatically increased the corrosion rate (Ref 8, 9). Thus, 600 °C (1110 °F) may be the limiting temperature for use of such alloys in draw salt.

Fluorides

Because of the Oak Ridge molten salt reactor experiment, a large amount of work was done on corrosion by molten fluoride salts (Ref 1). Because these molten salts were to be used as heat- transfer media, temperature gradient mass transfer was very important. Very small amounts of corrosion can result in large deposits, given that the solubility of the corrosion product changes drastically in the temperature range in question. Many other variables can also cause this phenomenon. Thus, a corrosion rate in itself does not provide complete information about corrosion.
Because the products of oxidation of metals by fluoride melts are quite soluble in the corroding media, passivation is precluded, and the corrosion rate depends on other factors, including the thermodynamic driving force of the corrosion reactions. The design of a practicable system using molten fluoride salts, therefore, demands the selection of salt constituents, such as lithium fluoride (LiF), beryllium fluoride (BeF_2), uranium tetrafluoride (UF_4), and thorium fluoride (ThF_4), that are not appreciably reduced by available structural metals and alloys whose components (iron, nickel, and chromium) can be in near-thermodynamic equilibrium with the salt.
A continuing program of experimentation over many years has been devoted to defining the thermodynamic properties of many corrosion product species in molten LiF-BeF_2 solutions. Much of the data has been obtained by direct measurement of equilibrium pressures for such reactions as:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$H_2(g) + FeF_2(d) \leftrightarrow Fe(c) + 2HF(g)$ (Eq 9)

and

$2HF(g) + BeO(c) \leftrightarrow BeF_2(l) + H_2O(g)$ (Eq 10)

where g, c, and d represent gas, crystalline solid, and solute, respectively, using the molten fluoride (denoted l for liquid) as the reaction medium. All of these studies have been reviewed, and the combination of these data with those of other studies has yielded tabulated thermodynamic data for many species in molten LiF-BeF_2 (Table 2). From these data, one can assess the extent to which a uranium trifluoride (UF_3)-bearing melt will disproportionate according to the reaction:

$4UF_3(d) \leftrightarrow 3UF_4(d) + U(d)$ (Eq 11)

Table 2 Standard Gibbs free energies (ΔG^f) of formation for species in molten 2LiF-BeF_2.

Temperature range: 733–1000 K

Material[(a)]	$-\Delta G^f = c - dT$[(b)] where:		$-\Delta G^f$ at 1000 K, kcal/mol
	c	***d***	
LiF(l)	141.8	0.0166	125.2
BeF_2(l)	243.9	0.0300	106.9
UF_3(d)	338.0	0.0403	99.3
UF_4(d)	445.9	0.0579	97.0

ZrF_4(d)	453.0	0.0651	97.0
NiF_2(d)	146.9	0.0363	55.3
FeF_2(d)	154.7	0.0218	66.5
CrF_2(d)	171.8	0.0214	75.2
MoF_6(g)	370.9	0.0696	50.2

(a) The standard state for LiF and BeF_2 is the molten 2LiF-BeF_2 liquid. That for MoF_6(g) is the gas at 1 atm. That for all species with *d* is that hypothetical solution with the solute at unit mole fraction and with the activity coefficient it would have at infinite dilution.

(b) Formula gives $-\Delta G^f$ in kcal/mol for temperature (*T*) in K in the range 733–1000 K. Source: Ref 10

For the case in which the total uranium content of the salt is 0.9 mol%, as in the Oak Ridge Molten Salt Reactor Experiment, the activity of metallic uranium (referred to as the pure metal) is near 10^{-15} with 1% of the UF_4 converted to UF_3 and is near 2×10^{-10} with 20% of the UF_4 so converted (Ref 11). Operation of the reactor with a small fraction (usually 2%) of the uranium present as UF_3 is advantageous insofar as corrosion and the consequences of fission are concerned. Such operation with some UF_3 present should result in the formation of an extremely dilute (and experimentally undetectable) alloy of uranium with the surface of the container metal. Operation with 50% of the uranium as UF_3 would lead to much more concentrated (and highly deleterious) alloying and to formation of uranium carbides. All evidence to date demonstrates that operation with relatively little UF_3 is completely satisfactory.

The data gathered to date reveal clearly that in reactions with structural metals, M:

$2UF_4(d) + M(c) \leftrightarrow 2UF_3(d) + MF_2(d)$ (Eq 12)

chromium is much more readily attacked than iron, nickel, or molybdenum (Ref 11, 12).

Nickel-base alloys, more specifically, Hastelloy N (Ni-6.5Mo-6.9Cr-4.5Fe) and its modifications, are considered the most promising for use in molten salts and have received the most attention. Stainless steels, having more chromium than Hastelloy N, are more susceptible to corrosion by fluoride melts but can be considered for some applications.

Oxidation and selective attack may also result from impurities in the melt:

$M + NiF_2 \leftrightarrow MF_2 + Ni$ (Eq 13)

$M + 2HF \leftrightarrow MF_2 + H_2$ (Eq 14)

or oxide films on the metal:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$NiO + BeF_2 \leftrightarrow NiF_2 + BeO$ (Eq 15)

followed by reaction of nickel fluoride (NiF_2) with M.

The reactions given in Eq 13, 14, and 15 will proceed essentially to completion at all temperatures. Accordingly, such reactions can lead (if the system is poorly cleaned) to a rapid initial corrosion rate. However, these reactions do not give a sustained corrosive attack.

On the other hand, the reaction involving UF_4 (Eq 12) may have an equilibrium constant that is strongly temperature dependent; therefore, when the salt is forced to circulate through a temperature gradient, a possible mechanism exists for mass transfer and continued attack. Equation 12 is of significance mainly in the case of alloys containing relatively large amounts of chromium.

If nickel, iron, and molybdenum are assumed to form regular or ideal solid solutions with chromium (as is approximately true), and if the circulation rate is very rapid, the corrosion process for alloys in fluoride salts can be simply described. At high flow rates, uniform concentrations of UF_3 and chromium fluoride (CrF_2) are maintained throughout the fluid circuit. Under these conditions, there exists some temperature (intermediate between the maximum and minimum temperatures of the circuit) at which the initial chromium concentration of the structural metal is at equilibrium with the fused salt. This temperature, T_{BP}, is called the balance point.

Because the equilibrium constant for the chemical reaction with chromium increases with temperature, the chromium concentration in the alloy surface tends to decrease at temperatures higher than T_{BP} and tends to increase at temperatures lower than T_{BP}. At some point, the dissolution process will be controlled by the solid-state diffusion rate of chromium from the matrix to the surface of the alloy.

In some melts ($NaF-LiF-KF-UF_4$, for example), the equilibrium constant for Eq 12 with chromium changes sufficiently as a function of temperature to cause the formation of dendritic chromium crystals in the cold zone. For LiF- BeF_2-UF_4-type mixtures, the temperature dependence of the mass transfer reaction is small, and the equilibrium is satisfied at reactor temperature conditions without the formation of crystalline chromium. Thus, the rate of chromium removal from the salt stream by deposition at cold-fluid regions is controlled by the rate at which chromium diffuses into the cold-fluid wall; the chromium concentration gradient tends to be small, and the resulting corrosion is well within tolerable limits. A schematic of the temperature gradient mass transfer process is shown in Fig. 2.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

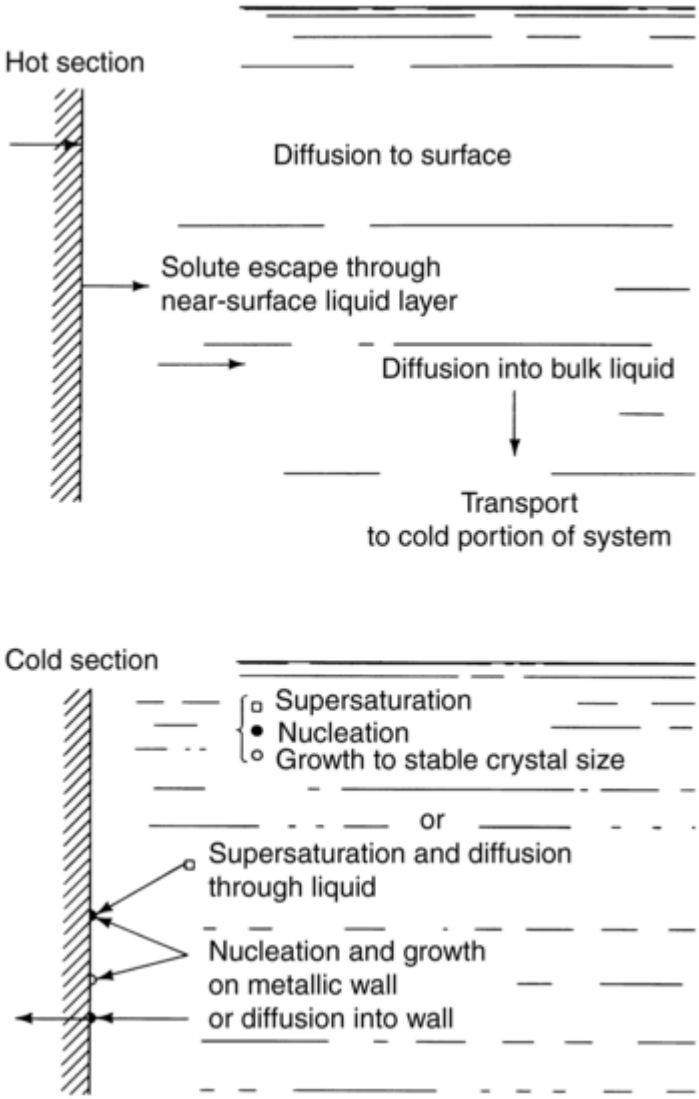

Fig. 2 Temperature-gradient mass transfer

Lithium fluoride/beryllium fluoride salts containing UF_4 or ThF_4 and tested in thermal convection loops showed temperature gradient mass transfer, as noted by weight losses in the hot leg and weight gains in the cold leg (Fig. 3). Hastelloy N was developed for use in molten fluorides and has proved to be quite compatible. The weight changes of corrosion specimens increased with temperature and time (Fig. 4, 5).

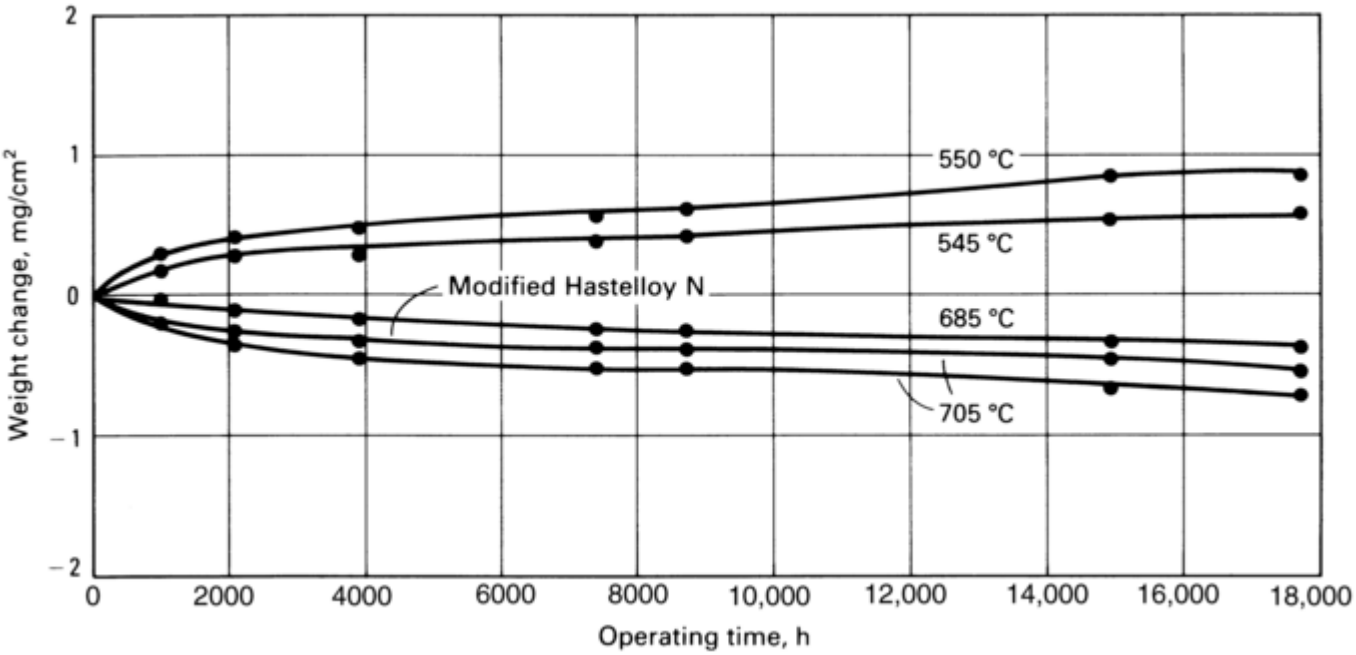

Fig. 5 Weight changes of Hastelloy N exposed to LiF-BeF_2-ThF_4-UF_4 (68, 20, 11.7, and 0.3 mol%, respectively) for various times

A type 304L stainless steel exposed to a fuel salt for 9.5 years (Fig. 6) in a type 304L stainless steel loop showed a maximum uniform corrosion rate of 22 μm/yr (0.86 mil/yr). Voids extended into the matrix for 250 μm (10 mils), and chromium depletion was found (Fig. 7) to extend to a depth of 28 μm (1.1 mil).

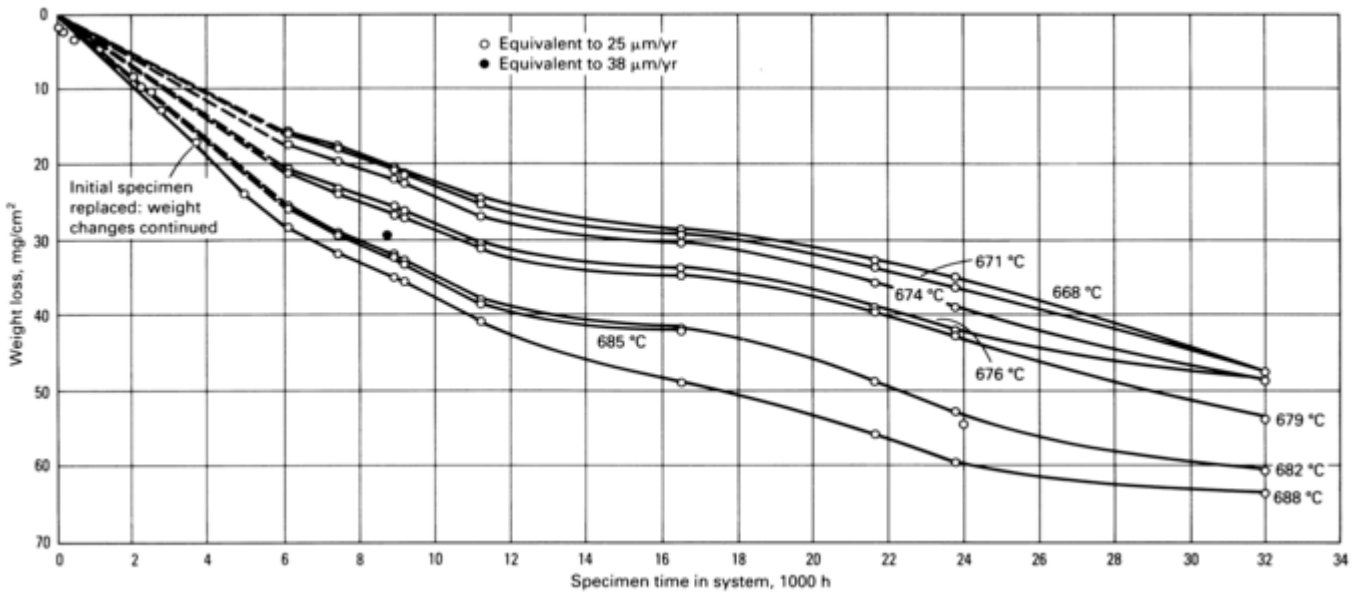

Fig. 6 Weight changes of type 304L stainless steel specimens exposed to LiF-BeF_2-ZrF_4-ThF_4-UF_4 (70, 23, 5, 1, and 1 mol%, respectively) for various times and temperatures

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

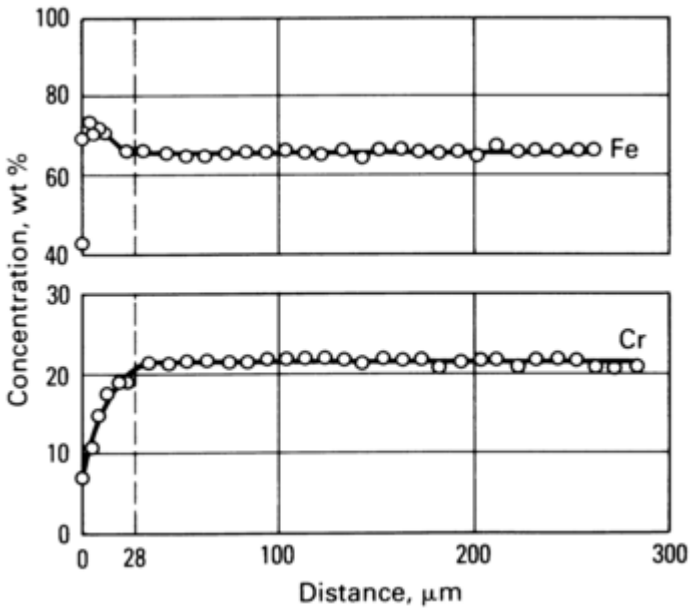

Fig. 7 Chromium and iron concentration gradient in a type 304L stainless steel specimen exposed to LiF-BeF_2-ZrF_4-ThF_4-UF_4 (70, 23, 5, 1, and 1 mol%, respectively) for 5700 h at 688 °C (1270 °F)

The corrosion resistance of a maraging steel (Fe-12Ni-5Cr-3Mo) at 662 °C (1224 °F) was better than that of type 304L stainless steel but was worse than that of a Hastelloy N under equivalent conditions. As shown in Table 3, the average uniform corrosion rate for the maraging steel was 14 μm/yr (0.55 mil/yr). Voids were seen in the microstructure of the specimens after 5700 h, and electron microprobe analysis disclosed a definite depletion of chromium and iron.

Table 3 Comparison of weight losses of alloys at approximately 663 °C (1225 °F) in similar flow fuel salts in a temperature gradient system

Alloy	Weight loss, mg/cm^2		Average corrosion	
	2490 h	**3730 h**	**μm/yr**	**mils/yr**
Maraging steel	3.0	4.8	14	0.55
Type 304 stainless steel	6.5	10.0	28	1.1
Hastelloy N	0.4	0.6	1.5	0.06

Type 316 stainless steel exposed to a fuel salt in a type 316 stainless steel loop showed a maximum uniform corrosion rate of 25 μm/yr (1 mil/ yr) for 4298 h. Mass transfer did occur in the system.

For selected nickel- and iron-base alloys, a direct correlation was found between corrosion resistance in molten fluoride salt and chromium and iron content of an alloy. The more chromium and iron in the alloy, the less the corrosion resistance.

Conclusions

In order to study the corrosion of molten salts or to determine what materials are compatible with a certain molten salt, the following questions must be answered. What is the purpose of the investigation? Is the researcher interested in basic studies, or is this work for information or work preliminary to assessment for a real system? For basic studies, capsule experiments or information from capsules is sufficient. Otherwise, flow systems or information from flow systems will be needed at some point to assess temperature gradient mass transfer. Salts to be used in either case need to be purified, and the same purity must be used in each experiment, unless this factor is a variable. Analytical facilities must be used for the chemistry of the salt, including impurity content and surface analysis of the metals in question.

Useful information can be obtained from capsule and flow experiments. It is hoped that the preceding information on specific systems provides an appreciation of the challenges involved and the materials information that can be obtained from various experiments.

Corrosion by Liquid Metals

P.F. Tortorelli and S.J. Pawel, Oak Ridge National Laboratory

Introduction

CONCERN ABOUT CORROSION of solids exposed to liquid metal environments, that is, liquid metal corrosion, dates from the earliest days of metals processing, when it became necessary to handle and contain molten metals. Corrosion considerations also arise when liquid metals are used in applications that exploit their chemical or physical properties.

Liquid metals serve as high-temperature reducing agents in the production of metals (such as the use of molten magnesium to produce titanium), and, because of their excellent heat- transfer properties, liquid metals have been used or considered as coolants in a variety of power- producing systems. Examples of such applications include molten sodium for liquid metal fast breeder reactors and central receiver solar stations as well as liquid lithium for fusion and space nuclear reactors.

In addition, tritium breeding in deuterium-tritium fusion reactors necessitates the exposure of lithium atoms to fusion neutrons. Breeding fluids of lithium or lead-lithium are attractive for this purpose. Molten lead or bismuth can serve as neutron multipliers to raise the tritium breeding yield if other types of lithium-containing breeding materials are used. More recently, in the United States, liquid mercury has been selected as the target for the spallation neutron source (SNS) at Oak Ridge National Laboratory. In the SNS scheme, 1 to 2 GeV protons will impinge on flowing mercury to generate an intense source of spallation neutrons. (Several other planned neutron sources worldwide may also use mercury for this application.) Liquid metals can also be used as two-phase working fluids in Rankine cycle power conversion devices (molten cesium or potassium) and in heat pipes (potassium, lithium, sodium, sodium-potassium). Because of their high thermal conductivities, sodium-potassium alloys, which can be any of a wide range of sodium-potassium combinations that are molten at or near room temperature, have also been used as static heat sinks in automotive and aircraft valves.

Whenever the handling of liquid metals is required, whether in specific uses as discussed previously or as melts during processing, a compatible containment material must be selected. At low temperatures, liquid metal corrosion is often insignificant, but in more demanding applications, corrosion considerations can be important in selecting the appropriate containment material and operating parameters. Thus, liquid metal corrosion studies in support of heat pipe technology and aircraft, space, and fast breeder reactor programs date back many years and, more recently, are being conducted worldwide as part of the fusion energy and spallation neutron programs. In this article, the principal corrosion reactions and important parameters that control such processes are briefly reviewed for materials (principally metals) exposed to liquid metal environments. Only corrosion phenomena are covered, and the discussion is limited to corrosion under single-phase (liquid) conditions.

Corrosion Reactions in Liquid Metal Environments

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Liquid metal corrosion can manifest itself in various ways. In the most general sense, the following categories can be used to classify relevant corrosion phenomena:

- Dissolution
- Impurity and interstitial reactions
- Alloying
- Compound reduction

Definitions and descriptions of these types of reactions are given subsequently. However, it is important to note that this classification is somewhat arbitrary, and, as will become clear during the following discussion, the individual categories are not necessarily independent of one another.
All of these reactions require the wetting of the solid by the liquid metal. This can be inherently problematic in certain systems or in cases when a solid that would normally be wet by the liquid metal has a surface film that prevents such wetting.

Dissolution

The simplest corrosion reaction that can occur in a liquid metal environment is direct dissolution. Direct dissolution is the release of atoms of the containment material into the melt in the absence of any impurity effects. Such a reaction is a simple solution process and therefore is governed by the elemental solubilities in the liquid metal and the kinetics of the rate-controlling step of the dissolution reaction. The net rate, *J*, at which an elemental species enters solution, can be described as:

$$J = k(C_0 - C) \qquad \text{(Eq 1)}$$

where J is the rate of mass loss of an element due to dissolution, C_0 is the solubility of that element in the liquid metal, C is its actual concentration in the bulk of the liquid, and k is the effective solution rate constant. Each constituent of the condensed phase is separately governed by Eq 1. Because J is proportional to $(C_0 - C)$, high solubilities do not necessarily translate into high dissolution rates, because the driving force for dissolution depends on the actual concentration of the solute in the liquid metal as well as C_0. This forms the crucial differentiation between isothermal liquid metal systems and nonisothermal dynamic ones regarding the stability of a material with respect to dissolution and mass transfer (see the following discusion).
Under isothermal conditions, the rate of this dissolution reaction would decrease with time as C increases. After a period of time, the actual elemental concentration becomes equal to the solubility, and the dissolution rate is then 0. Therefore, in view of Eq 1, corrosion by the direct dissolution process can be minimized by selecting a containment material whose elements have low solubilities in the liquid metal of interest and/or by saturating the melt before actual exposure. However, if the dissolution kinetics are relatively slow, that is, for low values of k, corrosion may be acceptable for short-term exposures. The functional dependence and magnitude of the solution rate constant, k, depend on the rate-controlling step, which, in the simplest cases, can be a transport across the liquid-phase boundary layer, diffusion in the solid, or a reaction at the phase boundary. Measurements of mass changes as a function of time for a fixed $C_0 - C$ (see subsequent discussion) yield the kinetic information necessary for determination of the rate-controlling mechanism.
Corrosion resulting from dissolution in a nonisothermal liquid metal system is more complicated than the isothermal case. Both solvation and solute deposition are normally occurring, and there is essentially a time-invariant $(C_0 - C)$ driving force for dissolution at a given temperature. This is because, after a short transient period, C is constant as the flow of the liquid metal quickly establishes a systemwide steady state. Specifically, the value of C is set by the dissolution and deposition rates, the temperature profile, and the functional dependence of C_0 on temperature. As such, C does not vary around a flowing liquid metal system and, at steady state, is constant with time. Unlike the isothermal case, J is only dependent on time through its dependence on k (Eq 1).
The flux description illustrated by Eq 1 applies equally well to deposition when $C > C_0$. Therefore, at temperatures where the solubility (C_0) is greater than the bulk concentration (C), dissolution of an element into the liquid metal will occur, but at lower temperatures in the circuit where $C_0 < C$, a particular element will tend to come out of solution and be deposited on the containment material (or remain as suspended particles). A schematic of such a mass-transfer process is shown in Fig. 1. Such mass-transfer processes under nonisothermal conditions can be of prime importance when, in the absence of dissimilar-metal effects (see subsequent

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

discussion), forced circulation (pumping) of liquid metals used as heat-transfer media exacerbates the transport of materials from hotter to cooler parts of the liquid metal circuit.

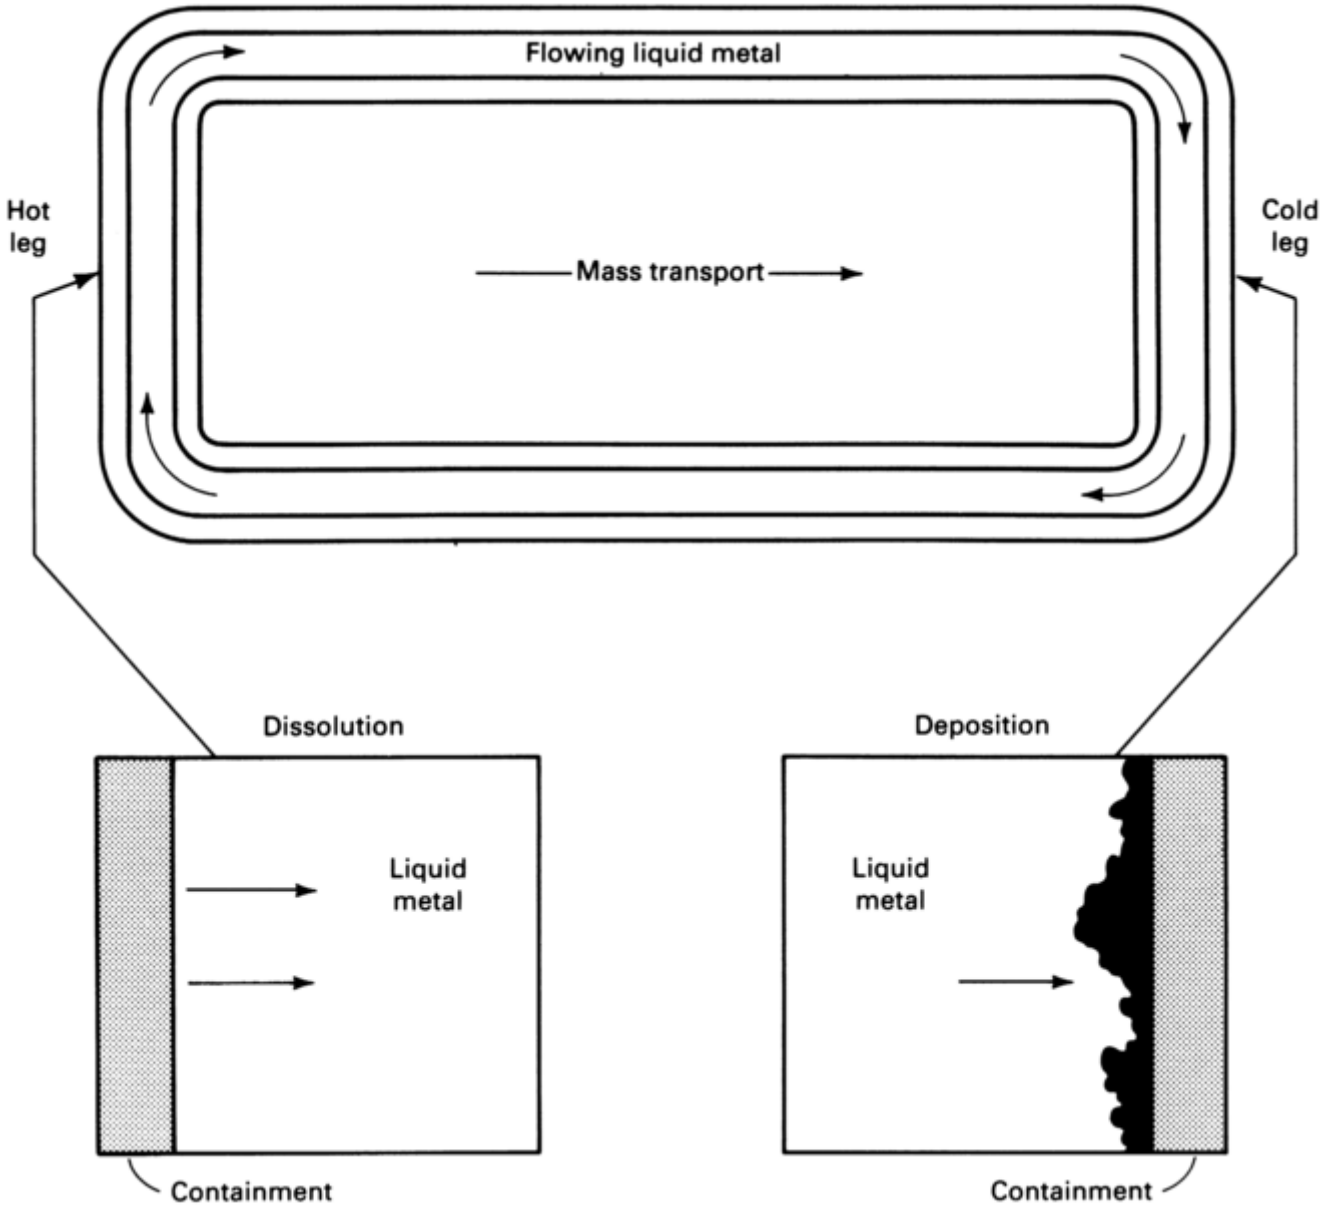

Fig. 1 Schematic of thermal gradient mass transfer in a liquid metal circuit. Source: Ref 1

If the dissolution and deposition behaviors are controlled by the respective forms of Eq 1, measurements of mass change as a function of loop position (x) should yield data resembling the schematic depiction shown in Fig. 2. Using the appropriate analysis methods and simplifying assumptions, measurements of the mass or, for alloys/compounds, composition change as a function of loop position (and, therefore temperature) can provide further data regarding kinetics and the rate-controlling mechanism of mass transport associated with a given material/liquid metal system. This can be computed for any element in a closed tubular liquid metal system where deposition occurs over an area A_p and dissolution over A_s, using the following equation:

$$G = \int A_s J_s \cdot 2\pi r dx - \int A_p J_p \cdot 2\pi r dx \quad \text{(Eq 2)}$$

where G is the net increase of an element in the circuit per unit time, r is the inside tube radius, J_s is as defined in Eq 1 for dissolution, and J_p is of the same functional form but applies to deposition of an element from the liquid metal with a rate constant k_p. Typically, $G \approx 0$ at steady state, so, using Eq 1 with Eq 2:

$$\int A_s k_s (C_0 - C) \cdot 2\pi r dx = \int A_p k_p (C_0 - C) \cdot 2\pi r dx \quad \text{(Eq 3)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

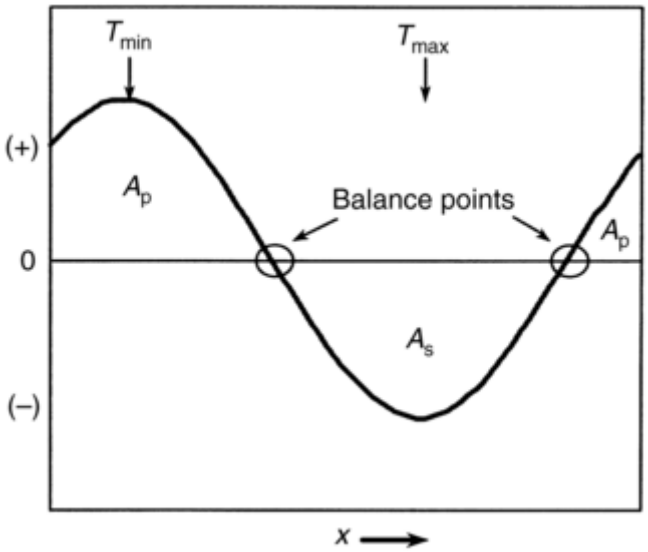

Fig. 2 Schematic depiction of idealized profile of mass change per unit surface area for a liquid metal circuit. T_{max} and T_{min} are maximum and minimum loop temperatures, respectively; x is loop position; A_p is deposition area; and A_s is dissolution area.

The respective areas of dissolution and deposition, A_s and A_p, are delimited by two balance points, which are the values of x at which $J = 0$ (Fig. 2). These balance points are experimentally accessible using an appropriately configured nonisothermal liquid metal loop and are important in determining the relative areas of dissolution and deposition and in modeling the relevant mass-transfer processes. Assuming a linear dependence of C_0 over the relatively small temperature range of most loop experiments, the mass balance represented by Eq 3 indicates that the ratio of the area measurements for dissolution and deposition is inversely proportional to the ratio of their respective rate constants:

$$A_s/A_p \propto k_p/k_s \qquad \text{(Eq 4)}$$

Thus, determination of mass change or surface composition profiles around a loop yields insight into the kinetics of the solution process relative to deposition for a given material/liquid metal system. Another use of mass or compositional profiles is to determine estimates of the activation energy for dissolution using reasonable assumptions about the temperature dependence of the solubility. Because the respective activation energies characteristic of the most important rate-controlling processes (surface reaction, liquid-phase diffusion through boundary layer, and solid-state diffusion) are significantly different from each other, such analyses can yield mechanistic information regarding dissolution processes.

Although the mass-transfer analysis described previously is somewhat simplified, experimental measurements of mass or composition changes around a nonisothermal liquid metal loop often yield results that can be described in this way. Figure 3 is an example of an experimentally determined mass-change profile consistent with the schematic one shown in Fig. 2. Sometimes, however, more elaborate analyses based on Eq 1 are required to describe nonisothermal mass transfer precisely. Such treatments must take into account the differences in k around the circuit as well as the possibility that the rate constant for dissolution (or deposition) may not vary monotonically with temperature because of changes in the rate-controlling step within the temperature range of dissolution (deposition). The presence of more than one elemental species in the containment material further complicates the analysis; the transfer of each element typically has to be handled with its own set of thermodynamic and kinetic parameters. Although a thermal gradient increases the amount of dissolution, plugging of coolant pipes by nonuniform deposition of dissolved species in cold zones often represents a more serious design problem than metal loss from dissolution (which sometimes may be handled by corrosion allowances). The most direct way to control deposition, however, is usually to minimize dissolution in the hot zone by use of more corrosion-resistant materials and/or inhibition techniques.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

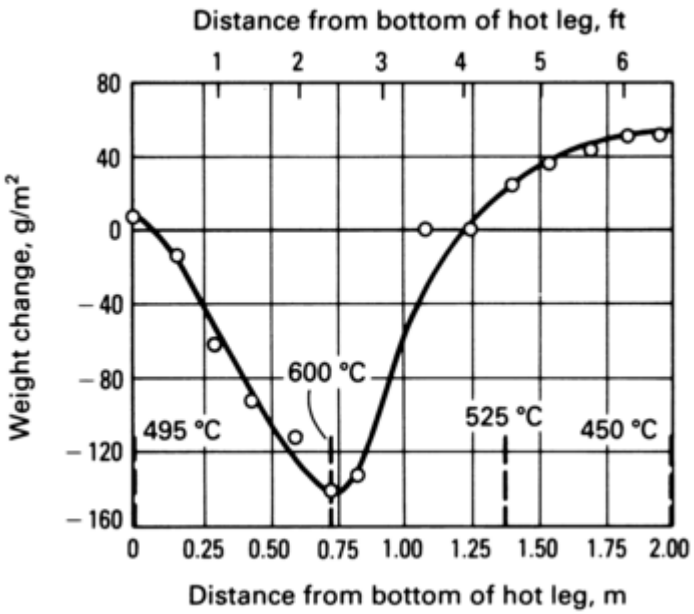

Fig. 3 Mass transfer as characterized by the weight changes of type 316 stainless steel coupons exposed around a nonisothermal liquid lithium type 316 stainless steel circuit for 9000 h. Source: Ref 2

Mass transfer may occur even under isothermal conditions if an activity gradient based on composition differences of solids in contact with the same liquid metal exists in the system. Under the appropriate conditions, dissolution and deposition will act to equilibrate the activities of the various elements in contact with the liquid metal. Normally, such a process is chiefly limited to interstitial element transfer between dissimilar metals, but transport of substitutional elements can also occur. Elimination (or avoidance) of concentration (activity) gradients across a liquid metal system is the obvious and, most often, the simplest solution to any problems arising from this type of mass-transport process.

Under certain conditions, dissolution of metallic alloys by liquid metals can lead to irregular attack (Fig. 4). Although such localized corrosive attack can often be linked to impurity effects (see subsequent discussion) and/or compositional inhomogeneities in the solid, destabilization of a planar surface can occur when there is preferential dissolution of one or more elements of an alloy exposed to a liquid metal. Indeed, the type of attack illustrated in Fig. 4 is thought to be caused by the preferential dissolution of nickel from an Fe-17Cr-11Ni (wt%) alloy (type 316 stainless steel). As such, this process resembles the dealloying phenomenon sometimes observed in aqueous environments. This type of attack has often been observed for austenitic stainless steels in molten lithium, sodium, lead, and other liquid metals when preferential dissolution of nickel occurs. In contrast, an Fe-12Cr- 1MoVW steel did not experience preferential loss of any of its elements and corroded uniformly (Fig. 5) when exposed under the same environment conditions that led to the irregular attack shown in Fig. 4. In cases where preferential dissolution and nonuniform corrosion occur (Fig. 4), the altered near-surface zone has diminished load-bearing capacity, and the section thickness of sound material remaining will be less than what would be calculated based on converting measured mass losses to a surface recession distance.

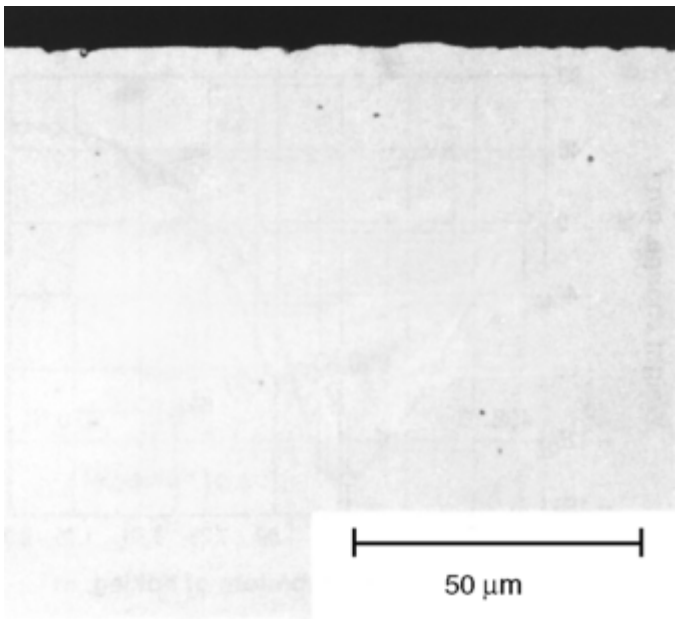

Fig. 5 Polished cross section of Fe-12Cr-1MoVW steel exposed to thermally convective Pb-17at.%Li at 500 °C (930 °F) for 2000 h. Source: Ref 3

Apart from possible effects on morphological development, the changes in surface composition due to preferential elemental dissolution from an alloy into a liquid metal are important in themselves. For example, in austenitic stainless steels, the preferential dissolution of nickel causes a phase transformation to a ferritic structure in the surface region. In many cases, an equilibrium surface composition is achieved, such that the net elemental fluxes into the liquid metal are in the same proportion as the starting concentrations of these elements in the alloy. Such a phenomenon has been rigorously treated and characterized for sodium-steel systems.

Impurity and Interstitial Reactions

For this discussion, impurity or interstitial reactions refer to the interaction of light elements present in the containment material (interstitials) or the liquid metal (impurities). Examples of such reactions include the decarburization of steel in lithium and the oxidation of steel in sodium or lead of high oxygen activity. In many cases, when the principal elements of the containment material have low solubilities in liquid metals (for

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

example, refractory metals in sodium, lithium, and lead), reactions involving light elements such as oxygen, carbon, and nitrogen dominate the corrosion process. Impurity or interstitial reactions can be generally classified into two types: corrosion product formation and elemental transfer of such species.

Corrosion Product Formation. The general form of a corrosion product reaction is:

$$xL + yM + zI = L_xM_yI_z \quad \text{(Eq 5)}$$

where L is the chemical symbol for a liquid metal atom, M is one species of the containment material, and I represents an interstitial or impurity atom in the solid or liquid (x, y, $z > 0$). The $L_xM_yI_z$ corrosion product that forms by such a reaction may be soluble or insoluble in the liquid metal. If it is soluble, the I species would cause greater dissolution weight losses and would result in an apparently higher solubility of M in L (Eq 1). This is a frequent cause of erroneous solubility measurements and is a good illustration of how dissolution and impurity reactions can be interrelated. Furthermore, if a soluble corrosion product forms at selected sites on the surface of the solid, localized attack will result. Under conditions in which a corrosion product is insoluble, a partial or complete surface layer will form. This can either have a detrimental effect on corrosion resistance or, if the product is continuous and protective (see subsequent discussion), limit further reaction. However, formation of a surface product does not necessarily mean that it can be observed. The product may be unstable outside the liquid metal environment or may dissolve in the cleaning agent used to remove the solidified residue of liquid metal from the exposed containment material.

A good example of the importance of impurity or interstitial reactions that form corrosion products can be found in the sodium-steel-oxygen system. It is thought that the reaction:

$$3Na_2O(l) + Fe(s) = (Na_2O)_2 \cdot FeO(s) + 2Na(l) \quad \text{(Eq 6)}$$

increases the apparent solubility of iron in sodium at higher oxygen activities, while the interaction of oxygen, sodium, and chromium can lead to the formation of surface corrosion products, for example:

$$2Na_2O(l) + Cr(s) = NaCrO_2(s) + 3Na(l) \quad \text{(Eq 7)}$$

This second type of reaction (Eq 7) is of primary importance in the corrosion of chromium-containing steels by liquid sodium. It can be controlled by reducing the oxygen concentration of the sodium to less than approximately 3 ppm and/or by modifying the composition of the alloy through reduction of the chromium concentration of the steel.

Such corrosion product reactions can also be observed in lithium-steel systems, in which nitrogen can increase the corrosiveness of the liquid metal environment. In particular, the reaction:

$$5Li_3N(\text{in } l) + Cr(s) = Li_9CrN_5(s) + 6Li(l) \quad \text{(Eq 8)}$$

or an equivalent one with iron, can play an important role in corrosion by liquid lithium. The Li_9CrN_5 corrosion product tends to be localized at the grain boundaries of exposed steels. Such reaction products can probably also be formed when there is sufficient nitrogen in the solid; experimental observations have indicated that nitrogen can increase corrosion by lithium, whether it is in the liquid metal or in the steel.

Corrosion product formation is also important when certain refractory metals are exposed to molten lithium. Despite their low solubilities in lithium, niobium and tantalum can be severely attacked when exposed to lithium if the oxygen activities of these metals are not low. At temperatures below approximately 900 °C (1650 °F), the lithium reacts rapidly with the oxygen and niobium or tantalum (and their oxides and suboxides) to form a ternary oxide corrosion product. Such reactions result in localized penetration along grain boundaries and selected crystallographic planes. This form of corrosive attack can be eliminated, however, by minimizing the oxygen concentration of these refractory metals (Fig. 6) and by using alloying additions that form oxides that do not react with the lithium and that minimize the amount of uncombined oxygen in the material (1 to 2 at. % Zr in niobium and hafnium in tantalum).

www.iran-mavad.com

Source: Ref 4

A final example of a corrosion product reaction that can occur in a liquid metal environment is the oxidation of a solid metal or alloy exposed to molten lead somewhat enriched in oxygen. In some cases, this reaction may actually be beneficial by providing a protective barrier against the highly aggressive lead. This barrier can act in a manner analogous to the behavior observed for the protective oxides formed in high-temperature oxidizing gases. However, this surface product will form and then heal only when the oxygen activity of the melt is maintained at a high level or when oxide formers, such as aluminum or silicon, have been added to the containment alloy to promote protection by the formation of alumina- or silica-containing surface products. Furthermore, reactions of additives to the melt with nitrogen in steel to form nitride surface films are thought to be the cause of reduced corrosion in lead and lead-bismuth systems.

Elemental Transfer of Impurities and Interstitials. The second general type of impurity or interstitial reaction is that of elemental transfer. In contrast to what is defined as corrosion product formation, elemental transfer manifests itself as a net transfer of interstitials or impurities to, from, or across a liquid metal. Although compounds may form or dissolve as a result of such transfer, the liquid metal atoms do not participate in the formation of stable products by reaction with the containment material. For example, because lithium is such a

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

strong thermodynamic sink for oxygen, exposure of oxygen-containing metals and alloys to this liquid often results in the transfer of oxygen to the melt. Indeed, for oxygen-contaminated niobium and tantalum, high-temperature lithium exposures result in the rapid movement of oxygen into the lithium.

The thermodynamic driving force for light element transfer between solid and liquid metals is normally expressed in terms of a distribution (or partitioning) coefficient. This distribution coefficient is the equilibrium ratio of the concentration of an element, such as oxygen, nitrogen, carbon, or hydrogen, in the solid metal or alloy to that in the liquid. Such coefficients can be calculated from knowledge or estimates of free energies of formation and activities based on equilibrium between a species in the solid and liquid. An example of this approach is its application to decarburization/carburization phenomena in a liquid metal environment. Carbon transfer to or from the liquid metal can cause decarburization of iron-chromium-molybdenum steels, particularly lower-chromium steels, and carburization of refractory metals and higher-chromium alloys. There have been many studies of such reactions for sodium-steel systems. Although less work has been done in the area of lithium-steel carbon transfer, the same considerations apply. Specifically, the equilibrium partitioning of the carbon between the iron-chromium-molybdenum steel and the lithium can be described as:

$$\frac{C_C(s)}{C_C(Li)} = (a_{Cr})^{x/y}\left[\frac{C_C^{\circ}(s)}{C_C^{\circ}(Li)}\right] e^{f} \cdot e^{g} \qquad \text{(Eq 9)}$$

where $C_c(s)$, $C_c(Li)$ is the concentration of carbon in the steel and lithium, respectively; a_{Cr} is the chromium activity of the steel; $C°_C(s)$, $C°_C(Li)$ represent the equilibrium solubilities of carbon in the steel and lithium, respectively; *x*, *y* is the stoichiometry of the chromium carbide; and:

$$f = +\Delta F_{(1/2)Li_2C_2} / RT$$

$$g = -\Delta F_{(1/y)Cr_xC_y} / RT$$

where ΔF represents the free energies of formation of the indicated compounds, *R* is the gas constant, and *T* is the absolute temperature.

Equation 9 indicates that in order to decrease the tendency for decarburization of an alloy— that is, to increase the partitioning coefficient, $C_c(s)/C_c(Li)$—the chromium activity of the alloy must be increased or a more thermodynamically stable carbide dispersion must be developed (by alloy manipulation or thermal treatment). Experiments in lithium and sodium have shown that these factors have the desired effect. Tempering of iron-chromium-molybdenum steels to yield more stable starting carbides can significantly reduce decarburization by these two liquid metals. With very unstable microstructures, the steel can be severely corroded because of rapid lithium attack of the existing carbides. Furthermore, alloying additions, such as niobium, form very stable carbides and can dramatically reduce decarburization. In addition, as shown by Eq 9, increasing the chromium level of a steel effectively decreases the tendency for carbon loss. With higher-chromium steels, for example, austenitic stainless steels, carburization can then become a problem. If two dissimilar steels of significantly differing chromium activities and/or microstructures are exposed to the same liquid metal, the melt can act as a conduit for the relatively rapid redistribution of carbon between the two solids. Similar considerations would apply for any light element transfer across a liquid metal in contact with dissimilar materials; this can be further complicated by concentration (activity) gradient mass transfer of substitutional elements, as discussed previously.

Alloying

Reactions between atoms of the liquid metal and those of the constituents of the containment material may lead to the formation of a stable product on the solid without the participation of impurity or interstitial elements:

$$xM + yL = M_xL_y \qquad \text{(Eq 10)}$$

This is not a common form of liquid metal corrosion, particularly with the molten alkali metals, but it can lead to detrimental consequences if it is not understood or anticipated. Alloying reactions, however, can be used to inhibit corrosion by adding an element to the liquid metal to form a corrosion-resistant layer by reaction of this species with the contaminant material. An example is the addition of aluminum to a lithium melt contained by steel. A more dissolution-resistant aluminide surface layer forms, and corrosion is reduced.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Compound Reduction

Attack of ceramics exposed to liquid metals can occur because of reduction of the solid by the melt. In very aggressive situations, such as when most oxides are exposed to molten lithium, the effective result of such exposure is the loss of structural integrity by reduction-induced removal of the nonmetallic element from the solid. The tendency for reaction under such conditions can be qualitatively evaluated by consideration of the free energy of formation of the solid oxide relative to the oxygen/oxide stability in the liquid metal. Similar considerations apply to the evaluation of potential reactions between other nonmetallic compounds (nitrides, carbides, and so on) and liquid metals.

Considerations in Materials Selection

The previously mentioned types of corrosion reactions must be considered in materials selection for liquid metal containment. In many cases, particularly at low temperature or with less aggressive liquids (such as molten steel), liquid metal corrosion is not an important factor, and many materials, both metals and ceramics, would suffice. Under more severe conditions, however, an understanding of the various types of liquid metal corrosion is necessary to select or develop a compatible containment material. For example, for applications in high-temperature molten lithium, most oxides would be unstable with respect to this liquid metal, low-chromium steels would decarburize, and alloys containing large amounts of nickel or manganese would suffer extensive preferential dissolution and irregular attack. Materials selection would then be limited to higher-chromium ferritic/martensitic steels or high-purity refractory metals and alloys.

A general summary of the types of the most common corrosion reactions and guidelines for materials selection and/or development is given in Table 1, which also includes typical examples for each category. Because two or more concurrent corrosion reactions are possible, and because consideration of all of the applicable materials consequences may lead to opposite strategies, materials selection for liquid metal environments can become quite complex and may require optimization of several factors rather than minimization of any particular one. In addition, an assessment of the suitability of a given material for liquid metal service must be based on the knowledge of its total corrosion response. As in many corrosive environments, a simple numerical rate is not an accurate measurement of the susceptibility of a material when reaction with the liquid metal results in more than one of the modes of attack shown in Fig. 7 and discussed previously. Under such circumstances, a

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

measurement reflecting total corrosion damage is much more appropriate for judging the ability of a material to resist corrosion by a particular liquid metal.

Table 1 Guidelines for materials selection and/or alloy development based on liquid metal corrosion reactions

Corrosion reaction	Guidelines	Example
Direct dissolution	Lower activity of key elements.	Reduce nickel for lithium, lead, or sodium systems.
Corrosion product formation	Lower activity of reacting elements.	Reduce chromium and nitrogen in lithium systems.
	In case of protective oxide, add elements to promote formation.	Add aluminum or silicon to steel exposed to lead.
Elemental transfer	Increase (or add) elements to decrease transfer tendency.	Increase chromium content in steels exposed to sodium or lithium.
	Minimize element being transferred.	Reduce oxygen content in metals exposed to lithium.
Alloying	Avoid systems that form stable compounds.	Do not expose nickel to molten aluminum.
	Promote formation of corrosion-resistant layers by alloying.	Add aluminum to lithium to form surface aluminides.
Compound reduction	Eliminate solids that can be reduced by liquid metal.	Avoid bulk oxide-lithium couples.

Introduction to Corrosion for Constructive Purposes

Małgorzata Ziomek-Moroz, Albany Research Center, U.S. Department of Energy

Introduction

PRINCIPLES OF METALLIC CORROSION play a fundamental role in developing industrial processes that employ corrosion for constructive purposes. These processes range from the spontaneous processes in galvanic cells, such as batteries and fuel cells, that convert energy for external applications, to electrolytic cell processes, such as electropolishing, electrochemical machining, and electrochemical refining, that consume energy from external sources. Each of these processes consists of an electrochemical cell with an anode, cathode, and conductive medium or electrolyte. Each of these processes involves electrochemical oxidation and reduction reactions.

The purpose of this introduction is to show the similarities that exist between galvanic and electrolytic cells, while noting that the net or overall reaction for each type of cell leads us to label the electrodes and processes differently. For this purpose, a relatively simple electrochemical system has been chosen, and the changes in kinetics that occur with differentially small potential changes around the equilibrium electrode potentials of two reversible electrodes, Cu and Ag, are examined. In doing this, it should be clear that while differences in the kinetics of the spontaneous galvanic cell and the electrolytic cell can themselves be made differentially small, the industrial processes that are born out of these processes are quite different.

The two reversible electrode systems chosen were a copper electrode immersed in a copper sulfate solution at unit activity of Cu^{2+} and a silver electrode immersed in a silver nitrate solution at unit activity of Ag^{+}. The choice of these electrodes (or half-cells) avoids the complexity that arises with many electrodes of commercial interest where oxides or other stable corrosion products form on the surface. It also avoids the complexity that arises with reactions involving chemical species from different redox systems, such as zinc in an aqueous solution where the reduction reaction can be the evolution of hydrogen or the reduction of dissolved oxygen. The solutions are connected by a porous barrier and are at an ambient temperature of 25 °C (77 °F).

The electrochemical reactions at each electrode are (for copper electrode):

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$Cu^{2+} + 2e^- \underset{I_{a,Cu}}{\overset{I_{c,Cu}}{\rightleftharpoons}} Cu \qquad \text{(Eq 1)}$$

(for silver electrode):

$$Ag^+ + e^- \underset{I_{a,Ag}}{\overset{I_{c,Ag}}{\rightleftharpoons}} Ag \qquad \text{(Eq 2)}$$

where I_a and I_c are now just labels indicating that some charges are moving.

Reversible Cell Potential

At equilibrium, the following conditions exist at each electrode:

copper electrode $I_{a,Cu} = I_{c,Cu} = I_{o,Cu}$

silver electrode $I_{a,Ag} = I_{c,Ag} = I_{o,Ag}$

where I_0 is the exchange current for the copper and silver electrochemical reactions, respectively. There is a characteristic electrostatic difference at these electrodes called the *electrode potential difference* that can be measured with respect to the standard hydrogen electrode (SHE).

$$E^\circ_{Cu^{2+}/Cu} = 0.340\ V_{SHE}$$

$$E^\circ_{Ag^+/Ag} = 0.799\ V_{SHE}$$

At equilibrium there is a zero net reaction or current at each electrode.

When the electrodes are connected through a high-impedance device such as an electrometer and the electrolytes are connected via a porous barrier to form the electrochemical cell:

$$Cu \,|\, Cu^{2+}\left(aq,\ a_{Cu(II)} = 1,\ 25^\circ C\right) |$$

$$| \, Ag^+\left(aq,\ a_{Ag(I)} = 1,\ 25^\circ C\right) | \, Ag$$

the net current in the external circuit is zero; that is, the cell current $I_{cell} = 0$. The copper electrode is more active or negative to the more noble or positive silver electrode (Fig. 1). The reversible cell potential ($e_{cell,rev}$) is determined by the electrode potentials:

$$e_{cell,rev} = E^\circ_{Ag^+/Ag} - E^\circ_{Cu^{2+}/Cu}$$

$$= 0.799\ V_{SHE} - 0.340\ V_{SHE} = 0.459\ V$$

This potential could be measured with a high- impedance electrometer between the two electrodes (Fig. 2). The cell is reversible because the electrode potentials remain at their equilibrium potential when perturbed by incrementally small shifts in the cell reactions to produce reversibly small net reactions in one direction or the other. It should be noted that unit activity is not a necessary condition of this example. The reversible electrode potential, E_{rev}, at any other activity of the metal ion, a, is given by the Nernst equation:

$$E_{rev} = E^o - (2.303RT/nF) \log a \qquad \text{(Eq 3)}$$

where R is gas constant; F is the Faraday constant, 96,500 C/gram-equivalent; T is the absolute temperature, K; and n is the number of electrons involved in the electrode reaction.

Introduction to Corrosion for Constructive Purposes

Małgorzata Ziomek-Moroz, Albany Research Center, U.S. Department of Energy

Irreversible Cell Potential

An electrode becomes irreversible when the electrode reactions are displaced from equilibrium and the electrode potential is no longer at the equilibrium potential. This happens in spontaneous processes when the cell is converting energy for external applications. It happens in electrolytic cells when energy from an external source is doing work on the electrodes. It happens in corrosion because the anodic and cathodic processes are coupled (or shorted) at a mixed or corrosion potential defining the kinetics of the corrosion reaction.

Galvanic Cells. The example of the copper and silver electrodes functions as a galvanic cell when there is a net flow of electrons through an external circuit from the copper electrode to the silver electrode. When this occurs the following conditions exist at the electrodes:

$$\text{copper electrode} \quad I_{a,Cu} > I_{c,Cu}$$

$$\text{silver electrode} \quad I_{a,Ag} < I_{c,Ag}$$

and the electrode potentials, *E*, shift to values between those of the initial equilbrium values and are no longer reversible:

$$E_{Cu^{2+}/Cu} > E^{\circ}_{Cu^{2+}/Cu}$$

$$E_{Ag^{+}/Ag} < E^{\circ}_{Ag^{+}/Ag}$$

The shift in potential, known as electrode polarization, is measured by the overpotential, η, which is the value by which the electrode potential has shifted from its equilibrium or reversible value (Fig. 3):

$$\eta = E - E_{rev}$$

The effect of overpotential on the rate of the electrode reactions controlled by activation polarization is given by the Butler-Volmer equation. This corresponds to the straight lines in Fig. 1 and 4 that describe the anode and cathode reaction rates as a function of potential (or overpotential).

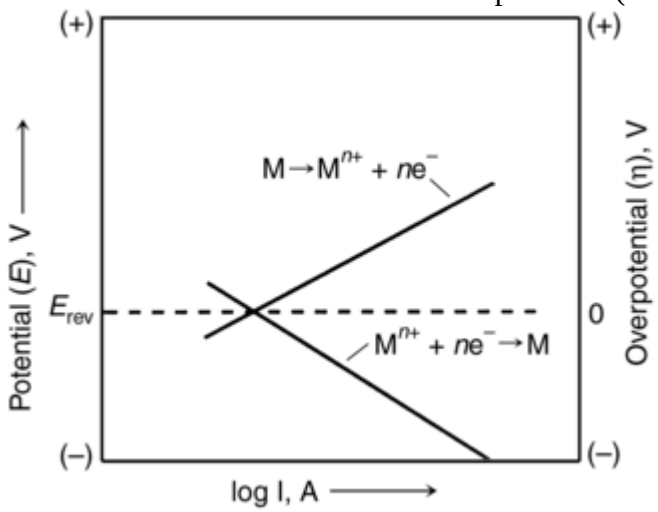

Fig. 3 Potential versus log current plot relating overpotential to potential scale for anodic and cathodic reactions. M is a metal, and *n* is a positive integer.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

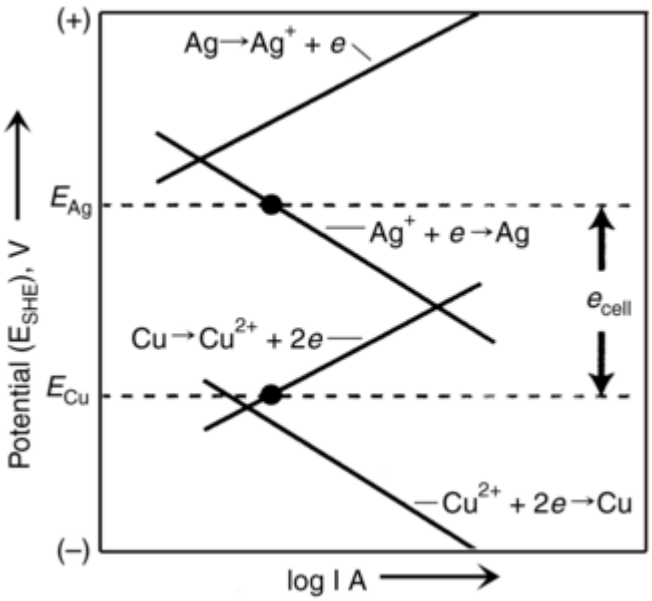

Fig. 4 Potential versus log current plot for galvanic cell with copper and silver electrodes

The set of lines in Fig. 4 allows us to conveniently describe anodic and cathodic reaction rates at the copper and silver electrodes as a function of potential. The shift in electrode potentials for the galvanic cell gives a cell potential, e_{cell}, that is less than the reversible cell potential of Fig. 1:

$$e_{cell} = E^{\circ}_{Ag^+/Ag} - \eta_{Ag,c} - \left(E^{\circ}_{Cu^{2+}/Cu} + \eta_{Cu,a}\right)$$

$$= e_{cell,rev} - \left(\eta_{Ag,c} + \eta_{Cu,a}\right)$$

$$e_{cell} < e_{cell,rev}$$

where the η-values are the overpotentials for the individual anodic and cathodic electrode reactions.
Figure 5 is a circuit that allows the cell potential to be varied in a controlled manner from the reversible cell potential. By reducing the potential between direct current (dc) below $e_{cell,rev}$, the spontaneous galvanic reaction is allowed to proceed. Since the anode reaction is larger than the cathode reaction at the copper electrode, the net reaction is:

$$Cu \rightarrow Cu^{2+} + 2e^-$$

The cathode reaction is larger than the anode reaction at the silver electrode, and the net reaction is:

$$Ag^+ + e^- \rightarrow Ag$$

The overall cell reaction that spontaneously occurs then is:

$$Cu + 2Ag^+ \rightarrow Cu^{2+} + 2Ag$$

and the cell current, $I_{cell} \neq 0$. The galvanic cell can be described as a constructive galvanic cell when $e_{cell} > 0$ and the call is delivering energy to an external device such as an electronic circuit, motor, or light.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

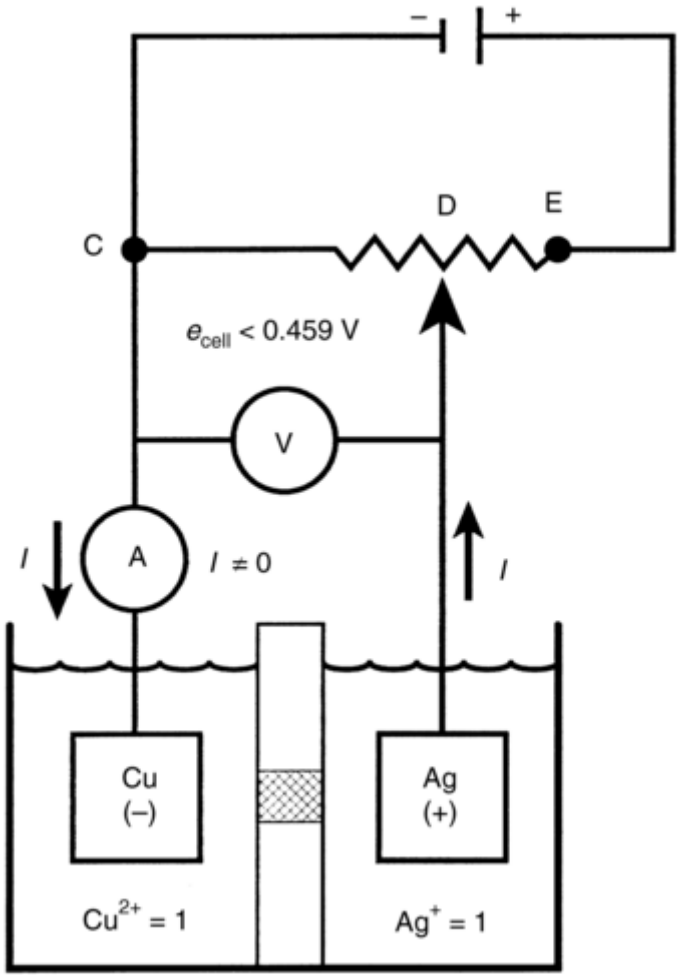

Fig. 5 Galvanic cell with copper and silver electrodes is connected to an external power supply through a voltage divider. The potential, $V_{C\text{-}D}$, can be varied. Voltage, V, is measured with a high resistance electrometer; current, A, is measured with a zero resistance ammeter.

Following the 1953 International Union of Pure and Applied Chemistry (IUPAC) convention, since oxidation occurs at the copper electrode, it is the anode. Reduction occurs at the silver electrode, and it is the cathode. In terms of polarity, the copper electrode is the negative or more active electrode; the silver electrode is the positive or more noble electrode. The flow of current (positive charge) in the external circuit is from the silver electrode to the copper electrode; the electron flow is in the opposite direction, from the copper electrode to the silver electrode.

Electrolytic Cells. The overall electrolytic cell process is not spontaneous because external work must be done on the system to produce the desired reaction. In the case of the copper and silver electrodes, this work is the deposition of copper instead of silver. There is a net flow of electrons through an external circuit from the silver electrode to the copper electrode. When this occurs, the following conditions exist at the electrodes:

$$\text{copper electrode} \quad I_{a,Cu} < I_{c,Cu}$$

$$\text{silver electrode} \quad I_{a,Ag} > I_{c,Ag}$$

and the electrode potentials, E, shift to values outside the range of the initial equilibrium values and are no longer reversible:

$$E_{Cu^{2+}/Cu} < E^{\circ}_{Cu^{2+}/Cu}$$

$$E_{Ag^{+}/Ag} > E^{\circ}_{Ag^{+}/Ag}$$

This shift in electrode potentials for the electrolytic cell gives a cell potential, e_{cell}, that is greater than the reversible cell potential:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$e_{cell} = E^{\circ}_{Ag^+/Ag} + \eta_{Ag,a} - \left(E^{\circ}_{Cu^{2+}/Cu} + \eta_{Cu,c}\right)$$

$$= e_{cell,rev} + \left(\eta_{Ag,a} + \eta_{Cu,c}\right)$$

$$e_{cell} > e_{cell,rev}$$

as in Fig. 6 compared to Fig. 1. Since the cathode reaction is larger than the anode reaction at the copper electrode, the net reaction is:

$$Cu^{2+} + 2e^- \rightarrow Cu$$

The anode reaction is larger than the cathode reaction at the silver electrode, and the net reaction is:

$$Ag \rightarrow Ag^+ + e^-$$

The overall cell reaction that occurs by the input of external energy is:

$$Cu^{2+} + 2Ag \rightarrow Cu + 2Ag^+$$

and the cell current, $I_{cell} \neq 0$. By increasing the potential between points D and C in Fig. 5 above $e_{cell,rev}$, the nonspontaneous electrolytic reaction proceeds in a controlled way, with the current now in the opposite direction from that of the galvanic cell and the cell potential greater than the reversible cell potential. Since oxidation occurs at the silver electrode, it is now the anode. Reduction occurs at the copper electrode, and it is the cathode. In terms of polarity, the copper electrode is still the negative or more active electrode, the silver electrode is still the positive or more noble electrode. The flow of current (positive charge) in the external circuit is from the copper electrode to the silver electrode; the electron flow is in the opposite direction, from the silver electrode to the copper electrode.

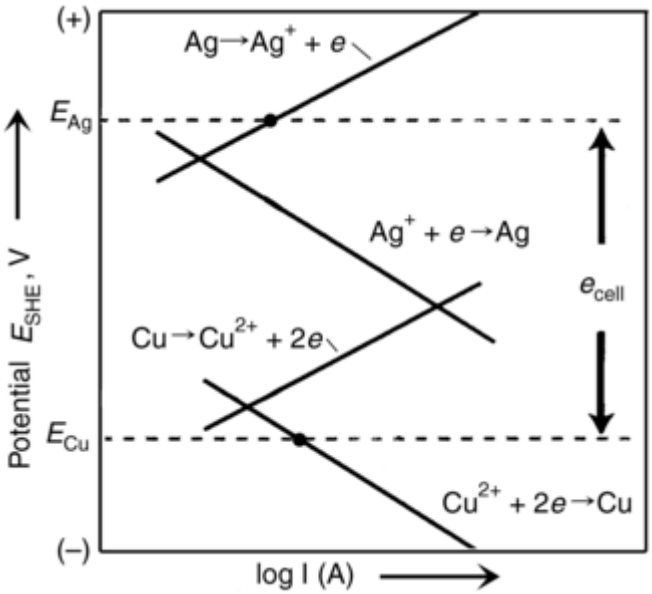

Fig. 6 Potential versus log current plot for electrolytic cell with copper and silver electrodes. The impressed potential difference is e_{cell}.

Corrosion Cells. The corrosion cell is a special case of a galvanic cell. The two electrodes are shorted together in a spontaneous process with both electrodes at the same potential, a mixed potential known as the corrosion potential (E_{corr}). Corrosion cells differ from constructive galvanic cells in that no electrical energy is produced for external application. While there is a net flow of electrons through the circuit from the copper electrode to the silver electrode, this flow produces no useful external work. The following conditions exist at the electrodes:

$$\text{copper electrode} \quad I_{a,Cu} > I_{c,Cu}$$

$$\text{silver electrode} \quad I_{a,Ag} < I_{c,Ag}$$

and the electrode potentials, E, shift to values between those of the initial equilbrium values. They are no longer reversible; that is;

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$E_{Cu^{2+}/Cu} > E^{\circ}_{Cu^{2+}/Cu}$$

$$E_{Ag^{+}/Ag} < E^{\circ}_{Ag^{+}/Ag}$$

In fact, they shift to the corrosion potential (E_{corr}) where:

$$E_{Cu^{2+}/Cu} = E_{Ag^{+}/Ag} = E_{corr}$$

The cell potential (Fig. 7) is:

$$e_{cell} = E_{Ag^{+}/Ag} - E_{Cu^{2+}/Cu} = 0$$

Since the anode reaction is larger than the cathode reaction at the copper electrode, the net reaction is:

$$Cu \rightarrow Cu^{2+} + 2e^{-}$$

The cathode reaction is larger than the anode reaction at the silver electrode, and the net reaction is:

$$Ag^{+} + e^{-} \rightarrow Ag$$

The overall cell reaction that spontaneously occurs is:

$$Cu + 2Ag^{+} \rightarrow Cu^{2+} + 2Ag$$

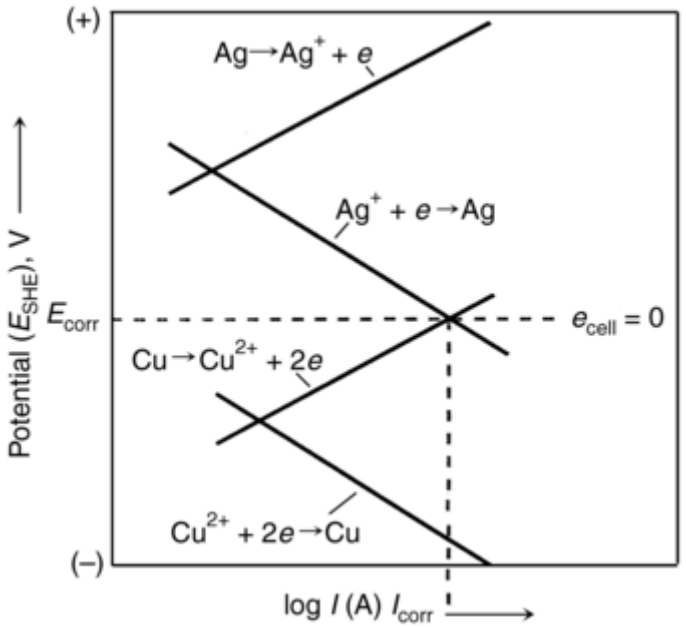

Fig. 7 Potential versus log current plot for corrosion cell with copper and silver electrodes

The cell current (I_{cell}), when measured by a zero resistance ammeter, is equivalent to the corrosion current, I_{corr}. Since oxidation occurs at the copper electrode, it is the anode. Reduction occurs at the silver electrode, and it is the cathode. While both electrodes are at the same potential, the copper electrode is the more active electrode and the silver electrode is the more noble electrode. The flow of current (positive charge) in the external circuit is from the silver electrode to the copper electrode; the electron flow is in the opposite direction, from the copper electrode to the silver electrode.

Table 1 summarizes the conditions that exist at the Cu and Ag electrodes in our example for the different types of cells: reversible, galvanic, electrolytic, and corrosion.

Electropolishing

M. Ziomek-Moroz, U.S. Department of Energy, Albany Research Center

Introduction

ELECTROLYTIC POLISHING, also known as electropolishing, is an electrochemical process that involves anodic dissolution of a metal specimen (anode electrode) in an electrolytic cell. An electrochemical cell is a combination of an anode (an electronic conductor), an electrolyte (an ionic conductor), and a cathode (an electronic conductor); electrochemical processes occur with the passage of electric current in the cell (Ref 1). Irregularities on the anode surface are dissolved preferentially so that the surface becomes smooth and bright (Ref 2). Due to requirements for surface quality, electropolishing is a specific case of anodic dissolution and is essentially the reverse of electroplating. Electropolishing is widely used in many branches of science for purposes such as specimen preparation for corrosion studies. Commercial applications include improving appearance and reflectivity, improving corrosion resistance, removing edge burrs produced by mechanical cutting tools, removing the stressed and disturbed layer of metal caused by mechanical action (mechanical cutting), improving surfaces of medical tools, and removing radioactive contamination from surfaces (Ref 3, 4, 5).

Electrical Circuits

Electropolishing can be carried out in two- electrode and three-electrode systems. A two- electrode laboratory setup is shown in Fig. 1. A workpiece or working electrode (WE), the anode, is connected to the positive terminal of a direct current (dc) power supply. The counterelectrode (CE), the cathode, is attached to the negative terminal. The variable resistor provides control of the current, which is monitored by the ammeter. In commercial use, a pulsed dc may be used.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

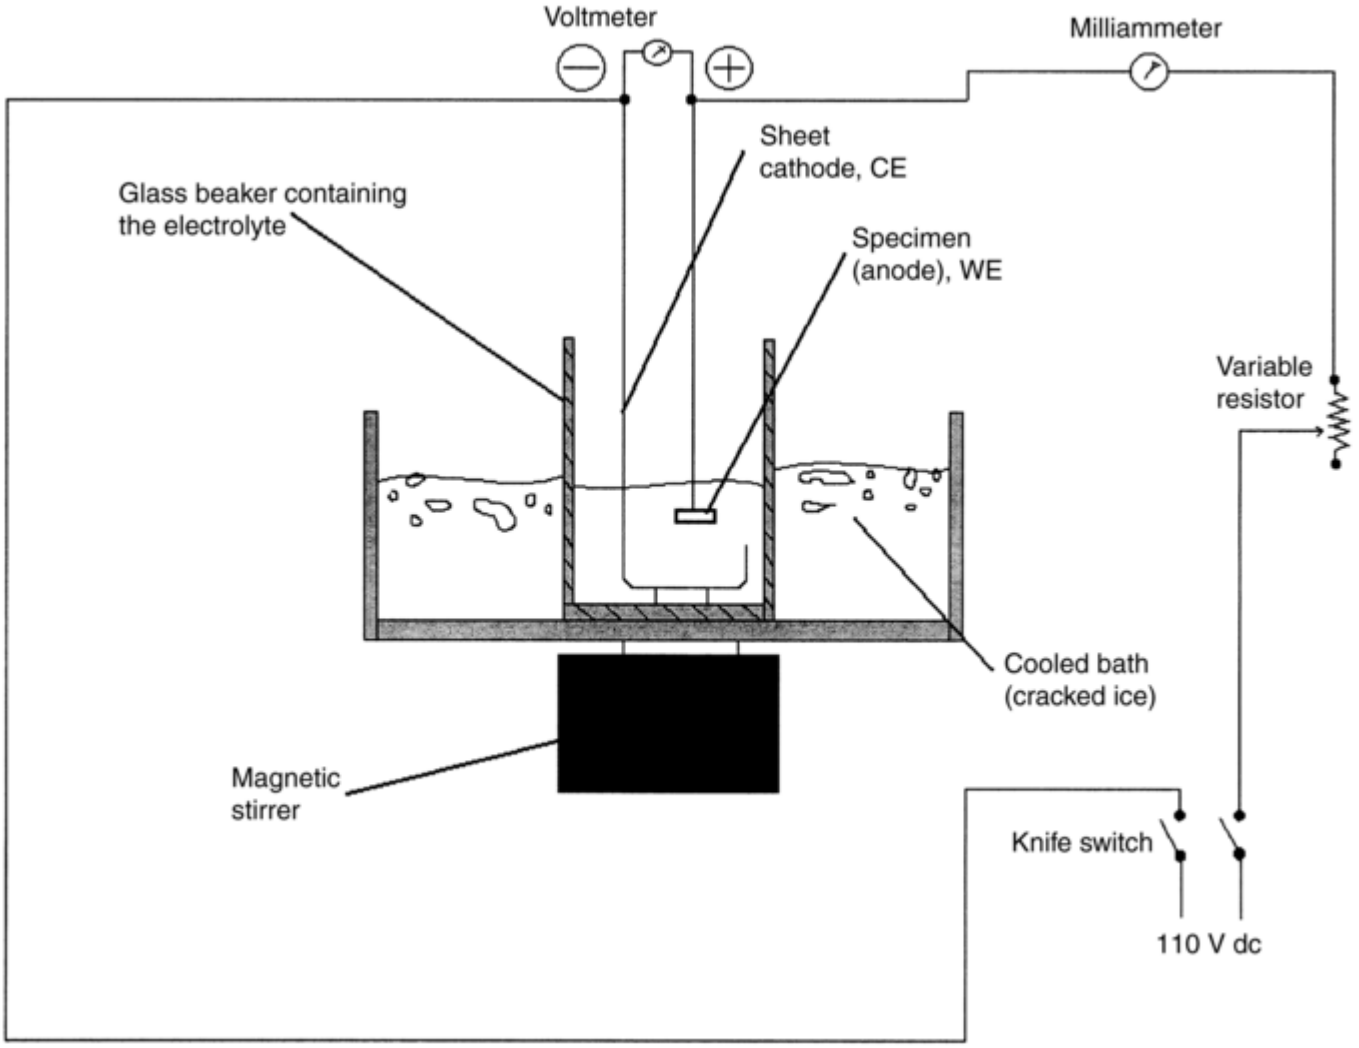

Fig. 1 Two-electrode laboratory setup for electropolishing. WE, working electrode; CE, counterelectrode; dc, direct current

In a three-electrode system (Fig. 2), a potentiostat regulates the dc power to the specimen (WE) and counterelectrode (CE) and receives information on the potential from the reference electrode (RE). The anode workpiece is connected to the working electrode terminal, and the cathode made of platinum or graphite is connected to the counterelectrode terminal. Finally a reference electrode, such as a saturated calomel electrode (SCE), is connected to the reference- electrode terminal to measure the potential of the workpiece.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

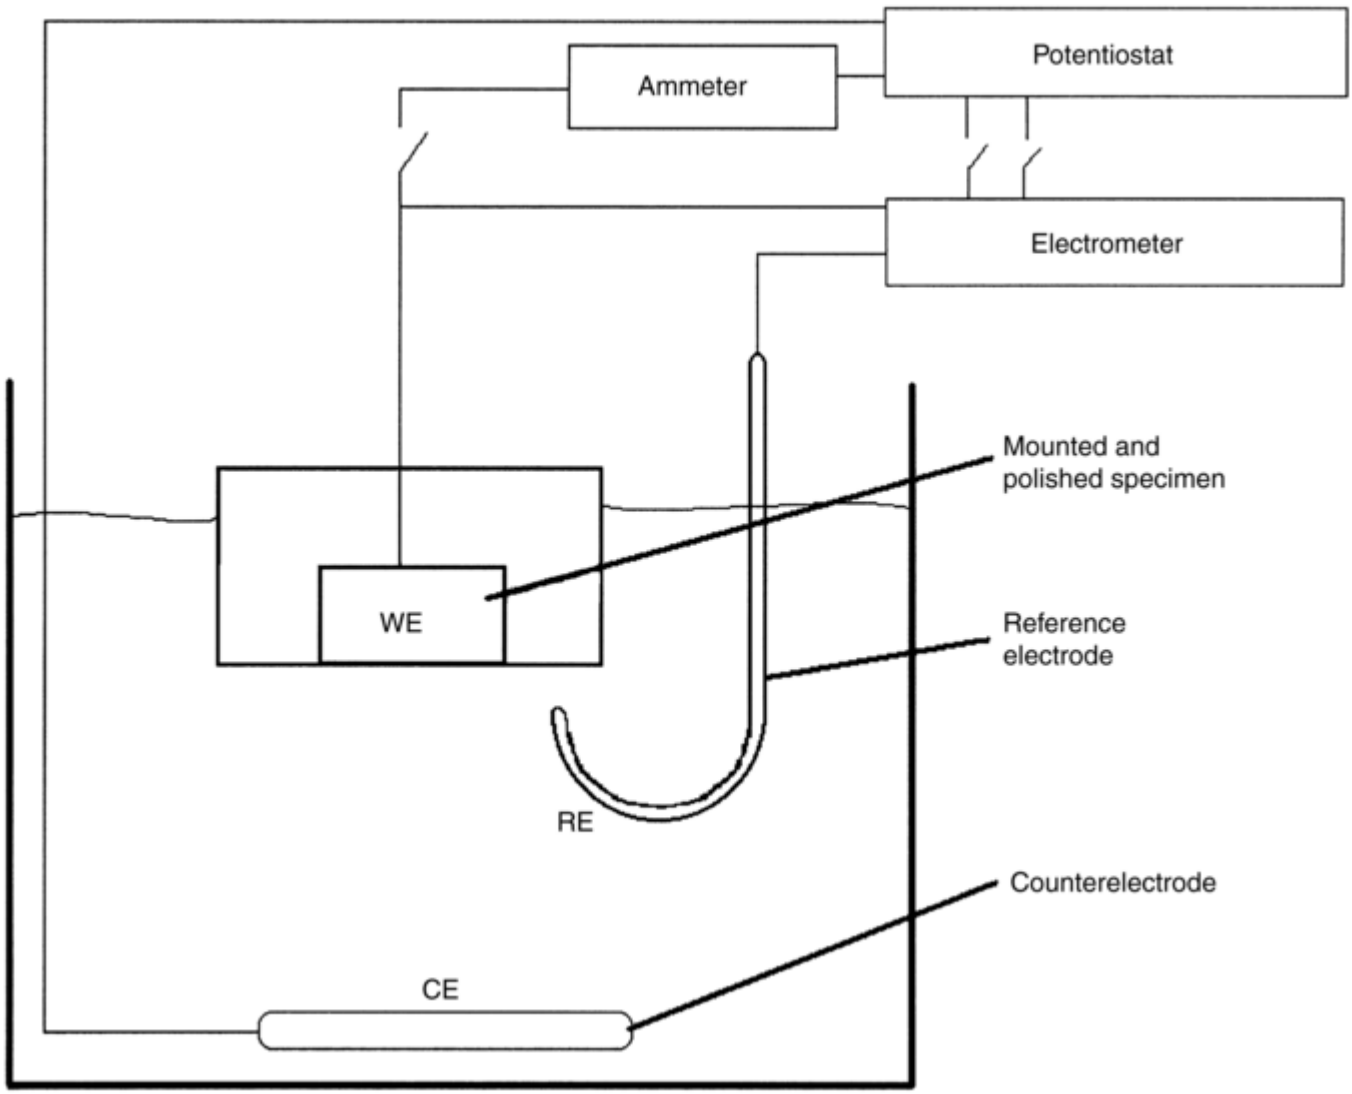

Fig. 2 Three-electrode laboratory setup for electropolishing. WE, working electrode; CE, counterelectrode; RE, reference electrode

The electrical potential of the power supply or potentiostat causes electronic conduction to the WE and CE and ionic conduction in the electrolyte. This may result in controlled anodic dissolution of the anode material and cathodic deposition on the CE of some species present in the electrolyte. During the electrolytic process, the products of the anodic metal dissolution react with the electrolyte to form a film at the surface of the metal as shown in Fig. 3.

Anodic Processes

Anodic dissolution processes are complex. Depending on the nature of the dissolving metal (M), the electrolyte composition, and the current density, the following anodic (oxidation) reactions may occur:

- Transfer of metal ions into the electrolyte:

$$Me \rightarrow Me^{2+} + 2e^{-} \quad \text{(Eq 1)}$$

- Formation of oxide layers:

$$Me + 2OH^{-} \rightarrow MeO + H_2O + 2e^{-} \quad \text{(Eq 2)}$$

- Evolution of oxygen:

$$4OH^{-} \rightarrow O_2 + 2H_2O + 4e^{-} \quad \text{(Eq 3)}$$

During electrolytic polishing, a voltage is applied between the anode and cathode, which are immersed in the electrolyte, through an external electrical circuit as shown in Fig. 1 and 2. If the current is monitored as a function of the cell voltage, polarization curves or current-voltage curves can be generated. Figure 4 shows an idealized anodic polarization curve with regions of cell voltage within which the reactions shown in Eq 1, 2, and 3 may occur.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

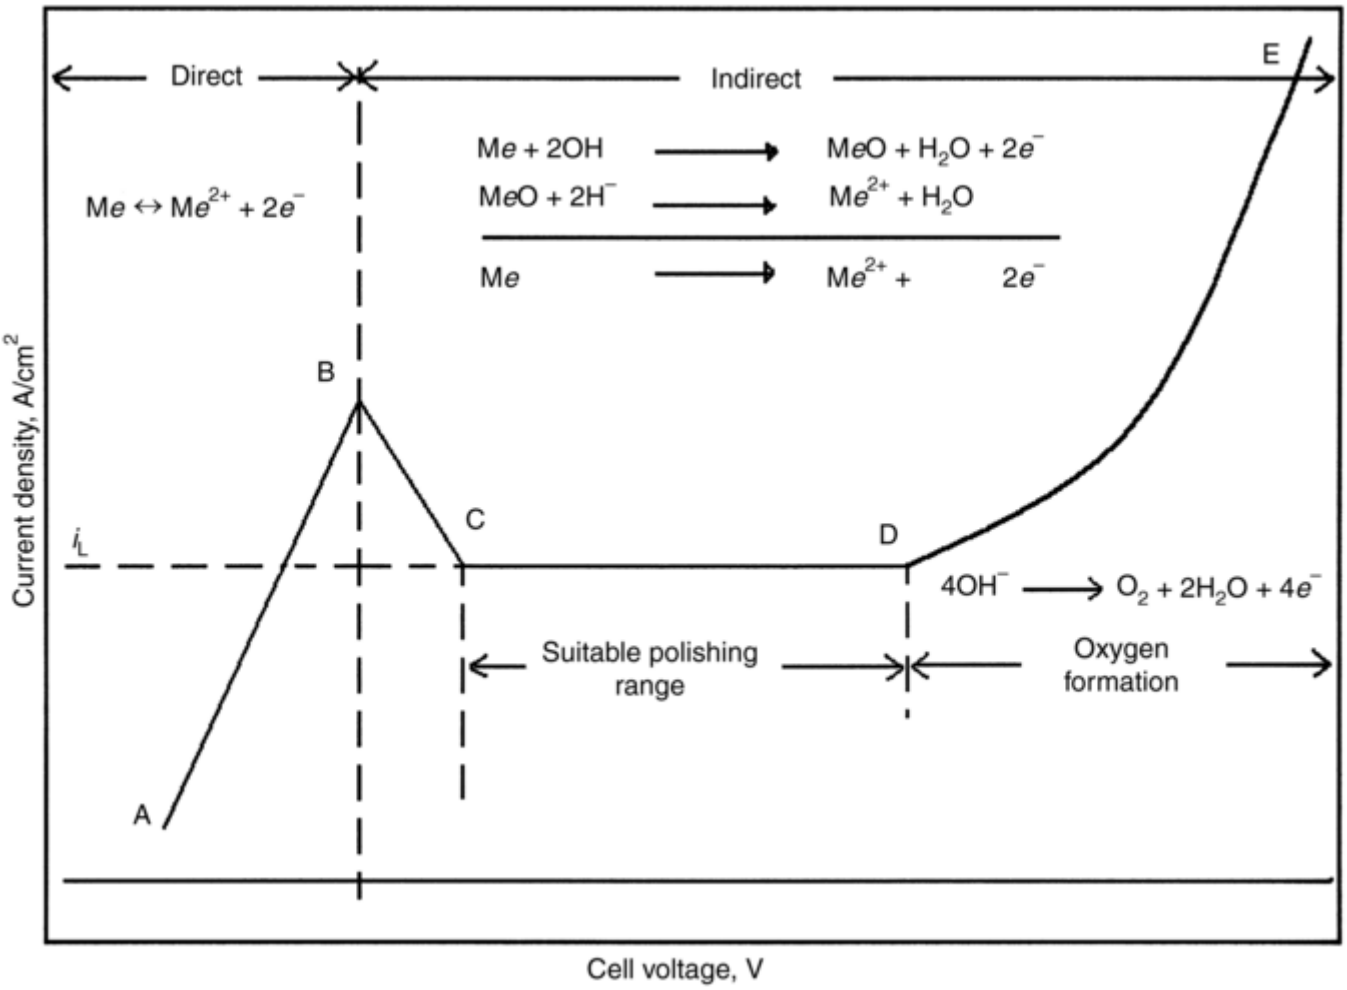

Fig. 4 Idealized anodic polarization curve useful for electropolishing of materials showing active-passive behavior

During electrolytic polishing, positive metal ions (cations) leave the specimen surface and diffuse into the electrolyte, and current increases with increasing applied voltage. In voltage region A-B, active dissolution or a direct etching takes place (the reaction represented by Eq 1). In the B-C voltage region, current decreases with increasing voltage, indicating unstable conditions on the metal surface. This represents active-passive behavior. Constant current with increasing voltage is observed in the C-D range when the anodic film is formed (the reaction shown in Eq 2). This represents passive behavior. At higher voltages (in the D-E range), current increases and the evolution of O_2 takes place (the reaction shown in Eq 3), which resembles transpassive behavior. This type of curve, showing active, active-passive, passive, and transpassive regions, is obtained for copper electropolished in orthophosphoric acid. Electropolishing is achieved by operating at the mass-transfer-limited rate of dissolution in the C-D region. The mass-transfer rate is represented by the limiting current density, i_L, which depends on electrolyte concentration, viscosity, density, and stirring of the electrolyte, as well as the diffusivity of the ionic species present.

Figure 5 is a polarization curve with two distinctive regions, namely: (a) film formation at low voltage and low current and (b) electrolytic polishing at higher voltage and current. Aluminum electropolished in perchloric acid exhibits this type of behavior. The difference in the shapes of the polarization curves for aluminum and copper indicate different electropolishing mechanisms.

Selection of Electrolytes

Anodic dissolution of a metal depends on its chemical and physical properties, surface state, the composition of an electrolyte, and process conditions such as temperature, stirring, and current density (Ref 6). For materials that exhibit active-passive behavior, the most suitable polishing range is the passive region (C-D of Fig. 4). During etching, metal dissolves into the electrolyte while during anodic oxidation, the oxide film is not dissolved. The thickness of the anodic film or passivating layer may change, depending on current and electrolyte composition. The ideal electrolyte for electropolishing (Ref 7) must:

- Provide high quality polishing at low voltages and current densities
- Have the ability to function over a large range of current densities and temperatures
- Offer stability and long service life
- Not dissolve the metal when no current is flowing; that is, no spontaneous corrosion occurs
- Be inexpensive, readily available, and safe
- Be recyclable
- Have an ohmic resistance (IR drop) that is sufficiently low to obtain the desired current density at low voltage
- Provide good throwing power; that is, a sample with complex geometry should dissolve uniformly over the entire surface

Electropolishing

M. Ziomek-Moroz, U.S. Department of Energy, Albany Research Center

Kinetics of Electropolishing

The kinetics of electropolishing is influenced by polishing current, temperature of electrolyte, polishing time, surface preparation, and agitation or stirring of electrolyte, which removes products and bubbles from the anode. The cathode area must be larger than the anode area in order to obtain an optimal polishing rate. Since the electropolishing process is a diffusion-controlled process, stirring or rotating the specimen significantly increases the rate of reaction. Under steady-state conditions, anodic reaction products accumulate on the surface and may interfere with the polishing process (Ref 4). Stirring or the use of a rotating disk electrode maintains a stable temperature and homogeneous composition of the electrolyte and prevents the buildup of corrosion products on the surface of the workpiece. The hydrodynamics of the electrolyte play a critical role in the diffusion control process characteristic of electropolishing as the transfer of reactants to the bulk solution is the rate-determining step in the electropolishing process (Ref 7).

Mechanism of Electropolishing. Surface roughness during electropolishing can vary significantly depending on the stability of the film formed during the passivation stage. Cavities and crevices on the metal surface (Ref 6) require much higher current densities to obtain a uniform polished surface. During electropolishing, a corrosion-product layer forms on the metal surface that has a higher viscosity than the bulk fluid (Ref 8). The thickness of this layer varies over the anode surface area and is greater in crevices. Greater thickness is a result of higher current density.

The leveling of the peaks and crevices of a rough surface follow a sequence where most peaks are dissolved in all directions while crevices are dissolved preferentially in one direction. The diffusion process during electropolishing is faster at the peaks than in the crevices. Unwanted selective etching, once a uniform surface is achieved, can be avoided by optimizing the electropolishing process conditions.

Defects in Electropolishing. Pitting can occur during electropolishing as a result of incorrect electrolyte composition or due to the formation of oxygen bubbles that attack the surface being polished. Blemishes can occur due to intermetallic compounds or inherent defect on the metal surface. Scratches may remain on the electropolished face after inadequate surface preparation (Ref 6, 9).

Hydrodynamic effects, kinematic viscosity, and concentration of electrolyte are the main variables that affect the removal rate during planarization. A rotating disk electrode is useful in the study of the hydrodynamic effects on an electrode. Rotational velocity is limited, so laminar flow is maintained. Generally, the rotating disk electrode is superior to static systems for study of the kinetics of heterogeneous reactions.

For electrolytes in a diffusion controlled process where a stationary condition exists and the process is dependent on mass transfer of solute in a liquid, the following equation governs the process:

$$V \cdot \nabla C = D\Delta C \qquad \text{(Eq 4)}$$

where D is diffusivity; ΔC is concentration gradient; and V is liquid velocity.

The diffusion layer is also controlled by removal of solute due to the electrochemical reaction and the boundary layer due to the changing velocity of the electrolyte.

The following equations proposed by Levich describe the system in a flow pattern (laminar flow) using a rotating disk electrode (Ref 7):

$$J = D\left(\frac{dC}{dt}\right)_{x=0} = D\frac{(C_0 - C_1)}{\delta} \qquad \text{(Eq 5)}$$

and

$$\delta = 1.61 D^{1/3} \nu^{1/6} \omega^{-1/2} \qquad \text{(Eq 6)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

where δ is diffusion layer thickness; J is the magnitude of diffusion flux; D is diffusion coefficient of a reactant, C_0; C_0 is concentration at the disk surface; C_1 is concentration in bulk; ν is kinematics viscosity; and ω is angular velocity of disk.

If the rate of reactant transport is slower than the rate of the chemical reaction, then $C_1 = 0$ and the reaction occurs under diffusion controlled conditions. In the case where reaction rate is slower than the rate of transport, $C_1 = C_0$ and the process is under activation control where corrosion film is not present and the metal continuously corrodes.

For a smooth disk in a laminar flow regime, the rotating disk electrode Reynolds numbers may be calculated by (Ref 7, 10) using the following equation:

$$\mathrm{Re} = r^2\omega/\nu \qquad \text{(Eq 7)}$$

where r is the radius of the disk.

In a diffusion process, where $C_1 = 0$, the rate of transfer of any reactant is greatly lower than the chemical change at interface. Combining Eq 5 and 6, one obtains:

$$J = 0.62 C_0 D^{2/3} \nu^{-1/6} \omega^{1/2} \qquad \text{(Eq 8)}$$

If one multiplies Eq 8 by a number of electrons participating in the reaction (n) and Faraday's constant (F), the removal rate current (I) in the electropolishing process can be obtained with:

$$I = 0.62 nF C_0 D^{2/3} \nu^{-1/6} \omega^{1/2} \qquad \text{(Eq 9)}$$

Physical properties of the electrolyte such as viscosity, density, concentration of solute and diffusivity play an important role in electrolytic polishing. The removal current density, ($i = I$/ area) is a linear relationship with the square root of angular speed of rotating electrode, ω.

Properties of Electropolished Surfaces

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The physical, corrosion, and mechanical properties of a polished metal surface depend on the nature and the surface state of the metal (Ref 6). The main variables are physical characteristics (crystalline lattice structure, stresses, strains), chemical nature, and surface geometry (distribution of peaks and crevices). Mechanically polished surfaces may have an amorphous or mechanically deformed layer that influences its corrosion behavior. However, this layer is gradually removed to the crystalline structure during electropolishing. Monitoring the chemical composition of the surface using scanning electron microscopy is a way to analyze surface heterogeneity and its effect on electropolishing.

Effect of Electropolishing on Properties of Metals. In general, some of the mechanical properties of electropolished surfaces, such as hardness and Young's modulus, are increased. In some materials, such as stainless steel, no change is observed in static strength parameters (Ref 6). An effect on the fatigue behavior of metals is difficult to determine (Ref 6, 8) due to the complex nature of failure involving stress concentration, cracks, and surface defects. Mechanical polishing produces a cold-worked surface layer that generally enhances the fatigue life of metals. Fatigue life may be reduced when this layer is removed by electropolishing. On the other hand, surface roughness of the metal is reduced, which may increase the fatigue life of steel (Ref 6). Stress concentrations are also reduced.

Magnetic properties of steel alloys are altered when the cold-worked layer is removed by electropolishing. Surface conductance is improved. The effect of electrolytic polishing on the corrosion properties of metals depends on the post- polished oxide that forms and how porous the protective film is. Resistance to uniform corrosion is generally improved following polishing (Ref 7). In the case of aluminum, the protective oxide film that is formed has proven to be beneficial.

Introduction

SALT SOLUTIONS (ELECTROLYTES)— unlike metallic conduction where only electrons are the charge carriers—conduct electrical charge by migration of ions in the medium. A feature of electrolysis is that electrical energy is used to produce an electrochemical reaction. The machining process based on this principle is known as electrochemical machining (ECM). In ECM, a small direct current electric potential (5 to 30 V) is applied across two electrodes, the cathode (tool) and anode (workpiece), immersed in an electrolyte. The

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

transfer of electrons between ions and electrodes completes the electrical circuit. Metal is detached, atom by atom, from the anode surface and appears in the electrolyte as positive ions, which react with hydroxyl ions to form metal hydroxides. During the process, H_2 gas is evolved at the cathode (Fig. 1a). When the workpiece is steel, the reactions are:

$$Fe + 2H_2O \rightarrow Fe(OH)_2 + H_2\uparrow \quad \text{(Eq 1)}$$

$$2H_2O + Fe(OH)_2 + O_2 \rightarrow Fe(OH)_3 \quad \text{(Eq 2)}$$

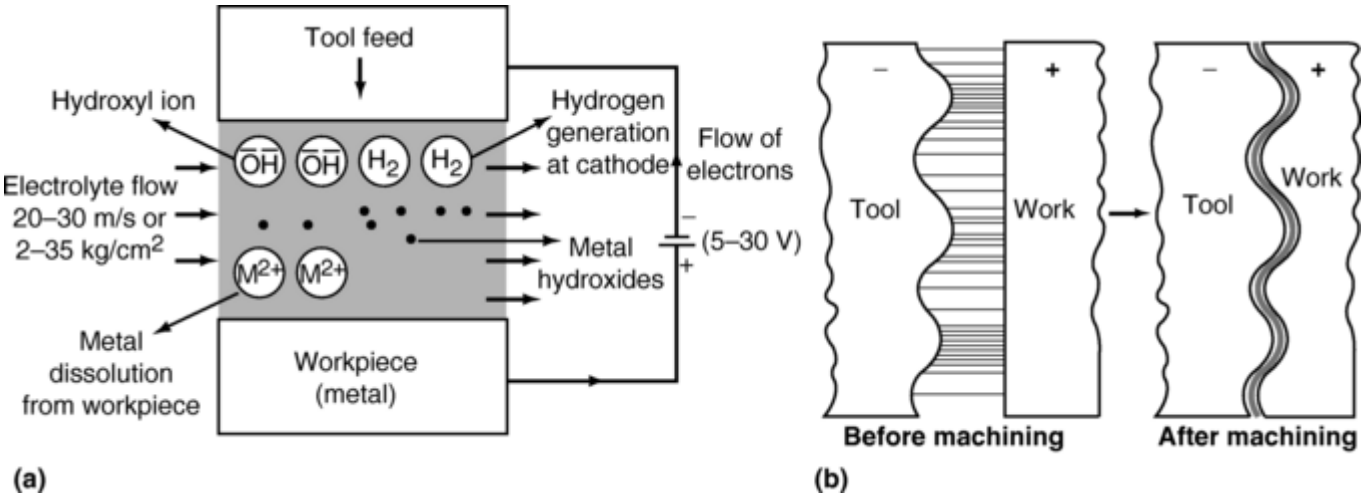

Fig. 1 Elements of electrochemical machining (ECM). (a) Diagram showing dynamics. (b) Tool and work before ECM and after ECM. The density of parallel lines indicates current density.

The smaller the interelectrode gap (IEG)— that is, the gap between anode and cathode—the greater the current flow (Fig. 1b) and the greater the metal-removal rate (MRR). The reaction products (metal hydroxides and gas bubbles) act as a barrier to the flow of electrolytic current. Their effect is minimized by supplying the electrolyte at a pressure varying in the range 2 to 35 kg/cm^2 (30 to 500 psi), leading to the electrolyte flow velocity of 20 to 60 m/s (65 to 195 ft/s). The optimal pressure and the resulting electrolyte flow velocity will depend on the size of the tool and workpiece and the IEG. Electrolyte flowing at high velocity dilutes electrochemical reaction products and removes them from the IEG. It dissipates heat and limits the concentration of ions at the electrode surface to give higher machining rates. The electrolyte conductivity, the voltage across IEG, the gap itself, and tool shape are controlled to define the final anode (workpiece) profile. The electrolyte electrical conductivity depends on composition, concentration, and temperature. Electrolyte temperature can be controlled (within ±1° C) by heating or cooling the electrolyte in the tank. Feed to the tool should be provided at the same rate at which the workpiece surface is descending, so that the IEG remains almost constant during the process. This is known as machining under equilibrium conditions.

Electrochemical machining principles have been used to perform a variety of machining operations (Ref 1), for example, turning, drilling, deburring, wire cutting, deep-hole drilling, and grinding. Electrochemical machining can be used to machine difficult-to-machine electrically conductive materials having complex shapes, deep holes with very high aspect ratio (up to 300:1), and three-dimensional profiles such as turbine blades. It is used in aerospace, automobile, and die-making industries.

Electrochemical Machining System

An ECM system consists mainly of four subsystems: power source, electrolyte cleaning and supply system, tool and tool-feed system, and workpiece and workpiece-holding system (Fig. 2).

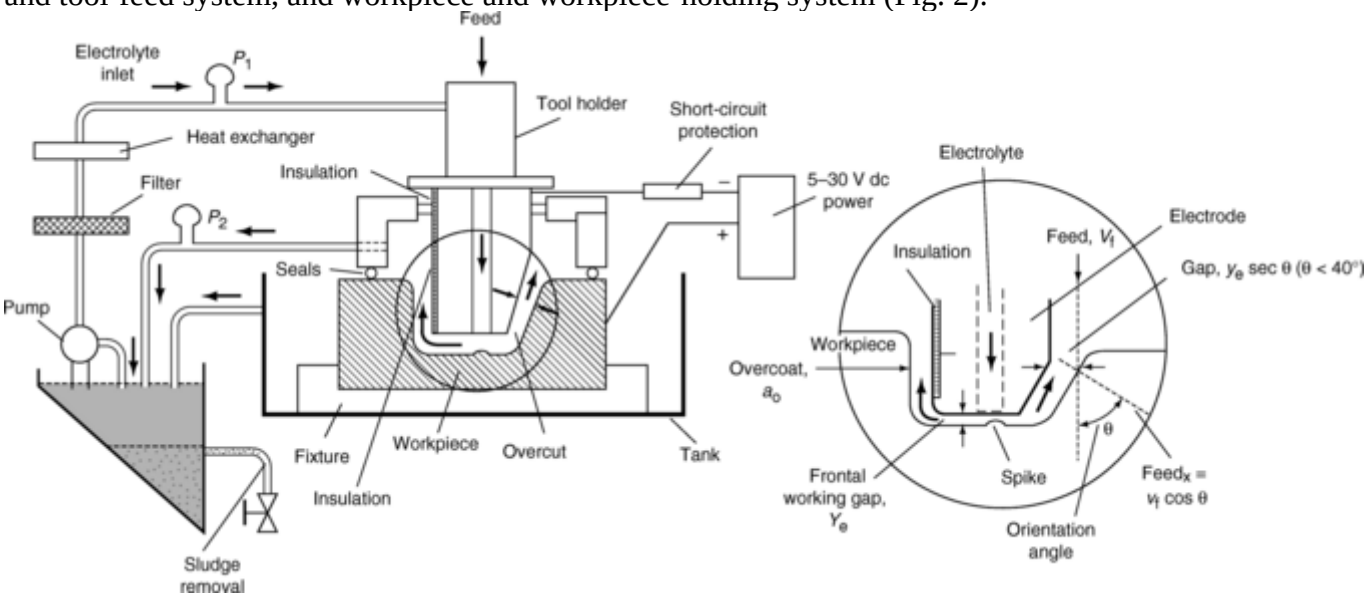

Fig. 2 Diagram of electrochemical machining systems

The power supply provides direct current as high as 40,000 A at low electric potential. Silicon-controlled rectifiers (SCR) are used for control because of their rapid response to the load and their compactness. Power is cut off within 10 μs in the event of sparking to avoid any damage to the tool and workpiece.

The electrolyte supply and cleaning system consists of a pump, filters, piping, control valves, heating or cooling coils, pressure gages, and one or more storage tanks. Electrolyte supply ports can be made in the tool, work, or fixture, depending on the requirements of the electrolyte flow. Electrolyte is cleaned by filters made of noncorroding materials such as Monel and stainless steel to avoid any blockage of the IEG, which is typically 0.3 to 1.0 mm (0.012 to 0.04 in.) by particles carried in the recycled electrolyte. Metallic piping should be grounded to prevent damage by corrosion. Tables and fixtures should also be grounded or should carry a cathodic potential to prevent corrosion. Further, ECM machines must be designed to withstand the hydraulic pressure of the electrolyte, which tends to separate tooling from the workpiece.

Tools and fixtures are made of materials resistant to the very corrosive environment of the system. High thermal and electrical conductivity is needed for tool material. Easy machining of tool material is equally important because dimensional accuracy and surface finish of the tool directly affects the workpiece accuracy and surface finish. Even a small defect on the surface of the tool may leave marks, scratches, nicks, burrs, or lines on the machined surface due to the disturbed flow of electrolyte and altered current density at such irregularities. Aluminum, brass, bronze, copper, and carbon are used. Titanium is used as a tool material when machining with an acid electrolyte that anodizes the cathode. To remove the plated deposits from the tool, the current is reversed periodically. Table 1 gives relative properties of metals used for making tools in ECM. Due to high thermal conductivity, copper and brass will be damaged less than stainless steel and titanium by short circuits. Copper tungsten is highly resistant to damage from short circuits because of its high melting point.

Table 1 Ranking of properties of commonly used tool materials

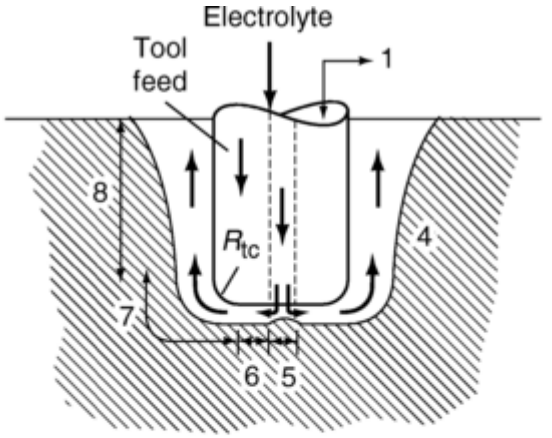
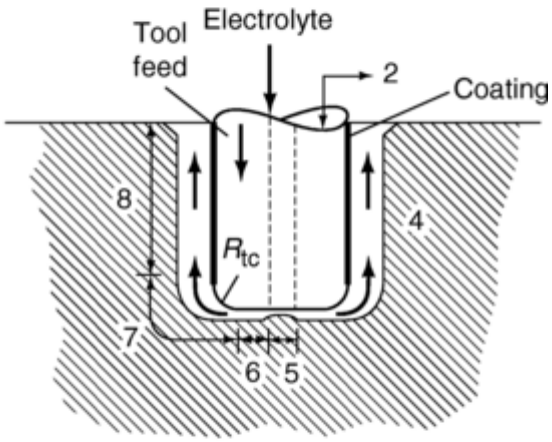
Source: Ref 2

There are three types of tools used in ECM— bare tool, coated tool, and bit-type of tool (Ref 3). Bare tools are usually not recommended, especially in cases of electrochemical drilling where straight-sided deep holes are needed. Areas on the tool where ECM action is not required should be insulated; however, due to the difficulties associated with achieving effective coatings, bit type of tools (Ref 3) are used (Fig. 3). As there is no wear and tear of the tool under normal ECM, theoretically tool life is infinite.



(a)



(b)

R_{tc}, tool corner radius; r_{ef}, electrolyte flow hole radius

Tool feed is controlled either by a stepper motor or a servosystem. Simple machines have manual control, while advanced machines have multiaxis computer control of feed and process parameters.

Workpiece. Electrochemical machining can only be used on electrically conductive workpiece materials. Proper cleaning of the workpiece is essential after ECM to prevent residue from hardening on it. A clean water rinse for corrosion-resistant metals and alkaline cleaning of corrosive materials (steel, cast iron, etc.) is recommended. The workpiece is cleaned with a mild hydrochloric acid solution before a clean water rinse. During ECM, hydrogen is evolved at the tool (cathode); therefore, the probability of hydrogen embrittlement of the workpiece (anode) is minimal. There is no effect of ECM on ductility, yield strength, ultimate strength, and microhardness of the machined component. However, the fatigue strength of conventionally premachined components is reduced after ECM because of the removal of layers having compressive residual stresses. Little information is available about the effect of microstructure on the performance of ECM process. However, grain size and insoluble inclusions also affect surface roughness. Insoluble inclusions can stall the ECM process. Intergranular attack and other defects (pitting, selective etching) induced during ECM seem to be secondary reasons for the reduction in fatigue strength. Intergranular attack can be controlled by appropriate selection of electrolyte and ECM parameters. No effect of hardness of the workpiece material on the process performance has been reported.

Workpiece-holding devices are made of electrically nonconducting materials—such as glass fiber reinforced plastics, plastics, and Perspex— having good thermal stability and low moisture absorption properties.

Theory of ECM

Electrochemical machining differs from other industrial processes based on Faraday's laws of electrolysis, such as electroplating. In ECM, the shape and size of the workpiece is changed in a controlled manner, and the minimum current density employed is higher than 8 A/mm^2.

Faraday's law of electrolysis is:

$$m = \frac{I(EW)t}{F} \qquad \text{(Eq 3)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

where m is mass (grams) removed in time t, I is current, t is time (seconds), EW is gram equivalent weight of workpiece metal ($EW = A_w/z$; A_w = atomic weight, z = valency of dissolution), and F is Faraday's constant (96,500 coulombs/gram equivalent, or ampere-seconds/gram equivalent).

Equation 3 does not account for the effects of some of the significant process variables, that is, overpotential, presence of passive film, variation in the electrical conductivity of the electrolyte due to temperature and void concentration along the electrolyte flow path and valence changes during electrochemical dissolution. Regarding the latter, dissolution of iron in NaCl solution depends on the machining conditions and may be either in the form of ferrous hydroxide (Fe^{2+}) or ferric hydroxide (Fe^{3+}) ions.

The mode of dissolution during alloy machining is still more difficult to identify (Ref 1). Since the workpiece is usually an alloy rather than a single element, the evaluation of m becomes difficult because electrochemical equivalent of an alloy (EW_a) is generally not well defined. However, two methods have been proposed (Ref 4) to solve this problem.

Method 1 is the percentage by weight method. The value of EW_a is calculated by multiplying the chemical equivalent of individual element (EW_i) by their respective proportion by weight percent (X_i), and then summing them up as given by:

$$EW_a = \frac{1}{100}\sum_{i=1}^{n}(EW_i)X_i \qquad \text{(Eq 4)}$$

where n is number of the constituent elements in the alloy.

Method 2 is the superposition of charge method. The amount of electrical charge required to dissolve the mass contribution of individual element of the alloy is calculated and then EW_a is evaluated as:

$$EW_a = \frac{100}{\sum_{i=1}^{n}(X_i/EW_i)} \qquad \text{(Eq 5)}$$

These two methods do not give exactly the same value of EW_a.

The total current (I) is not used in dissolving material from the workpiece. Actual MRR depends on the current efficiency (η), which ranges from 75 to 100%.

Metal-Removal Rate

It is desirable to have minimum possible IEG (≤0.5 mm) for accurate reproduction of tool shape on the workpiece. The analysis (Ref 1, 5) given in this section is based on the following assumptions:

- Electrical conductivity of electrolyte during the process remains constant.
- The surfaces of anode and cathode are considered to be equipotential.
- Effective voltage (V - ΔV) across the electrodes remains constant.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- The anode dissolves at one fixed valency of dissolution.

In the above assumptions, V is constant potential difference applied across the electrodes, and ΔV is sum of electrode overpotentials including reversible potential. The difference between the equilibrium and working values of the potentials is known as overpotential. This overpotential includes activation, concentration, and resistance overpotentials (Ref 4).

In the case of ECM with plane parallel electrodes, MRR (in gram MRR_g, in volume MRR_v) can be calculated as:

$$MRR_g = \frac{\eta I (EW)}{F} \quad \text{(Eq 6)}$$

$$MRR_v = \frac{\eta I (EW)}{F \rho_a} \quad \text{(Eq 7)}$$

where ρ_a is density of anode (workpiece).

Table 2 gives theoretical material-removal rate for different metals (Ref 4), assuming current efficiency as 100%. The MRR depends on the valence of dissolution and atomic weight of the material. Theoretical MRR ranges from 11 to 84 mm^3/s (2.4 to 18.5 $in.^3/h$).

Table 2 Theoretical metal-removal rate (MRR) for current of 1000 A

Linear metal-removal rate (or penetration rate, MRR_l) is given by:

$$MRR_l = \frac{\eta J (EW)}{F \rho_a} \quad \text{(Eq 8)}$$

where J is current density.

The current density in the IEG is a function of shapes of the electrodes, the distance separating the electrodes (y), and effective voltage between them:

$$J = \frac{I}{A} = (V - \Delta V) k / y \quad \text{(Eq 9)}$$

where k is electrical conductivity of electrolyte, y is IEG, and A is workpiece area under the tool.

The voltage applied across the IEG is a controllable parameter and greatly influences ECM performance. For a constant voltage power supply, the magnitude of current flow is controlled by the dynamics of IEG, y.

Interelectrode Gap

During ECM, the tool moves toward the workpiece at the feed rate (f), but at the same time, work surface moves away from the tool at a rate equal to the penetration rate (MRR_l). Therefore, the effective rate of change of IEG is given by:

$$\frac{dy}{dt} = \frac{J (EW) \eta}{\rho_a F} - f \quad \text{(Eq 10)}$$

Under equilibrium conditions ($dy/dt = 0$, IEG = y_e), the equilibrium gap distance (y_e) and the feed rate have the relationship:

$$f = \frac{(V - \Delta V) k}{y_e} \frac{(EW) \eta}{\rho_a F} \quad \text{(Eq 11)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Knowing the feed rate, the equilibrium gap (y_e) can be calculated from Eq 11. Equation 10 can be rewritten (assuming efficiency as 100%) as:

$$\frac{dy}{dt} = \frac{c}{y} - f \qquad \text{(Eq 12)}$$

where $c = (EW)(V - \Delta V)k/F\rho_a$; c is assumed to remain constant for a given workpiece and electrolyte combination only if $(V - \Delta V)$ and k remain constant during the process. In practice, two cases arise for which Eq 12 can be solved, that is, zero feed rate ($f = 0$) and finite feed rate ($f \neq 0$). In case of zero feed rate, the solution (Ref 5) of Eq 12 is given by Eq 13 for the initial condition, $y = y_0$ at $t = 0$.

$$y = \left(2ct + y_0^2\right)^{1/2} \qquad \text{(Eq 13)}$$

For finite feed rate, the IEG attempts to attain the equilibrium gap. The solution (Ref 4, 5) of Eq 12 is given by:

$$t = \frac{1}{f}\left[y_0 - y_t + y_e \ln\left\{\frac{y_0 - y_e}{y_t - y_e}\right\}\right] \qquad \text{(Eq 14)}$$

where y_t is IEG at any time t.

Generalized equation for IEG. Equation 13 predicts an infinite gap at $t = \infty$. Equation 14 is an implicit equation that is solved for y_t only by iterative process. Hence, Eq 14 is not especially convenient to handle in those cases where numerical methods such as finite-element methods, finite-difference methods, or boundary-element methods are applied to analyze the ECM process. A single equation has been derived (Ref 6) for numerical methods analysis. It is applicable simultaneously to both the cases, that is, for $f = 0$ and $f \neq 0$. Equation 10 can be written in the following form:

$$dy = \left(\frac{(EW)J\eta}{F\rho_a} - f\right)dt \qquad \text{(Eq 15)}$$

All the factors except J on the right-hand side of this equation can be treated as constant during ECM. The domain of interest in numerical methods is then divided into elements whose size is quite small; therefore, within an element J can be assumed to remain constant over a small interval of time dt. Therefore, Eq 15 can be written as:

$$dy = (c - f)dt \qquad \text{(Eq 16)}$$

where $c = \{[(EW)\eta]/F\rho_a\}$ and is assumed to be constant. After integration, Eq 16 can be written (for $y = y_0$ at $t = 0$) as:

$$y = y_0 + (c - f)t \qquad \text{(Eq 17)}$$

Equation 17 is valid only for a small interval of time ($t = \Delta t$). Hence, it can be written:

$$y = y_0 + (c - f)\Delta t \qquad \text{(Eq 18)}$$

Equation 18 is valid for both the cases for feed rate (Ref 7), and the total computer time is reduced.

Electrolyte Conductivity

Electrolyte electrical conductivity is a function of local temperature (T) and presence of sludge and gas bubbles (hydrogen, oxygen, vapor, and other gas bubbles) in the IEG. As a result, the IEG gets tapered along the electrolyte flow direction. For precision machining, temperature of the electrolyte should be controlled within ±1 °C (±1.8 °F). This may require heating or cooling the electrolyte. In the analysis given below, only the effects of temperature and hydrogen gas bubbles are taken into account.

Using the law of conservation of heat, the temperature gradient (dT/dx) along the path of electrolyte flow (x-direction) can be derived (Ref 8) as follows:

$$\frac{dT}{dx} = \frac{(V-\Delta V)^2}{U\rho_e C_e \bar{y}^2} \cdot k = \bar{A}k \qquad \text{(Eq 19)}$$

where the density (ρ_e) and specific heat (C_e) of the electrolyte are assumed to remain constant in the IEG. Average values of IEG ($\bar{y}$) and electrolyte flow velocity ($\bar{U}$) are also assumed to remain unchanged. Thus,

$$\bar{A} = \frac{(V-\Delta V)^2}{U\rho_e C_e (\bar{y})^2}$$

can be treated as constant.

Electrical conductivity (k) of the electrolyte varies linearly with temperature as:

$$k = k_0(1 + \alpha \cdot \Delta T) \qquad \text{(Eq 20)}$$

where α is a temperature coefficient of specific conductance [$\alpha = dk/(k_0 dT)$]. Solving after substituting Eq 20 in Eq 19 gives:

$$(T - T_0) = \frac{1}{\alpha}\left[\exp(\alpha \bar{A} k_0 x) - 1\right] \qquad \text{(Eq 21)}$$

It can also be shown that:

$$J = \frac{(V-\Delta V)}{y} k_0 \left[\exp(\alpha \bar{A} k_0 x)\right] \qquad \text{(Eq 22)}$$

To incorporate the effect of temperature as well as hydrogen gas bubbles on electrolyte conductivity, the following equation has been suggested (Ref 9, 10):

$$k = k_0\{(1 + \alpha \cdot \Delta T)(1 - \alpha_v)^n\} \qquad \text{(Eq 23)}$$

A value of exponent n between 1.5 to 2.0 has been used (Ref 9, 10, 11). This equation, however, does not account for the effect of size and distribution of H_2 bubbles. Effect of change in temperature and concentration of NaCl and HCl on their conductivity is shown in Fig. 4.

Process Control

Electrochemical machining has a unique self- regulating feature. Under the equilibrium condition ($f = MRR_l$), machining takes place at a constant IEG (that is, equal to y_e). If this were not true at all times during ECM, either $f < MRR_l$ or $f > MRR_l$.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

If $f < MRR_l$, initially IEG will increase and it will attain a value greater than the equilibrium gap value ($y > y_e$). Because of this, the current density will also decrease as compared to J_e (current density under equilibrium condition) and the MRR_l will also decrease. In other words, the difference between f and MRR_l will decrease, or the process will move toward the equilibrium gap condition.
If $f > MRR_l$, the reverse argument will be true, and again the IEG will converge to the equilibrium gap (or $MRR_l = f$). The self-regulating convergence is shown in the Fig. 5, where the IEG always attempts to reach the equilibrium gap value, y_e.

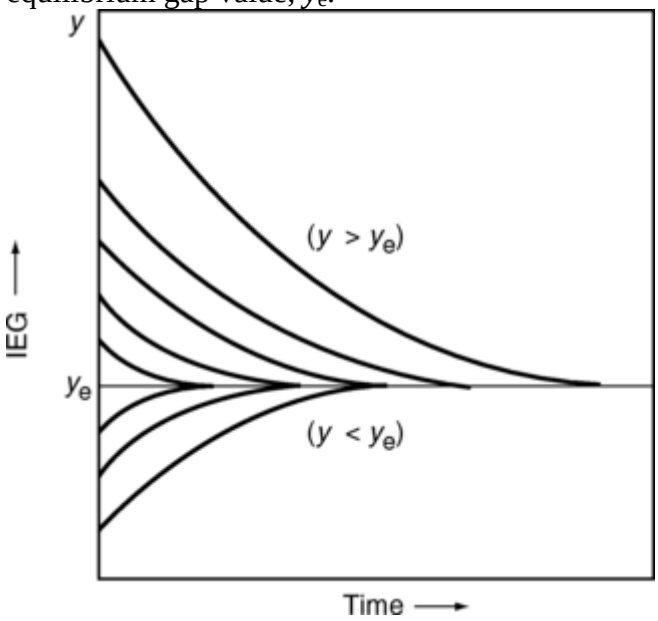

Fig. 5 The interelectrode gap (IEG) as a function of time the self-regulating feature of ECM is shown, as gaps with different initial values (y) converge to the equilibrium gap (y_e).

Electrolytes

A good electrolyte for ECM must have high electrical conductivity, high specific heat, good chemical and electrochemical stability, controllable passivating effect, low viscosity, and low toxicity and corrosivity (Ref 2, 12). Electrolyte in the IEG conducts current between anode and cathode, removes reaction products, and dissipates heat produced during the process. The electrolytes perform better when the crystal structure of the workpiece is fine grained, and its constituents (in case of an alloy) dissolve at uniform rate. Electrolytes used in ECM are classified in three categories: neutral salt, alkaline, and acidic. Each type has its own merits.
Sludging electrolytes produce hydroxide sludges that must be removed before recycling. Sodium chloride (NaCl) solutions are the most commonly used electrolytes in ECM. During ECM, water is depleted, producing H_2 gas and hydroxides (Eq 1 and 2), which are insoluble in water. NaCl electrolyte is corrosive in nature and produces large amounts of sludge. The ratio of the amount of sludge formed to the amount of metal dissolved ranges between 6 and 8 for NaCl electrolyte. There is no universal electrolyte that can be employed for every type of metal and alloy. Table 3 (Ref 12) recommends some electrolytes for a limited range of metals and alloys. Under certain circumstances, mixtures of electrolytes, such as $NaNO_3$ and NaCl or NaCl and HCl, are used. For instance, $NaNO_3$ is passivating and more expensive, but gives smoother surfaces in certain cases.

(e) Voltage must be greater than.
(f) NaOH used up in process and must be replenished.
(g) Minimum of 9 kg/L (0.75 lb/gal.)
(h) pH of electrolyte decreases with use; maintain pH by adding NaOH or KOH. Source: Ref 2

Nonsludging electrolyte such as NaOH solutions are used in ECM of heavy metals such as tungsten and molybdenum and their alloys. The electrolyte becomes depleted during ECM due to the formation of compounds such as sodium tungstate ($Na_2WO_4 \cdot 2H_2O$) and sodium molybdate ($Na_2MoO_4 \cdot 2H_2O$) while machining tungsten and molybdenum, respectively. These compounds are soluble in water (hence, no sludge), but these heavy metals tend to plate out onto the cathode, which is undesirable. However, a periodic voltage polarity reversal will keep the tool cathode surfaces clean.

Filtration. Effective filtration of sludge-forming electrolyte is very essential to maintain the performance of the ECM process. In no case should the electrolyte contain more than 2 wt% sludge when in use. Presence of sludge particles in the IEG can lead to short circuits. Filtering, centrifuging, and settling are used to remove sludge.

Electrolyte flow rate, controlled by pressure, in the IEG affects electrolyte conductivity by changing its temperature and the hydrogen gas bubble size and distribution in the IEG. Electrolyte flow rate must be high enough to remove machining by-products as quickly as possible. Electrolyte flow rate influences surface finish R_a value (centerline average value of surface finish is abbreviated as R_a) and current efficiency, η, as well as MRR. A high ratio of electrolyte flow rate to the current across the IEG is desirable, but the cost of pumping increases. A rule of thumb is approximately 1 L/min for each 100 A for machining steel with NaCl. High flow rate usually reduces the value of R_a and minimizes the formation of deposits on the cathode. Excessive flow rate can lead to local erosion of tool/ workpiece and sticking of precipitates on to the workpiece. To produce a smooth, uniform surface on the workpiece, the tool must be designed so there is uniform flow over the entire machining area. This is difficult at high flow velocities of 30 to 60 m/s (100 to 200 ft/s). The design of tools for complex-shaped workpieces requires an understanding of multiphase fluid flow (involving liquid, gas, and solid phases), electrical and electrochemical principles, as well as experience and ingenuity.

Back Pressure. Attempts have been made (Ref 2) to study the effect of back pressure in the IEG. Increased back pressure in ECM reduces imprints of flow lines on the workpiece and increase drilled-hole diameter, but results

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

in higher hydraulic forces and tooling cost. Hole diameter and current at constant voltage are increased with increase in back pressure because the resulting hydrogen bubbles are smaller, leading to increased conductivity (Fig. 6).

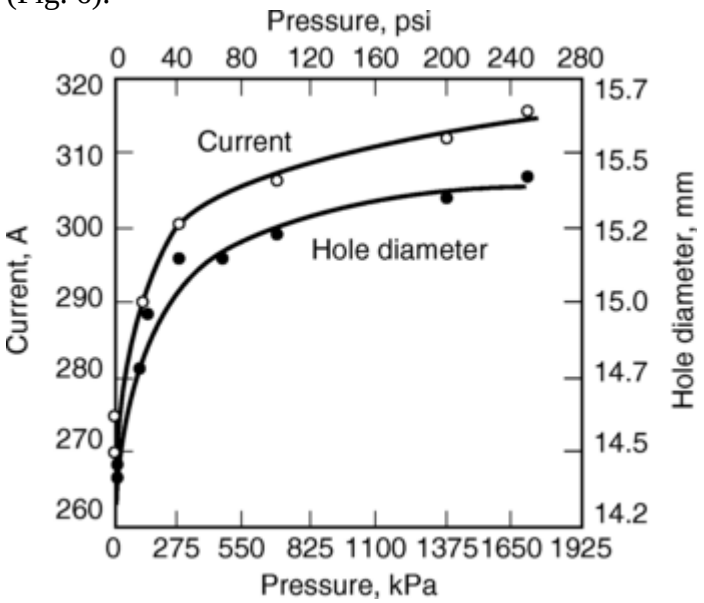

Fig. 6 Effect of electrolyte back pressure on hole size and current at constant voltage. Source: Ref 2

Safety precautions are important in ECM. Dry oxidizing salts such as sodium nitrate and sodium chlorate are hazardous. Mists, vapors, and dusts of alkaline electrolyte can damage body tissues. Appropriate ventilation of the work area and use of protective gloves, face shields, and masks are required. To prevent hydrogen explosion, hydrogen evolved during ECM must be vented from the work area. Proper storage, handling, and disposal of the electrolytes used in machining of heavy metals are also very important.

Workpiece Shape Prediction

Analytical and computational models (Fig. 7) for workpiece shape prediction have been developed (Ref 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28), ranging from the simple “cos θ” principle to those based on approximate numerical techniques. These models have been used to predict work profile in different zones of electrochemically drilled blind holes, that is, side, transition, front, and stagnation zones (Fig. 8). The ability to predict variations in IEG in different zones for any given tool and operating conditions is a prerequisite for proper design of ECM tools and anode shape prediction (Ref 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

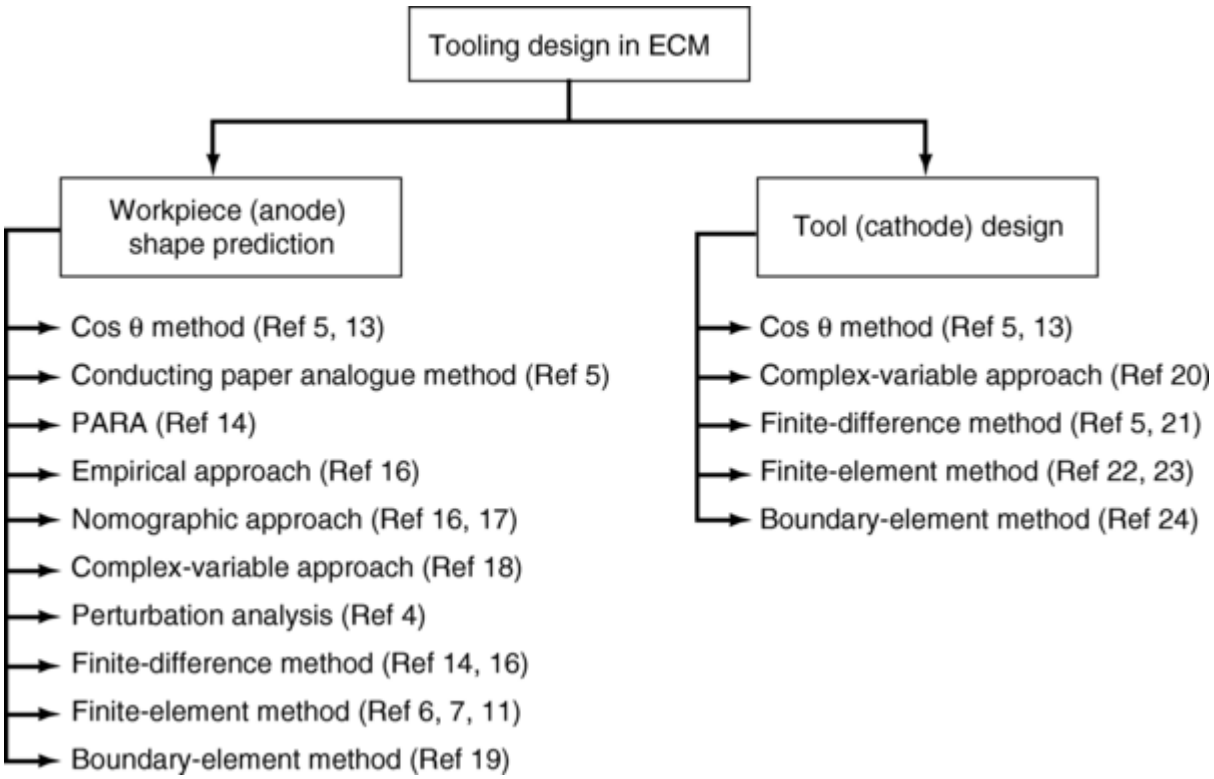

Fig. 7 Various proposed models for anode shape prediction and tool design in ECM

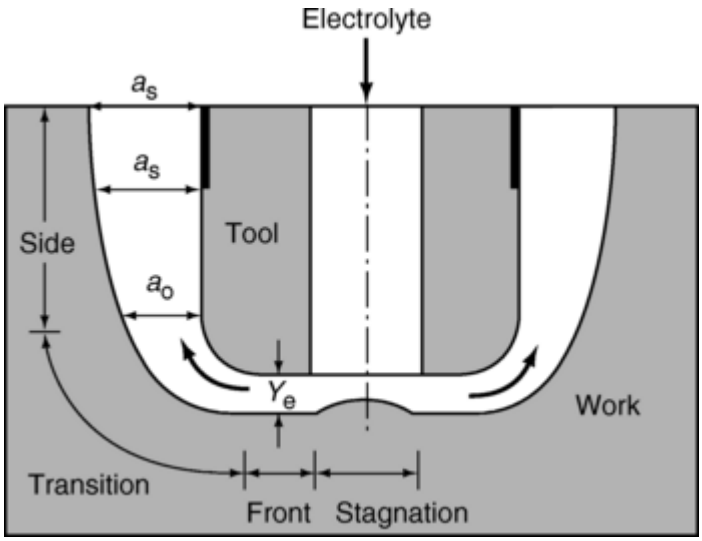

Fig. 8 Diagram of electrochemical drilling with outward mode of electrolyte flow showing various zones. a_s, side gap

Techniques for workpiece shape prediction require the use of high-speed computers. In cos θ method (Ref 5), equilibrium shape is computed corresponding to a tool whose profile is approximated by a large number of planar sections inclined at different angles. If the feed direction is inclined at an angle θ normal to the tool face, the equilibrium gap is equal to (y_e/cos θ). This approach is based on many simplified assumptions and is not recommended for complex- shaped workpieces (Ref 6).

Empirical methods attempt to derive equations based on the experimental observations of IEG in the transition and side zones to predict a complete anode profile. Various models (Ref 15, 16, 29) have been proposed in terms of equilibrium gap, tool corner radius (r_c), and bare length of the tool (b_b). Nomographic methods have been proposed (Ref 17, 29) for the evaluation of side gap for the known values of y_e, r_c, and b_b. Such methods have proved useful in planning an ECM operation. However, the empirical and nomographic methods cannot be generalized and are valid only for the specified machining conditions, tool and work material combination, and type of electrolyte.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

More complicated problems may require Laplace's equation to be solved to determine the operating potential, *V*, by numerical methods such as finite-difference method (Ref 14), finite- element method (Ref 11), or boundary-element method (Ref 19). The procedure followed to solve such problems is:

- The electric field potential at different points is calculated by solving Laplace equation using one of the numerical methods.
- Using the field-distribution data, current density is calculated.
- With the help of Eq 21, temperature distribution in the IEG is evaluated, and it is used to modify the electrolyte conductivity.
- The interelectrode gap is computed using Eq 18 at different points in the domain of interest to predict the anode shape.

Tool Design

Electrochemical machining tools used to be produced by experienced and skilled toolmakers using mostly hand finishing. Nowadays, computer-controlled machine tools can produce ECM tools more accurately while reducing time and cost.

Tool design involves the computation of tool shape and size, which would produce a workpiece having the desired shape, size, and accuracy when machined under the specified machining conditions (Ref 2, 12, 13, 14). Tool-design problems are still difficult to solve. Cumbersome and expensive, “trial-and-error” philosophy is often exercised on the shop floor. Several attempts have been made to develop a useful tool- design model (Fig. 7) (Ref 13, 20, 21, 22, 23, 24, 25, 27). The cos θ (Ref 13) method has been developed for designing cathode shape, but it has many limitations. The complex variable technique (Ref 20) is applicable only for simple shapes and is unable to tackle discontinuities of work and tool surfaces. The boundary-element method (Ref 24) has also been employed for the solution of tool-design problems.

A correction-factor method using finite-element analysis has been proposed (Ref 22, 23) for one- and two-dimensional tool-design problems. The concept of correction factor has been applied to modify the tool shape in each cycle of computation. The tool-shape-modification process continues until the difference between the work shape obtainable by the designed tool and the desired work shape is well within the specified tolerances.

The tool-design procedure involves five major steps:

1. Using the anode shape prediction model (based on finite-element analysis), the anode profile is estimated for an assumed (or modified) tool shape and specified machining conditions. The initial tool shape is assumed to be complementary to the workpiece shape.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

2. The computed and the desired work shapes are compared, and the difference between the two is evaluated as an error.
3. If the error is more than the specified tolerance value, a correction factor is calculated.
4. The tool shape is modified by applying the correction factor.
5. Steps 1 to 4 are repeated until the desired tool shape is achieved.

This concept of correction factor can be applied to other tool-design models employing finite-difference or boundary-element technique.

Figure 9 shows the computed work shape and the work shape obtained experimentally for a bit- type tool. The difference between the experimental and the computed work shapes at the top of the drilled hole is due to the effect of stray- current attack and was not incorporated in the present model. The difference between the designed tool shape and the used tool shape is attributed to inaccuracy in the anode shape prediction model and the measurement of overcut in the transition zone. Obtainable anode shapes indicate that to achieve taper-free cavities, either insulated or a bit-type tool should be used. Overcut and taper are governed by the bare part of the tool (b_b).

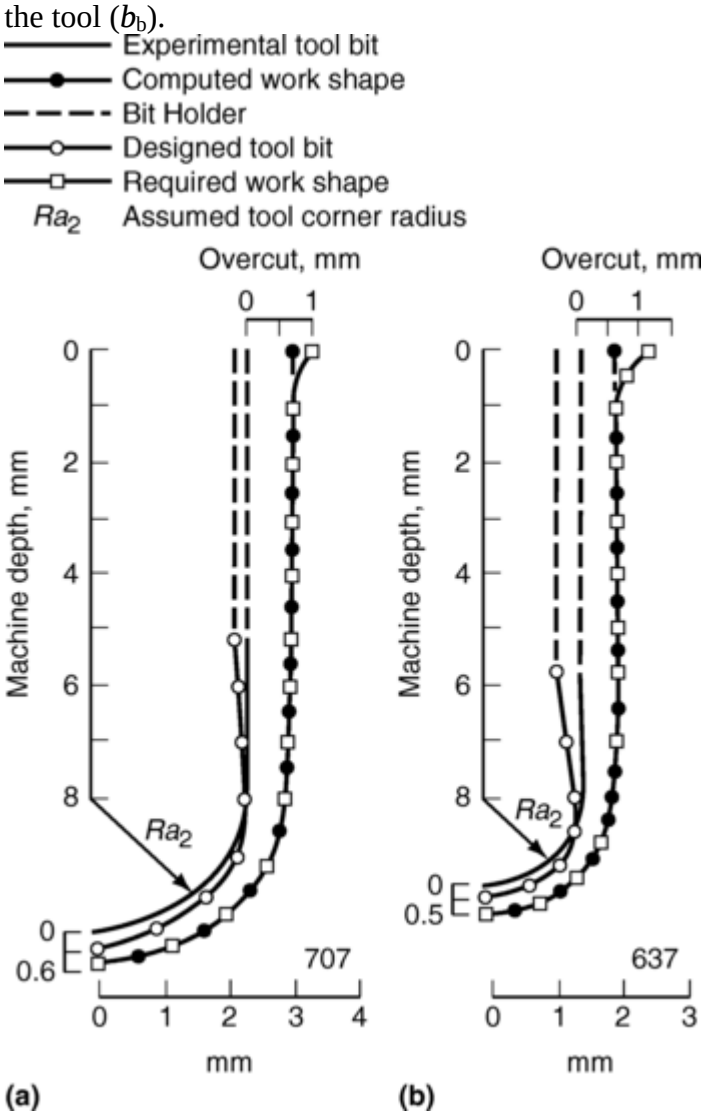

Fig. 9 Comparison of experimental and designed tool profiles used during electrochemical bit drilling, feed rate, f = 0.037 mm/min, electrolyte conductivity, k = 0.0007 Ω^{-1}/mm. (a) E_v = 6.54 V, r_t = 6.03 mm, r_{tc} = 2.39 mm, b_b = 5.22 mm. (b) E_v = 7.64 V, r_t = 5.50 mm, r_{tc} = 1.50 mm, b_b = 3.80 mm. Source: Ref 22

Different modes of electrolyte flow are shown in Fig. 10. Sudden changes in flow direction may lead to stagnation resulting in striations, ridges, or protuberances on the workpiece. This predicament can be resolved by having more than one hole (or slot) in the tool to deliver electrolyte to the IEG, but sometimes it is necessary to conduct an additional ECM operation to get rid of these irregularities.

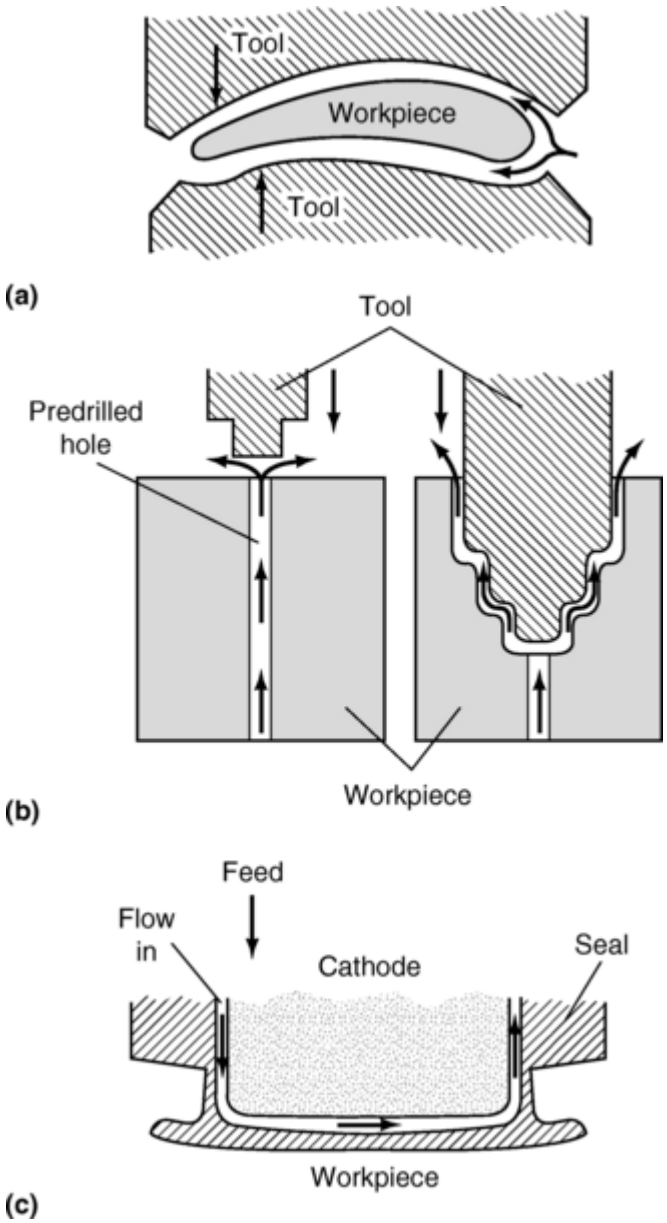

Fig. 10 Tools for electrochemical machining. (a) Dual external-cutting tool for a turbine blade, cross-flow type. Special fixtures are to confine electrolyte flow. (b) Tool for sinking a stepped-through hole with electrolyte entering through predrilled hole in the workpiece. (c) Cross-flow tool used to generate ribs on a surface without leaving flow lines on the part. Electrolyte is fed down one side, across the face, and up the second side. Source: Ref 2

Insulation is important to control the electric current. The insulating material should have high electrical resistivity, low (or no) water absorption, chemical resistance to the electrolyte, wear resistance, and resistance to heat at high working temperatures (200 °C, or 400 °F). It should be smooth and uniform in thickness (≥0.05 mm, or 0.002 in.). Preformed insulation can be shrink fitted with adhesives. At low electrolyte flow rates and low current density, materials like Teflon, epoxy, urethane, phenolic, and powder coating work satisfactorily. Tools with such insulation have enough life if the tool has a lip to protect the insulation from the flow force of the electrolyte. Sprayed or dipped epoxy resins are among the most effective insulating materials. Nylon, acetal, and fiberglass reinforced epoxy give better insulation.

Integrated Approach for Tool Design in ECM

The present status of tool design in ECM results in low productivity, high response time to the product changes, high lead and delivery times, and high overall cost. In the future, ECM activities will be integrated by employing the capabilities of high-speed computers. This would result in integration of computer-aided design (CAD) with process planning, including computer simulation and its testing, and finally computer-aided manufacturing (CAM). An attempt for such integration would lead to enhanced productivity, higher material and equipment utilization, and better consistency and quality.

When machining complicated components, it is not always possible to complete the machining process from raw material to the finished component in a single step (Ref 30). When a large amount of material is to be removed, or very high accuracy is required, the machining should be planned in two or more stages, rough and finish machining, as is done in conventional machining. The rules must be developed for the quantity of material left for finish machining so that the desired accuracy can be achieved with minimal cost (Ref 31). Sometimes machining may involve different types of ECM operations, such as die sinking, grinding, or wire cutting. Some components may need electric-discharge machining or conventional machining. The proper

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

sequence of these operations is important. Figure 11(a) shows high-velocity electrolyte impinging on a previously machined surface that could result in corrosion and product rejection. Figure 11(b) shows ECM in proper sequence of the same component (Ref 30).

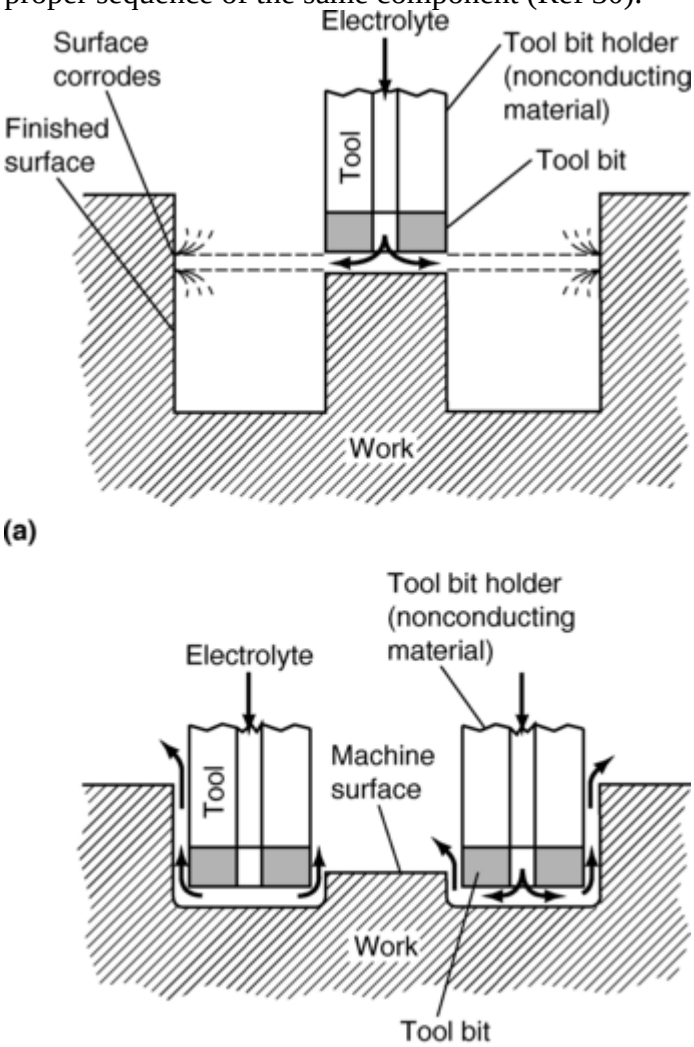

Fig. 11 Sequence of operations. (a) Improper sequencing would result in unwanted corrosion. (b) Proper sequencing where the center was machined first. Source: Ref 30

The integrated ECM process planning (Ref 31) scheme has three components: system input, optimization, and process simulation.

System input provides all the relevant data and initial information necessary to design the tool, validate the designed tool, and plan the machining of components.

Optimization of machining parameters (electrolyte flow velocity, voltage, and feed rate) must be established. This can be done by multicriteria optimization (Ref 32) rather than by single-objective optimization. In multicriteria optimization of ECM process, a linear goal programming technique is employed using geometrical accuracy, material-removal rate, and tool life as objective functions. Temperature, passivation, and choking are used as constraints. Voltage, feed rate, and electrolyte flow velocity are considered design variables. According to rough or finish machining, objective functions are assigned priorities and weights. For example, in finish machining, accuracy would have first priority and metal-removal rate second. This would be reversed for rough machining.

Process simulation can be used to evaluate alternative process plans and trade-offs. Process simulation is used to reduce lead time, lower cost, increase product quality, and provide a better understanding of the process (Ref 33). Simulation of the ECM process will significantly reduce and, in some cases, eliminate the iterative process of full-scale testing of tools before releasing them for actual production by the machine shop (Fig. 12).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

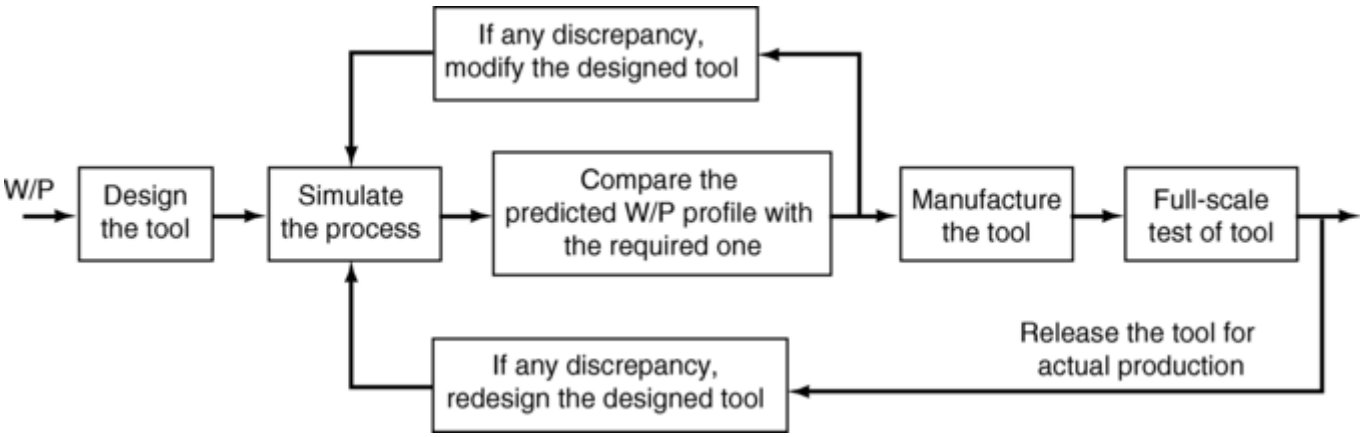

Fig. 12 Proposed procedure for designing and testing a tool for ECM. Workpiece (W/P). Source: Ref 25

A finite-element simulator for the ECM process generates an element mesh from the stored graphic description of the part. The finite-element nodes, elements, and boundary conditions are submitted to the simulation analysis program. A postprocessor or graphic output display of the results exhibits the expected and desired workpiece profile and the designed tool profile. The process plan displays the machining parameters, electrolyte and its concentration, the code of the selected machine tool, and the names and sequence of operations. Figure 13 shows a typical ECM process-simulation plan.

Process Capabilities and Limitations

Electrochemical machining can machine highly complicated and curved shapes in a single pass. Tool life is very high so a large number of pieces can be machined by the same tool. Machinability of work materials is independent of physical and mechanical properties. Machined surfaces are stress and burr free with good surface finish. Scrap production and overall machining times are reduced.

Electrochemical machining also has limitations. Accuracy of the machined component depends on tool design, degree of process control imposed, and complexity in the shapes produced. Machining of materials containing hard spots, inclusions, sand, and scale present some practical difficulties. Electrochemical machining cannot produce sharp corners and edges.

The roughness of the machined surface is controlled mainly by local current density. High current density in the front gap produces low values of surface roughness. The best surface roughness varies between 0.1 and 1.0 μm (0.004 and 0.04 mil), while low value of current density in the side gap results in the high values of surface roughness (may be as rough as 5 μm or more). Variables affecting local current density ultimately affect surface roughness.

The usual accuracy achievable in ECM is approximately ±0.013 mm (±0.0005 in. 0.005 in.) and ±0.25 mm (±0.010 in.) in front and side gaps, respectively. The best tolerance that can be achieved is ±0.025 mm (±0.001 in.), internal radius as 0.8 mm (0.030 in.), external radius as 0.5 mm (0.020 in.), 0.001 mm/mm (0.001 in./in.) as taper, and 0.05 mm (0.020 in.) as overcut.

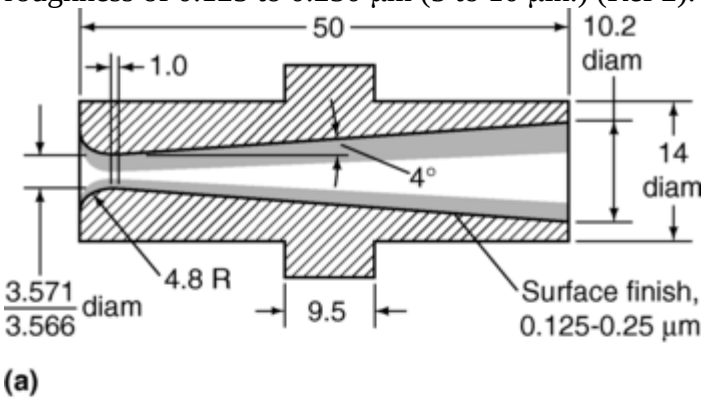
Application Examples

www.iran-mavad.com

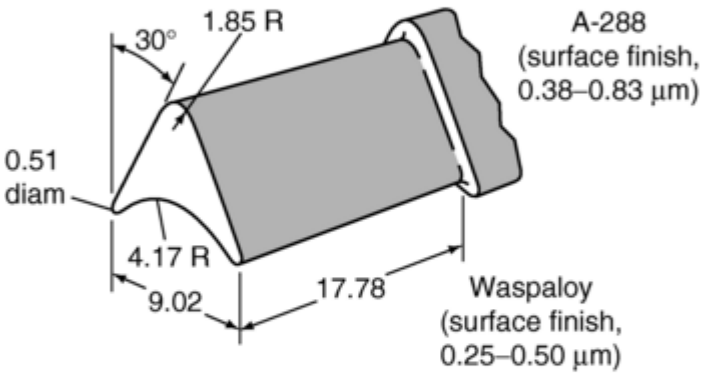
مرجع مهندسی مواد و متالورژی

It has been reported (Ref 12) that cost advantage of the ECM process over conventional machining varies from 4 to 1 to 9 to 1.

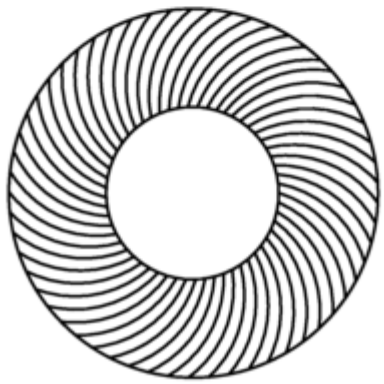
Example 1: ECM of a Stainless Steel Nozzle. A nozzle (Fig. 14a) is made from a 316 stainless steel tube using a machine that could provide maximum current of 500 A, voltage ≤ 24 V. A copper tool was fed into one end of the tube to make conical-shaped hole. The initial current was 20 A (voltage = 17 V) and ended with the current as 310 A. Electrolyte used was NaCl (0.12 kg/L, or 1 lb/gal, of water) at 27 °C (80 °F) and 550 kPa (80 psi) pressure. Feed rate of 5.8 mm/min (0.25 in./min) took a total of 7.6 min to produce the nozzle with a surface roughness of 0.125 to 0.250 μm (5 to 10 μin.) (Ref 2).



(a)



(b)



(c)

Fig. 14 Examples of applications. (a) Finishing a conical hole in a nozzle. (b) Contouring a turbine blade surface. (c) Cutting spiral grooves in a friction plate. Source: Ref 2

Another copper tool was used to machine the radius at the other end of the hole. Parameters used were: current varied from 20 to 220 A, f = 2.5 mm/min (0.100 in./min), total machining time = 2.00 min, penetration depth = 4.95 mm (0.19 in.), and internal finish obtained = 0.125 to 0.25 μm (5 to 10 μin.) (Ref 2).

Example 2: ECM of a Turbine Blade. The turbine blade (Fig. 14b) made of heat-resistant alloy (A-286 alloy) was machined by ECM that could provide maximum current of 5000 A at 2 to 20 V dc. A tool was made of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

copper-tungsten alloy. The $NaNO_3$ electrolyte (0.26 kg/L, 2.2 lb/ gal of water) at 43 °C (110 °F) was employed. Other parameters were:

- Current = 100 to 170 A
- Pressure = 900 to 1400 kPa (130 to 205 psi)
- Flow rate = 7.6 L/min (2 gal/min)
- f = 7.6 mm/min (0.3 in./min)

The surface roughness achieved was 0.38 to 0.63 μm (15 to 25 μin.) (Ref 2).
Example 3: ECM of Spiral Grooves in a Friction Disk. Seventy-two equally spaced spiral grooves (Fig. 14c), 0.38 mm (0.015 in.) deep and 1.0 mm (0.040 in.) wide were made in a friction disk (1020 steel, 60 to 75 HRB) using ECM machine, which could provide maximum current, $I \approx$ 600 to 650 A, voltage = 20 V, electrolyte → NaCl (0.15 kg/L, or 1.25 gal/lb of water), T = 30 to 32 °C (85 to 90 °F), P = 690 kPa (100 psi), electrolyte flow rate = 40 L/min (10 gal/min), f = 1.3 mm/min (0.050 in./min).

Introduction

SPECIFIC MACHINING PROCESSES that employ electrochemical machining (ECM) technology include deburring, and deep-hole drilling. The principles of electrochemical machining are presented in the article “Electrochemical Machining” in this Volume. This article shows the applications of ECM to specific processes and discusses a variation of the steady-state process, pulse machining.

Electrochemical Deburring

A designer usually considers aspects of a component such as material, form, dimensional accuracy, surface texture, and heat treatment, but perhaps not the surface integrity and edge quality (Ref 1). These last two factors are important aspects for the performance and life of a product, however.

When a component is processed by a conventional machining method, it is usually left with burrs along intersecting surfaces. Such burrs are unwanted and could be a hazard when handling the component, but they can be removed by one of several deburring processes.

In modern industrial technology, the deburring process has attained considerable importance because of stringent quality standards. Presence of burrs on a component affects its functional, physiological, and aesthetic requirements (Ref 2). Burrs create a hindrance in assembly, they may degrade corrosion preventive or aesthetic coatings, and loosened burrs may result in excessive wear of the sliding or rolling surfaces. Different types of burrs are listed in Table 1 (Ref 3).

Table 1 Types of burrs formed during different manufacturing methods

Type of burr	Schematic	Remarks
Compressive burr		The burr produced in blanking and piercing operations in which slug separates from the parent material under compressive stress
Cutting-off burr		A projection of material left when the workpiece falls from the stock
Corner burr		Intersection of three or more surfaces
Edge burr		Intersection of two surfaces
Entrance burr		Cutting tool enters in the workpiece
Exit burr		Cutting tool exits the workpiece
Feather burr		Fine or thin burr

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Flash burr		Portion of flash remaining on the part after trimming
Hanging burr		Loose burr not firmly attached to the workpiece
Rollover burr		Burr formed when it exits over a surface and allows the chips to be rolled away

Source: Ref 3

Deburring processes can be mechanical, abrasive, thermal, chemical, and electrochemical. Mechanical deburring using brushes or scrapers is unreliable and is a burr-minimizing process, which does not meet the requirements of high edge quality. The abrasive deburring processes (tumbling, sand blasting, or vibratory) have low reliability, poor uniformity, low metal removal rate, and tend to charge the workpiece with grit. In thermal deburring, the deburring chamber temperature is about 3500 °C (6330 °F), which burns out burrs and sharp edges on the component. In chemical deburring, burrs are dissolved in a chemical medium. In electrochemical deburring (ECD), the principle of anodic dissolution is applied to dissolve the burrs.

Electrochemical deburring works on the same principle as ECM. The tool is either insulated on all surfaces except the part that is adjacent to the burrs, or a bit type of tool is used (Ref 4). The tool tip (or bit) should overlap the area to be deburred by about 1.5 to 2.0 mm (0.06 to 0.08 in.). Electrochemical deburring is useful for burrs located in inaccessible areas where other deburring processes are not effective (Ref 5, 6). In ECD, the magnitude of current and electrolyte flow rate are lower than ECM. Secondly, the tool is stationary (Fig. 1). The current magnitude and its duration of flow to suit a particular component are determined by trial. The commonly used electrolytes are NaCl and $NaNO_3$. The interelectrode gap (IEG) is usually in the range of 0.1 to 0.3 mm (0.004 to 0.012 in.). A deburred steel component shows a localized deposit (Fe_3O_4— dark gray and ≤1 μm, or 4×10^{-6} in., thick) that is a reaction product of the process. This deposit is conductive and disappears during heat treatment of the components.

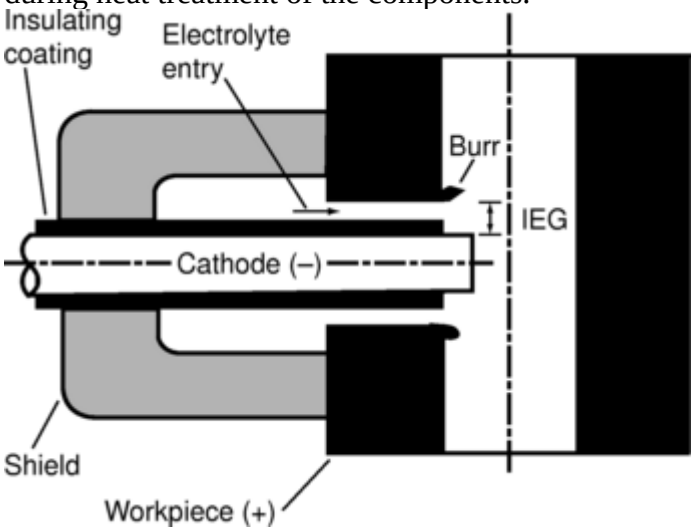

Fig. 1 Electrochemical deburring at the intersection of two holes

Machine tools for ECD are usually designed with multiple work stations served from a single power supply. Their elements and functions are the same as those of ECM tools except for the tool-feed system. Before applying ECD for a particular type of job, the thickness, shape, and repeatability of the burrs on the parts must be known. The more uniform the shape and size of the burrs, the more efficient the burr-removal operation. Further, the tool head that dissolves the burrs should be shaped as a replica of the contour of the work. Portable ECD units equipped with 50 A power supplies (Ref 4) are also available and are useful to deburr tubes and pipes of varying configuration, length, and cross- sectional area.

Applications in consumer appliances, biomedical, aerospace, and automobile industries include gears, splines, drilled holes, milled components, fuel supply and hydraulic system components, and intersecting holes in crankshafts (Ref 2).

Apart from economics, ECD gives higher reliability, reduced operation time, more uniformity, and it can be easily automated. Deburring components takes about 45 to 60 s cycle time on a 500 A machine. The hydroxides

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

removed during ECD can be safely used as a raw material for the lapping paste. The components should be thoroughly washed before deburring, and properly cleaned after deburring (Ref 2).

Electrochemical Deep-Hole Drilling

Deep small holes are required in many applications, such as turbine rotor and stator assembly for cooling, crankshaft oil holes, holes in fuel- injection nozzles, and holes in spinnerets. The principle of anodic dissolution has been applied for making such small-diameter deep holes in hard-to-machine materials. This process is also known as shaped-tube electrolytic machining (Ref 7). This process basically differs from conventional ECM in two aspects: either a mixture (neutral salt and acidic electrolyte) or acidic electrolyte is used, and a coated tubular cathode is used. The mixture or acidic electrolyte is added to circumvent the production of insoluble precipitate (sludge) during conventional ECM, which inhibits machining process by obstructing the flow path of the electrolyte. The coated tubular cathode controls the magnitude of overcut. Certain minimum overcut is desirable to serve as a return path for the electrolyte (Ref 8). If acid (HCl, H_2SO_4, or HNO_3) is used as electrolyte, then periodic reversal of the polarity for a very short duration of time (5–10 s) is essential to remove any film built up on the cathode.

Such reversal is usually not required if a mixture of the electrolytes is used (Ref 7, 8, 9). Simultaneous drilling of many holes is possible (Ref 7, 9). A modern air-pressure turbine rotor and stator assembly may have 20,000 cooling holes having diameters ranging from 1 to 4 mm (0.04 to 0.16 in.) and aspect ratios of 40 to 200. The rotor blades are subjected to high stresses, very high temperature and vibration, and are made of difficult-to-machine superalloys. Analysis of the data in Table 2 (Ref 8) indicates that laser-beam machining and electron-beam machining cannot be used because of upper limit of thickness of the workpiece (only 18 mm, or 0.7 in., or so) that can be drilled. Electrical discharge machining (EDM) suffers in comparison with electrochemical deep-hole drilling due to relatively lower aspect ratio, shallower depths, poorer surface finish, and surface integrity.

Other applications of deep-hole drilling include: oil passages in bearings where EDM will cause microcracks, fuel nozzles, and starting holes (depth ≥100 mm, or 4 in.,) for wire EDM. One of the major problems of deep-hole drilling is loss of electrolyte pressure upon breakthrough of the bottom of the workpiece. This problem has been successfully resolved by the use of thin, dummy workpieces at the bottom. Use of dummy workpiece (Fig. 2) at the top surface of the workpiece overcomes the problem of nonuniform diameter at the tool entry side due to stray cutting.

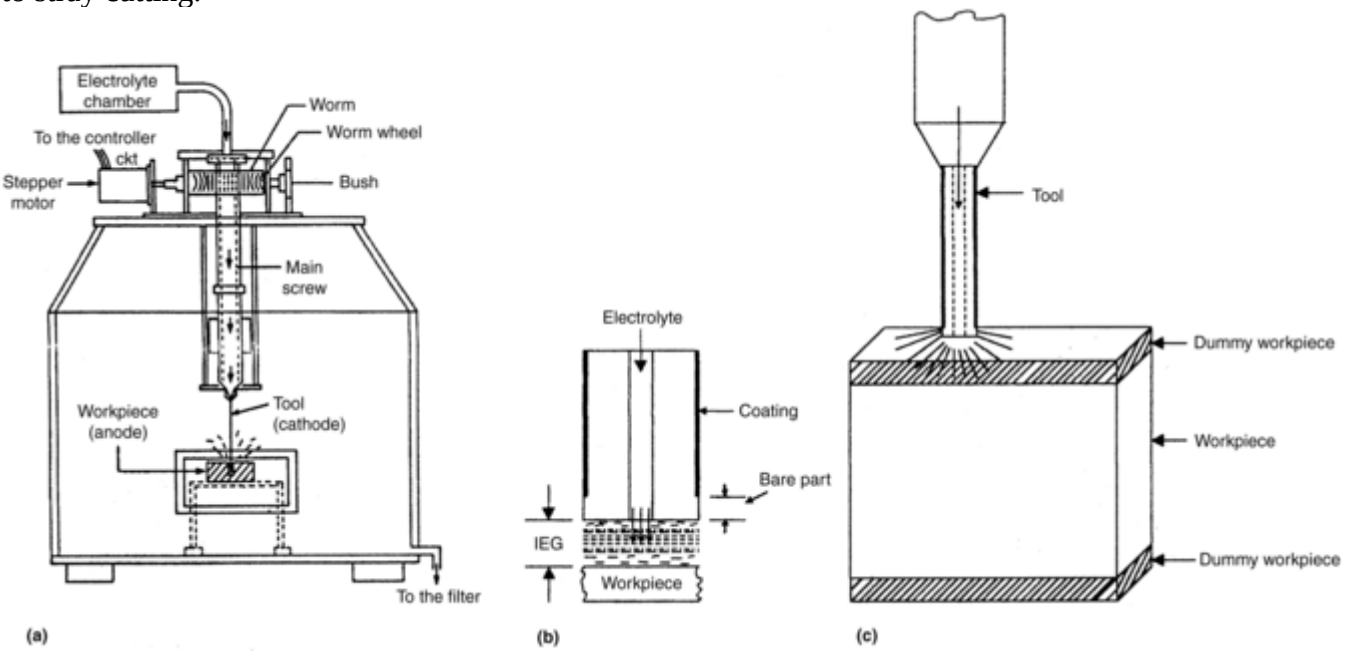

Fig. 2 System for electrochemical deep-hole drilling. (a) Equipment. (b) Enlarged view of tool and workpiece. (c) Dummy workpiece and tool. Source: Ref 8

The electrochemical deep-hole drilling system shown in Fig. 2 includes four subsystems: power supply, tool and tool feed, electrolyte cleaning and supply, and workholding and machining chamber.

The power supply subsystem gives comparatively low direct current at 5 to 20 V (between electrodes). The available current will limit the number of holes being drilled simultaneously; typically, 40 A/hole is required.

The cathode is tubular and is made of the same materials used in ECM tools. It has an insulation coating throughout its length except a small bare part (Fig. 2). Increase in the length of the bare part of the tool will

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

increase overcut, which will reduce the required pressure to pump electrolyte through the side gap. Pure titanium tubes coated with an appropriate resin are commonly used. The bare part of the cathode tip should have a slightly larger diameter than the diameter of the coated cathode for increased tool life.

The straightness of the tool is most critical, and it should be checked periodically. Cathode guides should also be provided to minimize tool wandering. Feed rate to the tool varies over a wide range: 0.76 to 2.00 mm/min (0.03 to 0.08 in./min) depending on the machining conditions and electrolyte conductivity in IEG.

The electrolyte system consists of a pump capable of supplying electrolyte in IEG at a pressure of 60 to 300 kPa (8.7 to 43.5 psi) and quantity 20 to 150 cm^3/min (1.2 to 9.2 $in.^3$/min). It also consists of filters and heat exchanger. The machining chamber should be well closed to eliminate spattering of the electrolyte. It should also have an exhaust fan to remove hydrogen gas from the machining and nearby area.

The workpiece holding fixture is usually made of electrically nonconducting materials such as acrylic plastics. The workpiece is a conducting material and is connected to the direct-current (dc) power supply.

Process capabilities. Hole diameter usually lies between 0.5 to 2.5 mm (0.02 to 0.1 in). Highest aspect ratio claimed is 300 to 1 (hole tolerance in diameter ±5%), and surface roughness may lie in the range of 0.8 to 3.2 μm (32 to 125 μin.). The machined component is stress- as well as burr-free. The hole wander ranges from 0.001 to 0.003 mm/mm. The axes of the holes drilled by this process need not be vertical to the workpiece surface and can have inclination as high as 20°.

Pulse Electrochemical Machining

During ECM, anodic dissolution takes place continuously throughout the process. As a result, a large amount of heat and gas bubbles are generated that should be dissipated from the interelectrode gap as fast as possible. For this purpose, a high-pressure pumping system is required so that the electrolyte flows at very high velocity in IEG. In turn, a heavy machine-tool structure is essential to maintain the rigidity against high hydraulic forces.

To moderate the aforementioned requirements associated with high-velocity electrolyte flow, researchers (Ref 10), have suggested the use of pulsed direct current in ECM, shown in Fig. 3(a). The period of the pulse (t_p) consists of an on- time (t_{on}) with high instantaneous current density and an off-time (t_{off}) when the system dissipates heat and pumps out the by-products produced during on-time. During pulse ECM, the IEG is usually less than or equal to 0.1 mm (0.004 in.), which yields better accuracy of the machined component than if the IEG were larger. In pulse ECM, the IEG distribution in the direction of electrolyte flow is more uniform. Further, the gradients of temperature, gas concentration, and conductivity along the electrolyte flow direction

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

are smaller than those in continuous ECM. This is true particularly when shorter on-time pulses are used, which also give better accuracy and higher metal-removal rate (MRR).

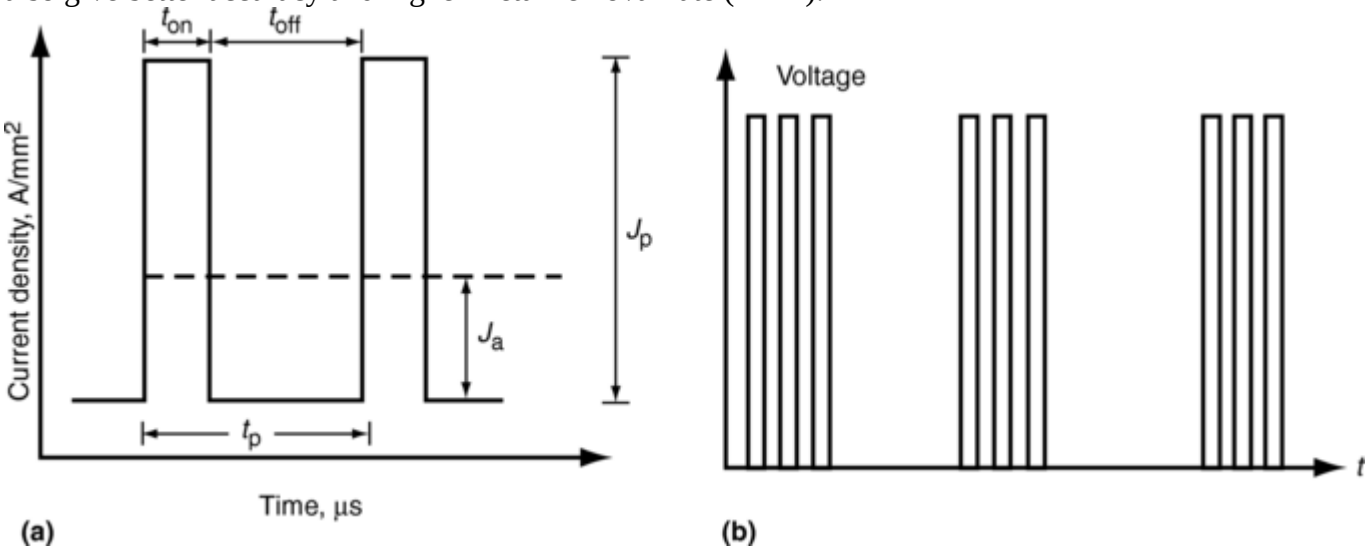

Fig. 3 Power input for pulse ECM system. (a) Current pulses. (b) Group of voltage pulses

The voltage pulses may be either in the form of single pulse (Fig. 3a) or groups of pulses (Fig. 3b) depending on the pulse-generator design. The effects of electrolytic flushing may be increased by retracting the tool from the workpiece during the pulse off-time, thus enlarging IEG while the system is at rest (Ref 11).

The peak current density (J_p) (Fig. 3a) and the duty cycle (t_{on}/t_p) can be independently controlled for regulating process performance. The average current density (J_a) is:

$$J_a = J_p(t_{on}/t_p) \qquad \text{(Eq 1)}$$

where $t_p = t_{on} + t_{off}$.

Electrolyte heating takes place during on-time and results in the instantaneous temperature change (ΔT_p) and average temperature change (ΔT_a). If only ohmic heating is considered, ΔT_p can be calculated as:

$$\Delta T_p = J_p^2 t_p \Big/ \left(k\rho_e C_p\right) \quad \left(\text{for } t_p \ll L/u\right) \qquad \text{(Eq 2)}$$

where k, ρ_e, and C_p are specific conductivity, density, and specific heat of electrolyte, respectively. L is electrode length, and u is electrolyte flow velocity. To remove all of the heated electrolyte from IEG between the consecutive pulses, t_{off} should be greater than L/u. Then:

$$\Delta T_a = J_a^2 L \Big/ \left(k\rho_e C_p u\right) = J_p^2 \left(t_{on}/t_p\right)^2 L \Big/ \left(k\rho_e C_p u\right) \qquad \text{(Eq 3)}$$

The pulse generator used has voltage as high as 100 V, current pulse of 100 A, frequency 0.5 to 5 kHz, and low duty cycle.

It has been reported (Ref 10) that during pulse ECM, metals can be dissolved at very high instantaneous current density (300 A/cm^2) with good surface finish and high metal dissolution efficiency (~100%) with comparatively low electrolyte flow velocity. The average current density is very low (3 A/cm^2), too small for industrial shaping operations but good enough for finishing operations. At low electrolyte flow velocity, electrolyte heating may lead to sparking due to the presence of large gas bubbles.

Theoretically, it has been found that the IEG variation during pulse ECM is more uniform than that in continuous ECM. For better performance of the ECM, small gap size should be accompanied by shorter pulse on-time.

The pulse ECM system has applications in automobile, aerospace, and die-making industries.

Electrochemical Hybrid Processes

V.K. Jain, Indian Institute of Technology at Kanpur (India)

Introduction

HYBRID PROCESSES are those in which two or more machining processes are combined to take advantage of the worthiness of each. For example, conventional grinding produces components with good surface finish and dimensional tolerances, but such components may have burrs, comparatively large heat-affected zones, and thermal residual stresses. Such weaknesses are not found in electrochemically machined (ECM) components. Hence, a hybrid process, electrochemical grinding (ECG), was developed, in which about 10% of the total material is removed by mechanical abrasive action while the remaining 90% is removed by anodic dissolution. In the same way, other processes like electrochemical spark machining (ECSM) (for electrically nonconducting materials), electrochemical arc machining (ECAM), and electrochemical spark grinding (ECSG), have been developed to achieve the end products with the desired dimensional and surface characteristics. Here, only ECG is discussed.

Electrochemical Hybrid Processes

V.K. Jain, Indian Institute of Technology at Kanpur (India)

Electrochemical Grinding

As in other anodic dissolution processes, the workpiece is electrically conductive. The workpiece is usually made of a difficult-to-machine alloy, heat treated hard (≥60 HRC) material, or thermosensitive material. Electrochemical grinding gives stress- and burr-free components with smooth surface finish. The working principle of ECG is illustrated in Fig. 1 in which the grinding wheel (cathode) is similar to a conventional grinding wheel, except that the bonding (or matrix) material is electrically conductive (metal). Electrolyte is supplied through an interelectrode gap (IEG) between the wheel and the workpiece. Electrolyte is recirculated, so an effective supply and filtration system is needed. The commonly used electrolytes are sodium chloride (NaCl) and sodium nitrate ($NaNO_3$).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

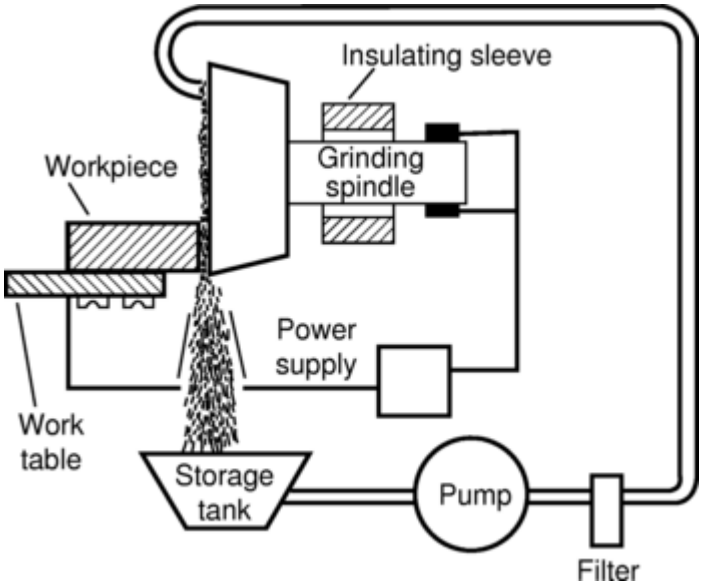

Fig. 1 Schematic of electrochemical grinding components

Abrasive particles protruding from the bonding material in the wheel help maintain a constant IEG as the particles act as spacers. The service life of the ECG wheel is about ten times that of the conventional grinding wheel because only 10% of the total removal is by abrasive action, and length of the contact arc is small.

Surface speed of the wheel ranges from 1200 to 1800 m/min (3900 to 5900 ft/min). The depth of cut is usually less than 2.5 mm (0.1 in.) and is limited by the wheel contact arc length, which should never exceed 19 mm (0.75 in.); otherwise, the electrolyte becomes ineffective because of higher concentration of H_2 gas bubbles and sludge (Ref 1).

In ECG, the area in which machining takes place can be divided into three zones (Fig. 2). In zone I, material removal is due to electrochemical dissolution that occurs at the leading edge of the ECG wheel. Rotation of the ECG wheel helps draw electrolyte into the IEG. As a result of electrochemical reaction in zone I, reaction products (including gases) contaminate electrolyte and change its conductivity. The presence of sludge, to some extent, increases conductivity of electrolyte (Ref 2), while the presence of gases decreases it. The net result is usually a decrease in the conductivity of the electrolyte in the direction of flow, resulting in a smaller IEG. As a result, abrasive particles touch the workpiece surface and start removing material by abrasive action. Thus, part of the material removed is in the form of chips. Further, electrolyte is trapped between the abrasive particles and the workpiece surface, and it forms a tiny electrolytic cell as shown in Fig. 2. In each electrolytic cell, a small amount of material from the workpiece is electrochemically dissolved.

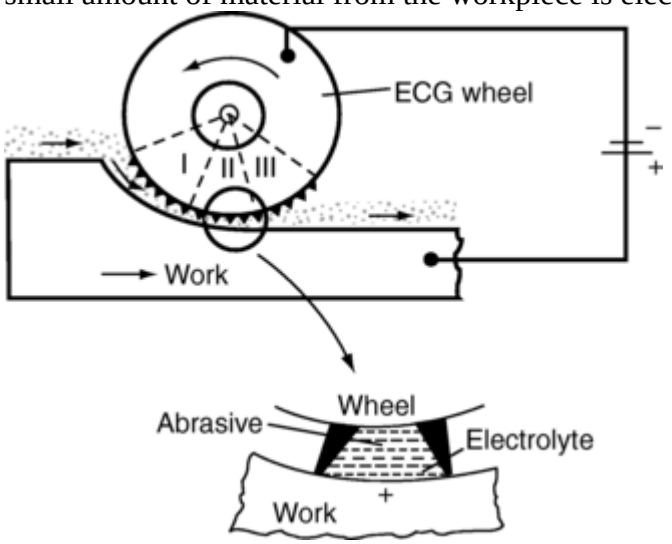

Fig. 2 The three working zones (I, II, III) are shown. Mechanism at work in each is detailed in the text. Tiny electrochemical cell formation in ECG is shown in the insert.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The electrolyte is forced into the IEG in zone II by rotational motion of the ECG wheel. Local electrolyte pressure increases, which suppresses formation of gas bubbles in the gap, yielding a higher metal-removal rate. Chemical or electrochemical reaction may result in the formation of a passive layer on the workpiece surface. In zone II, abrasive grains remove metal and the nonreactive oxide layer. Most of the metal oxides formed are insoluble in water and electrically nonconductive. Removal of the nonreactive oxide layer by protruding abrasive particles helps in electrolytic dissolution, exposing fresh metal for further electrolytic action. Hence, this process is also called mechanical assisted electrochemical grinding (Ref 3).

In zone III, material removal is totally by electrochemical dissolution. Zone III starts at the point where the ECG wheel lifts off the work surface. Pressure is released slowly. In this zone, scratches or burrs that might have formed on the workpiece in zone II are removed.

Five different kinds of ECG operations can be performed: (a) electrochemical (EC) cylindrical grinding, (b) EC form grinding, (c) EC surface grinding, (d) EC face grinding, and (e) EC internal grinding. Electrochemical cylindrical grinding is the slowest process because of the limited contact area between the wheel and the workpiece. Electrochemical face grinding is the fastest process, as it has the largest contact area between the anode and the cathode. In EC surface grinding, the workpiece reciprocates, which controls uneven wear on the wheel. Electrochemical internal grinding and EC form-grinding operations are similar to the conventional internal and form-grinding operations.

Electrochemical Hybrid Processes

V.K. Jain, Indian Institute of Technology at Kanpur (India)

The ECG Machine Tool

The ECG system is very similar to a conventional grinder. Machine tools for ECG may be either vertical- or horizontal-spindle types. Such machines can be used for internal as well as external EC grinding. Table feeds should be designed so that there is no slip-stick effect on the table or sliding when the motion is slow. The basic elements of the ECG machine tool are power supply, EC grinding wheel, feed system, cleaning system, and workpiece.

Power supply for ECG is usually 0 to 25 V (but the system usually operates below maximum levels 15 V to avoid sparkover). Current levels are up to 1000 A (with upper limit of 3000 A). It is advantageous to minimize current ripples.

The probability of short circuiting during ECG is very low because of the presence of the protruding abrasives, which create a positive IEG. There is less need to have short circuit cut- off devices in this system.

Wheels for ECG are made of abrasive particles, such as Al_2O_3 or diamond, a bonding agent (usually resin), and a conductive medium like copper. The particle size of the abrasive varies over a wide range (60 to 320 mesh number). The diamond wheel, with either metal bond or resin bond, is used for grinding heat treated steels with

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

hardness ≥60 HRC, carbides, and stellite. It is sometimes recommended that the diamond grit (Ref 4) should be blocky, to burnish the oxide residue from the workpiece, rather than sharp, to abrade.

Formed wheels are also used in ECG. Such wheels can be dressed by a single point diamond dresser or by reversing the wheel polarity. Since physical abrasion of the workpiece material is less, the ECG wheel retains its form for a much longer period than a conventional formed grinding wheel (4 to 8 hr before dressing). During dressing, not more than 0.025 mm (0.001 in.) per pass of material is removed with a cross feed of 300 to 380 mm/min (12 to 15 in./min. The wheel spindle must be electrically insulated from the rest of the machine (Ref 5).

The protruding abrasive grains on the wheel serve three important functions: (a) for abrasive action; (b) for tiny cell formation; and (c) as a spacer between electrodes. The electrolyte nozzle must ride against the wheel and be angled to break the air layer and allow the electrolyte to be absorbed into the cavities that exist around the grit.

In ECG, the rotating grinding wheel is only partially immersed in the electrolyte. It is important in ECG that the electrolyte reaches the interface of wheel and workpiece. The rotation of the wheel helps carry sufficient electrolyte into the area of contact between the workpiece and the wheel. The point at which electrolyte is applied to the wheel should be as close as practicable to the machining area. The grinding wheel speed should be such that there is neither a scarcity of fresh electrolyte nor throw from the wheel by excessive centrifugal force. The electrolyte supply should begin prior to starting the wheel rotating.

Declogging of the grinding wheel can be done by reversing its polarity (making the tool an anode) for a short period. It may, however, result in a longer machining time and degeneration of the wheel shape. During ECG, wheel-workpiece force is usually low (140 to 1400 kPa, or 0.02 to 0.20 ksi) and it depends on contact area.

Electrolytes used in ECG should be capable of forming oxide films on the workpiece to protect the surrounding metal from corrosion. This oxide film formed on the surface being machined is constantly removed by the abrasive particles to expose the nascent work surface for EC dissolution. There is no electrolyte that can be used for all workpiece materials. For ECG of tungsten, alkaline electolytes such as Na_2CO_3 or NaOH are used. Electrolytes for ECG usually have additives to provide corrosion inhibition.

Process Characteristics

Performance of ECG processes depends on various parameters such as wheel speed, workpiece feed, electrolyte type, electrolyte concentration, current density, and wheel pressure. By adjusting these parameters, the metal-removal rate (MRR) and surface finish can be varied (Ref 6).

Current Density. With higher current density, both MRR and surface finish improve. If the applied voltage is too high, it may deteriorate surface finish of the workpiece and damage the grinding wheel. The presence of such high voltage results in spark formation at the front of the wheel.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Feed Rate. If the feed rate is too high, the abrasive particles will prematurely detach from the wheel, leading to excessive wheel wear. If it is too low, a large overcut, poor tolerance, and poor surface finish will be produced. The feed rate should maintain the IEG at approximately 0.25 mm (10 mils) when a freshly dressed wheel is used. Optimal feed rate depends on current density, wheel speed, and wheel parameters. Typical parameters are feed-rate 1.9 mm/min, MRR = 1600 mm^3/min, current, I = 1000 A and current density, J = 1.2 A/mm^2.

Magnetism. The effect of magnetic fields on electrolytic grinding using diamond, SiC, and Al_2O_3 wheels has been studied (Ref 7). In the case of a diamond wheel, process performance was improved, but the same is untrue for the Al_2O_3 wheel. In the case of a SiC wheel, the improvement obtained is marginal. The magnetic field interacts with the moving charged particles and may affect the rates of both mass transport and charge transfer processes (Ref 8). The magneto-hydrodynamic force leads to stirring of electrolyte, particularly in the neighborhood of electrodes; enhanced mobility; and an increased rate of electrochemical reactions.

Temperature. ECG is a cold process (with bulk temperature <100 °C, or 212 °F), thus preventing structural damage and grinding cracks. However, electrochemically ground specimens show relatively poor fatigue strength, possibly due to stray current attack on the surface, which leaves a series of pits that would act as sites for fatigue crack initiation (Ref 9).

Process Capabilities

Metal removal achieved during ECG may be 10 times greater than for conventional grinding on hard materials (hardness ≥65 HRC). Abrasive particles maintain the electrical insulation between cathode and anode, and determine an effective gap that may be as low as 0.025 mm (1 mil). Metal removal in ECG depends on current density, abrasive type, size, electrolyte concentration, wheel speed, and metallurgical properties of the workpiece. In spite of more initial investment, the cost of EC grinding is lower than that of conventional grinding due to much higher MRR during ECG. Gedam and Noble (Ref 10) concluded that fine grits and low-concentration wheels show a tendency to draw more current and thereby achieve greater MRR than coarse grits and high concentration wheels.

For materials easily machined by conventional methods, ECG gives lower MMRs than the conventional method provides.

Surface finish obtained by ECG ranges from 0.12 to 0.80 μm. The surface produced by ECG is free of grinding scratches and burrs. Surface finish on nonhomogeneous materials during ECG is better than that produced

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

during conventional grinding. The surface finish generated in ECG also depends on the crystalline structure of the workpiece. The finer the crystalline structure, the finer is the surface finish. This process generates a surface that has the topography of a crystalline structure instead of the tool marks. Generally, the finished surface has gray to black matte finish, while in some cases it is bright.

To improve surface finish, a finish pass at low voltage and high feed rate should be made. The surface metal is burnished, with the crests of the hills being pushed into the valleys of the crystalline structure, thereby generating a smoother finish also known as sparkout pass. In this pass, selection of a proper ECG wheel with appropriate grit size and type is important because it determines the end-finish quality. Wheels of 200 to 320 grit size have been successful in finishing surgical instruments and industrial knives. Risk of thermal damage is also reduced.

Accuracy of the electrochemically ground surfaces depends on the current density, electrolyte flow rate, and metallurgical aspects of the workpiece material itself. Highly reactive metals such as alloys with high chromium content require mild electrolyte to produce low overcuts. The state of electrolyte conductivity should be monitored for good results. Achievable tolerance in ECG varies from ±0.010 to 0.025 mm (±0.4 to 1 mil) under well-controlled conditions. Achievable inside and outside corner radii during ECG have been in the range of 0.25 to 0.40 mm (10 to 16 mils) and 0.1 to 0.2 mm (4 to 8 mils), respectively. Finer grit wheels produce sharper corners but require more frequent wheel dressing because of more rapid wheel wear and form breakdown.

Workpieces have shown no evidence of hydrogen embrittlement due to H_2 evolved at the cathode. ECG produces workpieces without work hardening and grind burns.

Applications

Electrochemical grinding is economical for grinding carbide cutting-tool inserts. Microscopic study of electrochemically ground surfaces of the cemented carbide does not reveal microcracks or any other defects or damage to the microstructure. This process is also used to reprofile worn locomotive traction motor gears. Usually, wear marks from the gear tooth surfaces are removed by removing as much as 0.38 mm (15 mils) thickness of material. Electrochemical grinding does not affect gear hardness and does not impose residual stresses. The process is also used for burr-free sharpening of hypodermic needles, grinding of superalloy turbine blades, and form grinding of fragile aerospace honeycomb metals.

Electrochemical grinding of WC-Co has been reported (Ref 11). The initial specific etching rate of cobalt phase is higher than that of the WC phase. In addition to the direct dissolution of material, the electrolysis process in ECG weakens the cermet material by selective removal of cobalt. When the in-feed rate during ECG is less than the initial specific etching rate of the cobalt phase, selective etching of cobalt occurs that reduces mechanical power requirements for machining. At higher in-feed rates, the reduction in mechanical power requirement is marginal. Study of surface roughness produced during ECG clearly indicates that there is selective electrochemical etching of the metal phase (cobalt). It weakens the composite material and thereby reduces the forces required for mechanical grinding.

Introduction

ELECTROCHEMICAL REFINING is the purification process for producing commercially pure metals from crude metals. The process is carried out in an electrochemical cell with an external power supply where the anodic dissolution and cathodic deposition processes occur simultaneously. The objective of the electrochemical refining is to purify the crude metals, from thermally processed ores or scrap, and produce high- purity metals. This production is most efficient by maintaining precisely spaced, flat vertical anodes and cathodes. The cathodes are supplied with a warm, low-impurity electrolyte with a high concentration of metal ions. Careful process control of the supply of leveling and grain-refining agents, current density, and temperature is essential.

Electrochemical Cell

Both electrodes are immersed in suitable electrolytic solutions. The anode participates actively in the electrochemical refining reaction. The crude metal oxidizes at the metal-electrolyte interface, releases electrons, and dissolves as a metal ion into the aqueous solution. To maintain charge balance, the released electrons are transported to the cathode via an external circuit. At the cathode, the dissolved metal is deposited as a refined metals species. To refine effectively the impure metal, the impurities contained in the crude metal must be rejected from the final refined metal cathode. The principle of the process is that the impurities are either not dissolved and form “slimes” on the anode surface, or, if the impurities do dissolve, they are not redeposited on the cathode. Typical impurity distribution in the refining cell is summarized in Table 1.

Metals Purified

The electrochemical refining process is applied for the metal purifications of copper, nickel, silver, gold, tin, and lead (Ref 2). In the year 2000, approximately 1.04×10^7 tonnes (2.30×10^{10} lb) of copper were produced from electrochemical refining (Ref 3); about 1.23×10^6 tonnes (2.87×10^9 lb) of nickel were produced (Ref 2); and electrolytic tin production was 2.55×10^5 tonnes (5.62×10^8 lb) (Ref 4). Tonnes are metric tons equal to 10^3 kg. The purities of the refined electrolytic metals typically range from 99.99 to 99.999%.

From Table 1, it can be seen that in the gold, silver, copper, and lead refining processes, the impurities more noble than the refined metals remain undissolved in the anode slimes. Consequently, these impurities cannot plate and contaminate the cathodes. In nickel refining, on the other hand, some noble impurities partially dissolve in the electrolyte and will plate on the cathode if it is immersed in the same electrolyte. This is the main reason why nickel refining cells have porous diaphragms separating the catholyte (solution surrounding the cathode) from the anolyte (solution surrounding the anode). Anolyte solution is withdrawn from the refining cell and purified for noble metal impurities before being reintroduced into the catholyte compartment of the cell.

Principles of the Electrochemical Reactions

Electrochemical reactions are heterogeneous chemical reactions that occur via the transfer of charge across the interface between an electrode and an electrolyte. The features of electrode reactions in the refining process can be expressed as follows:

Anodic reaction: $M^0_{(s),impure} \rightarrow M^{n+}_{(aq)} + ne^-$ (Eq 1)

Cathodic reaction: $M^{n+}_{(aq)} + ne^- \rightarrow M^0_{(s),pure}$ (Eq 2)

Overall reaction (cell reaction):

$M^0_{(s),impure} \rightarrow M^0_{(s),pure}$ (Eq 3)

In contrast to a galvanic cell, the cell for the electrochemical refining is an electrolytic cell that requires an input of electrical energy to produce chemical transformations. Thus, the cell has a negative equilibrium cell potential and a positive value of the Gibbs free energy change. While the cell is under refining current load, the cell voltage increases and can be expressed as:

$$E_I = E_0 + \eta_{tc} - \eta_{ta} - IR_{int} \quad \text{(Eq 4)}$$

where

$$\eta_{ta} = \eta_a + \eta_{conc,a} \quad \text{(Eq 5)}$$

$$\eta_{tc} = \eta_c + \eta_{conc,c} \quad \text{(Eq 6)}$$

where E_I is the cell voltage; E_0 is the open-circuit cell voltage; I is the current; R_{int} is the internal resistance of the electrochemical cell; η_c and η_a are the cathode and anode polarization overpotentials; $\eta_{conc,c}$ and $\eta_{conc,a}$ are the cathode and anode concentration overpotentials; and η_{tc} and η_{ta} are the total overpotentials at the cathode and anode, respectively.

If impurities collect as a physical slime barrier on the surface of the dissolving anode, then the anode overpotential can be written as:

$$\eta_{ta} = \eta_a + \eta_{conc,a} + \eta_{sl} \quad \text{(Eq 7)}$$

and the internal resistance of the cell can be written:

$$R_{int} = R_{al} + R_{cl} + R_{sp} \quad \text{(Eq 8)}$$

where η_{sl} is the potential drop across the slime layer, R_{al} is the resistance of anolyte, R_{cl} is the resistance of catholyte, and R_{sp} is the resistance of the separator if required.

Physical Properties of Electrochemical Cells

The basic components required for the electrochemical refining cell are an electrochemically soluble anode, a cathode, ionic contact between the electrodes (via an electrolytic solution), and an electronic power supply connected to the anode and cathode. Monopolar cells are used in electrochemical refining. In this system, anodes and cathodes are placed alternately in the cell and are electrically connected in parallel. With this arrangement, alternate electrodes in the cell dissolve metal (anodes), and deposit refined metal (cathodes). This arrangement is shown in Fig. 1.

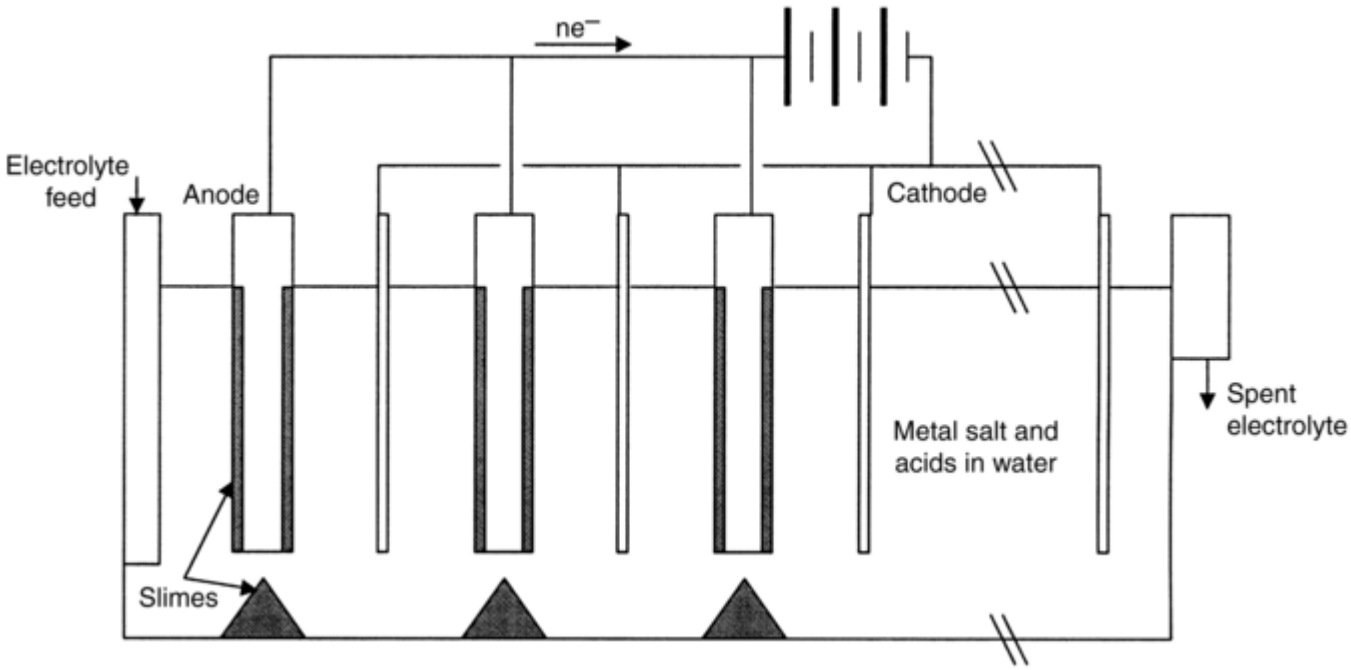

Fig. 1 Schematic of an electrochemical cell without separators for metal refining

A combination of diffusion and natural convection enhances the electrical transport of metal ions from the anode surface into the bulk electrolyte and, from there, onto the cathode surface. The concentration of metal ions near the anode is higher than in the bulk electrolyte, while near the cathode, the metal concentration is lower than in the bulk. These concentration gradients at the electrode surfaces cause the electrolyte near both electrodes to have a different specific gravity than the bulk electrolyte. The specific gravity differences induce a slow flow within the electrode diffusion layers-downward flow at the anode and upward flow at the cathode. This is shown schematically in Fig. 2. Note the presence of an anode slime layer, which adds an additional diffusion barrier to the movement of metal ions from the anode surface to the bulk electrolyte.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

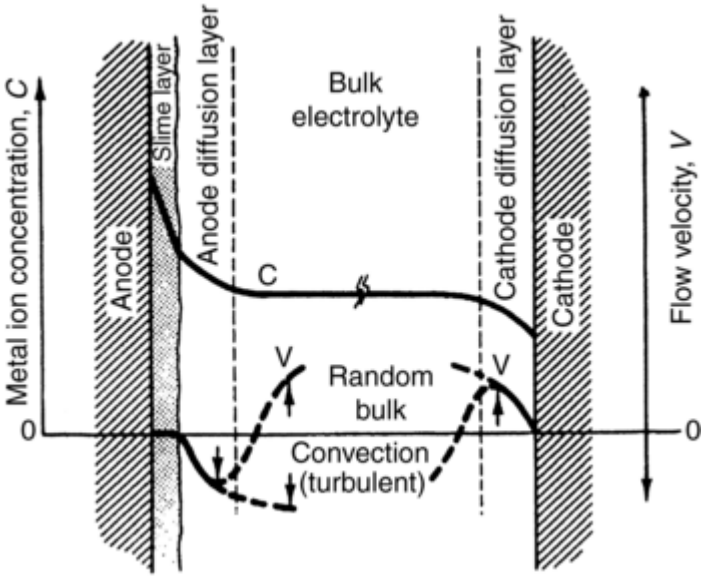

Fig. 2 Natural convection and concentration profiles in the metal refining electrolyte

The electrolytic solutions contain ions, which are atoms or groups of atoms that have lost or gained electrons and, as a result, are positively or negatively charged, respectively. Refining solutions are formed by dissolving metal salts and acid in water. These compounds may then be completely or partially dissociated into ions. Salts, such as copper sulfate ($CuSO_4$) and nickel sulfate ($NiSO_4$), and acids, such as sulfuric acid (H_2SO_4), hydrochloric acid (HCl), and hydrofluosilicic acid (H_2SiF_6), are often used in refining cells (Table 2).

Table 2 Electrolytes used in metal electrochemical refining

Electrolyte	Refining process					
	Cu	**Ni**	**Pb**	**Sn**	**Au**	**Ag**
Metal salt	$CuSO_4$	$NiSO_4$	$PbSiF_6$	$SnSO_4$	$AuCl_4$	$AgNO_3$
Acid	H_2SO_4	HCl, H_2SO_4	H_2SiF_6	H_2SO_4, $HOC_6H_4SO_3H$	HCl	HNO_3

Source: Ref 2

In electrochemical refining systems, supporting electrolytes are added to increase the solution conductivity, thereby decreasing the ohmic potential drop between electrodes. This makes the current density distribution more uniform in reactors with larger electrodes. For charged electroactive species, the mass transport limited current will be lower in the presence of a supporting electrolyte, since increasing the electrode potential does not then enhance the migrational component of the transport rate of electroactive species, as more of the current is being carried in the bulk solution by the supporting electrolyte. At the electrode, the net flux of all species is zero except for that of the reactant so that in the diffusion layer, the supporting electrolyte ions and the reactant counter ions have zero net velocity, adopting concentration distributions under the forces of migration and diffusion. Beyond the boundary layer, Ohm's law applies in a well- stirred bulk electrolyte. Generally, convection decreases the importance of the migrational flux of the supporting electrolyte and augments that of the reactant, as in the case of copper refining (Fig. 2).

The electrical circuit in the refining cell can be classified into two parts. Within the cell, current flows electronically within the structures of anode and cathode, and ionically in the electrolyte between them. In the external circuit, the current flows in the direction from cathode to anode that a positive charge would flow. The flow of electrons is shown in Fig. 1.

The separator, if present, serves as a barrier to lessen the mixing of anodic and cathodic solution species. Plastic meshes or filter cloths are used as separators. Separators also prevent interelectrode contact and may promote turbulence next to the electrodes in order to enhance mass transport of electroactive species.

Engineering Considerations in the Refining Process

It is desirable to operate at the maximum current density in order to deposit metal in the shortest time. The maximum current density for refining is determined by the mass transfer processes at the surface of the cathode or anode. The mass transfer processes are controlled by the thickness of the Nernst boundary layer at the surface of the electrode. The boundary layer can be decreased by increasing flow velocity of the electrolyte. In industrial practice, the current density is fixed at a value at which the deposit on the cathode is satisfactory in smoothness and brightness.

To minimize the energy consumption for the electrochemical cell, it is necessary to lower the electrolyte resistance and minimize the values of the respective overpotentials at the anode and cathode. Minimizing the distance between electrodes decreases the electrolyte resistance. Raising the temperature and increasing the concentration of dissolved metal salt can decrease the absolute values of the overpotentials. Typical refining conditions are summarized in Table 3.

Table 3 Operating parameters in metal electrochemical refining

Refining processes	Operating parameters

Source: Ref 2, 5

The general technological processes involved in electrochemical refining include:

- Continuous supply of fresh electrolyte to an individual cell
- Continuous withdrawal of the spent stream from the electrolyte circuit system
- Periodic removal of “finished” cathodes
- Supply of new cathodes
- Periodic removal of spent anodes
- Supply of soluble anodes
- Periodic removal of anode slimes

These principles are similar in the operations of all metal refining systems. The theoretical and technological principles are illustrated in detail in the individual example of metal refining processes.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Copper Electrochemical Refining Industrial Practice. Copper refining process serves two purposes (Ref 3). First, it produces copper essentially free of deleterious impurities; second, it separates valuable impurities from the copper for subsequent recovery as by-products. This process is the basis of purification of pyrometallurgical copper, which is used as the anode. The impure copper is cast in the shape of anodes approximately 1.0 × 1.0 × 0.05 m (40 × 40 × 2 in.) weighing 300 to 400 kg (660 to 880 lb). These anodes are cast with lugs that support the anodes off the walls of the cell. The lugs are used to make external electrical connection to the cell bus bars.
The starting cathodes can be pure copper sheets made by electrodeposition on smooth starting blanks of stainless steel or titanium. Many copper refineries have now adopted stainless steel sheets or blanks in place of the copper sheets. When using stainless steel sheets, the final copper product is stripped and the stainless steel cathode blank is returned to the cell. The electrode spacing from anode center to cathode center is approximately 5 cm (2 in.). The current density is about 250 to 300 A/m^2 (0.16 to 0.20 $A/in.^2$).
The anodes are consumed and replaced at regular intervals of 10 to 28 days. Up to two successive cathodes are harvested during the same period. The electrolytic solution contains approximately 40 to 50 g/L of copper as copper sulfate and about 160 to 200 g/L of sulfuric acid. The temperature is maintained at 65 to 70 °C (150 to 160 °F) to lower the resistance of the electrolytic solutions that are circulated through the cells. The lead or plastic-lined tanks of wood or concrete hold about 20 to 50 anodes and one more cathode than anode.
When a copper anode and a copper cathode are immersed in the acidified copper sulfate solution and the current is applied, copper will dissolve at the anode and be deposited at the cathode. Only those impurities in the copper anode with normal potentials negative of the working potential of anode, such as iron, nickel, and lead, will dissolve as ions. More noble metals, such as gold and silver, remain behind in finely divided metallic form and collect under the anode as anode “slime” or anode “sludge.” These slimes are processed further for the recovery of the valuable metals. However, at the working potential of the cathode, only copper will deposit; the metals less noble than copper do not deposit but accumulate in the solutions. This process requires periodic purification of the electrolytic solution.
In copper refining practice, it is found that three main factors influence the purity of copper cathodes:

- The physical arrangement of the anodes and cathodes in the cells
- Chemical conditions for refining
- Operating conditions

The physical arrangement in the cell is very important in a well-run refinery. Attention is paid to casting flat and identical weight anodes, pressing anodes and cathodes flat, machining the anode support lugs so the anodes hang vertically, and spacing the anodes and cathodes precisely in racks before loading them in the cells (Ref. 6). Bent anodes or starting sheets are not introduced into the refining system so the possibility of short circuits is minimized.
Optimizing chemical conditions for refining are maintaining constant and high concentration of copper ions over the faces of the cathodes; maintaining appropriate concentrations of leveling, and grain-refining agents over the faces of the cathodes; removing slime particles in the electrolyte; and lowering concentrations of dissolved impurities in the electrolyte. The common additive agents include:

Agent	Amount	
	kg per metric ton of cathode	**wt%**
Bone glue	0.03–0.2	0.003–0.02
Thiourea	0.03–0.15	0.003–0.015
Avitone (Du Pont)	0–0.06	0–0.006
Hydrochloride	0.035–0.08	0.0035–0.008

The removing of slime particles and the lowering of concentrations of impurities in the electrolyte can be achieved by continuously purifying an electrolyte bleed stream. About 0.1 to 0.2 m^3 of electrolyte bleed is purified per tonne of product cathode. (About 0.012 to 0.024 gal/lb. of product cathode).
Several factors impact the quality of electrolytic metals and the cost of metal production. Optimal operating conditions are obtained by maintaining high temperature, choosing appropriate cathode current density, and maximizing current efficiency. Although heating the electrolyte requires considerable energy, it increases electrolyte conductivity, decreases electrolyte density and viscosity, and increases the solubility of copper sulfate. These changes lead to decreased electrical energy consumption, minimizing the formation of floating slimes (precipitates of impurities), minimizing the contamination of cathodes, and preventing the precipitation

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

of copper sulfate. A high current density gives a high rate of copper deposition but also tends to cause dendritic growth and anode passivation. Furthermore, it tends to cause entrapment of electrolyte and slimes on the cathode and lowers cathode purity. Each refinery must balance these competing economic factors. Anode-to-cathode short circuits, stray current to ground, and reoxidation of cathode copper mainly cause a decrease in current efficiency (Ref 7). Short circuits can be minimized by improving physical arrangement and including additives. Stray current losses are due largely to current flow to ground via spilled electrolyte. Thus, avoiding spills can minimize the losses. Oxygen absorption in the electrolyte can result in the reoxidation of cathode copper. It is important, therefore, to keep the electrolyte flow quiescent to minimize the occurrence of reoxidation.

Nickel Electrochemical Refining Industrial Practice (Ref 8 and 9). The refining process of nickel metal anode serves two purposes. First, it produces nickel essentially free of deleterious impurities (such as iron, cobalt, lead, arsenic, and copper). Second, it separates valuable impurities (such as gold, silver, and platinum group metals) from the nickel for subsequent recovery as by-products. Nickel refining is carried out in sulfate and chloride electrolytes. This latter electrolyte system has two major advantages over the sulfate system. It has higher conductivity, which results in a lower cell voltage, and it permits the use of chlorine for electrolyte purification (Ref 9). To obtain the high purity nickel cathodes, the cathode is enclosed in a separate compartment formed by a modacrylic cloth diaphragm stretched over a wooden box frame. A hydrostatic head of electrolyte can be built up relative to the anolyte through the diaphragm. This hydrostatic head forces nickel-depleted electrolyte through the diaphragm, from the cathode compartment into the anolyte, at a rate sufficient to prevent the ingress of either anolyte itself, or impurity ions, by diffusion into the cathode compartment. Thus, the soluble impurities can be kept in the anolyte and removed through a solution purification process.

The nickel cathode starting sheets are made by deposition onto titanium or stainless steel blanks. After two days the nickel starting sheets are peeled from the inert blanks. These starting sheets are used as cathodes, and electrolytic nickel is built up for about 10 days in the refining cell. The final nickel metal that is obtained has a purity exceeding 99.9 wt%.

The purified electrolytic solutions, a mixed sulfuric acid and hydrochloride acid solution, are pumped continuously through the cathode compartment. The electrorefining process also facilitates the recovery of precious metals and other metals of value from anode slimes.

Lead Electrochemical Refining Industrial Practice. Most lead electrochemical refining is carried out in fluosilicic acid and lead fluosilicate electrolyte, which produces a lead cathode exceeding 99.99% purity. This electrolyte system has a major advantage over a sulfate system, as it has a higher solubility, which results in a lower cell voltage. In the refining process, more noble metals (gold, silver, and platinum) remain undissolved and accumulate in the anode slimes. The slime adheres on the anode and retains its initial form so that cells do not need to be cleaned and deslimed regularly. The cell voltage rises with the increasing thickness of the slime coating and may reach up to twice the initial voltage. Thus, the energy consumption imposes an economic limitation.

Metals with lower potential than lead, iron, nickel, and zinc dissolve into electrolyte. Since the lead bullion anode contains very low levels of the impurities, the enrichment of them in the electrolyte takes longer periods of time than it does in other types of metal refining. A small amount of electrolyte is lost because of fluosilicic acid decomposition (Ref 10).

Chemical-Mechanical Planarization for Semiconductors

Anne E. Miller, Paul B. Fischer, Allen D. Feller, Tatyana N. Andryushchenko, and Kenneth C. Cadien, Intel Corporation

Introduction

CHEMICAL-MECHANICAL PLANARIZATION (CMP) of metals has been described in the literature as (a) mechanically accelerated corrosion, (b) erosion corrosion, or (c) metallic corrosion enhanced by wear, during which the reaction products on the metal surface are removed by continuous abrasion. As a form of controlled corrosion, CMP has enabled significant advancements in the ultralarge-scale integration (ULSI) processes of the semiconductor industry. The history, process, chemistry, electrochemistry, and defect issues for CMP are reviewed in this article.

History

Chemical-mechanical planarization was first introduced as an integrated circuit (IC) manufacturing technology in early 1990. The first application for CMP was to planarize (or flatten) the topography in the interlayer dielectric (ILD), typically SiO_2, from underlying metal lines. Chemical-mechanical planarization prevented the topography of the lower metal layers from affecting upper metal layers and thereby had the beneficial effect of enabling the extension of optical lithography to the submicron regime by using deep ultraviolet (UV) wavelengths. It is now typical for leading edge devices to have more than seven layers of metals. Scanning electron microscopy cross-sectional micrographs are shown in Fig. 1, indicating the topography prior to the advent of CMP (a) and the planar surfaces available due to CMP (b).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

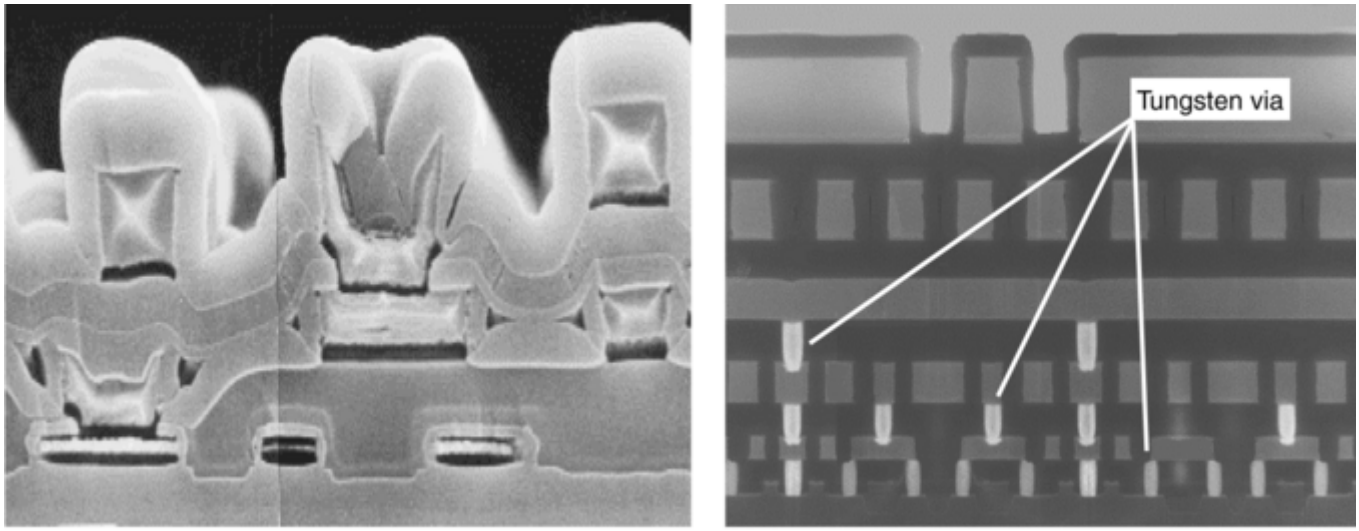

Fig. 1 Micrographs of semiconductor device cross sections. (a) 1.0 µm technology; two metal layers made before the advent of chemical-mechanical planarization (CMP). (b) 0.25 µm technology; five metal layers, using CMP technology. Tungsten vias provide electrical connection between layers.

Other applications of CMP for smoothing and/ or polishing followed. These included polycrystalline silicon polishing for polysilicon gate devices and shallow trench isolation polishing where SiO_2 overburden (excess material to ensure proper fill) is removed. The polishing stops on a Si_3N_4 layer, leaving behind a SiO_2-filled trench. These types of polishing primarily involved mechanical removal of the silicon or SiO_2 layers. Slurries with high pH (10 to 11) were used to soften the substrate surface to enhance removal rates.

In addition to ILD polishing, thin-film metal polishing emerged as the next major application for CMP technology. Metal polishing in the IC industry originated with tungsten (W). Metal CMP involves redox reactions and controlled corrosion of the metal in order to achieve a high removal rate with good selectivity or a low removal rate on the underlying ILD. Tungsten, in conjunction with a thin titanium nitride adhesion layer, is used in IC manufacturing to form vias, metal lines that interconnect metal layers. Vias are the bright, vertical cylinders in Fig. 1(b). Tungsten is deposited by chemical vapor deposition, forming a film that is conformal. The film is deposited uniformly and thus retains the existing topography. Prior to the advent of CMP, the tungsten overburden was removed by a plasma etchback process that left a large recess in the via. Tungsten polishing was found to remove tungsten uniformly and quickly while giving very small via recesses. A comparison of wafer surfaces after tungsten CMP and tungsten etchback is shown in Fig. 2(a) and (b). The figure shows atomic force micrographs of 10 by 10 micron square regions of the wafer surface. The scale orthogonal to the wafer surface is 250 nm per division in the *Z*-direction as indicated on the figure. This shows that not only is the post-tungsten CMP via recess less, but also the surface of the ILD is much smoother than with plasma etchback.

مرجع مهندسی مواد و متالورژی

Fig. 2 Atomic force micrographs of the surface of an integrated circuit wafer after (a) tungsten polishing and (b) tungsten plasma etchback. ILD, interlayer dielectric

Near the end of the 1990s, the delay in sending signals down metal interconnects became the limiter for device performance. This delay is related to the resistance of the metal as well as the capacitance between metal lines. This capacitance is a function of the dielectric constant of the ILD as well as the spacing between the metal lines. It became clear that the resistivity of aluminum was too high and it should be replaced by copper. In addition, the ILD, which traditionally had been SiO_2, would need to be replaced by low-dielectric-constant materials. Copper was first introduced in 1999 by IBM Corporation, using a novel patterning technique called damascene or inlaid copper. Unlike aluminum, copper is not easily plasma etched. The damascene process required first etching trenches and vias in the ILD where the metal lines are wanted. Next, the trenches were filled with a copper diffusion barrier layer of tantalum and/or tantalum nitride, a copper electroplate seed layer, and a thick copper electroplate layer. Finally, the copper and barrier layer overburden is then polished back to leave the copper damascene structure, as shown in Fig. 3.

Chemical-Mechanical Planarization Overview

A schematic of CMP process equipment is shown in Fig. 4. During CMP, a wafer is pressed down into a polyurethane polishing pad that is glued to a rotating base plate. Slurry is pumped onto the polishing pad and is distributed over the pad surface by centripetal force. Grooves in the pad aid the slurry flow. Chemical-mechanical planarization tools also have endpoint systems that can detect when a layer has been cleared. Commercial high-volume CMP tools have many variations on the basic configurations shown in Fig. 4. These include through-the-pad slurry delivery, linear pad motion, and integrated cleaning units. Discussion of these variations is beyond the scope of this article.

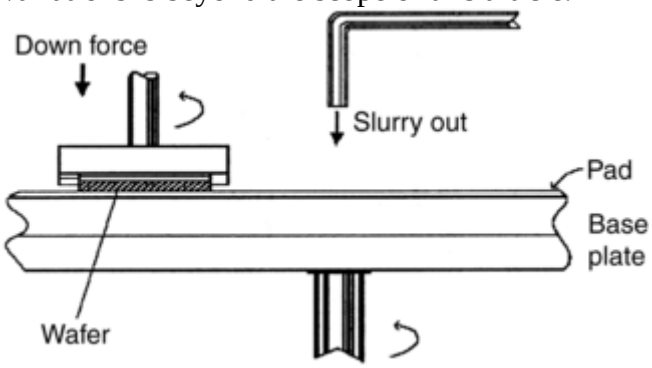

Fig. 4 Schematic of chemical-mechanical planarization setup

By definition, CMP consists of both mechanical and chemical components. The mechanical wafer environment during CMP consists of the pad, temperature, normal forces, shear forces, relative velocity of the wafer with respect to the pad, and slurry abrasive. The mechanical response of the polishing rate is typically described by the Preston equation, which states that the polishing rate is equal to the product of a process-dependent constant, the Preston coefficient, the polishing pressure, and the relative velocity between the polishing pad and the wafer (Ref 1).

The slurry also provides the wafer chemical environment. For metal CMP, it is the slurry that determines the redox potential and controls the beneficial corrosion of the wafer. The electrochemistry of metal CMP is discussed subsequently.

Chemistry of Metal CMP

In addition to an abrasive, a metal slurry may consist of an oxidizer, a corrosion inhibitor, a polishing rate accelerator, and a surfactant to modify the abrasives and metal surface. The reduction-potential difference between the metal and the oxidizer in the slurry is the thermodynamic driving force for the electrochemical reactions in metal polishing. The other nonoxidizing slurry components, such as accelerators and corrosion inhibitors, modify the electrochemical response and resulting polishing performance. The applications of CMP to tungsten and copper alloys are of prime interest in the semiconductor industry and are discussed in more detail.

Copper CMP. The formation of a corrosion product is a result of metallic oxidation occurring simultaneously with the reduction of the other available reactants. For example, the corrosion of copper during CMP can be expressed as an anodic reaction, where copper metal is oxidized:

$$Cu \rightarrow Cu^{+} + e^{-} \quad \text{(Eq 1)}$$

$$Cu^{+} \rightarrow Cu^{2+} + e^{-} \quad \text{(Eq 2)}$$

For film formation, the oxidation of copper to Cu_2O in aqueous solutions with dissolved oxygen is expressed as:

$$4Cu + 2H_2O \rightarrow 2Cu_2O + 4H^{+} + 4e^{-} \quad \text{(Eq 3)}$$

More typically in slurries, the oxidation is driven by reduction of an oxidizer (Ref 2). For the reduction of H_2O_2, the net reaction is:

$$2Cu + H_2O_2 \rightarrow Cu_2O + H_2O \quad \text{(Eq 4)}$$

The choice of oxidizer is dependent not only on the electrochemical reduction potential of the metal ion and oxidizer but also on the pH and other slurry additives, which can modify the thermodynamic regions of corrosion, passivation, and immunity that are typically described by the Pourbaix diagram (Ref 3). For CMP, it is advantageous to operate in a passivating region. For the copper-water system, this happens at intermediate pH range, where oxide film formation (as described by Eq. 3) occurs.

Copper readily corrodes in oxidizing solutions. In addition, under the right chemical conditions, copper forms an oxide film, but it is of poor quality. Copper is also a very soft metal, so high polishing pressures cannot be used to achieve high polishing rates, because copper smears.

To address these issues with copper, CMP slurries for copper are chemically complex. In addition to an oxidizer, a corrosion inhibitor is required to passivate the surface. The use of benzotriazole (BTA) as an inhibitor of copper corrosion was documented as early as 1947 (Ref 4). It is clear that BTA bonds to the copper oxide on the surface of copper and reinforces the protective nature of the copper oxide (Ref 5, 6). It has been proposed that BTA be used in copper slurries as an answer to the incomplete oxide passivation (Ref 7). A typical model of the copper-BTA polymer structure is shown in Fig. 5.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

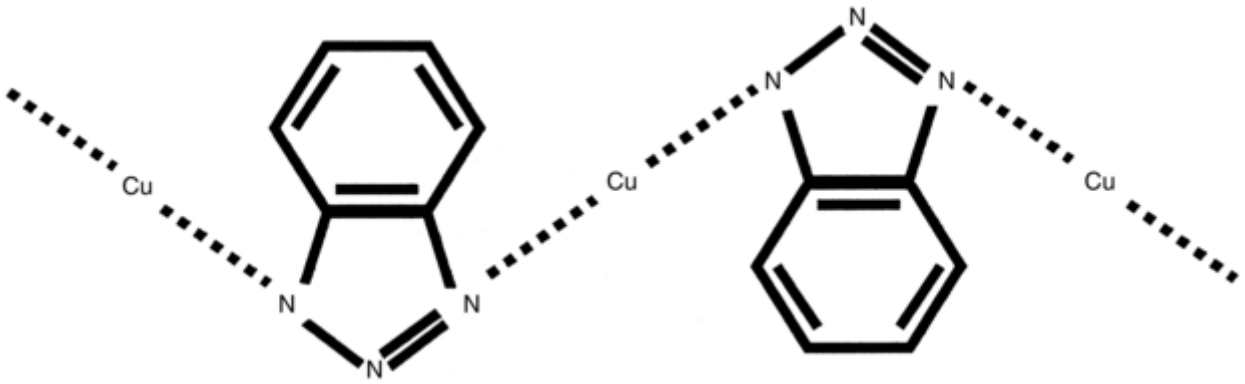

Fig. 5 Copper-BTA passive film structure

A corrosion inhibitor protects low-lying recessed areas while the high points in the topography are flattened (Ref 7, 8). The addition of the inhibitor tends to form a stable film that increases the pH range for passivation described by the Pourbaix diagrams (Ref 9).

For copper polishing, additives that improve solubility by complexing copper, such as ammonia (Ref 10) or glycine (Ref 11), have been used. Some of these additives, glycine in particular, have been shown to not only improve solubility of copper ions and thus reduce the pH range for passivation described by the Pourbaix diagram, but also aid in the reduction of peroxide oxidizer due to the catalytic effect of the glycine- copper complex (Ref 11). Surfactant additives have been used to enhance polish rate selectivity of the metal to underlying barrier or ILD layer and to ensure abrasive particles remain in suspension.

An abrasive such as silica or alumina is then used to remove the oxide-BTA film, exposing fresh copper and thus achieving a removal rate of 300 to 700 nm/min.

Tungsten CMP. The CMP of tungsten tends to require simpler chemistries than copper CMP. Kaufman and others (Ref 8) first proposed that tungsten be polished to form vias. They described a model of a tungsten slurry containing an etchant, a passivating agent (corrosion inhibitor), and an abrasive. In this model, elevated tungsten features contacting the polishing pad remove any passivation, thus exposing the metal to the etchant. Meanwhile, the passivation protects lower metal areas, thereby allowing the polishing process to planarize the tungsten film. Once the film is flat, polishing proceeds by subsequent steps of passivation, removal of the passivated layer by the polishing pad, etching, and then passivation. The process is repeated until the overburden is removed. The passivation also reduces via recess by protecting the via once it is recessed below the surface of the ILD.

The oxidizing agent, ferricyanide ($Fe(CN)_6^{3-}$), was first used as a metal etchant for tungsten (Ref 12). However, when ferricyanide reacts with tungsten, the product formed is either the stable passivating film (WO_3) or the soluble ion (WO_4^{2-}), as seen in the following equations:

$$W + 6Fe(CN)_6^{3-} + 3H_2O \rightarrow WO_3 + 6Fe(CN)_6^{4-} + 6H^+ \quad \text{(Eq 5)}$$

$$W + 6Fe(CN)_6^{3-} + 4H_2O \rightarrow WO_4^{2-} + 6Fe(CN)_6^{4-} + 8H^+ \quad \text{(Eq 6)}$$

The role of pH in these reactions has been studied (Ref 13). It was found that by lowering the pH below 4 and buffering the polishing slurry to the desired pH of 3, passivation of the tungsten surface was the predominant reaction, and any localized drop in pH during the polishing process was reduced. The selection of a pH range that allowed passivation of the tungsten surface was based on the Pourbaix diagram (Ref 3). Adjustment of abrasives such as silica or alumina, polishing pads, and mechanical parameters, such as downforce, rotational speed, and fluid flow, all contributed to the polishing performance, but the chemical control of corrosion was the key to tungsten polishing planarity.

Alternate slurries using the same pH range, 2 to 4, and the same abrasives, but using hydrogen peroxide (H_2O_2) or the Fe^{3+} in ferric nitrate ($Fe(NO_3)_3$) as the oxidizing agent, have been developed:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$W + 3H_2O_2 + 3H_2O + 6H^+ \rightarrow WO_3 + 6H^+ + 6H_2O \quad \text{(Eq 7)}$$

$$W + 3H_2O + 2Fe^{3+} \rightarrow WO_3 + 6H^+ + 2Fe \quad \text{(Eq 8)}$$

Because slurries using $Fe(NO_3)_3$ as the oxidizing agent actually have a pH of 1.5 to 1.8, corrosion of the manufacturing equipment and deposits of hydrolyzed iron are significant issues for tool reliability. Slurries based on ferricynanide at a pH of 3 avoid these issues.

A simple model for the the role of the abrasive during metal polishing is that abrasive particles impart the mechanical momentum that enables removal of the passive film. However, various metal oxide abrasive materials have been studied, showing that the abrasive surface is more chemically active when the abrasive surface charge is close to zero at its isoelectric point (IEP) (Ref 14). In neutral pH ranges, CeO_2 with an IEP of approximately 7 has been found to have high oxide polishing rates due to a high number of surface sites that form and break bonds during the polishing process. For tantalum barrier layers, polishing rates also depend on the abrasive hardness in addition to the availability of reactive surface sites (Ref 15). Additives such as H_2O_2 and $Fe(NO_3)_3$ reduce the tantalum polishing rate due to the relatively hard, passivating oxide(s) formed.

Electrochemical Theories and Methods in CMP

Electrochemical theories, such as the mixed- potential theory, are discussed elsewhere in this Volume. Analytical techniques, such as direct current (dc) potentiodynamic polarization and alternating current (ac) impedance measurements, may be applied to analyze the polishing mechanism during CMP.

The metallic polishing process is a corrosion- erosion process that involves a transfer of charge. The rate of chemical change is proportional to a flow of charge, so the polishing rate can be correlated with a reaction current or current density. As in typical potentiodynamic analysis, there is an exponential relationship between the current density and the overpotential or the potential difference between the applied and equilibrium potentials. Some electrochemical techniques used for studying corrosion phenomena for bulk materials are also applicable to CMP of the thin films used in ULSI fabrication processes.

In order to evaluate the corrosion rate by the electrochemical techniques, such as potentiodynamic measurements, the oxidation-reduction reactions are accelerated either in cathodic or anodic directions by the application of an external potential, and the net current is measured. At the intersection of the anodic and cathodic slopes, a mixed potential termed the *corrosion potential*, E_c, and the corresponding corrosion current, i_c, occurs. The corrosion current can be used to estimate the removal rate of metallic species from the surface in the absence of polishing.

The corrosion potential and corrosion current depend on several factors, including whether the reactions are controlled by Tafel kinetics or concentration polarization. Under Tafel kinetics, charge transfer is rate controlling and the current density increases proportionally to the overpotential. Concentration polarization means the rate-limiting step is mass transfer to or from the surface, and the current density increases very slowly with the overpotential. For example, in dc potentiodynamic polarization measurements, the potential is scanned within a relatively wide potential range around the corrosion potential. The dc polarization curves display the kinetics of the anodic and cathodic reactions, the corrosion rates, the dissolution mechanisms, and the ability of the metal to passivate itself (Ref 16).

It is known from the Pourbaix diagram for the copper-water system (Ref 3) that copper can be passivated in the pH range between 6.5 and 12.5, depending on the potential of the metal-liquid interface. Figure 6 shows that in the presence of a complexing agent, in this case, citrate ions, the active-passive polarization behavior of copper is not observed at pH 8.5 but is observed at pH 12. This indicates that the low pH boundary of the passivation region for the copper Pourbaix diagram is shifted to a higher pH.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

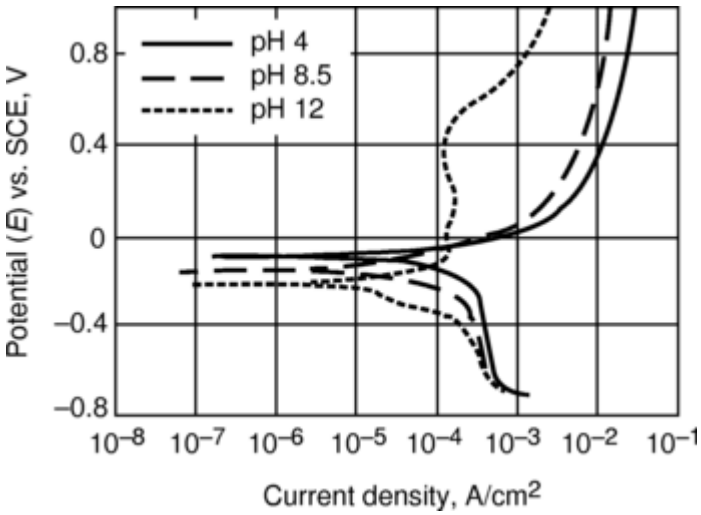

Fig. 6 Effect of pH on polarization behavior of copper in 0.01 *M* citrate solutions. SCE, saturated calomel electrode reference

With additions of hydrogen peroxide to the pH 4.5 solutions containing citrate ions, the driving force for copper oxidation increases, and the corrosion potential shifts in the noble direction (Fig. 7). Small concentrations of H_2O_2, up to 1%, increase the corrosion current and copper dissolution rate (or static etch rate) of copper. At higher concentrations of H_2O_2, the copper dissolution rate is suppressed, and passivation is observed at this lower pH. The copper polishing rate shows the same trend that was confirmed experimentally on the wafer scale.

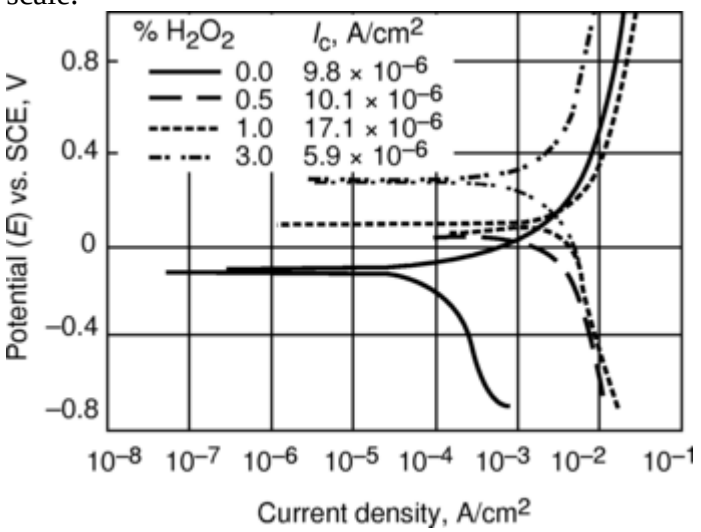

Fig. 7 Effect of H_2O_2 additions on polarization behavior of copper in 0.01 *M* citrate solutions. I_c, corrosion current density. SCE, saturated calomel electrode reference

Several investigators have reported the use of dc potentiodynamic polarization measurements performed with rotating disk electrodes made from bulk metals, without and with continuous abrasion of the electrode, which allows the simulation of the CMP process and relates the corrosion rate to the polishing rate (Ref 2, 17, 18, 19, 20).

Direct current potentiodynamic measurements have been used to predict CMP performance of the oxidizing/etching reagents for tungsten (Ref 17). The corrosion potential has been shown to decrease (become more active) and the corrosion current density to increase with abrasion of the surface. This indicates that the passivating layer is being removed by the abrasion process. Researchers have shown that the potentiodynamic curves of copper in 5% HNO_3 show only a very small difference between the corrosion potentials of the abraded and unabraded surfaces as well as a low Tafel slope in the anodic range (Ref 20). This indicates that there is no copper surface passivation in HNO_3. The dissolution of copper is the dominating reaction, and mechanical abrasion does not enhance the corrosion rate.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

It is clear from these studies that the magnitudes of the differences in corrosion potential and corrosion current with and without abrasion, as well as the Tafel slope for anodic polarization, indicate the presence or absence of the passivating layer.

A method was introduced of studying the electrochemistry of CMP by measuring the electrochemical mixed potential of copper during polishing. These measurements explained the polishing performance in several ammonia- based slurries (Ref 10). Once polishing began, the concentration of dissolved oxygen decreased, providing the cathodic half-cell reaction for copper dissolution. After the initial drop, the potential rose steadily in the NH_4OH and the NH_4NO_3 slurries during the polishing as copper ions built up, while the potential for the NH_4Cl slurry remained nearly constant. The polishing rate was shown to correlate with the change in potential during polishing. The greatest change in potential for the NH_4OH slurry corresponded to the highest polishing rate. Complexing of copper ions with dissolved ammonia increases the dissolution rate of the abraded material and therefore increases the polishing rate. Increases in mixed potential in the noble direction indicate relative increases in copper ion concentration and may also be used to predict polishing rate behavior (Ref 7).

Cyclic voltammetry was used to investigate the electrochemical behavior of copper in 1 *M* sodium acetate (NaAc) solution at pH 5.8, with and without the presence of BTA (Ref 21). The researchers found that the initial step in the inhibition is the adsorption of BTA onto the copper surface. The copper oxide film is not modified at the early stage of adsorption, and its cathodic reduction occurs at the same potential, regardless of the presence of BTA. At prolonged immersion and higher BTA concentrations, the cathodic current peak during reduction shifted toward more negative potentials, suggesting structural changes in the film. When Cu(I)-BTA complex is formed, ionic movement through the film becomes rate determining. The Cu(I)-BTA thickness and protection against corrosion increase by increasing the BTA concentration and immersion time.

The slurry composition is an important factor in the CMP step. Basic electrochemical theories may be very useful in the fundamental characterization and formulation of CMP slurries as well as in overall CMP process development. What follows are processes that can adversely affect CMP.

Uncontrolled Corrosion— Chemically Induced Defects

One of the challenges of CMP of thin-film metals is to minimize the localized, uncontrolled corrosion effects that cause defects. These critical defects derive from classical corrosion processes, such as pitting corrosion, galvanic corrosion, and excess etching. While changes in process conditions and post-polish buffing can assist in defect reduction, the most significant method of controlling these defects is in selection of the chemistry (Ref 22), as is discussed subsequently.

Pitting Corrosion. Classically, pitting corrosion occurs when an isolated region of the metal is exposed to an increasingly more aggressive corrosion environment than the bulk of the metal (Ref 23). For thin films as well as bulk materials, pitting corrosion initiates at impurities or local surface topography changes. Post-CMP, it is difficult to differentiate between pitting and crevice corrosion as the source of a defect.

For thin-film and bulk copper, the critical reaction for propagation of pits is the oxidation of copper to Cu_2O and a cathodic reaction, such as reduction of oxygen or other oxidizing species, in the slurry. While Cl^- is the classic metal-pitting agent, for copper, SO_4^{2-}, PO_4^{3-}, NO_3^-, and HCO_3^- are also known pitting agents (Ref 24, 25, 26). Figure 8 shows an example of pitting defects for a wafer polished with a peroxide-based copper slurry in the presence of 900 ppm of halide. For this slurry, there is no pH drop, because there is no net change in the number of hydrogen ions when the copper is oxidized by peroxide (Eq 4) (Ref 22). When used as an oxidant, ammonium persulfate has also been shown to induce deep pits through an entire 400 nm copper film thickness, due to formation of sulfate ions as a byproduct of the reduction of persulfate ($S_2O_8^{2-} + 2e^- \rightarrow 2SO_4^{2-}$). Unlike peroxide reduction, the persulfate reaction does not consume H^+ ions, and a substantial net drop in pH occurs when persulfate oxidizes copper, enhancing the corrosion and pitting rate (Ref 22). While the addition of corrosion inhibitors and pitting agent getters serves to minimize pitting, the key to prevention is eliminating the presence of the pitting agent.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

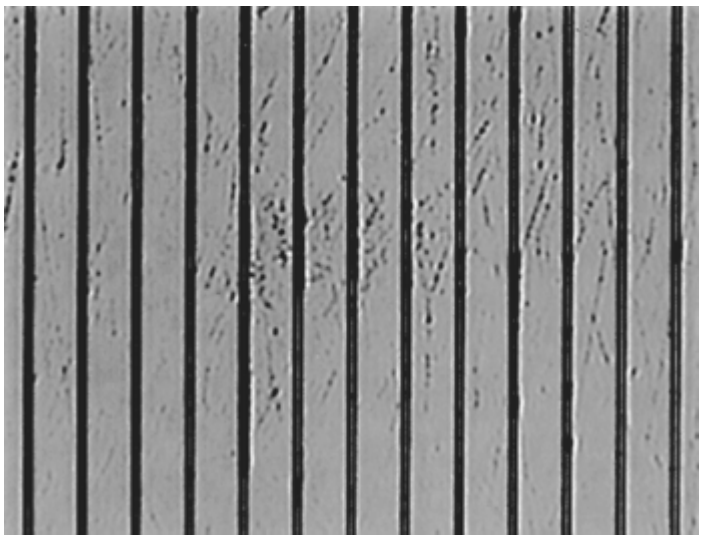

Fig. 8 An example of pitting corrosion induced by 900 ppm of halide. Source: Ref 22

Galvanic Corrosion. When two dissimilar metals are in contact with an electrolyte, oxidation occurs at one metal and reduction at the other, leading to etching of the first metal and redeposition of the second metal. For the copper damascene pattern with a titanium barrier, this causes recessing of the titanium barrier relative to the copper damascene line (Ref 2). For tantalum, another typical barrier, the galvanic couple is:

$$2Ta + 5H_2O \rightarrow Ta_2O_5 + 10H^+ + 10e^- \quad \text{(Eq 9)}$$

$$Cu^{2+} + 2e^- \rightarrow Cu \quad \text{(Eq 10)}$$

Galvanic corrosion resulting in reprecipitation of copper nodules has been observed for both titanium (Ref 2) and tantalum (Ref 22).

Chemical Etching. When high slurry dissolution rates or static etch rates are measured in the absence of polishing, it can lead to enhanced surface texturing. This is shown in Fig. 9 for a patterned wafer exposed to a peroxide-based copper slurry formulation and a static etch rate of 400 A/min. Texturing occurs in the center of wide structures conformally coated during copper electroplating. The center of these structures etches faster than the pad planarizes. In the presence of Cu^{2+} ions and complexing agents such as glycine (Ref 11), the activity of peroxide is significantly increased. Sixfold static etch rate increases have been observed (Ref 22), further contributing to the overall etch rate. Increased pH and inhibitors such as BTA can be used to control static etch rates. Polisher design, operating conditions, and consumable choices dictate mass-transport properties.

مرجع مهندسی مواد و متالورژی

Chemical effects are a significant consideration in CMP processes. During CMP, the wafers that are polished are exposed to a slurry consisting of particles and combinations of chemistries. The wafers need to be cleaned then dried prior to subsequent processing. Many commercial CMP tools include integrated cleaning and drying tools. This significantly reduces the time that post-CMP wafers are wet. It should be noted that deionized water is very corrosive.

Post-CMP cleaning systems typically consist of water rinses, cleaning in megasonic ultrasonic chemical baths, and/or dual-sided scrubbing. It is has been found that the mechanical action of scrubbing is required to return wafers to pristine condition post-CMP.

A detailed description of the subject of CMP cleaning is beyond the scope of this section. However, it is important to note that remarkable photoelectric effects have been observed during the cleaning phase of post-copper CMP. The CMP cleaning processes typically involve one or more aqueous scrub steps, followed by a spin- rinse-dry where the drying is expedited by a heat lamp. During these cleaning steps, light-induced copper dendritic growth has been observed. Figure 10 shows an example of copper dendrite growth occurring on the surface of a patterned copper wafer during the post-CMP cleaning step.

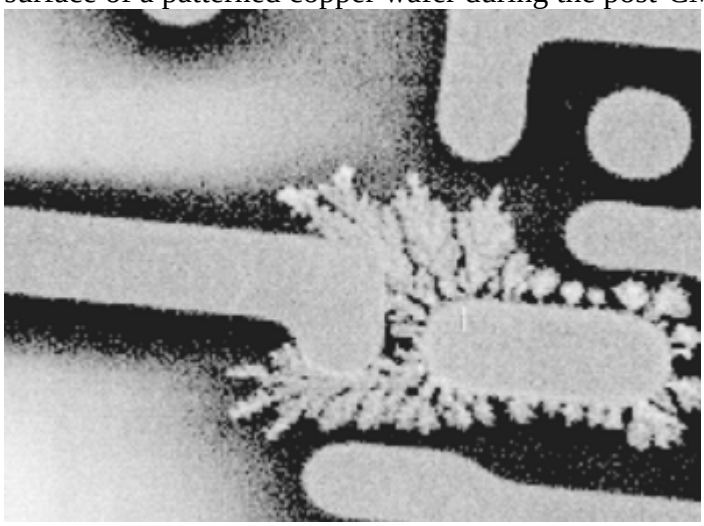

Fig. 10 Light-induced copper dendrite growth during post-CMP cleaning

The dendrite growth emanates from a copper pad connected to an *n*-type well that serves as the cathode. Incident photons excite electron- hole pairs in *p*-*n* junctions, as in photovoltaic cells. Electric fields within the *p*-*n* junction sweep the electrons toward the *n*-type material and the holes toward the *p*-type material. Copper connected to the *p*-type and *n*-type material forms the anode and cathode, respectively. Copper is oxidized at the anode (with the electrons being canceled by photo-induced holes), $Cu \rightarrow Cu^{2+} + 2e^{-}$. Copper is reduced at the cathode by the photo-induced electrons, $Cu^{2+} + 2e^{-} \rightarrow Cu$. The dendrite defect effect occurs primarily at lower metal layers and can be controlled by avoiding incident illumination during wet cleaning.

Conclusions

The beneficial effect of controlled corrosion during CMP of thin-film ICs has led to a significant decrease in topography variations and has enabled the required deep ultraviolet lithography methodology for multilayer ULSI metallization. In addition to a significant mechanically induced erosion or wearing process, the chemical and electrochemical corrosion effects are critical in controlling CMP of metals. Maintaining a balance between controlled and uncontrolled corrosion is responsible for the appreciable removal rates, low topography, and low surface defects on polished metallic interconnects.

Introduction

THIS ARTICLE examines constructive corrosion as it occurs in power-generating devices, specifically batteries. Because corrosion in batteries (as in many other systems) can take several forms, the distinction between constructive and destructive processes is first discussed. This distinction provides a framework for the subsequent discussion on the criteria used to select viable anodes for batteries. These criteria are based on measurements of the same fundamental thermodynamic and kinetic properties of metals that are germane to

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

destructive corrosion, but, in the case of batteries and other systems where constructive corrosion occurs, the objectives are completely opposite. The reason is obvious: instead of minimizing corrosion in these systems, the objective is generally to promote it.

Following a discussion of the thermodynamic principles of constructive corrosion in batteries, including a summary of parameters commonly used to rank performance based on these principles, the kinetic aspects of constructive corrosion in batteries is discussed. Several examples are provided to illustrate how the kinetics of the corrosion process varies among different battery systems. Another aspect of constructive corrosion in batteries is then described, specifically, situations where corrosion is promoted in battery manufacturing for the purpose of preparing electrochemically active material. Finally, a discussion is provided on a few important cases where destructive corrosion occurs in batteries. While other articles in this Volume focus on destructive corrosion, the discussion presented here is meant to emphasize how constructive and destructive processes in batteries can be very similar, both energetically and mechanistically, and how subtle variations in battery conditions can strongly influence which of the two competing processes occurs.

Constructive versus Destructive Corrosion in Batteries

There are three roles that corrosion, or oxidation of a metal, may play at anodes in batteries. Two of these are constructive and hence desirable. The third is destructive and therefore undesirable.

Two Constructive Roles. “A battery is a device that converts the chemical energy contained in its active materials directly into electrical energy by means of an electrochemical oxidation- reduction (redox) reaction” (Ref 1). The active material at the anode of a battery is the “fuel” that undergoes oxidation. When this anode material or fuel is a metal, the oxidation process consists of corrosion. In the general case, the anodic or corrosion reaction may be represented by the equations:

$$M(s) \rightarrow M^{n+}(dis) + ne^- \qquad \text{(Eq 1)}$$

or

$$mM(s) + nX^{m-}(dis) \rightarrow M_mX_n(s) + (n \cdot m)e^- \qquad \text{(Eq 2)}$$

where M(s) is the solid metal anode, $X^{m-}(dis)$ is a complexing anion dissolved in the electrolyte, and *m* and *n* are integers. Equation 1 represents anode reactions where the metal is oxidized and dissolves. Complexation of the dissolved cations usually occurs, but the reaction products remain soluble. Such soluble metal complexes are included in the designation $M^{n+}(dis)$. Equation 2 consists of oxidation reactions in which an insoluble reaction product is formed through complexation and precipitation. In aqueous electrolytes, the product is usually an oxide or hydroxide, and the reactants often include H_2O.

The previously mentioned form of corrosion in batteries is constructive, because it is part of the battery reaction that generates the desired electrical energy. Another type of constructive corrosion in batteries is oxidation of metals during battery manufacturing. This consists of purposeful oxidation of a metal to form an oxide that eventually serves as the active mass (usually for the positive electrode). The best example of this type of corrosion is in the manufacturing of the lead-acid battery, as described subsequently. Once the oxide or positive active mass (PAM) is formed, the metal at the electrode simply acts as a current source or collector while the electrochemical reactions involve the oxide.

A Destructive Role. Destructive corrosion in batteries can also occur. It usually consists of oxidation of the metal anode during storage; however, destructive corrosion can also occur in parallel with constructive corrosion while the battery is operating. In general, destructive corrosion involves the direct reaction of the metal anode with the electrolyte (Fig. 1). This corrosion results in loss of active material and is reflected in

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

shortening of shelf life and/or lowering of capacity. In addition, corrosion products from the direct reaction can include solid precipitates and gases. The former are problematic, because they can create barriers to the transport of electroactive species and increase internal resistance. The higher internal resistance causes undesirable voltage drops in the cell under load. Gases that are sometimes generated by direct reaction of the anode metal include hydrogen, whose presence poses an obvious safety hazard. Finally, metal anodes may undergo passivation by direct reaction with the electrolyte. While highly desirable in most instances for thermodynamically active metals, passivation at a battery anode is usually deleterious.

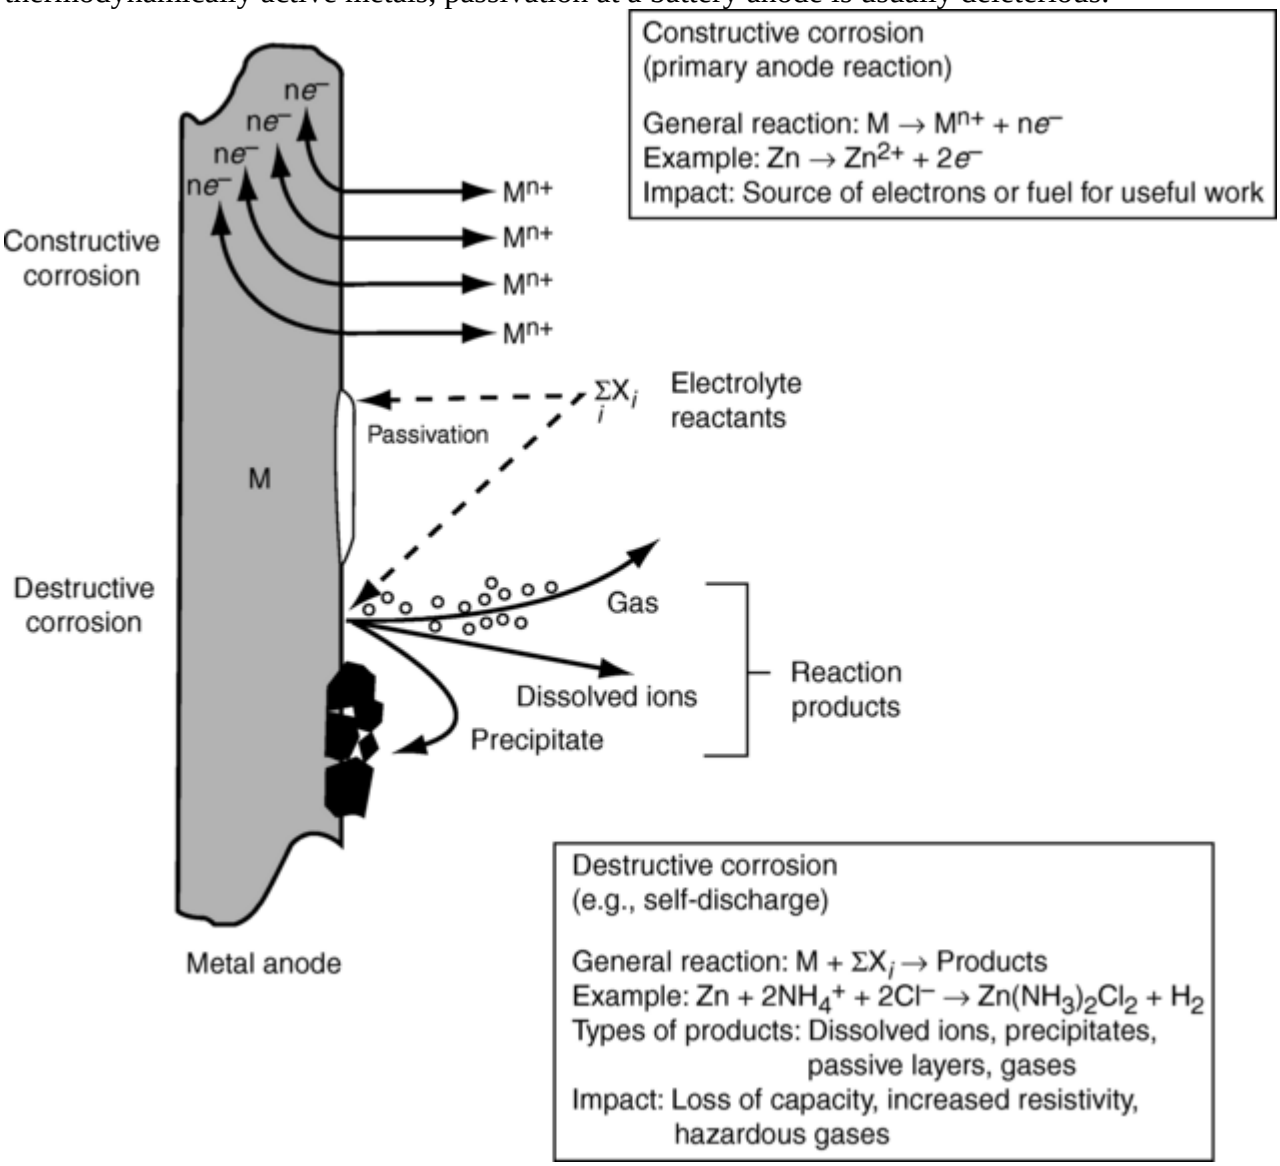

Fig. 1 Illustration of constructive and destructive corrosion reactions for a battery anode

By their nature, passive films inhibit the transport of ionic species. This is the reason why these films, once formed, reduce the corrosion rate of metals. Unfortunately, charge transport at battery anodes involves the metal ions that are the primary products of the constructive corrosion process. Passivation slows down the transport of these constructive ions even more effectively than precipitated films, increasing resistance dramatically and thereby adversely affecting battery performance. This is the reason why passivation-prone metals such as aluminum and titanium, which are highly active and have very large free-energy changes associated with their oxidation reactions in water and other electrolytes, are sparingly, if ever, used as anodes in battery systems.

The key to making sure that only constructive corrosion of the anode occurs is to select compositions of the electrodes and electrolyte, as well as an optimal design of cell geometry, that disfavors the formation of cathodes on the anode metal and minimizes the potential for direct reaction of metal with the electrolyte. Strategies for minimizing this type of corrosion usually involve alloying of the anode with metals that polarize

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

it and thus lower corrosion rates under open-circuit conditions, removing impurities in the metal that may act as depolarizers, and modifying the electrolyte with corrosion inhibitors.

Several examples of the two types of constructive corrosion in batteries are provided here, with a discussion of how thermodynamic and kinetic aspects of the corrosion processes influence the performance of the batteries. The discussion is not meant to be a comprehensive treatment of batteries. Its purpose is to illustrate the way in which techniques and concepts in corrosion science are relevant to batteries and where, in these particular instances, the focus is on making the corrosion reactions as favorable and as facile as possible, rather than on attempting to minimize their effects, as is usually the case in corrosion studies. In addition to the discussion of the constructive types of corrosion in batteries, some instances of the destructive type of corrosion are also given. The reason for including examples of the destructive form is to highlight their chemical similarity to the constructive types and to illustrate the endeavors of battery manufacturers to design systems that promote one type of corrosion over the other.

Constructive Corrosion as Part of Power Generation

Batteries that use metals as anodes that oxidize or corrode during discharge according to the reactions in Eq 1 or 2 are plentiful. The reason for this is that metals are easily fabricated, often inexpensive, and usually, as pure elements, chemically very simple materials. Most importantly, however, most metals are in a thermodynamically unstable state, typically able to oxidize in gaseous and especially aqueous environments under ambient conditions. This makes them good fuels for chemical reactions. Additionally, their high electrical conductivities make them excellent candidates for sources of electrochemical energy as well, specifically as anodes in many battery systems. In batteries, they are one of the two phases in an “electrode (anode or half-cell) of the first kind” (Ref 2), where the second phase is the electrolyte containing cations of the metal.

The tendency of metals to oxidize during battery discharge is reflected in the usually substantial negative Gibbs free-energy change for the reactions in Eq 1 or 2. Metals that oxide more readily have more negative Gibbs free-energy changes, and one might conclude that these metals should make better anodes for batteries. However, battery performance (even from a strictly thermodynamic viewpoint) depends not only on this free-energy change but on how much of this energy can be extracted from a given mass of metal. Batteries are often used as power supplies where size and weight are design constraints, so a quantity called the specific capacity or maximum electrical storage density is commonly used to compare the potential performance. The specific capacity is the maximum amount of charge that can be extracted from 1 kg of metal, assuming a certain number of moles of electrons (n) are transferred during oxidation of 1 mole of metal (Ref 3). Defined in units of Ah/kg, the specific capacity is:

$$\text{Specific capacity} = x[n \times F]/[3600 \times m] \qquad \text{(Eq 3)}$$

where F is the Faraday constant, 96,500 C/gram equivalent; m is the mass of the cell or half-cell; and x is the theoretical number of moles of reaction accompanying the complete discharge of the cell. Commonly, specific capacities are compared per unit mass of anode material, so, in this case, m is set equal to M, the atomic weight of the metal in kg/mol, and x is taken as unity:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Specific capacity (per unit anode mass) = $[n \times F]/[3600 \times M]$ (Eq 4)

The specific capacities for metals found in several common batteries, calculated using Eq 4, are listed in Table 1 (Ref 1, 3).

Table 1 Metals in common batteries

Metal	Reaction	Battery designation	Standard potential (E^0), V	Specific capacity, Ah/kg	Specific energy density, kWh/kg
Li	$Li \rightarrow Li^+ + e^-$	Lithium sulfur	-3.05	3860	11.76
Na	$Na \rightarrow Na^+ + e^-$	Sodium sulfur	-2.71	1170	3.17
Mg	$Mg \rightarrow Mg^{2+} + 2e^-$	Magnesium	-2.36	2210	5.22
Zn	$Zn \rightarrow Zn^{2+} + 2e^-$	Leclanche	-0.763	820	0.63
Cd	$Cd \rightarrow Cd^{2+} + 2e^-$	Nickel cadmium	-0.403	477	0.19
Pb	$Pb \rightarrow Pb^{2+} + 2e^-$	Lead acid	-0.126	259	0.03

In addition to specific capacity, two other properties of anodes, metals or otherwise, are useful in comparing battery performance. These are the specific energy (in kWh/kg) and the specific power (in kW/kg). Similar to specific capacity, the specific energy has a theoretical and practical value, with the theoretical value for complete discharged equal to:

Specific energy = $x[n \times F \times E_{cell}]/[3.6 \times 10^6 \times m]$ = [Specific capacity] $\times E_{cell}/1000$ (Eq 5)

where E_{cell} is the reversible electrode cell potential (Ref 1, 3). As in the case of the specific capacity, anodes can be compared by taking the E_{cell} as the standard half-cell potential for the oxidation reaction ($-E^0$ in Table 1, where E^0 is defined as the standard reduction potential, per common convention) and assuming m is then equal to M, the atomic weight of the electrode material (the metal). (Note that this is the same as coupling the anode reaction to the normal hydrogen electrode.) Specific energies for some important battery systems are given in Table 1.

The previously mentioned two parameters for rating battery performance, specific capacity and specific energy, are an indication of how well a metal can act as a vessel loaded with realizable electricity. They are maximum or theoretical values derived from summing up the total number of electrons available (Eq 3 or 4) and considering the reversible available Gibbs free energy embodied in E_{cell} (Eq 5). The extent to which these quantities are realized depends on many factors (Ref 2). Other factors affecting battery performance are:

- A consideration of the cathode reaction and its energetics. The total cell potential depends on the cathode reaction as well as the anode reaction. A given metal anode may show great potential (have a large theoretical specific energy), but difficulties in finding a compatible cathode with a moderately large half- cell potential (assuring a large cell potential) may limit the utility of this metal as an anode material.
- The mass, m, in Eq 3, Eq 4, Eq 5 was taken as the mass of the metal anode. In reality, performance (electricity produced per mass) is determined by the total mass of the battery, including grids, containers, electrolyte, and electrical connections.
- The potential in Eq 5 is a reversible thermodynamic potential that is lessened by the presence of ohmic drops in the cell and any overpotentials arising from activation, diffusion and other transport barriers, concentration gradients, undesirable chemical reactions and precipitate formation, refinement or changes in morphology at the anodes on prolonged cycling, as well as other kinetic factors.

Actual or practical specific energies of batteries are usually significantly less than the maximum values, as illustrated in Table 2 (Ref 1, 2, 3, 4). In fact, only approximately 25% of theoretical capacity is typically

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

attained under most conditions as a result of design and discharge requirement (Ref 1). Some of the electrochemical factors that contribute to these losses are discussed subsequently.

Table 2 Comparison of theoretical and practical specific energies for common batteries

Battery	Cell reaction [(a)]	E^0_{cell}, V	Specific energy, kWh/kg [(b)]	Practical specific energy, kWh/kg [(b)]
Lithium iodine	$Li(s) + 1/2I_2(s) \rightarrow LiI(s)$	2.80 (25 C)	1.9[(c)]	1.1[(c)]
Li-TiS_2	$xLi(s) + TiS_2(s) \rightarrow Li_xTiS_2(s)$	2.15	0.484	0.05–0.12
Lithium sulfur oxide	$2Li(s) + 2SO_2(g) \rightarrow Li_2S_2O_4(s)$	3.1	1.17	0.26
Sodium sulfur	$2Na(l) + 5S(l) \rightarrow Na_2S_5(l)$[(d)]	2.08 (350 C)	0.790	0.10
Magnesium	$Mg(s) + 2MnO_2(s) + H_2O(l) \rightarrow Mn_2O_3(s) + Mg(OH)_2(s)$	2.8	0.76	0.100
Zinc-silver oxide	$Zn(s) + AgO(s) + H_2O(l) \rightarrow Zn(OH)_2(s) + 2Ag(s)$	1.81	0.510	0.120
Air cell	$Zn(s) + 1/2O_2(g) \rightarrow ZnO(s)$	1.65 (65 C)	1.090	0.34
Alkaline zinc	$Zn(s) + MnO_2(s) + 1/2H_2O(l) \rightarrow MnOOH(s) + ZnO(s)$	1.5	0.336	0.038–0.125
Leclanche cell	$Zn(s) + 2MnO_2(s) + 2NH_4Cl(aq) \rightarrow 2MnOOH(s) + Zn(NH_3)_2Cl_2(s)$[(f)]	1.5–1.7 (20 C)	0.14[(e)]	0.085[(e)]
Nickel cadmium	$2NiOOH(s) + Cd(s) + 2H_2O \rightarrow 2Ni(OH)_2(s) + Cd(OH)_2$	1.35	0.244	0.020–0.035
Lead acid	$Pb(s) + PbO_2(s) + 2H_2SO_4(l) \rightarrow 2PbSO_4(s) + 2H_2O(l)$	2.1	0.252	0.035

(a) The state of the reactants is s, solid; g, gas; l, liquid; aq, aqueous solution.
(b) Includes mass of anode plus cathode materials only, unless noted. Practical values are obtained under typically specified conditions for these batteries and include a range spanned by different designs, e.g., button and cylinder.
(c) Units are Wh/cm^3.
(d) Initial cell reaction. As discharge progresses, cell reaction changes with the observed decrease in specific energy.
(e) Includes mass of all cell components.
(f) One of a number of reactions proposed for this complicated chemical process

The various kinetic factors alluded to in the last of the previous three bulleted items, which reduce the cell potential and limit battery performance, depend on current density. For a given current density at which it is desired to provide electricity, the various kinetic factors that reduce the cell potential should be as low as possible. Because the potential and current density cannot be varied indiscriminately, the selection of battery components, including the metal anode, becomes a complex process and relies on many electrochemical kinetics techniques that relate current and potential, similar to approaches used in corrosion science but with different objectives.

Because of the need to consider both potential and current at a specified external load, a useful parameter for comparing battery performance is the specific power (W/kg):

$$\text{Specific power} = [I \times E]/m \qquad \text{(Eq 6)}$$

where I is the current (in amperes) (Ref 1, 2), and E is the actual cell potential (in volts). Because E depends on current, the specific power may be a complex function of current, with the relationship depending on the collection of kinetic factors that diminish the cell potential from its maximum reversible value. The specific power parameter, therefore, captures the overall kinetic aspects of battery performance and is used to select battery systems where energy needs to be supplied at a given rate. A battery may have a large capacity for

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

storing energy (large energy density), for example, but if it has a low specific power, it would only be used where the energy is required at a very slow rate of delivery.

The typical relationship between power and current during battery discharge is illustrated in Fig. 2. Curve A is a typical polarization curve that shows how the voltage of the cell usually changes during discharge. There are three regions: (I) initially, there is a rapid fall in voltage at low current because of electrode polarization involving one or both electrodes; (II) next, there is an almost-linear region with a usually small slope dominated by the internal ohmic resistance of the cell; and (III) finally, at high current, the depletion of electrode material at the electrode surfaces causes a limiting current effect where the slope becomes very large. It should be cautioned that the curves in this figure are idealized and that there are often more complicated behaviors and usually a time dependency associated with the buildup or depletion of reaction products or subsequent morphologies. For this reason, discharge curves are also often shown in terms of how potential varies with time or fraction of discharge completed under fixed-load or fixed-current conditions. Curve B in Fig. 2 shows how the power varies for a cell with discharge characteristics shown in curve A. The power curve exhibits a maximum. At low-current draw, where the voltage of the cell is maximum (as is the efficiency), the power is low because current is low (Eq 6). At intermediate currents, where voltage decreases but current increases, the power increases due to the unusually small slope of the ohmic-dominated region II. It is important to remember that when the power is maximum (when energy is delivered most rapidly), the voltage (and efficiency) of the cell is not optimal. As current is increased further into region III, both power and voltage fall to 0.

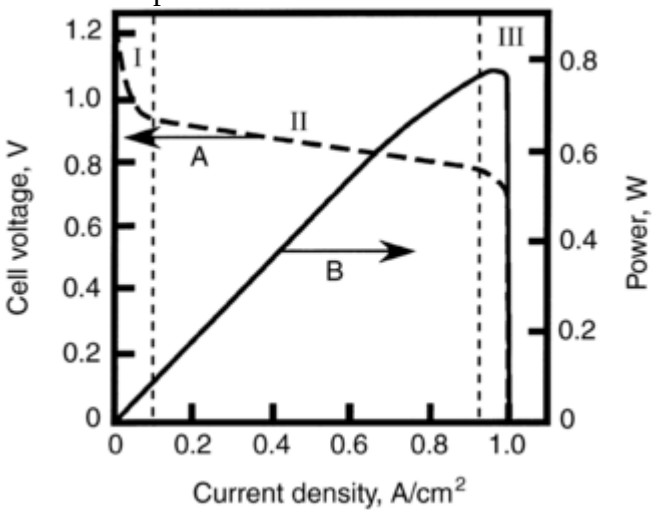

Fig. 2 Typical relationship between cell voltage, power, and current density for a battery. Conditions are divided into three regions: I, low current; II, linear midrange; III, high current. A, typical polarization curve; B, curve showing how power varies for a cell with discharge characteristics of curve A. Source: Ref 2

The curves in Fig. 2 illustrate changes in battery performance that are partly impacted by the kinetics of oxidation of the anode material. When the anode is a metal, the curves are influenced by the same types of activation and mass transport barriers that are commonly studied for controlling the corrosion of structural and electronic metal-based structures. In the case of batteries, however, the emphasis is usually on lowering these barriers to facilitate oxidation of the metal and thus maintain the anode potential as high as possible. Two important caveats are worth mentioning, however. First, the emphasis on lowering activation barriers relates to the primary anode discharge reaction only. Parasitic corrosion reactions involving the anode material often occur in batteries during normal use or storage, and the focus here is on eliminating or inhibiting these reactions (often with chemical inhibitors), much like the focus in other corrosion-related studies. Secondly, metal anodes in secondary batteries are unlike most metallic systems undergoing corrosion in that they are recycled many times so as to regenerate the metal. This recycling causes continued refinement of the metallic microstructure and composition, the extent of which depends on many factors, including discharging and charging rates, depth of discharge, temperature, and so on. To understand the effects of these changes, discharge curves are often obtained over many battery charge/discharge cycles. Application of other electrochemical techniques, including transient electrochemical measurements and impedance studies, is also helpful.

Because the focus here is corrosion or oxidation of metallic electrodes, further discussion of overall battery performance is limited. Rather, two battery systems are selected, and specific issues related to anode oxidation

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

in these batteries during discharge are briefly discussed. The purpose of this discussion is twofold: to show how the constructive corrosion reaction (primary discharge reaction) at the anode is typically monitored by electrochemical methods and to illustrate how various aspects of this corrosion reaction influence battery performance. The anodes selected for discussion are the zinc anode in the mercury battery (Zn/HgO) and the lithium metal anode in a rechargeable lithium battery.

Zinc Anode in the Mercury Battery. The mercury battery, often fabricated in the form of a button, is used in a wide range of applications where a miniature power source with a relatively constant voltage is required throughout long discharge periods (Ref 1, 2). As shown in the cross section in Fig. 3, the battery has an amalgamated zinc anode, a concentrated aqueous potassium hydroxide electrolyte that is saturated with zincate ions with ZnO, and a mercuric oxide/ graphitic carbon (HgO(s)/C) cathode. The anode is usually in the form of a porous, compressed cylindrical pellet or button of amalgamated zinc powder and gelled electrolyte. Alternatively, a spiral of corrugated zinc foil spaced with an absorbent paper layer is used in a wound configuration.

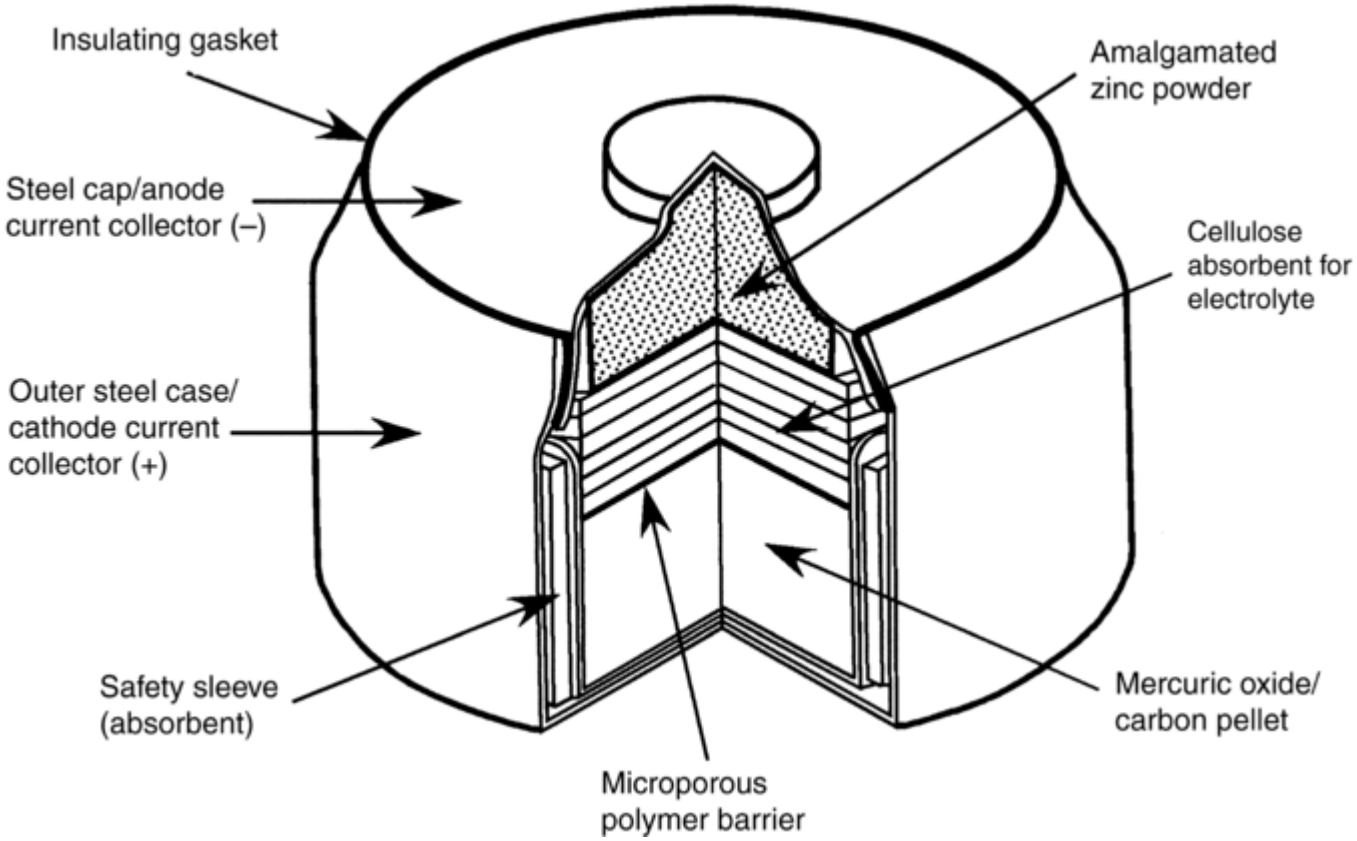

Fig. 3 Cross section of a typical mercury button cell. Source: Ref 2

The anode reaction (negative electrode) is:

$$Zn(s) + OH^-(aq) \rightarrow Zn(OH)_4^{2-}(aq) + 2e^- \quad \text{(Eq 7a)}$$

$$Zn(OH)_4^{2-}(aq) \rightarrow ZnO(s) + 2OH^-(aq) + H_2O(l) \quad \text{(Eq 7b)}$$

and the cathode reaction (positive electrode) is:

$$HgO(s) + H_2O(l) + 2e^- \rightarrow Hg(l) + 2OH^-(aq) \quad \text{(Eq 8)}$$

so that the overall reaction is:

$$Zn(s) + HgO(s) \rightarrow ZnO(s) + Hg(l) \quad \text{(Eq 9)}$$

In these reactions and those that follow, the state of the reactants is given: s, solid; l, liquid; aq, in aqueous solution; and g, gas.

Note that the sum of Eq 7a(a) and (b) is the half-cell corrosion reaction for zinc. It includes the oxidative dissolution of zinc metal, with the crystallization of ZnO from the electrolyte. How efficiently this reaction occurs, as well as how facile it is, partly determines the performance characteristics of this battery. The battery has a nominal cell voltage of 1.35 V and a typical practical specific energy of 0.100 kWh/kg at 20 °C (70 °F)

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

under favorable discharge conditions. The latter compares with a theoretical specific energy of 0.255 kWh/kg. Typical discharge curves (Ref 4) are shown in Fig. 4. Note that they have a particularly flat region II, extending to almost full cell capacity at low current drains, under constant discharge conditions. This behavior makes these batteries very stable voltage sources and explains why they are commonly used as reference standards in regulated power supplies and other devices.

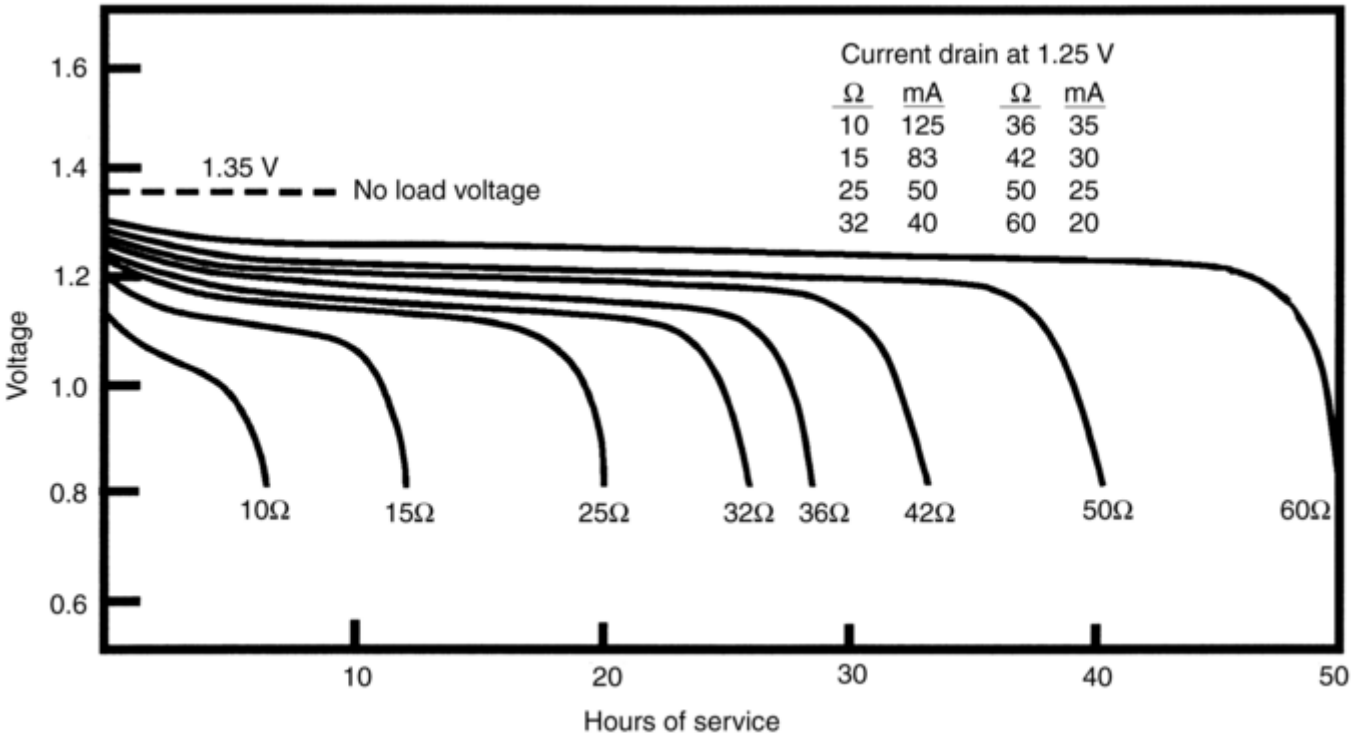

Fig. 4 Discharge curves for a typical Zn-HgO battery under various loads. Source: Ref 4

The mercury battery has some shortcomings, however. Low-temperature performance is not particularly favorable, especially when the current demands are low or intermittent. As shown in Fig. 5, there is a decrease in the capacity of the battery, similar, but to a different extent, for different configurations, when operated below room temperature (Ref 4). The behavior indicates a decreased rate of ion discharge of the zinc, which has been attributed to the growth of deposited ZnO on the anode. Low temperatures apparently favor precipitation of excessive ZnO, which functions as a resistive barrier and lowers the cell potential under constant current conditions. Again, note the focus here is on avoiding conditions where a resistive layer forms rather than on promoting their formation. Formation of protective films on battery metal anodes is favorable only when the films limit undesirable parasitic reactions, as discussed subsequently. If the films interfere in a negative way (by increasing overvoltage or limiting capacity) with the principal battery discharge reaction, they are undesirable. Over the years, much research in battery science has been devoted to controlling the growth of anode reaction products that adversely affect battery performance.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

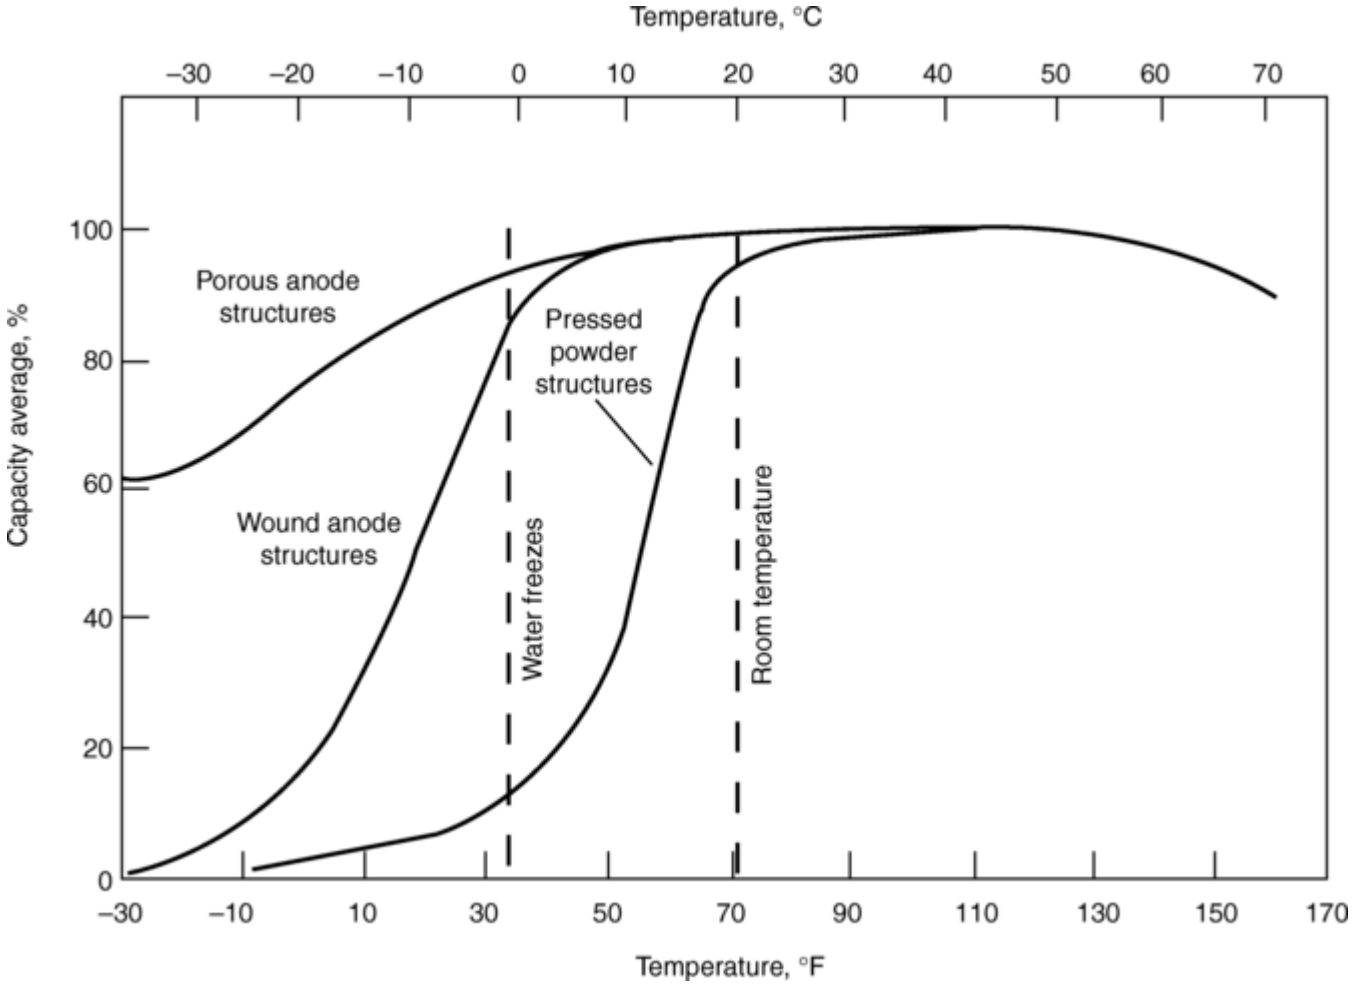

Fig. 5 Effect of temperature on the capacity of a Zn-HgO battery. The loss of capacity at lower temperatures due to ZnO formation is demonstrated, as is the sensitivity to anode morphology. Source: Ref 4

Another anode-related problem in the mercury battery system is the potential for hydrogen gas production. Usually, excess cathode material is incorporated in the battery to keep the battery reactions zinc-limited, (Ref 2), lessening the possibility that excess zinc in an exhausted battery could react directly with the electrolyte and liberate hydrogen. Even for a charged battery, however, the potential for hydrogen production is present, unless the overpotential for hydrogen is increased on the zinc anode. This is usually done by adding mercury or, preferably, another gassing inhibitor to the anode as an amalgam. Great attention is also paid to controlling impurities in the zinc, because minor amounts of these impurities can act as local cathodes on the zinc, promoting hydrogen generation.

Lithium Anode in the Rechargeable Lithium Battery. Primary batteries containing lithium-metal anodes have been available for some time and use a number of configurations employing several types of cathode materials, including both gases (SO_2) and solids (MnO_2, V_2O_5, FeS_2, and CuO). A cross-sectional view of a Li/MnO_2 coin cell is shown in Fig. 6. Secondary (rechargeable) versions of this battery system have been more problematic, however, largely because of safety issues related to hydrogen production and thermal runaway. These shortcomings, coupled with a continuous improvement in the performance of lithium-ion batteries, has largely halted further development of lithium-metal-based batteries in favor of their lithium-ion counterparts. This is unfortunate, because the highest energy densities available for lithium batteries are achieved using lithium metal as anodes. Batteries with lithium metal are also more likely to be cheaper than lithium-ion batteries containing composite anodes. More recently, developments involving new electrolyte systems (polyethylene oxide and its derivatives, and other organic electrolytes that polymerize or react to shut down the battery during runaway conditions) have shown promise in reducing some of the safety concerns and have caused somewhat of a revival in lithium-metal anode systems.

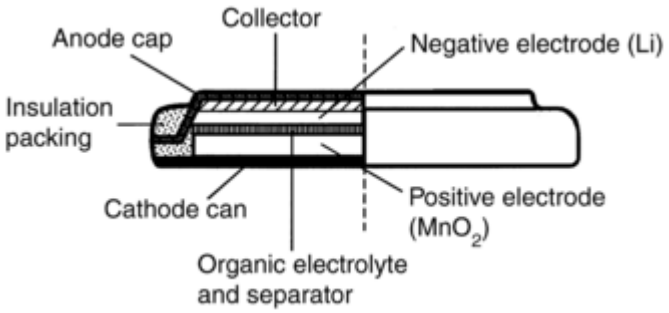

Fig. 6 Cross section of a Li/MnO_2 coin cell. Courtesy of Duracell, Inc.

A recent design for a rechargeable battery using a Li_xMnO_2 cathode was developed during the early 1990s (Ref 5). In this battery, the anode reaction (negative electrode) is the corrosion reaction for lithium:

$$Li(s) \rightarrow Li^+(dis) + e^- \qquad \text{(Eq 10)}$$

while the cathode reaction (positive electrode) involves intercalation of the Li^+ ions, similar to the electrode processes in the lithium-ion battery systems. Early versions of this battery exhibited capacities greater than 190 Ah/kg but also required slow charging rates in order to realize hundreds of cycles from them. Consequently, some of the focus of recent work on these batteries is in understanding the changes associated with the lithium-metal anode that occur during charging and how these changes influence the charging capacity. The results of these studies prove to be an interesting example of how the morphology of the lithium metal deposited during charging is influenced by the charging conditions and how this morphology, in turn, influences the oxidation or (desired) corrosion reactions that occur during discharge.

As shown in Fig. 7, the cycle life of the Li- Li_xMnO_2 cell is significantly reduced at charging current densities above 0.3 mA/cm^2, although the drop-off in capacity levels off at approximately 100 cycles. This dramatic decrease has been associated with a decrease in the available active electrode area and an increase in the cell impedance (Ref 6). Careful analysis of lithium- metal electrodes cycled at different charging rates showed very different morphologies. Low charging rates favored the formation of larger lithium grains, while higher rates of charging gave very small grains. Moreover, the grain size was similarly smaller when the charging rate exceeded the value where the capacity leveled off in Fig. 7, indicating a direct correlation between grain size and cycle life. The implications on battery performance are clear. As the grains of lithium formed during charging become smaller, the amount of active surface area increases. While a larger surface area might be expected to favor the anode half-cell reaction, they also make the anode more reactive toward solution species. Higher reactivity causes more depletion of electrolyte during cycling, the formation of lithium- electrolyte reaction products (confirmed by analysis), and eventually, cell failure due to an increase in battery impedance.

Constructive Corrosion as Part of Battery Manufacturing

In addition to corrosion reactions playing the constructive central role as one of the half-cell reactions during the operation (discharge) of batteries with metal anodes, corrosion processes sometimes are employed during battery manufacturing to generate the active mass for electrodes. An example of this secondary constructive role of corrosion is in the preparation of the oxide pastes used to make the positive plates (specifically, the positive active mass, or PAM, on these plates) of the lead-acid battery.

Oxide Paste Fabrication in the Lead-Acid Battery. Despite on-going efforts to develop smaller and lighter alternatives, the lead-acid battery has continued to serve as one of the most successful power sources in automotive and allied applications for combined vehicle starting, vehicle lighting, and engine ignition. It has been in commercial use for more than a century. Its key advantages include low cost, excellent rechargeability, high cell voltage (2.2 V), good high-rate performance, and lower sensitivity to temperature than other batteries (Ref 2, 7).

The anode reaction (negative electrode) is:

$$Pb(s) \rightarrow Pb^{2+}(aq) + 2e^- \quad \text{(Eq 11a)}$$

$$Pb^{2+}(aq) + SO_4^{2+}(aq) \rightarrow PbSO_4(s) \quad \text{(Eq 11b)}$$

and the cathode reaction (positive electrode) is:

$$PbO_2(s) + 4H^+(aq) + 2e^- \rightarrow Pb^{2+}(aq) + H_2O(l) \quad \text{(Eq 12a)}$$

$$Pb^{2+}(aq) + SO_4^{2-}(aq) \rightarrow PbSO_4(s) \quad \text{(Eq 12b)}$$

The overall cell reaction is:

$$Pb(s) + PbO_2(s) + 2H_2SO_4(l) \rightarrow 2PbSO_4(s) + 2H_2O(l) \quad \text{(Eq 13)}$$

The formation of barely soluble lead sulfate at both the anode and cathode is one of the unique characteristics of this battery and leads to the overall process being called double sulfatation. The anode reaction involves oxidation (constructive corrosion) of the lead. Because the battery is rechargeable, the lead-metal microstructure evolves during subsequent discharging and charging cycles, leading to surface area/microstructure effects on oxidation similar to those discussed previously for lithium-metal batteries. In

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

particular, much research has focused on the prevention of anode passivation using chemical additives that promote more desirable polymorphs of lead sulfate.

The constructive corrosion of lead plays another important role in the lead-acid battery, however. This role involves the fabrication of the PAM for the cathode (positive electrode). The cathode reaction in the lead-acid battery involves the reduction of PbO_2(s) in the form of a paste that is in electrical contact with a lead-metal grid (Ref 1, 2, 7). The PbO_2(s) paste must be prepared according to specific procedures, developed after years of testing by the battery industry, in order to meet performance targets for the batteries. These procedures involve oxidizing (corroding) highly refined (usually virgin or primary) lead metal using either a Barton pot or a ball mill. In the Barton pot process, molten lead, sprayed into droplets, is heated in a pot-shaped vessel where it reacts with air. This produces solid particles of lead metal coated with a lead oxide (PbO). The amount of free lead left over is between 15 and 30%. In ball milling, lead-metal pieces are put into a rotary mechanical mill, resulting in the formation of small flakes that are then oxidized by a stream of air. The resulting oxides contain 15 to 30% free lead in the shape of flattened platelets coated by oxide.

The PbO/Pb feedstock described previously is often mixed with additional oxide, red lead (Pb_3O_4), and then converted to a plastic, doughy material by mixing with water and sulfuric acid in a pony mixer. The resulting paste is used to coat the lead grids. Once the grids are coated, the paste is cured in air. Later, after battery assembly is completed, an additional formation step converts the paste to a fully charged active mass. During the curing process, at temperatures ranging between 25 and 90 °C (77 and 195 °F), depending on humidity, the balance of the metallic lead is oxidized (corroded). Proper curing conditions have been another area of extensive study by the industry. Different combinations of lead oxides and sulfates, with different degrees of hydration, are obtained under various conditions of temperature, airflow, and humidity. Clearly, corrosion of the residual free lead during curing partly determines the composition and structure of the final mixture of lead oxides that makes up the PAM, one of the most important determinants of lead-acid battery performance.

Destructive Corrosion

There are also a number of important examples of corrosion specific to batteries that are destructive and undesirable, and these have been the focus of extensive study by the battery industry. It would seem incomplete, therefore, if some discussion of at least one or two cases of this type of corrosion was not included here. These corrosion processes involve parasitic reactions that destroy electrode materials, with consequences including loss of active mass, pollution of the electrolyte, passivation or precipitate formation that increases internal resistance or interferes with the normal charging process, and the generation of gases, with associated safety risks.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Shelf Reactions in Zinc-Carbon Batteries. Shelf reactions in batteries are reactions that occur during storage or when the battery is not in use. One of the most important types of shelf reactions is corrosion of metallic electrodes, both anodes and cathodes. In zinc-carbon batteries, corrosion problems involve the zinc anode. Other components in this cell include a manganese dioxide cathode and an electrolyte of ammonium chloride and/or zinc chloride dissolved in water. When only zinc chloride is used, the battery is called a zinc chloride battery to distinguish it from the Leclanche cell, where ammonium chloride is the primary electrolyte component.

There is more than one proper discharge reaction for zinc-carbon cells, depending on the magnitude of discharge and the type of electrolyte (Ref 1). In all cases, the anode reaction involves the oxidation of zinc metal:

$$Zn(s) \rightarrow Zn^{2+}(aq) + 2e^- \qquad \text{(Eq 14)}$$

with the Zn^{2+} ions then undergoing various complexation reactions with hydroxide, chloride, and ammonia.

When undesirable corrosion of the zinc anode occurs during storage, the zinc reacts directly with the electrolyte according to three mechanisms (Ref 2). These reactions rob fuel from the battery and generate corrosion products that degrade battery performance and/or raise safety concerns. When oxygen is present:

$$Zn(s) + 2NH_4^+(aq) + Cl^-(aq) + 1/2O_2(g) \rightarrow Zn(NH_3)_2Cl_2(s) + H_2O(l) \qquad \text{(Eq 15)}$$

Obviously, this reaction can be minimized by proper sealing of the battery container.

In the absence of oxygen, however, corrosion can still occur according to the following reaction:

$$Zn(s) + 2NH_4^+(aq) + Cl^-(aq) \rightarrow Zn(NH_3)_2Cl_2(s) + H_2(g) \qquad \text{(Eq 16)}$$

This corrosion reaction is normally slow, because there is a significant overvoltage for H_2 generation on zinc under cell storage conditions. However, the presence of minor impurities in the metal (such as nickel, iron, and copper) can reduce this overvoltage significantly, allowing the reaction in Eq 16 to occur and H_2 to be generated. Interestingly, the metallic impurities can be generated by Ni^{2+}, Fe^{2+}, and Cu^{2+} ions in the electrolyte according to the following type of reaction, which is also the third mechanism for corrosion of the zinc anode:

$$Zn(s) + Fe^{2+}(aq) \rightarrow Zn^{2+}(aq) + Fe(s) \qquad \text{(Eq 17)}$$

The reaction in Eq 17 can also involve Ni^{2+} and Cu^{2+} ions in the electrolyte and usually occurs at local sites on the anode, as shown in Fig. 8. These local cells can generate large amounts of H_2 as well as the metallic impurities that promote additional corrosion according to the reaction in Eq 16. Furthermore, the reaction products may be generated in the form of large dendrites that result in short circuiting of the cells.

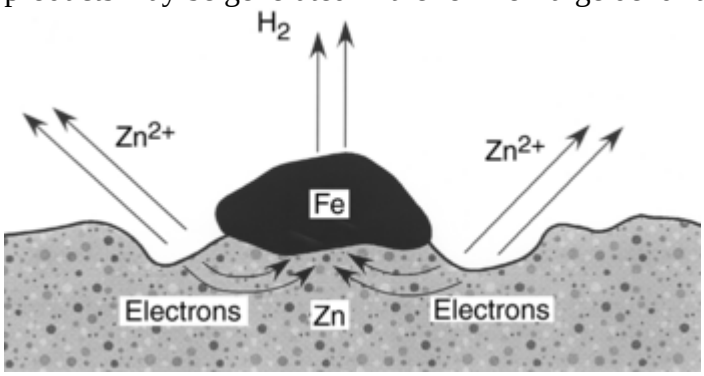

Fig. 8 Schematic showing zinc dissolution due to local corrosion of a zinc anode in a zinc-carbon battery. Source: Ref 2

Inhibition of the last two types of corrosion (i.e., occurring with or without oxygen) is usually accomplished by appropriately modifying the morphology and composition of the anode and the composition of the electrolyte. Amalgamation of the zinc with mercury, using a mercury salt added to the electrolyte, for example, results in an increase in overvoltage for hydrogen production and fosters the dissolution of surface impurities, lessening the possibility that they will form local electrochemical couples with the zinc. The mercury also promotes a more desirable smooth surface on the zinc that disfavors the occurrence of corrosion sites. Recent concerns about safety, however, have necessitated replacements for mercury. Current versions of zinc-carbon cells use higher-purity zinc anodes and electrolyte to lessen the role of the reactions in Eq 16 and 17, as well as tighter cell

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

casings to reduce air contamination. Other corrosion inhibitors are also used, including chromates, organic surfactants, and chelating agents.

Lead Grid Corrosion in the Lead-Acid Battery. The lead grids used in the lead-acid battery are subject to corrosion reactions during battery storage similar to the zinc anodes in the zinc- carbon battery. For the lead-acid battery, however, corrosion reactions can also occur and cause problems at the positive electrode (cathode), because both electrodes use a lead grid as part of the electrode assembly. Moreover, they can occur during battery operation. Premature capacity loss, an important mode of performance failure in lead-acid batteries, is sometimes attributed to the formation or changes of corrosion layers at the positive electrode during battery operation (Ref 8, 9, 10).

The corrosion reactions at the positive electrode (cathode) during battery operation usually involve the reaction of the lead in the grid with oxygen that diffuses through the oxide layers on the grid or by self-discharge, where lead reacts directly with PbO_2. The composition of these oxide layers is very complicated and has been the subject of much study by the lead-acid battery industry. In general, the oxide next to the grid is a corrosion layer, initially formed during one or more steps in the battery manufacture, and is composed of two parts (Ref 10), as shown in Fig. 9. Closer to the lead metal there is a thin, dense corrosion layer of oxide with the lead ions in a reduced state, nominally PbO, that can protect the grid from corrosion but can also add a resistive component to the circuit. A second, outer layer is porous and nominally composed of PbO_2. It should be recognized that both oxide layers are actually nonstoichiometric and vary through their thickness. Understanding the composition of these layers and how they are influenced by metal composition and treatment conditions is an area of major interest to the lead-acid battery industry. On top of the corrosion layer is the PAM, composed of mostly PbO_2, although, here again, the chemistry is more complicated, involving differing polymorphs of PbO_2 and distributions based on manufacturing conditions. Battery performance, of course, depends on many of these varying parameters, involving both the corrosion layers and the PAM.

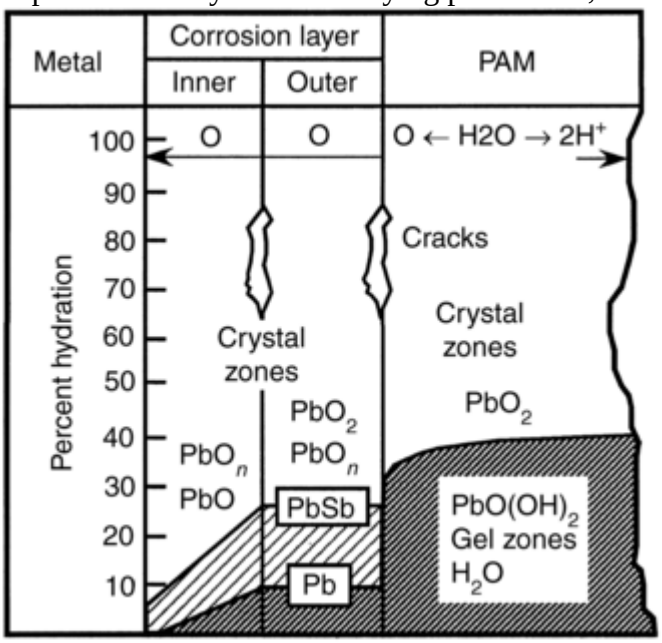

Fig. 9 Schematic of corrosion layers on Pb and Pb-Sb grids in the positive electrode in a lead-acid battery as proposed by Pavlov. The structural elements are positioned along the abscissa. The interface between the metal and the inner corrosion sublayer is used as the ordinate, where the percent of hydration of the separate structural elements of the plate are presented. In general, the outer corrosion sublayer is hydrated in the form of a gel. The degree of hydration is approximately 10% in pure Pb electrodes, whereas it varies between 15 and 25% in Pb-Sb electrodes. There is 30 to 35% hydration of the positive active mass (PAM). Percent hydration refers to percentage contributed by $Pb(OH)_2$, gel zones, and H_2O. Source: Ref 9

Corrosion of the positive electrode (cathode) during battery operation involves diffusion of oxygen through the corrosion layers. As it diffuses and before it reaches the metal grid, the oxygen also reacts with the various substoichiometric oxides that make up the corrosion layer:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$Pb + O \rightarrow PbO \quad \text{(Eq 18)}$$

$$PbO + (n - 1)O \rightarrow PbO_n \ (1 < n < 2) \quad \text{(Eq 19)}$$

$$PbO_n + (2 - n)O \rightarrow PbO_2 \quad \text{(Eq 20)}$$

Depending on the rates of the various reactions in Eq 18, Eq 19, Eq 20, corrosion layers of varying composition and properties are formed. If the reaction in Eq 18 is rapid, mostly PbO forms, and the corrosion layer evolves into a thin, highly resistive, passive layer. In other words, formation of the inner corrosion layer is favored. Alternatively, if the reactions in Eq 19 and 20 are favored, the corrosion products become more loaded with electrochemically active PbO_2. This more porous structure has lower ohmic resistance but, in the absence of an inner corrosion layer, offers little protection to the lead grid for further corrosion. Understanding how battery operating conditions and compositional parameters influence the various rates of the reactions in Eq 18, Eq 19, Eq 20, therefore, becomes important. Achieving an inner corrosion layer with good conductivity and adequate passivating quality, while at the same time affording an outer corrosion layer with good electrochemical activity and contact with the PAM, requires tailoring conditions to obtain appropriate reaction rates that favor PbO_n in the inner layer. Antimony, tin, and bismuth grid-alloy additives are commonly used for this purpose (Fig. 10).

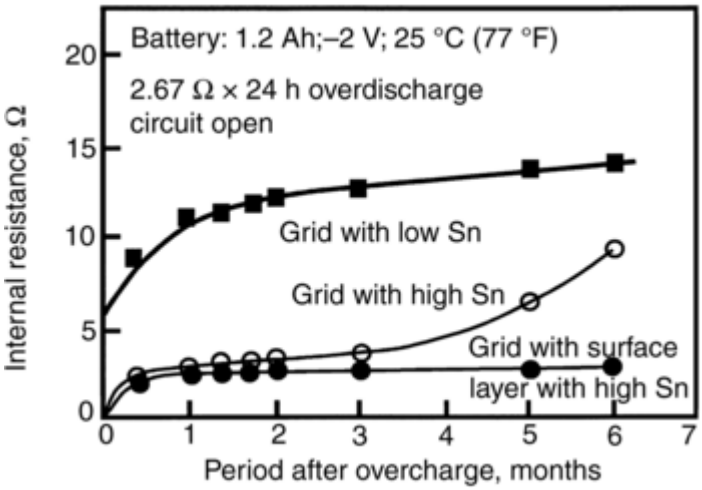

Fig. 10 Effect of tin on internal resistance of lead alloys or lead grids with a tin-rich coating during overcharge conditions in a lead-acid battery. Source: Ref 10

Conclusions

The previous discussion is a brief overview of how corrosion in batteries occurs, with both constructive and destructive results. Factors related to its constructive roles, both thermodynamic and kinetic, are virtually identical to those related to destructive roles, both in batteries and elsewhere. These factors include Gibbs free-energy considerations, the magnitude of overpotentials, and the presence and mechanisms of competing reactions. However, what scientists and engineers seek to do with these factors is completely opposite for the two cases. When corrosion is constructive, that is, metal anode oxidation during normal battery operation, the emphasis is on obtaining the most negative free- energy change and reducing overpotentials for the primary anode reaction. When corrosion is destructive, that is, self-discharge during storage or parallel corrosion reactions during operation, the focus is on the most positive free-energy change and finding ways to increase the overpotentials for these undesirable reactions.

Fuel Cells

Mark C. Williams, U.S. Department of Energy, National Energy Technology Laboratory

Introduction

FUEL CELLS are electrochemical devices that convert the chemical energy of a reaction directly into electrical energy, water, and heat. In principle, a fuel cell operates like a battery, but does not run down or require recharging as long as hydrogen-rich fuel is supplied. The basic physical structure or building block of most fuel cells consists of an electrolyte layer in contact with porous anode and cathode electrodes on either side. Figure 1 is a simplified diagram that demonstrates how a fuel cell works.

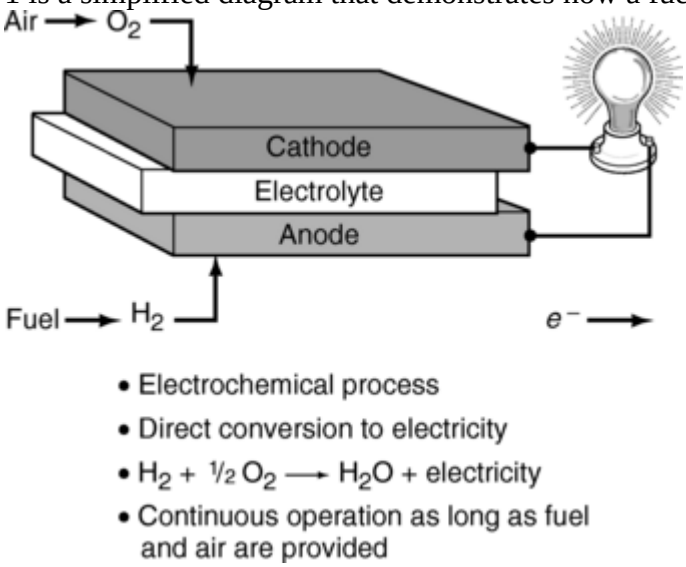

Fig. 1 Schematic of a fuel cell

In a typical fuel cell, gaseous fuels are fed continuously to the anode (negative electrode) compartment, and an oxidant, such as oxygen from air, is fed continuously to the cathode (positive electrode) compartment. Encouraged by a catalyst, the hydrogen atom oxidizes into a proton (H^+) and an electron (e^-) that take different paths to the cathode. The proton passes through the electrolyte. The electrons create a separate current that can be utilized before they return to the cathode to form O^{2-}. The oxygen ion then reunites with the proton to form a molecule of water.

A fuel-cell system that includes a fuel reformer can utilize the hydrogen from any hydrocarbon fuel, from natural gas to methanol, and even gasoline. Gaseous hydrogen has become the fuel of choice for most applications, because of its high reactivity when suitable catalysts are used, its ability to be produced from hydrocarbons for terrestrial applications, and its high energy density when stored cryogenically for closed-environment applications, such as in space. Similarly, the most common oxidant is gaseous oxygen, which is readily and economically available from air for terrestrial applications and is also easily stored in a closed environment. Since the fuel cell relies on chemistry and not combustion, emissions from this type of system would still be much smaller than emissions from the cleanest fuel-combustion processes.

مرجع مهندسی مواد و متالورژی

In reality, degradation primarily from corrosion limits the practical operating life of fuel cells. Components must meet certain general requirements in order to be useful. No components may exhibit any significant changes in volume between room temperature and the fabrication temperature. The components must be chemically stable in order to limit chemical interactions with other cell components. They must have similar thermal expansion in order to minimize thermal stresses that may cause cracking and delamination during thermal cycling or fabrication. It is also desirable that fuel-cell components have high strength and durability, are easy to fabricate, and are relatively inexpensive.

Performance

The ideal performance of a fuel cell depends on the electrochemical reactions that occur between different fuels and oxygen. Low-temperature fuel cells—polymer electrolyte (PEFC), alkaline (AFC), and phosphoric acid (PAFC)— require noble metal electrocatalysts to achieve practical reaction rates at the anode and cathode, and H_2 is the only acceptable fuel. With high- temperature fuel cells—molten carbonate (MCFC) and solid oxide (SOFC), for example— the requirements for catalysis are relaxed, and the number of potential fuels expands. (Other types of fuel cells are not addressed in this article.) For example, carbon monoxide “poisons” a noble metal anode catalyst such as platinum in low-temperature fuel cells, but it competes with H_2 as a reactant in high-temperature fuel cells where nonnoble metal catalysts such as nickel can be used. Table 1 shows the types and associated electrochemical reactions that occur in fuel cells.

Table 1 Electrochemical reactions in fuel cells

Fuel cell	Anode reaction	Cathode reaction
Polymer electrolyte (PEFC)	$H_2 \rightarrow 2H^+ + 2e^-$	$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O$
Phosphoric acid (PAFC)	$H_2 \rightarrow 2H^+ + 2e^-$	$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O$
Alkaline (AFC)	$H_2 + 2(OH)^- \rightarrow 2H_2O + 2e^-$	$\frac{1}{2}O_2 + H_2O + 2e^- \rightarrow 2(OH)^-$
Molten carbonate (MCFC)	$H_2 + CO_3^{2-} \rightarrow H_2O + CO_2 + 2e^-$ $CO + CO_3^{2-} \rightarrow 2CO_2 + 2e^-$	$\frac{1}{2}O_2 + CO_2 + 2e^- \rightarrow CO_3^{2-}$
Solid oxide (SOFC)	$H_2 + O^{2-} \rightarrow H_2O + 2e^-$ $CO + O^{2-} \rightarrow CO_2 + 2e^-$ $CH_4 + 4O^{2-} \rightarrow 2H_2O + CO_2 + 8e^-$	$\frac{1}{2}O_2 + 2e^- \rightarrow O^{2-}$

In addition to H_2, CO and CH_4 are shown in Table 1 as undergoing oxidation. In actuality, insignificant direct oxidation of the CO and CH_4 may occur. It is common systems-analysis practice to assume that H_2, the more readily oxidized fuel, is produced by CO and CH_4 reacting (at equilibrium) with H_2O through the water-gas shift ($CO + H_2O \rightarrow H_2 + CO_2$) and steam-reforming reactions ($CH_4 + H_2O \rightarrow 3H_2 + CO$), respectively. The H_2 calculated to be produced from CO and CH_4, along with any H_2 in the fuel- supply stream, is referred to as equivalent H_2. The temperature and catalyst of state-of-the-art MCFCs provide the proper environment for the water-gas shift reaction to produce H_2 and CO_2 from CO and H_2O. An MCFC that reacts only with H_2 and CO is known as an external-reforming (ER) MCFC. An internal-reforming (IR) MCFC has a reforming catalyst

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

placed in proximity to the anode to promote the reforming reaction to produce H_2 and CO_2 from CH_4 and H_2O. The direct oxidation of CO and CH_4 in a high-temperature SOFC is feasible without the catalyst, but again the direct oxidation of these fuels is not as favorable as the water-gas shift of CO to H_2 and reforming of CH_4 to H_2. These are critical arguments in determining the equations to describe the electrical characteristics and the energy balance of the various types of cells. It is fortunate that converting CO and CH_4 to equivalent H_2 then reacting within the cell simplifies the prediction of the electrochemical behavior of the fuel cell.

The actual cell potential is decreased from its equilibrium potential because of irreversible losses. Multiple phenomena contribute to irreversible losses in an actual fuel cell. These losses are called polarization, overpotential, or overvoltage (η), and they originate primarily from three sources: activation polarization (η_{act}), ohmic polarization (η_{ohm}), and concentration polarization (η_{conc}). These losses result in a cell voltage (V_{cell}) that is less than its ideal voltage (E). The summary equation

$$V_{cell} = \Delta E_e - |\eta_{cathode}| - |\eta_{anode}| - iR$$

where $\Delta E_e = E_{cathode} - E_{anode}$, i is the current flowing through the cell, and R is the total cell resistance including electronic, ionic, and contact resistances.

This equation shows that current flow in a fuel cell results in a decrease in the cell voltage because of losses by electrode and ohmic polarizations. The goal of fuel-cell developers is to minimize the polarization so that V_{cell} approaches ΔE_e. This goal is approached by modifications to fuel-cell design (improvement in electrode structures, better electrocatalysts, more conductive electrolyte, thinner cell components, etc.). For a given cell design, it is possible to improve the cell performance by modifying the operating conditions, for example higher gas pressure, higher temperature, or a change in gas composition to lower the gas-impurity concentration. However, for any fuel cell, compromises exist between achieving higher performance by operating at higher temperature or pressure and the problems associated with the stability or durability of cell components encountered under more severe conditions.

As shown in Fig. 2, the activation-polarization loss is dominant at low current density. At this point, electronic barriers must be overcome prior to current and ion flow. Activation losses increase as current increases. Ohmic polarization (loss) varies directly with current, increasing over the entire range of current because cell resistance remains essentially constant. Gas-transport losses (concentration polarization) occur over the entire range of current density, but they become prominent at high limiting currents where it becomes difficult to provide enough reactant flow to the cell-reaction sites.

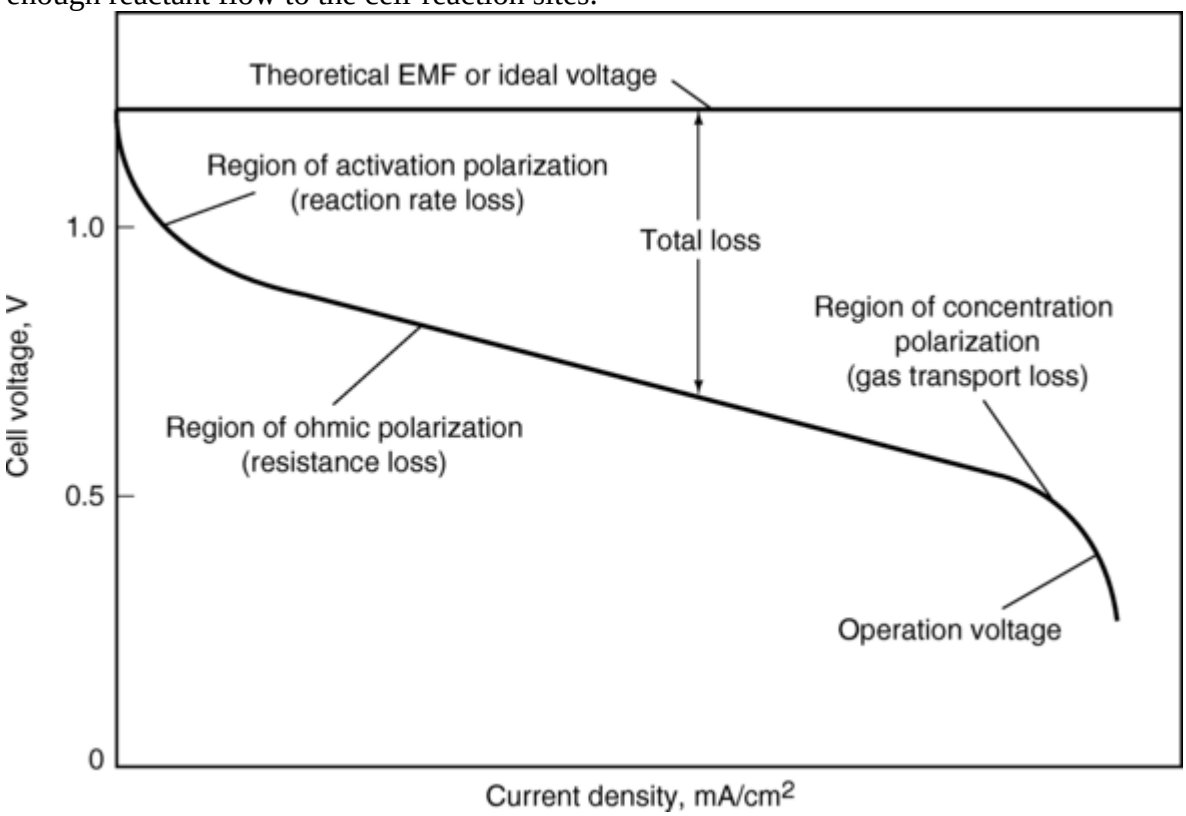

Fig. 2 Ideal and actual fuel-cell voltage versus current density characteristics

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Changing the cell-operating parameters (temperature and pressure) can have either a beneficial or a detrimental impact on fuel-cell performance and on the performance of other system components. These effects may be offsetting. Changes in operating conditions may lower the cost of the cell, but increase the cost of the surrounding system. Compromises in the operating parameters are usually necessary to meet the application requirements, obtain lowest system cost, and achieve acceptable cell life. Operating conditions are based on defining specific system requirements, such as power level, voltage, or system weight. From this and through interrelated systems studies, the power, voltage, and current requirements of the fuel-cell stack and individual cells are determined. It is a matter of selecting a cell operating point (cell voltage and related current density) until the design requirements are satisfied (such as lowest cost, lightest unit, highest power density). For example, a design point at high current density will allow a smaller cell size at lower capital cost to be used for the stack, but the result is a lower system efficiency (because of the lower cell voltage) and attendant higher operating cost. This type of operating point would be typified by a vehicle application where light weight and small volume are important drivers for cost effectiveness. Operating at a lower current density, but higher voltage (higher efficiency, lower operating cost) would be more suitable for stationary power- plant operation. It is evident that the selection of the cell design point interacts with the application objectives.

Fuel-Cell Technology Overview

The most common classification of fuel cells begins with the type of electrolyte used in the cells as listed in the order of approximate operating temperature:

Fuel cell	Approximate operating temperature	
	°C	**°F**
Polymer electrolyte (PEFC)	80	175
Alkaline (AFC)	100	212
Phosphoric acid (PAFC)	200	390
Molten carbonate (MCFC)	650	1200
Solid oxide (SOFC)	600–1000	1110–1830

The operating temperature and useful life of a fuel cell dictate the physicochemical and thermomechanical properties of materials used in the cell components such as electrodes, electrolyte, interconnect, and current collector. Aqueous electrolytes are limited to temperatures of about 200 °C (390 °F) or lower because of their high water vapor pressure and/or rapid degradation at higher temperatures. The operating temperature also plays an important role in dictating the type of fuel that can be used in a fuel cell. The low- temperature fuel cells with aqueous electrolytes are, in most practical applications, restricted to hydrogen as a fuel. In high-temperature fuel cells, CO and even CH_4 can be used because of the inherently rapid electrode kinetics and the lesser need for high catalytic activity at high temperature. However, descriptions later in this section note that the higher-temperature cells can favor the conversion of CO and CH_4 to hydrogen, then use the equivalent hydrogen as the actual fuel. Major differences among the various cells are shown in Table 2. A detailed description of these fuel cells can be found in Ref 1.

Table 2 Summary of major differences of the fuel-cell types

	PEFC	AFC	PAFC	MCFC	SOFC
Electrolyte	Ion-exchange membranes	Mobilized or immobilized potassium hydroxide	Immobilized liquid phosphoric acid	Immobilized liquid molten carbonate	Ceramic
Operating temperature °C (°F)	80 (175)	65–220 (150–430)	205 (400)	650 (1200)	600–1000 (1110–1830)
Charge carrier	H^+	OH^-	H^+	CO_3^{2-}	O^{2-}
External reformer for CH_4	Yes	Yes	Yes	No	No
Prime cell components	Carbon-base	Carbon-base	Graphite-base	Stainless-base	Ceramic
Catalyst	Platinum	Platinum	Platinum	Nickel	Perovskites
Product water management	Evaporative	Evaporative	Evaporative	Gaseous product	Gaseous product
Product heat management	Process gas + independent cooling medium	Process gas + electrolyte calculation	Process gas + independent cooling medium	Internal reforming + process gas	Internal reforming + process gas

Polymer-Electrolyte Fuel Cells. Because of the intrinsic nature of the materials used, the polymer-electrolyte fuel cell, also commonly referred to as proton-exchange membrane (PEM), operates at temperatures less than 100 °C (212 °F), typically in the 60 to 80 °C (140 to 175 °F) range. When compared to other fuel cells, PEFC technology has been capable of very high current densities: while most technologies can operate up to approximately 1 A/cm^2, the polymer-membrane cell has operated at up to 4 A/cm^2 (Ref 2). This ability is due primarily to the membrane used. Other desirable attributes include fast-start capability and rapid response times to load changes. Because of the high power density capability, smaller, lighter-weight stacks are possible. Other beneficial attributes of the cell include no corrosive fluid hazard and lower sensitivity to orientation. As a result, the PEFC is particularly suited for vehicular-power application. Transportation applications suggest that the fuel of choice might be of comparable energy density to gasoline, although hydrogen storage on board in the form of pressurized gas and the partial oxidation of gasoline are being considered. The PEFC is also being considered widely for stationary-power applications, perhaps using natural gas or other hydrogen-rich gases.

The low operating temperature of a PEFC has both advantages and disadvantages. Low-temperature operation is advantageous because the cell can start from ambient conditions quickly, especially when pure hydrogen fuel is available. It is a disadvantage in CO-containing fuel streams, because carbon will attack or poison the platinum catalyst sites, masking the catalytic activity and reducing cell performance. The effect is reversible by flowing a CO-free gas over the electrode. To minimize the CO poisoning, operating temperatures must be greater than 120 °C (250 °F), at which point there is a reduction in chemisorption and electrooxidation. Due to CO affecting the anode, only a few ppm of CO can be tolerated at 80 °C (175 °F). Because reformed and shifted hydrocarbons contain about 1% CO, a mechanism to eliminate CO in the fuel gas is needed. This can be accomplished with preferential oxidation (PROX) that selectively oxidizes CO relative to H_2 using a precious metal catalyst. The low operating temperature also means that little, if any, heat is available from the fuel cell for endothermic reforming (Ref 3).

Recent PEFC development has focused on operation in the 160 °C (320 °F) range using an ion-exchange membrane, polybenzimidazole (PBI). The higher operating temperature eliminates CO poisoning by eliminating CO occlusion of the platinum sites. Also, this operating regime provides higher-quality heat for possible use in stationary combined heat/power (CHP) applications. Because PBI requires significantly lower water content to facilitate proton transport, an additional benefit is that water management is dramatically simplified (Ref 4).

Both temperature and pressure have a significant influence on cell performance. Present cells operate at 80 °C (175 °F) over a gage pressure range of 0.0010 to 1.0 MPa (~0.1 to 150 psig). Nominally, 0.285 MPa (40 psig) is

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

used for some transportation applications (Ref 5). Using appropriate current collectors and supporting structure, polymer-electrolyte fuel cells and electrolysis cells should be capable of operating at pressures up to 20 MPa (3000 psi) and differential pressures up to 3.5 MPa (500 psi).

The standard electrolyte material in PEFCs belongs to the fully fluorinated Teflon-based family similar to that produced by E.I. DuPont de Nemours & Company, Inc. for space application in the mid-1960s. The membrane is characterized by its equivalent weight (inversely proportional to the ion-exchange capacity). A typical equivalent weight range is 800 to 1100 milliequivalents per dry gram of polymer. The type used most often in the past was Nafion No. 117, a melt-extruded membrane manufactured by DuPont. The perfluorosulfonic acid family of membranes exhibits exceptionally high chemical and thermal stability and is stable against chemical attack in strong bases, strong oxidizing and reducing acids, Cl_2, H_2, and O_2 at temperatures up to 125 °C (257 °F). Nafion consists of a fluoropolymer backbone, similar to Teflon, upon which sulfonic acid groups are chemically bonded (Ref 6). Nafion membranes have exhibited long life in selected operating conditions and electrochemical applications. In selected fuel- cell tests and water-electrolysis systems, lifetimes of more than 50,000 h have been demonstrated. The Dow Chemical Company produced an electrolyte membrane, the XUS 13204.10, that contained a polymeric structure similar to that of Nafion, except that the side chain length was shortened. As a result, the membrane properties were significantly impacted, including a higher degree of water interactions within the membrane. This translated to lower electrical resistance and permitted higher current densities than the Nafion membrane, particularly when used in thinner form (Ref 7). These short side- chain membranes exhibited good performance and stability, but are no longer being supplied by Dow. Furthermore, due to Nafion's present expense and other engineering issues, new alternative membranes are being developed by a number of companies.

The alkaline fuel cell was one of the first modern fuel cells to be developed, beginning in 1960. The application at that time was to provide on-board electric power for the Apollo space vehicle. Desirable attributes of the AFC include excellent performance compared to other candidate fuel cells due to its active O_2 electrode kinetics and flexibility to use a wide range of electrocatalysts. The AFC continues to be used: it now provides on-board power for the Space Shuttle Orbiter. These AFCs operate at relatively high temperature and pressure to meet the requirements for space applications. More recently, a major focus of the technology has been for terrestrial applications in which low-cost components operating at near-ambient temperature and pressure with air as the oxidant are desirable.

The AFC developed for space application was based, in large part, on work initiated by F.T. Bacon in the 1930s. By 1952, construction and performance testing of a 5 kW alkaline fuel cell, operating on H_2 and O_2, were completed. The fuel cell developed by Bacon operated at 200 to 240 °C (390 to 465 °F) with 45% KOH electrolyte. Pressure was maintained at 40 to 55 atm (4 to 5.5 MPa, or 590 to 800 psi) to prevent the electrolyte from boiling. At this relatively high temperature and pressure, performance of the cell was quite good (0.78 V at 800 mA/cm^2). The anode consisted of a dual-porosity nickel electrode (two-layer structure with porous nickel of 16 μm maximum pore diameter on the electrolyte side and 30 μm pore diameter on the gas side). The cathode consisted of a porous structure of lithiated NiO. The three-phase boundary in the porous electrodes was maintained by a differential gas pressure across the electrode, since a wetproofing agent was not available at that time. Polytetrafluoroethylene (PTFE) as a wetproofing material did not exist, and it would not have been stable in the high-temperature alkaline solution (Ref 8).

The unusual economics for remote-power applications—such as space, undersea, and military applications—result in the cell itself not being strongly constrained by cost. The consumer and industrial markets, however, require the development of low-cost components if the AFC is to successfully compete with alternative technologies. Much of the recent interest in AFCs for mobile and stationary terrestrial applications has addressed the development of low-cost cell components. In this regard, carbon-base porous electrodes play a prominent role. It remains to be demonstrated whether alkaline cells will prove commercially viable for the transportation sector (Ref 9).

The state-of-the-art AFC stacks in the Space Shuttle Orbiter are rectangular with a width of 38 cm (15 in.) a length of 114 cm (45 in.), and a height of 35 cm (14 in.). They weigh 118 kg, (260 kg), produce a peak power of 12 kW at a minimum of 27.5 V (end of life), and operate at an average power of 7 kW. They operate in the same pressure range of 4 atm (0.4 MPa, or 60 psi) as the Apollo cells, but at a lower temperature of 85 to 95 °C (185 to 200 °F) and higher current density (0.88 V at 470 mA/cm^2. The fuel cells demonstrate 3.4 W/cm^2 at 0.8 V and 4300 mA/cm^2 (Ref 10). The electrodes contain high loadings of noble metals: 80%Pt-20%Pd anodes are loaded at 10 mg/cm^2 on silver-plated nickel screen; 90%Au-10%Pt cathodes are loaded at 20 mg/cm^2 on silver-

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

plated nickel screen. Both are bonded with PTFE to achieve high performance at the lower temperature of 85 to 95 °C (185 to 200 °F). A wide variety of materials (e.g., potassium titanate, ceria, asbestos, zirconium phosphate gel) have been used in the microporous separators for AFCs. The electrolyte is 35% KOH and is replenished via a reservoir on the anode side. Gold-plated magnesium is used for the bipolar plates (Ref 11).

The life-limiting event in the present Orbiter cell is KOH corrosion of the cell frame (cell support). Present stack life is 2600 h. The cell stacks have demonstrated capability to reach this life in 110 flights and a total of ~87,000 h in the Orbiter as of July 2002. Present practice is to refurbish the power unit at 2600 h by installing a new stack and cleaning and inspecting the balance of equipment. The stack life is being improved to 5000 h by elongating the path length associated with KOH-induced corrosion of the cell frame. A 10-cell short stack has demonstrated the new 5000 h concept. The concept is now being qualified in a complete power plant (Ref 12).

Electrode development in circulating electrolyte AFCs has concentrated on multilayered structures with porosity characteristics optimized for flow of liquid electrolytes and gases (H_2 and air) and catalyst development. Another area for concern is the instability of PTFE, which causes weeping of the electrodes. Most developers use noble metal catalysts; some use nonnoble catalysts. Spinels and perovskites are being developed in an attempt to lower the cost of the electrodes. Development of low-cost manufacturing processes includes powder mixing and pressing of carbon-base electrodes, sedimentation and spraying, and high-temperature sintering. Other approaches to increasing life and reducing weight and cost include investigating epoxy resins, polysulfone, and acrylonitrile-butadiene-styrene (ABS). Framing techniques under development include injection molding, filter pressing, and welding (Ref 13).

The phosphoric-acid fuel cell (PAFC) was the first fuel-cell technology to be commercialized. There have been only minor changes in cell design in recent years. The major U.S. manufacturer has concentrated on improving cell stability and life and in improving the reliability of system components at reduced cost. Nevertheless, further increases in power density and reduced cost are needed to achieve economic competitiveness with other energy technologies.

The evolution of cell components from 1965 to the present day for PAFCs is summarized in Table 3. A major breakthrough in PAFC technology that occurred in the late 1960s was the development of carbon black and graphite for cell-construction materials (Ref 14, 15). Carbon black and graphite were sufficiently stable to replace the more expensive gold-plated tantalum cell hardware used at the time. The use of high- surface-area graphite to support platinum permitted a dramatic reduction in platinum loading without sacrificing electrode performance. However, carbon corrosion and platinum dissolution become an issue at cell voltages above ~0.8 V.

Table 3 Evolution of cell-component technology for phosphoric-acid fuel cells

Component	Circa 1965	Circa 1975	Current status[(a)]
Anode	PTFE-bonded Pt black	PTFE-bonded Pt/C	PTFE-bonded Pt/C
Anode loading	9 mg Pt/cm^2	0.25 mg Pt/cm^2	0.10 mg Pt/cm^2

(a) More than 40,000 h component life demonstrated in commercial power plants

In the mid-1960s, the conventional porous electrodes were PTFE—bonded platinum black, and the loadings were about 9 mg Pt/cm^2. During the past two decades, platinum supported on carbon black has replaced platinum black in porous PTFE-bonded electrode structures as the electrocatalyst. A dramatic reduction in

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

platinum loading has also occurred; the loadings are currently about 0.10 mg Pt/cm^2 in the anode and about 0.50 mg Pt/cm^2 in the cathode.

The operating temperatures and acid concentrations of PAFCs have increased to achieve higher cell performance. Temperatures of about 200 °C (390 °F) and acid concentrations of 100% H_3PO_4 are commonly used today. Although the present practice is to operate at atmospheric pressure, the operating pressure of PAFCs surpassed 8 atm (0.1 MPa, or 120 psi) in the 11 MW electric-utility demonstration plant, confirming an increase in power-plant efficiency. However, a number of issues remain, for example, whether to design and operate PAFC units at atmospheric versus pressurized conditions.

Another important issue, independent of power-unit size, is that pressure promotes-corrosion. Phosphoric-acid (H_3PO_4) electrolyte produces a vapor. This vapor, which forms over the electrolyte, is corrosive to cell locations other than the active cell area. These cell locations are at a mixed voltage (open circuit and cell voltage) that can be more than ~0.8 V/C. That is the limit above which corrosion occurs. An increase in cell total pressure causes the partial pressure of the H_3PO_4 vapor to increase, causing increased corrosion in the cell. Cell temperature must also be increased with pressurized conditions to produce steam for the steam reformer (Ref 16).

A bipolar plate separates the individual cells and electrically connects them in series in a fuel- cell stack. In some designs, the bipolar plate also contains gas channels that feed the reactant gases to the porous electrodes and remove the reaction products and inert gases. Bipolar plates made from graphite resin mixtures that are carbonized at low temperature (~900 °C, or 1650 °F) are not suitable because of their rapid degradation in PAFC operating environments (Ref 17). However, corrosion stability is improved by heat treatment to 2700 °C (4890 °F) (Ref 18). That is, the corrosion current is reduced by two orders of magnitude at 0.8 V in 97% H_3PO_4 at 190 °C (375 °F) and 4.8 atm (0.48 MPa, or 70.5 psi). The all- graphite bipolar plates are sufficiently corrosion resistant for a projected life of 40,000 h in PAFCs, but they are still relatively costly to produce.

Several important technology development efforts include catalyst improvements, advanced gas diffusion electrode development, and tests on materials that offer better carbon-corrosion protection. Transition metal (e.g., iron, cobalt) organic macrocycles from the families of tetramethoxyphenylporphyrins (TMPP), phthalocyanines (PC), tetraazaannulenes (TAA), and tetraphenylporphyrins (TPP) have been evaluated as oxygen-reduction electrocatalysts in PAFCs. One major problem with these organic macrocycles is their limited chemical stability in hot concentrated phosphoric acid. However, after heat treatment of the organic macrocycle, such as CoTAA, CoPC, CoTMPP, FePC, FeTMPP, on carbon at about 500 to 800 °C (930-1470 °F), the pyrolyzed residue exhibits electrocatalytic activity that, in some instances, is comparable to that of platinum and has promising stability, at least up to about 100 °C (212 °F) (Ref 19). Another successful approach for enhancing the electrocatalysis of oxygen reduction is to alloy platinum with transition metals such as titanium, chromium, vanadium, zirconium, and tantalum (Ref 20). The enhancement in electrocatalytic activity has been explained by a correlation between the optimal nearest-neighbor distance of the elements in the alloy and the bond length in oxygen (Ref 21).

Conventional cathode catalysts comprise either platinum or platinum alloys supported on conducting carbon black at 10 wt% Pt. Present platinum loadings on the anode and cathode are 0.1 and 0.5 mg/cm^2, respectively (Ref 22, 23). It has been suggested by researchers that the amount of platinum may have been reduced to the extent that it might be cost effective to increase the amount of platinum loading on the cathode (Ref 24). However, a problem exists in that fuel-cell stack developers have not experienced satisfactory performance improvements when increasing the platinum loading. Johnson Matthey Technology Centre (J-M) presented data that resulted in improved performance in nearly direct proportion to that expected based on the platinum increase (Ref 25). Initial tests by J-M confirmed previous results: using platinum alloy catalyst with a 10 wt% net platinum loading improves performance. Platinum/nickel alloy catalysts yielded a 49 wt% increase in specific activity over pure platinum. This translated into a 39 mV improvement in the air electrode performance at 200 mA/cm^2.

The anode of a phosphoric-acid fuel cell is subject to a reduction in performance when even low amounts of contaminants are preferentially absorbed on the noble catalysts. Yet, hydrogen- rich fuel gases, other than pure hydrogen, are produced with contaminant levels well in excess of the tolerance limit of the anode. Of particular concern are CO, COS, and H_2S in the fuel gas. The fuel stream in a state-of-the-art PAFC anode, operating at approximately 200 °C (390 °F), must contain 1 vol% or less of CO, less than 50 ppm by volume (ppmv) of COS plus H_2S, and less than 20 ppmv of H_2S. Current practice is to place COS and H_2S cleanup systems and CO shift converters prior to the cell (normally in the fuel processor before reforming) to reduce the fuel-stream

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

contaminant levels to the required amounts. Giner performed experiments to develop a contaminant-tolerant anode catalyst in order to reduce or eliminate the cleanup equipment (Ref 26). An anode catalyst, G87A-17-2, was identified that resulted in only a 24 mV loss from reference when exposed to a 75% H_2, 1% CO, 24% CO_2, 80 ppmv H_2S gas mixture at 190 °C (375 °F), 85% fuel utilization, and 200 mA/ cm^2. A baseline anode experienced a 36 mV loss from the reference at the same conditions. At 9.2 atm (0.92 MPa, or 135 psi) pressure, the anode loss was only 19 mV at 190 °C (375 °) and 17 mV at 210 °C (410 °F) (compared to pure H_2) with a gas of 71% H_2, 5% CO, 24% CO_2, and 200 ppmv H_2S. Economic studies comparing the trade-off between decreased cell performance with increased savings in plant cost showed no advantage when the new anode catalyst was used with gas containing 1% CO/200 ppmv H_2S. A $7/kW increase resulted with the 5% CO gas (compared to a 1% CO gas) at a 50 MW size. Some savings would result by eliminating the low-temperature shift converter. The real value of the catalyst may be its ability to tolerate excessive CO and H_2S concentrations during fuel- processor upsets and to simplify the system by eliminating equipment.

The molten-carbonate fuel cell operates at approximately 650 °C (1200 °F). The high operating temperature is needed to achieve sufficient conductivity of its carbonate electrolyte yet allow the use of low-cost metal-cell components. An effect associated with this high temperature is that noble metal catalysts are not required for the cell electrochemical oxidation and reduction processes. The higher operating temperature of MCFCs provides the opportunity for achieving higher overall system efficiencies (potential for heat rates below 7500 Btu/kWh) and greater flexibility in the use of available fuels. On the other hand, the higher operating temperature places severe demands on the corrosion stability and life of cell components, particularly in the aggressive environment of the molten-carbonate electrolyte. Another difference between PAFCs and MCFCs lies in the method used for electrolyte management in the respective cells. In a PAFC, PTFE serves as a binder and wetproofing agent to maintain the integrity of the electrode structure and to establish a stable electrolyte/gas interface in the porous electrode. The phosphoric acid is retained in a matrix of PTFE and SiC between the anode and cathode. There are no high-temperature, wetproofing materials available for use in MCFCs that are comparable to PTFE. Thus, a different approach is required to establish a stable electrolyte/gas interface in MCFC porous electrodes. The MCFC relies on a balance in capillary pressures to establish the electrolyte interfacial boundaries in the porous electrodes.

Table 4 provides a chronology of the evolution in cell-component technology for MCFCs. In the mid-1960s, electrode materials were, in many cases, precious metals, but the technology soon evolved to the use of nickel-base alloys at the anode and oxides at the cathode. Since the mid- 1970s, the materials for the electrodes and electrolyte structure (molten carbonate/$LiAlO_2$) have remained essentially unchanged. A major development in the 1980s was the evolution in the technology for fabrication of electrolyte structures (Ref 27, 28). Over the past 28 years, the performance of single cells has improved from about 10 to >150 mW/cm^2. During the 1980s, both the performance and endurance of MCFC stacks showed dramatic improvements. Several MCFC stack developers have produced cell stacks with cell areas up to 1 m^2 (10.8 ft^2) cells. Tall, full-scale stacks fabricated to date include several FuelCell Energy (FCE, formerly Energy Research Corporation) 300 plus cell stacks with ~9000 cm^2 (1395 $in.^2$) cell area producing >250 kW.

Table 4 Evolution of cell-component technology for molten-carbonate fuel cells

(a) A mole percent of alkali carbonate salt

The conventional process used to fabricate electrolyte structures until about 1980 involved hot pressing (~34 MPa, or 5 ksi) mixtures of $LiAlO_2$ and alkali carbonates (typically >50 vol% in liquid state) at temperatures slightly below the melting point of the carbonate salts (e.g., 490 °C, or 915 °F, for electrolyte containing 62 mol% Li_2CO_3-38 mol% K_2CO_3). These electrolyte structures also called electrolyte tiles, were relatively thick (1 to 2 mm, or 0.04 to 0.08 in.) and difficult to produce in large sizes because large tooling and presses were required. The electrolyte structures produced by hot pressing are often characterized by void spaces (<5% porosity), poor uniformity of microstructure, generally poor mechanical strength, and high ***iR*** drop. To overcome the shortcomings of hot- pressed electrolyte structures, alternative processes such as tape casting (Ref 27) and electrophoretic deposition (Ref 29) for fabricating thin electrolyte structures were developed. The greatest success to date with an alternative process has been reported with tape casting, which is a common processing technique used by the ceramics industry. This process involves dispersing the ceramic powder in a solvent that contains dissolved binders (usually an organic compound), plasticizers, and additives to yield the proper slip rheology. The slip is cast over a moving smooth substrate, and the desired thickness is established with a doctor blade device. After drying the slip, the “green” structure is assembled into the fuel cell where the organic binder is removed by thermal decomposition, and the absorption of alkali carbonate into the ceramic structure occurs during cell startup. The tape casting and electrophoretic deposition processes are amenable to scale-up, and thin electrolyte structures (0.25 to 0.5 mm, or 0.01 to 0.02 in.) can be produced.

The bipolar plates used in MCFC stacks are usually fabricated from thin (~380 μm, or 15 mil) sheets of a corrosion-resistant alloy such as Incoloy 825, 310S, or 316L stainless steel that are coated on one side, the side exposed to fuel gases in the anode compartment with a nickel layer. The nickel layer is stable in the reducing-gas environment of the anode compartment, and it provides a conductive surface coating with low contact resistance. There are approaches to circumvent the problems associated with gas leaks and corrosion of bipolar plates (Ref 30). Corrosion is largely overcome by application of a coating (~50 μm, or 2 mil, thickness) at the vulnerable locations on the bipolar plate. For example, the wet-seal area on the anode side is subject to a high chemical potential gradient because the fuel gas inside the cell and the ambient environment (usually air) on the outside of the cell promote corrosion (about two orders of magnitude greater than in the cathode wet-seal area) (Ref 31). A thin aluminum coating in the wet-seal area of a bipolar plate provides corrosion protection by forming a protective layer of $LiAlO_2$ after reaction of aluminum with Li_2CO_3 (Ref 32). Such a protective layer

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

would not be useful in areas of the bipolar plate that must permit electronic conduction because $LiAlO_2$ is an insulating material.

A dense and electronically insulating layer of $LiAlO_2$ is not suitable for providing corrosion resistance to the cell current collectors because these components must remain electrically conductive. The typical materials used for this application are type 316 stainless steel and nickel- plated stainless steels. However, materials with better corrosion resistance are required for long- term operation of MCFCs. Research is continuing to understand the corrosion processes of high-temperature alloys in molten-carbonate salts under both fuel-gas and oxidizing-gas environments (Ref 33) and to identify improved alloys for MCFCs. Stainless steels such as type 310 and 446 have demonstrated better corrosion resistance than type 316 (Ref 34).

There is a need to provide better tolerance to sulfur poisoning gases in systems using MCFCs, especially when considering coal operation. Sulfur-tolerant cells could eliminate cleanup equipment that impacts system efficiency. This is especially true if low-temperature cleanup is required, because the system efficiency and capital cost suffer when the fuel-gas temperature is first reduced, then increased to the cell temperature level. Tests are being conducted on ceramic anodes to alleviate the problems, including sulfur poisoning, being experienced by the anodes (Ref 35). Anodes are being tested with undoped $LiFeO_2$ and $LiFeO_2$ doped with manganese and niobium. Preliminary testing, where several parameters were not strictly controlled, showed that the alternative electrodes exhibited poor performance and would not operate over 80 mA/ cm^2. At the present time, no alternative anodes have been identified. Future work will focus on a better understanding of material behavior and developing alternative materials with emphasis on sulfur tolerance.

The solid-oxide fuel cell is viable for generating electricity from hydrocarbon fuels. The high operating temperature, from 700 to 1000 °C (1290 to 1830 °F), allows internal reforming, promotes rapid kinetics with nonprecious materials, and produces high-quality by-product heat for cogeneration or for use in a bottoming cycle. The high temperature of the SOFC, however, places stringent requirements on its materials. The development of suitable low-cost materials and low-cost fabrication of ceramic structures is presently the key technical challenge facing SOFC commercialization.

Two different design configurations are being developed for SOFCs motivated by considerations of how to seal the anode and cathode compartments, ease of manufacturing, and minimizing losses due to electric resistance. The two principal types are tubular and planar, as shown in Fig. 3. The tubular SOFC has undergone development since the late 1950s. Operating between 900 and 1000 °C (1650 and 1830 °F), the long tubes have relatively high electrical resistance but are simple to seal. Some tubular designs eliminate the need for seals and allow for thermal expansion. Several tubular units are presently operating in the field, with tens of thousands of hours of demonstrated operation. In the tubular configuration, bundles of tubes that are closed at one end are arranged in parallel. Air is introduced to the inside of each tube, while fuel flows over the outside of the cells. Oxygen ions migrate through the electrolyte to react with fuel; the flow of ions produces electricity.

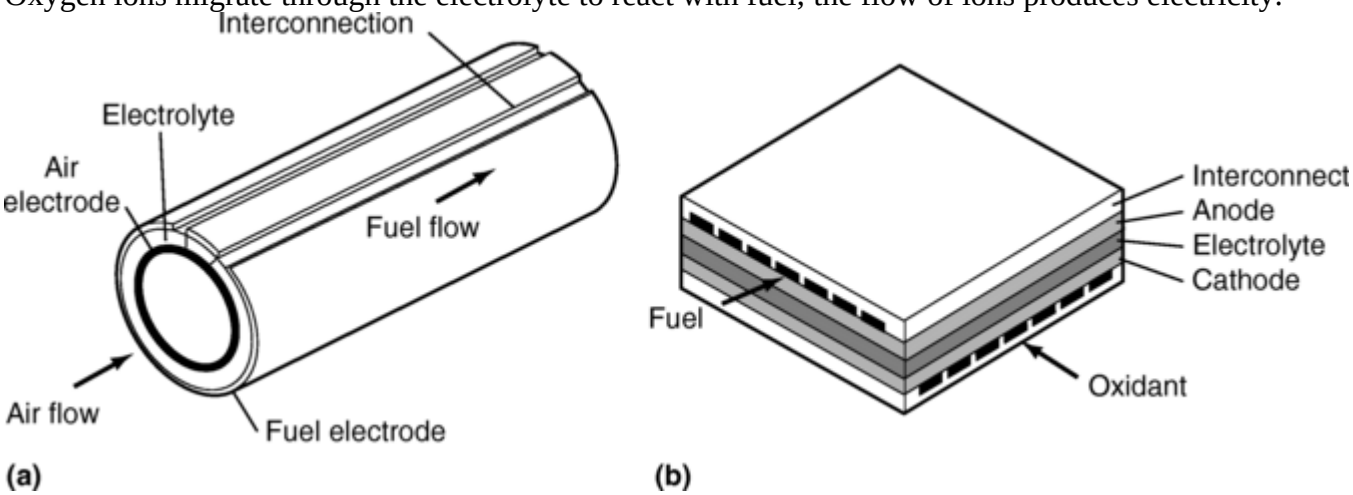

Fig. 3 Solid oxide fuel-cell configurations. (a) Tubular. (b) Planar

The planar solid-oxide fuel cell (PSOFC) is composed of flat, thin ceramic plates. The PSOFC operates at 800 °C (1470 °F) or even less. Ultrathin electrode/electrolyte sheets have low electrical resistance in order to achieve high efficiency. Operation at temperatures lower than the tubular SOFC enables less exotic materials of construction, thus saving on cost. In the planar configuration, the anode, electrolyte, and cathode form thin, flat

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

layers that are sintered together and then separated by bipolar plates similar to the design of other types of fuel cells. The plates can be rectangular, square, circular, or segmented in series and can be manifolded externally or internally. Many of the PSOFCs use metallic bipolar plates and are operated at a lower temperature than the all-ceramic tubular design.

To limit corrosion on the air side, the operating temperature of the PSOFC must be maintained below 800 °C (1470 °F). However, the conductivity of the electrolyte decreases with falling temperature. There are two options for mitigating decreased performance in this case. The well-established yttria-stabilized zirconia (YSZ) electrolyte can be used at temperatures as low as 700 °C (1290 °F) when the thickness is about 15 μm. To go to even lower temperatures, more conductive electrolytes such as lanthanum gallate, scandium-doped zirconia, or gadolinium-doped ceria (GDC) can be used (Ref 36, 37, 38, 39). At significantly reduced operating temperature, the lanthanum manganite cathode material becomes limited by kinetics to the point that it must be modified or replaced.

With respect to cathode materials, the choice depends on the specific ceramic electrolyte material, the desired operating temperature, the electrochemical cell design, and the specific ceramic fabrication methods. Perovskite-structured lanthanum strontium manganite (LSM) has been the most frequently used material for SOFCs, including both planar and tubular. Another perovskite material with similar properties is lanthanum calcium manganite (LCM). Both of these materials offer an excellent thermal expansion match with zirconia electrolytes and provide good performance above 800 °C (1470 °F). For applications requiring lower-temperature operation—600 to 800 °C (1110 to 1470 °F)—a range of alternative perovskite-structured ceramic electrodes are available. These include lanthanum strontium ferrite (LSF), lanthanum strontium cobalt ferrite (LSCF), lanthanum strontium manganese ferrite (LSMF), praseodymium strontium manganite (PSM), and praseodymium strontium manganese ferrite (PSMF). Improved performance of the cathode can be obtained by blending electrolyte material, such as YSZ, samarium-doped ceria (SDC) or GDC, with the perovskite material, such as LSM or PSMF. The incorporation of electrolyte material into the cathode materials has been shown to improve electrode performance at lower temperatures by increasing the volume of active sites available for electrochemical reactions. The electrolyte concentration is typically 40 vol%.

Based on the above, it can be seen that recent technology development in the PSOFC cell components and materials has been the change to a thinner electrolyte layer, anode-supported cells, the use of metallic interconnect plates, and more conductive materials for electrolytes. A summary of the advantages associated with these advances is presented in Table 5. From the table, it can be seen that the shift to thinner electrolytes has created the opportunity to reduce operating temperature and to use metal interconnects while still increasing power density. Development of higher-conductivity electrolytes will further enhance these benefits. Developers are also evaluating the anode-supported electrolyte layer with YSZ, a proven material. Higher-conductivity electrolytes may allow the use of thicker electrolyte layers at lower temperatures.

Table 5 Recent technology advances on planar cells and potential benefits

	Technology advance	Potential benefit
Design	Electrode (anode)-supported thin electrolyte unit cells	Lower resistance of electrolyte Increased power density
System	Lower temperature of operation	Use of metallic interconnects and manifolding possible
Materials	Metallic interconnect plates	Lower cost Lower resistance interconnect Mechanical solution to thermal expansion of stack
	More conductive electrolyte materials: Sc-Zr oxides Ce-Gd oxides	Reduced voltage drop across electrolyte

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The requirements for stack-seal materials are extremely stringent. To avoid stress due to thermal expansion mismatch with adjacent components, the coefficient of thermal expansion (CTE) must be similar to that of the other components, typically in the range of 10 to 13 × 10^{-6}/°C (5.6 to 7.2 × 10^{-6}/°F). Chemical compatibility with the stack components and gaseous constituents of the highly oxidizing and reducing environments is also of primary concern. In addition, the seal should be electrically insulating to prevent shorting within the stack. A principal advantage of glass seals is that the glass composition can be tailored to optimize physical properties such as the CTE. However, several problems remain with regard to the use of glass seals in PSOFCs. The two issues of concern are the brittle nature of glass ceramics, and glasses tend to react with other cell components, such as electrodes, at SOFC operating temperatures.

A possible alternative to glass is the use of compressive, nonbonding seals. This approach permits the individual stack components to freely expand and contract during thermal cycling. However, the use of compressive seals also brings several new challenges to SOFC stack design; a load frame must be included to maintain the desired level of compressive load during operation, and the stack components must be able to withstand the compressive load required for adequate sealing for the lifetime of the stack. Research is in the early stage and has focused on micas (Ref 40), which are composed of sheets of silicate platelets (Ref 41).

Tubular Solid-Oxide Fuel Cells. Table 6 briefly describes the materials now used in various cell components of the tubular SOFC and those that were considered during earlier development. Because of the high operating temperatures of the present tubular SOFCs—900 to 1000 °C (1650 to 1830 °F)—materials used in cell components are limited by chemical stability in oxidizing and reducing environments, chemical stability of contacting materials, conductivity, and thermomechanical compatibility.

(a) Specification for Siemens Westinghouse SOFC.

To make a tubular SOFC, the cathode tube is fabricated first by extrusion and sintering. As shown in Table 6, it has a porosity of 30 to 40% to permit rapid transport of the reactant and product gases to the cathode/electrolyte interface where the electrochemical reactions occur. The electrolyte is applied to the cathode tubes by electrochemical vapor deposition (EVD), which for many years has been the heart of Siemens Westinghouse technology (Ref 42). In this process, the appropriate metal chloride vapor is introduced on one side of the tube surface, and O_2/ H_2O is introduced on the other side. The gas environments on both sides of the tube act to form a galvanic couple. The net result is the formation of a dense, uniform metal oxide layer in which the deposition rate is controlled by the diffusion rate of ionic species and the concentration of electronic charge carriers. This procedure is used to fabricate the solid YSZ electrolyte.

Present fuel-cell designs make use of thin-film concepts where films of electrode and electrolyte material are deposited on one another and sintered, forming a cell structure. The fabrication techniques differ according to the type of cell configuration and developer. After the electrode has been prepared, the electrode is coated with the electrolyte. The coating may be applied using a variety of techniques, including tape calendering, dip coating, spray coating, electrophoretic deposition, or spin coating. In each case, developers strive for a thin, dense, pinhole-free electrolyte coating.

Alternative material research includes investigating materials that exhibit:

- Polarizable (easily weakened) metal oxygen bonds
- Open, layered structures for greater ion mobility
- Lower coordination numbers for the mobile ions

These are important criteria for high conductivity (Ref 43). This approach to electrolyte development is to stabilize a very conductive oxide by compound formation or by solid-solution formation with more stable oxides. Conductivity of $0.1/\Omega \cdot$ cm has been obtained with zinc-doped $La_{1-x}Bi_xAlO_3$ compared to $1.8 \times 10^{-2}/\Omega \cdot$ cm for YSZ at 700 °C (1290 °F) (Ref 44).

Advantages and Limitations of the Types of Fuel Cells

The fuel-cell types addressed in this overview have significantly different operating regimes. As a result, their materials of construction, fabrication techniques, and system requirements differ. These distinctions result in individual advantages and limitations that govern the potential of the various cells to be used for different applications.

Advantages and Limitations of Polymer- Electrolyte Fuel Cells. Polymer-electrolyte fuel cells, such as SOFCs, have a solid electrolyte. As a result, this cell exhibits excellent resistance to gas crossover. In contrast to the SOFC, the cell operates at a low 80 °C (175 °F). This results in a capability to bring the cell to its operating temperature quickly, but the rejected heat cannot be used for cogeneration or additional power. Test results have shown that the cell can operate at very high current densities compared to the other cells. However, heat- and water-management issues may limit the operating power density of a practical system. The PEFC tolerance for CO is in the low ppm level for low-temperature PEFC, but can be in many thousands of ppm for emerging high-temperature PEFC designs.

Advantages and Limitations of Phosphoric- Acid Fuel Cells. The CO_2 in the reformed fuel gas stream and the air does not react with the electrolyte in a phosphoric-acid electrolyte cell, but is a diluent. This attribute and the relatively low temperature of the PAFC made it a prime, early candidate for terrestrial application. Although its cell performance is somewhat lower than the alkaline cell because of the slow oxygen reaction rate of the cathode, and although the cell still requires hydrocarbon fuels to be reformed into a hydrogen-rich gas, the PAFC system efficiency improved because of its higher-temperature environment and less-complex fuel conversion (no membrane and attendant pressure drop). The need for scrubbing CO_2 from the process air is also eliminated. The rejected heat from the cell is high enough in temperature to heat water or air in a system operating at atmospheric pressure. Some steam is available in PAFCs, a key point in expanding cogeneration applications.

Phosphoric-acid fuel-cell systems achieve about 37 to 42% electrical efficiency based on the lower heating value (LHV) of natural gas. This is at the low end of the efficiency goal for fuel-cell power plants. Phosphoric-acid fuel cells use high-cost precious metal catalysts such as platinum. The fuel has to be reformed external to the cell, and CO has to be shifted by a water- gas reaction to below 3 to 5 vol% at the inlet to the fuel-cell anode or it will affect the catalyst. These limitations have prompted development of the alternate, higher-temperature cells, MCFC and SOFC.

Advantages and Limitations of Alkaline Fuel Cells. The AFC was one of the first modern fuel cells to be developed, beginning in 1960. The application at that time was to provide on- board electric power for the Apollo space vehicle. Desirable attributes of the AFC include its excellent performance on H_2 and O_2 compared to other candidate fuel cells due to its active O_2 electrode kinetics and its flexibility to use a wide range of

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

electrocatalysts, an attribute that provides development flexibility. Once development was in progress for space application, terrestrial applications began to be investigated. Developers recognized that pure hydrogen would be required in the fuel stream, because CO_2 in any reformed fuel reacts with the KOH electrolyte to form a carbonate, reducing the ion mobility of the electrolyte. Pure H_2 could be supplied to the anode by passing a reformed, hydrogen-rich fuel stream by a precious metal (palladium/silver) membrane. The H_2 molecule is able to pass through the membrane by absorption and mass transfer and into the fuel-cell anode. However, a significant pressure differential is required across the membrane and the membrane is prohibitive in cost. Even the small amount of CO_2 in ambient air, the source of O_2 for the reaction, would have to be scrubbed. At the time, U.S. investigations determined that scrubbing of the small amount of CO_2 within the air, coupled with purification of the hydrogen, was not cost effective and that terrestrial application of the AFC could be limited to special applications, such as closed environments, at best. Major research and development on AFC is no longer done in the United States, but recent development in Europe has created renewed interest in this fuel-cell type.

Advantages and Limitations of Molten- Carbonate Fuel Cells. Many of the disadvantages of the lower-temperature as well as higher- temperature cells can be alleviated with the higher operating temperature MCFC, ~650 °C (~1200 °F). This temperature level results in several benefits: the cell can be made of commonly available sheet metals that can be stamped for less costly fabrication, the cell reactions occur with nickel catalysts rather than with expensive precious metal catalysts, reforming can take place within the cell if a reforming catalyst is added (results in a large efficiency gain), CO is a directly usable fuel, and the rejected heat is of sufficiently high temperature to drive a gas turbine and/or produce high-pressure steam for use in a steam turbine or for cogeneration. Another advantage of the MCFC is that it operates efficiently with CO_2-containing fuels such as biofuel-derived gases. This benefit is derived from the cathode-performance enhancement resulting from CO_2 enrichment.

The MCFC has some disadvantages, however: the electrolyte is very corrosive and mobile, and a source of CO_2 is required at the cathode (usually recycled from anode exhaust) to form the carbonate ion. Sulfur tolerance is controlled by the reforming catalyst and is low, which is the same for the reforming catalyst in all cells. Operation requires use of stainless steel as the cell hardware material. The higher temperatures promote material problems, particularly mechanical stability, that impact cell life.

Advantages and Limitations of Solid-Oxide Fuel Cells. The SOFC is the fuel cell with the longest continuous development period, starting in the late 1950s, several years before the AFC. Because the electrolyte is solid, the cell can be cast into flexible shapes, such as tubular, planar, or monolithic. The solid ceramic construction of the cell also alleviates any cell-hardware corrosion problems characterized by the liquid electrolyte cells and has the advantage of being impervious to gas crossover from one electrode to the other. The absence of liquid also eliminates the problem of electrolyte movement or flooding in the electrodes. The kinetics of the cell are fast, and CO is a directly usable fuel as it is in the MCFC. There is no requirement for CO_2 at the cathode as with the MCFC. At the temperature of presently operating SOFCs, ~1000 °C (~1830 °F), fuel can be reformed within the cell. The temperature of an SOFC is significantly higher than that of the MCFC. However, some of the rejected heat from an SOFC is needed for preheating the incoming process air.

The high temperature of the SOFC has its drawbacks. There are thermal expansion mismatches among materials, and sealing between cells is difficult in the flat-plate configurations. The high operating temperature places severe constraints on materials selection and results in difficult fabrication processes. The SOFC also exhibits a high electrical resistivity in the electrolyte, which results in a lower cell performance than the MCFC by approximately 100 mV. Researchers would like to develop cells at a reduced temperature of 650 °C (1200 °F), but the electrical resistivity of the presently used solid electrolyte material would increase substantially.

This article was adapted from the National Energy Technology Laboratory's (NETL) *Fuel Cell Handbook, Sixth Edition,* October 2002; a free copy of this handbook, in CD-ROM format, may be requested at the website www.netl.doe.gov.
The U.S. Department of Energy (DOE) is the largest funder of fuel-cell technology research and development in the United States. The DOE Office of Fossil Energy (FE) 2002 Budget was more than $50 million for stationary fuel cells, and the DOE Office of Energy Efficiency and Renewable Energy (EE) budget was slightly smaller for transportation fuel cells. The National Energy Technology Laboratory (NETL) manages the FE program that has a future focus based on the Solid State Energy Conversion Alliance (SECA) with goals of $400/kW by 2010, 40–60% efficiency, and coal-fuel hybrid applications by 2015 for FutureGen and Vision 21 power plants (Ref 45). The EE program has a future focus based on FreedomCAR and Hydrogen Fuel with a decision in 2015.

B.S. Covino, Jr. and S.D. Cramer, Introduction to Forms of Corrosion, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 189

Introduction to Forms of Corrosion

Bernard S. Covino, Jr. and Stephen D. Cramer, U.S. Department of Energy, Albany Research Center

Introduction

WHILE CORROSION CAN TAKE MANY FORMS, it is most generally defined as a chemical or electrochemical reaction between a material and its environment that produces a deterioration (change) of the material and its properties. Organizing the forms of corrosion has the advantage that corrosion processes with similar mechanisms can be considered together. Categorization of the forms of corrosion has existed in various schemes for many years. A broad view would separate corrosion into two categories: corrosion that is not influenced by any other process and corrosion that is influenced by another process, such as the presence of stresses or erosion. A more focused view would categorize corrosion as uniform or localized, aqueous or gaseous, wet or dry, and so forth.

This Section, "Forms of Corrosion," contains six subsections. Four of them ("Uniform Corrosion," "Localized Corrosion," "Metallurgically Influenced Corrosion," and "Microbiologically Influenced Corrosion") fit under the classification of corrosion that is not influenced by any outside process. Two of them ("Mechanically Assisted Degradation" and "Environmentally Induced Cracking") address corrosion that is influenced by another process.

B.S. Covino, Jr. and S.D. Cramer, Introduction to Forms of Corrosion, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 189

Introduction to Forms of Corrosion

Bernard S. Covino, Jr. and Stephen D. Cramer, U.S. Department of Energy, Albany Research Center

Uniform Corrosion

Uniform corrosion processes include many corrosion phenomena that are encountered in the practice of corrosion engineering and corrosion science. The majority of those phenomena deal with either aqueous or gaseous corrosion, although there are concerns about materials for use in molten salt and liquid metal environments. Gaseous corrosion is usually associated with high-temperature environments. Atmospheric corrosion is not considered a part of gaseous corrosion because the corrosion reaction occurs in a thin aqueous layer on the surface of the metal. Galvanic and stray current corrosion are not environment specific but rather can occur in any of the environments mentioned earlier.

Bernard S. Covino, Jr. and Stephen D. Cramer, U.S. Department of Energy, Albany Research Center

Localized Corrosion

Localized corrosion is described as corrosion that occurs at discrete locations on a material. While this is true and accounts for the naming of this form of corrosion, it is also the localized state of the environment that causes the accelerated attack of materials. Thus the propagation of pits on passive metal surfaces, the aggressive attack where two metals overlap to form a crevice, and the distinctive filiform attack on metal surfaces coated with thin organic layers result from differences in the metallurgy of the alloy and because the localized chemistry of the environment is different from that of the bulk of the environment.

Introduction to Forms of Corrosion

Bernard S. Covino, Jr. and Stephen D. Cramer, U.S. Department of Energy, Albany Research Center

Metallurgically Influenced Corrosion

To understand “Metallurgically Influenced Corrosion,” it is first important to understand what is meant by *metallurgy.* It has been described as “the art and science of procuring and adapting metals to satisfy human wants” (Ref 1). As such, it includes the recovery of metals from ores (*extractive metallurgy*), the formation of metals into various forms (*mechanical metallurgy*), and the understanding of the interaction of the chemical species, crystal orientations, and dislocations in metals and alloys (*physical metallurgy*). All of these processes can influence the composition, structure, stress level, and impurities in metals and alloys and, thus, their corrosion behavior. Another process, welding, is usually applied after metals are formed and shaped by metallurgical techniques. Welding produces localized changes in the composition, structure, stress level, and impurities in the joined metals and thus also can affect corrosion.

Bernard S. Covino, Jr. and Stephen D. Cramer, U.S. Department of Energy, Albany Research Center

Mechanically Assisted Degradation

Mechanically assisted degradation involves processes where external interactions can influence the corrosion rate. Examples are fretting, cavitation, and impingement corrosion, and corrosion fatigue. This subsection includes two new articles on the interaction between wear and corrosion processes in aqueous and gaseous environments. Wear and corrosion can occur separately, but usually there is some synergy between them that requires special tools or procedures to investigate.

Introduction to Forms of Corrosion

Bernard S. Covino, Jr. and Stephen D. Cramer, U.S. Department of Energy, Albany Research Center

Environmentally Induced Cracking

Environmentally induced cracking is a form of corrosion in which the external influence on the corrosion process is stress. For stress-corrosion cracking, the stress is often externally applied. For hydrogen damage, liquid metal induced embrittlement, and solid metal induced embrittlement, the stress is induced by reactions with the environment.

Aqueous Corrosion

Revised by David C. Silverman, Argentum Solutions, Inc.

Introduction

CORROSION is a process created by the interaction (reaction) between a material, often a metal or alloy, and its environment that results in degradation of that material. Corrosion is affected by the properties of both the metal or alloy and the environment. In this brief overview focusing on degradation of metals and alloys in aqueous systems, the environment variables shown as follows are addressed:

- pH (acidity)
- Oxidizing power (electrochemical potential)
- Temperature and heat transfer
- Velocity (fluid movement)
- Solution components and their concentration

One point to bear in mind is that corrosion is a process, not a property. That distinction means that the corrosion resistance of a material depends as much on the environmental components and system dynamics to which the material is exposed as it does to the chemical composition and structure of the material itself. The discussion is not meant to be all-inclusive but to provide an overview of the complex effects that environmental variables can have on corrosion and to emphasize some of the more important relationships among them. Often, particular effects can only be deduced from carefully planned experimental testing designed to duplicate the actual system. The more understanding one has of how environmental variables might affect corrosion, the better the chances that the experiment will simulate the actual conditions. The influence of biological organisms on these environmental variables is also an important consideration.

Thermodynamics provides a theoretical framework within which the effects of several environmental variables might be pictured. In aqueous corrosion, the format often used is the potential-pH diagram, or Pourbaix diagram (Ref 1). The expanded portion of the potential-pH diagram of iron at 25 °C (77 °F) shown in Fig. 1 is considered as an example of how this framework might be used (Ref 2). These diagrams are thermodynamic

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

and show the most stable state of the metal in an aqueous solution. The dependence of iron corrosion on oxidizing power (electromotive force), acidity (pH), temperature, and species concentration is illustrated in Fig. 1. For example, suppose the corrosion potential lies at -0.5 V standard hydrogen electrode (SHE) at a pH of 8. The most stable state of iron is Fe^{2+}, indicating that iron dissolution is possible. If the pH is increased to 10 (the acidity is decreased), the most stable state becomes magnetite (Fe_3O_4), and most likely, the corrosion rate of iron would greatly decrease, its surface becoming oxidized. If the pH is then decreased to approximately 8.5, the most stable state (Fe^{2+} or Fe_3O_4) would depend on the concentration of the dissolved iron species. The concentration of dissolved species could influence the corrosion rate. A change in temperature would alter the entire diagram, changing both the areas of stability and the components within those areas.

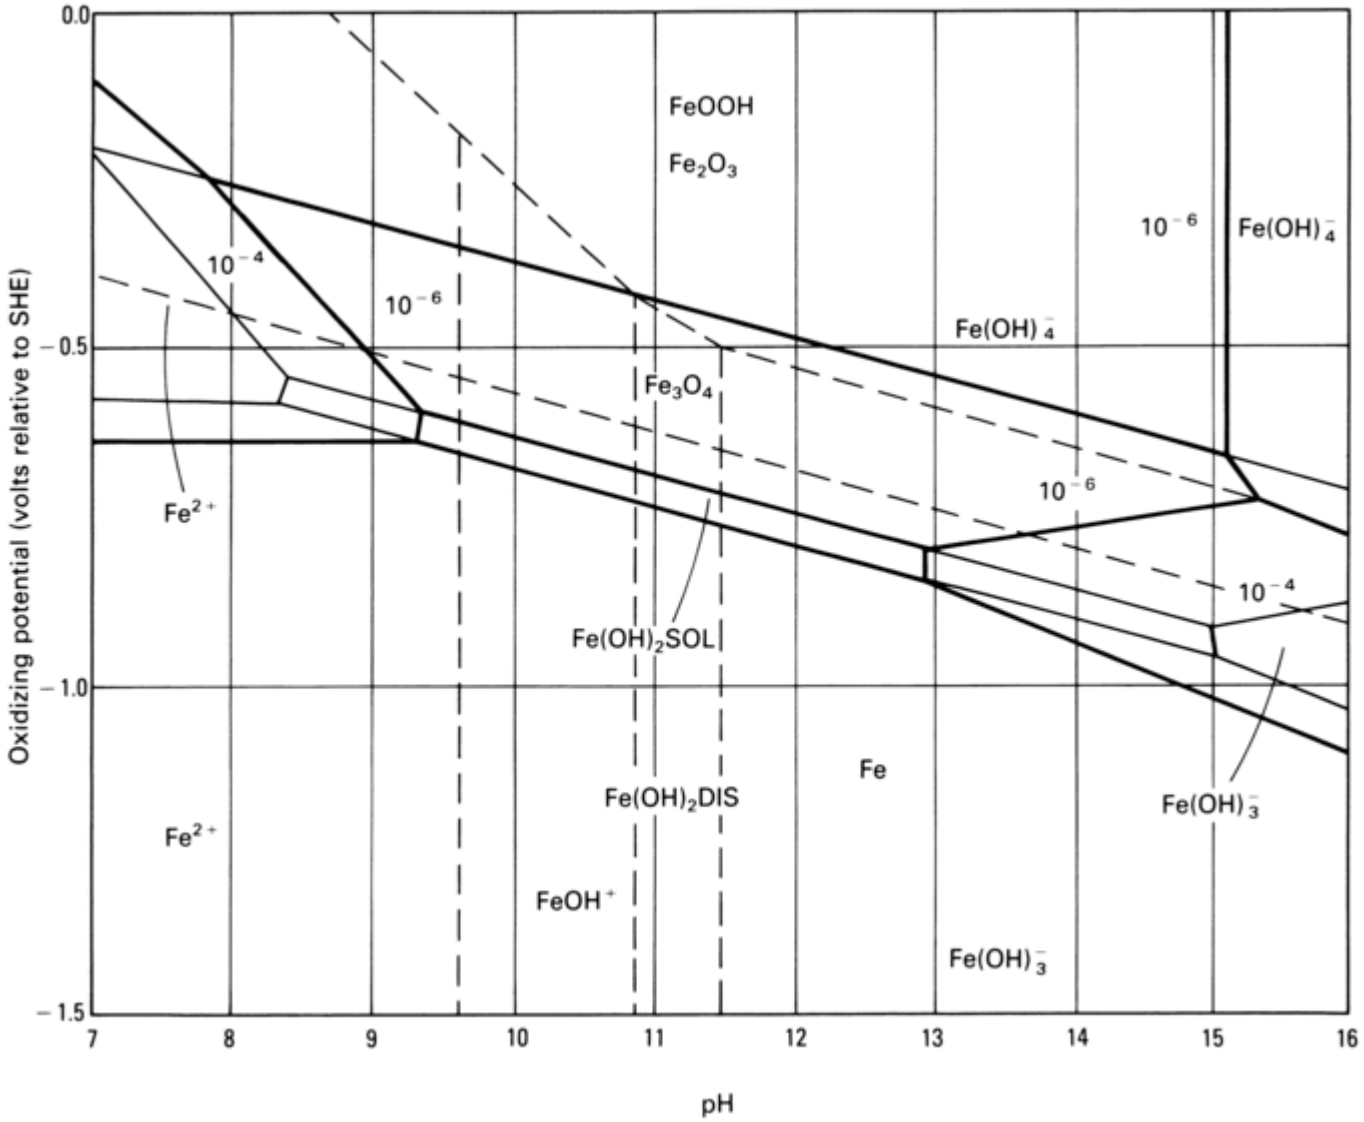

Fig. 1 Potential-pH (Pourbaix) diagram for iron at 25 °C (77 °F) in water. Ionic species are at activities of 10^{-6} and 10^{-4}. SHE, standard hydrogen electrode. SOL, in solution. DIS, dissolved. Source: Ref 2

The simple example of Fig. 1 shows the dominating role that environmental variables can play in corrosion. Complex interrelationships can exist. The combined values of the variables pH, potential, concentration, and temperature not only affect corrosion but also affect the action of each variable. For example, with respect to Fig. 1, the effect of a pH change depends on the concentration of the dissolved species, and vice versa. Although the variables are discussed individually, the important point is to realize that the effect of one variable can be influenced by the magnitude of another. This relationship appears throughout this article.

Aqueous Corrosion

Revised by David C. Silverman, Argentum Solutions, Inc.

Effect of pH (Acidity)

The concept of pH is complex. It is related to, but not synonymous with, hydrogen concentration or amount of acid. Before discussing how the magnitude of pH affects corrosion, some fundamentals are required. The pH is defined as the negative of the base ten logarithm of the hydrogen ion activity (Ref 3). This latter quantity is related to the concentration or molality through an activity coefficient. The term is expressed as

$$\mathrm{pH} = -\log a_{\mathrm{H}^+} = -\log \gamma_{\mathrm{H}^+} m_{\mathrm{H}^+} \qquad \text{(Eq 1)}$$

where a_{H^+} is the hydrogen ion activity, γ_{H^+} is the hydrogen ion activity coefficient, and m_{H^+} is the molality (mol/1000 cm^3 of water). The value of the activity coefficient is a function of everything in the solution (ions, nonionized species, etc.) as well as the environmental variables of temperature and pressure.

The pH is usually measured with a pH meter, which is actually an electrometer. The voltage of a hydrogen ion specific electrode is measured relative to a reference electrode. This voltage is compared to the internally stored calibration obtained from a defined standard to yield the unknown pH. The actual hydrogen ion concentration (acidity level) can be calculated from this measured pH if the activity coefficient is known. The calculated hydrogen ion concentration is at best an estimate (Ref 3, 4), because the test solution usually has constituents that are far different from those of the buffer. The hydrogen ion concentration estimated from the pH as measured by a pH meter and the actual amount of acid as defined by the actual hydrogen ion concentration are related but not necessarily equal.

The importance of the hydrogen ion lies in its ability to interact with an alloy surface. Many alloys of commercial interest form an oxidized surface region, the outermost atomic layer that often contains hydroxide-like species when water is present. The nature of such a structure would tend to depend on hydrogen ion concentration, possibly through a reaction such as Eq 2 that can be one step in the corrosion mechanism (Ref 5):

$$H_2O \leftrightarrow OH_{adsorbed} + H^+ + e^- \qquad \text{(Eq 2)}$$

Thus, under certain conditions, the hydrogen ion concentration can influence corrosion through the equilibrium that exists with it, water, and the hydroxide or oxide formed on the alloy surface. The interaction with the surface can, in principle, result in the sequence shown in Eq 3, which tends to be in the direction of increasing passivity of the metal M and increasing thickness of the surface region. The hydroxyl species in the first two steps tend to be derived from the dissociation of water (hydrolysis), in which hydrogen ions tend to be liberated. Water is a by-product created in the last step. The process can stop at any point, depending on the alloy and the environmental variables influencing the reaction (Ref 5):

$$M \rightarrow MOH \rightarrow M(OH)_n \rightarrow MO \qquad \text{(Eq 3)}$$

This type of interaction often results in a corrosion rate dependence on hydrogen ion concentration in the form of:

$$r = k\left(C_{\mathrm{H}^+}\right)^n \qquad \text{(Eq 4)}$$

where *r* is the corrosion rate, *k* is the rate constant, C_{H^+} is the hydrogen ion concentration, and *n* is an exponent. The value and sign of *n* can depend on the hydrogen ion concentration. This type of dependence of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

the reaction rate on the hydrogen ion concentration is found in a number of systems, which are discussed subsequently. This discussion is not meant to be all-encompassing but is meant to provide a flavor for how this dependence is observed in practice.

Strongly Acid Conditions (pH < 5). Iron or carbon steel shows a complex dependence of the corrosion rate on pH. At low pH, the corrosion mechanism depends not only on the hydrogen ion concentration but also on the counter-ions present. Thus, all discussion must include the total constituency of the fluid. For example, the corrosion rate of iron in sulfuric acid (H_2SO_4) between a pH of less than 0 and approximately 4 tends to be limited by the diffusion of and saturation concentration of iron sulfate ($FeSO_4$) (Ref 6, 7). In concentrated H_2SO_4, iron can initially form a salt layer of $FeSO_4$. Mass transfer becomes sensitive to fluid velocity, and the corrosion rate itself becomes sensitive to the fluid flow rate. The metal dissolution rate is so high that the corrosion rate is equal to the mass transfer rate of iron from this saturated film of $FeSO_4$ at the metal surface.

Corrosion of iron in hydrochloric acid (HCl) follows a different mechanism, and pH has a different effect on corrosion. The rate of corrosion is rapid at all acidic concentrations of pH < 3. Unlike the sulfate ion in H_2SO_4, the chloride ion seems to participate in and accelerate the corrosion rate (Ref 8). The corrosion rate increases with hydrogen ion concentration (decreasing pH). These effects are reflected in Eq 4, when *n* is a positive number. This behavior indicates that in HCl, the hydrogen ion directly influences the reaction kinetics. The ion does not influence corrosion through mass transfer.

Corrosion of iron in phosphoric acid (H_3PO_4) solution follows a similar mechanism but with a subtle twist. Again, no passive film exists on the surface; however, the corrosion rate, at least between a pH of 0.75 and 4, seems to be independent of phosphate ion concentration at constant pH (Ref 9).

The important point is that the pH effect on corrosion of carbon steel at low pH is not simple. Knowledge of how pH affects corrosion in one acid does not necessarily translate to knowledge in another acid. Very little fundamental information is available on the effect of acid mixtures on corrosion, so kinetic equations relating corrosion rate to concentration in these systems usually do not exist.

Ferritic iron-chromium alloys have been found to exhibit behavior in concentrated H_2SO_4 reminiscent of the behavior of carbon steel. A strong fluid velocity sensitivity has been noted in 1 *M* H_2SO_4 (5 to 10 wt%) (Ref 10) for those alloys with less than 12 wt% Cr and in the 68 to 93 wt% H_2SO_4 range (Ref 11) for E-Brite 26-1 (26 wt% Cr). The corrosion rate tends to be related to the rate of mass transfer of $FeSO_4$ from a saturated film on the surface. The one difference is that the presence of oxygen may impart a pseudopassivity that can be unstable. The major point is that the presence of chromium in the alloy does not necessarily increase protection in this environment. Both chromium content and H_2SO_4 concentration must be considered simultaneously, especially because an 18 wt% Cr ferritic alloy tends to be under activation control in 1 *M* H_2SO_4 (Ref 10).

The addition of nickel to create austenitic alloys alters this behavior in H_2SO_4 and eliminates, or at least diminishes, this sensitivity to fluid motion, especially in the hydrogen activity range of 10^{-3} to greater than 1 (pH range from approximately 3 to less than 0). At lower pH, the higher acid concentrations may produce a velocity sensitivity (Ref 12). Unfortunately, kinetic data are sparse on the effect of pH on the low corrosion rates expected for many of these alloys in this low pH range of -0.5 to 3. At still lower pH, the behavior is complex, and the particular literature on the alloy should be consulted. Impurities in the H_2SO_4 can significantly alter the corrosion resistance.

The behavior of austenitic alloys in HCl is far different from that in H_2SO_4, even at the same pH or hydrogen ion concentration. The change from sulfate to chloride anion tends to be detrimental. The presence of the chloride ion raises the possibility of localized attack, for example crevice corrosion, pitting, and stress-corrosion cracking (SCC) (Ref 13). Once again, behavior with respect to pH is complex. The literature on the particular alloy should be consulted to determine the actual behavior as a function of pH in acidic solutions.

Non Group VIII base alloys show different types of pH dependencies at low pH. For example, in HCl, titanium is passive to a pH of approximately 0 or slightly lower. Then, a fairly abrupt change in mechanism occurs at still lower pH. There, titanium begins to corrode rather rapidly (Ref 14). The hypothesis is that the titanium valence changes from +4 to +3 and that Ti^{3+} is soluble (Ref 14, 15). The behavior in H_2SO_4 is somewhat different.

Other metals and alloys are affected by acidic pH in different ways. Unfortunately, mechanistic data are less plentiful than for iron-base alloys. A number of metals show a very strong dependence of corrosion on pH. With aluminum, the rate increases exponentially as pH decreases in the acidic region (Ref 16). Indeed, the corrosion rate tends to have a very sharp minimum at a pH of 7 to 9, with sharp corrosion rate increases with both increasing and decreasing pH (Ref 1, 16).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

A similar effect of a sharp decrease in corrosion rate with increasing pH for pH < 4 has been noted for both zinc in HCl and lead in nitric acid (HNO_3) (Ref 17). Indeed, this type of behavior would be expected for any metal or alloy whose oxide is soluble in acids, such as zinc, aluminum, lead, tin, and copper.

Near-Neutral Conditions (5 < pH < 9). Corrosion behavior and alloy-environment interactions in the near-neutral pH region differ significantly from those under acidic conditions. In most cases, pH no longer plays a dominant role in corrosion.

Iron (as carbon steel) has been one of the most extensively studied metals in this environment. Under strongly acidic conditions, the oxide or hydroxide layers tend to dissolve. In the higher pH range, however, especially above a pH of approximately 5, these layers tend to remain on the surface. These layers have significant three dimensional structure, which tends to be determined by the anions present in the solution (Ref 18). In addition, the corrosion kinetics become independent of pH, and hydrogen ion reduction is no longer an important reaction (Ref 19). The major reaction governing corrosion in most practical applications tends to be the reduction of oxygen dissolved in solution. Under some conditions, magnetite Fe_3O_4 can be formed, which tends to passivate iron (Ref 18). Thus, pH in this range no longer plays a major direct role in corrosion of iron, although the pH can still affect the solubility and equilibrium of other ions such as sequestering agents and corrosion inhibitors. These other components can play a major role in corrosion in, for example, industrial cooling- water systems.

This characteristic of pH in the range of 5 < pH < 9 no longer playing a dominant role is found with other metals, such as zinc and lead (Ref 17). Aluminum shows a very sharp minimum in corrosion rate at approximately a pH of 7 to 9, with the minimum being somewhat dependent on the counter-ion in solution (Ref 16).

Alloys such as the austenitic iron-base and nickel-base alloys, ferritic alloys, and duplex alloys also tend to have general corrosion rates that are independent of pH in this range. Indeed, in pure water, these alloys would be passive. The presence of other species, such as chloride ions and oxygen, plays a much more dominant role, possibly changing the mechanism from uniform corrosion to localized attack.

Strongly Basic Conditions (pH > 9). Basic conditions offer yet another set of corrosion characteristics. In some cases, corrosion rate increases with pH (decreasing hydrogen ion concentration) or at least remains finite. In other cases, the increase in pH causes corrosion to occur when none was present at lower pH. These two types of behavior seem to encompass most metals and alloys, and representative examples are described subsequently to demonstrate this behavior.

Iron corrosion persists even at high pH. In fact, it can be greater than that under more neutral conditions. This persistence (or increase) is caused by soluble species $Fe(OH)_3^-$ or, at elevated potentials, $Fe(OH)_4^-$ being the most thermodynamically stable corrosion products (Ref 1, 2). Even though a number of iron hydroxide species can be found that can create a porous barrier (Ref 20), corrosion still persists, although usually at a fairly low rate, until very high pH is reached (Ref 17).

At very high pH (e.g., concentrated caustic) and especially at somewhat elevated temperatures, carbon steel can undergo SCC (Ref 21). Some environments that can cause SCC at high pH are sodium hydroxide (NaOH) at very high pH, carbonates and bicarbonates at moderately basic pH values, and possibly amines, although this point is controversial. Steel has been reported to suffer SCC at lower pH, but this behavior is less prevalent. Examples of these environments are hydrogen fluoride (HF) vapors and hydrogen sulfide (H_2S) in water. The mechanism in these cases may be one of hydrogen embrittlement (Ref 22).

A number of metals exhibit a sharp increase in corrosion rate with increasing pH. Among these are aluminum, zinc, and lead (Ref 16, 17). Aluminum corrosion increases very dramatically, changing by almost two orders of magnitude between a pH of 8 and 10. This increase is virtually independent of counter-ion and can be attributed to the formation of soluble aluminum hydroxide products (Ref 1).

Tantalum, which suffers virtually no corrosion under most acidic and neutral pH conditions, shows a significant increase in corrosion rate at high pH (Ref 24). The cause of this corrosion is believed to be a slow dissolution or flaking off of surface layers (Ref 24.) This dissolution is thought to be caused by the formation of soluble tantalum hydroxide corrosion products (Ref 14).

Some metals, such as nickel and zirconium, are very resistant to corrosion at high pH. Nickel and especially zirconium rely on the formation of insoluble oxides for their corrosion protection (Ref 23).

The austenitic and ferritic alloys tend to be immune to corrosion until very high pH or strong basicity is reached. One reason is that chromium, which is included in many of these alloys and which tends to accumulate on the surface, forms a passive oxide. This oxide, for example chromium oxide (Cr_2O_3), is insoluble under

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

these conditions. Changes in temperature, however, can affect corrosion at high pH. An example is initiation of SCC of type 304 or 316 stainless steel in very hot, concentrated caustic but not in cold caustic.

Oxidizing Power (Electrochemical Potential)

Oxidizing power, or potential, relates to the ability to remove or add electrons from the metal so as to oxidize or reduce the surface. This variable is separated from the discussions on solution chemistry because such a potential can be applied by an external voltage source, by galvanic coupling of different metals or alloys, or by other species present in the environment. Practical applications include increasing passivity by altering the surface oxide (anodic protection) or preventing corrosion by supplying electrons to the metal that would normally be yielded by metal corrosion (cathodic protection). The anodic reaction rate is shifted or changed in the protected metal.

The alteration of the surface state to impart passivity is normally accomplished by anodic polarization of the metal or alloy surface to a potential noble to the corrosion potential. If an external voltage source is used to change the voltage, the technique is known as anodic protection (see the article “Anodic Protection” in this Volume or Ref 25). Among the practical examples of using externally applied anodic potentials to mitigate corrosion are mild steel and type 304 or 316 stainless steel in concentrated H_2SO_4, H_3PO_4, and NaOH (Ref 22).

The addition of components to the environment may alter the surface potential to create a passive film. In this case, the species reacts with the metal to form a tenacious metal-oxide compound that passivates the surface. There are several well-known examples of anodic polarization of the surface by changing the environment. For example, the addition of small amounts of ozone to water decreases the corrosion of carbon steel in water (Ref 26). The hypothesis is that the corrosion potential moves in a noble direction, and the ozone reacts with the iron to create a more tenacious oxide. In another example, the addition of small amounts of HNO_3 to H_2SO_4 has

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

been shown to retard the corrosion of stainless steels. The hypothesis is that the potential is forced in the noble direction, and the surface oxide layer becomes more protective.

Polarization of the surface potential in the active or cathodic direction can also be used to decrease corrosion. When the potential is lowered by means of an external voltage source, the technique is known as cathodic protection (Ref 27). Many practical examples exist, such as the protection of steel at coating defects in underground carbon steel pipelines or the protection of ship hulls in seawater (see the article “Cathodic Protection” in this Volume). The electrons are supplied from either an inert or active counterelectrode.

Direct electrical coupling of a metal to a more active metal is another example of using cathodic potentials to affect corrosion. Coupling zinc to steel to protect the steel is a major example. In this case, zinc corrosion liberates electrons to the steel, and the steel potential moves in a cathodic or active direction (Ref 28).

Oxygen tends to polarize carbon steel in the noble direction and increase its corrosion. The addition of such species as sulfite (SO_3^{2-}) or hydrazine tends to cause a reaction with the oxygen and thus remove it (Ref 28). The effect of SO_3^{2-} tends to be to move the surface potential in the active direction. Such movement of potential may decrease the corrosion of iron (Ref 17). Any change in potential may depend on other components, especially if they can interact with the inhibitor and the metal surface. Also, if the alloy is passive and if this passivity is maintained by the oxygen, this addition could increase corrosion by moving the alloy into an active corrosion region (Ref 17).

Aqueous Corrosion

Revised by David C. Silverman, Argentum Solutions, Inc.

Temperature and Heat Transfer

Temperature is a complex external variable. Temperature is analogous to potential. A potential difference creates a current flow, the objective of which is to eliminate the potential difference. In a similar manner, a temperature difference creates a heat flow, the objective of which is to eliminate the temperature difference. Both potential and temperature are measures of energy.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Temperature can affect corrosion in a number of ways. If the corrosion rate is governed completely by the elementary process of metal oxidation (called activation control), the corrosion rate increases exponentially with an increase in temperature. This relationship is reflected in the Arrhenius expression:

$$r = A \exp\left(\frac{-E}{RT}\right) \qquad \text{(Eq 5)}$$

where r is the corrosion rate, A is a pre-exponential factor, E is an activation energy, R is the gas constant, and T is the absolute temperature.

The effect of temperature on corrosion rate is calculated by solving Eq 5 at two temperatures and taking the ratio of the rates:

$$\ln\left(\frac{r_1}{r_2}\right) = \left(\frac{-E}{R}\right)\left(\frac{\Delta T}{T_1 T_2}\right) \qquad \text{(Eq 6)}$$

where the subscripts 1 and 2 refer to the two temperatures, and ΔT is the difference in temperature (T_2 - T_1). Equation 6 can be used to evaluate the effect of a temperature change on corrosion rate for this simple rate process. Examples of corrosion that follow this simple rate law are iron in HCl (Ref 29) and iron in sodium sulfate (Na_2SO_4) at a pH of approximately 2 (Ref 30). This situation is most common for corrosion under acidic conditions.

The temperature of the metal and the temperature of the solution often cannot be discussed separately from other variables. If a component in the solution that is important in corrosion has limited solubility, a temperature change can alter the concentration of that component that can be dissolved in a solution. This increased solubility can have a profound effect on corrosion.

One classic example is the corrosion of iron in the presence of oxygen in systems both closed from the atmosphere and open to the atmosphere. The corrosion rate of iron in a system closed to the atmosphere has been shown to increase almost linearly with temperature from approximately 40 to 160 °C (105 to 320 °F). In the open system, the corrosion rate increases up to approximately 80 °C (175 °F) and then decreases (Ref 17). Oxygen mass transfer, which is proportional to the oxygen concentration in the liquid, controls the corrosion rate of steel in water. As temperature increases, oxygen solubility decreases so that the oxygen tends to leave the liquid. In the closed system, the oxygen cannot escape from the vapor space above the liquid. As temperature increases, the water vapor pressure increases, which tends to maintain the oxygen concentration in the liquid. The corrosion rate (mass transfer rate) continues to increase with temperature. In the open systems, oxygen can escape from the immediate vicinity of the liquid. The vapor pressure remains constant. Above a certain temperature, the liquid-phase oxygen concentration in equilibrium with oxygen in the atmosphere has decreased to the extent that the corrosion (mass transfer) rate decreases.

Another point often overlooked is that the ionization constant of water increases with temperature. Pure water with pH of 7 at one temperature has a lower pH at a higher temperature. Thus, an increase in temperature could affect corrosion by moving the pH from a neutral to an acidic value.

Fluid temperature changes can affect the polarity in galvanic corrosion. The corrosion potential of the anode might be more sensitive to temperature than that of the cathode. The anode potential can actually become noble with respect to that of the cathode (Ref 17). An example is the iron-zinc couple, the polarity of which can reverse as temperature increases. Iron actually protects the zinc. The temperature of this reversal is as low as 60 °C (140 °F), but there is some dependence of temperature on constituents.

Solution temperature can also affect the onset of localized attack of passive alloys such as type 304 and 316 stainless steels. The solution usually contains a species, such as chloride ion, that aids in the initiation process (Ref 31). The time to initiation of crevice corrosion has been shown to be a function of temperature. There are indications that such initiation times do not always decrease with increasing temperature (Ref 31). In addition, a critical crevice temperature can be defined for many of these alloys (Ref 32). This critical temperature determines the temperature boundary at which crevice corrosion can initiate. Indeed, the critical crevice temperature has been shown to be a function of the chromium and molybdenum content of austenitic and ferritic alloys.

In practice, elevated or depressed temperatures are often created by heat transfer through a metal wall. Thus, the metal wall can be at a temperature different from that of the bulk fluid. Controversy exists over whether corrosion in the absence of heat transfer is identical to corrosion in the presence of heat transfer, even if the metal temperatures are identical in the two situations (Ref 29).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The effect of a difference between wall and fluid temperatures on corrosion depends on the corrosion mechanism. If the corrosion rate is under activation control and follows Eq 5, the corrosion rate in the presence of heat transfer might be similar to that expected for corrosion at the same wall temperature in the absence of heat transfer. If the corrosion rate is controlled by the diffusion of a species such as oxygen to the surface, then heat transfer may greatly change the corrosion rate. This effect has several possible causes (Ref 33, 34). First, a temperature difference between the wall and bulk solution can affect the solubility and diffusion coefficient of the diffusing species. Second, boiling near or on the wall can increase turbulence and possibly cause cavitation or increased diffusion (mass transfer). Third, heat transfer in the absence of fluid flow, as in stagnant tanks, can cause natural convection currents that can enhance mass transfer. Thus, if heat transfer is present, it must be considered an environmental variable.

Aqueous Corrosion

Revised by David C. Silverman, Argentum Solutions, Inc.

Velocity and Fluid Movement

Fluid flow rate, or fluid velocity, is also a complex variable (Ref 35). Its influence on corrosion depends on the alloy, fluid components, fluid physical properties, geometry in which the fluid is contained, and corrosion mechanism. These relationships are best discussed in terms of specific examples. In a number of instances, the corrosion rate is determined by the rate of transfer of a species between the surface and the fluid. This situation arises when the corrosion reaction itself is very rapid and one of the corrosion reactants or products has low solubility in the bulk fluid. The corrosion rate becomes a function of the concentration gradient and is expressed by:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$r = k(C_W - C_B) \quad \text{(Eq 7)}$$

where r is the corrosion rate, k is a mass transfer coefficient, C_W is the concentration of the rate- limiting species at the metal wall, and C_B is the concentration of the rate-limiting species in the bulk fluid. The value of k can often be correlated with the dimensionless quantities Reynolds number (Re) and Schmidt number (Sc). The mass transfer coefficient is expressed in terms of the Sherwood number (Sh). These numbers are related to physical properties of the fluid and geometry by:

$$\mathrm{Re} = \left(\frac{vd}{\nu}\right) \quad \text{(Eq 8a)}$$

$$\mathrm{Sc} = \left(\frac{\nu}{D}\right) \quad \text{(Eq 8b)}$$

$$\mathrm{Sh} = \left(\frac{kd}{D}\right) \quad \text{(Eq 8c)}$$

where v is the fluid velocity, d is a characteristic length (for example, pipe diameter), ν is the kinematic viscosity (absolute viscosity divided by density), k is the mass transfer coefficient, and D is the diffusion coefficient.

For many geometries, these quantities can be related by:

$$\mathrm{Sh} = a\mathrm{Re}^b\mathrm{Sc}^c \quad \text{(Eq 9)}$$

where a, b, and c are constants. Equations 7, 8a, 8b, 8c, 9 indicate that the corrosion rate can be calculated if it depends on the mass transfer rate of a species from or to the bulk fluid. The only information required is the geometry, fluid velocity, and physical properties. There are a number of examples of corrosion that follow this behavior. The corrosion of carbon steel and E-Brite 26- 1 in concentrated H_2SO_4 is governed by the rate of mass transfer of $FeSO_4$ from a saturated layer on the surface (Ref 6, 7, 11). Carbon steel corrosion in water in the near-neutral pH range is usually governed by the rate of mass transfer of dissolved oxygen from the bulk fluid to the surface, even in the presence of a porous oxidized layer on the surface (Ref 36). If such a porous surface hydroxide layer becomes thick enough or dense enough, the mass transfer rate might become limited by diffusion through that porous film. Under these circumstances, the constants a, b, and c could change from those for a smooth surface. The equation itself may change, for example, by incorporating a term for the ratio of the surface roughness dimension to the length dimension.

This effect of velocity has ramifications for localized attack, especially pitting and crevice corrosion. The presence of fluid flow can sometimes be beneficial in preventing or decreasing localized attack. For example, type 316 stainless steel has been shown to pit in quiescent seawater but not in moving seawater (Ref 37). When the seawater is moving, the mass transfer rate of oxygen is high enough to maintain a completely passive surface, but in the absence of flow, the mass transfer of oxygen is too slow, and the surface cannot remain passive (Ref 38). This observation indicates that sometimes, fluid velocity can be beneficial even if the corrosion rate involves the mass transfer of a reactant or product. The propensity for localized attack to occur can sometimes be decreased by maintaining sufficient fluid motion.

Under other circumstances, fluid flow has been reported to cause a type of erosion of a surface through the mechanical force of the fluid itself. This process is called impingement. It involves the removal of loosely adhered corroded surface layers on the metal or alloy by the high wall shear stress created by the flowing fluid. Examples of such erosion occur either where fluid is forced to turn direction, for example, at pipe bends (Ref 22), or where high surface shear stresses can exist, for example on ship hulls (Ref 39).

Controversy surrounds the effect that fluid shear stress at the wall has on corrosion. Earlier work has suggested that a critical wall shear stress can be defined above which impingement of a single-phase fluid causes corrosion and below which such an effect is absent (Ref 39). However, the equations that relate fluid shear stress and mass transfer to Reynolds number are so closely related that differentiation between dependence on mass transfer and dependence on fluid shear stress at the wall becomes difficult (Ref 40). Current thinking leans toward most velocity-sensitive corrosion in single-phase fluids being largely caused by mass transfer between the fluid and the corroding surface and not by a removal of the passive film or oxidized surface layers by momentum transfer between the fluid and the wall (Ref 41). There remains the possibility at extremely high

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

flow rates or extremely high shear stresses that fluid motion could remove a weakly adsorbed inhibitor, but the evidence for such effects remains cloudy.

When solids are present in the liquid, they can cause wear or solid erosion-corrosion (Ref 42). This wear is caused by the relative movement of the solids with respect to the surface. Again, such wear is more prevalent where fluid is forced to change direction or where high shear stresses occur. The particles must penetrate the laminar sublayer with enough force to remove the passive film on the alloy. Therefore, high shear stresses are often required for this type of erosion to occur. This problem can be significant in systems carrying saltwater and solids (for example, sand or coal) and carbon steel carrying air plus particulates.

Aqueous Corrosion

Revised by David C. Silverman, Argentum Solutions, Inc.

Component Concentration and Composition

The concentration and makeup of components within the aqueous-based fluid often influence how the other variables manifest themselves. This brief overview discussion highlights how the concentration of dissolved species works with other variables to influence corrosion behavior.

During the previous discussion, the point was made that pH plays a major role in corrosion. For iron, the corrosion rate is large at very low pH, is independent of pH in the neutral pH range, decreases with increasing pH, and finally increases again at very high pH. Additions of small amounts of other components can change this behavior. For example, addition of chloride to H_2SO_4 increases the corrosion rate of iron. This increase is reported to be proportional to the chloride ion concentration raised to approximately the 0.5 power (Ref 43). A similar effect is reported for chloride ion in HCl (Ref 8). Thus, chloride ion accelerates the corrosion of iron in acidic solutions. However, bromide and iodide ions may inhibit corrosion (Ref 44), although this finding is controversial (Ref 17).

The addition of a second component can influence the effect of an already present component. For example, the dependence of the corrosion rate of iron on chloride ion concentration can significantly decrease in neutral solutions when oxygen is present (Ref 44). In addition, as salt concentration increases, the oxygen solubility decreases, masking the effect of chloride ion. The chloride ion effect depends on the cation in concentrated salt solutions, with the rate increasing in the order lithium chloride (LiCl), sodium chloride (NaCl), and potassium chloride (KCl) partially because of differences in oxygen solubility in the presence of these salts (Ref 17). These results illustrate that the effect of the concentration of one component on corrosion can often be influenced by the other environmental variables.

Small additions of certain inhibitors or passivators have a marked effect on corrosion. For example, as little as 0.0023 mol/L of sodium nitrite ($NaNO_2$) or sodium sulfite (Na_2SO_3) can decrease the pit initiation rate of aluminum. Little improvement is found at higher concentration for this system (Ref 45). This behavior is often found with many types of inhibitors. For example, small concentrations (10 ppm) of $NaNO_2$ (a passivator) can drastically inhibit the corrosion of iron, with little further decrease in corrosion found at higher concentrations (Ref 46). The critical concentration can depend on pH and on the presence of other dissolved ions or molecules. The actual concentration needed for a given system must be determined experimentally. Similarly, many organic inhibitors cause a drastic decrease in corrosion rate at very low concentrations, especially for iron in acidic solutions, with no benefit observed on increasing the inhibitor concentration (Ref 47). Inhibitors tend to interact with the surface in one of three ways: a gettering by a component, such as hydrazine, of a finite amount of impurity, such as oxygen, in the solution; oxidation (passivation) of the surface or incorporation in the three-dimensional oxide (nitrite, phosphate, or chromate); or adsorption on the exposed surface area to block corrosion (many organic inhibitors in acid) (Ref 47, 48). Adding an inhibitor to a fluid, even at low concentrations, has been found to change the sensitivity to fluid motion (Ref 49). Conversely, the amount of inhibitor required has been found to be affected by fluid motion, sometimes even decreasing with the onset of fluid motion.

Although this type of behavior is common even for iron in neutral, aqueous environments, exceptions do exist. Sometimes, corrosion can increase with inhibitor concentration until a maximum is reached, followed by a rapid decrease with still further increases in concentration (Ref 46). An example is chromate ion. Chromate ion is normally considered to be an inhibitor. However, at very low concentrations and in the presence of strong activating ions such as chlorides in acidic media, chromate ion can actually accelerate corrosion until enough chromate is present. Also, synergistic action may be observed in which the efficacy of one inhibitor depends on the presence of another species, for example, oxygen or other oxidizing agents. An example is the synergistic action of zinc ions and hydroxyethane diphosphonic acid (HEDP) to passivate the steel surface (Ref 48). Zinc

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

ions alone cannot passivate steel, and HEDP alone is only modestly successful. Together, they form a more potent inhibitor system, their action virtually independent of the concentration of dissolved oxygen.

A question often asked is, “What is the amount of chloride that is allowable before localized corrosion (crevice corrosion, pitting, or SCC) can occur in austenitic alloys?” The answer is not straightforward. Work with boiling, saturated magnesium chloride suggests that 42 wt% Ni in the alloy prevents SCC (Ref 22). This rule of thumb, however, does not answer the question. The maximum chloride concentration depends on the pH, other constituents, temperature, and other variables—some environmental, some metallurgical.

L. Veleva and R.D. Kane, Atmospheric Corrosion, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 196–209

Atmospheric Corrosion

Lucien Veleva, CINVESTAV-IPN, Yucatan, Mexico; Russell D. Kane, InterCorr International, Inc.

Introduction

ATMOSPHERIC CORROSION is the degradation and destruction of metallic materials and their structure and properties due to interaction with the terrestrial atmosphere at its characteristic air temperature, humidity, air chemistry, and climatic values (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13). Atmospheric corrosion is distinguished from the corrosion of metals exposed to high temperatures in an absence of moisture on the metal surface (dry or gaseous corrosion), which does not correspond to the terrestrial atmospheric humidity and temperature. The mechanism of high-temperature corrosion is a chemical corrosion, and it is quite different from atmospheric corrosion. (See the article “High-Temperature Gaseous Corrosion” in this Volume.)

The majority of metal structures and equipment are exposed to terrestrial air conditions to some degree and therefore can suffer from atmospheric corrosion. In some severe cases, the metal can be completely destroyed and converted to corrosion products. With background knowledge of the principal exposure conditions and their influence on metal corrosion, most serious corrosion problems can be prevented. It is recognized that several industries face difficult corrosion problems because of very aggressive atmospheres, including the electrical power transmission and distribution industry, chemical/ petrochemical production plants and equipment, aircraft, automotive manufacture and associated components, transportation infrastructure, offshore structures and equipment, the construction industry, and electronic devices.

Atmospheric corrosion occurs spontaneously but may be slowed, prevented, and controlled but never stopped. The reason is that the commonly used metals are not in a pure state in the earth, except for some noble metals. Metals usually are in ores, chemical compounds that include oxygen, hydrogen, and sulfur. These mineral compounds are the thermodynamic steady state of the metals, in which Gibbs free energy (ΔG) has a minimum value. For the separation of the metals from their ores and for metallurgical and manufacturing processes, energy, in the form of heat, chemical, electrical, or mechanical, elevates the metal to a higher energy level. The metal product is not in its most thermodynamically stable state. This fact drives metals to convert into corrosion products having a chemical composition similar to that of the original ores that are in a more thermodynamically stable state. When metals come in contact with the atmosphere (oxygen) and water (moisture) in the presence of corrosive species such as chlorides or sulfur dioxide, the corrosion process starts, and corrosion products such as oxides, hydroxides, or oxyhydroxides are formed. Table 1 shows the tendency for corrosion of some metals as a function of the energy required for their separation from ores.

Table 1 Position of some metals according to their standard electrode potentials in aqueous solutions at 25 °C (77 °F) in V (versus NHE)(a)

Metal	Standard electrode potential at 25 °C (77 °F), V
Higher excess of free energy **(very high corrosion tendency)**	
Potassium	-2.92
Magnesium	-2.34
Beryllium	-1.70
Aluminum	-1.67
Manganese	-1.05

Atmospheric Corrosion

Lucien Veleva, CINVESTAV-IPN, Yucatan, Mexico; Russell D. Kane, InterCorr International, Inc.

Elements of the Process

Atmospheric corrosion is an aqueous process, and its mechanism is electrochemical. There is not only a transfer of mass during the chemical reaction but also an interchange of charged particles (electrons and ions) at the interface of the metal (an electronic conductor) and the electrolyte (an ionic conductor). The transfer of electrons (flow of electric current) occurs because of the formation of a galvanic corrosion cell on the metal surface. Three elements are necessary for the cell operation: anode and cathode sites, an electrolyte, and an oxidizing agent.

Anode and cathode sites form multiple corrosion cells.

Anodes are the areas on the metal with a higher energy state, due to various factors such as inhomogeneous metal composition, grain boundary, multiple metallurgical phases, local metal defects, and nonuniform metal treatments. The oxidation corrosion reaction is done on the anodic sites:

$$Me - ne^- \bullet \quad Me^{n+} \cdot (mH_2O) \qquad \text{(Eq 1)}$$

where Me is the metal. The metal is dissolved at the anode to form cations (positively charged ions). These may originally appear as metal hydrated ions ($Me^{n+} \cdot (mH_2O)$) but subsequently convert into oxides and hydroxides, the metal corrosion products. For example, steel atmospheric corrosion products typically include α- and γ-FeOOH as main constituents.

Cathodes are the metal sites with a lower energy state, for example, inert non-metallic inclusions and lower active-metal phases or structures. The cathodic reaction occurs on these sites and involves the reduction of an oxidizing agent, such as air, oxygen, or hydrogen ions.

An electrolyte, such as moisture, comes in contact with the metal surface. The moisture contains dissolved ionic species (atmospheric pollutants) and is a good ionic conductor that can sustain electrochemical reactions.

An oxidizing agent, such as oxygen and hydrogen ions (H^+), is necessary for accepting the electrons emitted from the metal in the anode reaction (Eq 1):

$$Oxy + e^- \bullet \quad Red_{form} \qquad \text{(Eq 2)}$$

$$\frac{1}{2}O_2 + H_2O + 2e^- \bullet \quad 2OH^- \qquad \text{(Eq 3)}$$

$$2H^+ + H_2O + 2e^- \bullet \quad H_2 \uparrow (gas) \qquad \text{(Eq 4)}$$

where Oxy is the oxidizing agent, and Red is the reduced species.

Corrosion Reactions. Figures 1 and 2 illustrate the corrosion reactions (oxidation and reduction) that occur on the metal surface at the metal-electrolyte interface and the movement of electrons from the anodic to cathodic sites. The net electric current is zero, because the electrons liberated during the oxidation of the metal (Eq 1) are accepted by the oxidizing agent in the cathodic (reduction) reaction (Eq 2). In Fig. 2, the oxidizing agent is the H^+ ion (cation), a principal ion in the moisture formed on the metal surface exposed to industrial and urban atmospheres. Typically in these sites, the atmosphere may be contaminated by SO_2, which can be converted to H_2SO_3 and then to H_2SO_4 (sulfuric acid) in the presence of moist air. When this occurs in the atmosphere, acid rain is formed, which is a severe environment for metal structures. The movement of the electrons from anodic to cathodic sites in a metal is a result of the difference in Gibbs free energy between the anode (higher level) and the cathode (lower level). This results in a potential difference between both reaction metal sites, which yields a current flow from the anodic to cathodic sites. Detailed information about the possible corrosion reaction (and their metal potential values) as a function of aqueous electrolyte concentration and pH (acidity or alkalinity) in the presence of certain ions (atmospheric contamination) can be found using Pourbaix diagrams

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

(Ref 13). These diagrams are a useful tool for any corrosion engineer and scientist in evaluating and understanding the conditions that lead to specific corrosion reactions and their associated corrosion products.

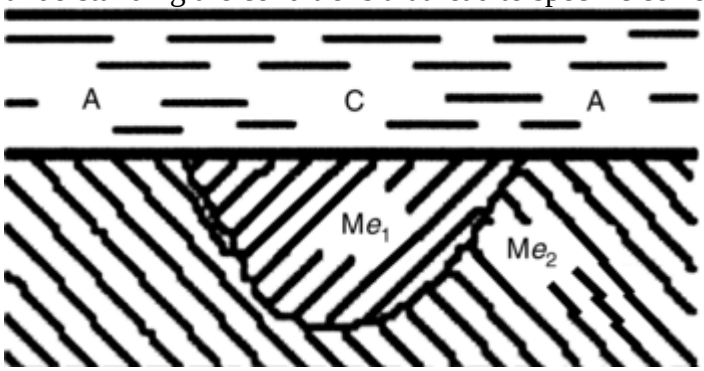

Fig. 1 Schematic presentation of corrosion metal cell formed by anodic (A) and cathodic (C) sites. The A sites (Me_2) have a more negative potential (E) relative to that of the C sites (Me_1).

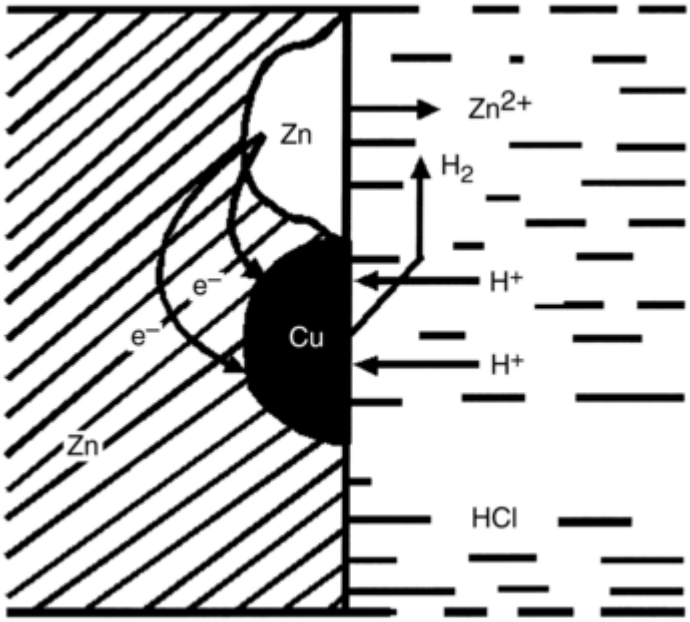

Fig. 2 Schematic presentation of the corrosion galvanic cell created in a zinc-copper alloy in an acid environment. The cathode is the copper-rich phase and the anode is the zinc-rich phase. The corrosion attack is selective to the zinc-rich phase.

Types of Atmospheric Corrosion Attack. Atmospheric corrosion can occur in two basic forms: uniform (general) and non-uniform (localized) attack. Uniform corrosion results at a similar corrosion rate over the metal surface and has the same appearance throughout (Fig. 3a). Uniform attack is typical for atmospheric corrosion of steel and copper. Localized corrosion usually occurs at small and specific locations on the metal surface where the corrosion process is focused, resulting in local acceleration of the corrosion rate (Fig. 3b). This type of corrosion attack is referred to as pitting corrosion and can be observed on aluminum and its alloys, zinc (hot dip zinc or electrodeposited zinc on steel), stainless steels, nickel, and other metals. It is often induced by the presence of chloride ions, which can be found in airborne salinity in marine-coastal environments. Localized attack of some aluminum alloys, such as those containing copper, can take the form of layered corrosion, exfoliation, detachment, and deformation, of thin layers within the metal surface when exposed to coastal environments.

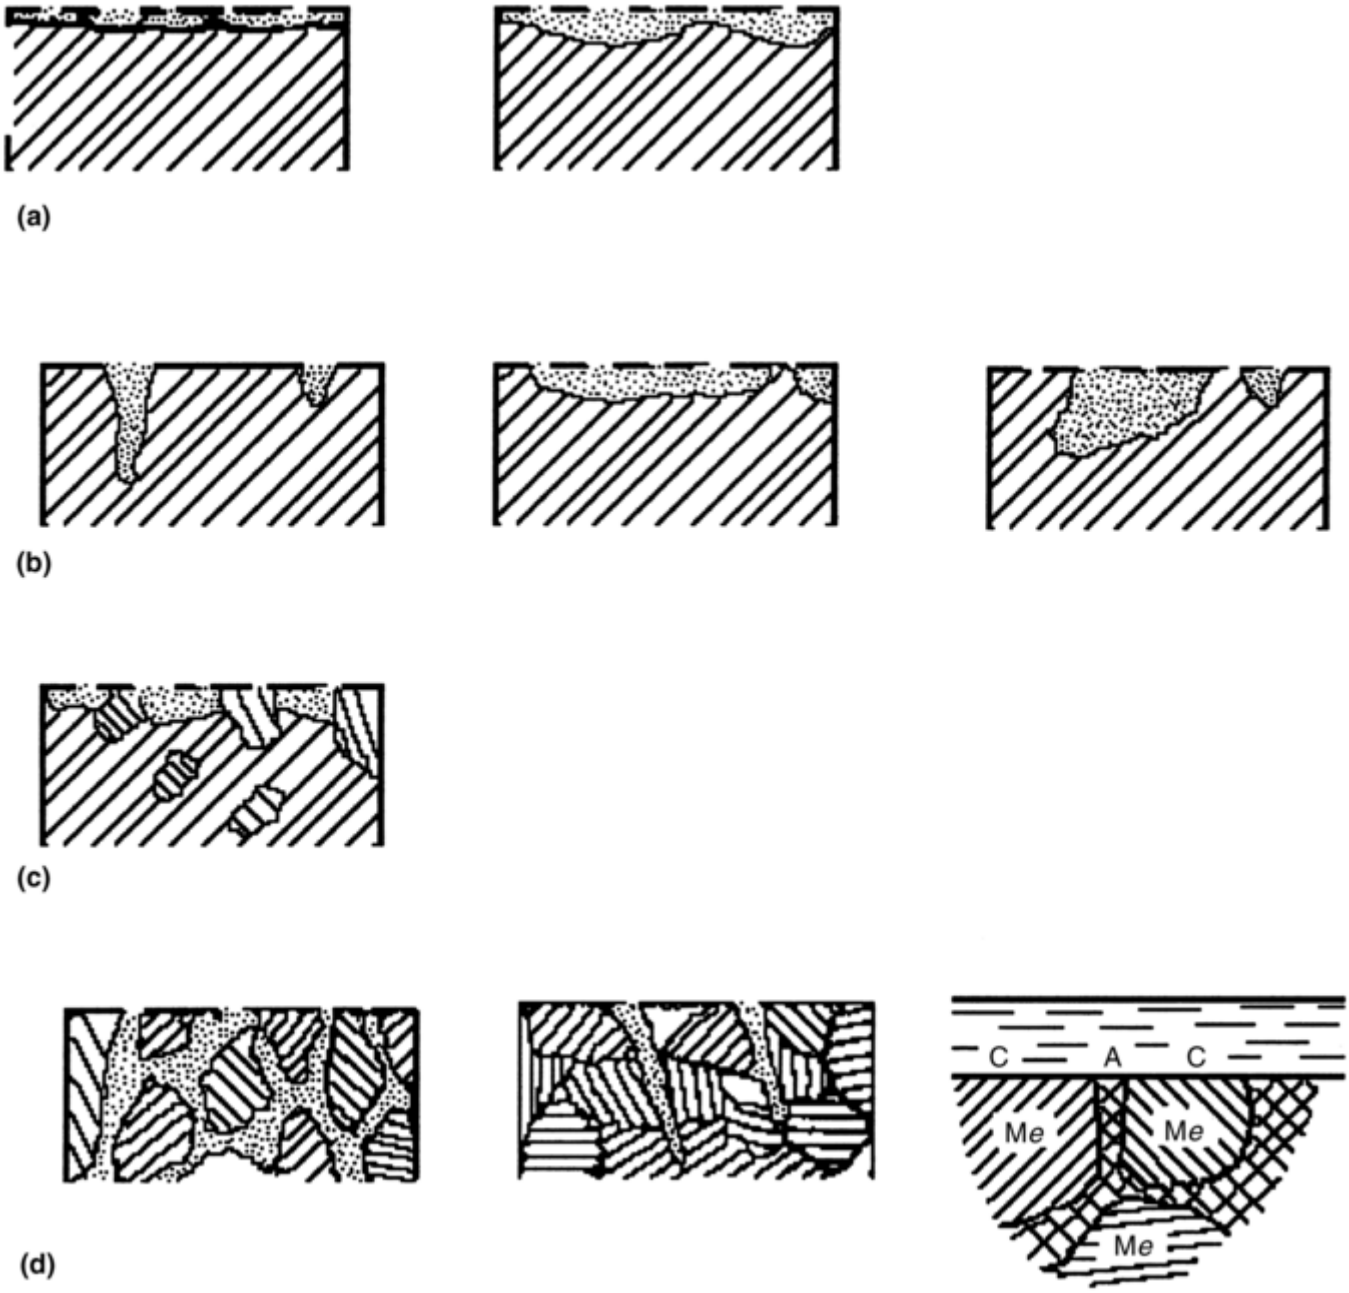

Fig. 3 Schematic presentation of cross sections of several forms of corrosion attacks. (a) Uniform. (b) Nonuniform (localized). (c) Selective. (d) Intergranular. C, cathodic areas (M*e*); A, anodic areas between the metal grains

Localized atmospheric corrosion can also be observed on the surface of brass and copper-zinc alloys due to the reaction of the distinct alloying metals in contact with the environment. In this case, the corrosion is referred to as selective corrosion (Fig. 3c). Some metals or alloys can be susceptible to localized attack that forms at locations of distinct phases on the grain boundaries. This corrosion is recognized as intergranular corrosion (Fig. 3d). An example is the corrosion in cast iron, which occurs around the boundary of the ferritic phase or at carbides in grain boundaries of stainless steels. The atmospheric corrosion process can also be increased when two or more different metals are in direct contact in a structure. This metal coupling allows the formation of a galvanic corrosion cell having different electromotive force (voltage), depending on the potential values of the metals in contact (Table 1) (Fig. 4).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

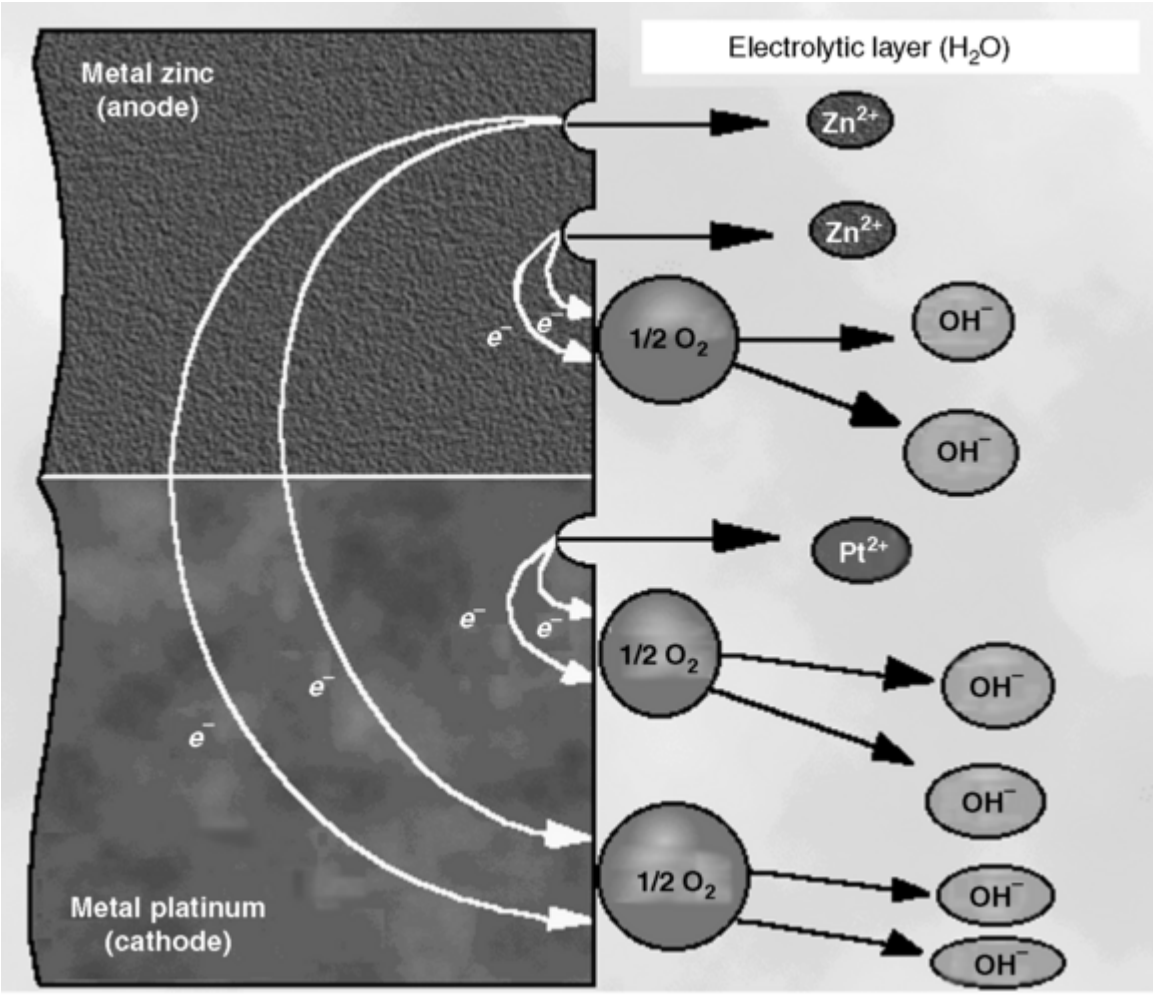

Fig. 4 Schematic presentation of corrosion reaction in galvanic coupling of zinc and platinum

A very dangerous type of atmospheric corrosion attack is metal cracking, which can occur when a metal structure such as a bridge is exposed to a corrosive environment and continuous or cyclic mechanical loading. This combination leads to surface or internal microcrevices, fissures, and cracks that result in stress-corrosion cracking (under relatively constant loads) or fatigue corrosion (under cyclic deformation).

Atmospheric Parameters and Their Influence

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

A variety of atmospheric factors, climatic conditions, and air-chemical pollutants determines the corrosiveness of the atmosphere and contributes to the metal corrosion process in distinct ways (Ref 1, 7, 8, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33).

Climatic characteristics play a major role in the atmospheric corrosion process. To fully understand atmospheric corrosion, it is important to properly describe and characterize the environment that causes metal degradation. Factors and the interaction between them that need to be considered are sun radiation, air temperature, relative humidity, air chemistry, precipitation, winds, and the mechanical and chemical action of natural forces such as sand and rock particles, soil dust, volcanic dust, organic matter, and industrial dust. Also, various physical, chemical, and biological factors, including manipulation of the environment as may occur in many engineering applications, must be considered. Such factors can directly affect the corrosion rate of metals exposed in outdoor or indoor atmospheres. The atmospheric corrosion process can be further complicated and accelerated when micro- and/or macroorganisms are present. In humid tropical and subtropical climates, microbial corrosion or biocorrosion is commonly observed.

When studying the atmospheric corrosion of engineering materials, the most important factors related to the climate and its effect on that material are represented by a combination of:

- Temperature (*T*) and relative humidity (RH), often described as the temperature-humidity complex (THC). Humidity is a measure of the amount of water vapor in air, and relative humidity is the ratio between absolute humidity and its saturation value, expressed in percentage. This percentage is a reverse function of the temperature (*T*); the RH increases while the *T* is decreasing, and vice versa.
- Annual values of pluvial precipitation (PP)
- Time of wetness (TOW), during which moisture exists on the metal surface, and corrosion may occur. This moisture layer on the metal surface can be generated by rain, fog, snow, dew condensation, and capillary condensation.

Standards that are useful in characterizing the environment, as well as atmospheric corrosion test standards, are listed in Table 2.

Table 2 Standards for testing and characterizing atmospheric corrosion

Time of Metal Wetness. In recent years, this parameter has received special attention, because it is the fundamental parameter that relates to the time during which the metal surface is covered by a thin electrolyte layer containing air contaminants and during which the corrosion cell can operate (Ref 19, 22, 25, 26, 27, 28, 29). The TOW is usually calculated in hours, according to International Organization for Standardization (ISO) 9223, “Corrosion of Metals and Alloys, Corrosivity of Atmospheres, Classification,” and includes the daily temperature/relative humidity (T-RH) complex, using 80% as a critical RH value for $T \geq 0$ °C (32 °F), when the condensation starts on the metal (Ref 1). Above RH 90% and $T < 25$ °C (77 °F), the dewpoint is reached, and the moisture formed on the metal surface is visible. The wet layer is actually thicker than that formed by initial condensation. This change of the moisture layer thickness, in turn, induces an alteration in the metal corrosion rate. The thinner layer of moisture is a minor barrier for the diffusion of molecular oxygen from the environment. The thin aqueous layer can be practically saturated in dissolved oxygen; thus, the corrosion rate of the metal is actually more rapid in the thinner layer formed by first condensation than in the relatively thick layer formed at higher RH.

The rain is a climatic factor that also contributes to moisture formation on a metal surface, but it can have additional effects. These include dilution and washing of the corrosive pollutants deposited on the metal surface. This situation results in a decrease of the corrosion rate, even when the TOW is prolonged. Precipitation can also dissolve some metal corrosion products soluble in water (zinc carbonate and hydroxide,

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

for example). A fresh metal surface will be in closer contact with the atmosphere, resulting in an increase in the corrosion rate. This situation is in contrast to the compact and well-adhered corrosion product layer, formed on the metal surface, that can act as a physical barrier for oxygen diffusion to cathodic sites and that results in a decrease in the rate of corrosion.

The environmental corrosion aggressiveness category of an atmosphere can be assigned based on the annual TOW value according to ISO 9223. However, this procedure is adequate to use only in an atmosphere free from chloride. In the presence of chlorides, the deposition of hygroscopic contaminants (for example, chloride salts in marine-coastal regions) occurs on the metal surface. This lowers the critical relative humidity value (RH_c), and corrosion can start at RH as low as ~40 to 50% (Ref 1). This fact implies that in a marine-coastal environment, the higher concentration of chlorides can increase the real TOW in a zone even far from the shore (Ref 25). The development of corrosion and TOW has been detected on samples exposed to the open atmosphere in the Antarctic when the temperature is below 0 °C (32 °F). Reduction of the RH_c value can be produced by deposition of ammonium sulfates on the metal surface, which are known to accelerate corrosion and provide sulfate ions. It was confirmed (Ref 29) by measuring TOW, using a copper-gold sensor according to ASTM G 84, that the annual TOW value was as large as 8500 h at a location 20 to 30 km (12 to 18 miles) from the seashore in a marine- coastal atmosphere in a humid tropical climate. This value is twice the value of 4500 to 4800 h for a typical rural-urban environment. This fact can explain the different corrosion rates observed for standard metals (low-carbon steel, copper, zinc) when exposed to these atmospheres. This difference in TOW values is due mainly to specific changes in their daily T-RH complex. Because of this, it is recommended that the daily T-RH complex be used rather than the annual *T* and RH average.

Figure 5 presents the daily T-RH complex of two atmospheres, marine-coastal and rural-urban, both part of a tropical humid climate. It can be seen that the corrosion cell can work almost all day in the marine-coastal environment at relatively constant *T* and RH values (due to the sea thermodynamic buffer capacity), while in the rural-urban atmosphere, the corrosion cell is interrupted during the daily hours and starts again when the RH reaches the critical value (≥80%) for formation of moisture on the metal surface. The results (Fig. 5) also indicate that the metal surface exposed in the rural-urban environment experiences wet/dry cycles. Such cycles affect the structure and morphology of corrosion products and promote micro- and macrocracking, as well as the detachment and exfoliation of internal corrosion layers. The difference in the daily T-RH complex of the marine-coastal and rural- urban environments also has another important effect on metal corrosion behavior. Because TOW occurs in different temperature ranges (Fig. 6, 7), this fact determines a distinct corrosion rate. Following the 10° rule, a 10 °C (18 °F) temperature difference can roughly change the corrosion rate by an order of magnitude.

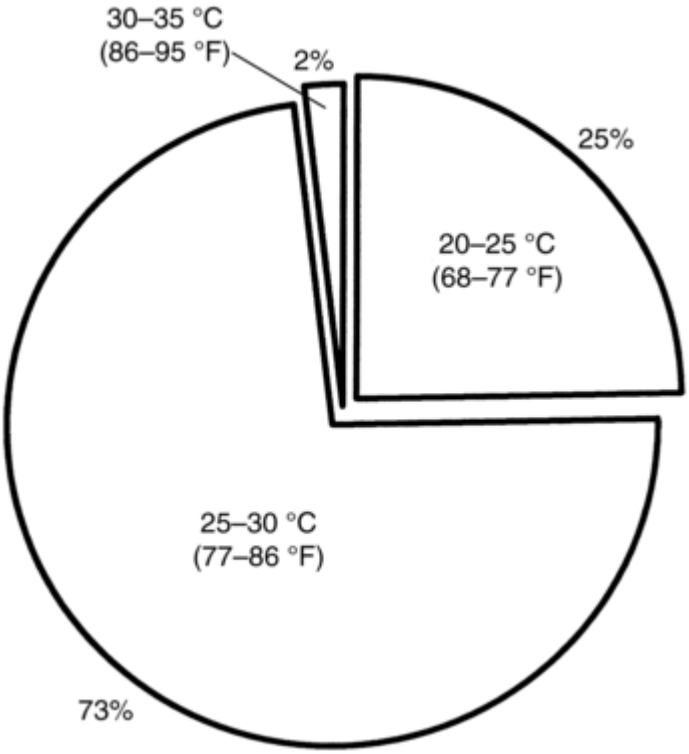

Fig. 7 Distribution of the annual time of wetness (%) in different temperature intervals presented in the marine-coastal tropical humid environment of the port of Progreso (Gulf of Mexico) in 1998

The nature and orientation of the metal surface and its inclination to the horizon or exposure angle also influence the real metal *T* and TOW values, due to the difference in solar absorbance, emissivity, and conductivity of the metal. The surface condition and color of the metal and its corrosion products are factors. These specific characteristics contribute to surface *T* and TOW changes. Exposed metals with corrosion products on the surface can have a higher *T* compared to that of the environment (Fig. 8, 9). In cold regions,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

this can result in the appearance of liquid on the metal surface, even when ambient temperature is below 0 °C (32 °F). This explains why metals having a similar TOW period can corrode at different rates when they are exposed in distinctly different climatic areas. Therefore, defining the T-RH complex is of primary importance in completely understanding the corrosion process. Local TOW values can also be extended, due to the porous cavity structure of corrosion products on the metal surface.

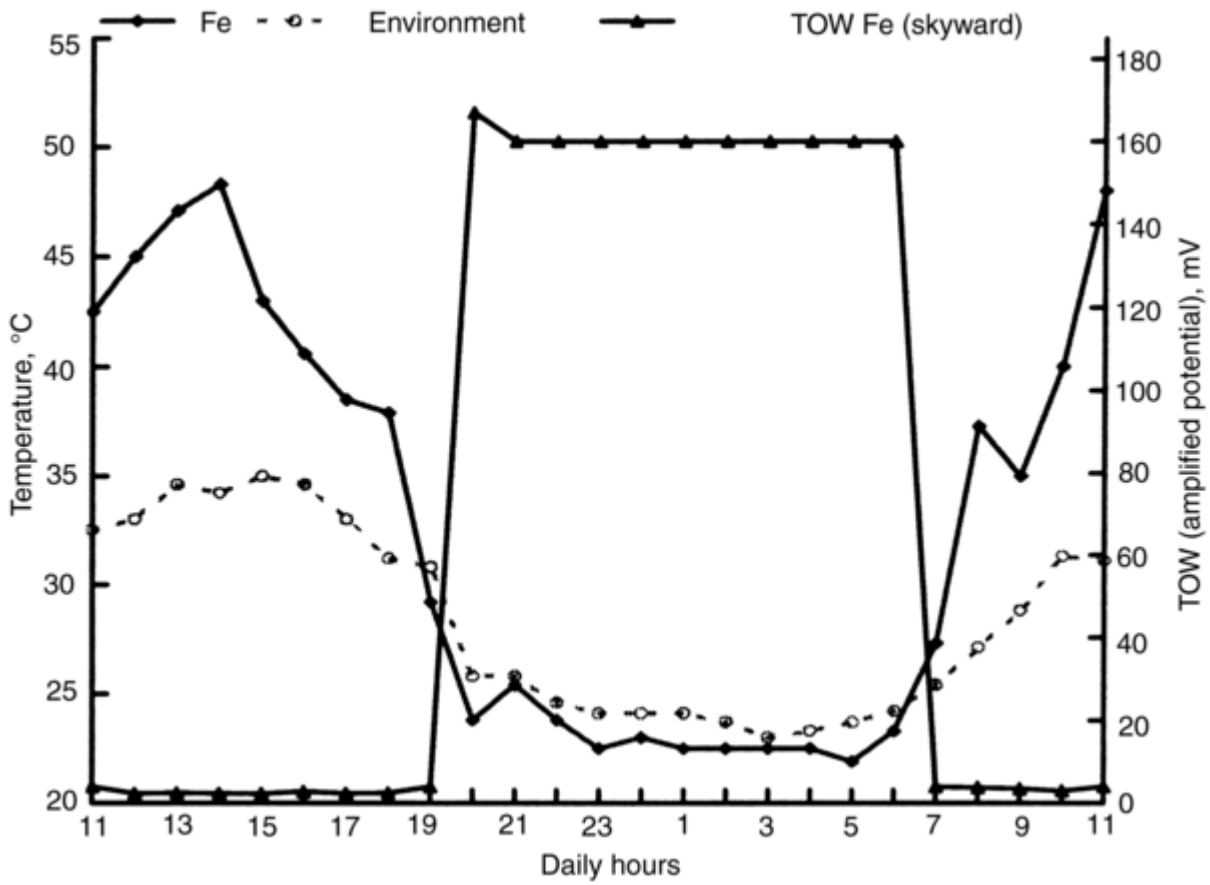

Fig. 9 Variation of environmental and low-carbon steel (Fe) sample temperatures and time of wetness (TOW) measured on the steel surface (an amplified potential of the gold-copper sensor). Registered over two days

Metal temperature and TOW values are influenced by winds and their predominate direction (north or south, continental or onshore). This can change the type and amount of atmospheric pollutants that settle on the metal surface. In some cases, winds can transport sand and other hard particles that provoke accelerated metal erosion or corrosion-erosion effects.

Air Chemistry and Principal Pollutants Inducing Corrosion

Air chemistry is closely related to the corrosion aggressiveness of the atmosphere and this fact needs careful attention (Ref 1, 7, 8, 9, 11, 12). It is recognized that *chlorides* (airborne salinity) and *sulfur dioxide* (SO_2) are the principal pollutants that can accelerate the atmospheric corrosion rate by several orders of magnitude.

The principal source of chlorides is aerosols, which are suspensions of small liquid or solid particles in the atmosphere that come from salt spray and salt fog in the vicinity of the seashore and from the contaminated environment around industrial plants producing hydrogen chloride and sodium hypochloride. Chloride ion (Cl^-) is one of the principal environmental agents that accelerates corrosion and, in particular, pitting attack. Chlorides do damage by penetrating and destroying the normally protective and passive layer of oxides and hydroxides formed under natural conditions. Such protective surface films on metals exposed to atmospheres free of chloride include copper (Cu_2O, copper patina), aluminum (Al_2O_3), and zinc (ZnO and $Zn(OH)_2$).

A second aggressive environmental pollutant for metals is SO_2 gas. It is found in urban and industrial atmospheres and, in the prescence of oxygen, is easily converted to sulfuric acid in the condensed moisture layer on the metal surface. The sulfuric acid dissociates to give H^+ ions ($H_2SO_4 \leftrightarrow 2H^+ + SO_4^{2-}$), which participate as the *oxidizing agent* in the *cathodic corrosion reaction* (Eq 1, 4 and Fig. 2). Due to the presence of H^+ ions, the moisture has a lower pH (often below 4.5). The addition of SO_2 air contamination, acid rain, results in a highly accelerated corrosion rate. Some metals, such as aluminum and zinc, are relatively resistant in pH-neutral atmospheres (pH ≈ 6 to 7.5) but corrode rapidly in an acid environment (Ref 12).

According to ISO 9223, the annual average deposition rate ($mg/m^2/day$) of chlorides (airborne salinity) and sulfur dioxide (SO_2) compounds is used to classify the atmospheric corrosivity. The recommended methods for measurement of chloride and sulfate levels are the wet candle and sulfation plate sampling apparatuses, as cited in ISO 9225, “Corrosion of Metals and Alloys, Corrosivity of Atmospheres, Measurement of Pollution.”

Some atmospheric gases, such as carbon dioxide (CO_2), nitrogen dioxide (NO_2), ozone (O_3), ammonia (NH_3), hydrogen sulfide (H_2S), and hydrogen chloride (HCl), and organic acids, such as formic (HCOOH) and acetic (CH_3COOH), are also known to be highly corrosive for several commonly used metals. After being dissolved in

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

the moisture layer on the metal surface, these gases result in a number of ions and ionic species, such as H^+, CO_3^{2-}, Cl^-, NH_4^+, NO_3^-, SO_4^{2-}, $COOH^-$, and CH_3COO^-, that may have a major influence on the corrosion mechanism process, which increases the corrosion current from electrochemical (galvanic) cells, and the resultant corrosion rate.
Most aerosol particles absorb water, leading to an increase in the TOW period and the corrosive process.

Thermodynamics of Atmospheric Corrosion and Use of Pourbaix Diagrams

When the question is asked, “Under what conditions can corrosion of metals occur in aqueous solutions?”, the answer can usually be found using Pourbaix diagrams, which show regions of metal stability and corrosion on axes of metal electrochemical potential as a function of pH of the electrolyte (Ref 13). It is well known that metals occur in different states, depending mainly on the pH of the environment and their electrochemical potential (e.g., Gibbs free energy, Table 1). Pourbaix diagrams show the forms of the metal that are thermodynamically stable over a range of pH and electrochemical potential.
Atmospheric Corrosion of Iron and Carbon Steels. The most-used metal for construction of structures and equipment is iron, because it is the main constituent of the carbon and alloy steels. The iron Pourbaix diagram (Fig. 10) demonstrates the possibility for multiple states: corrosion (active state), passivity and immunity (Ref 1, 13, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46).

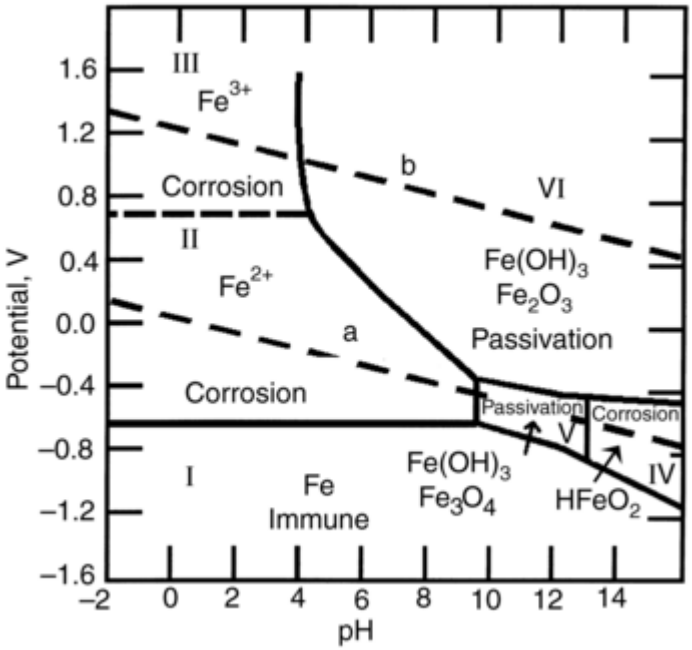

Fig. 10 Pourbaix diagram (metal potential versus pH) for iron in aqueous (water) solution

In the region of potentials and pH values defined by $Fe(OH)_3$ and Fe_2O_3 (the solid compounds thermodynamically stable in these conditions), the initial corrosion process forms a very dense and usually thin and impervious rust layer of iron oxide and oxyhydroxides that acts as an effective physical barrier between the metal and corrosive atmosphere. Due to this physical barrier, oxygen and water molecules cannot easily penetrate and reach the underlying metal surface. Therefore, the corrosion process is effectively stopped, and the metal is in a passive state.

Iron can also be observed in another passive region, that of Fe_3O_4 and $Fe(OH)_2$, when corrosion produces an oxide (magnetite, Fe_3O_4) that is a very thin, dense, and almost transparent rust layer. This layer can also act as an effective physical barrier that stops corrosion. However, for this passive state to exist, the metal needs be exposed to an environment at an alkaline pH higher than 8.5 to 9. This explains the passive carbon steel state when it is embedded in an alkaline (pH > 12 to 13) concrete environment, such as occurs in steel reinforcement. However, any changes of pH (below the pH 8.5 to 9) remove the metal from the passive state, and corrosion can resume. This is what happens in the case of the phenomenon referred to as carbonation of concrete. Reinforcing steel suffers serious and accelerated corrosion due to the lowering of concrete pH as a result of the penetration of CO_2 gas from the atmosphere into the concrete pores. This will cause subsequent dissolution of the steel in the moisture, filling the pores of the concrete.

A very dangerous pollutant for the destruction of the passive oxide layer, even in a favorable alkaline pH medium, is the chloride ion. The chloride ion has a relatively small ionic radius and high mobility in aqueous solutions. It can penetrate the oxide layer, resulting in its destruction, increasing the corrosion rate, and often leading to localized corrosion (pitting). It should be noted that the complete mechanism of chloride-induced corrosion and pit formation on iron alloys is still not well explained, and several models have been proposed (Ref 11).

Figure 10 shows two regions of corrosion (active) metal state, when the metal is corroded either to Fe^{2+} or Fe^{3+} ions, depending on pH and potential values. In natural atmospheric conditions, the standard potential of iron is negative (approximately -0.44 V, Table 1). This situation indicates that in neutral and low-acid industrial environments, the iron carbon steel and low- alloy steel will corrode whenever the pH of the environment is lower than 8.5 to 9. The corrosion attack on iron and steels generally occurs uniformly, extending on all metal surfaces to the same extent.

An interesting case is the immune-metal state, which is not present for all metals but is possible for iron. The corrosion of steel is not possible in the region of pH and potentials where iron is in the thermodynamically stable immune condition, as shown in Fig. 10. An external voltage can be applied to take the iron potential from its standard state (-0.44 V, Table 1) to more negative values (less than -0.6 to -0.7 V). This is the basis for the cathodic protection applied to underground metallic pipeline systems, steel-reinforced concrete bridges, ships, offshore platforms, and other metal structures.

مرجع مهندسی مواد و متالورژی

Atmospheric Corrosion of Aluminum. Another widely used metal for construction is aluminum. Thermodynamically, it is very active and immediately corrodes when produced (Table 1, high level of free energy and high negative potential value) (Ref 1, 13, 47, 48, 49, 50, 51, 52, 53). The Pourbaix diagram (Fig. 11) shows three states that are possible for this metal (and its alloys): passivity, immunity, and corrosion (active) (Ref 13). There is a region of pH and potentials where the metal is passivated and well protected from atmospheric corrosion, due to the formation of a very thin, transparent, and adherent low-porosity hydrated oxide layer ($Al_2O_3H_2O$). This layer, however, can be destroyed by the presence of chloride ions in the environment, which will produce pitting. The passive layer provides very good corrosion resistance when exposed to normal atmospheric conditions and lower resistance to corrosion when structures are exposed in marine-coastal environments. Aluminum and its alloys can also exhibit a layered corrosion exfoliation attack.

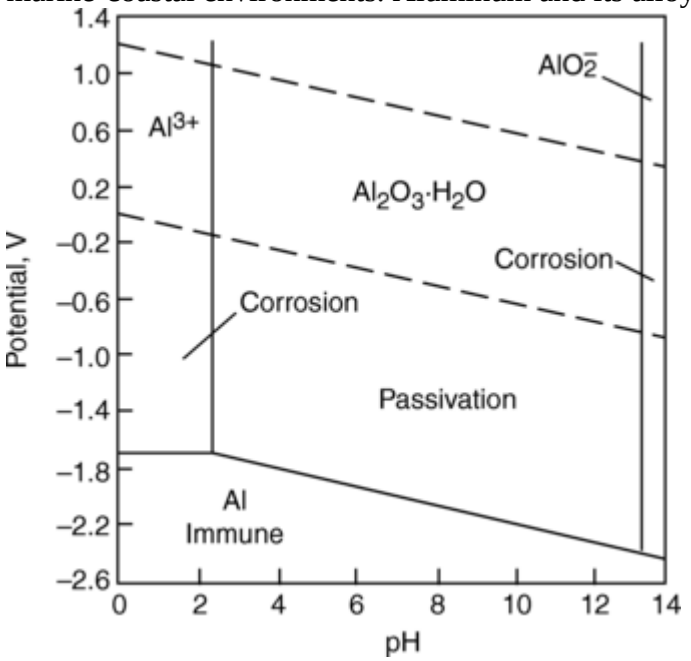

Fig. 11 Pourbaix diagram (potential versus pH) for aluminum in water at 25 °C (77 °F)

In natural conditions, aluminum has a high negative standard potential value (-1.67 V, Table 1), but due to the immediate formation of a passive oxide layer, it can be protected in environments where the pH is in the range of 2 to 14. However, the range of pH from 4 to 9 is the practical range for many applications where stability exists, and the highly passive layer forms and remains protective. This results in generally good corrosion resistance and the wide use of aluminum. The corrosion state is found in very polluted, mainly SO_2, industrial atmospheres, where pH is below 2, and also in alkaline environments over a substantial range of potentials (Fig. 11). In noncontaminated atmospheres, and after a long exposure time, small pits (100 μm, or 4 mil deep) can occur for aluminum in contact with water (high values of TOW). The presence of metal impurities (iron, copper) increases this pitting, which is rate controlled by oxygen cathodic reduction on the surface inclusion, Hence, the growth of the pit depth slows as the pit diameter increases. Galvanic couple corrosion (bimetallic corrosion) occurs when a metal having a less negative standard potential than that of aluminum (Table 1) is brought into contact. Copper is a cathode in the formed pair with aluminum.

The metal potential of aluminum must be shifted to values more negative than -1.7, using an external source of direct current to reach the immune state. Cathodic protection can be carried out but may run into difficulties arising from local pH increases, which could lead to the dissolution of the protective oxide film on the aluminum surface. Corrosion protection for aluminum can be obtained through anodizing, which is achieved by growing a thicker oxide film (approximately 20 μm, or 0.8 mil) under anodic polarization in appropriate electrolytes.

Pure aluminum is seldom used for structures, because its alloys have better mechanical properties. However, alloy corrosion resistance varies from less than that of pure aluminum when alloyed with magnesium and copper to much better when combined with tungsten and tantalum. One of the most widely used aluminum alloys is Duralumin, which contains 4% Cu and a small amount of other metals, such as iron. This alloy corrodes much more readily than pure aluminum. Localized pitting corrosion is usually observed as the failure mode, due to the breakdown of the passive oxide layer.

مرجع مهندسی مواد و متالورژی

Atmospheric Corrosion of Copper. Copper is widely used because of its good corrosion resistance in a variety of atmospheres (Ref 1, 13, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67), high electric and thermal conductivities, and attractive mechanical properties when exposed at low, moderate, and high temperatures (Ref 1). Its electrochemical potential value is positive (+0.34 V, Table 1) in natural environments, as compared to values observed for iron and aluminum, and close to the potentials for noble nonreactive metals. Therefore, copper is not very active chemically, and its rate of oxidation, when exposed to the atmosphere, is very low. The corrosion open-circuit potential (OCP) of copper is usually below the standard hydrogen reaction potential value (0.00 V, Table 1), and due to this fact, there is no participation by hydrogen ion (H^+) as an oxidizing agent in the cathodic corrosion reaction (Eq 4) when the atmosphere is very polluted (as in the acid pH range). According to the Pourbaix diagram (Ref 13) for copper (Fig. 12), three thermodynamic states are possible: corrosion, passivity, and immunity. It can be seen that in atmospheres with neutral and alkaline pH, copper is passive (at a standard metal potential of +0.34 V), due to the formation of an oxide layer of Cu_2O (cuprite). Another passive state can be obtained when the metal potential is shifted to more positive values, forming copper oxide (CuO). The immune state requires more negative potential values (using an external electric source), where the metal does not corrode regardless of pH value. The diagram in Fig. 12 shows two regions of the metal corrosion state: one at low (acid) pH and the other at higher (alkaline) pH values, when metal ions (Cu^{2+}) and complex anions (CuO_2^{2-}), respectively, are formed during the anodic corrosion reaction (Eq 1).

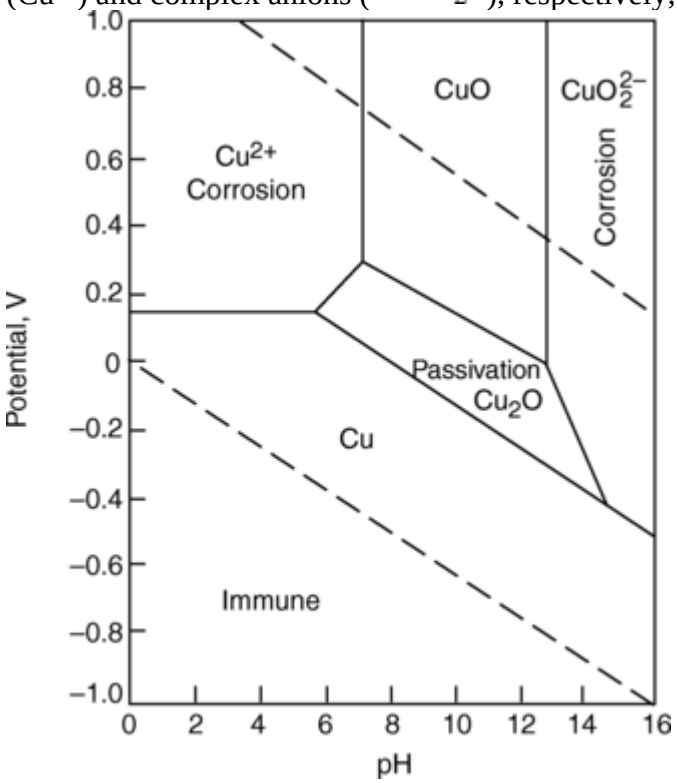

Fig. 12 Pourbaix diagram (potential versus pH) for copper in water at 25 °C (77 °F)

The atmospheric behavior and protection of copper against corrosion is of interest because it is a construction material in monuments, churches, and architectural objects. The oxide passive layer (Cu_2O, cuprite) formed during the initial stages of the copper corrosion process is called the patina, and extensive investigations have been dedicated to this subject, especially for restoration of monuments (Ref 56, 57, 58, 59, 60, 65). The patina layer is transparent (≈30 Å of thickness at the beginning) and changes color from orange to red-brown. The color deepens to dark brown when the thickness of this layer increases. Recent studies have revealed that copper patina consists of Cu_2O/CuO ($Cu(OH)_2$ or $CuO \cdot H_2O$). In marine-coastal and industrial atmospheres, the color of the patina can be superficially changed to a more greenish hue because of the formation of copper basic salts, such as sulfates in urban or rural environments, chlorides in marine atmospheres, nitrates, and carbonates. The knowledge of patina formation and its development in time is also used for the creation of an artificial copper patina. This type of surface treatment can be used to give a more antiquated appearance to copper objects.

مرجع مهندسی مواد و متالورژی

Atmospheric Corrosion of Zinc. The ability of zinc to galvanically protect steel, because of its more negative standard electrochemical potential, has given this metal a wide variety of application (Ref 1, 13, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80). Although zinc by itself is available in sheet, plate, strip, and pressure die castings, its principal uses for corrosion control are as a coating on steel and as zinc anodes for cathodic protection of steel on underground pipelines, oil rigs, offshore structures, and bridges.

Because of the low standard negative potential value for zinc (-0.76, Table 1), it is a very active metal and tends to corrode in contact with air and moisture, Figure 13 presents the Pourbaix diagram of zinc and shows that when a moisture layer forms on zinc with a neutral pH (pH ≈ 6 to 7), corrosion occurs, and the main corrosion product is $Zn_5(CO_3)_2(OH)_6$ (hydrozincite). In rural environments, this corrosion layer is dense and adherent; therefore, the metal is relatively well protected. In highly polluted industrial atmospheres, the corrosion rate may increase substantially with time of exposure. Strongly acid or basic environments tend to dissolve the stable corrosion film, leading to significantly higher corrosion rates. In acidic atmospheres, no protective corrosion films form on zinc, leading to very rapid metal dissolution. Certain ionic species, such as chlorides, also promote the dissolution of zinc corrosion products and lead to higher corrosion rates.

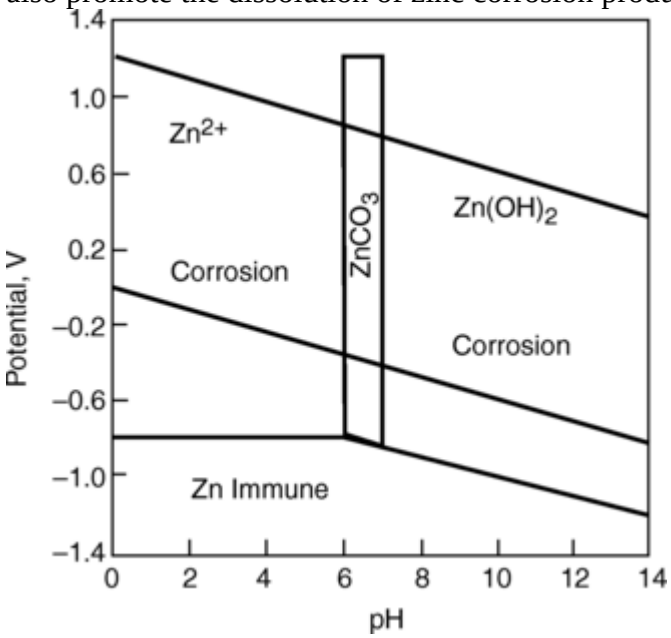

Fig. 13 Pourbaix diagram (potential versus pH) for zinc in water at 25 °C (77 °F)

When zinc is used as a coating on steel, the steel is a cathode, and the zinc coating is the anode. Corrosion protection in this situation is attributed to a combination of the corrosion resistance of zinc and the sacrificial protection that is afforded by zinc to the steel. This cathodic protection is also provided when zinc anodes are electrically connected to a steel structure and both are immersed in the same conductive electrolyte.

Note that Pourbaix diagrams do not give information about the kinetics or rate of the corrosion process. They indicate the thermodynamic conditions for the development of corrosion, the possibility for reaching other oxidation states, and the corrosion product composition. This information, in turn, indicates possible regimes for metal dissolution or protection. Moreover, these diagrams correspond to metals exposed in pure aqueous solutions that do not include other ions, such as SO_4^{2-}, Cl^-, NO_3^-, and CO_3^- contaminants. However, the effects of other species can be taken into account, using more complex Pourbaix diagrams (Ref 13) or through thermodynamic modeling software. For example, the presence of SO_4^{2-}, Cl^-, NO_3^-, and CO_3^- ions as atmospheric contaminants in the metal-moisture system can eliminate the immune copper state (Ref 13), as predicted using the Pourbaix diagram shown in Fig. 12. Therefore, when investigating the influence of service environments, it is necessary to analyze the atmosphere for all its parameters (T-RH complex and air chemistry) and to use the Pourbaix diagrams as a guide to the thermodynamics of the metal dissolution process.

Models for Prediction of Atmospheric Corrosion

Models predicting the corrosion damage of metals exposed to atmosphere have been a recent addition to understanding corrosion in atmospheric environments (Ref 12, 16, 18, 21, 23, 26, 32, 79, 80, 81, 82, 83, 84, 96). They are important and useful in predicting the durability of metallic structures and their degradation due to the corrosion process.

First-year atmospheric corrosion weight loss is a parameter that allows the classification of a given atmosphere into a corrosivity category. ISO 9223 uses the annual corrosion rate (weight loss per year) of four standard metals (low-carbon steel, copper, zinc, and aluminum) exposed according to ISO 9226. For this purpose, flat samples are exposed on racks, usually at 45° in Europe or 30° angle of inclination to the horizon for a period of 1 year. The formed corrosion products on the metal surface are removed from the coupons in accordance with ISO 8407, and the metal weight loss (g/m^2/year) or corrosion penetration (μm/year) is determined. Based on these results, corrosivity categories are assigned. Classification of the atmosphere is the basis for the design of good corrosion protection through material selection. Annual corrosion data are also used for prediction of longer-term service life of metal construction in given environments.

The corrosiveness of atmospheric sites can be determined according to ISO 9223, based on annual deposition rate (ISO 9226) of the principal pollutants, such as SO_2 and Cl^-. However, the evaluation of atmospheric corrosivity is more directly connected to metal performance when the aggressiveness category of a given atmosphere is assigned based on the annual corrosion rates of standard metal samples in combination with the annual deposition rate of the main contaminants.

The corrosion rate (C, in g/m^2) of a given metal after time (t, in years) depends directly on its first-year atmospheric corrosion rate (A, in g/ m^2 or μm) and its dependence with the time (n):

$$C = At^n \quad \text{(Eq 5)}$$

where A and exponent n are dependent on the type of metal and climatic parameters. Values of n typically range from 0.5 to 1, with most values being close to unity.

The bilogarithmic model of atmospheric corrosion gives a linear relationship between log C and log t:

$$\log C = A + n \log t \quad \text{(Eq 6)}$$

Parameter A depends on properties of the test site and suggests a correlation with climatic variables and air chemistry (TOW, T-RH complex, and pollution level). For this reason, it is often correlated to the pollutant level of SO_2 and Cl^- and to meteorological parameters, leading to a relationship such as the following:

$$A = a_1 + a_2\text{TOW} + a_3 C_{SO_2} + a_4 C_{Cl^-} \quad \text{(Eq 7)}$$

where a_1, a_2, a_3, and a_4 are coefficients, and C_{SO_2} and C_{Cl^-} are the deposition rates (mg/m^2/day) of these pollutants, measured according to ISO 9225.

A general model has been proposed that divides the total corrosion attack (K) into three dominating parts:

$$K = f_{dry}(SO_2) + f_{dry}(Cl) + f_{wet}(H^+) \quad \text{(Eq 8)}$$

where $f_{dry}(SO_2)$ is the effect of dry deposition of SO_2, $f_{dry}(Cl)$ is the effect of dry deposition of chlorides, and $f_{wet}(H^+)$ is the effect of wet deposition of H^+ (acid rain), which is not included in ISO 9223.

The terms of SO_2 and chlorides can be expressed as follows:

$$f_{dry}(SO_2) = A(SO_2)^B(TOW)^C \exp\{g(T)\} \quad \text{(Eq 9)}$$

$$f_{dry}(Cl) = D(Cl)^E(TOW)^F \exp\{kT)\} \quad \text{(Eq 10)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

where A, B, C, D, E, F, and *k* are constants; TOW is time of wetness; *T* is temperature, and *g*(*T*) is a temperature function.

Many dose/response relationships can be obtained, and the significance of factors can be judged. The results of these efforts are not yet suitable for general use at the international level. The main reason is that the physical-chemical background of the atmospheric corrosion is very complicated, and the interpretation of its kinetics is limited. One serious complication is the phenomenon of runoff on the corroded metal surface, which is difficult to involve in a general dose/response relationship because of its specific particularities of corrosion reactions and product-formation chemistry. For example, in marine-coastal areas or regions with a calcareous soil, dust of calcium compounds is deposited on the metal surface. Sulfur compound pollutants are absorbed in the surface, and a series of additional reactions begin, with gypsum (calcium sulfate) as the end product. Gypsum, which is more soluble than calcium carbonate, is then washed away by rain. An increase of volume and variations in temperatures can take place when calcium carbonate reacts to form gypsum.

Results from a number of atmospheric corrosion testing programs show that the bi-logarithmic model (Eq 6) for atmospheric corrosion is applicable to a number of commonly used metals (carbon steels, low-alloyed steels, galvanized steels, and aluminized steels) in many environments. Wide-ranging atmospheric corrosion tests of standard metals have been conducted to unify operational procedures and to acquire metal corrosion data for modeling and predicting atmospheric corrosion. Based on these efforts, corrosivity maps of atmospheres in a number of countries have been created. The bilogarithmic model is helpful in extrapolating short-term atmospheric corrosion data to longer time. When considering corrosion severity over the long term, changes in the environment may be more significant than deviations from the model.

Atmospheric Corrosion and Precipitation Runoff from Corroded Metals

Atmospheric corrosion of some metal structures, such as zinc and copper sheets commonly used for roofing and drain water systems, zinc anodes for cathodic protection, and zinc and zinc-aluminum coatings, involves the formation of protective oxide/hydroxide corrosion products that act as effective physical barriers between the metal and the aggressive atmosphere. However, due to interaction with the environment, the metal protective film could suffer modification into nonprotective corrosion products. Physical removal from the metal surface through dissolution of soluble corrosion products in precipitation runoff or by spalling could result (Ref 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96). Precipitation runoff is water from rain, dew, snow, or fog that drains from a surface and contains air- or waterborne deposited reactants and soluble ions from the metal surface. For that reason, traces of metals such as copper, zinc, lead, and iron are commonly detected in roof runoff water.

The use of copper as a roofing material has a long tradition, and zinc sheets have been used for over 200 years. During the last decade, a concern has been raised by legislators in Europe and the United States on the quantity of metal removed from a roof during precipitation and the potential effect that the released metal may have on the environment. Urban stormwater is recognized as a source of contaminants, including trace metals, and roof runoff is a contributor. It has been reported that galvanized roofs can contribute zinc concentrations of between 1 and 44 g/m^3, whereas tile roofs contribute between 0.01 and 2.6 g/m^3 of zinc in the runoff.

An extensive investigation in the last decade, with parallel field and laboratory exposures, was conducted to establish atmospheric corrosion and metal runoff processes, mainly on copper and zinc used for roofing applications. It has been proven that the runoff rate of zinc is considerably lower than its corrosion rate, varying between a quotient of 50 to 90% for zinc and 20 to 50% for copper during exposure of up to 5 and 2 years, respectively. Detailed studies have been performed to disclose the effect of various parameters on the runoff rate, including surface orientation and inclination, natural patinated copper, patina composition, rain duration and volume, rain pH, and length of dry periods in between rain events. Based on field exposures and literature data, a correlation has been established between runoff rate and the prevailing SO_2 environmental

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

concentration. The runoff rate of zinc and copper increases with increasing SO_2 level for exposure sites of similar annual precipitation quantities (500 to 1000 mm/year, or 20 to 40 in./year).

High metal concentrations have been found in the initial rain volume flushing the surface—the *first flush*, during which the most easily soluble and poorly adhesive corrosion products are washed off from the surface. The magnitude of first flush depends on the presence and amount of soluble corrosion products and also is associated with the capacity of the corrosion products to absorb and retain water. In turn, this is related with their adherence, morphology, thickness, porosity, and presence of internal micro- and macrocracks and defects. The precipitation volume is considered as the most important parameter affecting the runoff quantity of copper and zinc. Samples exposed in different environments exhibit large differences in the magnitude of the first flush. For copper and zinc panels preexposed in Swedish urban, rural, and marine environments, yearly runoff rates were 1.2, 0.7, and 1.7 g/m^2/year of copper and 2.6, 1.6, and 3.7 g/m^2/ year of zinc, assuming an annual precipitation of 500 mm/year (20 in./year).

The first-flush effect usually decreases to rather constant metal concentration during the subsequent rains. The metal concentration in runoff increases with rain acidity, decreases with rain intensity, and increases with length of the dry period preceding a rain event. Drizzle (<1 mm/h, or 0.04 in./h), with the longest surface contact period, results in an increased amount of released copper.

It is considered by researchers that the copper runoff is caused by proton- or ligand-induced water dissolution of the noncrystalline cupric sulfate as a part of copper corrosion products formed in environments polluted with SO_2, HCl, and NO_x. The runoff effect is more pronounced for aged copper (≥40 years old). No significant differences have been observed between episodes of light rain (≈8 mm/h, or 0.3 in./h) and moderate rain (≈20 mm/h, or 0.8 in./h).

In the case of copper patina formed in natural environments, a higher wetting capacity and absorption of rainwater have been found on green- patinated copper compared to brown-patinated, which explains a higher magnitude of copper being released during first flush. The total annual runoff rate of copper is significant for green-patinated samples, whereas it is negligible for brown-patinated samples.

Zinc commonly forms voluminous and highly porous atmospheric corrosion products. This may explain why no large differences in runoff rate have been seen between new and aged zinc samples in the reported field investigations. Rather, the reason may be related to a high susceptibility for proton-induced dissolution of zinc corrosion products by rain. During the dry period, neutral zinc salts with high solubility constants are frequently formed, such as $ZnSO_4$ or $Zn(NO_3)_2$. These are easily dissolved during the first-flush release; then, less soluble zinc salts are formed, including zinc hydrosulfates and zinc hydrocarbonates, which govern the dissolution rate during the steady-state runoff.

Lead ions may also be introduced into the environment by the flow of precipitation runoff from the surface of old lead structures, such as gutters, roofs, piping, siding, and sculptures. This metal is of particular concern to the public because of the adverse effect of even very small amounts on human health. The corrosion rate of lead depends on solubility and the physical characteristics of the corrosion products formed. Lead presents a high corrosion resistance in exposure to the atmosphere and to water, due to the formation of insoluble lead salts deposited on its surface. However, in natural and domestic waters, the corrosion rate depends on the degree of water hardness (calcium and magnesium salts content), the content of dissolved oxygen, and the CO_2 concentration. In the absence of passivating substances (such as carbonates), any oxidizing agent can cause lead to corrode. The presence of nitrate and chloride ions interferes with the formation of a protective layer or penetrates it, thus increasing the corrosion. Corrosion film studies indicate that lead in the runoff is primarily from solubility of lead carbonate (cerrusite) and lead hydroxyl carbonate (hydrocerrusite).

While atmospheric corrosion rates of metals usually exhibit a continuous decrease with time, the yearly runoff rates are fairly independent of time. The runoff process can be presented at any time t by the mass balance:

$$C(t) = T(t) + R(t) \qquad \text{(Eq 11)}$$

where $C(t)$ is the cumulative corrosion mass loss, $T(t)$ is the protective corrosion mass loss, and $R(t)$ is the cumulative nonprotective corrosion product (runoff effect).

In dry-season exposure of metals in polluted atmospheres (pH below 5), the environment reacts with the metal surface, forming neutral salts (soluble products), but there is little or no runoff. When the precipitation starts, these salts are dissolved in the presence of acid gases as pollutants of the atmosphere. In the absence of spalling or significant accumulation of nonprotective corrosion products, R in Eq 11 represents the cumulative loss of soluble corrosion products in precipitation runoff. The time derivative of Eq 11 shows that the corrosion rate is equal to the rate of protective film growth and the rate of corrosion film loss in precipitation runoff:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$dC/dt = dT/dt + dR/dt$ (Eq 12)

After long exposure, when the corrosion layer is developed and further corrosion film grows at a slower rate, dT/dt approaches 0, and the corrosion rate is equal to the rate of precipitation runoff loss. Recent results suggest that, following an inductive period when the corrosion film is establishing itself on the metal surface, the cumulative runoff from corroding metal surfaces (such as rolled zinc, thermal spray zinc, and zinc- aluminum and aluminum-zinc-indium alloys) is linear to time and precipitation volume and relatively insensitive to seasonal variations in precipitation chemistry, air chemistry, and meteorology.

Biologically Influenced Atmospheric Corrosion

Atmospheric corrosion can be accelerated in the presence of different types of bacteria and, specifically, anaerobic bacteria, which may convert a noncorrosive environment to a very aggressive one. Therefore, microbiologically induced corrosion (MIC) is given serious attention, because MIC failure in plant service systems can also have an ecological impact (Ref 97, 98, 99, 100, 101, 102, 103, 104, 105, 106). Microorganisms have been shown to play an important role in the corrosion of mild steel, austenitic alloys, and copper-base alloys, despite the fact that copper ions are toxic to most organisms. Failures in these materials are generally manifested by pitting, erosion-corrosion, and occasionally by stress-corrosion cracking.

The role of microbes or bacteria in the corrosion of metals is due to their chemical activities (metabolism) associated with microbial growth and reproduction. For example, the MIC of metals by sulfate-reducing bacteria (SRB) is a recognized problem in pipelines. This bacteria is anaerobic and also functions in poorly drained wet soil that has a pH from 6 to 8; contains sulfate ions, organic compounds, and minerals in the absence of oxygen; and has a temperature from 20 to 30 °C (70 to 85 °F). In well-aerated local sites, the anaerobic bacteria cause no problem. For metabolism of the bacteria, oxygen is extracted from the sulfate ions, and this reaction converts the soluble sulfates to sulfide (hydrogen sulfide), which is a pitting activator and attacks the metal surface, forming, for example, iron sulfide (FeS). It has also been suggested that hydrogen sulfide may be subsequently oxidized to thiosulfate, which is an even more aggressive pitting activator. The formed sulfides and other reduced-sulfur compounds can catalyze the anodic dissolution of stainless steels and lower their repassivation and pitting potential, which increases the metal susceptibility to pitting.

The corrosive microbial effect on metals can be attributed to the removal of electrons from the metal and the formation of corrosion products by:

- Direct chemical action of metabolic product, such as sulfuric acid, inorganic or organic sulfides, and chelating agents such as organic acid
- Changes in oxygen content, salt concentration, and pH, thus increasing the possibilities for differential diffusion, concentration gradients, and so on, which establish local electrochemical corrosion cells

One predominant mechanism for mild steel is the bacteria reduction of cathodic hydrogen, resulting in the depolarization of the cathode, which facilitates the cathodic corrosion reaction. The presence of hydrogenase in the SRB allows the use of hydrogen gas as an electron donor in place of carbohydrates as an energy source. In this case, the levels of assimilable carbon (usually organic) and energy sources (nitrogen, sulfate, and phosphate) in the water layer to support the growth and activity of SRB also need to be considered. This mechanism is valid where the cathodic reaction can involve the generation of hydrogen. The other mechanism is the bacterial production of sulfide, leading to the formation of FeS deposits. These deposits are hypothesized to act as large surface areas for the cathodic reaction and also as cathodic areas in a galvanic cell with the steel.

Rate and extent of corrosion are related directly to bacteria growth in contact with the metallic surface. Biofilm bacteria growing on a surface produce extracellular polymeric substances that promote sediment attachment, leading to the development of deposits and colonies of anaerobic bacteria, specifically SRB, which have been

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

implicated in most MIC failures. Bacteria have been found that are capable of growing on many kinds of coating materials (including hydrocarbons).

Monitoring is particularly important for early effective MIC control, because biofilms can form on metal surfaces very rapidly. Once a mature biofilm is established, the slime layer produced by the microorganisms, along with corrosion products, makes the biofilm extremely resistant to the effects of chemical treatments. The key symptom that usually indicates SRB involvement in the corrosion process of ferrous alloys is localized corrosion filled with black sulfide corrosion products. Tests for SRB include counts of total viable sulfate reducers. Other tests include measurement of the hydrogen uptake of a soil and the time for a soil sample to blacken a medium used to grow sulfate reducers. Chemical analysis of the water layer on the metal is helpful in determining the critical nutrients necessary to support microbiological activity. These tests should be conducted under the direction of a microbiologist who has experience in MIC. Field test kits are currently available that employ an antibody tagging technique to identify and facilitate the determination of the population of microbes.

Microbiologically influenced corrosion can be studied using field survey and different techniques, such as electrochemical polarization curves and polarization resistance, electrochemical impedance spectroscopy, thin-film electrical resistance probe, galvanic current measurement, scanning electron microscopy and energy-dispersive spectroscopy surface analysis, Mössbauer spectroscopy and x-ray diffraction for analysis of corrosion products, and so on. See the articles “Microbiologically Influenced Corrosion” and “Microbiologically Influenced Corrosion Testing” in this volume.

Trends in Atmospheric Corrosion Research and Methods

Atmospheric corrosion processes have been studied by exposure tests, accelerated corrosion testing, as well as electrochemical, surface analytical, and spectroscopic techniques (Ref 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155). These methods often give only integral information on corrosion processes (anodic and cathodic) occurring at the solid-liquid interface. The development of local electrochemical techniques, such as scanning vibrating electrode technique, localized electrochemical impedance spectroscopy, and scanning Kelvin probe, with different lateral resolutions and the increased use of various scanning probe microscopes (scanning tunneling microscope, atomic force microscope, electrochemical scanning tunneling microscope, electrochemical force atomic microscope, magnetic force microscope, scanning electrochemical microscope, and scanning near-field optical microscope) in corrosion science allow local processes (in situ) to be studied on an atomic scale.

Combining conventional electrochemical and surface analytical measurements with these local techniques permits the treatment of corrosion as a local phenomenon and contributes to a better understanding of the processes and the effects of the controlling factors. Currently, local atomistic events and effects of surface imperfections of different dimensionality on the interfacial processes can be directly analyzed. Since the development of in situ scanning probe microscopy techniques, the structures, thermodynamics, and kinetics of interfacial processes can be investigated directly in a real-time domain on an atomic scale at the solid-liquid interface. These technical achievements point out a new direction of corrosion research aimed toward elaborate new corrosion models based on the submicroscopic approach to the electrochemistry of corrosion metal processes. While these techniques are currently in the forefront of today's research, they will likely yield large future benefits in terms of better characterization of corrosion phenomena and prediction of corrosive degradation.

Galvanic Corrosion

Robert Baboian, RB Corrosion Service

Introduction

GALVANIC CORROSION occurs when a metal or alloy is electrically coupled to another metal or conducting nonmetal in the same electrolyte. The three essential components are:

- Materials possessing different surface potential
- A common electrolyte
- A common electrical path

When dissimilar metals or alloys in a common electrolyte are electrically isolated from each other, they do not experience galvanic corrosion, regardless of the proximity of the metals or their relative potential or size. When dissimilar metals are electrically coupled (i.e., galvanic coupling), corrosion of the less corrosion resistant metal increases, and the surface becomes anodic, while corrosion of the more corrosion resistant metal decreases, and the surface becomes cathodic. The driving force for corrosion or galvanic current flow is the potential developed between the dissimilar metals. The extent of corrosion resulting from galvanic coupling is affected by the following factors:

- The potential difference between the metals or alloys
- The nature of the environment
- The polarization behavior of the metals or alloys
- The geometric relationship of the component metals or alloys

The difference in potential between dissimilar metals or alloys causes electron flow between them when they are electrically coupled in a conductive solution. The direction of electron flow, and therefore the galvanic

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

behavior, depends on which metal or alloy is more active. The more active metal or alloy becomes anodic, and the more noble metal or alloy becomes cathodic in the couple.

Galvanic Corrosion

Robert Baboian, RB Corrosion Service

Galvanic Series

A galvanic series of metals and alloys is useful for predicting galvanic relationships. Such a series is an arrangement of metals and alloys according to their potentials as measured in a specific electrolyte. The galvanic series allows one to determine which metal or alloy in a galvanic couple is more active and which is more noble. In some cases, the separation between the two metals or alloys in the galvanic series gives an indication of the probable magnitude of corrosive effect.

The potential of a metal or alloy is affected by environmental factors. Corrosion product films and other changes in surface composition can occur in some environments; therefore, no one value can be given for a particular metal or alloy. This requires a galvanic series to be measured in each environment of interest. Most commonly, the galvanic series has been constructed from measurements in seawater, as shown in Table 1. With certain exceptions, this series is broadly applicable to other natural waters and in uncontaminated atmospheres.

Because most engineering materials are alloys, the measurement of galvanic corrosion employing actual materials is much more useful than predicting current flow from the electromotive force series. Therefore, tabulations such as Table 1 can be very useful.

Galvanic Corrosion

Robert Baboian, RB Corrosion Service

Polarization

As stated previously, electron flow occurs between metals or alloys in a galvanic couple. This current flow between the more active and more noble members causes shifts in potential due to polarization, because the potentials of the metals or alloys tend to approach each other.

The magnitude of the shift depends on the environment, as does the initial potential. If the more noble metal or alloy is more easily polarized, its potential is shifted more toward the more active metal or alloy potential. The shift in potential of the more active metal or alloy in the direction of the cathode is therefore minimized so that accelerated galvanic corrosion is not as great as would otherwise be expected. On the other hand, when the more noble metal or alloy is not readily polarized, the potential of the more active metal shifts further toward

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

the cathode (that is, in the direction of anodic polarization) such that appreciable accelerated galvanic corrosion occurs.

R. Baboian, Galvanic Corrosion, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 210–213

Robert Baboian, RB Corrosion Service

Area, Distance, and Geometric Effects

Factors such as area ratios, distance between electrically connected materials, and geometric shapes also affect galvanic-corrosion behavior.

Area effects in galvanic corrosion involve the ratio of the surface area of the more noble to the more active members(s). The area ratio is unfavorable when the surface area of the more noble metal or alloy is large in comparison to the more active member and the galvanic couple is under cathodic control. Under these conditions, the anodic current density on the more active metal or alloy becomes extremely large. The resulting polarization leads to increased corrosion of the active metal. The opposite area ratio—large active member surface, smaller noble member surface—(with the couple under cathodic control) produces only slightly accelerated galvanic effects because of the predominant polarization of the more noble material.

Effect of Distance. Dissimilar metals in a galvanic couple that are in close physical proximity usually suffer greater galvanic effects than those that are further apart. The distance effect is dependent on solution conductivity because the path of current flow is the primary consideration. Thus, if dissimilar pipes are butt welded with the electrolyte flowing through them, the most severe corrosion will occur adjacent to the weld on the anodic member.

Effect of Geometry. The geometry of the circuit also affects galvanic corrosion in that current does not readily flow around corners. This is simply an extension of the principle described previously, in which the current takes the path of least resistance.

R. Baboian, Galvanic Corrosion, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 210–213

Galvanic Corrosion

Robert Baboian, RB Corrosion Service

Modes of Attack

Corrosion of the anodic member(s) of a galvanic couple may take the form of general or localized corrosion, depending on the configuration of the couple, the nature of the corrosion film produced, and the nature of the metals or alloys involved. Generally, there are five major categories.

Dissimilar Metals. The combination of dissimilar metals in engineering design by mechanical or other means is quite common—for example, in heating or cooling coils, vessels, heat exchangers, and machinery. Such combinations often lead to galvanic corrosion.

Nonmetallic Conductors. Less frequently recognized is the influence of nonmetallic conductors as cathodes in galvanic couples. Carbon brick in vessels is strongly cathodic to the common structural metals and alloys.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Impervious graphite, especially in heat-exchanger applications, is cathodic to the less noble metals and alloys. Carbon-filled polymers can act as noble metals in a galvanic couple.

Another example is the behavior of conductive corrosion films, such as mill scale (magnetite, or Fe_3O_4) or iron sulfides on steel, or of lead sulfate on lead. Such films can be cathodic to the base metal exposed at breaks or pores in the scale (Fig. 1) or even to such extraneous items as valves or pumps in a piping system.

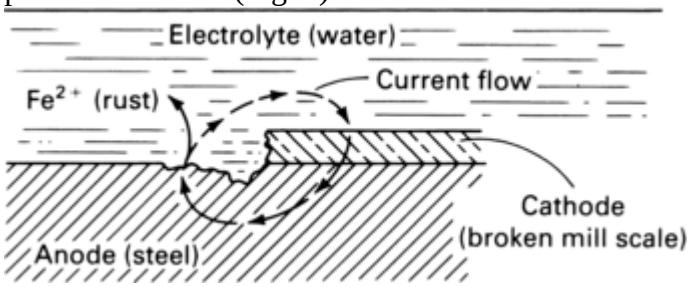

Fig. 1 Schematic showing how breaks in mill scale (Fe_3O_4) can lead to galvanic corrosion of steel

Metallic Coatings. Two types of metallic coatings are used in engineering design: noble metal coatings and sacrificial metal coatings. Noble metal coatings are used as barrier coatings over a more reactive metal. Galvanic corrosion of the substrate can occur at pores, damage sites, and edges in the noble metal coating. Sacrificial metal coatings provide cathodic protection of the more noble base metal, as in the case of galvanized steel or Alclad aluminum.

Cathodic Protection. Magnesium, zinc, and aluminum galvanic (sacrificial) anodes are used in a wide range of cathodic protection applications. The galvanic couple of the more active metal and a more noble structure (usually steel, but sometimes aluminum, as in underground piping) provides galvanic (sacrificial) cathodic protection, while accelerated corrosion of the sacrificial metal anode occurs.

Metal Ion Deposition. Ions of a more noble metal may be reduced on the surface of a more active metal—for example, copper on aluminum or steel, and silver on copper. This process is also known as cementation, especially with regard to aluminum alloys. The resulting metallic deposit provides cathodic sites promoting further galvanic corrosion of the more active metal.

R. Baboian, Galvanic Corrosion, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 210–213

Galvanic Corrosion

Robert Baboian, RB Corrosion Service

Predicting Galvanic Corrosion

The most common method of predicting galvanic corrosion is by immersion testing of the galvanic couple in the environment of interest. Although time-consuming, this is the most desirable method of investigating galvanic corrosion. Screening tests are conducted initially to eliminate as many candidate materials as possible. These screening tests consist of one or more of the following three electrochemical techniques: potential measurements, current measurements, and polarization measurements.

Potential measurements are made to construct a galvanic series of metals and alloys, as described previously. As a first approximation, the galvanic series is a useful tool. However, it has serious shortcomings. Metals and alloys that form passive films will exhibit varying potentials with time and are therefore difficult to position in the series with certainty. Also, the galvanic series does not provide information on the polarization characteristics of the materials and so is not helpful in predicting the probable magnitude of galvanic effects.

Measurement of galvanic currents between coupled metals or alloys is based on the use of a zero-resistance milliammeter (ZRA). Zero-resistance electrical continuity between the members of the galvanic couple is maintained electronically, while the resulting current is measured with the ammeter. Use of this technique

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

should take into account certain limitations. First, when localized corrosion such as pitting or crevice corrosion is possible in the galvanic couple, long induction periods may be required before these effects are observed. Test periods must be of sufficient duration to take this effect into account. Also, the measured galvanic current is not always a true measure of the actual corrosion current, because the galvanic current is the algebraic sum of the currents due to anodic and cathodic reactions. When cathodic currents are appreciable at the mixed potential of the galvanic couple, the measured galvanic current is significantly lower than the true corrosion current. Large differences between the true corrosion rate calculated by mass loss and that obtained by galvanic current measurements have been observed.

Polarization measurements on the members of a galvanic couple can provide precise information concerning their behavior. The polarization curves and the mixed potential for the galvanically coupled metals in a particular environment can be used to determine the magnitude of the galvanic-corrosion effects as well as the type of corrosion.

An important application in the use of polarization measurements in galvanic corrosion is the prediction of localized corrosion. Polarization techniques and critical potentials are used to measure the susceptibility to pitting and crevice corrosion of metals and alloys coupled in chloride solutions. In addition, this technique is valuable in predicting galvanic corrosion among three or more coupled metals or alloys.

R. Baboian, Galvanic Corrosion, *Corrosion: Fundamentals, Testing, and Protection,* Vol 13A, *ASM Handbook,* ASM International, 2003, p 210–213

Galvanic Corrosion

Robert Baboian, RB Corrosion Service

Performance of Alloy Groupings

Light Metals. Magnesium occupies an extremely active position in most galvanic series and is therefore highly susceptible to galvanic corrosion. It is widely used as a sacrificial anode in cathodic protection.

Aluminum and its alloys also occupy active positions in the galvanic series and are subject to failure by galvanic attack (Fig. 2, 3). In chloride-bearing solutions, aluminum alloys are susceptible to galvanically induced localized corrosion, especially in dissimilar-metal crevices. In this type of environment, severe galvanic effects are observed when aluminum alloys are coupled with more noble metals and alloys. Cementation effects are also observed in the presence of dissolved heavy-metal ions such as copper, mercury, or lead. Some aluminum alloys are used for sacrificial anodes in seawater. An active, anodic alloy is used to clad aluminum, protecting it against pitting in some applications.

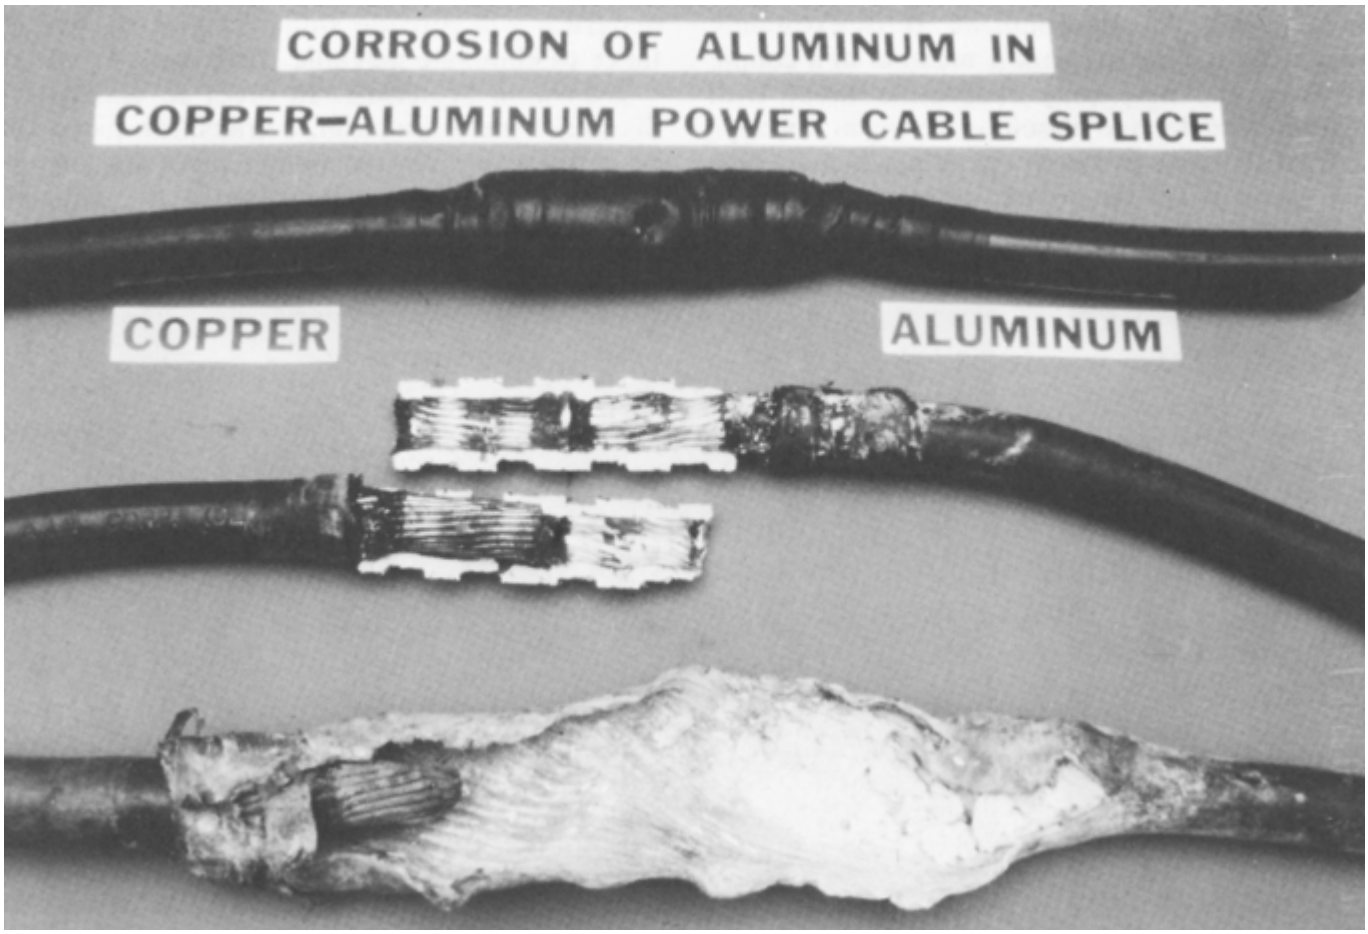

Fig. 3 Galvanic corrosion of aluminum in buried power cable splice (copper to aluminum). Courtesy of R. Baboian, Texas Instruments, Inc.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In the absence of chlorides or when chloride concentrations are low (as in potable water), aluminum and its alloys may be less active because of greater stability of the protective oxide film. Galvanic effects are not as severe under these conditions.

Iron and steel are fairly active materials and require protection against galvanic corrosion by less active, more noble, alloys. They are, however, more noble than aluminum and its alloys in chloride solutions. However, a reversal of potential can occur in low-chloride waters, which causes iron or steel to become more active than aluminum. A similar reversal can occur between iron and zinc in hot waters of a specific type of chemistry. Examples of galvanic corrosion of iron and steel are shown in Fig. 4 and 5.

Fig. 4 Galvanic corrosion of painted steel auto body panel in contact with stainless steel wheel opening molding. Courtesy of R. Baboian, Texas Instruments, Inc.

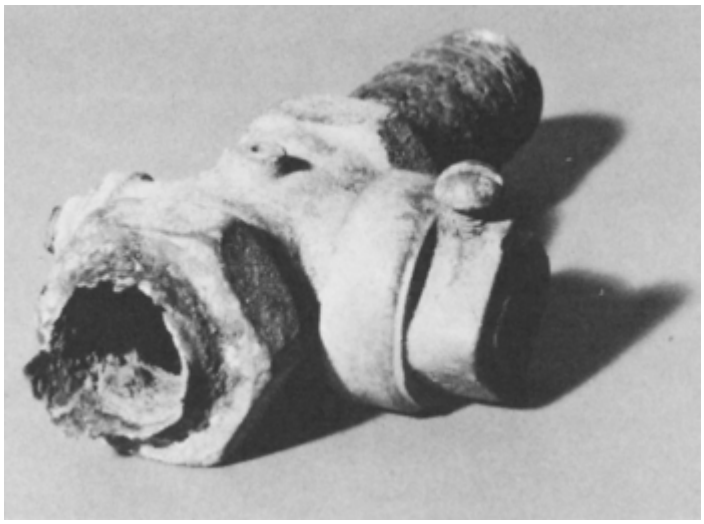

Fig. 5 Galvanic corrosion of steel pipe at brass fitting in humid marine atmosphere. Courtesy of R. Baboian, Texas Instruments, Inc.

Stainless Steels. Galvanic corrosion behavior of stainless steels is difficult to predict because of the influence of passivity. In the common galvanic series, a noble position is assumed by stainless steels in the passive state, while a more active position is assumed in the active state (Table 1). This dual position in galvanic series in chloride-bearing aqueous environments has been the cause of some serious design errors. More precise information on the galvanic behavior of stainless steels can be obtained by using polarization curves, critical potentials, and the mixed potential of the galvanic couple. In chloride-containing environments, galvanically induced localized corrosion of many stainless steels occurs in couples with copper or nickel and their alloys and with other more noble materials. However, couples of stainless and copper alloys are often used with impunity in freshwater cooling systems. Iron and steel tend to protect stainless steel in aqueous environments when galvanically coupled. The passive behavior of stainless steels makes them easy to polarize; thus, galvanic

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

effects on other metals or alloys tend to be minimized. However, galvanic corrosion of steel can be induced by stainless steels, particularly in aqueous environments and with adverse area ratios.

Lead, Tin, and Zinc. These three materials occupy similar positions in the galvanic series, although zinc is the most active. The oxide films formed on these materials can shift their potentials to more noble values. Thus, in some environments, they may occupy more noble positions than one might otherwise expect. For example, the tin coating in tin cans is anodic to steel under anaerobic conditions in the sealed container but becomes cathodic when the can is opened and exposed to air. Zinc is an active metal. It is susceptible to galvanic corrosion and is widely used for galvanic anodes in cathodic protection as a sacrificial coating (for example, galvanizing or electroplating) and as a metallic pigment in certain paints and coatings.

Copper Alloys. Copper and its alloys occupy an intermediate position in the galvanic series. They are not readily polarized in chloride-bearing aqueous solutions; therefore, they cause severe accelerated corrosion of more active metals, such as aluminum and its alloys and the ferrous metals. Somewhat similar to the nickel alloys, they lie between the active and passive positions for stainless steels (Table 1) and therefore induce localized corrosion of the active alloys.

Nickel Alloys. Nickel and its alloys are not readily polarized and therefore cause accelerated corrosion of more active materials, such as aluminum and ferrous alloys. In chloride-containing solutions, nickel is somewhat more noble than copper, and the cupronickels lie somewhere in between. Nickel and its alloys are similar to copper alloys in their effects on stainless steels. In some environments, the cast structure of a nickel weld may be anodic to the wrought parent metals.

The combination of a passive surface with the inherent corrosion resistance of nickel-chromium alloys, such as Inconel alloy 600 and Hastelloy alloy C-276, places them in more noble positions in the traditional galvanic series. In chloride-bearing solutions, Inconel alloy 600 is reported to occupy two positions because of the existence of active and passive states in a manner similar to stainless steels (Table 1). These alloys are readily polarized, and galvanic effects on other less noble metals and alloys therefore tend to be minimized.

Cobalt-base alloys, most of which are chromium bearing, are resistant to galvanic corrosion because of their noble position in the galvanic series. However, in environments in which their passive film is not stable, they occupy a more active position and can be adversely affected by more noble materials. The fact they they polarize readily tends to reduce their galvanic effects on less noble materials.

Reactive Metals. Titanium, zirconium, and tantalum are extremely noble because of their passive films. In general, these alloys are not susceptible to galvanic corrosion, and their ease of polarization tends to minimize adverse galvanic effects on other metals or alloys. Because of the ease with which they pick up hydrogen in the atomic state, they may themselves become embrittled in galvanic couples. Tantalum repair patches in glass-lined vessels have been destroyed by contact with cooling coils or agitators made of less noble alloys. Tantalum is susceptible to attack by alkalies, such as may form in the vicinity of a cathode in neutral solutions.

Noble Metals. The term *noble metal* is applied to silver-, gold-, and platinum-group metals. This designation in itself describes their position in the galvanic series and their corresponding resistance to galvanic corrosion. However, they do not polarize readily and can therefore have a marked effect in galvanic couples with other metals or alloys. This effect is observed with gold and silver coatings on copper, nickel, aluminum, and their alloys.

Methods of Control

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Materials Selection. Combinations of metals or alloys widely separated in the relevant galvanic series should be avoided unless the more noble material is easily polarized. Metallic coatings can be used to reduce the separation in the galvanic series, as described subsequently.

Environmental Control. In particular cases, it is possible to reduce or eliminate galvanic-corrosion effects between widely dissimilar metals or alloys in a particular environment. The use of corrosion inhibitors is effective in some cases. Elimination of cathodic depolarizers such as oxygen (deaeration of water by thermomechanical means plus oxygen scavengers such as sodium sulfite or hydrazine) is every effective in some aqueous systems.

Barrier coatings of a metallic nature have already been discussed. Inert barrier coatings, organic or vitreous, can effectively isolate the metals from the environment. It is extremely dangerous to coat the anodic member of a couple, because this only reduces its area to the holiday in the coating, with severely accelerated localized attack occurring at the holidays in the otherwise protective coating. If inert barrier coatings are employed, both the anode and cathode must be protected—for example, the heads, tubesheets, and tubes (for a distance of the first 4 to 6 tube diameters on the tube side) of a water- cooled heat exchanger.

Electrochemical techniques are comprised of three alternative methodologies: electrical isolation, use of transition materials, and cathodic protection.

Electrical Isolation. The joint between dissimilar metals can be isolated to break the electrical continuity. Use of nonmetallic inserts, washers, fittings, and coatings at the joint between the materials will provide sufficient electrical resistance to eliminate galvanic corrosion.

Transition Materials. In order to eliminate a dissimilar-metal junction, a transition piece can be introduced. The transition piece consists of the same metals or alloys as in the galvanic couple bonded together in a laminar structure. The transition piece is inserted between the members of the couple such that the similar metals mate with one another. The dissimilar-metal junction then occurs at the bond interface, excluding the electrolyte.

Cathodic Protection. Sacrificial metals, such as magnesium or zinc, may be introduced into the galvanic assembly. The most active member will corrode while providing cathodic protection to the other members in the galvanic assembly (for example, zinc anodes in cast iron waterboxes of copper alloy water-cooled heat exchangers). Impressed-current systems can provide the same effect.

Design. Unfavorable area ratios should be avoided. Metal combinations should be used in which the more active metal or alloy surface is relatively large. Rivets, bolts, and other fasteners should be of a more noble metal than the material to be fastened. Dissimilar-metal crevices, such as at threaded connections, are to be avoided. Crevices should be sealed, preferably by welding or brazing, although putties are sometimes used effectively. Replaceable sections of the more active member should be used at joints, or the corrosion allowance of this section should be increased, or both.

Stray-Current Corrosion

Revised by Harry R. Hanson, Bay Engineering, Inc.

Introduction

STRAY-CURRENT CORROSION is caused by an externally induced electrical current. Examples of this situation are commonly observed in rail transit systems, pipeline systems, and electric distribution systems (Ref 1, 2, 3). Detailed technical presentations of stray current corrosion can be found in the literature (Ref 4, 5, 6).

Stray currents (or interference currents) are defined as those currents that follow paths other than their intended circuit. Unfortunately, nearly all stray current discharges are very local and concentrated, ensuring accelerated corrosion will occur. They leave their intended path because the current finds a path with lower resistance, such as a buried metal pipe, some other metal structure, or an electrolyte with low resistance such as salt water. The current then flows to and from that structure and causes accelerated corrosion whenever it leaves a metallic structure and flows into an electrolyte.

For example, in a pipeline that is cathodically protected, if a foreign pipeline crosses or passes close to the protected pipeline, current from the cathodic protection system can gather onto the foreign pipeline and then be discharged from the foreign line when it crosses *or comes close to* the protected pipeline. This is particularly true in higher resistivity soil. Accelerated corrosion occurs on the foreign line at the point of current discharge. The location of the discharge can be detected because the pipe-to-soil potential is very low at that point.

Likewise in an oil or gas field, where the flowline system or the well casings from several wells are being protected using a centrally located rectifier and ground bed, the path of lowest resistance is usually to the nearest well, down the well casing until a low-resistant formation containing salt water is encountered. The current then travels through the salt-water formation to the other more remote wells in the field where it travels up the well casing to the flowline and then returns to the rectifier. Accelerated corrosion occurs on the well casings of the close wells where current is discharged from the casing to the formation. This corrosion is

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

extremely difficult to detect and is very expensive to correct. It can cause a blowout in the well to occur because of the corroded casing and can result in a fire or spill.
Insulating flanges can cause corrosion from stray currents. Usually the insulating flange is separating pipes that have different ownership or different levels of cathodic protection. If current collects on the pipeline downstream of the protected pipeline, this current may flow back to the insulated flange, discharge into the earth on one side of the flange, and flow to the other side of the flange that is connected to the protected pipeline. Corrosion occurs where the current discharges from the unprotected, downstream pipeline.

Stray-Current Corrosion

Revised by Harry R. Hanson, Bay Engineering, Inc.

Sources of Stray Currents

Almost any electrical systems that use grounds or grounding in their system can create stray direct current (dc) problems. In the past, electric railways were a major source of stray dc. This source became less common with the diminished use of electric rail systems, but modern urban/suburban transit systems still rely on electric light-rail systems. Stray-current control is a factor in the rehabilitation of electrified railways for urban/suburban transit systems (Ref 7) and in the development of improved materials and design techniques for stray-current control of electrified rail systems. Improvements include special insulation methods for rail systems (Ref 8) and the use of special materials and design techniques for the embedment of track in the congested downtown portion of the system to achieve levels of track-to-earth isolation (Ref 9).
In one case, extensive testing was performed on existing water piping in the vicinity of a light- rail transit system to assess the conditions on existing utility piping (Ref 10). Stray-current corrosion can readily be detected by taking pipe- to-soil potentials. Stray-current corrosion can usually be determined by studying the location and size of all the facilities in a system and their proximity to foreign structures.
Other important sources of stray current include cathodic protection systems, electrical welding machines, and other grounded dc electric sources. Stray currents are frequently encountered problems in cathodic-protection

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

systems. Figure 1(a) shows an arrangement in which stray currents were produced when the owner of a buried tank installed cathodic protection, not knowing of the presence of a nearby pipeline. The pipeline rapidly failed by corrosion because of the stray currents. If the pipeline had been cathodically protected, stray-current attack could have caused the buried tank to fail. The stray-current problem shown in Fig. 1(a) was corrected by electrically connecting the tank and the pipeline by an insulated buss connection and by installing a second anode (Fig. 1b). Thus, both pipe and tank were protected without stray- current effects.

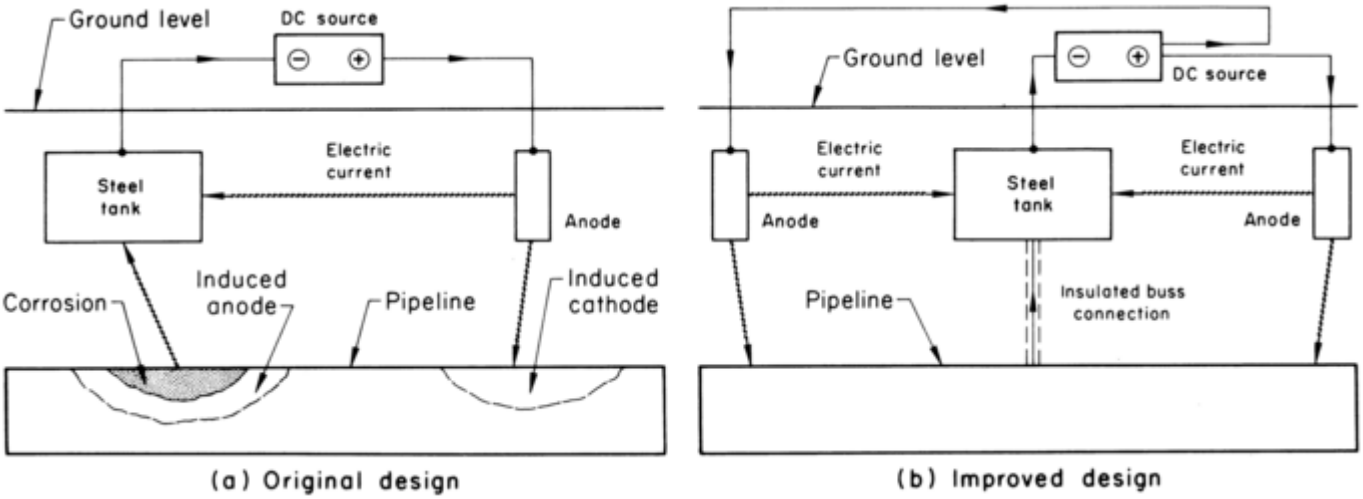

Fig. 1 Cathodic-protection system for a buried steel tank. (a) The original design that caused local failure of a nearby unprotected buried pipeline by stray-current corrosion. (b) Improved design. Installation of a second anode and an insulated buss connection provided protection for both tank and pipeline, preventing stray currents.

In another example, an on-board electric welding machine can create stray currents in a ship and can cause accelerated attack of the hull of the ship as the stray currents generated at the welding electrodes pass out of the hull through the water back to a grounded dc line located on shore. Work boats or construction barges that do welding of structures or pipelines in the water are always careful to ensure that grounds to the vessel make the vessel more negative and are essentially furnishing cathodic protection to the work vessel. If the grounds are not carried to the structure being constructed, it will cause severe stray-current damage to the structure. Another example is a steel-hulled vessel that is moored to a dock facility that is cathodically protected. The cathodic protection system on the dock can cause stray current damage to the vessel.

Stray currents cause accelerated corrosion to occur where they leave the metal structure and enter the surrounding electrolyte. The site where the current enters the structure will become cathodic in nature, while the site where the current leaves the metal will become anodic. These sites may be hundreds of yards apart. Stray current flowing along a pipeline typically will not cause damage inside the pipe, because of the high conductivity of the metal compared to the fluid in the pipe. However, internal corrosion can occur if an insulating flange is placed in the pipeline and the fluid stream (such as salt water) is highly conductive. In this case, the damage occurs at the point where the current enters the electrolyte from within the pipe. If the pipe is carrying a low resistivity fluid and is also buried, corrosion can occur on both the internal and external surface of the pipeline.

Stray currents are usually thought of as being dc currents. However, severe damage can be also caused by alternating currents (ac). Alternating currents are induced onto pipelines that run parallel and close to power lines. Alternating-current corrosion is less severe as the frequency increases. Stray-ac corrosion is also less severe if the pipeline is laid in clay soils containing high ion contents but can be severe if the pipeline is laid in high-resistivity sandy soils. Alternating currents induced in active-passive metals, such as stainless steel, can destroy the passivity of the metal, causing it to lose its corrosion resistance. Alternating reduction and oxidation of the surface layers resulting from the induced ac causes the passive layers to become porous and layered. Unlike dc stray-current corrosion, induced-ac corrosion cannot be mitigated by adjusting the pipe to soil potential of the pipe. It is controlled by removing the ac from the pipeline and flowing the current to earth via ground beds or zinc anodes.

Stray-Current Corrosion

Revised by Harry R. Hanson, Bay Engineering, Inc.

Prevention of Stray-Current Corrosion

There are several ways to prevent damage from stray currents. Foremost, the flow or leakage of current from the metal to an electrolyte (the ground) should be stopped. This is done by a method called bonding, which removes the stray current via a separate conductor. Bonding consists of connecting the stray-current conductor to the protected conductor with a wire, thus eliminating the need for the current to leave the metal and enter the soil. If both lines have cathodic protection systems, the bonding of the two lines can be achieved via an adjustable resistor. The amount of current can then be adjusted so that the pipe-to-soil potentials of each line are similar. Often the resistance of the bonding wire is adjusted so that the potential of either line is not changed when the rectifiers are cycled on and off.

Sacrificial anodes can also be used to prevent stray current corrosion. By connecting galvanic anodes to the unprotected pipeline that is being damaged by stray currents, the potential of the unprotected line can be changed and made equal to the protected line at the point of crossing. If the two lines have the same potential, there is no reason for the currents to leave one line for the other, and stray currents are eliminated. Pipe coatings used without cathodic protection are not an effective way to control stray current problems. Coating on lines that also are cathodically protected are beneficial and usually make the problems of stray currents less severe and more easily controlled.

Molten Salt Corrosion

Revised by Russell D. Kane, InterCorr International, Inc.

Introduction

THE CORROSION of metal containers by molten, or fused, salts has been observed for an extended period of time, but over the last several decades, more effort has been directed toward understanding corrosion phenomena at higher temperatures. Annotated bibliographies of molten salt corrosion for different media and metal combinations have been published and are cited in the Selected References for this article. Additional information on molten salt corrosion can be found in the articles “Molten Salt Corrosion Thermodynamics” and “Corrosion by Molten Salts” in this Volume.

R.D. Kane, Molten Salt Corrosion, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 216–219

Molten Salt Corrosion

Revised by Russell D. Kane, InterCorr International, Inc.

Mechanisms of Molten Salt Corrosion

Two general mechanisms of corrosion can exist in molten salts. One is the metal dissolution caused by the solubility of the metal in the melt. This dissolution is similar to that in molten metals but is not common. The second and most common mechanism is the oxidation of the metal to ions, a mechanism similar to aqueous

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

corrosion. For this reason, molten salt corrosion has been identified as an intermediate form of corrosion between molten metal and aqueous corrosion.

General, or uniform, metal oxidation and dissolution is a common form of molten salt corrosion but is not the only form of corrosion seen. Selective leaching is very common at higher temperatures, as are pitting and crevice corrosion at lower temperatures. All the forms of corrosion observed in aqueous systems, including stress-assisted corrosion, galvanic corrosion, erosion-corrosion, and fretting corrosion, have been seen in fused salts.

Electrochemically, the molten salt/metal surface interface is very similar to the aqueous solution/metal surface interface. Many of the principles that apply to aqueous corrosion, such as anodic reactions leading to metal dissolution and cathodic reduction of an oxidant, also apply to molten salt corrosion. Based on this concept, recent studies have been successful in using electrochemical test methods commonly used in aqueous solutions (e.g., electrochemical noise, linear polarization, and harmonic distortion analysis) to make measurements of corrosion and localization in laboratory studies. This work has even been carried on to use in commercial plant operations to help relate changes in process variables to periodic conditions of accelerated corrosion (Ref 1).

The concept of acid and base behavior of the melt is very similar to that of its aqueous counterpart. The corrosion process is mainly electrochemical in nature because of the excellent ionic conductivity of most molten salts. Some investigators feel that dissolved water enhances the electrochemical corrosion nature of the molten salts.

Even though the corrosion mechanism is similar, there are major differences between molten salt and aqueous corrosion. The differences arise mainly from the fact that molten salts are partially electronic conductors as well as ionic conductors. This fact allows for reduction reactions to take place in the melt as well as at the metal-melt interface. This behavior also allows increase in frequency of cathodic reactions and can therefore lead to a substantial increase in corrosion rate over a similar electrochemically controlled aqueous system, especially if the corrosion media contain very few oxidants. Because of property differences between water and molten salt, the rate-controlling step in most molten metal systems is ion diffusion into the bulk solution, not the charge transfer reaction that is typical of aqueous systems. Molten salt systems operate at higher temperatures than aqueous systems, which leads to different forms of corrosion attack. Electrochemical measurements have highlighted these differences between aqueous and molten salt environments, particularly in terms of characterizing their polarization through the classical Stern-Geary relationship. Values obtained in a molten salt system tend to be much different than those observed in an aqueous system, brought about by the simultaneous presence of many ionic species and the combined ionic and electronic conduction mechanisms in molten salts. However, use of these techniques has resulted in meaningful measurement of corrosion rates that correlate with actual mass losses in system components in combustion environments (Fig. 1, 2).

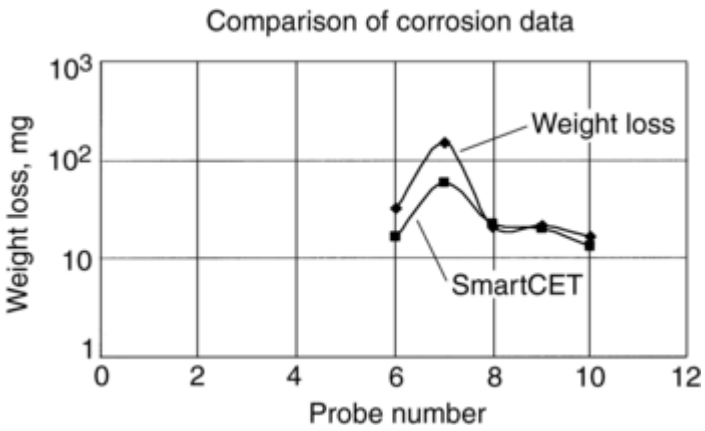

Fig. 2 Comparison of weight-loss data from electrochemical measurements in molten slag. Weight loss is from test coupons. SmartCET is a real-time corrosion-monitoring system (InterCorr International, Inc.). Field measurements were made on the fireside of a coal fueled boiler. Source: Ref 1

In aqueous systems in which specific elements are removed from alloys, such as the dezincification of zinc from brass, it is not clear whether the nobler element is oxidized at some stage in the process and is subsequently plated out or whether the element agglomerates by a surface diffusion mechanism. In both cases, bulk diffusion is unlikely to play a major role. In high-temperature molten salt systems, dissolution of the less noble element is the most probable mechanism and even occurs when the element is present at low concentration. Unlike aqueous systems, the rate of dissolution is therefore related to the bulk diffusion of the selectively leached element.

Because molten salt corrosion reactions are reduction/oxidation controlled, the relative nobilities of the salt melts and the metals are important. The corrosion potential of the melt is often controlled by impurities in the melt or gas phase, which increases the cathodic reaction rate or changes the acidic or basic nature of the melt. The aggressiveness of the salt melts is typically governed by its redox equilibria.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Thermal gradients in the melt can cause dissolution of metal at hot spots and metal deposition at cooler spots. The result is very similar to aqueous galvanic corrosion, and, like aqueous galvanic corrosion, a continuous electrical path is necessary between the hot and cold areas. Crevice corrosion has been observed, and wash-line attack caused by oxygen concentration corrosion is not uncommon at the metal/ molten salt/air interface.

High-temperature corrosion in molten salts often exhibits selective attack and internal oxidation. Chromium depletion in Fe-Cr-Ni alloy systems can occur by the formation of a chromium compound at the surface and by the subsequent removal of chromium from the matrix, leaving a depleted zone. Thus, the selectively removed species move out, while vacancies move inward and eventually form voids. The voids tend to form at grain boundaries in most chromium-containing metals, but in some high- nickel alloys, the voids form in the grains. Specific examples of the types of corrosion expected for the different metal-fused salt systems follow.

Molten Salt Corrosion

Revised by Russell D. Kane, InterCorr International, Inc.

Types of Molten Salts

Molten Fluorides. Fluoride melts are important because of their consideration for nuclear reactor cooling systems. Corrosion in many fluoride molten salt melts is accelerated because protective surface films are not formed. In fact, the fluoride salts act as excellent fluxes and dissolve the various corrosion products.

Typically, nickel-base alloys show better corrosion resistance than iron-base alloys. Studies have also shown that most nickel- and iron-base alloys that contain varying amounts of chromium show void formation to varying depths. In nonisothermal flow systems, the metallic material shows void formation in the hot section and deposits in the cold section. In most alloys that contain chromium, depletion of the chromium accompanies the void formation. Analysis of the attacked metal and salt clearly shows that selective removal and outward diffusion of chromium result from oxidation by the fluoride mixture.

Inconel alloy 600 and certain stainless steels become magnetic after exposure to molten fluoride salt. This magnetism is caused by the selective removal of the chromium and the formation of a magnetic iron-nickel alloy covering the surface. The conditions of the melt need to be controlled to minimize the selective removal of the alloying elements. This control can be done by maintaining the melt in a reducing condition. Addition of beryllium metal to the melt is one way to slow the corrosion rate. Examples of microstructures of nickel-base and stainless steels as a result of exposure to molten salts are shown in Fig. 3.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

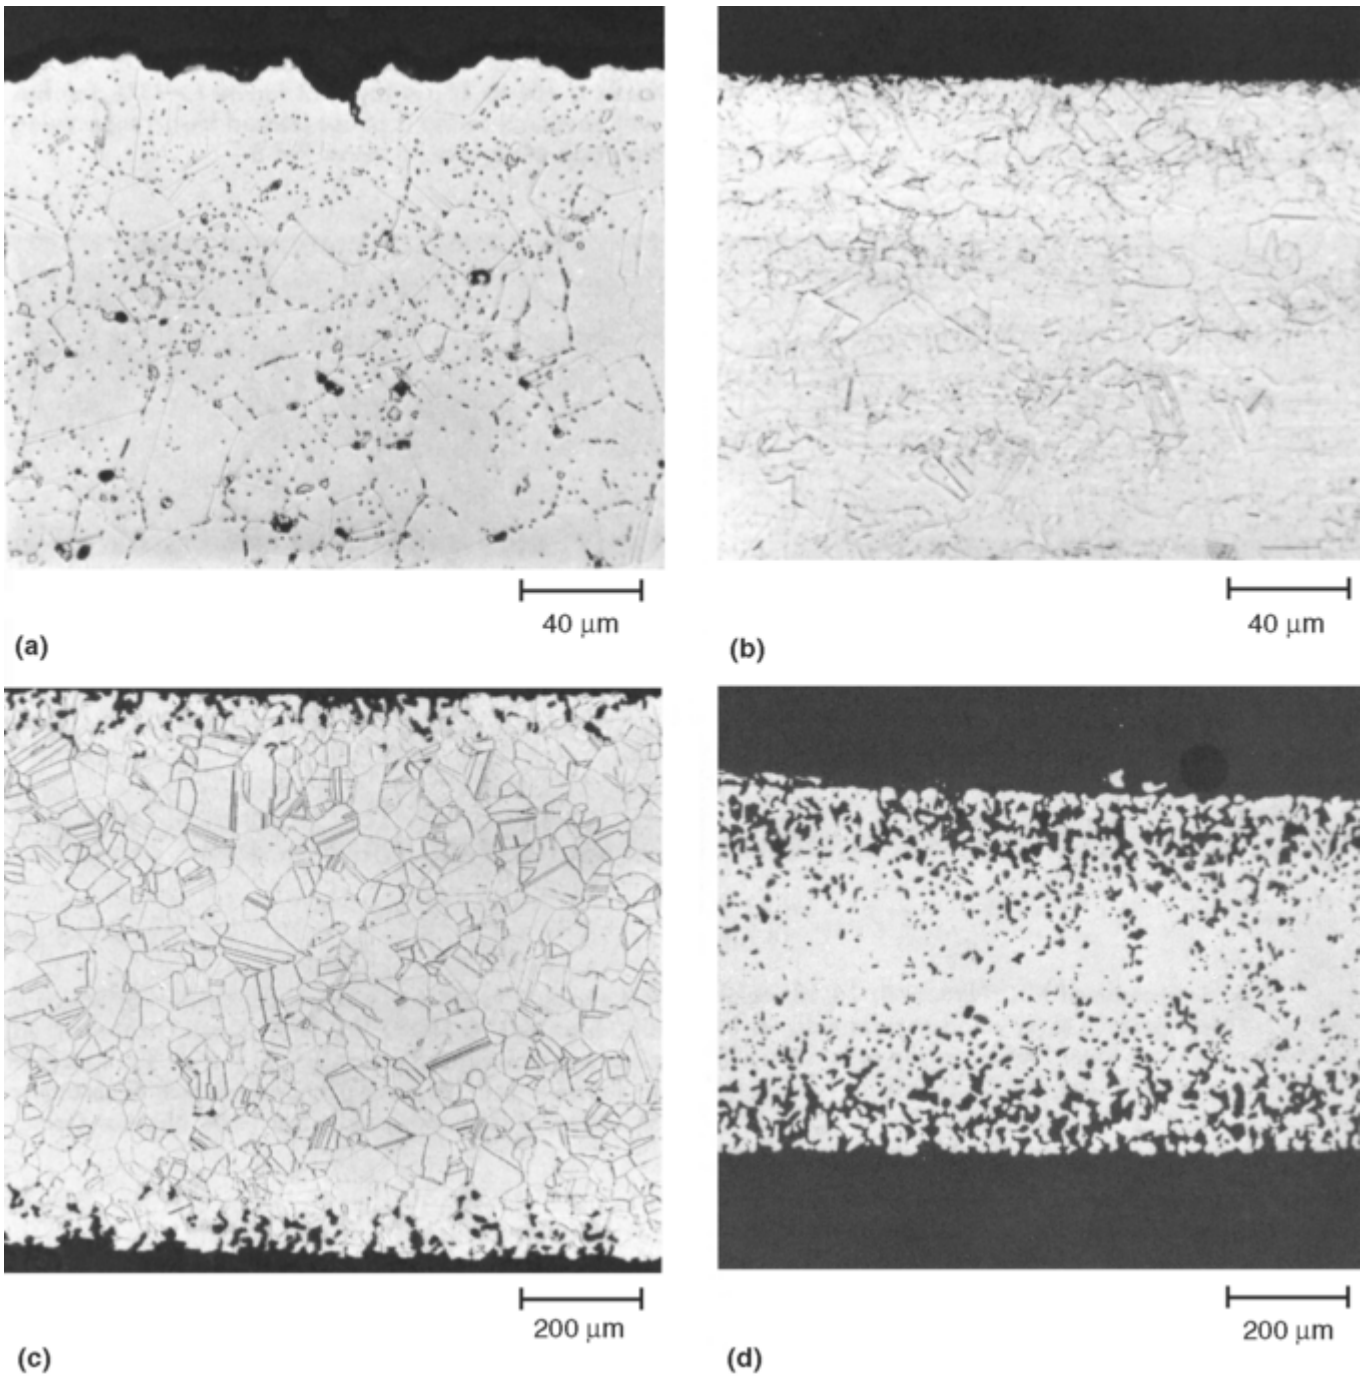

Fig. 3 Effect of molten salt corrosion on nickel-base and stainless steel alloys. In all four examples, chromium depletion (dealloying) was the result of prolonged exposure. Accompanying chromium depletion was the formation of subsurface voids, which did not connect with the surface or with each other. As chromium was leached from the surface of the metal, a concentration (activity) gradient resulted and caused chromium atoms from the underlying region to diffuse toward the surface, leaving behind a zone enriched with vacancies. These vacancies would then agglomerate at suitable sites—primarily at grain boundaries and impurities. The vacancies became visible as voids, which tended to agglomerate and grow with increasing time and temperature. (a) Microstructure of Hastelloy alloy N exposed to LiF-BeF_2-ThF_4-UF_4 (68, 20, 11.7, 0.3 mol%, respectively) for 4741 h at 700 °C (1290 °F). Chloride Salts. Molten salts consisting of chlorides are important and commonly used in the heat treating industry and for batteries and fuel cells. However, they have generally been less studied than fluoride systems. Some of the many systems include:

- NaCl-KCl
- KCl-Na_2CO_3
- NaCl-KCl-$BaCl_2$
- NaCl-$BaCl_2$
- NaCl-$BaCl_2$-$CaCl_2$

and many more.

In general, chloride salts attack steels very rapidly, with preferential attack of the carbides. Aluminum coatings on steels are not effective, but the addition of nickel to steel is beneficial. Nickel-base alloys decrease in resistance with increased oxygen partial pressure. In chloride salts, no protective oxide scale is formed on nickel-base alloys. The attack of metal surfaces in pure sodium chloride has been observed at temperatures above 600 °C (1110 °F).

In most cases with Fe-Ni-Cr alloys, corrosion takes the form of intergranular attack (Fig. 4). An increase of chromium in the alloy from 10 to 30% increases the corrosion rate by a factor of 7, while changes in nickel content have no effect. Thus, the intergranular attack is most likely selective with respect to chromium. The chromium removal begins at the grain boundary and continues with diffusion of the chromium from within the grain to the boundary layer, gradually enlarging the cavity in the metal. The gross corrosive attack is probably caused by the free chlorine, which is a highly oxidizing material, attacking the highly active structure-sensitive sites, such as dislocations and grain boundaries.

مرجع مهندسی مواد و متالورژی

Selective attack of Inconel alloy 600 is observed in molten chloride melts. The resulting attacked region is a layer of porous, spongelike material (Fig. 5). The pores are not interconnected and are typically located at the grain boundaries.

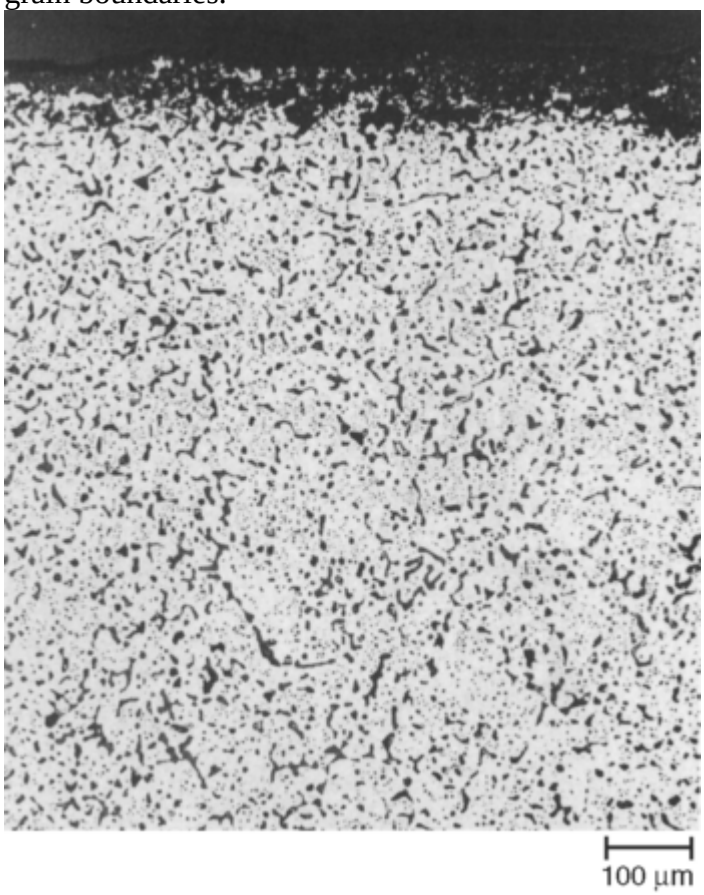

Fig. 5 Corrosion attack in a nickel-base alloy after two months at 870 °C (1600 °F) in a molten $BaCl_2$ salt bath. Source: Ref 2

Intergranular attack and rapid scale growth occur with zirconium alloys over 300 °C (570 °F). Platinum can be protected by the addition of oxide ions to the melt; this addition assists in the formation of a passive film.

Molten nitrates are commonly used for heat treatment baths; therefore, a great deal of material compatibility information exists. Plain carbon and low-alloy steels form protective iron oxide films that effectively protect the metal surface to approximately 500 °C (930 °F). Chromium additions increase the corrosion resistance of the steel, and hydroxide additions to the melt further increase the resistance of chromium-containing steels. Aluminum and aluminum alloys should never be used to contain nitrate melts, because of the danger of explosion.

Molten Sulfates. High-temperature alloys containing chromium perform well in sulfate salts because they form a protective scale. If the chromium content is not sufficient, the alloy suffers severe external corrosion and internal sulfidation. Non-film-forming metals, such as copper and silver, corrode very rapidly.

Hydroxide Melts. Stainless steels perform poorly in hydroxide melts because of selective oxidation of the chromium, which leads to pore formation in the metal. Nickel is more resistant than stainless steels or unalloyed steels.

The peroxide content of the melt controls the corrosion rate. An increase in water vapor and a decrease in oxygen pressure reduce the peroxide content and subsequently reduce the corrosion rate. An exception to this rule occurs with silver, which shows an increase in corrosion rate with increased water vapor. Most glass and silica are rapidly attacked by hydroxide melts, while alumina is more resistant.

Carbonate Melts. Austenitic stainless steels perform well in carbonate melts up to 500 °C (930 °F). If temperatures to 600 °C (1110 °F) are required, nickel-base alloys containing chromium are needed. For temperatures to 700 °C (1290 °F), high-chromium alloys containing at least 50% Cr are required. Above 700 °C (1290 °F), the passive films that form at lower temperatures break down and preclude the use of metals. Aluminum coatings on steel structures perform well to 700 °C (1290 °F). For higher temperatures, alumina is

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

required. Nickel does not provide adequate protection, because of intergranular attack caused by the formation of nickel oxides.

Prevention of Molten Salt Corrosion

There is a lack of reliable data for molten salts on structural material under industrial conditions, but several general rules should be observed. A material should be selected that will form a passive nonsoluble film in the melt, if possible. Material selection is the key to successful containment. Minimizing the entry of oxidizing species such as oxygen and water into the melt is very important. The oxidizing power of the melt or its redox potential should be kept as low as possible, which can be accomplished by additives. The temperature of the bath should be kept as low as possible. The lower temperature not only decreases the diffusion rates of the ions into the melt but lowers the solubility of potentially passive surface films. Temperature gradients should be eliminated within the melts to decrease the selective dissolution and plating at hot and cold sites.

Liquid Metal Corrosion

Revised by R.D. Kane, InterCorr International, Inc.

Introduction

LIQUID METALS have long been considered for the improvement of efficiency in heat-transfer systems. A recent example, from which many illustrations in this section are drawn (Fig. 1, 2, 3, 4, 5, 6), is the work that has been performed around the world on the sodium-cooled fast breeder reactor. This concept led to large-scale research and development programs that have continued through more than two decades. The result is a vast wealth of knowledge related to sodium corrosion behavior in all its varied aspects. The body of information

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

greatly overshadows the corrosion data compiled for other liquid metals. This type of reactor was in commercial operation in France and the former Soviet Union for power generation at the time this article was written. Development reactors were operating in the United Kingdom, Germany, Japan, India, and the United States.

Liquid Metal Corrosion

Revised by R.D. Kane, InterCorr International, Inc.

Experience in Systems Exposed to Liquid Metals

Liquid lithium systems have been designed for two widely different areas: space nuclear power and fusion reactors. These two applications draw on unique properties of this liquid metal and have led to studies with a wide range of containment materials and operating conditions. Space power reactors require low mass; this in turn demands high-temperature operation. Lithium, with its low melting point/high boiling point and high specific heat, is an ideal candidate heat-transfer medium. Refractory metal alloy containment is essential for these reactors, which may have design operating temperatures as high as 1500 °C (2730 °F).

Liquid lithium in fusion reactor concepts is selected because, here, the neutronics allow tritium fuel to be bred from the lithium; this is essential to viable economics of the reactor. Containment temperatures are below 700 °C (1290 °F); therefore, iron-base alloys can be used for construction.

The effects of liquid lithium on stainless steel, nickel, and niobium containment materials are shown in Fig. 7, Fig. 8, Fig. 9, Fig. 10, Fig. 11, Fig. 12, Fig. 13, Fig. 14, Fig. 15, Fig. 16.

Liquid mercury, potassium, and cesium have also been used for space and terrestrial applications. In some cases, these have involved two- phase systems in which the corrosion consideration became significantly altered. Lead, lead-bismuth, and lead-lithium alloys (Fig. 17) (Ref 10) have received attention for topping cycle heat extraction systems, heat exchangers, reactor coolants, and, more recently, fusion reactor designs.

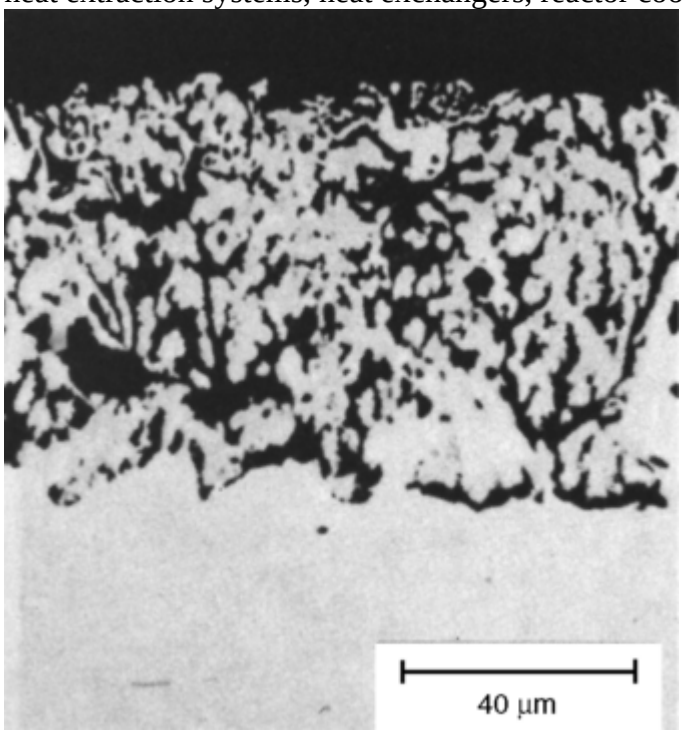

Fig. 17 Light micrograph of the polished cross section of a type 316 stainless steel exposed to thermally convective Pb-17at.% Li at 500 °C (930 °F) for 2472 h. Source: Ref 10

Many other combinations of containment and liquid metals have contributed to the knowledge of corrosion behavior; some have proved to be benign, while others have resulted in short-term catastrophic failures. For example, liquid mercury is also of potential interest, because it is an impurity, process additive, and/or by-product of many commercial industrial processes found in the refining and petrochemical industry. Exposure to liquid mercury can affect containment materials through a number of mechanisms, including amalgamation, galvanic acceleration of aqueous corrosion, and embrittlement.

In the discussion presented in this article, some brief notes are given regarding safety precautions for handling liquid metals, operating circulating systems, dealing with fire and spillage, and cleaning contaminated components.

Liquid Metal Corrosion

Revised by R.D. Kane, InterCorr International, Inc.

Forms of Liquid-Metal Corrosion

The forms in which liquid-metal corrosion are manifested can be divided into the following categories:

- Dissolution from a surface by (a) direct dissolution; (b) surface reaction, involving solid metal atom(s), the liquid metal, and an impurity element present in the liquid metal; or (c) intergranular attack
- Impurity and interstitial reactions
- Alloying
- Compound reduction

All the variables present in the system play a part in the form and rate of corrosion established. Several key factors have a major influence on the corrosion of metals and alloys by liquid- metal systems or liquid-vapor metal coolants. These are:

- Composition, impurity content, and stress condition of the metal or alloy
- Exposure temperature and temperature range
- Impurity content of the liquid metal
- Circulating or static inventory
- Heating/cooling conditions
- Single or two-phase coolant
- Liquid metal velocity
- Presence/control of corrosion inhibition elements
- Exposure time
- Monometallic or multialloy system components
- Wear or abrasion on metal surfaces
- Use of surface treatments designed to enhance passive surface films

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

These factors have a varied influence, depending on the combination of containment material and liquid metal or liquid-metal alloy. In many cases, such as with sodium, the initial period of exposure (of the order of 100 to 1000 h, depending on temperature and liquid metal involved) is a time of rapid corrosion that eventually reaches a much slower steady-state condition as factors related to solubility and activity differences in the system approach a dynamic equilibrium. In some systems, this eventually leads to the development of a similar composition on all exposed corroding surfaces. High-nickel alloys and stainless steel exposed together in the high-temperature region of a sodium system will, for example, all move toward a composition that is more than 95% Fe.

In the case of liquid mercury, its effects on aluminum or stainless alloys (e.g., stainless steels and nickel-base alloys) usually do not proceed automatically from the start of first exposure. The normal passive surface films (oxides) on aluminum and stainless alloys are a natural barrier to liquid-metal attack. It is only where these films are penetrated, mechanically damaged, or chemically attacked by other chemical species in the environment that liquid-metal corrosion proceeds. Mercury exposure of aluminum alloys can lead to at least three forms of attack: (a) amalgamation, a process by which aluminum and mercury form liquid solution (amalgamation does not require moisture); (b) amalgamation corrosion characterized by rapid weight loss, pitting, and possible intergranular corrosion and corrosion product formation in oxidizing environments; and (c) cracking, which involves rapid crack propagation and embrittlement at stresses substantially less than the normal material yield strength (Ref 11).

Compatibility of a liquid metal and its containment material varies widely, as illustrated in Fig. 1, Fig. 2, Fig. 3, Fig. 4, Fig. 5, Fig. 6, Fig. 7, Fig. 8, Fig. 9, Fig. 10, Fig. 11, Fig. 12, Fig. 13, Fig. 14, Fig. 15, Fig. 16, Fig. 17. For a pure metal, surface attrition may proceed in an orderly, planar fashion, being controlled by either dissolution or a surface reaction. For a multicomponent alloy, selective loss of certain elements may lead to a phase transformation. For example, loss of nickel from austenitic stainless steel exposed to liquid sodium may result in the formation of a ferritic surface layer (Fig. 1, 2a, 9, 11). In high-nickel alloys, the planar nature of the corroding surface may be lost altogether, and a porous, spongelike layer may develop (Fig. 4, 5). A more insidious situation can produce intergranular attack; liquid lithium, for example, penetrates deep into refractory metals if precautions are not taken to ensure that the impurity element oxygen is in an oxide form more stable than Li_2O or LiO solutions and is not left free in solid solution. Figure 15 illustrates intergranular attack in niobium.

Three factors—surface attrition, depth of depleted zone (for an alloy), and the presence of intergranular attack—should be evaluated collectively in any liquid-metal system. This evaluation leads to an assessment of total damage, which may be presented either as a rate or as a cumulative allowance that must be made for the exposure of a given material over a given time. A large body of literature exists in which rate relationships for numerous liquid-metal/containment combinations have been established (e.g., see the Selected References).

One vitally important aspect of liquid-metal corrosion that is often overlooked is deposition. Corrosion itself is very often not a factor of major concern, because surface recession rates in regions of maximum attack are often of the order of microns per year. The formation of compounds in the circulating liquid metal and the accumulation of deposits in localized regions where there is a drop in temperature, a change in flow rate or flow direction, or an induced change in surface roughness can, however, be very serious. If these deposits do not succeed in restricting flow channels completely, their nature is often such that they are only loosely adherent to deposition surfaces and may be dislodged by vibrations or thermal shock in the system, thus creating a major coolant flow restriction in a high-temperature region. Most deposits have a very low packing density; therefore, deposit growth can proceed at a rate that outstrips corrosion by several orders of magnitude. Examples of loosely adherent deposits are shown in Fig. 2(b), 6, 8, and 10. Figure 16 shows iron crystals that restricted flow in a pump channel of a lithium processing test loop.

Liquid-metal corrosion, as in other forms of corrosion, involves an appreciation for the source of corrosion in any system and an understanding of how potential sinks operate on the corrosion burden, particularly if the liquid metal is not static but is circulated in a heat-transfer system either by pumping or by thermal convection.

Liquid Metal Corrosion

Revised by R.D. Kane, InterCorr International, Inc.

Safety Considerations

The extensive work with the alkali and liquid metals has shown that such materials can be safely handled and used, provided certain precautions are heeded. The requirements for the safe use of liquid metals are, in essence, those of good industrial or laboratory practice, involving protection from contamination, chemical reactions, exposure to toxic or irritating substances, and protection from high temperatures. More specific information and details on safe operation and handling are available in Ref 12 and 13 and in the Materials Safety Data sheets issued by the Manufacturing Chemists' Association.

Chemical Reactivity. All the liquid metals react with oxygen and moisture to some degree; with the alkali metals, the reaction is vigorous enough to be potentially hazardous, particularly with potassium, rubidium, and cesium. Use of inert gas covers and the exclusion of moisture are the best defenses. Even with the nonalkali metals, where the reactions with water are slow, water, such as that found on equipment that is not completely dry, must not be brought in contact with liquid metals because of the danger of a steam explosion that can scatter liquid metal over a considerable area, damaging equipment and inflicting severe burns on unprotected workers. It goes without saying that workers in the vicinity of liquid-metal systems should wear appropriate protective clothing (Ref 12).

Potassium, rubidium, and cesium form higher oxides than the monoxide when exposed to air; these compounds are powerful oxidizing agents, often shock sensitive, and definitely hazardous in the proximity of organic materials. They form at room temperature in contact with the solid metals. The practical application of this information is the need for extreme caution when handling the metals or compounds of the heavier alkali metals, particularly when they have been stored for extended periods under less-than-ideal conditions or when cleaning spills or fire residues. It is noted that the sodium-potassium eutectic alloy (NaK) forms potassium superoxide when exposed to air or oxygen. Because NaK is liquid at normal room temperature, small leaks at low temperature do not necessarily freeze and self-seal.

Circulating Systems. It is usually convenient to provide a closed circulating system, or loop, in which to perform liquid-metal corrosion experiments. Reference 13 describes a simple system; the principles involved are the same for even very complex specialized devices. The loop provides the means for circulation of the liquid metal; it contains devices for on-line purification (if needed), while the inert cover gas protects against chemical contamination. Insulation and an enclosure protect against high temperatures and the spread of reaction products in case of a containment breach. Such systems provide a safe, convenient environment for handling liquid metals. Detailed operating procedures, involving common-sense principles such as maintaining the inert cover gas at all times and melting frozen metals by directionally heating away from a free surface, must be worked out for each system. The tens of millions of hours of safe operation of such systems, ranging from 1 L capacity test rigs to 4000 MW (thermal) nuclear reactors, validate the concept. References 14 and 15 describe many such test systems and the experiments performed in them.

Recovery from Spills and Accidents. It must be remembered that spills of the nonalkali metals, even though the chemical reactivity hazard may not be great, must be handled with care because of the toxic nature of many of the metals and their vapors. Leaks and spills of the alkali metals, particularly when some of the leaked material has burned, present a special hazard, because the spilled material often contains finely divided unreacted metal mixed with combustion products. Such mixtures can react vigorously with moist air, water, and alcohol. The products of the heavier alkali metals are the most reactive in this respect, but mixtures containing sodium and lithium are certainly not immune to violent reactions if carelessly handled. Cleanup of these residues must be approached with extreme care.

Removal of Residual Metals from Corrosion Specimens. Nonalkali metals often can be removed from corrosion specimens by draining, forming an amalgam or solution with an alkali metal, and then removing the mixture by

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

a technique discussed subsequently. Alkali metals can be removed from specimens by reaction with water or alcohols; the most vigorous reaction is with water, and the rate decreases as one progresses to heavier-weight alcohols. The reaction becomes more vigorous with increasing atomic weight of the alkali metals. Cesium-water reactions are definitely explosive. Use of ethanol and methanol is generally safe for sodium reaction, but one must remember the flammability hazard with alcohol vapors. The glycol ethers, such as butyl cellosolve, can also be used; they react more slowly than water, present less of a fire hazard than ethanol or methanol, but have toxic liquid and vapors. The water, alcohol, and glycol ether reactions all generate hydrogen; adequate ventilation must be provided to prevent the buildup of the hydrogen and the attendant danger of an explosion.

Anhydrous liquid ammonia forms a true solution with the alkali metals and can be used to remove adherent alkali metals from corrosion specimens. Precautions against the hazards of liquid ammonia must be taken; the alkali metal in solution with ammonia is then usually reacted with water or alcohol before the ammonia mixture is discarded. The conditions must be maintained truly anhydrous in order to avoid hydrogen generation and contamination of the samples. Hydrogen can become implanted in refractory metal samples and embrittle them even at subzero temperatures. If the proper equipment is available, evaporation of the residual metal from the surface can be done with excellent results.

Removal of alkali materials from pipework, if hydrogen generation is not a problem, can be accomplished with alcohol or gycol ether reaction, optionally followed by water rinsing to wash away the reaction products. It must be remembered that these reagents react very slowly, if at all, with oxides of the alkali metals. Another successful method in use is reaction with water vapor/inert gas (argon or nitrogen) mixtures, or water spray in an inert carrier gas, followed by water rinsing. Evaporation has also been successfully used and could be considered where hydrogen generation is not permitted. Ammonia- based systems have also been used for refractory metal pipework where hydrogen generation was prohibited. References 13, 14, and 15 contain more detailed information.

Fire Protection and First Aid. Firefighting and medical treatment should, of course, be left to the professionals. There are, however, several factors to keep in mind. An alkali metal fire does not expand, as does, for example, a petroleum fire. It does produce vast quantities of caustic smoke that react with moisture in or on the body, and this produces severe burns. The smoke must be avoided unless respiratory protection and protective clothing are worn.

Lithium presents a special hazard because of the toxic nature of some of its compounds and because it reacts with nitrogen. The combustion products of a lithium fire contain nitride and acetylide, which react with water to form ammonia and acetylene, respectively.

The only way to extinguish liquid-metal fires reliably is to smother them; various drying agents, such as sodium carbonate, sodium chloride, powdered dry graphite, or carbon microspheres, are effective. The sodium compounds should not be used on a lithium fire because of the chemical displacement reaction producing sodium metal that takes place. Instead, the graphite products should be used for extinguishment. It should be noted that few substances float on lithium; most tend to sink. Reference 16, however, describes the use of a ternary eutectic BaCl-NaCl-KCl salt for effective lithium fire extinguishment.

Inert gas blanketing is also effective for extinguishing fires; argon is preferred to nitrogen because of its higher density. Very effective fire suppression can be achieved by using inert gas blanketing in combination with a catch pan having a perforated floor to let the escaping liquid metal run to a second argon-blanketed chamber underneath the first. Of course, the hazards of oxygen-deficient atmospheres must be recognized and controlled when using inert gas flooding as fire suppression. Reference 17 provides more information about fire suppression in the alkali metals.

Emergency first aid treatment should concentrate on removing the victim from danger (for example, out of the smoke generated by a fire) and then removing the metal or compounds from skin and eyes. Running water is the most effective treatment, because the cooling and flushing effect overcomes any hazard from reaction of a small amount of metal on the skin or clothing. Safety showers and eyewash fountains should be readily available to workers involved with liquid metals; they should not be eliminated because of the presence of the alkali metals. More than one person has been spared serious injury because a safety shower was available to wash away a sodium spill.

High-Temperature Gaseous Corrosion

Revised by Russell D. Kane, InterCorr International, Inc.

Introduction

WHEN METAL IS EXPOSED TO AN OXIDIZING GAS at elevated temperature, corrosion can occur by direct reaction with the gas, without the need for the presence of a liquid electrolyte. This type of corrosion is referred to as tarnishing, high-temperature oxidation, scaling, or gaseous corrosion. As shown in Fig. 1 (Ref 1), the rate of attack (in terms of weight gain) increases substantially with temperature for many steels and stainless steel alloys. The surface film typically thickens as a result of reaction at the scale/gas or metal/scale interface due to cation or anion transport through the scale, which behaves as a solid electrolyte. For continuous, nonporous scales, ionic transport through the scale is the rate-controlling process. The thermodynamic stability, the ionic defect structure, and certain morphological features of the scale formed are key factors in determining the resistance of an alloy to a specific environment.

مرجع مهندسی مواد و متالورژی

Fig. 1 Oxidation resistance of carbon, low-alloy and stainless steels in air after 100 h at temperatures from 590 to 930 °C (1100 to 1700 °F). Source: Ref 1

Initial film growth is usually very rapid. If the scale is a nonporous solid and completely covers the metal surface, the reaction rate will decrease when the thickness reaches a few thousand angstroms as the transport of reactive species through the film becomes rate controlling. The subsequent corrosion rate depends on the details of this transport mechanism, which may be due to electrical potential or concentration gradients or to migration along preferential paths, and so may correspond to any of several rate laws, as shown in Fig. 2. Where a diffusion process is rate controlling, the kinetics usually follow a parabolic rate law, in which the rate progressively decreases with time (see Fig. 3) (Ref 2). Figure 4(a) illustrates the compact, continuous protective scale of essentially chromium oxide (Cr_2O_3) formed on alloy 800. If the scale is porous (or is formed as a vapor species) or does not completely cover the metal surface, a linear rate is usually experienced.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

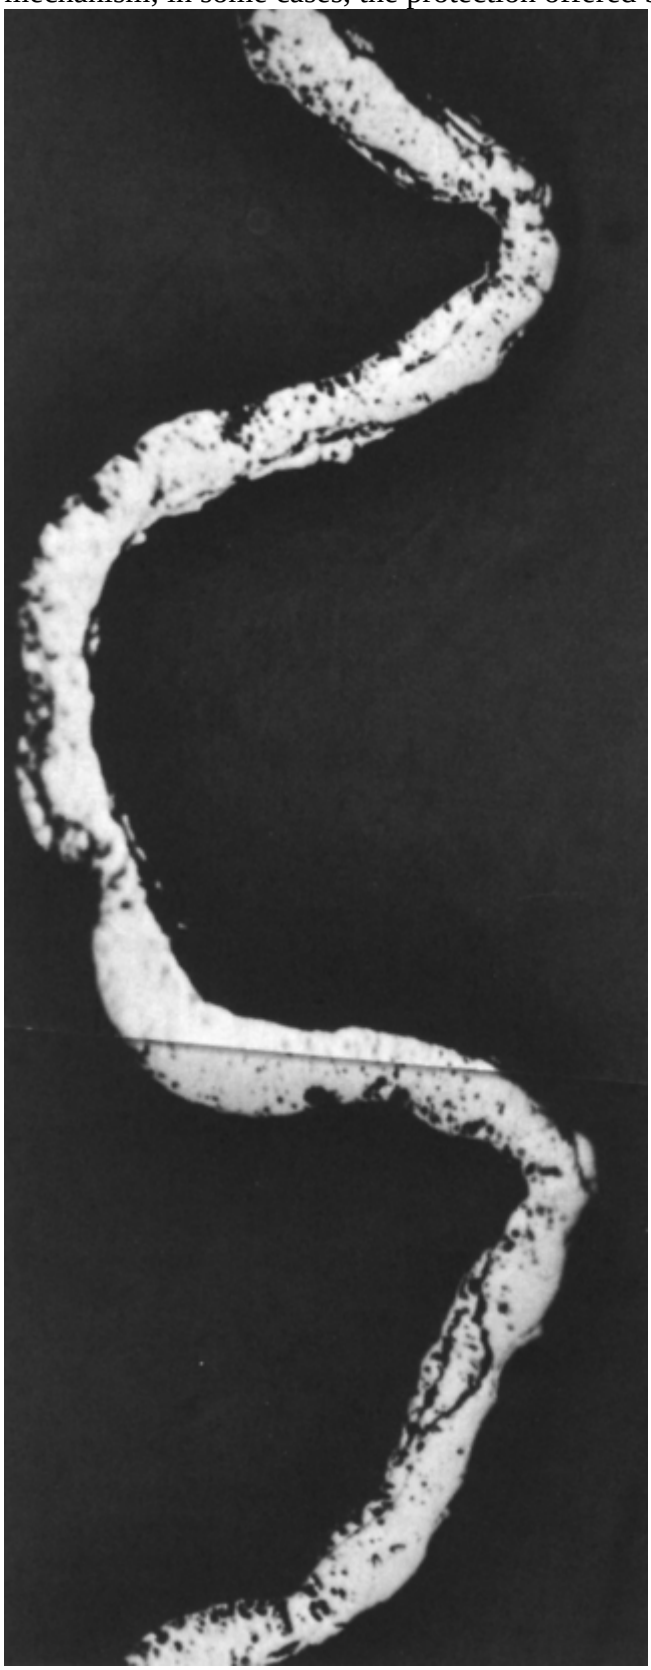
The latter circumstance can be assessed from the Pilling-Bedworth ratio, which is the ratio of the volumes of oxide produced to that of the metal consumed by oxidation; values of 1.0 or greater result in complete surface coverage by oxide and, usually, protective behavior. This is not a complete or foolproof measure for assessing the likelihood of protective scaling behavior. At high temperatures, the growth of nominally protective oxides may be sufficiently rapid that the compressive stresses resulting from a Pilling- Bedworth ratio greater than 1 become sufficiently great that the scale (or alloy) deforms, resulting in spalling that acts as a stress-relief mechanism; in some cases, the protection offered by such scales may be low at this point, as shown in Fig. 5.



www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 5 Cr_2O_3 scale formed on pure chromium at 1100 °C (2012 °F). A Pilling-Bedworth ratio of 2.0 results in high compressive stress in the scale, which is relieved by buckling and spalling. Courtesy of I.G. Wright, Battelle Columbus Division

The desired characteristics for a protective oxide scale include:

- High thermodynamic stability (highly negative Gibbs free energy of formation) so that it forms preferentially to other reaction products possible under the exposure conditions
- Low vapor pressure so that the oxide forms as a solid and does not evaporate into the atmosphere
- Pilling-Bedworth ratio greater than 1.0 so that the oxide completely covers the metal surface
- Low coefficient of diffusion of reactant species (metal cations and corrodent anions) so that the scale has a slow growth rate
- High melting temperature
- Good adherence to the metal substrate, which usually involves a coefficient of thermal expansion close to that of the metal, and sufficient high-temperature plasticity to resist fracture from differential thermal expansion stresses that can result particularly from thermal cycling

High-temperature scales are usually thought of as oxides, but may also be sulfides, possibly carbides, or mixtures of these species. Oxides and sulfides are nonstoichiometric compounds and semiconductors.
There are essentially two types of semiconductors: *p*-type (or positive carrier)—which may have vacancies in its metal lattice or an excess of anions contained interstitially—and *n*-type (or negative carrier)—which may have an excess of metal ions contained interstitially or vacant anion lattice sites. For diffusion-controlled scaling, the rate of scale growth can be altered by modification of the concentration of the particular defects involved. For example, *p*-type oxides exhibit increased cationic transport rates (increased oxidation rates) at increased oxygen pressures, while transport in *n*-type oxides is essentially independent of oxygen pressure. Both types of oxide can be doped by the addition of specific ions to the oxide lattice. For *p*-type metal deficit oxides, for example, the addition of cations of higher valence than the native cations results in an increase in the number of cation vacancies and therefore an increase in the oxidation rate, while lower-valence cation additions have the opposite effect.
Sulfides typically exhibit an intrinsically greater rate of transport of anions and cations than the oxides of the same metal and so provide scales that are significantly less protective than oxides.

High-Temperature Oxidation

Alloys intended for high-temperature applications are designed to have the capability of forming protective oxide scales. Alternatively, where the alloy has ultrahigh-temperature- strength capabilities (which is usually synonymous with reduced levels of protective scale- forming elements), it must be protected by a specially

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

designed coating. Oxides that effectively meet the criteria for protective scales listed previously and can be formed on practical alloys are limited to Cr_2O_3, alumina (Al_2O_3), and possibly silicon dioxide (SiO_2). In the pure state, Al_2O_3 exhibits the slowest transport rates for metal and oxygen ions and so should provide the best oxidation resistance.

Alloying requirements for the production of specific oxide scales have been translated into minimum levels of the scale-forming elements, or combinations of elements, depending on the base alloy composition and the intended service temperature. Figure 6 represents the oxidation rate of iron-chromium alloys (1000 °C, or 1832 °F, in 0.13 atm oxygen) and depicts the types of oxide scale associated with various alloy types in this range of chromium content. Figure 7 illustrates the morphology of a semiprotective scale formed on a cobalt-chromium alloy. Alloys based on these minimum specifications will form the desired protective oxide upon initial exposure, but because of the accompanying depletion of the scale-forming element, they will probably be unable to re-form the protective layer in the event of loss or failure of the initial scale.

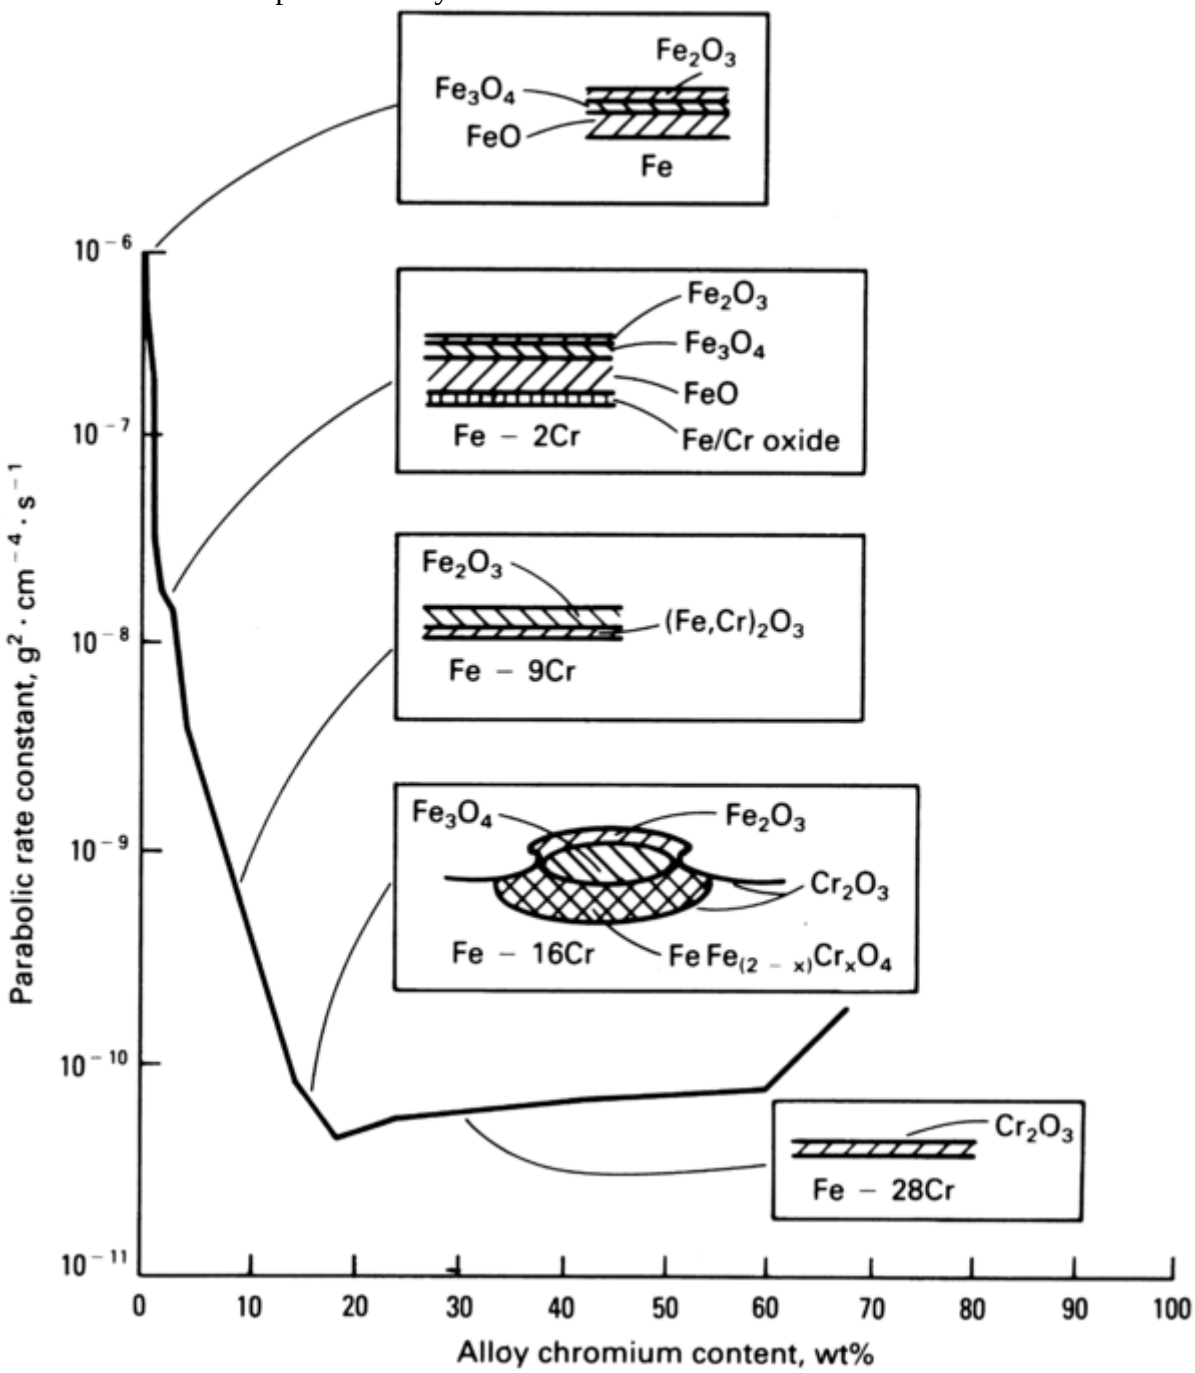

Fig. 6 Variation of the oxidation rate and oxide scale structure with alloy chromium content (based on isothermal studies at 1000 °C, or 1832 °F, in 0.13 atm oxygen)

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

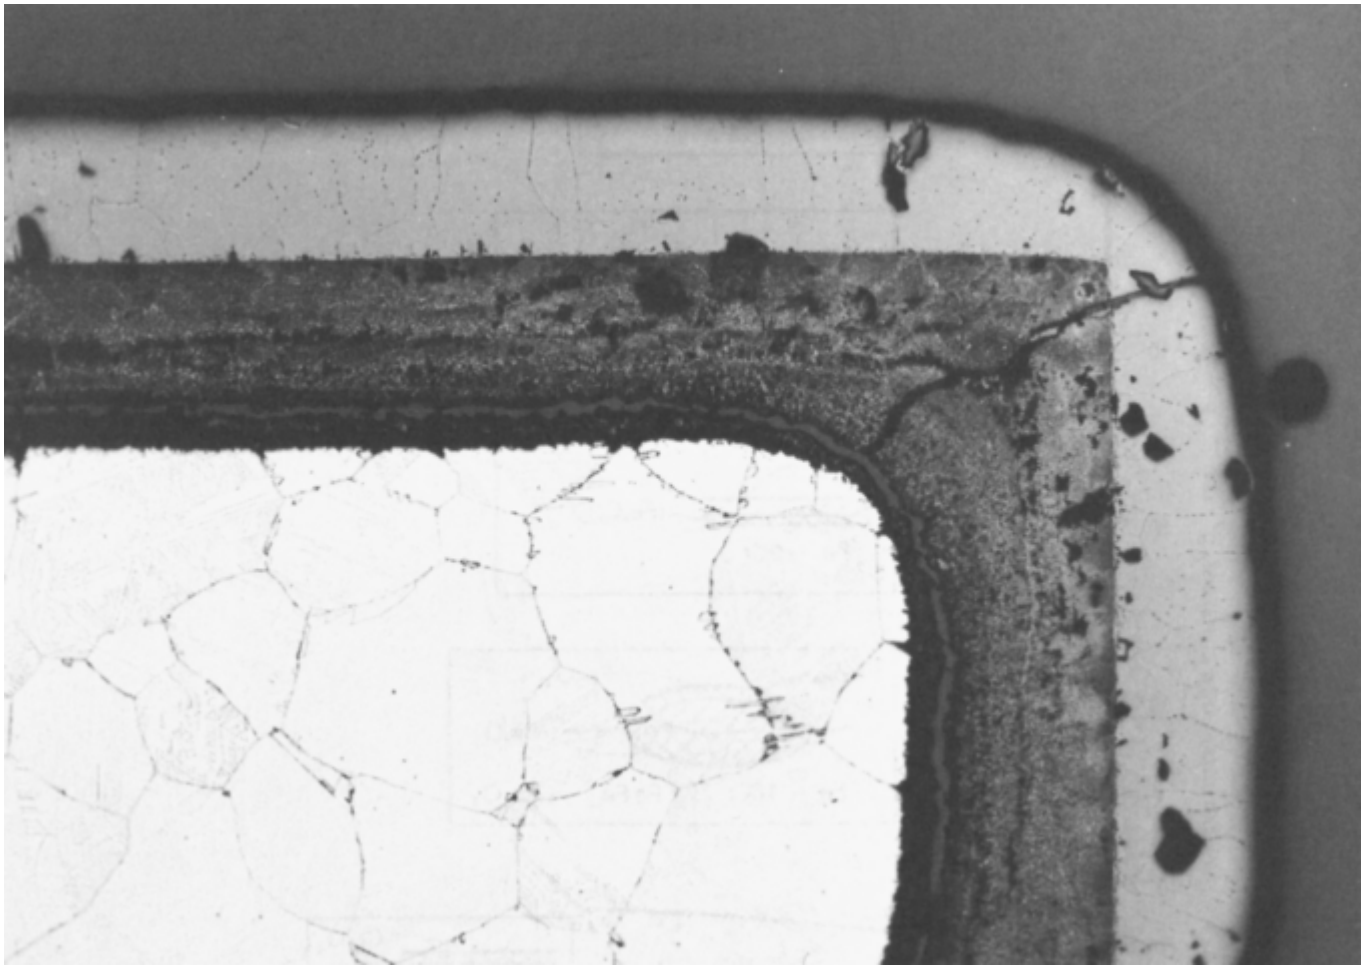

Fig. 7 Multilayer oxide scale formed on Co-10Cr alloy at 1100 °C (2012 °F). Outer layer is CoO; inner (mottled gray) layer is CoO containing dissolved chromium and particles of Co-Cr spinel. The chromium level in this alloy is insufficient to form a fully protective Cr_2O_3 scale. Courtesy of I.G. Wright, Battelle Columbus Division

A useful concept in assessing the potential high-temperature oxidation behavior of an alloy is that of the reservoir of scale-forming element contained by the alloy in excess of the minimum level (around 20 wt% for iron-chromium alloy at 1000 °C, or 1832 °F, according to Fig. 6). The more likely the service conditions are to cause repeated loss of the protective oxide scale through spalling, erosion, wear, or mechanical stresses, the greater the reservoir of scale-forming element required in the alloy for continued protection. Extreme cases of this concept result in chromizing or aluminizing to enrich the surface regions of the alloy or in the provision of an external coating rich in the scale-forming elements.

The breakdown of protective scales based on Cr_2O_3 or Al_2O_3 appears, in the majority of cases, to originate through mechanical means. The most common is spallation as a result of thermal cycling, or loss through erosion or abrasion. Typical scale structures on an Fe-18Cr alloy after thermal cycling are shown in Fig. 8. Cases in which the scales have been destroyed chemically are usually related to reactions occurring beneath deposits, especially where these consist of molten species. An additional mode of degradation of protective Cr_2O_3 scale is through oxidation to the volatile chromium trioxide (CrO_3), which becomes prevalent above about 1010 °C (1850 °F) and is greatly accelerated by high gas flow rates.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

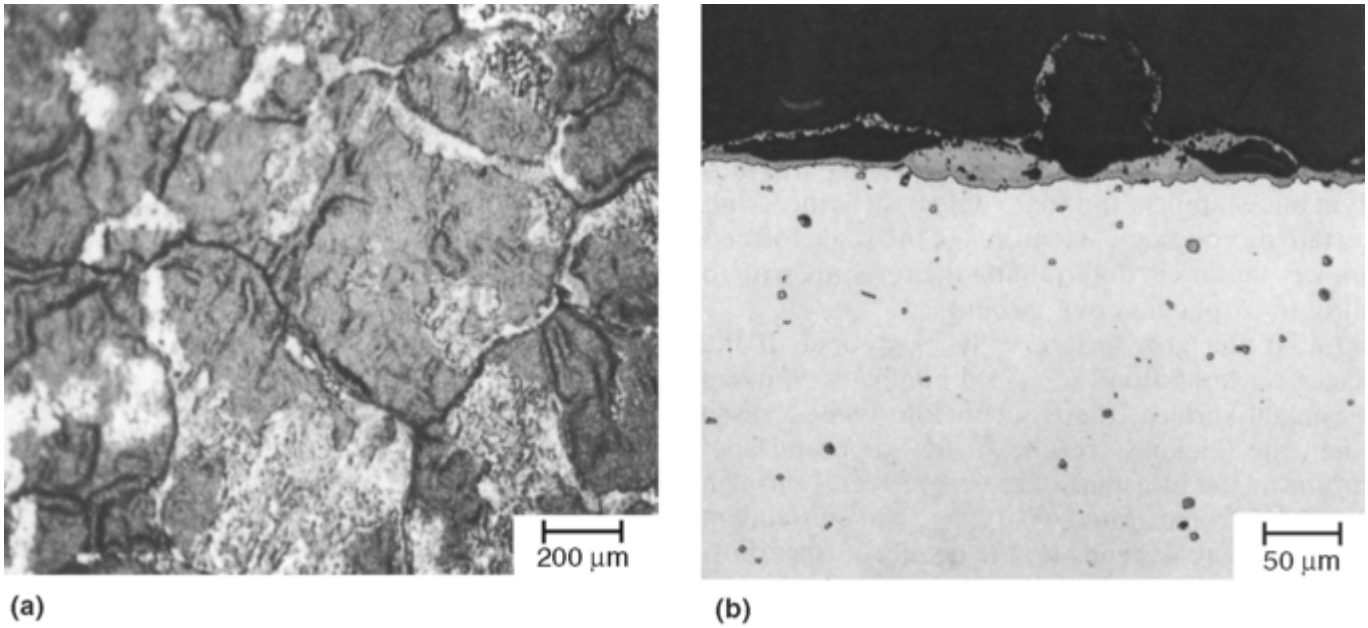

Fig. 8 Topography (a) and cross section (b) of oxide scale formed on Fe-18Cr alloy at 1100 °C (2012 °F). The bright areas on the alloy surface (a) are areas from which scale has spalled. The buckled scale and locally thickened areas (b) are iron-rich oxide. The thin scale layer adjacent to the alloy is Cr_2O_3, which controls the oxidation rate. Courtesy of I.G. Wright, Battelle Columbus Division

Because these protective oxide scales will form wherever the alloy surface is exposed to the ambient environment, they will form at all surface discontinuities; therefore, the possibility exists that notches of oxide will form at occluded angles in the surface, which may eventually serve to initiate or propagate cracks under thermal cycling conditions. The ramifications of stress-assisted oxidation (and of oxidation assisting the applied stress) in the production of failure conditions are not very well understood, but can constitute important considerations in predicting corrosion performance in actual operating systems and be of benefit in practical failure analysis.

Sulfidation

When the sulfur activity (partial pressure, concentration) of the gaseous environment is sufficiently high, sulfide phases, instead of oxide phases, can be formed. The mechanisms of sulfide formation in gaseous environments and beneath molten-salt deposits have been determined in recent years. In the majority of environments encountered in practice by oxidation-resistant alloys, Al_2O_3 or Cr_2O_3 should form in preference to any sulfides, and destructive sulfidation attack occurs mainly at sites where the protective oxide has broken down. The role of sulfur, once it has entered the alloy, appears to be to tie up the chromium and aluminum as sulfides, effectively redistributing the protective scale-forming elements near the alloy surface and thus interfering with the process of formation or re-formation of the protective scale. If sufficient sulfur enters the alloy so that all immediately available chromium or aluminum is converted to sulfides, then the less stable sulfides of the base metal may form because of morphological and kinetic reasons. It is these base metal sulfides that are often responsible for the observed accelerated attack, because they grow much faster than the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

oxides or sulfides of chromium or aluminum; in addition, they have relatively low melting points, so that molten slag phases are often possible. Figure 4 compares a protective (oxide) scale and a nonprotective (sulfide) scale formed on alloy 800. It is precisely this effect that provides the requirement for materials with higher alloy content of oxide-forming elements to impart increased sulfidation resistance.

Sulfur can transport across continuous protective scales of Al_2O_3 and Cr_2O_3 under certain conditions, with the result that discrete sulfide precipitates can be observed immediately beneath the scales on alloys that are behaving in a protective manner. For reasons indicated previously, as long as the amount of sulfur present as sulfides is small, there is little danger of accelerated attack. However, if oxidizing conditions exist, once sulfides have formed in the alloy, there is a tendency for the sulfide phases to be preferentially oxidized by the encroaching reaction front and for the sulfur to be displaced inward, forming new sulfides deeper in the alloy, often in grain boundaries or at the sites of other chromium- or aluminum-rich phases, such as carbides. In this way, fingerlike protrusions of oxide/sulfide can be formed from the alloy surface inward, which may act to localize stress or otherwise reduce the load-bearing section. Such attack of an austenitic stainless steel experienced in a coal-gasifier product gas is shown in Fig. 9. The sulfidation behavior of alloy 800 at temperatures and oxygen and sulfur potentials representative of coal-gasification processes is illustrated in Fig. 10, Fig. 11, Fig. 12. Additionally, as the oxygen and sulfur activities may vary in service, the tendencies for sulfidation and oxidation to persist or coexist change as well. Figure 13 (Ref 3) shows a stability diagram for the Cr-S-O system. This indicates how the dominant corrosion mechanism can change from oxidation or sulfidation depending on the availability of sulfur and oxygen. This figure also indicates the predominance of oxidation under all but the highly reducing conditions provided by very low oxygen partial pressure.

High-Temperature Gaseous Corrosion

Revised by Russell D. Kane, InterCorr International, Inc.

Carburization

As in the case of sulfide penetration, carburization of high-temperature alloys is thermodynamically unlikely except at very low oxygen partial pressures, because the protective oxides of chromium and aluminum are generally more likely to form than the carbides. However, carburization can occur kinetically in many carbon-containing environments. Carbon transport across continuous nonporous scales of Al_2O_3 or Cr_2O_3 is very slow, and alloy pretreatments likely to promote such scales, such as initially smooth surfaces or preoxidation, have generally been found to be effective in decreasing carburization attack. In practice, the scales formed on high-temperature alloys often consist of multiple layers of oxides resulting from localized bursts of oxide formation in areas where the original scale was broken or lost. The protection is derived from the innermost layer, which is usually richest in chromium or aluminum. Concentration of gaseous species such as carbon monoxide in the outer porous oxide layers appears to be one means by which sufficiently high-carbon activities can be generated at the alloy surface for carburization to occur in otherwise oxidizing environments. The creation of localized nonoxidizing, microenvironments is also possible under surface deposits that create stagnant conditions not permeable by the ambient gas, resulting in local regions of low oxygen activities where carburization can persist.

Once inside the alloy, the detrimental effects of the carbon depend on the location, composition, and morphology of the carbide formed. Austenitic steels should carburize more readily than ferritic steels because of the high solubility of carbon in austenite. Iron-chromium alloys containing less than about 13% Cr contain various amounts of austenite, depending on temperature, and should be susceptible to carburization, while alloys with 13 to 20% Cr will form austenite as a result of absorption of small amounts of carbon. Iron-chromium alloys containing more than ~20% Cr can absorb considerable amounts of carbon before austenite forms, becoming principally $(CrFe)_{23}C_6$ and ferrite. An example of rapid high-temperature carburization attack of an austenitic stainless steel is shown in Fig. 14.

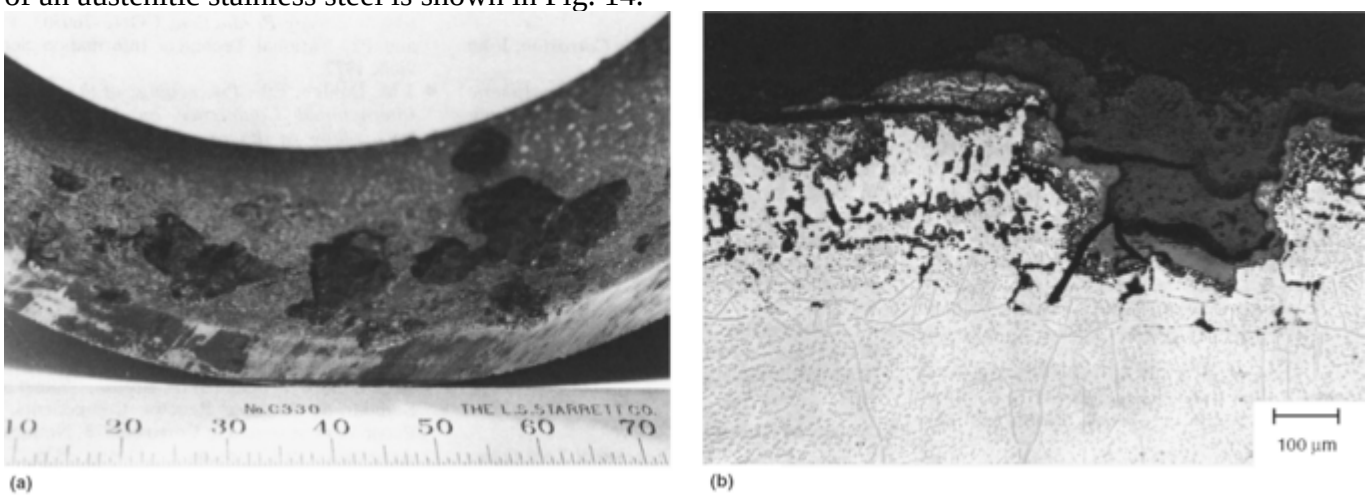

Fig. 14 Example of high-temperature carburization attack pitting in type 310 reactor wall after ~4000 h exposure to coal-gasification product gas. Alloying elements can exert an influence on the susceptibility to carburization of various alloys. In particular, silicon, niobium, tungsten, titanium, and the rare earths have been noted as promoting resistance to

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

carburization. The influence of silicon is particularly noteworthy as shown in Fig. 15 (Ref 4). It shows particular benefits in terms of reducing weight gain over the range of 1.5 to 2.5% in the bulk for Fe-Ni- Cr alloys of nominally 24 to 28% Cr and 20% Ni. Minor alloying additions of niobium in Ni- Cr-Fe alloys have been shown to reduce carburization rates by up to 25% over those without niobium additions. Experience with aluminum and manganese has been varied, although aluminum additions and diffusion coatings have shown particular promise in being able to set up a barrier to carbon ingress, thereby increasing resistance to carburization. Studies of alloy ratio of nickel and chromium have shown that alloys based on 50:50 nickel-to-chromium composition have generally better resistance than alloys where this ratio is 0.5 or 0.25. However, the presence of lead, molybdenum, cobalt, zirconium, and boron are considered detrimental to carburization resistance.

Other Forms of High-Temperature Corrosion

Hydrogen Effects. In hydrogen environments at elevated temperatures and pressures, there is increasing availability of atomic hydrogen that can easily penetrate metal structures and react internally with reducible species. An example is the attack experienced by carbon and low-alloy steels, in which atomic hydrogen reacts with iron carbide to form methane, which then leads to loss of strength from decarburization, formation of voids, and fissuring of the steel. Alloy steels with stable carbides, such as chromium carbides, are less

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

susceptible to this form of attack due to the greater stability of chromium carbide versus Fe_3C found in carbon steels. However, as the partial pressure of hydrogen and/or the temperature of exposure increases, a greater amount of these alloying additions are required to prevent such attack. One example is 2.25Cr-1Mo, a steel that undergoes some decarburization in high- temperature high-pressure hydrogen, but is less likely to fissure than carbon steel. However, as the conditions increase in severity, higher-alloy steels such as 5Cr-0.5Mo or 9Cr-1Mo may be required. The susceptibility of steels to attack by hydrogen can be judged from the Nelson Curves, which indicate the regions of temperature and pressure in which a variety of steels will suffer attack.

Another alloy susceptible to hydrogen attack is copper containing small amounts of cuprous oxide. This oxide reacts to form steam within the alloy, resulting in significant void formation.

Hot corrosion generally refers to a form of accelerated attack experienced by the hot gas path components of gas turbine engines. Two forms of hot corrosion can be distinguished; most of the corrosion encountered in turbines burning liquid fuels can be described as type I hot corrosion, which occurs primarily in the metal temperature range of 850 to 950 °C (1550 to 1750 °F). This is a sulfidation-based attack on the hot gas path parts involving the formation of condensed salts, which are often molten at the turbine operating temperature. The major components of such salts are sodium sulfate (Na_2SO_4) and/or potassium sulfate (K_2SO_4), apparently formed in the combustion process from sulfur from the fuel and sodium from the fuel or the ingested air. Because potassium salts act very similarly to sodium salts, alkali specifications for fuel or air are usually taken to be the sum total of sodium plus potassium. An example of the corrosion morphology typical of type I hot corrosion is shown in Fig. 16.

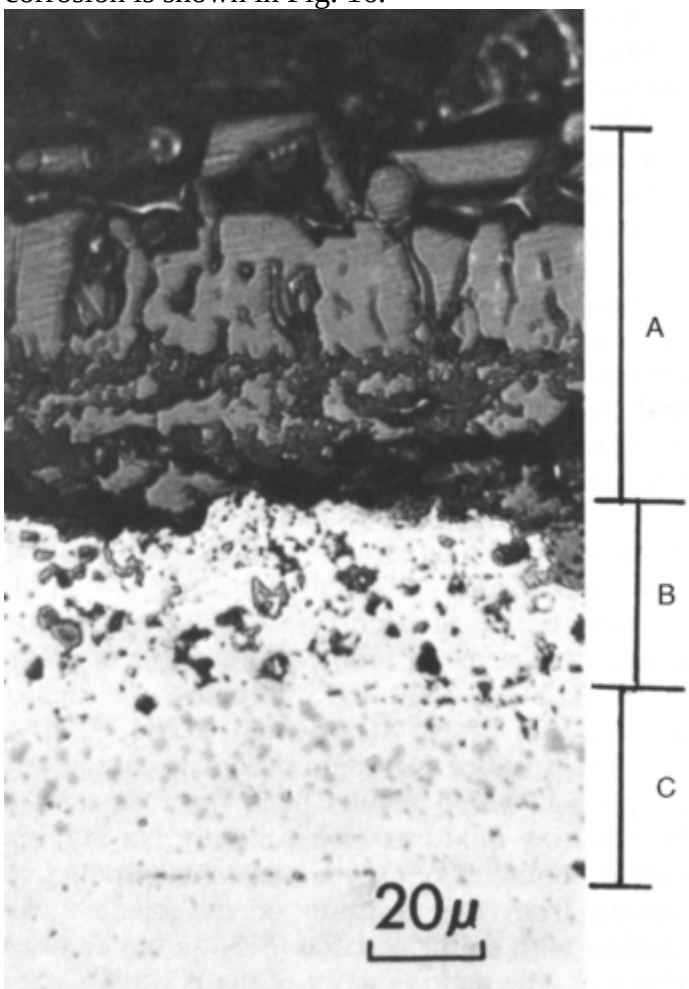

Fig. 16 Ni-20Cr-2ThO_2 after simulated type I hot-corrosion exposure (coated with Na_2SO_4 and oxidized in air at 1000 °C, or 1832 °F). A, nickel-rich scale; B, Cr_2O_3 subscale; C, chromium sulfides. Courtesy of I.G. Wright, Battelle Columbus Division

Very small amounts of sulfur and sodium or potassium in the fuel and air can produce sufficient Na_2SO_4 in the turbine to cause extensive corrosion problems because of the concentrating effect of turbine pressure ratio. For example, a threshold level has been suggested for sodium in air of 0.008 ppm by weight below which hot corrosion will not occur. Type I hot corrosion, therefore, is possible even when premium fuels are used. Other

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

fuel (or air) impurities, such as vanadium, phosphorus, lead, and chlorides, may combine with Na_2SO_4 to form mixed salts having reduced melting temperature and thus broaden the range of conditions over which this form of attack can occur. This is one of the major problems in combustion of impure fuels and incineration of municipal wastes. Also, agents such as unburned carbon can promote deleterious interactions in the salt deposits.

Research in the 1970s and 1980s led to greater definition of the relationships among temperature, pressure, salt concentration, and salt vapor- liquid equilibria so that the location and rate of salt deposition in an engine can be predicted. Additionally, it has been demonstrated that a high chromium content is required in an alloy for good resistance to type I hot corrosion. The trend to lower chromium levels with increasing alloy strength has therefore rendered most superalloys inherently susceptible to this type of corrosion. The effects of other alloying additions, such as tungsten, molybdenum, and tantalum, have been documented, and their effects on rendering an alloy more or less susceptible to type I hot corrosion are known and mostly understood.

Although various attempts have been made to develop figures of merit to compare superalloys, these have not been universally accepted. Nonetheless, the near standardization of such alloys as alloy 738 and alloy 939 for first-stage blades/ buckets, and FSX-414 for first-stage vanes/nozzles, implies that these are the accepted best compromises between high-temperature strength and hot-corrosion resistance. It has also been possible to devise coatings with alloying levels adjusted to resist this form of hot corrosion. The use of such coatings is essential for the protection of most modern superalloys intended for duty as first-stage blades or buckets.

Type II, or low-temperature hot corrosion, occurs in the metal temperature range of 650 to 700 °C (1200 to 1300 °F), well below the melting temperature of Na_2SO_4, which is 884 °C (1623 °F). This form of corrosion produces characteristic pitting, which results from the formation of low-melting mixtures of essentially Na_2SO_4 and cobalt sulfate ($CoSO_4$), a corrosion product resulting from the reaction of the blade/bucket surface with sulfur trioxide (SO_3) in the combustion gas. The melting point of the Na_2SO_4-$CoSO_4$ eutectic is 540 °C (1004 °F). Unlike type I hot corrosion, a partial pressure of SO_3 in the gas is critical for the reactions to occur. Knowledge of the SO_3 partial pressure-temperature relationships inside a turbine allows some prediction of where type II hot corrosion can occur. Cobalt- free nickel-base alloys (and coatings) may be more resistant to type II hot corrosion than cobalt-base alloys; it has also been observed that resistance to type II hot corrosion increases with the chromium content of the alloy or coating. Results from corrosion tests over several commercial alloys over a range of temperatures using a mixed-ash composition of Na_2SO_4 and K_2SO_4 is shown in Fig. 17 (Ref 5). It is the role of alloy composition and service temperature to define conditions for acceptable corrosion resistance and alloy use.

Pitting Corrosion

G.S. Frankel, The Ohio State University

Introduction

MANY ENGINEERING ALLOYS, such as stainless steels and aluminum alloys, are useful only because of passive films, which are thin (nanometer-scale) oxide layers that form naturally on the metal surface and greatly reduce the rate of corrosion of the alloys. Such passive films, however, are often susceptible to localized breakdown, resulting in accelerated dissolution of the underlying metal. If the attack initiates on an open surface, it is called pitting corrosion; at an occluded site, it is called crevice corrosion. These closely related forms of localized corrosion can lead to accelerated failure of structural components by perforation or by acting as an initiation site for cracking. Figure 1 shows an example of deep pits on a metal surface.

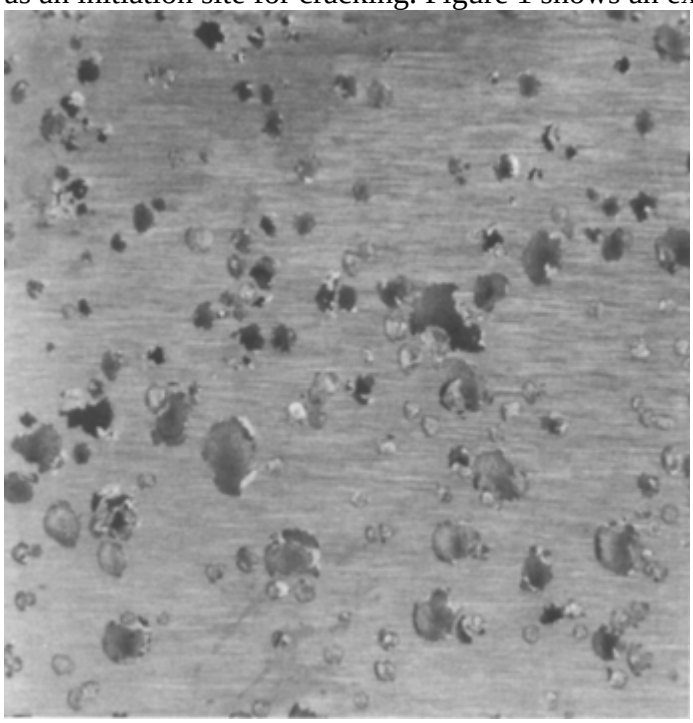

Fig. 1 Deep pits in a metal

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

It should be noted that, whereas localized dissolution following breakdown of an otherwise protective passive film is the most common and technologically important type of pitting corrosion, pits can form under other conditions as well. For instance, pitting can occur during active dissolution if certain regions of the sample are more susceptible and dissolve faster than the rest of the surface. This section concentrates on the better-known and widely studied phenomenon of pitting corrosion of passive metals.

Pitting corrosion is influenced by many different parameters, including the environment, metal composition, potential, temperature, and surface condition. Important environmental parameters include aggressive ion concentration, pH, and inhibitor concentration. Other phenomenological aspects of localized corrosion include the stochastic nature of the processes and the stages of localized attack, including passive film breakdown, metastable attack, stable growth, and perhaps eventual arrest.

G.S. Frankel, Pitting Corrosion, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 236–241

Pitting Corrosion

G.S. Frankel, The Ohio State University

Phenomenology of Pitting Corrosion

Environment and Development of Local Environment. Classical pitting corrosion caused by passive film breakdown will only occur in the presence of aggressive anionic species, and chloride ions are usually, although not always, the cause. The severity of pitting tends to vary with the logarithm of the bulk chloride concentration (Ref 1). The reason for the aggressiveness of chloride has been pondered for some time, and a number of notions have been put forth. Chloride is an anion of a strong acid, and many metal cations exhibit considerable solubility in chloride solutions (Ref 2). Chloride is a relatively small anion with a high diffusivity; it interferes with passivation, and it is ubiquitous as a contaminant.

The presence of oxidizing agents in a chloride-containing environment is usually extremely detrimental and will further enhance localized corrosion. It should be noted that chromate is an oxidizing agent that typically inhibits corrosion by reducing to form Cr^{III} film. Most oxidizing agents enhance the likelihood of pitting corrosion by providing extra cathodic reactants and increasing the local potential. Of course, dissolved oxygen is the most common oxidizing agent. One of the reactions by which oxygen reduction occurs is:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$$
$$E_{rev} = 1.23 - 0.059\ \text{pH}\ (\text{vs. SHE}) \qquad \text{(Eq 1)}$$

where E_{rev} is reversible potential, and SHE is standard hydrogen electrode.

Removal of oxidizing agents, such as removal of dissolved oxygen by deaeration, is one powerful approach for reducing susceptibility to localized corrosion. The influence of potential on pitting corrosion is described subsequently.

Pitting is considered to be autocatalytic in nature; once a pit starts to grow, the local conditions are altered such that further pit growth is promoted. The anodic and cathodic electrochemical reactions that comprise corrosion separate spatially during pitting (Fig. 2). The local pit environment becomes depleted in cathodic reactant (e.g., oxygen), which shifts most of the cathodic reaction (such as is given by Eq 1) to the boldly exposed surface outside of the pit cavity, where this reactant is more plentiful. The pit environment becomes enriched in metal cations as a result of the dissolution process in the pit (written for a generic metallic element, M):

$$M \rightarrow M^{n+} + ne^- \qquad \text{(Eq 2)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

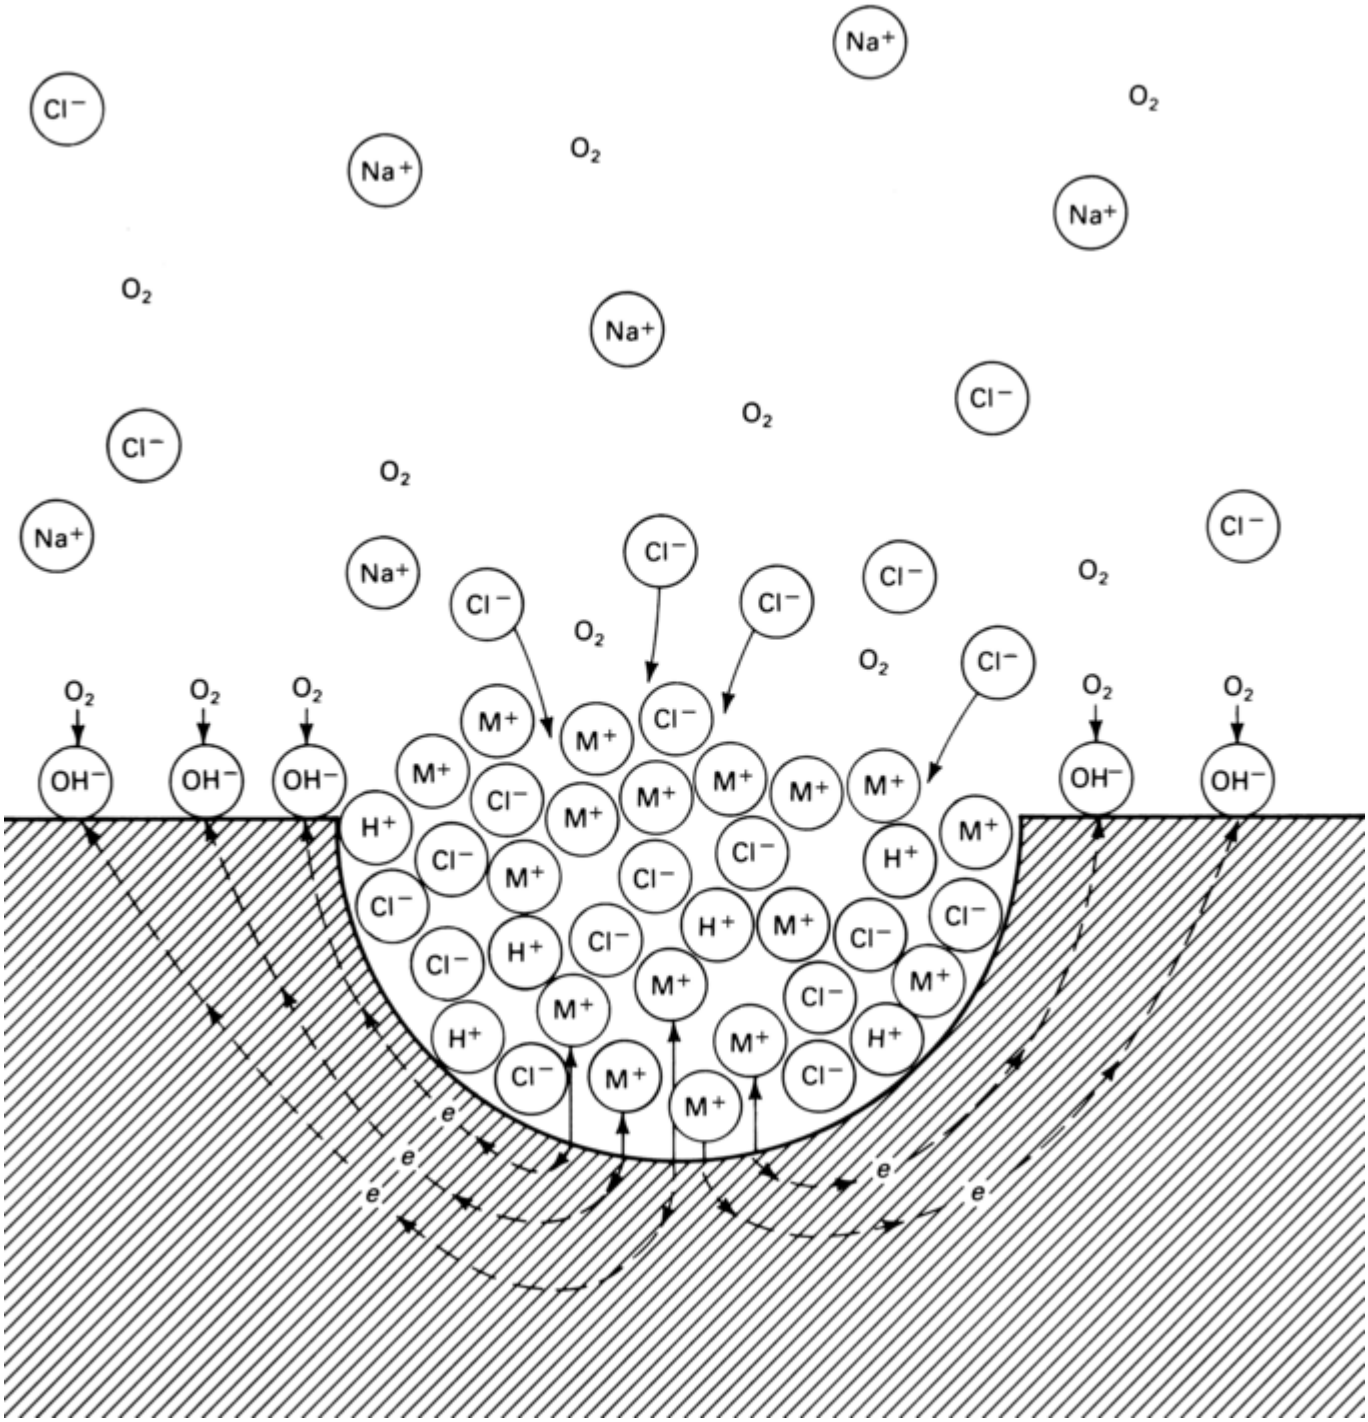

Fig. 2 Autocatalytic process occurring in a corrosion pit. The metal, M, is being pitted by an aerated NaCl solution. Rapid dissolution occurs in the pit, while oxygen reduction takes place on the adjacent metal surfaces.

The concentration of an anionic species such as chloride must also increase within the pit in order to balance the charge associated with the cation concentration and to maintain charge neutrality. This enrichment of anions occurs by electromigration from the bulk solution in response to the potential gradient that develops as a result of the ohmic potential drop along the current path between the inside of the pit and the cathodic sites on the boldly exposed surface. The final aspect of the local pit environment that must be considered is the pH, which decreases, owing to cation hydrolysis:

$$Me^{2+} + 2H_2O \rightarrow Me(OH)^{+} + H^{+} + H_2O$$
$$\rightarrow Me(OH)_2 + 2H^{+} \qquad \text{(Eq 3)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The common cathodic reactions that must accompany the dissolution occurring in the pit, such as the oxygen reduction reaction (Eq 1), result in a local increase in the pH at the cathodic sites. The acidity developed in the pit is not neutralized by the cathodic reaction because of the spacial separation of the anodic and cathodic reactions. In summary, the local pit environment is depleted in the cathodic reactant, such as dissolved oxygen; enriched in metal cation and an anionic species, such as chloride; and acidified. This acidic chloride environment is aggressive to most metals and tends to prevent repassivation and promote continued propagation of the pit.

A detailed analysis of the influence of pit chemistry changes on pit growth and stability is provided in Ref 2 and 3. The concentration of various ionic species at the bottom of a model one-dimensional pit geometry was determined as a function of current density based on a material balance that considered generation of cations by dissolution, outward diffusion, and thermodynamic equilibrium of various reactions such as cation hydrolysis (Eq 1). It was found that a critical value of the product $x \cdot i$, where x is pit depth and i is current density, corresponded to a critical pit acidification for sustained pit growth. Current density in a pit is a measure of the corrosion rate within the pit and thus a measure of the pit penetration rate. This $x \cdot i$ value can be used to determine the current density required to initiate or sustain pitting at a defect of a given size.

As the pit current density increases, the ionic concentration in the pit solution increases, often reaching supersaturation conditions. A solid salt film may form on the pit surface, at which point the ionic concentration would drop to the saturation value, which is the value in equilibrium with the salt layer. Under these conditions, the pit growth rate is limited by mass transport out of the pit. Salt films are not required for pit stability (although some have suggested that they are) (Ref 4, 5, 6, 7, 8, 9), but they enhance stability by providing a buffer of ionic species that can dissolve into the pit to reconcentrate the environment in the event of a catastrophic event, such as the sudden loss of a protective pit cover. Under mass- transport-limited growth, pits will be hemispherical with polished surfaces. In the absence of a salt film (at lower potentials), pits may be crystallographically etched or irregularly shaped in some other fashion.

Potential. Electrochemical studies of pitting corrosion have found that characteristic potentials exist. Stable pits form at potentials noble to the pitting potential, E_P, and will grow at potentials noble to the repassivation potential, E_R, which is lower than E_P. The effect of potential on pitting corrosion and the meaning of these characteristic potentials can best be understood with the schematic polarization curve shown in Fig. 3. This figure is a plot of the potential versus the logarithm of the current density. Potential is measured versus a reference electrode, commonly a saturated calomel electrode (SCE), and a potentiostat is used, along with an auxiliary or counter electrode, to make such measurements. As mentioned previously, current density is a measure of the rate of reaction. Common practice for measuring such curves involves potentiodynamic polarization or automatic scanning of the potential from a low value, such as the corrosion potential, to higher values (Ref 10).

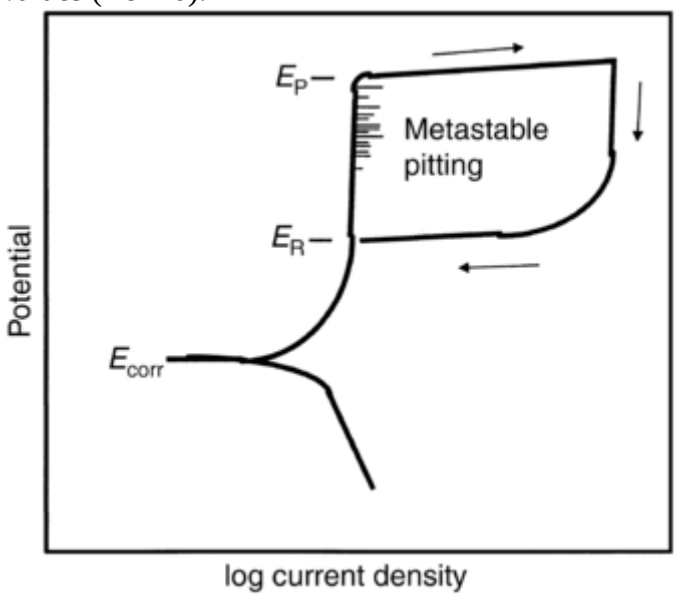

Fig. 3 Schematic of a polarization curve showing critical potentials and metastable pitting region. E_P, pitting potential; E_R, repassivation potential; E_{corr}, corrosion potential. Source: Ref 1

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The schematic polarization curve in Fig. 3 shows the case of a spontaneously passive material, meaning that a protective passive film is present on the metal surface at the open circuit or corrosion potential, E_{corr}. During upward scanning, breakdown occurs, and a stable pit starts growing at the pitting potential E_P, where the current increases sharply from the passive current level and, on reversal of the scan direction, repassivates at E_R, where the current drops back to low values representative of passive dissolution. Corrosion experts generally consider that materials exhibiting higher values of E_P and E_R are more resistant to pitting corrosion, and cyclic polarization experiments are commonly used for this purpose. In an oxidizing environment, or for a material that is very susceptible to pitting, the open circuit potential, which is determined by the intersection of the polarization curves associated with the anodic and cathodic partial reactions, will be above E_P, and the material will spontaneously pit at open circuit.

A correlation has been found such that metals with low experimentally determined pitting potentials have a higher tendency to form pits naturally at open circuit (Ref 1). If the E_{corr} is far below the E_P, then there is a low likelihood that the potential will ever go high enough to approach the E_P and initiate a pit. Therefore, the difference between the E_P and E_{corr} in a given environment is the margin of safety and is also used as a measure of the susceptibility to localized corrosion (Ref 11, 12, 13). Because the repassivation potential E_R is typically lower than E_P, the difference between E_R and E_{corr} is a more conservative measure of pitting susceptibility. If the corrosion potential were to always remain below the potential at which pits repassivate, then there is a very low likelihood that pitting will occur at all. A final measure of pitting susceptibility is the difference between E_P and E_R, which is related to the extent of hysteresis in a cyclic potentiodynamic polarization curve. Generally, alloys that are susceptible to pitting corrosion exhibit a large hysteresis.

It should be noted that several other names and subscripts have been used to describe these characteristic potentials. For instance, it is common to use the term *breakdown potential* (E_b) for the initiation potential, because one is not always sure if the form of localized attack is pitting, crevice corrosion, or intergranular corrosion, or if the current increase is the result of general transpassive dissolution. The pitting potential is sometimes referred to as the pit nucleation potential, E_{np}, and the repassivation potential is sometimes called the protection potential, E_{prot}. If creviced samples are used, the potentials might be referred to as crevice potential, E_{crev}, and crevice repassivation potential, $E_{r,crev}$.

The measures of susceptibility described previously are useful for comparing the vulnerability of various alloys to localized corrosion in a given environment or for comparing the relative aggressiveness of different environments. However, there is abundant experimental evidence suggesting that these interpretations of the characteristic potentials are simplistic and insufficient for the development of a fundamental understanding of the mechanism of pitting corrosion. For instance, the potentiodynamically determined pitting potential of many materials exhibits a wide experimental scatter, of the order of hundreds of millivolts. Furthermore, E_P is, in many cases, a function of experimental parameters, such as potential scan rate. As is described subsequently, so-called metastable pits initiate and grow for a period at potentials well below the pitting potential (Ref 14), which provides evidence in contradiction to the definition of the pitting potential as being the potential above which pits initiate. The meaning of the repassivation potential has also been called into question. The E_R of ferritic stainless steel decreases (i.e., moves in the active direction) with increasing values of the current density at which the potential scan direction is reversed (Ref 12, 15). So, deeper pits apparently repassivate at lower potentials. In contrast, the repassivation potential for pits in aluminum seems to be relatively independent of the extent of prior pit growth for a limited number of experiments (Ref 16). A similar lack of dependence of E_R on prior growth has been found for pits in stainless steel and other corrosion-resistant alloys but only after the passage of large charge densities (Ref 17). Furthermore, pits did not initiate at potentials below this limiting E_R, even after very long times (up to 38 months), which validates the use of the repassivation potential as a design criterion (Ref 18).

Alloy composition and microstructure can have strong effects on the tendency for an alloy to pit (Ref 19). Chromium concentration plays the dominant role in conferring passivity to ferrous alloys. The pitting potential was correspondingly found to increase dramatically as the chromium content increased above the critical 13% value needed to create stainless steel (Ref 20). Increasing the concentration of nickel, which stabilizes the austenitic phase, moderately improves the pitting resistance of iron-chromium (Ref 20). Small increases in certain minor alloying elements, such as molybdenum in stainless steels, can greatly reduce pitting susceptibility (Ref 19). Molybdenum is particularly effective but only in the presence of chromium. Small amounts of other elements, such as nitrogen and tungsten, also have a strong influence on the pitting resistance of stainless steels (Ref 21, 22).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Various measures have been developed to describe the beneficial effects of steel composition on resistance to localized corrosion. The pitting resistance equivalent number (PREN) was originally developed as a pitting index for stainless steels (Ref 22):

$$PREN = Cr + 3.3Mo + 16N \text{ (wt\%)} \quad \text{(Eq 4)}$$

The multiplier value for nitrogen could be as high as 30. The PREN has been correlated to various other measures of corrosion resistance for stainless steels, such as the critical pitting temperature, which is described in the next section.

Because aluminum is a very active and reactive metal, the homogeneous addition of almost any metal (except zinc, lead, and magnesium) into aluminum alloys results in an increase in pitting potential (Ref 23, 24, 25, 26, 27, 28). In order for this alloying to be beneficial, it is essential that the structure remain single phase. The pitting potential of binary aluminum-copper alloys increased with copper concentration as long as the copper was in solid solution (Ref 29).

Pits almost always initiate at some chemical or physical heterogeneity at the surface, such as inclusions, second-phase particles, solute-segregated grain boundaries, flaws, mechanical damage, or dislocations (Ref 19). Most engineering alloys have many or all such defects, and pits will tend to form at the most susceptible sites first. Pits in stainless steels are often associated with MnS inclusions, which are found in most commercial steels. The role of MnS inclusions in promoting the breakdown and localized corrosion of stainless steels has been recognized for some time (Ref 30, 31). Recent improvements in alloy production have led to steels with lower sulfur content to improve pitting resistance.

Pits in aluminum alloys are typically associated with intermetallic particles (Ref 32, 33). As described previously, copper additions to aluminum resulted in improvements in pitting resistance when the copper was in solid solution. However, when particles of the intermetallic θ phase (Al_2Cu) formed, the resistance to pitting decreased back to the range of aluminum alloyed with little copper (Ref 29). The decrease in pitting potential with formation of θ phase was explained by the existence of a copper-depleted region near the particles (Ref 29). This region would have a lower pitting potential, so pits would tend to form there first. Another study found that microsegregation of copper and iron impurities at nodes in high-purity aluminum was sufficient to increase the tendency for pitting corrosion at open circuit (Ref 34).

Temperature is also a critical factor in pitting corrosion, because many materials will not pit at a temperature below a certain value, which may be extremely sharp and reproducible (Ref 35, 36, 37, 38, 39, 40, 41). This effect can be seen either by varying the temperature at a range of fixed applied potentials or by varying the potential for a range of constant temperature experiments. Figure 4 is a plot of pitting and repassivation potentials for three different stainless steels in 1 *M* NaCl as a function of solution temperature (Ref 40). At low temperatures, extremely high breakdown potentials are observed, corresponding to transpassive dissolution, not localized corrosion. Just above the critical pitting temperature (CPT), pitting corrosion occurs at a potential that is far below the transpassive breakdown potential. This value of CPT is independent of environmental parameters and applied potential over a wide range and is a measure of the resistance to stable pit propagation (Ref 35). At higher temperatures, the pitting potential decreases with increasing temperature and chloride concentration. The CPT can be used, similar to pitting potential, as a means for ranking susceptibility to pitting corrosion; the higher the CPT, the more resistant the alloy is to pitting (Ref 35). If crevice corrosion is the primary concern, creviced samples can be used to determine a critical crevice temperature (CCT), which is typically lower than the corresponding CPT. Aluminum alloys do not exhibit a CPT in aqueous chloride solutions at temperatures down to 0 °C (32 °F) (Ref 42).

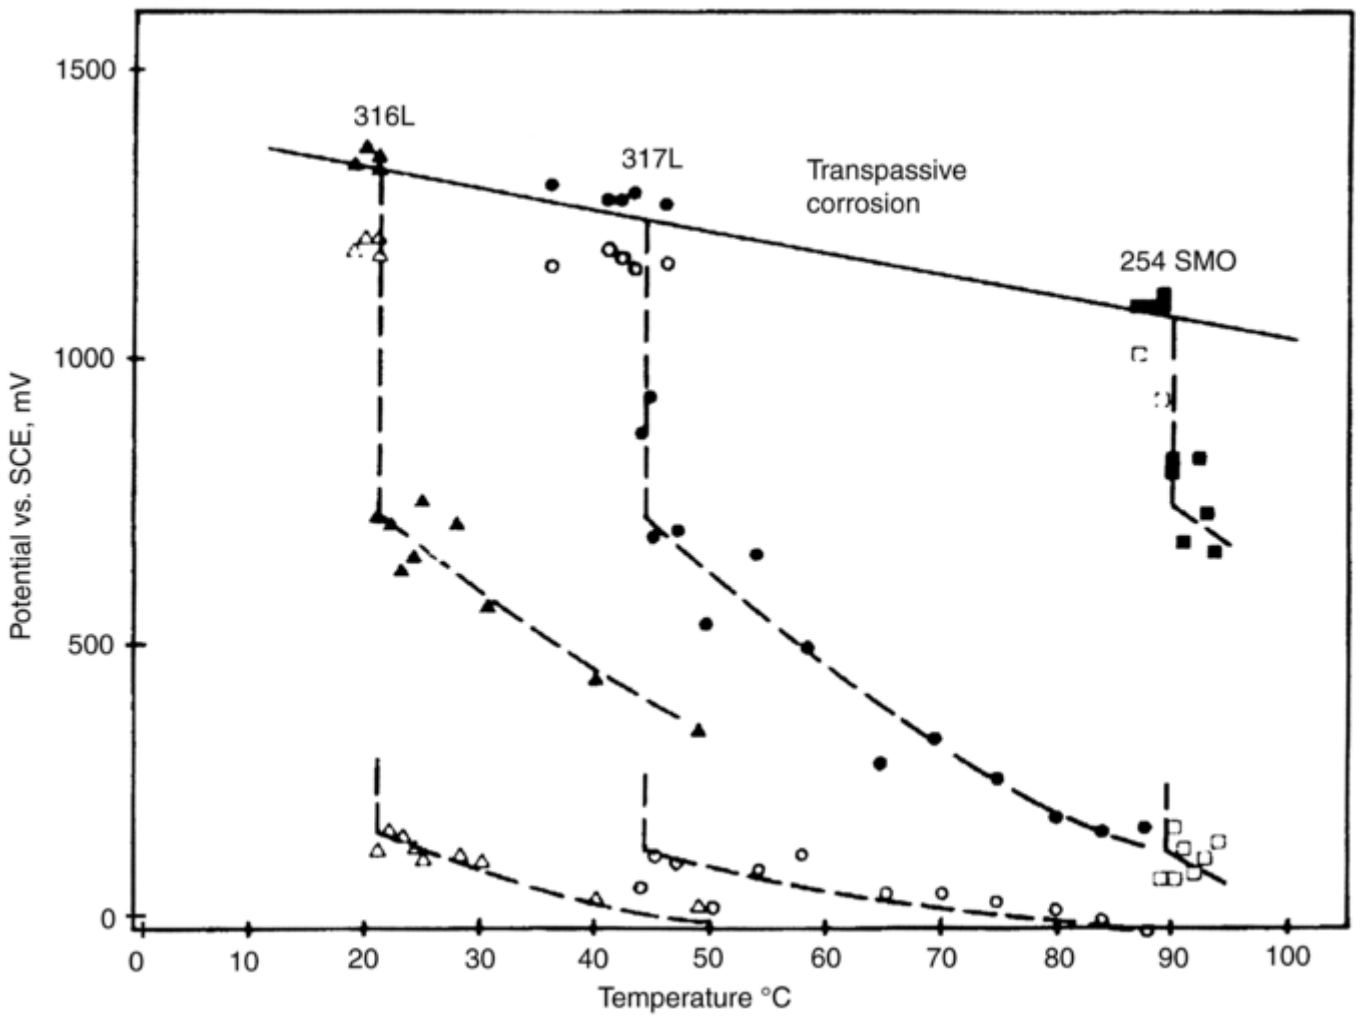

Fig. 4 Pitting (filled symbols) and repassivation (open symbols) in 1 *M* NaCl as a function of temperature for different grades of stainless steel. SCE, saturated calomel electrode. Source: Ref 40

Surface Condition. The exact condition of a surface can have a large influence on the pitting behavior of a material. In general, samples prepared with a rough surface finish are more susceptible to pitting and exhibit a lower pitting potential. For example, the pitting potential of type 302 stainless steel with a 120-grit finish was shown to be approximately 150 mV lower than that for the same material with a 1200-grit finish over a range of chloride concentrations (Ref 43). The effect of surface roughness on pitting is related to the stabilization criteria described subsequently. Rougher surfaces have more occluded sites, which can sustain the conditions required for active dissolution at lower current densities and thus lower potentials because of the longer diffusion path length and slower rate of diffusion.

For stainless steels, heat treatment, grinding, and abrasive blasting have been reported to be detrimental to pitting resistance, whereas pickling in HNO_3 + HF scales or passivation in HNO_3 is beneficial (Ref 22). Heat treatments in air generate a chromium oxide scale and a chromium-depleted region under the scale. The scale is typically removed mechanically, and the chromium-depleted region is removed by pickling (Ref 22). Other common surface defects include heat tint from welding, embedded iron particles from machining, and MnS inclusions. The detrimental effects of these defects are minimized and the overall surface condition improved by passivation in nitric acid, which increases the chromium content of the surface oxide film.

The effects of surface condition on localized corrosion are significant enough that care must be taken to not apply experimental data collected on samples with special preparation to a real application without taking the surface condition into account.

Inhibitors. Pitting can be inhibited by the same approaches that are commonly used to reduce corrosion in general. All of the factors described previously can be used to mitigate pitting corrosion: environment, alloy composition and structure, potential, and temperature. As mentioned previously, oxidizing agents accelerate

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

pitting by increasing the potential, so removal of oxidizing agents, for instance, by deaeration, reduces the tendency for pitting corrosion.

Various chemicals, when added to corrosive solutions, will inhibit pitting (Ref 19). Common inorganic inhibitors include sulfates, nitrates, chromates, and molybdates. Some, such as sulfate, may act simply by providing supporting electrolyte that reduces the migration of chloride ions into the pit. It was suggested that nitrate might reduce inside pits in aluminum, consuming protons and thereby reducing pH (Ref 44). Others might adsorb at active sites or reduce pit growth kinetics.

High-strength aluminum alloys, which are susceptible to pitting, owing to the influence of copper-containing intermetallic particles, are often protected using a system of coatings. The standard coating system uses a chromate conversion layer covered by organic paint coats. The primer coat might contain chromate pigments for further corrosion protection. The chromate conversion layer is formed by immersion into an acidic bath containing dichromate, fluoride, and ferricyanide. The fluoride destabilizes the aluminum oxide, allowing the following reaction to occur (Ref 45, 46):

$$Cr_2O_7^{2-} + 8H^+ + 2Al \rightarrow 2Al^{3+} + 2Cr(OH)_3 + H_2O \quad \text{(Eq 5)}$$

Chromate conversion layers also contain some amount of unreduced chromate ions as a result of adsorption of chromate onto a $Cr^{III}_x(OH)_y$ backbone (Ref 47). The resulting coating is a Cr^{III}-Cr^{VI} mixed oxide with an approximately 3 to 1 Cr^{III} to Cr^{VI} molar ratio. The chromate retained in the coating is critical for providing a self-healing capability (Ref 45, 46). Chromate- coated samples scratched to the substrate and exposed to a corrosive environment such as a salt spray will usually not exhibit severe corrosion at the scratch. Chromate in the conversion coating can be released into solution, where it is mobile and migrates to exposed areas on the aluminum alloy surface. Even at very dilute concentrations, chromate in solution adsorbs on active sites on the alloy and is reduced to form a monolayer of Cr^{III} species by a reaction similar to the one that occurs when the conversion coating forms (Eq 5). This layer is effective at reducing the activity of both anodic and cathodic sites on the alloy surface. Chromate pigment in primer should act the same way to protect a scratched area. Owing to the carcinogenic nature of chromate, considerable effort has been put into developing an equally effective and environment-friendly replacement system. However, nothing developed to date is as effective as chromate for reducing the corrosion of high-strength aluminum alloys (Ref 48).

Stochastics. Because pitting events are relatively rare and unpredictable, pit initiation may be considered to be random in nature. Stochastic or probabilistic approaches have been developed to handle this randomness and the large scatter typically observed in measurements of pitting potential and induction time (which is the time for a stable pit to form following a sudden increase in potential into the pitting range, or following the injection of chloride into a nonaggressive solution). A large ensemble of pitting potential values follows a normal distribution, suggesting random variation (Ref 49). The probability for pitting (P) can be determined by:

$$P(E) = n/(1 + N) \quad \text{(Eq 6)}$$

where N is the total number of samples studied, and n is the number of samples that had pitted at a potential of E or lower (Ref 49). The potential at P = 0.5 is a representative value for a given material and surface preparation. Induction times at a given potential can also be measured and the survival probability, $P(t)$, determined using Eq 6, except that n is the number of samples that initiate pits by time t after application of the potential. The pit-generation rate, λ, can then be given by (Ref 49):

$$\lambda(t) = -\frac{d}{dt}\ln P(t) \quad \text{(Eq 7)}$$

The value of the pit-generation rate can also be used as a measure of susceptibility to pitting.

Pitting Corrosion

G.S. Frankel, The Ohio State University

Stages of Pitting

Pitting can be considered to consist of various stages: passive film breakdown, metastable pitting, pit growth, and pit stifling or death. Any of these stages may be considered to be the most critical. For instance, once the passive film breaks down and a pit initiates, there is a possibility that a stable pit will grow. On the other hand, pits will not initiate if they cannot grow at least for a short while. The passive state is required for pitting to occur, but some researchers believe that details of the passive film composition and structure play a minor role in the pitting process. This view is supported by the fact that many observations of pitting tendency can be fully accounted for by growth considerations. Furthermore, pit growth is critical in practical applications of failure prediction. Finally, the metastable pitting stage may be thought to be the most important, because only pits that survive this stage become stable growing pits. Metastable pits exist on the edge of stability. Studies of metastable pits can therefore provide insight into fundamental aspects of pitting, because both initiation and stability are key factors in metastable pitting.

Pit Initiation and Passive Film Breakdown. The breakdown of the passive film and the details of pit initiation comprise the least understood aspect of the pitting phenomenon. Breakdown is a rare occurrence that happens extremely rapidly on a very small scale, making direct observation extraordinarily difficult. The passive film is often drawn schematically as a simple inert layer covering the underlying metal and blocking access of the environment to the metal. The reality is, of course, much more complicated. Depending on alloy composition, environment, potential, and exposure history, this film can have a range of thickness, structure, composition, and protectiveness. Typical passive films are quite thin and support an extremely high electric field (on the order of 10^6 to 10^7 V/ cm). The passage of a finite passive current density is evidence of continual reaction of the metal, to result in film thickening, dissolution into the environment, or some combination of the two. The view of the passive film as being a dynamic structure, rather than static, is critical to the proposed mechanisms of passive film breakdown and pit initiation.

Theories for passive film breakdown and pit initiation have been categorized into three main mechanisms that focus on passive film penetration, film breaking, or adsorption (Ref 50, 51). As with most such situations, different mechanisms or combinations of these mechanisms may be valid for different metal-environment systems. These mechanisms have been considered in terms of pure metal systems. However, pits in real alloys are most often associated with inclusions or second-phase particles, and these factors must also be taken into consideration.

Metastable Pitting. Metastable pits are pits that initiate and grow for a limited period before repassivating. Large pits can stop growing for a variety of reasons, but metastable pits are typically considered to be those of micron size, at most, with a lifetime on the order of seconds or less. Metastable pits are important to understand because, under certain conditions, they continue to grow to form large pits. Metastable pits can form at potentials far below the pitting potential (which is associated with the initiation of stable pits) and during the induction time before the onset of stable pitting at potentials above the pitting potential. These events are characterized by potential transients in the active direction at open circuit or under an applied anodic current, or anodic current transients under an applied anodic potential. Such transients have been reported in stainless steels (Ref 14, 52, 53, 54, 55, 56, 57, 58) and aluminum (Ref 59, 60) for many years. Individual metastable pit current transients can be analyzed for pit current density, and stochastic approaches can be applied to groups of metastable pits. It has been argued that when stable pits are small, they behave identically to metastable pits and, in fact, are metastable (Ref 14). Stable pits survive the metastable stage and continue to grow, whereas metastable pits repassivate and stop growing, for some reason.

Stable Pitting and Pit Growth. Pits grow at a rate that depends on material composition, pit electrolyte concentration, and pit-bottom potential. The mass-transport characteristics of the pit influence pit growth

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

kinetics through the pit electrolyte concentration. Pit stability depends on the maintenance of pit electrolyte composition and pit-bottom potential that are at least severe enough to prevent repassivation of the dissolving metal surface at the pit bottom.

In order to understand pit growth and stability, it is essential to ascertain the rate-determining factors. Pit growth can be controlled by the same factors that can limit any electrochemical reaction: charge-transfer processes (activation), ohmic effects, mass transport, or some combination of these factors. Pit growth at low potentials below the range of limiting pit current densities is controlled by a combination of ohmic, charge transfer, and concentration overpotential factors. At high potentials, mass transport may be rate controlling. Ultimately, however, mass transport determines the stability of pits even at lower potentials, because the local environment controls passivation. The rate of pit growth decreases with time for pitting controlled by either ohmic or mass-transport effects. The pit growth rate often varies with t^{-n}, where n is approximately equal to 0.5.

Pits often grow with a porous cover. This cover can make visual detection extremely difficult, so that the awareness of the severity of attack is overlooked and the likelihood of catastrophic failure is enhanced. The pit cover might be a thick, precipitated product layer that forms as the concentrated and acidic pit solution meets the bulk environment, which might be neutral or limited in water, as in the case of atmospheric corrosion. Small pits in stainless steels often have a pit cover that is a remnant of the undermined passive film (Ref 14). Larger pits in stainless steel can be covered by a layer with a considerable thickness of metal that is detached from the rest of the metal sample (Ref 61). These covers make optical detection extremely difficult, because they remain reflective. A short exposure to ultrasonic agitation, however, removes the cover and reveals the whole pit diameter.

Death and Pit Arrest. Despite the autocatalytic nature of pitting, large pits, which would be considered to be stable by any criterion, can stop growing or die. As mentioned previously, if the conditions (environment and potential) at the dissolving wall of a pit are not sufficiently aggressive, the pit will repassivate. The potential at the pit bottom is lower than that at the outer surface as a result of the ohmic potential drop associated with current flow out of the pit. As the pit deepens, the ohmic path length and ohmic resistance increase. This tends to cause an increase in the ohmic potential drop, a decrease in the local potential, and a decrease in the pit current density. The environment tends to be acidic and rich in chloride, owing to hydrolysis of the dissolved metal cations and electrolytic migration of chloride into the pit. The high concentration in the pit is depleted by transport out of the pit but is replenished by continued dissolution at the pit bottom. As the pit deepens, the rate of transport out of the pit decreases, so the pit can be stable with a lower anodic current density replenishing the environment. As mentioned previously, the pit current density tends to decrease with time, owing to an increase in the pit depth and ohmic potential drop. Repassivation might occur if a sudden event, such as loss of a pit cover, caused a sudden enhancement of transport and dilution of the pit environment to the extent that the rate of dissolution at the pit bottom would be insufficient to replenish the lost aggressive environment.

Crevice Corrosion

R.G. Kelly, University of Virginia

Introduction

CREVICE CORROSION, corrosion in occluded regions, is one of the most damaging forms of material degradation. Engineering structures as diverse as lap joints in aircraft, flanged pipes in chemical-processing plants, metal surfaces under initially protective coatings, and environmentally assisted cracks in metallic materials all have an occluded solution. This similitude was originally pointed out by Brown (Ref 1) and has gained general acceptance (Ref 2) due to the striking similarities in the chemical composition and behavior of occluded regions such as crevices, pits, cracks, and exfoliation sites. Thus, one can consider a crevice as a generic occluded system.

Crevice corrosion occurs when a wetted metallic surface is in close proximity to another surface, as shown schematically in Fig. 1. Typically, the average separation (called the gap, g) between the two surfaces is between 0.1 and 100 μm. For some material/environment combinations, this geometric arrangement can lead to accelerated attack of the metal surface, as shown in Fig. 2. There are numerous practical cases of geometries that lead to crevice corrosion. In almost any engineered structure there are many instances in which two or more materials are, by design, in close proximity as described previously. If electrolyte can be rigorously excluded from these regions, crevice corrosion is not possible, as one of the requirements for corrosion has been removed. Unfortunately, achieving and maintaining such complete exclusion of electrolyte is often impossible, so an appreciation of crevice corrosion becomes important.

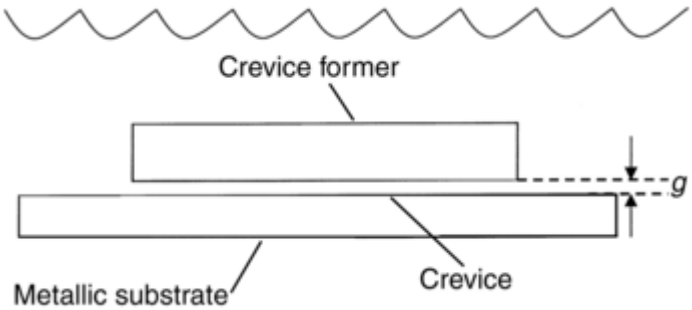

Fig. 1 Geometry of crevice corrosion. The average separation is the gap, *g*.

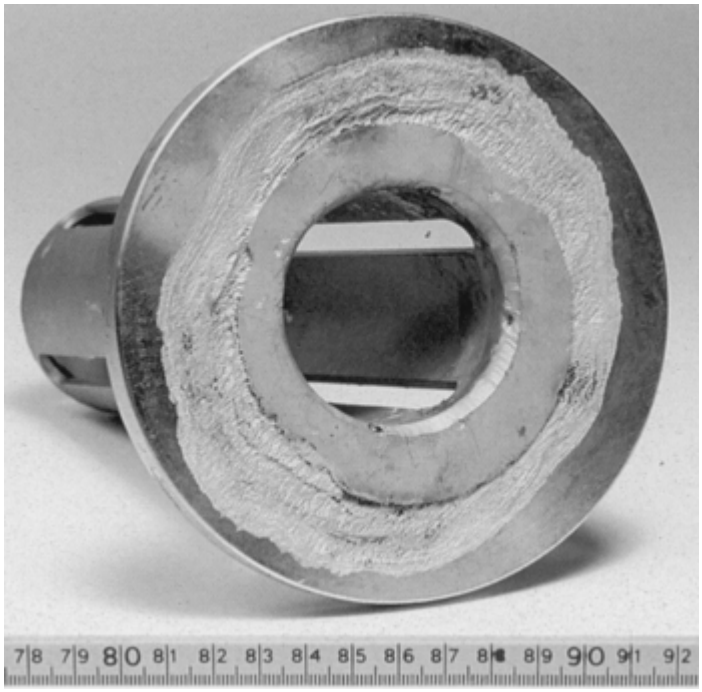

Fig. 2 Crevice corrosion under seal in type 316 stainless steel sieve from steam condenser cooling water system exposed to flowing seawater for two years at less than 40 °C (104 °F). Source: Ref 56

A generic geometry for crevice corrosion can be seen in Fig. 1 in cross section. The substrate is the metallic material of interest. It is separated from the crevice former by a gap, *g*, that, for an ideal crevice, is constant over the length of the crevice, *l*. The fully exposed surface is that area of the substrate outside the crevice former that is fully immersed in the electrolyte. The properties of the substrate can strongly influence the rate of crevice corrosion (Ref 2, 3).

Several examples of the results of crevice corrosion are shown in Fig. 3, Fig. 4, Fig. 5, Fig. 6. The similarities in topography among the examples include the accelerated attack of the substrate under the crevice former and the virtual absence of attack on the fully exposed surface. The accelerated attack within the crevice usually appears as uniform corrosion or pitting. In some cases, it is thought that the attack starts as metastable pits that coalesce into a more uniform attack.

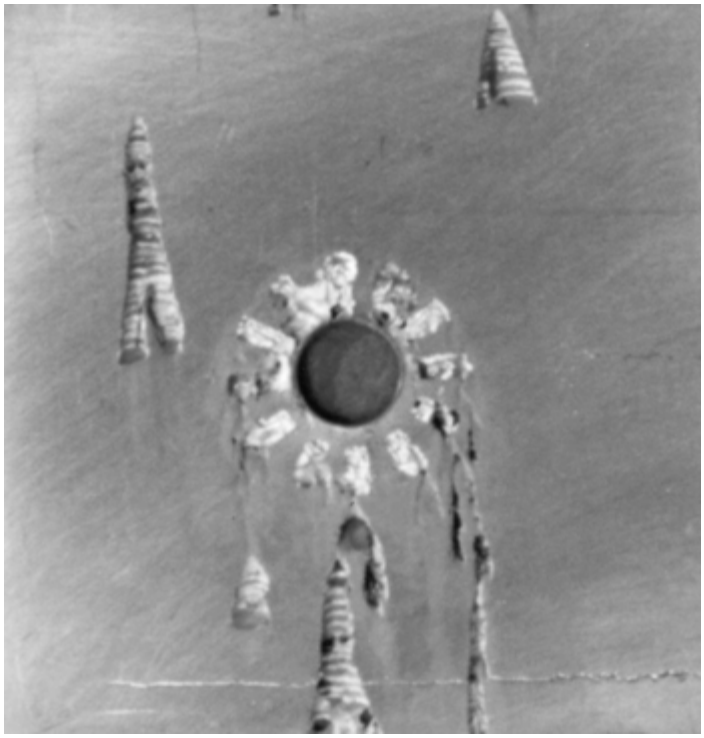

Fig. 4 Example of the results of crevice corrosion. Type 304 stainless steel exposed to 6 wt.% ferric chloride for 48 h at room temperature with castellated crevice washer applied around center hole. Pitting also occurred at several sites outside the crevice. The draining of the occluded solution from the crevice sites (and pits) led to the river pattern of attack outside the initial localized corrosion sites.

Crevice Corrosion

R.G. Kelly, University of Virginia

Critical Factors

Crevice corrosion involves three fundamental types of processes: electrochemical reactions, homogeneous chemical reactions, and mass transport. The electrochemical reactions include both dissolution and reduction reactions. The spatial variation of the rates of these reactions determines the development of the attack topography characteristic of crevice corrosion. The important types of homogeneous chemical reactions include hydrolysis, precipitation reactions, and homogeneous oxidation/reduction reactions of dissolved species. These reactions can have substantial effects on the corrosivity of the occluded environment, in particular with regard to the local pH. Mass transport by diffusion and convection generally tends to minimize differences between the occluded region conditions and those on the fully exposed surface. However, the tight geometry inherent in crevices leads to severe restriction of mass transport, allowing large differences in concentration and electrochemical potential to develop and be maintained between the fully exposed surface and the occluded crevice region.

The geometry of a crevice defines the phenomenon. The two dimensions that characterize a crevice, the gap, *g*, and the depth or length, *l*, exert a great deal of control on the initiation and propagation of crevice corrosion. In general, the tighter the crevice (i.e., the smaller the gap) the more severe the crevice attack. Note that the crevice in Fig. 1 is an idealized schematic of a real crevice. The gaps in real crevices are highly variable throughout the occluded region because they are defined by the meeting of asperities on the two surfaces as shown in Fig. 7. An actual crevice has a highly distributed geometry. Conventional methods of preparing occluded geometry samples, such as by pressing serrated polytetrafluoroethylene (PTFE) washers onto polished metal surfaces, do not allow rigorously defined crevices to be made. Conventional polishing does not make truly flat surfaces, but a series of ridges and asperities. Pressing the PTFE washer onto the polished metal surface forms an occluded region with a wide range of crevice gaps including small areas of intimate contact. Although the total crevice volume and nominal crevice gap of the occluded region can be determined with appropriate experiments (Ref 4, 7, 8), the local conditions within the occluded region will vary based on the surface finishes and relative hardness of the contacting surfaces. Variations in time will occur due to creep of the PTFE.

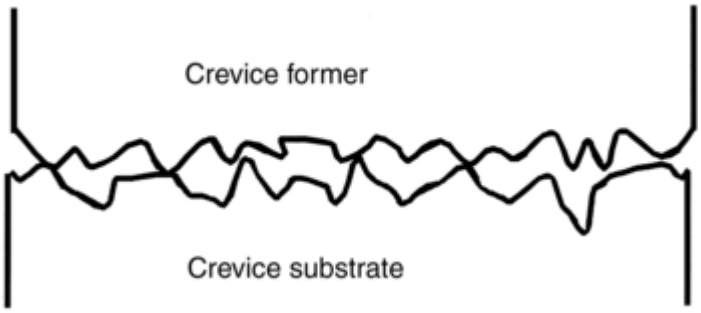

Fig. 7 Cross section of a crevice in which surface asperities cause variations in local gap

As mentioned previously, convection is usually not considered important in crevice corrosion due to the restricted geometry. There are some cases in which this assumption is not valid. Lott and Alkire (Ref 9) have investigated the effects of flow past the mouths of localized corrosion sites (pits). They found that a recirculation motion can develop within a localized corrosion site. Although this flow can mix the occluded solution, there was little mixing between the occluded region solution and the bulk solution. Flow *through* crevices can inhibit the initiation of crevice corrosion by making the development of the aggressive

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

environment in the occluded region more difficult. There are a variety of “flow-through” crevices, including support plates in heat exchangers in nuclear reactors (Ref 10).

Material. In order for crevice corrosion to occur, the vast majority of the surface must be passive. This is due to both the need to distinguish localized attack within the crevice and the need for the fully exposed surface to serve as a net cathode to support the high rate of anodic activity within the occluded region. Stainless steels are widely recognized as being susceptible to crevice corrosion (Ref 11). Other alloy systems that rely on passivation for corrosion protection—such as nickel-, titanium-, and aluminum- base alloys—can also be susceptible, although conditions for attack may differ. Titanium alloys are the most resistant to crevice corrosion with high temperatures and high chloride concentrations required.

Although stainless steels and nickel alloys are susceptible, alloying can improve the resistance dramatically. Additions of nickel and chromium, along with molybdenum and nitrogen, increase the resistance of the material to crevice corrosion. Chromium, molybdenum, and nitrogen are particularly potent, and there are beneficial synergistic interactions among them (Ref 11).

Copper-base alloys can suffer from a type of crevice corrosion known as metal-ion concentration-cell corrosion. Although there remains some controversy regarding the mechanism, it can be said that crevice-related attack for copper alloys is distinctly different from that for stainless steels. In the case of copper alloys, the most severe corrosion occurs *outside* the crevice, rather than inside. It is generally thought that the concentration of metal ions in the crevice electrolyte renders the crevice area cathodic to the area immediately outside the mouth of the crevice. Corrosion outside of the crevice (anode) progressed because the bulk environment contained a much lower concentration of metal ions (Ref 12).

Environment. The chemical composition of the environment affects crevice corrosion by providing a solution in which the material is passive while also containing anions that can lead to local breakdown (such as chloride ions). These aggressive anions will concentrate over time in the crevice to the point where localized depassivation occurs there. The bulk pH of the solution will tend to influence the time to the initiation of crevice corrosion, with more alkaline pH values tending to increase the initiation time. As with other forms of localized corrosion, more anodic (positive) potentials exacerbate crevice corrosion. This potential can develop due to the presence of oxidizers dissolved in solution, such as oxygen, chlorine, or ozone, or it can be imposed externally. One means of external imposition of potential is galvanic coupling to a more noble material.

Increased temperature is the clearest accelerant for crevice corrosion, and so it is the basis for several accelerated corrosion tests. For titanium alloys, there is a generally accepted lower limit of crevice corrosion of 70 °C (158 °F) (Ref 13).

Stifling of Crevice Corrosion. Crevice corrosion, like many other forms of localized corrosion, typically starts at a high rate and then slows with time. Under steady-state external conditions (i.e., chemical composition, temperature, potential), the rate decays somewhat to one controlled by the interaction between the steady- state conditions within the occluded region (i.e., occluded chemical composition, potential distribution, and dissolution kinetics) and those of the fully exposed surface (i.e., cathodic kinetics that are often diffusion controlled). While this steady state exhibits lower rates than the early transient, the rates can still be in the 25 to 250 μm/yr/ (1 to 10 mil/yr) range.

Relationships with Pitting. Crevice corrosion shares many characteristics and phenomenology with other forms of localized corrosion such as pitting, intergranular attack, environmentally assisted cracking, and dealloying. In all of those cases, the electrochemical and chemical conditions within an occluded region become altered with respect to the conditions on fully exposed surfaces. These variations can lead to rates of attack within the occluded region that are many orders of magnitude higher than those observed on the fully exposed surfaces. Generally, a material/environment combination that leads to pitting can also lead to crevice corrosion. Because of the many commonalities among the various types of localized corrosion, understanding crevice corrosion allows insights to be gained into the factors that influence the other forms of localized corrosion.

Crevice Corrosion

R.G. Kelly, University of Virginia

Selected Examples

Example 1: Crevice Corrosion of Stainless Steel in Aqueous Chloride. The most studied of all alloy systems for crevice corrosion is stainless steel. Since soon after their creation and establishment as “stainless” during exposure to marine atmospheres, iron-chromium-base alloys have been widely used in hopes of taking advantage of their superior inherent corrosion resistance. Unfortunately, that same widespread use has led to their use in environments in which they are susceptible to localized corrosion (Ref 11). Much of what is known about crevice corrosion is based on studies of stainless steels conducted to develop alloys more resistant to localized corrosion and to provide data for appropriate materials selection. The effects of alloy composition (Ref 14, 15), microstructure (Ref 16), crevice geometry (Ref 17), surface finish (Ref 18), and environmental parameters such as solution composition (Ref 19, 20, 21), temperature (Ref 22, 23, 24), and solution velocity (Ref 25) have been extensively studied.

Example 2: Crevice Corrosion of Nickel alloys in Chlorinated Seawater. Nickel-base alloys can be made very resistant to crevice corrosion through the addition of substantial amounts of chromium and molybdenum, along with minor additions of tungsten. Nonetheless, these highly resistant alloys are not immune. For example, alloy 625 tubes (Ni-Cr-Fe-Mo) were found to suffer crevice corrosion under vinyl hoses secured with serrated nylon hose clamps as part of a flow loop containing chlorinated seawater (Ref 26). The chlorine additions were sufficient to raise the potential of the material to the point that crevice corrosion initiated. Several studies have focused on the mechanisms underlying the initiation, demonstrating the need for an extremely aggressive occluded solution and high electrochemical potential (Ref 27, 28, 29).

Example 3: Crevice Corrosion of Aluminum Alloys in Aircraft Lap Joints. Corrosion of structural aluminum alloys can pose limitations on the service life of aircraft. The physical design of aircraft requires the formation of many regions that have an occluded geometry in which water and corrosive species can be trapped. For example, the areas of overlap between the inner and outer skins form an occluded site, referred to as a lap splice joint. During service, moisture is drawn into these sites by capillary action. Pollutant gases, such as SO_2 and NO_x, dissolve in the water, forming a corrosive solution that attacks the protective oxide on the material (Ref 30). Airplane takeoffs and landings near the ocean can lead to Cl^- ingress, acid rain can cause pH effects, and simple maintenance procedures (wash and deicing solutions) may lead to harmful crevice effects over the life of the aircraft.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Analyses of rehydrated corrosion products from lap joints have shown that more than 25 different ions can be present within these aircraft lap joints. These ions are present in low concentrations and have total ionic strength less than 80 mM (Ref 31). In fact, the highest concentration of chloride measured was 19 mM. Certain ions were commonly present in more than 75% of the samples. Although the ionic concentrations were low, Lewis (Ref 32) showed that some ions, even at these levels, had significant impact on the corrosion current density and/or corrosion potential.

The dilute ionic concentration and mildly alkaline pH found in this analysis is a chemical environment that is different than is generally thought to exist in a pit or crevice of aluminum (Ref 33). Pits and crevice sites usually involve acidic solutions because the metal cations formed by alloy dissolution react with water and form metal hydroxides and H^+ ions. For charge neutrality, anions such as chloride then migrate to the site from the bulk solution. Because of the geometry of the site, these ions become trapped and result in increasing concentration and higher rates of dissolution of the alloy. Therefore, the solution within pits and crevices tends to be acidic and highly concentrated.

In contrast, the lap-joint environment becomes neither concentrated nor acidic. This difference is due to the lack of an external cathodic reaction. In traditional pits and crevices, the majority of the cathodic reaction (e.g., $2O_2 + 2H_2O + 4e^- = 4OH^-$) occurs well away from the corrosion site. However, in lap-joint corrosion, the external surface often dries significantly before the occluded region (Ref 6). The lack of electrolyte on the external surface forces the cathodic reaction to occur within the occluded region. The production of OH^- ions in the cathodic reaction competes with the formation of H^+ ions in metal hydrolysis, and the result is a mildly alkaline environment in the case of aluminum (Ref 32).

Example 4: Crevice Corrosion of Titanium Alloys. Titanium alloys are among the most resistant to crevice corrosion. Extensive studies of crevice corrosion of these alloys have shown that these alloys do not suffer from crevice corrosion at temperatures less than 70 °C (158 °F). Ikeda et al. (Ref 34) have shown that by alloying with small amounts of molybdenum, nickel, or palladium, resistance to crevice corrosion is maintained to almost 200 °C (392 °F) in 10 wt.% $FeCl_3$.

Crevice Corrosion

R.G. Kelly, University of Virginia

Testing

An excellent review of testing methods has been presented by Kearns (Ref 35). This section briefly reviews the types of methods that have been developed for differentiating and ranking the resistance of alloys toward crevice corrosion. See also the article "Evaluating Crevice Corrosion" in this Volume.

Standardized Accelerated Tests. A variety of ASTM standards have been developed in which materials are exposed to severe environments for crevice corrosion. For example, the ferric chloride test (Ref 36) employs a high concentration of chloride at a low pH, with the ferric/ferrous ion couple providing an elevated potential. Increased temperature can also be used to accelerate the process.

To further exacerbate the situation, tight crevices can be imposed by using a multiple-crevice assembly (Ref 37) as shown in Fig. 8. The castellated washer provides up to 20 possible sites for crevice corrosion on each side of the coupon. By applying a consistent torque, several replicate samples can be used to develop a statistical basis for comparison of alloy resistance.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

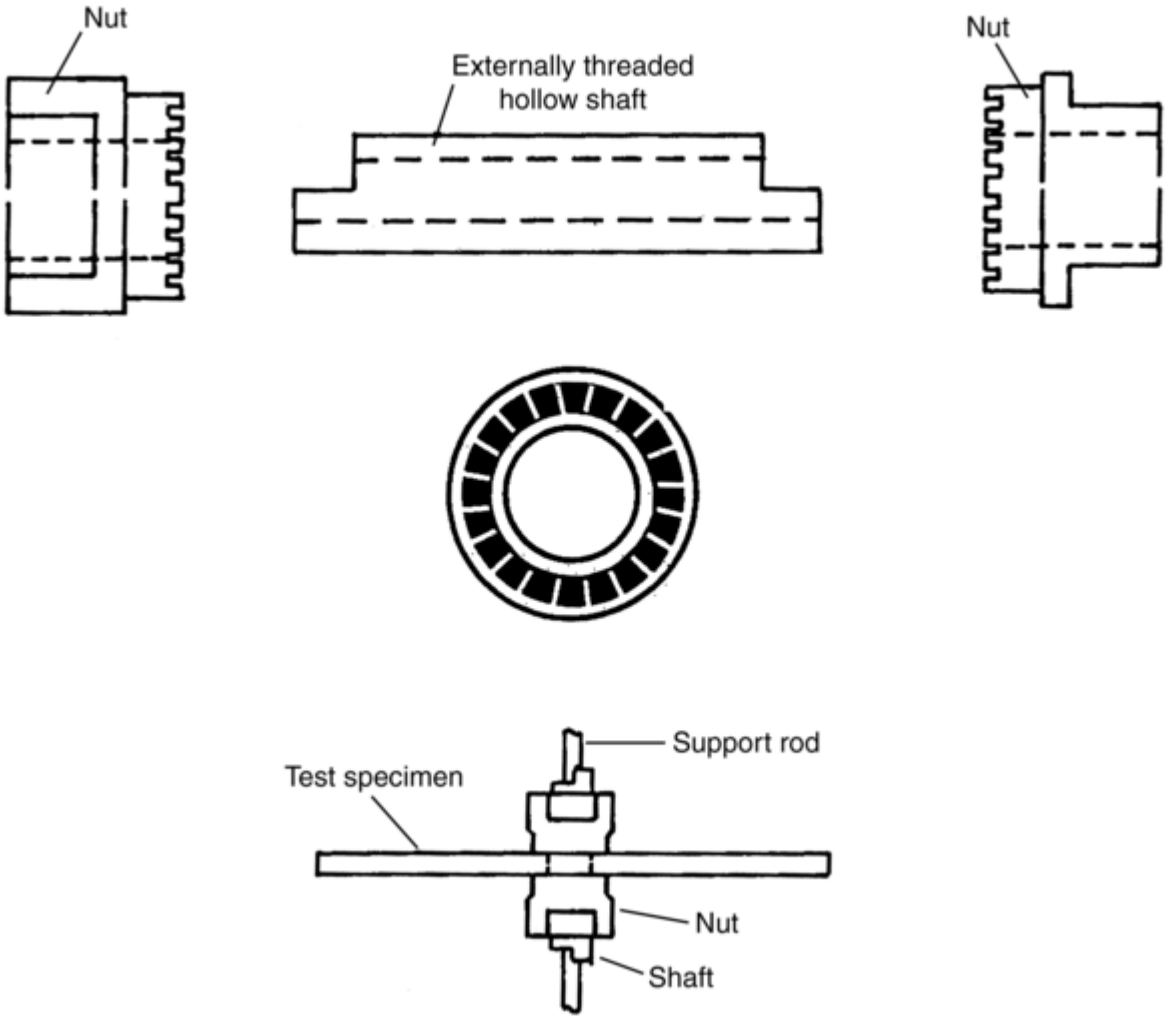

Fig. 8 Various views of the multiple-crevice assembly. Source: Ref 11

Electrochemical Testing. There are a number of tests that combine electrochemical polarization with elevated temperature to determine the critical crevice temperature (CCT). The CCT can then be used to rank the relative crevice-corrosion resistance. Typically, a constant positive potential is applied while a programmed temperature change is imposed. The current necessary to maintain the constant potential is monitored. When the applied potential and temperature combination is sufficient to cause crevice corrosion, the applied current increases dramatically and the CCT is thus determined. It has been found that this transition from passive to crevice corrosion is very sharp and reproducible (Ref 38).

Sridhar and coworkers (Ref 39) followed the work of Tsujikawa and Hisamatsu (Ref 40) by using a modification of ASTM F 746 (Ref 41) to determine the repassivation potential for crevice corrosion. In their approach, crevice corrosion is initiated under controlled conditions using a high applied potential. The ability of the material to resist localized corrosion is quantified by determining the highest applied potential at which the material can repassivate. They have shown that the repassivation potential determined in this way is an excellent measure of the long-term performance of stainless and nickel- base alloys as shown in Fig. 9 (Ref 39). They have demonstrated that a properly measured repassivation potential can be used as an engineering design criterion, not just as a comparative screening parameter. By maintaining the open-circuit potential of the surface of a material below the repassivation potential, significant localized corrosion is completely prevented. Although it has not been proved that absolutely no crevice corrosion initiates, propagation is stifled to the point of insignificance on a large engineering structure. This demonstration provides not only a valuable tool for preliminary design, but also a criterion to ensure that localized corrosion has been stopped once started.

Crevice Corrosion

R.G. Kelly, University of Virginia

Prevention or Mitigation of Crevice Corrosion

Strategies for the prevention of crevice corrosion or lessening its effects include design awareness, use of inhibitors, and electrochemical control methods.

Design. The primary means of preventing crevice corrosion is careful design. To the extent possible, passive materials should not be placed in crevice arrangements. Unfortunately, in most engineering structures complete avoidance of crevices is not practical; pipe sections must be connected via flanges, vessels are not made from a single sheet of material, and so forth. In these cases, careful design would dictate maximizing the gap and minimizing the length (depth) of any crevices created. By making the geometry less restricted, the development of an aggressive chemistry is more difficult, and the potential drop within the crevice will also be smaller.

Making a crevice so tight as to preclude electrolyte uptake is usually not practical in the long term. Extremely tight crevices that are *not* watertight exhibit tremendous capillary action, drawing in solution over long distances just as a large tree draws moisture from the soil to the top of its canopy. The extremely restricted geometry is perfect for the development of severe crevice corrosion. Even crevices that are initially “too tight for water uptake” will likely loosen with time, leading to electrolyte ingress.

Alkire and coworkers (Ref 42) have demonstrated the effects of flow on the inhibition of pitting. Similar ideas can be applied to crevice corrosion. In both instances, flow would act to inhibit *initiation* of attack to the extent that the flow lines enter the occluded region. For pit initiation, flow at the surface is very successful at delaying or preventing aggressive solution development. In a crevice, the large length-to-gap ratio makes initiation control much less effective than for pits.

Ironically, once a crevice has initiated, the flow of solution across the fully exposed surface generally acts to increase the propagation rate. This effect results from the increased flow on cathodic reactions on the fully exposed surface that are mass-transport controlled, such as oxygen reduction. As the cathodic reaction rate increases, the polarization of the internal, crevice anode increases as well, leading to increased dissolution rates. This effect is mitigated to the extent that the crevice is under ohmic control due to the restricted geometry (Ref 43).

Material selection for crevice-corrosion resistance normally follows that used for pitting resistance. Ratings based on composition have been published for ferrous materials, using the CCT as the figure of merit. There is a strong correlation between the CCT and the pitting resistance equivalence number (PREN) for stainless steels, as might be expected. In both cases, the more chromium, molybdenum, and nitrogen in the alloy, the higher the resistance. Note that the CCT is always lower than the critical pitting temperature (CPT). An example of this phenomenon (Fig. 10) shows the effect of alloyed molybdenum on the resistance of stainless steels.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

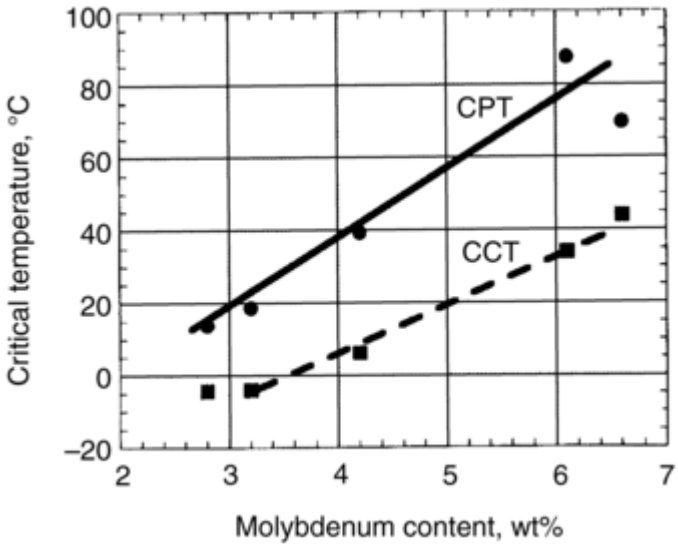

Fig. 10 Critical pitting and crevice temperatures (CPT and CCT, respectively) as a function of molybdenum content for commercial austenitic stainless steels. Source: Ref 35

In general, the lower the passive current density of the material, the smaller its active/passive transition, and the more stable its oxide, the more resistant it is to crevice corrosion. Of particular importance is the dependence of these parameters on the pH and chloride content.

Inhibitors. In addition to alloying, solution- phase inhibition has been shown to reduce the occurrence of crevice corrosion. Again, similarities to inhibitors for pitting have been observed, as expected. Inhibitors tend to be less effective for crevice corrosion than pitting because of the much longer transport lengths required for the inhibitor to move close to the active region. In order to arrive there in sufficient concentration to be effective, the bulk concentration generally needs to exceed the bulk chloride concentration by a factor of five or more (on a molar basis).

Many nonaggressive anions have been investigated as localized corrosion inhibitors in Cl^- solutions, including SO_4^{2-}, ClO_4^-, and NO_3^-(Ref 44). Anions that are not electroactive (e.g., SO_4^{2-} and ClO_4^-) have been suggested to function as inhibitors via a supporting electrolyte effect (Ref 45, 46, 47). A supporting electrolyte effect occurs when a species—for example, sulfate— competitively migrates and adsorbs on the metal surface with Cl^-, thereby slowing or preventing the increase in the Cl^- concentration in the occluded region. Thus, the relative concentration and mobility of the other anion compared to Cl^- are critically important. The presence of SO_4^{2-} would delay the accumulation of Cl^- in the occluded site, but the same occluded-site chemistry would be necessary for initiation to occur. Newman and Ajjawi (Ref 48) proposed that some inhibiting anions form a salt film during the early stages of localized corrosion initiation, under which passivation can occur via inward water diffusion. In the case of NO_3^-, an electroactive anion, Newman et al. (Ref 48, 49) proposed that inhibition occurs via one of three possible mechanisms:

- Electroreduction of NO_3^-, to NH_4^+, which consumes H^+ and produces water
- Electroreduction of NO_3^- to elemental nitrogen, which in turn blocks some proportion of the active kink sites on the surface at which dissolution occurs
- Formation of a redox couple between Fe^{2+} and NO_3^- that consumes H^+ at low pH and assists in the formation of an Fe-OH barrier film at high pH

In the case of crevice corrosion, Lu and Ives (Ref 50) has shown that cerium treatments of fully exposed surface can inhibit crevice corrosion of stainless steels. This effect is presumably by a poisoning of the rate of oxygen reduction (cerium oxides are poor oxygen reduction surfaces), which leads to an inability of the external surface to support the dissolution rate of the occluded region to the extent necessary to produce and maintain an aggressive occluded solution. Insulating coatings (e.g., paints) on the fully exposed surface can also mitigate crevice corrosion in a similar manner by reducing the ability of that surface to consume the electrons generated by the anodic dissolution within the crevice. This decrease in cathode area limits the rates of anodic dissolution

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

possible within the crevice and thereby can limit crevice corrosion. It should be noted that many corrosion-resistant alloys are notoriously difficult to paint due to poor adherence between the passive film and the organic coating. Loss of adhesion can lead to additional crevice sites.

Potential control can be effective in suppressing the initiation and propagation of crevice corrosion. The electrochemical potential of an interface can be controlled by maintaining the potential of the alloy/solution interface at sufficiently low potential; this has been shown to prevent crevice-corrosion stabilization (Ref 51). As shown in Fig. 11, the repassivation potential for crevice corrosion becomes independent of the amount of charge passed. Kehler *et al.* (Ref 5) have demonstrated the same for alloy 625 and alloy C-22, including the deleterious effects of increased temperature and concentration ratio of [Cl^-]:[other anions].

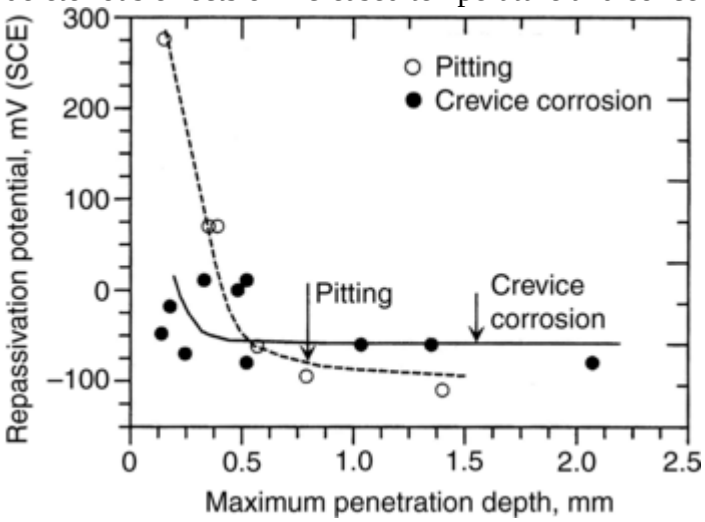

Fig. 11 The repassivation potential of alloy 825 as a function of prior crevice corrosion and pit depth. The results show a bounding value independent of penetration depth. Test conditions: 1000 ppm Cl^- at 95 °C (200 °F); back scan, 5 mV/s. Source: Ref 39

Cathodic protection can be used to combat crevice corrosion (Ref 28, 52), in some cases, with sufficiently low potentials preventing it altogether. It should be noted that anodic protection is generally not effective in preventing crevice corrosion. In fact, anodic polarization generally *increases* the rate of the crevice attack. The only situation for which anodic polarization would be useful in preventing crevice corrosion is for systems that can be completely described by the ohmic drop model and for which no changes occur in either the occluded solution composition or the electrochemical behavior of the material in the occluded region.

More information on mechanisms of crevice corrosion and the controlling factors can be found in reviews on the subject (Ref 43, 53, 54, 55).

Filiform Corrosion

Christopher Hahin, Illinois Department of Transportation; Rudolph G. Buchheit, Ohio State University

---

Introduction

FILIFORM CORROSION occurs on metallic surfaces coated with organic films that are typically 0.05 to 0.1 mm (2 to 4 mil) thick. Common objects such as a coated aluminum automobile wheel (Fig. 1) and a lacquered hammerhead (Fig. 2) are susceptible. The pattern of attack is characterized by the appearance of fine filaments emanating in random directions from one or more initiation sites. Filaments may propagate in one direction over relatively long distances. The source of initiation is usually a defect or mechanical scratch in the coating. The filaments are fine tunnels composed of corrosion products underneath a bulged and cracked coating. Filiform tracks are visible at arm's length as small blemishes. On closer examination, they appear as fine striations shaped like tentacles or cobweblike traces (Fig. 3). Though popular literature describes filiforms as “wormlike,” this corrosion is not biological in origin.

Fig. 1 Filiform corrosion on cast aluminum alloy automotive wheels that were lacquered with a clear coat to prevent dulling of the aluminum. Arrows indicate sites of significant activity. Note that each filiform originates at sharp corners where the clear coat is very thin, cracked, or severed.

Filiform Corrosion

Christopher Hahin, Illinois Department of Transportation; Rudolph G. Buchheit, Ohio State University

Occurrence of Attack

Filiform corrosion has been observed to occur under a wide range of organic coatings and proceeds with the same general characteristics on steel, aluminum, and magnesium. Filiform corrosion occurs on painted plain-carbon steel and aluminum sheet, coated steel cans, aluminum foil laminated packaging, and other lacquered metallic items placed in areas with high humidity. The susceptibility of a metal to filiform corrosion can be determined by placing coated and scribed samples in a warm humidified chamber. An initiating salt or vapor is used before humidification. If susceptible, filiform tracks will gradually grow outward from the scratches. Many of these filaments will later orient themselves in the rolling direction of the sample substrate.

Filiform attack occurs at ambient or slightly elevated temperatures when the relative humidity (RH) is between 65 and 90%. Blistering is favored over filiform corrosion when the RH approaches 100% (Ref 1). Blistering is believed to result from the fact that at high humidities organic coatings become water saturated and permeable to oxygen, making it difficult to sustain differential aeration and separation of anode and cathode. On the dry side of the humidity range, filiform corrosion of nitrocellulose lacquer coated steel has been reported at RH values as low as 58%. Filiform corrosion at even lower RH has been reported for aluminum in chemically aggressive environments (Ref 2). The average width of a filament varies between 0.05 and 3 mm (2 and 120 mils). Filament width depends on the coating, the ambient RH, and the corrosive environment. Typical filament height is about 20 μm (0.8 mil). The filament growth rate can vary widely, with rates ranging from 0.01 to 0.85 mm/day (0.4 to 35 mils/day). The depth of attack in the filiform tunnels can be as deep as 15 μm (0.6 mil) (Table 1). The fluid in the leading head of a filiform is typically acidic, with a pH from 1 to 4. Oxygen or air and water are needed to sustain filiform corrosion, indicating that filiform corrosion is a special differential-aeration cell.

Table 1 Filiform corrosion growth rates on various coated metals

Mechanism of Attack

The driving force for filiform corrosion is the voltage generated by differential aeration between its active head, which is deaerated and acidic, and a filamentous tail, which is aerated and alkaline (Fig. 4). Separation of anode and cathode is essential for filiform corrosion to occur. Substantial voltage differences of 0.3 to 0.4 V between head and tail can be measured, depending on conditions and amount of aeration. As the filiform track proceeds, the coating and metal are disbonded and the coating is lifted. The precise mechanism by which disbondment and lifting happens has not been established, but some metal dissolution is involved. Filiform corrosion will occur in environments that contain species aggressive enough to cause corrosion attack of the substrate metal. The presence of oxygen is a requirement for filiform-corrosion tracks to propagate. Oxygen is supplied to the cathodic regions behind the head of the track by diffusion through the corrosion product in the tail or by cracks in the coating uplifted by the passage of the head. A close-up of the head-tail interface is shown in Fig. 5. Filiform corrosion does not directly affect the mechanical integrity of the structure. However, it is aesthetically unpleasing and causes progressive degradation of the protective organic coating, which may lead to the onset of more damaging forms of localized corrosion. In the case of protective foils and packaging, filiform corrosion can lead to breaches in the foil barrier, allowing for vapor transmission, contamination, or slow loss of product.

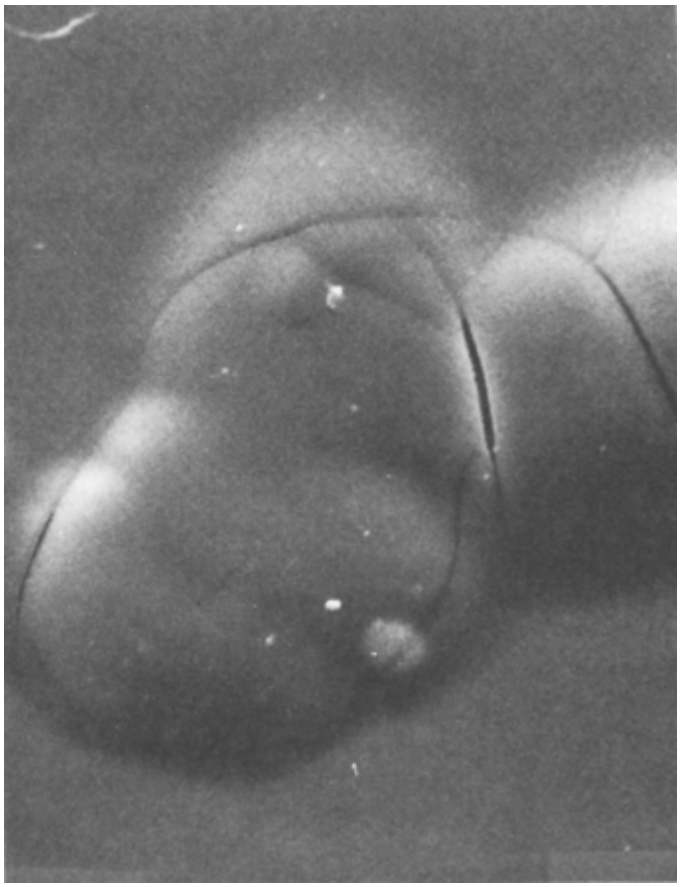

Fig. 5 Close-up of the advancing head shown in Fig. 4(a). Minute cracks can be seen at the head-tail interface of a filiform-corrosion cell. These cracks are entry points for water and air to provide a source of hydroxyl ions and an electrolyte. Intermediate corrosion products are just beginning to form in the head, and they undergo further reaction to form an expanded tail. The tail region is a progressive reaction zone that ultimately forms spent corrosion products. Between the head and porous end, ions gradually react with water and oxygen and are slowly transported in the direction of the tail to form final corrosion products. Scanning electron microscopy. 760×

Tests for Filiform Corrosion

There are numerous standard tests for filiform corrosion that involve scoring or scratching the coated specimen exposing it to corrosive fluid or vapor, and then placing it in a warm, humidified atmosphere. To accelerate filiform attack, chlorides are the commonly used corrosive ion, obtained from either from salt spray, fog, concentrated vapor, or dipping.

The standard test in the United States is ASTM D 2803, "Guide for Testing Filiform Corrosion Resistance of Organic Coatings on Metal." Coated metal specimens are scribed to bare metal and subjected to a salt fog atmosphere up to 24 h, rinsed in distilled water, and then placed wet in a closed cabinet at 25 °C (77 °F) and 85% RH. An accelerated alternate test exposes specimens in salt fog at 80% RH at 40 °C (104 °F). Time of exposure typically varies from 100 to 1000 h.

ISO 4623, "Paints and Varnishes—Filiform Corrosion Tests," is the international standard for determination of resistance and has two parts, one for steel (ISO 4623-1) and one for aluminum (ISO 4623-2). The ISO methods apply sodium chloride either by dipping specimens in solution for 60 s or by salt fogging for 24 h. Afterwards, specimens are humidified at 80% RH at 40 °C (104 °F) for a specified time. There are several other accelerated tests for aluminum used in the aircraft and automotive industries. Hydrochloric acid vapor is frequently employed as a filiform initiator.

However, the salt spray and salt fog filiform tests have been criticized as poor predictors of performance of metallic parts in actual environments. Corrosion mechanisms differ when subject to alternating wet-dry conditions rather than high concentrations of salt or continuous fog. Other atmospheres and salts besides the chloride ion can contribute to corrosive conditions (Ref 3).

Testing according to SAE J2334, "Cosmetic Corrosion Lab Test," has shown the best correlation to typical performance of automotive coatings in various locations throughout North America. The SAE J2334 test is an alternating wet-dry cycle, consisting of humidification, dipping in a combination of ionic salts, then drying at 60 °C (140 °F) and 50% RH, and then repeating this cycle up to 80 times or more. This corresponds to approximately 5 years of actual service (Ref 3). For filiforms to develop, the humidification stage should be 80 to 95% RH at 40 to 50 °C (104 to 122 °F). Many manufacturers provide a variety of humidity chambers and cabinets that are either manually operated or can automatically program test cycles for several of these standards. Additional information is provided in the article "Cabinet Testing" in this Volume.

Filiform Corrosion of Steels

Most of the early work on filiform-corrosion phenomenology and mechanisms was conducted to account for its occurrence on organically coated steel. However, as more recent research has shown, the understanding developed for filiform corrosion of steels extends with certain modifications to organically coated aluminum and magnesium alloys.

Characteristics of Filiform Corrosion in Coated and Tin-Plated Steels. Filiform corrosion has been noted for a wide range of low-alloy carbon steels and steels plated with tin. The general appearance of filiform cells on coated steels consists of an active head, which is blue, blue- green, or grayish in color, and a brownish, rusty filament-shaped tail. Filament growth tends to be more random when the steel surface has no burnished texture or pronounced rolling direction. Steels and tin-plated steels are routinely coated to provide resistance to atmospheric corrosion, to isolate foodstuffs from their containers, and to provide an adherent surface for ink and paint. Filiform corrosion is an important corrosion problem for these materials. Filiform corrosion of cast irons and high-alloy steels including stainless steels has not been reported.

The corrosion rate of steel itself is fairly low in alkaline environments but increases markedly in acidic environments, especially when the pH is less than 3. Steels can passivate under strongly oxidizing conditions. However, most natural environments are not sufficiently oxidizing to induce passivation in low-carbon steels. As a result, the primary oxidant in these environments, dissolved oxygen, serves to stimulate the corrosion of steel greatly.

Tin plating on steel is very thin, on the order of 1.5 μm (0.06 mil) thick, and is a porous barrier. In terms of corrosion, tin itself is amphoteric; it corrodes in alkaline and acidic solutions. However, it is also a seminoble metal and is not rapidly attacked in certain deaerated acids. In some environments, the porous tin layer is cathodic to the underlying steel. In aggressive environments, the tin plate provides little corrosion protection for the substrate. Steel and tin are both readily corroded by aerated acids, and conditions of low pH, aeration, and high-chloride concentrations are often found to exist in the active heads of filiform-corrosion cells.

Organic coatings are applied to steel and tin- plated steel to shield it from moist or humid environments to prevent rusting. Transparent organic coatings can also be lightly tinted with various dyes to impart a brass, bronze, or bluish cast to improve the appearance of the steel.

Filiform corrosion has been observed on steel and tin-plated steel coated with lacquers, varnish, polyurethane, boiled linseed oil, and various alkyd, urea, and epoxy paints. The coatings are applied by spraying, by direct contact with the rubber rolls, by dipping, or by electrostatic methods. Cured and dried coatings are uneven in thickness, with numerous hills and valleys. Lacquers can contain entrapped solvents if they are insufficiently cured. Scratches or scores in tin-plated cans may lead to filiform corrosion and eventual penetration of the can wall (Ref 4).

In general, organic coatings are flexible, and they tend to soften at higher temperatures. Coatings can separate from the steel substrate due to mechanical action. The ease of separation depends on how well the surface was prepared before it was coated. Organic coatings can be permeable to water and can have numerous flaws caused by inherent porosity, improper application of the coating, poor curing, or solvent entrapment. Coated articles may sustain some minor mechanical abrasions during their curing or storage. Coatings often crack if fast cured by radiant or forced-air heat, which causes shrinkage or uneven cross linking when polymerized. Coatings also crack when blistered by corrosion- product expansion, gas evolution, or water retention. Coatings, therefore, have many potential defect sources at which filiform corrosion can initiate. Heads of filiform cells will continue to remain active as long as the coating keeps expanding and cracking if moisture and oxygen are available.

Conditions Contributing to Filiform Attack. As indicated previously, filiform corrosion generally occurs in coated steels when the RH is between 60 and 95% in a temperature range of 20 to 40 °C (70 to 104 °F), though

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

the active range of RH differs for different coating systems. Filiform tracks initiate at coating defects such as cut edges, scratches, pinholes, or inclusions. Thin areas may sustain breaks caused by ultraviolet light or chemical degradation. Filiform susceptibility is increased by surface roughness and poor surface cleanliness. In terms of environmental conditions, filiform corrosion appears to occur in environments that would lead to corrosion attack of the unprotected substrate. For steels, filiform corrosion is observed to occur in chloride and sulfate electrolytes as well as in organic acids such as acetic acid.

Mechanism of Filiform Attack on Steel. As indicated previously, organic coatings on steels contain numerous defects where air and aqueous condensate can penetrate to the steel substrate and initiate corrosion. If the condensing atmosphere contains significant concentrations of salts, particularly those containing chlorides or sulfates, the substrate will corrode. Filiform attack may occur if a differential-aeration cell arises in the defect. In this situation, it is likely that the deaerated acidic anodic site is at the periphery of the defect and the aerated alkaline cathodic site is near the center of the defect. An example of such a configuration is a blister in a coating that is punctured near its center.

The solution in the advancing head of a filiform track is usually acidic, with moisture and oxygen entering primarily through the long tail or in cracks in the coating over the tail. The typical pH in the filiform head ranges from 1 to 4. Once established, potential-measurement regions normally indicate a potential difference of up to 0.3 V between the head and tail (Ref 5). Anions such as chloride, sulfide, or sulfate may enter the head from a corrosive atmosphere or by direct deposition on the surface and combine with the condensed water vapor that percolates through the cracked coating. Corrosive agents from the environment may be supplemented by continual leaching of solvents or unreacted constituents of the coating that combine with water. The head is filled with ferrous ions and the tail with ferric hydroxides and hydrated iron oxides, depending on the position in the tail and the age of the filaments.

During filiform propagation, the head moves along the coating metal interface, dissolving some of the substrate and forcing the coating from the steel substrate by corrosion product expansion. If the coating remains wet, adhesion to the substrate continues to decline (Ref 6). Behind the head, the new open space is filled with corrosion products or hydrogen gas from hydrogen reduction in the acidic filiform track head (Ref 7). The constant forward motion of a filament will cease if the tail is not continually aerated and supplied with water-vapor condensate. Interestingly, the advancing head of a filament is deflected or halted when it contacts a tail of another filiform. Why this occurs is not precisely known. The phenomenon may involve disruption of the differential-aeration cell on which filiform propagation depends, or a change in the acidic head chemistry as it encounters a filiform track, which may be more alkaline.

The mechanism of coating-substrate separation in the head region is not yet fully understood. Filiform heads tend to progress predominantly in the forward direction rather than spreading in a uniform radial manner. Microscopic valleys generated by rolling or grinding typically have less oxygenation when filled with the coating, whereas hills would have more aeration, and may be populated with harder, intermetallic cathodic sites. In advanced cases of filiform attack, head tunneling may appear to be more random. Corrosion product expansion and the undercutting of the coating-steel interface in the head are major contributors to filament head bulging (Ref 6). Head and tail solution chemistry may also affect the film strength of the coating and its bonding to the steel substrate. The head is a moving pool of acidic electrolyte, while the tail is alkaline and filled with corrosion products. The alkalinity of the tail region may lead to local saponification in susceptible resins causing cracking and debonding.

The size of a filament is apparently governed by the original defect size and the flexibility of the film. The texture of the rolled surface and the nature of the coating also shape the geometry and the spread rate of filiform attack. The ferrous ions formed in the head are transported toward the tail and further oxidized in the first section of the tail by forming ferric hydroxide.

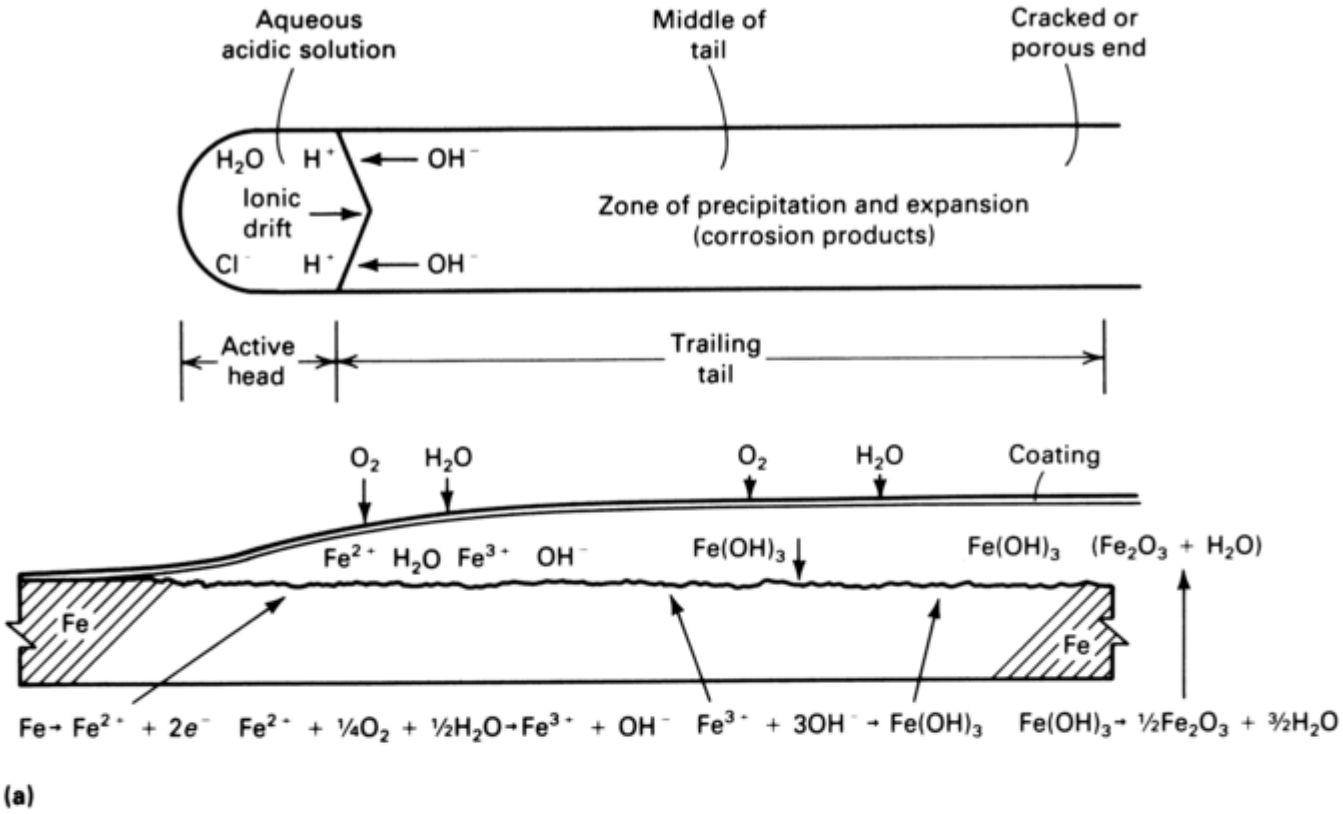
Water and oxygen can enter the cell at cracks in the coating in the tail region or at the head- tail interface. Water is either consumed by the head electrolyte or can be involved in cathodic reactions. Hydroxyl ions are generated by the oxygen-reduction reaction, which takes place in the tail:

$$O_2 + 2H_2O + 4e^- \leftrightarrow 4OH^- \qquad \text{(Eq 1)}$$

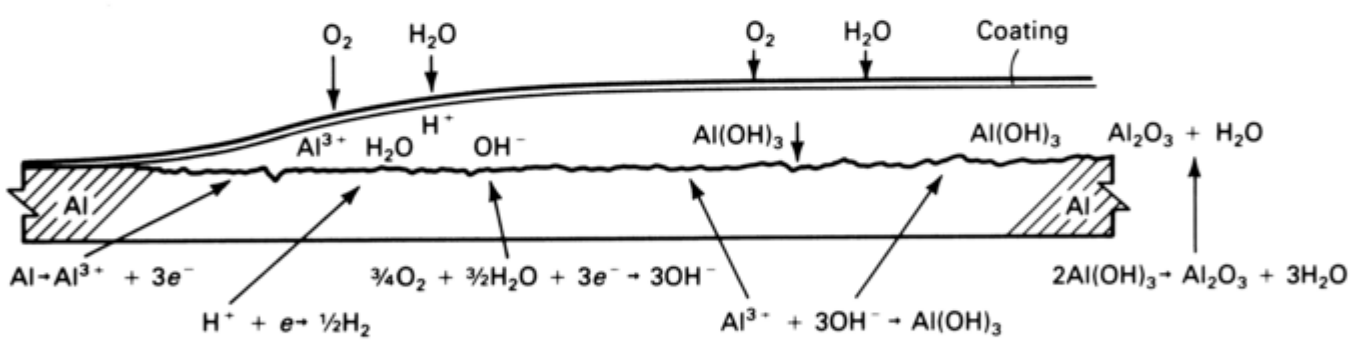
There is a general transport of iron ions toward the tail region, where they combine with hydroxyl ions to form ferric hydroxides. Toward the end of the tail, ferric hydroxide may decompose to ferric oxide and water. Other hydrated corrosion products may also form. Because the corrosion products of iron expand considerably, the coating bulges or splits. As the coating further cracks or splits, more oxygen and water can enter the tail, further stimulating filiform corrosion, blistering, or general corrosion of the substrate. In some brittle coatings, the head

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

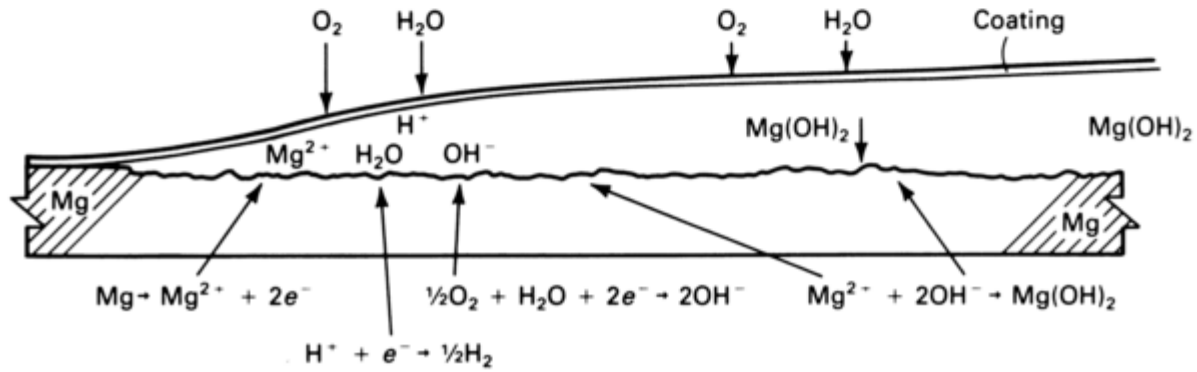
may be very small, and cracks may form rapidly. The filiform head is an advancing pool of acidic electrolyte, whereas the tail is a progressive zone of corrosion products and reactants converted to an expanded gel or perceptible iron oxides. A general diagram illustrating the mechanism of filiform corrosion in iron and steel is shown in Fig. 6(a).



(a)



(b)



(c)

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 6 Diagrams of the filiform-corrosion cell in steel (a), aluminum (b), and magnesium (c). Corrosion products and predominant reactions are labeled. Filiform corrosion is a differential-aeration cell driven by differences in oxygen concentration in the head versus the tail section. Potential differences between the head and tail are of the order of 0.1 to 0.2 V.

Water is required to form an electrolyte and to stimulate hydroxyl production. Water is necessary for the formation of new heads from a central defect source. The corrosivity of the head electrolyte is increased when salts are present on the surface or in the condensed water vapor. High salt concentrations in the head electrolyte decrease oxygen solubility and may further acidify the head solution. Several studies have shown that sealing the cracked tail halts filiform corrosion (Ref 8, 9, 10). By sealing the porous tail with epoxy, oxygen was prevented from entering. Similar effects were achieved by replacing oxygen with nitrogen gas. The driving force of the reaction—differential aeration—was stopped, and the filiform heads ceased to advance.

In the case of tin-coated steels, filiform corrosion is slowed if the tin coating weight is more than 0.35 g/m^2. However, if the coating weight is between 0.1 and 0.35 g/m^2, an acceleration of filiform corrosion is noted (Ref 11). Since heavier weight tin coatings are relatively more uniform than light coatings, the retardation of filiform corrosion is presumably due to polarization of the oxygen-reduction reaction. Stimulation of filiform corrosion by lower-weight coatings was attributed to reinforcement of local galvanic cells by the highly porous, light weight coating of tin.

Filiform Corrosion of Coated Aluminum and Magnesium

Filiform corrosion is frequently observed on coated aluminum sheet, plate, and foil, and on magnesium sheet and castings and is of interest to the automotive and aircraft industries. The appearance of filiform corrosion in aluminum and magnesium is similar to that of iron and steel, except that the corrosion products are gelatinous and milky in color. When dry, their filaments may take on an iridescent or clear appearance because of internal light reflection. Filament growth rates for aluminum are similar to those of coated steels. Magnesium has somewhat higher growth rates than aluminum. Filiform attack in both aluminum and magnesium is particularly severe in warm coastal and tropical regions where aerosolized salt occurs or in industrial areas where airborne-pollutant concentrations are high.

Aluminum is susceptible to filiform corrosion in RH ranging from 75 to 95%, and at temperatures between 20 and 40 °C (70 and 105 °F). Filiform corrosion at low RH can occur in the presence of HCl vapor (Ref 10). In such situations, filiform propagation has been reported for relative humidities as low as 30%. Filiform tracks grow most rapidly at 85% RH in aluminum. Typical filament growth rates average about 0.1 mm/day (4 mils/day). Filament width varies with increasing relative humidity—from 0.3 to 3 mm (12 to 120 mils). The depth of penetration in aluminum can be as deep as 15 μm (0.6 mil). Numerous coating systems used on aluminum are susceptible to filiform corrosion, including epoxy, polyurethane, alkyd, phenoxy, and vinyls. Condensates containing the chloride, bromide, sulfate, carbonate, and nitrate ions can stimulate filiform growth in coated aluminum alloys. Growth rates for filiform corrosion on aluminum and magnesium coated with lacquers and various slower drying resins are summarized in Table 1.

Tests for Filiform Corrosion of Aluminum Alloys. In addition to the standard ASTM and ISO tests for filiform corrosion on aluminum, several other tests are widely used in the aircraft industry. In DIN 65472, “Filiform Corrosion Test of Coatings on Aluminum” (sometimes referred to as the Lockheed test), the scribed samples are exposed to fuming hydrochloric acid (HCl) for 60 min. In the modified Lockheed test, specimens are immersed in saturated aluminum chloride ($AlCl_3$) solution for 120 min. Afterward, samples are placed in a humidity cabinet at 82% RH for 1000 h at 40 °C (104 °F). Lengths of filiforms are quantified in millimeters for comparison of different coatings and substrate treatments.

NATO endorses the use of British Standard EN 3665, whereby 2024-T4 clad aluminum panels of 100 by 40 by 0.8 mm (approximately 3.9 by 1.6 by 0.031 in.) are chromate pickled, coated, scratched through the clad layer, and then exposed to fuming HCl acid vapors for 1 h at 23 °C (73 °F). Panels are subsequently placed in a humidity chamber at 40 °C and 82% RH for 1500 h. The degree of filiform damage is also evaluated by filament length (Ref 12).

These tests provide for rapid screening and comparison of various coatings and treatments of aluminum-copper alloys. They can also be applied to screening and qualitative evaluations of other aluminum alloys of the 3*xxx*, 5*xxx*, 6*xxx*, 7*xxx* and 8*xxx* series.

Mechanism of Filiform Attack on Aluminum and Magnesium. In many respects, filiform corrosion on aluminum and magnesium is similar to that on steels. Filiform corrosion is driven by the formation of differential-aeration cells at defect sites on coated substrates. The filiform cell consists of an active head and a tail that receives oxygen and condensed water vapor through cracks in the applied coating. In aluminum, the head may be filled with alumina gel. Gas bubbles may be present if the head is very acidic. In magnesium, the head appears blackish because of the etching of the magnesium, but the corrosive fluid is clear when the head is broken. Filiform tails in aluminum and magnesium are whitish in appearance. The corrosion products are hydroxides and oxides of aluminum and magnesium, respectively. Anodic reactions produce Al^{3+} or Mg^{2+} ions, which react to form insoluble precipitates with the hydroxyl ions produced in the oxygen-reduction reaction occurring predominately in the tail.

www.iran_mavad.com

مرجع مهندسی مواد و متالورژی

The mechanism of initiation and activation in aluminum and magnesium are essentially the same as for coated steel, as shown in Fig. 6(b) and (c). The acidified head is a moving pool of electrolyte, but the tail is a region in which aluminum ion transport and gradual reaction with hydroxyl ions take place. The final corrosion products are partially hydrated and fully expanded in the porous tail. The head and middle sections of the tail are corresponding locations for the various initial reactant ions and the intermediate products of corroding aluminum in aqueous media.

In contrast to steel, aluminum and magnesium show a greater tendency to form blisters in acidic media, with hydrogen gas evolved in cathodic reactions in the head region. The corrosion products in the tail are either aluminum trihydroxide ($Al(OH)_3$), a whitish gelatinous precipitate, or magnesium hydroxide ($Mg(OH)_2$), a whitish precipitate.

Surface-Active Layers. A high incidence of filiform-corrosion damage on painted aluminum architectural alloys used in Western Europe triggered a systematic investigation of the origins of the problem in the late 1980s and early 1990s (Ref 13). One of the root causes was determined to be an electrochemically active layer that formed on the surface of hot-rolled aluminum sheet product. Such layers, termed surface-active layers (SALs), and their effect on filiform corrosion were characterized and described in several reports published through the late 1990s (Ref 14, 15, 16, 17, 18).

Surface-active layers have been found on 1*xxx*, 3*xxx*, 8*xxx* Al alloys and may exist on certain 5*xxx* and certain 6*xxx* alloys. These layers form during hot rolling or annealing heat treatments carried out either in air or vacuum. Surface active layers are about 1 μm (0.04 mil) thick and consist of small, submicrometer grains and a dispersion of small noble intermetallic and magnesium oxide particles. The anodic activity of SALs is primarily attributed to the fine grain size and enrichment of alloying and trace elements in the layer, most notably magnesium. Noble intermetallic particles such as Al_3Fe dispersed throughout the layer are believed to be important in triggering electrochemical activity of the layer by forming microgalvanic couples with the surrounding SAL matrix. When noble intermetallic particles are not present in the SAL, electrochemical activity of the layer is decreased, supporting the notion that intermetallic particles play a key role in determining SAL activity. Figure 7 shows an ultramicrotomed cross section of a SAL on Al alloy 8006-O, and Fig. 8 shows the key microstructural characteristics of SALs.

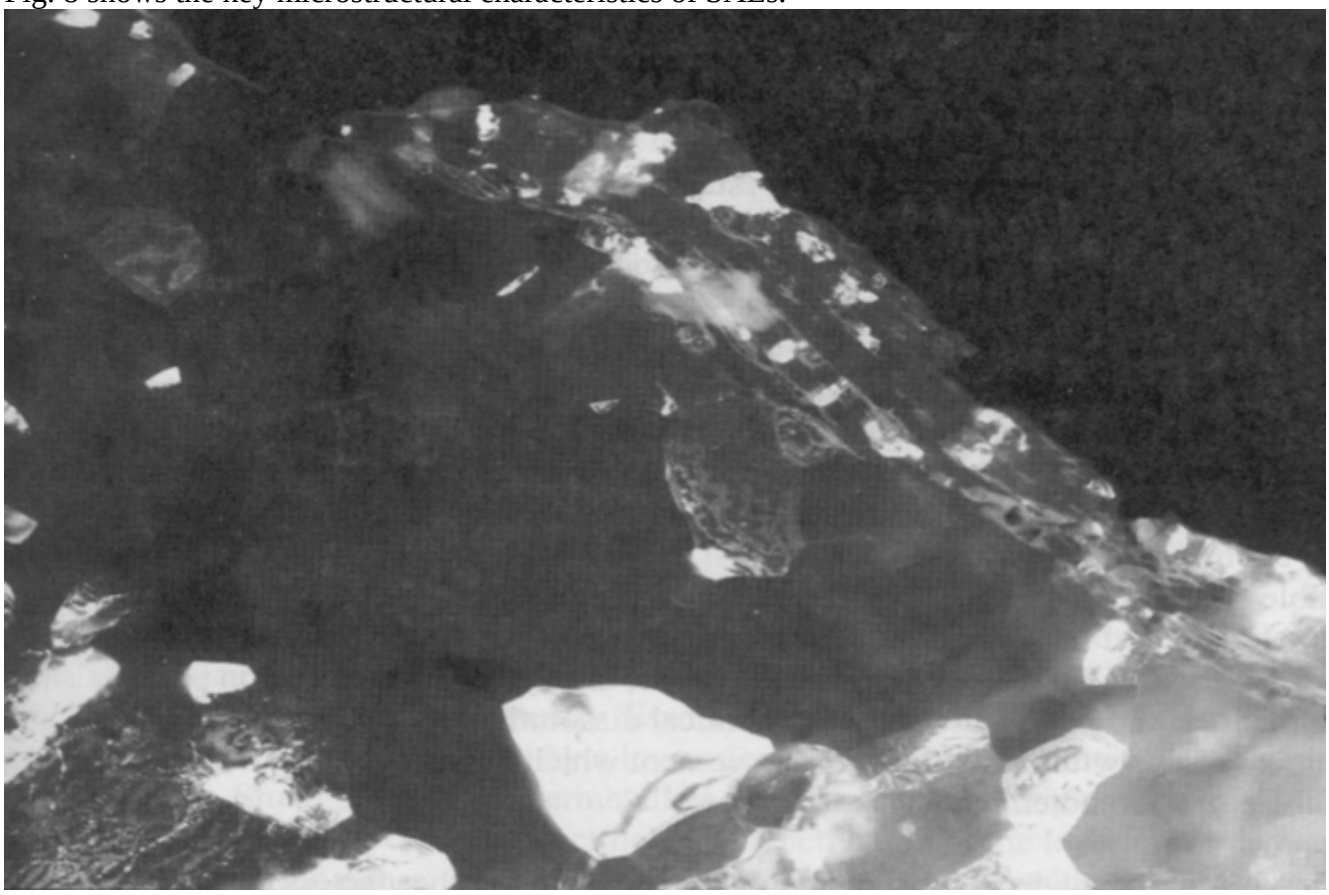

Fig. 7 Dark-field transmission electron micrograph showing a cross section through a surface-active layer on aluminum-iron alloy 8006-O

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

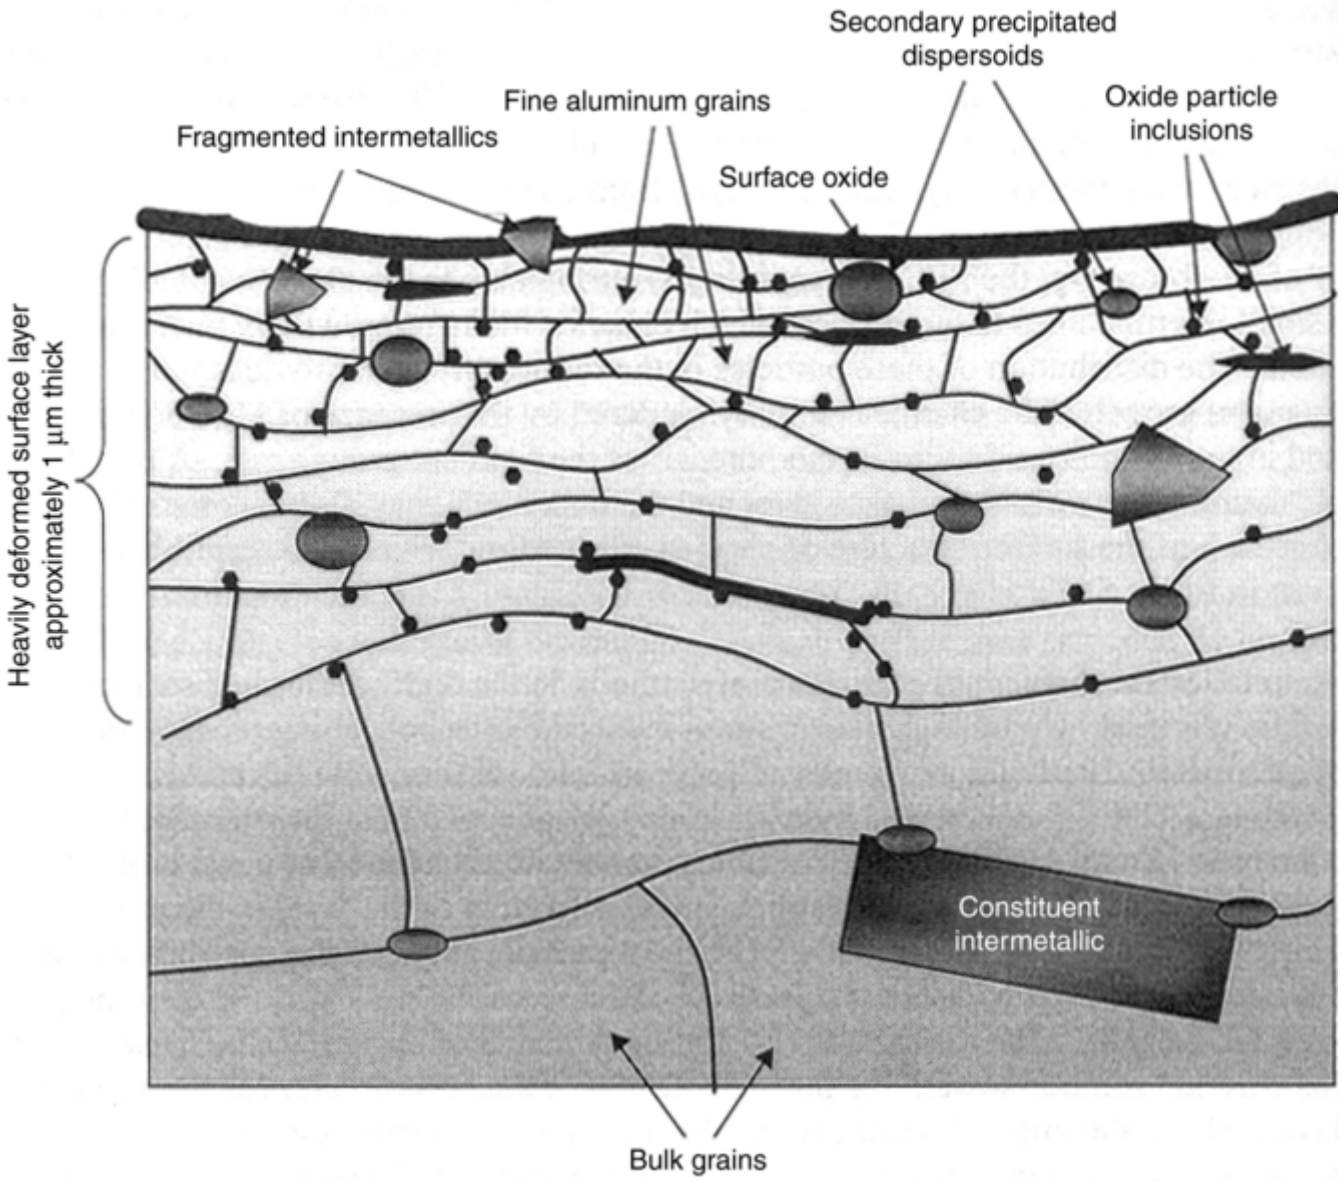

Fig. 8 Schematic of the near-surface microstructure of a rolled aluminum-manganese alloy showing the main microstructural characteristics of surface-active layers

Formation of SALs depends on alloy chemistry, thermal history, and to a lesser extent deformation processing by rolling. It has been observed that alloys with less than 100 ppm Mg develop less-active surface layers than alloys with magnesium contents greater than this threshold value. To activate this magnesium oxide particle-rich layer, noble alloying elements such as iron, copper, and silicon *must* be segregated into intermetallic particles at the surface. Manganese is also normally present in alloys that form active layers, but its role in the electrochemical aspects of the process is difficult to ascertain based on current reports. It is important to emphasize that electrochemical activity has only been observed when both a magnesium-rich oxide layer and noble intermetallic particles are present in the surface layer. Accordingly, the highest-purity aluminum alloys (1*xxx*) do not exhibit surface layers that are active.

In an interesting twist on the issue, it has been suggested that magnesium-oxide-rich layers may confer useful levels of sacrificial cathodic corrosion protection if the noble intermetallic particle population is small. In the thermomechanical processing of sheet product, elevated- temperature processes such as hot rolling and annealing stimulate SAL formation. In particular, elevated-temperature treatments promote segregation of trace elements to external surfaces and the high density of grain boundaries present in fine-grained surface layers. Very active layers have been formed by annealing at 440 °C (824 °F) for 1 to 2 h in air. Elevated-temperature processes may also promote precipitation of certain noble intermetallic particles. Rolling itself does not appear to greatly promote layer activity unless it is carried out at elevated temperature. However, cold rolling does tend to leave rolling marks on the sheet surface that preferentially orient filiform tracks along the rolling direction.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Surface-active layers can be detected by electrochemical corrosion tests, but since the layers are quite thin, transient approaches or experiments that can be completed in the short time before the layer dissolves must be used. Evidence of SALs can be detected in open-circuit potential measurements, where very active potential values are recorded at first. With time, the potential drifts in the noble direction as the layer dissolves away, exposing the underlying alloy substrate. Anodic current transients collected over several minutes during anodic polarization are strongly enhanced by the presence of SALs.

Other factors being equal, filiform-corrosion susceptibility is strongly enhanced when thin organic coatings are applied directly over SALs. Enhanced susceptibility is characterized by an increase in the number density of filiform tracks and an increase in the kinetics of filiform-track propagation. Often, filiform-track growth is strongly oriented in the rolling direction when SALs are affecting the process.

Remediation of filiform susceptibility due to SALs can be accomplished using standard metal-finishing practices. Chemical etching, chemical conversion coating, conversion coating with cerium chloride additions, or anodization can all be used to dissolve away the active layer. However, surface treatment must be sufficient to fully dissolve the SAL. Of these treatments, electropolishing reduced filament length the most. Electropolishing removed SALs and produced a microscopically flat surface (Ref 19).

Filiform Corrosion in Aircraft. Aircraft are routinely painted for corrosion protection, decreased drag resistance, and identification. Aircraft structural components and skins are routinely fastened with bolts and rivets and have numerous exposed faying surfaces where debris and moisture can lodge. These fasteners and other sharp skin edges are common initiation sites for filiform corrosion (Ref 20). Aircraft operating in warm, marine environments sustain considerable corrosion damage. In recent years, filiform corrosion was observed on 2*xxx* and 7*xxx* series aluminum alloys coated with polyurethane and other coatings (Ref 21, 22). Aluminum-copper alloy 2024-T4 is an aircraft material susceptible to filiform corrosion because of the presence of iron-bearing intermetallic compounds. The presence of 0.25% or more iron in 2024 accentuates the formation of long filiform threads (Ref 23). Filiform corrosion increased in severity when chloride concentrations on the metal were high, particularly when the aircraft were frequently flying over ocean waters or based in coastal airfields and hangars. Prepainted surface treatment quality and the choice of primers were also important in controlling filiform corrosion. Two-coat polyurethane and primed two-component epoxy paint systems experience far fewer incidences of filiform corrosion than single-coat systems did (Ref 24). Filiform corrosion rarely occurred when bare aluminum was chromic-acid anodized or primed with chromate or chromate-phosphate conversion coatings. Rougher surfaces also experienced a greater severity of filiform attack. If left unchecked, filiform corrosion may lead to more serious structural damage caused by other forms of corrosion such as pitting and intergranular corrosion.

Filiform Corrosion in Packaging. Aluminum is widely used for cans and other types of packaging. Aluminum foil is routinely laminated to paper, plastic film, or paperboard to form a moisture or vapor barrier. If the aluminum foil is consumed by filiform corrosion, the product may be contaminated, lost, or dried out because of breaks in the vapor barrier. Typical coatings on aluminum foil are nitrocellulose and polyvinyl chloride (PVC), which provide a good intermediate layer for colorful printing inks.

Degradation of the foil-laminated paperboard may occur during its production or its subsequent storage in a moist or humid environment (Figure 9). During the production of foil-laminated paperboard, moisture from the paperboard is released after heating in a continuous-curing oven. Heat curing dries the lacquer on the foil. Filiform corrosion can result as the heated laminate is cut into sheets and stacked on skids, while the board is still releasing stored moisture. As shown in Fig. 10, the hygroscopic paperboard is a good storage area for moisture. Packages later exposed to humidities above 75% in warm areas can also experience filiform attack. Coatings with water-reactive solvents, such as polyvinyl acetate, should not be used. Any solvents entrapped in the coating can weaken the coating, induce pores, or provide an acidic media for further filament propagation. Harsh curing environments can also result in the formation of flaws in the coating due to uneven shrinkage or rapid volatilization of the solvent. Rough handling can induce mechanical rips and tears.

Prevention of Filiform Corrosion

Prevention and mitigation of filiform corrosion is accomplished through adjustment of the environment and changes in the substrate and coating systems.

Reduction in Relative Humidity below 60%. Although the most direct method, reducing relative humidity is not practical if the metal is exposed to the elements or is in motion, as is the case for aircraft and automobiles. For

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

articles in longer-term storage, controlled environments are beneficial—for example, the use of drying fans and humidistats or the addition of desiccants to plastic packaging or to small, confined areas. Structural designs can prevent moisture entrapment by better drainage or by attempting to exclude moisture entry. Reducing the ambient temperature can also be beneficial because it results in a decrease in the amount of moisture the air can hold.

Use of Primers, Anodizing, and Other Preventatives. Filiform corrosion is reduced when the steel substrate is galvanized. Zinc-rich primers, chromated and phosphatized primers, with tough, slow curing intermediate coats of polyurethane and epoxy, have reduced filiform susceptibility on steel substrates. Zinc chromate primers, chromic acid anodizing, and chromate or chromate-phosphate conversion coatings have provided varying degrees of relief from filiform corrosion in aluminum alloys. Water-displacing oils and other penetrating film formers provide only temporary relief from filiform corrosion on aluminum surfaces (Ref 25).

Multiple-Coat Paint Systems and Powder Coatings. Multiple coats on metal surfaces slow down diffusion of moisture and have fewer penetration and defect sites than single-coat paint systems. Multiple-coat systems resist penetration by mechanical abrasion and have fewer hills and valleys. Thicker coatings achieved by layer buildup and slower curing have demonstrated substantially better resistance to filiform corrosion by decreasing oxygen and moisture penetration, decreased solvent entrapment, and fewer initiation sites. Powder coating systems are also beneficial, since they are thermally fused, resulting in tough coatings with better resistance to moisture permeability. Smooth, well-prepared primed metal surfaces generally have better resistance than rougher surfaces.

Use of Less-Active Metal Substrates. Steel, aluminum, and magnesium are all chemically active. Their alloys contain intermetallic compounds, which can be dispersed, precipitated, and agglomerated during hot rolling and annealing. Although these alloys generally have improved mechanical properties, recent work shows that their heterogeneity and presence of SALs increase their susceptibility to filiform corrosion. Careful surface preparation is important in limiting the effects of these detrimental active layers. The substitution of more-resistant materials exposed to the initiating environment, such as copper, austenitic stainless steel, or titanium, may be necessary. Unless a coating is mandatory, a material substitution may eliminate the central part of the problem. Economics and structural considerations, however, will usually dictate whether a material substitution is a practical solution.

Introduction to Metallurgically Influenced Corrosion

G.S. Frankel, The Ohio State University

Introduction

THE FUNDAMENTAL UNDERSTANDING of electrochemical corrosion kinetics is based on the uniform dissolution of an unfilmed, pure, homogeneous metal that is equally exposed at all locations to a homogeneous environment. Corrosion engineers know that this description does not reflect reality in practical situations. In many engineering structures, dissimilar alloys are connected in a variety of ways, crevices often exist, and the environment is variable and dependent on local flow conditions. Furthermore, metals and alloys are typically covered with a surface layer. Their corrosion behavior is influenced by the surface layer and by a host of metallurgical factors. Even extremely pure single crystals have defects that can affect corrosion, but impurities and alloying elements, grain boundaries, second phases, and inclusions often have a dominant effect. Finally, welded structures almost always corrode first at the welds because of metallurgical heterogeneities that exist in and near welds. In general, the most susceptible site or defect on a metal surface will be the first to be attacked when it is exposed to a corrosive environment. Sometimes such attack simply results in innocuous removal of the susceptible material, leaving a surface with improved corrosion resistance. The most susceptible defects that lead to sustained attack will control the form of corrosion.

The corrosion resistance of stainless steels and nickel-based alloys varies markedly depending on the alloying elements and processing conditions. Under many conditions, stainless steels exhibit localized corrosion, which is greatly affected by the alloy composition and metallurgical factors. Pitting corrosion in stainless steels often initiates at MnS inclusions owing to the reactivity of the sulfides and the effect of the S- containing dissolution products on the nearby passive film. The formation of carbides at grain boundaries can reduce corrosion resistance through the formation of susceptible Cr-depleted zones in the neighboring matrix. A continuous network of such Cr-depleted zones can render stainless steel sensitized, or extremely susceptible to sustained intergranular corrosion or stress corrosion cracking. Other phases, such as sigma and chi phases, can also be detrimental, especially in oxidizing environments. On the other hand, stainless steel does not always corrode by a localized form of attack. When a solutionized low-sulfur stainless steel is exposed to boiling nitric acid, the attack is not local in nature but rather is dominated by the orientation of the grains so that a stepped structure develops with the most susceptible orientations corroding faster.

The corrosion resistance of aluminum alloys is completely dominated by metallurgical factors. High-purity aluminum is rather resistant to corrosion in most neutral pH environments. The passive film is relatively insulating, protective, and noncatalytic. However, commercial aluminum alloys contain alloying elements, impurity elements, precipitated phases and intermetallic constituent particles. The precipitated phases and intermetallic particles can be anodic or cathodic relative to the matrix or can switch between the two with time as a result of selective dissolution. Anodic particles can be initiation sites for pitting corrosion, and cathodic particles can be active cathodes, supporting the cathodic reaction necessary for sustained attack. These phases can form at grain boundaries and result in a sensitized structure if the grain boundary precipitate or neighboring solute-depleted zone is susceptible to sustained attack. Wrought aluminum alloys often have an elongated grain

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

structure, which can result in susceptibility to exfoliation corrosion or orientation-dependent stress corrosion cracking. Solid solution alloying of aluminum can alter the susceptibility to localized corrosion, either decreasing, as with copper alloying, or increasing the susceptibility as in the case of zinc alloying. Clearly, the metallurgical effects on the corrosion of aluminum alloys are varied and complex.

When an alloy composed of a solid solution of various elements corrodes, it is typical that one or more elements dissolve preferentially, leaving other elements enriched on the surface. This dealloying process depends strongly on nonmetallurgical factors such as environment and potential. However, the dealloyed microstructure is vastly altered, often resulting in a reduction of strength and other properties.

Welded microstructures can be extremely complex and often change drastically over a very short distance. The fusion zone or weld metal is a dendritic structure that solidified from a molten state. Bordering the fusion zone are transition, unmixed and partially-melted zones, and the heat affected zone (HAZ). These zones can be reheated and altered by subsequent weld passes in multipass welding. For alloys with structures that depend strongly on thermal history, such as steels, the final microstructure can be extremely complex. Since welded structures are often quite susceptible to corrosion, over-alloyed filler metals are often used to enhance the weld corrosion resistance. For stainless steels with sufficiently high carbon content, sensitization in the HAZ is another major problem.

Corrosion is a reaction between a metal and its environment, and both are important in the process. The articles presented here focus on the metal side of the corrosion reaction and describe a wide range of metallurgical factors that influence corrosion.

Effects of Metallurgical Variables on Aqueous Corrosion

James J. Noël, University of Western Ontario

Introduction

THE CORROSION BEHAVIOR of a metal or alloy is determined by its composition and structural features, the environment and stresses to which it is exposed, and the behavior of any corrosion products generated (e.g., formation of passive films or hydrolysis to produce acidity). This article provides an overview of the ways in which the metallurgical variables, namely composition and structure, influence the corrosion properties of metals and alloys.

Effects of Metallurgical Variables on Aqueous Corrosion

James J. Noël, University of Western Ontario

Fundamentals of Pure Metals, Impure Metals, and Alloys

The fundamental nature of pure elements and materials containing alloying elements and impurities provides a starting point for a discussion of the metallurgical influences on corrosion.

Pure Elements. Nominally pure metals are crystalline in the solid state. Except in the very rare applications that make use of individual (single) crystals, masses of pure metal in practical use are polycrystalline; that is, they are made up of a large number of individual, irregular-shaped crystals (commonly called grains), fully joined together at the atomic level.

Usually, the spatial orientations of different grains (as defined by their intrinsic crystallographic planes) are random with respect to each other (Ref 1). This means that there must be a zone of transition over which the crystallographic orientation changes from that found in one grain to that found in its neighbors. This transitional zone is known as a *grain boundary* and is a three-dimensional region of little or no long-range crystallographic order, although some short-range order is usually present. This disorder makes grain boundaries energetically favorable sites of residence for impurities and other imperfections.

Other regions of atomic disarray can be found, even within individual crystals, in the form of *defects*—imperfections arising from a number of sources—the most significant of which are described in the following paragraphs. Defects may be classified according to their spatial dimensionality, which may be 0, 1, or 2.

Point defects (zero-dimensional) are atom- sized imperfections in crystals (Fig. 1). These include interstitial atoms, which are atoms present in the spaces between the lattice positions, vacancies (the absence of one or more atoms from the crystal lattice), and foreign atoms in lattice positions. Point defects may be present in the metal from the time of its solidification or introduced later by heating, plastic deformation, or bombardment with high-energy radiation.

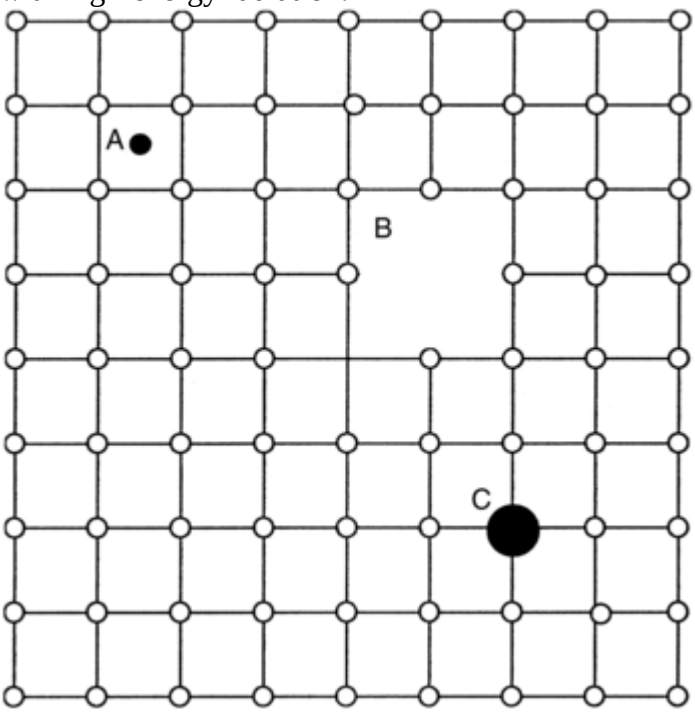

Fig. 1 Point defects. A, interstitial atom; B, vacancy; C, foreign atom in lattice site

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Line defects (one-dimensional) are of two types—edge dislocations and screw dislocations. An edge dislocation (Fig. 2) is the region of imperfection that lies along the internal edge of an incomplete plane of atoms within a crystal. In a screw dislocation (Fig. 3), a portion of the crystal is displaced such that the atom planes no longer have a separate existence but rather comprise a single, continuous ribbonlike structure in the form of a helical ramp or screw thread with a pitch of one interplanar spacing per turn. The screw dislocation is the line of distortion that lies along the axis of the ramps perpendicular to the atom planes.

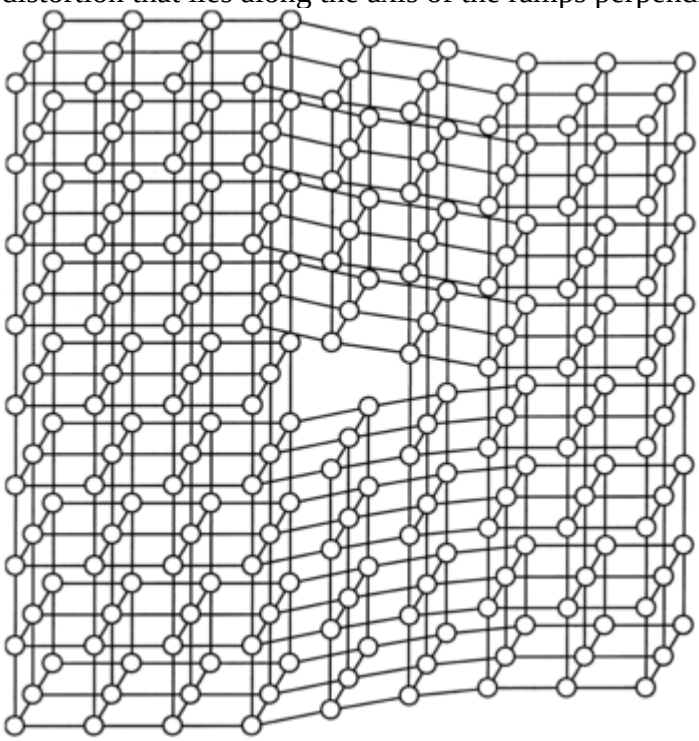

Fig. 2 Edge dislocation

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

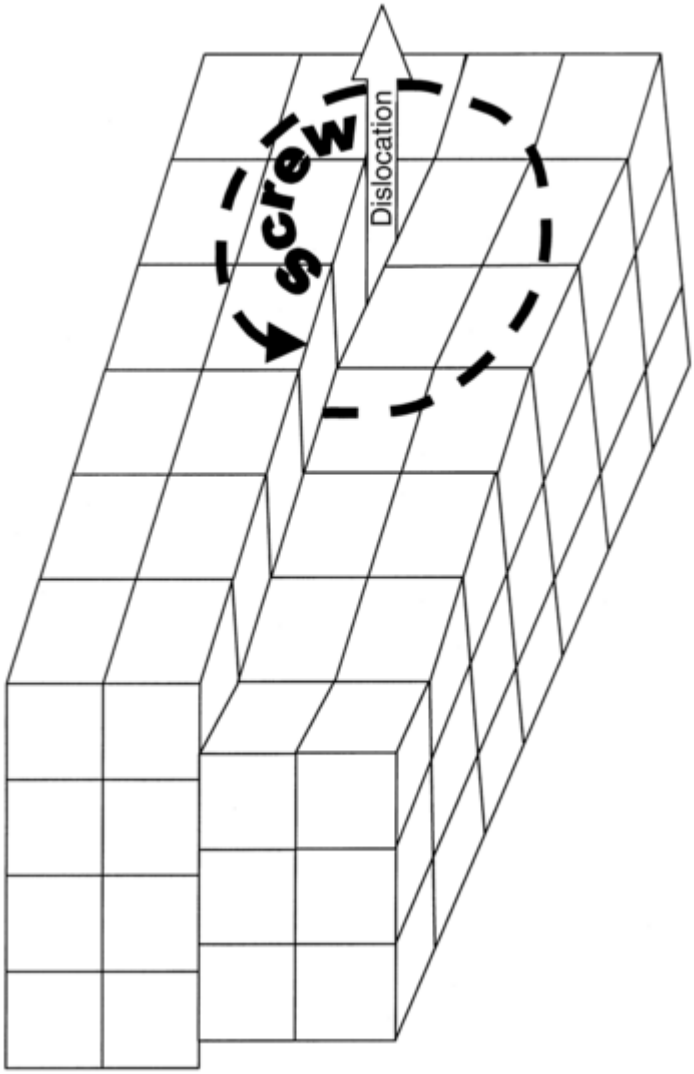

Fig. 3 Screw dislocation

It is geometrically impossible for a dislocation to have a terminus located within a perfect region of a crystal; it must terminate at a free surface, at a grain boundary, on another dislocation, or on itself. In principle, dislocations may lie on any crystallographic plane but are usually found along the planes of most-dense atomic packing. These two features promote the formation of networks of combined screw and edge dislocations, which can be quite extensive within the crystal along the most closely packed crystallographic planes. Dislocations can be created by plastic deformation of a crystal, and their movements are important in determining the deformation properties of a material (Ref 1).

Plane defects-stacking faults (two-dimensional) are imperfect regions of a crystal resulting from errors in the positioning of entire atomic layers. Stacking faults consist of an error in the sequence of crystallographic layering within a crystal that disrupts the expected order of a perfect crystal of that type. Stacking faults can arise during crystal growth or as a consequence of plastic deformation but can only occur along the close-packed planes within a crystal (Ref 1).

For example, both the face-centered cubic (fcc) and hexagonal close-packed (hcp) crystal types are built of stacks of the same type of close-packed atomic layers. The difference between the two lattices is in the registry between each close-packed plane and the ones above and below it. In a fcc crystal, three different alignments of the close-packed planes are required. These are denoted *a*, *b*, and *c*. Thus, a fcc crystal is built of stacks of these layers in the sequence *abcabcabc* and so forth. In a hcp crystal, only two different alignments of the close-packed layers are required, and the sequence is *ababab* and so forth. If, for instance, within a fcc crystal, an error is made in the sequencing of layers such that the order is abcababcabc and so forth, this constitutes a stacking fault. In this case one could consider the underlined portion of the sequence to be a thin slice of hcp crystal positioned within the fcc lattice. Stacking faults can extend across the entire width of a crystal and can

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

be produced during crystal formation or sometimes during plastic deformation by certain dislocation movements (Ref 1).

Grain boundaries are the transitional zones surrounding each crystal in a solid that mark the interfaces between the crystal and its neighbors. They are often only a few atoms wide and can be considered practically two-dimensional. The atoms in this region assume positions that come as close as possible to satisfying both adjacent lattices simultaneously. Their ability to find such sites depends on the difference in orientation between adjoining grains. Grain boundaries are also subject to the disarray caused by the many dislocations and stacking faults that terminate there. In spite of all this, the overall divergence from the crystalline order must be somewhat limited; otherwise the material would fail easily along the grain boundaries under tension. As at other surfaces, the free energy at grain boundaries is higher than that of the crystals themselves but not as high as at free surfaces. Impurities tend to find these regions to be energetically more favorable sites of residence than sites within the crystal lattice, especially if the impurities are present in concentrations beyond their solubility limits (Ref 1).

Inclusions are three-dimensional defects consisting of insoluble particles of foreign material in the metal and may be either intentionally or accidentally incorporated.

Voids (another type of three-dimensional defect) are empty or gas-filled spaces within the metal. They may be formed, for example, by bubbles of gas that were trapped in the metal on solidification, as a consequence of *shrinkage* (the contraction of the metal as it cools), or by coalescence of a number of vacancies in the metal (Ref 2). Inclusions and voids are normally orders of magnitude larger than single-impurity atoms or vacancies but could be considered to reduce to these point defects, respectively, in the limit of small size (Ref 3).

Impure Metals and Alloys. Pure metals have limited engineering applications due to their cost and frequently poor mechanical properties. Vast improvements in mechanical properties can often be achieved by combining two or more elements to form an alloy. Alloys or metals with significant levels of impurities (unintentional alloys) are usually crystalline like nominally pure metals, but it is sometimes possible to prepare them in amorphous forms (Ref 4, 5, 6, 7).

In crystalline form, alloys are subject to the same types of defects as pure metals. Additionally, crystalline alloys may consist of a solid solution of one or more elements (solutes) in the major (base) component, or they may contain more than one phase. That is, adjacent grains may have slightly or extremely different compositions and be of identical or disparate crystallographic types. Often, there is one predominant phase, known as the matrix, and other secondary phases, called precipitates. The presence of these kinds of inhomogeneities often results in the alloy having radically different mechanical properties and chemical reactivities than the pure constituent elements.

The grain boundaries in alloys and impure metals are preferred sites for accumulation (segregation) of solute atoms, since the latter fit more readily into disordered regions than into the perfect crystals (i.e., they have a higher solubility in the grain boundary regions). Likewise, solute atoms and impurities tend to congregate at defects within the grains as well. Grain boundaries are also the favored precipitation sites for secondary phases formed during solid-state transformations. Consequently, the grain boundaries are often more resistant to mechanical deformation and have different chemical reactivities than the grains themselves (Ref 1).

In amorphous form, alloys lack the long-range order that is characteristic of crystalline materials, although they do retain a short-range order similar to that of liquids and true glasses (thus the name glassy metals) (Ref 1). Traditionally, glassy metals have been formed by very rapid cooling on the order of ~10^6 K/s (2×10^6 °F/ s) during the solidification of a melt. This “freezes” the atoms almost instantly in nearly the same positions they occupied in the liquid state. There is insufficient time available during the solidification process for crystals to nucleate and grow or for impurities and alloying elements, which are dispersed uniformly throughout the melt, to segregate. The resultant material is thus chemically and structurally homogeneous and free from one- and two-dimensional defects, secondary phases, and grain boundaries. (In a sense, one could consider a glassy metal to consist entirely of a large three-dimensional defect.)

Alternative methods of preparing glassy metals include vapor deposition and electrodeposition techniques (Ref 1, 4). More recent efforts have generated metallic glasses by mechanical milling of crystalline powders (Ref 6), and certain alloy compositions that form glasses even when cooled from the melt at relatively low rates of less than 10 K/s (18 °F/s) have been discovered (Ref 5, 7). The latter two glass-forming methods have overcome some of the problems of the past (such as the tendency of metastable glassy metals to recrystallize and the requirement that at least one dimension of the glassy product be very thin to permit rapid cooling), thereby allowing production of bulk metallic glasses for use as structural components in engineered structures. New

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

classes of “nanocrystalline” materials, substances with a high grain- boundary to grain-volume ratio, are also offering novel possibilities in this area (Ref 5).

As a result of the extensive disorder, glassy metals often have physical, chemical, and mechanical properties that differ greatly from those of crystalline alloys of the same elemental compositions. They can be much more corrosion resistant than the compositionally equivalent crystalline alloys, in large part due to the absence of multiple phases, grain boundaries, and other defects.

Phase diagrams are graphical presentations of the ranges of temperatures and compositions over which the different phases and mixtures of phases are thermodynamically stable. This includes the boundaries between the solid and liquid states (i.e., melting points), as well as those between different solid phases. Phase diagrams are termed binary, ternary, or quaternary if they describe two-, three-, or four-element mixtures, respectively. This type of information is invaluable to those who are trying to understand the behavior of metals and alloys, and entire volumes of these data have been published (Ref 8, 9, 10). A phase diagram of a portion of the iron-carbon system (Ref 9) is shown (Fig. 4) as an example.

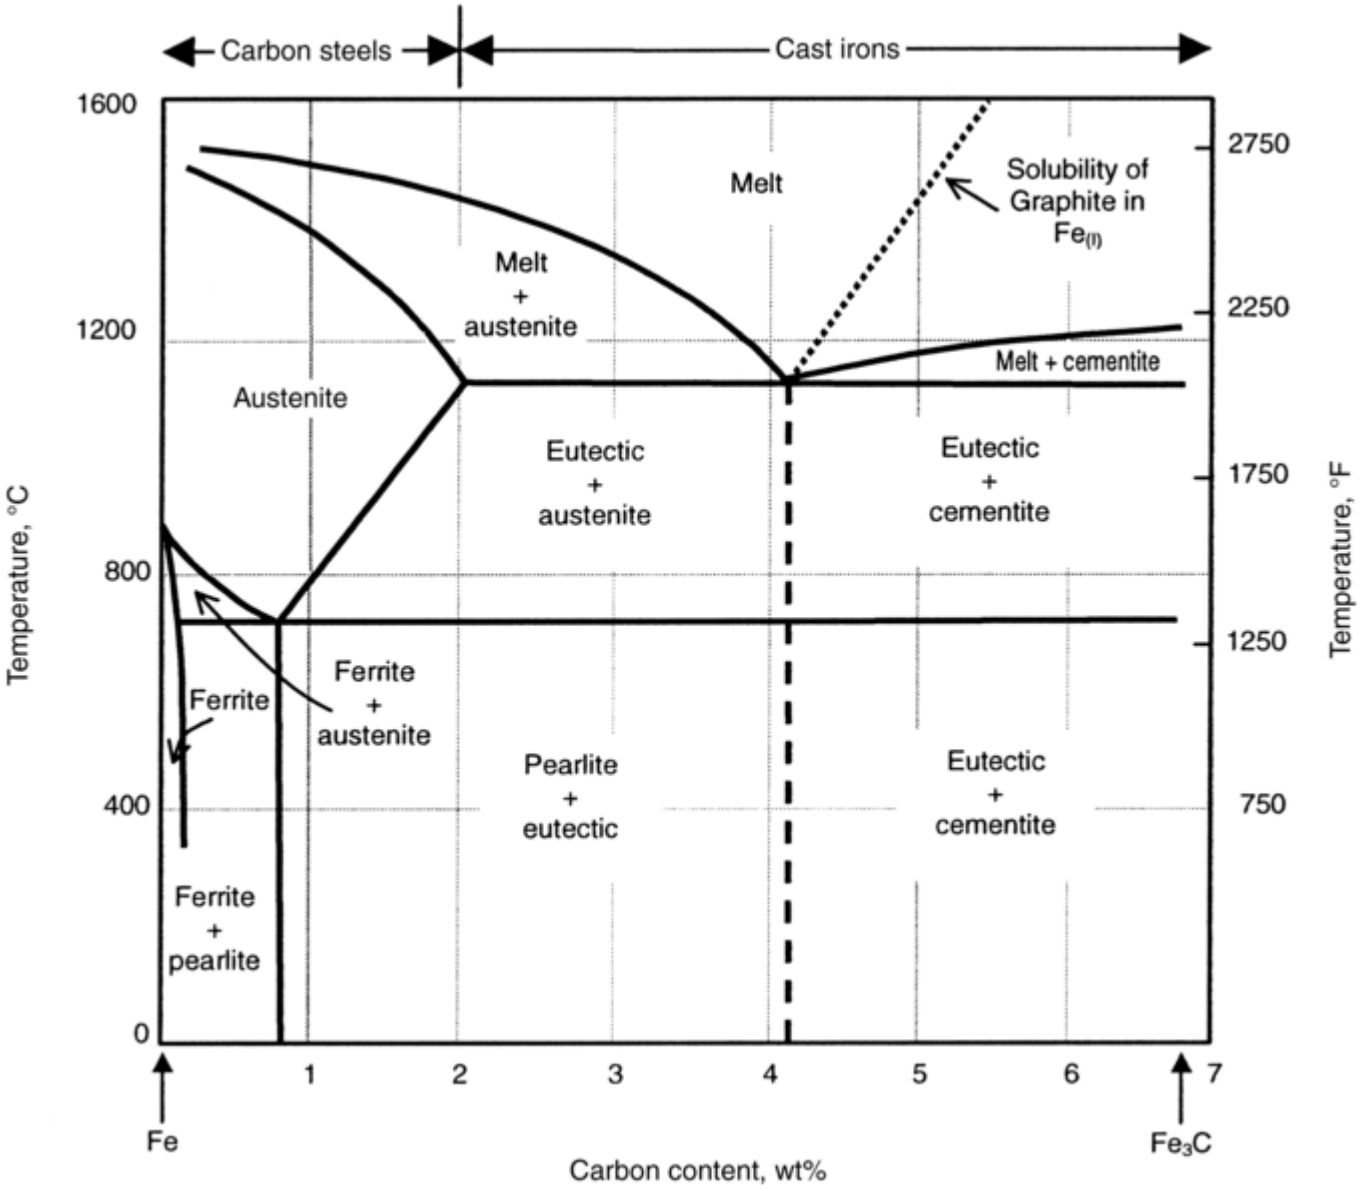

Fig. 4 A portion of the phase diagram for the iron-carbon system showing the many phases possible in steels and cast irons

The phase-temperature-composition relationships shown in phase diagrams are usually intended to represent the state of affairs in a system at true thermodynamic equilibrium; however, the observed phases of real materials may differ somewhat from those predicted by the phase diagram. Many metallic materials are metastable to some degree, and a number of nonequilibrium phase diagrams are also available (Ref 10). There are several possible origins of metastable phases, depending on the situation: “impurity” effects on the phase relationship

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

(some alloying additions and impurities act to stabilize, at room temperature, phases normally found at higher temperatures); or loss of atomic mobility before equilibrium is reached during solidification of a melt (this is how glassy metals are often prepared), during cooling of the solid to room temperature, or during subsequent heating and cooling events.

The various classes of metallic phases that may be encountered in crystalline alloys include substantially pure elements, solid solutions of one element in another, and *intermetallic compounds* (ionically, covalently, or metallically bonded intermediate phases of specific and relatively simple stoichiometry). All of these may be found in one or more allotropic forms (i.e., the same composition, but with different crystal packing orders), depending on the material. One may also find "metalloid" phases, such as carbides. (In metallurgy, as in this article, metalloid phases are considered to be those containing elements commonly present in simple steel: carbon, manganese, phosphorus, silicon, and sulfur. This differs from the way the term is used in chemistry to describe elements with properties intermediate between those of metals and nonmetals, specifically boron, silicon, germanium, arsenic, antimony, tellurium, and polonium.) Other nonmetallic phases may also be present in some cases, especially in the form of *inclusions,* which are particles of insoluble foreign material in the matrix. Particles composed of various oxides, sulfides, and silicates are common inclusions in metals and alloys (Ref 1); for example, manganese sulfide in stainless steels.

Effects of Metallurgical Variables on Aqueous Corrosion

James J. Noël, University of Western Ontario

Influence on Corrosion

The presence of impurities, alloying constituents, defects, multiple phases, and other metallurgical features, sometimes in very small amounts, can have a profound influence on the corrosion resistance of a material, affecting the susceptibility to, rate, mechanism, and form of corrosion. The exposure of structural and compositional inhomogeneities to corrosive environments invites the possibility of enhanced or preferential (localized) attack. This fact is used to great advantage in metallographic analysis, where chemical etching is frequently used to reveal the microstructural characteristics of a material for the optical microscope, but is usually a negative attribute in materials applications. Some of the corrosion consequences of common metallurgical practices and microstructural features are discussed individually in later sections of this article, but it should be noted that they are often not independent of each other.

Crystallography and Defects. Corrosion results in the removal of atoms from a metal by dissolution or conversion to an oxidized phase, such as an oxide or sulfide. The metal atoms most likely to undergo corrosion are those with the highest free energy. Thus, atoms located within the bulk of the material are much less susceptible to corrosion than those in the outermost layers of the metal surface, and corrosion reactions are generally considered to be surface chemistry.

Not all surface atoms have the same free energy, either. Depending on the orientation of the grains with respect to the metal surface, different crystallographic planes may be exposed to the environment, each one having a different reactivity. Even within a region of the surface having only a single crystallographic orientation, there will be variations in free energy (see Fig. 5). Atoms residing in close-packed planes are strongly coordinated on all but one side and would be at lower energy than atoms located on step edges, which have fewer nearest neighbors. Similarly, removal of atoms located at kink sites would be even more energetically favorable, and "adatoms," having the minimal degree of attachment to the metal, would be the easiest to detach.

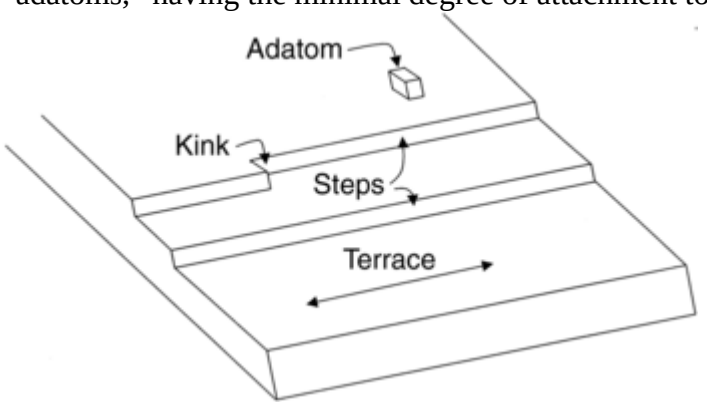

Fig. 5 Schematic depiction of the possible arrangements of residence sites for metal atoms on a surface. Steps are also called ledges

In electrochemical terms, the equilibrium corrosion potentials of these sites would be ordered:

$$E_{e(adatom)} < E_{e(kink)} < E_{e(step)} < E_{e(plane)} \quad \text{(Eq 1)}$$

where $E_{e(plane)}$ would be most noble. Likewise, kinks and other sites of reduced coordination to the underlying metal, such as sites where dislocations intersect the surface or where point defects are exposed, are energetically favorable points of corrosive attack. Since these defects tend to concentrate at grain boundaries, which are in themselves zones of disorder, one can expect that, in electrochemical terms again:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$E_{e(\text{grain boundary})} < E_{e(\text{grain})}$ (Eq 2)

The thermodynamic driving force for the corrosion reaction, ΔE_{therm}, is given by

$\Delta E_{therm} = E_{e(c)} - E_{e(a)}$ (Eq 3)

where $E_{e(c)}$ and $E_{e(a)}$ are the equilibrium potentials for the cathodic (reduction) and anodic (metal oxidation) reactions, respectively. Thus, on a given corroding metal surface (i.e., with a constant value of $E_{e(c)}$), the driving force for corrosion will be stronger at the grain boundaries than on the grains themselves.

In principle, therefore, preferential attack of the grain boundaries, known as *intergranular corrosion*, is a possible outcome, but in practice little corrosion damage of any consequence can actually be attributed to differences in the energetics of corrosion caused by atomic disorder, independent of compositional differences. The magnitude of electrochemical potential differences that can be generated by defects is, in fact, quite small (Ref 11, 12). The relationship between the free energy stored in defects (ΔG), and the resultant change in electrochemical potential (ΔE) is given by:

$\Delta G = -nF\Delta E$ (Eq 4)

where n is the change in oxidation number of the metal when it corrodes and F is Faraday's constant. For example, cold working a metal to introduce defects amounting to 100 kJ/kg of stored energy will afford only about 3 mV of potential difference. For an active corrosion process having anodic kinetics with a Tafel slope of 60 mV/ decade, this potential shift would correspond to a corrosion rate change of about 10%. Moreover, a slight initial grain boundary etching will remove many of the highest energy atoms, thereby decreasing the difference in equilibrium corrosion potentials between the grains and grain boundaries even further.

For a passive metal, the corrosion rate is much less dependent on potential, so intergranular corrosion driven by free energy differences arising from disorder in the metal are even less likely. However, on surfaces protected by a passive film, grain boundaries and defects can sometimes promote preferential attack by disrupting the formation of a continuous protective layer (Ref 11, 12). If the presence of defects results in imperfections or discontinuities in the overlying passive film, these sites may not be well protected by the passive film but instead can serve as initiation sites for localized corrosion processes.

The influence of compositional inhomogeneities resulting from impurity segregation and the formation of certain precipitate particles at grain boundaries usually outweighs the effects of any lattice disorder. Most serious cases of intergranular attack arise from compositional dissimilarities rather than structural defects (Ref 11). Conversely, kinetic limitations and compositional differences may completely eliminate preferential corrosion of grain boundaries or make the grain boundaries even more corrosion resistant than the grains.

One form of corrosion in which structural defects do seem to play a role is stress-corrosion cracking (Ref 12). The presence of a large number of stacking faults makes it easier for grains to slip (i.e., facilitates shear displacement of one part of the grain with respect to another). The material then has a greater tendency to creep rather than crack to relieve tensile stresses. In some materials, decreasing the free energy stored in stacking faults can change the nature of stress- corrosion cracking from intergranular to transgranular.

Another structural feature of metals, texture, the degree to which the orientations of different grains in a material deviate from a random distribution in favor of a preferred direction, can also influence material corrosion behavior. Passivation and repassivation tend to be enhanced on densely packed crystallographic planes because there are fewer steps and kinks, so texture can have an impact on the passivation characteristics. The susceptibility to stress-corrosion cracking can also be impacted by material texture, because the bias in grain orientation will favor alignment of stacking faults in different grains along preferred directions, with consequent effects on slip processes and, ultimately, stress-corrosion cracking, depending on the direction of any tensile stresses.

The grain geometry has a significant bearing on the corrosion properties of some metals (Ref 11). For example, rolled or extruded aluminum alloys tend to have flattened, elongated grains that are aligned parallel to each other as a consequence of the fabrication process. Because the material structure consists of sheetlike layers of thin grains, these materials are susceptible to a specific form of intergranular corrosion, called *exfoliation*, in which grain boundary attack strips layer after layer of grains from the surface. The corrosion products, which occupy a larger volume than that of the metal consumed in their formation, exert a wedging pressure between the layers of grains, helping to pry them apart and advance the intergranular attack. The lamellar structure of these materials also facilitates intergranular stress-corrosion cracking by providing aligned grain boundaries

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

along which the material can be relatively easily “unzipped” by a stress-corrosion process, especially when the stresses are acting in the direction perpendicular to the plane of the layers.

The grain size has been observed to influence crevice corrosion and stress-corrosion cracking processes on metals (Ref 12, 13). Fine-grained materials have more grain boundaries and a higher grain-boundary to grain-volume ratio than metals with larger grains. Crevice corrosion initiates most readily at weak points in the passive oxide film, which are most likely to be located over grain boundaries. Thus, small-grained metals present more susceptible sites for crevice corrosion initiation. In stress-corrosion cracking, for a given stress, the time to failure increases as the grain size decreases (Ref 13) due to an increased resistance to slip. A detailed description of the relationship between grain size and slip has been published (Ref 14).

Alloying. One of the principal reasons for alloying structural metals is, in many cases, to improve corrosion resistance. In alloys designed for specific mechanical properties, such as tensile strength or hardness, further alloying additions are commonly made to enhance the corrosion resistance as well.

Alloying can affect the corrosion resistance in many different ways. Changes in the nobility of the metal, the dissolution kinetics, the performance of a passive film, the phase structure of the material, the ability to catalyze the cathodic half-reaction, and other corrosion-influencing parameters can all result from alloying. Some of these changes help to decrease and others to increase the susceptibility, corrosion rate, and extent of corrosion damage. Some of these effects are described subsequently.

Genuine changes in the thermodynamic properties of the metal can be achieved by alloying. If alloying increases the nobility of a material (i.e., it results in an increase in the equilibrium potential of the anodic half-reaction ($E_{e(a)}$), perhaps by increasing the metal-metal bond energy), then the driving force for corrosion (ΔE_{therm}), will decrease. Thus:

$$E_{e(a)M} < E_{e(a)A} \qquad \text{(Eq 5)}$$

where M and A denote metal and alloy, respectively. From Eq 3:

$$[E_{e(c)} - E_{e(a)M}] > [E_{e(c)} - E_{e(a)A}] \qquad \text{(Eq 6)}$$

or

$$\Delta E_{therm\ M} > \Delta E_{therm\ A} \qquad \text{(Eq 7)}$$

The decrease in thermodynamic driving force for corrosion may result in a corresponding decrease in the corrosion current density (i_{corr}) as illustrated (Fig. 6). Alloy systems ennobled in this fashion are relatively uncommon and often require very system-specific alloying additions, habitually noble metals (e.g., platinum, gold, palladium, etc.). Frequently, ennoblement is achieved only after enrichment of the metal surface in the minor alloy constituent, which occurs via limited selective dissolution of the major component. Subsequent mechanical damage to the thin, enriched surface layer may result in temporary reinitiation of corrosion. The decrease in the anodic dissolution rate of titanium in hydrochloric acid solutions on alloying with Nb or Zr, for example, has been attributed to strong covalent bonding between neighboring Ti, Nb, and Zr atoms through sharing of unpaired d-electrons (Ref 15).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

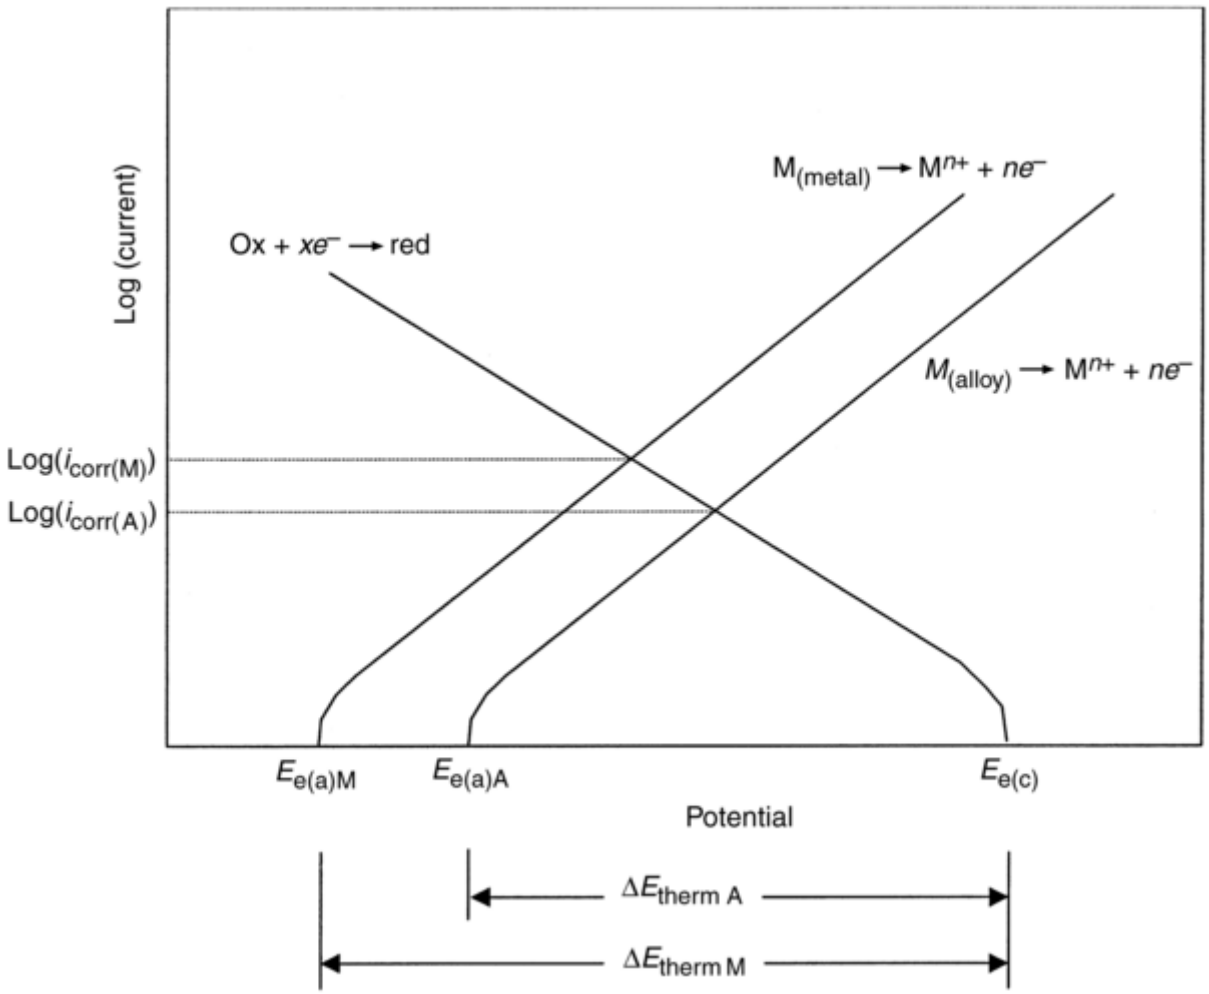

Fig. 6 Effect of increasing the nobility of a material by alloying on the thermodynamic driving force for corrosion (ΔE_{therm}), and on the corrosion rate (as represented by i_{corr})

On passive metals, the addition of controlled amounts of certain alloying elements is often used to improve the performance of the passive film. Such improvements can be effected by a variety of mechanisms, including increases in the thermodynamic stability of the passive film, an enhanced tendency to form a continuous barrier between metal and environment, decreases in the dissolution kinetics, a lower critical current for passivation, greater rates of repassivation, suppression of electron transfer, and superior wear resistance to diminish possibilities for erosion corrosion.

A well-known example of passive film enhancement by alloying is the addition of chromium to iron alloys. The beneficial effects of chromium in the alloy can be attributed to its incorporation into the passive oxide film, where it has a number of effects, (Fig. 7). As the chromium content of the alloy is increased, the solubility of the passive oxide layer decreases, the passivation potential (E_{pass}) and the entire passive potential range move to less noble potentials, the passive dissolution current density (i_{pass}) decreases, and the critical current density for passivation (i_{crit}) decreases. In Fig. 7, only alloy number 3 would spontaneously passivate under the influence of the cathodic half-reaction shown, since only in that case is i_{crit} exceeded by the rate of the cathodic half-reaction at the potential corresponding to the peak of the active-to-passive transition. Spontaneous passivation would occur in this case because the only potential at which the rates of the anodic and cathodic half-reactions are equal, as required for charge balance, lies within the passive region.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

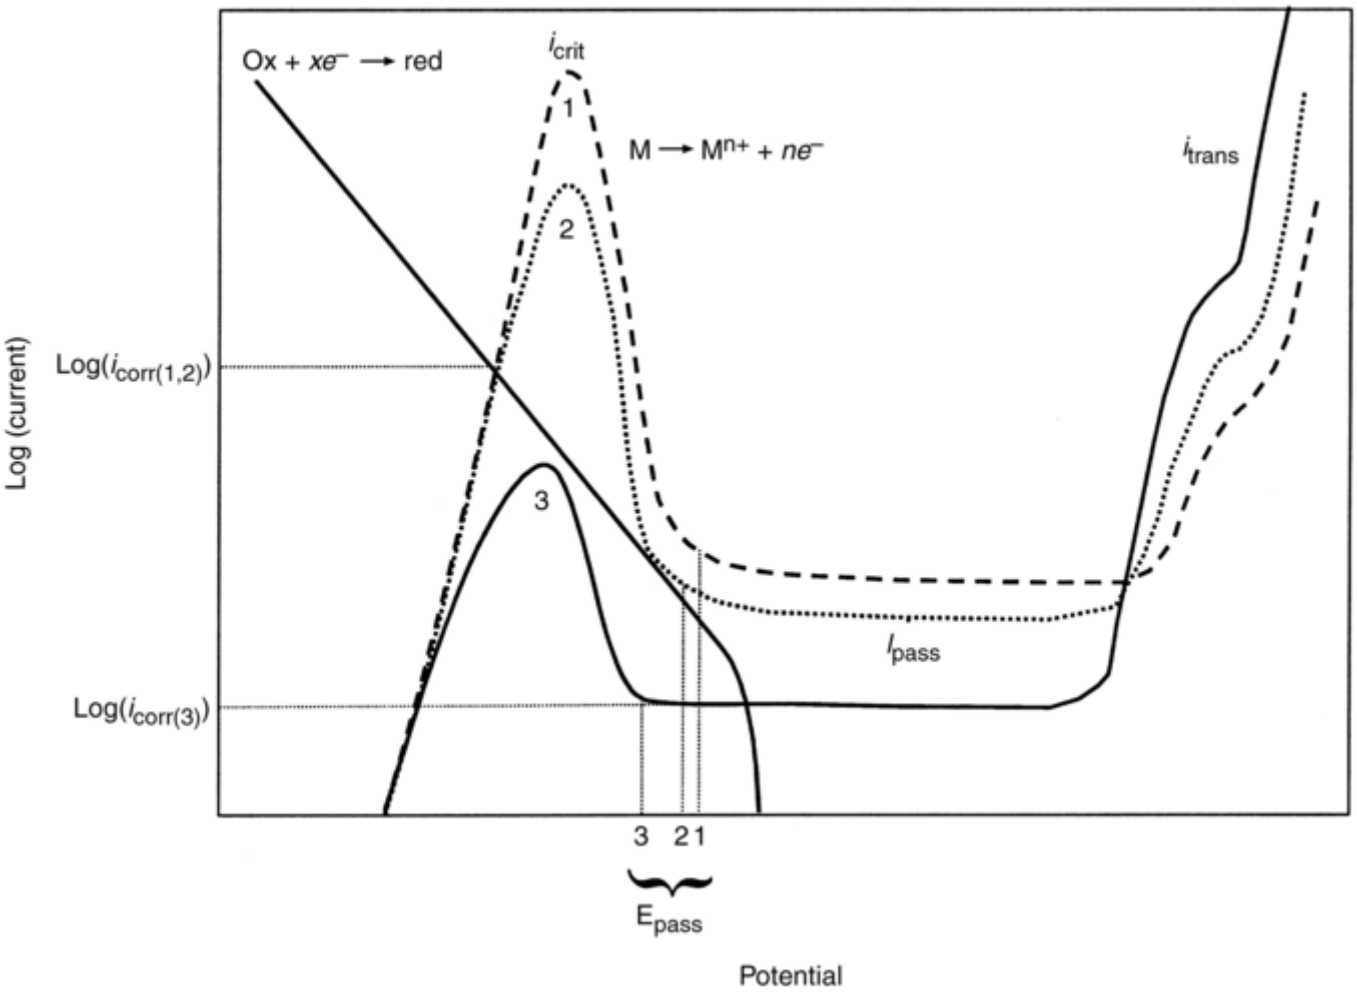

Fig. 7 Log (current) versus potential showing the effects of chromium content on the oxidation current of steels. Curve 1, low chromium content; curve 2, intermediate chromium content, curve 3, high (>12 wt%) chromium content

It has been empirically determined that a minimum of 11 to 12 wt% Cr is required to induce passivity in steels in common industrial environments. Improvements in passivity continue with increasing chromium content up to about 16 to 18 wt%, and the further addition of up to 8 wt% nickel enhances passivity even more and stabilizes the austenitic phase (Ref 16). The widely popular 18-8 stainless steels (Fe-18Cr-8Ni) are designed to take advantage of these effects.

One drawback of increasing the chromium content of these alloys is that it increases the likelihood and severity of transpassive dissolution (i_{trans} in Fig. 7). Transpassive dissolution can happen in metal and alloy systems in which the metal ions in the passive film have available a higher oxidation state that yields more soluble species. The higher oxidation state may be achieved if strong enough oxidizing conditions prevail. In the case of Cr and its alloys, transpassive dissolution can occur when conditions at the passive surface become sufficiently oxidizing that Cr ions in the highly insoluble Cr^{III} oxide are oxidized to the more soluble Cr^{VI} ions, and the material loses its passivity. Because the metal is very strongly polarized in the anodic direction when it loses its passivity, corrosion damage can be rapid and severe.

Many other systems show improved corrosion resistance due to improved passive film properties. Sometimes, even a small concentration of an alloying element has an important effect. Pitting resistance of type 316 stainless steel is improved with the addition of 2 to 3 wt% Mo (Ref 11), and decreased susceptibility to impingement attack is achieved in brass with 2 wt% Al and in cupronickel alloys to which 1 to 2 wt% Fe has been added. Detrimental effects are also possible, such as the reduction in pitting resistance that can result from the presence of small amounts of impurities in aluminum.

Changes in the phase structure of the material induced by alloying are also very common (Fig. 4). These can alter the corrosion properties of the material, often for the worse. For example, in austenitic stainless steels, the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

presence of ferrite decreases the pitting resistance, while martensite may increase the susceptibility to hydrogen embrittlement.

One of the most common and insidious effects of the presence of multiple phases is to enable galvanic corrosion effects. The situation is much more serious than simply grains of one phase having a higher corrosion rate than neighboring grains of another phase. In galvanic corrosion of an alloy, the sites of the anodic and cathodic half- reactions become spatially separated and fixed on grains of different phases. The corrosion of the least noble phase is accelerated by the presence of another phase that provides sites for the corresponding cathodic half reaction. The latter phase can potentially increase the rate of corrosion damage to the former by enhancing the cathodic half-reaction in two ways; first, by providing a larger surface area for the cathodic half-reaction, and second, by catalyzing the cathodic half-reaction (i.e., by increasing the cathodic current density). Acute local damage often ensues. Galvanic corrosion resulting in severe intergranular attack may even be promoted simply by segregation of small amounts of impurities to the grain boundaries. Even among corroding grains, there may be variations in corrosion rate; those grains with the highest rates will suffer more corrosion damage.

An example of severe galvanic corrosion that is so common and well known that it has its own name, graphitic corrosion, occurs on gray cast irons. (Graphitic corrosion is often called graphitization, but that term is more appropriately reserved for the high-temperature decomposition of iron carbide to form graphite particles in steels.) Gray cast irons consist of graphitic flakes in a matrix of ferrite or pearlite. When gray cast irons corrode, the graphite flakes are very noble, but the ferritic or pearlitic matrix corrodes readily, with the interconnected network of graphite flakes serving as the cathodic-charge distribution system. The metal matrix can be completely consumed by the anodic half-reaction. This is supported by the cathodic half reaction occurring on the graphite flakes, which offer a large and continually increasing cathode area. The end result is a lump of iron corrosion products held together by a network of graphite flakes. Galvanic effects are not so severe on ductile iron materials, due to differences in the morphology of the graphite particles. In the latter material, the graphite is found in the form of spherical particles, which do not remain electrically connected to each other once the metal between them has been oxidized and therefore do not offer such a large cathodic surface area to drive the anodic reaction (Ref 11).

In certain active-passive systems such as titanium alloys, galvanic effects can actually be used to help prevent corrosion by reinforcing passivity (Ref 16) (see Fig. 8). Based on the results of research on noble metal effects on the corrosion resistance of titanium (Ref 17), an extensive series of titanium alloys containing very small (<1%) concentrations of metals that are known to enhance hydrogen, water, or oxygen reduction (e.g., Pt, Pd, Ru, and even Ni) has been developed specifically to take advantage of this method of enforcing passivity. The exposed catalytic particles increase the rate of the cathodic reaction to such an extent that the magnitude of the cathodic current would be higher than that of the anodic current at any given potential except in the passive region of Ti. Thus, the metal could only adopt spontaneously a potential corresponding to passivation of the Ti, as shown in Fig. 8. On the other hand, alloying additions may also help to inhibit corrosion by suppressing cathodic electron transfer reactions, if the cathodic half-reaction is rate limiting. Such an effect has been observed on Ti alloys containing significant amounts (13 to 50%) of Zr or Nb (Ref 18).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

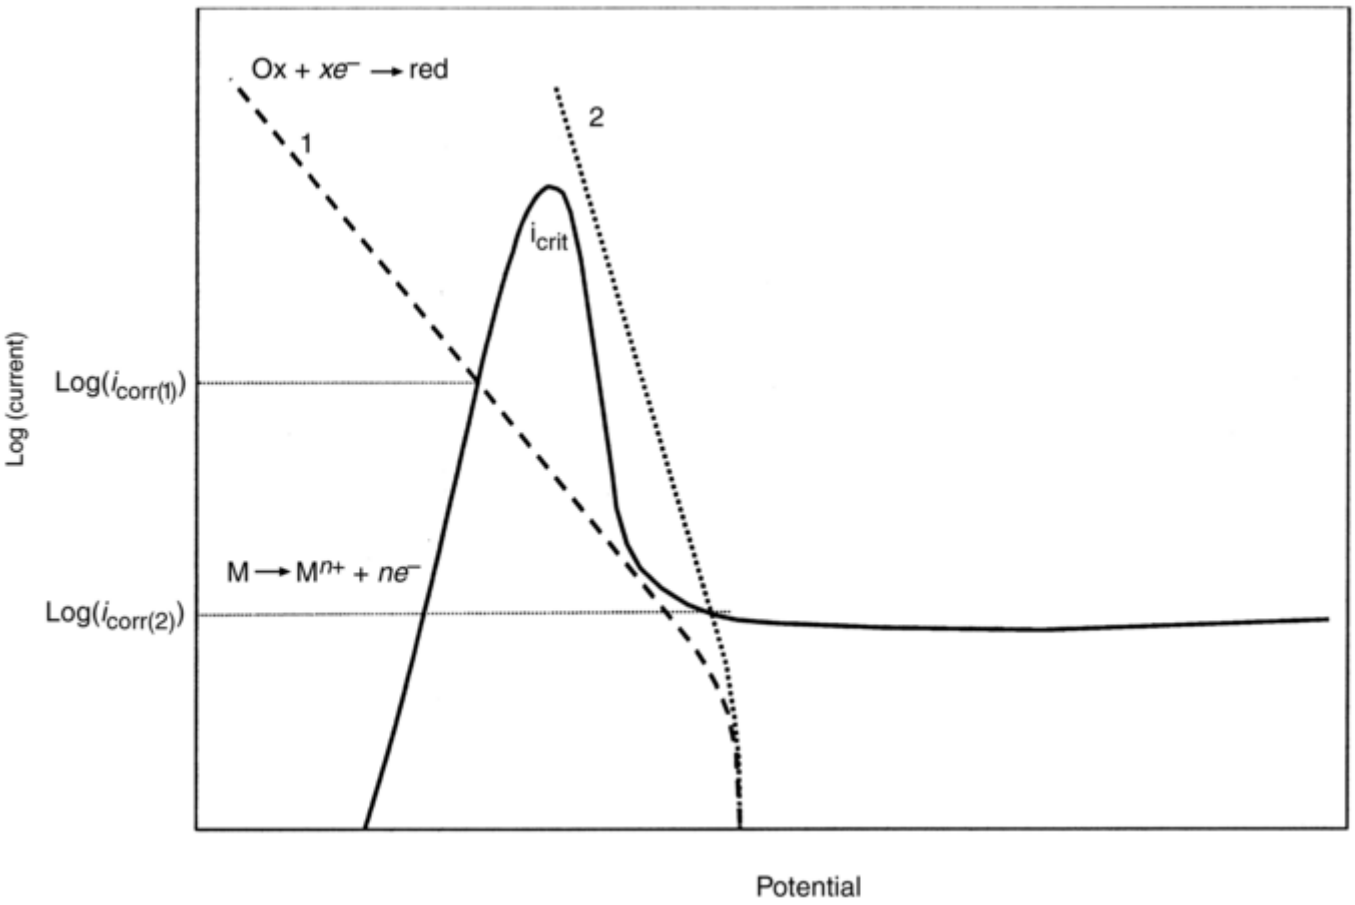

Fig. 8 Log (current) versus potential illustration of the influence of noble metal alloying on the kinetics of the cathodic half-reaction that reinforces spontaneous passivity on dilute titanium alloys. Curve 1, current of cathodic half-reaction on unalloyed titanium; curve 2, current of cathodic half-reaction on titanium with noble metal addition

Inclusions may be present in an alloy either as unintentional contaminants or purposeful additions intended to improve such features as weldability and machinability. Inclusions are not true alloying components but still can have detrimental effects on the corrosion performance of a material, often acting as preferential initiation sites for localized corrosion. The manganese sulfide inclusions commonly found in steels, for instance, are well known initiation sites for pitting corrosion.

Often unnoticed until after a metal component fails, *dealloying,* or *selective leaching,* is an alloying-related form of corrosion. In cases of dealloying, a process that is somewhat similar to galvanic corrosion but at the subgrain level, selective dissolution of one element from a homogeneous, single-phase alloy occurs. Dealloying affects many alloy systems, and the process is known by several very descriptive names that point to specific problems with particular alloying components, such as *decarburization, decobaltification, denickelification,* and *dezincification.*

The classic example of dealloying is the dezincification of alpha brasses (Ref 11). In this case, zinc is preferentially dissolved from the brass, leaving behind the copper in the form of a porous, mechanically weak residue. This can lead to instances of unexpected and sudden failure of brass components because the corrosion damage can appear to be superficial, and little dimensional change is usually observed, even when only a thin remnant of sound metal endures. Dealloying of brass can generally be avoided by maintaining a minimum of 85 wt% Cu in the alloy. Prevention of dealloying has been considered in terms of percolation theory, which is concerned with determining the minimum concentration of a single component that would be required in order to form a continuously interconnected layer within the material, thereby preventing further corrosion by providing an unreactive barrier between the active metal and its environment.

Additional information on dealloying is available in the article “Effects of Metallurgical Variables on Dealloying Corrosion” in this Volume.

Welding, Working, and Heat Treatments. The effects of welding, working, and the heat treatments applied to metals are numerous and frequently interrelated. All three of these actions can result in changes in the number

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

of defects in the metal, the size and shape of the grains, and the distribution of alloying elements, impurities, and minor phases. These parameters, in turn, have a very large impact on the corrosion properties of the material, as discussed earlier in this article. Thus, welding, working, and heat treatment are considered together in this article.

Welding is a joining method in which the metal parts to be joined are partially melted at the site of the intended joint, then resolidified to form a solid union. Sometimes a filler metal is used to facilitate the bonding. Welding has a number of effects on the metallurgy and corrosion resistance of the metal. Because the melting and resolidification are uncontrolled in terms of temperature and heating and cooling rates, the grain structure and size may be changed in an uncontrolled fashion. Areas adjacent to the weld, though not melted themselves, are heated to temperatures at which grain growth and significant segregation or mixing of alloy components and impurities can occur. The region is known as the ***heat-affected zone*** (HAZ).

The creation of a HAZ can result in a significant loss of corrosion resistance in alloys. This is especially true of stainless steels. To keep the chromium in these materials uniformly dispersed throughout, they are cooled rapidly from high temperatures (at which the chromium is completely dissolved in the alloy) so that there is insufficient time for the chromium to segregate before it becomes immobilized at lower temperatures. However, heating to temperatures in the range 400 to 800 °C (750 to 1470 °F), which happens in the HAZ, makes the atoms sufficiently mobile that chromium and carbon atoms are able to encounter each other and precipitate as chromium carbide particles. In the process, as chromium atoms from the surrounding matrix participate in the growth of the chromium carbide, the region surrounding each precipitate particle becomes depleted of chromium. When the chromium content of these regions drops below approximately 12 wt%, the local corrosion resistance diminishes dramatically and the material becomes readily susceptible to severe localized corrosion in those areas (Ref 11, 12, 13). This phenomenon is termed ***sensitization.*** Corrosion of sensitized alloys is exacerbated by the presence of large areas of passive metal surface surrounding the sensitized area. The passive regions can act as cathodic sites and thereby help to accelerate metal oxidation, a result made worse by the large cathodic-to-anodic area ratio. The tendency toward sensitization can be reduced by employing low-carbon stainless steels (such as type 304L) to avoid carbide formation, by adding other elements that strongly bind carbon (such as niobium or titanium), and by avoiding processes (such as welding) that generate temperatures in the 400 to 800 °C (750 to 1470 °F) range within the metal (Ref 11).

Structural and compositional differences between the base metal and the weld are also a source of potential corrosion problems. The weld metal tends to be inferior to the base metal due to inhomogeneities, a dendritic microstructure, and elevated concentrations of impurities. Occasionally, welding-introduced impurities can have beneficial effects too, such as the increase in pitting resistance of types 304 and 316 stainless steel welds on incorporation of nitrogen in the weldment during gas-tungsten arc welding. The type of welding process employed can also influence susceptibility to stress-corrosion cracking (Ref 12).

Certain heat treatments are known to sensitize some materials. In this case, sensitization occurs across the whole sample, not just along a narrow HAZ next to a weld. It is also possible to stabilize sensitized materials using heat treatments. For instance, chromium carbide precipitates in stainless steels can be redissolved by heat treatment above about 1035 °C (1895 °F). Rapid quenching after the homogenizing heat treatment prevents the chromium carbide particles from reforming, leaving the chromium well dispersed in the metal. Heat treatments can also help to anneal out crystal defects, thereby further reducing the impact on corrosion (Ref 12).

The growth of precipitate particles promoted by heat treatments can also lead to galvanic corrosion effects. Such is the case with precipitation-hardened Al-Cu, Al-Mg, and Al-Zn-Mg alloys (Ref 11). In Al-Cu alloys, $CuAl_2$ precipitates are nobler than the matrix, whereas $MgZn_2$ and Mg_2Al_3 are less noble than their Al- Zn-Mg or Al-Mg matrixes, respectively. The heat treatments that are beneficial mechanically, because they improve hardness by causing precipitate formation, are at the same time detrimental to the corrosion resistance because the growth of different phases within the material favors the possibility of galvanic corrosion. The severity of subsequent attack depends on the characteristics of the heat treatments to the extent that they control the size and distribution of intergranular precipitates. Generally, alloys that are heat-treated to peak hardness are most severely attacked by corrosion, while, those that are overaged are somewhat less susceptible (Ref 11).

The application of cold work to a metal may also alter its corrosion properties, but not necessarily by the mechanism that one might first expect. The creation of defects and high-energy atoms in the metal does little to change the corrosion potential (Ref 11, 12) and usually does not lead to serious corrosion damage, as was discussed previously. Instead, is seems to be the effects of cold work on the protectiveness of the passive film

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

and work-induced sensitization (Ref 12, 13) that more strongly determine the influence of cold work on corrosion properties.

Cold work has been found to lead to precipitation of fine particles of chromium carbide at grain boundaries in stainless steels. These grow coarser with increasing amounts of work, leading to sensitization. They also help increase the rate of sensitization during any subsequent heating events. The protectiveness of the surface oxide on stainless steels has been observed to increase after application of cold work as a result of a work-induced conversion of the single-layer mixed Fe_2O_3/Cr_2O_3 oxide to a double layer consisting of mixed Fe_2O_3/Cr_2O_3 on the outside and $Fe_{2-x}Cr_xO_4$ spinel mixed with Cr_2O_3 on the interior (Ref 12).

Cold work that shapes and orients grains, introduces texture, and changes the stacking fault density of a material can affect the corrosion properties in a variety of ways. The transition from intergranular to transgranular stress-corrosion cracking with increasing cold work, observed in a number of alloys (Ref 12), and the role of cold work in modifying the grain structure of aluminum alloys such that they become susceptible to exfoliation corrosion processes, (Ref 11) are two examples of the consequences of cold work, as described earlier. Cold work can also help in promoting stress-corrosion cracking in susceptible materials by introducing residual stresses. In this case, the influence on corrosion is a mechanical, rather than a chemical, consequence of metallurgical processing.

Effects of Metallurgical Variables on the Corrosion of Stainless Steels

James D. Fritz, TMR Stainless

Introduction

METALLURGICAL VARIABLES can influence the corrosion behavior of austenitic, ferritic, duplex, and martensitic stainless steels. The distribution of carbon is probably the most important variable influencing the susceptibility of these alloys to intergranular corrosion, but nitrogen and metallic phases are also important, particularly with the more highly alloyed stainless steel grades. This article describes the effects of important metallurgical and processing variables, on corrosion of stainless steels. Related information is provided in the article “Corrosion Resistance of Stainless Steels and Nickel Alloys” in this Volume.

مرجع مهندسی مواد و متالورژی

Intergranular Corrosion. At temperatures above approximately 1035 °C (1900 °F), chromium carbides are completely dissolved in austenitic stainless steels. However, when these steels are slowly cooled from these high temperatures or reheated into the range of 425 to 815 °C (800 to 1500 °F), chromium carbides are precipitated at the grain boundaries. These carbides contain more chromium than the matrix does.

The precipitation of the carbides depletes the matrix of chromium adjacent to the grain boundary. The diffusion rate of chromium in austenite is slow at the precipitation temperatures; therefore, the depleted zone persists, and the alloy is sensitized to intergranular corrosion. This sensitization occurs because the depleted zones have higher corrosion rates than the matrix in many environments. Figure 1 illustrates how the chromium content influences the corrosion rate of iron-chromium alloys in boiling 50% H_2SO_4 containing ferric sulfate, $Fe_2(SO_4)_3$. In all cases, the alloys are in the passive state. The wide differences in the corrosion rate are the result of the differences in the chromium content. With the lower-chromium-bearing stainless steels, the passive film is more soluble in the acid, and therefore, more metal must dissolve to repair the film.

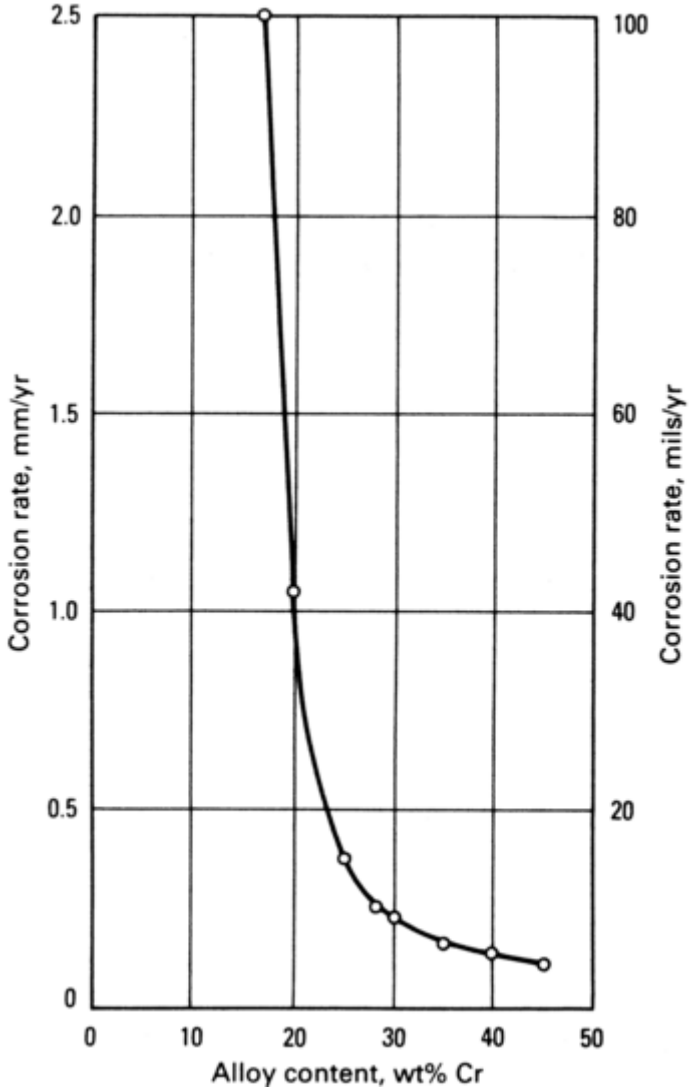

Fig. 1 The effect of chromium content on the corrosion behavior of iron-chromium alloys in boiling 50% H_2SO_4 with $Fe_2(SO_4)_3$. Source: Ref 1

If the austenitic stainless steels are cooled rapidly to below approximately 425 °C (800 °F), the carbides do not precipitate, and the steels are immune to intergranular corrosion. Reheating the alloys to 425 to 815 °C (800 to 1500 °F), as for stress relief, causes carbide precipitation and sensitivity to intergranular corrosion. The maximum rate of carbide precipitation occurs at approximately 675 °C (1250 °F). Because this is a common temperature for the stress relief of carbon and low-alloy steels, care must be exercised in selecting stainless steels to be used in dissimilar-metal joints that are to be stress relieved.

Welding is the common cause of the sensitization of stainless steels to intergranular corrosion. Although the cooling rates in the weld itself and the base metal immediately adjacent to it are sufficiently high to avoid carbide precipitation, the weld thermal cycle brings part of the heat- affected zone (HAZ) into the precipitation

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

temperature range. Carbides can precipitate, and a zone somewhat removed from the weld becomes susceptible to intergranular corrosion (Fig. 2). Welding does not always sensitize austenitic stainless steels. In thin sections, the thermal cycle may be such that no part of the HAZ is at sensitizing temperatures long enough to cause carbide precipitation. Once the precipitation has occurred, it can be removed by reheating the alloy to above 1035 °C (1895 °F) and cooling it rapidly. This thermal treatment dissolves the chromium carbide precipitates and restores the chromium-depleted zone. This practice is commonly termed solution anneal.

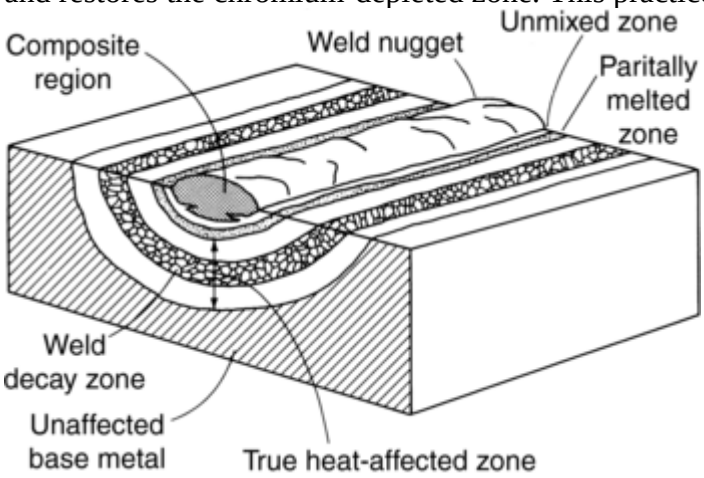

Fig. 2 Schematic diagram of the regions of a weld in austenitic stainless steel. Source: Ref 2

Avoiding Intergranular Corrosion. Susceptibility to intergranular corrosion in austenitic stainless steels can be avoided by limiting their carbon contents or by adding elements whose carbides are more stable than those of chromium. For most austenitic stainless steels, restricting their carbon contents to 0.03% or less prevents sensitization during welding and most heat treatment. This method is not effective for eliminating sensitization that would result from long- term service exposure at 425 to 815 °C (800 to 1500 °F).

At temperatures above 815 °C (1500 °F), titanium and niobium form more stable carbides than chromium and are added to stainless steels to form these stable carbides, which remove carbon from solid solution and prevent precipitation of chromium carbides. The most common of these stabilized grades are types 321 and 347. Type 321 contains minimum titanium content of 5 × (C% + N%), and type 347 a minimum niobium content of 8 × C%. Nitrogen must be considered when titanium is used as a stabilizer, not because the precipitation of chromium nitride is a problem in austenitic steels, but because titanium nitride is very stable. Titanium combines with any available nitrogen; therefore, this reaction must be considered when determining the total amount of titanium required to combine with the carbon.

The stabilized grades are more resistant to sensitization by long-term exposure at 425 to 815 °C (800 to 1500 °F) than the low-carbon grades are, and the stabilized grades are the preferred materials when service involves exposure at these temperatures. For maximum resistance to intergranular corrosion, these grades are given a stabilizing heat treatment at approximately 900 °C (1650 °F). The purpose of the treatment is to remove carbon from solution at temperatures where titanium and niobium carbides are stable, but chromium carbides are not. Such treatments prevent the formation of chromium carbide when the steel is exposed to lower temperatures.

Figure 3 illustrates how both carbon control and stabilization can eliminate intergranular corrosion in as-welded austenitic stainless steels. It also shows that the sensitized zone in these steels is somewhat removed from the weld metal.

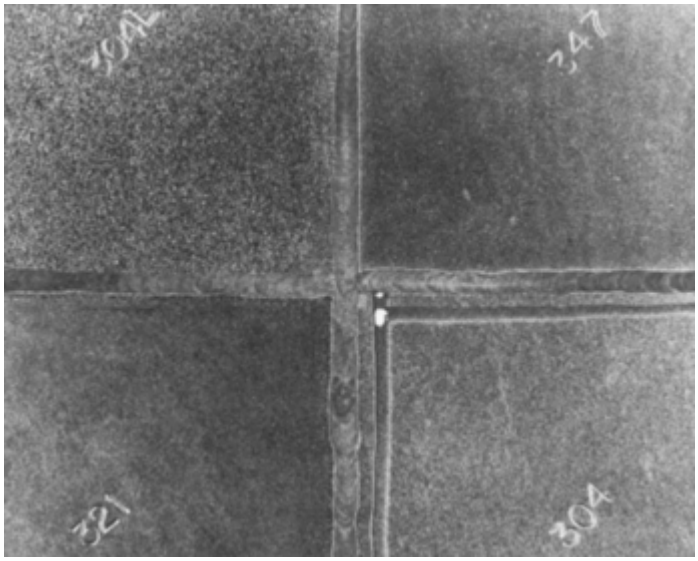

Fig. 3 Weld decay and methods for its prevention. The four different panels were joined by welding and then exposed to a hot solution of HNO_3/HF. Weld decay, such as that shown in the type 304 steel (bottom right), is prevented by reduction of the carbon content (type 304L, top left) or by stabilization with titanium (type 321, bottom left) or niobium (type 347, top right). Source: Ref 3

Knife-Line Attack. Stabilized austenitic stainless steels may become susceptible to a localized form of intergranular corrosion known as knife- line attack or knife-line corrosion. During welding, the base metal immediately adjacent to the fusion line is heated to temperatures high enough to dissolve the stabilizing carbides, but the cooling rate is rapid enough to prevent carbide precipitation. If weldments in stabilized grades are then heated into the sensitizing temperature range of 425 to 815 °C (800 to 1500 °F), for example, during stress-relieving treatments, high-temperature service, or subsequent weld passes, chromium carbide can precipitate. The precipitation of chromium carbide leaves the narrow band adjacent to the fusion line susceptible to intergranular corrosion.

Knife-line attack can be avoided by the proper choice of welding variables and by the use of stabilizing heat treatments.

Testing for Intergranular Corrosion. The common methods of testing austenitic stainless steels for susceptibility to intergranular corrosion are described in ASTM A 262 (Ref 4). There are five acid immersion tests and one etching test. The oxalic acid etch test is used to screen samples to determine the need for further testing. Samples that have acceptable microstructures are considered not to be susceptible to intergranular corrosion and require no further testing. Samples with microstructures indicative of carbide precipitation must be subjected to one of the immersion tests. Tests for intergranular corrosion are summarized in a table in the article “Evaluating Intergranular Corrosion” in this Volume. This table includes ferritic stainless steels and nickel-rich chromium alloys as well as austenitic stainless steels.

Several electrochemical tests based on the polarization behavior of stainless steels susceptible to intergranular corrosion have been proposed (Ref 5, 6, 7, 8, 9, 10, 11). Although the tests have received considerable attention, only the single-loop electrochemical potentiokinetic reactivation (EPR) test has been adopted in a national standard (Ref 12). With this test, a polished stainless steel surface is first held at the corrosion potential (≈-400 mV versus saturated calomel electrode, or SCE) for 1 to 2 min in a test solution of sulfuric acid and potassium thiocyanate (0.5*M* H_2SO_4 + 0.01*M* KSCN) at -1 °C (30 °F). The electrode potential is then raised to a passive potential of +200 mV versus the SCE and held for 2 min. After this passivation step, the potential is decreased to the corrosion potential at a constant potential scan rate of 6 V/h. If the specimen is sensitized, the chromium-depleted regions reactivate during the potential scan back to the corrosion potential, resulting in a well-defined current loop. The charge, *Q*, measured during the reactivation scan can be related to the degree of sensitization. With this technique, the grain size must be measured to approximate the area of attack of chromium-depleted material. The double-loop EPR test (Ref 9, 10, 11, 12) is a refinement of the single-loop technique and avoids the necessity of polishing the test surface and measuring the grain size.

Intergranular Stress-Corrosion Cracking (SCC). Austenitic stainless steels that are susceptible to intergranular corrosion are also subject to intergranular SCC. The problem of the intergranular SCC of sensitized austenitic

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

stainless steels in boiling high-purity water containing oxygen has received a great deal of study. This seemingly benign environment has led to cracking of sensitized stainless steels in many boiling water nuclear reactors (Ref 44, 45, 46).

Sensitized stainless alloys of all types crack very rapidly in the polythionic acid that forms during the shutdown of desulfurization units in petroleum refineries (Ref 13, 14). Because this service involves long-term exposure of sensitizing temperatures, the stabilized grades should be used.

Effect of Ferrite and Martensite. Phases other than carbides can also influence the corrosion behavior of austenitic stainless steels. Ferrite, which is the result of an intentional balancing of the composition of some stainless steels to obtain greater resistance to hot cracking, appears to reduce pitting resistance as well as the resistance to strong acids. The presence of martensite may render the steels susceptible to hydrogen embrittlement under some conditions. Martensite can be produced by the deformation of unstable austenite. Although this phenomenon can occur in a number of commercial stainless steels, it is most common in the lower-nickel steels such as type 301, in which the transformation is used to increase formability. The presence of strain-induced martensite has been shown to increase the corrosion rate of type 304L in 10% sulfuric acid (Ref 15). This increased corrosion rate is believed to be the result of preferential attack of the martensite phase.

Effect of Sigma Phase. The effect of σ phase on the corrosion behavior of austenitic stainless steel has received considerable attention. This hard, brittle intermetallic phase precipitates in the same temperature range as chromium carbide and may produce susceptibility to intergranular corrosion in some environments.

Because it is hard and brittle, σ phase affects mechanical as well as corrosion properties. Although it is often associated with δ-ferrite, it can form directly from austenite.

The effects of σ phase on the corrosion behavior of austenitic stainless steels are most serious in highly oxidizing environments. With standard grades such as 316L and CF3M, the problem is of practical concern only if the phase is continuous. Although discrete particles of σ phase may be attacked directly, such corrosion does not seem to contribute significantly to the penetration of the steel. With the more highly alloyed stainless steel grades, the precipitation of σ phase can result in a substantial loss in pitting and crevice corrosion resistance. This is discussed in the section “High-Performance Stainless Steels” in this article.

The most important corrosion problem with σ phase in austenitic stainless steels occurs before it is microscopically resolved (Ref 16). When the low-carbon molybdenum-containing austenitic stainless steels (such as type 316L and CF3M) or the stabilized grades (such as type 321 and type 347) are exposed at 675 °C (1245 °F), they may become susceptible to intergranular corrosion in nitric acid (HNO_3) and, in some cases, $Fe_2(SO_4)_3$-H_2SO_4. This susceptibility cannot be explained by carbide precipitation, and σ phase usually cannot be found in the optical microstructure. However, because some of the susceptible steels do exhibit continuous networks of σ phase, it has been assumed that this constituent is the cause of the intergranular corrosion. The hypothesis is that even when σ phase is not visible in the optical microstructure, its effects are felt through some precursor or invisible phase. Invisible σ phase must be considered when testing for susceptibility to intergranular corrosion, but it seems to affect corrosion resistance only in very oxidizing environments, such as HNO_3.

Unsensitized austenitic stainless steels (that is, solution-annealed material containing no carbides or other deleterious phases) are subject to intergranular corrosion in very highly oxidizing environments, such as HNO_3 containing hexavalent chromium (Ref 17). None of the regularly controlled metallurgical variables influences this type of intergranular attack. Additional information on, and micrographs of, σ phase in austenitic stainless steels can be found in the article “Wrought Stainless Steels” in *Metallography and Microstructures,* Volume 9 of *ASM Handbook,* 1985, formerly *Metals Handbook,* 9th edition.

مرجع مهندسی مواد و متالورژی

Intergranular Corrosion. The mechanism for intergranular corrosion in ferritic stainless steels is largely accepted as being the same as that in austenitic stainless steels. Chromium compounds precipitate at grain boundaries, and this causes chromium depletion in the grains immediately adjacent to the boundaries (Ref 18, 19). This lowering of the chromium content leads to increased corrosion rates in the oxidizing solutions usually used to evaluate intergranular corrosion.

There are several differences between the sensitization of ferritic and austenitic stainless steels to intergranular corrosion. The first is that the solubility of nitrogen in austenite is great enough that chromium nitride precipitation is not a significant cause of intergranular corrosion in austenitic steels. It is, however, a significant cause in ferritic stainless steels. The second is the temperature at which sensitization occurs. Sensitization in austenitic steels is produced by heating between 425 and 815 °C (800 and 1500 °F). In conventional ferritic alloys, sensitization is caused by heating above 925 °C (1700 °F). This difference is the result of the relative solubility of carbon and nitrogen in ferrite and austenite. Because the sensitization temperatures are different for austenitic and ferritic steels, it is not surprising that the welding of susceptible steels produces different zones of intergranular corrosion. In austenitic steels, intergranular corrosion occurs at some distance from the weld, where the peak temperature reached during welding is approximately 675 °C (1250 °F). Because the sensitization of ferritic stainless steels occurs at higher temperatures, the fusion zone and the weld itself are the most likely areas for intergranular corrosion.

The mere presence of chromium carbides and nitrides in ferritic stainless steels does not ensure that they will be subject to intergranular corrosion. On the contrary, the usual annealing treatment for conventional ferritic stainless steels is one that precipitates the carbides and nitrides at temperatures (700 to 925 °C, or 1300 to 1700 °F) at which the chromium can diffuse back into the depleted zones. These same treatments would, of course, sensitize austenitic stainless steels because of the much slower rate of diffusion of chromium in austenite.

Avoiding Intergranular Corrosion. Clearly, the most straightforward method of preventing intergranular attack in ferritic stainless steels is to restrict their interstitial contents. The results shown in Table 1 give an indication of the levels of carbon and nitrogen required to avoid intergranular corrosion of Fe-Cr-Mo alloys in boiling 16% H_2SO_4-copper-copper sulfate ($CuSO_4$) solutions. Evaluation was by bending. The samples that passed had no cracks after bending.

Table 1 Results of ASTM A 763, practice Z, on representative as-welded ferritic stainless steels

Welds were made using the gas tungsten arc welding technique with no filler metal added.

Alloy	Interstitial content, wt%		Result
	C	**N**	
18Cr-2Mo	0.002	0.004	Pass
	0.010	0.004	Fail
	0.002	0.009	Fail
26Cr-1Mo	0.002	0.005	Pass
	0.004	0.010	Partial failure
	0.003	0.016	Fail
	0.013	0.006	Fail

Source: Ref 20

For 18Cr-2Mo alloys to be immune to intergranular corrosion, it appears that the maximum level of carbon plus nitrogen is 60 to 80 ppm; for 26Cr-1Mo steels, this level rises to approximately 150 ppm. The notation of partial failure for the 26Cr-1Mo steel containing 0.004% C and 0.010% N indicates that only a few grain boundaries opened on bending and that it probably represents the limiting composition. Using the 50% H_2SO_4-$Fe_2(SO_4)_3$ test, it was determined that the interstitial limits for the 29Cr-4Mo steel were 0.010% C (max) and 0.020% N (max), with the additional restriction that the combined total not exceed 250 ppm (Ref 19). As their alloy contents increase, the iron-chromium-molybdenum steels seem to grow more tolerant of interstitials with regard to intergranular corrosion.

The levels of carbon and nitrogen that are needed to keep 18Cr-Mo alloys free of intergranular corrosion are such that very low interstitial versions of 18% Cr alloys have received little commercial attention. The 26Cr-1Mo and 29Cr-4Mo steels have been made in considerable quantity with very low interstitials, for example, 20 ppm C and 100 ppm N.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The low-interstitial ferritic stainless steels respond to heat treatment in a manner somewhat similar to that of austenitic stainless steels. As the results for weldments in Table 1 indicate, rapid cooling from high temperature preserves resistance to intergranular corrosion. However, depending on alloy content and interstitial levels, these alloys may be sensitive to a cooling rate from temperatures above approximately 600 °C (1110 °F) (Ref 21, 22). Less pure Fe-Cr-Mo alloys can also be affected by a cooling rate from approximately 800 °C (1470 °F), but at higher temperatures, it is impossible to quench them fast enough to avoid intergranular attack.

Isothermal heat treatments can also produce sensitivity to intergranular corrosion in low-interstitial ferritic stainless steels (Ref 22). For example, the effects of annealing at 620 °C (1150 °F) on the intergranular corrosion of 26% Cr alloys with 0 to 3% Mo were studied (Ref 23). The alloys contained 0.007 to 0.013% C and 0.020 to 0.024% N. As little as 10 min at temperature can lead to intergranular corrosion; however, continuing the treatment for 1 to 2 h can cure the damage (Table 2). Increasing the molybdenum content delays the onset of sensitization and makes it less severe. It does, however, delay recovery.

Table 2 Corrosion rates of 26% Cr ferritic stainless steels containing 0 to 3% Mo that were annealed for 15 min at 900 °C (1650 °F), water quenched, annealed for increasing times at 620 °C (1150 °F), then water quenched

Testing was performed according to recommendations in ASTM A 763, practice X (ferric sulfate/sulfuric acid test).

Alloy	Corrosion rate, $mg/dm^2/d$						
	900 °C (1650 °F) anneal	**Annealing time at 620 °C (1150 °F)**					
		10 min	**30 min**	**1 h**	**2 h**	**4 h**	**5 h**
26-0	50	15,700	270	62	81	85	43

(a) 56 h in test solution. Source: Ref 23

The very low levels of interstitials needed to ensure that ferritic stainless steels are immune to intergranular corrosion suggest that stabilizing elements might offer a means of preventing this type of corrosion without such restrictive limits on the carbon and nitrogen. Both titanium and niobium can be used, and each has its advantages (Ref 24). In general, weld ductility is somewhat better in the titanium-containing alloys, but the toughness of the niobium steels is better. As noted previously, titanium-stabilized alloys are not recommended for service in HNO_3, but the niobium-containing steels can be used in this environment.

Table 3 shows the results of Cu-$CuSO_4$-16% H_2SO_4 tests on 26Cr-1Mo and 18Cr-2Mo steels with additions of either titanium and/or niobium. Inspection of the data suggests that the required amount of titanium cannot be described by a simple ratio as it is in austenitic steels. The amount of titanium or niobium required for ferritic stainless steels to be immune to intergranular corrosion in the $CuSO_4$-16% H_2SO_4 test has been investigated (Ref 25). It has been determined that for 26Cr-1Mo and 18Cr-2Mo alloys, the minimum stabilizer concentration is given by:

$$Ti + Nb = 0.2 + 4\,(C + N) \qquad \text{(Eq 1)}$$

According to Ref 25, this minimum combination is valid for combined carbon and nitrogen contents in the range of 0.02 to 0.05%. It should be emphasized that the limits set in Eq 1 are truly minimal and are needed in the final product if intergranular attack is to be avoided.

Source: Ref 20

This guideline is empirical and cannot be explained on the basis of stoichiometry. The alloys in the study (Ref 25) were fully deoxidized with aluminum before the stabilizing additions were made. Therefore, it is unlikely that excess stabilizer is required for the purpose of reacting with oxygen.

The susceptibility of titanium-stabilized steels to intergranular attack in HNO_3 has been noted earlier. Because there is evidence that titanium carbide can be directly attacked by HNO_3, this mechanism is usually used to explain intergranular corrosion in titanium-containing steels. Another explanation that could be advanced about the intergranular attack of titanium-bearing steels under highly oxidizing conditions is an invisible σ phase such as that encountered in type 316L and discussed previously.

Testing for Intergranular Corrosion. Standardized test methods for detecting the susceptibility of ferritic stainless steels to intergranular corrosion are described in ASTM A 763 (Ref 26). The methods are similar to those described in ASTM A 262 (Ref 4) for austenitic stainless steels in that there is an oxalic acid etch test and three acid immersion tests. The principal difference between the two standards is the use of microscopic examination of samples exposed to the boiling acid solutions. The presence or absence of grain dropping becomes the acceptance criterion for these samples.

Effects of Austenite and Martensite. The austenitic and martensitic phases are discussed together for ferritic stainless steels because they are interrelated; one can occur as the result of the other.

High-purity iron-chromium alloys are ferritic at all temperatures up to the melting point if they contain more than approximately 12% Cr. However, the gamma loop in iron-chromium alloys can be greatly expanded by the addition of carbon and nitrogen. For example, it was found that the ferrite-austenite boundary was extended to 29% Cr in alloys that contained 0.05% C and 0.25% N (Ref 27).

Although the formation of austenite in ferritic stainless steels can be avoided by restricting their interstitial contents or by combining the interstitials with such elements as titanium or niobium, many of the ferritic stainless steels that are produced commercially undergo partial transformation to austenite. Once the austenite is formed, the question is how it is transformed. In one study, for example, the transformation products were dependent on the chromium content and the cooling rate (Ref 28). Slow cooling leads to the transformation of austenite into ferrite and carbides in all of the steels examined, but quenching can either produce martensite or retain the austenite.

The martensite start temperature (M_s) for a 17% Cr steel was measured at 176 °C (349 °F), and it was found that the transformation was 90% complete at 93 °C (199 °F) (Ref 28). The M_s for a 21% Cr steel was -160 °C (-256 °F), and martensite did not form in quenched 25% Cr alloys. Untempered martensite obviously reduces the toughness and ductility of ferritic stainless steels, and its presence is one cause of the poor ductility of welded type 430. In discussing this work (Ref 28), other researchers observed that welded type 430 (17% Cr) had poor ductility but that welded type 442 (21% Cr) had good ductility (Ref 29). These findings were attributed to the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

transformation of austenite to martensite in the lower-chromium steel (type 430) but not in the 21% Cr steel (type 442). Both weldments were subject to intergranular corrosion, however.

The austenite retained in the higher-chromium steels is saturated with carbon, and when it is heated into the carbide precipitation region, for example, 760 °C (1400 °F), it loses carbon and becomes unstable enough to transform to martensite on cooling. This transformation product must then be tempered to restore ductility.

Another study found that martensite in type 430 corroded at a higher rate than the surrounding ferrite in boiling 50% H_2SO_4 + $Fe_2(SO_4)_3$ (Ref 19). This difference was attributed to the partitioning of chromium between ferrite and austenite at high temperatures. Because the austenite is lower in chromium, the martensite that forms from it would also be lower in chromium. The 50% H_2SO_4-$Fe_2(SO_4)_3$ test is quite sensitive to changes in chromium content in the 12 to 18% Cr range (Fig. 1). The test is less sensitive at higher chromium contents; therefore, no preferential attack was noted in austenite formed in type 446. This same austenite was preferentially attacked by boiling 5% H_2SO_4, presumably because of its higher interstitial content.

These corrosion experiments help to elucidate the effect of metallurgical factors on the corrosion behavior of ferritic stainless steels. However, these experiments describe situations rarely encountered in practice, because the mechanical properties of steels with such microstructures limit their usefulness.

Effect of Sigma and Related Phases. In contrast to the case of austenitic steels, the occurrence of σ phase in most commercial ferritic stainless steels can be predicted from the iron- chromium phase diagram. Fortunately, the kinetics of σ formation are very sluggish, and σ phase is not normally encountered in the processing of commercial ferritic stainless steels.

The formation of σ phase in the iron-chromium system has been thoroughly researched, and the literature has been well summarized (Ref 30). The phase has the nominal composition of FeCr, but it can dissolve approximately 5% of either iron or chromium. It forms congruently from ferrite at 815 °C (1500 °F). The sluggishness of the reaction makes it difficult to define the low-temperature limits of the σ phase field, but the ferrite/ferrite + σ phase boundary has been estimated at 9.5% Cr at 480 °C (895 °F) (Ref 30). Cold work accelerates the precipitation of σ phase.

There is relatively little information on how σ phase affects the corrosion behavior of ferritic stainless steels; however, continuous networks would be expected to be more troublesome than isolated colonies. Because σ phase contains more chromium than does the ferrite, its presence could also affect the corrosion behavior by either local or general depletion of the chromium content of the matrix.

One study investigated the corrosion behavior of an Fe-47Cr alloy that was heat treated so that it was either entirely ferrite or entirely σ phase (Ref 31). These data are shown in Table 4. The types of environments studied induced reducing (active), oxidizing (passive), and pitting corrosion conditions. The differences were greatest in the oxidizing and pitting environments. These results indicate that σ phase is more likely to corrode than ferrite in many instances and that no chromium depletion mechanism need be invoked to explain how σ phase can reduce the corrosion resistance.

Table 4 The effect of crystal structure on the corrosion behavior of an Fe-47Cr alloy

Solution	Corrosion rate, g/dm^2/d		
	Ferrite	**σ phase**	**Ratio[(a)]**
Reducing			
10% HCl boiling	1461	7543	5.2

(a) Corrosion rate of σ phase ÷ corrosion rate of ferrite. Source: Ref 31

In molybdenum-containing ferritic steels, χ phase, which is closely related to σ phase, can be found (Ref 32). It occurs in the temperature range of 550 to 950 °C (1020 to 1740 °F). It has the nominal composition Fe_2CrMo,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

but there are deviations from stoichiometry. In an investigation of the effect of heat treatment on the microstructure of 29Cr-4Mo alloys, both χ and σ phases were found in material held in the 700 to 925 °C (1290 to 1695 °F) range (Ref 33). Long- term aging of the 29Cr-4Mo steel did not render it susceptible to intergranular corrosion in the boiling 50% H_2SO_4 + $Fe_2(SO_4)_3$ solution.

This work also included 29Cr-4Mo-2Ni alloys, and χ and σ phases were seen to form much more quickly in these steels than in nickel-free materials. This observation is consistent with earlier results that nickel additions up to approximately 2% can accelerate the formation of σ phase in iron-chromium alloys (Ref 34). At higher levels, nickel decreases the rate of σ- phase precipitation. Sigma and χ reduce the ductility of the 29Cr-4Mo-2Ni alloys but do not cause it to undergo intergranular corrosion. However, long-term aging at 815 °C (1500 °F) did render them susceptible to crevice corrosion in 10% hydrated ferric chloride ($FeCl_3 \cdot 6H_2O$) at 50 °C (120 °F). In this case, the ferrite was preferentially attacked, perhaps because it was depleted in chromium and molybdenum by precipitation of the second phase.

There is some evidence that the invisible χ or σ phase may affect the properties of stabilized 18Cr-2Mo ferritic stainless steels aged at approximately 620 °C (1150 °F). For example, it was shown that aging for even relatively short times could produce extensive intergranular corrosion in 18Cr-2Mo-Ti steels exposed to boiling 50% H_2SO_4 + $Fe_2(SO_4)_3$ (Ref 35). The steels were not subject to intergranular attack in 10% HNO_3 + 3% hydrofluoric acid (HF) or in boiling 16% H_2SO_4 + 6% $CuSO_4$ + Cu, and both of these solutions are known to produce intergranular attack in improperly stabilized ferritic stainless steels. Similar behavior has been noted in niobium-stabilized 18Cr-2Mo steels (Ref 36). In neither case was χ or σ phase clearly present at the grain boundaries.

Duplex Stainless Steels

Duplex stainless steels are those that are composed of a mixture of austenite and ferrite, most typically with each phase in the range of 25 to 75%. The common wrought austenitic stainless steels, such as types 304 and 316, are usually balanced to contain approximately 5% ferrite to facilitate welding, but this level would not be sufficient for the steel to be classified as a duplex stainless steel. The common cast stainless steels, such as CF-8 and CF-8M, are mostly austenite with some ferrite, perhaps 10 to 15% to aid in avoiding hot cracking during solidification, but these steels also would not typically be called duplex stainless steels. These steels are often considered to be simple analogs of wrought alloys with similar compositions; however, they do not always have the same response to heat treatment. The corrosion evaluation of these alloys deserves further study.

Wrought duplex stainless steel may have either a ferrite matrix (type 329) or an austenitic matrix (U50). The most common duplex alloys, such as 2205, typically contain 50 to 60% austenite in a ferrite matrix. The modern alloys are produced with low carbon contents, usually less than 0.03%, and intergranular corrosion resulting from carbide precipitation generally has not been a practical problem.

These alloys are usually high in chromium (22 to 27%) and molybdenum (2 to 4%). As a result, these alloys are prone to the formation of intermetallic phases such as σ and χ if they are not cooled rapidly through the 900 to 700 °C (1650 to 1290 °F) range (Ref 37). Although these intermetallic compounds do degrade the corrosion resistance of the alloys, they have a more drastic effect on the mechanical properties, particularly the impact properties. If a duplex alloy has satisfactory impact properties, it probably will not experience reduced corrosion resistance. In both wrought and cast duplex stainless steel alloys, it appears that the high rate of diffusion of chromium in the ferrite phase generally minimizes depleted zones and, therefore, intergranular corrosion.

Testing for the Presence of σ/χ Phases. Because of the necessity of avoiding detrimental intermetallic phases in duplex stainless steel, standard test methods have been developed to detect their presence in wrought products. The ASTM A 923 specification (Ref 38) covers test procedures for wrought 2205 material (S31803 and S32205) and for 2507 (S32750). This specification includes a sodium hydroxide etch test for rapid screening of material as well as a Charpy impact test and a ferric chloride corrosion test for detecting the presence of σ/χ phase.

High-Performance Stainless Steels

In the 1980s and 1990s, more highly alloyed grades of austenitic, ferritic, and duplex stainless steel were developed. These grades provide improved corrosion resistance and higher strength levels compared to commodity grades such as type 304 and 316 stainless steels. Although the terms *superaustenitic*, *superferritic*, and *superduplex* are often used to describe these alloys, there is no universally accepted definition for a "super" stainless steel.

The relative resistance of a stainless steel to chloride pitting and crevice corrosion can be related to an alloy composition by an empirical formula called the pitting resistance equivalent number (PREN). Over the years, various PREN expressions have been presented (Ref 47, 48, 49, 50, 51), but the most commonly used expression is:

$$PREN = \%Cr + 3.3[\%Mo + 0.5\,(\%W)] + x \cdot \%N \qquad \text{(Eq 2)}$$

where x is typically given as either 16 or 30, and composition is weight percent.

The choice of either 16 or 30 for the nitrogen coefficient is generally based on personnel preference. A systematic investigation (Ref 52) of the correlation between various PREN formulas and the critical pitting temperature revealed that all formulas show comparable correlation with a slight tendency towards decreased correlation with the higher nitrogen coefficients.

A grade is generally designated as a super stainless steel if its PREN approaches 40 or more. Some of the more common wrought austenitic, ferritic, and duplex stainless steels that fall into this category are presented in Tables 5, 6, 7, respectively.

Although these grades exhibit outstanding corrosion resistance, the high alloying content makes them susceptible to the formation of detrimental secondary phases. Table 8 lists the secondary phases that have been found in high-performance stainless steels. These phases can be classified as carbides, nitrides, or intermetallic compounds. High-performance stainless steels, in general, have low carbon levels, and the ferritic grades are

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

stabilized with titanium and/or niobium additions. Because of this, chromium carbide sensitization is generally not a concern. The most important phase in terms of its effect on corrosion resistance is σ and, to a lesser extent, the χ phase. These phases form over the same temperature range, approximately 550 to 1050 °C (1020 to 1920 °F), and have similar formation kinetics. Because of this, the precipitation of the χ phase is often concurrent with σ but usually in a much smaller volume fraction. As with σ phase, the formation of χ results in reduced corrosion resistance and loss of ductility and toughness. It is important to note the high solubility of nitrogen in the austenitic and duplex stainless steels. It is the effect of nitrogen delaying the precipitation of intermetallic phases that has allowed these highly alloyed stainless steels to see practical application, including regular use in the as-welded condition in highly corrosive environments.

The high-performance ferritic and duplex grades are also vulnerable to alpha-prime (α′) precipitation in the temperature range of 350 to 550 °C (660 to 1020 °F). This chromium-rich phase does not have a large impact on the corrosion resistance, but its formation can result in a substantial loss of toughness. This phenomenon has been termed 475 °C (885 °F) embrittlement.

The kinetics of the σ and χ transformations are dependent on the alloy composition. Higher chromium and molybdenum contents favor higher rates of formation and potentially larger volume fractions. Nitrogen

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

additions in austenitic and duplex steels retard the transformation reactions. Because of this, the tendency to form these detrimental phases can vary substantially from alloy to alloy as well as within a specific grade, depending on the composition of the alloy. A summary of the isothermal precipitation kinetics of important phases in some specific high-performance austenitic, ferritic, and duplex stainless steels is shown in Fig. 4, 5, and 6, respectively. These time-temperature-precipitation diagrams show that the σ/χ precipitation kinetics can be quite rapid, in the 800 to 900 °C (1475 to 1650 °F) temperature range. Because of this, temperature excursions and cooling rates must be designed to avoid the precipitation of these undesirable phases. If undesirable phases are present, they can be redissolved and the corrosion and toughness properties restored by a solution anneal heat treatment.

The presence of σ/χ formation can have a strong impact on the resistance of stainless steel to localized chloride attack. The effects of isothermal heat treatments in the temperature range of 550 to 1050 °C (1020 to 1920 °F) on the critical pitting and critical crevice corrosion temperatures of Unified Numbering System (UNS) N08367 alloy have been investigated (Ref 40). The resulting isocritical pitting temperature and isocritical crevice temperature curves are summarized in Fig. 7 and 8, respectively.

مرجع مهندسی مواد و متالورژی

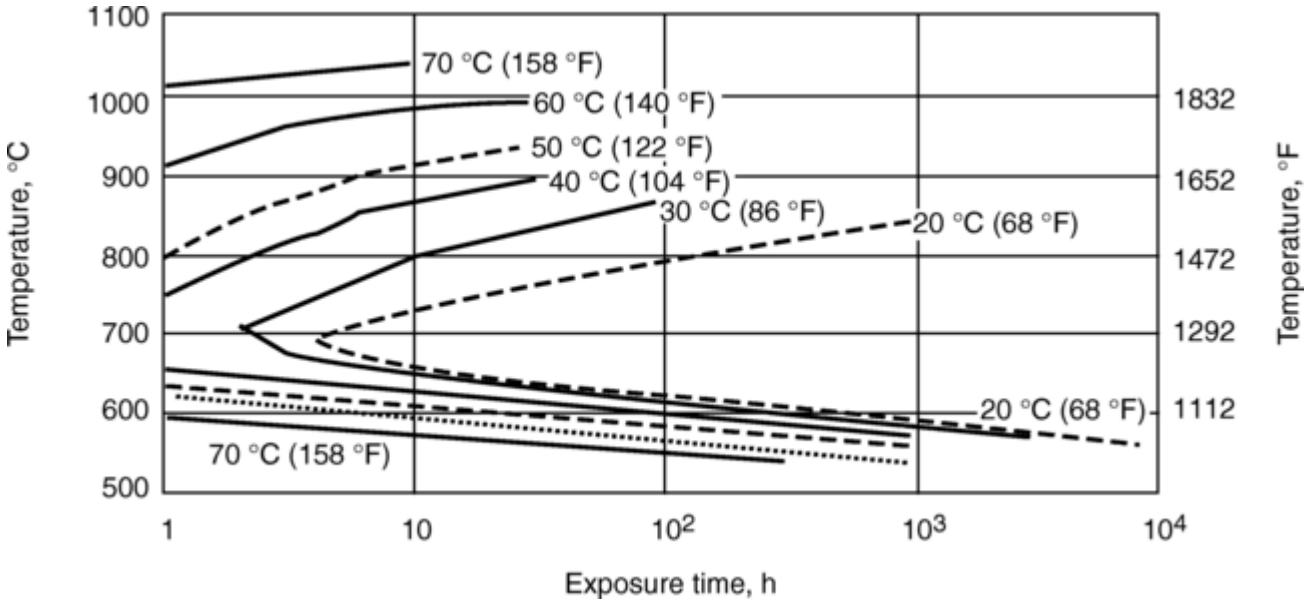

Fig. 7 Isocritical pitting temperature curves measured with the AL-6XN (N08367) alloy in 6% ferric chloride. Source: Ref 40

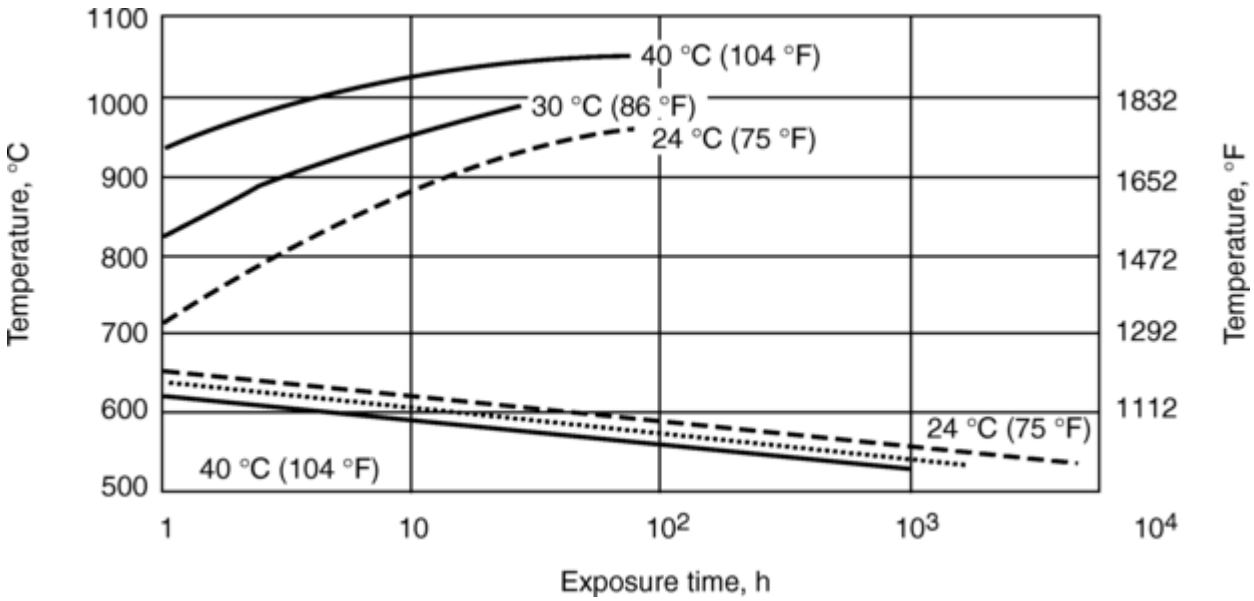

Fig. 8 Isocritical crevice corrosion temperature curves measured with the AL-6XN (N08367) alloy in 6% ferric chloride. Source: Ref 40

Similar drops in the critical pitting and critical crevice corrosion temperatures measured with 25% Cr superduplex stainless steels have been reported (Ref 41, 42). With ferritic stainless steels, the precipitation of σ/χ phase produces a loss of corrosion resistance (Ref 43). However, the loss of corrosion properties with ferritic stainless steels is usually of secondary concern compared to the loss in toughness. The change in the room-temperature impact properties of the UNS S44735 alloy after various isothermal anneals is given in Fig. 9. This plot shows a substantial loss of toughness in the 315 to 538 °C (600 to 1000 °F) range and the 593 to 900 °C (1100 to 1650 °F) range due to the formation of α′ and σ, respectively.

Effects of Metallurgical Variables on the Corrosion of Aluminum Alloys

Jim Moran, Alcoa

Introduction

THE METALLURGICAL EFFECTS on corrosion of aluminum can be classified into two categories. In the first category are effects from insoluble, intermetallic constituent particles. These can be formed from trace impurity elements, most notably iron, and/or from purposely added alloying elements such as Al-Cu-Mg constituents in 2*xxx* alloys. In this context the term *insoluble* can refer to "thermodynamically insoluble," as is the case for most Al-Fe-X particles, or to "commercially insoluble," in that the kinetics of dissolution are too sluggish to dissolve the particles during nominal thermal practices in production, as is the case for Al-Cu-Mg constituents in 2*xxx* alloys. The constituent particles play a predominant role in pitting corrosion. In the second general category are effects from precipitation of secondary phases, usually as a result of a controlled thermal process such as age hardening. This includes both intergranular and intragranular precipitation, as well as effects from solute remaining in solid solution.

Effects of Metallurgical Variables on the Corrosion of Aluminum Alloys

Jim Moran, Alcoa

Effect of Constituent Particles on Pitting Corrosion of Aluminum

In the commercial production of aluminum ingot and billet, some trace amount of impurities is incorporated into the alloy (Ref 1, 2, 3). Iron is common. Iron has an exceptionally low solubility in aluminum and precipitates out during ingot solidification in the form of various insoluble intermetallic phases, commonly referred to as constituent particles. These particles are on the order of a few microns to a few tens of microns in size and have various compositions, depending on the iron level and alloying elements. Commonly identified compositions include Al_3Fe, Al_7Cu_2Fe, and various other Al_x(Fe, Cu, Mn) type compounds. Other constituents are alloy specific. For example, alloy 2024 (Al-Cu-Mg) contains relatively large (on the same order of magnitude as the iron-bearing constituent particles) S-phase (Al_2CuMg) particles. Although these particles are thermodynamically soluble during solution heat treatment, the kinetics are insufficient for complete dissolution. Hence, the particles are present even after solution heat treatments, such as for T3 and T4 tempers.

Constituent particles are well known sites for pit initiation, due to galvanic interaction with the surrounding matrix (Ref 4, 5, 6, 7). Depending on initial composition, some constituent particles are cathodic to the matrix, and others are anodic. Some exhibit a changing galvanic effect as the corrosion process ensues. A compilation of the corrosion potentials for a large number of aluminum-based constituent particles is provided in Ref 8. These data can be used to help predict the galvanic polarity in a pit initiation event. The iron and manganese-bearing particles are considered to be cathodic to the matrix. Selective matrix dissolution surrounding the

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

cathodic particles promotes pit initiation. The severity of pitting is dependent on the degree of clustering of the particles (Ref 7). A region of smaller, isolated particles will promote a mild, shallow pitting attack. In a region with clustered particles, the smaller pits can link up to form larger pits. This clustering can be across the surface, or it can be subsurface, which would promote deeper pitting.

The Al-Cu-Mg particles inherent to 2*xxx* series alloys have been identified as anodic to the matrix (Ref 6). In this case the initial dissolution occurs in the particle, as opposed to the surrounding matrix. The net effect is similar, in that a pit is initiated at the location of galvanic attack. More discussion of the impact of these copper-bearing particles on corrosion performance is included in the section on 2*xxx* alloys.

While the mechanistic specifics can vary by particle type, the result is similar. The particle/ matrix interface is a site of preferential dissolution, resulting in the initiation of a pitting site.

Jim Moran, Alcoa

1*xxx* Series Alloys

These alloys are at least 99% pure aluminum. They are relatively corrosion resistant but can be susceptible to pitting, caused by Al-Fe-X constituent particles. However, the pitting severity is not great as in other alloy classes. The degree of pitting susceptibility is greater for the less pure 1*xxx* grades, such as those having greater iron content.

Jim Moran, Alcoa

2*xxx* Series Alloys

The alloying element common to all 2*xxx* alloys is copper. Several common alloys also contain magnesium and/or manganese. These alloys are precipitation hardened. After final fabrication, the alloys are solution heat treated and quenched. They are then frequently used in the as-quenched and naturally aged (room temperature) condition (T3 or T4 tempers) or artificially aged to increase strength via formation of Al- Cu(-Mg) strengthening precipitates (T6 or T8 tempers).

Similar to all aluminum alloys, constituent particles play a key role in pit initiation. In addition to the Al-Fe-*X* types of particles, 2*xxx* alloys contain Al-Cu and Al-Cu-Mg particles. The Al-Cu-Mg particles have been the subject of active research in recent years (e.g., Ref 6). These particles are initially anodic to the surrounding matrix. However, as a result of dealloying, they can become copper rich and cathodic. In either case, the galvanic interaction at the particle/matrix interface results in pit initiation.

Due to the copper content, 2*xxx* alloys tend to be more susceptible to pitting and general attack than other alloys. During dissolution of Al-Cu- Mg particles, regions of metallic copper are formed on the alloy, thereby promoting accelerated galvanic attack and increasing the pitting severity relative to non-copper-containing alloys (Ref 6). This copper can serve to initiate new pits or can assist in the propagation of already- established pits.

Depending on temper and processing specifics, the intergranular (IG) corrosion and stress- corrosion cracking (SCC) resistance of 2*xxx* alloys can vary significantly. The basic mechanism is galvanic interaction between the grain boundary region and the interior grain matrix (Ref 2, 3). Consider alloy 2024 in the solution heat treated temper (T3 or T4). If quenched too slowly, the alloy can be highly susceptible to IG corrosion. When poorly quenched, large Al- Cu(-Mg) precipitates form along the grain boundary. This produces a copper-depleted-zone along the boundaries, and a galvanic couple is then established. The copper-depleted zone is anodic with respect to the matrix, which still has considerable copper in solid solution. The boundary region is then preferentially attacked, promoting IG corrosion. When properly quenched, eliminating the precipitation of large grain boundary phases, the copper-depleted zone does not develop and IG corrosion susceptibility is low. In either case, fast or slow quench, artificial aging to peak strength greatly reduces the IG corrosion susceptibility. As the aging process ensues, copper is continually removed from solid solution to form Al-Cu(-Mg) precipitates, both intragranularly (these are the primary strengthening precipitates) and intergranularly. Sufficient copper is eventually removed from solid solution in the grain matrix such that the copper content is similar to that of the near-boundary region. Hence, the galvanic driving force is removed, and the IG corrosion susceptibility is greatly reduced.

Even in well-quenched 2024, the IG corrosion rate can be accelerated in underaged tempers. The mechanism is similar. Initially, precipitation can be favored on grain boundaries, and the galvanic process described previously ensues. Continued aging toward peak-aged eliminates this. A similar scenario exists for SCC and exfoliation corrosion. More quantitative information on acceptable quench rates and the effect of quench rate are provided in Ref 1 and 2.

The pitting behavior, on the other hand, is not significantly affected by quench rate and is only moderately affected by aging. The pitting behavior is predominantly determined by the constituent particles, as previously discussed, and these particles are not significantly affected by quench rate or aging time.

Much of the preceding discussion focuses on alloy 2024. The general trends and mechanisms are believed similar for other commercially used 2*xxx* alloys (e.g., 2014, 2008, 2036); however, the severity can differ from alloy to alloy. Pitting susceptibility is related to the copper content. Lower-copper alloys (2036, 2008) exhibit significantly better pitting resistance than higher- copper alloys, such as 2024. The variation in IG corrosion

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

susceptibility as a function of copper content is less pronounced. Effects of quench rate and aging time, as discussed previously, are more dominant factors in determining IG corrosion susceptibility.

Effects of Metallurgical Variables on the Corrosion of Aluminum Alloys

Jim Moran, Alcoa

3*xxx* Series Alloys

The alloys in this series contain primarily manganese (<1.5%). Several also contain magnesium (<1.5%). They are strengthened by work hardening and are produced in extruded, sheet, and plate forms. These alloys offer corrosion characteristics similar to those of 1*xxx* series alloys, with perhaps a slightly better resistance to corrosion. Manganese can be incorporated into the constituent particles, which results in corrosion potential more similar to that of the matrix: hence, less galvanic driving force for pitting. These alloys are generally considered to have excellent corrosion resistance. They commonly find use in beverage and food containers, building products, heat exchanger tubing, and other general uses requiring good corrosion resistance with moderate strength.

J. Moran, Effects of Metallurgical Variables on the Corrosion of Aluminum Alloys, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 275–278

Effects of Metallurgical Variables on the Corrosion of Aluminum Alloys

Jim Moran, Alcoa

4*xxx* Series Alloys

The alloys in this series contain primarily silicon (<14%). Because of their low melting point characteristics, these alloys are used primarily for braze and weld filler applications. These alloys are usually produced as sheet or wire, and are found in the as-cast condition following a thermal joining process. Much of the silicon in these alloys precipitates out as elemental silicon. Although elemental silicon is highly cathodic to the aluminum

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

matrix, the silicon particles are easily polarized to near the potential of the matrix; hence their effect on corrosion susceptibility is minimal. However, when silicon is used in a thermal joining process, there have been cases where it has diffused into the grain boundaries of the materials being joined and caused decreased corrosion resistance.

J. Moran, Effects of Metallurgical Variables on the Corrosion of Aluminum Alloys, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 275–278

Jim Moran, Alcoa

5*xxx* Series Alloys

The alloys in this series contain primarily magnesium (<6%). Several of the alloys also contain manganese. Alloys in this series are strengthened by work hardening and are produced primarily as sheet and plate. In general, 5*xxx* series alloys provide excellent resistance to all forms of corrosion. This accounts for their common use in a variety of applications requiring good corrosion resistance, including building products, chemical processing, and food handling. They are also alloys of choice for marine applications, including boat building. Magnesium additions generally improve the corrosion resistance in seawater.

There is one drawback to the use of 5*xxx* alloys in corrosive environments. Those alloys with greater than approximately 3% magnesium can become sensitized when exposed to moderate temperatures or after long time periods (many years) at room temperature. In this context, sensitization refers to selective precipitation of beta phase, Mg_2Al_3, along grain boundaries. Beta is highly anodic to the aluminum matrix and forms a continuous grain boundary network when exposed to moderately elevated temperatures. Once beta is formed, the material becomes highly susceptible to IG corrosion and, depending on specific alloy and grain structure, can also be rendered susceptible to exfoliation and stress- corrosion cracking (Ref 2). The time required to form a sensitized microstructure is dependent on the magnesium content, alloy temper, exposure temperature, and initial processing (Ref 2, 9). Some 5*xxx* alloys can be thermally processed to remove a significant amount of the magnesium during fabrication, thereby greatly lowering the propensity for sensitization (Ref 2, 9)

Effects of Metallurgical Variables on the Corrosion of Aluminum Alloys

Jim Moran, Alcoa

6*xxx* Series Alloys

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The alloys in this series contain primarily magnesium and silicon, some with additions of copper and/or manganese (<1.2%). These alloys are strengthened by precipitation hardening, with the primary precipitate being Mg_2Si. These alloys generally have good corrosion resistance. Those that contain copper have somewhat poorer corrosion resistance.

Similar to most commercial aluminum alloys, Al-Fe-X constituents play a dominant role in pit initiation. Most 6*xxx* alloys provide excellent resistance to pitting corrosion. Intergranular corrosion resistance can vary. Low copper alloys, such as 6061, the most common 6*xxx* alloy, with a stoichiometric balance of Mg and Si, exhibit good resistance to all forms of corrosion. Alloys with an excess of silicon (that is, more than is needed to form Mg_2Si), tend to be more susceptible to IG corrosion. The silicon segregates to the grain boundaries, producing a silicon-depleted zone along the boundaries, which is anodic to the boundary and the matrix. This produces preferential attack along the grain boundaries, similar to the mechanism discussed for copper-depleted zones in 2*xxx* alloys (Ref 1, 10, 11).

Copper is added to some 6*xxx* alloys to augment strength. Examples include 6013, 6056, and 6111. Although pitting susceptibility is only slightly worse than it is for copper-free 6*xxx* alloys, IG corrosion susceptibility can be significantly worse. The severity is dependent on copper content and temper. The general mechanism is similar to that for 2*xxx*, albeit some of the specifics are still areas of active research. In general, a copper-depleted region develops along the grain boundaries. Whether this is from precipitation of Al-Mg-Si-Cu phases (such as Q-phase) or copper substitution into Mg_2Si, or both, is not fully understood. In any event, the copper-depleted region is preferentially attacked by the copper-rich matrix and copper-containing boundary particles (Ref 12, 13, 14). This mechanism is similar to that considered dominant in 2*xxx* alloys. With sufficient aging, sufficient copper is removed from solid solution in the grain matrix, and the galvanic driving force is removed. Intergranular susceptibility is significantly decreased. Unlike 2*xxx* alloys, where the IG corrosion susceptibility can be decreased by artificial aging to peak strength, 6*xxx* alloys often require overaging beyond peak strength in order to significantly decrease IG corrosion susceptibility.

7*xxx* Series Alloys

The alloys in this series all contain zinc (<9%). In addition, nearly all of these alloys contain magnesium (<4%), and many of them contain copper (<3%). The alloys can be generally divided into two categories. The first category consists of the copper-containing, high- strength alloys (e.g., 7075, 7050, 7055). These alloys are available in various forms (sheet, plate, extrusion) and are used extensively in the aerospace industry. The second category is low- copper alloys (e.g., 7005, 7029). These alloys offer somewhat better resistance to general corrosion and pitting (due to low copper) and are used in structural applications and automotive applications such as bumpers.

The mechanisms of corrosion and environmental fracture of 7*xxx* alloys, particularly the role of the microstructure in corrosion behavior, have been studied for decades and continue to be an area of active research. An in-depth treatment of this topic is beyond the scope of this review section. Several thorough reviews of the mechanisms of environmental fracture of 7*xxx* aluminum alloys are available (Ref 11, 15, 16, 17).

High-strength, copper-containing 7*xxx* alloys are strengthened by a precipitation-hardening sequence, including solution heat treatment and quench, followed by artificial aging. The primary precipitation sequence is complex, with a series of Guinier-Preston (GP) zones and metastable phases, resulting ultimately in the equilibrium phase, M, (or η) ($MgZn_2$), and/or T ($Mg_3Zn_3Al_2$), depending on composition. Copper can also be incorporated into the precipitates (Ref 18, 19).

As in most aluminum alloys, in the 7*xxx* alloys, constituent particles play a dominant role in pit initiation. The severity of pitting is dependent on the copper content. Lower-copper alloys are somewhat less susceptible to pitting corrosion, due to the same basic mechanism previously described in detail for 2*xxx* alloys.

While the basic pitting performance and mechanism are similar to those for other aluminum alloys, the IG corrosion, exfoliation, and stress-corrosion cracking (SCC) susceptibility of this class of alloys is far more complex. The specific metallurgical features controlling the corrosion performance are equally complex. Metallurgical effects on corrosion behavior of these alloys have been studied for decades (Ref 11, 15, 16, 17) and continue to be areas of active research (Ref 19, 20, 21, 22). Much of the work is particularly focused on SCC. However, in many cases the exfoliation and IG corrosion performance will trend similarly with SCC. This is not a universal rule; there are some exceptions for commercial alloys and tempers. Here, however, the general assumption will apply unless specifically stated otherwise.

Key factors in determining the corrosion behavior are temper and copper content. The alloy class can be generalized by these two factors, with some specific deviations outlined below. First, consider the effect(s) of temper. Tempers of commercial significance include W, T6, and various overaged T7X tempers. Detailed definitions of temper designations can be found in Ref 1 and 2. A discussion of the corrosion performance of each is provided in subsequent paragraphs.

W temper refers to a material that has been solution heat treated and quenched but given no artificial aging. Given the low strength and instability of W temper, it is not commercially viable for final product. However, some manufacturing paths exploit its high formability, then age-harden to a commercially viable temper. Hence, 7*xxx* alloys can be shipped, stored, and worked in W temper. W temper can be highly susceptible to IG corrosion, exfoliation, and SCC if quenched slowly. This can occur in thin product, given an inadequate quench, or in thicker plate, where the cooling rate towards the midthickness is slow. The proposed mechanism is similar to 2*xxx* IG corrosion. Preferential precipitation at boundaries of copper-containing precipitates occurs during an inadequate quench. This promotes preferential galvanic attack in the copper-depleted regions near the boundaries.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The T6 temper, often referred to as peak-aged, indicates artificial aging to a peak strength level. Stress-corrosion cracking and exfoliation susceptibility are typically high in this temper.

Overaging to T7X tempers improves SCC and exfoliation resistance. Several T7 tempers are used commercially. T73 is significantly overaged and offers excellent resistance to SCC and exfoliation. However, there is a significant decrease in strength, relative to T6 temper. T76 temper is less overaged than T73. It is nominally defined as having higher strength than T73, good exfoliation resistance, and SCC resistance better than that of T6 but usually not as good as that of T73. The most overaged temper would be T73. The most recent T7X temper developed is T77. Products available in T77 offer good SCC and exfoliation resistance with less of a strength penalty than traditional T76 or T73 tempers. A more thorough review of the effect of temper is provided in Ref 1.

The mechanism by which overaging improves SCC and exfoliation resistance remains an area of active research. In the most general sense, there are two mechanistic categories proposed for SCC (Ref 11, 15, 16, 17). The first is anodic dissolution, which is characterized by one or more galvanic processes at or near the grain boundaries (e.g., similar to that discussed for IG corrosion in the 2*xxx* section). The second is hydrogen-assisted cracking, in which hydrogen, by one or more of several proposed mechanisms, enhances embrittlement at the crack tip, promoting mechanical fracture. There is evidence that more copper becomes incorporated into precipitates, both intragranular and intergranular, as 7*xxx* alloys are aged beyond peak age (Ref 18, 19). The role of increased copper in reducing SCC can be discussed in terms of either general mechanism (Ref 19, 20, 21, 22).

Copper content also plays a role. Consider the comparison of alloys 7075 and 7050, where 7050 has a higher copper content. For W temper, 7050 is more susceptible to IG forms of corrosion (SCC, IGC, exfoliation), than 7075. It is believed that the higher-copper alloy retains more copper in grain boundary precipitates during the quench. In T6 and T7X tempers, 7050 is less susceptible than 7075. A clear mechanism for this effect is still an area of active research. One hypothesis, based on a hydrogen embrittlement model, is that the additional copper content leads to more copper incorporation into precipitates, which in turn provides enhanced trapping of hydrogen, thereby slowing the rate of hydrogen embrittlement (Ref 21).

Low-Copper, 7*xxx* Alloys. Due to the low copper content, these 7*xxx* alloys exhibit excellent resistance to general corrosion and pitting. However, as a group, they are relatively more susceptible to SCC than higher-copper 7*xxx* alloys. Depending on composition and processing specifics, many low-copper 7*xxx* alloys have an unrecrystallized microstructure. This is beneficial to SCC resistance in applications where the dominant stresses are in the longitudinal and long transverse orientations. With proper engineering, such alloys are successfully used in commercial structural applications. Alloys that are recrystallized tend to be more susceptible to SCC. Whereas overaging improves the SCC resistance of copper-containing 7*xxx* alloys, it does not greatly improve the SCC resistance of the low-copper 7*xxx* alloys. For more information on low-copper 7*xxx* alloys, see Ref 1.

Effects of Metallurgical Variables on the Corrosion of High-Nickel Alloys

Raúl B. Rebak, Lawrence Livermore National Laboratory

Introduction

NICKEL-BASE ALLOYS are solid solutions based in the element nickel. Even though nickel base alloys, in general, contain a large proportion of other alloying elements, these alloys maintain the face-centered cubic lattice structure (fcc or gamma) from the nickel-base element. As a consequence of the fcc structure, nickel-base alloys have excellent ductility, malleability, and formability. Nickel alloys are also readily weldable.

There are two large groups of the commercial nickel-base alloys. One group was designed to withstand high-temperature and dry or gaseous corrosion, while the other is mainly dedicated to withstanding low-temperature aqueous corrosion. Nickel-base alloys used for low-temperature aqueous or condensed systems are generally known as corrosion-resistant alloys (CRA), and nickel alloys used for high-temperature applications are known as heat-resistant alloys (HRA), high-temperature alloys (HTA), or superalloys. The practical industrial boundary between high- and low-temperature nickel alloys is approximately 500 °C (or near 1000 °F). Most of the nickel alloys have a clear use either as CRA or HRA; however, a few alloys can be used for both applications (e.g., alloy 625, Unified Numbering Systems, or UNS N06625).

This article is dedicated mostly to the metallurgical effects on the corrosion behavior of CRA. For each specific alloy, a metallurgical effect is considered when the overall composition of the alloy is the same; however, the corrosion performance could change due to the presence of second phases or a weld seam. Before going into detail on the metallurgical effects, a brief introduction on the importance of alloying elements on the corrosion behavior of nickel alloys is presented. Moreover, a brief description is given of the corrosion applications of HRA.

R.B. Rebak, Effects of Metallurgical Variables on the Corrosion of High-Nickel Alloys, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 279–286

Effects of Metallurgical Variables on the Corrosion of High-Nickel Alloys

Raúl B. Rebak, Lawrence Livermore National Laboratory

Heat-Resistant Alloys

Unlike CRA, which are mostly selected for their capacity to resist corrosion in a given environment, most HRA need to play a dual role. Namely, besides the capacity to withstand the corrosive aggressiveness of the environment, HRA also need to keep significant strength at high temperatures. Near and above 1000 °C (1830 °F), alloy selection is dominated by how strong the alloy is in this temperature range. Table 1 shows a short compilation of the most common HRA engineering nickel alloys and a brief description of their application.

UNS, Unified Numbering System

There are many different industrial high-temperature environments. In general, practical use has divided these environments according to the most common causes of failure of a component in service. The most common failures are associated to the attack by a specific element, such as oxygen (which causes oxidation), carbon (carburization and metal dusting), sulfur (sulfidation), halogen (e.g., chlorination), and nitrogen (nitridation). Other modes of failure, such as molten metal attack and hot corrosion, are less specific. Detailed descriptions of

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

such modes of attack are given elsewhere is this Volume and in Ref 1 and 2. The most common high-temperature degradation mode is oxidation, and the protection against oxidation, in general, is given by the formation of a chromium oxide scale. The presence of a small amount of aluminum or silicon in the alloy may improve the resistance against oxidation of a chromia-forming alloy (Table 1). Attack by other elements, such as chlorine and sulfur, depends strongly on the partial pressure of oxygen in the environment (Ref 2).

Effects of Metallurgical Variables on the Corrosion of High-Nickel Alloys

Raúl B. Rebak, Lawrence Livermore National Laboratory

Effect of Chemical Composition on the Corrosion Behavior of Nickel Corrosion-Resistant Alloys

Nickel alloys are highly resistant to corrosion, and, in most environments, nickel alloys outperform the most advanced stainless steels. One of the reasons is because nickel can be alloyed more heavily than iron. That is, large amounts of specific elements can be dissolved purposely into nickel to tailor an alloy for a particular environment. In general, industrial environments can be divided into two broad categories: *reducing* and *oxidizing.* These terms refer to the range of electrode potential that the alloy experiences, and it is controlled by the cathodic reaction in the system. Thus, a reducing condition is generally controlled by the discharge of hydrogen from a reducing acid, such as hydrochloric acid. An oxidizing environment has a potential that is higher than the potential for hydrogen discharge. This potential may be established by cathodic reactions, such as reduction of dissolved oxygen (O_2) from the atmosphere, chlorine gas (Cl_2), hydrogen peroxide (H_2O_2), chromates (CrO_4^{2-}), nitrates (NO_3^-), and metallic ions in solution, such as ferric (Fe^{3+}) and cupric (Cu^{2+}). Nickel alloys, the same as other alloys, may suffer two main types of corrosion: *uniform* corrosion and *localized* corrosion. Uniform corrosion may happen under reducing conditions in the active region of potentials and also under oxidizing conditions in the form of a slow, passive corrosion. Localized corrosion, such as pitting and crevice corrosion, generally occurs under oxidizing conditions. Stress-corrosion cracking (SCC) or environmentally assisted cracking (EAC) could occur at any electrochemical potential range. Three conditions are necessary for the occurrence of SCC: a susceptible material composition and microstructure, a specific aggressive environment, and the presence of tensile stresses.

Based on chemical composition, corrosion-resistant nickel-base alloys can be grouped as commercially pure nickel, Ni-Cu alloys, Ni-Mo alloys, Ni-Cr-Mo alloys, and Ni-Cr-Fe alloys. Table 2 gives the composition of the most familiar commercial wrought nickel-base alloys. A brief description of the corrosion behavior of each group of alloys is given subsequently. More extended analyses are given elsewhere (Ref 3, 4).

UNS, Unified Numbering System

Commercially Pure Nickel. The most widely accepted application of commercially pure nickel is in the handling of highly concentrated caustic solutions. Nickel has lower corrosion rates in hot caustic solutions than alloyed nickel due to the preferential dissolution of elements such as chromium and molybdenum. Nickel can also tolerate cold reducing acids well because of the slow discharge of hydrogen on its surface. Hot reducing acids and oxidizing acids corrode pure nickel rapidly (Fig. 1).

www.iran–mavad.com

مرجع مهندسی مواد و متالورژی

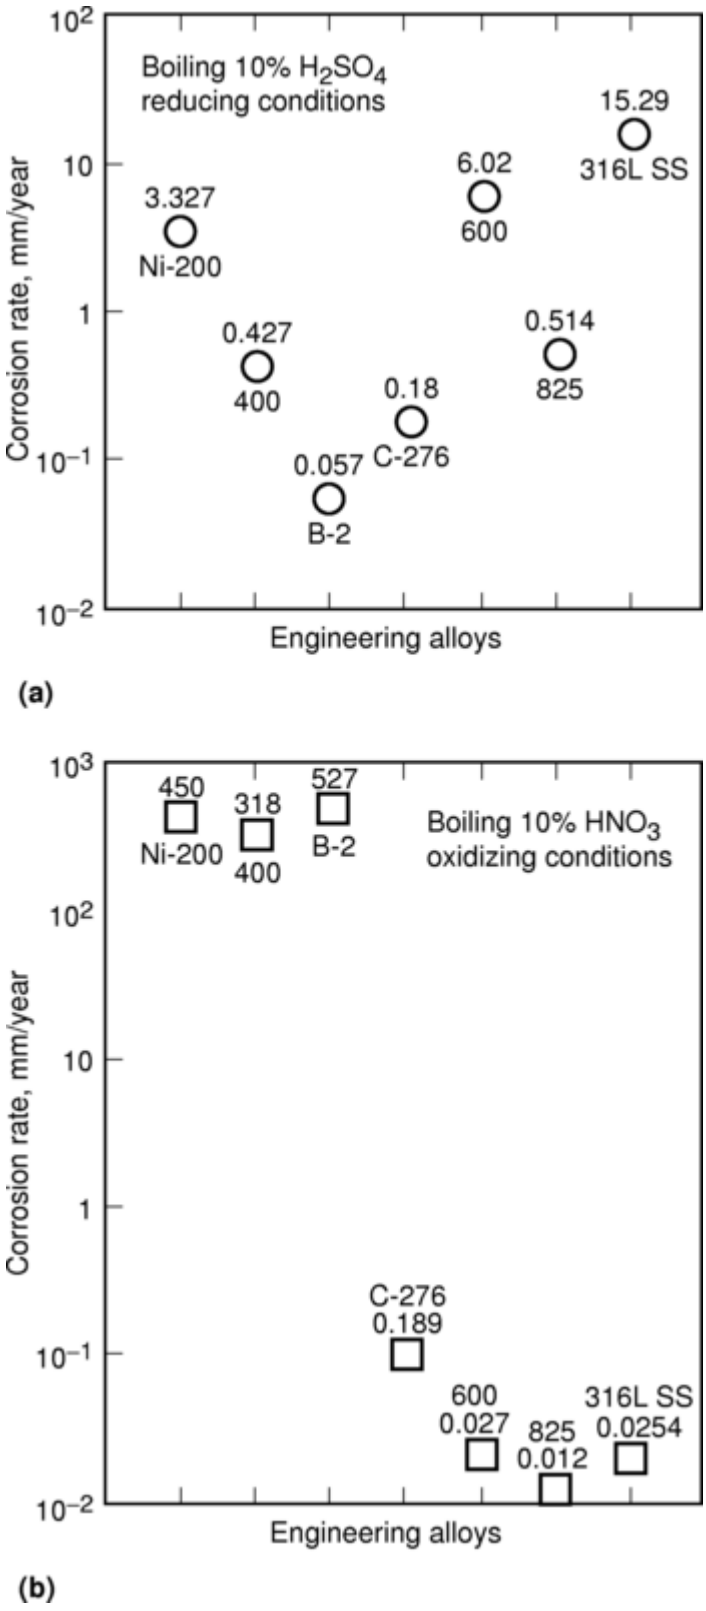

Fig. 1 Corrosion behavior of alloys from five nickel alloy groups compared to that of 316L stainless steel (SS). (a) In boiling 10% sulfuric acid, reducing conditions. (b) In 10% boiling nitric acid, oxidizing conditions. Source: Data from Ref 3

Nickel-Copper. A main application of nickel- copper alloys, alloy 400, K500, and Monel alloys, is in the handling of pure hydrofluoric acid. However, if oxidants such as oxygen are present in hydrofluoric acid, nickel-copper alloys may suffer intergranular attack (Ref 5). Nickel-copper alloys are slightly more resistant to general corrosion than Ni-200 in hot reducing and oxidizing acids, such as sulfuric acid and nitric acid (Fig. 1).
Nickel-molybdenum alloys (commonly known as B-type alloys) were specifically developed to withstand reducing HCl at all concentrations and temperatures. Besides expensive materials such as tantalum, nickel-

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

molybdenum alloys are the best alloys for hot hydrochloric acid (Ref 3). Nickel-molybdenum alloys are also used in the handling of other corrosive reducing environments, such as sulfuric, acetic, formic, hydrofluoric, and phosphoric acids. Figure 1(a) shows that B-2 has the lowest corrosion rate in boiling 10% sulfuric acid. However, nickel-molybdenum alloys perform poorly in oxidizing acids (Fig. 1b) or, for example, in HCl contaminated with ferric ions (Ref 6).

Nickel-Chromium-Molybdenum. There are many commercially available Ni-Cr-Mo alloys today. All these alloys were derived from the original C-alloy (N10002), which was introduced to the market in cast form in 1932. The more advanced Ni-Cr-Mo alloys are N06686, N06059 (alloy 59), and Hastelloy C-2000. However, the more common Ni-Cr-Mo alloy in industrial applications is alloy C-276 (N10276) which was introduced in the market in the mid- 1960s. Nickel-chromium-molybdenum alloys are the most versatile nickel alloys, because they contain molybdenum, which protects against corrosion under reducing conditions, and chromium, which protects against corrosion under oxidizing conditions (Ref 7). Figure 1 shows that C-276 has low corrosion rates both in reducing conditions (boiling 10% sulfuric acid) and oxidizing conditions (boiling 10% nitric acid). One of the major applications of Ni-Cr-Mo alloys is in the presence of hot chloride-containing solutions. Under these conditions, most of the stainless steels would suffer crevice corrosion, pitting corrosion, and SCC. However, Ni-Cr-Mo alloys are highly resistant, if not immune, to chloride- induced attack in most industrial applications (Ref 3).

Nickel-Chromium-Iron. The last group of nickel-base CRA is the group of Ni-Cr-Fe alloys. These alloys also may contain smaller amounts of molybdenum and/or copper. Nickel-chromium-iron alloys, in general, are less resistant to corrosion than Ni-Cr-Mo alloys; however, they could be less expensive and therefore find a wide range of industrial applications. Figure 1(a) shows that the corrosion rate of alloy 600 in sulfuric acid is higher than the corrosion rate of alloy 825. The latter contains small amounts of molybdenum and copper (Table 2), which are beneficial alloying elements for resistance to sulfuric acid. Also, alloy 825 has a lower corrosion rate in nitric acid (Fig. 1b), because it contains larger amounts of chromium. One of the most common applications of Ni-Cr-Fe alloys, such as alloy 33 and N06030, is in the industrial production of phosphoric acid and in highly oxidizing media such as nitric acid.

Factors Affecting the Corrosion Behavior of Nickel-Base Alloys

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The corrosion of metal and alloys depends on internal and external factors. Internal factors include chemical composition and microstructure of the alloy, and external factors include electrolyte composition, temperature, and electrode potential. In general, the use of nickel-base alloys in corrosive applications is based on their chemical composition. For example, a nickel-base alloy such as N06030 (Table 2) could be used under highly oxidizing acidic conditions, because it contains a large amount of chromium. Other alloys, such as B-3 (Table 2), are recommended for highly reducing acidic conditions, because they contain a large amount of molybdenum. However, for each alloy of unique chemical composition, the corrosion behavior also depends on the particular microstructural or metallurgical condition of its matrix. A typical example of this is the behavior of autogenously welded pipes in industrial corrosive applications. Both the weld seam and the wrought matrix from which the weld seam was derived have essentially the same overall chemical composition. However, it is commonly observed in specimen returned from the field that the weld seam and the immediately adjacent matrix have lower corrosion resistance than the contiguous unaffected wrought matrix. This dissimilar corrosion behavior is not due to a different chemical composition but to a different microstructure or metallurgical condition of the alloy. The weld seam would have a cast microstructure, which is generally anisotropic, with areas of high concentration of alloying elements, while other areas are impoverished in these same elements. The matrix area immediately adjacent to the weld is called the heat-affected zone (HAZ). The area of the HAZ still retains the overall wrought isotropic structure of the matrix; however, it can suffer solid-state transformations (intergranular precipitation) due to the higher temperature excursion during welding. The area immediately next to the HAZ has the isotropic fcc microstructure of a wrought matrix with equiaxed grains. Therefore, in a narrow region near the weld, there are three areas of equivalent chemical composition but of different microstructure. Each of these areas responds differently to the external corrosive environment.
Another effect of microstructure on the analysis of corrosion behavior is the orientation of the testing coupons. This detail is commonly overlooked. When a testing coupon is prepared from a plate material, there are two main directions in the coupon, that is, parallel to the rolling direction (longitudinal) and perpendicular (or transverse) to the rolling direction (across the thickness of the plate). Even though the coupon is fully mill annealed with isotropic chemical composition, it is not infrequent to observe that the perpendicular direction of the plate behaves in a different manner from the parallel direction, especially in cases where SCC and localized corrosion may be expected. The direction across the thickness of the plate, in general, has lower corrosion resistance than the parallel direction. The presence of nonmetallic inclusions elongated in the longitudinal direction sometimes leads to localized end-grain attack on transverse cut edges.

Changes in Microstructure

This section discusses in detail the corrosion implications of changing the alloy microstructure via three different processes: (a) solid-state transformation or second-phase precipitation, which includes the precipitation of intermetallic phases in a Ni-Cr-Mo alloy and the precipitation of secondary carbides in a Ni-Cr-Fe alloy; (b) cold work in Ni-Mo and Ni-Cr-Mo alloys; and (c) comparison of corrosion behavior between cast and wrought microstructures in Ni-Cr-Mo alloys.

Phase Stability of Nickel-Base Alloys and Corrosion Behavior

Second-Phase Precipitation. In general, Ni- Cr-Mo and Ni-Cr-Fe alloys (Table 2) contain a large amount of alloying elements, which determine their specific corrosion resistance and therefore field applicability. These elements are dissolved into the liquid metal at high temperature, and they remain in solid solution when the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

final product is cooled. At ambient temperatures, these alloys remain a single-phase fcc microstructure indefinitely. However, if most of these nickel-base alloys are exposed to temperatures above 500 °C (930 °F) for varying periods of time, they may develop second-phase precipitates, which in turn change the mechanical properties and corrosion resistance of these alloys. In general, the larger the amount of alloying elements, the more unstable the fcc microstructure of the alloy. Currently, there are several commercial Ni-Cr-Mo alloys (Table 2) that are highly alloyed to increase their corrosion resistance; however, this overalloying may adversely impact their phase stability. The effects on corrosion behavior of second-phase formation due to thermal instability is discussed in detail for Hastelloy C-22, but similar behavior may happen in alloys C-276, C-4, 686, and 59. Another type of phase instability is the formation of secondary carbides. In most of today's alloys, this issue is being resolved by keeping a low content of carbon in the alloy. However, since the 1970s, the presence of secondary carbides was an important issue in the resistance of Inconel 600 (Table 2) to SCC in deoxygenated high-temperature water. This issue is also subsequently discussed in detail.

Effect of Intermetallic Phases. Hastelloy C- 22 (UNS N06022) is a Ni-Cr-Mo alloy (Table 2) that contains approximately 22% Cr, 13% Mo, 3% W, and 3% Fe. Due to its high chromium content, this alloy remains passive in most industrial applications and therefore has a very low general corrosion rate. The combination of the alloying elements chromium, molybdenum, and tungsten imparts the alloy with an excellent resistance to pitting corrosion, crevice corrosion, and SCC, especially in halide-containing environments (Ref 8, 9, 10, 11, 12, 13, 14, 15).

Due to its overall resistance to corrosion, this alloy is a candidate material to fabricate the external layer of the high-level nuclear waste containers for the potential repository site that the Department of Energy is characterizing in Yucca Mountain, Nevada. As a result of the heat generated by the radioactive decay of the waste, the containers might experience temperatures as high as 160 °C (320 °F) during their first 1000 years of emplacement. The lifetime design of the containers is 10,000 years, and their maximum allowed temperature is 350 °C (660 °F). Because of concerns that alloy N06022 may suffer phase instability during the long predicted time of emplacement, systematic studies are being carried out to fully characterize the ranges of time and temperature at which the alloy might undergo solid-state phase transformation.

Haynes International started low-temperature aging studies of alloy N06022 and other alloys in 1989. The most recent results were obtained from samples removed after 40,000 h of aging. Laboratory studies of these aged samples have shown that the mechanical and corrosion properties of the alloy did not change after it was aged for up to 40,000 h at 427, 343, or 260 °C (800, 650, or 500 °F) (Ref 9, 10). The next test on these aged samples occurs for a total aging time of 100,000 h (~12 years).

It is known that precipitation of detrimental second phases occurs when alloy N06022 is aged at temperatures above 600 °C (1110 °F) for much shorter periods of time. Therefore, several studies have been carried out to fully characterize the second-phase precipitation in the alloy for shorter periods of time at higher temperatures (Ref 16, 17, 18, 19, 20). The precipitation of these secondary phases affects the corrosion resistance in aggressive acidic solutions and the mechanical properties of wrought and welded alloy N06022 (Ref 21, 22, 23, 24, 25). In the fully annealed condition, alloy N06022 is a metastable fcc solid solution. When the alloy is aged at intermediate temperatures (600 °C, or 1110 °F), it can precipitate several intermetallic phases (Ref 20). Two of the most common phases are μ phase and P phase, which are similar both chemically and crystallographically. Precipitation of the intermetallic detrimental phases, in general, begins at the grain boundaries, and for longer aging times, the precipitation starts growing at twin boundaries and later, inside the grains (Ref 20). Temperature-time-transformation diagrams and micrographs for alloy N06022 have been published (Ref 17, 20, 22). These intermetallic secondary phases tend to be rich in either chromium or molybdenum, which are the elements that give the alloy its excellent corrosion resistance. Therefore, it can be suggested that the formation of the intermetallic phases may leave a narrow adjacent area of the matrix depleted in these beneficial elements (chromium and molybdenum), causing an increase in the corrosion rate of the alloy in aggressive acidic solutions. On the other hand, the corrosion behavior of the aged alloy N06022 microstructure in multiionic underground water was the same as the corrosion behavior of the unaged microstructure (Ref 25). Similarly, the corrosion rate of aged alloy N06022 was the same as the corrosion rate of an unaged alloy when tested in boiling 10% NaOH (caustic solution) (Ref 21).

Changes in the Corrosion Rate of Alloy N06022 as a Consequence of Second-Phase Precipitation. Figures 2(a) and (b) show the corrosion rate of wrought and gas tungsten arc welded (GTAW) alloy N06022, respectively, in ASTM G 28 Method A solution for seven aging temperatures and thirteen different aging times (Ref 26). The ASTM G 28 Method A test involves the immersion of the testing coupon in an oxidizing acidic solution

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

consisting of boiling 50% sulfuric acid plus 42 g/L of ferric sulfate for 24 h. Details about testing coupon configuration, aging procedures, and corrosion testing are published elsewhere (Ref 26).

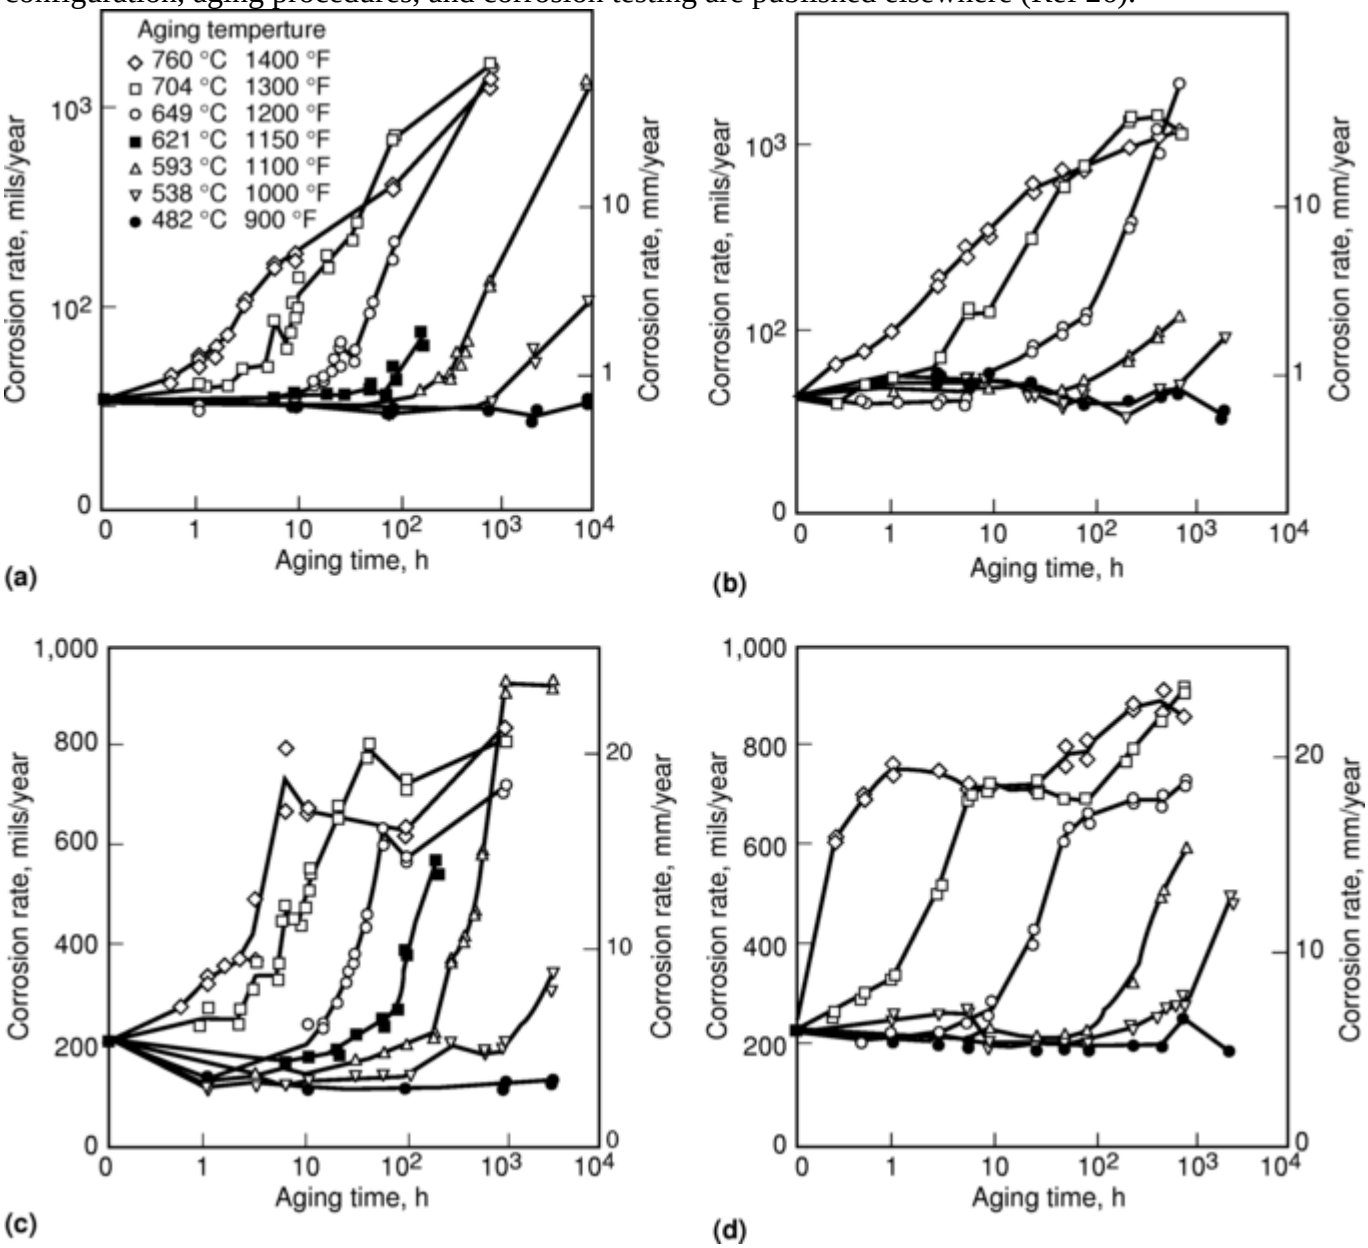

Fig. 2 Corrosion rate as a function of aging time and temperature for alloy C-22 (UNS N06022). (a) Aged wrought alloy in boiling sulfuric acid/ferric sulfate (ASTM G 28 Method A). (b) Gas tungsten arc welded (GTAW) alloy in boiling sulfuric acid/ferric sulfate (ASTM G 28 Method A). (c) Aged wrought alloy in boiling 2.5% HCl. (d) GTAW alloy in boiling 2.5% HCl. Source: Ref 26

The corrosion rate of aged alloy N06022 in this oxidizing solution increases gradually as the aging time and the aging temperature (*T*) increase, for $T \geq 538$ °C (1000 °F). For samples aged at 482 °C (900 °F), the corrosion rate remains the same, even after aging for 10,000 h (Fig. 2a). Coupons that were aged, for example, at 704 and 760 °C (1300 and 1400 °F) for times longer than 3 h show preferential corrosion at the grain boundaries. At higher aging times, deeper grain-boundary attack is observed, and in certain testing conditions, some grains fell away, because they became completely detached from the samples. Aging increases the susceptibility of attack of the HAZ in ASTM G 28 Method A solution. Figures 2(c) and (d) show the corrosion rate of wrought and GTAW alloy N06022, respectively, in boiling 2.5% HCl solution (Ref 26). For both types of coupons, the corrosion rate increases approximately 3 times after a certain threshold aging time at each temperature. The threshold time increases as the temperature decreases. Figure 2(c) shows that for the wrought coupons, the corrosion rate initially decreases slightly with the aging time. This behavior seems to suggest that a small amount of aging would be beneficial for corrosion resistance under reducing conditions (Ref 26). The reason for this behavior is still not fully understood. For the higher aging temperatures, 760, 704, and 649 °C (1400,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

1300, and 1200 °F), the corrosion rate seems to reach a plateau for an intermediate aging time. This behavior is more noticeable for the GTAW coupons (Fig. 2d). For both types of the samples aged at 482 °C (900 °F), the corrosion rate remains the same, even after aging for 3000 h. Observation of the tested coupons in boiling 2.5% HCl solution shows preferential intergranular attack that becomes deeper and wider as the aging time increases. At aging times of 1000 h and higher, preferential corrosion attack at twins inside the grains is observed. For the shorter aging times, there is preferential attack at the HAZ; however, for the longer aging times, the attack becomes more uniform across the testing coupon.

Figure 3 shows the effect of welding on the corrosion rate of alloy N06022. Figure 3(a) shows the corrosion rate in ASTM G 28 Method A for wrought and as-welded coupons at two aging temperatures, 760 and 538 °C (1400 and 1000 °F), as a function of aging time. For all aging times, the corrosion rate of welded coupons is always higher than the corrosion rate of wrought coupons. At the aging temperature of 760 °C (1400 °F) and at the aging time of 10 h, the corrosion rate of the welded coupons is approximately 2 times the corrosion rate of the wrought coupons. Figure 3(b) shows the corrosion rate in boiling 2.5% HCl solution for wrought and as-welded coupons at two aging temperatures, 760 and 538 °C (1400 and 1000 °F), as a function of aging time. For the shorter aging times (up to 3 to 6 h), the corrosion rate of the welded coupons is approximately 3 times the corrosion rate of the wrought coupons; however, for aging times of 6 h and longer, the difference in the corrosion rate is smaller.

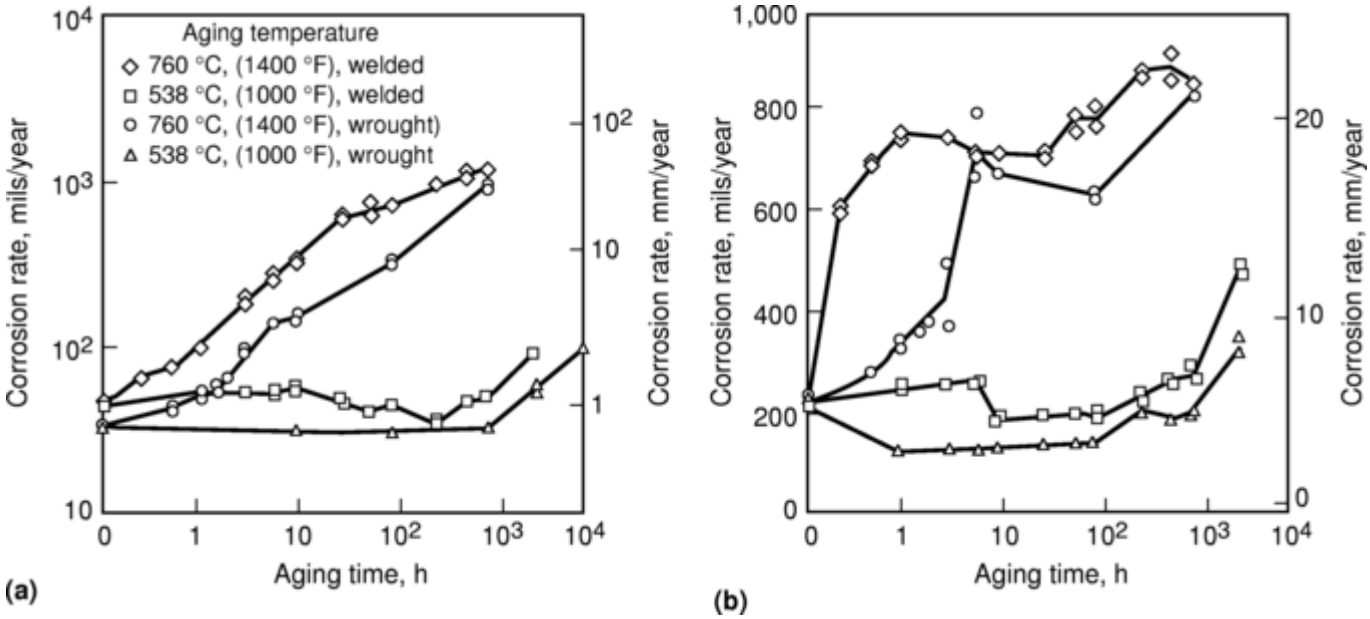

Fig. 3 Corrosion rates for wrought and for gas tungsten arc welded (GTAW) alloy C-22 (UNS N06022). (a) In boiling sulfuric acid/ferric sulfate (ASTM G 28 Method A). (b) In boiling 2.5% HCl solution. Source: Ref 25

The increase in the corrosion rate of high-temperature aged alloy N06022 is pronounced in highly reducing conditions (boiling pure HCl solutions) and highly oxidizing solutions (boiling 50% sulfuric acid plus 42 g/L ferric sulfate). However, at intermediate oxidizing potentials, the aged alloy is still able to maintain passivity. This was corroborated through potentiodynamic anodic polarization (Ref 23) and through corrosion immersion tests in boiling HCl solutions contaminated with different levels of ferric ions (Ref 21).

Secondary Carbide Effect in the Resistance of UNS N06600 to SCC in High-Temperature Water. Inconel 600 (UNS N06600) is a Ni-Cr- Fe alloy (Table 2) that contains approximately 16% Cr and 9% Fe. Because this alloy has excellent resistance to general corrosion in high- temperature water, it was selected for fabrication of the heat exchanger tubes in pressurized water reactor nuclear power plants. However, it was later found that alloy N06600 tubes cracked in service both from the primary and secondary side (Ref 27, 28). Factors that control the susceptibility of the alloy to SCC include grain- boundary microchemistry, thermal treatment or distribution of secondary carbides, presence of cold work, applied stress, temperature, solution pH, electrochemical potential, partial pressure of hydrogen, and so on (Ref 29). The first three factors are metallurgical or internal factors. Of these, only the thermal treatment or second- phase precipitation of carbides is discussed in this section.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

The presence of secondary carbides in alloy N06600 plays an important role in its resistance to SCC. It is known that precipitation of secondary carbides occurs when the alloy is exposed to temperatures between 500 and 900 °C (930 and 1650 °F) for varying periods of time (Ref 30). These carbides are generally rich in chromium; therefore, a secondary carbide precipitation is often accompanied by a chromium depletion zone. The formation of a chromium-depleted area is generally called sensitization. It has been suggested that sensitization or chromium depletion in alloy N06600 per se does not play any role in the susceptibility of the alloy to SCC in deoxygenated high-temperature water (Ref 29, 31).

The morphology and distribution of secondary carbides at the grain boundary plays the most important role in the resistance of alloy N06600 to SCC. An alloy exhibiting continuous or semicontinuous grain-boundary carbides has the highest resistance to SCC (Ref 32, 33). A microstructure with mainly intragranular carbides and widely spaced, discrete grain-boundary carbides is very susceptible to SCC in hydrogenated (deoxygenated) solutions Ref 32. This clear influence of carbide distribution on the susceptibility of the alloy to SCC was confirmed several times via laboratory testing and also through removal of tubes with different heat treatment from operating heat exchangers in nuclear power plants (Ref 29). There is no agreement among the corrosion engineers on why the presence of intergranular carbides is beneficial for the resistance to SCC. Some researchers correlated the presence of carbides at the grain boundaries with microdeformation mechanisms at the crack tip (Ref 34). It has been argued that intergranular carbides promote an easy source for dislocations and therefore reduce the crack tip stress state (Ref 34). Other authors explained the beneficial effect of carbides by the difference in electrochemical behavior between the carbides and the adjacent matrix in hydrogenated high-temperature water (Ref 35).

Effect of Cold Work on the Corrosion Resistance

Cold work (CW) is the result of the mechanical plastic deformation of a metal (alloy) at relatively low (ambient) temperatures. With increasing amount of CW, the hardness and strength of the material increases. That is, a CW microstructure has a higher yield stress and lower elongation to failure than a non-CW or annealed microstructure of the same chemical composition. In a CW microstructure, the grains of the metal are deformed, and the density of dislocations is several orders of magnitude higher than in an annealed microstructure.

Cold Work and the General Corrosion of Ni-Mo and Ni-Cr-Mo Alloys. Figures 4 and 5 show the effect of CW on the general corrosion behavior of nickel alloys. Figure 4 shows that the corrosion rate of N10665 (Hastelloy B-2) in boiling 20% HCl is approximately 0.34 mm/year (13 to 14 mils/year) and does not change in the range of CW between 0 and 50%. In this same range of CW, the hardness of alloy B-2 increases from 90 HRB to more than 40 HRC (Fig. 4). A boiling solution of HCl would be reducing and therefore promote a general or uniform corrosion rate in a nickel-molybdenum alloy such as B-2 (Table 2). Figure 5 shows that the corrosion rate of N06455 (Hastelloy C-4) in boiling 10% HCl is approximately 6 to 7 mm/year (250 to 275 mils/year) and does not change in the range of CW between 0 and 50%. Because a Ni-Cr-Mo alloy has a lower amount of molybdenum than a nickel-molybdenum alloy, the corrosion rate of Ni-Cr-Mo alloys in boiling HCl solutions is generally higher than the corrosion rate of nickel- molybdenum alloys in similar solutions (Ref 36). Figure 5 also shows that the corrosion rate of C-4 in ASTM G 28 Method A solution is approximately 3.56 mm/year (140 mils/year) and does not change with the amount of CW between 0 and 50%. For both reducing, 10% HCl, and oxidizing, ASTM G 28 Method A, solutions, the general corrosion rate does not change as the amount of CW is increased in the alloy. Results from Fig. 5 suggest that the higher presence of dislocations in a CW microstructure does not affect considerably the hydrogen evolution reaction under reducing conditions or the passivation characteristics under oxidizing conditions for nickel alloys.

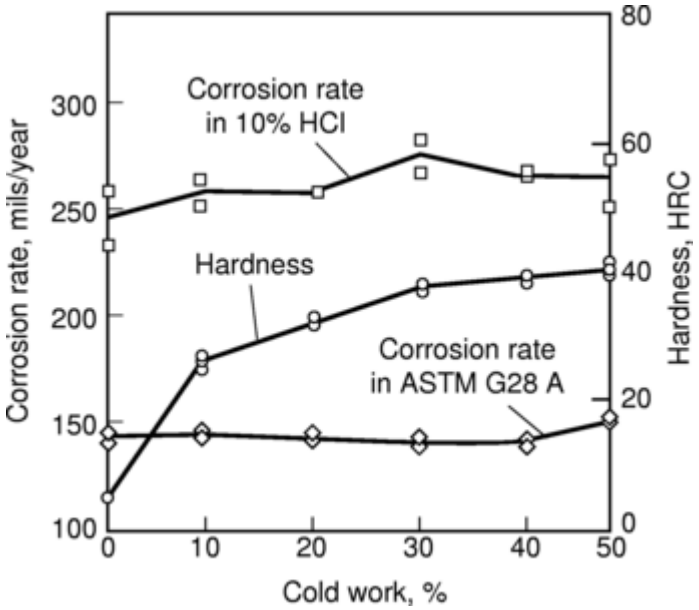

Fig. 5 Effect of cold work on the general corrosion behavior of alloy C-4 (UNS N06455) in boiling acid solutions

Cold Work and SCC of Ni-Cr-Fe Alloys. The SCC susceptibility of alloy N06600 depends, among other factors, on the amount of CW that the microstructure contains. For the same environmental conditions, alloys with similar chemical composition have different susceptibility to SCC, depending on their yield stress and ductility. The yield stress increases with the amount of CW; therefore, it could be inferred that a cold-worked microstructure would be more susceptible to SCC than an annealed microstructure. This is especially true for alloy N06600 in hydrogenated high-temperature water. Most of the failures of steam generator plant tubes occurred in the cold-deformed areas, such as in the expansion transition zone at the tube sheet and at the tightest radii in the U-bend area (Ref 27).

The enhanced susceptibility to SCC of CW tubes from field observations was repeatedly confirmed through laboratory testing. For example, it was reported that annealed alloy N06600 tubing did not suffer SCC using the slow strain-rate test in water at 350 °C (662 °F) even after 408 h of straining (Ref 37). However, after 35% CW was applied to the gage of the alloy specimen, the fracture surface was 65% intergranular after only 60 h of slow strain-rate testing. Another study has shown that the crack growth rate by SCC in alloy N06600 can be

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

increased 100 times if the alloy is 40% cold worked (Ref 38). Other researchers have shown that there is a monotonic increase in the crack growth rate in the alloy with the amount of applied CW to the specimens, following a power law (Ref 39). Even though it is known that the presence of CW increases the susceptibility of the alloy to SCC in deoxygenated water, there is not yet a fundamental understanding of the reason (Ref 29).

Another effect of microstructure on the susceptibility of alloy N06600 to SCC is the orientation of the test specimen from the original mill-processed plate. The orientation effect could be called a pure microstructural effect, because there is no induced CW or second-phase precipitation. For practical purposes, the etched microstructure of the alloy in the longitudinal direction (parallel to rolling) cannot be differentiated from the microstructure in the transverse direction (across the plate). However, SCC crack growth rates in the transverse direction are larger than in the longitudinal direction (Ref 40).

Cold Work and Environmentally Assisted Cracking (EAC) of Ni-Cr-Mo Alloys. Nickel alloys are used extensively in the oil and gas industry during the drilling of deep and corrosive oil and gas wells. One of the most common nickel alloys for these applications is C-276 (N10276) (Table 2). Other nickel alloys used include Incoloy 825 (N08825), Hastelloy G-3 (N06985) and G-50 (N06950) (Ref 41). These alloys are generally used in the form of tubular products for applications in sour wells; that is, wells containing high amounts of hydrogen sulfide (H_2S) combined with the presence of chlorides (Cl^-) and carbon dioxide (CO_2). Testing for susceptibility of alloys to EAC in oil and gas applications is generally conducted in aqueous solutions containing 5% NaCl + 0.5% acetic acid + saturation with H_2S solution (Ref 42), or in variations of this solution. These nickel alloys are generally used in the cold worked (CW) condition to increase their strength. For C-276, for example, the hardness may increase from 92 HRB in the mill-annealed condition to 41 HRC with a 50% cold reduction. This increase in hardness (or yield stress) of the alloy often manifests as a decrease in resistance to EAC, such as in sulfide cracking (Ref 43). As a consequence, the oil and gas industry prepared standards to limit the hardness of materials for applications in oilfield equipment. For example, according to NACE International standard MR0175-2002, the hardness limit for alloy C-276 (N10276) is 35 HRC (Ref 44).

Corrosion of Cast Forms as Contrasted to Wrought Forms

Versions of many wrought nickel-base alloys are available in cast form. The specifications for the castings are given in the ASTM A 494 standard. Table 3 gives the composition of the most popular cast nickel-base alloys and the approximate equivalent to the wrought versions. The main difference in the chemical composition between the cast alloys (Table 3) and their wrought versions (Table 2) is in the higher amount of impurities, such as carbon and silicon, allowed in the cast alloys. Carbon is naturally present in the melt and cannot be removed without special treatment, such as argon oxygen decarburization (AOD). Silicon is necessary in the melt, because it contributes to fluidity during pouring and filling of the molds.

Note: C and Si are maximum values.
(a) 95% Ni min

The cast versions of the nickel-base alloys do not have the same corrosion resistance as the corresponding wrought products, mainly due to the higher carbon and silicon contents and the anisotropic microstructure of the cast products. Carbon promotes the formation of carbides, and silicon is associated with the precipitation of intermetallic phases, such as μ phase. Secondary- phase compounds are formed during the slow cooling of the cast parts in the molds. After casting, high-temperature solution annealing followed by water quenching is necessary to remove the secondary phases. The specific heat treatment depends on the previous history of the castings, such as silicon content and cooling rate of the mold. A CX-2MW cast containing 0.52% Si requires a 20 min anneal at 1232 °C (2250 °F) followed by water quenching to redissolve most of the original precipitates. The performance of a cast nickel-base alloy is generally based on the microstructural quality, such as the amount of interdendritic segregation, secondary carbides, and intermetallic phases. Failures are commonly attributed to inappropriate casting techniques or heat treatments. Therefore, the corrosion rates of cast alloys vary significantly from one cast to another, even though the overall composition of the cast part is the same. Table 4 gives comparative corrosion rates of several cast alloys as well as the corrosion rates of the corresponding wrought alloys. In general, for all environments, the corrosion rate of the wrought alloys was lower than the corrosion rate of the cast versions. The smallest difference in behavior was given by the CW-2M/C-4 pair. For the other two alloys in Table 4, the corrosion rate of the wrought material was considerably lower than that of the cast version, especially in the oxidizing solutions containing chlorides (ASTM G 28 Method B and boiling 10% $FeCl_3$). The corrosion behavior of cast versus wrought material was inverted for the boiling 65% nitric acid (oxidizing conditions), probably due to the beneficial effect of silicon in the cast alloys.
