The relative wetted surface areas of the materials being tested will have an important effect on the magnitude of the galvanic attack. The larger the cathode-to-anode area ratio is, the larger the degree of attack will be; therefore, it would at first seem reasonable to accelerate the test by using a large ratio. This should not be done, because accelerating the attack may also change the mechanism of the attack, which would lead to erroneous conclusions. It is far more appropriate to use more accurate measurement techniques to determine the extent of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

the attack over a short period than to accelerate the test to obtain measurable attack quickly. If soldered or brazed connections are used for electrical connection, subsequent evaluation by weight loss is difficult; therefore, if weight loss is to be used to measure attack, threaded and sealed connections are preferred.

Measurement of the electrical current flowing between the metals can give a very sensitive indication of the extent of the galvanic attack and will allow the attack to be monitored over time. Coupled potential is another parameter that is useful to follow during the course of the exposure. The effect of exposure time on the rate of attack should be properly considered. Initially high rates of galvanic attack may decay to acceptable levels in a short period of time, or initially low attack rates may increase to unacceptable levels over time.

Current can be measured by inserting a resistor of 1 to 10 Ω in the current circuit and measuring the potential drop across this resistor with a voltmeter having an internal resistance of at least 1000 Ω. The resistor should be sized such that the voltage across it does not exceed 5 mV; thus, the resistor will not significantly impede the current flow. Alternatively, a zero-resistance ammeter (ZRA) can be used instead of the resistor. This device is an operational amplifier connected to maintain 0 V across its input terminals (Fig. 5). A current-measuring resistor placed in the feedback circuit may be as large as the amplifier will allow, thus enabling currents in the nanoampere range to be easily measured. One simple way of creating a zero-resistance ammeter is by using a potentiostat with the counter- electrode and reference electrode leads shorted together and set to a working electrode potential of 0 V (Fig. 6).

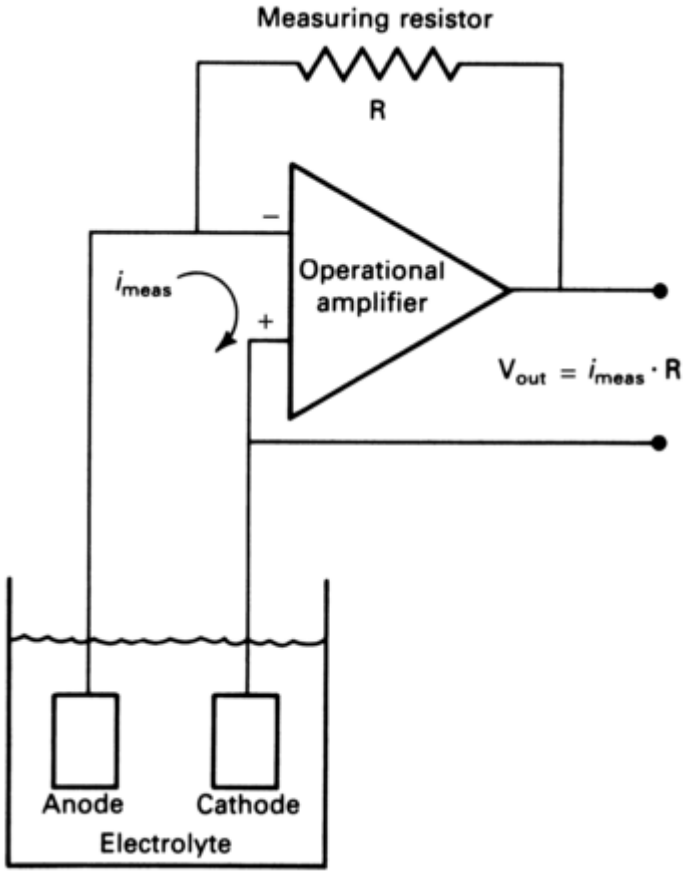

Fig. 5 Basic circuit for a zero-resistance ammeter

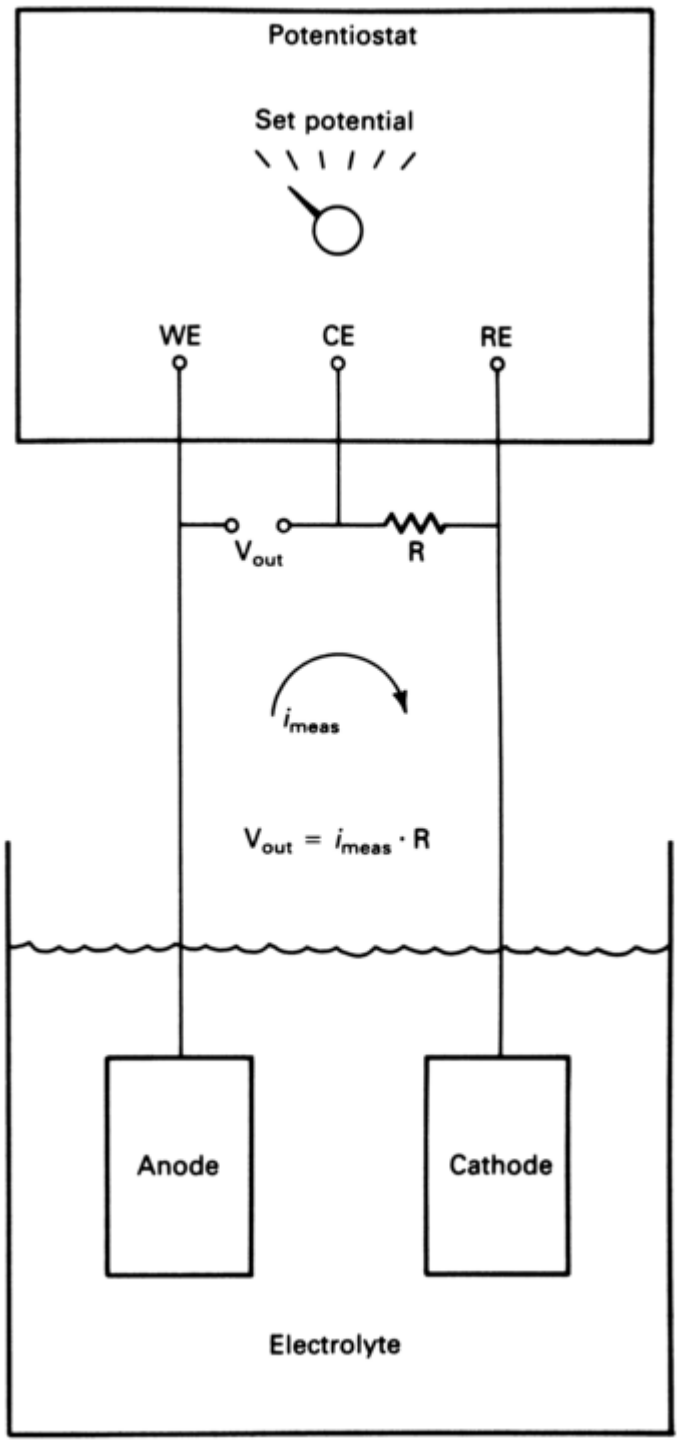

Fig. 6 Conversion of a potentiostat into a zero-resistance ammeter. WE, working electrode; CE, counter electrode; RE, reference electrode

For most electrochemical reactions it is possible to convert reaction current to corrosion rate using the expression:

$$CR = 0.1288 i_g EW/d$$

where CR is corrosion rate in mils per year, i_g is current density in microamperes per square centimeter, EW is equivalent weight of the corroding material, and d is density in grams per cubic centimeter. This conversion will frequently be inaccurate for calculating galvanic corrosion rate from galvanic current because corrosion may not be uniform, some current may go toward reactions at the anode other than metal loss, such as valence change of ions in solution, and additional corrosion at the anode is generated by cathodic reactions on the anode not measured by the galvanic current. Therefore, the preceding calculation will frequently underestimate the total corrosion of an anode in a galvanic corrosion cell. Estimation of galvanic corrosion rate from galvanic

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

current is worse for materials with high self-corrosion, such as metals in acids, and best when the anode and cathode open-circuit potentials are far apart so that after coupling, little cathodic activity occurs on the anode.

The importance of electrolyte flow in galvanic corrosion should not be overlooked in establishing the test procedure. A test apparatus should be used that reproduces the flow under service conditions. If this is not possible and flow must be scaled, the exact scaling method will depend on the assumed corrosion processes. Cathodic reactions, such as oxygen reduction, that are controlled by diffusion through a fluid boundary layer are likely to be properly scaled by reproducing the hydrodynamic boundary layer of the service application in the test. This should reproduce the diffusion boundary layer that controls the reaction.

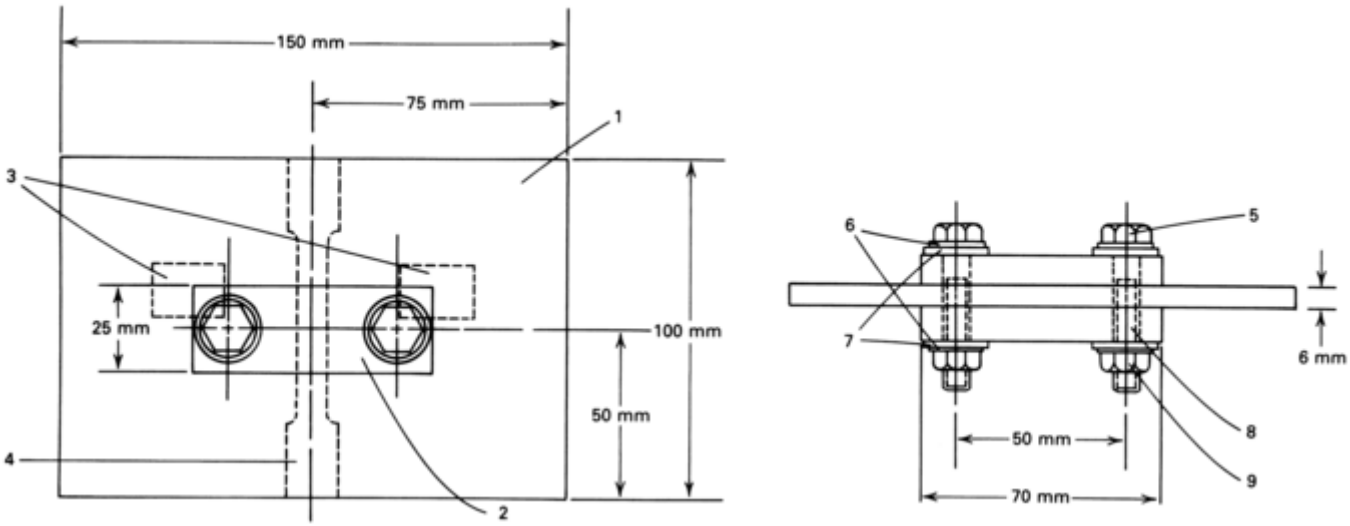
Alternatively, the rates of reactions controlled by films such as anodic brightening of copper alloys, other passivation-type reactions, or control by calcareous-deposit formation in seawater, may depend more on the shear stress at the surface required to strip off the film. In this case, surface shear stress may be a better hydrodynamic parameter to reproduce in the test.

Many different types of flow apparatus have been used, such as concentric tubes, in-line tubes, rotating cylinders, rotating ring-disks, rectangular flow channels with specimens mounted in the walls, and circulating foils. Each of these has its own hydrodynamic peculiarities, but one common area of concern is the leading edge of the specimen. It is difficult, even for specimens recessed in the walls of a flow channel, to avoid a step or gap that can create unexpected hydrodynamic conditions at the specimen surfaces downstream. Also, mounting to allow electrical connection must be considered, and crevice effects are essentially impossible to eliminate.

Atmospheric Tests. General testing guidelines become more complex when considering atmospheric or cabinet exposures. Testing in these environments differs markedly from immersion tests in a number of ways, most of which involve the insufficiency of electrolyte. Many of the variables that influence the behavior of specimens in the atmosphere are discussed in Ref 6.

The thinness of the electrolyte film and the normally low conductivity of the electrolyte combine to limit galvanic effects for bare metals to within approximately 5 mm (0.2 in.) of the dissimilar-metal interface (Ref 7). This distance may be somewhat greater if nonconductive coatings are present. Area ratio effects thus become relatively unimportant. Sealing the electrical connections becomes relatively less important than in immersion testing if the connections are more than 5 mm (0.2 in.) from the area to be evaluated and if corrosion products will not interfere with the continuity of the connection. Periodic checks of electrical continuity in atmospheric galvanic-corrosion tests are recommended. Geometrical effects also become unimportant, except as they relate to the entrapment of moisture. However, specimen orientation effects must be considered. The behavior of the galvanic couples will depend on whether they are exposed on the top or the bottom of the panel, whether they are sheltered or not, or other considerations, such as the effect of specimen mass on condensation.

It is surprising that several standard tests have emerged for atmospheric galvanic corrosion, since there are no standardized tests for galvanic corrosion immersed in electrolytes even though more testing has been done in this area. One of these tests is an International Organization for Standardization (ISO) standard (Ref 8). This test uses a 100 × 400 mm (4 × 16 in.) panel of the anodic material to which a 50 × 100 mm (2 × 4 in.) strip of the cathodic material is bolted (Fig. 7). After exposure, the anodic material can be evaluated for material degradation by weight loss and other corrosion measurements as well as by degradation of such mechanical properties as ultimate tensile strength.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 7 Specimen configuration for the ISO test for atmospheric galvanic corrosion. 1, anodic plate, 1 piece; 2, cathodic plate, 2 pieces; 3, microsection, 2 pieces; 4, tensile test specimen; 5, bolt, 8 × 40 mm, 2 pieces; 6, washers, 1 mm thick, 16 mm diameter, 4 pieces; 7, insulating washers, 1 to 3 mm thick, 18 to 20 mm diameter, 4 pieces; 8, insulating sleeve, 2 pieces; 9, nut, 2 pieces.

This test is relatively easy to perform but requires the availability of plates of the materials of interest and a prior knowledge of which material is anodic. Like any atmospheric galvanic- corrosion test, crevice effects cannot be adequately separated from galvanic effects in some cases; therefore, a coating is sometimes applied between the anode and cathode plates. The disadvantage of this test is the time required to obtain results; for systems with moderate corrosion rates, exposures of 1 to 5 years are not unusual.

Another commonly used atmospheric galvanic-corrosion test is the wire-on-bolt test, sometimes referred to as the CLIMAT test (Ref 9, 10, 11). In this test, a wire of the anodic material is wrapped around a threaded rod of the cathodic material (Fig. 8). Because corrosion can be rapid in this test, exposure duration should usually be limited. This makes the test ideal for measuring atmospheric corrosivity as well as material corrosion properties. Not all materials of interest are available in the required wire and threaded rod forms, and analysis is usually restricted to weight-loss measurement and observation of pitting. When the required materials are available, this test is less expensive and easier to conduct than the ISO plate test.

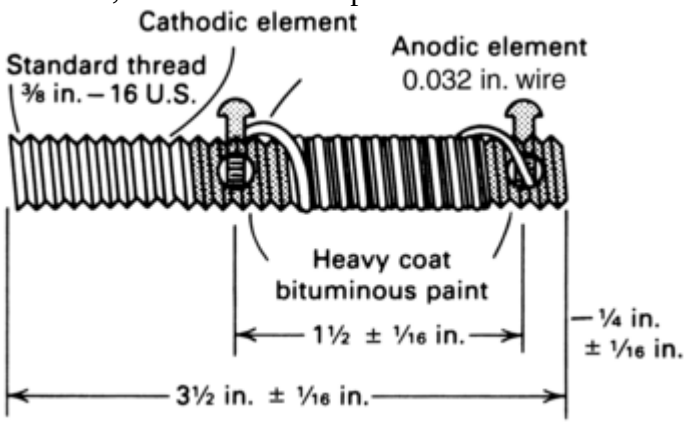


Fig. 8 Specimen configuration for the wire-on-bolt test for atmospheric galvanic corrosion

A third atmospheric galvanic-corrosion test has been used extensively by ASTM International but has not been standardized. This test (Ref 12) involves the use of 25 mm (1 in.) diameter washers of the materials of interest bolted together as shown in Fig. 9. The bolt that holds the washers together can also be used to secure the assembly in position. After exposure, the washers can be disassembled for weight loss determination. The materials needed for this test are not as large as those for the ISO plate test, but testing can take as long and cannot provide mechanical properties data.

Evaluating Intergranular Corrosion

Revised by Bopinder Phull, Consultant

Introduction

INTERGRANULAR CORROSION (IGC) is preferential attack of either grain boundaries or areas immediately adjacent to grain boundaries in a material exposed to a corrosive environment but with little corrosion of the grains themselves. *Intergranular corrosion* is also known as *intergranular attack* (IGA). *End-grain attack, grain dropping,* and *"sugaring"* are additional terms that are sometimes used to describe IGC. In certain materials, corrosion progressing laterally along planes parallel to rolled surfaces is known as exfoliation, and it generally occurs along grain boundaries—hence, intergranular corrosion. A layered appearance is a common manifestation of exfoliation (also referred to as *layer corrosion*), resulting from voluminous corrosion products prying open the material; for example, in aluminum alloys.

Most alloys are susceptible to IGA when exposed to specific environments. This is because grain boundaries are sites for precipitation and segregation, which make them chemically and physically different from the grains themselves. Intergranular attack is defined as the selective dissolution of grain boundaries or closely adjacent regions without appreciable attack of the grains themselves. This is caused by potential differences between the grain-boundary region and any precipitates, intermetallic phases, or impurities that form at the grain boundaries. The actual mechanism and degree of attack differs for each alloy system.

Precipitates that form as a result of the exposure of metals at elevated temperatures (for example, during production, fabrication, heat treatment, and welding) often nucleate and grow preferentially at grain boundaries. If these precipitates are rich in alloying elements that are essential for corrosion resistance, the regions adjacent to the grain boundary are consequently depleted of these elements. The metal is thus sensitized and is susceptible to IGA in one or more specific corrosive environments. For example, in austenitic stainless steels such as Type 304, intergranular attack is often associated specifically with precipitation of chromium-rich carbides ($Cr_{23}C_6$) at grain boundaries in the heat- affected zone. Precipitation of such carbides is often referred to as *sensitization.* When chromium-rich precipitates form, the surrounding areas are depleted in chromium. As a result, the depleted areas are more susceptible to corrosion in specific environments than regions away from the grain boundaries. Another example of grain boundary segregation is sigma-phase formation that results in a

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Cr- and Mo-rich constituent at grain boundaries in Cr- and Mo-containing alloys. Sigma-phase is usually more difficult to resolve visually in the microstructure than Cr-carbides.

Impurities that segregate at grain boundaries may promote galvanic action in a corrosive environment by serving either as anodic or cathodic sites. For example, in 2000-series (2*xxx*) aluminum alloys, the copper-depleted (anodic) band on either side of the grain boundary is dissolved while the grain boundary is cathodic due to the $CuAl_2$ precipitates. Conversely, in the 5000-series (5*xxx*) aluminum alloys, intermetallic precipitates such as Mg_2Al_3 (anodic) are attacked when they form a continuous phase in the grain boundary. During exposures to chloride solutions, the galvanic couples formed between these precipitates and the alloy matrix can lead to severe intergranular attack. Actual susceptibility to intergranular attack and degree of corrosion depends on the corrosive environment and on the extent of intergranular precipitation, which is a function of alloy composition, fabrication, and heat treatment parameters.

Evaluating Intergranular Corrosion

Revised by Bopinder Phull, Consultant

The Purpose of Testing

There is a perception in much of the industry that testing for susceptibility to IGA is equivalent to evaluating the resistance of the alloy to general and localized corrosion. Although the tests used for evaluating susceptibility to IGA are severe, they are not intended to duplicate conditions for the wide range of chemical exposures present in an industrial plant, even though some of these tests do simulate service conditions.

Testing for susceptibility to IGA, however, is useful for determining whether a vendor has supplied the correct material and in the proper metallurgical condition. There are some problems associated with quality assurance programs for purchased materials. Such programs are sometimes based on faith in what is supplied by a vendor or production mill and what is certified in the documentation sent with the material. However, such confidence may be misplaced. For example, there have been a number of accounts in which alloys have been substituted, resulting in premature failure. In one case, this occurred when Hastelloy B (UNS N10001) valves were substituted for the Hastelloy C-276 (UNS N10276) valves that were ordered to handle a hypochlorite solution. Not surprisingly, the Hastelloy B valves failed in about 3 months because this alloy is usually specified for reducing environments (e.g., HCl), whereas alloy C-276 is typically more suited to oxidizing environments (e.g., hypochlorite).

In addition, there are many examples in which the material supplied does not conform to its certified analysis. The problem of getting reliable certified analyses increases when documentation goes from a mill to an alloy supplier. In one case, for example, Type 304L stainless steel (UNS S30403) valves were ordered, but the vendor, having few orders for this alloy, substituted Type 316L stainless steel (UNS S31603) valves and sent certifications that purposely omitted the molybdenum analysis. Normally, this would have been a good substitution for improved corrosion resistance at a bargain price, but these valves were destined for hot, concentrated HNO_3 service and failed prematurely.

Therefore, it is essential that, for critical service, the correct alloys must be specified and in optimum metallurgical condition to resist IGA and other forms of corrosion associated with precipitates at the grain boundaries.

Evaluating Intergranular Corrosion

Revised by Bopinder Phull, Consultant

Tests for Stainless Steels and Nickel-Base Alloys

The austenitic and ferritic stainless steels, as well as most nickel-base alloys, are generally supplied in a heat treated condition such that they are free of carbide precipitates that are detrimental to corrosion resistance. However, these alloys are susceptible to sensitization from welding, improper heat treatment, and service in the sensitizing temperature range. The theory and application of acceptance tests for detecting the susceptibility of stainless steels and nickel-base alloys to intergranular attack are extensively reviewed in Ref 1, 2, 3. Corrosion tests for evaluating the susceptibility of an alloy to IGA are typically classified as either simulated-service or accelerated tests. The original laboratory tests for detecting IGA were simulated-service exposures. These were first used in 1926 when IGA was detected in an austenitic stainless steel in a copper sulfate-sulfuric acid ($CuSO_4$-H_2SO_4) pickling tank (Ref 4). Another simulated-service test for alloys intended for service in nitric acid (HNO_3) plants is described in Ref 5. In this case, for accelerated results, iron-chromium alloys were tested in a boiling 65% HNO_3 solution.

Over the years, specific accelerated tests have been developed and standardized for evaluating the susceptibility of various alloys to IGA. For example, ASTM A 262 contains six practices for detecting susceptibility to IGC in austenitic stainless steels (Ref 6). Practice A is an electrolytic oxalic-acid-etch screening test that can be performed in minutes on prepared samples followed by microscopic examination of the etched microstructure for $Cr_{23}C_6$ sensitization. Practice B is a 120 hour test in a boiling solution of ferric sulfate [$Fe_2(SO_4)_3$] + sulfuric acid (H_2SO_4); the weight-loss corrosion rate indicates degree of IGA due to $Cr_{23}C_6$ precipitation. A 240 hour test in boiling 65% HNO_3 constitutes Practice C; the degree of IGC due to $Cr_{23}C_6$ and sigma-phase formation is indicated by weight-loss corrosion rates. Practice D, which was an immersion test in 10% HNO_3 + 3% HF solution at 70 °C has been removed from ASTM A 262 (Ref 6). Practice E is a 24 hour test in boiling 6% $CuSO_4$ + 10% H_2SO_4 solution to which metallic copper is added; evaluation of IGC due to $Cr_{23}C_6$ formation is based on postexposure visual examination of specimens for fissures after bending. In Practice F, a 120 hour boiling test in $CuSO_4$ + 50% H_2SO_4 solution (with metallic copper present), weight-loss corrosion rates indicate the degree of sensitization due to $Cr_{23}C_6$ precipitation for molybdenum-bearing stainless steels.

Similarly, tests for detecting susceptibility to IGC in ferritic stainless steels have been incorporated into ASTM A 763 (Ref 7) and for wrought Ni-rich, Cr-bearing alloys, into ASTM G 28 (Ref 8). Acceptance criteria for ferritic and austenitic stainless steels, high nickel-base alloys, and aluminum alloys are summarized in Table 1.

(b) See ASTM G 67, section 4.1.

Because sensitized alloys may inadvertently be used, acceptance tests are implemented as a quality-control check to evaluate stainless steels and nickel-base alloys when:

- Different alloys, or alloys with “high” carbon content, are substituted for the low-carbon grades (for example, Type 316 substituted for Type 316L), and when welding or heat treatment are involved
- An improper heat treatment during fabrication results in the formation of intermetallic phases.
- The specified limits for carbon and/or nitrogen contents of an alloy are inadvertently exceeded.

Some standard tests include acceptance criteria, but others do not (Ref 4, 5). Suitable criteria are needed that can clearly separate material susceptible to IGA from that resistant to attack. Table 1 lists evaluation tests and acceptance criteria for various stainless steels and nickel-base alloys. Despite establishment of “standard” acceptance/rejection criteria, the buyer and seller can agree on a different criterion that meets their particular needs.

ASTM G 108 describes a laboratory procedure for conducting a nondestructive electrochemical reactivation (EPR) test on Types 304 and 304L stainless steel to quantify the degree of sensitization (Ref 9). The metallographically mounted and highly polished test specimen is potentiodynamically polarized from the normally passive condition, in 0.5 *M* H_2SO_4 + 0.01 *M* KSCN solution at 30 ± 1 °C, to active potentials—a process known as reactivation. The amount of charge passed is related to the degree of IGC associated with $Cr_{23}C_6$ precipitation, which occurs predominately at the grain boundaries. After the single loop EPR test, the microstructure is examined and:

1. The grain boundary area is calculated from the grain size and the total exposed area of the test specimen.
2. Relative proportions of grain boundary attack and non-grain-boundary pitting are determined.

A charge per unit grain-boundary area of <0.1 C/cm^2 (0.016 C/in.^{2}) generally indicates unsensitized microstructure, and >0.4 C/cm^2 (0.062 C/in.^{2}) indicates a heavily sensitized alloy. Although a double loop EPR method has been proposed (Ref 10, 11) to eliminate non-grain- boundary pitting and surface-finish effects, often observed in the single loop method, the double- loop technique is not presently included in ASTM G 108.

Evaluating Intergranular Corrosion

Revised by Bopinder Phull, Consultant

Tests for Aluminum Alloys

The electrochemically active paths at the grain boundaries of aluminum alloy materials can be either the solid solution or closely spaced anodic second-phase intermetallic particles. The identities of the specific actively corroding paths vary with the alloy composition and metallurgical condition of the product, as discussed in Ref 12 and 13. The most serious forms of such structure-dependent corrosion are stress-corrosion cracking (SCC) and exfoliation. Stress-corrosion cracking requires the presence of a sustained (residual and/or service) tensile stress, and exfoliation occurs only in wrought products with a directional grain structure. Not all materials that are susceptible to IGA, however, are susceptible to SCC or exfoliation.

Strain-Hardened 5*xxx* (Al-Mg) Alloys. Alloys in this series that contain more than approximately 3% Mg are rendered susceptible to IGA (sensitization) by certain manufacturing conditions or by being subjected to elevated temperatures up to approximately 175 °C (350 °F). This is the result of the continuous grain-boundary precipitation of the highly anodic Mg_2Al_3 phase, which corrodes preferentially in most corrosive environments.

ASTM G 67 is a method that provides a quantitative measure of the susceptibility to IGA of these alloys (Ref 14). This method consists of immersing test specimens in concentrated HNO_3 at 30 °C (85 °F) for 24 h and determining the mass loss per unit area of exposed surfaces as the measure of intergranular susceptibility. When the second phase is precipitated in a relatively continuous network along grain boundaries, the preferential attack of the network causes whole grains to drop out of the specimens. Such dropping out causes relatively large mass losses of the order of 25 to 75 mg/cm^2 (3.9 - 12 mg/in.^{2}), whereas specimens of materials resistant to IGC lose only about 1 to 15 mg/cm^2 (0.2 - 2.3 mg/in.^{2}). Intermediate mass losses occur when the precipitate is randomly distributed. The parallel relationship between the susceptibility to intergranular attack, SCC, and exfoliation of these particular alloys makes ASTM G 67 a useful screening test for alloy and process

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

development studies. A problem arises, however, in selecting a pass-or-fail value in relation to the performance of intermediate materials in environments other than HNO_3.

Heat Treated High-Strength Alloys. Materials problems caused by SCC, exfoliation, or corrosion fatigue of the early 2*xxx* (aluminum- copper) alloys were related to IGC, and the blame came to be associated with improper heat treatment. In 1944, an accelerated test for detecting susceptibility to IGC was incorporated into a U.S. Government specification for the heat treatment of aluminum alloys. Military Specification MIL-H-6088F has superseded this specification. Tests are required for periodic monitoring of 2*xxx* and 7*xxx* series alloys in all rivets and fastener components as well as sheet, bar, rod, wire, and shapes under 6.4 mm (0.25 in.) thick. Specimen preparation, test procedure, and evaluation criteria are detailed in Ref 15.

Other Tests for Aluminum Alloys. The volume of hydrogen evolved on immersion of etched 2*xxx* series (aluminum-copper-magnesium) alloys in a solution containing 3% sodium chloride (NaCl) and 1% hydrochloric acid (HCl) for a stipulated time has been used as a quantitative measure of the severity of IGA. A problem with this approach is that the correlation between the amount (or the rate) of hydrogen evolved is influenced by a number of factors, including alloy composition, temper, and grain size (Ref 16, 17).

Applied current or potential in neutral chloride solutions (for example, 0.1 *N* NaCl) provides another direct method of assessing the degree of susceptibility to intergranular attack when accompanied by a microscopic examination of metallographic sections (Ref 16, 18, 19).

As stated earlier, exfoliation is a form of corrosion that can occur in layers parallel to rolled surfaces, especially on aluminum alloys, and attack is generally along grain boundaries. ASTM G 34 is an accelerated test method to determine exfoliation corrosion susceptibility of 2*xxx* and 7*xxx* aluminum alloys (Ref 20); this is sometimes known as the EXCO test. Specimens of wrought material are immersed in 4 *M* NaCl + 0.5 *M* KNO_3 + 0.1 *M* HNO_3 solution at 25 ± 3 °C. Immersion times are 96 and 48 h for 2*xxx* and 7*xxx* alloys, respectively. Performance ratings are established by reference to standard photographs. An analogous exfoliation test for wrought 5*xxx* aluminum alloys, containing ≥2% Mg, is covered by ASTM G 66 in which test specimens are immersed in 1 *M* NH_4Cl + 0.25 *M* NH_4NO_3 + 0.01 *M* $(NH_4)_2C_4H_4O_6$ + 0.09 *M* H_2O_2 for 24 h at 65 ± 1 °C, followed by visual comparison with standard photographs (Ref 21). This test is sometimes known as "ASSET," an abbreviation for assessment of exfoliation corrosion test.

Tests for Other Alloys

Although IGC is present to some extent in metallic materials other than stainless steels and aluminum alloys, incidences of attack associated with this form of corrosion are few and are generally not of practical importance. Therefore, no attempts have been made to develop and standardize specific tests for detecting susceptibility to IGC in these alloys. However, certain media have been commonly used for evaluating the susceptibility to IGC of magnesium, copper, lead, and zinc alloys (Ref 16). These media are listed in Table 2. The presence or absence of attack in these tests is not necessarily a measure of the performance of the material in any other corrosive (test or service) environments.

Table 2 Media for testing susceptibility to intergranular corrosion

Alloy	Medium	Concentration %	Temperature °C (°F)
Magnesium alloys	Sodium chloride plus hydrochloric acid	…	Room
Copper alloys	Sodium chloride plus sulfuric or nitric acid	1 NaCl, 0.3 acid	40–50 (105–120)
Lead alloys	Acetic acid or hydrochloric acid	…	Room
Zinc alloys	Humid air	100% relative humidity	95 (205)

Source: Ref 16

Magnesium Alloys. There are rare instances of reported IGC of magnesium alloys, as in the case of chromic acid contaminated with chlorides or sulfates.

The copper alloys that appear to be the most susceptible to IGC are Muntz metal, admiralty brass, aluminum brasses, and silicon bronzes. Admiralty alloys have been observed to suffer IGC on exposure to saline cooling waters, although the incidence of attack is very low. The antimony-doped grades are reportedly superior to the arsenical grades in this respect. Similarly, arsenical and phosphorized grades of aluminum brass have been observed to suffer IGC in seawater-type exposures.

Zinc die casting alloys have reportedly suffered IGC in certain steam atmospheres. A laboratory test for simulating service failures, and particularly for alloy development work, has been in use for testing the susceptibility of zinc- base die-castings to IGC (Ref 22). The test consists of exposing samples to air at 95 °C (205 °F) and 100% relative humidity for 10 days under conditions permitting condensation of hot water on the metal. Susceptibility to IGC is assessed by the effect on mechanical properties, such as impact strength.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Experience has shown that castings with mechanical properties and dimensions that are not significantly altered by the 10 day exposure in this test will not suffer IGA in atmospheric service.

Intergranular corrosion at elevated temperatures can occur by formation of low melting phases (in certain alloy-environment combinations) that result in rapid attack commonly at grain boundaries. For example, the formation of nickel-sulfides in nickel-base alloys can cause catastrophic failures in high-temperature, sulfur-rich gaseous environments. This phenomenon is commonly referred to as sulfidation. Deep penetration can occur rapidly, including through the full thickness of the metal. The techniques for evaluating this type of IGC include (a) x-ray mapping during examination in a scanning electron microscope (equipped with an energy-dispersive x-ray detector) and (b) transmission electron microscopy.

Evaluating Exfoliation Corrosion

Revised by Bopinder Phull, Consultant

Introduction

EXFOLIATION is a structure-dependent form of localized (usually) intergranular corrosion that is most idiosyncratic in certain alloys and tempers of aluminum. It is also called layer corrosion or lamellar corrosion and is a form of subsurface attack that follows narrow paths (often grain boundaries) in the rolling direction of wrought materials and parallel to the rolled surfaces. Exfoliation corrosion often initiates at laterally sheared edges exposed to the environment. The corrosion products tend to swell or pry open the material, revealing alternate layers or leafing of corroded and uncorroded structure. Highly cold-worked materials, which have elongated grain boundaries, and thin-gage product forms tend to be most affected. Swelling associated with exfoliation corrosion can stress adjacent parts and cause overload failures—a phenomenon akin to packout rusting (Ref 1).

The occurrence of exfoliation in susceptible materials is influenced to a marked degree by environmental conditions. Figure 1 illustrates the broad range of behavior of aluminum alloy 2124 plate in different types of environments (Ref 2). The plate was heat treated to be susceptible to exfoliation. Performance can vary significantly, depending on the environment. For example, forged truck wheels made of an aluminum-copper alloy (2024-T4) give corrosion- free service for many years in the warm climates of the southern and western United States, but they exfoliate severely in only 1 or 2 years in the northern states, where deicing salts are used on the highways during the winter months.

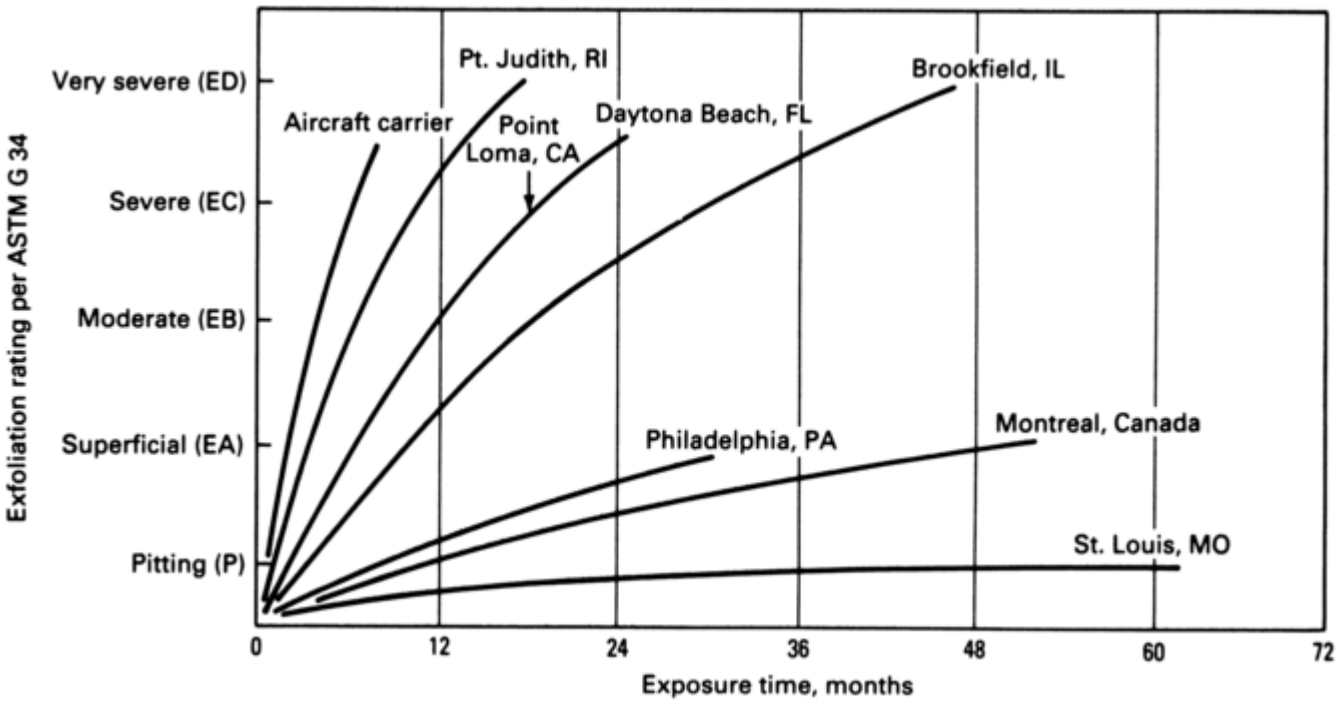

Fig. 1 Comparison of exfoliation of aluminum alloy 2124 (heat treated to be susceptible; EXCO ED rating) in various seacoast and industrial environments. Specimens were 13 mm ($\frac{1}{2}$ in.) plate. Source: Ref 2

Accelerated laboratory tests do not precisely predict long-term corrosion behavior; however, answers are needed quickly in the development of new materials. For this reason, accelerated tests are used to screen candidate alloys before conducting atmospheric exposures or other field tests. They are also sometimes used for quality- control tests. Several new laboratory tests for exfoliation corrosion have been standardized under the jurisdiction of American Society for Testing and Materials International (ASTM International) Committee G-1 on the Corrosion of Metals.

Spray Tests

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Three cyclic acidified salt spray tests have been widely used in the aluminum and aircraft industries. These are covered by the procedures described in Annexes A2, A3, and A4 of ASTM G 85 (Ref 3). This standard does not prescribe the particular practice, test specimen, or exposure period to be used for a specific product, nor does it define the interpretation to be given to the test results. These considerations are prescribed by specifications covering the material or product being tested or by agreement between the purchaser and the seller.

Annex A2 describes a cyclic salt spray test that uses a 5% sodium chloride (NaCl) solution, acidified to pH 3 with acetic acid, in a spray chamber at a temperature of 49 ± 1 °C (120 ± 2 °F). This test is applicable for exfoliation testing of 2*xxx* (dry-bottom operation) and 7*xxx* (wet-bottom operation; that is, with approximately 25 mm, or 1 in., of water present in the bottom of the test chamber) aluminum alloys with a test duration of 1 to 2 weeks. Results with 7075 and 7178 alloys in various metallurgical conditions have been shown to correlate well with results obtained in a seacoast atmosphere (4 year exposure at Point Judith, RI) (Ref 4).

Annex A3 describes another cyclic salt spray test that uses a 5% synthetic sea salt solution, acidified to pH 3 with acetic acid, in a spray chamber at a temperature of 49 °C (120 °F). The test is applicable to the production control of exfoliation-resistant tempers of the 2*xxx*, 5*xxx*, and 7*xxx* aluminum alloys (Ref 5, 6). Wet-bottom operating conditions are recommended with test durations of 1 to 2 weeks.

Annex A4 describes a salt/sulfur dioxide (SO_2) spray test that uses either 5% NaCl or 5% synthetic sea salt solution in a spray chamber at a temperature of 35 °C (95 °F). The spray may be either cyclic or constant. This, along with the type of salt solution and the test duration, is subject to agreement between the purchaser and the seller. The test is applicable for 2*xxx* and 7*xxx* aluminum alloys. Test duration is 2 to 4 weeks (Ref 2).

Immersion Tests

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Total-immersion tests were developed to provide simpler, more easily controlled test methods. Chloride solutions did not cause exfoliation during reasonable periods of immersion. However, formulations of chloride-nitrate solutions were found that produced severe exfoliation of susceptible alloys in only 1 or 2 days. Optimal test conditions differed for separate alloy families (Ref 7).

ASTM G 66 describes a procedure for the continuous-immersion exfoliation testing of 5*xxx* alloys containing 2.0% or more magnesium (Ref 8). Specimens are immersed for 24 h at 65 ± 1 °C (150 ± 2 °F) in a solution of 1 *M* ammonium chloride, 0.25 *M* ammonium nitrate, 0.01 *M* ammonium tartrate, and 0.09 *M* hydrogen peroxide. Susceptibility to exfoliation is determined by visual examination, using performance ratings established by reference to standard photographs. This method is stated to provide reliable prediction of the exfoliation corrosion behavior of 5*xxx* alloys in marine environments (Ref 9). The test is also useful for alloy development studies and quality control of mill products such as sheet and plate (Ref 10).

ASTM G 34 provides an accelerated exfoliation corrosion test for 2*xxx* and 7*xxx* aluminum alloys through the continuous immersion of test materials in an aqueous solution of 4 *M* NaCl, 0.5 *M* potassium nitrate, and 0.1 *M* nitric acid at 25 ± 3 °C (77 ± 5 °F) (Ref 11). Maximum recommended exposure periods for the 2*xxx* and 7*xxx* aluminum alloys are 96 and 48 h, respectively. Susceptibility to exfoliation is determined by visual examination, using performance ratings established by reference to standard photographs. This constant immersion exfoliation corrosion test method, also known as the EXCO test, is primarily used for research and development and quality control of such mill products as sheet and plate (Ref 10). However, it should not be construed as the optimal method for quality acceptance.

The ASTM G 34 method provides a useful prediction of the exfoliation behavior of 2*xxx* and 7*xxx* aluminum alloys in various types of outdoor service, especially in marine and industrial environments (Ref 4, 12). The test solution is very corrosive and represents the more severe types of environment service (Fig. 1). However, it remains to be determined whether correlations can be established between EXCO test ratings and practical service conditions for a given alloy. It has been reported that samples of 7*xxx* (Al-Zn- Mg-Cu) alloys rated EA (superficial exfoliation) or P (pitting) in a 48 h EXCO test did not develop more than superficial exfoliation (EA rating) during 6 to 9 year exposures to seacoast atmospheres, while EC- and ED-rated (severe and very severe exfoliation, respectively) materials developed severe exfoliation within 1 to 7 years at the seacoast (specimens rated EA to ED are shown in Fig. 2, Fig. 3, Fig. 4, Fig. 5) (Ref 12).

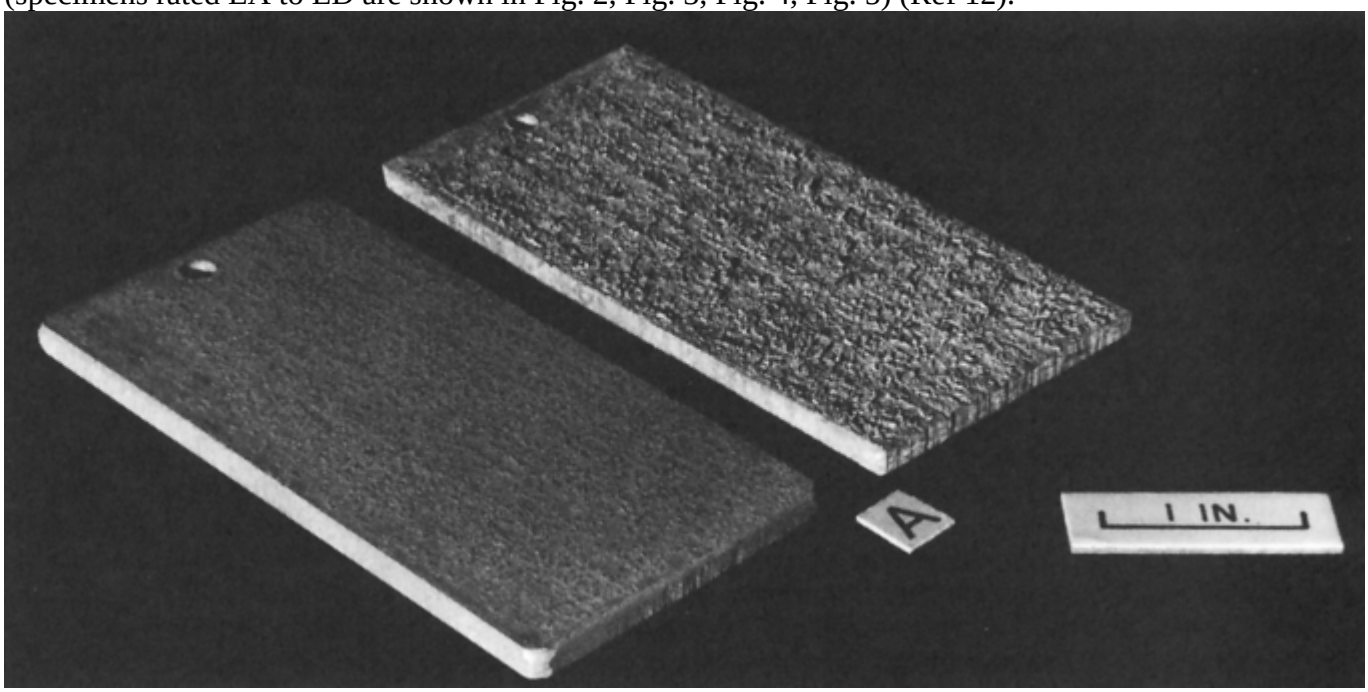

Fig. 2 Examples of exfoliation rating EA (superficial). Specimens exhibit tiny blisters, thin slivers, flakes, or powder, with only slight separation of metal. Source: Ref 11

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

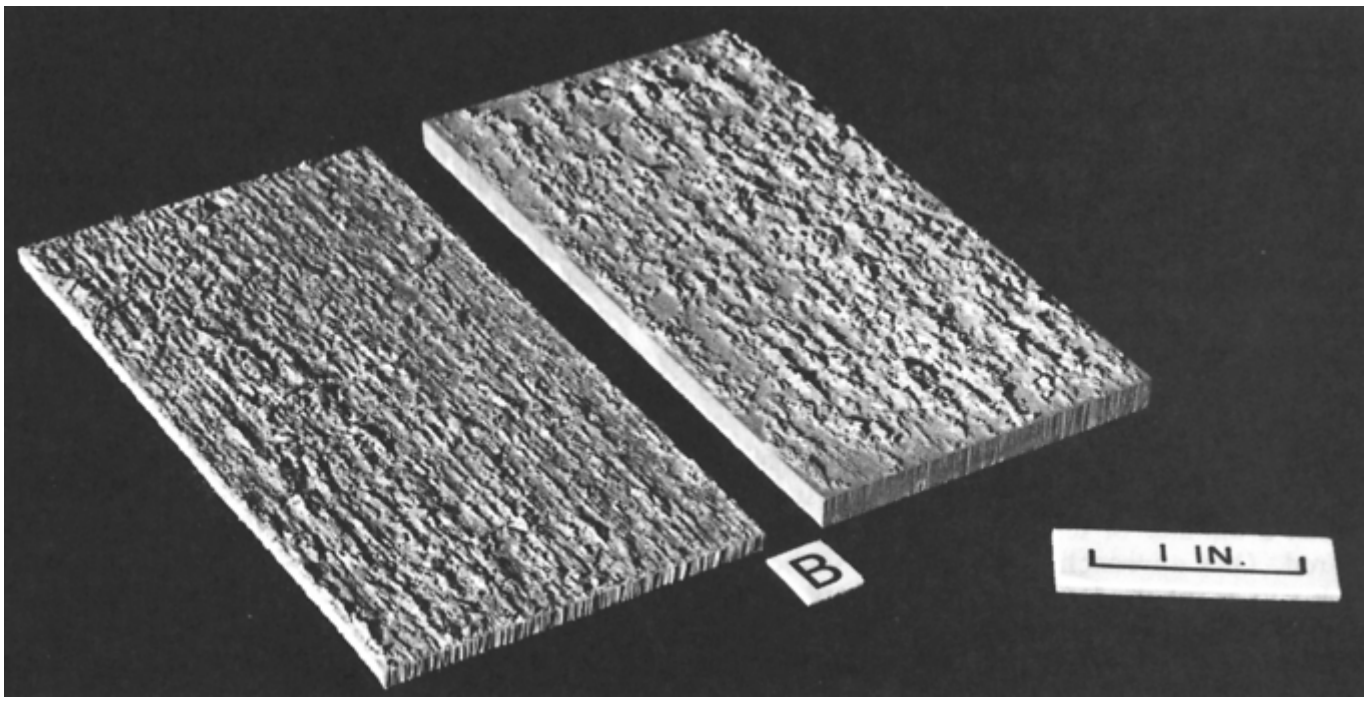

Fig. 3 Examples of exfoliation rating EB (moderate). Specimens show notable layering and penetration into the metal. Source: Ref 11

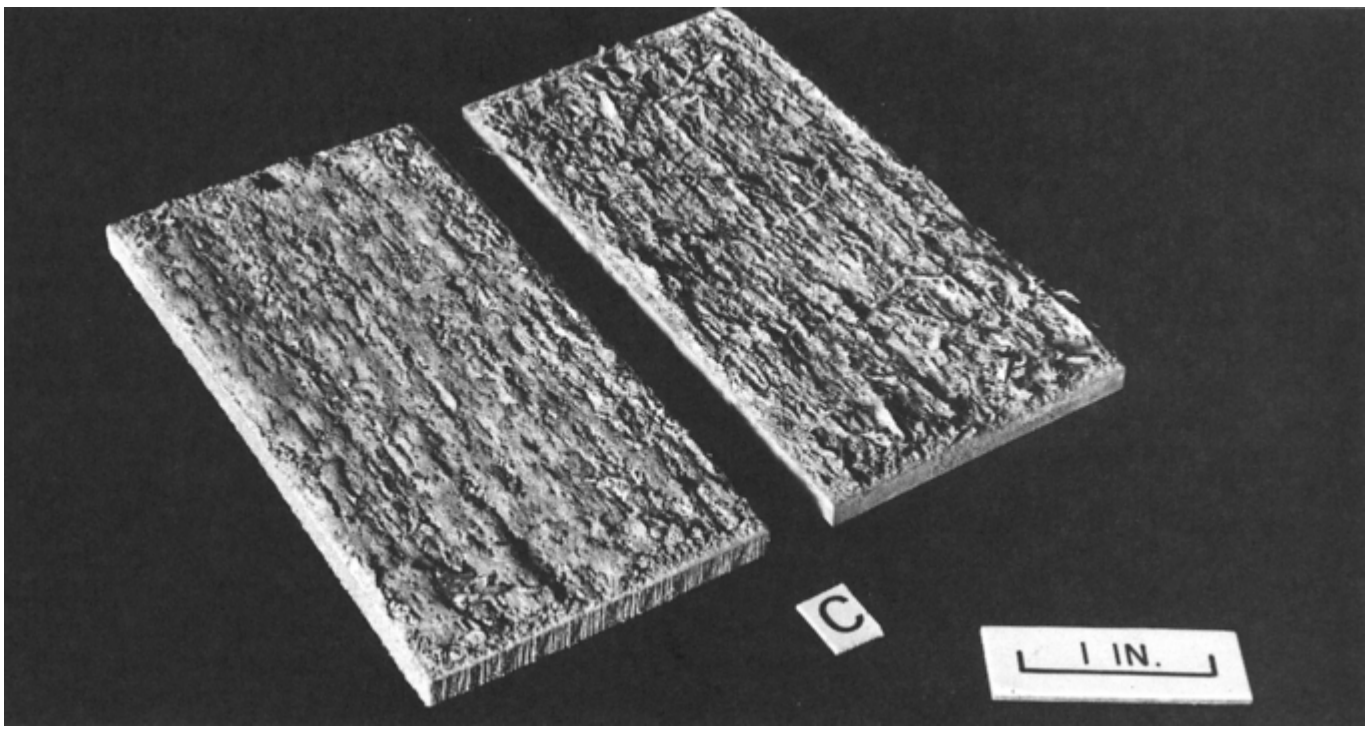

Fig. 4 Examples of exfoliation rating EC (severe). There is penetration to a considerable depth into the metal. Source: Ref 11

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

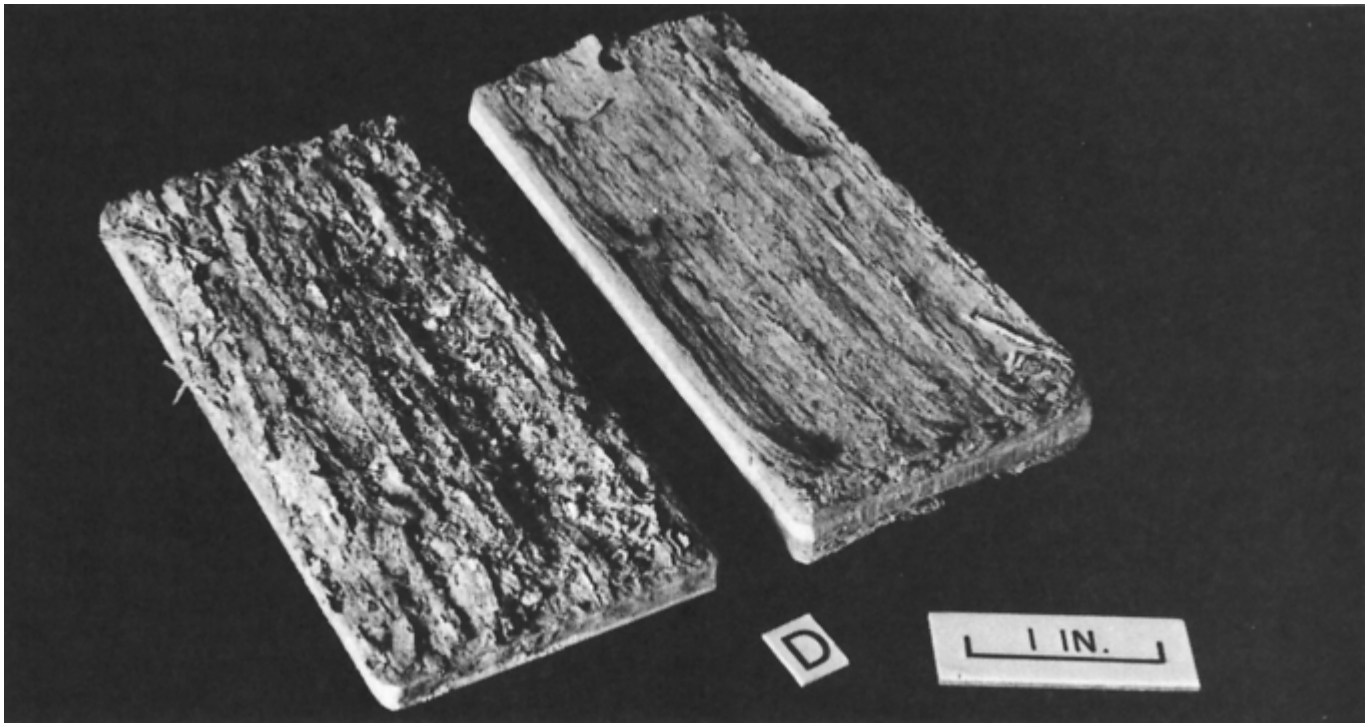

Fig. 5 Examples of exfoliation rating ED (very severe). Specimens appear similar to EC except for much greater penetration and loss of metal. Source: Ref 11

Performance differences between practical service and the EXCO test have been noted and indicate that the EXCO test may be too severe for some of the more recently developed 2*xxx* and 7*xxx* alloys. The testing program for evaluating new alloy materials should consist of multiple tests with one of the less aggressive ASTM G 85 salt spray methods supplemented by outdoor exposure tests. Caution must be exercised in setting limits for material procurement specifications based on accelerated tests (Ref 13).

Evaluating Stress-Corrosion Cracking

Revised by Bopinder Phull, Consultant

Introduction

THERE ARE A NUMBER of corrosion-related causes of the premature fracture of structural components. The most common of these are compared in Fig. 1. Cracking due to corrosion fatigue occurs only under cyclic or fluctuating operating loads, while failure resulting from the other processes shown occurs under static or slowly rising loads. With certain alloy systems, hydrogen embrittlement may have a contributory role in each of these failure processes. Appropriate tests for the different failure modes are discussed in other articles in this Section.

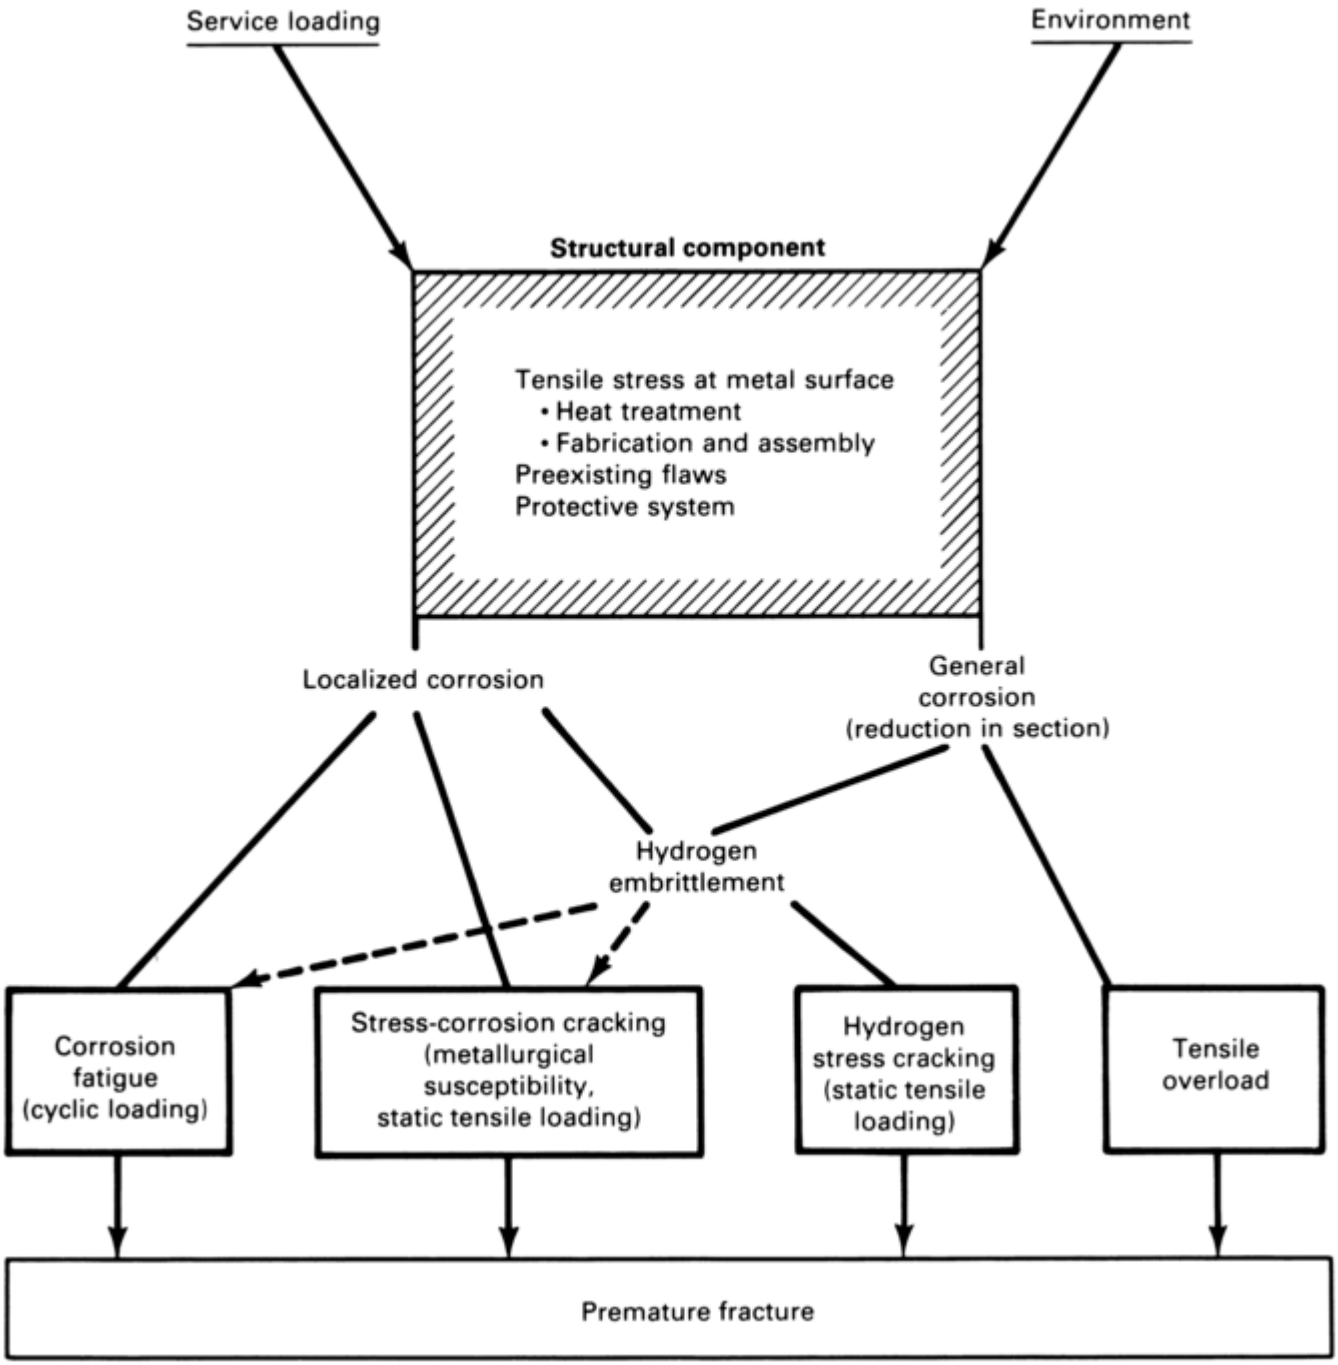

Fig. 1 Causes of premature fracture influenced by the corrosion of a structural component

The materials presented here are organized according to the following broad outline:

- General state-of-the-art
- Static loading of smooth specimens
- Static loading of precracked specimens
- Dynamic loading: slow-strain-rate testing
- Selection of test environments
- Appropriate tests for various alloy systems
- Interpretation of test results

Evaluating Stress-Corrosion Cracking

Revised by Bopinder Phull, Consultant

Static Loading of Smooth Specimens

Tests for predicting the stress-corrosion performance of an alloy in a particular service application should be conducted with a stress system similar to that anticipated in service. Table 1 lists the numerous sources of sustained tension that are known to have initiated SCC in service and the applicable methods of stressing. Most of the SCC service problems involve tensile stresses of unknown magnitude that are usually very high. Tests that incorporate a high total strain are usually the most realistic in terms of duplicating service.

Table 1 Stressing methods applicable to various sources of sustained tension in service

Source of sustained tension in service	Constant strain	Constant load
Residual stress		
Quenching after heat treatment	X	…
Forming	X	…
Welding	X	…
Misalignment (fit-up stresses)	X	…
Interference fasteners	X	…
Interference bushings		
Rigid	X	…
Flexible	…	X
Flareless fittings	X	…
Clamps	X	…
Hydraulic pressure	X	X
Deadweight	…	X
Faying surface corrosion	X	X

Note: The greatest hazard arises when residual, assembly, and operating stresses are additive.

The results are strongly influenced by the mechanical aspects of the tests, such as method of loading and specimen size. These mechanical aspects can have variable effects on the initiation and propagation lifetimes and can influence estimates of a threshold stress. Therefore, an apparent threshold stress for SCC is not a material property, and threshold estimates must be qualified with regard to the test conditions and the significance level.

Constant-Strain versus Constant-Load Tests

Constant-strain (fixed-displacement) tests are widely used, primarily because a variety of simple and inexpensive stressing jigs can be devised. However, there is poor reproducibility of the exposure stress with some of these techniques. Therefore, sophisticated procedures have been developed to improve this facet of testing.

Constant-strain tests are sometimes called decreasing-load tests, because after the onset of SCC in small test specimens the gross section exposure stress decreases. This results from the opening of the crack (or cracks) under the high stress concentration at the crack tip (or tips) and causes some of the applied elastic strain to change to plastic strain, with an attendant reduction in the initial load (Ref 6, 7). Such trends in changing stress during crack growth are shown in Fig. 4.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

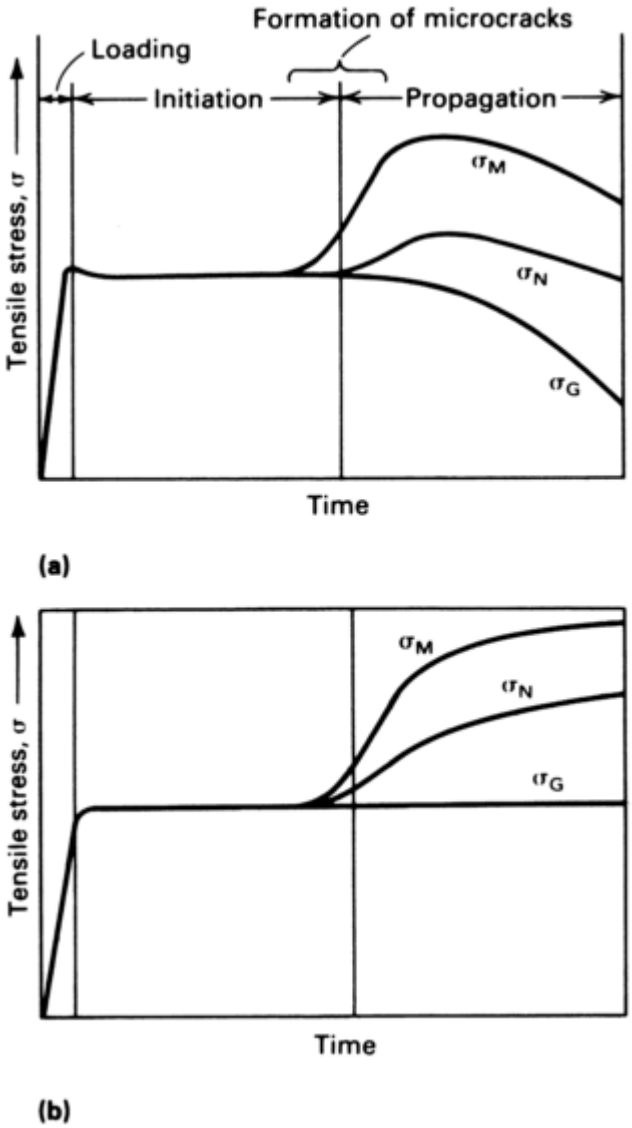

Fig. 4 Comparison of changing stress during initiation and growth of isolated SCC in constant-strain and constant-load tests of a uniaxially loaded tension specimen. (a) Constant-strain test. (b) Constant-load test. σ_M is the maximum stress at crack tip, σ_N is the average stress in the net section, and σ_G is the applied stress to the gross section. Source: Ref 7

Comparison of the stress trends for a constant- strain test (Fig. 4a) with those for a constant-load test (Fig. 4b) reveals that neither method of loading provides a constant-stress test after growth of microcracks has occurred. True constant-load (dead-load) tests result in increasing stress levels as cracking progresses and are more likely to lead to earlier failure with complete fracture and lower estimates of a threshold stress than constant-strain tests. Figures 4(a) and (b) illustrate basic trends that may be applied to all types of test specimens, including precracked specimens. Specific curves, however, will differ depending on other test conditions.

The stiffness of the combined stressing frame/ test specimen system can have a significant effect on materials evaluation if identical test procedures are not used (Ref 6). Many so-called constant-strain tests are not actually constant- strain tests, particularly if a spring is included in the stressing system, because a significant amount of elastic strain energy may be contained in the stressing system. Depending on the “softness” of the spring or the elasticity of the stressing jig, the stiffness (compliance) of the stressing system can be varied greatly between zero stiffness (dead load) and infinite stiffness (true constant total strain). Figure 5 shows the typical change in net section stress with the onset of SCC in an intermediate-stiffness stressing frame used in ASTM G 49 for loading direct-tension stress-corrosion test specimens (Ref 8).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

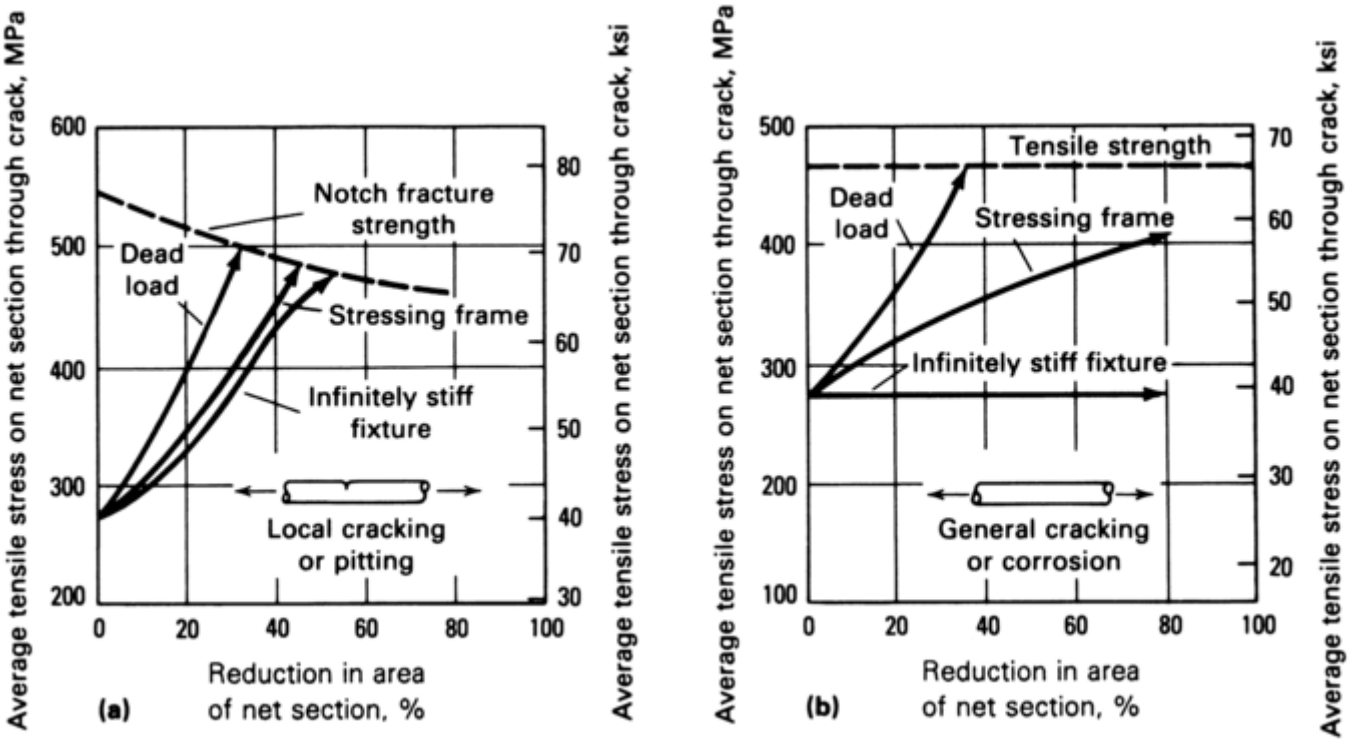

Fig. 5 Effect of loading method and extent of cracking or corrosion pattern on average net section stress in a uniaxially loaded tension specimen. Behavior is generally representative, but curves will vary with specific alloys and tempers. (a) Localized cracking. (b) General cracking. Source: Ref 8

The corrosion pattern on the test specimen, particularly the number and distribution of cracks, can impair the precision of results obtained by either constant-strain or constant-load tests. When isolated stress-corrosion cracks propagate in a specimen stressed by either method, the average tensile stress on the net section increases rapidly until the notch fracture strength is reached and the specimen breaks (Fig. 5a). Less penetration is required for fracture of specimens under dead load; this indicates that specimen life is shorter with lower-stiffness stressing frames. When microcracks initiate close to one another, their individual stress concentrations interact and are relaxed. Consequently, there may not be a sufficient stress concentration in the true constant-strain test to propagate further SCC, and the specimen will not break (Fig. 5b). Under a constant load, however, the growth of many cracks continues, and the specimen ultimately breaks.

With general cracking, crack propagation can be strongly influenced by frame stiffness. Therefore, SCC comparison of specimens tested at stress levels just above their thresholds is complicated by random variations in the cracking pattern, particularly when tested with a relatively stiff stressing system.

Although constant-load stressing appears to be advantageous for testing materials with relatively high resistance to SCC, difficulties arise when small-diameter specimens are utilized to avoid the use of massive loads or lever systems. In some test environments, highly stressed specimens may fail from general or pitting corrosion and an attendant increase in the effective stress. Such non-SCC failures complicate interpretation of test results, unless failure by SCC is confirmed by examination using a light microscope and/or a scanning electron microscope. Such extraneous failures are less likely to occur with specimens loaded under constant strain.

Therefore, small test specimens, which are generally preferred for laboratory screening tests and research studies, must be used with caution when estimates of serviceability are required. To determine serviceability, larger specimens should be used, and a stressing system should be selected that best duplicates the anticipated service conditions.

Bending versus Uniaxial Tension

Historically, the most extensively used stressing systems have incorporated constant-deformation specimens stressed by bending. This method is versatile because of the variety of simple techniques that can be used to test most metal products in all types of corrosive environments. The state of stress in a bend specimen, however, is

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

much more complex than in a tension specimen. Theoretically, tensile stress is uniform throughout the cross section in the tension specimen, except at corners in rectangular sections, but the tensile stress in bend specimens varies through the specimen thickness.

Tensile stress is at a maximum on the convex surface and decreases steeply to zero at the neutral axis. It then changes to a compressive stress, which reaches a maximum on the concave surface. Thus, only about 50% of the metal surface is under tension, and stress can vary from maximum to zero, depending on the stressing system. As SCC penetrates the metal, the stress gradient through the section thickness produces changes in stresses and strains that are different from those in a uniaxial tension specimen. This tendency yields significantly different SCC responses for the two types of stressing (Fig. 6).

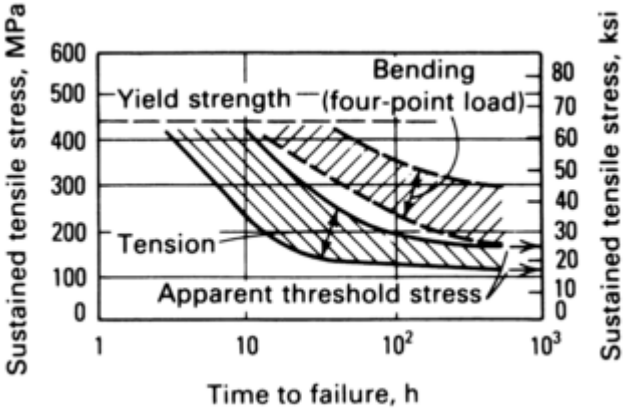

Fig. 6 Comparison of the SCC response with bending versus direct tension stressing under constant load for Al-5.3Zn-3.7Mg-0.3Mn-0.1Cr T6 temper alloy sheet. Tested to failure in 3% NaCl plus 0.1% H_2O_2. Source: Ref 9

Bending stress specimens experience other sources of variability in stress that are not present with direct tension stressing. Variations occur in the principal longitudinal stress across the width of the specimen as well as with the presence of biaxial stresses, both of which are influenced by the design of the specimen. Therefore, just as in the case of constant-load stressing, optimal control of stress and more severe testing conditions are provided by uniaxial tension stressing.

Statically loaded, smooth test specimens for SCC tests can be divided into three general categories: elastic-strain specimens, plastic-strain specimens, and residual-stress specimens. The commonly used specimen geometries for each of these categories are discussed in the sections that follow.

Elastic-Strain Specimens

To control the surface tensile stress applied by deformation loading, strain is usually restricted to the elastic range for the test material. The magnitude of the applied stress can then be calculated from the measured strain and modulus of elasticity. In constant-load stressing, the load typically is measured directly, and the stress is calculated by using the appropriate formula for the specimen configuration and the method of loading. Load cells or calibrated springs may be useful for applying and monitoring possible changes in load during the test. The commonly used types of specimens for tests under elastic- range stress are described in this section.

Bent-beam specimens can be used to test a variety of product forms. The bent-beam configuration is primarily used for sheet, plate, or flat extruded sections, which conveniently provide flat specimens of rectangular cross section, but it is also used for cast materials, rod, pipe, or machined specimens of circular cross section. This method is applicable to specimens of any metal that are stressed to levels less than the elastic limit of the material; therefore, the applied stress can be calculated or measured accurately (ASTM G 39, Ref 10; and ISO 7539-2, Ref 11).

Stress calculations by this method are not applicable to plastically stressed specimens. Bent- beam specimens are usually tested under constant-strain conditions, but constant-load conditions can also be used. In either case, local changes in the curvature of the specimen when cracking occurs result in changes in stress and strain during crack propagation. The “test stress” is taken as the highest surface tensile stress existing at the start of the test, that is, before the initiation of SCC.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Several configurations of bent-beam specimens and stressing systems are illustrated in Fig. 7 and are described in detail in ASTM G 39 (Ref 10) and in ISO 7539-2 (Ref 11). When specimens are tested at elevated temperatures, the possibility of stress relaxation should be investigated.

Fig. 7 Specimen and holder configurations for bent-beam stressing. (a) Two-point loaded specimen. (b) Three-point loaded specimen. (c) Four-point loaded specimen. (d) Welded double-beam specimen. (e) Bolt-loaded double-beam specimen. Formula for stressing specimen (e): $\Delta d = 2fa/3Et(3L - 4a)$, where Δd is deflection (in inches), f is nominal stress (in pounds per square inch), and E is modulus of elasticity (in pounds per square inch). Source: Ref 12

Two-point loaded specimens can be used for materials that do not deform plastically when bent to $(L - H)/H = 0.01$. The specimens should be approximately 25 × 250 mm (1 × 10 in.) flat strips cut to appropriate lengths to produce the desired stress after bending, as shown in Fig. 7(a). The maximum stress occurs at the midlength of the specimen and decreases to zero at specimen ends.

Three-point loaded specimens are flat strips that are typically 25 to 51 mm (1 to 2 in.) wide and 127 to 254 mm (5 to 10 in.) long. The thickness of a specimen is usually dictated by the mechanical properties of the material and the available product form. The specimen should be supported at the ends and bent by forcing a screw (equipped with a ball or knife-edge tip) against it at a point halfway between the end supports, as shown in Fig. 7(b). In a three-point loaded specimen, the maximum stress occurs at the midlength of the specimen and decreases linearly to zero at the outer supports.

Two- and four-point loaded specimens are often preferred over the three-point loaded specimen, because crevice corrosion often occurs at the central support of the three-point loaded specimen. Because this corrosion site is very close to the point of highest tensile stress, it may cathodically protect the specimen and prevent possible crack formation, or it may cause hydrogen embrittlement. Furthermore, the pressure of the central support at the point of highest load introduces biaxial stresses at the area of contact and can introduce tensile stresses where compressive stresses are normally present.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Four-point loaded specimens are flat strips that are typically 25 to 51 mm (1 to 2 in.) wide and 127 to 254 mm (5 to 10 in.) long. The thickness of a specimen is usually dictated by the mechanical properties of the material and the available product form. The specimen is supported at the ends and is bent by forcing two inner supports against it, as shown in Fig. 7(c). The two inner supports are located symmetrically around the midpoint of the specimen.

In a four-point loaded specimen, the maximum stress occurs between the contact points of the inner supports; the stress is uniform in this area. From the inner supports, the stress decreases linearly toward zero at the outer supports. The four-point loaded specimen is preferred over the three-point and two-point loaded specimens, because it provides a large area of uniform stress.

Welded double-beam specimens consist of two flat strips 25 to 51 mm (1 to 2 in.) wide and 127 to 254 mm (5 to 10 in.) long. The strips are bent against each other over a centrally located spacer until both ends touch. The strips are held in position by welding the ends together, as shown in Fig. 7(d).

In a welded double-beam specimen, the maximum stress occurs between the contact points of the spacer; the stress is uniform in this area. From contact with the spacer, the stress decreases linearly toward zero at the ends of the specimen, similar to a four-point loaded specimen.

A bolt-loaded double-beam specimen is shown in Fig. 7(e), along with suggested specimen dimensions for various thicknesses of plate and the formula for stressing such specimens (Ref 12). The beam deflections required to develop the intended tensile stress are calculated with the formula and are then applied by bolting the ends of the beams together. The deflections are measured with a dial gage to within ±0.0127 mm (±0.0005 in.). Thus, the error in stress application—if the beams are of homogeneous material and if the cross sections are uniform—is within 2%. The precision of the deflection measurement is within 0.5%, and the error in determining the modulus of elasticity, *E*, is within 1%.

Constant-moment beam specimens are designed such that a constant moment exists from one end to the other when the specimen is bent in the manner shown in Fig. 8 (Ref 13). This bending produces equal stress along the length of the specimen. The width-to-thickness ratio is less than 4 so that biaxial stresses are eliminated.

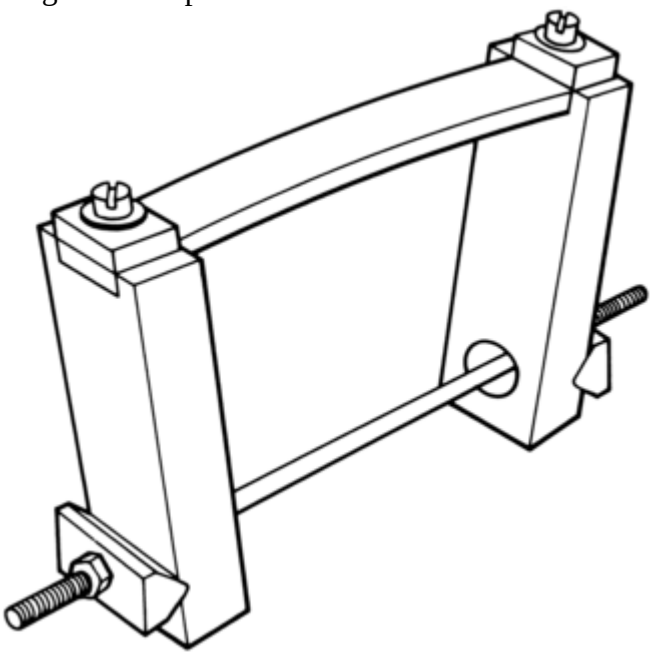

Fig. 8 Bent beam designed to produce pure bending. Source: Ref 13

This type of specimen offers the advantage of a relatively large area of material under a uniform stress. Such specimens can be used when the dimensions of the specimen are too small for other bent-beam specimens—for example, when specimens are taken in the short-transverse direction in plate (see Fig. 9c). The elastic stress σ in the convex surface is calculated by using:

$$\sigma = \frac{4Ety}{h^2} \qquad \text{(Eq 1)}$$

where *h* is the distance between inner edges of the supports, *y* is the maximum deflection between inner edges of the supports, *t* is the thickness of the specimen, and *E* is the modulus of elasticity.

C-Ring Specimens. As discussed in ASTM G 38 (Ref 14), the C-ring is a versatile, economical specimen for quantitatively determining the susceptibility to SCC of all types of alloys in a wide variety of product forms. It is particularly well suited for testing tubing and for making short- transverse tests on various product forms, as shown in Fig. 10. The sizes of C-rings can be varied over a wide range, but rings with outside diameters less than about 16 mm ($\frac{5}{8}$ in.) are not recommended because of increased difficulties in machining and decreased precision in stressing. The C-ring specimen is also covered by ISO 7539-5 (Ref 15).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

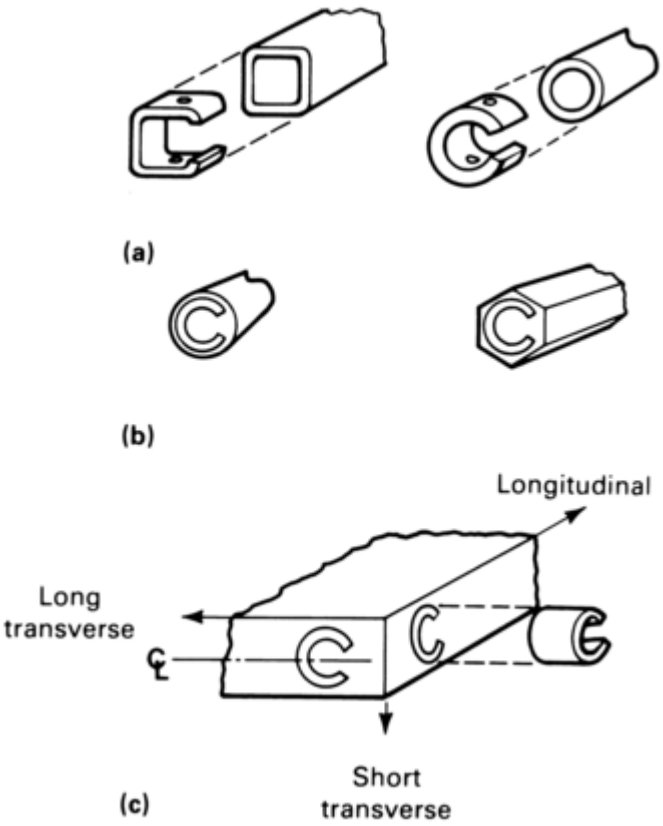

Fig. 10 Sampling procedure for testing various products with C-rings. (a) Tube. (b) Rod and bar. (c) Plate Source: Ref 14

The C-ring is typically a constant-strain specimen with tensile stress produced on the exterior of the ring by the tightening of a bolt centered on the diameter of the ring. However, an almost constant load can be developed by placing a calibrated spring on the loading bolt. C-rings can also be stressed in the reverse direction by spreading the ring and creating a tensile stress on the inside surface. These methods of stressing are shown in Fig. 11.

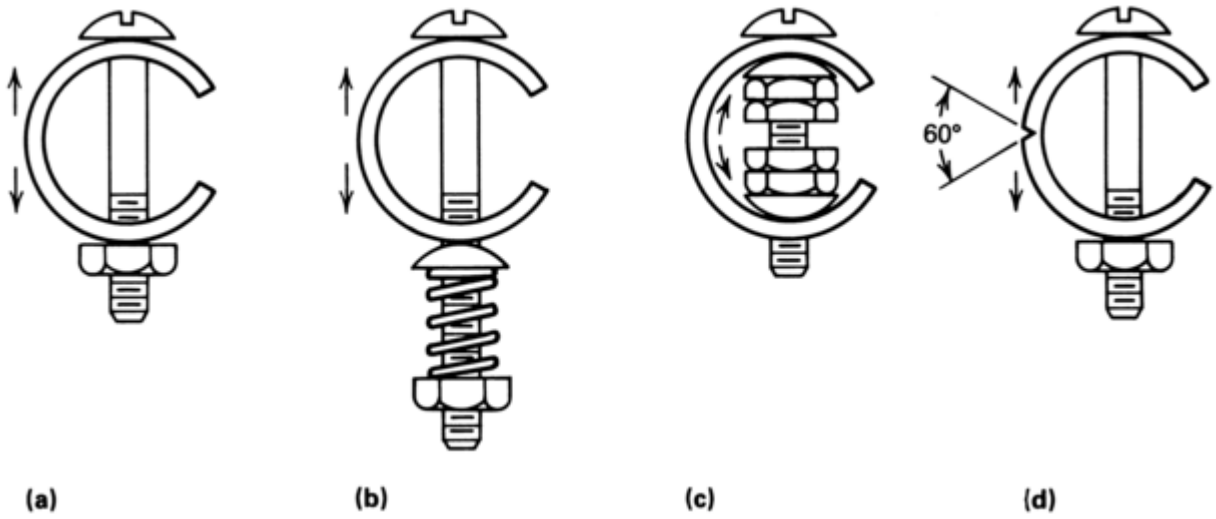

Fig. 11 Methods of stressing C-rings. (a) Constant strain. (b) Constant load. (c) Constant strain. (d) Notched C-ring; a similar notch could be used on the side of (a), (b), or (c). Source: Ref 14

Circumferential stress is of principal interest in the C-ring specimen. This stress is not uniform (Ref 16), as discussed previously in the section “Elastic-Strain Specimens” in this article. The stress varies around the circumference of the C-ring from zero at each bolt hole to a maximum at the middle of the arc opposite the stressing bolt. In a notched C-ring, a triaxial stress state is present adjacent to the root of the notch (Ref 17). For

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

all notches, the circumferential stress at the root of the notch is greater than the nominal stress and can generally be expected to be in the plastic range.

Generally, the C-ring can be stressed with high precision. The most accurate stressing procedure consists of attaching circumferential and transverse electrical strain gages to the surface stressed in tension, followed by tightening the bolt until the strain measurements indicate the desired circumferential stress.

The amount of compression required on the C-ring to produce elastic straining and the degree of elastic strain can be predicted theoretically. Therefore, C-rings can be stressed by calculating the deflection required to develop a desired elastic stress (ASTM G 38) (Ref 14). In notched specimens, a nominal stress is estimated using a ring outside diameter measured at the root of the notch and by taking into consideration the stress-concentration factor, K_t, for the specific notch.

O-ring specimens (Fig. 12) are used to develop a hoop stress in a particular part—for example, a cylindrical die forging in which a critical end-grain structure associated with the parting plane of the forging exists only at the surface of the forging. A relatively large surface area of metal is placed under a uniform tensile stress, and the O-ring stressing plug assembly simulates service conditions in structures containing interference-fit components. Stressed O- rings have also been used to evaluate protective treatments for the prevention of SCC (Ref 18).

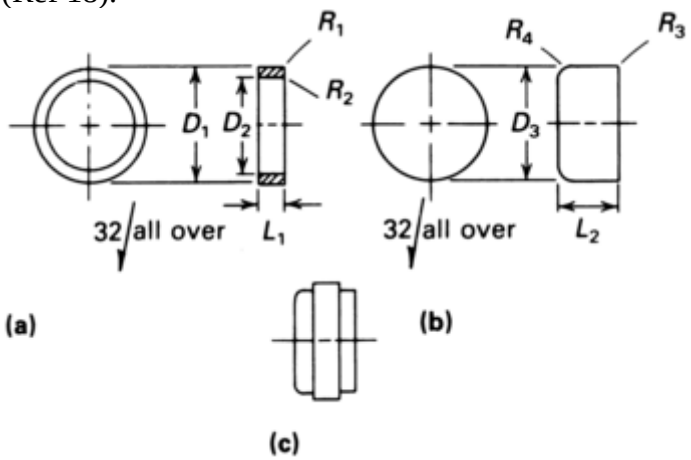

Fig. 12 O-ring SCC test specimen (a) and stressing plug (b). The O-ring is stressed by pressing it onto the plug, as shown in (c).

An O-ring is stressed by pressing it onto an oversized plug that is machined to a predetermined diameter to develop the desired stress at the outside surface of the ring. The nominal dimensions of this specimen can be varied to suit the part being tested, but certain characteristics should be observed to achieve adequate control of the stresses. The ring width should not be more than four times the wall thickness in order to ensure maximum uniformity of the hoop stress from the centerline to the edges of the ring. The tensile stress varies through the thickness of the ring and is highest at the inside surface. Interference required for stressing an O-ring can be calculated by using:

$$I = \frac{F(OD)^2}{E(ID)} \qquad \text{(Eq 2)}$$

where I is the interference (on the diameter) between the O-ring and the plug, E is the modulus of elasticity, ID is the inside diameter, OD is the outside diameter, and F is the circumferential stress desired on the outside surface. Additional information regarding the design and stressing of O-ring specimens is given in Ref 19.

Tension Specimens. Specimens used to determine tensile properties in air are well suited and easily adapted to SCC, as discussed in ASTM G 49 (Ref 8) and ISO 7539-4 (Ref 20). When uniaxially loaded in tension, the stress pattern is simple and uniform, and the magnitude of the applied stress can be accurately determined. Specimens can be quantitatively stressed by using equipment for application of either a constant load, a constant strain, or an increasing load or strain.

This type of test is one of the most versatile methods of SCC testing because of the flexibility permitted in the type and size of the test specimen, the stressing procedures, and the range of stress level. It allows the simultaneous exposure of unstressed specimens (no applied load) with stressed specimens and subsequent tension testing to distinguish between the effects of true SCC and mechanical overload.

مرجع مهندسی مواد و متالورژی

A wide range of test specimen sizes can be used, depending primarily on the dimensions of the product to be tested. Stress-corrosion test results can be significantly influenced by the cross section of the test specimen. Although large specimens may be more representative of most structures, they often cannot be prepared from the available product forms being evaluated. They also present more difficulties in stressing and handling in laboratory testing.

Smaller cross-sectional specimens are widely used. They have a greater sensitivity to SCC initiation, usually yield test results rapidly, and permit greater convenience in testing. However, the smaller specimens are more difficult to machine, and test results are more likely to be influenced by extraneous stress concentrations resulting from nonaxial loading, corrosion pits, and so on. Therefore, use of specimens less than about 10 mm (0.4 in.) in gage length and 3 mm (0.12 in.) in diameter is not recommended, except when testing wire specimens.

Tension specimens containing machined notches can be used to study SCC and hydrogen embrittlement. The presence of a notch induces a triaxial stress state at the root of the notch, in which the actual stress will be greater by a concentration factor that is dependent on the notch geometry. The advantages of such specimens include the localization of cracking to the notch region and acceleration of failure. However, unless directly related to practical service conditions, the results may not be relevant.

Tension specimens can be subjected to a wide range of stress levels associated with either elastic or plastic strain. Because the stress system is intended to be essentially uniaxial (except in the case of notched specimens), great care must be exercised in the construction of stressing frames to prevent or minimize bending or torsional stresses.

The simplest method of providing a constant load consists of a deadweight hung on one end of the specimen. This method is particularly useful for wire specimens. For specimens of larger cross section, however, lever systems such as those used in creep-testing machines are more practical. The primary advantage of any deadweight loading device is the constancy of the applied load.

A constant-load system can be modified by the use of a calibrated spring, such as that shown in Fig. 13. The proving ring, as used in the calibration of tension testing machines, has also been adapted to SCC testing to provide a simple, compact, easily operated device for applying axial load (Fig. 14). The load is applied by tightening a nut on one of the bolts and is determined by carefully measuring the change in ring diameter.

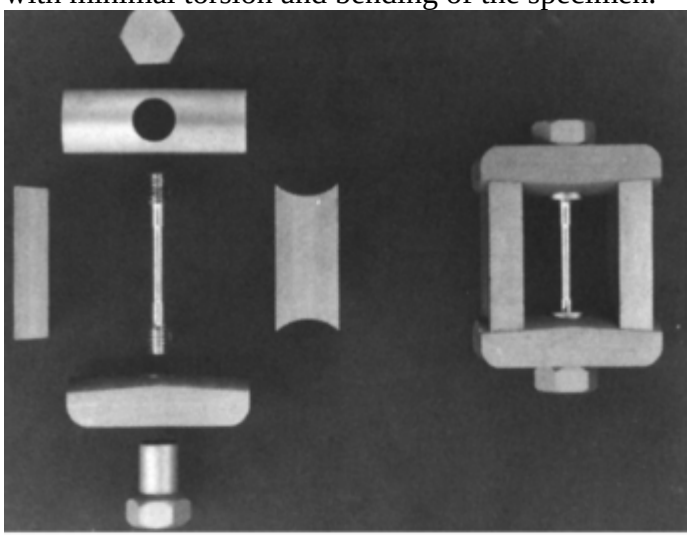
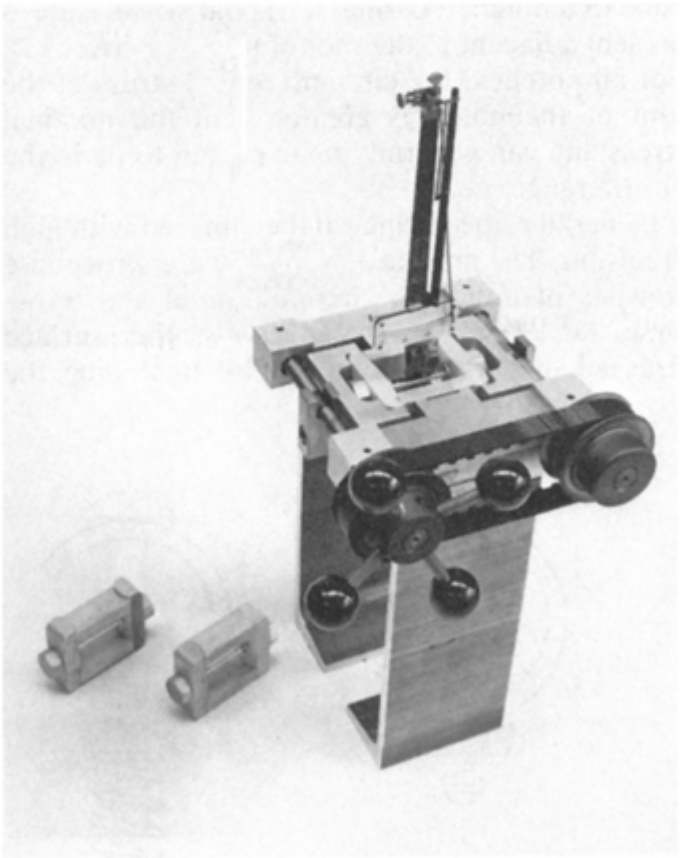
Constant-strain SCC tests are performed in low-compliance tension-testing machines. The specimen is loaded to the required stress level, and the moving beam is then locked in position. Other laboratory stressing frames have been used, generally for testing specimens of smaller cross section. Figure 15(a) shows an exploded view of such a stressing frame, and Fig. 15(b) illustrates a special loading device developed to ensure axial loading with minimal torsion and bending of the specimen.



(a)



(b)

(b) Synchronous loading device used to stress specimens. The specimen is loaded to a prescribed strain value determined from a clip-on gage. The applied stress is given by the product of the strain and the material elastic modulus. A stressed assembly and one assembled finger-tight ready for stressing are shown.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

For stressing frames that do not contain any mechanism for the measurement of load, the stress level can be determined from measurement of the strain. However, only when the intended stress is below the elastic limit of the test material is the average linear stress (σ) proportional to the average linear strain (ε), $\sigma/\varepsilon = E$, where E is the modulus of elasticity.

When tests are conducted at elevated temperatures with constant-strain loaded specimens, consideration should be given to the possibility of stress relaxation. When stress relaxation or creep occurs in the test specimen, some of the elastic strain is converted to plastic strain and the nominal applied test stress is reduced. This effect is particularly important when the coefficients of thermal expansion are different for the specimen and stressing frame. Frequently, nonmetallic (plastic) insulators are used between the specimen and stressing frame to avoid galvanic action. If such plastic insulators are part of the stress-bearing system, creep (even at room temperature) can significantly alter the applied load on the specimen.

Even though eccentricity in loading can be minimized to levels acceptable for tension-testing machines, tensile stress around the circumference of round specimens and at the corners of sheet-type specimens varies to some extent. Several factors may introduce bending moments on specimens, such as longitudinal curvature and misalignment of threads on threaded-end round specimens. These factors have a greater effect on specimens with smaller cross sections. Tests should be made on specimens with strain gages affixed to the specimen surface around the circumference of 90° or 120° intervals to verify strain and stress uniformity and to determine if machining practices and stressing jigs are of adequate tolerance and quality.

When SCC occurs, it generally results in complete fracture of the specimen, which is easy to detect. However, when testing relatively ductile materials at stress levels close to the threshold of susceptibility, fracture may not occur during the period of exposure. The presence of SCC in such cases must be determined by mechanical tests or by metallographic examination, as discussed previously.

To study trends in SCC susceptibility, such as in alloy development research, it is often necessary to detect small differences in susceptibility. For this purpose, it is advantageous to use replicate sets of specimens stressed at several levels, including zero applied stress. The sets are then removed for metallographic examination or tension tests after appropriate periods of exposure.

Figure 16 illustrates the use of this procedure with samples of 7075 aluminum alloy that have been given different thermal treatments to decrease susceptibility to SCC. Analysis of these breaking stress data by extreme value statistics enables calculation of survival probabilities and the estimation of a threshold stress, without depending on failures during exposure. By using an elastic-plastic fracture mechanics model, an effective flaw size is calculated from the mean breaking stress, the strength, and the fracture toughness of the test material. The effective flaw size corresponds to the weakest link in the specimen at the time of the tension test, and it therefore represents the maximum penetration of the SCC. An advantage to using flaw depth to examine SCC performance is that the effects of specimen size and alloy strength and toughness can be normalized. In contrast, the specimen lifetime and breaking strength are biased by those mechanical (non-SCC) factors.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Mean trends in the 207 MPa (30 ksi) exposure data for the three temper variants of aluminum alloy 7075 examined in Fig. 16 are shown in Fig. 17. These results clearly illustrate that the thermal treatments used to reduce the SCC susceptibility of the 7075-T651 decreased the SCC penetration (Ref 22). The equivalent performance of the 7075-T7X1 3.2 and 5.7 mm (0.125 and 0.225 in.) diam specimens is evident. In contrast, Fig. 18 shows the specimen biases in SCC ratings obtained by traditional pass-fail methods (Ref 23).

Tuning-fork specimens are special-purpose specimens with numerous modifications (Fig. 9). In Europe, the metal is strained into the plastic range, and stresses and strains are usually not measured (Ref 24, 26). In the United States, however, these specimens have been used with measured strains in the elastic and plastic ranges. Specimens of the type shown in Fig. 9(b) are convenient when a small self-contained specimen is required that will afford some insight into the applied stresses. Such a specimen is particularly well suited for testing thin plate material in the longitudinal or long-transverse direction while keeping the original mill-finished surface intact.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Tuning-fork specimens are stressed by closing the specimen tines and restraining them in the closed position with a bolt placed at the tine ends. The amount of closure is determined from Eq 3, which was derived from the data obtained with strain gages placed at the base of the tines on calibration specimens (Ref 1):

$$S = A\,\Delta x t \qquad \text{(Eq 3)}$$

where S is the maximum tension stress in the outer fiber of either tine, A is the calibration constant, Δx is the total amount of closure at the tine ends, and t is the thickness of the tines.

The stress on tuning forks with straight tines is greatest in a small area at the base of the tines. In tuning forks with tapered tines, the maximum stress extends uniformly along the tapered section. Tuning forks must be given the same consideration with regard to biaxial stresses as other flexurally loaded specimens.

The miniature tuning fork shown in Fig. 9(c) was devised to conduct short-transverse tests on sections that are too thin for tensile specimens or C-rings to be obtained (Ref 25). As with other tuning-fork specimens, the relationship between strain on the grooved surface and the deflection at the ends of the legs can be determined through the use of strain gages.

Plastic-Strain Specimens

Many accelerated SCC tests are performed with plastically deformed specimens, because these specimens are simple and economical to manufacture and use. These specimens are convenient for multiple replication tests of self- stressed (fixed-deflection) specimens in all environments. Because they usually contain large amounts of elastic and plastic strain, they provide one of the most severe tests available for smooth SCC test specimens.

Generally, the stress conditions are not known precisely. However, the anticipated high level of stress can be obtained consistently only if the precautions described for each type of specimen are observed. Another consideration is that the cold work required to form the test specimen can change the metallurgical condition and the SCC behavior of certain alloys.

Tests of this type are primarily used as screening tests to detect large differences between the SCC resistance of one alloy in several environments, one alloy in several metallurgical conditions in a given environment, and different alloys in the same environment. These tests are sometimes claimed to be too severe and therefore unsuitable for many applications, but the stress conditions are nevertheless representative of the high locked-in fabrication and assembly stresses frequently responsible for SCC in service.

U-bend specimens are rectangular strips bent approximately 180° around a predetermined radius and maintained in this plastically (and elastically) deformed condition during the test. Standardized test methods for this type of specimen are described in ASTM G 30 (Ref 27) and ISO 7539-3 (Ref 28). Bends slightly less than or greater than 180° are also used, but the term U- bend is generally applied to test specimens that are bent beyond their elastic limits. Figure 19 illustrates typical U-bend configurations showing several different methods of maintaining the applied stress.

Fig. 19 Typical U-bend SCC specimens. (a) Various methods of stressing U-bends. (b) Typical U-bend specimen dimensions. Source: Ref 27

U-bend specimens can be used for all materials sufficiently ductile to be formed into a U- configuration without cracking. A U-bend specimen is most easily made from strips of sheet, but specimens can be machined from plate, bar, wire, castings, and weldments. Of primary interest in U-bend specimens is circumferential stress, which is not uniform, as discussed previously in the section on “Bent-Beam Specimens” in this article. Stress distribution in the U- bend specimen is discussed in detail in Ref 29.

A good approximation of applied strain ε can be obtained by:

$$\varepsilon = \frac{t}{2R} \text{ when } t < R \qquad \text{(Eq 4)}$$

where t is the specimen thickness, and R is the radius of curvature at the point of interest. Knowledge of the stress-strain curve is necessary to determine the stress. When a U-bend specimen is formed, the material in the outer fibers of the bend is strained into the plastic portion of the true-stress/true-strain curve, such as in section AB in Fig. 20(a). Several other stress-strain relationships that can exist in the outer fibers of a stressed U-bend test specimen are shown in Fig. 20(b) through (e). The actual relationship obtained depends on the method of stressing used.

مرجع مهندسی مواد و متالورژی

Stressing is usually achieved by a one- or two- stage operation. Single-stage stressing is accomplished by bending the specimen into shape and maintaining it in that shape. The two types of stress conditions that can be obtained by single- stage stressing are defined by point X in Fig. 20(b) and (c). In Fig. 20(c), some elastic-strain relaxation has occurred by allowing the U-bend legs to spring back slightly at the end of the stressing sequence.
Two-stage stressing involves forming the approximate U-shape and then allowing the elastic strain to relax completely before the second stage of applying the test stress. The applied test strain can be a percentage (from 0 to 100%) of the tensile elastic strain that occurred during preforming (Fig. 20d) or can involve additional plastic strain (Fig. 20e). The convex specimen surface is stressed in tension in the region 0NM (Fig. 20d), and the concave surface is in compression. In the region MP, the situation is reversed; that is, compression is on the convex surface, and tension is on the concave surface.
The slope MN of the curve shown in Fig. 20(d) is steep. Therefore, it is often difficult to apply reproducibly a constant percentage of the total elastic prestrain, and the specimen surface may remain under compressive stress. Accordingly, the stress conditions in Fig. 20(b) and (e) are recommended because they result in a more severe test (that is, higher applied stress). Thus, the final applied strain prior to testing consists of plastic and elastic strain. To achieve the conditions illustrated in Fig. 20(b) and (e), springback of the U-bend legs after achieving the final plastic strain must be avoided. For materials with relatively low creep resistance, there will be some strain relaxation. It is important that the net residual stress be tensile. Compressively stressed surfaces are not normally prone to SCC. In fact, shot peening is a practical method for mitigating SCC by imparting a residual compressive stress on the metal surface before exposure to the service environment.

Residual-Stress Specimens

Most industrial SCC problems are associated with residual tensile stresses developed in the metal during such processes as heat treatment, fabrication, and welding. Therefore, residual- stress specimens simulating anticipated service conditions are useful for assessing the SCC performance of some materials in particular structures and in specific environments.
Plastic Deformation Specimens. Residual stresses resulting from such fabricating operations as forming, straightening, and swaging that involve localized plastic deformation at room temperature can exceed the elastic limit of the material. Examples of specimens of this type that have been used are shown in Fig. 21 and 22. Other specimen types used include panels with sheared edges, punched holes, or stamped identification numbers and specimens that show evidence of other practical fabricating operations.

(a) and (b) Annealed tubing that was cold formed before testing. (c) Cold-worked tubing tested in the as-received condition. Source: Ref 1

Weld Specimens. Residual stresses developed in and adjacent to welds are frequently a source of SCC in service. Longitudinal stresses in the vicinity of a single weld are unlikely to be as large as stresses developed in plastically deformed weldments, because stress in the weld metal is limited by the yield strength of the hot metal that shrinks as it cools. High stresses can be built up, however, when two or more weldments are joined into a more complex structure.

Test specimens containing residual welding stresses are shown in Fig. 23. In fillet welds, residual tensile stress transverse to the weld can be critical, as indicated in Fig. 23(a) for a situation in which the tension stress acts in the short-transverse direction in an Al-Zn-Mg alloy plate.

Evaluating Stress-Corrosion Cracking

Revised by Bopinder Phull, Consultant

Static Loading of Precracked (Fracture Mechanics) Specimens

The use of precracked (fracture mechanics) specimens is based on the concept that large structures with thick components are apt to contain cracklike defects. After a stress-corrosion crack begins to grow, or if the specimen is provided with a mechanical precrack, classical stress analysis is inadequate for determining the response of the material subjected to stress in the presence of a corrodent.

The mechanical driving force for cracks can be measured with linear elastic fracture mechanics theory in terms of the crack-tip stress-intensity factor, K, which is expressed in terms of the remotely applied loads, crack depth, and test specimen geometry. At or above a certain level of K, SCC in a susceptible material will initiate and grow in certain environments, but below that level no measurable propagation is observed (Ref 30).

The apparent threshold stress intensity for the propagation of SCC (assuming that crack nuclei form in a manner that cannot be described by fracture mechanics, such as localized corrosion) is designated K_{ISCC} (or

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

K_{th}). Therefore, in terms of linear elastic fracture mechanics theory, for a surface crack in a large plate remotely loaded in tension, the shallowest crack (of a shape that is long compared to its depth) that will propagate as a stress-corrosion crack is $a_{cr} = 0.2(K_{ISCC}/ TYS)^2$, where *TYS* is tensile yield strength. Thus, a crack that is shallower than this critical value will not propagate under the given environmental conditions.

The value of a_{cr} incorporates the SCC resistance, K_{ISCC}, and the contribution of stress levels (of the order of the yield strength) to SCC that are due to residual or assembly stresses in thick component sections (Ref 4). Therefore, the application of fracture mechanics does not provide independent information about SCC; it simply provides a usable method for treating the stress factor in the presence of a crack.

When the rate of SCC propagation is determined and plotted as a function of K_t (the crack- opening mode), the test results for a highly susceptible alloy will exhibit the general trend shown in Fig. 3. Actual curves vary depending on the SCC resistance and fracture toughness of the alloy.

Although precracking may shorten or modify the initiation period, it does not circumvent it. Therefore, this method of testing also requires arbitrary and sometimes long exposure periods.

Test Specimen Selection

Almost all standard plane-strain fracture toughness test specimens can be adapted to SCC testing. These standard configurations should be used to ensure valid fracture analyses. Comprehensive discussions on SCC testing with precracked specimens can be found in Ref 31, 32, 33. Precracked specimens are shown in Fig. 24 where they are classified with respect to loading methods and the relationship with the stress-intensity factor as SCC propagates. Preparation of fracture toughness test specimens and test procedures are detailed in ASTM E 399 (Ref 34), E 1820 (Ref 35), and G 168 (Ref 36). Some exemplar test specimen dimensions and tolerances are given in Fig. 25(a)(a) to (c). Minor modifications to accommodate different loading arrangements and to facilitate mechanical precracking can be made to these configurations without invalidating the plane-strain constraints on the specimens. Figure 26 illustrates alternative chevron-notch and face-groove designs.

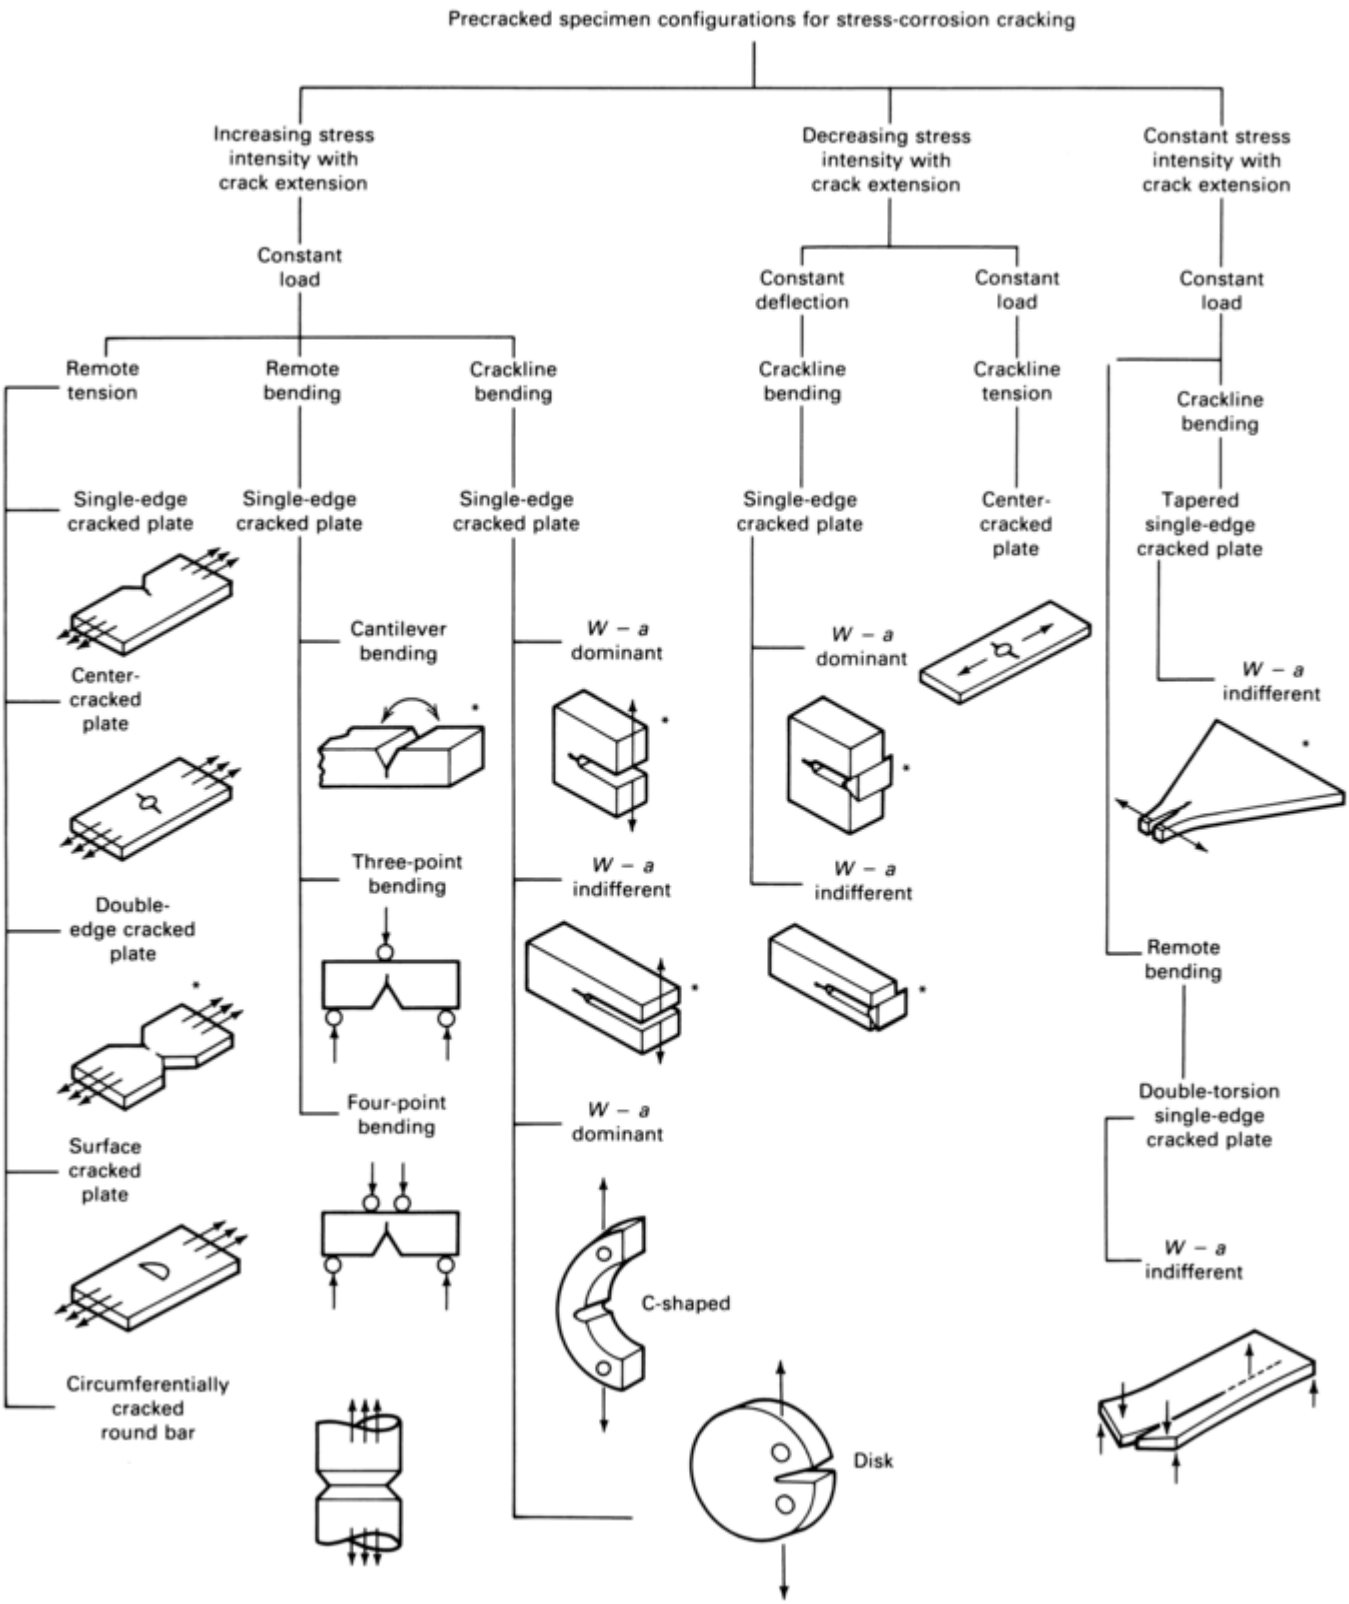

Fig. 24 Classification of precracked specimens for SCC testing. Asterisks denote commonly used configurations. Source: Ref 33

ASTM E 1681 (Ref 37) covers the determination of environment-assisted cracking threshold stress-intensity parameters, K_{IEAC} and K_{EAC} for metallic materials, using fatigue precracked beam or compact fracture specimens. Standard terminology relating to fracture testing is included in ASTM Standard E1823 (Ref 38).

Cantilever bend specimens (Fig. 25(a)a), sometimes referred to as single-edge-notched cantilever bend specimens, have been used in constant-load tests (*K*-increasing) for characterizing high-strength steels and titanium alloys (Ref 39). Equations 5, 6, 7 are recommended (Ref 40, 41):

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$K = \frac{6M}{BW^2}\left(\frac{2W}{\pi a}\tan\frac{\pi a}{2W}\right)^{1/2} \times \left[\frac{0.923 + 0.199\left(1 - \sin\frac{\pi a}{2W}\right)^4}{\cos\frac{\pi a}{2W}}\right] \quad \text{(Eq 5)}$$

$$\frac{EBW(2V_0)}{M} = e^x \quad \text{(Eq 6)}$$

$$\frac{EBWV_{LL}}{M} = e^y \quad \text{(Eq 7)}$$

where e is the base of natural logarithm (2.718), x = [0.1426 + 11.92(a/W) - 17.42(a/W)^2 + 15.84(a/W)^3 - 2.235(a/W)^4], y = [6.188 + 12.98(a/W) - 41.19(a/W)^2 + 54.98(a/W)^3 - 22.28(a/W)^4]. M is the applied bending moment, B is the specimen thickness (face grooves, when present, may be accounted for by replacing B with $\sqrt{BB_n}$, where B_n is the net thickness at the base of the face grooves; see Fig. 26b), W is the depth of the specimen, a is the depth of the notch plus crack, E is the modulus of elasticity, $2V_0$ is the total crack mouth opening displacement at the top face of the specimen, and V_{LL} is the total crack mouth opening displacement measured at the point of load application, which will vary depending on the load arm length.

Equation 5 is an expression for the stress intensity of a rectangular beam in pure bending and is valid over a wide range of a/W values. It applies to mode I loading only, however, and the usual tests include a mode II component from resulting shear stresses.

Equations 6 and 7 were determined by fitting experimental compliance data for cantilever bend specimens with a polynomial equation expressing the natural log of the normalized compliance as a function of a/W. These experimental values are in excellent agreement with those determined from Eq 5 for pure bending, even though the stress state at the crack tip will differ for cantilever bending. It has been suggested that analyses using pure bending expressions related to compliance measurement are suitable for testing with the cantilever bend configuration (Ref 40).

Crack growth measurements can be made with clip gage readings in conjunction with the crack- opening displacement calibrations given previously or by any other method that can be verified within ±0.127 mm (±0.005 in.). Examples of various methods are given in Ref 40 and 42.

Modified compact specimens (K-decreasing or K-increasing), as shown in Fig. 25(b)(b), are frequently referred to as 1T-WOL (wedge-opening loaded) or modified WOL specimens. Although most frequently used with constant-displacement (bolt) loading (Ref 39, 43), these specimens have also been used with constant load (Ref 3, 44, 45).

Equations 8, 9, 10, 11 can be used to calculate stress-intensity levels and normalized crack- opening displacements for fatigue precracking, for initiation of stress-corrosion testing, and for subsequent intervals during the test. These equations are based on boundary colocation values determined for this type of specimen configuration with face grooves and bolt loading (threaded bolt against a rigid loading tip) (Ref 40). The polynomial regression equation agrees with experimentally determined colocation values within 1% for 0.2 = a/W = 0.95:

مرجع مهندسی مواد و متالورژی

$$K_{Io} = \frac{P\left(2+\frac{a_0}{W}\right)}{B\sqrt{W}\left(1-\frac{a_0}{W}\right)^{3/2}}\left[1.308+5.278\left(\frac{a_0}{W}\right)\right.$$
$$\left.-19.67\left(\frac{a_0}{W}\right)^2+24.57\left(\frac{a_0}{W}\right)^3\right.$$
$$\left.-10.27\left(\frac{a_0}{W}\right)^4\right] \quad \text{(Eq 8)}$$

$$2V_0 = \frac{P}{EB}\times e^x \quad \text{(Eq 9)}$$

where $x = [1.830 + 4.307(a/W) + 5.871(a_0/W)^2 - 17.53(a_0/W)^3 + 14.57(a_0/W)^4]$.

$$2V_{LL} = 2V_0 \times \frac{e^y}{e^x} \quad \text{(Eq 10)}$$

where $y = [1.623 + 3.352(a_0/W) + 8.205(a_0/W)^2 - 19.59(a_0/W)^3 + 15.23(a_0/W)^4]$.

$$K_{Ii} = \frac{E(2V_{LL})\left(2+\frac{a_i}{W}\right)}{\sqrt{W}\left(1-\frac{a_i}{W}\right)^{3/2}}\left\{\left[1.308+5.278\left(\frac{a_i}{W}\right)\right.\right.$$
$$\left.-19.67\left(\frac{a_i}{W}\right)^2+24.57\left(\frac{a_i}{W}\right)^3\right.$$
$$\left.\left.-10.27\left(\frac{a_i}{W}\right)^4\right]\div e^z\right\} \quad \text{(Eq 11)}$$

where $z = [1.623 + 3.352(a_i/W) + 8.205(a_i/W)^2 - 19.59(a_i/W)^3 + 15.23(a_i/W)^4]$. In Eq 8, Eq 9, Eq 10, Eq 11, K_{Io} is the desired starting stress intensity, a_0 is the starting crack length, P is the load calculated to develop K_{Io} with measured a_0, W is the net width of the specimen measured from the load line, K_{Ii} is the stress-intensity after time interval i, a_i is the crack length after time interval i, and $2V_{LL}$ is the total crack mouth opening displacement at the load line. All other quantities are as defined previously.

Double-beam specimens (K-decreasing or K-increasing), which are also referred to as double-cantilever beam specimens, are similar to modified compact specimens, but because of their greater width or length, they are well suited for studying SCC growth rates over a greater range of K_I values. The smaller height of these specimens (Fig. 25(c)c) allows more versatility in performing short-transverse tests from moderate thicknesses of material. Like compact specimens, double-beam specimens are generally used with constant-displacement (bolt) loading for convenience, but they can also be used with constant load.

Bolt-loaded specimens used with a test procedure similar to that described in Ref 46 have been extensively employed for short-transverse tests of aluminum alloy products (Ref 45, 47, 48). Equation 12, Equation 13, Equation 14, Equation 15 are recommended for general use with double-beam specimens:

$$K_{Io} = \frac{P\sqrt{12}}{B\sqrt{H}}\left[\frac{a_0}{H}+0.6728+0.0377\left(\frac{H}{a_0}\right)^2\right] \quad \text{(Eq 12)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$2V_0 = \frac{4K_{I_0}\sqrt{H}}{\sqrt{3}E}\left(\frac{a_0}{H}+0.6728\right)^2 \times \left[1+1.5\left(\frac{C_0}{a_0}\right)-1.15\left(\frac{C_0}{a_0}\right)^2\right] \quad \text{(Eq 13)}$$

$$2V_{LL} = \frac{2V_0}{1+1.5\left(\frac{C_0}{a_0}\right)-1.15\left(\frac{C_0}{a_0}\right)^2} \quad \text{(Eq 14)}$$

$$K_i = \frac{\sqrt{3}E(2V_{LL})}{4\sqrt{H}\left(\frac{a_i}{H}+0.6728\right)^2} \quad \text{(Eq 15)}$$

Equation 12 is an expression reported in Ref 49. The simplified Eq 15 provides more versatility with high accuracy for a wider range of specimen configurations and K values (crack growth) than equations previously published (Ref 46).

Two early K_I calibrations based on stress analysis (Ref 50) and compliance (Ref 51) are shown in Fig. 27 and are in excellent agreement. The shape of these curves can also be used as a design guide for preparing specimens. If the test must be completed in the shortest possible time, a_0 should be short to capitalize on the fact that the rate of decrease of K_I with crack extension is maximum for shallow cracks. However, if maximum accuracy is desired, a deeper crack (effective notch length M, Fig. 25(c)(c) should be chosen so that errors in crack length measurement do not cause significant errors in K_I.

In early work with aluminum alloys (Ref 46, 47) a relatively short effective notch length was used ($a_0/H \approx 0.9$), followed later by deeper notches ($a_0/H \approx 1.2$ to 2.2), all with a $2H$ value of 25.4 mm (1.0 in.) (Ref 3, 45, 47, 48). The recommended starting a/H value shown in Fig. 25(c)(c) is about 2 to 2.2, depending on the length of the precrack. Limited tests of a smaller beam height of $2H$ = 12.7 mm (0.5 in.) have shown little effect on the amount and rate of crack growth in aluminum alloy 7075 plate (Ref 52).

An alternative double-cantilever beam specimen has been developed for testing relatively thin sections (typically 6.4 mm, or $\frac{1}{4}$ in., thick) of low-alloy steels (Ref 53). The specimen is stressed by forcing an appropriately dimensioned wedge into the slot. These specimens have been used to determine the effect of hardness of low-alloy steels on their resistance to SCC in environments containing hydrogen sulfide.

Constant K_I specimens are well suited for studying the mechanisms of SCC, because the stress intensity, K_I, is not dependent on crack depth and can be neglected in kinetic studies. Other attractive features are the relatively simple expressions for stress intensity and compliance and the apparent retention of plane-strain conditions in thin plate and sheet specimens. The cost of specimen preparation and instrumentation, however, prohibits its use for extensive SCC characterizations.

Reference 33 provides equations for the analysis of two types of constant K_I specimens: the tapered double-beam specimen and the double- torsion-loaded single-edge cracked specimen. A recent evaluation of the double-torsion method (Ref 54) used Al-Zn-Mg alloy sheet 3.2 mm (0.125 in.) thick. By using the double-torsion specimen, V-K curves were produced for aluminum alloy 7075-T651 sheet with conventional two-stage growth and plateau velocities that were only slightly higher than those for conventional double-cantilever beam tests of plate.

Other precracked specimen configurations, such as those shown in Fig. 24, can be used for special testing conditions. Information on the preparation and use of these specimens and the related fracture mechanics equations are given in Ref 33 and 55, 56, 57.

Preparation of Precracked Specimens

When using precracked SCC test specimens, the investigator must consider the dimensional (size) requirements of the specimen, its crack configuration and orientation, and machining and precracking of the specimen. These considerations are discussed in the sections that follow. Additional guidelines and recommendations on

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

specimen preparation in conjunction with fracture toughness testing are given in Ref 33, 34, 35, 36, 37 and 55, 56, 57.

Dimensional Requirements. A basic requirement of all precracked specimen configurations is that the dimensions be sufficient to maintain predominantly triaxial stress (plane- strain) conditions, in which plastic deformation is limited to a very small region in the vicinity of the crack tip. Experience with fracture toughness testing has shown that for a valid K_{Ic} measurement neither the crack depth a nor the thickness B should be less than $2.5(K_{Ic}/YS)^2$, where YS is the yield strength of the material (Ref 34, 39). Because of the uncertainty regarding a minimum thickness for which an invariant value of K_{ISCC} can be obtained, guidelines for designing fracture mechanics test specimens should be tentatively followed for SCC test specimens. The threshold stress-intensity value should be substituted for K_{Ic} in the aforementioned expression as a test of its validity.

If specimens are to be used for determination of K_{ISCC}, the initial specimen size should be based on an estimate of the K_{ISCC} of the material. Overestimation of the K_{ISCC} value is recommended; therefore, a larger specimen should be used than may eventually be necessary. When determining stress-corrosion crack growth behavior as a function of stress intensity, specimen size should be based on the highest stress intensity at which crack growth rates are to be measured (substitute K_{Io} in the $2.5(K_{Ic}/YS)^2$ expression).

Notch Configuration and Orientation. For SCC testing, the depth of the initial crack-starter notch—that is, the machined slot with a fatigue or mechanical pop-in crack at its apex—can be as short as $0.2W$. Guidelines for the depth of the notch depend on the limits of accurate K_I calibration with respect to the range of a/W or a/H and the considerations discussed previously for double-beam specimens.

Several designs of crack-starter notches are available for most plate specimens. The machined slot is used to simulate a crack, because it is impractical to produce plane cracks of sufficient size and accuracy in plate specimens. ASTM E 399 (Ref 34) recommends that the notch root radius should not be greater than 0.127 mm (0.005 in.), unless the chevron form is used, in which case it may be 0.25 mm (0.01 in.) or less (Fig. 26). This tolerance can be easily achieved with conventional milling and grinding equipment.

A significant factor in the SCC testing of thick sections of some metals, such as aluminum and titanium, is the direction of applied stress relative to the grain structure. A standardized plan for identifying the loading direction, the fracture plane, and the direction of crack propagation is shown in Fig. 28.

Machining. Specimens of the required orientation should be machined from products in the fully heat treated and stress-relieved condition to avoid complications due to residual stresses in the finished specimens. Safeguards against the presence of residual stresses are especially important for precracked specimens because these specimens are usually bulky and contain notches that are machined deep into the metal. For specimens of material that cannot easily be completely machined in the fully heat treated condition, the final thermal treatment can be given before the notching and finishing operations. However, fully machined specimens should be heat treated only when the heat treatment will not result in distortion, residual stress, quench cracking, or detrimental surface conditions.

Precracking. Fatigue precracking should be done in accordance with ASTM E 399, E 1820, G 168, and E 1681 (Ref 34, 35, 36, 37, respectively). The K level used for precracking each specimen should not exceed about two-thirds of the intended starting K-value for the environmental exposure. This prevents fatigue damage or residual compressive stress at the crack tip, which may alter the SCC behavior, particularly when testing at a K level near the threshold stress intensity for the specimen.

Aluminum alloy specimens can also be precracked by pop-in methods (wedge-opening loaded to the point of tensile overload), but steel and titanium alloys are usually too strong and tough to pop in without breaking off one of the specimen arms. Chevron notches are usually used to facilitate starting such mechanical precracks, and face grooves are sometimes necessary to produce straight precracks in tougher alloys (Fig. 26). These modifications may also be necessary to control fatigue precracking of some materials.

When a specimen is mechanically precracked by pop in, the load should be maintained and should not be reduced for testing at a lower initial K-value. Reducing the load (crack mouth opening displacement) required for pop in will result in residual compressive stress at the crack tip, which could interfere with SCC initiation. When testing specimens at a relatively low fraction of K_{Ic}, fatigue precracking is recommended.

Testing Procedure

For all methods using precracked specimens, the primary objective is usually to determine K_{ISCC} or K_{th}, threshold stress intensity for SCC for the alloy and environment combination. One procedure, similar to that

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

used with smooth specimens, depends on the initiation of SCC at various levels of applied K_{Io} values. Both constant- load (*K*-increasing) and constant-displacement (*K*-decreasing) tests can be used. The latter procedure, which is unique to precracked specimens, involves crack arrest. This technique requires a *K*-decreasing constant-displacement test. These methods are compared in Fig. 29, which illustrates the shift in the stress-intensity factor as SCC growth occurs.

K-Increasing versus *K*-Decreasing Tests. In constant-load specimens (*K*-increasing tests), stress parameters can be quantified with confidence. Because crack growth results in an increasing crack opening, there is less likelihood that corrosion products will block the crack or wedge it open. Crack-length measurements can be made readily with several continuous-monitoring methods.

A wide selection of constant-load specimen geometries are available to suit the test material, experimental facilities, and test objective. Therefore, crack growth can be studied under either bend or tension loading conditions. Specimens can be used to determine K_{ISCC} by the initiation of a stress-corrosion crack from a preexisting fatigue crack using a series of specimens or to measure crack growth rates.

The principal disadvantages of constant-load specimens are the expense and bulk associated with the need for an external loading system. Bend specimens can be tested in relatively simple cantilever beam equipment, but specimens subjected to tension loading require constant- load creep-rupture equipment or similar testing machines. In this case, expense can be minimized by testing chains of specimens connected by loading links that are designed to prevent unloading upon failure of individual specimens. Because of the size of these loading systems, it is difficult to test constant-load specimens under operating conditions, but they can be tested in environments obtained from operating systems.

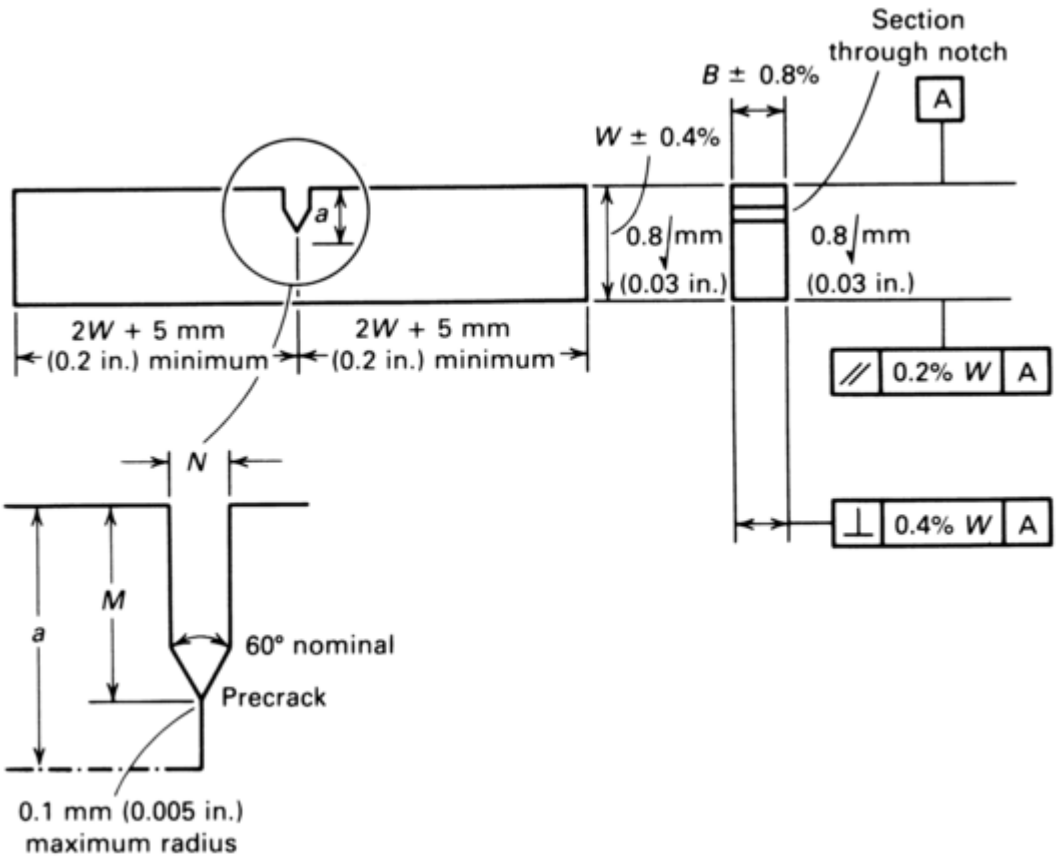

Fig. 25(a) Proportional dimensions and tolerances for cantilever bend test specimens. At each side, the point "B" should be equidistant from the top and bottom surfaces to within 0.001*H*. The bolt centerline (load line) should be perpendicular to the specimen centerline to within 1°. Bolt of material similar to specimen where practical; fine threaded, square or Allen head. Half height = *H*; thickness (*B*) = 2*H*; net width (*W*) = 10*H* minimum; total width (*C*) = *W* + *T*; thread diameter (*T*) = 0.75 *H* minimum; notch width (*N*) = 0.14*H* maximum; effective notch length (*M*) = 2*H*

Constant-displacement specimens (*K*-decreasing tests) are self-loaded; therefore, external stressing equipment is not required. Their compact dimensions also facilitate exposure to operating service environments. They can be used to determine K_{ISCC} by the initiation of stress-corrosion cracks from the fatigue precrack, in which case a series of specimens must be used to bracket the threshold value. This can also be achieved by the arrest of a propagating crack, because under constant-displacement testing conditions stress intensity decreases progressively as crack propagation occurs. In this case, a single specimen suffices in principle; in practice, the use of several replicate specimens is recommended to assess variability in test results.

Constant-displacement specimens are subject to several inherent disadvantages. Oxide formation or corrosion products can wedge the crack surfaces open, thus changing the applied displacement and load. Oxide formation or corrosion products can also block the crack mouth, thus preventing the entry of corrodent, and can impair the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

accuracy of crack length measurements by electrical resistance methods. Applied loads can be measured only indirectly by displacement changes or by other sophisticated instrumentation. Crack arrest must be defined by an arbitrary crack growth rate below which it is impractical to measure cracks accurately (commonly about 10^{-10} m/s, or 1.5×10^{-5} in./h).

Loading Arrangements and Crack Measurement. To monitor crack propagation rate as a function of decreasing stress intensity when testing constant-displacement loaded specimens, two of the three testing variables must be measured—crack depth (a_i) or load (P_i) and crack- opening displacement at the load line (V_{LL}). Although crack initiation and growth can be detected from change in either load or crack length, load change is usually more sensitive to these conditions. Therefore, crack advance is easier to detect in specimens loaded in a testing machine, an elastic loading ring, or an instrumented bolt than in specimens loaded with a bolt or wedge. Figures 30(a)(a) and (b) illustrate typical loading arrangements for which load changes can be automatically monitored (Ref 3, 44, 58).

than visual measurements made on the specimen surfaces. Various other techniques have been used, such as measurement of beam deflection for cantilever beam specimens (Ref 40) and changes in electrical resistance. Such arrangements, however, require calibration. It is feasible and desirable to obtain crack length measurements with a precision of at least ±0.127 mm (±0.005 in.).

Exposure to Environment. When practical for laboratory accelerated testing, the test environment should be brought into contact with the specimen before it is stressed or immediately afterward; this enhances access of the corrodent to the crack tip to promote earlier initiation of SCC and to decrease variability in test results. Similarly, in certain cases, it may also be beneficial to introduce the corrodent even earlier, that is, during precracking. However, unless facilities are available to begin environmental exposure immediately after precracking, corrodent remaining at the crack tip may promote blunting due to corrosive attack. In addition, corrosion of the specimen surfaces in the small volume of the precrack or the advancing stress-corrosion crack will change the composition of the environment that is in contact with the crack tip and can significantly affect the test results. For example, hydrolysis reactions can drastically reduce the pH of the aqueous test environment (Ref 59) and can induce embrittlement of some steels by corrosion-product hydrogen.

Selection of an appropriate test duration presents problems that vary with the testing system; this includes the alloy and metallurgical condition, the test environment, and the loading method. Errors in interpretation of the test results can be caused by test durations that are either too short or too long. The optimal length of exposure can be best approached through recognition of meaningful crack propagation rates. What is considered meaningful depends on the available precision of measurement of crack lengths and an acceptably low rate for the criterion of a stress-intensity threshold (Fig. 3). A problem also exists with the correlation of SCC crack growth rates in the laboratory test and in an anticipated service environment. The question leads ultimately to the intended application and a determination of what is a tolerable amount of SCC growth for a given length of time.

Calculation of Crack Growth Rates. There are several procedures for calculating crack growth rate, da/dt, as a function of stress intensity from crack growth curves. The simplest is a graphical $\Delta a/\Delta t$ technique that may incorporate smoothing of the a versus t curve (Ref 46, 47, 48). Another widely used approach is smoothing of the crack growth curve by computer techniques for curve fitting the entire a versus t curve by a multiple-term polynomial function (Ref 40). ASTM E 647 (Ref 60) is also a useful resource, although it is specifically for measuring fatigue crack growth rates.

Other techniques include a secant method and an incremental polynomial method, in which derivatives of the smoothed crack growth curve are calculated at various points to determine instantaneous crack growth rates. Instantaneous growth rates are then plotted against the instantaneous stress intensities, K_{Ii}, at corresponding time intervals to obtain graphs similar to that shown in Fig. 3.

A limited study of the aforementioned four methods of treating crack growth data is presented for a high-strength aluminum alloy in Ref 3. All of the methods used to calculate crack growth rates produced the same general results, which were difficult to interpret because of large amounts of scatter resulting from the use of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

small crack growth increments. Moreover, the significance of such graphs is dubious when the corrosivity of the environment and the length of exposure can invalidate the estimate of K by causing gross corrosion-product wedging effects and/or crack branching.

Reduction of crack length data becomes useless without prior subjective interpretation of crack length versus time curves. Allowances should be made for extraneous effects caused by erratic or apparent initiation of stress-corrosion crack growth, scatter in the measurement data due to excessive crack front curvature, multiple crack planes, crack-tip branching, and gross wedging caused by corrosion products.

A simple method of comparing materials by using crack growth curves is based on average growth rates taken from an exposure time of zero to an arbitrary time that is sufficient to achieve significant crack extension in the most SCC-susceptible materials being compared (Ref 52). This method not only rapidly identifies materials with relatively low resistance to SCC, but also provides numerical test results for highly resistant materials that may not develop a K_I versus da/dt curve with a definite plateau (see the section "Testing of Aluminum Alloys" in this article).

Evaluating Stress-Corrosion Cracking

Revised by Bopinder Phull, Consultant

Dynamic Loading: Slow-Strain-Rate Testing

An important method for accelerating the SCC process in laboratory testing involves relatively slow-strain-rate tension (SSRT) testing of a specimen during exposure to appropriate environmental conditions. In other words, the test specimen is stretched monotonically in axial tension at a slow rate until failure. This method is also known as constant extension-rate tensile (CERT) testing. The application of slow dynamic strain exceeding the elastic limit assists in the SCC initiation. This accelerated technique is consistent with the various proposed general mechanisms of SCC, most of which involve plastic microstrain and film rupture.

Slow-strain-rate tests can be used to test a wide variety of product forms, including parts joined by welding. Tests can be conducted in tension, in bending, or with plain, notched, or precracked specimens. The principal advantage of slow-strain-rate testing is the rapidity with which the SCC susceptibility of a particular alloy and environment can be assessed.

Slow-strain-rate testing is not terminated after an arbitrary period of time. Testing always ends in specimen fracture, and the mode of fracture is then compared with the criteria of SCC susceptibility for the test material. In addition to its timesaving benefits, generally less scatter occurs in the test results. Comprehensive discussions on the slow-strain-rate testing technique can be found in Ref 61, 62, 63, 64. Procedures for conducting SSRT tests are described in ASTM G 129 (Ref 65).

Critical Strain Rate. The most significant variable in slow-strain-rate testing is the magnitude of strain rate. If the strain rate is too high, ductile fracture will occur before the necessary corrosion reactions can take place. Therefore, relatively low strain rates must be used. However, at too low a strain rate, corrosion may be prevented because of repassivation or film repair so that the necessary reactions of bare metal cannot be sustained, and SCC may not occur. Although typical critical strain rates range from 10^{-5} to 10^{-7} s^{-1} depending on the alloy and environment system, the most severe strain rate must be determined in each case.

The repassivation reaction that is observed at very low strain rates and that prevents the formation of anodic SCC does not occur when cracking is the result of embrittlement by corrosion-product hydrogen. This mechanistic difference can be used to distinguish between anodic SCC (active path corrosion) and cathodic SCC (hydrogen embrittlement) as shown in Fig. 32.

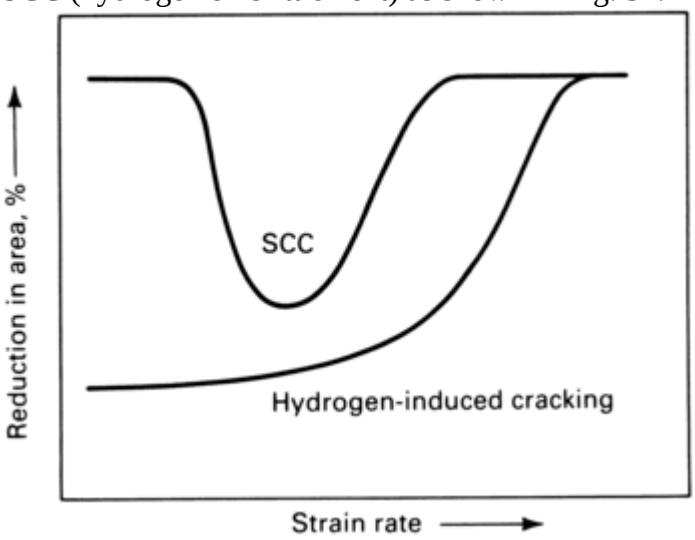

Fig. 32 Effect of strain rate on SCC and hydrogen-induced cracking. Source: Ref 66

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The fastest strain rate that will promote SCC in a given system depends on crack velocity. Generally, the lower the SCC velocity, the slower the strain rate required. Applied strain rates known to have promoted SCC in metal/ environment systems are listed in Table 2.

Table 2 Critical strain rate regimes promoting SCC in various metal/ environment systems

System	Applied strain rate, s^{-1}
Aluminum alloys in chloride solutions	10^{-4} and 10^{-7}
Copper alloys in ammoniacal and nitrite solutions	10^{-6}
Steels in carbonate, hydroxide, or nitrate solutions and liquefied ammonia	10^{-6}
Magnesium alloys in chromate/chloride solutions	10^{-5}
Stainless steels in chloride solutions	10^{-6}
Stainless steels in high-temperature solutions	10^{-7}
Titanium alloys in chloride solutions	10^{-5}

The most relevant strain rates for various aluminum alloys are shown in Fig. 33. These trends illustrate that slow-strain-rate tests should be performed in a strain-rate regime that is appropriate for the given alloy and environment system.

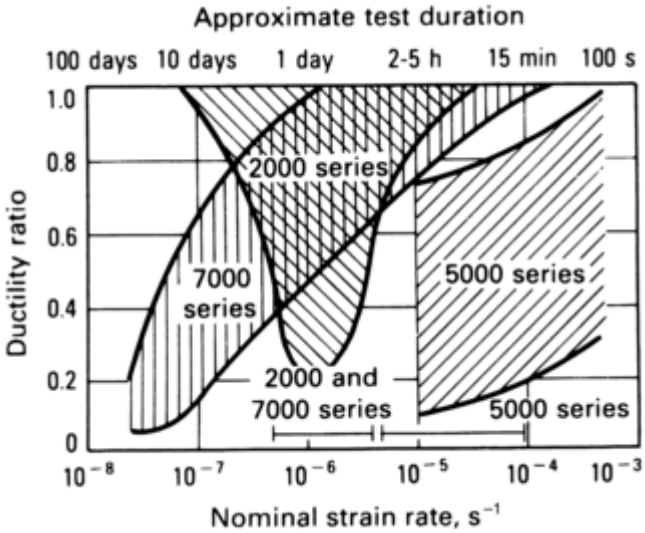

Fig. 33 Strain-rate regimes for studying SCC of various aluminum alloys. Corrodent: 3% sodium chloride plus 0.3% hydrogen peroxide. Source: Ref 64

Test Specimen Selection. Standard tension specimens (ASTM E 8) (Ref 67) are generally recommended for use with the specified conditions of gage lengths, radii, and so on, unless specialized studies are being conducted. For initially smooth specimens, the strain rate at the onset of the test is clearly defined: however, once cracks have initiated and grown, straining is likely to concentrate in the vicinity of the crack tip, and the effective strain rate is unknown. Rigorous solutions for determining the strain rate at crack tips or notches are not available, but effective strain rates are likely to be higher than for the same deflection rate applied to plain specimens.

Notched or precracked specimens can be used to restrict cracking to a given location—for example, when testing the heat-affected zone associated with a weld. Notched or precracked specimens can also be used to restrict load requirements where bending, as opposed to tensile loading, may offer an added benefit. The section thickness or diameter of such specimens is usually relatively small, so the testing duration is short.

Testing Equipment. Constant-strain-rate apparatus requirements include sufficient stiffness to resist significant deformation under the loads necessary to fracture the test specimens, a system to provide reproducible, constant strain rates over the range of 10^{-4} to 10^{-8} s^{-1}, and a cell to contain the test solution. Auxiliary equipment is used to control environmental conditions and to record test data. The testing equipment can also be instrumented to record load-elongation curves, which is convenient when testing at various strain rates. A typical constant-strain-rate unit is shown in Fig. 34. Various types of corrosion cells may be required to control the test conditions for specific studies.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

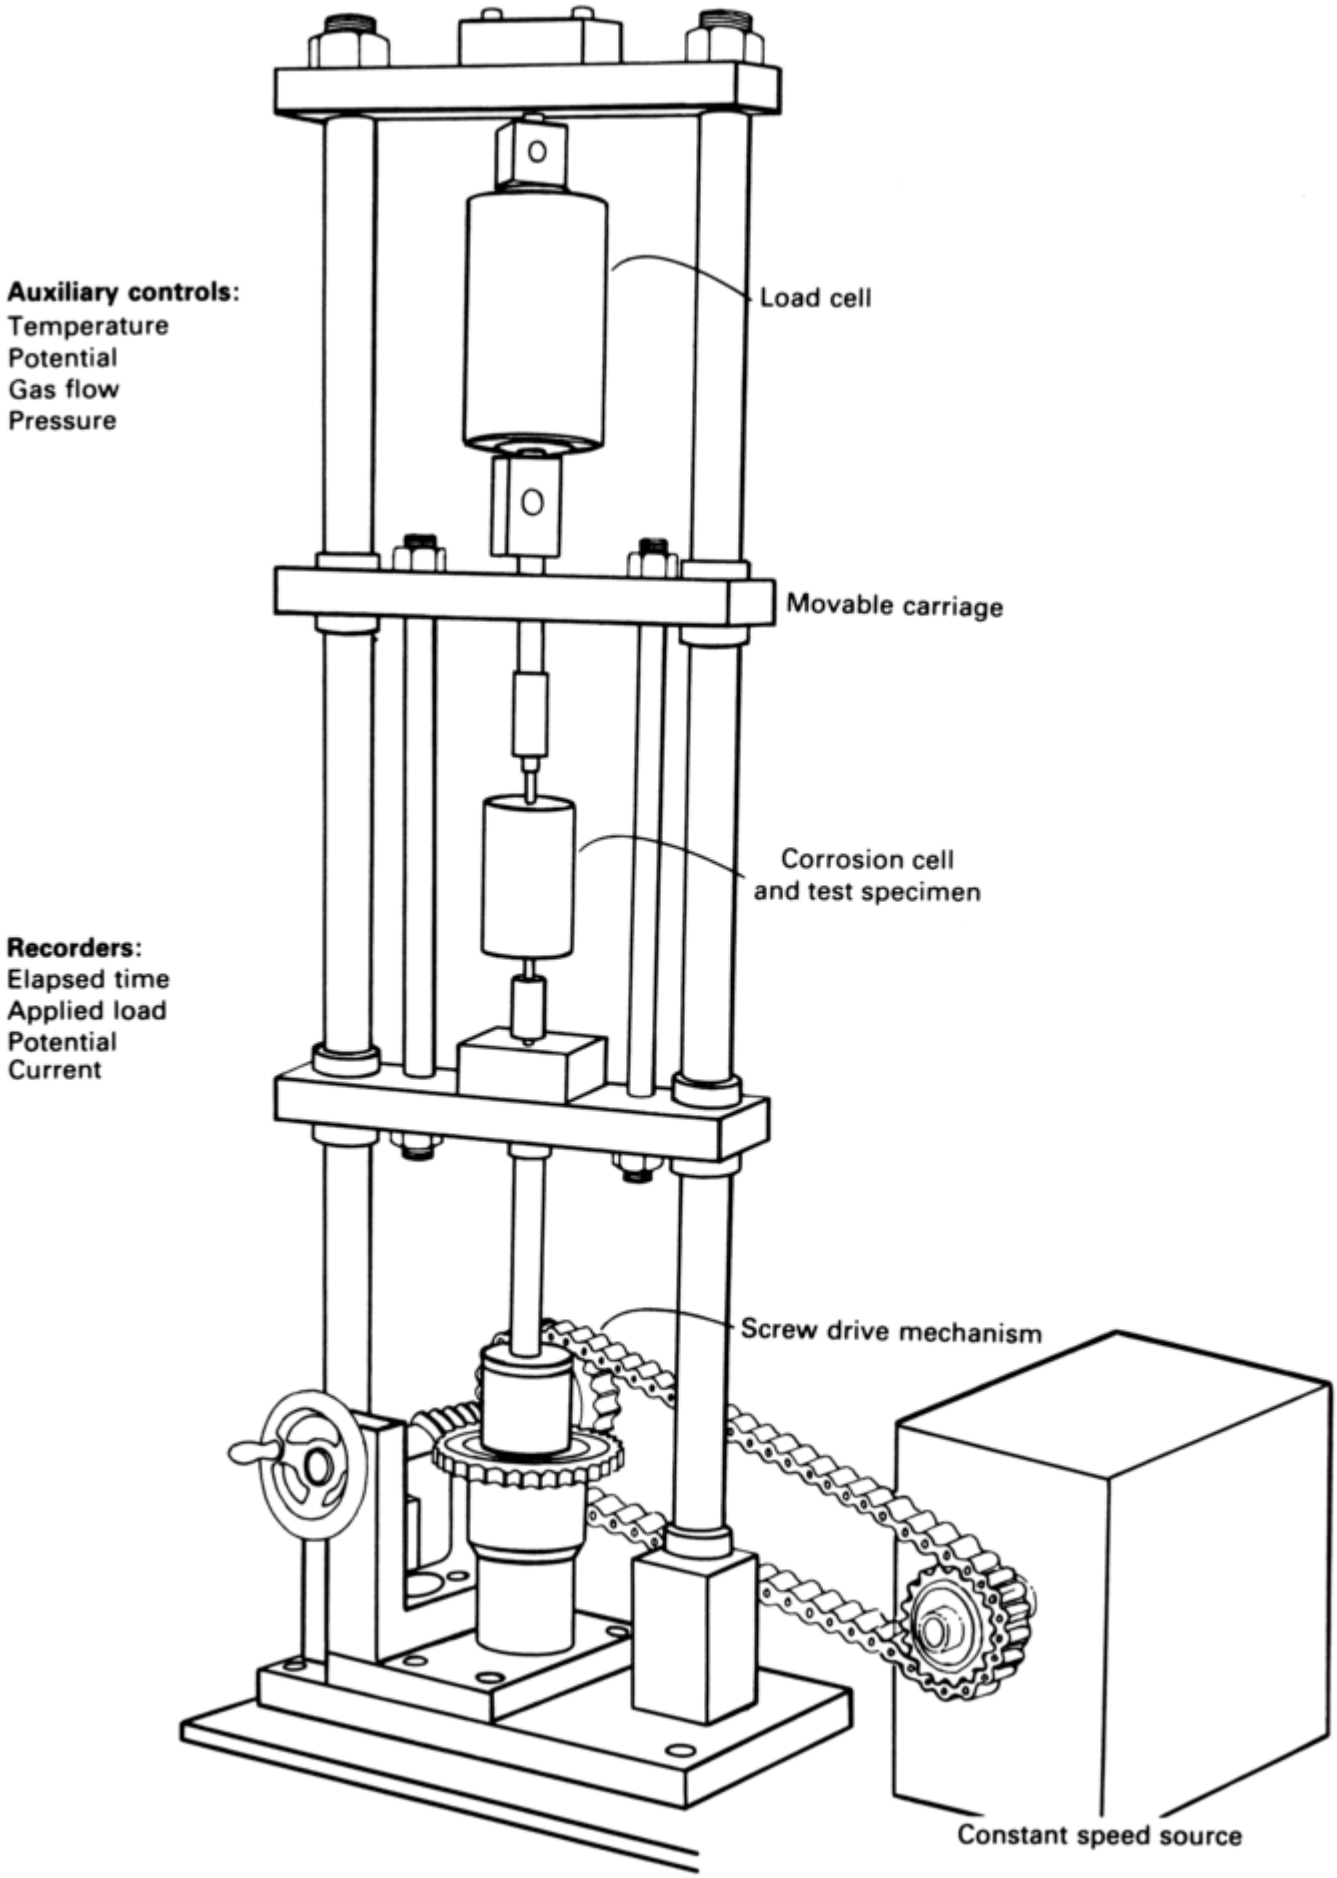

Fig. 34 Typical slow-strain-rate test apparatus. Source: Ref 63

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In addition to uniaxial tensile units, cantilever constant-strain-rate apparatus has also been used in which an extension arm attached to a cantilever beam specimen is lowered at a constant rate. This technique has been successfully used to study SCC of low-carbon steel in carbonate- bicarbonate environments to determine crack velocity, critical strain rates, and inhibitor effectiveness (Ref 68). Additional information on slow-strain-rate testing equipment and procedures is available in Ref 56 and 61.

Assessment of Results. Historically, the principal methods of SCC assessment derived from SSRT testing were based on time to failure, maximum gross section stress developed during the tension test, percent elongation, fracture energy (area bounded by the load-elongation curve), and reduction in area. Figure 35 depicts stress-elongation curves that illustrate how stress-corrosion cracks influence the elongation to fracture as well as the maximum load.

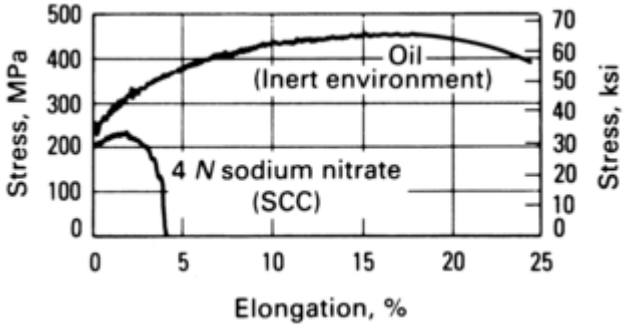

Fig. 35 Nominal stress versus elongation curves for carbon-manganese steel in slow-strain-rate test in boiling 4 *N* sodium nitrate and in oil at the same temperature. Source: Ref 62

To eliminate non-SCC effects, parallel tests are conducted in an inert environment, and a ratio of the result obtained in the corrodent divided by the result obtained in the inert environment is commonly used as an index of SCC susceptibility. For example, in Fig. 33, higher SCC resistance is denoted by higher ductility ratios.

Figure 36 shows a stress-corroded specimen containing many secondary stress-corrosion cracks and reduced ductility at fracture. Some alloys experience rapid deterioration of mechanical properties on contact with certain corrosive environments; any additional effect of applied straining can best be assessed by comparison with the behavior of unstrained specimens. Therefore, it is essential that the cause of environmental degradation be verified as SCC.

مرجع مهندسی مواد و متالورژی

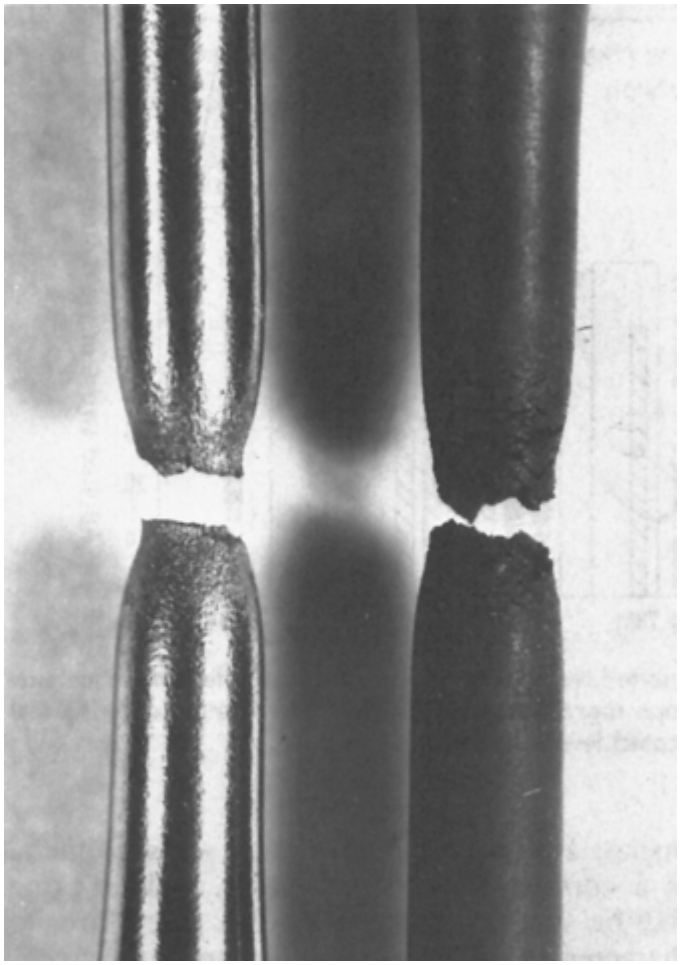

Fig. 36 Macrographs of two carbon steel specimens after slow-strain-rate tests conducted at a strain rate of 2.5×10^{-6} s^{-1} and 80 °C (180 °F). The ductility ratio in this example was 0.74 (original diameter: 2.54 mm, or 0.100 in.). Left: Ductile fracture in oil. Right: SCC in carbonate solution

Slow-strain-rate testing is very efficient in comparing environments in terms of their capability to produce SCC, for example, in steels having similar metallurgical characteristics. However, such comparisons are difficult and not very reliable when applied to groups of steels with different characteristics (Ref 66).

Slow-strain-rate testing as generally used does not provide data that can be used for design purposes. Recent work, however, has shown that average SCC velocities, threshold stresses, and threshold strain rates can be obtained with modified techniques combined with microscopy (Ref 62, 68, 69). For example, average SCC crack velocities can be determined from the depth of the largest crack measured on the fracture surfaces of specimens that have failed completely, or in longitudinal sections on the diameter of specimens that have not experienced total failure, divided by the time of testing. With this procedure, SCC is assumed to initiate at the start of the test, which is not always true.

With precracked specimens, other methods can be used to monitor crack growth and thus allow determination of crack velocities. The SCC behavior of a pipeline steel (Fig. 37) has been studied by using a precracked cantilever bend specimen in terms of threshold strain rate for crack growth and also in terms of crack growth rates analogous to the stage II plateau velocity shown in Fig. 3. Material properties, such as strength and toughness, that influence SCC performance when measured by tension testing are eliminated as factors; therefore, valid comparisons can be made of alloys with widely different structures and mechanical properties. Additional information on this method of assessment and the effects of strain rate can be found in Ref 70, 71, 72. Screening of alloys for sour oilfield service by the SSRT technique is covered by a NACE International test method (Ref 73). Reference 74 describes limitations of SSRT testing for evaluating SCC in the chemical-process industry.

Evaluating Stress-Corrosion Cracking

Revised by Bopinder Phull, Consultant

Selection of Test Environments

The primary environmental factors in SCC testing are the nature and concentration of anions and cations in aqueous solutions, electrochemical potential, solution pH, the partial pressure and nature of species in gaseous mixtures, and temperature. Separately or in combination, environmental variables can have a profound effect on the thermodynamics and kinetics of the electrochemical processes that control environmentally assisted fracture. Therefore, the choice of environmental conditions provides an important basis for developing accelerated SCC test methods.

The environmental requirements for SCC vary with different alloys. Although a mechanical precrack or a critical strain rate provides a worst case for SCC from a mechanical standpoint, there does not appear to be a generally applicable worst case from an environmental standpoint. However, because the presence of moisture and saltwater is universal, the SCC characteristics of alloys in these environments—as well as in any special environment a given engineering structure may experience—are always of interest.

Figure 38 illustrates that electrochemical factors can override mechanical factors in determining SCC initiation sites. Three cantilever beam specimens of PH13-8Mo stainless steel were tested in saltwater. Specimen A was tested at a high K level. With the participation of the chloride ions, the protective oxide film ruptured at the bottom of the precrack and initiated SCC, which was halted before the beam fractured completely. Specimen B was loaded at a lower K level. After 1300 h, a stress-corrosion crack initiated, but not in the precrack. Crack

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

initiation occurred under the wall of the cell that surrounded the central portion of the specimen and contained the saltwater.

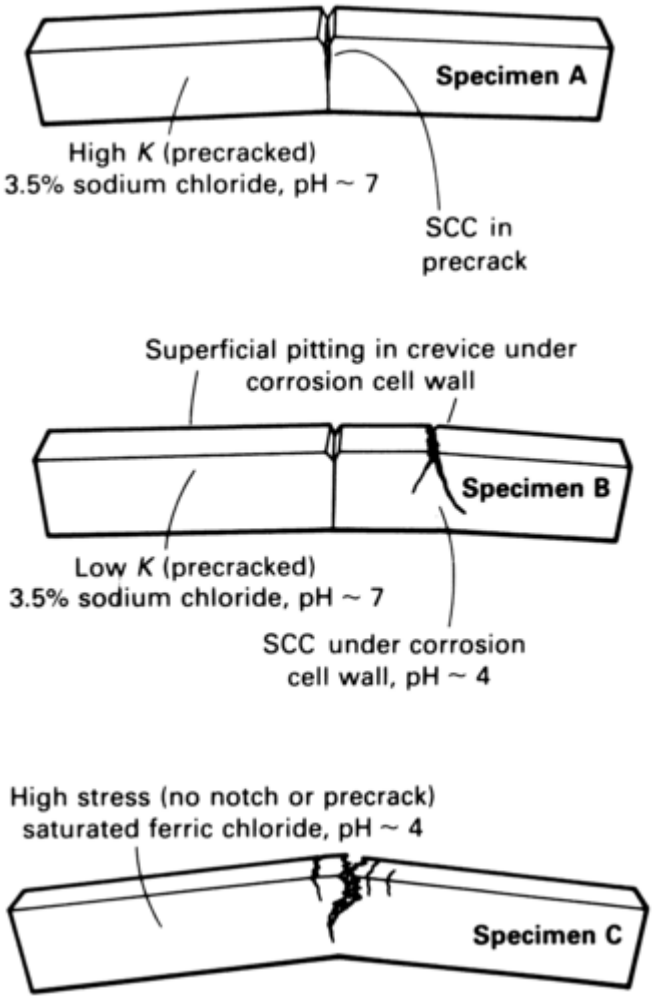

Fig. 38 Cantilever beam specimens of PH13-8Mo stainless steel after testing. Experiments demonstrate that electrochemical factors can override mechanical factors in determining initiation sites of SCC. See text for details. Source: Ref 75

Careful examination of this specimen and replicate specimens revealed small crevice-corrosion pits under the wall that initiated SCC in an almost smooth surface. Even if these small pits had been as sharp as a fatigue crack, the *K* level would have been much lower than at the machined and fatigued notch. In the stagnant situation under the cell wall, the stainless steel reacted with the saltwater to form hydrochloric acid and other corrosion products from the metal. Therefore, the low pH in a crevice, due to the hydrolysis of chromium corrosion product, overcame the mechanical disadvantage of the lack of a precrack. Specimen C was then tested to verify the effectiveness of electrochemical conditions in crack initiation. Saturated ferric chloride was selected to lower the pH to the range inside an active corrosion pit in the stainless steel; application of the solution to the unnotched beam resulted in the immediate initiation of many cracks in the smooth surface. Hydrochloric acid was found to be equally effective.

Stress-corrosion tests can be divided into two broad environmental classes: those conducted in actual service environments and those conducted under laboratory conditions.

Service Environments and Field Testing. The following examples illustrate the value, and in some cases the necessity, of exposure tests performed in actual service environments as an adjunct to laboratory evaluation. The standard 3.5% sodium chloride alternate immersion test data for aluminum alloys 2024 and 7075 proved useless in predicting the serviceability of these aluminum alloys for handling rocket propellant oxidizers such as nitrogen tetroxide and inhibited red fuming nitric acid (Ref 76). The alternate immersion test showed 2024-T351 and 7075- T651 to be susceptible to SCC at low short-transverse stresses, but 2024-T851 and 7075-T7351 were quite resistant even at high stresses. These data were supported by outdoor field tests in seacoast and industrial atmospheres.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

However, in proof tests consisting of exposure to the actual service environment—inhibited red fuming nitric acid at 74 °C (165 °F)—SCC occurred in both tempers of 7075 alloy and did not occur in either temper of 2024 alloy (Fig. 39). There were no unexpected failures with the 2219-T87 and 6061-T651 materials, however.

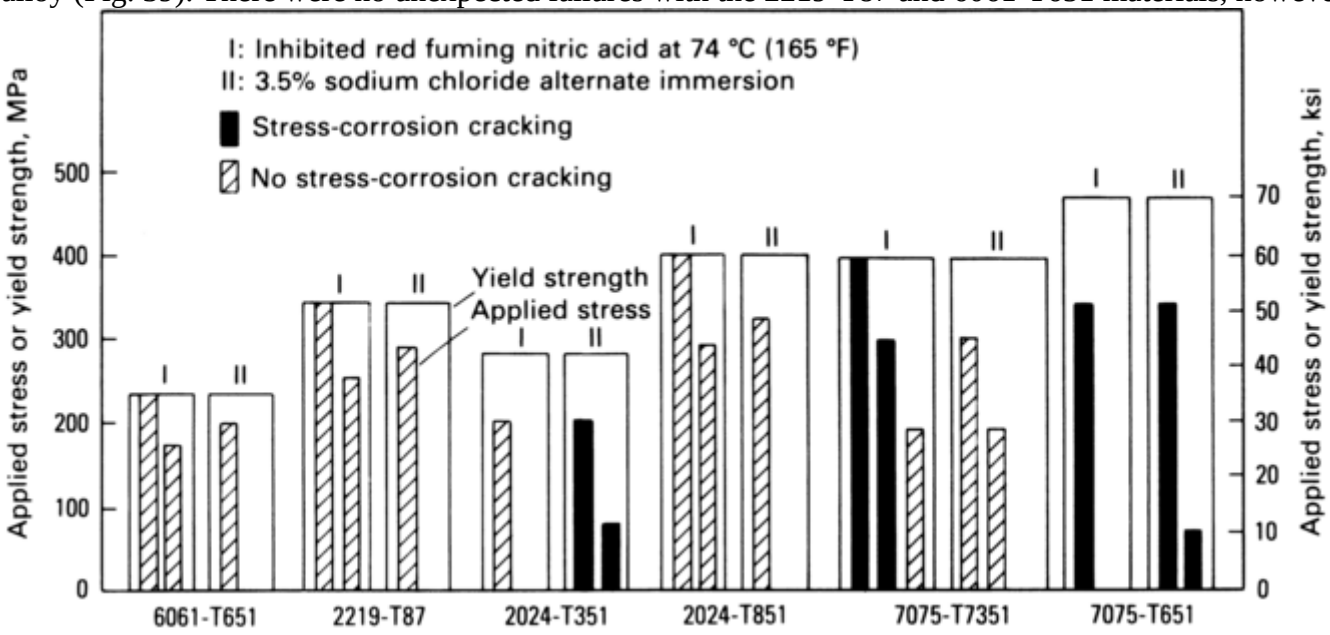

Fig. 39 SCC resistance of various aluminum alloys in inhibited red fuming nitric acid versus alternate immersion in 3.5% NaCl solution. Each bar graph represents an individual short-transverse C-ring test specimen machined from rolled plate and stressed at the indicated level. Source: Ref 76

Simulated-service tests should be conducted under conditions duplicating the service environment exactly, as illustrated by the following example with Ti-6Al-4V alloy pressure tanks for propellant-grade nitrogen tetroxide (<0.20 wt% moisture) (Ref 77). Preliminary laboratory SCC tests using specimens of Ti-6Al-4V demonstrated satisfactory compatibility with the nitrogen tetroxide and gave no indication of SCC.

In subsequent tests of actual pressurized tanks, however, SCC occurred rapidly, and the tanks failed. It was subsequently shown that the nitrogen tetroxide used in the tanks was of a higher- purity grade than that used in the laboratory tests. When test specimens were exposed to this grade of nitrogen tetroxide, they also failed. The small quantities of water and nitric oxide (impurities) present in the nitrogen tetroxide used in previous studies were sufficient to inhibit SCC of Ti-6Al- 4V in nitrogen tetroxide.

Field testing consists of placing a metal specimen in an environment in which conditions represent those anticipated in service. Typical examples include immersion in seawater, exposure to the atmosphere at marine or industrial sites, chemical plant streams, and so on. Field tests can be performed with test coupons or with actual or simulated structural components.

Laboratory Environments. Accelerated testing is conducted extensively in controlled laboratory environments for developmental studies in which it is not considered necessary that the test medium duplicate a particular service environment. Reliance should not be placed on such test results, however, unless they can be correlated with practical service experience or with the results of appropriate field tests.

Ideally, the results of a short exposure in a laboratory test will enable a reliable prediction of the SCC performance of an alloy over a long service period under particular environmental conditions. To fulfill this function, test conditions should be selected with regard to the anticipated service conditions. However, accelerated test media that yield reliable results for one alloy may not yield dependable results for another alloy, even though both alloys are of the same basic metal (Ref 9, 71). Therefore, caution must be exercised in the development and use of standardized test media. Recommended test media for various metals and alloys are discussed in later sections.

Mercury, other liquid-metal systems, and molten salts can also cause failure by cracking of metal under stress. In many cases of this type, oxidation-reduction reactions (corrosion) may not be involved; thus, the mechanisms of cracking under such conditions could be quite different from that of “classical” SCC.

Cracking caused by hydrogen embrittlement has been found to occur in titanium-base alloys and many high-strength ferrous alloys in various service environments. Hydrogen, under some conditions, enters the stressed

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

metal without the presence of a corrosion reaction, and cracking ensues. Hydrogen can also enter stressed metal as a corrosion reaction product, and cracking may be stimulated or may ensue. Therefore, to characterize adequately the environmental cracking of such alloys under sustained tensile stress, testing should be performed both with and without conditions that could involve hydrogen damage.

Length of Exposure. The question of appropriate test durations for the different material- environment combinations and the apparent need to establish them experimentally on a case- by-case basis has been a major stumbling block in the adoption of standard SCC test methods. The situation becomes acute when the results of an SCC test must be evaluated before all replicate specimens have cracked. In these cases, when a statistical probability evaluation must be performed, it should be recognized that time to failure is often normally distributed with respect to the logarithm of test time (see the section “Interpretation of Test Results” in this article). Exposure periods that are too short can result in a test that is trifling; when too long, they can introduce extraneous effects. An example is the excessive pitting of smooth test specimens that leads to failure by a different (and possibly unsuspected) mode of SCC, or by mechanical overload rather than by SCC (Ref 23). Problems in the case of precracked specimens can result from test periods being too short to develop a proper estimate of an apparent threshold stress intensity, especially in *K*-increasing tests; on the other hand, periods that are too long may result in corrosion-product wedging or crack tip blunting, both of which can invalidate calculations of the effective stress intensity and SCC growth rates in *K*-decreasing tests (Ref 32, Ref 47, Ref 48). Therefore, it is necessary to scrutinize test results carefully so that extraneous effects can be excluded from the analysis of the test results.

Electrochemical Tests. Recognition of the importance of electrical potential as one of the controlling parameters in SCC has resulted in increasing use of tests with potentiostatic control or impressed electrical current. No standards exist for such electrochemical tests, although several methods are routinely used. These tests involve specific conditions that are applicable only to given alloy and environment systems under consideration. These types of tests offer greater rapidity and precision than free corrosion tests.

Sophisticated approaches for studying systems involving active path corrosion use potentiodynamic methods. Anodic polarization curves can provide reasonably accurate predictions of the critical potential ranges and kinetic factors controlling SCC in a given system. One procedure (Ref 78) involves first scanning a range of potentials in the anodic direction at a relatively high scan rate (~1000 mV/min) to determine regions with high current density, in which intense anodic activity is likely. This is followed by a relatively low scan rate (~20 mV/min), which indicates regions where relative inactivity is likely.

Scans should be started at a potential at which the surface is film free. The rapid scan minimizes film formation so that the observed currents relate to relatively film-free conditions. The slow scan allows time for filming to occur. Comparison of the two curves reveals any ranges of potential within which high anodic activity in the film-free region reduces to insignificant activity when the time requirements for film formation are met, thus indicating the critical potential range in which SCC is likely.

Figure 40 illustrates this type of experiment for a low-carbon steel in a carbonate-bicarbonate solution with the predicted domains of behavior. Establishing a precise range of critical potentials for SCC requires subjective determination of boundary conditions relating to the current densities.

مرجع مهندسی مواد و متالورژی

Fig. 40 Potentiodynamic polarization curves for carbon-manganese steel in 1 *N* sodium carbonate plus 1 *N* sodium bicarbonate at 90 °C (195 °F) showing the domains of behavior predicted from the curves. Source: Ref 78

A different approach with the use of anodic polarization curves has been used to characterize the SCC behavior of aluminum alloys (Ref 79). Corrosion of a susceptible microstructure in aqueous chloride solutions was exclusively intergranular only for a limited range of potentials between the first and second breakdown potentials, E_{BR}, determined from the anodic polarization curve, where E_{BR1} approximates the critical pitting potential of the active corrosion path at the grain boundaries and E_{BR2} approximates the critical pitting potential of the grain bodies. Figure 41 depicts an anodic polarization curve for aluminum alloy 7075-T651, illustrating the predicted domains of behavior.

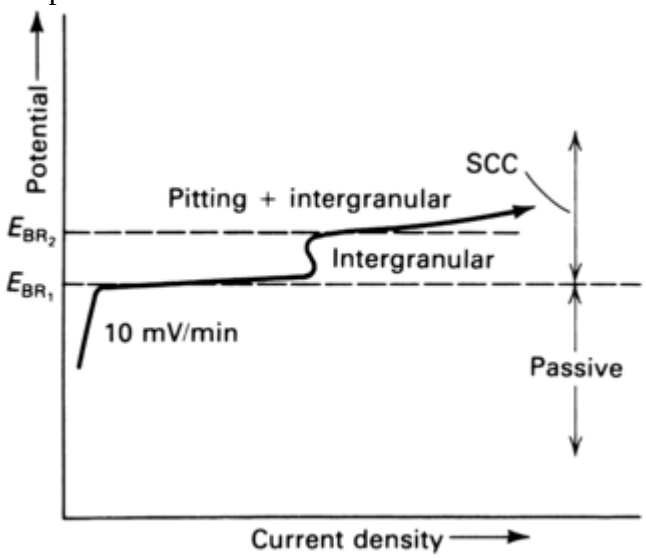

Fig. 41 Anodic polarization curves for aluminum alloy 7075-T651 in deaerated 3.5% sodium chloride solution showing the domains of behavior predicted from the curve. Source: Ref 80

The use of anodic polarization curves and related measurements is discussed in ASTM G 5 (Ref 81). Information obtained from the anodic polarization curve can be useful for screening environmental test media to reduce the number of actual SCC tests required. However, such electrochemical tests are concerned with testing a bulk environment in contact with an exposed surface, and it should not be assumed that such measurements represent the crack tip under conditions of crack growth. Therefore, even when an environment is identified as innocuous, a potent local environment may exist, such as in a pit when the pitting potential is exceeded or in a crevice or precrack.

Moreover, when laboratory SCC tests involve cracks or crevices, the potential at the crack tip may differ appreciably from that measured at the surface where the crack or crevice emerges. In laboratory tests, it must be considered whether or not environmental changes in composition or potential are involved and how they may relate to service conditions (Ref 71).

Evaluating Stress-Corrosion Cracking

Revised by Bopinder Phull, Consultant

Testing of Aluminum Alloys

Stress-corrosion cracking of susceptible high- strength aluminum alloys can occur in moist air, seawater, and potable waters, and it varies with the alloy and temper and the magnitude of sustained tensile stress. Chloride solutions are generally favored for laboratory tests because sodium chloride is widely distributed in nature, and the test results are potentially relatable to stress- corrosion behavior in natural environments.

Testing with Smooth Specimens

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Historically, stress-corrosion testing of aluminum alloys has been done with smooth (notch-free) specimens, and most published SCC ratings of aluminum alloys are based on such tests.

Alternate Immersion in 3.5% Sodium Chloride. Exposure to 3.5% sodium chloride or to substitute ocean water (ASTM D 1141) by alternate immersion (ASTM G 44) (Ref 82) is a widely used procedure for testing smooth specimens of aluminum alloys. Aeration of the specimens, achieved by the alternate immersion, enhances the corrosion potential (Ref 83) and produces more rapid SCC of most aluminum alloys than continuous immersion. The ASTM G 44 standard practice consists of a 1 h cycle that includes a 10 min soak in the aqueous solution followed by a 50 min period out of solution in air at 27 °C (80 °F) and 45% relatively humidity, during which time the specimens are air dried. This 1 h cycle is repeated continuously for the total number of days recommended for the particular alloy being tested. Typically, aluminum alloys are exposed from 20 to 90 days, depending on the resistance of the alloy to corrosion by saltwater. This test method is widely used for testing most types of aluminum alloys with all types of smooth specimens.

The alternate immersion test is primarily used for alloy development studies and for quality control of alloys with improved resistance to SCC (Ref 9, 84). This test method is specified in ASTM G 47 (Ref 85), which covers the method of sampling, type of specimen, specimen preparation, test environment, and method of exposure for determining the susceptibility to SCC of high-strength 2000-series alloys (1.8 to 7.0% Cu) and 7000-series alloys (0.4 to 2.8% Cu). Alternate immersion in 3.5% sodium chloride is also specified in ASTM G 64 for SCC testing of heat treatable aluminum alloys (Ref 86).

The parallel SCC behavior of a variety of aluminum alloys in the ASTM G 44 test and in a severe seacoast atmosphere is shown in Table 3. Additional comparisons may be found in Ref 23 and Ref 88. The relatively conservative estimate of the SCC behavior of an intermediate-resistance alloy in the ASTM G 44 test compared to that in various atmospheric environments is shown in Fig. 42, which also illustrates the wide range of behaviors in various atmospheric environments.

Tests were made on short-transverse 3.2 mm (0.125 in.) diam tension specimens from 7075-T7651 type plate stressed 310 MPa (45 ksi). Parenthetical values indicate replication of tests. Source: Ref 3

Although ASTM G 44 is a good general-purpose test for aluminum alloys, it is not equally discriminating of all alloys at near-threshold stress levels. This tendency has been reported for 7000-series (Al-Zn-Mg-Cu) alloys containing less than about 1% Cu (Ref 9, 21, 88). Also, the test is not representative of special chemical environments, such as inhibited red fuming nitric acid (Fig. 39).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Continuous Immersion in Boiling 6% Sodium Chloride. A four-day exposure by continuous immersion in boiling 6% sodium chloride solution is widely used by U.S. aluminum producers for testing smooth specimens of 7000- series alloys containing no more than 0.26% Cu. Comparison of this test and a modified ASTM G 44 test to the industrial atmospheric exposure shown in Fig. 43 illustrates the advantage of the boiling salt test, ASTM G 103 (Ref 89).

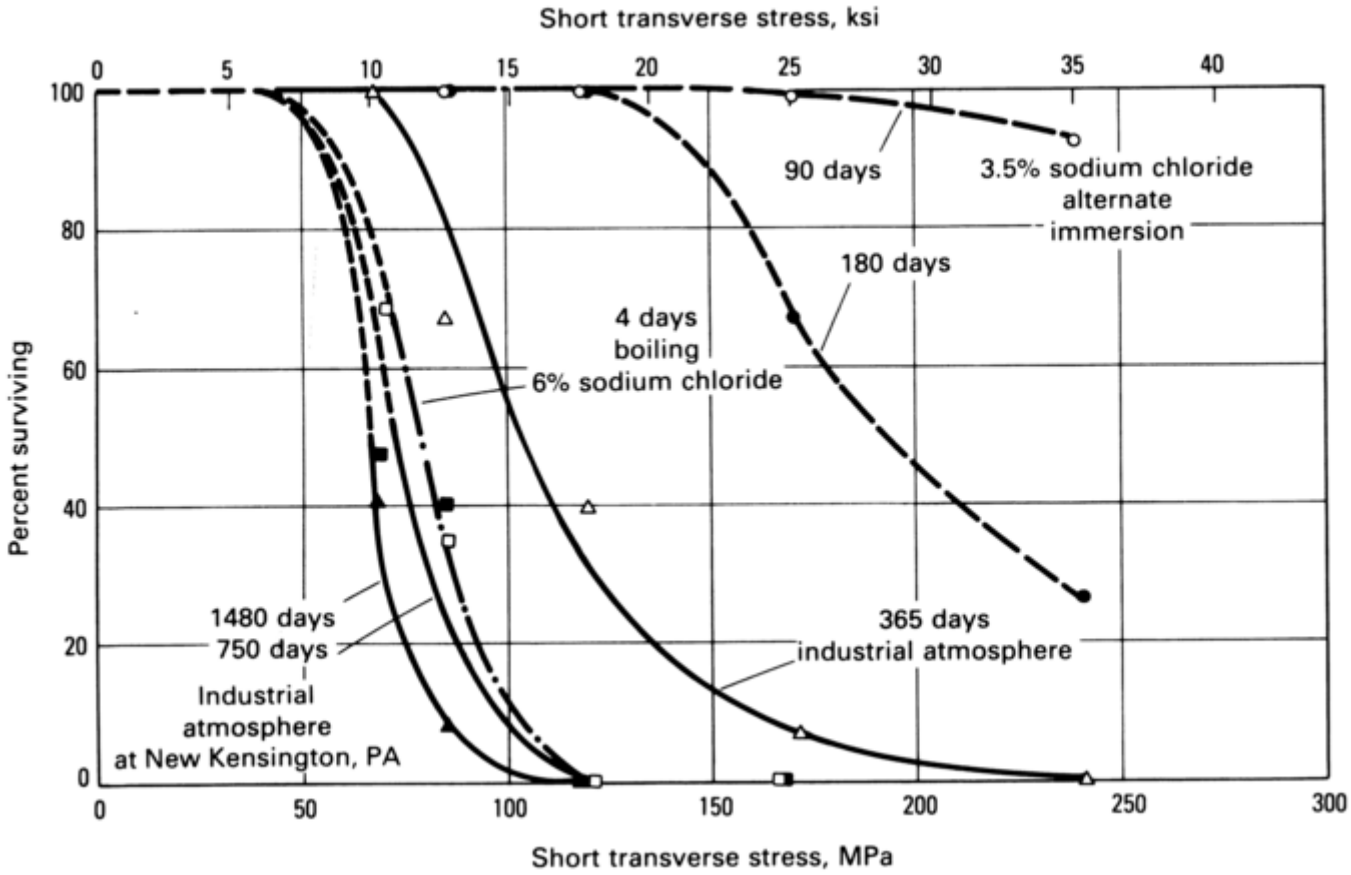

Fig. 43 Correlation of accelerated test media with service environment (industrial atmosphere). Combined data for five lots of rolled plate of aluminum alloy 7039-T64 (4.0Zn-2.8Mg-0.3Mn-0.2Cr). Tests in 3.5% sodium chloride were similar to ASTM G 44, except salt solution was made with commercial grade sodium chloride and New Kensington tap water. Source: Ref 9

This test is not effective for, and therefore not recommended for, the 2000-series (aluminum- copper) alloys, or the 5000-series (aluminum- magnesium) alloys. It is intended for statically loaded smooth nonwelded or welded specimens of 7000-series (Al-Zn-Mg-Cu) alloys containing <0.26% Cu. It appears to correlate better with outdoor atmospheric exposure than the ASTM G 44 procedure for the foregoing 7000-series aluminum alloys.

The impressed-current test for 5000-series alloys was developed for rapid evaluation of smooth coupon specimens of the 5000-series (aluminum-magnesium) alloys. The test solution is 3.5% sodium chloride, and the acceleration is provided by impressing on the test specimen a dc electrical current of 6.2×10^{-2} mA/mm^2 (40 mA/in.^{2}) of specimen surface. Good correlation with natural environment exposures is reported in Ref 90.

Other Testing Media. Although nitrates and sulfates, when dissolved in distilled water, tend to retard SCC, their presence in chloride environments can produce a synergistic stimulation of intergranular corrosion and SCC (Ref 80, 91, 92). Stress-corrosion cracking can also be accelerated for certain alloys by increasing acidity (lower pH), increasing temperature, adding oxidants, or electrochemically driving the SCC process by impressing an appropriate potential or electrical current density. These procedures, either singly or in combination, have been used to create various special-purpose tests:

- Continuous immersion test for 7000-series (Al-Zn-Mg) alloys (Ref 93): aqueous solution containing 3% sodium chloride, 0.5% hydrogen peroxide (30%), 100 mL/L 1 *N* sodium hydroxide, and 20 mL/L acetic acid (100%); pH 4.0

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

- Continuous immersion test for high-strength aircraft alloys (Ref 94): aqueous solution containing 2% sodium chloride plus 0.5% sodium chromate
- Impressed-current test for 7000-series (Al- Zn-Mg) alloys (Ref 95): aqueous solution containing 2% sodium chloride plus 0.5% sodium chromate; pH 8.1, current density 4.65×10^{-4} mA/mm^2 (0.3 mA/in.^{2}); 30 day maximum exposure time
- Alternate immersion test using an aqueous solution containing 2.86% sodium chloride plus 0.52% magnesium chloride (total chloride equal to that in ocean water): proposed in Ref 96 as a less corrosive substitute for 3.5% sodium chloride solution for ASTM G 44
- Continuous immersion test for 2000-series (aluminum-copper) and 7000 series (Al-Zn- Mg-Cu) alloys (Ref 97): aqueous 1% sodium chloride plus 2% potassium dichromate at 60 °C (140 °F); 168 h maximum exposure time
- Continuous immersion test for 2000-series (aluminum-copper) and 7000-series (Al-Zn- Mg-Cu) alloys (Ref 47, 48): aqueous solution containing 0.6 *M* sodium chloride, 0.02 *M* sodium dichromate, 0.07 *M* sodium acetate, plus acetic acid to pH 4; used principally for testing precracked specimens

Testing with Precracked Specimens

Testing aluminum alloys with precracked specimens, especially the bolt-loaded double- beam type, has been performed extensively, and the ranking of materials by this method is generally in good agreement with that established with smooth specimen tests. However, a number of problems in the interpretation of test results must be taken into account (Ref 45, 46, 47, 48, 98, 99, 100, 101).

The bolt-loaded *K*-decreasing type of test is attractive because no complicated apparatus is required to perform the tests, and the results appear to be relatable to the control of SCC problems in engineering structures. Distinction among test materials or test environments is based on the amount and the rate of penetration by SCC, with the results being expressed in terms of crack depth, a threshold stress-intensity factor (K_{ISCC} or K_{th}), or plateau velocity (V_{pl}) (Fig. 3).

For example, the relative susceptibilities of various alloys can be determined from crack depth versus time curves after testing for exposure periods as short as 150 to 200 h (Ref 46). This is shown for an extreme range of susceptibilities in Fig. 44. Plateau velocities in this example are indicated by graphical estimates of the average slopes of the initial portions of the crack growth curves, beginning at the time when growth started and extending until the curves definitely started to bend over toward an arrest. An arrest would indicate K_{th}, but real arrests (zero crack growth) may not occur; therefore, it is customary to define K_{th} as the crack tip stress intensity at which the crack growth rate has decreased to the limit of measuring capability. This is usually about 10^{-10} m/s (1 to 2×10^{-5} in./h), that is, where the growth is less than 0.2 mm (0.008 in.) within 30 days.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

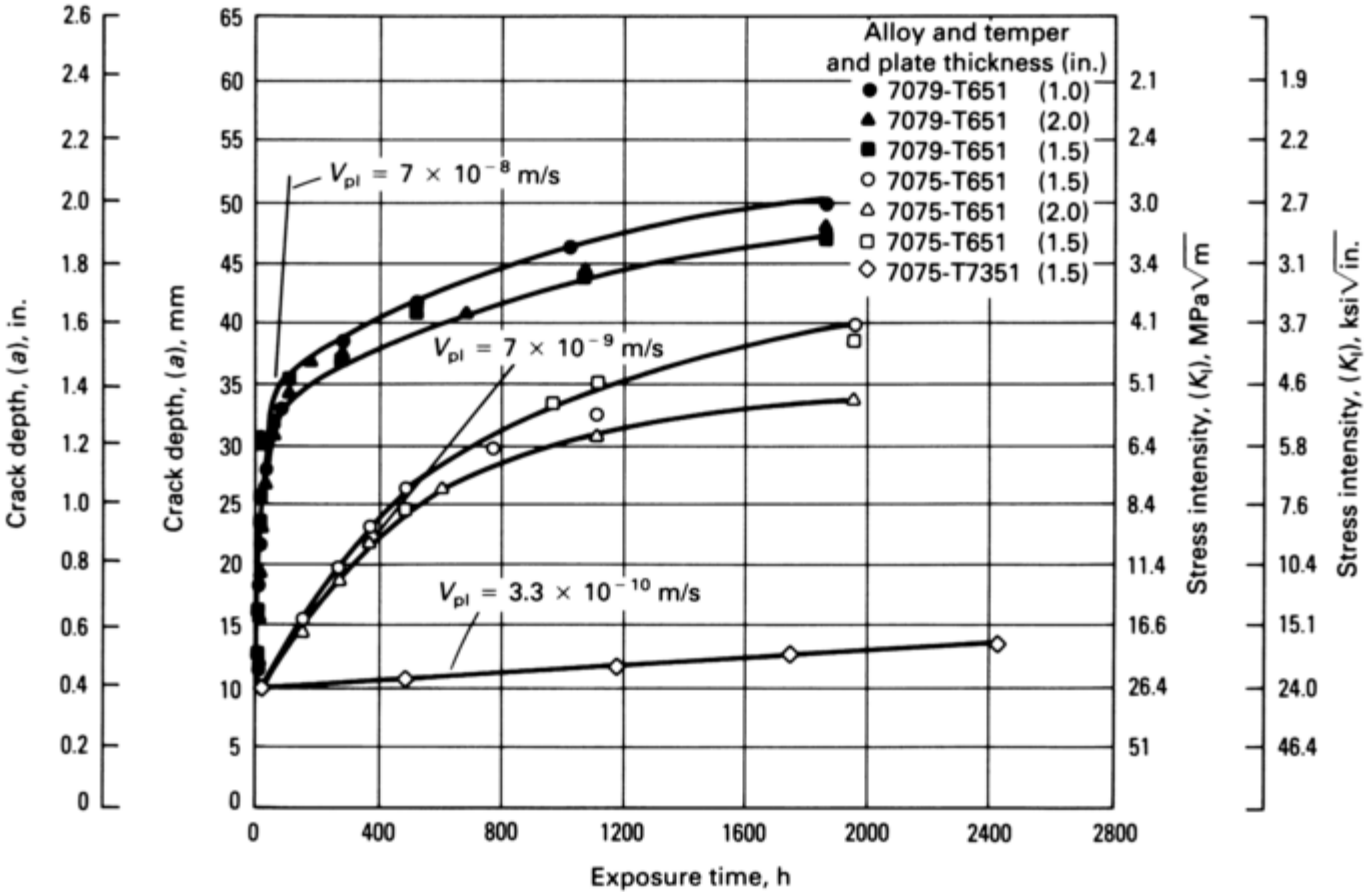

Fig. 44 Crack depth and stress intensity versus time curves for double-beam specimens of aluminum alloys 7075-T651, 7079-T651, and 7075-T7351 having nearly identical deflections and starting crack depths. Specimens with S-L orientation (see Fig. 28) measuring 25 × 25 × 127 mm (1 × 1 × 5 in.) bolt loaded to pop-in and wetted three times daily with 3.5% sodium chloride. Source: Ref 46

Plateau velocities can be readily determined for materials having a relatively low resistance to SCC, such as 7075-T651 and 7079-T651 alloy plates when stressed in the short-transverse direction. Such tests have been effectively used for the evaluation of corrosive environments and the study of SCC trends with the artificial aging of 7000-series (Al-Zn-Mg-Cu) alloys (Ref 98, 99). However, the use of plateau velocities for comparing materials with higher resistance to SCC becomes complicated when only small amounts of crack growth occur in normal exposure periods. In such cases, the initial penetration of SCC, even at near-critical stress intensities, may be delayed by an initiation (incubation) period and then may begin at small independent sites along an uneven mechanical crack front. The crack measurements are erratic, and the interpretation of the crack growth curves is subjective. Comparisons among relatively resistant materials are difficult.

Figure 45 shows a number of crack growth curves for several resistant materials. It is evident that the estimated plateau velocities are quite variable and do not correlate consistently with the total crack growth in a given exposure time. For these more SCC-resistant materials, average growth rates for the first 15 days of exposure appear to relate much better to the actual amount of crack growth and to smooth specimen ratings according to ASTM G 64 (Table 4).

مرجع مهندسی مواد و متالورژی

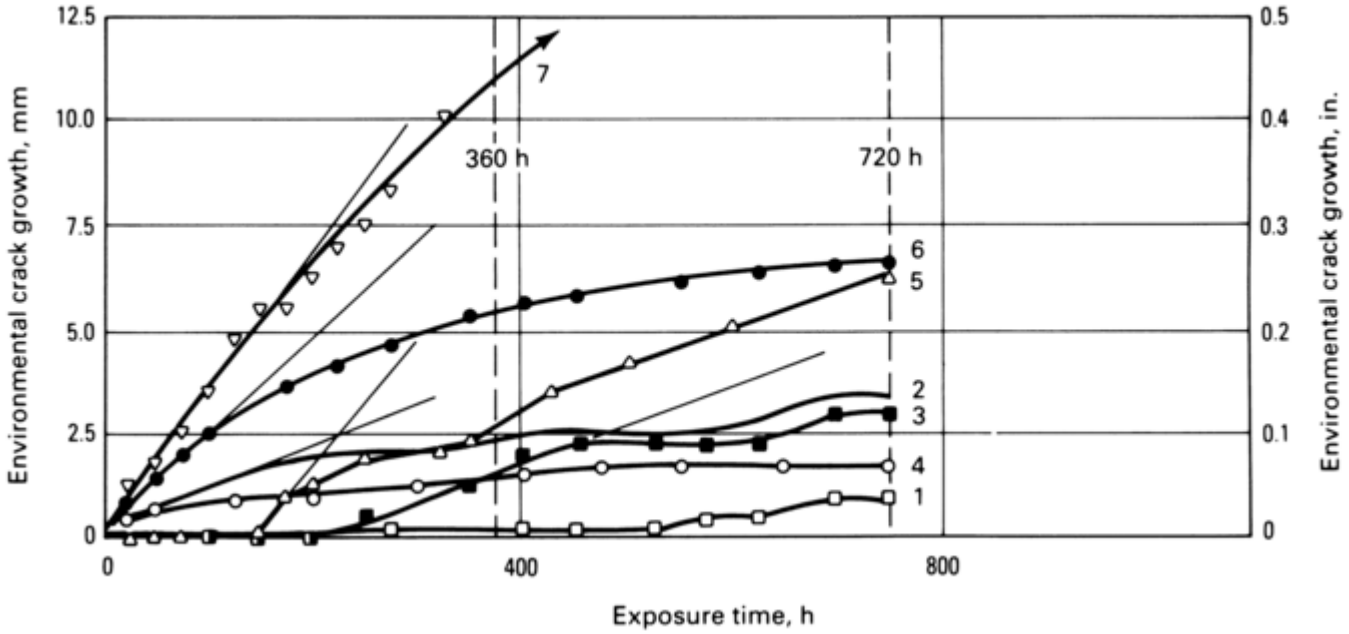

Fig. 45 Examples of SCC crack growth in various aluminum alloys with relatively high resistance to SCC. S-L (see Fig. 28) double-beam specimens bolt-loaded to pop-in and wetted with 3.5% sodium chloride three times daily; relative humidity 45%. The numbers 1 to 7 indicate different test materials listed in order of decreasing resistance to SCC (see Table 4); dashed lines indicate plateau velocities. The alloy 2 specimen failed by mechanical fracture rather than intergranular SCC. Source: Ref 47, 52

Table 4 Correlation of SCC plateau crack velocities with smooth specimen SCC ratings

Alloy	Smooth specimen rating[a]	Plateau crack velocity			
		First growth		**Average (0 to 15 days)**	
		m/s	**in. × 10^{-5}/h**	**m/s**	**in. × 10^{-5}/h**
1	A	6×10^{-10}	10	2×10^{-10}	3
2	A	7×10^{-9}	100[b]	1.8×10^{-9}	27[b]
3	B	2.1×10^{-9}	30	1.2×10^{-9}	19
4	B	4.2×10^{-9}	60	1.3×10^{-9}	20
5	B	7×10^{-9}	100	2.1×10^{-9}	30
6	C	6.3×10^{-9}	90	4.2×10^{-9}	60
7	D	1.1×10^{-8}	160	8.4×10^{-9}	120

Note: S-L (see Fig. 28) double-beam specimens bolt-loaded to pop-in and wetted three times daily with 3.5% sodium chloride.

(a) Short-transverse ratings per ASTM G 64 (Ref 86).

(b) Fractographic examination revealed mechanical fracture rather than the intergranular SCC verified in all other materials. Source: Ref 52

The performance of alloy 2 in Table 4 indicates another potential problem with tests performed at very high stress intensities; that is, with some very resistant materials, environmental crack growth will possibly be the result of mechanical fracture rather than of SCC. Therefore, it is necessary when testing SCC-resistant materials to verify that the crack growth is in fact SCC.

The determination of threshold stress intensities by the arrest method is frequently complicated by corrosion-product wedging, which changes the stress state at the tip of the crack and invalidates the calculation of effective stress intensities from the crack lengths. With low-resistance alloys, such as 7075-T651, an arrest may never occur, because the crack is continually driven ahead by the advancing wedge of insoluble corrosion products (Ref 47, 99). An indication of this was shown by the initiation of SCC in precracked specimens exposed with no applied load for just a few months in a seacoast atmosphere (Ref 47). Experimental evidence of a threshold stress intensity will depend on the amount of corrosion occurring in a given alloy/ environment system (Fig. 46).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

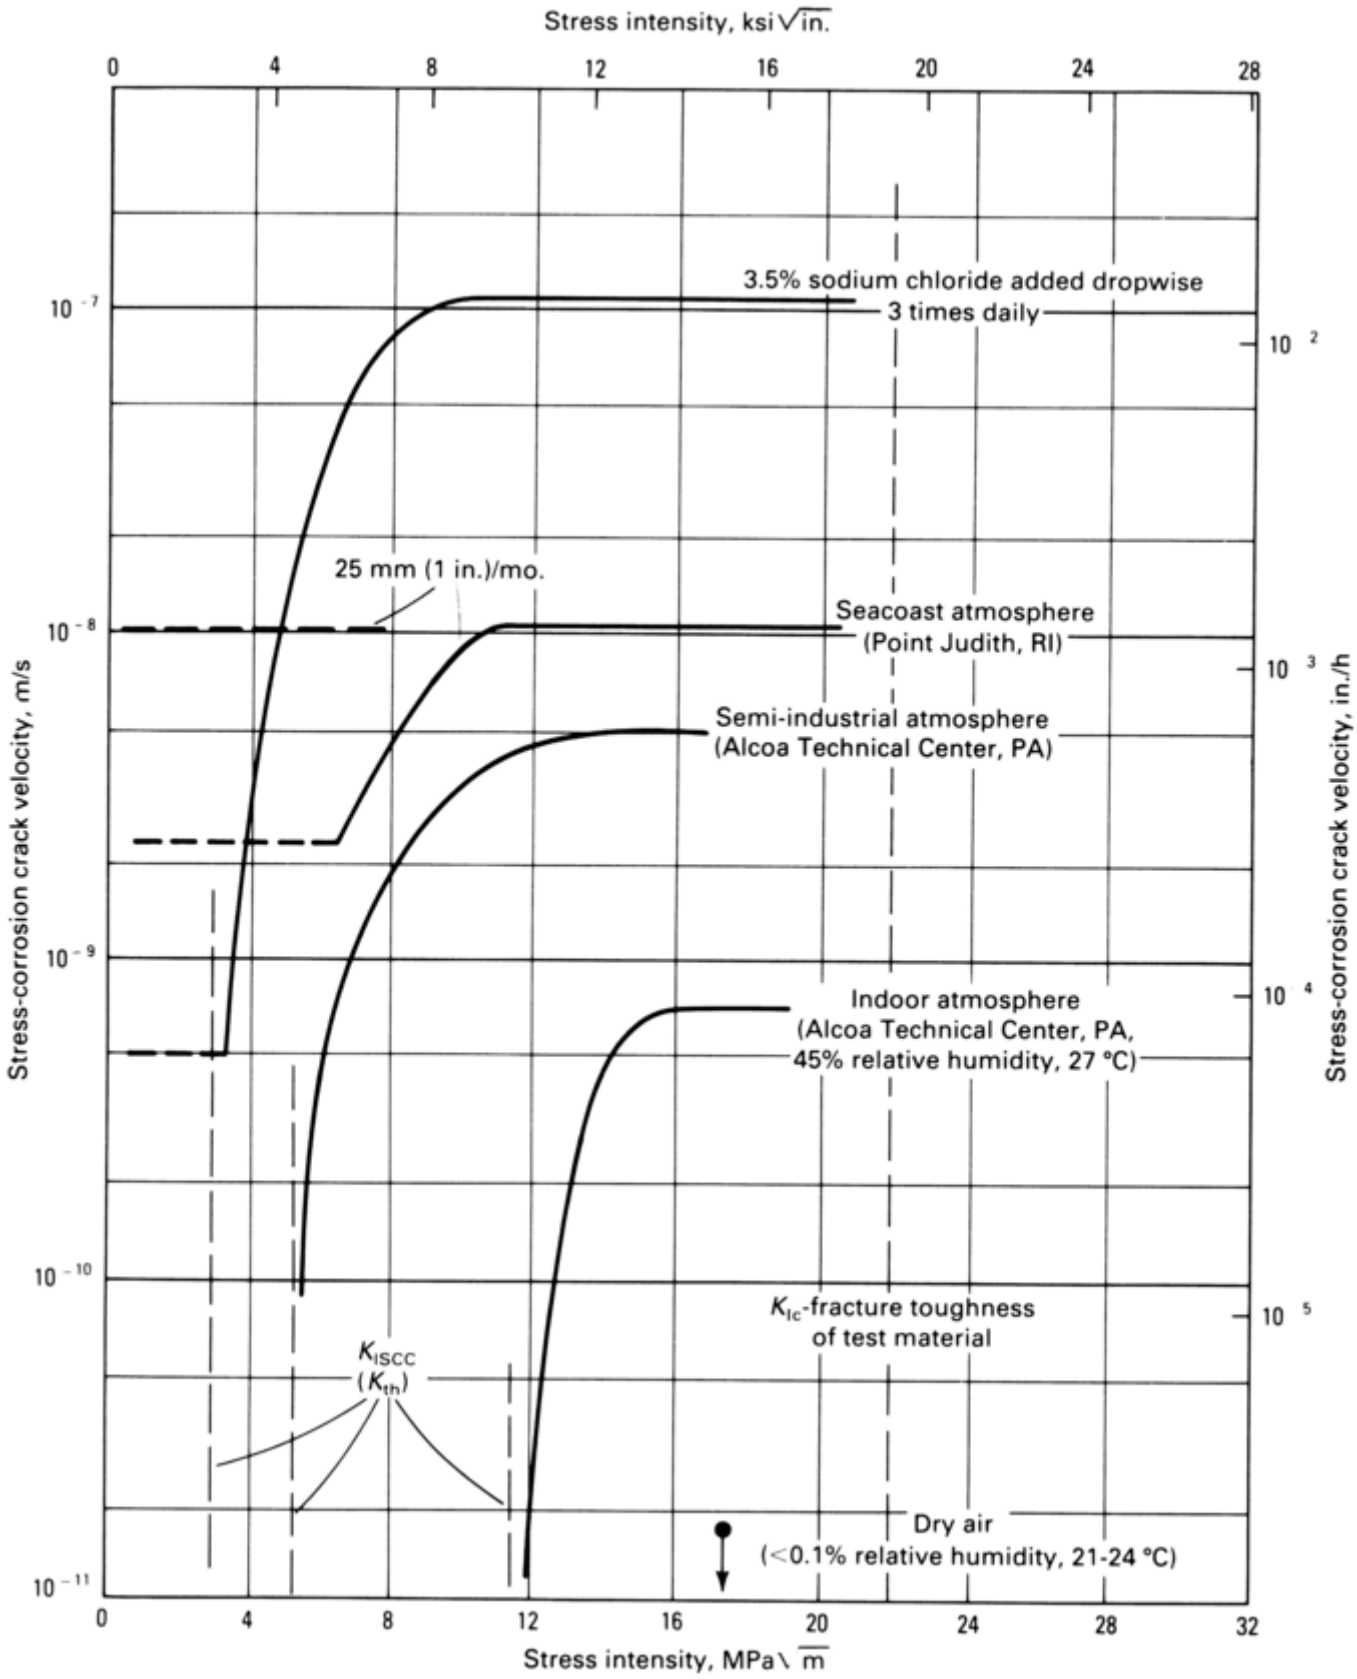

Fig. 46 Effect of corrosive environment on SCC velocity and threshold stress intensity for 7079-T651 plate (64 mm, or 2.5 in., thick) stressed in the short-transverse direction (S-L; see Fig. 28). Double-beam specimens bolt-loaded to pop-in. No SCC occurred during 3 years of exposure to dry air in a desiccator; however, the plateau velocity (horizontal part of each curve) and the apparent threshold stress intensity (K_{ISCC} or K_{th}) vary with the environment. Dashed portions of the curves represent the effect of corrosion-product wedging. Source: Ref 52

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

With intermediate-resistance materials, the growth curves may develop prominent steps indicative of temporary arrests. Figure 47 shows some of the various curves that may be obtained, depending on the resistance to corrosion and SCC of the test material, the corrosivity of the test medium, the magnitude of the applied stress intensity, and the length of exposure. The significant portion of the curve is that which goes from the beginning of the test to the first appreciable cessation of the crack growth. It is assumed that if it were not for the intervention of the corrosion-product wedging the curve would proceed to an arrest.

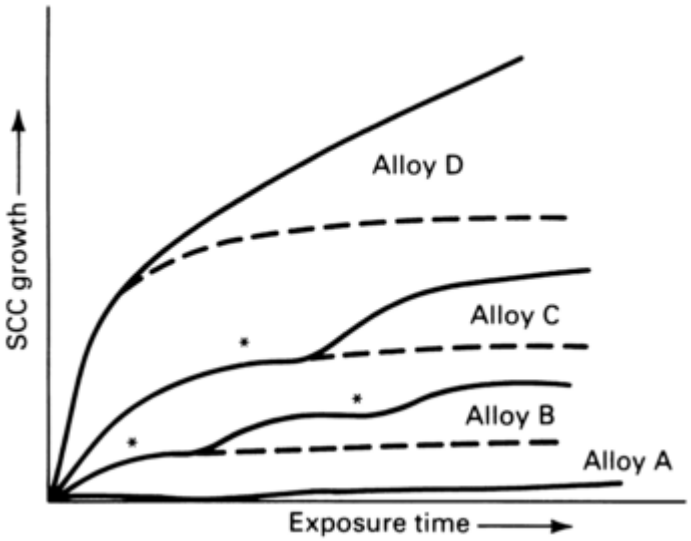

Fig. 47 The variable effects of corrosion-product wedging on SCC growth curves in a *K*-decreasing test. Solid lines: measured curve. Dashed lines: estimated true curve excluding the effect of corrosion-product wedging. Asterisks indicate temporary crack arrests.

The threshold stress intensities determined by this method can be useful for ranking materials, but usually cannot be considered valid. Therefore, they cannot be used in design calculations based on fracture mechanics. Displays of complete *V–K* curves provide convenient comparisons of various materials, as shown in Fig. 48. Problems with the control of the testing procedure and of correlations with service conditions have impeded the standardization of this test method (Ref 31, Ref 45).

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Deadweight loading, or a simulated deadweight loading system used in conjunction with automatic data logging equipment (Fig. 30(b)b), has proved to be a rigorous method for evaluating threshold stress intensities by SCC initiation (Ref 44, 45). Because crack growth results in increasing stress intensity and an increasing crack opening, corrosion-product wedging is minimal, and each test usually has a definite end point (fracture). In these tests, fatigue precracked compact or modified compact specimens (Fig. 25(c)b) are loaded to various initial stress intensities K_{Io} and exposed until fracture or until completion of a designated time period (Fig. 29). The designated cutoff period should be long enough for extended initiation times and yet not long enough to allow corrosion-product wedging to exert a dominant influence.

The test results shown in Fig. 49 indicate that near-threshold values were reached within 1200 h, as judged by the flattening tendency of the curves. The slight downward slope of some of the curves after 1200 h may be the result of wedging by corrosion products, but this was not determined. The effect of such wedging would be to give lower estimates of the threshold stress intensity.

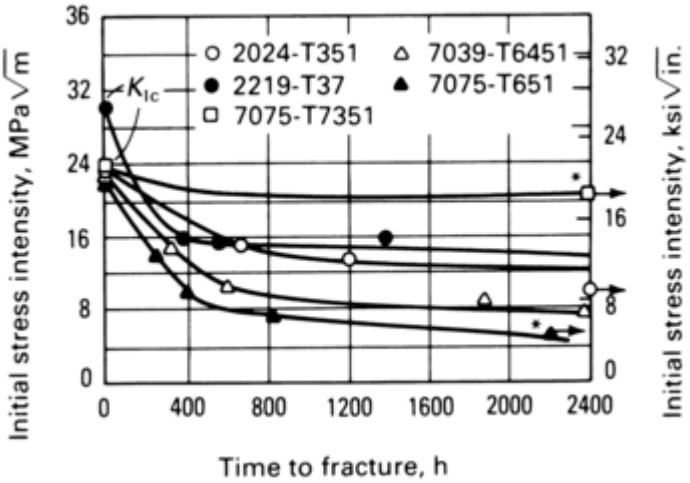

Fig. 49 Initial stress intensity versus time to fracture for S-L (see Fig. 28) compact specimens of various aluminum alloys exposed to an aqueous solution containing 0.06 *M* sodium chloride, 0.02 *M* sodium dichromate, 0.07 *M* sodium acetate, and acetic acid to pH 4. Asterisk indicates metallographic examination showed that SCC had started. Source: Ref 44

The testing of longitudinal (L-T, L-S in Fig. 28) and long-transverse (T-L, T-S in Fig. 28) specimens presents special problems with materials having typical directional grain structures. Stress-corrosion cracking growth is small and tends to be in the L-T plane, which is perpendicular to the plane of the precrack (Ref 103). Such out-of-plane crack growth invalidates calculations of the plane-strain threshold stress intensity K_{ISCC}. On the other hand, the testing of materials having an equiaxed grain structure also presents problems with stress-intensity calculations because of gross crack branching; this would be applicable to specimens of any orientation.

The most widely used corrodent for testing precracked specimens is 3.5% sodium chloride solution applied dropwise to the precrack two or (usually) three times daily (Ref 45, 46, 47, 48). This intermittent wetting technique accelerates SCC growth, but it also causes troublesome corrosion of the mechanical precrack. Less *aggressive* corrodents that have been used include substitute ocean water (ASTM D 1141) and an inhibited salt solution containing 0.06 *M* sodium cloride, 0.02 *M* sodium dichromate, 0.07 *M* sodium acetate, and acetic acid to pH 4 (Ref 48, 101). Some investigators have tested 7000-series alloys in distilled water (Ref 98) and in water vapor at 40 °C (104 °F) (Ref 104). Typical test durations that have been used range from 200 to 2500 h.

With low-resistance alloys, both of the first two corrodents listed in the preceding paragraph ranked alloys similarly and in agreement with exposure to a seacoast and an inland industrial atmosphere. Plateau velocities in the laboratory tests were about five to ten times faster than in the seacoast atmosphere and ten times faster than in the industrial atmosphere. In these *K*-decreasing laboratory tests, corrosion-product wedging effects dominated after exposure periods of about 200 to 800 h. The length of exposure time before the intervention of corrosion-product wedging varies with several factors, including the magnitude of K_{Io} and the inherent resistance to crevice corrosion of the test material in the corrosive environment (Ref 52).

Slow-Strain-Rate Testing

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Slow-strain-rate testing is covered by ASTM G 129 (Ref 65). If there is no specific environment of interest, a 3.5% sodium chloride solution is often used. More corrosive test media can be used, including oxidant additions to the sodium chloride solution or more acidic solutions, such as aluminum chloride (Ref 64, 105).
In a round-robin testing program using several aluminum alloy types and several corrodents, a solution containing 3% sodium chloride plus 0.3% hydrogen peroxide was considered the most promising candidate for possible standardization (Fig. 33). Additional study is needed to determine the optimal composition of these constituents. Another promising candidate was a solution of 2% sodium chloride plus 0.5% sodium chromate having a pH of 3.

Evaluating Stress-Corrosion Cracking

Revised by Bopinder Phull, Consultant

Testing of Copper Alloys (Smooth Specimens)

Testing in Mattsson's Solution. According to ASTM G 37 (Ref 106), a stressed test specimen must be completely and continuously immersed in an aqueous solution containing 0.05 g-atom/L of Cu^{2+} and 1 g-mol/L

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

of ammonium ion (NH_4^+) with a pH of 7.2. The copper is added as hydrated copper sulfate, and the NH_4^+ is added as a mixture of ammonium hydroxide and ammonium sulfate. The ratio of the latter two compounds is adjusted to achieve the desired pH.

Mattsson's pH 7.2 solution is recommended only for brasses (copper-zinc base alloys). This test environment may give erroneous results for other copper alloys and is not recommended. This is particularly true for alloys containing aluminum or nickel.

This test environment is believed to provide an accelerated ranking of the relative or absolute degree of susceptibility to SCC for different brasses. The test environment correlates well with the corresponding service ranking in environments that cause SCC, which may be due to the combined presence of traces of moisture and ammonia vapor. The extent to which the accelerated ranking correlates with the ranking obtained after long-term exposure to environments containing corrodents other than ammonia is not known. Such environments may be severe marine atmospheres (chloride), severe industrial atmospheres (predominantly sulfur dioxide), or superheated ammonia-free steam.

It is currently not possible to specify a time to failure in Mattsson's pH 7.2 solution that corresponds to a distinction between acceptable and unacceptable SCC behavior in brass alloys. Such correlations must be determined on an individual basis. Generally, the longest recommended test duration is 1000 h since failures are not usually observed after this period.

Mattsson's pH 7.2 solution may also cause some stress-independent general and intergranular corrosion of brasses. Therefore, SCC failure may possibly be confused with mechanical failure induced by corrosion-reduced net cross section. This is most likely with small cross-sectional specimens, high applied stress levels, long exposure times, and SCC-resistant alloys. Careful metallographic examination is recommended for accurate determination of the cause of failure. Alternatively, unstressed control specimens can be exposed to corrosive environments in order to determine the extent to which stress-independent corrosion degrades mechanical properties.

Other Testing Media. The most widely used SCC agent for copper and copper alloys is ammonia (NH_3) (Ref 107). The NH_4^+ ion does not appear to cause cracking in a stable salt, such as ammonium sulfate. Cracking will occur in a salt that dissociates (such as ammonium carbonate) to form ammonia.

The $Cu(NH_3)_x^{2+}$ ion (x is usually 4 to 5) is thought to be necessary to induce SCC in copper metals (Ref 108). Amine groups also cause cracking or are easily converted to ammonia. Amines and sulfamic acid also cause cracking. Dry ammonia does not cause SCC of brass, as demonstrated by the successful use of brass valves and gages on tanks of anhydrous ammonia.

Stress-corrosion cracking of copper metals in ammonia will not occur in the absence of oxygen or an oxidizing agent. Carbon dioxide is also a requisite (Ref 109). Therefore, air rather than pure oxygen is necessary, and as a practical matter, moisture is essential. When other factors are favorable, a very small amount of NH_3 is sufficient to cause cracking. The controlling factor may therefore be moisture, because cracking may appear to be caused by the presence of a condensed moisture film.

Other than ammonia, the most effective agents for causing cracking are the fumes from nitric acid or moist nitrogen dioxide. Sulfur dioxide will also crack brass; however, both maximum and minimum concentration limits exist, and the reaction is slow (Ref 107). Alloy development studies have been conducted with a moist ammoniacal test atmosphere containing 80% air, 16% NH_3, and 4% water vapor at 35 °C (95 °F). However, none of these corrodents has received the attention that ammonia has garnered (Ref 108).

Historically, immersion of a copper alloy product in a mercurous nitrate solution has been used to test for residual stresses (Ref 110, 111). Because these residual stresses are possible sources of failure by SCC in other environments, some have regarded this test as a stress-corrosion test. However, it is only an indirect method of identifying SCC tendencies and does not correlate to the presence of SCC as well as test methods based on specific attack by ammonia (Ref 107). It does indicate, however, that mercury and other low-melting liquid metals can cause embrittlement and failure due to cracking.

Evaluating Stress-Corrosion Cracking

Revised by Bopinder Phull, Consultant

Testing of Carbon and Low-Alloy Steels

Generally, steels with lower strengths are susceptible to SCC only upon exposure to a small number of specific environments, such as the hot caustic solutions encountered in steam boilers, hot nitrate solutions, anhydrous ammonia, and hot carbonate-bicarbonate solutions (Ref 112, 113).

Boiler Water Embrittlement Detector Testing. Caustic cracking failures frequently originate in welded structures in the vicinity of faying surfaces, where small leaks cause soluble salts to accumulate in high local concentrations of caustic soda and silica. As a general rule, crevices or splash areas on hot metal surfaces where the concentration of dissolved soluble salts can occur are likely sites for SCC. This type of intergranular cracking failure has been produced with concentrations of sodium hydroxide as low as 5%, but a concentration of 15 to 30% is usually required at 200 to 250 °C (390 to 480 °F) to produce this phenomenon. The apparatus and procedures used to determine the embrittling or nonembrittling characteristics of the water in an operating boiler are detailed in ASTM D 807 (Ref 114).

Other Testing Media. Caustic cracking occurs in digester vessels used in the chemical-processing industries, and laboratory studies have been conducted using sodium hydroxide concentrations of about 30 to 35% (Ref 115). Tests in boiling nitrate solutions have frequently been used to study the effects of composition and metallurgical variables (Ref 113). In studies of low- carbon steel in boiling nitrate solutions having different cations, solutions containing the more acidic cations in greater concentrations were found to be the most potent. This tendency is illustrated by the apparent threshold stresses for failure of a 0.05% C steel in nitrate solutions with a range of concentrations, as shown in Table 5.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Table 5 Apparent threshold stress values for 0.05% C steel in nitrate solutions of varying concentrations

Nitrate solution	Apparent threshold stress values at a solution concentration of:							
	8 *N*		**4 *N***		**2.5 *N***		**1 *N***	
	MPa	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**
Ammonium nitrate	14	2	21	3	48	7	83	12
Calcium nitrate	34	5	48	7	83	12	159	23

Sodium nitrate	55	8	131	19	152	22	179	26

Source: Ref 113

Cracking can be accelerated by the addition of small amounts of acid or oxidizing agents, such as potassium permanganate, manganese sulfate, sodium nitrite, and potassium dichromate, but hydroxides and other salts, particularly those forming insoluble iron products, such as sodium carbonate or sodium hydrogen phosphate, retard or prevent failure. Sodium nitrite is also a known inhibitor if the nitrite concentration is equal to that of the nitrate ion. A standard test environment has not been established, and conditions should be tailored to individual testing requirements.

The ranking of a given series of alloys may vary with exposure conditions (Ref 71). Consequently, selection of a particular alloy for use in an environment that varies from that used in laboratory ranking tests may result in unexpected service failure. This tendency is illustrated by the effects of alloying additions in ferritic steels on cracking in two different environments (Fig. 50). Figure 50(a) shows that each of the alloying additions is beneficial in the carbonate-bicarbonate solutions, with molybdenum having the greatest effect. However, the molybdenum addition has an adverse effect in the 35% sodium hydroxide solution, although the beneficial effects of nickel and chromium additions remain the same (Fig. 50b). Although nickel additions are beneficial in the above example, a similar addition of nickel to a carbon-manganese steel produced susceptibility to SCC in boiling magnesium chloride; this did not occur in the steel without the addition of nickel (Ref 117).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

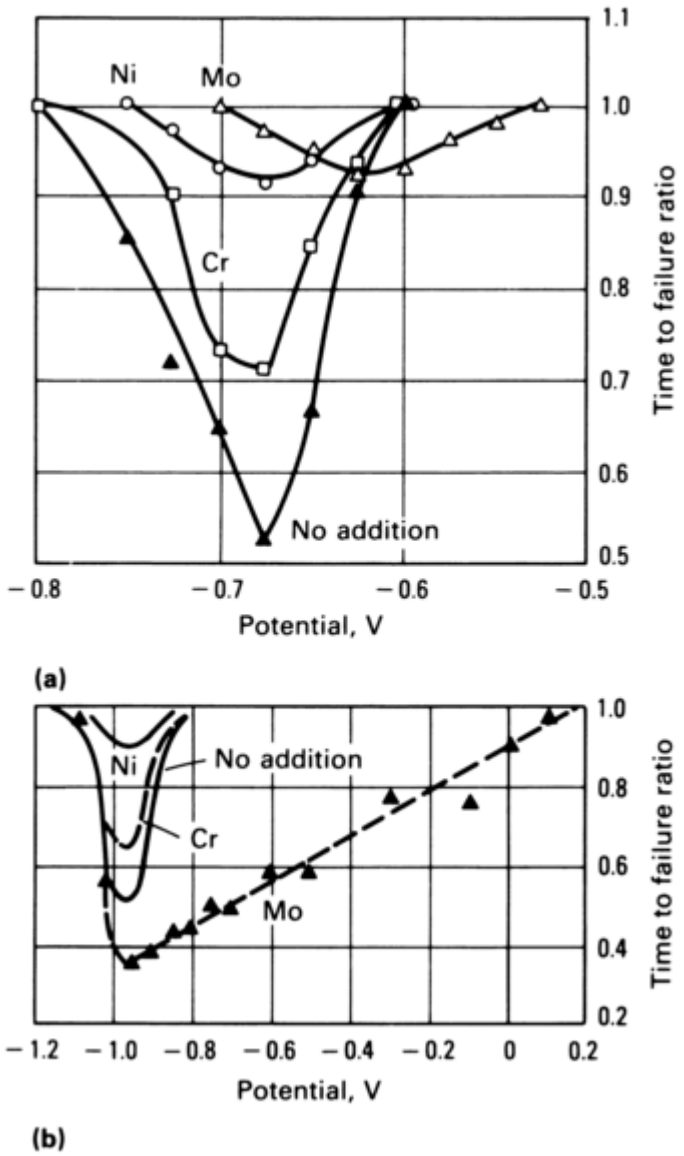

Fig. 50 Effect of various alloying elements on the SCC behavior of a low-alloy ferritic steel in two different corrosive environments. Behavior indicated by time-to-failure ratios in a slow-strain-rate test. (a) Immersed in 1 *N* sodium carbonate plus 1 *N* sodium bicarbonate at 75 °C (165 °F). (b) Immersed in boiling 35% sodium hydroxide. Source: Ref 116

The use of laboratory testing media that duplicate service conditions is equally important when accelerated tests are used for quality control through the acceptance or rejection of production lots of a particular alloy. Reference 118 discusses tests of prestressing steels intended for use as concrete reinforcing bars (rebars) in which an ammonium thiocyanate solution was used to discriminate between heats of steel.

Use of the carbonate-bicarbonate solutions for testing pipeline steels by the slow-strain-rate method revealed that the susceptibility to SCC was dependent on the electrochemical potential of the specimen surface in the test environment, as shown in Fig. 50(a). A critical range in which SCC occurred was established. The critical range varies with the test environment and alloy composition. Several tests at various carbonate-bicarbonate concentrations, temperatures, pH levels, and corrosion potentials indicated that test conditions using an impressed potential of -650 mV versus the saturated calomel electrode (SCE) and a temperature of 75 °C (165 °F) were optimal for SCC (Fig. 37).

Evaluating Stress-Corrosion Cracking

Revised by Bopinder Phull, Consultant

Testing of High-Strength Steels (Ref 4, Ref 119)

For steels with yield strengths greater than about 690 MPa (100 ksi)—such as low-alloy and alloy steels, hot-work die steels, maraging steels, and martensitic and precipitation-hardenable stainless steels—the environments that cause SCC are not specific. In many alloy systems, the phenomena of SCC and hydrogen embrittlement cracking are indistinguishable (Fig. 1). This is particularly the case in environments that contain sulfides or other promoters of hydrogen entry.

Environments of major concern are natural waters—for example, rainwater, seawater, and atmosphere moisture. Any of these environments may become contaminated, which significantly increases the likelihood of SCC. Contamination with hydrogen sulfide is particularly serious; consequently, the presence of hydrogen sulfide in high concentrations in saltwater associated with certain deep oil wells (termed sour wells) places an upper limit of approximately 620 MPa (90 ksi) on the yield strength that can be tolerated in stressed steel in such environments without cracking.

Sulfide Stress Cracking. Determination of sulfide stress cracking is covered in NACE TM- 01-77 (Ref 120). Stressed specimens are immersed in acidified 5% sodium chloride solution saturated with hydrogen sulfide at ambient pressure and temperature. The solution is acidified with the addition of 0.5% acetic acid, yielding an initial pH of approximately 3. Applied stress at convenient increments of the yield strength is used to obtain cracking data that are plotted as shown in Fig. 51. A 30-day test period is considered sufficient to reveal failure of susceptible material in most cases.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

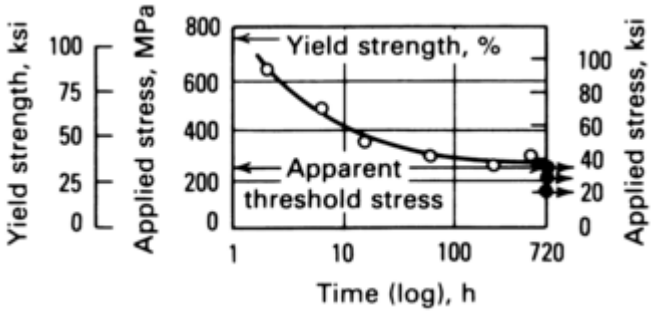

Fig. 51 Method of plotting results of sulfide stress cracking tests. Open symbols indicate failure; closed symbols indicate runouts. Source: Ref 120

The purpose of this test standard is to facilitate conformity in testing. Evaluation of data requires individual judgment on several points based on the specific requirements of the end use. Consequently, the test should not be used as a single criterion for evaluating an alloy for use in environments containing hydrogen sulfide or other hydrogen-charging elements. Attention should be paid to other factors that may affect SCC, such as pH, temperature, hydrogen sulfide concentration, corrosion potential, and stress level, when determining the suitability of a metal for use.

The NACE test method recommends the use of smooth, small-diameter tension specimens stressed with constant-load or sustained-load devices (Ref 120). However, different types of beam and fracture mechanics specimens may be included in the testing standard in the future.

Another test method, known as the Shell Bent Beam Test, has been used for 45 years in the petrochemical industry to rank various materials for use in sour environments (Ref 121). However, acceptance has not been sufficient to generate the interest for standardization.

Testing in sodium chloride solution constitutes a worst-case determination for high- strength steels; as such, it is generally considered unrealistically aggressive for the useful ranking of steels in service environments that do not contain hydrogen sulfide or other conditions favoring entry of hydrogen. Tests are usually performed in 3.5% sodium chloride solution, artificial seawater, natural seawater (rarely), or a marine atmosphere (Ref 4), unless specific environmental conditions are under study. ASTM G 44 (Ref 82) is used where applicable.

In saltwater and freshwater, a true threshold K_{ISCC} exists for high-strength steels that is useful for characterizing resistance to SCC. Ideally, K_{ISCC} defines the combination of applied stress and defect size below which SCC will not occur under static loading conditions in a given alloy and environment system. However, the reported value of K_{ISCC} for a given system often reflects the initial K_I level and the exposure time associated with the testing. Table 6 shows the risk of overestimating K_{ISCC} by terminating the exposure test too soon when using the SCC initiation method (Ref 30, Ref 31). A similar risk exists in tests conducted with the arrest method. Table 7 shows that K_{ISCC} values determined by the initiation and arrest methods may be the same when testing times are sufficiently long and when compatible criteria are used for establishing the threshold (Ref 31).

Table 6 Influence of cutoff time on apparent K_{ISCC} using the SCC initiation method

Exposure time, h	Apparent K_{ISCC}	
	MPa$\sqrt{m}$	**ksi$\sqrt{in.}$**
100	187	170
1000	127	110
10,000	28	25

Note: The initiation method was used on a constant-load cantilever bend specimen (*K*-increasing) of alloy steel with a yield strength of 1240 MPa (180 ksi). Test environment was synthetic seawater at room temperature. Source: Ref 31

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Table 7 Comparison of K_{ISCC} values determined by initiation and arrest methods

Steel alloy	K_{ISCC}, MPa$\sqrt{m}$ (ksi$\sqrt{in.}$)	
	Initiation	**Arrest**
10Ni, normal purity	24 (22)	26 (24)
10Ni, high purity	59 (54)	57 (52)
18Ni, normal purity	22–33 (20–30)	28 (25)
18Ni, high purity	<33 (<30)	<33 (<30)

Note: Based on a crack growth rate of 2.5×10^{-4} mm/h (10^{-5} in./h). Modified compact specimens: constant load for initiation and wedge- loaded with a bolt for arrest. Test environment: saltwater at room temperature. Source: Ref 31

Figure 52 illustrates a method used to compare various high-strength steels (Ref 4, 122). Data were obtained in saltwater or seawater, and K_{ISCC} values are plotted versus yield strength. Envelopes are used to enclose all known valid data for the various steels. The crosshatched envelopes or individual data points represent the featured steels, which allows comparison with characteristics of the other steels. The straight lines in Fig. 52 illustrate how K_{ISCC} values relate to the maximum depth of long surface flaws that can be tolerated without stress-corrosion crack growth.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

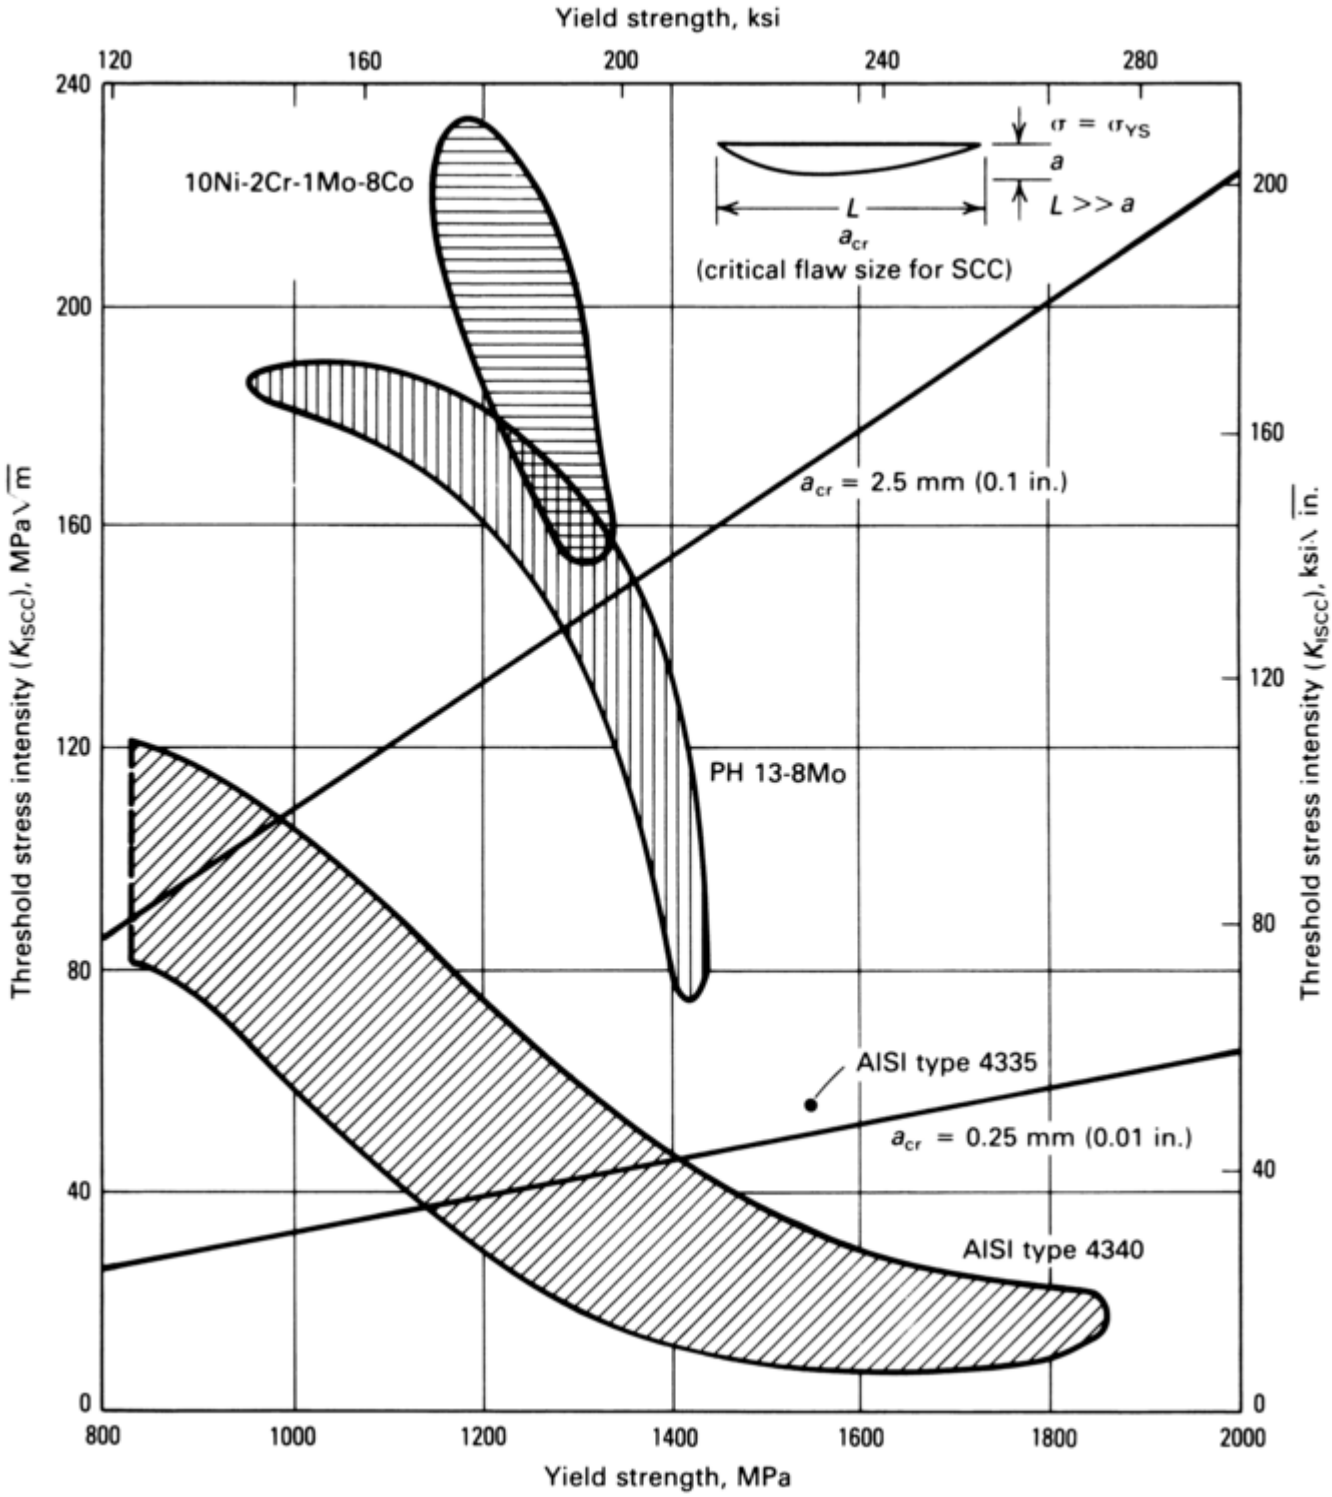

Fig. 52 Comparison of SCC behavior of several high-strength steels based on threshold stress-intensity (K_{ISCC}) values in saltwater. Source: Ref 122

Electrochemical Polarization. Although the mechanism of cracking in hydrogen sulfide environments is predominantly one of hydrogen embrittlement, the mechanism of environmentally induced failures in environments not containing sulfides or other promoters of hydrogen entry is not clearly agreed upon (Ref 119). Time to failure in a sodium chloride solution depends on the corrosion potential (Ref 4, 123), which determines whether failure results from active path corrosion or hydrogen embrittlement cracking. Electrochemical studies have shown that embrittlement of high-strength steels by corrosion-product hydrogen occurs when, for a given environment, the electrochemical potential of the metal is equal to or more electronegative than the reversible hydrogen potential, that is, for thermodynamic conditions that favor the deposition of hydrogen on the surface of the steel.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Figure 53 compares the various types of cracking behavior that can be expected from electrochemical polarization (Ref 124). All of the curves except curve G were obtained experimentally. Curve A represents the case in which only hydrogen embrittlement is obtained; curve B shows only active path corrosion. Both processes are shown in curves C and D.

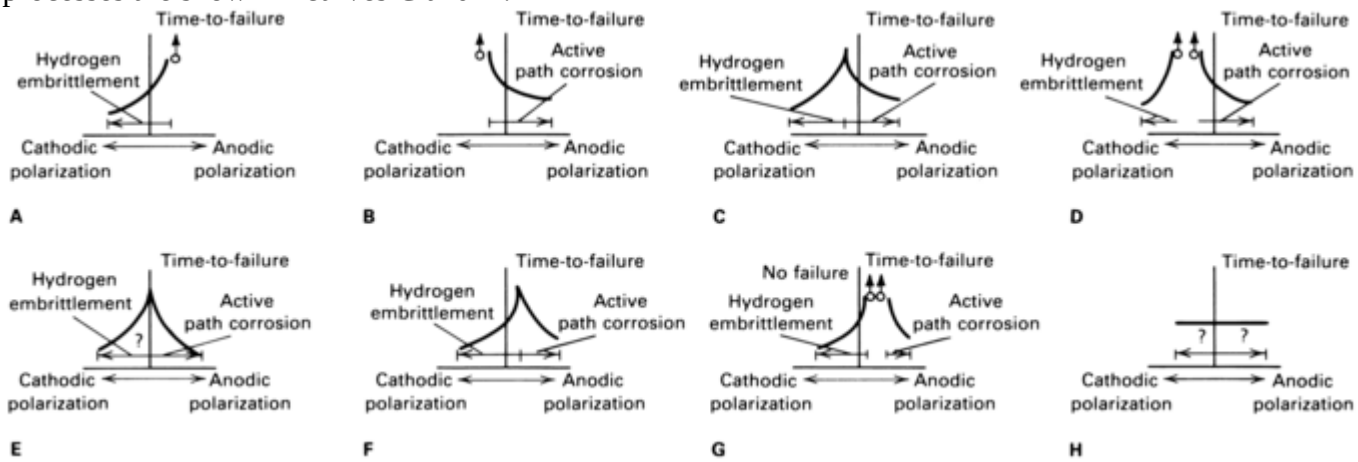

Fig. 53 Use of electrochemical polarization to distinguish between SCC and hydrogen embrittlement mechanisms in a high-strength steel immersed in sodium chloride solution. See text for explanation of curves A through H. Source: Ref 124

When both anodic and cathodic polarization shorten the cracking time, as in curve E, it is not possible to determine which mechanism prevails without applied current. Curves F and G can be expected in acid solutions when the corrosion potential is anodic to the reversible hydrogen potential.

In curve H, neither anodic nor cathodic polarization has any effect on cracking time. Therefore, it is possible that a hydrogen embrittlement mechanism is involved. However, the mechanism by which hydrogen enters the steels is not electrochemical. To perform realistic accelerated tests, the end use of the material and the environmental conditions involved should be considered so that the test procedure involves the appropriate cracking mechanism. It should be noted that hydrogen embrittlement cracking can also occur as a result of galvanic action between the test specimen and components of the stressing system. In all SCC testing, therefore, all electrical contact between the specimen and ancillary fixtures must be avoided, except when galvanic effects are desired.

Testing of Non-Heat-Treatable Stainless Steels

The environments causing SCC that are encountered in the chemical industry are specific and are limited primarily to chloride and caustic solutions at elevated temperatures and sulfide environments at ambient temperatures. In seawater at or near room temperature, austenitic (Fe-Cr-Ni) and ferritic (Fe-Cr) steels do not generally experience SCC. However, occasionally, SCC of susceptible austenitic stainless steels can occur in ambient-temperature chloride-containing environments due to development of locally acidic conditions, for example, in pits and crevices. Fully ferritic stainless steels are highly resistant to SCC in chloride and caustic environments that cause austenitic stainless steels to crack. However, laboratory studies have shown small additions of nickel or copper to ferritic steels may render them susceptible to SCC in severe environments (Ref 4).

Testing in Boiling Magnesium Chloride Solution. ASTM G 36 (Ref 125) is applicable to wrought, cast, and welded austenitic stainless steels and related nickel-base alloys. This method determines the effects of composition, heat treatment, surface finish, microstructure, and stress on the susceptibility of these materials to chloride SCC. Although this test can be performed with various concentrations of magnesium chloride, ASTM G 36 specifies a test solution maintained at a constant boiling temperature of 155.0 ± 1.0 °C (311.0 ± 1.8 °F), that is, approximately 45% magnesium chloride. Also described is a test apparatus capable of maintaining solution concentration and temperature within the recommended limits for extended periods of time. Typical exposure times are up to 1000 h. However, historically, most of the SCC data on austenitic stainless steels were obtained by using a boiling 42% $MgCl_2$ solution (boiling point: 154 °C, or 309 °F). For this reason, testing is still done at the lower concentration.

Most chloride cracking testing has been carried out in accelerated test media such as boiling magnesium chloride (Ref 4, 126, 127). All austenitic stainless steels are susceptible to chloride cracking as shown in Fig. 54. It is noteworthy, however, that the higher-nickel types 310 and 314 were appreciably more resistant than the others (Fig. 55). Although this solution causes rapid cracking, it does not necessarily simulate the cracking observed in field applications.

Other ions in addition to chloride can cause cracking. Of all halogen ions, chlorides cause the most cases of SCC in austenitic stainless steels. Known cases of fluoride and bromide SCC are few, and iodide is not known to produce SCC. In addition, cations, such as Li^+, Ca^{2+}, Zn^{2+}, NH_4^+, Ni^{2+}, and Na^+, affect test results to varying degrees (Ref 130). Although chloride SCC occurs primarily at temperatures above about 90 °C (190 °F), acidified chloride solutions can produce SCC at lower temperatures (Ref 130, 131, 132). Therefore, in diagnosing service failures, it is necessary to establish which ions (and other environmental and stress conditions as well) have caused the failure. In this manner, an appropriate test procedure can be designed for the evaluation of alternative materials.

Reference 133 discusses laboratory reproduction of an environment that caused SCC at the top of a distillation tower in a crude oil refinery. The service environment consisted of a very dilute hydrochloric acid solution (36 ppm chloride) with a pH of 3 saturated with hydrogen sulfide gas at 80 °C (175 °F). In this test environment, austenitic stainless steels, such as type 304 or 316 failed, but the ferritic types 430 and type 434 did not.

ASTM G 123 (Ref 134) covers a procedure for evaluating SCC of stainless alloys, with different nickel content, in boiling 25% NaCl solution acidified to pH 1.5 with phosphoric acid. U-bend specimens are used, and the test method is designed to provide better correlation with chemical-process industry experience for stainless steels than the more severe boiling $MgCl_2$ test of ASTM G 36. Although the test can be run for as long as necessary, 6 weeks (~1000 hs) is expected to be sufficient to crack susceptible materials. Samples of susceptible materials, for example, type 304 or 316 stainless steel, are recommended as controls when evaluating more resistant materials.

Testing in Polythionic Acids. Petrochemical refinery equipment is subject to polythionic acid cracking, which may occur after shutdown. Polythionic acid forms by the decomposition of sulfides on metal walls in the presence of oxygen and water. ASTM G 35 (Ref 135) describes procedures for preparing and conducting exposures to polythionic acids ($H_2S_nO_6$ where n is usually 2 to 5) at room temperature to determine the relative susceptibility of sensitized stainless steels or related materials (high Ni-Cr-Fe alloys) to intergranular SCC.

This test method can be used to evaluate stainless steels or other materials in the as-received condition or after high-temperature service (480 to 815 °C, or 900 to 1500 °F) for prolonged periods of time. Wrought products, castings, and weldments of stainless steels or other related materials used in environments containing sulfur or sulfides can also be evaluated. Other materials that are capable of being sensitized can also be tested.

A variety of smooth SCC test specimens, surface finishes, and methods of applying stress can be used. Stressed specimens are immersed in the polythionic acid solution, which can be prepared by passing a slow current of hydrogen sulfide gas for 1 h through a fritted glass tube into a flask containing chilled (0 °C, or 32 °F) 6% sulfurous acid, after which the liquid is kept in a stoppered flask for 48 h at room temperature. Solutions can also be prepared by passing a slow current of sulfur dioxide gas through a fritted glass bubbler submerged in a container of distilled water at room temperature. This is continued until the solution becomes saturated. The hydrogen sulfide gas is then slowly bubbled into the sulfurous acid solution.

Prior to use, the polythionic acid solution should be filtered to remove elemental sulfur and then tested for acid content. This can be done by analytical tests or by using a control test specimen of sensitized type 302 or 304 stainless steel. The control should fail by cracking in less than 1 h.

The wick test can be used to evaluate the chloride cracking characteristics of thermal insulation for applications in the chemical-process industry. ASTM C 692 (Ref 136) covers the methodology and apparatus used to conduct this procedure. When a dilute aqueous solution is transmitted to a metal surface by capillary action through an absorbent fibrous material, the process is called wicking. Cracking occurs at much lower temperatures when alternate wetting and drying is used than when the specimens are kept wet continuously.

Other Testing Media. Hot concentrated caustic solutions are another type of environment encountered in chemical industries that causes SCC of stainless steels. However, the conditions leading to caustic cracking are more restrictive than those leading to chloride cracking, and caustic environments have not received the attention that chlorides have. There is little difference in the susceptibilities among types 304, 304L, 316, 316L, 347, and USS 18-18-2 austenitic steels. All of these alloys crack rapidly in solutions of 10 to 50% sodium hydroxide at 150 to 370 °C (300 to 700 °F) (Ref 4, 127, 137).

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Certain strong acid solutions containing chlorides, such as 5 *N* sulfuric acid plus 0.5 *N* sodium chloride, 3 *N* perchloric acid plus 0.5 *N* sodium chloride, and 0.5 to 1.0 *N* hydrochloric acid, are capable of causing SCC in austenitic stainless steels at room temperature (Ref 4). Cracking in these environments is similar to the type of cracking that occurs in hot chloride environments.

Electrochemical Polarization. Stress-corrosion cracking in austenitic and ferritic stainless steels can be delayed or prevented by the application of cathodic current; however, if ferritic and martensitic steels are overprotected by relatively large cathodic current, they are apt to blister or crack due to the hydrogen discharged by the cathodic protection action. Anodic polarization significantly accelerates the initiation of SCC, but appears to have a smaller accelerating effect on crack propagation (Ref 138).

Testing of Magnesium Alloys

There is no standard accelerated test environment recommended for assessing the susceptibility of magnesium-base alloys to SCC. Exposure of stressed specimens to the atmosphere has generally been used to determine the SCC susceptibility of specific products.

The chloride-containing solutions typically used in accelerated tests for aluminum alloys are unsatisfactory for SCC tests of magnesium alloys because of excessive general corrosion. In one investigation, a chromate-inhibited chloride solution (35 g/L sodium chloride plus 20 g/L potassium chromate; pH 8) was found to be suitable for testing magnesium alloys (Ref 139). Good correlation was observed between the SCC behavior of Mg-Al-Zn alloys exposed by total immersion in this solution and the behavior of the same alloys exposed to an industrial atmosphere. Cracking of highly stressed susceptible alloys occurs within a few hours, but exposures can be continued up to 1000 h without incurring excessive pitting. Laboratory tests also have been conducted using potassium hydrogen fluoride and a dilute solution of sodium chloride plus sodium bicarbonate as the test medium (Ref 140).

Testing of Titanium Alloys

Although titanium alloys are not susceptible to SCC in either boiling 42% magnesium chloride or boiling 10% sodium hydroxide solutions, which are commonly used to study SCC in stainless steels, the susceptibility of titanium and its alloys to SCC has been demonstrated in several environments. This information is given in Table 9.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Table 9 Environments and temperatures conducive to SCC of titanium alloys

Environment	Temperature, °C (°F)
Hot dry chloride salts	260–480 °C (500–900 °F)
Seawater, distilled water, and aqueous solutions	Ambient
Nitric acid, red fuming	Ambient
Nitrogen tetroxide	Ambient to 75 °C (165 °F)
Methanol, ethanol	Ambient
Chlorine	Elevated
Hydrogen chloride	Elevated
Hydrochloric acid, 10%	Ambient to 40 °C (105 °F)
Trichloroethylene	Elevated
Trichlorofluoroethane	Elevated
Chlorinated diphenyl	Elevated

Testing in a Hot Salt Environment. The hot salt test consists of exposing a stressed salt- coated test specimen to an elevated temperature for various predetermined lengths of time. The exposure periods are determined by the alloy, stress level, temperature, and selected damage criterion (that is, embrittlement, cracking, or rupture, or a combination of these phenomena). Exposures are typically carried out in laboratory ovens or furnaces equipped with loading equipment for stressing specimens. Environmental conditions, the degree of control required, and the means for obtaining control are described in ASTM G 41 (Ref 144).

This test method can be used to test all metals if service conditions warrant. The test limits maximum operating temperatures and stress levels, or it categorizes different alloys according to their susceptibility if hot salt damage has been found to accelerate failure by creep, fatigue, or rupture. Although limited evidence relates this phenomenon to actual service failures, cracking under stress in a hot salt environment is a potential design-controlling factor.

The hot salt test should not be construed as being related to the SCC of materials in other environments. It should be used only in an environment that may be encountered in service.

Hot salt testing can be used for alloy screening to determine the relative susceptibility of metals to embrittlement and cracking and to determine the time-temperature-stress threshold levels for the onset of embrittlement and cracking. However, certain types of specimens are more suitable for each of these types of characterizations. Precracked specimens are unsuitable for testing of titanium alloys, because cracking reinitiates at salt/metal/air interfaces and results in many small cracks that extend independently. Therefore, smooth specimens are recommended.

Testing in Water and Aqueous Solutions. Water, seawater, and almost any neutral aqueous solution (except atmospheric water vapor) can cause SCC in many titanium alloys in the presence of preexisting cracklike flaws, although susceptibility in these environments cannot be detected by smooth specimens. Therefore, fracture mechanics type characterizations are necessary. For titanium alloys, the extremely rapid growth of stress-corrosion cracks in saltwater and the dependency on specimen geometry preclude the possibility of using crack growth rate data for design purposes.

Therefore, ranking of materials must be based on K_{ISCC} values, and a true threshold stress intensity for SCC apparently does exist (Ref 145). Titanium alloys do not exhibit stage I type crack growth kinetics (Fig. 3) in neutral aqueous solutions. Tests have been performed for sufficient periods of time to allow detection of crack growth rates of 10^{-9} m/s (1.4×10^{-4} in./h), but SCC has not been observed. The slowest crack velocity that has been detected is 10^{-8} m/s (1.4×10^{-3} in./h). Therefore, in neutral aqueous solutions, a threshold K_{ISCC} exists at which SCC will not propagate (Ref 4, 145). The above rates, however, are not as slow as those observed in high-susceptibility aluminum alloys (Fig. 46). Tests are commonly performed in water containing about 3.5% sodium chloride, artificial seawater, or natural seawater unless specific environments are being tested.

Electrochemical Polarization. The halide ions (chloride, bromide, and iodide) are SCC agents unique for titanium alloys in aqueous solutions at room temperature. The crack initiation load and velocity are controlled by the applied potential, as illustrated for the crack initiation load in Fig. 56. At potentials more negative than about -700 to -1400 mV, depending on the solution, specimens were cathodically protected. Sodium fluoride solution and solutions of the other anions that do not produce SCC (hydroxide, sulfide, sulfate, nitrite, nitrate, perchlorate, cyanide, and thiocyanate) yielded results at all potentials in the same scatterband as the air values.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

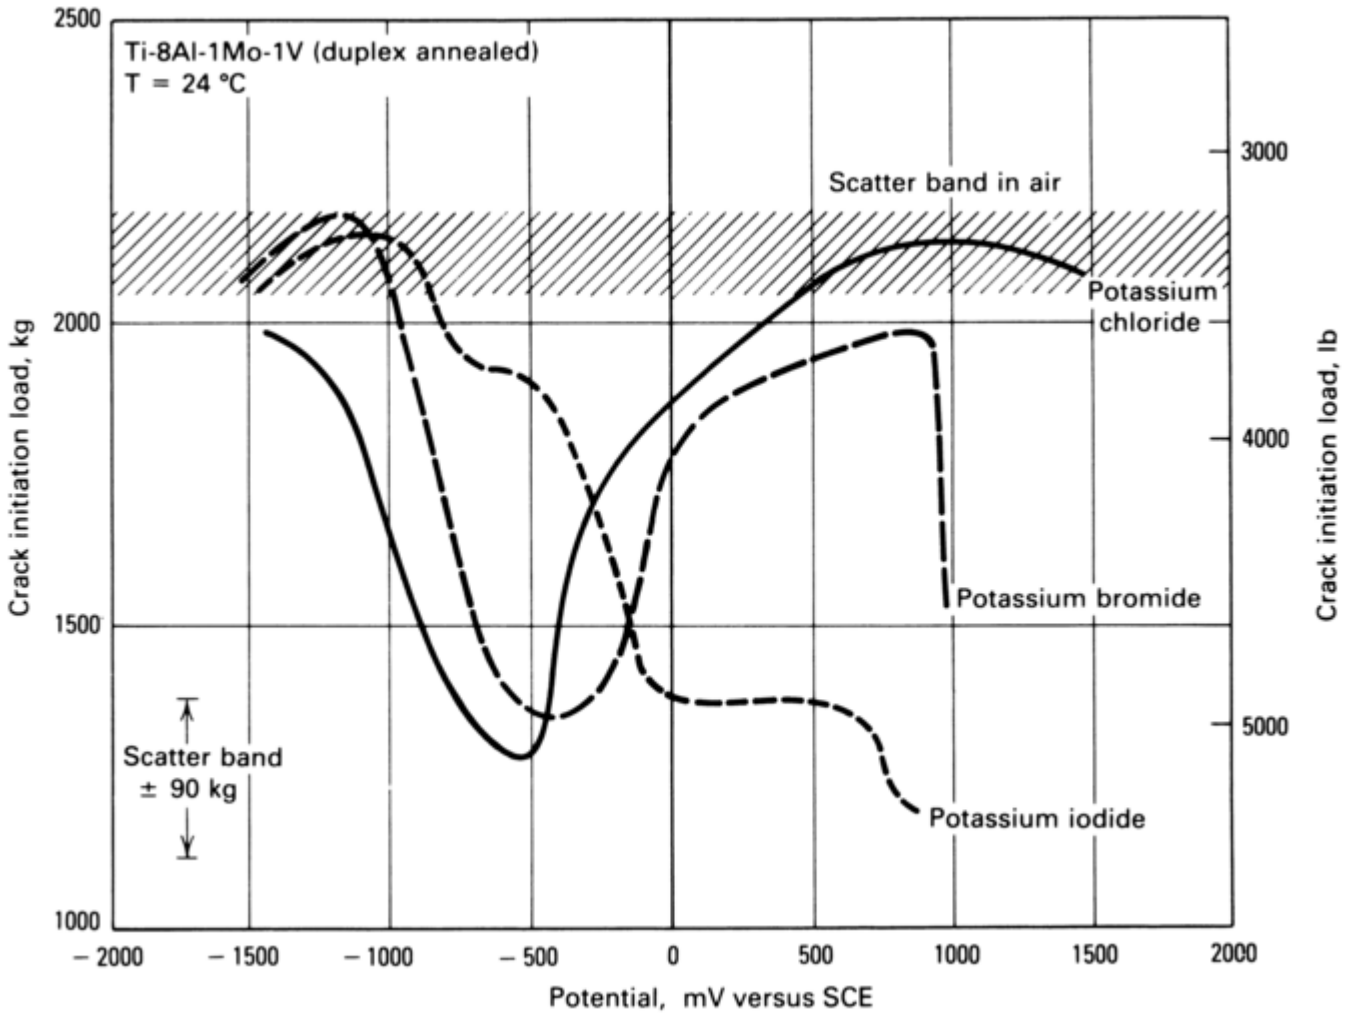

Fig. 56 Variation of crack initiation load with potential in 0.6 *M* halide solutions for Ti-8Al-1Mo-1V. Specimen: single-edge cracked sheet that was tension loaded by constant displacement. Source: Ref 145, 146

At potentials more positive than the above values, susceptibility of varying degrees occurred in the chloride, bromide, and iodide solutions. The width of the critical potential range and the potential for maximum susceptibility varies with the anion. A region of anodic protection occurred in the chloride and bromide solutions, but not in the iodide solution.

Crack propagation can be halted by switching the potential to either the anodic or cathodic protection zone. The corrosion potential of titanium alloys in 3.5% sodium chloride and seawater—about -80 mV versus SCE—is similar (slightly more negative) to the potential at which SCC susceptibility reaches a maximum (Ref 145).

Testing in Organic Fluids. A wide variety of organic fluids can cause SCC in some titanium alloys under specific test conditions (Table 9). Most of these fluids attack the passive surface film that is characteristic of titanium alloys. Consequently, precracked specimens do not have to be used to accelerate the SCC initiation. A standard environment does not exist; test conditions must be selected with appropriate consideration given to the type of environmental service required.

Sustained-Load Cracking in Inert Environments. High-strength titanium alloys for use in highly stressed components for military aircraft and other similar applications may be susceptible to sustained-load cracking in inert environments (including dry air). Sustained-load cracking is similar to SCC except that it is much slower and occurs in the total absence of a reactive environment. Sustained-load cracking is caused by, or is greatly aggravated by, hydrogen dissolved in the titanium during processing. Vacuum annealing can reduce the hydrogen level to less than 10 ppm, at which concentration the tendency toward sustained-load cracking is greatly reduced (Ref 4, 147).

Figure 57 illustrates an example of sustained- load cracking in mill-annealed plate of Ti-8Al- 1Mo-1V containing 48 ppm hydrogen. As shown in Fig. 57, the threshold stress-intensity factor for sustained-load cracking in dry air is designated K_{IH} because it is attributed to hydrogen in the metal. When the hydrogen

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

concentration was reduced to 2 ppm by vacuum annealing, the K_{IH} value was increased to equal the inherent plane-strain fracture toughness, K_{Ic}. However, the K_{ISCC} value was not affected (Ref 148). Therefore, in addition to the practical importance of sustained-load cracking, its potential contribution to cracking should be taken into account when evaluating environmental effects, particularly in mechanistic studies.

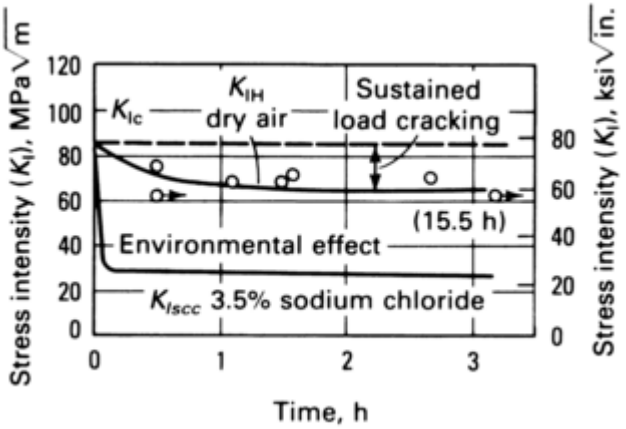

Fig. 57 Effect of sustained-load cracking compared to SCC in Ti-8Al-1Mo-1V mill-annealed sheet. Hydrogen concentration, 48 ppm; yield strength, 850 MPa (123 ksi); cantilever bend specimen (T-S); *B* = 6.35 mm (0.25 in.). Special Considerations for Testing of Weldments

ASTM G 58 (Ref 149) covers test specimens in which stresses are developed by the welding process only (that is, residual stress, Fig. 23), an externally applied load in addition to the stresses due to welding (Fig. 7e), and an externally applied load only, with residual welding stresses removed by annealing.

The National Materials Advisory Board Committee on Environmentally Assisted Cracking Test Methods for High-Strength Weldments published the following guidelines on SCC testing of weldments (Ref 31). Fracture mechanics of cracked bodies was found to be a valid and useful approach for designing against environmentally assisted cracking, although several limitations and difficulties must be taken into consideration. For static loading, K_{ISCC} and da/dt versus K_I are useful parameters. They are specified to a material, temperature, and metal/ environment system and are functions of local chemical composition, microstructure, and so on.

Superimposed minor load fluctuations and infrequent changes in load can alter environmental cracking response. This effect, which cannot be predicted from K_{ISCC} and da/dt values, may be significant and detrimental. Reexamination of static loading as a design premise may be required. Existing test methodology or environmentally assisted cracking tendency is applicable to the evaluation of weldments. As in other structural components, residual stress must be treated in a quantitative and realistic manner.

The National Materials Advisory Board report supports current design emphasis based on the presumption of preexisting cracklike flaws in the structure and covers testing with precracked (fracture mechanics) specimens only. It contains a critical assessment of the problems associated with environmentally assisted cracking in high- strength alloys and of state-of-the-art design and test methodology.

Surface Preparation of Smooth Specimens

The pronounced effect of surface conditions on the time required to initiate SCC in test specimens is well known (Ref 5). Unless the as-fabricated surface is being studied, the final surface preparation generally

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

preferred is a mechanical process followed by degreasing. However, chemical etches or electrochemical polishes can be used to remove heat treating films or thin layers of surface metal that may have become distorted during machining.

Care should be exercised to select an etchant that will not selectively attack constituents or phases in the metal and that will not deposit undesirable residues on the surface. Etching or pickling should not be used with alloys that are susceptible to hydrogen embrittlement.

Precautions should be taken when machining specimens to avoid overheating, plastic deformation, or the development of residual stress in the metal surface. Machining should be performed in stages so that the final cut leaves the principal surface with a clean finish of 0.7 μm (30 μin.) rms or smoother. The required machining sequences, types of tools, and feed rate depend on the alloy and metallurgical condition of the test piece. Lapping, mechanical polishing, and similar operations that produce flow of the metal should be avoided.

Evaluating Stress-Corrosion Cracking

Revised by Bopinder Phull, Consultant

Interpretation of Test Results

This is the most fallible part of SCC testing and evaluation; it includes the analysis that leads to the conclusions and recommendations. Stress- corrosion test data are at best imprecise and test dependent, and they must be qualified with the testing conditions. It is important to verify the mode of environmental cracking (Fig. 1) and then to review the data to exclude all extraneous results, as discussed previously with the individual test methods. Following are some comments on the nature of the test dependency of the most commonly used criteria of SCC behavior.

Criteria of SCC Behavior

Specimen Life (Time to Failure). Stress-corrosion testing frequently involves determining the lives of specimens under specific test conditions. This includes the initiation (or incubation) of a stress-corrosion crack and its propagation to the point of fracture (Fig. 2). Such a determination is easily accomplished when only a single crack forms and the specimen fractures within the chosen test period. However, it often happens that SCC occurs but the specimen does not fracture. This is especially likely when testing relatively low-strength materials by constant strain loading (Fig. 5b) and when testing at applied-stress or stress-intensity levels only slightly above the threshold (Fig. 29a). Cracks may initiate at multiple sites in constant-strain loaded smooth specimens with relatively low applied stress, and a difficult problem arises in deciding when to consider a specimen failed if it does not fracture visibly.

It is often found that the majority of specimens in a set of replicates in a test fail rapidly; this leaves a few specimens that fail at much longer times or do not fail at all before the test is discontinued. Such behavior presents difficulties, both theoretical and practical, in deciding when to terminate a test, choosing a satisfactory representative value, and comparing such values.

The arithmetic mean specimen life is widely used for smooth specimens because it can be manipulated algebraically and can be used in many standard statistical tests of significance. It should be remembered,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

however, that extremely large or extremely small values may cause the mean to be atypical of the true distribution. Moreover, in using the arithmetic mean, it is assumed that the population is normally or very nearly normally distributed. The median, on the other hand, has the advantage that it is influenced less by extreme values, requires no assumption about the population distribution, and can be obtained much faster than arithmetic mean values because only about half the number of replicates exposed need to be tested to failure. The median is used in a German specification (Ref 24) that also provides for the use of the geometric mean if the replication is small.

References 1 and 150 contain examples for highly susceptible steel and aluminum alloys, respectively; these examples demonstrate the normal distributions for the logarithms of the specimen lives. With such distributions, a geometric mean would be the best representative value of the specimen life. It has also been shown that a Weibull distribution can be appropriate for the nonnormally distributed test data for a relatively resistant aluminum alloy (Ref 151). Thus, it should not be assumed that any one distribution is applicable for all testing situations.

Comparisons of alloys with differing strength and fracture toughness based on time to failure can be completely misleading. For example, SCC growth curves are shown in Fig. 58 for alloys with different fracture toughnesses. Curves A, B, and C represent materials with decreasing toughness, with curve C showing fast fracture initiated by corrosion pits or fissures with no SCC.

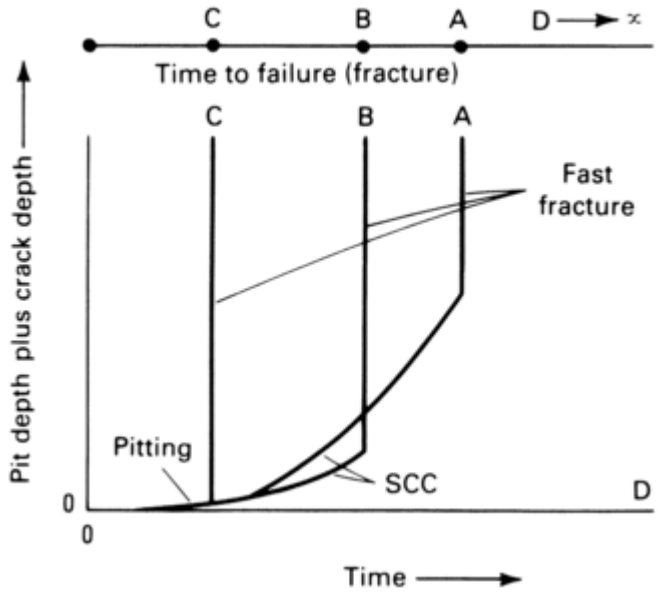

Fig. 58 Various processes in SCC as influenced by the fracture toughness of the metal. Kinetics for pitting (or, in material D, nonpitting), SCC (materials A and B only), and fast fracture. Line at top illustrates how time to failure data can be misleading. Source: Ref 152

The behavior of a material that does not develop localized pitting or intergranular attack is represented by a line coincident with the abscissa, designated D in Fig. 58. The time-to-failure ranking above the graph indicates D as best and A, B, and C as poorest. Actually, the SCC responses of C and D were not measured, and the true SCC ranking of A and B (indicated by depth of SCC at the time of fracture) exhibits a trend opposite to that inferred from the time-to- failure data above.

Further difficulties may arise, because the total time to fracture is also influenced by non- SCC factors, such as specimen type and size, method of loading, initial stress level, and initiation behavior of the alloy. Consequently, the SCC ranking of materials may vary among investigators using different testing techniques. Nevertheless, comparisons of specimen lives derived from smooth specimens can be useful in certain mechanistic studies and in tests for comparing environmental variations if the mechanical aspects of the investigation are held constant.

Threshold Stress (Stress-Time Curve). More information about the resistance to SCC of a material can be obtained when testing smooth specimens by using a range of applied stresses. Such data are usually presented graphically with the applied gross section stress plotted against specimen life (Fig. 54). The primary interest is generally in the long-life portion of the curve to obtain an estimate of the threshold stress.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

A common method of estimating threshold stress involves the experimental determination of the lowest stress at which cracking occurs in at least one specimen and the highest stress at which cracking does not occur in several specimens (for example, three or more, depending on variability). An average of the lowest failure and highest no-failure stresses is usually taken as the threshold stress. Such determinations of critical stresses are carried out at specified test times that are known through experience or preliminary tests to be sufficient to produce SCC in the alloy- environment system of interest. Statistical methods are available for determining threshold stresses more precisely (for example, the Probit method or staircase method) and are commonly used for the determination of fatigue limits. However, the additional testing involved can be quite extensive.

Apparent threshold stresses determined in laboratory tests of coupon specimens are useful for ranking the SCC susceptibility of various materials, but, because such data are dependent on test conditions, they are not realistic for the purpose of engineering design (Ref 4). Also, when using such data as an aid in selecting the material for a specific structure, caution should be exercised in trying to relate the laboratory test conditions to the anticipated service conditions. Not only the environmental condition but also the geometry and size of the test specimens and the method of stressing should be compared (Fig. 6, 18). Further, threshold stresses obtained with statically loaded smooth specimens are likely to be nonconservative; it has been shown in tests on carbon-manganese steel that the threshold stress obtained by static loads is reduced by applied constant slow strain rates and that it can be reduced even further with cyclic loading (Ref 61). With appropriate frequency, load change, and temperature, average creep rates can be sustained over extended periods, but with static loading, the creep rate may fall below the level needed to promote SCC. In general, experimentally determined threshold stresses for materials with only limited susceptibility to SCC are more sensitive to variations in testing conditions than in the case of highly susceptible materials.

Percent Survival (Curve). This method of analyzing stress-corrosion test results is especially useful when some of the specimens in a group survive the duration of the test. Examples of various comparisons by this technique are shown in Fig. 18, 42, and 43. Although the curves can be drawn on regular coordinate graph paper, the percent survival values will often lie along a straight line when plotted on normal probability paper, as shown in Fig. 59. The linearity of this plot indicates that the statistical distribution of the test results is logarithmic-normal. The vertical positions of the lines indicate the cracking ability of the environment, which can be represented by median cracking times. The slopes of the lines correspond to the variance, which can be used to calculate confidence limits.

Threshold Stress Intensity (K_{ISCC}, K_{th}). Linear elastic fracture mechanics is well established as a basis for materials characterization, including environmental cracking (Ref 31, 154, 155). In practice, it is most practical to define K_{ISCC} as the K_I level associated with some generally acceptable and definably low rate of crack growth that is commensurate with the design service life. When K_{ISCC} values are reported, the criterion for their assessment and the exposure time in the environment must accompany the threshold values. A rational approach to the development of useful data for design is to establish an operational definition of K_{ISCC} that is appropriate for the structure under consideration.

Such characterization requires that linear elastic fracture mechanics and plane-strain conditions be satisfied. However, for certain low- strength steels and aluminum alloys, existing data show that SCC can occur under conditions that deviate substantially from plane strain, and that SCC is by no means limited to or is most severe under plane-strain loading conditions (Ref 156, 157). In these cases, the application of linear elastic fracture mechanics is no longer valid, and the parameter K_{ISCC} is no longer meaningful. Similarly, when testing materials with a high resistance to SCC, loading to high percentages of K_{Ic} may cause a relaxation of stress due to creep. In this case also, the apparent K_{ISCC} values are meaningless. Constant-load tests, therefore, are preferred for lower-strength materials (Ref 158).

The symbol K_{th} has been used to identify threshold stress-intensity factors developed under test conditions that do not satisfy all the requirements for plane-strain stress. Design calculations using such values should not be employed unless it is clear that the laboratory tests exhibit the same stress state as that for the intended application. Nevertheless, properly determined K_{th} values can be useful for ranking materials.

In principle, experimentally determined K_{ISCC} values should be the same whether they are determined by the initiation or the arrest test method (Fig. 29). In both tests, there are dimensional requirements for ensuring that the test results are independent of geometrical effects (see the section “Preparation of Precracked Specimens” in this article). However, precautions must be exercised during testing to avoid the potential problems involved with the environmental exposure (incubation, corrosion-product wedging, crack branching, crack tip blunting, and so on). Comparisons of K_{ISCC} values determined for selected steels by both methods, along with examples

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

of overestimated values resulting from insufficient length of exposure, are shown in Tables 6 and 7. It is advisable, when practicable, to use a test that matches the type of loading encountered in the anticipated service.

From the parameter K_{ISCC}, a value of a_{cr} can be calculated using the relation $a_{cr} = 0.2 (K_{ISCC}/ TYS)^2$ (see the section “Static Loading of Precracked (Fracture Mechanics) Specimens” in this article). This is the shallowest crack (surface length is long compared to its depth) that will propagate as a stress-corrosion crack at a yield strength level of gross stress under the given environmental conditions. This can be a very useful parameter for comparing materials, especially when the measured a_{cr} values can be related to the capability of the flaw inspection system used for a given engineering structure (Fig. 52). Straight lines representing assumed values of a_{cr} in Fig. 52 illustrate how K_{ISCC} values for the various steel alloys relate to the maximum depth of long surface flaws that can be tolerated without growth of SCC.

Such a plot can be used as follows. If the inspection system to be used can detect all long surface flaws deeper than 0.25 mm (0.01 in.), then the materials engineer would select an alloy with a K_{ISCC} above the 0.25 mm (0.01 in.) line. Conversely, if the K_{ISCC} and tensile yield strength of a material are known, the equation can be used to estimate the maximum tolerable flaw size. Substitution of an anticipated design stress in terms of percentage of tensile yield strength in the formula for a_{cr} will generate a new series of a_{cr} lines of lower slope.

Alternatively, the following method, which is specific for a given loading method, can be used, inasmuch as the flaw depth and applied stress are uniquely related for a specific loading situation, a family of curves for constant K_{th} values can be developed within these parameters. Figure 60 shows such curves for long, shallow flaws; the curves were generated according to the following equations (Ref 160, 161, 162):

$$K_1 = M_B\sqrt{\frac{\pi a}{Q}} \qquad \text{(Eq 16)}$$

$$M_B = \frac{Y}{6}\sqrt{\frac{t}{\pi a}} \qquad \text{(Eq 17)}$$

$$Y = \sqrt{139\frac{a}{t} - 221\left(\frac{a}{t}\right)^2 + 783\left(\frac{a}{t}\right)^3} \qquad \text{(Eq 18)}$$

where K_I is stress intensity, s is applied stress, a is flaw depth, Q is a shape parameter, and t is thickness. When K_{th} is substituted into Eq 16 and a flaw shape is assumed (Q = 0.8), this parameter is related to the flaw size and the applied stress. In this representation, SCC growth will not occur below the curve for the appropriate K_{th}. For example, for a steel with K_{th} of 60.5 MPa$\sqrt{m}$ (55 ksi$\sqrt{\text{in.}}$), a very deep flaw (6 mm, or 0.25 in.) would be required to cause crack propagation in hydrogen gas of a steel component stressed to 360 MPa (52 ksi) in bending. Such representations are useful for relating test data and K_{th} in design and in the development of crack inspection requirements, as well as for ranking alloys.

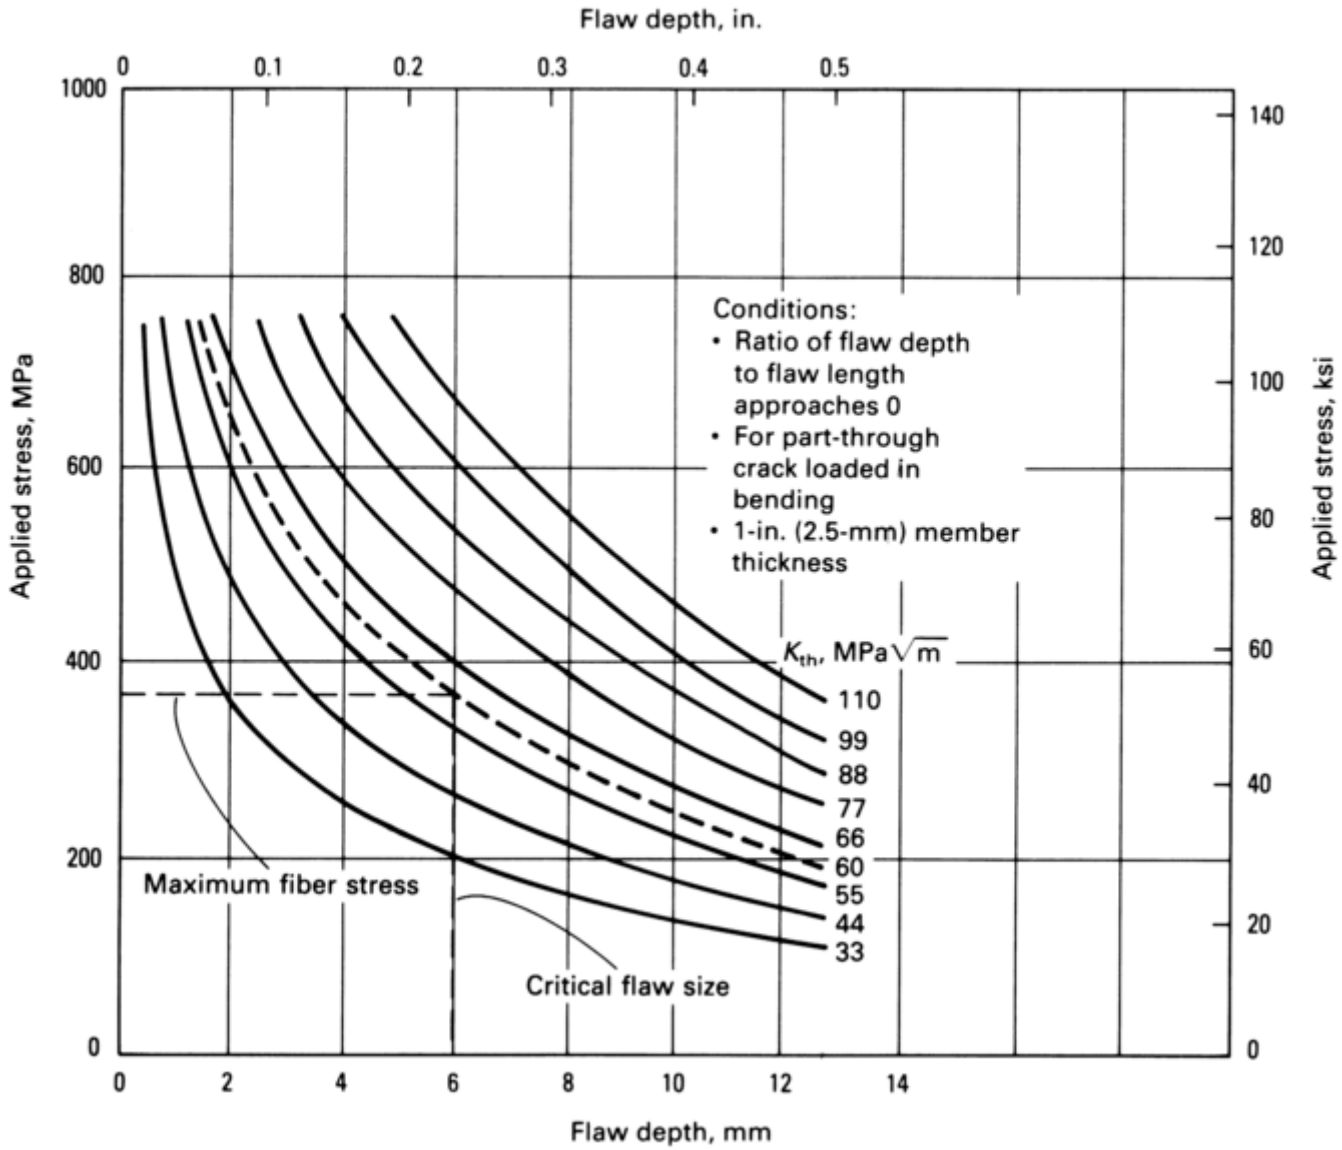

Fig. 60 Relationship of applied stress and flaw depth to crack propagation in hydrogen gas. Dashed lines show an example of the use of such a chart for a steel with K_{th} of 60.5 MPa$\sqrt{m}$ (55 ksi$\sqrt{in}$. at an operating stress of 359 MPa (52 ksi). Source: Ref 159

The requirements for K_{ISCC} tests, as well as for other fracture mechanics tests, include very explicit criteria regarding the minimum crack length for ensuring that the test results can be analyzed properly using existing linear fracture mechanics concepts. Therefore, a typical K_{ISCC} test uses a relatively large starting crack of the order of 25 mm (1 in.) long in a 25 mm (1 in.) thick specimen. In many types of service, however, initial defects of this size are rare. For example, damage-tolerant design criteria for military aircraft specify a flaw size of the order of 1.27 mm (0.05 in.) as the initial worst-case damage assumption upon introduction of a new part into service (Ref 155). Experimental work on high-strength steels exposed to hydrogen sulfide gas indicates that for a given combination of materials and applied stress there may indeed be a defect size below which the direct applicability of linear elastic fracture mechanics is questionable (Ref 163). Because of their susceptibility to SCC, however, high-strength steels should not be contemplated for service in the presence of hydrogen sulfide.

For example, Fig. 61 represents a concept of combining SCC thresholds based on smooth specimen and linear elastic fracture mechanics tests of aluminum alloy plate to give a conservative estimate of materials for design. As shown in Fig. 61, the threshold stress-intensity analysis breaks down in the small flaw region (ABE) when the smooth specimen threshold stress is exceeded. Therefore, the definition of a safe zone requires results from both types of tests; the exclusive use of either one of the test methods can yield nonconservative conclusions. It is anticipated that application and further development of elastic-plastic fracture mechanics theory will lead to

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

improved estimates of critical-stress/flaw-size combinations for the onset of SCC and tensile fracture, as proposed in Fig. 62.

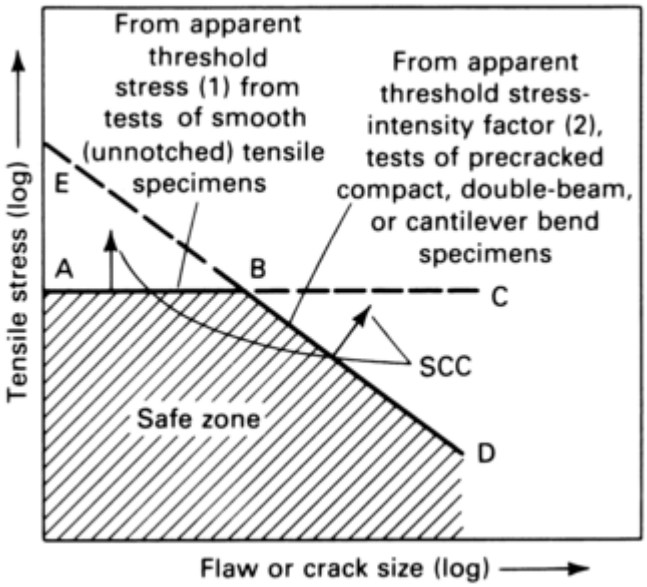

Fig. 61 Concept for combining SCC thresholds obtained on smooth and linear elastic fracture mechanics specimens to yield a conservative assessment of materials. SCC Velocity (V-K_I Curves). The issues of crack initiation and crack growth must be addressed for proper consideration of SCC response (Fig. 2). The use of mechanically precracked specimens provides a convenient approach for kinetic measurements where the crack growth rate can be determined as a function of the crack-tip stress-intensity factor (Fig. 3). Current emphasis, however, is on the identification of a steady-state response (plateau velocity) for the ranking of materials (Fig. 46). A disadvantage of this approach is that in some testing situations a plateau velocity is not observed (Fig. 63). However, for design purposes, the phenomena of incubation and the non-steady state response (stage 1, Fig. 3) must also be taken into account. However, these latter requirements are not well understood.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

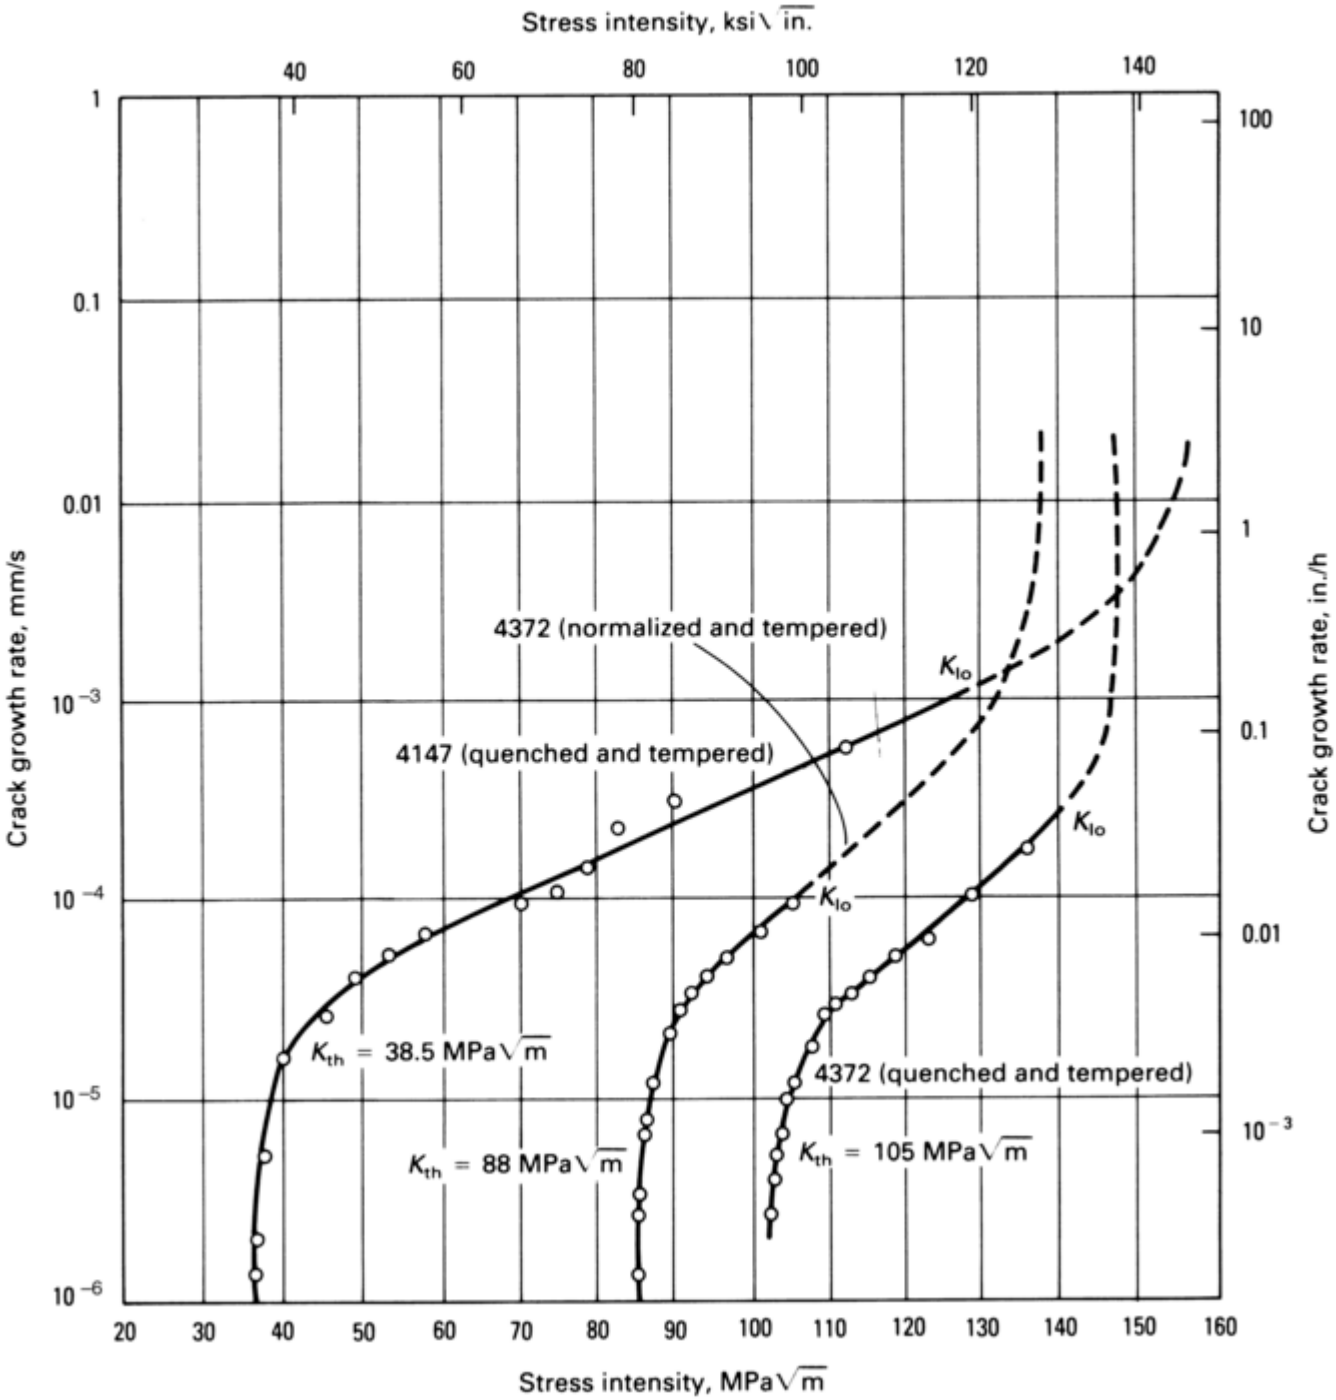

Fig. 63 Crack growth kinetics of three steels in hydrogen at 21 MPa (3000 psi). Source: Ref 159

An approximate approach to this problem of involving both the time of incubation (initiation) and the maximum crack growth rate of SCC at high stress intensities (plateau velocity) was proposed earlier in this article for use with testing of aluminum alloys with constant crack-opening displacement tests (Fig. 45 and Table 4). This involves a simple average rate taken from time zero to a judiciously chosen test duration. Useful ranking of materials can be displayed on V-K_I diagrams such as that shown in Fig. 48.

Another approach to the average velocity concept is available through an elastic-plastic fracture mechanics interpretation of breaking load test data obtained from stress corrosion tests of smooth tension specimens (Ref 22). The stress- corrosion crack growth rates estimated from the slopes of the curves in Fig. 17 from 0 to 4 or 6 days are shown in Table 10 to agree reasonably well with the plateau (K-independent) growth rates determined from conventional fracture mechanics tests using bolt-loaded double-beam specimens. It is also noteworthy that a distinction between the intermediate resistance T7X1 temper and the nearly immune T7X2 temper was made more readily using either the smooth specimen test or the average crack growth over 42 days with the double-beam specimen. Fractographic examination confirmed that this was a correct distinction.

Table 10 Stress-corrosion crack growth rates in aluminum alloy 7075 obtained by different test methods

Test method	Stress-corrosion crack growth rate					
	7075-T651		**7075-T7X1**		**7075-T7X2**	
	m/s	**in. × 10^{-5}/h**	**m/s**	**in. × 10^{-5}/h**	**m/s**	**in. × 10^{-5}/h**
Breaking load test using smooth tensile bar stressed 207 MPa (30 ksi); 4 or 6 days	>3.8 × 10^{-9}	>54[a]	7 × 10^{-10}	10[b]	1.3 × 10^{-10}	2[b]
Bolt-loaded double-beam, pop-in stress	3.1 × 10^{-9}	44	7.5 × 10^{-10}	11	[c]	[c]
Plateau velocity obtained from V-K_I curves						
Average growth 0–15 days	3.4 × 10^{-9}	48	4 × 10^{-10}	6	4 × 10^{-10}	6
Average growth 0–42 days	2.8 × 10^{-9}	40	4 × 10^{-10}	6	2 × 10^{-10}	3

(a) Over 4 days.
(b) Over 6 days.
(c) No plausible estimate could be made, because of the slight crack growth.
Source: Ref 3

The implication here, which needs further investigation, is that from a single test method it is possible to compare materials (1) on the basis of their probabilities of initiating and propagating SCC flaws to an arbitrary depth or (2) by their respective crack growth rates, both being meaningful engineering descriptors of SCC damage. An additional advantage to this approach is that the effects of specimen size and alloy strength and toughness can be normalized (Fig. 17).

Ductility Ratio (DR versus Strain-Rate Curves). Various ratio criteria, such as reduction of area, elongation, fracture stress, fracture energy, and time to failure, have been found to be useful in environmental studies with the slow- strain-rate test method. However, such criteria have limited use in comparing various materials because of their dependence on the strength and toughness of the alloy and the specificity of the critical strain rate and the environmental species (Fig. 33 and Table 2). Recent work has shown that average SCC growth rates, threshold stresses, and threshold strain rates can be obtained with modified techniques combined with microscopy. (Ref 62, 68, 69).

Other Criteria. Several other more specialized criteria can be found in the literature, such as:

- The Jones Stress Corrosion Index (Ref 90, 165)
- Critical Strain (Ref 121)
- Mean Critical Stress (Ref 166)

Precision of SCC Data

Variability in the measured values for SCC behavior arises from three primary sources: uncertainties associated with the measurement methods, variation in the test materials, and variation in the test environment. Suitable investigations must minimize the contributions from the first source and allow for quantitative assessment of the latter.

In the production of sophisticated high- strength and high-toughness alloys, close metallurgical control of the fabricating and thermal treatments is necessary to ensure that the required mechanical properties satisfy specifications. It is equally important from the standpoint of SCC that the metallurgical condition of the alloy be properly controlled. Just as there is a range of applicable mechanical properties for a given alloy and metallurgical condition (temper), a range in the SCC behavior can be expected from one heat (or lot) to another. Also, there can be an appreciable variation in the behavior of different-size mill products of the same material. An example of the variations in the SCC behavior of different lots and various mill products is shown in Fig. 48 for aluminum alloy 7050. When selecting a material for a particular structural component, SCC tests should be made on the specific products and sizes that will be required. Costly mistakes have been made in the past in the evaluation of prototype structures by testing parts fabricated from different products for economic expediency.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

It is an unfortunate circumstance that the precision of SCC test results is generally lower for materials with an intermediate resistance to SCC than for materials with a very low or a very high resistance. This presents a special challenge in the comparison of competitive materials with improved resistance to SCC. Unfortunately, there is a scarcity of test data for determining what portion of the scatterbands shown in Fig. 48 is due to material variations and how much is due to the precision of the test measurements.

Variability can occur even in carefully controlled investigations. Reference 167 reports results of measurements of K_{ISCC} for a 4340 steel made in numerous laboratories by different test methods.

In another investigation, the precision in the measurement of plateau velocities was determined for a number of replicate bolt-loaded double-beam specimens of short-transverse orientation from a sample of 25 mm (1 in.) thick 7075-T651 aluminum alloy plate (Ref 168). Tension pop-in specimens were exposed by continuous immersion in aqueous solutions of 1 *M* sodium chloride and 1 *M* sodium perchlorate. For six tests in the chloride solution, the mean plateau velocity was 1.4×10^{-8} m/s (1×10^{-3} in./h) with a standard deviation of 0.2×10^{-8} m/s (0.1×10^{-3} in./h), and the range was 1 to 2×10^{-8} m/s (7×10^{-4} to 1.4×10^{-3} in./h) (±35%). For nine tests in the perchlorate solution, the mean plateau velocity was 8×10^{-9} m/s (6×10^{-4} in./h) with a standard deviation of 0.2×10^{-9} m/s (1.4×10^{-4} in./h), and the range was 5×10^{-9} to 1×10^{-8} m/s (4 to 8×10^{-4} in./h) (±31%).

Normalizing SCC Data

It is often necessary to normalize test results with respect to one of the mechanical properties of critical interest for a given engineering structure in order to place the SCC response in proper perspective. This is commonly done by expressing the exposure stress (or stress intensity) and the apparent threshold values in terms of percent yield strength (or percent critical stress intensity) rather than in absolute units. This process can sometimes result in a different ranking order of alloys, and controversy can arise over which ranking is more pertinent. The use of normalized data is usually most appropriate when the utmost resistance to SCC is required; that is, the material should be resistant even when stressed to nearly 100% of the normalizing property. For alloy development screening tests, consideration should be given to evaluating materials in both ways.

Predicting Service Life

Life predictions are difficult and should be made with caution because there are no workable mathematical models. The field is plagued with confusion created to a large extent by:

- The complex, multifaceted nature of the phenomenon, which involves metallurgy, mechanics, chemistry, and time
- The large number of variables known to affect SCC behavior
- Relatively poor correlation between laboratory test results and service experience
- Extensive data scatter
- Difficulty in assessing precisely the service conditions that the part must withstand

Designing to avoid SCC has traditionally taken the approach of preventing the initiation of SCC (safe-life concept). There is considerable service experience to justify this; one factor is that the materials that have given the most service problems are capable of developing relatively high SCC propagation rates (of the order of 25 mm, or 1 in., per month as shown in Fig. 46). Growth rates of this order, combined with relatively low thresholds of stress or stress intensity, make the fail-safe concept rather impractical. However, with the availability of advanced materials with higher thresholds for initiation of SCC and lower propagation rates, the damage- tolerant concept of design may become more practical for SCC and corrosion fatigue.

Selection of Test Method

The SCC test method selected should not be so severe that it rejects a material that is adequate for a particular application. On the other hand, the test should not be so mild that it passes materials that will fail in service. For tests of new and unfamiliar materials or environments, it is expedient to perform more than one type of test. Although standardized tests, which can be specified for screening tests in alloy or process development or quality control, are an essential link between research and engineering, there is a need for much freer choice of test conditions for research studies of SCC mechanisms.

The appropriate SCC test method is the one that is best adapted to test the material product form to be evaluated and the one that will yield the type of test results that best address the test objective(s). The newer methods that use fracture mechanics type specimens and loading by means of a constant slow strain rate are more severe, when applicable, than the older techniques that use smooth (defect-free) specimens. However, the results of all tests require interpretation. The application of linear elastic fracture mechanics has opened the way to the correlation of the mechanical aspects of SCC test methods. It is anticipated that further development of the science of elastic-plastic fracture mechanics will enhance the application of test data to service needs.

Evaluating Hydrogen Embrittlement

Revised by Bopinder Phull, Consultant

Introduction

HYDROGEN EMBRITTLEMENT of metals is an old, frequently encountered, and often misunderstood phenomenon. It is most commonly thought to occur by subcritical crack growth, often producing time-delayed fractures in production parts, even with no externally applied stress. Many problems still exist, starting with a basic definition of hydrogen embrittlement, in addition to identifying its source, controlling its effects, and preventing its occurrence. This wide range of problems makes the evaluation of hydrogen embrittlement a multifaceted technical activity.

Research investigations on the phenomenon range from studies of crack nucleation and growth, including such parameters as incubation time, crack growth rates, and threshold stress intensities, to studies on the relative susceptibility of materials to hydrogen embrittlement. Practical implications of hydrogen embrittlement are discussed in the article “Hydrogen Damage and Embrittlement” in *ASM Handbook*, Volume 11 (2002), *Failure Analysis and Prevention.*

Evaluating Hydrogen Embrittlement

Revised by Bopinder Phull, Consultant

Toward a Definition (Ref 1)

Much confusion exists in the published literature over the definition of hydrogen embrittlement. Metal processing, chemical, and petrochemical industries have experienced various types of hydrogen problems for many years. The aerospace industry has experienced new and unexpected hydrogen embrittlement problems, principally in dealing with high-strength steels. There are many sources of hydrogen, several types of embrittlement, and various theories for explaining the observed effects.

Hydrogen embrittlement is often classified into three types:

- Internal reversible hydrogen embrittlement
- Hydrogen environment embrittlement
- Hydrogen reaction embrittlement

If specimens have been precharged with hydrogen from any source or in any manner and embrittlement is observed during mechanical testing, then embrittlement is caused by either internal reversible embrittlement or by hydrogen reaction embrittlement. If hydrides or other new phases containing hydrogen form during testing in gaseous hydrogen, then embrittlement is attributed to hydrogen reaction embrittlement. For all embrittlement determined during mechanical testing in gaseous hydrogen other than internal reversible and hydrogen reaction embrittlement, hydrogen environment embrittlement is assumed to be responsible.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Internal reversible hydrogen embrittlement has also been termed *slow strain rate embrittlement* and *delayed failure.* This is the classical type of hydrogen embrittlement that has been studied quite extensively. Widespread attention has been focused on the problem resulting from electroplating, particularly of cadmium, on high-strength steel components. Other sources of hydrogen are processing treatments such as melting and pickling. More recently, the embrittling effects of many stress-corrosion processes have been attributed to corrosion-produced hydrogen. Hydrogen that is absorbed from any source is diffusible within the metal lattice. To be fully reversible, embrittlement must occur without the hydrogen undergoing any type of chemical reaction after it has been adsorbed within the lattice.

Internal reversible hydrogen embrittlement can occur after a very small average concentration of hydrogen has been absorbed from the environment. However, local concentrations of hydrogen can be substantially greater than the average bulk value. For steels, embrittlement is usually most severe at room temperature during either delayed failure or slow strain rate tension testing. This time-dependent nature (incubation period) of internal reversible embrittlement suggests that diffusion of hydrogen within the lattice controls this type of embrittlement. Cracks initiate internally, usually below the root of a notch at the region where the triaxial stress (tensile hydrostatic stress) is maximum. Embrittlement in steel is reversible (ductility can be stored) by relieving the applied stress and aging at room temperature, provided microscopic cracks have not yet initiated. Internal reversible hydrogen embrittlement has also been observed in a wide variety of materials, including nickel-base alloys and austenitic stainless steels, provided they are severely charged with hydrogen.

Hydrogen environment embrittlement was recognized as a serious problem in the mid- 1960s when the National Aeronautics and Space Administration (NASA) and its contractors experienced failure of ground-based hydrogen storage tanks. These tanks were rated for hydrogen at pressures of 35 to 70 MPa (~5 to 10 ksi). Consequently, the failures were attributed to high-pressure hydrogen embrittlement. Because of these failures and the anticipated use of hydrogen in advanced rocket and gas turbine engines and auxiliary power units, NASA initiated both in-house and contractual research. The contractual effort had to define the relative susceptibility of structural alloys to hydrogen environment embrittlement. A substantial amount of research was concerned with the mechanism of the embrittlement process. Disagreement remains on whether hydrogen environment embrittlement is a form of internal reversible hydrogen embrittlement or is truly a distinct type of embrittlement.

Hydrogen Reaction Embrittlement. Although the sources of hydrogen may be any of those mentioned previously, this type of embrittlement is quite distinct from hydrogen environment embrittlement. Once hydrogen is adsorbed, it may react near the surface or diffuse substantial distances before it reacts. Hydrogen can react with itself, with the matrix, or with a foreign element in the matrix. The chemical reactions that comprise this type of embrittlement or attack are well known and are encountered frequently. The new phases formed by these reactions are usually quite stable, and embrittlement is not reversible during room temperature aging treatments.

Atomic hydrogen (H) can react with the matrix or with an alloying element to form a hydride (MH_x). Hydride phase formation can be either spontaneous or strain induced. Atomic hydrogen can combine to form molecular hydrogen (H_2). This problem is frequently encountered after steel processing and welding; it has been termed *flaking* or "*fisheyes.*" Atomic hydrogen can also react with a foreign element in the matrix to form a gas. A prime example is the reaction with carbon in low-alloy steels to form methane (CH_4) bubbles. Another example is the reaction of atomic hydrogen with oxygen in copper to form steam (H_2O), resulting in blistering and a porous metal component.

Although hydrogen reaction embrittlement is not a major topic in this article, its definition is included for the sake of completeness and in the hope of establishing a single definition for each of the various hydrogen embrittlement phenomena to avoid problems with semantics.

Further confusion results from the relation of stress-corrosion cracking (SCC) to hydrogen embrittlement, because the crack-growth mechanism is often found to be the same in both cases. On the surface, the active corrosion process produces the hydrogen that is the cause of the failure. In SCC, the pits or crevices (polarized anodically) are initiation sites, and therefore, although the growth mechanisms are the same, the method of prevention based on initiation can be different.

Evaluating Hydrogen Embrittlement

Revised by Bopinder Phull, Consultant

Sources of Hydrogen

Hydrogen embrittlement generally occurs in service either in association with self-corrosion in acidic environments or when the part is being protected from corrosion; for example, during cathodic protection of high-strength steel. Atomic hydrogen is generated at the metal surface either due to reduction of hydrogen ions (in acidic environments) or due to dissociation of water in neutral-pH environments (e.g., when cathodic protection is applied). Failures that occur after a period of time are related to the diffusion of atomic hydrogen into the metal. The fracture path is usually intergranular in steels. Not all intergranular failures in steels however, are due to hydrogen embrittlement. In addition, not all hydrogen embrittlement failures in other metals and alloys are intergranular.

Time-delayed embrittlement failures are caused by the residual atomic hydrogen in the steel from the making or melting process and the atomic hydrogen introduced into the steel during processing and subsequent manufacture (for example, plating, machining with hydrocarbon- based oils, pickling, and welding). The atomic, diffusible, or nascent hydrogen (H) is the cause of the problem, not the total hydrogen that includes molecular hydrogen (H_2). Also necessary is applied stress or residual stress from welding or heat treating. Hydrogen embrittlement is generally found in high-strength steels, but hydrogen stress cracking (HSC) has been reported for other materials, such as refractory metals, superalloys, and even austenitic steels, when tested under high-pressure hydrogen gas.

Evaluating Hydrogen Embrittlement

Revised by Bopinder Phull, Consultant

Source of Stress

Cracking studies of high-strength steels in aqueous chloride solutions at potentials more electronegative than the open-circuit potential of about -0.6 V versus a saturated calomel electrode (SCE) are, in reality, hydrogen embrittlement tests, because the steel is at a cathodic potential; that is, hydrogen is produced at the surface of the steel. The worst case, or the most severe condition that produces cracking, is generated when atomic hydrogen is produced while the part (or test coupon) is under stress. This is the reason hardware is processed (plated) with no stress (except unavoidable manufacturing-induced residual stresses) and then stress relieved or baked before being placed in service. If residual stresses exist during plating, the part could break or at least have microcracks that subsequently lead to an early service failure.

Hydrogen relief or baking treatments can be effective in removing atomic hydrogen from steel. However, this does not ensure that hydrogen is removed from the part. The hydrogen can reside as molecular hydrogen at the interface between the steel part and a plating or coating. Sulfur, in the form of manganese-sulfide inclusions commonly found in steel, can act as a poison to dissociate the molecular hydrogen to atomic hydrogen. At the point of high stress, atomic hydrogen will then diffuse back into the steel part and eventually lead to time-delayed hydrogen embrittlement failure.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Because there are three sources of hydrogen— the manufacture of steel (melting), processing and manufacturing, and in-service (environment)—and because there are three sources of stress—applied, residual from heat treatment, and residual from welding or plastic deformation—nine possible combinations exist. Therefore, it is not always easy to identify the specific cause of a hydrogen embrittlement service failure. A comprehensive evaluation of hydrogen embrittlement service failures should include all nine possibilities. An evaluation of the possible controls that avoid in-service hydrogen embrittlement failures must focus on either eliminating the sources of hydrogen or operating at a sufficiently low stress (below the threshold) to prevent cracking.

Current hydrogen embrittlement prevention and control procedures are primarily directed at the plating process and use of in-service maintenance chemicals. These procedures are covered in ASTM F 519 (Ref 2). Over 30 military and federal specifications include hydrogen embrittlement relief treatments. Hardware, such as springs or structural fasteners, is tested directly by sustained or step-load stress tests to evaluate the effectiveness of the hydrogen embrittlement relief treatments.

Evaluating Hydrogen Embrittlement

Revised by Bopinder Phull, Consultant

Testing

Tests for hydrogen embrittlement are performed to determine the effect of hydrogen damage in combination with residual or applied stresses. In the past decade, conventional testing methods have been modified to incorporate fracture mechanics, and the various types of hydrogen damage have been further classified in terms of crack nucleation, crack growth rates, and threshold stress intensity measurements.

This section discusses the current methods of hydrogen embrittlement testing and focuses on accelerated small-specimen testing methods for failure analysis and production control of hydrogen embrittlement. Additional information on hydrogen damage in metals and on test methods for hydrogen embrittlement can be found in Ref 1, 2, 3, 4, 5, 6, 7, 8, 9.

Standardized Tests. The only current ASTM standards for hydrogen embrittlement testing are F 519 (Ref 2) and F 326 (Ref 3). These standards are based on (a) not putting hydrogen into the steel by keeping the hydrogen in the plating bath at acceptably low levels (ASTM F 326) and (b) using mechanical tests to ensure that the amount of residual hydrogen after baking is below acceptably low levels (ASTM F 519).

ASTM F 326. This standard method covers an electronic hydrogen-detection instrument procedure for the measurement of plating permeability to hydrogen, a variable that is related to hydrogen absorbed by steel during plating and to the hydrogen permeability of the plate during post-plate baking. A specific application of this method involves controlling cadmium-plating processes in which the plate porosity relative to hydrogen is critical, such as for high-strength steels.

This method uses a metal-shelled vacuum probe as an ion gage. A section of the probe shell is cadmium plated at the lowest current density encountered in the electroplating process. The probe ion current, proportional to hydrogen pressure, is recorded as a function of time during subsequent baking. The slope of this curve has an empirical relationship to failure data, such as those discussed in ASTM F 519.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

ASTM F 519. This method covers the evaluation of the hydrogen-generating potential of fluids (aircraft maintenance chemicals) and the hydrogen embrittlement control of electroplating processes. Test specimens are installed to indirectly monitor the amount of hydrogen in the plating bath when actual hardware is being plated. The acceptable level of hydrogen is determined by a go/no-go situation established by the failure of a sustained-loaded, stressed specimen that has been baked at 191 °C ± 14 °C (375 °F ± 25 °F) for a minimum of 23 h. The procedures and requirements are specified for the following five types of AISI 4340 steel test specimens:

- Type 1a: notched round bars, stressed in tension, under constant load
- Type 1b: notched round bars loaded in tension with stressed O-rings
- Type 1c: notched round bars loaded in bending with loading bars
- Type 1d: notched C-rings loaded in bending with loading bolt
- Type 2a: unnotched ring specimens loaded in bending with displacement bars

For plated parts, no stress is applied until they have been baked; baking is specified to occur within 1 h after plating. For maintenance chemicals and cleaners, stress is applied before the test specimens are exposed to the environment. The latter condition is much more severe and discriminates against much lower levels of hydrogen but is more representative of the end use of a part.
The cantilever beam (CB) test is a constant- load test in which a V-notched specimen of a rectangular cross section is subjected to a bending load via a moment arm. A precrack at the root of the V-notch is initiated and extended by fatigue before testing. The area with the precrack is enclosed by an environmental chamber, which contains the environment during the test (Fig. 1a). The specimen is subjected to a constant load over a predetermined time period. The actual stress intensity, K_I, is a complex function of the bending moment, crack length, and specimen geometry:

$$K_1 = 4.12 \cdot M_0 \cdot \sqrt{\left(1/\alpha^3 - \alpha^3\right)/\left(B \cdot W^{3/2}\right)} \qquad \text{(Eq 1)}$$

where $\alpha = 1 - (a/W)$ and where M_0, B, and W are as defined in Fig. 1(b). The range of applicability for Eq 1 is $0.2 \leq (a/W) \leq 0.6$. ASTM E 1681 provides detailed descriptions of specimen preparation, testing, and interpretation of results (Ref 11). Other methods of loading or using nonrectangular test specimens are described in ASTM E 399 (Ref 12). As the crack grows, the stress intensity increases. Time to failure is plotted versus applied stress intensity. The lower limit of the resultant curve is a threshold stress intensity for hydrogen embrittlement, K_{IHE}, as shown in Fig. 2.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 2 Procedure to obtain K_{IHE} with precracked cantilever beam test specimen. Source: Ref 10

The K_{IHE} results of a cantilever beam test depend on how much time elapses before the test is terminated. Recommended test periods for establishing the true stress intensity threshold range from 200 h, which is typical for hydrogen embrittlement testing, to as long as 5000 h (Ref 13). Another limitation of this test method is that it can be expensive in terms of materials and machining. As many as 12 specimens placed under different loads in separate test machines are needed for each test in order to obtain valid K_{IHE} values.

The wedge-opening load (WOL) test applies a constant wedge- or crack-opening displacement. The actual stress intensity is a complex function of load, crack length, and specimen geometry. As the crack extends, stress intensity decreases until crack arrest occurs (Fig. 3). Crack growth can be monitored either by direct optical means (e.g., vernier microscope) or indirectly from strain gages attached to the back face. The initial load is assumed to be slightly above K_{IHE}. The specimen is maintained under these conditions for about 5000 h to establish the threshold. The crack grows to a point after which further growth is not measurable (K_{IHE}). However, it is difficult to determine precisely when the no- growth criterion is met. In some cases, it may be necessary to assume some minimum threshold crack growth rate such as 10^{-7} mm/s. Crack tip opening displacement should also be monitored. Corrosion reactions, accompanied by expansion in volume, may occur at the crack tip. This changes the opening displacement and increases the load, thus altering the desired testing conditions.

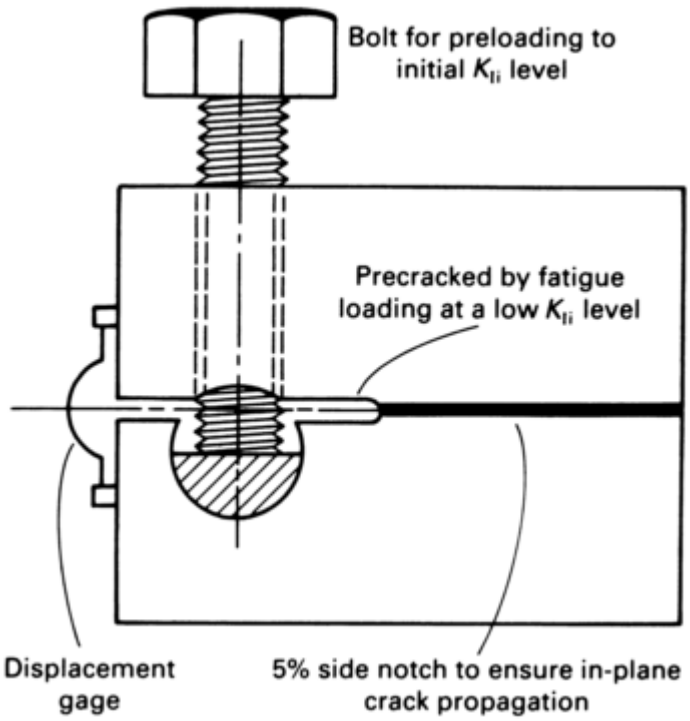

Fig. 3 Schematic showing basic principle of modified wedge-opening load test specimen

As subcritical crack extension occurs, stress intensity increases in the cantilever beam test and decreases in the WOL test (Fig. 4). Generally, the threshold stress intensity measured with the WOL test is lower than that measured with the cantilever beam test (Ref 14). A major advantage of the WOL test is that, in principle, only one specimen is required to measure K_{IHE}. In practice, if possible, it is prudent to test several replicate specimens concurrently.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

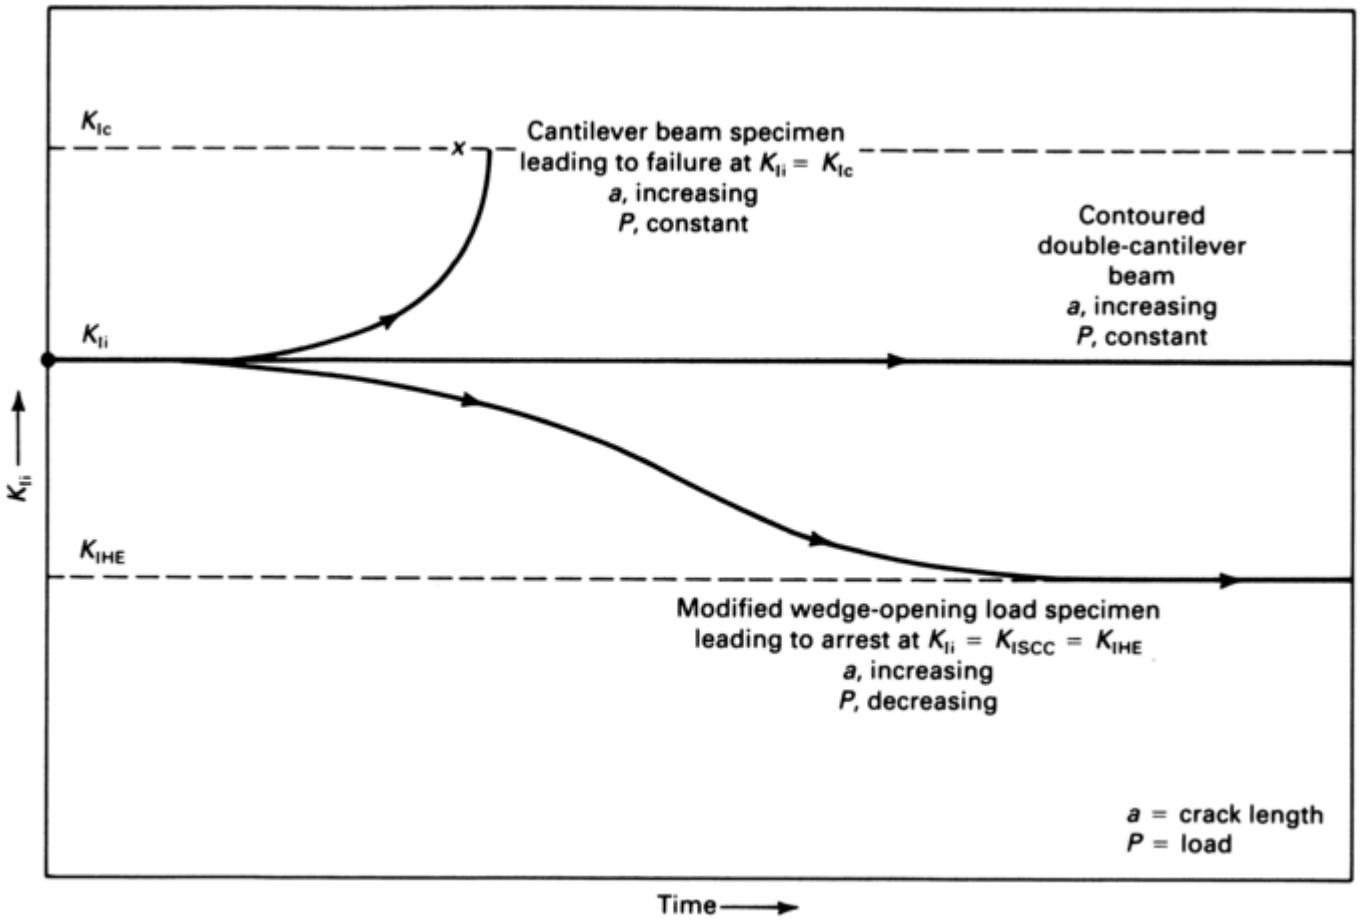

Fig. 4 Influence of time, crack extension, and load on stress-intensity behavior of modified wedge-opening load, cantilever beam, and contoured double-cantilever beam test specimens. Source: Ref 10

In long-term tests, it is essential to ensure that the concentration and the composition of the environmental solution do not change over time. For example, evaporation increases concentration and possible “salting” out at the waterline. Ultimately the solution level may drop below the crack line of the specimen. Such factors can render the test results invalid.

Figure 5 shows the results of WOL and cantilever beam tests on 25.4 mm (1 in.) thick iron- nickel-cobalt alloy steel specimens. The data imply that the wedge-opening load K_{IHE} crack- arrest result is the lower limit for the cantilever- beam K_{IHE} threshold.

www.iran–mavad.com
مرجع مهندسی مواد و متالورژی

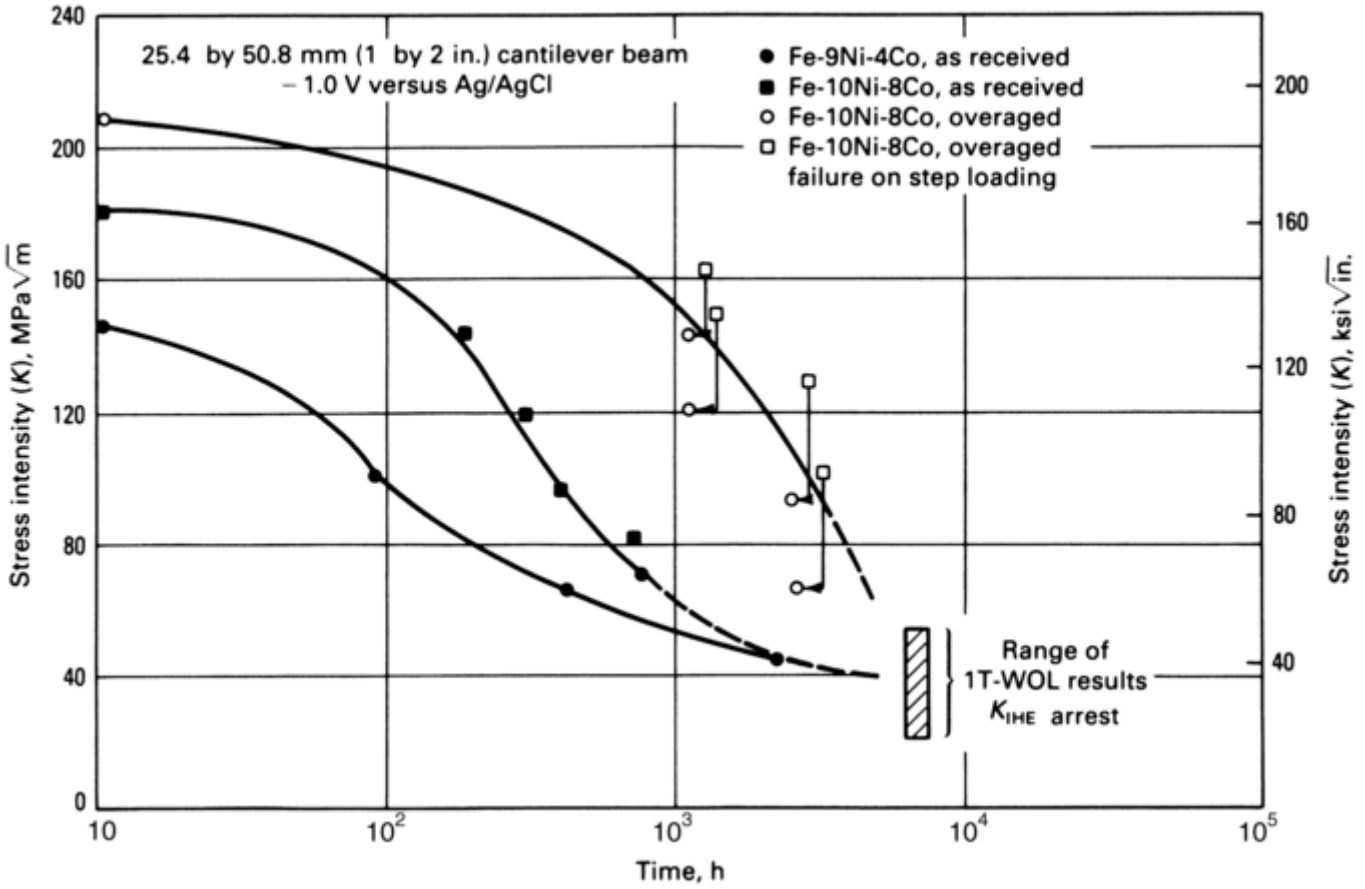

Fig. 5 Comparison of single-edge-notched cantilever beam and wedge-opening load test results for hydrogen embrittlement cracking of iron-nickel-cobalt steels. Source: Ref 15

The open circles in Fig. 5 represent “no fracture” at various exposure times for an overaged Fe-10Ni-8Co alloy in a cantilever beam test. The open squares indicate failure at increased stress intensities, following step loading at various exposure times at the lower stress intensity. The results suggest that increasing the load during the test produces more aggressive hydrogen-embrittlement conditions than a constant load.

This may be due to the possible formation of an oxide film on the surface. When the load is increased, the oxide film is broken, exposing fresh metal; more hydrogen is produced at the crack tip. For this reason, the test should use a rising load, because the constant-load cantilever beam test does not provide worst-case (fresh- metal-exposed) loading conditions.

The data also suggest that the cantilever beam test can generate an artificially high K_{IHE} threshold, depending on the time limit selected. If the test had been terminated at 200 h rather than at 5000 h, the reported K_{IHE} values from the cantilever beam test (Fig. 5) would have been four times higher than those measured after the longer time period. Similarly, the incubation period may not be exceeded, and no crack growth will occur if insufficient time is allowed in the wedge-opening load test.

Both testing methods require costly and time- consuming steps and result in a parameter, K_{IHE}, whose design significance is questionable. However, the parameter does provide a relative ranking of susceptibility to hydrogen embrittlement and, more generally, to SCC.

The contoured double-cantilever beam (DCB) test is used to measure crack growth rate at a constant stress intensity factor. This test simplifies the calculation of stress intensity by using a contoured specimen so that stress intensity is proportional to the applied load and is independent of the crack length. Thus, under a constant load, stress intensity remains constant with crack extension. For the test geometry shown in Fig. 6, the stress intensity factor equals 20 times the load ($K = 20P$).

مرجع مهندسی مواد و متالورژی

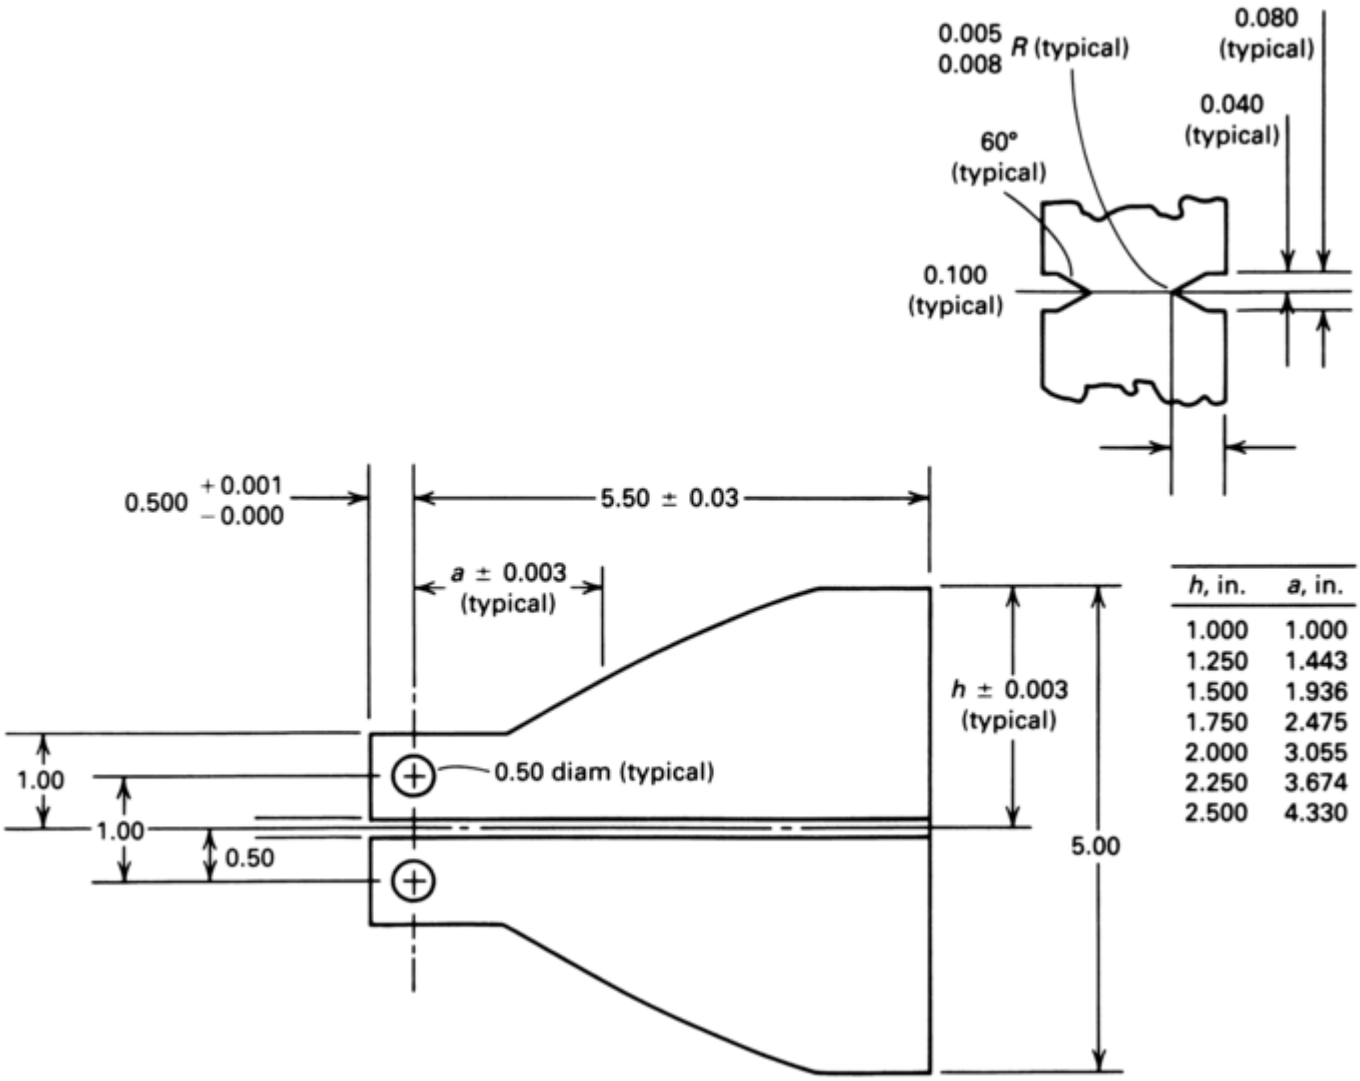

Fig. 6 Dimensions and configuration for double-cantilever beam test specimen. Specimen contoured to $3a^2/h^3 + 1/h = C$, where C is a constant. All values given in inches (1.0 in. = 25.4 mm)

Data on hydrogen embrittlement can be obtained with specimens of lower thickness (Ref 16) that do not otherwise meet the ASTM requirement of $K^2_{max} < 0.4\ B/(YS)^2$ (where B is the thickness and YS is the yield strength of the specimen), by using side grooves. Side grooves provide additional constraint on the material being tested. They also enable the maintenance of a plane-strain condition in a thin specimen by enhancing the triaxial state of the stress. This method has been extensively used to study the effect of heat treatment (hardness) and environment on the hydrogen stress cracking (HSC) of AISI 4340 steels (Fig. 7).

مرجع مهندسی مواد و متالورژی

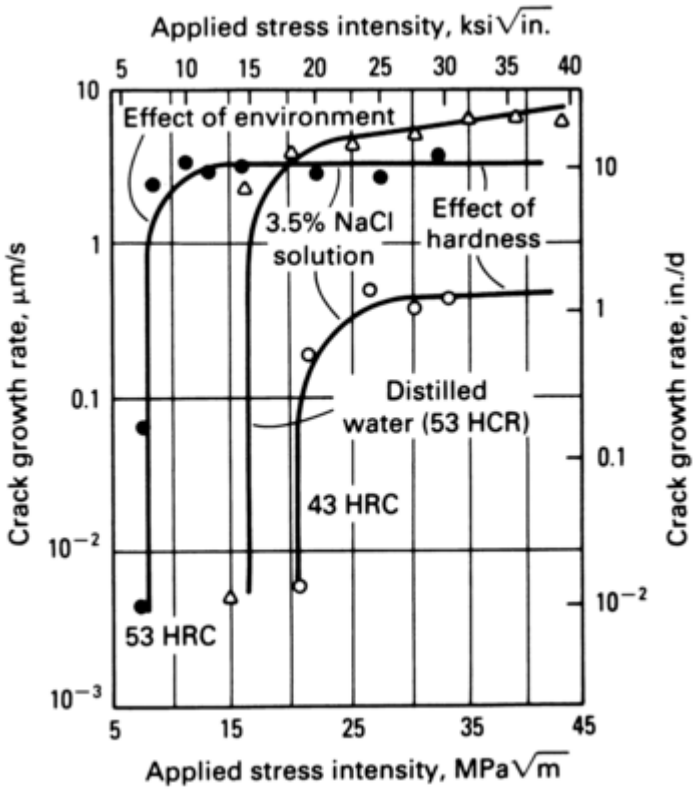

Fig. 7 Hydrogen embrittlement crack growth rate as a function of applied stress intensity for two different hardnesses and environments for an AISI 4340 steel, contoured double-cantilever beam test specimen

The contoured double-cantilever beam test has also been used to study the stress history effect that produces an incubation time before HSC. Figure 8 shows that incubation time is dependent on the type of steel. A decrease in the stress intensity factor from 44 to 22 MPa$\sqrt{m}$ (40 to 20 ksi$\sqrt{\text{in.}}$) may change the incubation time from less than 1 h for AISI 4340 steel to about 1 year for type D6-AC steel.

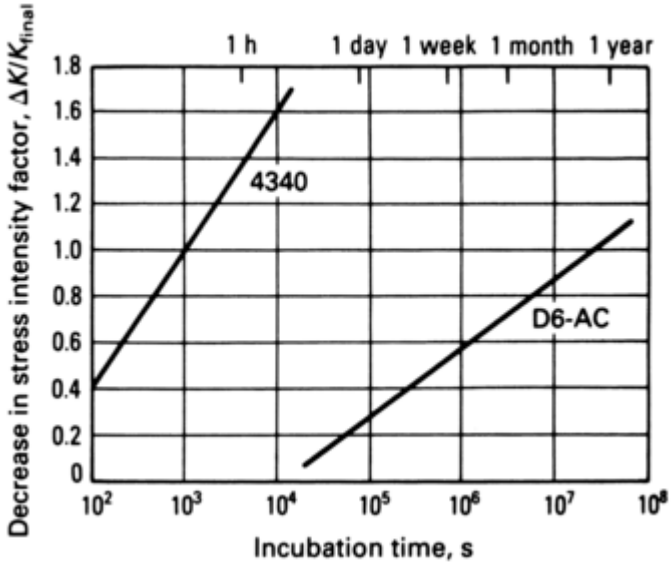

Fig. 8 Incubation time for crack growth in AISI type 4340 and type D6-AC steel contoured double-cantilever beam test specimens as a function of decrease in stress intensity. Source: Ref 17

Three-Point and Four-Point Bend Tests. The contoured double-cantilever beam test uses a constant load to maintain a constant stress intensity factor with crack extension. The same effect can be produced by using a three- or four- point bend test under displacement control. These tests use heavily side-grooved Charpy V-notch specimens (Fig. 9). Because crack-opening displacement is constant as the crack extends, the load

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

decreases. However, there is a slight initial increase in stress intensity to a maximum value that drops slightly as the ratio of crack depth to specimen width exceeds 0.5. Typically, stress intensity is constant within a small range. Figure 10 compares the change in stress intensity factor with crack extension for load control to that of displacement control for a three-point bend specimen.

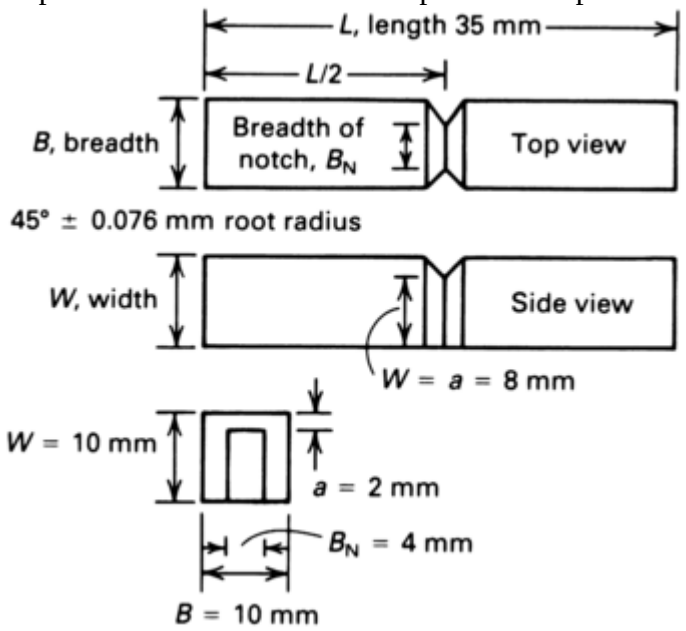

Fig. 9 Side-grooved Charpy V-notch test specimen used for three- and four-point bend tests

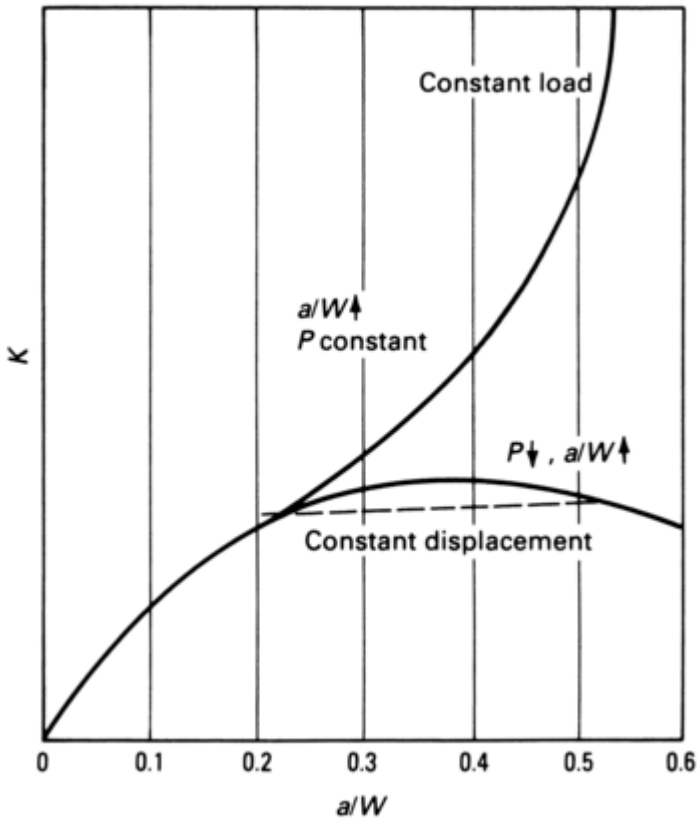

Fig. 10 Change in stress intensity factor with crack extension as a function of load control and displacement control for a three-point bend specimen

The rising step-load test provides a stress intensity that is different at each load but remains constant with crack extension as the load level is sustained. Crack initiation is signaled by a drop in load (Fig. 11). The rising step-load test was developed as an accelerated low-cost test for measuring the resistance of steels (particularly weldments) to hydrogen embrittlement (Ref 13, 17). The threshold obtained by this method could be slightly

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

higher if the test duration of each load is too short, but the test duration can be extended near the initiation loads in duplicate tests in order to obtain a more accurate measurement.

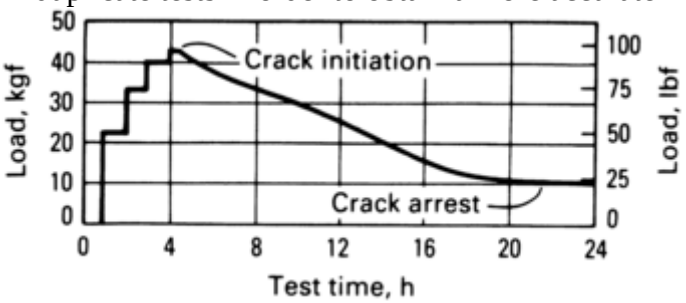

Fig. 11 Typical load-time record for four-point rising step-load test. Source: Ref 18

To index susceptibility to hydrogen-assisted cracking, the test should last no longer than 24 h, and the hydrogen source should reflect the most aggressive environment. In one experiment, a 3.5% sodium chloride solution was selected to simulate seawater, and a cathodic potential of -1.2 V versus SCE was used to generate hydrogen in order to reflect worst-case conditions of cathodic protection on a ship hull.

A Charpy specimen was chosen because such specimens are small and easy to machine and handle. In this test, however, the specimen was modified. Instead of using fatigue precrack, the notch-root radius was machined to less than 7.6 μm (3 mils). This was done to lower the cost and to give less ambiguous environmental conditions at the crack tip. Also, hydrogen cracks nucleate below the surface.

The specimen was deeply side grooved, a common practice used in crack growth rate tests to prevent the crack from branching. Side grooves are also used in crack-opening displacement or *J*-integral testing in order to cause load displacement curves to increase monotonically to fracture by inducing a highly triaxial stress field at the crack tip. Because a Charpy specimen is small, deep side grooves produce a triaxial stress field at the notch and thus promote crack initiation. The extent of the side grooving is such that the remaining ligament is only 40% of the original thickness. The modified Charpy specimen dimensions are shown in Fig. 9.

The specimen was loaded by means of beams and an instrumented bolt (Fig. 12). Four-point bending under constant displacement control and stress intensity results in crack growth. Once cracking initiates at the notch (a/W = 0.2, where a is crack length and W is width of the specimen), arrest does not occur until the crack is nearly through the specimen. The load is manually increased at 1 h intervals. An environmental chamber encompasses the specimen and includes a potentiostat to produce hydrogen while the specimen is under stress.

مرجع مهندسی مواد و متالورژی

Fig. 12 Loading frame used for rising step-load test

The rising step-load test was used to evaluate high-strength HY ship steels and weldments in an environment simulating seawater under conditions of cathodic protection commonly employed to protect ship hulls (Ref 17). Samples from the heat-affected zone (HAZ) and other locations in the weld metal were tested. Interlayer gas tungsten arc heating was evaluated as a means of providing a refined, homogeneous, tempered microstructure with improved resistance to HSC. As a baseline, HY-130 and HY- 180 steels were compared.

Figure 13 plots rising step-load test results for HY-130 and HY-180 base metals, in addition to combinations of modified HY steel compositions and programmed-cooling-rate thermal cycles for the base metal and the weld wire. The vertical axis is a plot of a parameter derived from the specimen strength ratio in ASTM E 399— that is, 6 $P_{max}/B(W - a)^2$YS, where P_{max} is the maximum load that the specimen is able to sustain, B is the specimen thickness, W is the specimen width, a is the crack length, and YS is the yield strength in tension. For the data shown in Fig. 13, P_{max} was replaced by the crack initiation load. The horizontal axis is a ratio of K_{IHE}/YS, which was measured in a separate test program with cantilever beam and wedge-opening load specimens.

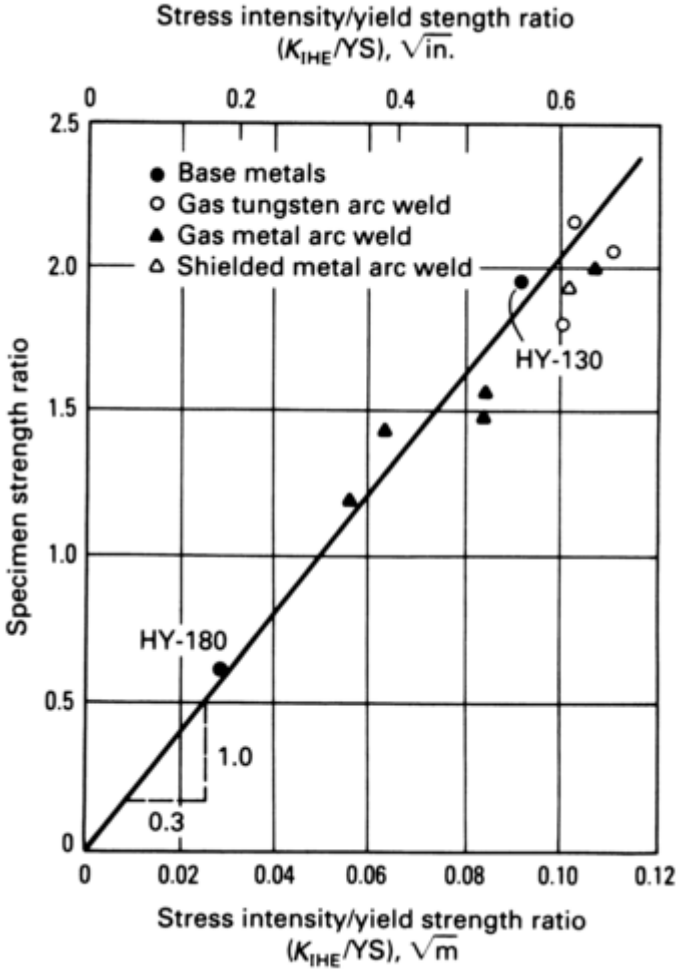

Fig. 13 Analytical correlation of strength ratio with threshold stress intensity data

The resistance to hydrogen embrittlement of the two base metals and six locations in HY-130 weldments was ranked by using this testing method. Test results showed that HY-180 is more susceptible to HSC than HY-130 and that the resistance to hydrogen embrittlement of specimens taken from the HAZ and the fusion line is consistently higher than that of weld metal specimens. The HSC resistance of the weld metal is affected by grain structure. Interlayer gas tungsten arc reheating homogenized the weld structure but did not temper the weld metal. Specimens from the gas tungsten arc reheated weldment consistently exhibited higher hardness and lower resistance to hydrogen embrittlement than similar specimens from the standard HY- 130 weld metal (Ref 14, 19).

The disk-pressure testing method measures the susceptibility to hydrogen embrittlement of metallic materials under a high-pressure gaseous environment (Ref 20). The test is used for the selection and quality control of materials, protective coatings, surface finishes, and other processing variables.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

In this test, a thin disk of the metallic material to be tested is placed as a membrane in a test cell and subjected to helium pressure until it bursts. Because helium is inert, the fracture is caused by mechanical overload; no secondary physical or chemical action is involved. An identical disk is placed in the same test cell and subjected to hydrogen pressure until it bursts. Metallic materials that are susceptible to environmental hydrogen embrittlement fracture at a pressure lower than the helium-burst pressure. Materials that are not susceptible fracture under the same pressure for both hydrogen and helium.

The ratio, S_{H2}, between the helium-burst pressure, P_{He}, and the hydrogen-burst pressure, P_{H2}, indicates the susceptibility of the material to environmental hydrogen embrittlement: $S_{H2} = P_{He}/P_{H2}$. If S_{H2} is equal to or less than 1, the material is not susceptible to environmental hydrogen embrittlement. When S_{H2} is greater than 2, the material is considered to be highly susceptible. At values between 1 and 2, the material is moderately susceptible, with failure expected after long exposure to hydrogen. The material must be protected against such exposure.

A compilation of test results is shown in Fig. 14. The alloys having little or no sensitivity are 7075-T6 aluminum; Haynes 188 (cobalt base); beryllium copper (copper base); types 304, 316, and 310 austenitic stainless steel; type 430 ferritic steel; and age-hardened austenitic A 286 steel. Titanium-base alloy Ti-6Al-4V exhibits moderate sensitivity. Alloys with high sensitivity are Haynes 25 (cobalt base) and iron-base alloys, including medium- and high-strength steels. Conventional testing methods, such as the cantilever beam, wedge-opening load, and contoured double-cantilever beam tests, have also been adapted for testing in high-pressure gaseous hydrogen environments.

Slow strain rate tensile tests can be used to evaluate many product forms, including plate, rod, wire, sheet, and tubing, as well as welded parts. Smooth, notched, or precracked specimens can be used. The principal advantage of this standardized test is that the susceptibility to HSC for a particular metal-environment combination can be rapidly assessed (Ref 21).

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

A variety of specimen shapes and sizes can be used. The most common is a smooth bar tensile coupon, as described in ASTM E 8 (Ref 22). The specimen is exposed to the environment and stressed monotonically at a slow but constant rate until complete fracture occurs. Typically, the output is a stress versus elongation. Tests are usually conducted over a range of strain rates; for example, 10^{-5} to 10^{-8} mm/mm/s. Interpretation of test results is based on one or more of the following parameters:

- Time to failure
- Ductility, for example, % elongation and/or reduction in cross-sectional area at the fracture
- Maximum stress (ultimate tensile strength, or UTS) achieved
- Fracture energy; that is, the area bounded by the stress-elongation curve

Potentiostatic Slow Strain Rate Tensile Testing. Studies have been conducted on the use of dissociated water under potentiostatic conditions that produce hydrogen on the surface of the tensile test specimen while under slow strain rate displacement control. Results suggest that hydrogen is the most significant parameter in hydrogen-sulfide SCC found in oil fields (Ref 23).

Evaluating Hydrogen Embrittlement

Revised by Bopinder Phull, Consultant

Interpretation of Test Results

The phenomenon of hydrogen embrittlement or SCC is very complex. The test results depend on environmental conditions (potential, pH, oxygenation level, temperature, environment), material and melting procedure (air, vacuum, electroslag remelting, vacuum arc remelting, and so on); test specimen geometry (notched tensile or bend specimens, cantilever beam specimens, wedge-opening loaded specimens), and specimen preparation (grinding, polishing, fatigue precracking, etc.). Because of the complex interactions between these factors, characterization of resistance (or conversely, susceptibility) to HE in absolute terms is almost impossible. The purpose of testing is to address a very specific set of conditions. Evaluation is, therefore, typically based on comparing data from controls (not subjected to HE) and specimens exposed to hydrogen—usually for various time periods.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The existing standard, ASTM F 519, is based on the assumption that air-melted AISI 4340 (Rockwell hardness 53 ± 1 HRC) is a worst- case condition. If no fracture occurs in this specimen after 200 h at 75% of the notched strength, then other 4340 steels processed by alternate melting processes (even steels with higher hardness levels because of vacuum melting) will not have residual levels of atomic hydrogen that would produce sustained-load failure in the environment of concern. Data to support this claim are shown in Fig. 15, which shows the extreme susceptibility of air melted 4340 steel as compared to electroslag remelted or vacuum arc remelted 4340 steel. This test is a “go/no-go” test intended to indicate relative susceptibility to HE of air-melted 4340 according to MIL S-5000E.

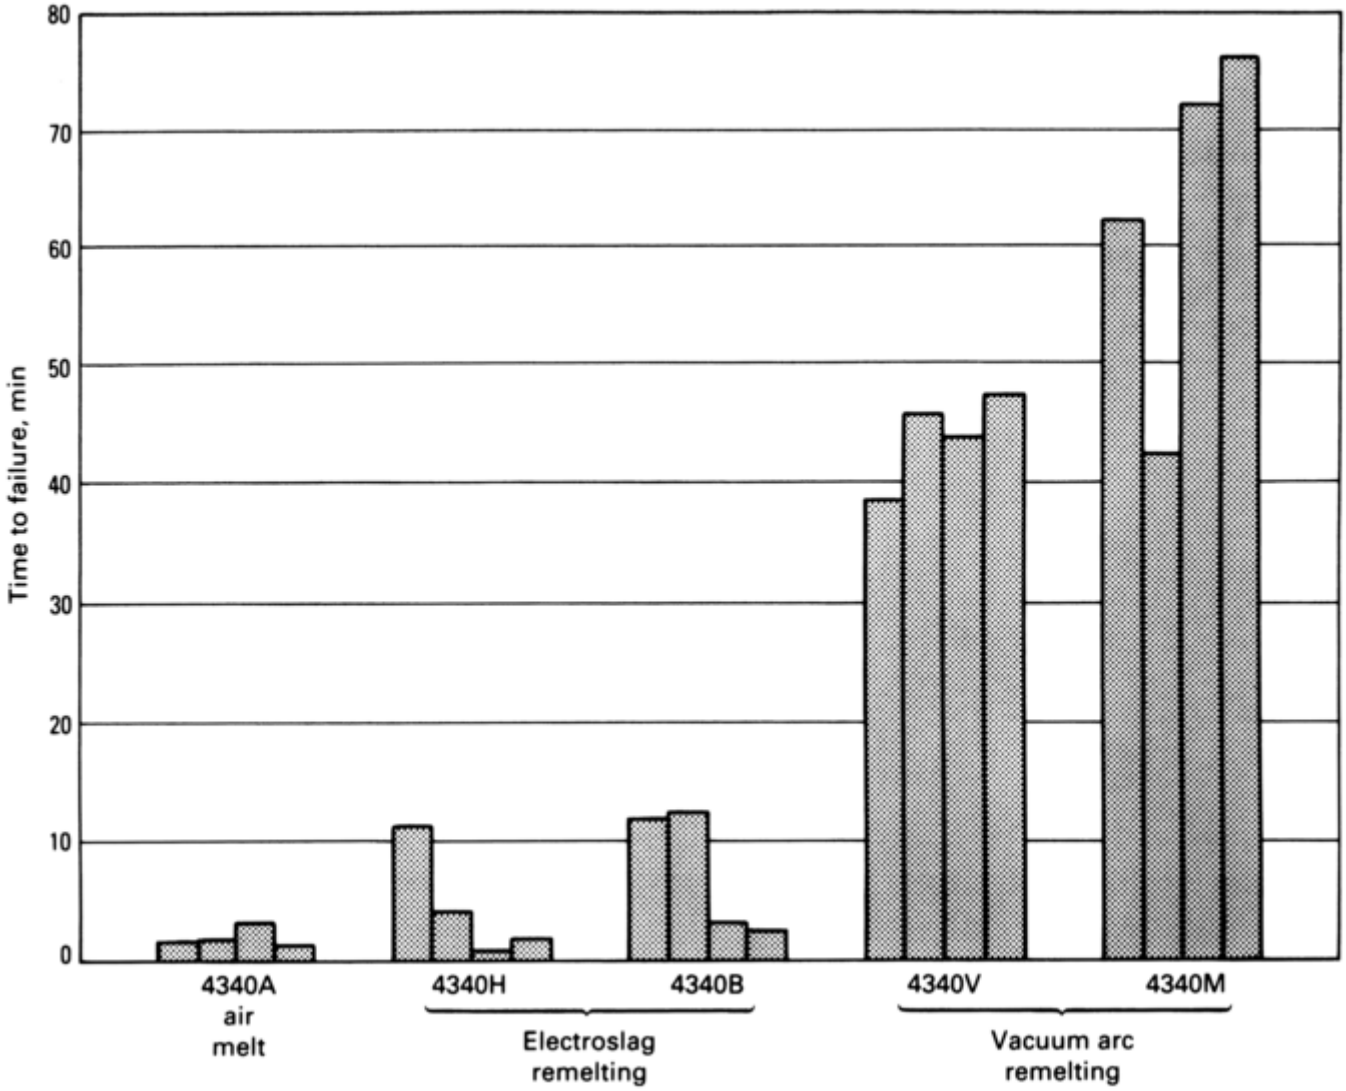

Fig. 15 Time to failure for AISI 4340 high-strength steels with an ultimate tensile strength range of 1790–2070 MPa (260–300 ksi) using ASTM F 519, Type 1c bend specimens. Source: Ref 24

This quality-control method suffers from the fact that manufacturing-induced stresses in the part might not be the same as in the representative test coupon. This is why stress-relief before plating is advised. If the coupon is stress free but the parts have a high residual stress, the coupons will pass the 200 h sustained-load test, but the parts, which might have cracked during plating, may inadvertently be put into service, or vice- versa.

To prevent misrepresentation, hardware or parts are often tested directly, such as in the case of fasteners or springs, and the use of representative test coupons is completely avoided. The problem with testing actual hardware is twofold. First, the test is destructive and can be costly, depending on the type of hardware being evaluated. Second, the method of applying the stress and the magnitude of the applied stress are not always easily obtained. It can be dangerous to reuse parts that have been proof tested by the application of a stress above the anticipated service stresses.

Prevention and Control

The potential for hydrogen embrittlement must be evaluated before any prevention and control procedures are implemented (Ref 25). The sources of hydrogen must be examined with regard to three possibilities: the manufacture of the alloy, the manufacture and processing of the part, and the environmental service conditions. A source of hydrogen and a sufficient stress must exist in order for hydrogen embrittlement to occur. If either condition is eliminated, hydrogen embrittlement will not occur.

From a control viewpoint, the attempt is first made to eliminate the hydrogen and to ensure that no hydrogen is introduced during the manufacture and processing of the part. It is then anticipated that no problem will exist in service. This approach focuses on the hydrogen embrittlement process that has classically been referred to as internal hydrogen embrittlement, which is introduced, for example, during the manufacture and processing of the steel part. Once the part is in service, potential hydrogen embrittlement failure can result from hydrogen produced from a corrosion reaction, electrochemical (cathodic) protection, or from operation in high-pressure hydrogen. This is referred to as environmental hydrogen embrittlement.

Hydrogen embrittlement failures are prevented by controlling the amount of hydrogen introduced during the manufacture and processing of the hardware or part. Consideration must be given to the amount of hydrogen introduced during the melting of the alloy, the manufacture of the part, and the in-service environment, which should also include cleaners and paint strippers. The necessary controls are covered in ASTM F 519. The major difficulty appears to involve identifying the manufacturing-induced residual stresses that result from heat treatment and, especially, welding. Much more attention must be given to evaluating the potential for hydrogen embrittlement failures in the presence of residual stresses. The source of the residual stress must be identified in each piece of production hardware, or the assumption of high residual stresses in the manufactured part, especially in welded structures, must be included in the design analysis.

The usefulness of the threshold stress-intensity parameter, K_{IHE}, has yet to be established. Its main function appears to be its use in designing against the service-induced or application- induced possibilities of hydrogen embrittlement failure. This can be done only by controlling the applied stress and geometrical factors, such as root radius, in a given environment in order to maintain the effective applied stress intensity at a level below the threshold for subcritical crack growth. Although methodology for measuring K_{ISCC} is gradually being standardized, its significance in design is not yet completely understood.

Evaluating Corrosion Fatigue

Revised by Bopinder Phull, Consultant

Introduction

FATIGUE is a common cause of the premature fracture of structural components. In corrosive environments, susceptible materials can fail even more quickly due to corrosion fatigue. Corrosion-fatigue cracking (CFC) is not limited to certain metallurgical conditions of the metal or to critical environmental species, as are other forms of environmentally assisted cracking. Classical CFC, stress-corrosion cracking (SCC), and hydrogen embrittlement cracking (HEC) failures are separated by a spectrum of behaviors dictated by a large number of factors, for example, metallurgical condition of the material, the method of stressing, and the electrochemistry of the metal-environment system.

Relationship between Corrosion- Fatigue Cracking, Stress-Corrosion Cracking, and Hydrogen Embrittlement Cracking

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Figure 1 (Ref 1) illustrates a conceptual interrelationship of corrosion fatigue, stress corrosion, and hydrogen embrittlement. The most serious practical situations involving ductile-alloy/ environment systems are in the crosshatched regions. These regions indicate the combination of any two failure mechanisms. In the center, all three phenomena interact, which is probably representative of many practical situations involving ductile-alloy/aqueous environment systems. For example, in CFC and SCC, a surface pit constitutes a stress raiser, especially in the initiation process. Electrode potential and pH at an active crack tip may be significantly different from those on boldly exposed surfaces of a material. On the one hand, low-pH conditions can lead to local dissolution of metal and crack-tip blunting, which reduces stress-concentration effects. In contrast, low-pH conditions favor hydrogen generation and, consequently, increased risk of HEC. Reduction in local ductility associated with HEC is more likely to produce sharp crack tips, which, in turn, can exacerbate stress-concentration effects for any synergistic SCC or CFC. For materials that exhibit classical active- passive behavior, passivation is more conducive under static rather than dynamic conditions. For the latter, frequency of cyclic loading is often one of the critical factors that influences CFC in corrosive environments. Conversely, for corrosion control, cathodic protection generally mitigates CFC and SCC but increases the probability of HEC of susceptible materials. Thus, it is apparent from the foregoing that complex relationships can exist between CFC, SCC, and HEC. Although much research has been published in this area (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17), many unanswered questions remain. It has been postulated that the danger of cracking in practical situations and the applicability of various testing techniques can be assessed from a mechanistic base as well as from the existing foundation of empirical experience (Ref 1). Some of the experimental evidence relating CFC to SCC is cited in later sections of this article that discuss specific aspects of corrosion-fatigue testing.

Prediction of Corrosion-Fatigue Life

While significant advances have been made, the methodology for the interpretation and use of standard test method data for environmental cracking is not fully developed. Moreover, to the extent that the two phenomena can interact synergistically under some conditions, existing approaches to standard test development may produce nonconservative data in some cases (Ref 18). A scientific basis for a reliable estimate of fatigue life for all conceivable load and environmental combinations remains elusive, despite the estimated billions of dollars spent combating fatigue (Ref 19).

A designer may rely on experience with similar components in service. However, such know- how is not available routinely. Therefore, fatigue data are often generated from accelerated laboratory tests. Fracture mechanics test specimens, for example, now provide very useful data for design engineers as well as for understanding fatigue behavior.

Types of Corrosion-Fatigue Tests

Laboratory corrosion-fatigue tests can be classified as either cycles-to-failure (complete fracture) or crack propagation (crack growth) tests. In cycles-to-failure testing, specimens or parts are subjected to a sufficient number of stress cycles to initiate and propagate cracks until complete fracture occurs. Such data are usually obtained by testing smooth or notched specimens. However, it is difficult to distinguish between CFC initiation and CFC propagation life with this type of testing.

In crack propagation testing, fracture mechanics methods are used to determine the crack growth rates of preexisting cracks under cyclic loading. Preexisting cracks or sharp defects in a material reduce or eliminate the crack initiation portion of the fatigue life of the component. Both types of testing are important. However, it appears that crack initiation is of more significance in the failure process of relatively thin sections, while crack growth appears to dominate thick- section component endurance (Ref 20).

The usual approach to corrosion-fatigue testing is to perform a state-of-the-art fatigue test in the presence of the environment of interest. This article emphasizes important factors that should be recognized and controlled in corrosion-fatigue tests and provides references to published standard methods and recommended practices.

Standards and Recommended Practices for Fatigue Testing

Only a few standardized procedures for fatigue testing are available, because many of the testing machines are custom built. However, several types of fatigue-testing machines, testing methods, and test specimens are accepted as standard. In the United States, the ASTM International issues voluntary standards and recommended practices. Those related to fatigue testing are:

Evaluating Corrosion Fatigue

Revised by Bopinder Phull, Consultant

Cycles-to-Failure Tests

In cycles-to-failure (crack initiation followed by propagation) tests, a specimen or part is subjected to cyclic loading until complete fracture results. A large portion of the total number of cycles in these tests is associated

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

with crack initiation. Although cycles-to-failure tests conducted on small specimens do not precisely establish the fatigue life of a large part, such tests do provide empirical data on the intrinsic fatigue crack initiation behavior of a metal or alloy. As a result, such data can be used to compare the effects of alloying additions, heat treatments, surface finishes, corrosion-control methods, and so on, and to develop empirical failure-prevention criteria for engineering design. Examples of the use of small-specimen fatigue test data can be found in the basis of the fatigue design codes for boilers and pressure vessels; complex welded, riveted, or bolted structures; and automotive and aerospace components.

Fatigue-Testing Regimes

The magnitude of the nominal applied stress on a cyclically loaded component is often measured by the amount of overstress, that is, the amount by which the nominal stress exceeds the fatigue limit or the long-life fatigue strength of the material used in the component. The number of load cycles that a component under low overstress can endure is high; therefore, high-cycle fatigue is often applied. Because high-cycle fatigue tests require uninterrupted operation for long periods of time, test machines that are simple and reliable are used. Either constant-load amplitude or constant deflection tests can be conducted.

As the magnitude of the nominal applied stress increases, the initiation of multiple cracks is more likely. Also, the spacing between fatigue striations, which indicate the progressive growth of the crack front, is increased, and the region of final fast fracture is increased in size.

Low-cycle fatigue is the regime characterized by high overstress. The commonly accepted dividing line between high-cycle and low-cycle fatigue is considered to be typically in the range of 10^4 to 10^5 cycles. In practice, this distinction is made by determining whether the dominant component of the strain imposed during cyclic loading is elastic (high cycle) or plastic (low cycle), which in turn depends on the properties of the metal as well as the magnitude of the nominal applied stress.

Different test techniques may be required for the control and monitoring of low-cycle fatigue tests. Typically, strain-controlled tests (constant strain amplitude) are used, and often, the test specimen is subjected to alternating tension and compression loading cycles.

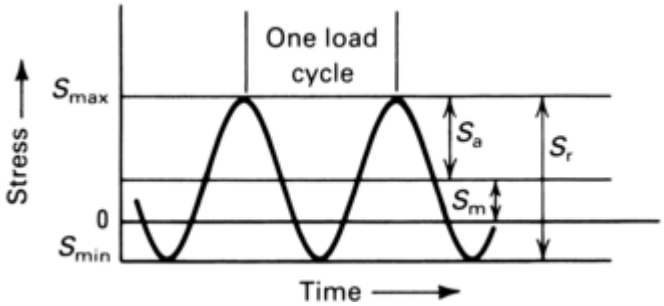
In routine low- and high-cycle fatigue crack initiation testing, complete fracture of a small specimen is generally the failure criterion. Approximately 30 to 40% of the low-cycle fatigue life and approximately 80 to 90% of the high- cycle fatigue life, measured by cycles to failure, involve nucleation of the dominant fatigue crack that eventually causes failure.

Loading Parameters

Most laboratory fatigue testing is done either with axial loading or in bending. The stress is usually cycled between a maximum and a minimum tensile stress or between a maximum tensile stress and a maximum compressive stress. The latter is considered a negative tensile stress, is given an algebraic minus sign, and is therefore known as the minimum stress.

Applied stresses are described by three parameters. The mean stress, S_m, is the algebraic average of the maximum and minimum stresses in 1 cycle, $S_m = (S_{max} + S_{min})/2$. In the completely reversed cycle test, the mean stress is 0. The range of stress, S_r, is the algebraic difference between the maximum and minimum stresses in 1 cycle, $S_r = S_{max} - S_{min}$. The stress amplitude, S_a, is one-half the range of stress, $S_a = S_r/2 = (S_{max} - S_{min})/2$.

During a fatigue test, the stress cycle is usually maintained constant so that the applied stress conditions can be written $S_m \pm S_a$, where S_m is the static or mean stress, and S_a is the stress amplitude, which is equal to half the stress range. The nomenclature used to describe test parameters involved in cyclic stress testing is shown in Fig. 2.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 2 Nomenclature used to describe test parameters involved in cyclic stress testing. S_a, stress amplitude; S_m, mean stress; S_r, stress range

The stress ratio is the algebraic ratio of two specified stress values in a stress cycle. Two commonly used stress ratios are the ratio A of the stress amplitude to the mean stress ($A = S_a/S_m$) and the ratio R of the minimum stress to the maximum stress ($R = S_{min}/S_{max}$).

If the stresses are fully reversed, the stress ratio R becomes -1; if the stresses are partially reversed, R becomes a negative number less than 1. If the stress is cycled between a maximum stress and no load, R becomes 0. If the stress is cycled between two tensile stresses, R becomes a positive number less than 1. A stress ratio R of 1 indicates no variation in stress, making the test a sustained-load SCC test rather than a corrosion-fatigue test.

Presentation of Fatigue Data

High-cycle fatigue data are presented graphically as *S-N* curves, where *S* is stress and *N* is cycles to failure.

S-N Curves. The results of fatigue-cycles-to- failure tests are usually plotted as maximum stress, minimum stress, or stress amplitude versus number of cycles, *N*, to failure, using a logarithmic scale for the number of cycles. Stress is plotted on either a linear or a logarithmic scale. Three typical *S-N* curves are shown in Fig. 3.

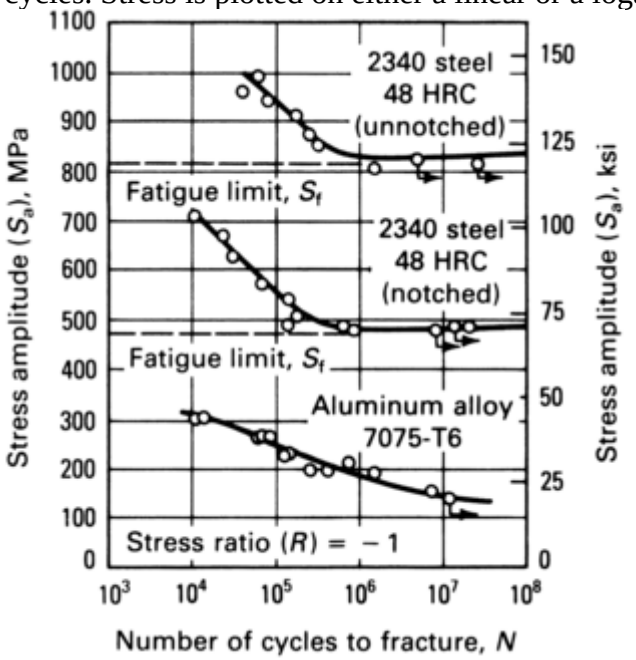


Fig. 3 Typical *S-N* curves for constant amplitude and sinusoidal loading

Fatigue Limit and Fatigue Strength. The horizontal portion of a *S-N* curve represents the maximum stress that the metal can withstand for an infinitely large number of cycles with 50% probability of failure. This maximum stress is known as the fatigue (endurance) limit, S_f. Most nonferrous metals do not exhibit a fatigue limit. Instead, their *S-N* curves continue to drop at a slow rate at high numbers of cycles, as shown by the curve for aluminum alloy 7075-T6 in Fig. 3.

For these types of metals, fatigue strength, rather than fatigue limit, is reported. Fatigue strength is the stress to which the metal can be subjected for a specified number of cycles. Because there is no standard number of cycles, each table of fatigue strengths must specify the number of cycles for which the strengths are reported. The fatigue strength of nonferrous metals at 10^8 or 5×10^8 cycles is sometimes erroneously called the fatigue limit.

Low-Cycle Fatigue. For the low-cycle fatigue region ($N < 10^4$ cycles), tests are conducted with controlled cycles of elastic plus plastic (total) strain range, rather than with controlled load or stress cycles. Under controlled-strain testing, fatigue-life behavior is represented by a log-log plot of the total strain range, $\Delta\varepsilon_t$, versus the number of cycles, *N*, to failure (Fig. 4).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

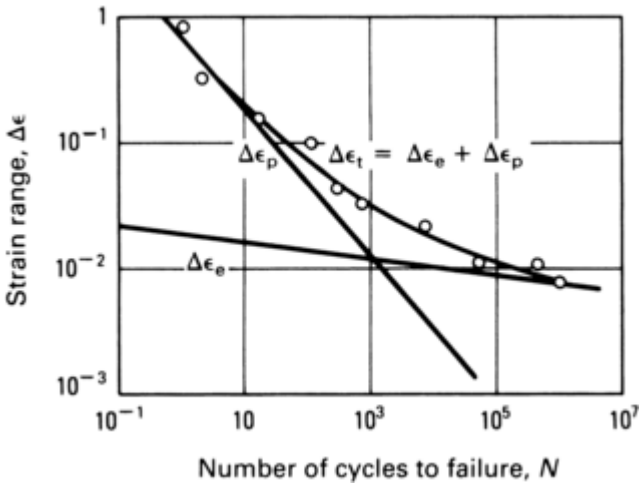

Fig. 4 Typical plot of strain range versus cycles to failure for low-cycle fatigue. $\Delta\varepsilon_t$, total strain range; $\Delta\varepsilon_e$, elastic strain range; $\Delta\varepsilon_p$, plastic strain range

The total strain range may be separated into elastic and plastic components. For many metals and alloys, the elastic strain range, $\Delta\varepsilon_e$, is equal to the stress range divided by the modulus of elasticity. The plastic strain range, $\Delta\varepsilon_p$, is the difference between the total strain range and the elastic strain range.

When curves are drawn for fatigue data, the equation and the method of the curve fit should be indicated. Any presentation of corrosion-fatigue data should include the following pertinent information, when applicable, regarding the material and the test:

- Material identification (product form)
- Mechanical properties, for example, yield strength (YS), ultimate tensile strength (UTS), percent elongation, hardness
- Orientation of the specimen
- Surface condition
- Notch description (stress-concentration factor)
- Type of fatigue test (mode of loading)
- Controlled test parameters
- Stress ratio
- Stress cycle frequency
- Stress wave shape
- Test temperature and environment

Fatigue Test Specimens

A typical fatigue test specimen has three areas: the test section and the two grip ends. The grip ends are designed to transfer load from the test machine grips to the test section and may be identical, particularly for axial fatigue tests. The transition from the grip ends to the test area is designed with large, smoothly blended radii to eliminate stress concentrations in the transition.

The design and type of specimen depend on the fatigue-testing machine and the objective of the fatigue study. The test section in the specimen is reduced in cross section to prevent failure in the grip ends and should be proportioned to use the middle to upper ranges of the load capacity of the fatigue machine. That is, it is best to avoid low load amplitudes where sensitivity and response of the system are decreased. Several types of fatigue test specimens are illustrated in Fig. 5.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

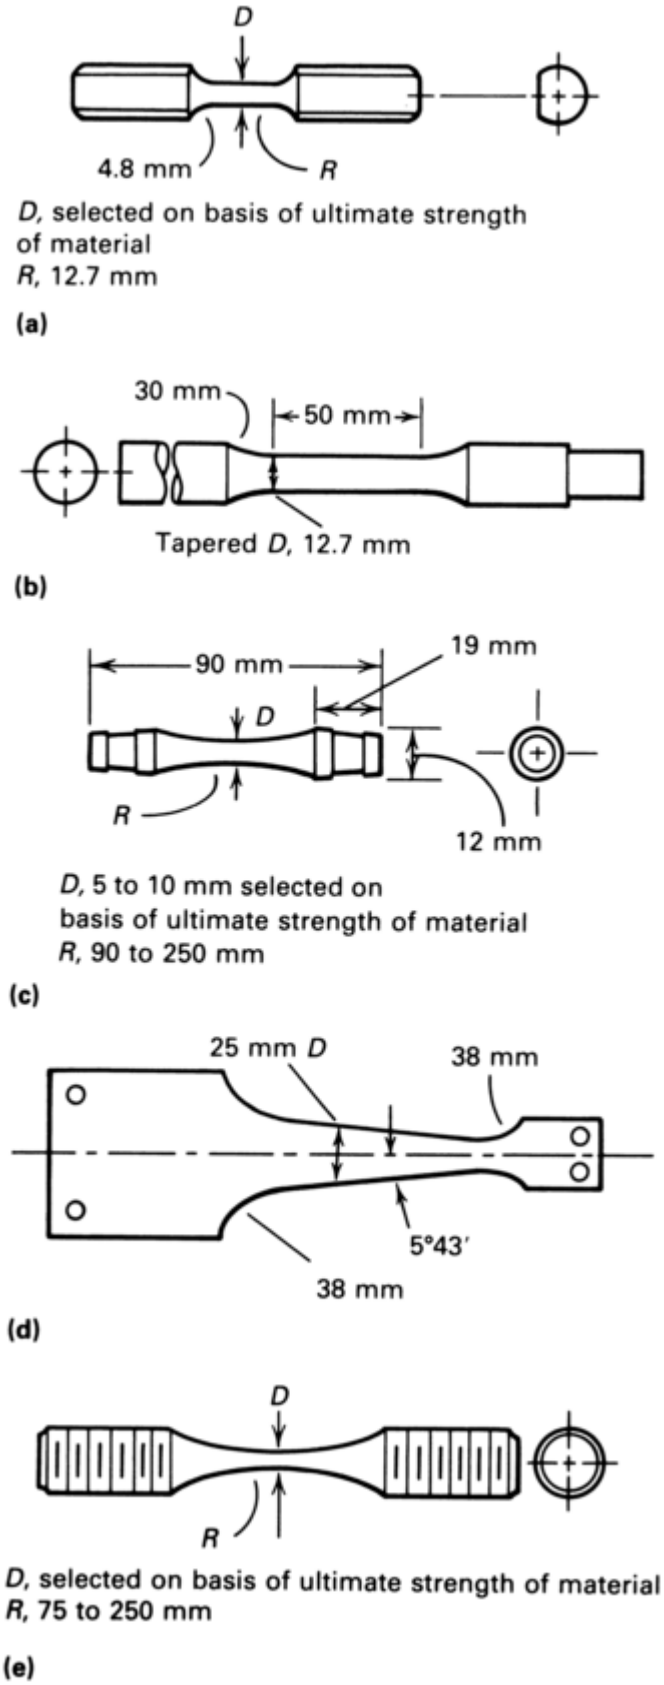

Fig. 5 Typical fatigue test specimens. (a) Torsional specimen. (b) Rotating cantilever beam specimen. (c) Rotating beam specimen. (d) Plate specimen for cantilever reverse bending. (e) Axial loading specimen. *R*, radius; *D*, diameter

Cylindrical Specimens. Three types of specimens with circular cross sections are commonly used:

- Specimens with a continuous radius between the grip ends with the minimum diameter at the center (Fig. 5c, e); referred to as hourglass specimens

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- Specimens with tangentially blending fillets between the test section and the grip ends (Fig. 5a)
- Specimens for use in cantilever beam loading with tapered diameters proportioned to produce nominally constant stress along the test section (Fig. 5b), sometimes known as McAdam specimens

The design of the grip ends depends on the machine design and the gripping devices used. Round specimens for axial fatigue machines may be threaded, buttonhead, or constant-diameter types for clamping in V-wedge pressure grips.

For rotating-beam machines, short, tapered grip ends with internal threads are used, and the specimen is pulled into the grip by a draw bar. A long constant-diameter grip end shank is used on machines with lathe-type collet chucks as grips. Torsional fatigue specimens are generally cylindrical; however, there is usually a flat or keyway in the grip ends to transmit torque from the machine into the specimen (Fig. 5a).

Flat Sheet and Plate Specimens. Flat specimens for either axial or bending fatigue tests are generally reduced in width in the test section but may also have thickness reductions. The most commonly used types include:

- Specimens with tangentially blending fillets between the test section and the grip ends; used in both axial and bending fatigue tests
- Specimens with a continuous radius between the grip ends; also used in both axial and bending fatigue tests
- Specimens for use in cantilever reverse bending tests with tapered widths (Fig. 5d).

Flat specimens are generally clamped in flat wedge-type grips, or they can be held with a stiff bolted clamp/joint friction grip for reversed axial loading. Pin loading can be used when compression loads are not encountered. When pin loading is used, the holes drilled in the grip end must be designed to avoid shear or bearing failures at the holes, tensile failure between the holes at maximum load, and fatigue cracking at the holes in the grip end. In the axial fatigue testing of flat sheet specimens, the test length must be designed to prevent premature buckling of the specimen.

Effect of Test Specimen Size (Ref 31)

It is difficult to predict the fatigue performance of large machine members directly from the results of laboratory tests on small specimens. In most cases, a size effect exists; that is, the fatigue strength of large members is lower than that of small specimens. Even if the microstructure is the same, simply increasing specimen size increases the surface area and hence the probability of containing manufacturing flaws, which represent potential fatigue or corrosion- fatigue initiation sites. In reality, it is extremely difficult to prepare geometrically similar specimens of increasing diameter that have the same metallurgical structure and residual-stress distribution throughout the cross section. The problems in fatigue testing of large specimens are considerable, and few fatigue machines can accommodate specimens with a wide range of cross sections.

Changing the size of a fatigue specimen usually results in variations of two factors. First, increasing the diameter increases the volume and surface area of the specimen. The change in amount of surface is significant, because fatigue failures usually initiate at the surface. Second, for smooth or notched specimens loaded in bending or torsion, an increase in diameter usually decreases the stress gradient across the diameter and increases the volume of material that is highly stressed.

Experimental data on the size effect in fatigue typically show that the fatigue limit decreases with increasing specimen diameter. The data for steel shafts tested in reversed bending given in Table 1 show that the fatigue limit can be appreciably reduced in large section sizes.

Table 1 Effect of specimen size on the fatigue limit of normalized plain carbon steel in reversed bending

Specimen diameter		Fatigue limit	
mm	**in.**	**MPa**	**ksi**
7.6	0.30	248	36
38	1.50	200	29
152	6.00	144	21

Source: Ref 32

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

No size effect was found for smooth fatigue specimens of plain carbon steel with diameters ranging from 5 to 35 mm (0.2 to 1.4 in.) when tested in axial tension-compression loading (Ref 33). However, when a notch was introduced into the specimen, so that a stress gradient was produced, a definite size effect was observed. Therefore, it can be concluded that a size effect in fatigue is primarily due to the existence of a stress gradient.
The fact that large specimens with shallow stress gradients have lower fatigue limits supports the concept that a critical value of stress must be exceeded over a given finite depth of material for failure to occur. This appears to be a more realistic criterion of size effect than the ratio of the change in surface area to the change in specimen diameter. The importance of stress gradients in size effect explains why correlation between laboratory results and service failure is often poor. Actual failures in large parts are usually directly related to stress concentrations, either intentional or accidental, and it is usually impossible to duplicate the same stress concentration and stress gradient in a small laboratory specimen.

Effect of Stress Concentration

Fatigue strength is significantly reduced by the introduction of a stress raiser, such as a notch, hole, or corrosion pit. Because actual machine elements invariably contain such stress raisers as fillets, keyways, screw threads, press fits, and holes, fatigue cracks in structural parts usually initiate at such geometrical irregularities.
An optimal means of minimizing fatigue failure is the reduction of avoidable stress raisers through careful design and the prevention of accidental stress raisers by careful machining and fabrication. Stress concentration can also arise from surface roughness and metallurgical stress raisers, such as porosity, inclusions, local overheating in grinding, and decarburization. The effect of stress raisers on fatigue is generally studied by testing specimens containing a notch, usually a V-notch or a U-notch. The presence of a notch in a specimen under uniaxial load introduces three effects:

- There is an increase or concentration of stress at the root of the notch.
- A stress gradient is set up from the root of the notch toward the center of the specimen.
- A triaxial state of stress is produced at the notch root.

The ratio of the maximum stress in the region of the notch (or other stress concentration) to the corresponding nominal stress is the stress-concentration factor, K_t. In some situations, values of K_t can be calculated by using the theory of elasticity or can be measured by using photoelastic plastic models. Values for K_t are reported in Ref 34, 35, 36, 37.
The effect of notches on fatigue strength is determined by comparing the *S-N* curves of notched and unnotched specimens (Fig. 3). The data for notched specimens are usually plotted in terms of nominal stress based on the net cross section of the specimen. The severity of the notch in decreasing the fatigue limit is expressed by the fatigue notch factor, K_f. This factor is the ratio of the fatigue limit of unnotched specimens to the fatigue limit of notched specimens.
For materials that do not exhibit a fatigue limit, the fatigue notch factor is based on the fatigue strength at a specified number of cycles. Values of K_f have been found to vary with the severity of the notch, the type of notch, the material, the type of loading, and the stress level. Published values of K_f are subject to considerable variability and should be carefully examined for their limitations and restrictions. However, two general trends are usually observed for test conditions of completely reversed loading. First, K_f is usually less than K_t, and second, the ratio of K_f/K_t decreases as K_t increases.
The notch sensitivity of a material in fatigue is expressed by a notch sensitivity factor, q:

$$q = \frac{K_f - 1}{K_t - 1} \qquad \text{(Eq 1)}$$

A material that experiences no reduction in fatigue behavior due to a notch ($K_f = 1$) has a factor of $q = 0$, but a material in which the notch has its full theoretical effect ($K_f = K_t$) has a factor of $q = 1$. However, q is not a true material constant, because it varies with the severity and type of notch, the size of the specimen, and the type of loading. As shown in Fig. 6, notch sensitivity increases with tensile strength. Therefore, it is sometimes possible to degrade fatigue performance by increasing the hardness or tensile strength of a material.

Surface Effects and Fatigue

Fatigue properties are generally very sensitive to surface conditions. Except in special cases involving internal defects or case hardening, all fatigue cracks initiate at the surface. Factors that affect the surface of a corrosion-fatigue specimen can be divided into four categories:

- Surface roughness or stress raisers at the surface
- Changes in the properties of the surface metal
- Changes in the residual stress condition of the surface
- Corrosion

Surface Roughness. In general, fatigue life increases as the magnitude of surface roughness decreases. Fatigue life is the number of cycles of a specified character that a given specimen sustains before failure of a specified nature occurs, for example, crack initiation to a given depth, reaching a certain crack growth rate, or complete fracture. Decreasing surface roughness minimizes local stress raisers. Therefore, special attention must be given to the surface preparation of smooth, unnotched fatigue test specimens. Typically, a metallographic finish, free of machining grooves and grinding scratches, is required. Figure 7 illustrates the effect various surface conditions have on the fatigue properties of steel.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

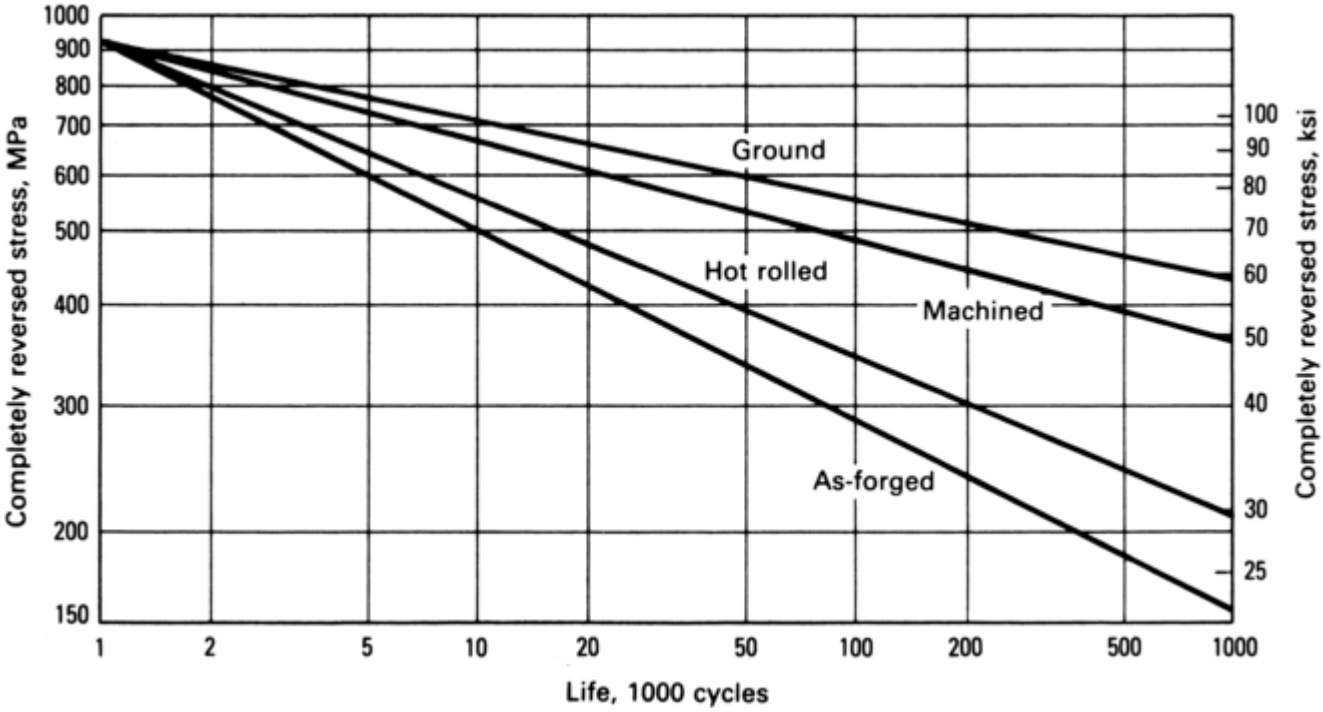

Fig. 7 Effect of surface conditions on the fatigue properties of steel (302 to 321 HB)

Changes in Surface Properties. Because fatigue failure is dependent on surface condition, any phenomenon that changes the fatigue strength of the surface material will greatly alter fatigue properties. For example, decarburization of the surface of heat treated steel is particularly detrimental to fatigue performance. Similarly, the fatigue strength of aluminum alloy sheet is reduced when a soft aluminum coating (cladding) is applied to the stronger age-hardenable aluminum alloy sheet.

Marked improvements in fatigue properties can result from the formation of harder and stronger surfaces on steel parts by carburizing and nitriding (Ref 39). However, because favorable compressive residual stresses are produced in the surface by these processes, the improved fatigue properties are not exclusively due to the formation of higher-strength material on the surface. The effectiveness of carburizing and nitriding in improving fatigue performance is greater when a high stress gradient exists (as in bending or torsion) than in an axial fatigue test.

The greatest improvement in fatigue performance occurs in notched fatigue specimens that are nitrided. The amount of strengthening depends on the diameter of the part and the depth of surface hardening. Improvements in fatigue properties similar to those caused by carburizing and nitriding may also be produced by flame hardening and induction hardening. In surface- hardened parts, failure initiates at the interface between the hard case and the softer core, rather than at the surface.

Electroplating of the surface generally decreases the fatigue limit of steel, because the coating, especially chromium plating, inherently contains cracks. The plating conditions used to produce an electroplated surface can have a significant effect on fatigue properties, because large changes in the residual stress, adhesion, porosity, and hardness of the plate can result. Anodized coatings on aluminum alloys may also decrease fatigue strength.

Surface Residual Stresses. Processing, such as grinding, polishing, and machining, that work hardens or increases residual stress on the surface can influence fatigue strength. However, there is no generalization that predicts the extent of improved fatigue strength from the results of work hardening and residual stress. Compressive residual surface stresses generally increase fatigue strength; tensile residual surface stresses do not. There may be a gradual decrease in residual stress if the cyclic stresses cause some plastic deformation. Compressive residual surface stress provides greater improvement in the fatigue strength of harder materials (such as alloy spring steel). In softer materials (such as low- carbon steel), work hardening effectively improves fatigue strength.

In a notched high-strength steel, the beneficial effect of prestretching and the detrimental effect of precompression are much greater than in a plain carbon steel because of the type of residual stress present at the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

notch. In addition, compressive residual stress introduced during quenching from a tempering temperature will increase the fatigue strength, particularly in notched specimens.

In general, residual stresses are introduced by the poor fit of structural parts, a change in the specific volume of a metal accompanying phase changes, a change in shape following plastic deformation, or thermal stresses resulting from rapid temperature changes, such as occur in quenching. The influence of residual stress on fatigue strength is similar to that of an externally applied static stress. A static compressive surface stress increases the fatigue strength, and static tensile surface stress reduces it.

Specimen Preparation. Because both fatigue crack initiation and corrosion are typically surface dependent, proper machining and surface preparation of test specimens is critical. Unless care is taken, scatter caused by variable surface conditions will mask the scatter that is typical for the material being studied.

One of the primary aims of fatigue or corrosion-fatigue testing is the comparative performance of materials. Therefore, uniform specimen-preparation procedures must be established. Machining operations must not alter the surface structure of the metal. Heat generation, heavy cutting, and severe grinding are prohibited. For as-machined surfaces, the final machining direction should be oriented in the direction of the stress. Transition fillets must be blended into the test area without steps or undercutting. Surface polishing using metallographic techniques is preferred for smooth specimens, in which machining marks are removed by a sequence of grinding steps.

The final polishing is not a buffing operation but a cutting operation that uses lapping compounds or aluminum oxide powder in a liquid medium to remove grinding scratches. For flat sheet or plate specimens, edges should be slightly rounded and ground to eliminate nicks, dents, cuts, and sharp edges, which cause early crack initiation.

Evaluating Corrosion Fatigue

Revised by Bopinder Phull, Consultant

Environmental Effects and Fatigue

In corrosion fatigue, the magnitude of the cyclic stress and the number of times it is applied are not the only critical loading parameters. Time-dependent environmental effects are also of primary importance. When failure occurs by corrosion fatigue, stress cycle frequency, stress wave shape, stress amplitude, and stress ratio all affect the cracking processes, depending on the resistance to SCC of the material.

Environmental Effects on Fatigue Strength. For any given material, the fatigue strength, or fatigue life at a given value of maximum stress, generally decreases in the presence of an environment that is aggressive to the material. This effect varies widely, depending primarily on the characteristics of the material-environment combination. The environment affects the probability of fatigue crack initiation, crack growth rate, or both. For many materials, the stress range required to cause fatigue failure diminishes progressively with increasing time and with the number of cycles of applied stress.

A corrosive environment reduces the crack initiation time by any form of localized attack to form a stress concentration. Corrosion attack is favored at new unfilmed metal surfaces formed at established slip bands, inclusions, second- phase particles, and so on. A clear example of the importance of stress concentration due to corrosion is illustrated in Fig. 8, which shows fatigue endurance results for plain and notched specimens of a 13% Cr ferritic steel in distilled water and saltwater. These environments are seen to cause a massive reduction in the endurance limit of the smooth specimens but only a relatively modest effect on the notched specimens. The importance of surface finish and the adverse effect of corrosion, even when only allowed to occur before a fatigue test, is of course well known and included in standard texts on fatigue test design (Ref 41).

Effect of Frequency and Stress Wave Form. In nonaggressive environments, stress cycle frequency generally has little effect on fatigue behavior. On the other hand, in aggressive environments, fatigue strength is strongly dependent on frequency. Corrosion-fatigue strength will generally decrease as the cycle frequency is decreased. This effect is generally most prevalent at frequencies less than 10 Hz.

The frequency dependence of corrosion fatigue is thought to result from the fact that the interaction of a material with its environment is essentially a rate-controlled process. Low frequencies, especially at low strain amplitudes or when there is substantial elapsed time between changes in stress levels, allow longer times for interaction between material and environment. At high frequencies, particularly when high strain amplitude is also involved, the effects of corrosion may be masked, because contact time with the environment is short. In other words, mechanical failure due to high frequency and stress levels can occur well before significant corrosion effects can initiate and have a significant influence on the fatigue process.

The effect of stress frequency on low-cycle corrosion fatigue is also very dependent on susceptibility to SCC. For example, at low intermediate frequencies, material sensitive to SCC can fracture by the propagation of fatigue cracks; but at even lower frequencies, damage due to SCC during the period of maximum strain can become greater. In fact, the fatigue strength at extremely low frequencies can be markedly decreased. For example, in one case, for materials that were insensitive to SCC, failure occurred due to the propagation of CFC over the entire range of stress frequencies tested (0.02 to 17.3 cycles/min, or cpm) (Ref 42).

Historically, CFC is not considered to be a problem at very high frequencies. However, an ultrasonic corrosion-fatigue-testing system now exists for examining the corrosion-fatigue strength of engineering materials in the very high cycle regime (10^9 to 10^{10} cycles) typical of many design lifetimes. Central to this resonant fatigue-testing system is a high-efficiency, large-displacement piezoelectric transducer that operates at a frequency of 20 kHz. This transducer enables the accumulation of large numbers of cycles within a reasonable amount of time. The apparatus, environmental controls, and testing method are described in Ref 43.

www.iran–mavad.com
مرجع مهندسی مواد و متالورژی

Experimental 20 kHz and low-frequency corrosion-fatigue results obtained with this method for a number of engineering materials, including a 12% Cr stainless steel, show similar reductions in fatigue limit despite differences in frequency. The results hold for a variety of aqueous environments with and without electrochemical controls imposed during testing. The data illustrate the capabilities of the ultrasonic corrosion-fatigue technique and are analyzed to assess its advantages and limitations.

In some cases, corrosion-fatigue strength is strongly affected by the form of the stress wave as well as by the stress frequency. The period of zero stress, the period during which the stress changes, and the period of application of maximum stress in a single cycle each have an effect on the specimen life. Corrosion-fatigue damage is greatest during the period in which the stress is changing, while the protective effect of the stress-free time decreases the damage.

Effect of Stress Amplitude. In general, a low amplitude of cyclic stress favors relatively long fatigue life, permitting greater opportunity for involvement of the environment in the fatigue process. However, environmental interaction in certain alloy-environment systems may be insignificant unless the strain rate is in a critical range for SCC.

Stress amplitude must be considered together with mean stress and frequency. Low stress levels may allow more time for environmental interaction, but if the frequency is high, the crack tip may not be exposed to the environment for a time sufficient for the corrosion processes to do significant damage.

Evaluating Corrosion Fatigue

Revised by Bopinder Phull, Consultant

Crack Propagation Tests

In large structural components, the existence of a crack does not necessarily imply imminent failure of the part. Significant structural life may remain in the cyclic growth of the crack to a size at which a critical failure occurs. The objective of corrosion-fatigue crack propagation testing is to determine the rates at which subcritical cracks grow under cyclic loading before reaching a size that is critical for fracture under specified environmental conditions.

مرجع مهندسی مواد و متالورژی

Fracture Mechanics Approach to Corrosion Fatigue

Fracture mechanics provides the basis for many modern fatigue crack growth studies. Fracture mechanics is based on the concept of similitude, in which cracks of different geometries grow at equal rates when subjected to equal near- tip driving forces, usually ΔK. ΔK is the stress- intensity range (K_{max} - K_{min}), where K is the magnitude of the mathematically ideal crack-tip stress field in a homogeneous, linear-elastic body; K is a function of applied load and crack geometry. The growth or extension of a fatigue crack under cyclic loading is principally controlled by maximum load and stress ratio (minimum/maximum stress). However, as in crack initiation, there are a number of additional factors that may exert a strong influence, especially with the presence of an aggressive environment. Most CFC growth-rate investigations attempt to follow the general provisions of standard test method ASTM E 647 (Ref 25).

In this constant-load-amplitude method, crack length is measured visually or by an equivalent method as a function of elapsed cycles, and these data are subjected to numerical analysis to establish the rate of crack growth. Crack growth rates are then expressed as a function of crack tip stress-intensity range, ΔK, which is calculated from expressions based on linear-elastic stress analysis.

Background information on the rationale for employing linear-elastic fracture mechanics for this purpose is given in Ref 44. Expressing the crack growth rate da/dN (where a is crack length and N is number of cycles) as a function of ΔK provides results that are independent of specimen geometry, and this enables the exchange and comparison of data obtained from a variety of specimen configurations and loading conditions. Moreover, this feature enables da/dN versus ΔK data to be used in the design and evaluation of engineering structures. It is important in the generation of CFC growth data, however, that there be judicious selection, monitoring, and control of mechanical, chemical, and electrochemical test variables in order to ensure that the data are truly applicable to the intended use.

Results of fatigue crack growth rate tests for many metallic structural materials have shown that complete da/dN versus ΔK curves have three distinct regions of behavior (Fig. 9). In an inert (or benign) environment, the rate of crack growth depends strongly on K at K levels approaching K_{Ic} (plane-strain fracture toughness) at the high end (region III) and at levels approaching an apparent threshold, ΔK_{th}, at the lower end (region I), with an intermediate region II that depends on some power of K or ΔK of the order of 2 to 10 (Ref 44). This is described by the power-law relationship:

$$\frac{da}{dN} = C(\Delta K)^n \qquad \text{(Eq 2)}$$

where C and n are constants for a given material and stress ratio. In an aggressive environment, the CFC growth curve can be quite different from the pure fatigue curve, depending on the sensitivity of the material to the given environment and the occurrence of various static stress- fracture mechanisms. The environmental effects are quite strong above some threshold for SCC (K_{ISCC}) and may be negligible below this level (K_{ISCC} is the stress-intensity threshold for plane- strain environment-assisted cracking). In addition, certain loading factors, such as frequency, stress ratio, and stress waveform, can have marked effects on the crack growth curves in aggressive environments. Therefore, a variety of curves can be expected from the broad range of material-environment-loading systems that produce various CFC behaviors.

Figure 10 shows an example of a high- strength aluminum alloy with a high resistance to SCC. This alloy had a CFC growth rate ranging up to 1 order of magnitude higher in 3.5% sodium chloride (NaCl) solution compared to that in dry air. These data also illustrate that CFC behavior is similar when tested in the same environment with either a *K*-increasing (remote load) or a *K*-decreasing (wedge force) loading method.

Corrosion-fatigue growth rate versus stress- intensity data have been extensively produced (Ref 2, 3, 4, 5, 6, 7, 8, 47, 48) and can be used for mitigating corrosion fatigue from several perspectives. Laboratory crack growth rate data are scalable quantitatively for predicting component performance. The da/dN versus ΔK curve for a given material and environment is integrated; it is then used in conjunction with the stress-intensity solution for a component to predict corrosion-fatigue life (Ref 44). A specific example reported in Ref 49 is illustrated in Fig. 11. The predicted 85 year life of a welded pipe is based on week-long laboratory measurements of da/dN versus ΔK for steel in an oil environment.

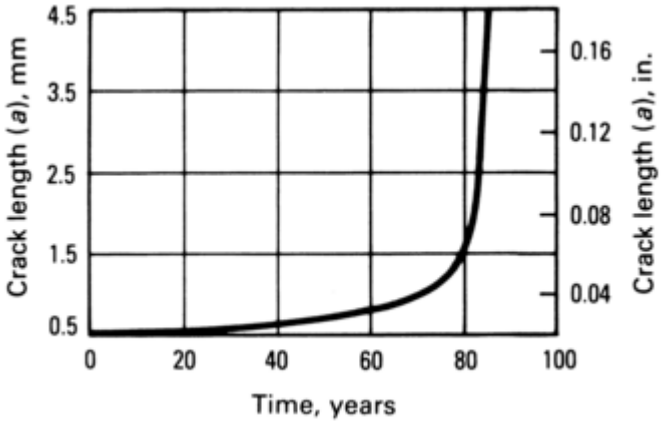

Fig. 11 Predicted fatigue crack extension from a weld toe crack in an American Petroleum Institute (API) 5LX52 carbon steel pipeline carrying hydrogen-sulfide-contaminated oil. Temperature: 23 °C (73 °F). Source: Ref 49

Alloy development for optimized corrosion- fatigue resistance, defined in terms of da/dN versus ΔK for different metallurgical conditions, is directly related to component life goals based on fracture mechanics. Similarly, the effects of mechanical and chemical variables on corrosion fatigue and component performance are defined through measured changes in crack growth rate at different applied stress-intensity levels.

Crack growth rate data are important to fundamental studies of corrosion-fatigue mechanisms. The fracture mechanics approach isolates crack propagation from initiation in terms of a precise near-tip mechanical driving force, ΔK. Crack growth rates are related directly to the kinetics of mass transport and the chemical reactions that constitute embrittlement. As shown in Fig. 12, prediction of the effect of loading frequency on crack growth rate in saltwater (normalized to vacuum) identifies important rate- limiting crack tip electrochemical reactions. Modeling and measurements in Fig. 12 provide a sound basis for extrapolating short-term laboratory data in order to predict long-term component cracking.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

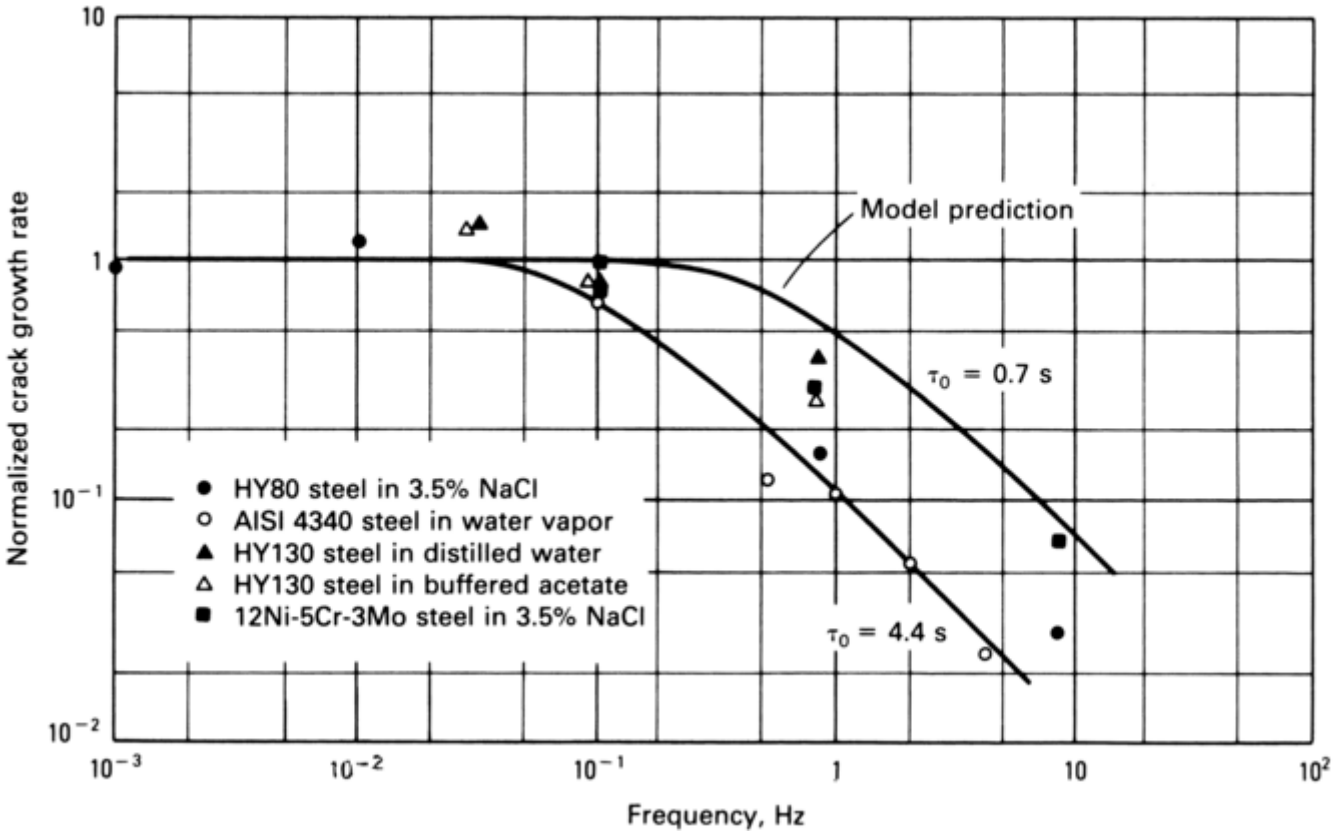

Fig. 12 Modeled effect of loading frequency on corrosion-fatigue crack growth in alloy steels in an aqueous chloride solution. The determination of the normalized crack growth rate and the time constants, τ_0, from the model can be found in Ref 50.

However, the fracture mechanics approach to corrosion fatigue is not valid in all cases. Discussion in this article is limited to crack growth in conjunction with net section elastic loading and small-scale plasticity confined to the crack tip. Studies of crack growth under large-scale cyclic plasticity have not been extended to consider environmental effects (Ref 51, 52). Also, while stress intensity provides a mechanical description of similitude, it may not completely describe crack growth because of interacting chemical and mechanical driving forces.

Results of investigations indicate that simple *K*-based approaches can be compromised for (a) small corrosion-fatigue cracks below 5 mm (0.2 in.), (b) cases in which varying crack shape and load transients alter crack chemistry and embrittlement, and (c) situations in which surface roughness or corrosion products impede crack displacement (Ref 51, 52, 53, 54, 55). Reference 51, 52, 53, 54, 55 should be consulted if an application includes plasticity, small crack, load transient, or crack closure effects.

Variables Influencing Corrosion Fatigue

Although corrosion-fatigue phenomena are diverse and specific to the environment, several variables are known to influence crack growth rate. The following factors must be considered in any study of corrosion fatigue:

- Stress-intensity range
- Load frequency
- Stress ratio
- Electrode potential in aqueous environment
- Environment composition
- Alloy composition, microstructure, and yield strength

Moreover, the effects of such variables as temperature, load history and waveform, stress state, and environment composition may be unique to specific materials and environments.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Stress-Intensity Range. Corrosion-fatigue crack growth rates generally increase with increasing stress intensity; however, the precise dependence varies markedly. It is incorrect to assume that the three regimes (near threshold, power law, and fast fracture; see Fig. 9) of fatigue cracking observed for benign environments simply shift to higher crack speeds at all ΔK levels. Although such behavior may actually occur, as illustrated in Fig. 10 for the aluminum/dry air system, the data provided in Fig. 13 and Fig. 14 are more typical of complex stress-intensity dependencies for aggressive environments.

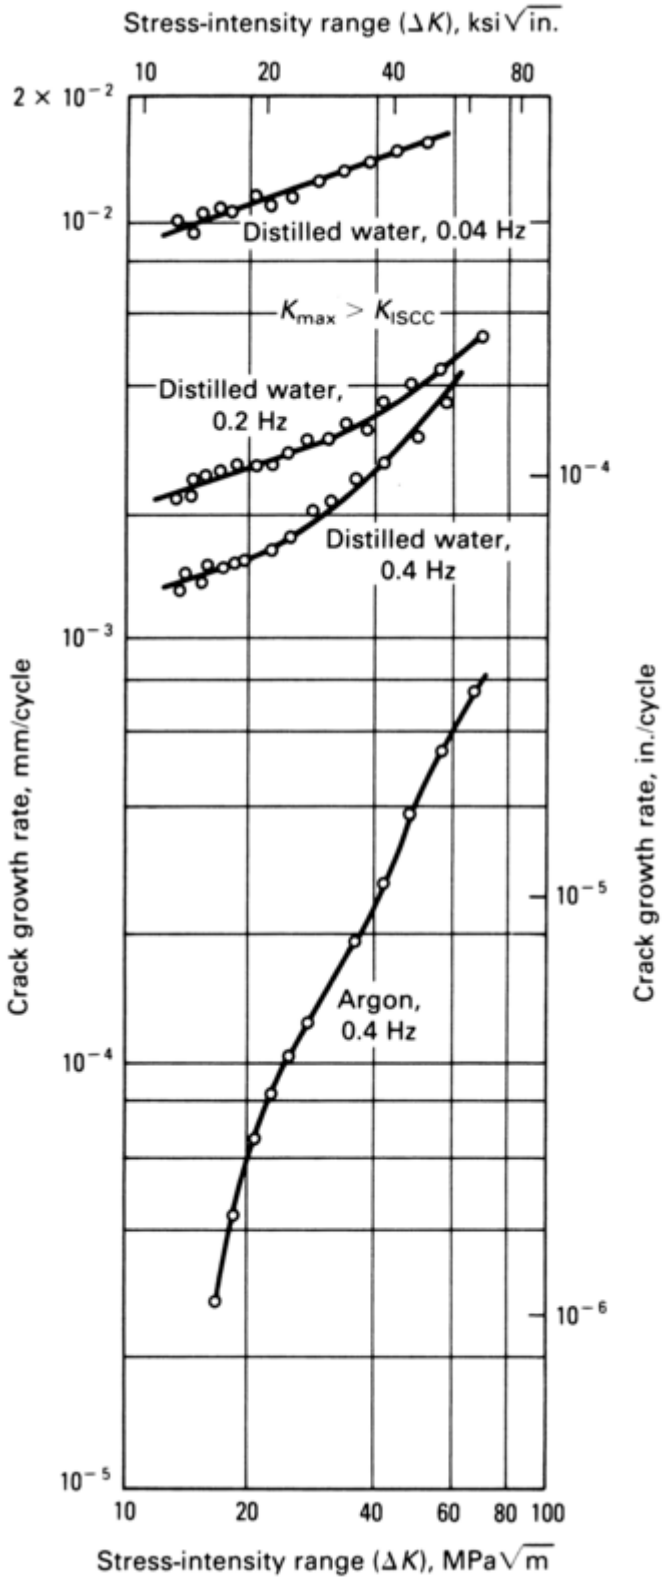

Fig. 13 Effect of stress-intensity range and loading frequency on corrosion-fatigue crack growth in ultrahigh-strength 4340 steel exposed to distilled water at 23 °C (73 °F). Materials that are extremely environment sensitive, such as ultrahigh-strength steel in distilled water (Fig. 13), are characterized by high crack growth rates that are influenced less by ΔK. Time-dependent corrosion-fatigue crack growth occurs predominantly above the threshold stress intensity for static load cracking and is modeled through linear superposition of SCC and inert environment fatigue rates (Ref 28, 34). Time- dependent crack growth is the part of the crack extension that is attributable to the constant or rising-load portion of the cyclic load cycle, when SCC and hydrogen embrittlement mechanisms may be operative. Factors such as stress wave form and stress hold-time are particularly significant under these circumstances.

Cycle-dependent corrosion-fatigue crack propagation often occurs below the threshold for time-dependent SCC (Ref 57). Typical ΔK dependencies for this mode of cracking are complex, as illustrated in Fig. 14 for Ti-6Al-4V exposed to aqueous sodium chloride. The mechanistic implications of the various stress- intensity dependencies are detailed in Ref 28, 57, and 58. The influences of such variables as frequency, stress ratio, and metallurgical factors depend on the proportions of time- and cycle-dependent corrosion fatigue.

Frequency. The frequency of cyclic loading is the most important variable that influences CFC for most material, environment, and stress- intensity conditions. The rate of environmental cracking above that produced in vacuum generally increases with decreasing frequency. Frequencies exist above which CFC is diminished. The dominance of frequency is directly related to the time dependence of mass transport and chemical reaction steps required for environmental cracking. Basically, insufficient time is available for chemical embrittlement at rapid loading rates, that is, high frequencies, when damage is only mechanical and is equivalent to crack growth in vacuum. It is impossible to predict the frequency range at which corrosion fatigue is severe because of the numerous chemical processes. It is also difficult to extrapolate short- term (high-frequency) laboratory crack growth rate data in order to predict long-term component performance.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The literature provides qualitative guidance in terms of frequency effects on CFC. Crack growth in environmentally sensitive materials stressed above the stress-corrosion threshold proceeds at rapidly increased rates with decreasing frequency, as illustrated in Fig. 13. The frequency effect is predicted through the integration of static load data throughout each load cycle (Ref 50). For such systems, the chemical contribution to fatigue cracking is suppressed above 0.5 to 5 Hz, with higher critical frequencies associated with more aggressive environments and sensitive microstructures.

Frequency effects on cycle-dependent cracking are complex and unpredictable. The data given in Fig. 12 and 14 provide typical examples. For steels in saltwater (Fig. 12), CFC is suppressed at approximately 10 Hz. Crack speed increases with decreasing frequency and reaches a plateau between 0.5 and 0.1 Hz. In contrast, CFC in Ti-6Al-4V occurs at loading frequencies at least as high as 10 Hz (Fig. 14).

Stress Ratio. The rates of corrosion-fatigue crack propagation generally are increased by higher stress ratios. The deleterious effect of increased stress ratio is illustrated in Fig. 15 for carbon steel stressed cyclically in pressurized nuclear reactor water at 288 °C (550 °F). The extent of the corrosion-fatigue effect relative to dry air increased from approximately a factor of 4 at low R (0.11 to 0.24) to as much as 20- to 30-fold at high R (0.61 to 0.71) (Ref 59). Corrosion fatigue in this system probably proceeds by repeated passive film formation and rupture. Increased stress ratio at constant ΔK results in increased crack tip strain and strain rate, enhanced film rupture, and therefore increased corrosion-fatigue crack propagation (Ref 60).

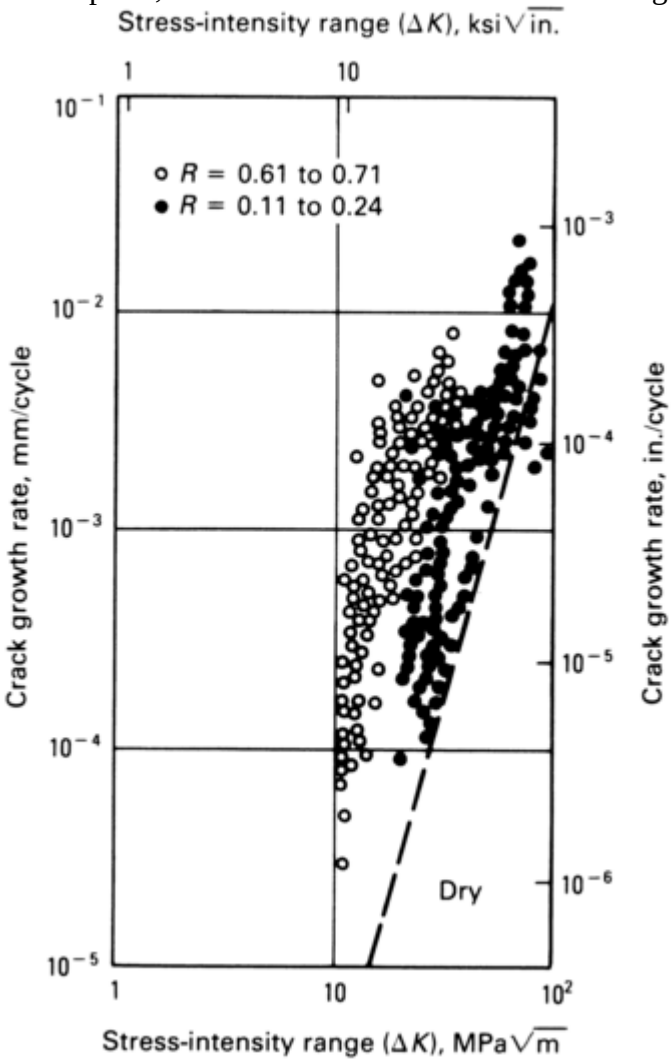

Fig. 15 Effect of stress ratio (R) on corrosion-fatigue crack propagation in ASTM A533 B and A508 carbon steels exposed to pressurized high-purity water at 288 °C (550 °F). Frequency: 0.017 Hz. Average behavior in air is represented by the dashed line labeled "Dry." Source: Ref 59

Electrode Potential. Like loading frequency, electrode potential strongly influences rates of corrosion-fatigue crack propagation for alloys in aqueous environments. Controlled changes in the potential of a specimen can result in either the complete elimination or the dramatic increase of fatigue cracking. The precise influence

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

depends on the mechanism of the environmental effect and on the anodic or cathodic magnitude of the applied potential.

For ferrous alloys that crack by hydrogen embrittlement when stressed in aqueous solutions, CFC is increased by high cathodic polarization from the free corrosion potential. Specific data are given in Fig. 16 for three steels stressed at constant ΔK in aqueous chloride environments (Ref 51, 61, 62). For each steel, the crack growth rate in saltwater is approximately three times faster than that reported for air at the free corrosion potential and is enhanced by a factor of 5 at a very high cathodic potential. For the low- strength BS4360:50D grade (similar to Unified Numbering System, or UNS, K02601), intermediate potentials appear to be mildly beneficial. Corrosion fatigue parallels electrode-potential- induced changes in the amount of cathodically evolved hydrogen in the crack tip. Precise modeling of this reaction sequence is complex and only partially completed (Ref 63).

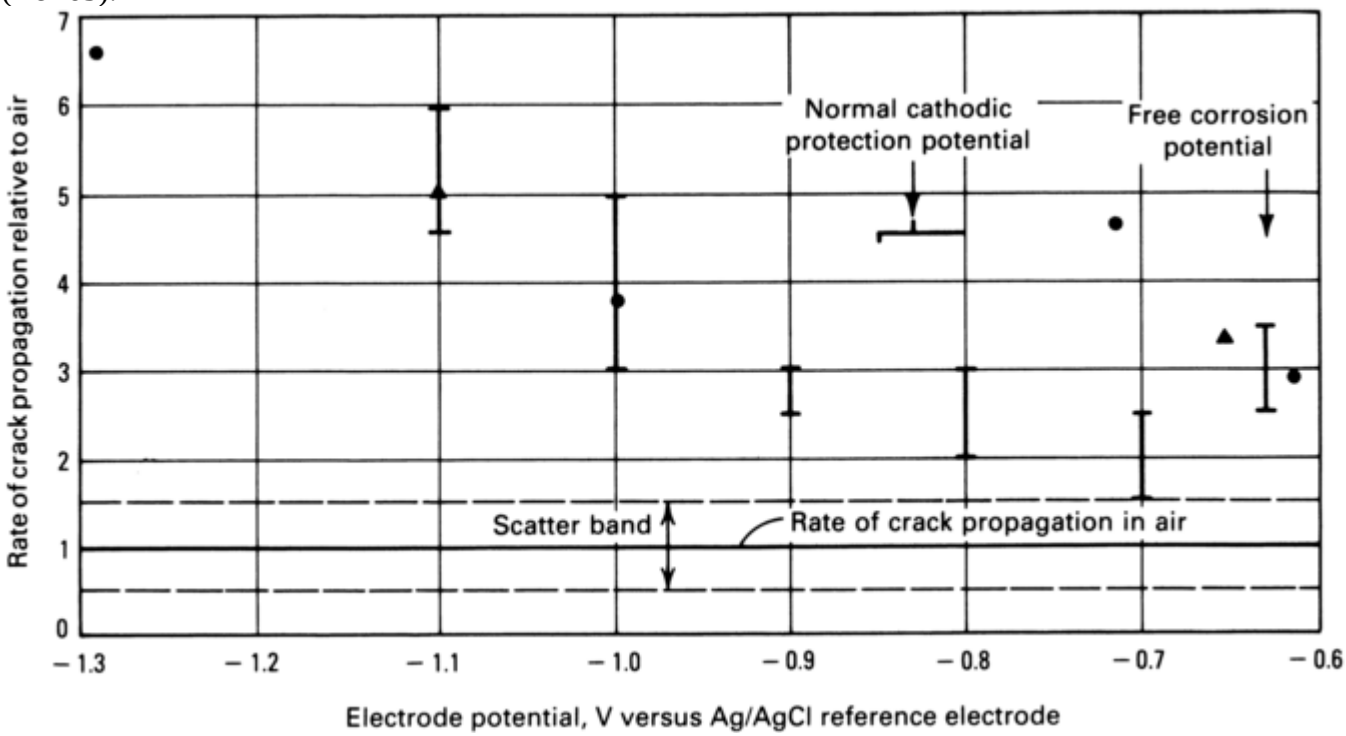

Fig. 16 Effect of applied electrode potential on corrosion-fatigue crack propagation in several steels exposed to seawater or 3% sodium chloride at constant ΔK between 20 and 40 MPa$\sqrt{m}$ (18 and 36 ksi$\sqrt{\text{in.}}$). AISI 4130	▲	750	110	3% NaCl	62

Electrode potential control can suppress corrosion fatigue for alloys that crack through anodic dissolution/film rupture or anion adsorption mechanisms (Ref 64). For example, corrosion fatigue of austenitic stainless steel in chloride solutions at elevated temperatures is probably suppressed by polarization active to the critical potential for SCC.

Another example is illustrated in Fig. 17. Aluminum alloy 7079-T651 is degraded by corrosion fatigue in several aqueous halide solutions at the free corrosion potential. Compared to dry argon, cracking in potassium iodide is enhanced by more than an order of magnitude (Fig. 17a). The CFC growth rate was further increased by anodic polarization at potentials more electropositive than -0.6 V versus standard hydrogen electrode (SHE) but was suppressed by cathodic polarization (Fig. 17b).

potential at ΔK of 6.7 MPa $\sqrt{m}$ (6 ksi $\sqrt{\text{in.}}$) in 25% potassium iodide solution. SHE, standard hydrogen electrode. Source: Ref 65

Electrode potential should be monitored and, if appropriate, maintained constant during corrosion-fatigue testing. Apparent effects of variables, such as the dissolved oxygen content of the solution, flow rate, ion concentration, and alloy composition on corrosion fatigue, can often be traced to changing electrode potential.

Crack Closure Effects. Premature crack surface contact during unloading, or crack closure, can greatly reduce rates of fatigue crack propagation. The true (or effective) crack tip driving force is reduced below the applied ΔK because of the reduced crack tip displacement range. Closure phenomena are produced by a variety of mechanisms and are particularly relevant to fatigue crack propagation in the near-threshold regime, after large load excursions, and for embrittling corrosive mechanisms, as reviewed in Ref 53, 66, and 67.

Two mechanisms of crack closure are relevant to corrosion fatigue. Rough, intergranular crack surfaces, typical of environmental embrittlement, promote crack closure because uniaxially loaded cracks open in a complex three-dimensional mode, allowing for surface interactions and load transfer. Roughness-induced closure is most relevant to corrosion fatigue at low ΔK and at stress ratio levels where absolute crack opening displacements (0.5 to 3 μm) are less than fractured grain heights (5 to 50 μm).

Alternatively, crack closing is impeded by dense corrosion products within the pulsating fatigue crack. For mildly oxidizing environments, such as moist air, this closure mechanism is relevant at low stress-intensity levels and contributes to the formation of a threshold, as described in Ref 67.

For corrosive bulk environments, cracking at high ΔK values may be retarded below growth rates observed for air or vacuum due to corrosion product formation within the crack. The engineering significance of beneficial crack closure influences depends on the stability of the corrosion product during complex tension-compression loading and fluid conditions. An example of crack closure is presented in Fig. 18 for ASTM A 471 steel exposed to either moist air or steam at 100 °C (212 °F). Crack growth is reduced for the latter environment because of crack surface oxidation and enhanced closure. It should be noted that oxide-induced closure influences cracking even at a relatively high stress ratio of 0.35. The data presented in Fig. 18 were obtained at a high loading frequency of 100 Hz, and chemically enhanced crack growth was essentially precluded.

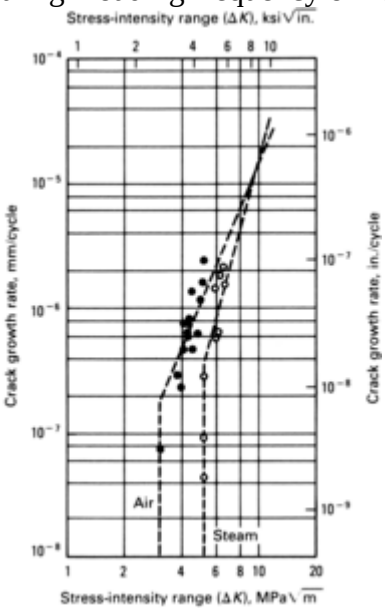

Fig. 18 Corrosion-fatigue crack propagation in ASTM A 471 steel exposed to moist air and steam. Temperature: 100 °C (212 °F); frequency: 100 Hz; stress ratio: *R* = 0.35. Source: Ref 68

Crack growth at lower frequencies could be deleteriously influenced by metal embrittlement and beneficially influenced by increased oxide formation and closure. The complexity of predicting environmentally enhanced cracking is clear, as emphasized by data given in Fig. 19 for a 2.25Cr-1Mo steel (ASTM A 542, class 3) stressed in dry hydrogen at 23 °C (73 °F). At high ΔK levels and low loading frequencies, cracking was accelerated in hydrogen as compared to moist air. This was due to classical hydrogen embrittlement. For low stress intensities, cracking was also increased by hydrogen exposure; however, the effect was not due to hydrogen embrittlement because of the rapid loading frequencies. Oxides form on crack surfaces through a

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

fretting mechanism during cycling in air, and crack growth rates are reduced by oxide-induced closure. However, oxide formation is precluded for cycling in pure hydrogen, crack closure is absent, and growth rates are increased relative to those in moist air. Equally rapid rates of fatigue cracking have been reported for low ΔK cycling in hydrogen and in helium. Equal rates of cracking are observed for hydrogen, helium, and moist air at high R (stress ratio) levels where closure was absent (Ref 66, 67).

CFC Growth Characterization

Experimental characterizations of corrosion- fatigue crack propagation are complicated by the numerous variables that influence the failure process. Both the mechanics of loading and the composition of the environment must be controlled. Standard methods of measurement and fracture mechanics analysis of fatigue crack propagation in benign environments can be found in ASTM E 647 (Ref 25).

Four problem areas are relevant to corrosion- fatigue testing. First, the environment must be contained about the cracked specimen without affecting loading, crack monitoring, or specimen-environment composition. Parameters such as environmental purity, composition, temperature, and electrode potential must be monitored and controlled.

Second, the deleterious effect of low cyclic frequency dictates that crack growth rates be measured at low frequencies (often <0.2 Hz). This leads to long test times—often several days to weeks. Load-controlled equipment, crack- monitoring sensors and signal conditioners, and test environment composition must be stable throughout long-term tests.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Third, crack length must be measured for calculations of stress intensity and crack growth rate. Optical methods are often precluded by the environment and test chamber. Indirect methods, which are based on specimen compliance (Ref 69) or electrical potential difference (Ref 70), have been successfully applied to the monitoring of crack growth in a wide variety of hostile environments. Experimental and analytical requirements, however, are complex for indirect crack monitoring.

Nonvisual techniques will often have greater accuracy and less variability in crack length measurement than optical observations. In addition, the nonvisual techniques are generally more consistent and reliable, especially where long periods of unattended testing are anticipated. Beyond that, nonvisual techniques are absolutely essential where the test temperature or the environment prohibits direct visual observation. Nonvisual methods are more precise than visual techniques and allow for automation of the test beyond the mere acquisition of the crack growth rate data (Ref 71, 72).

Finally, specimen geometry and size requirements for ΔK-based crack propagation data, which are scalable to components through similitude, have not been established completely for subcritical crack growth. In-plane yielding must be limited to the crack tip by ensuring that net section stress is below yield and that the maximum plastic zone size, defined as approximately 0.2 $(K_{max}/\sigma_{YS})^2$ (where σ_{YS} is yield strength), is much less (for example, 10- to 50- fold) than the uncracked ligament. Specimen thickness, as it influences the degree of plane-strain constraint, and crack size, as it influences the chemical driving force, may affect corrosion- fatigue crack speeds. Such effects are currently unpredictable, and specimen thickness and crack geometry must be treated as variables.

CFC Growth in Specific Environments

Corrosion-fatigue crack growth studies in aqueous solutions and gaseous environments at ambient temperature present fewer problems experimentally than many of the other environments considered in this article. Nevertheless, simulation of practical conditions in relation to a specific engineering application requires careful consideration if the data are to be relevant. Similarly, in an academic investigation, comparison of the results of different pieces of work is possible only if the mechanical, metallurgical, and chemical variables are properly characterized and controlled. It is often the case, however, that the most frequent problem in determining the validity of corrosion-fatigue data lies with the control and monitoring of the bulk environment chemistry and the monitoring and recording of the electrochemical potential in aqueous solutions.

Corrosion-fatigue crack growth data are required for practical engineering applications in many diverse and specialized environments. An excellent overview of the following eight specific types of environments is given in *Mechanical Testing and Evaluation,* Volume 8 of *ASM Handbook,* and will not be repeated in this article:

- Vacuum and gaseous environments at ambient temperatures
- Vacuum and oxidizing gases at elevated temperatures
- Aqueous solutions at ambient temperatures
- Acidified chloride environments at ambient and elevated temperatures
- High-temperature pure water under aerated conditions
- High-temperature pure water under deaerated conditions
- Liquid metal environments
- Steam or boiling water with contaminants

Evaluating Corrosion Fatigue

Revised by Bopinder Phull, Consultant

Crack Propagation Tests

In large structural components, the existence of a crack does not necessarily imply imminent failure of the part. Significant structural life may remain in the cyclic growth of the crack to a size at which a critical failure occurs. The objective of corrosion-fatigue crack propagation testing is to determine the rates at which subcritical cracks grow under cyclic loading before reaching a size that is critical for fracture under specified environmental conditions.

Fracture Mechanics Approach to Corrosion Fatigue

Fracture mechanics provides the basis for many modern fatigue crack growth studies. Fracture mechanics is based on the concept of similitude, in which cracks of different geometries grow at equal rates when subjected to equal near- tip driving forces, usually ΔK. ΔK is the stress- intensity range (K_{max} - K_{min}), where K is the magnitude of the mathematically ideal crack-tip stress field in a homogeneous, linear-elastic body; K is a function of applied load and crack geometry. The growth or extension of a fatigue crack under cyclic loading is principally controlled by maximum load and stress ratio (minimum/maximum stress). However, as in crack initiation, there are a number of additional factors that may exert a strong influence, especially with the presence of an aggressive environment. Most CFC growth-rate investigations attempt to follow the general provisions of standard test method ASTM E 647 (Ref 25).

In this constant-load-amplitude method, crack length is measured visually or by an equivalent method as a function of elapsed cycles, and these data are subjected to numerical analysis to establish the rate of crack growth. Crack growth rates are then expressed as a function of crack tip stress-intensity range, ΔK, which is calculated from expressions based on linear-elastic stress analysis.

Background information on the rationale for employing linear-elastic fracture mechanics for this purpose is given in Ref 44. Expressing the crack growth rate da/dN (where a is crack length and N is number of cycles) as a function of ΔK provides results that are independent of specimen geometry, and this enables the exchange and comparison of data obtained from a variety of specimen configurations and loading conditions. Moreover, this feature enables da/dN versus ΔK data to be used in the design and evaluation of engineering structures. It is important in the generation of CFC growth data, however, that there be judicious selection, monitoring, and

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

control of mechanical, chemical, and electrochemical test variables in order to ensure that the data are truly applicable to the intended use.

Results of fatigue crack growth rate tests for many metallic structural materials have shown that complete *da*/*dN* versus ΔK curves have three distinct regions of behavior (Fig. 9). In an inert (or benign) environment, the rate of crack growth depends strongly on K at K levels approaching K_{Ic} (plane-strain fracture toughness) at the high end (region III) and at levels approaching an apparent threshold, ΔK_{th}, at the lower end (region I), with an intermediate region II that depends on some power of K or ΔK of the order of 2 to 10 (Ref 44). This is described by the power-law relationship:

$$\frac{da}{dN} = C(\Delta K)^n \qquad \text{(Eq 2)}$$

where C and n are constants for a given material and stress ratio. In an aggressive environment, the CFC growth curve can be quite different from the pure fatigue curve, depending on the sensitivity of the material to the given environment and the occurrence of various static stress- fracture mechanisms. The environmental effects are quite strong above some threshold for SCC (K_{ISCC}) and may be negligible below this level (K_{ISCC} is the stress-intensity threshold for plane- strain environment-assisted cracking). In addition, certain loading factors, such as frequency, stress ratio, and stress waveform, can have marked effects on the crack growth curves in aggressive environments. Therefore, a variety of curves can be expected from the broad range of material-environment-loading systems that produce various CFC behaviors.

Figure 10 shows an example of a high- strength aluminum alloy with a high resistance to SCC. This alloy had a CFC growth rate ranging up to 1 order of magnitude higher in 3.5% sodium chloride (NaCl) solution compared to that in dry air. These data also illustrate that CFC behavior is similar when tested in the same environment with either a *K*-increasing (remote load) or a *K*-decreasing (wedge force) loading method.

Corrosion-fatigue growth rate versus stress- intensity data have been extensively produced (Ref 2, 3, 4, 5, 6, 7, 8, 47, 48) and can be used for mitigating corrosion fatigue from several perspectives. Laboratory crack growth rate data are scalable quantitatively for predicting component performance. The da/dN versus ΔK curve for a given material and environment is integrated; it is then used in conjunction with the stress-intensity solution for a component to predict corrosion-fatigue life (Ref 44). A specific example reported in Ref 49 is illustrated in Fig. 11. The predicted 85 year life of a welded pipe is based on week-long laboratory measurements of da/dN versus ΔK for steel in an oil environment.

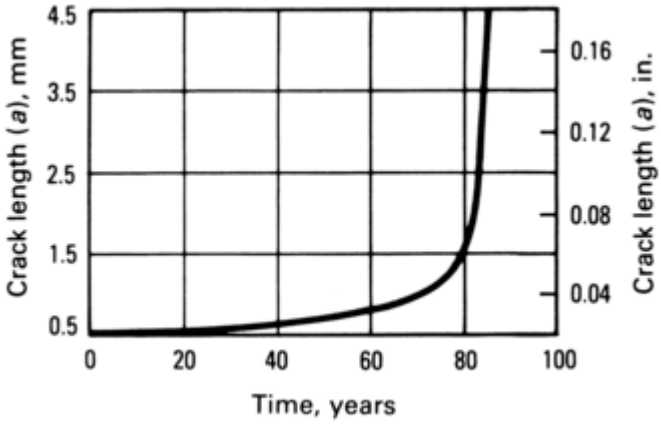

Fig. 11 Predicted fatigue crack extension from a weld toe crack in an American Petroleum Institute (API) 5LX52 carbon steel pipeline carrying hydrogen-sulfide-contaminated oil. Temperature: 23 °C (73 °F). Source: Ref 49

Alloy development for optimized corrosion- fatigue resistance, defined in terms of da/dN versus ΔK for different metallurgical conditions, is directly related to component life goals based on fracture mechanics. Similarly, the effects of mechanical and chemical variables on corrosion fatigue and component performance are defined through measured changes in crack growth rate at different applied stress-intensity levels.

Crack growth rate data are important to fundamental studies of corrosion-fatigue mechanisms. The fracture mechanics approach isolates crack propagation from initiation in terms of a precise near-tip mechanical driving force, ΔK. Crack growth rates are related directly to the kinetics of mass transport and the chemical reactions that constitute embrittlement. As shown in Fig. 12, prediction of the effect of loading frequency on crack growth rate in saltwater (normalized to vacuum) identifies important rate- limiting crack tip electrochemical reactions. Modeling and measurements in Fig. 12 provide a sound basis for extrapolating short-term laboratory data in order to predict long-term component cracking.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

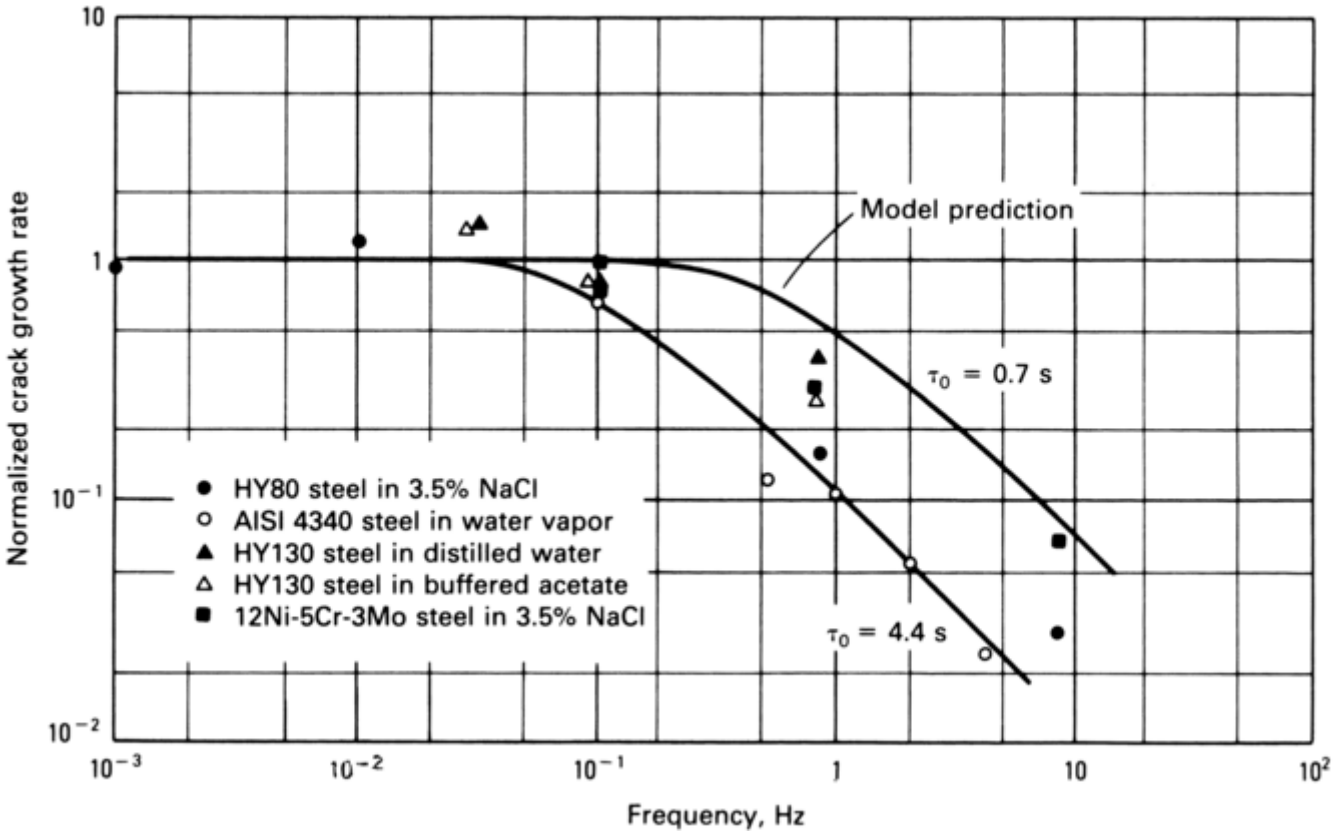

Fig. 12 Modeled effect of loading frequency on corrosion-fatigue crack growth in alloy steels in an aqueous chloride solution. The determination of the normalized crack growth rate and the time constants, τ_0, from the model can be found in Ref 50.

However, the fracture mechanics approach to corrosion fatigue is not valid in all cases. Discussion in this article is limited to crack growth in conjunction with net section elastic loading and small-scale plasticity confined to the crack tip. Studies of crack growth under large-scale cyclic plasticity have not been extended to consider environmental effects (Ref 51, 52). Also, while stress intensity provides a mechanical description of similitude, it may not completely describe crack growth because of interacting chemical and mechanical driving forces.

Results of investigations indicate that simple *K*-based approaches can be compromised for (a) small corrosion-fatigue cracks below 5 mm (0.2 in.), (b) cases in which varying crack shape and load transients alter crack chemistry and embrittlement, and (c) situations in which surface roughness or corrosion products impede crack displacement (Ref 51, 52, 53, 54, 55). Reference 51, 52, 53, 54, 55 should be consulted if an application includes plasticity, small crack, load transient, or crack closure effects.

Variables Influencing Corrosion Fatigue

Although corrosion-fatigue phenomena are diverse and specific to the environment, several variables are known to influence crack growth rate. The following factors must be considered in any study of corrosion fatigue:

- Stress-intensity range
- Load frequency
- Stress ratio
- Electrode potential in aqueous environment
- Environment composition
- Alloy composition, microstructure, and yield strength

Moreover, the effects of such variables as temperature, load history and waveform, stress state, and environment composition may be unique to specific materials and environments.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Stress-Intensity Range. Corrosion-fatigue crack growth rates generally increase with increasing stress intensity; however, the precise dependence varies markedly. It is incorrect to assume that the three regimes (near threshold, power law, and fast fracture; see Fig. 9) of fatigue cracking observed for benign environments simply shift to higher crack speeds at all ΔK levels. Although such behavior may actually occur, as illustrated in Fig. 10 for the aluminum/dry air system, the data provided in Fig. 13 and Fig. 14 are more typical of complex stress-intensity dependencies for aggressive environments.

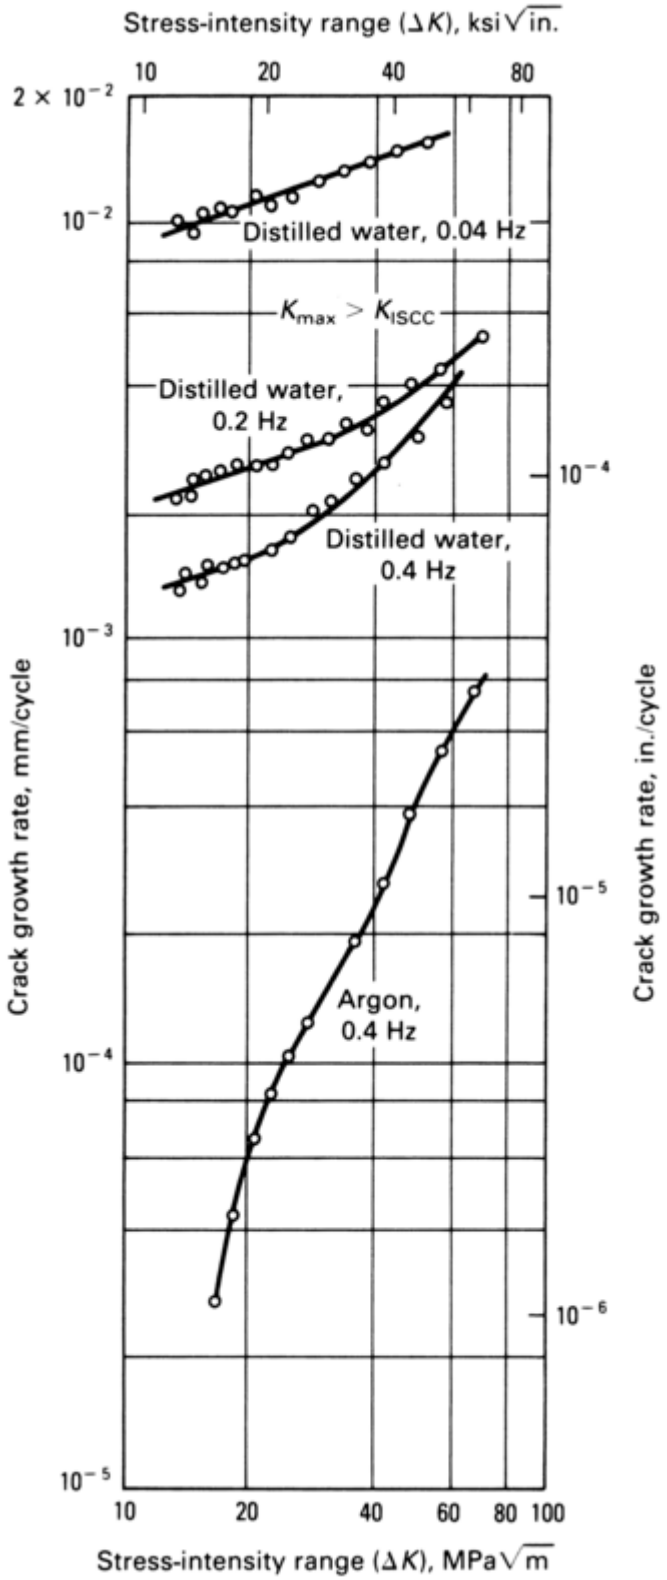

Fig. 13 Effect of stress-intensity range and loading frequency on corrosion-fatigue crack growth in ultrahigh-strength 4340 steel exposed to distilled water at 23 °C (73 °F). Fig. 14 Effects of stress intensity and frequency on corrosion fatigue in Ti-6Al-4V in aqueous sodium chloride at 23 °C (73 °F). Stress ratio: R = 0.1. K_{max}, maximum stress-intensity factor; K_{ISCC}, threshold stress intensity for stress-corrosion cracking. Source: Ref 57

Materials that are extremely environment sensitive, such as ultrahigh-strength steel in distilled water (Fig. 13), are characterized by high crack growth rates that are influenced less by ΔK. Time-dependent corrosion-fatigue crack growth occurs predominantly above the threshold stress intensity for static load cracking and is modeled through linear superposition of SCC and inert environment fatigue rates (Ref 28, 34). Time- dependent crack growth is the part of the crack extension that is attributable to the constant or rising-load portion of the cyclic load cycle, when SCC and hydrogen embrittlement mechanisms may be operative. Factors such as stress wave form and stress hold-time are particularly significant under these circumstances.

Cycle-dependent corrosion-fatigue crack propagation often occurs below the threshold for time-dependent SCC (Ref 57). Typical ΔK dependencies for this mode of cracking are complex, as illustrated in Fig. 14 for Ti-6Al-4V exposed to aqueous sodium chloride. The mechanistic implications of the various stress- intensity dependencies are detailed in Ref 28, 57, and 58. The influences of such variables as frequency, stress ratio, and metallurgical factors depend on the proportions of time- and cycle-dependent corrosion fatigue.

Frequency. The frequency of cyclic loading is the most important variable that influences CFC for most material, environment, and stress- intensity conditions. The rate of environmental cracking above that produced in vacuum generally increases with decreasing frequency. Frequencies exist above which CFC is diminished. The dominance of frequency is directly related to the time dependence of mass transport and chemical reaction steps required for environmental cracking. Basically, insufficient time is available for chemical embrittlement at rapid loading rates, that is, high frequencies, when damage is only mechanical and is equivalent to crack growth in vacuum. It is impossible to predict the frequency range at which corrosion fatigue is severe because of the numerous chemical processes. It is also difficult to extrapolate short- term (high-frequency) laboratory crack growth rate data in order to predict long-term component performance.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The literature provides qualitative guidance in terms of frequency effects on CFC. Crack growth in environmentally sensitive materials stressed above the stress-corrosion threshold proceeds at rapidly increased rates with decreasing frequency, as illustrated in Fig. 13. The frequency effect is predicted through the integration of static load data throughout each load cycle (Ref 50). For such systems, the chemical contribution to fatigue cracking is suppressed above 0.5 to 5 Hz, with higher critical frequencies associated with more aggressive environments and sensitive microstructures.

Frequency effects on cycle-dependent cracking are complex and unpredictable. The data given in Fig. 12 and 14 provide typical examples. For steels in saltwater (Fig. 12), CFC is suppressed at approximately 10 Hz. Crack speed increases with decreasing frequency and reaches a plateau between 0.5 and 0.1 Hz. In contrast, CFC in Ti-6Al-4V occurs at loading frequencies at least as high as 10 Hz (Fig. 14).

Stress Ratio. The rates of corrosion-fatigue crack propagation generally are increased by higher stress ratios. The deleterious effect of increased stress ratio is illustrated in Fig. 15 for carbon steel stressed cyclically in pressurized nuclear reactor water at 288 °C (550 °F). The extent of the corrosion-fatigue effect relative to dry air increased from approximately a factor of 4 at low R (0.11 to 0.24) to as much as 20- to 30-fold at high R (0.61 to 0.71) (Ref 59). Corrosion fatigue in this system probably proceeds by repeated passive film formation and rupture. Increased stress ratio at constant ΔK results in increased crack tip strain and strain rate, enhanced film rupture, and therefore increased corrosion-fatigue crack propagation (Ref 60).

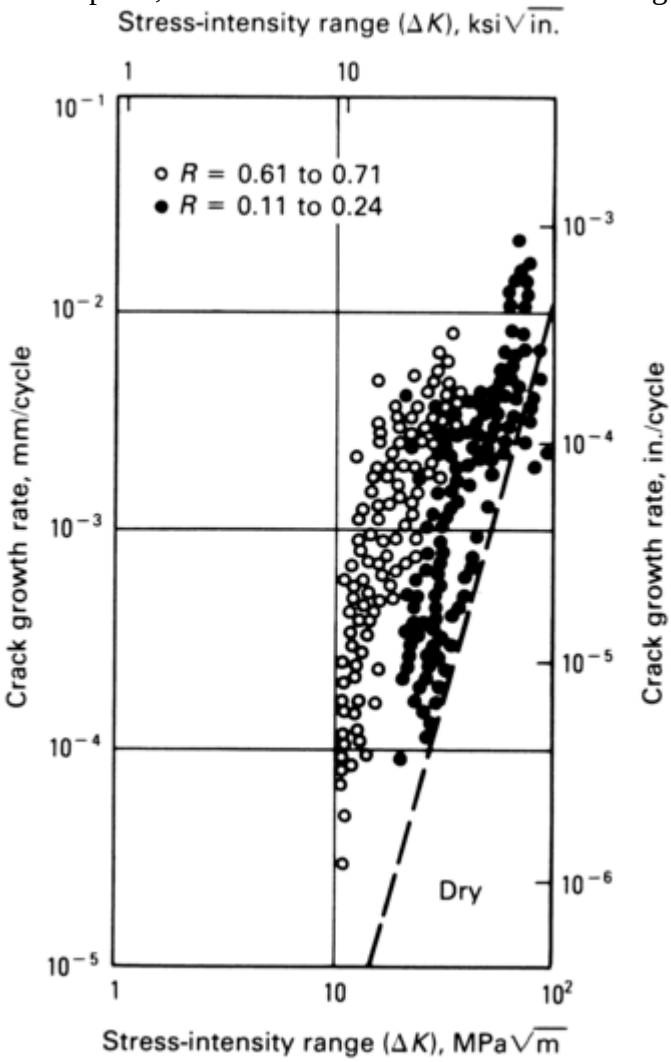

Fig. 15 Effect of stress ratio (R) on corrosion-fatigue crack propagation in ASTM A533 B and A508 carbon steels exposed to pressurized high-purity water at 288 °C (550 °F). Frequency: 0.017 Hz. Average behavior in air is represented by the dashed line labeled "Dry." Source: Ref 59

Electrode Potential. Like loading frequency, electrode potential strongly influences rates of corrosion-fatigue crack propagation for alloys in aqueous environments. Controlled changes in the potential of a specimen can result in either the complete elimination or the dramatic increase of fatigue cracking. The precise influence

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

depends on the mechanism of the environmental effect and on the anodic or cathodic magnitude of the applied potential.

For ferrous alloys that crack by hydrogen embrittlement when stressed in aqueous solutions, CFC is increased by high cathodic polarization from the free corrosion potential. Specific data are given in Fig. 16 for three steels stressed at constant ΔK in aqueous chloride environments (Ref 51, 61, 62). For each steel, the crack growth rate in saltwater is approximately three times faster than that reported for air at the free corrosion potential and is enhanced by a factor of 5 at a very high cathodic potential. For the low- strength BS4360:50D grade (similar to Unified Numbering System, or UNS, K02601), intermediate potentials appear to be mildly beneficial. Corrosion fatigue parallels electrode-potential- induced changes in the amount of cathodically evolved hydrogen in the crack tip. Precise modeling of this reaction sequence is complex and only partially completed (Ref 63).

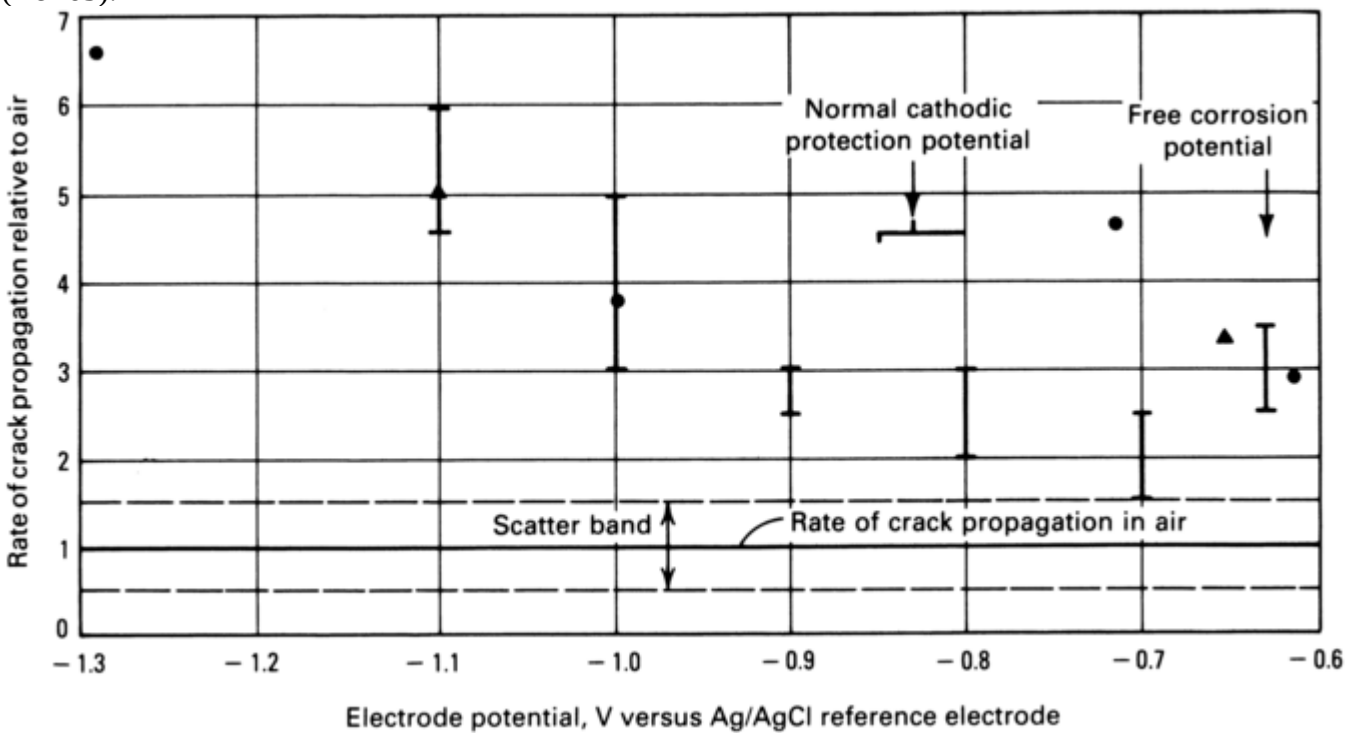

Fig. 16 Effect of applied electrode potential on corrosion-fatigue crack propagation in several steels exposed to seawater or 3% sodium chloride at constant ΔK between 20 and 40 MPa$\sqrt{m}$ (18 and 36 ksi$\sqrt{\text{in.}}$). Temperature: 23 °C (73 °F); frequency: 0.1 Hz; stress ratio: R = 0.1[ep[ol6p]

BS4360:50D	I	450	65	Seawater	60
HY80	•	600	85	3% NaCl	61
AISI 4130	▲	750	110	3% NaCl	62

Electrode potential control can suppress corrosion fatigue for alloys that crack through anodic dissolution/film rupture or anion adsorption mechanisms (Ref 64). For example, corrosion fatigue of austenitic stainless steel in chloride solutions at elevated temperatures is probably suppressed by polarization active to the critical potential for SCC.

Another example is illustrated in Fig. 17. Aluminum alloy 7079-T651 is degraded by corrosion fatigue in several aqueous halide solutions at the free corrosion potential. Compared to dry argon, cracking in potassium iodide is enhanced by more than an order of magnitude (Fig. 17a). The CFC growth rate was further increased by anodic polarization at potentials more electropositive than -0.6 V versus standard hydrogen electrode (SHE) but was suppressed by cathodic polarization (Fig. 17b).

مرجع مهندسی مواد و متالورژی

potential at ΔK of 6.7 MPa $\sqrt{m}$ (6 ksi $\sqrt{\text{in.}}$) in 25% potassium iodide solution. SHE, standard hydrogen electrode. Source: Ref 65

Electrode potential should be monitored and, if appropriate, maintained constant during corrosion-fatigue testing. Apparent effects of variables, such as the dissolved oxygen content of the solution, flow rate, ion concentration, and alloy composition on corrosion fatigue, can often be traced to changing electrode potential.

Crack Closure Effects. Premature crack surface contact during unloading, or crack closure, can greatly reduce rates of fatigue crack propagation. The true (or effective) crack tip driving force is reduced below the applied ΔK because of the reduced crack tip displacement range. Closure phenomena are produced by a variety of mechanisms and are particularly relevant to fatigue crack propagation in the near-threshold regime, after large load excursions, and for embrittling corrosive mechanisms, as reviewed in Ref 53, 66, and 67.

Two mechanisms of crack closure are relevant to corrosion fatigue. Rough, intergranular crack surfaces, typical of environmental embrittlement, promote crack closure because uniaxially loaded cracks open in a complex three-dimensional mode, allowing for surface interactions and load transfer. Roughness-induced closure is most relevant to corrosion fatigue at low ΔK and at stress ratio levels where absolute crack opening displacements (0.5 to 3 μm) are less than fractured grain heights (5 to 50 μm).

Alternatively, crack closing is impeded by dense corrosion products within the pulsating fatigue crack. For mildly oxidizing environments, such as moist air, this closure mechanism is relevant at low stress-intensity levels and contributes to the formation of a threshold, as described in Ref 67.

For corrosive bulk environments, cracking at high ΔK values may be retarded below growth rates observed for air or vacuum due to corrosion product formation within the crack. The engineering significance of beneficial crack closure influences depends on the stability of the corrosion product during complex tension-compression loading and fluid conditions. An example of crack closure is presented in Fig. 18 for ASTM A 471 steel exposed to either moist air or steam at 100 °C (212 °F). Crack growth is reduced for the latter environment because of crack surface oxidation and enhanced closure. It should be noted that oxide-induced closure influences cracking even at a relatively high stress ratio of 0.35. The data presented in Fig. 18 were obtained at a high loading frequency of 100 Hz, and chemically enhanced crack growth was essentially precluded.

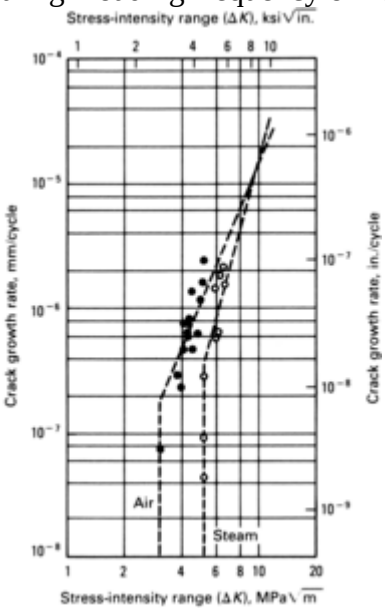

Fig. 18 Corrosion-fatigue crack propagation in ASTM A 471 steel exposed to moist air and steam. Temperature: 100 °C (212 °F); frequency: 100 Hz; stress ratio: *R* = 0.35. Source: Ref 68

Crack growth at lower frequencies could be deleteriously influenced by metal embrittlement and beneficially influenced by increased oxide formation and closure. The complexity of predicting environmentally enhanced cracking is clear, as emphasized by data given in Fig. 19 for a 2.25Cr-1Mo steel (ASTM A 542, class 3) stressed in dry hydrogen at 23 °C (73 °F). At high ΔK levels and low loading frequencies, cracking was accelerated in hydrogen as compared to moist air. This was due to classical hydrogen embrittlement. For low stress intensities, cracking was also increased by hydrogen exposure; however, the effect was not due to hydrogen embrittlement because of the rapid loading frequencies. Oxides form on crack surfaces through a

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

fretting mechanism during cycling in air, and crack growth rates are reduced by oxide-induced closure. However, oxide formation is precluded for cycling in pure hydrogen, crack closure is absent, and growth rates are increased relative to those in moist air. Equally rapid rates of fatigue cracking have been reported for low ΔK cycling in hydrogen and in helium. Equal rates of cracking are observed for hydrogen, helium, and moist air at high R (stress ratio) levels where closure was absent (Ref 66, 67).

CFC Growth Characterization

Experimental characterizations of corrosion- fatigue crack propagation are complicated by the numerous variables that influence the failure process. Both the mechanics of loading and the composition of the environment must be controlled. Standard methods of measurement and fracture mechanics analysis of fatigue crack propagation in benign environments can be found in ASTM E 647 (Ref 25).

Four problem areas are relevant to corrosion- fatigue testing. First, the environment must be contained about the cracked specimen without affecting loading, crack monitoring, or specimen-environment composition. Parameters such as environmental purity, composition, temperature, and electrode potential must be monitored and controlled.

Second, the deleterious effect of low cyclic frequency dictates that crack growth rates be measured at low frequencies (often <0.2 Hz). This leads to long test times—often several days to weeks. Load-controlled equipment, crack- monitoring sensors and signal conditioners, and test environment composition must be stable throughout long-term tests.

مرجع مهندسی مواد و متالورژی

Third, crack length must be measured for calculations of stress intensity and crack growth rate. Optical methods are often precluded by the environment and test chamber. Indirect methods, which are based on specimen compliance (Ref 69) or electrical potential difference (Ref 70), have been successfully applied to the monitoring of crack growth in a wide variety of hostile environments. Experimental and analytical requirements, however, are complex for indirect crack monitoring.

Nonvisual techniques will often have greater accuracy and less variability in crack length measurement than optical observations. In addition, the nonvisual techniques are generally more consistent and reliable, especially where long periods of unattended testing are anticipated. Beyond that, nonvisual techniques are absolutely essential where the test temperature or the environment prohibits direct visual observation. Nonvisual methods are more precise than visual techniques and allow for automation of the test beyond the mere acquisition of the crack growth rate data (Ref 71, 72).

Finally, specimen geometry and size requirements for ΔK-based crack propagation data, which are scalable to components through similitude, have not been established completely for subcritical crack growth. In-plane yielding must be limited to the crack tip by ensuring that net section stress is below yield and that the maximum plastic zone size, defined as approximately 0.2 $(K_{max}/\sigma_{YS})^2$ (where σ_{YS} is yield strength), is much less (for example, 10- to 50- fold) than the uncracked ligament. Specimen thickness, as it influences the degree of plane-strain constraint, and crack size, as it influences the chemical driving force, may affect corrosion- fatigue crack speeds. Such effects are currently unpredictable, and specimen thickness and crack geometry must be treated as variables.

CFC Growth in Specific Environments

Corrosion-fatigue crack growth studies in aqueous solutions and gaseous environments at ambient temperature present fewer problems experimentally than many of the other environments considered in this article. Nevertheless, simulation of practical conditions in relation to a specific engineering application requires careful consideration if the data are to be relevant. Similarly, in an academic investigation, comparison of the results of different pieces of work is possible only if the mechanical, metallurgical, and chemical variables are properly characterized and controlled. It is often the case, however, that the most frequent problem in determining the validity of corrosion-fatigue data lies with the control and monitoring of the bulk environment chemistry and the monitoring and recording of the electrochemical potential in aqueous solutions.

Corrosion-fatigue crack growth data are required for practical engineering applications in many diverse and specialized environments. An excellent overview of the following eight specific types of environments is given in *Mechanical Testing and Evaluation,* Volume 8 of *ASM Handbook,* and will not be repeated in this article:

- Vacuum and gaseous environments at ambient temperatures
- Vacuum and oxidizing gases at elevated temperatures
- Aqueous solutions at ambient temperatures
- Acidified chloride environments at ambient and elevated temperatures
- High-temperature pure water under aerated conditions
- High-temperature pure water under deaerated conditions
- Liquid metal environments
- Steam or boiling water with contaminants

Evaluating Erosion Corrosion, Cavitation, and Impingement

Revised by Denise Aylor, Naval Surface Warfare Center, Carderock Division, and Bopinder Phull, Consultant

Introduction

EROSION, CAVITATION, AND IMPINGEMENT are mechanically assisted forms of material degradation. Erosion, in the context of this article, is defined as the progressive loss of material from a solid surface due to mechanical interaction between that surface and a fluid; therefore, any equipment that is exposed to moving fluids may be susceptible to erosion. Cavitation is caused by the formation and collapse of vapor bubbles in a liquid near a metal surface. Impingement refers to damage caused by liquid jets, droplets, or solid particles impacting a solid surface.

Mechanical damage to metal surfaces removes protective films. These films can be air- formed passive oxides, as in the case of stainless steels, nickel-base alloys, and titanium alloys; or corrosion-product films, as in the case of copper- base alloys. Any process that removes the protective films and interferes with their quick reformation exposes the substrate to electrochemical corrosion. Hence the terms *erosion corrosion, cavitation corrosion,* and *impingement corrosion* connote material damage caused by the conjoint action of mechanical and electrochemical factors. More information on the mechanisms of these forms of attack is available in Ref 1 and 2.

Erosion, cavitation, impingement, and even corrosive wear are often “interrelated,” which is why it is not always possible to easily distinguish between them, especially in actual component failures in service environments. The presence of entrained solids can also contribute significantly to erosion (abrasive wear) of materials. Laboratory tests used to evaluate erosion, cavitation, and impingement damage on metals include the following (Ref 3, 4, 5, 6, 7, 8, 9):

- High-velocity flow tests, including venturi tubes, rotating disks, and ducts containing specimens in throat sections
- High-frequency vibratory tests using either magnetostriction devices or piezoelectric devices
- Impinging jet tests using either stationary or rotating specimens exposed to high-speed jet or droplet impact

These tests are generally designed to provide high-erosion intensities on small specimens in relatively short times. These methods may not closely simulate service conditions, but they are useful for ranking candidate materials.

Evaluating Erosion Corrosion, Cavitation, and Impingement

Revised by Denise Aylor, Naval Surface Warfare Center, Carderock Division, and Bopinder Phull, Consultant

Standard Test Methods

There are four ASTM International standards related to the evaluation of erosion, cavitation, and impingement. These are designations G 32 (Ref 4), G 73 (Ref 5), G 75 (Ref 6), and G 76 (Ref 7). All of these standards include definitions of terms related to cavitation, erosion, and impingement as well as information on specimen preparation, test conditions and procedures, and data interpretation.

ASTM G 32 is based on the generation and collapse of cavitation bubbles on a specimen surface vibrating at high frequency. It is used to evaluate the relative resistances of different materials to cavitation erosion.

Test Specimen. Reference 4 specifies a test specimen measuring 15.9 mm ± 0.05 mm (0.625 ± 0.002 in.) in diameter and not less than 4 mm (0.157 in.) and not more than 10 mm (0.393 in.) in thickness. More details on specimen requirements are provided in Ref 4.

The test apparatus (Fig. 1) produces axial oscillation of the test specimen, which is partially immersed in the test liquid. This is accomplished using either a magnetostrictive or piezoelectric transducer driven by an electronic oscillator or amplifier. The transducer vibrates at a frequency of 20 kHz. The apparatus must include some method of measuring the displacement amplitude of the transducer as well as a means of maintaining the specified test temperature.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

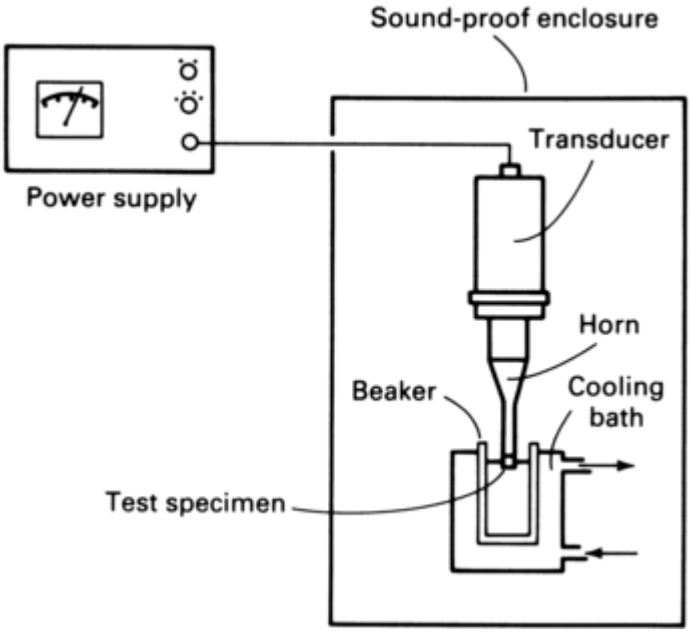

Fig. 1 Schematic of a typical vibratory erosion/cavitation test apparatus. Source: Ref 4

Test Conditions. The standard test liquid is distilled or other reagent water meeting the specifications of ASTM D 1193 (“Standard Specification for Reagent Water”) maintained at a temperature of 25 ± 2 °C (77 ± 3.6 °F). Air is maintained over the test liquid at a pressure of not less than 6% from one standard atmosphere (101.3 kPa; 760 mm, or 29.92 in., of mercury). A peak-to-peak displacement amplitude of 0.05 mm (0.002 in.) ± 5% is specified for the oscillation of the test specimen. Alternatively, for weak, brittle, or nonmetallic materials that may be damaged too rapidly, a peak-to-peak displacement amplitude of 0.025 mm (0.001 in) is suggested.

Test conditions can be varied by using different test liquids, temperatures, and pressures. Any such variations must be noted when results are reported. Liquids other than reagent water that have been used include petroleum derivatives, glycerin, and liquid metals. Tests have shown that the erosion rate peaks strongly at a temperature about midway between the freezing point and the boiling point of the test liquid. Therefore, the erosion rate of a material in water at normal atmospheric pressure peaks at about 50 °C (122 °F) and falls off on either side of this value. The decrease in erosion rate is most dramatic as temperature rises above 50 °C (122 °F).

Test Procedure. The specimen must be cleaned and accurately weighed before testing, then immersed in the test liquid to a depth of 12 ± 4 mm (0.47 ± 0.16 in). The peak-to-peak displacement amplitude should be monitored constantly. The test should be interrupted periodically to determine the mass loss of the specimen, which should be carefully cleaned and dried before reweighing. The time between measurements should be such that a plot of cumulative mass loss versus exposure time can be established. The time between measurements, therefore, depends on the specimen material; softer materials (for example, aluminum alloys) can be examined every 15 min, while the interval between measurements for a harder material, such as Stellite alloy 6B, may range from 8 to 10 h. Testing should be continued at least until the erosion rate reaches a maximum and begins to diminish. When several materials are being compared, all should be tested until they reach comparable mean depths of erosion.

Data Acquisition and Reporting. The mean depth of erosion of the specimen should be calculated based on the full area of the test surface of the specimen. The report should include the following information:

- Alloy type, metallurgical condition, composition, and mechanical properties (including hardness)
- Specimen preparation, preferably including initial surface roughness measurement
- The number of specimens tested
- Tabulation of cumulative mass losses and cumulative exposure time for each specimen
- Plots of cumulative mean depth versus cumulative exposure time for each specimen

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

To facilitate comparisons between different materials, results are often expressed in terms of a single number based on the erosion resistance of the test specimen relative to that of a standard reference material. These types of ratings are discussed more fully in Ref 5.

The report should also include information on any deviations from the standard test procedure; for example, test liquid, temperature, or pressure as well as any unusual occurrences or observations. In addition, each test should include at least one of the standard reference materials to facilitate calculation of the normalized erosion resistance of the test materials. Annealed wrought Nickel 200 (UNS N02200), conforming to ASTM B 160, is a standard reference material. Reference materials of lesser and greater resistance, respectively, are: aluminum alloy 6061-T6 (UNS A96061) and annealed Type 316 stainless steel (UNS S31600; hardness 150–175 HV). These materials are also used to calibrate the testing apparatus.

ASTM G 134 (Ref 8) provides an alternative to ASTM G 32. A submerged cavitating jet, emanating from a nozzle, impinges on a test specimen causing cavities to collapse on it. This method allows comparison of the relative cavitation erosion resistance of solid materials as may be encountered in pumps, valves, ship propellers, diesel engines, and so forth. Although the test fluid is usually water, this test method can be used to compare the cavitation capacity in other liquids. The test apparatus, test specimens, reference materials, calculations, and data interpretation are detailed in Ref 8.

ASTM G 73 provides guidelines for liquid drop or jet impingement testing that, in addition to evaluating the resistance of metals, can be used to evaluate the degradation of optical properties of window materials and the destruction of coatings by the impinging liquid (Ref 5). The standard does not outline a single test method or apparatus but instead gives guidelines for setting up tests and specifies test and analysis procedures and the reporting of data.

Test Specimens. Metallic test specimens can be chosen to present a curved (airfoil or cylindrical) or flat surface to the impinging liquid. They can be machined from a solid bar or can be cut from sheet. If specimens are machined, care should be taken to avoid work hardening of the surface. Surface finish should range from 0.4 to 1.6 μm (16 to 63 μin.) rms (root mean square). If another surface finish is employed, it should be noted in the test report.

Test Apparatus. ASTM G 73 mainly addresses liquid-drop or jet-impingement test devices of the rotating disk type. In these tests, the specimen or specimens are attached to a rotating disk or arm, and their circular paths pass through one or more liquid jets or sprays, resulting in discrete impacts between the specimen and the droplets or the cylindrical surface of the jets. Peripheral velocities (and therefore impact velocities) ranging from about 50 m/s (165 ft/s) to as high as 1000 m/s (3280 ft/s) may be obtained, depending on the particular apparatus used. Figure 2 illustrates two examples of rotating disk test apparatuses.

Fig. 2 Examples of rotating disk and rotating arm erosion/cavitation test apparatuses. (a) Small, relatively low-speed rotating disk and jet apparatus. (b) Large, high-speed rotating arm spray apparatus. Source: Ref 5

Droplet or jet diameters also vary from about 0.1 to 5 mm (0.004 to 0.2 in.). Droplets can be generated by spray nozzles, vibrating hollow needles, or rotating disks with water fed onto their surfaces. The typical droplet or jet diameter and the volume of liquid impacting the specimen per unit time should be determined within 10%. Jet diameter is usually assumed to be the same as the nozzle diameter. Other types of liquid-impact erosion test devices are also briefly described in Ref 5.

Test procedures for various materials vary to some extent. The standard gives procedures for structural materials and coatings, including metals, structural plastics, composites, and metals with ceramic or metallic coatings; elastomeric coatings; window materials; and transparent thin-film coatings on window materials. Details on these procedures are outlined in the standard.

Calculation of Erosion Resistance. Because it is currently not possible to define “absolute” erosion resistance, most investigators use comparative evaluations of different materials to quantify relative erosion resistance. ASTM G 73 details several approaches for calculating and presenting relative or normalized measures of erosion resistance for the various classes of materials considered. These include evaluation based on time to failure, total material loss, erosion rate-time patterns, incubation period, maximum erosion rate, and terminal erosion rate. Results for different materials can also be normalized by direct comparison to one of the designated reference materials: aluminum alloys 1100-0 or 6061-T6; annealed commercially pure 99.98% nickel (Nickel 270 used originally in the development of the standard may no longer be available; the alternative material is Ni 200, which has erosion resistance ~40% higher and incubation time ~60% greater than Ni 270); and Type 316 stainless steel, with a hardness between 155 and 170 HV. Indirect comparison to a standardized reference scale may also be done. Details on these procedures, as well as on the calculation of an apparatus severity factor, are given in ASTM G 73.

A jet-impingement test specifically designed for evaluating erosion-corrosion resistance of heat-exchanger tubing alloys is described in Ref 9. A submerged jet of liquid, emerging from a small orifice in a disc (made from a highly erosion-resistant material, e.g., titanium), is directed at a stationary test-specimen target. The degree of erosion corrosion is determined from overall mass loss and depth of attack at the impact area. The mean jet velocity is varied by using orifices of different sizes and selecting the appropriate liquid pressure. Multiple specimens can be tested at the same time at different impingement velocities. In addition to comparing performance of different alloys, the basic test setup can be used to evaluate efficacy of other corrosion control methods for mitigating erosion corrosion, for example, coatings, corrosion inhibitors, and cathodic protection.

ASTM G 75 (Ref 6) provides a test method to determine the relative abrasivity of a slurry or the resistance of different materials to the abrasivity of different slurries. Abrasion specifically refers to erosion caused by solid particles. The data are used to calculate a Miller number (slurry abrasivity) or a SAR number (material response to slurry abrasivity). These calculations provide useful information in selecting pumps and other equipment as well as in predicting the service life of pumps and related parts. The Miller number, which ranks abrasivity of slurries based on the wear of a standard reference block, increases as the wear damage on the reference block increases. The SAR number ranks the abrasion response of a material when tested in a slurry of interest and can be used to determine the most appropriate materials for use in particular slurries. Like the Miller number, the SAR number increases as the slurry damage on the test specimen increases.

Test Specimen. The test specimen used in assessing the slurry abrasivity (Miller number) is a standard wear reference block of a proprietary iron-chromium alloy (nominally 28% Cr, 2.5% C, 1% Mn, 0.8% V, 0.6% Si, 0.3% Mo, 0.25% Ni). The reference block is heat treated and machined to an approximate 25 × 13 × 5 to 7 mm (1 × 0.5 × 0.20 to 0.28 in.) size. The same specimen configuration is used for the SAR number test specimen, machined from the selected candidate material(s). Specimens should be wet ground flat using 320-grit silicon carbide paper prior to testing to remove any damage due to machining. After grinding, specimens should be scrubbed with detergent and water, rinsed, dried with a clean cloth, put under a heat lamp or blown dry for about 5 min, and then weighed.

Test Apparatus and Procedure. The test apparatus, which may be obtained commercially, positions the test specimen on a pivoted arm with a direct load applied. The specimen is driven in a horizontal, reciprocating motion along the bottom of a tray containing the slurry material. Each apparatus contains two to four operating arms, with a separate plastic tray for each arm. The specimen is lifted at one end of each stroke to allow fresh

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

slurry to flow underneath. Each tray holds about 300 mL (10.6 fluid oz) of slurry. The test is conducted in 2 h increments for a total test time of 6 h. Before each 2 h run, any slurry that has settled in the bottom of the trays is remixed using a suitable paddle. After each 2 h run, the specimens are removed from the test machine, scrubbed in water and detergent, rinsed, dried under a heat lamp or in an oven at about 175 °C (347 °F) for 15 min, and weighed. The specimens are then repositioned in the test machine at a 180° orientation to the first 2 h run. This method of alternating the specimen orientation before each 2 h run provides an averaging of the wear pattern on the specimen surface. A schematic of a typical Miller number test machine is included in Fig. 3.

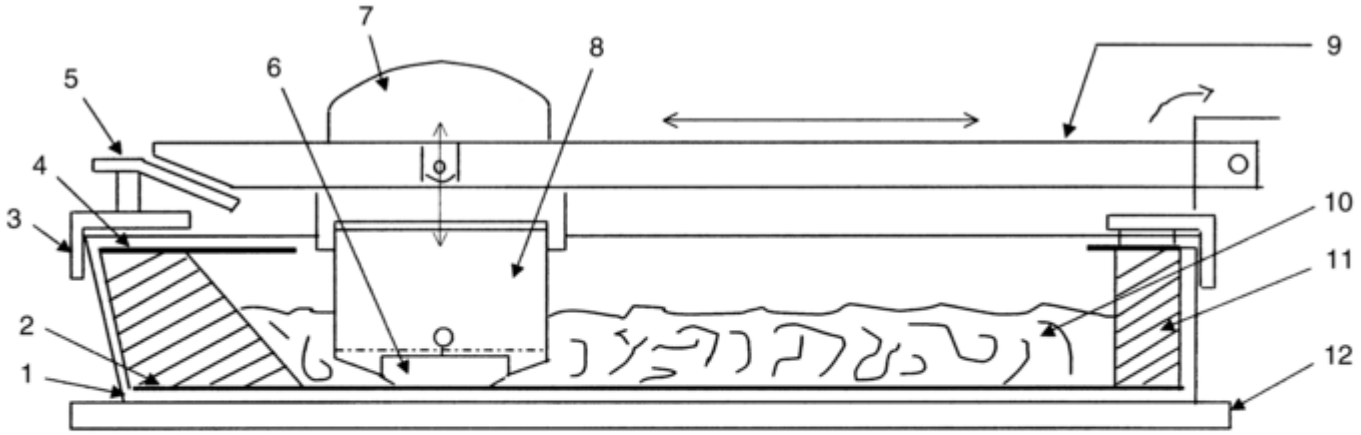

Fig. 3 Miller number machine layout. Source: Ref 6

Calculation of Miller Number and SAR Number. Mass measurements are recorded for the specimens initially and after a cumulative test time of 2, 4, and 6 h. The cumulative mass losses are averaged based on duplicate runs in a given slurry material. These test data are used to calculate both the Miller number and the SAR number. The Miller number is an index measuring slurry abrasivity and is related to the mass loss rate of duplicate reference-material wear blocks in a given slurry material. The SAR number is an index measuring material response to slurry abrasivity and is related to the mass loss rate of duplicate materials in a given slurry. Specifics of calculating these indexes are found in Ref 6; a computer program for calculating these indexes is also included in this standard.

ASTM Standard G 76 (Ref 7) describes a set of standard laboratory test conditions to determine material erosion from solid-particle impingement. This method can be used as a screening tool for evaluation of solid-particle erosion rates of different materials in simulated service environments. The test consists of repeatedly impacting gas-containing abrasive particles against the surface of a test specimen.

Test Specimen. A range of specimen sizes and configurations can be used for this test method as long as they are documented. A rectangular strip of size 10 × 30 × 2 mm (0.4 × 1.2 × 0.1 in.) is suggested as an appropriate specimen for this method.

Test Apparatus. The solid-particle erosion equipment available commercially must be capable of eroding material from a test specimen under controlled exposure conditions. A schematic of the equipment is shown in Fig. 4. The test apparatus must have the capability of controlling and adjusting the impact velocity of the particles, the particle flux, and the positioning of the specimen in relation to the impinging particle stream. Various systems, such as a vibrator-controlled hopper or a screw-feed system, can be utilized for injecting particles into the gas stream; however, the particle feed must be uniform and adjustable to allow the intended particle flow rate. The nozzle should be made of an erosion-resistant material like tungsten carbide or aluminum oxide, and the recommended size is 1.5 mm (0.06 in.) inner diameter by 50 mm (2.0 in.) long. The nozzle length-to-diameter ratio should be a minimum of 25 to 1 so that the particle velocity distribution in the gas stream is adequate.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

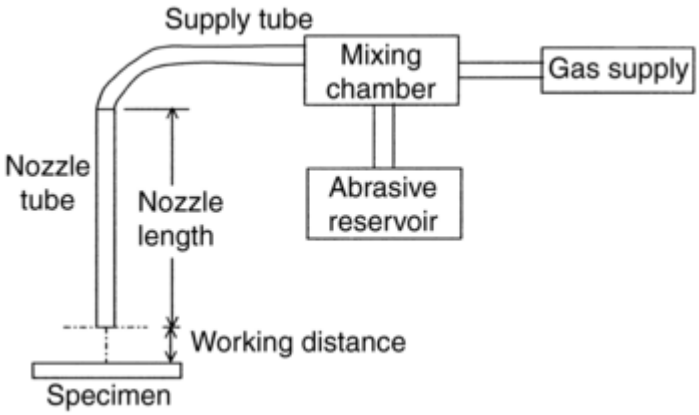

Fig. 4 Schematic drawing of solid particle erosion equipment. Source: Ref 7

The test apparatus must be calibrated to confirm satisfactory performance of the equipment. Calibration is recommended after every 50 tests or at the beginning of a new test program if the equipment has been inactive for a period of time. The calibration procedure utilizes Type 1020 steel specimens with 50 μm (0.002 in.) Al_2O_3 particles.

Test Conditions and Procedure. A summary of standard test conditions specified in ASTM G 76 is provided here:

- Nozzle tube dimensions: diameter 1.5 ± 0.075 mm (0.06 ± 0.003 in.); length, ≥50 mm (≥2 in.)
- Test gas: dry air, -50 °C (-60 °F) dew point or lower
- Abrasive particles: nominal 50 μm angular Al_2O_3; particles used only once
- Particle velocity: 30 ± 2 m/s (100 ± 7 ft/s)
- Gas flow rate ~8 L/min (0.3 ft^3/min) at 140 kPa (20 psig)
- Particle feed rate: 2.0 ± 0.5 g/min
- Test temperature: ambient (approximately 18–28 °C, or 65 to 80 °F)
- Test time: minimum 10 min to achieve steady state conditions; longer times permitted if final erosion crater no deeper than 1 mm (0.04 in.)
- Angle between nozzle axis and specimen surface: 90° ± 2°
- Distance from specimen surface to nozzle end: 10 ± 1 mm (0.4 ± 0.04 in.)

The test specimens are prepared for testing by grinding to a final surface roughness of 1 μm (40 μin.) rms or smaller. Specimens are then cleaned, weighed, and subjected to the particle impingement stream for a selected time interval. After each interval, specimens are removed from the test apparatus, recleaned, and reweighed. At least four test intervals are required for a total time of 10 min or more. For type 1020 steel, recommended cumulative test times are 2, 4, 8, and 16 min. Specimen mass loss is then plotted as a function of time, and the steady-state erosion rate of the material is determined from the slope of this plot.

Other Tests

Numerous other techniques are available for evaluating cavitation, erosion, and impingement in the laboratory. Most of these are variations on the methods already described, employing rotating disks, vibrating devices, or venturi tubes to achieve the required fluid velocities (Ref 10). Another device used to produce cavitation, erosion, and impingement is the liquid gun, which projects short, discrete slugs of liquid from a nozzle onto the specimen (Ref 11). Another method includes evaluation of materials or prototype components in simulated service conditions such as seawater valves in a test piping loop (Ref 12). Details of other nonstandard test procedures are available in Ref 13 to 16.

Effects of Test Parameters (Ref 10)

Test conditions—including the temperature, pressure, flow velocity of the test liquid, frequency, amplitude, and distance between the specimen and the vibrating surface in a vibrating fluid—all influence the incubation and intensity of cavitation. The effects of varying these test parameters are described in the following paragraphs.

Variations in velocity and pressure should not be considered separately, because the intensity of erosion cavitation is a function of both parameters. Generally, erosion rates increase with velocity. A common technique used to evaluate the effect of velocity is to determine the number and size of pits produced in a soft material, such as aluminum, per unit time as velocity is varied (Ref 17). Although the number of pits observed increases over a wide range with velocity, the variation in pit size is relatively insignificant.

The influence of pressure has been investigated for both flow and vibratory cavitation (Ref 18, 19). In the former investigation, velocity was held constant and pressure was increased. Cavitation damage increased to a maximum and then decreased to zero at the pressure corresponding to cavitation inception (Ref 18). In vibratory testing, the erosion rate increased steadily with increasing pressure up to 4 atm, the maximum pressure obtainable in the device used (Ref 19). The authors noted, however, that at sufficient pressure, the cavitation rate would in fact drop to zero.

Temperature. As mentioned earlier in this article, erosion rate increases with temperature to a maximum and then decreases near the boiling point of the test liquid. The decrease in erosion rate near the boiling point is attributed to the increase in vapor pressure of the test liquid (Ref 10). The effect of temperature on the erosion rate of plain carbon steel in three aqueous environments is shown in Fig. 5.

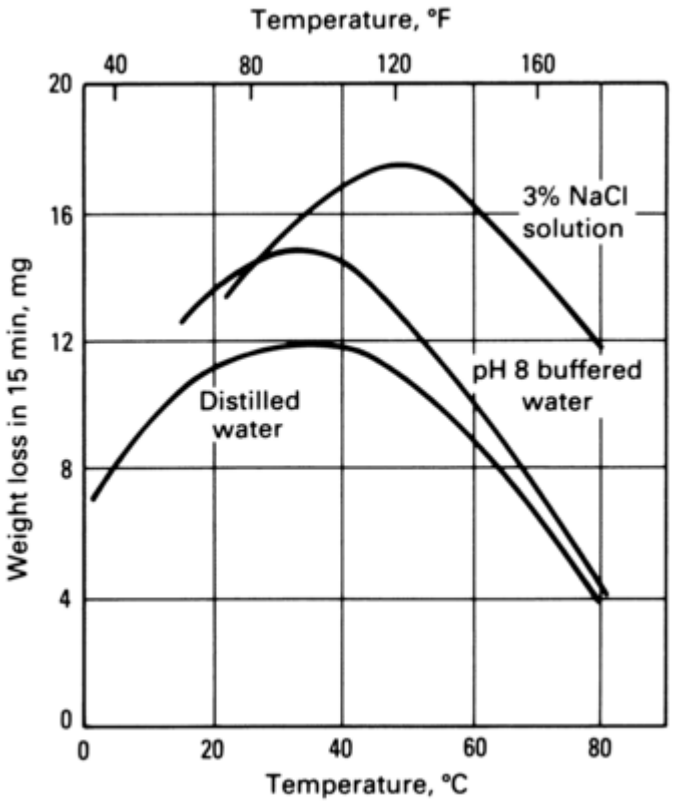

Fig. 5 Influence of temperature on the erosion rate of plain carbon steel in a vibratory cavitation device. Source: Ref 10

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Amplitude and frequency in vibratory devices influence the degree of damage. In tests at constant frequency, erosion rate increased slightly with increasing amplitude (Ref 20). The incubation period for damage decreased with increasing amplitude.

Most vibratory devices operate at the resonant frequency of a piezoelectric crystal. Therefore, frequency cannot be easily varied over a significant range. In one investigation, three different devices with frequencies of 10, 20, and 30 kHz were used to determine the effect of frequency on erosion rate (Ref 20). The stress produced by the cavitation increased as frequency decreased, but the effect was not as significant as that caused by changes in amplitude.

Distance between Specimen and Vibrating Surface. The amount of erosion damage to a specimen rises to a maximum as the distance between the specimen and the vibrating surface decreases. At a frequency of 20 kHz, the position that results in maximum erosion rates is approximately 0.5 mm (0.02 in.) from the vibrating surface (Ref 10). The position of the maximum is independent of amplitude, but no data are available on the influence of frequency on this position.

The influence of fluid properties has been studied by several investigators. Unfortunately, most of them made little attempt to identify those properties of the fluid that affect erosion rates. One investigator, however, considered fluid viscosity, vapor pressure, surface tension, and specific gravity for water, gasoline, and the sodium- potassium eutectic (Ref 21). The temperature dependence of erosion rates was attributed to the effects of velocity and surface tension at low temperatures and to the increase in vapor pressure at high temperatures. By comparing the temperature dependence of properties of the different fluids, he was able to predict the variation in erosion damage in the three fluids. The resulting equation, however, cannot be used to predict erosion rates in other fluids.

Data Correlations

Correlations among Test Methods (Ref 3). Investigations have indicated that there are considerable differences in the erosion intensities produced by different test techniques (that is, high-velocity flow, vibratory, and impingement) and test parameters (vibratory frequency and specimen size and shape). There is, however, general agreement on the ranking of test materials. When the erosion resistance of a material is expressed as a

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

normalized erosion resistance (NER), which is the ratio of the erosion rate of the test material to that of a standard material, results from different test methods and different laboratories can be directly compared and are reasonably consistent (Ref 22). Calculation of NER values and statistical analysis of erosion- rate data are discussed in detail in Ref 5, which also reports on the results of interlaboratory testing using a liquid impingement testing method at three specified velocities.

Correlations between Laboratory Results and Service (Ref 3). Methods to identify service-erosion intensities under conditions of controlled operation include: aluminum panels attached to hydraulic turbine vanes (Ref 23), a strain gage technique for measuring the relative intensities of laboratory and service devices (Ref 24), and the use of a radioactive paint to correlate the erosion intensity of an operating turbine with an erosion-rate index (Ref 25). This latter investigation led to the establishment of relative resistance scales, in which laboratory exposures of 1 to 2 h in a vibratory apparatus can be compared with 16 to 100 h exposures in a venturi apparatus and with months of operation in full-scale turbines. Another investigation (Ref 26) used a combination approach to determine erosion characteristics by (1) measuring (with the aid of a magnetic thickness gage) “wear” of an epoxy coating applied to a pump casing and impeller and (2) computing “wear” of the substrate metal by the thin-layer-activation technique (i.e., monitoring loss of radionuclides induced on the original surfaces).

Evaluating Microbiologically Influenced Corrosion

James F.D. Stott, CAPCIS Ltd., Manchester, United Kingdom

Introduction

MICROBIOLOGICAL CORROSION, more accurately termed microbiologically influenced corrosion (MIC), is not fundamentally different from other types of aqueous electrochemical corrosion; it is simply that the chemical or physical conditions giving rise to the aggressive environment are produced by microorganisms as by- products of their energy-obtaining metabolism. This may involve the production of an aggressive chemical agent such as hydrogen sulfide (H_2S) or acidity. Microorganisms may also consume chemical species that are important in corrosion reactions (e.g., oxygen or nitrite inhibitors). Alternatively, their physical presence may form a slime or poultice, which leads to differential aeration cell attack or crevice corrosion. They may also break down the desirable physical properties of lubricating oils or protective coatings (Ref 1, 2, 3). Microorganisms can therefore be viewed as catalytic entities, effectuating chemical reactions that would otherwise be negligible because of their high activation energy.

Microorganisms, including the corrosion-inducing microorganisms, are present almost everywhere in soils, freshwater, seawater, and air. Therefore, the mere detection of microorganisms in an environment does not necessarily indicate a corrosion problem. What is important is the number of microorganisms of the relevant types.

The salient characteristics of microorganisms from the engineer's viewpoint are that they are small, ubiquitous, potentially very rapid growing, and subject to certain common restraints, such as temperature, pH, and nutrient availability. A problem exists only when conditions become favorable for a specific microbial population to explode, giving rise to thousands or even millions of cells per gram of environmental material. Even then, most microorganisms are harmless from the standpoint of the corrosion engineer; therefore, it is important that the microbiological assessment is type-specific.

The purpose of this article is to address the issue of how an engineer might go about assessing the risk of MIC in an industrial situation. It is not the author's intent to describe in detail the mechanisms of microbiologically mediated corrosion nor to address remedial measures. The role of microorganisms in the corrosion of metals was the subject of a number of classic review articles in the 1970s and 1980s (Ref 4, 5, 6, 7). For more detailed recent reviews of the subject, the reader is referred to the article “Microbiologically Influenced Corrosion” in this Volume and the articles cited under the Selected References at the end of this article. However, it is useful to begin with some limited background information about MIC.

Attack by Sulfate-Reducing Bacteria

The most important group of bacteria associated with corrosion is the sulfate-reducing bacteria (SRB). Most reviewers have approached the subject of MIC from the viewpoint of the microbiologist and have emphasized the complexity and diversity of metabolic processes. In practice, the great majority of MIC failures are related to the activities of SRB. Sulfate-reducing bacteria are anaerobic (oxygen-free) bacteria that obtain their required carbon from organic nutrients and their energy from the reduction of sulfate ions to sulfide.

Sulfate-reducing bacteria will only flourish and cause damage if they obtain sufficient sulfate. Sulfate is abundant in freshwaters, seawater, and soils. Sulfide appears as H_2S (dissolved or gaseous), HS^- ions, S^{2-} ions, metal sulfides, or a combination of these, according to conditions. Sulfides are highly corrosive to many materials. In the case of iron and mild steel, the characteristic black iron sulfide (FeS) corrosion products liberate H_2S on acid treatment, distinguishing them from black iron oxide (magnetite). The corrosion products are often loose and, when dislodged, exhibit pits lined with bright metal corresponding to areas of anodic dissolution.

Bacteria of this type can also use hydrogen by sulfate reduction:

$$4H_2 + SO_4^{2-} \rightarrow S^{2-} + 4H_2O$$

The most commonly encountered SRB type is known as *Desulfovibrio* (Fig. 1).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

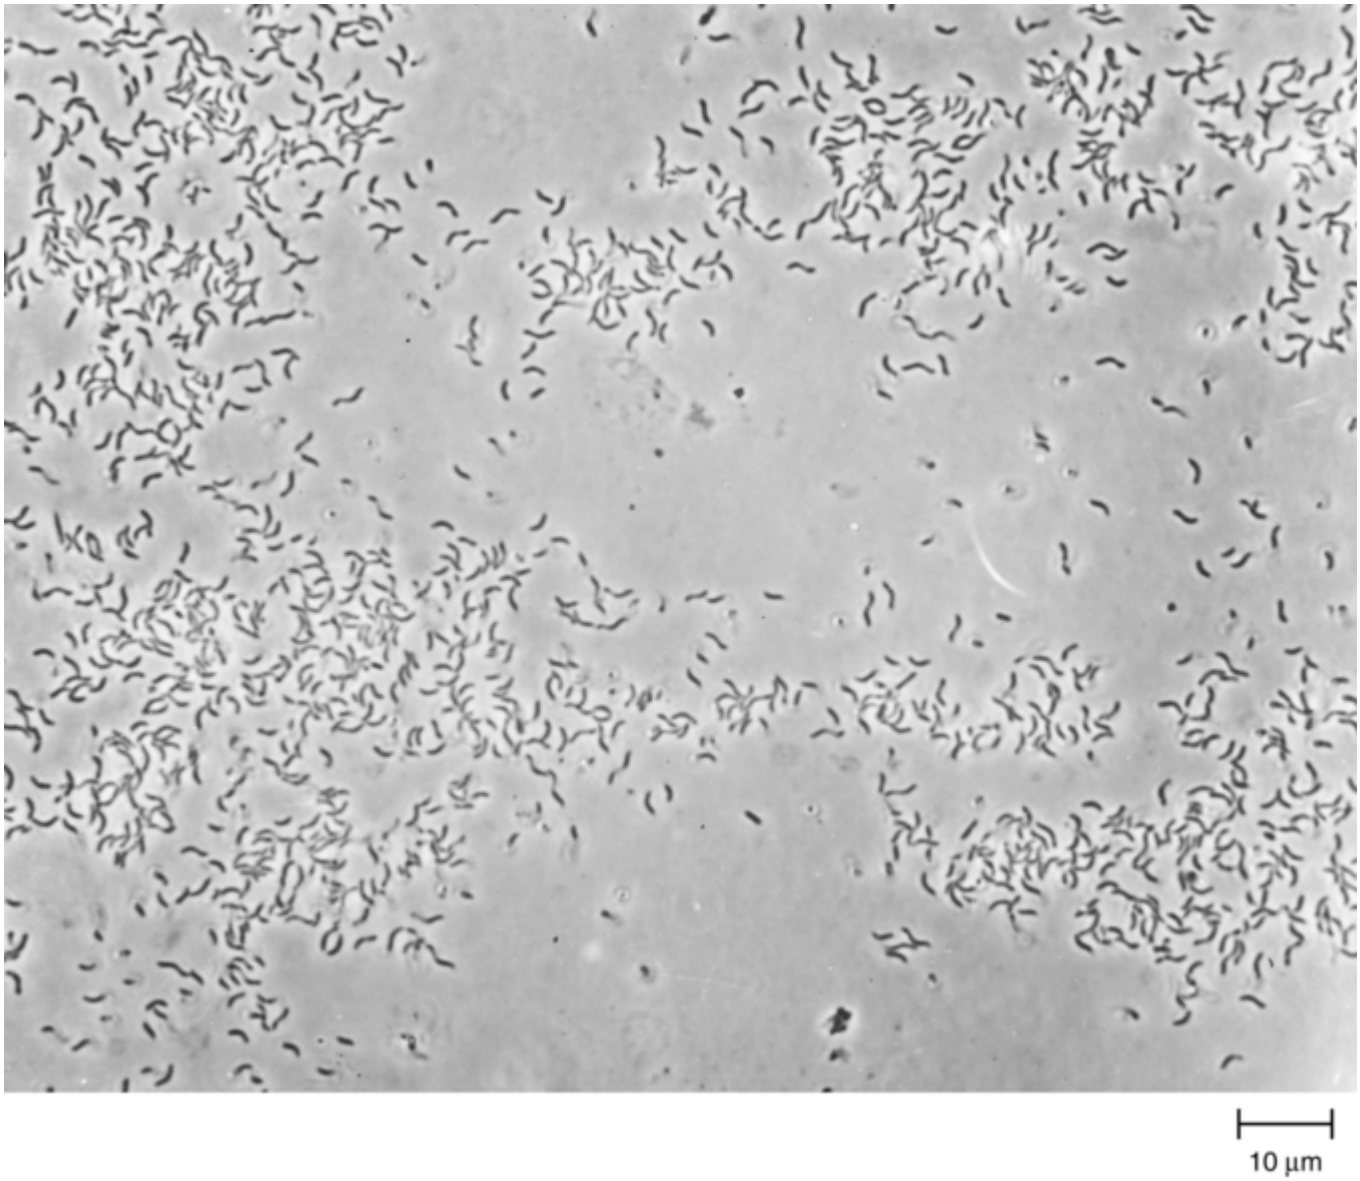

Fig. 1 Sulfate-reducing bacteria from the water bottom of an offshore oil storage tank

In natural conditions, SRB grow in association with other microorganisms and use a range of carboxylic acids and fatty acids, which are common by-products of other micro-organisms. Biological slimes are commonly found in the water phases of industrial process plants (Fig. 2). A wide range of common bacteria (e.g., *Pseudomonas* and *Flavobacterium*) can secrete large amounts of organic material under both aerobic and oxygen-free (anaerobic) conditions. Conditions at the base of even thin slimes (biofilms) can be ideal for the growth of SRB, with high organic nutrient status, no oxygen, low redox potential, and protection from biocidal agents. Figure 3 illustrates the steps in biofilm formation. The SRB can thereby produce active sulfide corrosion even in systems where the bulk liquid phase has a low nutrient status, a high oxygen concentration, and will not support growth of anaerobic bacteria.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

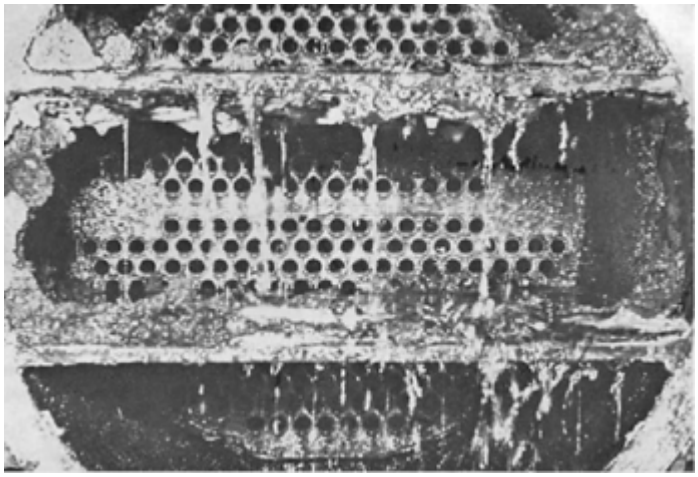

Fig. 2 Biofouling in a heat exchanger

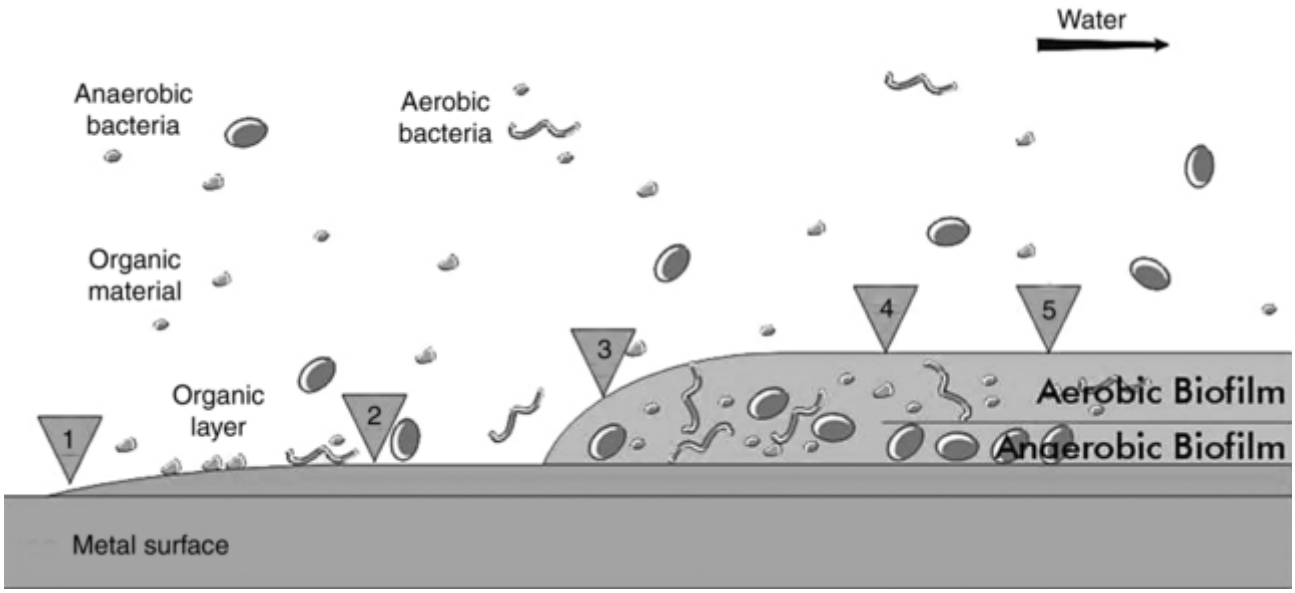

Fig. 3 Steps in biofilm formation

Most *Desulfovibrio* will only grow in the pH range 5 to 10 and the temperature range 5 to 45 °C (40 to 115 °F), up to a pressure limit of approximately 50 MPa (500 atm) (Ref 8). Some less common groups of SRB have the ability to grow at elevated temperatures up to at least 70 °C (160 °F). Reference 9 cites two cases of corrosion by thermophilic SRB activity: one case being in a tank of hot molasses at a sugar refinery, the second being a transformer tank buried in London clay, where the temperature was 60 to 80 °C (140 to 175 °F) for long periods.

Systems that are susceptible to the effects of MIC by SRB include oil fields (due to use of contaminated drilling mud and injection water), low-velocity lines and storage tanks, aircraft jet fuel tanks and lines, hydrotest waters, cooling waters, and wastewaters.

The petroleum-production industry has been particularly plagued by the activities of SRB, because it handles large volumes of deaerated water. These waters can become very sour with H_2S if infection with SRB occurs. The situation in the oil industry is the subject of a useful, practical review by NACE International (Ref 10). The phenomenon of unexpected increase in H_2S levels in produced fluids from petroleum reservoirs (reservoir souring) has been observed over a period of many years in different areas of the world (Ref 11, 12, 13, 14, 15, 16). Most workers in the field have directed attention to the activities of the SRB, and considerable money has been invested in biocide treatment programs for water injection, with the principal aim of killing or controlling this group of microorganisms (Ref 8).

The mechanism of SRB-mediated sulfide corrosion of ferrous metals has been well reviewed (Ref 17). It involves H_2S and FeS. Corrosion rates tend to be slow at first and then accelerate with time (Ref 18).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The muddy bottom of any relatively stagnant body of water with a high biological oxygen demand often supports massive growth of SRB, as may waterlogged soils. Any metallic installations buried or immersed in such environments can be expected to suffer badly from microbiological corrosion. The most serious economic problem is to pipelines, although sheet piles, hulls of ships, piers, and so on are frequently attacked. In some instances, cast iron pipes of 6.3 mm (0.25 in.) thickness have become perforated within 1 year under such conditions, while perforation in 3 years is common.

A large-scale study of many factors at 59 sites in the United Kingdom (Ref 19, 20) led to the suggestion that aggressive sites were characterized by soil resistivity of less than 20 Ω · m (2000 Ω · cm) or a mean redox potential more negative than +400 mV (on the hydrogen scale) at pH 7. Borderline cases were classified according to water content—those containing more than 20% water being deemed aggressive soils. Similarly, all soils with a mean soluble iron content of over 120 μg/g were found to be aggressive. A particularly corrosive situation is when H_2S diffuses upward into the aerated zone, where it becomes oxidized by air to sulfur (Ref 21).

There is a widespread belief that copper and its alloys are toxic to microorganisms and therefore are not susceptible to MIC. This notion is false. Copper alloys are much less toxic to bacteria than they are to macrofouling organisms, such as seaweed or shellfish, and suffer severe attack by sulfide if conditions allow the growth of SRB. A gun-metal impeller that was located in a polluted harbor (Fig. 4) failed in a matter of weeks after the pump was switched off, due to the growth of SRB in the stagnant pump. The component had previously given 2 years of trouble-free operation in aerated seawater.

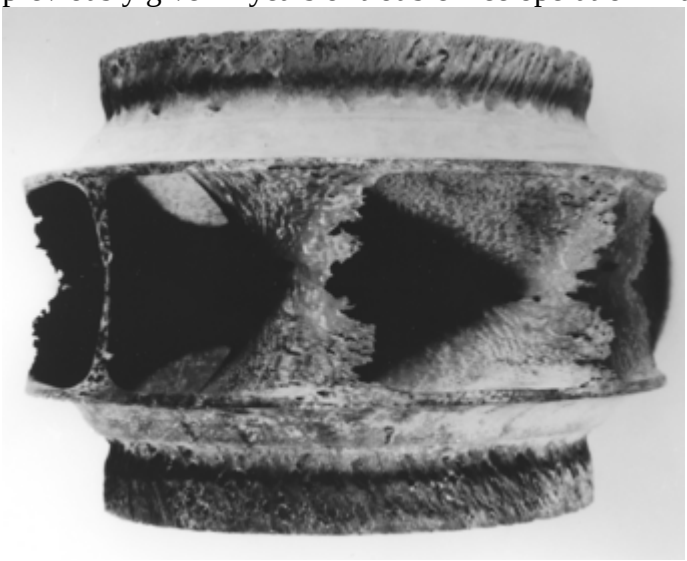

Fig. 4 Copper alloy impeller failure due to sulfate-reducing bacteria in stagnant seawater

Cases of mysterious underdeposit or underfouling pitting corrosion of copper-nickel heat-exchanger tubes have been observed. Many of these failures are demonstrably due to biogenic sulfide produced by SRB. When copper alloys are electrically linked into a cathodic protection system, they tend to lose their antifouling properties and become susceptible to attack by SRB colonies underneath the consequent fouling mat if insufficient protective current is reaching the substrate surface to polarize it into the immunity zone. Silver suffers very severe attack by SRB in a similar way to copper.

Numerous examples of corrosion of stainless steel and higher active/passive alloys involving sulfide production by SRB have been published (Ref 22, 23). This phenomenon is best termed microbiologically assisted, chloride-induced pitting attack. Active/passive alloys are susceptible to localized pitting by chloride ions. Reduced sulfur compounds produced by SRB appear to bind to the metal surface and catalyze the initiation of this process at much lower chloride concentration and at lower temperatures than would otherwise be the case.

Once a pit is established, the anodic reaction generates acidic conditions, accelerating the corrosion rate and causing flask-shaped cavities to form (Fig. 5). This is totally different from the shallow pitting attack of low-alloy materials exemplified in Fig. 6. The pits may be concealed beneath ferric hydroxide, and the process is often associated with copious amounts of brown-colored biological slime containing iron-oxidizing bacteria known as *Gallionella.* A typical example is shown in Fig. 7.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

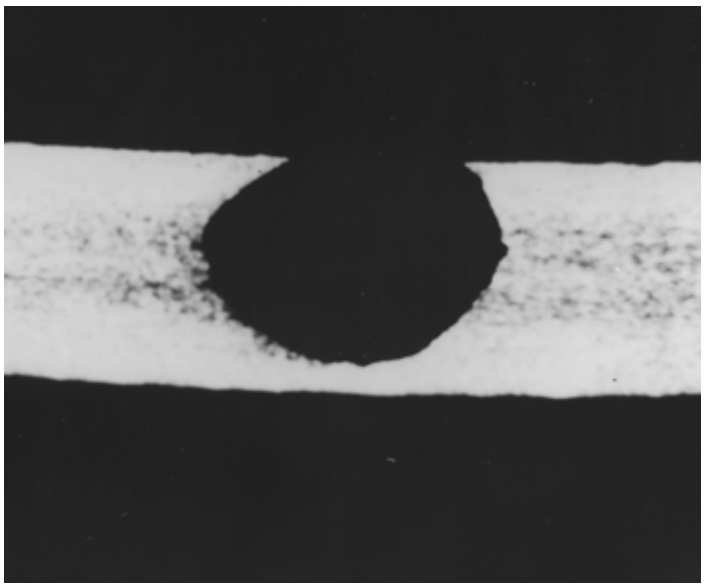

Fig. 5 Flask-shaped pit in an American Iron and Steel Institute (AISI) 304 (Unified Numbering System, or UNS, S30400) stainless steel pipe of 5 mm (0.2 in.) wall thickness

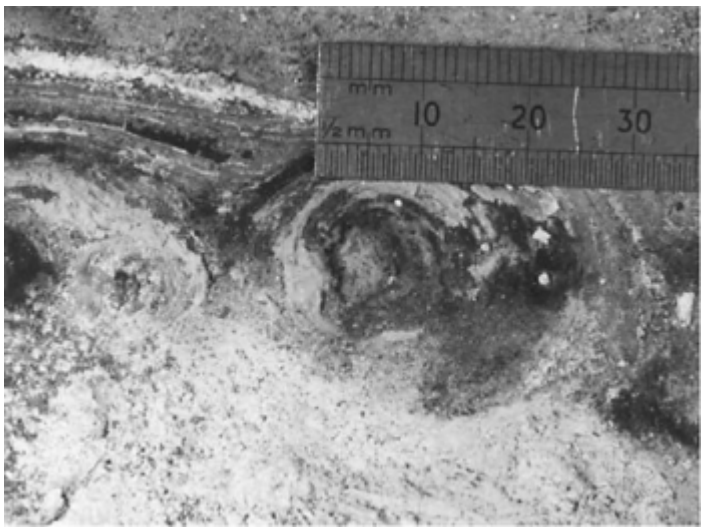

Fig. 6 Microbiologically influenced corrosion in a water pipe due to sulfate-reducing bacteria

Fig. 7 Slime formation by iron bacteria, *Gallionella,* in the pitted stainless steel pipe shown in Fig. 5

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Bacterial metabolism is only involved in the pit initiation stage. Once the pit has formed and acidic chloride conditions develop within, the pit propagation process is the same as with any other case of chloride-induced pitting. Claims that MIC of stainless steels is characterized by a particular pit morphology, different from conventional chloride-induced pitting attack, should therefore be viewed with some skepticism.

Attack by Organisms Other Than SRB

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

As already discussed, biological slimes are commonly found in the water phases of industrial process plants. A wide range of bacteria can secrete large amounts of organic material under both aerobic and anaerobic conditions.

Some components of slimes also use nitrogen- containing compounds as an energy source. They are involved in the cycling of nitrogen in the environment. Ammonia and amines are produced by microbial decomposition of organic matter under both aerobic and anaerobic conditions (ammonification). These compounds are oxidized to nitrite and nitrate by aerobic bacteria such as *Nitrosomonas* or *Nitrobacter* species. *Nitrobacter* is very efficient at destroying the corrosion-inhibition properties of nitrite-based corrosion inhibitors by oxidation, unless a biocidal agent is included in the formulation (Ref 24). The detrimental effects on brass of the release of ammonia at the surfaces of heat-exchanger tubes have also been highlighted (Ref 25).

The bacteria of the genus *Thiobacillus,* of which there are several types, belong to an unusual group of microorganisms called chemolithotrophs. These organisms obtain energy not by oxidation of organic compounds but by oxidation of inorganic sulfur compounds (including sulfides) to sulfuric acid. The organisms build up their cell material by fixation of carbon dioxide. The following interlinked reactions are performed by mixed cultures of *Thiobacilli* acting on elemental sulfur or sulfides (Ref 26):

$$2H_2S + 2O_2 \rightarrow H_2S_2O_3 + H_2O$$

$$5S_2O_3^{2-} + 4O_2 + 4H_2O \rightarrow 5SO_4^{2-} + H_2SO_4 + 4S$$

$$4S + 3O_2 + 2H_2O \rightarrow 2H_2SO_4$$

Certain of the *Thiobacilli* will also leach metal sulfide ores according to the following reaction (Ref 27):

$$4FeS_2 + 15O_2 + 2H_2O \rightarrow 2Fe_2(SO_4)_3 + 2H_2SO_4$$

The important points to note are that these bacteria require oxygen (the opposite of the situation with SRB) and a source of reduced sulfur. The end product is sulfuric acid; one species (*Thiobacillus thioxidans*) is said to remain active at pH 0.7, corresponding to more than 5% sulfuric acid (Ref 28).

Although fairly commonly encountered in nature, *Thiobacillus* proliferation only causes problems in a relatively few specialized industrial situations. One such condition can arise in sewage systems, in which sulfide concentration may be high, owing to the action of putrefactive bacteria, unless aeration is efficient. Suitable conditions can also arise locally in made-up ground into which industrial waste material sometimes finds its way. For this reason, sulfuric acid corrosion of underground pipelines is sporadic and unpredictable.

Attack by sulfuric acid produced by sulfur- oxidizing bacteria such as *Thiobacillus* can be a severe problem in concrete sewers, mortar-lined ductile iron pipes, concrete manholes, and wastewater treatment plants and equipment (Fig. 8).

Fig. 8 Corrosion of a mortar-lined ductile iron wastewater pipe

Figure 9 illustrates schematically the typical corrosion/deterioration of septic sewage systems in hot climates such as the Middle East. The problem starts with growth of anaerobic SRB in the sewage, producing H_2S. This gas migrates to the air space at the top of the line, where it is oxidized into sulfuric acid in the water droplets at the crown of the pipe by *Thiobacillus.* The corrosion problem is due to the combination of the bacterial action that results in dissolution of the alkaline mortar by the acid, followed by corrosion of the ductile iron.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

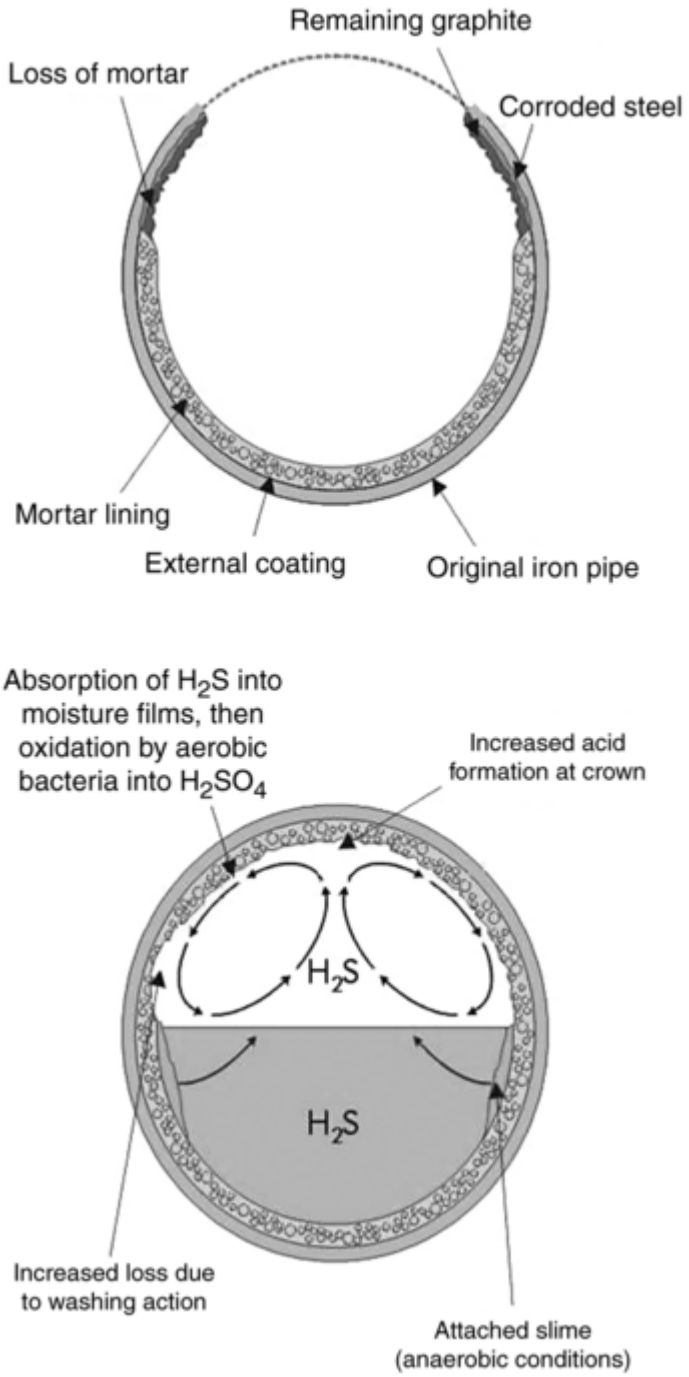

Fig. 9 Microbiologically influenced corrosion processes leading to collapse of a ductile iron sewer

A completely different type of organism from the various groups of bacteria are the fungi. The cells are much larger and grow in dense mats of material. Filamentous fungi are aerobic in nature and are involved in a wide range of biodeterioration problems.

Timber, paper, fuel oils, cloth, and so on can be attacked by fungi. Fungal activity generates organic acids, leading to a low pH in the water and under the microbial mat. In addition to direct acid corrosion, oxygen concentration cells are set up between zones of metal covered with oxygen-depleted fungal mats and those areas where no fungi are present. This electrochemical cell drives the metal dissolution reaction beneath the fungal mat.

By far, the most troublesome fungus in engineering systems is a type commonly called *Cladosporium resinae,* although now reclassified as *Hormoconis resinae* (Fig. 10). *Hormoconis resinae* has the ability to thrive in the presence of kerosene and other hydrocarbons, which it uses as a carbon source for oxidation. It also produces spores, which can survive extremes of temperature, only to germinate when more moderate conditions prevail. *Hormoconis resinae* is a continuing problem in fuel storage tanks and in aluminum integral fuel tanks of aircraft (Ref 29).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

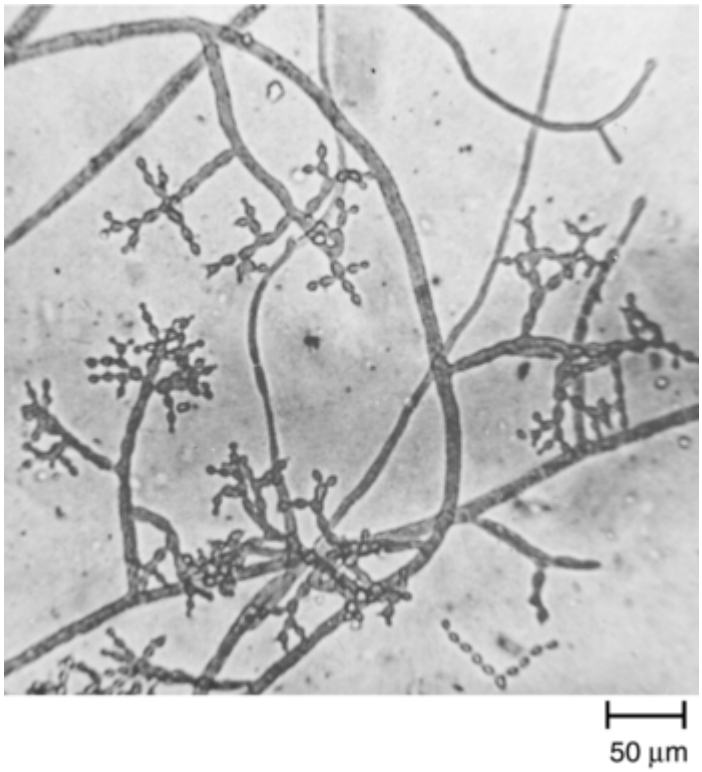

Fig. 10 *Cladosporium resinae* from an aircraft fuel tank

Brown, slimy mats of *Hormoconis resinae* may cover large areas of aluminum alloy (Fig. 11), causing pitting, exfoliation, and intergranular attack due to organic acids produced by the microbes and the differential aeration cells. This type of problem is largely confined to tropical, humid locations and is particularly severe in short-haul aircraft and those that experience a lot of idle time, where condensation builds up.

Fig. 11 Example of fungal growth in a jet aircraft fuel tank

The previously mentioned problem was unknown until the 1950s, when it became prevalent after the introduction of gas-turbine-engined aircraft, which use kerosene rather than gasoline as a fuel, and the adoption of integral or wet wing fuel tanks to replace the earlier rubberized fabric bay tanks (Ref 28). The problem of fungal growth in the fuel tanks of jet aircraft has generally diminished as the design of fuel tanks has improved to facilitate better drainage of condensed water and as biocides such as organoboranes have gained acceptance as fuel additives.

Testing for Microbiological Activity

Assessment of a microbiological population is generally carried out using culture techniques using specific growth media. Enumeration of SRB and total viable bacteria is most commonly by a serial extinction dilution technique using vials containing specially formulated SRB growth medium (Ref 30). The test comprises a serial dilution step followed by an incubation step. Ideally, the serial dilution part of the test should be carried out within a few hours of obtaining the subject samples (typically done on site); however, that is frequently not possible. The results become less reliable with increasing sample age. At the end of the incubation period, the SRB population density in the original sample is determined to the nearest order of magnitude by the number of vials in each dilution series that turn black due to bacterial sulfide production. An example is shown in Fig. 12.

Fig. 12 Test used to enumerate sulfate-reducing bacteria populations

Similar serial dilution tests, using a different type of growth medium, are used to enumerate total bacteria; the vials that show growth turn cloudy rather than black, often accompanied by a color change of an indicator dye to indicate organic acid production.

For the most accurate assessment, threefold or fivefold replicate serial dilution enumeration is carried out; this allows the mean probable number (MPN) of bacteria to be derived from standard MPN tables.

Test kits are commercially available, sometimes in a simplified form. There are also some rapid assay kits based on antibody reactions to SRB enzymes that do not require an incubation period to obtain a result. All simplified and rapid kits compromise accuracy and reliability to a greater or lesser degree. They should be regarded as no more than crude indicators, unless calibrated against standard serial dilution techniques for a specific environment.

مرجع مهندسی مواد و متالورژی

Microorganisms that float or swim in water are called planktonic, whereas those that attach to the metal surface in biofilms are called sessile microorganisms. Most of the SRB and other bacteria present in water systems are sessile. Microbiologically influenced corrosion usually occurs as a result of the local environment created by the activity of bacteria attached to the metal surface. Planktonic bacterial counts are often misleadingly low, whereas much larger populations may be concealed in sediments, deposits, and biofilms on metal surfaces.

Increasingly, there is a trend to monitor SRB and microorganisms, using metal coupons similar to corrosion test coupons. Indeed, coupons may serve a dual purpose of corrosion monitoring and biofilm monitoring. Such coupons are sometimes termed bioprobes or biostuds and, for ease of recovery, are often placed in side-stream devices in flowing pipelines. One such sidestream device incorporating biostuds is known as the Robbins device.

If surface deposits or coupons are available, they should be sonicated or scraped into vials of culture medium, serially diluted on site, then incubated in the manner of water samples. In order of priority, samples from industrial systems should be taken from bottoms, metal surfaces, dead ends, and sumps. Sampling should be on a regular basis—weekly, monthly, or quarterly, depending on the extent of concern.

Low sessile population counts of below ~1000 SRB colony-forming units (cfu) per gram of deposit or per square centimeter of surface are not levels about which much concern needs to be expressed. However, regular testing should be undertaken to check trends. Populations will oscillate, but if they show a general upward drift, then action will be necessary sooner or later.

Planktonic SRB counts provide a less reliable indicator than sessiles. However, recurrent counts of greater than approximately 10 cfu/mL, any general upward trend, or any positive planktonic SRB counts in a nominally biocide-treated system are cause at least for further investigation of sessiles. Any planktonic SRB counts above approximately 1,000 cfu/mL is indicative of a heavy proliferation somewhere in the system, probably in deposits on surfaces, especially in stagnant or low-flow areas.

Total viable bacteria counts are usually much higher than SRB counts. Planktonic counts of up to 100,000/mL are common in many natural waters and industrial systems. Population densities higher than 100,000/mL probably indicate a significant buildup of slime somewhere. In biocide- treated systems, total viable bacteria counts should be several orders of magnitude lower than in the untreated water. The incubation period for total viable bacteria counts is only approximately 3 days, considerably shorter than SRB. Therefore, these counts can give a useful early warning of any problem with biocide-treatment efficiency.

Sulfate-reducing bacteria counts and total viable bacteria counts are relatively straightforward, routine analytical techniques. Tests for nitrite-utilizing bacteria or sulfur oxidizers are more complex, specialist techniques. However, problems associated with these organisms are usually clearly evident from the undesirable chemical changes they bring about.

As a supplement to microbiological testing, it is useful to carry out some chemical analyses. An important test is for sulfide in black corrosion deposits, such as those shown in Fig. 6 and 13. In the case of iron sulfide, a simple test is to warm a small sample of the solid with a few milliliters of hydrochloric acid in a glass test tube. If sulfide is present in the deposit, a slightly moistened strip of lead acetate paper in the mouth of the tube will turn brown, indicating H_2S evolution. If a lot of sulfide is present, the characteristic “bad egg” odor will also be apparent. This test needs to be undertaken within a short time of removing samples of deposit from the corrosion site, because wet or damp iron sulfide will eventually oxidize in air to brown rust. The color change of corrosion deposits from black to brown is, in itself, a good indication of sulfide corrosion product. Any such deposits that are taken back to the laboratory for more sophisticated chemical analysis should be preserved in anaerobic bags to prevent the oxidation of FeS that would otherwise occur.

Fig. 13 Iron sulfide on carbon steel tubulars from the stagnant annulus of a sulfate-reducing-bacteria-infected deep water well

Tests for sulfate, total organic carbon (TOC), pH, and oxygen concentration are also useful indicators of the potential for SRB growth. If sulfate concentration is low, then there is little hazard of SRB activity. The pH range most suited to SRB growth is 5 to 10. Outside these limits, bulk phase growth of SRB is very limited. Oxygen concentration will also affect SRB growth in bulk phases, but a high value does not mean that SRB are not present in pockets or under debris. A high oxygen concentration may allow other organisms to develop. The interpretation of those tests, together with other operating parameters, is discussed in the following section of this article.

Evaluating Microbiologically Influenced Corrosion

James F.D. Stott, CAPCIS Ltd., Manchester, United Kingdom

Risk Assessment Based on Operating Conditions

Frequently, an engineer may be required to make an appraisal of the MIC risk with limited information on the corrosion history and little or no historic microbiological test data. The conclusions that may be drawn about the risk of MIC in such cases are largely based on consideration of operating parameters. This is often the situation with the assessment of the internal corrosion risks of hydrocarbon pipelines, water- handling systems, or process plants. The discussion that follows refers specifically to SRB-related problems, which are, by far, the most common MIC issue.

A group of researchers at Shell Petroleum Company have developed an approach to risk assessment of carbon steel pipelines, based on the details of water chemistry and operation parameters (Ref 31). Their MIC corrosion rate (CR) calculation is based on the following equation:

$$\mathrm{CR(mm/year)} = C \times F^{p}$$

with

$$F = f_1 \times f_2 \times, \ldots, f_n$$

where C is a constant (C = 2 mm/year, or 0.08 in./year), the fs are factors for the various influencing parameters, and p is a power-law index (0.57).

While such an approach does provide a valuable empirical recognition of the relative contribution of the factors that encourage or inhibit MIC, the calculation of actual corrosion rates on such a basis should be viewed with great caution, given the present limited understanding of the imbricated effects of the various factors.

Presence of Water. All bacteria require free water in order to proliferate. In the case of oil pipelines, MIC needs only to be considered under separated flow conditions; if all water is entrained in the hydrocarbon, there is no risk of MIC (Ref 31).

In the author's experience, it is unwise to rely on dispersions to provide fully oil-wetted surfaces when the bottom solids and water content is in the order of 2% or greater, except under very turbulent hydrodynamic conditions. It is best to take an empirical and conservative view as to whether lines may be wet enough to sustain SRB growth at the present time and during their future operating life.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Salinity. According to results presented in Ref 9, if the salinity of water, expressed as weight percent NaCl, is more than approximately 7%, there is unlikely to be any SRB growth. That observation broadly agrees with the author's own experience, and a similar statement is reiterated in the more recent Shell Petroleum Company work (Ref 31). However, it should be noted that other workers have suggested that some SRB strains may be tolerant to much higher salt concentration.

Temperature. Most types of SRB grow optimally at temperatures between 10 and 45 °C (50 and 115 °F), which is the highest risk-temperature range. However, there are thermophilic strains of SRB that grow at higher temperatures, up to at least 70 °C (160 °F), and their activity cannot be discounted.

pH. Generally, there is unlikely to be SRB proliferation below pH 5 or above approximately pH 10, although the pH range for SRB that are protected in heavy deposits may be somewhat wider.

Anaerobic Conditions. Sulfate-reducing bacteria will only proliferate and produce sulfide in the absence of oxygen. Clearly, anaerobic situations are most at risk; however, there are many cases of SRB causing problems in slimes and deposits where the bulk water phase is essentially aerobic, for example, in cooling waters. This is especially the case for static or slow-flow conditions.

Nutrient Status of Water Phase. Sulfate-reducing bacteria growth is much less likely if the aqueous sulfate concentration or the organic carbon content is below approximately 10 mg/L or the ammoniacal nitrogen (not nitrate or nitrite) is below approximately 1 mg/L. An exception, in the author's experience, is the case of a plant under long-term lay-up with static, high-sulfate water (e.g., seawater), where a corrosive black water condition may develop over a period of months, even with very low organic carbon content. This is believed to be due to the reduction of sulfate by SRB using cathodic hydrogen formed by corrosion on steel surfaces.

Flow rate influences the nature of biofilm formation and the rate of nutrient delivery. As flow rate increases, biofilms become less bulky, and only the more adherent films remain on the metal surface. However, above a certain threshold, the initiation of biofilm formation is significantly limited. The transition zone is considered to be between 2 and 3 m/s (6.5 and 9.8 ft/s). At the other extreme, stagnation is often associated with the severest MIC incidents.

Cleaning Frequency. In order to initiate the MIC process, the free-floating, planktonic SRB cells need to attach themselves to a metal surface, that is, become sessile and proliferate to form a biofilm with its own entrained microenvironment. This process is disturbed by regular physical cleaning, such as brush pigging of pipelines. The incipient biofilm is disrupted and largely removed, and this is the most effective means of minimizing SRB growth and obviating MIC. Microbiologically influenced corrosion is uncommon in pipelines that are frequently pigged, even without biocide treatment. The more frequent the pig runs, the less time the biofilm has to recover.

Biocide Treatment. Any operation that disrupts the biofilm and thereby limits its proliferation will act to alleviate MIC. Biocide treatment is one such factor, provided the concentration, duration, and frequency of that biocide treatment is adequate. Just because some form of biocide treatment is in use, it should not be assumed that it must be effective. Biocides have very limited ability to penetrate existing deposits and are therefore much more effective when used in conjunction with frequent pigging or other cleaning processes.

The first stage of biocide selection is a laboratory evaluation of candidate biocides, using a time-kill test (Ref 30). In the case of once- through cooling water systems, the choice is between continuous low-dose treatment with oxidizing biocides (e.g., chlorine, bromine, chlorine dioxide peroxide, or ozone) or periodic shock dosing with much higher concentrations of organic biocide. Environmental constraints sometimes negate the latter possibility. Continuous low-level injection of organic biocide is of no value. Indeed, continuous low-level exposure may possibly be detrimental in the long term, because there is some possibility that it may encourage the development of more biocide-tolerant strains of bacteria.

For recirculating systems and hydrotest waters, organic biocides are often the treatment of choice. After the completion of laboratory tests for biocides in a given application (which should include economic considerations and chemical compatibility tests), a program of site monitoring is recommended.

The site monitoring should ensure that the chemical injection rate is giving the correct concentration of biocide and is changed accordingly when water throughput rate is altered and should monitor any major perturbations of the system that may affect biocide efficiency. Such perturbations include changes in contact time; flow rates; temperature; pH, use of a new chemical, for example, corrosion inhibitor, scale inhibitor, or oxygen scavenger; or shutdown periods.

High-Temperature Gaseous Corrosion Testing

David A. Shifler, Naval Surface Warfare Center

Introduction

HIGH-TEMPERATURE CORROSION occurs in various environments and is affected by numerous factors, such as temperature, alloy or protective coating composition, time, and gas composition. High-temperature exposure of materials occurs in many applications, such as power plants (coal, oil, natural gas, and nuclear), pulp and paper mills, petrochemical and chemical industries, land-based gas turbine and diesel engines, gas turbine engines for aircraft, marine gas turbine engines for shipboard use, waste incineration, high-temperature fuel cells, and spacecraft components. Exposure in high-temperature environments can cause materials degradation and lead to problems that often bring about unscheduled outages, resulting in loss of reliability, decreased safety, and increased economic costs.

Predicting corrosion of metals and alloys or coated alloys is often difficult because of the range of composition of the corrosive gaseous or molten environments and the variety of materials that may be used. Moreover, corrosion prediction is further complicated, because materials often degrade in a high-temperature environment of a given application by more than a single corrosion mechanism.

There is a great need for materials testing, both for research and development of new materials (alloys, high-temperature coatings, refractories, etc.) and processes and to simulate industrial and application environments to understand the interactions that occur with current materials choices. There are, in general, few standards or guidelines for materials testing for high-temperature corrosion, which lead to errors in performance evaluation and a wide range of results on oxidation and corrosion-resistance measurements.

The goals of laboratory and field testing are to characterize materials performance in specific applications and to evaluate the effects of environmental changes on candidate materials. The test conditions should simulate, as much as possible, the environment of the specific application of interest. This includes duplicating the chemical composition of the atmosphere, liquid, or molten salt, the temperature and thermal cycle profiles, the stress states of the materials, fatigue conditions, and the design parameters.

The objective for performing a given high- temperature corrosion test should be identified during the initial phase of designing the testing procedure. Testing should be properly planned, relevant, and correlated with actual field use. Accelerated tests often provide useful information, but degradation processes in such tests may not reflect the actual corrosion mechanisms by which the materials naturally deteriorate. Testing may require laboratory, field, simulated service evaluations, or a combination of the tests. Details on general test planning are found in Ref 1.

Test parameters that should be considered include specimen size and preparation, isothermal or thermal cycling, test environment versus service environment, geometry, temperature, flow velocity, potential, and type of corrosion.

There also should be an idea of the type and degree of complexity of testing desired (Ref 1). In general, before testing components in most practical applications, one should be knowledgeable of the corrosion properties of

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

possible candidate materials and understand the possible materials interactions that a component may have with other material components in order to interpret and translate the test results into the requirements of the service application.

The high-temperature corrosion behavior of materials is often evaluated in the laboratory rather than in an actual service environment due to time and/or budget limitations. Laboratory evaluation is generally of relatively short duration and is often used to study environmental effects on the corrosion behavior of a metal, because the specific environmental conditions can be controlled. The major disadvantage of testing in the laboratory is that the actual service environment and conditions may not be evaluated. When service conditions are being simulated, certain assumptions are usually made. It is important when testing in the laboratory to correlate field data with laboratory data, so that the validity of the laboratory information can be assessed.

In-service testing provides the advantage of examining the corrosion behavior of a metal in the actual service environment. However, in-service testing is generally expensive, and variables are usually not well characterized or controllable. Small-specimen testing allows a large number of variables to be evaluated at minimal cost. Small specimens can be designed to determine specific types of corrosion. Although small-specimen testing allows examination in the actual service environment, the corrosion rate determined on small specimens may not be consistent with the corrosion rate of a large-scale piece of equipment, predominantly because it is difficult to duplicate all of the metallurgical conditions and the local environment of the large equipment on a small specimen. Similar to in- service testing, simulated service testing provides the advantage of exposure to the actual environment.

Factors Affecting High-Temperature Corrosion and Materials Properties

The rate by which a material may degrade in a high-temperature environment will depend on the reaction or range of operative reactions, the reaction thermodynamics, kinetics, and chemical and physical properties of the material exposed to this environment. A material can degrade at high temperatures on exposure to gaseous, liquid (molten ash, salts, or metal/alloys), or solid-state reaction processes, such as diffusion and interdiffusion, precipitation, and creep.

Thermodynamics

The thermodynamics of high-temperature corrosion reactions reveals what reactions are possible under certain conditions and is dependent on reactants and the possible products that may form. The overall driving force for any chemical reaction can be assessed by the change in the Gibbs free energy, ΔG, for that reaction. Strictly on the grounds of thermodynamics, a reaction will proceed from left to right, as written, if its ΔG is negative. For a metal (M) reacting with oxygen to form an oxide, the reaction is:

$$xM + yO_2 \rightarrow M_xO_y \qquad \text{(Eq 1)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

For this reaction, the free energy may be written as:

$$\Delta G_{yO_2/MO} = \Delta G^{\circ}_{yO_2/MO} + RT \ln \frac{a_{M_xO_y}}{\left(a_M^x\right)\left(a_{O_2,MO}^y\right)} \qquad \text{(Eq 2)}$$

where ΔG^{o} is the standard free energy change when all reactant and product species are in their standard states, a_i is the chemical activity of species *i*, *R* is the gas constant (8.314 J/mol · K), and *T* is the absolute temperature (Ref 2). If the standard state for the reacting O_2 in Eq 1 is taken to be 1 atm, then the O_2 activity can be equated to its partial pressure, p_{O_2}, in Eq 2. Further, because the activity of stable pure solids is defined as unity at all temperatures and pressures, and $\Delta G = 0$ at equilibrium, the free energy of the simple oxidation reaction given in Eq 1 simplifies to:

$$\Delta G_{O_2/MO} = RT \ln p_{O_2/MO} \qquad \text{(Eq 3)}$$

Thus, Eq 3 defines the free energy change, $\Delta G_{O_2/MO}$, for the formation of a pure oxide, M_xO_y, on the base metal, M, and the characteristic equilibrium pressure, $p_{O_2/MO}$ for the dissociation of that oxide at some defined temperature. Because $\Delta G = \Delta H + T\Delta S$, where ΔH and ΔS are changes in enthalpy and entropy, respectively, a plot of ΔG versus *T* approximates a straight line, with changes in slope where new phases form, such as occurs during melting, boiling, or sublimation. The oxygen dissociation pressures leading to oxide formation or reduction for pure metals can be found graphically using an Ellingham diagram, such as the one shown in Fig. 1 (Ref 3). The procedure consists of passing a straight line through the point “O” (upper left-hand corner of the diagram) and a second point that intersects the temperature of interest for the metal/oxide system and extending the line to the oxygen nomographic scale, the intersection of which gives the dissociation p_{O_2}. Because oxidation can occur in the presence of water vapor and carbon dioxide, the diagram also displays nomographic scales with differing CO-to-CO_2 and H_2-to-H_2O ratios. Ellingham or Gibbs free energy-temperature diagrams for selected oxides are given in Ref 2. Similar Gibbs energy-temperature diagrams are available for other gaseous reactions such as sulfur, fluorine, chlorine, bromine, iodine, and nitrogen (Ref 4). A practical limitation of the Ellingham diagrams is that they are completely thermodynamic and therefore do not provide any information pertaining to the kinetics of a given metal corrosion reaction.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

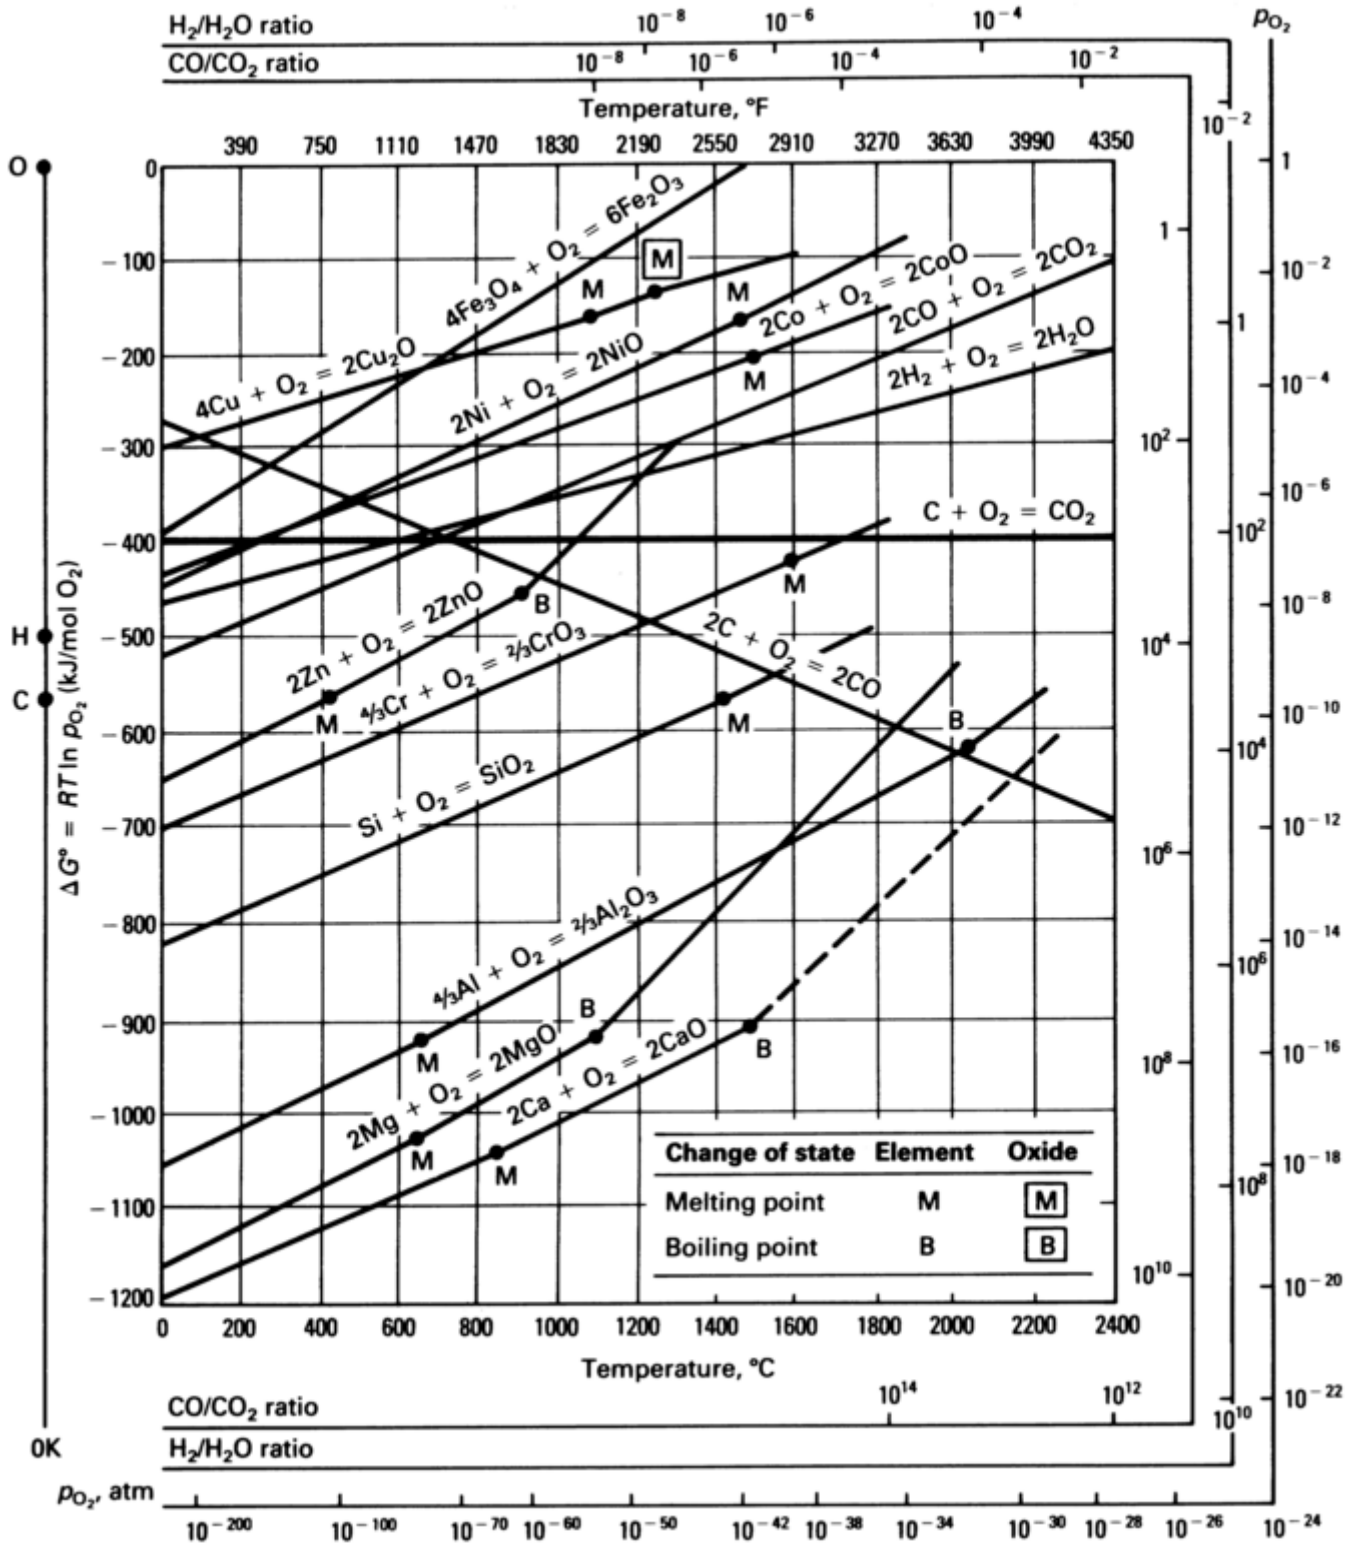

Fig. 1 Ellingham diagrams of selected oxides as a function of temperature. 1 atm = 101.3 kPa

The thermodynamics of a high-temperature reaction such as oxidation was described in the previous paragraph as a function of temperature, with pressure considered constant. If there are no volumetric changes in a given reaction, pressure will have no effect on corrosion thermodynamics. However, for some high-temperature applications, pressure is an important factor in determining which reactions transpire. For a metal at a constant temperature, the change in the free energy of a reaction (Ref 5) is due to a change in pressure from P_1 to P_2 and can be written as:

$$\left(\Delta G^{\circ}\right)_T = VdP = nRT\frac{dP}{P} = nRT\ln\frac{P_2}{P_1} \qquad \text{(Eq 4)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

where *V* is volume and *n* is the number of molecules.

Isothermal stability diagrams are used for more complicated situations where a metal may be exposed to more than one oxidizing gas or when an alloy is exposed to a gaseous environment. In these situations, it is customary to fix the temperature at some practical value and plot variations of gas pressure or alloy composition against each other. This produces isothermal stability diagrams, or predominance area diagrams, that will illustrate the phases or species that are most stable in any set of circumstances.

One Metal and Two Gases (Ref 6). These diagrams, often called Kellogg diagrams, are constructed from the standard Gibbs free energies of formation, ΔG^o, of all elements and compounds likely to be present in the system. For example, in the Ni-O-S system, ΔG^o values of nickel monoxide (NiO[s]), nickel monosulfide (NiS[l]), nickel sulfate ($NiSO_4$[s]), sulfur dioxide (SO_2[g]), sulfur trioxide (SO_3[g]), and sulfur (S[l]) are needed.

In Fig. 2, the boundary between the Ni(s) and the NiO(s) regions represents the reaction $Ni(s) + \frac{1}{2}O_2(g) \leftrightarrow NiO(s)$ at equilibrium; therefore, the diagram shows that at 1250 K (1790 °F) and O_2 pressure above approximately 10^{-11} atm, NiO will tend to form from the metallic nickel if p_{S_2} is low. Similarly, S_2 gas pressure greater than approximately 10^{-7} atm will form NiS from nickel at low p_{O_2}. A mixed gas of 10^{-5} atm each of S_2 and O_2 should form nearly the equilibrium ratio of NiO(s) and $NiSO_4$(s).

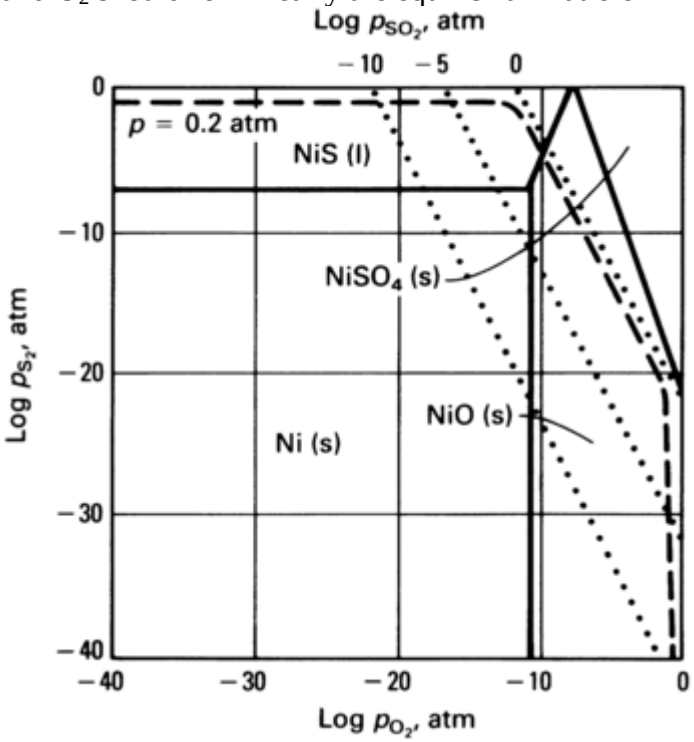

Fig. 2 The Ni-O-S system at 1250 K (1790 °F). Source: Ref 6

If the principal gases of interest were SO_2 and O_2 the same ΔG^o could be used to construct a diagram of log p_{O_2} versus log p_{SO_2}, or, as in Fig. 2, p_{SO_2} isobars can be added to the figure (dotted lines). Thus, a mixed gas of 10^{-5} atm each of SO_2 and O_2 will form only NiO at 1250 K (1790 °F), with neither the sulfide nor the sulfate being as stable.

When nickel metal is heated to 1250 K (1790 °F) in the open air with sulfur-containing gases, $p_{SO_2} + p_{S_2} + p_{O_2} \approx 0.2$ atm. The situation is shown by the dashed line in Fig. 2 labeled "*p* = 0.2 atm."

An Alloy System and a Gas (Ref 6). Isothermal stability diagrams for oxidation of many important alloy systems have been worked out, such as the Fe-Cr-O system shown in Fig. 3. In this diagram, the mole fraction of chromium in the alloy is plotted against the log p_{O_2}, so that for any alloy composition, the most stable oxide or mixture of oxides is shown at any gas pressure.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

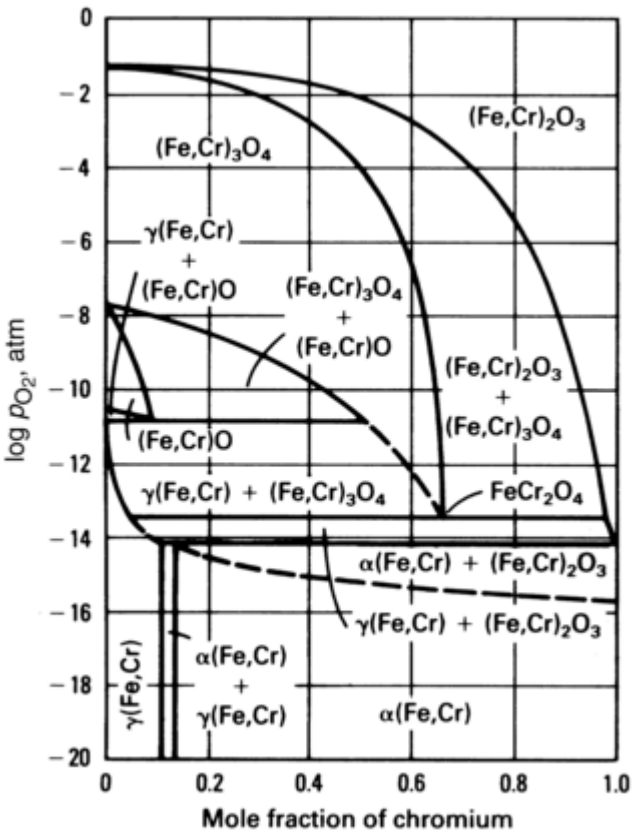

Fig. 3 Stability diagram of the Fe-Cr-O system at 1300 °C (2370 °F). Source: Ref 6

For any alloy system in a gaseous environment containing more than one reactive component, the pressures of all but one of the gases must be fixed at practical values to be able to construct an isothermal stability diagram in two dimensions. Figure 4 shows an example of such a situation: the iron-zinc system in equilibrium with sulfur and oxygen-containing gases, with SO_2 pressure set at 1 atm (101.3 kPa) and temperature held at 1164 K (1636 °F).

Use of Isothermal Stability Diagrams. Each area on the diagram is labeled with the stable phase that is in contact with the environment at the specified temperature and pressure conditions; other phases may also be stable beneath this outer phase. The boundary line between two phases shows the conditions for their equilibrium, that is, coexistence as stable products.

As with all thermodynamic diagrams, the use of these isothermal stability, or predominance area diagrams have specific rules that must be understood:

- Each area on the diagram is labeled with the predominant phase that is stable under the specified conditions of pressure or temperature. Other phases may also be stable in that area but in smaller concentrations.
- The boundary line between two predominance areas shows the conditions of equilibrium between the two phases.

The use of thermodynamically derived diagrams has limitations:

- The diagrams are based on thermodynamic data and do not predict reaction kinetics.
- The diagrams are for equilibrium conditions. Equilibrium may be reached quickly in high- temperature oxidation, but if the metal or alloy is then cooled, equilibrium may not be reestablished.
- Microenvironments, such as gases in voids or cracks, may create conditions that differ considerably from the diagram situations expected for the bulk reactant phases.
- The diagrams also do not show the effects that minor impurities or alloy additions may have on corrosion performance.

The Gibbs free energy change of a high-temperature reaction that is experienced in a high- temperature application or during a high-temperature test can be understood by considering the chemical potential ($\mu_i = [\partial G/\partial n_i]_{T,p,nj}$) of the species participating in the reaction. For multicomponent systems, the Gibbs free energy is

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

a function of temperature, pressure, and composition, such that $G = f(T, p, n_1, n_2, \ldots)$, where n_i is the number of moles of the ith component. Fundamentally, the free energy change can be written as (Ref 7):

$$dG = \sum_i n_i d\mu_i + \mu_i dn_i \quad \text{(Eq 5)}$$

$$dG = -SdT + Vdp + \sum_i \mu_i dn_i \quad \text{(Eq 6)}$$

For a process with fixed compositions and carried out under isothermal and isobaric conditions and at equilibrium, then $(dG)_{T,p,n} = 0$, leaving:

$$\Sigma n_i d\mu_i = -SdT + Vdp = 0$$
$$n_1 d\mu_1 + n_2 d\mu_2 = 0 \quad \text{(Eq 7)}$$

which is referred to as the Gibbs-Duhem equation (Ref 7, 8). The equation is extremely important in solution or molten electrolyte chemistry.

The accuracy of using thermodynamics to predict possible reactions of a metal or an alloy that may occur in a given environment are dependent on the similarity of the test environment with the available thermodynamic data used to construct a diagram. The performance of alloys in a given test environment is affected by the environment and/or the similarity of the alloy performance to that of a metal in a given environment.

Kinetics

While thermodynamics predicts what reactions may be possible, kinetics explains how fast these possible reactions will proceed. The reaction rate is affected by a number of complex interactions between the test material and the test environment during the test. Environmental contributions that affect reaction kinetics include (Ref 9):

- Temperature
- Time/thermal cycle conditions
- Corrosive species and their activity (concentration)
- Chemisorption and dissociation characteristics
- Stress states and cyclic strains

Materials characteristics that can affect high- temperature corrosion and other high-temperature materials processes include (Ref 9):

- Free energy of formation of scales (oxides, sulfides, chlorides, nitrides, etc.) of the alloying elements
- Scale integrity
- Alloy composition
- Alloy structure
- Alloy transformations, if any, that may occur in the operational service or test temperature
- Presence of materials combinations, such as high-temperature coatings on superalloys
- Material interdiffusion coefficients between the materials and its high-temperature reaction product or between two dissimilar materials (i.e., coatings on superalloys)
- Coefficient of thermal expansion differences in the scale and the materials substrate
- Scale adhesion
- Mechanical strength of the scale
- Solubility of gaseous products of the environment in the scale and the substrate
- Scale formation during different stages of the test
- Specimen size and shape

Materials frequently undergo changes in corrosion mechanisms that complicate reaction kinetics and the explanation of the reactions that may occur. High-temperature corrosion reactions are usually classified as following one of the reaction kinetics: linear, parabolic, logarithmic, or cubic (Ref 10). However, high-

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

temperature oxidation and corrosion processes may deviate from these rate-law kinetics, or the high-temperature reactions may be a combination of more than one rate.

Linear kinetics are typically associated with either a surface reaction step being rate controlling or nonprotective scaling. In the case of the latter, the corroding material may form a scale that is porous, crackprone, or nonadherent. The integrated rate equation describing linear kinetics is:

$$x = k_L t \qquad \text{(Eq 8)}$$

where x is the scale thickness or mass gain per unit area, k_L is the linear rate constant, and t is time. The units of k_L depend on the test parameters used in measuring the kinetics: if the scale thickness is measured, k_L has units of centimeters per second, while if mass gain is measured, the rate constant has the units of $g/cm^2 \cdot s$. Figure 5 shows the linear relationship between mass gain versus oxidation time.

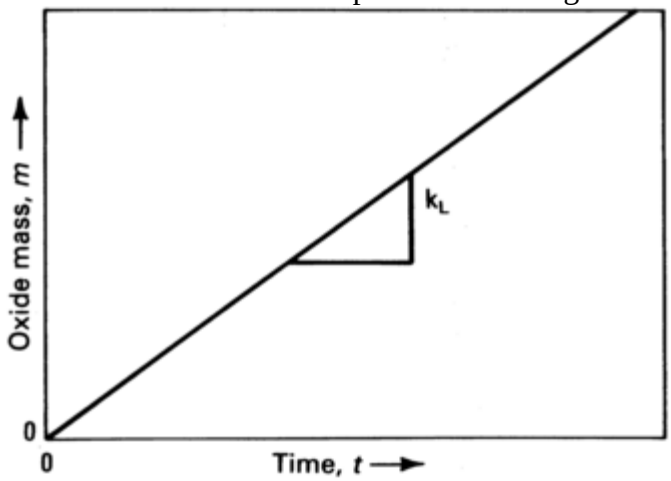

Fig. 5 Linear oxidation kinetics showing relationship between oxide mass and time

Parabolic kinetics describe high-temperature corrosion reactions where the rate-determining step is the diffusion of ions, either inward toward or outward from the substrate, with a chemical potential gradient as the driving force. Integrated, the parabolic rate equation is:

$$x^2 = k_p t \qquad \text{(Eq 9)}$$

where k_p is the parabolic rate constant, and x is the thickness (centimeters per second) or mass gain per unit area ($g/cm^2 \cdot s$). Figure 6 shows the parabolic relationship between mass gain versus oxidation time. The high-temperature corrosion resistance of most chromia (Cr_2O_3) and alumina (Al_2O_3) scale-forming alloys follows parabolic rate kinetics.

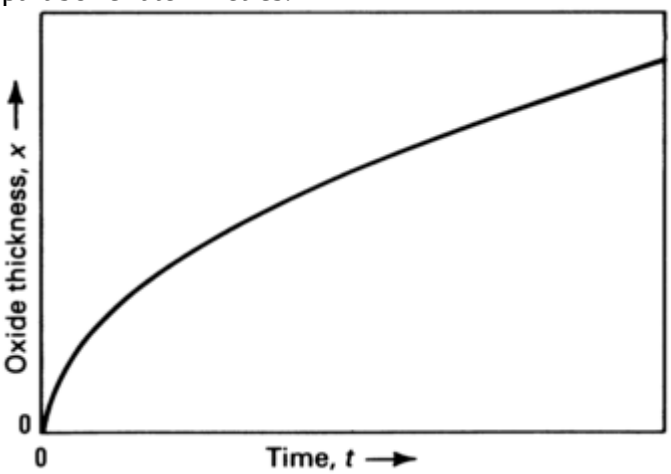

Fig. 6 Parabolic oxidation kinetics

Periodic cracking of a protective oxide results in the parabolic oxidation being interrupted by a sudden increase in rate, when the gas can react directly with the bare metal surface. As oxide begins to cover the metal surface again, parabolic oxidation is resumed. The time periods between successive parabolic steps are sometimes

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

fairly uniform, because a critical scale thickness is reached that causes cracks to be initiated. The overall oxidation of the metal becomes approximately a slow linear process.

Internal penetration and attack often can be described by parabolic kinetics (Ref 9). This characterizes the formation of precipitates (either intra- or intergranular) by the interaction of one or more species from the environment with the substrate. Internal penetration occurs when the reactive substrate component diffuses outwardly more slowly than the gaseous species diffuses inwardly. A simplified equation to describe internal attack in the absence of any external scale formation has been proposed (Ref 11):

$$X = \left[\frac{2N^S D^t}{\nu N_B^i}\right]^{1/2} \qquad \text{(Eq 10)}$$

where X is the depth of internal penetration at time, t, N^s is the mole fraction of reactive gaseous species in the substrate at the surface, D is the diffusion coefficient of the oxidant in the substrate, ν is the atom ratio of oxidant to metal for the internally precipitating phase BO_ν, and N_B^i is the mole fraction of reactive component in the bulk substrate.

Logarithmic kinetics are often associated with the initial stages of oxidation, low-temperature service tests, or conditions where cavities and precipitates in a thick scale interfere with ion or vacancy diffusion mechanisms. Logarithmic scaling behavior on alloys is affected by precipitates that grow slowly within the scale or at the scale-substrate interface and restrict the growth of a scaling constituent (Ref 9). Growth stresses in the scale may cause development of cracks in the scale parallel to the substrate, thus leading to logarithmic or inverse logarithmic kinetics from the transport of electrons or ions. The rate equations describing logarithmic reaction kinetics are:

Logarithmic $x = k_{log} \log(t + t_o) + A$ (Eq 11)

Inverse logarithmic $1/x = B - k_{inv} \log t$ (Eq 12)

where A, B, k_{log}, and k_{inv} are constants at isothermal temperatures. Figure 7 shows the variation of direct logarithmic and inverse logarithmic kinetics.

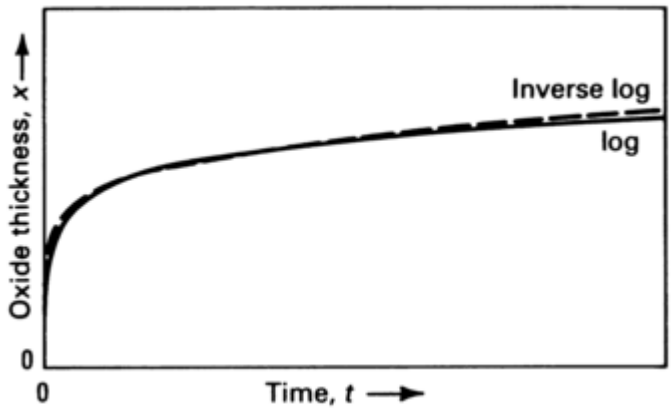

Fig. 7 Logarithmic and inverse logarithmic oxidation kinetics

Cubic Kinetics. In certain situations, scales form on some metals according to a cubic rate law:

$$x^3 = k_c t \qquad \text{(Eq 13)}$$

where k_c is the cubic rate constant. Usually, such behavior is limited to short exposures (Ref 10). The cubic kinetics reported for the oxidation of zirconium or hafnium are explained as a combination of diffusion-limited scale formation and oxygen dissolution into the metal (Ref 12). In other cases, cubic kinetics have been explained as a superposition of a morphological complication and ionic diffusion through the scale (Ref 12). Figure 8 shows the comparison of the cubic rate kinetics with linear, parabolic, and logarithmic rate kinetics.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

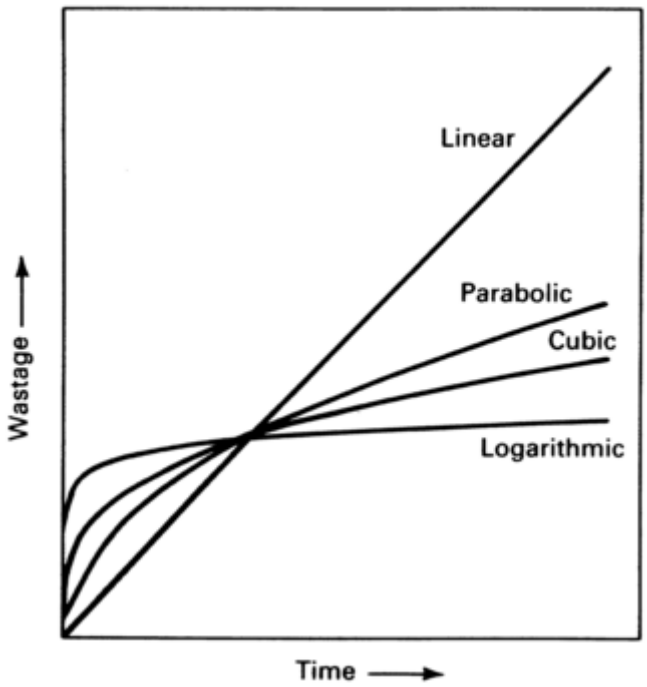

Fig. 8 Comparison of linear, logarithmic, parabolic, and cubic kinetics found in various thermal degradation processes. Source: Ref 13

Some high-temperature corrosion reactions cannot be described by the simple rate equations discussed previously. Occasionally, a metal oxidizes parabolically until the scale cracks or spalls off, and from that time on, until a new scale is formed, the oxidation is linear. Breakaway corrosion often occurs when numerous cracks continuously form through the scale to the substrate or when the principal component for forming the most stable scale is either effectively depleted at the alloy surface through repeated scale formation and spallation cycles or through selective internal compound formation.

Catastrophic corrosion occurs when a liquid phase is a product of a corrosion process. This may happen as a result of metal or alloy exposure to vapors of a low-melting compound or during the substrate corrosion, when one or more components of the material forms a low-melting compound with one or more corrosive species of a test or service gaseous environment. The liquid phase first forms at the scale/atmosphere interface and permeates through the scale to the substrate along defects such as grain boundaries and pores. Once at the substrate/scale interface, the molten phase spreads by capillary action and destroys scale adhesion (Ref 9). Table 1 lists oxides, sulfides, and chlorides that may lead to catastrophic corrosion.

Diffusion

Diffusion occurs due to the differences in chemical potential to the extent that a component always diffuses down its potential gradient. Note that by this definition, it is possible in multi- component systems for a given component to diffuse up its concentration gradient. When two isolated chambers kept at different temperatures are suddenly connected, the temperature in each chamber rises or falls to a common, equilibrated temperature that is driven by thermodynamics. Chemical, compositional, or defect differences in materials exposed to high-temperature gaseous environments will attempt to equilibrate via diffusion to form oxides, sulfides, and other metal-anion species or to level compositional differences.

Diffusion processes in solids play a key role in oxidation and other gaseous reactions with metals. Mass transfer may be the result of metal ion diffusion from the metal surface through the oxide, nitride, sulfide, or chloride (and other such metal compounds) layer to the absorbed anions at the oxide, nitride, sulfide, or chloride/gas interface or the result of diffusion of anions inward through the scale to the metal or alloy. Within the alloy, the diffusion of reacting metal atoms toward the surface and the back diffusion of unreactive atoms from the metal surface inward to the unaltered alloy can occur. The diffusion of interstitial atoms such as carbon, nitrogen, hydrogen, and oxygen can also be involved.

Atoms or ions can diffuse through solids by several mechanisms. The most common is vacancy diffusion, because a metal crystal always contains a high concentration of point defects, such as atomic vacancies, while ionic oxides contain Schottky and Frenkel defects that involve vacancies. An atom or ion sitting on a lattice site can diffuse by jumping to adjacent vacant sites. For metal atoms, this is relatively easy because of the short jump distances. The jump distances in ionic crystals are much longer, because cation and anion sites are surrounded by oppositely charged species.

Small, interstitial atoms diffuse readily from one interstitial position to another. In ionic oxides, the cations may diffuse interstitially, but the anions are usually not small enough to do so. In ionic crystals, an interstitial ion may crowd into a regular lattice site, displacing an ion, which is forced to move into an interstitial position or to the next lattice site.

Diffusion can be described by Fick's two laws, as noted in many texts (Ref 6, 14, 15). Fick's first law states that the rate of mass transfer is proportional to the concentration gradient:

$$J = D\left(\frac{\partial C}{\partial t}\right) \qquad \text{(Eq 14)}$$

The flux, J, is the mass diffusing per second through a unit cross-sectional area due to the concentration gradient, $(\partial C/\partial t)$, and D is the diffusion coefficient, expressed in square centimeters per second. The diffusion coefficient is a function of diffusing atoms, the structure through which the diffusion takes place, and the temperature.

Under most conditions, the concentration gradient does not remain fixed with time and distance. For instance, the concentration of carbon diffusing into a metal (for example, a steel) changes with time and depth into the metal. Fick's second law describes this change under isothermal conditions as:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(D\frac{\partial C}{\partial x}\right) \qquad \text{(Eq 15)}$$

The diffusion coefficient is assumed to be independent of distance, x, to a first approximation, and the concentration, C, is dependent on the distance x. Equation 14 must be solved for the particular geometry and boundary conditions involved (flat, round, or spherical specimens, etc.). For carbon atoms diffusing inward from a flat surface, with constant composition-independent diffusivity, no subsurface phase change in the metal or movement of the metal surface, and a constant surface concentration, the solution to Eq 14 for the concentration of carbon at any distance x from the metal surface is:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\frac{C_M - C_X}{C_M - C_o} = \text{erf}\left(\frac{x}{2\sqrt{Dt}}\right) \quad \text{(Eq 16)}$$

where C_M is the carbon concentration at the metal/carburizing environment interface, C_X is the concentration at time t and distance x from the surface, and C_o is the initial constant concentration at any distance x when $t = 0$. The concentrations here are in moles of carbon per cubic centimeter of metal. The error function of the argument z, erf(z), is tabulated in many books on probability. As carburization proceeds, C_M and C_o remain constant; therefore, for any fixed value of C_X, the depth of penetration, x, of the carburization diffusion reaction is dependent on diffusion time:

$$x \propto \sqrt{t}$$

The diffusion coefficient D in rather stoichiometric compounds can usually be assumed to be proportional to the defect concentration. The diffusion coefficient can also vary with crystal orientation in noncubic crystals. For oxides that are epitaxial or have a preferred orientation, the diffusivity can be several times more or less than it would be for a random oxide. Temperature has a major effect on D by increasing it exponentially, according to the Arrhenius equation:

$$D = D_o e^{(-Q/RT)} \quad \text{(Eq 17)}$$

where D_o is a temperature-independent constant called the frequency factor that is a function of the diffusing species and the diffusion medium, and Q is the activation energy for the diffusion (Ref 6).

The activation energy is a measure of the temperature dependence of a diffusion process. A high value of Q means that diffusion proceeds much more rapidly at high temperatures but very slowly at low temperatures. Typical values of D_o and Q in oxides are listed in Table 2 of the article “Kinetics of Gaseous Corrosion Processes” in this Volume.

When two metals with a large difference in their diffusion coefficients interact, there is a net transport of material across a plane that initially separated them. This phenomenon is called the Kirkendall effect. Multicomponent interdiffusion is a complex process that requires use of multivariable diffusion couples in a phase field approach (Ref 16) or knowledge of diffusion pathways in multicomponent phase diagrams (Ref 17) to model the process and provide an understanding of the contributions to interdiffusion. These methods are based on the formalism of Fick's law, which includes diffusion interactions among the chemical species (Ref 18).

Protective coatings and superalloy substrates generally have widely diverse compositions due to the intended balancing between mechanical properties and corrosion resistance. Depending on the actual temperature, chemical gradients between the coating and superalloy substrate may cause interdiffusion phenomena to occur. Interdiffusion between the coating and the substrate (Ref 19) can modify the oxidation and corrosion resistance of the coating and the mechanical properties of the coating-substrate system. Interdiffusion slowly changes the chemical composition of both the coating and the alloy and subsequently may alter the microstructure of the coating and/or the substrate. In addition, selective oxidation reactions can induce alloy phase transformations (Ref 20, 21). In a hot corrosion environment, the formation of metal sulfides in the protective coating may eventually lead to diffusion via grain boundaries or other relatively easy diffusion pathways into the coating, which may alter the long-term performance of a coating/alloy system versus that observed in an oxidation environment.

In gaseous reactions with metals and alloys, metal ions are formed at the metal/scale interface, and the gaseous species, such as oxygen, is reduced at the scale/gas interface. All metal oxides, nitrides, and sulfides conduct both ions and electrons that are associated with diffusion processes. The electronic conductivities of oxides are usually several orders of magnitude greater than their corresponding ionic conductivities; thus, the diffusion of cations or gaseous ions (i.e., oxygen, sulfur, nitrogen, hydrogen, etc.) controls the reaction rate (Ref 12). Almost without exception, cations and gaseous ions do not diffuse at comparable rates in a given scale, because lattice defects for one of the component species typically predominate. Thus, growth of the scale for gaseous reactions with a metal or alloy should result in scale growth at either the metal-scale or the scale-gas interface if the reactions are controlled by diffusion (Ref 12).

In general, all oxides, sulfides, nitrides, and so on are nonstoichiometric compounds, because their actual, compositions deviate from their respective ideal molecular formulas. Some scales have an excess and others have a deficiency of metallic ions or a corresponding deficiency or excess of gaseous ions.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Nickel oxide (NiO) is an example of a metal- deficient oxide. For each nickel cation vacancy, there are two trivalent nickel cations in the normal lattice positions, as shown in Fig. 2 of the article “Kinetics of Gaseous Corrosion Processes” in this Volume. The trivalent ions are considered the combination of a divalent nickel cation and an associated positive-charged electron hole, or absence of an electron (Ref 12); hence, this is termed a *p*-type semiconductor. Ionic transport occurs by the diffusion of nickel vacancies from the nickel/gas interface to the Ni/ NiO interface. Electronic conduction occurs by the predominant diffusion of the electron holes. Accordingly, electrons migrate from the metal surface, by electron holes, to the adsorbed oxygen atoms, which then become oxygen anions. In this way, while Ni^{2+} cations and electrons move outward through the scale toward the gas, cation vacancies and electron holes move inward toward the metal. Consequently, as the scale thickens, cation vacancies may tend to accumulate to form voids at the nickel/NiO interface.

A metal-excess oxide carries the excess as either interstitial cations or as oxygen anion vacancies. Interstitial cations are small enough to fit into interstitial spaces in the oxide lattice and jump from one interstitial position to another during diffusion. Beryllium oxide (BeO) typifies a cation-excess, *n*-type semiconductor oxide, because the beryllium ion (Be^{2+}) is small enough to move interstitially through the BeO scale. Its structure is shown in Fig. 3 of the article “Kinetics of Gaseous Corrosion Processes” in this Volume.

Oxygen in the gas adsorbs on the BeO surface and picks up free electrons from the BeO to become adsorbed O^{2-} ions, which then react with excess Be^{2+} ions that are diffusing interstitially from the beryllium metal. The free electrons generated at the metal surface from beryllium ionization travel rapidly through vacant high-energy levels. As with *p*-type oxides, the cation-excess, *n*-type oxides grow at the oxide/gas interface as cations diffuse outwardly through the scale (Ref 6).

For *n*-type semiconducting oxides where the cations are too large or too highly charged to assume an interstitial position, anion vacancies are required to form the metal-excess structure. This group of anion-deficient, *n*-type semiconducting oxides is exemplified by zirconium dioxide (ZrO_2). In this case, although most of the cations are contributing four electrons to the ionic bonding, a small fraction of the zirconium cations only contributes two electrons to become zirconium ion, Zr^{2+}. Therefore, to maintain electrical neutrality, an equal number of anion vacancies must be present in the oxide. This arrangement is shown in Fig. 4 of the article “Kinetics of Gaseous Corrosion Processes” in this Volume. The oxide grows at the metal/oxide interface by inward diffusion of O^{2-} through the anion vacancies in the oxides (Ref 6, 22).

A number of compounds that can be nonstoichiometric with either a deficiency of cations or a deficiency of anions are amphoteric. An example is lead sulfide (PbS), which has a minimum in electrical conductivity at the stoichiometric composition. Thus, if the composition is $Pb_{1-x}S$, it is *p*-type, and if it is PbS_{1+x}, it is *n*- type. Similarly, intrinsic semiconductors, such as cupric oxide (CuO), have a few electron holes in their valence band and an equal number of free electrons in their nearly vacant conduction band. Electronic current is carried both by migration of electron holes in the low-energy bonding levels and by free electrons in the higher-energy conduction levels (Ref 6). Examples of *p*-type, *n*-type, and amphoteric superconducting sulfides, oxides, and nitrides are listed in Table 1 of the article “Kinetics of Gaseous Corrosion Processes” in this Volume.

All oxides contain some substitutional impurity cations from the alloy before oxidation or other gaseous high-temperature reaction. Although the solubility limit for foreign ions is low, they can have a great effect on diffusivity in the oxide and consequently, on the oxidation rate. By doping alloys with certain elemental additions, high-temperature gaseous reaction rates can be reduced.

In the very early stages of oxidation and especially at low temperatures, some oxides appear to grow with an amorphous structure. In general, these oxide glasses contain more oxygen than metal in their formulas, so that oxygen networks form around each of the metal ions. The random network ring structures that result allow large anions or molecular oxygen to move through them more readily than the smaller cations do. Amorphous oxides tend to crystallize as they age. Examples are silicon dioxide (SiO_2), Al_2O_3, tantalum pentoxide (Ta_2O_5), and niobium pentoxide (Nb_2O_5).

As a crystalline oxide grows on a metal surface, the oxide often aligns its crystal structure to be compatible with the structure of the metal substrate. This epitaxy finds the best fit, but not a perfect fit, between the oxide or scale and the substrate crystal structures.

Additional Aspects of Scale Growth

Stress develops in an epitaxial scale layer as it grows, due to the slight misfit between the scale and metal crystals. The stress is likely to produce dislocation arrays in the scale that could be paths of mass transport

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

through the film via diffusion. A mosaic structure, consisting of small crystallites with orientations very slightly tilted or twisted with respect to each other, may develop in the scale because of the growth stresses. The boundaries between the crystallites are dislocation arrays that serve as easy diffusion paths (Ref 6). Recrystallization of either the scale or the substrate may alter the stress conditions substantially.

Stresses in epitaxial layers increase as the films grow thicker, until, at some point, the bulk scale tends to become polycrystalline, and epitaxy is gradually lost. Epitaxy may last up to approximately 50 nm in many cases, but it is seldom strong over 100 nm. As the scale grows thicker, crystals that are favorably oriented for growth will grow at the expense of their neighboring grains until the scale surface consists of a few large grains with similar orientation. The variation in growth rate of different scale grains produces the roughening of the scaled surface that is commonly observed (Ref 6).

A pure metal that can oxidize to more than one valence will form a series of oxides, usually in separate layers. For example, iron has valences of +2 and +3 at high temperatures and forms wustite (FeO), magnetite (Fe_3O_4), and hematite (Fe_2O_3) scale layers. The scale layers will be arranged with the most metal-rich oxide species appearing next to the metal, and progressively less metal content is found in each succeeding layer toward the outside layer. In addition, a concentration gradient exists with each layer, with higher metal ion concentration closest to the metal/scale interface.

If the oxygen partial pressure in the gas is so low that it is below the dissociation pressures of the outer oxygen-rich oxides, then only the thermodynamically stable inner oxides will form. In general, the lowest-valence inner oxide will usually be *p*-type because of the ease with which electron holes and cation vacancies can form. The outermost oxide is often *n*-type because of its anion vacancies. A scale consisting of an inner layer with cations diffusing outward and an outer layer with anions diffusing inward will grow at the oxide/oxide interface (Ref 6).

Polycrystalline oxides develop stresses along their grain boundaries because of enhanced growth of oxide grains in preferred orientations. Short-circuit diffusion along grain boundaries may lead to oxide or high-temperature scale formation at the boundaries that imparts increased compressive stresses. Second-phase inclusions may oxidize at a different rate than the parent metal or alloy and lead to high stresses within the scale. Composition variations within a high- temperature coating or within gaseous-formed scales may also create stresses within the scale. Alloying constituents may react to a gaseous environment at different rates, leading to preferential growth of a scale from one or more elemental metal components. If diffusion is too slow to maintain constant composition within the scale, stress can develop in the alloy (Ref 6).

The activation energies for diffusion along line and surface defects in solids are much less than those for volume diffusion. Dislocations, grain boundaries, porosity networks, and external surfaces offer rapid diffusion paths at low temperatures, at which volume diffusion is extremely slow. In metals, diffusion along dislocations is more important than volume diffusion below approximately one-half of the absolute melting point. At high temperatures, volume diffusion predominates in both metals and oxides.

At very high temperatures, oxides and high- temperature scales may evaporate entirely or limit the protective nature of these protective scales. Platinum and refractory metals tend to have volatile oxides (Ref 6). As evaporation removes material from the scale layer, diffusion through the scale increases until the evaporation and diffusion rates are equal. The scale thickness remains constant, and the scale or oxide of the metal or alloy grows paralinearly. If more than one oxide or scale layer protects the substrate, the higher-valent outermost oxide/scale always has the higher vapor pressure and is thus more volatile.

Sample geometry may influence the stresses within a scale. The stress state (compressive or tensile) depends on whether the surface profile of the sample is convex or concave and whether the scale grows at the scale/gas interface or at the metal/scale interface. Figure 9 shows how the stress state may be altered in an oxide scale as it grows, assuming the original growth stresses were compressive. Other scales formed from gaseous reactions will behave similarly.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

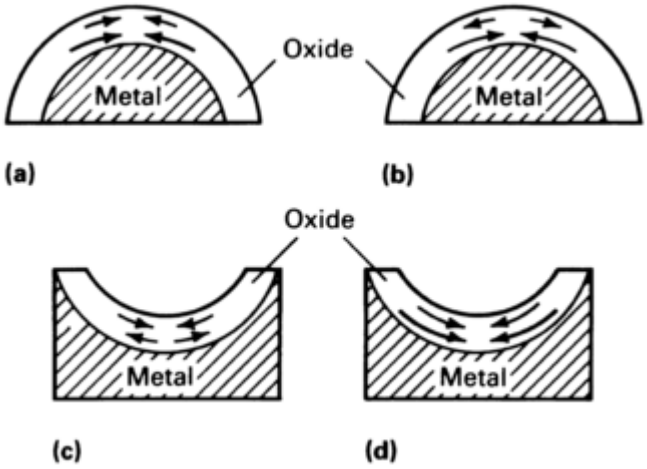

Fig. 9 Stress development on curved surfaces. (a) Oxide grows by cation diffusion on a convex surface. (b) Oxide grows by anion diffusion on a convex surface. (c) Oxide grows by cation diffusion on a concave surface. (d) Oxide grows by anion diffusion on a concave surface

In Fig. 9(a), for a convex surface on which oxide grows at the oxide/gas interface by cation diffusion outward through the scale, the metal surface will gradually recede, increasing the compressive stresses at the metal/oxide interface. If adhesion is to be maintained, the oxide has to follow the retreating interface, generating further compressive stresses in the scale. Stress relief can occur by either shear fracture, if the scale is extremely adherent, or by oxide buckling due to decohesion that could lead to local tensile failure. Figure 9(b) shows oxidation of a convex surface on which the oxide grows at the metal/ oxide interface by anion diffusion inward. The compressive stresses that develop at the metal/ oxide interface are due only to the volume change of the reaction oxide (volume generated is greater than the volume of metal consumed). Oxide that is pushed away from the growth area will gradually reduce its compressive stress until the outer surface may even be in tension. This may lead to the development of a laminated oxide structure, because new oxide forms under the older, buckled, decoherent oxide layer (Ref 6, 15).

For concave surfaces,Fig. 9(c) illustrates oxide growth at the oxide/gas interface by outward diffusion of cations. As the metal surface recedes, the compressive stresses due to oxide growth are reduced. If further adhesion is weak, further oxidation may lead to spallation of the oxide. If adhesion forces at the oxide/substrate interface are strong, further scale growth will cause development of tensile stresses in the oxide adjacent to the substrate. Figure 9(d) shows growth on a concave surface by anion diffusion inward for reaction at the metal-oxide interface. Very high compressive stresses develop during growth, until they exceed the cohesive strength of the oxide, and shear cracking results (Ref 6, 15).

A preferential reaction of a gaseous species (oxygen, sulfur, nitrogen, etc.) with one constituent in an alloy or refractory may alter the chemical composition of the material to the point where crystallographic phase transformation is experienced. A change in temperature may also cause transformations. Volume changes associated with these phase transformations can induce significant stresses in both the alloy and scale or high-temperature coating.

For oxides that grow by cation diffusion outward through cation vacancies (*p*-type oxides, such as NiO), the vacancies are created at the oxide/gas interface and diffuse inward through the scale as they exchange places with an equal number of outward-diffusing cations. The vacancies are annihilated within the oxide, at the metal/oxide interface, or within the metal, depending on the type of oxide system. In some oxides, the vacancies collect together within the oxide to form approximately spherical cavities. The preferred sites for cavity formation are along paths of rapid diffusion, such as grain boundaries and dislocation lines.

Vacancies that are annihilated at the metal/oxide interface may cause detachment of the scale, because voids that form reduce oxide-to-metal adhesion. If attachment is only partial, the oxidation rate slows down, because the cross-sectional area available for diffusion decreases (Ref 6).

Measurement of High-Temperature Degradation

Sample Preparation for Testing

For high-temperature testing, samples need to be prepared and processed in a similar manner as they would for actual service. The materials should be characterized by chemical composition, fabrication history, and by morphology or microstructure (Ref 23).

The size and shape of laboratory and field test samples can vary, but samples should be large enough to obtain meaningful quantitative information on exposure to the test environment. The samples should be large enough that the corrosion reaction being tested does not fully consume the material exposed. Geometry asperities, such as corners and edges, should be eliminated, if possible, because they tend to be less corrosion resistant than planar surfaces. The geometry, on the other hand, should reflect the part, component, or system as much as possible. Samples need to be identified, but any markings should not influence the test performance of the sample.

The samples should be prepared for testing in a specified manner so that the sample surfaces are clean, uniform, and defect-free to minimize conditions that may affect the testing results. Carburized, decarburized, or cold-worked layers should be removed (Ref 23). The samples should be handled carefully to avoid contamination. Before testing, each sample must be measured precisely to calculate the surface area and/or accurately weighed (for small samples, generally to a precision of 0.1 mg). Testing will alter the dimensions or the mass during exposure. After measuring the samples, they should be either inserted into the test setup or stored in a dessicator until needed.

Because deviations in test parameters may vary slightly over time and with sample placement within the test apparatus, replication is necessary. Samples in duplicate or triplicate will often be sufficient, but larger sample sizes are strongly advised when the test materials are highly variable. The consistency of the test results will be improved and the test result scatter decreased when the test parameters are tightly controlled and multiple samples are used (Ref 23).

If a test is often repeated, a pedigreed control sample should be used to calibrate the experimental laboratory or service test. This will verify whether test parameter abnormalities exist or if breakdown in operational controls has occurred during a test. Use of the control samples provides this measure of assurance. Control samples should be thoroughly characterized (chemical composition, fabrication history, microstructure, and physical and mechanical properties) (Ref 23).

Mass Change

Mass changes, either losses or gains, are determined by calculating the weight change per unit area, usually as a function of time, temperature, and pressure. Mass change is calculated as follows:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$\text{Mass change} = \frac{W_f - W_o}{A} \qquad \text{(Eq 18)}$$

where W_f is the final weight in grams, W_o is the initial weight in grams, and A is the original area in centimeters squared or meters squared. A plus or minus sign indicates a net gain or loss. It is important to record whether the test sample has been descaled or not and by what method. The scale may be difficult to remove if it is tightly adhered or part of an oxide substructure. There are standard methods used for descaling.

It is misleading if single data point or single analytical measurements are made over a long time duration, because corrosion rates and modes usually vary with time. The use of the mass change method to measure corrosion rate will also be inaccurate if spallation of the surface layer occurs during the test duration. Three additional limitations of the mass change method are that (a) it lacks the registering of subsurface attack, such as intergranular attack, which, at times, is quite deep; (b) deep localized corrosion (e.g., pitting) is averaged over the weight of the entire specimen, and thus, the extent of the attack is minimized; and (c) weight gains due to oxygen or sulfur absorption would interfere with weight loss measurements.

Structural Changes

Structural changes in a high-temperature test sample can result in depletion of a constituent in the material or thermal effects on the stability of the material. An example of alloy depletion is the dissolution of carbides near the substrate surface because of high-temperature exposure. A common thermal effect is the precipitation of topologically close-packed phases, such as mu, Laves, and sigma, over time within certain temperature ranges. Analytical methods, discussed later, can be used to confirm these structural changes.

Metallographic Analysis

Analysis can be most easily performed by optical metallography but may be done using scanning electron microscopy or transmission microscopy. Metal loss is defined as one-half the difference between the original thickness and the remaining thickness after exposure, as shown in Fig. 10 (Ref 24). Thickness extends to just beneath the scale/surface surface and excludes the thickness of internal attack:

$$\text{Metal loss} = \frac{t_o - t_m}{2} \qquad \text{(Eq 19)}$$

where t_o is the original thickness or diameter, and t_m is the sample thickness or diameter after a term of exposure.

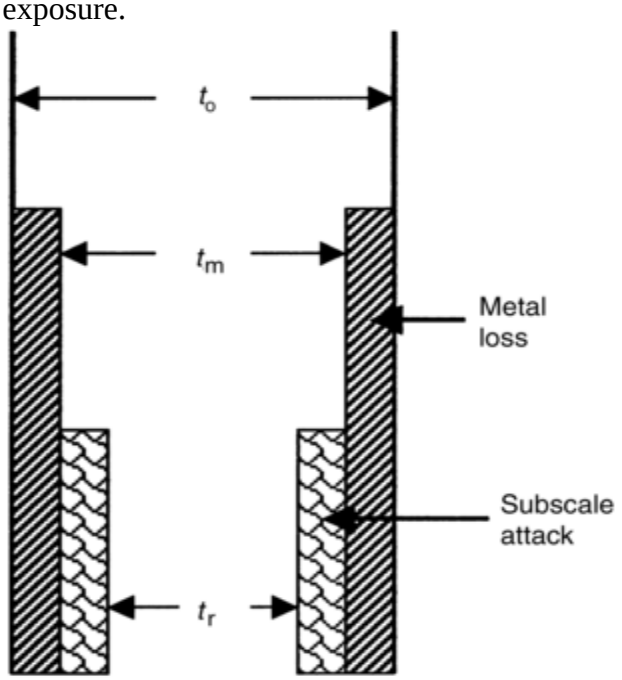

Fig. 10 Schematic showing thickness measurements t_o, original thickness; t_m, sample thickness after a term of exposure; and t_r is the remaining good metal thickness. Source: Ref 24

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Depth of attack describes the formation of voids, internal precipitation, or penetration due to corrosion. This is termed depth of penetration or, in the case of oxidation, as internal oxidation. This attack may be due to loss of a material constituent to a high-temperature gaseous environment or internal reaction in the material. Voids are often associated with grain boundaries, because the boundaries are a major route for fast diffusion of the alloying element lost. Alloying elements of high vapor pressure or those that form volatile products with the gaseous environment are prone to cause voids.

It often is more convenient to test round samples, such as rods or pins. Corrosion attack of such test samples can be measured by metallographic examination at a specified magnification at designated intervals around the specimen circumference. The readings at each site around the circumference consist of the outer diameter of the remaining material and the inner reading marking the maximum corrosion penetration at a specific interval site. The measurements reported for round samples are described subsequently, with differences noted based on whether or not the samples are coated.

Uncoated alloy pin measurements affected by corrosion include average material loss on a radius and maximum material penetration.

Average Material Loss on a Radius. This is the combination of the average change of specimen diameter (original diameter minus the remaining diameter after full test exposure) and the average radius of corrosion loss due to all forms of oxidation and sulfidation ([outer diameter minus inner diameter]/2), as shown in Fig. 11. This measurement is usually averaged from a total of all measurements; however, because of the occasional variations in the original pin diameters, the average material loss on a radius is measured at specified intervals of each test specimen. Because these measurements are performed at discrete sites around the circumference, the average material loss on a radius is a statistical average:

$$\text{Average metal loss} = \frac{1}{N}\sum_{i}^{i=N}\left(\frac{D - D_1}{2}\right) \qquad \text{(Eq 20)}$$

where D is the original diameter, D_1 is the diameter of the structurally intact alloy, and N is the number of measurements on the test sample. Measurements are made to the nearest 0.02 mm (0.001 in.).

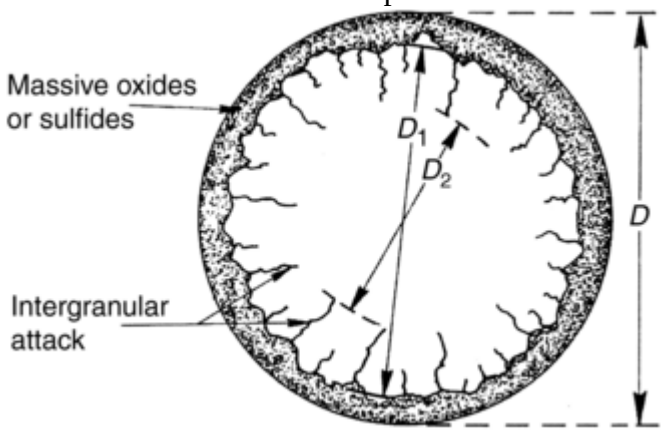

Fig. 11 Schematic of measuring high-temperature corrosion of uncoated metals and alloys on round specimens

Maximum Material Penetration. This measurement includes surface loss plus the depth of all oxides and sulfides that may be scattered or in local concentrations, such as grain boundaries. Only the greatest depth value is reported as the maximum penetration, that is:

$$\text{Maximum material penetration} = \frac{D - D_2}{2} \qquad \text{(Eq 21)}$$

where D is the original diameter, and D_2 is the diameter of the alloy pin unaffected by oxides and sulfides or any other form of corrosion (such as intergranular corrosion or void formation) caused by the high-temperature exposure. Measurements are made to the nearest 0.02 mm (0.001 in.). This type of measurement is most relevant to high-stress applications, such as turbine blades or critical incinerator components. Subsurface attack in local areas may also promote failures through fatigue or thermal cycling.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Coating Measurements Affected by Corrosion. High-temperature components are sometimes coated to provide improved protection. Depth of attack can be measured for these materials as well. Measurements of interest are average coating loss on a radius and maximum coating penetration on a radius.

Average Coating Loss on a Radius. This measurement reflects loss in coating thickness due to all forms of oxidation and sulfidation. An average of all measurements is made per test specimen, as depicted in Fig. 12:

$$\text{Average coating loss on a radius} = \frac{1}{N}\sum_{i}^{i=N}\left(C_o - (X_1 - Y_1)\right) \qquad \text{(Eq 22)}$$

where C_0 is the original coating thickness, X_1 is the coating attack due to all forms of oxidation and corrosion, and Y_1 is the coating-substrate interface.

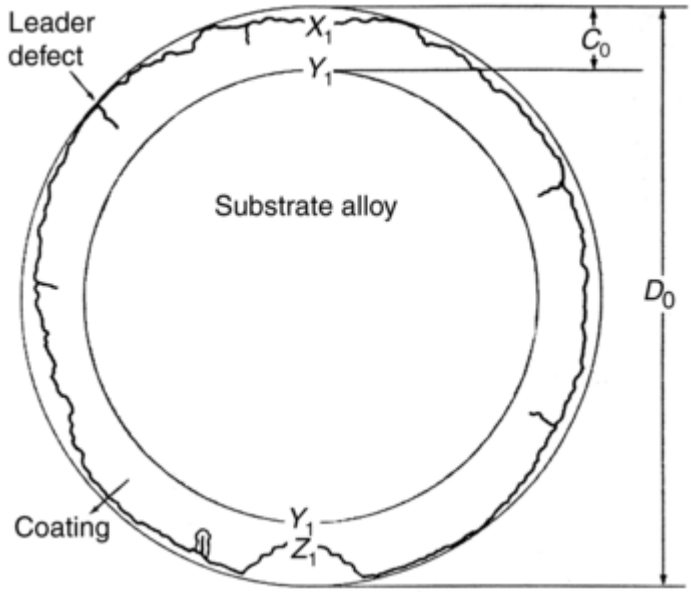

Fig. 12 Schematic of measuring high-temperature corrosion of coated materials on round specimens. C_0, original coating thickness; D_0, original coating plus substrate diameter; X_1, coating attack; Y_1, coating/substrate interface; Z_1, maximum coating attack

Maximum Coating Penetration on a Radius. This is a measurement of the deepest attack found anywhere along the test sample (Eq 23). This number yields a measurement of maximum depth-of-coating attack. Maximum penetration numbers are typically used to rank coating performance in these tests, under the assumption that once the coating has been completely penetrated, it no longer provides the intended protection to the substrate. Although average coating loss may be considerably less than the maximum penetration, the greatest degree of attack is determined to be the most critical measurement for coating assessments.

$$\text{Maximum coating penetration on a radius} = C_0 - (Y_1 - Z_1) \qquad \text{(Eq 23)}$$

where C_0 is the original coating thickness, Z_1 is the maximum coating attack due to all forms of oxidation and corrosion, and Y_1 is the coating- substrate interface. Unlike the average coating loss, which is an average of a number of measurements, the maximum coating loss is a single measurement where the penetration was greatest.

Round specimens are preferred because they can be measured accurately by metallographic techniques across any diameter, which is an important consideration, because an uneven attack frequently occurs. Round specimens also minimize the influence of thermal stresses on the corrosion properties of materials. Sharp corners on test specimens may initiate spalling and premature oxide/coating failure that may not be characteristic of the material in actual service. Wedge, airfoil, or other unevenly shaped specimens are generally more difficult to analyze, except when using the weight-change method for measuring the degree of corrosion. However, weight change is not always an accurate quantification of the corrosion process.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Statistical Analysis of Corrosion Measurements. For better assurance of uncoated or coated corrosion measurements, multiple test specimens are recommended. Five multiple samples provide good statistical averaging (Ref 25). Because of the redundancy of the multiple test specimens, it is possible to perform a statistical analysis of the measurement data (Ref 26). This is accomplished by using the two-sample t-test, unequal variance, for examining the existence of real versus random differences between the corrosion data of any two given coatings or alloys. This statistical method tests the hypothesis (commonly referred to as the null hypothesis) that the means of the sets of data from two alloys or coating samples are equal against the alternative hypothesis that the mean on one alloy or coating set of data is greater than that of the second set. This statistical test is performed at a specified probability level (usually set at 90%) that the differences in the means are real and are not due to random variations. This statistical analysis does not project which alloy or coating is better or worse; it only examines the probability that the observed difference is real and not due to random variations. See also the articles “Statistical Interpretation of Corrosion Test Results” and “Statistics for the Corrosionist” in this Volume.

Analysis of Corrosion Products. It is usually desirable to analyze corrosion products and degradation phenomena for both composition and morphology. Such analysis may be performed by in situ methods or ex situ techniques that may require special handling and sample preparation. Compositional analysis can be done by wet chemistry, x-ray diffraction, high- and low-energy electron diffraction, x-ray fluorescence, electron probe microanalysis, inductively coupled atomic emission spectroscopy, atomic absorption spectroscopy, Fourier transform infrared spectroscopy, mass spectroscopy, and other methods. Structural morphology and analysis may be done using light microscopy image analysis, microhardness measurements, transmission electron microscopy, scanning electron microscopy, scanning Auger microscopy, field emission microscopy, plus other techniques. For details of these analytical methods, see *Materials Characterization,* Volume 10 of *ASM Handbook,* and Ref 10.

High-Temperature Corrosion and Degradation Processes

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Testing of high-temperature corrosion requires a degree of understanding of the major corrosion processes, based in large part on the material being exposed and the environment to which the material is exposed, along with the other basic factors discussed earlier. It must be realized that actual service environments and conditions may be far more complicated than simple laboratory tests may provide. High-temperature corrosion or degradation of materials may occur through a number of potential processes:

- Oxidation
- Carburization and metal dusting
- Nitridation
- Sulfidation
- Hot corrosion
- Chloridation and other halogenization reactions
- Hydrogen interactions
- Molten metals
- Molten salts
- Aging reactions, such as sensitization
- Creep
- Erosion-corrosion and wear
- Environmental cracking (stress-corrosion cracking and corrosion fatigue)

Oxidation. Most metals and alloys oxidize on exposure to temperatures above 300 °C (570 °F) in environments containing greater than 1 vol% O_2. Alloys are protected to varying degrees by the oxide layer. The thickness of the protective oxide often follows parabolic rate kinetics. Gas composition influences the rate of oxidation. The effects of oxygen concentration and temperature are specific to each alloy. Scale growth rates increase with a rise in temperature. Oxidation environments may be classified on the basis of the oxygen activity. Oxidizing environments contain an excess of free oxygen, while reducing environments contain no free oxygen at equilibrium in the gas mixture. Mixed-oxidant environments that are reducing tend to be more corrosive than oxidizing conditions.

Preferential grain-boundary oxidation, thermal cycling, the presence of moisture, and chloride- or sulfur-containing gases cause service lives much shorter than those predicted from isothermal oxidation. Small additions of rare earths, such as lanthanum, cerium, and yttrium, or the presence of dispersed oxides, such as yttria, ceria, zirconia, and lanthania, improve the scale adhesion and scale resilience of chromia-forming alloys to cyclic oxidation of Cr_2O_3-forming alloys, such as austenitic stainless steels and chromium-nickel alloys (Ref 27). These effects may include (a) more rapid formation of a continuous Cr_2O_3 scale, (b) reduction in the oxidation rate, (c) improved scale adherence, and (d) a change in the scale-forming reaction location from the scale-gas interface to the scale-alloy interface. Reactive elements are known to improve the oxidation resistance of many high-temperature alloys, particularly if the resistance is dependent on Cr_2O_3 formation.

Loss of oxide adhesion and integrity may be caused by mechanical damage via spallation or cracking of the oxide film from cyclic oxidation of chromia and alumina oxides formed on nickel-base alloys due to the mismatch of thermal expansion coefficients between the oxide and the base alloy (Ref 28).

Carburization of metals and alloys is a form of internal attack where the formation of carbide corrosion products occurs on exposure to temperatures above approximately 760 °C (1400 °F) in gases containing methane, carbon monoxide, hydrocarbons, carbon, or other carbonaceous compounds. Carburization alone usually does not result in corrosion or alloy wastage, but adsorption and diffusion of carbon into the base alloy can lead to significant changes in the alloy mechanical properties, leading to possible alloy embrittlement. Variables that affect the carburization rate are the temperature, exposure time, alloy composition, and the partial pressures of H_2, CH_4, and H_2S. The H_2S tends to slow alloy carburization rates.

Carburization is usually controlled by both carbon and oxygen activities. Carbon activity is a function of both the environment and of the metal or alloy. The carbon activity of a metal or alloy can be determined by thermodynamics. Generally, the lower the oxygen activity, the greater the tendency for carburization to occur. Carburization is a diffusion-controlled reaction where the maximum carbon gradient occurs at the reaction surface. Grain-boundary diffusion of carbon tends to be significantly faster than intragranular diffusion (Ref 23). It is often observed that there is a change of the carbide species from the surface to the interior.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Carbon dioxide produced in an oxidizing environment is less corrosive than carbon monoxide, CO, which is the prevalent carbonaceous gaseous species in a reducing environment. Reducing or oxidizing environments will usually be dependent on the stability of the oxide formed; the relative oxidizing or reducing atmosphere can be determined, to a first approximation, by use of the Ellingham diagrams discussed earlier.

Under simultaneous oxidizing and carburizing conditions where hydrocarbons are present in the gas stream and/or with the introduction of oily components, stainless steels and nickel-base alloys are susceptible to severe carburization called green rot (Ref 29). Green rot occurs when internal chromium carbides are formed during carburization; subsequent oxidizing of the carbides at the grain boundaries may result in embrittlement. Corrosion products in the pits consist of metal carbides, metal oxides, and graphite. The attack is localized, and carburization is confined to the pit.

Carburization may be tested in several gaseous environments, such as CH_4-H_2 (reducing) or CO_2-H_2-H_2O mixtures, or under pack carburization, where active charcoal is packed around the sample in a steel box and tested to the desired testing temperature. The carbon reacts with open pockets of air to generate carbon monoxide, which, in turn, disproportionates via the Boudouard reaction—C (s) + CO_2 (g) = 2CO (g), where "s" and "g" represent solid and gas, respectively—into an oxidizing mixture of carbon dioxide and carbon.

Carburization testing in the laboratory offers the convenience of access to the necessary equipment for precise control of conditions along with the ability to control measurement schedules. However, the laboratory test may not mimic all environmental and mechanical conditions, such as stress, design effects (corners, crevices, dead zones, etc.), thermal fluctuations in service abrasive damage, flow stream effects, and metal-to-metal contact reactions. Thus, the investigator may not be able to reproduce the complete atmosphere that is being simulated in the laboratory and thereby runs the risk of missing a key element in determining the rate of carburization degradation. Reference 30 reviews the phenomenon of carburization and procedures for testing and evaluating carburization.

Metal dusting can be described as a catastrophic form of carburization occurring under conditions where the carbon activity (a_C) in the gaseous atmosphere is much greater than that in the metal. The degradation takes place in strongly carburizing atmospheres (a_C » l). Although metal dusting has taken place at temperatures as high as 1095 °C (2000 °F) in strongly reducing gaseous environments, it generally occurs at temperatures from 480 to 815 °C (900 to 1500 °F). Deterioration and material wastage by metal dusting in carburizing gases at 425 to 815 °C (800 to 1500 °F) result in pitting and overall wastage of stainless steels with or without an oxidizing environment (Ref 31, 32, 33, 34, 35).

Slight modifications in the process conditions may significantly affect the occurrence and extent of metal dusting attack. The phenomenon can produce rapid metal wastage, producing pits and grooves as the affected metal disintegrates into a mixture of powdery carbon and metal particles. Metal dusting corrosion occurs in processes from numerous industries that include petrochemical processing (processes involving steam reforming of methane or natural gas, such as ammonia and methanol production), direct iron-ore reduction, coal degasification, and heat treating.

Nitridation of alloys in ammonia environments is well known in ammonia and heat treating industries (Ref 36). Nitridation characteristics are similar to carburization but are not as commercially common in occurrence. As with carburization environments, increasing oxygen activity decreases nitridation at a given temperature. It has been shown that the kinetics of nitridation in N_2 are much higher than that found in contact with NH_3 at high temperatures (980 to 1090 °C, or 1800 to 2000 °F) (Ref 37). Heat treating furnaces and accessories for heat treating powder metal products are typically exposed to N_2 or N_2-H_2 atmospheres at elevated temperatures (≈1090 °C, or 2000 °F). Alloys can be susceptible to nitridation attack in combustion environments even when such environments are oxidizing.

The internal precipitation of nitrides in heat- resisting alloys containing chromium or aluminum has been known to follow parabolic kinetics, indicating the diffusion of nitrogen is the rate-controlling step. Thermal cycling, which leads to cracking of the oxide scale and/or spallation, destroys the effectiveness of the barrier oxide, leading to internal nitridation.

Sulfidation is most often a reaction of a metal or alloy with gaseous species, although reaction with molten sulfur-containing species is possible. Sulfidation produces a metal-sulfur compound that forms on or beneath the surface of the material. The extent of corrosion depends on the partial pressure of sulfur relative to oxygen at a given temperature and the relative stability of the oxides and the sulfides at the same temperature.

Sulfidation may involve the formation of oxides plus sulfides in reducing gases, such as hydrogen/hydrogen sulfide mixtures, or in oxidizing gases, such as air-sulfur dioxide or air-sulfur dioxide water. In most

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

environments, Al_2O_3 or Cr_2O_3 form preferentially to the sulfides, but destructive sulfidation attack may occur at oxide crack sites (Ref 38). The reduced species, H_2S, is more corrosive than the oxidized species, SO_2 Gaseous reactions or molten phases, such as low-melting-point metal-sulfide eutectics, cause sulfidation. Sulfidation of nickel results in the formation of eutectic Ni_3S_2 that has a melting point of 635 °C (1175 °F) with a sulfur solubility of 0.005% (Ref 39). The eutectic formation causes the initiation and propagation of intergranular corrosion. The sulfidation rate of metals and alloys is usually many times higher than the corresponding oxidation rate. Metal sulfides generally are more complex and have lower melting temperatures than the corresponding oxides (Ref 40).

Adding chromium improves resistance to sulfide attack and increases the operating temperature limit of an alloy in a sulfidizing environment. Chromium sulfide formed below the surface of the protective oxide layer may lead to depletion of chromium and breakaway corrosion of the alloy. Once sulfur has entered into the alloy, sulfur tends to react preferentially with chromium or aluminum to form additional sulfides; this may cause redistribution of the scale-forming elements or interfere with the formation of protective oxide scales. Nickel-chromium alloys have been successfully used at service temperatures of 750 to 1200 °C (1400 to 2200 °F). Manganese, silicon, and aluminum additions improve the resistance of nickel alloys to sulfur attack (Ref 41).

Scaling rates of high-temperature stainless steels are higher in dry sulfur dioxide environments than in air, due to the formation of chromium sulfides below the protective chromia scale. The introduction of water vapor into air- sulfur dioxide environments accelerates sulfidation attack (Ref 13).

Sulfur can be transported through the Al_2O_3 and Cr_2O_3 protective scales under certain conditions, resulting in discrete sulfide precipitates observed at the scale/alloy interface. Sulfide concentrations above approximately 10 to 20 ppm have been shown to modify the adhesion strength and cyclic oxidation resistance of the protective oxide scales. Generally, cobalt-chromium binary alloys have resistance to sulfidation superior to nickel-chromium binary alloys because of the slower outward diffusion of cobalt ions through the scale during sulfidation and the relatively high melting point of the cobalt-Co_4S_3 eutectic (Ref 42).

Hot corrosion is a complex process involving both sulfidation and oxidation (Ref 43). Hot corrosion is a form of accelerated oxidation that affects alloys and coatings exposed to high-temperature gases contaminated with sulfur and alkali metal salts (Ref 44). These contaminants combine in the gas phase to form alkali metal sulfates; if the temperature of the alloy is below the dewpoint of the alkali sulfate vapors and above the sulfate melting points, molten sulfate deposits are formed (Ref 44). Molten sodium sulfate is the principal agent in causing hot corrosion (Ref 45, 46). Sulfide formation results from the interaction of the metallic substrate with a thin film of fused salt of sodium sulfate (Ref 47, 48, 49). Sulfur compounds come from two sources in a marine gas turbine engine: sulfur from the combustion fuel, which often ranges from 0.1 to 1 wt% (or more), depending on the grade of fuel, and sulfate salts contained in marine air that are ingested into the hot section of the turbine engine.

Chloride salts can act as a fluxing agent and dissolve protective oxide films or cause alloy oxides to fracture and spall. Air in a marine environment ingested into the combustion zone of any marine gas turbine engine will be laden with chlorides unless properly filtered. Sodium chloride (NaCl) has been viewed as an aggressive constituent in the hot corrosion of gas turbine components in the marine environment (Ref 50, 51).

Two general forms of sulfate hot corrosion exist. Type I, high-temperature hot corrosion (HTHC), occurs through multiple mechanisms. It is generally thought to transpire by basic fluxing and subsequent dissolution of the normally protective oxide scales by molten sulfate deposits that accumulate on the surfaces of high-temperature components, such as hot section turbine blades and vanes. The HTHC usually occurs at metal temperatures ranging from 850 to 950 °C (1560 to 1740 °F). Type I hot corrosion involves general broad attack caused by internal sulfidation above 800 °C (1470 °F); alloy depletion is generally associated with the corrosion front. This basic fluxing attack involves raising the Na_2O activity in the molten sulfate by formation of metal sulfides (Ref 52). Very small amounts of sulfur and sodium or potassium can produce sufficient Na_2SO_4 or K_2SO_4. In gas turbine environments, a sodium threshold level below 0.008 ppm by weight precluded type I hot corrosion (Ref 13).

Type II, low-temperature hot corrosion (LTHC), occurs in the temperature range of 650 to 750 °C (1200 to 1380 °F) where p_{SO_3} is relatively high or melts are deficient in the oxide ion concentration, leading to acidic fluxing of metal oxides, which results in pitting attack (Ref 53). Sulfides are found in the pitted area (Ref 54). The LTHC may involve a gaseous reaction of SO_3 or SO_2 with CoO and NiO, which results in pitting from the formation of low-melting mixtures of Na_2SO_4 and $NiSO_4$ or Na_2SO_4 and $CoSO_4$ in nickel-chromium, cobalt-

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

chromium, cobalt-chromium-aluminum, and nickel-chromium-aluminum alloys (Ref 13, 55). The interaction of these oxidation products with salt deposits forms a complex mixture of salts with a lower melting temperature (Ref 15). When the salt mixture melts, the corrosion rate increases rapidly. If other reactants are added, melting temperatures of the resultant salts can be further lowered. High chromium content (>25 to 30 wt% Cr) is required, generally, for good corrosion resistance to hot corrosion. Nickel-base alloys with both chromium and aluminum show further improvement in hot corrosion resistance.

Acid-base oxide reactions with molten sulfate through the measurement of oxide solubilities as a function of Na_2O activity in fused Na_2SO_4 were examined (Ref 56). Oxide solubility is dependent on Na_2O activity, which also serves to rank the acid-base character of individual oxides.

Other impurities, such as vanadium (≥0.4 ppm), phosphorus, lead, chlorides, and unburned carbon, can be involved in lowering salt melting temperatures, altering the sulfate activity, or changing the solution chemistry and acidity/basicity that leads to accelerating hot corrosion. Vanadic hot corrosion appears to be potentially more complex, because five compounds exist in the sodium, vanadium, oxygen system (Ref 57). The high-temperature reaction of sulfate and vanadium with ceramic oxides involved a Na_2O- V_2O_5 system that could be explained by Lewis acid-base chemistry (Ref 58). Basic zirconia (ZrO_2)-stabilizing oxides, such as Y_2O_3, do not react with Na_3VO_4 (or $3Na_2O$-V_2O_5) but do react with the V_2O_5 component of $NaVO_3$ (Na_2O- V_2O_5) and V_2O_5 itself to form YVO_4 (Ref 59). Acidic oxides, such as Ta_2O_5, react with the Na_2O component of Na_2VO_4 and $NaVO_3$ to form sodium tantalates and yield α-$TaVO_5$ with V_2O_5. The vanadate that is most corrosive in the initiation of vanadic attack will depend on the acidity/basicity of the coating or alloy oxide. No reaction occurs when the acid-base properties of a stabilizing oxide are equal (Ref 60). The thermochemistry of vanadate and sulfate melts and reaction with different stabilizing oxides with SO_3-$NaVO_3$ was studied (Ref 61).

High chromium content (>25 to 30% Cr) is required for good resistance to hot corrosion. Nickel alloys with both chromium and aluminum show improved hot corrosion resistance. However, inspection of phase stability diagrams for the systems M-Na-O-S, where M can be nickel, cobalt, iron, aluminum, or chromium, indicates that there are no combinations of melt basicity and oxygen activity where these metals, absent of a protective oxide film, are stable in contact with fused sodium sulfate (Ref 62). The relative hot corrosion resistance of a number of alloys has been evaluated in incinerator environments where hot corrosion can occur (Ref 38, 63, 64).

Yttria-stabilized zirconia (YSZ) is attacked at high temperatures and destabilized by phosphorus impurities in fuel (Ref 65). The acid P_2O_5 reacts with basic Y_2O_3 to form the salt YPO_4. Zirconia also synergistically reacts with sodium and P_2O_5 to form $NaZr_2(PO_4)_3$. The YSZ thermal barrier coatings (TBCs) have been exposed to $PbSO_4$-Na_2SO_4 molten salts without observable destabilization or reaction with this ceramic (Ref 66). However, lead, as PbO, appears to cause TBC failures by reacting with chromium in the NiCrAlY bond coat to form $PbCrO_4$.

Chloridation. Chlorides often accumulate rapidly on metallic surfaces of test samples. In one study, typical deposits contained 21 to 27% Cl when the flue gas contained 40 to 140 ppm HCl (Ref 67). Municipal wastes were characterized as having a 0.5% halide dry content, of which 60 wt% was derived from organic polymer sources (Ref 68). Chloride salts have melting temperatures as low as 175 °C (347 °F), which can act as fluxing agents that dissolve protective oxide films. High-temperature components exposed to air from a marine environment will be laden with chlorides. The following compounds may cause rapid corrosion of carbon steel, if present:

Compound	Melting point	
	°C	**°F**
Molten $SnCl_2$	246	474
$SnCl_2$ + NaCl	199	390
$ZnCl_2$	283	541
Eutectic $PbCl_2$/$FeCl_3$	175	347
Eutectic $ZnCl_2$/NaCl	262	504

Attack by halogens at elevated temperatures occurs through the volatility of the reaction products. Oxides that form in combustion gases will be porous and prone to fracture. Stainless steels are generally passive, but surface pitting may occur in chloride-containing environments. Nickel- base alloys can be expected to have superior corrosion resistance, as compared to stainless steel alloys (Ref 69). Clay containing aluminum silicate may inhibit chloride-related corrosion by raising the melting points of chloride salts through the formation of sodium aluminum silicates, which expel HCl and SO_3 (Ref 70). Problems with chlorides can be mitigated if

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

plastics and other sources of halogens are removed or minimized from the waste stream. Increasing the oxygen content and adding water vapor has also reduced the corrosion rate of various alloys by chlorides in a simulated waste incinerator environment (Ref 67). Hydrogen chloride can be formed from the combustion from chlorine-containing polymers and can dissociate into hydrogen and chlorine gases. Low pCl_2 will generate a reducing environment. However, HCl can react with oxygen (generally, catalyzed by surface oxides) to generate water and possibly very high Cl_2 pressures. The corrosion products of chloridation tend to be volatile and have low melting points. Other halogens may also affect metals and alloys in a manner similar to chlorides.

Laboratory halogenization testing environments are divided into two groups: those possessing no measurable oxygen and those containing measurable oxygen. In the oxygen-free environments, liquid phases and volatile reaction products may lead to erratic corrosion attack. Halogen-plus-oxygen environments often exhibit paralinear behavior as oxide scale and volatile halide reactions occur simultaneously.

Corrosion-resistance testing of materials is properly conducted in electrically heated furnaces using ceramic tubes with end caps containing pusher rods to manipulate the corrosion specimens under atmosphere. The end caps should be coated with a castable material to protect them from corrosion. Gas composition may be either purchased or synthesized from the components, using halogen-resistant electronic flow controllers or mixers. The specimens may be in the form of pins with dimensions similar to those mentioned for sulfidation testing. Gas flow streams of a total flow rate of 500 cm^3/min (30.5 $in.^3$/min) are considered adequate to ensure a consistent environment for all specimens. The effluent stream should be reacted with a caustic solution before venting to remove the reacted and unreacted halogens. At the completion of testing, the specimens should be examined metallographically for evidence of voiding or liquid-phase corrosion. Scale identification by x- ray diffraction or electron-dispersive spectrometry can be helpful in clarifying reaction mechanisms.

Hydrogen Interactions. In selected high- temperature reactions, steam may decompose on metal surfaces to form hydrogen and oxygen. The resulting chemisorbed hydrogen may diffuse into the metal to an appreciable level. Loss in tensile ductility of steels and nickel-base alloys has been observed in gaseous environments with a total hydrogen content of 0.1 to 10 ppm at -100 to 700 °C (-150 to 1300 °F). Hydrogen attack occurs when hydrogen diffuses into the metal (typically steel) and reacts with the carbides to form methane, $4H + Fe_3C \rightarrow CH_4 + 3Fe$; the methane causes subsequent internal microcracks that lead to brittle rupture. The larger methane gas molecules also tend to concentrate at the grain boundaries. When methane gas pressures exceed the cohesive strength of the grains, a network of discontinuous, intergranular microcracks is produced. The reaction rate depends on the amount of carbon in the alloy, the hydrogen concentration, diffusion, total gaseous pressure, and temperatures in the range of 200 to 600 °C (400 to 1110 °F). Hydrogen damage has been observed in utility boilers at temperatures as low as 316 °C (600 °F) (Ref 71). Hydrogen damage can occur in high-strength alloys, resulting in loss of tensile ductility. Nickel-base alloys are much less susceptible to hydrogen damage than ferrous-base alloys.

Nickel and nickel-base alloys are susceptible to attack in gaseous hydrogen environments. The same factors that affect hydrogen interactions in ferrous alloys are also operative for nickel-base alloys, although to a slightly lesser degree, because face-centered cubic metals have a greater number of slip planes and have lower solubilities for hydrogen than body-centered cubic metals (Ref 72). Hydrogen in nickel-base alloys may lead to intergranular, transgranular, or quasi- cleavage cracking. The Fe-Ni-Cr (Incoloy) and Inconel alloys show ductility reductions when exposed to hydrogen, particularly age-hardenable alloys (Ref 72).

Molten Metals. Corrosion may cause dissolution of an alloy surface directly, by intergranular attack, or by leaching. Liquid metal attack may also initiate alloying, compound reduction, or interstitial or impurity reactions. Carbon and low-alloy steels are susceptible to various molten metals or alloys, such as brass, aluminum, bronze, copper, zinc, lead-tin solders, indium, and lithium, at temperatures from 260 to 815 °C (500 to 1500 °F). Plain carbon steels are not satisfactory for long-term use with molten aluminum. Stainless steels are generally attacked by molten aluminum, zinc, antimony, bismuth, cadmium, and tin (Ref 73). Nickel, nickel-chromium, and nickel-copper alloys generally have poor resistance to molten metals, such as lead, mercury, and cadmium. In general, nickel-chromium alloys also are not suitable for use in molten aluminum (Ref 74). There are no metals or alloys known to be totally immune to attack by liquid aluminum (Ref 75). Liquid metal embrittlement (LME) is a special case of brittle fracture that occurs in the absence of an inert environment and at low temperatures (Ref 76). Decreased stresses can reduce the possibility of failure in certain embrittling molten alloys. Stainless steels suffer from LME by molten zinc. Small amounts of lead will embrittle nickel alloys, but molybdenum additions appear to improve lead LME resistance. The selection of fabricating processes must be chosen carefully for nickel- base superalloys. Liquid metal embrittlement can

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

occur when brazing precipitation-strengthened alloys, such as Unified Numbering System (UNS) N07041 (Ref 77). Many nickel superalloys crack when subjected to tensile stresses in the presence of molten (B-Ag) brazing filler alloys.

Molten salts are often involved in sulfidation, chloridation, hot corrosion, or high-temperature coatings, as discussed previously. The corrosiveness of the environment depends on the surface temperature and the condition of and/or the corrosive ingredients in the medium. Molten salts are employed in a number of applications, including metal heat treating; nuclear, fossil, and solar energy systems; reactive-metal extraction; high-temperature batteries; and fuel cells.

Molten salts tend to flux the inherent scale that forms on heat-resistant alloys. In the presence of molten ash products, the oxide, even in oxidizing environments, becomes unstable and dissolves. Oxygen and water vapor tend to accelerate molten salt corrosion. Molten salt corrosion can take the macroscopic form of uniform thinning, pitting, or internal or intergranular attack.

Alkali sulfates deposited on the fireside surfaces of boilers may react with SO_3 or SO_2 to form mixtures of alkali pyrosulfates (melting point: 400 to 480 °C, or 750 to 900 °F) or alkali- iron trisulfates (melting point: 550 °C, or 1020 °F) that cause fireside corrosion of reheater and superheater tubes (Ref 78). Molten sodium pyrosulfates ($Na_2S_2O_7$) (melting point: 400 °C, or 750 °F) or potassium pyrosulfates ($K_2S_2O_7$) (melting point: <300 °C, or 570 °F) react with carbon steels by dissolving the protective oxide film and then reacting with iron to cause accelerated wastage. A few parts per million of vanadium accelerate this reaction. The melting point of these deposits on waterwall tubes ranges from 300 to 410 °C (570 to 770 °F).

Testing is often done in quartz or platinum crucibles, either in air or in a controlled atmosphere. Molten salts can induce significant mass transport due to thermal gradients within the crucible. Molten salt corrosion generally involves dissolution of an alloying element in the higher- temperature regions and subsequent deposition of the element in the cooler parts of the system.

Aging Reactions. Long-term aging effects in service can cause metallurgical changes that alter the mechanical and corrosion properties of materials. Testing should reflect long-term aging effects on materials properties. Graphitization is a microstructural change that can occur in carbon and low-alloy steels. Pearlite (alternating ferrite and Fe_3C platelet structure) normally found in such steels will transform in time to graphite and ferrite at temperatures above 425 °C (800 °F), which causes loss of ductility and promotes embrittlement. Alloying additions of at least 0.7% Cr and 0.5% Mo markedly improve resistance of carbon steels to graphitization. Weld sites are particularly susceptible to graphitization. Treatments or operating conditions that heat ferritic and austenitic stainless steels to 500 to 900 °C (930 to 1650 °F) can cause segregation at the grain boundaries by the precipitation of complex chromium carbides (if carbon content is less than approximately 0.03 wt%), the formation of sigma phase, or the precipitation of other deleterious phases. Nickel-base superalloys are also susceptible to grain-boundary segregation. Nickel-base superalloys can be embrittled by less than 20 ppm sulfur segregation to alloy grain boundaries.

Grain-boundary segregation may result in localized corrosion if the grain boundaries are not as resistant as the alloy matrix, which may be a consequence of segregation causing depletion of corrosion-resistant elements. Pitting is another form of localized corrosion. Both dissolved oxygen and carbon dioxide can promote pitting of carbon steels. An alkaline pH can diminish corrosion, with the evolved gases likely to be neutral to acidic. Ash deposition, thermally induced stress, and particulate erosion may cause conditions that accelerate localized corrosion by cracking the protective oxide layer.

Iron, nickel, and cobalt superalloys owe their unique strength, up to a fairly high threshold temperature, to the presence of strengthening particles, such as inert oxide dispersoids, carbides, coherent ordered precipitates, and solid- solution-strengthening agents, in a face-centered cubic (with appropriate nickel additions) structure. Introduction of precipitates into the alloy through solid-solution reactions requires specific alloy chemistries and heat treatments to achieve the desired mechanical properties. However, at prolonged exposures to high temperatures (760 to 1000 °C, or 1400 to 1830 °F), the phase rule alone suggests that a large number of new phases could nucleate within multicomponent superalloys to form a number of microstructural instabilities (Ref 79). These instabilities can include transformation of a metastable phase to a more stable but incoherent phase, as in carbide transformation, stress-induced differential diffusion of solute atoms (coarsening of $M_{23}C_6$ at grain boundaries), or dissolution of strengthening precipitates in critical areas of the microstructure. Structural instabilities of austenitic high-temperature alloys at elevated temperatures can also include the formation of new topologically close-packed (tcp) phases, such as sigma, mu, and Laves phases, which are brittle and possess

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

cracklike morphologies that can adversely affect alloy tensile and stress-rupture ductility and impair resistance of the alloy to crack growth (Ref 79).

Intergranular corrosion occurs at or adjacent to grain boundaries, with little corresponding corrosion of the grains. Intergranular corrosion can be caused by impurities at the grain boundaries or enrichment or depletion of one of the alloying elements in the grain-boundary area. Austenitic stainless steels, such as type 304 (UNS S30400), become sensitized or susceptible to intergranular corrosion when heated in the range of 510 to 790 °C (950 to 1450 °F). In this temperature range, $Cr_{23}C_6$ precipitates, thus depleting chromium from an area along the grain boundaries below the level required to maintain stainless mechanical and corrosion-resistant properties. The depleted area is a region of relatively poor corrosion resistance. Controlling intergranular corrosion of austenitic stainless steels occurs through: (a) employing high-temperature solution heat treatment; (b) adding elements (stabilizers) such as titanium, niobium, or tantalum that are stronger carbide formers than chromium; and (c) lowering the carbon content below 0.03%.

Creep. Dislocations form in the oxide as it grows epitaxially on the metal because of the crystallographic lattice mismatch between oxide and metal. As the growth continues, these glissile slip dislocations move out into the oxide by the process of glide. Once out in the oxide, they become sessile growth dislocations. Creep may also develop in the alloy. Creep can affect the alloy, the protective films formed on the alloy, or the coating performance.

Although dislocations are present in the oxide, slip is not an important process in relieving growth stress (Ref 79). Plastic deformation of the oxide occurs only at high temperatures, at which creep mechanisms become operative. The three important creep mechanisms in oxides are grain-boundary sliding, Herring-Nabarro creep, and climb (Ref 80). Grain-boundary sliding allows relative motion along the inherently weak boundaries. Herring-Nabarro creep allows grain elongation by diffusion of ions away from grain- boundary areas in compression over to boundaries in tension (Ref 81). Within the grains, dislocation climb is controlled by diffusion of the slower-moving ions. The creep rate increases with the amount of porosity in the oxide.

The strength of a component within the creep range decreases rapidly when the material temperature increases. Creep entails a time-dependent deformation involving grain sliding and atom movement. When sufficient strain has developed at the grain boundaries, voids and microcracks develop. With continued operation at high temperatures, these voids and microcracks will grow and coalesce to form larger and larger cracks, until failure occurs. The creep rate will increase and the projected time to rupture will decrease when the stress and/or the metal temperature are increased. In gas turbines, the use of directionally solidified or single-crystal alloys with chemistries that promote high-temperature strength minimize degradation by creep.

Creep may be affected by gaseous reactions. Metal components in steam turbines and jet engines must withstand high stresses for long times at high temperatures. Specimens undergoing creep testing should be representative of a service component. A creep test is generally run under constant load and constant temperature for periods of 1000 to 10,000 h or more. Because the creep rate is a function of stress, a rise in stress will normally cause a corresponding increase in the creep rate. The temperature should be maintained within close tolerances, such as specified by the ASTM E 139, “Standard Test Methods for Conducting Creep, Creep Rupture and Stress-Rupture Tests of Metallic Materials.”

A stepped isothermal method has been developed to predict long-term creep performance in much less time than the traditional constant-load test. This test avoids stress variations by using single specimens and performs the tests within days. It forecasts long-term creep performance by increasing the temperature in steps; the creep curve is mapped out in sections, and change in creep rate between each temperature step determines the level of acceleration. This creep test method also provides a rapid method of studying creep behavior, residual strength, and the effects of other forms of degradation.

Erosion-corrosion and wear accelerate or increase the deterioration of a metal because of the relative movement between a corrosive fluid and the metal surface. Erosion may accelerate corrosion of high-temperature components discussed previously. Generally, mechanical wear, abrasion, or abrupt changes in flow direction are involved. Metal or alloy loss results when the protective, passive surface films are damaged or worn, and rapid attack comes about. Metals or alloys that are soft and readily damaged or mechanically worn, such as copper or lead, are susceptible to erosion. Impingement by solid particles may contribute to erosion-corrosion, which accelerates several forms of corrosion in the various gaseous or molten environments. Other factors controlling the rate of metal loss are related to the quantity, impact angle, speed, and density of the eroding medium.

www.iran_mavad.com

مرجع مهندسی مواد و متالورژی

The appearance of erosion-corrosion is characterized by grooves, gullies, waves, and rounded holes, which usually exhibit a directional pattern. Increases in velocity may cause no increase in attack until a critical velocity is reached. Erosion-corrosion can occur on metals and alloys that are completely resistant to a particular environment at low velocities. Greater velocity may either increase or decrease attack, depending on the nature of the corrosion or passivating mechanisms. Increasing the oxygen, carbon dioxide, or hydrogen sulfide concentration in contact with the metal surface may accelerate the attack of steel. Reduced attack may occur from increased velocity either by raising the diffusion or transfer of ions that diminish the stagnant surface film or by preventing deposition of salt or dirt that could cause crevice corrosion. Coal-fired generation systems are subject to erosion-corrosion conditions. Several laboratory techniques and methodologies have been established to study erosion-corrosion (erosion-oxidation and erosion-sulfidation) at high temperatures. How these laboratory methods simulate plant conditions and the limitations of each method are reviewed in Ref 82.

Wear is defined as damage to a solid surface that generally involves progressive loss of material and is due to relative motion between that surface and a contacting substance or substances. Tribocontacts cause damage to surfaces at high temperature, usually by many consecutive steps by several different mechanisms. Material loss from the surface can cause wear marks. Fundamental causes of material removal can be shear fracture, extrusion, fracture, chip formation, tearing, brittle fracture, fatigue fracture, chemical dissolution, and diffusion (Ref 83). The rate at which surfaces wear depends on the characteristics of each surface, the presence of abrasives, the speed and angle of contact, and other environmental conditions. There are several modes of wear (abrasive, polishing, solid-particle erosion, cavitation erosion, liquid impingement, slurry erosion, sliding and adhesive wear, fretting, corrosive and oxidative wear, and others) that are discussed in more detail in *Friction, Lubrication, and Wear Technology*, Volume 18 of *ASM Handbook*. Wear tests designed to closely simulate the condition of specific processes are discussed in Ref 84. There are no standardized tests for wear at high temperatures at this time.

Environmental cracking can occur with a wide variety of metals and alloys in specific environments. Environmental cracking is defined as the spontaneous brittle fracture of a susceptible material (usually quite ductile itself) under tensile stress in a specific environment over a period of time. Stress-corrosion cracking (SCC) and corrosion fatigue are two forms of environmental cracking that can lead to failure.

Stress-corrosion cracking results from the conjoint, synergistic interaction of residual or applied tensile stress and a specific corrodent for an otherwise ductile alloy. The tensile stress may be either applied (such as caused by internal pressure) or residual (such as induced during forming processes, assembly, or welding). Stress-corrosion cracking involves the concentration of stress and/or the concentration of the specific corrodent at the fracture site. Stress-corrosion cracking fractures may be oriented either longitudinally or circumferentially, but the fractures are always perpendicular to the stresses. Stress-corrosion cracking may be reduced either by removing applied or residual stresses or by avoiding concentrated corrodents.

Alloy composition, heat treatment, the exposure time, temperature, and solution media affect SCC. Fluctuating temperatures can accelerate SCC of austenitic stainless steels in the presence of chlorides, particularly at high-stress points from design, operation, or fabrication. Nickel alloys exhibit improved resistance to environmental cracking, as compared to carbon and stainless steels, although nickel alloys are not immune to SCC. Stress-corrosion cracking of certain nickel alloys has occurred in high-temperature halogen ion environments, high-temperature waters, and high-temperature alkaline systems and environments containing acids and H_2S. Stress-corrosion cracking of nickel-base alloys is dependent on the stress level, chloride concentration, alloy composition, and temperature. Susceptible temperature ranges vary from 175 to 330 °C (345 to 625 °F). Higher temperatures tend to lower the chloride threshold concentration and stress levels required for cracking. Ferritic stainless steels are usually not considered susceptible to SCC, but stressed martensitic stainless steel grades can crack in chloride environments.

Fatigue involves cyclic stresses applied to the component or system during service. Cyclic stresses below the yield stress of a material can reduce its expected life through the initiation and propagation of transgranular cracks. The number of cycles required to produce cracking depends on the level of strain and the environment. Vibration and thermal cycling can lead to initiation and propagation of fatigue degradation. Vibration fatigue cracks originate and propagate as a result of flow-induced vibration. Circumferential orientations are common to vibration fatigue cracks.

Corrosion fatigue failures are caused by the combined effects of a corrosive environment and cyclic stresses of sufficient magnitude. A corrosive environment accentuates this form of degradation by initiating stress raisers

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

for corrosion fatigue to start and/or lowering the stress necessary to continue the propagation of this cracking process. Corrosion usually lowers the minimum stress level and/or the number of cycles that will cause failure, compared to an inert environment. Corrosion fatigue cracks may develop at stress-concentration sites (stress raisers) such as pits, notches, or other surface irregularities. Corrosion fatigue is commonly associated with rigid restraints or attachments.

Thermal fatigue cracks develop from excessive strains induced by rapid cycling and sudden fluid temperature changes in contact with the tube metal across the tube wall thickness. This can be caused by rapid thermal fluctuations above proper process operational parameter limits. Water quenching by spraying also can induce thermal fatigue cracks by suddenly cooling component surfaces. This causes high tensile stresses between the component surface and the bulk metal or alloy; the cooled surface metal tends to contract, while this metal surface becomes restricted by the hotter metal below the surface.

Stress Rupture. Although not strictly a corrosion-related phenomenon, stress rupture is often involved when the component is subjected to high temperatures where changes in the microstructure or corrosion of the substrate reduce the effective thickness of the component to the point where failure occurs. Stress and temperature influence the useful life of materials in a given gaseous environment.

Most metals and alloys in an oxidizing environment are protected to varying degrees by an oxide layer. Alloy oxidation from air or steam forms an oxide scale along the metal surface that grows and thickens with time. The degree of protection of these formed surface scales and resistance of the alloy in a given environment will depend on factors such as chemical composition, thermodynamic stability, cation or anion transport through the scale, ionic defect structure, and morphological features of the scale.

High-Temperature Gaseous Corrosion Testing

David A. Shifler, Naval Surface Warfare Center

High-Temperature Materials

High-temperature coatings provide a barrier from corrosive or highly oxidative environments that may degrade the substrate alloy. To provide optimal performance, coatings need to have good adherence to the substrate, ductility to resist thermal cycling, few or no defects that may provide easy pathways to deleterious gases, good compatibility with the substrate, and maintain corrosion resistance over the design life of the high-temperature component. There is a wide range of coatings and coating processes for protecting components in a variety of operating conditions (Ref 85).

Diffusion Coatings. Aluminide coatings on transition metals and alloys based on iron, nickel, and cobalt are β-FeAl, β-NiAl, and β- CoAl, respectively. Diffusion aluminide coatings are typically processed via pack cementation, slurry diffusion, or chemical vapor deposition (Ref 86). Subsequent heat treatments help develop the proper mechanical properties and trigger further diffusion within the coating. The principal protective oxide generated by the high- temperature oxidation of these aluminide intermetallics is Al_2O_3, which causes subsequent improved oxidation and corrosion resistance of aluminide coatings; however, less-protective oxides can form if other alloying elements are present in the substrate, either in solution or as precipitated phases (Ref 87).

Modified aluminide coatings designate an aluminide class that is altered by the addition of a secondary element such as chromium, platinum, a reactive element, or a combination of these elements (Ref 89). These coatings are generated either by incorporating the secondary element into the coating by pack codeposition or by deposition of the modifying element prior to an aluminization process by electroplating, electrophoresis sputtering, chemical vapor deposition, or pack cementation (Ref 86).

Overlay coatings are MCrAlY-type coatings (where M is iron, cobalt, nickel, or a combination of these elements) applied by either electron beam physical vapor deposition (EB-PVD) or by thermal or plasma spraying. Typically, these coatings initially contained cobalt or nickel, with 15 wt% Cr, 12 wt% Al, and 0.1 to 0.9 wt% Y. To improve its resistance to low-temperature type II hot corrosion, the cobalt was partially replaced with nickel, the aluminum content was reduced somewhat, and the chromium content was increased from 15 to 20 wt% to almost 32 wt%. Hafnium was used as a replacement for yttrium in some MCrAlX coatings, where X (yttrium or hafnium) promoted coating adhesion and oxidation resistance under thermal cycling conditions. The MCrAlY coatings have been air plasma sprayed (APS) as a cost-savings procedure, but it often produces a poor-quality coating. There are various procedures and methods by which plasma spraying may be done, many of which are proprietary or patent protected. Low-pressure plasma spraying (LPPS) and argon-shielded spraying produce better-quality coatings.

The principal oxide in the outer portion of a MCrAlY overlay coating is Al_2O_3. Yttrium is more prevalent in the outer scale and promotes oxidation resistance. Hafnium also promotes oxidation resistance and prevents sulfur from segregating to the coating-substrate interface, thus providing one mechanism of improving the overlay coating adhesion.

Nickel, cobalt, or both and chromium are found in the inner half of the coating nearer to the coating-substrate interface. Increases in chromium content improve both the hot corrosion resistance and the oxidation resistance of the overlay coating but tend to make the coating less ductile.

Thermal barrier coatings (TBCs) usually consist of a porous layer of zirconia, ZrO_2, that is stabilized in the metastable tetragonal phase by approximately 8 wt% yttria, Y_2O_3. The yttria- stabilized zirconia (YSZ) is applied using either plasma spraying or by EBPVD over a bond coat, which is usually MCrAlY (where M is cobalt and/or nickel) or a diffusion aluminide. The bond layer is typically 75 to 125 μm (0.003 to 0.005 in.), and the TBC is 125 to 375 μm (0.005 to 0.015 in.) thick. Application of the TBC system to hot section components in a gas turbine has been able to decrease metal surface temperature by approximately 150 °C.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

(270 °F). The TBCs also smooth out hot spots, thus reducing thermal fatigue stresses. A thermally grown oxide (TGO) layer is formed between the bond coat and the TBC during fabrication and tends to grow thicker on high-temperature exposure of the TBC.

The EB-PVD-applied TBCs tend to produce a columnar structure with fine, ribbonlike voids, porosity within the columns aligned normal to the plane of the coating, and superior compliance to residual stresses. Plasma-sprayed TBCs have disklike voids aligned parallel to the coating plane and promoting superior insulating efficiency.

There are a number of degradation modes that can limit the life of a TBC (Ref 54) as a result of oxidation due to the possible porosity network in the TBC. By understanding the specific thermomechanical failure modes, TBCs can be designed for greater reliability and durability (Ref 88). The EB-PVD thermal barrier coatings tend to spall at the TGO/bond coat interface or in the alumina layer (Ref 89). It was observed that intermittent water vapor degraded the adherence of alumina to the bond coat under a TBC layer more severely than alumina formed on the same bond coat in the absence of a TBC (Ref 57).

Hot corrosion exposure to vanadium salts and sulfur trioxide promotes corrosion of stabilized zirconia by acid leaching of yttria. Yttria loss destabilizes the zirconia, and thermal cycling causes rapid coating failures. This is potentially serious when burning low-grade fuels (Ref 90). For engine use, ZrO_2 must be stabilized in its high-temperature tetragonal structure to avoid a destructive monoclinic-to-tetragonal phase transformation at 1100 °C (2010 °F). Scandia, Sc_2O_3, improves vanadate hot corrosion resistance of stabilized zirconia (Ref 59).

Refractories. The corrosion resistance of refractories is based on the thermodynamics of the potential corrosion reactions, the reaction rates and kinetics of these possible reactions, the composition and form of the refractory material, and the surface chemistry of the refractory with corrosive gaseous, liquid, or solid environments. The spontaneous direction of the possible corrosion chemical reactions can be calculated, which can indicate the reactions that are theoretically possible. The reaction kinetics will be dependent on the specific environment (gaseous, liquid, or solid), surface chemistry, the material microstructure and composition, refractory phase(s), and the temperature. All ceramics or refractories used in an oxygen-rich environment are oxides or develop a protective oxide on their surface (such as SiO_2 on SiC or Si_3N_4). Although oxide ceramics are inert and resist oxidation and reduction, they are not chemically inert. Ceramic corrosion between ceramic oxides and molten salt deposits generally can be explained as oxide/ acid-base reactions (Ref 57).

To determine if a particular slag is acidic or basic, the ratio of lime to silica in the slag is commonly used. As a general rule, the slag is basic if the CaO-to-SiO_2 ratio (or CaO + MgO to SiO_2 + Al_2O_3 ratio) is greater than 1. If the ratio is less than 1, the slag is considered acidic (Ref 91). Gases and liquids can penetrate deeply into highly porous refractories that can exacerbate spalling and accelerated corrosion. Oxidizing gases, such as NO_x, Cl_2, O_2, CO_2, H_2O, and SO_2, reducing gases (NH_3, H_2, C_xH_y, CO, and H_2S), and vapors of volatile elements and compounds may react with different refractories. Hydrodynamic mass transport by either convection or diffusion can markedly affect the corrosion rate of a refractory in an environment. Nonwetting refractories are relatively resistant to corrosion with liquids or gases. Molten aluminum, iron, silica, and other constituents derived from the incinerator waste streams can react with refractories to form new compounds or phases that can have different melting temperatures, dimensional stabilities, and corrosion resistances. The new phases or compounds can cause dimensional changes that can cause problems in the chamber. High-purity refractories are more corrosion resistant, because certain minor impurity components have microstructures, phases, and defect structures that can introduce significant corrosion. High-purity refractories improve corrosion resistance by avoiding low-melting eutectics. Alkali impurities should be minimized as much as possible. Solids, either as fine particulates or dust, can cause degradation of refractories through abrasion or deposition.

Test Standards. Since the 1990s, worldwide work has focused on formulating standard tests for physical and mechanical property determinations (Ref 92). Oxidation and corrosion standards have received attention more recently. Oxidation should be relatively straightforward, thus allowing current test methodologies to be used. Methodologies for hot corrosion resistance of superalloys can be adaptable to ceramics; guidelines for hot corrosion testing have been published by a technical working group of the Versailles Agreement on Advanced Materials and Standards (VAMAS) (Ref 93). The Japanese Industrial Standard JIS R 1609, “Testing Methods for Oxidation Resistance of Nonoxide High-Performance Ceramics,” published in 1990, was the first standard developed for ceramics.

ASTM International has several standards for measuring corrosion resistance:

ASTM designation	Title
C 621	"Standard Test Method for Isothermal Corrosion Resistance of Refractories to Molten Glass"
C 863	"Standard Test Method for Evaluation Oxidation Resistance of Silicon Carbide Refractories at Elevated Temperatures"
C 288	"Standard Test Method for Disintegration of Refractories in an Atmosphere of Carbon Monoxide"
C 454	"Standard Practice for Disintegration of Carbon Refractories by Alkali"

More information on ceramic corrosion testing can be found in Ref 94.

High-Temperature Gaseous Corrosion Testing

David A. Shifler, Naval Surface Warfare Center

Testing Methods Used for Materials at High Temperatures

As mentioned previously, high-temperature corrosion may occur in numerous environments and is affected by numerous factors, such as temperature, alloy or protective coating composition, time, and gas composition. There is a great need for materials testing, both for research and development of new materials (alloys, high-temperature coatings, refractories, etc.) and processes and to simulate industrial and application environments to understand the interactions that occur with current materials choices. The goals of laboratory and field testing are to characterize materials performance in specific applications and to evaluate the effects of environmental changes on candidate materials. The test conditions should simulate, as much as possible, the environment of the specific application of interest.

In the case of gas turbines, fuel and air quality and the specific engine environment in which it operates influence the corrosion of turbine components significantly. Aeroengines use relatively pure fuels with low sulfur contents, and the air quality is generally good, unless there are recurrent low-altitude flights or operations over marine environments. Industrial and shipboard turbine engines use lower-grade fuels with 0.3 to 1.0 wt% S content as well as other less-pure fuels. Unfiltered air intake for marine gas turbines may contain up to 2600 ppm Na_2SO_4, 19,000 ppm NaCl, and possibly, sand-derived deposits. Filtration may reduce the NaCl content in air to ≤0.01 ppm, but this is still sufficient to generate Na_2SO_4 (as well as Na_2SO_4 directly created from sulfur in the fuel), which can lead to sulfidation and hot corrosion. Fuel quality may vary during the service life of the engine. The use of less- refined, heavy fuels may contain up to 200 ppm vanadium that, when combined with Na_2SO_4, accelerates hot corrosion reactions. Engine temperatures may also vary with operational loads by 400 to 500 °C (720 to 900 °F) on going from idle to full power (Ref 95). The engine may ingest solid particles (sand, ash, dust, and sea salt) or generate pyrolytic carbon from uncombusted or poor oxidizing conditions that will contribute to metal wastage by erosion and impact turbine components. Carbon may also accentuate corrosion by reducing sodium sulfate to sulfides. Thermal cycling or transient conditions may further increase the corrosivity of salt deposits by cracking protective oxide layers. The complexity of the turbine operating environment and other high-temperature applications makes it impossible to develop simple tests to simulate all the pertinent parameters. Figure 13 shows the variation of the chemical species within the combustion flame as a function of the fuel-to-air ratio at a given turbine pressure and inlet temperature (Ref 96). Changing the fuel source, the amount of salt in the intake air, the inlet temperature, and/or the turbine pressure will change the speciation and the relative distribution of the chemical products.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

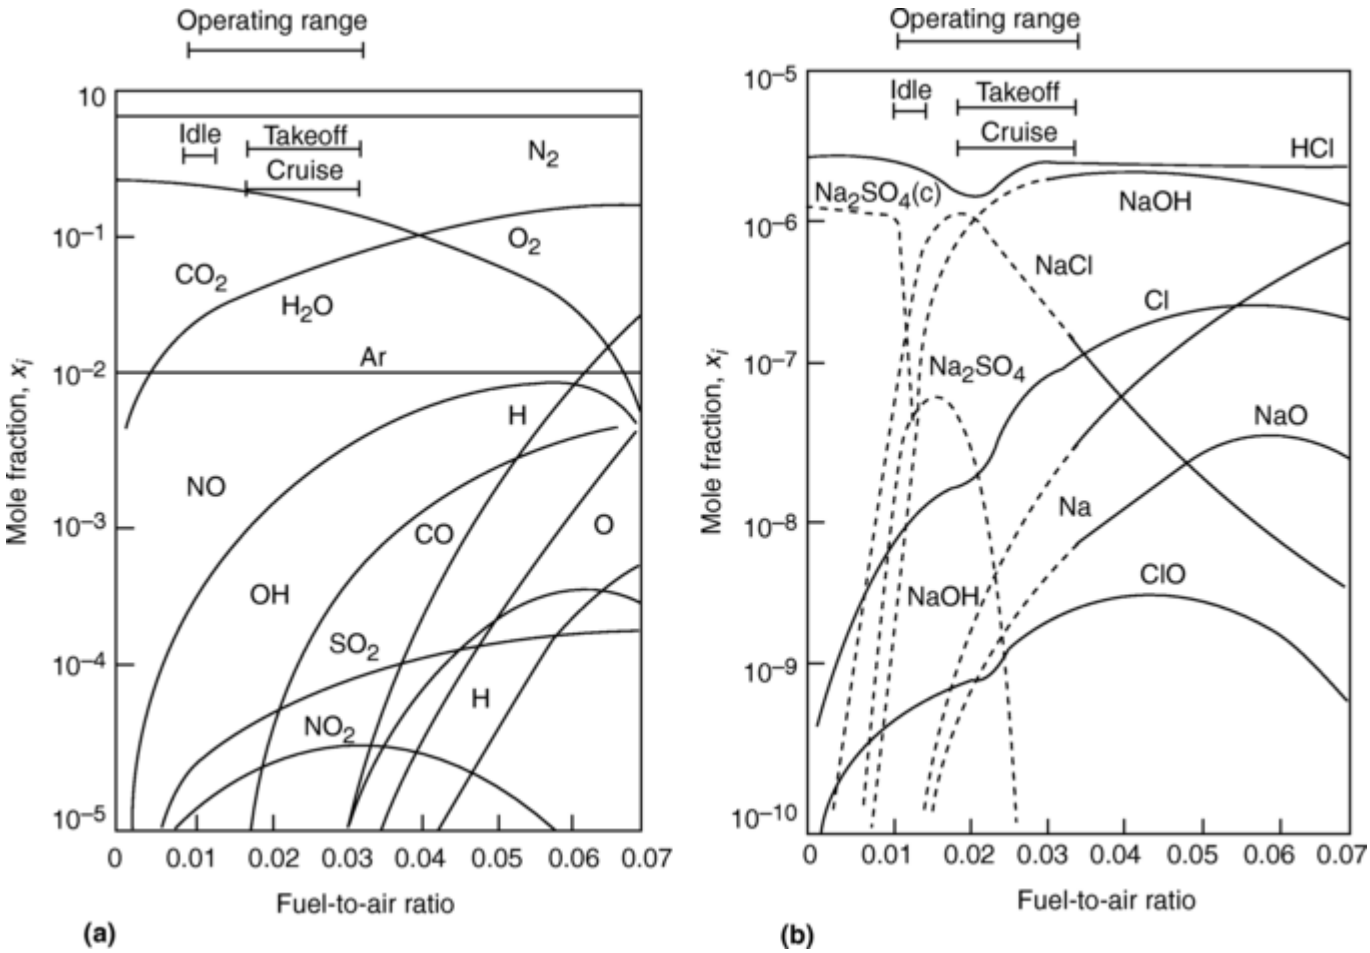

Fig. 13 Variation in equilibrium composition of the combustion flame as a function of the fuel-to-air ratio when pressure p = 22.1 atm (2.24 MPa) and the inlet temperature T_0 = 811 K (1000 °F) (for fuel jet A + 0.3% S; air, 5 ppm sea salt). (a) The major products formed. (b) Sodium- and chlorine-containing species. Source: Ref 96, 97, 98

Incinerators are also inherently complex high- temperature environments. The corrosiveness of the incinerator environment depends on the relative stream of wastes that are generated and the efficiency of removing potential wastes that have been proven to be severely corrosive, such as chlorine-containing plastics.
However, laboratory tests can be representative of in-service conditions by choosing the appropriate deposit or gas compositions, the temperature, and other operational aspects that can be controlled with a given test apparatus. Testing may include furnace testing, crucible tests, thermogravimetry or its derivatives, various burner rig tests, or autoclave testing with a host of analytical techniques to evaluate corrosion products or materials chemistries. Because some high-temperature reactions are electrochemical in nature, electrochemical tests (corrosion-potential monitoring, current measurements, and polarization to determine the acido-basicity of salts) can be employed in test programs (Ref 56, 99).

Furnace Tests

Both horizontal and vertical furnace geometries are widely used in high-temperature testing. High-temperature oxidation generally leads to external oxide scale together with the formation of internal oxidation products, particularly in mixed-oxidant or under salt deposit conditions. Furnace exposure methods may involve isothermal oxidation in air, oxygen, or reduced p_{O_2}conditions; cyclic oxidation exposures; gas-phase corrosion; hot salt corrosion (crucible, salt coat method, or burner rig testing); or diffusion studies at a temperature range of 250 to 1500 °C (480 to 2730 °F) or higher, depending on the focus of the parameter, material, and environment being tested. In conjunction with a thermobalance and other ancillary equipment (discussed later), furnace tests can generate kinetic data and analyze the corrosion products formed as a result of high- temperature gaseous reactions.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Furnace testing has been used to evaluate and measure the diffusion of chromium to the alloy- scale interface in several chromia-forming alloys during extended exposures at elevated temperatures. When the alloys were placed into a furnace and exposed to air at 1050 °C (1920 °F) for 720 h, the depth of chromium depletion could be measured due to the chromium interdiffusion to the surface. Other alloying elements can have a marked effect on chromium interdiffusion rate (Ref 100).

Another furnace test involves spraying an aqueous solution, saturated with salt, on specimens heated to a moderate temperature (approximately 200 °C, or 392 °F) to form a dry salt layer. Once samples are coated with this salt layer, testing can occur in a furnace at the prescribed temperature in a controlled atmosphere and a given length of time to monitor the corrosion on the sample (Ref 99). It is fairly simple to recoat coupons with Na_2SO_4 or other salts at various intervals in a furnace test.

Molten Salt Tests

The molten salt test is used to determine the susceptibility of materials (alloys, ceramics, and protective coatings) to corrosion attack from molten salts (Ref 55, 101). It consists of immersing selected samples in the molten salt for a given period of time and then examining the samples for evidence of attack. The half-cell potentials are measured in some molten salt immersion tests to study film integrity as a function of such parameters as oxide thickness, salt composition, and atmosphere. Test parameters in a crucible test are well defined and can be closely monitored.

For gas turbine applications, experiments are conducted in a resistance-wound electric furnace containing a high-purity platinum crucible with approximately 50 g (1.8 oz) of reagent-grade sodium sulfate (Na_2SO_4), as shown in Fig. 14. Potential measurements are made using platinum as a reference electrode that monitors the corrosion activity, because in molten salts, corrosion occurs via electrochemical processes (Ref 99). For sulfidation of alloys, a sustained rise in potential can be observed (Ref 99). A new batch of sodium sulfate is prepared prior to each exposure to eliminate any possible contamination from other sample immersions. All specimens are immersed in the molten Na_2SO_4 for up to 1000 h. A sample examination can be made after 500 h, and, if desired, the samples can be returned to the molten salt bath for an additional 500 h. The molten Na_2SO_4 salt temperature typically is maintained at 899 °C (1650 °F). The melting temperature of Na_2SO_4 is 884 °C (1623 °F). Still air or argon are used as atmospheres over the molten salts to achieve two levels of oxidizing conditions (Ref 101). Adding NaCl to the sodium sulfate can test the effects of slag. The crucible test is the simplest evaluation method to discern the relative resistances of materials in sulfidation and hot corrosion environments.

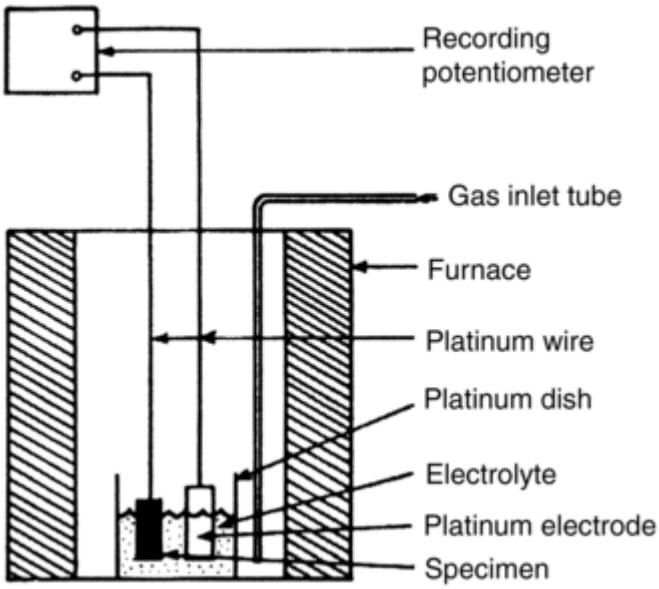

Fig. 14 Schematic of molten salt test apparatus with test specimen. Source: Ref 101

In molten salt tests, if the test sample is not completely immersed, there may be three distinct environments to which the test specimen is exposed. The first is immersion in the molten salt, the second is at the interface between the molten salt and its vapor, and the third specimen exposure is to the salt vapor. In the Dean test,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Na_2SO_4 is heated to above 1100 °C (2012 °F) to establish an appropriate vapor pressure, and the sample is maintained at a temperature below the dewpoint where condensation occurs, so that the SO_2/SO_3 in the furnace atmosphere should be controlled (Ref 102).

Table 2 shows how the crucible and other hot test methods compare to actual gas turbine service environments in terms of simulation, cost, and time (Ref 103). Stability of samples can be monitored by electrochemical-potential measurements.

Table 2 Accuracy of simulations of hot corrosion test methods, cost, and test times as compared to service experience of actual gas turbine engines

Type of test	Simulation with respect to:[a]					Cost[b]	Test time[b]
	Chemistry		**Aerodynamics**				
	Gas	**Solid or liquid species**	**System pressure**	**Gas velocity**	**Deposition rate (*dm*/*dt*) of condensable species**		
Engine	10	10	10	10	10	1	1
High pressure, high velocity	10	9	10	9	8	2	2
High velocity	5	8	4	9	7	3	7
Burner rigs	5	7	3	2	4	7	8
Thermogravimetric analysis	5	6	3	1	2	7	3
Crucible	2	5	1	1	1	10	10

(a) Simulation: 10 is best simulation of given factor; 1 is worst simulation of actual service.

(b) Relative cost, test time: 10 is lowest cost, shortest time; 1 is highest cost, longest time. Source: Ref 103

It has been found that certain molten mixtures of NaCl and Na_2SO_4 are more corrosive to superalloys than Na_2SO_4 alone (Ref 55). Sodium chloride (NaCl) also lowers the melting temperature of the NaCl-Na_2SO_4 mixtures relative to Na_2SO_4. The possibility exists that turbine components downstream of the power turbine will be exposed to both NaCl and Na_2SO_4. The NaCl is usually not deposited in the hot sections of the marine gas turbine engine, but sodium sulfate does form deposits in the hot sections. Vapors of NaCl react with SO_2 and SO_3 (formed from sulfur in the fuel) to produce Na_2SO_4. Thermodynamic equations for the formation of Na_2SO_4 are (Ref 104):

$$2NaCl + SO_2 + \tfrac{1}{2}O_2 + H_2O \leftrightarrow Na_2SO_4 + 2HCl(g) \quad \text{(Eq 24)}$$

$$2NaCl + SO_3 + H_2O \leftrightarrow Na_2SO_4 + 2HCl(g) \quad \text{(Eq 25)}$$

Sample preoxidation before molten salt testing can prolong the period of time before the oxide is penetrated and the onset of sulfidation begins (Ref 100). The half-cell potential measurements rise with the initiation of corrosion and generally correlate well with sulfidation attack. Other salts, such as V_2O_5, that are found in some fuels in service can be tested in a molten salt crucible test (Ref 105).

After exposure, samples are cleaned of salt by prolonged boiling in distilled or deionized water, oven dried, and weighed (samples are initially weighed before the molten salt test). The weight change is recorded. Optical microscopy or scanning electron microscopy is used, where warranted, to examine the specimen surface. X-ray energy-dispersive spectroscopy, x-ray diffraction, and/or emission spectroscopy are used to identify the corrosion products formed on the surface. Figure 15 show the relative resistance of two different nickel-base alloys after immersion for 150 h in a molten salt bath of 75 wt% Na_2SO_4-25 wt% NaCl at 899 °C (1650 °F). Figure 15(a) shows the broad corrosion front and the associated development of porosity and void formation that is typical of high-temperature type I hot corrosion. Figure 15(b) shows catastrophic corrosion of another nickel-base alloy.

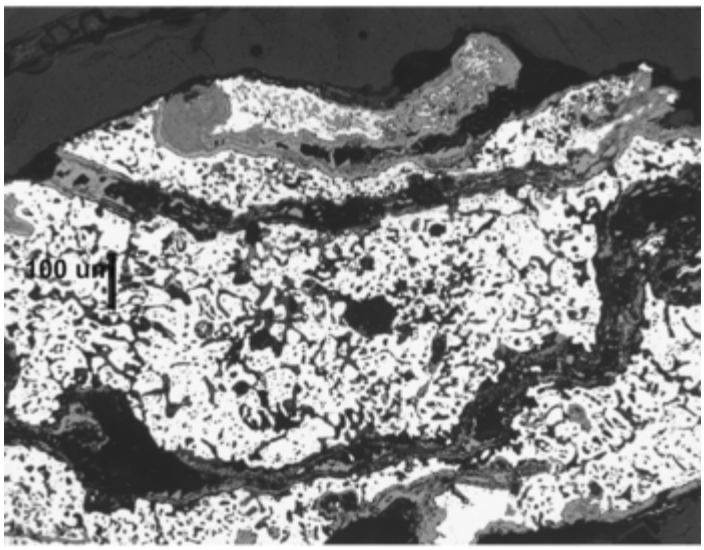
(a)



(b)

Fig. 15 Corrosion performance of two different nickel-base alloys after 150 h in molten Na_2SO_4-NaCl at 899 °C (1650 °F). Alloy (a) shows typical type I hot corrosion attack, while alloy (b) shows catastrophic corrosion attack.

Crucible tests are also conducive to studying the corrosion resistance of alloys in molten chlorides (NaCl-KCl) and eutectics of several mixed salts, such as NaCl-KCl-Na_2SO_4-K_2SO_4. The actual composition and the ratio of components in salt mixtures can vary the degree of acidity or basicity. This will determine, in large part, the stability of oxides when exposed to a corrosive environment such as a waste incinerator. The stability of Cr_2O_3, NiO, Co_3O_4, Fe_3O_4, and SiO_2 has been studied in different molten salt bath combinations with varying basicity that represent possible waste incinerator environmental interactions, as described in Ref 106.

Sodium sulfate can be described by acid-base chemistry in a similar manner as for pH in aqueous solutions. Specifically, the dissociation of sodium sulfate can be written as $Na_2SO_4 = Na_2O + SO_3$, for which the $\log_{10}$ of the condensed Na_2O activity is a quantitative measure of melt basicity, and the $\log_{10}$ of the gaseous SO_3 activity defines the melt acidity (Ref 62). In the same way as aqueous corrosion, corrosion in fused sodium sulfate is an electrochemical process. The soluble oxidant, SO_3 or $S_2O_7^{2-}$, is reduced in the cathodic step for acidic melts. The sites where cathodic reduction occurs result in a local increase in basicity, to the extent that a sulfide corrosion product may result. In salt films containing significant concentrations of multivalent transition-metal cations, the oxidation reaction can occur at the substrate/salt interface, and the cathodic reaction can occur at the salt/ gas interface through the interactions of the cations, in deference to SO_3, with a counterdiffusion of these metal ions carrying the current through the salt film (Ref 106). Electrochemical reactions affect the acid-

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

base chemistry of salt films. Electrochemical reactions in molten Na_2SO_4 have been monitored by a doped zirconia-oxygen sensor and Ag/Ag^+ mullite-sodium sensor during potentiodynamic polarization and cyclic voltammetry experiments (Ref 107).

Acid-base oxide reactions with molten sulfate through the measurement of oxide solubilities as a function of Na_2O activity in fused Na_2SO_4 were examined (Ref 56). Oxide solubility is dependent on Na_2O activity, which also serves to rank the acid-base character of individual oxides. The solubilities of NiO, Co_3O_4, Fe_2O_3, CeO_2, Cr_2O_3, Al_2O_3, and SiO_2 have been determined as a function of melt basicity for fused Na_2SO_4 at fixed temperatures (Ref 108, 109, 110, 111, 112, 113, 114, 115). The presence of more than one oxide contained in a salt film will cause greater dissolution than if only one oxide was present. The more basic oxide would exhibit acidic dissolution that releases oxide ions as corrosion products. The more acidic oxides would react with the oxide ions to promote basic dissolution (Ref 62).

The melt acidity can be determined by measuring the potential between a reference electrode and a working electrode contacting a melt of the same composition (Ref 107). Researchers proposed that a negative solubility gradient was a general criterion for hot corrosion to continue (Ref 116).

There are two major drawbacks to crucible test results when related to gas turbine engines (Ref 96). First, with the exception of the Dean test, the procedures involve a one-time application of Na_2SO_4, whereas in service, there is continuous or near-continuous deposition of Na_2SO_4 in turbine engines. Secondly, during service, material surfaces are exposed to temperatures, pressures, velocities, or gas compositions that vary significantly and rapidly with time, which cannot be easily reproduced in a furnace or crucible (Ref 96, 99, 117, 118).

Thermogravimetric Analysis

Thermogravimetric analysis (TGA), also known as thermogravimetry (TG), can complement the laboratory testing of materials in gaseous, high-temperature corrosive environments by determining the kinetics and mechanisms of high-temperature corrosion by measuring the oxide growth and associated change of sample mass over time at temperature (Ref 119). In this technique, changes in the mass of a sample are studied while the sample is subjected to a controlled-temperature program. The temperature program is most often a linear increase in temperature, but isothermal studies can also be carried out, when the changes in sample mass with time are followed. Thermogravimetry is inherently quantitative and therefore an extremely powerful thermal technique, but it gives no direct chemical information. Test temperatures may range up to 1700 °C (3092 °F).

The ability to analyze the volatile products during a weight loss is of great value. Additional information can be obtained by integrating mass spectroscopy or Fourier transform infrared spectroscopy (FTIR) with the TGA instrumentation. The main high-temperature processes amenable to TGA study (either by measuring weight losses or weight gains as a function of time) are listed in Table 3.

Table 3 Processes measurable by thermogravimetric analysis

Process	Weight gain	Weight loss
Adsorption or absorption	X	…
Desorption	…	X
Dehydration/desolvation	…	X
Sublimation	…	X
Vaporization	…	X
Decomposition	…	X
Solid-solid reactions	…	X
Solid-gas reactions	X	X

The essential components of the TGA instrument are an electrobalance, furnace, temperature programmer, sample holder, an enclosure for establishing the required atmosphere, and a means of recording and displaying the data (Ref 120). Balance sensitivity is usually approximately 1 μg, with a total capacity of a few hundred milligrams. In oxidation or high-temperature corrosion tests, depending on the capacity of the balance (500 mg to 100 g), the sample size, and other experimental factors, the actual sensitivity may be a few micrograms to 100 to 200 μm. A typical operating range for the furnace is ambient to 1000 °C (1832 °F), with heating rates up to 100 °C/min (212 °F/min), but materials may be exposed and measured by TGA to 1700 °C (3100 °F). The control of the furnace atmosphere requires careful attention, particularly the ability to establish an inert

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

(oxygen-free) atmosphere, and it is useful to be able to quickly change the nature of the atmosphere. Compatibility between the materials of construction, the sample, its decomposition products, and the gaseous atmosphere must be considered. Sample holder materials commonly available include aluminum, platinum, silica, and alumina. Indication of the sample temperature is by a thermocouple close to the sample. Careful calibration for temperature is important, especially for kinetic studies. Various means are available for temperature calibration, which is not a trivial matter, although reproducibility is often more important than absolute accuracy. Weight calibration is readily achieved using standard weights.

Many factors influence the shape of the TG curve, both sample- and instrument-related, some of which are interactive. The two primary factors are heating rate and sample size, an increase in either of which tends to increase the temperature at which sample decomposition occurs and to decrease the resolution between successive mass losses. The particle size of the sample material, the way in which it is packed, the crucible shape, and the gas flow rate can also affect the progress of the reaction. Careful attention to consistency in experimental details normally results in good repeatability. On the other hand, studying the effect of deliberate alterations in such factors as the heating rate can give valuable insights into the nature of the observed reactions.

Table 4 lists a set of recommended atmospheres and temperatures for testing materials by TGA under conditions closely related to certain environments or processes (Ref 119). Continuous TG permits the automatic recording of mass change for a single sample over a period that is generally 1 to 100 h. Discontinuous thermogravimetry (DTG) is more widely used when there is an attempt to simulate industrial service. This is particularly true for complex gaseous atmospheres, under salt deposits, or for long term (100 to >10,000 h in oxidation or corrosion studies) (Ref 122). Discontinuous methods do present mass gain data per specimen and impose a thermal shock when the specimens are removed from measurement, but they provide a simple experiment to be exposed to complex environments and to evaluate a wide variety of alloys in a single test.

Table 4 Recommended testing atmospheres and temperatures for testing materials by thermogravimetric analysis

Environment	Gas composition	Temperature	
		°C	**°F**
Air	Air, 2.5% H_2O	450–1200	850–2200
Flue gas	Air, 2.5% H_2O, 0.1–1% SO_2	400–1000	750–1850
Waste incineration	Air, 2.5% H_2O, 0.1–1% SO_2, 0.05–0.1% HCl	400–850	750–1550
Sulfidizing environment	0.1–1% H_2S, balance H_2	300–600	570–1100
Carburizing environment	1% CH_4, balance H_2, dew-point -45 °C (-50 °F)	800–1100	1450–2000
Nitriding environment	90% N_2, 10% H_2, dewpoint -45 °C (-50 °F)	800–1300	1450–2350
Metal dusting environment	25% CO, 73% H_2, 2% H_2O	350–750	660–1380
Coal gasification (wet)	0.1–1% H_2S, 5% CO, 2.5% H_2O, balance H_2	400–700	750–1300
Coal gasification (dry)	0.1–1% H_2S, 70% CO, 2.5% H_2O, 25% H_2	400–700	750–1300
Waste gasification (pyrolysis)	90% H_2O, 5% H_2, 5% CO, 0.1% HCl, 0.05% H_2S	400–700	750–1300

Source: Ref 121

The ability of TGA to generate fundamental quantitative data from almost any class of materials has led to its widespread use in every field of science and technology. Key application areas are:

- *Thermal stability:* Related materials can be compared at elevated temperatures under the required atmosphere. The TG curve can help to elucidate decomposition mechanisms.
- *Kinetic studies:* A variety of methods exist for analyzing the kinetic features of all types of weight loss or gain, either with a view to predictive studies or to understanding the controlling chemistry.
- *Materials characterization:* The TG and DTG curves can be used to “fingerprint” materials for identification or quality control.
- *Corrosion studies:* Thermogravimetry provides an excellent means of studying oxidation or reaction with other reactive gases or vapors.
- *Simulation of industrial processes:* The thermobalance furnace may be thought of as a mini-reactor, with the ability to mimic the conditions in some types of industrial reactor.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- *Compositional analysis:* By careful choice of temperature programming and gaseous environment, many complex materials or mixtures may be analyzed by selectively decomposing or removing their components. This approach is regularly used to analyze, for example, filler content in polymers, carbon black in oils, ash and carbon in coals, and the moisture content of many substances.

Differential thermal analysis (DTA) measures the temperature difference between a reactive sample and a nonreactive reference and is determined as a function of time, providing useful information about the temperatures, thermodynamics, and kinetics of reactions. The DTA is a dynamic method detecting the heat of reaction (exothermic or endothermic) of a physical or chemical change of the measured system. A sample to be analyzed and an inert substance are heated up in a furnace simultaneously under the same conditions. Within the sample and the inert substance there are mounted thermocouples that are connected against each other, so that the temperature difference between sample and inert substance is measured.

Differential scanning calorimetry (DSC) measures temperature and heat flows associated with thermal transitions in a material. It is thus the most generally applicable of all thermal analysis methods, because every physical or chemical change involves a change in heat flow. Differential scanning calorimetry involves recording the energy necessary to establish a zero temperature difference between a substance and a reference material against either time or temperature as each specimen is subjected to an identical temperature regime in an environment heated or cooled at a controlled rate. The resulting DSC curve represents the amount of heat applied per unit time as the ordinate value against either time or temperature as the abscissa; this is related to the kinetics of the process (Ref 123).

Temperature calibration is carried out by running standard materials, usually, very pure metals with accurately known melting points. Energy calibrations may be carried out by using either known heats of fusion for metals, commonly indium, or known heat capacities. Synthetic sapphire (corundum or aluminum oxide) is readily available as a heat capacity standard, and the values for this have been accurately determined over a wide temperature range. Typical purge gases are air and nitrogen, although helium is useful for efficient heat transfer and removal of volatiles. Argon is preferred as an inert purge when examining samples that can react with nitrogen. Experiments can also be carried out under vacuum or under high pressure, using instruments of the appropriate design.

In the absence of any discrete physical or chemical transformations, the baseline signal in DSC is related to the heat capacity of the sample. Differential scanning calorimetry allows this parameter to be determined with good accuracy over a wide temperature range. The conventional approach is to compare the signal obtained for the sample above that given by an empty pan, with the signal obtained for a standard material, usually sapphire, under the same conditions. Careful experimental technique is required to obtain accurate results, but heat capacities can be routinely measured to an accuracy of better than ±1%.

Other techniques are available for heat capacity measurement by DSC. Accurate data can be obtained in narrow temperature intervals by using a nonequilibrium pulse technique, which is particularly useful when measurements need to be made in a region constrained by adjacent complicating phase transitions. Less time-consuming experiments than those described previously can generate data more rapidly but at the expense of accuracy and precision, which may be adequate for a given purpose. Modulated- temperature differential scanning calorimetry (MTDSC), a recent enhancement of DSC, routinely generates heat capacity data from a standard experiment and can, in fact, measure this in a nominally isothermal condition. However, the classical method is still recommended for the best-quality results.

Use of DSC provides a cost-effective method for obtaining kinetic and thermodynamic data for condensed phase phenomena. Observable processes include simple phase transitions, characterization of polymorphism, and the kinetics and thermochemistry for a variety of complex reactions. Thermodynamic data for pure substances include melting and boiling points, heat capacity, heat of fusion, heat of solution, and heat of vaporization.

The DSC-DTA curve may show an exothermic or endothermic peak. The enthalpy changes associated with the events occurring are given by the area under the peaks. In general, the heat capacity will also change over the region, and problems may arise in the correct assignment of the baseline. In many cases, the change is small, and techniques have been developed for reproducible measurements in specific systems.

Some possible processes giving enthalpy peaks are listed in Table 5.

Burner Rig Testing

Experiences in the 1960s and 1970s led to the discoveries of severe high-temperature corrosion in shipboard gas turbine engines that usually did not occur in aircraft turbine engines. Early observations noted severe corrosion attack on the first-stage blade and vane components of a shipboard marine gas turbine engine was sufficiently rapid to cause engine failure in several hundred hours (Ref 124). The ingestion of sea salt and the combustion of fuels containing some measure of sulfur by gas turbine engines operating in marine environments can lead to corrosion of hot section components, particularly turbine vanes (nozzles) and blades (buckets). This attack was documented in the early open literature as hot corrosion, as discussed earlier (Ref 124, 125, 126). Accelerated high-temperature corrosion was later observed in shipboard waste incinerators (Ref 41, 63).

The laboratory technique that was found to most nearly approximate the operating conditions of a gas turbine engine was the burner rig (Ref 117). Burner rig tests provide a compromise between simple laboratory and field tests (Ref 96). Burner rigs are versatile: they may be used with very-low-sulfur fuel to simulate oxidation conditions at high temperatures; they may be used with 1 to 6 wt% S, vanadium, and/or high- carbon-residue fuels to simulate sulfidation and hot corrosion conditions; and they may be used with injection of NaCl to simulate hot corrosion conditions in a marine environment. Laboratory evaluations are employed as a sorting test for materials (alloys and coatings) resistant to hot corrosion, sulfidation, and other high-temperature gaseous corrosion reactions. The basic definition of a burner rig is a device that burns fuel to produce the high-temperature corrosive environment. There are several variations of burner rigs, each compromising certain aspects of a gas turbine environment while minimizing costs for testing (Ref 117). There are basically three types of burner rigs: low-velocity atmospheric pressure rigs, high-velocity atmospheric pressure rigs, and high-velocity, high-pressure rigs. Table 6 compares the test parameters of low-velocity atmospheric pressure, high-velocity atmospheric pressure, and high-velocity, high-pressure burner rigs in use (Ref 117).

The flow and heat-transfer characteristics around a cylindrical specimen are well documented and can be readily reproduced from one laboratory to another (Ref 96). Therefore, cylindrical test pins are normally used for burner rig testing. Specimens are usually rotated to keep all specimens at the same temperature and to ensure uniform exposure of contaminants from the combustion stream. In general, the specimens are removed from the test chamber periodically and cooled to achieve thermal cycling. Test cycles may range from every 10 min to once every 24 h, depending on the laboratory and the service application that is being simulated during the burner rig test. There is no accepted specification for burner rig testing. A recommended test practice was issued by the working group on hot salt corrosion testing of the Versailles Agreement on Advanced Materials and Standards (VAMAS) (Ref 127).

Likely, the most important factor as to how well a burner rig simulates gas turbine conditions is the contaminant flux rate deposited on the test specimens (Ref 102, 128, 129). The corrosion rate dependence on salt deposition rate is nonlinear and depends on the composition of the salt and the substrate alloy or coating (Ref 130).

There appears to be no unique salt level at which burner rigs are conducted in different laboratories, and there are wide variations of salt concentration used. In simulation tests, 1 ppm salt is considered realistic, but 10 ppm is often used. The corrosion rate typically increases with an increase in salt levels from 0 to 10 ppm. However, according to one report, varying the salt concentration from 10 to 50 ppm in air has little effect on low-temperature type II hot corrosion (Ref 131).

Due to the complexity of the turbine service environment and the impossibility for any burner rig test to fully simulate the service conditions, the results from burner rig testing should be used to rank the relative corrosion performance of alloys and of high-temperature coatings and should not be used to predict the actual corrosion rates or service life of these materials in an operating turbine.

Low-velocity atmospheric pressure burner rigs (LVBR) operate at low velocity (0.1 to 10 m/s, or 0.33 to 33 ff/s) (Ref 101). In ducted rigs, specimens are directly exposed to the hot gases from the combustion flame in an unrestricted manner. Under such conditions, it is impossible to maintain the critical partial pressure of SO_3/ SO_2 for hot corrosion to proceed (Ref 96).

Ducted LVBR rigs are used to gain better control of the test environment. The dimensions of a ducted combustion environment influence the aerodynamic flow and the heat-transfer characteristics around the test specimens (Ref 131). The combination of duct configuration, specimen design, and flow characteristics can alter the boundary layer at the specimen surface sufficiently to give variations in deposition rates (Ref 96). The Lynn ducted burner rig is shown in Fig. 16.

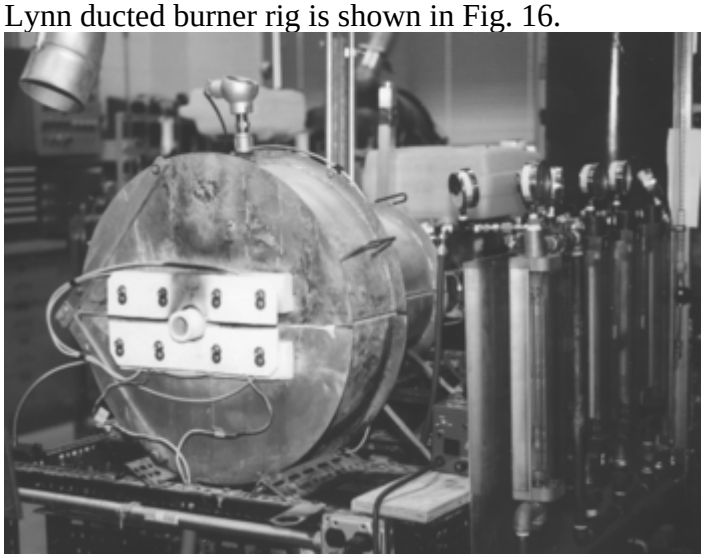

Fig. 16 Lynn ducted low-velocity atmospheric pressure burner rig used for hot corrosion testing

As shown in the LVBR schematic diagram (Fig. 17), the air, fuel, and sea salt are injected into the burner rig. The spray is injected into the forward combustion zone to duplicate high-temperature reactions occurring in gas turbines. The LVBR has been used for testing with 0.5, 5.0, 10, 100, and 200 ppm sea salt. The lower salt tests are run for 500 and 1000 h, the 100 ppm salt level for 100 to 500 h (Ref 132), and the 200 ppm salt tests for 100 h. The higher sea salt tests, especially at 200 ppm, are heavily oriented toward sulfidation effects; oxidation

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

does not appear to play a dominant role. On the other hand, the 0.5 ppm sea salt test yields more of an oxidation-oriented reaction, as evidenced in past efforts to more oxides and smaller (and fewer) sulfides.

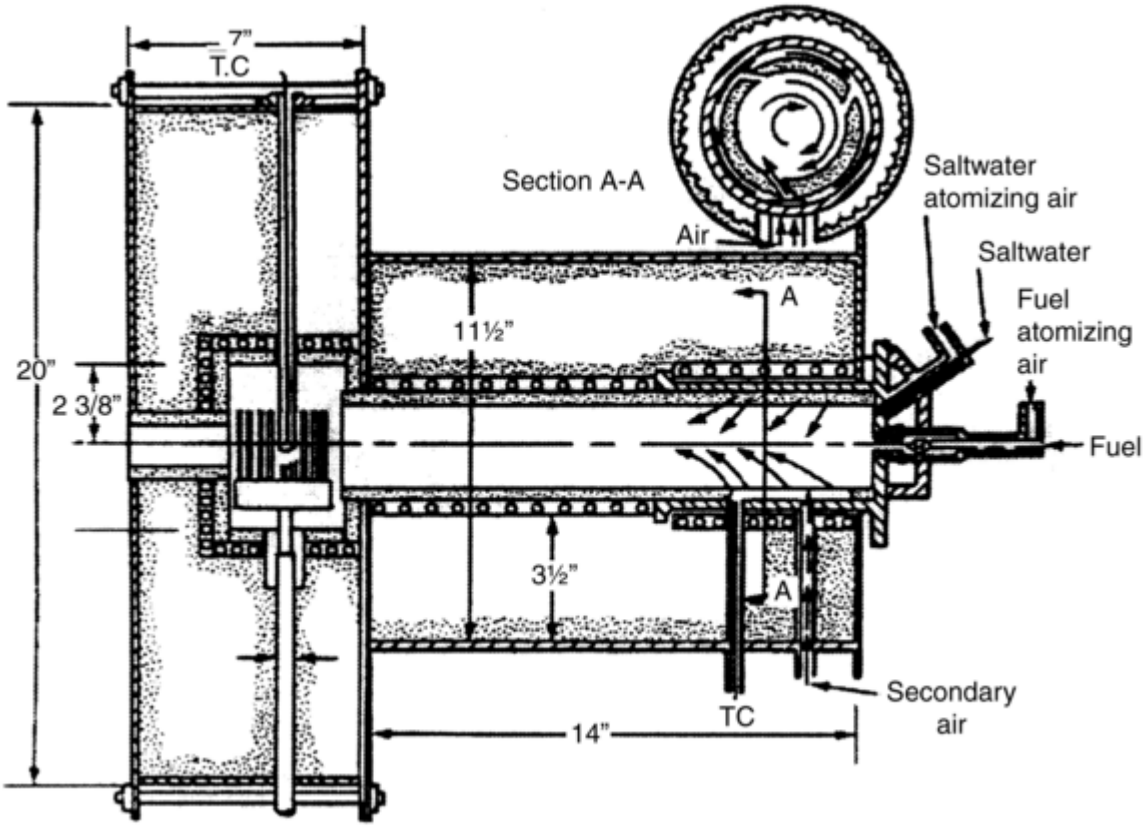

Fig. 17 Schematic of a low-velocity atmospheric pressure burner rig. TC, thermocouple

The important factors that influence hot corrosion in gas turbines are composition of the gas, condensate composition and deposition rate, and temperature. In order to simulate gas turbine conditions in a LVBR, it is desirable to duplicate all the variables. However, it is not possible to duplicate exactly, due to the pressure differentials between the gas turbine (5 to 15 atm, or 500 to 1500 kPa) and the 1 atm (101 kPa) LVBR (Ref 131). Table 7 shows a comparison of the partial pressures of gaseous species in the gas turbine and the LVBR. The corrosion rate depends on the salt deposition rate, which is nonlinear, and the corrosion depends on the composition of the salt and the substrate alloy or coating (Ref 130). It is desirable to represent an accelerated test of the turbine conditions with LVBR testing. This is accomplished by using impurity concentrations of the gas composition and the salt condensate that are similar between the rig and the turbine and by having a salt deposition rate that is higher in the rig, usually by a factor of 10, than occurs under turbine operating conditions.

Table 7 Typical operating conditions for gas turbines and low-velocity atmospheric pressure burner rigs (LVBR)

	Gas turbine conditions	LVBR conditions

Source: Ref 130

The SO_2/SO_3 equilibrium is a function of the partial pressure of oxygen. Because of the pressure differential between the gas turbine and the LVBR, the SO_2/SO_3 partial-pressure ratio in a LVBR cannot be equivalent to that in the turbine, and it is not possible to simulate the partial pressures of both SO_2 and SO_3. To simulate the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

turbine conditions as nearly as possible in an LVBR environment, the choices are to use (SO_3 + SO_2) summation of partial pressures or the partial pressure of only SO_3 or SO_2 (Ref 130). The sulfur levels must be much higher than in the turbine because of the pressure difference. For an equivalent air/fuel ratio, the sulfur level in the 1 atm (101 kPa) LVBR test should be *p* times higher than in the turbine if the use of (SO_3 + SO_2) partial pressures are simulated, where *p* is the pressure in the turbine (Ref 130).

In actual operation, metered fuel is atomized and injected into the combustion chamber. Sea salt or other soluble contaminants are atomized and injected into the forward combustion area, as shown in Fig. 17. The gases, sea salt, or other solutions added to the fuel stream are thoroughly mixed by the swirl action of air entering through tangential slots in the combustion tube. This design precludes stagnation or stratification of the combustion gases. Downstream, the test specimens are exposed to the products of combustion and sea salt (or other contaminants, such as artificial urea).

Diesel and high-distillate fuels (NATO F76, JP4, and JP5) (Ref 129), as well as other commercial-grade liquid fuels, have been used for burner rig testing. Di-tertiary butyl disulfide may be added to NATO F76 diesel fuel to increase the sulfur concentration to 1% by weight, the maximum prescribed sulfur level for this military-specified fuel. Other contaminants (vanadium, carbon residue, or other species) can be added to study the individual or synergistic effects on the resistance of alloys (Ref 133) or protective coatings (Ref 134, 135) to high-temperature corrosion reactions. As discussed earlier, sulfur and sulfur-containing species have been shown to be a major reactant in hot corrosion. Fuel flow may be in the range of 4 to 6 cm^3/min, or approximately 1.5 to 2.3 gal, during a 24 h period. The fuel is atomized into a fine dispersion by low-pressure air and introduced into the forward combustion end of the furnace. The combination of a fine spray of fuel, excess air, and sufficiently high temperatures achieves instantaneous combustion.

Temperature is attained by the combustion of the fuel and is supplemented by heat from heating elements that surround the test chamber. The heaters reduce temperature gradients and provide stable, controllable temperatures between 815 and 1150 °C (1500 and 2100 °F). One control thermocouple is used, which is positioned in the center of the rotating specimen carousel approximately 25 mm (1 in.) above the refractory surface and is connected to a controller. The thermocouple allows the rig to normally run at its set temperature ±2 °C (±4 °F). Test temperatures for type I hot corrosion are run between 800 and 950 °C (1472 and 1742 °F), while type II hot corrosion tests are run between 600 and 800 °C (1112 and 1472 °F). Because of small variations of construction and operating parameters between LVBR test apparatuses and variations in carousel configurations, each rig should be calibrated prior to testing.

Air/fuel ratios are often set at 30 to 1 but may range from 15 to 1 (approximately stochiometric conditions) to approximately 60 to 1. Within very specific limits, temperature changes can be made without changing combustion conditions. Flame impingement on the specimens is always avoided. On the other hand, fuel-rich conditions or flame impingement can be obtainable as a special test condition.

The LVBR uncoated or coated test specimens (Fig. 18) are electrically and thermally isolated from one another by insertion into a moldable ceramic that is placed into a metallic carousel. The carousel rotates at a speed (such as 30 rpm) sufficient to assure equal thermal exposure of all test specimens.

The LVBR tests are used to simulate gas turbine conditions and, more recently, the high- temperature, hot corrosion environment that occurs in waste incinerators. For laboratory testing of the waste environment, urine, if available, or artificial urine is used to duplicate the corrosive conditions on shipboard incinerators. Sea salt should be added to either urine solution to further simulate this corrosive marine environment. Therefore, all contaminants (fuel sulfur content, sea salt, urine, and others) should be determined during the design of the accelerated test to best simulate the environment under consideration.

Figure 19 shows the effects of type I hot corrosion on materials after 1000 h LVBR exposures at 899 °C (1650 °F). Type I high-temperature hot corrosion (HTHC) occurs through basic fluxing and subsequent dissolution of the normally protective oxide scales by the molten sulfate deposits at metal temperatures ranging from 850 to 950 °C (1562 to 1742 °F); alloy or coating depletion is generally associated with the corrosion front caused by type I hot corrosion.

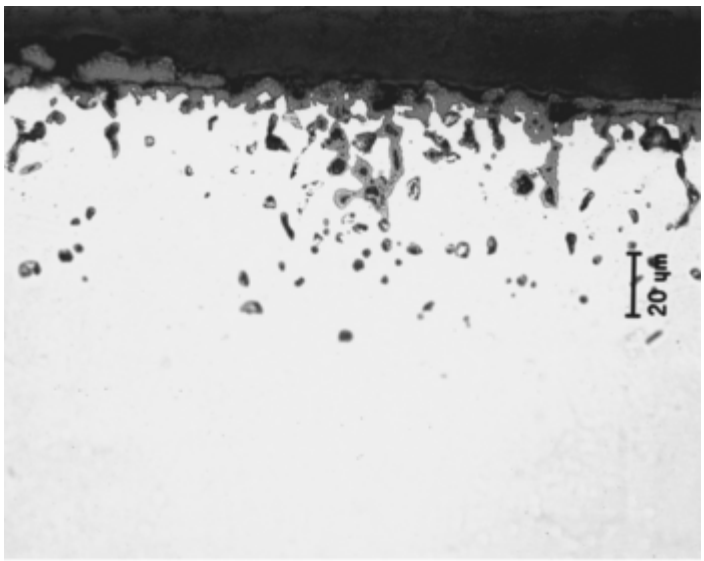
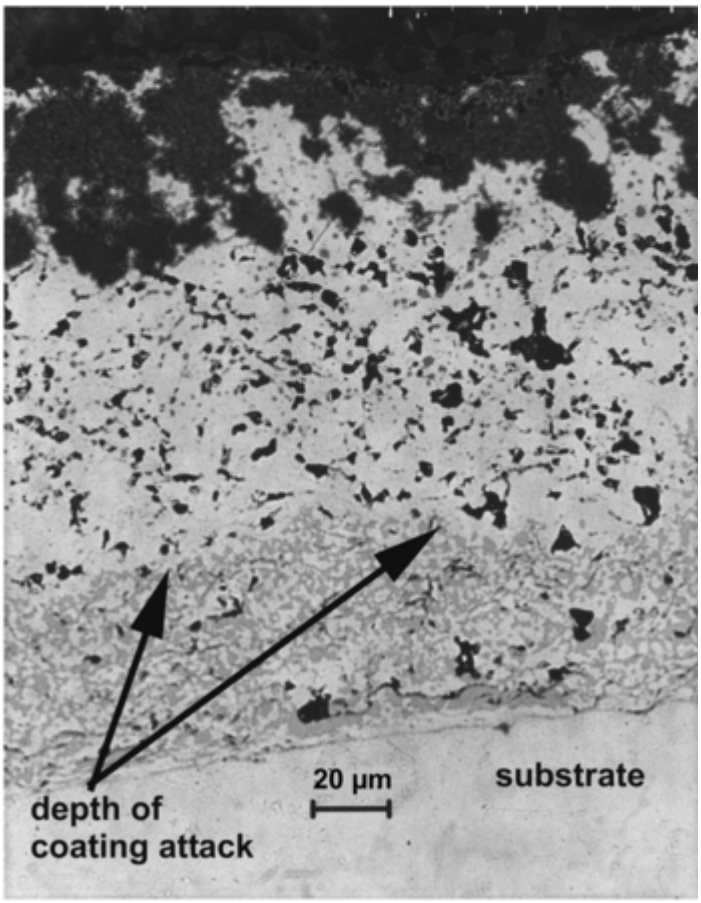
مرجع مهندسی مواد و متالورژی



(a)



(b)

Fig. 19 Low-velocity atmospheric pressure burner rig test results at 900 °C (1650 °F). The nickel-base alloy (a) and the CoCrAlY-type coating (b) were both attacked by type I hot corrosion. Depletion of an alloy constituent or coating phase was found along a broad front, with an associated generation of small voids when the constituent/phase is depleted. Depth of penetration in the coating is 115 to 125 µm (4.5 to 5 mils).

As mentioned previously, the use of cheaper, lower-grade fuels may have some undesired consequences. The use of a LVBR test can determine whether certain fuel contaminants have an adverse effect on the performance and service life of hot section turbine coatings. Figure 20 shows the effects on a diffusion nickel aluminide coating after a 1000 h LVBR test conducted at 704 °C (1300 °F). The fuel parameter being tested in this case

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

was the fuel carbon residue (on 10% bottoms). Increased carbon residue content in the fuel, in this case, led to enhanced type II low- temperature hot corrosion (LTHC) (Ref 135). Type II corrosion occurs in the temperature range of 650 to 750 °C (1202 to 1382 °F), where p_{SO_3} is relatively high or melts are deficient in the oxide ion concentration, leading to acidic fluxing that results in pitting attack where the sulfides are found in the pitted area. The carbon may cause erosion, or its presence in the deposit may promote reduction of sodium sulfate to sodium sulfide. At a threshold fuel carbon-residue content between 0.19 and 0.33 wt%, type II hot corrosion vastly increases the average coating loss on a radius (from 23 to 30 μm, or 0.9 to 1.2 mils, to approximately 70 μm, or 2.75 mils), as shown in Fig. 21 (Ref 135) by enhancing the effective sulfate activity.

High-velocity atmospheric pressure burner rigs (HVBR) shown as a schematic in Fig. 22, operate at a velocity of approximately 0.5 Mach (331 m/s or 1086 ft/s). Other HVBR listed earlier in Table 8 operate from 65 to 330 m/s (213 to 1080 ft/s). Test rigs delivering pressures slightly above atmospheric pressure (up to 1.45 bar or 145 kPa) operate between 0.2 to 0.75 Mach (132 to 496 m/s or 433 to 1630 ft/s) (Ref 160). Like LVBR apparatus, HVBR test setups may be unducted or ducted. A HVBR can evaluate materials of various geometries and chemical compositions from 371 to 1371 °C (700 to 2500 °F) under oxidation or corrosive environments. The test temperature at the center of the specimen carousel is maintained to ±15 °C (±27 °F) (Ref 136).

Hot corrosion burner rig tests help to evaluate the potential durability of turbine engine materials, which are expected to breathe sea salt air from aircraft carriers and coastal bases of operation. This test is accomplished by injecting a controlled amount of sodium chloride solution into the burner flame.

Materials are subject to thermal cycling that duplicates the flight cycles experienced by aircraft making many takeoffs and landings daily. The test rigs can heat advanced materials and coatings to the extreme temperatures and hostile environments in which they are expected to operate by only burning several gallons of jet fuel per hour rather than full-scale engine tests.

Corrosion rates in HVBR and LVBR correlate with the contaminant flux rate and the amount of salt present on the test sample surfaces (Ref 117). Deposition efficiency changes with temperature from 10 to 12% at 750 °C (1382 °F) to 8 to 9% at 850 °C (1562 °F) and approximately 4% at 900 to 950 °C (1652 to 1742 °F) (Ref 137). Under high-velocity conditions at temperatures of 750 °C (1382 °F) and below, injection of salt particulates has been shown to result in increased corrosion of corrosion-resistant alloys, while no effect was noted for less resistant alloys. Such behavior is consistent with mechanical damage to the protective scale formed on corrosion-resistant alloys by particulate impact (Ref 138, 139). At 850 °C (1562 °F), the salt was semi- molten and therefore would more likely deposit on the surface rather than fracture the oxide.

To generate similar corrosion rates, salt deposition rates in LVBR tests were required to be much higher than the contaminant flux in HVBR tests. Table 8 compares the burner rig deposition rates, sodium, and chlorine mass fluxes (Ref 136).

If the contaminant fluxes are similar, material losses will be higher in the HVBR tests than observed in the LVBR in the type II hot corrosion existing at 750 °C (1382 °F). In the temperature regime where the type I hot corrosion predominates, the HVBR metal losses are higher than LVBR results exposed to low-salt fluxes, but the LVBR results are equal to or higher than the HVBR results, as shown in Table 9 (Ref 136).

Due to the impact of salt particulates, discussed previously, the incubation time for hot corrosion to initiate is generally shorter in the HVBR test environment than noticed in LVBR tests. Although the metal losses from HVBR tests are lower than those measured after LVBR exposures, the test time was 2 to 15 times shorter in the HVBR tests compared to the LVBR test runs. The propagation rates for the two alloys illustrated in Table 10 were similar in both burner rigs.

The HVBR tests are also conducive to other gaseous reaction studies. Nitridation of several nickel-base alloys used as transition liners in the combustor section of a gas turbine engine was tested in a dynamic oxidation high-velocity (100 m/s, or 330 ft/s) burner rig operating for 100 h at 980 °C (1796 °F) (Ref 37). In this test, a fuel oil mixture was burned with an air-to-fuel ratio of approximately 50 to 1. The specimens were removed from the test chamber every 30 min and rapidly fan cooled for 2 min before returning the specimens to the test chamber. Due to the high- velocity combustion gas stream with frequent thermal cycling, all test specimens experienced oxide spallation and relatively uniform metal loss. The internal attack, measured by metallography, included both internal oxidation and nitridation, as shown in Fig. 23. Bulk carbon and nitrogen for the test specimens were analyzed. Iron, aluminum, and titanium alloying additions were found to be detrimental to resisting nitridation attack.

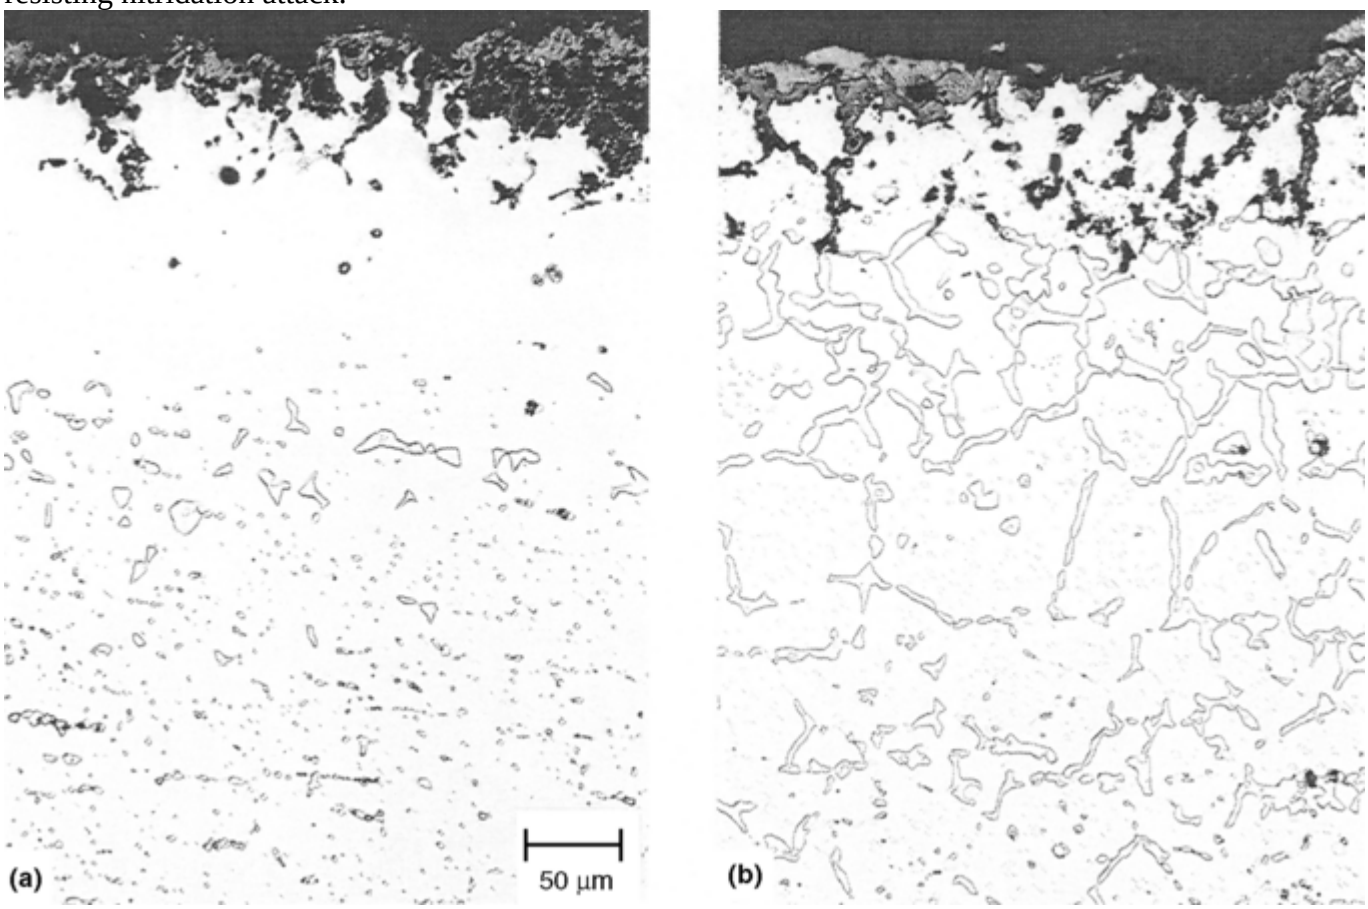

Fig. 23 Optical micrographs showing internal oxidation and nitridation after the dynamic oxidation burner rig testing at 980 °C (1800 °F) for 1000 h with 30 min cycling. (a) 230 alloy. High-velocity, high-pressure burner rigs (HPBR), such as the one shown in Fig. 24, are more complex than the previous two rigs, but this test apparatus most accurately simulates the high-pressure, high-temperature

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

conditions in a gas turbine engine. Pressure and temperature can be adjusted to duplicate the conditions of a given engine. A HPBR requires compressors and other ancillary equipment to maintain the desired conditions in the combustor and the specimen chamber. The combustor and the specimen chamber must be designed to withstand the imposed pressures at the test temperatures.

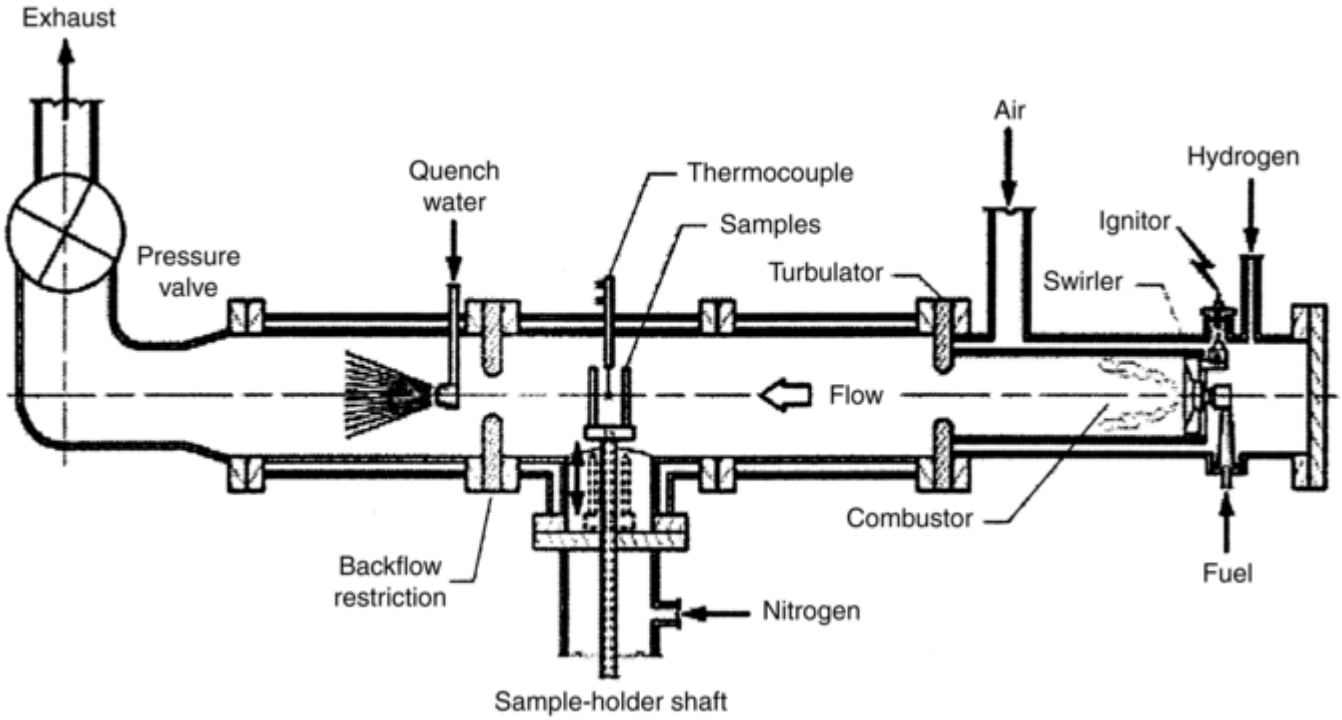

Fig. 24 Schematic of high-velocity, high-pressure burner rig

The HPBR is a combustion test rig used for high-temperature environmental durability studies of materials for advanced aircraft. The facility burns jet fuel and air in controlled ratios to produce combustion gas chemistries and temperatures that are realistic to those in gas turbine engines. In addition, the test section is also capable of simulating the pressures and gas velocities representative of today's aircraft. Test samples are easily accessible for ongoing inspection and documentation of weight change, thickness, cracking, and other metrics. The test pressures range from 3 to 50 atm (304 to 5066 kPa) and with gas flow velocities of 20 to 305 m/s (65 to 1000 ft/sec) (Ref 117). Conditions of one rig reportedly operated at pressures up to 30 bars (3000 kPa) with gas velocities of 0.25 to 0.9 Mach (166 to 596 m/s or 544 to 1960 ft/s) and temperatures between 700 to 1100 °C (1292 to 2012 °F) (Ref 161).

Testing at High Temperature, High Pressure

Test temperature and total system pressure (and the partial pressures of various soluble gaseous species) are two major factors affecting materials corrosion. There are several commercial and industrial processes that occur at both high temperatures (HT) and high pressures (HP). Table 11 lists a number of common commercial HT/HP environments (Ref 140). For simple HT/ HP exposure tests involving aqueous or nonaqueous phases, the total pressure of the constituents in the test chamber varies with temperature.

The simplest type of HT/HP corrosion test involves a sealed, static, pressurized autoclave vessel, as shown in Fig. 25. The test vessel contains a solution and vapor space above the solution. The ratio of liquid to gaseous phases is determined by the amount of each constituent, the vapor pressures of the constituents, and the temperature. Corrosion samples may be placed in the liquid phase, the gaseous phase(s), or at the phase interfaces, depending on the type of information required (Ref 140).

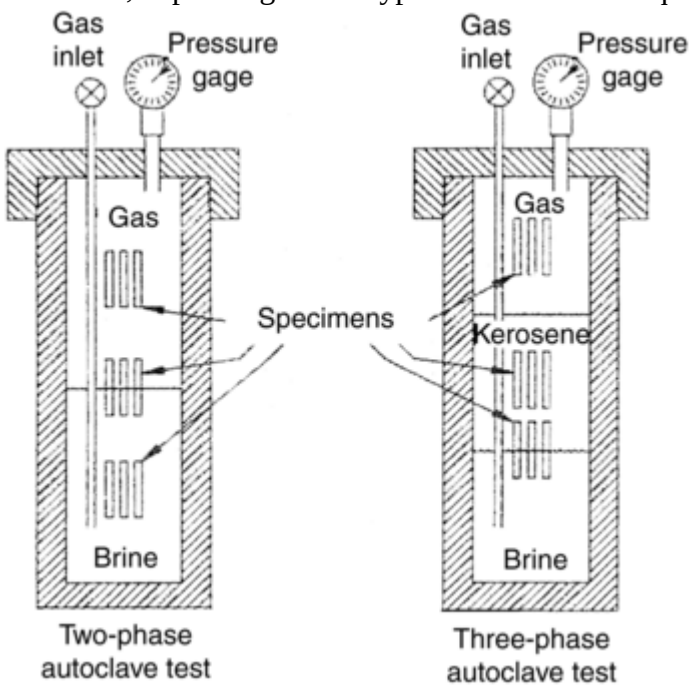

Fig. 25 Simple static high-temperature, high-pressure autoclave test vessel configuration. Source: Ref 140

In cases where susceptibility to hydrogen embrittlement cracking (HEC), Stress-corrosion cracking (SCC), liquid metal embrittlement (LME), or other environmentally assisted cracking (EAC) mechanisms may be suspected, it is common to evaluate the actual mechanical behavior of the alloys under consideration in the corrosive environment of interest. Slow strain rate testing (SSRT) or constant extension rate testing (CERT) may be used in a HT/HP environment. The important aspect of such techniques is the requirement for these

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

tests to be conducted in a range of strain rate or cross-head extension rate in which the material under evaluation is going to experience cracking, if it is susceptible (Ref 140).

In general, it is necessary to conduct such tests slowly enough so that the environment has adequate time to affect the material and produce cracking. These strain rates are typically in the range of 10^{-4} to 10^{-7}/s for SCC in many common metal-environment systems. For HEC, the critical strain rate is somewhat higher (i.e., 10^{-2} to 10^{-4}/s) in most susceptible iron, nickel, and titanium alloys. The SSRT is particularly adapted to HT/HP in simulated environments (Ref 140). Because the test is accelerated mechanically by the application of the dynamic straining, it is possible to use simulated test environments rather than the overly aggressive chemical environments commonly used in conventional standardized tests.

Figure 26 shows a vessel that can be used to conduct SSRT under HT/HP conditions. In aqueous environments, the heating is accomplished from the outside of the vessel to uniformly heat the entire test solution surrounding the specimen. For high-temperature gaseous environments, it may be possible to heat the specimen within the pressurized test vessel.

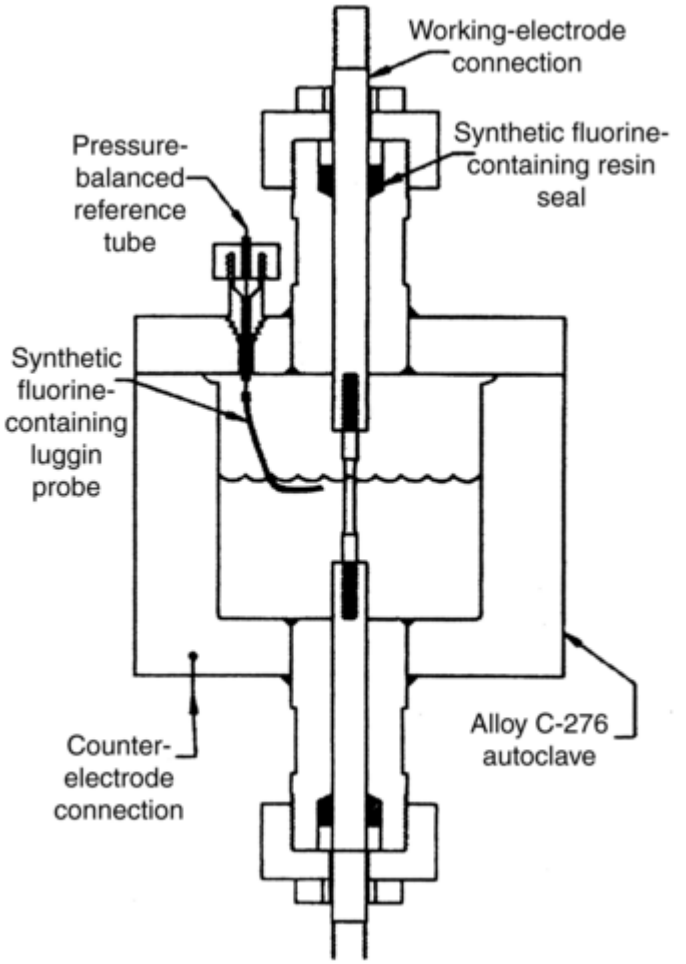

Fig. 26 High-temperature, high-pressure test vessel for slow strain rate testing. Source: Ref 140

In some cases, it may be possible to use the similarly designed HT/HP test vessel to conduct fracture or fatigue loading or both (Ref 140). For such tests, accommodations must be made to be able to handle the generally larger specimen configuration of fracture mechanics specimens. Additionally, there is the need to closely monitor crack opening displacement or crack growth or both directly, using various methods that include (a) pressure and environmentally compatible clip gages, (b) mechanical fixtures that exit the pressure vessel, or (c) potential drop across the specimen. In the case of potential-drop techniques, as the specimen cross section is reduced due to crack growth, the electrical resistance measured across the cracked region increases and can be monitored as a measure of crack growth. Alternately, in some cases, direct measurements of crack opening displacement can be conducted, using special mechanical feedthroughs in the test vessel. This technique, while cumbersome, is preferred where the test environment is particularly corrosive and may attack clip gages and interfere with electrical penetrations for the use with potential-drop techniques.

مرجع مهندسی مواد و متالورژی

ASTM G 111, “Guide for Corrosion Tests in High-Temperature or High-Pressure Environment, or Both,” establishes basic considerations that are necessary for conducting corrosion tests on metallic materials under conditions of high pressure or a combination of high temperature and pressure, and that will promote consistency in laboratory results.

Thermal Cycling

Many applications of high-temperature materials require repeated heating and cooling cycles that demand that materials be resistant to the mechanical stresses and subsequent damage during cycling. As noted in earlier sections, stresses are generated in the oxide or other gaseous-derived scale formed on metals and alloys in isothermal exposures. Alloys operating in high-temperature applications can exist if protective oxide films are formed or protective coatings are applied. For alloys with oxides, operation conditions usually apply large compressive stresses in the oxide scales due to the thermal expansion coefficients between substrates and oxides differing by 30 to 50%. A third source of stress in the oxide scale can be from scale growth itself, because of geometric effects or intrinsic oxide growth from counterdiffusion of oxide-forming species (Ref 28, 141). Table 12 gives the expansion coefficients of some metal-oxide systems. Figure 27 illustrates the strains that are generated by differential thermal expansion.

Table 12 Linear expansion coefficients of metals and oxides

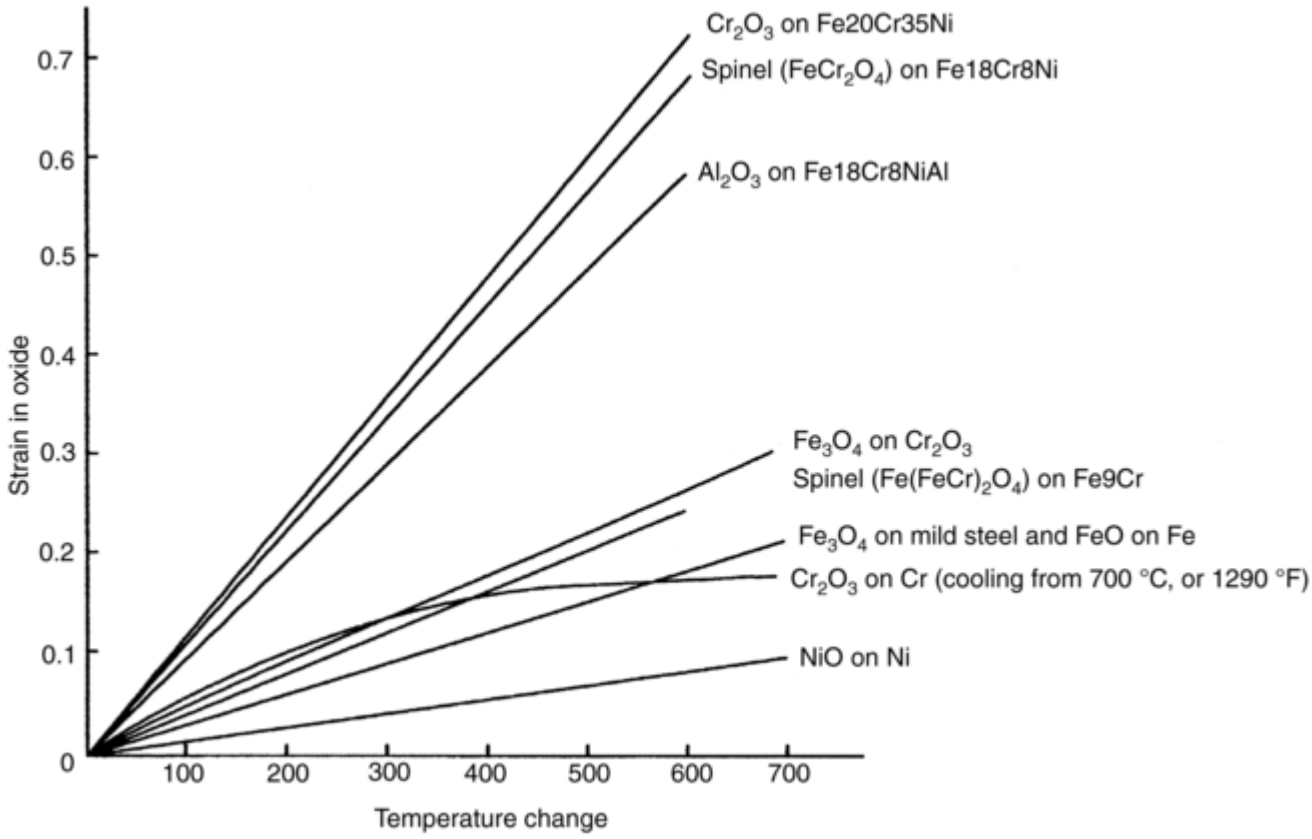

Fig. 27 Strains generated at the interface between various oxides and substrates by differential thermal expansion. Source: Ref 15

However, when metals and alloys are exposed in an oxidizing environment subjected to thermal changes, additional stresses impact on the high- temperature scale, which may alter its service life. If the sum of all these stresses reaches a critical value, the scales crack, detach, or spall, depending on the stress state (Ref 141) and the fracture toughness of the interface. The greater the disparity of coefficients of thermal expansion between the alloy and the oxide, the less adherent the oxide becomes during cooling, although other factors, such as fracture toughness of the interface, also can contribute to loss of adherence.

It is desirable that product scales, such as metal oxides or high-temperature coatings covering alloys that are subjected to stresses during thermal cycles, are resistant and adherent during these thermal cycles. It has been shown that degradation of an aluminized MAR-M-200 subjected to small, 2.8 °C (5 °F) rms wave, temperature variations at 1150 °C (2102 °F) suffered severe weight loss in 150 h (Ref 142). There have been several reviews on the effects of thermal cycling on high-temperature materials (Ref 143, 144, 145, 146, 147). Discussion of the mechanisms and testing methods for evaluating thermal cycling effects occurred during a recent workshop (Ref 143).

Thermal cycling of the test samples is preferred to simulate operations that exist in many high-temperature applications. The imposition of thermal cycling during oxidation or other gaseous reaction leads to enhanced metal-gas reaction rates due to scale failure from either decohesion or cracking and subsequent exposure of the newly bared alloy to the gaseous environment. Stresses related to thermal cycling increase the spallation of surface oxides, thereby increasing the propensity toward high-temperature corrosion. Thermal cycling can also lead to the growth and volume changes of the thermally grown oxide, leading to spallation of thermal barrier coatings (Ref 148). The effect of cycle frequency is highly dependent on the scale adherence to the substrate, the type of defect controlling spallation, the total test time, and probably, the test temperature. Water vapor and humidity may also alter the performance of alloy protective scale during prolonged cooling cycles away from the furnace; cold spalling may occur. Cycle frequency also affects how the cycling test is performed (Ref 149, 150, 151). A rapid temperature cycling (over 100 cycles/day) was developed to evaluate coated parts from 600 to 1000 °C (1112 to 1832 °F) in air, depending on the alloy substrate. This procedure was able to predict performance of these coated parts (Ref 152).

Computer programs have been developed to predict cyclic oxidation behavior of superalloys (weight change, amounts of retained and spalled oxide, total oxygen and metal consumed, and terminal rates of weight loss and metal consumption), based on models of oxidation-growth laws and input on spalling geometry, oxide phase, growth rate, spall constant, and cycle-duration parameters. This has provided success in some alloy systems, but such programs may not predict behavior in all systems (Ref 153, 154).

Table 13 lists the performance of several nickel-base and cobalt-base alloys in different corrosive environments (Ref 155). Exposure to dynamic oxidation generally causes accelerated corrosion or metal loss, as compared to static, isothermal oxidation tests. Depending on the composition of the alloy, the corrosion resistance may be superior in some environments but suffer severely in other high-temperature corrosive atmospheres.

Note: UNS, Unified Numbering System.

(a) Static oxidation in air; lab test for 1008 h, with specimens cycled to room temperature once every 168 h.

(b) Large internal voids not included for N06601 reading.

(c) Dynamic oxidation in air; lab test for 1000 h, with specimens cycled to room temperature once every 30 min.

(d) Ar, 5% H_2, 5% CO, 1% CO_2, 0.15% H_2S; $p_{O2} = 3 \times 10^{-19}$ atm; duration 500 h, except for 310 stainless steel, which was for 215 h.

(e) H_2, 46% CO, 0.8% CO_2, 1.7% H_2S at designated temperatures.

(f) Recuperator of aluminum remelting furnace flue gases. Mode of corrosion: combined attack by alkali sulfates, chlorides, with oxidation for 1150 h.

(g) Burner rig test with combustion products of No. 2 fuel oil (1.0% S); thermal shock frequency $\frac{11}{500}$h; corrodent urine.

(h) Ar + 20% O_2, 0.25% Cl_2 for 400 h at 1000 °C (1830 °F).

(i) Carburization resistance for 500 h in packed graphite. Source: Ref 155

Service Testing

Simulating the environment of an industrial process or application is a compromise in most situations. Most atmospheres consist of mixed oxidants of varying partial pressures (activities), temperature gradient profiles, and, in some cases, velocity and erosion parameters as well. Key application variables should be identified and care should be taken to see that these variables are suitably simulated in the service test. Characterization of gas composition is as essential as the control of temperature and gas flow rate. Atmosphere synthesis may require a stream of apparatuses consisting of such units as an inlet saturator, exhaust condensers, gas preheater beds, catalyst beds, heat shields, bubblers, mass flow meters, and analytical instrumentation. Corrosive gases, such as sulfur trioxide, will require corrosion-resistant materials of construction (Ref 9).

One standard wire-heater test is described by ASTM B 76, "Accelerated Life of Nickel-Chromium and Nickel-Chromium-Iron Alloys for Electrical Heating." The useful life of a material is determined by electrically heating a section of wire in air to a given temperature, where it is held for 2 min, followed by 2 min of cooling. This cycle is repeated until a 10% increase in electrical resistance is noted and reported as the useful life of the material. This testing can take approximately 1 week.

ASTM G 79, "Standard Practice for Evaluation of Metals Exposed to Carburization Environments," covers procedures for the identification and measurement of the extent of carburization in a metal sample and for the interpretation and evaluation of the effects of carburization. It applies mainly to iron- and nickel- base alloys for high-temperature applications. Four methods are described: method A, total mass gain; method B, metallographic evaluation; method C, carbon diffusion profile; and method D, change in mechanical properties.

Carburization testing in the field usually requires dedicating all or a portion of a particular piece of equipment for evaluating alloy performance or for evaluating the effect of process variables on the materials of construction (Ref 23). Such testing is performed to confirm laboratory data because of a lack of access to laboratory equipment or professional material expertise, or because of difficulty in duplicating certain carburization conditions in the laboratory. Atmospheres of low oxygen potential have proven difficult to duplicate in the laboratory. Direct simulation of ethylene furnaces is difficult in the laboratory because of the simultaneous interaction of long-term creep and high-temperature corrosion by carbonaceous atmospheres on the inner diameter and by oxidizing combustion gases on the outer diameter of the furnace tubes (Ref 23). A new carburization standard test method has been developed to generate carburization data for different materials under the same test parameters and procedures (Ref 156). This test method is conducted at 982 °C (1800 °F) for 96 h in H_2 containing 2% CH_4.

An excellent example of field testing in conjunction with laboratory testing to solve a heat- exchanger corrosion problem in an industrial chlorinated solvent incinerator is described in Ref 157. A corrosion rack containing three stainless steels, two high-nickel austenitic alloys, and three nickel-base alloys was placed within the gas hot stream of a heat exchanger containing HCl and chlorine. The in-situ test results were correlated with laboratory tests of the same alloys for this application.

Waste incinerator effluent streams contain halogen compounds arising principally from the burning of plastics and organic matter. A 10 year study of candidate alloy boiler tubes in several field test sites is described in Ref 158. Again, these field tests were confirmed by simulated laboratory test. Metallography and scanning electron microscopy were used to define the corrosion modes of this mixed-oxidant environment. Ultrasonic thickness-measuring equipment was used to follow the tube corrosion/ erosion rates at the field site. Tubes were periodically removed from service for laboratory evaluation. Test tracks have proven to be a valuable source of performance information on candidate materials in waste incinerator environments (Ref 3, 159).

Introduction to Methods of Corrosion Protection

Paul Natishan, Naval Research Laboratory

Introduction

CORROSION is an oxidation reaction where the corroding metal is the anode in an electrochemical cell. In addition to the anode, there are three other components that are necessary for corrosion to occur: an aggressive environment, a cathode where the reduction reaction occurs, and an electron-conducting path between the anode and the cathode. The basic concept for most methods of corrosion protection is to remove one or more of these cell components so that the pure metal or metal alloy of interest will not corrode. Another widely used corrosion protection approach is to change the nature of the anode so that it becomes the cathode (cathodic protection). These methods of corrosion protection are briefly reviewed as follows.

Factors Affecting Corrosion Behavior

A primary factor in determining corrosion behavior of metals is their chemical composition. Alloying, which is adding other element(s) to a metal, is one of the major means used to improve the corrosion resistance of the base material. Alloys with varying degrees of corrosion resistance have been developed in response to an ever-increasing number of severe service environments. An example of improved corrosion resistance by modifying the chemical composition is the alloying of steels. Carbon and low-alloy steels are less costly but also less corrosion-resistant. At the higher end of the alloying scale are the more costly and significantly more corrosion-resistant stainless steels. The corrosion resistance of stainless steels is due to the protective nature of the surface oxide film that forms a barrier between the environment and the alloy. The physical and chemical properties of the oxide film and the service environment determine the corrosion resistance of the alloy. In addition to alloying, there are metallurgical factors, often referred to as microstructure, such as crystal form, grain size and shape, grain heterogeneity, second phases, impurity inclusions, and residual stress that can influence corrosion. In addition, mechanical treatments can have effects on the corrosion properties, both positive and negative. Thus, alloying, metallurgical treatments, and mechanical treatments can greatly affect the corrosion resistance of the resulting alloy.

Galvanic Couples

Galvanic corrosion occurs when two or more dissimilar metals or alloys immersed in the same electrolyte are in electrical contact. The metal in the galvanic couple with the lower corrosion (electrochemical) potential has its potential pulled in the positive direction by the metal that has the higher corrosion potential. This generally causes the metal or alloy with the lower potential to experience accelerated corrosion. On the other hand, the metal with the higher corrosion potential undergoes a negative shift in potential, causing it to support additional cathodic reaction and thus to corrode less. The principles of galvanic corrosion can be and often are used as means of corrosion protection. In this case, a sacrificial metal (a sacrificial anode) is attached to a structure having a higher corrosion potential to intentionally lower the potential of the higher- potential metal or alloy and thus decrease the corrosion rate. This type of protection is called sacrificial cathodic protection (SACP). The lowering of potential can also be accomplished by applying a direct electrical current from an external source. This is impressed-current cathodic protection (ICCP). An undesired consequence of excessive cathodic protection (CP) or the use of cathodic protection with an inappropriate metal is that the potential can be pulled down to values where the hydrogen evolution reaction occurs. This, in turn, can lead to one of the forms of corrosion called hydrogen-induced cracking.

The lower-potential metal in a galvanic couple does not always have its corrosion rate accelerated. For metals that form a passive film, coupling with another metal of higher potential can cause the potential of the film-forming metal to shift from a value where it corrodes to one where a passive film is formed. When this is done intentionally, the procedure is referred to as anodic protection. Corrosion protection is achieved by moving the potential of the component to be protected in the positive direction. The passive film that forms acts as a barrier between the environment and the more active metal. However, the higher-potential metal in a galvanic couple is not always rendered less corrodible. A passive metal can sometimes be pulled out of its passive region and into a more corrosive region. A break in the passive film can lead to aggressive localized corrosion.

Introduction to Methods of Corrosion Protection

Paul Natishan, Naval Research Laboratory

Coatings

Coatings generally protect the metal by imposing a physical barrier between the metal substrate and the environment. Three common types of coatings are organic, inorganic, and metallic.

Organic coatings afford protection by providing a physical barrier between the metal and the environment. These coatings can also contain corrosion inhibitors. Organic coatings include paints, resins, lacquers, and varnishes. The properties of the coating depend on the formulation of the coating. To achieve the desired protection, the proper application of an organic coating on an appropriately prepared substrate is required. Organic coatings protect more metal on a weight basis than any other means of corrosion protection.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Inorganic coatings are also used to provide a barrier between the environment and the metal. Inorganic coatings include enamels, glass linings, and conversion coatings. Porcelain enamel coatings are inert in water and resistant to most weather. They are common on appliances and plumbing fixtures. Glass-lined metals are used in process industries where there is concern over corrosion or contamination of the product. Conversion coatings are produced by intentionally corroding the metal surface in a controlled manner. This is done to produce an adherent corrosion product that protects the metal from further corrosion. Anodization of aluminum, one of the more commonly used conversion coating techniques, produces a protective aluminum oxide film on the aluminum metal. Another example of a chemical conversion coating is phosphatizing for the protection of automobile bodies.

Metallic coatings create a barrier between the metal substrate and the environment. In addition, metallic coatings can sometimes provide cathodic protection when the coating is compromised. Metallic coatings and other inorganic coatings are produced using a variety of techniques, including hot dipping, electroplating, cladding, thermal spraying, chemical vapor deposition, or surface modification using directed energy (laser or ion) beams.

Introduction to Methods of Corrosion Protection

Paul Natishan, Naval Research Laboratory

Inhibitors

Corrosion inhibitors are substances that slow or prevent corrosion when added to an environment in which a metal usually corrodes. The effectiveness of corrosion inhibitors is dependent on the metal to be protected as well as on the operating environment. In addition, many inhibitors, most notably, chromates, are toxic, and environmental regulations limit the use of these agents. Some inhibitor types include anodic, cathodic, organic, precipitation, and vapor-phase inhibitors.

An understanding of the means of corrosion and corrosion protection methods can aid in the selection of materials and design of systems to protect the materials in their service environment. The following articles discuss traditional and emerging techniques used to improve corrosion resistance.

Alloying

Chemical composition is a primary factor in determining corrosion behavior of metals. Alloying has been the major means used to change the properties of metals (including corrosion). Alloys with varying degrees of corrosion resistance have been developed in response to ever- changing service environments. A good example of how corrosion resistance has been changed successfully by modifying the chemical composition is the alloying of iron to produce steels. Steels at the lower end of the alloying scale are less costly but also less corrosion resistant. These alloys are iron-base and contain a small amount (usually in the 0.5 to 3.0 wt% range) of nickel, molybdenum, chromium, or copper. They also generally have small amounts of phosphorus, nitrogen, and sulfur. At the higher end of the alloying scale are the more costly and significantly more corrosion-resistant stainless steels. Stainless steels contain a minimum amount (approximately 10.5 wt%) of chromium and, depending on the alloy, other elements such as nickel, molybdenum, and nitrogen. Figure 1 shows the effects of selected alloying elements on a 19Cr-9Ni stainless steel casting alloy. The corrosion resistance of stainless steels is based on the protective nature of the surface oxide film. The physical and chemical properties of the oxide film and the service environment determine the corrosion resistance of the alloy. Additional details on the stainless steels are presented in the following articles.

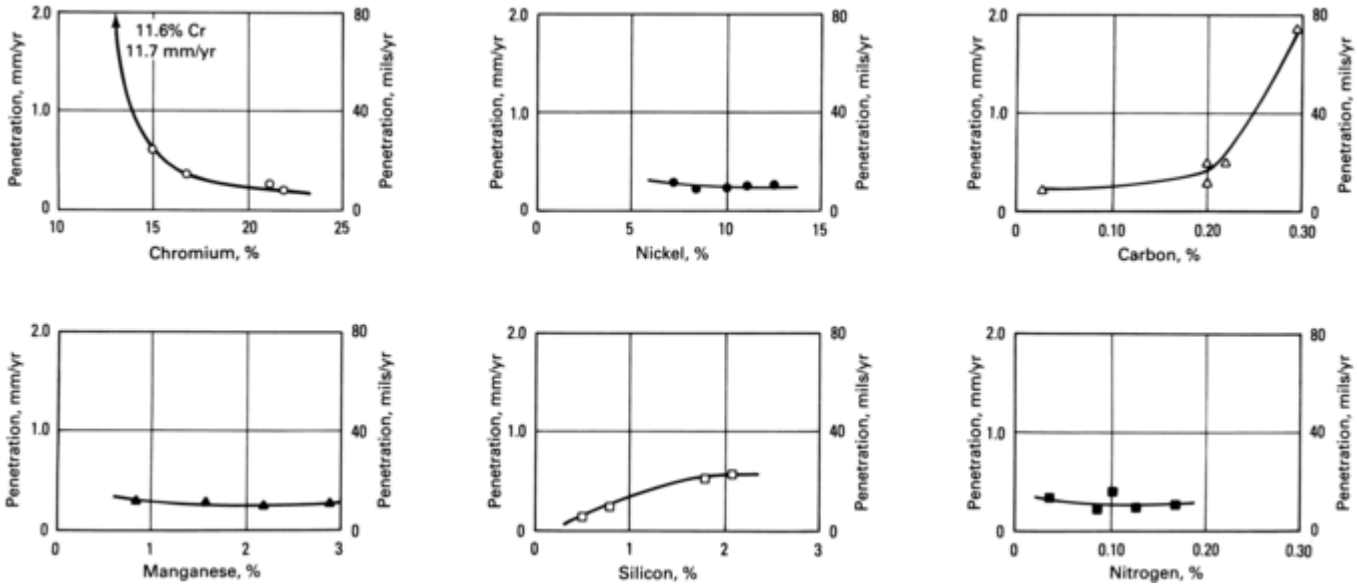

Fig. 1 The effect of alloying is shown as the influence that various elements have on the corrosion rate of a base 19Cr-9Ni casting alloy in boiling 65% nitric acid. The specimens were solution annealed and quenched. Composition of the base alloy was 19Cr, 9Ni, 0.09C, 0.8Mn, 1.0Si, 0.04P (max), 0.035S (max), and 0.06N (Ref 1).

Alloying does not always lead to better corrosion resistance. This can occur if the element being alloyed for corrosion resistance has a low solubility in the metal/alloy to which it is being added. The low solubility can result in the formation of a second phase, which can degrade, rather than enhance, the corrosion properties. This is the case for most aluminum alloys. Alloying elements that are typically used to increase the corrosion resistance have low solubility in aluminum when alloyed using conventional techniques.

Metallurgical Factors

In addition to alloying, there are metallurgical factors, such as crystallography, grain size and shape, grain heterogeneity, second phases, impurity inclusions, and residual stress, that can influence corrosion. Most metals/alloys of technological importance are polycrystalline aggregates, with each individual crystal referred to as a *grain.* Grain orientation can affect corrosion resistance, as evidenced by metallographic etching rates and pitting behavior. Grain shape and size likewise may vary greatly, depending on the alloy and processing history. Alloys, particularly in the as-cast condition, generally exhibit chemical inhomogeneity, such that there is segregation of alloying elements and impurities to the grain-boundary regions. These heterogeneities, which can also develop during subsequent processing such as welding or heat treatment, can produce different electrochemical characteristics at the grain boundary relative to the grain interior and can lead to intergranular corrosion. This problem can be of great practical importance, especially to wrought stainless steels and nickel alloys. Second phases, such as ferrite grains in an otherwise austenitic stainless steel and beta grains in an otherwise alpha brass, can be of considerable importance in some alloy systems and to some forms of corrosion. Figure 2 illustrates the relationship between microstructure and corrosion behavior.

Corrosion Resistance of Aluminum Alloys

Introduction

THIS ARTICLE addresses the general effects of composition, mechanical treatment, surface treatment, and processing on the corrosion resistance of aluminum and aluminum alloys. Most of the techniques used to alter the properties of aluminum are intended to improve mechanical and physical properties, but these techniques may actually cause degradation of corrosion resistance.

Most aluminum alloys can be produced with good corrosion resistance in natural atmospheres, such as freshwater, seawater, many soils and chemicals, and most foods. Thin-walled aluminum food containers, however, are coated to resist perforation (Ref 1). Corrosion resistance of a material must be defined in terms of the use of the material. For example, a pinhole perforation in a thin-walled food or beverage container is a corrosion failure, whereas pits of the same dimensions in an aluminum plate would not be considered corrosion failure. On the other hand, an aluminum roofing sheet may experience some shallow pitting and staining to the extent that its appearance changes. This can be considered either an aesthetic corrosion failure or acceptable corrosion resistance, because the roof has no perforations.

Thermodynamically, aluminum is a very active metal. Pure aluminum and all aluminum alloys depend on a naturally occurring aluminum oxide film to provide corrosion protection. This oxide film is adherent, transparent, stable in the pH range of approximately 4 to 9, self-healing, and an electrical insulator. While being protected from uniform corrosion, the most common form of corrosion found on aluminum alloys is localized pitting. This form of corrosion occurs when a corrosive species such as chloride ions compromises the integrity of the oxide film at local sites.

Alloying to Improve Corrosion Resistance

There are five major alloying elements—copper, manganese, silicon, magnesium, and zinc— that significantly influence the properties of aluminum alloys. Other alloying components that are less significant from a corrosion-resistance standpoint are iron, chromium, titanium, zirconium, lithium, and nickel. These are frequently included to improve mechanical and other physical properties. The effects of each of the five major alloying elements are discussed briefly. Some aluminum alloys are binary, while others are multiconstituent, containing three or four major alloying additions. The alloys are grouped by series, based on the alloy designations for wrought aluminum of The Aluminum Association International (Ref 2). The following sections describe the corrosion behavior of each general alloy class. While this discussion is specifically focused on wrought product forms, castings of similar compositions generally behave similarly.

1*xxx* Series. The alloys in this series are at least 99% pure aluminum. These materials are really not alloys but rather are pure aluminum with various levels of impurities. The major impurities are iron and silicon. These materials are relatively corrosion resistant. In compositions with higher iron content, there is a tendency toward pitting corrosion, especially in aqueous chloride solutions.

2*xxx* Series. The alloys in this series contain primarily copper, up to 7%. Several also contain magnesium and/or manganese. The alloys in this series are strengthened by thermal processing. These alloys attain high strengths and are used in sheet, plate, and extruded forms, primarily in aerospace applications. Copper in aluminum alloys generally decreases the resistance to general corrosion and pitting. With proper heat treatment, quenching, and aging, these alloys can achieve moderately good resistance to stress- corrosion cracking and other forms of intergranular corrosion. The resistance to general and pitting corrosion is strongly influenced by the copper content in these alloys, regardless of thermal processing control. Several of the alloys in this series contain lithium (<2.5%), and a few also contain silver (<1%). The corrosion resistance of these low-density alloys is similar to other alloys in this series. A special group of alloys in this series contains nickel (<2.5%), which imparts high-temperature corrosion resistance for applications such as internal combustion engine pistons.

3*xxx* Series. The alloys in this series contain primarily manganese, up to 1.5%. Several also contain magnesium, up to 1.5%. The alloys in this series are strengthened by work hardening and are produced in extruded, sheet, and plate forms. Manganese has minimal impact on the corrosion resistance of aluminum alloys. These alloys have only moderate strengths and good corrosion resistance. Alloys in this series find use in beverage and food containers, building products, heat-exchanger tubing, and other general uses requiring good corrosion resistance.

4*xxx* Series. The alloys in this series contain primarily silicon, up to 14%. Because of their low melting points, these alloys are used primarily for braze and weld filler applications. These alloys are usually produced as sheet or wire and are found in the as-cast condition following a thermal joining process. The silicon in these alloys generally does not promote corrosion of the alloy itself. However, when used in a thermal joining process, there have been cases where the silicon has diffused into the grain boundaries of the materials being joined, causing decreased corrosion resistance.

5*xxx* Series. The alloys in this series contain primarily magnesium, up to 6%. Several of the alloys also contain manganese. Alloys in this series are strengthened by work hardening and are produced primarily as sheet and

plate. Several of the alloys that are produced as drawn wire are used in the production of window screens and as weld filler. The magnesium additions generally improve the corrosion resistance of these alloys, especially in saltwater. The 5*xxx* series of alloys can be divided into two groups: low magnesium (under 3%) and high magnesium (3 to 6%). The low-magnesium alloys have very good corrosion resistance in a broad range of environments. The high-magnesium alloys have greater strength than the low-magnesium alloys, and they have outstanding corrosion resistance in saltwater environments. The only drawback to the high-magnesium alloys is that they can be susceptible to intergranular forms of corrosion, including exfoliation and stress-corrosion cracking. This corrosion susceptibility can be avoided by using particular tempers and by limiting the maximum service temperatures to 65 °C (150 °F). The high- magnesium alloys are used extensively in marine vessels and structures.

6*xxx* Series. The alloys in this series contain primarily magnesium (<2%) and silicon (<2%), which form a strengthening constituent, magnesium silicide. Several of the alloys in this series also contain copper (<1.2%) and/or manganese (<1.2%). The alloys in this series are strengthened by thermal processing to have moderate strength; they generally have good corrosion resistance. Those that contain copper have somewhat poorer corrosion resistance than those without copper. The range of alloys in this series is very broad. Some of the alloys are produced only as sheet products for applications such as automotive body panels; others are produced only as extrusions for use as structural shapes. Still others are produced as extrusions and sheet. At least one of the alloys is produced as extrusions, sheet, and plate.

7*xxx* Series. The alloys in this series all contain zinc, up to 9%. In addition, nearly all of these alloys contain magnesium (<4%), and many of them contain copper (<3%). The alloys in this series are strengthened by thermal processing, resulting in several that are among the strongest commercially available aluminum alloys. Most of the alloys in this series are produced in both sheet and plate products; several of the alloys are also produced as extrusions. Because of their significant copper content, most of these alloys have only moderate resistance to general corrosion and pitting. When overaged tempers are used, these alloys have good-to-excellent exfoliation and stress-corrosion-cracking resistance. A few of the alloys in this series have very little copper and are used for special corrosion-related applications, such as sacrificial cladding on alclad sheet products.

8*xxx* Series. The alloys in this series do not fit into any of the previous series. Most of these alloys contain significant quantities of iron (<10%). A number of these alloys are produced as foils for consumer and commercial food wraps. In these applications, the alloys have very good corrosion resistance. Also, several of these alloys contain copper (<2%), magnesium (<2%), and lithium (<3%), with little or no iron. The lithium is added to reduce the density of the alloys for weight-critical aerospace applications. These low-density alloys are produced as sheet and plate that are thermally processed to develop strength. These alloys have corrosion resistance similar to many of the 7*xxx* alloys.

Mechanical Treatments to Improve Corrosion Resistance

The major impact of mechanical treatment on corrosion of aluminum alloys is the application or removal of stresses that could lead to stress- corrosion cracking. Operations such as forming, bending, and machining can

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

create residual stress in aluminum alloys. Assembly will inpart stresses on components. When tolerances are tight for interference fits or loose due to misalignment, stresses are introduced. Stresses created by forming and machining can be relieved by shot peening the stressed area. This replaces the surface tensile stress with compressive stress that will not cause stress-corrosion cracking. Care should be taken when shot peening to avoid embedding metallic particles into the relatively soft aluminum surface. Fit-up stresses can be minimized by careful selection of tolerances during design and by applying adequate quality- control procedures during manufacture of parts.

Surface Treatment to Improve Corrosion Resistance

Surface treatments that aid in preventing corrosion are of several different types. There are organic coatings or paints that provide a barrier between a corrosive environment and the aluminum surface. (See the article “Organic Coatings and Linings” in this Volume.) There are inorganic coatings, including claddings, and enhanced oxides, such as anodized films, Boehmite films, and conversion coatings. Each of these is discussed in more detail in the following paragraphs.

Organic coating systems are frequently applied to aluminum for strictly decorative purposes. For example, they are applied to aluminum siding and exposed automobile body panels to obtain desired color and to prevent natural weathering that is aesthetically unacceptable but structurally insignificant. Organic coatings may also be applied to aluminum for corrosion protection in special situations. In both cases, adequate surface preparation and careful coating selection are important to achieve the desired coating life.

Most organic coatings provide corrosion protection by forming a physical barrier between the aluminum surface and the environment. Some contain inhibitors, such as chromate primers. Aluminum insulation jacketing and refrigerator liners are coated on the back with a vapor barrier to prevent poultice and crevice corrosion when condensation collects between foamed insulation and the aluminum. Clear organic coatings are used where the look of a natural aluminum surface is desired and where weathering must be prevented. Temporary organic coatings are sometimes used to protect aluminum surfaces from corrosion during storage and transit. Heavy organic coatings, such as mastics and coal tars, are sometimes used to protect aluminum surfaces that are embedded in soils and concrete.

The performance of organic coating systems can be maximized by following the specific recommendations of suppliers regarding surface preparation; pretreatment; selection of compatible conversion coat, primer, and topcoat; application; and curing. If continuing maximum corrosion protection is required, the organic coating systems must be maintained.

Alclad aluminum is a duplex product in which a thin surface layer of one aluminum alloy (usually 5 to 10% of the total thickness) is metallurgically bonded to the main core alloy selected for strength. In order to ensure effective sacrificial cathodic protection of the core alloy, the clad alloy is usually selected to be at least 100 mV anodic to the core (Ref 3).

The surface layer is normally 1*xxx* for 2*xxx* cores, or 7072 for 3*xxx*, 5*xxx*, 6*xxx*, and 7*xxx* cores. The alclad aluminum alloys provide resistance to perforation by pitting corrosion. Pits do not penetrate into the core alloy, so loss of mechanical properties on long-term exposure to corrosive atmospheres is minimized. As an example, a kitchen kettle fabricated from sheet with a 5% layer of 7072 alloy on a 3003 core alloy resisted perforation in an aggressive water for 5 to 10 times the life of an unclad 3003 alloy kettle in the same water. Another example is the alclad 3004 roofing and siding on the hangar for Howard Hughes' *Spruce Goose* in a Long Beach, CA harbor that, after 33 years, had pitted only to the depth of the clad layer, 76 μm (3 mils). Further, the cladding

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

of thin-wall (1.5 mm, or 0.060 in.) irrigation pipe and culvert sheet greatly extends the time to perforation in aggressive waters.

Anodized Films. A commercial surface treatment unique to aluminum is anodizing. (See the article “Aluminum Anodizing” in this Volume.) The object to be treated is immersed as the anode in an acid electrolyte, and a direct current is applied. Oxidation of the surface occurs to produce a greatly thickened, hard, porous film of aluminum oxide. This film is then normally immersed in boiling water to seal the porosity and render the film impermeable (Ref 1).

Before sealing, the film can be colored by impregnation with dyes or pigments. Special electrolytes are sometimes used to produce colored anodic films directly in the anodizing bath. The degree of protection conferred to the surface depends on the thickness of the film, which may be 8 μm (0.3 mils) in the case of shiny automobile trim moldings, to 25 μm (1.0 mil) or more on the aluminum facade of a monumental building. These represent a thickening of the natural oxide film by a factor of approximately 1000 and 3000 times, respectively.

Architectural aluminum, such as handrails, doors, windows, and facades, is often anodized. The surface retains less atmospheric dirt and is much easier to clean. The anodic film has the same chemical characteristics as the natural oxide film and is corroded by strong alkalis and strong acids. In industrial atmospheres, the film tends to pit, with the time to initiation depending on the film thickness. To preserve the initial appearance of anodized aluminum facades, thick anodic films are coated with clear organic coating. The main virtues of an anodic film are its decorative appeal and the ease of cleaning. Anodizing is rarely the solution to a field corrosion problem.

Boehmite Films. The natural surface oxide film can be thickened by exposure to moving water, hot soft water, or steam. If this is done before exposure to a pitting-type environment, pitting is sometimes prevented. In one experiment, a specimen of 1200 alloy sheet that had previously been exposed for 1 year in a nonpitting freshwater with an estimated film thickness of 80 nm failed to pit in 16 days when immersed in a very aggressive water that produced a 965 μm (38 mil) pit on a fresh sheet specimen in the same period (Ref 1).

Conversion Coatings. A number of proprietary chemical immersion treatments, such as Alodine (Henkel Surface Technologies), Bonderite (Henkel Surface Technologies), Iridite (MacDermid Inc.), and others, are used to produce a complex surface conversion coating approximately 20 nm thick on aluminum sheet and extrusions before painting in a factory operation, compared to 5 nm for an untreated surface. The proprietary solutions are acidic and contain chromates, phosphates, and other chemicals. Such films greatly improve paint adhesion (Ref 1). (See the article “Chromate and Chromate-Free Conversion Coatings” in this Volume.)

The films, which contain chromates, have corrosion-preventive properties in their own right and are used on some aircraft and automotive components. However, they are relatively soft and can be used for corrosion prevention without overcoating only where there is no abrasion expected in service.

Processing to Improve Corrosion Resistance

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Processing steps that lead to improved corrosion resistance fall into two groups: those that increase the uniformity of the distribution of alloying elements, constituents, and impurities, and those that decrease residual stresses. Nearly all of these are thermal processing steps that occur either during production of sheet, plate, and extrusions or following fabrication of the sheet, plate, and extrusions into semifinished or finished parts. The steps that can have relatively significant impact on corrosion resistance are enumerated in the following paragraphs.

Homogenization. Following casting, extrusion billets and rolling ingots are homogenized to make the composition more uniform and to improve workability. The uniformity of composition generally leads to improved corrosion resistance. This step includes holding the cast shape at an elevated temperature for a period of time that is usually measured in hours.

Rolling and Extrusion Temperatures. The temperature at which rolling and extrusion are performed can have an impact on intergranular corrosion resistance of the resulting product. The temperature at which products exit the deformation process can have an especially significant impact on the grain morphology and the composition at the grain boundaries. These temperatures are especially important for the 3*xxx*- and 5*xxx*-series alloys, because they are work hardened and often receive no further thermal treatments.

Quenching. The rate of cooling (quench rate) of aluminum products following either elevated- temperature fabrication or heat treatment can have a significant impact on the corrosion resistance of heat treated alloys. Rapid quenching generally freezes the metal with a more uniform composition than if the quench is slow, which allows composition gradients at grain boundaries. This is especially true for 2*xxx*- and 7*xxx*- series alloys that can be susceptible to intergranular forms of corrosion (exfoliation and stress-corrosion cracking) if not quenched properly. The 6*xxx*-series alloys can also have intergranular corrosion problems if not quenched properly, although the corrosion problems are not as severe as those found with the 2*xxx*- and 7*xxx*-series alloys.

Aging. The artificial aging process that is used to strengthen the heat treatable 2*xxx*-, 6*xxx*-, and 7*xxx*-series alloys can have a significant impact on corrosion resistance, even though it is conducted at relatively low temperatures. In many cases, the peak aged condition that provides maximum strength also provides reduced corrosion resistance, especially in the 7*xxx*-series alloys. By overaging, there is a small decrease in strength but a significant improvement in exfoliation and stress-corrosion-cracking resistance. Careful aging can also improve the corrosion resistance of several of the 6*xxx*-series alloys that find use as automotive body sheet. The aging of the automotive body sheet alloys is frequently accomplished by the paint bake cycle that is applied during the coating process. In addition to impacting grain-boundary chemistry, aging may serve to relieve stresses created in the material during rolling or extrusion.

Annealing is a moderate temperature treatment that relieves residual stress, lowers strength, and increases ductility and formability. Annealing improves corrosion resistance, but the accompaning loss of strength may be too great to be practical. In applications where strength is not of primary importance, aluminum alloys in the annealed condition provide the best corrosion resistance available.

Corrosion Resistance of Aluminum Alloys

Jack Snodgrass and Jim Moran, Alcoa, Inc.

Selection of Fabrication Operations

Fabrication operations that create residual stress, change grain shape, and alter boundary composition can negatively impact corrosion resistance. Operations of particular concern include bending, stretching, shearing, punching, and welding. All of these operations increase residual tensile stresses. To reduce the impact of these operations on stress-corrosion-cracking resistance, the material can be stress relieved following the operation by the controlled application of heat or by shot peening. Alternately, the fabrication operation can be performed on

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

a material with a lower-strength temper, followed by an appropriate thermal strengthening treatment to the desired temper. In some alloys, especially those that are work hardened, several of these operations can cause changes in grain structure, such as grain growth and grain-boundary composition changes. Attention to these details can improve corrosion resistance.

Corrosion Resistance of Magnesium Alloys

Revised by Barbara A. Shaw, Pennsylvania State University

Introduction

MAGNESIUM AND MAGNESIUM ALLOYS are often thought of as rapidly corroding metals because of their active positions in both the electromotive force (EMF) series (Table 1) and the galvanic series for seawater (see Fig. 1 in the article “Evaluating Galvanic Corrosion” in this Volume). However, depending on the environment and certain design considerations, the corrosion of magnesium can be well within acceptable design limits. Knowledge of environmental factors that influence degradation, types of corrosion to which magnesium alloys are most susceptible, protection schemes, and design considerations can significantly minimize corrosion and increase use of this family of lightweight structural metals.

When unalloyed magnesium is exposed to the air at room temperature, a gray oxide forms on its surface. Moisture converts this oxide to magnesium hydroxide, which is stable in the basic range of pH values, but is not in the neutral or acid ranges as shown in the Pourbaix diagram (Fig. 1). The immunity region of the diagram is well below the region of water stability; as a result, in neutral and low pH environments magnesium dissolution is accompanied by hydrogen evolution. In basic environments, passivation is possible as a result of the formation of a $Mg(OH)_2$ layer on the metal surface. Since the films that form on unalloyed magnesium are slightly soluble in water, they do not provide long-term protection (Ref 2). When chloride, bromide, sulfate, and chlorate are present, the surface films break down. Likewise, as the CO_2 in air acidifies water, the films are not stable. Corrosion potentials for magnesium electrodes in a variety of aqueous solutions are presented in Table 2, while corrosion rate data in water and several other media are presented in Fig. 2 and Table 3.

Unalloyed magnesium is not extensively used for structural purposes. Consequently, the corrosion resistance of magnesium alloys is of primary concern. Two major magnesium alloy systems are available to the designer.

The first includes alloys containing 2 to 10% Al, combined with minor additions of zinc and manganese. These alloys are widely available at moderate cost, and their room-temperature mechanical properties are maintained to 95 to 120 °C (200 to 250 °F). Beyond this, elevated temperatures adversely affect mechanical properties and the corrosion properties deteriorate rapidly with increasing temperature.

The second group consists of magnesium alloyed with various elements (rare earths, zinc, thorium, and silver) except aluminum, all containing a small but effective zirconium content that imparts a fine grain structure and thus improved mechanical properties. These alloys generally possess much better elevated-temperature properties, but the more costly elemental additions combined with the specialized manufacturing technology required result in significantly higher costs. Table 4 lists some of the compositions commonly available in both systems. Note the aluminum group alloy designations begin with “A.”

Corrosion Resistance of Magnesium Alloys

Revised by Barbara A. Shaw, Pennsylvania State University

Metallurgical Factors

Chemical Composition. As the galvanic series in seawater reveals, magnesium is anodic to all other structural metals and, as a result, galvanic interactions between magnesium and other metals are a serious concern. The influence of cathodic iron impurities on the corrosion of commercially pure magnesium is presented in Fig. 3. Above the tolerance level of 170 ppm for iron in magnesium, the corrosion rate increases dramatically. Figure 4 shows the effects of iron and 13 other elements on the saltwater corrosion performance of magnesium in binary alloys with increasing levels of the individual elements. Six of the elements included in Fig. 4 (aluminum,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

manganese, sodium, silicon, tin, and lead), as well as thorium, zirconium, beryllium, cerium, praseodymium, and yttrium, have little if any deleterious effect on the basic saltwater corrosion performance of pure magnesium when present at levels exceeding their solid solubility or up to a maximum of 5% (Ref 6). Four elements in Fig. 4 (cadmium, zinc, calcium, and silver) have mild-to-moderate accelerating effects on corrosion rates, whereas four others (iron, nickel, copper, and cobalt) have extremely deleterious effects because of their low solid-solubility limits and their ability to serve as active cathodic sites for the reduction of water at the sacrifice of elemental magnesium. Although cobalt is seldom encountered at detrimental levels and cannot be introduced even through the long immersion of cobalt steels in magnesium melts, iron, nickel, and copper are common contaminants that can be readily introduced through poor molten-metal-handling practices. These elements must be held to levels under their individual solubility limits, or their activity must be moderated through the use of alloying elements such as manganese or zinc, to obtain good corrosion resistance. These limits are stated in Table 5 for die-cast products.

AZ91B	0.35	0.03	0.3[(b)]	0.13–0.50
AZ91D	0.30	0.002	0.005[(a)]	0.15–0.50[(b)]

Per ASTM B 94.

(a) In alloys AS41B, AM50A, AM60B, and AZ91D, if either the minimum manganese limit or the maximum iron limit is not met, then the iron/manganese ratio shall not exceed 0.010, 0.015, 0.021, and 0.032, respectively.

(b) Not specified, but included in the limits for “other metals”

Figure 5 illustrates the effect of increasing iron, nickel, and copper contamination on the standard ASTM B 117 salt-spray performance of die-cast AZ91 test specimens as compared to the range of performance observed for cold-rolled steel and die-cast aluminum alloy 380 samples. Such results have led to the definition of the critical contaminant limits for two magnesium-aluminum alloys in both low- and high-pressure cast form and the introduction of improved high- purity versions of the alloys. Table 6 lists some of the critical contaminant limits defined to date. The iron tolerance for the magnesium-aluminum alloys depends on the manganese present, a fact suggested many years ago but only recently proved. For AZ91 with a manganese content of 0.15%, this means that the iron tolerance would be 0.0048% (0.032 × 0.15%) (Ref 11).

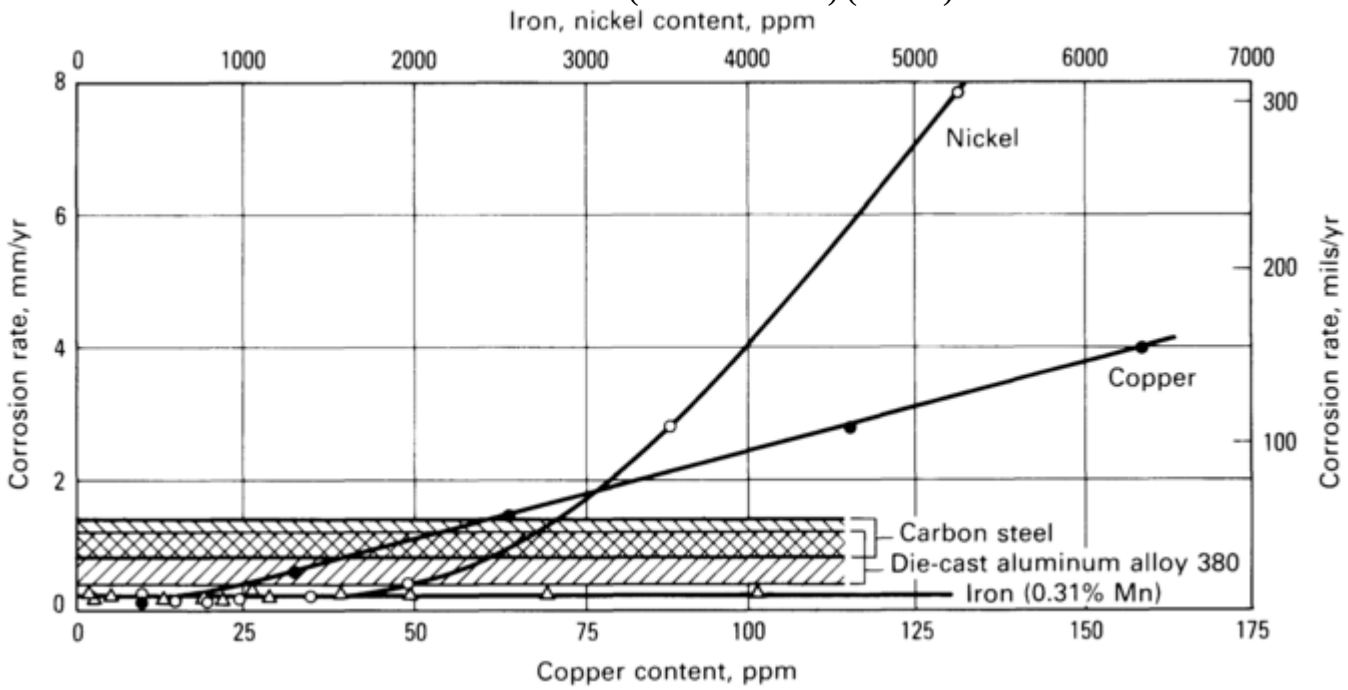

Fig. 5 Effect of nickel and copper contamination on the salt-spray corrosion performance of die-cast AZ91 alloy. Source: Ref 7

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Table 6 Known contaminant tolerance limits in high- and low-pressure cast forms

Alloy/form	Grain size, μm	Critical contaminant limit, %			Ref
		Fe	**Ni**	**Cu**	
Unalloyed magnesium	…	0.015	0.0005	0.1	5
AZ91/high pressure	5–10	0.032 Mn[(a)]	0.0050	0.040	8
AZ91/low pressure	100–200	0.032 Mn[(a)]	0.0010	0.040	8
AM60/high pressure	5–10	0.021 Mn[(b)]	0.0030	0.010	7
AM60/low pressure	100–200	0.021 Mn[(b)]	0.0010	0.010	9
AZ63/low pressure	…	0.003[(c)]	0.0040	>0.45	5
K1A/low pressure	…	>0.003	0.003	…	10

(a) Iron tolerance equals manganese content of alloy times 0.032.
(b) Iron tolerance equals manganese content of alloy times 0.021.
(c) Magnesium content of AZ63 reported as 0.2%

It should also be noted that the nickel tolerance depends strongly on the cast form, which influences grain size, with the low-pressure cast alloys showing just a 10 ppm tolerance for nickel in the as-cast (F) temper. Therefore, alloys intended for low-pressure cast applications should be of the lowest possible nickel level (Ref 8). The low tolerance limits for the contaminants in AM60 alloy when compared to AZ91 alloy can be related to the absence of zinc. Zinc is thought to improve the tolerance of magnesium-aluminum alloys for all three contaminants, but it is limited to 1 to 3% Zn because of its detrimental effects on microshrinkage porosity and its accelerating effect on corrosion above 3%.

For magnesium-rare earth, -thorium, and -zinc alloys containing zirconium, the normal saltwater corrosion resistance is only moderately reduced when compared to high-purity magnesium and magnesium-aluminum alloys—0.5 to 0.76 mm/yr (20 to 30 mils/yr) as opposed to less than 0.25 mm/yr (10 mils/yr) in 5% salt spray—but contaminants again must be controlled. The zirconium alloying element is effective in this case because it serves as a strong grain refiner for magnesium alloys, and it precipitates the iron contaminant from the alloys before casting. However, if alloys containing more than 0.5 to 0.7% Ag or more than 2.7 to 3% Zn are used, a sacrifice in corrosion resistance should be expected (Fig. 4). Nevertheless, when properly finished these alloys provide excellent service in harsh environments.

Heat Treating, Grain Size, and Cold-Work Effects. Heating influences the salt-spray corrosion rate of die-cast commercial magnesium-aluminum alloys as shown in Fig. 6, which shows that alloys with higher residual-element (iron, nickel, and copper) concentrations were more negatively impacted by temperature. Using controlled-purity AZ91 alloy cast in both high- and low-pressure forms, the contaminant-tolerance limits have been defined as summarized in Table 7 for the as-cast (F), the solution treated (T4, held 16 h at 410 °C, or 775 °F, and quenched), and the solution treated and aged (T6, held 16 h at 410 °C, or 775 °F, quenched, and aged 4 h at 215 °C, or 420 °F).

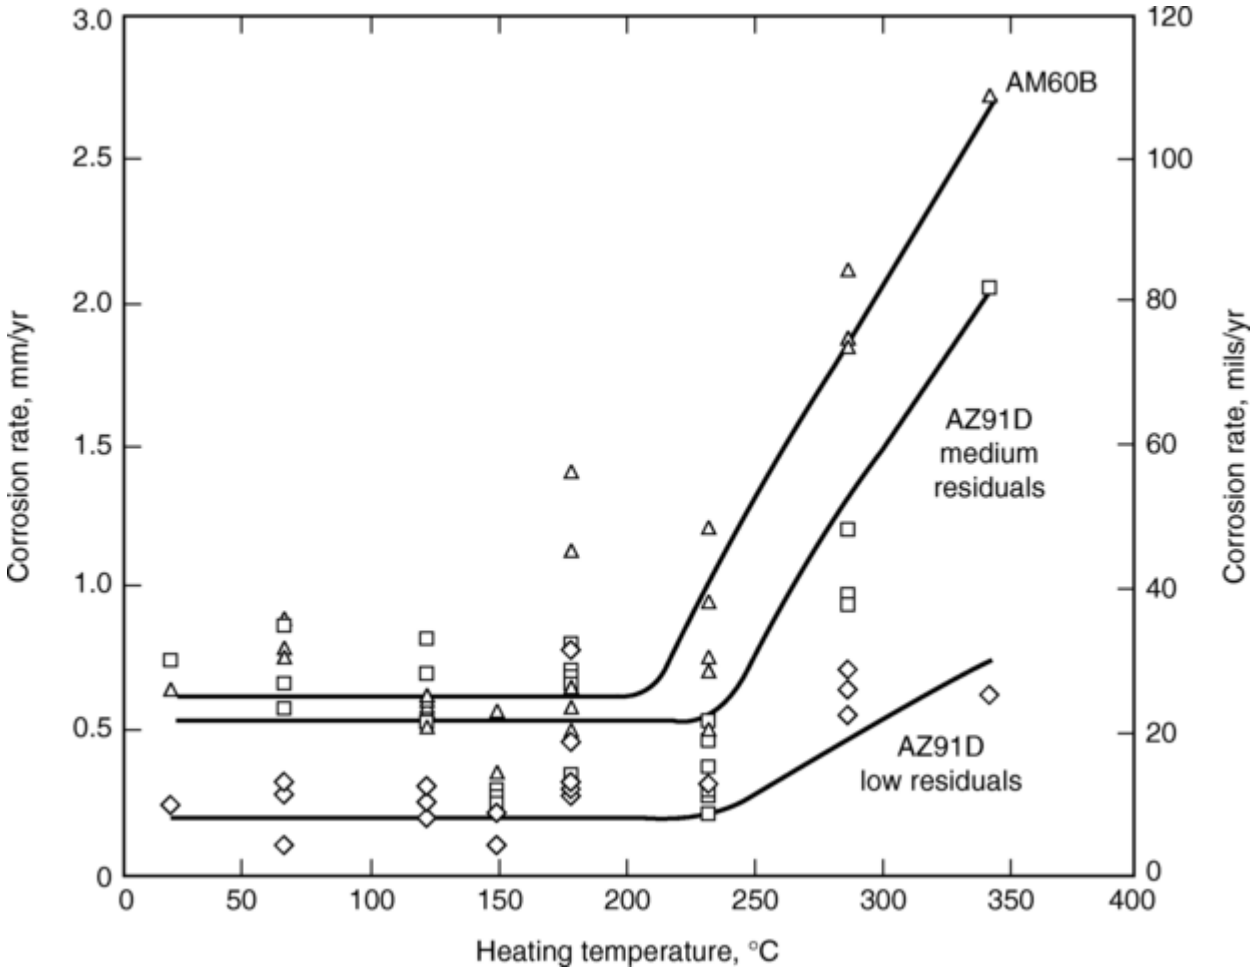

Fig. 6 Effect of heating temperature on corrosion rate of die-cast AZ91D and AM60B in salt-spray test for 10 days using ASTM B 117 method. Data are for test specimens that were heated from 0.5 to 36 h. Source: Ref 12

Table 7 Contaminant tolerance limits versus temper and cast form for AZ91 alloy

High-pressure die cast, 5–10 μm average grain size; low- pressure cast, 100–200 μm average grain size

Contaminant, %	Critical contaminant limit[(a)]			
	High pressure	**Low pressure**		
	F	**F**	**T4**	**T6**
Iron	0.032 Mn	0.032 Mn	0.035 Mn	0.046 Mn
Nickel	0.0050	0.0010	0.001	0.001
Copper	0.040	0.040	<0.010	0.040

(a) Tolerance limits expressed in wt% except for iron, which is expressed as the fraction of the manganese content (for example, the iron tolerance of 0.2% Mn alloy = 0.0064% Fe in F temper)

Table 8 compares the average 5% salt-spray corrosion performance of sand-cast samples produced in a standard AZ91C and a high-purity AZ91E composition. The alloys were cast with and without standard grain-refining practices used to evaluate physical and compositional effects. The cast samples were then tested in the F, T4, T6, and T5 (aged 4 h at 215 °C, or 420 °F) tempers. In the case of the high-iron-containing AZ91C, none of the variations tested significantly affected the poor corrosion performance resulting from an iron level two to three times the alloy tolerance. In the case of the high-purity alloy, however, the T5 and T6 tempers consistently gave salt-spray corrosion rates less than 0.25 mm/yr (10 mils/yr), whereas the as-cast and solution-treated samples exhibited an inverse response to grain size and/or the grain-refining agents. Welds on Mg-Al-Zn alloys should be aged or should be solution treated and aged to obtain good corrosion resistance in harsh environments and to reduce the risk of failure due to stress-corrosion cracking (SCC).

Table 8 Typical corrosion rates versus temper and grain size for two magnesium alloys

Cold working of magnesium alloys, such as stretching or bending, has no appreciable effect on corrosion rate. Shot- or grit-blasted surfaces often exhibit poor corrosion performance—not from induced cold work but from embedded contaminants. Acid pickling to a depth of 0.01 to 0.05 mm (0.0004 to 0.002 in.) can be used to remove reactive contaminants, but unless the process is carefully controlled, reprecipitation of the contaminant is possible, particularly with steel shot residues. Therefore, fluoride anodizing is often used when complete removal of the contaminant is essential (Ref 9).

Corrosion Resistance of Magnesium Alloys

Revised by Barbara A. Shaw, Pennsylvania State University

Causes of Corrosion Failures in Magnesium Alloys

Causes of corrosion failures typically include heavy-metal contamination, blast residues, flux inclusions, and galvanic attack.

Heavy-metal contamination often results in general pitting attack that is unassociated with fasteners or dissimilar-metal attachments. The rate of attack on unpainted surfaces will be essentially unaltered by surface condition, that is, freshly sanded, machined, or acid pickled. Figure 7 illustrates the effect of heavy-metal contamination on the ASTM salt-spray corrosion performance of low-pressure cast AZ91.

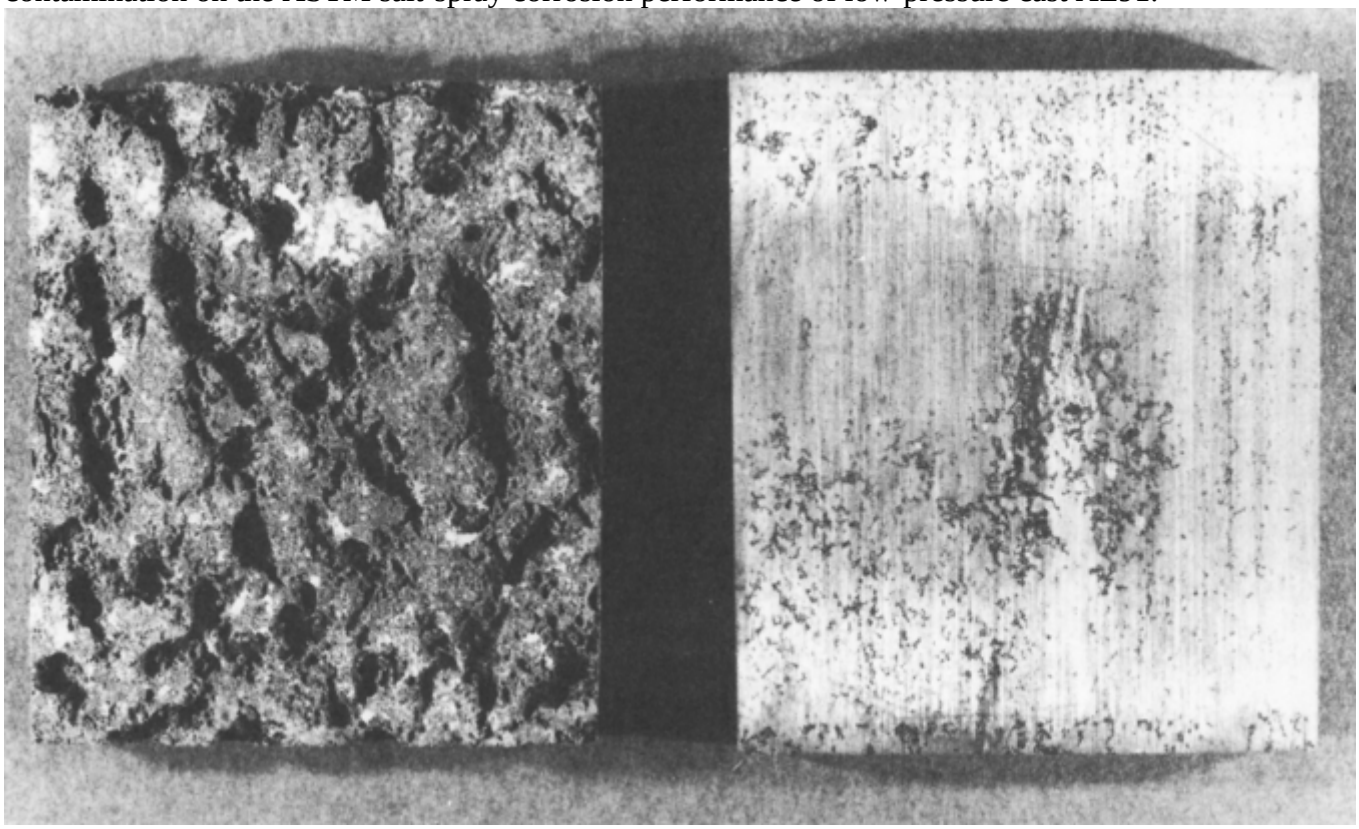

Fig. 7 Effect of heavy-metal contamination on the salt-spray performance of sand-cast AZ91 samples in the T6 temper, as determined by ASTM B 117 method. The samples, containing less than 10 ppm Ni and less than 100 ppm Cu, were simultaneously exposed for 240 h. The sample at left contained 160 ppm Fe and had a corrosion rate of 15 mm/yr (591 mils/yr). The sample at right contained 19 ppm Fe, and the corrosion rate was 0.15 mm/yr (5.9 mils/yr).

Blast residues can cause general pitting attack in saline environments. Attack is normally limited to unmachined surfaces of sand castings. Sanded or acid-etched (2% H_2SO_4 for 15 to 30 s) samples will show vastly improved performance in saltwater immersion or salt-spray tests because of removal of the contaminant. Scanning electron microscopy and energy-dispersive x-ray analysis samples cleaned in chromic acid (H_2CrO_4) can be used to confirm and identify the presence of the contaminant, which is usually iron (from steel shot blasting) or silica (from sand blasting).

Flux inclusions result in localized attack that is clustered or distributed randomly on machined surfaces of castings. Freshly machined surfaces exposed to 70 to 90% relative humidity will develop active corrosion sites

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

overnight. Scanning electron microscopy/energy-dispersive x-ray analysis of a freshly machined surface (free of fingerprints or other sources of contamination) will reveal pockets of magnesium and potassium chloride, as well as possible traces of calcium, barium, and sulfur. In zirconium-bearing alloys, elemental zirconium and zirconium-iron compounds may also be associated with the deposits. Chromic-acid pickling followed by chemical treatment and surface sealing can alleviate the problem of inclusions in finished castings. With the use of sulfur hexafluoride (SF_6) rapidly replacing fluxes for the protection of melts during casting, this problem should be eliminated in the future.

Galvanic attack is usually observed as heavy localized attack on the magnesium, normally within 3.2 to 4.8 mm ($\frac{1}{8}$ to $\frac{3}{16}$in.) of fasteners or an interface with other parts of dissimilar metal. Proper design and assembly methods, especially in the area of joints, can minimize galvanic attack.

Corrosion Resistance of Stainless Steels and Nickel Alloys

A. John Sedriks, Office of Naval Research

Introduction

STAINLESS STEELS AND NICKEL-BASE ALLOYS are recognized for their resistance to general corrosion and other categories of corrosion. The effects of specific alloying elements, listed in Tables 1 and 2, metallurgical structure, and mechanical conditioning on corrosion resistance are examined in this article.

Corrosion Resistance of Stainless Steels and Nickel Alloys

A. John Sedriks, Office of Naval Research

Stainless Steels

Stainless steels are corrosion-resistant iron- base alloys containing a maximum of 1.2% carbon and a minimum of 10.5% chromium by weight. This is the minimum amount of chromium that prevents the formation of rust in humid, unpolluted atmospheres, hence the designation “stainless.” The corrosion resistance of stainless steels is provided by a very thin and protective surface film, known as the passive film, which, when damaged, is self-healing in the presence of a wide variety of environments.

The Fe-Cr-Ni and Fe-Cr-Ni-Mn-N grades of stainless steels are austenitic and are popularly known by the former American Iron and Steel Institute (AISI) type numbers in the 300 and 200 series, respectively. The Fe-Cr grades are martensitic at lower chromium levels, ferritic at higher chromium levels, and are known by numbers in the 400 series. The most popular austenitic, ferritic, and martensitic grades have been type 304 (containing 19% Cr, 10% Ni, and also known by the Unified Numbering System (UNS) number, S30400), type 430 (17% Cr, S43000), and type 410 (12% Cr, S41000), respectively. Another popular grade has been type 409 (11% Cr, S40900) because of its use in automobile exhaust systems. Duplex grades (containing approximately 50% austenite and 50% ferrite) and precipitation-hardening grades (mostly martensitic) are also available for higher strength applications.

Stainless steels are used for consumer products; for machinery; in architecture; for military applications (particularly for nonmagnetic hulls of submarines and mine countermeasure vessels); and for equipment in the petroleum, chemical, aerospace, power, and process industries. Environmental initiatives, such as flue gas desulfurization in the power industry and the adoption of closed-loop (zero discharge) processes in the pulp and paper industry, have increased the demand for stainless steels.

The manufacturers of stainless steels have tended to specialize as either flat-product producers or long-product producers. Flat products include plate, sheet, strip, and foil, whereas long products include bar, rod, wire, and forging billets. Products such as forgings, welded pipe and tube, seamless pipe and tube, fittings, and weld fillers are made from either long or flat products by mills dedicated to their production. Castings and powder metallurgy products are typically custom melted by specialty producers. Some 180 different alloys can be recognized as belonging to the stainless steel group and currently are produced, with alloy content adjusted to give improved resistance to pitting and crevice corrosion, intergranular corrosion caused by sensitization, stress-corrosion cracking (SCC) and hydrogen embrittlement, general corrosion, and attack by high-temperature gases (Fig. 1).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

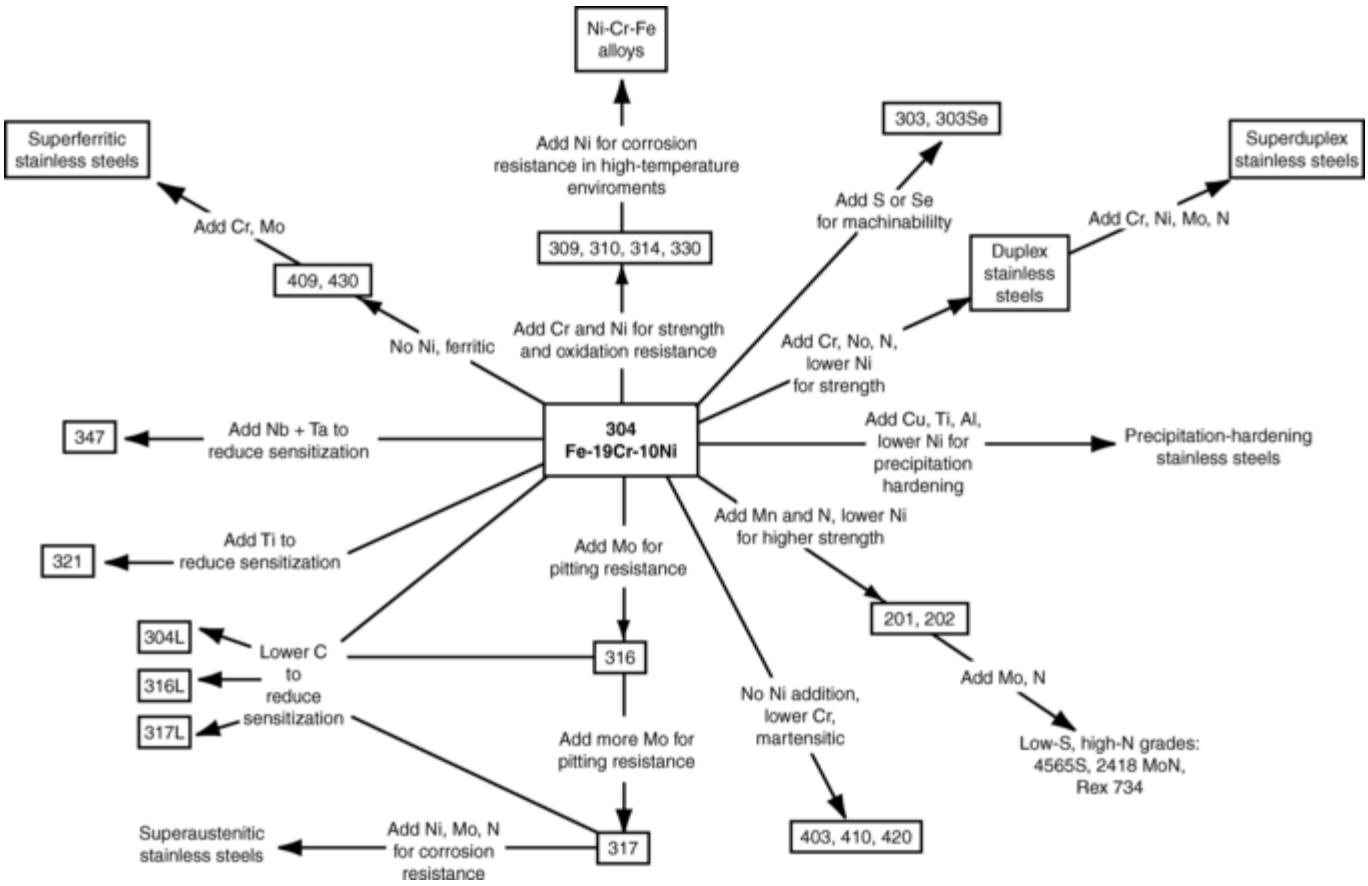

Fig. 1 Compositional and property linkages for stainless steels

Pitting and Crevice Corrosion. Resistance to pitting and crevice corrosion usually is improved by alloying the austenitic and duplex grades further with chromium, molybdenum, and nitrogen, and the ferritic grades with chromium and molybdenum. The beneficial effects of these alloying elements are complex and interactive. Attempts have been made by suppliers of stainless steels and nickel-base alloys to develop a compositionally derived pitting- and crevice-corrosion-resistance index known as the pitting-resistance equivalent number (PREN). The PREN is given by the alloying-element parameter %Cr + 3.3%Mo + 16%N + 1.65%W. In general, the larger the numerical value of PREN is, the higher the pitting and crevice-corrosion resistance will be, although a high numerical value of PREN should not be viewed as an absolute guarantee of freedom from localized attack. The major drawback in using a parameter based only on alloy content is that it ignores the often-found detrimental effects of microstructural constituents such as manganese sulfide inclusions, sigma and chi phases, chromium depleted zones, and alloying element segregation due to coring produced by weld solidification. However, PREN provides some guidance for alloy selection for service in oxidizing chloride or acidic environments. Among the proprietary stainless steels with a large numerical value of PREN are the superaustenitics, such as 254SMO (S31254), AL6XN (N08367), 925hMo (N08925), and 654SMO (S32654); the superferritics, such as 29-4C (S44735), Sea-Cure (S44660), and Monit (S44635); and the superduplexes, such as DP-3W (S39274), Ferralium 255 (S32550), SAF 2507 (S32750), Zeron 100 (S32760), and Uranus 52N+ (S32520).

Intergranular corrosion results from chromium depletion in the alloy matrix near grain- boundary chromium carbides (and sometimes nitrides). These can be precipitated during welding or some other high-temperature exposure. This depletion occurs at certain time-temperature combinations that are sufficient to precipitate chromium carbide but insufficient to rediffuse chromium back into the austenite near the carbide. For example, heating type 304 stainless steel containing 0.039% carbon for 10 h at 700 °C (1290 °F) results in the formation of chromium carbides that reduce the chromium level from 19% to less than 13% in the region next to the grain-boundary carbide precipitate, resulting in a loss of corrosion resistance in this region. This depletion is known as *sensitization.* Similar chromium depletion occurs in high-nitrogen duplex stainless steels due to the formation of chromium nitrides. Remedial measures for sensitization include alloying-element control procedures such as lowering the carbon content to 0.03% maximum, as in 304L (S30403), or stabilizing with titanium or niobium plus tantalum alloying additions (Fig. 1), or metallurgical treatments such as postweld

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

annealing to re-diffuse chromium back into the depleted regions. It should be noted that duplex stainless steels do not exhibit sensitization at the austenite-ferrite grain boundaries because of faster chromium diffusion and carbide growth kinetics in the ferrite phase. Nickel-base alloys are generally resistant to sensitization, because they are usually made either with sufficiently low carbon content or are stabilized with niobium.

Stress-corrosion cracking may occur in the presence of a tensile stress and a specific corrodent. Corrodents known to cause SCC in stainless steels are chloride solutions at elevated temperatures, caustic solutions, acids, aqueous solutions containing sulfur compounds, and high-temperature (300 °C, or 570 °F) water containing traces of dissolved oxygen. For SCC caused by sensitization, the remedies are the same as for intergranular corrosion. In other cases, susceptibility to SCC can be minimized or eliminated by alloying additions, metallurgical treatments, mechanical treatments, and chemical/electrochemical treatments. For example, susceptibility to SCC can be minimized by increasing the nickel content of the alloy (for austenitics only), selecting a suitable ferritic or duplex stainless steel instead of an austenitic one, lowering the service temperature, stress-relief annealing, shot peening to introduce compressive surface stresses, adding chemical corrosion inhibitors to the service environment, and cathodic protection. The last procedure should not be used for martensitic or precipitation-hardening stainless steels, which crack by a hydrogen embrittlement mechanism. For martensitic or precipitation-hardening stainless steels, tempering heat treatments to produce lower strengths may improve cracking resistance.

General corrosion (i.e., nonlocalized corrosion) can be encountered in strong acids or alkalies. Corrosion resistance in sulfuric and organic acids is promoted by alloying with copper, molybdenum, and nickel. Among alloys used in the chemical industry for sulfuric acid service are the copper-containing stainless steels and higher alloys, such as alloy 904L (N08904), 20Cb-3 (N08020), alloy 825 (N08825), and the cast stainless steel CN-7M (J95150), whereas higher-silicon stainless steel, such as S32615, has been used for handling hot, concentrated sulfuric acid. Phosphoric acid is handled by high- molybdenum grades, such as alloy 28 (N08028), G-30 (N06030), and 3127hMo (N08031). Nitric acid at most concentrations and temperatures can be handled by less highly alloyed stainless steels, such as type 304L (S30403), although higher- chromium stainless steels, such as type 310S (S31008) and alloy 800 (N08800), as well as silicon-containing stainless steels, such as S30600 and S30601, have been used for very hot, concentrated nitric acid. The ferritic stainless steel E-Brite (S44627) as well as the low-carbon version of commercially pure nickel, Nickel 201 (N02201), have been used to handle elevated- temperature caustic environments.

High-Temperature Corrosion. The various types of attack by high-temperature gases usually are referred to as oxidation, sulfidation, carburization, nitriding, and halogen-gas corrosion. In oxidizing, sulfidizing, and carburizing gases, high chromium contents, such as in type 310 (25% Cr, S31000) or its cast variant HK (J94224), improve resistance to attack. In addition, alloying with aluminum and silicon can be beneficial to oxidation resistance, as in type 406 (3.5% Al) and in type 302B (S30215, 2.5% Si), respectively. Resistance to nitriding is improved by alloying with nickel, as in RA-330 (N08330). For stainless steels, the upper temperature limit for operation in dry chlorine is approximately 320 °C (600 °F), with the presence of water vapor accelerating corrosion.

A.J. Sedriks, Corrosion Resistance of Stainless Steels and Nickel Alloys, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 697–702

Corrosion Resistance of Stainless Steels and Nickel Alloys

A. John Sedriks, Office of Naval Research

Nickel-Base Alloys

Nickel-base alloys make up an important segment of the corrosion-resistant materials, taking over from stainless steels and other alloys as service temperature or environment corrosivity increases. Commercially pure nickel, Nickel 200 (N02200), or its low-carbon version, Nickel 201 (N02201), is used as a corrosion-resistant material in food processing and in high-temperature caustic and gaseous chlorine or chloride environments.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

However, alloying of nickel with other elements (e.g., chromium, copper, or molybdenum) greatly broadens its use in corrosion- resistant applications (Fig. 2).

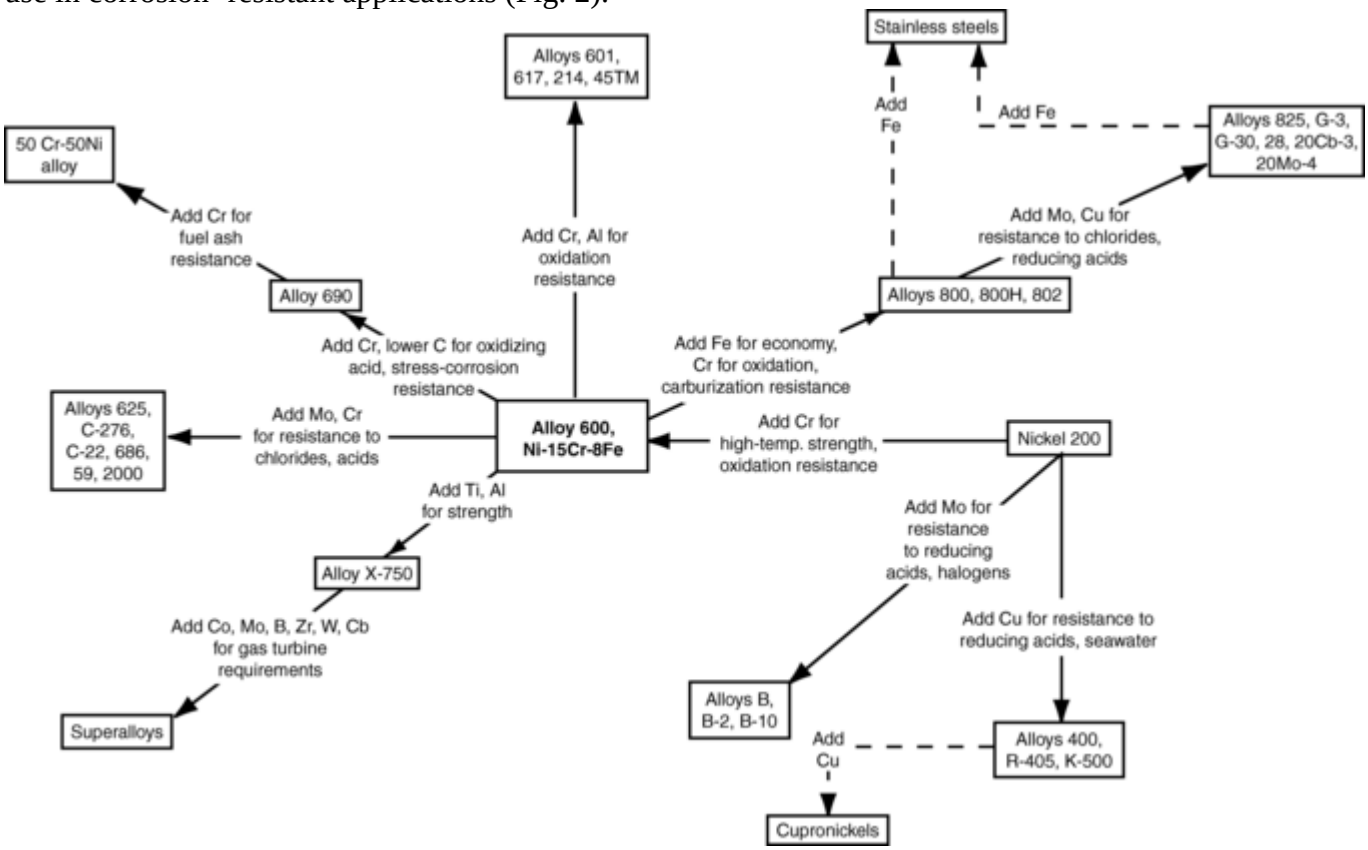

Fig. 2 Compositional and property linkages for nickel-base alloys

Nickel-Chromium Alloys. By far, the largest family of nickel alloys is that based on the nickel-chromium system, with alloy 600 (N06600) being the prototype (Fig. 2). Chromium imparts resistance to oxidizing environments and high-temperature strength. Increasing chromium to 30%, as in alloy 690 (N06690), also increases resistance to SCC in high-temperature (300 °C, or 570 °F) water and to corrosion in nitric acid solutions, steam, oxidizing gases, and shipboard waste-incinerator environments. Increasing chromium to 50%, as in IN- 657 (N07765), increases resistance to melting sulfates and vanadates found in fuel ash.

High-temperature oxidation resistance of nickel-chromium alloys is improved further by alloying with aluminum, as in alloys 601 (N06601) and 617 (N06617). Alloying additions of silicon and rare earth elements (e.g., cerium, yttrium, and lanthanum) also increase oxidation resistance. Among alloys that take advantage of the benefits of rare earth element additions on oxidation resistance are the silicon-containing alloys, such as 353MA (S35315) and 45TM (N06045), and the aluminum-containing alloys, such as 602CA (N06025) and 214 (N07214).

Of importance for use in aqueous reducing acids, oxidizing chloride solutions, and seawater in the presence of crevices and tight joints are the Ni-Cr-Mo alloys, such as 625 (N06625), C-276 (N10276), C-22 (N06022), 59 (N06059), 686 (N06686), and C-2000 (N06200). For these alloys to exhibit the maximum resistance to crevice corrosion in seawater environments, they should be free of deleterious precipitate phases and chromium-depleted surface layers. It is important, therefore, to remove by pickling, electropolishing, or mechanical processes, such as abrasion or grinding, any surface layers that have become depleted in chromium during high-temperature (above 980 °C, or 1800 °F) manufacturing steps.

Low-level titanium and aluminum alloying additions to nickel-chromium alloys and to Ni- Cr-Mo alloys result in strengthening by the precipitation of the γ′ phase, without loss of corrosion resistance, as in alloys X-750 (N07750) and 725 (N07725), respectively.

Cobalt and other alloying additions provide to jet engine materials (superalloys) a combination of high-temperature strength and creep resistance, with oxidation and sulfidation resistance. Oxide dispersion strengthening, in addition to γ′ strengthening, is used in the mechanically alloyed materials MA 754 (N07754) to provide high-temperature strength and oxidation resistance at the very high temperatures (approximately 1200 °C, or 2200 °F) encountered in molten glass processing and in reheating furnaces used in steel production.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Nickel-molybdenum alloys, such as B-2 (N10665), have excellent corrosion resistance in hydrochloric acid with low oxidizer content, whereas nickel-silicon alloys, such as D-207, have good corrosion resistance in hot, concentrated sulfuric acid.

Another technologically important group of materials are the lower-nickel (30 to 40%) Ni- Cr-Fe alloys that were originally developed to conserve nickel. The prototype, alloy 800 (N08800), is a general-purpose alloy with good high-temperature strength and good corrosion resistance in steam and in oxidizing or carburizing gases. Further alloying with molybdenum and copper, as in alloys 825 (N08825), G-3 (N06985), G-30 (N06030), 28 (N08028), 20Cb- 3 (N08020), and 20Mo-4 (N08024), improves resistance to localized corrosion in chlorides and resistance to general corrosion in reducing acids.

Nickel alloys exhibit high resistance to corrosive attack under nitriding conditions (e.g., in dissociated ammonia) and in chlorine or chloride gases. Corrosion in the latter at elevated temperatures proceeds by the formation and volatilization of chloride scales. High nickel contents in the alloys are beneficial, because nickel forms one of the least volatile chlorides. Conversely, in sulfidizing environments, high-nickel alloys without chromium can undergo corrosive attack due to the formation of a low-melting-point eutectic.

Nickel-copper alloys represent another technologically important group of materials. At higher nickel contents are alloys 400 (N04400), R-405 (N04405), and K-500 (N05500), which are used for certain corrosive chemicals, such as hydrofluoric acid, and for seawater. At higher copper contents are the cupronickels, such as 706 (C70600) and 715 (C71500), which are widely used for seawater applications because of their corrosion resistance and the ease with which marine fouling can be removed by mechanical processes.

Corrosion Resistance of Titanium Alloys

Steven Yu, 3M Company

Introduction

TITANIUM AND ITS ALLOYS are valuable engineering materials due to their combination of light weight, high strength-density ratio, and stability in a wide range of environmental conditions (Ref 1, 2, 3, 4, 5, 6). Yet, historically high cost per weight has limited the use of titanium and titanium-base alloys to mission-critical engineering applications such as aerospace, military, or biomedical industries. Recent availability of commercial-grade titanium from the Russian Federation and the People's Republic of China has made the application of titanium-base alloys more accessible for the general consumer industry. Information on the engineering applications of titanium, its mechanical properties, and its alloy variants is readily available in literature (Ref 1, 2, 3, 4, 5, 6). The scope of this article is to provide the reader with a background in the complex relationship between titanium and its alloys with aqueous environments, which is dictated by the presence of a passivating oxide film.

Corrosion Resistance of Titanium and Titanium-Base Alloys in Aqueous Environments

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Pure titanium is highly corrosion resistant in aqueous environments that encompass any pH > 2, even those that contain aggressive anionic species (including Cl^-) (Ref 6, 7). Nevertheless, metallic titanium is thermodynamically reactive, as indicated by its relatively negative reversible potential on the electromotive force (emf) scale (E_0 = -1.63 V_{NHE}). (NHE is normal hydrogen electrode.) As a result of its reactivity, metallic titanium readily oxidizes during exposure to air as well as during exposure to aqueous and nonaqueous electrolytes (Ref 6, 8, 9, 10, 11, 12, 13, 14, 15). Such oxidation leads to the formation of titanium-base oxides, hydrated complexes, or aqueous cationic species as a result of active anodic dissolution. The oxide and hydrated-complex layers function as barriers between the surrounding environment and the underlying metallic titanium, which inhibit the subsequent oxidation of metallic titanium across the metal/barrier layer/solution interface. Therefore, further oxidation of titanium can only occur by anion and cation movement across the oxide through diffusion and migration by potential field-assisted movement through this barrier (Ref 15, 16, 17, 18).

Coherent titanium oxide films resist uniform corrosion in many environments, such as all natural waters, including distilled, fresh, and seawater (aerated and deaerated), as well as brine solutions, to temperatures in excess of 200 °C (390 °F) (Ref 6). Furthermore, titanium is generally corrosion resistant in the presence of oxidizing-acid media. Oxidizing acids, including chromic, nitric, perchloric, and hypochloric acids, readily oxidize titanium to form thermodynamically stable TiO_2 where oxide formation and further oxide thickening promotes additional passivity. In contrast, passivated titanium exhibits poor resistance to corrosion in reducing-acid environments, such as hydrochloric or sulfuric acids, where the passivating TiO_2 can be reduced to a soluble form of oxidized titanium. Therefore, alloying additions that can promote the stability of protective titanium oxide films in reducing-acid environments are beneficial in inhibiting corrosion of titanium-base alloys.

Passivating Titanium Oxides

Titanium is one of the thermodynamically reactive metals generally described as valve metals due to the ability of these metals to allow relatively fast cathodic reaction rates while limiting the reaction rate of the anodic reactions (Ref 19). Limited anodic reaction rates result from the formation of thermodynamically or kinetically stable oxide films. Such oxide films reduce reactivity and enhance corrosion resistance of titanium within a wide range of pH, as shown in Fig. 1. Moreover, titanium oxides, formed near the respective open-circuit potentials (OCPs) of titanium, have been generally agreed on to be amorphous (Ref 20, 21, 22). The amorphous nature of titanium oxide is attributed to a cation egress mechanism due to an applied potential field gradient, which results in the formation of the oxide primarily at the solution-oxide interface (Ref 22, 23). Therefore, there is limited epitaxial constraint to form a crystalline oxide. However, titanium oxides can undergo a phase transformation from amorphous to one of the following crystalline structures during anodic polarization or during heat treatments: (a) anatase (tetragonal), (b) rutile (tetragonal), or (c) brookite (orthorhombic) (Ref 22, 24). The lattice parameters of TiO_2 are presented in Table 1.

The morphology of anodically formed oxides on valve metals, specifically titanium, has been described as a dual-layered oxide structure (Ref 14, 15, 25). The dual-layered oxide structure is composed of the following: (a) an inner compact and protective oxide at the metal-oxide interface, and (b) a porous outer oxide structure. The inner compact layer is primarily responsible for the passivation behavior of the oxide and is also responsible for the majority of the potential drop across the oxide film. The outer layer is a defected and porous oxide that has limited passivation characteristics (Ref 15). However, anodic polarization to more noble potentials within the passive potential range of titanium results in the thickening of the compact protective oxide by the following: (a) growth of the thin and protective oxide by metal cation egress, and/or (b) the conversion of the outer oxide into the more protective oxide (Ref 15).

Alloying additions, which can improve the efficiency of passivation, enhance the resistance of the passivating films to chemical dissolution, and/or inhibit the direct electrochemical dissolution of titanium through the oxide, should reduce passive current densities. This becomes crucial for cases of non-steady-state or rapid oxide formation, during which a majority of the anodic charge (~95%) is accounted for by the introduction of oxidized titanium into solution through the direct anodic dissolution of titanium (Ref 15, 26).

Corrosion Resistance of Titanium Alloys

Steven Yu, 3M Company

Corrosion Vulnerability of Titanium and Titanium Oxides: The Effect of Selected Environments

The presence of a coherent air-formed or an anodically formed titanium oxide surface film inhibits corrosion and reduces active dissolution rates of metallic titanium. However, titanium oxide films are susceptible to failures that lead to accelerated mass loss rates. Oxide failure mechanisms can be classified in the following categories:

- Spatially localized oxide film breakdown by the ingress of aggressive anions, such as chlorides (Cl^-) and bromides (Br^-)
- Spatially local or homogenous chemical dissolution of the oxide in a strong reducing-acid environment
- Mechanical disruptions or depassivation, such as scratching, abrading, or fretting

Aggressive Anions. The presence of TiO_2 is a formidable barrier to uniform corrosion, but it can fail and lead to localized corrosion, including pitting, in the presence of aggressive anion species. Aggressive anion species, especially halide ions such as Cl^-, cause pitting (Ref 6, 22, 27, 28, 29). A possible mechanism of TiO_2 failure, which subsequently leads to pitting, is anion migration to the Ti/TiO_2 interface to form $Ti/Ti\text{-}X/TiO_2$, where X is the aggressive anion species. According to one theory, the internal stresses associated with the Ti-X formation lead to rupture of the covering oxide film (Ref 19, 30). However, pitting of passivated titanium is limited to high anodic overpotentials, E_{app} > 5 V above OCP, even in aggressive halide-containing solutions, as indicated in Table 2. It is evident that titanium is highly resistant to pitting in solutions containing aggressive anion species, including Cl^- and Br^-, at temperatures of 25 °C to 100 °C (77 to 212 °F) and pH > 0.

Table 2 Pitting potential of commercially pure titanium

Environment	Temperature		Pitting potential	Source
	°C	°F		
1 *M* NaBr	30	86	+6 V_{SCE}	Ref 31
5% NaCl-HCl, pH = -0.05	25	77	+8.5 V_{SCE}	Ref 30
5% NaCl-HCl, pH = 3.5	**Boiling**		+6 V_{SCE}	Ref 6
1 *M* KCl	25	77	+14 V_{SCE}	Ref 33

Potential reference is saturated calomel electrode (SCE).

In addition to a resistance to pitting, titanium exhibits resistance to crevice corrosion that is a result of: (a) deaeration, (b) separation of anode and cathode, (c) metal-ion hydrolysis, (d) localized acidification, and (e) a breakdown mechanism. As a general rule, titanium is not susceptible to crevice corrosion at T < 70 °C (158 °F), regardless of the solution pH or chemistry, as shown in Fig. 2 (Ref 6, 34). At T > 70 °C (158 °F), initiation of crevice corrosion on titanium can be attributed to crystallization of titanium oxide, and increased passive dissolution, which lead to the five-stage process discussed previously (Ref 34). The anodically formed titanium oxide is amorphous at T < 60 °C (140 °F). The phase transformation of amorphous titanium oxide to a crystalline oxide can occur by anodic polarization (Ref 15, 22, 35). However, at T > 60 °C (140 °F), compressive stresses within the oxide can cause crystallization of the oxide. The resulting crystalline oxide film contains defects such as grain boundaries and intersections of screw dislocations with free surfaces, which can act as preferential sites for oxide failure or dissolution (Ref 9, 13, 36). The formation of grain boundaries, which can act as ionic diffusion pathways, allows for anion transport into the oxide (Ref 34). Moreover, increased passive dissolution at elevated temperatures can lead to metal-ion hydrolysis that generates acidity in an occluded geometry (Ref 22). Consequently, titanium with crystalline oxide films can be susceptible to crevice corrosion as well as pitting corrosion. Nevertheless, resistance to crevice corrosion at T < 70 °C (158 °F) does not preclude the possibility of a localized solution acidification mechanism leading to accelerated passive dissolution, because anodic dissolution rates of active and passive titanium are inversely proportional to related solution pH (Ref 12). The topic of local acidification is addressed subsequently. Note that alloying additions of molybdenum, zirconium, and palladium to titanium do raise the critical temperature of 70 °C (158 °F), as shown in Fig. 2.

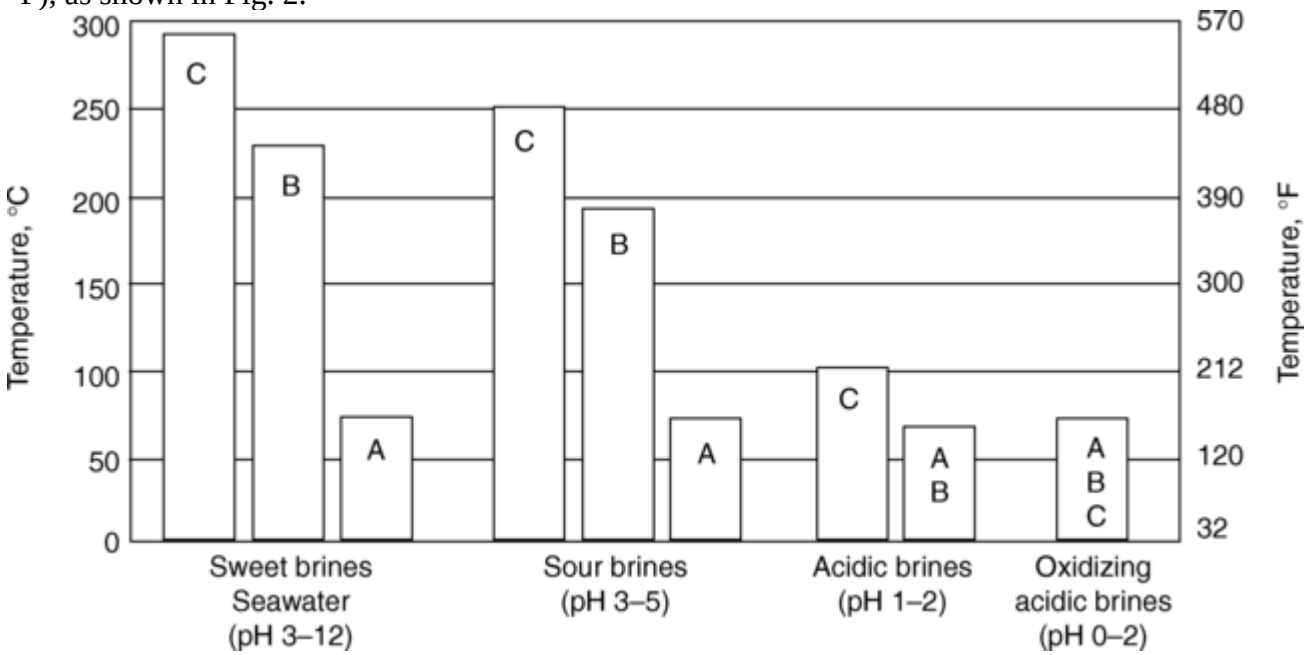

Fig. 2 Approximate temperature limits for crevice corrosion resistance of titanium alloys by group in various chloride brines. Group A: commercially pure titanium (grade 2) and beta titanium alloys. Group B: Beta-C (Ti-3%Al-8%V-6%Cr-4%Zr-4%Mo), Transage-207 (Ti-8%Mo-2.5%Al-9%Zr-2%Sn), and Ti-8-8-2-3 (Ti-8%Mo-8%V-2%Fe-3%Al). Group C: Beta-C/Pd (Ti-3%Al-8%V-6%Cr-4%Zr-4%Mo-0.05%Pd), Beta-21S (Ti-15%Mo-2.7%Nb-3%Al-0.2%Si), Ti-15-5 (Ti-15%Mo-5%Zr), and Beta III (Ti-

مرجع مهندسی مواد و متالورژی

11.5%Mo-6%Zr-4.5%Sn). It is evident that the alloying additions of molybdenum, zirconium, and palladium were beneficial in raising the 70 °C (158 °F) threshold for crevice corrosion. Source: Ref 6

Reducing Acids. Titanium is generally corrosion resistant in the presence of oxidizing-acid media but exhibits performance limitations in the presence of reducing-acid media. Oxidizing acids, such as chromic, nitric, perchloric, and hypochloric acids, can oxidize titanium to form TiO_2, where further oxide thickening promotes passivity. In contrast, passivated titanium may undergo activation through the dissolution of TiO_2 in a reducing environment. As Ti^{4+} is reduced to a more soluble Ti^{3+}, passive film dissolution can occur, as previously discussed. The dissolution of titanium in the form of Ti^{3+} can occur in reducing acids such as hydrochloric acid. Interestingly, alloying additions can improve the corrosion resistance of titanium-base alloys in such an environment (Ref 6, 15). Some common acids, which are classified as reducing acids, are hydrochloric, sulfuric, phosphoric, and hydrofluoric acids.

The breakdown of anodic or air-formed titanium oxide has been correlated with the conversion of TiO_2 to hydrated TiOOH and the presence of Ti^{3+} (Ref 37, 38). It has been proposed (Ref 37) that the formation of Ti^{3+} in the form of TiOOH or its hydrated form of $TiOOH \cdot H_2O$, for example, $Ti(OH)_3$, through the reduction of Ti^{4+} in TiO_2 can occur at the oxide-solution interface. This can result in oxide film failure, because $TiOOH \cdot H_2O$ should readily dissolve in acidic solutions. The potential-pH equilibrium diagram for the Ti-H_2O system should be modified to include TiH_2 (Ref 39). In such a case, an equilibrium involving only the hydrated form of trivalent titanium may occur between the regions of TiO_2 and TiH_2 equilibrium (Ref 37). The formation of Ti^{3+} is critical, due to the higher solubility of Ti^{3+} at low pH in comparison to Ti^{4+}, as shown in Fig. 1. The solubility of Ti^{3+} accounts for active anodic dissolution of titanium in reducing acids.

Mechanical Attack. Mechanical disruption of TiO_2 by scratching, abrading, or fretting can also result in the exposure of the underlying thermodynamically reactive metallic titanium to an aqueous environment. However, repassivation can occur to reform an oxide layer to isolate the underlying reactive metal from the aqueous environment. When repassivation occurs, the high current densities associated with repassivation do not all go into the formation of passive oxides. Current densities have been recorded as high as 100 A/cm^2 (645 A/in.^{2}) for thin-film fracture tests of metallic titanium in deaerated 5 *M* HCl at 25 °C (77 °F) (Ref 40). However, it was recorded that the overall current efficiency for oxide formation on decay to steady state was less than 10% (Ref 40). Therefore, a majority of the repassivation charge went into metallic titanium dissolution, either as Ti^{3+} or TiO^{2+} (Ref 40, 41). Consequently, there can be a significant introduction of dissolved metallic ionic species into the local solution chemistry during repassivation. Within a tight geometry, such influx of titanium ions or other metal ions can lead to localized solution acidification by metal-ion hydrolysis. The low current efficiency associated with repassivation contrasts the near 100% charge efficiency associated with the slower passive film growth during anodic potentiostatic polarization of titanium in 0.5 *M* H_2SO_4 at temperatures ranging from 303 to 353 K (86 to 176 °F) (Ref 22). Therefore, reactivation current efficiency during repassivation and film growth during exposure to reducing acids may depend critically on the rate of oxidation and the disordered state of the oxide.

The release of titanium ions into the surrounding aqueous environment, as a result of metallic dissolution, is a critical issue with respect to corrosion in reducing acids. Introduction of titanium ions into the surrounding aqueous environment can lead to solution acidification by metallic-ion hydrolysis (Ref 42). It was shown that the dominant dissolved titanium species resulting from scratch-repassivation of titanium disks was Ti^{3+}, which was reported as being hydrolyzable (Ref 41, 42). In addition, it has been shown that the production of Ti^{3+} occurs over the duration of repassivation, due to the low overall current efficiency of TiO_2 formation immediately after rapid mechanical depassivation of microelectrodes that enabled high dissolution rates (Ref 40). Trivalent titanium ions (Ti^{3+}) can undergo metal-ion hydrolysis primarily by the following reaction:

$$Ti^{3+} + H_2O \rightarrow TiOH^{2+} + H^+ \qquad \text{(Eq 1)}$$

The resulting hydrolysis of Ti^{3+} can produce a solution with a pH as low as 0, as shown when 1 *M* $TiCl_3$ is added to deaerated water (Ref 40). Indeed, the pH near a crack tip in Ti-8%Al- 1%Mo-1%V has been reported to be as low as 1.7 (Ref 43). Also, a pH < 1.3 was reported near a corroding pit on titanium that was exposed to neutral chloride solution (Ref 41). The decrease in localized solution pH due to hydrolysis can lead to enhanced titanium dissolution in reducing acid that, in turn, further acidifies the surrounding solution and causes even more dissolution of titanium, because the active and passive dissolution rates for titanium are well known to be functions of pH, as shown in Fig. 3 (Ref 26, 41, 44).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

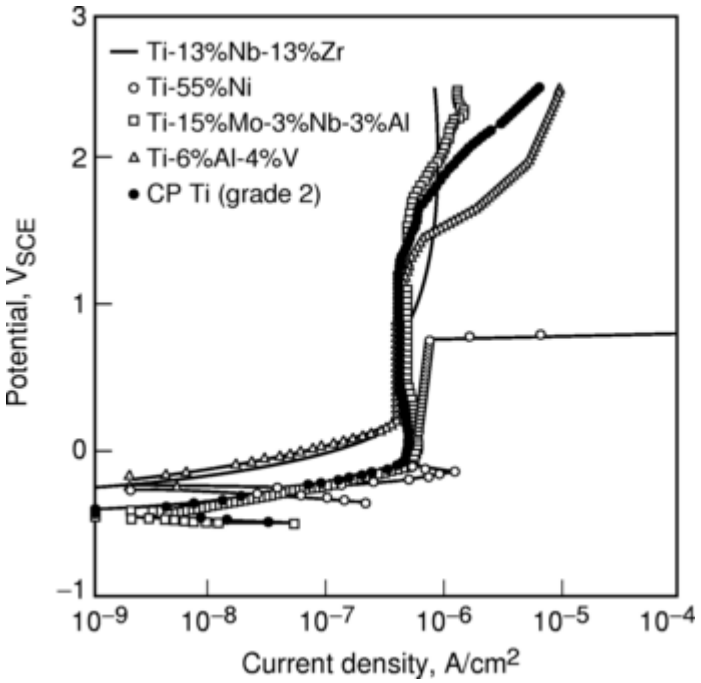

Fig. 3 Electrochemical polarization tests of titanium and titanium-base alloys, including Ti-6%Al-4%V (Ti-6-4), Ti-15%Mo-3%Nb-3%Al (Ti-15-3-3), Ti-13%Nb-13%Zr (Ti-13-13), Ti-55%Ni, and commercially pure (CP) titanium (grade 2), revealed that titanium and titanium-base alloys are spontaneously passive in a deaerated 0.1 *M* NaCl solution. The potentiodynamic scans were conducted at a scan rate of 0.1 mV/s. SCE, saturated calomel electrode

The resulting critical corrosion-related issues for titanium alloys include the possibility of: (a) occluded site deaeration, (b) partial or complete separation of anode and cathode sites, and (c) the metal dissolution/hydrolytic acidification/chloride ion (Cl^-) migration mechanism promoting a local buildup of acidity and high Cl^- concentrations adjacent to the alloy structures. In titanium applications that combine abrasive actions in a crevice, local acidification may be accelerated by the film rupture and repassivation mechanisms. The issues of local solution acidification and Cl^- accumulation do point toward crevice corrosion. However, crevice corrosion, which is defined by local depassivation and active dissolution in the absence of active abrasion, is not expected of titanium unless it is exposed to low- pH solutions at temperatures above 70 °C (158 °F), (Ref 1, 6, 34, 45, 46, 47, 48). It is yet unknown whether abrasion in crevice geometry could activate crevice corrosion at $T < 70$ °C (158 °F).

Corrosion Resistance of Titanium Alloys

Steven Yu, 3M Company

Effects of Alloying on Active Anodic Corrosion of Titanium

Titanium alloys can be classified into three primary groups: (a) α titanium alloys with hexagonal close-packed (hcp) crystallographic structure; (b) β titanium alloys with body-centered cubic (bcc) crystallographic structures, including metastable β alloys; (c) and α+β titanium alloys, including near-α and near-β titanium alloys. Details regarding the alloy families are described in Ref 2 and 3. For titanium- base alloys containing β stabilizing elements, a molybdenum equivalency has been determined as:

$$\begin{aligned}\%\text{Mo(equivalent)} = {} & \text{Mo} + 0.67(\%\text{V}) \\ & + 0.28(\%\text{Nb}) + 2.9(\%\text{Fe}) \\ & + 1.6(\%\text{Cr}) + 0.9(\%\text{Ni}) \\ & - \text{Al(wt\%)}\end{aligned} \qquad \text{(Eq 2)}$$

where approximately 10% Mo equivalency is sufficient to stabilize completely the beta phase on quenching to room temperature from above the beta-transus temperature.

Active Anodic Polarization Behavior of Titanium and Titanium-Base Alloys. Electrochemical polarization tests of titanium and titanium-base alloys, including Ti-6%Al-4%V (Ti-6-4), Ti-15%Mo-3%Nb-3%Al (Ti-15-3-3), Ti-13%Nb-13%Zr (Ti-13-13), Ti-55%Ni, and Ti-50%Cr, showed that titanium and the tested titanium-base alloys are spontaneously passive in a deaerated 0.1 *M* NaCl solution, as shown in Fig. 3. This is consistent with the stability of dominant TiO_2 at these OCP values and pH, as shown in Fig. 1. From OCP to +2.5 V_{SCE}, the tested alloys exhibited similar passive current densities of ~5×10^{-7} A/cm^2 (3.2×10^{-6} A/ in.^{2}).

The corrected critical current densities (i_{crit}) of the solution-treated alloys Ti-13-13, Ti-15-3-3, as well as commercially pure (CP) titanium (grade 2) were compared as functions of their respective molybdenum equivalency, as shown in Fig. 4. The corrected i_{crit} was defined as the following:

$$\text{Corrected } i_{crit} = i_{crit}(\text{measured}) + i_{cathodic} \qquad \text{(Eq 3)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

where the $i_{cathodic}$ can be determined by Tafel extrapolation to the E_{app}, where the apparent i_{crit} is observed. The i_{crit} determined from the anodic polarization data, shown in Fig. 4, has been corrected to account for the cathodic current densities. Of the three alloys, solution-treated (ST) Ti-15-3-3, a metastable beta alloy, exhibited the lowest i_{crit} in 5 *M* HCl. Moreover, ST Ti-15-3-3 did not exhibit an active/passive transition in the 5 *M* HCl, as shown in Fig. 4. Instead, spontaneous passivity was observed at the OCP of Ti- 15-3-3. Researchers also reported that Ti-15-3-3 was spontaneously passive at its OCP in 5 *M* HCl at room temperature (Ref 40).

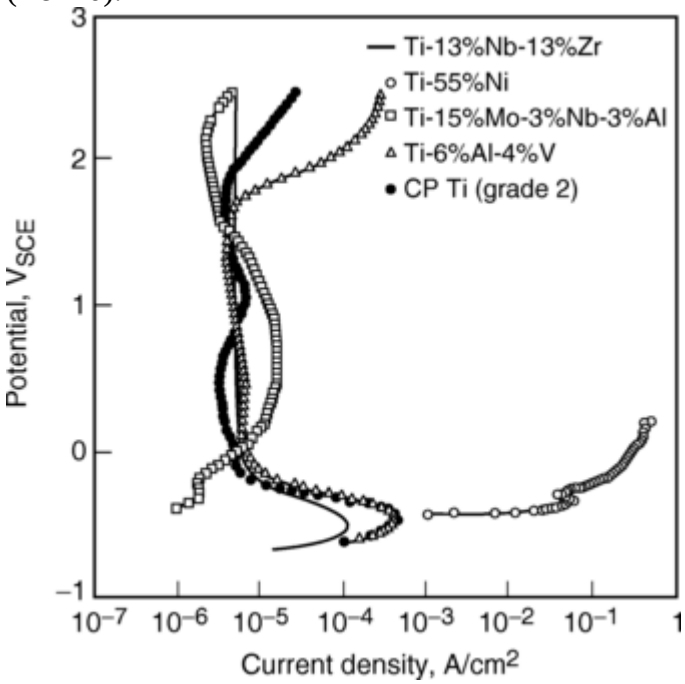

Fig. 4 Electrochemical polarization tests of titanium and titanium-base alloys, including Ti-6%Al-4%V (Ti-6-4), Ti-15%Mo-3%Nb-3%Al (Ti-15-3-3), Ti-13%Nb-13%Zr (Ti-13-13), Ti-55%Ni, and commercially pure (CP) titanium (grade 2), in a deaerated 5 *M* HCl solution. The potentiodynamic scans were conducted at a scan rate of 0.1 mV/s. SCE, saturated calomel electrode

Depassivation and Activation: Effects of Alloying Additions on Titanium at OCP. The dissolution of the respective native oxides and the subsequent surface activation of CP titanium as well as binary alloys, including Ti-45%Nb and Ti-50%Zr with native air-formed oxides (~2 to 3 nm in thickness) in 5 *M* HCl, were indicated by decreasing OCP. The decreasing OCP was followed by a sudden potential drop, as shown in Fig. 5 and 6. In 5 *M* HCl, the OCPs of CP titanium, Ti-45%Nb, and Ti-50%Zr were within the thermodynamically stable region of Ti^{3+} after the 12 h immersion, that is, after the potential drop, as revealed by the overlay of the OCPs onto the revised Pourbaix diagram of titanium at 37 °C (99 °F), as shown in Fig. 7. Similar decreases and step-function drops in OCPs of titanium were recorded in sulfuric and hydrochloric acids (Ref 38, 49, 50). It was confirmed that the OCP breakdown of the passive film on titanium was by chemical dissolution (Ref 38). The potential drops were not observed in deaerated 0.1 *M* NaCl (pH $\simeq$ 6.8) for CP titanium and the titanium-base alloys (Fig. 5, 6). In this near-neutral pH solution, the air-formed oxides of all these materials were thermodynamically stable and resisted chemical dissolution, in contrast to what was experienced in deaerated 5 *M* HCl for the titanium-base materials (Fig. 5, 6). An overlay of the OCPs of CP titanium, Ti-45%Nb, and Ti-50%Zr on the Pourbaix diagram of titanium at 37 °C (99 °F) indicates that at pH = 6.8, CP titanium and the alloys were well within the thermodynamic stability regime of TiO_2 at 37 °C (99 °F), as shown in Fig. 7. The stability of the air- formed oxides in 0.1 *M* NaCl is confirmed by the spontaneous passivity of titanium, niobium, zirconium and the titanium-niobium- and titanium-zirconium-base alloys.

Effects of Alloying Additions on Titanium Passivity

The exact manner in which alloying additions improve passivating oxides is yet unclear. Therefore, possible mechanisms by which alloying additions can enhance the resistance to active anodic dissolution and inhibit the chemical dissolution of passive films are reviewed. The following theories are by no means the only theories with regards to passivity and effects of alloying additions on passivation.

Promoting Active/Passive Transition. The alloying addition of small concentrations of palladium to titanium induces spontaneous passivation of titanium-palladium alloys in reducing environments where titanium, by itself, exhibits active/passive transitions, as shown in Fig. 8. (Ref 16, 17, 33). In such cases, spontaneous passivation of titanium is due to enhanced cathodic kinetics associated with hydrogen evolution instead of expanded thermodynamic stability of oxide passivity. The presence of palladium and other noble-metal additions, such as iridium, platinum, and rhodium, at the solution-metal or solution/oxide/metal interface modify the kinetics of hydrogen evolution by: (a) increasing the exchange current density of hydrogen evolution, and/or (b) reducing the cathodic Tafel slope associated with hydrogen evolution. Increased cathodic exchange current densities and/or reduced cathodic Tafel slopes can result in passivity if the resulting OCP is above the active/passive transition potential of the binary alloy (i.e., TiO_2 is not converted to TiOOH). Moreover, changes in the cathodic Tafel slope of titanium- palladium alloys would indicate that the rate-determining step during hydrogen evolution is no longer a slow discharge reaction step, as described for

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

titanium (Ref 49). Instead, the rate- determining step during hydrogen evolution on titanium-palladium alloys is more consistent with the chemical hydrogen recombination step (Ref 49).

Formation of Amorphous or Vitreous Oxide

It has been asserted that alloying additions such as chromium and manganese that reduce passive current densities do so by reducing the density of crystal defects in oxide films and thereby reducing the ionic conductivity across the oxide (Ref 15). For example, the improved corrosion resistance associated with the addition of 12 wt% chromium to iron to form stainless steel can be attributed to the formation of an amorphous iron-chromium-base oxide (Ref 52). The formation of an amorphous oxide or possibly a vitreous oxide film, for example, short- range order and structure, can offer improved resistance to ion migration due to the absence of grain boundaries and dislocations that can act as low-energy conduits for ion migration (Ref 52). Moreover, the formation of either an amorphous or vitreous oxide enhances resistance to corrosion due to the flexibility of the atomic bonds between metallic cations with O^{2-} or OH^-. The benefits of bond flexibility are the following: (a) it allows for tolerance of the misfit strain associated with the presence of halide, specifically Cl^-, at the oxide-metal interface, and (b) almost all the surface atoms can bond with oxygen or OH^- without requiring an almost perfect epitaxial relationship between metal and oxide (Ref 52). Chromium and molybdenum also have been shown to improve the corrosion resistance of base metals such as iron and titanium by inhibiting anodic dissolution and enhancing passivation in reducing environments such as 6 and 12 *M* HCl, respectively (Ref 9, 53). Researchers associated the enhanced corrosion resistance and the improved passivity due to the formation of a passivating film consisting of double oxyhydroxides of molybdenum-titanium and chromium-titanium, which have a ratio of O^{2-} to OH^- of approximately 2. The double oxyhydroxides on molybdenum-titanium and chromium-titanium have been shown to be amorphous in structure, where molybdenum or chromium ions are bonded directly to titanium ions (Ref 9, 53). The amorphous and homogenous structure of the oxyhydroxides may account for the enhanced resistance to anodic dissolution in comparison to the respective molybdenum, chromium, and titanium oxides. The formation of oxyhydroxides will be helpful for construction of homogenous surface films without defects, which act as weak points for corrosion (Ref 53). Furthermore, it has been shown that zirconium, when alloyed with molybdenum and anodically polarized in 12 *M* HCl, will form complex double oxyhydroxides, where zirconium and molybdenum are covalently bonded as first nearest neighbors (Ref 54). Therefore, the alloying additions of niobium and zirconium may lead to the formation of amorphous oxyhydroxides when alloyed with titanium.

Reduction of the Potential Gradient across Surface Film

Anodic dissolution of metal is controlled by the applied electrode potential difference between metal and electrolyte. On a bare metal surface in contact with solution, the potential difference is located across a thin electrical double layer, the Helmholtz layer, which separates the bare metal surface from the hydrated ions and is approximately 0.5 nm in thickness (Ref 55). However, the presence of a compact oxide surface film results in a multilayered interface consisting of metal/compact surface film/double layer/solution, as shown in Fig. 9. Therefore, on an oxide-covered surface, metal dissolution reaction transpires as a series of consecutive reaction steps: (a) metal ions are transferred from the underlying surface of the metal to the metal- oxide interface, (b) ions migrate through the oxide film, and then, (c) metal ions are transferred across the Helmholtz double layer to the film- solution interface under the applied potential field. It is generally accepted that the last step, the transfer of ions across the Helmholtz double layer to the film-solution interface, which results in the hydration of the metal ions, is the rate- controlling step in metal dissolution across an oxide-covered interface (Ref 55). The potential difference (φ_c) across the Helmholtz double layer between a thin compact oxide and electrolyte is a function of the overall potential difference between the metal and solution (φ_m) as well as the geometry and physical characteristics of the multilayered film (Ref 55). The relationship between φ_c and φ_m has been defined as the following:

$$\phi_c = \phi_m \left(1 + \frac{L}{\delta_{dl}} \frac{\varepsilon_H}{\varepsilon_m}\right)^{-1} \quad \text{(Eq 4)}$$

where L is the semiconductor film thickness, ε_H is the dielectric constant of the Helmholtz layer, ε_m is the dielectric constant of the metal oxide, and δ_{dl} is the thickness of the Helmholtz layer. Therefore, if there is no oxide (surface) film, then $\varphi_c = \varphi_m$. However, the presence of a thin oxide film can reduce φ_c and therefore reduce the driving force necessary for metal-ion transfer across the Helmholtz layer and consequently reduce metallic dissolution. Two factors can be controlled with respect to the oxide: first, oxide thickness (L) and second, the oxide dielectric constant (ε_m). Thus, it is possible to reduce the potential drop across the Helmholtz layer and, accordingly, the potential field-driven anodic dissolution of the underlying metal by increasing the oxide thickness and/or decreasing the oxide dielectric constant. Consequently, any alloying additions that can increase the compact oxide thickness and/or reduce the dielectric constant of the oxide film can reduce anodic dissolution and enhance corrosion resistance.

Enhancement of Atomic Bond Strength

The resistance of metals to dissolution and the propensity for passivation are functions of the atomic bond strengths (Ref 56). Metallic-to-metallic atom bonds and bonds between metallic atoms and oxygen or hydroxyl ions form an adsorbed hydroxyl layer (Ref 56). Relative metallic-to-metallic atom bond strength ($\varepsilon_{M\text{-}M}$) is shown in Eq 5. Similarly, the relative bond strengths between metallic atoms and oxygen can be approximated by the enthalpies (ΔH) of oxygen adsorption at a surface coverage (θ) of zero:

$$\varepsilon_{M\text{-}M} = \frac{\Delta H_{sub}}{\left(\frac{Z}{2}\right)} \qquad \text{(Eq 5)}$$

where Z is the coordination number of atom M. The specific enthalpies of oxygen adsorption are provided in Table 3. In comparing the enthalpy of sublimation (ΔH_{sub}) and the enthalpy of oxygen adsorption, one can determine the relative abilities of elements to resist dissolution by creating strong metal-to-metal bonds and to enhance passivity by increasing the bond strengths between metal and oxygen. A high probability of passive oxide formation is indicated by: (a) a high negative energy change associated with oxygen adsorption, for example, metal bonding with oxygen; and (b) the ease by which initial metal-metal bonds can be broken, for

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

example, low enthalpy of sublimation. A net negative energy change as a result of a metal-metal bond breaking and a metal-oxygen bond forming would indicate the thermodynamic propensity for the formation of oxides. However, the presence of weak metal-metal bonds implies a high rate of metallic dissolution when bare metal is exposed to solution. In contrast, a metal with high metal-metal bond strengths is less likely to undergo dissolution (Ref 56, 57). Such metal will resist the formation of strong bonds with oxygen in favor of forming strong bonds between metallic atoms (Ref 56). Therefore, the mechanisms for stable passivity and stable resistance to dissolution are competitive. As such, two types of alloying elements exist: (a) passivity promoters that possess high enthalpies of oxygen adsorption and relatively low metal-metal bond strength, and (b) dissolution blockers that have high metal-metal bond strengths to inhibit metallic bond failures. However, by adding alloying elements with both characteristics, it would be possible to create an alloy that exhibits both resistance to anodic dissolution and stable passivity.

A classic example of both alloying types being used is chromium and molybdenum in stainless steels. Chromium, with its high enthalpy of oxygen adsorption, is added to iron to enhance oxide formation on stainless steel, as shown in Table 3. It is possible that chromium easily promotes the nucleation of chromium oxides on the surface of stainless steels at lower anodic overpotentials in comparison to the passive potentials of iron, thereby widening the potential range of passivity of iron-chromium-base alloys. In addition, molybdenum has a high metal-metal bond strength that indicates high resistance to reduce metallic dissolution, as shown in Table 3. Niobium exhibits a heat of adsorption of oxygen of 875 kJ/mole, which would classify niobium as a strong oxide former. Therefore, the alloying addition of niobium to titanium should result in improved passivation characteristics in comparison to pure titanium.

Lowering of the pH of Zero Charge

The relationship between the resistance of an oxide to anion uptake and the pH of zero charge (pH_{pzc}) has been investigated on aluminum-base alloys (Ref 58). An important parameter governing the surface charge and, consequently, the adsorption characteristic of an oxide is the pH_{pzc} (Ref 58, 59). The pH_{pzc} of an oxide is the pH at which the surface has no net charge. Therefore, at a pH lower than the pH_{pzc}, the surface has a net positive charge, and aggressive anions are electrostatically attracted to the surface and can be adsorbed, which can possibly lead later to oxide failure. In contrast, at a pH higher than the pH_{pzc}, the surface has a net negative charge, and cations are attracted to the surface. Therefore, alloys containing elements that form oxides, which have relatively low pH_{pzc}, should exhibit superior resistance to aggressive anion uptake. The alloying additions of niobium and zirconium, which exhibit pH_{pzc} of 2.8 and 5.5, respectively, to aluminum, with a pH_{pzc} of 9.4, have been shown to enhance the resistance to anion uptake, for example, increase the pitting potential (Ref 58). Consequently, an alloy of niobium (pH_{pzc} ~ 2.8) to titanium (pH_{pzc} ~ 5), when oxidized, should exhibit superior resistance to chloride uptake and possible oxide failure in comparison to titanium. In contrast, it is possible that zirconium should have no measurable benefit to oxide failure resistance due to the similarity of the pH_{pzc} of titanium and zirconium. A limitation of the pH_{pzc} theory is its inability to predict a pH_{pzc} for mixed oxides.

Repassivation Behavior of Titanium and Titanium-Base Alloys

The electrochemical behavior of bare metal surfaces and their repassivation properties are important factors in environmentally assisted cracking (EAC), erosion-corrosion, and tribological applications. With the exception of gold, all metals oxidize reactive in aqueous environments, and almost all are protected from corrosion by the formation of a surface oxide film or an adsorbed film structure. This passivating behavior is clearly seen in valve metals, including titanium, niobium, zirconium, tantalum, and aluminum, that rely on kinetic barriers to

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

oxidation instead of thermodynamic stability of the metal for corrosion resistance. Therefore, passivating oxide films are crucial in the technological utility of valve metals. However, the failure of such oxides as a result of mechanical abrasion, anion interaction, or chemical dissolution is a dilemma that must be addressed.

The formation of a passivating film transpires in parallel with the active dissolution of the bare metal. During the formation of passivating film, the following steps can occur: (1) adsorbed film formation, (2) formation and growth of islands of oxides to cover the surface, (3) oxide film thickening, and (4) minimization of disorder in the oxide film. Opposing such reactions during passive film formation, the following reactions can occur: (a) active dissolution of metal across the passivating film; (b) dissolution in bare areas, which undercuts the islands of oxides; and (c) allocation of anodic charge to other competing oxidation reactions that do not contribute to oxide formation or consolidation of a compact oxide. Therefore, repassivation of the activated metal surface is achieved when the reaction rates for the formation of passivating film are greater than the rates of reactions opposing stabilization and thickening of the film. However, if the active dissolution mechanism dominates the net anodic reaction at such a site, then this site can become a stable location for localized corrosion. Therefore, an understanding of the mechanisms behind repassivation kinetics as well as the competing reactions are important for understanding the resistance of a metal to EAC, erosion-corrosion, localized corrosion, and tribology.

Repassivation Kinetics. During the repassivation of titanium, a minimum of four reactions can occur on the newly formed bare metal surface in deaerated reducing acid (Ref 39, 60):

$$Ti \rightarrow Ti^{3+} + 3e^- \quad \text{(Eq 6)}$$

$$Ti + 2H_2O \rightarrow TiO_2 + 4H^+ + 4e^- \quad \text{(Eq 7)}$$

$$H^+ + e^- \rightarrow H \quad \text{(Eq 8)}$$

$$Ti^{3+} + H_2O \rightarrow TiO^{2+} + 2H^+ + e^- \quad \text{(Eq 9)}$$

The extent to which the anodic charge is consumed by Eq 6 can be addressed by inductively coupled plasma (ICP) solution analysis and gravimetric mass loss measurements. The thickening of titanium oxide, as described in Eq 7, can be measured by methods including electrochemical impedance spectroscopy (EIS). In contrast, nascent hydrogen formation cannot be measured by the experimental methods that are available to this researcher. However, the hydrogen-evolution reaction step is not possible at potentials greater than $E(V_{NHE})$ = 0.0 - 0.06 pH. Further oxidation of dissolved Ti^{3+} to Ti^{4+} in the form of TiO^{2+} can be measured by a scratched disk/gold ring oxidation test, as described in Ref 60.

The reaction step described by Eq 6 is reported to be the dominant mechanism that occurs during the repassivation of titanium in reducing acids, where greater than 90% of the applied anodic charge prior to steady-state passivation is consumed by the dissolution of metallic titanium into Ti^{3+} (Ref 40, 60). Moreover, the active anodic dissolution of titanium to Ti^{3+} occurs both on the bare metal surface and through the reforming oxide layer, due to the large potential gradient across the oxide. The following are possible reaction steps for metallic titanium dissolution to Ti^{3+} in deaerated solution, as described by Eq 6:

$$Ti \rightarrow Ti^{2+} + 2e^- \quad \text{(Eq 10)}$$

$$Ti^{2+} + H^+ \rightarrow [Ti^{3+}H]_{ads} \quad \text{(Eq 11)}$$

$$[Ti^{3+}H]_{ads} \rightarrow Ti^{3+} + H^+ + e^- \quad \text{(Eq 12)}$$

where the final product is aqueous Ti^{3+} at low potentials (Ref 7, 50). The alloying additions of species such as molybdenum, niobium, and zirconium to titanium could reduce active anodic dissolution rates of titanium-base alloys in comparison to pure titanium by enhancing the atomic bond strengths between titanium, molybdenum, niobium, and zirconium. Suffice it to say that molybdenum, niobium, and zirconium alloying additions can be beneficial in reducing the active anodic dissolution of titanium (Ref 56, 57). It is reasonable to assume that alloying additions of molybdenum, niobium, and zirconium to titanium increase the activation energy that is necessary to remove the valence electrons from titanium that are bonded to molybdenum, niobium, or zirconium in comparison to titanium bonded to titanium. This increase in activation energy required to oxidize titanium in titanium- molybdenum, titanium-niobium, and titanium- zirconium alloys is attributable to confirmed stronger *d-d*-level electron interaction between titanium-molybdenum, titanium-niobium, and titanium-zirconium near-neighbors in comparison to titanium-titanium. Therefore, the reaction rates for the

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

titanium-molybdenum, titanium-niobium, and titanium-zirconium alloys undergoing active anodic dissolution should be reduced in comparison to pure titanium.

Effects of Alloying Additions on Repassivation Kinetics of Titanium. Active anodic dissolution consumed approximately 90% of the total anodic charge for titanium, Ti-45%Nb, and Ti-50%Zr during galvanostatic polarization at 1 A/cm^2 (6.5 A/in.^{2}) (Ref 61). Similar high anodic-dissolution-charge consumption was recorded by researchers during repassivation tests of titanium, which indicates that the majority of the applied anodic charge density was consumed by active anodic dissolution of titanium, niobium, and zirconium from the bare surface (Ref 15, 40, 60). However, the anodic charge densities associated with active anodic dissolution diminished to approximately 10% of the total applied charge densities for Ti-45%Nb and Ti-50%Zr at lower anodic current densities approaching steady-state passivation densities, albeit at a high potential. In contrast, titanium still exhibited greater anodic dissolution charge densities at low current densities, which clearly indicates that the rapidly formed oxides on the titanium-niobium and titanium-zirconium binary alloys are more protective in comparison to TiO_2 formed on CP titanium.

Mechanisms by which Alloying Elements Inhibit Active Anodic Dissolution during Repassivation. It is reasonable to assume that similar dissolution inhibition mechanisms, as described in “Effects of Alloying on Active Anodic Corrosion of Titanium” are also applicable in inhibiting active anodic dissolution during repassivation. Researchers have explored the issue of enhanced resistance to metallic dissolution, from an atomic bonding approach (Ref 56, 57). They hypothesized that the formation of strong covalent bonds between the titanium and alloying species such as molybdenum, niobium, and zirconium atoms results in reduced rates of active metallic dissolution. Therefore, it reasonable to assume that the reaction rates for titanium-molybdenum, titanium-niobium, and titanium-zirconium alloys, which govern the active anodic dissolution, should be diminished, even at high- voltage driving force, in comparison to pure titanium.

Once a passive film has formed, the potential gradient across the metal/passive film/double layer/solution interface is defined by Eq 4, which is dependent on the oxide thickness, the Helmholtz double-layer thickness, as well as the dielectric constants of the oxide and the double layer. It can be assumed that the dielectric constant of the mixed oxides on titanium-base alloys will remain relatively constant (Ref 61). Moreover, assuming that the Helmholtz double-layer thickness as well as the dielectric constant of the double layer remain constant, the primary variable in determining the potential gradient across the oxide film is the oxide thickness (d_{ox}). An evaluation of the oxide-thickening ratios for titanium, Ti-45%Nb, and Ti-50%Zr revealed that both Ti-45%Nb and Ti-50%Zr exhibited higher oxide-thickening ratios, 3.1 and 2.2 nm/V, respectively, in comparison to titanium, which exhibited a $\Delta d_{ox}/\Delta E_{app}$ ratio of approximately 1.1 nm/V (Ref 61). Subsequently, there is a reduced potential gradient driving anodic dissolution of the underlying metal on Ti-45%Nb and Ti- 50%Zr in comparison to CP titanium. It is evident that such a primary condition for the high field model, for example, ~100% charge efficiency during oxide formation, is violated during galvanostatic polarization at high current densities, that is, $i > 0.0001$ A/cm^2 (0.00065 A/in.^{2}) (Ref 61). All of the tested samples exhibited significant active anodic dissolution, as measured by gravimetric mass loss measurements and ICP solution analysis. Therefore, the high field approximation for oxide growth cannot be used to describe the repassivation behavior of titanium and its alloys, including Ti-45%Nb and Ti- 50%Zr.

Phosphate Conversion Coatings

Kevin Ogle, Irsid, Arcelor R&D (Maizières-lès-Metz, France); Michael Wolpers, Henkel KGaA (Düsseldorf, Germany)

Introduction

PHOSPHATING is used in the metalworking industry to treat substrates like iron, steel, galvanized steel, aluminum, copper, and magnesium and its alloys. Most automobile bodies are zinc phosphated prior to painting to increase corrosion resistance and paint adhesion. The cold extrusion of steel would not be economically feasible without phosphating as a lubrifying film. Other applications include providing temporary corrosion resistance for unpainted metal and electrical resistance (Ref 1, 2, 3). This article gives an overview of the types, uses, and theory of phosphate coatings and their formation. It also discusses the composition of phosphating baths, phosphate layers, and their analysis, as well as the process hardware necessary to realize these treatments.

Structure and Function of the Phosphate Film

Phosphate conversion coatings are composed of insoluble tertiary metal (Me) phosphates, $Me_3(PO_4)_2 \cdot xH_2O$. In this formula, Me represents divalent metallic cations of one or more metallic elements. The phosphate layer or coating is formed on a metal substrate by exposing the metal to a phosphating bath.

A summary of different types of phosphate layers is given in Table 1. A major distinction can be made between crystalline and amorphous phosphate layers. Figure 1 shows the morphological differences between crystalline and amorphous phosphate layers on zinc coated steel substrates. X-ray diffraction (XRD) spectra support the crystalline and amorphous character of the layer respectively. In Fig. 1(a) (on the left side), the phosphate crystals are clearly visible, giving a characteristic XRD pattern. By contrast, in Fig. 1(b) (on the right side), the amorphous layer is characterized by irregular structure in the scanning electron micrograph (SEM) and no pattern in the XRD spectra.

Table 1 Characteristics of different types of phosphate coatings and associated processes (general formulas)

Free acid is defined as the number of mL of 0.1 *M* NaOH required to reach the first endpoint during titration of 10 mL bath sample. Total acid is related to the second endpoint.

Characteristic	Amorphous phosphate layers		Crystalline phosphate layers		
	Alkali phosphating (iron phosphating)	**No-rinse-phosphating (dry-in-place phosphating)**	**Low-zinc phosphating Standard-zinc phosphating[(a)]**	**Heavy phosphating**	
				Zn cation	**Mn cation**

(a) The standard zinc phosphating is comparable to the low-zinc process. Values in angular brackets belong to the standard-zinc phosphating. The main differences are the zinc and the phosphate concentrations. Standard zinc baths contain 3–7 g/L Zn^{2+} and 6–9 g/L PO_4^{3-}, and low-zinc baths contain 0.5–2 g/L Zn^{2+} and 12–16 g/L PO_4^{3-}. These ranges are not strict.

(b) In several cases the deposition of phosphate takes place under galvanostatic polarization.

(c) Small concentrations are possible.

(d) These ions are mainly used instead of manganese and/or nickel.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

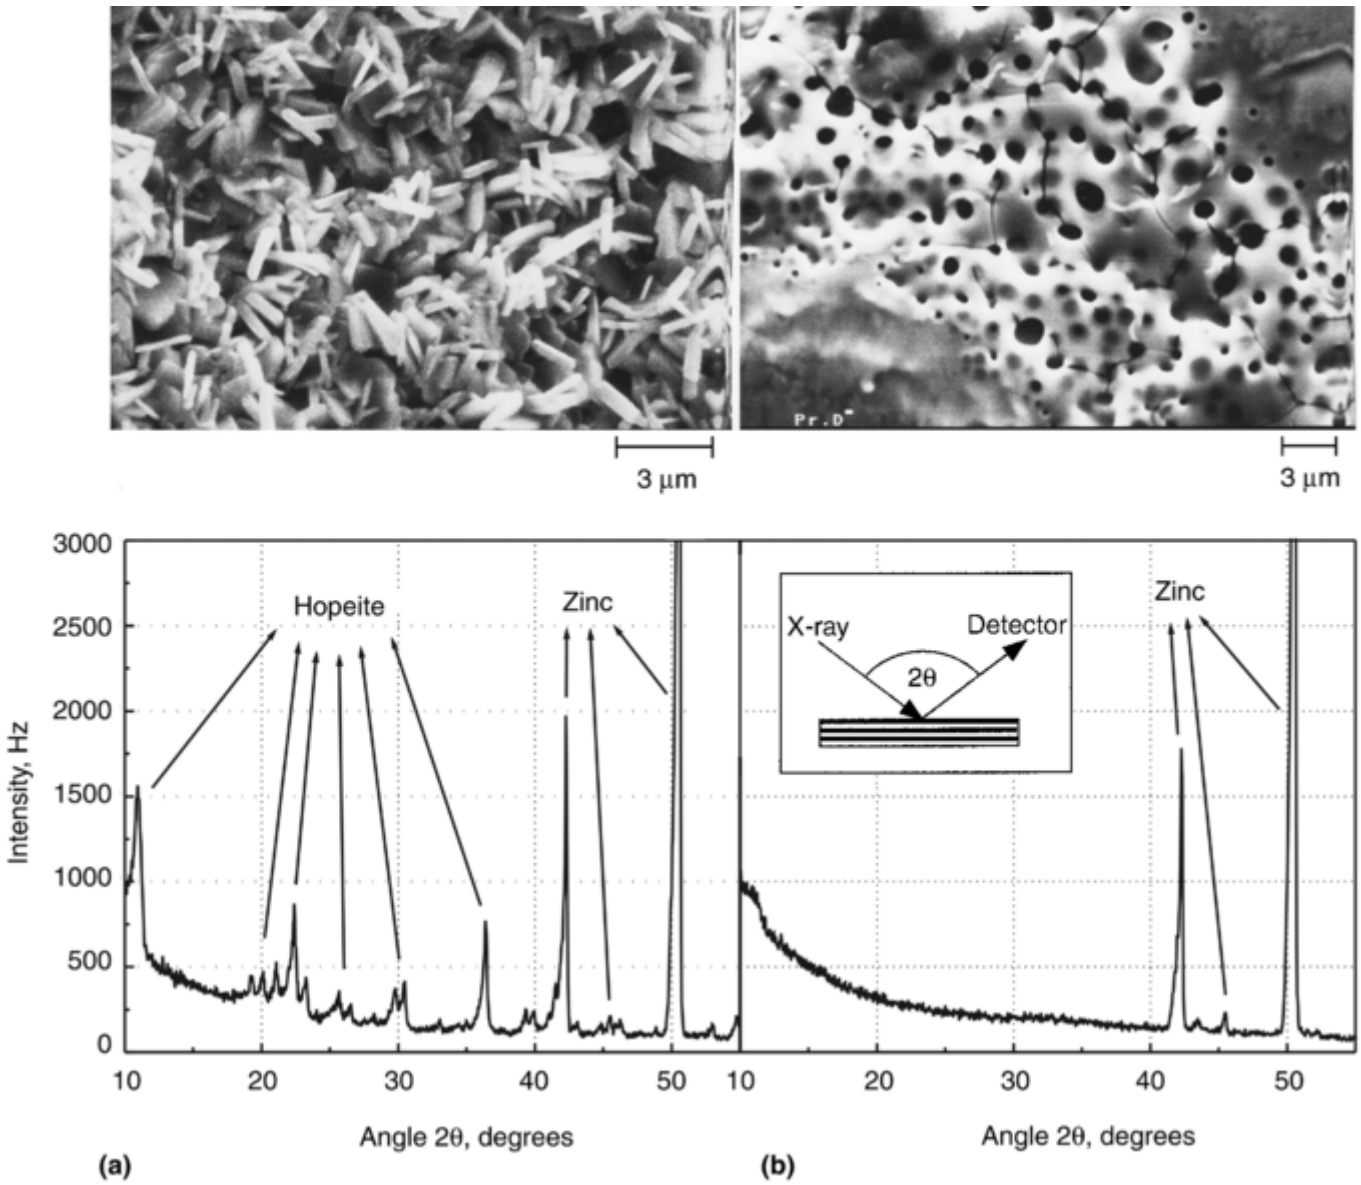

Fig. 1 Scanning electron micrographs and x-ray diffraction patterns comparing crystalline and amorphous phosphate layer. (a) Tri-cation phosphate layer of a spray process. (b) Tri-cation phosphate layer of a no-rinse process. Substrate is electrogalvanized steel.

The amorphous layers are commonly used for temporary corrosion protection, with coating weight ranging from 0.1 to 4.0 g/m^2 (0.00033 to 0.013 oz/ft^2). These layers are formed by alkali phosphating or by no-rinse phosphating. No- rinse phosphatation is mainly used in the coil- coating industry and means that the phosphating solution is applied directly to steel strips and dried without rinsing. Amorphous phosphate layers are formed using both iron- and zinc- based solutions.

Crystalline phosphate layers are most easily categorized by their intended application. For underpaint applications zinc-based phosphate layers formed by low-zinc or standard-zinc processes are used with coating weights ranging from 1 to 7 g/m^2 (0.0033 to 0.023 oz/ft^2). Values around 7 g/m^2 can be obtained on galvannealed and high-strength-steels. For cold forming and lubrification, coating weights of up to 60 g/m^2 (0.20 oz/ft^2) are common. These layers are sometimes referred to as “heavy phosphating” and are often, but not always, based on manganese- rather than zinc-phosphate layers.

Table 2 gives the formula for a number of different phosphate compounds that are theoretically possible in crystalline phosphate layers. The hopeite and phosphophyllite compounds are the most commonly observed. At the time of this writing, most commercial “state of the art” conversion coatings (pretreatment for painting) consist of Zn^{2+} in combination with one or more coatings of Mn^{2+}, Ni^{2+}, and Fe^{2+} (Ref 4).

Table 2 Phosphate compounds found in conversion coatings

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Compound name[(a)]	Chemical formula	Structure
Vivanite	$Fe_3(PO_4)_2 \cdot 8H_2O$	Monoclinic
Iron-hureaulite[(b)]	$Fe_5H_2(PO_4)_4 \cdot 4H_2O$	Monoclinic
Strengite	$FePO_4 \cdot 2H_2O$	Orthorhombic
Hopeite	$Zn_3(PO_4)_2 \cdot 4H_2O$	Orthorhombic
Phosphophyllite[(b)]	$Zn_2Fe(PO_4)_2 \cdot 4H_2O$	Monoclinic
Scholzite	$Zn_2Ca(PO_4)_2 \cdot 4H_2O$	Orthorhombic
Phosphonicollite[(c)]	$Zn_2Ni(PO_4)_2 \cdot 4H_2O$	Orthorhombic
Phosphomangallite[(b)]	$Zn_2Mn(PO_4)_2 \cdot 4H_2O$	Orthorhombic
Manganese-hureaulite[(b)]	$Mn_5H_2(PO_4)_4 \cdot 4H_2O$	Monoclinic
Klinovariscite, variscite	$AlPO_4 \cdot 2H_2O$	Orthorhombic

(a) Hopeite and phosphophyllite are the most common.

(b) Phosphophyllite is (Fe, Mn)$Zn_2(PO_4)_2 \cdot 4H_2O$; hureaulite is (Mn, Fe_5)$H_2(PO_4)_4 \cdot 4H_2O$. The names used in this article were chosen to avoid confusion as to the actual composition.

(c) No mineralogical name known

The “crystalline” phosphate layer is not a simple film. The surface consists of an array of distinct phosphate crystals, which are often a mix of crystalline and x-ray amorphous phases. Figure 2 shows typical electron micrographs of crystalline phosphate films on steel, galvanized steel, and aluminum substrates. In between the phosphate crystals, bare metal may be exposed, but often it is not the metal of the original substrate. Ni^{2+}, Co^{2+}, or Cu^{2+} ions are frequently added to the phosphate bath, and these will deposit by a cementation reaction on the exposed metal surface (Ref 5). Further, the metallic surface between the crystals may be passivated by an amorphous phosphate film. In the case of phosphating followed by a passivating rinse, a chromate or other conversion coating may form between the crystals. The use of a chromate posttreatment may alter the outer surface of the phosphate crystals by producing a thin chromate-containing layer of enhanced chemical stability.

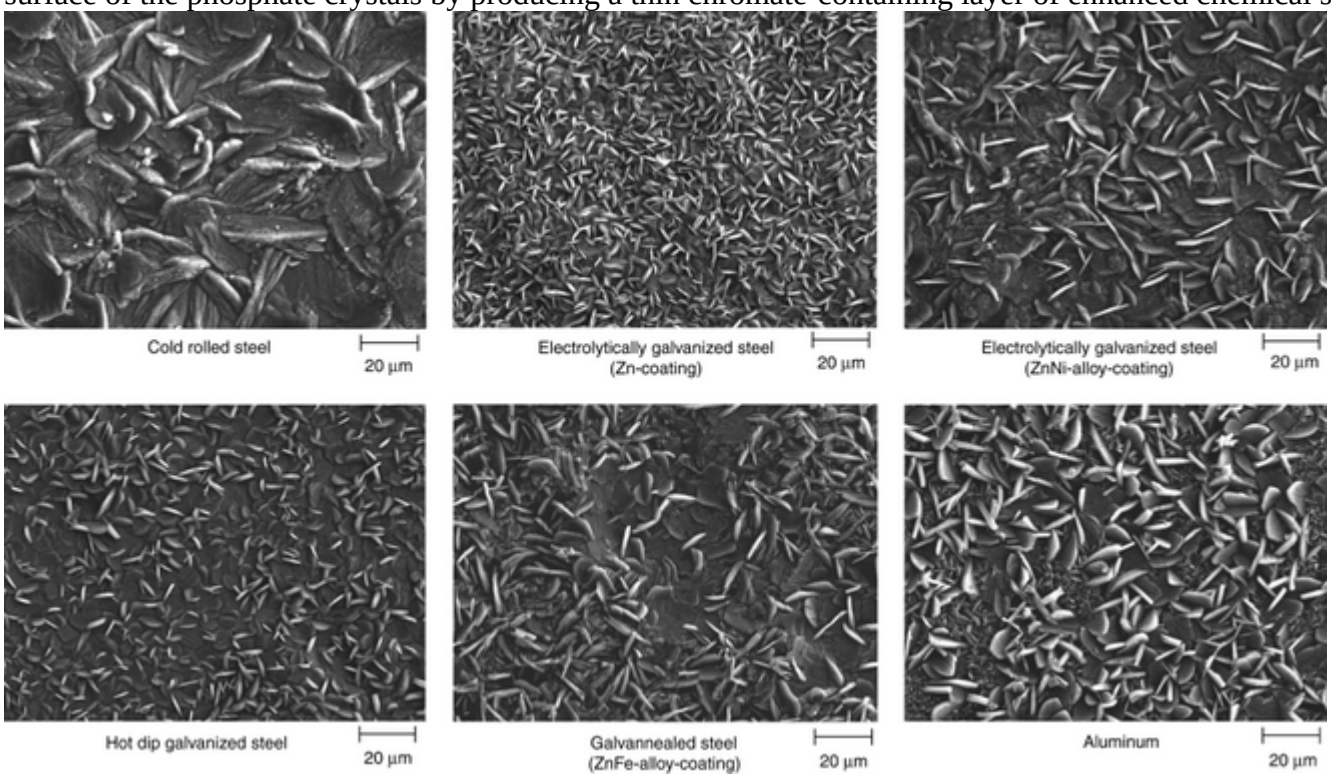

Fig. 2 SEM pictures of crystalline phosphate layers on steel, four different types of galvanized steel, and aluminum. All micrographs are shown at the same magnification.

Several functions may be attributed to the “crystalline” phosphate layer. The nonconducting nature of the phosphate crystal imparts a barrier property with excellent corrosion protection. The voids between the crystals provide anchorage for paint layers, increasing paint adherence. The exposed metal between the crystals is important for providing enough conducting surface to permit the cathodic deposition of paint primers as used in

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

the automotive industry. The fact that the paints are electrophoretic ensures that the deposition process begins at the bottom of the pore and builds up toward the exterior.

For the purpose of lubrication, the porosity of the surface leads to very good oil retention. Further, the oil may chemically bind to the phosphate layer by a saponification reaction. Lastly, on compression, the crystals can form a glass phase at the surface of the metal, imparting extremely low friction for deep drawing applications.

Figure 3 compares creepage behavior of three different painted steel products with and without phosphatation. Creepage is the distance between an artificial damage (scratch, cut, edge, stone chipping) and the border of the delaminated paint. The delaminated paint can be easily removed by scalpel.

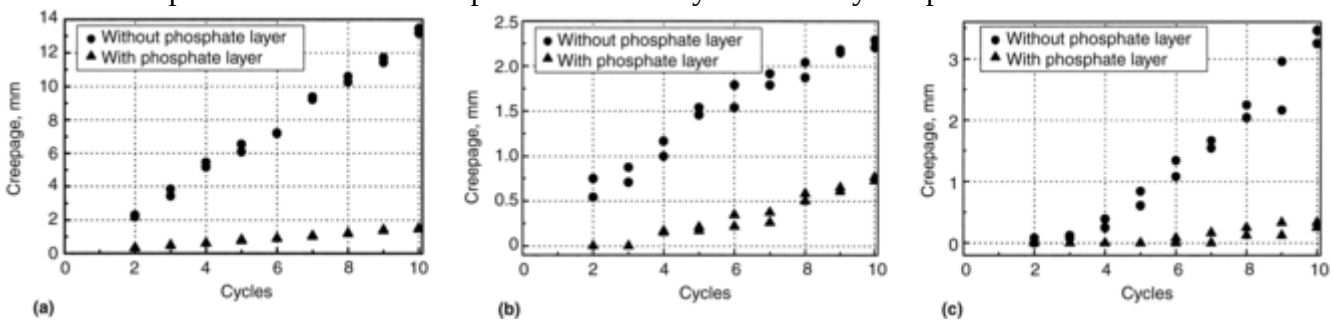

Fig. 3 Trend of paint delamination of steel products. (a) Cold rolled steel. (b) Hot dip galvanized steel. (c) Galvannealed steel (Fe-Zn alloy). Coating is approximately 25 µm electrophoretic paint with and without phosphate treatment. Artificial damage by Van Laar scratch, scalpel comparable to a ball-point pen, then exposed in a cyclic corrosion test. Test cycle was 1 day salt spray fog, plus 4 days condensed water exposure plus 2 days dry period. Creepage is defined as the distance between the artificial damage and the border of delamination. Note that the y-axes are different in scale. Source: Ref 6

Crystalline phosphate layers are often classified by the types of divalent cations present in the phosphating bath: mono-cation (essentially Zn^{2+}), bi-cation (Zn^{2+} and either Ni^{2+}, Ca^{2+}, Mg^{2+}, or Mn^{2+}) and tri-cation (Zn^{2+}, Ni^{2+}, Mn^{2+}). In these formulas, Ni^{2+} is sometimes replaced by Cu^{2+} for environmental reasons, as copper can be used at much lower concentrations. Tri-cation phosphating is considered the state of the art, giving the overall best performance in corrosion resistance and paint adhesion. A comparison of the corrosion behavior of some different types of phosphate layers is given in Fig. 4.

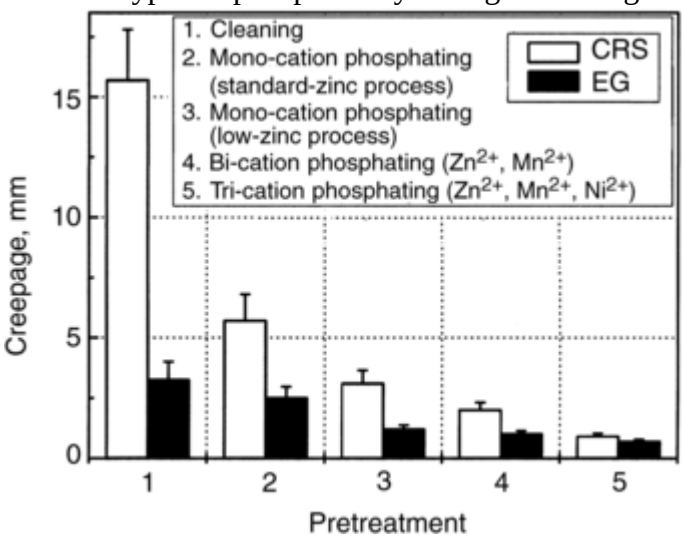

Fig. 4 Delamination of painted steel substrates treated with different zinc phosphatations after 1 year outdoor exposure. Substrate CRS, cold rolled steel; EG, electrogalvanized. Coating electrophoretic paint + filler + top-coat. Artificial damage by Clemen scratch, like a cut with a scalpel

Alkali phosphating, which mostly leads to amorphous coatings, is very different in terms of application and use (Ref 7) from crystalline phosphating. It is usually only applied as a pretreatment for iron and steel, but in principle it could also be applied for zinc, zinc- coated steel, and aluminum. It is used as a low-cost

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

pretreatment for paint or sometimes as an acidic cleaner. The general characteristics of alkali phosphatings are given in Table 1.

There are different types of alkali phosphate layers. On iron or steel, the phosphate layers are a mixture of iron phosphate ($Fe_3(PO_4)_2 \cdot 8H_2O$), iron oxides, and iron hydroxides. The treated surfaces may appear shiny and iridescent with temper colors. The phosphate coating weight lies between 0.1 and 0.4 g/m^2 (0.00033 to 0.0013 oz/ ft^2). Due to organic accelerators such as nitrobenzenesulfonic acid, it is possible to achieve phosphate-coating weights up to 1.0 g/m^2 (0.0033 oz/ft^2). In these cases the surfaces have a gray and dull appearance. The use of additional accelerators and chromium-free posttreatments leads to an optimization of corrosion resistance and paint adhesion. Figure 5 illustrates this development.

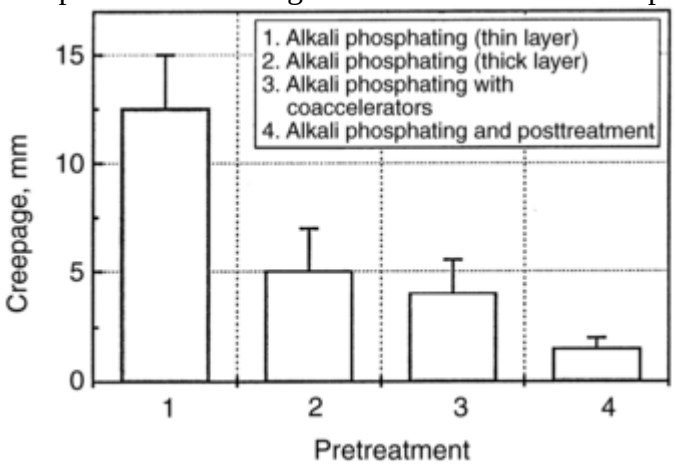

Fig. 5 Delamination of painted steel substrates treated with four different alkali phosphatations after 504 h exposure in salt spray fog. Coating, electrophoretic paint + filler + top-coat. Artificial damage, Van Laar scratch

Phosphating Steps

There are four chemically important steps in the phosphating sequence: cleaning, activation or conditioning (mainly for zinc phosphating), phosphating, and posttreatment plus standard rinsing steps. When used as a pretreatment for paint, the phosphate layer may also undergo phase changes associated with dehydration

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

reactions during painting. Table 3 gives the integration of phosphating processes in different applications, and Fig. 6 illustrates the process sequence and application conditions for the car industry.

Table 3 Typical process sequences in different industries

Industry	Typical process sequence
Car, truck	Cleaning, water rinsing, activating, zinc phosphating, water rinsing, sealing, water rinsing, drying
Galvanizing line	Activating, zinc phosphating, water rinsing, drying
Coil coating line	Cleaning, water rinsing, alkali phosphating (or alternative activating, zinc phosphating), water rinsing, sealing, water rinsing, drying
Household, appliance	Cleaning, water rinsing, alkali phosphating (or alternative activating, zinc phosphating), water rinsing, sealing, water rinsing, drying
Wire-drawing	Pickling, water rinsing, plating, water rinsing, manganese phosphating (not always electrochemical), posttreatment with lime, borax or soaps, water rinsing, drying

Conditioning is an alternative term for activation.

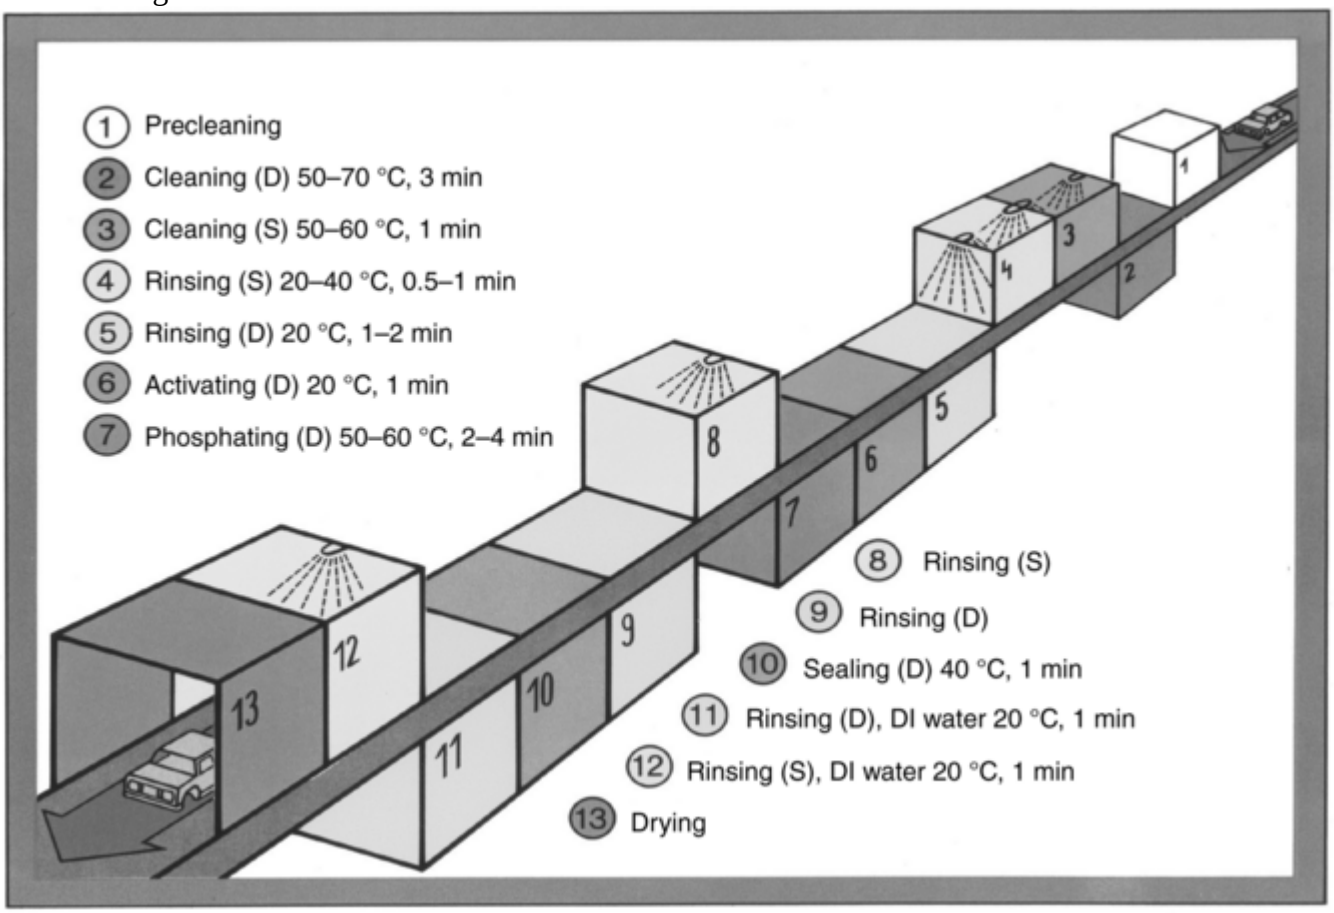

Fig. 6 Typical sequence of pretreatment process for car bodies. D, dipping; S, spraying; DI, deionized water

Cleaning

The degreasing process using aqueous solutions or organic solvents is an extremely important preconditioning step for phosphating (Ref 8, 9). Chlorinated hydrocarbons are very effective at removing oils and grease, but environmental laws strictly limit the use of such solvents. Treatment with alkaline solutions is also quite effective in removing oils and grease and also serves to increase the wettability of the metal surface and to remove oxide layers.

Alkaline degreasing agents consist of builders, complexants, and surfactants. Builders are inorganic salts and hydroxides. NaOH and KOH are responsible for the high pH values and make the primary contribution to the

مرجع مهندسی مواد و متالورژی

ionic conductivity of the aqueous solutions. NaOH and KOH will also hydrolyze animal and plant oil and grease. Degreasing baths using these bases are usually in the pH 12 to 14 range. Iron and steel are normally passive in these high pH cleaning baths. Zinc and aluminum are normally degreased at lower pH because of their increased corrosion rate at high pH.

Commercial alkaline degreasing baths contain numerous additives. Silicates have good emulsifying action and dispersing properties. During cleaning of aluminum, zinc, and zinc-coated steel, a thin layer of silicate deposits on the surface and inhibits the attack of the metal by the alkaline solution. Phosphates, pyrophosphates, and polyphosphates soften the water and partly remove metal oxides and hydroxides. Borates and carbonates have good buffering properties, stabilize the pH, and inhibit the alkaline attack. Zinc and aluminum are normally degreased using cleaning systems based on borates and carbonates.

Surfactants are organic molecules composed of hydrophilic and hydrophobic groups. Due to this structure they cluster at the metal/solution interface. Depending on whether the hydrophilic group is cationic or anionic, the surfactant is called cation-active or anion-active. Nonionics are built up of polyethylene glycol or polypropylene glycol groups and aliphatic chain molecules, and aromatic groups. The surfactants dissolve and emulsify non-hydrolyzable components like mineral oils. Complexing agents like ethylenediamine tetraacetic acid (EDTA), nitrilotriacetic acid (NTA) or gluconates are added to cleaning baths to reduce undesirable precipitation. Table 4 gives an overview of degreasing solution additives.

Table 4 General formulas of alkaline cleaning products

Treated metals	pH[(a)]	Components	Temperature		Time, s[(a)]	Comments
			°C	°F		
Steel	7–14	Alkali, carbonates, phosphates, silicates, borates, complexing agents, surfactants	50–80	122–176	5–300	…
Zinc	7–11 [12–13]	Phosphates, carbonates, borates, silicates, complexing agents, surfactants	50–60	122–140	120–240 [3–15]	Pickling rate rises with alkalinity
Aluminum	7–10 [11–13]	Phosphates, carbonates, borates, complexing agents, surfactants	50–60	122–140	120–240 [3–15]	Pickling rate rises with alkalinity, mostly in combination with acid pickling
Prephosphated substrates	7–9	Phosphates, silicates, borates	50–60	122–140	120–240	Phosphate layer could be removed at higher pH, no tripolyphosphate
Magnesium	12–14	Alkali, carbonates	50–60	122–140	…	Mg is stable at higher pH. Alkaline cleaning is usually followed by acid pickling to remove hydroxide layers.

(a) Values in brackets belong to short processes, like coil coating lines

Activation (or Conditioning)

The activation step consists of exposure to a titanium colloid solution of near-neutral pH (Ref 10). The Ti colloids adsorb on the surface of the metal and serve as nucleation sites for the growth of the phosphate layer. Aqueous dispersions of sodium titanium phosphate are well suited for this preconditioning. A number of other chemicals, such as oxalic acid, amine soaps, or finely ground zinc phosphates have a similar effect. Activation increases the number of phosphate crystals per unit area while decreasing crystal size, coating weight, and the minimum reaction time. Many zinc phosphating systems are totally dependent on the preconditioning stage to deposit a beneficial zinc-phosphate layer. The preconditioner can be applied either as a portion of the final cleaning stage or, preferably, as a separate stage immediately before phosphating. Due to their colloidal character, the activation dispersions are not stable, and the colloids have a tendency to coagulate. This lowers

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

the frequency of nucleation and thus the rate of film growth. The coagulation process is very sensitive to pH, temperature, and water hardness, and these parameters must be precisely controlled (Ref 11, 12).
Phosphate layer nucleation and the effect of the activation step are not clearly understood. It is known from atomic force microscopy (AFM) studies that the colloids in the aqueous dispersion are disc-shaped and adsorb physically with the flat side against the metal surface (Ref 13). It is thought that an ion-exchange reaction occurs on the colloid surface between the sodium ions of the colloids and the zinc ions of the phosphating solution (Ref 14) and that this reaction initiates the growth of the phosphate layer.

Phosphating

The function of the constituents is described in the following discussion.
Basic Function of the Bath. The zinc phosphating bath consists mainly of phosphoric acid and divalent metal cations. The rate controlling step for the growth of the phosphate film is the reaction of H^+ ion and/or other oxidizing agents present as additives at the metal surface. The solution is inherently aggressive to the substrate metal, and the acidic attack of the metal surfaces leads to a local increase in pH and metal ion concentration (Ref 15, 16). When the solubility product of the tertiary metal phosphate is reached, then the corresponding phosphate compound will precipitate. In the case of zinc, the solubility product is $K_L\{Zn_3(PO_4)_2 \cdot 4H_2O\} = 5 \times 10^{-36}$. Additionally, the stability constants of $ZnH_2PO_4^+ (10^{3.3})$ and $ZnHPO_4 (10^{1.6})$ have to be taken into account (Ref 17, 18). The basic chemical reactions involved in the phosphating process are:

$$Me \rightarrow Me^{2+} + 2e^- \quad \text{Metal dissolution}$$

$$2H^+ + 2e^- \rightarrow H_2 \quad \text{Hydrogen evolution}$$

$$\begin{aligned} H_3PO_4 &\leftrightarrow H_2PO_4^- + H^+ \\ H_2PO_4^- &\leftrightarrow HPO_4^{2-} + H^+ \\ HPO_4^{2-} &\leftrightarrow PO_4^{3-} + H^+ \end{aligned} \quad \text{Protolytic equilibria of phosphoric acid}$$

$$2PO_4^{3-} + 3Me^{2+} + 4H_2O \rightarrow Me_3(PO_4)_2 \cdot 4H_2O\downarrow$$

Metal phosphate layer precipitation

where Me^{2+} is one of several possible metal ions. The growth of the phosphate crystals continues until the coverage of the surface stops by self-inhibition as insoluble phosphate crystals block the metal dissolution and the consumption of H^+. The formation of $Me_3(PO_4)_2 \cdot 4H_2O$ is applicable to many crystalline phosphate coatings. Other phosphates may also precipitate, such as:

$$5Me^{2+} + 2HPO_4^{2-} + 2PO_4^{3-} + 4H_2O \rightarrow Me_5H_2(PO_4)_4 \cdot 4H_2O\downarrow$$

Metal Ions. In the phosphate layer, metal ions come from both the substrate metal and from the solution. For example, a zinc phosphate bath used to treat steel will contain hopeite ($Zn_3(PO_4)_2 \cdot 4H_2O$) and phosphophyllite ($Zn_2Fe(PO_4)_2 \cdot 4H_2O$), where the Fe^{2+} in the later species comes from the steel substrate. Other metal ions used in the phosphating bath are Mn^{2+}, Ni^{2+}, Co^{2+}, Cu^{2+}, Ca^{2+}, and Mg^{2+}. More noble metal ions like Ni^{2+}, Co^{2+}, or Cu^{2+} deposit by a cementation reaction on substrates like steel, zinc, and aluminum (Ref 5, 19, 20).
The development of zinc phosphating began with the so-called standard-zinc process. These baths contain approximately 3 to 7 g/L zinc and 6 to 9 g/L phosphate. It has been found, however, that a reduction of zinc (to ~1 g/L) and an increase of phosphate (to ~15 g/l) significantly improve the performance of the phosphate layers because of the greater formation of phosphophyllite or phosphonicollite. These processes are called low-zinc phosphatation. The concentration ranges are not so strict and could overlap in some cases.
Metal Surface. The reactivity of the metal surface being treated plays an important role in the phosphating process. Zinc and steel are readily attacked by phosphoric acid solution and are fairly easy to treat. Magnesium is highly reactive, which may cause problems. Aluminum requires the addition of fluoride ions to maintain sufficient reactivity. Passivating materials like stainless steel are difficult to phosphate. In general, the effect of alloying elements on the phosphating process can be predicted by their effect on the overall reactivity of the metal being treated. For the steel surface, most segregated oxides will block the phosphating reaction (for

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

instance, Cr_xO_y, Si_xO_y, Al_xO_y, …) (Ref 21, 22); occasionally this is a problem. Some oxides, in particular manganese oxides, actually increase the reactivity of the steel surface and are incorporated into the phosphate layer, yielding particularly good phosphating activity. Additionally, the roughness of the surface being treated plays an important role in the phosphating reactivity. For instance, skin passing is a rolling-mill process that increases surface roughness and substrate hardness. It breaks up oxide layers and increases the surface reactivity.

Accelerators. Modern phosphating baths use additives called accelerators to hasten the phosphating process. In the absence of accelerators, H^+ ion is the principal oxidant, and the formation of hydrogen bubbles at the surface disturbs the phosphating process. Therefore, it is necessary to suppress hydrogen evolution by another suitable reaction in order to accelerate the phosphatation step. Oxidants such as nitrate, nitrite, chlorate, bromate, peroxy compounds, ozone, organic nitro substances, hydroxylamine, and molybdate can play the role of a cathodic depolarizer. These substances are consumed reductively prior to the hydrogen evolution. Some of these reactions are:

$$NO_2^- + 2H^+ + e^- \rightarrow NO + H_2O$$
$$NO_3^- + 10H^+ + 8e^- \rightarrow NH_4^+ + 3H_2O$$
$$R - NO_2 + 6H^+ + 6e^- \rightarrow R - NH_2 + 2H_2O$$

where R is an organic group

$$ClO_3^- + 6H^+ + 6e^- \rightarrow Cl^- + 3H_2O$$
$$BrO_3^- + 6H^+ + 6e^- \rightarrow Br^- + 3H_2O$$
$$H_2O_2 + 2H^+ + 2e^- \rightarrow 2H_2O$$
$$O_3 + 2H^+ + 2e^- \rightarrow O_2 + 2H_2O$$

$$NH_2OH + 3H^+ + 2e^- \rightarrow NH_4^+ + H_2O$$
$$2NH_2OH \rightarrow N_2O + H_2O + 4H^+ + 4e^-$$ Disproportionation

$$2MoO_4^{2-} + 10H^+ + 2e^- \rightarrow 2Mo(OH)_3 + 2H_2O$$

In the redox system (NO_2^-, NO_3^-), a variety of oxidation states between +5 and −3 are possible. Hydroxylamine has both oxidative and reductive properties (disproportionation reaction), whereas the others show only oxidative behavior. Molybdates are only used in the amorphous alkali phosphating process. Molybdenum could also vary in the oxidation state, which is again related to the color and iridescent appearance of the alkali phosphate coating.

These accelerators will readily oxidize iron so that it will precipitate as $FePO_4$ and be eliminated from the bath. The advantages and disadvantages of common accelerators are listed in Table 5. Many phosphating processes use combinations of two or more accelerators. Common combinations are nitrite/nitrate, nitrite/chlorate/ nitrate, peroxide/chlorate, and chlorate/nitrobenzene sulfonic acid. Some accelerators form by- products that build up in a bath and, over time, could be detrimental to performance.

Table 5 Comparison of accelerators used in the phosphating process

System	Nitrite/nitrate	Hydroxylamine	Peroxide	Nitroguanidine	Chlorate, nitrobenzene sulfonic acid
Concentration	0.05–0.1 g/L NO_2^-	0.5–1.5 g/L	30–50 mg/L	0.1–1.0 g/L	1–3 g/L ClO_3^- 0.4–1.0 g/L $C_6H_4(SO_3H)NO_2$
Control	Simple, often	Simple, sporadic	Complex, often	Sporadic, very complex	Sporadic, very complex
Replenishment	Separately	Internal	Separately	Separately	Separately

Fluorides. When phosphating aluminum, high-strength steels containing silicon and/or aluminum or galvanized steel using zinc-aluminum alloys, such as hot-dip galvanized (0.14 to 0.30% Al-Zn), Galfan (5% Al- Zn), Galvalume (40% Al-Zn) or Galvannealed (Fe-Al-Zn), sufficient fluoride ions must be available to remove silicon oxide or aluminum oxide layers and complex the Al^{3+} or the Si^{4+} ion. Once in the bath, the aluminum will precipitate in the form of cryolithe, Na_3AlF_6, or elpasolithe, NaK_2AlF_6. Aluminum ions must be removed from the phosphating bath, because Al^{3+} disturbs the phosphating reaction. Fluorides can be added as HF, NaF, KF, HBF_4, or H_2SiF_6.

$$AlOOH + 3HF \rightarrow Al^{3+} + 3\,F^- + 2H_2O$$

$$Al^{3+} + 6F^- + 3Na^+ \rightarrow Na_3AlF_6\downarrow$$

Bath Pollution. There are several ions and substances that may disturb the phosphating reaction, and their build up in the bath must be avoided. Table 6 gives an overview of the problem ions. In the presence of such compounds, passivation, inhibition, complexation, cementation, or pitting corrosion (technical term: *white spotting*) (Ref 23) may occur instead of the phosphating reaction (Ref 24).

Table 6 Common pollutants for the phosphating reaction

Compound	Limiting concentration, mg/L	Consequence
Al^{3+}	3	Amorphous layer
V^{6+}	3	Passivation
Cr^{6+}	3	Passivation
Cr^{3+}	10	Passivation
Mo^{6+}	15	Passivation
Pb^{2+}	10	Cementation
As^{3+}, As^{5+}	3	Passivation
Ti^{4+}	5	Passivation
Zr^{4+}	5	Passivation
Sn^{2+}	5	Cementation
Cl^-	30–40	White spotting (pitting corrosion)
Cationic surfactants	20	Inhibition
Polyphosphate	20	Complexation, inhibition

Posttreatment. The pores between the phosphate crystals, although necessary to allow sufficient conduction for the electrodeposition of paint, may also represent failure points (Ref 2, 19, 25). A subsequent post treatment step may therefore prove necessary to protect these spaces. Sealing is done by substances that form insoluble oxides, hydroxides, phosphates, and so forth on the metal surface. Historically, the sealer of choice is chromate. The aqueous acidic solutions of chromium (VI) compounds and additives are applied in a kind of rinsing process on the phosphated metallic surface. Chromium (VI) is reduced to the basic chromium (III) and leads to a deposition of a gel-like film containing primarily chromium (III), with smaller amounts of chromium (VI), cations of the treated metal, and other components. The final phosphate conversion layer is completed after aging and drying.

There are two basic types of chromate sealing rinses. One type contains only chromic acid, and the other is a mixture of CrO_4^{2-} and Cr(III). Similar results can be obtained with solutions containing only Cr(III) (chromitation). Due to ecological hazard and noxious problems of Cr(VI), alternative treatments are needed.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Such posttreatments can contain other polyvalent metal cations and/or organic compounds such as monomers, oligomers, or polymers. Some popular examples are the fluoro-complexes of Zr^{4+} and Ti^{4+}, Cu^{2+} ions, MoO_4^{2-} (Ref 26), polyacrylates, silanes, and other organic compounds. Regardless which final rinse is used, the optimum pH is in the range of 3.8 to 5.0 to avoid dissolving the phosphate layer.

Physical and Chemical Properties

Gravimetric Analysis. Coating weight per unit area is the most characteristic measure of phosphate layers. Phosphated panels are weighed before and after stripping the phosphate layer. Oil, wax, grease, organic anticorrosive agents, and lacquer coatings must be removed prior to the analysis using organic solvents, and great care must be taken to ensure that the phosphate layer is not damaged in the process. Table 7 gives a list of phosphate-stripping solutions for a variety of phosphate layers and metals. In general, coating weight alone is a poor indicator of quality. It is more useful as a test of the consistency of the bath.

Table 7 Stripping solutions for phosphate layers

Metal	Stripping solution composition, wt%	Temperature		Time, min	Total metal removed, g · m^2
		°C	°F		
Iron, steel	12Na_4-EDTA, 4TEA, 9NaOH, 75H_2O	70	158	2–5	0.1
	5CrO_3, 95H_2O	70	158	15	0.05
Zinc	2.2$(NH_4)_2Cr_2O_7$, 27.4NH_3, 70.4H_2O	25	77	5	0.01
	5CrO_3, 95H_2O	25	77	5	0.05
Aluminum	65HNO_3, 35H_2O	25 (75)	77 (167)	15 (5)	0.1
Magnesium	0.5CrO_3, 99.5 H_2O	25	77	1–3	(a)

(a) Insufficient experience available

Chemical Analysis. The composition of the phosphate layer influences its performance and is therefore an important property. Elemental composition can be analyzed by wet analysis, x- ray fluorescence spectroscopy, and glow-discharge optical emission spectroscopy. Phase analysis is performed by x-ray diffraction and sometimes by Raman spectroscopy. Oxidation states and molecular information may be obtained from x-ray photoelectron or Auger electron spectroscopy (Ref 19). Wet chemical analysis of stripping solutions is typically used for determination of the composition of phosphate layers.

Structure and Morphology. A further consideration in the quality of crystalline phosphate layers is the structure of the coating (Ref 27). It is desirable that the phosphate crystals cover the surface homogeneously and have a fine crystalline, needle-, and shingle-like structure. Characterization includes light microscopy, scanning electron microscopy (SEM), field emission microscopy (FEM), and atomic force microscopy (AFM). The use of SEM is preferred over light microscopy because of the higher depth of focus, while FEM permits characterization of the phosphated surface with very low excitation voltage, yielding a higher surface sensitivity. A three-dimensional picture of the phosphated surface can be obtained by AFM or confocal laser microscopy.

Coverage. Complete coverage of the metal surface is also an important property of phosphate coatings, because paint adhesion is based on the mechanical locking of the paint into the voids between the crystals (Ref 25). Therefore, characterization of the so-called porosity of the layer and the determination of the degree of coverage and the volume of the pores is important. The simplest method is the visual or microscopic observation. Phosphated surfaces should appear dull and matte; the presence of shiny areas indicates the absence of the phosphate film.

More sophisticated chemical and electrochemical methods rely on the principle that a specific reaction may occur on the “free” metal surface. Turnbull's blue reaction (on steel substrates) and the cementation of copper (on zinc and zinc coated steel) are popular techniques to detect uncovered spots. The metallic surface between

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

the crystals may also be characterized by electrochemical methods since the phosphate layers are electronic insulators. Typical examples of experiments are the diffusion-limited currents for the reduction of oxygen (Ref 28), anodic charging curves corresponding to the oxidation of the metal surface (Ref 29), estimation of the polarization or charge transfer resistance (Ref 30), and measurement of the double-layer capacitance (Ref 27).

Thermal Analysis. The behavior of phosphate layers at higher temperatures is of technical importance. For example, at the drying temperatures of electrophoretic paints (150 to 200 °C or 302 to 392 °F), (Ref 31), the dehydration of hopeite occurs in two steps. Two crystal water molecules are lost in the temperature range of 80 to 120 °C (176 to 248 °F). The remaining two water molecules are lost around 250 °C (482 °F). The first dehydration step is reversible in the presence of moisture. After rehydration, the phosphate crystals are finer and orientations are different. Manganese and nickel increase the temperature of dehydration. In contrast to hopeite, the phosphophyllite phase becomes amorphous and the dehydration is irreversible.

Alkaline Resistance. An important chemical property of phosphate layers is their resistance to alkaline electrolytes (Ref 31, 32, 33, 34). Such an exposure may occur during cathodic deposition of paint (cathodic polarization of the substrate), during alkaline degreasing processes (for example prephosphated steel products) and under the paint coating during cathodic delamination (Ref 35, 36, 37). In these cases the stability of the phosphate layer can be increased by modifying the phosphating bath with Mn^{2+}, Ni^{2+}, Fe^{2+}, Mg^{2+}, Cu^{2+}, and Co^{2+}. The alkaline resistance of phosphophyllite is higher than that of hopeite.

Phosphate Conversion Coatings

Kevin Ogle, Irsid, Arcelor R&D (Maizières-lès-Metz, France); Michael Wolpers, Henkel KGaA (Düsseldorf, Germany)

Processing Equipment and Control

Phosphating solutions are usually applied by spraying or immersion, and the choice depends on the number, size, and shape of the parts to be treated. At coil coating or galvanizing lines, zinc-coated steel strips may be phosphated by a roll-on, dry-in-place, or no-rinse-process, during which the phosphating solution is applied to the strip and is dried without rinsing.

Spray Treatment. Spray phosphating is done in cabinets or tunnels. It involves pumping the bath through a series of risers that have spray nozzles aligned to coat all areas of the workpiece. Depending on the work being treated, different kinds of spray nozzles are used, such as flat-jet nozzles, full-cone nozzles, hollow-cone nozzles, and spoon nozzles. The spray treatment leads to rapid formation of the phosphate layer, because spraying guarantees a good exchange of the solution at the surface due to the strong solution impingement with the metal surface. Complex parts are difficult to treat. Movable robotic arms equipped with tank nozzles spraying in all directions are used to treat the internal areas of car bodies.

At coil coating or galvanizing lines, spraying is mainly used to phosphate zinc-coated steel strips. The solutions are applied in cabinets with spray beams on the top and bottom sides of the strip. Different spray zones are separated by squeeze rollers to avoid delay in the following stages.

Immersion Treatment. The advantages of the immersion treatment method are better treatment of surfaces of the workpiece (box sections), better drainage between stages with less drag- through of contaminants from one stage of the process to another, less maintenance and repair, lower bath-heating costs, and generally better coating performance than that for sprayed work. Also, large baths are less sensitive to changes such as depletion of chemicals or bath contamination; temperatures are more stable in the larger baths. Both facts are important for controlling and monitoring the bath. There are two major disadvantages. First, dipping is slower because mass transfer at the solution-metal interface is less intensive. Second, dipping requires the use of a larger volume of bath than spraying. This, in turn, implies more floor space, higher equipment costs, and a higher cost for recharging and waste disposal.

The process engineering of immersion treatment is comparable to spray treatment. The baths are aligned in series in cabinets or a tunnel with access at the entrance and exit. In the car industry, different engineering systems have been developed:

- Simple horizontal dipping
- Combination of dipping and spraying, with upper part sprayed and bottom part dipped
- To save floor space and shorten the treatment line, vertical dipping of car bodies. This process is called VERTAK (Dürr) and is a special technology for the phosphating process.
- To remove sludge on horizontal surfaces and to avoid air bubbles under roofs, the RO-DIP (Dürr) process involves the turning of car bodies several times.
- To improve the streaming behavior at the solution-metal interface, the installation of wing lamellas on the interior sides of the bath provides a constant and uniform stream to the part to be treated.

Materials. Tanks may be made from low-carbon steel for alkali cleaners, conditioners, and final rinses. If deionized water is used for these processes, stainless steel or plastic is indispensable. Phosphate systems may require stainless steel, depending on the presence of F^- or NO_3^-, acidity, operating temperature, and the desired lifetime of the tank. Nozzles must be stainless steel. Polypropylene, glass-fiber reinforced plastic, synthetic fluorine-containing resins, or plastic-lined steel can be substituted for stainless steel in some circumstances, but the use of plastics is limited to lower-temperature applications. These materials can also be used for pipes, pumps, and storage tanks.

مرجع مهندسی مواد و متالورژی

Removal of Sludge and Scale. Sludge is formed by the undesirable precipitation of metal ions in the phosphating solution. One source of sludge is the oxidation of iron or manganese to form insoluble phosphates. In addition, precipitation for coating formation may produce phosphate that does not deposit on the workpiece. Scale is the phosphate coating that forms on processing equipment. A major cause of scale is excessive heating of the bath. Because most divalent metal phosphates are less soluble at higher temperatures, the localized heating that occurs with raising or maintaining the bath temperature can cause scale to form on heating elements. Sludge usually settles to the bottom; it can then be pumped to a filtration unit. In some cases, solution is pumped to a temporary storage tank and the sludge-rich solution from the bottom is removed. Scale is more difficult to remove. The most expedient method is to use an inhibited acid to dissolve it.

Solution Heating and Mixing. The optimum method of heating depends on the process equipment, but the following points should be kept in mind:

- Because phosphates precipitate at higher temperature, heating surfaces should be easy to clean.
- Spot heating should be avoided.
- The heat source should not be at the bottom of the tank, since settling sludge will insulate it.

Direct heating such as steam, electric, or gas heating should be avoided, because phosphates can precipitate on the surfaces of the heating system, blocking further heat transfer. Secondary heating—for example, external heat exchangers with hot water or oil—gives more satisfactory results. The temperature difference (ΔT) across heat exchanger plates (between the phosphating solution and the heating media) should be in the range of 5 °C (9 °F) to avoid scaling. The ΔT should never exceed 15 °C (27 °F).

For immersion phosphating, the last method would also be a useful source of solution mixing. The solution must be pumped in spray phosphating, but solution pumping is also necessary to obtain optimum results in some immersion systems. Barrel phosphating can provide considerable mixing around the part by rotation of the barrel; additional mixing is usually not required. Conveyor applications may or may not need additional mixing.

Replenishment. The solution should be replenished continuously to get a uniform coating. Automatic devices, such as dosing pumps which run continuously, are useful in controlling solution composition. Replenishment should be done in places in the phosphating system where rapid mixing occurs. It is not useful to dose the replenisher on the pressure side of the phosphating system, especially before the heating system. This can lead to additional sludge and scale and, therefore, to poor heating efficiency.

Chemical Analysis and Bath Control. The primary methods of bath control are acid-base titrations that measure the amount and type of acid present. Phosphoric acid has three dissociation steps. The so-called free acid is related to the first point of equivalence and is the amount (in milliliters) of 0.1 *N* sodium hydroxide (NaOH) needed to neutralize the strong acidity from 10 mL of the bath. The total acid correlates to the second dissociation step, a weak end point. It is the amount (in milliliters) of 0.1 *N* NaOH needed to neutralize all the acid in 10 mL of solution including the acidic metal-aquo complexes. The third dissociation equilibrium is not detectable by NaOH titration. Under several circumstances a back titration with 0.1 *N* sulfuric acid (H_2SO_4) is necessary to determine the free acid. In these cases the free acid becomes negative. Results are stated in points; for example, 2 mL = 2 points.

Metal concentrations can be checked by spectroscopic methods like atomic absorption spectroscopy, inductively coupled plasma atomic emission spectroscopy, flame emission spectroscopy, and so forth. Zinc concentration can be determined by a potentiometric titration with $K_4[Fe(CN)_6]$.

Accelerator concentrations are often determined by redox titration. The following methods are commonly used:

- Permanganate titration for NO_2^-
- Gas generation with urea and sulfamic acid for NO_2^-
- Acid-base titration of the free acid without and with acetone for NH_2OH
- Thiosulfate titration with potassium iodide for H_2O_2

Fluoride (F^-) is determined most efficiently by the use of an ion-sensitive electrode. This is of particular interest when processing aluminum, because one of the important uses of F^- is to keep the concentration of aluminum down by the formation of AlF_6^{3-} ions.

مرجع مهندسی مواد و متالورژی

Ionic conductivity measurements can be related to the concentration of the solution constituents in the phosphating bath and, thus, can serve as a test for replenishment.
Conductivity measurements are simple to run on a phosphate bath; therefore, they are more widely used than titrometric-type controllers are. Unfortunately, because conductivity does not directly measure the relevant parameters, some systems require adjustment of replenishment levels as the phosphate bath ages and require recalibration when a new bath is built up.

Chromate and Chromate-Free Conversion Coatings

Introduction

CHROMATE CONVERSION COATINGS (CCCs) are thin (0.01 to 3 μm, or 0.0004 to 0.012 mil) amorphous inorganic films formed by contacting a metallic surface with an aqueous solution whose main film-forming agent is a soluble chromate species. Chromate conversion coatings form spontaneously without application of current or voltage and are applied most commonly to aluminum-, zinc-, magnesium-, iron-, cadmium-, and tin-base alloys. The coatings are primarily used to improve adhesion of subsequently applied organic coatings or to impart corrosion resistance during atmospheric exposure. Two important coating subtypes are chromium chromate and chromium phosphate coatings. Coatings consist of mixed metal oxides and hydroxides derived from chemical oxidation of the substrate and electrochemical and chemical reaction of species present in the coating solution. Coating thickness, color, and corrosion resistance depend on contact times, temperatures, solution chemistry, application method, and substrate composition. Certain types of CCCs contain labile hexavalent chromium (Cr(VI)), which can leach from the coating into an attacking liquid environment. Leached Cr(VI) can be transported through a contacting liquid phase to coating defects, where it may act to stifle further corrosion. In this sense, some CCCs are “self- healing.” The self-healing effect diminishes as CCCs dehydrate. As a result, the corrosion protection provided by stand-alone CCCs may decrease during exposure to ambient environments and elevated temperatures.

Historical Perspective

The use of inorganic chromate surface treatments can be traced to the early 20th century (Ref 1, 2). Alkaline carbonate-chromate solutions were devised for early aluminum-copper alloys in the 1920s (Ref 3, 4). Chromium phosphate coatings evolved prior to and during World War II (Ref 4). Formulations of this type are still in use today for zinc and zinc-aluminum metallic coatings on steel. Chromium chromate coatings with excellent corrosion resistance were developed in the 1950s (Ref 5, 6). These types of coatings were among the first to be recognized as self-healing (Ref 7). Accelerated chromium chromate formulations were introduced around 1970 (Ref 8) and are commonly used with aluminum alloys for stand-alone corrosion protection or as a base for paints.

The primary film-forming agent in CCC baths is Cr(VI). This compound is a potent human toxin and known cancer-causing agent (Ref 9, 10, 11, 12, 13, 14). There is a great demand to eliminate chromium from conversion coating processes to reduce health risks in the workplace and to reduce the potential for damage to the environment. Since the 1980s, there has been significant growth in research and development efforts aimed at identifying chromate-free coatings that match the ease of applicability and excellent performance of CCCs. While chromate replacement has occurred in certain applications (Ref 15), CCCs are still used in the most demanding applications.

Chromate Conversion Coating Formation

The following factors affect the formation of CCCs.

Bath pH and Cr(VI) Concentration. Cr(VI) speciation in coating baths is an important variable in CCC formation. Cr(VI) in solution speciates via hydrolysis and dimerization to chromate, CrO_4^{2-}, dichromate, $Cr_2O_7^{2-}$, or bichromate $HCrO_4^-$ (Ref 16). The predominant species present depends on Cr(VI) concentration and pH as shown in Fig. 1. Formation of chromium chromate coatings is normally carried out at pH values where dichromate is the predominant Cr(VI) species. Solution concentrations of 50 mM Cr(VI) and a pH of 1.2 to 3.0 are typical of modern commercial CCC bath formulations, because the most robust coatings form under these conditions. The total chromate concentration in the coating bath solution may vary by a factor of two or more without a significant impact on film formation rate (Ref 17).

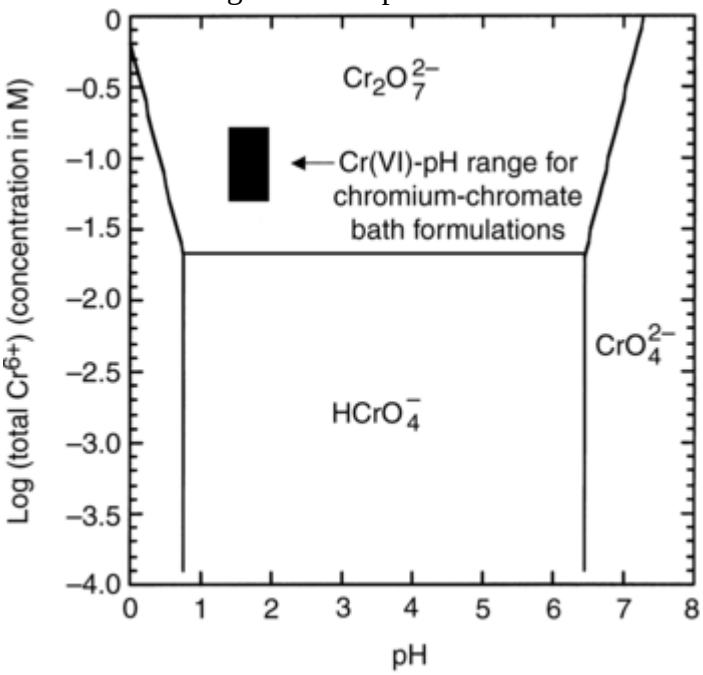

Fig. 1 Speciation of soluble Cr(VI) as a function of pH and concentration. The labels indicate the predominant soluble chromium species in a given pH-concentration domain. Many commercial CCC bath formulations have Cr(VI) concentrations that fall in the shaded box so that the primary film-forming species is dichromate. (Equilibrium constants from Ref 16)

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Activators and Accelerators. CCC formation is greatly aided by “activating” species such as fluoride, sulfate, nitrate, formate, and acetate, among others (Ref 2). Fluoride is particularly effective in promoting film growth and is often added to both chromium chromate and chromium phosphate baths. Fluoride is typically added as NaF and mixed metal fluoride salts whose total concentration is in the 30 to 40 mM range. Fluoride attacks existing surface films, particularly on aluminum. It readily complexes Al^{3+} in solution and has the effect of lowering the aluminum content in CCCs (Ref 18). Consequently, CCCs are thicker and richer in chromium when F^- is added to the bath.

The use of “accelerators” in chromium chromate coating formulations began about 1970 (Ref 8). Accelerators used in commercial CCC formulations include: ferricyanides, acetates, formates, and chlorides, among others (Ref 17). Of these, potassium ferricyanide, $K_3Fe(CN)_6$, has been widely studied and described in the scientific and technical literature. Potassium ferricyanide is added to CCC formulations in 2 to 5 mM concentrations to increase coating weight. The active component in this compound is the ferricyanide anion, $Fe(CN)_6^{3-}$, which accelerates chromate reduction reaction kinetics, which are otherwise slow on oxide-covered surfaces (Ref 19). For example, on aluminum, $Fe(CN)_6^{3-}$ is readily reduced to ferrocyanide, $Fe(CN)_6^{4-}$. Ferrocyanide is oxidized by Cr(VI), which reduces to Cr(III) and contributes to film formation. Coupling substrate oxidation to chromate reduction by this mediation mechanism increases the film formation rate, which results in a more corrosion-resistant coating. Ferricyanide is also incorporated into the CCC, with iron-to-chromium ratios of 1 to 10 reported in at least two studies (Ref 19, 20). Ferricyanide has also been proposed to exist as mixed metal cyanide in CCCs (Ref 21, 22, 23). Direct effects of these compounds on coating corrosion resistance or paint adhesion have not been clearly established.

Experimental evidence from Raman spectroscopy suggests that ferricyanide adsorbs preferentially on copper-rich inclusions in Al-Cu-Mg alloys in a way that can interfere locally with CCC formation (Ref 24). This adsorbed layer forms rapidly and appears to suppress the Cr(VI) to Cr(III) reduction process that leads to film growth. This results in a thinner, chromium-deficient coating on the inclusion. How this affects subsequent corrosion protection has not been clearly established.

Chromium Chromate Coatings. Modern coating chemistries typically consist of 50 mM CrO_3, 30 to 40 mM mixture of fluoride and fluoro salts, and 2 to 5 mM potassium ferricyanide. Commercial formulations often include other minor ingredients and may have alternate activators and accelerators. The bath may be acidified with addition of nitric acid to bring the pH into the desired range.

In the case of aluminum alloys, and probably zinc and magnesium as well, chromium chromate conversion coating formation involves both chemical and electrochemical reactions. The classic formation reaction for a chromium chromate coating on aluminum is stated as (Ref 25):

$$Cr_2O_7^{2-} + 2Al + 2H^+ + H_2O \rightarrow 2CrOOH(s) + 2AlOOH(s) \quad \text{(Eq 1)}$$

This reaction scheme illustrates the coupling of aluminum oxidation to chromate reduction and the subsequent formation Cr(III) or mixed chromium/aluminum hydroxide, but chromium chromate coatings are usually more chromium-rich than the stoichiometry of Eq 1 suggests (Ref 26, 27). CCCs also contain Cr(VI), which is not indicated by Eq 1.

CCC formation does not occur entirely by electrochemical reaction. Rather, there appears to be two distinguishable phases to CCC growth: one that is characterized by intense net electrochemical activity and one that occurs with comparative electrochemical quiescence (Ref 28, 29). At times less than 30 s, coating growth occurs with significant detectable electrochemical activity (Ref 29). Coating weight (Ref 30) and thickness (Ref 18) are observed to increase rapidly. Cr(III) and Cr(VI) are detected in the coating (Ref 31), and coating morphology is characterized by a compact mass of nodules that cover the surface very quickly at the beginning of coating growth (Ref 32, 33, 34). Preferential nucleation and growth of the coating on local cathodic sites defined by local impurity element enrichment, and second-phase particle inclusions have also been reported (Ref 28, 34) (Fig. 2). Coatings formed in just several seconds confer useful levels of corrosion resistance, but are not as corrosion resistant as coatings formed by longer immersion times. At coating times greater than 30 s, detectable electrochemical activity diminishes. Coating weight continues to increase, but coating thickening slows (Ref 30) or stops (Ref 18). The Cr(III) and Cr(VI) concentrations in the coating both increase, but the Cr(VI) to Cr(III) ratio also increases indicating a greater rate of Cr(VI) uptake (Ref 27, 29). Terminal Cr(VI) concentrations expressed as a percentage of total chromium in the coating are typically about 30% (Ref 27).

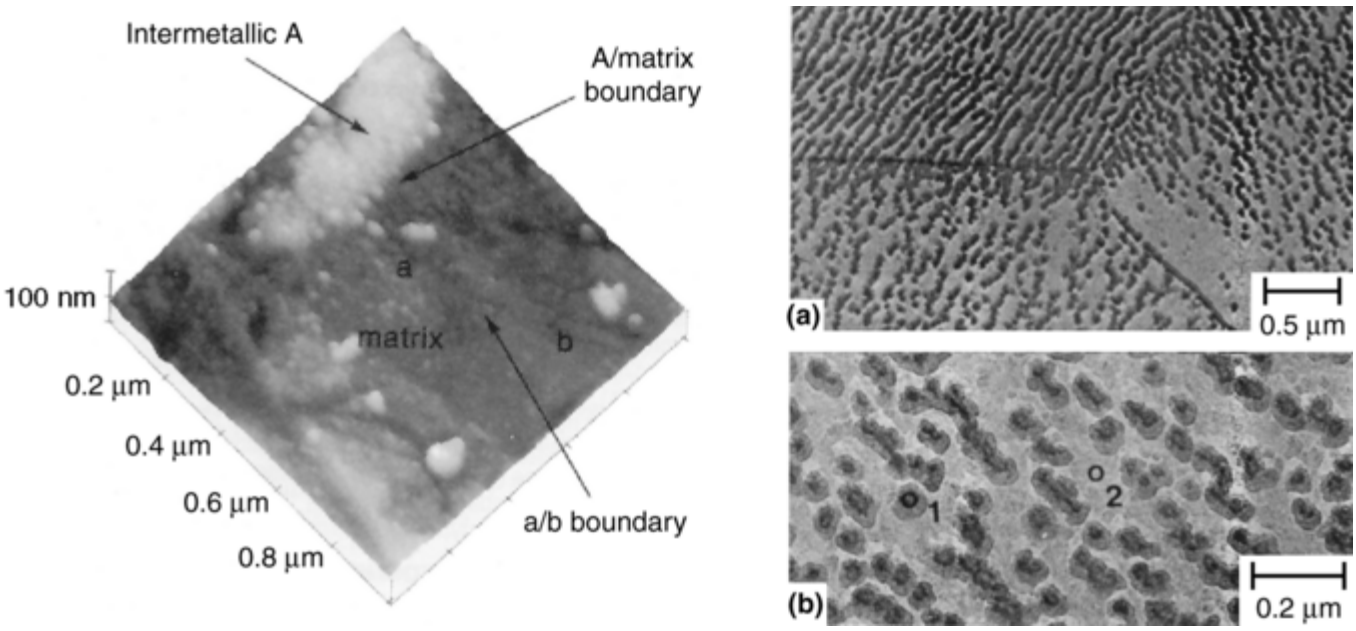

Fig. 2 Nodular morphologies associated with the nucleation stage of CCC growth. Left, AFM image of a CCC formed on freshly polished 2024-T3 exposed for 1 s to a commercial bath formulation chilled to <5 °C (<40 °F) illustrating nodular CCC morphology. Rapid CCC nucleation on Al-Cu-Fe-Mn-type particles is suggested by a thicker deposit. Sluggish nucleation on Al-Cu-Mg particles is suggested by a thinner deposit. Source: Ref 34. Right, Transmission electron micrograph of a CCC stripped from a 99.98% pure Al substrate. CCC was formed by a 5 s immersion in $Cr_2O_7^{2-}$/F^- solution at subambient temperature. Local chromium-rich deposits (location b) are located on grain boundaries or pre-existing metal ridge. Microchemical analysis of regions away from nodules (location a) suggest nonuniform CCC formation across the surface. Source: Ref 35

Newer interpretations of CCC growth are based on a sol-gel process (Ref 36) where film formation is triggered by reduction of Cr(VI) to Cr(III). The formation process involves condensation and polymerization of a $Cr(OH)_3$ inorganic polymer "backbone" as shown in Fig. 3 (Ref 37). In this scheme, once sufficient Cr(III) is formed near the metal surface by electrochemical reduction, film formation may proceed by purely chemical processes.

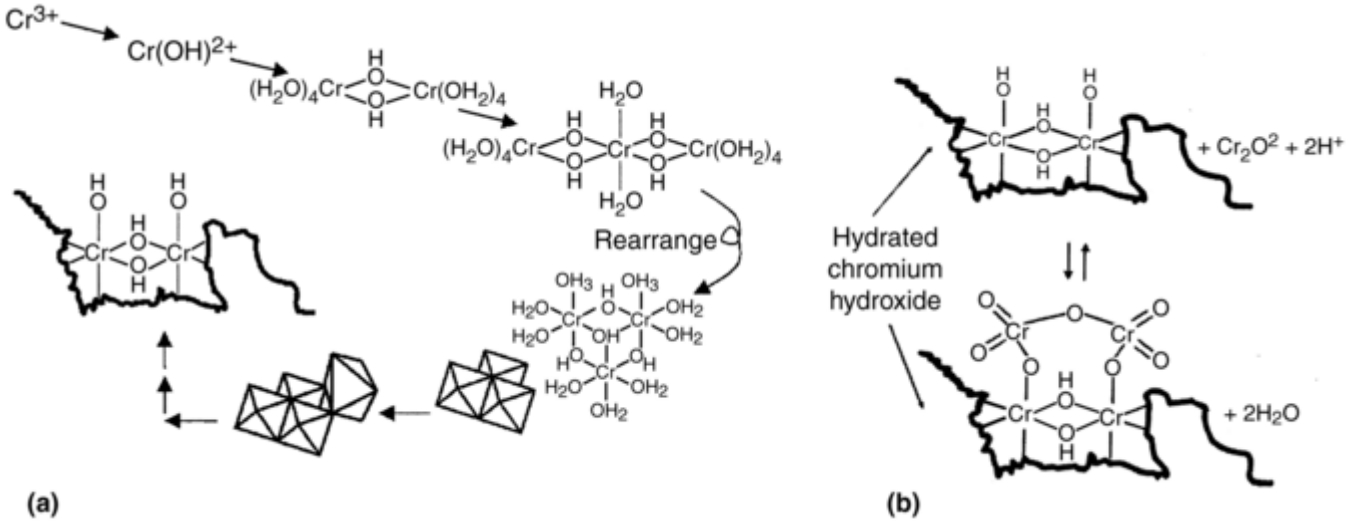

Fig. 3 (a) Hydrolysis-polymerization-precipitation mechanism for $Cr(OH)_3$ "backbone" formation. (b) Condensation of Cr(VI) on the Cr(III) backbone by nucleophilic attack of hydroxyl ligands in the backbone. Source: Ref 37

Throughout CCC formation, the chromium- to-aluminum and Cr(VI)-to-Cr(III) ratios increase (Ref 27). Cr(VI) buildup in the coating has also been proposed to occur by an adsorption reaction involving nucleophilic attack

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

of hydroxyl ligands on the $Cr(OH)_3$ backbone by dichromate (Fig. 3) (Ref 37, 38). This results in the formation of Cr(III)-O-Cr(VI) linkages. These linkages are characteristic of CCCs and are readily detectable by Raman spectroscopy.

Freshly formed CCCs are fragile and easily damaged by mechanical or chemical action. Immediately after CCC formation, it is possible to wipe the deposit off a metal surface with a sponge. If a CCC is to be used for stand-alone corrosion protection, it is usually allowed to harden for at least 24 h before any further handling (Ref 39). However, if CCCs are allowed to dehydrate over long periods of time, they may become decreasingly receptive to organic overcoats. Therefore, it is common for conversion- coated surfaces to be painted within the first 24 to 48 h after coating application (Ref 40).

Chromium phosphate conversion coatings (CPCCs) are used in aluminum alloys to promote corrosion resistance and paint adhesion in manufacturing operations where short contact time spray application is required. CPCCs are formed by contact with acidic solutions containing CrO_3, H_3PO_4, and NaF as the primary ingredients. Fluoride serves to dissolve the air-formed oxide and activate the surface, while $CrPO_4$ and H_3PO_4 are the primary film-forming agents. Coating formation occurs by reduction of Cr(VI) to Cr(III) and precipitation of hydrated $CrPO_4$ and Cr(III) and Al(III) hydroxides (Ref 41, 42, 43). Depending on the bath formulation, substrate type, contact time, and temperature, CPCCs can be either amorphous (Ref 44) or crystalline (Ref 45). Chromium phosphate is often the predominant compound in the coating, comprising up to 80% of freshly formed films (Ref 22, 46, 47, 48). Most or all of the chromium in CPCCs is present in an insoluble Cr(III) form. Little or no Cr(VI) is present in the coating. As such, these coatings do not possess the self-healing characteristics of chromium chromate conversion coatings.

Conversion Coatings Formed from Trivalent Chromium Solutions. Chromium-containing conversion coatings can be formed from baths containing trivalent chromium compounds (Ref 49, 50, 51). These processes are comparatively new and are not in widespread commercial use. Cr(III) coatings possess good corrosion resistance and provide for good paint adhesion in standardized testing. Coatings are formed on aluminum alloy substrates by contact with a dilute chromic sulfate-sodium fluosilicate solution with a pH range of 3.3 to 5.5. Coating formation occurs spontaneously in a matter of minutes. The coatings appear to form on activated aluminum alloy surfaces by polymerization of hydrolyzed Cr(III) ions. The corrosion resistance of these coatings is improved if they are subsequently contacted with hydrogen peroxide or a permanganate-containing solution. This step oxidizes some of the Cr^{3+} in the coating to Cr^{6+} and in the case of the permanganate treatment may result in the deposition of some hydrated manganese oxide on the surface.

Processing of CCCs. Chromate conversion coating is not a single process, but rather a family of processes that are used in a wide range of industrial applications. The “generic” processing sequence for CCCs involves chemical cleaning, acid deoxidation, conversion coating, rinsing, and drying. Removal of bulk oils and greases is essential before any immersion-based degreasing or deoxidation. Chemical cleaning of remnant molecular organic contamination is often carried out in an inhibited alkaline solution. Immersion periods range from several seconds to several minutes. Cleanliness is assessed visually. A favorable indication of cleanliness is solution running off the surface smoothly without spotting or “breaking.” Such surfaces are said to be “break-free.” If surfaces are contaminated, solution will spot or bead on the metal surface when it is removed from solution. In this case, further immersion cleaning is needed. Darkening of the surface during degreasing may signal formation of smut films, which consist of insoluble substrate alloying elements accumulated at the metal surface. Acid deoxidation can be carried out using a strongly acidic oxidizing solution. Immersion periods for deoxidation range from a few seconds to several minutes. The effectiveness of deoxidation is also assessed visually. Surfaces may be overcleaned, resulting in corrosion and contamination of the surface with corrosion products. Excessive etching may be indicated by dull or matte appearance on the metal surface. Contamination after deoxidation may manifest itself as loose particulate that must be washed or aggressively rinsed from the surface. Table 1 lists generic chemistries for alkaline degreasing and acid deoxidizing. Many commercial formulations based on other chemistries exist. Some of these can be found in Ref 2.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Table 1 Generic degreasing and deoxidizing chemistries for aluminum alloy surfaces

Step	Chemistry	Temperature	Time
Degreasing	32.4 g/L Na_2SiO_3 48 g/L Na_2CO_3	65 °C (149 °F)	Several second dip to 120 s immersion as necessary
Deoxidizing	75 g/L $(NH)_4HF_2$ in concentrated HNO_3	Ambient	Several second dip to 300 s immersion as necessary

Properly prepared surfaces are very receptive to CCCs. CCCs are formed by immersing into the coating solution or spraying or brushing the metallic object with the coating solution. Coating color and thickness change with coating time (Ref 39). Coatings with weights ranging from 10 to 160 mg/m^2 (1 to 15 mg/ft^2) are colorless to light yellow and are formed in a few seconds. Coatings with weights ranging from about 215 to 430 mg/m^2 (20 to 40 mg/ft^2) can be colorless, iridescent, light yellow, or tan depending on substrate type. These coatings are formed in several tens of seconds and are used where low electrical contact resistance is required. General-purpose coatings for corrosion resistance and paint adhesion range from 54 to 970 mg/m^2 (5 to 90 mg/ft^2). To form such coatings requires contact times of 2 or more minutes. The appearance of these coatings varies from iridescent blue to dark yellow or brown. Use of contact times longer than 4 min is unusual in industrial practice because it is possible to degrade surface properties by overcoating.

Thorough rinsing of objects between steps ensures good CCC formation. Unreacted chemical components are removed from the surface and drag-in of chemicals from one processing bath to the next is minimized. CCC formation can be extremely sensitive to small changes in the chemistry of pretreatment or conversion coatings baths. The importance of bath cleanliness and strict adherence to manufacturer's recommendations on bath maintenance cannot be overemphasized.

Freshly coated surfaces should be rinsed to remove excess acid, but should be handled with care because of their gel-like quality. Coatings to be used for stand-alone corrosion protection should be allowed to dry for about one day before any further handling. Painting should be carried out within 24 to 48 h of coating formation. Paintability may be lost if coatings are allowed to dry for extended periods of time.

Chromate and Chromate-Free Conversion Coatings

R.G. Buchheit, The Ohio State University; A.E. Hughes, CSIRO

Morphology, Structure, and Composition

Morphology and Structure. Thin chromium chromate coatings formed in just several seconds of contact with coating solution consist of a mass of small, nanometer-sized particles that nucleate and cover the entire alloy surface. Thicker coatings formed using longer contact times are three- dimensional structures with distinct horizontal layering and compositional variation, based on characterization of microtomed coating cross sections (Ref 28, 33, 35, 52, 53, 54) (Fig. 4). Thicker coatings develop shrinkage cracks as the coating dries and hardens (Ref 21, 55) (Fig. 5). Both thin and thick coatings are conformal and readily form in pits and scratches on the alloy surface left over from acid deoxidation and surface machining.

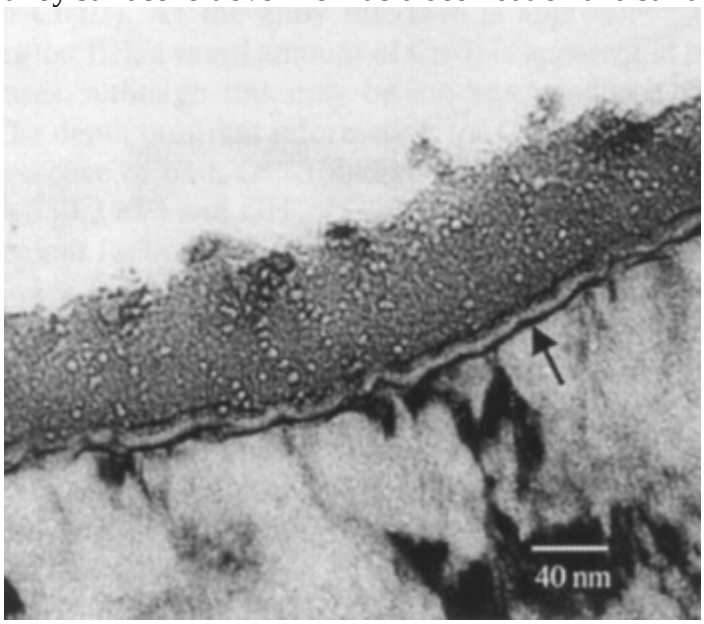

Fig. 4 Transmission electron micrograph of an ultramicrotomed CCC on 2024-T3. The CCC was formed on an acid etched surface by immersion in a CrO_3-$Na_2Cr_2O_7$-NaF solution for 5 min at ambient temperatures. The arrow points to a dark band believed to be caused by copper surface enrichment. Source: Ref 33

Thick and thin chromium chromate coatings are amorphous and remain so even after heating at temperatures up to 300 °C (570 °F). CCCs do exhibit short-range atomic order. Cr(III) in the coating is octahedrally coordinated by hydroxyl and oxygen ligands. $Cr(OH)_3$ octahedra share edges and corners forming an extended network or "backbone" that comprises the coating (Ref 37, 55, 56). Cr(VI) is bound to this backbone as described earlier.

Composition. There is general agreement that CCCs consist primarily of a mixture of Cr(III) and Cr(VI) compounds, other bath ingredients, and elements from the substrate. The precise composition depends on alloy substrate, bath formulation, processing parameters, and coating age. Reports vary on the specific compounds present and their relative abundance in the coating. Compounds proposed to exist within accelerated chromium chromate coatings include: Cr_2O_3, $Cr_2O_3 \cdot nH_2O$, $Cr(OH)_3$, CrOOH, $Cr(OH) \cdot CrO_4$, $Cr_x(CrO_4)_y$, CrF_3, $CrFe(CN)_6$, AlOOH, Al_2O_3, and AlF_3 (Ref 18, 21, 22, 56, 57).

Figure 6 shows a generalized physical-chemical model for CCCs based on a range on electron and x-ray analysis techniques. Composition depth profile data supporting this model are also provided. In the model, the external surface of the coating consists of hydrated chromium oxides and fluorides, ferricyanide, and chromate. The bulk of the coating below the topmost surface is a mixture of chromium oxides and hydroxides, oxyhydroxides, fluorides, and chromium ferricyanide. The coating nearest the aluminum substrate contains hydrated aluminum oxides, metallic and oxidized forms of copper on copper-bearing aluminum alloys, and chromium and aluminum oxyfluorides.

Fig. 6 (a) and (b) Composition depth profiles for the major elements found in chromium chromate CCCs. Source: Ref 22. (c) CCC structural model illustrating the distribution of compounds through the thickness of a CCC. Source: Ref 25

More recent characterization of CCCs by Raman spectroscopy is in general agreement with the model of Fig. 6 showing that a significant component of the coating is a $Cr(OH)_3$ polymer to which chromate or dichromate is bound (Ref 37).

Conversion coating chemistry evolves as the coating thickens. Thin coatings are mixtures of hydrated chromium and aluminum oxides with a comparatively small amount of Cr(VI) present in the outer regions of the coating (Ref 27, 31, 58). As coatings thicken, the chromium-to-aluminum and Cr(VI)-to-Cr(III) ratios increase. In thicker coatings, the Cr(VI) to total chromium ratio is commonly in the 20 to 40% range with 30% taken as a nominal value (Ref 27, 31, 58, 59). Composition depth profiles indicate that the Cr(VI) resides predominantly in the outer portions of the coating.

Measurement of the Cr(VI) content of CCCs has attracted special attention because it is related to the self-healing characteristic of CCCs. Determination of Cr(VI) in CCCs is complicated by the fact that the specie can be inadvertently reduced by photoreduction or ultrahigh vacuum exposure (Ref 26, 27, 60, 61). Inadvertent Cr(VI) reduction must be considered in measurements of CCC chemistry by x-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES). X-ray synchrotron techniques such as x-ray absorption near-edge spectroscopy (XANES) and x-ray absorption fine structure (EXAFS) provide a significant advantage in this regard, as these measurements can be made with minimal risk of Cr(VI) reduction. Additionally, these measurements can be carried out under ambient environmental conditions, which is often a considerable experimental convenience (Ref 62).

The use of XANES to characterize the chemistry of CCCs is noteworthy. X-ray absorption spectra for chromium are distinguished by a progressive increase in the absorption edge energy with increasing oxidation state and by a discrete absorption peak associated with Cr(VI), which occurs at energies just below the main Cr Kα absorption edge (Fig. 7) (Ref 27, 63). This greatly facilitates Cr(VI) determinations in a CCC. XANES has also been used to study chromate leaching, the effects of aging, and the effects of different processing chemistries and procedures (Ref 27, 64, 65, 66, 67). See “Extended X-Ray Absorption Fine Structure” in *Material Characterization,* Vol 10, *ASM Handbook,* 1986, p 406.

Chromate and Chromate-Free Conversion Coatings

R.G. Buchheit, The Ohio State University; A.E. Hughes, CSIRO

Coating Properties

Corrosion Protection and Corrosion Protection Mechanisms. CCCs can be regarded as physical barriers that prevent contact of the attacking environment with the underlying metal. The effectiveness of the barrier is determined by insolubility of components that make up the coating. However, experimental evidence shows that CCC protection consists of several distinguishable components beyond simple barrier protection.

Electrochemical measurements show that CCCs inhibit anodic reactions and localized corrosion on aluminum alloys surfaces. The primary evidence for this effect is an increase in pitting potential on conversion-coated electrode surfaces compared to uncoated control samples. Anodic inhibition measured in this way is modest, however. For example, in a 0.1 *M* Na_2SO_4 plus 0.005 *M* NaCl solution, a passive region is detected and the pitting potential is elevated by conversion coatings on 2024-T3 (Ref 68). However, in a more concentrated 0.1 *M* NaCl solution, no increase in pitting potential is detected in anodic polarization curves of the same alloy (Ref 25). The ability to detect an elevated pitting potential also appears to depend on electrode area and alloy substrate purity. With relatively large electrodes (>1.0 cm^2, or 0.16 $in.^2$) of heavily alloyed aluminum, increased pitting potentials are not usually observed in chlorides solutions of concentration greater than 0.1 *M*. However, with small area electrodes of higher- purity aluminum, the metallurgical or coating defect density is lower and increased pitting potentials are more regularly observed (Ref 29). This effect should be considered when interpreting pitting potential data from coated metal surfaces.

Electrochemical measurements also show that CCCs inhibit cathodic reactions. Cathodic polarization curves measured for conversion- coated aluminum alloys in near-neutral chloride solutions show that oxygen and water-reduction reaction kinetics are slowed by the presence of a freshly formed CCC (Ref 68). After several days, cathodic inhibition will diminish (Ref 25). Loss of corrosion resistance in this component may be associated with the formation of shrinkage cracks, which form as the coating dehydrates.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Perhaps the best-known aspect of corrosion protection by CCCs is “self-healing.” Self-healing refers to the ability of a chromate conversion coating to heal small chemical or mechanical defects that could serve as initiation sites for corrosion. The self-healing process is thought to involve 1) liberation of Cr(VI) into an attacking aqueous environment, 2) transport of the Cr(VI) through a contacting liquid phase to an incipient defect, and 3) reduction to insoluble Cr(III) hydroxide or interaction with the corrosion product to stifle further corrosion (Ref 69). The key attribute of CCCs in this regard is the ability to store and release Cr(VI) into an attacking solution. The Cr(VI) reservoir in CCCs is a function of coating weight or thickness and has been estimated to be on the order of 10^{-7} mol Cr(VI)/ cm^2 of CCC (Ref 70). Release of dichromate is proposed to occur by hydrolysis of Cr(III)-O- Cr(VI) when the following reaction occurs in the forward direction (Ref 70):

$$\mathrm{Cr(III)\text{-}O\text{-}Cr(VI)O_3^-(s) + H_2O \leftrightarrow Cr(III)\text{-}OH(s) + Cr(VI)O_4^{2-}(aq) + H^+(aq)} \quad \text{(Eq 2)}$$

Cr(VI) then diffuses through the $Cr(OH)_3$ backbone, provided the network is sufficiently open. In Eq 2, equilibrium between the Cr(III)/Cr(VI) mixed oxide of the CCC and dichromate in solution, hence the extent of dichromate release is proposed to be governed by Langmuir-like adsorption behavior that depends on solution ionic strength, pH, and the ratio of CCC surface area to solution volume. As a result, the extent of Cr(VI) release is not simply governed by solubility of dichromate in solution, or total amount of Cr(VI) in the mixed oxide, as is more closely the case for $SrCrO_4$ pigments in primer coatings (Ref 71). Kinetically, the rate of chromate release appears to be well described by diffusion-controlled transport of Cr(VI) in the CCC (Ref 72).

Equation 2 also shows that the Cr(III)/Cr(VI) equilibrium is pH dependent in a manner that favors Cr(VI) uptake during coating formation and Cr(VI) release during service. Specifically, chromate adsorption is favored at low pH, typical of coating baths. Dichromate release is favored under higher pH conditions, more typical of service conditions where release and self- healing are necessary.

Opinions vary on how important self-healing is to overall corrosion resistance in coating systems (conversion coating, primer, topcoat), since the soluble chromate reservoir in a CCC is small compared to that in $SrCrO_4$-bearing primer coatings. While coating systems involving chromium-free conversion coatings and nonchromated topcoats are being used in certain applications, chromium-free organic coatings have not yet demonstrated acceptable corrosion protection in demanding aerospace qualification testing, unless they are applied on top of a self- healing chromate conversion coating (Ref 73).

Self-healing is only associated with CCCs that contain leachable Cr(VI) such as chromium chromate coatings. Chromium phosphate coatings, which contain primarily Cr(III) are not self- healing. Additionally, Cr(VI) in chromium chromate that have aged, dehydrated, or heated can become immobilized and unleachable. In these cases, the self-healing component of corrosion protection is lost.

Test Methods for Corrosion Resistance. Accelerated-exposure testing is widely used to assess corrosion protection by CCCs. The most commonly used environment is a 5% salt fog. In these tests, corrosion resistance is determined by visual inspection of a coated surface after some predetermined exposure period. The extent of corrosion damage is usually evaluated against some established metric such as number of pits per unit area visible to the unaided eye. Coated samples are normally given a pass or a fail ranking depending on whether the observed corrosion exceeds the metric or not. This type of test is simple and relevant to certain types of service conditions. Such evaluations can be very useful for process and quality control.

The most commonly used exposure regimen is neutral salt-spray (fog) exposure, described in ASTM B117 (Ref 74). In this test, conversion- coated panels are exposed in a chamber containing a fog generated from a 5% saltwater solution. The temperature is controlled at 35 °C (95 °F). Panels are periodically inspected for evidence of corrosion. Conversion-coated surfaces that resist corrosion in ambient atmospheres for years will show visible evidence of corrosion in tens to hundreds of hours in a salt-spray chamber. ASTM B 117 establishes the methodology, but does not specify failure criteria. Failure criteria are established in various military and industrial specifications (Ref 39, 40, 75). Other accelerated-exposure tests methods include the acetic acid salt-spray test (ASTM B 278), the copper accelerated salt-spray (CASS) test (ASTM B 368), the sulfur dioxide test (ASTM B 605), and the humidity test (ASTM D 2247).

Despite its apparent utility, accelerated-exposure testing is criticized for a variety or reasons. Exposure durations of 100 to 1000 h or more may be required for discriminating results to develop. These time frames are too long for quality control in many manufacturing operations. Exposure testing will separate excellent and

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

poor coatings easily, but differentiating good and very good coatings is usually much more difficult. This is often a problem when results from salt- spray testing are used as a response variable for studying the effects of processing or bath chemistry changes. Data from accelerated testing for life prediction is sometimes challenged on the basis that alteration of exposure environment to accelerate corrosion may change the corrosion mechanism itself. This calls into question the usefulness of these tests for assessing performance in service. Finally, there is the issue of variability in exposure aggressiveness from cabinet to cabinet and from one exposure cycle to the next. This may introduce uncertainties in comparisons of results from different tests and different facilities.

Perhaps the most unsatisfying aspect of exposure testing is subjectivity associated with a visual determination of corrosion. Evaluation specifications attempt to limit subjectivity, but they cannot eliminate it. For example, U.S. military specifications (Ref 40, 75) establish failure criteria in salt-spray testing as the presence of five or more pits per 30 $in.^2$, or 15 or more pits on five 30 $in.^2$ panels. Pits are defined as localized regions of corrosion with diameters greater than 0.8 mm (0.31 in.). Pits of this size are believed to be the smallest pits to leave corrosion product stains that are visible to the unaided eye. While these failure criteria are precisely articulated, they are still affected by the evaluator's prior experience, judgment, and attention to detail.

Electrochemical Impedance Spectroscopy (EIS). Until the 1980s, corrosion testing of conversion-coated surfaces was conducted almost exclusively by exposure testing (Ref 40) or spot testing (Ref 76). Since the introduction of EIS to corrosion research, the use of this technique to evaluate the protectiveness of CCCs has steadily increased.

A common way to employ EIS is to expose conversion-coated surfaces to an aggressive electrolyte, usually a chloride solution, for some period of time during which coating and substrate damage will occur (Ref 77, 78, 79). Exposure times must be long enough to induce some limited amount of pitting damage. Time scales on the order of hours are commonly used. An impedance spectrum is collected and evaluated using a suitable equivalent circuit model or some other quantitative method. A simple model consisting of a parallel combination of resistor and capacitor, in series with a solution resistance, is frequently used. The numerical value of the parallel resistance and capacitance are used to judge the extent of corrosion damage. Resistances and capacitances may be determined after some fixed period of exposure, or they can be measured periodically over time to track the progression of corrosion damage. Table 2 gives typical values of the total impedance of various coated and passivated substrates. While EIS is used with increasing regularity for evaluation of CCCs, standardized methods for evaluating conversion coatings by EIS do not yet exist.

Table 2 Coating resistance ranges for various surface treatments and substrates

Coating	Coating resistance, $\Omega \cdot cm^2$
Bare aluminum alloys	0.005
Sputter-deposited high-purity aluminum	0.5–1.0
Poor conversion coatings	0.1–1.0
Good conversion coatings	1–5
Sealed anodized coatings	10
Painted surfaces	>10

The EIS approach has several advantages for evaluations of conversion coatings. First, it is a small signal technique, and the electrode is never polarized very far away from its steady-state corrosion potential as the measurement is made. Second, a numerical characterization of coating protectiveness is rendered by this method. For this reason, the technique may be better suited than exposure-test methods for discriminating small differences in corrosion protection among coatings. Third, after the samples have been exposed to develop some pitting damage, the measurement is very rapid. Meaningful characterizations of the impedance response can be obtained from spectra collected between 10 kHz and 10 mHz, which is a measurement that can be completed in a matter of minutes. To shorten the measurement time even further, it may be possible to determine the impedance at one or several properly selected frequencies to estimate coating protectiveness. Finally, EIS measurement equipment, which consists primarily of potentiostat, impedance analyzer, computer, and operating software has become increasingly affordable and portable over the past decade.

Electrochemical impedance spectroscopy methods are not without drawbacks. Coating evaluations by EIS are based on a very complex analytical technique. Skill, knowledge, and attention to detail are required to conduct the evaluations and interpret the data properly. Additionally, the exposure protocol involves immersion of the

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

coated surface in an aggressive aqueous environment. CCCs are not intended to provide long-term corrosion protection under such conditions. Therefore, interpretation of results from these evaluations must be used with this fact in mind.

Tests for Self-Healing. Self-healing is an important component of CCC corrosion protection, but rigorously testing for this property is challenging. The familiar example of self-healing ability is the absence of corrosion in a scribed coating after exposure to an aggressive environment. A simple cell, termed the "simulated scratch" cell, mimics this situation, but allows an experimenter to check more rigorously for the key elements of the self-healing process. These elements include release of inhibitor from the coating, interaction of the inhibitor with the simulated scratch surface, and increased corrosion resistance of the simulated scratch (Ref 69). This cell (Fig. 8) consists of two metal surfaces, normally several square centimeters in area opposing one another and separated by several millimeters. One metal surface is conversion coated, while the other is left bare to simulate a defect or "scratch." The two metal surfaces are separated by a gap of several millimeters, which is filled with an attacking electrolyte like a dilute chloride solution. The cell may be equipped with a counter and reference electrode, and either the coated or defect sides of the cell can be interrogated using electrochemical methods. Simulated scratch cells have been used to show that certain chromium-free conversion coatings containing can also be self-healing (Ref 80).

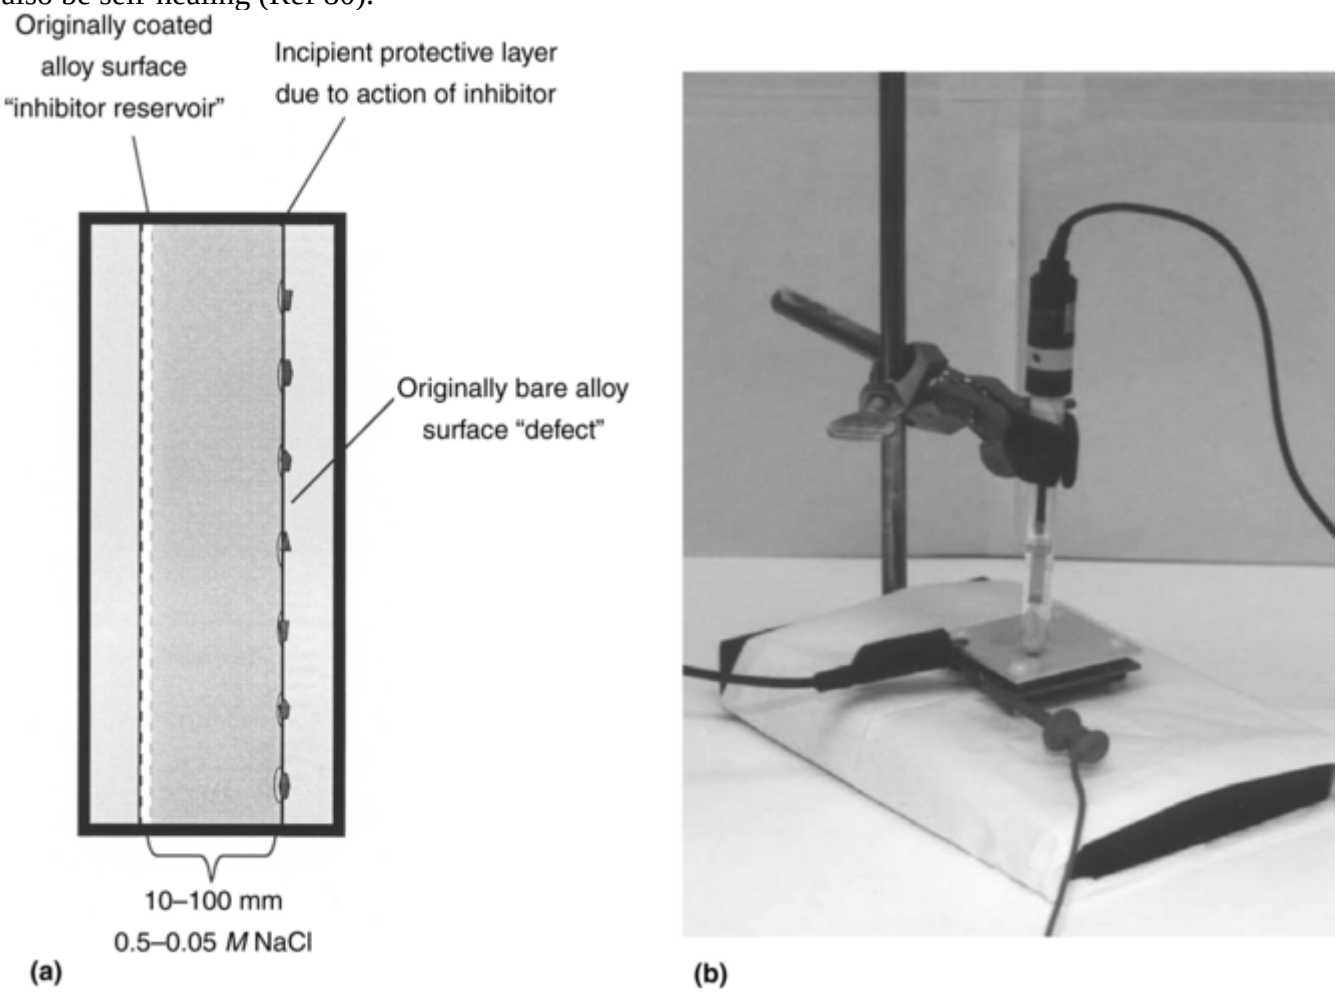

Fig. 8 (a) Cross section of the simulated scratch cell. (b) Photograph of an artificial scratch cell modified to make in situ electrochemical measurements to test for self-healing by conversion coatings. Source: Ref 70

Paint Adhesion. Typical aircraft coating systems consist of a CCC foundation layer, a primer coating, and a topcoat (Ref 81). In these systems, the primary function of the CCC is to promote initial and long-term adhesion of the organic coating on the metal substrate. Organic coating adhesion is promoted by surface topography, surface cleanliness, and possibly coating acidity (Ref 23, 82). Long-term interfacial adhesion is fostered by the high corrosion resistance provided by the inhibiting effects of Cr(VI) leached from the primer and the CCC (Ref 1).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Mechanical Stability. Freshly formed coatings are gelatinous and can be damaged easily. As the coating dries, it hardens considerably. CCCs dried for at least 24 h are considerably more robust. Coating weight determinations by chemical stripping of the CCC are nearly impossible to carry out by nitric acid immersion after this time. Hardened coatings will withstand some mechanical damage, but are not nearly as abrasion resistant as anodized coatings.

Electrical contact resistance is an issue for metallic electrical connectors. Connections are chromate conversion coated to increase corrosion resistance, but electrical continuity across the connection must not be degraded by the presence of the coating.

Chromated metal surfaces exhibit low electrical contact resistance as measured with a flat metal electrode applied with a small impinging load (Ref 75). Since dried CCCs are thin, they are easily breached, allowing metal-to-metal contact. In service, mechanical breaches caused by contacting metal surfaces can sometimes be tolerated without risk of corrosion due to the self-healing nature of the coating. In other cases, mechanical damage is too severe and atmospheric corrosion assisted by galvanic interactions or crevice corrosion will increase the contact resistance to such an extent that rework of the electrical contact is required (Ref 83). Low electrical contact resistance also makes conversion-coated surfaces amenable to various types of spot welding and arc welding procedures.

The intrinsic resistivity of CCCs is distinct from electrical *contact* resistance. Intrinsic resistivity of conversion coatings can be quite high (Ref 84, 85). Direct-current (dc) resistances of CCCs measured with a small (4×10^{-3} cm^2) mercury droplet that does not breach the CCC range from 10^{10} to 10^{12} Ω (Ref 85).

Aging and Heating. CCC properties are very dynamic once removed from the coating bath. The film transforms from a fragile gel to a robust, damage-tolerant coating in a few hours. Aging effects appear to be due to consolidation in the Cr(III) backbone, which can be detected by EXAFS measurements (Ref 86, 87). How this consolidation occurs is still a matter of speculation, but the structural rearrangement appears to be closely linked to coating dehydration (Ref 86). Shrinkage cracking also appears to be a consequence of backbone consolidation. Backbone rearrangement over the time frame of days to months produces profound changes in coating properties. Cathodic inhibition as measured in cathodic polarization testing is lost in tens of hours (Ref 25). In EIS testing, losses in corrosion resistance begin to be detected in times as short as 20 days after coating formation (Fig. 9) (Ref 86). In an extreme case, after 100 days exposure to ambient laboratory air, there was no evidence of corrosion protection in EIS testing of a 1 minute CCC on 2024-T3 exposed chloride solution. Chromate leaching also diminishes with time even though the Cr(VI) content of the coating remains the same. This well-known behavior may also be linked to backbone consolidation, which traps Cr(VI) in the coating (Ref 87, 89). Ultimately, over tens of years the Cr(VI) content of CCCs diminishes. After seven years, aging under ambient indoor exposure the Cr(VI) CCCs on aluminum alloy 3003 (Al-1.0Mn) was measured by XANES to decrease from about 30% to levels undetectable by XANES (Ref 59).

Fig. 9 Corrosion resistance measured as parallel coating resistance, R_c, from electrochemical impedance spectroscopy experiments of conversion-coated 2024-T3 exposed to aerated 0.5 *M* NaCl determined after aging in air. Source: Ref 88

As is well known, CCCs are not heat tolerant (Ref 90, 91). Exposure to elevated temperature accelerates dehydration, consolidation of the Cr(III) backbone, and losses in properties described previously. Losses in CCC corrosion protection, Cr(VI) leaching, and increases in shrinkage cracking are profound when coatings are subject to temperatures in excess of 60 °C (140 °F). Corrosion resistance in salt-spray exposure testing and electrochemical testing can be completely lost when CCCs are heated for more than 15 min at temperatures in excess of this 60 °C (140 °F) threshold (Ref 89).

Chromate-Free Conversion Coatings

Due to pressures from health and environmental legislation, there has been a move away from chromate-containing products over a number of years. The prospect of replacing chromate conversion coatings has brought with it considerable investigation of potential alternatives based on a broad range of chemistries. Furthermore, within each chemical category there is the potential for a broad range of formulations, most of which will not result in viable industrial processes due to processing or performance limitations.

A review of all these alternatives is complicated by the range and quality of performance data for these processes, since different processes are targeted toward different parts of the metal-finishing industry that have different performance requirements. Some comparative studies have been carried out and are a good source of performance data, but do not include all the processes described herein (Ref 92, 93, 94). Furthermore, developments in chromate alternatives are progressing rapidly, and those tested in comparative reports may not reflect the current performance of processes.

The aim of this section is to give an indication of the market sector for which a class of processes is being developed, some idea of the chemistry and processing involved, an indication of process control, and, finally,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

structure and method of deposition of the coating. Readers are referred to several reviews that have been recently published (Ref 95, 96, 97). A total market review of the introduction of replacement technologies was not attempted since this is continually changing as more knowledge is gained about the alternatives.

Chromate conversion coatings found a range of applications in industry, especially in aluminum finishing. The development of alternatives is complicated by both the performance and processing requirements of different sectors of industry (Table 3). Currently, several chromate alternatives have gained acceptance in specific sectors of the market. These markets can be divided into those that require protection in the unpainted condition and those that require performance under paint. For the latter category, many alternatives demonstrate good performance characteristics. The aerospace industry falls into the former case, and a drop-in replacement still does not exist in this high-performance end of the market, which has very high standards for corrosion resistance of the unpainted conversion-coated surface in the neutral salt-spray test.

Table 3 Major classes of chromate alternatives

Coating type	Industry sector	Status[(a)]
Titanium and zirconium fluorocomplexes	Sheet stock for canning	Mature
	Automotive	Developing
Cerium-base	Architectural	Developing
	Aerospace	Evaluation
Cobalt-base	Marine	Developing
	Auto	Developing
	Aerospace	Evaluation
Molybdenum-base	Tin and galvanized product	Developing
Hydrotalcites	Aerospace	Evaluation
Manganese-base	Some sheet product	Developing
	Aerospace	Evaluation
Boehmite coatings	Aerospace	Evaluation
Silane coatings	Automotive	Developing
Conducting polymers	Ferrous metals	Evaluation
Self-assembled monolayers	Automotive Al/Mg alloys	Developing

(a) Mature, in the industry for a number of years. Developing, may be introduced soon. Evaluation, still undergoing trials

General features of these alternative processes are described in the sections that follow. Table 3 lists the major types of chromate alternatives in use or under development and the industries that are currently targeted by the manufacturers of these products. The majority of these processes are still under development. Fluorozirconoic and fluorotitanic acid coatings are the most mature of these replacement technologies with products on the market for a number of years.

Two final points should be made, however, with respect to chromate. First, it should be noted that chromate is often considered as a single process suitable for all aluminum alloys under all processing conditions. In reality, this is not the case since different formulations are used for different applications. Indeed there is no single, published database comparing the performance of chromate on a range of alloys cast or wrought in a range of tempers. The available performance data place a strong emphasis on sheet 2024-T3 with some 7075-T6 and 6061-T6 data.

Second, conversion coating is a multistep process usually involving both cleaning and deoxidizing/desmutting prior to conversion coating. Over many years, the metal-finishing industry has optimized the pretreatment steps for chromate conversion coating, and it is not surprising that a chromate-base deoxidizer is often used since it sets up a surface more amenable to chromate conversion coating than other deoxidizers. Chromate alternatives may have their own requirements for pretreatment, which may not be the same as the current process steps. These two factors should be taken into account when considering the development of replacements for chromate.

Chromate and Chromate-Free Conversion Coatings

R.G. Buchheit, The Ohio State University; A.E. Hughes, CSIRO

Chromate-Free Processes

Titanium and zirconium fluorocomplexes have a well-established market use in the container, coil coating, aluminum appliance, transportation, magnesium, aerospace, and extrusion industries and are offered by a number of suppliers. More than 100 customers have converted to these titanium and zirconium chemistries from chromate. In addition, National Aerospace and Space Administration (NASA) has used these coatings for a few years on the solid rocket boosters of the space shuttle (2219 alloy) with completely chromium-free paint systems. These coatings also find use in aluminum and titanium fighter jet applications. Earlier versions of these coatings were inorganic, but current versions contain polymeric components (Ref 95). Processing is relatively simple, involving up to eight steps, although five is the most common. These usually include (depending on the manufacturer) an alkaline clean, rinse, coat, rinse, and dry, sometimes at elevated temperature. The conversion coating bath is acidic (pH < 4) and operated at room temperature up to 40 °C (104 °F).

The conversion coating solutions generally contain an acidic hexafluoro metal complex (H_2ZrF_6, or H_2TiF_6) or Group IVa,b of the CAS classification of the periodic table, oxyfluoro compounds, excess fluoride, and commonly, a polymer. The added polymers improve corrosion resistance and overlayer adhesion. Two examples are polyacrylic acid (Ref 98) or phenolic resins (Ref 99). Other inorganic acids and phosphates may be added to the composition; phosphates have been reported to improve the corrosion resistance of the coating (Ref 100).

Process control is through titration for free fluoride, pH, and titanium. Coating weight is determined by x-ray fluorescence (XRF) of titanium or in the zirconium/polymer versions of the coating (Ref 96). XRF determination for zirconium can be done, but it is much less accurate and not particularly reliable. A typical dry-in- place version of this system can be applied in as little as 0.5 s for a roll coater on a coil line, and coating weights are in the range of 1 to 1300 mg/ m^2 (0.1 to 120 mg/ft^2) (Ref 98). These types of processes demonstrate

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

excellent performance in standard industry adhesion tests (Ref 98), but generally do not have very good corrosion resistance in the unpainted state (Ref 93, 94).

Characterization of the conversion coating indicates a thin, multilayer structure, depicted in Fig. 10. In the absence of polymer additives, the coating consists of three distinct layers. Adjacent to the metal an aluminum oxide develops, then a zirconia (ZrO_2) layer develops on top of the aluminum oxide, and this is capped by a mixed Zr/O/F layer. In the presence of a polymeric component, the ZrO_2 and mixed Zr/O/F layers are replaced by a mixed Al/O/Zr/F coating containing the polymer. The polymer tends to be more concentrated toward the surface (Ref 101). Coatings produced in this process are very thin, being typically in the range 10 to 25 nm (0.4 to 1.0 µin.) depending on composition, but may be 500 nm (20 µin.) in some applications.

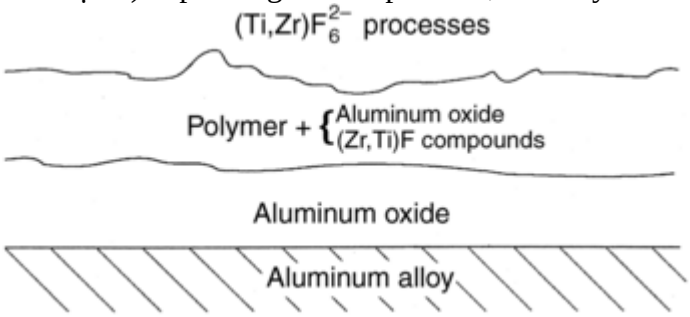

Fig. 10 Titanium/zirconium fluorocomplexes. The total coating thickness is <25 nm (<0.98 µin.).

Based on the characterization studies, it has been proposed that the conversion coating develops in the following manner. On immersion into the coating solution, the aluminum oxide on the surface of the metal is activated by either excess fluoride or the fluoro complex in solution (or both) and becomes hydrated. Aluminum- fluoride bonds are more stable than Al-OH bonds and fluoride substitution of hydroxyl groups quickly takes over. This is probably assisted by the alumina surface having a net positive charge at the low operating pH of the bath. In this fashion, the Zr/O/F-containing-layer begins to develop and in the case of added polymer also incorporates polymeric material.

Cerium-Base Coating Processes. There are a number of chromate alternatives based on cerium described in the literature (Ref 102, 103, 104, 105). Some of these are true conversion coatings, whereas others involve the development of boehmite coatings with incorporated cerium ions on aluminum.

Cerate. The term “cerate” as a process name is a popularization derived from “chromate” terminology and is misleading since the cerate process does not contain any oxyanions of cerium. Recognition of cerium ions as inhibitors goes back to the mid 1980s with the work of Hinton et al. (Ref 106).

Cerate processes are under development for the architectural market (aluminum extrusions) and are expected to be released by one supplier in 2003. A two-step cerate process involving a final seal, usually silicate, is also being evaluated for aerospace applications. For the architectural market, processing is relatively simple, involving up to six steps, with the cerate process as a drop-in replacement for chromate. The steps include an alkaline clean, rinse, desmut, rinse, coat, and rinse with no specific drying requirements. Conversion coating takes place at 45 °C (113 °F) in either spray or immersion processing, and coating time is typically 30 s to 2 min (Ref 102). The coating has a light yellow to golden color. For the aerospace applications, the process is longer and involves an additional seal with dry and rinse steps. The seal is silicate-base and applied between 20 and 80 °C (68 and 176 °F).

The conversion coating solutions are acidic (pH 1.7 to 2.2) and contain cerium chloride, hydrogen peroxide, hydrochloric acid for acidification, and, for architectural applications, a bismuth complex to act as an accelerator. The unsealed version used in nonaerospace applications typically gives performance similar to chromate in filiform, CASS, wet adhesion, and outdoor exposure tests (Ref 107).

Process control for cerium in the cerate bath can be done either by titration for cerium using argenic ($Ag^{I}Ag^{III}O_2$) oxide followed by titration, for example, with ferrous ammonium sulfate in the presence of ferroin or gravimetrically with excess fluoride addition. Hydrogen peroxide levels can be monitored by a permanganate titration. Coating weights are determined by standard acid dissolution used for chromate coatings. Coating weights are typically in the range (323 to 538 mg/m^2 (30 to 50 mg/ft^2).

Investigations of the structure and composition of the cerate process has focused on the version for aerospace applications. The proposed aerospace process produces a bilayered structure (Fig. 11) of aluminum oxide adjacent to the metal beneath a ceria (CeO_2) overlayer coating with a total thickness of 100 to 200 nm (4 to 8

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

μin.) for typical processing times (1 to 2 min). Thicker coatings can be produced with longer immersion times, but coatings become powdery and nonadherent for longer immersions, depending on the alloy type. (In this respect, the cerate coating is very similar to the chromate coating.) The thickness of the aluminum oxide layer depends on the deoxidizer and is thickest with low- etch-rate deoxidizers, although again this is dependent on the alloy type. Often there is enrichment of alloying components (particularly copper with the copper-rich alloys) at the interface of this oxide with the metal. This phenomenon also occurs in chromate processes, but is a function of the deoxidizer rather than the coating solution and is therefore common to most conversion coatings. The sealing process produces a silicate layer on top of the CeO_2 coating. The silicate layer can add up to another 200 nm (8 μin.) to the coating thickness.

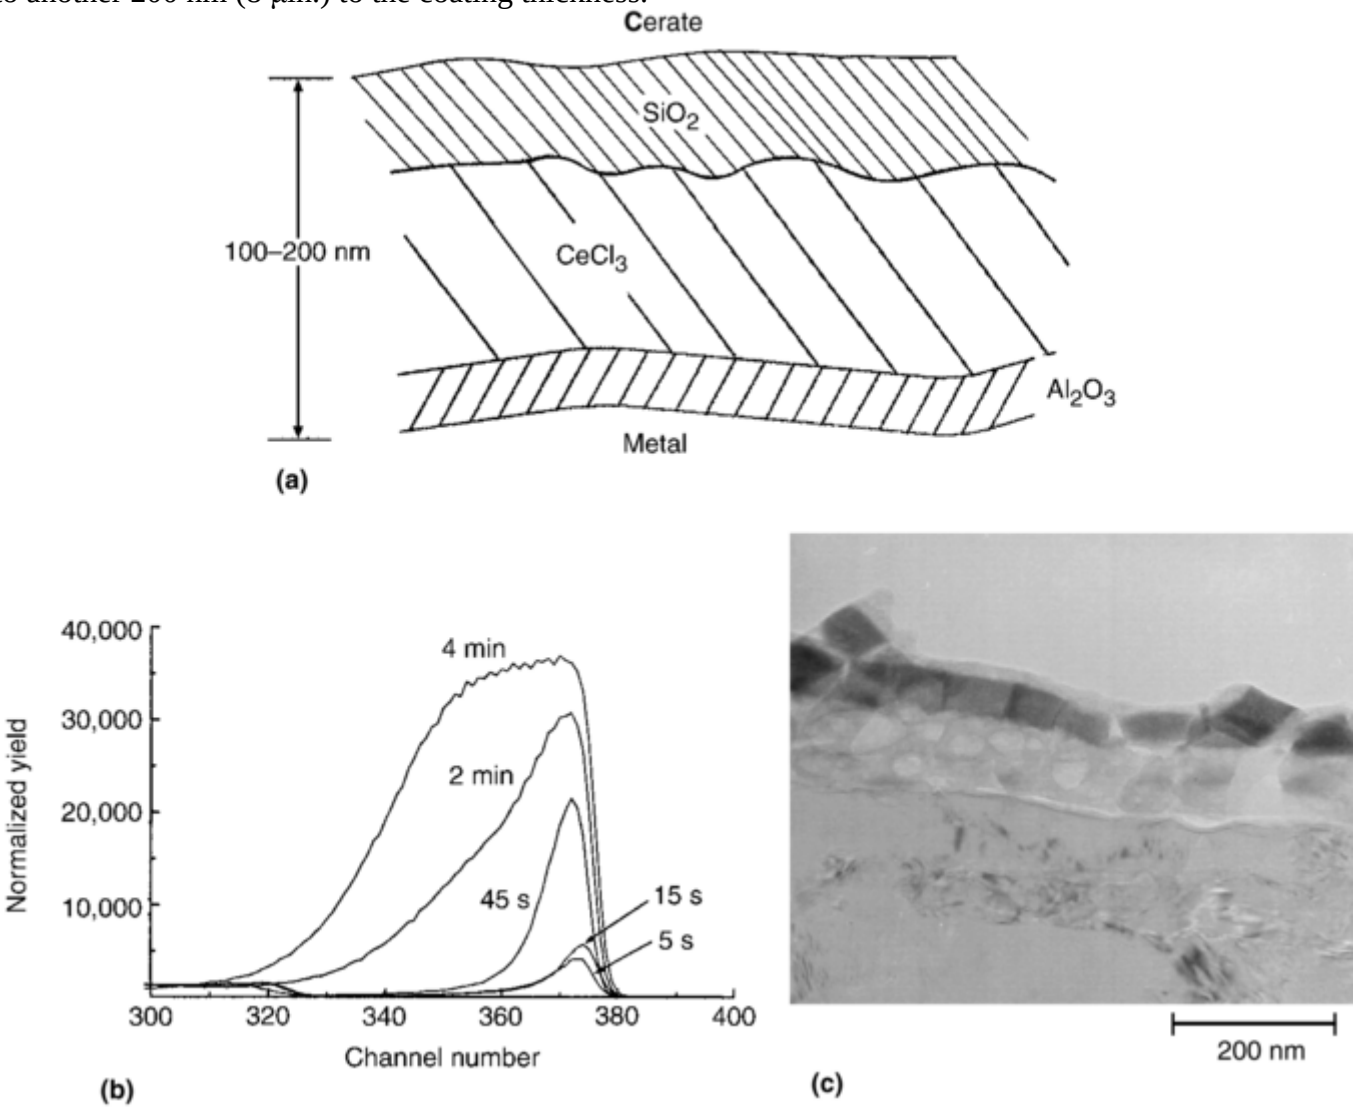

Fig. 11 Cerate conversion coating. (a) Silicate sealed coating. (b) Rutherford backscattering spectroscopy spectra of the cerium region indicating the buildup of cerium. (c) Transmission electron microscopy section of an unsealed coating showing the aluminum oxide and the ceria overlayer.

Based on characterization studies that have focused on the low-etch-rate deoxidizers, it is clear that coating begins over the cathodic intermetallics particles and is thicker there than over the matrix. The majority of these particles then appear to be deactivated. Simultaneously, the aluminum oxide over the matrix thickens to 100 nm (4 μin.) (induction period) before cerium oxide deposits on top of the aluminum oxide. The mechanism of this delayed deposition is still not well understood (Ref 107).

Hybrid Cerium Process. With a number of inhibitors being tried for chromate-free coatings, it is not surprising that processes are developed that combine a number of different types of inhibitors. Miller developed a nine-step process for the proposed aerospace market (Ref 104). The steps include an alkaline clean, rinse, desmut, rinse, coat, rinse, seal, rinse, and then swab with adhesion promoter.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The cerium-conversion coating solutions are neutral to basic (since they can contain NaOH), operate at room temperature, and can contain potassium permanganate and/or strontium chloride. The seal contains sodium molybdate, nitrite, and silicate and is applied at 90 to 95 °C (195 to 205 °F). The adhesion-promoting step is a swab with a silane (glycidoxy(ethoxy)polyfunctional methoxysilane).

No information has been published on process control; however, cerium and manganese levels can probably be ascertained by titration. The silicate solution may be more difficult to keep in optimal condition since adsorption of carbon dioxide from the air can affect its performance. No information on coating weight is available, but it can probably be determined by standard acid stripping. This process demonstrated good corrosion resistance in the unpainted condition and passed wet paint adhesion testing (Ref 94).

Cerium Boehmite Processes. There are a number of processes based on developing a boehmite coating on aluminum surfaces either in the presence of cerium and other salts, or using the rare earth salts as seals (Ref 103, 105, 108). Like cerating, these treatments became prominent in the late 1980s and early 1990s. One of these cerium- base, boehmite growth treatments was developed by Mansfeld et al. (Ref 103). The term "stainless aluminum" was coined by Mansfeld to describe the process (Ref 109). Other boehmite processes have also been reported. For example, Kindler reported a process based on oxide growth in the presence of $CeCl_3$ alone or with lithium and aluminum nitrates (Ref 108). Hughes et al. (Ref 105) reported a process based on oxide growth in $Ce(NO_3)_3$, followed by a silicate seal. A further boehmite process was developed on oxide growth in the presence of $LiNO_3$ and $Al(NO_3)_3$ followed by sealing in $KMnO_4$. See the discussions of permanganates.

To the authors' knowledge, none of the boehmite processes based on cerium is currently under commercial development for the aluminum market. Part of the problem with the industrial application of the boehmite processes is that they usually require ten or more process steps, particularly for aerospace applications, with up to two requiring processing temperatures of 90 to 100 °C (195 to 212 °F).

The cerium-containing process solutions are slightly acidic to neutral and contain cerium nitrate or cerium chloride alone or with other salts. Sealing usually involves immersion in silicate solutions at elevated temperature, although silanes or permanganates have also been used (Ref 104). The cerium-molybdenum process (Ref 109) involving three different steps, which can be arranged in different orders, has been most studied. Oxide growth is involved in two process steps either following one another or separated by an anodic polarization in sodium molybdate solution. Alternatively, the first two steps involve oxide growth then anodic polarization. Performance of the cerium-molybdenum process is reported to be poor for the unpainted coating in neutral salt spray and paint adhesion is variable (Ref 93, 94).

Very little information is available on process control for these types of processes. Boehmite growth, however, is particularly sensitive to the presence of silicon in solution, which must be kept at low levels. Constant operation of baths close to boiling results in polymerization and condensation reactions of cerium solution species to form CeO_2 (Ref 110). Boehmite coatings are generally colorless or slightly iridescent, so it is not easy to determine the evenness of a coating on a part visually. Sealing can improve the color definition. For example, a silicate seal produces a purple to green iridescence. Because of the lack of color in the coating and the use of silicate or organic seals, coating weight determination by immersion in concentrated acid is problematic.

Characterization of the cerium-molybdenum process indicates that processing in hot aqueous cerium salt solutions generates a self-limiting oxide with the typical porous boehmite structure. The thickness of this layer is generally up to 1 μm. No additional oxide growth is observed after anodic polarization in molybdate solution. Anodic polarization may result in anodic growth over areas that have a thin oxide. The molybdate ions also penetrate the oxide, leaving available Mo^{6+} for repair, but some of the molybdate reacts with the cerium and is probably immobilized (Ref 111).

It seems likely that oxide growth occurs in a similar fashion to that described by Alwitt (Ref 112) with the cerium ions playing some modifying effect on oxide generation through incorporation of cerium species into the boehmite oxide. In addition, deposition of a cerium oxide layer over cathodic intermetallics may reduce the overall susceptibility of the surface to corrosion.

Sol-Gel Methods. Sol-gel processing has wide application in many industries outside metal finishing. It has gained interest in metal finishing, particularly for aerospace repair applications.

Aqueous sol-gel processes have been tried primarily for adhesive bonding applications (Ref 113) and anodizing/chromate conversion coating replacements (Ref 114) in the aerospace market. Products are offered by numerous suppliers. The chemistry of these coatings lies largely in the hydrolysis and condensation

مرجع مهندسی مواد و متالورژی

reactions that occur on mixing metal alkoxides or a mixture of alkoxides and silanes in water. Processing is relatively simple, typically involving up to five steps. These usually include an alkaline clean, rinse, surface activation, rinse, coat, and dry. The drying stage can be at elevated temperatures. Variations from this sequence of steps occur in the activation and drying stages.

The coating solutions generally contain aluminum, titanium, or zirconium alkoxides mixed with silicon alkoxides, polymers or silanes (Ref 114). The hydrophilic components of the condensed film gravitate toward the metal, whereas the hydrophobic components gravitate toward the external surface. In this case, the number of coatings applied can be important since the final coat has to have the organic components exposed to promote good paint adhesion. Hydrolysis of the complexes on the metal surface is quite common, and the inorganic polymerization yields a chemically bonded conversion coating. However, organic solvents are emitted during this “curing” reaction.

Since the majority of these coatings are sprayed or swabbed, traditional process control is not necessary. The processing solutions, however, need to be prepared on a batch basis and have a limited lifetime. It is important to age the solutions prior to use to allow polymerization of the alkoxides and silanes. The differential rate of polymerization between metal alkoxides and the silicon-containing components is important for the final film structure. Thin coatings are hard to characterize, but if the coating thickness is significant, then eddy-current measurement can be used to determine the thickness. These coatings demonstrate good adhesion for paints and adhesives as long as the correct functional groups are included to bond to the paint. They are claimed to provide good corrosion resistance under paint in scribe tests on a range of substrates.

Models of the deposition process propose that, upon immersion into the coating solution the activated, hydrophilic aluminum oxide surface reacts preferentially with the aluminum, titanium, and zirconium alkoxides over the silicon alkoxides. These are less stable and form an oxide layer on the surface adjacent to the metal surface. As the reaction proceeds, the silicon-containing components are incorporated to a greater extent, with the external surface containing mostly the organic silicon components and functional groups appropriate for the adhesive or primer attachment. With multiple-step coating, the hydrophobic top surface of the first layer attracts the organic components of the fresh sol-gel solution. This means that the external surface of the second layer may be hydrophilic, which is undesirable for the applications of some paint systems and adhesives.

Manganese-base coating systems are described in the following paragraphs.

Oxide Growth Containing Manganese in Alkaline Conditions. One of the earliest patents for the boehmite permanganate processes was granted in 1987 (Ref 115). This process was developed into both immersion and steam treatments, with processing temperatures close to 100 °C (212 °F) or above. At these elevated temperatures boehmite production will be involved, and metal salts incorporated into the bath act to modify the properties of the boehmite coating. The process is available commercially.

The boehmite steam version of the permanganate processes are being used for coating U.S. post boxes (Ref 116), but has also been involved in a number of trials for aerospace applications (Ref 92, 94). There are two versions of this process. The first involves 10 steps including clean, rinse, deoxidation, rinse, boil in deionized water, oxide sealing, rinse, permanganate treatment, rinse, and silicate seal. The second was a four- step process, involving an alkaline clean, rinse, then a treatment in alkaline permanganate solution, and rinse.

For the 10-step process, the oxide-sealing step contains aluminum and lithium nitrate and is operated at boiling; the permanganate step contains potassium permanganate at 60 °C (140 °F) and the silicate seal at boiling. All these steps are neutral to alkaline with the pH of permanganate coating solution in the range 7 to 12.5 (Ref 117). The permanganate-step (five-step process) contains potassium permanganate and a borate to act as a buffer and is operated at 70 °C (158 °F) (Ref 115).

As for other boehmite processes, very little information is available on process control, although it is reported to be simple due partly to the low concentrations of ingredients used in the baths (Ref 92). As noted earlier, boehmite growth is sensitive to the presence of silicon in solution, which must be kept at low levels. Boehmite coatings are generally colorless or slightly iridescent so it is not easy to visually determine the evenness of a coating on a part. The presence of manganese in the coating may, however, impart a slight brown appearance to the coating. Silicate sealing may increase the intensity of the iridescence of the coating.

The reported paint adhesion results were generally good, although there was some uncertainty over wet paint adhesion, but the results of corrosion resistance were mixed, with good and poor results reported (Ref 92, 93, 94).

مرجع مهندسی مواد و متالورژی

Manganese Conversion Coatings. Concurrently with the development of the manganese- containing boehmite coatings has been the development of a manganese conversion coating produced from acidic permanganate-containing solutions (Ref 118). The process is available commercially.

The conversion coating versions are shorter; they are being tried for aerospace applications and show some promise. The conversion coating process involves an alkaline clean, rinse, deoxidize, rinse, permanganate conversion coating, rinse, and for aerospace applications an organic seal and dry.

The conversion coating bath is acidic (pH 2.5–4.0) and contains aluminum nitrate and permanganate ions (Ref 118); the preferred operating temperature is 60 °C (140 °F). The acidic conversion coating process also has an optional organic seal step to improve paint adhesion, particularly with waterborne paints. These coatings typically give performance similar to chromate under waterborne paint, but the corrosion resistance of either the sealed or unsealed versions is usually poor.

Process control for manganese determination in the acidic process can be done using a ferric sulfate/sulfuric acid titration. Since the conversion coating bath is only slightly acidic, there is little aluminum dissolution and bath performance remains good until the permanganate begins to become depleted, at which stage the bath is discarded. The coating has a colorless to golden/brown color, so quality control on the process line can be performed visually. Coating weight determination of the manganese-containing, inorganic part of the coating can be carried out using standard techniques; however, total coating weight including the polymeric seal becomes more problematic.

A model of the conversion coating covering the matrix is presented in Fig. 12. Characterization of the acidic permanganate conversion process has revealed that a mixed manganese and aluminum oxide layer up to 70 nm (2.75 µin.) develops on the surface of the alloy for typical processing times. The thickness of this aluminum/manganese oxide increases with immersion time, but appears to display a logarithmic growth behavior and after 4 min processing approaches a limiting thickness (Fig. 12b). The oxide coating appears to be made of fine particles (Fig. 12c), whose coverage of the surface increases with immersion. The manganese incorporated into the coating was mostly in the Mn(VII) state, suggesting that the permanganate ion is incorporated into the surface aluminum oxide. The seal increases the thickness markedly and improves the corrosion resistance.

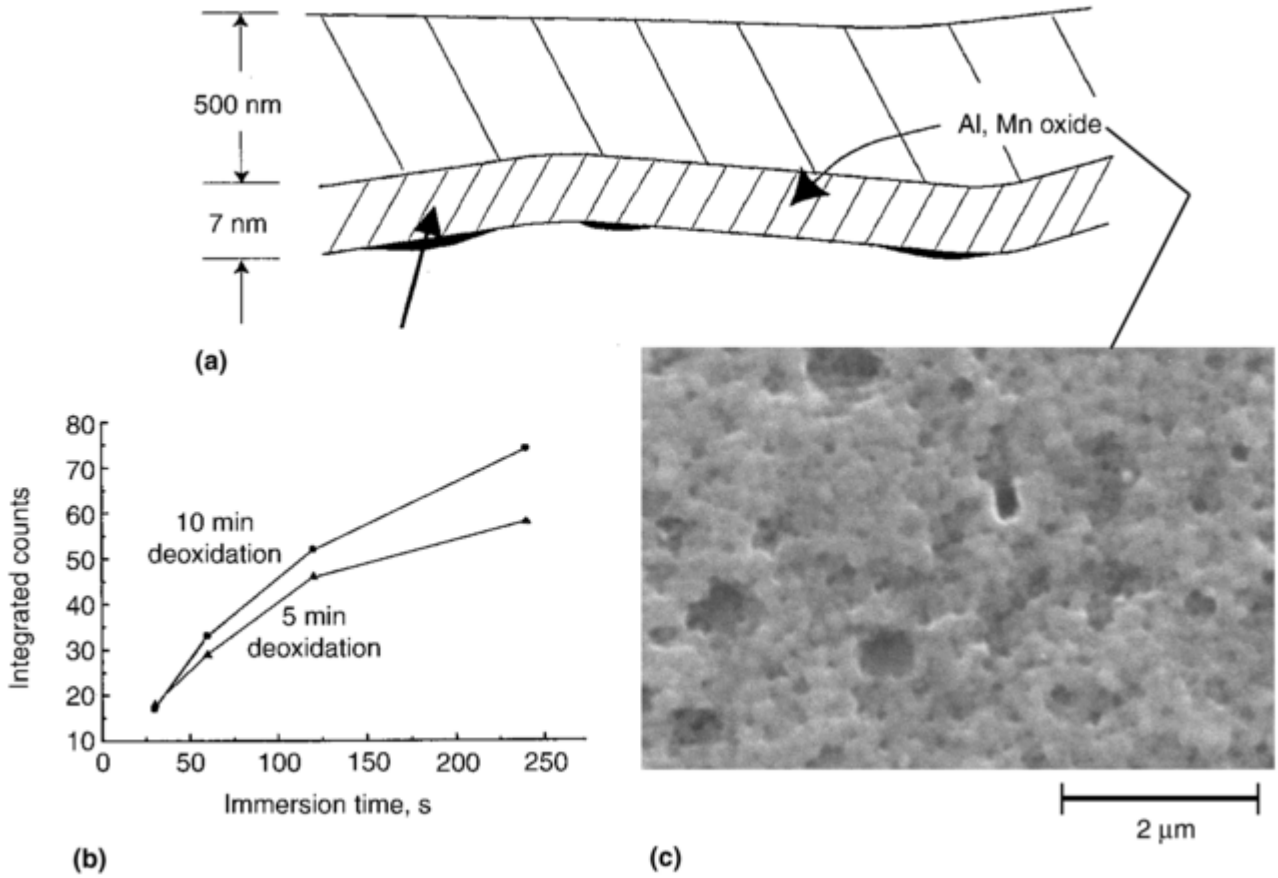

Fig. 12 Manganese coating produced in the acidic process with a polymeric topcoat. (a) Schematic. (b) Increase in manganese counts as a function of immersion time as measured by Rutherford backscattering spectroscopy. (c) Plan view (secondary electron image)

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

This suggests that the deposition process is relatively simple. Upon immersion of the freshly deoxidized surface, there is oxidation of the surface by either nitrate or permanganate ions, which results in thickening of the oxide. Given that little Mn(III) has been detected in the coating, it seems likely that the nitrate assists in oxide generation. During oxide growth, permanganate ions become incorporated into the coating.

Cobalt-base conversion coatings are commercially available for the marine and automotive industry and have been tried for aerospace applications for a number of years. It has given excellent adhesion and corrosion resistance in automotive applications. The marine version of the cobalt process involves an inorganic conversion coating step followed by an organic seal, for other applications (e.g., aerospace) an inorganic seal is preferred for better corrosion resistance in the unpainted condition. Processing is relatively simple, involving up to eight or nine steps. These include an alkaline clean, rinse, deoxidize, rinse, conversion coat, rinse, seal, and rinse. A drying step is required with the polymer seal. The conversion coat and seal baths are operated at 60 °C (140 °F).

According to the patent literature, the conversion coating solutions generally contain a complex cobalt (preferably cobalt hexanitrite ion) generated through the reaction of a metal nitrite with a Co(II) salt, hydrogen peroxide, and an accelerator (Ref 119). The commercially available process is based on carboxylates and nitrate complexes (Ref 120). This bath is free of fluoride and operates at neutral pH. Nonetheless, there is some etching of the aluminum since peroxide, dissolved oxygen, and Co^{3+} are powerful oxidizers in water at pH 7.0. Treatment of car wheels, for example, reveals that very little aluminum dissolves in the bath, but it is incorporated into the coating. The inorganic seal can contain a range of salts, but vanadate and tungstate oxyanions are preferred in a solution that operates at neutral pH. A polymeric version of the seal has also been used for marine applications. Both types of seals are designed to improve corrosion resistance and overlayer adhesion, although the paint adhesion for the inorganic and polymeric seals may vary with the paint system.

The reported performance of the cobalt processes is mixed with both poor corrosion resistance in neutral salt spray in the unpainted condition and poor paint adhesion (Ref 92) to good performance on both accounts (Ref 93, 94). It is important to realize that the best chromium-free products pass unpainted salt fog about 50 to 80% of the time; however, chromate consistently passes 90 to 95% of the time on specified alloys. Due to the enormous potential liability, only painted applications will be quickly converted to chromium-free in aerospace uses.

Process control for the cobalt-containing solution is carried out by titration for cobalt levels and addition of additive as necessary. The vanadate sealing solution can be titrated using ferrous ammonium sulfate in the presence of sulfuric acid and ferroin. Coating weights can be determined by the normal acid-stripping processes for the version using the inorganic seal, but may require a two-step process for the organically sealed version. In this latter case, there would be an initial alkaline strip to remove the organic seal followed by the acid strip (Ref 92). Coating weights are typically 215 to 2580 mg/ m^2 (20 to 240 mg/ft^2).

Earlier reports on the structure of the cobalt- base coating produced from $Co(NO_3)_2$ baths indicated a layered (or possibly graded) structure. An alumina layer develops adjacent to the metal that gradually changed to a mixture of CoO, Co_3O_4, and Co_2O_3, and finally to a top layer composed of Co_3O_4 and Co_2O_3. The total layer thickness is estimated to be 1200 to 1400 nm (47 to 55 μin.) (Ref 119). A model of the cobalt conversion coating/vanadate seal processes that develops on 2024-T3 aluminum is presented in Fig. 13. An open porous structure develops on the surface during immersion in the cobalt-containing bath (see SEM inset in Fig. 13). Rutherford backscattering spectroscopy (RBS) analyses indicate that cobalt is incorporated into the aluminum oxide coating, and determination of width of the cobalt peak indicates that the oxide thickness is typically 500 nm (20 μin.) after 10 min processing (see inset). Treatment in the vanadate solution results in partial filling of the porous surface oxide containing (see inset), but RBS analyses indicate that no additional increase in thickness results from treatment in the vanadate solution.

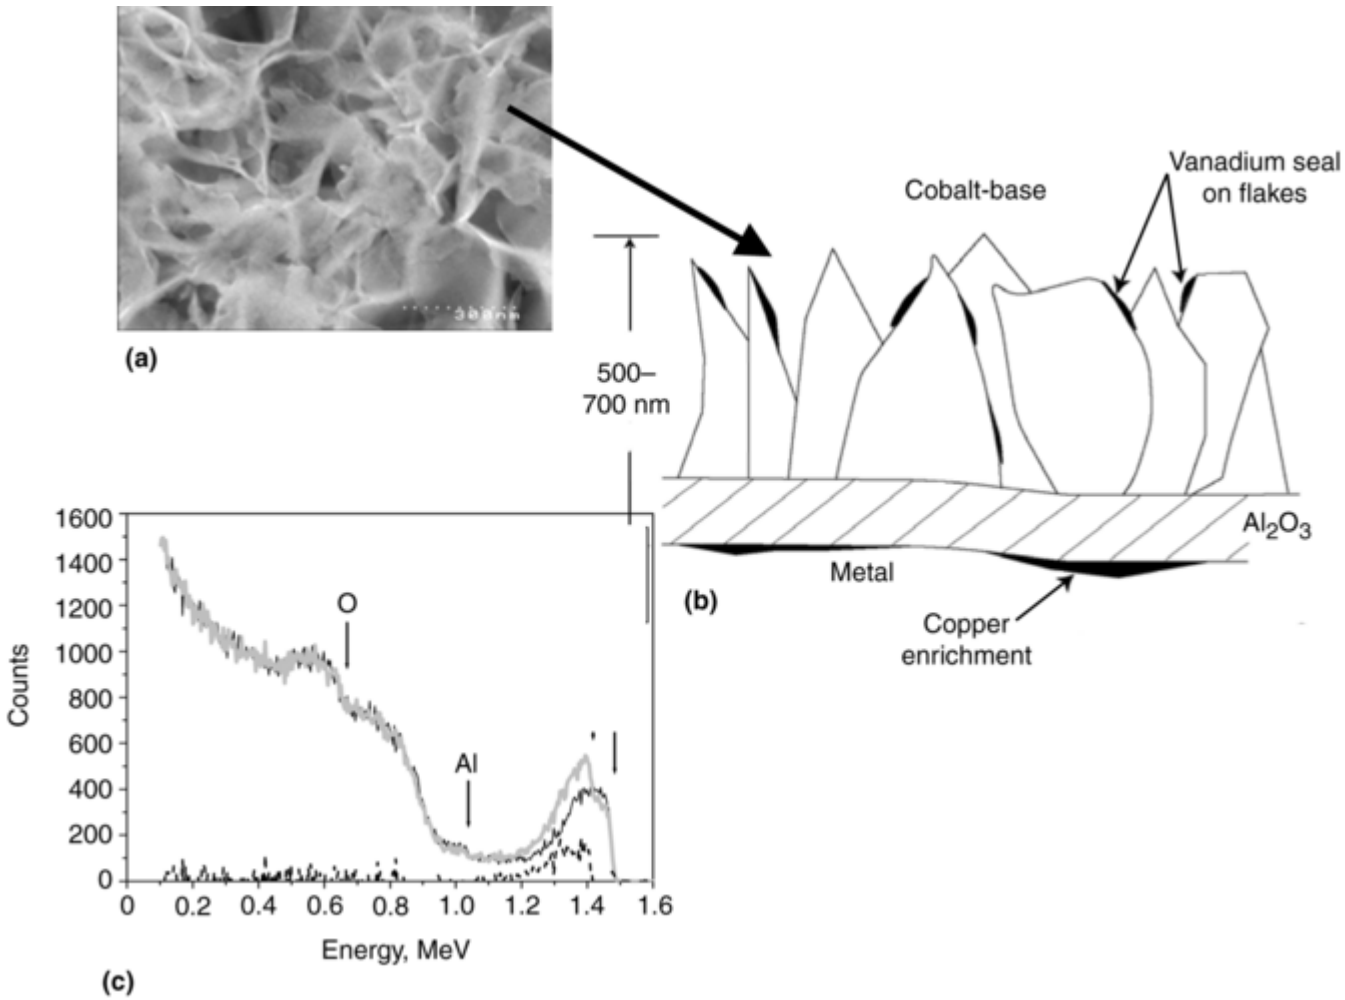

Fig. 13 (a) (b) Structure of the surface oxide after treatment of deoxidized 2024-T3 in Alodine 2000 at 60 °C (140 °F) for 10 min followed by sealing in Deoxylyte NC 200. (b) In the Rutherford backscattering spectroscopy inset, the black is the cobalt step and the gray is cobalt and vanadium steps. A difference spectrum in which the cobalt spectrum is subtracted from the cobalt and vanadium spectrum is displayed beneath the other two. This difference peak is the vanadium spectrum.

Based on the characterization studies, it is proposed that the conversion coating develops in the following manner. Upon immersion into the coating solution, the aluminum oxide on the surface of the metal thickens under the combined influences of thermal activation and oxidant in the solution. During processing, which is ultimately self-limiting, significant amounts of cobalt ions are incorporated into the oxide structure. Immersion in the vanadate-containing solution results in reaction with the surface and deposition of vanadium oxides within the cobalt/ aluminum oxide pores.

Molybdenum, in the form of molybdate oxyanions, has been tried as conversion coatings, alone and as an additive to other processes used on aluminum (see the cerium-molybdenum and hydrotalcite processes) (Ref 121). As a conversion coating, most of the published work has examined deposition on tin and zinc for tinplate and galvanized product, respectively. There are a number of manufacturers who are developing processes for the tin, zinc, and aluminum markets. Molybdate-base conversion coatings have met with little success on aluminum.

Many of these processes are phosphate-base and acidic (Ref 122), while others do not contain phosphate and operate at closer to neutral pH (Ref 123). Processing can contain up to six steps if a seal is used. Goodreau reports a process that involves a clean, rinse, conversion coat, dry, polymer seal, and dry (Ref 124). The polymer seal provides most of the corrosion protection.

Simpler process formulations have also been investigated in which the conversion coating solutions contain sodium molybdate or molybdic acid and may contain buffer or acid to adjust the pH (Ref 121, 125). The process bath is operated at pH 4 to 6, with better performance tending toward the lower end of the range. Coatings can be deposited near 20 °C (68 °F) in less than 10 min.

www.iran–mavad.com
مرجع مهندسی مواد و متالورژی

No details are available for process control, but it seems likely that molybdenum levels could be monitored by titration. Given the sensitivity to pH, this would also need to be monitored. For the formulations that operate near neutral pH, aluminum buildup may not be a problem. Quality control for coating weight is likely to be achieved using the normal one-step acid-stripping processes for the inorganic version. The performance of the coatings is variable, as summarized by Nylund (Ref 100). Coating weights for the polymeric version are typically 35 mg/ m^2 (3.3 mg/ft^2) measured as molybdenum atoms (Ref 124).

Characterization studies of the molybdenum- base conversion coatings are not as common as some other of the chromate-free coatings and has often focused on the use of XPS to determine the oxidation state of the molybdenum incorporated into the coating (Ref 121). The incorporation into the coating of oxidation states lower than Mo(VI) has been seen as detrimental and related to the pH of formation of the coating (Ref 123). In simple molybdate solutions at pH 3 and 20 °C (68 °F), the coating thicknesses were reported to be 0.1 μm (0.004 mil) for 5 min immersion and 2.0 μm (0.079 mil) for 30 min immersion. No doubt, the thickness will depend on the solution composition, deposition pH, and immersion time.

Hydrotalcite coatings take their name from a class of layered, claylike mineral compounds typified by the compound hydromagnesite, $Mg_6Al_2(OH)_{16}{\cdot}CO_3{\cdot}4H_2O$ (Ref 126, 127), which is naturally occurring. Synthetic hydrotalcite compounds can be formed as a coating on aluminum alloy surfaces by contact with an alkaline lithium salt solution. This leads to the formation of polycrystalline compounds containing the hydrolithisite compound $Li_2[Al_2(OH)_6]_2{\cdot}X{\cdot}nH_2O$, where X is one of several inorganic anions such as CO_3^{2-}, NO_3^-, or Cl^- (Ref 128). Patents covering the hydrotalcite coating process (Ref 129) and sealing processes (Ref 130) exist. Variants of the coating process are suitable for architectural, aerospace, and perhaps automotive applications, but none are commercially available at the present time.

As with many conversion coating processes, the hydrotalcite process involves degreasing and deoxidation steps prior to coating. Coating is carried out by immersion or spray of the coating bath solution on a metal surface. Elevating the temperature of the bath above 40 °C (104 °F) enhances coating formation kinetics and baths yielding highly corrosion-resistant coatings. Sealing for enhanced corrosion resistance is optional and is carried out in a second step. Sealing with a wide range of compounds has been reported (Ref 131, 132, 133). Noteworthy improvements in corrosion resistance are obtained by sealing in cerium, manganese, or magnesium acetate solutions (Ref 131, 132). A two-step process has been developed for removing copper contamination from coatings formed on aluminum-copper-base alloys (Ref 134). Use of oxidizing agents such as nitrates or persulfate accelerates the coating formation process and leads to coatings with excellent corrosion resistance on Al-Cu-Mg alloy substrates (Ref 135).

In terms of appearance, hydrotalcite coatings are white or gray and do not fully obscure the luster of the underlying metal. In some cases, coated surfaces have a matte finish. When sealed, they may take on a color characteristic of the sealing agent. In scanning electron micrographs, the coating exhibits a distinctive morphology consisting of a mass of intersecting bladelike crystals that form a continuous layer across the surface of the metal (Fig. 14). Coating cross sections reveal that the coating is really duplex in nature, consisting of a polycrystalline outer layer and an inner barrier layer. The inner layer is poorly crystalline and contains lithium from the coating bath.

مرجع مهندسی مواد و متالورژی

Hydrotalcite coatings provide good corrosion resistance on commercially pure aluminum, aluminum-manganese, and Al-Mg-Si alloys. Use of oxidizing bath chemistries or sealing is necessary to achieve acceptable levels of corrosion resistance on Al-Cu-Mg and Al-Zn-Mg-Cu alloys. Coatings for casting alloys with high alloying element content have not been developed. Organic coatings will adhere to hydrotalcite-coated surfaces. Care must be taken not to overcoat the substrate. Low coating adhesion, disbondment, and filiform corrosion will result if hydrotalcite coatings are too thick or contain soluble constituents (Ref 136).

Self-Assembled Monolayers (SAM). Self- assembling of molecules on metal surfaces represents a newer area of metal finishing. The process has been demonstrated to work well on aluminum-magnesium alloys in automotive applications and is likely to see use in the European automotive market, but it is used in combination with zirconium and titanium processes in the United States.

This coating process works on the following fundamental principles. Polar compounds are attracted to metal surface. When this functionality is combined with a long chain alkyl group, the attraction of the polar group for the metal surface remains intact while the organic chains tend to line up pointing away from the surface. At the other end of the molecule, a second group can be added to promote overlayer adhesion. Thus, the molecules "self-assemble" on the surface.

Little is available on the processing solutions or process control. The conversion coating solutions can contain a range of different chemicals in different processes. The more favored polar functional groups for aluminum involve phosphates or perfluorinated carboxylic acids (10 to 18 carbons).

Characterization studies of the adsorption of phosphonic acids on aluminum and AlMg1 indicated that the adsorption takes place in approximately 60 s with the phosphate group oriented toward the surface of aluminum oxide. Adsorption also occurred on iron-containing inclusions. The process of self-assembly, however, took up to three days (Ref 137).

Organic Coatings. Another field of research into chromate alternatives examines the deposition or even generation of polymers on the surface of a metal. This is covered elsewhere in this Volume. The use of polymers as sealants for conversion coatings has been discussed previously.

Conducting Polymers. Research into conducting polymers gained notoriety in 1977 with the publication of a paper describing the generation of polyacetylene polymer with an electrical conductivity many orders of magnitude greater than ordinary polymers (Ref 138).

The current focus of conducting polymers includes polypyrroles, polythiophenes, and particularly polyaniline (Ref 139). Much of the work is targeted on electrochemical and chemical deposition onto ferrous metals. Formulations produce thick coatings (up to 20 μm, or 0.8 mil), more akin to primers than to conversion coatings. Several forms are available commercially for different applications.

Characterization of the coating reveals that it is produced by chemical reaction of iron with polyaniline dispersed in a polymer matrix, resulting in the formation of αFe_2O_3 up to 1 μm (0.04 mil) thick with up to 20 μm (0.8 mil) of conducting polymer/matrix above the oxide (Ref 140). The dispersion itself contains polyaniline particles about 70 nm (2.75 μin.) in diameter, as the dispersion is in sufficient concentration to form a "chain of pearls" in the coating, thus providing the conducting pathways.

The protection is reported to be imparted in two ways on ferrous metals. First, the application of the conducting polymer ennobles the surface by shifting the potential many hundreds of millivolts. Second, the polyaniline, known as the emeraldine salt is reduced to the leucoemeraldine base oxidizing the underlying metal [Fe metal to Fe(II)]. Cathodic reactions occur resulting in the reduction of oxygen and further oxidation of Fe(II) to Fe(III) generation of OH^- for deposition of Fe_2O_3 and oxidation of leucoemeraldine to emeraldine via an emeraldine base. Thus, the polyaniline acts as a mediator in the formation of a passive layer (Ref 140). A similar mechanism is likely to ensue for aluminum alloys.

Silanes. For the purposes of metal finishing, silanes that can be applied to metals fall in the category of trialkoxy esters of the form *R*-Si- $(OR')_3$ where *R* is an alkyl ligand with an organofunctional group and *OR′* is usually a methoxy or epoxy ligand (Ref 141, 142). Silanes have been used successfully on steel, galvanized products, and aluminum alloys, and at least one manufacturer offers products in this area (Ref 141).

The use of silanes for metal finishing is still a developing area, and care needs to be taken in choosing and preparing the silane solution for a particular application. Parameters that affect the bonding are the surface energies of the oxides of the metals to be treated, the acidity of the organofunctional group, and its relationship to the basic surface hydroxyl groups and the makeup of the silane solution that may rapidly move into a condensation reaction phase. The earliest successful silanes include γ-APS and γ-UPS, but more recently bis-

مرجع مهندسی مواد و متالورژی

1,2-(triethoxysilyl)ethane (BTSE) and bis-1,2-(triethoxysilylpropyl) tetrasulfide (BTESPT), also known as sulfane, have shown more general applicability.

Silane solutions are prepared on a batch basis as required. Pretreatment for silane coatings is relatively simple, involving an organic degrease (acetone/ethanol) followed by an alkaline clean then rinse. The silane solution tends to be dilute and acidic (pH 4 to 6). Dilution and an acid environment limit the amount of condensation reaction, but hydrolysis of the first methoxy or ethoxy group is rapid.

Reaction with the surface is proposed to happen via elimination reactions between the silanol groups and surface hydroxyl groups resulting in metal-oxygen-silicon bonds. With the BTSE, the coating is strengthened by the formation of siloxane bonds (Si-O-Si) bridging between the BTSE molecules. The thickness of the surface coatings tends to be in the range 30 to 100 nm (1.18 to 3.93 μin.).

BTSE films alone provide good corrosion resistance since there is a lack of organofunctional groups; the surface silanol groups tend to form siloxane bonds as a function of aging. A quick second silane treatment (e.g., γ-APS) can be applied to the BTSE surface to produce a surface with better adhesion to paint systems. The BTSE/γ-APS film has given filiform corrosion resistance in auto applications.

Aluminum Anodizing

Hideaki Takahashi, Hokkaido University

Introduction

ABOUT 25 MILLION TONS of aluminum is produced from bauxite ore and scrap every year, and most aluminum products are subjected to surface treatments such as anodizing, chemical conversion coating, painting, and metal plating. Anodizing is one of the most common surface treatments of aluminum and is performed for corrosion protection as well as a wide variety of purposes (Ref 1, 2, 3). Table 1 shows application examples of anodic oxide films on aluminum.

Table 1 Application of anodic oxide films on aluminum

Property class	Attribute	Application
Physical and mechanical	Hardness Wear resistance	Screw thread, gear, bolt, nut, brake disk clutch, fan, nozzle, valve, cam track, fuel pump, injector
	Lubrication	Piston, piston ring, roller, bearing
	Membrane	Gas separator, molecule separator, super grid, template for plasma etching
Chemical	Corrosion resistance	Aircraft, vehicle, boat, train, architecture, household and sporting goods, office supplies
	Wettability	Presensitized plate, Al lithograph
	Adhesion	Organic coating
	Catalytic properties	Catalysis, catalysis support
Electromagnetic	Insulating properties	Printed circuit board, integrated circuit board, electric cable
	Dielectric properties	Electrolytic capacitor, humidity sensor, gas sensor, printing roller
	Magnetism	Magnetic recording device, rotary encoder
Optical	Luminescence	Electroluminescence display
	Absorption	Sunlight energy absorbing plate
Thermal	Emittance	Far-infrared emitter, heat sink

Anodizing is performed for the corrosion protection of aircraft, vehicles, boats, trains, buildings, household articles, sporting goods, office articles, and electronics. Hard anodizing is performed to improve the hardness and wear resistance of machinery parts, such as screw threads, gears, and brake disks. To improve the lubricating performance of pistons, piston rings, rollers, and bearings, the pores of porous anodic oxide films are filled with MoS_2. Porous anodic oxide films are removed from the substrate where they were formed and used as membranes for the separation of gases and other chemical compounds. Adhesion with organic coatings and wettability of anodic oxide films play an important role in presensitized plates for offset printing. The high inner surface areas of porous anodic oxide films are useful as catalysts and catalyst supports. Barrier-type anodic oxide films with high insulating and dielectric properties are used in printed circuit boards, integrated-circuit-supporting plates, aluminum cables, electrolytic capacitors, and humidity sensors. Deposition of ferromagnetic substances, iron, nickel, and cobalt into the pores of porous anodic oxide films causes anisotropy of magnetic properties, allowing their use as memory devices. Electroluminescence of anodic oxide films on aluminum is applied to the fabrication of luminescent display plates, and black coloring with metal deposition

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

is used for sun- energy absorbing plates. Far infrared emitters can also be made, using aluminum alloys covered with anodic oxide films.

Aluminum Anodizing

Hideaki Takahashi, Hokkaido University

Structure of Anodic Oxide Films

When aluminum and aluminum alloys are polarized anodically in electrolytic solutions, oxide films are formed on the substrates. This procedure is termed “anodizing,” and the oxide film formed by this procedure is called “anodic oxide film.” Anodic oxide films can be classified into two groups: barrier and porous-type oxide films. The structure and growth characteristics of these anodic oxide films is described in this section.

Barrier-type oxide films are obtained in neutral solutions containing borate, phosphate, and adipate and consist of a thin compact amorphous oxide layer (Fig. 1a). The film thickness, δ_{bf}, in nm, is proportional to the potential, E_a, in volts, applied during anodizing and is expressed as:

$$\delta_{bf} = K \cdot E_a \qquad \text{(Eq 1)}$$

where K is 1.3 to 1.6.

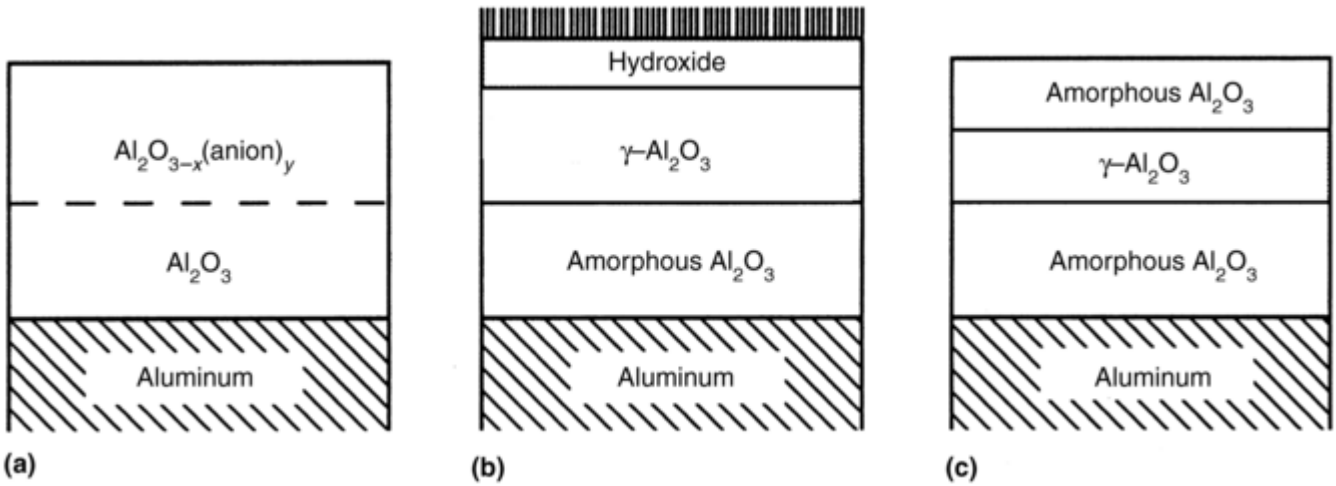

Fig. 1 Structure of barrier type oxide films formed on aluminum after (a) electropolishing, (b) hydrothermal treatment, and (c) thermal treatment

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Galvanostatic anodizing in the neutral solutions gives rise to a linear increase in δ and potential E_a with time, and then the oxide formation stops abruptly, at "film breakdown" potential, E_{bd}, which is significantly dependent on the kind and the concentration of anodizing solution. Processing in diluted boric acid solutions with E_{bd} values as high as 1000 V, results in film thicknesses of 1.3 to 1.6 μm.

Barrier-type anodic oxide films contain small amounts of anions of the electrolyte, which are included only in the outer part of the barrier oxide film. The thickness ratio of the outer anion- incorporated layer to the inner pure Al_2O_3 layer depends on the kind of anodizing solution. This suggests that the transport of anions depends on the interactions of anions with the molecular network of the oxide film. Anodizing in neutral solutions after hydrothermal treatments in pure water leads to composite oxide films, which consist of an inner amorphous Al_2O_3 and an outer γAl_2O_3 (Fig. 1b). The hydroxide film formed by the hydrothermal treatment converts to crystalline oxide by dehydration under a high electric field during anodizing. Anodizing after heat treatment also causes the formation of anodic oxide films containing γAl_2O_3 in the middle part (Fig. 1c).

The porous-type anodic oxide film is obtained by anodizing in acid solutions such as H_2SO_4, oxalic acid, H_3PO_4, and H_2CrO_4. The film possesses a unique morphology, a "hexagonal cell model structure," as shown in Fig. 2. The oxide film consists of numerous fine hexagonal cells perpendicular to the metal substrate, and each cell has a pore at the center. The pores are separated from the metal substrate by a thin hemispherical "barrier layer," existing at the interface between the oxide film and the metal substrate.

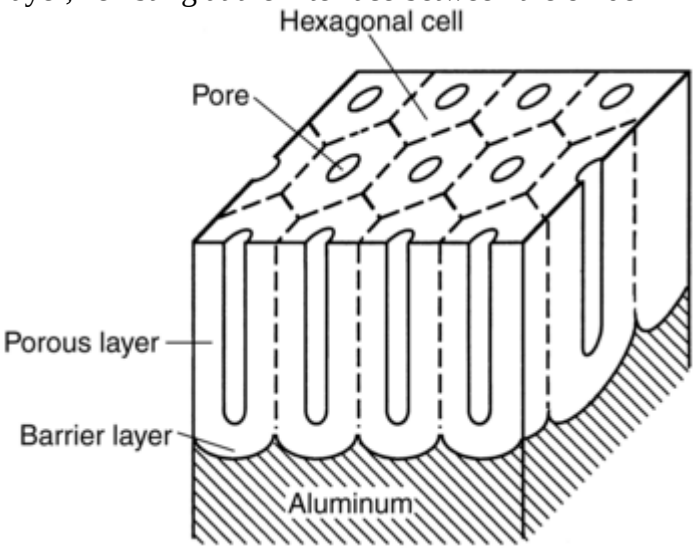

Fig. 2 Structure of porous type anodic oxide film formed on aluminum in acid solutions

Galvanostatic anodizing gives rise to a steady value of the potential, E_s, after an initial transient period and permits a steady increase in the film thickness, keeping the number of cells per m^2, N_c, the size of cells, D_c, and size of pores, D_p, and barrier layer thickness, δ_b (all measured in nm), constant during anodizing. The thickness of porous anodic oxide films, d_{pf}, in μm is proportional to anodizing time, t_a, in seconds, and current density, i_a, in A/m^2.

$$d_{pf} = k \times i_a \times t_a \qquad \text{(Eq 2)}$$

where k (3.6 to 4.5 × 10^{-5} μm C^{-1} m^2) is the proportionality constant, which is higher at lower temperatures and lower acid concentrations. Aluminum alloys with high copper contents show lower film growth rates, due to a preferential dissolution of copper and aluminum intermetallic compound phases.

Longer anodizing time causes the chemical dissolution of oxide, leading to the formation of cone-shaped pores (Fig. 3). At the final stage of anodizing, the pore walls become substantially thinner and are finally destroyed, resulting in "powdering" of the oxide film. The onset of powdering determines the termination of the film growth in practice. Lower temperatures and lower acid concentrations enable the formation of thicker films without powdering, and the maximum thickness may be several hundred μm.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

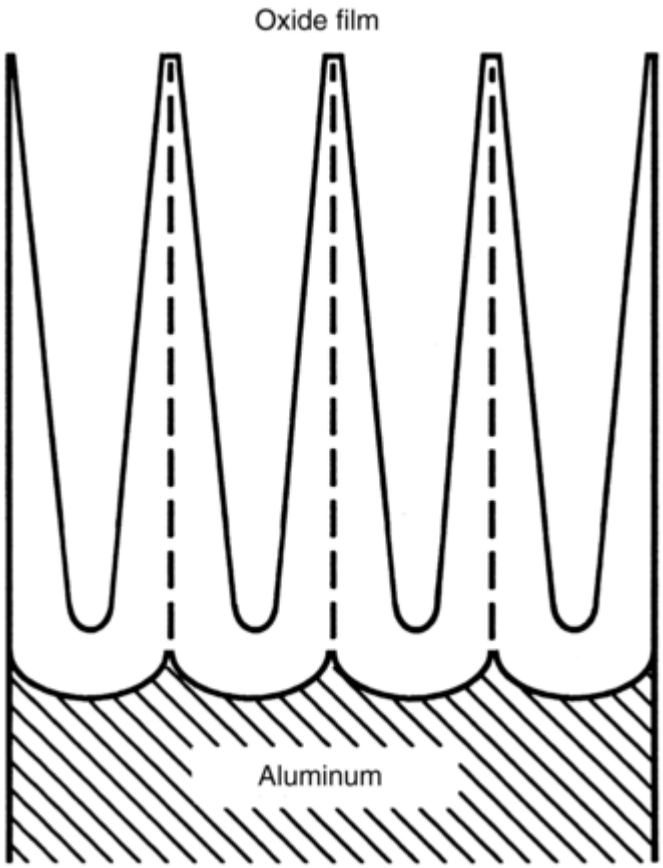

Fig. 3 Cone-shaped pores formed by chemical dissolution during long anodizing

Figure 4 shows the relationship between the current density, i_a, plotted logarithmically, and steady values of the anode potential, E_s, obtained in H_2SO_4 and oxalic acid solutions (Ref 4). The E_s versus log i_a relationship is an "S-shaped curve" in both solutions, and it shifts to higher current density regions at higher temperatures and higher acid concentrations. The "S" shape is observable if the vertical scale is expanded. The anodizing in H_2SO_4 solutions results in lower E_s than in oxalic solutions, suggesting an advantage of H_2SO_4 anodizing in lower electric power consumption. Anodizing should be performed under the conditions at the mid-regions of the E_s versus log i_a relationship since anodizing at the lower regions easily leads to the "powdering" of oxide and in the high regions to "burning" of the oxide. Burning is the phenomenon where the oxide film grows nonuniformly by local heating, due to nonuniform current distribution.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

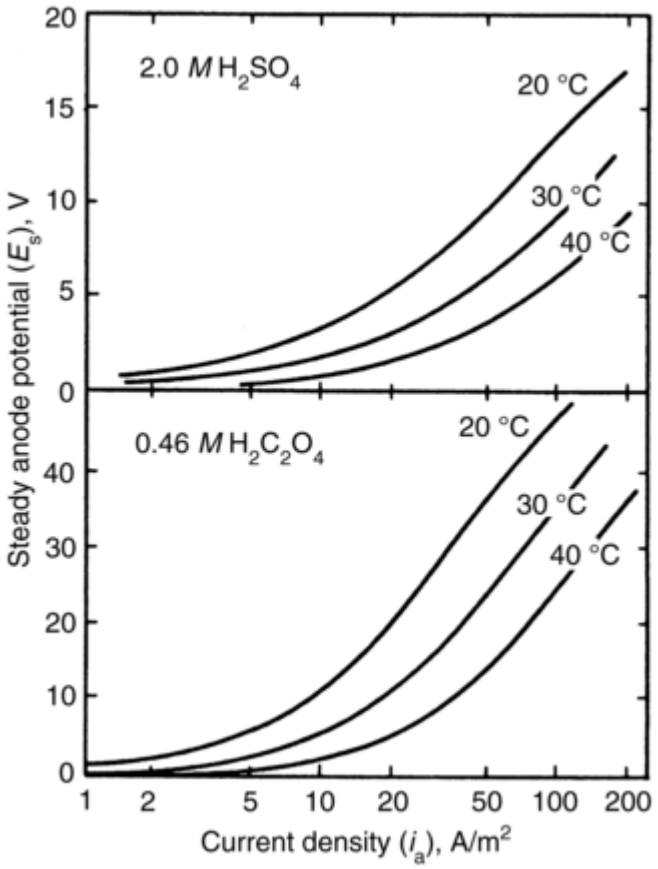

Fig. 4 Relationship between steady anode potential, E_s, and current density, i_a, in 2 *M* H_2SO_4 and 0.46 *M* $H_2C_2O_4$ solutions

The values of N_c, D_c, D_p, and δ_b are functions of E_s as shown in Fig. 5, slightly dependent on temperature, kind of acid solution, and acid concentration (Ref 4). With increasing E_s, the values of N_c decreases, while D_c, D_p, and δ_b increases. The curves in Fig. 4 and 5 lead to:

$$N_c = 14 \times 10^{15} \times E_s^{-1.27} \quad \text{(Eq 3)}$$

$$D_p = 14 + 0.21 \times E_s \text{ when } E_s < 15 \text{ V} \quad \text{(Eq 4)}$$

$$D_p = 4.2 + 0.84 \times E_s \text{ when } E_s > 15 \text{ V} \quad \text{(Eq 5)}$$

$$D_c = 6.5 + E_s \quad \text{(Eq 6)}$$

$$\delta_b = 2.1 \times E_s^{0.83} \quad \text{(Eq 7)}$$

where units of D_p, D_c, δ_b are nm; N_c is m^{-2}; and E_s is V.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

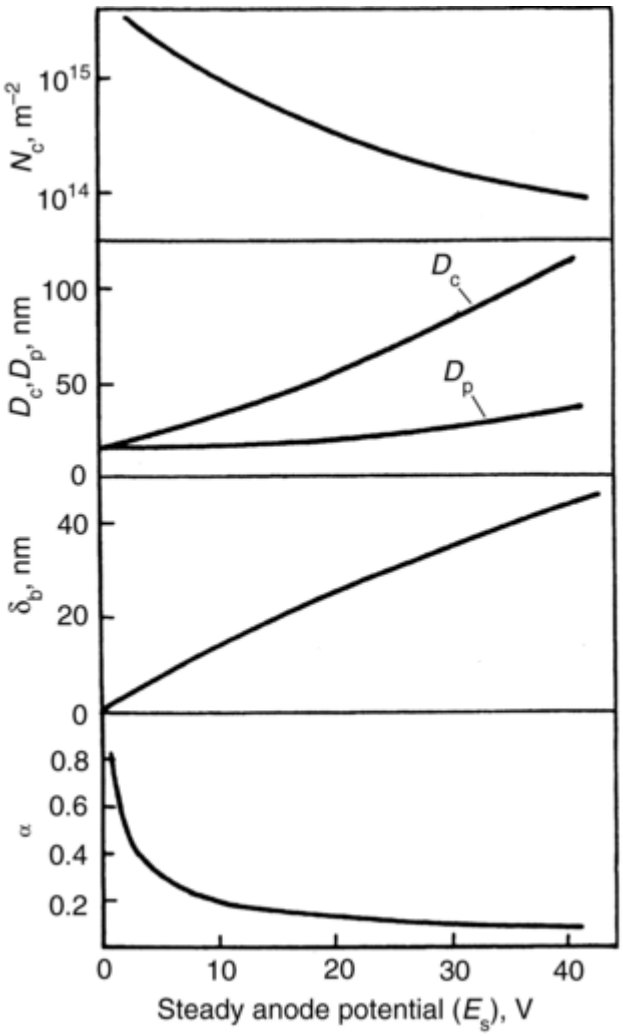

Fig. 5 Changes in cell number, N_c; cell size, D_c; pore diameter, D_p; barrier layer thickness, δ_b; and porosity, α, with steady anode potential, E_s, obtained in $H_2C_2O_4$ solutions

Hence, the porosity, $\alpha = N \pi D_p^2/4$, of the oxide film can be expressed as:

$$\alpha = 0.8 \times E_a^{-0.59} \qquad \text{(Eq 8)}$$

The α value decreases sharply with increasing E_a (see Fig. 5).

Porous-type anodic oxide films basically consist of amorphous Al_2O_3, containing small amounts of water and anions of the electrolyte used. These anions distribute across the pore wall and barrier layer as shown in Fig. 6. Oxide films formed in chromic acid solutions, however, consist of almost pure Al_2O_3.

Aluminum Anodizing

Hideaki Takahashi, Hokkaido University

Anodizing

In general, the anodizing process of an aluminum or aluminum alloy specimen consists of pretreatments (degreasing, etching, and polishing), anodizing, coloring, and sealing. Each step is described in this section.

Pretreatments. Degreasing is performed by dipping the specimen in organic solvents, alcohol, acetone, kerosene, or trichloroethylene, or by wiping with cloths permeated with solvent. Etching and polishing are important pretreatments for conversion coating, metal deposition, and organic coating as well as for anodizing, and typical etching and polishing processes are listed in Table 2. Both acid etching and alkaline etching are

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

possible, and the latter requires a posttreatment of “desmutting” in a nitric acid solution. Electrograining—electrochemical roughening of the surface—is important as a pretreatment in the fabrication of presensitized plates in offset print.

Table 2 Procedures of etching and polishing

Procedure	Solution	Processing conditions
Acid etching	10 vol% (40 wt%) hydrofluoric acid 10 vol% (72 wt%) nitric acid 80 vol% water	Dip, room temperature bath, 2–5 min
Acid electrograining	1–2 wt% hydrochloric acid	Power: 8–15 V_{ac} 200–500 A/m^2 (0.15–0.30 A/in.^{2}); 20–30 °C (70–85 °F), 5–10 min
Alkaline etching	4–10 wt% sodium hydroxide	Dip, 40–90 °C (105–195 °F), 1–10 min, desmut posttreatment: dip, 25–50 vol% nitric acid, ambient temperature, 3–5 min
Electropolishing	22 vol% (60 wt%) perchloric acid 78 vol% acetic acid	Anodic, 25–30 V, 5–15 °C (40–60 °F), 2–5 min
Chemical polishing	86 vol% (85 wt%) phosphoric acid 14 vol% (72 wt%) nitric acid	Dip, 80–90 °C (175–195 °F), 2–5 min
Oxide film removal	0.5 *M* phosphoric acid 0.2 *M* chromic acid	Dip, 85–95 °C (185–205 °F), 10–30 min

Electropolishing generally enables a smoother surface than chemical polishing. In order to dissolve oxide films on the aluminum, a mixture of chromic acid and phosphoric acid is used, and very little of the aluminum substrate is dissolved. Table 3 shows the chemical composition and thickness of surface films formed by electropolishing, chemical polishing, and chromic acid and phosphoric acid solution treatments (Ref 5). A 3 to 5 nm thick oxide film is formed by these treatments. The oxide films formed by electropolishing contain small amounts of chloride ions, which are produced by the decomposition of perchlorate ions during electropolishing. Chemical polishing results in the formation of oxide films containing phosphate and nitrite (NO_2^-) ions. Chromic acid/phosphoric acid treatment after electropolishing replaces the oxide films formed by the electropolishing with oxide films containing Cr (III) and phosphate ions.

Table 3 Chemical composition and thickness of surface films formed by electropolishing, chemical polishing, and film removal treatment

Treatment	Thickness, nm	Chemical composition
Electropolishing[(a)]	3.6	$AlO_x(OH)_{2.91-2x}Cl_{0.09}$ (x - 0.62)H_2O
Chemical polishing[(b)]	4.7	$AlO_x(OH)_{2.45-2x}(PO_4)0.17(NO_2)_{0.04}\cdot(x$ - 0.73)H_2O
H_3PO_4/H_2CrO_4 treatment[(c)]	4.2	$AlCr(III)_{0.43}O_x(OH)_{3.3-2x}(PO_4)_{0.33}\cdot(x$ - 0.07)H_2O

Treatment details:
(a) 13 °C (55 °F), 3 min, 30 V.
(b) 85 °C (185 °F), 3 min.
(c) 90 °C (194 °F), 30 min. Other experimental conditions are described in Table 2.

Typical anodizing procedures are listed in Table 4. Anodizing in sulfuric acid solutions is common, and results in transparent anodic oxide films, which are adequate for dyeing. These films may be dyed into almost any color in practice and can produce strong colors. Oxalic acid solution gives yellowish oxide films, and chromic

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

acid solution results in gray colors. Table 4 suggests that the steady anode potential, E_s, during anodizing strongly depends on the kind of acid used, decreasing in the following order: phosphoric acid, chromic acid, oxalic acid and sulfuric acid. Phosphoric acid gives the highest E_s, suggesting the formation of anodic oxide films with thick pore walls and low porosity. Sulfuric acid solution, by contrast, gives the lowest E_s, leading to thin pore walls and high porosity. Anodizing in sulfuric acid solutions, therefore, tends to cause "powdering" during anodizing, and phosphoric acid solutions tend to cause "burning."

Table 4 Procedures of anodizing

Procedure	Chemical composition	Temperature		Voltage, Vdc	Current density		Appearance and other characteristics
		°C	°F		A/dm^2	A/ft^2	
Sulfuric acid	5–25 wt% sulfuric acid 0.1–5 wt% aluminum sulfate	15–25	60–75	15–20	0.8–3	7.5–28	Transparent
Oxalic acid	3–5 wt% oxalic acid	20–30	70–85	25	1–1.5	9.5–14	Yellowish
Chromic acid	10 wt% chromic acid	45–55	115–130	40–50	0.3–1	28–9.5	Grayish
Phosphoric acid	3–10 wt% phosphoric acid	20–30	70–85	40–100	0.5–2	4.75–18.5	Light blue
Hard anodizing	10–20 wt% sulfuric acid 0.1–10 wt% aluminum sulfate 1 wt% oxalic acid	0–5	32–40	25–60	2–4	18.5–37	Transparent, hardness, >600 HV
Kalcolor	5 wt% sulfuric acid 10 wt% sulfosalicylic acid	22–25	70–75	25–70	2–3.2	18.5–29.75	Bronze-black
Alkaline anodizing	8–12 wt% sodium hydroxide 2–3 wt% hydrogen peroxide 0.1–0.5 wt% sodium phosphate	10–20	50–70	30–70	1–4	9.5–37	Resistant in basic solutions
Alternating current anodizing	15–30 % sulfuric acid	0–40	32–105	15–30[(a)]	3–12	28–112	Soft, flexible, sulfide included
Molten salt anodizing	66 mol% potassium bisulfate 33 mol% sodium bisulfate	180	355	>160	1	9.5	α-alumina

(a) Alternating current

Anodizing in sulfuric acid solutions containing sulfosalicylic acid leads to the formation of anodic oxide films with brown to blackish colors, the Kalcolor method. Anodizing at temperatures as low as 0 °C gives hard anodic oxide films with a hardness of 500 HV. Anodizing in alkaline solutions containing hydrogen peroxide

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

gives porous anodic oxide films with a high resistance to alkali, and anodizing with alternative current in sulfuric acid solution gives flexible anodic oxide films.

Coloring of anodic oxide films is classified into three groups: integral coloring, dyeing and electrolytic coloring. In integral coloring, many kinds of organic acids, oxalic acid, sulfosalicylic acid, sulfophthalic acid, maleic acid, succinic acid, sulfamic acid, and so forth, are mixed with sulfuric acid, and the anodic oxide films formed in the mixed solutions give brown, grayish, and blackish colors in general (Fig. 7a). The advantage of this method is to obtain anodic oxide films that are highly resistant to the deterioration of color, and integral coloring has been applied extensively in architecture, curtain walls, window frames, and roofing materials.

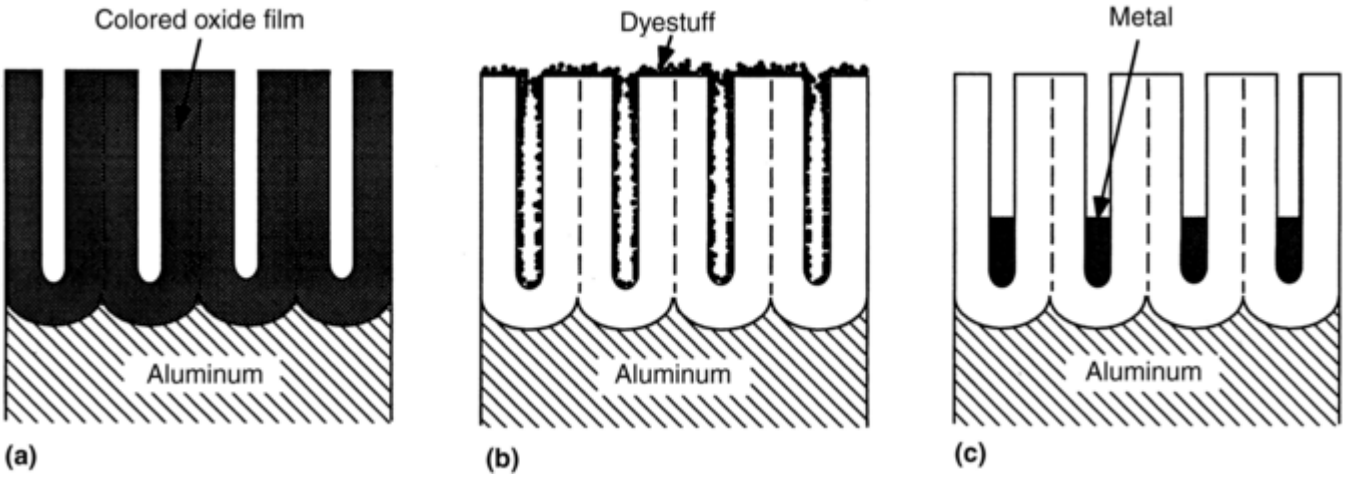

Fig. 7 Coloring of porous type anodic oxide films on aluminum by (a) integral coloring, (b) dyeing, and (c) electrolytic coloring

Porous anodic oxide films have a large internal surface and easily absorb dyestuff on the pore wall (Fig. 7b). Many organic dyestuffs, such as, Alizaline Blue, Alizaline Red-S, Naphtol Green- B, Chromolan Blue-NGG, and Anthraquinone, are used to give flashy colors: gold, yellow, blue, green, and so forth. Some inorganic dyestuffs are also used, and the process involves the precipitation of metal salts with low-solubility products, $Ag_2Cr_2O_7$, PbS, and $Co(OH)_3$ into the pores. The color range of the inorganic dyeing is more restricted than that of organic dyeing, but the inorganic dyestuff is much more resistant to heat and light.

Electrolytic coloring is generally a method where metal is deposited at the bottom of the pores by applying alternative voltage (Fig. 7c). Nickel, cobalt, tin, and copper are mainly deposited to color in bronze and maroon to black. Typical conditions of electrolytic coloring are listed Table 5. The electrolytic coloring is much more advantageous from an energy-consumption viewpoint than the integral coloring and does not require the use of special alloys. The light fastness of the finishes with electrolytic coloring is also excellent. Integral coloring is, therefore, being replaced with electrolytic coloring in architectural applications.

Table 5 Procedures of electrolytic coloring

Metal	Composition	Time, min	Voltage, V	Appearance and other characteristics
Nickel	30 g/L nickel sulfate 30 g/L boric acid 15 g/L ammonium sulfate	10	20 (ac)	Blue
	50 g/L nickel sulfate 25 g/L ammonium chloride 25 g/L boric acid	1–5	10–14 (dc)	Light brown-black
Cobalt	20 g/L cobalt sulfate 25 g/L boric acid	10	15 (ac)	Black

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

	15 g/L ammonium sulfate			
Copper	20 g/L cupric sulfate 5–6 g/L sulfuric acid	10	13 (ac)	Red
Tin	20 g/L stannous sulfate 15–20 g/L sulfuric acid 1–2 g/L phenol sulfonic acid	5–15	5–8 (ac)	Bronze-black

Sealing. Porous anodic oxide films without sealing are not protective against the corrosion of the substrate since aggressive ions easily penetrate through pores. The dyestuff also tends to move out, leading to fading. Sealing is essential as a posttreatment to ensure resistance and durability of finishes. Sealing is usually performed by dipping in boiling water. During sealing, anhydrous anodic oxide films react with hot water to convert to a crystalline hydroxide, a pseudoboehmite, as described by:

$$Al_2O_3 + xH_2O = Al_2O_3 \cdot xH_2O \qquad \text{(Eq 9)}$$

where x is 1.5 to 2. The volume expansion by the formation of pseudoboehmite causes the pores to be sealed, as shown in Fig. 8 (Ref 6). A 10 min sealing treatment is sufficient to seal the pores completely in boiling water, and afterward water penetrates across the hydroxide slowly to allow the further progress of the hydration. In addition, the outermost part of anodic oxide films becomes highly crystallized. Pressurized steam enables quick sealing, but the equipment needed is more difficult to operate.

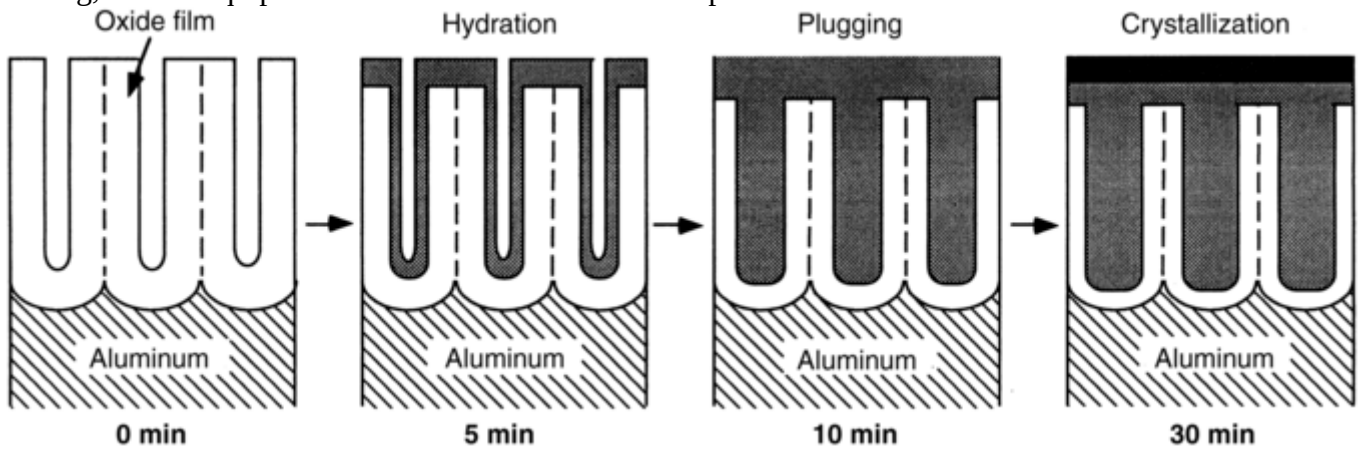

Fig. 8 Process of pore sealing with hydroxide during dipping in boiling pure water

A cold sealing, which is performed in solutions containing Ni^{2+} and F^- ions at ambient temperatures, has become popular because of low energy consumption (Ref 7). The reaction during the cold sealing is considered to be:

$$Al_2O_3 + xNi^{2+} + yF^- + 3H_2O = Al_2Ni_x F_y(OH)_z + (6 - z)OH^- \qquad \text{(Eq 10)}$$

Aluminum-nickel-fluoro-complexes are deposited in the pores to seal them.

Testing of Film Properties

The morphology of anodic oxide films can be observed by transmission electron microscopy (TEM) and scanning electron microscopy (SEM). In TEM, oxide films are removed from the metal substrate by immersing anodized specimens in a saturated $HgCl_2$ solution to examine N_p and D_p of porous anodic oxide films. Thin slices of vertical sections of oxide films are obtained by the ultra thin sectioning technique (UTST) (Ref 8) with a diamond knife ultramicrotome to examine film thickness, crystal structure, and chemical compounds deposited in the pores (Ref 8). An example obtained by TEM with UTST is given in Fig. 9, showing the vertical section of a porous type oxide film formed on aluminum. Focused ion beam (FIB) technique is also used to make slices of oxide films, and confocal scanning laser microscopy (CSLM) is useful in examining the distribution of imperfections in the anodic oxide film as well as determining film thickness (Ref 9).

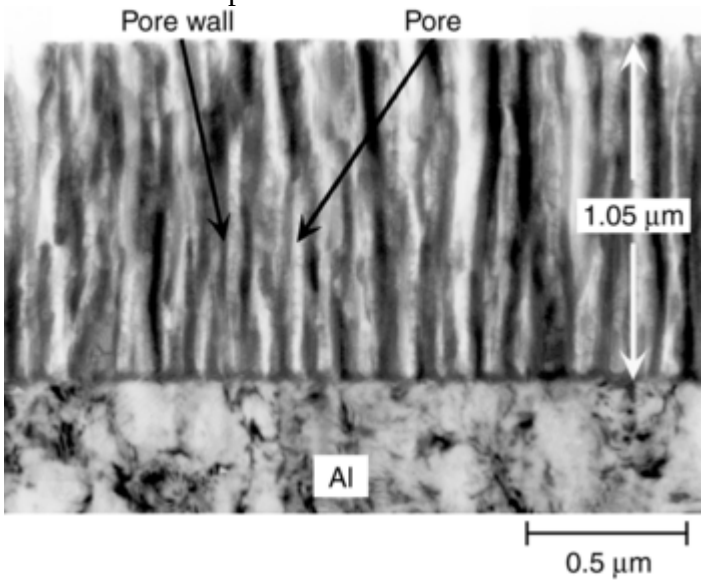

Fig. 9 TEM image of the vertical section of a porous type anodic oxide film on aluminum. The aluminum specimen was anodized for 5 min at 30 V in 0.16 *M* oxalic acid solution at 40 °C (140 °F) and then immersed for 1 h on open circuit in the same solution.

The hardness of oxide films can be found using microvickers measurements, but the hardness values can be affected by the hardness of the metal substrate, especially for thin oxide films. Nano-indentation methods have become popular in examining the hardness of anodic oxide films accurately and are useful in measuring the hardness at a local small area. Abrasion resistance measurements have been performed using conventional abrasive test instruments, jet assembly, and Taber abraser. It is difficult to compare the abrasion resistance obtained by one method with that by another method quantitatively, but a comparison of data obtained by one method for different specimens gives a significant order of abrasion resistance. Scratching by an atomic force microscope probe is also a method of examining the wear durability at the local micro area of anodic oxide films (Ref 10).

Corrosion resistance of anodized aluminum is evaluated by conventional corrosion tests, such as CASS tests, salt spray tests, and other exposure tests. Galvanic corrosion tests are important because the corrosion rate of aluminum in contact with other metallic materials can be much higher than that of aluminum alone in many atmospheres.

Surface Modification Using Energy Beams

Revised by R.D. Granata, Florida Atlantic University

Introduction

SURFACE MODIFICATION, in the context of this article, is the alteration of surface composition or structure by the use of energy or particle beams. Elements may be added to influence the surface characteristics of the substrate by the formation of alloys, metastable alloys or phases, or amorphous layers. Surface-modified layers are distinguished from conversion or coating layers by their greater similarity to metallurgical alloying versus chemically reacted, adhered, or physically bonded layers. However, surface structures are produced that differ significantly from those obtained by conventional metallurgical processes. This latter characteristic further distinguishes surface modification from other conventional processes, such as amalgamation or thermal diffusion. Two different modification methods are discussed. The first, ion implantation, is the introduction of ionized species (usually elements, for example, Ti^{+}) into the substrate using kilovolt to megavolt ion accelerating potentials. The second method, laser processing, is high-power laser melting with or without mixing of materials precoated on the substrate, followed by rapid melt quenching.
The advantages of the surface modification approach to promoting corrosion resistance include (Ref 1):

- Alteration of the surface without sacrifice of bulk properties
- Conservation of scarce, critical, or expensive alloying elements
- Production of novel surface alloys (unattainable by conventional metallurgical techniques) with superior properties
- Avoidance of coating adhesion problems

The disadvantages of the surface modification techniques include:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- Processing materials having deep or hidden contours
- Cost of processing equipment
- Substrate sensitivity to high energy input (for example, thermal instability)
- The thinness (susceptibility to damage) of the coatings

Ion implantation and laser processing are discussed separately in the following sections.

Surface Modification Using Energy Beams

Revised by R.D. Granata, Florida Atlantic University

Ion Implantation

Surface modification by ion implantation is a technique that was derived from the semiconductor industry. Specimens for corrosion research were initially prepared by using high-energy research instrumentation or commercial semiconductor implanters. Equipment for surface modification of metal parts by batch processing has been built, and production capabilities of the equipment have been evaluated for particular applications. Ion implantation is reaching a stage of development in which specific advantages are being recognized and exploited for enhancing the corrosion and wear resistance of critical metal parts (Ref 2). For wear resistance, ion implantation has been used for the hardening and friction reduction of metal surfaces (Ref 3). Related techniques are also used in conjunction with ion implantation to increase the ratio of material introduced into the substrate per unit area, to provide appropriate mixtures of materials, or to overcome other difficulties involved in surface modification by ion implantation alone. These techniques include:

- *Ion beam sputtering:* An ion beam of argon or xenon directed at a target sputters material from the target to a substrate; the sputtered material arrives at the substrate with enough energy to promote good adhesion of the coating to substrate.
- *Ion beam mixing:* Deposited layers (electroplating, sputtering) tens or hundreds of nanometers thick are mixed and bonded to the substrate by an argon or xenon ion beam.
- *Plasma ion deposition:* Ion beams are used to create coatings having special phases, especially ion-beam-formed carbon coatings in the diamond phase or ion-beam-formed boron nitride coatings.
- *Ion beam assisted deposition:* Ion beams are combined with physical vapor deposition.

Materials Processing and Product Characteristics. The ion implantation technique consists of introducing the target (substrate material) into the implanter vacuum chamber, vaporizing and ionizing the implant species, and electrostatically accelerating the ionized species into the target. Figure 1 shows schematics of research and semiconductor production ion implantation devices. A production-type implanter for materials surface modification is shown in Fig. 2.

The implant species may be most any element that can be vaporized and ionized in a vacuum chamber. The material used to generate the implant species is usually in the form of a chloride salt of a metal, a gaseous compound, or the pure element. Solid materials are heated to provide an adequate vapor pressure of the implant species. The vaporized material is ionized and accelerated toward the target. Magnetic fields separate various mass/charge ratios and enable the selection of specific implant species. A selected species impacts the target material and is implanted within, producing a surface-modified substrate. The depth to which the species is implanted depends on the accelerating voltage and the atomic numbers of the implant versus target species (Ref 4). Commonly used acceleration voltages are 20 to 200 keV. The typical average implantation depth (range) is 10 to 100 nm. The distribution of implanted species versus range is roughly Gaussian, with the surface distribution determined by relative sputtering (ion etching) ratios.

Figure 3 shows a diagram illustrating calculated concentration profiles of cobalt, aluminum, and boron implanted in iron at 50 keV to a dose of 10^{17} ion/cm^2 (6.45×10^{17} ion/in.^{2}). Implantation causes removal (sputtering) of the surface layers, but the thickness of the sputtered layer is generally less than the implantation thickness. Sputtering rates of elements differ and depend on such factors as substrate composition, chemical bonding, metallurgical structure, beam energy, and angle of the incident beam. In some cases, sputtering rate becomes equal to the implantation rate; an equilibrium is achieved (saturation), and no net addition of ions to the substrate occurs. Maximum concentrations of implanted species may be as high as 50 at.%.

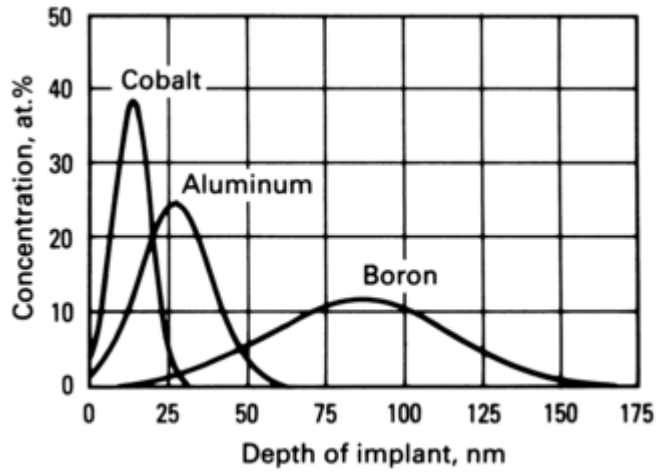

Fig. 3 Concentration profiles for cobalt, aluminum, and boron implants in iron approximated using methods described in Ref 4. Energy: 50 keV. Dose: 10^{71} ion/cm^2 (6.45×10^{71} ion/in.^{2})

The advantages of the ion implantation surface modification process include (Ref 1):

- No sacrifice of bulk properties
- Solid-solubility limit can be exceeded.
- Alloy preparation is independent of diffusion constants.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- No coating adhesion problems, because there is no interface
- No significant change in sample dimensions
- Depth concentration distribution is controllable.
- Composition can be changed without affecting grain sizes.
- Precise location of implanted area(s)
- Clean vacuum process
- Allows screening of the effects of changes in alloy composition

The implantation process can be viewed as a means of changing the material properties of an item only at the surface. An item can be fabricated from a material having desirable bulk properties (machinable, low-cost) and can be modified to provide the requisite surface properties (corrosion resistance, wearability). However, the disadvantages of the process must be kept in mind:

- The ion beam cannot process deep or hidden contours (approximately ±30° incidence).
- Processing equipment may be too costly.
- The substrate may be excessively heated by high energy input; for example, the typical energy flux of 2 W/cm^2 (13 $W/in.^2$) can heat a substrate 500 °C (930 °F).
- Inclusions in substrate material may bridge the depth of the surface-modified region, producing sites with undesirable properties.
- Treatment depth may be inadequate for some applications, resulting in galvanic effects with localized corrosion or in implant layer removal by abrasion or erosion.

Problems associated with thermal effects and sample handling have been discussed and technical solutions proposed (Ref 4, 5, 6). For example, nitrogen-implanted surfaces must be kept below 200 °C (390 °F), the temperature at which outward diffusion of nitrogen occurs. Many sample types have been implanted while keeping their surface temperatures below 100 °C (212 °F) by using heat sinks and by modifying processing conditions.

Gaseous Corrosion Properties. Gaseous corrosion or thermal oxidation, in the absence of a liquid phase, is primarily governed by the transport processes in the oxide and the ability of the oxide to resist spalling and breakdown or abrasion and erosion. The ion implantation process has provided a means for studying and modifying the surface layers active in gaseous corrosion. Interesting results have been obtained with implanted materials, as in the following five examples:

- In one study, the effects of the implanted material were found to persist to a much greater depth than the thickness of the implanted layer (Ref 7). Oxide layer growths of more than 100 times the implant depth showed the persistence of the implanted element effects. An Ni-20Cr alloy developed a complete, protective Cr_2O_3 scale more rapidly when implanted with cerium, yttrium, calcium, or aluminum, but implanted zirconium or chromium had no effect. Scale adherence was increased by ion implantation with cerium, yttrium, calcium, or zirconium. For yttrium- implanted Ni-20Cr, the weight change was approximately 25% that of unimplanted material after 24 h at 1000 °C (1830 °F) in 101 kPa (1 atm) oxygen.
- A stainless steel implanted with 10^{17} ion/cm^2 (6.45×10^{17} $ion/in.^2$) of yttrium gave no observable spalling of the oxide after more than 6500 h as compared to unimplanted material, which spalled more than 2 mg/cm^2 (Ref 8).
- Implantation of aluminum into an Fe-Cr- 1.4Al alloy increased the surface aluminum concentration to 10% and promoted the formation of a thick, protective, pure Al_2O_3 scale (Ref 9).
- High doses of silicon ion implanted into low- silicon-containing substrates did not provide the desired corrosion resistance associated with their conventional high-silicon counterpart materials. However, ion beam mixing of deposited silicon films with argon at 500 °C (930 °F) produced silicon-rich films on iron or titanium that are thicker than those obtained by ion implantation alone (Ref 10). These thick silicon layers should provide enhanced corrosion resistance. Attempts are being made to produce highly oxidation-resistant $MoSi_2$ by ion beam mixing of molybdenum and silicon layers (Ref 11).
- Zirconium was implanted with such elements as iron, cobalt, or nickel to help relieve internal stresses within the oxide film that result in the break-away oxidation associated with protective oxide fracture (Ref 12).

مرجع مهندسی مواد و متالورژی

Aqueous Corrosion Properties. There are two approaches to using ion implantation for increasing the corrosion resistance of substrates; the first is to enhance passivation characteristics, and the second is to create novel materials. In the first approach, implantation creates a surface composition based on conventional metallurgical experience that reacts to form a passive layer. In the second approach, implantation creates a surface composition and a structure that are difficult, impossible, or impractical to achieve by conventional metallurgy.

The two main problems in applying ion implantation methods for creating corrosion-resistant surfaces are producing a surface layer that has a corrosion rate low enough to prevent penetration to the base material during the designed lifetime of the item and producing a surface that is self-repairing. The first problem is approached by introducing elements that enhance corrosion resistance, as in conventional metallurgy—for example, chromium (Ref 13) or molybdenum (Ref 14) in ferrous metals. Another approach is to create combinations of elements in the surface layers that cannot be produced by conventional metallurgical methods—for example, tantalum in iron (Ref 15) or phosphorus in iron-chromium alloys (Ref 16). Tantalum forms intermetallic compounds with iron, but conventional alloys with sufficiently high tantalum content are not readily produced. Other examples are chemically resistant amorphous layers produced, for example, on iron-chromium alloys implanted with phosphorus, carbon, silicon, or boron. These materials passivate spontaneously in hot 25% hydrochloric acid (HCl) (Ref 16).

The second problem is approached by the introduction of elements that are not soluble in or removed by the environment, for example, palladium in titanium. Titanium passivation is strongly promoted by palladium and can be alloyed with it to provide lasting self-passivation properties in acidic media. However, palladium is required only at the interface as a catalyst for the hydrogen reduction reaction and is not readily soluble. Thus, it may be more cost-effective to modify the surface by implantation than to use palladium in the bulk alloy. The palladium-assisted passivation of titanium is a persistent effect with research specimens (Ref 17).

Substantial efforts have been made in the search for effective applications of ion implantation for enhancing corrosion resistance (Ref 18, 19, 20, 21, 22, 23, 24). The greatest difficulty lies in the thinness of the implanted layer; corrosion-resistant layers must not be entirely consumed or damaged. Many research efforts have attempted to mimic conventional alloy compositions. However, the corrosion rates of conventional alloy systems are usually too high relative to the thinness of the implanted layer. The most successful approaches have involved detailed knowledge of a specific material and environmental corrosion conditions or have created unconventional materials. The palladium-implanted titanium, tantalum-implanted iron, and phosphorus- or boron- implanted iron-chromium systems described previously are good examples. Another example of adapting ion implantation to a specific application is its use for interfacial reactions. Implantation of aluminum or titanium in 1010 steel significantly decreased the cathodic delamination rates of organic coatings from the implanted substrates (Ref 25).

Wear resistance enhancement by ion implantation is included in the discussion of surface- modified corrosion-resistant surfaces, because erosion, cavitation, and fretting corrosion are important forms of corrosion. Ion implantation has been shown to have a major effect on wear-resistance properties. The combined effects of ion implantation on corrosion and wear resistance are particularly well suited in applications in which bearings or sliding surfaces are subjected to intermittent use or experience long periods of storage.

Wear resistance is a property that has shown significant improvement for some substrates after surface modification by ion implantation. Activity in this area has been increasing at research laboratories, and specialized equipment has been developed for commercialization. Some of the work on the development of wear-resistant ion- implanted materials is focusing on quantification and lifetime predictions.

Adhesion and abrasion are the most specific wear mechanisms, with corrosive and surface- fracture-related mechanisms making contributions in certain cases. In adhesive wear, surfaces under sufficient local pressure deform plastically and weld at the contact points. When the surfaces separate, the contact point welds break, resulting in the formation of debris and in surface roughening. The oxidized debris causes most of the subsequent wear. Abrasive wear is simply the cutting of one surface by another edged or pointed surface. Abrasive wear decreases as the hardness of the cut surface approaches that of the cutting surface. Abrasion is dramatically lower when both material hardnesses are equal. Adhesive and abrasive wear as well as tribomechanical properties for ion-implanted materials are discussed in Ref 26 and 27, respectively.

There are many examples of ion implantation studies for increasing wear resistance of materials. Many studies have used nitrogen-implanted steel because of the readily available high-current nitrogen beams and because direct comparison to thermal nitriding processes is possible. Increases of the order of two to three times in the microhardness of steels due to nitrogen implantation have been reported (Ref 28). However, large reductions in wear rate often result from relatively small increases in microhardness. Extrusion dies for TiO_2-pigmented

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

plastics fabricated from low-carbon steel often wear rapidly, yet nitrogen implantation increases the die lifetime by up to ten times. This modification suggests that the microhardness of the steel has been raised above that of TiO_2 (Ref 26). Extended tool life has been demonstrated for plastic molding machines, with estimated ion implantation costs as low as 10% of the ordinary part costs (Ref 3). Nitrogen implantation of a titanium alloy (Ti- 6Al-4V) has been found to decrease the wear rate by more than two orders of magnitude (Ref 29). Data suggest that wear rates have been reduced by almost three orders or magnitude in a titanium alloy designed for hip joint prostheses (Ref 26).

Wear reduction can be attributed to factors other than microhardness. The residual carbon films introduced during implantation of other elements may decrease the occurrence of adhesive wear by providing lower friction coefficients. Implantation of titanium or tantalum usually results in the coimplantation or inward diffusion of carbonaceous matter present in the vacuum system. In the case of titanium-implanted steel, the wear reduction has been attributed to the formation of an amorphous iron-titanium-carbon film. Other systems are being studied—examples include tin-implanted iron, yttrium- and nitrogen-implanted chromium steels, and nitrogen implantation in cobalt-cemented carbide. It has been suggested that deep- penetrating interstitially active elements, such as nitrogen, be used to ion beam mix thin coatings of oxide-modifying materials into substrates for synergistic wear reduction (Ref 26). However, another opinion is that implanted ions do not migrate below the surface. Four mechanisms have been identified as contributing to the reduction of sliding wear of ion-implanted metals (Ref 27):

- Production of low-friction surfaces by altering surface chemistry
- Modification of microstructure to harden the surface
- Stabilization of microstructure against deleterious work-hardening effects
- Introduction of residual (compressive) stresses to combat fracture

Impact wear with and without sliding wear was also studied for various materials implanted with nitrogen (Ref 30). The materials used in the study were:

- *Soft:* aluminum alloy 2024, aluminum alloy 7075, and oxygen-free high-conductivity copper (Unified Numbering System, or UNS, C10100)
- *Medium:* cartridge brass (UNS C26000) Cu10Sn, aluminum bronze (Cu-18Al), and sintered iron (Fe-5Cu-lC)
- *Hard:* America Iron and Steel Institute (AISI) 1018 carbon steel and AISI type 304 stainless steel

Impact wear improved significantly, but the combination of impact and sliding wear showed only a very small effect. Interestingly, one of the materials, cartridge brass, showed no significant improvement.

Critical Evaluation of Product Utility. Numerous examples have been given to define application areas that may benefit from the use of implantation techniques for materials processing. The advantages and disadvantages relate to the small dimension of implantation depth (nanometers). Significant niches are being created for materials processed by ion implantation and related techniques. These surface modification techniques for industrial applications are perhaps best appraised by considering the information presented in Table 1.

Table 1 Successful applications of ion implantation for industrial exploitation

Application	Material	Typical results
Orthopedic implants (artificial hip and knee joints)	Ti-6Al-4V	Significant (400 times) lifetime increase in laboratory tests
Bearings (precision bearings for aircraft)	M50 tool steel, 440C stainless steel, or 52100 bearing steel	Improved protection against corrosion, sliding wear, and rolling-contact fatigue
Extrusion tools (spinnerettes, nozzles, and dies)	Various alloys	Four to six times normal performance
Punching and stamping tools (pellet punches for nuclear fuel, scoring dies for cans)	D2 tool steel	Three to five times normal life and better end products

Other examples of possible interest include the following. Implantation of nitrogen into as- cast Ti-6Al-7Nb alloy was characterized for in vitro behavior using electrochemical methods and grazing incidence x-ray diffraction (XRD). Results showed favorable repassivation kinetics (Ref 31). Shape memory alloy, NiTi, was implanted with nitrogen and boron to enhance the surface properties, corrosion, wear, and fatigue resistance for dental applications (Ref 32). The corrosion resistance of cobalt-chromium alloy in contact with ultrahigh-molecular-weight polyethylene for hip joint replacements was improved using plasma-based ion implantation of nitrogen (Ref 33). The corrosion resistance of uranium in air has been improved by implantation of nitrogen and carbon (Ref 34). The corrosion resistance of uranium and uranium-niobium alloy has been improved by implantation of niobium (Ref 35). Nitrogen plasma source ion implantation improved the corrosion resistance of bearing steel (52100) (Ref 36). The corrosion resistance of 430 stainless steel was improved by combined vapor deposition and ion implantation of silicon and titanium dioxide (Ref 37). Ion implantation and ion beam assisted deposition are considered for improvement of aluminum corrosion (Ref 38).

Surface Modification Using Energy Beams

Revised by R.D. Granata, Florida Atlantic University

Laser Surface Processing

Lasers with continuous outputs of 0.5 to 10 kW can be used to modify the metallurgical structure of a surface and to tailor the surface properties without adversely affecting the bulk properties. The surface modification can take the following three forms. The first is transformation hardening, in which a surface is heated so that thermal diffusion and solid-state transformations can take place (Ref 39, 40, 41). The second is surface melting, which results in a refinement of the structure due to the rapid quenching from the melt (Ref 40, 41, 42, 43, 44, 45). The third is surface alloying, in which alloying elements are added to the melt pool to change the composition of the surface (Ref 46, 47, 48, 49, 50, 51, 52). The novel structures produced by laser surface melting and alloying can exhibit improved electrochemical behavior.

Materials Processing

The processing parameters necessary for laser surface processing depend on the type of modification to be done (for example, transformation hardening or surface alloying) and the properties of the material that are being treated (for example, thermal diffusivity, heat capacity, and transformation temperatures). Figure 4 shows typical ranges of conditions for various processes. The laser power, power density, and interaction time are the primary variables. Other variables, such as the composition of the atmosphere during treatment or the rate of material addition, are determined by the details of the processing—for example, the necessity of shielding against oxidation and the desired thickness, composition, and structure of the surface layer.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

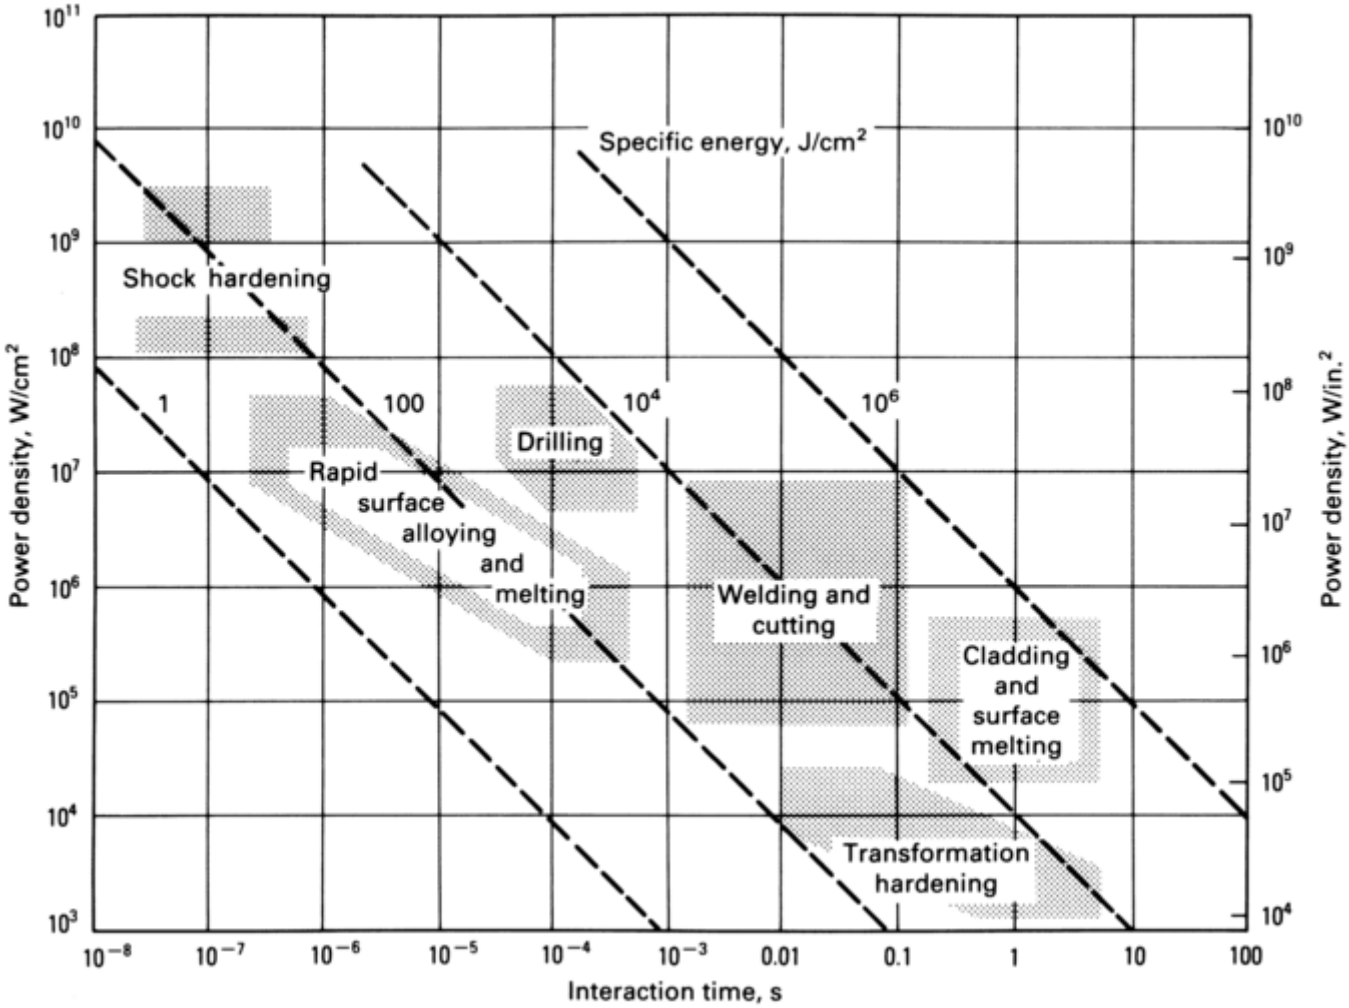

Fig. 4 Interaction times and power densities necessary for various laser surface modification processes

The laser-beam-modified layer can range in thickness from 0.01 to 5 mm (0.4 to 200 mils), depending on the processing variables, although thicknesses of 0.05 to 1 mm (2 to 40 mils) are more common. The longer the interaction time of the laser beam with the material, the deeper the processed layer will be. Of the processes shown in Fig. 4, the areas labeled “Cladding and surface melting” and “Transformation hardening” delineate process parameters that typically affect the material to depths from 0.5 to 5 mm (20 to 200 mils) and result in metallurgical structures similar to welded structures. The parameters designated “Rapid surface alloying and melting” affect a surface layer only 0.02 to 0.6 mm (0.8 to 24 mils) thick but result in quench rates to 10^7 K/s and therefore allow for the production of novel metallurgical structures and alloys.

The procedure for laser beam surface modification is shown in Fig. 5. A high-power laser beam is brought to a focus near the surface of the workpiece. After a melt pool is established, the laser beam can be rastered across the surface, melting a strip of material with each sweep, until the entire surface has been processed. The processing is performed in an inert gas atmosphere or vacuum to protect the metal from oxidation. In practice, it is more convenient to move the workpiece rather than the laser beam.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

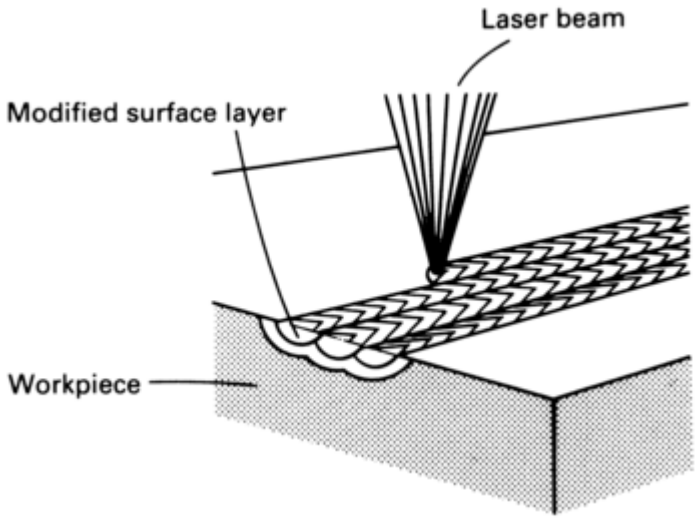

Fig. 5 Schematic of the procedure for the laser processing of metals

Figure 6 shows a schematic of an apparatus for processing laboratory specimens. The specimen is passed through the laser beam by the rotation of the turntable, and the entire apparatus is translated a fraction of a melt width between passes to process a larger area. The process is varied by changing the power level of the laser beam, the power density (or spot diameter), or the sweep speed. The effects of these variables on the depth of melting for three materials are shown in Fig. 7. As can be seen, the melt depth can be varied by an order of magnitude simply by changing the sweep speed. The width of the melt pass is determined primarily by the diameter of the laser spot and the thermal properties of the material and is very slightly dependent on the sweep speed. The rate at which a surface can be processed is typically approximately 1 cm^2/s (0.16 $in.^2/s$) for a variety of conditions and materials.

Product Characteristics

Solidification Effects. The heat flow characteristics of such processing can reasonably be described by one-dimensional heat flow in which the rate at which energy enters the surface is balanced by the rate at which heat is conducted away by the cool substrate (Ref 53). A number of studies have been devoted to characterizing the temperature profiles that result from the laser and electron beam processing of materials (Ref 39, 41, 54). The character of the temperature profiles experienced by material at various depths below the surface of the metal is shown in Fig. 8. The three reference temperatures indicated represent liquidus (T_L), solidus (T_S), and solid- state transformation (T_R) temperatures. As the laser beam sweeps across the surface of a metal sample, the surface begins to heat. When the melting temperature of the material is exceeded, a melt front is established and moves from the free surface of the sample toward the bulk. Shortly after the beam is turned off (or has moved away), the melt front slows and then stops. It then moves back toward the free surface as a solidification front. The unique characteristics of this solidification front are the high cooling rates (such as 10^7 K/s) and the steep temperature gradient (such as 10^5 K/cm). These characteristics promote the formation of metastable compositions and structures.

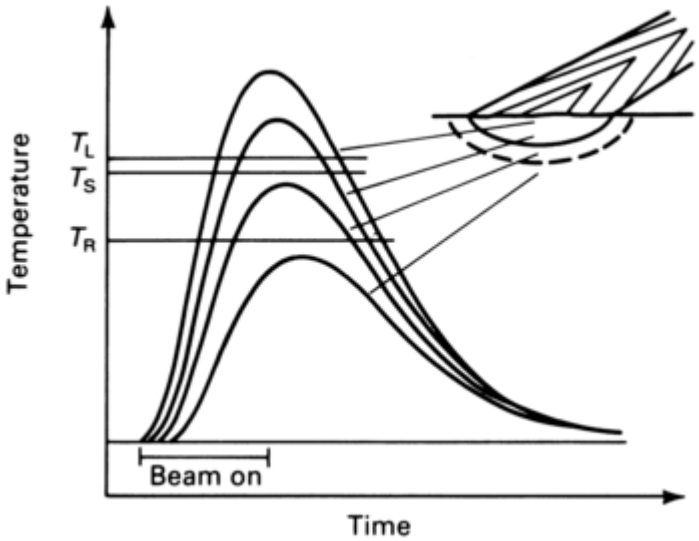

Fig. 8 View of laser-melted surface and temperature profiles experienced at different points on the surface during laser melting. Liquidus (T_L), solidus (T_S), and solid-state transformation (T_R) temperatures are indicated.

Because of this steep temperature gradient, there is only a thin layer of metal that is cool enough to solidify. The material above this layer is above the liquidus temperature, and the material below this layer has already solidified. There is a strong epitaxial character to the resolidification as a result of the steep temperature gradients (Ref 55, 56). This is illustrated in Fig. 9. The two effects that compete during the solidification are the regrowth of grains from the substrate and the heterogeneous nucleation and growth of new grains in this thin layer of chilled metal. For most alloys, grains from the substrate will grow into the chilled zone, and any grains that may have nucleated within the melt pool will either redissolve or be transported by the melt front to the free surface. As an example of this, Fig. 10 shows a β-titanium alloy that has been laser processed.

The epitaxial solidification can have a striking effect on the grain size of the surface layer and on the crystallographic texture. Because some crystal planes grow faster than others—for example, (100) for cubic crystals and (1010) for hexagonal close-packed crystals—those substrate grains having a large component of these orientations in the direction of the temperature gradient will grow at the expense of less favorably oriented grains. As these grains grow, they will tend to squeeze out less favorably oriented grains. This affects the crystallographic texture in two ways. First, there is a higher probability for grains at the free surface to be oriented with the fast-growing direction normal to the free surface, and second, low-angle grain boundaries will occur with a higher frequency than in the substrate. As shown in Fig. 11, when the grain size of the metal before processing is small compared to the depth of melting, there is a coarsening of the grain size, and the texture effects are more pronounced. Examples of these effects are shown in Fig. 9 for a large-grain material and in Fig. 12 for a fine-grain material.

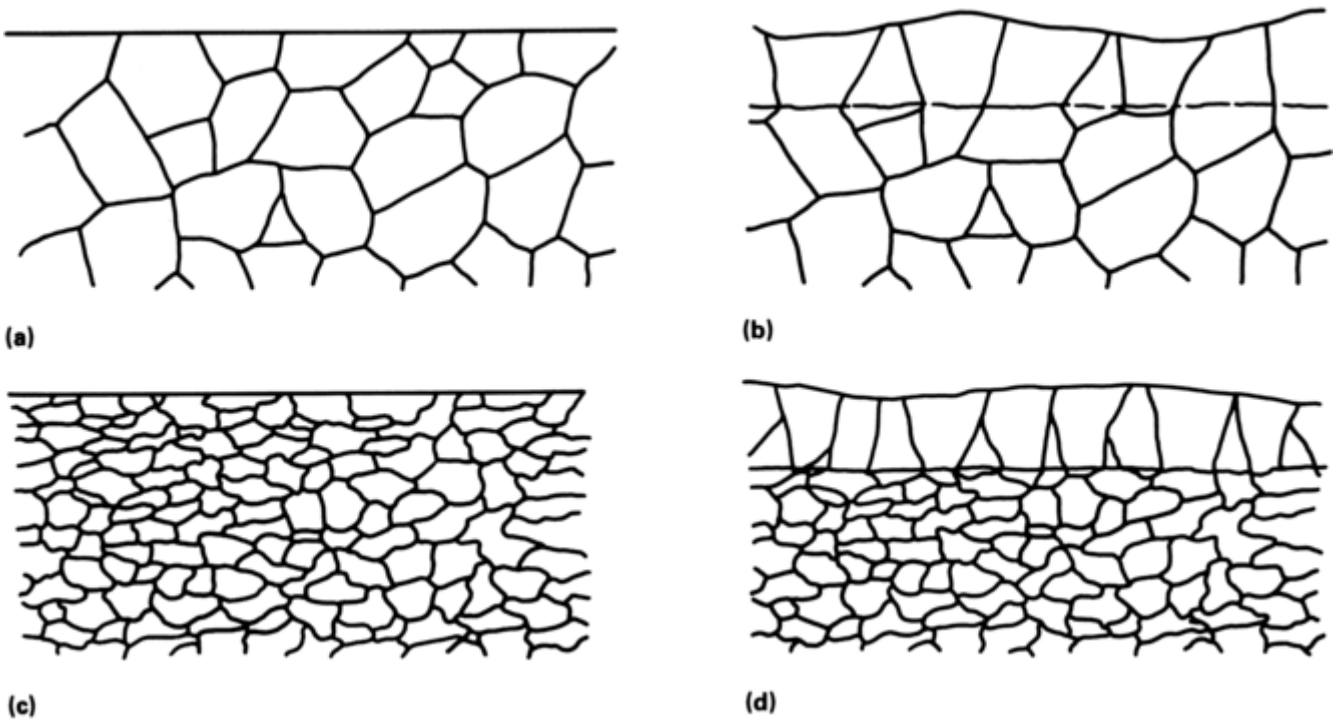

Fig. 11 Effect of epitaxial resolidification on grain size for a material with large original grain size (a and b) and a material with small original grain size (c and d) compared to the melt depth. (a) and (c) Before processing. (b) and (d) After processing

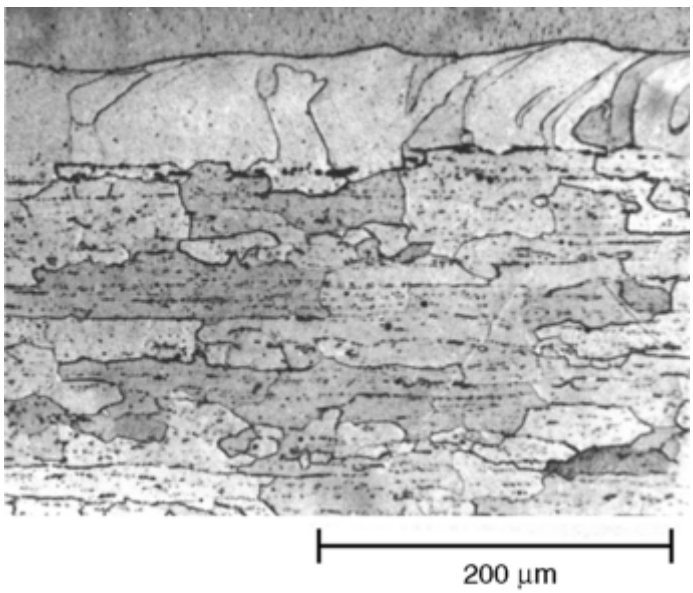

Fig. 12 Coarsening of grain size in a ferritic stainless steel by laser melting

During the solidification process, there is generally a redistribution of solute atoms away from the solidification front, so that the interface can remain as close to equilibrium as possible (Ref 57). After an initial transient, this partitioning results in the geometrical destabilization of the solidification front, and dendritic solidification results. For a single-crystal alloy that undergoes rapid surface melting, the dendritic character of the resulting melt is shown in Fig. 13. This effect was documented by the laser melting of single crystals of a nickel-base superalloy (Ref 55). The high-temperature gradient affects the character of the dendritic growth in two ways. First, it restrains crystal growth to the directions of the fast-growing crystal planes, as described previously, and second, it minimizes the amount of segregation because of the short times allowed for lateral diffusion. An example of the dendritic character of laser-processed material is shown in Fig. 14. The diameter of the dendrites can be used to estimate the cooling rates experienced by the material as it resolidified. Higher cooling rates result in less lateral diffusion and smaller dendrites, while lower cooling rates result in more lateral diffusion and larger-diameter dendrites.

To the extent that equilibrium cannot be maintained at the solidification front by partitioning, as described in the previous paragraph, more than the equilibrium amount of solute atoms will be incorporated into the solidification structure. An increase in the cooling or solidification rates results in still greater deviations from the equilibrium concentrations (Ref 58, 59). In systems that exhibit solubility at all compositions, for example, the aluminum-manganese system, the solubility limits can be extended. Deviations from equilibrium can also result in the formation of metastable crystal structures when the system has several phases with comparable free energies of formation (Ref 60, 61). Amorphous or glassy surface layers can be produced by laser processing only when the system has several energetically and structurally similar crystalline phases; thus, atoms attaching to the solidification front will have a variety of closely spaced lattice sites with similar energies to choose from. This confuses the long-range order and destroys the crystalline character of the solid.

Changing the Chemical Composition. In addition to the structural modifications described in the previous section, the composition of the surface layer can also be changed to form surface alloys whose compositions can be tailored to suit surface requirements. Changes in composition have been accomplished with several techniques (Ref 39, 47, 49, 50, 62). For example, the specimen can be coated before laser processing with a thin layer of the desired alloying element or elements. Such coatings have been applied by vacuum deposition, electroplating, spraying, or the use of a slurry. The alloying elements can also be introduced directly into the melt pool during processing in the form of wire or as an injected powder. When the composition is changed,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

care must be taken to ensure that the alloying elements are distributed uniformly in the surface layer. Three mechanisms have been identified for facilitating the mixing of components: liquid-state diffusion, convection currents within the melt pool, and agitation of the melt pool by a laser-sustained plasma (Ref 50). A uniform composition can generally be obtained by processing two or more times, as shown in Fig. 15. The first set of passes disperses the alloying elements to the desired depth and determines the overall composition of the surface alloy. Subsequent passes (using processing conditions selected to obtain slightly shallower melt depths) further homogenize the surface.

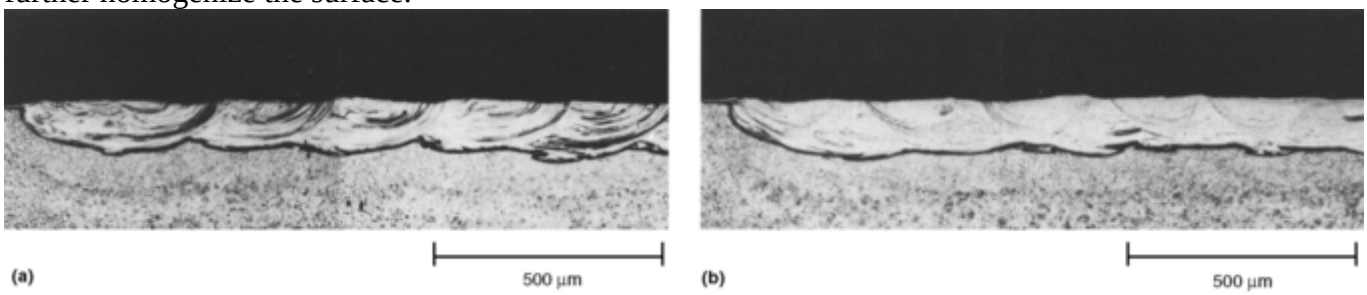

Fig. 15 Laser surface alloying of molybdenum into Ti-6Al-4V showing the effectiveness of multiple passes in homogenizing the chemical composition. (a) Single pass. (b) Double pass

Effects of Microstructure on Properties. The microstructural changes that result from laser processing can take several forms: a redistribution of major alloy components, a redistribution of any second phases or precipitates, a change in the crystalline character of the surface, or a change in the composition. The melting process results in a leveling of any large-scale composition variations, but the solidification transients can also result in a surface that is enriched in one or more of the alloy components. The high cooling rates during solidification and the accompanying extension of solid-solubility limits often result in either the elimination of second phases or a fine distribution of second phases or precipitates. Alloying may be necessary to take advantage of the higher solubility limits. The steep temperature gradients present during processing generally result in epitaxial resolidification, which introduces some crystallographic texture of the surface grains and grain boundaries (Ref 63). The modification of composition holds the most promise for improving electrochemical behavior, because the surface chemistry can be adjusted so that a solidification structure is obtained on quenching that exhibits more corrosion resistance than the base alloy (Ref 64).

Corrosion Properties

The corrosion resistance of laser-processed materials has been studied by several research groups. For example, laser beam processing was used in one study to melt and rapidly solidify type 304 stainless steel (UNS S30400) and ferritic Fe-13Cr-*x*Mo (x = 0, 2, 3.5, or 5) stainless steels (Ref 65). The critical current density for the passivation of laser-processed type 304 stainless steel in 1 *N* sulfuric acid (H_2SO_4) decreased two orders of magnitude compared to unprocessed material. The width of the active peaks decreased for ferritic stainless steels versus unprocessed material. Pitting potentials increased by approximately 150 mV for type 304 stainless steel and 5% Mo ferritic stainless steel. Ferritic steels with 0, 2, or 3.5% Mo showed decreases in the pitting potentials.

In another case, the corrosion behavior of iron-aluminum bronzes was studied electrochemically in 5% H_2SO_4 (Ref 66). Substantial beneficial effects were observed and attributed to homogenization of the complex microstructure.

Lastly, laser surface alloying was performed to incorporate chromium in Society of Automotive Engineers (SAE) 1018 steel (UNS G10180) and molybdenum in type 304 stainless steel (Ref 67). The SAE 1018-Cr materials passivated similarly to corresponding bulk alloys (5 to 80% Cr). The 304-3Mo material was similar in pitting resistance to type 316 stainless steel (UNS S31600). The 304-9Mo material was superior to type 316 stainless steel and showed no pitting up to oxygen evolution potentials. Table 2 shows some of the results for the 304-Mo materials. Plasma-sprayed titanium coatings on steel were consolidated by laser processing to remove residual porosity, which is the major obstacle to enhanced corrosion resistance (Ref 68).

Table 2 Effect of laser surface alloying with molybdenum on pitting potentials of austenitic stainless steels in 0.1 *M* NaCl

Critical Evaluation of Product Utility

Laser processing provides unique opportunities for producing corrosion-resistant surface layers. High-performance surface layers can be designed while conserving scarce, expensive, or critical materials. However, the major limitations associated with laser processing are the compatibility of substrates with thermal conduction requirements and the current restriction to planar substrates.
Other examples include:

- The intergranular corrosion resistance of Al 6013-T651 was improved by excimer laser surface treatment in nitrogen atmosphere, resulting in formation of AlN (Ref 69).
- The pitting corrosion resistance of Ti-6Al-4V alloy (UNS R56400/R56401) was improved by excimer laser surface treatment in argon atmosphere and, to a lesser extent, in nitrogen atmosphere (Ref 70).
- The cavitation erosion resistance of brass was improved by laser surface modification using an alloying powder of NiCrSiB (Ref 71).
- Laser hardfacing of mild steel AISI 1050 was achieved by flame spraying NiCoCrB powder, followed by laser treatment. Cavitation erosion resistance was increased by factors of 4 and 8 in distilled water and 3.5% NaCl, respectively (Ref 72).

Porcelain Enamels, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 750–754

Porcelain Enamels

Introduction

PORCELAIN ENAMELS are glass coatings applied primarily to products or parts made of sheet steel, cast iron, or aluminum to improve appearance and to protect the metal surface. Porcelain enamels are distinguished from other ceramic coatings on metallic substrates by their predominantly vitreous nature and the types of applications for which they are used. These coatings are differentiated from paint by their inorganic composition and coating properties. They are fused to the metallic substrate at temperatures above 425 °C (800 °F) during the firing process.

The most common applications for porcelain enamels are major appliances, water-heater tanks, sanitary ware, and cookware. In addition, porcelain enamels are used in a wide variety of coating applications, including chemical-processing vessels, agricultural storage tanks, piping, pump components, and barbecue grills. They also are used for coatings on architectural panels, signage, specially executed murals, and substrates for microcircuitry. Porcelain enamels are selected for products or components where there is a need for one or more special service requirements that they can provide. These include chemical resistance, corrosion protection, weather resistance, abrasion resistance, specific mechanical or electrical properties, appearance or color needs, cleanability, heat resistance, or thermal-shock capability.

Porcelain Enamels, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 750–754

Porcelain Enamels

Types of Porcelain Enamels

Porcelain enamels for sheet steel and cast iron are classified as either ground-coat or cover-coat enamels. Ground-coat enamels contain metallic oxides, such as cobalt oxide and/or nickel oxide, that promote adherence of the glass/enamel to the metal substrate. Cover-coat enamels are applied over fired ground coats to improve the appearance and properties of the coating. Also, cover-coat enamels may be applied over unfired ground coats, with both coats being fired at the same time (i.e., two-coat/one-fire systems). Cover coats may also be applied directly to properly prepared decarburized steel substrates. The color of ground coats is limited to various shades of blue, black, brown, and gray. Cover coats— which may be clear, semiopaque, or opaque— may be pigmented to take on a great variety of colors. Colors may also be smelted into the basic coating material. Opaque cover coats are usually white.

Porcelain enamels for aluminum are normally one-coat systems. They are applied only by spraying. When two coats are desired, the first coat can be any color. Frits for porcelain enamels for aluminum are usually transparent and may be colored and opacified with inorganic pigments to produce the desired appearance.

Porcelain Enamels, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 750–754

Frits for Porcelain Enameling

The basic material of the porcelain-enamel coating is called frit. Frits are smelted complex borosilicate glasses that are produced by quenching a molten glassy mixture. Frits generally consist of from 5 to 20 components, which are thoroughly mixed together and melted into a glassy system. The molten glass is then quenched to a friable (easily broken up) condition by being either poured into water or rolled into a thin sheet between water-cooled rolls. When quenched in water, the frit is dried before use. The sheet is ordinarily shattered into small flakes by mechanical means before use or shipment. Because porcelain enamels are usually designed for specific applications, the compositions of the frits from which they are made vary widely. A number of compositions of frits for enamels for sheet steel, cast iron, and aluminum are discussed in the paragraphs that follow; however, many variations of these compositions are used commercially.

Enamel Frits for Sheet Steel. The frit compositions given in Table 1 are classified as alkali borosilicates and are used as ground coats on sheet steel. One of the functions of ground-coat enamels is to promote bond to the steel substrate. The addition of cobalt oxide and/or nickel oxide promotes adherence to the substrate. Compositions differ, depending on the end-use application of the enameled product. For example, acid resistance is obtained by the addition of titanium dioxide and high levels of silicon dioxide with a corresponding decrease in the boron level. Resistance of the enamel to alkalis or to water can be improved by adding zirconium oxide or aluminum oxide (usually as zircon or alumina) to the frit while maintaining a high content of silicon dioxide. It is common practice to blend soft (low-melting temperature), medium, and hard (high melting temperature) frits to obtain the maximum desired properties.

Table 1 Melted-oxide compositions of frits for ground-coat enamels for sheet steel

BaO	9.24	8.59	…	…

Weather resistance has been shown to be a function of acid resistance. Porcelain enamels for use outdoors are made from various types of frits that produce the necessary acid resistance along with the specific color desired. Resistance to thermal shock and to high temperature is obtained by controlling the coefficient of thermal

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

expansion of the glass coating; this is accomplished by adjusting the frit composition and adding refractory materials, such as silicon dioxide, aluminum dioxide, and zirconium oxide, to the mill formula.

Cover coats for sheet steel are applied over ground coats or directly to properly prepared decarburized steel. Compositions of frits for cover- coat enamels are shown in Table 2. Electrostatic dry powder cover coats may be applied over an electrostatic dry powder base coat; then the entire two-coat/one-fire system is matured in a single firing. Electrostatic dry powder cover coats may also be applied over fired ground coats in a two-coat/two-fire process.

Table 2 Melted-oxide compositions of frits for cover-coat enamels for sheet steel

F_2	2.21	3.27	2.91

Cover-coat enamels fall into three groups: clear, semiclear or semiopaque, and opaque. The clear frits do not contain high levels of titanium dioxide, and they remain clear when fired. The semiopaque frits are translucent and are used for light colors. The opaque frits, which contain high levels of titanium dioxide, become white upon firing.

Cover-coat enamels made from titanium-dioxide-opacified frits are generally quite acid resistant; even in amounts too small to provide any opacity, titania imparts acid resistance. For alkali resistance, zirconium oxide is a desirable constituent. Clear frits containing 8 to 11% TiO_2 are used for strong to medium-strength colors. Semiopaque frits containing 12 to 15% TiO_2 are used for medium-strength colors, and opaque frits containing 17 to 20% TiO_2 are used for pastel colors.

Enamel Frits for Cast Iron. Compositions of frits for enamels for cast iron vary, depending on whether the frit is applied by the dry process or by the wet process (Table 3). Dry-process enamels are commonly used for large cast-iron plumbing fixtures, such as bathtubs and sinks, where the brilliance of the enamel and its ability to cover small surface irregularities in the casting itself are useful characteristics. Acid resistance is imparted to these enamels by reducing the alumina content, increasing silica, and adding up to about 8% TiO_2. Ground coats are normally used to fill surface voids in castings. Ground coats for wet-process enamels often are mixtures of frit, enamel reclaim, and refractory raw material used at very low application weight. Ground coats for the dry-process method are applied and fused to thin, viscous coatings that protect the casting surface from excessive oxidation while it is heated to enameling temperature.

Enamel frits for aluminum are usually based on lead silicate or on cadmium silicate, but they may also be based on phosphate, vanadium, or barium. Table 4 gives the compositions of some frits for aluminum. Enamels for aluminum have a high gloss, good acid and weather resistance, and good mechanical properties. They melt at relatively low temperatures.

Porcelain Enamels, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 750–754

Properties of Porcelain Enamels

Porcelain enamels possess an array of properties that can be specially designed and formulated for a variety of demanding environments. Some of the special properties are summarized in the paragraphs that follow. The Porcelain Enamel Institute bulletins in the Selected References have more detailed information.

Appearance for Indoor Exposure. Where corrosive attack is unlikely and appearance is the principal requirement, enamel selection and processing are directed toward providing reproducible color matching and optimal gloss and smoothness. Often, different enamels are used on different parts of the same product to ensure the best balance of properties and cost, particularly if high volume is involved. For example, somewhat different enamel compositions are used for range tops and dishwasher liners because of differing property and appearance requirements, even though these parts may be processed in the same plant. Appearance standards, in particular, are established to respond to end-use requirements. Small surface defects may be tolerated in areas not heavily used or readily seen in the finished part, provided that they do not affect basic serviceability.

Thermal shock intensifies the effect of elevated temperature, as does operation under severe temperature gradients. Enamels are formulated so that expansion characteristics place the enamel in compression under

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

service conditions. If combinations of mechanical stress and elevated temperatures place the enamel in tension, crazing forms a pattern of fine cracks perpendicular to the tensile stress. The resistance of an enamel to thermal shock varies inversely with its thickness. Thermal-shock failure occurs when the temperature gradient perpendicular to the surface is large enough to cause excessive differential shrinkage and tensile stress. Thermal- shock resistance also depends on the design and section thickness of the coated part. Flexing of the metal due to localized thermal gradients parallel to the surface can produce bending and tensile stresses in the coating; therefore, an increase in the strength or rigidity of the part increases the resistance of the coating to thermal shock. Most porcelain enamels applied at conventional thickness can withstand abrupt temperature changes of 110 to 165 °C (200 to 300 °F).

Abrasion Resistance. The hardness of porcelain enamels ranges from 3.5 to 6.0 on the Mohs scale. Porcelain enamels show a high degree of abrasion resistance. Under abrasive test conditions where plate glass retains 50% specular gloss, porcelain-enamel compositions retain from 35 to 85% specular gloss. Subsurface abrasion resistance varies with processing variables that affect the bubble structure of the enamel, that is, gas bubbles frozen in during cooling of the enamel. A decrease in abrasion resistance occurs with an increase in the number or size of gas bubbles. Enamel compositions are available that contain crystalline particles (from mill additions or devitrification heat treatment) that increase abrasion resistance as much as 50%.

Porcelain Enamels, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 750–754

Corrosion Resistance of Porcelain Enamels

Porcelain enamels possess excellent resistance to corrosion in a variety of environments.

Chemical Resistance. Porcelain enamel is widely used because of its resistance to household chemicals and foods. Mild alkaline or acid environments are generally involved in household applications. Table 5 presents examples of corrosive environments for which porcelain enamels are widely used for long periods of service. Special enamel compositions are available to resist most acids, except for hydrofluoric or concentrated phosphorics, to 230 °C (450 °F). These compositions also resist alkali concentration to pH 12 at temperatures to 100 °C (212 °F).

Table 5 Applications in which porcelain enamels are used for resistance to corrosive environments

Application	Corrosive environment			
	Temperature		**pH**	**Corrosive medium**
	°C	**°F**		
Bathtubs	To 49	To 120	5–9	Water, cleansers
Chemical ware	To 100	To 212	12	Alkaline solutions
	To 100	To 212	1–2	All acids except hydrofluoric
	175–230	350–450	1–2	Concentrated sulfuric acid, nitric acid, and hydrochloric acid
Home laundry equipment	To 71	To 160	11	Water, detergents, bleach
Range exteriors	21–66	70–150	2–10	Food acids, cleaners
Range oven liners, conventional	66–315	150–600	2–10	Food acids, cleaners
Range burner grates	66–590	150–1100	2–10	Food acids, cleaners
Refrigerators	-18 to 66	0–150	2–10	Food acids, cleaners

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Kitchen sinks	To 71	To 160	2–10	Food acids, water, cleaners
Water heaters	To 71	To 160	5–8	Water
Industrial heat exchangers				Depends on application[(a)]

(a) Applications include coal- and oil-fired boilers and black liquor evaporators; corrosive media would include ash from coal-fired boilers, corrosive condensates, and exhaust from black liquor evaporators.

Weather Resistance. Indicators of the weather resistance of porcelain enamels are chemical durability, color stability, cleanability, and continuity of coating. Gloss and enamel texture do not necessarily affect weather resistance, but retention of gloss can be a criterion. Porcelain enamels have excellent resistance in atmospheric exposure, including corrosive industrial atmospheres, gases, smoke, salt spray, and seacoast exposures. Enamels formulated for acid resistance usually have better atmospheric-corrosion resistance than other types. These enamels have shown no appreciable change in appearance after 15 years of exposure.

Waters. All porcelain enamels are completely resistant to water at room temperature. Resistance decreases at higher temperatures. Special porcelain enamels have been developed for hot- water storage tanks that can withstand continuous exposure to hot water for periods of 10 to 20 years. Natural waters, because of their varying compositions, have varying effects on porcelain enamels. Aerated water with a low dissolved solids content, for example, has been found to be more corrosive than hard water. Freezing and thawing cycles can cause some porcelain enamels to spall or disintegrate; however, properly formulated and applied enamels can withstand thousands of freezing and thawing cycles without failure. Porcelain enamels can withstand salt-spray tests (ASTM B 117) for days and even weeks without evidence of corrosion (Ref 1), and they can provide excellent service in intermittent or continuous exposure to seawater.

Soils. Porcelain enamels formulated to withstand both acid and alkaline attack provide good service in soils.

Acids. Resistance to acids varies widely, depending on composition and the application process used. The degree of attack by acids appears to depend less on the type of acid (with the exception of hydrofluoric) than on pH. Special formulations can provide excellent protection against aqueous solutions of most acids except hydrofluoric. The highest degree of acid resistance is obtained by sacrificing resistance to other media, such as alkalies. Figure 1 shows weight loss of a porcelain enamel in boiling mineral acids and in boiling water.

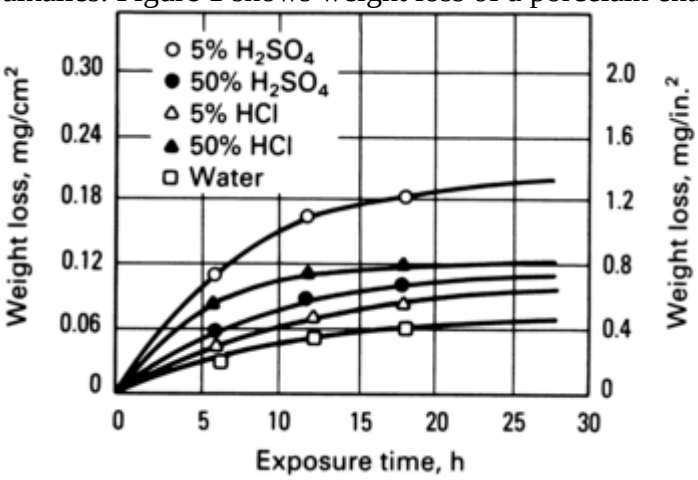

Fig. 1 Corrosion of a porcelain enamel in boiling water and boiling mineral acids. Source: Ref 2

Alkalies. Most porcelain enamels are unaffected by alkalies at room temperature. Special formulations provide alkali resistance to solutions with a maximum pH of 12 at temperatures to 100 °C (212 °F).

Organics. Porcelain enamels are completely resistant to attack by common organic solvents, dyes, greases, and oils. Enamels are not dissolved by these materials and do not absorb them. Acid-resistant porcelain enamels are required for organic material that hydrolyzes upon contact with moisture to form acid solutions.

High Temperatures. Porcelain enamels greatly reduce high-temperature oxidation of the base metal. This ability is largely due to the fact that the enamels themselves are fully oxidized and do not suffer further oxidation at elevated temperatures. They also form an effective barrier to the diffusion of oxygen into the metal. Protection depends on the temperature at which the enamel begins to soften and become more fluid. This temperature is normally about 220 °C (400 °F) below the firing temperature, but specially formulated enamels can provide oxidation protection to metals at temperatures to 1095 °C (2000 °F). Maximum service temperatures for porcelain enamels are shown in Table 6. Softening of the glassy matrix limits use to these exposure

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

temperatures. Softening releases gases remaining from reactions between the enamel and the metal substrate, producing random defects known as reboil.

Table 6 Maximum service temperatures for porcelain enamels

Service temperature		Limiting conditions
°C	**°F**	
425	800	Usual limit for enamels maturing at about 815 °C (1500 °F)
540	1000	Maximum for enamels maturing at about 815 °C (1500 °F), without reboil
760	1400	Operating limit for special high-temperature enamels
1095	2000	Refractory enamels useful for short periods for protection of stainless steels and special alloys

Evaluation of Porcelain-Enameled Surfaces

Specifications and quality control for porcelain-enamel coatings require the evaluation of a range of properties for the intended service of the porcelain-enameled product. Although material and process variables can be brought into approximate control using small test panels, process control is maintained by the evaluation of finished parts, even though some of the mechanical and chemical tests are destructive. Standard test procedures are available for many porcelain- enamel properties. Specific test methods for various properties are listed in Table 7. Some of these tests are discussed in the paragraphs that follow.

(a) This test, while withdrawn from the latest ASTM list because of inability to obtain the required equipment, continues to be used by laboratories that possess the equipment.

Adherence refers to the degree of attachment of enamel to the metal substrate. A number of tests regularly used in the industry provide adherence criteria, but none gives the force per unit area required to detach the enamel by tensile force normal to the interface. ASTM C 313 for porcelain enamel on steel deforms the metal and measures the area from which the porcelain enamel is removed. The indicator of adherence is the adherence index, which is the ratio of the porcelain enamel remaining in the deformed area to that in the same measured area prior to deformation. Enamels for cast iron pose a special problem because of the relatively greater thickness of the coating, the rigidity of the metal substrate, and the brittleness of the iron. Here, simple nonstandard impact tests are used. Resistance to spalling, a defect characterized by separation of porcelain enamel from the base metal without apparent external cause, is the indicator used to measure adherence of porcelain enamel on aluminum. Spalling can result from the use of improper alloys, improper enamel formulations, incorrect pretreatment of the base metal, faulty application, or unsatisfactory firing procedures. The most common test for spall resistance is ASTM C 703.

Thickness. A number of specifications for products and applications require a specific thickness for porcelain-enamel coating. The procedure used to measure the thickness depends on the type of base metal used. For porcelain-enamel products with a steel substrate, enamel thickness is measured according to ASTM D 1186. For porcelain-enamel products with an aluminum substrate, enamel thickness is measured according to ASTM E 376. (Neither of these tests is listed in Table 7 because they are not under the jurisdiction of ASTM Porcelain Enamel Subcommittee B.08.12.) In some cases, such as laboratory investigations, enamel thickness is measured according to ASTM C 664.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Resistance to Chipping. Relatively thick layers of porcelain enamel are fractured when subjected to severe bending or other substrate deformation. However, thin coatings of 125 μm (5 mils) or less that are well bonded to a relatively thin metal substrate (for example, 26-gage 0.4546 mm, or 0.0179 in., or less) can withstand the bending of the substrate to radii of curvature within its elastic limit and return to the original shape with little or no apparent damage. Chipping of typical porcelain enamel on sheet iron occurs at about the strain required for permanent deformation of the metal base.

Abrasion Resistance. The resistance of porcelain enamel to various types of abrasion is measured by ASTM C 448, which consists of three parts. The first determines the resistance to surface abrasion of porcelain enamels for which the unabraded 45° specular gloss is more than 30 gloss units. The second determines the resistance to surface abrasion of porcelain enamels for which the unabraded 45° specular gloss is 30 gloss units or less. The third measures the resistance of porcelain enamels to subsurface abrasion.

Acid Resistance. Porcelain enamels can be formulated to exhibit high resistance to all acids except hydrofluoric or concentrated phosphoric. This resistance to food acids and certain chemical cleaners is of particular importance to manufacturers of ranges and other kitchen and household appliances, as well as plumbing fixtures and various industrial and chemical processing products.

The acid resistance of enamels under boiling conditions is important for certain uses, such as cookware. ASTM C 283 is used for evaluation. Similarly, acid resistance is a major consideration for predicting the weatherability of architectural porcelain-enamel components. Extensive testing under controlled-exposure conditions has shown a distinct correlation between acid resistance and weatherability. Here the test for determining acid resistance is ASTM C 282.

Alkali Resistance. Home laundry equipment, dishwashers, and similar applications normally exposed to an alkaline environment at elevated temperatures require an alkali-resistant coating. The standard test for alkali resistance is ASTM C 614.

Resistance to Organic Solvents. Porcelain enamels are inert to all common organic solvents; however, there is no standard procedure for determining this special performance characteristic.

Resistance to Hot Water. Federal specification W-H-196J, “Heater Water, Electric and Gas Fired, Residential,” specifies a solubility test to determine the resistance of porcelain enamels to hot water.

Weather Resistance. Actual weathering performance of porcelain-enamel panels has been documented in a series of on-site exposure tests carried out for up to 30 years by the National Bureau of Standards (now the National Institute of Standards and Technology) in cooperation with the Porcelain Enamel Institute. As mentioned previously, acid resistance as measured by ASTM C 282 is important.

Weathering of porcelain enamel is evaluated in terms of the changes in gloss and color that occur during outside exposure. Multiyear weathering tests demonstrate that porcelain enamels have considerable inherent gloss and color stability. ASTM C 346 and ASTM D 2244 are used (the latter is not under B.08.12 jurisdiction). Spalling resistance of weathered porcelain enamel on aluminum is best ascertained by ASTM C 703.

Torsion Resistance. In transit and during service, porcelain-enamel products may be subject to distortion through bending, twisting, or a combination of both. This can cause coating failures from fractures originating at the outer surface and normal to the tensional stress. ASTM C 409 evaluates the relative resistance to torsion-induced failure of laboratory test specimens for steel-substrate thicknesses of 24 to 12 gage.

Thermal shock resistance of a porcelain-enamel surface varies inversely with the thickness of the enamel. It is also affected by the compressive stress present in the enamel at room temperature. Most porcelain enamels can be quenched in ice water from 205 °C (400 °F) without thermal shock failure. Some porcelain enamels specifically designed for resistance to thermal shock will not fail when quenched in ice water from 650 °C (1200 °F). ASTM C 385 is the standard for evaluating the durability of porcelain- enamel utensils when subjected to thermal shock.

Continuity of Coatings. Ensuring continuity of coating after manufacture is important in porcelain-enamel (“glassed-steel”) applications where a prime purpose of the coating is to protect the substrate against corrosion. Test methods used to determine either discontinuity of coverage or potential discontinuity through too-thin coverage are ASTM C 536 and ASTM C 743. Both tests essentially involve the use of electrical probes of relatively high voltage to discern either discontinuities in the coating or insufficient coverage for coating integrity in service use.

Chemical-Setting Ceramic Linings

Introduction

INORGANIC CHEMICAL-SETTING CERAMIC LININGS have become one of the most widely used construction materials in designing protective linings for industrial installations in which high temperatures, aggressive corrosive media, and complicated substrate geometry exist, such as floors, trenches, sumps, reaction vessels, tanks, scrubbers, ducts, chimneys, and other air pollution control equipment. They are used in various industries, including power, steel- and metalworking, chemical, pulp and paper, refinery, waste treatment, and mining.

Inorganic monolithic linings have proved themselves in these industries because of their chemical resistance to both high and low concentrations of strong acids and solvents, thermal insulation that protects the substrates from extremely high temperatures, temperature resistance to 870 °C (1600 °F), good compressive and flexural strength for environments in which stress and strain are factors, and abrasion resistance. Monolithic linings can be applied by cast or gunite (shotcreting) methods over old and new steel or concrete as well as brick and mortar masonry. This article discusses the function of monolithic linings, the use of these materials, the types of applications in which these materials can be successfully used, and the limitations of these linings.

Chemical-Setting Ceramic Linings

History of Chemical-Setting Silicates

The progress of silicate cement development has changed over the years with growing technology to meet industry needs. The first silicate cements were composed of a sodium silicate (Na_2SiO_3) liquid and a combination of fillers, such as silica flour, clay, silica aggregates, and barytes, and were formulated as chemical-resistant mortars for use in ambient or high-temperature acid lining construction. This type of silicate cement was very slow in setting and had to be exposed to the open air or heat cured, which created construction delays. Another problem was that these cements were not water resistant. These problems were resolved by the use of acid washing, which helped set the cements and make them water resistant.

In the early 1920s, Na_2SiO_3 mortars were introduced that used an acid catalyst to insolubilize the silica gel; this produced a mortar that cured faster and was water resistant. The physical properties of the silicate mortar were unchanged; that is, the acid, temperature, and solvent resistance were maintained. Because the acid-catalyzed mortar was chemically activated on mixing, it could set within 24 to 48 h. This was a distinct advantage for the construction industry, because it allowed brick to be laid continuously without concern over the mortar being squeezed out of the joints or the brick sliding out of line. Typical setting agents used are ethyl acetate ($C_4H_8O_2$), zinc oxide (ZnO), sodium fluorosilicate (Na_2SiF_6), glyceryl diacetate, formamide (CH_3ON), metallic polyphosphates, and other amides or amines.

It was later determined that when Na_2SiO_3 mortars were exposed to sulfuric acid (H_2SO_4), the reaction product was sodium sulfate (Na_2SO_4), which is a salt that expands and grows through hydration. This sodium salt can pick up as much as 10 mol of water of crystallization with a resultant size increase of 150%, thus creating internal stresses in the structure in which it was used. As a result, monolithic linings and brick surfaces would sometimes crack or spall.

As time passed, industry required silicate technologies that would meet changing applications and structural designs. By the 1950s, potassium silicate (K_2SiO_3) cements were introduced using methods of insolubilizing the silicate. The K_2SiO_3 cements possess enhanced corrosion resistance, particularly in H_2SO_4 environments. Potassium silicate cements react with H_2SO_4 to form potassium sulfate (K_2SO_4), which is not a growth salt. This eliminates the problem of internal stresses when the mortar is exposed to H_2SO_4 solutions.

The introduction of K_2SiO_3 cements was a positive step in producing a material that was more suited for application technology and corrosive environments. The K_2SiO_3 cements offer improved physical properties, which are particularly beneficial in monolithic applications. Furthermore, K_2SiO_3 cements provide better workability with less tackiness and longer working times than Na_2SiO_3 cements. Additional advantages include greater resistance to strong acid solutions and sulfation, more refractoriness, and no efflorescence as with Na_2SiO_3 cements. By this time, Na_2SiO_3 and K_2SiO_3 materials were not only being used as mortars but were also being introduced in new areas of monolithic application as both castable and gunite grades.

Modified silicates were developed in the 1980s. Modified silicates are manufactured by the addition of a powder form of Na_2SiO_3 in conjunction with a proprietary ingredient added directly to the powder fillers. This process eliminates the need to have both powder and liquid on the job site; water is the only required addition. Although these products have been commercially available, high cost and potential for sulfation have limited their use. The modified silicates do not have the chemical properties of the other silicates. The only advantage appears to be their simplicity of mixing.

Advantages and Disadvantages

The Na_2SiO_3 and K_2SiO_3 cements were developed because a material was needed that was acid resistant in dilute-to-strong concentrations and that offered higher temperature resistance than chemical-resistant organic materials. The development of these silicate-base acidproof cements resulted in many advantageous characteristics, such as a 100% K_2SiO_3-bonded system that had resistance to most solvents and acids over a pH range of 0 to 7; that was water and vapor resistant without special treatment; and that could withstand all concentrations of H_2SO_4, nitric acid (HNO_3), hydrochloric acid (HCl), and phosphoric acid (H_3PO_4). In addition, the Na_2SiO_3- and K_2SiO_3-bonded cements can be applied over damp acid-attacked concrete or brick surfaces as long as these substrates have acid pH surfaces, and they cure chemically within 36 h, thus decreasing construction delays. These cements can be applied by gunite or cast methods. Detailed information on guniting (shotcreting) can be found in American Concrete Institute publication ACI 547R on refractory concrete.

Certain disadvantages were encountered during the development of the acid-resistant silicate cements. It was common knowledge that the silicate cements were not resistant to alkalis, hydrofluoric acid (HF), and fluoride salts. As previously mentioned, the Na_2SiO_3 cements formed a growth salt when exposed to H_2SO_4 that put undue internal stresses on the structure of the material.

Inorganic monolithic linings also have a certain amount of permeability compared to organic surfacing materials. Over time, acid can penetrate the lining and eventually reach the surface of the substrate. This problem is now being combated by using a dual-lining system, which includes a chemically resistant elastomeric membrane applied to the surface of the substrate.

Chemical-Setting Ceramic Linings, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 755–758

Chemical-Setting Ceramic Linings

Current Technologies

Monolithic and Membrane Dual Linings. Organic linings or coatings have been used in stacks and ducts, but they will usually deteriorate if temperatures exceed 260 °C (500 °F) in high- sulfur gases. There are many types of lining materials for stacks and ducts; however, because of unpredicted environmental conditions within a stack or duct, it may be difficult to select the best candidate material. Stacks that are designed with heat recovery units and/or scrubbers, combined with one or more flues inside the shell that can control the temperature, should be considered for dual-lining applications.

In recent years, the trend toward using the superior technology of dual linings has emerged and is being recommended where corrosion problems occur throughout industry. Figure 1 illustrates the design of a typical membrane/ monolithic system in the chemical industry.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

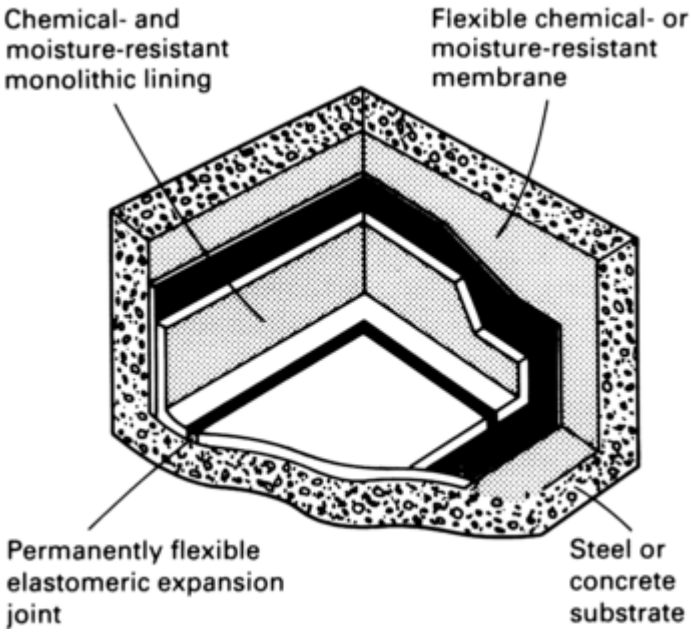

Fig. 1 Schematic of a chemical-resistant dual-lining system that provides double protection to the substrate in the form of a flexible membrane and a rigid surface layer. The flexible corrosion-resistant membrane is applied in direct contact with steel or concrete substrates. It is then covered by the monolithic cement lining, which provides protection over a broad pH range as well as against high temperatures.

There are numerous reasons for this new construction process. Condensation occurs not only on the face of the acid-resistant lining but can also penetrate and condense on the substrate to be protected. Although acidproof monolithic linings offer the proper chemical resistance, they are inherently inelastic, or brittle. In time, monolithic linings may tend to crack and absorb acids or acid gas condensate; therefore, it is advantageous to have a backup membrane. In many applications, the coefficient of thermal expansion of the monolithic lining may not match that of the substrate. Therefore, a flexible membrane helps accommodate stresses resulting from these differences in thermal expansion as well as other mechanically induced stresses.

For many applications, the monolithic lining should not be bonded to the substrate, and the membrane acts as a bond barrier. The concept of placing an impervious membrane between the substrate and inorganic linings has become a recommended practice. Some corrosion-resistant gunite manufacturers have installation specifications for use with membranes.

Membrane choices include asphaltics, resins, and synthetic elastomers. The membrane selected should resist the maximum acid concentrations and temperature expected. Organic linings can fail by disbonding, swelling, abrasion, and blistering from high temperature. Protection of an organic membrane with an inorganic barrier will minimize thermal exposure and mechanical abrasion to the membrane as well as the corrosive media that reach the membrane. An organic membrane compensates for some of the shortcomings of inorganic linings, such as cracking or spalling due to mechanical stresses from shrinkage, induced stresses, insufficient thermal expansion allowances, the anchoring system, vibration, and thermal or other stresses. To provide an effective barrier, inorganic linings are applied much thicker than typical organic coatings. They often contain fillers to act as reinforcement and to decrease shrinkage. Fillers are also incorporated to provide wear resistance for abrasive conditions.

The installation procedure for a dual-lining system is basically the same as if each component were being applied separately. These procedures are established for both organic coatings and inorganic monolithic linings. The condition of the working area and preparation of the surfaces follow standard practices used throughout the industry. Anchors are usually installed on the steel or concrete substrates before the organic membrane is applied.

Lightweight Insulating Materials. Industry has recently seen the development and application of improved lower-density, lightweight, insulating corrosion-resistant lining materials. The evolution of these products has followed the need to accommodate load limitations of structural supports and improved thermal protection of membrane coatings where substrate temperatures can range from 40 to 150 °C (100 to 300 °F) and even higher if process limits or gas cleanup systems experience frequent excursion or bypass conditions. Membranes

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

require adequate thermal protection to retain physical and chemical properties throughout their service life. Because the membrane will also coat the studs, the inorganic coating must be thick enough to protect the membrane on the highest point of the studs. Therefore, the inorganic lining material must not only protect the membrane from physical abuse but must also protect it from thermal deterioration.

When membranes are not used, condensation of chemicals from hot process streams should be designed to occur within a lining and not at the substrate. However, when membranes are used, the condensation can occur at the membrane, thus possibly reducing the required lining thickness. Therefore, inorganic silicate lining materials with lower thermal conductivity and density have been developed to meet these needs.

Application Procedures. Through the use of current technology, such as the dual-lining system and the availability of improved application techniques, corrosion protection practices have been greatly enhanced. Observations of successes and failures in various applications have led to the development of the following parameters, which must be addressed to specify the proper material. In any application, the primary consideration is the exposure environment. This includes the types and concentrations of chemicals, physical abuse, and temperatures. In this evaluation, it is important to remember that both the silicate monolithic lining and the membrane must resist the corrosive environment. The next consideration is the thickness of the monolithic lining. In high-temperature environments, the monolithic lining must be able to decrease the temperature through its thickness to a level that does not burn out the membrane applied to the substrate or the anchoring system. Once the materials that can resist the corrosive environment have been selected, the physical structure must be considered.

Steel. When a steel substrate is being used, sources of variation in electrical potential on the metal surfaces must be considered. These include mill scale, metal impurities, localized strains on parts of the metal, junctures of dissimilar metals, movement of electrolytes, weld joints, concentration cells, and externally imposed currents. Some or all of these differences in potential can occur on the surface and must be considered in the recommendation of a protective coating. The protective coating must provide the following properties to protect the steel:

- Physical protection to surface
- Prevention of concentration cells
- Dielectric properties
- Lower surface temperatures
- Prevention of electrolyte flow
- Deprivation of free oxygen from the surface
- Stress relief

Stress relief is an important factor in the design of a system. If a system does not compensate for relief in areas of high stresses, cracking will occur that can severely damage the entire system. Stresses on the system of major concern could result from vibration, unsupported surfaces, changes in planes, and welds.

The following five steps are application procedures that should be followed to ensure proper installation of a dual-lining system. First, all areas of high stress that result in movement of the steel structure, such as oil canning or vibration, must be externally supported. Second, the anchoring system should then be applied to the substrate. Anchors, such as V-type or longhorn studs, should be installed on the proper centerlines in a diamond or staggered pattern with the tines randomly oriented. Third, the steel surface must be stripped of all oil and grease by chemical cleaning. The metal should then be sandblasted to an SP 10 Near-White Blast (SSPC: The Society for Protective Coatings designation) with a nominal 64 μm (2.5 mils) profile. Welds should be ground to a smooth, rounded radius with no sharp edges before blasting. Fourth, the appropriate membrane should be applied, ensuring that all of the studs are completely coated and that the system is free of pin holes.

The final step is to apply the monolithic lining. The two available methods of application should be considered. A castable material will shrink more than the gunitable material; therefore, expansion joints must be planned into the system in areas exceeding 6 by 6 m (20 by 20 ft) or where changes in planes will cause stresses to occur. A gunitable material will shrink less and therefore does not require expansion joints. Figure 2 illustrates the gunite application of K_2SiO_3 cement over steel ductwork in a fossil fuel power plant.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

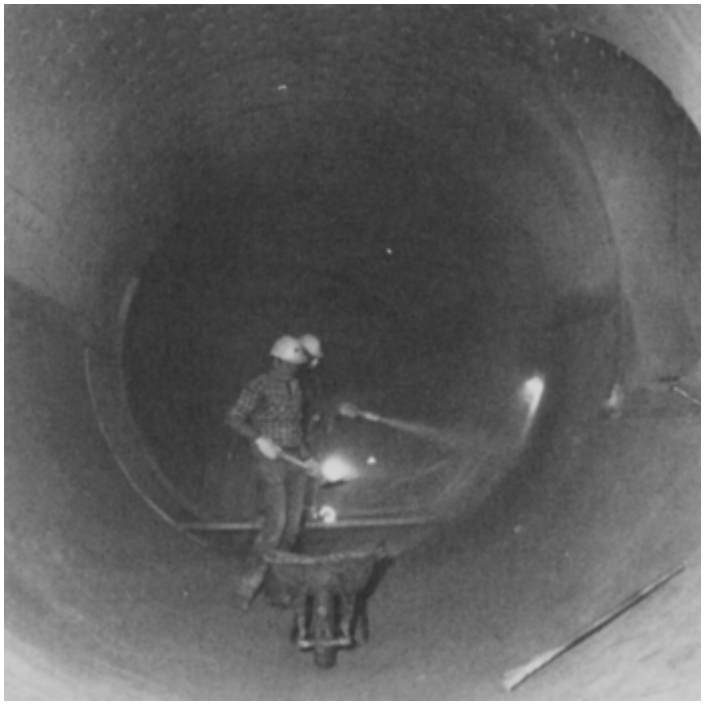

Fig. 2 Gunite application of 50 mm (2 in.) of K_2SiO_3 cement over steel ductwork in a coal-fired power plant

Concrete. In applications over concrete, as with steel, the first considerations are the corrosive environment and the thickness of the material. Once the materials have been selected, the physical structure must be considered. When the substrate is concrete, factors different from those associated with steel must be considered. Inorganic monolithics can be applied over old or new concrete surfaces. When concrete substrates are being used, the following questions should be answered:

- Is the concrete old acid-attacked concrete or new concrete?
- Is the concrete capable of supporting loads?
- Is the structure above grade or below grade?
- Does the concrete need to be waterproofed from the outside?
- Does the concrete structure have existing cracks?
- Is the concrete surface a high or low pH?

A combination of many of these items may apply and should be considered in the recommendation of the proper system. The following are the criteria for a concrete surface before a system may be applied. When working with old acid-attacked concrete, all loose and deteriorated concrete should be removed. The surface should be firm, hard, and at a minimum pH of 5, and all surfaces should be brought back to grade and the slopes reestablished. When working with new concrete, the concrete should be firm and sound. All structural cracks should be repaired, and it should be cured for a minimum of 7 days. Slopes should be a minimum 3.2 mm (0.125 in.) to a maximum 6.4 mm (0.25 in.) per linear foot and should have attained a minimum compressive strength of 21 MPa (3000 psi).

The following five steps are application procedures that should be followed to ensure proper installation of a dual-lining system. First, the concrete should meet the standards outlined previously. Second, the concrete should be cleaned of all oil, grease, and form release compounds by chemical cleaning, waterblasting, or scarifying. Third, the anchoring system should be placed at the specified centerline distance in a diamond-shaped pattern with a random orientation of anchor tines. The anchoring system should consist of V-type or longhorn studs. Fourth, the membrane should be applied to the recommended thickness, ensuring that all studs are completely coated and that the coating is free of pinholes.

The final step is to apply the monolithic. The castable and the gunitable methods should both be considered. As stated previously, when applying by the gunite method there is less shrinkage; therefore, there is no need for expansion joints in the monolithic. However, the lining will require control joints in the normal manner. Expansion joints are recommended with cast applications and should be installed at the perimeter of floor areas,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

equipment pads, and floor trenches; around floor drains, column bases, and protrusions; at changes in planes; and over expansion joints in concrete slabs not to exceed 6 m (20 ft) on centerlines.

Brick. A monolithic lining can be applied over acid-attacked masonry construction. The first step is the surface preparation of the brick. Fly ash and other contaminants should be removed by sandblasting or waterblasting. All attacked or unsound mortar should be removed from the joints. Mortar joints should be cleaned to a depth of at least 13 mm (0.5 in.) to provide support for the monolithic lining. If the joints cannot be cleaned to this depth, it is necessary to set longhorn or V-type anchors in the joints. The preferred method of application in this case is to gunite the material. Guniting allows the material to be applied under pressure, thus enabling the material to be packed into the 13 mm (0.5 in.) open joints and allowing the system to be supported by the studs or keying into the joints.

Chemical-Setting Ceramic Linings, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 755–758

Corrosion Resistance

Monolithic linings are among the fastest growing products in the corrosion protection field because of their resistance to a wider range of corrosive media than most other construction materials. The following industrial applications illustrate the corrosion resistance and some uses of monolithic linings.

Wastewater treatment systems in the southern United States have experienced corrosion problems in areas of high temperatures, high humidity, and slow drainage. Consequently, millions of dollars have been spent in replacing the corroded concrete infrastructures in these wastewater treatment systems in wet wells, grit chambers, sewer lines, and aeration basins. This corrosion went unnoticed throughout the years because the corrosion mechanism was not understood. Most of the corrosion was not caused by discharged chemicals but was microbiologically induced. The concrete infrastructures are seldom completely filled, and the combination of high temperatures and high humidity creates a perfect breeding ground for bacteria, fungi, algae, and gaseous products from decomposing sewage.

Carbon dioxide (CO_2), combined with hydrogen sulfide (H_2S) from the slightly warm and fermenting sewage, reacts with the damp concrete surfaces to form carbonates and calcium sulfate ($CaSO_4$). As this process proceeds, the pH becomes more acidic. Bacterial action results in the production of elemental sulfur from various sulfate reactions, with subsequent oxidation of elemental sulfur to H_2SO_4, which the bacteria secrete.

The H_2SO_4 then directly attacks the underlying portland cement concrete substrate and causes destruction of the infrastructure. There are documented cases of microbiologically induced corrosion having proceeded to the point at which structures collapsed in as few as 6 years or required major rehabilitation in as few as 4 years.

A proven method of rehabilitating deteriorated concrete wastewater structures involves applying a urethane-based membrane to the properly prepared substrate, followed by the pneumatic application of a 100% K_2SiO_3-bonded acid-resistant concrete. The urethane- based membrane is a two-component material with a high solids content and very low permeability. To ensure pinhole-free coatings, the membrane is applied in two or more coats to a wet film thickness ranging from 1.6 to 3.3 mm (63 to 130 mils). These membranes are applied by airless spray with a spray tip pressure of approximately 28 MPa (4000 psi). The high pressure further helps to ensure pinhole-free application of the membrane. The substrate must be dry enough to accommodate the urethane membrane without reacting with the polyisocyanate catalysts usually used.

Therefore, it is sometimes desirable to apply a moisture-tolerant primer, such as a suitable formulated epoxy, to the damp concrete or to apply a fresh layer of concrete first. Following the proper application and cure of the urethane membrane, a veneer of a 100% K_2SiO_3 acidproof cement is applied over the membrane and anchors.

The chemical industry can be the most difficult of all industries in which to design a protective lining. The conditions within one plant can be staggering; there may be acids, alkalies, and solvents, along with extremely high temperatures and physical abuse. Potassium-silicate- base cements satisfy most of these conditions while maintaining economy. The combination of a wide range of chemical resistance, high physical strength, and refractoriness makes these cements leading candidates for many chemical plant applications.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

For example, at a major Midwest chemical plant, the action of HCl by-products and ambient moisture on floors, digester tank supports, trenches, and sumps in $NiCl_2$- and $NiSO_4$-processing units produced very corrosive conditions. Restoration of the existing structures was accomplished with a K_2SiO_3 cement and an appropriate membrane.

In the $NiCl_2$ unit, the existing concrete floor was chipped out, and new concrete was poured; the steel beam supports for the digester tanks were also encapsulated with regular concrete. Both floor and digester foundations then received a trowel-applied asphaltic membrane. The membrane provided a flexible acid-, water-, and alkali-resistant barrier between the concrete substrate and the monolithic surfacing. The trowel-applied membrane system is applied at room temperature and offers the chemical resistance of hot-applied membranes for those areas where a hot membrane may not be practical or advisable.

The next step was to apply a K_2SiO_3 monolithic lining by casting into forms. The lining was 38 mm (1. 5 in.) thick over foot traffic areas near the digesters; 38 to 50 mm (1.5 to 2 in.) thick around the encapsulated digester foundation, creating a collar; and 50 mm (2 in.) thick in forklift truck aisles. Finally, at the interface of the digester tank wall and the collar, an elastomeric urethane-based compound was used as a permanently flexible expansion joint.

In the $NiSO_4$-processing unit, the problem areas included trenches running among process equipment in two different buildings. In addition, the various collection sumps into which these trenches drained required restoration. As was done in the $NiCl_2$ area, the deteriorated concrete was reconstructed with new concrete. The asphaltic membrane was trowel applied. A K_2SiO_4 monolithic lining was cast over the membrane to 25 mm (1 in.) in the trenches, 25 to 38 mm (1 to 1.5 in.) in the sumps, and 38 mm (1.5 in.) on the floors, and the elastomeric urethane expansion joint compound was applied.

The service conditions for the two processing areas included a pH of 1 to 2 due to concentrations of HCl up to 32%, water, temperatures to 95 °C (200 °F), and vibrations from imposed loads as great as 3630 kg (8000 lbs) in the truck aisles. These applications were done by the casting method, but they could have easily been done by the gunite method.

CVD and PVD Coatings

Introduction

VAPOR-DEPOSITED COATINGS modify the surface properties of materials. They are widely used and have been particularly successful in improving such mechanical properties as wear, friction, and hardness in cutting applications. Their use as corrosion-resistant coatings is also becoming widespread.

CVD and PVD Coatings, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 759–762

CVD and PVD Coatings

Deposition Processes

The vapor-deposition processes fall into two major categories—physical vapor deposition (PVD) and chemical vapor deposition (CVD)— which in turn comprise various subcategories. Although these divisions often appear confusing and arbitrary, each has its own well-defined technical and economic advantages and disadvantages. This is also true of the materials used in vapor deposition. Therefore, the need for a thorough understanding of both processes and materials is needed for the selection of the optimal combination.

The major deposition processes that are reviewed in this article are sputtering, evaporation, ion plating, and CVD. These processes all have one characteristic in common: the deposition species are transferred and deposited onto the substrate in the form of individual atoms or molecules. In this respect, they are fundamentally different from particulate- or liquid-deposition processes, such as thermal spraying or electroplating, and ion-beam processes where ions are implanted beneath the surface of the material (see the articles “Thermal Spray Coatings,” “Electroplated Coatings,” and “Surface Modification Using Energy Beams” in this Volume). A primary benefit of vapor deposition is that it is essentially nondamaging to the environment, because there are no solvents or chemicals to dispose of. With the current awareness of environmental, safety, and health considerations, this crucial factor favors vapor deposition over other processes that may be more harmful to the environment and health.

Sputtering is the principal PVD process. It involves the transport of a material from a source (target) to a substrate by bombardment of the target by gas ions that have been accelerated by a high voltage. Atoms from the target are ejected by momentum transfer between the incident ions and the target. These ejected particles move across the vacuum chamber to be deposited on the substrate.

Figure 1 is a schematic of the sputtering process. In its simplest form, the process occurs in an inert (noble) gas at low pressure (0.13 to 13 Pa, or 1×10^{-3} to 0.1 torr); in most cases, the gas is argon. Argon has higher mass than other noble gases, such as neon or helium, and is easier to ionize. Higher mass gives a higher sputtering

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

yield, especially if the mass of the bombarding particle is the same order of magnitude or greater than the mass of the target atom. Other gases, such as oxygen or nitrogen, can also be used, but they may react chemically with the target. The sputtering process begins when an electric discharge is produced and the argon becomes ionized. The low-pressure electric discharge is known as glow discharge, and the ionized gas is termed plasma.

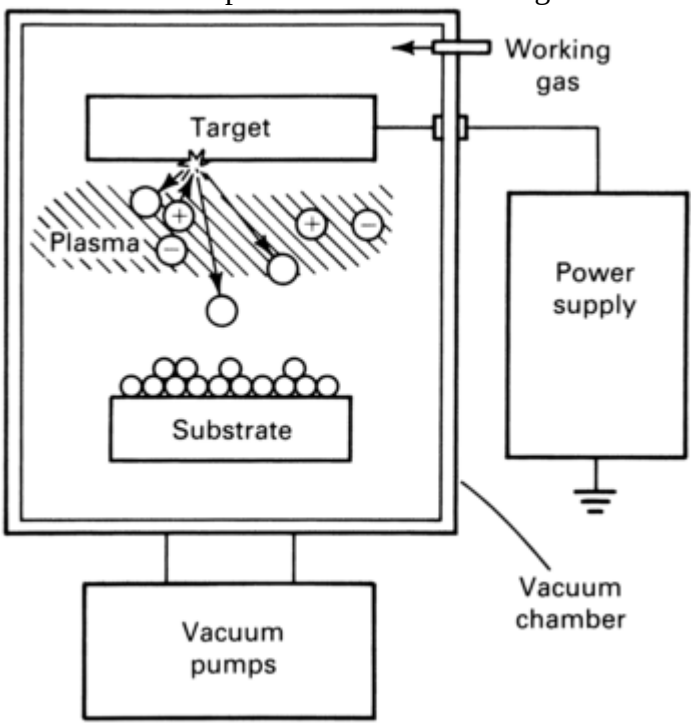

Fig. 1 Basic sputtering process

The argon ions hit the solid target, which is the source of the coating material (not to be confused with the substrate, which is the item to be coated). The target is negatively biased and therefore attracts the positively charged argon ions, which are accelerated in the glow discharge. This attraction of the ions to the target (also known as bombardment) causes the target to sputter, which means that material is dislodged from the target surface because of momentum energy exchange. The higher the energy of the bombarding ions, the higher the rate of material dislodgement.

Sputtering developed very rapidly in the 1970s in the semiconductor industry, in which the technique is essential for mass production. Sputtering is used in corrosion-abatement applications such as high-chromium and nickel-chromium alloy coatings, MCrAlY (where M stands for nickel, cobalt, or iron or a combination of them), and some polymers. Titanium nitride, other nitrides, tungsten, molybdenum, carbides, borides, and diamondlike carbon are sputtered for wear resistance (Ref 1).

For the deposition of thin metal films (in the 0.1 μm, or 4 μin., range), sputtering is the best technique. Deposition is feasible in a controllable manner for both compound and elemental targets (the source of the coating material). Adhesion is good and can be further improved by sputter cleaning the substrate or by bias sputtering. Large equipment is readily available, and sputtering has become a highly automated process. The quality, structure, and uniformity of the deposit are excellent. The disadvantages of sputtering include its thickness limitation, the need for a vacuum, and high cost. It is also a line-of- sight process that requires special fixtures and shaped targets to coat uniformly; furthermore, the coating of compound curves, recesses, and holes is difficult. The substrate being processed must be capable of withstanding processing temperatures of 260 to 540 °C (500 to 1000 °F).

Evaporation was the first PVD process used on an industrial basis for the aluminum metallization of plastics and glass for decorative purposes. Originally the most widely used process, evaporation has now been overtaken by sputtering. The metallization process is relatively simple and well adapted to mass production.

The basic evaporation process involves the transfer of material to form a coating by physical means alone, essentially vaporization. Practically all metals can be evaporated, making evaporation a universal process. The source material may be heated by bombardment with an electron beam or heated by thermal conduction. Like sputtering, it is a line-of-sight process; therefore, to achieve efficiency of coverage and uniformity it is necessary to use multiple evaporation sources and to rotate or move the substrate uniformly to expose all areas.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Unlike other vapor-deposition processes, evaporation is a low-energy process, with particle energy averaging 0.2 to 0.3 eV as compared to 10 to 40 eV for sputtering, 200 eV or more for ion plating, and 100 keV for ion implantation. The term “low energy” means that adhesion of the particle to the substrate may be marginal. In addition, the temperature of the substrate is not increased by the deposition, which means there is little or no diffusion. Because no strong physical or chemical action takes place at the interface, particular care must be taken to remove all impurities in the chamber and to have a very clean substrate. The basic process (with an electron-beam source) is shown in Fig. 2.

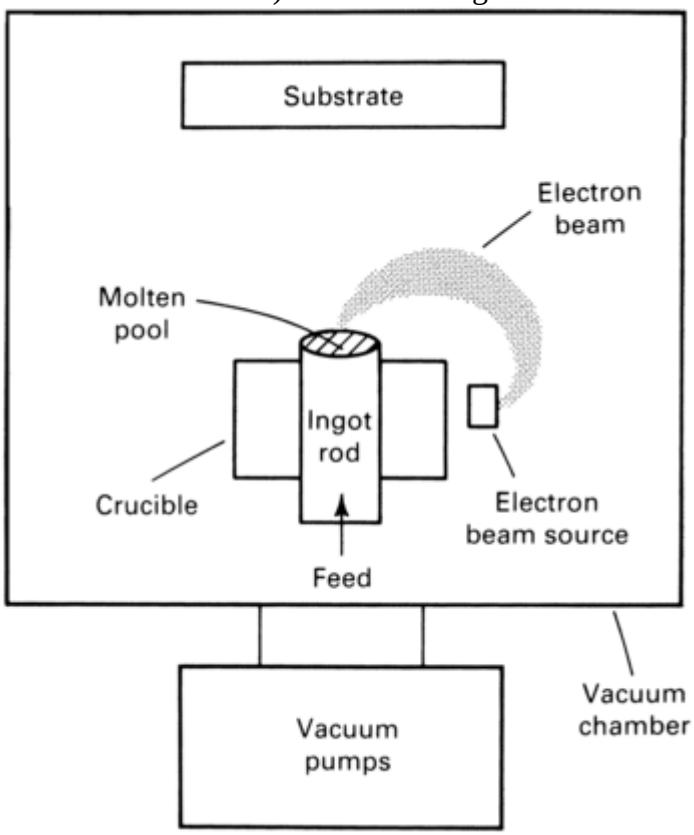

Fig. 2 Basic evaporation process

Very large evaporation equipment, which was developed for the optical industry, is commercially available. Coatings of several microns in thickness can be rapidly deposited. The disadvantages of this method are nonuniform coverage (limited to line of sight) and relatively low adhesion unless glow-discharge cleaning is used (glow-discharge cleaning removes surface atoms from the substrate). Evaporation is very successful in applications in which adhesion and good structure are not critical, such as decorative and optical uses. Aluminum is the principal evaporation material; chromium and stainless steel are also widely used. Evaporation is not generally used for critical corrosion-control applications.

Ion plating is a generic term for the hybrid process based on the evaporation (or sputtering) mechanism coupled with a flux of high-energy particles (Fig. 3) imparting a large increase in the energy of the deposition species, which is atomistic.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

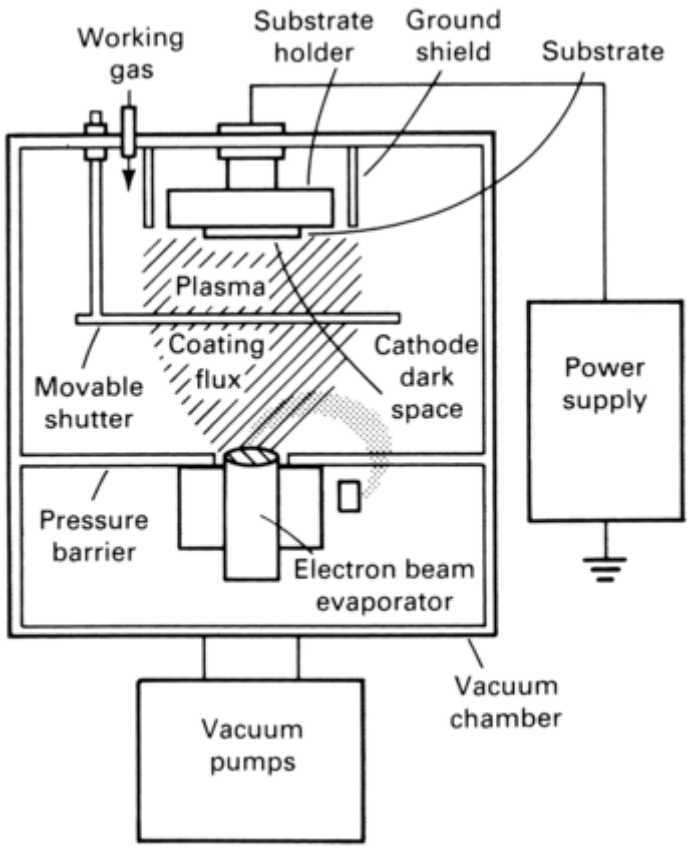

Fig. 3 Basic ion plating process

Ion-beam-assisted deposition (IBAD) and ion- beam-enhanced deposition (IBED) refer to the process wherein evaporated atoms produced by physical vapor deposition (PVD) are simultaneously struck by an independently generated flux of ions (Fig. 4) (Ref 2). The extra energy imparted to the deposited atoms causes atomic displacements at the surface and in the bulk, as well as enhanced migration of atoms along the surface. These resulting atomic motions are responsible for improved film properties—including better adhesion and cohesion of the film, modified residual stress, and higher density— when compared with similar films prepared by PVD without ion bombardment. When the ion beam or the evaporant is a reactive species, compounds such as refractory silicon nitride (Si_3N_4) can be synthesized at very low temperatures. Furthermore, adjustment of the ratio of reactive ions to atoms arriving at the substrate surface allows adjustment of the stoichiometry of solid solutions.

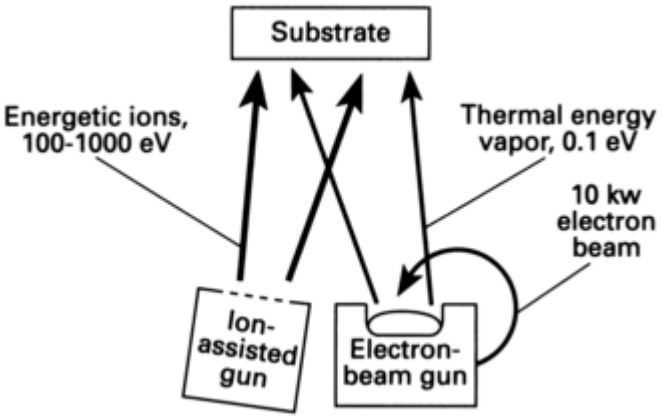

Fig. 4 Ion-beam-assisted deposition (IBAD)

It is generally accepted that plasma plays the same part as high temperature in improving the adhesion and increasing the reactivity of the coating; an ion passing through a potential of 100 eV acquires an equivalent temperature of 106 K. While the PVD process uses temperatures of approximately 538 °C (1000 °F), the IBED process deposits hardcoats below 93 °C (200 °F) (Ref 3).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The simplest forms of ion plating are ion nitriding and ion carburizing, in which nitrogen or carbon ions react with a steel substrate to form nitrides or carbides. If the deposition species is ionized in a reactive gas, a compound is formed with some of the gas atoms, and deposition of the compound occurs. Ion plating is widely used and is gradually replacing pack cementation or diffusion.

With ion implantation, the objective is to modify the properties of the surface, such as corrosion behavior, by embedding atoms from a beam of ionized particles into the near surface of the target.

Because ion plating is a glow-discharge process in which a plasma is formed, it is necessary to have at least a threshold gas pressure to maintain the plasma. This is different from standard nonionized evaporation, in which the minimum pressure obtainable is preferred. The net effect of this higher gas pressure is to increase the number of collisions with gas molecules and therefore produce more scattering of the deposition species, which in turn diminishes the importance of the line-of-sight principle and improves coverage.

The deposited species in ion plating have higher energy than those of evaporation or sputtering processes; this results in improved adhesion as well as a deposit with improved structure and fewer imperfections. In addition, if a sputtering system is used, it is easy to sputter the surface of the substrate to clean it before deposition.

However, the ion equipment is more complicated and therefore more expensive than either evaporation or sputtering equipment, and the process is more exacting.

Chemical vapor deposition is a well-established deposition process that is used extensively in the semiconductor and cutting-tool industries. It has the unique ability to deposit thick, dense, high-quality films (up to 6.4 mm, or 0.25 in., thick or more) at a cost that is generally lower than that of PVD processes. The high temperature, about 1000 °C (1830 °F), necessary for CVD promotes good adhesion, but also considerably restricts the type of substrate that can be coated to ceramics, refractory metals, and special alloys.

In most cases, steel will require heat treatment in a vacuum or protected atmosphere after CVD coating and will often change dimensions sufficiently to require postdeposition machining if close tolerances are required. Another constraint resulting from the high temperature of deposition is the stress in the deposit due to the difference in thermal expansion between substrate and deposit. These stresses may be sufficient to cause cracking, spalling, and loss of adhesion. The technique of plasma CVD can be used at much lower temperatures in, for example, semiconductor applications, but the resulting films tend to incorporate impurities.

The materials that can be easily deposited by CVD are more limited than with PVD. Chemical vapor deposition is particularly useful for depositing compounds and refractory metals and lends itself very well to corrosion applications.

Figure 5 is a schematic of thermal CVD equipment. The reactive gases are metered in the mixing chamber. They then pass into the deposition chamber and contact the heated part to be coated (sample); at this point, they react and deposition occurs. By-products are removed through the vacuum system.

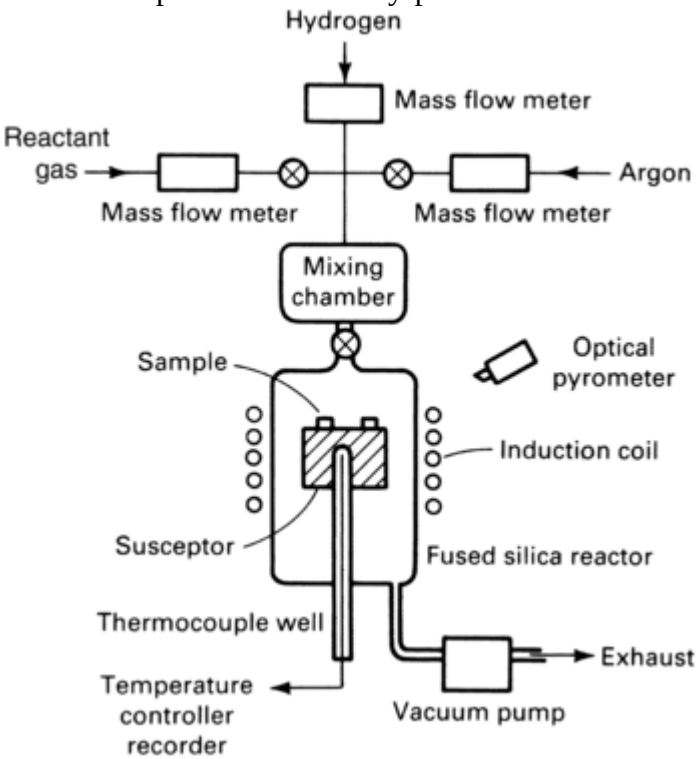

Fig. 5 Thermal CVD reactor

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Chemical vapor deposition reactions can occur over a range of pressures. Low pressure increases boundary-layer diffusion and uniformity, often at the expense of deposition efficiency. Each application and each reaction must be analyzed to determine the optimal conditions for deposition.

Coating Materials and Applications

The list of materials that can be vapor deposited is extensive and covers almost any coating requirement. The most important materials are given in Table 1. Aluminum and aluminum alloys are among the most widely used deposition materials and are gradually replacing cadmium in many corrosion applications. Sputtered chromium and stainless steel are also making great inroads in corrosion applications. A promising material is titanium nitride. It is hard, very stable, and refractory, and it has good lubricating characteristics and a pleasing gold appearance. It is widely used in wear applications, such as cutting tools, and in decorative applications. It is usually applied by sputtering or ion plating, and it holds potential for corrosion protection.

Table 1 Some corrosion-resistant vapor- deposited materials

Material	Deposition process
Aluminum	Evaporation
Chromium	Sputtering
Nickel	CVD, sputtering
Rhenium	CVD
Tantalum	Sputtering, CVD
Titanium	Evaporation, sputtering
Tungsten	CVD, sputtering
Boron	CVD
Carbon	CVD, ion plating
Titanium diboride	Evaporation, CVD
Silicon carbide	Sputtering, CVD
Titanium carbide	Sputtering, evaporation, CVD
Tungsten carbide	Sputtering, CVD
Boron nitride	CVD
Silicon nitride	Sputtering, ion plating
Titanium nitride	CVD, sputtering, ion plating

Nickel-chromium alloys	Sputtering
Gold alloys	Evaporation
Borazon	CVD
MCrAlY	Evaporation, sputtering
Bronze	Evaporation, sputtering

The properties of these materials vary widely and reflect the complexity of selecting a corrosion-resistant coating for a given substrate or a given environment and the need to conduct a thorough analysis of the problem. This is especially true when cost is the primary factor. For example, gold is an ideal material for many corrosion applications, but would of course be cost prohibitive in most cases. Before selecting a material and process for a corrosion-resistance application, the following considerations should be reviewed:

- Availability and cost of the coating material
- Cost, size, complexity, and availability of the deposition equipment
- Resistance to the chemical environment of the coating material
- Compatibility with the substrate, especially thermal expansion mismatch
- In special applications, such as aerospace, high-temperature resistance, radiation resistance, and high-vacuum stability

Chemical vapor deposited and PVD coatings have the advantage that the film (if thick enough) is essentially pore free and fully dense. Penetration by moisture and gases to the substrate is greatly reduced, if not eliminated. Despite this, the role played by CVD and PVD coatings in corrosion protection remains small. Some current applications are discussed in the paragraphs that follow.

Coating for Graphite. Graphite is perhaps the best material for applications requiring high strength and low density at very high temperatures. It is used as a hot-pressed material or as a carbon-carbon composite, which is a combination of graphite fibers and a carbonized resin matrix. Graphite is used in such applications as rocket nozzles or advanced turbine components. However, its disadvantage is a lack of oxidation resistance above 500 °C (930 °F). By using CVD to coat the graphite with silicon carbide, it is possible to provide oxidation protection up to 1650 °C (3000 °F). Silicon carbide oxidizes to form a silicon oxide surface that will prevent further oxidation. Advanced studies to further increase the oxidation temperature of graphite are in progress using such oxides as hafnia.

Aluminum Coating of Steel. The coatings of steel (and other metals) with aluminum by ion plating is an industrial process with excellent potential for large-scale production. It replaces hot dipping of aluminum on steel, which has been used for many years. During immersion in hot dipping, a brittle intermetallic compound layer of iron-aluminum is formed; this limits the formability of the steel. In addition, the coating contains iron impurities, which may be a severe shortcoming in highly corrosive environments (Ref 4).

Electroplated cadmium is another commonly used system for the corrosion protection of steel and other metals. However, it can cause hydrogen embrittlement of high-strength steel and titanium. In addition, cadmium has a low melting point (320 °C, or 608 °F) and presents environmental problems because of its toxicity. A process has recently been developed for applying aluminum on metals by ion-vapor deposition, which has none of the restrictions of hot dipping or cadmium electroplating. This process falls under military specification MIL-C 83488 (Ref 5).

Vapor deposition of aluminum does not produce hydrogen; therefore, it does not cause embrittlement. Vapor-deposited aluminum protects against stress-corrosion cracking (SCC) and has a temperature limit of 495 °C (925 °F). It is less expensive than most other barrier coatings. Applications for vapor-deposited aluminum in the aerospace industry include fuel and pneumatic line fittings (in place of anodizing), electrical connectors to replace cadmium, powder-metallurgy parts, fasteners, electrical black boxes, corrosion and SCC protection of depleted uranium and titanium alloys, and electromagnetic interference compatibility (Ref 6).

One of the first industrial applications of the IBAD process was the coating of stainless steel electric razor screens with TiN for aqueous corrosion protection (Ref 7).

Alloy Coatings for Gas Turbines. Gas turbines are used as aircraft turbines using highly refined fuels with operating temperatures between 900 and 1150 °C (1650 and 2100 °F) or higher; marine turbines using moderately refined fuels, which operate at 700 to 870 °C (1290 to 1600 °F) and are exposed to salt corrosion; and industrial turbines that may operate at 760 to 925 °C (1400 to 1700 °F) and use moderately refined fuels,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

often with high sulfur contents. Industrial turbines may use a variety of fuels and operate in marine, arctic, or more benign environments. Along with the need for high-temperature mechanical strength, materials in these applications must resist oxidation and high-temperature corrosion. These problems are becoming more acute with the trend toward higher operating temperatures for better performance and improved fuel economy.

Coatings were initially used in the 1960s to protect turbine hot section components from oxidation and high-temperature corrosion. Physical vapor deposition coating by electron-beam evaporation and sputtering of chromides and aluminides were used as temperature requirements increased, and these are still used in a majority of applications 30 to 40 years after their introduction. Overlay coatings of chromium, aluminum, and yttrium with cobalt, nickel, or iron are known generically as MCrAlY and are successfully used on aircraft turbines for resistance to hot corrosion. They are applied either by electron-beam PVD or plasma thermal spray.

In the 1980s thermal barrier coatings (TBCs) were introduced for the purpose of reducing the operating temperature beneath the coating. Recent developments using platinum-modified aluminides increase the oxidation resistance of these thermal barriers (Ref 8).

Marine gas turbines are subject to severe sulfidation, oxidation, and hot corrosion, especially in the presence of sodium sulfate (Na_2SO_4). Electron-beam-evaporated CoCrAlY coatings have considerably increased the service lives of first-stage blades. Further improvements have been achieved by using high-chromium low- yttrium alloys.

Industrial turbines may not require the degree of corrosion protection of other applications unless high-sulfur fuels are used or the atmosphere is aggressive. In such cases, the hot-corrosion problem can be solved by using thin-film CoCrAlY coatings and a very large (200 kW) electron-beam coater capable of handling industrial turbine parts weighing up to 40 kg (90 lb). Now TBC coatings are used for industrial turbines in relatively lower temperature components. Failures of turbine blades due to corrosion-assisted fatigue can have catastrophic results even in the compressor portion of the turbine, and these can be protected with PVD coatings and IBED coating (Ref 9).

Introduction

METALLIC MATERIALS used in harsh environmental conditions undergo degradation in various ways. Several forms of corrosion, that is, uniform, galvanic, pitting, and crevice corrosion (Ref 1), have been observed, reported, and analyzed in aqueous environments. Similarly, at high temperatures, alloys can degrade in different ways: by oxidation (Ref 2), sulfidation (Ref 3), halogen attack (Ref 4), and hot corrosion (Ref 5). Two general approaches are used to mitigate the corrosive effects of high-temperature environments:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- *Alloy design:* The alloy composition and/or structure are altered in specific ways to address the specific environment.
- *Surface modification:* Coatings are applied where the surface structure and/or composition is engineered appropriately while retaining the same substrate.

Coatings containing aluminum, chromium, and silicon are effective against oxidation and hot corrosion by forming protective Al_2O_3, Cr_2O_3, and SiO_2 scales, respectively. Some of the key characteristics of a successful coating are:

- The ability to resist damage in the desired service conditions (corrosion, erosion, erosion- corrosion, stress-related corrosion problems, etc.)
- The integrity of the coating-substrate interface (an ideal interface would be continuous and free from interfacial stresses)
- The adherence of the coating to the substrate under mechanical and thermal cycles

Several coatings and associated processes are available to protect metallic substrates from a range of corrosive environments. Table 1 (Ref 6) indicates one method of classification of coating processes. Although not exhaustive, the table illustrates an important distinction between two major classes of coatings: overlay and diffusion (surface modified). In the former, the coatings are applied with minimal change to the substrate. In the latter, however, the coating constituents diffuse into the substrate, resulting in chemical and microstructural changes to the substrate surface.

Table 1 Classification of coating processes

Category	Description	Processes
Overlay coatings	Deposition with minimal interdiffusion of coating with substrate	• Hot spraying (flame spraying, plasma spraying, detonation coatings) • Chemical vapor deposition • Physical vapor deposition (thermal evaporation, ion sputtering, ion plating)
Surface modified coatings	Diffusion-induced modification of chemical composition and/or microstructure of substrate	• Pack cementation • Slurry cementation • Metalliding • Hot dipping • Surface alloying (ion implantation, laser surface alloying)

Source: Ref 6

Each coating and its associated processes has features that make it suitable for certain applications and unsuitable for others. The focus in this article is pack-cementation coatings and, in particular, halide-activated pack cementation coatings on nickel alloys, although the principles are generally applicable to Fe- and Co-base alloys.

Halide-Activated Pack Cementation

Halide-activated pack cementation (Ref 7) is a coating process in which the elements to be deposited are converted into halide vapor species. These halide vapors then diffuse through a porous pack to the surface of the substrate to be coated, where they undergo disproportionation reactions resulting in the deposition of the desired elemental species. The coating material then diffuses into the substrate with subsequent modification of the substrate microstructure. A typical pack (Fig. 1) (Ref 8) consists of:

- Filler
- Master alloy
- Activator salt
- Substrate to be coated

Powders of the filler, master alloy, and activator are blended together and placed in a container with the substrate buried in it.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

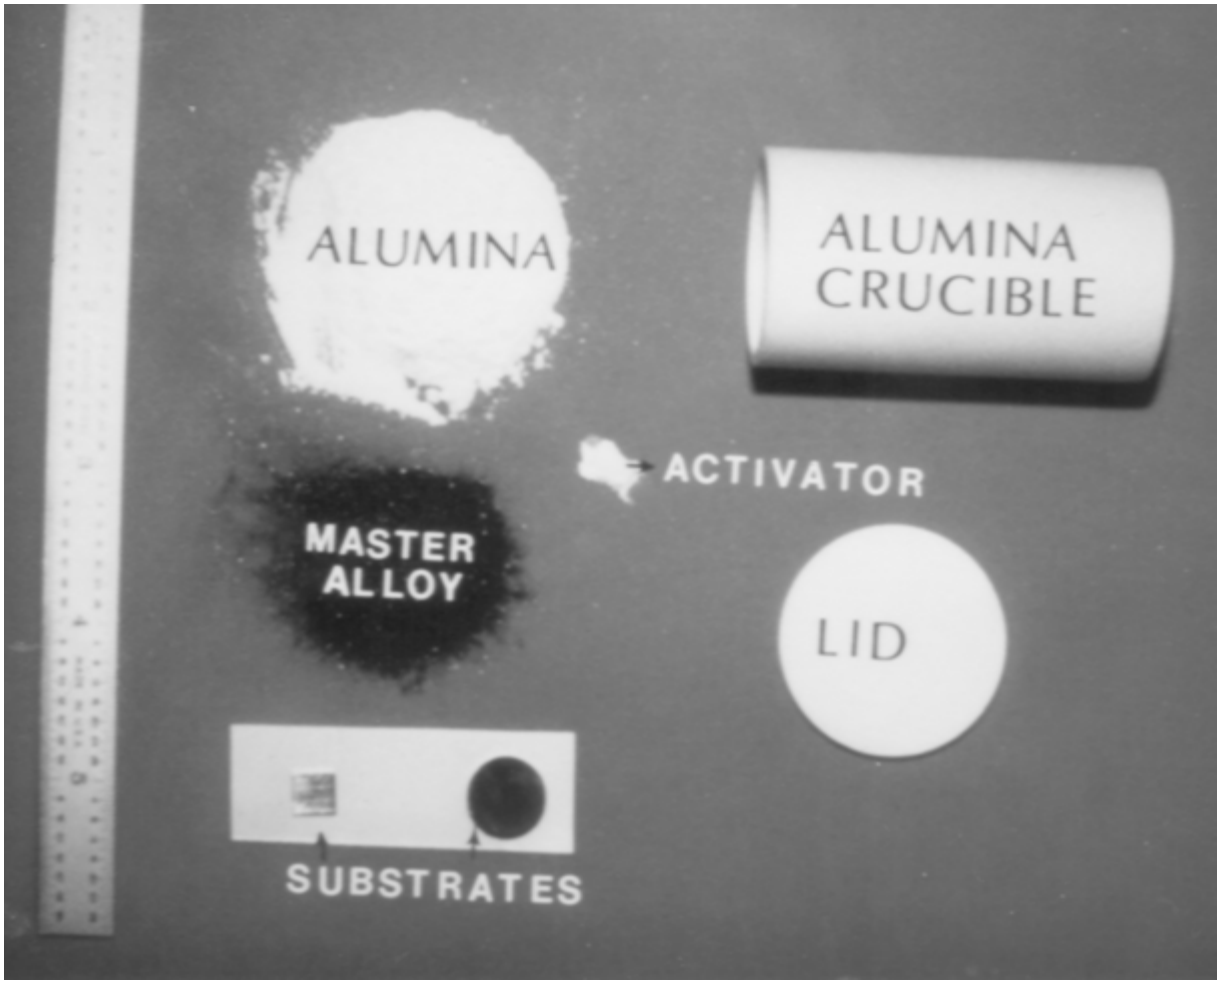

Fig. 1 Typical pack of constituents for a laboratory scale cementation pack

A filler, such as Al_2O_3, allows the active pack constituents (the master alloy and activator salt) to be well distributed. This allows the halide vapors to easily reach the substrate surface, resulting in an overall uniform coating.

The activator salt, a halide compound such as NaCl, $CrCl_2$, NH_4Cl, or AlF_3, reacts with the master alloy to produce gaseous halide compounds of the element(s) to be deposited.

The master alloy, such as Fe-Al or Ni-Al, contains the element(s) to be deposited. However, the elemental forms of Al, Cr, or Si can also be used. The alloy compositions are customized to achieve the desired coating composition

Substrates are typically nickel- or iron-base alloys. Their forms can have a wide range of geometries, for example, flat plates, pipes, and turbine blades. It is important that the substrates are not positioned too close together in the pack, to avoid nonuniformity in the coating thickness.

Pack Cementation Coatings

Vilupanur A. Ravi, California State Polytechnic University, Pomona

Types of Pack Cementation Processes

Pack aluminizing, chromizing, and siliconizing are some distinct classes of pack cementation coating processes. These processes are based on coating the substrate with a single element, that is, aluminum, chromium, or silicon. It is also possible to achieve simultaneous deposition of more than one element.

Pack Aluminizing

The original process, attributed to Van Aller (Ref 9), used a pack consisting of aluminum, ammonium chloride, and graphite powders placed in a drum along with iron or copper substrates. The coating process was carried out around 450 °C (840 °F). Gilson (Ref 10) replaced the graphite powder with aluminum oxide. These early processes remain essentially the same today. The current versions, however, involve a range of master alloys and activators. Other researchers (Ref 11, 12, 13) have classified aluminizing packs, for example, as “high-” or “low-” activity packs. In high-activity packs, aluminum diffuses inward into the substrate (Fig. 2) and forms a solid solution intermetallic such as NiAl with the nickel in the substrate. In low-activity aluminum packs, on the other hand, the outward diffusion of nickel from the substrate dominates. Figure 3 (Ref 11) depicts the microstructure of a nickel-base superalloy aluminized in a low-activity aluminum pack.

Figures 4 and 5 (Ref 12) are schematics of coating formation in low- and high-activity Al packs as discussed in Ref 12. Figure 4(a) shows markers placed on the surface of pure nickel. When exposed to a low-activity aluminum pack, the outward diffusion of nickel is much faster than the inward diffusion of aluminum. Thus the coating grows outward, as indicated by intermediate positions e_1 and e_2. The net outward diffusion of nickel results in the formation of Kirkendall pores close to the original interface. Figure 4(b) (Ref 12) represents the situation for a nickel-base superalloy in which the outward diffusion of nickel leads to corresponding nickel-depleted areas within the alloy. Thus when a layer (position e_1) forms by outward nickel diffusion, a corresponding layer of nickel depletion (position e'_1) forms within the alloy. Likewise, e_2 corresponds to e'_2, e_3 corresponds to e'_3, and so forth. The loss of nickel leads to the formation of intermetallics like NiAl and is accompanied by precipitates like TiC, which are not soluble in the intermetallic matrix. This is further illustrated in Fig. 4(c).

In high-activity aluminum packs, inward diffusion of aluminum dominates as illustrated in Fig. 5 (Ref 12). Figure 5(a) shows the position of the markers originally placed on the free surface of nickel, moving to e_1, e_2, e_3, and so forth, as a function of time; that is, the markers remain on the outer surface. The inward diffusion is accompanied by the formation of an intermetallic like Ni_2Al_3. Figure 5(b) shows the progress of aluminization in a nickel-base superalloy. The markers stay on the outer surface, indicative of the inward diffusion of aluminum. The formation of aluminum-rich Ni_2Al_3 leads to the precipitation of chromium-rich precipitates in the matrix alloy.

Figure 6 (Ref 12) shows the effect of annealing on aluminized nickel (Fig. 6a) and nickel- base superalloys (Fig. 6b). In both cases, the Ni_2Al_3 layer transforms to NiAl. In the case of pure nickel, the conversion of Ni_2Al_3 to NiAl is fairly straightforward. However, in the case of superalloys, this transformation is characterized by precipitates in the outer zone, a central precipitate-free zone, and an inner zone with precipitates similar to those for low-activity aluminum packs.

Others (Ref 14) have shown that the structures in Fig. 2 and 3 are limiting cases with a range of intermediate structures existing due to the variation of the interdiffusion coefficient in the β- NiAl phase of the aluminum-nickel system.

Thermodynamics of Pack Aluminizing. If a pure nickel substrate is aluminized in a pack containing pure aluminum (thermodynamic activity = 1) as the source, and NaCl is the activator, the following equilibria pertain:

$$Al(l) + NaCl(l) \rightleftharpoons AlCl(v) + Na(v) \qquad \text{(Eq 1)}$$

$AlCl_2(v)$ and $AlCl_3(v)$ are also formed in the pack. The most important reaction occurring on the substrate surface is the disproportionation of the metal halide vapors AlCl or $AlCl_2$:

$$2AlCl(v) \rightleftharpoons AlCl_2(v) + \underline{Al}_{Ni} \qquad \text{(Eq 2)}$$

where $\underline{Al}_{Ni}$ indicates Al is in solid solution in the Ni substrate. Direct transfer of aluminum by forming Al(v) occurs only to a very small extent. Displacement reactions with the substrate such as:

$$Ni + 2AlCl(v) \rightleftharpoons NiCl_2(v) + 2Al_{Ni} \qquad \text{(Eq 3)}$$

do not occur because the standard Gibbs energies of formation of the aluminum halides are significantly more negative than those for the nickel halides (Ref 15). Thus, if pure aluminum is used as the source for aluminizing pure nickel, the NiCl and $NiCl_2$ partial pressures are significantly lower than the partial pressures of AlCl, $AlCl_2$, and $AlCl_3$ (per mole of Cl_2) so that nickel does not participate in interchange reactions with aluminum chloride.

The chemical reactions in the pack are only one of a series of steps in pack cementation processes. Walsh (Ref 16) has broken down the pack cementation process into the following steps:

1. Reactions in the pack
2. Gas diffusion through the pack

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

3. Reaction on the substrate surface, which can involve disproportionation of halide vapors, precipitation of activator salt, and/or reactions with the environment and substrate

Therefore, in addition to understanding the thermodynamics, it is also necessary to analyze the kinetics to gain a full appreciation of the process.

Kinetics of Pack Aluminizing. Several models for the aluminizing of nickel and iron-base alloys have been proposed (Ref 17, 18, 19, 20). All of them are based on the existence of a depletion zone.

A kinetic model of pack aluminizing based on the assumption of local thermodynamic equilibrium at both the pack-gas and the substrate-gas interfaces was proposed (Ref 17). The authors also assumed that the transport of gases through the pack was purely diffusional. Instantaneous fluxes of the species to and from the substrate were calculated under conditions of 1 atm total pressure and an activity of aluminum equal to 0.01 at the substrate surface. Figure 7 (Ref 17) shows the model for NaX and NH_4X activated packs where X = F, Cl, Br, or I. The diffusion direction for each species in the depletion zone is obtained by computing the instantaneous fluxes. Then, depending on the temperature and the choice of X, certain pressure gradients (e.g., p_{AlX_3}, $p_{Al_2X_6}$) will be opposite to those shown schematically. Figure 7(a) is a simplified model in which the formation of liquid NaX is neglected. Figure 7(b) is more complete since the liquid NaX film on the substrate is taken into account while computing fluxes. Figure 7(c) is a complete model for NH_4X-activated packs. The direction of the diffusion of AlX_2, AlX_3 and $Al_{12}X_6$ depends on X. In NH_4F activated packs, AlF and AlF_2 diffuse inward while AlF_3 and Al_2F_6 diffuse outward. In NH_4Cl, NH_4B_4 and NH_4I activated packs, AlX alone diffuses inward. In all cases, aluminum deposition in the NH_4X and NaX-activated packs is primarily done by AlX. The NaX(l) condensation on the substrate surface aids in aluminum deposition since there is no requirement for halogen removal by the diffusion of AlX_2 and AlX_3 away from the substrate surface.

The model described in Ref 17 was applied to the aluminizing of the IN 100 superalloy. Loss of alloying elements during the coating treatment, especially chromium, had to be considered. The nickel and chromium can be removed from the surface either in the metal vapor form or by forming volatile halides. The loss of nickel and chromium only by forming a metal vapor was considered. The nickel flux leaving the substrate is negligible while the chromium flux is about 1% of the aluminum weight gain. The loss of nickel by forming a halide would also be negligible, but the loss of chromium by forming chromium halides could make the chromium loss somewhat higher than the 1% used in Ref 17. However, this model is comprehensive and provides an adequate description of the pack aluminizing of superalloys.

Other authors (Ref 18) point out that in a NaX or AlF_3 activated pack, condensation of activators such as NaX(l) or AlF_3(s) on the substrate result in a net flux of activator from the pack to the specimen. Therefore, in addition to an aluminum-depleted zone, an activator-depleted zone forms adjacent to the substrate. If the amounts of activator and aluminum were stoichiometrically comparable, the activator- and aluminum-depletion zones would coincide. However, the amount of activator used in pack aluminizing is much less than the amount of aluminum, and the activator-depleted zone is thus wider than the aluminum-depleted zone (Fig. 8). These researchers have shown that it is possible to maintain a minor difference in total pressure between the pack-gas interface and the substrate- gas interface.

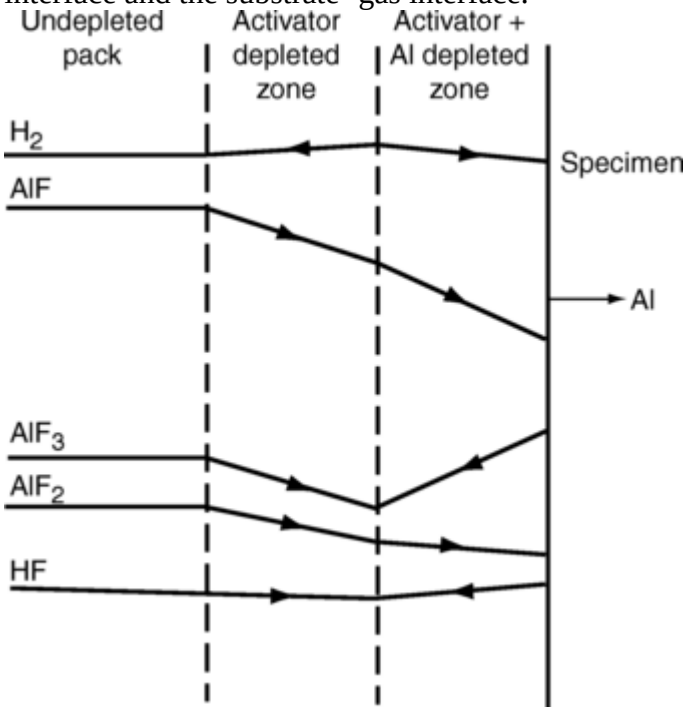

Fig. 8 The Kandasamy-Seigle-Pennisi model with mixed aluminum transport through activator and activator + Al-depleted zones. Source: Ref 18

Another pair of researchers (Ref 19) modified the two models described earlier by including bulk flow of the vapors as an additional feature. This flow occurs due to the difference in the number of moles of gas involved in reactions at the interface. However, no difference in total pressure was allowed, as in the model described in Ref 18.

Other researchers (Ref 20) have developed a more complete model taking into account the total pressure differential (Ref 18 model) as well as the viscous flow of the halide vapors through the porous pack (Ref 19 model) (Fig. 9). Aluminum transport rate constants and partial pressure values for NH_4Cl and AlF_3 activated packs have been calculated. The values obtained fall between those obtained by the models described in Ref 19 and 17, which represent limiting cases for packs with zero resistance to viscous flow (large particle size of the pack powders) and infinite resistance to viscous flow (small particle sizes).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

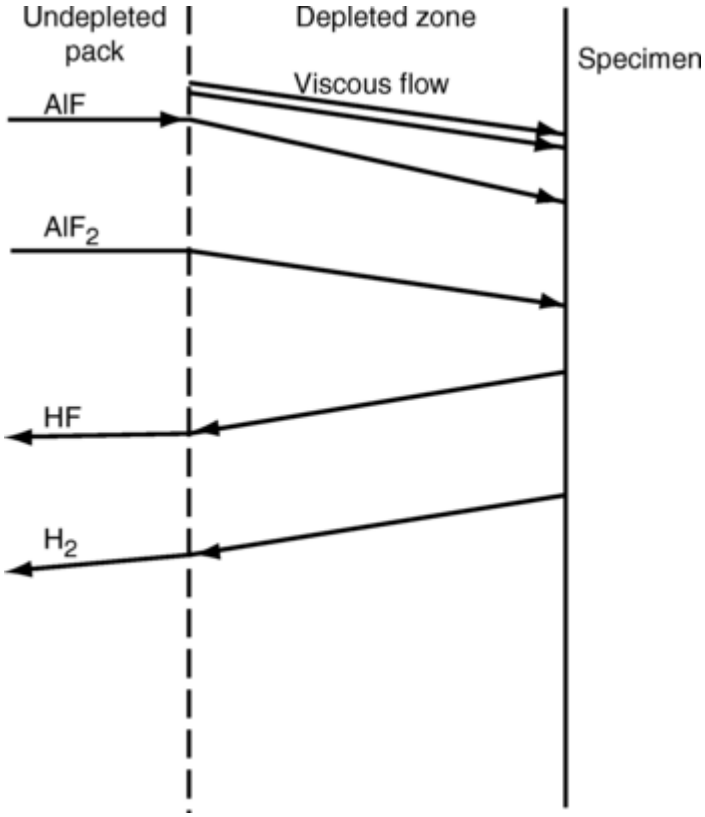

Fig. 9 The Wang-Seigle model for aluminum transport incorporating diffusional flux and viscous flow in the depleted zone. Source: Ref 20

The aluminizing of iron through a fixed porous barrier (ceramic felt wrapping) was studied (Ref 21), and a model based on the following assumptions was proposed: (a) local equilibrium at the pack-gas and substrate-gas interfaces, and (b) rate control by diffusion of gases through a porous barrier surrounding the substrate in series with solid-state diffusion and condensation of activators such as NaCl(l) and AlF_3(s) on the specimen surface. Figures 10 and 11 (Ref 21) indicate the direction of fluxes of the species involved. The authors of Ref 21 did not consider a total pressure difference between the pack-gas interface and the substrate-gas interface but did consider viscous flow. Good agreement between theoretical and experimental values for rates of aluminum gain was obtained for NaCl-activated packs.

Others (Ref 22) have determined the surface aluminum concentration based on the formation of a liquid aluminum-enriched layer of variable aluminum composition on an iron substrate (Fig. 12). The two novel features of this model are: (a) the formation of a thin liquid metal layer of almost constant thickness on the substrate (allowing an aluminum flux balance to be set up), and (b) the concentration of aluminum at the transition boundary layer, M, given by the solidus composition of the iron-aluminum equilibrium diagram. The model prediction in Ref 22 of the surface aluminum concentration agrees reasonably well with experimentally obtained values.

Pack Chromizing

Kelley (Ref 23) is generally acknowledged as the inventor of pack chromizing. The enhanced resistance to aqueous corrosion of these coatings was initially used to improve the surface stability of steam turbine blades. Later, chromium coatings were used to protect gas turbine blades and vanes against hot corrosion (Ref 13).

A typical chromium coating on a nickel-base superalloy, coated in a pack containing chromium, ammonium chloride, and alumina, is a γ- Ni-Cr solid solution with a discontinuous α-Cr outer layer. This outer layer contains Al_2O_3 particles that are attributed in Ref 11 to internal oxidation of aluminum in the substrate. Ref 11 further points out that other investigators (Ref 24, 25) have prevented this by adding aluminum to the chromium source in the pack. In Ref 24, a mixture of nickel, cobalt, chromium, and aluminum powders was preheated in a pack containing NH_4Cl, $MgCl_2$, and Al_2O_3 to approximately 1040 °C (1900 °F) and held it there for 20 h. The pack was then cooled and substrates introduced before reheating to 1040 °C in a hydrogen atmosphere. In Ref 25, the coating treatment was performed in air with chromium and aluminum present in the pack. The aluminum in the pack functions as an oxygen getter and permits the chromium coating to be applied without internal oxidation.

Literature on the structure and properties of chromium coatings for nickel-base superalloys is sparse. References 26 and 27 present structural and kinetic data for chromide coatings on steel, but these are expected to be different for nickel- base alloys.

Thermodynamics of pack chromizing. Hoar and Croom (Ref 28) have suggested that incorporation of chromium into substrates was achieved by one or more of the following reactions:displacement reactions with the substrate

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$CrCl_2(v) + Fe(s) \rightleftharpoons FeCl_2(g) + \underline{Cr} \qquad \text{(Eq 4)}$$

where $\underline{Cr}$ is in solid solution and reduction of halide vapor (in a reducing hydrogen atmosphere):

$$CrCl_2(v) + H_2(g) \rightleftharpoons 2HCl(g) + \underline{Cr} \qquad \text{(Eq 5)}$$

Thermal decomposition of halide vapor is represented as:

$$CrCl_2(v) \rightleftharpoons Cl_2(g) + \underline{Cr} \qquad \text{(Eq 6)}$$

Displacement reactions are important only if the substrate element forms volatile halide vapors of appreciable partial pressure (e.g., iron). Displacement reactions with the substrate such as Ni:

$$Ni + CrCl_2(v) \rightleftharpoons NiCl_2(v) + \underline{Cr}_{Ni} \qquad \text{(Eq 7)}$$

are not expected to occur because the standard Gibbs energies of formation of the chromium halides are more negative than those for the nickel halides (Ref 15, 29). Thus, if pure chromium is used as the source for chromizing pure nickel, the NiCl and $NiCl_2$ partial pressures are lower than the partial pressures of $CrCl_2$ and $CrCl_3$ (per mole of Cl_2) so that nickel is not expected to participate in interchange reactions with chromium chloride.

In Ref 28, it is pointed out that since displacement reactions are insignificant for nickel substrates, a hydrogen atmosphere is essential for chromizing nickel. However, it is possible that a reaction of the type:

$$3CrCl_2(v) \rightleftharpoons 2CrCl_3(v) + \underline{Cr}_{Ni} \qquad \text{(Eq 8)}$$

could provide for chromium transport. Therefore, it should be possible to chromize nickel in an inert atmosphere.

In Ref 30, pure nickel in NH_4Cl-activated packs containing pure chromium was chromized. The investigator correctly points out from free energy considerations that displacement reactions of the type shown in Eq 7 are not responsible for the coating process. The most important coating reaction was attributed to:

$$CrCl_2(v) + H_2(v) \rightleftharpoons 2HCl(v) + \underline{Cr}_{Ni} \qquad \text{(Eq 9)}$$

Once again, the possibility of disproportionation of $CrCl_2$ was not considered.

Another researcher (Ref 14) points out that the presence of HCl in NH_4Cl-activated packs results in a side reaction:

$$Al_2O_3(s) + 6HCl(g) \rightleftharpoons 2AlCl_3(g) + 3H_2O(v) \qquad \text{(Eq 10)}$$

with the inert filler. The $H_2O(v)$ can undergo a further reaction:

$$2CrCl_2(s) + 3H_2O(g) \rightleftharpoons Cr_2O_3(s) + 4HCl(g) + H_2(g) \qquad \text{(Eq 11)}$$

with condensed $CrCl_2$.

Kinetics of Chromizing. Mazille (Ref 30) investigated the kinetics of chromizing pure Ni in an ammonium chloride pack containing pure chromium as the source. He obtained an outer α-Cr layer after chromizing for 16 h at 950 °C (1740 °F). This outer layer is an α-Cr region with an inner single-phase, Ni-rich γ-solid solution. It was estimated that the chromium content of the outer layer exceeded 90% by weight Cr. From the activity-composition plot for chromium in a nickel-chromium alloy, shown in Fig. 13 (Ref 31) this composition is in the two-phase α + γ region and the activity of chromium is approximately 0.96.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

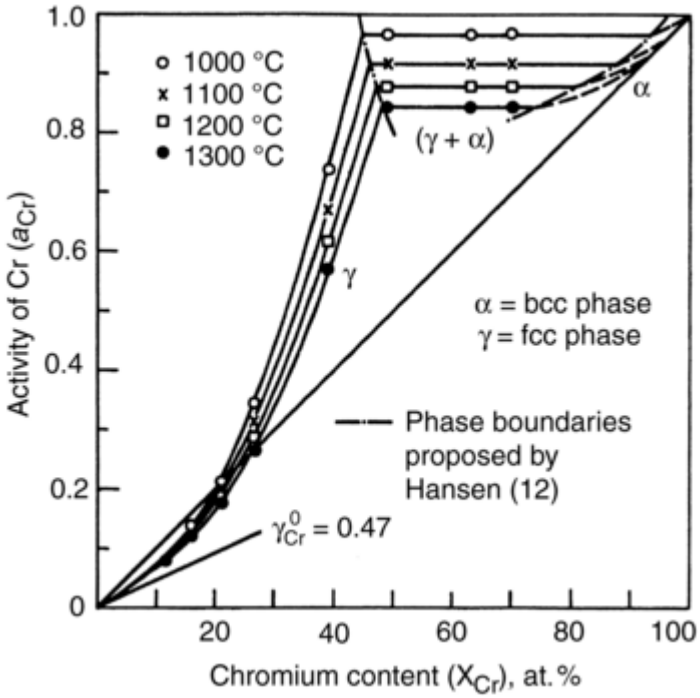

Fig. 13 The activity of chromium in solid nickel-chromium alloys (referred to as solid pure Cr) for various temperatures. Source: Ref 31

From Fig. 14(a), it was concluded that the chromizing of nickel is controlled by the slow solid state diffusion into austenitic nickel and not by transport in the gas or reactions at the substrate surface. The change of slope for the 950 °C (1740 °F) curve is attributed to the slower formation of the external α-phase when compared to the 1000 or 1050 °C (1830 or 1920 °F) treatments. Once α forms, diffusion occurs more rapidly since it is a body-centered cubic structure.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

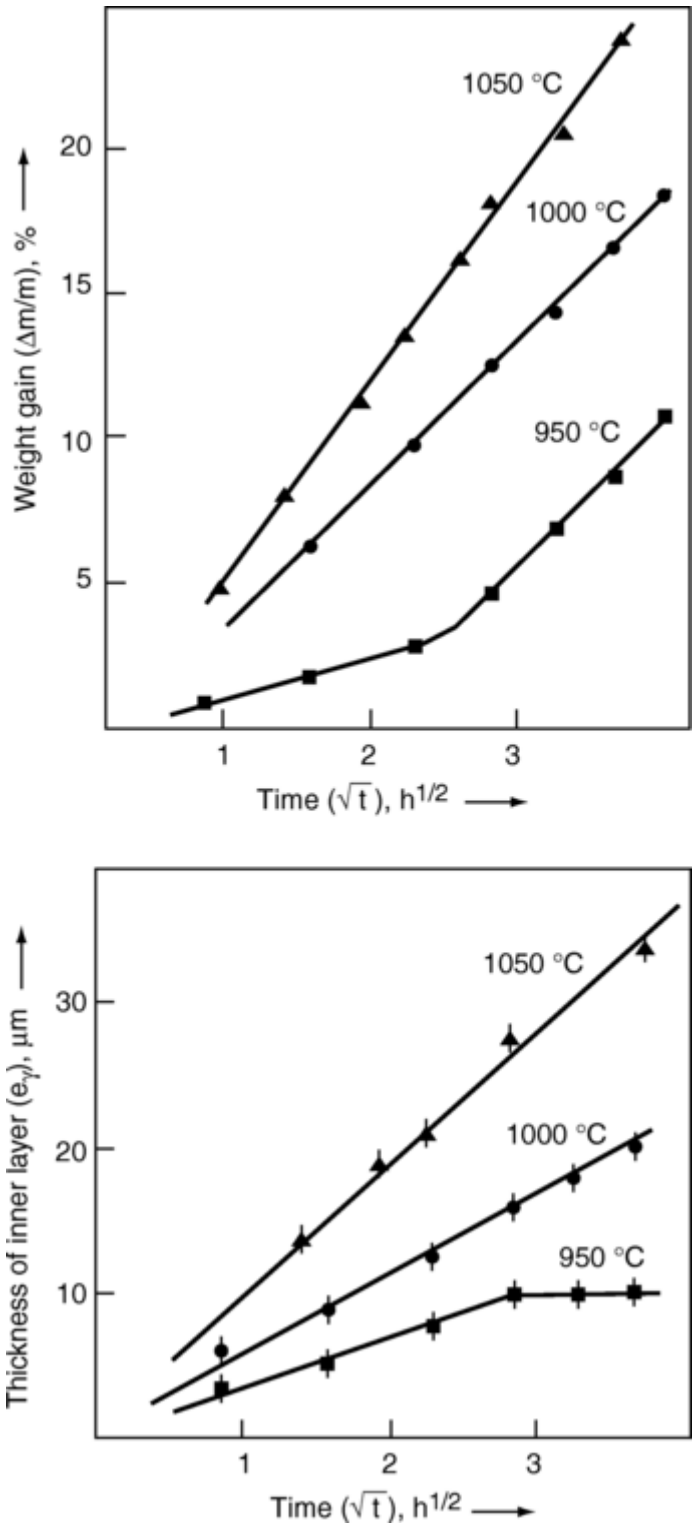

Fig. 14 Kinetic data for the chromizing of pure Ni. (a) The specific weight gain as a function of time at different temperatures. (b) Variation of thickness of the inner layer with time at different temperatures. Source: Ref 30

Figure 14(b) shows the growth rate of the γ- phase. While a parabolic relation is observed at 1000 and 1050 °C (1830 and 1920 °F), the shape of the 950 °C (1740 °F) curve is different. This is attributed to the approximately equal diffusion rates through the γ-α and γ-pure nickel phase boundaries. This suggests that the inner γ-layer remains approximately of constant thickness once the slower growing outer α-layer forms.

Information on the effects of coating variables such as the type of halide activators and fillers on coating characteristics such as microstructure and composition for the chromizing of ferrous alloys can be found in Ref 32.

Simultaneous Chromizing-Aluminizing

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Initial studies in the area of simultaneous chromizing and aluminizing were directed toward a two-step chromizing-aluminizing process. Chromium coatings were initially obtained in a pack containing pure chromium, and the chromized coupons subsequently were aluminized in low- or high-aluminum activity packs (Ref 33).

Galmiche (Ref 34, 35) proposed a technique for simultaneous chromizing-aluminizing of nickel-, iron-, and cobalt-base alloys. The process, called chromaluminization, consists of heating the substrates in a pack containing ultrafine chromium powder (40 wt%), very fine aluminum powder (10 wt%), fine-calcined alumina (49.2 wt%), and ammonium chloride (0.8 wt%) to temperatures in the range 750 to 1200 °C (1380 to 2190 °F). Figure 15 (Ref 34) shows the composition profile of a chromaluminized coating on a nickel-base superalloy. Galmiche explained that chromium is preferentially supplied during the first "phase" of the "chromaluminizing" treatment, while aluminum is preferentially supplied during the second "phase." This is somewhat unexpected because the partial pressures of aluminum halides are significantly higher than those of the chromium halides, and a pack containing a mixture of pure chromium and pure aluminum would thus be expected to aluminize the substrate.

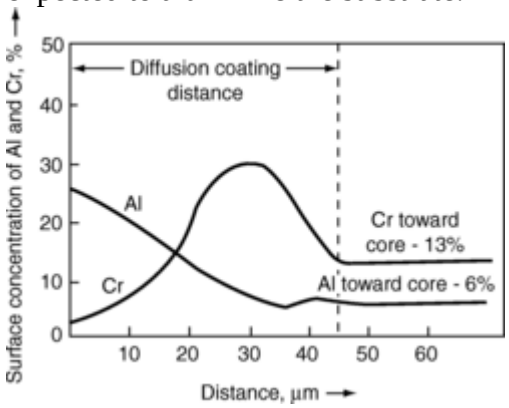

Fig. 15 Concentration profiles of chromium and aluminum in the chromaluminized regions of a nickel-base superalloy. Source: Ref 34

Galmiche and Hivert's patent (Ref 35) reveals that pure Cr (40 wt%) and pure Al (40 wt%) were preheated in a pack containing alumina and ammonium chloride for 1 h in the temperature range 1000 to 1100 °C (1830 to 1210 °F). Under these conditions, aluminum chloride vapor pressures are much higher than the chromium chloride vapor pressures, and it follows that aluminum ought to be deposited on the chromium particles. It is also indicated (Ref 35) that additions of 0.5 to 1.0 wt% AlF_3 to the pack will be advantageous to the coating process. It is known that the AlF_3 is a strong aluminizing agent. It is thus possible that during pretreatment, aluminum is deposited on the chromium particles by AlF_3 and $AlCl_3$ (NH_4Cl-assisted) vapors. During the coating process, a significant amount of $AlCl_3$ vapors are expected to be generated. Furthermore, in the proposed mechanism, the aluminum-coated chromium particles are expected to generate only marginal amounts of chromium-containing vapors. Conditions in the pack are thus expected to be conducive for aluminization, while conserving the chromium content of the alloy. Based on this model, the sharp increase in chromium content in the inner diffusion zone (Fig. 15) can be attributed to outward nickel diffusion and consequent nickel depletion in this region.

Other authors (Ref 16, 36) have pointed out that it is not possible to codeposit aluminum and chromium in a one-step process if pure aluminum and pure chromium are used as the source. Others (Ref 29) have shown that at temperatures in the 1100 to 1500 K (1520 to 2240 °F) range, where most coating operations are carried out, the vapor pressures of the AlCl species (mostly responsible for aluminizing) are orders of magnitude higher than the $CrCl_2$ vapor pressures (mostly responsible for chromizing) in chloride- activated packs using pure aluminum and pure chromium as the sources. They obtained even greater differences in aluminum- and chromium- fluoride vapor pressures in fluoride-activated packs, concluding that at unit thermodynamic activity of aluminum, codeposition of aluminum and chromium is not possible.

A clear perspective on the difficulties of codeposition of aluminum and chromium is obtained by examination of the thermodynamic activities of aluminum and chromium in binary aluminum-chromium alloys.

Others (Ref 37) have determined the activities of aluminum and chromium in binary aluminum- chromium alloys (Ref 38) (Fig. 16). The maximum solubility of aluminum in chromium is 43 a/o aluminum; for aluminum compositions lower than this, the activity of aluminum is much lower than that of chromium in chromium-rich, chromium-aluminum alloys. This highly negative deviation from thermodynamically ideal behavior is

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

demonstrated by the low aluminum activity (0.001) at 9 at.% Al. Therefore, adjusting the composition of a chromium-aluminum master alloy is one of the keys to achieving codeposition. In addition, the choice of the activator is also important.

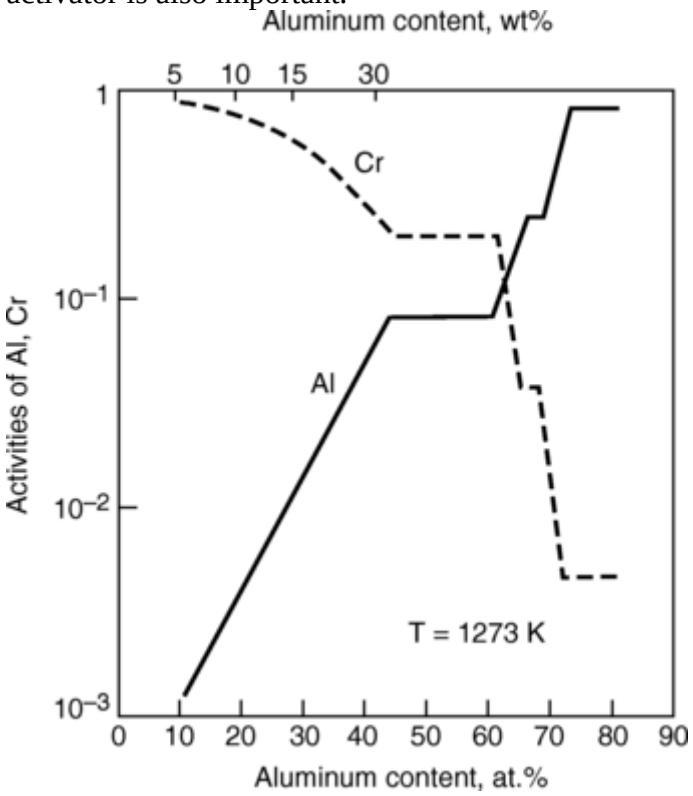

Fig. 16 Activities of aluminum and chromium as a function of the aluminum content of aluminum-chromium alloys at 1273 K (1830 °F). Source: Ref 36, based on data from Ref 37

Still another investigator (Ref 39) has shown experimentally that by choosing a special pack composition, simultaneous deposition of chromium and aluminum into a nickel-base alloy at 1100 °C (2010 °F) is possible. The following reaction is proposed as the basis for codeposition:

$$AlCl_2(v) + Cr \rightleftharpoons 2CrCl_2(v) + Al \qquad \text{(Eq 12)}$$

From Eq 12, it follows that the partial pressure of $CrCl_2$ is given by:

$$p_{CrCl_2} = K_p a_{Cr} p_{AlCl_2} / a_{Al} \qquad \text{(Eq 13)}$$

where K_p is the equilibrium constant, a_{Cr} and a_{Al} are the activities of chromium and aluminum, respectively, and p_{CrCl_2} and p_{AlCl_2} are the partial pressures of the chromium and aluminum chlorides. By reducing the thermodynamic activity of aluminum (a_{Al}) in the pack, one should expect a reduction in the partial pressure of the aluminum halides, thus leading to codeposition of aluminum and chromium.

Ravi et al. (8, 40, 41, 42) have shown that chloride activators and chromium-rich chromium-aluminum master alloys result in chromium-rich chromium-aluminum codeposited coatings on nickel and nickel-base superalloy substrates. They also show that the use of fluoride activators favors aluminum deposition, even with the use of chromium-rich chromium-aluminum master alloys. Detailed thermodynamic calculations and microstructural/compositional analysis are provided.

Other researchers (Ref 43) have identified process conditions (chromium-aluminum master alloy composition, $NaCl/NH_4Cl$ ratios) for achieving simultaneous deposition of chromium and aluminum at temperatures on the order of 1100 °C (2010 °F) onto a nickel-base superalloy. They established that codeposition of chromium and aluminum can be achieved with chromium-rich chromium-aluminum master alloys and mixed activator ($NaCl + NH_4Cl$) packs. Also studied were the kinetics and nonequilibrium effects in the coating process (Ref 44, 45). One of the key findings was that the master alloy composition and activator-mixture content change during the coating process. Based on these findings, the authors have proposed a time-dependent mechanism for chromium-aluminum codeposition.

Other authors (Ref 46) have developed a single-step process for chromium/rare-earth (RE) modified and RE-doped aluminide coatings by using appropriate chloride activators and chromium-aluminum master alloys. A model for coating formation based on their analyses of the microstructures, phase equilibria, and kinetic data

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

was proposed. The results of experiments aimed at reducing pack entrapment (Al_2O_3 and RE oxide particles) in the coatings have been discussed. Results from environmental testing of these coated coupons under different conditions, that is, isothermal oxidation at 1100 °C (2010 °F) in air, cyclic oxidation at 1100 °C in static air, and type 1 hot-corrosion behavior at 900 °C (1650 °F) in 0.1% SO_2/O_2 gas mixtures have been discussed (Ref 47). In general, the Cr/RE- doped coatings resulted in improved performance relative to RE-free coatings.

Another pair of researchers (Ref 48) coated a 2.25 Cr-1Mo low alloy steel with RE modified chromium-aluminide coating. They report improved cyclic oxidation performance of these steels in air at 800 °C (1470 °F) relative to the uncoated alloy.

Kim et al. (Ref 49) described a new pack process for the codeposition of chromium and aluminum. In this process, low-alloy steels were coated in a pack containing aluminum and Cr_2O_3 powders blended with an activator salt mixture of NaCl + NH_4Cl. The authors propose that chromium halides are produced as a result of reactions between the aluminum or aluminum halides and the Cr_2O_3, leading to deposition of chromium along with the expected deposition of aluminum by aluminum halides created by reaction between the aluminum and the activator salts. The authors present microstructures and compositional profiles, although detailed thermodynamic evaluations have not been carried out, and have also extended the work by coating austenitic stainless steels (Ref 50).

Pack Siliconizing

Another researcher (Ref 51) siliconized pure iron and steels in packs containing pure silicon and NH_4Cl as the activator. Gorbunov (Ref 52) has reported microstructural and kinetic data for siliconized iron and steel. The siliconizing was performed using pure silicon powder and gaseous chlorine. Recently, Hsu and Tsai (Ref 53) reported that siliconized AISI type 310 stainless steel (UNS S31000) has shown better resistance to high-temperature corrosion in air and in reducing gases in comparison with the base alloy. However, there are several problems with siliconized coatings. It has been pointed out (Ref 54) that silicon can cause embrittlement of the substrate. In addition, silicon can form low- melting oxide eutectics with iron and low-melting metallic eutectics with nickel substrates. Therefore, industry has not widely adopted siliconizing due to some of the aforementioned problems.

Simultaneous Chromizing-Siliconizing

The codeposition of chromium and silicon onto iron-base alloys by halide-activated pack cementation has been reported (Ref 55). Different binary chromium-silicon master alloys, ranging from a minimum of 10 wt% Si to a maximum of 40 wt% Si, and different activators (NaCl, NaF, $FeCl_2$, and $CrCl_2$) were used in the study. Its authors performed a comprehensive computer-assisted thermodynamic analysis to obtain insights into pack chemistries. Using these computations as a guide, they selected appropriate pack chemistries and presented the microstructures of coated plain carbon, low-alloy, and austenitic steels. The authors report that selected coated coupons performed very well in cyclic oxidation and in oxidation-sulfidation tests.

Germanium- and boron-doped silicide coatings on niobium- and titanium-base alloys have been studied in great detail (Ref 56, 57). The thermodynamics, kinetics of growth, and oxidation studies in these materials are reported. Cockeram and Rapp (Ref 58) also report on the thermodynamics, microstructural analysis, and kinetics of titanium silicide coatings formed on commercially pure titanium. Others (Ref 59) have studied the deposition of aluminide and silicide coatings on γ-TiAl.

Simultaneous Aluminizing-Siliconizing

A pack cementation process for the codeposition of aluminum and silicon onto a low carbon steel has been developed (Ref 60). The pack contains aluminum and SiO_2 powders and is activated by a NaCl+KBF_4 mixture. Compositional profiles and microstructures of the coated coupons are reported. The authors propose that the following reaction is responsible for silicon deposition, although no detailed thermodynamic analysis is provided:

$$3SiO_2 + 4Al \rightleftharpoons 3Si + 2Al_2O_3 \qquad \text{(Eq 14)}$$

Xiang et al. (Ref 61) report that codeposition of aluminum and silicon onto γ-TiAl is possible in packs containing aluminum and silicon powders (in elemental form) and NH_4Cl and $AlCl_3$ activators. They have

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

shown microstructures that contain an outer silicide layer and an inner aluminide layer and propose a sequential mechanism, that is, aluminum deposition followed by silicon deposition, to explain the two-layer morphology. They also report that results of oxidation tests were favorable.

Electroplated Coatings

Revised by Ted Mooney, Finishing.com, Inc.

Introduction

ELECTROPLATED COATINGS can be very effective in reducing the cost of corrosion, estimated in 2001 to be $276 billion, or 3.1% of the U.S. gross domestic product. Even when metallic coatings are applied to a substrate to provide decorative effects or to enhance material properties, such as wear or electrical contact resistance, the corrosion performance of the coating- substrate system must be carefully considered to avoid future degradation. Metallic coatings can be very useful in providing optimal properties for a part not obtainable if it were fabricated from a single material.

The overall properties of coated parts are determined by the properties of the coating itself and by defects in the coating. The understanding of how defects in a coating affect the corrosion performance is critical in designing an effective coating system.

Electroplating is the electrodeposition of an adherent metallic coating on an electrode to secure a surface with properties or dimensions different from those of the base metal (Ref 1). Electrodeposits are applied to metal substrates for one or more of the following reasons: decoration, protection, corrosion resistance, chemical inertness, wear resistance, buildup of substrate dimensions, electrical properties, magnetic properties, solderability, reflectance, and reduction of friction (Ref 2). For example, decorative and protective plating are combined in such applications as steel automobile bumpers, trim items made of zinc die castings or steel, trim items on large and small appliances, costume jewelry, electronic circuits, piano strings, construction and architectural hardware, plumbing fittings, electrical contacts, plastic items, and magnetic memory devices (Ref 2).

This ability to be decorative as well as protective to substrates distinguishes electrodeposited coatings from metallic coatings applied by hot dipping or spraying. Metallic luster, achieved by bright plating or by polishing after plating, lends a distinctive appearance not provided by other types of coatings. However, corrosion resistance is the primary reason for the use of electrodeposited coatings. Electrodeposited coatings are also applied to protect substrate metals. Examples of this application include:

- Tin, as well as chromium, plating of steel strip for food packaging and other container uses
- Electrogalvanizing, or zinc plating, of steel strip, sheet, stampings, forgings, wire, and screw machine products
- Zinc and cadmium plating of fasteners and other hardware items
- Chromium plating of gun bores

Electrodeposits are used to enhance properties other than corrosion protection. For example, many fasteners are coated with a bright cadmium or zinc deposit supplemented with a clear or colored chromate conversion film. This results in coatings that are both protective and decorative. Chromium plating, electroless nickel plating, and anodizing of aluminum (not actually an electroplating process, but an electrochemical process widely practiced at electroplating installations) impart very hard and exceptionally wear-resistant surfaces while simultaneously deterring corrosion.

This article discusses the various factors that affect the corrosion performance of electroplated coatings, the effects of environment and the deposition process on substrate coatings, and the electrochemical techniques capable of predicting the corrosion performance of a plated part. Because the practical aspects of electroplating are covered in such publications as *Surface Engineering*, Volume 5 of the *ASM Handbook* (1994) and Ref 3, 4, 5, 6, this article is primarily concerned with the corrosion resistance of electrodeposited coatings. An exception is the discussion of mill- applied finishes, about which the open literature is sparse and limited in scope. Special attention is given to the design of coating systems for optimal protection of the substrate. An ideal electroplated

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

coating system is defined. Finally, attention is given to controlled weathering tests and accelerated tests used to predict and determine the relative durability of the coating.

Idealized Coating

Coatings are either anodic or cathodic to the substrate. Only a very rough idea of which situation applies can be obtained from the electromotive force (emf) series (Table 1). Coatings that are anodic to a substrate in one environment may be cathodic to the same substrate in a second environment. The environment itself may change from the surface of the coating to one that exists within any defects, such as scratches, cracks, or corrosion pits. These defects are particularly important if the coating is cathodic to the substrate; in this case, if the substrate becomes exposed, rapid corrosion of the substrate may occur as it attempts to protect the coating. If the coating is anodic to the substrate, defects are somewhat less important, although they still must be considered. Thus, if the substrate becomes exposed, it will be protected by the corrosion of the coating. However, if the corrosion should proceed to such an extent that a large area of the substrate is exposed, the coating will lose its effectiveness, because the electrical resistance of the substrate limits the area that the coating can protect.

Table 1 Electromotive force series of metals and alloys

Solution concentration: 1 *N*; temperature: 25 °C (75 °F)

Metal	Ion	Standard reduction potential (E_0), V
Calcium	Ca^{2+}	-2.87
Sodium	Na^{+}	-2.71
Magnesium	Mg^{2+}	-2.37
Aluminum	Al^{3+}	-1.66
Zinc	Zn^{2+}	-0.763
Chromium	Cr^{3+}	-0.71
	Cr^{6+}	-0.56

Iron	Fe^{2+}	-0.44
Cadmium	Cd^{2+}	-0.40
Nickel	Ni^{2+}	-0.25
Tin	Sn^{2+}	-0.136
Lead	Pb^{2+}	-0.126
Hydrogen	H^{+}	0
Copper	Cu^{2+}	0.337
	Cu^{+}	0.521
Silver	Ag^{+}	0.799
Platinum	Pt^{4+}	0.90
Gold	Au^{+}	1.68

Source: Ref 2

The nature of any corrosion products formed also must be taken into account. For example, in industrial environments, zinc is more protective of steel than cadmium is because the zinc sulfate ($ZnSO_4$) corrosion product formed has a lower solubility than cadmium sulfate ($CdSO_4$); $ZnSO_4$ thus provides a blocking action to reduce subsequent corrosion. This situation is reversed in marine environments, in which the corrosion products are more likely to be carbonates and chlorides. Zinc produces more soluble corrosion products than cadmium does in this environment. The most desirable situation is to have the coating anodic to the material beneath it and at the same time to have a very low corrosion rate.

This general rule has been exploited to a high degree of sophistication by the automotive industry. Chromium-plated exterior steel parts have a coating system consisting of several layers of metals, each of which is anodic to the layer beneath it. There are accurate lifetime predictions based on the electrochemical potential differences and the thicknesses of the layers. Multilayer corrosion standards that ensure that the coatings meet specifications are available from the National Institute of Standards and Technology (NIST). Even the chromium layer has been designed to be microcracked or microporous to spread the corrosion reactions over a large area. Corrosion is then distributed over a large area, and localized pitting is minimized. This is discussed in more detail in the section “Applications for Electrodeposited Coatings” in this article.

Substrates

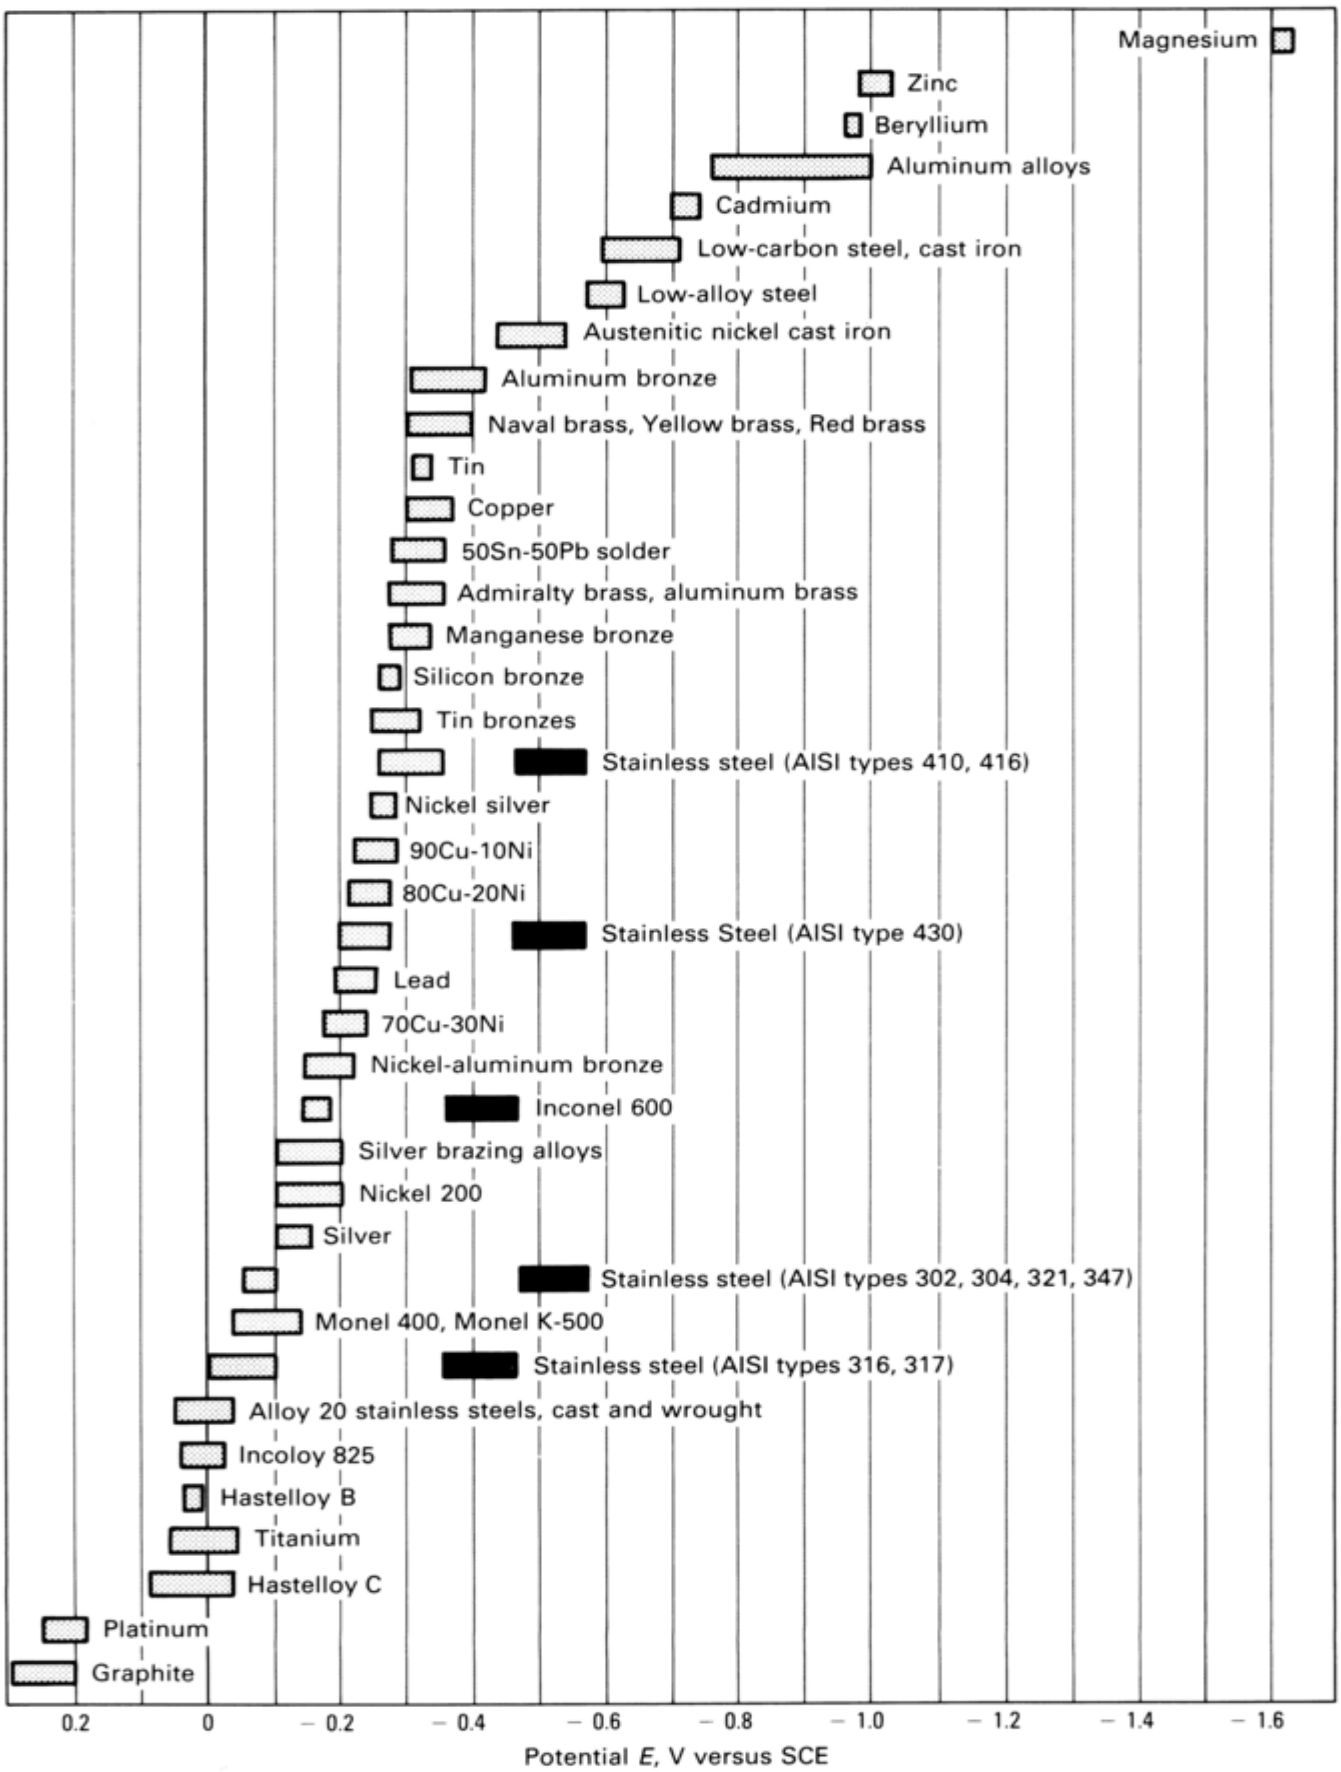
The emf series is a table that lists in order the standard electrode potentials of specified electrochemical reactions (Ref 1). The potentials are measured against a standard reference electrode when the metal is immersed in a solution of its own ions at unit activity (Table 1).

Similarly, the galvanic series is a list of metals and alloys arranged according to their relative potentials in a given environment (Ref 1). Figure 1 shows a galvanic series of commercially used metals and alloys in seawater. The positions of metals and alloys in a galvanic series—and the corrosion behavior of metals and alloys—depend on the specific environment to which the materials are exposed. Therefore, there are as many galvanic series as there are aqueous environments. Generally, the relative positions of metals and alloys in both emf and galvanic series are the same. An exception is the position of cadmium with respect to iron and its

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

alloys. In the emf series, cadmium is cathodic to iron, but in the galvanic series (at least in seawater) cadmium is anodic to iron. Thus, if only the emf series were used to predict the behavior of a ferrous metal system, cadmium would not be chosen as a sacrificial protective coating, yet this is the principal use for cadmium plating on steel.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 1 Galvanic series of metals and alloys in seawater. Alloys are listed in order of the potential they exhibit in flowing seawater; those indicated by the black rectangle were tested in low-velocity or poorly aerated water and at shielded areas may become active and exhibit a potential near -0.5 V. Source: Ref 7

The importance of knowing the position of substrates in the emf and a specific galvanic series is frequently overlooked. The sole consideration is often the position of the protective coating in these series. It is prudent, however, to select a coating as close as possible in potential to the substrate in moist environments, because few coatings are completely free of pores, cracks, and other defects. Even if a coating does start out defect free, scratching, normal wear, or gouging can change this condition. Accordingly, in a corrosive environment, plated components present at least two (not one) metal to the hostile galvanic-corrosion forces (see the section "Electrochemical Predictions of Corrosion Performance" in this article).

Cleanliness of the Substrate

Regardless of the composition and metallurgical condition of a substrate, its surface must be free from soils and oxides before being plated. The ASTM International Committee on Selection of Cleaning Processes classifies soil into six groups: pigmented drawing compounds, unpigmented oil and grease, chips and cutting fluids, polishing and buffing compounds, rust and scale, and miscellaneous surface contaminants, such as lapping compounds and residue from magnetic- particle inspection. Cleaning methods are discussed in Ref 2, 3, 4, 5, 6. Although these methods are beyond the scope of this article, the point is made that unclean substrates often defeat the purpose of electrodeposited or other plated coatings.

Freedom from water break after the activating rinse and before immersion of a part in the plating tank is an essential prerequisite for satisfactory plating. Water break is defined as the appearance of a discontinuous film of water on a surface, signifying nonuniform wetting and usually associated with surface contaminations (Ref 1). A false reading of freedom from water break often occurs if the inspection is made after the rinse following a surfactant-laden alkaline cleaner. This misleading conclusion is nullified by inspection after acid dipping and rinsing.

Knowledge of the Nature of Substrates

Before designing or applying a protective coating to a metal, the plater must know the nature and essential properties of the substrate. Generally, a substrate is known to be ferrous or nonferrous, but these generic terms are inadequate. For example, there are thousands of ferrous metals and alloys, ranging from cast iron (high carbon) to ingot iron (very low carbon) and the entire range of carbon and alloy steels. Also, the microstructure, hardness, yield and tensile strengths, and internal stress of the substrate have major influences on the protective quality and durability of plated coatings. High-strength, high-carbon, high-hardness steels are susceptible to hydrogen embrittlement when subjected to alkalies, acids, and plating processes. Aluminum and zinc alloys and, to a lesser extent, chromium are amphoteric (soluble in both acidic and alkaline solutions). Accordingly, these metals must be treated with inhibited solutions to prevent chemical attack. Methods of determining the nature and condition of the substrates are described in the following sections.

Information on the Substrate. A design engineer, draftsman, engineer, or project manager in an organization with in-house plating facilities should have detailed information on the analysis, microstructure, and mechanical properties of the substrate. In a plating job shop, the customer should have someone informed on the subject. The plater is advised to ask these potential sources for as much information about the substrate as can be obtained.

Engineering Drawings and Associated Lists. Study of engineering drawings, parts lists, bills of materials, and pertinent manuals will usually clear up questions concerning the substrate submitted for plating. The bill of material, for example, may simply specify 1095 steel. This informs the plater that he is dealing with a high-carbon (0.95% C) and steel that can be heat treated to a high degree of hardness (for example, 50 to 60 HRC). This alerts the plater to be concerned with hydrogen embrittlement. As another example, if a drawing or associated list specifies aluminum alloy 6061-T*x*, the plater can deduce that the substrate is heat treatable by precipitation hardening to various tempers (degrees of hardness). Such an alloy is subject to developing a smut or to leaving a heavy oxide layer after being alkaline etched or cleaned. An experienced plater will recognize this and will know to treat the cleaned and etched part in a desmutter/deoxidizer in the treating sequence before undertaking the plating process.

مرجع مهندسی مواد و متالورژی

Chemical Spot Tests. A simple chemical spot reaction test is documented in Ref 6 and 7. This method is based on the use of a magnet and five chemicals. Three of the chemicals are different concentrations of nitric acid (HNO_3), another is concentrated hydrochloric acid (HCl), and the fifth is a 10% solution of potassium ferricyanide ($K_3Fe(CN)_6$). Although it tests for only one element at a time, this simple test distinguishes among a large number of commonly used steels and nickel alloys.

Electrolytic Spot Test Method. This is a commercially available method, complete with chemicals, a power source, and instructions. The operation is divided into four steps. First, a test paper moistened with a conductive solution is placed in contact with the unknown metal. Second, using a direct-current (dc) power source with the unknown metal connected to the anode terminal (+) and a metal probe to the cathode terminal (-), a small amount of the unknown metal is dissolved into the test paper. Dissolution is brought about by electrolytic action when the dc current is switched on. Third, a few drops of a specific color developer are added to the wet spot on the paper. The developer reacts chemically with a characteristic component of the dissolved metal. Fourth, almost immediately, a color appears on the paper if a specific suspected alloying element is present in the unknown. This method is semiquantitative because the relative color intensity is proportional to the amount of alloying element or major metallic constituent. By comparing the results of the unknown with those of standard alloy samples, the nature of the unknown substrate can be adequately identified.

Electronic Alloy Identification. This method is quite rapid and depends on the Peltier Effect (also the basis of the thermocouple). If a current of electricity is sent through a circuit containing two dissimilar metals, heat is emitted at one junction and absorbed at the other junction. A characteristic voltage (potential) is generated at the thermocouple junction that causes an electrical current to flow. This voltage varies with the metals that constitute the couple. The electronic alloy identification meter operates on this principle. It measures the voltage generated by the action of a file of known composition scratched along the surface of an unknown alloy. The file acts as the positive meter input probe, with a clip-on providing negative reference. In a commercially available apparatus, the thermocouple voltage is shown on a battery-powered digital display. This voltage is characteristic of specific alloys or classes of alloys. Again, the instrument can be calibrated against known alloy specimens that are sold as standards.

Physical and Mechanical Properties of Substrates

The susceptibility to corrosion of a plated substrate depends on physical properties and mechanical condition. For example, surface profile (roughness, presence of scratches, pits, lapped metal, and so on) can profoundly affect the durability of plated ware. Some of the harmful effect can be avoided by mechanical or electropolishing, polishing and buffing, shot peening, or glass beading. Internal stresses can also be harmful. These may dictate heating for stress relief or shot peening or glass beading to convert surface tensile stresses to compression. The physical properties of a substrate, particularly at the surface, are often as important to the metal finisher as its composition. Porosity, hardness, melting point, coefficient of thermal expansion, and permeability to hydrogen (nascent, or atomic, and gas) are vital to many operations. Porosity of substrates, particularly in castings and sintered powder metal compacts, causes many problems because of the difficulty of rinsing processing solutions. Capillary action tends to hold solutions with forces that defy normal rinsing efforts. This results in spotting out of corrosive liquids, which appear as stains and corrosion products on the plated surface. It also causes contamination of processing baths.

Some surface irregularities of substrate can be compensated for by the leveling properties of specially formulated plating solutions. Leveling action is the ability of a plating solution to produce a surface smoother than that of the substrate. The property of the plating solutions that produces leveling is also referred to as microthrowing power.

Another property of substrates that can cause difficulties is susceptibility to hydrogen absorption. High-carbon and, particularly, hardened steels and titanium are susceptible to embrittlement when processed by methods that subject them to atomic or gaseous hydrogen. Recognizing this weakness of such substrates, the designer or specifier of plating sequences must select alkaline cleaning and oxide removal (pickling agents, activators) procedures that lessen or avoid hydrogen evolution. Mechanical cleaning and mechanical plating (also known as peen plating) are examples of the methods used to avoid hydrogen embrittlement. Because total avoidance of hydrogen evolution is often not possible, a step or steps must be added to the plating sequence to remove hydrogen. This usually consists of baking plated parts at low temperatures (205 °C, or 400 °F) to release absorbed hydrogen. Time and temperature is also an important variable in ensuring the release of hydrogen and restoration of the mechanical properties of the plated substrate.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Substrate metals that have been heavily worked by such operations as deep drawing, swaging, polishing and buffing, grinding, machining, forging, and die drawing often come to the plating shop with a damaged layer on the surface. This heavily worked layer is termed a Beilby Layer in honor of Sir George T. Beilby, who stated that this layer was amorphous or vitreous rather than crystalline. He compared this weak, somewhat brittle layer to substances that resemble the glasslike form assumed by the silicates when they are solidified from the molten state (Ref 8). X-ray analyses in later years proved that severe cold working causes fragmentation of crystals into particles of different orientations, but that the surface metal is not vitreous or amorphous. However, this smeared, shattered layer is inherently low in ductility and fatigue strength and is therefore a weak foundation for plated coatings. This is particularly true of metal objects that require a surface of substantial corrosion resistance and high mechanical properties as well as metal objects that will be further formed or distorted in service. To avoid the weakness introduced by such layers, abrasive cleaning, machining, or electrolytic polishing are required to remove them before plating.

Stresses in Substrates

Substrates with locked-in stress reduce the corrosion resistance of electroplated coatings relative to the same coating on an annealed substrate. Stressed metal is anodic to annealed or lesser-stressed metals and is therefore more prone to corrosion in unfavorable service conditions. Substrates with flaws on the surface, stress-raising or stress-localizing scratches, or abrupt changes in section are less resistant to corrosion than smooth, streamlined parts. The coefficients of thermal expansion of the coating and substrate should also be matched as closely as possible to minimize stresses caused by differential expansion during temperature cycling.

Stress-Corrosion Cracking of Substrates

Stress-corrosion cracking (SCC) is a cracking process that requires the simultaneous action of a corrodent and sustained tensile stress. Certain alloys are susceptible to SCC when subjected to certain corrosive environments. Examples are copper alloys, such as Cu-30Zn (cartridge brass), and nickel-chromium alloys. Ammoniacal materials, such as aqueous ammonia (NH_4) and amines, produce such failures in stressed copper alloys. Halides, such as chlorides and bromides, attack certain nickel-chromium alloys with this type of corrosion.
The basic characteristics of SCC are summarized in Ref 9. There is no available evidence that plated coatings on substrates susceptible to SCC will prevent its occurrence. Stress relief of susceptible alloys is often adequate for avoiding SCC. For example, brass cartridge cases, which are made by a deep-drawing process (leaving high residual stress), are stress relieved in a temperature range that produces recovery without recrystallization. Stress relieving at a higher temperature would produce recrystallization and an unacceptable reduction in mechanical properties. Avoidance of the use of SCC-susceptible alloys in known hostile environments is another approach to avoiding this mode of failure, but this is not always feasible. For example, for the brass cartridge case cited previously amine stabilizers in the smokeless powder propellant obviated control of the environment; therefore, stress relief was required. However, use of SCC-susceptible metals in corrosion-cracking environments should be avoided whenever possible.

Electroplated Coatings

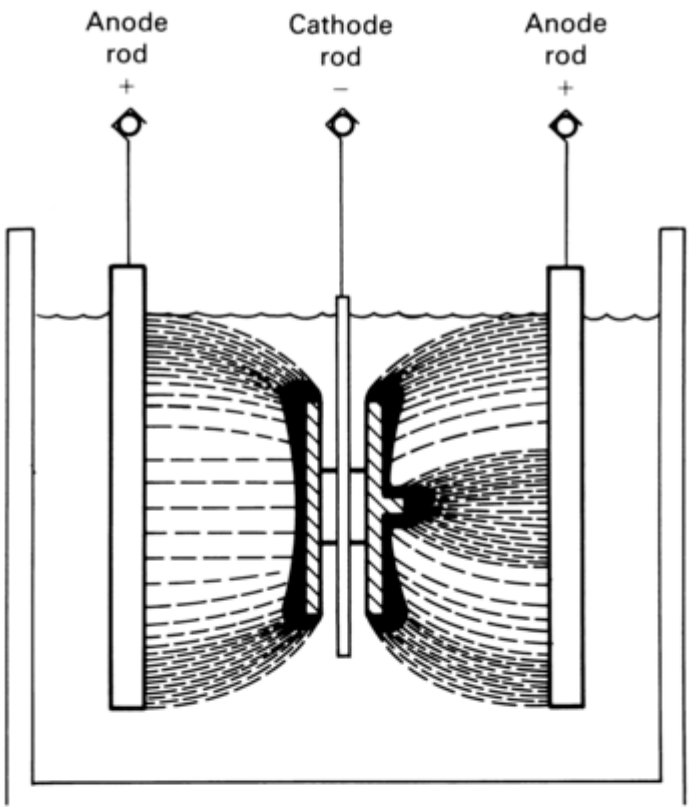
Revised by Ted Mooney, Finishing.com, Inc.

Design for Plating

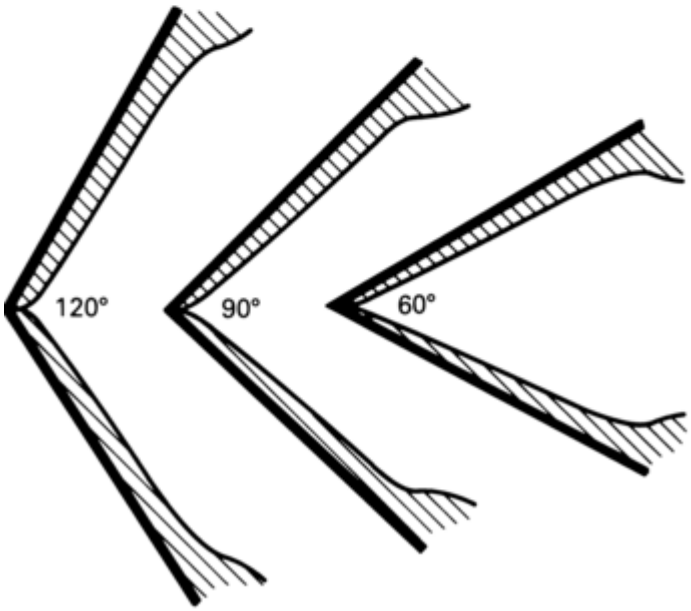
Much can be done at the design stage to improve the plateability of metal stampings, castings, forgings, and extruded shapes. In doing so, the corrosion protection afforded by the plating can be enhanced. Corrosion resistance of a plated object depends on coating thickness and distribution, and these factors depend largely on the design of the parts. ASTM B 507 (Ref 10) covers practices for the design of articles to be electroplated on racks with nickel, but its significance goes beyond nickel plating. It also applies in most respects to all rack-plated coatings. The general principles of design are discussed in Ref 10, which states that the electrodeposition of one metal onto another follows a pattern such as that exemplified in Fig. 2, showing current distribution and the distribution of the resultant electrodeposit (Fig. 2).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی



(a)



(b)

Fig. 2 Current distribution (a) and effect of substrate geometry (b) on thickness of electroplated nickel deposits. For the 120° substrate in (b), the ratio of average coating thickness to minimum coating thickness is 1.9; for the 90° substrate, 2.7; and for the 60° substrate, 3.3. Source: Ref 10

Distribution of the deposit will vary slightly as a function of bath type, additives, current density, and temperature. The coating is preferentially deposited at protuberances, sharp corners, edges, fins, and ribs on the component being plated; to avoid coating buildup, these areas should be rounded with a minimum radius of 0.4 mm (0.015 in.). A 0.8 mm (0.03 in.) radius is preferable. Conversely, the base of any cavity, recess, or depression in the component being plated will be deficient in plate thickness; these features should be designed

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

to avoid sharp fillets. In general, such features should be designed so that the ratio of width to depth of the depression is held to a minimum of 3, and the minimum radius at the edge and base of an indentation should be one-fourth of the depth of the indentation. When sharp angles are required for functional purposes, the electroplater cannot be expected to meet minimum coating thickness requirements in these areas and corrosion resistance may be inadequate.

When designs cannot be changed, electroplaters resort to one or more of the following methods to overcome the aforementioned difficulties: provision of inside anodes, use of thieves or robbers (nonconductive shields that slow or prevent deposition) to lower the cathodic current density at protuberances, bipolar electrodes, changing electroplating baths to ones with greater covering power, and switching from electroplating to autocatalytic (electroless) plating. This last method is widely used on parts that cannot be properly plated by electrodeposition. The limitation is that the most prevalent coating applied autocatalytically—electroless nickel—deposits an alloy of nickel and phosphorus (phosphorus content varies with the solution used and the deposition condition), not unalloyed nickel. There is also an economic disadvantage in switching to these processes. However, in most cases in which electroless processes have been adopted, they have been specified for reasons other than merely to compensate for part designs that cannot be readily electroplated with uniform coatings.

An article should not be designed for plating, but rather to perform its intended function (Ref 11). If the part is successfully designed, provision will have been made for corrosion resistance, hardness, lubricity, decorative appeal, or whichever required property the finish process is to supply. Function, fit, form, and aesthetics—the major dictates of design criteria—often take precedence over the practicality of corrosion prevention by plated coatings; this need not be the case. Design manuals must be instructional with regard to the effects of geometry on function, and designers should be taught these principles.

Additional information on design for electroplating is available in Ref 12. Table 2 lists proper and improper designs for various features of electroplated components. Plating of relatively small parts in rotating containers is termed barrel plating. This differentiates it from rack plating, in which individual parts are held in a rack or fixture during plating. Fastening hardware, such as nuts, bolts, washers, screws, and studs, are barrel plated, as are numerous critical electrical and electronic components. Many of these parts are as important from the corrosion resistance standpoint as rack-plated parts are—perhaps more so because such parts as fasteners and connectors are used in, and therefore coupled to, other materials. This raises the problem of galvanic corrosion.

Table 2 Influence of substrate design features on electroplateability

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Feature	Poor design	Influence on electroplateability	Better design
Convex surfaces		Ideal shape. Easy to plate uniformly, especially where edges are rounded	Flat surfaces		Use a 0.4 mm (0.015 in.) crown to minimize undulations caused by uneven buffing.	
Sharply angled edges		Undesirable. Reduced coating thickness at center areas requires increased plating time to obtain a minimum thickness of durable electroplate. All edges should be rounded. Edges that will contact painted surfaces should have a minimum radius of 0.8 mm (0.03 in.).	
Flanges		Large flanges with sharp inside angles should be avoided to minimize plating costs. Use a generous radius on inside angles and taper the abutment.	Slots		Narrow, closely spaced slots and holes reduce electroplateability and cannot be properly plated unless corners are rounded.	
Blind holes		Must usually be exempted from minimum thickness requirements. Where necessary, limit depth to 50% of width. Avoid diameters of less than 6 mm (0.24 in.).	
Sharply angled indentations		Increase plating time and costs for a specified minimum thickness, and reduce the durability of the plated part.	

Bulk parts in a plating barrel are subject to a greater variation in cathodic current density than parts plated on racks. Cathode contact is made by danglers, chains, buttons, or studs near the bottom of the load, while the plating occurs only at the surface of the load. This produces a large statistical variation in thickness of the electrodeposits on barrel-plated parts; this is not the case for rack-plated parts. Corrosion of a plated part is often controlled by the minimum thickness of protective coating; therefore, if parts are to be barrel plated, special design practices should be observed, including (Ref 12):

- Avoid blind holes, recesses, and joint crevices that can retain tumbling compounds and metal debris from previous operations.
- Avoid intricate surface patterns that will be blurred by barrel finishing.
- Design parts to withstand the multiple impacts of barrel rotation.
- Design small, flat parts with ridges or dimples to prevent nesting.
- Design for good entry and drainage of solutions during rotation by using simple shapes.
- Design surfaces to be plated so that they undergo proper mechanical preparation and cleaning and to ensure that they receive their share of metal deposit. They should be convex, if possible, rather than recessed.

In a larger sense, the design of parts for plating parallels good design practice for corrosion resistance. Avoidance of sharp edges, burrs, or other areas of high free energy, avoidance of abrupt changes in section, recesses, and other traps for moisture, and avoidance of scratches, notches and other anodic-site producers are common design criteria for parts in general as well as for plated parts. More information on designing to minimize corrosion is available in the article “Designing to Minimize Corrosion” in this Volume.

Electroplated Coatings

Revised by Ted Mooney, Finishing.com, Inc.

Advantages and Disadvantages of Electroplated Coatings

Alternatives to electroplating for the protection of metal surfaces against corrosion include organic finishing, hot dip coating, metal spraying, chemical vapor deposition (CVD) and physical vapor deposition (PVD), vacuum deposition by sputtering and ion implantation, and ceramic coating. (See the articles “Organic Coatings and Linings,” “Continuous Hot Dip Coatings,” “Batch Process Hot Dip Galvanizing” “Thermal Spray Coatings,” “CVD and PVD Coatings,” “Surface Modification Using Energy Beams,” and “Chemical-Setting Ceramic Linings” in this Volume). The decision to use one or more of these methods must consider at least the following factors:

- Applicability to the substrate in question (For example, zinc plating is applicable as a protective coating to steel, but not cast iron.)
- Purposes of the finish (Is color a requirement? Will the object to be finished fit into available plating equipment?)
- Cost of suitable electroplating versus alternative methods of coating the part (What finish will be functionally adequate and applicable at the least cost?)
- Anticipated service conditions and length of service desired under these conditions (SC5, extended very severe; SC4, very severe; SC3, severe; SC2, moderate; SC1, mild) (Ref 13)

Advantages of Electroplating

Variety of Coatings. The principal metals that are widely plated are cadmium, zinc and its alloys, chromium, copper, gold, nickel, tin, and silver. Other metals that are plated by in-house shops and some job platers are cobalt, indium, iron, lead, palladium, platinum, rhenium, and rhodium. Plateable alloys add versatility to the catalog of plated coatings. The commonly plated alloys are brass, bronze, copper-cadmium, tin- lead (solder), tin-zinc, gold alloyed with many metals, and nickel alloys with iron and cobalt. Zinc alloy platings, including zinc-cobalt, zinc- iron, zinc-nickel, and tin-zinc are of ever-growing importance. Ternary alloys, such as karat gold alloys and Cu-Sn-Zn, are also available. Nickel-phosphorus and nickel-boron are readily plated by the autocatalytic (electroless) process. Nickel-phosphorus can also be electrodeposited. Coatings of many types can be codeposited with occluded particles by electrodeposition or electroless deposition to modify friction and wear properties. Particles used for these applications range from deposited or occluded abrasives such as diamond, silicon carbide (SiC) to lubricious materials such as polytetrafluoroethylene (PTFE).

Versatility of Application. Plated coatings can be applied to racked parts, in barrels (both by immersion in tanks and manually), semiautomatically, or on microprocessor-controlled fully automatic machines. Local, selective

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

application of a coating, if necessary, can be accomplished by such methods as brush plating (also known as electrochemical metallizing and tampon plating). Similarly, precious metals, such as gold and palladium, have been conserved in electronics applications by selective plating on continuous strips. This is referred to as reel-to-reel plating. The adaptability of plating methods to the job at hand is limited only by the imagination and skill of the plater.

Availability of Applicators. Plating job shops and in-house applicators are plentiful in the United States and throughout the world. The technology is popularized and nurtured by such technical societies and trade associations as the American Electroplaters and Surface Finishers Society, the National Association of Metal Finishers, the Metal Finishing Suppliers' Association, and the Society of Automotive Engineers Airline Plating Forum.

The electrical conductivity of electrodeposited and other metallic coatings gives them an advantage over most organic and ceramic-base coatings in applications that require this characteristic. Applications in which electrical conductivity is necessary include the welding, electrical bonding, or grounding of objects as well as electrical and electronic circuitry.

Galvanic Protection of Substrates. Zinc and cadmium deposits are anodic to steel and protect steel substrates by sacrificial action in many wet environments. In aircraft and other aerospace applications, cadmium plating is used on steel components in contact with aluminum alloys because cadmium is closer in potential to aluminum than steel is (Fig. 1). On coil-coating lines for prepainted steel sheet and strip, electrogalvanizing stages are provided in the wet section to protect the substrate at points of failure of the organic overcoating. Electrogalvanized steel, often further treated with chromate conversion coatings, is used for various purposes because of the sacrificial protective value of the zinc coating. Duplex or triplex coatings of nickel, often with a final thin coating of chromium, are another example of a more complex galvanic protective system.

Weldability and Solderability. Metal deposits are amenable to welding and soldering—an advantage over most organic coatings and porcelain enamel. Certain coatings are more weldable and solderable than others, which leads to the application of special types of plating to facilitate a specific type of joining or fabricating method.

Control of Thickness. Unlike hot dip coating, electrodeposition affords a means of predicting and controlling the amount of metal deposited. This is possible through the validity and knowledge of Faraday's laws, which are as follows (Ref 2):

- The quantity of any element discharged at an electrode is proportional to the quantity of electricity that is passed.
- The quantities of different ions of elements discharged by a given amount of electricity are proportional to the electrochemical equivalents of those elements.

The quantity of electricity is measured in Coulombs (C) (C = A · s), and the electrochemical equivalent of an element is its atomic weight divided by its valence. It is known that 96,480 C, or 1 Faraday will deposit 1 g equivalent weight of any element at 100% electrode efficiency. Electrode efficiencies are a function of plating electrolytes and conditions. They can be determined by coulometric measurement and are published for most plating processes. Because most plants control plating by measuring ampere hours, the amount in grams of metal plated, M_d, is calculated by the relationship:

$$M_d = \frac{A \cdot h}{26.8} EE_M CE_M$$

where EE_M is the electrochemical equivalent of metal M (atomic weight of M divided by valence of M), and CE_M is the cathode efficiency of the plating bath and conditions.

Ductility and Formability. Substrate metals coated by electrodeposition can be formed more readily than some metals coated by hot dipping or certain organic coatings. They do not result in intermetallic alloy layers of the type common to ordinary hot dip galvanizing, for example. Diffusion of some electrodeposits into substrates, and vice versa, occurs after plating as a function of temperature, time, and the diffusion tendencies of the metals involved. These diffused layers are normally thin and require protracted periods of time to develop, usually after the component has been formed to a desired shape.

Electroless Plating. The coating of the interiors of tubes or other recessed areas uniformly and with controlled thickness is the special province of autocatalytic, or electroless, plating.

Mechanical Plating. Mechanical, or peen, plating is a method of coating substrates, principally steel, with malleable metals, such as zinc, cadmium, tin, or their alloys. In mechanical plating, hard, small, spherical objects, such as glass shot, are tumbled against the parts to be plated in the presence of finely divided metal

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

powder, such as zinc dust, and appropriate chemicals. Special advantages of this method over electroplating are the relative absence of problems with hydrogen embrittlement, the simplicity of operation with small parts in a single rotating container, and the ability to deposit desirable alloys that cannot be electroplated. As an example of the latter, tin and cadmium alloys have been found to provide excellent protection of steel against corrosion in marine environments.

Disadvantages of Electroplating

Color Limitations. The colors of electrodeposited coatings are limited to copper, silver metallic, brass, bronze, and gold and its alloys; black, iridescent, or olive drab chromate conversion coatings; and patinas formed on copper and its alloys by chemical and electrochemical treatments.

Colored Anodic Coatings on Aluminum. Anodic oxidation of aluminum, an electrochemical frequently employed at electroplating shops, provides a protective coating that can be colored. The coating is integral to the substrate and can be colored by dyeing, integral color anodizing, or electrolytic coloring (Ref 6, 14). These coatings are highly resistant to abrasion and corrosion and are widely used on architectural forms. More information on these types of coatings is available in the article “Aluminum Anodizing” in this Volume.

Inhospitable Substrates. Some substrates, such as cast iron, and certain substrate conditions, such as porosity, require special plating procedures. Unimpregnated powder-metal compacts and porous castings that can be plated are subject to spotting out, or bleeding, because of retention in pores of cleaning and plating alkalies, acids, and salts.

Limitations of Design. Parts are designed to function in the most economical manner. This is not always compatible with plating. Where the geometry of a part is such that cathodic current distribution will be unfavorable to uniform coatings, it is sometimes wise to seek an alternative protective coating. The criteria here are that the coating must achieve the required minimum thickness on significant surfaces, must meet all functional and dimensional requirements, and must accomplish these objectives at a reasonable cost.

Size Limitations. Large metal structures are often beyond the capabilities of electrodeposition. The limitation lies in the capacity of tanks to contain the electrolyte. Exceptions are certain architectural structures and statuary, which may be brush plated. Such coatings are almost always on copper or bronze and consist of nickel topped with gold electrodeposits. Steel structures, such as bridges, dams, and building elements, are more advantageously hot dip galvanized and painted, or painted without zinc but with specially designed organic coating systems.

Environmental Issues. Electroplating as a whole has been under enormous environmental pressures worldwide since the late 1970s. Intrinsic to virtually all electroplating processes is a requirement for washing the plating solution off of the ware with copious volumes of fresh rinse water, which then presents the operator with the problem of dealing with large volumes of water contaminated with salts of heavy metals. It is expensive and often impractical or impossible to return these diluted plating solutions to the process tanks, while also unacceptable to discharge them untreated to surface waters or sanitary sewer systems. Similarly, it is inherent in the process that cleaning solutions, activating solutions, posttreatment dips, and even some plating solutions become exhausted or hopelessly contaminated and require treatment and disposal to a secure landfill. Many plating operations require mist evacuation, which holds the potential of polluting the air unless adequate fume scrubbing is ensured. None of these problems are insurmountable, but the triple threat of the potential for contaminating water, land, and air has made pollution avoidance an expensive and knotty problem for plating practitioners.

Additionally, some of the individual plated metals and processes present problems. Cadmium is now recognized as a biocumulative poison with toxic effects similar to those of mercury and lead; cadmium plating is expressly forbidden on most or all parts in many countries. Nickel plating is no longer permitted in jewelry applications in much of the world. The hexavalent chromate dips traditionally used on zinc- plated surfaces to forestall white rust are now forbidden in enough of the world that they are no longer used anywhere in the manufacture of automobiles.

Effects of Deposition Parameters

The process used to apply the coating may have an important effect on the properties of the entire coating system. One of the more important considerations is the effect of hydrogen formation during electroplating. Hydrogen may embrittle the substrate. This is particularly important when cadmium, chromium, or zinc is used as a coating over high-strength steel. Atomic hydrogen can combine to form high-pressure hydrogen gas at defects or regions of poor adhesion, causing blisters in the coating. Appropriate standards have been developed to cover relief from hydrogen embrittlement in high-strength steels (Ref 15). Hydrogen can also be introduced into the coating system during one of the cleaning or pickling steps conducted before electroplating.

Electroplated Coatings

Revised by Ted Mooney, Finishing.com, Inc.

Mechanisms of Corrosion Prevention of Plated Coatings

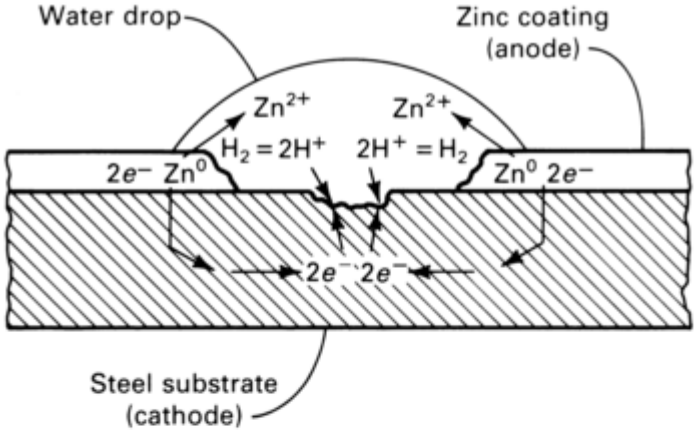
Coatings applied by electrodeposition or electroless plating protect substrate metals in one of three ways. The first is cathodic protection of the substrate by sacrificial corrosion of the coating—for example, zinc and cadmium coatings are electronegative (or anodic) to steel. Second is barrier action, that is, interposing a more corrosion-resistant coating between the environment and a less corrosion-resistant substrate. Examples of this are Cu-Ni-Cr and Ni-Cr coating systems over steel and zinc alloy automotive parts. Third is environmental

www.iran-mavad.com

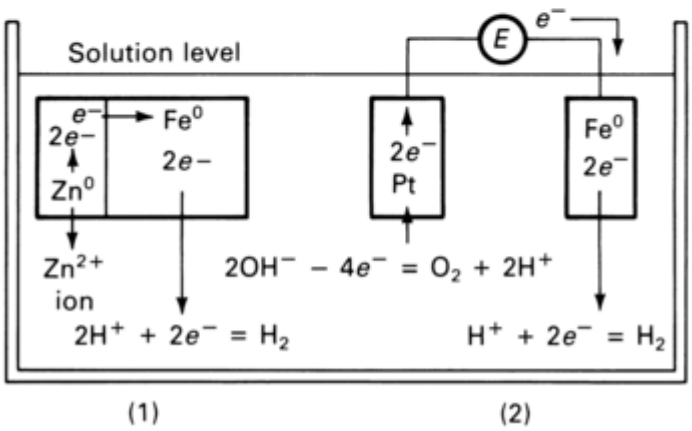
مرجع مهندسی مواد و متالورژی

modification or control in combination with a nonimpervious barrier coating. An example of this type of protection is the electrolytic tinplate used in food packaging.

Anodic Coatings. Zinc and cadmium deposits will protect steel at pores and other discontinuities by cathodic protection. Observation of the emf series (Table 1) shows that zinc is electronegative to steel in potential when these metals are immersed in solutions of their own ions. Under the same conditions, cadmium is more noble than iron, but in actual service under several environmental influences, cadmium is anodic to iron and is therefore sacrificially protective. Figure 3 shows the galvanic protection offered by a zinc coating to a steel substrate. This mechanism of galvanic protection gives rise to the term galvanized steel, which refers only to zinc-coated steel. This old, but commonly used term is modified to electrogalvanizing when referring to electrodeposited zinc in order to differentiate it from hot dip galvanizing.



(a)



(b)

Fig. 3 Principles and mechanism of galvanic protection of a substrate by a coating. (a) Galvanic protection of a steel substrate at a void in a zinc coating. Corrosion of the substrate is light and occurs at some distance from the zinc. (b) Galvanic protection of a steel member (1) by a zinc member and by an impressed electric current flowing from an external dc power source (E) using an insoluble platinum electrode (2). Source: Ref 2

Cathodic Coatings. With reference to Table 1, it is apparent that the metals commonly plated, other than zinc and cadmium, are electropositive (more noble or cathodic) to steel. This is also evidenced by Fig. 1. Such coatings on steel are therefore expected to act strictly as barriers to prevent corrosion of the steel substrate. For this to be successful, the coatings must be pore free and flaw free. It is very difficult to obtain impervious coatings of more noble metals on steel or zinc alloys. Substantial metal thicknesses, usually 25 μm (1 mil) or more, are required. With some of these metallic deposits, particularly the noble metals, thinner coatings applied by pulse plating are more impervious than conventional plated metals, but this is the exception.

Generally, electroplated or hot dipped coatings that are completely free of pores and other discontinuities are not commercially feasible (Ref 2). Pits eventually form at coating flaws, and the coating is penetrated. The substrate exposed at the bottom of the resulting pit corrodes rapidly (Fig. 4). A crater forms in the substrate, and because of the large area ratio between the more noble coating and the anodic crater, the crater becomes anodic

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

at high current density. Electrons flow from the substrate to the coating as the steel dissolves. Hydrogen ions (H^+) in the moisture accept the electrons and, with dissolved oxygen, form water at the noble metal surface near the void. Use of an intermediate coating that is less noble than a surface coating but more noble than the base metal may result in the mode of corrosion shown in Fig. 5. This would be typical of a costume jewelry item with the substrate being brass, the intermediate coating nickel, and the topcoat tarnish-resistant gold. It is also exemplified by nickel-chromium coating systems.

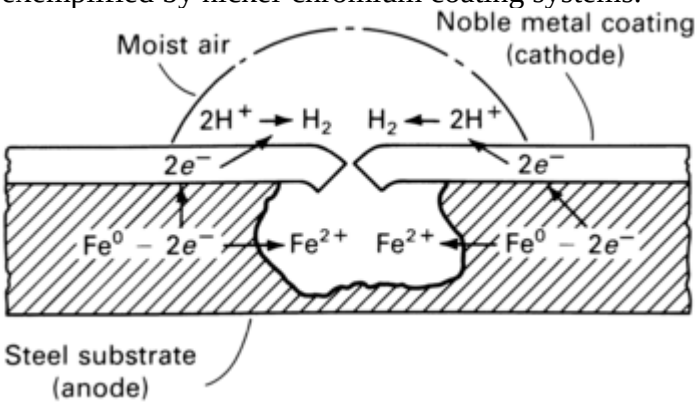


Fig. 4 Crater formation in a steel substrate beneath a void in a noble metal coating, for example, passive chromium or copper. Corrosion proceeds under the noble metal, the edges of which collapse into the corrosion pit. Source: Ref 2

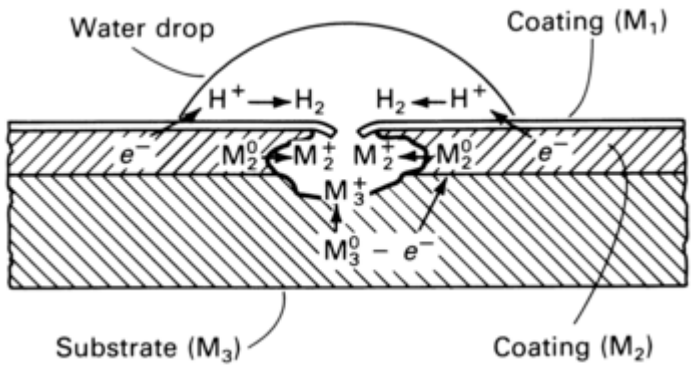

Fig. 5 Corrosion pit formation in a substrate beneath a void in a duplex noble metal coating. The top coating layer (M_1) is cathodic to the coating underlayer (M_2), which is in turn cathodic to the substrate (M_3). As in Fig. 4, the coating tends to collapse into the pit. Source: Ref 2

Exceptions to Predictions. The durability of a plated coating system cannot always be accurately predicted by conventional analysis of the potentials shown in the emf or galvanic series. Much depends on environmental exposure and the oxidized films formed in pores and discontinuities of plated coatings.

For example, some corrosion specialists predicted copper-plated zinc one-cent pieces would be unsuitable coinage because of rapid corrosion. The coating is barrel-plated copper on a zinc-rich alloy, with the coating thickness varying from 4 to 8 μm (0.15 to 0.3 mil). In this thickness range, the coating is far from impervious, or pore free. In the 1970s, before the minting of these coins, pictures were published showing exfoliated, voluminous zinc corrosion products on sample pennies after exposure to the ASTM B 117 neutral salt-spray test (Ref 16). The predicted result did not occur after more than 10 years of service. This indicates that the service conditions to which these coins were subjected are more forgiving than a salt-spray test.

Another example is the case of lead-plated steel, which is quite durable despite the fact that lead is more noble than iron. This is the case because a lead corrosion product develops in the pores (most likely lead sulfate $PbSO_4$) and arrests the progress of corrosion.

Importance of Thickness of Plated Coatings. In general, the thicker a metallic coating is, the less porous it is and the better it serves as a barrier against corrosion. Therefore, the measurement of thickness is a most important feature of testing electrodeposited and electroless coatings. Table 3 indicates the applicability of coating thickness measuring methods. American Society for Testing and Materials (ASTM) and International Standards Organization (ISO) standards covering thickness measurement methods are given in Ref 17.

Porosity is another coating property that is very sensitive to deposition parameters and to substrate preparation. For very thin gold coatings (less than about 1 μm, or 0.04 mil), substrate texture controls coating porosity. At greater thicknesses, porosity is controlled by the coating properties. The variation in porosity with coating thickness is shown in Fig. 6, which shows three distinct phases: substrate dominated, transition, and coating dominated. Porosity can also be controlled to a large extent through deposition parameters, and this effect is attributed to a reduction in deposit grain size. The effects of porosity with thickness for pulsed-plated gold are shown in Fig. 7; again, the same three phases are apparent, although they are displaced downward.

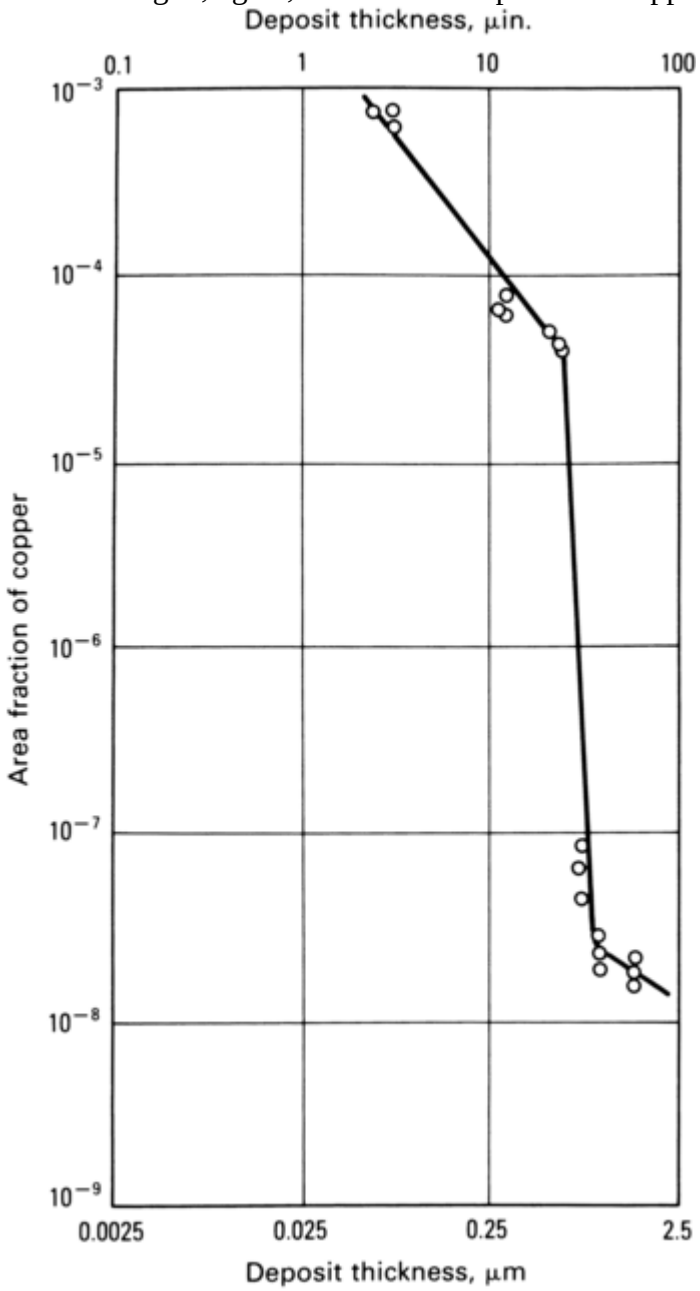

Fig. 6 Porosity versus deposit thickness for electrodeposited, unbrightened gold on a copper substrate. Compare with Fig. 7.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

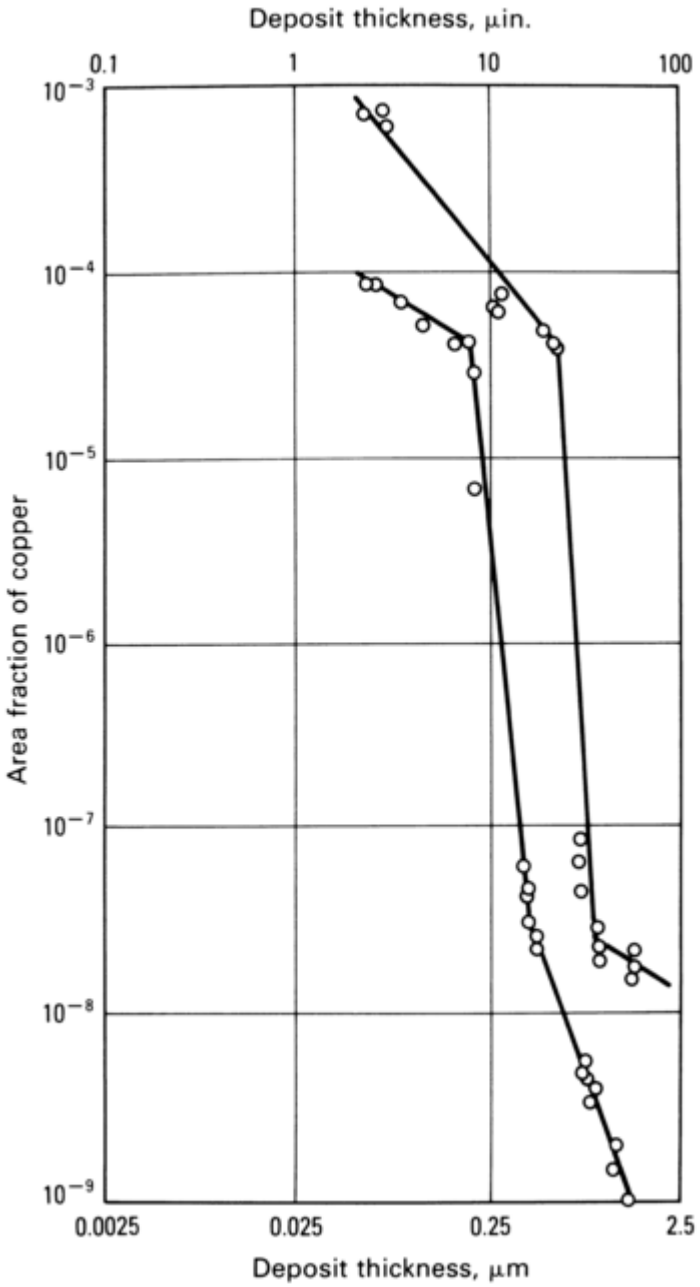

Fig. 7 Porosity versus deposit thickness for pulse-plated gold on a copper substrate. The curve for an unbrightened gold deposit on a copper substrate (top) is shown for comparison (see also Fig. 6).

Electrodeposited coatings applied to thicknesses of less than about 25 μm (1 mil) are porous. Porosity decreases with thicknesses, but it is present even at greater thicknesses. One of the reasons for this is the codeposition of hydrogen at cathodes, owing to the fact that most plating processes operate at less than 100% cathode efficiency. With sacrificially protective coatings, such as zinc and cadmium on steel, porosity is of little significance. Within limits, substrate steel exposed in the pores will be cathodic to the zinc or cadmium coating. Thus, the coatings will corrode under adverse conditions to protect the exposed cathodic steel, at least until the coating has been consumed by conversion to corrosion products. With the exception of chromium, coatings that are cathodic to the substrate depend on freedom from porosity for protection of the less noble substrate. Accordingly, such coatings must be tested for porosity as well as for thickness. Examples of ASTM standards for porosity testing are given in Ref 16 and 18, 19, 20, 21.

Adhesion is very important in the electrodeposition of a metallic coating, as implied in the definition of electroplating given earlier in this article. Therefore, it is logical for many end- product specifications for plated components to contain adhesion tests for verification of this requirement. ASTM B 571 (Ref 22) covers the following adhesion tests for metallic coatings: the burnishing tests, the chisel-knife test, the draw test, the file test, the grind-saw test, and the heat- quench test.

مرجع مهندسی مواد و متالورژی

Corrosion. Testing for corrosion resistance is an important part of evaluating electroplated coatings and allied finishing techniques. Standard methods of corrosion testing are given in Ref 16 and 23, 24, 25, 26, 27. Accelerated tests of corrosion resistance of electroplated coatings can often lead to misleading conclusions. Claims that a certain number of hours in a particular test is equivalent to so many months or years of actual service should be viewed with suspicion.

Electroplated Coatings

Revised by Ted Mooney, Finishing.com, Inc.

Applications for Electrodeposited Coatings

Nickel is widely used as a corrosion-resistant coating and as an undercoat for subsequent coatings. It is not resistant to HNO_3 or to environments containing chloride ions (Cl^-). However, it corrodes slowly in environments that do not contain Cl^- ions. Nickel is widely used by the automotive industry as an underlayer for microcracked chromium to protect steel. As previously discussed, nickel is usually plated as part of a multilayer coating system in which the electrode potential of each layer is different from those of other layers. The outer layer in such systems is often 130 mV more noble or cathodic than the layer beneath it. Nickel is also used over copper as an underlayer for gold to prevent rapid diffusion of the gold into the copper substrate. Nickel and its reaction products are toxic and a substantial percentage of the public suffer “nickel itch,” an allergic reaction to prolonged intimate contact with nickel metal. Nickel with organic additives to produce a very bright finish is widely used, although these coatings are much more brittle than the semibright nickel.

Nickel-phosphorus can be electrolessly or electrolytically deposited as a metallic coating. In general, its corrosion performance exceeds that of nickel in all environments. If the phosphorus content is above about 10 wt%, the coating is amorphous and therefore lacks grain boundaries or other crystalline defects at which corrosion can initiate. Electroless nickel has some advantage over electrolytic nickel in that its thickness and phosphorous content are uniform over the substrate and independent of substrate geometry. Electroless nickel is not resistant to hot caustic solutions. Heat treating nickel-phosphorus coatings above 350 to 400 °C (660 to 750 °F) results in recrystallization and loss of some corrosion resistance even though other properties, such as wear or hardness, may be enhanced. Diamond dust, Teflon globules, and other discrete particles are routinely plated into the nickel-phosphorus matrix to deliver wear characteristics not achievable from any other finish.

Cadmium and zinc are compared in the section “Idealized Coatings” in this article. Cadmium is generally preferred for the protection of steel in marine environments, and zinc is preferred in industrial environments. Cadmium tends to embrittle high-strength steel somewhat less than zinc does (being process related, new deposition processes may change this). The coefficient of friction of cadmium is less than that of zinc; therefore, cadmium is preferred for fastening hardware and connectors that have to be taken on and off repeatedly. Cadmium is much more toxic than zinc, and applications in which its corrosion products can get into the environment must be avoided. There is worldwide movement toward restricting cadmium plating to critical applications or banning its use outright. Cadmium should be specified only after exhaustive investigation of the implications and alternatives. The corrosion performance of both zinc and cadmium is greatly enhanced by chromate conversion coatings (see the article “Chromate and Chromate-Free Conversion Coatings” in this Volume).

Chromium is very resistant to atmospheric corrosion, but is soluble in HCl or in alkaline (caustic) solutions. Its resistance to corrosion is thought to be due to the formation of an amorphous chromium oxide that acts as a passive film to protect the metal. The hardness, low coefficient of friction, and ability to retain oil of heavy chrome deposits has made them an indispensible finish in thousands of moving-part applications. Chromium is deliberately deposited for decorative and wear applications as a microcracked coating over nickel so that corrosion currents are uniformly distributed over a large area. Chromium may be deposited as a noncracked coating both from hexavalent chromium (Cr^{6+}) and from trivalent chromium (Cr^{3+}) electrolytes.

Tin is widely used as a barrier and as an anodic coating for steel and copper. Because it is readily solderable and its oxide is conducting, it finds application in electrical conductors and contacts. Its corrosion products are not toxic; therefore, tinned containers are widely used in the food industry. Recommended thicknesses for application over copper components are given in Table 4 and over ferrous components in Table 5.

Lead is stable in most atmospheres and in both chromic (H_2CrO_4) and sulfuric acid (H_2SO_4) electrolytes. However, it is affected by chlorides. Lead electrodeposits form very inert passive films that tend to reduce the effects of galvanic corrosion.

Copper is not particularly corrosion resistant in the atmosphere, and it tarnishes rapidly. When used alone, it should be protected by an appropriate corrosion inhibitor, such as benzotriazole. On the other hand, copper is often present in coating systems because bright copper is leveling, and its small grain size tends to reduce the porosity and thus improve the corrosion resistance of subsequent coatings.

Gold is often used decoratively and for electrical contact applications. Gold that is plated directly over copper will increase the corrosion rate of the copper through the unavoidable porosity of the gold deposit. Gold will also rapidly diffuse into copper. Therefore, electroplated nickel or cobalt barrier coatings are normally plated underneath the gold coating. For wear applications, alloys with nickel or cobalt are preferred; however, pure gold has a lower contact resistance. Pulse plating will reduce porosity and increase the hardness of electrodeposited gold.

Electroplated Coatings

Revised by Ted Mooney, Finishing.com, Inc.

Selection of Coatings

Tables 6 and 7 represent current practice in guiding designers and platers to minimum thickness of the two principal classes of protective and decorative/protective coatings used in product finishing: zinc and cadmium coatings and bright nickel-chromium. Specification guides for these coatings are given in Ref 1 and are also contained in Federal and Military Specifications (Ref 6, 29). Frequently cited specifications in these documents are:

Specification	Title
ASTM A 165	"Standard Specification for Electrodeposited Coatings of Cadmium on Steel"
SAE-AMS-QQ-P-416	"Plating, Cadmium Electrodeposited" (Replaces MIL-QQ-P-416, cancelled 28 March 2002)
ASTM B 633	"Standard Specification for Electrodeposited Coatings of Zinc on Iron and Steel"
ASTM B 456	"Standard Specification for Electrodeposited Coatings of Copper plus Nickel plus Chromium and Nickel plus Chromium"
SAE-AMS-QQ-C-320	"Chromium Plating (Electrodeposited)" (Replaces MIL-QQ-C-320, cancelled 3 May 2001)
MIL-A-8625	Anodic Coatings for Aluminum and Aluminum Alloys

International Standards Organization (ISO) standards often govern international transactions involving the buying and selling of plated parts. These standards are available from the American National Standards Institute (ANSI) or from ISO.

(a) Nickel classifications: b, fully bright; p, dull or semibright; d, double-layer or triple-layer nickel coating, with the bottom layer containing less than 0.005% S and the top layer more than 0.04% S. If there are three layers, the middle layer should contain more sulfur than the top layer. Chromium classifications: r, regular (conventional) chromium; mc, microcracked chromium having more than 750 cracks/in.; mp, microporous chromium containing a minimum of 64,500 pores/in.^{2} that are visible to the unaided eye. Source: Ref 12

Nickel-Chromium Coatings. Because of their importance in the automotive industry, nickel-chromium (with or without a copper underlayer) coatings have been subjected to many changes and exhaustive testing over a long span of years. Results of extensive field experience and testing of variations dating from the days of buffed nickel coatings (1870 to 1924) are reported in Ref 30. Figure 8 shows a history of the development and use of nickel-chromium coatings. Significant developments in this history were the determination that the basic corrosion resistance of these systems is controlled by the thickness and composition of the nickel layer, the invention of the leveling copper and nickel plating processes, the development of semibright and bright nickel plating, the emergence of crackfree and microcracked chromium, and the evolution of duplex and triplex (multilayer) nickel-chromium systems.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

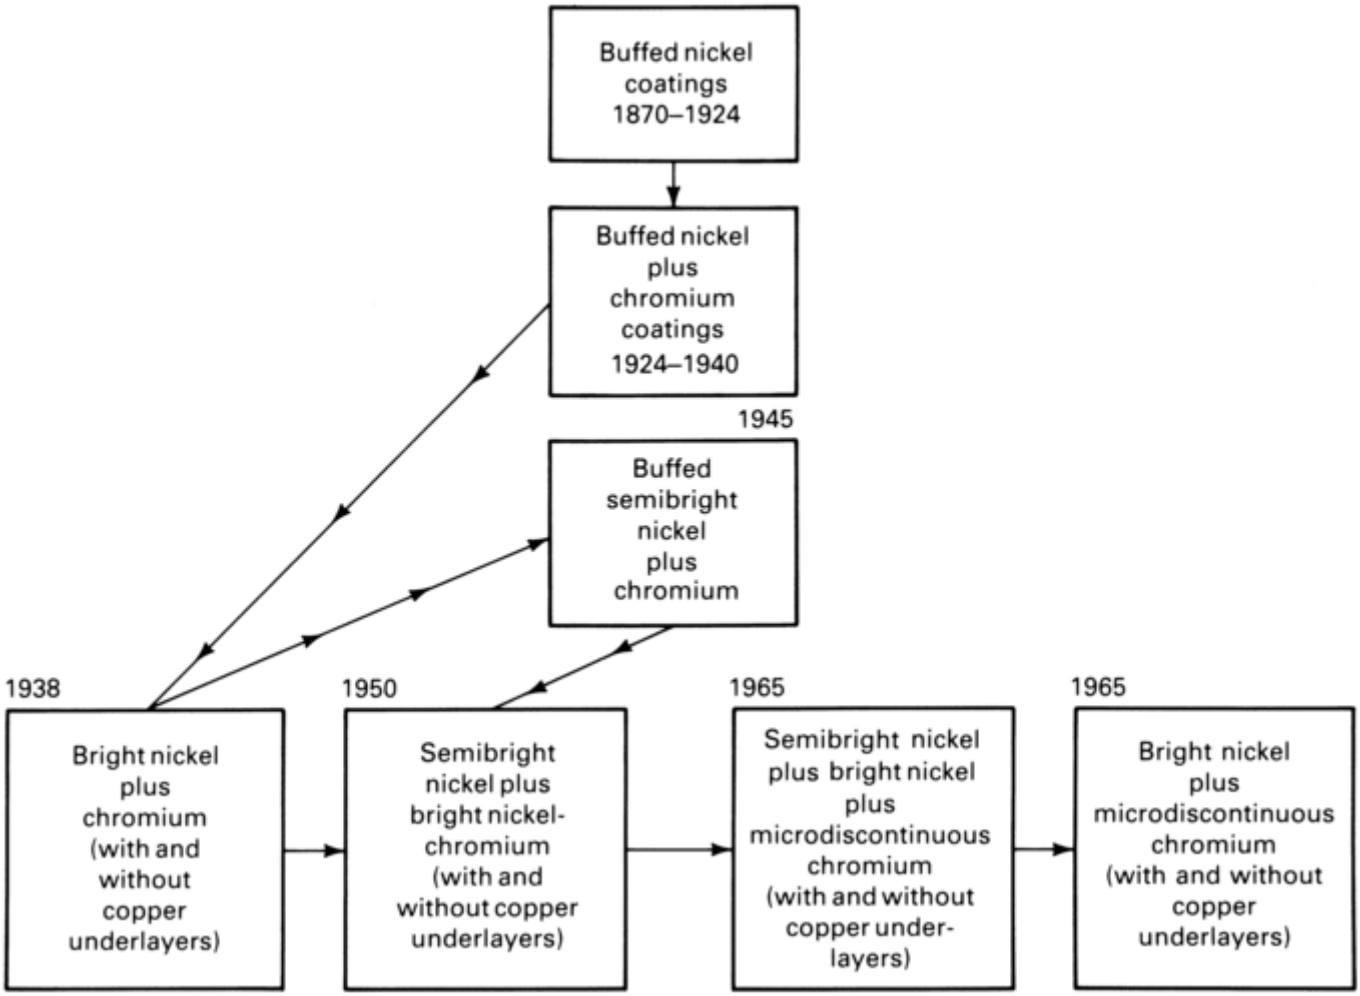

Fig. 8 History of the development of nickel and nickel-chromium coatings showing time of introduction and periods of use. Source: Ref 30

Reference 30 also discusses the application of these coatings on steel, zinc, plastics, and aluminum. In these systems, the chromium layer is very thin—of the order of only 0.25 μm (0.01 mils). However, the corrosion resistance of chromium plate depends not so much on its thickness as on its physical state. Crackfree, or nonporous, chromium is excellent, but does not remain crackfree in service. A small number of cracks are detrimental, but the presence of many fine microcracks may be beneficial (Ref 2). Microcracked chromium deposits cause the galvanic- corrosion action to be spread over a very wide area and therefore do not suffer from localized corrosion. Microcracked chromium, in combination with duplex or triplex nickel, is the most durable of these coatings. The results of marine exposure for 36 months on variations of these coatings on steel are shown in Fig. 9. Figure 10 shows results of a similar program for Ni-Cr and Cu-Ni-Cr coatings on zinc.

Electroplated Coatings

Revised by Ted Mooney, Finishing.com, Inc.

Plating of Mill Products

A trend toward applying tin and zinc coatings by electrodeposition to sheet and strip in tandem with continuous pickling and cold-rolling lines developed just before and during World War II. Much earlier, processes were developed in Germany and the United States to electrogalvanize wire. Advantages claimed over hot dip galvanizing were control of thickness, the fact that the substrate is not affected by heat, and that the ductility and formability of the substrate is not limited by the iron-zinc intermetallic compound layer formed on hot dip galvanized steel. In hot dip galvanizing, the edges, especially of strip steel, tend to destroy wipes. Therefore, special care is required to secure a uniform smooth coating (Ref 31).

Electrolytic tinning was commercially introduced in 1927 (Ref 31). Before that time, all of the tinplate on the market was manufactured by hot dip processes. Again, because of the amenability of electrodeposition to close thickness control and the development of highly efficient pretreating and plating processes, electrotinning has captured practically all of the food packing business. Various electrolytic processes have been used for producing tinplate, including the acid processes—sulfate, fluoborate, phenolsulfonic, and halide (fluoride-chloride)—and the alkaline sodium stannate bath.

In addition to electrogalvanizing and electrotinning, continuous plating or cold-rolled sheet and strip is performed by integrated steel mills as well as specially continuous strip producers and coil coaters. The specialty houses continuously plate nickel on steel for the battery (mostly alkaline dry cell) industry. They also plate alloy coatings such as nickel-zinc for protective/decorative uses and copper- and copper alloy-plated steel for postfabrication of decorative items. Copper-nickel-chromium on nonferrous metals and wide-strip steel is also available. Reference 32 lists typical examples of decorative/protective applications of continuously plated Cu-Ni-Cr plated steel strip. Among these are various components for household appliances, dispensers, handles, lamps, cover plates for switches and outlet boxes, and furniture trim. Functional applications for copper-plated strip include flashlight shells and alligator clips for jumper cables. Nickel-plated strip is used in battery cans and caps and for paintbrush ferrules. There are few companies in the continuous strip plating field because of the high initial investment required and the specialized knowledge needed to operate this process successfully.

Coil coaters, the name given to manufacturers of prepainted sheet and strip (mostly steel and aluminum substrates), apply thin zinc coatings plus chemical conversion coatings before applying organic coatings. Products of this segment of the industry are used in postforming operations.

Excellent control of plating conditions and the absence of complex substrate geometries provide a high degree of uniformity in coatings on preplated strip. This is reflected in predictable corrosion resistance because uniform thickness leads to uniform corrosion resistance.

Chromium plating has also penetrated the tin mill product field in such applications as food can ends. Thin coatings of tin and chromium act as a base for can varnishes and lacquers and for pigmented outer coatings. On the interior of cans, tin or chromium coatings are claimed to prevent filiform corrosion under the clear organic coatings—an insidious type of underfilm corrosion characteristic of clear and sparsely pigmented organic coatings. Information on equipment and processing is available in Ref 4, 31, and 33; Ref 33 also discusses corrosion of tinplate.

Immersion Plating. Immersion, or chemical, deposition has a long history of limited industrial use—for example, tin immersion deposits on mill wire products (called liquor finishing), immersion nickel plating of steel before porcelain enameling and many types of ceramic coatings, and the immersion copper plating of wire to be used in inert-gas shielded arc welding. In the last application mentioned, pure copper and copper- tin (gold-colored) coatings have both been used as aids to wet drawing of the wire to finished size and to furnish a highly conductive surface in the welding gun. Both tin and copper have been used in wire mills for the wire used for such products as paper clips and staples. According to the corrosion theory, these coatings, which are

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

much more noble than the substrate, would be expected to hasten corrosion of the substrate. However, this is not the case, probably because the porosity is so widely distributed that whatever current is available for corrosion is so spread out as to be ineffective. This is similar to the effect of microdiscontinuous chromium (MDC).

Electrochemical Predictions of Corrosion Performance

Accelerated tests used for the prediction of corrosion performance for a particular application of a coating system have a certain risk associated with them. It is very difficult to design a test environment to simulate the actual environment, but there is often no alternative. A number of accelerated electrochemical tests are given in Ref 34, 35, 36, 37.

Sample Preparation. The preparation of the sample to be tested requires a great deal of care for a number of reasons. On an actual part, the geometry is rarely designed so that the current density is uniform over the entire part. Because such coating properties as grain size and porosity are critically affected by local current density, the ability of a coating to protect the part would be expected to vary from one point on the part to another. When conducting accelerated tests on flat samples (usually required by the tests listed in Ref 34, 35, 36, 37), the current density used to apply the coating(s) must be typical of that used on the real part. Equally important, the surface finish of the specimen substrate should be comparable to that of the actual substrate. The above tests usually require that the surface finish be produced by wet grinding on 600-grit SiC paper. Electrodeposited coatings are sometimes used without additional surface finishing. Grinding and electropolishing will certainly affect test results.

Test Selection. Very high localized currents can exist during these tests and may result in rapid removal of the coating. The desired information is usually the corrosion current i_{corr}, which can be correlated with actual weight loss. The polarization resistance measurement (Ref 34) is probably the safest of the tests for this determination. The suitability of the test should be determined by correlating actual performance with test results whenever possible. Crevice corrosion under the gaskets used in the tests may affect results and should be considered.

Future Trends

Due to the pressure to get cadmium out of the environment, and the fact that simple zinc plating is not a satisfactory substitute in many instances, the application of such alloys as tin-zinc, zinc-cobalt, zinc-iron, and zinc-nickel is growing rapidly. Aluminum coatings, whether applied by proprietary electroplating processes or other methods, are additional cadmium substitutes. The desire to remove nickel plating from jewelry and other applications where it can cause sensitivity reactions is fueling the development of alloy replacements. Chromium plating, while not considered a threat to the environment in its metallic form, does pose a threat to health and the environment during its application. Add the potential chromium plating has for hydrogen embrittlement, and substitutes such as cobalt plating, HVOF coatings, and TiN coatings applied by PVD are making inroads into some of its former strongholds. The hexavalent chromate coatings traditionally used to forestall white rust on aluminum, cadmium, and zinc have effectively been banned from automotive use. While trivalent chromate conversion coatings are the usual replacement, when this substitute is not adequate for specific applications, the aluminum or zinc plating may be foregone and electroless nickel plating used instead.
The continuing miniaturization of the electronics world is impelling changes both toward and away from electroplating. Zinc plating has been found to cause troublesome zinc whiskers that foul computer cleanrooms and to which hot dip galvanizing is not vulnerable. While not strictly a corrosion-resistant application, copper electroplating is replacing aluminizing in electronic circuits and is the technology of choice for micro electro mechanical systems (MEMS) fabrications. Nickel electroplating/electroforming continues to grow stronger with society's ever-increasing reliance on miniature precision optics and electronics.

Continuous Hot Dip Coatings

Ralph W. Leonard, Coated Steels Technology, LLC

Introduction

HOT-DIP COATING is a process that primarily refers to the application of a low melting point metal as a coating on steel wherein the material to be coated is immersed into a molten bath of the coating metal. Hot-dip coating may involve the coating of steel sheet, strip, or wire, or it may involve the application of a coating onto forms such as pipe and structural shapes. The coating of steel sheet is defined as *continuous* hot-dip coating while the coating of piping, structural shapes, and discrete parts such as nails, screws, bolts, and nuts is called batch coating. Batch galvanizing was, in fact, done many years before the continuous coating process was developed. The earliest record of the use of zinc to protect steel dates back to 1836 (Ref 1). In batch galvanizing, the steel is fabricated into a finished part, cleaned to remove residual oils, pickled to remove oxides from the surface, and then dipped into molten zinc to apply the coating. As a result of long experience, the excellent protection that a zinc coating provides to steel was well known long before the continuous galvanizing process was developed more than 50 years ago. See the article “Batch Process Hot Dip Galvanizing” also in this Section.

By far, the most common continuous hot-dip coated product is galvanized steel sheet. Galvanized sheet has a coating that is essentially zinc metal. Its companion product, galvannealed sheet, is produced in a similar way except that the coating of zinc, while molten, is alloyed via a diffusion process with iron from the steel sheet. The resultant coating has approximately 9 to 10% iron. Since steel sheet is the most commonly manufactured hot-dip coated product today, most of the ensuing discussion focuses on steel sheet issues, but much of the information would apply to hot-dip coated steel wire as well.

The *continuous hot-dip process* is called “continuous” simply because the product intended to be coated, steel sheet for example, is passed in a continuous manner into a bath of the molten coating metal. As applied to steel sheet, the leading end of one coil of steel is welded onto the trailing end of the coil ahead of it in the processing line. With the use of an accumulator, which stores up to perhaps 1000 ft or more of sheet ahead of the central part of the processing line, these coil ends can be joined without stopping the central processing section. As a result, the sheet being processed through the coating bath never stops; the process is truly “continuous.”

The primary reason that the hot-dip process is restricted to the application of low melting point metals is that the product to be coated (steel sheet) needs to have some amount of tensile strength as it is pulled through the coating line. Low carbon steel sheet, the most common hot- dip coated product, cannot be heated to temperatures much above 870 °C (1600 °F) without literally tearing apart as it is being transported through a large processing line. Thus, the coating metal has to have a lower melting point than 870 °C (1600 °F). Today, the highest melting point metal being applied to steel sheet is aluminum, which has a melting temperature of 660 °C (1220 °F).

Since the continuous sheet-coating process was developed over 50 years ago for the application of zinc (*galvanizing*) onto steel sheet, the process has been employed for the application of other metallic coatings including aluminum and several aluminum/zinc alloys. Each of these coating types has special attributes that make them more suitable than galvanized sheet for specific types of applications. These coatings and their specific attributes will be discussed in the subsequent sections.

Continuous Hot Dip Coatings

Ralph W. Leonard, Coated Steels Technology, LLC

Basic Principles

Steel sheet is passed as a continuous ribbon through a bath of molten metal at speeds up to approximately 200 m/min (650 ft/min). A simplified schematic drawing of the strip as it is passed through the coating bath is shown in Fig. 1. One of the requirements of the process is that, while in the molten metal bath, the steel strip must react with the molten metal to form an intermetallic bond (often referred to as the *alloy layer*) across the entire surface of the steel sheet. This bond is present as a thin distinct region between the coating metal and the steel sheet. It is necessary for two reasons. One is that without the intermetallic-alloy layer the coating would *dewet* from the steel when the sheet exits the coating bath, and this would lead to either uncoated areas (voids) or a very nonuniform coating thickness. A uniform coating thickness is very important to achieve good corrosion resistance. Second, without the alloy layer, the coating would not adhere to the sheet when it is subsequently formed into a shaped part.

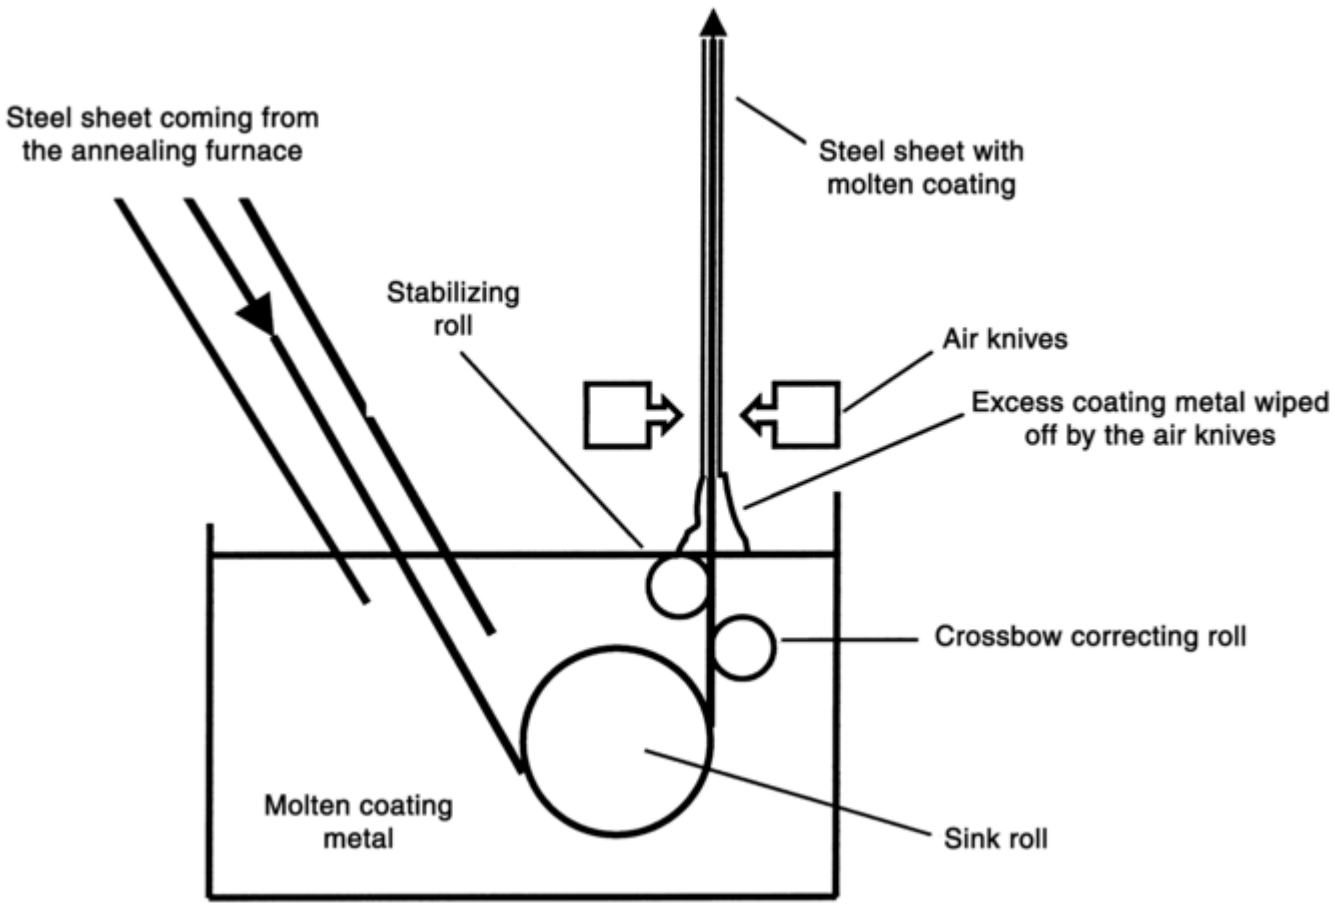

Fig. 1 Basic arrangement of the coating bath in a continuous hot-dip coating operation

Wetting is the term describing the interfacial tension between a solid and a liquid. Here, *dewetting* is used to define the absence of the diffusion reaction between the steel surface and the molten coating metal. It is very important that this reaction take place across the entire surface area of the steel sheet.

The intermetallic-bond layer has several important features. The inherent nature of the alloy layer formed on all hot-dip coated products, whether the coating is zinc, aluminum or one of the aluminum/zinc alloys, is that it is composed of one or more intermetallic compounds. These can be zinc-iron, aluminum-iron, or aluminum- zinc-iron compounds. By its nature, the bond layer is hard and brittle. For galvanized sheet, the alloy layer is

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

approximately ten times harder than the zinc coating outer layer. Thus, in order to be able to form the sheet without loss of coating adhesion, the alloy bond thickness must be kept as thin as possible.

As the strip emerges from the molten bath at high speeds, it drags out excess metal, much like when an object is pulled rapidly from a container of water. The amount of excess metal depends on the speed at which the sheet is moving, the viscosity of the coating metal, and a number of other variables such as the surface roughness of the sheet, the presence of oxides on the surface of the bath metal, and the temperature of the bath metal. Through the use of an air-wiping process, a controlled amount (thickness) of molten coating, usually expressed as weight of coating per unit area, is allowed to remain on the strip surface. The molten coating is cooled, and then, following several other processing steps that may be used to modify the surface roughness, flatten the steel, and apply a rust-inhibitive surface treatment, the steel is recoiled at the exit end of the processing facility.

No matter which type of coating metal is applied, the common features of hot-dip coated sheet products are shown schematically in Fig. 2. There is an outer coating layer that has essentially the same composition as the bath metal. This is followed by the intermetallic bond layer, a layer that forms by diffusion between the coating bath and the steel substrate. Beneath the alloy layer is the steel substrate.

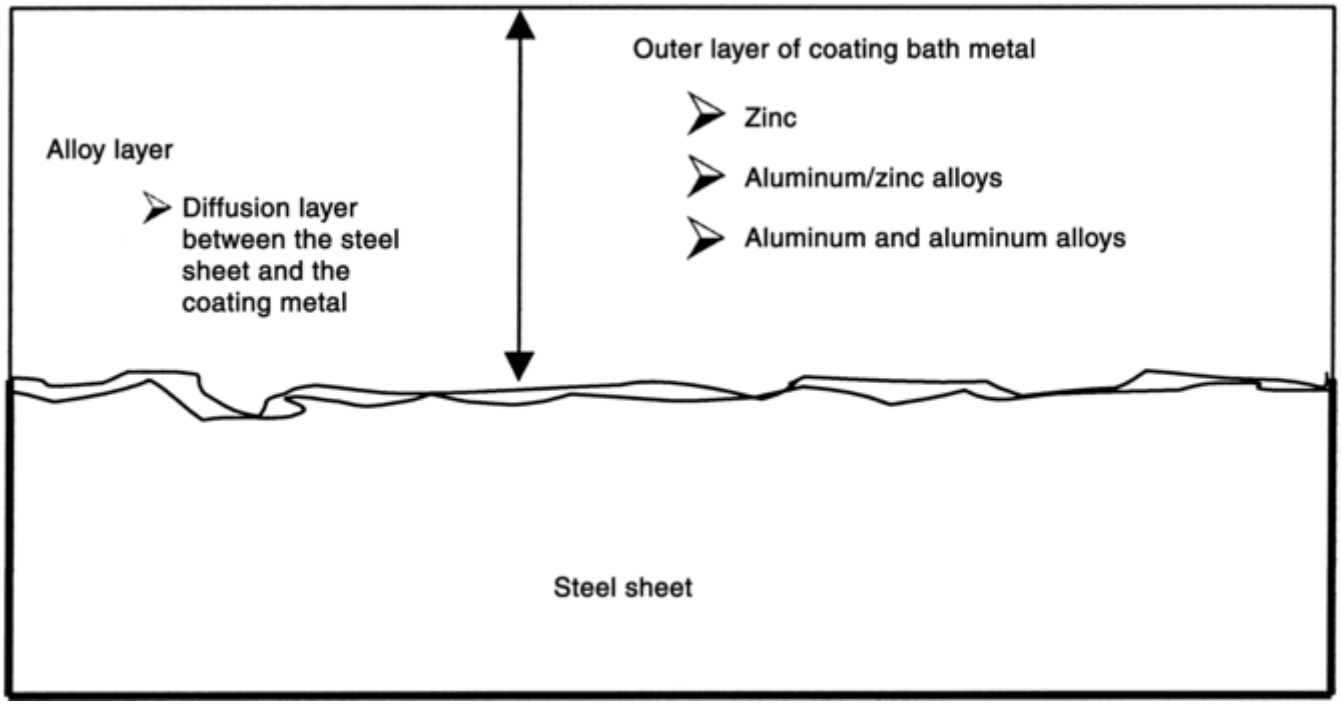

Fig. 2 Schematic drawing of the cross section of a hot-dip coated sheet product showing the three features of all hot-dip coated sheet products—the outer coating layer, the intermetallic alloy bond zone, and the steel sheet substrate

Process Details. Most commonly, the hot-dip process for steel sheet involves the following sequential steps:

1. An entry-end welder joins the trailing edge of one coil to the leading edge of the succeeding coil to allow the process to be truly continuous.
2. An alkaline cleaning section removes the rolling oils, dirt, and iron fines (surface contaminants from the cold reduction process) that are on the sheet surface.
3. An annealing furnace heats the steel to high temperatures to impart the desired mechanical properties (strength and formability) to the steel sheet.
4. A bath of molten metal contains the metal being applied to the steel surface.
5. A cooling section cools the strip and solidifies the coating as it emerges from the coating bath.
6. A temper mill imparts the desired surface finish to the coated steel.
7. A tension leveler flattens the strip to meet the end-use requirements.
8. A treatment section applies a clear, water- base treatment to the coating to prevent storage stains that can form on the coating surface when moisture is present (as condensation and/or water infiltration originating from improper shipping or storage).
9. An oiling section is used most often to apply a rust-inhibitive oil. At times, it can be used also to apply a forming oil.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

10. A recoiler rewinds the finished coil of steel.

At this point, the finished coil of coated steel has:

- The desired steel strength and formability
- An adherent, uniformly thick, corrosion resistant coating
- The desired surface finish and sheet flatness
- A clear chemical treatment and/or oil to help maintain the bright metallic finish that is a characteristic of hot-dip coated sheet products

Not all hot-dip coating lines include all the previously listed processing steps. For example, some do not include the aqueous cleaning stage, relying instead on flame cleaning in the entry end of the annealing furnace. Others might not have a temper mill; temper rolling is not necessary and perhaps not desired for some applications of hot-dip coated products. Also, there is a type of hot-dip coating process commonly called flux galvanizing that relies on using fluxes to apply a uniform and continuous coating. The final product is very similar to that obtained using the process described earlier, especially with respect to corrosion resistance. This process is not used much today, and it is used only for making galvanized sheet. None of the other aluminum or aluminum/zinc alloy coatings are applied using the flux process. Some references to the flux- coating process refer to it as the *cold process* in contrast with the term *hot process* used to define the lines that have in-line annealing furnaces. By far, the number of hot lines exceeds the number of cold lines. In North America, only several flux lines are operating as of 2003.

Benefits of Coating Steel. It is well known that low-carbon steels are susceptible to corrosion when exposed to moisture. Not only is the corrosion aesthetically undesirable in most applications, but the corrosion rate can reduce the design life of the component. It is not unusual for steels to corrode at a rate of several mils of thickness per year (Ref 2). Not only does the surface take on the reddish color of iron oxide, but also, over time, the steel may lose a significant amount of its thickness, with a corresponding loss in mechanical properties.

Steels can be painted to reduce the rate of corrosion and to make the product more attractive in appearance. However, the presence of paint alone does not ensure that steel is fully protected from corrosion. This is especially true at sheared edges or at scratches in the paint where rusting of the steel can cause paint blistering and continuing disbondment between the paint and the steel sheet (Fig. 3). Often, more protection is needed to reduce the corrosion rate of steel so that the aesthetic requirements are met and the strength and integrity of the steel sheet are not lost.

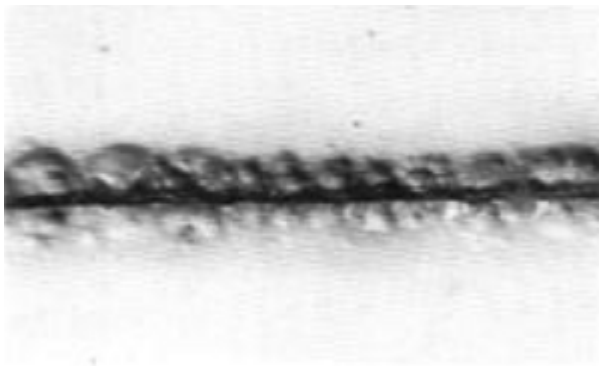

Fig. 3 Paint blistering and red rust staining at a scratch in painted cold-rolled sheet

Continuous Hot Dip Coatings

Ralph W. Leonard, Coated Steels Technology, LLC

Hot-Dip Coatings

The six principal types of coatings currently being applied by the hot-dip process are:

- Galvanized (zinc or zinc with aluminum added)
- Galvannealed (zinc with 8 to 10% Fe)
- 55Al-Zn coating
- 95Zn-Al coating
- Aluminized with pure aluminum
- Aluminized with aluminum plus silicon

Additionally, a product called terne-coated sheet is produced. Terne-coated sheet has a coating of lead plus 3 to 15% tin. Years ago, terne- coated sheet was the primary product used to manufacture fuel tanks. Also, it was used for roofing applications. Today, these markets are quite small.

Each of these coatings except the galvannealed sheet are produced using a specific coating- bath composition. Galvannealed sheet is not produced from a zinc and iron coating-bath composition. Instead, the coating bath is the same as that used to make galvanized sheet except that the aluminum level in the coating bath is reduced from approximately 0.17 to 0.20% to 0.14% or less. The iron is derived from the substrate. The 95Zn-Al coating may contain either a small addition of mischmetal (a combination of rare earth elements) or magnesium.

Galvanized Sheet. It was discovered more than 200 years ago that zinc, in intimate contact with steel, will protect the steel. This protection takes place by two mechanisms; one is simple barrier protection wherein the zinc simply prevents contact between the steel and the environment of moisture and oxygen. The second is *galvanic* protection that protects steel even at exposed areas such as sheared edges of a sheet or scratches in the coating. In order to galvanically protect steel, a metallic coating such as zinc has to be electrochemically more active than the steel in the specific environment where the product is being used. Fortunately, zinc is indeed more chemically active than steel in almost all environments. In the chemical reaction that takes place when galvanic protection occurs, zinc becomes the anode of a corrosion cell and protects the steel from corroding by making the steel the cathode. Reference 2 contains a very detailed description of the fundamentals of the corrosion and electrochemistry of zinc.

Galvanic protection can be accomplished whether the zinc is attached to the steel with a wire or is in intimate contact. Since corrosion is an electrochemical reaction, the zinc and steel need to be ***attached*** in a fashion that allows free electron flow between the steel and zinc. One of the classic examples of the galvanic protection obtained with the use of zinc is the protection of steel ship hulls from corrosion in sea water by selective placement of zinc anodes around the outside of a ship.

When zinc is applied over the entire surface of a steel as in the hot-dip galvanizing process, the steel is fully protected from corrosion by the presence of the zinc coating. The intimate bond that occurs between the steel and the coating metal offers complete electrical contact so that free flow of electrons necessary for galvanic protection can occur.

One needs to keep in mind that, as the zinc is protecting steel on a galvanized product, it undergoes corrosion. That is, the zinc itself corrodes and is consumed over time. The benefit afforded to steel is that, in most environments, zinc corrodes at a significantly lower rate than steel. Thus, a thin zinc coating can provide long-term protection to steel.

The reason that zinc normally corrodes at a much lower rate than steel is that the products of corrosion that form on the surface of the zinc develop a protective, somewhat passive film. When steel corrodes in the environment, the iron oxide that forms as a result of the corrosion reaction is not usually retained on the surface

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

of the steel as a protective, passive film. Typically, it spalls off and continually exposes a fresh steel surface to the air and moisture. The protective, passive film that forms on zinc in most atmospheres is a zinc carbonate film (Ref 3). This carbonate film forms by a reaction between the zinc corrosion products (zinc hydroxide and zinc oxide) with carbon dioxide in air. This carbonate film is often stable and remains as a protective covering over the zinc coating.

Typically, the zinc carbonate film does not completely protect the zinc from further corrosion; it simply slows down the corrosion reaction. The zinc surface exposed to the atmosphere is not completely passivated, so corrosion of the zinc can continue. This phenomenon is actually needed to continue to provide galvanic protection to steel. If the passive film were complete and corrosion of the zinc stopped completely, the galvanic protection to steel at exposed edges and scratches would be lost. Zinc carbonate films can be broken down (dissolved) by reaction with moisture in the environment, especially acid rain. Thus, even though zinc corrodes at a much lower rate than low carbon steel, it does corrode in most atmospheres, and the net result is that the zinc is eventually consumed.

The actual rate of corrosion is highly dependent on the type of exposure. References 2 and 4 contain extensive information on the corrosion rates for zinc in many different types of environments. Table 1 (Ref 5) contains a summary of the relative corrosion rates for steel versus zinc in various types of atmospheric environments. These data provide general guidance only; more detailed information for specific environments is contained in Ref 2 and 4.

Table 1 Typical corrosion rates for zinc and steel

Environment classification	Corrosion rate			
	Zinc		**Steel**	
	µm/yr	**mil/yr**	**µm/yr**	**mil/yr**
Mild	<1	<0.04	<10	<0.4
Moderate	<2	<0.08	10–20	0.4–0.8
Tropical	<2	<0.08	20–50	0.8–2.0
Industrial	2–4	0.08–0.16	20–50	0.8–2.0
Marine	2–4	0.08–0.16	20–80	0.8–3.1
Severe marine	4–>10	0.16–0.4	80–200	3.1–7.9

Source: Ref 4

Within these general environmental-classification types, there can still be substantial differences in the rates of corrosion for a galvanized coating. Table 2, for example, contains data for the corrosion performance of galvanized product in various marine environments. There are considerable differences in corrosion rate depending on whether the samples are close to the ocean or somewhat further away. Then, too, the corrosion rate is very dependent on whether the samples are exposed directly to rainfall or are placed in a sheltered location (exposed to the atmosphere but sheltered from direct rainfall). It is important to apply general corrosion-rate data cautiously, as the rate can be very dependent on some very specific issues at any given exposure site.

Table 2 Variation in corrosion rates in marine environments

Location	Exposure[(a)]	Zinc corrosion rate	
		µm/year	**mils/yr**
Severe marine	Open	6.2	0.244

In soils, the corrosion rate of galvanized coatings can also be quite variable. It can vary from very aggressive corrosion to very low corrosion rates. Table 3 contains data showing the extent of variability in the corrosion rate of galvanized sheet in different types of soil.

Table 3 Corrosion of galvanized steel in various soils

Coating weight: 300 g/m^2 (1 oz/ft^2)

Soil description	Soil corrosivity	Coating life, years
Poor drainage, low resistivity	High	1–2
Poor drainage, high salt content	Moderate	4–6
Good drainage, high resistivity, low salt content	Low	18–25

Source: Ref 7

Because galvanized coatings protect steel by undergoing bulk corrosion of the coating layer, it is important to define the coating weight (thickness) when using galvanized sheet for a specific application. The life of the product before the onset of steel rusting is very dependent on the coating thickness. If the environment to which the product will be exposed is mild, light coating weights might suffice to meet the desired life expectancy. However, if the application is harsh, a heavy coating weight should be specified. Since the rate of corrosion for the galvanized coating is approximately linear in most environments, as shown in Fig. 4, one can readily predict the benefit of using a thicker coating in any specific environment type. Table 4 contains the coating weight categories that are commonly produced on current production lines. Detailed information about the coating weight requirements is contained in ASTM A 653 (Ref 8). As noted in this table, there are practical limits to the coating thickness. On the low end, it is difficult to achieve better air-knife wiping for producing coatings less than G30 (as defined in Table 4), while at the high end, it is difficult to achieve a sufficiently uniform coating thickness across the entire sheet surface as excessive sags can develop in the coating layer before it solidifies.

Aluminum Addition to the Galvanizing Bath. Hot-dip galvanized coatings typically contain between 0.16 and 0.25% aluminum. The aluminum is not added to influence the corrosion resistance of the coating but to enhance the development of a thin alloy-layer bond zone between the steel and zinc coating layer. In principle, the only function of the aluminum is to restrict the growth rate of the intermetallic compound(s) that form(s) as the steel and zinc diffuse into one another during the coating process. When the process is properly controlled, the alloy layer is almost indistinguishable (Fig. 5). Thus, the addition of aluminum is very important to the process, but there has not been any evidence to show that its addition influences the corrosion resistance of the galvanized coating.

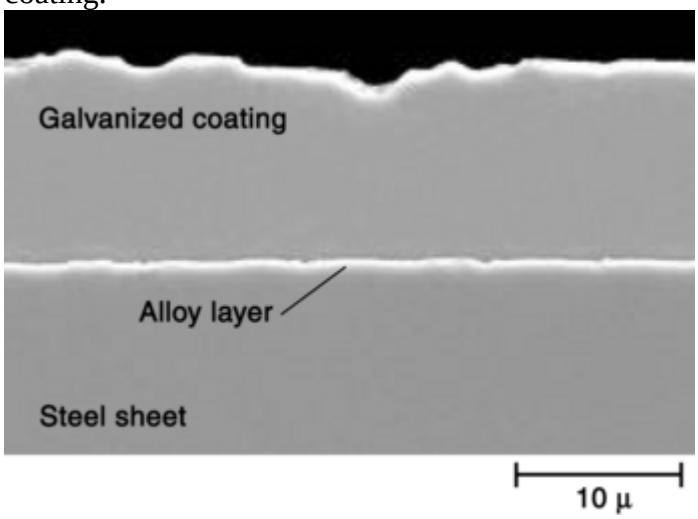

Fig. 5 Microstructure of continuously galvanized sheet product. Note the thin, almost indistinguishable alloy bond layer.

Influence of Spangle Cracking. When hot-dip galvanized coatings are bent or drawn, the coating often develops cracks that are visible to the unaided eye. The coating can be thought of as a thin casting in that the zinc is applied from the molten state and the final structure of the coating is large grained. The coating is prone to intergranular cracking or intragranular cleavage cracking. These large grains, or spangles, typically exhibit the large, dendritic structure of an as-solidified metal as shown in Fig. 6. Although today the coating metal usually contains fewer impurities such as lead and the spangle pattern is, thus, often less distinct than on product made years ago, the as-solidified grain size is still much larger than that of a cold-worked and annealed metal. This large-grained structure combined with the hexagonal crystal structure of zinc tends to make the coating sensitive to both intergranular grain-boundary cracking and intragranular cleavage during bending and other forming operations (Ref 10). However, this behavior generally has little impact on the life of the coating in that the life of a galvanized coating is mostly dependent on the quantity of zinc on the surface of the steel. The galvanic nature of the zinc protects the underlying steel, and the onset of steel corrosion does not occur until the coating is essentially completely consumed in any given area of the surface.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

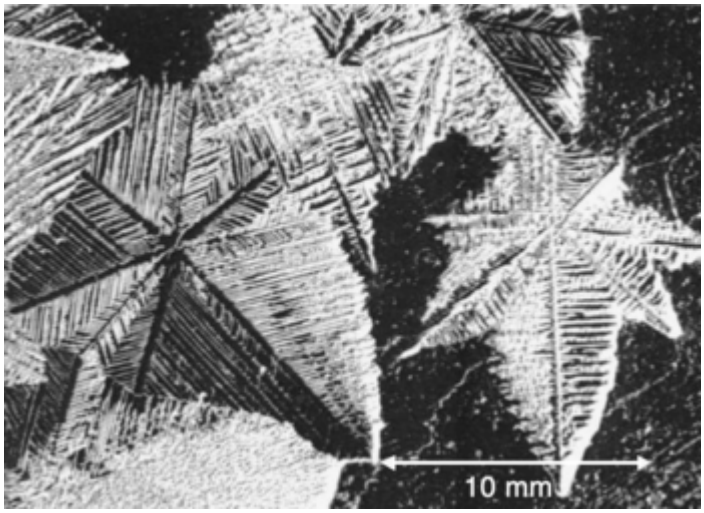

Fig. 6 Enlarged view of the dendritic structure within the spangles of a hot-dip galvanized coating.

Humid Storage Corrosion. Perhaps one of the least considered issues related to the performance of galvanized steel sheet is the issue of humid-storage stain. *Humid-storage stain* refers to the corrosion of the galvanized coating if it gets wet during shipment or storage in coil form or stacked sheets. Wetting occurs either by ingress of moisture or by condensation, and the galvanized coating will not dry when moisture gets between the wraps of a coil or the sheets. Zinc is a chemically active metal in the presence of moisture, and its corrosion resistance depends on the formation of adhering oxide/carbonate films. The stable, adhering oxide/carbonate passive film never forms, and a relatively high rate of zinc corrosion occurs. Typically, the corrosion product is zinc hydroxide, a white-colored compound; hence, “white rust” is visible.
The common ways to minimize the occurrence of humid-storage stain include the following:

- Applying an invisible inorganic corrosion-inhibiting compound to the sheet surfaces during production
- Applying a rust-inhibitive oil to the surfaces of the sheet during production
- Storing the product under temperature- and humidity-controlled conditions
- Packaging carefully for shipment

The application of surface treatments to prevent storage stain are not foolproof. Galvanized products have to be produced, stored, and transported properly for storage stain to be prevented.
Other Metallic Coating Types. The most common metallic coating for corrosion protection of steel is a zinc (galvanized) coating. As described in the previous section, it offers a very good combination of galvanic and barrier protection. However, through the years, other types of hot-dip coatings have been developed to target specific improvements in one or more features related to corrosion protection. An aluminized coating applied by the continuous hot-dip process was developed during the 1950s. It was claimed to offer better barrier corrosion protection than a galvanized coating for applications where the product is exposed to the atmosphere and better resistance to corrosion at elevated temperatures. Over time, these attributes of aluminum-coated steel sheet have proven to be correct, but the lack of offering galvanic protection at sheared edges in most environments has prevented aluminized steel from displacing galvanized sheet for many applications.
Since galvanized coatings on steel sheet were used commercially a long time before any other commercial product came into the marketplace, it is usual to compare all the other types of metallic coatings on steel sheet with reference to their performance versus a galvanized coating.
Galvannealed Coatings. Galvannealed coatings are made by heating the molten coating and steel sheet after the sheet emerges from the coating bath. The sheet is heated to approximately 480 to 565 °C (900 to 1050 °F) for approximately 10 s. During this time, the zinc becomes completely alloyed with the iron from the steel. The result is a coating layer that contains layers of zinc/iron intermetallic compounds. The stages of development of the galvannealed coating structure that occur during the heating cycle are shown in Fig. 7. As one might expect from a diffusion reaction of this nature, the outermost layer (often the δ-zinc/iron phase and, at times, the ζ-phase) contains the least amount of iron while the innermost layer (usually a very thin γ- phase) contains the highest percentage of iron. This coating is characterized by its high hardness and brittle nature.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

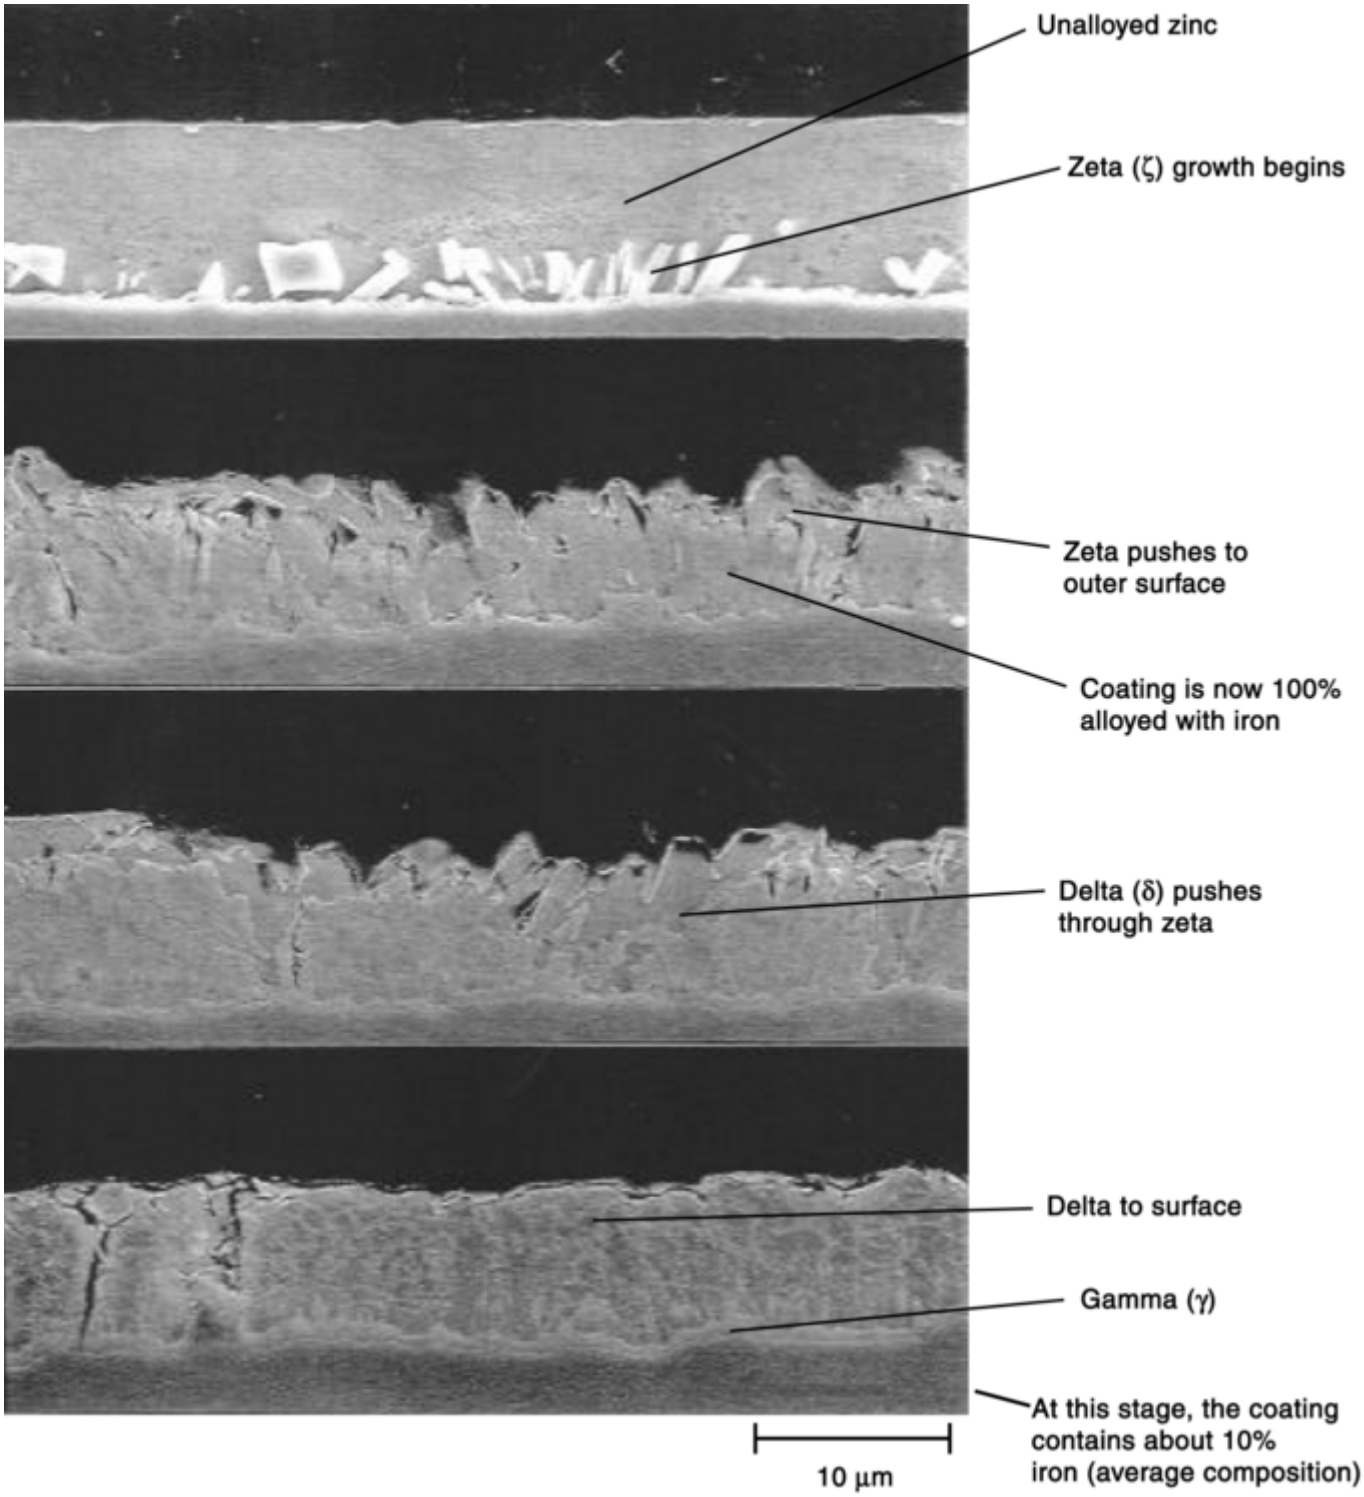

Fig. 7 Stages in the development of a galvannealed coating structure

When galvannealed sheet is formed, the usual reaction is for the coating to undergo some amount of *powdering.* Powdering of the galvannealed coating is simply the breakup of the coating into very small, hard, sandlike particles. It is a form of coating delamination. The key to successful product use is to limit the amount of powdering to an acceptably low level. Excessive powdering obviously can lead to more rapid local corrosion failure in that excessive powdering removes much of the metallic coating, leaving behind an area of uncoated steel. The key manufacturing steps required to achieve acceptably low levels of powdering have been thoroughly investigated during the past ten years. For detailed information on this topic, one should refer to many papers contained in the seven *Proceedings of the International Conference on Zinc and Zinc Alloy Coated Steel Sheet.* These conferences have been held every two years since 1989, and they contain a number of papers on the topic of galvannealed coatings, their production, and their use.

The key characteristics of galvannealed coatings versus regular galvanized coatings that make them useful for some applications are decreased galvanic activity and ease of painting and achieving good paint adhesion.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

For most applications, galvannealed sheet is intended to be painted prior to being placed in service. Thus, any discussion on the corrosion behavior needs to take into consideration the corrosion performance under a paint coating. Failure of painted steel sheet often takes place as excessive paint blistering and bulk loss of coating metal from beneath the paint. This is especially true at edges that have been sheared or at scratches in the paint, typically areas where failure occurs first.

The inclusion of up to 10% iron in the coating causes the electrochemical potential difference between steel and the coating to be considerably less than the potential between relatively pure zinc coatings on galvanized sheet and steel. This decreased electrochemical potential difference typically leads to a decrease in corrosion rate for a galvannealed coating. The galvannealed coating is still galvanically protective to steel; thus, the steel is still protected at exposed areas. But since the coating is less reactive, the rate of undercutting corrosion beneath the paint at an area adjacent to a scratch is lessened. This translates to less visible paint blistering and loss of paint adhesion along a scratch, stone chip, or sheared edge.

One has to keep in mind that galvannealed coatings are usually thinner than galvanized coatings. The most commonly produced coating weights are given in Table 5. The use of thinner galvannealed coatings is possible primarily because galvannealed coatings are intended to be painted. If left unpainted, the coating will often develop a light red stain when it is exposed to the environment due to the presence of iron in the coating. The additional barrier protection offered by the paint allows the use of a thinner metallic coating. The synergistic behavior of the combined paint plus metallic coating offers excellent corrosion resistance.

55Al-Zn Coatings. The 55Al-Zn coating composition is more precisely 55% aluminum, 43.5% zinc and 1.5% silicon. The silicon concentration may vary slightly from one manufacturer to another, but its primary purpose is to minimize the growth of the alloy layer, and thus enhance the adhesion of the coating during forming. It does not improve the corrosion performance.

This product has been made commercially since the 1970s. Its main attribute is that the coating offers improved long-term corrosion resistance in many applications compared with galvanized coatings. Low-slope roofing is an example where the benefits of improved corrosion resistance are important. Typically, low-slope roofing products are used unpainted and are exposed to the elements. In this application, the 55Al-Zn coating has shown to last more than 20 years and in some instances more than 30 years without failure (Ref 11).

The microstructure of the 55Al-Zn coating is shown in Fig. 8. The coating has a two-phase microstructure. This is best explained by reference to the aluminum/zinc phase diagram. One phase is the primary aluminum-rich dendritic phase that begins to grow initially during solidification. The other is an interdendritic zinc-rich region that forms when the zinc concentration in the solidifying liquid reaches a high level. This microstructure, aluminum-rich dendrites plus a network of zinc-rich interdendritic areas, is important to obtain the desired corrosion resistance (Ref 12). Thus, control of the cooling rate during the solidification stage is an important aspect of the production of 55Al-Zn-coated steel sheet. Other phases in the microstructure of the coating layer include particles of silicon, which are typically present as small discrete particles of elemental silicon, and an iron-rich phase which results because the coating bath becomes saturated with iron during the production process.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

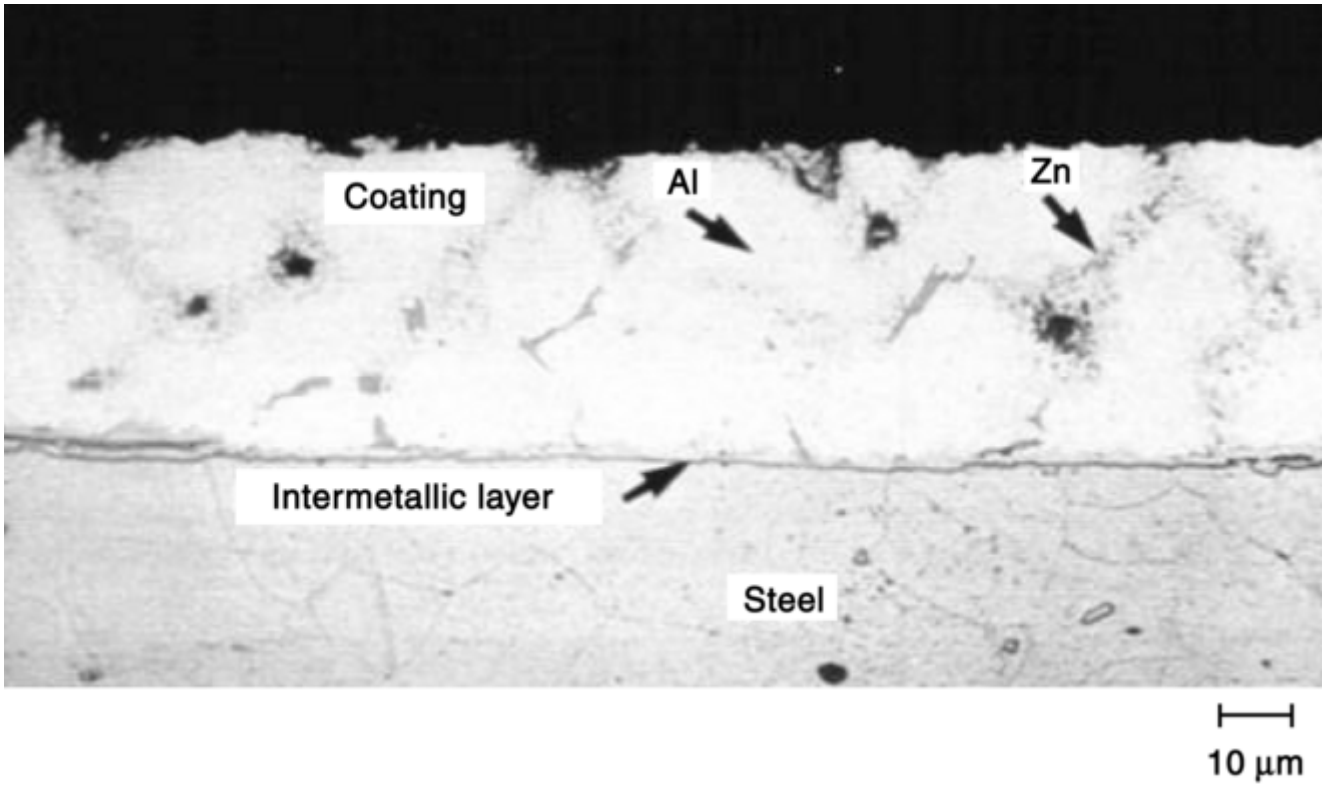

Fig. 8 Microstructure of 55Al-Zn coated sheet. Note the interdendritic zinc-rich areas.

Table 6 contains corrosion performance data comparing the performance of 55Al-Zn with galvanized coatings. The data indicate that the performance is superior versus galvanized in all three types of environments, marine, industrial and rural. The unique dendritic structure of the coating is given as the primary reason for the improved corrosion resistance. When the coating is exposed to the environment, the zinc-rich areas are corroded first. Since these areas are located in a labyrinth of interdendritic regions in the coating, the products of corrosion tend to fill the interdendritic interstices and the corrosion rate decreases. This leads to a parabolic corrosion rate in most environments. This contrasts with the linear behavior typical for galvanized.

Table 6 Ratios of average corrosion rates of 55Al-Zn and galvanized coatings

Location	Ratio of average corrosion rates 55Al-Zn: Galvanized[(a)]
Kure Beach, NC 25 m (severe marine)	4.2
Kure Beach, NC 250 meters (moderate marine)	2.3
Bethlehem, PA (industrial)	6.2
Saylorsburg, PA (rural)	3.4

(a) Ratio gives the relative improvement of the 55Al-Zn coating versus galvanized. Source: Ref 13

Corrosion of the coating for the 55Al-Zn product is not a uniform-thinning process as that noted for galvanized coating. During the early stages of the product life, the aluminum-rich dendrites stay fairly much unaffected in most environments. In a sense, the aluminum-rich dendrites perform like a barrier coating while the zinc-rich areas provide the galvanic protection that is needed to minimize the tendency for rust- staining at sheared edges and other areas of exposed steel.

Because the corrosion resistance depends on the microstructural features of the coating, it is more important to have the right microstructure than a thick coating to develop the desired performance. It has been found that in order to achieve the desired microstructure, the coating thickness should not be too thin. For this reason, the most common coating designations for products to be used outdoors in the environment are:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

ASTM A 792/A 792 M coating designation	Minimum coating weight[(a)], oz/ft^2
AZ50	0.50
AZ55	0.55
AZ60	0.60

(a) Total both sides, based on a specific test

The AZ50 coating is approximately as thick as a G90 galvanized coating. The SI unit designations are:

ASTM A 792/A 792 M coating designation	Minimum coating weight[(a)], g/m^2
AZ150	150
AZ165	165
AZ180	180

(a) Total both sides, based on a specific test

There are several notable exceptions to the improved corrosion performance of 55Al-Zn- coated sheet versus galvanized. Perhaps, the most important one is the performance in closed animal-confinement structures in cold climates. The 55Al-Zn coating is not recommended for concentrated confinement of cattle and pigs (Ref 14) in cold climates, regions where overnight condensation is a usual condition. In these types of applications, the coating is susceptible to pitting corrosion. For poultry buildings, the product has been observed to perform well.

95Zn-Al Coating. Another continuous hot- dip zinc/aluminum alloy coated product that is being produced globally today is one that contains 95% zinc and 5% aluminum. There are two types of 95Zn-Al coating. One contains a small addition of mischmetal while the other type being made commercially contains a small addition of magnesium. These additions are claimed to offer improvement in obtaining smooth and uniformly thick coatings.

There are a number of papers reporting results on the relative corrosion resistance of the 95Zn- Al coating versus a galvanized coating. Outdoor performance is reported in Ref 15, 16, 17. The data in Table 7 (Ref 17) show the outdoor performance in three marine locations. Except for the sheltered severe marine site, the 95Zn-Al coating outperforms the galvanized coating. These data show that the presence of 5% aluminum in this zinc-base coating contributes to improved corrosion resistance versus a pure zinc-containing galvanized coating. This improvement might be related to the influence of aluminum on the nature of the surface-passivating film, or, perhaps, the eutectic structure of the coating (Fig. 9) may alter some aspect of the corrosion mechanism at the outer surface of the coating such as influencing the anode-cathode geometry on the surface.

Table 7 Two-year corrosion rates of galvanized, 95Zn-Al, and 55Al-Zn coatings

Aluminized Steel. There are two types of aluminum coatings applied to steel sheet by the continuous-coating method. One is applied from a coating bath that contains an aluminum alloy consisting of aluminum plus approximately 5 to 11% silicon. Typically, the silicon concentration is about 8 to 9%. This product is designated type 1 aluminized sheet. The other aluminized coating is essentially pure aluminum. This coating is designated type 2 aluminized sheet. Aside from the obvious difference in coating bath composition, the hot-dip process to make both of these coated-sheet products is very similar to that used to make continuous hot-dip coated galvanized sheet.

The sheet product made from the silicon-containing bath is used for applications where exposure to elevated temperatures is involved. These applications include fireplace and furnace parts and automotive exhaust systems. Unlike galvanized sheet that is somewhat prone to embrittlement (Ref 18) when exposed at temperatures greater than 200 °C (400 °F) where the zinc diffuses into the steel sheet, type 1 aluminized low-carbon steel sheet performs well at elevated temperatures. Up to approximately 480 °C (900 °F), interdiffusion between the steel sheet and the coating is somewhat slow, and the sheet remains bright in appearance. At higher temperatures, iron from the steel sheet does diffuse into the coating, and the bright appearance is lost. Even though the coating and steel diffuse into one another at high temperatures, there are data (Ref 19) that show type 1 aluminized can be used for applications up to about 650 °C (1200 °F).

The silicon in the coating bath has a somewhat similar effect on the growth rate of the alloy bond zone during production as the use of silicon in a 55Al-Zn bath. That is, it reduces the rate of growth of the alloy layer and thereby provides better coating adhesion during forming operations. The microstructure of the type 1 aluminized coating is shown in Fig. 10. Note that the alloy layer is not pencil-thin like that for galvanized sheet (Fig. 5) but is more like the thickness of the alloy layer on 55Al-Zn.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

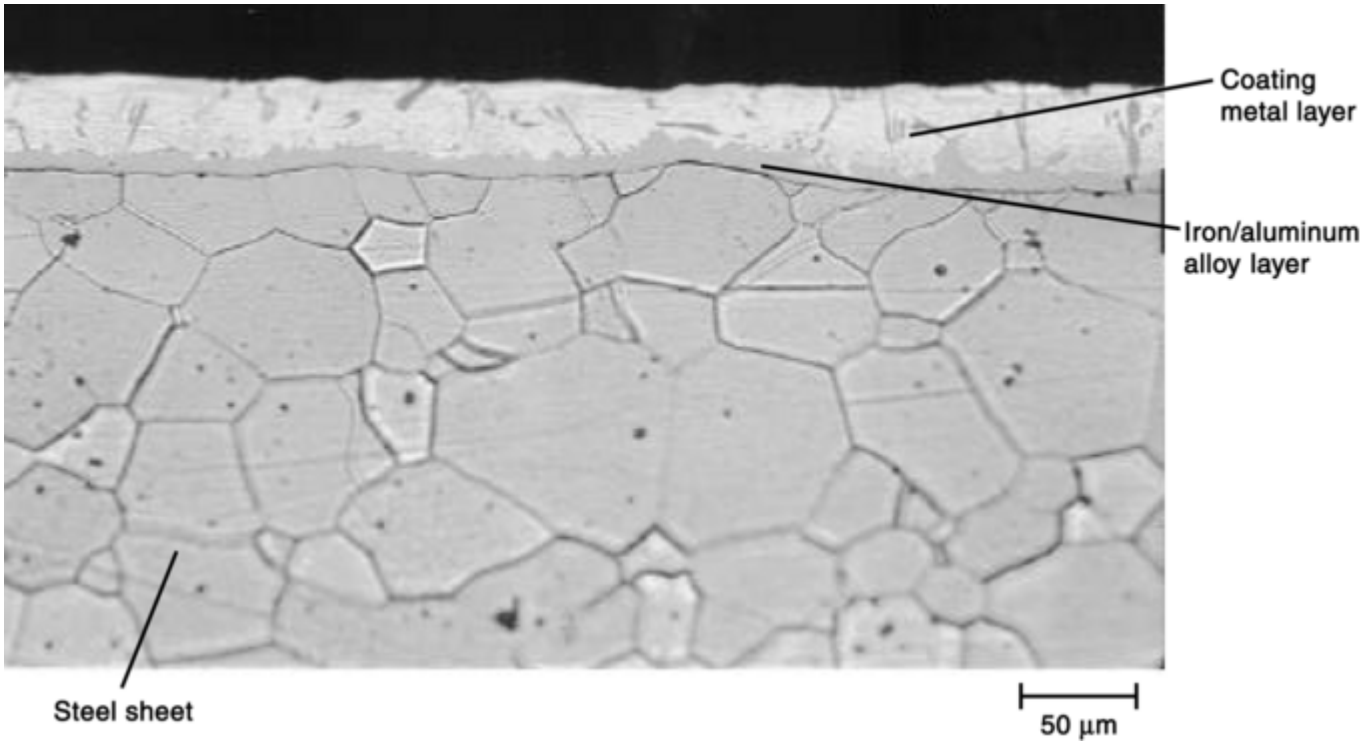

Fig. 10 Microstructure of the coating and alloy layer of a hot-dip coated type 1 aluminized steel sheet

In recent years, type 1 aluminized coating has been applied onto 400 Series stainless steels. The push by the automotive industry to develop a 10 year exhaust system has promulgated the use of 400 Series stainless steels for most original equipment exhaust systems. Even with this upgrade, however, there are problems with stainless steel that an aluminum-coated stainless product can help to overcome (Ref 20). One is the discoloration (heat tint) that is evident on stainless. The aluminized surface helps to maintain a good cosmetic appearance. Also, the aluminized coating can be used effectively to help avoid pitting corrosion of the stainless steel that is caused by the presence of chlorides.

Figure 11 shows the typical microstructure and alloy layer for product made using a pure aluminum coating bath. Note the increased thickness of the alloy layer compared with the coating in Fig. 10. Since the ability to form the sheet into a shaped final part while maintaining good coating adhesion is highly dependent on the thickness of the alloy layer, type 1 product can be used for more severely formed parts than the type 2 product.

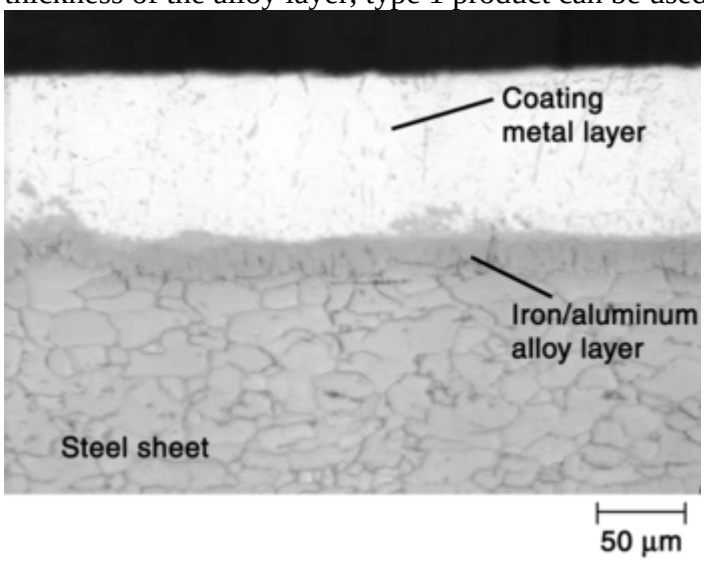

Fig. 11 Microstructure of the coating and alloy layer of hot-dip coated type 2 aluminized sheet

Type 2 aluminized sheet is used for applications where excellent *barrier* corrosion protection is needed; one application is aluminized culverts. Here, the barrier-layer protection is sufficient for many in-ground applications. There are many types of soils, and the suitability of type 2 aluminized for a specific site versus

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

galvanized culvert depends on many factors, including pH and resistivity of the soil. Aluminized steel has been shown to exhibit good performance in environments within the pH range of 5 to 9 and in soils with resistivities as low as 1500 Ω · cm. (590 Ω · in.).

Because aluminum in the atmosphere reacts to form a protective oxide layer on its surface, the surface becomes highly passivated in most environments. This passivating film is very stable; thus in most environments, the corrosion rate is much lower than for a galvanized coating. Table 8 contains data that show the difference in corrosion rates for type 2 aluminized versus galvanized coatings (Ref 21). Clearly, the bulk corrosion rate for the aluminized coating is less than that for galvanized coatings.

Table 8 Coating thickness losses for galvanized steel and type 2 aluminized steel in atmospheric exposure

Years exposed	Coating thickness loss in industrial environment			
	G90 galvanized		**Type 2 aluminized**	
	µm	**mils**	**µm**	**mils**
1	2.6	0.1	0.5	0.02
2	5.2	0.2	0.7	0.03
4	9.3	0.37	1.2	0.05
6	14.5	0.57	3.1	0.12
10	24.4	0.96	2.9	0.11
15	…	…	5.3	0.21

Source: Ref 21

In spite of these differences in corrosion rate, aluminized steel has not displaced galvanized for many applications. The key reason is that the aluminized coating does not provide galvanic protection in most environments at places where the steel is exposed. The strong tendency for the coating to become completely passivated in the atmosphere simply prevents galvanic corrosion protection. Thus, rust staining develops at areas where steel is exposed, and this rusting can then lead to *bleeding* (staining formed by the oxidation products of steel corrosion) onto larger areas of the sheet. This is an aesthetic issue, but one that is important to many users of coated-steel sheet product.

Batch Process Hot Dip Galvanizing

Thomas J. Langill, American Galvanizers Association

Introduction

THE METALLIC COATING produced by the hot dip galvanizing process is the result of a metallurgical reaction called diffusion. Diffusion occurs when iron from the steel and zinc from the molten bath intermix to form specific coating layers. In this reaction, zinc diffuses inward and iron diffuses outward; together they form separate coating layers of specific composition. The finished product consists of four layers on the steel; the outer layer is 100% zinc. The inner three layers are separate intermetallic layers of slightly different zinc and iron composition that are metallurgically bonded to each other and the steel. Thus, a galvanized coating has extremely high bond-strength relative to other coatings.

For the diffusion reaction to occur, the zinc must wet the steel surface. The presence on the steel surface of foreign materials such as rust, scale, paints, or lubricants can prevent the zinc from wetting and reacting with the steel surface. Therefore, all contaminants must be removed before galvanizing.

The batch hot dip galvanizing process consists of two basic steps: surface preparation; that is, cleaning the steel surface, and immersion of the steel part in the bath of molten zinc, galvanizing. Within each of these broad steps, a series of operations is essential to the production of a quality galvanized coating.

Surface Preparation

Dirt, oils, lubricants, greases, and other impurities, as well as normal oxidation products such as mill scale or rust, may be deposited on the steel during fabrication, transportation, or storage. These impurities must be removed so that iron and zinc may intermix to form the galvanized coating. These surface contaminants are typically removed by immersion in cleaning solutions followed by rinsing in clean water.

Alkaline Degreasing. The first step in the process is treatment in an alkaline solution. Oils, greases, and other saponifiable compounds are removed in this step. Most of the various proprietary compounds available for this purpose consist of a mixture of basic sodium salts.

Acid Degreasing. An alternate method to alkaline cleaning is acid degreasing using a dilute hydrochloric acid bath. The acid bath with appropriate additives will also remove organic materials.

Acid Pickling. The steel article is usually rinsed after alkaline degreasing and before pickling to avoid neutralization and weakening of the pickle acid. The pickling process removes surface oxides and mill scale. The pickle acid is an aqueous solution of a mineral acid, usually hydrochloric acid (HCl) or sulfuric acid (H_2SO_4). Acid concentrations and pickling temperatures vary from galvanizer to galvanizer but are within a narrow range. An inhibitor is sometimes used to avoid attack of the base metal.

Abrasive Cleaning. As an alternative to cleaning in solutions, abrasive grit-blasting or sand-blasting may be used, followed by a flash (less than 30 s) immersion in pickle acid to remove any surface oxides that may

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

develop between cleaning and further processing. Abrasive cleaning may not be practical for the galvanizer who handles a variety of sizes and shapes of material. Abrasive cleaning provides rapid and complete cleaning and is particularly effective in cleaning iron castings because casting sands are easily removed and surface uniformity is promoted. This method is also useful for cleaning fabricated products composed of different ferrous materials that may pickle at different rates or for removing welding slag or other impurities that are difficult or impossible to remove using chemical solutions.

Fluxing. The final step in the surface preparation is an immersion in a flux solution to dissolve any oxide films formed on the steel after pickling but before galvanizing and to ensure that a clean metal surface contacts the molten zinc. The fluxing procedures are classified as the wet process and the dry process:

- *Wet process.* Steel is passed through a layer of molten flux floating on the surface of the molten zinc.
- *Dry process (prefluxing).* Steel is immersed in an aqueous flux solution and dried before galvanizing.

In both cases, a flux composed of zinc ammonium chloride ($ZnCl_2 \cdot nNH_4Cl$) is used. Because both flux processes have advantages, selection of a method is based on individual galvanizer choice. The ratio of zinc chloride to ammonium chloride in the flux may vary based on the application.

Galvanizing

The molten zinc metal is contained in a kettle made of firebox-quality steel. The zinc is maintained at a temperature of 438 to 454 °C (820 to 850 °F). The kettle should be large enough to accommodate the steel parts and should have sufficient heat capacity to prevent significant thermal drops when steel is immersed in the molten zinc.

There are some hot dip galvanizers who use a higher temperature zinc bath, from 540 to 570 °C (1004 to 1058 °F). The higher temperature galvanizing baths are used for structural reactive steels or for fasteners that are fabricated from reactive steel. For this process, the galvanizing kettle must be fabricated from ceramic materials since steel kettles cannot operate at this high a temperature due to interactions between zinc and iron. Coatings from high-temperature galvanizing are dull gray due to the growth of iron-zinc alloy layers. The process for galvanizing is the same for normal- or high-temperature zinc baths.

The clean iron or steel part is immersed (dipped) directly into the molten zinc, or it is passed through a molten flux blanket into the molten zinc. The material is immediately wetted, and as it reaches the temperature of the molten zinc, the diffusion reaction begins, resulting in the formation of a series of iron-zinc alloy layers. For most steel compositions, the interdiffusion reaction is rapid at first but subsequently slows. The final thickness of the coating does not increase substantially with longer immersion times in the molten zinc.

The coating produced consists of a series of zinc-iron alloy layers, with increasing zinc content occurring toward the outer coating surface. When the coated steel part is withdrawn from the kettle, a thin layer of free zinc remains on the zinc-iron alloy layers, resulting in the characteristic bright, shiny, galvanized coating finish when allowed to cool quickly in air. The thickness of the free zinc layer varies with the speed of withdrawal from the molten bath.

Smaller parts are hot dip galvanized in steel baskets that are placed in a centrifuge immediately after withdrawal from the zinc bath. The parts are spun in the centrifuge to remove the excess zinc metal. This operation produces higher quality coatings on threaded articles.

Most galvanized articles are air cooled after coating, although centrifuged parts and smaller items are often water cooled (quenched). Water quenching halts the alloying reaction by diminishing the heat retained by the

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

steel part; this prevents the continued diffusion reaction that will continue to produce zinc-iron intermetallics until the steel part drops below approximately 288 °C (550 °F). In some galvanizing facilities, the water quench contains chromates or there is a separate bath of chromate solution. The chromates are used to form a conversion coating on the surface of the zinc. This conversion coating prevents the formation of excessive amounts of zinc oxide and zinc hydroxide on the surface of the zinc coating in the first week after hot dip galvanizing. Excessive oxide and hydroxide formation is known as wet storage stain since it forms when hot dip galvanized parts are exposed to high amounts of water in their first few days after galvanizing. The chromate conversion coating should not be used if the hot dip galvanized part is to be painted since it interferes with paint adhesion on zinc coatings. More information on chromate conversion coatings can be found elsewhere in this Volume.

Coating Weight and Thickness

Galvanizing specifications in the United States require the coating thickness to be measured by one of a number of techniques. For wire, sheet, or small parts and fasteners, the procedure involves stripping the coating, determining the weight loss of the item, then calculating the coating weight. Stripping of zinc coatings may be done by immersion in either hydrochloric acid-antimony trichloride solution or dilute hydrochloric acid. For large iron and steel structural materials, this may be impossible or impractical. The coating weight can be determined by measuring the coating thickness with a calibrated magnetic thickness gage. The weight to thickness conversion is 305 g/m^2 of zinc equals 43 μm of thickness (1 oz of zinc/ft^2 equals a thickness of 1.7 mils). Therefore, 100 g/m^2 of zinc equals 14 μm.

Factors Affecting Coating Thickness and Structure

For most steel compositions, the coating thickness and structure are relatively insensitive to differences in the galvanizing process. However, variations in steel chemistry; zinc bath temperature; the physical condition of the steel surface (grain size, stresses, microstructure, roughness); zinc chemistry; the amount of wiping, shaking, or centrifuging; and the rate of cooling after galvanizing can affect the thickness, metallurgical characteristics, and appearance of the coating (Ref 1).

Metallurgy. The hot dip galvanized coating consists of three separate layers of zinc-iron intermetallics, formed by interdiffusion of zinc and iron, and a fourth and final layer of zinc bath metal with no iron. The first intermetallic layer, gamma layer, contains 75% zinc and 25% iron and is typically very thin and uniform. The second intermetallic layer, delta layer, contains 90% zinc and 10% iron and is very dense and uniform. The third intermetallic layer, zeta layer, contains 94% zinc and 6% iron and grows in a columnar structure. This layer can be quite different from spot to spot on the final product. When there are very thick coatings on steel parts, it is usually the zeta layer that grows very thick. The final layer, eta layer, is deposited from the zinc bath as the part is withdrawn from the bath. Galvanizers attempt to draw the parts from the bath at a slow, steady speed so the excess zinc will drain off the part back into the bath. A fast withdrawal will result in a lumpy and runny coating that is very irregular in coating thickness.

Steel Chemistry. Although most steel can be galvanized, steel chemistry can have a marked effect on the thickness, structure, and appearance of the galvanized coating. Silicon, phosphorus, carbon, and manganese may be present in the steel and can influence the zinc-iron reaction mechanism, depending on their concentration (Ref 2).

The most influential steel constituent is silicon, which is added to molten steel to remove oxygen before casting. Figure 1 shows the effect of increasing silicon content in the steel versus time at two different galvanizing temperatures. In high-silicon (reactive) steels, the increase in coating thickness results from the accelerated growth of the zinc-iron alloy layers. This growth is due to the formation of loosely packed small grains or long-stem crystals in the outermost alloy layer of the coating, allowing zinc from the bath to penetrate to the steel surface with continuation of the reaction (Ref 3). In general, steels with the following maximum impurity levels are best suited to galvanizing: 0.04% Si, 0.04% P, 0.25% C, and 1.3% Mn.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

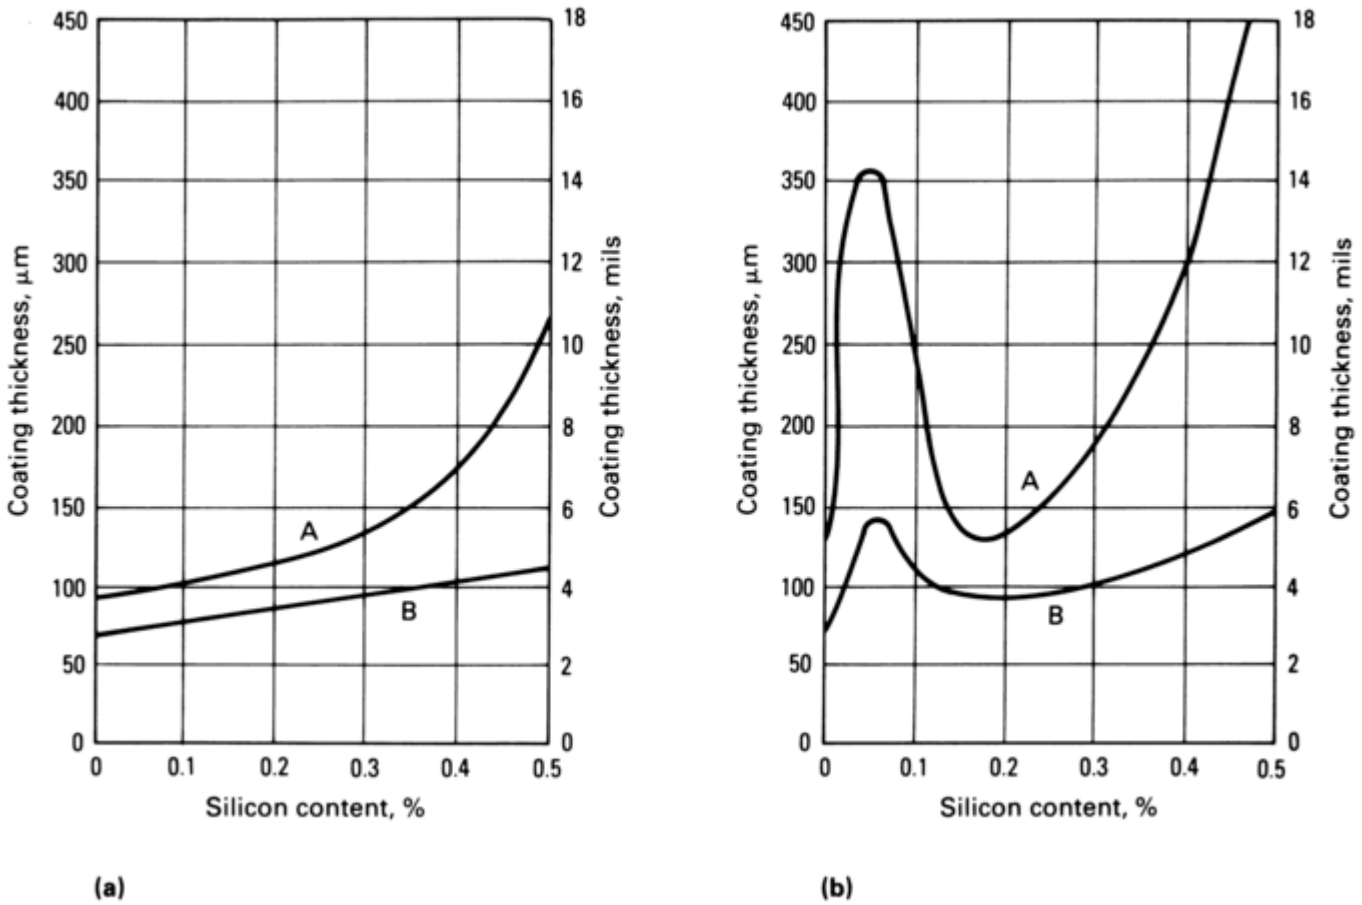

Fig. 1 Effect of silicon content of steel, immersion time, and galvanizing temperature on the thickness of hot dip galvanized coatings. Curves A and B are for 9 min and 3 min immersions, respectively. (a) Galvanizing temperature: 430 °C (805 °F). (b) Galvanizing temperature: 460 °C (860 °F). Source: Ref 2

Zinc Bath Temperature. For normal steels, an increase in the zinc bath temperature not exceeding the normal operating range results in reduced immersion time and improved drainage of free zinc when the steel part is removed from the galvanizing kettle. The coating thickness for silicon-containing steels is very temperature dependent (Fig. 1), with higher temperatures producing a thicker galvanized coating. The galvanizer must trade off more consistent coating thickness at low temperatures for high-silicon steel with higher production rates at higher temperatures for lower silicon steels.

Steel Surface Condition. The condition of the steel surface with respect to roughness and microstructure can affect the thickness of the galvanized coating. Roughening of the surface increases the profile and thus the effective surface area of the material, resulting in increased coating thickness. Fine-grain microstructures can result in lower coating weights (Ref 3).

Zinc Chemistry. Trace elements in the molten zinc, present either as impurities or intentionally added to the zinc to achieve beneficial results, can affect the appearance of the galvanized coating. Prime Western zinc (UNS Z19001), one of the grades normally used for batch process galvanizing, can contain up to 1.4% Pb, 0.2% Cd, 0.05% Fe, and must contain a minimum of 98% Zn. Other grades of zinc used for hot dip galvanizing are High Grade (UNS Z15001) with a maximum impurity level of 0.10% and Special High Grade (UNS Z13001) with a maximum impurity level of 0.010%

Although the lead content of Prime Western zinc can be as high as 1.4%, a typical galvanizing bath will contain 1% or less, and the actual hot dip galvanized coating contains approximately half of the bath lead concentration; that is, about 0.5% lead in the coating. Lead has no effect on the viscosity of molten zinc, but it does affect the surface tension. This results in better drainage of zinc from the galvanized product, an important consideration when galvanizing complex shapes or wire fabrics.

Aluminum is usually not found in the grades of zinc normally used for galvanizing but is occasionally added to improve the finish of the work. Aluminum at a concentration of 0.005% in zinc will result in coatings with improved brightness and uniformity. It also retards the surface oxidation of the molten zinc, resulting in a smoother flow of zinc over the work and improved drainage characteristics. Other elements that are added to

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

the zinc bath in small quantities are bismuth and nickel to improve the bath fluidity and the coating thickness control respectively.

The typical galvanizing zinc bath may contain other trace elements that were originally present in the zinc or that resulted from the chemistry of the steel processed. These trace elements, including cadmium and copper, are usually present in concentrations too low to affect the coating structure or appearance.

Degree of Wiping, Shaking, or Centrifuging. These techniques are used for the efficient removal of excess zinc after galvanizing and result in a coating with a very uniform surface appearance. These techniques are particularly important when galvanizing threaded materials.

Rate of Cooling. Silicon-containing steels that are allowed to cool slowly after galvanizing will continue to react until the temperature decreases to below approximately 288 °C (550 °F). This may result in the iron-zinc alloy layers extending to the coating surface and an almost total absence of the free zinc layer. The result is a gray coating instead of a bright, shiny finish. The service life of the coating is not adversely affected and may in fact be greater with these coatings because of their increased thickness.

If the material is not water quenched after galvanizing and a bright, shiny surface is desired, then close stacking of material while still hot should be avoided. Close stacking may allow heat retention, which could permit the zinc- iron alloying reaction to continue. Material should be well spaced with good air circulation for cooling efficiency.

Mechanical Properties of the Coating and Steel Substrate

Hardness and Abrasion Resistance. The layers that compose the galvanized coating, being discrete zinc-iron alloys, vary in hardness. The outer layer of 100% zinc is relatively soft, but the alloy layers are very hard, harder even than ordinary structural steels. Typical values for the microhardness and other properties of the various alloy layers are given in Table 1.

Table 1 Properties of alloy layers to hot dip galvanized steels

Layer	Alloy	Iron, %	Melting point		Crystal structure	Diamond pyramid microhardness (vickers scale)	Alloy characteristics
			°C	°F			
Eta	Zinc	0.03	419	787	Hexagonal	70–72	Soft, ductile
Zeta	$FeZn_{13}$	5.7–	530	986	Monoclinic	175–185	Hard, brittle

www.iran–mavad.com

مرجع مهندسی مواد و متالورژی

		6.3					
Delta	$FeZn_7$	7.0–11.0	530–670	986–1238	Hexagonal	240–300	Ductile
Gamma	Fe_3Zn_{10}	20.0–27.0	670–780	1238–1436	Cubic	…	Thin, hard brittle
Steel base metal	Iron	…	1510	2750	Cubic	150–175	…

The alloy layers are from four to six times more resistant to abrasion than pure zinc. Galvanized coatings exhibit better abrasion resistance than paints with the same coating thickness and can be effectively used where excessive abrasive wear is expected, for example, floor gratings, stairs, conveyors, and storage bins.

Adhesion and Impact Resistance. Unlike other coatings that are mechanically or chemically bonded to the steel, the galvanized coating is metallurgically bonded to and integral with the steel, making conventional measures of bond strength inappropriate for this coating. As a result of the metallurgical bond, the galvanized coating has bond strength on the order of several thousand pounds per square inch (psi).

The structure of the galvanized coating, particularly the relative thickness of the delta and zeta alloy layers (Table 1), is primarily influenced by the steel chemistry and, to a lesser extent, by the galvanizing bath temperature and the duration of immersion. Coating structure has the greatest effect on the impact resistance of the coating. A high relative proportion of zeta phase in the iron-zinc alloy may result in localized flaking if the coating is subjected to heavy impact or excessive twisting or bending. Semikilled steels with silicon contents of 0.05 to 0.12% are the most susceptible to coating brittleness and less adherent coatings.

Steel Strength and Ductility. The effects of hot dip galvanizing on the mechanical properties of steels have been thoroughly researched. This research has shown that galvanizing causes no significant alteration in the bend, tensile, and impact properties of the commonly galvanized steels produced throughout the world (Ref 4). Galvanizing slightly reduces the impact toughness of cold-rolled steels, but this reduction is generally not sufficient to affect the applicability of the steel. Of course, typical items that are batch processed are not intended to be subsequently cold rolled. Steels coated by the batch galvanizing process are not generally intended to be bent or roll formed after galvanizing.

Weld Stresses. Welded structures have higher strength in the galvanized condition than in the uncoated condition. Hot dip galvanizing reduces weld stresses by 50 to 60% (Ref 4).

Fatigue Strength. For most steel, little reduction in fatigue strength occurs as a result of galvanizing. Fatigue tests comparing hot dip galvanized steels with uncoated steels usually compare uncoated steel with mill scale and the same steel after galvanizing. The results show a slight edge to the uncoated steel samples, but these tests do not consider that uncoated steel exposed to an outside environment begins to rust immediately. The rusting action results in the formation of pits that may be five to seven times deeper than the general corrosion and will cause a rapid decrease in fatigue strength. The reduction in fatigue strength due to corrosion attack is much more significant than any reduction due to hot dip galvanizing.

Embrittlement. It is relatively rare for steel to be in the embrittled condition after hot dip galvanizing. The amount of cold working (plastic straining) of steels susceptible to strain aging is the single most important factor where strain- age embrittlement is of concern. The temperature of the galvanizing process accelerates the aging process; generally, susceptible materials fail almost immediately after removal from the bath. Research has shown that a minimum cold- bend radius of three times the section thickness will preclude sufficient cold working and prevent the embrittled condition from occurring (Ref 3, 4).

If possible, steel fabrications should use steels with a low susceptibility to strain-age embrittlement. When cold working is necessary, the guidelines and limitations contained in ASTM A 143 (Ref 5) should be observed.

Hydrogen embrittlement does not occur when ordinary carbon or low-alloy steels are galvanized. Hardened steels may become embrittled if the hydrogen picked up during pickling is not expelled during immersion in the molten zinc bath. Precautions should be taken with steels having an ultimate tensile strength exceeding 1034 MPa (150 ksi). Steels of medium-to-high strength that have been severely cold worked may have local areas that also approach this threshold limit for susceptibility to hydrogen embrittlement.

Fabrication Details for Galvanizing

The design and fabrication of materials to be hot dip galvanized involve a few basic rules that are easy to apply and are necessary to the production of quality galvanized articles meeting intended functional requirements. Foremost among these rules is the interrelationship among the design engineer, fabricator, and galvanizer. Although this interrelationship becomes increasingly important with the complexity of the configuration of the material to be galvanized, most problems relating to design can be eliminated if it becomes an integral part of the design and fabrication program.

Steel Selection. As previously discussed, steel chemistry can affect the nature and extent of the zinc-iron alloy layers formed during galvanizing. Some steels that are commonly used for galvanized products are ASTM A 36 (with <0.04% Si specified) for structural shapes and plate, A 120 for pipe, A 569 for sheet, and A 615 for reinforcing bar.

Combining Different Materials. Optimum galvanizing quality is seldom obtained when ferrous materials that have different chemistries or different surface conditions, or those that are constructed by different fabrication methods, are combined. Different pickling and immersion times are required for different materials, and combinations may result in over- or under-treatment of the combined parts of the fabricated article. Different material types for which combinations should be avoided include excessively rusted items, material with machined or pitted surfaces, cast iron and steel, malleable iron, hot- rolled steel, cold-rolled steel, and reactive steels.

Castings. The cleaning of castings requires special attention. Burned-on sand from the casting process is nearly impossible to completely remove by conventional pickling methods, and the use of hydrofluoric acid (HF), although effective, can be extremely dangerous to galvanizing personnel. Castings should be shot-blasted or grit-blasted by the fabricator before delivery to the galvanizer.

Castings that consist of two or more different metals may pickle and galvanize differently. The designer and fabricator should be aware of this. Abrasive cleaning may moderate these effects and provide for a more uniform coating appearance. Alternatively, the materials may be galvanized separately and assembled after galvanizing.

Surface Contaminants. Residue materials resulting from fabrication or storage should be removed before delivery of the steel part to the galvanizer, unless special arrangements have been made. Typical contaminants include welding slag and paints or other labeling compounds. Welding slag results from the use of coated welding rod. Weld slag cannot be removed by conventional pickling, and if the use of uncoated rod is not possible, weld slag should be removed by mechanical methods. Paints or other labeling compounds often used to identify the work are sometimes difficult or impossible to remove by alkaline cleaning methods. Permanent markings for identification, if needed, should be punched or embossed in the steel, applied to the part as weld metal, or punched into 12-gage or thicker steel tags and wired securely to the part with heavy-gage steel wire.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Size of Material. Various sizes of hot dip galvanizing kettles exist throughout North America. Designing and fabricating in modules suitable for the available galvanizing facilities allows almost any component to be galvanized. If the material is too long or too deep to be completely immersed in the molten zinc in one dip, it may still be possible to galvanize by immersing one- half of the article in the kettle, withdrawing, and then immersing the other half. By using this procedure, known as progressive dipping, materials up to 75% longer than the length of kettle may be successfully galvanized, depending on the depth of the item and other kettle dimensions. Although progressive dipping is an accepted galvanizing practice, special attention to galvanizing details and proper inspection are essential to its use on tubular items.

Threaded and Movable Parts. For threaded parts, such as nut and bolt assemblies, it is advisable to tap the nut threads after galvanizing to ensure a proper fit. For movable parts, such as shackles or shafts, a radial clearance of 1.6 mm ($\frac{1}{16}$ in.) is usually sufficient to allow free movement after galvanizing.

Drainage. When designing for hot dip galvanizing, consideration must be given by the designer and fabricator to providing a way for cleaning solutions and zinc to flow into, through, and out of the item so that all surfaces can be properly galvanized.

Venting. The opening of holes or slots for the release of trapped gases in hollow objects is necessary for proper treatment of exterior and interior surfaces. More important, venting is essential for avoiding the extreme explosion hazard that can result from heating a closed or improperly vented hollow object to the galvanizing temperature. Discussions of proper venting techniques become very complex when intricate configurations are under consideration. Venting practices for various configurations, as well as additional fabrication techniques, are discussed in Ref 6, 7, 8.

Overlapping or Contacting Surfaces. When designing parts that are to be hot dip galvanized, it is best to avoid narrow gaps less than 2.4 mm ($\frac{3}{32}$ in.), between plates, overlapping surfaces, and back-to-back angles and channels. When overlapping or contacting surfaces cannot be avoided, the edges should be completely sealed by welding; otherwise, pickle liquids can enter and result in conditions that permit the generation of high pressures and steam, delayed weeping, or improperly cleaned and galvanized areas. This may not be possible with large overlapping areas, so consult ASTM A 385 when using steel parts with overlapping surfaces.

Welding for Hot-Dip Galvanizing. When materials are welded before hot dip galvanizing, the cleanliness of the weld area and the composition of the weld metal can affect the quality and appearance of the galvanized coating. Specific welding information can be obtained from the American Welding Society (Ref 9) or welding suppliers. Several welding techniques have been found to be satisfactory for materials to be galvanized:

- An uncoated electrode should be used to prevent flux deposits.
- If a coated electrode is used, all flux residues must be removed because they are chemically inert to pickling acids.
- A welding process such as metal inert gas, tungsten inert gas, or CO_2 shielded arc should be used because virtually no slag is produced.
- In the case of heavy welds, a submerged arc method is recommended.
- If none of the above is available, a coated rod specifically designed for self-slagging, as recommended by welding equipment distributors, should be selected.
- A welding rod that will provide a deposited weld composition as close as possible to that of the parent steel should be chosen. This will prevent differential reaction rates during cleaning and uneven galvanized coating thickness.
- High-silicon welding rods may cause excessively high coating weights or darkened coatings.

Galvanized Coatings in Corrosion Service

Protection Mechanism. Galvanized coatings protect steel in two ways: barrier protection and cathodic protection. Barrier protection is provided by the galvanized coating and is further enhanced by the formation of a thin, tightly adherent layer of zinc corrosion products on the coating surface (Ref 1). On initial weathering in the open atmosphere, ZnO forms on the freshly galvanized surface. It is converted to $ZnOH_2$ in the presence of moisture. Over the period of 6 to 24 months, further reaction of the zinc corrosion products with CO_2 in the air results in the formation of basic $ZnCO_3$, which is relatively insoluble in water and impedes the growth of further corrosion products. The gray patina normally associated with weathered galvanized coatings is the result of this thin layer of basic $ZnCO_3$.

Cathodic protection is provided to the steel because zinc is anodic to steel in most environments. Minor discontinuities or small areas of exposed steel resulting from drilled holes or cut edges are protected from corrosion by the sacrificial protection afforded by zinc. The corrosion products of zinc that result from this cathodic action provide further protection by depositing on the exposed steel and forming another barrier protection.

Atmospheric Exposure. Zinc, steel, and hot- dip galvanized coatings have been the subject of long-term atmospheric studies conducted throughout the world (Ref 10, 11). From these studies, the behavior of these materials in a specific atmospheric environment can be reasonably estimated. An exact determination of corrosion behavior is complicated by several factors: the frequency and duration of exposure to moisture (rain, sleet, snow, and dew), the type and concentration of corrosive pollutants, the prevailing wind direction and velocity, and exposure to sea- spray or wind-borne abrasives. All atmospheres contain some type of corrosive material, and the concentration of these materials, as well as the frequency and duration of moisture contact, determines the corrosion rate of galvanized coatings.

Figure 2 shows the results of outdoor atmospheric-exposure tests designed to measure the protective life of galvanized coatings in various atmospheric environments. The sites were selected as representative of various broad environmental classifications: moderate industrial (urban), suburban, rural, and marine. Within these broad classifications, the following factors are most significant in influencing the rate of corrosion of the galvanized coating.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

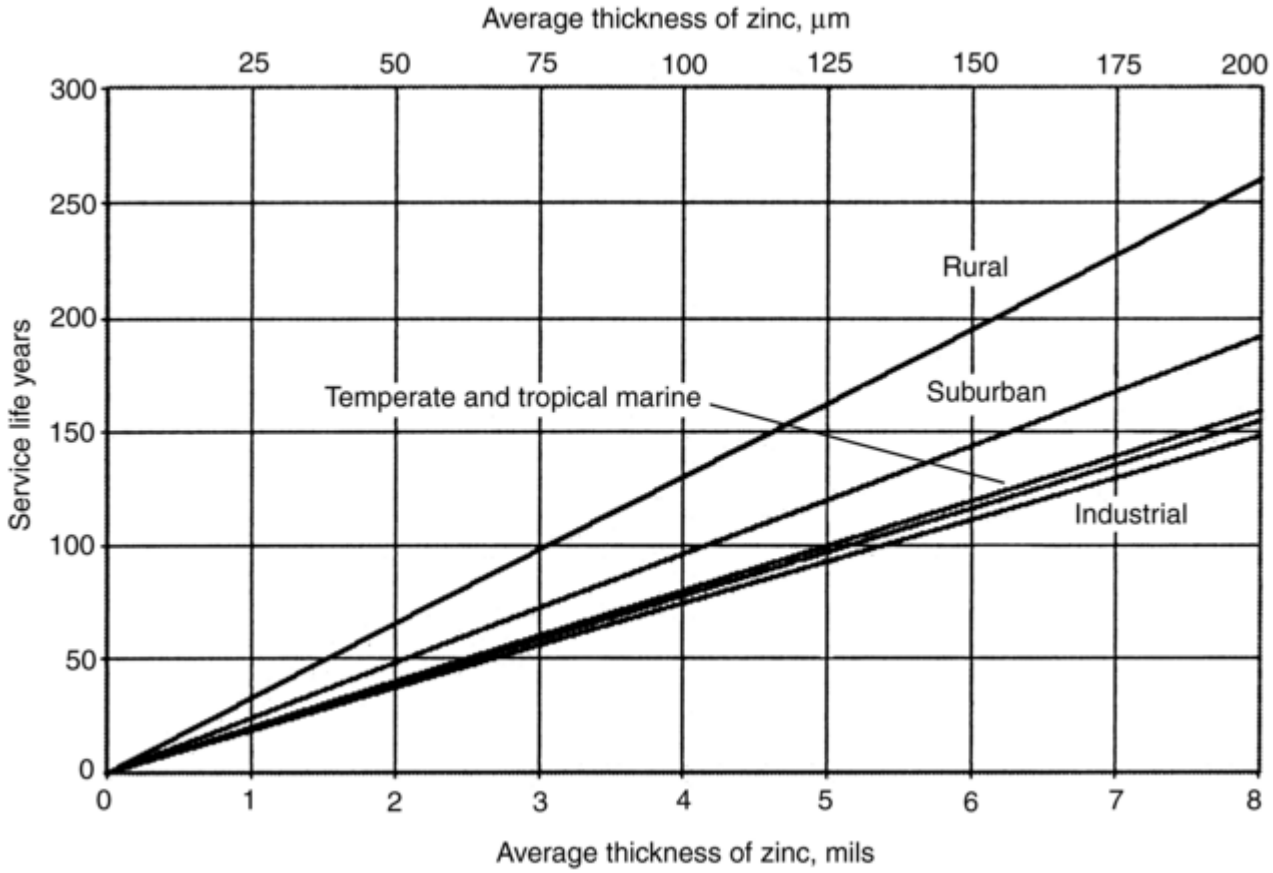

Fig. 2 Service life versus coating thickness for hot dip galvanized steel in various atmospheres. Service life is defined as the time to 5% rusting of the steel surface.

Industrial and Urban Environments. Corrosive conditions are most pronounced in areas with highly developed industrial complexes that release sulfurous gases and corrosive fumes and mists to the atmosphere. These corrosive materials react with the normally impervious basic $ZnCO_3$ film to produce $ZnSO_4$ and other soluble zinc salts that, in the presence of moisture, are washed from the surface. This exposes fresh zinc to the atmospheres, and another corrosion cycle begins.

Rural and Suburban. The corrosion rate of zinc in these areas is relatively slow compared to that in industrial settings. Once the original weathering occurs, there is little in the atmosphere to convert the basic zinc salts to water- soluble compounds.

Marine Atmospheres. The corrosion rate of zinc and galvanized steel in marine atmospheres is influenced by several factors. Zinc forms a soluble corrosion product, zinc chloride ($ZnCl_2$), in marine atmospheres; therefore, the corrosion rate is influenced by salt spray, sea breezes, topography, and proximity to the coastline. For example, one investigation found that the corrosion rate for zinc exposed 24.4 m (80 ft) from the ocean was three times that for zinc exposed 244 m (800 ft) from the ocean (Ref 12).

The corrosion product formed in a given type of atmosphere (industrial, marine, and so on) determines the corrosion rate of zinc in that atmosphere. Results from exposures in a variety of atmospheres show that zinc is 20 to 30 times more resistant to corrosion than steel.

Seawater and Salt Spray Performance. Table 2 gives the approximate corrosion rates of zinc in various waters, and Figure 3 illustrates the expected service life of galvanized coatings in areas exposed to salt spray influences (Ref 13). Sea salts are mainly NaCl, with small amounts of calcium, magnesium, and manganese salts. Typical pH is about 8. Compared to other metals and alloys, galvanized coatings provide considerably more protection to steel than many other metals and alloys, even though the anticipated coating life is shorter in seawater and salt spray exposures than a number of other corrosion protection systems.

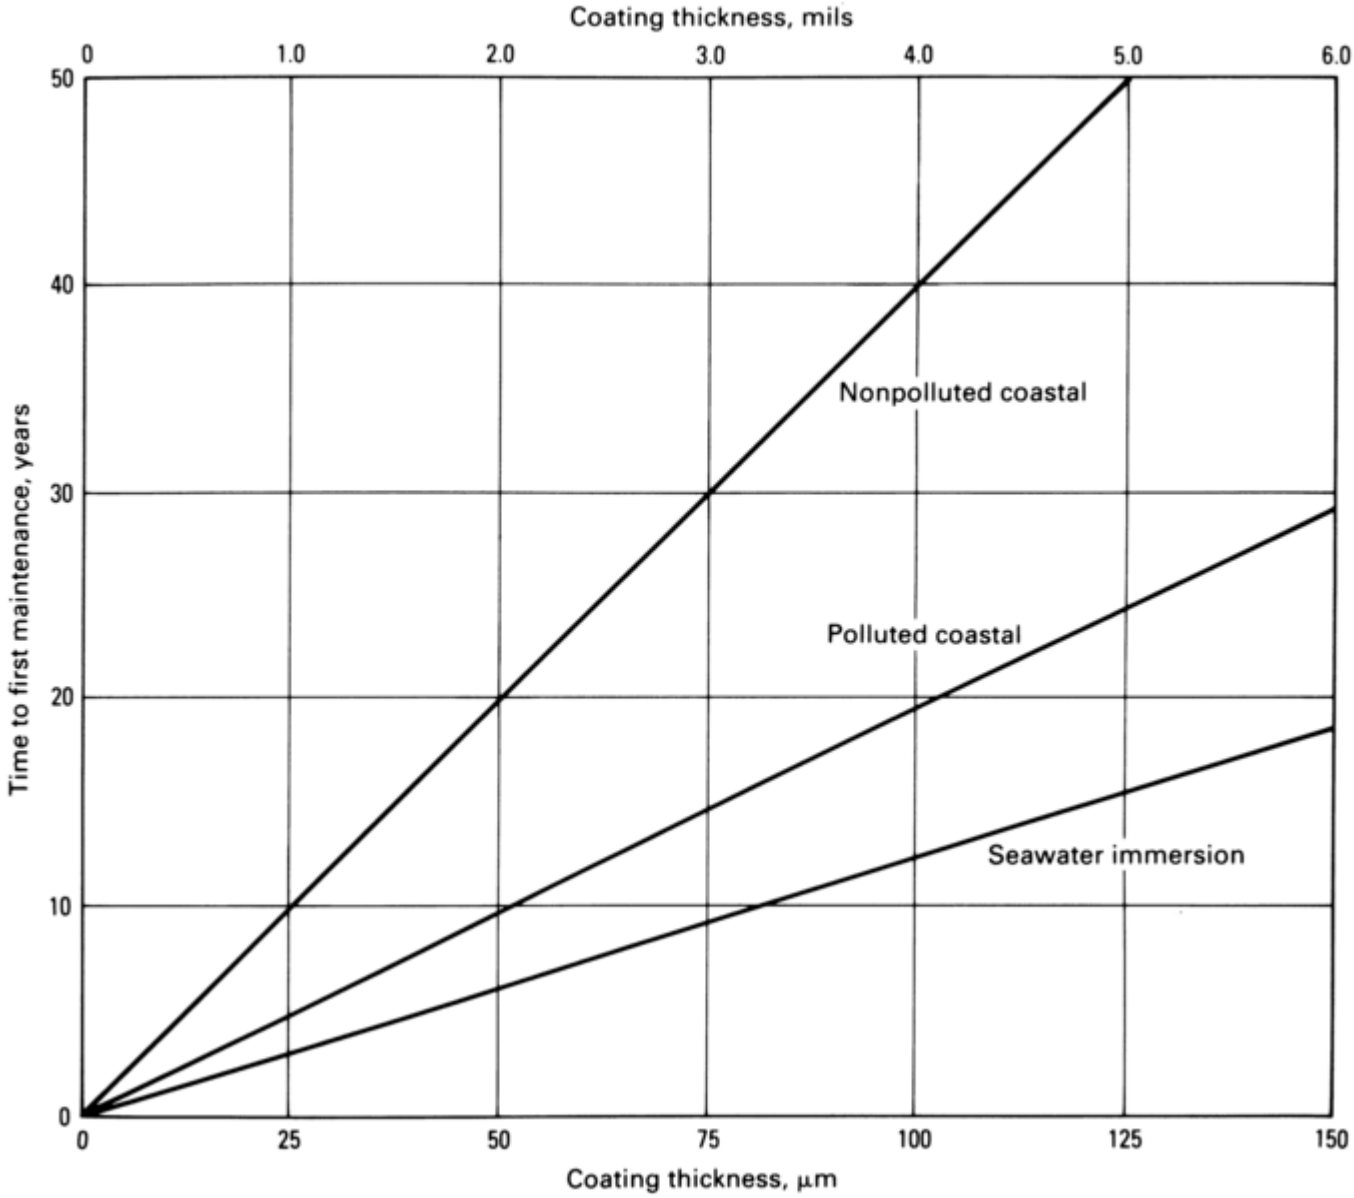

Fig. 3 Time to first maintenance versus coating thickness for hot dip galvanized coatings in seawater immersion and sea spray exposures. Source: Ref 13

Freshwater Performance. The corrosion protection mechanism of zinc in freshwater is similar to that in atmospheric exposures. The corrosion rate depends on the ability of the coating to develop a protective layer of adherent basic zinc salts. This layer denies access to the coating by oxygen and slows the rate of attack. The

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

ability of the water to form scale depends on a number of variables, such as the pH of the water, hardness, total alkalinity, and total dissolved solids. Table 3 demonstrates the effects of various water chemistries on the relative corrosion rates of zinc (Ref 13).

Table 3 Corrosion of zinc in different types of water

Water type	Attacking substances	Passivating substances	Properties of corrosion products		Relative corrosion rate
			Solubility	**Adhesion**	
Hard water	Oxygen, CO_2	Calcium, magnesium	Very low	Very good	Very low
Seawater	Oxygen, CO_2, Cl^-	Calcium, magnesium	Low	Very good	Moderate
Soft with free air supply	Oxygen, CO_2	…	High	Good	High
Soft or distilled with poor air supply	Oxygen	…	Very high	Very poor	Very high

Source: Ref 12

Water Temperature. The corrosion rate of zinc in water, and therefore that of the galvanized coating, increases with temperature to between 65 and 70 °C (150 and 160 °F), at which point the rate begins to decrease (Fig. 4).

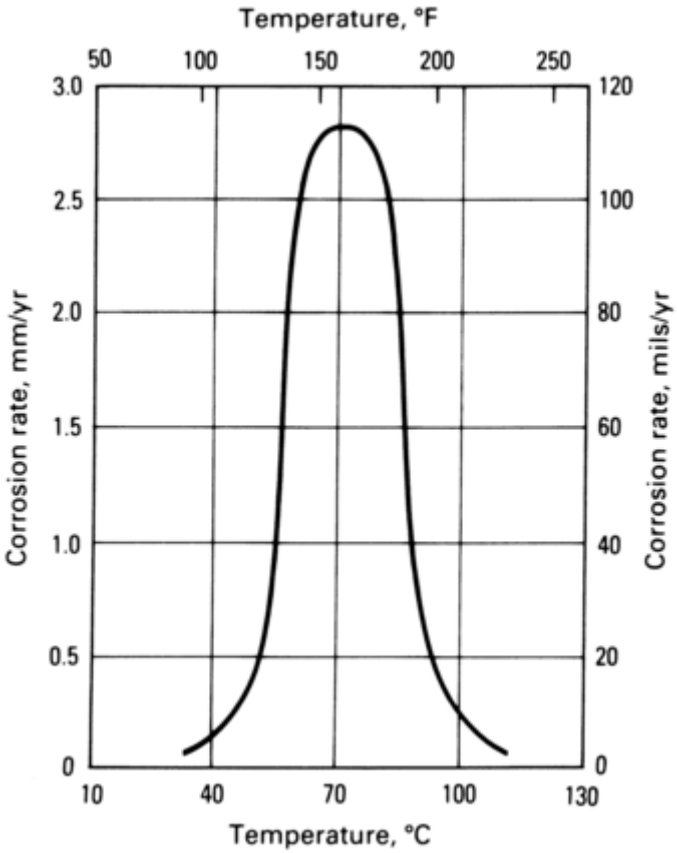

Fig. 4 Influence of water temperature on the corrosion rate of zinc in distilled, aerated water. Source: Ref 13

Water pH. Zinc is an amphoteric metal with the capacity to passivate by means of protective layers. The corrosion rate of zinc decreases with increasing pH and reaches a minimum at 12.0 to 12.5. Most waters are in the pH range of 6 to 8. The scale-forming ability of the water and the concentration of dissolved ions in the water are more important influences on the corrosion rate than pH in this practical exposure range.

Performance in Soils. The corrosion rate and performance of galvanized steels in soils are a function of the type of soil in which the steel is located. Soils can vary considerably in composition and can contain bound and unbound salts, organic compounds, products of weathering, bacteria and other microorganisms, dissolved gases

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

(such as hydrogen, oxygen, and methane), acids, and alkaloids. Soils vary in permeability, depending on the soil structure. Although the concentration of oxygen is lower in soils than in air, the CO_2 concentration is higher. Variation among soils is high, and corrosion conditions are complicated.

In general, soils in coarse, open textures are often aerated, and the performance of galvanized steel would be expected to be similar to that in air. In soils with fine textures and high water- holding capacities such as clay and silt-bearing soils, corrosion rates are likely to be higher.

Soil resistivity is recognized as a reliable method of predicting the corrosivity of soils. High-resistivity (poor conducting) soil would be less corrosive than low-resistivity (good conducting) soil. Dry soils are poor conductors and are the least corrosive to zinc.

Performance in Contact with Other Metals. The galvanic behavior of dissimilar metals in electrical contact is a complex corrosion problem, partly because of the large number of metals used in various applications. Copper and brass in contact with zinc or a galvanized coating in a moist environment can cause rapid galvanic corrosion of the zinc. Installations that use zinc and copper or copper alloys should provide for electrical insulation between the two, and because zinc may also be attacked by dissolved copper, copper materials should be located downstream of the zinc in nonrecirculating water systems. With aluminum or stainless steel, the performance of hot dip galvanized steel is good if the environment is dry. In humid environments, isolation may be required.

Performance of Fully Alloyed Coatings. Coatings that consist entirely of iron-zinc alloy layers (without the 100% zinc outer layer) result from the galvanizing of reactive steels. These coatings are characterized by a matte gray or mottled appearance. Fully alloyed coatings may exhibit premature rust-colored staining due to iron in the coating, but this should not be considered failure of the coating, because base metal rusting has not occurred. Fully alloyed coatings with coating thickness similar to normal coatings will give similar corrosion protection service.

High-Temperature Performance. When galvanized steel is continuously exposed to temperatures above about 200 °C (390 °F), the 100% zinc outer layer may peel off the intermetallic layers (Ref 13). The remaining alloy layers will not be affected and will continue to provide useful service life. Short time excursions above this temperature will not affect the coating and its performance.

Joining of Galvanized Structural Members

Bolting is the most widely used method of joining galvanized steel. A number of standard galvanized fasteners are available for use with galvanized steel structural members (Table 4).

Table 4 Some standard galvanized fasteners

Description	ASTM specification	Grade or type
Carbon steel bolts	A 307	Grade A, B
High-strength bolts	A 325	Type 1
Transmission tower bolts	A 394	Type 0, 1
Quenched-and-tempered alloy steel bolts	A 354	Grade BC

(a) Consult ASTM A 563 for suitable bolt/nut combinations.

Galvanized coatings in bearing-type connections, which develop shear resistance by allowing the bolts to bear on the plates, are not detrimental to performance and have a long history of use—for example, in electrical utility transmission line towers. In friction-type connections, all loads in the plane of the joint are transferred by the friction developed between the connected surfaces. The load that can be transmitted is determined from the clamping force applied to the bolts and the coefficients of friction of the faying surfaces. Clean, galvanized mating surfaces have a coefficient of friction that is slightly lower than that of as-rolled steel. The coefficient of friction of galvanized surfaces can be made equal to that of uncoated steel surfaces by wire brushing or light grit-blasting (Ref 14, 15). Neither treatment should be severe enough to produce breaks or discontinuities in the galvanized coating. The fatigue behavior of galvanized steel connections equals that of uncoated steel connections, regardless of whether the galvanized surfaces were wire-brushed or grit-blasted after galvanizing (Ref 14, 15, 16, 17).

Welding. Zinc-coated steel can be satisfactorily welded by all common welding methods, but attention must be given to the possible generation of zinc fumes. For the best weld quality, grind away the galvanized coating in the area of the weld for ~2.5 cm (1 in.) on either side of the weld site before welding. There will be no zinc fumes generated, and the weld can be performed as on uncoated steel. When burning off zinc in the case when the coating is not ground off, adequate ventilation, operator respiration units, or a fume-extracting welding unit must be used to avoid potential harmful effects. Extensive tensile, bend, radiographic, and fatigue tests show that the properties of sound metal inert gas or metallic arc welds on galvanized steel are equivalent to those on uncoated steel (Ref 4).

Penetration of molten zinc into the weld metal is the primary factor in cracking of galvanized steel weldments. The crack begins at the root of the weld and may or may not extend to the surface. Recommendations to avoid fillet weld cracking include (Ref 9):

- Treat the base metal to reduce the amount of available zinc by, for example, beveling the standing plate in a tee joint at an angle of 15 to 45°.
- Remove zinc from both faying surfaces by shot-blasting.
- Provide a parallel gap of 1.6 mm ($\frac{1}{16}$ in.) between the weld elements.
- Choose consumables that will give low-silicon content weld, for example, manganese silicate flux and 2% low manganese/low silicon electrodes for submerged arc welding. For CO_2 welding, low-silicon filler wire gives freedom from zinc penetration cracking but causes a small amount of porosity. For shielded arc welds, use a low-silicon electrode and a rutile covering.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Weld Porosity. A small void can occur in the weld bead because of the volatilization of zinc during welding. Porosity can be reduced by making adequate provision for the escape of gases evolved during welding. Normal porosity does not reduce the static tensile strength below that specified for satisfactory low-carbon steel weld metal, but it will affect the fatigue strength of a fillet weld.

Weld Damage Repair. Galvanized materials damaged by field welding can be touched in with an organic or inorganic zinc-rich paint. Organic paint does not require a high degree of surface preparation and dries quickly. The paint must have a zinc dust content according to approved standards and should be applied in several coats to a thickness of twice the galvanized thickness to a maximum of 100 μm (4 mils) to provide equivalent protection.

Low-melting zinc-cadmium or zinc-tin-lead alloy rods can also be used for repair. The rod is heated to about 330 °C (625 °F) with an oxyacetylene torch, and the melted alloy is rubbed and spread over the damaged area. This gives protection equal to that of the surrounding hot- dip galvanized coating. The damaged area can also be zinc metallized by thermal spraying. Additional information on repair techniques is given in ASTM A 780 (Ref 18).

Painting Galvanized Steel

Galvanized coatings, when used without further treatment, offer the most economical corrosion protection for steel in many environments. The galvanized coating makes an excellent base on which to apply a paint system. Painting of galvanized steel is desirable for aesthetics, as camouflage, as warning or identification markings, to prevent bimetallic corrosion, or when the anticipated environment is particularly severe (see the article

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

"Organic Coatings and Linings" in this Volume for supplementary information on painting for corrosion protection).

In corrosive atmospheres, a duplex system of galvanized steel top-coated with paint has several advantages that make it an excellent system for corrosion prevention:

- The life of the galvanized coating is extended by the paint coating.
- The sacrificial and barrier properties of the zinc coating are used if a break occurs in the paint film.
- Undercutting of damaged paint coatings, a major cause of failure of paints on steel, does not occur with a zinc substrate (Figure 5).
- Surface preparation of a weathered zinc surface for maintenance painting is easier than that for rusted steel.

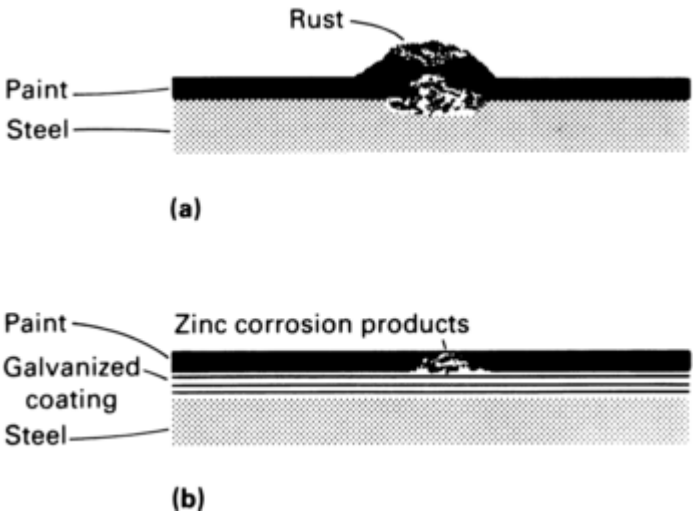

Fig. 5 Illustration of the mechanism of corrosion for (a) painted steel and (b) painted galvanized steel. (a) A void in the paint results in rusting of the steel, which undercuts the paint coating and results in further coating degradation. (b) A void in the coating of a painted galvanized steel is sealed with zinc corrosion products; this avoids the undercutting seen in (a) and prevents further deterioration of the painted coating.

Synergistic Effects of Galvanized and Painted Systems. The galvanized coating prevents rusting of steel by acting as a barrier against the environment and by sacrificially corroding to provide cathodic protection. Painting the galvanized coating extends the service life of the underlying zinc because the barrier property of the paint delays the reaction of zinc with the environment. If a crack or other void occurs in the paint and exposes the galvanized coating, the zinc corrosion products formed tend to fill and seal the void; this delays further reaction.

When painted ungalvanized steel is exposed to the environment, rust forms beneath any holiday or damage to the paint at the steel/paint interface. Because rust occupies a volume several times that of the steel, the expansion resulting from rusting leads to rupture of the steel/paint bond. Further, rust is porous; it accumulates moisture and other reactants. This increases the rate of attack on the steel. The result is undercutting, flaking, and blistering of the paint film, leading to failure of the paint coating (Figure 5). Zinc corrosion products occupy a volume only slightly greater (20 to 25%) than zinc. This reduces the expansive forces and conditions that lead to paint failure.

A coating system consisting of painted galvanized steel provides a protective service life up to 1.5 times that predicted by adding the expected lifetimes of the paint and the galvanized coating in a severe atmosphere (Ref 19). The synergistic improvement is even greater for mild environments (Ref 20, 21).

Paint Adhesion. Adherence of the paint to the galvanized surface is the primary concern in painting galvanized steel. The surface of the zinc is nonporous and does not allow mechanical adhesion of the paint. Surface contaminants such as oils, waxes, or post-galvanizing treatments also affect adhesion. A fresh zinc surface is reactive to certain paint ingredients, such as fatty acids; this can produce zinc soaps and disrupt the zinc-paint bond. Good practices for preparing galvanized surfaces to be painted are described in ASTM D 6386 (Ref 22).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Galvanized coatings can be successfully painted immediately after galvanizing or after extended weathering. The deliberate use of weathering is not recommended, because weathering may not be uniform, the time required is long (6 to 12 months), hygroscopic impurities can form that may be difficult to remove, and there is exposure to atmospheric pollutants.

Chemical etchants such as acids or copper sulfate should not be used. The action of these chemicals is difficult to control, and surface preparation may be nonuniform. The galvanized coating could be damaged if allowed to remain in extended contact with the chemicals. Long- term adhesion will suffer with this type of treatment, although initial adhesion may be obtained.

Mechanical roughening of the zinc surface through the use of a light blast can provide a good surface for painting. However, careful control of the blast pressure and flow rate must be exercised to avoid excessive removal of the galvanized coating.

Initial adhesion of the paint can be achieved through the use of a pretreatment primer to provide an adequate base for further coating. Long- term adhesion is obtained by the selection of a topcoat paint that is compatible with the primer and galvanized steel.

Pretreatment Methods. As with all painting operations, the surface to be painted must be free of contaminants that could affect the adhesion of the paint or the appearance of the painted article. Nonoily substances can be removed by brushing or scrubbing and then rinsing with water. Oily materials should be removed with an approved solvent followed by a final wiping with clean cloths and clean solvent to avoid spreading oil films on the surface.

Two-component wash primers meeting The Society for Protective Coatings (SSPC) specification SSPC-Paint 27 are ideal pretreatments. The primer is applied by spraying thin coats according to the recommendations of the manufacturer. The freshly prepared primer should be applied to a dry film thickness of 7.6 to 13 μm (0.3 to 0.5 mils).

Finish Coating. The primed material should be finish-coated as soon as possible after priming treatment. Wash primers are moisture sensitive, and the vehicle may gel under high-humidity conditions and lose adhesion. The primer usually dries in 15 to 30 min, and it is dry enough to apply a second coat after 30 to 60 min. Almost all paints will adhere to the wash primer.

Economics of Hot-Dip Galvanizing

Corrosion control is an expense for the owner of any facility. In selecting a system for corrosion control, the economic consequences of the selection should be determined. Initial cost should not be the sole determining factor in selecting a system. Instead, the desired service life of the project should be reasonably estimated and the life-cycle cost of several systems should be evaluated to determine the most economical system for the particular project.

A number of models have been developed for the economic evaluation of corrosion protection (Ref 23, 24, 25). The projected structure life, inflation and discount (cost of capital) rates, number of years in the maintenance cycle, estimated costs for future maintenance, and original system costs must be determined based on discounted cash flow techniques. In the private sector, tax and investment incentives must also be considered. Table 5 illustrates a simple analysis that takes tax and investment incentives into account. Although the initial cost of hot dip galvanizing is in the same range as paint systems, the life- cycle cost is significantly lower because hot dip galvanized coatings need no maintenance during the 30 year cycle described in this example.

Table 5 Applied cost of hot dip galvanized protection compared to four selected paint systems

Coating system	Original cost		Life cycle cost 30 year project performance[(a)]	
	$/m^2	**$/ft^2**	**$/m^2**	**$/ft^2**
Hot dip galvanizing	17.97	1.67	17.97	$1.67
Inorganic zinc	9.36	0.87	29.27	$2.72
Acrylic waterborne primer/topcoat	14.31	1.33	45.19	$4.20
Inorganic zinc primer/high-build epoxy/acrylic urethane	24.53	2.28	57.46	$5.34
Latex primer/latex intermediate/latex topcoat	18.40	1.71	69.08	$6.42

Note: The cost comparison is based on US dollars, 2003. The galvanizing data came from a U.S. nationwide survey in 2001. The paint information is from a 1998 NACE International study (Ref 25).

(a) The projected life cycle costs assume a 5% annual increase in the cost of paint materials and a 3% annual increase in paint preparation costs from 1998. The maintenance cycle calls for repainting when surface is degraded with 5% rust and assumes a moderate industrial environment.

Selected Applications of Hot Dip Galvanized Steel

Hot dip galvanized coatings are found in a wide variety of applications requiring long-term, maintenance-free corrosion protection. The examples in this section will demonstrate the scope of galvanized steel use.

Example 1: Bridges. The first all hot dip galvanized bridge in the United States was erected in 1966 at Stearns Bayou, Ottawa County, MI. The bridge is 128 m (420 ft) long and has a 9.1 m (30-ft) wide roadway with a 1.5 m (5 ft) walkway on each side. All the components of this bridge were hot dip galvanized. To avoid possible effects from road salting, telescoping splash plates in the joints were installed to divert deck drainage away from the beams.

When inspected in 1997, the average coating thickness was 160 μm (6.3 mils), which is enough to last another 45 to 65 years. The bearing pads, the most deteriorated component of the bridge, showed a coating thickness of 74 μm (2.9 mils).

Example 2: Pulp and Paper Mills. Typical pulp and paper mills contain a number of areas that, in the absence of corrosion protection, would rapidly deteriorate because of exposure to various chemicals. A paper mill in the northwest United States used galvanized structural steel pipe supports, ladders, cages, and miscellaneous steel items in the stock tank, black liquor, lime kiln, and paper machine areas. Galvanized steel was used during the original construction 33 years ago and for subsequent expansions. All of the galvanized steel is located outside in a humid environment subject to salt spray. When inspected in 1985, coating thickness ranged from 90 to 160 μm (3.5 to 6.5 mils).

Example 3: Recreation. A galvanized roller coaster located on the beach near Wildwood, NJ was constructed in 1997 to a very exacting production schedule. All 350 tons of steel making up the framework, angle materials, bolts, and nuts were hot dip galvanized including the 20 foot-deep cement-covered piles that anchor the ride. At high tide, parts of the coaster go out over the water, making the hot dip galvanized coating and its corrosion performance an even more essential part of the structure.

Example 4: Utility Industry. A galvanized electrical utility substation located near Knoxville, TN and owned by the Tennessee Valley Authority was constructed in 1936 to handle 100,800 kW of electricity produced by a nearby dam. Substation structures are of a bolted-lattice construction. The minimum coating thickness measured in a 1997 inspection were 70 μm (2.75 mils) on lattice angles and 50 μm (2.5 mils) on bolt heads with an overall average of 83 μm (3.3 mils). Based on estimations of the original coating weight, this substation will last another 20 years before maintenance coating will be required.

Other Applications. Hot dip galvanized steel coated by the batch process is used in oil refineries and petrochemical industries and for miscellaneous highway uses, such as guard rail, light and sign standards, and fencing. The coating has found extensive use in water and wastewater treatment plants, both in atmospheric and immersion service. Applications such as electrical utility transmission towers, microwave transmission stations, pole line hardware, cooling towers and cooling tube bundles, nuts, bolts, and various fasteners, all involve extensive use of galvanizing.

Galvanized reinforcement bars, ties, and lintels for concrete and masonry reinforcement and support provide long-term corrosion protection in vital areas that are not normally visible. The use of galvanized materials in concrete reinforcement and masonry applications is ideal because the normal pH of these materials before setting is approximately 12 to 12.5, which corresponds to the pH range in which corrosion of zinc is at a minimum (Ref 26).

Galvanizing Specifications

Galvanized coatings produced by the hot dip (batch) process are covered by numerous specifications. The following are pertinent specifications under the authority of ASTM:

- A 123 “Standard Specification for Zinc (Hot- Dip Galvanized) Coatings on Iron and Steel Products”
- A 143 “Standard Recommended Practice for Safeguarding Against Embrittlement of Hot- Dip Galvanized Structural Steel Products and Procedure for Detecting Embrittlement”
- A 153 “Standard Specification for Zinc Coating (Hot Dip) on Iron and Steel Hardware”
- A 384 “Standard Practice for Safeguarding Against Warpage and Distortion During Hot- Dip Galvanizing of Steel Assemblies”
- A 385 “Standard Practice for Providing High- Quality Zinc Coatings (Hot-Dip)”
- A 767 “Standard Specification for Zinc- Coated (Galvanized) Steel Bars for Concrete Reinforcement”
- A 780 “Standard Practice for Repair of Damaged and Uncoated Areas of Hot-Dip Galvanized Coatings”
- D 6386 “Standard Practice for Preparation of Zinc (Hot-Dip Galvanized) Coated Iron and Steel Product and Hardware Surfaces for Painting”
- E 376 “Standard Practice for Measuring Coating Thickness by Magnetic-Field or Eddy- Current (Electromagnetic) Test Methods”

Thermal Spray Coatings

Marita L. Berndt, Brookhaven National Laboratory; Christopher C. Berndt, State University of New York, Stony Brook

Introduction

THERMAL SPRAY COATINGS are a versatile and well-established means of protecting metals from corrosion in a wide variety of environments (Ref 1, 2). Many different materials can be used to produce thermal spray coatings, thereby providing effective solutions to diverse corrosion problems. These materials—including metals, ceramics, polymers, and combinations thereof—may be used to provide reliable long- term corrosion protection to substrates. Another use of thermal spray coatings is production of anodes for cathodic protection of steel reinforcement in concrete. Thermal spraying is virtually unlimited in scale and complexity of applications, ranging from small fasteners to structures. Production of coatings is rapid and can be automated. Other advantages of thermal spray coatings include portability, ability to seal or topcoat, abrasion and erosion resistance, and lack of curing requirements.

Thermal Spray Processes

Thermal spray (TS) is a generic term used to describe a group of processes, including flame spraying, plasma spraying, arc metallization, detonation gun (D-gun), high-velocity oxyfuel (HVOF), and cold spray, that can be used to apply a variety of different coating materials for corrosion protection (Ref 3). Although these processes encompass a wide range of equipment needs, costs, materials selection and application, they can all be treated as belonging to the same family since the processing variables that are being altered are temperature and particle velocity. Figure 1 depicts the temperature-velocity processing envelope that allows materials engineers

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

to create a vast array of coatings for applications that include coatings for orthopedic hips, thermal barrier coatings for aerospace hardware, rebuilding of original equipment manufacturer components, and coatings to protect against corrosion.

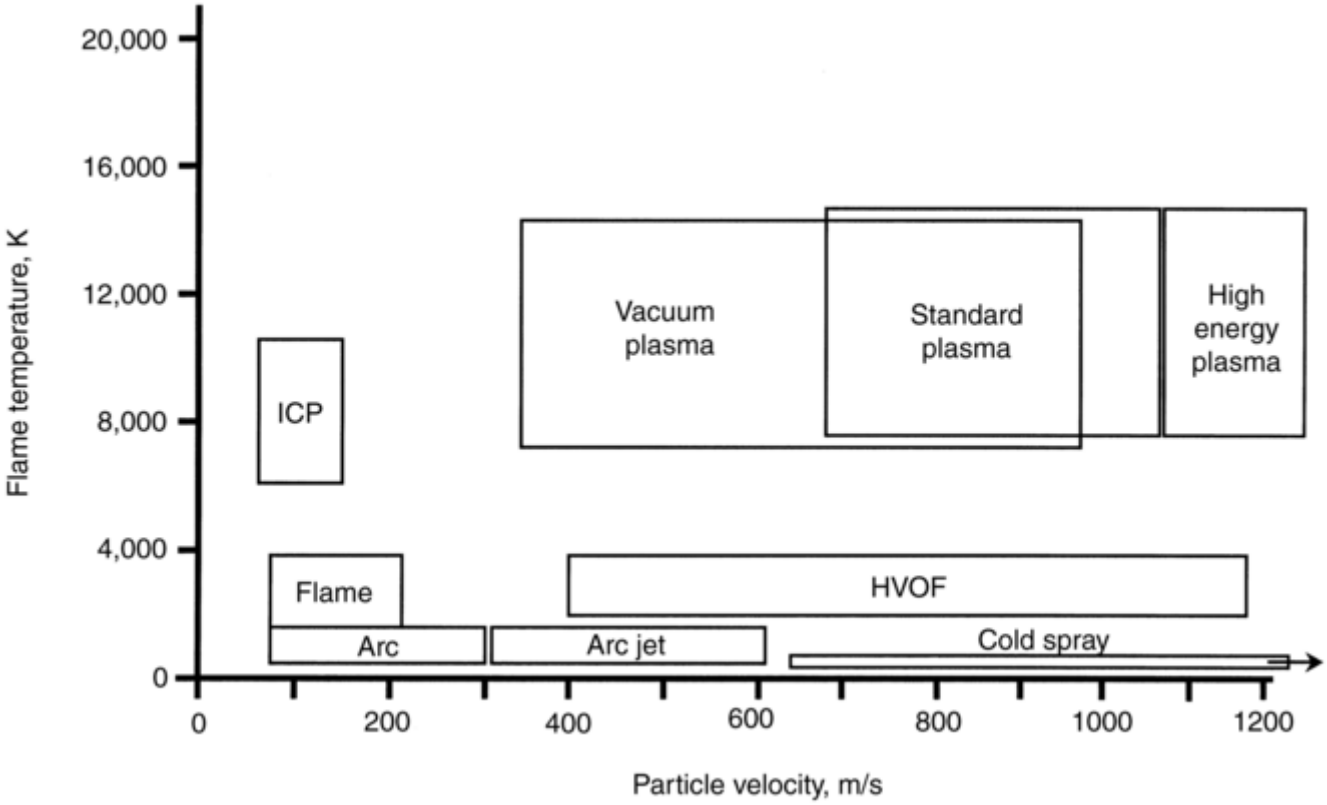

Fig. 1 The temperature-velocity distribution envelope of thermal spray processes. HVOF, high-velocity oxyfuel; ICP, induction coupled plasma

Besides temperature and velocity, another variable is the nature of the material that is used to form the coating. The material can be a powder, rod, wire, or liquid. The material that is fed into the TS process is termed feedstock, with the most common forms being powder and wire (Ref 4, 5). The feedstock morphologies are selected according to the process. Arc metallization and the wire flame processes require wire as the feedstock, whereas the most common renditions of the gas flame, plasma, and HVOF processes require powders.

Table 1 lists thermal spray processes. Those that are based on similar technological principles or that have equivalent names are grouped onto the same lines. The choice of process or material depends on the engineering application. Ceramic TS coatings generally require processes with higher velocities and temperatures than lower- melting point materials. Therefore, plasma, D- gun, and HVOF are the preferred techniques for deposition at high rates. The deposition of ceramics is more sensitive to spray parameters than is the deposition of metals.

Table 1 Thermal spray process parameters

Process	Temperature		Velocity	
	°C	**°F**	**m/s**	**ft/s**
Oxyacetylene gas flame spraying, flame spraying	3,000	5,430	150	490
Atmospheric plasma spraying, APS	12,000	21,630	900	2,955
Low-pressure plasma spraying, LPPS, VPS	1,200	2,190	900	2,955
Detonation gun spraying, D-gun	300	570	1,000	3,280
Ceramic rod process, Rokide process	3,000	5,430	150	490
Hypersonic plasma spraying, diamond jet gun (DJ gun), JetKote, High-velocity oxyfuel process (HVOF), J-gun, Topgun, Nova-jet, Plazjet	3,000	5,430	800	2,625
Arc metallization, wire spraying	1,500	2,730	200	655

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Generic figures that demonstrate the principles behind TS processes are shown in Fig. 2. Wire flame, powder flame, electric arc, and plasma spray processes are depicted. The same principle applies in all cases; a feedstock is rapidly heated and then accelerated toward a suitably prepared substrate where on impact it consolidates to form an adherent coating.

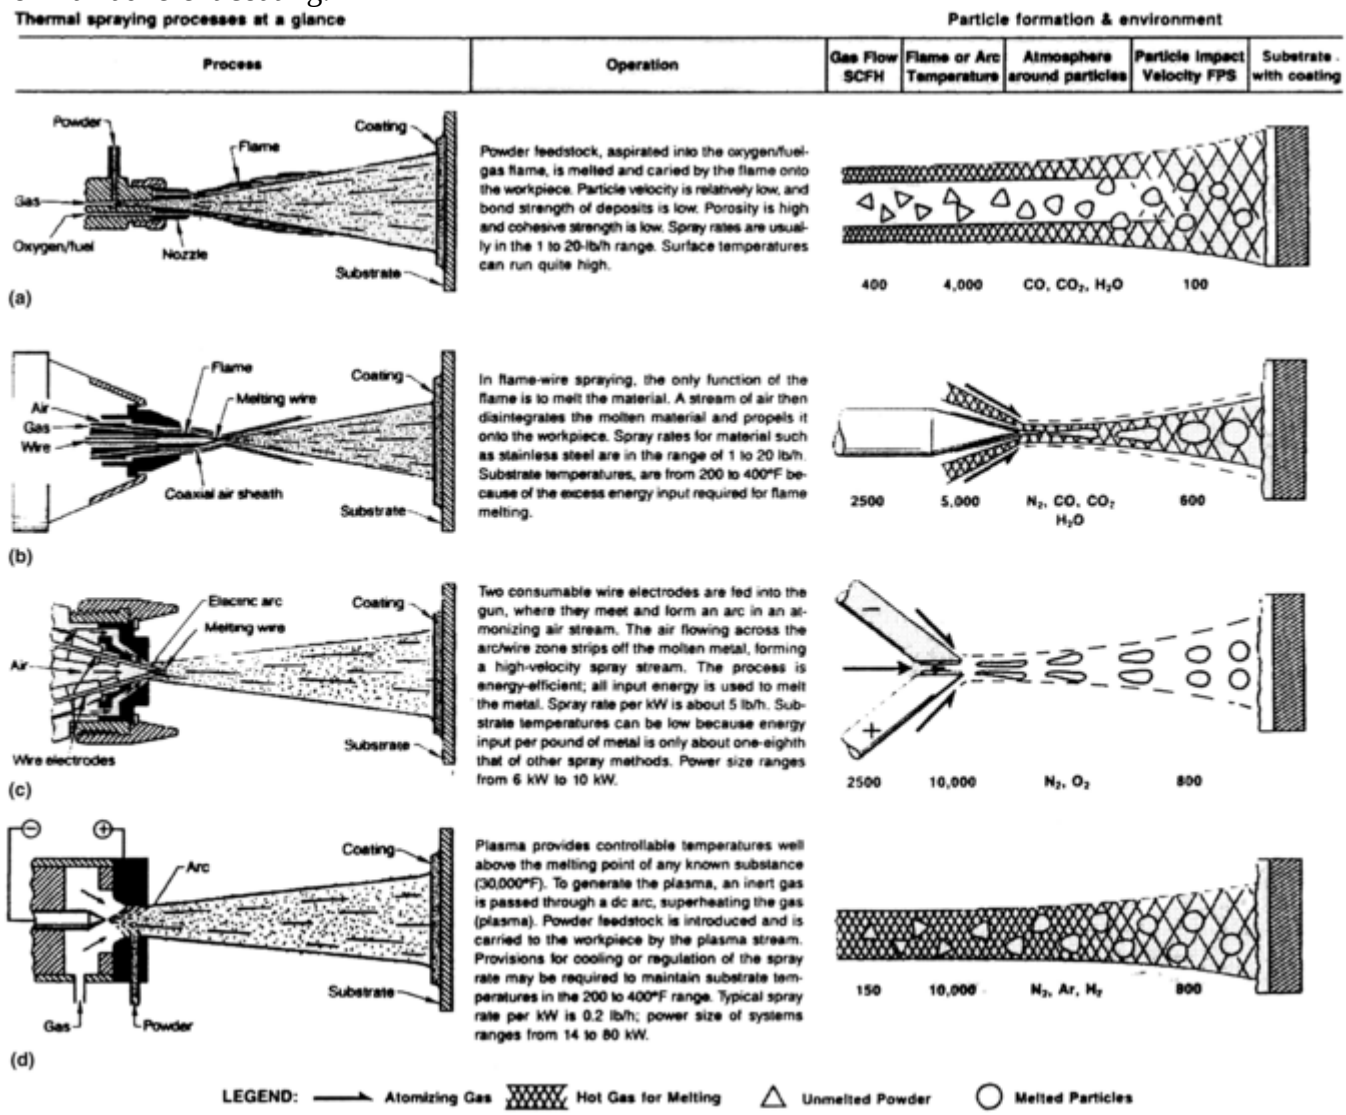

Fig. 2 Generic process schematics for (a) flame powder, (b) flame wire, (c) wire arc, and (d) plasma spray. Gas flow SCFH, standard cubic feet per hour; temperature, Kelvin; impact velocity FPS, feet per second. Source: Ref 6 (courtesy of Praxair-Tafa, Concord, NH)

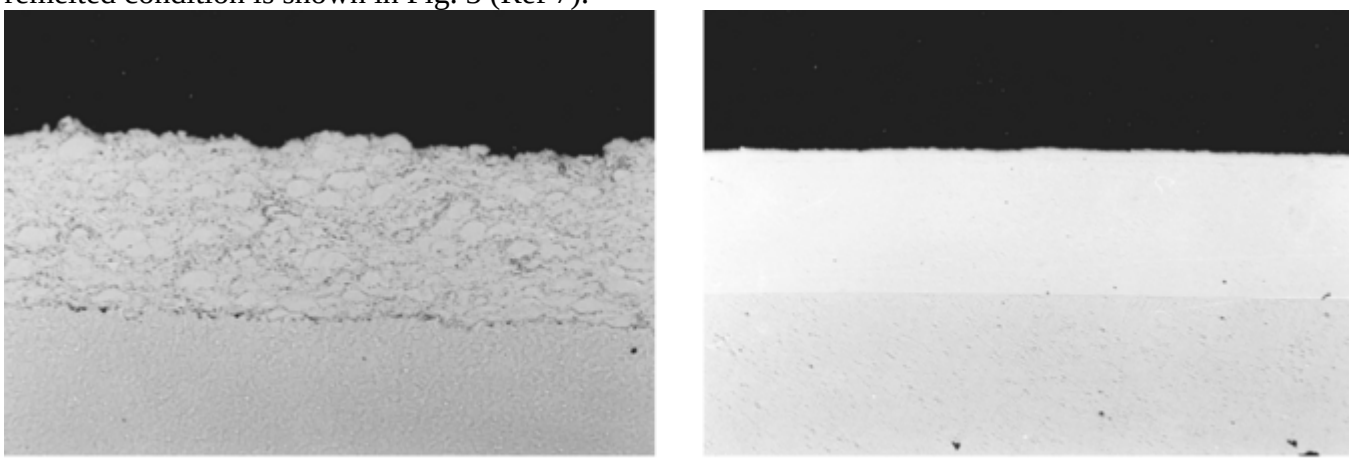
The coating structure is often nonuniform and an example of an HVOF-sprayed Inconel 625 coating and the remelted condition is shown in Fig. 3 (Ref 7).



(a) (b)

Fig. 3 Optical micrograph of high-velocity oxyfuel sprayed, Inconel 625 coating in (a) as-sprayed and (b) laser-remelted conditions. Coating thickness is 300 and 400 µm (12 and 16 µin.), respectively. Source: Ref 7

Coatings applied by the same technique can exhibit a wide variability (Ref 8, 9, 10) that arises from processing variables such as gas flow rates, the rate of coating deposition, the coating thickness, substrate preparation (e.g., preheat, postheat, and surface preparation schedules), type of spray material used, and the torch-to-substrate distance. These thermal spray parameters influence the quality of the adhesion to the substrate and the material properties such as electrical conductivity, density, and porosity. It is incorrect to assume that all thermal spray coatings of a particular material are identical in performance. The process must be "optimized" for each particular application.

Coatings are suited to specific applications because they retain some intrinsic material characteristics of the original coating powder. However, it must be emphasized that "bulk" material performance cannot be directly correlated to any property of the coating. The structure of a coating is quite dissimilar to that of a material produced by a bulk-fabrication process. Properties of the coating that may limit its utility include the physical, mechanical, thermal, electrochemical, and electrical properties. An additional property of great interest is adhesion to the substrate, since good adhesion is crucial for the coating to retain functionality throughout its intended service life.

Controlling the Structure, Properties, and Performance of Coatings

The Microstructural Character of Thermal Spray Coatings. It is the structure and chemistry of TS coatings that ultimately define their utility. Thermal spray coatings are produced from the repeated deposition of particles that are in the diameter range of 10 to 120 μm (0.4 to 4.7 mils). The coating structure is of lamellar morphology, much the same way as cards stacked on top of each other. Distinctive processing advantages of TS technology include the ability to coat most materials with an almost unlimited range of other materials, be they metals, ceramics, polymers, or combinations thereof. It is also possible to produce thick coatings from 0.1 to 2 mm (0.004 to 0.08 in.) routinely and to precisely control the coating formulation and chemistry.

The performance of a TS coating is directly related to this lamellar morphology. The resultant lamellar dimensions are about 60 μm (2.4 mils) in diameter and from 1 to 2.5 μm (0.04 to 0.1 mil) thick. Every coating structure is highly oriented with the lamellae parallel to the surface of the substrate.

Important microstructural artifacts, especially for corrosion-control applications that require a barrier to conducting and corrosive liquids, include porosity and microcracks.

It has been estimated (Ref 11, 12) that the real contact area of lamellae with the substrate and within the coating is 30% of the available boundary area. Direct measurements of interlamellar porosity have shown that the porosity is about 10 to 100 μm (0.4 to 4 mils) in size. Unmolten particles become incorporated into the coating and these, along with the interlamellar boundaries and porosity, constitute regions of poor bonding that may lead to failure of the coating system. The control of porosity is critical to the performance of any corrosion-control coating. Any defects that allow ingress of aggressive species will accelerate the coating-degradation process. Much attention has been paid to the control and modification of porosity that is inherent to the majority of conventional TS processes.

In one study (Ref 13), the porosity of thermal spray coatings was classified according to the potential mechanism of formation (Fig. 4). Type 1 porosity was exhibited between lamellae and was caused by the stacking of separate particles. This porosity can be directly related to the particle size and distribution characteristics of the spray material. Type 2 porosity was distinguished as trapped gas pockets caused by the turbulence of the gas flow during the TS process. Type 3 porosity was manifested in the form of gas bubbles caused by the dissolution of gas into the molten metal that evolved upon freezing of the metal. Type 4 porosity was caused by the disintegration of spray particles upon impact during the coating-deposition process. Type 5 porosity evolved from the condensation of partially evaporated particles and could be identified very often by containing powdery residues. Type 6 porosity arose due to solidification shrinkage, as observed between dendrites. Type 7 porosity results in microcracks regardless of their formation origin. Thus, although there may be some differences of opinion concerning the precise formation mechanism of porosity, there is general agreement that it can be controlled in a quite reproducible fashion by selection of appropriate TS parameters. Therefore, as mentioned previously, the control of temperature and velocity during the TS process is distinctly related to the deformation mechanism of the impacting lamellae and the formation of porosity.

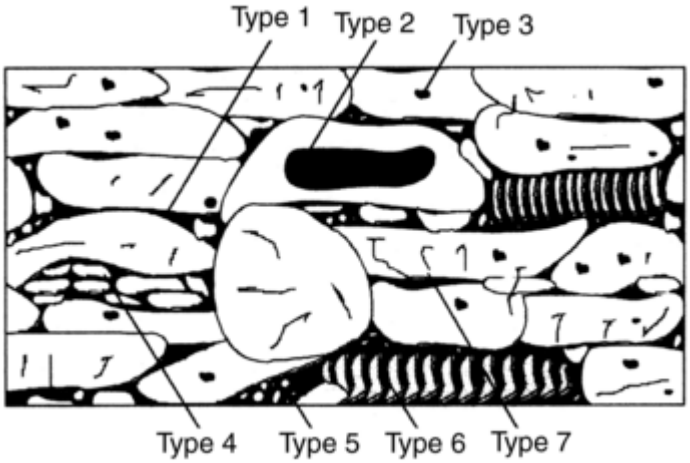

Fig. 4 Forms of porosity can be categorized within a thermal spray coating. Explanation in text. Source: Ref 13

Process Optimization and Parameterization. Optimization involves the study and analysis of operational parameters and their influence on a particular property. Single-wire arc spraying and powder flame spraying are two processes for manufacturing a corrosion-control coating.

When spraying a new material, the processing parameters are developed by taking the powder/ wire manufacturer's recommendation or that of an experienced TS engineer. Much of the TS industry uses such an experience base. This type of experience is valuable, but a trial-and-error method is not time or cost effective in spraying new materials or developing new microstructures. It is necessary to understand the relationship between properties and parameters for a given process and to present this relationship in a form that can be easily understood. Simple experiments can be set up to map a region of interest (Ref 14, 15). The map is referred to as a response over a region of parameters that needed evaluation.

Six primary process variables are:

- Enthalpy input into the particular TS process, whether it be gained from a combusting gas, the transfer of particle momentum to kinetic energy on impact against a substrate, or the use of direct-current electrical energy
- Feedstock delivery rates and the corresponding coating buildup per pass and the application rate in quantities of “mils per square foot per hour” or “micrometers per square meter per hour”
- Gas pressures and flow rates used for the combustion or arc processes
- The standoff distance between the TS device and substrate
- The surface preparation of the substrate
- Pre- or postconditioning of the substrate by heating or cooling

Control of these spray variables leads to the design of the microstructure and control of physical properties such as tensile adhesion strength, coating density, and surface roughness. They also relate to the deposition efficiency of the process, and this is directly correlated to the process economics. The role of these variables in the control of bond durability is often measured by a bond-strength technique, such as ASTM C 633 (Ref 16).

Surface Preparation. The most critical step is the preparation of the surface to be sprayed. The ideal surface is one that is roughened by grit blasting and that is contaminant free; that is, no oil, water, or blast media residues. It is recommended that the coating process take place within several hours of the surface preparation so that atmospheric oxidation of the highly energetic surface will not cause formation of a poorly bonded coating.

Coating Sealers and Surface Treatments. The material properties of coatings are a direct consequence of their complex structure and determine the overall coating behavior. Not all coatings are used in their as-sprayed condition. Metallic and ceramic coatings are often sealed to extend the protective properties and service life, particularly in immersed or severe environments. Sealers are typically low-viscosity liquids that penetrate and seal the coating pores. Commonly used sealers include vinyls, epoxies, epoxides, polyurethanes, phenolics, and silicones. Sealers are also used to produce decorative and smooth surface finishes. Other postprocessing surface treatments such as laser glazing and hot-isostatic pressing have been used to densify coatings and improve

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

corrosion resistance. More information on sealers and surface treatments can be found in Ref 7 and 17, 18, 19, 20.

Criteria for Coating Selection

Selection According to the Corrosion Environment. Table 2 lists engineering components that have benefited in mitigating the stated corrosion-related environment. It is difficult to specify one coating for any one set of operational conditions since the coating choice will be dictated by the environment, temperature, component dimensions, any requirement for postprocessing of the coatings such as reduction of surface roughness, and other practical factors.

Table 2 Categorization of engineering components by anticipated type of corrosion

Corrosion type	Component
Cavitation	Water turbine buckets, wear rings in hydraulic turbines, impeller pump housings
Particle erosion	Exhaust fans, cyclone dust collectors, exhaust valve seats
Heat and oxidation resistance	Tuyeres for liquid metal, continuous casting molds, heat treating fixtures and brazing jigs, exhaust mufflers
Atmospheric and immersion corrosion	Electrical conduits, bridges, transformer cases, steam-cleaning equipment, ship superstructures, ship holds and tanks, storage tanks for oils, fuels, and solvents, power-line hardware, heat exchangers

Common atmospheric and immersion service environments with typical TS coatings for corrosion protection are given in (Table 3) (Ref 21) and elevated-temperature service is addressed in Table 4.

Table 3 Thermal spray coatings for atmospheric and immersion service

Exposure environment	Thickness of coating systems for 20-year expected service							
	Unsealed zinc		**Sealed zinc**		**Unsealed aluminum**		**Sealed aluminum**

	Aluminum[(a)]	100	4

(a) Coating system consists of aluminum layer deposited on top of a nickel-chromium layer.

Applications for Metallic Coatings. Uses of metallic coatings for corrosion protection include bridges, buildings, marine vessels and structures, pipelines, chemical-processing equipment, power plants, exhaust flues, water-storage tanks, and boilers. Specific examples for use of HVOF nickel alloy C-276 and 316L stainless steel in petrochemical applications are given in Ref 22 and 23. Table 5 (Ref 6) details other TS applications in this highly demanding petrochemical environment.

Table 5 Petrochemical application of thermal spray coating

Component	Coating use	Process	Coating
Ball valves	Wear/corrosion	HVOF	Tungsten carbide
Gate valves	Wear/corrosion	HVOF	Tungsten carbide
Piston rods	Wear	Flame spray	Chrome oxide
Offshore oil rigs	Corrosion	Flame spray	Aluminum
Pump housings	Restore dimension	Arc spray	Aluminum bronze
Compressor cylinders	Restore dimension	Arc spray	420 stainless steel
Processing tanks	Corrosion resistance	Flame spray	Aluminum

Thermal sprayed metallic zinc and aluminum alloys coatings are commonly used for corrosion protection of steel substrates. Such coatings are sacrificial. It is also possible to thermal spray many other protective coatings such as nickel- base alloys, stainless steel, bronze, tin, and more exotic materials. These coatings are cathodic to the steel substrate, and it is important that they act as a barrier. For this reason, cathodic coatings are often sealed or surface treated to prevent penetration of corrosive species to the steel substrate. Furthermore, it is preferable that cathodic coatings are applied using a process that minimizes coating porosity such as HVOF. Selection of coating thickness depends on the severity of the environment and typically ranges between 50 and 500 μm (2 and 20 mils).

Experience with metallic TS coatings for infrastructure applications extends back to the 1940s. Sluice gates and canal lock gates that have been zinc coated have remained in perfect condition with virtually no maintenance for decades: the St. Denis Canal Lock Gates in France, coated in the early 1930s, are an outstanding example. The locks of the Panama Canal have also been zinc sprayed. In the United Kingdom, the suspension chains and other components of the Menai Straits Bridge were zinc sprayed just before World War II. During the war, the bridge received no maintenance. When it was inspected after the end of the war, the sprayed areas of the bridge were found to be in excellent condition. The steel deck structure, on the other hand, which had been painted but not sprayed, was rusting. The obvious reduction in required maintenance of the bridge prompted the British to apply sprayed metal coatings to numerous other road and railway bridges over the past 40 years. In the United States, metal sprayed coatings are presently being specified and used by departments of transportation (DOT) in Florida, Connecticut, California, Oregon, and Ohio.

The use of TS metallization makes it possible to achieve fully effective, maintenance-free protection of corrosion and corrosion-enhanced mechanical failure of steel structures for more than 30 years. Fifty-year protection effectiveness has been documented in rural environments and more than 20 years in harsh industrial, urban, and coastal regions. On an overall cost basis that includes maintenance, TS metallization has long been competitive with comparable corrosion- protection systems. Recent studies indicate that TS is now competitive on an initial cost basis alone. The conservative lifetime for a 255 μm (10 mil) thickness of zinc (or zinc-aluminum alloy) is approximately 25 years, which can be extended 15 years by the application of a vinyl paint as a topcoat to seal any porosity. Initial application costs of TS zinc (in 1998 U.S. dollars) are $10 per square foot or $0.40 per square foot per year for 25 years. Further examples and information on TS coatings for protection of steel structures can be found in Ref 24, 25, 26, 27.

In the case of cathodic protection (CP) of steel reinforcement in concrete, the TS coating is used as an anode. Zinc is the most common material for this purpose, although titanium has also been used. The coating is applied directly to the concrete substrate. The type of connection to the reinforcement depends on the CP system. It is more common to use impressed-current systems, although galvanic systems with zinc may also be effective in situations where the concrete exhibits low resistivity. Advantages of thermal sprayed anodes include ability to cover complex surfaces, uniform current distribution, and redundancy of an overlay as required with alternative mesh systems. Methods used to TS zinc onto concrete include oxyacetylene wire flame spraying, twin-wire arc

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

spray, and single-wire arc plasma spraying. These methods may form coatings that display different properties and process economics. Plasma and arc spraying have been used to produce titanium anodes.

Early applications that detailed the modern development of these coatings by regional DOTs in the United States are documented in Ref 28, 29, 30, 31. Updates of this area are covered in Ref 32 and 33 and field applications and the practical experience gained from the thermal spraying of zinc are described in Ref 34, 35, 36, 37. The development of new materials, especially titanium, is covered in Ref 38 and 39, while specific attention to bond strength, or adhesion, studies is the focus of the work reported in Ref 40 and 41. Reference 42 specifically discusses process development and the parameterization of the thermal spray variables in order to obtain the best coatings.

Applications for Ceramic Coatings. Ceramic coatings are used from 200 to 1150 °C (390 to 2100 °F). In such instances a metal-based “bond coat” (Ref 43, 44, 45) may be used as a compliant layer to compensate for thermally induced stresses that arise from the ceramic overlay. A 0.1 to 0.2 μm (0.004 to 0.008 mil) thick metallic layer is applied to the substrate by conventional TS methods prior to the ceramic coating. Such layers improve the bonding property of any subsequent thermal spray layer that is deposited. Bond coatings are based on alloys of nickel, chromium, molybdenum, and aluminum, with some additions of yttrium in special cases.

Applications for Polymer Coatings. Polymer spraying (Ref 46, 47, 48, 49) has gained significant commercial attention within the United States since the mid-1990s. Its acceptance as a replacement for paint is due to:

- No need for a primer
- A one-step process with no need for multiple passes
- No need for a topcoat
- Virtually zero volatile organic compounds (VOCs)
- Improved weathering resistance
- Excellent impact resistance

Thermal spray technology is also well suited for automation and can be adapted to existing robotic and automatic applicators. Polymer spraying is a one-coat process that acts as both the primer and the sealer, with no additional cure times, unlike the traditional multicoat painting processes. Thermal spraying is ideally suited for large structures that otherwise could not be dipped in a polymer suspension. Thermoplastic coatings can be repaired by simply remelting or applying extra material to the desired location. In addition, reports have shown that functionalized polyethylene polymers such as ethylene methacrylic acid copolymer (EMAA) and ethylene acrylic acid (EAA) can be applied in high humidity as well as at temperatures below freezing.

Polymer powders are specified by their chemistry, morphology, molecular weight distribution or melt-flow index, and particle size distribution. Spray parameters must be selected to accommodate each particular polymer formulation. A narrow particle size distribution is preferred to produce a homogeneous coating structure. A larger thermal input is required to melt larger particles and higher molecular weight organics. A large particle size or molecular weight distribution will facilitate the formation of numerous heterogeneities within the coating microstructure, creating voids, a range of splat aspect ratios, and degraded material. A processing window therefore exists for each polymer where poor particle coalescence defines the lower limit and pyrolization defines the upper limit. It is also important to note that the polymer may also cross link, undergo chain scission, and/or oxidize during processing.

Polymer powder is axially fed into the combustion zone via a carrier gas. The polymer particulates are propelled through the flame where, upon melting, they become droplets and are transported to the preheated substrate. As the molten particles impinge on the substrate, they deform and solidify, forming an interlaced network of splats. Porosity within the coating depends on the nature of the substrate surface, polymer melt viscosity, and decomposition products. The thickness of the coating is governed by the number of repeated passes of the spray gun across the substrate.

The heat source of the TS torch can be a plasma, combustion flame, or combustion exhaust as in the HVOF process. The technique is chosen on the basis of the polymer-melting characteristics. A simple combustion torch is well suited for low-melting-point polymers with a large processing window, such as polyethylene. High-melting-point polymers may require plasma deposition for maximum quality to melt the polymer without causing oxidation. Therefore, processing parameters must be selected for each polymer chemistry and deposition technique.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Two sets of distinct processes illustrate two fundamentally different spheres of polymer coatings. Both processes can generically be referred to as thermal spray; however, one process relies on a propane torch and the other class of processes uses the heat source of either a direct- current (dc) plasma torch or a HVOF gun. Thermal spraying of polymer powder is a 100% solids process. Polymers that can be applied using this process are listed in Table 6 and also include polyaryletherketone (PAEK), fluoropolymers, polyesters (Ref 51), and others.

Table 6 Selection of polymers applied as coatings via thermal spray processes

Polymer	Maximum temperature resistance	
	°C	**°F**
Ethylene methacrylic acid copolymer (EMAA)	40–60	105–140
Polyethylene (PE)	40–80	105–175
Polypropylene (PP)	70	160
Nylon 6,6 (PA)	65	150
Polyphenylene sulfide (PPS)	110	230
Polyethylene-tetrafluoroethylene copolymer (PE-TFE)	160	320
Polyetheretherketone (PEEK)	125	255
Liquid-crystal polymers (LCPs)	250	480
Phenolic epoxy	130	265
Polyimide (PI)	300	570

Source: Ref 50

Intrinsic properties of the polymers of interest include melt processibility, high chemical and impact resistance, electrical insulation, low coefficient of friction, ductility, and high toughness. Certain polymers also exhibit stability at elevated temperatures up to 300 °C (570 °F). Examples of thermal spraying of polymers are described in Ref 51, 52, 53, 54, while the thermal spraying of composites is detailed in Ref 56, 57, 58.

Thermal spraying of polymers is receiving increased attention in military and civil engineering sectors. The ability to apply thin (about 0.13 mm, or 0.005 in.) and thick (up to 6.4 mm, or 0.25 in.) coatings of polymers onto a variety of metals, ceramics, and composites of complex geometry provides solutions to component manufacture and on-site or factory rehabilitation. The development of complex coating chemistries then may be dual phase; for example, composites of plastics and metals or plastics and ceramics is an area that needs further research.

Applications of polymer coatings currently include snowplow blades, pump impellers, tank linings, external pipe coatings, structural steel coatings, transfer chutes, and vacuum systems. Here the intrinsic properties of polymers—such as high chemical resistance, high impact resistance, and high abrasion resistance—are used to advantage. One study has focused on incorporating recycled polymers in the feedstock (Ref 59).

Costs of Thermal Spray Coatings

Experience with the Oregon DOT in the rehabilitation of the Cape Creek, Depoe Bay, and Yaquina Bay bridges indicated an expense of $19.1 million (in 1995 U.S. dollars) compared to a replacement cost of $70 million (Ref 60).

Reference 31 specifically details financial aspects of a ConnDOT bid. It is stated that the bid price for the field metallizing of five bridges comprising a total area of 5866 m^2 (62,950 ft^2) amounted to $110/$m^2$ ($10/$ft^2$) in 1995 U.S. dollars. The bid price for class 3 containment of waste generated during the rehabilitation contract was $50/$m^2$ ($4.50/$ft^2$), and the disposal of this debris was $3.30/$m^2$ (0.30/ft^2).

A detailed cost analysis indicates that the most expensive item in either the twin-wire arc (to spray zinc) or a gas flame technique to spray polymer is the feedstock. The materials used during an arc wire process will constitute ~73% of the total running cost, while the polymer feedstock is ~93% of the total cost (Table 7). As well, a polymer coating process (by a gas flame thermal spray method) is about 330% more expensive than zinc sprayed by two-wire arc. Table 7 also indicates the relative startup costs with polymer spraying being about one-half that of two-wire arc. The prorated power and labor costs for both of these processes are approximately equivalent.

Table 7 Percent costs of twin-wire arc and polymer spray methods

Cost factor	Cost, %	
	Zinc by twin-wire arc	**Polymer by gas flame process**
Power	2	0.5
Labor	18	5.5
Materials	73	93
Equipment	7	1
Total cost	**100**	**100**
Relative total cost, $	1	3.3

Case Studies

Example 1: Adhesion of Polymer Coatings. This case history of EMAA applied to steel does not constitute a recommendation for a specific application, but it does demonstrate the unique characteristics of TS polymeric coatings applied by a gas flame process with fluidized powder feed.

The coating was studied for application in an environment involving biochemical treatment of geothermal sludge. An Atlas cell (ASTM C 868) arrangement was used. The test solution was hypersaline brine with composition of:

Compound	Content, ppm
NaCl	58,000
$CaCl_2$	25,000
KCl	15,000
$FeCl_2$	1,000
$MnCl_2$	930
$SrCl_2$	430
LiCl	410
$ZnCl_2$	370
H_3BO_3	300
$BaCl_2$	130

The pH of the brine was 4.15. The test temperature was 55 °C (130 °F), and the duration was 12 weeks.

At the completion of the tests, the coated panels were visually examined for signs of deterioration such as blistering, discoloration, and loss of gloss. The residual adhesion was determined for EMAA coatings by measuring the peel strength (ASTM D 3167). The plates were cut into strips 25 mm (1 in.) wide, and the orientation was vertical so that the strip traversed the vapor and immersion-exposed zones. The strips cut from the outer edges of the plates were beyond the exposure zone. The coatings were peeled back approximately 40 mm (1.6 in.) using a razor blade to enable the coating to be gripped. An Instron tensile testing machine was used, and the crosshead speed was 152 mm/min (6 in./ min).

Figure 5 depicts the peel force versus displacement curve for a strip cut from the edge of one of the panels (Ref 61). The coating in this location was not exposed to brine. The peel force was relatively constant, and the failure mode was adhesive. The average peel strength was 4.33 Pa (0.0006 psi) Figure 5 also shows the results for a strip cut through an exposed area. The peel force was low in the initial region, and this corresponded to the presence of corrosion products at the interface. The increase in peel force at higher displacement occurred outside the exposed area. Peel strength varied from 1.97 to 6.97 Pa (0.0003 to 0.001 psi). Plastic deformation of the coatings occurred during peeling, and this was concentrated in the areas outside the test cell where greater force was required to remove the coating.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

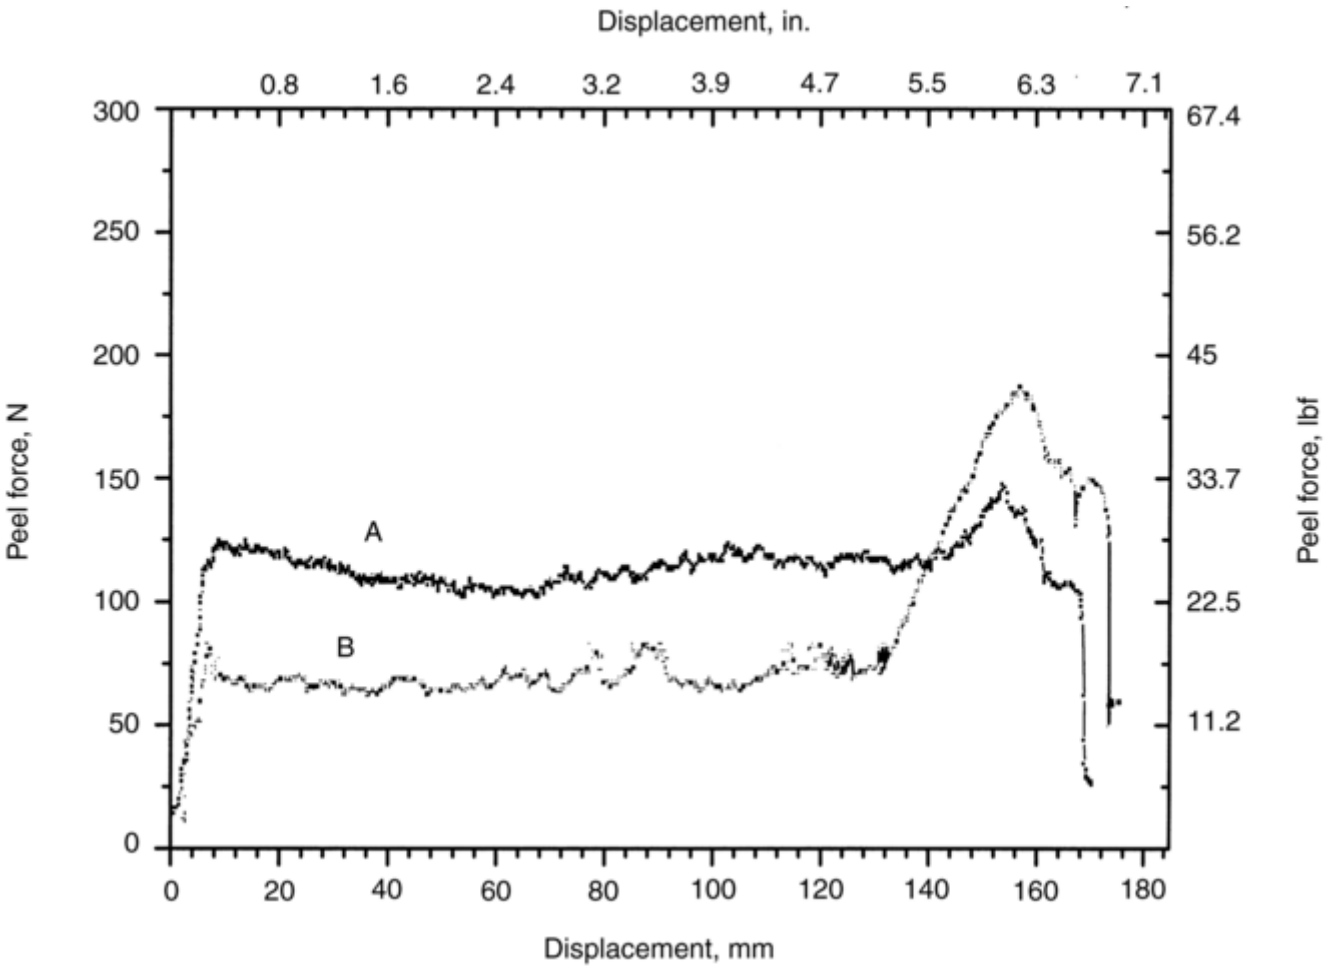

Fig. 5 Peel-force measurements for thermal spray coatings applied to as-received (curve A) and environmentally exposed (curve B) polymeric coatings. Source: Ref 61

Fracture surfaces from the EMAA mild-steel peel tests were examined under a scanning electron microscope (SEM). An example of mixed adhesive/cohesive failure in an uncorroded area is shown in Fig. 6(a). The dark areas are polymer adhering to the steel surface. Spherical pores, 100 to 200 μm (4 to 8 mil) diameter, in the polymer are evident, and failure often has occurred through these pores. Ductile tearing, indicative of a well-formed coating, may be observed around the edges of a pore (Fig. 6b).

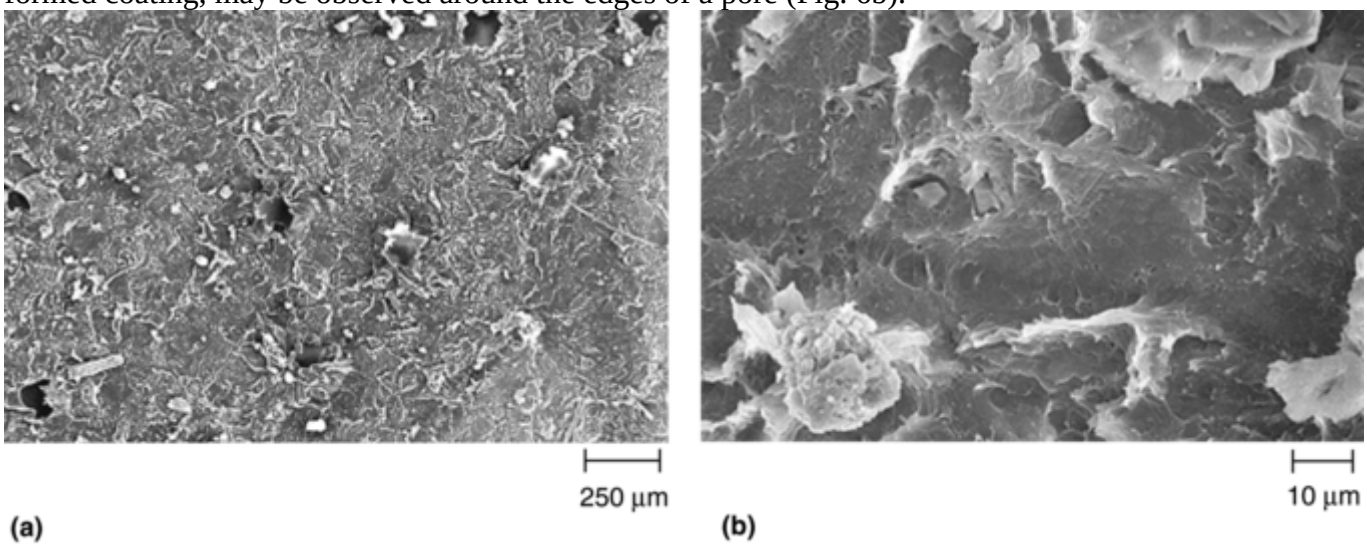

Fig. 6 Fracture surface morphology of a polymeric coatings that exhibits (a) porosity artifacts and (b) ductile tearing. Source: Ref 61

مرجع مهندسی مواد و متالورژی

Example 2: Thermal Spray Process to Remove Lead-Base Paint. An alternative means of surface preparation, patented by the U.S. Army Corps of Engineers, is on-site vitrification of hazardous waste. Thermal spraying of specially developed molten glass is used to encapsulate and chemically stabilize lead-base paint and rust (Ref 62). The encapsulant is then removed by chipping off relatively large chunks, which are readily removed for disposal. The objective has been to develop technology and guidance for maintenance where work will involve the removal of a coating material containing lead-base paint or other hazardous waste. Spray techniques, glass deposit chemistries, and encapsulation effectiveness are being testing and optimized.

The U.S. Environmental Protection Agency (EPA) regulations have necessitated the removal and containment of toxic lead from lead oxide containing organic paints. Traditional grit blasting of hydraulic structures and highway bridges potentially involves the wide distribution of lead contaminant some distance from work sites and inflicting unacceptable health risks. The thermal spray vitrification process (TSVP) is an elegant technique that has been proposed to alleviate this problem. The TSVP is a “green technology” that seeks to provide an economic solution to the maintenance of existing structures, for example, bridges and other infrastructure. In this process, glass powder is melted in a high-temperature flame and sprayed onto the lead painted surface. On impact of the molten glass droplet, lead diffuses and dissolves from the paint into the glass and forms a stable glass network that is resistant to lead leaching by acid attack.

When a molten droplet of glass strikes a lead painted surface, the following phenomena occur. First, the droplet will spread, splatter, and deform to form an intimate contact layer between the glass and the painted surface. The molten glass will penetrate and fill the pores and cavities in the surface by capillary transport. Mass transport rates and extent of reaction will depend on the properties of the molten glass such as surface tension, kinematic viscosity, and heat-transfer coefficient and on the properties of the coated surface. Next, there is diffusion, dissolution, and natural and forced convection of lead into the molten glass. The kinetics of this reaction will be controlled by the diffusivity of lead in the paint. The temperature and vapor pressure of the lead as well as the pore structure of the glass are the deciding factors for this phenomenon. There may also be solid-state interdiffusion of cationic species at the interface between the glass and painted surface, and the reaction layer will grow into the glass and the substrate surface. The cation with the lowest diffusivity will be the rate-limiting specie for this reaction. In summary, the lead can be absorbed into the glass by gas-phase transport, dissolution into liquid slag, and solid- state interdiffusion of cationic species.

Dissolution and diffusion of lead into the glass are determined by the time duration for which the glass particles remain molten and at high temperatures, respectively. In thermal spray processes, the coating material is melted in a flame and then quenched on impact onto a cold underlayer. The heating and cooling of the particles depend on the thermophysical properties of the particles in their liquid and solid states and their processing environments.

The composition of the glass basically decides its thermophysical properties. Selection of the glass composition for the lead-vitrification application should follow the following three criteria:

- Lead dissolution into the glass should follow the congruent path of the phase equilibrium diagram.
- The kinematic viscosity should be low.
- The glass should be stable in the desired range of lead concentrations.

Glass modifiers such as alkali oxides break the glass network and thereby reduce the melt viscosity. However, breaking of the network also weakens the glass structure and affects the stability of the glass. Intermediate oxides such as alumina, titania, and lead oxide, for example, increase the stability of the glass, but since they increase the surface energy of the melt, the kinematic viscosity of the glass melt also increases with the addition of the intermediate oxides. Thus, the composition of the glass should be optimized so that it will have high lead absorptivity and lead-leaching resistivity.

The processing environment that decides the rate at which the heat and momentum transfer to and from the particle occur are controlled by a large number of spray-process parameters such as the operating power level, stand-off distance, powder feed rate, gas flow rates, carrier gas flow rate, and gun traverse. Considerable amount of information already exists on the effect of spray variables on the properties of the coatings.

Specification and Quality Control for Coatings

Specifications and Guidelines for TS Applicators. Several professional and industrial organizations in the United States have developed guidelines with the intent of assisting those people who need to specify coatings for a particular application as well as helping practical TS operators accomplish a specific task. The listing below indicates the organization that generated the particular document as well as a very brief description of the content of the document. It should be noted that several of these documents are still being refined.

- **AWS C2.16-92,** "Guide for Thermal Spray Operator Qualification." This guide recommends thermal spray operator qualification procedures. It covers applicable documents relating to thermal spray equipment, consumables, and safety. It also contains operator qualification and coating system analysis forms. Note: this standard is being revised; see C2.16A standard in preparation.
- **AWS C2.18-93,** "Guide for the Protection of Steel with Thermal Sprayed Coatings of Aluminum and Zinc and Their Alloys and Composites." This guide sets forth recommended thermal spray operator qualification procedures. It covers applicable documents relating to thermal spray equipment consumables and safety. It also contains operator qualification and coating analysis forms. Note: this standard is being revised; see C2.18A Part A and Part B standard in preparation.
- **AWS C2-18A, NACE (designation to be determined), and SSPC CS 23.00A, Part A,** "Specification for the Application of Thermal Spray Coatings (Metallizing) of Aluminum, Zinc, and Their Alloys and Composites for the Corrosion Protection of Steel," Draft No.3, 2001-05-22 (45 pages). This standard is a procedure for the application of metallic TS coatings of aluminum, zinc, and their alloys and composites for the corrosion protection of steel. Required equipment, application procedures, and in-process quality-control (QC) checkpoints are specified. This standard may be used as a procurement document. Appendices include a "model procurement specification." Note: this standard is the update that will be the permanent standard to replace the interim standard SSPC CS 23.00(I) (1999–present).
- **AWS C2-18A, NACE (designation to be determined), and SSPC CS 23.00A,** "Application of Thermal Spray Coatings (Metallizing) of Aluminum, Zinc, and Their Alloys and Composites for the Corrosion Protection of Steel, Part B: Guide," Draft No.2, 2001- 10-10 (47 pages). This guide presents additional information and recommendations on safety, selection of TS coatings, inspection guide and checkoff list, bend testing, thermal spray operator qualification, thermal spray equipment qualification, and the maintenance and repair of TS coatings (1993–present).
- **AWS C2.19-XX,** "Machine Element Repair with Thermal Spray Coatings," CD No.3, 5 May 2000 (52 pages). This standard covers thermal spray processes for machinery element repair of ferrous and nonferrous substrates. Included are requirements for the qualification of thermal spray procedures and operators, requirements and guidance for use of thermal spray material and equipment, quality

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

assurance requirements, and descriptions of applicable qualification tests. Note: the Navy requested AWS incorporate MIL- STD-1687A(SH) into an AWS standard, April 1998 (1998–present).

- **AWS C2.20-XX,** "Specification for Thermal Spraying Zinc Anodes on Steel Reinforced Concrete," CD No.3, 16 Jan 2001 (25 pages). This AWS standard is a specification for thermal spraying zinc anodes on steel reinforced concrete. The scope includes: job description, safety, pass/fail job reference standards, feedstock materials, equipment, a step-by-step process instruction for surface preparation, thermal spraying, and quality control. There are three annexes: job control record, operator qualification, and portable adhesion testing (1995–present).
- **AWS C2.21-XX,** "Specification for Thermal Spray Equipment Acceptance Inspection," WD-4, 15 May 1998 (19 pages). This standard specifies the thermal spray equipment acceptance requirements for plasma, arc wire, flame powder, wire, rod, cord, and HVOF equipment. The equipment supplier shall provide proof of suitability. Example inspection reports are provided in four nonmandatory appendices.
- **AWS C2.25-XX,** "Specification for Solid and Composite Wires, and Ceramic Rods for Thermal Spraying," DS 1; 7-11-2001 (25 pages). This specification defines the as-manufactured, chemical-composition classification requirements for solid and composite wires and ceramic rods for thermal spraying. Requirements for standard sizes, marking, manufacturing, and packaging are included. 100 materials are listed (1985–present).
- **SSPC-QP 6,** "Standard Procedure for Evaluating Qualifications of Thermal Spray (Metallizing) Applicators," Draft No.2, 2001-21 (23 pages). This standard describes a method for evaluating the qualification of thermal spray (metallizing) applicators to apply thermal spray coatings per SSPC CS 23.00(I), "Interim Specification for the Application of Thermal Spray Coatings (Metallizing) of Aluminum, Zinc and Their Alloys and Composites for the Corrosion Protection of Steel," (latest edition), that is, the surface preparation, thermal spraying, and sealing or sealing and topcoating of components/assemblies in the shop and complex structures in the field. These procedures are applicable to a fabricating shop, shipyard, or other entity that applies coatings in the shop, even though providing coating application services is not the primary function (2001–present).
- **SSPC CS 23.00(I),** "Interim Specification for the Application of Thermal Spray Coatings (Metallizing) of Aluminum, Zinc and Their Alloys and Composites for the Corrosion Protection of Steel," 1 March 2000. This interim specification covers the requirements of thermal spray metallic coatings, with and without, sealers and topcoats, as a means to prevent the corrosion of steel surfaces. Types of metallic coatings include pure zinc, pure aluminum, and zinc/aluminum alloy, 85% Zn/ 15% Al by weight. Note: this standard is being incorporated into AWS C2.18A/NACE (designation to be determined) SSPC CS 23.00A Part A, standard in preparation.

The AWS C2.18 documentation recommends guidelines for thermal spraying zinc and aluminum wires and powders (Table 8). The prime quality-control checkpoints are stated as measurement of substrate temperature; measurement of air temperature, dew point, and humidity; appropriate measurement of the TS coating thickness; measurement of the TS coating ductility; and evaluation of representative bend coupons, companion coupons, and other samples.

Table 8 AWS guidelines for thermal spraying of zinc and aluminum

Feedstock	Flame spray		Arc spray	
	Deposit efficiency, %	**Material required, lb/ft^2/0.001 in.**	**Deposit efficiency, %**	**Materials required, lb/ft^2/0.001 in.**
Aluminum wire	80–85	0.014	70–75	0.017
Aluminum powder	85–90	0.014	NA	NA
Zinc wire	65–70	0.050	60–65	0.054

Standards for Coatings. A great challenge for TS coatings is their specification and standardization since, as described previously, the character of a TS coating is controlled greatly by their manufacturing method. Much of the history of TS coatings has relied on internal company specifications so that reproducible coatings might be produced, and the outgrowth of such documentation now constitutes accepted practice. With regard to testing practices, the standard methods developed by ASTM (or equivalent organizations) are a good basis on which to recommend procedures that rank coatings or different materials. Table 9 lists those ASTM standards that are most appropriate to TS coatings, but it should be kept in mind that these often provide only qualitative, ranking data rather than quantitative, life-prediction, and performance data.

Table 9 ASTM standards related to thermal spray

ASTM designation	Title
Corrosion	
B 117-95	Practice for Operating Salt Spray (Fog) Testing Apparatus
G 3-89 (1994)	Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing
G 5-94	Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements
G 15-97	Terminology Relating to Corrosion and Corrosion Testing
G 78-95	Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments
G 85-94	Practice for Modified Salt Spray (Fog) Testing
Wear	
G 40-96	Terminology Relating to Wear and Erosion
G 65-94	Test Method for Measuring Abrasion Using the Dry Sand/Rubber Wheel Apparatus
G 73-93	Practice for Liquid Impingement Erosion Testing
G 76-95	Test Method for Conducting Erosion Tests by Solid Particle Impingement Using Gas Jets
G 77-93	Test Method for Ranking Resistance of Materials to Sliding Wear Using Block-on-Ring Wear Test
G 81-97	Practice for Jaw Crusher Gouging Abrasion Test
G 98-91 (1996)	Test Method for Galling Resistance of Materials
G 99-95	Test Method for Wear Testing with a Pin-on-Disk Apparatus
G 105-89	Test Method for Conducting Wet Sand/Rubber Wheel Abrasion Tests
G 115-93	Guide for Measuring and Reporting Friction Coefficients
G 119-93	Guide for Determining Synergism between Wear and Corrosion
G 132-96	Test Method for Pin Abrasion Testing
G 133-95	Test Method for Linearly Reciprocating Ball-on-Flat Sliding Wear
G 134-95	Test Method for Erosion of Solid Materials by a Cavitating Liquid Jet

Adhesion of Coatings. Adhesion is a property of major concern for thermal sprayed coatings since it is necessary for the coating to adhere to the substrate throughout the design life of the system. Numerous adhesion tests can be used to evaluate the adhesion strength of TS coatings and thereby ascertain the utility of coatings. For example, bond-strength measurements allow optimization of different grit blast media and the angle of grit blasting, as well as establishing the best coating thickness for aluminum coatings (Ref 63). Other workers (Ref 42, 64) have optimized plasma spray parameters with respect to strength. In recent years, with the adoption of design of experiment methods, bond strength measurements along with other physical measurements, such as roughness and porosity, have been used to select coatings for industrial specifications.

Adhesion is a property of major consideration when thermal spraying coatings since it is necessary for the coating to adhere to the substrate throughout the design life of the system. Numerous adhesion tests can be used to evaluate the adhesion strength of TS coatings. The most common test is the tensile adhesion test (TAT), which, being simple to perform, is a widely used method as a quality-control tool (Ref 65).

The TAT has been standardized, and there are four main standards: ASTM C 633-79 (United States), AFNOR NF A91-202-79 (France), DIN 50 160-A (Germany), and JIS H8666-80 (Japan). The test configurations of

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

these standards are essentially the same; however, each standard specifies a different design and dimensions of substrate; that is, the diameter varies from 25.4 to 40 mm (1 to 1.57 in.) and the length is from 25.4 to 50 mm (1 to 1.97 in.).

The TAT arrangement involves attaching a support fixture to the coated specimen with an epoxy so that a tensile force may be applied. The stress at failure is called the *tensile adhesion strength* or *bond strength* and is an important property to characterize coatings. However, there are some shortcomings of the TAT procedure, such as variations in the penetration of epoxy and in the alignment of test fixtures. The mixed mode of failure may also occur, and this makes the interpretation of results difficult.

The adhesion strength or cohesion strength can be influenced by many factors. Some of them are intrinsic; that is, related to the spray variables, such as powder characteristics, spray parameters, substrate preparation, and so forth. The others are extrinsic, which include post-treatment and service conditions. However, adhesion tests are usually performed at room temperature under laboratory conditions on “witness samples” and do not consider in-service conditions that may decrease the adhesion strength. It is important for materials designers to keep in mind that the adhesion strength is highly related to service conditions. As well, the confidence-interval estimation for such coatings enables the reliability of the so-determined property to be ascertained.

The measurement of adhesion of thermal spray materials is, at least on the conceptual level, a routine operation. The tensile adhesion method as detailed in ASTM C 633 is simple and often used in industry for ranking different coatings. However, the major shortcoming of this test is that it does not promote any understanding of coating performance; that is, how coatings can be designed to be more functional.

Summary

The coating should be considered as part of the overall component system and, therefore, current trends are to design the coating as an integral part of the component assembly rather than as an add-on to the substrate. Whereas the property of coating adhesion to the substrate is of principal interest, there is still no single measurement which can satisfy all the requirements for determining material properties. Standardization of measurements, which may be achieved by improving existing experimental techniques or the combination of two or more techniques, will aid future coating development. Finally, a coating design encompassing both

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

microstructural and mechanical engineering designs, which is based on lifetime modeling should be forthcoming from any test method. Such designs will increase the knowledge-base and understanding of thermal sprayed materials and coatings so that their reliability and application will grow.
The use of thermal spray coatings makes it possible to achieve fully effective, maintenance- free protection of steel and concrete structures for more than 30 years in rural environments and more than 20 years in harsh industrial, urban, and coastal regions. On an overall cost basis, with the expense of maintenance factored in, thermal spray coatings have long been competitive with comparable corrosion protection systems. Studies over the last 2 decades indicate that this is now often true even on an initial cost basis alone.

Further Literature Sources for Thermal Spray

The major forum for thermal sprayers and technologists to meet since 1956 has been at the International Thermal Spray Conferences. The first seven of these meetings up to 1973 were known as International Metal Spraying Conferences. Since the mid-1980s, several other meetings have been convened: the National Thermal Spraying Conferences (organized by ASM International), the Plasma-Technik (Ref 66) meeting (a former Swiss company), and the Advanced Thermal Spraying and Allied Coatings Symposium (Ref 67) (organized by the High Temperature Society of Japan). The ITSC-2002 was convened in Essen, Germany, in March 2002 (Ref 68) and ITSC-2003 was held in Orlando, FL, in May 2003 and organized by the Thermal Spray Society of ASM International.
Other organizations such as the National Association of Corrosion Engineers (NACE International) and the American Welding Society (AWS) (Ref 69) have also convened focused conference sessions that specifically address TS under corrosive environments. The SSPC often documents TS coatings within their publication *The Journal of Protective Coatings and Linings,* JPCL.

Introduction

THE TOTAL NATIONAL YEARLY COST of metallic corrosion in the United States was estimated at $275 billion, or 3.1% of the U.S. gross domestic product (GDP) of $8790 billion, in 1998 (Ref 1). This total includes replacement costs and lost production costs as well as the decrease in lifetime and the expected replacement value of a given component subject to damage by corrosion. The cost of corrosion also includes the means by which the effects of corrosion are mitigated, such as the use of cathodic protection, inhibitors, alternative materials of construction, overdesign, and protective coatings. Studies done for other countries arrive at similar estimates of the total annual cost of corrosion, ranging from 1 to 5% of each country's GDP. A summary of the 1998 United States Federal Highway Administration study is provided in the article “Direct Costs of Corrosion in the United States” in this Volume.

The use of protective coatings is, in itself, a very substantial category. According to the U.S. Department of Commerce Bureau of Census, the total amount of organic coating material sold in the United States in 1997 was 5.56×10^9 L (1.47×10^9 gal), at a value of $16.56 billion. These sales can be categorized into architectural

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

coatings, product original equipment manufacturer (OEM) coatings, general-purpose coatings, and miscellaneous paint products. A portion of each of these was classified as corrosion protective coatings, at a total worth estimated at $6.7 billion. Because the cost of the coating material is from 4 to 20% of the cost of the applied coating system, the total applied cost of protective coating systems thereby ranges from $33.5 to $167.5 billion. Using the average of these figures, $100 billion, this cost is 36% of the total cost of corrosion in the United States and 1.1% of the entire United States' GDP.

Therefore, the use of protective coatings and linings and the costs associated with such use are considerable. More metal surfaces are protected by organic coatings and linings than by all other methods combined. In addition to protecting against corrosion, coatings often beautify and provide an aesthetic appeal. Safety colors are used to mark pipes, to indicate their contents, and to provide warnings of hazardous or dangerous work areas. Automotive coatings and house paints provide both beauty and weather protection. Coatings reflect light, thereby protecting the highway-traveling public, and reduce energy costs, because less lighting is needed for illumination. The use of protective and decorative coatings pervades all aspects of our lives.

Introduction to Coatings and Linings

Kenneth B. Tator, KTA-Tator, Inc.

The Effect of Legislation on the Coatings Industry

Legislation concerning worker health and environmental protection has had a marked impact on the coatings industry. For example, although the practice of blast cleaning a steel surface and applying an alkyd, epoxy, or polyurethane coating system remains one of the best methods of corrosion protection for many steel surfaces, the alkyds, epoxies, and polyurethanes themselves have changed as a result of legislation restricting the release of volatile organic compounds (solvents) and the use of toxic pigments.

Surface preparation techniques have also changed drastically; silica sand as a blast-cleaning abrasive has been banned in virtually all western countries except the United States and Canada (and there is a strong movement to ban it in these countries as well). The containment and safe disposal of spent blast-cleaning abrasives are required in most localities to prevent environmental damage caused by contamination by airborne particulate containing lead, chromate, and other toxic paint pigments removed during blast cleaning. Therefore, although a paint layer over a properly cleaned surface still acts as a barrier against a corrosive environment in most cases, the components that constitute this barrier have changed considerably within the past 10 years, and the means by which the surface is properly cleaned and the coating material is applied are evolving rapidly.

The following articles in this subsection present an overview of the different types of coating and lining materials available, along with information on the various means of surface preparation and the equipment and techniques of coating application. However, it must be recognized that all facets of coating technology are strongly influenced by legislative decree; the alkyds, epoxies, polyurethanes, and other generic types of coating materials currently in use are being reformulated, and although the names will be the same, the compositions of these coatings (and their potential protective capabilities) will be considerably different within the next few years. Furthermore, surface preparation and application techniques in current use are also under considerable legislative pressure and are also evolving.

Introduction to Coatings and Linings

Kenneth B. Tator, KTA-Tator, Inc.

Coating Industry Response to Legislative Pressure

The coating industry has been very responsive to enacted legislation and to proposed legislation limiting the use of potentially harmful or toxic raw materials or surface preparation and/or application techniques. As a result of this positive industry reaction, the legislators as a whole have been pragmatic in their laws. For example, it is widely recognized that lead, when ingested by the body, results in anemia, damage to the central nervous system, disruption of the reproductive system, and retardation in child development. Therefore, in 1973, Congress, under the impetus of the Food and Drug Administration, limited the lead content in all paints for consumer use to 0.06% solids by weight.

This law effectively banned the use of lead pigments in all paints used around the home. However, because lead-containing paint pigments, such as red lead, lead chromate, and lead suboxide, are perhaps the best pigments in use for corrosion protection, they were not outlawed for paints used for corrosion protection purposes in industry. In fact, even today, no legislation restricts the use of such pigments for industrial and marine corrosion protection purposes.

However, legislation regarding worker and environmental protection has curtailed drastically the use of lead pigments as well as other toxic pigments, such as those in the chromium, mercury, and tin families. Although such pigments can be used legally in paint, the substantial costs due to worker protection and the high costs associated with containment and disposal of paints containing such pigments are effectively precluding their use in most new coating formulations.

Similarly, restrictions regarding volatile organic compounds (VOCs) in coatings have been enacted gradually over the last 10 years in order to allow formulators to develop comparable paint materials with complying solvents. Although solvent restrictions were originally enacted against what were believed to be photochemically reactive solvents (solvents that reacted under the influence of ultraviolet light and degraded to form smog and to deplete the ozone layer), it was later found that virtually all volatilizing solvents photochemically degraded and were therefore environmentally detrimental. This realization, together with the potential for further legislative restriction, has motivated coating formulators to develop water-based paints or high-solids (low-solvent) coating materials.

Conversely, there are many industrial facilities and highway bridges that are coated with old lead-containing paints. Environmental Protection Agency (EPA) legislation requires the disposal of removed paints (and spent abrasive) in hazardous waste disposal sites if the leachate after acid digestion (pH 5) contains more than 5 ppm of lead or chromate and 2 ppm of mercury. The costs of such a disposal, not including collection costs, are estimated by many painting contractors to be from 6 to 10 times as much as disposal costs in a normal sanitary landfill. The cost of containing the spent abrasive and paint, as opposed to letting the spent abrasive fall to the ground during blast cleaning, may in itself double or triple the cost of a paint job.

While government enforcement of Occupational Safety and Health Administration (OSHA) and EPA legislation may have been lax in some areas in the past, the consequence of violation is severe and mandated in the Code of Federal Regulations. Penalties consist of fines, with the potential for incarceration for willful violations, which are specifically defined. In July 2001, OSHA announced the launch of a National Emphasis Program (NEP) to reduce occupational lead exposures. The NEP expects to attain a 15% reduction in employee exposures to airborne lead in targeted standard industry classification (SIC) codes (Table 1) (Ref 2).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Table 1 Industries targeted for increased enforcement of U.S. environmental and safety regulations

SIC code (a)	Classification
1611	Highway and street construction
1622	Bridge, tunnel, and elevated highway construction
1623	Water, sewer, pipe construction, and communication
1629	Heavy construction NEC (not elsewhere classified)
1721	Painting and paperhanging
1791	Structural steel erection
1795	Wrecking and demolition
1799	Special trade contractors NEC (not elsewhere classified)
3731	Shipbuilding and repair
4499	Water transportation services NEC (not elsewhere classified)
5093	Scrap waste

Industries targeted under the National Emphasis Program (NEP) of the U.S. Occupational Safety and Health Administration (OSHA).

(a) Standard industrial classification codes. Source: Ref 2

While OSHA previously has focused on painters on large projects, the NEP's new target parameters, particularly in the areas of heavy construction (16xx SIC codes), increase the potential for all trades on a project to receive scrutiny by OSHA.

The EPA is also systematically reducing VOC levels in paints and allied products and strengthening regulations regarding air, soil, and water contamination.

A summary of current regulations affecting the coatings industry is presented in Table 2 (Ref 3). A listing of specific existing federal regulations is presented in Table 3 (Ref 3).

Table 2 Summary of existing federal regulations affecting the coatings industry

Category	Summary
Environmental Protection Agency (EPA)	
Hazardous waste management	The Resource Conservation and Recovery Act (RCRA) governs the handling, storage, and disposal of wastes. The RCRA applies to the generators (usually owners and contractors), transporters, and disposers of waste.
Soils	Federal EPA does not have any specific regulations addressing soils contamination. However, EPA has taken the position that discharge of lead onto soils during paint removal may be regulated as illegal disposal and operation of an unlicensed treatment, storage, and disposal facility under RCRA (Ref 4).
Water	The Clean Water Act encompasses the body of regulations applicable to surface, ground, and storm water. The National Pollutant Discharge Elimination System establishes a permit system for allowable discharge into water. These regulations allow for EPA enforcement actions on industrial painting project sites where contaminated materials may have escaped the containment and are present on the ground or could be carried into drains or waterways.
Spills, cleanup, and reporting	The Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) or superfund addresses the current release of hazardous substances (e.g., solvents, lead, etc.) and addresses the cleanup of EPA-identified waste sites. CERCLA is enforceable on owners and contractors during industrial painting operations that result in excessive releases and can be applied to coatings manufacturers during the production of coatings. An amendment to CERCLA, known as the Emergency Planning and Community Right-to-Know Act (EPCRA), broadens the applicability of CERCLA to include facilities at which hazardous substances are present. The EPCRA standards are typically enforceable on coatings manufacturing facilities and fixed-site (e.g., shop) blasting and painting facilities.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Air	The Clean Air Act (40 CFR 50-99) limits the volatile organic compound (VOC) content for 61 categories of coatings. It also requires manufacturers and transporters to include VOC limits on labels and to provide recommendations regarding training.
Occupational Safety and Health Administration (OSHA)	
Lead exposure	The regulation for lead in construction (29 CFR 1926.62) requires employers to perform airborne assessments of employees' exposures when any lead is present. These assessments are compared to the action level and permissible exposure levels (PELs) of lead to trigger the implementation of exposure assessment, medical surveillance, employee information and training, signs/regulated areas, and record-keeping requirements. Employers must institute engineering and work practice controls to the extent feasible to reduce exposures to as low as achievable, preferably below the PEL.
Other toxic metals	OSHA has issued similar regulations for cadmium (29 CFR 1926.1127) and inorganic arsenic (29 CFR 1926.1118). Combined, these regulations have substantively influenced the coating removal industry by introducing the concepts of containment and ventilation, initial and periodic medical surveillance, worker training, and nontraditional paint removal methodologies.
Safety	OSHA has also issued or revised a number of construction regulations (29 CFR 1926) addressing fall protection, scaffolding, and aerial lifts, which significantly alter how access and working platforms are installed and maintained for field operations. In 1998, OSHA revised its respiratory protection standards for both the general (29 CFR 1910.134) and construction (29 CFR 1926.103) industries. The revisions directly impact both the removal and application of coatings. The revised standard requires more thorough assessment of potential inhalation hazards such as paints and solvents, increased engineering controls, and formal oversight of the implementation of respiratory protection programs.
Other regulations[(a)]	
Federal Department of Transportation (DOT)	Federal DOT regulations are included in 49 CFR. Federal DOT regulations govern all transportation, packaging, and handling of hazardous materials. 49 CFR is incorporated by reference in Environmental Protection Agency RCRA regulations.
U.S. Coast Guard (USCG)	USCG regulations can apply to the coatings industry when projects involve navigation or navigable waters (33 CFR) or shipping (46 CFR).
OSHA	In addition to specific regulations relative to the construction industry (29 CFR 1926), OSHA also regulates activities in other major industry categories (some of which also involve the coatings industry), including but not limited to general industry (29 CFR 1910), longshoring (29 CFR 1917), and marine terminals (29 CFR 1918).
Military	All phases of the military, i.e., Army Corps of Engineers, also have their own internal regulations, directives, and guidelines relative to worker safety and health and environmental protection that may impact the coating industry.

(a) More information can be found at www.epa.gov and www.osha.gov. CFR, Code of Federal Regulations. (a) Specific industry regulations may also affect painting operations in specific industries. Source: Ref 3

The high costs of surface preparation and coating application, along with those for worker and environmental protection, have motivated improvements of many existing technologies and development of new methods for conducting coating work. For example, powder coating technologies have captured a significant share of the OEM and product manufacturing markets, including the automotive market (the largest single user of protective and decorative coatings). Powder coatings have developed solely as a result of restricted VOC emissions mandated by the government. However, the development of improved electrostatic application methods (both fluidized bed and spray gun techniques); lower-temperature curing powders; and improved systems for conveyance, application, curing, handling, and recycling have made powder coatings viable for automotive and truck manufacturers and for many other industries. Similarly, improvements in electrostatic spray application equipment have been significant and are making that lower VOC technology competitive with liquid sprayed coatings.

An entire industry has developed to contain airborne blastcleaning residues and old lead and chromate hazardous paints removed during blastcleaning. Hazardous waste management techniques have been developed specifically for the coatings industry. Equipment and procedures for monitoring the effectiveness of worker and environmental protection during painting operations have spawned new technologies and launched entirely new industries.

Thus, when the cost of an existing technology becomes high enough, newer technologies are improved/invented to improve efficiencies and lower costs. Capitalism and free market enterprise are working at their best!

Despite the pending health and environmental legislative influences and the rapidly occurring changes in the coatings industry, corrosion continues, and painting for corrosion protection must be done. Therefore, the following articles discuss the more commonly used coating and lining materials; their characteristics,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

advantages, and disadvantages; surface preparation equipment and techniques; application and inspection methods; and equipment.

Introduction

PAINTS OR LININGS that act as a protective film to isolate the substrate from the environment exist in a number of different forms. Sheet linings, commonly of the vinyl or vinylidene chloride family, are one such type of coating that can be either adhered to the surface to be protected or suspended as a bag within a tank, for example, to provide protection. Hot-applied organisols, or plastisols, again usually of the vinyl family, can also be applied to a surface, typically by dipping or flow coating, to provide a protective film.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Powder coatings are being increasingly used to protect concrete-reinforcing rod, as pipeline coatings, and as coating materials in the original equipment manufacturer (OEM) markets. Fine powders produced from high-molecular-weight resins of the thermoplastic vinyl and fluorinated hydrocarbon families, or from thermoset resins of the epoxy and polyester families, are applied to the surface to be protected by either electrostatic spray or fluidized-bed deposition. The metal being protected is usually preheated at the time of application, and after application it is reheated to an elevated temperature, generally from 150 to 315 °C (300 to 600 °F). The specific time/temperature baking schedule depends on the metal temperature at the time of application and the type of powder being applied.

The coatings and linings discussed previously are mentioned here in summary only; a more thorough description is beyond the scope of this article. Powder coatings and coil coatings are discussed in more detail in the section "Powder Coating" in the article "Painting" in *Surface Engineering*, Volume 5 of *ASM Handbook*.

Alternatively, some coating systems are characterized by the application method used. For example, for coil-coated metal sheet (commonly steel or galvanized steel), very specialized high- speed roller application equipment is used to coat the sheet steel as it is unwound from a coil. The paint used in the coil-coating process can be of virtually any generic type, although alkyds, polyesters, epoxies, and zinc-rich epoxy coatings are the most prevalent.

Certain lining materials, such as hand lay-up fiberglass-reinforced plastics, are also used to protect steel from corrosion. Such coating systems usually consist of an epoxy primer applied to a blast-cleaned steel surface, followed by one or more polyester or epoxy gel coats, with one or more layers of a fiberglass veil or woven roving mat laid within the gel coats as reinforcement. The system is then sealed with a final layer of the polyester or epoxy resins as a gel coat (a semiclear, 100% solids resin coat). Similarly, rubber linings are used to protect against corrosion. There are various types of rubbers, but they can generally be categorized as prevulcanized or postvulcanized (vulcanized after application). Similarly, rubbers can be formulated with different hardnesses and chemical resistances. Commonly, a rubber lining is a composite of two or three different types of rubbers adhered to each other and to the surface. More information on rubber linings is presented in the article "Rubber Coatings and Linings" in this Volume.

This article is limited to the liquid coating (usually applied by brush, roller, or spray) and lining materials that are commonly used for corrosion protection in atmospheric or immersion service. The rate of base metal corrosion where such coatings or linings are used should not exceed approximately 1.3 mm/yr (50 mils/yr). For more severe corrosion rates, both in atmospheric and immersion service, or where catastrophic failure modes could occur, liquid-applied coatings probably should not be used. Corrosion protection measures such as the use of more corrosion-resistant alloys, sheet or rubber coatings and linings, or fiberglass lay-ups, can be employed for these applications.

The coating systems discussed in this article are categorized by the generic type of binder or resin and are grouped according to the curing or hardening mechanism inherent within that generic type. Although the resin or organic binder of the coating material is most influential in determining the resistances and properties of the paint, it is also true that the type and amount of pigments, solvents, and additives such as rheological aids dramatically influence the application properties and protective capability of the applied film. Furthermore, hybridized systems can be formulated that are crosses between the categories. For example, an acrylic monomer or prepolymer can be incorporated with virtually any other generic type of resin to produce a product with properties that are a compromise between the acrylic and the original polymer. In many cases, this is advantageous, as in the mixing of polyurethanes and acrylics or heat-curing alkyds and acrylics. In other cases, such as with an epoxy, acrylic modification may be a detriment. Table 1 lists the advantages and limitations of the principal coating resins.

Table 1 Advantages and limitations of principal coating resins

Resin type	Advantages	Limitations	Comments
Autooxidative cross-linked resins			
Alkyds	Good resistance to atmospheric weathering and moderate chemical fumes; not resistant to chemical splash and spillage. Long	Not chemically resistant; not suitable for application over alkaline surfaces, such as fresh concrete, or for water immersion	Long oil alkyds make excellent primers for rusted and pitted steel and wooden surfaces. Corrosion resistance is adequate for

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

	oil alkyds have good penetration but are slow drying; short oil alkyds are fast drying. Temperature resistant to 105 °C (225 °F)		mild chemical fumes that predominate in many industrial areas. Used as interior and exterior industrial and marine finishes
Epoxy esters	Good weather resistance; chemical resistance better than alkyds and usually sufficient to resist normal atmospheric corrosive attack	Generally the least resistant epoxy resin. Not resistant to strong chemical fumes, splash, or spillage. Temperature resistance: 105 °C (225 °F) in dry atmospheres. Not suitable for immersion service	A high-quality oil-based coating with good compatibility with most other coating types. Easy to apply. Used widely for atmospheric resistance in chemical environments on structural steel, tank exteriors, etc.
Thermoplastic resins			
Acrylics	Excellent light and ultraviolet stability, gloss, and color retention. Good chemical resistance and excellent atmospheric weathering resistance. Resistant to chemical fumes and occasional mild chemical splash and spillage. Minimal chalking, little if any darkening on prolonged exposure to ultraviolet light	Thermoplastic and water emulsion acrylics not suitable for any immersion service or any substantial acid or alkaline chemical exposure. Most acrylic coatings are used as topcoats in atmospheric service. Acrylic emulsions have limitations described under “Water emulsion latex.”	Used predominantly where light stability, gloss, and color retention are of primary importance. With cross linking, greater chemical resistance can be achieved. Cross-linked acrylics are the most common automotive finish. Emulsion acrylics are often used as primers on concrete block and masonry surfaces.
Water emulsion latex	Resistant of water, mild chemical fumes, and weathering. Good alkali resistance. Latexes are compatible with most generic coating types, either as an undercoat or topcoat.	Must be stored above freezing. Does not penetrate chalky surfaces. Exterior weather and chemical resistance not as good as solvent or oil-based coatings. Not suitable for immersion service	Ease of application and cleanup. No toxic solvents. Good concrete and masonry sealers, because breathing film allows passage of water vapor. Used as interior and exterior coatings
Asphalt pitch	Good water resistance and ultraviolet stability. Will not crack or degrade in sunlight. Nontoxic and suitable for exposure to food products. Resistant to mineral salts and alkalies to 30% concentration	Black color only. Poor resistance to hydrocarbon solvents, oils, fats, and some organic solvents. Does not have the moisture resistance of coal tars. Can embrittle after prolonged exposure to dry environments or temperatures above 150 °C (300 °F), and can soften and flow at temperatures as low as 40 °C (100 °F)	Often used as relatively inexpensive coating in atmospheric service, where coal tars cannot be used. Relatively inexpensive. Most common use is as a pavement sealer or roof coating.
Coal tar pitch	Excellent water resistance (greater than all other types of coatings); good resistance to acids, alkalies, and mineral, animal, and vegetable oils	Unless cross linked with another resin, is thermoplastic and will flow at temperatures of 40 °C (100 °F) or less. Hardens and embrittles in cold weather. Black color only; will alligator and crack	Used as moisture-resistant coatings in immersion and underground service. Widely used as pipeline exterior and interior coatings below grade. Pitch emulsions used as pavement sealers.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

		on prolonged sunlight exposure, although still protective	Relatively inexpensive
Cross-linked thermosetting resins			
Bisphenol-F epoxies	Lower volatile organic compound (VOC) content than Bis-A epoxies. Better temperature and chemical resistance than Bis-A types. Intermediate temperature and chemical resistance between Bis-A and novolacs	Less flexible; requires thorough blast cleaning surface preparation	Increasing use due to high reactivity and low VOC content
Epoxy novolacs	Greatest chemical resistance and highest temperature resistance of all epoxy resins used for most severe immersion service	Least flexible of epoxy resins. Costly.	Used for high-temperature chemical immersion service
Polyamide-cured epoxies	Superior to amine-cured epoxies for water resistance. Excellent adhesion, gloss, hardness impact, and abrasion resistance. More flexible and tougher than amine-cured epoxies. Some formulations can cure on wet surfaces and underwater. Temperature resistance: 105 °C (225 °F) dry; 65 °C (150 °F) wet	Cross linking does not occur below 5 °C (40 °F). Maximum resistances generally require 7 day cure at 20 °C (70 °F). Slightly lower chemical resistance than amine-cured epoxies	Easier to apply and topcoat, more flexible, and better moisture resistance than amine-cured epoxies. Excellent adhesion over steel and concrete. A widely used industrial and marine maintenance coating. Some formulations can be applied to wet or underwater surfaces.
Polyurethanes (aromatic or aliphatic)	Aliphatic urethanes are noted for their chemically excellent gloss, color, and ultraviolet light resistance. Properties vary widely, depending on the polyol coreactant. Generally, chemical and moisture resistances are similar to those of polyamide-cured epoxies, and abrasion resistance is usually excellent.	Because of the versatility of the isocyanate reaction, wide diversity exists in specific coating properties. Exposure to the isocyanate should be minimized to avoid sensitivity that may result in an asthmatic-like breathing condition on continued exposure. Carbon dioxide is released on exposure to humidity, which may result in gasing or bubbling of the coating in humid conditions. Aromatic urethanes may darken or yellow on exposure to ultraviolet radiation.	Aliphatic urethanes are widely used as glossy light-fast topcoats on many exterior structures in corrosive environments. They are relatively expensive but extremely durable. The isocyanate can be combined with other generic materials to enhance chemical, moisture, low-temperature, and abrasion resistance.
Amine-cured epoxies	Excellent resistance to alkalies, most organic and inorganic acids, water, and aqueous salt solutions. Solvent resistance and resistance to oxidizing agents are good as long as	Harder and less flexible than other epoxies and intolerant of moisture during application. Coating chalks on exposure to ultraviolet light. Strong solvents may lift coatings. Temperature resistance: 105	Good chemical and weather resistance. Best chemical resistance of epoxy family. Excellent adhesion to steel and concrete. Widely used in maintenance coatings and tank linings

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

	not continually wetted. Amine adducts have slightly less chemical and moisture resistance.	°C (225 °F) wet; 90 °C (190 °F) dry. Will not cure below 5 °C (40 °F); should be topcoated within 72 h to avoid intercoat delamination. Maximum properties require curing time of approximately 7 days.	
Epoxy powder coatings	Good adhesion, chemical and moisture resistance. Allows cathodic protection in shielded areas on pipelines	Color change is difficult due to extensive cleanup of old powder. Like all epoxy resins, chalks on ultraviolet exposure. Must be applied in shop. Hard to field repair	Applied by electrostatic spray/fluidized bed. Increasing use because of VOC used as pipeline, original equipment manufacturer coatings
Coal tar epoxies	Excellent resistance to saltwater and freshwater immersion. Very good acid and alkali resistance. Solvent resistance is good, although immersion in strong solvents may leach the coal tar.	Embrittles on exposure to cold or ultraviolet light. Cold weather abrasion resistance is poor. Should be topcoated within 48 h to avoid intercoat adhesion problems. Will not cure below 10 °C (50 °F). Black or dark colors only. Temperature resistance: 105 °C (225 °F) dry; 65 °C (150 °F) wet	Good water resistance. Thicknesses to 0.25 mm (10 mils) per coat. Can be applied to bare steel or concrete without a primer. Low cost per unit coverage
Epoxy phenolics	Excellent hot water resistance and acid resistance. More flexible than phenolic. Better alkali resistance than phenolics	Not as alkali resistant as other epoxy resins. Applies in thin films; somewhat brittle	Linings for food and beverage processing and storage tanks
Phenolics	Greatest solvent resistance of all organic coatings described. Excellent resistance to aliphatic and aromatic hydrocarbons, alcohols, esters, ethers, ketones, and chlorinated solvents. Wet temperature resistance to 95 °C (200 °F). Odorless, tasteless, and nontoxic; suitable for food use	Must be baked at a metal temperature ranging from 175 to 230 °C (350 to 450 °F). Coating must be applied in a thin film (approximately 0.025 mm, or 1 mil) and partially baked between coats. Multiple thin coats are necessary to allow water from the condensation reaction to be removed. Cured coating is difficult to patch due to extreme solvent resistance. Poor resistance to alkalies and strong oxidants	A brown color results on baking, which can be used to indicate the degree of cross linking. Widely used as tank lining for alcohol storage and fermentation and other food products. Used for hot water immersion service. Can be modified with epoxies and other resins to enhance water, chemical, and heat resistance
Polyureas	Extremely fast curing, highly elastic thick film coatings with good strength. Abrasion resistance, chemical resistance	Requires specialized spray equipment due to fast curing	Concrete coatings for use in secondary containment of chemical tanks. Elastomeric roof coatings

Autooxidative Cross-Linked Resins

These coating types dry and ultimately cross link by reaction with oxygen from the atmosphere. All such coatings in this class contain drying oils, which consist mainly of polyunsaturated fatty acids, and undergo film formation by oxidative drying. The drying reaction is accelerated by the presence of metallic salts such as cobalt, manganese, and lead napthenates or octoates. The drying reaction results in a reduction of unsaturated groups, commonly ethylenic carbon double bonds. The autooxidation reaction occurs at a relatively fast rate shortly after application of the wet paint, and it continues throughout the life of the coating, although at a much slower rate with time.

The autooxidative reaction is a decomposition reaction that results in the formation of hydroperoxides. Although autooxidative cross linking is necessary to attain the ultimate resistant properties of the film (such properties are generally attained within weeks after application), with time, the hydroperoxides formed as a result of the autooxidative cross linking decompose into organic acid constituents, leading to chemical deterioration of the film. Similarly, the autooxidative reaction results in the hardening and ultimate embrittlement of the film, causing reduced distensibility and flexibility with the passage of time. This brittleness and accompanying hydroperoxide decomposition result in an aging deterioration of the film and the ultimate loss of protective capability. The rate at which the coating loses its protective capability is determined by temperature, thickness, solar exposure, and the types of pigmentation (for example, zinc oxide and lead-containing pigments are particularly useful in absorbing hydroperoxides and slowing the rate of film deterioration).

Autooxidatively cross-linked films, in every case, contain a drying oil; this is usually a vegetable oil, such as tung, oiticica (similar to tung; obtained from the seeds of a South American tree), castor, linseed, safflower, soybean, and tall oil, or a fish oil (menhaden). The drying oil can be mixed directly with the pigment (such as red or white lead, with the addition of the metallic dryer) to form the complete coating. More commonly, however, the drying oil is combined with a resin, such as an alkyd, epoxy ester, or polyurethane, by heating or cooking. The resin adds toughness and chemical resistance to the oil, increasing its chemical and moisture resistance.

The amount of oil combined with the resin influences the protective capability of the applied film. Long oil modifications result in less chemical resistance and longer drying times but increased penetrability and a greater ability to protect over a poorly cleaned surface. A lesser oil modification results in a short oil that must be applied over a relatively clean substrate and dries quickly. Some short oils are commonly used in fast-drying coatings that fully cure after baking for a few minutes at approximately 95 °C (200 °F). Short oil coatings have good moisture and chemical resistance but are relatively hard and brittle. The medium oil modifications are a compromise between the long and short oil modifications. Most commonly, alkyds, epoxy esters, and urethane resins are used in combination with drying oils to form autooxidatively cross-linked coatings.

Alkyd resins are derived as the reaction product of polyhydric alcohols and polybasic acids. This definition also includes polyester resins, of which alkyds are a specific type. The basic difference between an alkyd and a polyester is that the alkyd uses a polybasic acid derived from semidrying or drying oils such that the resin so formed can undergo autooxidation at ambient temperatures through reaction with atmospheric oxygen at the unsaturated groups present in the fatty acid molecules. Polyesters, on the other hand, do not undergo the autooxidative drying mechanism, because the dibasic acid used, commonly a glycerol, has very few free unsaturated groups available for autooxidative cross linking. The curing reaction of polyester resins is a free-radical-initiated cross linking, and polyesters are therefore described as chemically cross-linked coating systems.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The properties of alkyd coatings are derived predominantly from the properties of the drying oil used in the manufacture of the resin. Drying time, hardness, color, and moisture sensitivity all depend to a great extent on the drying oil used and its type and degree of unsaturation (available cross-linking sites). For example, the use of pentaerythritol as the polyhydric alcohol leads to faster drying, greater hardness, better gloss and gloss retention, and better water resistance than alkyds based on glycerols of equal fatty acid content. Similarly, the drying oil also affects resin properties. Soybean oil has been shown to give good drying rates and good color retention; therefore, the standard alkyds are usually soybean alkyds. Linseed oils, on the other hand, generally dry faster but darken on light exposure. The chemical structure of a linseed oil alkyd is shown in Fig. 1. Castor and coconut oils have good color-retentive properties and are used as plasticizing resins because of their nonoxidizing character.

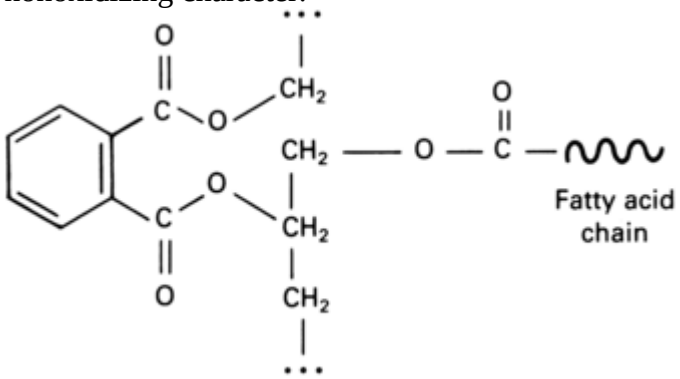

Fig. 1 Molecular structure of a linseed oil alkyd. The molecule is obtained through the reaction of a linseed oil monoglyceride and phthalic anhydride.

Phthalic anhydride and ter- and isophthalic acids are the most common polybasic acids used in alkyd preparation. The main advantage of ter- and isophthalic acids compared with phthalic anhydrides is that they provide polymers with a higher molecular weight and higher viscosity. Furthermore, they exhibit somewhat faster-drying, more flexible, tougher films and greater thermal stability than orthophthalic alkyds.

As a class, alkyd coating systems are still the workhorse of the corrosion protection industry, accounting for perhaps as much as two-thirds of all paints sold for corrosion protection. Although they have limited chemical and moisture resistance and relatively poor alkaline resistance, their low cost, ease of mixing and application, and excellent ability to penetrate and adhere to relatively poorly prepared, rough, dirty, or chalked surfaces make them the coating system of choice on steel exposed to nonchemical atmospheric service. Thus, alkyds are widely used for structural steel exposed in chemical plants away from the chemical processes. They are also used in such applications as water tank exteriors, highway bridges, boat and ship superstructures above the waterline, and in baking formulations as coatings for containers, appliances, and machinery and equipment housings.

Alkyd Modification. Alkyds are amenable to modification with a variety of other different resins to improve specific properties, such as drying time, color retention, and moisture and chemical resistance. For example, modification with a chlorinated rubber resin results in improved toughness and adhesion as well as an increase in acid, alkali, and water resistance. Such modified paints are used on concrete floors and as highway-marking paints.

Modification with a phenolic resin improves gloss retention and water and alkali resistance. Phenolic alkyd resins have performed satisfactorily in water immersion—a service in which nonphenolic-modified alkyd resins are not suitable.

Alkyd resins with vinyl modification are commonly formulated as universal primers (primers that, after application, can be topcoated with most generic-type intermediate and topcoats). The alkyd constituent improves adhesion, film build, solvent resistance, and thermal resistance, and the vinyl modification enhances recoatability, chemical, and moisture resistance.

Silicone modification of alkyd resins is perhaps the most widely promoted modification for corrosion-protective coatings. A silicone intermediate is added to the alkyd resin in quantities up to 30% to provide polymers with greatly improved durability, gloss retention, and heat resistance. Moisture resistance is greatly improved by the silicone modification, and such paints are extensively used as marine and maintenance paints.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Unmodified alkyds of medium-to-long oil length are familiar to homeowners as the oil- based paints used extensively around the home. Their ability to penetrate and adhere to wood and masonry surfaces, their availability in wide color ranges and glosses ranging from flat to high gloss, and their ease of application and cleanup make them ideal for a do-it-yourself homeowner.

Highly thixotropic alkyds are being promoted for both home and industrial use. Thixotropic paints remain in a semisolid or jellylike state when at rest but become thinner and spread easily with the shearing action caused by brushing. As soon as the brushing action is stopped, the paints again recover their jellylike characteristics. Such paints reduce pigment settling, reduce tendencies to run or sag, and make possible the application of thicker coats that have a longer wet-edge time due to the use of slower-evaporating solvents, which otherwise cannot be used because they may cause sagging. Dripping from the brush is minimized, and the thixotropy prevents absorption on porous surfaces. Thixotropic paints are usually not recommended for spray application. The thixotropy is introduced by modification with a polyamide resin, and the jellylike behavior of the combined resin has been attributed to hydrogen bonding between the carbonyl group of the alkyd and the amide group of the polyamide coreactant.

Alkyds can be modified with polyisocyanates to improve drying rates and chemical and abrasion resistance. Such resins, commonly called uralkyds, are available in a variety of colors and generally exhibit excellent gloss and color retention. Similarly, epoxy resins are combined with the alkyd to obtain coating formulations having improved adhesion to metal, better gloss and color retention, and much improved water and chemical resistance.

Epoxy esters differ from epoxy-modified alkyds in that the epoxy is a direct esterification product of an epoxy resin and a fatty acid, such as a vegetable oil or rosin. Like alkyds, epoxy ester resins are usually prepared by reacting the drying oil with the epoxy resin at a temperature of approximately 220 to 290 °C (425 to 550 °F) in the presence of esterification catalysts. The same drying oils used to prepare alkyd resins are also used to prepare epoxy esters. As with alkyds, the oil length can be categorized as long, medium, and short, and the properties accruing to the resin derive predominantly from the amount and type of drying oil modification to the resin. As a general rule, compared with alkyds, epoxy resins have better adhesion and moisture and chemical resistance, although they are slightly more expensive.

Thermoplastic Resins

Thermoplastic resins are characterized, as their name implies, by a softening at elevated temperatures. Although the resins within thermoplastic paint systems are commonly co- or ter-polymers, the molecular structure is not cross linked into a rigid molecule, as are the chemically cross-linked or the autooxidized coating systems. Rather, the resinous binder is dissolved in a suitable solvent, mixed with the pigment and other constituents comprising the formulated paint, and packaged. On application, the solvent volatilizes, and the resinous binder, along with the pigment, is deposited onto the surface being coated as a solid film. The molecular entanglement of the relatively linear (although perhaps coiled or tangled) molecule segments provides a layering effect that, with pigmentation and sufficient thickness, provides the characteristic moisture and chemical resistance of the resin system used.

There are two types of coatings based on thermoplastic resins: those deposited by evaporation of a solvent—commonly called lacquers—and those deposited by evaporation of water—a class of coatings called water-borne coatings.

Lacquers. The most useful solvent-deposited thermoplastic resins for corrosion protection are the vinyls, chlorinated rubbers, thermoplastic acrylics, and bituminous resins (coal tar and asphalt). Each resin type has its

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

own characteristic qualities, specific resistances, and susceptibilities, and each is discussed subsequently in greater detail. However, in all cases, because no chemical change takes place to the resin on application and drying, it stands to reason that the applied coating redissolves if it is exposed to the same solvents that it was originally dissolved in on formulation. This is precisely what happens, and such coatings have no resistance to the solvents in which they were originally dissolved or in solvents of equal or greater solvency for that particular resin. This, however, is not usually a disadvantage; although solvent resistance may be poor, such coatings are rarely, if ever, exposed in a solvent-laden atmosphere. Instead, they are called on to resist weathering, acid or alkali exposures, and moisture. As a rule, all have good resistance in these applications, and the vinyls, chlorinated rubbers, and coal tars have excellent moisture resistance as well.

Conversely, the solvent susceptibility of these thermoplastic coatings is often an advantage. When maintenance repainting is necessary, the same system can be reapplied, and the solvents in the new topcoat partially redissolve the existing old coat, resulting in intermolecular entanglement of the new coating with the old and giving excellent adhesion. Thus, solvent solutions of these thermoplastic resins have excellent recoatability with the same system, even after extended periods of time. This cannot be said for either the autooxidative cross-linking coatings or the chemically cured coatings.

The principal disadvantage of a solvent-deposited lacquer system is that large amounts of solvent must be used to dissolve the relatively high-molecular-weight resins used in the coating. Accordingly, most lacquer coatings cannot comply with the lower volatile organic compound (VOC) legislation in effect today. Thus, while such coating systems were widely used as little as ten years ago, they are rarely used. However, because there are still many structures painted with lacquer coating systems, a brief description of the most common types is presented, as follows.

Vinyls. Vinyl coatings are usually applied as a solvent-deposited solution consisting of either a polyvinyl chloride-polyvinyl acetate (PVC- PVA) copolymer in the ratio of approximately 86% PVC to 13 to 14% PVA.

The vinyl solution coatings are generally very low-solids, high-solvent materials that have been preempted by restrictive VOC legislation. Most thermoplastic vinyl solution coatings contain solvents (generally oxygenated solvents such as ketones and glycol ethers) ranging from 75 to 90% of the total volume of the formulated paint. Figure 2 shows an example of a PVC-PVA vinyl. Vinyl solution coatings are noted for their outstanding toughness and water resistance.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

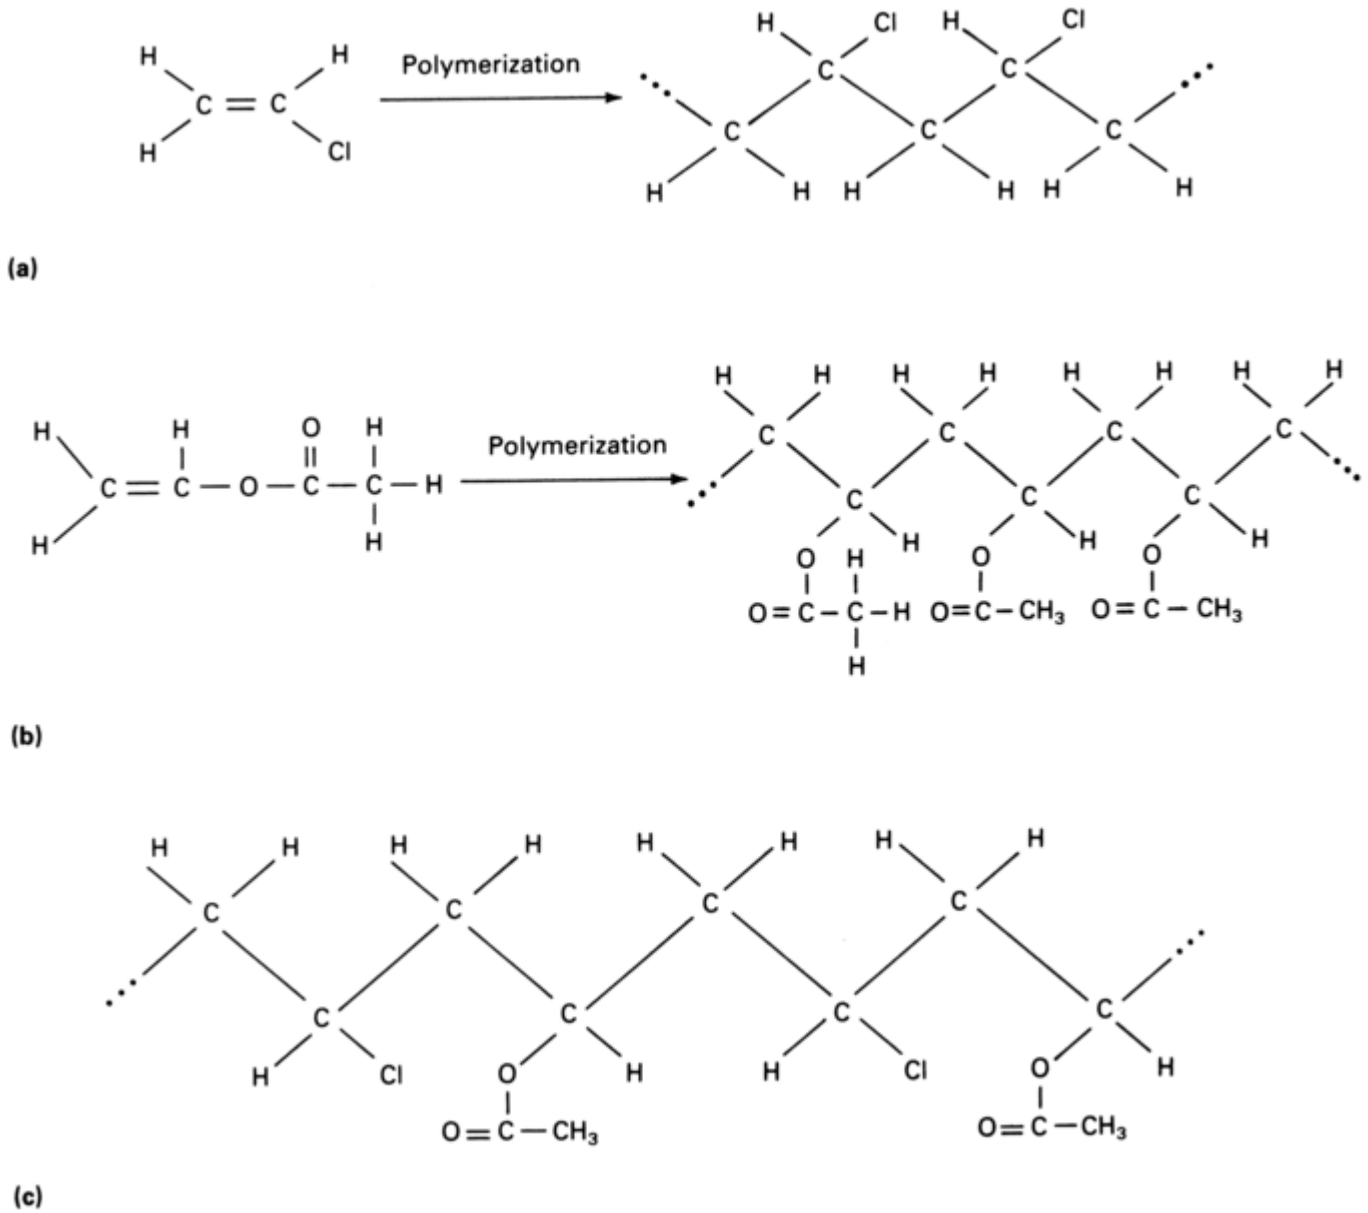

Fig. 2 Reaction of polyvinyl chloride (PVC) and polyvinyl acetate (PVA) polymers to form a PVC-PVA copolymer. (a) Polymerization of PVC. (b) Polymerization of PVA. (c) PVC-PVA copolymer

Vinyl paints are used as complete systems (vinyl primer, intermediate, and topcoat) or as topcoats over zinc-rich primers for the protection of highway bridges throughout the United States. The relative inertness of the vinyl topcoat, coupled with good adhesion (when formulated with maleic acid), protects the relatively reactive zinc in an organic or inorganic zinc-rich primer from reaction with environmental moisture, acid rain, and other atmospheric contaminants. The zinc- rich primer provides galvanic protection to the underlying steel. See the article “Zinc-Rich Coatings” that follows in this Volume.

Chlorinated rubber coatings are also solvent-deposited coatings in that there is no chemical change that occurs during application, and the coating film forms on the surface after application as the solvent evaporates. Similar to the vinyl coating materials, solvent-deposited chlorinated rubber coatings cannot be used in most areas of the United States due to their high VOC content. Chlorinated rubber coating systems had been much more widely used in Europe than in the United States, and systems based on chlorinated rubbers have excellent resistance to acids, alkalis, oxidizing agents and have very low water vapor transmission rates (approximately one- tenth that of an alkyd resin coating). In addition, they are generally nonflammable (due to their chlorine content) and nontoxic. Chlorinated rubber paints were used principally as chemical- and corrosion-resistant coatings, marine coatings, building masonry and swimming pool paints, highway-marking paints, fire-retardant and mold-resistant paints, and primers for hot- applied coal tar or asphaltic enamels (to provide good adhesion to steel).

Chlorinated rubber resins are manufactured by chlorinating natural rubber with approximately 65 to 68% Cl. The resulting resin must be plasticized and stabilized against light, heat, and gellation in order to be used as a

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

binder in protective coatings. Heat stability is obtained by incorporating low-molecular-weight epoxy compounds or epoxidized oils into the resin. Light-fast plasticizers such as dialkyl phthalates and acrylic resins are used. For severe chemical service, chlorinated paraffins or chlorinated diphenyls should be used because of their high resistance to saponification.

The chemical structure of a chlorinated rubber resin is shown in Fig. 3.

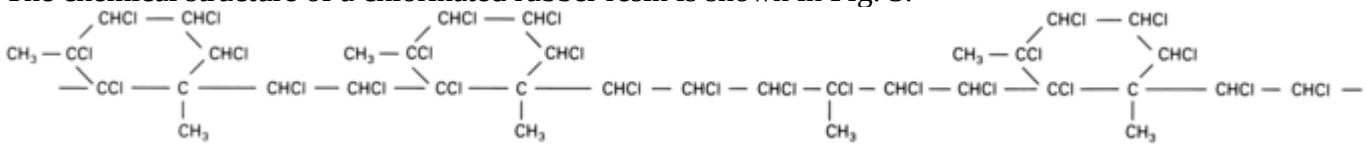

Fig. 3 Molecular structure of a chlorinated rubber resin. Source: Ref 1

Acrylic coatings can be formulated as thermoplastic solvent-deposited coatings, cross- linked thermoset coatings, and water-based emulsion coatings. Acrylic resins that are used for protective coatings consist of polymers and copolymers of the esters of methacrylic and acrylic acid. The chemical structure of these acrylics is shown in Fig. 4. The resulting resins, with suitable pigmentation, provide excellent film-forming coatings characterized by excellent light fastness, gloss, and ultraviolet stability. Chemical resistance to weathering environments is generally excellent, as is resistance to moisture. Most acrylic coatings are not suitable for immersion service or strong chemical environments because of attack of the ester group present on both the polymethyl methacrylate and ethyl acrylate resins. This ester group, however, is present only as a pendant sidechain; accordingly, the carbon-to-carbon backbone chain of the acrylic resins does provide very good chemical and moisture resistance, which enables these resins to be used in most chemically moderate atmospheric services.

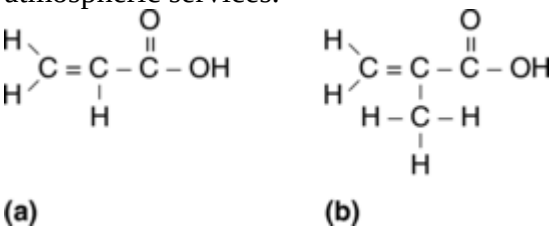

Fig. 4 Molecular structure of (a) acrylic acid and (b) methacrylic acid polymers

Coatings can be formulated with acrylate, methacrylate, or higher homopolymers. Blends of both resin types are also commonly used for corrosion protection. Generally speaking, those coatings formulated from the acrylates or from copolymers with a preponderance of the acrylate ester are softer and more flexible than the corresponding methacrylates. The ultraviolet resistance of the acrylate is somewhat lower than that of the methacrylate because of the presence of a tertiary hydrogen attached directly to a carbon comprising the molecular backbone. This active hydrogen is vulnerable to photooxidative and thermooxidative attack. Consequently, acrylate esters have a greater susceptibility to ultraviolet light and oxygen, leading to yellowing or darkening in comparison with the methacrylates. The methacrylates, although providing a harder and more brittle film with less adhesion, are more chemical and moisture resistant and have a greater heat tolerance.

With both resin types, greater flexibility, toughness, and resistance to abrasion can be obtained by increasing the molecular weight. Hardness decreases, although flexibility and elongation increase in both resin families. However, with too great an increase in molecular weight, solution viscosity becomes excessive, and solvent release in a formulated paint becomes excessively slow.

Acrylic resins are characteristically soluble in moderately hydrogen-bonded solvents, such as ketones, esters, aromatic hydrocarbons, and certain chlorinated hydrocarbons. Excellent color retention, gloss, and ultraviolet stability, coupled with very good moisture and chemical resistance, make acrylic coatings quite popular in protecting steel in atmospheric service.

Thermoplastic Acrylics. Similar to all thermoplastic coatings, thermoplastic acrylics are essentially solvent-deposited resins that do not undergo any chemical change after, or at the time of, application. On application, the solvent carrier volatilizes, and the coating system sets, hardens, and attains its final resistant properties as the solvent evaporates. Heating or baking is often used to hasten solvent evaporation. However, because of their high VOCs, thermoplastic acrylic coatings are not widely used.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The resins used in these coatings are polymers and copolymers of high-molecular-weight esters of methacrylic and acrylic acids. These resins, when suitably pigmented, have excellent gloss, color retention, and ultraviolet light stability.

Probably the major use of thermoplastic acrylics is in automobile finishing and refinishing. Advantages include the ease of tinting and coloration, excellent dispersion of metallic reflective pigments, high gloss and ultraviolet stability, and thermal reflow. Thermal reflow is important because, after the original factory coating is applied, minor imperfections, sanding marks, and other irregularities can be overcome by reheating the coating under heat lamps or in an oven. The surface of the coating partially melts and reflows to form the smooth, glossy appearance one expects with an automotive finish.

Another major market is aerosol can paint, which is widely sold throughout the world. These paints are thermoplastic acrylics, and they dry and harden through solvent evaporation.

Solvent-deposited acrylics are also used for maintenance finishes, but more commonly, the acrylic monomer or copolymer is added to an alkyd. This results in an acrylic-modified alkyd with the excellent penetration properties, adhesion, and ease of application of the alkyd, combined with the improved ultraviolet resistance, gloss, and color retention of the acrylic.

Thermosetting Acrylics. Thermosetting, or cross-linking, acrylics can be obtained by combining the methacrylate or acrylate esters with reactive nonacrylic polymers. The most common cross-linking agents in use are the epoxy resins, the urea or melamine-formaldehyde resins, and the vinyl resins. Generally, the nonacrylic polymer is the predominant structure present in the coating film, and the acrylic modification is done only to enhance the color, gloss, and ultraviolet stability of the nonacrylic constituent. The resulting thermoset acrylic finishes are generally harder, tougher, and more resistant to heat and solvents than thermoplastic acrylics. On the other hand, thermoset acrylic finishes are also generally less resistant to ultraviolet light and usually require heating or baking after application to attain the desired physical properties.

Acrylic finishes based on urea or melamine- formaldehyde resins cross linked with acrylic monomers are widely used for coating such home appliances as refrigerators, washing machines, dryers, dishwashers, freezers, and air conditioners. The coatings have excellent adhesion and detergent resistance, and they have short curing times at relatively low curing temperatures. The major advantages of such coatings are the high gloss, range of colors available, and lack of yellowing or darkening on exposure to sunlight.

Photopolymerization of acrylic homo- and copolymers is, for the painting industry, an emerging—and very interesting—technology. The wavelength ranges of ultraviolet light (approximately 200 to 400 nm) and visible light (approximately 400 to 800 nm) can initiate cross linking in a susceptible binder system. Acrylic esters show a very rapid response to photoinitiation as compared to all other commonly used coating resins. Within the acrylic family, the acrylate is at least ten times more reactive to ultraviolet or visible light radiation than the methacrylate. All types of resins used in conventional paint systems (such as alkyds, epoxies, polyesters, and urethanes) can be modified with acrylate esters, and the combination can be combined with a suitable photoinitiator to aid in the radical polymerization mechanism.

High-solids, low-molecular-weight, light- cured coatings can be applied by brush, roller, and spray. After setting up and exposure to an intense source of ultraviolet or visible light, they cross link through a photoinitiated free radical polymerization, which leads to thorough cross linking, hardening, and almost immediate attainment of moisture and chemical resistance. The potential of this technology for exterior painting is evident; the sun itself might act as the cross- linking agent. However, such technology with regard to corrosion-protective coatings is far from perfected. Current problems include the extremely high cost of formulated paints, the requirement for intense ultraviolet or light energy in order to initiate curing, and the curing problems with pigmented coatings or coatings more than a few mils thick.

Therefore, although photochemically cured coatings for corrosion protection have not been developed, the technology is viable, and some radiation-curable coatings have been developed. Commercial applications include clear coatings, thin films of pigmented printing inks, coatings pigmented primarily with inert pigments (for example, paste fillers for particleboard), and paper coatings. Light-cured acrylic laminates and overlays, applied as an adhesive or paste on tooth enamel, have been developed for dental practice.

Water-borne coatings are defined as coatings where water has been purposely introduced into the coating. There are essentially four classes of water-borne coatings:

- Water-reducible coatings
- Water emulsion coatings

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- Latex coatings
- Alkali silicate coatings

The coatings in each of these classifications are formulated differently and have significantly different curing and performance properties. While all four categories can be used for heavy- duty corrosion-resistant coatings, to date, the most commonly used coatings for air-dry maintenance and marine protection are latex-based coatings based on acrylic polymers, and inorganic zinc-rich coatings based on alkali silicate resins. Increasingly, however, two-package epoxy and polyurethane water emulsion coatings are being used. Water-reducible coatings are used predominately in baking applications, because air-dry water reducibles do not perform well. Each of the four classes of water-borne coatings is discussed in the following section.

Water-Reducible Coatings. Resins in these coatings are not soluble in water and are high- solid solutions in water-miscible solvents with either carboxylic acid groups of the resin neutralized with low-molecular-weight amines or with amine groups of resins that are partially neutralized with low-molecular-weight acids. The pigment is dispersed in the partially neutralized resin solution, the cross linker is added along with additives such as catalyst, and the mixture is diluted with water to application viscosity. The water-reducible binders commonly used are alkyds, polyesters, epoxies, and polyurethanes. Electrodeposition coatings, including automotive coatings, are based on water-reducible resin technologies. Additionally, interior linings for beverage cans and dip coating applications commonly use water-reducible technology.

After heating in a baking oven, the water evaporates, and the reactive moieties come together and react at the elevated baking temperature. Water in the coating must evaporate prior to cross linking. This is done by having a longer flash-off time before entering the baking oven or by having a two-stage oven, the first stage at lower temperature to promote water evaporation and the second at a higher temperature to induce the cross-linking reaction.

Water-dispersible air-dry coatings have not achieved viable commercialization. This is due to hydrolytic instability that leads to limited in- can storage life, a slow rate of air-dry cure at lower temperatures, and an excessively water- sensitive film until complete cure has been attained. A water-dispersible polyurethane has recently been commercialized. A hydrophylic- modified polyester polyisocyanate in one package is combined with a second package of a hydroxy-terminated water-reducible polyol with carboxylic acid modification. An excess of the NCO to OH is used to offset the slow isocyanate reaction with water. On air drying, cross linking and good moisture and chemical resistance develop. However, the performance of water-dispersible polyurethane is not yet as good as that of the solvent-based variety.

Emulsion Coatings. True emulsion coatings consist of dispersions of liquids in liquids. Many people refer to latex coatings as latex emulsions, but technically, that is a misnomer.

True emulsion coatings are the least used of the four categories described herein. However, two-package, epoxy-based emulsions have been commercially available for over 25 years. These materials consist of a liquid epoxy resin solution in one package and a second package containing an amine-terminated cross-linking agent with a nonionic surfactant or with nitroethane. The amine cross-linker package is diluted with water, and on application, the epoxy resin solution is added with vigorous stirring. As the water evaporates, the epoxy resin reacts with the amine groups to cross link in conventional fashion. Epoxy emulsion paints are used in hospitals and food-processing plants, where a solvent odor is not acceptable and hard, easily cleaned wall and/ or floor coatings are needed.

Nitrocellulose lacquers emulsified into water are used as topcoats for wood furniture. These emulsions have significantly lower VOC than solvent-borne lacquers but require a longer dry time.

Bituminous emulsions are used as pavement and parking lot surfaces and are discussed in a later section entitled “Bituminous Coatings.”

Latex Coatings. Latex-based coatings are dispersions of solid polymer particles in water. The solid polymer particles are most commonly based on polyacrylate resins (usually the acrylates and methacrylates) but can include vinyl chloride-vinyl acetate copolymers, styrene-butadiene, and others. Usually, a high-molecular-weight resin is suspended in a water medium. The suspension is accomplished by the use of a surfactant on the polymer surface, which charges the surface, in turn repelling similarly charged particles. After application, the water evaporates, and the polymer particles coalesce (come together). The latex forms a film by coalescence of the polymer particles. Coalescence can occur only if the film-formation temperature is higher than the glass transition temperature (T_g) of the polymer particles. The T_g is the temperature at which the polymer softens. In the case of most air-dry coatings, slow final coalescence is not a real problem, so the film-formation

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

temperature needs to be only a little above the T_g. In the case of baked coatings, film formation must be complete by the end of the baking time; therefore, baking temperatures should be significantly above the T_g.

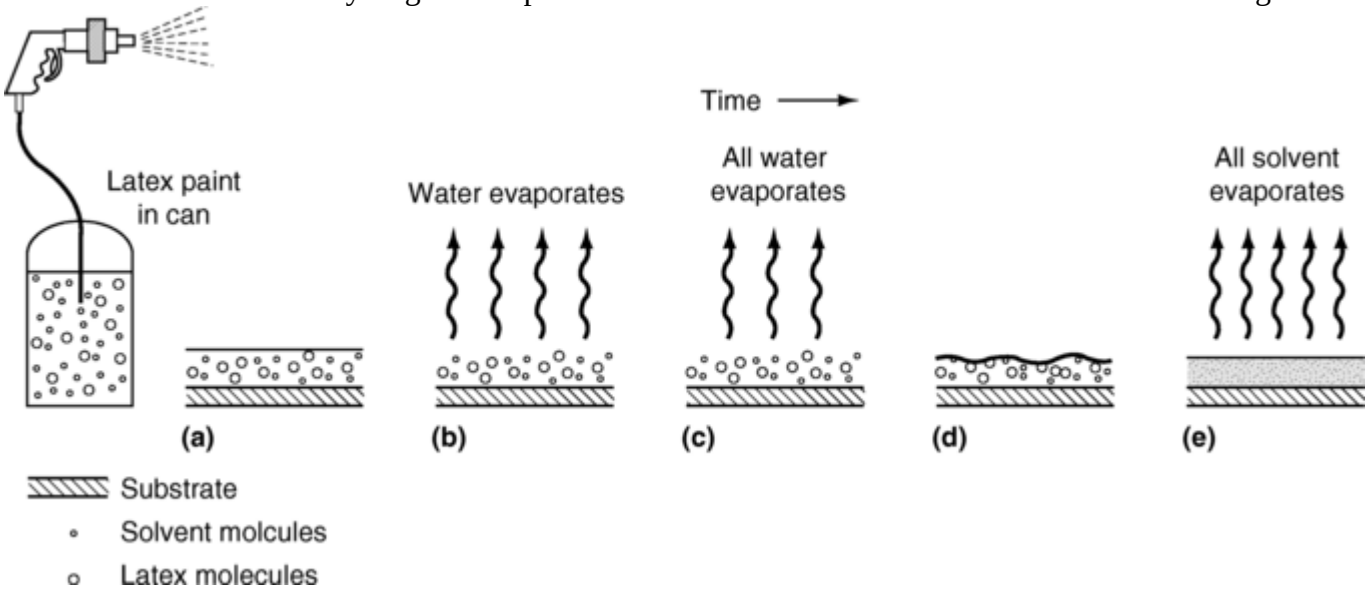
A major coating market has been the water- based acrylic paints widely used by the homeowner for indoor and exterior painting purposes. Compared to oil-based coatings, the other major homeowner-type paint, the water-based acrylics have a number of advantages. They have a much faster drying time and can be recoated within 1 h. They have better alkali resistance, excellent adhesion, come in a variety of colors and maintain their color and gloss in the presence of sunlight and ultraviolet light, and have excellent long-term flexibility and toughness. The major advantage, of course, is the ease of cleanup with water-based paints.

The disadvantages are that the oil-based paints have greater penetrability, particularly on wood and porous surfaces, and have better initial adhesion. On smooth surfaces, water-based paints may peel or lose adhesion, while an oil-based paint may wet sufficiently to maintain good adhesion. However, acrylic paints have better resistance to blistering because of their breathing ability and have much better resistance to chalking and yellowing. Water-based coatings may provide better adhesion to damp wood and masonry substrates than oil-based paints.

The chemistry of latex coatings is extremely complex. Generally, high-molecular-weight acrylic polymers are polymerized in a water emulsion. The desired pigments are dispersed in the emulsion, and the required additives are added, followed by tinting and color pigments. Titanium dioxide is the most widely used white-hiding pigment, although most other water-insoluble alkali-resistant organic and inorganic pigments can also be used. Wetting agents are added to ensure complete pigment wetting in the water vehicle, and antifoaming additives are used to prevent foaming during manufacture and at the time of application. Thickening additives (for proper application viscosity) are used to prevent pigment settling as well as runs and sags after application.

Surfactants are added to enhance pigment dispersion, and it is these additives that provide the water sensitivity that most water-based coatings have after application. Briefly stated, most surfactants have a hydrophobic (water-hating) and a hydrophilic (water-loving) end, which orients around the emulsified resin and the pigment particles. The hydrophobic end is adjacent to the resin particle surface, while the hydrophilic end is attracted to the water carrier. After application of the paint, many of these surfactants remain entrapped within the film cross section, and the hydrophilic end of the surfactant attracts water from the environment, which tends to soften and swell the coating. In atmospheric service, there is insufficient water—or insufficient wet time— to cause a problem. However, in prolonged water immersion, water may be attracted by the surfactant, penetrate the film, and cause softening and swelling of the coating, with a loss of adhesion. Consequently, water-based coatings, as currently formulated, are not suitable for prolonged water immersion.

For most air-dry (nonbaking) applications, a coalescing solvent is added. This very slow- evaporating organic solvent, which is miscible with water, is added to the water carrier. As the water evaporates, the concentration of the solvent becomes higher and higher in the water- solvent mixture. Ultimately, in the drying film, the solvent reaches a sufficient concentration that it can partially solvate the resin particles, causing them to soften and meld together on further drying. The coalescing solvent helps convert the emulsified particles into a relatively smooth, homogeneous film. However, residual solvent may be entrapped within the film, and it too can lead to water sensitivity. Figure 5 depicts the coalescence and film formation of a latex coating.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 5 Schematic of the stages of coalescence and film formation of a latex coating. (a) Coating on substrate immediately after application. (b) As water evaporates, the solvent-to-water ratio increases, and latex particles close together. (c) All water evaporates, and only latex particles and solvent remain. (d) Solvent melts latex particles together. (e) All solvent evaporates, and latex particles form a firm, dry coating.

For wood or masonry surfaces where water vapor transmission may be a problem, latex paints may be suitable, because they are said to breathe. This breathing occurs as a result of irregularities during the coalescence part of the film forming; the particles may not align themselves properly relative to other emulsified particles. A series of pores or defects in the coalesced film results. Such discontinuities are extremely small, and the surface tension of water in liquid form does not enable penetration through the coating to the underlying substrate. However, water vapor may readily pass through such discontinuities, resulting in its breathing ability.

Water-based paints develop poor film properties when applied during cold, damp weather. In order for proper weather and chemical resistances to develop in a water emulsion film, water evaporation and proper drying must occur. If water evaporation is retarded and if the drying sequence is upset by becoming either too slow (or in some cases too rapid), proper coalescence and film formation do not occur. The result can be a soft, poorly adherent film that, when drying does finally occur, shows cracking; this film may also be brittle and adhere poorly. Too fast a water evaporation rate on a hot surface or a fast-evaporating coalescing solvent can lead to a powdery, poorly adherent paint film or a film with many voids, pinholes, or cross-sectional porosities.

Acrylic paints for interior use are similar to those for exterior use, except that a higher pigment volume can be used, and less expensive pigments that are not as light-fast as those for exterior use can be used. The major competition for acrylic interior paints comes from lower-cost polyvinyl acetate (PVA) or butadiene-styrene-based latex coatings.

Alkali Silicate Coatings. For industrial maintenance and marine coatings, the most common coatings of this type are used as alkali silicate binders for inorganic zinc-rich coatings and as surfacers and waterproofers for masonry. The binders are water-soluble silicates of alkali metals (sodium, potassium lithium) and related quaternary ammonium silicates. The zinc-rich coatings are pigmented with zinc-dust particles, and other coatings may be pigmented using titanium dioxide (titanates).

After application, water evaporates, and the alkali silicates concentrate as a silica gel. The silica gel is still water soluble, but gradually it hydrolyzes to form silicic acid, which in turn reacts with the pigment, the substrate, or both. This makes the gel increasingly insoluble. Further hydrolysis and alkali neutralization occur by reaction with an acid curing solution or carbonic acid formed from the atmospheric reaction of carbon dioxide and water. This neutralization reaction forms a silicate matrix holding the pigment particles together and to the substrate. However, a by-product of the neutralization reaction is the formation of water-soluble reaction salts that may lead to blistering of topcoated silicates in water immersion. Inorganic alkali-silica-based zinc-rich paints, concrete surface hardeners, and other silicate-based masonry water-repellent coatings are all based on this technology.

Characteristics of Water in a Water-Borne Coating. Water, as a constituent of the environment, is environmentally friendly. Accordingly, water-borne coatings are generally environmentally acceptable, although most of them use a cosolvent as a coalescing aid, freeze-thaw stabilizers, and/or wet-edge aids to adjust the drying rate and improve flow and leveling. These cosolvents are generally added in volumes of 20% or less of the water constituent.

Water-borne coatings are not flammable and do not support combustion during application and while liquid. Moreover, there is no objectionable solvent odor (although, depending on the formulation and the use of cosolvents, they do have a mild, nonlingering odor).

As is evident with all four classes of water- borne coatings, water is a major constituent. Furthermore, in each case, the water must evaporate in order for a subsequent film-forming mechanism to occur and for the coating to attain its final moisture and chemical resistance.

Water-borne coatings are significantly different than solvent-borne coatings, due entirely to the character of water. In solvent-borne coatings, blends of solvents with different solvency can be used to dissolve a resin. Those solvents then volatilize with different evaporation rates from the applied coating. There are no such things as blends of water, and the freezing temperature and boiling point of water are constant. The evaporation rate of water is highly dependent on temperature and humidity. As water evaporates from a coating, the humidity above the coating surface increases such that water evaporation is low. If there is no air movement or

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

circulation above the coating surface, humidity may reach 100%, at which time no further water evaporates from the coating. Moreover, if temperatures are low, the ability of the air to contain moisture is substantially diminished. At low temperatures (much below 10 °C, or 50 °F), water evaporation is slowed sufficiently that many water-borne coatings may not form a suitable film. This is not the case with organic solvents, which can volatilize independent of humidity (however, the organic solvent vapor pressure is a function of the solvent concentration at the coating-air interface). The film formation of water-borne coatings may be further disrupted when the temperature falls below the T_g of the resin, preventing the resin particles from properly flowing or coalescing.

The high polarity of the water molecules, and their strong tendency to hydrogen bond, is responsible for the unique properties of water. This hydrogen bonding is responsible for the slow water evaporation rate and the tendency for water to solidify at relatively low temperatures (compared to organic solvents). Additionally, the hydrogen bonding results in a high surface tension of water that prevents its penetration into dirty, dusty, or relatively porous surfaces (again, compared to organic solvents). Thus, initial adhesion of most water-borne organic coatings is poor, although over time (sometimes two weeks or more), adhesion to most surfaces becomes tight. Figure 6 illustrates the hydrogen bonding attractions between the oxygen atoms of one molecule for the hydrogen atoms of another molecule.

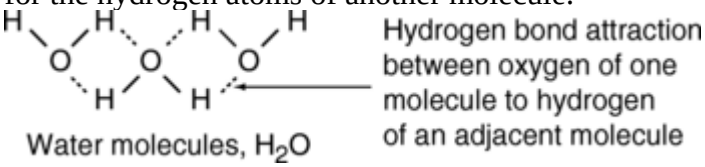


Fig. 6 Hydrogen bonding of water molecules

Everyone knows that oil and water do not mix. Even with slight oil contamination of a substrate, water-borne coatings do not properly wet a substrate (even when solvents are a part of the formulation). The surface-free energy of the substrate is depressed with only a slight amount of oil contamination, such that it cannot be wet by a water-borne coating. Accordingly, any oil must be removed from the substrate prior to application of any water-borne coating.

As previously mentioned, water does freeze. With water-borne coatings, the expansion of the freezing water can cause coagulation of dispersed latex or emulsion particles, resulting in settling or agglomerations in the can prior to application. Freezing of water in a water-borne coating system after application upsets coalescence and cross linking. Often, high-molecular- weight polyfunctional alcohols (such as diethylene glycol) are mixed into the water to reduce the hydrogen bonding density, thereby reducing surface tension and lowering the freezing point.

Water dissolves and disassociates salts. Salts on a surface beneath a water-borne coating may be dissolved and accelerate corrosion. Additionally, many of the surfactants and neutralization by-products of the curing reaction result in salts that, when dispersed through a cross section of the coating, may increase water permeability. This is a particular concern, because water is an inherent constituent of most exterior environments. Thus, dissolving, suspending, or emulsifying a resin in a water solution may result in atmospheric moisture susceptibility.

Bituminous Coatings. The bitumens used in the coatings industry are coal tar and asphalt. Although these materials are distinctly different physically and chemically, in appearance they are essentially identical black thermoplastic tar materials. As coatings, the bitumens can be applied as hot melts, solvent cutbacks, or emulsions. However, similar to all other solvent-deposited coatings, the bitumen cutback violates most VOC regulations. Accordingly, hot melt and water emulsion applications are most popular.

Hot melt application involves heating the bitumen to a temperature of 175 to 245 °C (350 to 475 °F) such that its viscosity at that temperature is very low—almost waterlike. Hot melt asphalts and coal tar materials are usually applied with mops or swabs to the surface being coated, although brush, roller, or spray application is sometimes used. Flow coating of the interiors of pipes and small vessels is also done. In this method, the hot melt is flowed into the pipe or vessel, and the item is rotated or turned to cover all surfaces before the coating cools and hardens. The interiors and exteriors of pipeline sections are often flow coated at pipeline-coating facilities.

Water emulsions are prepared by suspending minute particles of the bitumen in water using emulsifying agents and by combining with inert fillers, such as pulverized talcs of hydrated magnesium and aluminum silicates,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

coal dust, powder silica, mica, and limestone dust. After application, the water evaporates. Coalescence occurs in the fashion typical of any emulsion coating, and a protective film is formed.

Asphaltic or coal tar bitumens dissolved in a suitable solvent (normally aliphatic and aromatic hydrocarbons) are termed solvent cutbacks. Dissolving the bitumen in a solvent lowers its viscosity sufficiently that the cutback can be applied by spray, brush, or roller, as appropriate. After application, the solvent volatilizes, and the bitumen resolidifies into a film. The coating thicknesses of solvent cutbacks are generally considerably less than those achieved by hot melt application, but the convenience of not having to heat the bitumen at the job site immediately before application is a major advantage.

In general, hot melt application provides the best moisture and chemical resistance, followed in order by the solvent cutback and water emulsions. Asphaltic and coal tar bitumens applied as emulsions or as hot melts have widespread use as roof coatings, highway or pavement sealers, and underground coatings or waterproofing compounds.

Asphalts. Natural asphalt, or gilsonite, is a hard, brittle resin that is mined predominantly in Utah, Colorado, and Trinidad. Increasingly, asphalts obtained as residues from the distillation of crude petroleum are replacing the natural asphalts because of better uniformity, fewer impurities, and lower transportation costs. Asphaltic compounds are comprised of complex polymeric aliphatic hydrocarbons, and they have good water and chemical resistance; similar to coal tars, they are sensitive to oils and solvents. Asphaltic coatings have much greater ultraviolet resistance than coal tars do and are therefore used for above-grade weathering applications in which coal tars are not suitable. These asphaltic coatings are used above grade in atmospheric service.

Coal tar enamels or pitches are derived from the coking of coal. When coal is heated in the absence of air to a temperature of approximately 1095 °C (2000 °F), it decomposes partially into a gas and coke. The gas is subsequently condensed, and coal tar is formed. Lighter fractions are removed from this tar by subsequent heating and gas extraction until the desired coal tar fraction for use in coatings is obtained. The compounds in coal tar range from low-boiling, low- molecular-weight benzene to complex, high-molecular-weight, aromatic hydrocarbons.

Essentially, there are three types of coal tar enamels:

- A straight pitch base that is relatively hard and brittle but has the greatest moisture and chemical resistance
- A plasticized enamel that is more flexible and has greater cold weather application tolerance but the least chemical and moisture resistance
- An intermediate grade (containing approximately 50% of each of the first two) that is also intermediate in its properties

For best adhesion, preheating of the object being coated is preferred; if this is not feasible, a primer can be used to promote adhesion of the coal tar. Many of the primers are solvent cutbacks of coal tar pitch combined with a chlorinated rubber resin, plasticizers, highly volatile solvents, and some color pigment. The primer is of a lower viscosity and can more readily wet the steel surface. In addition, it dries faster and leaves a firmly bonded layer on the steel. Subsequently applied coal tar adheres more readily to steel that is primed in this manner.

Coal tar coatings (whether applied as hot melts, cutbacks, or emulsions) are subject to ultraviolet light degradation and resultant cracking. The cracking results from the volatilization or evaporation of lower-molecular-weight constituents from the surface and attendant shrinking. The surface of the coating contracts and cracks, while the underlying thicknesses remain plastic. Such “alligator” cracking (Fig. 7) is not detrimental, although it does diminish the thickness of the coating within the crack fissures. Because of this phenomenon, coal tar coatings are used in underground or immersion service, in which they are not subject to ultraviolet light. As roof coatings, they must be shielded by a subsequent coat of noncoal tar material or by gravel or pebbles applied for this purpose.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

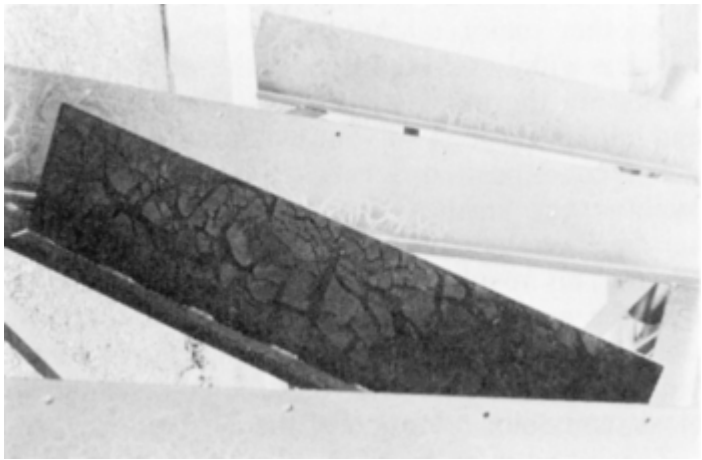

Fig. 7 “Alligator” cracking of a coal tar coating caused by volatilization of low-molecular-weight constituents from the surface and by coating shrinkage

Coal tar coatings have much better resistance to moisture, acids, and alkalies than the asphaltics. The coal tars and asphalts are generally incompatible as a result of their chemical makeup and usually should not be used as mixtures or applied one type over another.

Cross-Linked Thermosetting Coatings

Chemically cured coatings, in the context of this article, refer to coatings that harden or cure and attain their final resistant properties by virtue of a chemical reaction either with a copolymer or with moisture. Examples of coatings that chemically cross link by copolymerization include epoxies, unsaturated polyesters, urethanes in which the isocyanate is reacted with a polyol, high-temperature curing silicones, and phenolic linings. Chemically cured coatings that react with water include moisture-cured polyurethanes and most of the inorganic zinc-rich coatings. Although drying-oil-based coatings (see the section “Autooxidative Cross-Linked Resins” in this article) are also chemically cross linked on their reaction with oxygen from the air, they are excluded from this category, because the autooxidative cross-linking mechanism is a sufficiently distinct category of chemical cross linking to merit a separate discussion.

The fundamental principle of chemical cross linking is to formulate a coating using a resin or binder of low molecular weight. When mixed and applied, reaction with moisture from the atmosphere or with a coreactant takes place, resulting in cross linking and a much larger three- dimensional molecular structure. In fact, it is possible to begin the application of a cross- linked coating system to the interior of a large tank or vessel, and on completion of the application many hours later, the film may cure into one large macromolecule that may cover many thousands of square feet of surface area. Such a coating or lining, if suitably formulated, provides a tough, flexible, and highly chemical-resistant corrosion protection barrier over the underlying substrate. Such a

www.iran–mavad.com

مرجع مهندسی مواد و متالورژی

large macromolecule with the attendant corrosion-resistant properties would be impossible to obtain in a prereacted binder system.

Coatings and linings based on chemically converted binders can be formulated to have excellent resistance to acids, alkalies, and moisture and can be formulated to resist abrasion, ultraviolet degradation, and thermal degradation. As a general rule, toughness and flexibility of the coating increase as the molecular length increases. Similarly, chemical and moisture resistance increase as the cross-linking density increases within the macromolecule. However, as with any coating, constituent chemical groups within any molecular structure may result in characteristic strengths or weaknesses within the molecular chain. Furthermore, the arrangement and composition of pendant sidegroups may further alter the properties of any given molecular structure. Also, unreacted moieties (reactive sites) within the molecule may lead to decreased chemical, moisture, or thermal resistance.

The rate at which the molecule cross links is dependent not only on the reacting moieties but also on the cross-linking mechanism (for example, addition, condensation, or free-radical- initiated cross linking). Most importantly, external factors such as temperature and (with moisture reactions) atmospheric humidity affect the rate and extent of cross linking. Thus, chemically converted coatings must set after application through solvent or water volatilization and then harden and attain their final cured properties by the cross-linking reaction, which is temperature and/or moisture dependent. Too slow a rate of reaction may lead to an insufficiently cross-linked coating that, although hard and having a suitable appearance, has poor chemical and moisture resistance. Too fast a rate of reaction may lead to an overcured, hard, impervious coating that cannot be recoated or topcoated with a properly adherent subsequent coat.

Overcuring is often a problem in maintenance repainting, when a renewal coat is applied to the original cross-linked coating system after an extended period of time. In extreme cases, however, the recoat interval within which no recoat problems may be anticipated could be as short as a few hours for certain coatings or under certain ambient conditions. Amine-cured coal tar epoxy coatings are a good example, and the recoat window may be less than 16 h, after which intercoat adhesion may become a problem.

The curing and hardening of some chemically cross-linked systems, such as most polyesters and vinyl esters, is so rapid that plural-component spray application systems are required. Such systems mix the coreactants at the time of spray application within the spray gun or outside the spray gun nozzle. The chemical cross-linking reaction occurs so rapidly that by the time the coating has deposited on the surface, the coating is beginning to set up. Although such coatings are hard to the touch within minutes, solvent volatilization and additional cross linking should be allowed to continue for days prior to exposure in a severe chemical environment. As a general rule, curing of most chemically cross-linked systems should proceed for approximately 7 days at 25 °C (75 °F) before the coating system is exposed to severely corrosive conditions, immersion, or acid or alkali splash or spillage. The more common chemically cross-linked binders or resins used for coatings and linings are discussed subsequently.

Epoxies

Chemically cross-linked epoxies usually come in two packages; the first usually consists of the epoxy resin, pigments, and some solvent, and the second is the copolymer curing agent. The two packages are mixed immediately before application and, on curing, develop the large macromolecule structure. The properties of the epoxy coating derive both from the type and molecular weight of the epoxy resin and from the copolymer curing agent that is used to cross link with it.

Epoxy Resins. There are three principal epoxy resin chemistries: bisphenol-A, derived from bisphenol acetone and epichlorohydrin; bisphenol-F, derived from bisphenol formaldehyde and epichlorohydrin; and novolac, a modification of the bisphenol-F resin using excess phenol.

The bisphenol-A epoxy resins are still the industry workhorse, but the use of bisphenol-F and novolac resins has increased substantially over the past few years because of their lower molecular weight compared with the bisphenol-A resin. This allows formulators greater flexibility when developing VOC-compliant coatings. Bisphenol-F and novolac epoxy resins also have higher functionality, which, when properly cross linked, results in a coating with greater chemical, moisture, and heat resistance than the bisphenol- A-type epoxy coatings.

Each of these resin types is discussed subsequently.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Bisphenol-A Resins. Bisphenol acetone (commonly, bisphenol-A) is a reaction product of phenol and acetone. The resulting resin is further reacted with epichlorohydrin to form the diglycidyl ether of bisphenol-A resin. The molecular structure of the bisphenol-A epoxy resin is shown in Fig. 8.

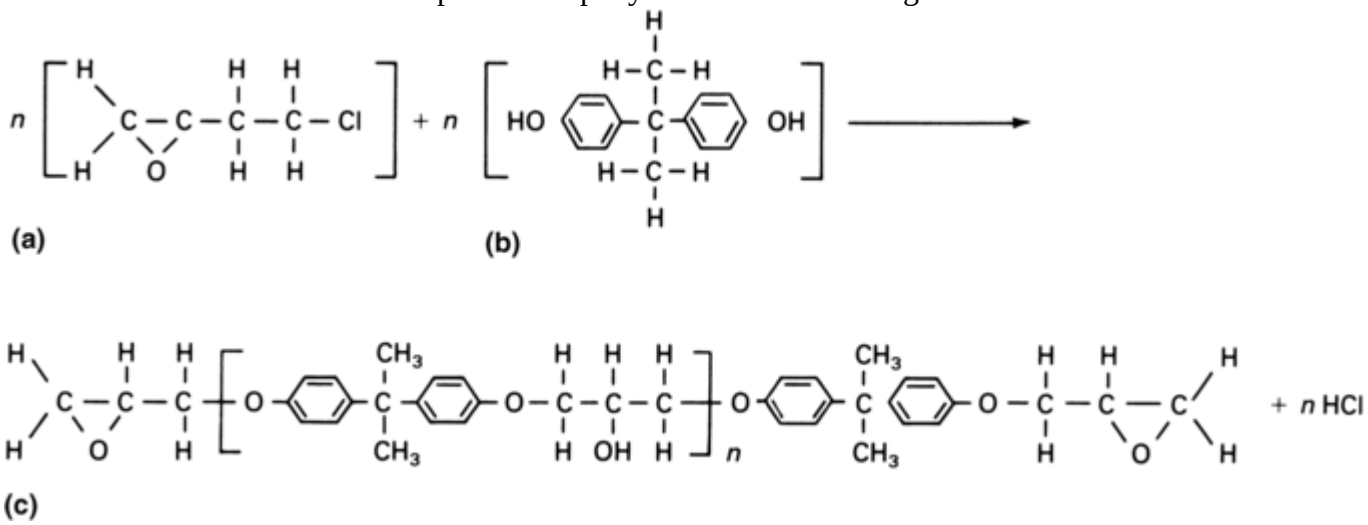

Fig. 8 Reaction of epichlorohydrin (a) and bisphenol-A (b) to form a glycidyl-ether-type epoxy resin (c)

When the repeating unit *n* is one or less, the resin is a liquid with a honeylike consistency. These liquid epoxies are used for high-solids, ambient-temperature-cure epoxies. When the average molecular weight of the resin is increased by increasing *n* to approximately 2, the resin becomes a solid and must be dissolved with suitable thinners in order for it to be used as a coating material. Traditionally, an *n* of approximately 2 and a molecular weight of 800 to 1000 have been used in the formulation of the typical workhorse epoxies that are widely used in industrial maintenance and marine coatings.

Increasing *n* to even higher numbers raises the molecular weight. If sufficient reactive functionality is added (for example, addition of pendant amine and hydroxyl moieties), such bisphenol- A epoxy resins are used as epoxy ester resins and powder coats (*n* equals approximately 3.7) and epoxy/phenolic and amino epoxy coatings that are cured by baking (*n* equals 8 to 12).

Traditionally, bisphenol-A 2-type epoxies have long been used to produce the 45 to 65% volume solids amine- and polyamide-cured coatings that for years have provided protection of steel and concrete in the industrial and marine markets. The resulting epoxy systems (when cross linked with the active hydrogen from an amine or amine functionality of a polyamide co- reactant) have very good water and chemical resistance and are tough and resistant to abrasion and thermo- and mechanical shock. However, because the resin is an amorphous solid and must be dissolved in solvents in order to liquefy it and make it suitable for use as a paint or coating, lower-molecular-weight liquid resins such as bisphenol-F and epoxy novolac resins are increasingly being used by coating formulators.

Bisphenol-F Resins. Bisphenol-F resin has a lower molecular weight (approximately one- third that of a bisphenol-A resin with equivalent functionality). Bisphenol-F resins are similar to those of bisphenol-A except that phenol is reacted with formaldehyde rather than acetone to form the intermediate product, after which it is again reacted with epichlorohydrin to form the finalized bisphenol-F resin. The molecular structure of the reactants is shown in Fig. 9.

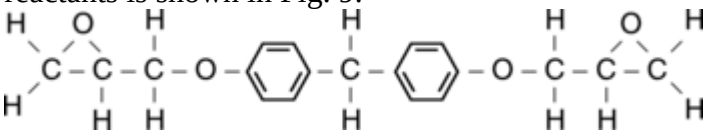

Fig. 9 Bisphenol-F epoxy resin

Bisphenol-F resins have greater chemical and heat resistances than the bisphenol-A epoxy resins but are less tough and flexible. These properties and the fact that they do not need solvent reduction to make them liquid have increased their use for VOC-compliant coatings.

Bisphenol-F resins, when coreacted with aromatic amine and amine addicts, can be formulated as high solids and 100% solid epoxies (with little or no solvent).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Novolac Epoxies. These epoxy resins are modifications of bisphenol-F resins that are formed using an excess of phenol. Bisphenol-F is the simplest novolac resin, and all other novolac resins have significantly higher viscosity than the bisphenol-F resins. Equally important, the functionality of the novolac is also considerably greater, leading to an even better chemical moisture and heat resistance than the bisphenol- F. The molecular structure for two novolac resins, the epoxy phenol novolac and the epoxy cresol novolac, are presented in Fig. 10.

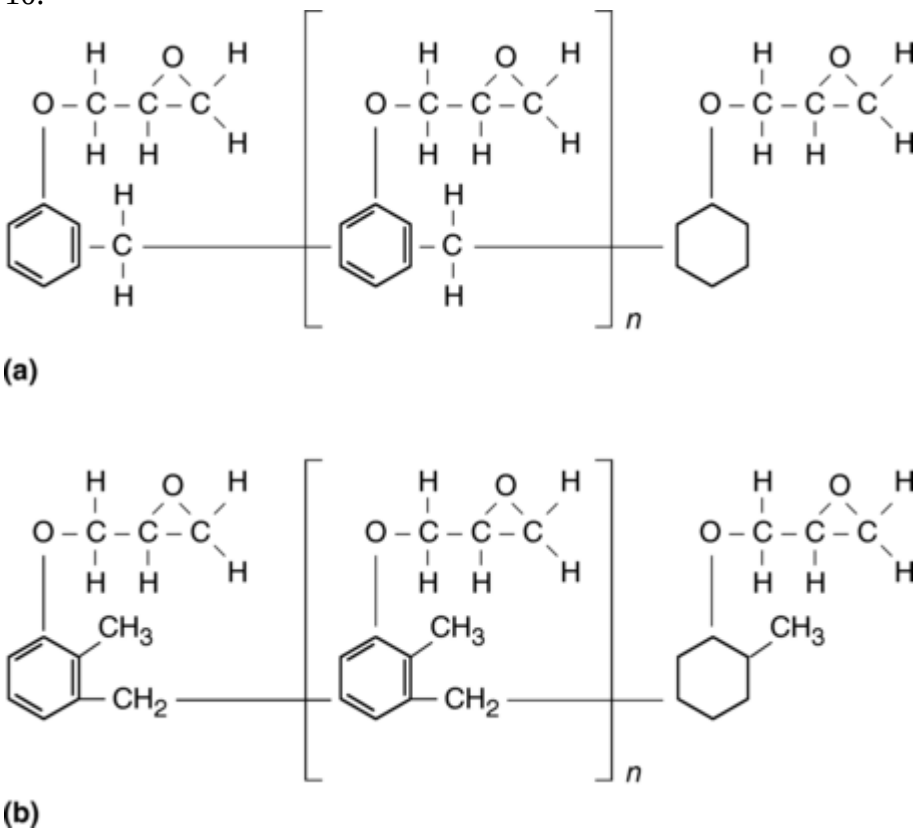

Fig. 10 Epoxy novolacs. (a) Epoxy phenol novolac. (b) Epoxy cresol novolac

The epoxy phenol novolacs are very high-viscosity liquid and semisolid materials. The epoxy cresol novolacs are solids and used most often in powder coatings. Both epoxy resins have higher epoxy functionalities than the bisphenol- A and bisphenol-F resins. Their high cross-link density leads to extreme heat, chemical, solvent, and moisture resistances, and they are often used for solvent service and for resistance to mineral acids at elevated temperatures. Novolac epoxy resins are formulated for use in deep-well oil- recovery tubing exposed to high-temperature wet and dry acid and alkali service and high abrasion.

However, because of their higher cross-link density, care must be used in choosing an appropriate cross-linking coreactant curing agent. Otherwise, the coating is extremely brittle and cracks.

Other Epoxy Resins. Other less common epoxy resins have been developed for use in specialized coatings. A flexible epoxy based on the oil of the cashew nut shell is called a cardanol epoxy. Epoxidation of the oil is induced, and the resin is used in room-temperature curing systems or as an additive to provide flexibility, toughness, impact resistance, and adhesion even at low temperatures.

Brominated epoxies have been developed for use as fire-retardant coatings and laminates. The fire retardancy occurs by degradation of the epoxy resin and liberation of the bromine as a gas. The gas is heavy and a fire retardant. Bromine is typically added to a bisphenol-A resin as a substitute on the aromatic ring. The typical structure of a brominated epoxy resin is shown in Fig. 11.

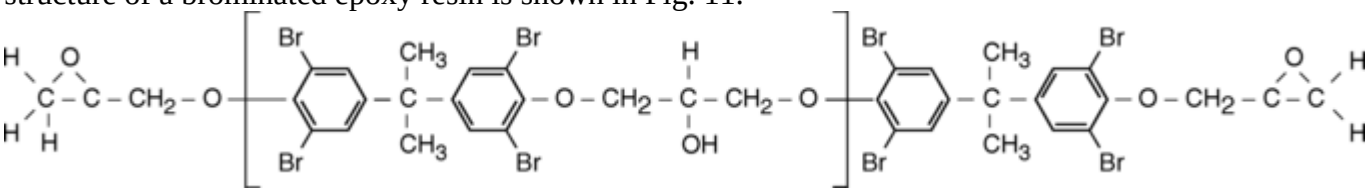

Fig. 11 Brominated bisphenol-A epoxy resin

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

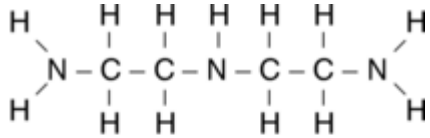
Curing Agents for Epoxy Resins. The second portion of a two-pack epoxy coating system is the curing agent. The curing agent is a coreactant, which, when mixed with the epoxy resin, cross links to form a chemical bond that increases the molecular weight of the coating molecule. The resulting resin, often modified with additives to enhance flow, surface appearance, and other factors, also encapsulates the pigment particles. Each of these constituents is critical to the ultimate properties of the reacted and cured coating system. However, the formulator's choice of the curing agent is crucial to the derivation of the finalized coating properties.

Although epoxies are generally thought of as catalyzed, the cross-linking reaction is, in fact, a copolymerization. The reaction occurs primarily through the epoxy ring end groups or the mid- chain hydroxyls of the epoxy resin. The curing agent is usually an amine or polyamide, with cross linking derived through the active hydrogens attached to the amine nitrogen. Although a variety of cross-linking agents can be used (including mercaptans, polybasic acids and anhydrides, and phenol-formaldehyde and phenol resins), the most common are the polyamines, the amine adducts, and the polyamides.

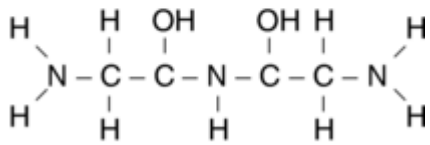
Polyamines. The polyamines (for example, diethylene triamine, hydroxyethyl diethylene triamine, and bishydroxydiethylene triamine) are relatively small molecules with a low molecular weight compared to the epoxy resin. As a consequence, when reacted, they lead to tight cross linking and high chemical and moisture resistance. However, during the cross-linking reaction, any unreacted amine may be squeezed out of the cross-linked film to the surface, developing the so-called amine blush, a hazy white coloration on the coating surface. The amine blush is a reaction of the amine with carbon dioxide in the air to form an amine carbonate. If on the topcoat, the blush is not detrimental in atmospheric service and can be allowed to remain on the surface. However, it is a good practice to wash or wipe it from the surface (it is water soluble) before application of a subsequent epoxy coat, particularly for immersion service.

To minimize the formation of the amine blush, many formulators specify a 15 to 30 min induction period after mixing, prior to application. This allows the reaction to begin and initial cross linking to occur before the paint is applied. Some of the small amine molecules partially cross link with epoxy resin molecules, increasing their size and reducing the tendency to migrate to the surface to form the amine blush.

Aliphatic amines have a high reactivity and therefore a fast cure at ambient temperatures and produce a highly cross-linked coating as a result of their low molecular weight and high functionality. This, however, results in limited flexibility and potentially incomplete chemical reaction with the epoxy resin due to its low molecular weight. Examples of these aliphatic amines are diethylene triamine, ethylene diamine, and triethylene tetramine. Higher-molecular-weight aliphatic amines include hexamethylene diamine and trimethyl hexamethylene diamine. These later aliphatic amines provide more flexibility because of the greater molecular distance between the diamine reactants at either end of the molecule. Figure 12 depicts the molecular structure of some of these amines.



(a)



(b)

Fig. 12 Polyamines. (a) Diethylene triamine. (b) Hydroxyethyl diethylene triamine

Amine Adducts. Because of the problems with small-molecule reactants, many coating manufacturers supply the amine as a prereacted amine adduct. In this case, the epoxy pigment and solvents are packaged as before in one container, but an excess of the amine is prereacted with some of the epoxy resin to increase its molecular size. The prereacted amine adduct is then packaged in a separate container, sometimes with additional pigment and solvent. On application, both containers are mixed, and the cross-linking reaction goes to completion.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Chemical cross linking of the resultant applied film is not considered to be quite as tight as that provided by a nonprereacted amine, and the chemical resistance is somewhat less. However, application is much easier and not nearly as dependent on thorough mixing of the reactants and induction time.

Polyamides. Polyamide curing agents are the condensation products of a dimerized fatty acid with a polyamine, as shown in Fig. 13. Polyamides, and other amine curing agents, result from the addition of amine (NH_2) functionalities into the backbone of a fatty acid, commonly a tall oil fatty acid. The fatty acid results in improved flexibility and substrate wetability, improved adhesion, and outstanding water resistance. Terminal amine functionality allows cross linking to occur as with a straight amine, although the polyamide molecule is much larger. The cross-linked film has improved flexibility, improved gloss and flow, excellent water resistance, and good chemical resistance. Polyamide- cured coatings, however, have somewhat less solvent and alkali resistance than amine- and amine-adduct-cured epoxies.

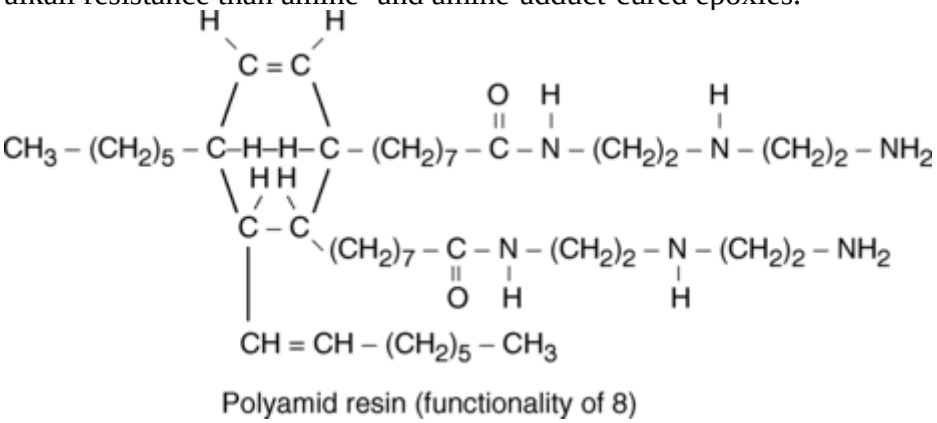


Fig. 13 Polyamide, the product of a fatty acid (commonly a tall oil) with a polyamine (NH_2) functionality

Specially formulated polyamide-cured epoxies have the ability to displace water from the substrate surface. Such materials can even be applied and cured underwater to form corrosion- resistant coatings.

Amino Amines. If a polyamine is reacted with a monofunctional fatty acid instead of using a fatty acid dimer, the condensation product is an amino amine instead of a polyamide. The fatty acid has simply increased the molecular weight of the amine at the expense of reducing its amine hydrogen functionality. The most attractive feature of the amino amines is that their equivalent weight remains quite high. The equivalent weight is the number of grams of resin containing one equivalent of a functional group. High equivalent weight allows for low viscosity in a mixed system, which is desirable for low-VOC formulations. The amino amines are most often used with low-molecular-weight liquid epoxies and high- and 100% solids coatings. The U.S. Navy standard epoxy MIL-P-24441 is based on an amino-amine-modified polyamide curing agent.

Ketimines. One other type of curing agent, ketimine, is worthy of note. The ketimine curing agent allows the application of a high-molecular- weight, high-solids, or solventless epoxy resin with standard spray equipment. These more viscous epoxies can be mixed with the low-molecular-weight ketimine curing agent and sprayed onto the surface. No reaction occurs until the ketimine decomposes in the presence of atmospheric moisture to form a polyamine and a ketone. The ketone volatilizes from the film, and the amine reacts as described previously to cross link the epoxy resin after application. These systems result in a tightly cross-linked epoxy film but require relative humidity in excess of 50% and good ventilation to expose the ketimine to moisture and to remove the residual ketone and other solvents from the paint film. The ketimine curing reaction is shown in Fig. 14.

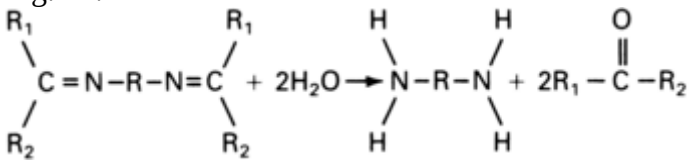

Fig. 14 Curing reaction of ketimine-cured epoxies. Ketimine decomposes in the presence of atmospheric moisture to form a polyamine plus a ketone. R, R_1, and R_2 are alkyl groups. Source: Ref 2

Cycloaliphatic Amines. This class of amine is characterized by an amino (NH_2) group attached to a cycloaliphatic (nonring) moity. When the amino group is attached to a cycloaliphatic structure, the resultant

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

resin has greater light stability and better heat resistance than the linear aliphatic amines. All cycloaliphatic amines are slower reacting than linear amines, but they react faster than the polyamides. Chemical resistance of the linear aliphatic amine is superior to both the cyclo-aliphatic and polyamides, although the resulting molecule is more rigid and less flexible. The structures of cycloaliphatic amines diaminocyclohexane and isophorone diamine are shown in Fig. 15.

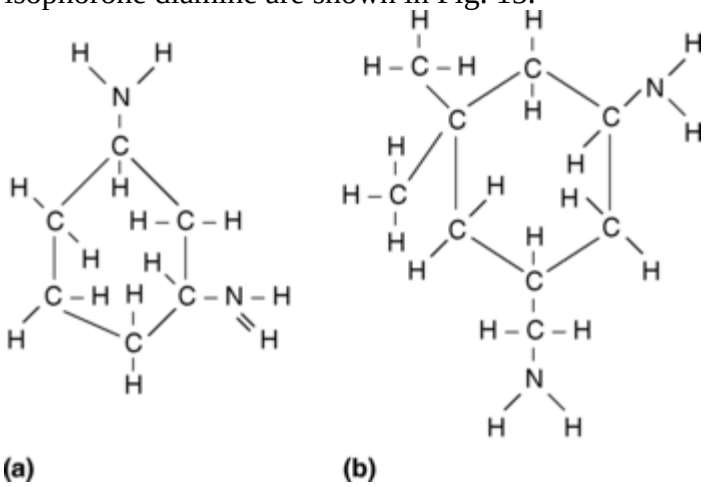

Fig. 15 The structure of cycloaliphatic amines. (a) Diaminocyclohexane. (b) Isophorone diamine

A relatively new cycloaliphatic amine is bis- (p-aminocyclohexyl) methane. This amine has the heat resistance and mechanical strength typical of other cycloaliphatic amines but has a better low-temperature cure and yields a tougher, more flexible coating due to its bulky structure, which results in a lower cross-link density. The molecular structure of this amine is shown in Fig. 16.

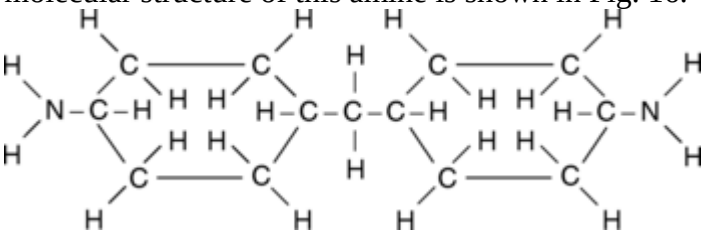

Fig. 16 The structure of cycloaliphatic amine bis-(p-aminocyclohexyl) methane

Aromatic Amines. For years, methylene dianaline, an aromatic amine, was widely used to cure epoxy resins. It had a very long pot life, excellent acid and heat resistance, moisture insensitivity, and flexibility. However, it yellowed and darkened on ultraviolet light exposure and was listed as a carcinogen by the Occupational Safety and Health Administration (OSHA). Accordingly, most formulators do not use methylene dianaline and have found substitute aliphatic or cycloaliphatic amines to replace it.

Mannich bases are formed by the reaction of a methyol phenol and a multifunctional primary amine. They are used principally for low-temperature-curing (-1 to 2 °C, or 30 to 35 °F) epoxies and for coatings that cure under damp conditions, including underwater-cured epoxies. They are also used in coal tar epoxy systems. The free phenol content often found with this curing agent may limit the use of a mannich base curative. The formation of a mannich base curing agent is illustrated in Fig. 17.

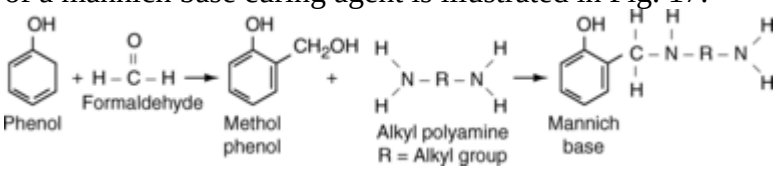

Fig. 17 Formation of mannich base curing agent

Mannich bases can be adducted with metaxylylene diamine, which produces a coreactant that cures at lower temperatures than any other amine-based curing agent. The mannich-based adduct is also useful in formulation of high-solids, low-VOC maintenance paints.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Dicyandiamide is a solid curing agent often marketed as a prepackaged form including flow- control agents and other additives. It is used almost exclusively for curing epoxy powder coatings.

A typical powder coating consists of a solid epoxy resin (often a high-molecular-weight bisphenol-A epoxy) that is heated to melting and mixed with polyacrylic flow-control additives and pigments. The melt is cooled, extruded, and ground to a powder.

The dicyandiamide is also powdered, directly or as an adduct, and mixed with the epoxy powder. Its chemistry is illustrated in Fig. 18.

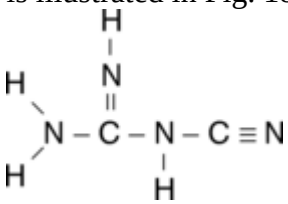

Fig. 18 Structure of dicyandiamide

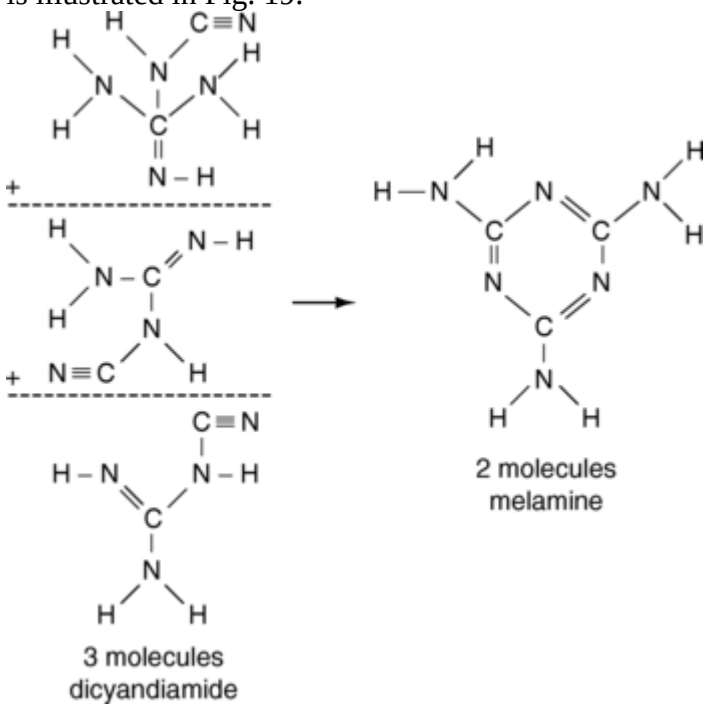
The mixed powders are applied to a preheated substrate by electrostatic spray. The object is coated until there is no further electrostatic attraction due to the buildup of coating thickness. The coated article then passes into an oven where it is heated to a temperature generally from 175 to 230 °C (350 to 450 °F), melting the coating and allowing the cross-linking reaction to occur between the epoxy and the dicyandiamide curing agent.

Powder coatings are increasing in use, because they are 100% solids, no VOC materials. The coating cures to a tough, abrasion-resistant, thick film. Powder coatings are used extensively on below-grade pipelines due to their chemical resistance, thick film, and tough, durable nature. They are said to have sufficient water permeation to enable cathodic protection and to prevent cathodic shielding in areas where the coating may disbond.

Powder coatings are being widely used on many consumer products, such as outdoor furniture, automotive parts, and undercarriage components. Properly cured powder coatings have excellent adhesion, flexibility, and impact resistance and good resistance to chemicals and solvents.

Amino Resins. Melamine and urea-formaldehyde-cured epoxy resins are used as baking primers and finished coats and as curatives for epoxy coil coatings. Urea formaldehyde systems are used for finishes that require faster cure at a lower cost than is possible with the melamines. Melamine curing agents are used in baking finishes where color is more critical and where good gloss is required. Melamine epoxies are used as coatings for the interior and exterior of food and beverage containers, because they do not affect the taste of the food stored within the metal beverage container. Beer and soft drink cans are often coated with melamine epoxy resins. Melamine resins are formed by reacting three molecules of dicyandiamide. The chemistry of these resins is illustrated in Fig. 19.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 19 Melamine, formed by the reaction of three molecules of dicyandiamide to form two molecules of melamine

Coal tar epoxies are a combination of a coal tar blended with an epoxy resin packaged in one container. The curing agent is an amine, amine adduct, or polyamide, as described previously, packaged in a separate container. The cross-linking reaction is the same as that described previously. The coal tar acts as a filler within the cross-linked epoxy matrix, and the resulting film has the good toughness, adhesion, ultraviolet resistance and thermal stability of the epoxies, combined with the extremely high moisture resistance afforded by coal tar. As might be expected, the amine-cured coal tar epoxies generally have greater chemical and moisture resistance but are more brittle and harder to apply and topcoat than the amine adduct- and polyamide-cured coat tar epoxies. On the other hand, the polyamide coal tar epoxies are more flexible, easier to topcoat, and more tolerant of application variables.

Epoxy-Phenolic Coatings. Phenolic cross- linked epoxy coatings are extremely resistant to acids, alkalies, and solvents, and they are widely used as linings for tank cars, drums, cans, process tanks, and equipment. High-molecular- weight epoxies with a high proportion of hydroxyl functional groups available for reaction are used. During manufacture, the epoxy is packaged with a phenolic resin (commonly a phenolformaldehyde resin), pigment, and an acid catalyst. After mixing, the coating is applied by spraying and then baked at temperatures from 150 to 205 °C (300 to 400 °F) in order for cross linking to occur. Multiple-coat systems require brief intermediate baking between coats; longer baking times are commonly used after application of the final coat.

Systems with ambient-temperature cure are now also available. With a lesser amount of phenolic modification to the epoxy resin, air drying of the coating without baking can be done. Such coatings have excellent moisture and chemical resistances. Care must be taken to ensure that the coating is not too thick, thus entrapping solvents, and that curing temperatures are satisfactory, generally at least 24 °C (75 °F). Baking of these air-dry coatings will enhance performance, particularly in immersion service.

The resulting coatings have the excellent acid and solvent resistance associated with the phenolics as well as the flexibility, adhesion, and toughness of epoxies. Epoxy phenolics have the good alkali resistance of the epoxy constituent, but straight phenolic linings have very poor alkali resistance.

The cross linking that occurs is between the hydroxyl groups along the epoxy chain and the methylol groups present in the phenolic resin. A possible secondary reaction is the reaction between the terminal epoxide groups of the epoxy resin and the hydroxyl groups of the phenolic resin.

Phenolic Linings

Phenolic resins are formed by the reaction of phenol with formaldehyde to form phenolformaldehyde. The methylol group can react on the two ortho positions and the paraposition on the benzene ring to form phenolformaldehydes with functionalities (possible reaction sites) up to 3. On heating, a condensation reaction occurs between methylol groups on adjacent molecules that cross link the film and liberate water. The reaction of phenol and formaldehyde to form a cross-linked film is shown in Fig. 20.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

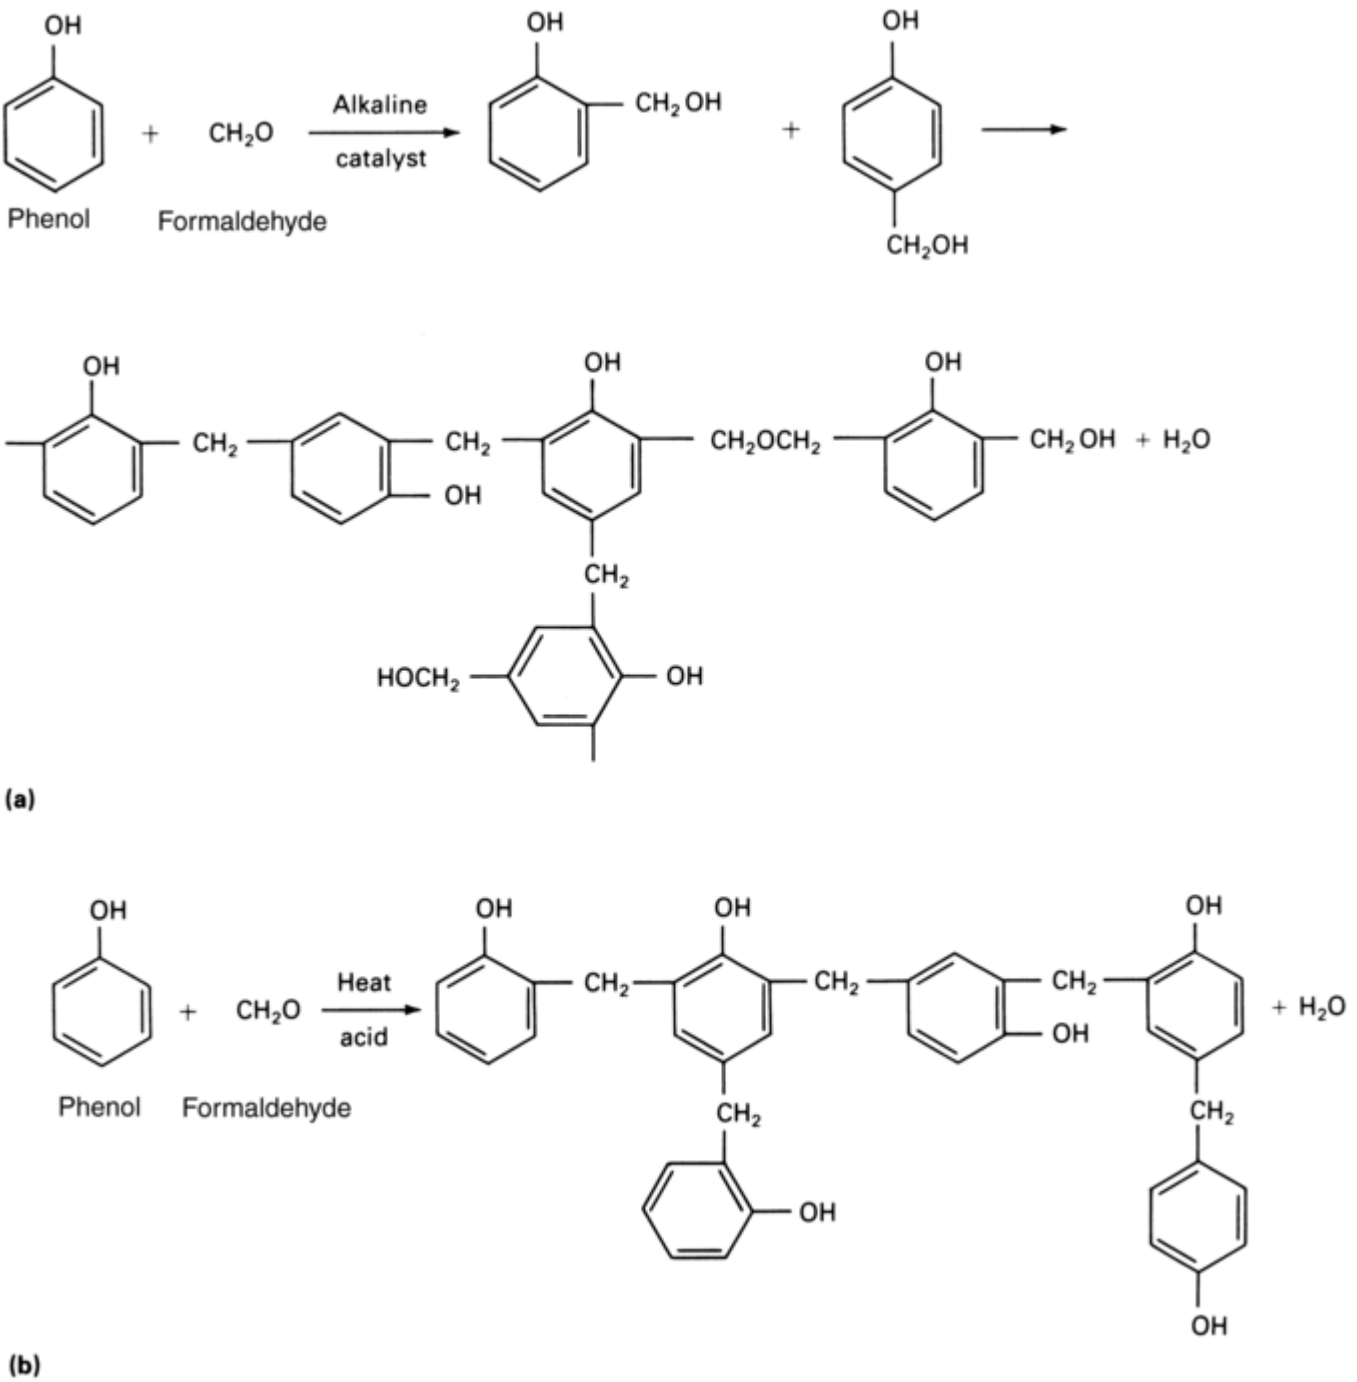


Fig. 20 Reaction of phenol and formaldehyde to form a phenolic resin. (a) Reaction using an alkaline catalyst. (b) Reaction using an acid catalyst. Source: Ref 3

The phenolformaldehyde resins are usually dissolved in alcohol and applied by spray, dip, or roller. The fact that water is liberated during the cross-linking reaction is important. The coatings must be applied in multiple-coat systems; each coat is approximately 0.025 mm (1 mil) thick and must be baked for a few minutes at 120 to 205 °C (250 to 400 °F) between coats. This partially cross-links the coating, but more importantly, it volatilizes the water formed during the cross-linking reaction. Subsequent coats are applied and baked until, after the final application, a postbake at higher temperatures and longer durations is performed. It is easy to determine when the coating has been baked sufficiently to ensure proper curing and cross linking. The phenolic resin darkens on heat exposure, and a thoroughly cured coating is a relatively uniform, light chocolate-brown color.

Because they are odorless, tasteless, and nontoxic after full curing, phenolics are often applied as linings for vessels and tanks used for the processing and storage of such food products as beer, wine, and sugar syrups. They also have excellent resistance to boiling water and hot aqueous solutions of mild acids. Thus, they often find application as linings for steel exposed to high- temperature freshwater and saltwater as well as mild acids.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

A major weakness, however, is the lack of alkali resistance. Unless phenolic coatings are modified with epoxies, they should not be used for alkaline service.

Urethane Coatings

Urethane coatings have chemical- and moisture-resistant properties similar to those of the epoxies, but they can also be formulated in a variety of light-stable colors that maintain their gloss and “wet look” on prolonged exposure. The chemistry involved in urethane coating curing is not unduly complex and typically consists essentially of the reaction of an isocyanate-containing (-N═C═O) material with a polyhydroxylated (-OH-containing) coreactant (Fig. 21). Cross linking occurs because of the high reactivity and affinity of the isocyanate group for the active hydrogen of the polyol hydroxyl or any active hydrogen atom attached to a nitrogen or oxygen atom. The rate of this cross-linking reaction depends on a number of factors, such as the type and configuration of both the isocyanate and polyol materials and the temperature. However, the reaction is such that with most formulations, cross linking can occur at temperatures of -18 °C (0 °F) or less.

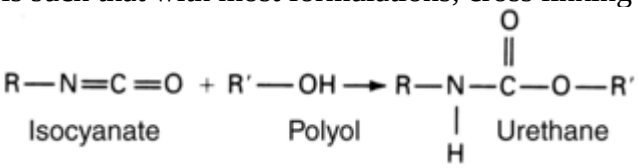

Fig. 21 Reaction of an isocyanate and a polyol to form a urethane. R and R′ are different aromatic or aliphatic groups. Source: Ref 4

A number of different types of isocyanate materials are used in urethane coatings. The molecular weight and structure as well as isocyanate functionality (the number of isocyanate groups available for reaction) can affect the final properties of the coating. Similarly, different polyol structures, such as acrylics, epoxies, polyesters, polyethers, and vinyls, when reacted with a given isocyanate to form a cross-linked coating, result in variations of physical and chemical properties. Described subsequently are some of the general properties of the isocyanate and polyol constituents that are coreacted to form urethane coatings.

The isocyanates are commonly categorized as either aromatic (containing the benzene ring) or aliphatic (straight-chain or cyclical) hydrocarbons. The first isocyanate used in urethane coatings was an aromatic isocyanate, toluene diisocyanate (TDI) (Fig. 22). When reacted, TDI resulted in a suitable chemical-resistant urethane coating, but it was generally undesirable because of its low viscosity and toxic, irritating vapors. To form a safer, more suitable coreactant, TDI was further reacted to provide a higher-molecular-weight polyisocyanate that contained less than 1% of the original TDI monomer (Fig. 23).

These higher-molecular-weight aromatic isocyanates, when reacted with a polyol (usually a polyester, polyether, or epoxy), formed useful chemical-resistant coatings that could be cured at low temperatures. However, the urethanes so formed tend to chalk, yellow, and darken somewhat on exposure to sunlight.

In the early 1970s, aliphatic isocyanates were commercially developed. Although they were considerably more expensive than the aromatic isocyanates, they allowed the formulation of nonyellowing, light-stable, high-gloss finish coats. The appearance of urethane coatings formulated with aliphatic isocyanates is unmatched by the epoxies, acrylics, or any other coating material available in the industrial marketplace. In spite of the high cost of the aliphatic polyurethanes, the coatings were increasingly specified in high-visibility applications, such as city water tanks, railroad tank and hopper car exteriors, and other areas where visibility or aesthetic appeal were valued.

An important aliphatic isocyanate is hexamethylene diisocyanate (HDI) (Fig. 24). In its monomeric form, HDI is an irritant. Similar to TDI, however, HDI can be reacted (commonly with water) to form a larger molecule.

Fig. 24 Molecular structure of hexamethylene diisocyanate, an aliphatic isocyanate used in urethane coatings. Source: Ref 5

Various combinations of aromatic and aliphatic isocyanates can be produced, including specialty isocyanates, to make high-solids or solvent-free coatings, elastomeric coatings, or coatings designed for baking or curing at elevated temperatures. Specialty isocyanates can be either aromatic or aliphatic; if aromatic, they discolor. Both

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

straight-chain and cyclical aliphatic isocyanates, although nonyellowing, are much slower to react and cross link than aromatic isocyanates.

Polyols. As stated previously, polyols coreact with isocyanates in order to form the polyurethane film. Accordingly, the polyol is packaged separately from the isocyanate, and the polyol package always contains the pigment, most of the solvent, and any additives used for flow, thixotropy, antisetting properties, and so on. The major properties of the cross-linked urethane film, such as chemical resistance, toughness, lightfastness, and flexibility, derive principally from the polyol constituent. Long, repeating carbon- to-carbon backbone chains with little branching (for example, vinyl) result in tough, flexible resins. Aromatic groups add rigidity to the chain, as does cross linking. The presence of numerous ester, ether, and urethane groups reduces chemical and moisture resistance.

For corrosion-protective coatings, the polyol coreactant is usually one of the following: acrylic, polyester, polyether, epoxy, vinyl, or alkyd. Asphalts and coal tars can be added with any of the polyols. Because they are essentially nonreactive, however, it is felt the bitumen acts predominantly as a filler in the urethane matrix, providing the cured coating with the attendant properties of good chemical resistance, high moisture resistance, and high film build at a relatively low cost.

Acrylic urethanes are perhaps the most widely used urethanes for corrosion protection in atmospheric service. These coatings, when properly formulated, have excellent weatherability, gloss, and color retention and have good chemical and moisture resistance. They can be readily tinted and pigmented to provide a variety of deep and pastel colors at a lower cost per gallon than the next most popular class, the polyester urethanes.

As with conventional acrylic coatings, the acrylate polymer family is softer and more flexible than the corresponding methacrylates, although an increase in the molecular weight of the monomers, such as methyl acrylate to butyl acrylate, leads to softer, more flexible polymers for both families. Acrylate and methacrylate blends are also used as reactive polyols.

Acrylic urethanes are not used for immersion service, and, for the most part, they do not have the chemical resistance of the polyester urethanes. However, they do have excellent weathering properties when an aliphatic isocyanate is used.

Polyesters result from the condensation reaction of a dibasic acid and a polyhydric alcohol. To form a hydroxylated polyester, an excess of the hydroxyl functionality from the alcohol is allowed over that of the acid. The result is a polyester molecule with a midchain and end-chain hydroxyl functionality.

Because of their high isocyanate demand when coreacted, polyesters result in relatively hard chemical-resistant polymer films. Impact resistance is not as great as with the acrylic urethanes, but, as a rule, chemical and moisture resistance are better. However, because ester linkages occur in the molecular backbone, alkaline attack and water sensitivity may occur at locations where the ester group is exposed, that is, at areas of low cross-link density or where less branching of adjacent molecules occurs. Accordingly, polyester urethanes, similar to acrylic urethanes, are not normally used for immersion service.

Polyethers are often the polyol of choice for use as elastomeric coatings, coal tar urethanes, and other urethane coatings that are sheltered or protected from light. The polyether prepolymer is considerably less expensive than acrylic or polyester polyols; polyethers, however, are sensitive to ultraviolet-induced oxidative degradation. Furthermore, the ether linkages (-C-O-C-) are water sensitive, and in polyethers, they are repeated throughout the polymer chain without separation by long water-insensitive hydrocarbon chains or aromatic groups that can minimize water sensitivity.

Epoxies. The reaction of an epoxy with an isocyanate would seem to be a natural one, because of the midchain hydroxyl functionality of the epoxy molecule. However, there are very few epoxy urethanes on the market, and those being promoted are used predominantly as primers or intermediate coats. This is due to:

- The tendency of the epoxy and the epoxy urethane to chalk
- The lower moisture resistance resulting from the urethane link, which gives a less chemical- and moisture-resistant polymer than a straight epoxy coating
- The greater expense of a urethane epoxy compared to a conventional amine or polyamide cross-linked epoxy

As a result, most epoxy urethanes are formulated with the less expensive aromatic isocyanate and are promoted primarily as low-temperature curing epoxies or fast-curing, chemically resistant urethanes for interior use.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Vinyl urethanes use a long-chain, linear, hydroxyl-bearing PVC/PVA resin reacted with a polyfunctional isocyanate prepolymer. Urethane coatings using vinyl polyols combine the abrasion resistance of the urethane with the toughness, flexibility, and chemical resistance of the vinyl. Such urethane coatings are promoted for use where flexibility and abrasion resistance are important; vinyl urethane coatings, however, are subject to some chalking or fading on exterior exposure and do not have the color, gloss, weatherability, or solvent resistance of the acrylics and polyesters. Because the vinyl is thermoplastic and is attacked and softened by solvents, recoatability after extended times is not a problem and is a major advantage of vinyl urethane systems.

Alkyds are commonly reacted with isocyanates to form a so-called uralkyd or urethane oil coating. The isocyanate reaction decreases the drying time of the coating and provides enhanced resistance to chemicals, moisture, weathering, and abrasion. Uralkyd (urethane oil) coatings harden by autooxidation of their unsaturated oleoresinous sidechains. The result is an upgraded coating system with enhanced performance over the nonurethane system. Because of the isocyanate reaction, however, the cost of such a system is somewhat higher than those systems that are not urethane modified. A uralkyd is prepared by replacing some of the dibasic acid with an isocyanate to form a urethane cross-linked polymer. The resulting urethane alkyd resin still has the oleoresineous sidechains, and although it is cross linked and upgraded by the isocyanate, it is still sensitive to water and chemicals through the ester and urethane links.

Moisture-Cured Urethanes. Isocyanates can also react with the hydroxyl group in water to form a class of coatings known as moisture- cured urethanes. Single-package moisture-cured urethanes use an isocyanate prepolymer that, when applied, reacts with the humidity in the air to form a hard, tough, resinous film. Because of their rapid rate of reaction, aromatic isocyanates are used almost exclusively in moisture- cured urethanes. The pigments must be essentially nonreactive with the isocyanate; although it is possible to use a number of pigments, aluminum leaf is most common. The reaction of a single-package urethane with moisture is illustrated in Fig. 25. It should be noted that the isocyanate-water reaction produces gaseous carbon dioxide. In fact, some carbon dioxide is evolved in the curing of all urethane coatings, because moisture (humidity) is present in the atmosphere during curing.

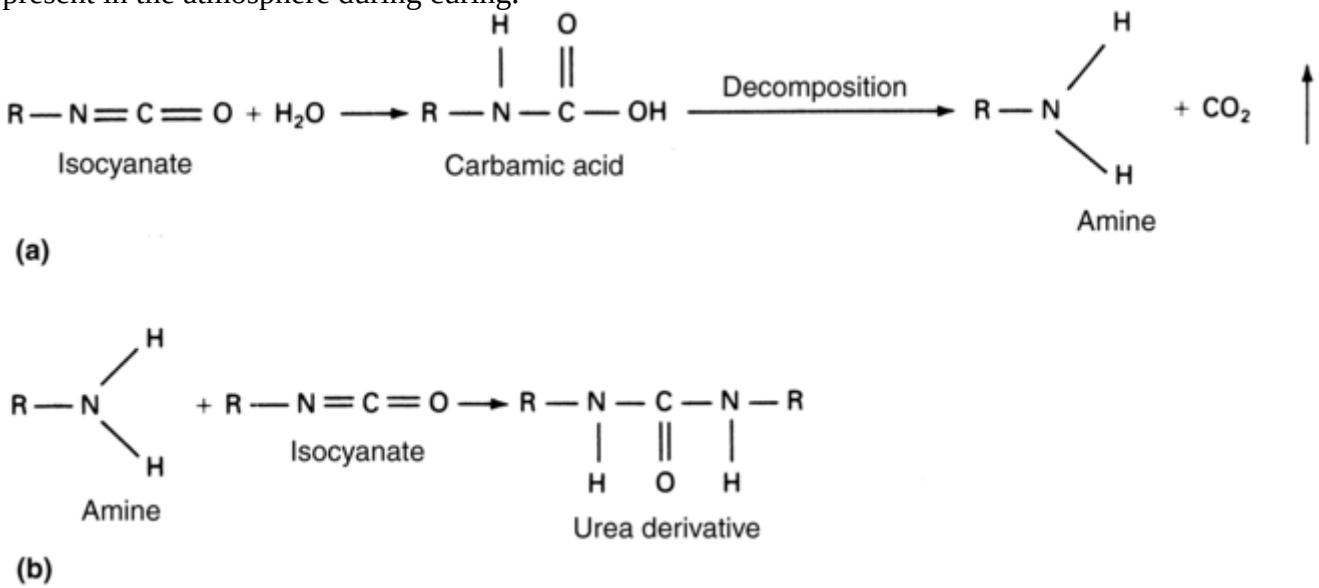

Fig. 25 Curing reaction of a single-package moisture-cured urethane. (a) The isocyanate reacts with water to form unstable carbamic acid, which decomposes into an amine plus carbon dioxide gas. (b) The amine then reacts with isocyanate to form a urea derivative. R indicates an aromatic or aliphatic group. Source: Ref 5

In areas where the relative humidity is expected to be low or where assurance of a more complete cure is necessary, a small amount of a tertiary amine catalyst, such as dimethyl-ethanolamine, can be added. This catalyst is packaged separately from the isocyanate and added just before use. Although it comes as a two-package system, this type of catalyzed urethane can be considered to be an extension of a single- package moisture-cured urethane.

Polyurea Coatings

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Until recently, many coating manufacturers did not differentiate between isocyanate reactions with polyester/polyether hydroxyl functionality resins and resins based on the reaction of an isocyanate with a polyether amine. In both cases, the resultant resin was generically called a polyurethane. However, only the resin resulting from the isocyanate reaction with a hydroxylated polyester or polyether (or, for that matter, a hydroxylated acrylic or epoxy) actually contains the urethane linkage as a constituent within the resin. In the urethane reaction, cross linking occurs as the isocyanate group reacts with the hydroxyl to form a urethane linkage (Fig. 26a). Only those resins are true polyurethanes and, as such, are discussed in the section “Urethane Coatings.”

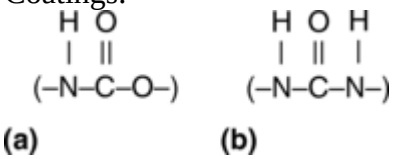

Fig. 26 Difference between polyurethane and polyurea resins. (a) Urethane link in polyurethane. (b) Substituted urea link in polyurea

The isocyanate reaction with a polyether amine or an amine-terminated polyol results in a substituted urea linkage (Fig. 26b), and these resins, often formulated into extremely fast-curing, thick elastomeric coatings, have earned a distinct generic category: polyurea coatings. The resin chemistry of a typical polyurea resin is illustrated in Fig. 25.

An advantage of the polyurea coating is that the reaction between component A (polyisocyanate) and component B (polyamine) is so fast, generally within 5 to 15 s for complete cure, that the coating system does not react with moisture or humidity, nor does it produce carbon dioxide bubbles, as does the polyurethane.

Because of the fast-reacting nature of the polyurea chemistries, specialized application equipment is necessary. Recent advances in plural-component spray equipment has enabled formulators to develop 100% solids polyurea coatings with good chemical and weathering resistance and good compatibility with steel, concrete, and other substrates.

Aliphatic polyurea coatings based on polyaspartic esters have been developed using proprietary chemistry (Ref 5). The principal purpose of this work was to slow the reaction and extend the pot life, such that long whip hoses and conventional spray guns may be used. It is believed that steric hinderance around the isocyanate group is responsible for the slower reaction time and increased pot life. The more complex and bulkier the aspartic ester, the slower the reaction and gel time. The properties of these polyureas include, besides a pot life up to 1 h, a fast gel time, extensibility, elongation, and flexibility approaching the fast-cure ureas. Spray- and squeegee-applied floor coatings have been formulated using aspartic esters to produce a smooth, high-gloss, clear, light-stable finish. Polyaspartic ester products are illustrated in Fig. 27.

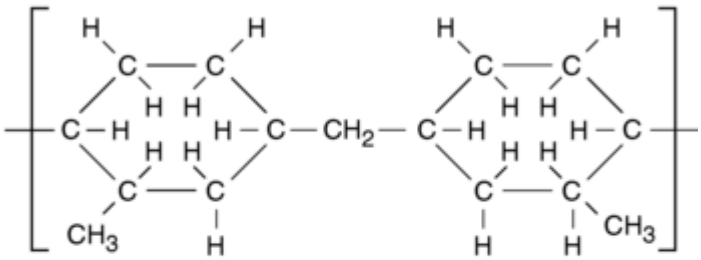
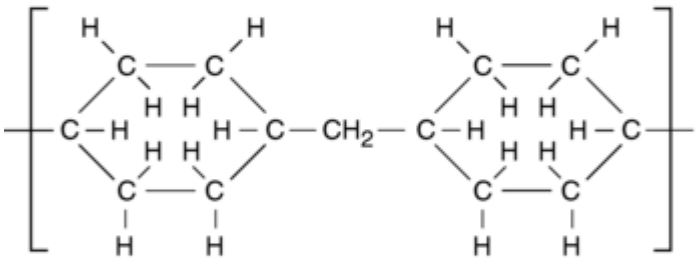
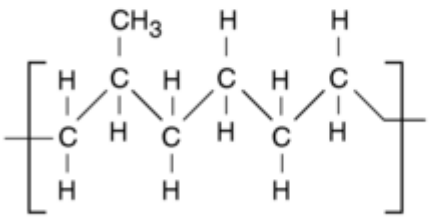
X is one of the following:



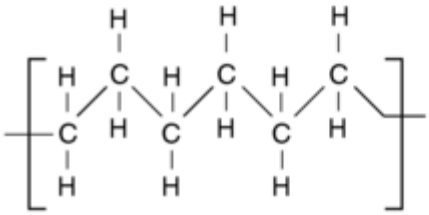
(a)



(b)



(c)



(d)

Fig. 27 Structure of aliphatic polyurea coatings. X is one of the polyaspartic esters shown as (a), (b), (c), and (d). The speed of reaction and therefore the pot life and cure time increase from (a) (the slowest) to (d) (the fastest). (d) is the most flexible and has the greatest elongation.

In general, polyurea and polyurethane systems have similar properties. Both have high tensile strength, flexibility, impact resistance, abrasion resistance, and can be formulated into a wide variety of coatings with variable property ranges. However, polyureas compared to polyurethanes have certain advantages and disadvantages. Polyureas can be applied to a lower temperature (-7 °C, or 20 °F) than an equivalently formulated polyurethane. Polyureas have higher heat resistance than comparably formulated polyurethanes.
Conversely, however, polyurethanes have two to three times better abrasion resistance than polyurea systems, and they can be formulated to a smooth, glossy appearance. Because of its fast reactions, the polyurea does not

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

have time to flow, level, and smooth, and accordingly, polyureas generally have an “orange peel” surface texture.

However, because of their better oil and solvent resistance and lower cost than most polyurethane systems, the use of thick, elastomeric polyurea coatings over concrete in secondary containment for hydrocarbon and fuel oil storage tanks has developed into a major market.

While both polyureas and polyurethanes can be formulated in systems based on aliphatic isocyanate prepolymers that have good weatherability and color retention, most polyurea systems in the market are derived from an aromatic isocyanate. Accordingly, these systems yellow, darken, and chalk more than polyurethanes. The polyether amine and other amine reactants in a typical polyurea formulation also tend to yellow and darken as a result of these amino chromophores.

Zinc-Rich Coatings

Kenneth B. Tator, KTA-Tator, Inc.

Introduction

ZINC-RICH COATINGS combine advantages of hot dip galvanizing protection systems with application methods of paint systems. Cured inorganic zinc-silicate films can be thought of as a cross between hot dip galvanizing and fused ceramic (Ref 1). Zinc-rich coatings are available with organic and inorganic binders, and both formulations are discussed in this article. These coatings, used as primers, combined with organic topcoats provide superior paint systems for severe chemical-industrial environments.

Zinc-Rich Coatings

Kenneth B. Tator, KTA-Tator, Inc.

Characteristics of Zinc-Rich Coatings

The dry film of zinc-rich coatings is typically approximately 90% Zn by weight. Zinc-rich coatings, often called zinc-rich primers, are a unique class of cross-linked coatings that provide galvanic protection to a ferrous substrate. As the name implies, the binder is highly loaded with a metallic zinc-dust pigment. After the coating is applied to a thoroughly cleaned substrate, the binder holds the metallic zinc particles in contact with the steel and with each other. Thus, metal-to-metal contact of two dissimilar metals is made, resulting in a galvanic cell. In this couple, zinc becomes the anode and sacrifices itself to protect the underlying cathodic steel. The articles “Continuous Hot Dip Coatings” and “Batch Process Hot Dip Galvanizing” in this Volume contain more information on corrosion of galvanized steels.

The major advantage of corrosion protection using zinc-rich coatings is that pitting corrosion and subfilm corrosion are eliminated, even at voids, pinholes, scratches, and abrasions in the coating system. This cannot be said of any other type of protective coating, and it is this protective capability that makes zinc-rich coatings unique and widely used.

This advantage, however, comes with certain disadvantages. The underlying steel substrate must be cleaned of all rust, old paint, and other contaminants that may interfere with metal-to- metal contact. Thus, the degree of surface preparation must be quite thorough; blast cleaning should produce a commercial blast cleaning minimum and, for immersion service, a white or near-white surface. SSPC: The Society for Protective Coatings (SSPC), NACE International, and other organizations issue standards for the surface preparation of metals for organic coatings; these are discussed in more detail in the sections “Surface Preparation” and “Coating

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Application” in the article “Paint Systems” in this Volume. When power tool cleaning, cleaning to bright metal is necessary. Zinc-rich coatings can be applied to pickled steel, although, again, the surface must be perfectly clean.

Because of the high reactivity of the zinc-dust pigment, zinc-rich coatings are not suitable in condensing or hydrolyzing environments outside the pH range of approximately 5 to 10. Acids and alkalies attack the zinc-dust pigment; even if topcoats are used, chemicals may penetrate through pinholes, scratches, voids, or discontinuities within the topcoat and cause aggressive attack of the zinc-rich primer.

In addition, because of the high zinc loading, the zinc-dust pigment should be suspended in the spray pot during spray application. Thus, the use of an agitator or stirrer in the spray pot is mandatory. Similarly, the weight of the paint, as a result of its high pigment loading (often 2.2 to 3 kg/L, or 18 to 25 lb/gal), prohibits long hose lengths from the spray pot to the spray gun in order to minimize settling in the lines. If the spray gun is elevated too high above the spray pot, air pressure to the spray pot may not be sufficient to push the heavy zinc-rich coating material through the spray line to the gun.

When spraying on warm days, care must be taken that the primer does not begin to set up in the spray lines. This is a particular problem with most inorganic zincs, especially if a spray application is interrupted for more than just a few minutes without first draining paint from the fluid hose. With no movement in a relatively warm paint hose, plugs of paint may begin drying and hardening such that when spraying operations begin, the paint does not readily move through the fluid line to the gun. Blockages occur, the gun works only intermittently, and, in the worst cases, hardening of the paint may occur to such an extent that the entire line must be discarded.

This rapid-drying characteristic, which is particularly evident with the inorganic zincs, may also result in a greater amount of dry spray than usually occurs with conventional non-zinc-rich coatings. Thus, particular care should be taken during application to ensure that the zinc-rich primer is deposited in a smooth, wet application.

Because of high zinc loading over the pigment volume concentration of the binder, the zinc-rich coatings are more porous than any other generic type of paint. Because of this porosity, they are harder to topcoat. Topcoats applied over both organic and inorganic zinc-rich primers often have voids or bubbles in their cross-sectional thickness and bubbles or pinholes extending down through their surface to the underlying zinc-rich coating. This is because of entrapped air, solvents, and moisture within the zinc-rich primer before or during topcoating. The entrapped liquids or gases must pass through the topcoat in order to escape into the atmosphere. As the topcoat dries, escaping gases are held as bubbles or blisters, or the path of such an escaping gas hardens into a pinhole.

Insufficient curing of the zinc-rich binder before application of the topcoat can sometimes lead to poor adhesion or cohesion within the zinc and can ultimately lead to peeling or disbonding of the topcoat. However, despite these disadvantages, the advantage that accrues by the elimination of subfilm and pitting corrosion makes zinc-rich coatings, either topcoated or untopcoated, one of the most widely used corrosion prevention coatings for painting steel in industrial, marine, and other severe service environments.

Zinc-rich coatings used as primers with topcoats or as complete one-coat systems are widely used for the corrosion protection of steel substrates. Organic zinc-rich systems are used in the automotive industry to protect car body rocker panels, wheel wells, and other corrosion-prone interior steel parts. Inorganic zinc-rich coatings are also used extensively in the marine industry for the protection of exterior hulls, cargo and ballast tanks, offshore platforms, and other areas of high marine corrosion. Inorganic zinc-rich coatings are used in these same environments and in applications requiring high abrasion and high heat resistance to 370 °C (700 °F) when untopcoated. Both organic and inorganic zinc-rich coatings are extensively used for steel protection on bridges and highway structures, chemical and petrochemical plants, sewage and water treatment, and any area where freshwater or saltwater corrosion, mild fumes, and high humidity and resultant corrosion is a problem.

Zinc-rich coatings can be subcategorized according to the type of binder material used. Zinc- rich coatings with organic binders are similar in many ways to the coating systems previously discussed, except that sufficient zinc-dust pigment is added to provide galvanic protection. The inorganic zinc-rich coatings, on the other hand, use an entirely different binder chemistry and are therefore quite unlike the organic zinc- rich coatings. As a general rule, organic zinc-rich coatings are more widely used in Europe and Asia than inorganic zinc-rich coatings; in the United States and Canada, the inorganic zinc- rich coatings are more widely used.

Zinc-Rich Coatings with Organic Binders

Organic zinc-rich coatings are most commonly formulated from epoxy polyamide and polyurethane binders. Alkyds have been used for some air-dry formulations, but they are most commonly used with baking formulations, notably in the automotive industry. Vinyl and chlorinated rubber binders are not volatile-organic-compound compliant and are not currently in use.

To manufacture a successful organic zinc-rich coating, one does not simply substitute the zinc- dust pigment for the normal inhibitive and filler pigments commonly used. Instead, skillful formulation is required to achieve galvanic protective capability while also maintaining suitable storage, application, and physical properties of the applied film. When such formulation is achieved, the result is a protective coating having the physical attributes determined by the organic binder, along with the galvanic capability and chemical susceptibilities inherent in the use of the zinc-dust pigment. However, the untopcoated zinc-dust pigment is attacked by acids and alkalies, and even though the binder is resistant to such chemicals, organic zinc-rich primers should not be used in aggressive chemical environments.

The drying, hardening, and ultimate curing of the organic zinc-rich coating is determined by the type of binder used. The hardening and curing mechanisms of the various binders have been described previously and are the same for zinc- rich coatings. Organic zinc-rich primers are more tolerant of deficient surface preparation, because they wet more readily and seal poorly prepared surfaces where residues of rust or old paint may remain. Similarly, topcoating with the same generic type of topcoat (for example, an epoxy zinc-rich coating topcoated with an epoxy topcoat) is more readily accomplished, because organic zinc-rich coatings of all types generally have a less porous surface and are more similar to conventional organic coatings than the inorganic zinc-rich coatings.

Zinc-Rich Coatings with Inorganic Binders

The SSPC has categorized inorganic zinc-rich coatings as being of three major groups:

- Postcured water-based alkali metal silicates
- Self-cured water-based alkali metal silicates
- Self-cured solvent-based alkyl silicates

Although the binder, in all cases, is an inorganic silicate (sometimes called waterglass, it is essentially the same material as glass or sand), the curing of the binder is different in all three cases.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Postcured water-based inorganic silicates come as three-package systems; the zinc dust, silicate binder, and curing solution are packaged separately. If elevated baking temperatures can be achieved, the curing solution may not be necessary.

The earliest postcured zinc-rich coatings were based on a sodium silicate vehicle, and the most popular commercial products available have essentially the same chemistry. There are other inorganic zinc-rich coatings based on lithium or potassium silicates that self-cure, but curing can be accelerated by the use of a curing solution, if desired. The following steps summarize the curing of postcured water-based inorganic zinc-rich coatings.

The first step is primarily a dehydration process in which the water, which is the basic solvent for the silicate, evaporates from the clean steel surface, leaving the zinc and the alkali silicate on the surface as a coating. At this point, when the coating is free of water, it is very hard and metallic. Scraping with a coin merely polishes the zinc in the coating.

Second, once the initial drying process has taken place, an acid phosphate curing solution is sprayed or brushed over the zinc-rich coating in order to wet out the surface thoroughly. The initial reaction is for the acid to gradually neutralize the sodium in the sodium silicate solution and to create a mildly acidic surface condition.

Third, during initial curing, the pigment constituents may react with the silica matrix. This, together with further neutralization of the silicate alkalinity, insolubilizes the film. The addition of the acidic curing solution on the surface of the zinc coating ionizes the zinc in the coating as well as the lead oxide pigment mixed with it. As this takes place, there is a rapid reaction between the active silicate groups and the lead and zinc, insolubilizing the silica matrix.

The acid phosphate also reacts with the zinc and lead to form very insoluble zinc and lead phosphates within the silicate matrix. At this point, the coating has become insoluble to water and resistant to exposure to weather.

Lastly, after initial curing, further hydrolysis and improvement of film properties continue over time. Following the application and reaction of the curing agent, the remaining soluble salts on the surface are removed with clean water or by weathering. The coating at this point is dense and relatively nonporous, insoluble in water, and resistant to marine and mild chemical atmospheres.

Postcured coatings are, in the author's opinion, the best performing of the inorganic zinc- rich materials. The reason for this is most likely the relatively complete, insolubilizing hard cure that is attained after application of the curing solution. By applying the curing solution and thoroughly curing the coating, the maximum protective properties of the coating are attained shortly after application. In contrast, self-cure coatings rely on ambient atmospheric conditions in order to cure completely. Research indicates that many self-cured coatings do not achieve their ultimate resistance and protective capability until long after their original application.

Self-Curing Water-Based Alkali Silicates. The most common of these silicate binders is based on potassium and lithium silicates or combinations of these. In addition, lithium hydroxide-colloidal silica and quaternary ammonium silicate binders are also included in this category.

The reaction chemistry of the water-based self-cure inorganic zinc-rich silicates is similar to that of the postcured sodium silicates, with the exception that the curing solution is not applied. The metal silicate vehicle, before field addition of the zinc-dust pigment, has a higher ratio of silica to metal oxides and a lower alkalinity than the postcured vehicles. Therefore, after water evaporation and insolubilization resulting from the silica reaction with the pigment, sufficient neutralization and cure are attained by further reaction with acid formed by the atmospheric hydrolysis of carbon dioxide (reaction of CO_2 and atmospheric moisture to form a weak carbonic acid).

Self-curing alkali silicate zinc-rich coatings become hard within minutes and are considered generally resistant to precipitation within 30 min after application. If a more rapid insolubilization or cure is desired, heat or an acidic curing solution can be applied. The reaction chemistry would then be essentially identical to that of the postcured sodium silicate matrix. When final curing is ultimately attained, most water-based zinc-rich coatings, whether post- or self-cured, experience a color change, often from a reddish gray or light gray to a darker bluish gray.

Self-Cured Solvent-Based Alkyl Silicates. The binders for this class of coatings are essentially modified alkyl silicates consisting of partially hydrolyzed members of the series methyl through hexyl or glycol ether silicates. Of these, the ethyl silicate type is most commonly used.

The reaction chemistry of ethyl silicates can be best demonstrated by the hydrolysis of tetraethyl orthosilicate in the presence of an acid or alkali catalyst. The reaction is carried to partial completion with a degree of hydrolysis ranging from 70 to 95%. The reaction is irreversible, because of the volatilization of the alcohol that

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

results from the ester exchange; however, should premature gelling of the silicate occur, alcohol may be added to redissolve the gel. During the condensation phase of the reaction, the partially polymerized silicate combines with atmospheric moisture to eliminate alcohol, which vaporizes.

After complete hydrolysis, the cross-linked network forms a matrix to hold the pigment particles. In addition, it is conceivable that the zinc and other metallic pigment additives (and perhaps the underlying ferrous surface) may react with the silicate in a manner similar to that described for postcured sodium silicate. The matrix formation of an ethyl silicate is illustrated in Fig. 1.

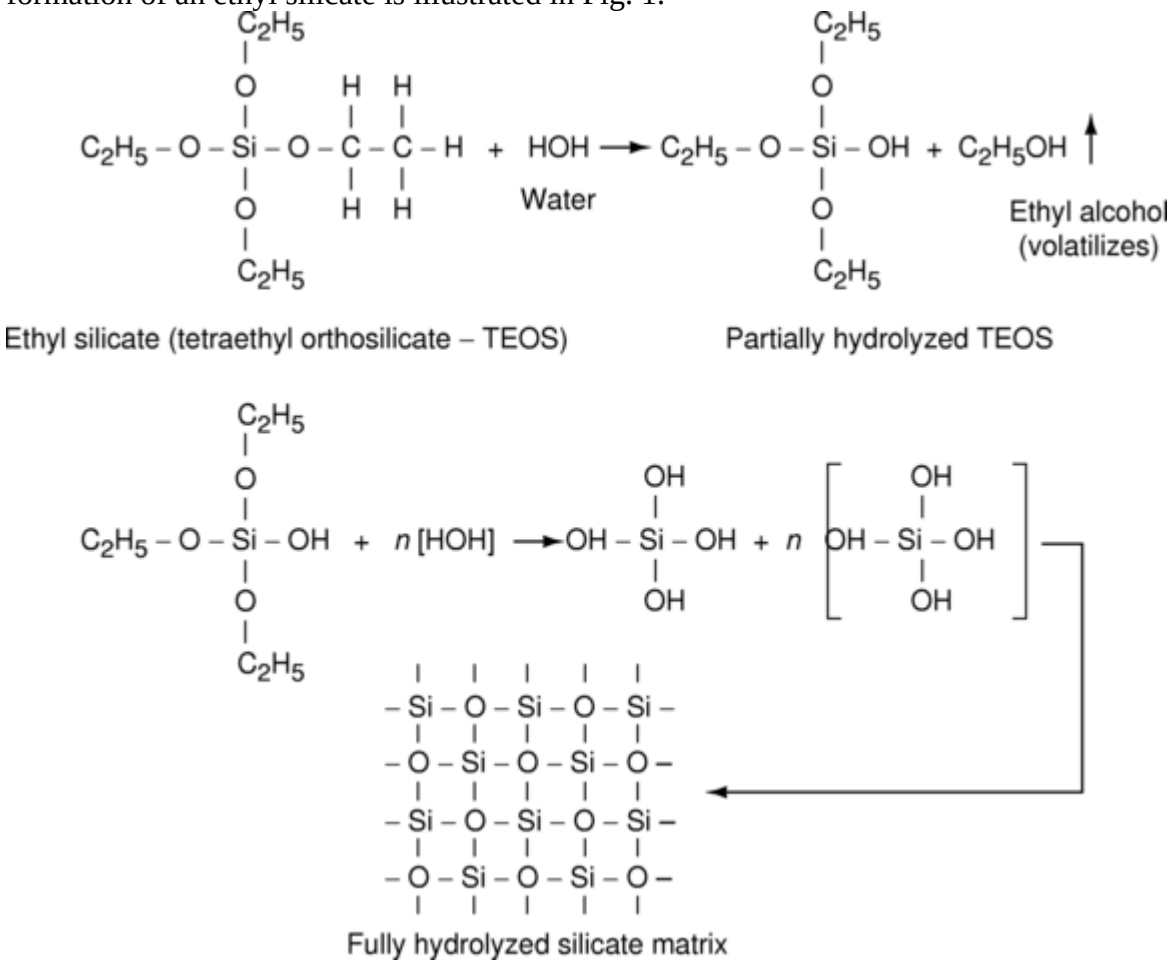

Fig. 1 Matrix formation of ethyl silicate. *n* represents the number of molecules.

Single-package inorganic zinc-rich primers based on the ethyl silicate chemistry described previously have been developed. Instead of packaging the zinc dust separately from the ethyl silicate binder, the coating manufacturer adds the zinc dust in the manufacturing plant, along with additives that keep the zinc dust in suspension. Careful quality control of raw materials, particularly zinc-dust pigment and additives, is exercised to ensure they are dry and moisture-free. Also, the ethyl silicate vehicle is somewhat less prehydrolyzed and is usually catalyzed with an acid catalyst such that on application and curing, the rate of reaction with moisture occurs at a faster rate than with two-package ethyl silicate zinc-rich primers. However, depending on temperature and (especially) atmospheric humidity, the full cure of a single pack inorganic zinc-rich primer may take significantly longer than that of two-pack silicates.

The properties of the single-package ethyl silicate zinc-rich primers are similar to those of the dual-package primers (where the zinc dust is packaged separately from the liquid silicate binder); but in general, single-package inorganic zinc-rich coatings do not cure as hard or as fast as dual-package products, and they do not provide quite as long a corrosion protection, although corrosion protection is still excellent. On the other hand, they are much easier to mix and apply, and these application advantages have resulted in their increased use.

Comparisons of Inorganic and Organic Zinc-Rich Coatings

In general, the inorganic zinc-rich coatings provide somewhat longer galvanic protection than the organics do, but they are less tolerant of deficient surface preparation, are somewhat harder to mix and apply, generally have a greater tendency toward mudcracking at excessive thickness, and are more difficult to topcoat. The organic zinc-rich coatings have limited temperature resistances that are determined by their organic binder. In contrast, inorganic zinc-rich coatings resist dry heat to over 370 °C (700 °F), and when topcoated with a silicone or ceramic coating, they can be used at temperatures of 650 °C (1200 °F) or higher. The abrasion and impact resistance of the inorganics are unsurpassed. The comparison of zinc-rich coatings with organic and inorganic binders is summarized in Table 1.

Table 1 Advantages and limitations of zinc-rich coatings

Resin type	Advantages	Limitations	Comments
Organic zinc-rich	Galvanic protection afforded by the zinc content, with chemical and moisture resistance similar to that of the organic binder. Should be topcoated in chemical environments with a pH outside the range 5–10. More tolerant of surface preparation and topcoating than inorganic zinc-rich coatings	Generally have lower service performance than inorganic zinc-rich coatings, but ease of application and surface preparation tolerance make them increasingly popular.	Widely used in Europe and the Far East, while inorganic zinc-rich coatings are most common in North America. Organic binder can be closely tailored to topcoats (for example, epoxy topcoats over epoxy-zinc-rich coatings) for a more compatible system. Organic zinc-rich coatings are often used to repair galvanized or inorganic zinc-rich coatings.
Inorganic zinc-rich	Provides excellent long-term protection against pitting in neutral and near-neutral atmospheric, and some immersion, services. Abrasion resistance is excellent, and dry heat resistance exceeds 370 °C (700 °F). Water-based inorganic silicates are available for confined spaces and compliance with regulations regarding volatile organic compounds.	Inorganic nature necessitates thorough blast-cleaning surface preparation and results in difficulty when topcoating with organic topcoats. Zinc dust is reactive outside the pH range of 5–10, and topcoating is necessary in chemical fume environments. Somewhat difficult to apply; may mudcrack at thicknesses in excess of 0.13 mm (5 mils)	Ethyl silicate zinc-rich coatings require atmospheric moisture to cure and are the most common type. Widely used as a primer on bridges, offshore structures, and steel in the building and chemical-processing industries. Used as a weldable preconstruction primer in the automotive and shipbuilding industries. Use eliminates pitting corrosion.

All water-based zinc-rich coatings, whether post- or self-cured, require somewhat greater surface cleanliness in order to achieve suitable adhesion and environmental protection. Water- based zinc-rich coatings have a greater tendency to mudcrack at excessive thicknesses than solvent-based inorganics do, and there is also an increased tendency to form zinc surface reaction products, particularly with sodium and lithium silicate vehicles. A major advantage of all water- based zinc-rich coatings is that they do not have a flash point and can be used in tanks, ship holds, and other confined or poorly ventilated areas without danger. However, such coatings do require

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

good ventilation or dehumidification to cure properly. Solvent-based inorganic zinc-rich coatings that are modified to have a tag open cup flash point higher than their normal 20 to 30 °C (70 to 90 °F) often form a softer, less resistant film.

Introduction

PAINT SYSTEMS and, more generally, coating systems encompass not only the materials as discussed in the previous articles but all the processes that impact the success of the corrosion protection scheme. This includes proper selection of materials or combinations of materials, use of the appropriate tools, the proper execution of surface preparation, coating applications, and inspection methods.

Coating System Selection

The selection of the proper corrosion-resistant coating system depends on a number of factors:

- *Environmental resistance:* The coating system should be resistant to the chemical, temperature, and moisture conditions expected to be encountered in service.
- *Appearance:* In high-visibility areas (for example, water tanks, railroad cars, and appliances), color, gloss, and a pleasing appearance may be very important.
- *Safety:* Toxic pigments and solvents may prohibit the use of some coatings; future removal and disposal problems should be considered. Coatings with volatile explosive solvents may be dangerous in enclosed, poorly ventilated spaces.
- *Surface preparation:* Surface preparation restrictions must be considered. For example, blast cleaning may be prohibited in some refineries or near electrical and hydraulic machinery.
- *Skill of the labor force:* Certain coating systems require more application expertise than others. Generally, inorganic zincs, vinyl esters, polyesters, vinyls, and chlorinated rubbers are less application tolerant than some of the other coating systems.
- *Substrate to be coated:* Coating systems for aluminum, lead, copper, concrete, masonry, and wood may differ from those for ferrous metals.
- *Available equipment:* The more resistant coating systems generally require spray application over a blast-cleaned surface. For some polyesters and vinyl esters, plural-component spray equipment may be required.
- *Design life:* If a structure is intended to have a long service life, the use of a more resistant coating system may be justified than if a shorter service life is intended.
- *Cost:* Generally speaking, the applied cost of a more resistant coating system is greater than the applied cost of a less resistant system.
- *Accessibility for future repair:* If future repair will be difficult or expensive, perhaps a longer-lasting coating system should be specified.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- *Consequences of coating failure:* If a coating failure will be disastrous, such as in tanks holding highly corrosive materials or in nuclear power plants where peeling or disbonding coating may clog sumps and screens, a more resistant coating system should be selected.
