Each of these factors, to varying degrees, directly influences the choice of the coating system selected to protect a metal in a given environment. Once the choice is made, it is usually necessary to prepare appropriate specifications detailing the surfaces to be painted and the surfaces to be protected from paint. In addition, the surface preparation and coating application details should be delineated. At a minimum, the thickness of each coat and the total coating thickness should be specified, and the surface profile of a blast-cleaned surface, the interval between coats, and other factors (such as testing for holidays and pinholes and for adhesion) should also be specified. Although the preparation of a proper specification is beyond the scope of this article, a good specification is not only an important contractual document but is also the means of conveying the owner's (or specifier's) intentions and instructions regarding the painting to be accomplished. Thus, the potential importance of a good specification cannot be overestimated.

Surface Preparation

The selection of the coating material to be used to protect a given metal from an environment usually determines the surface preparation that is required. For example, zinc-rich coatings almost always require blast cleaning, while many alkyd and oil-based coating systems can be applied over rust, mill scale, or a poorly cleaned surface.

Surface Preparation Process Steps

Surface preparation consists of: (1) removal of visible contaminants, (2) removal of invisible contaminants, and (3) roughening the surface.

Removal of Visible Contaminants. Cleanliness is essential in the preparation of a surface that will receive protective coatings. Most, but not all, coating systems require some degree of surface preparation. Generally, higher-performance coating systems require a higher degree of cleanliness. Paint applied over rust, dirt, or oil bonds poorly (or not at all) to the substrate, and early paint failure usually results. A clean surface is free of such contaminants as rust, flash rust, dirt and dust, salts, oil and grease, old paint, and mill scale.

NACE International and the former Steel Structures Painting Council (SSPC) have jointly issued a series of surface preparation standards that are used widely throughout North America. The SSPC is now known as SSPC: The Society for Protective Coatings.

Similar standards issued by the International Organization for Standardization (ISO) are widely used in Europe and Asia. These ISO surface preparation standards consist of photographs of four starting grades of steel that are wire brush cleaned or blast cleaned to various degrees of cleanliness (Ref 1, 2, 3). Table 1 presents an abstract of the SSPC/NACE International standards.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Table 1 Uses and applicable standards for various surface preparation techniques

Technique	Applicable standards	Uses
Solvent cleaning	SSPC-SP1	Used to remove oil, grease, dirt, soil, drawing compounds, and various other contaminants. Does not remove rust or mill scale. No visual standards are available.
Hand tool cleaning	SSPC-SP2	Used to remove loose rust, mill scale, and any other loose contaminants. Standard does not require the removal of intact rust or mill scale. Visual standards: SSPC-VIS 3—BSt3, CSt3, and DSt3[(a)]
Power tool cleaning	SSPC-SP3	Same as hand tool cleaning. Visual standards: SSPC-VIS 3—BSt3, CSt3, and DSt3[(b)]
White-metal blast cleaning	SSPC-SP5; NACE 1	Used when a totally cleaned surface is required; blast-cleaned surface must have a uniform, gray-white metallic color and must be free of all oil, grease, dirt, mill scale, rust, corrosion products, oxides, old paint, stains, streaks, or any other foreign matter. Visual standards: SSPC-VIS I—ASa3, BSa3, CSa3, and DSa3[(a)]; NACE 1
Commercial blast cleaning	SSPC-SP6; NACE 3	Used to remove all contaminants from surface, except the standard allows slight streaks or discolorations caused by rust stain, mill scale oxides, or slight, tight residues of rust or old paint or coatings. If the surface is pitted, slight residues of rust or old paint may remain in the bottoms of pits. The slight discolorations allowed must be limited to one-third of every square inch. Visual standards: SSPC-VIS I—BSa2, CSa2, DSa2[(a)]; NACE 3; SSPC-VIS 5/NACE VIS 9[(d)]
Brush-off blast cleaning	SSPC-SP7; NACE 4	Used to remove completely all oil, grease, dirt, rust scale, loose mill scale, and loose paint or coatings. Tight mill scale and tightly adherent rust and paint or coatings may remain as long as the entire surface has been exposed to the abrasive blasting. Visual standards: SSPC-VIS I—BSa1, CSa1, DSa1[(a)]; NACE 4
Pickling	SSPC-SP8	Used for complete removal of all mill scale, rust, and rust scale by chemical reaction, electrolysis, or both. No available visual standards
Near-white blast cleaning	SSPC-SP10; NACE 2	Used to remove all oil, grease, dirt, mill scale, rust, corrosion products, oxides, paint, or any other foreign matter. Very light shadows, very slight streaks, and discolorations caused by rust stain, mill scale oxides, or slight, tight paint or coating residues are permitted to remain but only in 5% of every square inch. Visual standards: SSPC-VIS I—ASa2-1/2, BSa2-1/2, CSa2-1/2, and DSa2-1/2[(a)]; NACE 2; SSPC-VIS 5/NACE VIS 9[(d)]
Power tool cleaning to bare metal	SSPC-SP11	Used to completely remove all contaminants from a surface using power tools. Equivalent to SSPC-SP5, “White-Metal Blast Cleaning.” Requires a minimum 1 mil anchor pattern. Visual standard: SSPC-VIS 3[(b)]
Waterjetting	SSPC-SP12; NACE 5	Cleaning using high- and ultrahigh-pressure waterjetting prior to recoating. Visual standard: SSPC-SP4/NACE 7. Photos depict degrees of cleanliness and flash rusting[(c)].
Mechanical, chemical, or thermal preparation of concrete	SSPC-SP13; NACE 6	Prepares cementitious surfaces for bonded protective coating or lining systems
Industrial blast cleaning	SSPC-SP14; NACE 8	Used to clean painted or unpainted steel surfaces free of oil, grease, dust, and dirt. Traces of tight mill scale, rust, and coating residue are permitted. Visual standard: SSPC-VIS 1[(a)].
Commercial grade power tool cleaning	SSPC-SP 15	Used for power tool cleaning of steel surfaces while retaining or producing a minimum 25 μm (1 mil) surface profiles. This standard requires higher degree of cleanliness than SSPC-SP 3, but allows stains

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

of rust, paint, and mill scale not allowed by SSPC-SP 11.

(a) SSPC-VIS 1, “Guide and Reference Photographs for Steel Surfaces Prepared by Dry Abrasive Blast Cleaning” is the most commonly used standard for evaluating the cleanliness of a prepared surface. The use of these standards requires a determination of the extent of rust on the uncleaned steel; this is graded from A to D.

(b) SSPC-VIS 3, “Visual Standard for Power- and Hand-Tool Cleaned Steel.”

(c) SSPC-VIS 4/NACE VIS 7, “Guide and Reference Photographs for Steel Surfaces Prepared by Waterjetting.”

(d) SSPC-VIS 5/NACE VIS 9, “Guide and Reference Photographs for Steel Surfaces Prepared by Wet Abrasive Blast Cleaning”

Although there are other national or corporate standards, the SSPC/NACE International and ISO standards are perhaps the most widely used. However, these standards (and most others) specify only the visual degree of cleaning and do not define the surface roughness or profile obtained by cleaning or by the removal of invisible contaminants.

Removal of Invisible Contaminants. The removal of invisible contaminants is more difficult to assess. Chemical contamination after surface preparation and before coating may result in blistering, poor adhesion, or other defects in the applied coating system. It is less evident that such chemical contamination may be inherent in a metal after it has been exposed and corroded in a chemical environment. Even thorough blast cleaning to white metal may not remove chemical species (notably chloride ions) that may have penetrated into the grain boundaries or microstructure of the metal. If such penetrating anions can react to form a water-soluble salt, such as ferrous chloride, then an aggressive underfilm corrosion may occur if water permeates the coating.

As might be expected, the presence of invisible water-soluble contaminants is more detrimental in immersion service than in dry atmospheric service. Methods for removing such contaminants are usually based on water blasting or water flushing in order to dissolve and flush the water-soluble contaminants from the surface. Other approaches are the use of chelating primers, which react with and complex the soluble salts and render them inactive and noncorrosive, and the application of a porous coating, such as an inorganic zinc-rich primer, that allows passage of water-soluble corrosion products.

A major detriment to removal is, of course, the inability to adequately detect the presence of contaminants. Although indicator kits and chemically treated papers have been developed for this purpose, more work is needed in this area. Furthermore, very little work has been done to establish the tolerance of various coatings, surfaces, or exposure environments to the presence of differing amounts of contaminants. Investigations into the tolerance of coating systems for water-soluble salt contamination on the surface prior to painting have disclosed that many researchers believe that the maximum salt concentration in immersion service should not exceed 3 to 10 μg/cm^2 (Ref 4).

Roughening of the Surface. In addition to cleanliness, the surface must be roughened to provide for a mechanical bond of the paint to the substrate. This roughening is termed *anchor pattern, profile,* or *tooth,* and it is essentially a pattern of peaks and valleys on the steel surface. This pattern is obtained by abrasive blasting, and it must be carefully controlled according to the coating system being applied. If the peaks are too high, they will project above the coating and cause pinpoint rusting. A rule of thumb for surface profile is that it should be approximately one-third of the required coating system thickness up to a coating thickness of 0.3 mm (12 mils).

The roughness or surface profile imparted to the metal during the course of cleaning preparatory to painting influences adhesion. As a rule, greater roughness results in greater adhesion, although excessive roughness may result in high spots or peaks that are not covered adequately by the thickness of the applied coating. Such peaks may be initiation sites for pinpoint rusting and corrosion. As a general rule, most mineral abrasive blast-cleaning materials impart a profile or roughness ranging from 13 to 100 μm (0.5 to 4 mils), depending on particle size and impact velocity. Metallic grits may have deeper profiles, approaching 178 μm (7 mils) or more, but metallic shot and grit, when sized properly, usually impart profiles within the 50 to 115 μm (2 to 4.5 mil) range. Such surface roughnesses are suitable for most of the coating systems discussed in this article, although some of the more highly stressed systems, such as the vinyl esters and polyesters, may require a deeper profile to ensure adequate adhesion.

Other areas of the surface also must be addressed before the actual cleaning. Coatings generally do not cover weld spatter properly. Weld spatter may also become dislodged in service, exposing the unprotected substrate. Sharp edges cause paint to draw thin because of surface tension effects and should be eliminated by grinding. Inside corners provide a collection site for excess paint and/or abrasive and should be filled. Crevices and pits should be filled with weld metal, if necessary, and smoothed. Some pits, because of their sharp, angular edges,

www.iran_mavad.com

مرجع مهندسی مواد و متالورژی

require extensive welding and grinding before surface preparation. Other pits, because they consist of smooth, even depressions, need only be cleaned for coating.
In addition, for maintenance painting, thick layers of stiff, old paint should be removed, and glossy painted surfaces must be roughened. Nonferrous surfaces also frequently require some type of pretreatment. In the case of aluminum or galvanized steel, degreasing and the application of a wash primer are often employed to provide proper adhesion.

Methods of Surface Preparation

A variety of surface preparation methods are available, including:

- Solvent or chemical washing
- Steam cleaning
- Hand tool cleaning
- Power tool cleaning
- Water blasting
- Abrasive blast cleaning

Each of these preparation methods is discussed subsequently.
Solvent cleaning (SSPC-SP1) removes oil and grease and is usually used in conjunction with or before the mechanical methods of preparation. Because of rapid contamination, fresh solvent must be used continuously, and the rags or cloths must be turned and/or replaced frequently. If this is not done, the grease and oil are spread across the surface rather than removed. The final wash should be made with clean solvent. The organic solvents used should not contact the eyes or skin and should not be used near sparks or open flames. The disadvantages of solvent cleaning are that it has no effect on rust or mill scale, it is very slow and labor intensive, and the materials are rapidly used up and need constant replacement. In addition, many of the solvents used are highly flammable and toxic. Natural or mechanical exhaust ventilation for diluting the concentration of vapors in an enclosed working space should be employed during the entire work period.
Steam cleaning uses high-temperature, high- velocity wet steam to remove heavy soil, oil, or grease. It does not remove rust or mill scale, nor does it etch or roughen the surface. Commercial detergents can be added to the steam to improve cleaning. On steel, steam cleaning is sometimes followed by spot blast cleaning or wire brushing on areas exhibiting coating failure or rusting.
Hand tool cleaning (SSPC-SP2) is used only for removing loosely adherent paint, rust, or mill scale. Because this method is slow, it is primarily used for spot cleaning. Hand tools include scrapers, wire brushes, abrasive pads, chisels, knives, and chipping hammers. The disadvantages of using these tools, in addition to the lack of speed, are that they do not remove tightly adherent contaminants (for example, dirt trapped in crevices, or oil or grease) and that they may raise burrs or dent the surface, actually causing some damage to the surface. In addition, these tools generally do not provide a surface profile.
Power tool cleaning (SSPC-SP3) is faster than hand tool cleaning; it removes loose paint, rust, and scale; and it is good for the preparation of welded surfaces. Power tool cleaning is also good for removing old paint that has been lifted by rust. It provides a duplication of hand tools in power-driven equipment (electric or pneumatic), such as sanders, wire brushes, grinders, clippers, needle guns, and rotary descalers. Generally, power tool cleaning is suitable only for small areas because it is relatively slow. Power tools do not leave as much residue or produce as much dust as abrasive blasting, and they are frequently used where blasting dust could damage sensitive surroundings. However, they may polish the surface if they are used at too high a speed or kept in one spot for too long.
Water blast cleaning (SSPC-SP12/NACE 5) may be high or low pressure, hot or cold, and with or without a detergent, depending on the type of cleaning desired. This process removes loose, flaky rust, paint, and mill scale. It has gained wide acceptance where abrasive blast cleaning, dust, and contamination present a hazard to either personnel or machinery. Low-pressure washing (<14 MPa, or 2000 psi) is effective in removing dirt, mildew, and chalk from the coating surface, and it is generally safe on concrete or masonry surfaces. Low-pressure water blast units use the same components as high- pressure water blast equipment. Low-pressure cleaning is referred to as power washing, and it should be recognized as such. For cleaning steel, water pressures as high as 68 MPa (10,000 psi) or more and volumes from 30 to 38 L/min (8 to 10 gal/min) are used.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Water alone at pressures less than 136 MPa (20,000 psi) does not etch a metal surface or remove tight paint, rust, or mill scale. Therefore, abrasives can be injected into the water stream to remove tightly adhering materials, to hasten the cleaning, or to roughen the surface profile. Any type of abrasive that is commonly used with abrasive blast cleaning can be used in water blast cleaning. Because the abrasive is normally not dried, screened, and recycled, less expensive abrasives are commonly selected in this application. The abrasive is injected into the system after water is pressurized by means of a suction head to prevent pump damage. Injecting abrasives into the water eliminates the dust that normally accompanies dry use of such abrasives.
Water at pressures in excess of 136 MPa (20,000 psi) removes tightly adherent materials, including rust and rust scale, but a minimal profile of a sound steel substrate results. If the original surface was previously blastcleaned, that original profile will be revealed. If the steel surface was smooth, little additional roughening from the water will result, unless abrasive has been added. In the latter case, if roughening is desired, it is usually obtained by mechanical means (needle gun, flapper wheel abrading, or blastcleaning) or by water blasting at lower pressures with abrasive injection.
Flash rusting is a concern when using these methods. Flash rust is a light rust layer that forms on steel after cleaning, particularly after water or wet abrasive blasting, or in humid marine environments. To avoid flash rusting, rust inhibitors such as sodium and/or potassium dichromate or phosphate are often used during or after water blasting. These inhibitors may retard rusting for up to 7 days. The disadvantage of using these corrosion inhibitors is that the solutions, on drying, leave salts that can produce adhesion problems for protective coatings. The primary consideration, therefore, should be to determine if the protective coating is compatible with the inhibitor that was used.
Abrasive blast cleaning is the preferred surface preparation method for paints and coatings that require an anchor pattern and a high degree of cleanliness. Blast cleaning is the only method that can completely remove intact mill scale and give an even roughness with a controlled anchor pattern. Abrasive blasting is the propelling, or shooting, of sand or other types of small, hard particles at a surface. In nozzle blasting, the force that propels the abrasive is compressed air. The abrasive strikes the surface at speeds of 320 to 640 km/h (200 to 400 mph), breaking and loosening the rust or scale.
The cleaning principle is the same in centrifugal wheel blasting. In this case, the spinning of large paddle wheels creates the force that throws the abrasive at the surface. This method is usually confined to shop use with units approximately the size of a large trailer, although smaller one-man units have been developed for preparing floors or ship hulls. In contrast with open blast cleaning, the abrasives used are recyclable steel grit or shot.
Vacuum blasting is another option for dust- free blast cleaning. With this technique, the blast nozzle is surrounded by a brush, and a vacuum is created within the annular space. The spent abrasive and removed paint, rust, and debris are contained by the brush, removed by the vacuum, and transported to a separator. The debris and fine particles are removed, and the abrasive is returned for reuse. This method is very slow, because the blast pattern is approximately 25 mm (1 in.) in diameter. However, for small areas or where dust cannot be tolerated, it may be the best alternative.
The grades of cleaning, from least to most thorough, are identified as:

- Brush-off blast cleaning (SSPC-SP7/NACE 4)
- Industrial blast cleaning (SSPC-SP14/NACE 6)
- Commercial blast cleaning (SSPC-SP6/ NACE 3)
- Near-white blast cleaning (SSPC-SP10/ NACE 2)
- White blast cleaning (SSPC-SP5/NACE 1)

The specific definitions are provided later in this section. Abrasive blasting is ideally suited for high-production work because it rapidly cleans large areas. In spite of its efficiency and good results, some problems still occur, such as the accumulation of used abrasives in low-lying areas and the attendant difficulty in removing them. Airborne dust and abrasive can interfere with machinery and the work of persons nearby and can contaminate adjacent locations. Airborne dust can be a hostile environment for the blast operator, and an air-fed hood must be worn while operating the air blast cleaning equipment. In addition, open nozzle blast abrasives are expensive and are usually not recycled in the field.
Open nozzle blasting equipment has six basic components:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- Air compressor
- Air hose
- Blasting machine, with a safety valve
- Blast hose
- Nozzle
- Moisture and oil separator

The function of each part is described subsequently.

The air compressor is the source of energy for the blasting job. The constant supply of a high- volume high-pressure air stream hour after hour is the most critical part of blast operations. Work is done in direct proportion to the volume and pressure of air at the nozzle. The larger the compressor, the larger the nozzle it can operate. The larger the nozzle at the proper pressure, the faster the job can be completed.

The air hose connects the compressor to the blast pot. For efficient blasting, the air hose should have as large an inside diameter as practical in order to reduce friction and avoid air pressure loss (a minimum 32 mm, or $1\frac{1}{4}$ in., inside diameter air hose is usually recommended). A 15% production loss can result from a 69 kPa (10 psi) drop in pressure. The air hose should also be as short as practical to reduce leakage and should contain as few couplings as possible.

The blasting machine or sandpot is a pressurized container that holds the abrasive. A valve at the bottom measures and controls the amount of abrasive fed into the blast hose. Efficient abrasive blast operations require the right size pot for the job, which enables very few refill stops, and the releasing of an even flow of abrasive with the air stream. A deadman control valve is a required safety feature for operation of the blast pot.

To start the machine, the operator presses down on the deadman valve with one hand; this allows the air inlet valve to open and the air outlet valve to close, at which time blasting begins. Should the operator want to stop the operation, releasing hold on the deadman valve closes the air inlet valve, shutting off any incoming air from the compressor to the machine and instantly opening the bleed-off or depressurizing valve.

Consider the possibility of an operator who faints, collapses, or falls off the scaffold. This person may be within the range of the nozzle, which, in effect, is an automatic shot gun. Many injuries have been caused by such incidents. With remote-control deadman valves, the machine shuts off the moment the grip on the nozzle is relaxed.

The blast hose connects the blast pot and nozzle and carries both air and abrasive. It is treated to prevent electrical shock by the installation of a grounding line. Sturdily constructed, multiple- ply hose with a minimum inside diameter of 32 mm ($1\frac{1}{4}$ in.) is required in most work. A short length of lighter, more flexible hose with a 25 or 32 mm (1 or $1\frac{1}{4}$ in.) inside diameter is sometimes joined in at the end. These sections, called *whips,* are easier to handle and are effective for work in areas with many angles, pipes, and stiffeners. The use of whips, however, effectively reduces the pressure at the nozzle and cancels the advantage gained by a large-diameter blast hose; therefore, their use should be discouraged except where necessary.

The nozzle is a major element in the blasting operation. Nozzle sizes are identified by the diameter of the orifice. Diameters are measured in sixteenths of an inch. A 4.8 mm ($\frac{3}{16}$ in.) diameter orifice is designated No. 3; a 7.9 mm ($\frac{5}{16}$ in.) diameter nozzle, No. 5; and so forth. Nozzles are commonly available up to 12.7 mm ($\frac{1}{2}$ in.) (No. 8) in diameter. The rate of surface cleaning is a function of the volume of air pushed through the nozzle at high pressure. For example, if a cleaning rate of 9 m^2/h (100 ft^2/h) can be attained with a 6.4 mm ($\frac{1}{4}$ in.) nozzle, a rate of 37 m^2/h (400 ft^2/h) can be attained with a 12.7 mm ($\frac{1}{2}$ in.) nozzle. However, the nozzle can be too large for the air volume. This results in insufficient air pressure, and production drops. Therefore, nozzle size should be as large as permitted by the air supply to maintain air pressure of 620 to 690 kPa (90 to 100 psi) at the nozzle.

Nozzles should use the venturi design, have as long a nozzle length as practical, use a tungsten carbide or other wear-resistant lining, and have as large an orifice size as possible with a given compressor. For difficult-to-reach places, nozzles also come in shapes such that they can propel abrasives around corners, in a 360° arc, or even backwards.

Moisture and Oil Separators. The large consumption of compressed air in an abrasive blasting operation introduces the problem of contamination by moisture (especially in high-humidity areas) and oil mists from

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

compressors. This is especially true of portable compressors. To combat this, an adequately sized moisture and oil separator should be installed at the blast machine (at the most distant point from the compressor). Separators are usually of the cyclone type and employ expansion chambers and small micron filters to eliminate up to 95% of moisture and contaminants. They require solvent cleaning to remove oil and regular replacement of filters.

Abrasives. The proper abrasive is the one that provides the necessary cleanliness and profile. The characteristics of such an abrasive related to performance include size, hardness, shape, and material.

Size. A large abrasive particle cuts deeper than a smaller particle of the same composition and shape and therefore provides a deeper surface profile. However, the greatest cleaning rate is achieved with the smaller abrasive because of a larger number of impacts per unit area.

Hardness. Hard abrasives generally cut deeper and faster than softer or brittle abrasives. A hard but brittle abrasive shatters on impact; this reduces its cleaning power accordingly.

Shape. The shape and size of abrasive grains determine the type of surface profile achieved by blast cleaning. Steel shot, because it is round, peens the surface to give a wavy profile. Therefore, shot is particularly effective at removing brittle deposits, such as mill scale. Grit, on the other hand, is angular, and when blast cleaning, produces a jagged finish that is generally preferred for coating adhesion. A wide variety of surface patterns are available from different grits. Use of sand and slag abrasives that are semiangular results in a pattern somewhat between that of shot and grit.

Materials. The abrasive should have a neutral pH, that is, between 6 and 8. It should not be washed with seawater or other contaminated water. Four types of abrasive materials are commonly used on a nonrecycled basis, as follows.

The first type of abrasives are the natural oxides. Silica sand is the most widely used natural oxide because it is readily available, low in cost, and effective. The hazards of sand have recently been elucidated by the Environmental Protection Agency and by the Occupational Safety and Health Administration, and the use of silica sand abrasives has been restricted in many areas. Another natural silica material has received attention in recent years. It consists of a blend of coarse and fine staurolite sands mined from certain mineral deposits in Florida. It is characterized as efficient cutting, and it has less dusting and a lower breakdown rate than silica sand.

Metallic abrasives are the second type. Steel shot and grit abrasives are efficient, hard, and dust-free, but care must be taken in their storage to prevent rusting. Although their initial cost is higher, they may be recycled many times to make them cost-effective. A mixture of both shot and grit abrasives in blasting may combine the advantages of both.

Slag abrasives are the third type. Copper and nickel abrasives are a by-product of the ore- smelting industry. Coal slags result from the burning of coal. These abrasives are fast cutting, but they have a high breakdown rate and are generally not recycled. Slag abrasives are most likely to exhibit an acidic pH.

Synthetic abrasives are the fourth type of abrasive. Aluminum oxide and silicon carbide are nonmetallic abrasives that have cleaning properties similar to the metallics, without the problem of rusting. They are very hard, fast cutting, and low dusting, but they are quite costly and must be recycled for economical use.

Paint Systems

Kenneth B. Tator, KTA-Tator, Inc.

Coating Application

In a most basic sense, coating application can be described as getting the paint from the can to the surface being coated. There are a number of ways of accomplishing this, and often the type of paint material determines the selection of the most appropriate method. For example, zinc-rich coatings should always be sprayed (except for very small areas), and agitation must be used when spraying to keep the heavy pigment particles from settling. Vinyls and chlorinated rubbers are not usually formulated for brush or roller application, and they too should be sprayed. On the other hand, alkyds and oil-based coatings are often applied by brush or roller but can be readily sprayed as well. For most corrosion-protective coating systems, airless or conventional spraying is preferred; spraying deposits a more uniform film with greater thickness control and a better appearance. The rate of application is much faster with spraying, particularly airless spray, than with brush and roller application. The more common application techniques and equipment are described subsequently.

Brushing

Brushing is an effective, relatively simple method of paint application, particularly with primers, because of the ability to work the paint into pores and surface irregularities. Because brushing is slow, it is used primarily for smaller jobs, surfaces with complex configurations (edges, corners, cuts, and so on), or where overspray may constitute a serious problem. The other disadvantage of brushing is that it does not produce a very uniform film thickness. Natural brush bristles of good quality are preferred, but synthetic bristles resistant to strong paint solvents can also be used. Bristles that are naturally or artificially flagged, that is, with split tips, are preferred, because they hold more paint. Nylon and polyester bristles are more water resistant than natural fibers and are preferred for latex paints.

Paint Mitts. A paint mitt can hold more paint than a brush and is faster, but it produces a very nonuniform thickness. Therefore, paint mitts are generally used only for hard-to-reach areas or oddly shaped objects, such as small pipes and railings.

Rolling

Rollers are best used on large, flat areas that do not require the surface smoothness or uniformity achievable by spraying. Rollers are also used in interior areas where overspray presents a cleaning and masking problem. However, the brush is preferred over a roller for applying primers because of the difficulties in penetrating pores, cracks, and other surface irregularities. In rolling, air mixes with the paint and leaves points for moisture to penetrate the cured film. Rolling is generally more suitable for topcoating a primer that has been applied by some other method.

The nap (fiber length) of a roller normally varies from 6.4 to 19 mm ($\frac{1}{4}$ to $\frac{3}{4}$ in.). A longer nap holds more paint but does not give a smooth finish; therefore, it is used on rough surfaces. Rollers with extralong naps (32 mm, or $1\frac{1}{4}$ in.) are used for chain-link fencing. Handle extensions up to 3 m (10 ft) in length or longer allow a painter

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

to reach otherwise inaccessible areas, but the net effect is usually a reduction in the quality of the application. High-performance coatings for immersion service are seldom applied by roller because of nonuniform thickness, wicking caused by roller residue, and the rapid drying properties of some coatings, such as vinyls.

Spray Painting

Spray painting of coatings results in a smoother, more uniform surface than that obtained by brushing or rolling, because these application methods tend to leave brush or stipple marks and irregular thicknesses. The most common methods of spray painting are conventional and airless.

The conventional spray method of spraying relies on air for paint atomization. Jets of compressed air introduced into the stream of paint at the nozzle break the stream into tiny droplets that are carried to the surface by the current of air.

Because large amounts of air are mixed with the paint during conventional spray application, paint losses from bounce back or overspray can be high. Such losses have been estimated to be as much as 30 to 40%, depending on the configuration of the substrate. However, the ability to vary fluid and air independently gives conventional spray the versatility to provide a wide choice of pattern shapes and coating wetness by infinitely varying the atomization at the gun. Spray gun triggering is more easily controlled for precise spraying of irregular shapes, corners, and pipes than with airless spray. Conventional spraying provides a finer degree of atomization and a higher quality surface finish than airless spray gives.

However, some of the disadvantages of conventional air spray application are:

- It is slower than airless application.
- More overspray results than with other methods.
- It is hard to coat corners, crevices, and so on, because of blowback.

Nonetheless, conventional spray is still one of the most frequently used application methods. The equipment required for conventional spray application of coatings is discussed subsequently.

Air compressors can be of various types, with the size usually dependent on the amount of air required to operate the spray gun. Hoses must be properly sized to deliver the proper amount of air volume and pressure to the gun. It takes approximately 276 to 414 kPa (40 to 60 psi) and 0.25 m^3/min (8.5 ft^3/min) to operate most production spray guns with medium-viscosity paint.

An oil and moisture separator should be set up between the air compressor and the paint pot to prevent moisture and oil from getting into the paint and ruining the quality of the finish. This component of the conventional spray setup should be considered as a standard item that cannot be omitted, because of potential paint contamination and equipment damage.

Pressure Feed Tanks (Paint Pots). The amount of fluid material delivered to the spray gun is regulated by the pressure set by the fluid pressure regulator of the feed tank pressure pot. The pressure pot should contain 19 to 38 L (5 to 10 gal) of paint for most jobs. Pressures of 55 to 83 kPa (8 to 12 psi) at the gun are commonly used; excessive fluid pressure can cause the fluid stream to exit the fluid nozzle at too high a velocity for the air jets in the nozzle to atomize the fluid stream properly.

Connecting Hoses. Two hoses are used in conventional air spray painting: the air hose and the fluid hose. Air hoses supply air from the compressor to the paint pot and should be at least 12.7 mm ($\frac{1}{2}$ in.) in inside diameter. The air hose from the paint pot to the spray gun should be 6.4 to 7.9 mm ($\frac{1}{4}$ to $\frac{5}{16}$in.) in inside diameter and as short as possible.

The fluid hose usually has a solvent-resistant liner. It should have a 7.9 to 9.5 mm ($\frac{5}{16}$ to $\frac{3}{8}$in.) inside diameter for medium-viscosity materials and should be as short as possible. Hoses with inside diameters up to 12.7 mm ($\frac{1}{2}$ in.) are commonly used. Excessive hose length allows the solids to settle in the line before reaching the spray gun. This leads to clogging and the application of a nonhomogeneous film.

The spray gun is used to atomize the paint by mixing it with air under pressure in order to apply the coating material to the surface. Various spray patterns can be obtained by changing the volume of both air and fluid. The selection of the fluid nozzle and the needle size is another way to regulate the amount of paint exiting the fluid nozzle. If it is found that excessive amounts of paint are flowing through the fluid nozzle at low pressures

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

(55 to 83 kPa, or 8 to 12 psi), the fluid- adjusting knob can be used to reduce the flow, or a smaller fluid nozzle/needle combination may be needed. Paint manufacturers normally recommend at least one set of sizes known to work for their product.

Airless spray provides a rapid film build, greater paint flow into surface irregularities, and rapid coverage. In airless spraying, paint is forced through a very small nozzle opening at very high pressures to break the existing paint stream into tiny particles (similar to water exiting a garden hose). Because of the high fluid pressure of airless spray, paint can be applied more rapidly and at greater film builds than in conventional spraying. The high-pressure paint stream generated by airless spray penetrates cavities and corners with little surface rebound. If airless spray is used, proper spraying technique is essential for quality paint films. Poor technique can result in variations in paint thickness, holidays, and a host of other film defects in addition to wasted time and materials.

Some of the advantages of airless spray as compared with conventional spray include:

- Higher film builds are possible (heavier coatings).
- Less fog or rebound
- Easier to use by the operator, because there is only one hose
- Higher-viscosity paints can be applied.
- Easier cleanup

The disadvantages of the airless spray process include:

- Relies on dangerous high pressure
- Fan pattern is not adjustable.
- Many more working parts that can cause difficulty
- Higher initial cost than other forms of spraying
- Requires special care to avoid excessive buildup of paint that causes solvent entrapment, pinholes, runs, sags, and wrinkles

The equipment and materials for airless spraying are discussed subsequently.

Power Source. An electric motor can be used instead of an air compressor to drive the fluid pump. The electric airless is a self-contained spray outfit mounted on wheels and designed to use commercial 115 V electrical power.

An air compressor, usually with a 1 hp, 690 kPa (100 psi) electric motor or a $1\frac{1}{2}$ hp gasoline engine, is required to operate one gun with a 0.46 mm (0.018 in.) tip. For two or more guns or heavy materials, a greater capacity is needed.

Air Hose and Siphon Hose. A 12.7 mm ($\frac{1}{2}$ in.) inside diameter hose is generally used to deliver air from the compressor to the pump. The most common hose length is 15 m (50 ft). However, as hose length and pump size increase, the inside diameter of the hose must be increased as well.

A siphon hose is required, and it must have an inside diameter of 12.7 to 19 mm ($\frac{1}{2}$ to $\frac{3}{4}$in.) to provide adequate fluid delivery. Also, the hose material must be resistant to the fluid solvent and other materials. A paint filter should be used to prevent dirt from clogging the fluid hose and tip. This hose is often eliminated, and the pump is immersed directly into the paint.

High-Pressure Fluid Pump. The fluid pump is the most important part of the hydraulic airless system; it multiplies the air input pressure to deliver material at pressures up to 31 MPa (4500 psi). Pumps are offered with delivery ranges from 0.8 L/min (28 oz/min) (one gun) up to 11.4 L/min (3 gal/min) (three to four guns). The pump used for many airless outfits converts 0.45 kg (1 lb) of air input into 13.5 kg (30 lb) of fluid pressure. This is referred to as a 30 to 1 ratio. Pump ratios as high as 45 to 1 are common.

Some airless spray units use an electric-hydraulic power pack. These units can supply two guns with airless spray tips of up to 0.53 mm (0.021 in.) and long spray lines, or one gun for high-volume delivery with an airless tip of up to a 0.79 mm (0.031 in.) orifice. These electric units are wheel mounted and use a long-stroke slow-speed pump. The unit is equipped with an explosion-proof motor and can deliver as much as 3.8 L/min (1 gal/min) at pressures up to 21 MPa (3000 psi).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

A paint filter should be attached to the pump at the fluid hose connection. The filter prevents dirt and particles from clogging the gun and being sprayed onto the work surface.

The fluid hose is made to withstand high operating pressures. It is made of vinyl-covered, reinforced nylon braid and can handle approximately 2040 kg (4500 lb) of pressure. The hose is designed to resist the solvent action of the various coatings being sprayed. A wire is often molded into the hose assembly to prevent any possible static electrical charge. The hose inside diameter should be at least 6.4 mm ($\frac{1}{4}$ in.), and the length should not be longer than necessary to do the work (ideally, 15 to 30 m, or 50 to 100 ft). Fluid hose diameters up to 12.7 mm ($\frac{1}{2}$ in.) are commonly used.

The airless spray gun is designed for use with high fluid pressures. It is similar in appearance to the conventional gun but has a single hose for the fluid. The hose may be attached to the front of the gun or to the handle. Atomization occurs when fluid is forced through the small orifice in the spray tip at high pressures.

A variety of spray tips are available to suit the type of material being sprayed and the size of spray pattern desired. The orifice, or hole, in the tip and the fan angle control the pattern size and fluid flow. There are no controls on the gun itself. Tip orifices vary to fit the viscosity of the paint being applied; fan angles range from 10 to 95°.

Quality Assurance

To obtain the desired protection of a metal substrate from a coating system, it is important not only to choose the proper coating materials but also to ensure that they are properly applied. On most jobs, such assurance is provided by a reputable painting force, or contractor, but on many other jobs, surveillance by plant personnel or thorough inspection by independent third- party organizations is done. In all cases, the rudiments of quality are the same:

- Proper masking and protection of surfaces not to be blast cleaned or painted
- Removal of rust and contaminants and suitable roughening of the surface
- Application of the specified coating system to the proper thickness
- Observation of application parameters, such as minimum and maximum temperatures, interval between coats, and induction times
- Verification of proper hardening or cure of the coating
- Testing to ensure that defects such as pinholes, skips, or holidays are minimized or avoided
- Tests for adhesion, color, gloss, and other parameters that may affect appearance or protective capability of the coating

Coating inspection requires training, experience, and familiarity with the instrumentation the inspector must use. Inspector training courses are available, and certification of inspectors is available from some training organizations, such as NACE International. A brief overview of some of the more common coating inspections and inspection equipment is subsequently presented.

Inspection Sequence

Inspection often begins with a prejob conference at which the ground rules are set, but when the work begins, the inspector is responsible for witnessing, verifying, inspecting, and documenting the work at various

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

inspection points. The inspector should be aware of the following inspection points and should witness or conduct the operation if feasible:

- Presurface preparation inspection
- Measurement of ambient conditions
- Evaluation of compressed air cleanliness and surface preparation equipment
- Determination of surface preparation, cleanliness, and profile
- Witnessing coating mixing and thinning
- Inspection of application equipment
- Inspection of coating application
- Determination of wet-film thickness
- Determination of dry-film thickness
- Evaluating cleanliness between coats
- Pinhole and holiday testing
- Evaluation of adhesion and cure

Presurface Preparation Inspection. Prior to the start of surface preparation and other coating activities, it is necessary to inspect the base in order to determine if the work is ready to be prepared and painted. Heavy deposits of grease, oil, dust, dirt, and other contaminants must be removed. Removal of this miscellaneous debris before blast cleaning ensures that these materials are not redeposited onto the freshly blast-cleaned surfaces.

In addition, the specifications may require that weld spatter be ground or otherwise removed and that sharp edges be rounded (customarily to a 3.2 mm, or $\frac{1}{8}$ in., radius). Unusual pitting in the steel substrate should be examined; the pits are either accepted as they are or are ground or filled. Areas that do not need to be cleaned or coated should be masked to protect them from the cleaning and coating operations.

Measurement of Ambient Conditions. Before final blast cleaning and before any paint is applied, the inspector or painter should check the ambient and expected weather conditions. This is especially important in the early morning when the weather is changing or during seasonal changes when condensation is common. The presence of a thin film of condensed moisture on the surface may be visually imperceptible, but a quick check of the dew point and the surface temperature determines if such a condition exists.

Dew point is calculated by using temperature readings from a psychrometer and the appropriate psychrometric tables. A psychrometer is an instrument used for determining relative humidity and dew point. The temperature of the surface to be coated should be at least 3 °C (5 °F) higher than the dew point. The temperature must be within the range specified by the coating manufacturer.

Evaluation of Compressed Air Cleanliness and Surface Preparation Equipment. The air supply should be tested for cleanliness at frequent intervals during the day. This is done by holding a blotter or cheesecloth in the air stream for a minimum of 2 min. The blotter or cheesecloth should be held at a distance of 0.5 to 0.6 m (18 to 24 in.) from the source of the air stream being tested. The test material should be examined immediately after the test is complete for evidence of contamination by oil or moisture. Examination should be made visually as well as by touching and smelling the test material. If there is no discoloration on the blotter, the air quality is excellent, while moisture and oil on the blotter indicate unsatisfactory air.

Determination of Surface Preparation, Cleanliness, and Profile. Surface preparation is believed to be the most important factor affecting the performance of the coating. Any compromise in surface preparation usually reduces the performance of the applied material as well. The primary goals of surface preparation are, first, to provide a satisfactory, clean surface free of detrimental contaminants and, second, to provide an anchor pattern and to increase the steel surface area to improve bonding of the applied coating or lining to the steel surface.

Surface cleanliness should be inspected visually to verify that it is in conformance with the specified cleanliness standard.

The removal of invisible water-soluble salts may be assessed by a number of test protocols, all of which dissolve the salt from a known unit area of the surface being painted and measure its concentration.

Surface profile can be determined by using any of several instruments, including surface profile comparators, which give a visual and tactile comparison to a known profile; replica tape with a spring micrometer, in which a tape is pressed into the valleys of a profile and the profile height measured with a micrometer; and dial surface

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

profile gages, where the base of a depth micrometer rests on the profile peaks while a needle penetrates into the valleys.

Witnessing Coating Mixing and Thinning. Before a coating can be applied to a substrate, it must be thoroughly mixed to ensure that the material is homogeneous. During storage, most coatings tend to show some separation of the lighter and heavier components. Heavier pigments settle to the bottom of the can and sometimes appear as a hard cake, while other materials settle as a soft sludge. Some binders and some paints curdle or gel when stored for too long a period. Stirring may reconstitute the paint to a homogeneous liquid; if not, then the paint must be discarded.

Inspection of Application Equipment and Techniques. A lack of cleanliness is the predominant failure associated with spray guns and spray pumps. Paint chips or residues of previous coating materials can lodge in the pump, lines, or guns and cause clogging. Cleanliness of mixing equipment, lines, spray pots, guns, tips, and other application equipment is important and necessary.

During application, the safety and respiration equipment of the operator should be verified to be in working order, and the spray technique should be reviewed. For example, is the spray gun the proper distance from the work? Is there pattern overlap, uniform speed, and triggering before and after each stroke? Is the gun perpendicular to the surface?

Wet-film thickness readings are used as an aid to the painter in determining how much material to apply to the surface in order to achieve the specified dry film. Wet-film thickness gages are of value only if one knows how heavy a wet film to apply. The wet-film thickness/dry-film thickness ratio is based on knowing the percent solids by volume of the specific coating material:

$$\text{Wet-film thickness} = \frac{\text{Desired dry-film thickness}}{\%\ \text{solids by volume}}$$

If the paint is thinned at the time of use:

$$\text{Wet-film thickness} = \frac{\text{Desired dry-film thickness}}{(\%\ \text{solids by volume})/(100\% + \%\ \text{thinner added})}$$

Dry-film thickness measurements are made after complete drying of the coating. They are used to determine if the desired coating thickness is obtained. Dry-film thickness gages for steel surfaces are almost always of the magnetic type. If properly calibrated and operated, they have an error of only approximately 5 to 15% at normal temperatures (-18 to 100 °C, or 0 to 212 °F). Dry-film thickness instruments fall into four basic categories, as follows.

Magnetic pull-off instruments rely on the attraction of a magnet to an underlying steel surface. The stronger the attraction, the greater the force necessary to pull off the magnet. This pulling force can be calibrated to indicate coating thickness.

Magnetic fixed probe instruments measure the strength of the magnetic flux in a steel substrate exerted by a permanent magnet. Thickness can be measured by nulling the wheatstone bridge circuitry at various known thicknesses.

In eddy current inspection, a fluctuating electrical current induces residual eddy currents in an underlying metallic (aluminum, copper, stainless steel, and so on) substrate. The strength of the induced currents is a function of the distance of the induction probe from the substrate, that is, separation by paint thickness. The strength of the induced eddy current is measured and converted into paint thickness.

Destructive Inspection. The most common instrument for destructive coating thickness measurement cuts a small “V” into the paint at a known angle. By measuring the width of the slope of the “V” incision, a measurement of coating thickness can be obtained. The advantage is that each coat of a multiple-coat system can be measured and that thickness measurement is independent of substrate (steel, concrete, wood, and so on).

Evaluating Cleanliness Between Coats. When a multiple-coat system is to be applied, the surface between coats should be examined to ensure that all grease, oil, dirt, bird droppings, pebbles, sand from abrasives, dry spray, and the like have been removed before the application of the next layer of coating.

Pinhole and Holiday Testing. Many coating systems, particularly those for immersion or splash zone service, require additional testing with holiday detectors after the coating has dried. Pinhole and holiday detectors are of two basic types: low-voltage wet sponges and direct current high voltage. The basic function of a holiday tester

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

is to detect minute pinholes, holidays, skips, or misses in coating systems, all of which can cause premature coating failure.

The low-voltage (30 and 67.5 V are common) wet-sponge holiday detectors are used for locating discontinuities in nonconductive coatings applied to metal bases. The low-voltage detector is suitable for use on coatings up to 0.5 mm (20 mils) in thickness. The basic unit consists of the detector, a ground cable, and a sponge electrode. The ground cable is firmly attached to the bare substrate, and the sponge electrode is saturated with tap water. The electrode is moved across the entire surface at a speed of approximately 4.5 to 6 m/min (15 to 20 ft/min); the water permits a small current to flow through the pinholes down to the substrate. Once the current reaches the substrate, the circuit is completed to the detector unit, and an audible signal indicates that a pinhole or discontinuity has been found.

High-voltage holiday detectors basically function on the same operating principle as the low- voltage instruments described previously, except that a sponge is not used. The instrument consists of a testing unit that can produce various voltage outputs, a ground cable, and an electrode made of conductive neoprene, brass, or steel. High-voltage units are available up to 20,000 V and more. The rule of thumb for high-voltage detectors is to apply approximately 4000 V per mm (100 V per mil) of dry-film thickness. High- voltage detectors are used for nonconductive coatings applied to conductive substrates. The ground wire should be firmly attached to a section of the bare substrate and the electrode passed over the entire surface. A spark jumps from the electrode through the air gap down to the substrate at pinholes, holidays, and so on, simultaneously activating a signaling device in the unit.

Adhesion Testing. Occasionally, there is a need to test the adhesion of the coatings after application in the field. Different types of adhesion-testing methods are used, ranging from the simple penknife to the more elaborate tensile- testing units. The use of a penknife generally requires a subjective evaluation of the coating adhesion based on some previous experience. Generally, one cuts through the coating and probes at it with the knife blade, trying to lift it from the surface to ascertain whether or not the adhesion is adequate.

A modified version of this type of testing is the cross-cut test. The cross-cut test consists of cutting an “X,” or a number of small squares or diamonds, through the coating down to the substrate. Tape is then rubbed vigorously onto the scribed marks and removed briskly. The crosshatch pattern is evaluated according to the percentage of squares delaminated or remaining intact. A cross-cut guide can be used to cut a precision crosshatch pattern.

Another technique involves adhering a small dolly to the coated surface, scoring around the dolly periphery, and using a tensile-pulling device to pull it from the surface. The tensile pressure required to disbond, as well as the nature of the disbondment, is used to characterize adhesion.

Tests for Cure. The rate of cure of organic coating materials is affected by surface temperature, ambient conditions, coating formulation, and film thickness. Laboratory testing of paint chips is the only true means for verifying cure. Field techniques include the following.

Solvent Rub. On thermosetting cross-linked coatings, a clean cloth saturated with a strong solvent such as methyl ethyl ketone (MEK) or methyl isobutyl ketone (MIBK) can be used to rub the surface of the coating. If the material is properly mixed and cured, no color is transferred to the cloth. If the coating is improperly mixed or cured, it may partially redissolve, and the color is seen on the cloth. Of course, the solvent rub test cannot be used on certain solvent-sensitive coatings, such as alkyds, vinyls, and chlorinated rubbers.

Sandpaper Test. When a properly cured film is abraded with fine sandpaper, a fine, powdery residue is observed. Coating material that remains on the face of the sandpaper may indicate an uncured, slightly tacky coating.

Hardness Tests. A penetrating needle hardness tester or pencil hardness tester can be used to check film cure. The use of such instruments entails exerting a light perpendicular pressure on an instrument, which holds a hardened steel indenter ground to microscopic accuracy. The penetration of the spring-loaded indenter, which indicates hardness, is read directly from a scale dial. Pencil hardness is established by the lead hardness that just scratches the paint surface.

Rubber as a Protective Lining

Since 1839, when Charles Goodyear discovered the process known as *vulcanization*, whereby a soft, amorphous mass of natural rubber cross-linked into a resilient, elastomeric material with excellent elongation, modulus, and tensile strength, rubber has been used as a material in manufacturing. While the uses of rubber are many and varied, including the manufacture of vehicle tires, roofing materials, latex surgical gloves, erasers, pond liners, and many other products, it is the use of sheet rubber linings for corrosion protection that is covered herein. Rubber applied as a liquid for corrosion protection is discussed in the article “Organic Coatings and Linings” in this Volume.

Rubber, in the form of prefabricated sheets, has been used successfully as a lining material in storage tanks (Fig. 1), water boxes, condensers, flue gas desulfurization (FGD) units, chemical scrubbers, pipelines, mixers, valves, and pumps. Because of superior impact, abrasion, and chemical resistance, rubber linings in the range of 3 to 6 mm ($\frac{1}{8}$ to $\frac{1}{4}$ in.) thickness can often outperform conventional liquid-applied linings by a performance life of many years. In many installations, rubber linings have a service life expectancy of 25 to 30 years.

Commercial Lining Products

Rubber lining products are manufactured in a broad range of compositions and configurations tailored to meet specific requirements for resistance to chemicals, abrasion, impact, and temperature. The comparative ability of various types of rubber to resist degradation is given in Table 1. The ability of various rubbers to resist environments is given in Table 2. Service temperatures and mechanical and physical properties for rubber lining materials are given in Table 3.

Typically, rubber sheet is supplied at a thickness of 3, 4.75, and 6.35 mm ($\frac{1}{8}$, $\frac{3}{16}$, and $\frac{1}{4}$ in.). Most industrial lining work uses 6.35 mm ($\frac{1}{4}$ in.) sheet stock. Standard widths of rolls are usually 1 and 1.22 m (42 and 48 in.) (Fig. 2). Most rubber manufacturers extrude the compounded rubber in sheets to a desired thickness. Many rubber sheets used for corrosion protection comprise two or more rubbers laminated together to form the finalized sheet in a process known as *calendering.* Sheet laminates made by calendering have the advantage that a tear or weak spot in one calender can be covered by other calendered layers. Thus, the strength, thickness, and other properties are more uniform, and pinholing through the lining is minimized. In addition, calendering allows different types of rubber sheets with distinct properties to be laminated into a single ply that can have improved performance over plies of identical sheets. A sheet with superior chemical, ultraviolet, or abrasion resistance can be laminated to a softer material that conforms better to an irregular substrate.

Types of Rubbers

Rubbers can be categorized as natural rubbers and synthetic rubbers. Natural rubbers are manufactured from tree sap from the Far East. Synthetic rubbers were developed on a commercial scale by researchers of the War Production Board in the United States in the early 1940s as a substitute for the natural rubber sources that were under control of the Axis forces (notably Japan) during World War II. The chemical structures are given in Table 4.

Natural Rubber (NR)

The precursors of rubber and rubberlike compounds are examples of some of the earliest materials that civilized man learned to extract and process from plant sources. Many plants produce a milky sap that can be harvested, coagulated, and converted to a crude elastomer. The earliest natural rubber was named *caoutchouc,* and was derived from an East Indian word meaning *weeping tree.* The term survives today and is used to designate a family of raw, plant-derived, macromolecular compounds that can be converted to more complex, cross-linked materials. Caoutchoucs are the precursors to natural rubber (Ref 6). Modern analytical analysis has identified these materials as variations of naturally occurring polyisoprene. Latex-producing plants, of which there are hundreds, are found predominately in tropical climates. The plantation economies of Malaysia, Indonesia, and Thailand account for nearly 90% of the global production of raw natural rubber.

The collection and production of raw natural rubber from plantations rely principally on acid coagulation to concentrate the latex (caoutchouc). The raw plant sap (latex) is collected and processed in large tanks, where formic or acetic acid is introduced as the coagulating agent. Subsequent drying, curing, and rolling produce several different intermediate products called *smoked sheets* or *pale crepe* that are graded by color, purity, and strength. Both intermediates are the principal raw feedstock for natural rubber production.

Conversion of the raw natural rubber into usable products involves additional compounding and processing. Compounding introduces solid materials into the raw rubber that improve such properties as abrasion and tear resistance. Compounding ingredients include carbon black, curatives, accelerators, antidegradents to slow weathering deterioration, and other processing aids. Other fillers are used to alter density, color, and the cost. Compounding, involving the introduction of modifying organic and inorganic chemicals into the solid raw rubber mass, usually requires some level of high-shear processing known as *mastication.* The mastication takes place in twin-roll mills that also disperse the additions to the rubber mass, producing a homogeneous dispersion. The mixed rubber mass is then sent to sheeting mills, where the rubber shape and dimensions are reduced to facilitate end use.

Natural rubbers are compounded in three forms: soft, semihard, and hard. Soft NRs have excellent physical properties, such as tensile strength, abrasion resistance, and elongation. Soft NRs have good resistance to most inorganic chemicals, with the exception of strong oxidizing agents, to a temperature of 60 °C (140 °F). They are flexible and expand and contract with thermal variations of metal when attached to a metal substrate.

Semihard and hard natural rubbers exhibit better chemical and heat resistance than soft NR. These linings are applied where exposure to organic acids, inorganic acids, and chlorine gas is anticipated. The linings exhibit heat resistance of up to 93 °C (200 °F). The harder grades offer higher resistance to permeability but have less flexibility. Ebonite, which is the hardest of the natural rubbers, is a graphite-filled material resembling a thermoset plastic with a very high cross-linked density. The properties of ebonite are achieved by vulcanization in the presence of a high sulfur content. There is approximately a 10 to 1 ratio between the sulfur content of hard (ebonite) and soft natural rubbers. The hard rubbers can be machined after vulcanization to make acid-resistant seals, valves, and pump bodies. Hard rubbers resist extreme corrosive exposure from wet and dry chlorine gas. They offer chemical resistance to a broad range of chemicals at a level between 65 and 93 °C (150 and 200 °F).

Multiple-Ply Rubber. Multiple-ply rubber linings are the combination of two or three layers (plies) of soft and hard rubbers combined to achieve specific properties of flexibility, chemical resistance, and/or permeability resistance. The softer layers impart flexibility and allow maximum adhesion to the steel substrate. The exterior layer, which is frequently semihard or hard rubber, is selected for enhanced chemical resistance. Other layered arrangements may include a tie gum, which is an intermediate soft layer to promote the bonding of top and bottom layers.

Synthetic Rubber

Synthetic rubber is the general term used for rubber manufactured from other than natural (plant) feedstocks. In today's economy, the principal feedstock for synthetic rubber production is petroleum. The basic monomers for many synthetic rubbers are 1,3-butadiene, isobutylene, isoprene, chloroprene, and acrylonitrile. Following are characteristics of the principal synthetic rubber compounds used in lining applications.

Neoprene or Chloroprene Rubber (CR). Chloroprene (2-chlorobutadiene) rubber was initially compounded in 1939 as neoprene (Ref 7). Chloroprene rubber is a polar rubber because it contains a ratio of carbon atoms to

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

chlorine atoms of 4 to 1. Chlorine content also imparts better flame resistance, weatherability, and ozone resistance than experienced with diene rubbers. The swelling resistance of CR to mineral, vegetable, and animal oils is also better than the nonpolar diene-based rubbers. Chloroprene rubber has good resistance to paraffinic and naphthenic oils of high molecular weight but swells extensively in aromatic oils of low molecular weight. Chloroprene rubber is degraded (swells) by contact with motor fuels, but its resistance can be improved through higher levels of filler loading and degrees of cross-linking. In lining service, with general chemical exposure, CR has heat resistance to 65 °C (150 °F) with strong acids (sulfuric acid) and 93 °C (200 °F) with strong bases (sodium hydroxide).

Butyl rubber (IIR), a blend of isoprene and isobutylene copolymers, is, along with nitrile and neoprene, one of the oldest synthetic rubber lining products (Ref 8). The large-scale production of IIR began in 1943. Typically, the rubber exhibits a high level of heat and heat-aging resistance to 107 °C (225 °F). It has good resistance to a broad array of general chemical solutions at 82 to 93 °C (180 to 200 °F). Because IIR is nonpolar, it swells on contact with lubricating oils and fuels.

Chlorobutyl rubber (CIIR) is manufactured by the chlorination of IIR (Ref 1). Chlorobutyl rubber has better properties of heat resistance to 93 °C (200 °F), gas permeability, weatherability, and ozone than IIR has. Along with ethylene- propylene rubber, it is one of the most chemically resistant lining materials. Chlorobutyl rubber withstands exposure to the highly aggressive environments within FGD units and acid gas processing towers. Chlorobutyl rubber also provides good resistance to concentrated alkalis (NaOH) at 93 °C (200 °F) and wet chlorine gas to 126 °C (260 °F). Because CIIR is nonpolar, it swells on contact with lubricating oils and fuels.

Ethylene-propylene rubber (EPDM) is manufactured by the copolymerization of ethylene and propylene with the addition of a diene monomer to create an unsaturated rubber terpolymer (Ref 1). Sulfur added during vulcanization completes the cross-linking that produces a usable rubber product. Ethylene-propylene rubbers exhibit excellent heat, aging, and weathering resistance. The rubber exhibits excellent resistance to chemicals such as acids, alkalis, acetone, alcohol, hydraulic fluids, and steam. Service temperatures in the range of 82 to 93 °C (180 to 200 °F) are possible with EPDM. However, concentrated and/or strongly oxidizing acids may attack EPDM. The use in acid service depends strongly on operating temperature and acid concentration. Because EPDM is a nonpolar material, contact with aromatic and chlorinated hydrocarbons causes swelling.

Nitrile rubber (NBR) is a product formed by the copolymerization of acrylonitrile and butadiene. Many grades of NBR are available in which the acrylonitrile content varies from 18 to 51% by weight (Ref 6). The addition of acrylonitrile enhances swelling resistance and impermeability. Nitrile rubber is a polar-type rubber used where exposure to aliphatic hydrocarbons is a service condition. Nitrile rubber exhibits good resistance to swelling when immersed in liquids that are non- or weakly polar, such as gasoline, grease, mineral oil, and animal or vegetable fats and oils. Polar and aromatic solvents attack NBR. It should not be used with such aromatic solvents as benzene, toluene, or xylene. Nitrile rubber is less permeable to gases than is NR or styrene-butadiene rubber. However, it exhibits significantly improved heat and aging resistance to a level of 93 °C (200 °F).

Styrene-butadiene rubber (SBR) is a product formed by the copolymerization of styrene and butadiene. Many grades of NBR are available in which the styrene content varies from 23 to 40% by weight (Ref 1). Styrene-butadiene rubber has better heat resistance to 77 °C (170 °F) than NR has. Styrene-butadiene rubber has superior impact and abrasion-resistant properties. Its principal use is in troughs, chutes, hoppers, and ball mills to protect metallic substrates from mechanical damage. However, SBR also has good resistance to water and weak chemical solutions. As a nonpolar rubber, contact with aliphatic, aromatic, and chlorinated hydrocarbons causes swelling.

Chlorosulfonated polyethylene (CSM) is produced on a large scale by Du Pont, where it is marketed as Hypalon (E.I. Du Pont de Nemours & Co., Inc.). Hypalon is an amorphous, elastomer-like polymer that is fully saturated and exhibits excellent resistance to the effects of weathering, aging, ozone, and chemical degradation to 93 °C (200 °F). It has excellent resistance to high concentrations of sulfuric, nitric, chromic, and other strong oxidizing acids. Formulation variations that alter the chlorine content can optimize such properties as heat resistance, electrical resistivity, or flame resistance (Ref 1).

Vulcanization

Vulcanization (curing), a critical stage of processing, is necessary to enhance the performance properties of raw compounded rubber through cross-linking of its molecular structure. Cross- linking (polymerization) is accomplished through reaction with accelerators such as organic peroxides or sulfur that are mixed into the raw rubber base. Vulcanization is the conversion of gum-elastic, raw rubber material into a rubber-elastic end product (vulcanate). The degree of vulcanization is directly related to the degree of cross-link density achieved by the process. The properties of the rubber depend on the conditions of the vulcanization process and the choice of vulcanization chemicals. Important rubber properties, such as hardness, tensile strength, elongation, elasticity, low-temperature flexibility, and swelling stability, can be affected by vulcanization rate. Natural rubbers can be overvulcanized and undergo a decrease (reversion) in optimal cross-link density that results in a lowering of mechanical properties. Synthetic rubbers are less susceptible to overvulcanization due to prolonged heating. For this reason, many synthetic rubber formulations display improved resistance to thermal exposure and heat aging. The four basic methods for vulcanizing or curing rubber linings are autoclave, internal steam, atmospheric steam, and ambient (chemical cure).

Autoclave cure involves placing the object(s) to be covered or lined with rubber inside a pressure vessel termed an *autoclave.* A controlled and continuous flow of steam from a boiler is introduced into the vessel. At the start of the process, air is purged from the autoclave. The temperature and pressure are monitored carefully. Because an autoclave offers the best form of control over the vulcanization process, it offers the greatest potential for producing uniform and high-quality products. However, to achieve these goals, it is recommended that the autoclave be equipped with precise controls for air pressure and steam. Variations in steam pressure and temperature lead to undesirable anomalies in the cured rubber. Once started, an autoclave cure should never be interrupted. Prompt cooldown at the termination of cure is also important. Proper cooldown of the autoclave prevents postcuring and precludes the possibility of blistering and cracking hard rubbers. Chart recorders (Fig. 3) provide evidence of the temperature profile during the process.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

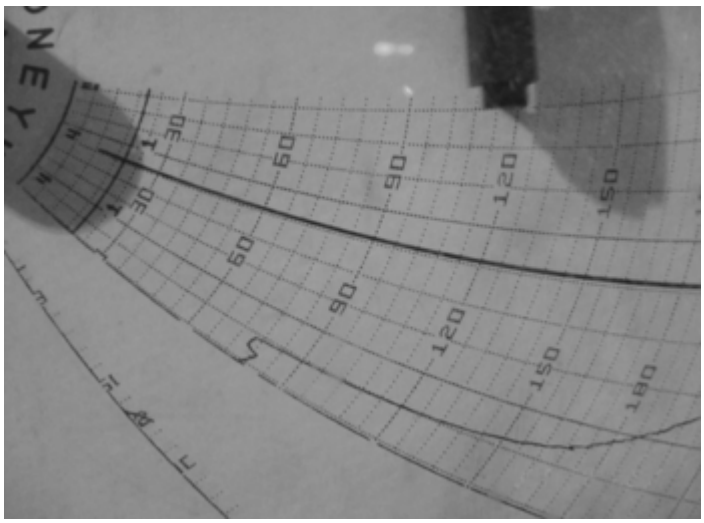

Fig. 3 Temperature chart recorder provides evidence of the proper temperature profile during curing. Courtesy of Blair Rubber Company, Akron, OH

While autoclaves can offer precise management of the vulcanization process, they have size limitations. Large tanks, water boxes, and other process equipment cannot fit inside. Rubber applied to these units must be vulcanized by other means.

Internal Steam Cure. Internal steam pressure vulcanization is used on vessels that are designed to operate at elevated pressures and are too large to be placed in an autoclave. By this method, units can be installed and the linings cured in place. Internal curing should be accompanied by the installation of drains and traps to collect steam condensate. Recording thermometers and pressure gages installed near the bottom of the vessel are used to monitor the process. Blind flanges should be installed at other openings. Bottom outlets should initially be left open to purge the vessel of air. Boiler capacity should be sufficient to raise the ambient temperature from ambient to cure temperature in a relatively short period. Long runs of uninsulated pipe between the boiler and lined vessel should be avoided. Once started, the vulcanization process should not be interrupted. Once the endpoint of the cure is reached, the vessel is cooled down by the introduction of air. Any steam-induced curing cycle should include an appropriate vacuum-break device to prevent a vacuum collapse of the vessel on cool down.

Atmospheric Steam Cure. Atmospheric steam normally is used for field vessels that have open tops or bottoms or that cannot withstand elevated pressures. With the case of open tanks, suitable temperature-resistant, steam-tight covers must be fabricated for all openings. Steam is introduced through an insulated steam line through a piping connection or opening in the top of the vessel. Provisions must be made to drain all condensate that collects at the tank bottom. Other outlets should be closed with blind flanges drawn up to within 0.79 mm ($\frac{1}{32}$ in.) of the flange rubber. Vulcanization at atmospheric pressure allows entrapped air under linings to form blisters. Some procedures call for a precure steaming period of 1h, followed by an internal inspection of the tank to locate and repair spontaneous blisters. In this method, entrapped air is removed by deflating the blister with a hypodermic needle and applying a small patch of uncured rubber. The vulcanization process then proceeds to completion.

Ambient (Chemical) Cure. Rubber is cured at ambient temperatures when heat cannot be applied to surfaces to achieve vulcanization. The method is used most commonly when patches must be applied to vulcanized rubber surfaces. A chemical cure may also be used when surfaces such as flanges are shielded from steam exposure. These methods expose the raw rubber to a sulfur-bearing chemical for a sufficient period to complete cure. The chemicals include carbon disulfide and sulfur dichloride. They are used as either a solution applied to the rubber surface or vapor form. Vulcanization is accomplished in periods of up to one week. If the vessel operates at temperatures of up to 65 °C (150 °F), the chemical cure can be shortened.

Self-Vulcanizing (Cold Cure). In the case of some on-site rubber linings where other curing methods are impractical, self-vulcanizing rubber sheets have been developed. The rubber in these sheets, specific soft rubber mixtures based on polychloroprene and halogenated butyl rubber, is mixed with curing agents, such that curing and cross-linking commences at ambient temperatures of approximately 25 °C (77 °F) at normal pressure levels. Because the rubber sheets are pliant and malleable on completion of the manufacturing process, they can

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

be handled and installed quite easily. However, because the rubber commences cross-linking at ambient temperature immediately at the time of formation into sheet material, refrigeration is necessary if there is a delay between manufacturing and installation and if the temperature exceeds 25 °C (77 °F). To achieve maximum cross-linking, approximately eight weeks at 25 °C (77 °F) are required. Forced curing at higher temperatures may reduce the vulcanization time to as little as two weeks, depending on the specific rubber mixture and elevation in temperature. Self-vulcanizing sheets can also be precured at elevated temperatures, stored indefinitely, and installed as fully vulcanized linings. As such, they are immediately resistant to the operational environment. Because of the difficulty of handling during installation, only soft rubber linings are used for this purpose.

Rubber Coatings and Linings

E. Bud Senkowski and Kenneth B. Tator, KTA-Tator, Inc.

Rubber Lining Application

Once the proper type of rubber for a given service is chosen, it could be hung loosely similar to a bag in a tank. More commonly, the lining is made to conform and attach to the material it is protecting by applying it in five basic steps:

1. Prepare the surface for rubber application, usually by solvent cleaning and blast cleaning to remove all contamination and to roughen the surface for better adhesion.
2. Apply the adhesive system to the surface to be lined. The adhesive may be a single coat or a multicoat system.
3. Apply cut-to-fit rubber sheets to the surface, using rollers and stitchers to press out air pockets and to press the sheet into the adhesive.
4. Cure, or vulcanize, the rubber lining by steam in an autoclave, exhaust steam, or by chemical application to the rubber surface.
5. Inspect visually for bubbles or blisters and for pinholes, using a high-voltage holiday (spark) detector.

The tools of the trade are shown in Fig. 4.

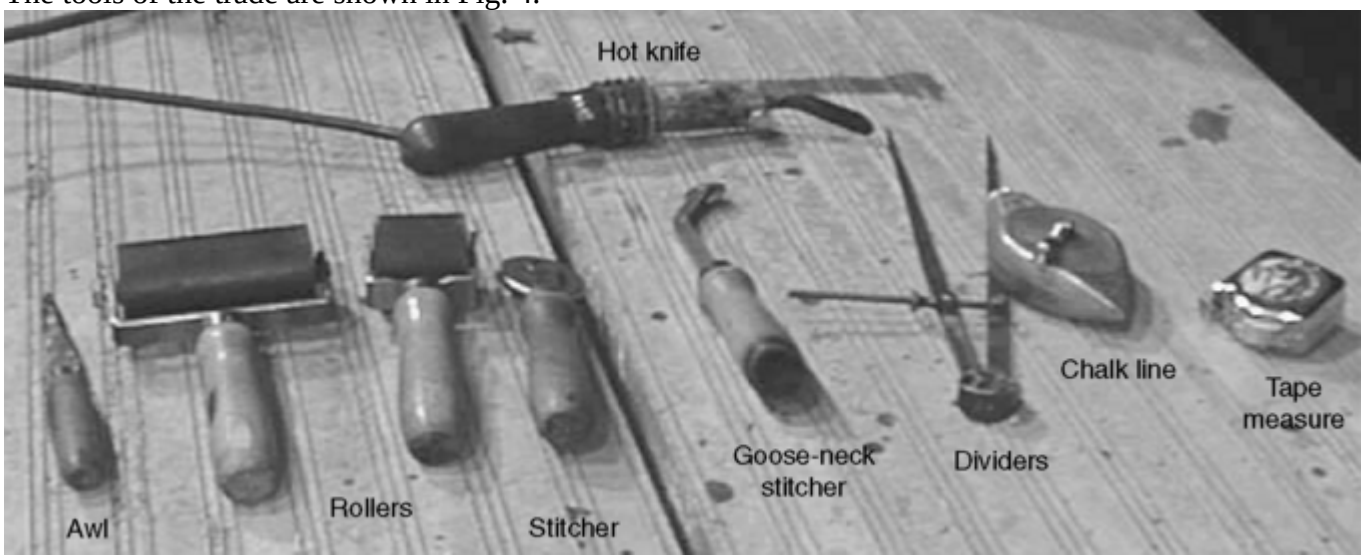

Fig. 4 Typical hand tools needed for custom installation of rubber lining. Courtesy of Blair Rubber Company, Akron, OH

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Joints are usually necessary in lining work, because many sheet rubber materials are supplied in widths up to only 1.22 m (48 in.). Five methods of construction are typically used to join rubber panels, with the selection determined by the type of elastomeric used (Ref 9):

- *Butt joint:* a joint where the two rubber panels are laid edge to edge without any tapered mating surface. Butt joints are usually covered with an additional cap strip (Fig. 5).
- *Lap joint:* a joint where one rubber panel overlays the next. A minimum overlap of 50 mm (2 in.) is recommended at the joint (Fig. 5, 6).
- *Skive joint:* a joint where the edges of the rubber panels interface at an angle through their thickness. Skives should be cut at a 45° angle.
- *Closed skive joints:* a joint where a reverse 45° angle cut is made between the adjoining rubber panels. The reverse skive is the recommended joint for all rubber panels. It is required whenever a multilayer rubber sheet containing a tie gum is used. The reverse cut allows the installer to stitch down the cut edge, so that the tie gum is protected from chemical attack.
- *Stitching:* a method of joining two pieces of uncured rubber. It uses a hand-held tool called a stitching roller. The tool is a narrow wheel with a serrated edge that applies a continuous line of localized compression points to drive the rubber panel into the adhesive layer.

Joint construction should comply with both the specification and the manufacturer's recommendations for the rubber product used in the installation.

Inspecting Rubber Lining Work

Inspection Before Lining. Surfaces to be covered with rubber should be cleaned by abrasive blasting to achieve a cleanliness equivalent to Steel Structures Painting Council specification SSPC SP-5, “White Metal Blast Cleaning” (Ref 10). The cleaned surfaces should have a minimum surface profile of 2 mils. The surfaces to be coated should be free of all oil, grease, mill scale, rust, corrosion products, oxides, or other foreign matter. Sharp edges and corners and weld splatter that could damage the liner must be removed. Primer should be applied immediately after cleaning and before any visible surface oxidation has occurred. Precautions must also be taken to avoid condensation when applying primers and cements to metallic surfaces. No operations should be conducted when the metal temperature is within 3 °C (5 °F) of the dew point.

Inspection during Lining Operations. The installation of a rubber lining system involves a series of steps. Each step requires surveillance to ensure that the specification representing the manufacturer's recommendations is being followed. Liquid primers, used to prepare the metal surface, and liquid cements, used to create an adhesive bond at the metal-rubber and rubber- rubber interfaces, are generally applied by hand brushing. It must be verified that the primers and cements specified for the rubber system, substrate, and service conditions being encountered are being used. Separate brushes and rollers should be maintained for each type of primer and cement used in the installation. In this work, the sequence of application, drying time, and selection of the mating surfaces is critical to the success of the work. The manufacturer's recommendations should be enforced diligently.

After the rubber sheet is applied to the cured cement, it must be rolled tightly against the metal to remove any trapped air and to ensure intimate contact across the metal-rubber joint. Joints should be examined to verify that the seams are straight and that all edges are stitched down tightly.

Inspection Before Cure. Immediately following the application of the rubber to the metallic surfaces, the lining should receive an inspection to ensure that the following parameters have been met:

- The lining should be checked to assure that the physical dimensions of protected surfaces and the thickness of linings comply with the requirements of the specification. Modifications are more easily made before the system has been cured (vulcanized). Unacceptable areas should be marked with chalk to indicate the need for corrective action.
- Prior to vulcanization, all lined surfaces should be inspected for blisters, wrinkles, pulls, lifted edges (bond failures), or surface defects. All splices (joints) in the lining system should be inspected for integrity and uniformity. Whenever layered rubber stock is used, stitched-down splices are necessary to protect the tie gum.
- Air trapped under the rubber sheet should be located and removed. Air bubbles can be located by lighting the surface from an oblique angle and looking for shadows cast by the high spots. The air can be released with a hypodermic needle and the site stitched down or patched. This step is especially important when atmospheric cures are used with no applied pressure to force out air or flatten the lining.
- The lining should be examined for pinholes, punctures, and cuts with a high-voltage spark tester (Fig. 7). Both the Rubber Manufacturers Association (Ref 11) and ASTM International (Ref 12) have written

www.iran_mavad.com

مرجع مهندسی مواد و متالورژی

standards for the spark testing of elastomeric sheet linings. High-frequency alternating-current-type spark testers, capable of producing sufficient voltages to achieve proper calibration, should be used. Voltages should comply with those recommended by the rubber manufacturer and will vary with thickness and rubber type. The inspection voltage range for most rubbers is between 10,000 and 15,000 V. Lined tanks must be purged of all volatile vapors and solvents before high-voltage spark testing is applied. Metal filings must not be allowed on the rubber.

Fig. 7 Spark testing for discontinuities. Probe is flexible wire to conform to surface while minimizing physical damage to rubber. Courtesy of Blair Rubber Company, Akron, OH

Postcure Inspection. Following completion of the vulcanization process, the rubber surfaces should be inspected for signs of obvious imperfections. These flaws may take the form of loose splices, trapped air, blisters, and breaks in the lining.

The hardness of the cured rubber should be checked with an appropriate durometer in accordance with a standard test procedure (Ref 13). Durometer (indentation hardness) measurements should cover the entire rubber surface. One reading per 10 m^2 (100 ft^2) of surface should be taken and recorded. The measurements should fall within the tolerances recommended by the manufacturer's specifications for the vulcanized product. Areas of the lining that fall below the manufacturer's tolerances should be isolated and cured through localized exposure to additional hot air or steam.

The retreated rubber surfaces should again be inspected, using the calibrated high-voltage spark tester. Pinholes and flaws located by spark testing should be repaired in accordance with specified procedures and vulcanized through exposure to hot air, steam, or infrared lamps. If cold patches are used, they should receive an appropriate chemically induced cure (Fig. 8).

مرجع مهندسی مواد و متالورژی

Postinstallation Inspection of Rubber Linings. Periodic inspections of rubber linings are usually conducted to determine if there are any flaws or lining anomalies that have developed during the course of operations within vessels, tanks, pipelines, and other lined equipment. Among the parameters that can be investigated are appearance, hardness, and electrical integrity.

Appearance. A visual inspection can be conducted to locate such lining anomalies as blisters, bubbles, open or loose seams and patches, pinholes, or discoloration. In steel tanks, breaks in the lining are often associated with corrosion products that cause localized disbondment and staining.

Hardness is measured by using either the Shore A or Shore D durometer on the cured (vulcanized) rubber system. Durometer measurements can be made to determine if there has been a significant change from the initial rubber hardness recorded after vulcanization and before vessel operation. These could be due to hardening from overheating or softening from exposure to aggressive chemicals.

Electrical Integrity. A high-voltage inspection can be conducted of the rubber-lined surfaces. However, such an inspection should only be made with the concurrence of the rubber manufacturer, using recommended AC or DC voltage levels (Fig. 7). Some rubber linings that have been in immersion or chemical service undergo resistivity changes from absorbed moisture and/ or chemicals. These changes either preclude the use of high-voltage inspection or require reduced voltages.

Material and Installation Costs

Material costs for sheet rubber are in the range of \$32 to 86/m^2 (\$3.00 to 8.00/ft^2) (U.S. dollars in 2003) for 6.35 mm ($\frac{1}{4}$ in.) thick material. Most rubber lining installations use a three-part, four-coat adhesive system that has an additional cost of \$8.60 to 10.76/m^2 (\$0.80 to 1.00/ft^2). Material costs are summarized in Table 5. Rubber lining costs vary according to job location, size, and availability of vulcanization equipment. The shop installation of linings is estimated to be in the range of \$107 to 130/m^2 (\$10 to 12/ft^2), including materials. Field application, with materials, can be expected to be in the range of \$430 to 540/m^2 (\$40 to 50/ft^2). Scrubber (FGD) installations using rubber are typically in the \$300 to 330/m^2 (\$28 to 30/ft^2) range.

Anodic Protection

Carl E. Locke, Jr., University of Kansas

Introduction

ANODIC PROTECTION is one of the more recently developed electrochemical methods of corrosion control. The method was first used to protect plant-sized equipment in the late 1950s and became commercially successful in the early 1970s. It is currently used on a smaller scale than other corrosion control techniques due to the fundamental electrochemistry involved. This article provides a brief history of the technique, discusses anodic protection use, and compares anodic and cathodic protection. A more complete description of all aspects of anodic protection is available in Ref 1.

Anodic Protection

Carl E. Locke, Jr., University of Kansas

History

The scientific principles of passivity, on which anodic protection is based, can be traced to experiments by Faraday and Schöbein in the 19th century (Ref 1). Work by C.D. Edeleanu published in 1954 (Ref 2) triggered further investigations and development at Continental Oil Company. This later work resulted in several installations of anodic protection to control the corrosion of chemical plant equipment (Ref 3, 4, 5, 6). Simultaneous investigations at the Pulp and Paper Institute of Canada led to installation of anodic protection to protect pulp and paper digesters (Ref 7, 8, 9).

Commercialization of anodic protection was begun by Continental Oil Company through license agreements. Independently and simultaneously, Corrosion Services in Canada began commercialization of anodic protection primarily in the pulp and paper industry. Since these early beginnings, several organizations now offer anodic protection equipment and services.

Anodic Protection

Carl E. Locke, Jr., University of Kansas

Anodic Protection Uses

Anodic protection has been used most extensively to protect equipment for storage and handling of sulfuric acid (Ref 10, 11). Several companies advertise their capabilities in serving the sulfuric acid industry with anodic protection (Ref 12, 13, 14, 15). These organizations have applied anodic protection to storage vessels and heat exchangers in the manufacturing process.

Anodic protection has also been applied in the pulp and paper industry. Digesters and storage tanks holding green and white kraft liquors have been protected (Ref 16, 17, 18, 19).

Early in the development of anodic protection, there were attempts to apply it to a wide range of different metal-chemical systems. The pace of those development programs has slackened a bit, particularly in the United States and Canada. A review of the different applications from the 1980s can be found in the literature (Ref 20). Other papers that describe new applications have recently been published (Ref 21, 22).

Anodic protection is used to a lesser degree than the other corrosion control techniques, particularly cathodic protection; see the article “Cathodic Protection” in this Volume. This is because of the limitations on metal-chemical systems for which anodic protection reduces corrosion. In addition, it is possible to accelerate corrosion of the equipment if proper controls are not implemented. The understanding of anodic protection is not as widespread as for other techniques. Anodic protection does have a place among methods of corrosion control, because it is the most feasible and economical technique for selected applications.

Anodic Protection

Carl E. Locke, Jr., University of Kansas

Comparison of Anodic and Cathodic Protection

Cathodic protection has been used since the middle of the 19th century and has gained widespread acceptance. Anodic protection is sometimes confused with cathodic protection, but the two techniques are fundamentally different. Basically, the difference involves the electrode that is protected; the cathode is protected in cathodic protection, and the anode is protected in anodic protection. Stating this another way, the difference is in how the metal to be protected is polarized. The component requiring protection is made the anode in anodic protection. The metal to be protected is made the cathode in cathodic protection. Protecting an electrode by making it a cathode is easily understood, because reduction reactions occur at cathodes. Oxidation reactions occur at the anode, and thus, it is not so readily apparent that an anode can be protected from corrosion, because oxidation reactions involving metals usually lead to dissolution of the metal.

Cathodic protection is based on using electrochemistry to slow or stifle the corrosion reaction. Direct currents (dc) generated by galvanic metallic couples or external power sources flow in such a direction as to shift the potential of the cathode to a value at which the corrosion reaction does not occur. Other descriptions of cathodic protection state that the currents result in the metal to be protected becoming a cathode over the entire metal surface and shifting the anodic reaction to an external electrode. In principle, any corrosion system can be cathodically protected as long as there is a continuous ionic path between the external anode and the metal to be protected. The only limitations are ones of economics and practicality due to current and voltage requirements.

Anodic protection, like cathodic protection, is an electrochemical method of controlling corrosion but is based on a different electrochemical principle. Anodic protection is based on the phenomenon of passivity. A limited number of metals in a limited number of chemical environments have the property of passivity. The electrochemical nature of achieving passivity requires that the potential of the metal be controlled. This is not necessary for most of the applications of cathodic protection. Current requirements for anodic protection can be much lower than those required for cathodic protection, but this is not the case for all systems.

Anodic Protection

Carl E. Locke, Jr., University of Kansas

Background and Theory

Anodic protection can be used to control the corrosion of metals in chemical environments that exhibit very interesting behavior when subjected to anodic polarization. This behavior can be studied with an experimental setup, which is shown in block-diagram fashion in Fig. 1. When the potential of the working electrode relative to the reference electrode is controlled and shifted in the more anodic (positive) direction, the current required to cause that shift varies. If the current required for the shift has the general behavior with respect to potential shown in the Evans diagram in Fig. 2, the metal is termed active-passive and can be anodically protected. Few systems exhibit this type of behavior. Some metals and solutions that have been found to have active-passive properties and can be anodically protected include:

Metals	**Steels**
	Stainless steels
	Nickel
	Nickel alloys
	Chromium
Solutions	Sulfuric acid
	Phosphoric acid
	Nitric acid
	Nitrate solutions
	Aqueous ammonia
	Organic acids
	Caustic solutions
	Kraft liquors

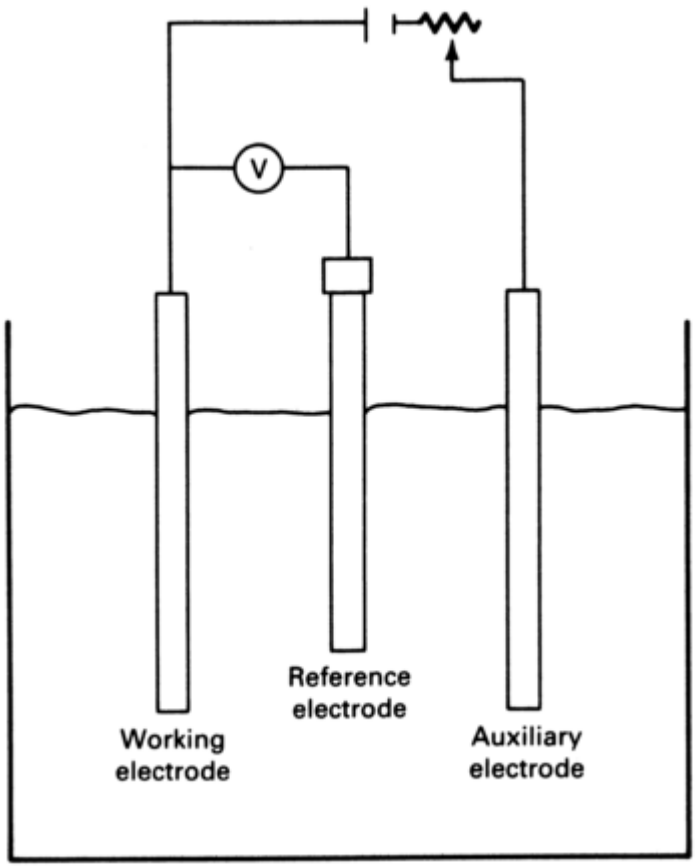

Fig. 1 Schematic of experimental apparatus used for anodic polarization studies. Current flow between the working electrode and the auxiliary electrode forces a shift in potential between the working electrode and the reference electrode. V, voltmeter. Source: Ref 23

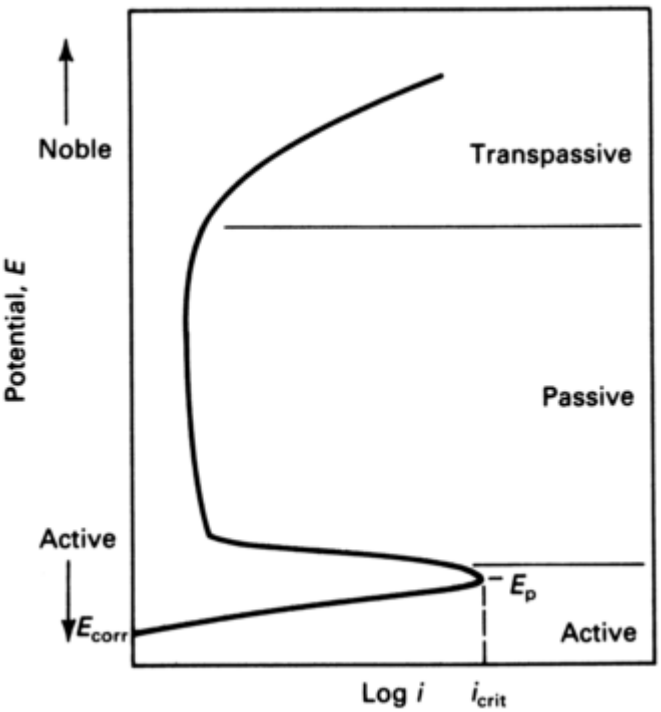

Fig. 2 Schematic anodic polarization curve. Metal-environment systems that have this type of anodic polarization behavior are termed active-passive and can be anodically protected. Source: Ref 23

The corrosion rate of an active-passive metal can be significantly reduced by shifting the potential of the metal so that it is at a value in the passive range shown in Fig. 2. The current required to shift the potential in the anodic direction from the corrosion potential, E_{corr}, is several orders of magnitude greater than the potential at a

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

passive value. The current peaks at the primary passivation potential value, shown as E_p (Fig. 2). The current density required to achieve passivity (protection) is typically a few thousand mA/m^2 (a few hundred mA/ft^2) of wetted area. The current necessary to maintain passivity is usually 10 μA/m^2 (1 μA/ft^2) or less.

This interesting anodic polarization behavior results from the formation of a surface layer on the metal that is both electrically resistive and relatively insoluble in the chemical environment. The metal is termed passive when this layer is formed.

Passivity is the phenomenon responsible for the corrosion resistance of stainless steels. It can be defined in various ways, but a reasonable definition is that passivity is the loss of chemical reactivity experienced by some metals in special environments. These metals and alloys, when passive, behave similar to noble metals. This noble behavior is attributed to the presence of the thin oxide layer on the metal surface. The mechanism of formation and the structure of the passive film have been extensively studied but are still not completely understood.

Passivity can be achieved by alloying and by chemical means in addition to the electrochemical method described in this section. Anodic protection can be used to form the passive film on metals in chemical systems that would normally be corrosive; at other times, anodic protection can be used to maintain the passivity of the metal, so that the process changes do not force the metal to become active and corrode.

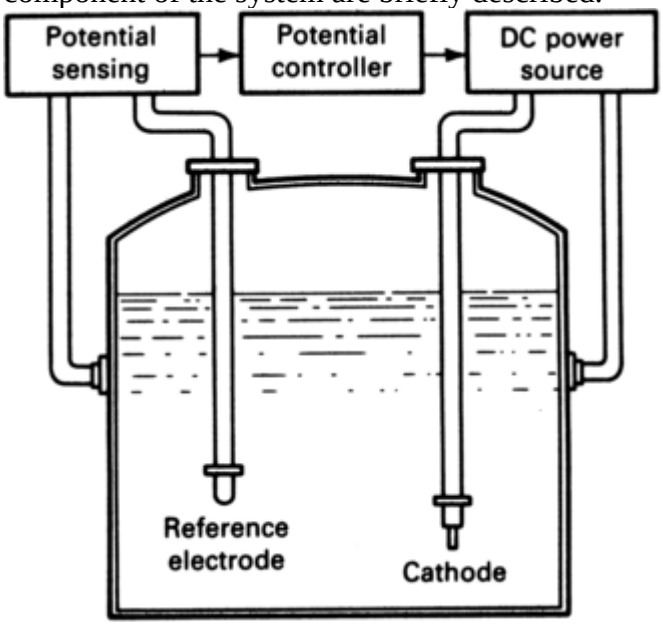
Equipment Required for Anodic Protection

Figure 3 is a schematic diagram of an anodic protection system for a storage vessel. Each of these components has specific requirements that are discussed subsequently. In addition, the various items used for each component of the system are briefly described.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 3 Schematic of an anodic protection system. One or more cathodes, a reference electrode, a potential sensing and controlling circuit, and a dc power supply are required for each anodic protection system. The vessel wall is made the anode of the circuit by current forced between the cathode and the tank wall. The currents are controlled so that the potential of the wall with respect to the reference electrode is shifted and maintained in the passive region (see Fig. 2). Source: Ref 1

Electrodes

The cathode should be a permanent-type electrode that is not dissolved by the solution or the currents impressed between the vessel wall to be protected and the electrode. The cathodes used in most of the initial applications were made of platinum-clad brass (Ref 1, 3, 4, 5, 6). These cathodes were excellent electrochemically but were costly, and the area contacting the solution was limited by the cost. Because the overall resistance between cathode and vessel wall is inversely proportional to the electrode surface area, it is advantageous to use large surface area electrodes. Therefore, other, less costly metals have been used for cathodes in anodic protection systems. These cathode and chemical environment combinations include:

Cathode metal	Environment
Platinum on brass	Various
Steel	Kraft digester liquors
Illium G (Ni Cr Cu)	Sulfuric acid (78–105%)
Silicon cast iron	Sulfuric acid (78–105%)
Copper	Hydroxylamine sulfate
Stainless steel	Liquid fertilizers (nitrate solutions)
Nickel-plated steel	Chemical nickel-plating solutions
Hastelloy C (UNS N10002)	Liquid fertilizers (nitrate solutions), sulfuric acid, kraft digester liquors

UNS, Unified Numbering System

The cathode size is chosen to conform to the geometry of the vessel and to provide as large a surface area as possible. The location of the cathode is not a critical factor in simple geometries, such as storage vessels, but in heat exchangers, it is necessary to extend the electrode around the surface to be protected. Multiple cathodes can be used in parallel to distribute the current and decrease circuit resistance.

Reference electrodes must be used in anodic protection systems, because the potential of the vessel wall serving as the anode must be measured and controlled. The reference electrode must have an electrochemical potential that is constant with respect to time and is minimally affected by changes in temperature and solution composition. Reference electrodes used for anodic protection include:

Reference electrode	Environment
Calomel	Sulfuric acid
Ag-AgCl	Sulfuric acid, kraft liquors, fertilizer solutions
Mo-MoO_3	Sodium carbonate solutions
Bismuth	Ammonia hydroxide
Type 316 stainless steel	Fertilizer solutions, oleum
Hg-$HgSO_4$	Sulfuric acid, hydroxylamine sulfate
Pt-PtO	Sulfuric acid

The reference electrode has been a source of many problems in anodic protection installations, because it is more fragile than the cathode.

Potential Control and Power Supply

Potential Control. As mentioned previously, the potential of the vessel wall to be protected with respect to the reference electrode must be controlled in anodic protection installations. The potential control circuitry has two functions. First, the electric potential must be measured and compared to the desired preset value. Second, a control signal must then be sent to the power supply to regulate the dc current between the cathode and vessel wall. In early systems, this control function was done in an on-off manner because of the high cost of vacuum-tube-based electronic circuitry. The more sophisticated and extremely low-cost circuitry currently available has

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

resulted in all systems having a continuous, proportional-type control. The amount of current forced through the circuitry is that required to maintain the potential at the preset control.
The dc power supplies are similar to the dc rectifiers used for cathodic protection, with one exception. Because of the nature of the active- passive behavior of anodic protection, the currents required to maintain the potential of the vessel wall in the passive range can become very small with time. Some designs of dc power supplies must be specifically modified to lower the minimum current that can be regulated from the power supply.
The packaging of these electronic components occasionally involves special design requirements, because most of the installations are in chemical plants. Explosion-proof enclosures are sometimes required, and chemically resistant enclosures are necessary in other installations.

Anodic Protection

Carl E. Locke, Jr., University of Kansas

Design Concerns

Design of an anodic protection system requires knowledge of the electrochemical parameters of the metal-solution system, the geometry of the equipment, any special operational conditions, and the special requirements of the environment around the system. The electrochemical parameters of concern are the potential at which the vessel must be maintained for corrosion protection, the currents required to establish passivity, and the solution conductivity. The electrode potential can be determined directly from the polarization curve. Currents needed to establish and maintain passivity can be estimated from the laboratory polarization data, but they are time dependent. Variation of the current with respect to time must be estimated. Empirical data available from field installations are the best source of this information (Ref 1).
Solution conductivity is an important component of the total circuit resistance. The solution conductivity is usually sufficiently low that the circuit resistance is controlled by the cathode surface area. The power requirements for the dc power supply should be as low as possible to reduce operating costs.

Anodic Protection

Carl E. Locke, Jr., University of Kansas

Applications

Anodic protection has been used for storage vessels, process reactors, heat exchangers, and transportation vessels. The largest number of storage tanks and other equipment under anodic protection are those used in handling sulfuric acid. Anodic protection has been successful in preserving product quality through reduction of metal pickup by the solution, in extending the useful life of the vessels, and allowing the use of lower-cost alloys. Examples of these applications are given as follows.

Storage Vessels. Storage of sulfuric acid in strengths of 93% and above in low-carbon steel has met with some success in terms of vessel life. Anodic protection has been successful in reducing the amount of iron dissolved during storage. This enhances the economic worth of the product, in that pure acid is more valuable than the contaminated acid. Field studies have shown that the iron content of sulfuric acid in concentrations of 93% and above increases at rates of 5 to 20 ppm per day of storage, depending on the concentration, vessel size, acid residence time, and storage temperature (Ref 1). Several anodic protection systems have been successful in reducing the rates of iron pickup to 1 ppm or less per day (Ref 1, 11, 12, 13). The level of purity of the acid has been sufficient to meet market demands for low-iron-content acid.

Tanks constructed since the 1970s have been made with steel containing low amounts of copper. Steel with low copper content corrodes readily in sulfuric acid (Ref 24). Anodic protection of vessels made of this low-copper steel has been successful in lowering the corrosion rate by a factor of 4 to 5, and vessel life has increased accordingly.

Hydrogen gas is produced as a by-product of acid corrosion. This gas can damage steel tanks, particularly in the upper half of the manhole area of a storage vessel. This damage is caused by the gas streaming up the manhole and disrupting the solid corrosion product on the surface of the vessel, thus grooving the vessel. Anodic protection reduces the corrosion reaction and also the by- product evolution of hydrogen. This accompanying hydrogen grooving damage is thus prevented by anodic protection (Ref 11).

Heat Exchangers. A large market has developed for anodically protected heat exchangers, which are used in the manufacturing process for sulfuric acid. These stainless steel exchangers replace cast iron coolers that were normally used several years ago. Shell and tube, spiral, and plate-type exchangers have been sold complete with anodic protection as an integral part of the equipment (Ref 1, 10, 11, 12, 13, 15, 20). Sulfuric acid of 96 to 98% concentration at temperatures up to 110 °C (230 °F) has been handled in type 316 stainless steel exchangers by the use of anodic protection. Corrosion rates have been reduced from unprotected rates of more than 5 mm/yr (200 mils/yr) to less than 0.025 mm/yr (1 mil/ yr). Cost savings have been substantial because of extended equipment life in comparison with that of cast iron coolers. Higher-purity acid can be produced by using the anodically protected heat exchangers. Other corrosive liquid systems have also been handled in anodically protected heat exchangers (Ref 1, 21).

Transportation Vessels. Anodic protection has been applied to tank trucks, railroad cars, and barges carrying sulfuric acid. These applications were installed to maintain the purity of the acid and to extend the life of the vessels (Ref 10, 20, 25).

Pulp and Paper Mills. One of the initial practical applications of anodic protection was to protect batch digesters in a kraft process paper mill (Ref 7, 8, 9). Several commercial applications of anodic protection now exist to protect batch and continuous digesters and kraft liquor storage tanks (Ref 12, 14, 16, 17, 18, 19).

Galvanic Cathodes. The potentials of metals have been maintained in the passive region by using the galvanic potential differences of metals to achieve anodic protection. This galvanic method of anodic protection differs from galvanic cathodic protection in that nothing is sacrificed, but protection is achieved.

A titanium pipe has been used to protect a steel vessel containing ammonium hydroxide, and platinum has been used to protect a stainless steel tank containing sulfuric acid (Ref 26, 27). A combination of galvanic and

impressed current protection for an anodic protection system is described in Ref 28. The graphite galvanically supplies sufficient current to maintain protection, but additional current can be supplied from a dc power supply through the graphite electrodes to establish and maintain protection.

Anodic Protection

Carl E. Locke, Jr., University of Kansas

Economics

Economic justification of anodic protection is based on the same factors as in any comparison of corrosion control methods. Anodic protection is an alternative for linings or higher alloys in the storage of sulfuric acid, for example. Because an anodic protection system has some basic requirements (electrodes, potential controller, and power supply) that are independent of tank size, anodic protection is more economically feasible for larger tanks (Ref 1, 11).

Anodically protected heat exchangers used in sulfuric acid manufacturing have been shown to reduce maintenance costs by almost 95% (Ref 28).

Many other applications of anodic protection have also been found to be economically feasible, by using standard methods of engineering economic comparisons.

The increase in the number of companies supplying anodic protection commercially speaks to the positive economic position of anodic protection. After close to 50 years of field applications, anodic protection has been established as a viable, effective, economical method of corrosion control.

Cathodic Protection

Robert H. Heidersbach, Dr. Rust, Inc.

Introduction

CATHODIC PROTECTION is an electrochemical means of corrosion control in which the oxidation reaction in a galvanic cell is concentrated at the anode, which suppresses corrosion of the cathode in the same cell. Figure 1 shows a simple cathodic protection system. The steel pipeline is cathodically protected by its connection to a sacrificial magnesium anode buried in the same soil electrolyte.

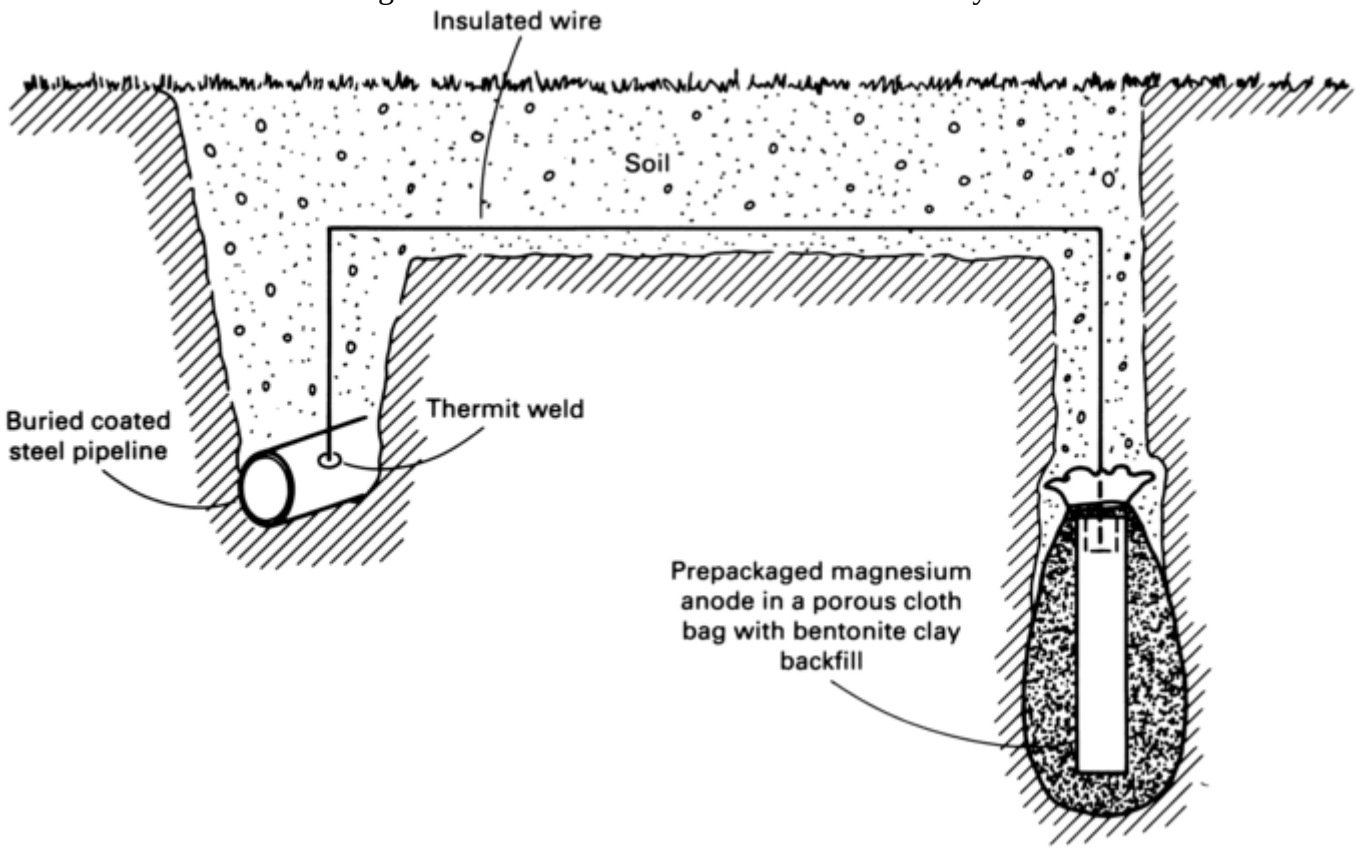

Fig. 1 Cathodic protection of buried pipeline using a buried magnesium anode

Cathodic protection differs from anodic protection. In cathodic protection, the object to be protected is the cathode; however, in anodic protection, the object to be protected is the anode. Anodic protection can be used on a limited number of alloys in certain restricted environments, but cathodic protection can, in principle, be applied to any metal. In practice, cathodic protection is primarily used to protect carbon steel structures. Cathodic protection allows carbon steel, which has little natural corrosion resistance, to be used in such

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

corrosive environments as seawater, acid soils, salt-laden concrete, and many other corrosive environments. Properly designed and maintained cathodic protection systems can prevent corrosion indefinitely in these environments.

Cathodic protection was first suggested by Sir Humphrey Davy in the 1820s as a means of controlling corrosion on British naval ships (Ref 1). It became common in the 1930s on the Gulf Coast of the United States, where it was used to control the corrosion of pipelines carrying high- pressure natural gas and petroleum products. Much of the terminology of cathodic protection still relates to corrosion control of onshore buried steel pipelines.

Virtually all modern pipelines are coated with an organic protective coating that is supplemented by cathodic protection systems sized to prevent corrosion at gaps or holidays in the protective coating. This combination of protective coating and cathodic protection is used on virtually all immersed or buried carbon steel structures, with the exception of offshore petroleum- production platforms and reinforced-concrete structures.

Offshore platforms are usually uncoated, but cathodically protected. Cathodic protection causes changes in the chemistry of seawater near the protected structure, and this causes the precipitation of a natural coating on the structure that reduces the need for cathodic protection current. Concrete structures normally rely on the protection of the concrete cover to prevent the corrosion of embedded steel. When corrosion of embedded steel occurs because of a loss of this protection due to ingress of moisture, cathodic protection is sometimes used to extend the life of the already deteriorated structure.

Fundamentals of Cathodic Protection

Table 1 shows the theoretical electrochemical potentials obtained by pure metals in 1 *N* solutions of their own ions. More detailed electromotive series are described in most chemistry or corrosion textbooks (Ref 2) and in the article “Electrode Potentials” in this Volume.

Table 1 Standard electromotive force series for selected metals

Metal-metal ion equilibrium (unit activity)	Potential at 25 °C (77 °F), V
Noble or cathodic (protected)	
Ag/Ag^{+}	+0.80
Cu/Cu^{2+}	+0.34
H_2/H^{+}	(reference) 0
Fe/Fe^{2+}	-0.44
Zn/Zn^{2+}	-0.76
Al/Al^{3+}	-1.66
Mg/Mg^{2+}	-2.36
More active or anodic	

Figure 2(a) shows two of these metals—iron and zinc—separately immersed in a weak mineral acid. The chemical reactions that occur in Fig. 2(a) are:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$Fe \rightarrow Fe^{2+} + 2e^-$$

Oxidation reaction

$$2H^+ + 2e^- \rightarrow H_2$$

Reduction reaction

$$2H^+ + Fe \rightarrow Fe^{2+} + H_2$$

Net reaction

$$Zn \rightarrow Zn^{2+} + 2e^-$$

Oxidation reaction

$$2H^+ + 2e^- \rightarrow H_2$$

Reduction reaction

$$2H^+ + Zn \rightarrow Zn^{2+} + H_2$$

Net reaction

Both metals corrode, and both oxidation reactions are balanced by an equal reduction reaction, which in both cases involves the liberation of hydrogen gas from the acid environments. The two corrosion reactions are independent of each other and are determined by the corrosivity of hydrochloric acid on the two metals in question.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

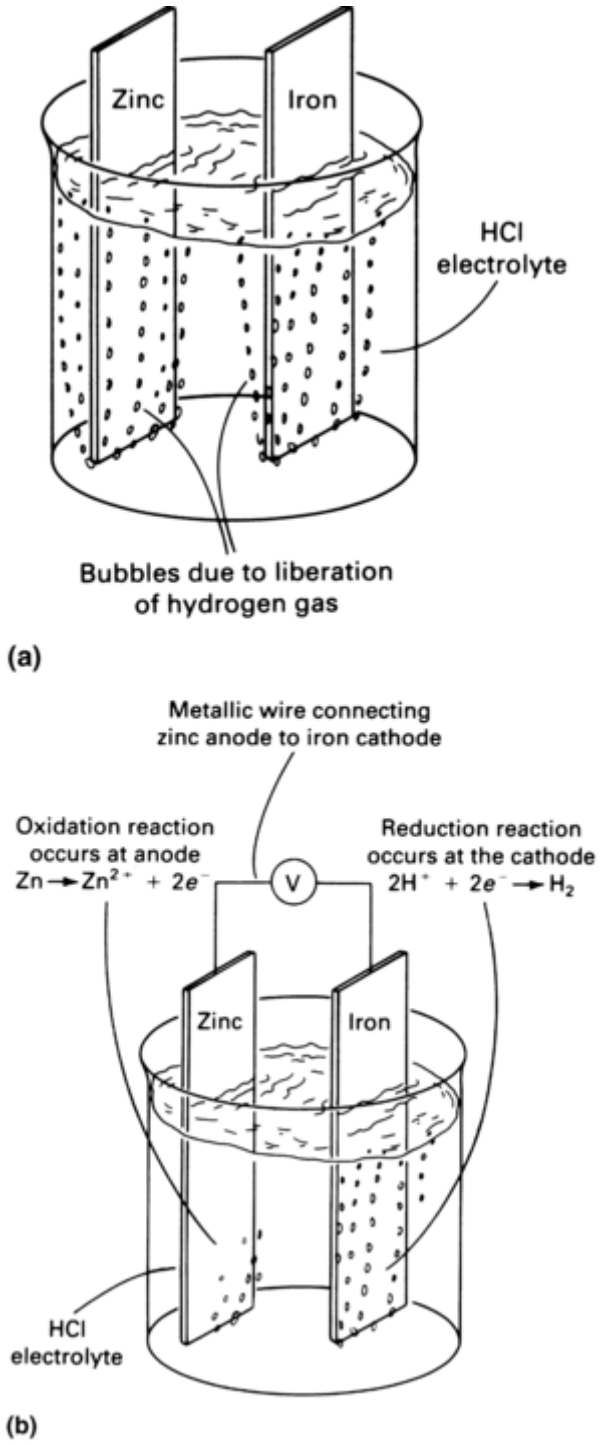

Fig. 2 Iron and zinc in hydrochloric acid. (a) Corrosion of zinc and iron in hydrochloric acid. (b) Cathodic protection of iron by zinc in hydrochloric acid

If the two metals were immersed in the same acid and electrically connected (Fig. 2b), the reactions would become:

$$Zn \rightarrow Zn^{2+} + 2e^{-}$$

Oxidation

$$2H^{+} + 2e^{-} \rightarrow H_2$$

Reduction

Almost all of the oxidation reaction (corrosion of zinc) has been concentrated at the zinc electrode (anode) in Fig. 2(b), and almost all of the reduction reaction (hydrogen liberation) has been concentrated at the iron electrode (cathode). The oxidation of the zinc anode in Fig. 2(b) is much faster than that in Fig. 2(a). At the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

same time, most of the corrosion of iron in Fig. 2(a) has stopped in Fig. 2(b). The zinc anode (Fig. 2(b) has been used to cathodically Open cross-sectional areaprotect the iron cathode.

Of course, some corrosion of the iron may still occur; whether or not this happens depends on the relative sizes of the zinc and iron electrodes. Some reduction of hydrogen may still occur on the zinc anode. The anode is the electrode at which a net oxidation reaction occurs, whereas cathodes are electrodes at which net reduction reactions occur. With proper design, the oxidation rate on the cathode will be suppressed to the point at which it becomes negligible and effective cathodic protection has been achieved.

All cathodic protection systems require an anode, a cathode, an electric circuit between them, and an electrolyte. Cathodic protection will not work on structures exposed to air environments. Air is a poor electrolyte, and it prevents current from flowing from the anode to the cathode.

The reduction reactions that accompany cathodic protection are normally the reduction of dissolved oxygen from the water surrounding the cathode. All reduction reactions result in an increase of the alkalinity (pH) in the electrolyte near the cathode surface. This increase in alkalinity causes the precipitation of mineral deposits on the cathodically protected structure. Figure 3 shows these deposits on an offshore platform.

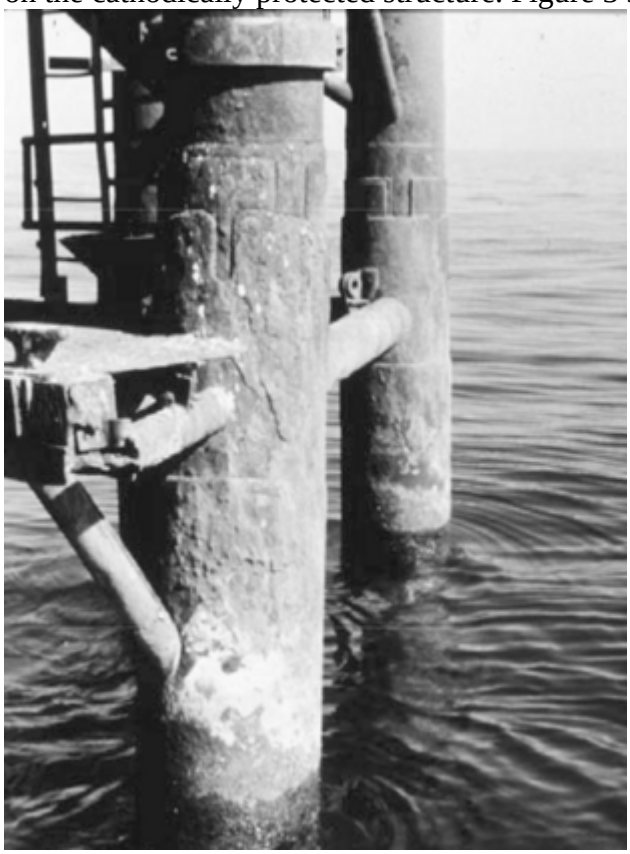

Fig. 3 Calcareous deposits in the tidal region of an offshore platform. Courtesy of NACE International

The presence of these deposits means that protective coatings applied to buried structures must be resistant to alkaline (high pH) environments. Offshore oil and gas platforms are usually not coated (Fig. 4) and rely on the presence of these deposits to partially cover the submerged metal surface and reduce the electrical current demand for cathodic protection. These minerals are more soluble in cold waters than in warm waters, which has led to problems where inadequate cathodic protection currents were applied to offshore structures in cold waters.

Cathodic Protection

Robert H. Heidersbach, Dr. Rust, Inc.

Types of Cathodic Protection

There are two types of cathodic protection: sacrificial-anode (passive) systems and impressed-current (active) systems. Sacrificial-anode systems are simpler. They require only a material anodic to the protected steel in the environment of interest (Fig. 1).

Figure 5 shows an impressed-current system used to protect a pipeline. The buried anodes and the pipeline are both connected to an electrical rectifier, which supplies direct current (dc) to both. Unlike sacrificial anodes, impressed-current anodes need not be naturally anodic to steel, and in fact they seldom are. Most impressed-current anodes are made from nonconsumable electrode materials that are naturally cathodic to steel. If these electrodes were wired directly to a structure, they would act as cathodes and would cause accelerated corrosion of the structure they are intended to protect. The dc source reverses the natural polarity and allows the materials to act as anodes. Instead of corrosion of the anodes, some other oxidation reaction—that is, oxygen or chlorine evolution—occurs at the anodes, and the anodes are not consumed.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

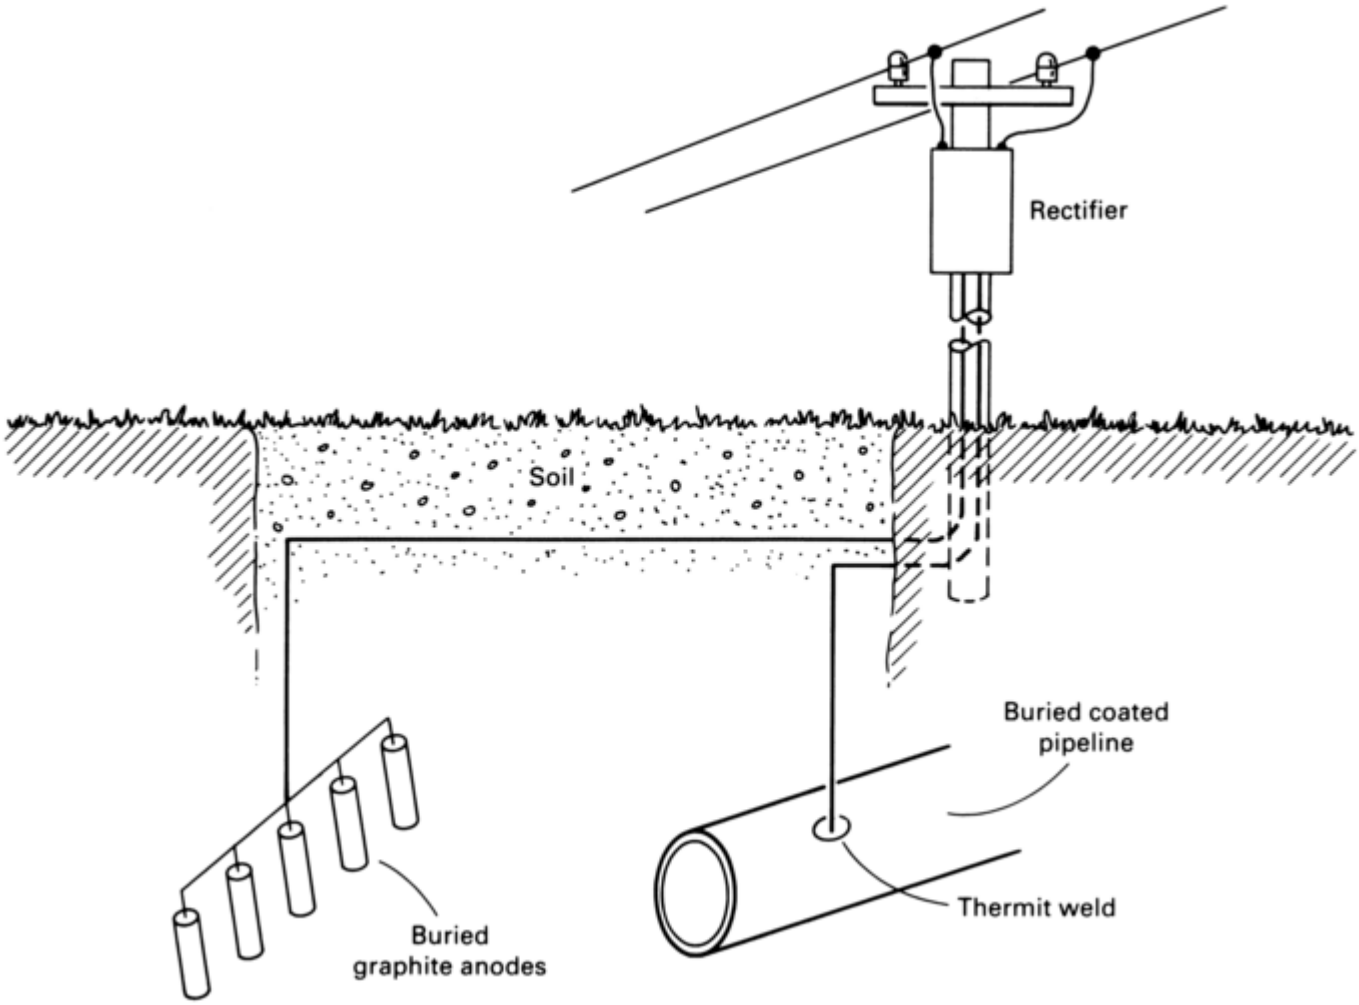

Fig. 5 Impressed-current cathodic protection of a buried pipeline using graphite anodes

In recent years, small steel tanks intended for burial have usually been sold with prepackaged sacrificial anodes (Fig. 6). These systems do not require a cathodic protection system, but it is important to install them correctly. Some of these anodes, either zinc or magnesium, may be inappropriate for the local soil-resistivity conditions.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 6 Underground storage tanks with prepackaged sacrificial anodes

In sacrificial-anode systems, the maximum voltage between anode and cathode is approximately 1 V, depending on the anode material and the specific environment. Impressed-current systems can use larger voltages; this allows anodes to be located more remotely, producing more efficient current-distribution patterns on the protected cathode. These larger voltages are also useful in low-conductivity environments, such as freshwater and concrete, in which sacrificial anodes would have insufficient power.

Larger voltages can have disadvantages. It is possible to overprotect high-strength steels and cause hydrogen embrittlement. Coating debonding is also possible (Fig. 7). Debonding occurs when moisture penetrates a coating and hydrogen is generated at the metal surface beneath the coating. The gas can accumulate until pressure causes blisters or cracks in the protective coating. Once this coating damage occurs, the demands for protective current increase and may exceed the capabilities of the system.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

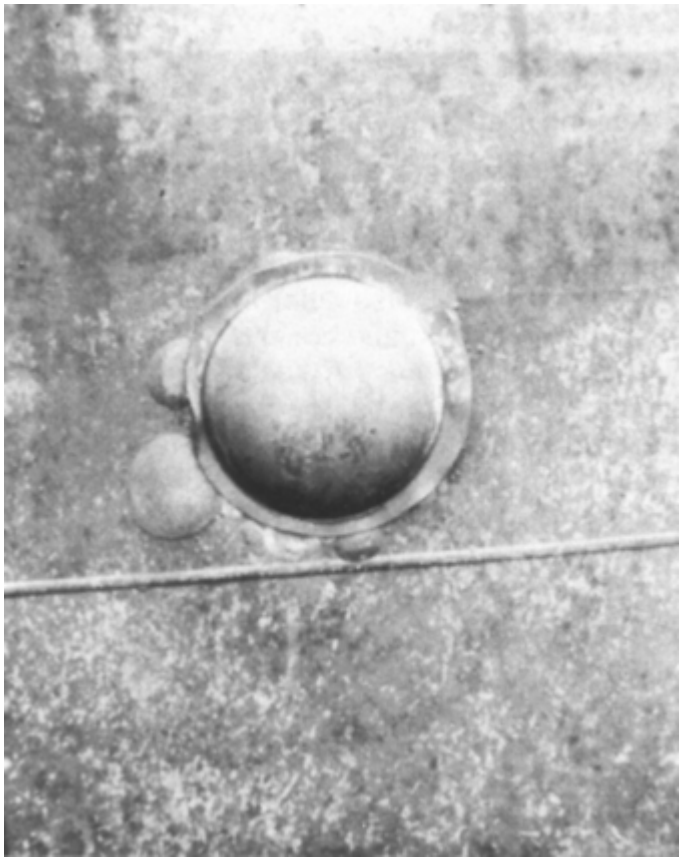

Fig. 7 Debonded organic coating near a high-silicon cast iron button anode

Aluminum is especially vulnerable to overprotection. All cathodic reactions cause the immediate environment to become somewhat more basic (less acidic). Unlike steel, aluminum is an amphoteric metal with increased corrosion susceptibility in acids and bases. If the environment around an aluminum structure becomes too basic, it will corrode at an accelerated rate. Thus, the cathodic protection of aluminum can cause cathodic corrosion if too much current is supplied to the cathode.

Table 2 lists some of the important differences between impressed-current and sacrificial-anode cathodic protection systems. Selection of a cathodic protection system usually depends on trade- offs among the advantages of each type of system. For example, most offshore petroleum- production platforms use sacrificial anodes because of their simplicity and reliability, even though the capital costs would be lower with impressed-current systems.

Table 2 Comparison between sacrificial- anode and impressed-current cathodic protection systems

Sacrificial-anode system	Impressed-current system
Simple	Complex
Low/no maintenance	Requires maintenance
Works best in conductive electrolytes	Can work in low-conductivity electrolytes
Lower installation costs for smaller installations	Remote anodes possible
Higher capital investment for large systems	Low capital investment for large systems
	Can cause the following problems:
	Stray current corrosion

www.iran_mavad.com

Cathodic Protection

Robert H. Heidersbach, Dr. Rust, Inc.

Cathodic Protection Criteria

Catastrophic corrosion failures such as the one shown in Fig. 8 have become less common in recent years as the implementation of cathodic protection on buried pipelines and other structures has become a standard practice in many countries.

Fig. 8 Catastrophic pipeline failure involving corrosion. Courtesy of *Corrosioneering—the On-line Corrosion Journal*

The criteria for cathodic protection have become controversial in recent years, because of two situations: first, a lack of understanding of the basis for the original criteria for protection of steel and cast iron; second, the several notable apparent corrosion failures of structures that were allegedly cathodically protected. It is likely that the criteria discussed in the paragraphs that follow will continue to be discussed and changed in the future.
Origins of Cathodic Protection Criteria. In the early days of cathodic protection there were several ideas on how cathodic protection could be achieved:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- Maintain uniform potentials on a structure, thus eliminating galvanic cells between different regions on the same structure.
- Shift the potential from a native, or unprotected potential, to a more negative protected potential (-50 to -300 mV)
- Shift the potential of a structure to a potential at which current would flow into the structure instead of away from it.

While all of the above criteria had advocates, and the merits of each were actively debated, it became apparent that each had serious limitations. Any complex structure such as a cross- country pipeline would invariably have different potentials depending on variables in the environment. Shifting a potential from a native, or unprotected, potential would require long-term records of what the unprotected potential had been and would also require that the environment remain unchanged over the useful life of the structure. Construction, changes in agricultural practices, and changes associated with shifts from rural to urban environments make the idea of an unchanging native potential relatively unlikely. Measuring current flow onto a structure is difficult to determine and requires trained personnel. A simpler criterion was obviously more desirable.

The -850 mV $Cu/CuSO_4$ Criterion. Many cathodic protection advocates had been using a criterion based on maintaining the potential at -850 mV with respect to a saturated copper/ copper-sulfate electrode (CSE) (Fig. 9). This practice had been used since the 1920s with apparent success (Ref 4, 5). During the time when cathodic protection criteria and standards were discussed, a series of studies of the native potentials of carbon steel and cast iron became available. These studies were summarized in a report by Romanoff at the U.S. National Bureau of Standards (Ref 4). Table 3 shows the potentials of carbon steel and cast iron in ambient temperature soils throughout North America (Ref 5). Based on these data, it is apparent that any carbon steel or cast iron structure that is at a potential of -850 mV is polarized by at least 50 mV. Since a shift of -70 mV will usually reduce the corrosion rate by a factor of 10 (Ref 6), it is obvious that using the -850 mV CSE criterion will limit corrosion of most steels to a small fraction of the corrosion of the same unprotected structure. Most structures at -850 mV will be shifted by hundreds of millivolts, and their corrosion rates will have been reduced to negligible amounts.

مرجع مهندسی مواد و متالورژی

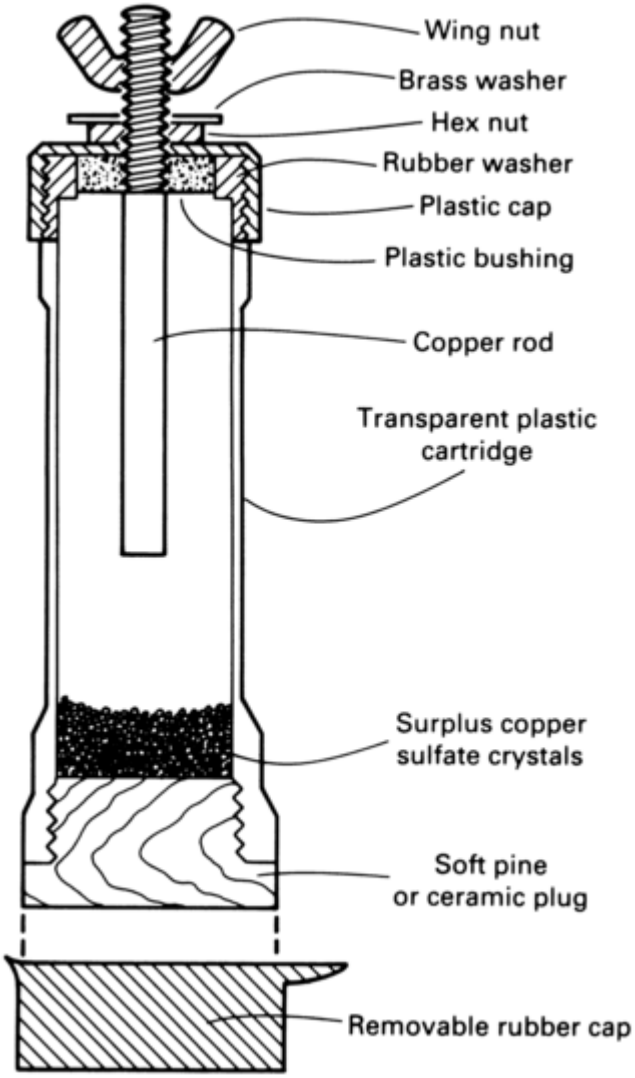

Fig. 9 Copper-saturated copper sulfate reference electrode

Table 3 Potentials of iron and steel in soil

Metal	Potential[(a)], mV
Mild steel (clean and shiny)	-500 to -800
Mild steel (rusted)	-200 to -500
Cast iron (not graphitized)	-500
High-silicon cast iron	-200
Mill scale on steel	-200

(a) Typical potential normally observed in neutral soils, and water, measured with respect to copper sulfate reference electrode. Source: Ref 5

This criterion has been adopted by many organizations worldwide (Ref 6, 7, 8, 9) due to its advantages:

- Technicians can easily learn how to measure this potential.
- Measurements are quick with simple field equipment.
- Historical records of previous measurements are not required.
- Potential is measured while the cathodic protection current is being applied. For many structures, it is difficult if not impossible to disconnect the cathodic protection current, so a “current-off” potential cannot be measured.

There is a disadvantage in that current-resistance (*IR*) losses must be considered.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Alleged Failures of Cathodic Protection Criteria. Unfortunately, a limited number of corrosion failures have been reported on structures where the -850 mV criterion has allegedly been maintained. Possible reasons for this discrepancy between predicted and actual performance are: (1) the potential was inaccurately measured, and (2) the conditions were not appropriate for this criterion. Several of the alleged failures of the -850 mV criterion were due to the presence of debonded organic coatings that made measurement of the potential of the steel underneath the debonded coating impossible.

Other problems have been identified on elevated-temperature pipelines and in anaerobic conditions. Both of these conditions have the effect of altering the polarization characteristics of cathodes, and it has become common practice to use -950 mV CSE as the protection potential in these conditions (Ref 9).

The Instant-Off Cathodic Protection Criterion. The -850 mV CSE criterion with the cathodic protection applied does not compensate for the *IR* potential drop that can be significant, especially in high resistivity environments. In recent years it has become common to apply an "instant-off" criterion, termed a "polarized potential" in the 1996 version of NACE RP0169 (Ref 7). The potential of the structure is measured immediately after the current is off and the voltage decays. The idea is to require that the structure surface be at -850 mV after the *IR* drop at the electrode surface is considered. The justification for this idea has been debated, but it becomes a more conservative criterion than the -850 mV with the current applied criterion. Unfortunately, the definition of "instant off" is subject to debate. Many structures, especially those with galvanic anodes, do not lend themselves to turning off their cathodic protection systems, so the applicability of this criterion is limited.

Other Criteria. In conditions where using one of the -850 mV criteria would require too much current it is common to use a -100 mV cathodic potential shift as the inspection criterion (Ref 6, 10, 11, 12, 13). It is sometimes impossible to measure the potential of a cathode surface. In these circumstances, a Tafel extrapolation (*E* log *i*) technique is commonly used (Fig. 10) (Ref 14). Other criteria such as a net current flow onto a structure and the use of test probes are also used, although they are no longer included in recent versions of NACE RP0169.

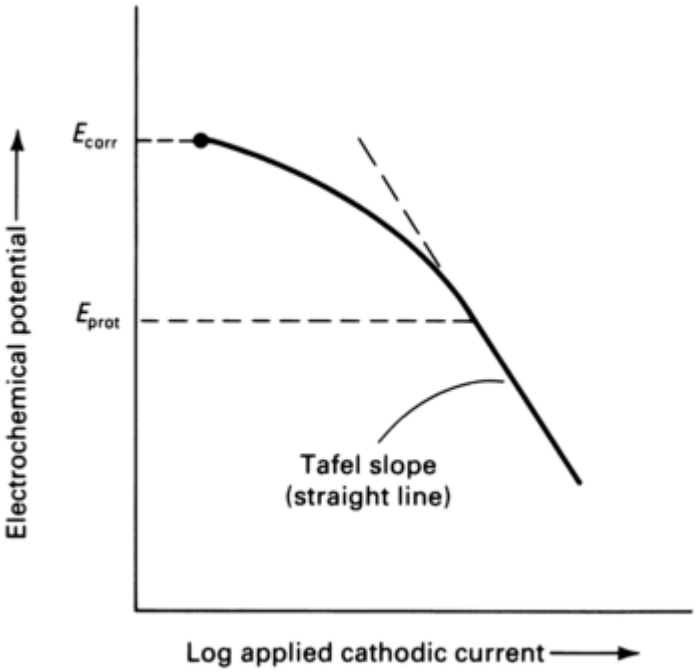

Fig. 10 Tafel slope criterion for determining cathodic protection (Ref 14). See the article "Kinetics of Aqueous Corrosion" in this Volume for detailed explanations of these diagrams.

Copper sulfate electrodes can become contaminated by seawater, so -800 mV versus silver/silver chloride is commonly used as the protection potential for marine structures. Both criteria are the same; only the reference electrode material is different.

Note that the sign convention used in this article agrees with that used by the U.S. cathodic protection industry. Much of the scientific and international literature uses the opposite sign convention for positive and negative electrical terminals. Regardless of the sign convention chosen, the important point is that electrons should flow into the protected structure from the external circuit.

Cathodic Protection

Robert H. Heidersbach, Dr. Rust, Inc.

Anode Materials

Different requirements for sacrificial anodes and impressed-current anodes lead to the use of different materials for these applications. Sacrificial anodes are anodic to steel in the environment of interest and must corrode reliably, avoiding passivation. Impressed-current anodes can be cathodic to steel, but they must have low consumption rates when connected to a cathodic protection power source.

Sacrificial Anodes

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Commercial sacrificial anodes include magnesium, zinc, and aluminum alloys. The energy characteristics of these alloys are given in Table 4.

Table 4 Energy characteristics of sacrificial anode alloys

Alloy	Energy capability		Consumption rate	
	A · h/kg	**A · h/lb**	**kg/A · yr**	**lb/A · yr**
Aluminum-zinc-mercury	2750–2840	1250–1290	3.2–3.0	7.0–6.8
Aluminum-zinc-indium	1670–2400	760–1090	5.2–3.6	11.5–8.0
Aluminum-zinc-tin	920–2600	420–1180	9.4–3.4	20.8–7.4
Zinc	810	370	10.7	23.7
Magnesium	1100	500	7.9	17.5

Magnesium anodes are the only sacrificial anodes that are routinely specified for use in buried-soil applications. Most magnesium anodes in the United States are supplied with a prepackaged bentonite clay backfill in a permeable cloth sack (Fig. 1). This backfill ensures that the anode will have a conductive environment and will corrode reliably. The additional materials are less expensive than the soil-resistivity surveys that would be needed to determine whether the backfill is necessary.

Some magnesium anodes have been used offshore in recent years to polarize the structures to a protected potential faster than zinc or aluminum alloy anodes. Magnesium tends to corrode quite readily in salt water, and most designers avoid the use of magnesium for permanent long- term marine cathodic protection applications. Figure 11 shows a commonly used magnesium anode that controls corrosion on a glass-lined domestic water heater.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

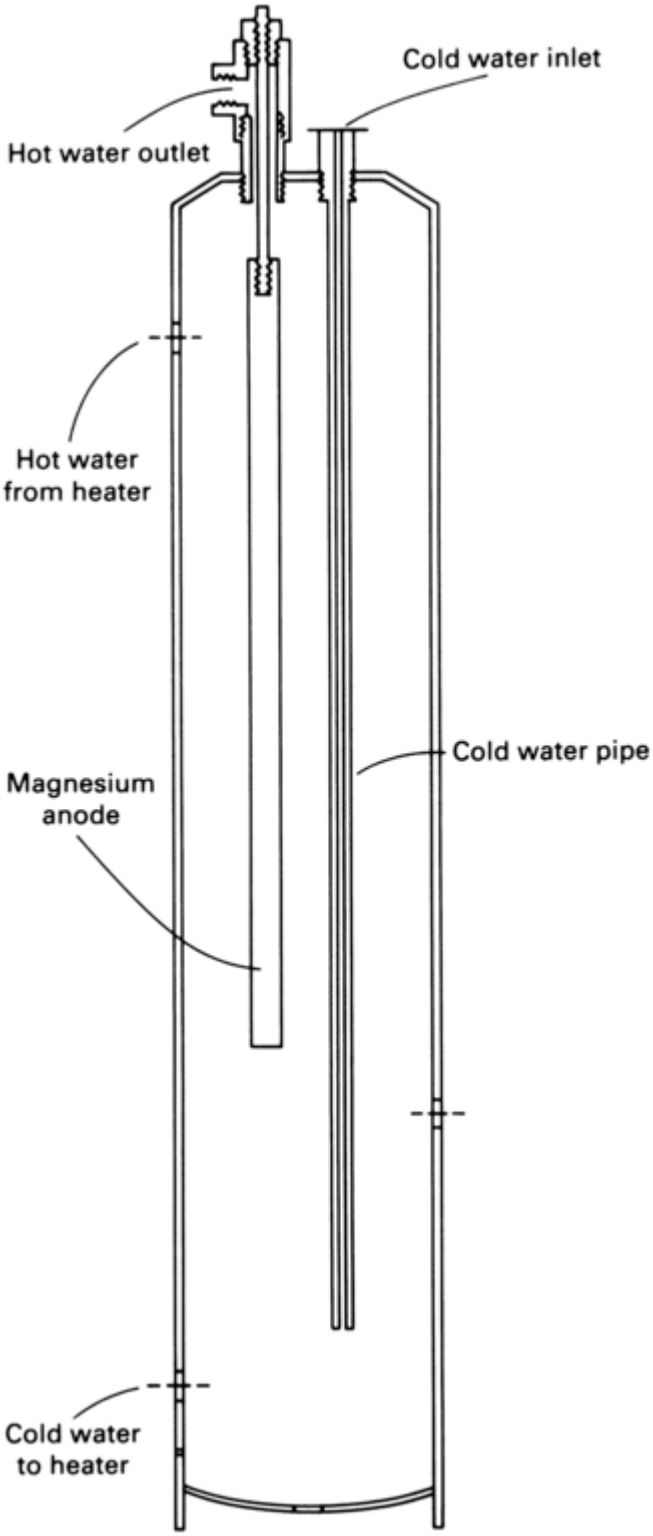

Fig. 11 Magnesium anode used to cathodically protect glass-lined steel water heater

Zinc is used for cathodic protection in freshwater and salt water. Zinc is especially well suited for cathodic protection on ships that move between salt water and harbors in brackish rivers or estuaries. Figure 12 shows zinc anodes on the underside of a small fishing boat. Aluminum anodes would passivate in the harbors and might not work when they return to sea. Zinc anodes are also used to protect ballast tanks, heat exchangers, and many mechanical components on ships, coastal power plants, and similar structures.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

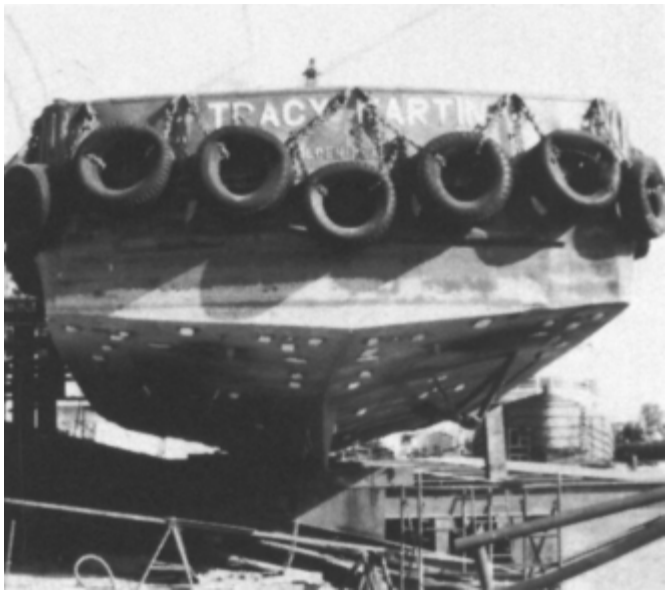

Fig. 12 Zinc anodes on the underside of a fishing boat

The weight of zinc is an advantage for marine pipelines. Bracelet anodes (Fig. 13) are attached at pipe joints to provide ballast and to prevent corrosion in the water-mud environment, in which aluminum might passivate.

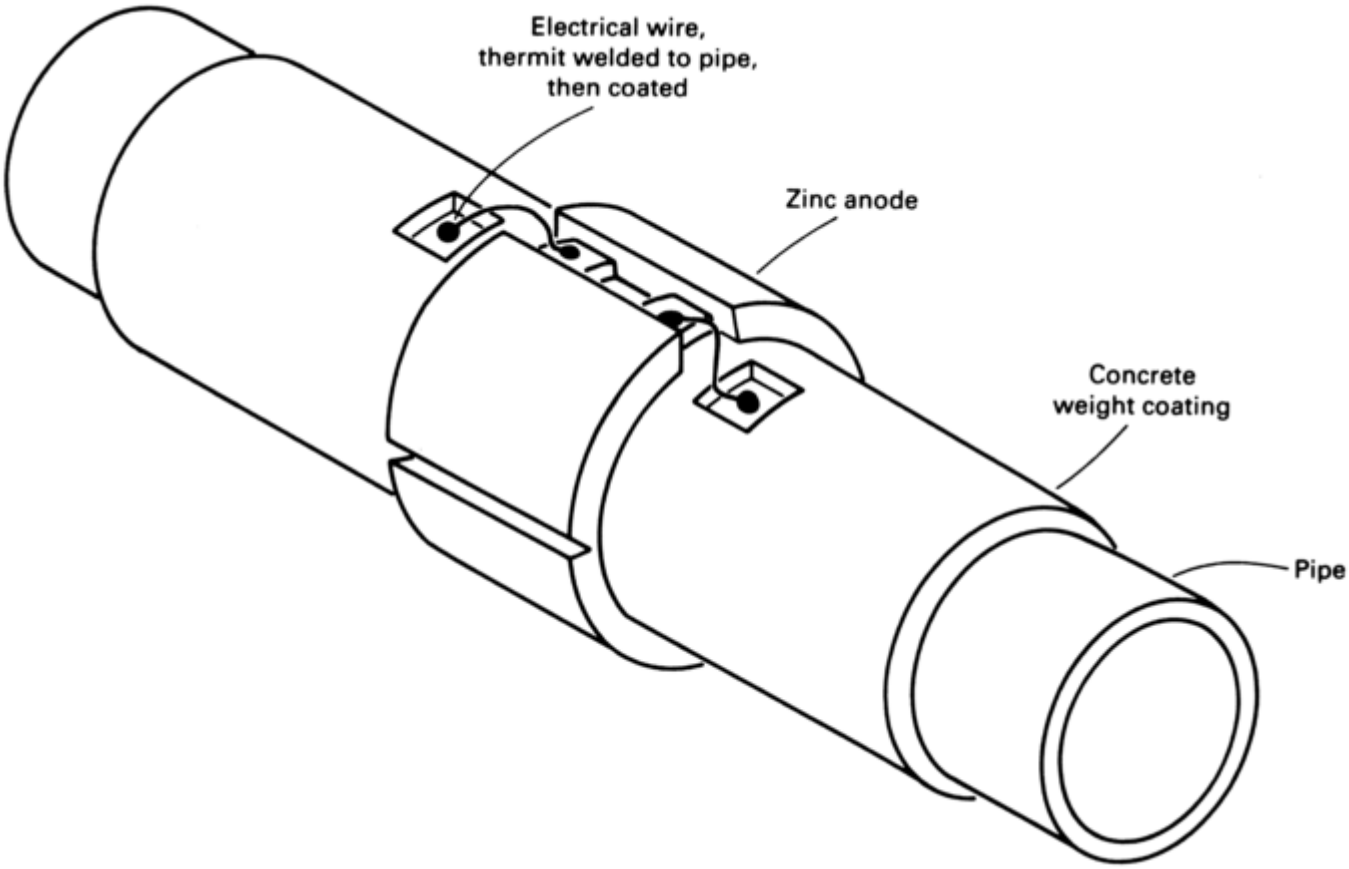

Fig. 13 Zinc bracelet anode at a joint in an offshore pipeline

Aluminum is used on offshore structures where its light weight provides significant advantages. Welded-on aluminum anodes for an offshore platform are shown in Fig. 4 and 14. Aluminum does not passivate in salt water if certain alloying elements, such as tin, antimony, and mercury, are present. Toxicity questions prevent the use of aluminum alloys with mercury additions in U.S. waters.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

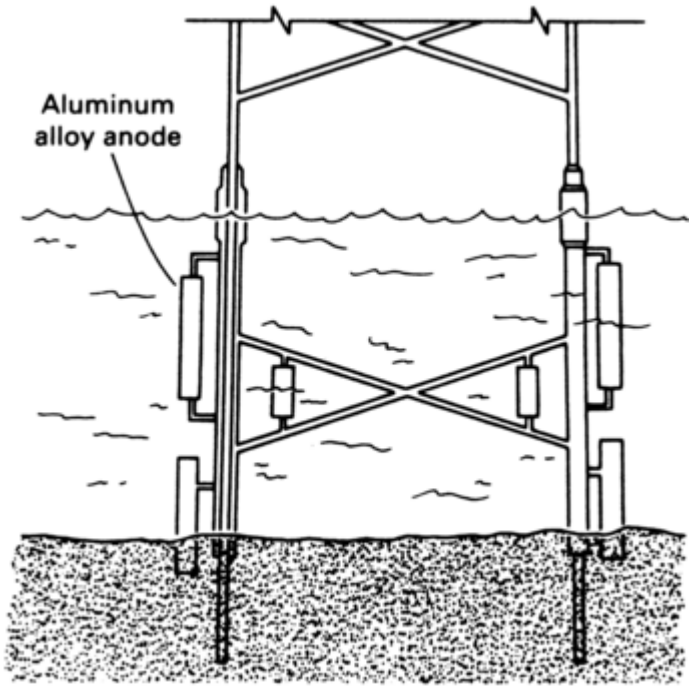

Fig. 14 Welded-on aluminum sacrificial anodes used to protect an offshore platform

Segregation of the alloying elements can lead to localized corrosion, which causes premature failure of the anodes. Figures 15(a) and (b) show examples of aluminum anodes that corroded differently because of differences in foundry practice.

Impressed-Current Anodes

Impressed-current anodes must be corrosion resistant and otherwise durable in the environment in which they are used. Consumption rates for lead alloy, platinum, graphite, and high-silicon cast iron impressed-current anode materials are given in Table 5.

Table 5 Consumption rates of impressed-current anode materials

Material	Typical anode current density		Consumption rate per A · yr
	A/m^2	**A/ft^2**	
Pb-6Sb-1Ag	160–220	15–20	0.045–0.09 kg (0.1–0.2 lb)
Platinum (plated on substrate)	540–1080	50–100	0.006 g (0.0002 oz)
Platinum (wire or clad)	1080–5400	100–500	0.01 g (0.0004 oz)
Graphite	10.8–40	1–4	0.225–0.45 kg (0.5–1.0 lb)
Fe-14Si-4Cr	10.8–40	1–4	0.225–0.45 kg (0.5–1.0 lb)

High-silicon cast iron (Fe-0.95C-0.75Mn- 14.5Si-4.5Cr) is used for onshore cathodic protection applications and in locations where abrasion resistance and other mechanical damage considerations are important. High-silicon cast iron anodes are available in solid rods, tubular form, and various cast shapes in a variety of sizes to meet the demands of specific applications. For example, solid rods range from 30 mm diameter by 230 mm long ($1\frac{1}{8}$ by 9 in.) at 0.45 kg (1 lb) to 115 mm diameter by 1525 mm long (4.5 by 60 in.) at 100 kg (220 lb). The smaller rods are used for protecting underground freshwater storage tanks, and the larger rods are used in more aggressive seawater or ground bed applications. Figure 7 shows a high-silicon cast iron button anode on a navigational lock on the Tennessee River. This anode must withstand collisions with small vessels, trees, rocks, and so on. The coating debonding shown in Fig. 7 is due to improper circuit design and cannot be attributed to the use of high-silicon cast iron anodes. Detailed information on designing impressed-current cathodic protection systems with high-silicon iron anodes is available in Ref 15.

Graphite anodes are extensively used for onshore pipelines where they can be buried in multiple-anode ground beds (Fig. 5). Graphite anodes, which have very low electrode-to-environment resistances, are normally available in 75 mm diameter by 1525 mm long (3 by 60 in.) and 100 mm diameter by 2000 mm (4 by 80 in.) rods. Because of the brittle nature of the material, graphite must be stored and handled carefully.

Polymeric anodes are used to mitigate the corrosion of reinforcing steel in salt-contaminated concrete (Fig. 16). The system consists of a mesh of wirelike anodes, which are made of a conductive polymer electrode material coated onto copper conductors. The conductive polymer not only serves as an active anode material, but it also shields the conductors from chemical attack. These mesh anodes are designed and spaced to provide long-term uniform protection at low current densities. The anode mesh is placed on the surface of a reinforced-concrete structure, covered with an overlay of Portland cement or polymer-modified concrete, and then connected to a low-voltage dc power source. The properties of polymeric anodes used for construction applications are given in Table 6.

Table 6 Properties of polymeric mesh anodes used for construction applications

Properties	Typical data
Recommended maximum design current output in soil	52 mA/m (16 mA/ft) length[(a)]
Recommended maximum design current output in water	10 mA/m (3 mA/ft) length
Maximum pressure rating (hydrostatic)	7 MPa (100 psi)
Maximum temperature rating	65 °C (150 °F)
Minimum installation temperature	-18 °C (0 °F)
Chemical resistance per ASTM D 543 for 7 days at ambient conditions with weight gain less than 1%	
3% NaCl	Pass
3% Na_2SO_4	Pass
10% NaOH	Pass
ASTM oil No. 1	Not recommended
Crude oil	Not recommended

(a) Average current output for anode in coke breeze backfill when maximum current density is 82 mA/m (25 mA/ft). ASTM D 543, “Standard Test Method for Resistance of Plastics to Chemical Reagents.”

Precious metals are used for impressed-current anodes because they are highly efficient electrodes and can handle much higher currents. Precious metal anodes are platinized titanium or tantalum anodes; the platinum is either clad to or electroplated on the substrate. The small precious metal anode shown in Fig. 17 performs the same function as materials weighing several times more.

مرجع مهندسی مواد و متالورژی

Lead alloy anodes, containing 2% Ag, or 1% Ag and 6% Sb, are used for cathodic protection systems in seawater. Lead alloy anodes should not be buried in the sea bottom or used in freshwater applications.

Ceramic anodes, also called mixed metal oxide anodes, are the newest materials available for anodes. They are supplied either as oxide coatings on transition metal substrates or as bulk ceramics. Their use as cathodic protection anodes for protecting reinforcing steel in concrete is new, but the oxide-coated transition metal anodes have been used since the late 1960s in industry as anodes for chlorine production and seawater electrolysis and cathodic protection of water tanks and buried steel structures, among other industrial processes.

The oxide/metal composite anodes for chlorine environments consist of a mixed ruthenium dioxide (RuO_2) and titanium oxide (TiO_2) coating sintered onto a pure titanium (grade 1) substrate (Ref 16). Such materials, which are produced in sheet, mesh, and wire form, are based on patented dimensionally stable anode (DSA) technology (Ref 16). These anodes are so named because they remain unchanged with regard to their shape, geometry, and dimensions during their entire operating life. Figure 18 shows examples of a mixed oxide/titanium mesh anode, based on DSA technology, that is used to prevent corrosion of reinforcing steel in concrete. The basic chemical constituents of the bulk ceramic anodes are suboxides of titanium, with Ti_4O_7 and Ti_5O_9 being the principal components. Such conductive ceramics are resistant to both oxidation and reduction in strong acid and basic environments. Some characteristic properties of conductive ceramics are given in Table 7.

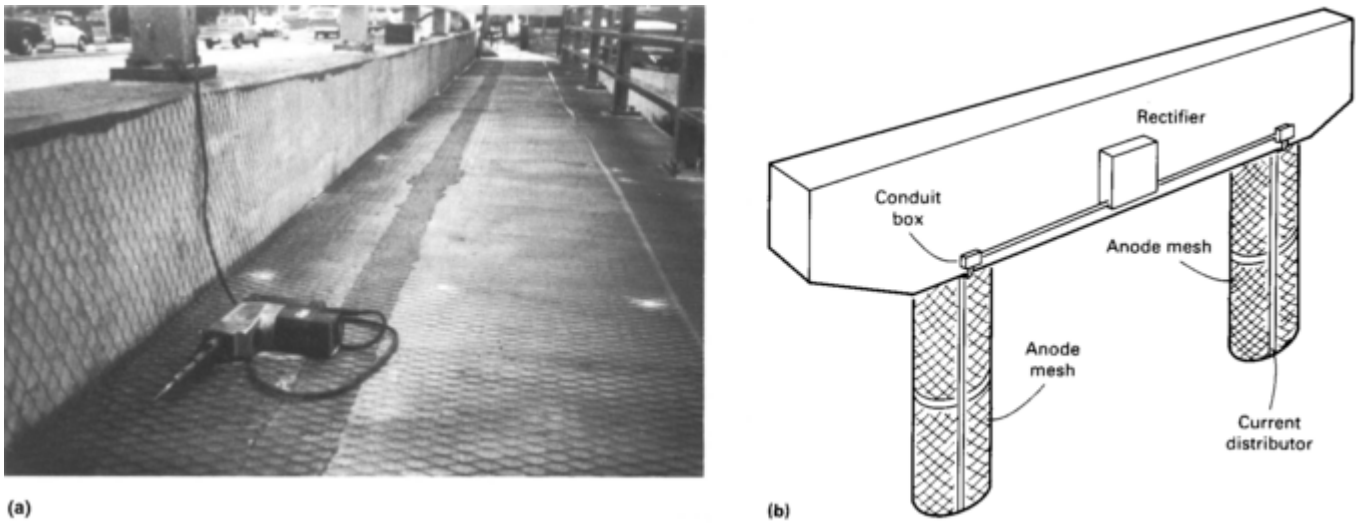

Fig. 18 Use of mixed oxide/titanium anode mesh for cathodic protection. (a) Sidewalk and barrier-wall installation. (b) Installation of anode mesh on a bridge substructure. Courtesy of ELTECH Systems Corporation

Table 7 Properties of bulk ceramic anode materials

Property	Value
Electrical resistivity	250–1000 × 10^{-6} Ω · cm. Resistivity decreases as density increases.
Thermal expansion	5 × 10^{-6}/°C
Thermal conductivity	10–20 W/m · K
Modulus of rupture	100 MPa (14.5 ksi) and higher. Some grades are 24–34 MPa (3.5–5.0 ksi) for special applications.
Melting point	1400 °C (2550 °F)
Density	2.5–4.0 g/cm^3
Thermal stability	Stable to 350 °C (660 °F) in air Stable to 1350 °C (2460 °F) for nonoxidizing atmosphere

Power Sources

Impressed-current cathodic protection requires a dc power source, the most common being rectified power from a local utility. Remote locations can use solar cells (Fig. 19), thermoelectric current sources, special fuel-driven electric generators, or windmills.

Design

Most cathodic protection systems are designed by consulting companies that specialize in corrosion control. Design procedures vary among organizations, but the following general guidelines are frequently followed for onshore buried structures (Ref 17):

- Decide whether impressed-current or sacrificial anodes will be used.
- Decide on the design life of the system.
- Determine or assume the condition of the coating. From this, the current density for cathodic protection can be estimated.
- Calculate the maximum electric current required.
- Determine the number and type of anodes required and their respective spacing.
- Calculate the ground bed resistance. Figure 20 shows the effect of soil resistivity and pH on the corrosion of zinc sacrificial anodes.
- Calculate the lead wire size.
- Calculate the required dc voltage.
- Determine the rectifier size.
- Locate the ground bed.

Computers have changed some cathodic protection design, test, and inspection procedures (Ref 18, 19, 20), but most cathodic protection is still designed and tested in the manner described in U.S. government publications from the 1960s and 1970s (Ref. 17, 21, 22, 23).

Case Histories

The examples in this section have been selected to familiarize the design engineer with the steps to follow in selecting a specific corrosion- control method. Other examples are available in Ref 17, and 21 to 23 and in the cathodic protection training course offered by NACE International.

Resistance Calculations*

The resistance of impressed-current anodes buried in soil can be lowered by surrounding them with carbonaceous backfill material, such as coke breeze (crushed coke) or flake graphite. This is particularly beneficial in high-resistance soils. If soil resistance is ten or more times the backfill resistivity—500 to 1000 Ω · cm—the voltage drop of anode current passing through the backfill may become negligible with respect to the voltage drop through the soil. Thus, the resistance of a backfilled anode can be considered to be lower than that of a nonbackfilled anode because the backfilled anode is effectively longer and of greater diameter.

Increasing the diameter and/or the length of a cylindrical anode will decrease its anode-to-electrolyte resistance. Changes in length have a greater effect.

Many engineers first measure structure-to-anode resistance by actually impressing current into installed anodes. In this way, a rectifier can be sized to fit the circuit resistance without relying on questionable test and empirical data. Testing installed anodes for the purpose of sizing rectifiers has the disadvantage of delaying completion of an installation. However, it means that sufficient cathodic protection current will be supplied in an efficient manner.

Single Anode Resistance (Ref 15). For a vertical anode, the electrolyte-to-anode resistance (R_v) is:

$$R_v = \frac{0.0052\rho}{L}\left(2.3\log 10\frac{8L}{d} - 1\right)$$

For a horizontal anode:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$R_h = \frac{0.0052\rho}{L}\left(2.3\log 10\frac{4L^2+4L\sqrt{s^2+L^2}}{ds} + \frac{s}{L} - \frac{\sqrt{s^2+L^2}}{L} - 1\right)$$

where resistance is to remote reference (in ohms), ρ is the electrolyte resistivity (in Ω · cm), L is the length of anode (in feet), d is the diameter of anode (in feet), and s equals twice the depth of the anode (in feet).
For a single vertical anode, a simplified expression can be used:

$$R_v = \frac{\rho}{L}K$$

where R_v, ρ, and L are as given previously, and K is the shape function representing the anode length to anode diameter ratio, which can be obtained from Table 9.

Table 9 The shape function, *K*, obtained by dividing the anode length by the anode diameter in any units

A vertical anode group composed of two or more rows, separated by a distance substantially larger than that between the anodes within a single row, has a total resistance approximately equal to the total parallel resistance of all the rows. The formula for parallel resistance is used:

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots$$

Vertical and Horizontal Anode Groups— Simplified. If vertical anode dimensions are assumed to be 8 to 12 in. in diameter and 10 ft in length and if the horizontal anode dimensions are assumed to be 1 ft^2 in cross section, 10 ft in length, and 6 ft below the surface of the electrolyte (these assumptions are useful when designing anode system with high-silicon cast iron anodes in soils in which effective backfill has been installed around the anodes), then the following empirical formula can be used:

$$R_v = \frac{\rho F}{537} \qquad R_h = \frac{\rho F}{483}$$

where R_v is the electrolyte-to-anode resistance, any number of vertical anodes to remote reference (in ohms), R_h is the electrolyte-to-anode resistance, any number of horizontal anodes to remote reference (in ohms), ρ is the electrolyte resistivity (in Ω · cm), and F is the adjusting factor for groups of anodes (from Table 11). Note: where only one anode is used, F = 1.0.

Approximate anode-to-electrolyte resistance values for single anodes are quickly and easily obtained from:

- $R_v = 0.002\rho$ for a vertically installed 60 in. anode in a 10 ft column of backfill, 1 ft in diameter
- $R_v = 0.005\rho$, for a vertically installed 2 by 60 in. anode, without backfill
- $R_v = 0.006\rho$, for a vertically installed $1\frac{1}{2}$ by 60 in. anode, without backfill
- R = anode-to-electrolyte resistance for a single anode (Ω)
- ρ = resistivity of electrolyte (Ω · cm)

Cathodic Protection of Steel Structures*

Example 1: Use of Zinc Sacrificial Anodes to Protect a Pipe Pile Structure. A pier structure 20 ft wide extending 150 ft from the shore consists of sixteen 16 in. diam steel pipe piles, 40 ft long, that support the pier deck. The piles will be driven so that 14 ft will be in the soil zone, 8 ft in the submerged zone, 3 ft in the tidal zone, and 5 ft in the atmospheric/splash zone (Fig. 21).

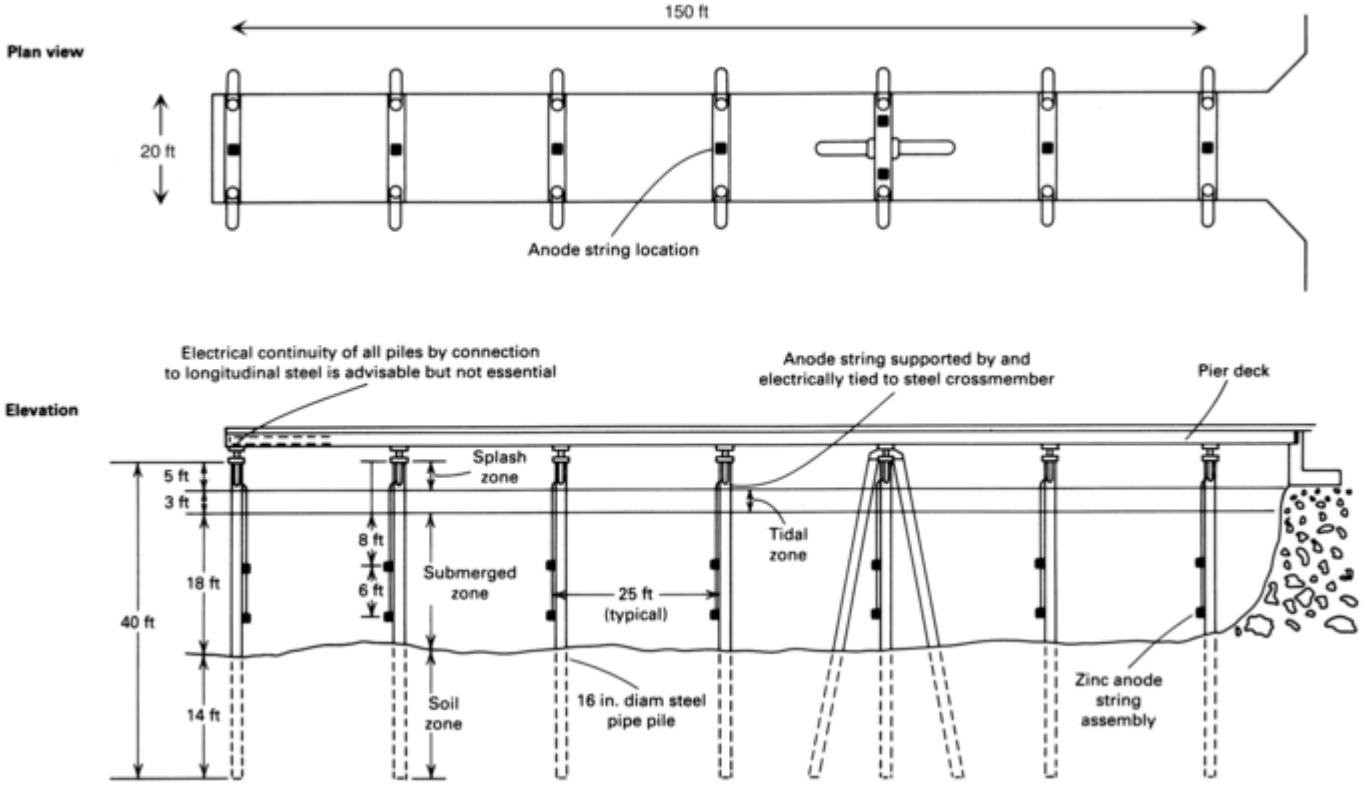

Fig. 21 Example 1. Outline of pier protected with a protective coating and sacrificial anodes

The pier is located in a calm saltwater bay. The water is not badly polluted and has an average temperature of 62 °F. The water samples taken at three different locations show an average resistivity of 25 Ω · cm. A decision

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

has been made to coat the piles with 16 mil dry-film thickness of coal tar epoxy and to apply cathodic protection in the form of a sacrificial-anode system. The design life is 20 years.
Calculation of Steel Areas Exposed to the Specified Zones. Table 12 is a guide to required current densities. For this example, the areas and current requirements are summarized in Table 13.

Table 12 Current densities required for coated and uncoated steel in moving and stagnant seawater and in soil areas

Environment	Current density, mA/ft^2

Anode Design Calculations. The average total current ($\bar{I}$) required to maintain protection of the entire structure for 20 year life is:

$$\bar{I} = \frac{I_{prot} + I_{prot20}}{2}$$

$$\bar{I} = \frac{5.8 + 12.3}{2} = 9.1 \text{ A}$$

where I_{prot} is the current to initially maintain the structure and I_{prot20} is the current required after 20 years (Table 13).

The total weight of high-purity zinc anode material required for 20 year life expectancy is:

$$W = \frac{CR + L \times ATC}{E \times U}$$

where W is the weight (in pounds), CR is the consumption rate (in lb/A · yr), L is the life (in years), ATC is the average total current (in amps), E is the efficiency factor, and U is the utilization factor:

$$W = \frac{23.585 \times 20 \times 9.1}{0.90 \times 0.85} = 5611 \text{ lb}$$

Based on the structure description and the amount of zinc required, it is determined that for this structure eight strings of two 390 lb (10 by 10 by 15 in.) zinc anodes (6240 lb) suspended at the locations shown in Fig. 21 should afford adequate protection for the 20 year life expectancy. The other factor to consider in a galvanic anode system is the amount of current that can be discharged from the anodes.

Resistance of the Anode Systems. The 390 lb anode measures 10 by 10 by 15 in. The outside perimeter of the anode is 40 in. The diameter of a cylindrical object whose circumference is 40 in. is 12.73 in., or 1.06 ft. The anode spacing is 25 ft. Using the formula from the section “Resistance Calculations” in this article for a single anode, the resistance of one 390 lb anode is:

$$R_v = \frac{0.0052\rho}{L}\left[2.3 \log \frac{8L}{d} - 1\right]$$

$$= \frac{(0.0052)(25)}{(15/12)}\left[2.3 \log \frac{(8)(15/12)}{1.06} - 1\right]$$

$$= 0.129 \ \Omega$$

The resistance of the anode system from the Sunde equation is (Ref 25):

$$R_s = \frac{0.00521\rho}{nL}\left[2.3 \log \frac{8L}{d} - 1 + \frac{2L}{S} 2.3 \log 0.656n\right]$$

where R_v is the resistance of one vertical anode (in ohms), R_s is the resistance of the anode system (in ohms), n is the number of anodes, L is the length of anode (in feet), ρ is the water resistivity (Ω · cm), d is the diameter of anode (in feet), S is the spacing between anodes (in feet):

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$R_s = \frac{(0.0052)(25)}{(8)(2)(15/12)}\left[2.3\log\frac{(8)(2)(15/12)}{1.06} - 1 + \frac{(2)(2)(15/12)}{25}2.3\log 0.656(8)\right]$$
$$= 0.0147 \text{ ohm}$$

Anode system output:

$$I = \frac{E}{R_s}$$

where E is the driving potential.

Driving voltage of galvanic anode to polarized coated steel is of the order of 0.10 V:

$$E = 1.1 \text{ V} - 1.00 \text{ V} = 0.10 \text{ V}$$

$$I \text{ available after polarization} = \frac{0.10}{0.0147} = 6.8 \text{ A}$$

The 6.8 A output after polarization is greater than the 5.8 A required for the total current requirements given above. Therefore, the current requirement is satisfied.

To verify that life expectancy is met, the average total current $\bar{I}$ output for 20 year life is calculated:

$$I = \frac{6.8 + 12.3}{2} = 9.6 \text{ A}$$

Total weight of anode material required:

$$W = \frac{23.585 \times 20 \times 9.6}{0.90 \times 0.85}$$
$$= 5919 \text{ lb}$$

The total weight of the anode material used is 8 × 2 × 390 = 6240 lb. Therefore, the life expectancy is satisfied.

Example 2: Use of Impressed-Current Anodes to Protect an H-Pile Structure. A 30 ft wide pier structure that extends 200 ft from shore is supported by 20 H-piles that are 92 ft long. The H-piles are connected in four-pile clusters by W shapes. The piles are to be driven so that 50 ft will be below the dredged mud line, 30 ft in the submerged zone, 4 ft in the tidal zone, and 8 ft in the atmospheric/splash zone (Fig. 22). The pier is located in a saltwater bay in a highly commercial and industrial area. There are commercial, industrial, chemical, and sewage pollutants. The water samples taken at three different locations show an average resistivity of 30 Ω · cm.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

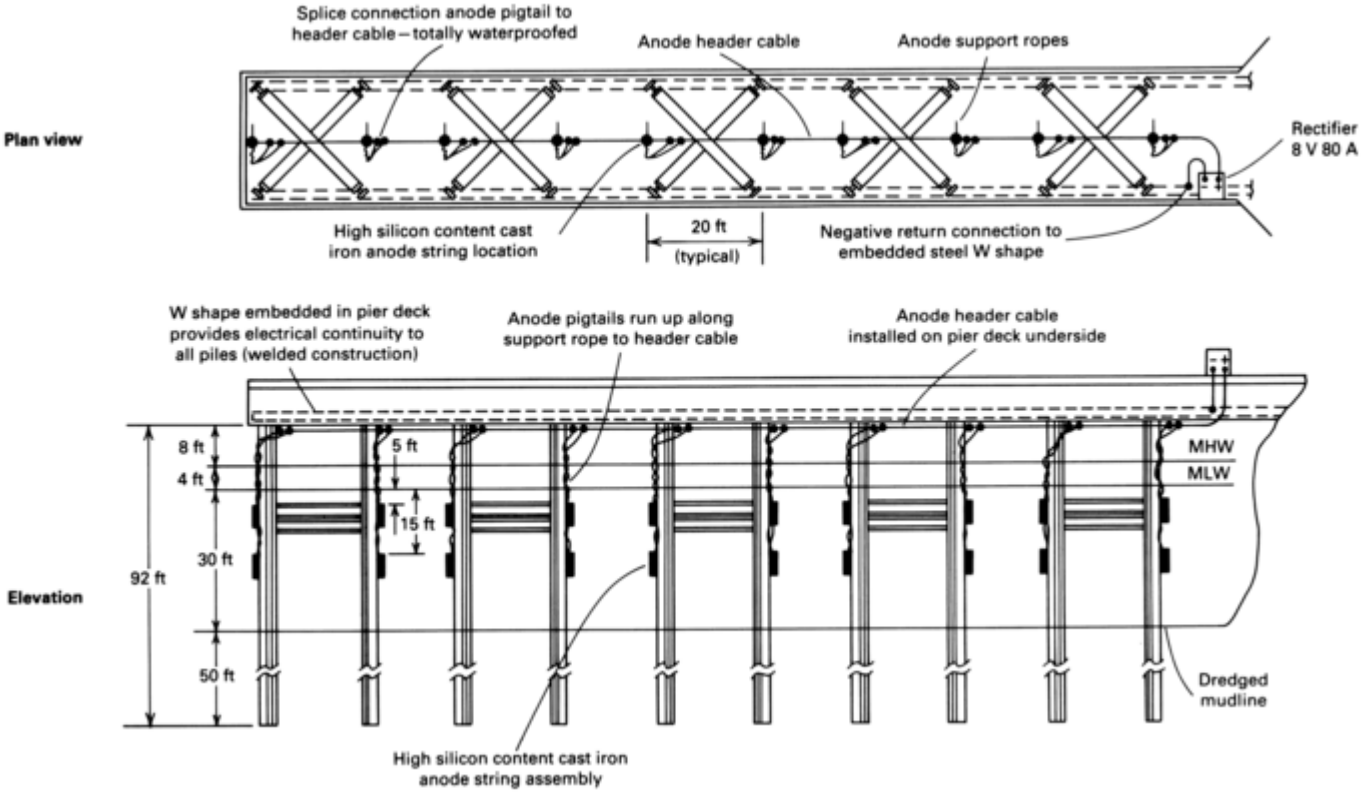

Fig. 22 Example 2. Outline of H-pile pier protected using a protective coating and impressed-current anodes

A decision has been made to coat the H-piles and beams with a vinyl coating of 10 mil dry- film thickness and to apply cathodic protection in the form of an impressed-current system. The cathodic protection system should be designed and a cost estimate of the coating and cathodic protection system should be made for a 20 year life expectancy. The 10 cross braces and the 20 vertical H-piles have a surface area of 8 ft^2 per linear foot. Exposed areas of steel in specific zones are calculated in Table 14. The required impressed current is then determined based on the current density guide of Table 11.

Current to maintain entire structure, 47.6 A	$I_{prot20} = \Sigma I_{mb20} + \Sigma I_{mc20}$				

Anode Design Calculations. The anode material is high-silicon content cast iron. Consumption rate is 0.75 lb/A · yr. The average total current $\bar{I}$ required for 20 year life is:

$$\bar{I} = \frac{I_{prot} + I_{prot20}}{2} = \frac{26.8 + 47.6}{2} = 37.2 \text{ A}$$

Total weight of anode material required for 20 year life expectancy:

$$W = \frac{CR \times L \times ATC}{U}$$

where *CR*, *ATC*, and *U* are as given in Example 1. In impressed-current systems, the efficiency factor, *E*, is 100% (compared to 90% for sacrificial-anode systems):

$$W = \frac{0.75 \text{ lb/A} \cdot \text{yr} \times 20 \text{ yr} \times 37.2 \text{ A}}{0.50} = 1116 \text{ lb}$$

The total number of anodes will be determined by taking into consideration the water depth, number and spacing of piles, amount of current available from each anode, and the current distribution to the structure.

For this structure, twenty 2 in. diam by 60 in. long anodes with enlarged heads have been chosen; the anodes are to be hung in ten strings of two anodes each. The top of the upper anode is to be 5 ft below the mean low water (MLW) level, and the top of the lower anode will be 15 ft below MLW level. See Fig. 22 for anode locations.

Resistance of Anodes (Ground Bed Resistance). The resistance of one vertical anode is:

$$R_v = \frac{0.0052\rho}{L}\left[2.3 \log \frac{8L}{d} - 1\right]$$

where R_v is the anode-to-electrolyte resistance (in ohms), ρ is the electrolyte resistivity (in Ω·cm), *L* is the length of the anode (in feet), and *d* is the diameter of the anode (in feet):

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$R_v = \frac{(0.0052)(30)}{(60/12)}\left[2.3\log\frac{(8)(60/12)}{(2/12)} - 1\right]$$

$$R_v = 0.140\ \Omega$$

The calculations for the resistance of several anodes in parallel are made by using the following formula:

$$R_s = \frac{0.00521\rho}{nL}\left[2{,}3\log\frac{8L}{d} - 1 + \frac{2L}{S}2.3\log 0.656n\right]$$

where R_s is the resistance of vertical anodes in parallel to electrolyte (in ohms), and ρ, *n*, *L*, *d*, and *S* are as given previously.

Where two anodes are installed vertically in the same string, assume length, *L*, as equal to length of both anodes combined. From Fig. 22, the spacing is 20 ft:

$$R_s = \frac{(0.00521)(30)}{(10)(120/12)}\left[2.3\log\frac{(8)(120/12)}{(2/12)} - 1 + \frac{(2)(120/12)}{20}2.3\log 0.656(10)\right]$$

$$R_s = 0.11\ \Omega$$

Total dc Circuit Resistance. The total dc circuit resistance (R_{tot}) is the total of:

- Anode-to-electrolyte resistance, R_s
- Circuit cable resistance, R_{dcc}. Determine with common circuit analysis formula. Cable resistance is a function of cable size, conductor type, and length. Let $R_{dcc} = 0.0305\ \Omega$
- Structure-to-electrolyte resistance (negligible)

Thus, the circuit resistance is:

$$R_{tot} = R_s + R_{dcc} = 0.0415\ \Omega$$

Rectifier voltage output, V_{dc} is:

$$V_{dc} = I_{max} \cdot R_{tot} = 78.1\ \text{A} \times 0.0415\ \Omega = 3.24\ \text{V}$$

The maximum current, I_{max}, is that needed for polarization, I_{pol}. Add 2 V for anode back voltage, and the total becomes 5.24 V. Allow 20% for stack aging (1.05 V), and the rectifier voltage required = 6.29 V. So, the rectifier output required is 6.29 V and 78.1 A. The closest available rectifier is 8 V dc, 80 A dc.

Example 3: Condenser Waterbox/Impressed-Current System.* The main surface condensers at a power plant have been refitted with titanium tubes and tube sheets. The waterboxes are constructed of epoxy coated steel. The cooling water is seawater with a conductivity 29,000 to 40,000 μS (microSiemens equivalent to 25 and 35 Ω · cm resistivity).

Titanium is an active metal (like aluminum) that rapidly forms a highly protective film in seawater. It is this film that permits the use of titanium as a substrate for platinum and mixed- metal oxide impressed-current anodes. In the presence of aerated seawater, titanium exhibits a relatively noble (cathodic) potential, which is generally between +0.200 and -0.200 V versus a silver/silver chloride reference. In seawater, steel (at a potential of -0.5 to -0.7 V versus silver/silver chloride) will undergo rapid corrosion when directly connected to a large titanium surface.

There is justified concern that the coated steel waterbox will corrode at an unacceptable rate at coating faults and penetration of the steel box will result. Application of cathodic protection for the waterboxes can be used to polarize the titanium to a more active potential (-0.550 to -0.650 V with respect to a silver/silver chloride reference electrode). This will eliminate the otherwise harmful galvanic potential difference between the titanium and the steel.

Cathodic polarization of the titanium must not be sufficiently negative to produce hydrogen at the titanium surface. If hydrogen is produced, the titanium can form hydrides, which make the metal brittle and can result in tube cracking and other forms of mechanical failure. The equation for the potential at which hydrogen ions in water can be reduced to hydrogen gas at 1 atm of pressure (Ref 27) is:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$E_o = 0.000 - 0.0591 \text{ pH (volt versus SHE)}$$

Referenced to a silver/silver chloride electrode in seawater, the equation becomes:

$$E_o = (0.000 - 0.0591 \text{ pH}) - 0.254 \text{ V}$$

At a pH of 8.0 (normal for seawater), the potential for production of hydrogen is:

$$E_o = (-0.0591 \times 8) - 0.254$$

$$E_o = -0.727 \text{ volt versus silver/silver chloride}$$

Polarizing the titanium to between -0.550 and -0.650 versus silver/silver chloride will not result in formation of titanium hydrides. This potential will eliminate the galvanic potential difference between the titanium and the steel.

Given the following data, design an impressed-current cathodic protection system for the waterboxes on this condenser. Anodes shall have a nominal 10 year life expectancy.

Data. From laboratory tests at flow rates matching those in the condenser tubes, 1.8 m/s (6 ft/s), the current density required to polarize titanium to -0.650 V to a silver/silver chloride reference is about 75 μA/cm^2. From laboratory studies, the effective distance that polarization occurs down a tube is about 5 tube diameters. There are 5140 titanium tubes entering each waterbox. Tube diameter is 2.22 cm ($\frac{7}{8}$ in.). The average water resistivity is 30 Ω · cm.

All large connecting pipes to the condenser have a protective coating within five pipe diameters of the condenser. A conservative estimate is 10% of all coated steel surfaces as exposed metal. Assume all surfaces beyond 5 pipe diameters will not receive significant current density. Assume waterbox dimensions are as indicated in Fig. 23(a). For this problem, inlet and outlet tube sheets are mirror images of each other. Water velocity through the condenser tubes is 1.83 m/s (6 ft/s).

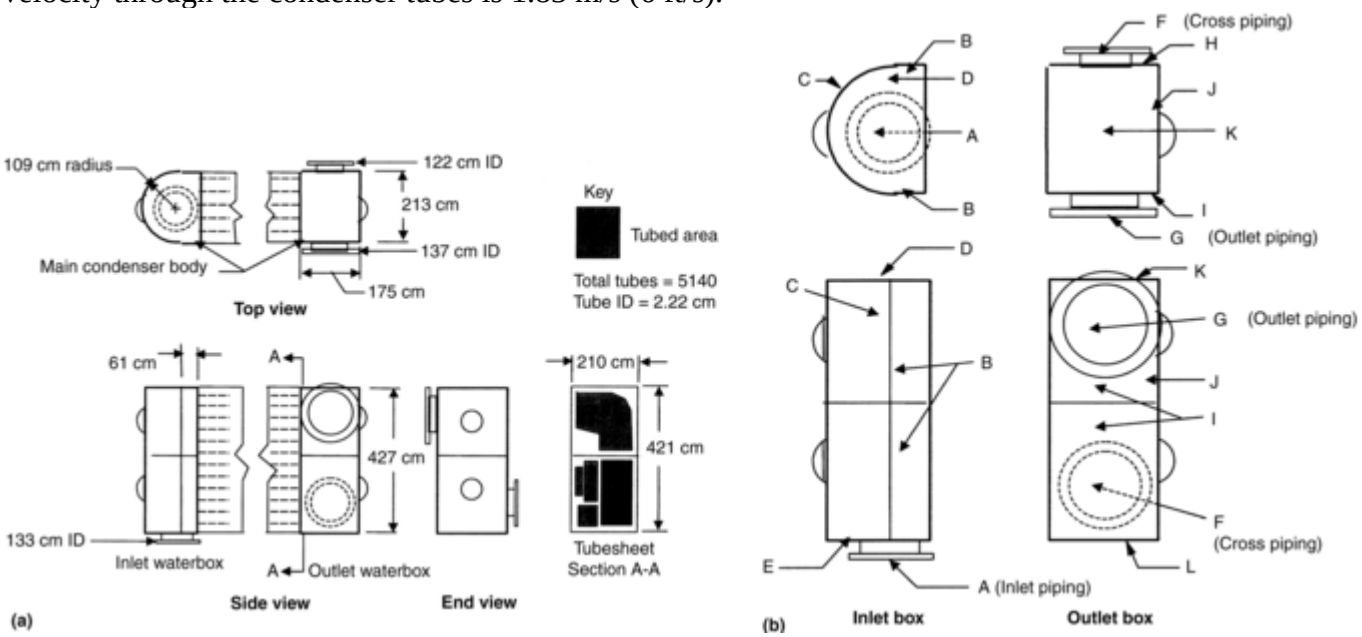

Fig. 23 Example 3. Diagram of condenser waterbox. (a) Dimensions and views. ID, inside diameter. (b) Identification of steel surfaces

The procedure is:

- Calculate surface areas.
- Estimate current required to meet criteria.
- Select anodes.
- Estimate minimum number of anodes to meet life and current distribution requirements.
- Estimate rectifier rating.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Calculations. Results of surface area calculations are listed in Table 15. Effective area of titanium tubes that will receive current is five tube diameters into the end of the tube. This criterion applies to large-diameter connecting piping, as well.

Table 15 Design of condenser waterbox impressed-current system

Total bare metal steel and Ti, cm^2(ft^2)	$A_{TOB} = A_{sOBB} + A_{Ti}$	543,622 (585)

For the cross piping (F), a short connection to the adjacent condenser waterbox, there is a bare metal gate valve in the connection. Assume exposed metal area is equal to the area of the pipe inside diameter. There had been an assumed 10% degradation of the coated steel.

Estimate Current Required to Meet Criteria for Exposed Areas. From given laboratory studies, current density (i) required to polarize titanium to -0.650 V (silver/silver chloride) is 75 μA/cm^2. Assume the same current density is required to equalize potentials of all steel and titanium surfaces in the waterboxes.

Inlet Waterbox. The estimated current required for the inlet waterbox (I_{IB}) is calculated:

$$I_{IB} = iA_{TIB}$$

$$I_{IB} = 75 \times 10^{-6}\ \text{A/cm}^2 \times 518{,}986\ \text{cm}^2$$

$$I_{IB} = 38.9\ \text{A}$$

Outlet Waterbox. The estimated current required for the outlet waterbox (I_{OB}) is calculated:

$$I_{OB} = iA_{TOB}$$

$$I_{OB} = 75 \times 10^{-6}\ \text{A/cm}^2 \times 543{,}622\ \text{cm}^2$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$I_{OB} = 40.8 \text{ A}$$

Anode Selection. This design requires control of the polarized potential on the titanium surfaces. This means that the cathodic protection must be an impressed-current system operated under potential control. For service in waterboxes of this type, bayonet (rod) anodes are convenient. These anodes (either platinum clad titanium or niobium or mixed metal oxide coated titanium) work well in highly conductive seawater. The anodes are small, and their effect on the cooling water flow patterns is minimal.

Minimum Active Anode Surface Area. Figure 24 is a graph derived from published consumption rates of platinum-clad anodes in fresh and seawater. For a design life of 10 years for the anodes, the consumption rate is:

$$CR = 6.35 \text{ μm/10 yr} = 0.635 \text{ μm/yr}$$

From Figure 24, in seawater, this consumption rate corresponds to a maximum current density of about 100 mA/cm^2 of platinum surface.

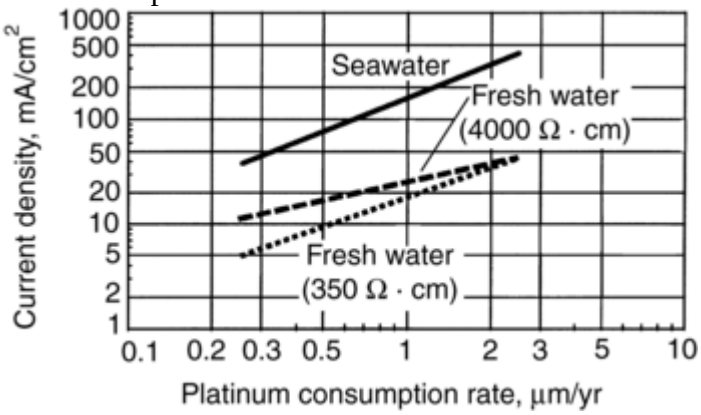

Fig. 24 Consumption rate of platinum anode

Assuming a design current of 50 A (125% of outlet box estimated current requirement) for each waterbox, the total active anode surface required would be:

$$A_A = I/i_a = 50 \text{ A}/0.1 \text{ A/cm}^2 = 500 \text{ cm}^2$$

Platinum-clad titanium or niobium rods are available in diameters of 0.635 cm (0.25 in.), 0.953 cm (0.375 in.), and 1.27 cm (0.500 in.). For mechanical reasons (flow rates in the waterboxes), the 1.27 cm (0.500 in.) rods are selected. The total length of rod required in each waterbox will be:

$$L = A_A/\pi d$$

$$L = 500 \text{ cm}^2/\pi \text{ (1.27 cm)} = 125 \text{ cm}$$

Examine Anode Remoteness. Figure 25 is a plot of the effective anode remoteness for a 30 cm long (11.8 in.) 1.27 cm (0.500 in.) diam anode placed against a nonconducting (coated) surface. The dimensions of the waterboxes severely limit the separation of anodes from the bare titanium tube sheets. In the inlet waterbox the maximum separation of the anodes from the tube sheet is 170 cm (67 in.). Figure 25 indicates that the tube sheet will be outside 80% of the above gradient if the anodes are at least 1 m (39 in.) away from the tube sheet. Variations in current density reaching the tube sheet because of differences in anode gradient would be less than 10% (the difference between the gradient at 1.7 and 1 m, or 67 and 39 in.). The object then is to locate the probe anodes in a pattern on the coated steel walls of the waterboxes such that the closest anode is no nearer the tube sheet than about 1 m (39 in.). Figure 26 shows one possible arrangement in which the anodes are relatively evenly distributed and that meet the 1 m criteria.

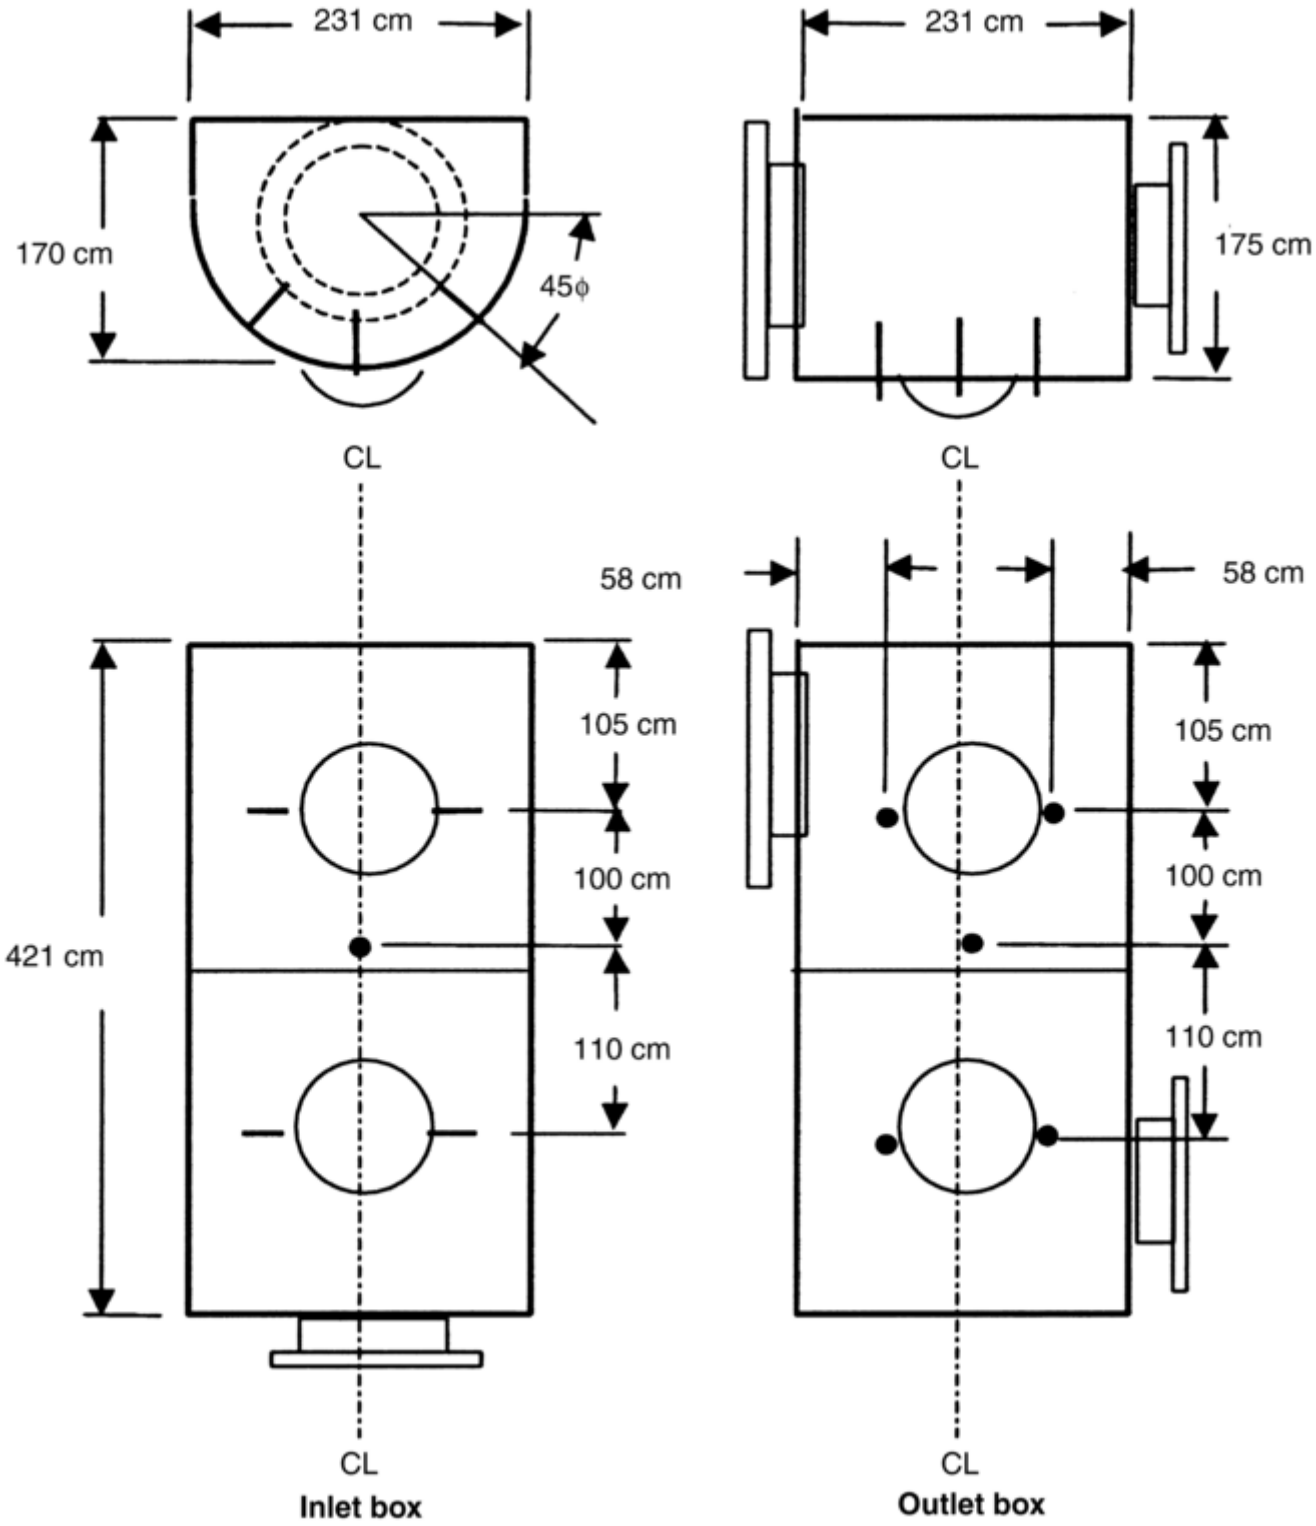

Fig. 26 Example 3. Bayonet anode locations

Rectifier Rating and Control. The approximate anode resistance using Dwight's formula for a vertical anode is:

$$R = \frac{0.005\rho}{\pi L}\left(\ln\left(\frac{8L}{d}\right) - 1\right)$$

where $\rho = 30\ \Omega \cdot \text{cm}$, $L = 0.30$ m, and $d = 0.0127$ m.

$$R = \frac{0.005\ \text{m/cm} \cdot 30\ \Omega \cdot \text{cm}}{\pi 0.30\ \text{m}}\left(\ln\left(\frac{8 \cdot 0.30\ \text{m}}{0.0127\ \text{m}}\right) - 1\right)$$

$$= 0.675\ \text{ohm per anode}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The approximate resistance of five anodes in parallel is:

$$R = 0.675\ \Omega/5 = 0.135\ \text{ohm}$$

The voltage required to provide 50 A per waterbox is by Ohm's law:

$$E = IR$$

where I = design current (50 A), R = anode to waterbox resistance (0.135 Ω), and E = 50 A × 0.135 Ω = 6.75 V. Taking into account back potential and polarization of the anodes and waterbox, select a potential controlled rectifier with separate units for each waterbox having a rating of 50 A and 12 V dc.

Location and Type of Reference Electrodes. The cathodic protection system must hold the potential of the titanium tube sheet at no more than -650 mV versus silver/silver chloride. The reference used to control the power supply should be located at the tube sheet in a location that is nearest to an anode. Other references are desirable at additional locations to verify effectiveness of the cathodic protection.

References are available that can be fitted into a tube opening. This prevents the use of such tubes for cooling. However, the large number of tubes (>5000) in this type of condenser makes this a negligible problem. Figure 27 shows a typical tube-mounted reference electrode (silver/silver chloride) and suggested locations for installing these in the typical waterbox.

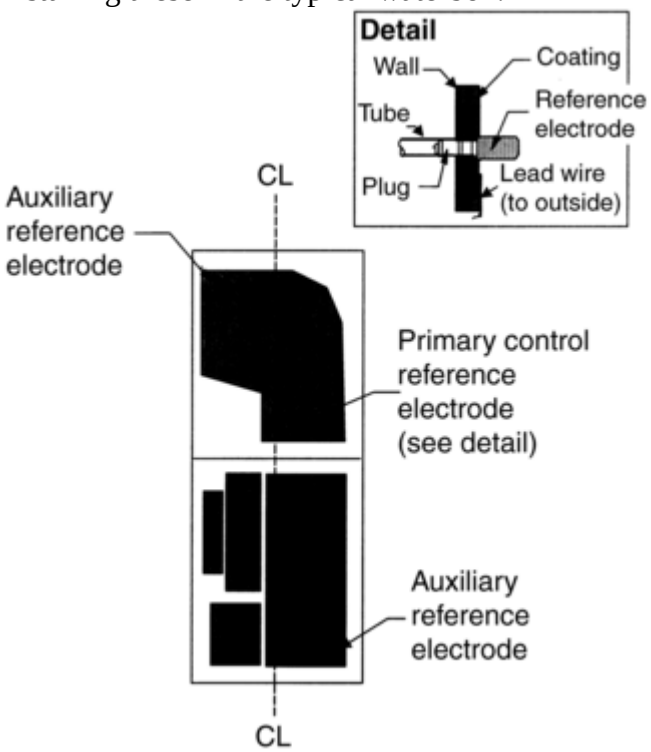

Fig. 27 Example 3. Placement of reference electrodes

Vapor Phase Corrosion Inhibitors

Kunigahalli L. Vasanth, Naval Surface Warfare Center

Introduction

METALLIC CORROSION costs the United States about $300 billion a year (Ref 1). Approximately one-third of the cost of corrosion ($100 billion) is avoidable and could be saved by using corrosion-resistant materials and the application of state-of-the-art corrosion control technologies. Atmospheric corrosion of metals and alloys is responsible for a large percentage of the total corrosion cost. Indirect consequences of corrosion, such as depletion of the natural resources and structural damage leading to failure of industrial and military systems, are also critical. The use of inhibitors is one of the corrosion- control technologies directed toward combating corrosion. Definitions, classifications, structural features, corrosion inhibition mechanisms, and methods of evaluation of vapor-phase-corrosion inhibitors, or volatile corrosion inhibitors (VCIs) are discussed in this article. Practical methods of using VCIs for corrosion protection of ferrous and nonferrous alloys are discussed with some specific examples.

Vapor Phase Corrosion Inhibitors

Kunigahalli L. Vasanth, Naval Surface Warfare Center

Definition and Classification

The definition of an inhibitor used by NACE International (formerly the National Association of Corrosion Engineers) is “a substance that retards corrosion when added to an environment in small concentrations” (Ref 2). It is well established that inhibitors function in one or more ways to control corrosion: (a) by adsorption of a thin film onto the surface of a corroding material; (b) by inducing the formation of a thick corrosion product, or (c) by changing the characteristics of the environment, resulting in reduced aggressiveness (Ref 3). One of the recent classifications of inhibitors given by Uhlig and Revie (Ref 4) is that inhibitors are designated as passivators, organic inhibitors, and vapor-phase inhibitors.

Passivating inhibitors are usually inorganic oxidizing chemicals such as chromates, nitrites, and molybdates that passivate the metal and shift the corrosion potential several tenths of a volt in the noble direction. In general, the passivating- type inhibitors are very efficient and reduce corrosion rates to very low values. Primers containing hexavalent chromium have been the workhorse for passivating aluminum alloys and steel. Because it is known as a carcinogen, several research programs are ongoing to replace the hexavalent chromium. There is a critical concentration for passivators at which they show optimum inhibition. Subcritical concentrations of

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

passivators will lead to localized corrosion. Some alkaline compounds such as NaOH, Na_3PO_4, and Na_2B_4O are known to facilitate passivation of iron by favoring adsorption of dissolved oxygen.

Organic inhibitors are also called adsorption-type inhibitors since the organic compounds adsorb on the metal surface and suppress metal dissolution and reduction reactions. These affect both anodic and cathodic processes (Ref 5). Organic amines and carboxylates are typical examples of this class. Typical effective organic pickling inhibitors for steel are quinolinethiodide, *o*- and *p*-tolylthiourea, propyl sulfide, formaldehyde, and p-thiocresol. These are used to remove mill scale and can reduce the loss of steel, the use of acid, and generation of acid fumes caused by hydrogen evolution (Ref 4).

Vapor-phase corrosion inhibitors or volatile corrosion inhibitors (VCIs) are similar to organic adsorption-type inhibitors. These possess moderately high vapor pressure and consequently can be used to inhibit atmospheric corrosion of metals without applying VCIs directly on the metal surface. Volatile corrosion inhibitors are usually effective if used in enclosed spaces such as closed packages or the interior of machinery during shipment (Ref 6). The advantage of VCIs is that the volatilized molecules can reach hard-to-reach spaces commonly found in electrical and electronic enclosures, between two metal flanges, void spaces, and similar systems.

In the case of precise scientific instruments and electrical and electronic equipment, VCIs offer a definite advantage over classical methods of corrosion protection. A VCI can be defined as a single chemical or combination of chemicals (mostly organic) having high vapor pressure that can prevent atmospheric corrosion of metallic materials. According to Miksic and Miller, “Volatile corrosion inhibitors are secondary-electrolyte-layer inhibitors that possess appreciable saturated vapor pressure under atmospheric conditions, thus allowing vapor-phase transport of the inhibitive substance” (Ref 7).

Fodor (Ref 8) has documented an extensive literature review on vapor-phase corrosion inhibition. His report discusses theoretical and practical considerations, including definitions, classifications, corrosion-inhibition mechanisms, and evaluation of VCIs. Protection of ferrous and nonferrous alloys is discussed with some specific examples. Also included in Fodor's report are the structural identification of several VCI organic compounds and a summary of commercial preservation procedures.

A review by Miksic (Ref 9) discusses the atmospheric corrosion inhibition of both ferrous and nonferrous metals using VCIs. To be effective VCIs, the chemical compounds need to possess high passivating properties, strong tendencies toward surface adsorption, and the ability to form a comparatively strong and stable bond with metal surfaces. The delicate and yet complex nature of atmospheric corrosion processes occurring under thin films of electrolytes preordains the transport mechanism of the corrosion inhibitor that, in order to become effective, must diffuse through the electrolyte film and cover a substantial portion of the metal surface. Certain physical and chemical properties such as vapor pressure, molecular structure, availability of functional groups for surface physical and chemical bonding, the polarity, contamination, and the conductivity of the electrolyte are critical. Miksic (Ref 9) also states that there is considerable controversy over the importance of and the relationship between the saturated vapor pressure and its influence on the effectiveness of the specific compound.

In a relatively comprehensive recent review by Singh and Banerjee (Ref 10), the authors categorized VCIs based on their application to specific groups of metals; for example, for ferrous metals and alloys, for copper and copper alloys, and for silver and for aluminum.

VCI Action Mechanism

It is widely accepted that a VCI must be a volatile compound or a mixture of such compounds. It must also be capable of forming a relatively stable bond at the metal interface, thus producing a protective layer that limits the penetration of corroding species (Ref 11, 12). According to Balezin (Ref 11) every corrosion inhibitor, including volatile ones, should:

- Be capable of establishing a stable bond with the metal surface in a given environment of certain range of acidity and pressure
- Create an impenetrable layer for corroding ions

The mechanism of inhibition is shown in Fig. 1. Two functional groups are attached to the nucleus, $R_o \cdot R_1$ is responsible for adsorption of the inhibitor on the metal, and surface R_2 gives the thickness and impenetrable nature to the protective inhibitive layer.

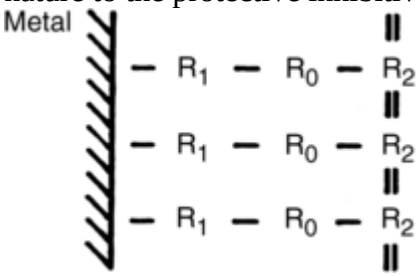

Fig. 1 The mechanism of corrosion inhibition. Functional groups R_1 and R_2 attach to nucleus, R_0, Source: Ref 11

Vapor pressure is a critical parameter in determining the effectiveness of a VCI. A VCI reaches the metal surface that it must protect through the vapor phase. This transport mechanism requires the VCI to possess an optimum vapor pressure. Too low a vapor pressure, of the order of 10^{-6} torr (1.3×10^{-4} Pa, or 2×10^{-8} psi) at

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

room temperature, leads to slow establishment of a protective layer that may result in insufficient corrosion protection. Furthermore, if the space that houses the equipment and the VCI is not sealed, sufficient inhibitor concentration may not be reached. On the other hand, if the vapor pressure is too high, approximately 0.1 torr (13 Pa, or 0.002 psi) at ambient conditions, VCI effectiveness will be limited to a short time period, as its consumption rate will be high. Therefore, a VCI must not have too low or too high a vapor pressure but some optimum vapor pressure. Both corrosion rate of a metal and the volatilization of a VCI are a function of temperature. Because of this similar temperature-dependent nature, the available vapor-phase concentration of a VCI may adjust to aggressiveness of the environment (Ref 12, 13).

The role of irreversible adsorption in the protective action of simple amines and heteroalkylated amines such as diamines, aminoalcohols, or aminoketones on steel, copper, and zinc has been studied (Ref 14). The author concluded that VCIs of the amine type are capable of forming the protective layers for up to 3 months and exhibit a posttreatment effect on the metal surfaces due to irreversible adsorption. The tendency of irreversible adsorption of a VCI depends on its chemical structure. As a rule, low-molecular- weight amines are inclined to desorption and do not exhibit posttreatment effect on steel or zinc, and they initiate copper corrosion. However, some higher-molecular-weight amines have hydrophobicity and can exhibit a posttreatment effect. Low volatility of these higher molecular weight amines limits their application. The best results were obtained with certain heteroalkylated amines that have more stable adsorption due to cyclic structure and presence of two reactive groups. According to Kuznetsov, the most effective VCIs, as a rule, form protective polymolecular films on metal surfaces that consist of thin chemisorbed and physically adsorbed layers.

Andreev and Kuznetsov (Ref 15) have provided some basics of the theory of VCIs. They discussed the role of volatility, solubility, basicity, and other features of VCIs towards their efficiency against CO_2 corrosion. According to them, the effect of chemical structure on these parameters can be quantitatively estimated using the linear free energy relationship.

Structure of VCIs

The efficiency of a VCI depends on its ability to adsorb on the surface of a metal, which in turn is related to its vapor pressure. Both adsorption and vapor pressure depend on the chemical structure of the inhibitor

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

compound. Rosenfeld (Ref 16) studied the effect of structure and the influence of substituents (OH, NO_2, NH_2) on the effectiveness of inhibitors. It was shown that for ferrous metals, aromatic nitrogen bases were ineffective corrosion inhibitors, even when additional hydroxyl or nitro groups were introduced. The majority of strong bases of aliphatic and alicyclic compounds were effective VCIs. He found that cyclohexylamine, hexamethyleneimine, piperidine, morpholine, and benzylamine were the most effective bases. It was claimed that the effectiveness of benzoates could be increased by the introduction of a highly electrophilic nitro group into the ortho-position or two nitro groups into the meta-positions with respect to the carboxyl group. These groups reduce the electron density in the aromatic ring. Miksic (Ref 17) claims that the nitro-group-induced polarization shifts the steady-state potential of the metal in the positive direction (more noble potential), inhibiting the anodic reaction. The introduction of a carboxylic group into the compound promotes the reduction of the nitro group and thus increases the oxidizing properties of the inhibitor. Complex ethers and weak aromatic amines were unsuitable inhibitors. Rosenfeld et al. also evaluated several inorganic salts and found ammonium carbonate and copper-ammonium carbonate to be effective inhibitors (Ref 16).

Trabanelli listed the inhibiting efficiency values of various aliphatic, alicyclic, and aromatic amines deduced from accelerated corrosion tests on Armco iron (Ref 18) in presence of 10 ppm of sulfur dioxide (Ref 19). These values are given in Table 1. He concluded that the aliphatic and alicyclic compounds are superior to those of the aromatic substances having similar vapor pressures. Trabanelli also listed several references that dealt with organic compounds for VCI purposes and that have been documented by Fodor (Ref 8).

In a recent paper, Andreev et al. (Ref 20) reported the study of adsorption on iron and the protective aftereffect of some ethanolamines on ferrous and nonferrous metals. They report that N, N-diethylaminoethanol, the most volatile and effective ethanolamine, forms a polymolecular film. The effect of the chemical structure of VCIs of this type on desorption kinetics and protective aftereffect of adsorption films on the metal surface in air has been analyzed. IFKhAN-111, a new VCI composition based on N,N-diethylaminoethanol, effectively protects both ferrous and nonferrous metals.

Kuznetsov et al. (Ref 21) have reported the protective action of beta-aminoketones ($R(1)R(2)(CH2)_nCH(R(3))C(O)(CH2)_mCH3$) as volatile corrosion inhibitors in systems supersaturated with water and the effect of preliminary exposure to inhibitor vapor on the passive state of metals. The protective

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

action of VCIs under a thin electrolyte and the kinetics of VCI adsorption and desorption has been determined by electrochemical and ellipsometric measurements. Subramanian et al. (Ref 22) synthesized morpholine and its derivatives, such as carbonate, borate, and phosphate, and evaluated their performance on protecting mild steel using weight loss and visual methods under a continuous condensation test. A comparative assessment of their performances is given.

Cole, Dixon, and Keohan (Ref 23) have reported their work on the synthesis and evaluation of new low-toxic, multimetal VCIs. Their approach consisted of reacting potential corrosion inhibitors having active hydrogens with appropriate silylating agents. The most versatile silylating agents were trimethylsilylacetamide, bis (trimethylsilyl)acetamide, hexamethyldisilazane, and trimethylchlorosilane. Skinner's method and a slow-scan potentiodynamic method were used to evaluate the effectiveness of these VCIs on cold rolled steel, brass, Al 7075-T6, and 70-30 Cu-Ni alloy. Several combinations of new compounds showed significant vapor-phase corrosion inhibition compared to any single component on all four alloys.

Vapor Pressure of VCIs

It is well known that a chemical compound used as a volatile inhibitor must possess neither too high nor too low a vapor pressure but an optimum vapor pressure. Two methods, the Rosenfeld-Martin-Knutsen effusion method (Ref 24) and the dynamic flow method (Ref 25) have been used for determining the saturated vapor pressure of VCIs and its dependence on temperature. There are certain inconsistencies in vapor pressure values published by different authors. It is believed that the reproducibility of data depends on experimental parameters that are inherent properties of the test method used. It was shown that measured vaporization rates in vacuum and in the atmosphere are not equal and that differences for the same compound could be relatively large (Ref 26). According to Rosenfeld (Ref 26), the following effects are possible:

- The change in the total pressure modified the Gibb's free energy for the components of the condensed phase.
- An extraneous gas slows down the vaporization of the condensed phase components (kinetic effect).
- Part of the vapor, for example, water vapor, dissolves in the condensed phase and modifies the Gibb's free energy of the latter.

In 1996, Andreev and Kuznetsov (Ref 27) documented the capabilities of correlation methods based on linearization of free energy and constants of volatility for estimation of the vapor pressure of organic VCIs. Ways to optimally choose a VCI and control modification of the structures of compounds belonging to various classes for achieving optimum volatility of inhibitors are given. Andreev (Ref 28) has shown how the volatility of organic substances can be predicted from their boiling points and has given examples of calculating the vapor pressure of several inhibitors.

Most of the effective VCIs are the products of a weak volatile base and a weak volatile acid. Such substances, although ionized in aqueous solutions, undergo substantial hydrolysis, the extent of which is almost independent of concentration (Ref 9). In the case of amine nitrites and amine carboxylates, the net result of those reactions may be written as:

$$RNH_2NO_2 + H_2O \rightarrow (RNH_2)^+{:}OH^- + H^+{:}(NO_2)^-$$

In further support of VCI transport mechanism, it can be noted that amine salts, such as dicyclohexylammonium nitrate or diisobutylammonium sulfate, which are not extensively dissociated by water, do not give significant vapor- phase inhibition. The same is true for slightly hydrolyzed alkali metal salts such as sodium nitrite or sodium benzoate, although the latter is an excellent rust inhibitor when its solutions are in direct contact with a metal surface (Ref 9).

Baker and Zisman (Ref 29) stated that the three nitrite compounds, diisobutyl, diisopropyl, and dicyclohexylammonium nitrite sublime readily at room temperature and inhibit rusting by adsorbing onto exposed metal surfaces to form a protective film. A hydrophobic monolayer is formed, on top of which there may deposit a loosely adhering layer of crystalline inhibitor. The hydrophobic film has a contact angle of 55° for the diisopropyl and 50° for the dicylohexylammonium nitrite at 20 °C (70 °F). The hydrophobic property is attributed to the polar- nonpolar structure of the substituted ammonium nitrite molecule. Because of the low molecular weight of the hydrocarbon portion of the organic nitrite molecule, prolonged contact with bulk water will result in dissolution or desorption of the protective film and allow corrosion of the substrate. Film desorption and solubility of the inhibitor in water lead to limited vapor-phase inhibition under conditions of extreme humidity. Recent developments suggest the use of a mixture of two or more corrosion inhibitors to provide protection in extreme humidity conditions.

VCI Evaluation Methods

According to Romanov and Khanovich (Ref 30) the effectiveness of VCIs can be evaluated in terms of several parameters:

- Time of inhibitor loss
- Relative loss of inhibitor
- Time of appearance of first corrosion products
- Relative residual quantity of inhibitor when corrosion starts
- Rate of corrosion
- A factor that allows for the nature of corrosion

Various accelerated corrosion tests are in use. Before using any of these tests, one must exercise caution (Ref 9); experimental results of accelerated tests in which artificially increased concentrations of corrosive agents, for example, SO_2, H_2S, or NaCl, are used should be compared to actual field performance only after proper calibrations. A similar warning was also expressed by Rosenfeld: "Reproducibility of data depends upon experimental parameters that are inherent properties of the test method employed" (Ref 26).

A widely used evaluating method to describe the relative abilities of inhibitors to prevent rusting of steel is described under ASTM D 1748 (Ref 31). In this method, steel panels are prepared to a prescribed surface finish, dipped in the test oil, allowed to drain, and then suspended in a humidity cabinet at 48.9 ± 1.1 °C (120 ± 2 °F) for a specified number of hours. The oil fails or passes the test according to the size and number of rust dots on the test surfaces of the panels. An essentially identical test method is described under Federal Test Method Standard No. 791B, Method 5329.1, "Corrosion Protection (Humidity Cabinet)." Federal Test Method Standard No.101C, Method 4031 (Ref 32) consists of two procedures: procedure A is for testing VCI materials

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

in crystalline or liquid form, and procedure B is for testing VCI-coated or VCI-treated materials. Determinations may be made in the “as received” condition or on samples exposed to accelerated conditions.

The German vapor-inhibiting ability (VIA) test method (Ref 33) is used to determine the corrosion inhibiting effect of VCI papers or foils. A test object of nonalloyed construction steel with high corrosion sensitivity in regard to condensation, together with the VCI packing aid to be tested, is placed inside a tightly sealed Erlenmeyer flask. The flask is stored at 23 ± 2 °C (73 ± 4 °F) for 20 h. At the end of storage time, a freshly prepared glycerol/water mixture is poured into the flask and it is closed immediately. During handling of the flask, care is taken not to submerge the samples in the glycerol/water mixture. The test flask is stored in a thermostat maintained at 40 ± 1 °C (104 ± 2 °F) for 2 h ± 10 min. At the completion of the test, the test sample of steel is examined visually for signs of corrosion. A control test is run using the test object of steel without a VCI paper/foil. A number grading system of 0 to 3 is used to rate the extent of inhibiting effect, 0 being no corrosion-inhibiting effect and 3 being good corrosion-inhibiting effect.

Kraemer (Ref 34) reported a VCI foil testing procedure that can be used for testing five different metals simultaneously. The basic principle of the test is similar to the German VIA test. The author claims that this is a quick and easy-to- implement VCI testing procedure. It demonstrates various approaches on how deficiencies in the existing test procedures can be avoided with regard to practice orientation, lack of alignment to meet the demands of new VCI recipes, and the usability of the test results for marketing purposes. Another test similar in principle to the German VIA test is the Japanese Industrial Standard for VCI treated paper, JIS Z 1535 (Ref 35).

Skinner (Ref 36) describes a new method for quantitative evaluation of VCIs. The experimental assembly was a preserving jar with a lid that had drilled openings. Any type of inhibitor, including a VCI, is placed at the bottom of the jar. Prepared metal samples are mounted on the openings of the lid using a rubber seal ring. Metal weights are used to keep the metal samples in place. The whole assembly is then placed in a heated water bath. After a suitable inhibitor film-forming period, electrolyte is added. Condensation takes place on the inner surfaces of the jar and the metal samples. After the test duration, metal samples are removed for visual inspection and mass loss determinations. Inhibitor effectiveness is calculated, based on corrosion rates with and without an inhibitor. Skinner writes that the assembly enables a fairly accurate simulation of operational conditions and that reliable quantitative results are obtained by using a new set of jars, lids, glasses, and seal rings for each test.

Jaeger, Garfias-Mesias, and Buchler (Ref 37) have described the use of a four-point-probe method based on resistance measurements. Other test methods used to evaluate VCIs include electrochemical (Ref 38, 39, 40), quartz microbalance (Ref 41), capacitance measurements of the electrical double layer (Ref 42), radiochemical (Ref 43), mass spectroscopy (Ref 44), and IR spectroscopy (Ref 45) methods. Typical slow potentiodynamic scans of Al 6061-T6 in 3.5% NaCl with and without a proprietary inhibitor spray, VCI F (ACF 50, Lear Chemical Corp., Dallas, TX), is shown in Fig. 2 to illustrate the application of an electrochemical method in the evaluation of VCIs (Ref 39).

VCI Applications

Just as catalysts are unique in catalyzing a reaction, VCIs are unique in their corrosion protection capabilities. In other words, compounds that protect ferrous alloys may not protect nonferrous alloys. Instead, they may cause corrosion and vice versa. It is, therefore, important that the user take utmost precaution in the selection of VCIs for a given application. In the absence of supporting data, VCIs must be tested using samples of the materials that need to be protected in a simulated environment that mimics actual conditions.

The applications of different VCIs used for protecting ferrous metals, copper and its alloys, and silver are summarized in Tables 2, 3, and 4.

Table 2 Volatile corrosion inhibitors for protection of ferrous metals

Compound	Details of protection and conditions	Ref
Dicyclohexylamine, dicyclohexylammonium nitrite (DICHAN)	Protection of ferrous metals and alloys	46, 47
Amino nitrobenzoate	Effective passivator	48
Dintroresorcinate hexamethylenetetramine	Protects iron in humid environment	49
Tall oil plus industrial oils	Considerable protection of steel in sulfur dioxide atmosphere	50
Ricinoleic acid hydroxide or its derivatives with ethylene oxide. General formula: $CH_3(CH_2)_5\ C(OH)HCH_2CH{=}CH(CH_2)CONHNH_2$	Protects iron, cast iron, and steel	51
Naphthalene vapors at 250–350 °C (480–660 °F)	Effective for steel in 1 *N* HCl vapors	52
Hexamethylene tetramine with various binders, fillers, and reducing agents $C_6H_{12}N_4 + 4\ NaNO_2 + 10\ H_2O = 6HCHO + 4NH_4NO_2 + 4\ NaOH$ **$4NH_4NO_2 = 4\ NH_3 + 4\ HNO_2$**	Reduces iron corrosion	53
$NaNO_2$, triethanolamine and a low molecular weight surfactant, for example, naphthanic or aliphatic acids	Good for protecting ferrous alloys in field tests	54
Acylation product of lanolin or multibasic alcohols as erythritol, glycerol, sorbitol in oil/organic solvents	Good for protection of iron and steel in humid atmosphere	55
Patented formulation of aliphatic amines, R.CH=NR where R = alkyl group	Good for protection of steel in acid and NaCl atmosphere	56
Alkylation product of 3- and -5 methyl pyrazoles	Protection of steel in H_2S environment	57

Table 3 Volatile corrosion inhibitors for protection of copper and copper alloys

Compound	Details of protection and environment	Ref
Thiourea derivatives, e.g., phenylene thiourea	Protection of brass	58
Acetylenic alcohols	Protection of atmospheric corrosion of copper	59
Triazole compounds, for example, tolyltriazole, benzotriazole ($C_6H_5N_3$)	Excellent protection of copper and copper alloys	49, 60
Aqueous solution of 5–50% complex phenol, carboxylic acid, or its esters (tannic, caffeic, gallic, etc.) and 0.1–20% water soluble heterocyclic compounds such as ethylene thiourea, mercaptobenzothiozole, etc.	Protection of copper from aggressive environments during storage	61
Sodium mercaptobenzothiozole	Protection of copper in the presence of soaps	62

Protection of Aluminum

Aluminum and its alloys are very susceptible to attack in marine environments. Lee et al. (Ref 66) prepared VCI papers, powders, and tablets from a mixture of hexamethylenetetramine and sodium nitrite in a molar ratio of 1 to 4 (Ref 67). They used 6% milk casein or 7% gum arabic as binders. They showed that aluminum samples exposed to 90% relative humidity at 40 °C (104 °F) could be protected using these inhibitors. These researchers claim that the rust-inhibiting mechanism of this system is due partially to the fact that both the ingredients are hygroscopic; as they reduce moisture, corrosion is controlled. More importantly, both ingredients decompose as they absorb water-forming formaldehyde and nitrous acid that prevents surface corrosion of aluminum due to their reducing action. Another decomposition product, ammonia, neutralizes the acidic substances in the sealed atmosphere (Ref 8).

Protection of Ferrous and Nonferrous Metals

In practice, there are generally several metals such as steel, aluminum, copper, and brass are involved in the system requiring protection, and it is important to know the combination of VCIs that can be used to protect them from corrosion. Singh and Banerjee (Ref 10) have given such information in their review article; it is summarized in the following paragraphs.

Benzimidazole, 2-benzimidazolethiol, benzotriazole, and 2-mercaptobenzotriazole are reported to be effective for Cu, Al, Zn, and their alloys (Ref 68). Reaction products of methylbenzotriazole with the water-soluble guanidine class of compounds such as guanidine carbonate or nitrate, or methyl, dimethyl, trimethyl, ethyl, or diethyl guanidine in a molar ratio of 1:0.5 to 1:2 (methylbenzotriazole to guanidine compound) are effective atmospheric-corrosion inhibitors for Cu, brass, Sn, tin plated steel, and Al (Ref 69). Products obtained by reaction of benzotriazole, ethylbenzotriazole, and methylbenzotriazole with soluble urea compounds, such as urea, methyl, ethyl, propyl, or dimethyl urea in a molar ratio of 1:0.5 to 1:2 (triazole to urea compound) at 10 to 60 °C (50 to 140 °F), are effective for Cu, steel, Al, and Zn (Ref 70).

Products of the reaction of 1 *M* benzotriazole, ethyl, or methylbenzotriazole, and 1 to 5 *M* amino compounds such as methylmorpholine, tridodecylamine, didodecylamine, dicyclohexylamine, and dimethylamine are effective for Fe, Cu, Al, Zn, and other metals (Ref 67). The resultant inhibitor is soluble in machine, transformer, engine-lubricating, and other mineral and vegetable oils.

For protecting metals during storage, a compound formed by an incomplete reaction at 110 to 170 °C (230 to 340 °F) for 0.5 to 2 h of glycerine or ethyleneglycol with nitric acid and an alkanolamine with a primary or secondary alkylamine having more than six carbon atoms is used. The product is dissolved in a mineral oil. Mineral oil solution of salts of Zn, Mg, or Pb in naphathenic acid, together with 1-aminoethlimidazoline, is found suitable for temporary protection against atmospheric corrosion (Ref 71).

The reaction product of benzotriazole with a polyamine (for example, ethylene diamine and carboxylic acid) dissolved in spindle oil, effectively resists atmospheric corrosion of Fe, Cu, Al, and Zn (Ref 72).

Baligim et al. (Ref 73) have reported that the mixtures of benzotriazole with benzoates of ammonia, guanidine, hexamethylene-diamine, and monoethanolamine showed a synergistic protective action to steel, Zn, and Cd. A mixture of benzotriazole with guanidine benzoate and ammonium benzoate afforded the best protection. Solidified products of cyclohexylamine, dicyclohexylamine, propylamine, and butylamines with a concentrated solution of benzylidene sorbite in organic acid are reported to have good protecting properties towards ferrous and nonferrous metals. Also 3,5-diphenyl or 3,5-bis-(R-phenyl)- 2,2,4-triazole, where R is hydrogen, alkyl, or hydroxyl, is reported to protect gaseous or aqueous attack on Cu, Ag, Fe, Al, Ni, and their alloys (Ref 74).

Quaternary ammonium salts such as tetra-butyl, tetra-methyl of valeric, caprioic, caprilic, butyric, lauric, myristic trydecylic, palmitic, stearic, benzoic, and carbamic acids and also 0- and p-nitrophenalates are effective for steel, Cu, and brass (Ref 75). In another study, tetrabutyl ammonium 0-nitro phenate is most effective for steel and has no effect on Cu and brass (Ref 76).

In atmospheres polluted with SO_2 and H_2S, 4- H-1, 2, 4 triazole or its derivatives in combination with known inhibitors such as dicyclo-oxylamine nitrite, urea, and $NaNO_2$ is effective for Fe, Al, steel, Cu, Ag, Zn, Ni, Sn, Cd, Mg, Pb, and their alloys (Ref 77). A Dutch patent (Ref 78) describes the solution of an aromatic hydrocarbon, an alkyl-metal nitrate, and alkyl-substituted benzotriazole impregnated in paper to be effective for metal articles made of Al, Zn, Cu, steel, and other metals and alloys.

Substituted pyrazoles dissolved in water, methanol, or ethanol and impregnated in paper offer more protection than dicyclohexylamine nitrite towards atmospheric attack on Al, Cu, Zn, Sn, and other nonferrous metals (Ref 79) Anan et al. (Ref 80) have tested a number of wood industry products as vapor phase inhibitors and have reported that 2,5-dimethylfuran is an excellent inhibitor for nonferrous metals. Cast iron, steel, copper,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

aluminum, solder, and other metals may be protected by the reaction product of 1 mole of cinnamic acid with 1 to 1.05 mole amine (diethylamine, triethylamine, diethanolamine, cyclohexylamine, etc.) with or without a solvent like water (Ref 81). A product of 4- or 5-halohydroxy and/or nitro-substituted benzotriazole with a primary, secondary, or tertiary amine is reported to be highly effective for Al, cast iron, steel, brass solder, copper, and other metals and alloys (Ref 82).

A mixture of benzotriazole with an oxidative character, for example, nitromethane, nitronaphthalene, dinitrophenol, or m-nitrobenzoic acid, dissolved in acetone or dimethylphthalane provided good protection to steel, gray cast iron, Cu, brass, galvanized iron, and Pb in a humid atmosphere (Ref 83). A ternary mixture of benzotriazole, sodium carbonate, and urotropine is highly effective towards steel and Cu (Ref 84). A composition containing (by parts) 3-30 of benzotriazole and higher aliphatic amine (octadecylamine) ensures protection of ferrous metals, Cu and Cu alloys, Al and Al alloys, Zn, Cd, Pb, Ni and Cr, and phosphate and oxide coatings (Ref 84).

In a long-exposure test conducted for six years in a humid atmosphere by Komrova (Ref 85) on steel, Cu, brass, and galvanized iron using dibutylphthalate, isoamylcinnamate, triamylborate, or the nitrobenzoate and other esters, it was concluded that these esters (apart from dibutylphthalate) provide complete corrosion protection towards steel, Cu, and brass at relative humidity values up to 98% and of galvanized iron at relative humidity values up to 85%.

Quraishi et al. (Ref 86, 87, 88, 89) have synthesized several VCIs, measured their vapor pressure at 40 °C, and tested their corrosion-protection efficiencies on common metals such as mild steel, brass, copper, aluminum, and zinc. These VCIs are listed in Table 5.

Table 5 Efficiencies of various volatile corrosion inhibitor compounds

Compound	Vapor pressure (mm Hg) at 40 °C (105 °F)	Efficiency based on weight loss method, %, for protection of					Ref

Protection of Ferrous and Nonferrous Metals

In practice, there are generally several metals such as steel, aluminum, copper, and brass are involved in the system requiring protection, and it is important to know the combination of VCIs that can be used to protect them from corrosion. Singh and Banerjee (Ref 10) have given such information in their review article; it is summarized in the following paragraphs.

Benzimidazole, 2-benzimidazolethiol, benzotriazole, and 2-mercaptobenzotriazole are reported to be effective for Cu, Al, Zn, and their alloys (Ref 68). Reaction products of methylbenzotriazole with the water-soluble guanidine class of compounds such as guanidine carbonate or nitrate, or methyl, dimethyl, trimethyl, ethyl, or diethyl guanidine in a molar ratio of 1:0.5 to 1:2 (methylbenzotriazole to guanidine compound) are effective atmospheric-corrosion inhibitors for Cu, brass, Sn, tin plated steel, and Al (Ref 69). Products obtained by reaction of benzotriazole, ethylbenzotriazole, and methylbenzotriazole with soluble urea compounds, such as urea, methyl, ethyl, propyl, or dimethyl urea in a molar ratio of 1:0.5 to 1:2 (triazole to urea compound) at 10 to 60 °C (50 to 140 °F), are effective for Cu, steel, Al, and Zn (Ref 70).

Products of the reaction of 1 *M* benzotriazole, ethyl, or methylbenzotriazole, and 1 to 5 *M* amino compounds such as methylmorpholine, tridodecylamine, didodecylamine, dicyclohexylamine, and dimethylamine are effective for Fe, Cu, Al, Zn, and other metals (Ref 67). The resultant inhibitor is soluble in machine, transformer, engine-lubricating, and other mineral and vegetable oils.

For protecting metals during storage, a compound formed by an incomplete reaction at 110 to 170 °C (230 to 340 °F) for 0.5 to 2 h of glycerine or ethyleneglycol with nitric acid and an alkanolamine with a primary or secondary alkylamine having more than six carbon atoms is used. The product is dissolved in a mineral oil. Mineral oil solution of salts of Zn, Mg, or Pb in naphthenic acid, together with 1-aminoethlimidazoline, is found suitable for temporary protection against atmospheric corrosion (Ref 71).

The reaction product of benzotriazole with a polyamine (for example, ethylene diamine and carboxylic acid) dissolved in spindle oil, effectively resists atmospheric corrosion of Fe, Cu, Al, and Zn (Ref 72).

Baligim et al. (Ref 73) have reported that the mixtures of benzotriazole with benzoates of ammonia, guanidine, hexamethylene-diamine, and monoethanolamine showed a synergistic protective action to steel, Zn, and Cd. A mixture of benzotriazole with guanidine benzoate and ammonium benzoate afforded the best protection.

مرجع مهندسی مواد و متالورژی

Solidified products of cyclohexylamine, dicyclohexylamine, propylamine, and butylamines with a concentrated solution of benzylidene sorbite in organic acid are reported to have good protecting properties towards ferrous and nonferrous metals. Also 3,5-diphenyl or 3,5-bis-(R-phenyl)- 2,2,4-triazole, where R is hydrogen, alkyl, or hydroxyl, is reported to protect gaseous or aqueous attack on Cu, Ag, Fe, Al, Ni, and their alloys (Ref 74).

Quaternary ammonium salts such as tetra-butyl, tetra-methyl of valeric, caprioic, caprilic, butyric, lauric, myristic trydecylic, palmitic, stearic, benzoic, and carbamic acids and also 0- and p-nitrophenalates are effective for steel, Cu, and brass (Ref 75). In another study, tetrabutyl ammonium 0-nitro phenate is most effective for steel and has no effect on Cu and brass (Ref 76).

In atmospheres polluted with SO_2 and H_2S, 4- H-1, 2, 4 triazole or its derivatives in combination with known inhibitors such as dicyclo-oxylamine nitrite, urea, and $NaNO_2$ is effective for Fe, Al, steel, Cu, Ag, Zn, Ni, Sn, Cd, Mg, Pb, and their alloys (Ref 77). A Dutch patent (Ref 78) describes the solution of an aromatic hydrocarbon, an alkyl-metal nitrate, and alkyl-substituted benzotriazole impregnated in paper to be effective for metal articles made of Al, Zn, Cu, steel, and other metals and alloys.

Substituted pyrazoles dissolved in water, methanol, or ethanol and impregnated in paper offer more protection than dicyclohexylamine nitrite towards atmospheric attack on Al, Cu, Zn, Sn, and other nonferrous metals (Ref 79) Anan et al. (Ref 80) have tested a number of wood industry products as vapor phase inhibitors and have reported that 2,5-dimethylfuran is an excellent inhibitor for nonferrous metals. Cast iron, steel, copper, aluminum, solder, and other metals may be protected by the reaction product of 1 mole of cinnamic acid with 1 to 1.05 mole amine (diethylamine, triethylamine, diethanolamine, cyclohexylamine, etc.) with or without a solvent like water (Ref 81). A product of 4- or 5-halohydroxy and/or nitro-substituted benzotriazole with a primary, secondary, or tertiary amine is reported to be highly effective for Al, cast iron, steel, brass solder, copper, and other metals and alloys (Ref 82).

A mixture of benzotriazole with an oxidative character, for example, nitromethane, nitronaphthalene, dinitrophenol, or m-nitrobenzoic acid, dissolved in acetone or dimethylphthalane provided good protection to steel, gray cast iron, Cu, brass, galvanized iron, and Pb in a humid atmosphere (Ref 83). A ternary mixture of benzotriazole, sodium carbonate, and urotropine is highly effective towards steel and Cu (Ref 84). A composition containing (by parts) 3-30 of benzotriazole and higher aliphatic amine (octadecylamine) ensures protection of ferrous metals, Cu and Cu alloys, Al and Al alloys, Zn, Cd, Pb, Ni and Cr, and phosphate and oxide coatings (Ref 84).

In a long-exposure test conducted for six years in a humid atmosphere by Komrova (Ref 85) on steel, Cu, brass, and galvanized iron using dibutylphthalate, isoamylcinnamate, triamylborate, or the nitrobenzoate and other esters, it was concluded that these esters (apart from dibutylphthalate) provide complete corrosion protection towards steel, Cu, and brass at relative humidity values up to 98% and of galvanized iron at relative humidity values up to 85%.

Quraishi et al. (Ref 86, 87, 88, 89) have synthesized several VCIs, measured their vapor pressure at 40 °C, and tested their corrosion-protection efficiencies on common metals such as mild steel, brass, copper, aluminum, and zinc. These VCIs are listed in Table 5.

Table 5 Efficiencies of various volatile corrosion inhibitor compounds

Compound	Vapor pressure (mm Hg) at 40 °C (105 °F)	Efficiency based on weight loss method, %, for protection of					Ref

Corrosion Inhibitors for Oil and Gas Production

Revised by Richard L. Martin, BJ Unichem Chemical Services

Introduction

CORROSION INHIBITORS historically used in the oil field can be grouped into several common types or mechanistic classes: passivating, vapor phase, cathodic, anodic, film forming, neutralizing, and reactive. The common material of construction in oil and gas production is carbon or low-alloy steel, so the primary aim is steel inhibition; other metals can also benefit from many of these inhibitors (Ref 1, 2). Inorganic inhibitors, such as sodium arsenite (Na_2HAsO_3) and sodium ferrocyanide, were used in early days to inhibit carbon dioxide (CO_2) corrosion in oil wells, but the treatment frequency and effectiveness were not satisfactory. This led to the development of many organic chemical formulations that frequently incorporated film-forming amines and their salts.

In the mid-1940s, long-chain polar compounds were shown to have inhibitive properties. This discovery dramatically altered the inhibitor practices on primary production oil wells and gas wells. It permitted operation of wells that, because of the corrosivity and volume of water produced along with the hydrocarbons, would not have been used due to economics. Perhaps entire reservoirs would have been abandoned because of the high cost of corrosion. Inhibitors also allowed the injection and production of high volumes of corrosive water resulting from the secondary-recovery concept of waterflooding. Tertiary recovery floods, such as CO_2, steam, polymer, and in situ combustion floods, would usually be uneconomical without the application of corrosion inhibitors (Ref 3).

At first, it was thought that organic compounds inhibit corrosion by adsorbing at the metal-solution interface. Three types of adsorption could be possible with organic inhibitors: π- bond orbital adsorption, electrostatic adsorption, and chemisorption. A more simplistic view of this mechanism of corrosion inhibitors can be described as controlled precipitation of the inhibitor from its environment (water and hydrocarbons) onto metal surfaces. A more recent view of the mechanism of oil/gas field corrosion inhibitors invokes the incorporation of the inhibitor into a thin corrosion-product film. This film then becomes more resistant to the flow of ions and electrons, so the corrosion reaction is slowed (Ref 4, 5).

Over the years, many improvements in inhibitor technology have been made in formulation and methods of applying inhibitors. The methods of evaluating the performance during their use have also advanced considerably.

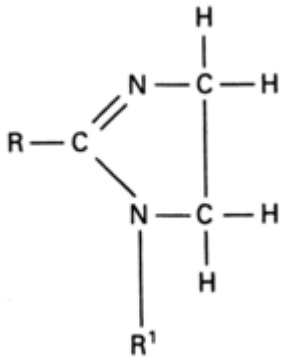
Corrosion Inhibitors for Oil and Gas Production

Revised by Richard L. Martin, BJ Unichem Chemical Services

Inhibitor Formulations

Many different inhibitor formulations are available. However, most of these inhibitors are produced from only a few basic types of starting molecules. Fatty acids and some form of basic nitrogen-containing precursor are the principal active-ingredient sources. Historically, the first proprietary organic inhibitors were fatty imidazolines made from by-product fatty acids and polyethylene amines. The reaction is a condensation reaction that produces the following structure:



in which R is a chain of carbon molecules (average: C_{18}), and R^1 is a hydrogen atom or C_2H_4N group.

The molecules produced from these products were dissolved in hydrocarbon solvent or water- alcohol-based solvent, depending on whether they were further reacted. Typical further reactions were salting with acetic acid (CH_3COOH) or quaternizing with a short-chain alkyl chloride. Highly corrosive wells, such as those found in the Talco Field (Texas), required daily batch treatments with these early inhibitors.

The inhibitors currently in use are generally more complex mixtures of reaction products and have been formulated to meet the demands of a very competitive industry. Some of these demands on inhibitor formulation are discussed subsequently.

Pour Point. Because inhibitors are usually stored and used outdoors, they must remain liquid at low temperatures. A pour point of -30 °C (-20 °F) is usually required. Some areas of the world may have an even lower pour point requirement (-40 to -45 °C, or -40 to -50 °F). The required pour point often dictates the activity and solvent system of a particular inhibitor.

Solubility. Solubility/dispersibility characteristics of an inhibitor are dictated by the intended use. By their very nature, most inhibitors are not truly soluble in either hydrocarbons or water; degrees of dispersibility are more descriptive.

Performance. The end user of corrosion inhibitors will often specify a laboratory test that the inhibitor must pass before a field trial or purchase is considered. The wheel test is sometimes used in the oil- and gas-producing industry. Therefore, many inhibitors are formulated to pass the wheel test (see the section “Laboratory Testing of Corrosion Inhibitors” in this article).

Emulsion Tendencies. The application of the inhibitor must not cause secondary problems. Batch treatments have often caused emulsions of the hydrocarbons and water that, relative to normal operations, are extremely difficult to break. In some cases, the emulsions resulting from batch treatments were so viscous that the surface separation equipment was plugged by the emulsion formed in the presence of high inhibitor concentrations.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Therefore, inhibitors are specifically formulated to be nonemulsifying. Alternatively, emulsion-breaker chemicals are added to formulations in small amounts to prevent emulsions.

Table 1 lists the cationic molecular structures found in many commercial inhibitors. These amines or cationic molecules are often neutralized with an organic acid or quaternized to achieve a final basic product. In many inhibitor formulations, the choice of the acid or anionic molecule is critical to the performance of the final product. Also, a mixture of acids is sometimes used to obtain a desired property. In addition, Table 2 lists the anionic molecular structures found in many commercial inhibitors. The compositions of fatty acids used in inhibitor production are given in Table 3.

Table 3 Sources of fatty acids used in corrosion inhibitors

Data obtained from literature sources and from Procter & Gamble analyses. Crude tall oil, distilled tall oil, and distilled tall oil fatty acids are the most common sources for oleophilic groups of inhibitor molecules. Tall oil is a by-product of pulping wood chips (usually pine wood) by the kraft process. Although tall oil is removed from the wood as a sodium salt, 10 to 15% inert unsaponifiable material is present. Crude tall oil is one of the cheapest raw materials known to the industry, but due to the variability of composition from tree to tree, experience and care are required in its use.

Corrosion Inhibitors for Oil and Gas Production

Revised by Richard L. Martin, BJ Unichem Chemical Services

Varying Characteristics of Oil and Gas Wells

The varying characteristics and number of organic inhibitors are explained by the varying characteristics of oil and gas wells. In this article, systems are characterized as oil wells, gas wells, water injection systems, or pipelines.

Oil Wells. Wells that produce liquid hydrocarbons and water can be divided into two basic types: flowing wells, which have a natural flow of hydrocarbons and water to the surface, and artificially lifted wells, which require some form of pump. The latter type includes rod-pumped wells, which use a positive-displacement downhole pump connected to the surface by rods; gas- lifted wells, in which gas in injected at some point down the hole to lighten the fluid and cause flow; electrical submerged-pump wells, which use multistage centrifugal pumps placed near the bottom of the well; and hydraulically pumped wells, which use positive-displacement pumps driven hydraulically by oil or water from a surface motor and pump.

Gas Wells. Most gas wells flow naturally. These include dry gas wells, which produce mainly gaseous hydrocarbons, and gas-condensate wells, which produce significant quantities of liquid hydrocarbons, sometimes water, liquid petroleum gas (LPG), and methane at high pressures from high-temperature reservoirs. Lower- pressure gas wells sometimes incorporate artificial lift to prevent liquids from accumulating at the well bottom. These wells can also be produced with plunger lifts or injected foamer to keep liquids moving up so that pressure buildups do not occur.

Water injection systems are used for disposal, waterflood, or tertiary recovery.

Each of the previously mentioned categories can be divided into a sweet or sour designation, which is a function of the absence or presence of hydrogen sulfide (H_2S). Corrosion is usually defined as sour when any phase of the produced fluids contains measurable H_2S. Sweet corrosion is caused by the presence of CO_2, formic acid (HCOOH), CH_3COOH, or other short-chain acids in the produced gas and/or fluids. Because corrosivity is usually related to the ratio of produced water to hydrocarbons, the volume and composition of the produced water and oil will influence the application method and performance of the inhibitor. Oxygen entry into either a sweet or sour corrosion system results in significant corrosion consequences. Corrosion is accelerated, deposition is increased, and inhibitor function is altered (Ref 6, 7). Many corrosion systems are considered to be oxygen influenced if the dissolved oxygen concentration exceeds 25 parts per billion (ppb).

Pipelines conduct produced fluids from or injection water toward the aforementioned wells. These lines are subject to the same corrosion conditions as described for wells. For example, sour corrosion can be accelerated by oxygen dissolved in methanol added for hydrate control. Application of corrosion inhibitors depends on the location (flow regime) and amount (production rate) of the aqueous phase. Computer programs are available to assist in this evaluation. After oil/water separation or gas processing, pipelines are commonly termed transmission lines. Transmission lines are less subject to the previously mentioned corrosion conditions. Corrosion in transmission lines is more often due to microbiologically influenced corrosion factors.

Corrosion Inhibitors for Oil and Gas Production

Revised by Richard L. Martin, BJ Unichem Chemical Services

Influence of Well Depth and Completion Method

The industry is continuously seeking new oil and gas reserves. New finds are generally deeper and/or more inaccessible. As the depth increases in the newer wells, the bottom hole temperature increases. Bottom hole temperatures of 205 °C (400 °F) have been encountered in several deep reservoirs. High labor and equipment costs in offshore production and remote areas plus safety and environmental concerns have caused the risk of equipment malfunction due to inhibitor failure (incorrect method of application or poor inhibitor performance) to become increasingly important. This has forced the industry to screen inhibitors carefully and to select application methods that are highly reliable.

R.L. Martin, Corrosion Inhibitors for Oil and Gas Production, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 878–886

Corrosion Inhibitors for Oil and Gas Production

Revised by Richard L. Martin, BJ Unichem Chemical Services

Factors Influencing Corrosivity of Produced Fluids

Characteristics of Fluids. Produced fluids vary from noncorrosive hydrocarbons to extremely corrosive brines. The amount of water in the produced fluids may vary from 1 to 99%. In general, the higher the concentration of dissolved acid gases (and oxygen), the higher the uninhibited corrosion rate (Ref 3, 7).

Temperature, Pressure, and Velocity Effects. The effect of temperature is not straightforward. Chemical reaction rates double with each 10 °C (18 °F) temperature increase. However, the solubility of the acid gasses decreases with temperature; therefore, a smaller increase in corrosivity is seen with temperature rise. Additionally, above approximately 65 °C (150 °F), the nature of the surface corrosion product changes to become more protective; this is an especially important factor in sweet systems. The effect of increased pressure is to raise the solubility of acid gases, thus increasing the corrosivity of the water. Bottom hole pressures exceeding 138 MPa (20 ksi) are occasionally encountered.

Pressure is related to corrosivity in sweet gas wells as follows (Ref 8):

- A partial pressure of CO_2 below 48 kPa (7 psi) is considered noncorrosive.
- A partial pressure of CO_2 between 48 and 207 kPa (7 and 30 psi) may indicate corrosion.
- A partial pressure of CO_2 above 207 kPa (30 psi) usually indicates severe corrosion.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Although this general rule is widely accepted, many exceptions have been noted.

Cyclic Loading, Stress, and Wear. Corrosion inhibitors can be specially formulated to control corrosion that is accelerated by cyclic loading, stress, and wear. Methods of evaluating inhibitors for inhibition of corrosion accelerated by stress and fatigue are discussed in Ref 9, 10, 11, 12, 13, 14. Because most oil wells are not perfectly vertical holes, wear of tubing by rods becomes a problem in wells that are highly deviated or crooked. Rod guides and inhibitors are sometimes effective in controlling wear and corrosion.

Erosion and Abrasion. Many wells produce fine sand along with the fluids. This fine sand may remove inhibitor films, depending on the velocity of the fluids. Also, erosion by this fine sand is the primary cause of equipment failure in artificially lifted wells. Sand control, a process of permanently preventing movement of fine sand particles from the formation, is often necessary for good corrosion inhibition.

Water Volume. Severe corrosion can begin at initial water production (Ref 15). Corrosion usually develops in wells as increasing percentages of water are produced. Corrosion in this type of well may begin after several years of production.

A 1953 survey of corrosive oil wells showed that no oil wells were corrosive when the water production was under 40%. Water contents from 0 to 40% usually represent well-emulsified water. Because oil is the continuous phase, the production equipment is considered to be oil-wet (Ref 16, 17, 18, 19, 20). However, oil production in the North Sea and Alaska's North Slope has shown that water contents of approximately 4% may be highly corrosive (Ref 21). Many fields have produced sour water from the outset, although many have changed from sweet to sour during the water injection phase. Bacterial activity is commonly responsible. (A waterflood is the injection of water into a field to displace hydrocarbon from the field.) Sour fluids in these mature waterfloods are generally regarded as being corrosive.

Corrosion Inhibitors for Oil and Gas Production

Revised by Richard L. Martin, BJ Unichem Chemical Services

Methods of Inhibitor Application

Continuous treatment of producing wells and waterflood injection systems is accomplished by a chemical-proportioning pump that operates constantly. Continuous treatment of artificially lifted wells is carried out by continuously injecting a small quantity of inhibitor into the annulus with a portion of the produced fluid. This technique is known as slip-stream flushing. After an initial treatment of several gallons of inhibitor, the inhibitor is continuously injected in order to maintain an inhibitor concentration of 15 to 100 ppm in the produced fluid. The mechanical setup of continuous treatment is simple in artificially lifted wells, because the annulus is usually open to the tubing. Gas-lifted wells can be continuously inhibited by injection into the lift gas. When the lift gas is dry, inhibitor formulations are available that will remain flowable until they contact produced liquids. A treating system of inhibiting gas-lifted wells is described in Ref 22.

Continuous treatment of flowing oil and gas wells requires certain types of completion. The following completion techniques are engineered for continuous treating:

- *Dual completion (either concentric or parallel):* In this completion technique, two separate strings of tubing are run in the same hole and may or may not be the same size.
- *Capillary or small-bore treating string:* involves using a string of continuous, small- diameter tubing strapped to the outside of the well tubing or pipe. This type of completion provides excellent inhibitor injection control with superior results (Ref 23, 24, 25, 26). Disadvantages are the cost and the mechanical difficulties.
- *Side pocket mandrel valve:* The annulus is filled with liquid inhibitor solution, and continuous injection on the surface is used to apply pressure to the annulus so that the injection valve opens. Mechanical difficulties with the valve and the stability of the inhibitor solution are disadvantages.
- *Packerless completion:* No downhole valves are involved, but inhibitor solution stability must be considered (Ref 27, 28). At high bottom hole temperatures, continuous treatment is generally selected when production rates are such that the expected treatment life of batch treatments is economically prohibitive.
- *Low-cost continuous method for marginal gas wells:* involves perforating the tubing above the packer, filling the annulus with an inhibitor solution, and then continuously pumping inhibitor solution into the annulus at the surface (Ref 29)

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Hydraulically pumped wells are usually inhibited by injection into the power fluid; some wells have oil as the pressurized liquid (power oil), and some use produced brine (power water).

Intermittent Treatment of Gas Wells. Batch or intermittent treatment of flowing gas or oil wells may be effective at low fluid-production volumes. Treatment is accomplished by diluting the inhibitor into hydrocarbons or water, then shutting in the well long enough for the inhibitor solution to fall to the bottom of the well. Because the liquid fluid level is unknown, the depth to which the inhibitor solution will fall is unknown; consequently, the results of the application are difficult to predict. Regular treatment intervals from 3 to 6 months can be obtained under optimal conditions in low-volume wells. A more positive approach to batch treating is full tubing displacement. This is accomplished by pumping a solution into the well and displacing the solution with water or hydrocarbon to the bottom of the well. Another approach would be to displace the inhibitor solution with an inert gas, such as nitrogen; nitrogen is less likely than water or hydrocarbon to stop the flow of the well.

Squeeze Treating. Successful squeeze treatments were first reported in 1955 in the Placido Field of Victoria County, TX (Ref 30, 31). Since that time, the method of squeezing inhibitor into the formation has been refined.

Squeeze treating is applicable to all oil and gas wells with sufficiently porous and permeable producing zones. It will result in essentially continuous treatment, because it has been found that some inhibitors will adsorb rapidly onto sand and will desorb slowly into produced fluids from the producing sand. The inhibitors used for this technique should be very film persistent. The most widely used technique is to mix one to two 208 L (55 gal) drums of inhibitor with 10 to 20 barrels of diesel, kerosene, lease crude, or condensate. The inhibitor solution is displaced to the bottom of the well, and an overflush of 200 to 500 barrels or more of oil or brine is then used to push the inhibitor into the formation. This technique often leads to continuous feedback lasting anywhere from 3 months to 2 years. The advantages of this method are that it will successfully treat wells with high fluid levels, the frequency of treatment is drastically reduced, and it is more reliable than some batch methods. Also, the entire length of the tubing is treated. However, squeeze treating is not recommended for all wells.

The major concern with squeeze treating is the possibility of plugging the formation by emulsion blocks or wettability reversal in the producing formation. The possible plugging effect of inhibitor squeezes on cores was studied in the laboratory, and it was reported that various sandstone formations differed in adsorption characteristics and that limestones were markedly different from sandstones (Ref 32, 33). This work was expanded on in a field study, which is discussed in Ref 34. Tracer studies on formation squeezes were also conducted (Ref 35).

In a unique variation of the formation squeeze, the corrosion inhibitor/hydrocarbon diluent is atomized with an inert gas, such as nitrogen, and displaced down the tubing and into the formation with the same inert gas (Ref 36). Longer squeeze life and better inhibition have been claimed. The method is advantageous in wells with low bottom hole pressures, because the low density of the nitrogen eases the resumption of production in such wells.

Batch Treatment of Pumping Wells. Corrosion problems in pumped wells are directly related to the production volume and water content of producing wells. This will be the case whether the lift method is sucker rod pump, electric submersible pump (ESP), or progressive cavity pump. Severe corrosion problems can be identified by excessive rod, pump, and tubing failures. Embrittlement and pitting result in reduced rod life and fatigue failures, which are greatly accelerated by the presence of H_2S. Hydrogen sulfide and high water volumes are common to most waterfloods.

The most common way of treating pumped wells consists of batch treating with a pump truck, equipped to flush the inhibitor down the annulus with produced fluids or water. In some wells, batch treatment is accomplished without treating trucks by the use of wellhead inhibitor lubricator pots and manual flushing with produced fluids.

The methodology of batch treating involves the development of guidelines for each field. The required guidelines are volume of inhibitor per treatment, volume of flush, and treatment frequency. General rules for batch volume are based on barrels of fluid produced per day (BFPD). One set of general rules for frequency is given in Ref 37 and 38:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Volume of total fluid, BFPD	Frequency
0–50	Monthly
50–150	Every 2 weeks
150–350	Weekly
350–800	Twice weekly

Another set of recommended guidelines for treating frequency is given in Ref 39.

Flush volume is usually based on the nature of the inhibitor and the height of the liquid column in the annulus above the pump. Usually, two to four barrels of produced water are used per 300 m (1000 ft) of liquid level above the pump when the following guidelines are followed:

Annular liquid level above pump		Optimal corrosion inhibitor type
m	**ft**	
0–150	0–500	Oil soluble, limited brine dispersibility
150–300	500–1000	Oil soluble, brine dispersible
300+	1000+	Highly dispersible or soluble in brine

Successful batch treating of rod-pumped wells also involves the following factors:

- Circulation of high-volume wells is often necessary. In high gas-oil ratio (GOR) wells, it may be necessary to isolate the annulus for approximately 2 h after treatment to allow the inhibitor slug to fall.
- Calculation of inhibitor volume based on the frequency of treatment and fluid production is an accepted procedure; inhibitor concentration is generally maintained at 25 to 35 ppm.
- Determination of the correct minimum overflush
- Selection of the proper inhibitor

Automatic computer-controlled chemical injectors are available for batch treating. The cost advantages and disadvantages of computer-controlled chemical injectors are discussed in Ref 39. Corrosion fatigue in rod-pumped wells is as important as weight loss corrosion. A corrosion fatigue testing apparatus is described in Ref 40 that can be used to field test corrosion inhibitors specially formulated to prevent corrosion fatigue (Ref 14).

Treatment With High-Density Corrosion Inhibitors. Most liquid inhibitors have a density of 910 to 980 g/L (7.6 to 8.2 lb/gal). High-density liquid corrosion inhibitors are formulations that have been coupled with weighting agents. Their high density (1200 g/L, or 10 lb/gal) and their immiscibility with hydrocarbons and water enable them to fall through static columns of hydrocarbons. Continuous treating can be accomplished by using frequent small-volume batch treatments. Some applications for these unique inhibitors are high-fluid-level pumping wells and/or high- and low-pressure gas wells.

The weighting agent in high-density inhibitors is often zinc chloride ($ZnCl_2$), which may precipitate as zinc sulfide (ZnS) or zinc oxide (ZnO) when applied to sour wells. Data on the fall rates of high-density and regular inhibitors are given in Ref 41 and 42. Other forms of weighted inhibitors, such as solid sticks and capsules, are available. More detailed information on liquid weighted inhibitors is available in Ref 43.

Green Inhibitors. Especially for offshore applications, the final fate of corrosion inhibitors relative to the environment becomes important. Ideally, green corrosion inhibitors should have low toxicity to organisms (marine when applied offshore), be biodegradable, and not partition into fatty tissues of organisms, so as not to enter the food chain. To achieve all these properties and still have effective corrosion inhibition usually requires the cooperation of multiple disciplines (Ref 44).

Miscellaneous Treatments. Slow-dissolving solids, sticks, pellets, microencapsulated droplets, and other configurations are used as vehicles for corrosion inhibitors. In addition, downhole dump bailers and concentric kill strings are used for both batch and continuous treatment.

Corrosion Inhibitors for Oil and Gas Production

Revised by Richard L. Martin, BJ Unichem Chemical Services

Corrosion Problems and Inhibition in Waterfloods

Corrosion inhibition in waterfloods involves protecting surface-gathering lines and tanks used to recycle produced water, water-treating equipment, and the surface lines and downhole tubing of injection wells. The primary causes of corrosion in waterfloods are oxygen contamination and acid gasses dissolved in the brine. Due to the large amount of water handled, the cost of corrosion failures in repair and downtime can be substantial (Ref 45).

Oxygen Corrosion. Oxygen may be present in the supply water when the water source is surface or shallow ground water. Seawater is commonly used in near-shore or offshore fields and usually contains approximately 8 ppm dissolved oxygen. Another oxygen source is small amounts of contamination into closed water-handling systems through nongas-blanketed holding tanks, open vents, thief hatches of water holding tanks, as well as around the shaft of the suction side of centrifugal transfer pumps (Ref 46). Crude oil or diesel oil blankets on the water surface in tanks do not stop oxygen from contaminating the water. Oxygen corrosion can be controlled by removing the oxygen or by using inhibitors.

Oxygen removal by mechanical means applies mainly to high-oxygen-containing waters, such as seawater. Oxygen is removed by the following mechanical processes:

- Countercurrent gas-stripping towers represent the simplest and most economical method, if large amounts of natural gas are available at low cost.
- Vacuum tower removal is applicable where no gas is available (Ref 47).
- The water can be gas lifted from its source— for example, lifting seawater from a depth of 30 m (100 ft) by the same technology used to lift fluids in gas-lift oil wells.
- Usually, none of the previously mentioned methods will reduce the oxygen to the required point; therefore, chemical oxygen scavengers must be used to remove the last traces.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Oxygen scavenging refers to removal of the oxygen by chemical reactions. Oxygen scavengers can reduce the oxygen content of the water to less than 10 ppb, a level that is considered insignificant from the corrosivity standpoint. The most commonly used oxygen scavengers are:

- Sulfite ion (SO_3^{2-}), which may come from sulfur dioxide (SO_2) gas generated on the site, from solutions of sodium sulfite (Na_2SO_3) or sodium bisulfite ($NaHSO_3$), or from a solution of ammonium bisulfite (NH_4HSO_3). Ammonium bisulfite is the most commonly used because of its stability in storage and its ability to exist as a highly concentrated liquid solution. Solutions containing 60 to 70% NH_4HSO_3 are commercially available.
- Hydrazine, which is a practical oxygen-scavenging chemical only at elevated temperatures, such as in boilers or steam generators
- Sodium hydrosulfite ($NaHSO_2$) is recommended for scavenging oxygen, with much less polymer degradation than SO_3^{2-}, in polymer flood applications. However, $NaHSO_2$ is very unstable in solution and requires storage of a solid and solution preparation daily.

The reaction of the oxygen scavengers listed previously involves a free-radical mechanism that necessitates an initiating step. Very small additions (<1 ppm) of transition-metal ions, such as cobalt, will catalyze the reaction.

The variables affecting the rate and completeness of the SO_3^{2-} reaction are important in designing a waterflood. Sodium sulfite used in a 1 to 2 ppm stoichiometric excess plus 0.1 to 0.2 ppm cobalt chloride ($CoCl_2$) at ambient temperature often completely removes oxygen in an acceptable time period (usually a few minutes). When the rate or degree of completeness of the reaction is not satisfactory, an investigation into possible interferences with the reaction may be necessary. The most common problems are deactivation and insufficient reaction time at the service temperature of the catalyst. All transition metals are not equally effective, and pH affects the various possible metal ions differently (Ref 48, 49). In waters containing sulfide, the catalyst can be precipitated as an insoluble solid (Ref 50), or it can be complexed with a chelating agent, such as ethylenediamine tetraacetic acid (EDTA). In both cases, the catalyst is rendered inactive.

Water used for cyclic steam injection and steam floods must be given greater attention with regard to oxygen corrosion. Corrosion and other water-treating problems in steam injection systems are discussed in Ref 51.

When removal of oxygen is not practical because of small volumes of water to be treated or other factors, two organic inhibitors are available. The first, a zinc amino methyl phosphonate, reportedly achieves excellent oxygen corrosion control in fresh to slightly brackish supply waters (Ref 52, 53, 54). The second, an organic sulfophosphate, exhibits inhibition of produced water-handling systems processing sour brine contaminated with oxygen (Ref 55). The inhibitor is dispersible only in water and is said to inhibit better when H_2S and hydrocarbons are present in the water in addition to oxygen. Other inhibitors have been developed in recent years for control of oxygen-accelerated corrosion (Ref 7).

Alternatives to oxygen removal and/or organic corrosion inhibitors are the use of internally coated steel pipe with either plastic or cement lining, corrosion-resistant alloys, fiberglass-reinforced plastic, or other nonmetals in place of carbon steel. Finally, inorganic inhibitors used in aerated water—for example, cooling towers and radiators—are usually not effective and are too expensive to be applied to waters on a once-through basis, as would be the case in a waterflood.

Corrosion by Acid Gases. The corrosive acids found in waterflood systems are usually encountered because produced water is recycled and mixed with the supply water. In a few fields, the produced water has been kept separate from the supply water.

Experience has shown that the presence of H_2S in injection water is much more troublesome with regard to corrosivity and handling problems than waters containing only CO_2 or short-chain acids. This is the case primarily because iron sulfide (FeS), the product of H_2S corrosion, is very insoluble. The FeS corrosion product may deposit on downstream equipment, may plug injection wells, and may cause difficulties in oil-water separation. An inhibitor has not yet been discovered to prevent the precipitation of FeS.

The corrosion inhibitors designed for acidic corrosion are usually film-forming amine salts. Water-soluble or dispersible modifications of these materials are used in waterflood applications. Experience has shown that the system must be free of oxygen contamination for most of these materials to be effective. Therefore, the previously mentioned materials are usually used in conjunction with oxygen scavengers.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Film-forming ability and stability are determined by the interplay of a number of factors involving both the oleophilic hydrocarbon chain and the polar portion of the molecule. Changes in the oleophilic portion of the molecule that promote water solubility tend to decrease filming ability. The conflict between solubility and film stability is one of the basic obstacles in formulating inhibitors for waterfloods. Water compatibility or solubility is important if the water is to be injected into a low-permeability reservoir.

The chemistry and ideas used in inhibitor molecules for producing wells have been extended or modified for use in waterfloods. Sufficient dispersibility (added to the inhibitor so that the inhibitor may be effectively transported from the injection point to the farthest injection well) must be balanced with the film-forming ability of the inhibitor. Aside from the solubility or dispersibility requirement, the same molecules can be used for waterfloods. The required concentration of inhibitor, however, is usually increased by the absence of the hydrocarbon phase. For example, addition of a hydrocarbon phase to sour brine was found to lower the inhibitor requirement for equal inhibition from 25 to 5 ppm (Ref 56). Many other investigations and field experience show that the presence of hydrocarbons augments film formation and persistence.

Corrosion Inhibitors for Oil and Gas Production

Revised by Richard L. Martin, BJ Unichem Chemical Services

Bacteria-Induced Corrosion

Sulfate-reducing bacteria (SRB)(genus *Desulfovibrio*) reduce sulfate (SO_4^{2-}) to H_2S, often converting a noncorrosive source water into an aggressively corrosive water. Changes in the biological environment, such as temperature, velocity, pressure, shielding debris (in the bottom of tanks), deposits (organic and inorganic), and nutrients, cause bacteria to grow. The change that appears to cause the greatest increase in growth consists of transporting the water to a surface holding tank having many static areas and letting the water warm up or cool to 40 ± 6 °C (100 ± 10 °F). Sulfate-reducing bacteria also produce tubercles or biomass in conjunction with other bacteria. The SRB have, in many cases, produced enough H_2S to make a sweet surface system sour and have been thought to be the cause of producing a reservoir change from sweet to sour. The injection of seawater into offshore fields has probably been the worst offender in introducing SRB to production equipment. Changes in temperature can increase SRB growth from zero to high levels. Additional information on this subject is available in the article “Microbiologically Influenced Corrosion” in this Volume. Another type of bacteria common in the petroleum industry is termed acid- producing bacteria (APB). These bacteria produce simple carboxylic acids. Colonies of these bacteria can produce small, deep corrosion pits. These bacteria can be identified and controlled by the same methods as SRB.

Solutions to bacteria corrosion problems include avoiding static or dead areas in initial surface system design, keeping the system clean, and using a bactericide. Cleaning the physical surface system consists of yearly removal of settled solids in surface tanks and separation vessels. Tanks left uncleaned may contain 1 to 2 m (4 to 6 ft) of solids and sludge after 5 to 10 years of operation. Surface water transmission lines are kept clean by regular pigging, which is the most effective method of controlling bacteria corrosion. The surface piping system must be designed for pig launchers and traps.

Bactericides are chemicals that kill or control microorganisms. Many of the chemicals are surface-active cationic materials and must be used with care relative to compatibility with anionic chemicals, such as scale inhibitors. The most common surface-active bactericides are dimethyl coco amine quaternized with methyl chloride; coco diamine acetate, benzoate, or adipate; 3-alkoxy*-2hydroxy-*n*-propyl trimethylammonium chloride (where * denotes a linear primary alcohol, C_{12}-C_{15}) (Ref 57); and dimethyl coco amine quaternized with 2,2-dichloro-diethyl ether. The most common nonsurface-active bactericides are formaldehyde, glutaraldehyde, acrolein, chlorine dioxide (ClO_2), chlorine, sodium hypochlorite (NaClO), isothiazolone, dibromonitrile proionamide, sodium dimethyldithiocarbamate, and tetrakishydroxymethyl phosphonium sulfate. The mechanisms and examples of biological corrosion are discussed in Ref 58, 59, 60.

A method of enumerating bacteria is discussed in Ref 61. Other useful procedures include a quick field method for enumerating total bacteria and studying the effect of bactericides (Ref 62), a method of studying biofilms and the effect of bactericides on them (Ref 63), and a rating system for evaluating bacterial problems in waterfloods (Ref 64). A summary of papers on microbiologically influenced corrosion is given in Ref 65 and 66.

Corrosion Inhibitors for Oil and Gas Production

Revised by Richard L. Martin, BJ Unichem Chemical Services

Laboratory Testing of Corrosion Inhibitors

Many testing methods designed to simulate field conditions have been reported in the literature. However, only a few of these methods survive, and none has become the standard test. Most investigators have found that combinations of test methods can be predictive of field performance, but there still remains only a rough correlation between laboratory and field performance of corrosion inhibitors. Therefore, field corrosion monitoring remains an important consideration.

Static Test. After several years of use, a static test was formalized, based on work described in Ref 67. In the test, coupons are exposed for approximately 1 week in fluids with and without inhibitors and are evaluated on a weight loss basis (Ref 68). Another static inhibitor screening test consists of short-term static exposure in field fluids, followed by immersion in a copper ion solution to determine filming ability (Ref 69).

Wheel Test. One of the first written reports on the wheel test dates from 1963 (Ref 70). After years of use and many series of multilaboratory comparative inhibitor tests, no consensus has been reached on a standardized version of the wheel test. Results of round-robin testing are available in Ref 71 and 72. A wheel test procedure (not a standard) is described in Ref 73.

The wheel test is a dynamic test performed by placing synthetic or field fluids in a 200 mL (7 oz) beverage bottle containing a metal coupon. The bottle and its contents are purged with CO_2 or H_2S, and the bottle is capped. The bottles are then agitated for approximately 2 h by securing them to the circumference of a wheel and rotating the wheel. After the first agitation period, the coupons are transferred to a rinse bottle containing

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

fluids with inhibitor and are agitated again. The coupons are then transferred to another bottle containing only corrosive fluids (no inhibitor) and are agitated for a longer period of time, usually 24 h. At the end of this time, the metal coupon is removed and cleaned, and weight loss is measured. The maximum temperature at which this test can be safely conducted is 80 °C (180 °F). High-temperature versions of the wheel test are discussed in Ref 74. Temperatures of 150 to 205 °C (300 to 400 °F) and pressures of several thousand pounds per square inch are achieved by the use of high-alloy pressure bombs. Agitation of the bombs is usually accomplished in the same manner as in the low-temperature wheel test. The results of one series of high-temperature wheel tests indicate a maximum corrosion rate at 105 °C (225 °F), with an unexpected decrease at 165 °C (325 °F) (Ref 75). Wheel tests have been very popular over the years. However, investigators have found a wide discrepancy between wheel test results and many applications of corrosion inhibitors in the field.

Kettle tests, also known as beaker tests or bubble tests, involve a sealed container (often a glass resin kettle) filled with a corrosive media that simulates the corrosion mechanism expected in the actual application. Corrosion can be monitored with linear polarization resistance electrodes or other monitoring methods (Ref 6). The temperatures, pressures, and corroding metal surface velocities are all limited to mild corrosion conditions in these tests. However, they have been found to be useful in many cases (Ref 3, 6).

These tests can be modified so that the test metal becomes a rotating disk or cylinder. This allows for higher metal surface velocities. Because of the rotary seal complexity, these tests are usually only run in the sweet (CO_2 only) condition; this fact limits the utility of the test in potential applications that are sour (contain significant H_2S).

Flow Loop Tests. An assembly of pipes and pumps can be used to more closely simulate many field corrosion conditions. The test metal can be configured as pipe electrodes, where the inner diameter of the pipe becomes the test electrode. Weight loss of these pipe sections can also be used as a corrosion measurement. High velocities can be simulated.

One variation of this test impinges the test stream onto a test electrode. This test is usually termed a jet impingement test.

Autoclave Tests. For temperature and pressure conditions that cannot be produced by the previously mentioned tests, corrosion conditions can be simulated in autoclaves (Ref 76). These tests commonly are used relative to hot, high- pressure gas wells. Sometimes, the autoclave metal of construction is corrosion resistant; Hastelloy C 276 (Haynes International, Inc.) UNS N10276 is common. Sometimes, the autoclave contains a metallic or nonmetallic liner. Corrosion monitoring can be by weight loss coupons (spinning or static) or by polarization resistance measurements made through feed-through fittings.

The last two tests described previously are more expensive to assemble and more labor-intensive to operate than the tests discussed earlier. The choice of test methodology depends on the intention of the testing. Again, no laboratory test has been found that duplicates field experience exactly. Again, field corrosion monitoring is important to successful applications.

Monitoring Results of Inhibition in the Field

The following methods are used to monitor corrosion rates and inhibitor effectiveness:

- Coupons (NACE International standard method)
- Spools, pup joints, and pony rods
- Iron/manganese ion analysis
- Copper ion displacement
- Probe measurements, such as linear polarization resistance, electrical resistance, and, less commonly, electrochemical noise, and direct current potentiodynamic polarization (Ref 77). Alternating current impedance probes see laboratory use but rarely are used in the field.
- Caliper and "smart pig" surveys
- Hydrogen probes
- Radioactive tracer methods have been used occasionally for research purposes but seldom for routine field monitoring.
- Copra correlation can be used to assess corrosion in deep, hot gas wells (Ref 78).
- Last but not least, good failure records and failure examination

Quality Control of Inhibitors

The materials used in most corrosion inhibitors are sometimes by-products of many chemical industries. Although major inhibitor formulators and manufacturers adhere to rigid specifications and procedures, it is difficult to correlate product-manufacturing specifications with field performance. One early report on quality-control procedures used by inhibitor manufacturers showed that only 19% of the manufacturers checked performance and only 10% made compositional analyses (Ref 79).

In recent years, however, most major inhibitor formulators and manufacturers have become certified by the International Organization for Standardization (ISO). Better analytical equipment is now available, and field testing has become more rigorous, so the relationship between chemical structure and field performance is much tighter (Ref 80).

Computerization of Inhibitor Treating Programs

Problem areas and problem wells have existed since the beginning of corrosion inhibition. Wells or batteries (geographical groups of wells) that do not respond satisfactorily to current chemical corrosion programs are defined as problem wells. Computers can effectively handle large volumes of data and, coupled with their

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

sorting capability, can identify problem wells, changes in conditions, and other factors that influence repair costs. Computer programs can also be used as an accounting tool to monitor corrosion costs and optimize corrosion inhibitor programs (Ref 81).

Corrosion Inhibitors for Crude Oil Refineries

J.D. Poindexter, BJ Unichem Chemical Services

Introduction

CORROSION has a major economic impact on the oil refining industry. The replacement cost of damaged equipment is a substantial capital expense. Unplanned outages reduce throughput, lowering revenue and profit. More importantly, due to the extremely hazardous nature of the fluids and gases processed in refineries, the safety and well being of both plant employees and the public are put at risk by corrosion. Catastrophic failures could result in severe damage to entire process units, neighboring communities, and the environment. In the United States, representing 23% of the oil refining capacity of the world, corrosion-related direct costs in the oil refining sector were recently estimated to be $3.7 billion annually (Ref 1).

Of course, corrosion of metals used in construction of refining equipment is an expected phenomenon. Metals and alloys, unhindered by external influences, seek to return to their disordered, but natural, state. Outside

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

influences, such as inhibitors, can effectively slow the rate at which this process occurs, even to the extent that rate is practically immeasurable. Mechanisms of refinery corrosion and methods of prevention have been studied by metallurgists, engineers, and chemists for many years, and significant improvements have been accomplished. However, refining processes are complex, and corrosion problems require thorough analysis and systematic solutions.

Areas of Corrosion in the Refinery

Table 1 lists various refinery units and process streams that are often susceptible to corrosion and effectively treated with process additives. Discussion of a few of the processes helps in the understanding of corrosion inhibitors that are used in a typical refinery environment. Corrosion inhibitors are also applied in numerous water treatment processes within a refinery, such as in cooling water and steam generation systems. Discussions of these inhibitors can be found in the article, “Corrosion Inhibitors in the Water Treatment Industry” in this Volume.

Table 1 Typical applications for refinery corrosion inhibitors

Unit	Process stream	Filming inhibitor	Neutralizer
Crude distillation	Crude tower overhead	X	X

The refining of crude oil into useful fuels and other products produces a number of corrosive environments. The most common is an aqueous environment containing inorganic and organic acids. However, other aqueous corrosion processes in the refinery can also be due to the presence of oxygen, bisulfide, cyanide, microbiological growth, or other corrosion-inducing species. Nonaqueous corrosive environments also exist in refining processes. Foremost is corrosion caused by organic acids at high temperatures, commonly termed *naphthenic acid corrosion.* Sulfide and other sulfur species contained in the hydrocarbon stream can also be corrosive at high concentrations and at high temperatures.

Many processes in the refinery involve distillation, often fractional, of hydrocarbons. In most of these distillation processes, water is present in the feedstock or by addition of steam for processing purposes. The water and steam can contain some corrosive species and are usually contaminated by corrodents from the hydrocarbon stream. Corrosion most commonly occurs as the water condenses in the distillation process and the corrosive species dissolves into the condensed water. This is often termed initial condensate corrosion. The prime example of a refinery distillation process is the crude unit.

The crude unit is the initial processing unit in most refineries. The raw crude oil enters the unit and after being heated somewhat, it enters the desalting phase. After desalting, the crude oil continues to be heated by exchangers and direct fired furnaces, normally reaching a temperature in excess of 315 °C (600 °F). The oil then enters a distillation column where it is fractionated into various streams such as naphtha, kerosene, diesel, and other fuel oils. Stripping steam is normally added to the distillation column to aid in separation of the various fractions. Generally, water distills along with the naphtha fraction into the condensing section of the system, commonly referred to as the “overhead.” In a few process units, a portion of the water may condense in the column and be removed along with a heavier hydrocarbon fraction.

In the desalting process, water is mixed into the crude oil to dissolve salts (primarily chloride salts) for removal by separation of the water in the desalting vessel. Salt is a common contaminant in crude oil due to production and transportation processes. Removal of chloride salts is critical because they hydrolyze to form hydrochloric acid when the crude oil is heated. Calcium and magnesium chloride hydrolyze more easily than sodium chloride. Removal of salts and other undesirable contaminants such as solids is usually aided by a small amount of a desalting additive injected into the raw crude charge. Caustic, a dilute sodium hydroxide solution, is occasionally added after the desalter to convert much of the remaining chloride to sodium chloride.

While the desalting process is designed to prevent the formation of hydrochloric acid, some will always be present. The acid is distilled and concentrated in the overhead section of the crude oil distillation column. As water condenses during the cooling of the overhead vapor, the hydrochloric acid gas dissolves into the water, creating an excess of hydrogen ions and resulting in a low pH environment. Other contaminants, carbon dioxide, oxides of sulfur and nitrogen, hydrogen sulfide, oxygen, and low-molecular- weight organic acids will also dissolve into the condensed water. The concentration and resulting corrosive effect of these materials is generally much less than that of hydrochloric acid but should be considered.

Water washing of the overhead piping and exchangers is a common practice in many refineries. Water washing is intended to reduce corrosion primarily by dilution of the corrosive species and removal of deposits. Ideally, the aqueous dewpoint is shifted by the addition of the water wash. This practice must be carefully studied to determine the proper amount and injection location due to the complexities of the multiphase system (Ref 3).

Catalytic and thermal cracking units such as fluid catalytic cracking units (FCCU) and delayed coking units typically require corrosion- inhibition applications. In these units, considerable amounts of hydrocarbon and inorganic gases are produced. Ammonia, hydrogen sulfide, hydrogen cyanide, and other gases formed in the cracking process are removed overhead in fractionation columns along with significant quantities of water. Typically, this leads to a corrosive environment of sulfide-type corrosion in an alkaline aqueous environment.

The presence of hydrogen cyanide seems to aggravate the corrosion problem by promoting entry of atomic hydrogen into the metal. The ability of filming inhibitors to prevent this entry is limited. In some instances, the cyanide ion is removed from the system through a reaction with an inhibitor based on an inorganic polysulfide solution (Ref 4).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Nonaqueous corrosion is also a concern in many areas of a refinery. High temperatures encountered in processing units have led to corrosion by naphthenic acids and sulfur-containing species. High-temperature corrosion is not a new problem in refineries; however, crude quality continues to decline and economic incentives can force the refiner to process a higher-corrosivity crude oil. Typically, this type of corrosion has occurred in units handling heavy fractions (atmospheric gas oil, atmospheric residual oil, vacuum gas oil, FCCU feedstock). *Naphthenic acid* is a generic term for all organic acids found in crude oil. The acids of concern in refining are primarily complex, high-molecular weight acids that concentrate in high boiling fractions at temperatures ranging from 220 °C to 400 °C (430 °F to 750 °F). Since crude oils contain a whole range of naphthenic acids, the corrosive potential can only be determined by thorough assessment and experience (Ref 5).

Hydroprocessing (hydrodesulfurization, hydrocracking, hydrofining) units operate under high pressures and temperatures and are susceptible to various corrosion mechanisms. Hydroprocessing severity has increased due to higher levels of sulfur in feedstocks and the demand to lower sulfur content of product streams. In these high severity units, substantial quantities of ammonia, hydrogen sulfide, and hydrogen chloride are produced. High-temperature sulfidation and hydrogen attack, ammonium bisulfide corrosion, underdeposit corrosion, and chloride stress cracking have all been identified (Ref 6, 7).

Amine sweetening units are used to remove acid gases, primarily hydrogen sulfide, and carbon dioxide from light hydrocarbons produced in the refinery. Aqueous solutions of alkanolamines, such as monoethanolamine (MEA), diethanolamine (DEA), and methyldiethanolamine (MDEA) are most commonly used. These processes are plagued with corrosion and fouling problems, especially in lean/rich heat exchangers, stripper overheads, and reboilers. Especially severe and potentially catastrophic corrosion is attributed to several cracking mechanisms (Ref 8). Improper control of operation variables and trace contaminants is often the cause of these problems. Corrosion inhibitors are effective in controlling many amine-unit corrosion problems.

Sour water units handle process waters that contain ammonia, hydrogen sulfide, cyanide, and other corrosives. Sour water or “foul water” is a collection of water from the various processing units. In the sour-water stripper, the process water is heated and stripped with steam. This process removes the dissolved and entrained gases that are less soluble at elevated temperatures. The water is often reused as desalter or overhead-wash water after removal of the undesirable contaminants. Various streams in this unit can be quite corrosive due to the high concentration of corrosive materials, especially in the overhead system.

Types of Inhibitors

Neutralizers are added to increase the pH of condensed water in refinery distillation units. An effective neutralizer will be present in a sufficient quantity at the point of water condensation to raise the pH to an appropriate level. The appropriate pH is somewhat dependent on the acids present and the hydrogen sulfide concentration. At pH value near neutral (7.0), corrosion due to hydrogen ions is reduced but corrosion due to bisulfide from the ionization of hydrogen sulfide increases. Copper alloys, such as admiralty brass and Monel, become susceptible to corrosion at values of pH above 7.0, especially in the presence of ammonia or amines. The ideal pH in most systems is determined by monitoring the corrosion rate at various pHs between 5.5 and 7.0.

Neutralizer formulations contain one or more low-molecular-weight amines that have good neutralization values with little or no adverse side effects. These side effects include the formation of corrosive salts in areas where there are a limited amount of water and poor water-solubility characteristics of the neutralizer or its salts. The appropriate neutralizer formulation must be selected based on process conditions and stream composition. Ammonia gas and ammonium hydroxide have been used but generally are limited in use due to poor solubility at the initial water condensation point and adverse salt characteristics.

Filming inhibitors are added to many refinery distillation-column overheads to lower the rate of corrosion under slightly acidic conditions (pH 5–7). In other units, such as the main fractionator overhead of a FCCU, a filmer is often used to minimize corrosion under slightly alkaline conditions. Filming inhibitors promote an “oil-wet” metal surface to provide the metal with a barrier from water and corrosive species. The filmers used in refinery distillation systems are organic compounds that have a polar group attached to a hydrocarbon “tail.” The polar group is attracted to the metal surface and the thin passive film that forms on the metal surface. The hydrocarbon tail attracts other hydrocarbons, forcing the potentially corrosive water away from the surface.

Numerous refining units have distillation systems. Each may have a need for a filming corrosion inhibitor and must be evaluated individually due to varying process conditions. Filming inhibitors have also been found somewhat useful in mitigating corrosion in various water wash systems such as effluent exchanger washing in hydroprocessing units.

Naphthenic acid corrosion has been successfully inhibited with filming inhibitors that are specifically designed to be heat stable and effective under these extreme conditions. High-temperature, nonaqueous corrosion from naphthenic acids and sulfur-containing molecules seems to be especially sensitive to high wall-shear stress. High-velocity fluids are likely to strip away natural protective films from the metal and expose metal surfaces to the corrodents. In many instances, the best solution for high-temperature corrosion is an upgrade in metallurgy. Suitable materials are typically high chrome alloys such as type 316 or 317 stainless steel, or even higher- alloyed materials in the most severe service areas.

Specialized filming inhibitors prevent corrosion in fuel pipelines and storage tanks. Fuel pipelines and storage tanks can exhibit light corrosion due to water condensation on the surface of the metal and to oxygen ingress. Red-orange rust particles dislodged from the metal surface contaminate the fuel and lead to filter plugging.

Filming inhibitors are generally organic compounds containing relatively small amounts of nitrogen, oxygen, or occasionally sulfur or phosphorous. Various imidazolines, amidoamines, alkyl amines, and alkyl quaternary amines are used, depending on the particular application. The “film” formed is a very thin absorption layer that is only a few molecules thick. The inhibitor is in equilibrium with the system fluids flowing near the metal surface. Proper design and selection of the inhibitor will allow the film to be as persistent as possible without causing fouling or “gunking” on the metal surface. The filming inhibitor must have solubility and dispersibility characteristics that will allow it to be transported to the corroding surface. The ideal filmer also performs

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

effectively under various process conditions at low concentrations. The filming inhibitor selected should not cause an emulsion of the overhead fluids or adversely affect downstream processing units.

Scavengers perform as corrosion inhibitors by removing the corrosive species from the process. Scavengers are used to remove oxygen, cyanide, hydrogen sulfide, and mercaptans from water and process streams. The products from the chemical reaction are noncorrosive.

Microbiocides control microbiological growth. Microbes cause underdeposit corrosion, and some bacteria utilize metals in their metabolic processes. Storage tanks of fuel and other materials often contain small amounts of water that supports microbiological growth.

Antifoulants and scale inhibitors prevent the precipitation and accumulation of solids in processing units. Deposition on metal surfaces leads to underdeposit corrosion. Fouling also prevents filming-type inhibitors from coming in contact with the metal surface.

Application of Inhibitors

Corrosion inhibitors are added in such small amounts that it is important to insure adequate distribution of the inhibitor in the process system. Full consideration of process unit dynamics must be considered for designing the proper injection scheme. In many cases, special injection nozzles called atomizers are used to mist the inhibitor into the flowing stream. Dilution streams are often used in an effort to increase process injection rates and increase mixing. Traditionally, crude unit overhead neutralizers and filmers are added via dilution streams that are injected into the horizontal section of the overhead vapor line; however, many variations exist. Details of refinery inhibitor injections are difficult to generalize due to the uniqueness and variety of each situation. Numerous publications exist, including a NACE International Technical Committee Report that details inhibitor injection methods (Ref 9).

Corrosion Monitoring

The refining industry is a mature industry, and much of the existing process equipment has been in service for many years. Due to the potential hazards of a corrosion failure, it is important to detect and quantify corrosion.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Typically, indications of corrosion are found on inspection during turnarounds and planned maintenance events. While these inspections are important, corrosion monitoring during operating periods is important to reduce equipment damage due to corrosion events and to assess the reliability and useful service life of process equipment. The corrosion monitoring program must be well designed, thorough, and sustained.
Corrosion monitoring techniques either measure corrosion directly or measure parameters that are indicative of corrosion (Ref 10). Direct measurement techniques used at refineries include the following:

- Nondestructive inspection
- Use of coupons
- Cyclic potentiodynamic polarization
- Use of electrical resistance probes
- Use of linear polarization resistance
- Use of galvanic currents
- Electrochemical impedance spectroscopy
- Use of electrochemical noise measurement

Indirect methods include:

- pH
- Conductivity
- Temperature
- Metal ion analysis (iron, manganese, copper, zinc, nickel, and so forth)
- Hydrogen
- Biological assay

Any one technique may give erroneous results; therefore, a combination of methods is usually employed. Measurements made over a relatively short period allow operational or process changes to be applied in an effort to impede the rate of corrosion. Corrosion monitoring instrumentation continues to be improved and become more sophisticated. Effective methods to detect localized corrosion have been challenging, but newer instrumentation measures pitting rates, hydrogen penetration, and other localized corrosion. Indirect measurements are important ongoing gages to examine both corrosion-condition trends and daily operating parameters.

Corrosion Inhibitors in the Water Treatment Industry

Bennett P. Boffardi, Bennett P. Boffardi and Associates, Inc.

Introduction

THE CORROSION PROCESS that occurs in industrial systems is insidious and all-encompassing. This process is often difficult to discern until extensive deterioration has occurred. Corrosion robs industry of millions of dollars annually through loss or contamination of products, replacement cost and overdesign of equipment, reductions in efficiency, high maintenance expense, and waste of valuable resources. Corrosion also restrains technological progress and jeopardizes human safety.

Water, the most commonly used cooling fluid, removes unwanted heat from heat-transfer surfaces. However, water is corrosive to most alloys and contributes to the buildup of insulating deposits through water-formed and water-borne foulants.

Boiler Systems

For boilers (steam-generating plants) to function properly, the incoming water must be processed to meet the water quality required for the boiler. The higher the operating pressure in the boiler, the more restrictive are the properties of the feedwater to the boiler. The high quality standards for the incoming water have led to a variety

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

of mechanical and chemical processes to meet the demanding specifications. These processes are referred to as a pretreatment.

Pretreatment

Pretreatment can encompass many different processes, depending on the desired water quality. Waters for most industrial applications come from either wells or from a surface source such as lakes and rivers. In either case, the waters may contain suspended solids, color, and dissolved solids. These constituents must be removed to prevent water-related problems in the boiler system.

Clarification removes turbidity (suspended solids) and color by a process of coagulation and filtration. The addition of such chemicals as aluminum sulfate (alum), ferrous or ferric sulfate, and lime or soda ash produces floc that absorbs the color and entangles the suspended solids. The floc is then filtered out or allowed to settle. The water passing through the filter is devoid of color and particulate material. However, the water can still contain dissolved matter.

Removal of Hardness Ions. The most troublesome dissolved materials that can have a negative impact on boiler operations are the hardness ions, calcium and magnesium. These ions, when concentrated, can form sparingly soluble salts (scales) and deposit on internal heat-transfer surfaces. Scale is very detrimental to boiler performance because it substantially retards heat transfer and, in severe cases, leads to boiler failure due to metal overheating. Removal of hardness ions from incoming water can be accomplished in a variety of processes.

Precipitation softening is a chemical process that is used to remove hardness ions and alkalinity from water. Cold lime softening uses a coagulant and alkali to precipitate the hardness ions in the water as calcium carbonate ($CaCO_3$) and magnesium hydroxide [$Mg(OH)_2$]. At elevated temperatures, hot-process softening can reduce the solubility of precipitated materials even further. However, hot processes require the input of heat that speeds up rates of reactions compared to cold lime processes that operate at ambient temperature.

Ion exchange is another process to remove dissolved hardness ions. The dissolved ions in the water have either positive or negative electrical charges. The softening technology exchanges the hardness ions for ions of like charge. Resin beads made from polymeric materials contain a high level of exchangeable ions and are used to remove the undesirable charge species from water. Cation resins only exchange positively charged ions or cations, whereas anionic resins exchange anions, or negatively charges ions.

Softening, the most common ion-exchange process, removes hardness ions by replacing them with sodium ions. For complete removal of all dissolved salts (demineralization), a strong acid exchanger in the hydrogen cycle (acid) is used in combination with a strong base exchanger in the hydroxyl cycle (caustic). The combination of hydrogen and hydroxyl ions produces ion-free water at a neutral pH.

For low-pressure (<1 MPa, or 150 psig) boiler systems, the most common ion-exchange process in use for softening water is the sodium- cycle cation exchange. This process is extremely efficient, and the operation of sodium-cycle softeners does not affect the finish-water pH or other dissolved solids other than removing raw water hardness.

Reverse Osmosis. Improved operation of ion- exchange units for complete demineralization can be accomplished by passing the water stream first through a reverse-osmosis (RO) unit for partial demineralization, followed by ion-exchange units. This process lowers the salt loading to the resin and extends operating time between regenerations of the ion-exchange resins.

Reverse osmosis forces water through a membrane filter, producing high-quality water. The process can remove 95 to 99% of the dissolved solids and many different types of organisms from all waters including brackish and seawater.

The superfine porous RO membrane removes dissolved materials. For the RO process to function, a pressure greater than the natural osmotic backpressure must be applied to the water system. Osmotic pressure is proportional to the salt concentration and temperature and depends on the type of ionic species present. For waters containing predominantly sodium chloride at ambient temperature, a rule of thumb is that osmotic pressure is 0.07 MPa (10 psi) per 1000 mg/L concentration.

Reverse osmosis reverses the natural flow of dissolved ions into water, by forcing the ions to flow in the opposite (reverse) direction, producing pure water. Ordinary filtration allows the water containing dissolved material to pass through the media, leaving behind solid materials that were present in the water.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The rate of water transport across the RO membrane depends on the membrane properties, the water temperature, and the difference in applied pressure across the membrane minus the difference in osmotic pressure between the concentrated and dilute water.

Preboiler Corrosion Protection

The choice of boiler water treatment depends on two main considerations: boiler operating pressure and boiler feedwater hardness. Approaches used to pretreat the makeup water and remove hardness are discussed in the previous section. As boiler pressures increase, there is a greater need to control feedwater quality, chemical treatments, and cycles of concentration. Boiler operation is much more critical at higher pressures, demanding essentially no hardness and no dissolved solids.

Boiler water treatments are used to control scale, corrosion, and carryover/foaming. Scale is generally the result of poor pretreatment, that is, control over calcium, magnesium, and silica in the boiler water.

Scale is controlled by either internal treatment or a combination of internal treatment and external treatment. Corrosion is primarily caused by oxygen in the feedwater. Oxygen corrosion is prevented by chemically reducing or scavenging the oxygen in the system and by mechanically deaerating the feedwater before it enters the boiler. Foaming or carryover can be controlled by blowdown or with chemicals.

Deaeration. Mechanical deaeration is the removal of noncondensable dissolved gasses. While the removal of oxygen is paramount, other gases such as CO_2 and NH_3 can magnify the deleterious effect of oxygen attack on the internals of the boiler. For example, CO_2 corrosion is 2.5 to 3 times as aggressive in the presence of oxygen.

Deaeration is achieved by heating the water to saturation temperature at the process pressure in equipment known as a deaerator. Deaerators also provide feedwater storage. The most common types of deaerators are either the spray or tray type.

A spray deaerator sprays feedwater into a steam-filled space where the feedwater is heated and scrubbed to release gases. As fresh steam enters the unit, water undergoes a second agitation to liberate most remaining impurities.

Tray deaerators direct feedwater into a series of cascading trays. Water falls from tray to tray by overflowing or passing through small holes. Steam, which engulfs the bays, heats and deaerates the feedwater as it falls.

Finally, a combination of spray- and tray-type heaters can be used. Feedwater is first sprayed into a steam-filled space, then cascades down on a series of trays through which it passes for further agitation and scrubbing. Live steam entering the deaerator meets the hottest water first, stripping it of dissolved gas. Carrying this gas along, the steam moves across and up through cascading water, gathering additional impurities as it flows. Steam is gradually condensed as it moves upward in the deaerator. Noncondensable gases are drawn off at a high point in the unit, where little steam remains.

One additional type of deaerator should be noted—the vacuum deaerator. In the vacuum deaerator, water cascades over packing such as rasching rings. The pressure of the environment above the water is reduced using vacuum pumps or steam ejectors. The degree of oxygen removal obtained in vacuum degasification will depend on a variety of variables. While finished oxygen limits have not been established, typical degasification achieved with vacuum-type deaerators will range from 50 to 500 μg/L (parts per billion, or ppb) of dissolved oxygen by volume. Because of these limits, boiler systems that utilize vacuum deaerators will generally have another type of deaerator following the vacuum unit.

Feedwater leaving the deaerator is usually specified as having 7 μg/L (ppb) dissolved oxygen or less, assuming the deaerator is functioning per design specifications. Further reduction of oxygen levels requires the use of chemical- reducing agents. Free carbon dioxide levels should be reduced to zero. Removal of corrosive gases from boiler feedwater is imperative in order to protect downstream metallurgy.

Oxygen Scavenging. Residual dissolved oxygen remaining in the feedwater will cause pitting corrosion of the feedwater lines, heaters, economizers, boilers, and condensate lines. Therefore, oxygen-scavenging chemicals are added to the deaerator storage tank for removal of all traces of oxygen (Ref 1).

The most common oxygen scavengers for many years were sodium sulfite (Na_2SO_3) and hydrazine (N_2H_2). When hydrazine became a suspected carcinogen, replacement chemistry was rapidly pursued. It became apparent that strong reducing agents (oxygen scavengers) should more than react with dissolved oxygen; they should also form protective oxide films on the metal surfaces.

Sulfite reacts and consumes dissolved oxygen in water according to:

$$2Na_2SO_3 + O_2 \rightarrow 2Na_2SO_4 \qquad \text{(Eq 1)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Sodium sulfite reduction of oxygen adds sodium sulfate, or dissolved solids, to the boiler water. Sodium sulfite is thermally unstable at high pressure. Thermal decomposition results in the formation of sulfur dioxide and hydrogen sulfide:

$$Na_2SO_3 + H_2O + Heat \rightarrow SO_2 + 2NaOH \quad \text{(Eq 2)}$$

$$4Na_2SO_3 + 2H_2O + Heat \rightarrow 3Na_2SO_4 + 2NaOH + H_2S \quad \text{(Eq 3)}$$

The hydrazine reaction with dissolved oxygen is slow at ambient temperature, but increases as temperature and pH increases. Neither hydrazine nor its products contribute dissolved solids to boiler water:

$$N_2H_4 + O_2 \rightarrow 2H_2O + N_2 \quad \text{(Eq 4)}$$

Hydrazine also reacts with CuO and Fe_2O_3 forming protective oxide films:

$$6Fe_2O_3 + N_2H_4 \rightarrow 4Fe_3O_4 + 2H_2O + N_2 \quad \text{(Eq 5)}$$

$$4CuO + N_2H_4 \rightarrow 2Cu_2O + 2H_2O + N_2 \quad \text{(Eq 6)}$$

At high temperatures, hydrazine will decompose to ammonia.

Another oxygen scavenger is carbohydrazide $[(NH_2NH)_2CO]$, which is the dihydrazide of carbonic acid. It reacts directly with oxygen:

$$(NH_2NH)_2CO + 2O_2 \rightarrow 2N_2 + 3H_2O + CO_2 \quad \text{(Eq 7)}$$

It also reacts indirectly through hydrolysis to form hydrazine:

$$(NH_2NH)_2CO + H_2O \rightarrow 2N_2H_4 + CO_2 \quad \text{(Eq 8)}$$

$$2N_2H_4 + 2O_2 \rightarrow 4H_2O + 2N_2 \quad \text{(Eq 9)}$$

Carbohydrazide reacts with iron and copper to form protective passive oxides.

Hydroquinone $[C_6H_4(OH)_2]$, reacts with dissolved oxygen in the feedwater. The reaction is a function of temperature, pH, and the ratio of hydroquinone to dissolved oxygen. The reduction reaction is a multistep process, producing benzoquinone, which further reacts with dissolved oxygen to form end products consisting of ketones, alcohols, and carbon dioxide. Hydroquinone will also form protective passive oxides with iron and copper.

Diethylhydroxylamine (DEHA) $[(C_2H_5)_2NOH]$ reacts with dissolved oxygen in a complex process involving several steps, which are dependent on temperature, pH, and the concentrations of both DEHA and oxygen. The overall reaction of DEHA with oxygen can be summarized as:

$$4(C_2H_5)_2NOH + 9O_2 \rightarrow 8CH_3COOH + 2N_2 + 6H_2O \quad \text{(Eq 10)}$$

The total oxidation of DEHA produces acetic acid, nitrogen, and water. DEHA will also react with iron and copper to form a protective passive film.

Methylethyl ketoxime (MEKO) $[(CH_3)(C_2H_5)CNOH]$ does not react significantly with dissolved oxygen at room temperature. However, at boiler conditions MEKO reacts with oxygen, producing ketones, nitrous oxide, and water. MEKO will degrade under boiler conditions producing ammonia.

Erythorbate reacts with dissolved oxygen in the boiler feedwater through a series of complex reactions.

$$RC_6H_6O_6 + O_2 \rightarrow C_6H_5O_6 + ROH \quad \text{(Eq 11)}$$

Final products of the reactions will depend on the amount of oxygen, feedwater pH, and temperature during the reaction. Under alkaline conditions, the end products are CO_2 and water.

Erythorbate is a relatively strong reducing agent capable of reducing oxidized forms of iron and copper to Fe_3O_4 and Cu_2O, respectively.

With the boiler feedwater free of both dissolved ions and oxygen, the water can proceed to the boiler. It is important that the boiler feedwater chemistry be controlled. A minimum pH of 8.5 is required to minimize corrosion attack on steel, with an optimal pH range of 9.2 to 9.5. For copper alloys, the preferred pH range is 8.5 to 9.2. Since both steel and copper alloys are common in boiler systems, a compromise range of 8.8 to 9.2 is recommended.

Internal Treatment

The traditional method of controlling scale and deposits in low- to medium-pressure boilers (pressures less than 1 MPa, or 150 psig, for low pressure, and 4 MPa, or 600 psig, for medium pressure) is a phosphate/dispersant chemical- treatment program operating with excessive hydroxide alkalinity (Ref 2).

Phosphate programs are designed to react with calcium in the boiler water to produce a calcium precipitate while maintaining an excess of phosphate. In the absence of excess alkalinity, the phosphate will precipitate as calcium orthophosphate, which is a sticky deposit and difficult to remove. Sufficient alkalinity, either naturally occurring or added, will produce hydroxyapatite [$Ca_{10}(OH)_2(PO_4)_6$], a nonadherent calcium deposit that is easily fluidized with dispersants. Similarly, magnesium impurities can react with OH^- alkalinity to produce magnesium hydroxide [$Mg(OH)_2$]. If silica is present, serpentine is produced ($3MgO{\cdot}2SiO_2{\cdot}2H_2O$) under high alkaline boiler conditions.

Conventional phosphate treatment control involves maintaining a phosphate residual and a hydroxide residual in the boiler water. Phosphate residuals are typically maintained in the range of 20 to 40 mg/L (parts per million, or ppm) PO_4^{3-}. Hydroxide alkalinities, if controllable without excessive blowdown, are maintained in the range 125 to 400 mg/L (ppm) as $CaCO_3$ This treatment provides the ideal conditions for precipitation of calcium as hydroxyapatite and magnesium as serpentine. It also provides a residual of alkalinity to neutralize any acidic contamination. It may, however, promote foaming, especially if organic contaminants enter the boiler.

Application of this treatment to boilers operating at pressures above 7 MPa (1000 psi) can result in an increased probability of concentrated sodium hydroxide attack. Boiler failures due to concentrated caustic attack are rare at pressures below 7 MPa (1000 psi).

Coordinated phosphate control was developed to eliminate the problem of concentrated sodium hydroxide attack. This approach requires an alkalinity-free makeup. Coordinated phosphate control is commonly achieved by either evaporator or demineralized pretreatment. Phosphate residuals are typically maintained in the range 5 to 25 mg/L (ppm) PO_4^{3-}.

However, small concentrations of hydroxide will exist due to hydrolysis of the orthophosphate ion. The sodium hydroxide formed by hydrolysis is then available to concentrate on the tube surfaces. This is most likely to occur under heavy accumulations of corrosion products or in sloped tubes where pockets of steam may accumulate and prevent rinsing of concentrated solids from the tube wall.

The cause of the sodium hydroxide attack in coordinated phosphate treatment results, indirectly, from the phenomenon of hideout. Hideout is the apparent loss of phosphate in the boiler water in high-pressure power boilers operating under high load conditions. The lost phosphate reappears and can be analyzed when the load is reduced. Congruent boiler water control was developed to ensure that hydroxide formation does not occur under hideout conditions. This treatment is based on the premise that the Na/PO_4 ratio in the boiler water should be no greater than the congruent ratio. Congruent control programs are designed to prevent the formation of hydroxyl alkalinity (excess caustic) in the boiler by maintaining the Na/PO_4 ratio at a maximum of 2.6 to 1.

Chelant treatments are typically used in systems where the feedwater hardness is low, below 5 mg/L (ppm) as $CaCO_3$. The major reason for using chelant treatments ethylenediaminetetraacetic (EDTA) acid or nitrilotriacetic (NTA) acid is the chelates of calcium and magnesium are soluble. Iron is not significantly solubilized by chelant treatment due to the competition of the hydroxide ion. However, iron may be effectively removed by combining a dispersant with a chelant treatment.

Chelant treatments have been effective for industrial boilers operating up to 7 MPa (1000 psi). This type of program is not recommended for low-pressure boilers, below 1034 kPa (150 psi).

High-pressure utility boilers operating above 14 MPa (2000 psi) require an all-volatile treatment (AVT) program. On the other hand, utility boilers operate on essentially pure water, which contains zero dissolved solids. The only chemicals added to the system in utility boilers are ammonia or a neutralizing amine in conjunction with a volatile oxygen scavenger.

Condensate Treatment

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Corrosion in condensate/feedwater systems occurs because of low pH induced by carbonic acid, resulting from the reaction of water with CO_2 gas coming from the boiler. The CO_2 may originate from condenser air-inleakage or bicarbonate alkalinity in the feedwater. The buildup of the acid reduces the condensate pH and leads to corrosion typically in the form of grooving of the condensate piping. This effect is accelerated in the presence of O_2. Volatile, alkaline-neutralizing chemicals are traditionally added to offset the low pH.

Among chemicals preferred for the control of condensate corrosion are morpholine, cyclohexylamine, diethylaminoethanol (DEAE), 2- amino-2-methyl-1-propanol (AMP-95), and ammonia (Ref 3). Each functions by neutralizing the carbonic acid. The amines are fed into the feedwater/boiler, where they volatilize and are carried over with the steam, dissolving in the condensate.

The extent of the amine reaction with carbonic acid depends on the dissociation constant of the amine as well as its basicity. Its efficiency in neutralizing carbonic acid also depends on the volatility of the amine. Amine volatility determines the location in the condensate section of the boiler where the amine will be most effective. It also determines the amount of amine that will be lost with wasted steam through the vent in a deaerating heater or in steam leaks, as well as the amount that will be lost with boiler blowdown.

The vapor-to-liquid distribution ratio (DR) of a neutralizing amine also helps determine the location in the condensate section where it will be most effective. Amines with higher DRs tend to remain in the steam, enabling them to control corrosion in equipment and piping located far from the boiler or where pressures are lowest. Lower-ratio amines tend to condense with the first steam that condenses and thus will control corrosion in locations closest to the boiler, or those where steam is condensing at higher pressures.

It is desirable to employ a low DR amine, such as morpholine, if most of the steam condenses early in the system. Most of the amine comes out early and is thus present to neutralize the carbonic acid produced in that vicinity. Cyclohexylamine tends to carry further, so it will provide better protection for more distant reaches of the system. Ethanolamine condenses very early in the system and therefore provides improved pH control at the earliest point in the system where wet steam conditions first occur. Distribution ratios of the neutralizing amines are listed in Table 1.

Table 1 Characteristics of neutralizing amines

Amines	Basicity constant	Molecular weight	Distribution ratio (DR) at indicated pressure					Hydrothermal stability
			0 MPa (0 psig)	**0.7 MPa (100 psig)**	**3.5 MPa (500 psig)**	**6 MPa (900 psig)**	**8 MPa (1200 psig)**	
Ammonia	15	17	1.0	7.5	4.9	4.4	3.1	Excellent
Cyclohexylamine	457	99	4.0	7.5	6.8	6.2	4.6	Good
Diethylaminoethanol (DEAE)	63	1171	1.4	3.4	3.8	3.3	2.5	Fair
Methoxypropylamine (AMP-95)	125	89	1.0	2.2	1.9	1.6	1.3	Good
Morpholine	2.1	107	0.3	1.1	1.1	1.2	1.1	Good

Cooling Systems

An understanding of the relationship among cooling water, the buildup of deposits, and corrosion of heat-transfer surfaces requires an awareness of cooling system characteristics. There are basically three types of cooling systems: once-through, open recirculating, and closed recirculating systems (Fig. 1).

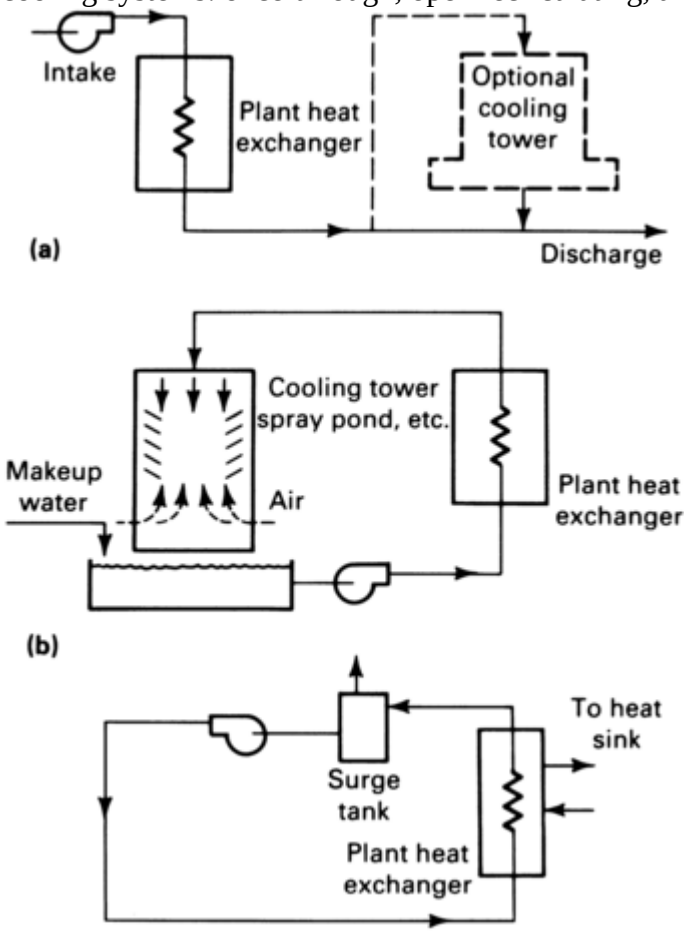

Fig. 1 Schematics of three types of cooling systems. (a) Once-through system. (b) Open recirculating system. (c) Closed recirculating system

In once-through systems, the cooling water passes through the heat-transfer equipment only once before it is discharged. Large volumes of water are used with only a small temperature increase across the exchanger. The mineral content of the water remains essentially the same. Water is usually drawn from such sources as rivers, lakes, and wells.

Open recirculating systems continuously reuse the water that passes through the heat- transfer equipment. Circulated water can be drawn from spray ponds or cooling tower basins. Evaporative cooling to the atmosphere dispels the unwanted heat transferred to the cooling water. The water then returns to the source and recirculates. In cooling-tower operations, the water cascades over and down the tower, where evaporative heat transfer takes place. Makeup water is added to replace the evaporative losses. Additional makeup water replaces the intentionally discharged water (blowdown) to maintain an acceptable level of dissolved minerals and suspended solids in the cooling water.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Open recirculating cooling systems are oxygen saturated and may contain a high level of dissolved solids. Inlet temperatures to the heat- transfer equipment are usually higher than those for once-through cooling systems. Also, there may be a larger temperature differential across the exchanger. These factors can significantly affect the buildup of deposits and the deterioration of the heat-transfer equipment.

Closed recirculating systems have little water loss and continuously recirculate the same water. The heat absorbed from the heat-transfer equipment is dissipated to another heat sink, which is cooled by other methods. Because there are no evaporative losses, the makeup water is minimal, and the mineral content remains essentially constant. However, corrosion by-products can easily accumulate and foul heat-transfer equipment because there are no methods for removing them from the system. Operating temperatures of the closed recirculating systems range from cold (as in chilled-water systems) to hot (for engine cooling jackets).

Corrosion Processes in Water-Recirculating Systems

Corrosion processes and the fouling of heat- transfer equipment must be understood if long- term reliability is to be achieved. Corrosion can be defined in a very practical sense as the deterioration of metal caused by the reaction with its surrounding environment. Because water is one of the most common heat-transfer fluids, it is not surprising that most of the problems associated with corrosion and deposits are water related. However, dissolved gases (such as oxygen, carbon dioxide, ammonia, and chlorine), dissolved ions (such as calcium, magnesium, chloride, sulfate, and bicarbonate), and suspended solids make water something other than pure H_2O.

For the corrosion reactions to take place between water and the metal surface, a potential difference must exist between different areas on the surface. This potential difference causes the passage of electrical current through the metal from areas of high potential to low potential. Thus, corrosion of metals in contact with water is electrochemical in nature. The basic reactions occur at the region of lower potential, which is the anode. The dissolution reaction causes metal ions to form and go into solution. The anodic oxidation reaction can be generally represented by:

$$M \rightarrow M^{n+} + ne^- \quad \text{(Eq 12)}$$

where M represents the metal that has been oxidized to its ionic form and having a valence of $n+$ and resulting in the release of n electrons. For the more common heat-transfer materials, the individual reactions are:

$$Fe \rightarrow Fe^{2+} + 2e^- \quad \text{(Eq 13a)}$$

$$Cu \rightarrow Cu^{+} + e^- \quad \text{(Eq 13b)}$$

$$Al \rightarrow Al^{3+} + 3e^- \quad \text{(Eq 13c)}$$

The liberated electrons that migrate through the metal to areas of higher potential are used in the reduction of other ions or oxygen in the water. These reactions occur at the cathodic site on the metal surface:

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \quad \text{(Eq 14)}$$

(Reduction of oxygen in acid solution)

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad \text{(Eq 15)}$$

(Reduction of oxygen in neutral or alkaline solution)

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$2H^+ + 2e^- \rightarrow H_2$
(Hydrogen evolution) (Eq 16)

$Cu^{2+} + 2e^- \rightarrow Cu$
(Metal deposition) (Eq 17)

$Fe^{3+} + e^- \rightarrow Fe^{2+}$
(Reduction of metal ions) (Eq 18)

Interaction between the products of the anodic and cathodic reactions can occur, forming solid corrosion products on the metal surface. For example, ferrous ions (Fe^{2+}) coming from the corrosion of metallic iron will react with the hydroxyl ions (OH^-) produced from the reduction of dissolved oxygen:

$Fe^{2+} + 2OH^- \rightarrow Fe(OH)_2$ (Eq 19)

Ferrous hydroxide [$Fe(OH)_2$] is further oxidized to form ferric hydroxide [$Fe(OH)_3$], which is unstable and subsequently transformed to hydrated ferric oxide (Fe_2O_3)—common red rust:

$4Fe(OH)_2 + O_2 + 2H_2O \rightarrow 4Fe(OH)_3$ (Eq 20)

$2Fe(OH)_3 \rightarrow Fe_2O_3 + 3H_2O$ (Eq 21)

A buildup of rust occurs at the anodic sites, forming mounds known as tubercles. Under these mounds, localized corrosion continues to accelerate (Fig. 2) (Ref 4). Not all corrosion products are detrimental. The protective oxide films on copper (cuprous oxide, Cu_2O) and aluminum (aluminum oxide, Al_2O_3) are the result of corrosion:

$2Cu^+ + 2OH^- \rightarrow Cu_2O + H_2O$ (Eq 22)

$Al^{3+} + 3OH^- \rightarrow Al(OH)_3$ (Eq 23)

$2Al(OH)_3 \rightarrow Al_2O_3 \cdot 3H_2O$ (Eq 24)

These films are self-limiting, inhibiting the corrosion process once they are fully developed. The corrosion process between water and metal surfaces can take many forms (Ref 5). The characteristics of the more common forms that have been observed in heat-transfer equipment are discussed in the following sections.

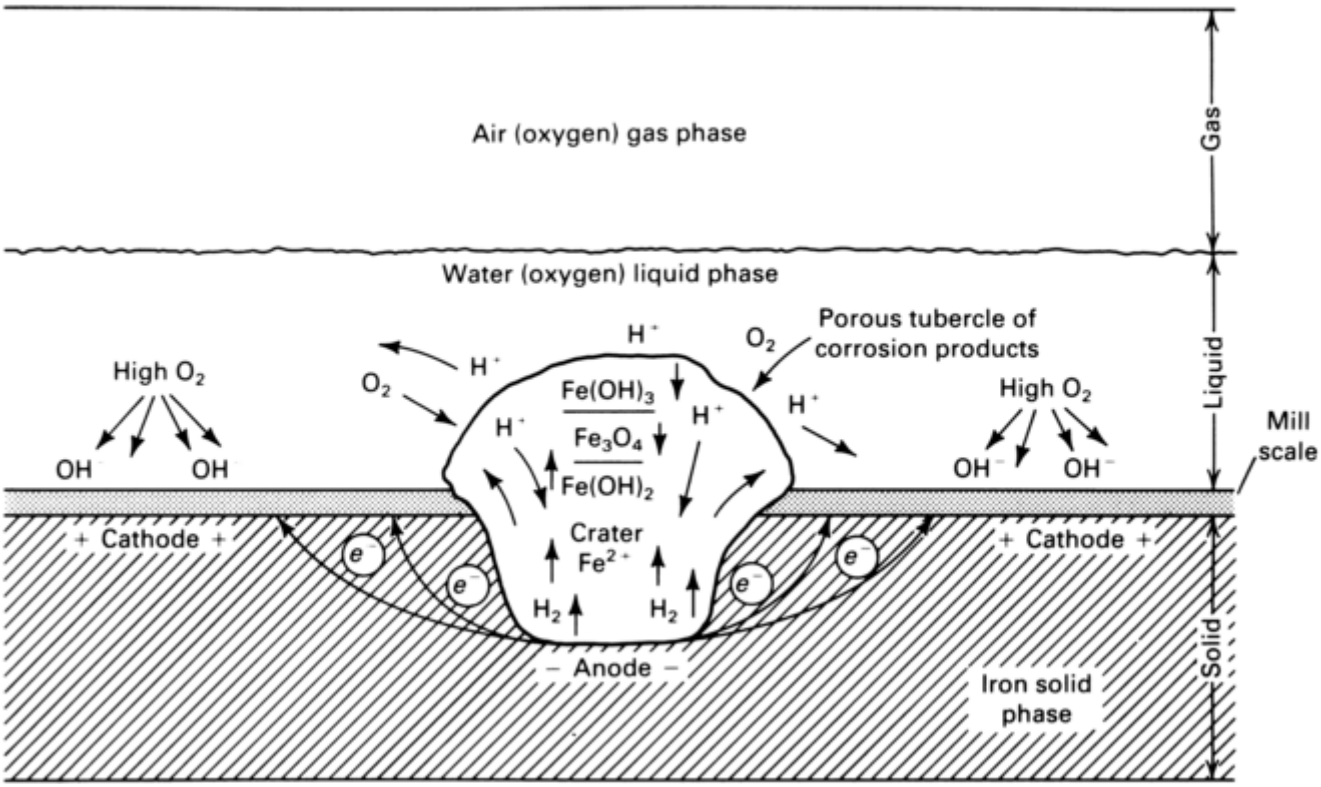

Fig. 2 Localized corrosion under a rust tubercle. Source: Ref 4

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

General corrosion, or uniform attack, occurs when the anodic areas on the metal surface keep shifting to different sites. This continual shifting results in relatively uniform metal removal. Because this type of corrosion can often be predicted, material loss can be taken into account.

Galvanic corrosion occurs when dissimilar materials are in contact in a conducting fluid (water). Accelerated corrosion occurs on the least resistant alloy, while the more resistant alloy is protected. The resistance of alloys can generally be described by the galvanic series, which ranks materials according to their chemical reactivity in seawater. The metals closer to the active end of the series will behave as the anode and will corrode, but those closer to the noble end will behave as the cathode and will be protected. Table 2 lists an abridged galvanic series. The intensity of attack is related to the relative surface areas of the metals in electrical contact. Large cathodic areas coupled to small anodic areas will aggravate galvanic corrosion and cause severe dissolution of the more active metal. The reverse situation—large anodic areas coupled to small cathodic areas—produces very little galvanic current.

Active or anodic

Source: Ref 5

Galvanic corrosion obviously must be considered in the design of heat-transfer equipment. Alloys close to one another in the galvanic series should be used. Less obvious are the damaging effects that can occur when a dissolved noble metal is transported through the water and is capable of depositing on an active metal. For example, copper ions can plate out onto steel heat- transfer tube surfaces, setting up local corrosion cells.

Erosion-corrosion is normally restricted to copper-base alloys. It occurs in areas where turbulence at the metal surface is high enough to cause mechanical or electrochemical disruption of the protective film. Corrosion occurs at these sites and forms horseshoe-crescent-shaped indentations facing upstream of the water-flow direction. The process is usually accelerated when abrasive solid particles, such as sand, are entrained in the water. Because turbulence increases with velocity, areas having higher water velocities are prone to attack. For example, turbulence is much higher at tube inlets than it is several feet down the tube, resulting in the phenomenon of inlet-end erosion-corrosion.

Crevice corrosion is electrochemical attack that is due to differences in the corrosive environment between a shielded area (crevice) and its surroundings. Attack usually occurs in areas having a small volume of stagnant solution, such as at tube sheet supports, under deposits or tubercles, and at threaded joints. Corrosion is usually initiated because the oxygen concentration within the crevice is lower than that of the surrounding area. The outside area is higher in oxygen concentration and becomes the predominant cathodic region. Anodic dissolution occurs at the stagnant area. Once attack is underway, the area in the crevice or under a deposit becomes increasingly more aggressive because of pH depression and an increase in electrolyte concentration.

Pitting corrosion is one of the most insidious forms of attack. It takes place at small discrete areas where overall metal loss is negligible. The pit develops at a localized anodic site on the surface and continues to grow because of a large cathodic area surrounding the anode. High concentrations of metal chlorides often develop within the pit and hydrolyze to produce an acidic pH environment. This solution remains stagnant, having a high salt content and low oxygen concentration. The reactions within the pit become self-sustaining (autocatalytic) with very little tendency for them to be suppressed, ultimately causing penetration through the base metal. Pitting corrosion has also been associated with both crevice and galvanic corrosion. Metal deposition (copper ions plated on a steel surface) can also create sites for pitting attack.

Influence of Water Quality

The corrosivity of water is significantly influenced by concentrations of dissolved species, including gases, pH, temperature, suspended matter, and bacteria. The effects of these entities on corrosion are assumed to be independent; although this is not totally correct—interactions do exist—it is easier to visualize their contribution when they are considered separately.

Dissolved Gases

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Dissolved oxygen is a major factor contributing to the natural corrosion of low-carbon steel. It has been shown that oxygen is part of the overall electrochemical reactions occurring at the interface between the aqueous phase and the metal surface. Therefore, it is not surprising that low-carbon steel corrosion is proportional to the oxygen content in the water. Oxygen solubility in water will vary with temperature, pressure, and electrolyte concentration. Increasing the temperature decreases oxygen solubility, but increasing the partial pressure of oxygen increases its solubility. Concentrated electrolytes decrease oxygen solubility (molar salt concentrations exist in pit cavities and crevices). For open recirculating cooling water systems, the concentration of dissolved oxygen is approximately 6 mg/L (ppm). The presence of oxygen is necessary for the formation of protective oxides on copper (Cu_2O), aluminum (Al_2O_3), and steel (γFe_2O_3). In the absence of dissolved oxygen, the corrosion of low-carbon steel is greatly reduced. A uniform protective film of magnetite (Fe_3O_4) is formed according to:

$$3Fe + 4H_2O \rightarrow Fe_3O_4 + 4H_2 \qquad \text{(Eq 25)}$$

Overall, oxygen can have either a negative or a positive impact on the corrosion of low-carbon steel. In aerated systems, uneven distribution of corrosion products can form on the metal surface, giving rise to localized corrosion. Under deaerated conditions, the Fe_3O_4 film isolates the base metal from the water, sharply reducing corrosion.

Carbon dioxide is more soluble than oxygen in pure water (1.3 g/L, or parts per thousand, ppt, at 30 °C, or 85 °F) and will convert to carbonic acid (H_2CO_3), producing a solution having a pH of less than 6 where acid attack can predominate:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \qquad \text{(Eq 26)}$$

Adjusting the pH of the water upward redistributes the ratio of dissolved carbonic species. Carbonic acid will dissociate to form bicarbonate ions (HCO_3^-) and subsequently carbonate ions (CO_2^{2-}). The ratio of the various components can be calculated from the pH of the system. In open recirculating cooling water systems, the pH is usually controlled within the range of 7 to 8.5. Only the CO_2/HCO_3^- ratio is important within this range (the CO_2^{2-} concentration is negligible). Calcium ions (Ca^{2+}) in the water will react with bicarbonate species to produce calcium carbonate ($CaCO_3$). Calcium carbonate has a low solubility and will precipitate onto heat-transfer surfaces. The effect of CO_2 is most important in boiler condensate systems. The carbonic acid, H_2CO_3 reacts with steel to form ferrous bicarbonate [$Fe(HCO_3)_2$], a highly soluble salt. Rapid general thinning of steel can occur by this reaction. The addition of soluble amine inhibitors neutralizes the H_2CO_3 to suppress the corrosive attack. Copper alloys are also susceptible to increased attack in the presence of CO_2.

Chlorine is not a natural constituent of cooling waters, but is added for biological control. When dissolved in water, chlorine will convert to hypochlorous acid (HClO) and hydrochloric acid (HCl), which will lower the pH:

$$Cl_{2(g)} + H_2O \rightarrow HClO + HCl \qquad \text{(Eq 27)}$$

Acid attack on low-carbon steel is a concern when the pH falls below 7. Above this pH, the deleterious effects of chlorine are reduced. Adequate biological control can be achieved if the pH is maintained at approximately 7.5. However, chlorine will accelerate the corrosion of copper alloys, even at alkaline pHs. Chlorine in cooling waters is one of the most aggressive species for copper alloys; it can induce localized attack and degrade the protective Cu_2O film.

Ammonia (NH_3) is another gas that can affect heat-transfer equipment. Although its effect on ferrous alloys is minimal, it has a drastic impact on copper-rich brasses and alloys. These alloys can experience both rapid general thinning and stress-corrosion cracking (SCC). Ammonia is formed from the thermal degradation of various nitrogen-containing compounds added to boiler water to reduce ferrous corrosion. It forms a soluble complex with copper that can autocatalytically deteriorate the alloy in a short period of time.

Temperature

An increase in temperature will cause an increase in corrosion rates. Temperature plays a dual role with respect to oxygen corrosion. Increasing the temperature will reduce oxygen solubility. In open systems, in which oxygen can be released from the system, corrosion will increase up to a maximum at 80 °C (175 °F) where the oxygen solubility is 3 mg/L (ppm). Above this temperature, the reduced oxygen content limits the oxygen-

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

reduction reaction, reducing the rate of the iron dissolution reaction. Thus, the low- carbon steel corrosion rate decreases and at boiling water conditions, the corrosion rate is approximately the same as it is at room temperature. For closed systems, in which oxygen cannot escape, corrosion continues to increase linearly with temperature. The other physicochemical properties affected by temperature are the diffusion of oxygen to the metal surface, the viscosity of water, and solution conductivity. Increasing the temperature will increase the rate of oxygen diffusion to the metal surface, thus increasing corrosion rate because more oxygen is available for the cathodic-reduction reaction. The viscosity will decrease with increasing temperature, which will aid oxygen diffusion. Ionic mobility will also increase with temperature, increasing the overall conductivity of water.

An unusual temperature effect can occur with copper alloys (Ref 6). Temperature differences of at least 65 °C (115 °F) between the ends of copper conduits will cause the cold end to be cathodic to the hot end. Copper ions will dissolve (corrode) at the hot end and migrate to the cold end. At the cathode (cold end), copper ions will plate out. At the anode (hot end), the surface will become rough pitted. This effect is known as thermogalvanic attack.

Another important effect of temperature should be noted. An increase in temperature will decrease the solubility of many sparingly soluble inorganic salts. The solubility of $CaCO_3$ and calcium sulfate ($CaSO_4$) will decrease with an increase in temperature, precipitating and forming a thick barrier (insulating) deposit at the hottest areas.

Suspended Solids

Suspended matter, such as clays, silt, and corrosion products, is always present in open recirculating cooling water systems. Particulates scrubbed from the air add to the suspended solids loading. These materials are usually soft and nonabrasive. They are capable of depositing in low-flow areas, forming a physical barrier, and preventing oxygen from reaching the metal/solution interface. This buildup will contribute to the formation of differential aeration cells (crevice corrosion) and promote localized corrosion attack.

Effect of pH

The normal pH range for an open recirculating cooling water system is 6.5 to 9. Closed systems operate at a pH of 8.5 to 9; in boilers, the pH of the water is often 11. These pH values are the bulk pH of the water. The actual pH at the metal surface can be different, depending on prevailing surface reactions. Oxygen-reduction reaction will produce OH^- ions, raising the pH. Underdeposit corrosion products can depress the pH.

When the bulk water pH is moderately acidic (pH 5), uniform corrosion is the predominant form of attack, which increases with decreasing pH. At pH 4 or below, the protective oxide film dissolves, exposing bare metal to the environment. Corrosion is further accelerated at low pH when dissolved oxygen is reduced at the metal surface. Both hydrogen evolution and oxygen reduction contribute to the cathodic reaction rate. As the pH increases above 4, iron oxides precipitate from solution to form deposits. Uniform corrosion gradually decreases, but underdeposit attack begins because of the formation of Fe_2O_3 layer (rust) adhering to the surface. These deposits impede the diffusion of oxygen to the metal surface. As the pH increases, the nature of the iron oxide deposits changes from loosely adherent at pH 6 to hard and tenacious at pHs above 8. Although the corrosion of low-carbon steel in aerated waters decreases within the normal operating pH range of 6.5 to 9, the rates are sufficiently high that chemical treatments must be added to these systems to bring the rates within a manageable level of less than 0.13 mm/yr (5 mils/yr).

Copper alloy corrosion reactions are not as sensitive to pH as those for low-carbon steel. Acid pHs will accelerate general corrosion. As the pH increases, uniform corrosion decreases significantly. However, general thinning is not as severe a problem as the formation of cupric ions (Cu^{2+}), which can cathodically deposit on low- carbon steel and create active sites for pitting attack.

Aside from the effect of pH on corrosion, increasing the pH of waters having moderate levels of calcium and alkaline values can result in the precipitation of $CaCO_3$. The deposition of this alkaline scale can impede the diffusion of oxygen to the metal surface in addition to forming a heat-transfer barrier.

Dissolved Salts

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Dissolved constituents in water can have a variety of effects, both individually and through their interactions. In addition to scale and deposit formation, the effects include increased corrosion. Increasing the dissolved solids content of the waters increases its conductivity. Galvanic effects due to the coupling of dissimilar metals are extended in waters having a higher salt content compared to waters of low conductivity.

Hardness ions (calcium and magnesium) and HCO_3^- ions are inhibitive and will suppress corrosion, but chloride (Cl^-) and sulfate (SO_4^{2-}) ions are antagonistic and will increase the rate of some forms of corrosion. The aggressiveness of water can be reduced by an increased concentration of hardness ions. Most waters used for cooling have pHs in the vicinity of neutral or above. This environment is very conducive to the formation of a protective film scale of $CaCO_3$, even when the water is below the saturation level for this salt. The actual mechanism that occurs at the water/metal interface is more involved than simple scale deposition. It is quite probable that $CaCO_3$ formation is due to electrochemical changes at the metal surface. The pH at the surface is usually higher than that of the bulk water because of an increase in OH^- ion concentration, a reaction product of oxygen reduction.

The overall aggressiveness of water is related to its hardness and alkalinity. Soft waters, which are low in calcium, are more corrosive than hard waters. Laboratory studies using three different waters of various compositions have shown that increased calcium concentration reduces general corrosion (Ref 7), as shown in Fig. 3. The HCO_3^- ion is the predominant alkaline species in natural waters within the 6.5 to 9 pH range. Alone, it is a mildly inhibitive species. Its reaction with Ca^{2+} ions is quite obvious, producing bulk precipitation of $CaCO_3$ once saturation is reached. Localized corrosion cells normally develop under the deposits. Increasing the bicarbonate concentration beyond that required for $CaCO_3$ saturation can be aggressive to low-carbon steel due to the formation of nonprotective iron carbonate ($FeCO_3$) scales.

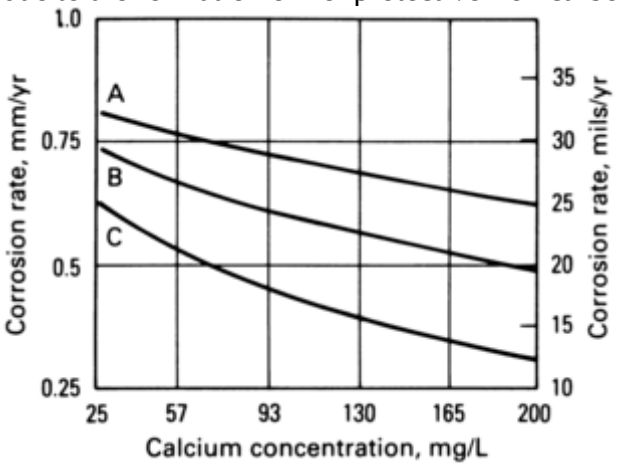

Fig. 3 Corrosion rate versus calcium concentration in three different waters. A, HCO_3^- = 38 mg/L, Cl^- = 78 mg/L, SO_4^{2-} = 78 mg/L; B, HCO_3^- = 100 mg/L, Cl^- = 224 mg/L, SO_4^{2-} = 224 mg/L; C, HCO_3^- = 266 mg/L, Cl^- = 644 mg/L, SO_4^{2-} = 644 mg/L

Copper alloys are also attacked by high HCO_3^- concentrations. Greenish-blue nodules that consist of basic copper salts usually form at active pit sites. Chloride and SO_4^{2-} ions are known to have a deleterious effect on low-carbon steel. Much of the antagonistic nature of Cl^- ions is due to their ability to adsorb on the metal surface and interfere with the formation of passive films. Pitting is the most common form of attack. The small exposed areas where Cl^- ions have adsorbed are anodic to the large cathodic passive oxide surface. High current densities are generated at the Cl^- site. Once corrosion begins, hydrolysis of the metal ions from the anodic reaction causes a decrease in pH, which discourages film repair and accelerates attack. The level of Cl^- ions needed to initiate attack can be as low as a few mg/L (ppm) for some stainless steels in high-purity waters. The more susceptible an alloy is to general attack, the less effect there is from Cl^- ions. Low-carbon steel will corrode in chloride-containing waters primarily from uniform corrosion rather than localized attack.

Copper alloys are subject to degradation by Cl^- ions that modify the Cu_2O structure. The small, negatively charged Cl^- ion can migrate through the Cu_2O film to areas of high positive charge density (Cu_2O is a *p*-type semiconductor). Substitution of a monovalent-charged chloride species for a divalent-charged oxygen species

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

can occur. To maintain electroneutrality, cuprous ions (Cu^+) are ejected (dissolved) into the aqueous phase, a loss that is by definition corrosion.

Sulfate ions are somewhat more elusive in their effect on corrosion. These ions do not appear to have the film-penetrating properties of Cl^- ions. In fact, there is evidence that SO_4^{2-} ions may inhibit corrosion of some stainless steels (Ref 8).

Other ions found in cooling waters that have an effect on corrosion are manganese (Mn^{2+}), sulfide (S^{2-}), phosphate (PO_4^{3-}), and nitrate (NO_3^-). Sodium (Na^+) and potassium (K^+) ions are considered neutral species and have no discernible effect. Manganese is found in both well and surface waters and can cathodically deposit on stainless steels and copper-base alloys. Attack usually occurs under these deposits. Sulfide ions from decay of organic matter, sulfate-reducing bacteria, and pollution will cause corrosion of copper-base alloys and steels. The Cu_2O film becomes nonprotective through a substitution of S^{2-} ions for the oxygen ion, accelerating corrosion. Attack occurs on low-carbon steel through the formation of ferrous sulfide (FeS). Deep pits will develop in both alloys. Phosphate ions can act as an accelerator or as an inhibitor for steel corrosion, depending on its concentration. At low concentrations, PO_4^{3-} ions will cause pits to develop on the surface of the metal. Higher concentrations of 15 to 20 mg/L (ppm) reverse this role, and the ion contributes to the stabilization of γFe_2O_3. Nitrate ions can be reduced on low-carbon steel surfaces, producing nitrites, NH_3, and OH^- ions. Nitrite ions (NO_2^-) inhibit corrosion of copper and steel alloys, but NH_3 will attack copper alloys.

Scale Deposition

Water-formed deposits, commonly referred to as scale, can be defined as a crystalline growth of an adherent layer (barrier) of insoluble salt or oxide on a heat-exchanger surface. The rate of formation is a complicated function of many variables, including temperature, concentration of scale-forming species, pH, water quality, and hydrodynamic conditions. Solubilities of scales typically increase with temperature. A few scales, for example, $CaCO_3$ and $CaSO_4$, have the reverse trend. Unfortunately, these scales are commonly found in cooling water systems.

Calcium carbonate is perhaps the most commonly found scale in cooling water systems. Calcium and bicarbonate alkalinity are both needed to form this extremely tenacious scale (alkalinity is the total concentration of HCO_3^-, CO_3^{2-}, and OH^- ions present in the water). An increase in heat and/or pH will cause the HCO_3^- ions to decompose to CO_2 and $CaCO_3$:

$$Ca(HCO_3)_2 \rightarrow CaCO_3 + CO_2 + H_2O \qquad \text{(Eq 28)}$$

The greatest concentration of $CaCO_3$ will occur at the hottest areas on the heat-transfer surface.

Many methods have been proposed to predict the formation of $CaCO_3$. They are all based on the thermodynamic equilibria of H_2CO_3 and are alkalinity corrected for temperature and dissolved solids (ionic strength). The more commonly used equations or indices are the Ryznar Stability Index (RSI) (Ref 9) and the Langelier Saturation Index (LSI) (Ref 10). The LSI is defined as:

$$LSI = pH - pH_s \qquad \text{(Eq 29)}$$

where pH is the actual measured value in the water, and pH_s is the pH of saturation calculated from:

$$pH_s = \left(pK_2' - pK_{sp}'\right) + p\text{Ca} + p\text{Alk} \qquad \text{(Eq 30)}$$

where pK_2' is the $-\log_{10}$ second dissociation constant of H_2CO_3, pK_{sp}' is the $-\log_{10}$ solubility product of $CaCO_3$, *p*Ca is $-\log_{10}[Ca^{2+}]$ in moles/L, and *p*Alk = $-\log_{10}$ [total alkalinity] in equivalents/L. The complexity of these expressions has been reduced to nomographs (Ref 11). The RSI is an empirical expression:

$$RSI = 2pH_s - pH = pH_s - LSI \qquad \text{(Eq 31)}$$

where pH and pH_s have the same meaning as previously described. Interpretations of LSI and RSI values are listed in Table 3.

Table 3 Prediction of water characteristics by LSI and RSI values

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Index		Tendency of water
LSI	**RSI**	
2.0	<4	Heavy scale forming, nonaggressive
0.5	5–6	Slightly scale forming and mildly aggressive
0	6–6.5	Balanced or at $CaCO_3$ saturation
-0.5	6.5–7	Nonscaling and slightly aggressive
-2.0	>8	Undersaturated, very aggressive

LSI, Langelier Saturation Index; RSI, Ryznar Stability Index

These values indicate only the tendency for $CaCO_3$ to deposit, not the rate or capacity for deposition. They do not take into account the tendency for $CaCO_3$ to supersaturate, its rate of formation, or whether the water contains an inhibitor to prevent deposition.

Calcium carbonate formation can be controlled by adding acids or specific chemicals tailored to inhibit its formation or modify the crystal lattice. Sulfuric acid (H_2SO_4), which is inexpensive, is most often used. Other acids, such as HCl, citric, or sulfamic acid (NH_2SO_3H), are also suitable. Acid addition produces salts that are more soluble than $CaCO_3$. These salts can reach saturation and must be controlled to prevent precipitation on heat-transfer surfaces:

$$Ca(HCO_3)_2 + H_2SO_4 \rightarrow CaSO_4 + 2CO_2 + 2H_2O \quad \text{(Eq 32)}$$

Calcium carbonate precipitation can also be inhibited by chemical treatment. A cost-effective group of materials is the polymeric inorganic phosphates. This class of compounds includes the salts of pyrophosphate, tripolyphosphate, and hexametaphosphate. Approximately 1 mg/L (ppm) of active material can stabilize 44 times the $CaCO_3$ equilibrium saturation concentration. This concentration is well below the stoichiometric values required for complexing calcium hardness and is termed threshold treatment. At these concentrations, the polyphosphates inhibit the formation of $CaCO_3$ crystallites by suppressing both nucleation and crystal growth. The polyphosphates are partly adsorbed on the surface of the growing crystals and partly included in incipient crystal nuclei. A disadvantage of the polyphosphates is their ability to hydrolyze or revert to PO_4^{3-} ions, which have no scale-inhibiting properties.

Other phosphate compounds found to be effective belong to the class known as phosphonates. Two of the more common compounds are nitrilotris(methylene phosphonic) acid (AMP) and 1-hydroxyethylidine-1,1-diphosphonic acid (HEDP). Threshold treatment inhibitor concentrations range from 0.25 to 0.5 mg/L (ppm), although higher concentrations are often used. The compounds AMP and HEDP have greater hydrolytic stability than the polyphosphates. It should be noted that AMP will degrade in the presence of chlorine to PO_4^{3-} ions. The addition of zinc ions (Zn^{2+}) significantly stabilizes the AMP molecule while still maintaining its control over $CaCO_3$ scale. Although HEDP is less affected by chlorine ion than AMP, at least 50% of the HEDP is degraded to PO_4^{3-} at residual chlorine concentrations of 0.2 to 0.5 mg/L (ppm) (Ref 12).

Organic polymers have also been found to be effective $CaCO_3$ inhibitors. These include polycarboxylates, such as polyacrylates, polymethacrylates, polymaleates, and their copolymers. Treatment levels are higher than the phosphorus- bearing materials, usually in the range of 2 to 4 mg/L (ppm). The molecular weights of these polymers should range from 1000 to 10,000 atomic mass units (amu) for effective scale control.

The polymers adsorb onto the $CaCO_3$ crystal structure, limiting the growth of $CaCO_3$ and ultimately limiting scale formation. These polymers are more frequently considered dispersants. They retard $CaCO_3$ scale by maintaining small particles of distorted crystalline material in suspension.

Bifunctional compounds are a recent development for $CaCO_3$ control. Phosphinocarboxylic acids contain both organic phosphorus and carboxylic acid groups (Ref 13). Simple molecules combining both the phosphono and carboxylic groups have also emerged and are very effective $CaCO_3$ inhibitors (Ref 12). However, these bifunctional compounds may be more expensive than the traditional low-molecular-weight polymers, polyphosphates, or phosphonates.

Calcium sulfate can exist in various forms in cooling water systems, the most common form being gypsum ($CaSO_4 \cdot 2H_2O$). The hemihydrate ($CaSO_4 \cdot \frac{1}{2}H_2O$) and anhydrous forms are much less common. Their solubilities as a function of temperature are shown in Fig. 4. Because $CaSO_4 \cdot 2H_2O$ is more soluble than $CaCO_3$ by at least a factor of 50, it will precipitate only after the latter scale has been formed, within the normal pH range of 7 to

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

9. This phenomenon provides the basis for H_2SO_4 addition to control $CaCO_3$ in recirculating cooling water systems. The normal upper limit for calcium and sulfate concentration in the absence of an inhibitor is expressed:

$$\left[Ca^{2+}\right]\cdot\left[SO_4^{2-}\right] = 500{,}000 \qquad \text{(Eq 33)}$$

where the bracketed values are the ionic concentrations expressed in mg/L (ppm).

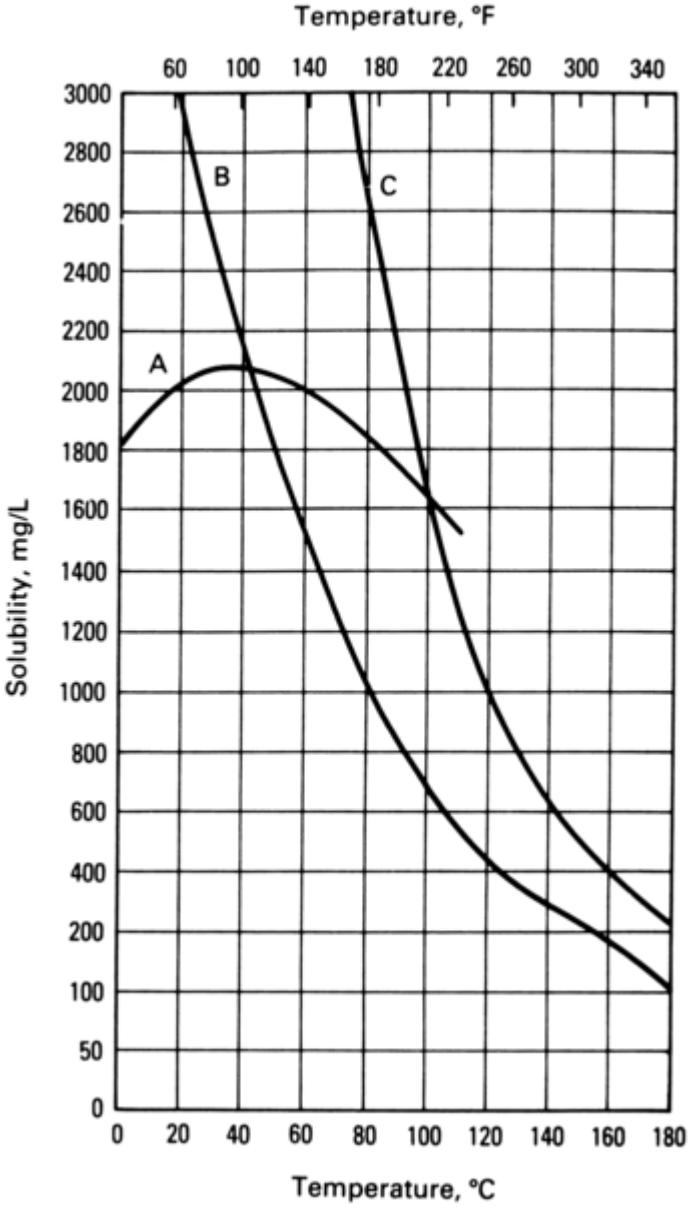

Fig. 4 Solubility of three forms of $CaSO_4$ versus water temperature. A, $CaSO_4 \cdot 2H_2O$; B, anhydrous $CaSO_4$; C, hemihydrate ($CaSO_4 \cdot \frac{1}{2}H_2O$). Source: Ref 14

Calcium sulfate scale can be most effectively controlled with polyacrylates (Ref 15), their copolymers, and phosphinocarboxylates (Ref 13). As with $CaCO_3$, excellent calcium scale control is achieved with polymers having low molecular weights in the range of 1000 to 10,000 amu. Concentrations of 1 to 2 mg/L (ppm) can increase $CaSO_4$ solubility by a factor of 20. This is similar to maintaining the $[Ca^{2+}]\cdot[SO_4^{2-}] > 10^7$ compared to 500,000 in the absence of chemical treatment. These polycarboxylates are stable over a wide range of pH and temperature. The basic mode of inhibition is through a combined threshold crystal distortion and dispersancy mechanism that prevents or delays precipitation.

Another chemical that controls $CaSO_4$ precipitation efficiently is the phosphonate AMP. In fact, the family of aminophosphonates has been found to be extremely effective. The level of AMP needed is approximately 0.5 mg/L (ppm).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Calcium phosphate [$Ca_3(PO_4)_2$] scale has become more common in recirculating cooling water systems. Increasing pH, calcium concentration, and phosphate addition from chemical treatment have provided the potential for this deposit to form on heat-transfer surfaces. Other water sources have also contributed to the increased level of phosphate. Makeup waters obtained from agricultural runoff and partly treated sewage can have high levels of PO_4^{3-} ions—at least 10 mg/L (ppm).

The solubility of $Ca_3(PO_4)_2$ decreases with increasing pH. It is essentially unaffected from 25 to 75 °C (75 to 165 °F). These deposits are usually amorphous and eventually transform to a more crystalline hydroxyapatite—$Ca_{10}(OH)_2(PO_4)_6$. Because of the low solubility of $Ca_3(PO_4)_2$ 2×10^{-29} deposits can easily form in waters containing 5 mg/L (ppm) of PO_4^{3-} ions and 300 mg/L (ppm) of Ca^{2+} ions at pH 7 to 7.5. The scale-forming tendency of $Ca_3(PO_4)_2$ is a complex function of pH, calcium hardness, PO_4^{3-} concentration, ionic strength, and temperature. Rule-of-thumb relationships between these variables do not exist. In the absence of any phosphate deposit, the PO_4^{3-} ions can contribute to the corrosion inhibition of low-carbon steel.

Calcium phosphate is an extremely difficult scale to inhibit. Intensive research has brought forth new chemistry to control this tenacious deposit. These new inhibitors include acrylic acid- hydroxypropylacrylate copolymer (Ref 16), styrene sulfonic acid-maleic acid copolymer, acrylic acid-sulfonic acid copolymer (Ref 17), and phosphino/acrylic acid-organo-sulfonic acid copolymer. They function by markedly modifying the morphology and size of the $Ca_3(PO_4)_2$ deposit while acting as a dispersant to prevent adherence of $Ca_3(PO_4)_2$ to heat-transfer surfaces. Concentrations of these copolymers are 10 to 15 mg/L (ppm) under conditions of moderate calcium hardness (about 500 mg/L, or ppm, as $CaCO_3$) and 10 mg/L (ppm) of PO_4^{3-} ions at pH 8 to 8.5. Increasing any of these parameters will require an increase in polymer concentration.

Silicate Scales. Calcium silicate ($CaSiO_3$) and magnesium silicate ($MgSiO_3$) scales tend to develop under more alkaline cooling water conditions, in which the pH is approximately 8.5 or greater. These scales are very tenacious, dense, and difficult to remove from heat-transfer surfaces. Although the solubility of silica (SiO_2) increases with pH, the solubility of the alkaline silicate decreases with increasing pH.

An upper limit for SiO_2 concentration is 150 mg/L (ppm) in the recirculating water, although other factors affect this value. Magnesium silicate can precipitate on heat-transfer surfaces with magnesium concentrations as low as 50 mg/L (ppm) and 150 mg/L (ppm) SiO_2. A rule-of-thumb pseudosolubility product of $[Mg]\cdot[SiO_2] \leq 8400$ has been developed (bracketed values are in mg/L, or ppm). The addition of chemical treatment as a preventive measure is essentially nonexistent. The most effective method of control is to keep the SiO_2 concentration in the recirculating cooling water below the 150 mg/L (ppm) limit.

Fouling Deposits. Water-borne deposits, commonly known as foulants, are loose, porous, insoluble materials suspended in water. They include such diverse substances as particulate matter scrubbed from the air; migrated corrosion products; silt, clays, and sand suspended in makeup water; organic contaminants (oils); biological matter; floc carryover from clarifiers; and such extraneous materials as leaves, twigs, and wood fibers from cooling towers. Fouling interferes with the flow of cooling water as compared to the reduction in heat transfer caused by barrier scales. However, fouling can reduce heat-transfer efficiency by plugging of the exchanger. Adequate water flow through the tubes is essential.

High flow rates (1.5 to 2.5 m/s, or 5 to 8 ft/s) can sweep away ordinary deposits, but low flow rates (less than 0.6 m/s, or 2 ft/s) cause the suspended foulants to drop out and deposit. Regions of low velocity include shell-side coolers, compressor jackets, water boxes, and cooling-tower basins.

Mechanical methods can be used to reduce fouling. In once-through cooling systems, coarse filters (bar screens, trash tracks, traveling screens) are used to remove large debris. Fine filtration is not practical. This is not the case with open recirculating systems. When the makeup water contains an appreciable concentration of suspended matter, it is advantageous to use side- stream filtration. In general, passing a few percent of the recirculating water through the side- stream filter will reduce the suspended solids loading 80 to 90%.

Another effective mechanical method used to control foulants is to pass scrapers, brushes, or balls through the heat-exchanger tubes, wiping them free of deposits. The technique is most frequently used in power utility surface condensers or other critical exchangers.

Chemical treatment has also been found to be an effective control method. Synthetic polymers are the chemicals more commonly used to disperse foulants. Polyacrylates, polymaleates, partially hydrolyzed polyacrylamides, and their copolymers constitute the majority of dispersant chemicals. The most important aspect of these materials is their molecular weights. An effective dispersant has a molecular weight of 1000 to

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

10,000 amu—the same range as for scale control. Concentrations of a few mg/L (ppm) are required in open recirculating systems, but lower levels are normally used in once-through systems.

Natural dispersants, such as tannins, lignin sulfonate, and carboxymethyl cellulose, are occasionally used, but they are not as effective as the synthetic polymers. The natural materials require higher concentrations to produce good dispersion of foulants, may not be cost effective, and may contribute to foaming. The synthetic polymers are not as easily degraded by biological organisms as are the natural polymers.

Increasing the molecular weight of the synthetic polymers into the million range changes the characteristics of the treatment from dispersion to flocculation. These high-molecular- weight polymers consist of polyacrylamides, polyamines, and polyacrylates and their various copolymers. Fouling is controlled by agglomeration of the suspended solids into nonadherent larger particles. To settle deposits, the polymers are usually added at concentrations of 0.2 to 0.5 mg/L (ppm) to clarifiers or thickeners. Similar concentrations are used in open recirculating systems. The deposit will accumulate in low- flow or stagnant areas in the recirculating systems. Heat transfer will not be seriously reduced, because of the low bulk density of these deposits. However, buildup of sludge in the cooling tower basins will necessitate periodic cleaning.

Biological Fouling. The presence and growth of living matter is commonly referred to as biofouling. Biofouling can interfere with the flow of water through heat exchangers and other conduits. This inhibits heat transfer and contributes to corrosion and general deterioration of the entire cooling system.

Recirculating cooling water systems are ideal incubators for the growth and proliferation of microorganisms. Water saturated with oxygen, exposed to sunlight, maintained at 30 to 60 °C (85 to 140 °F), and having a pH of 6 to 9 and abundant nutrients can readily sustain the growth of microorganisms. Although biofouling interferes with heat transfer, it does so in a manner quite different from that of inert deposits.

Biofilm buildup is initiated with the adsorption of organic material on the metal surface from the bulk water. Transport of microbial particles to the surface occurs as the result of turbulent flow. Microorganisms attach to the surface, and growth occurs through the assimilation of nutrients. Eventually, some of the biofilm is sheared away and reentrained in the flowing water to repeat the process of biofilm development. These steps are shown in Fig. 5.

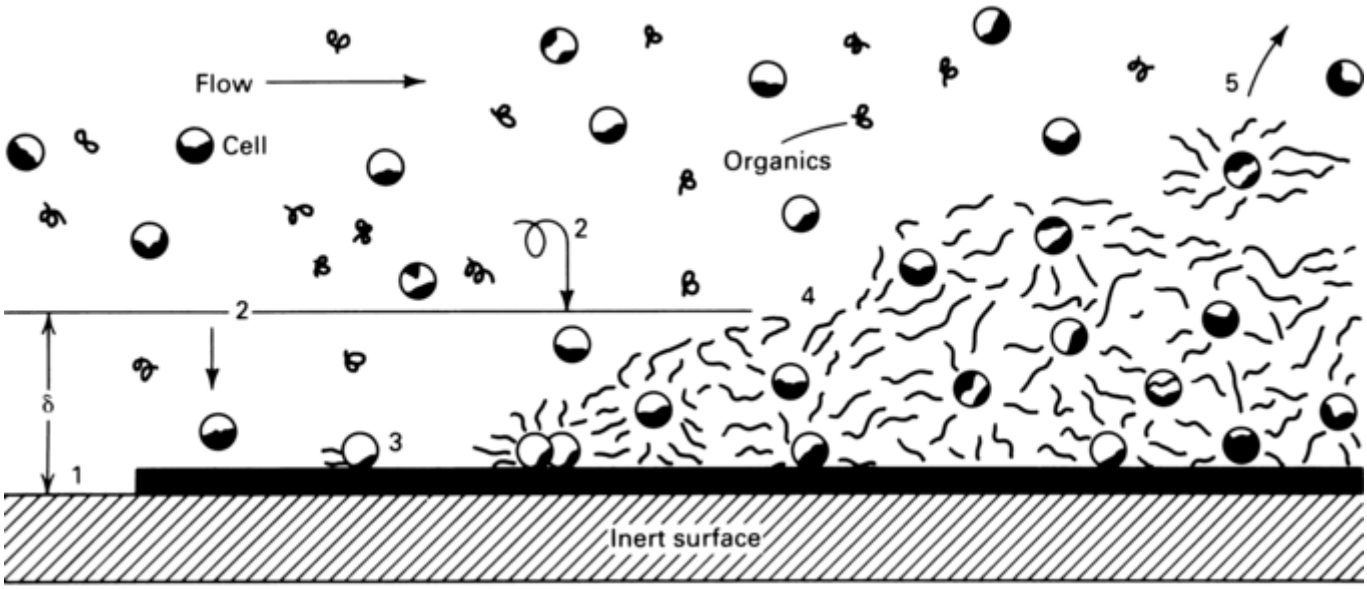

Fig. 5 Steps in biofilm formation. Formation is initiated when small organic molecules become attached to an inert surface (1) and microbiological cells are adsorbed onto the resulting layer (2). The cells send out hairlike exopolymers to feed on organic matter (3), adding to the coating (4). Flowing water detaches some of the formation (5), producing an equilibrium layer δ. Source: Ref 18

The biofilm can cause losses in heat transfer because of its insulating properties. Kinetic energy is absorbed from the flowing water through the rippling biofilm surface. Increased pumping energy is required to overcome the frictional resistance of the biofilm. Even though the film is 95 to 98% H_2O, the pressure decrease produced by a 500 μm (20 mils) thick film is substantial.

Three major classes of microorganisms are associated with recirculated cooling water systems: algae, fungi, and bacteria. Algae can range from very simple single-cell (unicellular) plants to multicellular species. The latter

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

include diverse forms and shapes, including slimy masses composed of several cells or long strands (filaments). All algae contain colored pigments, the most important of which is chlorophyll. Algae usually flourish on wetted surfaces exposed to oxygen and sunlight, such as cooling tower exposed lumber, mist eliminators, screens, and distribution trays.

Their impact on metal corrosion can be severe. The large slime mass contributes to crevice corrosion and pitting. Massive growths can inhibit proper water distribution by plugging screens, restricting flow, and interfering with pump suction.

Fungi are similar to algae, but do not contain chlorophyll. The major forms of interest are yeast and molds. They require moisture and air but not sunlight and exist on nutrients found in water or substances to which they are attached, for example, bacteria and algae. Mold fungi are filamentous in form, but most yeast are unicellular. Fungi consume wood components, causing serious wood surface deterioration and internal decay (wood rot).

Bacteria are unicellular microscopic plantlike organisms that are similar to algae, but lack chlorophyll. They exist in three basic forms: rod shaped (bacillus), spherical (coccus), and spiral (spirillus). The nutrients required for growth must be in solution, which necessitates a certain amount of moisture in their environment. Some bacteria require other carbon forms in addition to CO_2 in order to produce carbohydrates for food. Therefore, water or wet environments high in organic content are suitable for the proliferation of bacteria slime. Heat exchangers are ideal incubators for this biomass. Bacteria slime can significantly reduce heat-transfer efficiency and aggravate underdeposit corrosion attack.

The presence of oxygen is not required by all species of bacteria. Aerobic bacteria require free oxygen for growth, but anaerobic bacteria grow in the absence of oxygen.

Acidic waters produced by some forms of bacteria will directly attack metal surfaces. One species that is quite common is sulfate-reducing bacteria (SRB). These organisms are anaerobic and convert dissolved sulfur compounds, that is, SO_4^{2-}, to hydrogen sulfide (H_2S). Carbon steel, stainless steel, and copper-base alloys can be severely corroded by H_2S. ***Desulfovibrio desulfuricans*** is the most prevailing sulfate-reducing species. It exists mainly under deposits devoid of oxygen. The corrosive attack on carbon steel by these bacteria is quite distinctive; it is recognizable by smooth disk-shaped concentric rings formed on the metal surface. Corrosion rates as high as 2.5 mm/yr (100 mils/yr) can occur under optimal growth conditions. The following general reactions occur:

$$10H^+ + SO_4^{2-} + 4Fe \rightarrow 4Fe^{2+} + H_2S + 4H_2O \qquad \text{(Eq 34)}$$

$$H_2S + Fe^{2+} \rightarrow FeS + 2H^+ \qquad \text{(Eq 35)}$$

The formation of black iron sulfide deposits in conjunction with a rotten egg odor is also characteristic of attack by SRB.

The aerobic sulfur bacteria ***Thiobacillus*** can oxidize sulfur, or sulfides, to H_2SO_4. Localized pH depression as low as pH 1 can occur, causing severe thinning of steels where these organisms contact the metal. ***Thiobacillus*** and ***Desulfovibrio*** bacteria can exist simultaneously in close proximity. In doing so, the anaerobic SRB survive beneath the aerobic sulfur bacteria deposits.

Another organism common to cooling water systems is the nitrifying bacteria, which can oxidize NH_3 to nitrate. This is accompanied by a decrease in pH and occurs according to the reaction:

$$NH_3 + 2O_2 \rightarrow HNO_3 + H_2O \qquad \text{(Eq 36)}$$

Rapid general thinning of copper-base alloys and steels can occur. Nitrite-base steel corrosion inhibitors can be rendered ineffective because of their oxidation to nitrate by these bacteria.

Several other groups of bacteria exist in cooling water environments. Iron-depositing bacteria can oxidize water-soluble Fe^{2+} ions to insoluble Fe_2O_3, which will subsequently deposit on the inside of piping, reduce flow, and aggravate crevice corrosion. Slime-forming bacteria form dense, sticky biomasses that impede water flow and contribute to fouling by sustaining the growth of other organisms.

The most practical and efficient method of controlling microbiological activity in cooling waters is through the use of biocides (Ref 19). These chemicals have the ability to kill the organisms or inhibit their growth and reproductive cycles. Biocides perform their function in various ways. Some biocides alter the permeability of the microbe cell wall, thus interfering with their vital life processes. Others damage the cell by interfering with the normal flow of nutrients and discharge of waste (Table 4).

Table 4 Biocides used in cooling water systems

Microbiocide	Effectiveness[(a)]			Comments
	Bacteria	**Fungi**	**Algae**	
Chlorine	E	S	E	Oxidizing; reacts with $–NH_2$ groups: effective at neutral pH; loses effectiveness at high pH. Use concentration: 0.1–0.2 mg/L continuous free residual; 0.5–1.0 mg/L intermittent free residual
Chlorine dioxide	E	G	G	Oxidizing; pH insensitive; can be used in presence of $–NH_2$ groups. Use concentration: 0.1–1 mg/L intermittent free residual
Bromine	E	S	E	Oxidizing; substitute for Cl_2 and ClO_2; effective over broad pH range. Use concentration: 0.05–0.1 mg/L continuous free residual; 0.2 to 0.4 mg/L intermittent free residual
Organo-bromide (DBNPA)	E	NA	S	Nonoxidizing; pH range 6–8.5. Use concentration: 0.5–24 mg/L intermittent feed
Methylene bisthiocyanate	E	S	S	Nonoxidizing; hydrolyzes above pH 8. Use concentration: 1.5–8 mg/L intermittent feed
Isothiazolinone	E	G	E	Nonoxidizing; pH insensitive; deactivated by HS^- and $–NH_2$ groups. Use concentration: 0.9–13 mg/L intermittent feed
Quaternary ammonium salts	E	G	E	Nonoxidizing; tendency to foam; surface active; ineffective in highly oil- or organic-fouled systems. Use concentration: 8–35 mg/L intermittent feed
Organo-tin/quaternary ammonium salts	E	G	E	Nonoxidizing; tendency to foam; functions best in alkaline pH. Use concentration; 7–50 mg/L
Glutaraldehyde	E	E	E	Nonoxidizing; deactivated by $–NH_2$ groups; effective over broad pH range. Use concentration: 10–75 mg/L intermittent feed

(a) E, excellent; G, good; S, slight; NA, not applicable

Biocides can be either oxidizing or nonoxidizing toxicants. Chlorine gas is the most prevalent industrial oxidizing biocide. It rapidly hydrolyzes in water to form hypochlorous acid (HClO) and HCl:

$$Cl_{2(g)} + H_2O \rightarrow HClO + HCl \qquad \text{(Eq 37)}$$

HClO is the active species and dissociates as a function of pH:

$$HClO \leftrightarrow H^+ + ClO^- \qquad \text{(Eq 38)}$$

At pH 7.5, equal concentrations of HClO and hypochlorous ions (ClO^-) exist. Above this pH, ClO^- predominates, with essentially total ionization at pH 9.5. As a consequence, chlorine becomes less effective in the more alkaline environments. Generally, the pH range of 6.5 to 7.5 is considered practical when chlorine is used as a biocide. Lower pHs will accelerate corrosion. Continuous treatment levels of 0.1 to 0.2 mg/L (ppm) are common. Intermittent treatment requires levels of 0.5 to 1.0 mg/L (ppm). Chlorine is both an excellent algaecide and bactericide. However, *Desulfovibrio* can develop a strong resistance to chlorine, requiring an increase in chlorine concentration or a change to an alternate biocide. Other sources of chlorine are salts of HClO, such as sodium hypochlorite (NaClO) and calcium hypochlorite [$Ca(ClO)_2$]. Both of these salts function in much the same way as chlorine.

Another oxidizing biocide is chlorine dioxide (ClO_2). This gas does not form HClO in water, but exists solely as ClO_2 in solution. It is used more extensively in the pulp and paper industry for bleaching than as a biocide. ClO_2 is extensively used in cooling waters contaminated with NH_3 or phenols due to the low demand for reaction with these species.

www.iran–mavad.com
مرجع مهندسی مواد و متالورژی

Brominated compounds that form hypobromous acid (HBrO) are very effective over a broader pH range than HClO. At pH 7.5, 50% of the chlorine is present as HClO, but more than 90% of the bromine is present as HBrO. Increasing the pH to 8.7 reduces the HClO concentration to 10%, but 50% of the HBrO remains.

Nonoxidizing biocides can be more effective than oxidizing biocides because of their overall control of algae, fungi, and bacteria. They have greater persistence, and the performance of many of them is pH independent.

An organobromine broad-spectrum nonoxidizing toxicant is 2,2-dibromo-3-nitrilopropionamide (DBNPA). This molecule is an extremely potent bactericide. It is slightly effective as an algaecide. It has little fungicide activity, and its toxicity decreases with an increase in alkaline pH.

Organosulfur compounds include a wide variety of different biocides, of which methylene bisthiocyanate is the most common. Their mode of activity is through the inhibition of cell growth by preventing the transfer of energy or life-sustaining chemical reactions from occurring within the cell. Methylene bisthiocyanate is effective in controlling algae, fungi, and bacteria, most notably *Desulfovibrio*. A shortcoming of methylene bisthiocyanate is its pH sensitivity and rapid hydrolysis in the alkaline pH range. Methylene bisthiocyanate is not recommended for use in cooling water systems having pH above 8.

Under broader alkaline conditions, sulfur-base biocides, such as bistrichloromethylsulfone and tetrahydro-3,5-dimethyl-2H-1,3,5-thiadiazine-2- thione, are more appropriate. The former is active in the pH range of 6.5 to 8, and the latter in more alkaline cooling water systems.

Isothiazolinone is a relatively new sulfur-containing biocide. It is very effective in controlling algae and bacteria. Isothiazolinone can be used over a broad pH range with no decrease in activity.

Quaternary ammonium salts are generally most effective against algae and bacteria in the alkaline pH range. The quaternary compounds cause cell death by reducing the permeability of the cell wall, preventing the intake of nutrients necessary to sustain life. Because of their surface-active nature, these compounds are easily rendered ineffective in systems heavily fouled with dirt, oil, and debris.

Organic tin compounds, such as bistributyl-tin oxide are very effective against algae and fungi. They function best in the alkaline pH range and provide synergistic biocidal activity when combined with quaternary ammonium salts.

Glutaraldehyde (1,5-pentanedial) is an effective broad-spectrum biocide capable of controlling slime-forming and SRB, fungi, and algae (Ref 20). It functions over broad pH and temperature ranges and is compatible with chlorine. Glutaraldehyde is deactivated in systems containing NH_3 and other primary amines that contain $-NH_2$ groups.

Corrosion Control in Cooling Water Environments. Aqueous corrosion has been shown to consist of electrochemical processes. The detrimental effects of these processes in cooling water environments can be significantly reduced by various methods, such as designing systems with more corrosion-resistant materials, applying protective coatings (paints, epoxy), using sacrificial anodes (cathodic protection), and chemical treatments.

For chemical-treatment or corrosion-inhibitor programs to be effective, they must protect all exposed metal from corrosive attack, must be effective at low concentration, must not cause deposits on the metal surface, must remain effective under a broad range of pH, temperature, water quality, and heat-flux conditions, must prevent scale formation and disperse deposits, and must have minimal toxicological effect when discharged. Economics should also be considered when assessing the merits of a chemical- treatment program. In once-through cooling systems, protection must be achieved with a few mg/L (ppm), or the cost may be prohibitive. Use of more corrosion-resistant alloys is often a more economical approach to corrosion control in once-through cooling systems. With respect to open recirculating cooling systems, chemical addition to the makeup water are typically in the range of 10 to 50 mg/L (ppm) (active). Cost is not as prohibitive, because the recycling of the water also includes the inhibitor. Closed recirculating cooling water systems require high active treatment levels (in the range of several thousand mg/L, or ppm). These systems have very small water losses.

Inhibitors can be broadly classified according to the rate process being controlled. Anodic inhibitors suppress anodic reactions; that is, the rate of metal ions transferred into the aqueous environment is reduced. Cathodic inhibitors impede the cathodic reaction—for example, the oxygen-reduction reaction. Mixed inhibitors hinder both reactions. The performance of an inhibitor can be assessed by its effectiveness in reducing the corrosion rate. This is generally expressed as a rate of thinning or penetration in microns/year or mils/year.

Inorganic inhibitors usually affect the anodic process. Rapid suppression of general corrosion occurs after anodic inhibitor treatment. However, when anodic inhibitors are below a critical concentration, they can stimulate localized pitting attack and therefore must be used with caution. Cathodic inhibitors reduce corrosion

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

primarily by interfering with the oxygen-reduction reaction. This family of inhibitors decreases general corrosion and does not stimulate pitting attack.

The current approach to cooling water treatment is toward more alkaline or high-pH conditions. This was not always the case. Historically, acid treatment was widely used to prevent scale deposition on heat-transfer surfaces. The system pH was slightly acidic (pH 6.5 to 7.0), and corrosion was controlled by using highly effective anodic inhibitors, the most effective being chromates, which have since been phased out.

Anodic Inhibitors

Nitrites. Sodium nitrite ($NaNO_2$) is an anodic inhibitor and requires a critical concentration for the protection of steel. Nitrites are extensively used as inhibitors in closed recirculating systems. The level of inhibitor depends on the aggressive species in solution. Sulfate ions interfere with nitrite protection to a greater extent than Cl^- ions. Treatment level should be at least the concentration of $NaNO_2$ required to produce a weight ratio of 1 with the aggressive ion concentrations ($[NaNO_2]/[NaCl + Na_2SO_4] = 1$). This concentration is normally in the range of 500 to 750 mg/L (ppm) at pH above 7.5. Nitrite may contribute to pitting of carbon steel if the concentration falls below this critical level.

Nitrites are easily oxidized to nitrates and therefore are not suitable for use in open recirculating cooling water systems. However, when formulated with borax, nitrites are excellent corrosion inhibitors for closed systems. The borax buffers the water to a pH above 8.5. Dosage levels for the borax-nitrite systems are 1500 to 2000 mg/L (ppm), with a nitrite concentration near 800 mg/L (ppm). It should be noted that NO_2^- ions are nutrients for some species of bacteria, which can oxidize the NO_2^- ions and render the treatment ineffective, producing slime deposits and a low pH. Biocides (isothiazolinone) are often used in conjunction with borax-nitrite programs for optimal protection.

Molybdates have been available for corrosion protection for more than 60 years, but have never been widely used. Molybdates are classified as anodic inhibitors. In waters having moderate Cl^- concentration (200 mg/L, or ppm), the level of sodium molybdate (Na_2MoO_4) needed for protection is at least 1000 mg/L. In dilute electrolytes, the concentration can be reduced to 150 mg/L (ppm). Normal treatment practices consist of combinations of molybdates with other inhibitors to produce synergistic treatments. This reduces the high level of molybdate ions (MoO_4^{2-}) needed when used alone. Combinations with zinc salts, phosphonates (AMP and HEDP), inorganic phosphates, nitrites, and carboxylates, such as long-chain acrylates and azoles (benzo- or tolyltriazoles), are effective in controlling corrosion of multimetal systems (Ref 21).

Sodium molybdate is a nonoxidizing inhibitor and requires a suitable oxidizing agent to augment the inhibitor and to impart a protective film. In aerated systems, the most abundant oxidizer is oxygen. Any of the above combinations are applicable except nitrites. A typical treatment consists of MoO_4, HEDP, zinc, and benzotriazole in a 3-to-3-to-1-to-1 weight ratio (Ref 21). A wide range of ratios has been used in specific formulations.

The use of molybdates in closed systems requires an oxidizing salt, such as $NaNO_2$. The optimal composition for the Na_2MoO_4:$NaNO_2$ system consists of a 60-to-40 weight ratio of the two salts (Ref 21).

Molybdate treatments have minimal pH dependency and can be used over a pH range of 5.5 to 8.5. They are sensitive to electrolyte concentration and are adversely affected by aggressive ions, such as Cl^- and SO_4^{2-}, when used alone. Temperature dependency is minimal. Molybdate treatments are known to inhibit both pitting and differential aeration attack. The precipitation of calcium molybdate [$Ca(MoO_4)$] is a concern in waters with moderate to high calcium hardness.

The mechanism by which molybdates inhibit the corrosion of ferrous metals is uncertain and complex. Simplistically, when iron corrodes, MoO_4^{2-} ions, in conjunction with other anions adsorb to form a nonprotective complex with Fe^{2+} ions. Because of dissolved oxygen or other oxidizers in the water, some of the Fe^{2+} ions are oxidized to the ferric (Fe^{3+}) state, and the ferrous-molybdate is transformed to ferric-molybdate, which is both insoluble and protective in neutral and alkaline waters.

Phosphates. Sodium phosphate (Na_3PO_4) is an anodic inhibitor and is effective in the presence of oxygen. Its protective properties toward steel are a function of pH. The monosubstituted phosphate (MH_2PO_4, where M is a metal) is the least protective, and the trisubstituted phosphate (M_3PO_4) is the most protective. Use of phosphate as a corrosion inhibitor should be relegated to more alkaline environments (pH > 8).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In open recirculating waters, phosphate treatment levels should be 15 to 20 mg/L (ppm). At lower concentrations of a few mg/L (ppm), PO_4^{3-} ions will cause pitting attack. The ability of phosphate to inhibit steel is primarily due to the oxygen content of the system (Ref 22). The dissolved oxygen produces a defective thin film of γFe_2O_3. The PO_4^{3-} fills in the voids and accelerates film growth. This prevents further diffusion of Fe^{2+} ions from the metal surface.

Inhibition by PO_4^{3-} ions is sensitive to electrolyte concentration; Cl^- ions can promote pitting attack. Because the protective oxide film contains voids and other inclusions, Cl^- ions are easily adsorbed to form soluble complexes. Hydrolysis of these complexes produces acid domains, which leads to localized acidic attack. Film breakdown is a function of the aggressive ion concentration, but film repair will depend on PO_4^{3-} levels and oxygen concentration.

Inhibition by PO_4^{3-} ions is sensitive to water quality and pH. There is minimal temperature sensitivity. One word of caution regarding PO_4^{3-} ions as low-carbon steel corrosion inhibitors: with waters of high calcium hardness, the potential for deposit formation increases with hardness, phosphate level, pH, and temperature. These deposits will stimulate crevice (underdeposit) corrosion. The need for an inhibitor to prevent calcium deposits becomes exceedingly more important as cooling waters increase in cycles of concentration and pH.

Cathodic Inhibitors

Cathodic inhibitors suppress corrosion by reducing the effectiveness of the cathodic process. They do not cause intense local attack and are generally considered to be safe inhibitors. Cathodic inhibitors are not as effective as anodic inhibitors in reducing corrosion.

Precipitating inhibitors fall under the domain of a cathodic inhibitor. They produce insoluble films on the cathode under conditions of locally high pH and isolate the cathode from the solution. Calcium bicarbonate [$Ca(HCO_3)_2$] will react with the alkaline medium at the cathode to form $CaCO_3$. The increase in alkalinity is due to the oxygen-reduction process, generating OH^- ions:

$$Ca(HCO_3)_2 + OH^- \rightarrow CaCO_3 + HCO_3^- + H_2O \qquad \text{(Eq 39)}$$

At the correct pH, $CaCO_3$ will precipitate to form a hard, smooth deposit that prevents oxygen from diffusing onto the metal surface. The tendency of water to form a $CaCO_3$ deposit is given by the LSI value.

Zinc ions are used to achieve a general reduction in corrosion by precipitating as zinc hydroxide [$Zn(OH)_2$] at the locally elevated pH of the cathode. Zinc is usually combined with phosphonates, polyphosphates, or orthophosphate. The durability of $Zn(OH)_2$ is tenuous at best. Although not normally used alone in cooling systems, zinc is synergistic when combined with other inhibitors as part of a multicomponent treatment program.

Zinc causes rapid development of a protective film over the metal surface. Above pH 7.5, the solubility of zinc is rapidly reduced to a few tenths of 1 mg/L (ppm). Its solubility can be significantly enhanced when combined with phosphonates or with some of the polymers used for $Ca_3(PO_4)_2$ control.

Polyphosphates are widely used cathodic inhibitors. They have been used for more than 60 years and are among the most economical of all inhibitor treatments. Sodium salts of the polyphosphates are normally used for corrosion control. They exist as linear polymers having the general structure shown in Fig. 6. The lower members of the series having “x” equal to or less than 2 are crystalline in nature, that is, $x = 0$, orthophosphate; $x = 1$, pyrophosphate; $x = 2$, tripolyphosphate. Higher members of the series are glassy and have no definitive structure. Varying the ratio of $n Na_2O$ to $m P_2O_5$ will produce species of different chain lengths and physicochemical properties, even though the inhibitive action of these polyphosphates is not significantly altered. The pH of the environment directly affects the protective properties of the phosphates. Orthophosphate inhibits corrosion in a more alkaline environment than does pyrophosphate. The crystalline phosphates protect low-carbon steel at higher pHs than the glassy phosphates, which function better near neutral pH. Normal concentrations in recirculating waters are 15 to 20 mg/L (ppm). The pH should be maintained in the range of 6.5 to 7.5 if low-carbon steel and copper alloys are both part of the system metallurgy.

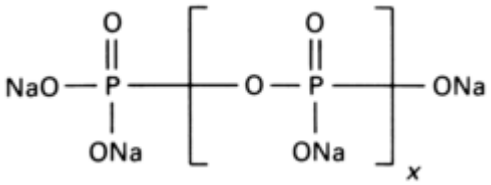

Fig. 6 General structure of sodium polyphosphate. *x* = 0, sodium phosphate; *x* = 1, sodium pyrophosphate; *x* = 2, sodium tripolyphosphate; *x* = 12 to 14, sodium polyphosphate

The polyphosphates are relatively insensitive to electrolyte concentrations, but do require an increase in dosage level with an increase in water corrosivity. They are effective inhibitors in controlling galvanic attack between two dissimilar metals (Ref 23), but do not prevent deposition of cathodic species on the more active metal, that is, copper deposition on steel.

Divalent metal ions, and Ca^{2+} in particular, are needed with the polyphosphates for effective inhibition of steel corrosion. The ratio of Ca^{2+} ion concentration to polyphosphate concentration should be at least 0.2, and preferably 0.5. The protective film develops through the formation of a positively charged colloidal complex that migrates to the cathode, forming an amorphous protective barrier. The cationic complex is accounted for by assuming that the calcium insets itself in the polyphosphate chains. The colloidal particles are the result of numerous cationic complexes loosely knit one to another through the Ca^{2+} ions. Polyphosphates will slowly revert to PO_4^{3-} ions, in the presence of Ca^{2+} ions and alkaline pH.

The phosphonates differ from the polyphosphates by a direct bond formation between the phosphorus and carbon atoms, rather than an oxygen-phosphorus bond in the polyphosphate. This linkage creates greater hydrolytic stability, which reduces the problem of reversion common to the polyphosphates. Two classes of materials are extensively used: AMP and HEDP. Their structures are shown in Fig. 7 and 8. When used alone, both compounds are marginally good low- carbon steel inhibitors, especially at high pH (pH 8.0). They protect ferrous metals through a mixed mode of inhibition. Incipient local attack occurs, but is rapidly arrested. Normal treatment levels are in the range of 15 to 20 mg/L (ppm). The hydrolytic stability of the phosphonates eliminates the problem of $Ca_3(PO_4)_2$ deposition in moderately to highly alkaline waters. However, AMP will degrade in the presence of chlorine, producing PO_4^{3-} ions and therefore should not be fed concurrently with chlorine. The phosphonates form very stable complexes with a variety of nonferrous metal ions and thus accelerate their corrosion, especially the copper-base alloys. The addition of zinc significantly suppresses this antagonistic attack. Calcium phosphonate deposits will form in moderate-hardness high-alkaline waters, that is, 400 to 500 mg/L (ppm) calcium hardness at pH 8 to 8.5. These deposits can be controlled with some of the new polymers available for $Ca_3(PO_4)_2$ control.

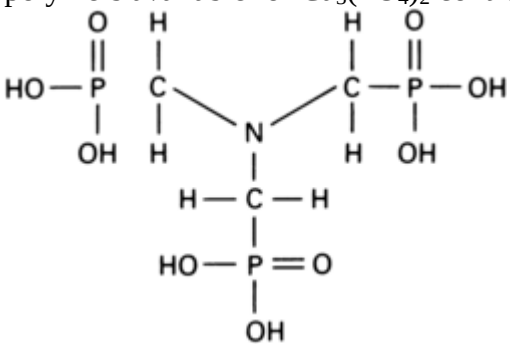

Fig. 7 Structure of nitrilotris(methylenephosphonic) acid, AMP

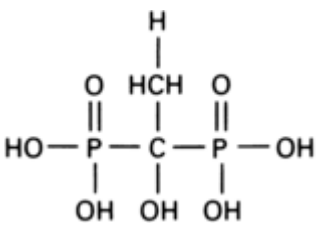

Fig. 8 Structure of 1-hydroxyethylidene-1,1-diphosphonic acid, HEDP

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The phosphonates are sensitive to overall water quality. The protection afforded to low-carbon steel decreases with increasing aggressive ion concentration. Sensitivity to temperature is also exhibited. The major difference between AMP and HEDP is that the latter resists oxidation to a greater extent and can therefore be used in the presence of chlorine.

Multicomponent Systems. Cooling water formulations containing mixtures of inhibitors usually offer increased protection to ferrous metals. Such mixtures are synergistic in their action. Many combinations have been developed to achieve enhanced protection under a wide variety of plant operating conditions. Heavy-metal formulations containing zinc and/or chromate have been widely used in industry, where environmentally acceptable, particularly for severe corrosion problems. Nonheavy-metal treatment programs (no zinc or chromium) are receiving increased attention because of government discharge restraints. Complex blends of PO_4^{3-}, polyphosphate, phosphonate, copper corrosion inhibitor (see the section “Copper Inhibitors” in this article), and $Ca_3(PO_4)_2$ dispersants are probably the most widely used multicomponent inhibitors.

Zinc Polyphosphate. The addition of zinc to the polyphosphates does not appreciably change the general nature of the polyphosphates. This system retains its insensitivity to electrolyte concentration, its threshold inhibition of $CaCO_3$ and $CaSO_4$, its ability to protect ferrous and nonferrous metals, and its detergent properties. Zinc polyphosphate inhibitors also enable multivalent metal ions to form positively charged colloidal complexes.

Zinc increases the rate at which the protective film is formed on the metal surfaces (Ref 24). This rapid protective film formation improves the general corrosion protection to the system. It is also synergistic in combination with polyphosphates. The amount of treatment needed using a zinc-polyphosphate inhibitor combination is less than that required for the polyphosphates alone.

The mode of inhibition is cathodic, similar to the polyphosphates in calcium-containing waters. The zinc accelerates film formation, restraining attack until a thin, tenacious, durable film is developed. The deposition of zinc phosphate [$Zn_3(PO_4)_2$] does not seem to be involved in the inhibition process.

Approximately 10 to 20% of the combined zinc polyphosphate blend is zinc. Good corrosion control is achieved through the synergistic interaction of zinc with polyphosphate. Beyond 20% Zn, little improvement in low-carbon steel corrosion protection is observed. Maintenance concentrations are usually 10 mg/L (ppm) as polyphosphate. Good practice requires a dosage of two to three times the maintenance level as a pretreatment to the system for a short time, that is, less than 1 week. A pH range of 6.8 to 7.2 is required for good control. This limitation in pH is necessary to prevent excessive attack on copper-base alloys (the lower the pH, the greater the attack on copper). Sensitivity to bulk water temperatures is minimal.

Zinc Phosphonates. The combination of zinc with phosphonates provides significantly improved protection compared to phosphonates alone. The addition of zinc makes this formulation synergistic in its protection to carbon steel. Good corrosion control can be attained using 20 to 80% of the combined zinc phosphonate blend as zinc, with 30 to 60% being optimum (Ref 25). Overall treatment levels are 8 to 10 mg/L (ppm) phosphonate with 2 to 3 mg/L (ppm) Zn^{2+} ions. The need for zinc becomes paramount in the presence of copper-base alloys. When used alone, the phosphonates are aggressive to copper and form a strong copper-phosphonate complex. Zinc negates this antagonistic effect by forming a stronger and more stable complex, significantly reducing attack on the alloys. The effectiveness of the zinc-phosphonate combination is due to increased cathodic protection. The zinc effectively counteracts the anodic character of the phosphonates through the formation of a phosphonate-zinc complex, which is cathodic compared to the phosphonates alone.

Due to this complex, broad pH application becomes possible. The zinc phosphonate treatment can be used over a pH range of 6.5 to 9. Zinc is held in solution at these more alkaline pH levels, and protection actually improves with an increase in pH.

Little sensitivity is shown with increased salt or electrolyte concentration, and temperature effects are minimal. Thus, the zinc phosphonate systems can be used over a wide range of water quality, at high bulk water temperatures, 70 to 75°C (160 to 170°F), and with pH levels up to 9.0.

Degradation of phosphonates to PO_4^{3-} ions by chlorine is significantly reduced with a phosphonate-zinc system, and the latter can be used in chlorine environments because of diminished chlorine demand. The zinc stabilizes the complex, preventing the deterioration of the carbon- phosphorus bond in the oxidizing environment.

Nonheavy-Metal Systems. Many combinations of building blocks are currently being used in nonheavy-metal formulations. Some of the systems in use include combinations of the phosphonates, AMP/HEDP; polyphosphate/ phosphonate mixtures, polyphosphate/HEDP; polyphosphate or phosphonate/orthophosphate

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

(HEDP/PO_4^{3-}). These systems are synergistic in protecting low-carbon steel. They combine the many advantages of the individual components, including:

- Complex formation with calcium and numerous polyvalent metal cations required to form the protective film over the metal surface. The polyphosphates still form the colloidal species for cathodic protection, and the phosphonate serves as a cathodic polarizer
- Threshold inhibition of slightly soluble inorganic salts, such as $CaCO_3$ and $CaSO_4$
- Detergent and dispersive action on surface deposits

Most nonheavy-metal treatments for carbon steel function best in more alkaline or elevated- pH systems. Waters are less corrosive, but more prone to form scale or deposit. Therefore, good scale control is absolutely necessary. These treatments are generally not as effective as heavy- metal formulations. However, because of the less corrosive nature of the recirculating cooling system, good overall protection can be achieved. More care and attention are required to operate these nonheavy-metal treatments because they are less tolerant of system upsets and function under more contained ranges of water corrosivity, pH, and temperature.

The AMP/HEDP nonheavy-metal inhibitor pair is classified as a cathodic inhibitor. A critical AMP/HEDP ratio of 1.5 to 1 is needed for optimal carbon steel protection (Ref 26). Performance improves with pH and should be used in systems having a pH of at least 7.5. The combined phosphonate program is not as sensitive to temperature as the individual components, nor is it adversely affected by high levels of Cl^- and SO_4^{2-} ions.

Normal treatment levels of at least 15 mg/L (ppm) total phosphonate can be used to achieve good corrosion protection, <75 μm/yr (3 mils/ yr). Adequate pretreatment of at least two to three times normal concentration for 1 week is required before reducing the concentration to a maintenance level. With good pH control, normal treatment levels can be reduced and still achieve the desired corrosion protection. Concern over attack on copper-base alloys still exists such that the addition of a specific copper inhibitor is highly recommended.

Polyphosphate/HEDP. The second nonheavy- metal system—polyphosphate/HEDP—is also cathodic in nature while being synergistic in protecting low-carbon steel. Approximately 40 to 80 wt% of the HEDP-polyphosphate blend is polyphosphate and is needed for good corrosion protection of carbon steel. Corrosion control of approximately 50 μm/yr (2 mils/yr) can be achieved with 15 mg/L (ppm) total phosphate content. The sensitivity of polyphosphate/HEDP to pH is minimal over the range of pH 6 to 8. Temperature sensitivity is minor. Good corrosion control is achieved at bulk water temperatures exceeding 60 °C (140 °F). As with the AMP/ HEDP system, sensitivity to water aggressiveness is not a major concern. The antagonistic effects of Cl^- and SO_4^{2-} ions are subdued by this treatment program.

Treatment levels are approximately 15 to 20 mg/L (ppm), which can be reduced if the system is pretreated at two to three times maintenance concentration for at least 1 week. Attack on copper-base alloys is reduced compared to the AMP/ HEDP system; however, as with the combined phosphonate system, there is a need for a specific copper inhibitor. Concern over reversion still exists, because the polyphosphates are subject to hydrolysis. The PO_4^{3-} ions generated will improve the overall corrosion protection, assuming $Ca_3(PO_4)_2$ precipitation is controlled.

The polyphosphate/PO_4^{3-} combination functions in a mixed mode. The cathodic portion comes from either the polyphosphate or phosphonate (HEDP), while the anodic portion derives from the PO_4^{3-} ion. The addition of PO_4^{3-} improves protection to carbon steel through a synergistic interaction with either polyphosphate or phosphonate (Ref 17). The level of polyphosphate or phosphonate is not critical and can range from 20 to 80% of the total inhibitor blend. The corrosion rate of carbon steel can be easily controlled to 25 μm/yr (1 mil/yr) with 15 to 18 mg/L (ppm) total phosphate.

This system is applicable over a broad pH range of 6.0 to 8.5. There is little sensitivity to pH. The lack of sensitivity to pH refers only to corrosion control, and the inhibitors remain active in solution. The formation of a $Ca_3(PO_4)_2$ precipitate is prevented by the addition of an appropriate additive that inhibits its growth and adherence to the metal surface. Sensitivity to temperature is also minimal. The inhibitor pair has applicability to very hot systems having bulk water temperatures as high as 70 °C (160 °F). Reversion of the polyphosphate molecules to PO_4^{3-} will be accelerated at the higher temperature, but will also enhance overall protection due

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

to the inhibitive activity of its product (PO_4^{3-} ion). The system is moderately sensitive to aggressive ions, specifically Cl^- which can promote pitting attack. PO_4^{3-} is an anodic inhibitor, and there is a critical concentration that must be maintained that is a function of the electrolyte composition. Treatments containing polyphosphate will revert to PO_4^{3-}, and a sufficient amount of a $Ca_3(PO_4)_2$ inhibitor should be present to suppress its formation.

Attack on copper-base alloys is not a major concern when polyphosphates are used. However, the phosphonate can be aggressive to copper-base alloys. The addition of a specific copper inhibitor is recommended.

Copper Inhibitors

Most of the steel inhibitors that have been discussed exert some degree of control over corrosion of copper-base alloys. However, system upsets, such as pH excursions and process leaks, can dissolve copper into the cooling water, where it can interfere with steel protection. Concentrations of at least 0.1 mg/L (ppm) or more of dissolved copper can deposit on steel conduits, accelerating localized attack. Ancillary inhibitors are available that are very effective in controlling corrosion of copper-base alloys and preventing galvanic deposition of dissolved copper onto ferrous metals.

Three specific inhibitors have been extensively used: mercaptobenzothiazole (MBT), benzotriazole, and tolyltriazole. Mercaptobenzothiazole is an extremely effective inhibitor for copper-base alloys. Its inhibitive properties are attributed to the formation of an adherent protective film on the metal oxide surface. The inhibitor reacts with the metal surface to form a chemisorbed barrier. The initial corrosion product of Cu^+ ions reacts with the MBT molecule to form a three-dimensional complex of Cu(1)MBT. The film growth rate is rapid, reaching a self-limiting thickness within a short period of time.

Mercaptobenzothiazole is susceptible to oxidizing agents, such as air, chlorine, and ultraviolet light from sunlight, which can degrade the molecule into a disulfide having no inhibitory properties. This degradation occurs only to the molecule in solution, not the complex on the metal surface. Because of the sensitivity of MBT toward chlorine, the inhibitor should be used only if there is no residual chlorine present. Thus, MBT should not be added to open recirculating cooling water systems, in which continuous chlorination is often practiced.

Cupric ions (Cu^{2+}) can be effectively inhibited from cathodically depositing onto more active metals, such as steel and aluminum, by reacting with MBT in a 2-to-1 molar ratio of MBT to Cu^{2+}. In the absence of complicating factors, such as copper concentrations exceeding 0.1 mg/L (ppm) in the cooling water or residual chlorine, the concentration of MBT required for good copper inhibition is approximately 4 mg/L (ppm). A feeding procedure based on 3 mg/L (ppm) followed by 1 mg/l (ppm) addition 12 h later has been very successful.

Benzotriazole and tolyltriazole function similarly in controlling copper corrosion. Structurally, tolyltriazole differs from benzotriazole in that the former has a methyl group attached to the benzene ring. Both materials behave similarly in cooling waters, reacting with the metal surface to produce a three-dimensional chemisorbed layer.

The azoles are classified as cathodic inhibitors because they adsorb at cathodic sites and interfere with the oxygen-reduction reaction. These molecules are more resistant to oxidation than MBT. In the presence of chlorine, 1-chlorobenzotriazole (or 1-chlorotolyltriazole) is probably formed, having minimal inhibitory properties. Upon dissipation of residual chlorine, the chloro- compound reverts back to the active azole. Chlorination does not affect the integrity of the complex on the metal surface.

The azoles can deactivate dissolved copper in cooling water systems and prevent its deposition onto steel or other active metals. A 2-to-1 molar ratio of inhibitor to copper ions is required, similar to the MBT reaction.

The concentration of azoles necessary for copper inhibition is approximately 1 to 2 mg/L (ppm) in the absence of any residual chlorine. The optimal practice is to pretreat the system with two to three times normal concentration for 1 to 2 days, then control at a maintenance dosage. Under chlorination conditions, the azole should be fed after the dissipation of residual chlorine. If continuous chlorination is practiced and cannot be changed to intermittent practice, the level of treatment should be increased to 4 to 5 mg/L (ppm). In the presence of continuous chlorination, overall copper corrosion protection will be less than with intermittent chlorination.

Corrosion Inhibitors in the Water Treatment Industry

Bennett P. Boffardi, Bennett P. Boffardi and Associates, Inc.

Corrosion Control in Municipal Water Systems

Chemical treatment in municipal systems can be used to protect the distribution system from corrosion, prevent the formation of calcium carbonate scale, and stabilize iron or manganese from forming “red waters” or “black waters” (Ref 27). There are fundamentally three basic chemicals to provide the required protection: zinc, phosphates, and silicates. However, any drinking water treatment chemical must conform to ANSI/NSF Standard 60. The specific limitations on the three chemical treatments are as follows:

- *Zinc:* Concentration may not exceed 2 mg/L (ppm) calculated as zinc ion (Zn^{2+}).
- *Phosphates:* Concentration may not exceed 10 mg/L (ppm) calculated as phosphate ion (PO_4^{3-}).
- *Silicates:* Concentration may not exceed 10 mg/L (ppm) calculated as silicon dioxide (SiO_2).

Zinc-Based Treatments. With respect to zinc-containing treatments there are two basic programs: zinc polyphosphate (PP) and zinc orthophosphate. Polyphosphates cover the range from pyrophosphate (two repeating units of O-P) to chain lengths of approximately 21 repeating units. The most common form of polyphosphate has 12 to 14 repeating units of O-P. Normal treatment levels for zinc polyphosphate are 0.15 mg Zn^{2+}/L (ppm) and 1.5 mg PP/L (ppm). Zinc orthophosphate concentrations can range from 0.20 to 2.0 mg Zn^{2+}/L (ppm) with 1.0 mg PO_4^{3-} /L (ppm).

Zinc polyphosphates have been an effective chemical-treatment program for steel corrosion control for more than 60 years. Zinc-based treatments are capable of forming tenacious protective films over the metal surface that are very persistent. The film is not easily disrupted. With a zinc polyphosphate program, the film provides protection at dead-end areas. Zinc also reduces the rate of reversion of polyphosphate to orthophosphate. Zinc polyphosphate is superior to the use of polyphosphate without zinc for steel corrosion control. The addition of zinc does not affect the calcium carbonate scale control properties of polyphosphate as shown in Table 5 and its ability to stabilize iron and manganese as shown in Tables 6 and 7.

Table 5 Calcium carbonate scale control

Concentration mg/L (ppm) as PO_4	Calcium carbonate inhibition, %		
	1:10 zinc:polyphosphate	**Polyphosphate**	**1:3 zinc:orthophosphate**
0.1	14	10	0
0.2	55	58	0
0.3	71	69	0
0.4	81	80	0
0.5	95	93	0
0.6	100	97	0
0.7	100	100	0

Conditions: 500 mg/L (ppm) calcium hardness, 500 mg/L (ppm) alkalinity, pH = 8.0, 65 °C (150 °F), 24 h duration, LSI = 2.0

Table 6 Iron stabilization

Concentration mg/L (ppm) PO_4	Iron stabilization, %			
	1:1 zinc:polyphosphate	**Polyphosphate**	**1:3 zinc:orthophosphate**	**1:1 ortho:polyphosphate**
0.5	6	7	3	…
1.0	82	84	13	…
1.5	88	87	18	…
2.0	100	100	25	27

Conditions: 2.0 mg/L (ppm) Fe(II), pH = 7.0, 25 °C (77 °F), 4 h duration, 25 μm filtration

Table 7 Manganese stabilization

Concentration mg/L (ppm) as PO_4	Manganese stabilization, %			
	1:10 zinc:polyphosphate	**Polyphosphate**	**1:3 zinc:orthophosphate**	**1:1 ortho:polyphosphate**
0.5	85	75	79	100
1.0	92	85	85	100
1.5	95	89	90	100
2.0	100	100	97	100
2.5	100	100	100	100

Zinc orthophosphate is a very effective multimetal corrosion control treatment. It provides corrosion protection to steel, copper, and lead (Ref 28). The ratio of zinc to orthophosphate is not critical. Most ratios provide similar corrosion protection at the same concentrations. This treatment also forms a rapid protective film on metal surfaces, consequently preventing corrosion and “red water” problems. Its utility lies in low hardness and low to moderate alkalinity waters. Zinc orthophosphate has little to no calcium carbonate scale inhibitory properties. This treatment program will not stabilize dissolved iron (Fe^{2+}) in well waters, but will stabilize dissolved manganese (Mn^{2+}) in well waters, thus eliminating “black” water problems. Manganese stabilization requires the zinc orthophosphate treatment to be added prior to the water contacting air or any other source of oxidation (oxygen, chlorine). Zinc orthophosphate treatments require a higher concentration of zinc for corrosion control than zinc polyphosphate.

Although the orthophosphate species alone will provide protection to lead, their effect on carbon steel can be detrimental. Orthophosphate, which is an anodic inhibitor, can intensify localized corrosion of carbon steel by accelerating pitting attack.

Non-Zinc Based Treatments. In essence, there are three non-zinc chemical inhibitor treatment programs that are applicable to potable water systems: polyphosphate, blended polyphosphate-orthophosphate, and silicates. Sodium silicates have been used for many years as corrosion inhibitors in potable water systems. A typical SiO_2-to-Na_2O ratio is 3.22 to 1. Silicates afford good corrosion protection to carbon steel, galvanized steel, and copper. They are also effective in controlling lead leaching from soft solder (Ref 29). Silicate chemistry is usually applied in soft waters, such as found in southeastern United States. They are capable of providing corrosion protection over clean and corroded surfaces (Ref 30). Sodium silicate has no calcium carbonate scale inhibitory property. However, silicate chemistry is effective in stabilizing iron to prevent “red” water problems but is less effective in stabilizing manganese ions, or “black” water (Ref 31).

In the treatment of potable waters, high levels of silica (8 to 16 mg SiO_2/L, or ppm) are maintained above the naturally occurring silica in the water. In low alkaline waters, high concentrations of silica may increase the pH of the system to 8 or above. The high pH can impact upon trihalomethane (THM) formation during the addition of chlorine for disinfection. Silicate chemistry is environmentally friendly and is not affected by the 503 rule. The U.S. Environmental Protection Agency 503 rule regulates the disposal of hazardous materials from publicly owned treatment works (POTW).

Polyphosphates have been used in potable water for more than half a century. They are effective in controlling steel corrosion and lead dissolution (Ref 32). Polyphosphates are effective in controlling steel corrosion over a pH range of 6 to 7.8. Below pH 6 there is an increase in water corrosivity due to acidity. Above pH 7.8, there is a tendency for increased tuberculation. Normal active treatment levels are approximately 2 mg/L (ppm)

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

polyphosphate, although American National Standards Institute/National Sanitation Foundation (ANSI/NSF) Standard 60 limits are 10 mg/L (ppm). Polyphosphates are known to prevent calcium carbonate scales. Usually 0.6 mg/L (ppm) active polyphosphate is required for scale control. Stabilization of iron and manganese can be achieved with approximately 1 to 2 mg/L (ppm) polyphosphate per mg of total Fe^{2+} plus Mn^{2+} to prevent "red" or "black" waters. Polyphosphates are more effective than silicates, but less effective than the zinc counterpart for steel corrosion protection.

Blended polyphosphate-orthophosphate is synergistic in controlling steel corrosion. The polyphosphate component also provides calcium carbonate scale control, whereas the orthophosphate species enhances steel, copper, and lead protection. The pH range is 6 to 7.8 for steel corrosion control, and a pH above 7 for lead and copper inhibition. Active treatment concentrations are 1.5 to 2 mg/L (ppm) total phosphate. Excellent manganese stabilization is achieved with this pair; however, no iron stabilization is possible due to the formation of iron phosphate and its subsequent precipitation. This treatment is the best available technology to replace zinc- containing chemistry.

Materials Selection for Corrosion Control

Revised by Peter Elliott, Corrosion & Materials Consultancy, Inc.

Introduction

MATERIALS SELECTION AND DESIGN are of equal importance in achieving the desired performance and life expectancy of components and equipment (Ref 1, 2, 3, 4). From a corrosion standpoint, the following factors play an integral and often critical role in the anticipated outcome:

- Specification
- Fabrication and quality control
- Storage and transportation
- Operation
- Maintenance

In weighing the relative importance of these factors, the designer and materials engineer must work closely together to ensure that premature failure will not occur because of design defects and improper or inadequate materials selection.

The type and extent of corrosion is dictated by the unique environmental conditions that pertain to a specific application—at all stages in a component lifetime—including procurement, fabrication, transportation, storage, installation, commissioning, operation, and maintenance. Corrosion failures have occurred because of unexpected causes that resulted from a lack of appreciation about corrosion, sometimes the direct result of poor communication and/or a lack of appreciation of the true service conditions (Ref 5). As an example, a type 316 stainless steel (Unified Numbering System, or UNS, S31600) pipe was considered a suitable choice for admitting steam and subsequently air into a chemical slurry in a reaction vessel; however, it experienced localized pitting corrosion even before the anticipated service (Fig. 1). The damage occurred during storage, because the new (replacement) stainless steel pipe sections were in direct contact with mists of brackish water that arose in an unsheltered location immediately adjacent to a marine estuary.

Fig. 1 Localized corrosion of stainless steel pipes from direct exposure to marine mists, compounded by plastic wraps

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The pipe failure just described was exacerbated because site maintenance personnel “improved” the storage by partially wrapping the pipes with plastic sheet, which created sweatbox conditions. Offload corrosion (typically, corrosion that occurs on site while materials are in storage after they have been offloaded) occurred because of condensation and evaporation cycles. Plastic wrapping can cause moisture to be effectively trapped in the closed space; plastic is also not impervious to moisture penetration.

This article outlines the step-by-step processes by which materials are selected in order to prevent or control corrosion and includes information on materials that are resistant to the various forms of corrosion.

Materials Selection for Corrosion Control

Revised by Peter Elliott, Corrosion & Materials Consultancy, Inc.

The Materials Selection Process

Review the Operating Conditions. The first step in the materials selection process is a thorough review of the corrosive environment, the operating conditions of the equipment, and the circumstances pertaining thereto. Not to be excluded are offload conditions (e.g., Fig. 1) and excursions or downtimes (expected or otherwise) that occur during service. Input from knowledgeable process engineers is recommended.

Precise definition of the chemical environment, including the presence of trace compounds, is vital. For example, the nickel-molybdenum alloy B-2 (UNS N10665) is highly resistant to hydrochloric acid (HCl) up to the atmospheric boiling point. However, the presence of small quantities of oxidizing metal ions, such as ferric ion (Fe^{3+}), will result in severe corrosion.

Other operating conditions that require definition, especially for equipment used in the chemical-processing industry, include temperatures, pressures, flow rates, liquid versus gaseous phases, slurries versus deposits, aqueous versus anhydrous phases, continuous versus intermittent operation, media used for cooling or heating, external versus internal environment, and product purity.

Abnormal or upset conditions are often overlooked during the selection process. For example, plain carbon steel may be the optimal choice for vessels and piping used to contain non-corrosive hydrocarbon gases, such as ethylene, under pressure at normal temperatures. However, the cooling effect that occurs during venting to the atmosphere, for whatever reason, may lower the temperature of vessels, piping, and relief valves to below the ductile-to-brittle transition point, causing catastrophic brittle fracture. The selection of special steels, qualified by impact testing at the lowest expected temperature, may be appropriate.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Review the Design. The type and design of the equipment and its various components should be considered, along with size, complexity, and criticality in service. Selecting a material for a simple storage tank generally does not require the same attention and effort as choosing the material of construction for a highly sophisticated chemical-process reactor. This is especially true when considering critical, unique pieces of equipment in large, single-train, continuous process plants in which a failure would shut down the entire operation, with potentially large financial implications that include materials replacement, fabrication, recommissioning, and lost product and sales. Where risks are potentially high, great effort is expended to select the optimal material for safe, low-maintenance service.

The materials used to join the components into an assembly will require as much attention as the component materials themselves. Many bolted agitator assemblies in reactors, as well as riveted wheels in centrifugal compressors, have failed catastrophically because the bolts or rivets did not have adequate strength or corrosion resistance.

When welding is the joining method, the materials engineer is challenged to ensure that the welds are as corrosion resistant as the base metals. Generally, the weld metal must equal the base metal in chemical composition and must be virtually free of surface defects, such as porosity, slag inclusions, incomplete penetration, or lack of fusion, for long, maintenance-free service. The challenge is even greater when dissimilar- metal welds are required. Improper selection may allow local attack due to weld-metal dilution or may allow hydrogen-assisted cracking due to hard heat-affected zones (HAZs). More information on preventing corrosion of welds is available in the articles “Corrosion of Carbon Steel Weldments,” “Corrosion of Stainless Steel Weldments,” and “Corrosion of Nonferrous Alloy Weldments” in this Volume.

Materials Selection. Candidate materials can be considered once the chemical environment, operating conditions, and type and design of the equipment have been as fully defined as possible. Occasionally, the selection is based on reliable, pertinent past experience and, as such, is well defined. More often, selection is not straightforward for a number of reasons, such as complex chemical environments and stringent code requirements.

The list of materials to choose from is large and continues to increase. Ferrous and nonferrous metals and alloys, thermoplastics, reinforced thermosetting plastics (RTPs), nonmetallic linings, glass, carbon and graphite, and catalyzed resin coatings are among the various materials available. Many materials are immediately excluded because of service conditions, that is, pressures too high for RTP; temperatures too high for nonmetallic linings and coatings, such as rubber or epoxy resins; environments too aggressive for carbon steel; and so on. The remaining choices may still be great in number.

It is always desirable to minimize the list of materials. This allows in-depth evaluation of those that remain. In other cases, the initial list may be exceptionally small because of limited knowledge about the operating conditions or the complexity of the chemical environment. A search of data sources should follow in either case.

Literature Survey. Data sources include abstracts, data surveys (Ref 6), and texts that advise on materials selection and are based primarily on in-service experiences (Ref 7). Computerized reference data on materials selection, with expert or materials advisor systems, which are computer programs containing methods and information developed by experts, have been developed during the past 15 years (e.g., Ref 8, 9, 10). Expert systems are designed to solve problems, make predictions, suggest possible treatments, and offer materials and corrosion advice with a degree of accuracy equaling that of their human counterparts. Unfortunately, some advisor systems that are available are not updated into current software programs (Ref 11). Data also are found in a wide variety of handbooks, conference proceedings, and literature compilations published by professional organizations worldwide; see the Selected References at the end of this article and the article “Information Sources and Databases for the Corrosionist” in this Volume).

Experience and data generated in-house often serve as the most reliable bases for materials selection. Ideally, this is coupled with outside experience, when available, from materials vendors and equipment fabricators to complete the initial screening process. Contacts with clients referred by vendors should not be overlooked for their added experience.

At this point, the list of candidate materials should be narrowed to a reasonable number for in-depth evaluation. Final selections should not be based solely on the previously mentioned data sources, because, in most cases, the data provided are insufficient for the complete characterization of an environment or a set of operating conditions.

مرجع مهندسی مواد و متالورژی

Evaluating Candidate Materials. The in- depth evaluation of each candidate material requires a thorough understanding of the product forms that are available and the ease of fabrication by standard methods. For example, it would be wasteful of time and money to evaluate an Fe-14.5Si alloy for anything but a cast component such as a pump casing or valve body; the alloy is unavailable in any other form. It would be eliminated because of its poor weldability for applications involving welding.

Corrosion testing in representative environments is generally the next step. The extent of the investigation (and the determination of test conditions) depends on such factors as (Ref 12):

- Degree of uncertainty after available information has been considered
- The consequences of making a less-than-optimal selection
- The time available for evaluation

Laboratory testing of candidate materials is common and, in some cases, may be the only means available for final determination. Wherever possible, the actual process fluids, or, at least, mixtures that simulate the actual environment, should be used. There is considerable risk in using the latter, because undefined constituents can have a significant effect on the performance of a particular material.

Depending on the application, weighed and measured coupons of candidate materials are exposed to the corrosive fluids under a variety of conditions ranging from simple static immersion at a controlled temperature to complex testing under combined heat-transfer and velocity conditions. Guidance for conducting laboratory corrosion tests is available in Ref 13, 14, 15, 16, 17. After exposure for a specified length of time (generally, a minimum of 1 week), the coupons are, in the case of metals and alloys, cleaned and reweighed, and a corrosion rate is calculated based on mass loss and exposed surface area. The rate is commonly expressed in millimeters of penetration per year (mm/yr) or inches or mils (1 mil = 0.001 in.) of penetration per year (mils/yr)

Localized attack, such as pitting, crevice corrosion, and exfoliation, are determined from a microscopic examination of the test coupons. Special coupons, such as galvanic couples, welded, and stressed coupons, are often exposed to determine if other forms of corrosion may occur on certain metals and alloys. These coupons may require metallographic examination for evidence of dealloying, stress-corrosion cracking (SCC), intergranular corrosion, and other corrosion phenomena.

Nonmetallic materials, such as thermoplastics, coatings, reinforced thermosetting resins, elastomers, and ceramics, are also evaluated in laboratory tests, but the criteria used are different from those used for metals. First, exposure time must generally be longer (often, a minimum of 1 to 3 months) before significant changes occur. Exposure times of 6 months to 1 year are common. Also, corrosion rate calculations based on mass loss and surface area are not applicable in most cases. Of more importance are changes in weight, volume, hardness, strength, and appearance before and after exposure. Corrosion testing and evaluation are covered in detail in the Section “Corrosion Testing and Evaluation” in this Volume.

If possible, candidate materials should be tested under conditions more similar to the final application rather than in laboratory glassware. The tests should be conducted in a pilot operation or in full-scale equipment. Data are more reliable when test coupons are integrated into the process and are exposed to the same conditions as the actual equipment. Because of nonuniform conditions (flows, composition) within process equipment, coupon locations should be carefully selected (see the article “Corrosion Monitoring Techniques” in this Volume).

Reliability is further enhanced when it is possible to test full-size components fabricated from candidate materials (Ref 16). Examples include:

- Flanged sections of selected alloys and/or nonmetallic materials installed in a pipeline
- Experimental alloy impellers in pumps for corrosion and cavitation studies
- Tubing installed in a full-size operating or miniature test heat exchanger to evaluate materials with optimal resistance to corrosion under heat-transfer conditions
- Paddles of candidate materials bolted to a reactor agitator for erosion-corrosion studies

The primary disadvantages of this method of testing are the cost of fabrication, installation, removal, and evaluation; the downtime resulting from equipment being taken out of service and dismantled for evaluation; and the fact that a test component could fail prematurely and cause a unit shutdown and/or equipment damage.

مرجع مهندسی مواد و متالورژی

Specifications. Once the candidate materials have been thoroughly evaluated (along with the economics) and the materials of construction have been selected for the particular application, then clear and concise specifications must be prepared to ensure that the material is obtained as ordered and that it meets all the requirements of the application.

Perhaps the best known and most widely used specifications are the standards of ASTM International, which presents thousands of specifications for virtually all metal and nonmetal materials of construction; special volumes apply to the chemical-process industry (Ref 16) and to corrosion testing (Ref 17). Similar standards in countries other than the United States include DIN (Germany), BS (Great Britain), AFNOR (France), UNI (Italy), NBN (Belgium), and JIS (Japan). Other materials specifications that are well known but are more limited in application are those of the Society of Automotive Engineers (SAE), the Aerospace Material Specification (AMS), the American Welding Society (AWS), the American Petroleum Institute (API), and the American National Standards Institute (ANSI).

Fabrication requirements must also be spelled out in detail to avoid mistakes that could shorten the life of the equipment and to satisfy the requirements of state and federal regulatory agencies and insurance companies. The American Society of Mechanical Engineers (ASME) code governs the fabrication of equipment for the chemical, power, and nuclear industries, and the API code governs the fabrication of equipment for the refining industry. Piping for these industries is generally fabricated according to applicable ANSI codes. In these codes, allowable stresses for design calculations have been determined for virtually all metals and alloys that might be selected for corrosive (and noncorrosive) service. Where welding is the primary joining method, welding procedures and welders must be qualified before fabrication begins. Testing and quality-assurance requirements, such as radiography, hydrostatic testing, and ultrasonic inspection, are also covered in the codes and are specified, where applicable, to ensure compliance.

The fabricator is generally required to provide detailed drawings that list dimensions, tolerances, all pertinent materials specifications, fabrication and welding details, and testing and quality-assurance requirements for review. Prefabrication meetings are held for final review of all drawings and details, so that customer and vendor are in agreement. Thus, problems or errors that could lead to costly delays in fabrication or failures in service can be detected early and corrected.

Money spent on inspection and monitoring during equipment fabrication/erection to ensure compliance with specifications is repaid by trouble-free startup and operation of the fabricated assembly. In some cases, every component of an assembly must be tested to avoid excessive corrosion and/or premature failure. For example, an additional quality check of a vessel fabricated from AISI type 316L stainless steel (UNS S31603) for hot acetic acid service might be to test every plate, flange, nozzle, weld, and so on for the presence of molybdenum by using a chemical spot test method (Ref 18). The absence of molybdenum, which might indicate the mistaken use of a different stainless steel, such as type 304L (UNS S30403), would result in accelerated corrosion in this service. Another example is the testing of every component (including weld metal) of a heat exchanger fabricated from chromium-molybdenum steels for hot high-pressure hydrogen service to avoid possible catastrophic failure by hydrogen attack. The use of portable x-ray fluorescence analyzers for this type of quality-assurance testing of critical service components has become quite popular in recent years (Ref 19).

On-Line Monitoring. Once built, installed, and commissioned in service, the equipment, piping, reactor, heat exchanger, and so on should be monitored by the materials engineer to confirm the selection of materials of construction and all other requirements for the intended application. Frequent shutdowns for thorough inspections (visually and with the aid of applicable nondestructive examination methods) and periodic evaluation of corrosion coupons exposed at key locations in the equipment represent both the ideal and the most difficult corrosion monitoring activities to achieve. In actual practice, equipment is generally kept on-stream continuously for long periods of time between shutdowns, so on-stream monitoring techniques must also be used.

In the petroleum industry, the internal corrosion in oil and gas production operations is often monitored with hydrogen probes (Ref 20). These instruments measure hydrogen created by corrosion reactions. A portion of the hydrogen penetrates the vessel or pipeline wall, and the rest of the hydrogen is dissolved in the process fluid or released as gas bubbles. Hydrogen probes measure hydrogen permeation and provide information on the rate of corrosion.

Other on-stream corrosion monitoring techniques that are used in the petroleum and chemical-process industries are:

www.iran_mavad.com

مرجع مهندسی مواد و متالورژی

- *Electrochemical techniques:* includes monitors that use electrical resistance and linear polarization methods (Ref 21). The former technique determines corrosion trends with time, and the latter determines an instantaneous corrosion rate. Other techniques, such as the alternating-current impedance method, measure corrosion rates and also provide information about the type of corrosion process that is occurring.
- *Ultrasonic thickness measurement:* a useful monitoring tool, especially when baseline readings are taken at selected locations before the equipment is placed in service. The inspection locations can be changed if erosion or corrosion areas are localized.

With these methods, the materials engineer is able to determine the adequacy of the materials selected and to predict remaining life, so that replacements and/or repairs can be scheduled well in advance of failure. The corrosion test methods discussed previously can also be used to evaluate alternate materials that might be more cost-effective at the time of replacement of the vessel or a component.

Materials Selection for Corrosion Control

Revised by Peter Elliott, Corrosion & Materials Consultancy, Inc.

Selecting Materials to Prevent or Control Corrosion

This section addresses materials selection to prevent or control general (uniform) corrosion, localized corrosion, galvanic corrosion, intergranular corrosion, stress-corrosion cracking, hydrogen damage, erosion-corrosion, and other selected forms of corrosion.

General Corrosion

Of the many forms of corrosion, general, or uniform, corrosion is the easiest to evaluate and monitor. Materials selection is usually straightforward. If a material shows only general attack, a low corrosion rate, and negligible contamination of the process fluid, and if all other factors, such as cost, availability, and ease of fabrication, are favorable, then that is the material of choice. An acceptable corrosion rate for a relatively low- cost material, such as plain carbon steel, is approximately 0.25 mm/year (10 mils/year) or less. At this rate and with proper design and adequate corrosion allowance, a carbon steel vessel will provide many years of low-maintenance service.

For more costly materials, such as the austenitic (300-series) stainless steels and the copper- and nickel-base alloys, a maximum corrosion rate of 0.1 mm/yr (4 mils/yr) is generally acceptable. However, it should never be assumed without proper evaluation that the higher the alloy, the better the corrosion resistance in a given environment. A good example is seawater, which corrodes plain carbon steel fairly uniformly at a rate of 0.1 to 0.2 mm/yr (4 to 8 mils/ yr) but severely pits certain austenitic stainless steels.

At times, nonmetallic coatings and linings ranging in thickness from a few tenths to several millimeters are applied to prolong the life of low-cost alloys, such as plain carbon steels, in environments that cause general corrosion. The thin-film coatings that are widely used include baked phenolics, catalyzed cross-linked epoxy-phenolics, and catalyzed coal tar/epoxy resins (see the article “Organic Coatings and Linings” in this Volume). It is advisable not to use thin- film coatings in services where the underlying base-metal corrosion rate exceeds 0.5 mm/yr (20 mils/yr), because corrosion is often accelerated at holidays (for example, pinholes) in the coating. Thick-film linings include glass, fiber-reinforced and flake-reinforced furan, polyester and epoxy resins, hot-applied coal tar enamels, and various elastomers, such as natural rubber.

A special case for materials selection under general corrosion conditions is that of contamination of the process fluid by even trace amounts of corrosion products. In this case, product purity, rather than corrosion rate, is the prime consideration. One example is storage of 93% sulfuric acid (H_2SO_4) in plain carbon steel at ambient temperature. The general corrosion rate is 0.25 mm/yr (10 mils/yr) or less, but traces of iron impart a color that

www.iran-mavad.com

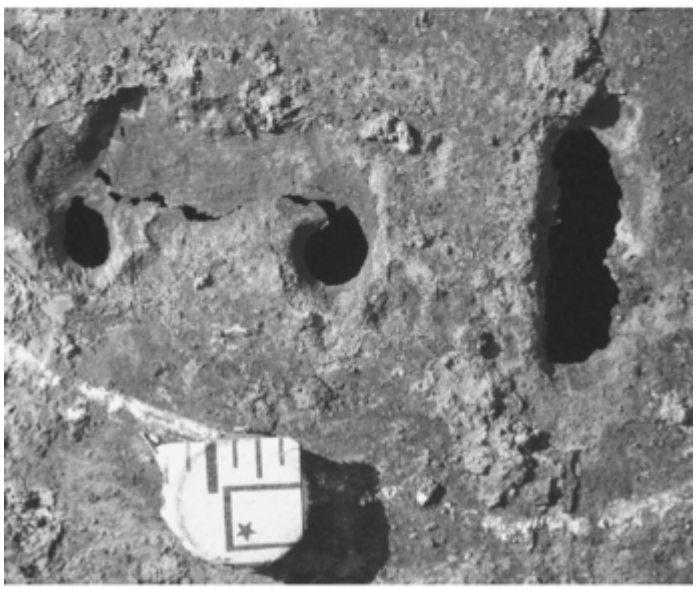
مرجع مهندسی مواد و متالورژی

is objectionable in many applications. Therefore, thin-film baked phenolic coatings are used on carbon steel to minimize or eliminate iron contamination. In the same way, thin-film epoxy-coated carbon steel or solid or clad austenitic stainless steels are used to maintain the purity of adipic acid for various food and synthetic fiber applications. Taste concerns are noted from copper ions that taint butters and dairy products. More information on general corrosion is available in the Section “Forms of Corrosion” in this Volume.

Localized Corrosion.

General corrosion is relatively easy to evaluate and monitor. Localized corrosion in such forms as pitting, crevice corrosion, and weld- metal attack presents a challenge—materials selection is difficult. Localized corrosion is insidious and often results in failure or even total destruction of equipment without warning. All metals and alloy systems are susceptible to most forms of localized corrosion by specific environments. For example, carbon or alloy steel pipelines will pit in aggressive soils because of local concentrations of corrosive compounds, differential aeration cells, corrosive bacteria, stray direct currents, or other conditions. These pipelines generally require a combination of nonmetallic coatings and cathodic protection for long service life. Underground storage tanks (USTs) display similar damage for the same reasons (Fig. 2).

(a)



(b)

Fig. 2 (a) Pitting and underdeposit attack on underground storage tank. (b) Close-up view of area at left in (a)

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Holidays in mill scale left on plain carbon steels are sites for pitting, because the mill scale is cathodic to the steel surface exposed at the holiday. For this reason, it is advisable to remove all mill scale by sand- or grit blasting before exposing plain carbon steels to corrosive environments.

Pitting. Aqueous solutions of chlorides, particularly oxidizing acid salts such as ferric and cupric chlorides, will cause pitting of a number of ferrous and nonferrous metals and alloys under a variety of conditions. The ferritic (400-series) and austenitic stainless steels are very susceptible to chloride pitting (as well as to crevice corrosion and SCC, which are discussed later in this section). Molybdenum as an alloying element is beneficial, and molybdenum-containing stainless steels, such as types 316 and 317, are more resistant than non-molybdenum-containing stainless steels. However, most chloride environments require higher alloys containing greater amounts of chromium and molybdenum, such as alloy G-3 (UNS N06985), alloy 625 (UNS N06625), and alloy C-22 (UNS N06022), for optimal corrosion performance (Ref 22). Exceptions are titanium and its alloys, which show exceptional resistance to aqueous chloride environments (including the oxidizing acid chlorides), and copper, copper-nickel, and nickel- copper alloys, which are widely used in marine applications.

Other noteworthy combinations of metals and corrosive fluids to avoid when selecting materials because of pitting tendencies include:

- Aluminum and aluminum alloys in electrolytes containing ions of heavy metals such as lead, copper, iron, and mercury
- Plain carbon and low-alloy steels in waters containing dissolved oxygen or in waters and soils infected with sulfur-reducing bacteria
- Austenitic stainless steel weldments exposed to stagnant natural waters, particularly certain well waters, which are infected with iron and/ or manganese bacteria (Ref 23)

An unusual form of localized corrosion known as end-grain attack has occurred in chemical-processing plants with specific metal-fluid combinations, such as austenitic stainless steels in hot nitric acid (HNO_3) and organic acids, and commercial-purity titanium in mixed-acid service.

When certain forms of these metals (for example, plates, threaded rods, or pipe nozzle ends) are cut normal to the rolling direction, the ends of nonmetallic inclusions at the cut edges are attacked by the process fluid. This results in small-diameter but deep pits. The solution is to seal the cut edge with a layer of weld metal that is equal to the base metal in composition.

Crevice corrosion can occur not only at metal-metal crevices, such as weld backing rings, but also at metal-nonmetallic crevices, such as nonmetal gasketed pipe flanges or under deposits. In some fabricated assemblies, it is possible and cost-effective to avoid crevices by careful design. For example, crevice corrosion occurred behind a weld backing strip at the closing seam in a type 304L stainless steel reactor handling hot HNO_3. A small amount of corrosion by stagnant acid in the crevice created hexavalent chromium ions (Cr^{6+}), which caused accelerated attack. Other exposed surfaces in the vessel were unaffected. To prevent crevice corrosion, the closing seam could have been welded from both sides or from one side with a consumable insert ring. Similar attack has occurred in stainless shell and tube heat exchangers at the rolled tube-to-tubesheet joints and has been solved by seal welding the joints with appropriate weld filler metal and process parameters.

In many cases, crevices are either too costly or impossible to design out of a system, so careful selection of materials is the answer. Titanium is susceptible to crevice corrosion in hot seawater and other hot aqueous chloride environments. Therefore, for a flanged and gasketed piping system in these fluids, commercially pure titanium grade 55 (UNS R50550) may be acceptable for piping, but flanges require the more crevice-attack-resistant grade 7 (UNS R52400), which contains 0.15% (nominal) Pd, or grade 12 (UNS 53400), which contains small amounts of molybdenum and nickel. This is more cost-effective than selecting the more expensive alloys for the piping as well. Another approach that has been successfully used in these fluids is installation of nickel-impregnated gaskets with grade 55 titanium flanges.

The austenitic stainless steels are susceptible to crevice corrosion in media other than HNO_3 solutions. For example, type 304L stainless steel exhibits borderline passivity in hot acetic acid solutions, particularly in crevices. Accordingly, the materials engineer will specify the more crevice-corrosion-resistant type 316L stainless steel where crevices cannot be avoided, such as piping and vessel flanges, or for the entire fabricated assembly, because the cost differential between materials in this case may be negligible.

Weld-metal preferential attack is another form of localized corrosion that can be avoided by the judicious selection of weld filler metal or weld process. Weld-metal corrosion in high nickel-chromium-molybdenum

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

alloy C-276 (UNS N10276) in a hot oxidizing H_2SO_4 process stream containing chlorides was eliminated by repair welding with alloy C-22 (UNS N06022). In applications in which type 304L stainless steel is selected for use in hot HNO_3 solutions, welds exposed to the process are frequently made by an inert gas process, such as gas tungsten arc or gas metal arc, rather than a flux-utilizing process, such as shielded metal arc. This prevents weld corrosion by eliminating the minute particles of trapped slag that are sites for initiation of local corrosion. Many other examples of preferential weld-metal attack and their solutions are discussed in the articles "Corrosion of Carbon Steel Weldments," "Corrosion of Stainless Steel Weldments," and "Corrosion of Nonferrous Alloy Weldments" in this Volume.

Nonmetallic materials of construction are widely used where temperatures, pressures, and stresses are not limiting and in such media as aqueous chloride solutions, which cause localized corrosion of metals and alloys. Examples in which lower-cost nonmetallic constructions are selected over expensive high alloys include the following:

- Rubber-lined steel for water treatment ion exchange resin beds, which must be periodically regenerated with salt brine or dilute mineral acids or caustic solutions
- Glass-lined steel for reaction vessels in chlorinated hydrocarbon service
- Acid-proof brick and membrane-lined steel for higher temperature, and solid RTP polyester and vinyl-ester construction for lower temperature, flue gas and chlorine neutralization scrubbers

It should be apparent that an in-depth evaluation of candidate materials for environments that can cause localized corrosion is imperative in order to select the optimal material of construction. In particular, corrosion test coupons should reflect the final fabricated component— that is, include crevices and weldments where applicable—and should be examined critically under the microscope for evidence of local attack. In cases in which the more common 300- and 400-series stainless steels fall short, the newer ferritics, such as 26Cr-1Mo (UNS S44627) and 27Cr-3Mo-2Ni (UNS S44660), the nickel-rich high-performance alloys with 3 to 6% Mo (UNS N08825, N06007) and without molybdenum (UNS N08800), and the duplex ferritic-austenitic alloys, such as 26Cr-1.5Ni- 4.5Mo (UNS S32900) and 26Cr-5Ni-2Cu- 3.3Mo (UNS S32550), should be evaluated as potentially lower-cost alternatives to higher alloys (Ref 22).

Finally, proven nonmetallic materials (for example, the RTPs), used either as linings for lower-cost metals (such as plain carbon steel) or for solid construction, should not be overlooked. Additional information on the mechanisms of localized corrosion is available in the articles "Pitting Corrosion," "Crevice Corrosion," and "Filiform Corrosion" in this Volume.

Galvanic Corrosion

Galvanic corrosion can be beneficial as well as harmful. The materials engineer will frequently select galvanic corrosion—that is, cathodic protection using sacrificial metal anodes or coatings of magnesium, zinc, or aluminum—to stifle existing, or prevent new, corrosion of structures fabricated primarily from plain carbon or low-alloy steels. Such structures include bridges, underground and underwater pipelines, auto frames, off-shore drilling rigs, and well casings. All too often, however, galvanic corrosion caused by contact between dissimilar metals in the same environment is harmful. Examples are:

- Unprotected underground plain carbon steel pipelines connected to above-ground tanks and other structures that are electrically grounded with buried copper rods or cables
- Stainless steel shafts in "canned" pumps rotating in carbon or graphite bushings in a strong electrolyte
- Copper-nickel or stainless steel heat-exchanger tubes rolled in plain carbon steel tubesheets exposed to river water for cooling
- Aluminum thermostat housings on cast iron auto engine blocks in contact with glycol-water mixtures

Newer designs that require several different metals for various reasons—such as cost and physical, mechanical, and/or electrical properties—present a challenge to the materials engineer with regard to selection for the avoidance of galvanic corrosion. Knowledge of the galvanic series of metals based on the electrochemical potential between a metal and a reference electrode in a given environment is essential. A practical galvanic series for metals and alloys in seawater is given in Table 1 (Ref 24).

It is important to note that metals behave differently in different environments—the relative positions of metals and alloys in the galvanic series can vary significantly from one environment to another. In fact, variations within the same environment can occur with changes in such factors as temperature, solution concentration, degree of agitation or aeration, and metal surface condition. Thus, galvanic series that are based on seawater or other standard electrolytes are worthwhile for initial materials selection for multiple metal/alloy systems in a given environment. However, additional tests should be carried out in the stated environment by using the anodic polarization measurements described in ASTM G 5 (Ref 15). Suitable metal combinations can be determined by examining and superimposing polarization curves of candidate metals and by estimating the mixed potential values (Ref 13, 25).

In conclusion, the selection of dissimilar metals that are far apart on any galvanic series should be avoided unless provisions are made for sacrificial corrosion of one for another, as in cathodic protection. Otherwise, dissimilar-metal applications in corrosive environments should be approached with extreme caution and should be thoroughly investigated before making the final selections. The article “Galvanic Corrosion” in this Volume contains more information on galvanic attack.

Intergranular Corrosion

Intergranular corrosion is a selective form of corrosion that proceeds along individual grain boundaries, with the majority of the grain being unaffected. Intergranular corrosion can affect certain alloys that are highly resistant to general and localized attack. Particularly noteworthy are several of the 300- and 400-series stainless steels and austenitic higher-nickel alloys. These alloys are made susceptible to intergranular corrosion by sensitization, that is, the precipitation of chromium carbides and/or nitrides at grain boundaries during exposure to temperatures from 450 to 870 °C (840 to 1600 °F), with the maximum effect occurring near 675 °C (1250 °F). Exposure to such temperatures can occur during processing at the mill, welding and other fabrication operations, or by plant service conditions. The resulting depletion in chromium adjacent to the chromium-rich

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

carbides/nitrides provides a selective path for intergranular corrosion by specific media, such as hot oxidizing (nitric, chromic) and hot organic (acetic, formic) acids.
Susceptible stainless steels are those with normal carbon contents (generally >0.04%) without carbide-stabilizing elements (titanium and niobium). Examples are AISI types 302, 304, 309, 310, 316, 317, 430, and 446. Susceptible higher- nickel alloys include alloy 600 (UNS N06600), alloy 601 (UNS N06601), alloy 800 (UNS N08800) (despite the presence of titanium), alloy 800H (UNS N08810), alloy 200 (UNS N02200), alloy B (UNS N10001), and alloy C (UNS N10002). Intergranular corrosion in these alloys is avoided by one or more of the following:

- Keeping the alloy in the solution heat treated condition at all times
- Limiting interstitial elements, primarily carbon and nitrogen, to the lowest practical levels
- Adding carbide-stabilizing elements, such as titanium, niobium, and tantalum, along with a stabilizing heat treatment where necessary

In general, these alloys are purchased from the mill in the solution heat treated condition, a requirement of most specifications. With regard to the austenitic stainless steels, solution heat treating consists of heating to a minimum temperature of 1040 °C (1905 °F) to dissolve all the carbides, followed by rapid cooling in water or air to prevent sensitization.
Preserving the solution-treated condition is difficult, except for certain applications where reheating is not a requirement of fabrication. One example is a pump shaft machined from forged or rolled and solution heat treated bar stock. However, most applications for these alloys, such as piping components and pressure vessels, require hot rolling (for example, of plate) or hot bending (for example, of pipe) and welding; these practices, as discussed earlier, can cause sensitization. Solution heat treating after fabrication is generally impractical because of the possibility of irreparable damage due to distortion or excessive scaling or because of the inability to cool rapidly enough through the critical sensitization temperature range.
In most applications involving exposure to environments that cause intergranular corrosion, the low-carbon/nitrogen or stabilized alloy grades are specified. The new ferritic stainless steel UNS S44800 with 0.025% C (maximum) plus nitrogen is replacing the higher-carbon 446 grade in applications in which resistance to intergranular corrosion is a requirement. Types 304L, 316L, and 317L, with carbon and nitrogen contents limited to 0.03% (maximum) and 0.10% (maximum), respectively, are used instead of their higher-carbon counterparts. The newer nickel-chromium alloy 904L (UNS N08904), with 0.02% maximum carbon, and the high-nickel alloys C-22 (UNS N06022) and B-2 (UNS N10665), which have maximum carbon contents of 0.015% and 0.01%, respectively, are now being used almost exclusively in the as- welded condition without intergranular corrosion problems.
These low carbon levels are readily and economically achieved with the advent of the argon oxygen decarburization (AOD) refining process used by most alloy producers. By limiting the interstitial element content, sensitization is limited or avoided entirely during subsequent welding and other reheating operations. However, designers should be aware of the fact that lowering the carbon/nitrogen content also lowers the maximum allowable design stresses, as noted in appropriate sections of applicable fabrication codes, such as ASME section 8, division 1 for unfired pressure vessels and ANSI B31.3 for process piping.
Commercially pure alloy 200 is a special case. With a maximum carbon content of 0.15%, alloy 200 will precipitate elemental carbon or graphite in the grain boundaries when heated in the range of 315 to 760 °C (600 to 1400 °F). This results in embrittlement and susceptibility to intergranular corrosion in certain environments, such as high-temperature caustic. Where embrittlement and intergranular corrosion must be avoided, alloy 201 (UNS N02201), with a maximum carbon content of 0.02%, is specified.
Titanium as a carbide-stabilizing element is used in several ferritic and austenitic stainless steels, including types 409, 439, 316Ti, and 321, as well as the higher-nickel alloy 825 (UNS N08825), at a minimum concentration of approximately five times the carbon plus nitrogen content. In the same way, niobium, generally with tantalum, is used in types 309Cb, 310Cb, and 347 austenitic stainless steels at a minimum combined concentration of approximately ten times the carbon content. The higher-nickel alloys 20Cb-3, alloy 625, and alloy G contain even higher concentrations of niobium—up to a maximum of approximately 4% in the case of alloy 625. In general, when stabilized alloys are heated in the sensitizing temperature range, chromium depletion at the grain boundaries does not occur, because the stabilizing elements have a greater affinity for carbon than does chromium.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Under certain conditions, however, stabilized alloys will sensitize, especially during multi- pass welding or cross welding. They are also susceptible to a highly localized form of intergranular corrosion known as knife-line attack, which occurs in the base metal at the weld fusion line. In some cases, these alloys are given stabilizing heat treatments after solution heat treatment for maximum resistance to intergranular corrosion in the as-welded condition. For example, type 321 stainless steel is stabilize annealed at 900 °C (1650 °F) for 2 h, and alloys 825 and 20Cb-3 at 940 °C (1725 °F) for 1 h, before fabrication to avoid sensitization and knife-line attack. So treated, type 321 may still be susceptible, because titanium has a tendency to form an oxide during welding. As a result, its role as a carbide stabilizer may be diminished. For this reason, type 321 is always welded with a niobium-stabilized weld filler metal, such as type 347 stainless.

Some specialty alloys have low interstitial element content plus the addition of stabilizing elements for resistance to intergranular corrosion. These alloys include the higher-nickel alloy G-3 (UNS N06985), which contains 0.015% C (maximum) and niobium plus tantalum up to 0.5%, and the newer ferritic stainless steels (Ref 3, 22, 26, 27) listed as follows:

UNS No.	Common name	Content, %					
		Cr	**Ni**	**Mo**	**C (max)**	**N (max)**	**Other (max)**
S44627	…	26	…	1	0.01	0.015	0.2 Nb
S44635	Nu Monit	25	4	4	0.025	0.035	0.80 Ti+Nb
S44660	Sea Cure	26	2	3	0.03	0.04	1.0 Ti+Nb
S44735	AL 29-4C	29	0.5	4	0.03	0.045	1.0 Ti+Nb

The newer ferritic stainless steels were developed primarily for heat-exchanger tubing applications for use in place of the higher-carbon unstabilized type 446 stainless steel (UNS S44600). These ferritic stainless steels have many useful properties.

As discussed previously, specific corrosion environments cause intergranular corrosion in specific metal and alloy systems. A wealth of information, both published (Ref 28) and unpublished, has been developed on corrodents that cause intergranular corrosion in sensitized austenitic stainless steels; a partial listing appears in Table 2. The low-carbon/nitrogen or stabilized grades are specified for applications in which the austenitic steels have satisfactory general and localized corrosion resistance in these environments and in which sensitization by such operations as welding and hot forming will undoubtedly occur.

Table 2 Partial listing of environments known to cause intergranular corrosion in sensitized austenitic stainless steels

Environment	Concentration, %	Temperature, °C (°F)

Evaluation tests for intergranular corrosion are conducted to determine if purchased materials have the correct chemical composition and are in the properly heat treated condition to resist intergranular corrosion in service (Ref 29). Evaluation testing is imperative for a number of reasons:

- The stainless steels and nickel-base alloys to which these tests are applied are relatively expensive.
- These materials are frequently specified for critical applications in the petrochemical, process, and power industries.
- The principal cost associated with a corrosion failure is generally that of production loss, not replacement.
- For maximum cost-effectiveness, these materials should be used in their best possible metallurgical and corrosion-resistant conditions.

Most of the evaluation tests are described in detail in ASTM standards (Ref 13, 15, 16, 17). Appropriate evaluation tests and acceptance criteria for wrought alloys are listed in Table 1 in the article “Evaluating Intergranular Corrosion” in this Volume.

Intergranular corrosion is rare in nonsensitized ferritic and austenitic stainless steels and nickel- base alloys, but one environment known to be an exception is boiling HNO_3 containing an oxidizing ion such as dichromate (Ref 30), vanadate, and/or cupric. Intergranular corrosion has also occurred in low-carbon, stabilized and/or properly solution heat treated alloys cast in resin sand molds (Ref 31). Carbon pickup on the surface of the castings from metal-resin reactions has resulted in severe intergranular corrosion in certain environments. Susceptibility goes undetected in the evaluation tests mentioned previously, because test samples obtained from castings generally have the carbon-rich layers removed. This problem is avoided by casting these alloys in ceramic noncarbonaceous molds.

Other metals, such as magnesium, aluminum, lead, zinc, copper, and certain alloys, are susceptible to intergranular corrosion under very specific conditions. A copper pipe that ostensibly conveyed grade 2 fuel oil from an UST to a furnace displayed intergranular attack (Fig. 3); the mechanism is not properly understood. Very few case histories are reported in the literature.

Fig. 3 (a) Intergranular cracking in 9.5 mm ($\frac{3}{8}$ in.) diameter copper pipe that conveyed No. 2 fuel oil from an underground storage tank. (b) Micrograph of intergranular crack. Dichromate etch. 63×

An unusual form of intergranular corrosion known as exfoliation, which occurs in aluminum-copper alloys, is discussed in the section “Exfoliation” in this article. Intergranular SCC is discussed in the following section.

Stress-Corrosion Cracking

Stress-corrosion cracking is a type of environmental cracking caused by the simultaneous action of a corrodent and sustained tensile stress. The following discussion deals primarily with anodic SCC. Anodic SCC is believed to be a delayed cracking phenomenon that occurs in normally ductile materials under the stress resulting from accelerated electrochemical corrosion at anodic sites of the material as well as at the crack tip. Other types of environmental cracking, such as hydrogen stress cracking and liquid metal embrittlement, are discussed later in this article.

Table 3 condenses several sources of published data on corrodents known to cause SCC in various metal-alloy systems (Ref 6, 32, 33). These data cover the SCC environments of major importance to the materials engineer. This table, as well as other data published in the literature, should be used only as a guide for screening candidate materials for further in-depth investigation, testing, and evaluation.

Stress-corrosion cracking is not a certainty in the listed environments under all conditions. Metals and alloys that are indicated as being susceptible can give good service under specific conditions. For example, referring to Table 3:

- Anhydrous ammonia will cause SCC in carbon steels but rarely at temperatures below 0 °C (32 °F) and only when such impurities as air or oxygen are present; addition of a minimum of 0.2% H_2O will inhibit SCC.
- Aqueous fluorides and hydrofluoric acid (HF) primarily affect alloy 400 (UNS N04400) in the nickel alloys system; other nickel alloys are resistant.
- Steam is known to cause SCC only in aluminum bronzes and silicon bronzes in the copper alloys system.
- Polythionic acid only cracks sensitized austenitic stainless steels and nickel alloys; SCC is avoided by solution annealing heat treatments or selection of stabilized or low-carbon alloys.

Stress-corrosion cracking is often sudden and unpredictable, occurring after as little as a few hours exposure or after months or even years of satisfactory service. Cracking occurs frequently in the absence of other forms of corrosion, such as general attack or crevice attack. Virtually all alloy systems are susceptible to SCC by a specific corrodent under a specific set of conditions, that is, concentration, temperature, stress level, and so on. Only the ferritic stainless steels as a class are resistant to many of the environments that cause SCC in other alloy systems, but they are susceptible to other forms of corrosion by some of these environments.
SCC of Stainless Steels. The combination of aqueous chlorides and austenitic stainless steels is probably the most important from the standpoints of prevalence, economics, and investigation. Although the mechanism and boundary conditions for chloride SCC are still not fully defined, it is reasonably safe to state that chloride SCC of austenitic stainless steels:

- Seldom occurs at metal temperatures below 60 °C (140 °F) and above 200 °C (390 °F)
- Requires an aqueous environment containing dissolved air or oxygen or other oxidizing agent
- Occurs at very low tensile stress levels, such that stress-relieving heat treatments are seldom effective as a preventive measure
- Affects all the austenitic stainless steels approximately equally with regard to susceptibility, time to failure, and so on
- Is characterized by transgranular branchlike cracking, as seen under a metallurgical microscope

So many materials and environments are sources of chlorides that they are hard to avoid (Ref 32). Significant costs for repairs and replacements, as well as lost utility, have occurred through the years in the petrochemical industry as a result of chloride SCC:

- In water-cooled heat exchangers from chlorides in the cooling water
- Under thermal insulation allowed to deteriorate and become soaked with water that leached chlorides from the insulation
- Under chloride-bearing plastics, elastomers, and adhesives on tapes

In the case of shell and tube heat exchangers, in which chloride-bearing waters are used for cooling, a number of preventive measures are available. In vertical units with water on the shell side, cracking occurs most often at the external surfaces of the tubes under the top tubesheet (Ref 32). This is a dead space (air pocket) at which chlorides are allowed to concentrate by alternate wetting and drying of tubing surfaces. Adding vents to the top tubesheet sometimes alleviates this problem by eliminating the dead space and allowing complete water flooding of all tubing surfaces (Ref 32). See Fig. 4(f) in the article “Designing to Minimize Corrosion” in this Volume.

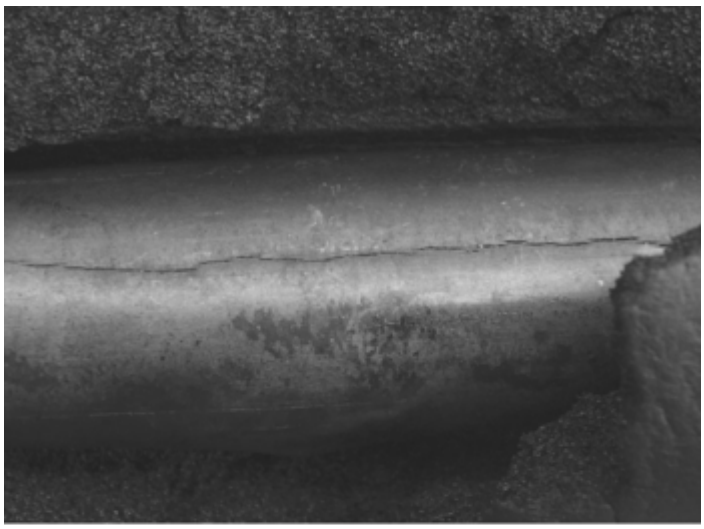
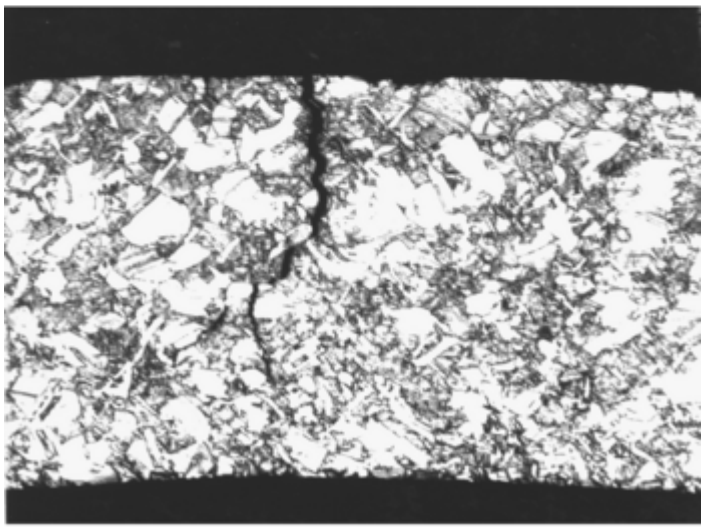
مرجع مهندسی مواد و متالورژی



(a)



(b)

Fig. 4 (a) Stress-corrosion cracking of copper pipe under elastomeric insulation from an in-ground installation. (b) Micrograph of crack. Etched. 50×

However, in many cases, this approach results in only a nominal increase in time to failure or no benefit whatsoever because of other inherent deficiencies, such as low water flows or throttling water flow to control process temperatures. Thus, a material more resistant to chloride SCC is required, such as the austenitic higher-nickel alloys 800 (UNS N08800) and 825 (UNS N08825); alloy 600 (UNS N06600); ferritic stainless steels such as type 430 (UNS S43000), 26Cr-1Mo (UNS S44627), and SC-1 (UNS S44660); duplex stainless steels such as alloys 2205 (UNS S31803), 255 (Ferralium 255, UNS S32550), and 2507 (UNS S32750); AISI type 329 (UNS S32900); or titanium. In this case, selection depends primarily on economics, requiring the least expensive material that will resist process-side corrosion as well as water-side SCC.

Alloys are said to be either resistant or immune to chloride SCC, depending on how they perform in accelerated laboratory tests. In general, an alloy is immune if it passes the boiling 42% magnesium chloride test conducted according to ASTM G 36. Examples are alloy 600, 26Cr-1Mo, and grade 3 commercially pure titanium (UNS R50550). Industry has recognized the severity of this test and has devised other accelerated laboratory tests, such as boiling 25% sodium chloride and the Wick test (ASTM C 692), that are more representative of actual conditions in the field (Ref 34). Thus, alloys that fail the G 36 test but pass the C 692 test, such as alloy 800, alloy 2205 (UNS S31803), and 20 Mo6 (UNS N08026), typically provide many years of service as tubes in water-cooled heat exchangers. (The 300-series austenitic stainless steels, as a class, fail all the accelerated laboratory chloride SCC tests mentioned previously.)

Unfortunately, all of the immune and resistant alloys are more expensive than most of the austenitic stainless steels. A more cost-effective application of some of these alloys involves a procedure known as safe ending, in

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

which short lengths (for example, 0.3 to 0.6 m, or 12 to 24 in.) are butt welded to the austenitic stainless steel tubes. The SCC-resistant ends are positioned in the exchanger at the point of greatest exposure to SCC conditions, that is, under the top tubesheet. Safe-ended tubes have extended the life of austenitic stainless steel tubing severalfold, with only a nominal increase in cost. Of course, the dissimilar metals must be weld compatible; this eliminates the use of titanium for safe ending.

Another cost-effective answer to chloride SCC in heat exchangers is bimetallic tubing, in which the austenitic stainless steel required for process-side corrosion resistance is clad with a water-side SCC- and corrosion-resistant material such as 90Cu-10Ni (UNS C70600) (Ref 32). Still another answer is cathodic protection with a sacrificial metal coating such as lead containing 2% Sn and 2% Sb applied by hot dipping or flame spraying (Ref 32).

Chloride SCC under insulation can be prevented by keeping it dry, but this is easier said than done in many cases. It is particularly difficult in humid, high annual rainfall climates and where insulated equipment must be washed down periodically or is exposed to fire control deluge systems that are periodically activated (Ref 35). Under these conditions, three preventive measures are applied:

- *Addition of sodium metasilicate as a SCC inhibitor to the insulation:* At a minimum concentration of ten times the chloride content, the inhibitor is activated when the insulation becomes wet and is effective only when it wets the stainless steel surface. For maximum protection, metasilicate is painted on the vessel or piping before the installation of inhibited insulation. However, SCC has occurred after many years of service under inhibited insulation that was allowed to become so wet that the water-soluble inhibitor was leached out to a point below the minimum concentration required for prevention of SCC.
- *Protective coating of the vessel or piping before insulation:* Catalyzed high-build epoxy paints are effective to approximately 100 °C (212 °F), catalyzed coal tar/epoxy enamels to approximately 150 °C (300 °F), and silicone- base coatings to approximately 200 °C (390 °F). These coatings are even more effective if the stainless steel surfaces are heavily sandblasted before coating. Sandblasting peens the surface to a depth of 0.01 to 0.1 mm (0.4 to 4 mils), and this results in a layer under compressive stress that counteracts the tensile stresses required for SCC.
- *Cathodic protection of the vessel or piping with aluminum foil under insulation (Ref 36):* This method is claimed to provide both a physical barrier to chloride migration to stainless steel surfaces as well as cathodic protection when the insulation becomes wet, and it is effective at vessel temperatures between 60 and 500 °C (140 and 930 °F). However, the foil is attacked by the alkaline (generally) leachates from the insulation and must be renewed periodically.

Other important environments that cause SCC of stainless steels are hydroxide (caustic) solutions, sulfurous acid, and polythionic acids. Caustic SCC of austenitic stainless steels can be both transgranular and intergranular and is a function of solution concentration and temperature. It seldom occurs at temperatures below 120 °C (250 °F). At higher temperatures, the newer ferritic stainless steels, nickel, and high-nickel alloys provide outstanding service; 26Cr-1Mo stainless steel has found widespread application in heat-exchanger tube bundles serving caustic evaporators at 170 to 200 °C (340 to 390 °F). Nickel 200, nickel 201, and alloy 600 are resistant to 300 °C (570 °F) in caustic at concentrations up to 70% (Ref 11).

Polythionic acid and sulfurous acid will cause SCC in sensitized nonstabilized austenitic stainless steels and nickel-base alloys. Cracking is always intergranular and requires relatively low tensile stresses for initiation and propagation. As-welded, normal carbon grades, such as types 304 and 316 and alloy 800, are particularly susceptible to SCC in weld HAZs. Low-carbon (<0.03% C) and stabilized grades, such as types 321 and 347, are resistant, especially after receiving a stabilizing heat treatment. The normal carbon grades in the solution heat treated condition are also resistant. Susceptibility to polythionic acid SCC can be determined by laboratory corrosion testing according to ASTM G 35.

Polythionic acid and sulfurous acid SCC are major considerations in the petroleum-refining industry, especially in desulfurizer, hydrocracker, and reformer processes (Ref 32, 37). These acids form in process units during shutdowns when equipment and piping containing sulfide deposits and scales are opened and exposed to air and moisture. Preventive measures include flushing with alkaline solutions to neutralize sulfides before shutdown and purging with dry nitrogen during shutdown, according to recommended practices (Ref 38).

Cast austenitic stainless steels, such as Alloy Casting Institute (ACI) types CF-8 (UNS J92600) and CF-8M (UNS J92900), are inherently more resistant (but not immune) to chloride SCC than their wrought counterparts

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

(types 304 and 316, respectively) for several reasons. Castings generally have lower residual stresses than wrought alloys after solution-annealing heat treatments, and service-applied stresses are often lower because of heavy section thicknesses. However, the principal reason for improved SCC resistance is the presence of varying amounts of free ferrite, resulting in a duplex austenitic-ferritic microstructure. Free ferrite is primarily attributed to additions of 1 to 2% Si to improve fluidity during pouring and to resist hot cracking during cooling of the casting.

During development work on the duplex cast ACI alloy CD-4MCu (UNS J93370), researchers noted improved resistance to chloride SCC in cast alloys containing high ferrite. This confirmed similar observations in the field by materials engineers (Ref 39). A significant improvement in SCC resistance occurred with ferrite contents in the range 13 to 20 vol% and greater, which resulted in the development of alloys with ferrite content controlled by balancing chemical composition. Ferrite formation is promoted by chromium and by elements that act like chromium, such as silicon, niobium, and molybdenum. Nickel and elements that act like nickel (carbon, manganese, and nitrogen) retard ferrite formation. When specified, ferrite is typically controlled at the foundry by adjusting chromium toward the upper end of the specification range, and nickel toward the lower end, while establishing the desired silicon concentration.

Resistance to SCC in these alloys is believed to be a result of the keying action of ferrite particles (Ref 40). This action blocks direct propagation of SCC through the austenitic matrix. Along with this benefit, however, are improvements in strength, weldability, and resistance to general corrosion, particularly in hot concentrated nitric, acetic, phosphoric, and sulfuric acids and mixed nitric-hydrofluoric acid (Ref 40). Alloys produced with controlled ferrite content are recognized in ASTM A 351. Users are cautioned to limit applications to a maximum temperature of 425 °C (800 °F) because of the thermal instability of these grades.

A number of measures for preventing SCC of austenitic stainless steels have already been discussed. Two additional measures worthy of consideration are stress-relieving heat treatments and shot peening. The typical stress-relieving temperature for plain carbon steels (595 °C, or 1100 °F) is only slightly effective for the austenitic stainless steels, which require slow cooling from approximately 900 °C (1650 °F) for effective relief of residual stresses from operations such as welding. However, such treatments may not prevent but only prolong the time to failure, because chloride SCC of austenitic stainless steels can occur at very low stress levels. Also, the elevated temperatures required for stress relieving may cause unwanted distortion of complex and/or highly stressed structures and will sensitize susceptible alloys. This sensitization will result in intergranular corrosion or intergranular SCC.

Shot peening is the controlled bombardment of a metal surface with round, hard steel shot for the purpose of introducing compressive stresses in surface layers. These compressive stresses counteract the tensile stresses required for SCC. The depth of the resultant cold-worked layers is generally in the range of 0.1 to 0.5 mm (4 to 20 mils); 100% coverage is required. In laboratory tests in boiling 42% magnesium chloride, shot- peened type 304 stainless steel U-bend samples showed no SCC after more than 1000 h of exposure, but nonpeened control samples all cracked in approximately 1 h (Ref 41). Successful applications in the chemical-processing industries include a type 316 stainless steel centrifuge exposed to an organic chloride process stream (Ref 32) and numerous storage tanks exposed to a variety of SCC conditions (Ref 42).

The exposure of shot-peened surfaces to excessive temperatures or to environments that cause excessive general or pitting corrosion should be avoided. Temperatures above 565 °C (1050 °F) will relieve the beneficial compressive stresses and reduce the overall benefits of shot peening. Stress-corrosion cracking can occur once the relatively thin layers of residual compressive stress are penetrated by general corrosion or pitting.

SCC of Carbon and Alloy Steels. Plain carbon steels are susceptible to SCC by several corrodents of economic importance, including aqueous solutions of amines, carbonates, acidified cyanides, hydroxides, nitrates, and anhydrous ammonia. Susceptible steels in common use throughout the petrochemical-processing industry include ASTM A106 grade B for piping, A285 grade C for tanks, and A-515 grade 70 for pressure vessels. Cracking is both intergranular and transgranular; the former occurs in hot hydroxides and nitrates, and the latter in warm acidified cyanide solutions.

The temperature and concentration limits for the SCC susceptibility of carbon steels in caustic soda (sodium hydroxide) are fairly well defined; they have been derived from field experience and reproduced in chart form (Fig. 5). These limits for the other aqueous SCC environments mentioned previously are not nearly as well defined. For example, SCC was not considered to be a problem at temperatures below 88 °C (190 °F) in aqueous monoethanolamine and diethanolamine solutions used for scrubbing carbon dioxide and hydrogen sulfide out of natural gas and hydrogen-rich synthesis gas streams. However, recent experience in petroleum

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

refineries has resulted in general agreement that SCC preventive measures, such as thermal stress relief, must be applied to plain carbon steels used in aqueous amines at all temperatures and concentrations.

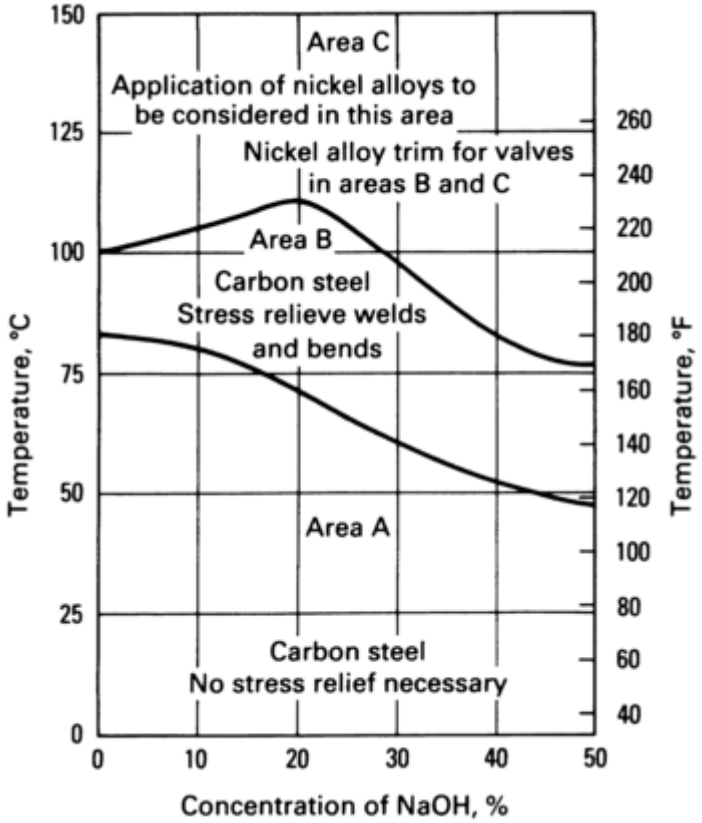


Fig. 5 Temperature and concentration limits for stress-corrosion cracking susceptibility of carbon steels in caustic soda. Source: Ref 6, 11

With regard to anhydrous ammonia, the SCC of plain carbon and low-alloy steels occurs at ambient temperatures when air or oxygen is present as a contaminant at concentrations of only a few parts per million (Ref 43). Most of the adverse experience has been with the non- stress-relieved higher-strength quenched-and-tempered steels, such as the grades covered in ASTM A 517. Cracking seldom occurs at temperatures below 0 °C (32 °F) and is virtually nonexistent at or below -33 °C (-28 °F), a common temperature for storage at atmospheric pressure. Water is an effective SCC inhibitor at a minimum concentration of 0.2% by weight.

Thermal stress relief is perhaps the single most effective measure for preventing, or at least greatly prolonging, the time to SCC of plain carbon and low-alloy steels in all of the environments mentioned previously. However, temperature is a more important factor than time at temperature. There is general agreement that stress-relieving temperatures below 595 °C (1100 °F), regardless of the hold time, are not effective for preventing SCC. In fact, the recommended minimum temperature for some environments, such as aqueous acidified cyanides, is 650 °C (1200 °F). As with any thermal treatment, special precautions must be observed, such as adequate support to avoid distortion and the removal of dirt, grease, and other foreign material that might react with the structure at elevated temperatures.

The previous comments on thermal stress relief apply to new carbon steel piping and vessels. Stress-corrosion cracking has been found in such vessels as horizontal pressure storage tanks (“bullets”) that were stress relieved after SCC was found in the original as-welded vessels and were repaired by grinding and welding (Ref 43). Undoubtedly, the stress-relieving temperatures propagated tiny cracks that were not detected during repairs.

SCC of Copper Alloys. Just as aqueous chloride is a potent SCC environment for austenitic stainless steels, aqueous ammonia causes extensive cracking in copper-base alloys. Virtually all copper alloys, as well as pure copper itself, can be made to crack in this environment.

The most susceptible alloys to SCC are the brasses containing more than 15% Zn, such as admiralty brass (UNS C44300, 28% Zn), yellow brass (UNS C27000, 34% Zn), and Muntz metal (UNS C28000, 40% Zn), followed by red brass (UNS C23000, 15% Zn) and several bronzes. The least susceptible alloys are 90Cu-10Ni (UNS C70600), 70Cu-30Ni (UNS C71500), and unalloyed copper.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The conditions that are conducive to SCC by aqueous ammonia are water, ammonia, air or oxygen, and tensile stress in the metal. Cracking is always intergranular, requires only trace quantities of ammonia in many cases, and occurs at ambient temperature. For example, U-bends in admiralty brass condenser tubes cracked in warm water from a cooling tower that contained 15 to 25 ppm ammonia because of close proximity to an ammonia plant. Other sources of ammonia include the decomposition of amines and the microbiological breakdown of organic matter. Stress-corrosion cracking failures in copper pipe under elastomeric insulation (Fig. 4) have been attributed to wet ammoniacal species (Ref 44); elastomeric insulation should not be used around buried (underground) pipes.

Thermal stress relief is generally not one of the better preventive measures, because ammoniacal SCC occurs at relatively low stress levels. In fairly mild ammoniacal environments, such as the cooling tower water system mentioned previously, the copper-nickel alloys, particularly 90Cu-10Ni, give good service. Small quantities of hydrogen sulfide have been found to inhibit SCC of brasses in petroleum refinery process streams, probably by reducing the dissolved oxygen content (Ref 32).

Another potent SCC environment for copper alloys is steam, but susceptibility is limited primarily to the higher-strength bronzes alloyed with aluminum (for example, UNS C61400) or silicon (for example, UNS C65500). In this regard, one noteworthy design to avoid is dimpled jacket construction. Severe SCC occurred at plug welds in a silicon bronze steam jacket on a similar alloy vessel used for heating a waste H_2SO_4 stream.

SCC of Aluminum Alloys. Stress-corrosion cracking of aluminum and its alloys in the chemical-processing industries is rare, because the lower-strength alloys in predominant use are resistant. These include the commercially pure alloy 1100 (UNS A91100), aluminum-manganese alloy 3003 (UNS A93003), and aluminum-magnesium alloys 5052 (UNS A95052) and 5083 (UNS A95083). Susceptible alloys are the high-strength grades of economic importance in the aircraft and aerospace industries, such as the aluminum-copper alloys 2014 (UNS A92014) and 2024 (UNS A92024) and the aluminum-copper- zinc-magnesium alloys 7075 (UNS A97075) and 7178 (UNS A97178). These alloys, heat treated to maximum strength levels, are susceptible to SCC in humid air containing traces of chlorides (Ref 45).

SCC of Titanium Alloys. Titanium (UNS R50550 and other unalloyed grades) has found increasing application in the chemical-processing industries, primarily as a replacement for austenitic stainless steels, because of outstanding resistance to corrosion by hot, concentrated oxidizing acids, such as HNO_3, and virtual immunity to pitting and SCC by hot aqueous chloride solutions. However, titanium and, to a greater extent, its higher-strength alloys (for example, Ti-6Al-4V, UNS R56400) are susceptible to SCC in a variety of environments, including anhydrous alcohols (methanol, ethanol) containing traces of halides, anhydrous red fuming HNO_3, anhydrous hot chlorides, some important industrial organic solvents (carbon tetrachloride, trichloroethane, and so on), anhydrous nitrogen tetroxide, and HCl.

In general, SCC preventive measures, such as thermal stress relief, cathodic protection, or inhibition, have not been used to any great extent with titanium and its alloys, although water additions are reported to inhibit cracking in anhydrous red fuming HNO_3, in methanol, and in anhydrous nitrogen tetroxide (Ref 46). Rather, SCC of titanium and its alloys is prevented by avoiding contact with specific cracking agents.

SCC of Zirconium Alloys. Zirconium (UNS R60702) and, to a greater extent, its alloys (for example, grade 705, UNS R60705) exhibit SCC behavior similar to that of titanium and its alloys in anhydrous alcohols containing traces of halides and in chlorinated organic solvents. Stress- corrosion cracking also occurs in aqueous ferric and cupric chloride solutions and hot concentrated HNO_3, especially when sustained tensile stresses are high. Because threshold stresses for SCC are high in comparison to yield strengths, thermal stress relief is a practical preventive measure. Holding temperatures between 650 and 850 °C (1200 and 1560 °F) are reported to be effective (Ref 32).

SCC of Nickel Alloys. As a class, nickel-base alloys are susceptible to SCC by a wide variety of corrodents. However, in most cases, the corrodents are specific to a few, but not all, of the alloys in this class. For example, sensitized alloys 800 (UNS N08800) and 600 (UNS N06600) crack in thiosulfate solutions and polythionic acids, but the stabilized alloys 825 (UNS N08825) and 625 (UNS N06625) are resistant. The latter alloys are particularly applicable in petrochemical process streams containing chlorides along with polythionic acids. In the nuclear power industry, alloy 600 and weld-metal alloys 82 (UNS N06082) and 182 (UNS W86182) crack intergranularly in crevices in high-purity water containing oxygen at elevated temperatures and pressures (Ref 47). In the absence of crevices, these alloys are resistant. Alloy 690 (UNS N06690) is resistant under all conditions.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Alloys 200 (UNS N02200), 201 (UNS N02201), 400 (UNS N04400), 600, 690 (UNS N06690), and 800 are susceptible to SCC in caustic solutions over a wide range of concentrations and at temperatures above 290 °C (550 °F) (Ref 11). Cracking is predominantly intergranular. The presence of oxygen and chlorides, which are common contaminants, tends to accelerate cracking, especially in alloy 600. Fairly high stress levels are generally required. Failures have occurred in steam generator tubes serving nuclear power plants from caustic concentrated on tube surfaces in crevices or as a result of a hot wall effect and/or poor water circulation. This experience prompted considerable research (Ref 48, 49, 50, 51). In general, alloys 200 and 201 and the nickel-chromium-iron alloys 690 and 600 appear to be the most resistant under the various conditions tested, although they are not immune to caustic SCC.

Other SCC environments of importance with regard to nickel-base alloys, especially alloy 400, are acidic fluoride solutions and HF. Alloy 400 is susceptible to SCC in cold-worked or as- welded conditions but is resistant in annealed or thermally stress-relieved conditions (Ref 52). Free air or oxygen accelerates corrosion rates and SCC tendency. However, alloy 400 has excellent general corrosion resistance over a broad range of temperatures and concentrations, so its use in HF alkylation units and other process streams containing HF or fluorides is widespread (Ref 53). Thermal stress relief at a minimum temperature of 540 °C (1000 °F), followed by slow cooling, will prevent SCC or will greatly prolong time to failure.

Environmental Cracking of Polymers. Corrosion-resistant polymers, such as thermoplastic and thermosetting resins, that are of interest to the materials engineer are susceptible to two forms of cracking in specific environments (Ref 54):

- Environmental stress cracking, which occurs when the polymer is stressed (residual or applied) and exposed to an organic solvent or aqueous solution of a wetting agent
- Craze cracking, which consists of a multitude of fine cracks that develop in contact with organic liquids or vapors, with or without the presence of mechanical stresses

For example, high-density polyethylene may crack in the presence of benzene or ethylene dichloride, and polystyrene may crack in the presence of aliphatic hydrocarbons (Ref 55). The mechanisms for these phenomena are not completely understood. Cracking may initiate at minute particles of low-molecular-weight polymers in the higher-molecular-weight polymer matrix. Thus, when evaluating polymers for corrosive service, test specimens should be stressed before exposure and should be carefully examined after exposure for evidence of environmental stress cracking and craze cracking.

Additional information on SCC is available in the article “Stress-Corrosion Cracking” in this Volume.

Hydrogen Damage

The entry of hydrogen into metals and alloys can result in several forms of damage:

- Loss of ductility and/or fracture strength
- Internal damage due to defect formation
- Sustained propagation of defects at stresses well below those required for mechanical fracture
- Macroscopic damage due to entrapment at mechanical interfaces

Although atomic, rather than molecular, hydrogen is the detrimental species within metals, it may be absorbed from a molecular hydrogen gas atmosphere. Hydrogen itself may be introduced during several stages of equipment or component manufacture (before any period of service). Heat treating of the metal (or alloy) in a hydrogen-containing furnace atmosphere, such as cracked ammonia, can result in absorption. Acid pickling, plating, and welding operations can each introduce hydrogen into the lattice of the metal.

Subsequent chemical service involving aqueous corrosion or high-temperature, hydrogen- containing environments may also introduce hydrogen. It is important to realize that many ductile metals and alloys, such as copper or austenitic stainless steels, will show a definite loss in ductility when exposed to environments that strongly promote the entry of nascent hydrogen (Ref 56).

Because iron-base alloys are principal materials of construction, these alloys have been the focus of most of the studies relating to hydrogen effects. In addition, ferritic (body-centered cubic, or bcc) steels have a particular

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

sensitivity to hydrogen. For these reasons, the present discussion focuses on hydrogen effects on steel. Such hydrogen effects have been thoroughly described in a review of hydrogen damage (Ref 57).

In ferrous alloys, embrittlement by hydrogen is generally restricted to those alloys having a hardness of 22 HRC or greater. However, other forms of hydrogen damage, such as hydrogen attack or hydrogen blistering, are associated with unhardened low-alloy or carbon steels.

As the result of hydrogen absorption, embrittlement of a metal or alloy may influence subsequent mechanical behavior without producing immediate and resolvable damage within the metal structure. In this respect, it is an insidious and somewhat reversible process, unlike hydrogen attack or blistering.

Hydrogen embrittlement may occur as a result of acid pickling, electroplating, and aqueous corrosion, which are electrochemical processes involving the discharge of hydrogen ions. The resulting nascent hydrogen is a chemisorbed species on the metal surface and, if not evolved as a molecular product, can enter the metal. This entry (or charging) of hydrogen has been described in detail (Ref 58). For the case of pure iron, introduction of hydrogen into the metal at high rates can produce irreversible effects (Ref 58). The solubility of hydrogen in the lattice is known to increase with applied tensile stress (Ref 59). Its solubility in metals obeys Sievert's law, with the concentration being directly proportional to the square root of the pressure (or fugacity). Within the lattice, hydrogen has been shown to interact with dislocations in iron (Ref 60, 61) and can thus affect subsequent plastic deformation.

In the case of pure titanium, as well as in alloys of titanium or zirconium, the entry of hydrogen can result in the formation of a hydride phase, thus reducing the ductility (Ref 56). A surface hydride phase has also been produced by hydrogen charging of nickel (Ref 62). An iron- chromium-nickel hydride has been proposed for austenitic stainless steel (Ref 63). Hydrogen charging of austenitic stainless steels is known to produce a martensite phase responsible for microcracking (Ref 64). Similar microcracks have been reported for cold-worked alloy 600 (Ref 65). Studies of hydrogen effects on aluminum alloys have not been conclusive (Ref 66).

It is known for the case of low-carbon steel that hydrogen absorption is enhanced by plastic deformation (Ref 67). This occurs up to 76% cold reduction, as shown in Fig. 6. However, the hydrogen permeation rate is increased by reductions of up to only 15% and is decreased by further plastic deformation (Ref 57). In the presence of an applied stress, the deleterious effect of hydrogen on delayed failure is increased by the triaxiality of the stress state, as shown in Fig. 7.

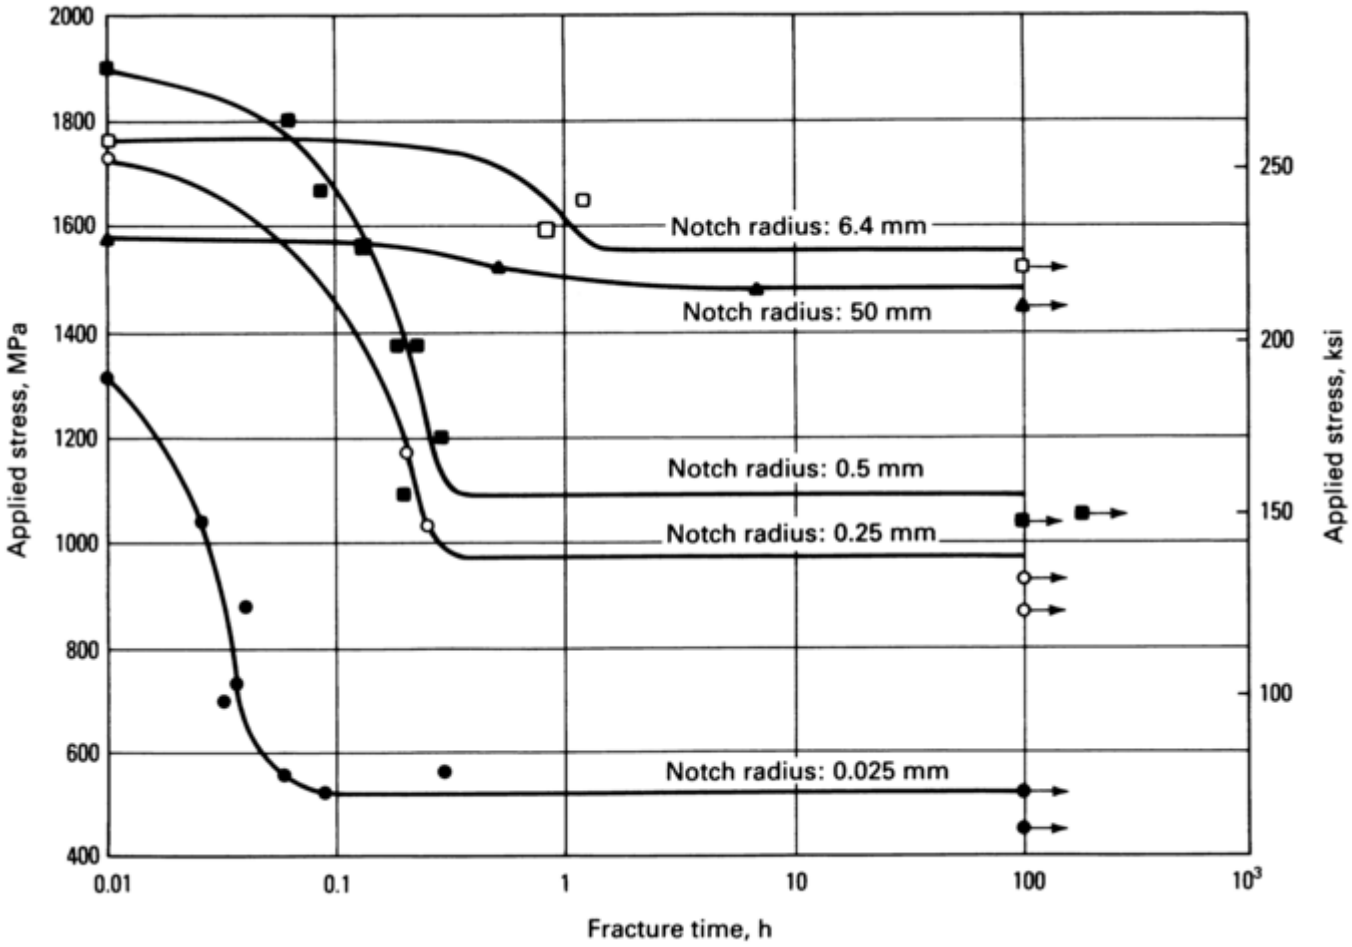

Fig. 7 Static fatigue curves for specimens of different notch sharpness. All specimens were baked for 30 min at 150 °C (300 °F). Source: Ref 68

For heat treated steels, sensitivity to hydrogen is a strong function of strength level. Figure 8 shows substantial embrittlement in a quenched- and-tempered steel with a tensile strength of 1860 MPa (270 ksi). The deleterious hydrogen content of 0.5 cm^3/100 g corresponds to approximately 1 hydrogen atom per 40,000 metal atoms (Ref 69). Other studies have shown substantial embrittlement of high-strength steels at hydrogen contents of 2 to 3 ppm (Ref 70, 71).

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

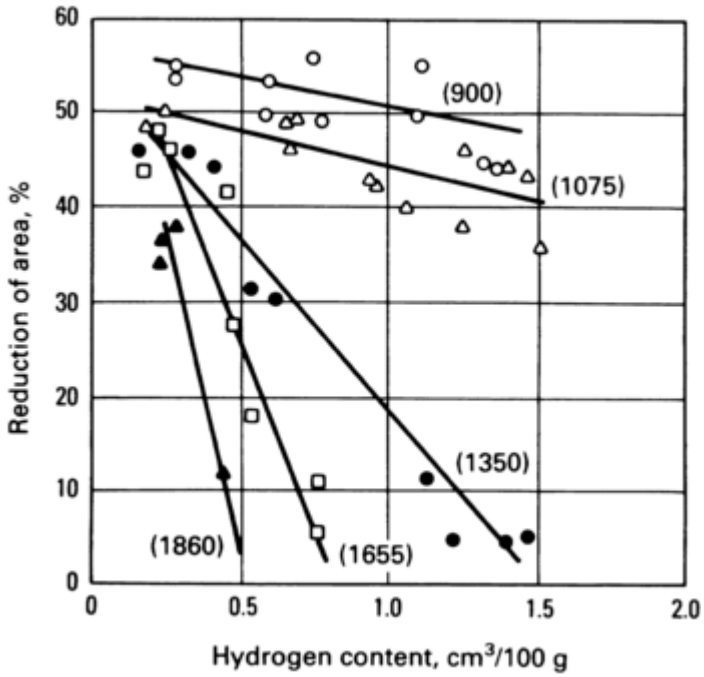

Fig. 8 Ductility (measured as percent reduction of area) versus hydrogen content for quenched-and-tempered steel at various strength levels. Ultimate tensile strength in megapascals is indicated in parentheses beside the curves. Source: Ref 69

The effects of temperature and strain rate on the embrittlement of carbon steel have been carefully studied (Ref 72). For a spheroidized AISI 1020 steel charged with hydrogen, the maximum embrittling effect appears to occur in the temperature range of -31 to 24 °C (-25 to 75 °F). Lower strain rates (5×10^{-2}/min) enhance embrittlement. Embrittlement is insignificant at higher strain rates of the order of 2×10^{4}/min. Figure 9 shows such an effect of strain rate. A similar effect of strain rate has been shown for nickel and for an iron-nickel alloy charged with hydrogen (Ref 73).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In aqueous systems, the entry of hydrogen is promoted by cathodic poisons that inhibit the recombination of adsorbed, discharged nascent hydrogen on the surface of the corroding metal. These poisons include cyanide and ionic species of sulfur, arsenic, selenium, bismuth, tellurium, phosphorus, iodine, and antimony.

Embrittlement by hydrogen-containing gas species may manifest itself in the stress-assisted propagation by preexisting surface defects (cracks). In the case of high-strength steels, such a phenomenon has been observed in H_2, H_2S, HCl, and HBr gas environments (Ref 74, 75, 76). A hydrogen sulfide (versus H_2) environment will result in a much higher crack velocity for the same steel, applied mechanical stress, and gas pressure (Ref 76).

One key to removing detrimental atomic hydrogen derives from its mobility at higher temperatures. A bake-out cycle, involving temperatures of 175 to 205 °C (350 to 400 °F), allows the diffusion and escape of hydrogen from the metal or alloy. If the hydrogen charging conditions were not severe enough to cause internal damage, the bake-out cycle described in Federal Specification QQC-320 restores full ductility.

In aqueous systems, the entry of hydrogen can be promoted by galvanic coupling to a more active metal. Therefore, cadmium or zinc platings containing defects or holidays can promote the hydrogen charging and embrittlement of susceptible metals or alloys. Such platings, or hot dip galvanizing, should be avoided in the case of low-alloy high-strength steels. As another example, titanium has been found to embrittle by hydriding when it is coupled with carbon steel in acidic environments or when it is exposed to moist environments after the application of a zinc chromate paint primer.

Susceptibility to hydrogen embrittlement is strongly influenced by the strength level of the metal or alloy. Wet hydrogen sulfide environments are considered to be among the most aggressive in promoting hydrogen entry. In such environments, common metals and alloys are qualified according to strength level and/or heat treatment in terms of their resistance to hydrogen-induced failure. These qualifications are summarized in NACE International standards MR-01-75, MR-01-76, and RP-04-75.

In general, iron-base alloys with a ferritic or martensitic structure are restricted to a maximum hardness of 22 HRC. Most other alloys are restricted to a maximum hardness of 35 HRC. There are exceptions in both cases. The procedures for materials testing in a wet hydrogen sulfide environment are discussed in NACE TM- 01-77.

Face-centered cubic (fcc) metals or alloys generally have more resistance to hydrogen embrittlement than those having a bcc lattice structure. However, cold work can increase the susceptibility of either structure. As a more direct effect of hydrogen entry, formation of a hydride phase can be expected to reduce the ductility of any metal or alloy.

In the pickling of steel, the level of hydrogen absorption is strongly affected by both the bath temperature and the nature of the acid (Fig. 10). Cathodic poisons have been ranked according to their effectiveness in increasing the permeation rate of hydrogen through low-carbon steel, as follows (Ref 78):

$$As > Se > Te > S > Bi \qquad \text{(Eq 1)}$$

The role of sulfur as a poison is particularly important, because sulfur is commonly encountered and because the chemical form of the sulfur greatly influences its effectiveness as a hydrogen entry promoter. The susceptibility to embrittlement by hydrogen can be demonstrated by the relative resistance to cracking in such environments as wet hydrogen sulfide. In such tests, microstructure has a definite effect on susceptibility. In steels, untempered martensite is the most susceptible phase. Lamellar carbide structures are less desirable than those with spheroidized structures. Quenched-and-tempered microstructures are more resistant than those that have been normalized and tempered (Ref 79). For the same strength level in low-alloy steel, it has been shown that a bainitic structure is more resistant to hydrogen-assisted cracking than a quenched- and-tempered martensitic structure (Ref 80).

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

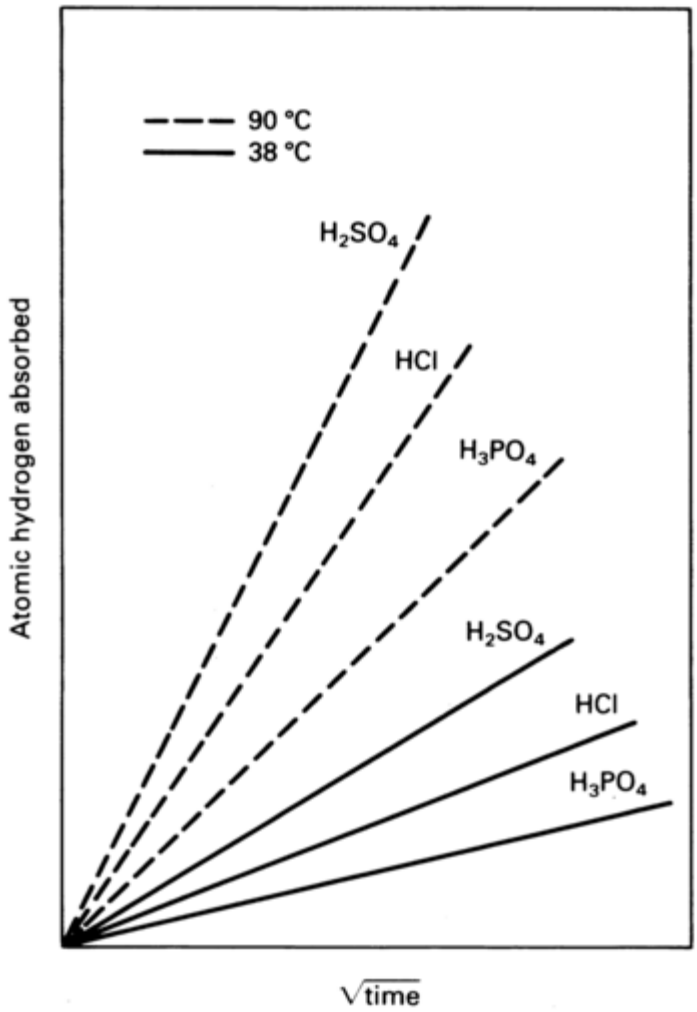

Fig. 10 Effect of anion and temperature on hydrogen absorption in a low-carbon steel. All acid concentrations were 2 *N*. Source: Ref 77

Embrittlement by gaseous hydrogen environments at ambient temperature has been effectively inhibited by the addition of 0.4 to 0.7 vol% oxygen (Ref 74). However, similar additions to a hydrogen sulfide gas environment did not halt the growth of cracks (Ref 81).

Because of the higher hydrogen solubility in the high-temperature fcc structure of iron (versus the low-temperature bcc structure), cooling of steel in hydrogen atmospheres from temperatures of the order of 1100 °C (2010 °F) can result in internal damage. Exceeding the solubility limit for hydrogen will result in the embrittlement of hydrogen-sensitive microstructures, such as martensite, formed by rapid cooling of some ferritic alloys. The internal precipitation of hydrogen is believed to be responsible for the generation of fissures, delaminations, or other defects. Such defects have been termed flakes, shatter cracks, fisheyes, or snowflakes. The defects are generally associated with hydrogen precipitation at voids, laminations, or inclusion-matrix interfaces already present in the steel. A reduced cooling rate, which allows hydrogen to be slowly released from the steel, is a general solution to the problem. Slower cooling will also inhibit the formation of hydrogen-sensitive microstructures.

Underbead cracking is an embrittlement phenomenon that is associated with absorption of hydrogen by molten metal during the welding process. Sources of hydrogen include moisture or organic contaminants on the surface of the prepared joint, moisture in low-hydrogen coated electrodes (such as E7018), moisture in flux- cored wire (such as M16), or a high-humidity environment. On rapid cooling of the weld, entrapped hydrogen can produce internal fissuring or other damage, as described earlier. In addition, the weld HAZ may contain the martensite phase in quench-hardenable alloys. The HAZ is then embrittled by high levels of entrapped hydrogen. Several steels have exhibited susceptibility to such embrittlement—for example, carbon steels containing 0.25 to 0.35 wt% C, low-alloy steels (such as AISI 4140 to 4340), and martensitic or precipitation-hardening stainless steels. Solutions to the hydrogen damage problems associated with welding include the use of dry welding electrodes,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

proper cleaning and degreasing procedures for prepared weld joints, the use of an appropriate preheat before welding, and an adequate postweld heat treatment.

Welding electrodes should be kept dry by using a heated rod box. The electrodes should be removed only as needed. If they are moistened or exposed in the ambient atmosphere for prolonged periods, low-hydrogen coated electrodes must be heated at 370 to 425 °C (700 to 800 °F) to remove moisture (Ref 57). Recommended preheat temperatures for steels, as a function of steel composition, section thickness, and electrode type, have been published (Ref 82). Welding procedures for the avoidance of hydrogen cracking in carbon-manganese steels have also been published (Ref 83). Appropriate postweld heat treatments for steels can range from a hydrogen bake-out at 175 °C (350 °F) to a martensite tempering treatment at temperatures as high as 705 °C (1300 °F) (Ref 57).

Hydrogen attack is a damage mechanism that is associated with unhardened carbon and low-alloy steels exposed to hydrogen-containing environments at temperatures above 220 °C (430 °F) (Ref 57). Exposure to the environment is known to result in a direct chemical reaction with the carbon in the steel. The reaction occurs between absorbed hydrogen and the iron carbide phase, resulting in the formation of methane:

$$2H_2 + Fe_3C \rightarrow CH_4 + 3Fe \qquad \text{(Eq 2)}$$

Unlike nascent hydrogen, the resulting methane gas does not dissolve in the iron lattice. Internal gas pressures develop, leading to the formation of voids, blisters, or cracks. The generated defects lower the strength and ductility of the steel. Because the carbide phase is a reactant in the mechanism, its absence in the vicinity of generated defects serves as direct evidence of the mechanism itself. The recommended service conditions (temperature, hydrogen pressure) for carbon and low-alloy steels are shown by the respective Nelson curves in Fig. 11. Chromium and molybdenum are beneficial alloying elements. This is most likely the result of their high affinity for carbon as well as the stability of their carbides. Hydrogen attack does not occur in austenitic stainless steels (Ref 57). In carbon or low- alloy steels, the extent of hydrogen attack is a function of exposure time.

Hydrogen blistering is a mechanism that involves hydrogen damage of unhardened steels near ambient temperature. It is known that the entry of atomic hydrogen into steel can result in its collection, as the molecular

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

species, at internal defects or interfaces. If the entry kinetics are substantial (promoted by an acidic environment, high corrosion rates, and cathodic poisons), the resulting internal pressure will cause internal separation (fissuring or blistering) of the steel. Such damage typically occurs at large, elongated inclusions and results in delaminations known as hydrogen blisters. Field experience indicates that fully killed steels are more susceptible than semikilled steels (Ref 84), but the nature and size of the original inclusions appear to be the key factors with regard to susceptibility. Rimmed steels or free-machining grades with high levels of sulfur or selenium would most likely show a high susceptibility to blistering. Stepwise cracking at the ends of blisters indicates an effect of elongated inclusions in the delamination process (Ref 57, 84). Similar stepwise cracking occurs in the hydrogen-induced failure of low-alloy pipeline steels (Ref 85). Both stepwise cracking and blistering appear to be limited to environments in which acidic corrosion occurs and in which cathodic poisons, such as sulfide, are present to promote hydrogen entry.

Solutions to the blistering problem include the use of low-sulfur calcium-treated argon-blown steels. Hot-rolled or annealed (as opposed to cold-rolled) steel is preferred (Ref 57). Silicon- killed steels are preferable to aluminum-killed steels. Also, treatment with synthetic slag or the addition of rare-earth metals can favor the formation of less detrimental globular sulfides (Ref 86). Ultrasonic inspection of the steel (according to ASTM E 114 and A 578) should be done before fabrication to detect laminations and other discontinuities that will promote blister formation. Equipment inspection and blister-venting procedures require unusual care (Ref 57). In services in which blistering can be expected, external support pads should not be continuously welded to the vessel itself; continuous welding of the support pads can cause hydrogen entrapment at the interface.

Examples of Hydrogen Damage. The permeation of hydrogen through ferritic steels can produce physical separation at mechanical joints. For example, bimetallic tubes, with a carbon steel inner liner, exhibited collapse of the liner due to its exposure to HF. Acid corrosion of the inside surface allowed nascent hydrogen to permeate the steel. Molecular hydrogen gas was formed, and trapped, at the interface with the outer tube section (brass). The accumulation of pressure was found to collapse the inner steel liners (Ref 57).

In high-temperature H_2/H_2S service, weld- overlaid 2.25Cr-1Mo steel (UNS K21590) was found to disbond at the weld interface (Ref 87). In this case, a weld overlay of type 309 stainless steel (UNS S30900), followed by type 347 stainless steel (UNS S34700), was applied. Hydrogen-induced cracking was found to occur in the transition zone below the weld metal after approximately $3\frac{1}{2}$ years of service. The disbonding was found to be more severe with higher cooling rates after hydrogen absorption. Outgassing treatments during the cool-down were found to prevent disbonding (Ref 88).

Figure 12 shows an example of hydrogen-assisted SCC failure of four AISI 4137 (UNS G41370) steel bolts having a hardness of 42 HRC. Although the normal service temperature (400 °C, or 750 °F) was too high for hydrogen embrittlement, the bolts were also subjected to extended shutdown periods at ambient temperatures. The corrosive environment contained trace hydrogen chloride and acetic acid vapors as well as calcium chloride if leaks occurred. The exact service life was unknown. The bolt surfaces showed extensive corrosion deposits. Cracks had initiated at both the thread roots and the fillet under the bolt head. Figure 12(b) shows a longitudinal section through the failed end of one bolt. Multiple, branched cracking was present, typical of hydrogen-assisted SCC in hardened steels. Chlorides were detected within the cracks and on the fracture surface. The failed bolts were replaced with 17-4PH stainless steel (UNS S17400) bolts (condition H1150M) having a hardness of 22 HRC (Ref 57).

As an example of hydrogen attack, a section of plain carbon steel (0.22% C and 0.31% Si) had been mistakenly included as a part of a type 304 stainless steel (UNS S30400) hot-gas bypass line used to handle hydrogen-rich gas at 34 MPa (5000 psi) and 320 °C (610 °F). After 15 months of service, the steel pipe section ruptured, causing a serious fire. Figure 13 shows a section of the 44 mm (1.75 in.) Outside diameter pipe near the fracture. The pipe had been weakened by hydrogen attack through all but 0.8 mm ($\frac{1}{32}$ in.) of the 8 mm ($\frac{5}{16}$ in.) thick wall. As a result of the hydrogen attack and the internal methane formation, the microstructural damage consisted of holes or voids near the outer surface as well as interconnected grain-boundary fissures in a radial alignment near the inner surface (Fig. 13b). The radially aligned voids preceded both the circumferential crack and pipe rupture (Ref 57).

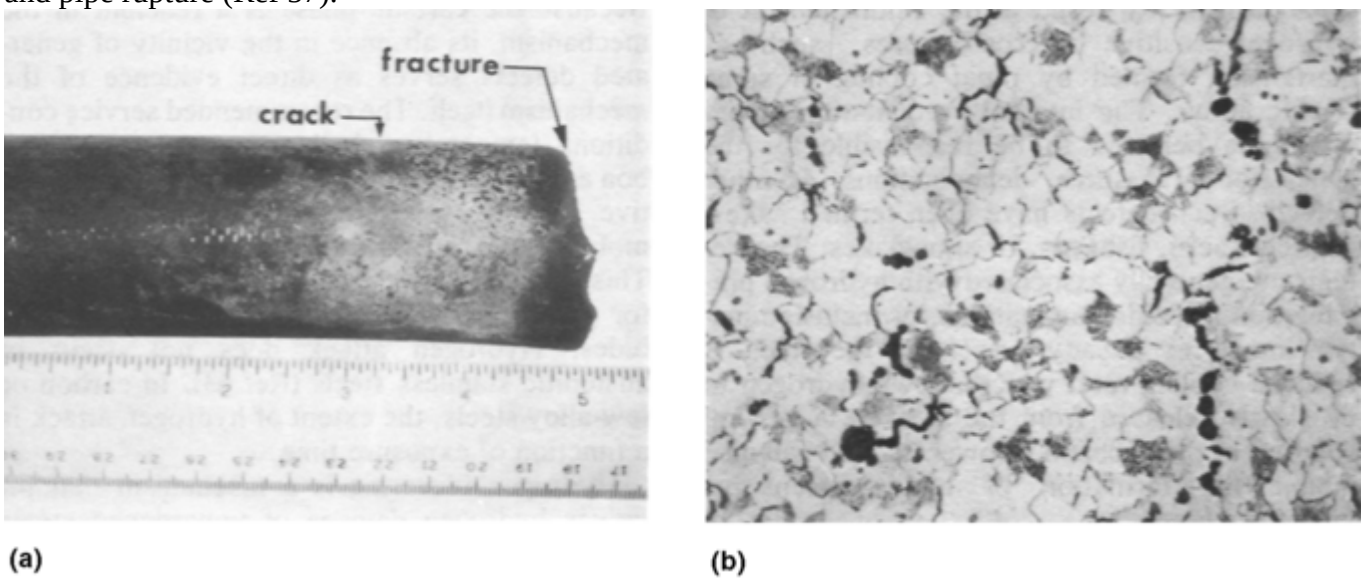

Fig. 13 Section of ASTM A106 carbon steel pipe with wall severely damaged by hydrogen attack. The pipe failed after 15 months of service in hydrogen-rich gas at 34.5 MPa (5000 psig) and 320 °C (610 °F). (a) Overall view of failed pipe section. (b) Microstructure of hydrogen-attacked pipe near the midwall. Hydrogen attack produced grain-boundary fissures that are radially aligned. Source: Ref 57

Hydrogen blistering is illustrated in Fig. 14, which shows a cross section of a 152 mm (6 in.) diameter blister that formed in the wall of a steel sphere. The sphere had been used to store anhydrous HF for 13.5 years at

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

ambient temperatures. The source of nascent hydrogen gas was the cathodic hydrogen generated by the corrosion reaction between the acid and the steel. The corrosion rate was less than 0.05 mm/yr (2 mils/ yr). Figure 14(b) shows the propagation of the blister, with the stepwise cracking (arrow) at its edge caused by the buildup of hydrogen pressure within the blister itself (Ref 57). More information on hydrogen attack is available in the article “Hydrogen Damage” in this Volume.

Erosion-corrosion

Erosion-corrosion is a frequently misinterpreted type of metal deterioration that results from the combined action of erosion and corrosion. Three types—liquid erosion-corrosion, cavitation, and fretting—are discussed. Abrasive wear, which is erosion without corrosion, also is discussed for comparison purposes.

Liquid erosion-corrosion is the accelerated wastage of a metal or material attributed to the flow of a liquid (Ref 89, 90, 91). Liquid erosion-corrosion damage is characterized by grooves, waves, gullies, rounded holes, and/or horseshoe- shaped grooves. Analysis of these marks can help determine the direction of flow. Most metals are susceptible to liquid erosion-corrosion under specific conditions. Carbon steels, for example, can be severely damaged by steam containing entrained water droplets. By contrast, the 300- series stainless steels at approximately the same hardness and strength level are very resistant to flowing wet steam. Virtually anything that is exposed to a moving liquid is susceptible to liquid erosion-corrosion. Examples include piping systems, particularly at bends, elbows, or wherever there is a change in flow direction or increase in turbulence; pumps; valves, especially flow control and pressure let-down valves; centrifuges; tubular heat exchangers; impellers; and turbine blades.

Surface films that form on some metals and alloys are very important in their ability to enhance resistance to liquid erosion-corrosion. Titanium is a reactive metal but is resistant to liquid erosion-corrosion in many environments because of its very stable titanium dioxide surface film. The 300-series stainless steels, as mentioned previously, are also resistant because of their stable passive surface films.

Both carbon steel and lead have relatively good resistance to certain concentrations of H_2SO_4 under low-to-moderate flow conditions. Both depend on a metal sulfate corrosion film for resistance; however, both fail fairly rapidly after removal of the sulfate film, even at low velocities.

Another example is the carbon steel and some low-alloy steels used to handle petroleum refinery fluids that contain hydrogen sulfide. At low velocities or under stagnant conditions, these materials are normally satisfactory because of the formation of a tenacious protective iron sulfide film. However, with increased velocity, the film is eroded away, followed by very rapid corrosion attack.

Velocity often increases attack, but it may also decrease attack, depending on the material of construction and the corrosive environment. For example, increasing the velocity causes accelerated attack of carbon steel in

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

steam condensate by increasing the supply of dissolved oxygen and/or carbon dioxide to the steel surface. In cooling water, however, increased velocity often reduces the attack of carbon steel by improving the effectiveness of inhibitors and by reducing deposits and pitting in stagnant areas.

Many 300-series stainless steels are subject to pitting and crevice corrosion in seawater. However, they may exhibit good corrosion resistance if the seawater is kept flowing at a minimum critical velocity. This prevents the formation of deposits and retards general corrosion, pitting, and crevice attack. Table 4 shows the effects different seawater velocities have on the liquid erosion-corrosion of various metals.

Table 4 Corrosion of metals and alloys in seawater as a function of velocity

Cavitation is a form of erosion-corrosion that is caused by the formation and collapse of vapor bubbles in a liquid against a metal surface (Ref 91, 92, 93, 94, 95). Cavitation occurs in hydraulic turbines, on pump impellers, on ship propellers, and on many surfaces in contact with high-velocity liquids subject to changes in pressure. Cavitation can occur if the pressure on a liquid is reduced sufficiently to cause boiling even at room temperature. Boiling produces bubbles that collapse on the high-pressure cycle. Rapidly collapsing vapor bubbles produce shock waves that have developed pressures as high as 414 MPa (60 ksi).

The appearance of cavitation (Fig. 15) is similar to pitting except that the surfaces in the cavitation pits are usually much rougher. Most investigators believe that cavitation damage is caused by a combination of corrosion and mechanical effects. Apparently, the collapsing vapor bubbles mechanically destroy the protective surface films. Thus, fresh surfaces are exposed to corrosion and the reestablishment of protective films, which is followed by more cavitation, and so on. Damage occurs when the cycle is allowed to repeat over and over again, for example, when a pump is operated, or “dead headed,” against a closed valve. Table 5 shows the relative cavitation resistance of a variety of metals and alloys in water and seawater.

Fretting is erosion-corrosion that occurs at the contact area between two metals under load and subject to slight relative movement by vibration or some other forces (Ref 97, 98, 99, 100). Damage begins with local adhesion between mating surfaces and progresses when adhered particles are ripped from a surface and react with air or other corrosive environment. Affected surfaces show pits or grooves with surrounding corrosion products. On ferrous metals, the corrosion product is usually a very fine, reddish iron oxide; on aluminum, it is usually black.

Fretting is detrimental not only because of the destruction of metallic surfaces but also because of a severe effect on the fatigue life. It has been shown that fretting can reduce the endurance limit of a metal by 50 to 70% (Ref 98).

The relative motion necessary to cause fretting is very small. Displacements as small as 10^{-8} cm (4×10^{-9} in.) have produced fretting. Fretting generally does not occur on contacting surfaces in continuous motion, such as ball or sleeve bearings.

Fretting can be minimized or eliminated, in many cases, by one or more of the following:

- Increasing the hardness of contacting surfaces. This may mean increasing the hardness of both or just one of the components. Surface-hardening treatments such as shot peening, nitriding, chrome plating, and carburizing are beneficial.
- Increasing the friction between the mating members by roughening or by plating (lead, copper, nickel, silver, gold)
- Applying phosphate coatings to exclude air or applying anaerobic sealants or adhesives to increase the tightness of the fit
- Increasing the fit interference, which reduces slippage by increasing the force on mating components
- Switching to materials with more fretting resistance, as shown in Table 6

Table 6 Relative fretting resistance of various material combinations

Combination	Fretting resistance
Aluminum on cast iron	Poor
Aluminum on stainless steel	Poor
Bakelite on cast iron	Poor
Cast iron on cast iron, with shellac coating	Poor
Cast iron on chromium plating	Poor
Cast iron on tin plating	Poor
Chromium plating on chromium plating	Poor
Hard tool steel on stainless steel	Poor
Laminated plastic on cast iron	Poor
Magnesium on cast iron	Poor
Brass on cast iron	Average

Abrasive wear is damage that results from the action of hard particles on a surface under the influence of a force that is oblique to the surface (Ref 101, 102, 103, 104, 105, 106). This is not, strictly speaking, a form of erosion-corrosion but is briefly discussed for comparison with the forms of erosion-corrosion mentioned previously.

Three common forms of abrasive wear are erosion abrasion, grinding abrasion, and gouging abrasion. Erosion abrasion usually involves low velocities and weak support of the abrasive material. Examples are wear on a plowshare in sandy soil and polishing of a metal surface with an abrasive held in a soft cloth. Thus, the energy of the abrasive is quite low, and impact is absent.

Grinding abrasion is the fragmentation of the abrasive, usually between two strong surfaces. Examples are a lapping operation in a machine shop and ball/rod mill grinding. Thus, impact is low to moderate, but the gross stress may be quite high, at least on a microscopic scale.

Gouging abrasion is recognized by the prominent grooves or gouges that are present on the wearing surfaces. Examples include abrasive disk grinding, machine tool cutting, and wear of power shovel bucket teeth. Heavy impact is generally associated with this type of abrasion, along with gross stress.

To alleviate these forms of abrasion, a careful study of the type of abrasion and an understanding of the service conditions are required. The materials selection should be based on the known properties of materials versus service requirements. More information on metal wear and corrosion is available in the article “Aqueous Corrosion-Wear Interactions” in this Volume.

Other Forms of Corrosion.

There are many different forms of corrosion (Ref 1, 2, 3, 13, 19, 89), and much can be learned from reported failures (Ref 107, 108, 109, 110, 111). The following paragraphs cite further forms of corrosion that warrant attention.

Selective leaching, also known as dealloying or parting corrosion, occurs when one element is preferentially removed from an alloy, leaving an often porous residue of an element that is more resistant to the environment. It is a problem of commercial significance in copper alloy systems (Ref 112), primarily copper-zinc and copper-aluminum and, to a lesser extent, copper-nickel. The terms *dezincification*, *dealuminization*, and *denickelification* (Fig. 16) describe the selective leaching of zinc, aluminum, and nickel, respectively, from the alloys. In these cases, a porous residue of copper remains, either as a fairly uniform layer or in plugs. The latter is more damaging in that the effect is similar to pitting corrosion.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

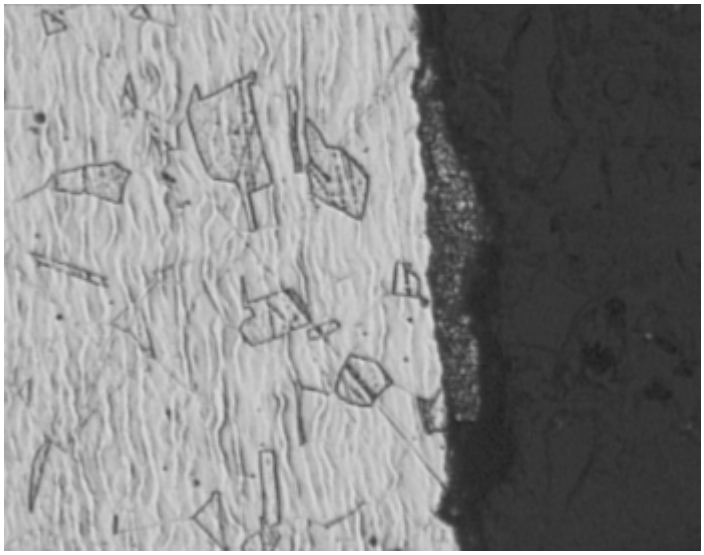

Fig. 16 Denickelification of cupronickel pipe exposed to a polluted marine estuary

Selective leaching in copper alloy systems occurs primarily in certain waters, especially under deposits in stagnant areas in heat exchangers. Alloy additions of arsenic, antimony, or phosphorus are effective in inhibiting this attack but only in copper-zinc alloys. Thus, arsenical or antimonial admiralty brass (UNS C44300 and C44400, respectively) is specified, for example, where this alloy is required for water service.

Graphitic corrosion of cast iron is another commercially important form of selective leaching. In this case, the iron matrix corrodes, leaving behind a porous graphite mass that can be carved with a pocket knife. Cast iron underground municipal watermains (Ref 113), fire watermains at petrochemical plant sites, and certain sprinkler systems (Ref 114) are affected by graphitic corrosion from both the soil and water sides. Internal cement linings and external protective coatings, with cathodic protection in severely corrosive soils, are relatively low-cost solutions to watermain corrosion problems. The article “Effects of Metallurgical Variables on Dealloying Corrosion” in this Volume contains more information on the phenomenon of dealloying.

Exfoliation is a form of localized corrosion that primarily affects aluminum alloys. Corrosion proceeds laterally from initiation sites on the surface and generally proceeds intergranularly along planes parallel to the surface. The corrosion products that form in the grain boundaries force metal away from the underlying base material, resulting in a layered or flakelike appearance. Extruded products from the 2000-series copper-magnesium alloys, the 7000-series zinc-copper-magnesium alloys, and, to a lesser extent, the 5000-series alloys are particularly susceptible to exfoliation in both marine and industrial environments. Also, at least one case affecting 6000-series magnesium-silicon alloys in freshwater service has been reported (Ref 115).

This attack is generally associated with the alloy fabrication method and temper, impurities in the alloy matrix, and the distribution of intermetallic compounds at the surface and in grain boundaries. Aluminum alloys 1100 (UNS A91100), 3003 (UNS A93003), and 5052 (UNS A95052) are resistant. Standard test methods for determining susceptibility to exfoliation corrosion in aluminum alloys are covered in ASTM G 34 and G 66.

Liquid metal induced embrittlement (LMIE), also known as liquid metal assisted cracking, is not considered to be a corrosion phenomenon, except in cases involving aqueous mercury compounds (Ref 32). However, LMIE is discussed here because it is a problem sometimes encountered by materials engineers. Liquid metal induced embrittlement is the penetration, usually along grain boundaries, of metals and alloys by such metals as mercury, which are liquid at room temperature, and metals that have relatively low melting points, such as bismuth, tin, lead, cadmium, zinc, aluminum, and copper. Stress, temperature, and time are the factors that facilitate and accelerate LMIE. Virtually all metal and alloy systems are subject to LMIE by one or more of these metals at or above their melting points.

Zinc is a prime offender because of widespread use throughout industry in the form of corrosion-resistant coatings applied to carbon steels by hot dip galvanizing, electroplating, tumbling, and spray painting. Plain carbon steels are embrittled by zinc at temperatures above 370 °C (700 °F) for long periods of time, especially when the steel is heavily stressed or cold worked.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Austenitic stainless steels and nickel-base alloys will also crack in the presence of molten zinc. These alloys usually crack instantly when welded to galvanized steel, a fairly common occurrence in the chemical-processing industry. In addition, austenitic alloy failures have occurred:

- In high-temperature bolting fastened with galvanized steel nuts
- During welding or heat treating of components contaminated by grinding with zinc- loaded grinding wheels, contact with zinc- coated structurals or slings, or exposure to zinc paint overspray
- During process industry plant fires involving piping and vessels (thin-wall expansion joint bellows are especially susceptible) sprayed with molten zinc from coated steel structures

It is imperative that all traces of zinc be removed from coated steel members before welding to austenitic alloys and before intimate contact with these alloys at temperatures above 370 °C (700 °F). Also, austenitic stainless steels and nickel-base alloys should be handled with non- coated steel hoist chains, cables, and structurals. They should be dressed and cleaned with new grinding wheels and stainless steel brushes, and they should be marked with materials (paints, crayons, and so on) free from zinc and other low- melting metals.

Cadmium is probably second to zinc in importance as an agent of LMIE because of its application as a corrosion-resistant coating to a variety of hardware, particularly fasteners. Failures by cadmium LMIE of bolting operating at temperatures above 300 °C (570 °F) and fabricated from such high-strength alloy steels as AISI 4140 (UNS G41400) and 4340 (UNS G43400) and austenitic stainless steels are fairly common. In fact, some high-strength steels and high- strength titanium alloys are embrittled by cadmium at temperatures below its melting point by mechanisms not yet understood. The solution to LMIE by cadmium is similar to that of zinc, that is, avoid contact with, and contamination of, susceptible metal and alloy systems at temperatures above the 321 °C (610 °F) melting point of cadmium (and at all temperatures when high- strength steels and titanium alloys are involved).

Metal systems that are embrittled by contact with mercury include copper and its alloys, aluminum and its alloys, nickel alloys 200 (UNS N02200) (at elevated temperatures) and 400 (UNS N04400), and titanium and zirconium and their alloys. Cracking is intergranular except in zirconium alloys; in these alloys, cracking is transgranular. Mercury LMIE of aluminum and copper alloys was more common years ago in the petrochemical industry when mercury-filled manometers and thermometers were extensively used. Failures or upsets would release mercury into process or service (steam, cooling water, and so on) streams, causing widespread cracking of piping, heat-exchanger tube bundles, and other equipment. Under these conditions, even pure aluminum and pure copper are susceptible. With regard to the titanium system, the commercially pure grades used in the chemical-processing industry are less sensitive than the alloys. In addition, LMIE in aqueous solutions of mercurous salts, such as mercurous nitrate, is possible because the mercurous ion can be reduced to its elemental form at local cathodic sites.

Although not a metal, sulfur will penetrate the grain boundaries of nickel and nickel alloys at elevated temperatures in much the same way as in the low-melting metals mentioned previously. Damage is particularly bad under reducing conditions (low oxygen potential), because sulfur forms a very aggressive low-melting nickel/ nickel sulfide eutectic ($Ni\text{-}Ni_3S_2$) that melts at approximately 625 °C (1157 °F). Sources other than elemental sulfur include organic compounds (greases, oils, cutting fluids) and sulfates. Thus, contamination from these sources before welding, hot forming, annealing, and other heating operations must be avoided (see the article “Liquid Metal Induced Embrittlement” in this Volume).

Materials Selection for Corrosion Control

Revised by Peter Elliott, Corrosion & Materials Consultancy, Inc.

Economics

Cost-Effective Materials Selection. Two extremes for selecting materials on an economic basis without consideration of other factors have been promulgated (Ref 111, 116):

- *Minimum cost or economic design:* selection of the least expensive material, followed by scheduled periodic replacements or correction of problems as they arise
- *Minimum corrosion:* selection of the most corrosion-resistant material regardless of installed cost or life of the equipment

These factors can be modified (Ref 111) to include:

- *Minimum investment:* materials selection for a short-term design where corroded parts are replaced as required (e.g., cheap labor, areas of political unrest)
- *Minimum maintenance:* an overdesign (thicker section of material or improved alloy) to reduce costs of maintenance (high labor costs) or where spare parts (replacements) are not easily available

Cost-effective selection generally falls somewhere between these extremes and includes consideration of other factors, such as availability and safety. For example, critical components in a large single-train chemical-processing plant should be fabricated from materials that tend toward the minimum corrosion extreme, because failure could shut down the entire operation. However, component materials for a multitrain or batch operation, especially one that processes a relatively short-lived product, might tend toward the minimum cost extreme, even to the point of purchasing used equipment at a fraction of the cost of new fabrication. Thus, different strategies are appropriate for different situations.

Materials that are considered expensive when compared directly with carbon steel or non-metallic materials are generally cost-effective when the overall life-cycle costs are taken into account. Factors that affect the cost-effective choice of higher-alloyed materials include maintenance and replacement costs (as mentioned previously), accounting procedures that give tax relief, and discounted cash flows (see the article "Corrosion Economic Calculations" in this Volume).

مرجع مهندسی مواد و متالورژی

Industrial losses caused by corrosion account for enormous sums, typically a few percentage of the gross national product (GNP) of a country. A 1978 survey (Ref 118) showed the total direct cost of corrosion to the U.S. economy at approximately $280 billion/year; see the article “Direct Costs of Corrosion in the United States” in this Volume for more recent estimates.

Not always shown in surveys are the indirect costs of corrosion, which include lost product, lost sales, and lost customers. Indirect losses are generally more than double the direct costs. For example, corrosion surveys focused on the agricultural sector gave the following results: a U.S. National Bureau of Standards survey (Ref 117) found direct losses of $1171 million (in 1978), with indirect losses of $2943 million; a survey (Ref 118) of British agriculture, which identified direct losses (in 1993) of £180 million sterling, estimated indirect losses associated with depreciation and consequential losses to be £500 million. A survey of the horticultural sector (Ref 119) showed direct losses of £10 million (in 1993) inflated to £24 million when consequential losses were included.

Designing to Minimize Corrosion

Peter Elliott, Corrosion and Materials Consultancy, Inc.

Introduction

UNEXPECTED and frequently costly failures occur without sound and reliable engineering design, which includes the effective and correct choice of materials and the economic use of efficient controls and monitoring measures. Fine details of engineering design may be missed because of poor communication channels, sometimes compounded by human errors and a lack of proper care and attention. Unexpected premature failures can be harmful to personnel and adjacent equipment or parts. On occasion, a poor design can cause premature failure of even the most advanced corrosion-resistant materials.

Designing to Minimize Corrosion

Peter Elliott, Corrosion and Materials Consultancy, Inc.

Design Considerations

Design can never be absolute; often, decisions are a compromise based on cost and availability of materials and resources. Designing for corrosion control can only be effective if it is part of the overall design philosophy.

There are numerous textbooks, handbooks, and articles on corrosion; several offer choices for specific materials/environment systems (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17). These reference sources provide a useful starting point for selecting materials, but a designer is seldom a corrosion engineer, so it is necessary to further convey essential corrosion knowledge to designers (Ref 18, 19, 20, 21, 22, 23, 24, 25, 26, 27). Unlike conventional engineering, the basic difficulty is that corrosion is not a tangible property; it is more a behavioral pattern. Thus, to realize safe, reliable designs, it is essential that there be a rigid control on materials and fabrication and an extensive effort to eliminate human errors or misunderstandings that result from poor communication.

The results of a survey of chemical-processing plants (Ref 28) showed that design faults ranked highest (58%) in the reasons for failure. Of almost equal ranking was the incorrect application of protective treatments (55%), followed by categories that demonstrate a lack of knowledge about the operating conditions (52%), lack of process control (35%), and an unawareness that there was actually a corrosion risk (25%).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

In an ideal world, designers would call for some corrosion assessment prior to preparing the detailed engineering design. Typically, schemes would permit some form of evaluation with respect to both function and the necessary action, for example, from the proposal-to-production planning stages (Fig. 1) (Ref 28). In the practical, real world, however, communication of agreed reasons for failures may not always reach the designer. Indeed, communication to contractors, who are closest to the application, is even poorer (Ref 28, 29). Studies have shown that, while management is always informed of the reasons for failure in the chemical-processing industry, site personnel are informed only 77% of the time; designers, 55%; materials suppliers, 37%; and contractors, only 11% of the time.

مرجع مهندسی مواد و متالورژی

Drafter's Delusions. A further complication in designing against corrosion relates to the general interpretation of design drawings in what has been referred to as drafter's delusions. For example, the drafter might be considering a certain piece of equipment without knowledge of the fact that there may be unusual shapes, moving parts, or environmental issues. A lack of attention to design detail causes many premature failures by corrosion-related processes. All too often, the designer will have in mind one thing, which, in reality, becomes totally different. For example, a simple crossover line between two reactor vessels might, in practice, become an extended line with several turns, merely to position a shutoff valve at a more convenient and accessible position closer to ground level. There are countless examples of this situation in real-world failure analysis, where the actual designs were not those originally intended (Ref 29, 30, 31, 32, 33, 34, 35); further examples are provided in the following pages.

Quality assurance and control usually ensure that the requested material is what it should be and that it was inspected and tested as specified. However, materials controls at fabrication are sometimes less than perfect. In one case, an inspector noticed a blemish on the outside of a steel pressure vessel. On closer scrutiny (from the vessel interior), the problem was found to be a steel bolt that had been inadvertently rolled into the steel plate during fabrication (Fig. 2).

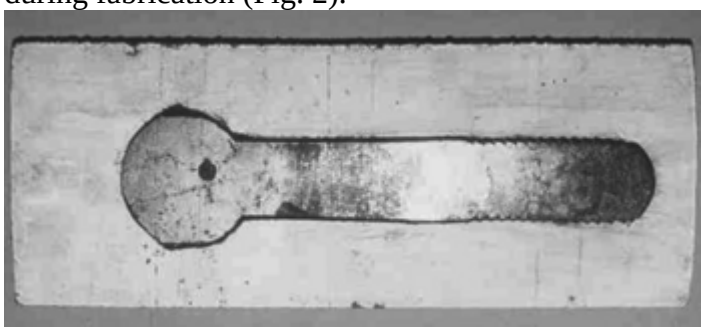

Fig. 2 An unexpected guest—a rolled-in bolt that dropped onto the plate during hot rolling

While considering materials, it is important to avoid nonspecific descriptions or terms in reference to design drawings and specifications. There are many instances where generic terms, such as *stainless steel, bronze, Hastelloy,* or *Inconel,* are too vague, and the ultimate choice is far from what was expected and required. Wherever possible, and notably, in high-risk areas, materials should be selected and tested according to code requirements (Ref 7, 36). Substitutes, if requested, should be properly evaluated before use.

Reliability Engineering. The designer should play a significant role in reliability management. The communication chain, or the reliability loop, from the designer, to the manufacturer, then to the user, and back to the designer is a key factor (Ref 29, 37). When a risk is well documented, it should be possible to overdesign or at least isolate the area to minimize risk to users. Where a risk of failure is high, the emphasis should be toward a fail-safe or no-fail/replace procedure. Failures vary considerably; the design function can be partially or totally affected, or the onset of failure can be gradual or sudden. The combination of sudden and total failure represents the worst catastrophic situation (e.g., explosions, fires, and total structural collapse), many of which can be attributed to a small design detail.

Corrosion Awareness

This article is intended to improve corrosion awareness, but clearly, this is only a starting point. To be effective, the user must also be willing to take action, and the designer should insist on appropriate codes and/or recommended working practices. Whether the necessary action will be taken is affected by financial, technical, safety, social, and/or political issues (Ref 37).
To prevent corrosion/degradation, the designer can:

- Avoid obvious design weaknesses (see subsequent examples)
- Use more reliable materials, even if this entails greater cost
- Introduce additional precautions, such as monitoring (Ref 38), inhibitors, cathodic protection, and coatings (Ref 39, 40)
- Establish efficient maintenance/repair teams having detailed procedures and including qualified surveyors, inspectors, and supervisors
- Ensure that standby products are available, fully labeled, and properly stored (using desiccants and noncorrosive packaging)

As noted previously, the planned approach for reliable engineering design should include corrosion control and/or preventive measures, for which standards and specifications are available. Actual (real-world) approaches vary from plant to plant (or component to component) and include:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- The avoid-failure approach
- The keep-it-working approach
- The let-it-fail-then-repair approach

Aspects germane to these approaches are summarized in Table 1 (Ref 29, 37).

Table 1 Design aspects for reliability

Approach	Factors to be taken into account (typical)
Avoid-failure approach	
Control product duty	Fail-safe; visible instrumentation
Keep product simple	Fewer functions; fewer joints
Predict reliability	Maintain in fixed limits; overdesign (thicker), etc.
Study variable interfaces	Contact faces, bearings; lubrication (wear, friction); seals; consult experts and test work
Instill care for familiar items or designs	Complacency; negligence
Study innovation	Consult experts and test work; records of operation; records of failure mode/frequency
Redundant items	Stand-by units in good repair; storage; handling; vibration, impact, wear, etc.
Recognize human limits	Misreading of instructions; sequence of controls (hypnosis?); adequate housekeeping; user attitudes
Test product design	Proving the design; variables; safety limits; pilot plant and real-life testing
Control malfunctions	Human; automatic; mixture; important for software/hardware
Keep-it-working approach	
Maintainability	Access
Short-term items	Replace routinely before failure; regular inspection; monitoring
Spares	Identity correctly coded; location known; easy access replacement; avoid identical mating systems
Built-in adjustments	Corrects for progressive deterioration; manual/automatic
Let-it-fail-then-repair approach	
Defects	Subtle or catastrophic
Spares	Need quantified reliability (difficult for corrosion)
Minimize off-period	Keep repair time low; speedy fault diagnosis; speedy removal of failed part(s); speedy replacement; speedy check of assembly; experts, inspectors

Source: Ref 29

New plants and process equipment are commonly designed to prevent or reduce problems that have occurred previously. Updated and improved procedures are of little use, however, if no action is made until after the equipment fails. Situations have occurred where cathodic protection was ineffective because the anode material was not connected to the structure it was protecting; a monitoring signal (a bell) was ignored because of noise; on-line monitoring data were estimated (guessed at), so that the inspector could avoid travel in blizzard conditions; and a sentinel hole (weep hole) leaked for weeks without any investigation as to the cause until the vessel exploded.

Designing to Minimize Corrosion

Peter Elliott, Corrosion and Materials Consultancy, Inc.

Why Failures Occur

In the context of design, there are several factors that relate to materials-component failure:

- Overload suggests a weakness in plant control instrumentation or operation.
- Abnormal conditions can result from a lack of process control or variations in raw materials (alloy type or chemical inhibitors, etc.).
- Poor fabrication may result from inadequate instructions or inspection (e.g., excessive cold work, overmachining, flame cutting, or excessive torque loading).
- Poor handling. Scratches or machine marks can result from poor detailing or poor instruction. Not to be excluded are identity marks (incised codes) and inspection stamps.
- Assembly (if incorrect), welds, and fasteners can seriously influence stress, flow, and compatibility.
- Storage and transportation can significantly influence materials performance, especially for items shipped to/from tropical, humid climates where heavy rains, violent seas, storms, and cargo sweat may each contribute to materials degradation unless adequate precautions are taken (Ref 41). Proper design and effective corrosion-control management normally should accommodate these aspects of materials handling.
- Accessibility. Some structures or components may not be accessible for remedial work, even if a corrosion risk is recognized. Buried structures can be affected where soil and bacterial corrosion might apply (Ref 42, 43).

Designing to Minimize Corrosion

Peter Elliott, Corrosion and Materials Consultancy, Inc.

Design and Materials Selection

Corrosion control measures are best initiated at the design stage (Fig. 1). Materials are usually selected to perform a basic function or to provide a functional requirement. In many instances, the materials choice is dictated not by corrosion but by characteristics such as strength, reflectivity, wear resistance, and dimensional stability. In some situations, a corrosion-resistant alloy may not be satisfactory.

High-Temperature Service. The subject of designing for high-temperature service is outside the scope of this article (Ref 26, 44, 45, 46). High temperatures always accelerate corrosion processes, and certain gases or liquids, which are considered innocuous under ambient conditions, become aggressive to materials when hot. A tenfold change in corrosion rate is not uncommon for a temperature change of 30 °C (54 °F) under aqueous conditions. The same tenfold change (or considerably worse) can occur with a 20 °C (36 °F) change under high-temperature conditions. If temperatures are too high, the material might oxidize (i.e., scale). Thick scales and metal loss result from overheating, which could be due to loss of water cooling or the absence of insulation. Heat transfer will decrease as the scale/deposit thicknesses increase.

Candidate high-temperature materials need to be strong and resistant to oxidation or to other corrosion processes that might involve complex multi-oxidant environments having highly volatile phases and molten salts. It is important for designers and others to recognize that several corrosion elements might simultaneously be involved in an application (e.g., oxygen, halogen, and sulfur) (Table 2). Materials selection for high-temperature service needs to be reviewed for each individual part and application. Alloy steels and more sophisticated alloys based on nickel and cobalt, in which key elements for high-temperature corrosion resistance include chromium, aluminum, silicon, and rare-earth additions for scale retention, are must commonly used.

Table 2 Types of corrosion and corrodents encountered in high-temperature processes or components

Process components	Temperature		Types of corrosion or corrodent
	°C	**°F**	
Chemical/petrochemical			
Ethylene steam cracking furnace tubes	to 1000	to 1830	Carburization, oxidation
Steam reforming tubes	to 1000	to 1830	Oxidation, carburization
Vinyl chloride crackers	to 650	to 1200	Halide gas
Hydrocracking heaters, reactors	to 550	to 1020	H_2S and H_2
Petroleum coke calcining recuperators	816	1501	Oxidation, sulfidation
Cat cracking regenerators	to 800	to 1470	Oxidation
Flare stack tips	950–1090	1740–1995	Oxidation, thermal fatigue, sulfidation, chlorination, dewpoint
Carbon disulfide furnace tubes	850	1560	Sulfidation, carburization, deposits
Melamine production (urea) reactors	450–500	840–930	Nitriding
Other processes			
Titanium production reactor vessels	900	1650	Oxidation, chlorination

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Nitric acid—catalyst grid	930	1705	Oxidation, nitriding, sulfidation
Nuclear reprocessing reactors	750–800	1380–1470	Oxidation (steam), fluorination (HF)
Oil-fired boiler superheaters	850–900	1560–1650	Fuel ash corrosion
Gas turbine blades corrosion	to 950	to 1740	Sulfates, chlorides, oxidation, ash
Waste incinerators—superheaters	480	895	Chlorination, sulfidation, oxidation, molten salts
Fiberglass manufacturing recuperators	1090	1995	Oxidation, sulfidation, molten salts

Source: Ref 26

Different behavior can arise at similar temperatures, depending on the source of heat, such as electrical heating elements, fuel combustion, flue gases and deposits, flame impingement, friction, and wear. When hot gases cool, condensation can cause acid dewpoint conditions, thereby changing the materials choice to a corrosion-resistant alloy.

Design Factors That Influence Corrosion

The basic factors that most influence design for corrosion resistance are summarized in Table 3. Each factor plays a unique yet not always unrelated role with other factors (Ref 26). For example, localized corrosion damage adjacent to the spindle support of a stainless steel paddle stirrer (Fig. 3) resulted not only from crevice corrosion (oxygen differential cell) but also because of galvanic corrosion, caused by a small carbon steel retaining screw (anodic) that had been used inadvertently for assembly. Ultimately, the stirrer support loosened, which allowed further deterioration by fretting.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Table 3 Corrosion factors that can influence design considerations

Basic Factor	Design detail
Environment	Natural
	Chemical
	Storage/transit
Stress	Residual stress from fabrication
	Operating stress—static, variable, alternating
Shape	Joints, flanges
	Crevices, deposits
	Liquid containment and entrapment
Compatibility	Metals with metals
	Metals with other materials
	Quality control
Movement	Flowing fluids
	Parts moving in fluids
	Two-phase fluids
Temperature	Oxidation, scales
	Heat-transfer effects
	Molten deposits
	Condensation and dewpoint
Control	Surface cleaning and preparation
	Coatings
	Cathodic protection
	Inhibitors
	Inspection
	Planned maintenance

Fig. 3 Crevice corrosion of a stainless steel paddle stirrer, exacerbated by galvanic corrosion by a steel retaining pin

Design details that can accelerate corrosion follow.

Location. Exposure to winds and airborne particulates can lead to deterioration of structures. Designs that leave structures exposed to the elements should be carefully reviewed. Prevailing winds and seasprays have to be taken into account in many applications, including buildings, the storage of spare parts, and the location of air intake fans to gas turbines and other equipment (Fig. 4). Atmospheric corrosion is significantly affected by temperature, relative humidity, rainfall, and pollutants. Also important are the season and location of on-site fabrication, assembly, and painting. Codes of practice must be adapted to the location and the season.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

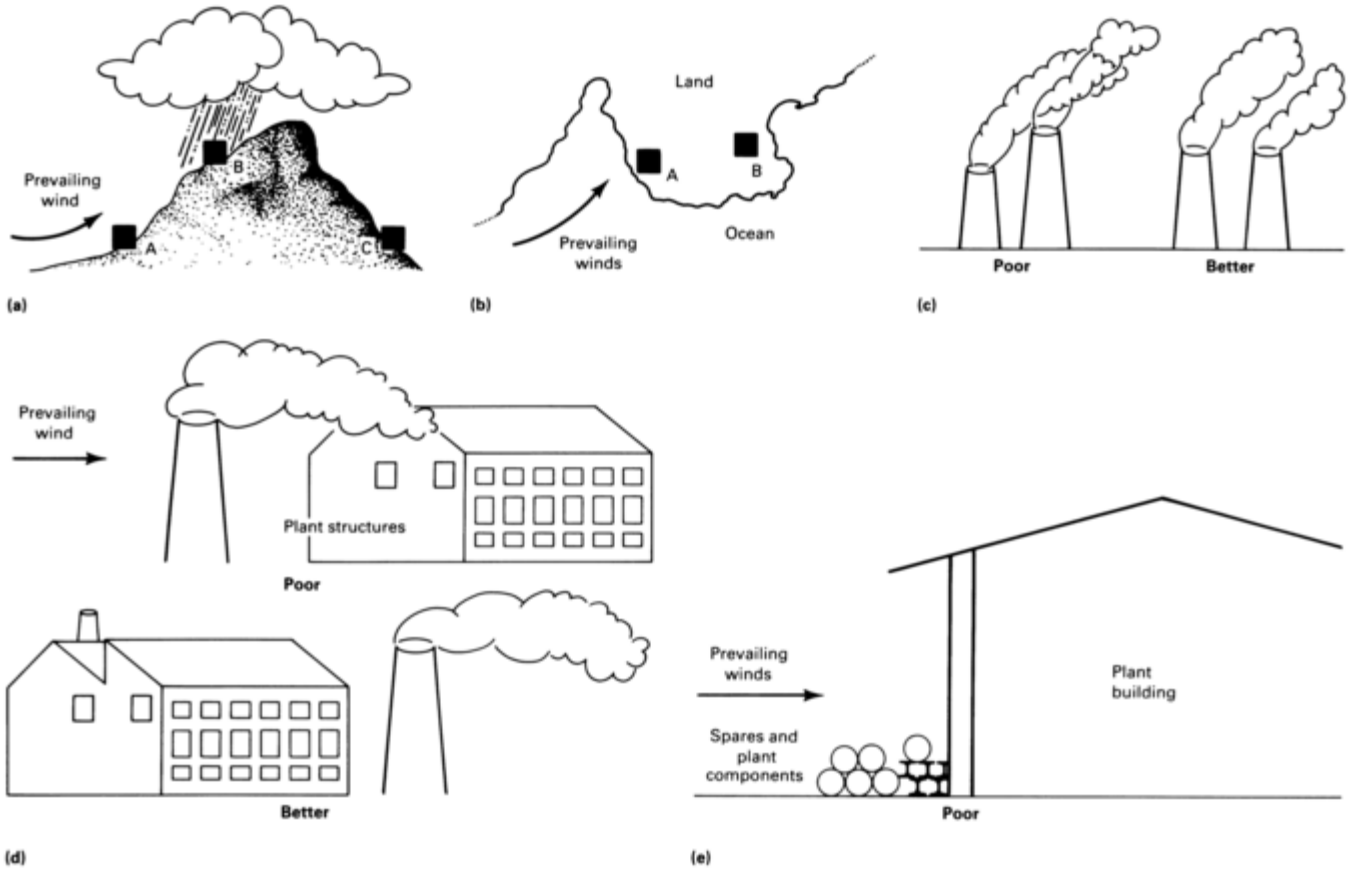

Fig. 4 Site location as a design consideration. (a) Topographic features favor some sites over others. Location C would be the preferred site for corrosion considerations. (b) In marine atmospheres, prevailing winds should be taken into account, making location B the preferred site. (c), (d), and (e) Carry-over effects from prevailing winds should be evaluated.

Shape. Geometrical form is basic to design. The objective is to minimize or avoid situations that worsen corrosion. These situations can range from stagnation (e.g., retained fluids and/ or solids, contaminated water used for hydrotesting) to sustained fluid flow (e.g., erosion/cavitation in components moving in or contacted by fluids, as well as splashing or droplet impingement).

Common examples of stagnation include nondraining structures, dead ends, badly located components, and poor assembly or maintenance practices (Fig. 5). General problems include localized corrosion associated with differential aeration (oxygen concentration cells), crevice corrosion, and deposit corrosion.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

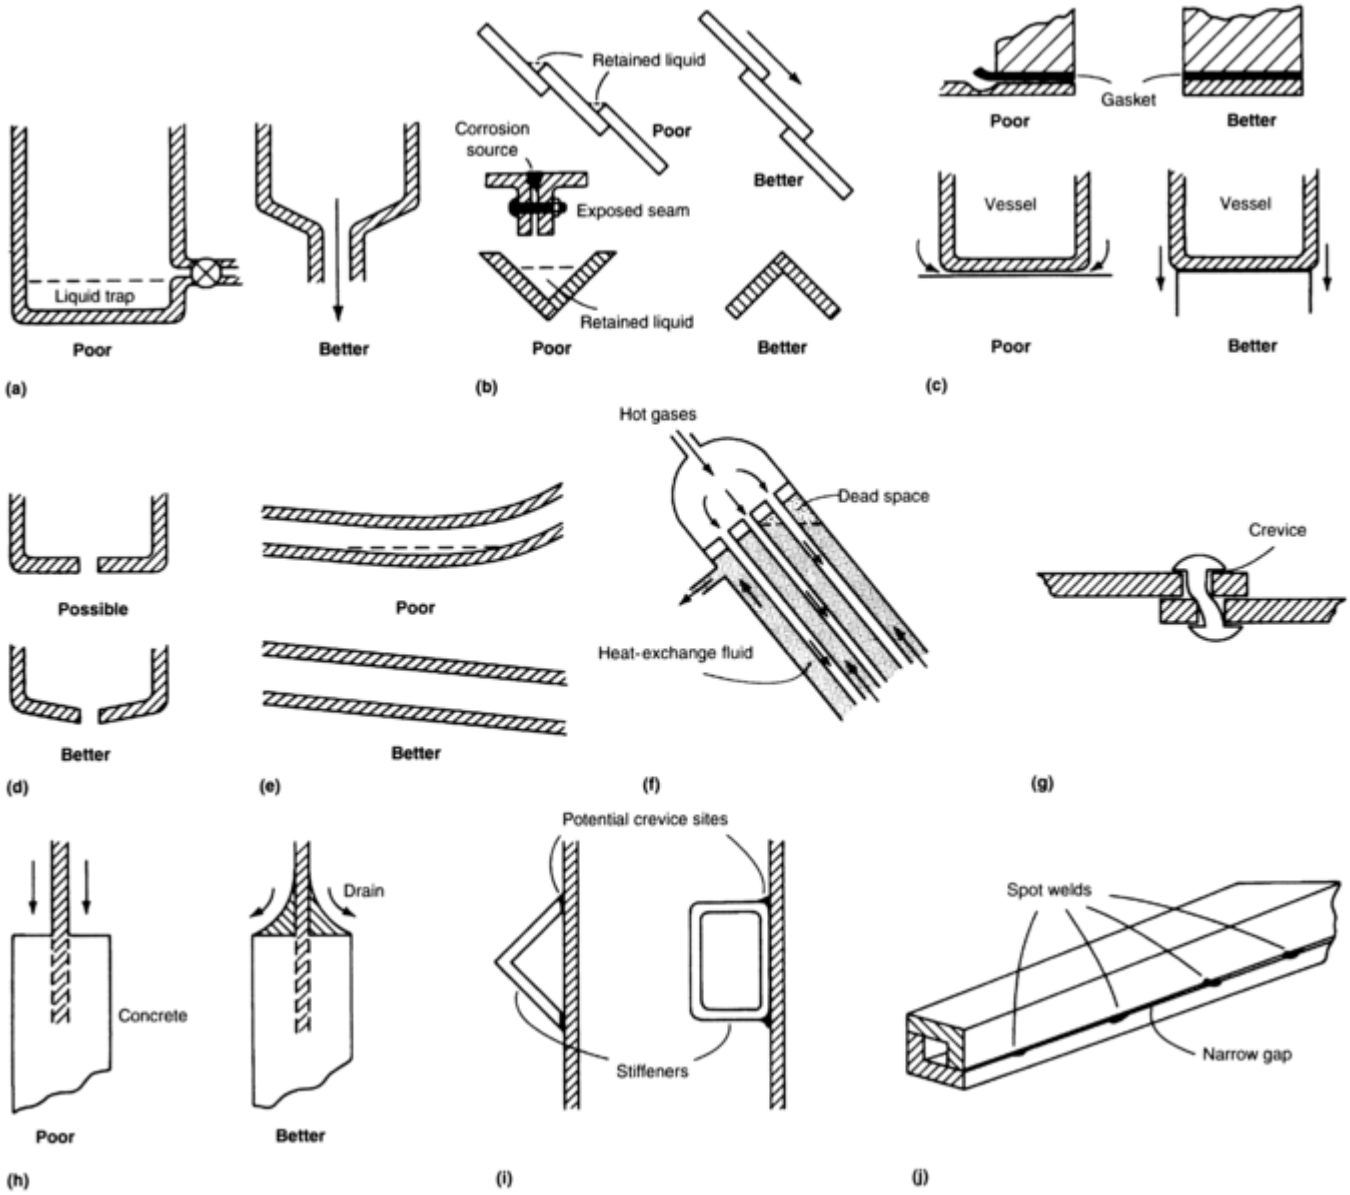

Fig. 5 Examples of how design and assembly can affect localized corrosion by creating crevices and traps where corrosive liquids can accumulate. (a) Storage containers or vessels should allow complete drainage; otherwise, corrosive species can concentrate in vessel bottom, and debris may accumulate if the vessel is open to the atmosphere. (b) Structural members should be designed to avoid retention of liquids; L-shaped sections should be used with open side down, and exposed seams should be avoided. (c) Incorrect trimming or poor design of seals and gaskets can create crevice sites. (d) Drain valves should be designed with sloping bottoms to avoid pitting of the base of the valve. (e) Nonhorizontal tubing can leave pools of liquid at shutdown. (f) to (j) Examples of poor assembly that can lead to premature corrosion problems. (f) Nonvertical heat-exchanger assembly permits dead space that is prone to overheating if very hot gases are involved. (g) Nonaligned assembly distorts the fastener, creating a crevice that can result in a loose fit and contribute to vibration, fretting, and wear. (h) Structural supports should allow good drainage; use of a slope at the bottom of the member allows liquid to run off, rather than impinge directly on the concrete support. (i) Continuous weld for horizontal stiffeners prevents traps and crevices from forming. (j) Square sections formed from two L-shape members need to be continuously welded to seal out the external environment.

Movement. Fluid movement need not be excessive to damage a material. Much depends on the nature of the fluid and the hardness of the material. A geometric shape may create a sustained delivery of fluid or may locally disturb a laminar stream and lead to turbulence. Replaceable baffle plates or deflectors are beneficial where circumstances permit their use; they eliminate the problem of impingement damage to the structurally significant component.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Careful fabrication and inspection should eliminate or reduce poor profiles (e.g., welds, rivets, and bolts), rubbing surfaces (e.g., wear, fretting), and galvanic effects due to the assembly of incompatible components. Figure 6 shows typical situations in which geometric details influence flow.

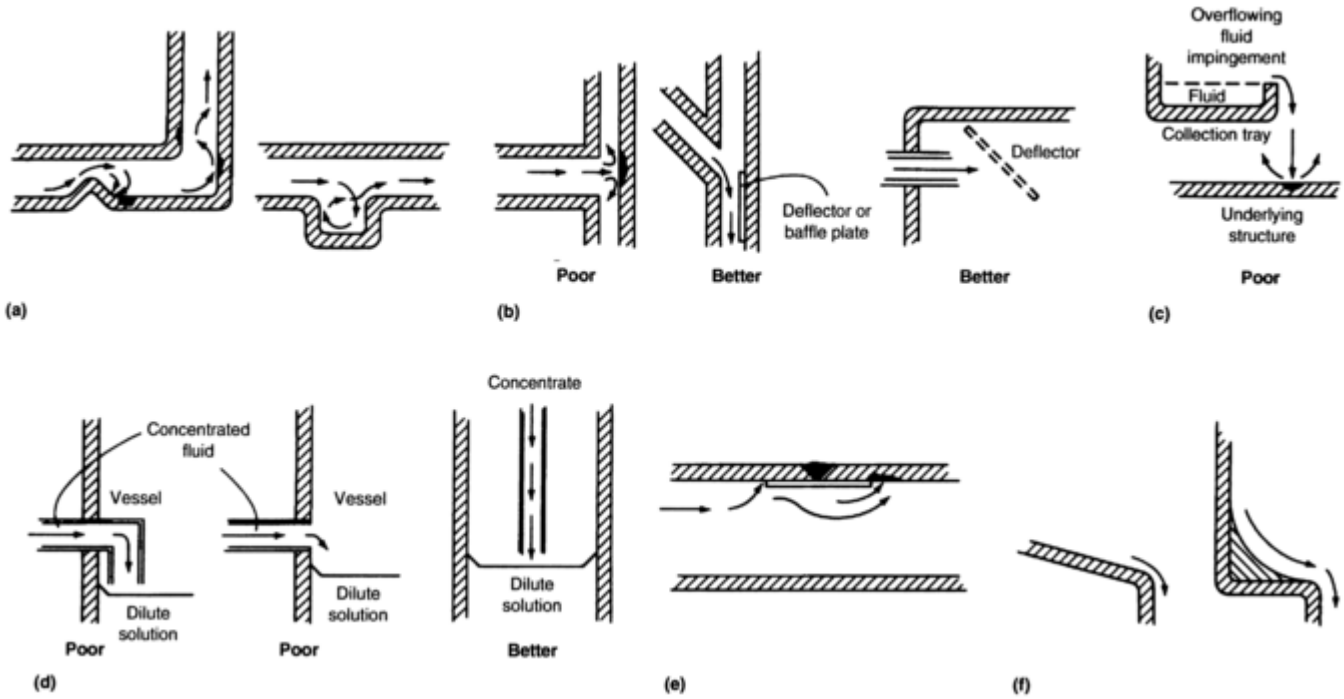

Fig. 6 Effect of design features on flow. (a) Disturbances to flow can create turbulence and cause impingement damage. (b) Direct impingement should be avoided; deflectors or baffle plates can be beneficial. (c) Impingement from fluid overflowing from a collection tray can be avoided by relocating the structure, increasing the depth of the tray, or using a deflector. (d) Splashing of concentrated fluid on container walls should be avoided. (e) Weld backing plates or rings can create local turbulence and crevices. (f) Slope or modified profiles should be provided to permit flow and minimize fluid retention.

Compatibility. In plant environments, it is often necessary to use different materials in close proximity. Sometimes, components that were designed in isolation can end up in direct contact in the plant (Fig. 7). In such instances, the ideals of a total design concept become especially apparent but usually in hindsight. Direct contact of dissimilar metals introduces the possibility of galvanic corrosion, and small anodic (corroding) areas should be avoided wherever this contact is apparent.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

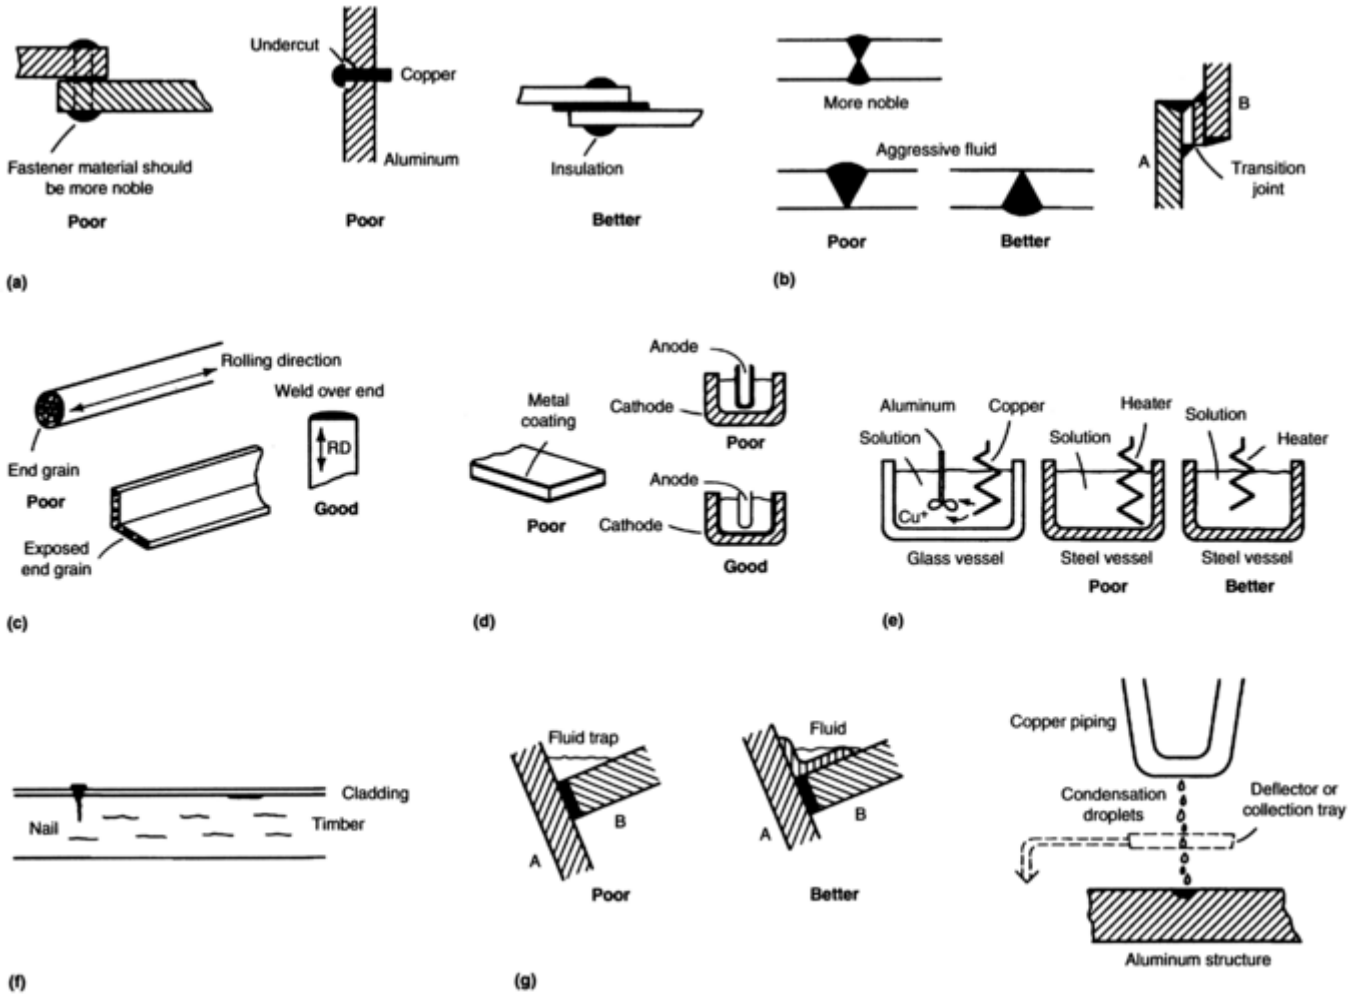

Fig. 7 Design details that can affect galvanic corrosion. (a) Fasteners should be more noble than the components being fastened; undercuts should be avoided, and insulating washers should be used. (b) Weld filler metals should be more noble than base metals. Transition joints can be used when a galvanic couple is anticipated at the design stage, and weld beads should be properly oriented to minimize galvanic effects. (c) Local damage can result from cuts across heavily worked areas. End grains should not be left exposed. RD, rolling direction. (d) Galvanic corrosion is possible if a coated component is cut. When necessary, the cathodic component of a couple should be coated. (e) Ion transfer through a fluid can result in galvanic attack of less noble metals. In the example shown at left, copper ions from the copper heater coil could deposit on the aluminum stirrer. A nonmetallic stirrer would be better. In the center, the distance from a metal container to a heater coil should be increased to minimize ion transfer. (f) Wood treated with copper preservatives can be corrosive to certain nails, especially those with nobility different from that of copper. Aluminum cladding can also be at risk. (g) Contact of two metals through a fluid trap can be avoided by using a drain, collection tray, or a deflector.

Galvanic corrosion resulting from metallurgical sources is well documented. Problems such as weld decay and sensitization can generally be avoided by materials selection or suitable fabrication techniques. Less obvious instances of localized attack occur because of end-grain attack and stray-current effects, which can render designs ineffective.

End-grain attack, or preferential attack of grains exposed by crosscutting through a metal plate or rod (Fig. 7c), occurs in many corrosive fluids. An example is the cut edges and punched- out holes in a stainless steel reactor tray (Fig. 8).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

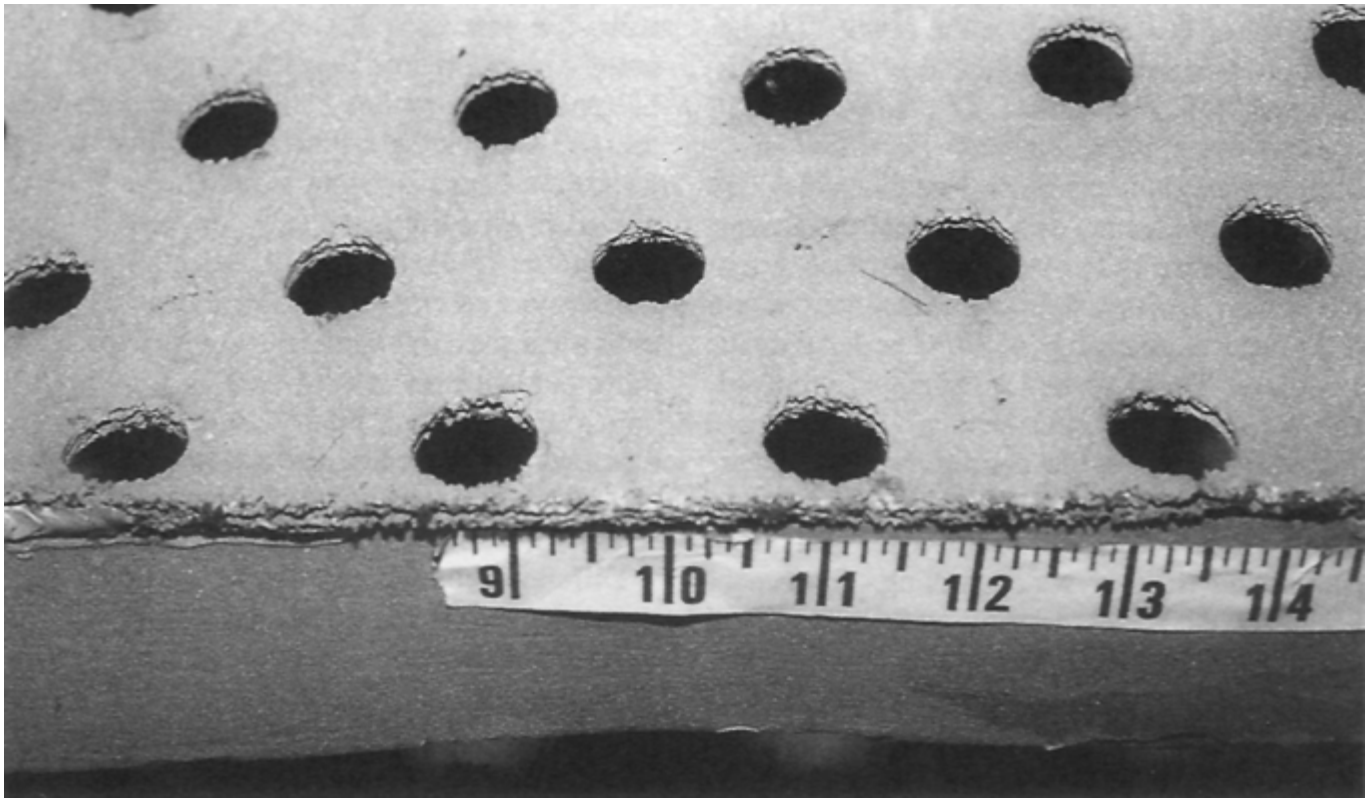

Fig. 8 End-grain corrosion along cut edges and punched holes in a reactor tray made from type 316 (Unified Numbering System, or UNS, S31600) stainless steel

Stray-current effects are common on underground iron or steel pipelines that are located close to electrical supply lines, or where stray currents can cause active corrosion at preferred sites. For example, stray-current attack caused a titanium flange spacer to become anodic during service due to inappropriate grounding of welding equipment on an adjacent part of the plant structure.

Designers, when aware of compatibility effects, need to exercise their ingenuity to minimize the conditions that most favor increased corrosion currents. Table 4 provides some suggestions.

Table 4 Sources of increased corrosion currents and related design considerations

Source	Design considerations
Metallurgical sources (both within the metal and for relative contact between dissimilar metals)	Difference in potential of dissimilar materials; distance apart; relative areas of anode and cathode; geometry (fluid retention); mechanical factors (e.g., cold work, plastic deformation, sensitization)
Environmental sources	Conductivity and resistivity of fluid; changes in temperature; velocity and direction of fluid flow; aeration; ambient environment (seasonal changes, etc.)
Miscellaneous sources	Stray currents; conductive paths; composites (e.g., concrete rebars)

Galvanic corrosion is a potential problem when designs include jointed assemblies (Fig. 5, 7). Where dissimilar metals are to be used, some consideration should be given to chosing compatible materials with similar potentials. Care should be exercised, because the galvanic series is limited and refers to specific environments, usually seawater.

Where noncompatible materials are to be joined, it is advisable to use a more noble metal in a joint (Fig. 7b). Effective insulation can be useful if it does not lead to crevice corrosion. Some difficulties arise in the use of adhesives, which are not usually sealants.

The relative surface areas of anodic and cathodic surfaces should not be underestimated, because corrosion at a small anodic zone can be several hundred times greater than that for the same bimetallic components of similar area. As noted previously, synergistic effects must also be recognized, such as failure resulting from a

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

combination of galvanic and crevice attack. One failure was attributed to the unfortunate choice of a carbon steel bolt to tighten a spindle support for a stainless steel paddle stirrer (Fig. 9). The result was crevice corrosion at the stirrer support (Fig. 3), which was exacerbated by the galvanic action caused by the carbon steel/stainless steel metal- to-metal contact.

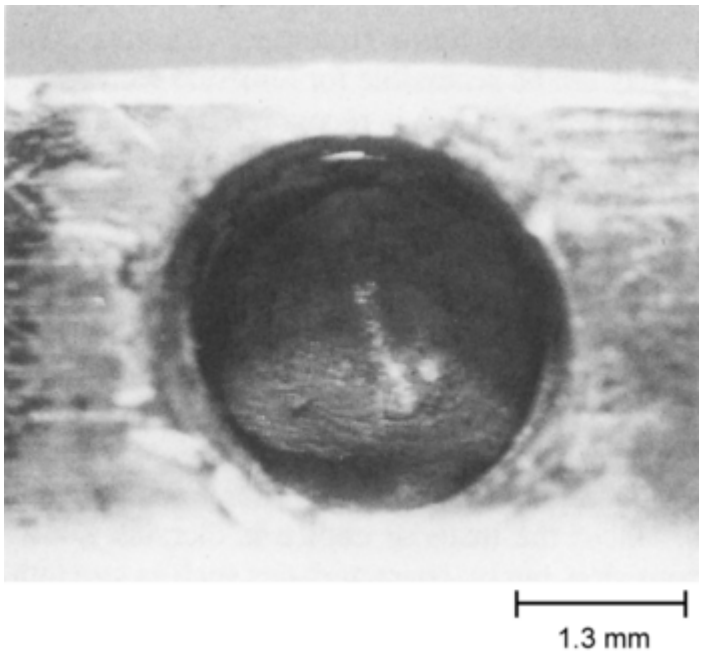

Fig. 9 The incorrect choice of a carbon steel retaining bolt for a stainless steel spindle resulted in localized galvanic corrosion of the paddle-stirrer assembly (Fig. 3).

Less obvious examples of galvanic corrosion occur when ion transfer results in the deposition of active and noncompatible deposits on a metal surface. For example, an aluminum stirrer plate used in water was extensively pitted because a copper heater coil (Fig. 7e) heated the water bath. The pits resulted from deposition of copper ions from the heater element. Localized corrosion of zinc-coated steel results from contact of water droplets falling from copper pipe onto galvanized ducting (Fig. 10). More rapid but similar damage occurred when a dental aspirator (Teflon-coated aluminum) was attacked by mercury from a tooth filling. These two metals rank as a high-risk combination for galvanic corrosion (see Fig.1 in the article “Electroplated Coatings” in this Volume). The aluminum section was rapidly pitted, once sharp fragments of tooth enamel first wore away the synthetic fluorine-containing resin.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 10 Initiation of corrosion (white rust) on galvanized ducting by water droplets, accelerated by galvanic corrosion due to copper ions in solution from overhead copper pipes

An anodic component can, on occasion, be initially overdesigned (made thicker) to allow for the anticipated corrosion loss during its service life. In other instances, easy replacement is a cost-effective option (Table 1).

Where metallic coatings are used, there may be a risk of galvanic corrosion, especially along the cut edges. Rounded profiles and effective sealants or coatings are beneficial. Transition joints can be introduced when different metals are to be in close proximity. These and other situations are illustrated in Fig. 7. Another possibility is coating of the cathodic material for corrosion control. Ineffective painting of an anode in an assembly can significantly reduce the desired service lifetime, because local defects (anodes) effectively multiply the risk of localized corrosion.

Corrosion Under Insulation. Insulation can create an area for potential corrosion attack, although most problems arise because of poor installation. Insulation types and properties vary considerably, and expert advice from suppliers is recommended. The most common corrosion problems include crevice corrosion (where insulation and/or adhesives are tightly held against a metal surface, for example, when straps or ties are too tight) and pitting corrosion (where moisture condenses on the metal, usually because the insulation barrier was too thin or was improperly installed). Moisture-absorbing tendencies vary from one insulation to another (Ref 47).

Wet-dry cycling has been known to lead to concentration effects (e.g., chloride ions from calcium silicate insulation). There have been reported instances of chloride stress-corrosion cracking (SCC) in certain stainless steel pipes and vessels, or pitting of these and other materials, such as aluminum, when contacted by insulation. The early instances of SCC failure were mainly attributable to high chloride levels (500 to 1500 ppm) associated with asbestos-type materials. The chloride levels have been significantly reduced in recent years to a level that is not expected to cause SCC. Standards are now available, as are tests to evaluate insulation materials

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

(Ref 48). A parallel German standard calls for zero nitrite content and <0.2% ammonia levels in elastomeric insulation that is used for copper and copper alloy piping, to reduce the risk of SCC (Ref 49).
Figure 11 shows some typical examples in which design and installation procedures could have been improved. Other problems occur when insulation is torn or joints are misaligned or incorrectly sealed with duct tape or similar bandaging, none of which is recommended by insulation suppliers.

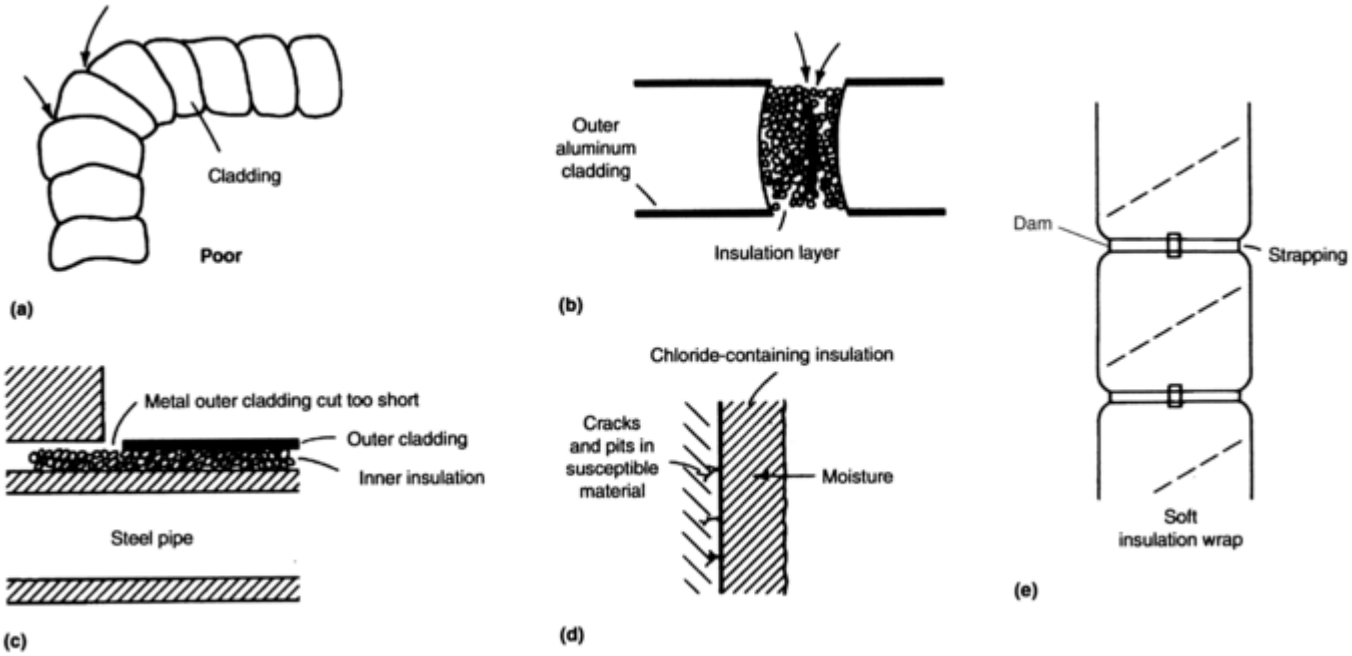

Fig. 11 Corrosion problems associated with improper use of insulation and lagging. (a) Incorrect overlap in lobster-back cladding does not allow fluid runoff. (b) Poor installation left a gap in the insulation that allows easy access to the elements. (c) Outer metal cladding was cut too short, leaving a gap, with the inner insulation exposed. (d) Insufficient insulation can allow water to enter; chloride in some insulation can result in pitting or stress-corrosion cracking of susceptible materials. (e) Overtightened strapping can damage the insulation layer and cause fluid dams on vertical runs.

Stress. From a general design philosophy, environments that promote metal dissolution can be considered more damaging if stresses are also involved. In such circumstances, materials can fail catastrophically and unexpectedly, with safety and health implications.
A classic example of chloride SCC occurred in a type 304 (Unified Numbering System, or UNS, S30400) stainless steel vessel (Fig. 12). The stress-corrosion cracks extended radially over the area where a new flanged outlet was welded into the vessel. Residual stresses (from flame cutting) and the fluids inside the vessel (acidic with chlorides) were sufficient to cause this failure in a matter of weeks.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

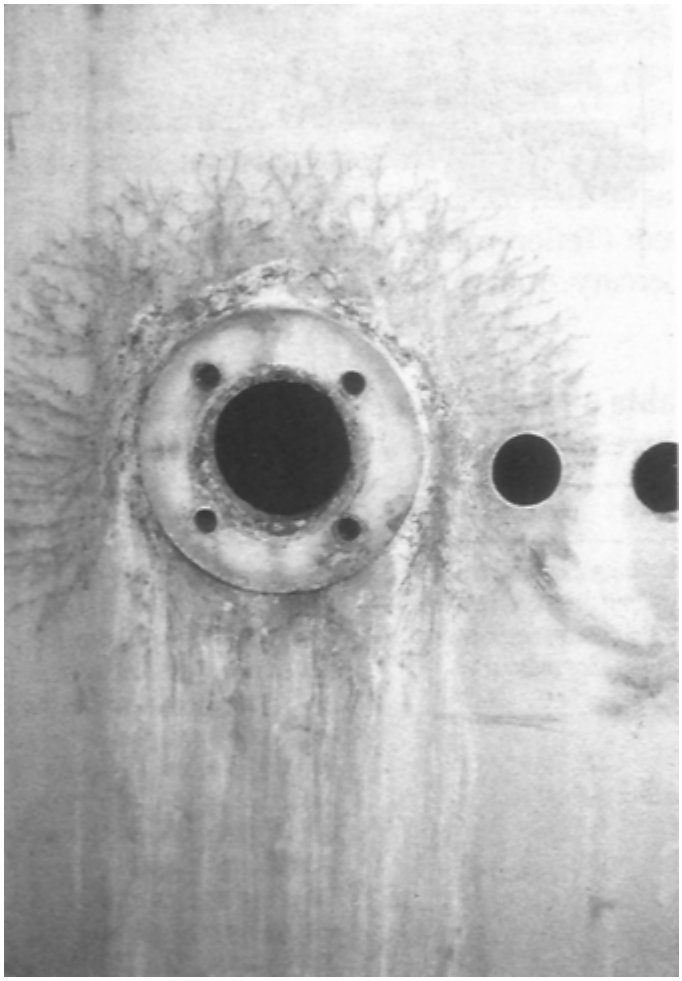

Fig. 12 Chloride stress-corrosion cracking in a type 304 (Unified Numbering System, or UNS, S30400) stainless steel vessel after a new flange connection was welded into place

Figure 13 shows examples of using design detail to minimize stress. Perfection is rarely attained in general practice, and some compromise on materials limitation, both chemical and mechanical, is necessary. Mechanical loads can contribute to corrosion, and corrosion (as a corrosive environment) can initiate or trigger mechanical failure. Designs that introduce local stress concentrations directly or as a consequence of fabrication should be carefully considered.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

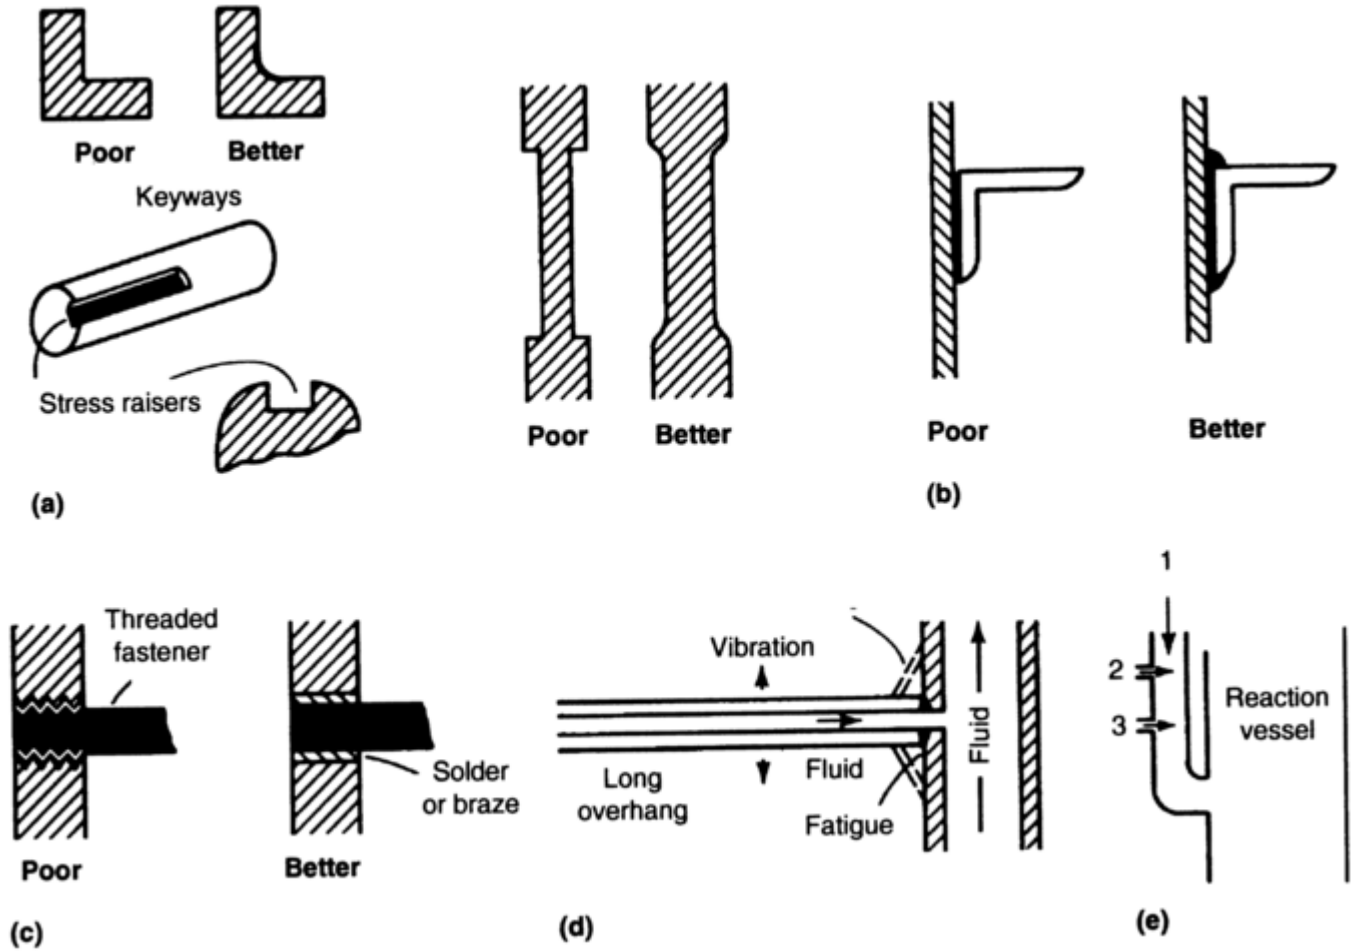

Fig. 13 Design details that can minimize local stress concentrations. (a) Corners should be given a generous radius. (b) Welds should be continuous to minimize sharp contours. (c) Sharp profiles can be avoided by using alternative fastening systems. (d) Too long an overhang without a support can lead to fatigue at the junction. Flexible hose may help alleviate this situation. (e) Side-supply pipework may be too rigid to sustain thermal shock from a recurring sequence that involves (1) air under pressure, (2) steam, and (3) cold water.

Of particular importance in design are stress levels for the selected material: the influence of tensile, compressive, or shear stressing; alternating stresses; vibration or shock loading; service temperatures (thermal stressing); fatigue; and wear (fretting, friction). Profiles and shapes contribute to stress-related corrosion, especially if materials selection dictates the use of materials that are susceptible to failure by SCC or corrosion fatigue (Ref 2, 3, 50).

Materials selection is especially important wherever critical components are used. Also important is the need for correct procedures at all stages of operation, including fabrication, transport, storage, startup, shutdown, and normal operation.

Surfaces. Corrosion is a surface phenomenon, and the effects of poorly prepared surfaces, rough textures, and complex shapes and profiles can be expected to be deleterious (Ref 39). Figure 14 shows some examples in which design details could have considerably reduced the onset of corrosive damage resulting from ineffective cleaning or painting.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

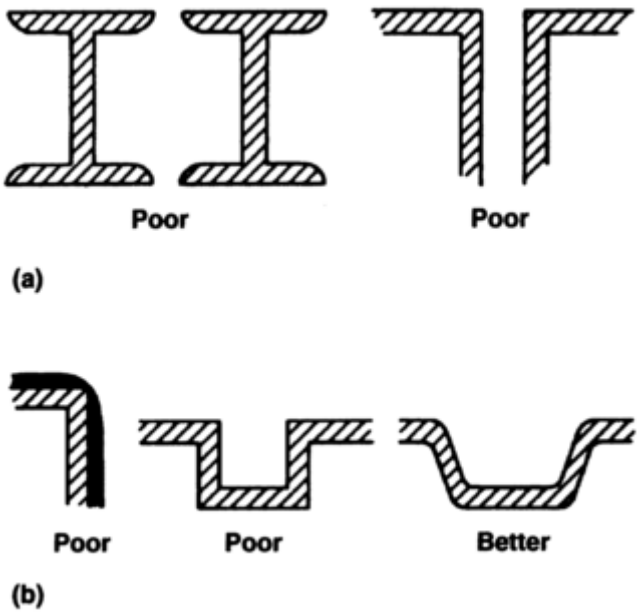

Fig. 14 Effects of design on effectiveness of cleaning or painting. (a) Poor access in some structures makes surface preparation, painting, and inspection difficult; access to the types of areas shown should be maintained at a minimum of 45 mm (1.75 in.) or one-third of the height of the structure. (b) Sharp corners and profiles should be avoided if the structure is to be painted or coated.

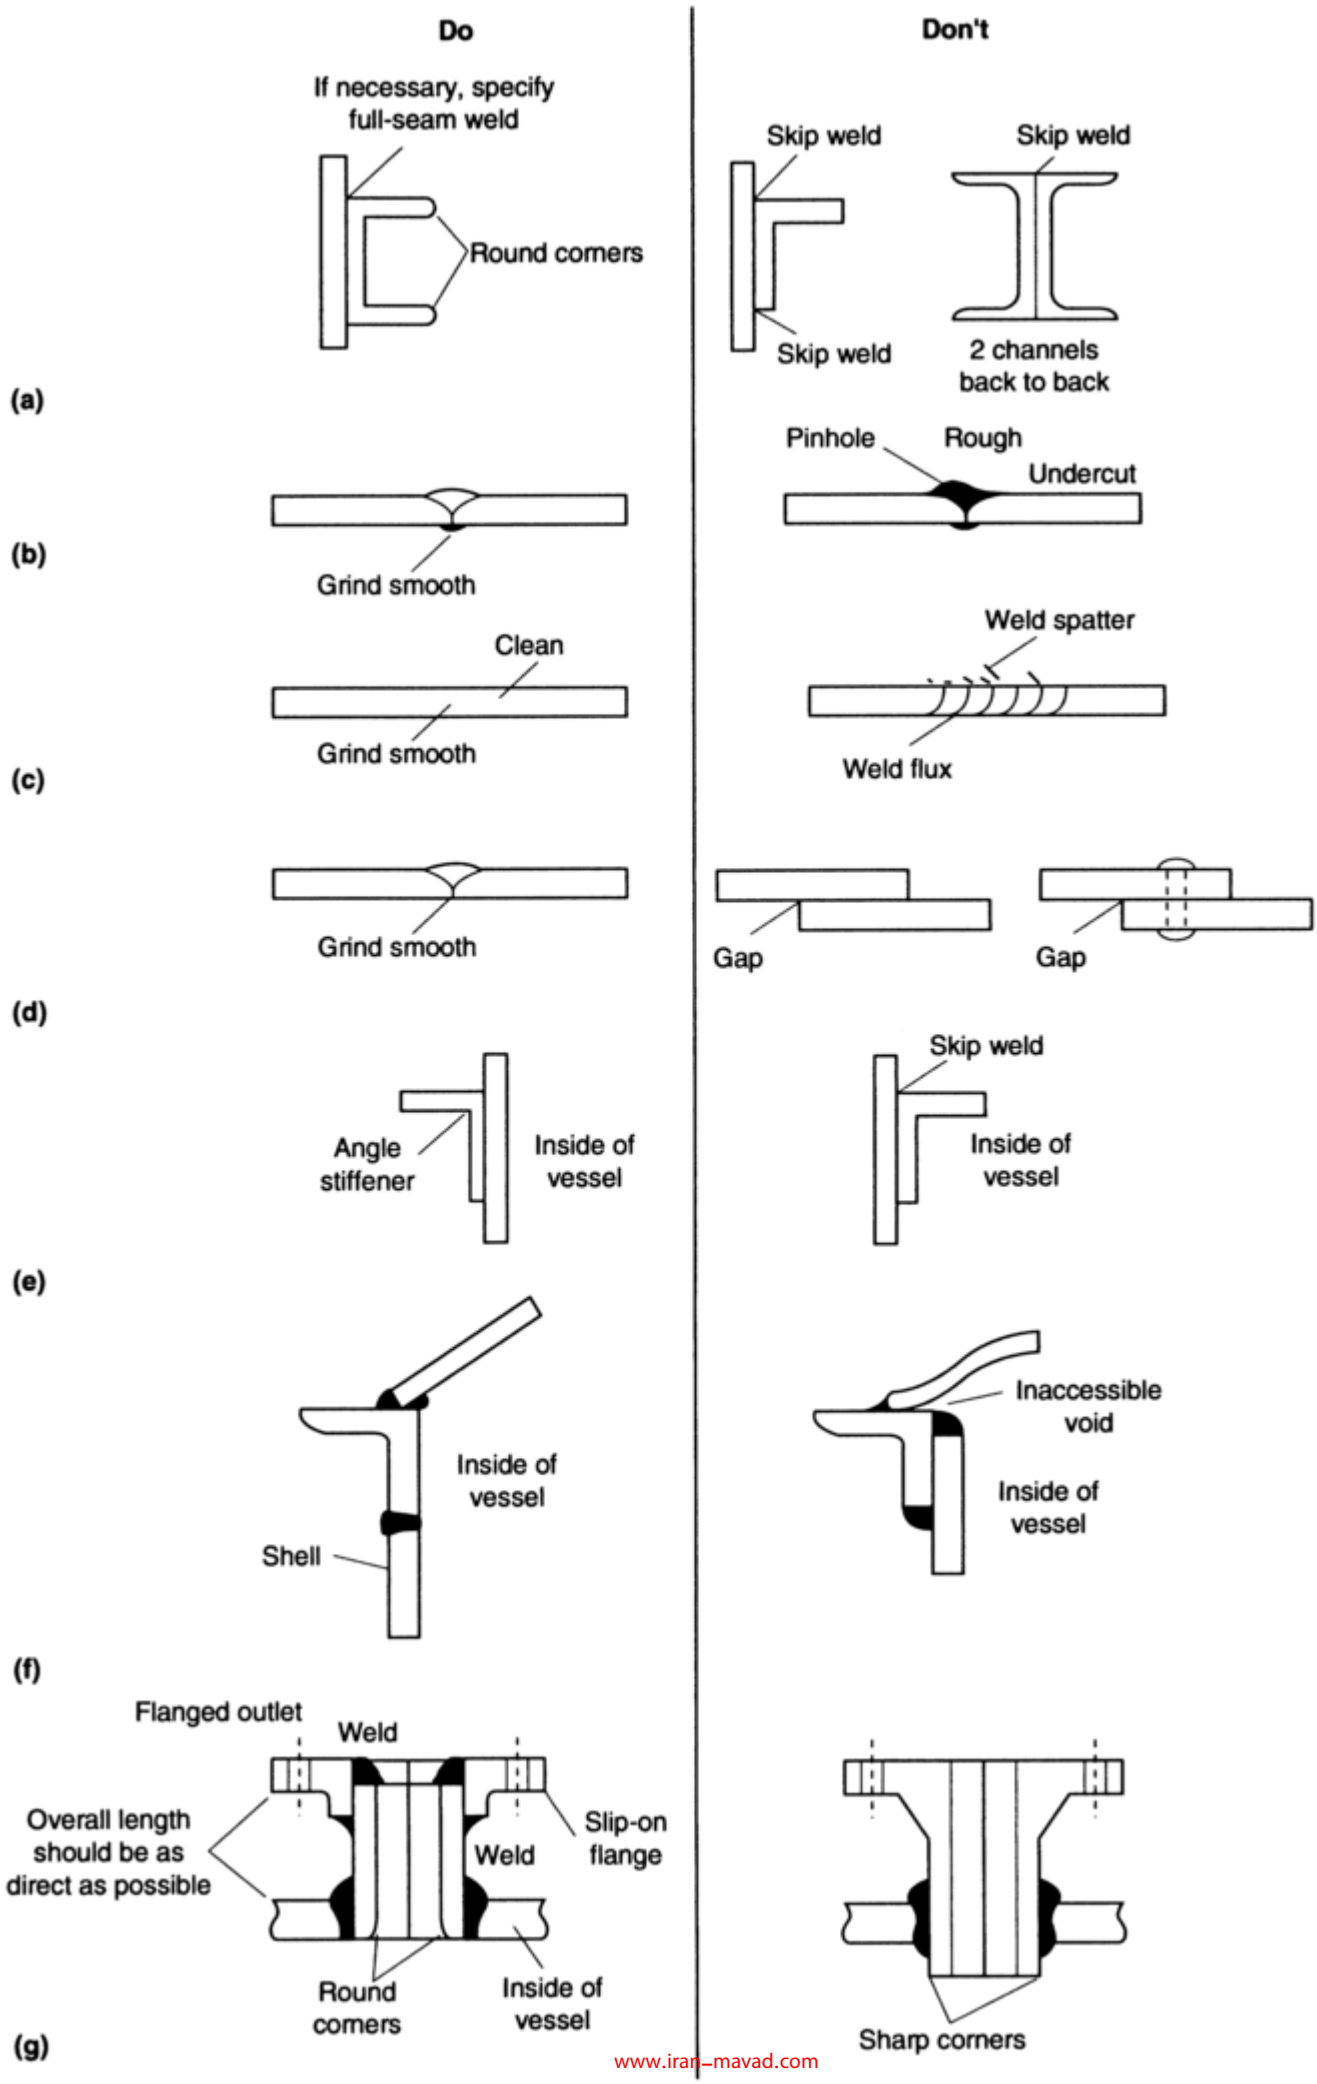
Designs should provide for: surfaces that are free from deposits; access to remove retained soluble salts before painting; free-draining assemblies; proper handling of components to minimize distortion, scratches, and dents; and properly located components relative to adjacent equipment (to avoid carryover and spillages). Other recommended procedures for coating constructional materials are shown in Fig. 15 (Ref 40).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 15 Suggestions for steel construction to be coated. (a) Avoid pockets or crevices that do not drain or cannot be cleaned or coated properly. (b) Joints should be continuous and solidly welded. (c) Remove weld spatter. (d) Use butt welds rather than lap welds or rivet joints. (e) Keep stiffeners to outside of tank or vessel. (f) Eliminate crevice (void) at roof-to-shell interface in nonpressure vessel. (g) Outlets should be flanged or pad type, not threaded. Where pressure limits allow, slip-on flanges are preferred, because the inside surface of the attaching weld is readily available for radiusing and grinding. Source: Ref 40

Neglect and poor (or no) maintenance caused localized pitting on the underside of a type 304 stainless steel vessel lid that was exposed to high humidity, steam, and chloride vapors. Access in this example was possible but not used. Common engineering structural steelwork requires regular preventive maintenance, and restricted access makes this impossible. Figure 14 shows situations in which surface cleaning and/or painting is difficult or impossible.

A less recognized but serious corrosion phenomenon (formicary corrosion) results from oil residues remaining on copper surfaces, for example, from lubricating oils used in finning or forming operations. Formicary corrosion, also known as ant-nest corrosion because of the nature of the microscopic damage in the metal (Fig. 16), occurs when oxygen, moisture, and a specific corrodent, usually an organic acid, are simultaneously present on a copper surface (Ref 51, 52, 53). Damage is worse if fluids are stagnated in crevices. Formicary corrosion has been attributed to many corrodent sources, including synthetic lubricating oils, degreasing and cleaning fluids, braze fluxes, volatile species from timber and building materials, liquid smoke, certain vegetable oils, and cosmetics. Carboxylic acids (formic, acetic, and propionic) are the most common acids associated with formicary corrosion. Damage can occur in weeks, and the site of attack is usually so localized and microscopic that it is not obvious to the unaided eye.

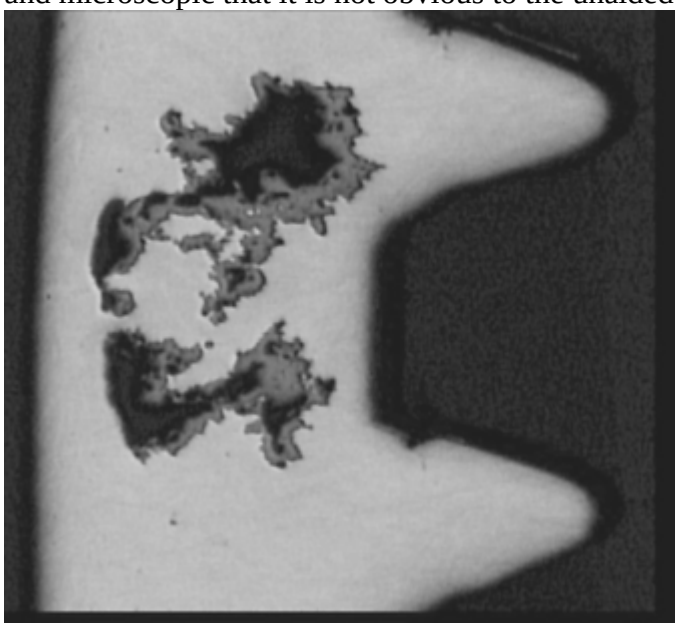


Fig. 16 Formicary (ant-nest) corrosion in a copper air conditioning tube

Condensation in critical areas can contribute to corrosion. Typical structures susceptible to this phenomenon include automobile exhaust systems and chimneys or exhausts from high- temperature plants, such as boilers, kilns, furnaces, or incinerators.

Painting and surface-coating techniques have advanced in recent years and have provided sophisticated products that require careful mixing and application. Maintenance procedures frequently require field application where some control (use of trained inspectors) is essential, as in offshore oil and gas platforms. Inspection codes and procedures are available, and total design should incorporate these wherever possible. In critical areas, design for on-line monitoring and inspection will also be important.

The human factor in maintenance procedures is often questionable. Adequate training and motivation are of primary importance in ensuring that design details are appreciated and implemented.

Corrosion Economic Calculations

Introduction

ENGINEERING ECONOMY is a discipline that can be used to assist engineers and engineering managers in measuring the economic impact of their decisions on the financial goals of a business. Basically, engineering economy is concerned with money as a resource and as the price of other resources. Business success requires the prudent and efficient use of all resources, including money. The principles of engineering economy permit direct comparisons of potential alternatives in monetary terms. In this way, they encourage efficient use of resources.

Corrosion is basically an economic problem. Thus, the corrosion behavior of materials is an important consideration in the economic evaluation of any project. It is not always wise to select the material with the lowest initial cost, because the initial cost is not necessarily the last cost. Overall costs include maintenance, downtime, time value of money, tax aspects, and obsolescence.

This article discusses the principles and terminology of engineering economy and their application to a number of generic corrosion-related problems. Several of these problems appeared in NACE standard RP0272 (Ref 1).

Corrosion Economic Calculations, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 940–945

Money and Time

Consider the effects of time and earning power on $20. If $20 is placed in the bank and earns interest at a rate of 5% per year, it grows to $21 when the interest, $1, is paid at the end of the year. Thus, $20 today at 5% is equivalent to $21 a year from now. Stated another way, in order to have $21 one year from now, only $20 need be deposited today if the interest rate is 5%. The $20 is termed the discounted present value of the $21 needed 1 year from now. The initial deposit as well as the earned interest left in the account have earning power, because the interest is compounded, which means that it is computed on both the principal and the accrued interest.

Suppose the $20 were used to pay four equal, annual installments of $5 each. Without interest, the $20 would be exhausted after making the last payment. If the $20 is deposited in the bank at 5% interest, it will be worth $21 at the end of the first year. Paying out $5 would leave $16 to be held at interest the second year. The $16

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

invested at 5% will earn $0.80 in 1 year. Subtracting $5 from $16.80 leaves $11.80 to be held at 5% interest for the third year. A sum of $11.80 will earn $0.59 by the end of the third year at 5%. Another annual payment of $5 leaves $7.39 to earn interest during the fourth year. Adding the $0.37 interest earned during the fourth year and subtracting the final $5 annual payment leaves a balance of accrued interest of $2.76.

The earning power of money permits another strategy. If the initial deposit were reduced to $17.73 at 5% interest, $5 can be paid out each year for 4 years, leaving nothing. This example illustrates the distinction between the terms *equivalent* and *equal.* Twenty dollars is equal to four payments of $5 each. It would also be equivalent to four $5 annual payments (only) if the interest rate were 0. The $17.73 is not equal to the sum of four payments of $5 each. However, when $17.73 is invested at 5%, it is equivalent to four annual payments of $5.

The term *equivalent* implies that the concept of the time value of money is applied at some specific interest rate. Therefore, for an amount of money to have a precise meaning, it must be fixed both in time and amount. Mathematical formulas and tables are available to translate an amount of money at any particular time into an equivalent amount at another date.

Many kinds of translations are possible. For example, a single amount of money can be translated into an equivalent amount at either a later or an earlier date. This is accomplished by calculating the present worth (PW) or the future worth (FW) as of the present date. Single amounts of money can be translated into equivalent annuities, *A*, involving a series of uniform amounts occurring each year. Conversely, annuities can be translated into equivalent single amounts at an earlier or later date. The present worth of an annuity, *P*/*A*, is the single amount of money equivalent to a future annuity. The single amount equivalent to a past annuity is referred to as the future worth of an annuity, *F*/*A*.

It also is possible to calculate the amount of money that would be equivalent to a nonuniform series of cash flows. Two types of nonlinear series that find application are an arithmetic progression, in which the series changes by a constant amount, and a geometric progression, in which the series changes by a constant rate. The arithmetic progression is considered to be representative of variable costs, such as maintenance costs, which may increase as equipment ages. The geometric progression is used to represent the effects of inflation or deflation.

Notation and Terminology

American National Standards Institute (ANSI) standard Z94.5 (Ref 2), a compilation of the symbology and terminology of the field, offers to practitioners the improved communication benefits of standardization. A redesignation and consolidation standard of Z94.5 with other standards is proposed, with the title “Modeling and Analysis,” BSR Z94.5.

Table 1 lists the definitions and symbols used for parameters. Table 2 lists functional forms of compound interest factors. Table 3 is an explanatory supplement to Table 2, and it represents diagrams, algebraic forms, and uses for compound interest factors.

Table 1 Suggested standard definitions and symbols used for parameters

Definition of parameter	Symbol
Effective interest rate per interest period (discount rate)	*i*
Nominal interest rate per year	*r*
Number of compounding periods	*n*
Number of compounding periods per year	*m*
Present sum of money. The letter *P* implies present (or equivalent present value).	*P*

18.	Continuous compounding capital recovery factor (continuous, uniform payments)	$\frac{re^{rn}}{e^{rn}-1} = \frac{(1+i)^n\ln(1+i)}{(1+i)^n-1}$	Given *P*, to find *A*
19.	Continuous compounding compound amount factor (continuous, uniform payments)	$\frac{e^{rn}-1}{r} = \frac{(1+i)^n-1}{\ln(1+i)}$	Given *A*, to find *F*
20.	Continuous compounding present worth factor (continuous, uniform payments)	$\frac{e^{rn}-1}{re^{rn}} = \frac{(1+i)^n-1}{(1+i)^n\ln(1+i)}$	Given *A*, to find *P*

The basic form of the notation used for all time value factors consists of a ratio of two letters representing two amounts of money—for example, *P*/*A* or *F*/*P*—plus an interest rate, *i*%, and a number of periods, *n*. These are customarily written as (*P*/*A*, *i*%, *n*) or (*F*/*P*, *i*%, *n*). The present worth, *P*, of a known annuity, *A*, can also be expressed as:

$P = A(P/A)$ (Eq 1)

Or the future worth, *F*, of a known present amount, *P*, as:

$F = P(F/P)$ (Eq 2)

Other forms are also common, such as PW( ) or FW( ), which are called operators, because they represent some computational operation, such as the present worth or future worth of whatever is inside the parentheses.

It should be evident that (*F*/*P*) is the reciprocal of (*P*/*F*) and that (*F*/*A*) and (*A*/*F*) are also reciprocals. This observation is useful, because it means that only three time factors need to be tabulated in order to conduct six operations. Another algebraic relationship shows that if two time value factors are multiplied, the product is a third time value factor. For example:

$(A/F)(P/A) = (P/F)$ (Eq 3)

Methods of Economic Analysis

Economic analysis methods that concern the entire service life are sometimes called life-cycle-cost methods. Those methods that lead to single measure numbers include:

- Internal rate of return (IROR)
- Discounted payback (DPB)
- Present worth (PW), also referred to as net present value (NPV)
- Present worth of future revenue requirements (PWRR)
- Benefit-cost ratios (BCR)

All five methods use the concept of present worth. Although each method has certain advantages, the individual methods vary considerably with regard to their application and complexity.

The IROR method compares the initial capital investment with the present worth of a series of net revenues or savings over the anticipated service life. Expenses include operation, maintenance, taxes, insurance, and overheads but do not include return on (or of) the invested capital. From an economic standpoint, IROR consists essentially of the interest cost on borrowed capital plus any existing (positive or negative) profit margin. The disadvantage of this measure of economy is that it ignores benefits extending beyond the assumed life of the equipment and thus may omit a substantial part of the actual service life. This may lead to unnecessarily pessimistic measures of long-range economy.

The PWRR method is particularly applicable to regulated public utilities, for which the rates of return are more or less fixed by regulation. It is also applicable where it has already been determined by IROR analysis that a project is economically viable; the engineer must determine which is the most economic alternative under circumstances in which several alternatives produce the same revenue, with some creating less expense (requirement for revenue) than others and consequently a greater profit margin (or lower losses). The principal objection to the PWRR method is that it is inadequate where alternatives are competing for a limited amount of capital, because it does not identify the alternative that produces the greatest return on invested capital.

The DPB and BCR methods are somewhat more complicated than the PWRR method. The BCR method is similar to the IROR method in that both require that alternatives be examined not only for economic measures compared to a “do nothing” scenario but also for incremental measures associated with incremental capital investments.

The PW method, also referred to as the net present value method, is considered the easiest and most direct of the five methods and has the broadest application to engineering economy problems. Many industries refer to this method as the discounted cash flow method of analysis. This method is often used to test the results of other methods of analysis. Therefore, because this method is often preferred, it is given primary attention in this article.

Annual versus Continuous Compounding

For completeness, Tables 1, 2, and 3 contain formulas involving annual and continuous compounding. Because actual cash flow (both inward and outward) is continuous, continuous compounding might seem to be the more accurate assumption for engineering economy studies. In reality, although the overall cash flows tend to be continuous, the cash flow data are seldom precise enough in economy studies to take full advantage of continuous compounding. It is also true that the normal purpose of the economy study is to analyze some specific event that will occur at a specific time; therefore, a procedure that is readily associated with a specific time seems appropriate. For these reasons, and because it is conceptually easier to understand and apply, annual compounding is used in this article.

The present worth method is a form of discounted cash flow in which cash flow data (which must include dates of receipts and disbursements) are discounted to present worth. Before applying these methods, a management decision must be made regarding the desired life (usually expressed as a number of years, *n*) and the minimum acceptable rate of return on invested capital for a project (expressed in terms of the effective interest rate, *i*, or the nominal rate of return, *r*). Rates of return (before taxes) vary among industries, ranging from 10 to 15% where obsolescence is not high to 25 to 40% (or perhaps higher) for more dynamic industries. It would be convenient if the minimum acceptable rate of return were known in advance of making engineering economy analyses; however, it is not always easy to learn what rate of return is considered to be acceptable. Under such circumstances, it is helpful to prepare a series of economic alternatives in which the rate of return is varied in order to provide management with options.

Applying the Present Worth Method. To illustrate the features of this method, it is determined whether an expenditure of $15,000 should be made to reduce labor and maintenance from $8200 to $5100 per year. Money is worth 10%, and the life of the project is 10 years. The effects of taxes and depreciation have been omitted for simplicity.

Table 4 shows the projected pattern of cash flow for plan A (the present method, which consists of paying $8200 per year for labor and maintenance) and for plan B (the proposed method, which consists of an initial expenditure of $15,000 plus $5100 per year for labor and maintenance over the life of the project). A minus sign means that money leaves the bank; a plus sign means that the bank balance increases in size. The net cash flow for each year appears in the right-hand column under the heading “B - A.”

Table 4 Tabulation of cash flow

Period, years	Plan A (the present method)	Plan B (the proposed method)	B - A, dollars
0	…	-15,000	-15,000
1	-8200	-5100	+3100
2	-8200	-5100	+3100
3	-8200	-5100	+3100
4	-8200	-5100	+3100
5	-8200	-5100	+3100
6	-8200	-5100	+3100
7	-8200	-5100	+3100
8	-8200	-5100	+3100
9	-8200	-5100	+3100
10	-8200	-5100	+3100
Totals	**-$82,000**	**-$66,000**	**+$16,000**

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Selection of plan B will result in a net positive cash flow; that is, the net amount of money in the bank is increased over the life of the project when plan B is selected. Before concluding that plan B should be implemented, it is necessary to reduce these cash flows to a common basis for comparison and to determine whether the objective of a 10% rate of return has been achieved. The present worth (or present value) of these cash flows provides such a basis. The rate of return for plan B is calculated by iteration, using interest tables and interpolating between values.

First Iteration. Assume a rate of return of 10% and refer to Table 5:

$$\begin{aligned} PW &= -15{,}000 + 3100\left(\frac{P}{A}, 10\%, 10 \text{ years}\right) \\ &= -15{,}000 + 3100(6.145) \\ &= +\$4047.95 \end{aligned} \qquad \text{(Eq 4)}$$

The rate of return for which the discounted cash flow is equal to 0 (that is, the first term on the right in Eq 4 is balanced by the second term) is the actual rate of return. From the first iteration, it is already evident that plan B returns in excess of 10%, because the net cash flow is positive. Thus, plan B is preferred. The numerical value of the actual rate of return can be determined by additional iterations. Such an exercise will reveal that the rate of return in this case is 16.1%.

In this example, plans A and B could represent alternative materials of construction having different corrosion rates, with the annual dollar difference being related to the consequences of corrosion on maintenance costs. This presupposes the availability of corrosion data that can be used to estimate expected life, maintenance costs, and so on. Other examples illustrate how to account for the effects of salvage value, taxes, and depreciation.

Corrosion Economic Calculations, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 940–945

Depreciation

Depreciation has been defined as the lessening in value of an asset with the passage of time. All physical assets (except land) depreciate with time. There are several types of depreciation. Two of the more common types are physical depreciation and functional depreciation. Accidents can also cause loss of value, but this cause is often accommodated in other ways, such as insurance and reserves, and therefore is not considered in this article.

Physical depreciation includes such phenomena as deterioration resulting from corrosion, rotting of wood, bacterial action, chemical decomposition, and wear and tear, which can reduce the ability of an asset to render its intended service. Functional depreciation does not result from the inability of an asset to serve its intended purpose but rather from the fact that some other asset is available that can perform the desired function more economically. Thus, obsolescence, inadequacy, and/or the inability to meet the demands placed on the asset lead to functional depreciation. Technological advances produce improvements that often result in the obsolescence of existing assets.

The manner in which depreciation can be accounted for is largely a tax question. The tax laws specify the procedures that are permissible. Because tax laws change occasionally, procedures that are attractive under a given set of circumstances may become unattractive (or even forbidden) under other circumstances. Some of the more common methods of depreciation include:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- Straight line
- Declining balance
- Declining balance switching to straight line
- Sum of the year's digits
- Accelerated cost recovery system (ACRS) and the modified accelerated cost recovery system (MACRS)

The straight-line depreciation method assumes that the value of an asset declines at a constant rate. If the original cost *P* of the asset was $6000 and the asset had a salvage value *S* of $1000 after a service life of 5 years, the annual depreciation would be ($6000 - 1000)/5 = $1000 per year. Annual depreciation *D* can be expressed as:

$$D = (P - S)/n \qquad \text{(Eq 5)}$$

The book value of the asset would decrease at the end of each year by the amount of the annual depreciation until, at the end of the fifth year, the book value would be the same as the salvage value.

The declining-balance method assumes that the asset depreciates more rapidly during the early years of its service life than in the later years. A certain percent depreciation is applied each year to the remaining book value of the asset. Under these circumstances, the size of the depreciation declines with each successive year until the asset is fully depreciated.

The sum of the year's digits method assumes that the value of an asset decreases at a decreasing rate. Assume that an asset has a 5 year life. The sum of the year's digits equals 1 + 2 + 3 + 4 + 5 = 15. For the $6000 asset mentioned previously, which has a salvage value after 5 years of $1000, depreciation for the first year would be ($6000 - 1000) (5/15) = $1666.67. Depreciation for the second year would be ($6000 - 1000) (4/15) = $1333.33, and so on, until the asset is fully depreciated.

Other Methods. For property placed in service after 1980 and before 1987, the ACRS prescribed a different method for recovering the cost of depreciable property. In 1987, the ACRS was modified and became known as the MACRS. There are presently certain bonuses in effect, so the current tax codes must be consulted.

Corrosion Economic Calculations, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 940–945

Generalized Equations

It is possible to prepare generalized equations that will simplify the solution of a large percentage of engineering economy problems. These equations take into account the influence of taxes, depreciation, operating expenses, and salvage value in the calculation of present worth and annual cost. Using these equations, a problem can be solved merely by entering data into the equations with the assistance of the compound interest tables and solving for the unknown value. The tax rate *t* is expressed as a decimal. Operating expense is represented by *X*. The letter *S* represents salvage value. The other symbols are explained in Tables 1, 2, and 3.

For straight-line depreciation:

$$\begin{aligned} \mathrm{PW} = -P &+ \left\{\frac{t(P-S)}{n}\right\}\left(\frac{P}{A}, i\%, n\right) \\ &- (1-t)(X)\left(\frac{P}{A}, i\%, n\right) \\ &+ S\left(\frac{P}{F}, i\%, n\right) \end{aligned} \qquad \text{(Eq 6)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

where *P*, the first term, is the cost at time zero of the initial investment. The value at time zero is a definition of present worth (at time zero). Therefore, it is not necessary to translate this amount to another date, because the evaluation will be made as of time zero. The investment involves flow of money out of the bank; therefore, the sign of this term is minus.

The second term in Eq 6 concerns depreciation. The depreciation method will influence the mathematical formation of this term. The portion enclosed in braces expresses the annual amount of tax credit permitted by this method of depreciation—in this case, straight-line depreciation. The portion in parentheses translates these equal annual amounts back to time zero by converting them to present worth. The ACRS and MACRS depreciation methods allow specific straight-line depreciation options. When one of these options is chosen, the formulation of this term remains the same as shown previously, with the exception that salvage is ignored. If the straight-line option is not chosen, this term in the generalized formula becomes a series of terms, each having the tax rate multiplied by the appropriate depreciation percentage of the initial cost (in accordance with Table 6) multiplied by the appropriate single-payment present worth factor, *P*/*F*, for the applicable year and interest rate. The sum of these terms will represent the effect of depreciation on present worth.

Table 6 Depreciation percentages for the modified accelerated cost recovery system (MACRS)

Recovery year	Recovery period, years					
	3	**5**	**7**	**10**	**15**	**20**
1	33.33	20.00	14.29	10.00	5.00	3.750
2	44.45	32.00	24.49	18.00	9.50	7.219
3	14.81	19.20	17.49	14.40	8.55	6.677
4	7.41	11.52	12.49	11.52	7.70	6.177
5	…	11.52	8.93	9.22	6.93	5.713
6	…	5.76	8.92	7.37	6.23	5.285
7	…	…	8.93	6.55	5.90	4.888
8	…	…	4.46	6.55	5.90	4.522
9	…	…	…	6.56	5.91	4.462
10	…	…	…	6.55	5.90	4.461
11	…	…	…	3.28	5.91	4.462
12	…	…	…	…	5.90	4.461
13	…	…	…	…	5.91	4.462
14	…	…	…	…	5.90	4.461
15	…	…	…	…	5.91	4.462
16	…	…	…	…	2.95	4.461
17	…	…	…	…	…	4.462
18	…	…	…	…	…	4.461
19	…	…	…	…	…	4.462
20	…	…	…	…	…	4.461
21	…	…	…	…	…	2.231

This schedule is for the half-year convention. Quarter-year convention is also allowed. This schedule is for example only. See current tax code.

The third term in Eq 6 actually consists of two terms. One is [(*X*)(*P*/*A*, *i*%, *n*)], which represents the cost of items properly chargeable as expense, such as the cost of maintenance or insurance and the cost of inhibitors. Because this term involves expenditure of money from the bank, it carries a minus sign. The term [*t*(*X*)(*P*/*A*, *i*%, *n*)] accounts for the tax credit for this business expense. Because it represents a savings, the sign is plus.

The fourth term translates the anticipated (future) value of salvage to present value. This is a one-time event rather than a uniform series and therefore involves the single-payment present worth factor. As noted previously, the ACRS and MACRS depreciation methods ignore the salvage value of an asset; therefore, when using these methods, the fourth term is 0.

Present worth can be converted to equivalent annual cost *A* by:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$A = (\mathrm{PW})\left(\frac{A}{P},\ i\%,\ n\right) \qquad \text{(Eq 7)}$$

Alternative materials with the same life can be compared from an engineering economy standpoint merely by comparing the magnitude of their present values. However, if the candidate materials have different life expectancies, it is necessary to convert present worth to equivalent annual cost *A* to compare the materials from an engineering economy standpoint. The material with the lowest annual cost is the material of choice.

Corrosion Economic Calculations, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 940–945

Examples and Applications

Example 1 A new heat exchanger is required in conjunction with a rearrangement of existing facilities. Because of corrosion, the expected life of a carbon steel exchanger is 5 years. The installed cost is $9500. An alternative to the carbon steel heat exchanger is a unit fabricated of American Iron and Steel Institute (AISI) type 316 stainless steel with an installed cost of $26,500 and an estimated life of 15 years to be written off in 11 years. The minimum acceptable rate of return is 10%, the tax rate is 48%, and the depreciation method is straight line. It is necessary to determine which unit would be more economical based on annual costs.

Because the lives of the two heat exchangers are unequal, the economic choice cannot be based merely on the discounted cash flow over a single life of each alternative. Instead, comparison must be made on the basis of equivalent uniform annual costs, commonly referred to as annual cost, as mentioned previously. In this example, data are given for only the first two terms of Eq 6. The third term, which involves maintenance expense, and the fourth term involving salvage value are both assumed to be 0.

The first step is to compute the discounted cash flow over one life span for each alternative. This involves calculation of the present worth for each material:

(Eq 8)

$$\mathrm{PW}_{316} = -\$26{,}500 + \left\{0.48\frac{(26{,}500 - 0)}{11}\right\}(6.495) \qquad \text{(Eq 9)}$$

$$= -\$18{,}989$$

To compare the two alternatives, both discounted cash flows (the present worths) must be converted to annual costs:

$$A_{\text{steel}} = -\$6043(0.2638) \qquad \text{(Eq 10)}$$

$$= -\$1594$$

$$A_{316} = -\$18{,}989(0.15396) \qquad \text{(Eq 11)}$$

$$= -\$2924$$

Therefore, the carbon steel heat exchanger, which has the lower annual cost, is the more economical alternative under these conditions.

Example 2 In this case, the carbon steel heat exchanger in Example 1 will require $3000 in yearly maintenance (painting, use of inhibitors, cathodic protection, and so on). This example determines whether carbon steel would remain the preferred alternative under these conditions.

Maintenance costs are treated as expense items with a 1 year life (end-of-year costs). This example involves the third term in Eq 6. In Example 1, the annual cost without the yearly maintenance cost was calculated; therefore,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

in this example, the annual cost including maintenance ($3000 per year) can be obtained simply by subtracting the after-tax maintenance costs from the result given in Example 1:

$$A_{steel} = -\$1594 - (1 - 0.48)(\$3000) = -\$3154 \quad \text{(Eq 12)}$$

Because this is an after-tax cash flow, the quantity [(1 - 0.48)($3000)] is the after-tax maintenance cost; 0.48 is the tax rate expressed as a decimal. The $3000 is the present value of the maintenance for the first year; therefore, no further discounting is necessary in this case. Comparing this result with the annual cost of AISI type 316 stainless steel in Example 1, it is evident that if $3000 is required each year to keep the carbon steel unit operative, the stainless steel unit would be more economical.

Example 3 Given the conditions described in Example 1, this example determines the service life at which the carbon steel heat exchanger is economically equivalent to the type 316 stainless steel unit if it is not certain that a 5 year life will be attained for unprotected carbon steel.

The carbon steel heat exchanger will be economically equivalent to the type 316 stainless steel heat exchanger when their annual costs are equal. Therefore, the problem can be solved by determining how many years of life for steel will be equivalent to an annual cost of $2924. Trial- and-error methods are useful for such problems. Trying n = 3 years gives:

$$PW_{steel} = -\$9500 + \left\{0.48\frac{(9500 - 0)}{3}\right\}(2.487) = -\$5719 \quad \text{(Eq 13)}$$

$$A_{steel} = -\$5719(0.40211) = -\$2300 \quad \text{(Eq 14)}$$

Trying n = 2 years yields:

$$PW_{steel} = -\$9500 + \left\{0.48\frac{(9500 - 0)}{2}\right\}(1.736) = -\$5542 \quad \text{(Eq 15)}$$

$$A_{steel} = -\$5542(0.57619) = -\$3193 \quad \text{(Eq 16)}$$

Thus, a carbon steel heat exchanger must last more than 2 years but will be economically favored in less than 3 years under the conditions given.

Example 4 Under the conditions described in Example 3, it is determined how much product loss X could be tolerated after 2 of the 5 years of anticipated life, for example, from roll leaks or a few tube failures, before the selection of type 316 stainless steel could have been justified. Equating:

$$A_{316} = A_{steel} + A_{product\ loss}$$
$$-\$2924 = -\$1594 + [(1 - 0.48)(X)(0.8264)][0.2638] \quad \text{(Eq 17)}$$

Solving for X:

$$-\$1330 = 0.1134(X)$$
$$X = -\$11,728 \quad \text{(Eq 18)}$$

The term (1 - 0.48) will be recognized from the third term of Eq 6 as (1 - t), where t is the tax rate. The quantity 0.8264 is the single-payment present worth factor (P/F, 10%, 2 years) and translates the product loss X to its present worth at time zero. The quantity [0.2638] is the uniform series capital recovery factor (A/P, 10%, 5 years) and translates the present worth of the product loss to annual cost so that it can be added to the annual cost of steel for comparison with the annual cost of AISI type 316 stainless steel. If production losses exceed $11,728 in year two (no losses in other years), the AISI type 316 heat exchanger could be justified.

Introduction

CORROSION FATIGUE has been identified as a significant safety issue in the world aircraft fleets. The in-flight failure of a large section of fuselage on an Aloha Airline Boeing 737 in 1988 is certainly a spectacular example of corrosion degradation exacerbating fatigue damage during normal aircraft operation (Ref 1). There is ample evidence that the deleterious effects of corrosion have significant maintenance and safety implications for the continued long-term operation of other aircraft, commercial and military (Ref 2), and for ground vehicles (Ref 3). This article addresses corrosion fatigue, its effects on the damage tolerance of aircraft, and its predictive modeling. A framework is presented that incorporates two distinctive cyclic-based life-prediction philosophies and expands them both to include the time domain in order to consider the effects of corrosion. The framework is presented in terms of its application to the aircraft industry, but it is applicable anywhere that structures require assessment in multiple complex environments, such as those often encountered by corrosion scientists and engineers.

Design Philosophies

Crack Initiation Used for Safe-Life Design

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Crack initiation (intended to represent the crack nucleation or formation process in metals) used in the safe-life design philosophy primarily focuses on the concept of designing structure to requirements that would result in crack-free structure for the life of the design. To achieve this goal, the state of local stress in the structure is limited to a maximum value as determined by crack initiation predictions (with appropriate scatter factors). These predictions consider the cyclic response of a structure to a design usage spectrum. This usage spectrum is often based on a critical *usage* point, resulting in a lower bound limit on fatigue life for analysis and testing. Typically, the structure is considered to have consumed its service life and is replaced when this fatigue life limit is reached, but exceptions are sometimes made if costly recurring inspection and maintenance programs are implemented.

The crack initiation methods used for these predictions are empirical and typically consist of equations correlated and fit to the specimen lives as limited by a specified crack length during coupon, element (a simple structural detail configuration specimen), and component tests. (This approach to qualification is detailed in the article "Testing and Analysis Correlation" in *Composites*, Volume 21 of *ASM Handbook*.) The test specimens should be manufactured under the same process specifications as the production structure and tested to the design usage spectrum intended to simulate the cycles expected in service. Using these prediction techniques and tools, each structural component is assumed to be capable of exceeding service-life requirements without initiation or nucleation of a crack greater than the specified length. This philosophy is reasonably effective in many applications when coupled with adequate safety factors, but the empirical nature of the philosophy does not allow external processes, such as corrosion, to have a quantifiable effect on the analyses.

Inspection and maintenance programs are based extensively on user-specific experience and operations. The adaptation of this to a different service usage may or may not be optimal; for example, one user may experience a hostile corrosive environment coupled with severe load spectrum requirements, while another user may experience a relatively benign environment and operational load spectra. Problems associated with severe operational spectra (environment and load) could differ significantly from relatively benign spectra. Hence, a successful maintenance program requires careful consideration of all operational environments, in addition to the load spectra, across the fleet.

Crack Growth Used for Damage Tolerance Philosophy

Crack growth methods, as used in the damage tolerance philosophy, primarily focus on the concept of designing and maintaining the structure to requirements that are perceived to ensure that the structure is capable of meeting service-life requirements with consideration for inherent, manufacturing, and accidental damage. To accomplish this, the approach requires analyses and tests using fracture mechanics techniques coupled with residual-strength analysis of the structure. The crack growth life of a component is influenced by the local state of stress as well as the gross section stress distribution. The residual strength ensures the ability of the structure to redistribute loads and tolerate particular levels of incremental damage by a ready detection prior to catastrophic failure. These prediction methods also consider the cyclic response of the structure to the design usage spectrum and environment. Typical design spectra are used to represent the average use of the structure.

The crack growth methods used for incremental crack growth predictions are based on theoretical solutions that have been developed and correlated with coupon, element, and component tests. The life predictions are calibrated to represent the effects of the geometries with the intended operational use. The life assessments are based on the time to grow an appropriate initial crack and/or the time from initial crack to failure of the structure. Components designed and analyzed using this philosophy are considered capable of meeting service-life requirements yet still are often inspected and maintained in order to use the full economic service life of the structure and/or to detect potential problems not captured in the design process.

The damage tolerance philosophy tailors the maintenance program to the operational usage for each particular component and aircraft. The methodology provides a measurable attribute, that is, detectable crack length in which to measure the remaining life of the structure. Although the intent is not to operate a structure with cracks, it is beneficial to understand the impact of potential cracking. Crack growth analyses are almost exclusively used to determine the inspection details and intervals, and problematic areas will often have fleetwide mandated inspections. The economies of these approaches are dependent on the customer's historical experience, fleet size, philosophy, logistics, and facilities.

Both of the previously mentioned two philosophies have been effective in providing a means to design, build, and maintain aircraft systems. Both philosophies have merits and can benefit from continuing advancements in

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

technology. The following framework attempts to establish a foundation on which both philosophies can be merged, enhanced, and incorporated with age- based structural degradations, such as corrosion, in order to better simulate damage progression and more accurately assess the economic service life of a structural component.

Conceptual Framework

Holistic Life Analysis

Technologies have matured sufficiently to allow improved incorporation of corrosion and age-degradation effects into a systematic damage tolerance (DT) framework (Ref 4). The integration of these technologies into current fleet management infrastructures, such as the United States Air Force (U.S.A.F.) Aircraft Structural Integrity Program (ASIP), is feasible. Combining the impacts of damage accumulation from operational stress excursions of a structure with the impacts of damage accumulation caused by environmental exposure while at rest or in operation is key to this holistic life analysis concept.

A conceptual framework that has the flexibility to represent material and structural behavior in two different domains is in development: the *cyclic crack growth domain* and the *time domain.* Just as time never stands still, the time domain is always active in this framework. Various damage progression scenarios, such as crevice-corrosion-induced pillowing and associated environmentally assisted cracking in lap joints, can and do occur when a structure is not in use. In this example, the material will thin, and residual stresses will increase to the point where structural integrity will be compromised sooner than predicted under safe-life or damage-tolerant philosophy. When the cyclic crack growth domain does become active, the solutions given by traditional damage tolerance analyses will be altered by combinations of thinned structure, accumulating residual stresses, and environmentally assisted crack growth.

The basic framework has been demonstrated on several levels, ranging from simple coupons, in which predicted lives of controlled corrosion fatigue experiments were correlated with the measured fatigue lives (Ref 5), to actual aircraft components, in which unanticipated field cracking problems were predicted and explained (Ref 6).

Although development of this framework has been focused on aircraft, the framework is readily adaptable to multiple flight vehicle systems as well as rail, automotive, and mechanical equipment systems. A description of the basic model framework is documented in Ref 7. The stages of holistic damage progression are schematically shown in Fig. 1.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

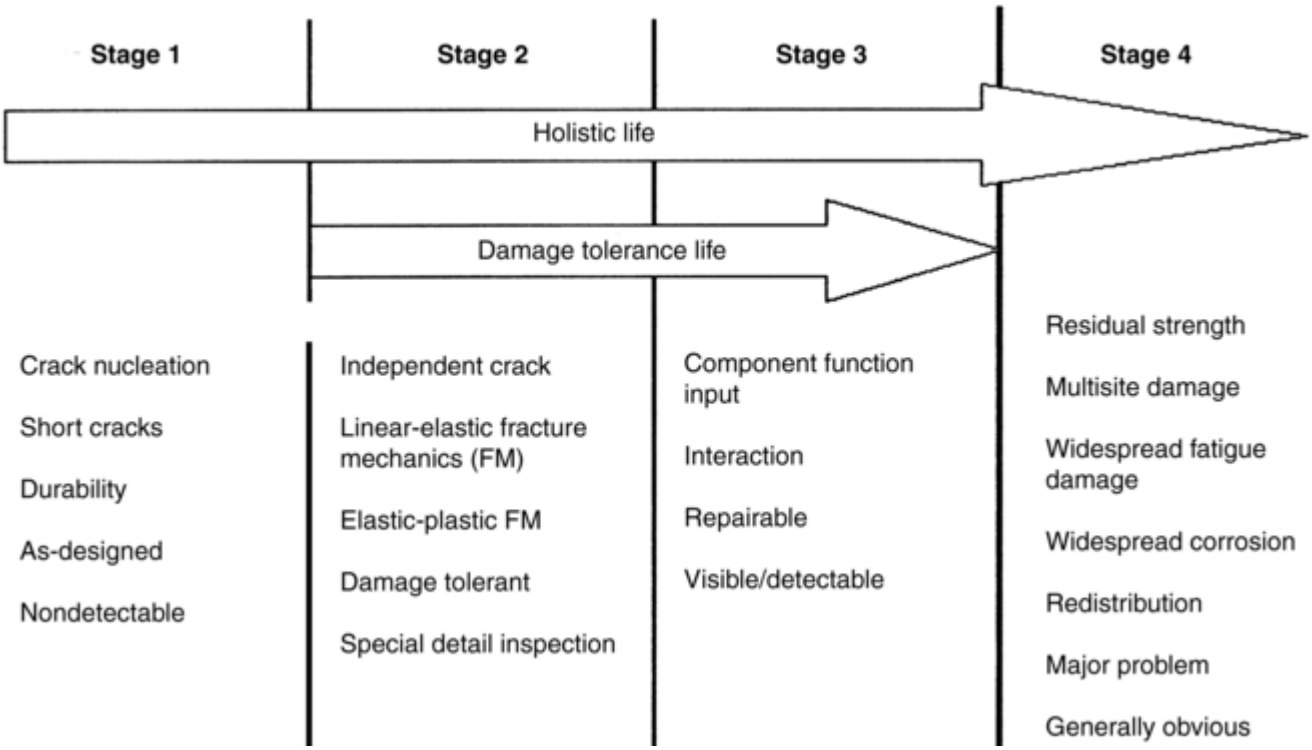

Fig. 1 Four stages of service life. The goal of the holistic approach is to account for all known effects, quantify them, and determine all states of damage from stage I (as-manufactured) through stage IV (too late). Cyclic damage from operating stress and age degradation, including corrosion, are considered.

Current damage tolerance procedures tend to focus on the center stages (stage II and III), whereas the holistic concept attempts to account for and compute age degradation with cyclic stress effects in all four stages. This allows analysts to account for critical stages when and where they are important, rather than forcing potentially conservative procedures at all locations.

Initial Discontinuity State

The initial discontinuity state (IDS) concept is the heart of holistic life analyses. The IDS concept is similar to the equivalent initial flaw size (EIFS) concept (Ref 8) first used in the early 1970s. In EIFS applications, flaw sizes are computed for the component, material, and load spectrum of interest; however, these flaw sizes seldom have any physical relationship to the features that cause failures in experiments. In the IDS framework, attempts are made to relate the IDS size distributions with the physical features that cause fatigue failures in pristine coupons. Researchers (Ref 9, 10) have shown that second- phase particles associated with fatigue failures in common aircraft aluminum alloys are among the largest particles present. The goal, then, is to try to link the material model to these features. A key difference between IDS and EIFS is that IDS should be coupled to the physical material features. These features can be determined and quantified for the alloy system and then consistently used within the analytical process that captures the probabilistic nature of the IDS. Also, the IDS concept uses more stringent requirements than the EIFS concept, such as:

- The material crack growth curves should be documented and available, along with their corresponding IDS distribution.
- Physical effects (such as plasticity and crack nucleation modes) on extreme value subsets of the IDS should be understood, helping enforce that the IDS distribution should be independent of stress ratio, maximum stress level, and global geometric stress concentrations when computations include the physical density of the IDS relative to the high-stress regions.

Note that the particle sizes that nucleate fatigue failure should follow an extreme-value distribution, one that represents the upper (largest discontinuity size) tail of an IDS distribution obtained by progressive sectioning and polishing. Some of the previously mentioned IDS requirements may need to be addressed by considering

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

the effects of the external parameters (maximum stress level, global stress concentrations) on both the sizes and the total volume of discontinuities exposed to those parameters.

Distributions of IDS sizes extracted from experimental data represent the number of cycles required to obtain known test termination events, for example, failure in coupon, in the material tested. The computed IDS sizes are derived from many stress ratios and at several different constant amplitude peak stresses and also represent several lots of the sheet material of interest. Ideally, the IDS distribution should be independent of constant amplitude test *R*-ratio (minimum applied stress divided by maximum applied stress) and maximum stress. The results characterize the statistical nature of the flaw sizes by using crack growth analysis techniques and approximate the time in the initial stages of crack formation.

To date, determination of IDS distributions has focused on two common aircraft aluminum alloys, 7075-T6 and 2024-T3. These distributions were determined several years ago through analysis of *MIL-Handbook 5* data (Ref 11) and, due to a lack of particle distribution information, the IDS was not tied to physical features. Results from the 2024-T3 sheet analysis are combined with similar 7075-T6 (bare) results (Ref 8) and fit to a Weibull distribution (Fig. 2) to represent the beginnings of a probabilistic-based framework. The specimens were smooth sections with low or no stress concentrations and thus represent bulk material behavior on a global scale. Test data obtained using specimens with stress concentrations, preferably open holes of sizes typical of fasteners, might provide more representative distributions of flaw size distributions applicable to fastener hole regions. The IDS distributions and their appropriate subsets represent the inherent condition of the as-manufactured material, and thus, any corrosion attack as well as the fatigue cycle crack extension will start from these quantifiable initial conditions. However, corrosion IDS subsets may be different from fatigue IDS subsets, as well as alloy dependent.

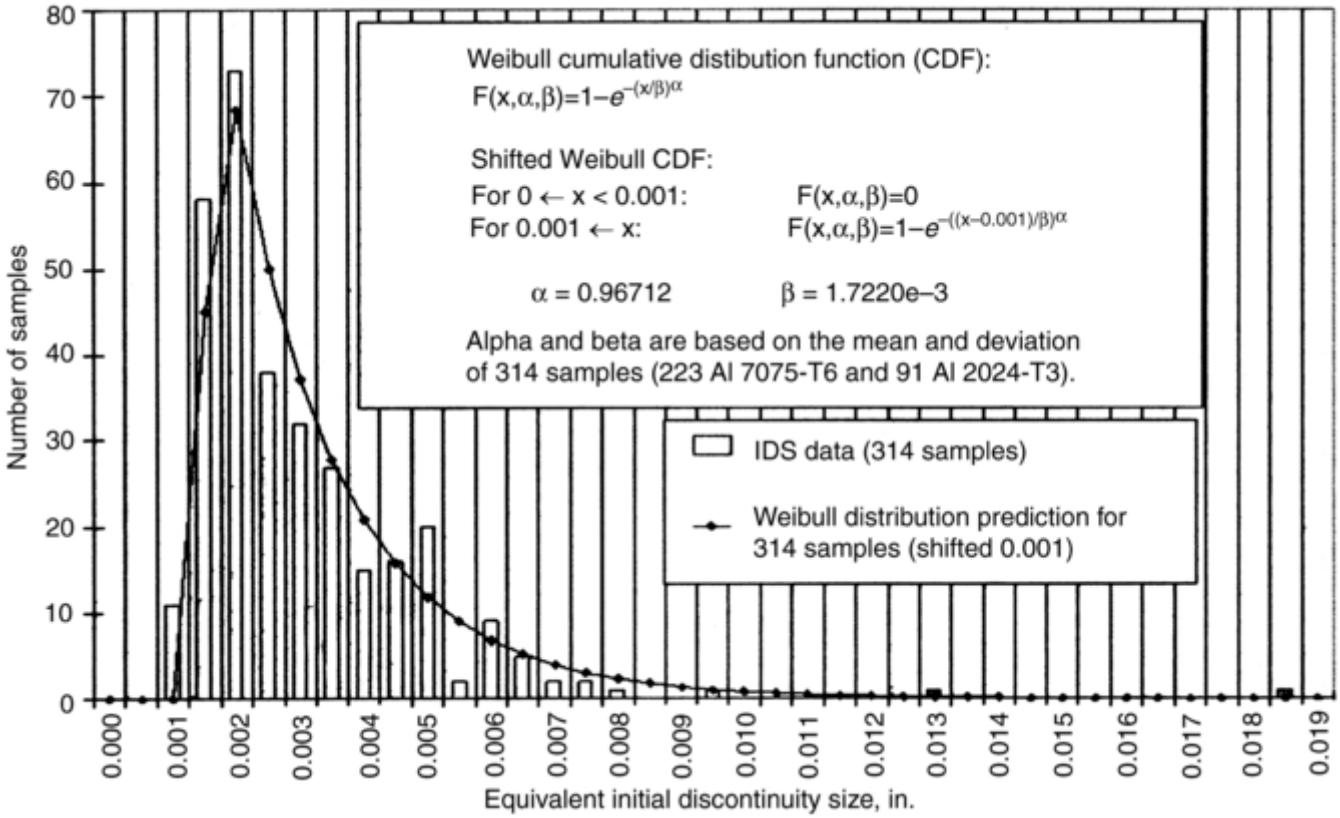

Fig. 2 Initial discontinuity state (IDS) distribution for 2024-T3 and 7075-T6 aluminum with the Weibull probability distribution. α is a scale parameter, and β is a shape parameter.

Age-Based Structural Degradation

Corrosion is defined as the chemical or electrochemical reaction between a material, usually a metal, and its environment that produces a deterioration of the material and its properties (Ref 12). Some common types of corrosion that affect structures are uniform or general corrosion, galvanic corrosion, pitting corrosion, and intergranular or exfoliation corrosion. In addition to these forms, corrosion often interacts with sustained loads

www.iran–mavad.com
مرجع مهندسی مواد و متالورژی

to cause stress-corrosion cracking. In other cases, corrosion may act conjointly with fatigue and work to accelerate both crack formation and propagation of fatigue cracks.

Corrosion is a challenging issue, because it can affect structures in a variety of ways. In severe forms of thinning attack, such as general corrosion and exfoliation, corrosion may degrade the static-strength capability of a structure. Such was the fate that befell a commercial airliner in 1981 (Ref 1, 13). Perhaps more perplexing, though, are the many corrosion and fatigue interactions. Only the first of the following definitions is standard:

- *Corrosion fatigue:* the process in which a metal fractures prematurely under conditions of simultaneous corrosion and repeated cyclic loading at lower stress levels or fewer cycles than would be required in the absence of the corrosive environment (Ref 12)
- *Corrosion-nucleated fatigue:* the process in which physical corrosion damage (e.g., exfoliation, pitting) and/or chemical damage (e.g., embrittlement) accelerates the formation of fatigue cracks in a component or structure. The corrosive environment need not be present during the time of fatigue cycling for this type of interaction to occur.
- *Prior-corrosion fatigue:* occurs when a propagating fatigue crack encounters a prior-corroded region. Note that a propagating fatigue crack in a prior-corroded region may be propagating by corrosion fatigue if an aggressive chemical environment is still present and assists in altering crack propagation in a synergistic manner.
- *Corrosion-induced fatigue via load transfer:* occurs when corrosion damage or environmental degradation in a structure causes load to be transferred to nearby structures. The increased stresses and strains associated with the transfer may exacerbate the situation and promote fatigue cracking. The concepts surrounding this last definition may seem obscure, but the review of case studies, such as the Aloha accident (Ref 1), helps reveal some of the ways in which this failure mode works.

In the development of holistic life analyses to date, intense focus has been placed on the impact of corrosion-nucleated fatigue, particularly from pitting and exfoliation damage. Inputs required are a physical description of the corrosion morphology and, in cases where corrosion is still active, corrosion rates. In situations where the corrosion is still active during fatigue cycling, the analyses cross over into pure corrosion fatigue.

Key to understanding the application of this framework to corrosion-nucleated fatigue, for instance, is visualizing how this prior-corrosion damage interacts with the foundation of holistic life analyses, the IDS. The next section expands on this interaction.

Interdependency of Corrosion and Fatigue

The interaction of corrosion and fatigue cracking is complex within the holistic life analysis model. Fatigue crack sizes change as a function of time, as does the topography of a corroded surface. This effect is captured by topography correction factors (TCFs) within the holistic analysis framework. In essence, TCFs take into account the effects of local stress raisers associated with corrosion damage. The TCFs are realized as an amplification to the geometric factor, β (also known as beta solution), to the stress- intensity factor, K_I, associated with the IDS. As an example, Fig. 3 shows the current modeling processes that account for the influence of pitting on the cyclic fatigue domain. The models that determine this influence are based on two-dimensional, closed-form fracture mechanics K_I for a single-edge through crack in uniaxially stressed infinite plate, shown at top right in Fig. 3. Important notes on the current modeling procedure include:

- The IDS is ever-present and is represented as a through crack of depth *a*.
- If exposed to fatigue (stress) cycling, the IDS may grow into a modified discontinuity state (MDS).
- If exposed to a corrosive environment, general attack, pitting, or exfoliation may form. No corrosion damage is allowed to consume or reduce the IDS or MDS (corrosion has rarely been shown to improve coupon fatigue life experimentally), so, at any point in time, the effects of a given topography on the fatigue domain are obtained by adding the pit depth, *d*, to the IDS or MDS depth.
- To eliminate the influence of backface corrections (finite width influences) on the TCFs, these solutions are based on infinitely thick plates, and the addition of the pit depth is shown above the initial reference measurement line for the IDS. This prevents the corrosion from consuming the IDS or MDS and prevents a shifting reference frame for the crack-length measurement when the topographies are

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

modeled in finite-thickness plates. For any given pit depth d and crack length a, a value can be obtained that represents the ratio of the infinite-plate K_I for the pit and crack to the crack alone (K_{a+d}/K_a), where K_a is calculated for a crack in the single-edge through crack in uniaxially stressed infinite plate. This ratio is called a TCF and can be applied either to the fracture-mechanics- based beta solution or directly to the K_I. As the crack length a varies, a TCF curve can be constructed for a given topography.

- As time progresses, the pit depth typically grows, so the TCF curve changes as a function of time. The IDS or MDS also grows in the cyclic domain, either by fatigue cycles alone or by fatigue cycles acting on a crack with a TCF applied. The holistic life analysis computations alternate rapidly between the cyclic domain crack extensions and re-computations of the TCF curve to account for the interacting effects of corrosion and fatigue. Figure 4 shows a sample of TCF curves for various topographies. The TCF curves can be rapidly generated by closed-form methods for specific depths of an isolated pit or generated using finite-element techniques for specific surfaces under general corrosion attack.

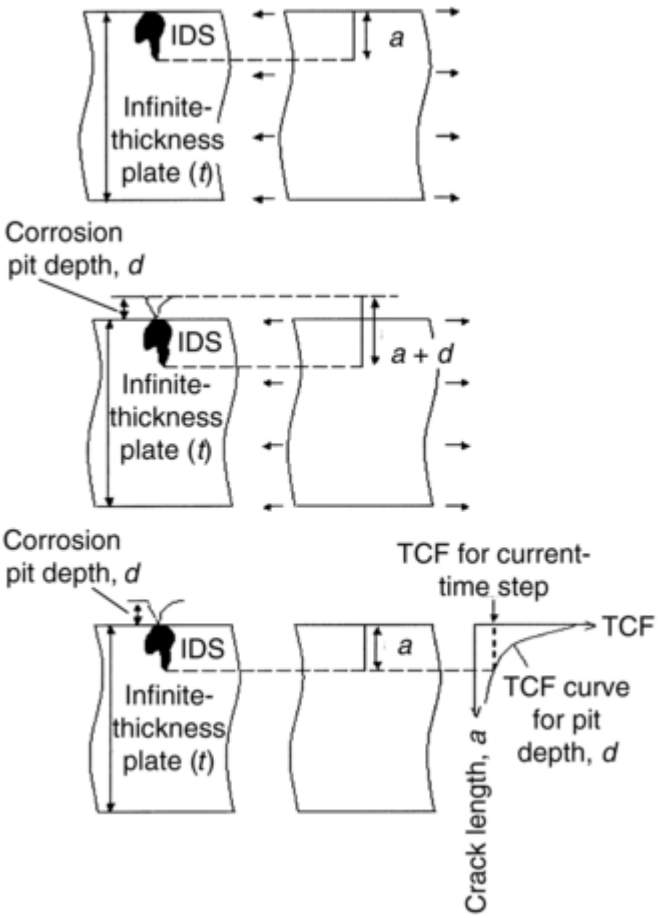

Fig. 3 A two-dimensional fracture mechanics representation of corroded surface topography effects on crack stress intensities. Holistic analyses model the topography correction factor (TCF) curve changes in calendar time. IDS, initial discontinuity state

مرجع مهندسی مواد و متالورژی

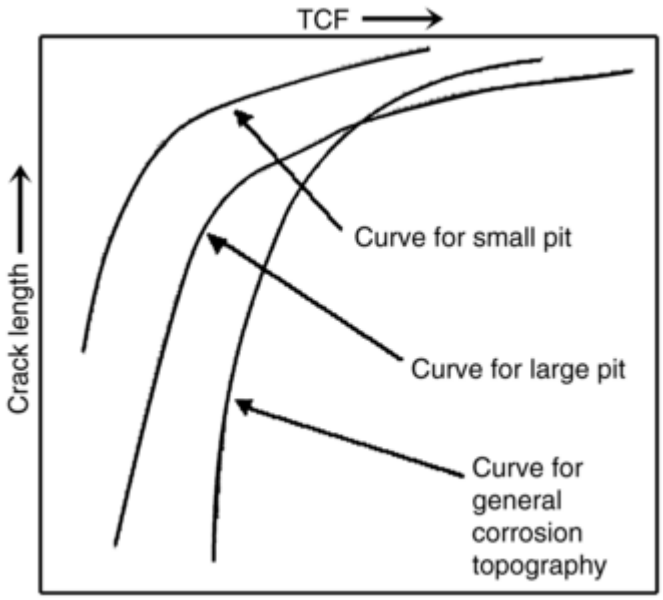

Fig. 4 Topography correction factor (TCF) curves change in time with corroded surface evolution.

General Attack. Topography correction factors were determined for both general attack and pitting (Ref 14). The TCFs for three representative levels of general corrosion were determined from samples of 2024-T3 aluminum. The topographies were determined from profilometry, and these profiles were constructed into two-dimensional finite-element models. Then, cracks were placed at various locations under the profiles to determine families of K_I corrections for the different combinations of topography and crack size. An example of this work is given in the next section.

Pitting Corrosion. Only limited work has been completed toward defining TCFs for pitting corrosion. Some collaborative work was accomplished with the Defense Science and Technology Organization/Aeronautical and Maritime Research Laboratory (DSTO/AMRL) in Melbourne, Australia, to investigate the effects of pit shape on K_I. Conclusions showed that pit tip radius was the most influential parameter (Ref 15). The work also showed that the K_I response was quite similar to that of a crack, which formed the early hypothesis that pits could be treated as cracks within a fracture mechanics framework. Some finite-element results supporting this hypothesis are shown in the next section. Thus, the TCFs for pitting within the framework are calculated using a ratio of two-dimensional K_I: one for the crack length and one for the crack length plus the pit depth. The shortcoming of this approach is that it is based on extremely limited data. Efforts are currently underway to determine more precise K_I distributions for surface cracks (three-dimensional) at the base of hemispherical pits. This will greatly increase the robustness of the TCFs for pitting and increase model performance.

Exfoliation Corrosion. Topography corrections for exfoliation corrosion essentially borrow from the pitting corrections, because the two failure modes have very similar effects in fatigue of aluminum alloys. Extensive fractographic analyses (Ref 16, 17) have shown similar damage morphologies between exfoliation and pitting, too, in that the surface of the material below the exfoliated grains contains pitlike discontinuities that serve as fatigue crack nucleation sites. Thus, exfoliation is modeled as pitting in the presence of thinning, a model that borrows heavily from the process zone concept developed at the DSTO/AMRL. The process zone model has been widely published in conference proceedings (Ref 18, 19).

Corrosion Pillowing. Another interaction that can be modeled within the holistic life analysis framework is that of corrosion pillowing (Ref 20). This model was developed to address problems associated with crevice corrosion in lap joints where the corrosion by-products produce volumetric expansion, which results in increased pressure or deflections, leading to sustained stress. This sustained stress builds as corrosion by-products increase at certain locations within that geometry. These sustained stresses can produce independent cracking, as described by Ref 14, while aircraft are at rest. Combined with operational stress cycles, they can result in more damaging cyclic crack extension than that which would occur without the superimposed pillowing sustained stresses. This interaction and damage effect is intended to consider the effect of the corrosion-induced sustained stress conditions on the cyclic crack extension of operation (for example, fuselage pressurization) damage. It also includes the loss of material associated with the by-products creating the sustained stresses.

مرجع مهندسی مواد و متالورژی

Each of the previous degradation effects is included in a life-assessment framework to simulate their respective influences on the life analyses. The framework and associated analytical tools allow any or all of the degradation effects to vary as a function of time, so that the effects become functions of both cyclic stress and calendar time. The modeling procedure allows the analyst to control the amount and levels of influence of each effect, either independent of cyclic mechanisms or interactively affecting the cyclic contributions to damage. This allows the analyst to quantify the impact of each degradation mechanism, acting independently and in concert with other mechanisms.

Corrosion Fatigue Model Applications

A basic engineering approach to compute the effects of corrosion on structural capability is described and exercised for two types of corrosion: crevice and pitting. The analyses use fracture mechanics methods and fundamental engineering principles. Engineering computations are combined with damage tolerance assessment concepts to formulate a model that approximates the life degradation effects of corrosion with both sequential and concurrent fatigue. Although the life predictions are calculated using deterministic techniques, sensitivities to key parameters can be determined, and therefore, probabilistic life predictions can be approximated. The results of this approach provide the analyst with numerical impacts of potential scenarios and a means for quantifying the effects of corrosion with fatigue.

Crack growth life analyses of a particular airplane geometry configuration are used to show the relative life impact of corrosion metrics, although models are flexible enough to be applied to ground vehicles and other systems that may need to be damage tolerant. A simulation of a pressurized fuselage skin splice is used to illustrate the analytically derived impact to the life and safety of the joint in the presence of corrosion. Analyses take into account all documented damage modes and time-dependent effects. Results of the analysis indicate that corrosion is a potential structural problem for the particular aircraft locations that are experiencing this type of corrosion attack.

مرجع مهندسی مواد و متالورژی

This section presents the methodology for computing the effects of real-time age degradation on an aircraft structure for two different corrosion types: crevice and pitting corrosion. Reference 21 documents a process for incorporating these aspects into the existing infrastructure of the design, manufacturing, and maintenance of aircraft or ground systems.
It must be noted that the two applications of the holistic analysis framework presented in this article use supporting data and implementations that are immature, because more field and experimental information is being sought to further substantiate the engineering application. Details of the analysis methods are still being revised, subject to ongoing tests that are producing robust supporting data. However, the framework demonstrates that the engineering fundamentals of age degradation can be applied to life-prediction methods with reasonable results, whereas current modeling philosophies that do not consider the time domain quantify the structural degradation due to corrosion by relying on empiricism.

Crevice Corrosion Model

The modeling of crevice corrosion in a life- prediction framework is described. Fatigue, crack growth, and finite-element modeling algorithms, each with corrosion interaction effects, are tools that can be readily adapted to provide adequate assessments to determine the magnitude of the corrosion problem, resulting in a basic engineering approach. The fundamentals of the proposed approach are to:

- Determine the initial as-built quality condition of the structure and basic material for the initial starting condition
- Model the effects of micro- and macrosurface topography changes in time due to corrosion growth
- Include the time dependence of any mechanically induced deflections due to corrosion by-products and effects of material loss
- Superimpose corrosion effects with cyclic fatigue crack growth using realistic environments

This procedure requires establishing the effective characteristics of material and structural discontinuity states to provide an initial starting condition. Important data include industry strain/ stress crack initiation test data, surface topography, local and global deflections and loads, crack growth rate data, corrosion rate data, related experimental test data, field aircraft findings, and experience.
By using AFGROW (a crack growth analysis tool available from the U.S.A.F.) and the *p*-version finite-element method software StressCheck (Engineering Software Research and Development Inc.), state-of-the art fracture mechanics and structural analysis tools, and by taking advantage of significant improvements in personal computing power, an engineering method for integrating life impacts due to corrosion degradation can be incorporated into structural life assessments. With these tools and concepts, it becomes feasible to determine the economic impact of corrosion and to improve the structural airworthiness of all aging systems.
Corroded surfaces from both experimentally corroded and in-service corroded sheets were studied to evaluate surface topography and material loss influences on damage tolerance of thin sheets typically found in lap joints. Local macrosurface stress effects due to the topography produced by surface corrosion and pitting amplify the mode I K_I. (Mode I is the opening mode for cracks, mode II is the sliding mode for cracks, and mode III is the twisting mode for cracks.) Results from analysis of typical transport aircraft fuselage lap-splice joints are presented here. Corrosion causes pits, waviness, and variable surface roughness that produce local stress raisers and effective concentrations, as shown in Fig. 5(a). The normal stress in the applied load direction is shown in Fig. 5(b). Some of the pit sizes were on the order of 25% of the corroded sheet thickness, and some were as small as a few thousandths of an inch. In addition, the corrosion process results in more global surface decay or material thickness losses, which result in additional stress raisers.

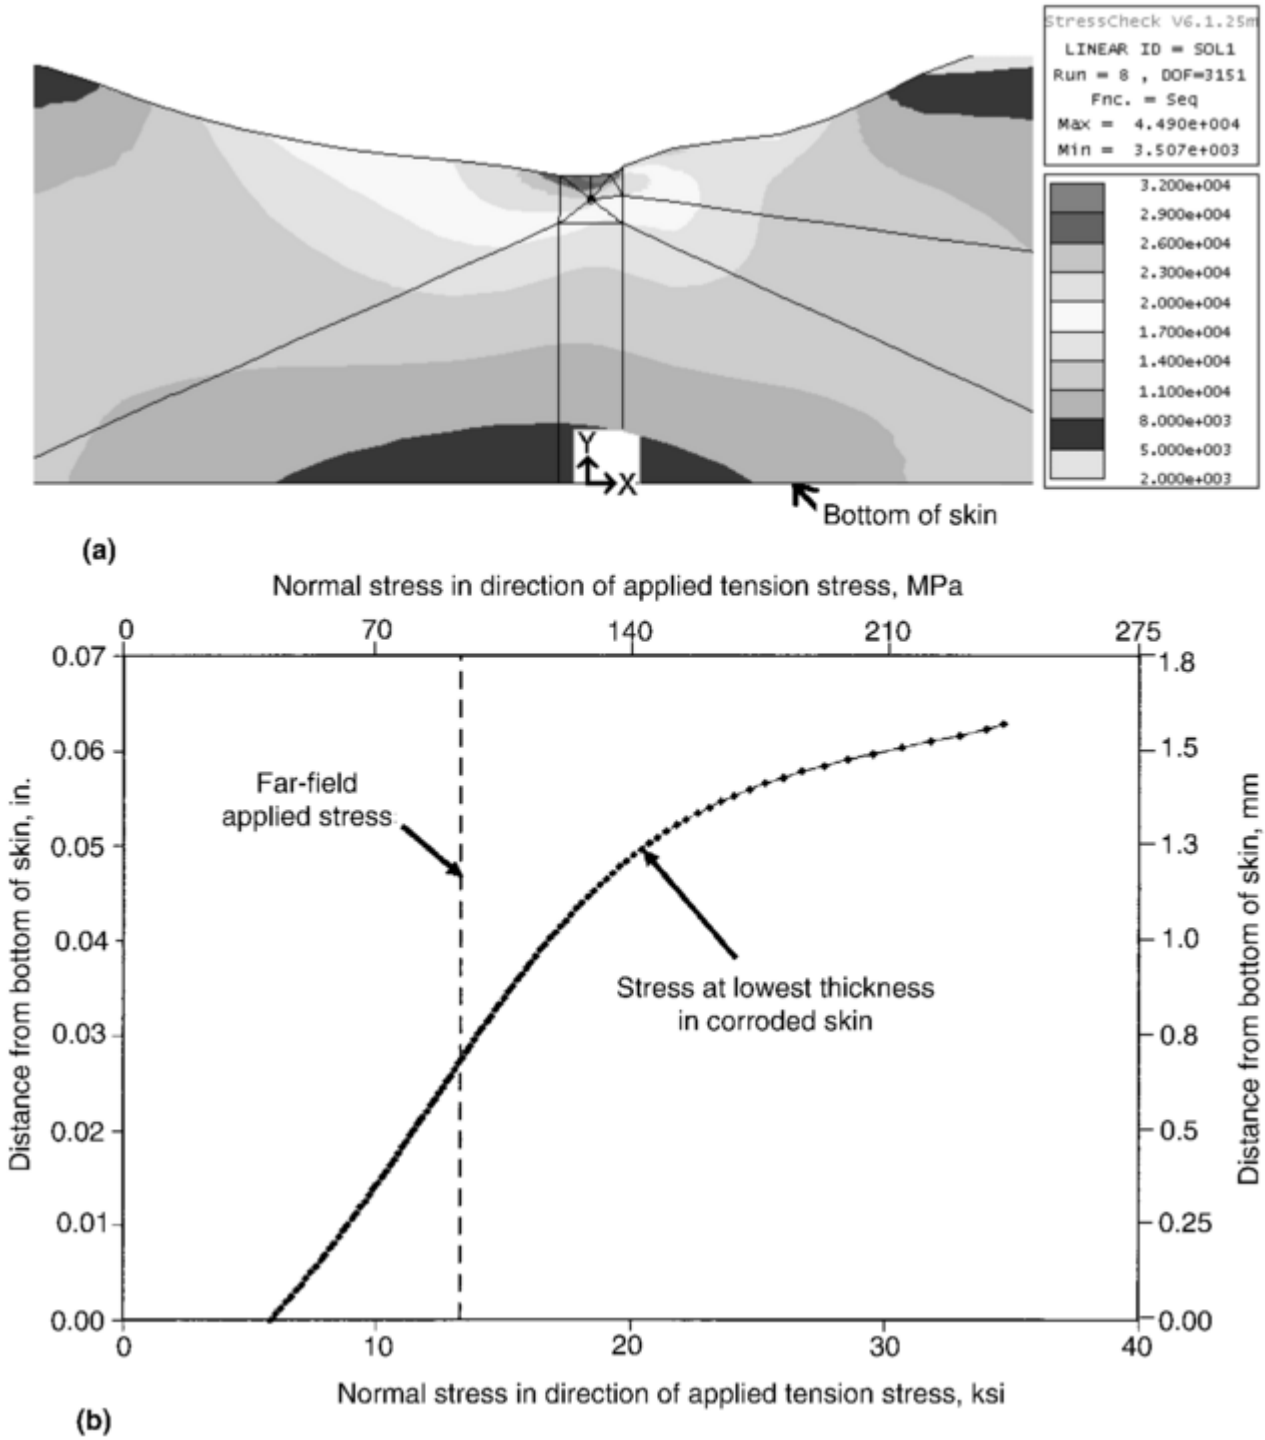

Fig. 5 Stress amplification due to corrosion topography. (a) von Mises stress contours. (b) Normal stresses versus height at the thinnest part of the skin

Surface profiles were modeled using a *p*-version finite-element analysis code, StressCheck (Ref 22). A typical finite-element model of a skin sample taken from a lap joint on an in-service aircraft is shown in Fig. 6. The profile was obtained by a high-resolution optical scan and converted to a data file of *x*-*y* coordinates of the surface. Crack tip K_I computed in StressCheck was used to study the effects of different corrosion scenarios on several different profiles. Figure 7 shows the results of two types of profiles (skin 1 was a profile similar to Fig. 6, and skin 2 was a single pit).

(a) and (b) Skin 1 is a profile similar to Fig. 6; skin 2 is a single pit. Smooth K_I is for the classical edge crack solution (β = 1.12). (b) The influence of backface, the thickness of the plate, is demonstrated.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Figure 7(a) shows the K_I of the crack located at the base of the deepest depression in the corroded skin topography of Fig. 6, normalized by the classical edge crack in tension solution (geometric factor $\beta = 1.12$) as a function of crack length. Figure 7(b) shows the influence of the backface on the K_I that results from both thickness loss and stress concentrations caused by the near-notched surfaces of the corroded topography. Through-cracks of varying lengths were introduced in the skins at the many locations but predominately at the highest stress locations and therefore represent a conservative case. It is clear from Fig. 7(a) that the corroded skin significantly amplifies K_I, especially for small cracks (0.25 mm, or 0.01 in., and smaller). Figure 7(b) shows that the amplification of K_I by the corroded skins is more than an area correction, because the corroded skin K_I is compared directly to the edge crack in finite-width plate solutions (labeled "Smooth (analytic) skin"), suggesting that K_I corrections in crack growth analyses of these corroded skins need to account for more than uniform thickness loss. This corroded topography amplification or correction is more important in the early crack growth stages for these samples, which were taken from fuselage lap splices that typically experience relatively low stresses, typically leading to a long number of initiation cycles (defined here as the number of cycles from the initial crack lengths to 0.25 mm, or 0.01 in.).

Corrosion Pillowing. In addition to the effects that corrosion has on lap joints in the form of thickness loss, early crack initiation, stress- corrosion cracking, pitting, and corrosion pillowing can occur. The National Research Council of Canada (NRCC) has investigated and documented this phenomenon extensively (Ref 20). Corrosion pillowing is caused by the additional volume that corrosion by-products occupy, over and above the material volume lost to corrosion—the volume of corrosion by-products can be as much as $6\frac{1}{2}$ times greater than the volume of parent material lost. Fastener constraints in the lap joint prevent uniform deformation of the skins—skins deform most in the middle of the ligaments between rivets, a phenomenon referred to as pillowing. The result is that the skins act much like plates fastened at all four corners, with a uniform out-of-plane pressure applied. Large bending stresses near the rivets result. These large bending stresses have adverse effects on the structural integrity of lap joints. Three-dimensional finite-element simulations (Ref 23) conducted by the NRCC were used to estimate stress fields caused by corrosion pillowing. Figure 8 shows the individual stress state for a skin with a countersunk fastener. The effects of this buildup of sustained stress in time are simulated to estimate the impact on the joint integrity.

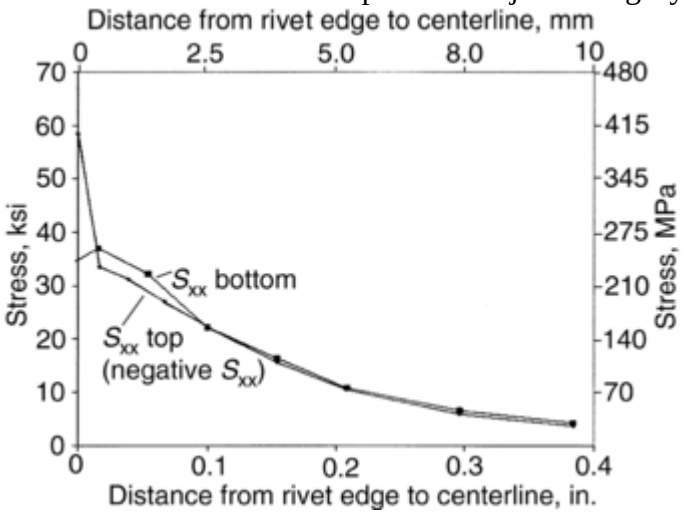

Fig. 8 Sustained stress levels due to pillowing. Corrosion pillowing and resulting bulging in a lap-splice skin were modeled for a four-square fastener pattern. Graph shows normal stress (S_{xx}) in direction of applied in-plane hoop stress, for top and bottom faces of the outer skin, in the region of a countersunk fastener relative to a rivet or hole edge. Centerline is the center between two fasteners that aligned perpendicular to the applied in-plane hoop stress direction.

Multisite Damage. Since the Aloha Airlines B-737 accident in 1988, a paradigm shift in the aircraft structural integrity community has occurred, as far as age-degradation effects on aircraft structure are concerned. Namely, there became a realization that age degradation can have significant safety impact during the life of the structure and that these effects have not been adequately addressed in past or current structural integrity programs for aircraft. Many organizations, including the Federal Aviation Administration (FAA) and the Department of Defense in the United States, initiated major research programs to address aging structural

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

system challenges and issues. These issues include widespread fatigue damage (WSFD) and its two subsets, multisite damage (MSD) and multiple- element damage (MED) (Ref 24), and how these failure modes reduce the capability and residual strength of the structure, as identified in Fig. 1, especially in the later stages of the life of the structure. Widespread fatigue damage is characterized by fatigue damage across wide or broad areas of the structure—across many structural subcomponents and structural features, such as over many holes, such that (Ref 24) “the structure no longer meets its damage tolerance requirements.” Multisite damage is similar to WSFD but is generally restricted to a much smaller area—over one structural subcomponent or element. Multiple-element damage is characterized by many cracks in similar and adjacent structural elements.

The primary issue regarding MSD is its effect on the integrity or damage tolerance of a structure. Reference 24, which addresses damage tolerance in the presence of MSD, is an excellent reference for further study of this issue. It outlines approaches for including MSD in damage tolerance and residual-strength calculations and presents some examples that account for its effect. One significant conclusion of this analysis is that, depending on the structure and the magnitude of the MSD problem, the residual strength of a structure might be greatly reduced in the presence of MSD cracks that are less than a generally inspectable size, and that inspection alone may not be adequate to ensure safety of the aging system. The structural system could be in bridges, power plants, heavy and light equipment, as well as aircraft. Each structural system must be analyzed in detail to identify failure modes, cyclic and environmental loads, and other damage mechanisms. As a result, some additional considerations may need to be accounted for, similar to those considerations discussed in Ref 4, to better focus on the role and effects that age-degradation mechanisms, such as corrosion, have on structure integrity. These effects could include, but not be limited to, widespread corrosion damage (WSCD) and multisite corrosion damage (MSCD), which both could significantly reduce the time to the onset of WSFD and MSD or just result in general degradation that could rapidly deplete the remaining service-life capability.

Correlation with Test Data. The AFGROW software program and the ECLIPSE software program (APES, Inc.) (a custom-made tool that reflects the holistic assessments advocated here) were used to predict pristine fatigue lives and corroded fatigue lives for riveted aluminum lap- splice specimens that were fabricated and tested at the NRCC. The specimen consisted of two 1.02 mm (0.040 in.) 2024-T3 aluminum sheets lap spliced with twenty-four 3.97 mm ($\frac{5}{32}$ in.) diameter rivets in three rows of eight rivets each (Fig. 9). The typical fatigue failure mode for this type of structure is cracking in an outer row of fasteners, which leads to eventual failure at the critical crack length.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

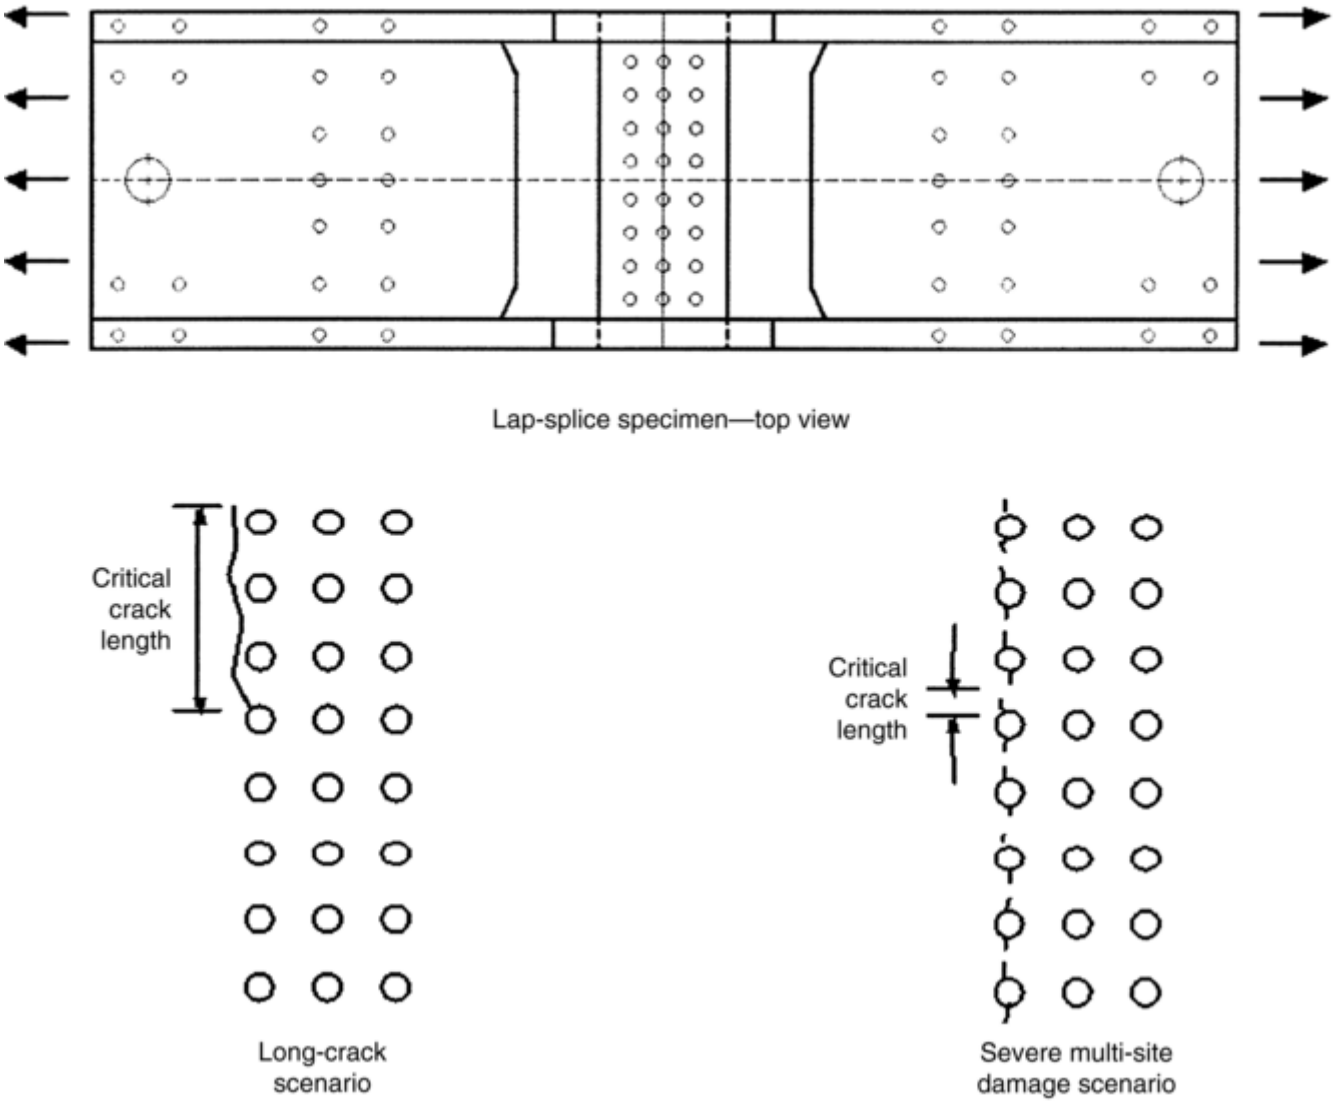

Fig. 9 Two lap-splice failure scenarios for the splice shown on top: long crack and severe multisite damage

General Analysis Assumptions. It is expected that the actual lap-splice failure mechanism is between a long-crack scenario and a severe MSD scenario (Fig. 9). Therefore, the predicted values are the average of a long-crack prediction—a single flaw, ignoring surrounding holes, with critical crack length of approximately 76 mm (3 in.)—and a severe MSD prediction—the same size flaw is assumed to exist at every hole in the splice, and the critical crack length is approximately 10 mm (0.40 in.). A single corner crack at a hole was used for all predictions; however, the MSD analysis corrections account for the presence and influence of other cracks in the lap splice.

For performing the corroded life predictions using the ECLIPSE software, the average thickness loss of the lap specimens was 56 μm (0.0022 in.). A moderate topography beta correction was applied during the analysis. The thickness loss and corroded topography did not change in time, because these were precorroded specimens tested in laboratory air at highly accelerated fatigue cycle rates (accelerated compared to fleet fatigue cycle rates).

Four different models were used to make the pristine and corroded predictions (Fig. 10). The first three (A, B, and C) used one set of material fatigue crack growth rate (da/dN) curves with different initial crack lengths (IDS); the fourth (D) used a different material da/dN curve and IDS condition obtained from the Advisory Group for Aerospace Research and Development (AGARD) research (Ref 25). The predicted lives using the long-crack scenario and the MSD scenario were averaged and plotted with the actual test lives to show correlation in Fig. 10.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

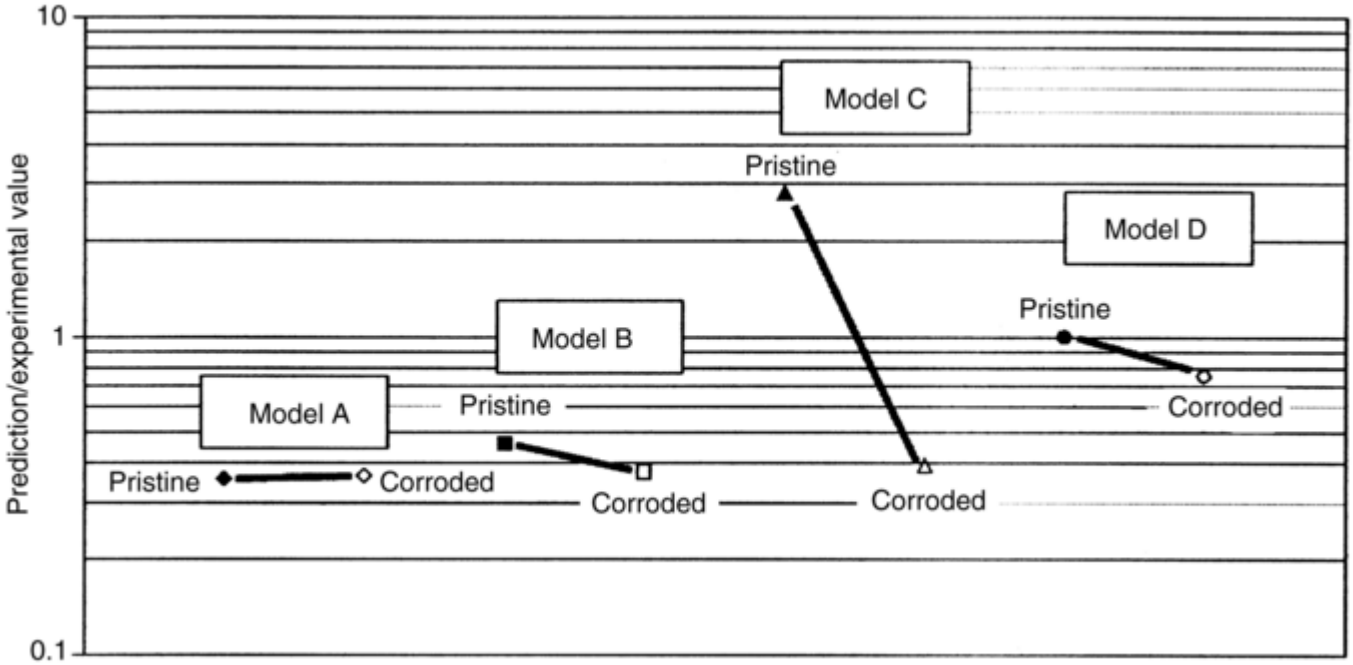

Fig. 10 Lap-splice predictions. Model A: fatigue crack growth rate (*da*/*dN*) curve set 1, initial discontinuity state (IDS) = 84 μm (0.0033 in.); model B: *da*/*dN* curve set 1, IDS = 64 μm (0.0025 in.); model C: *da*/*dN* curve set 1, IDS = 43 μm (0.0017 in.); model D: *da*/*dN* curve set 2, IDS = 6 μm (0.00024 in.)

Ideally, crack length versus number of cycles (*a* versus *N*) information could be obtained from these tests, which would allow correlation at different points during the holistic life, not just correlation at the end point of life, as was shown here. However, difficulties in obtaining crack growth measurements for small crack sizes or under rivet heads often preclude this.

From Fig. 10, it is clear that for this case, models A, B, and C are very sensitive to starting IDS condition in the pristine state. They are relatively insensitive to the starting IDS condition in the corroded state. Also, the combination of material curve and starting IDS condition in model D performs best. However, the reader is cautioned to keep in mind that this conclusion can be reached only for this specific test and the specific analysis geometries and assumptions. Ideally, a much larger database of experimental results should be built, in which case, the model performance can be examined for varying stress levels, stress ratios, and mechanical test conditions.

Pitting Corrosion Model

Pit-as-Crack. The early stages of general corrosion attack in aluminum alloys are generally characterized by isolated pitting—a number of grains very near the surface are attacked by the corrosive agent, and either the grains dissolve, a material discontinuity dissolves, or the grain boundaries weaken, and the grain breaks away or dissolves. This section describes a model to approximate the effects of pitting corrosion on structural life. The goals were to characterize real corrosion pits using pit width, pit depth, pit radius near the crack origin, and other geometric descriptions, as necessary, and also to determine the radius of influence of a corrosion pit, that is, how far the stress-concentration influence extends from the bottom of a corrosion pit.

The Aeronautical and Maritime Research Laboratory (AMRL) of Australia (Ref 26) cut a large set of experimental test coupons from the same sample of aluminum alloy 7050-T7451. The specimens had rectangular cross sections 32.00 by 9.91 mm (1.26 by 0.39 in.). Centered holes had diameters of 6.35 mm (0.25 in.). Test coupons were artificially precorroded in 3.5% NaCl solution for 24 h. Coupons were then bagged in a controlled environment with less than 40% relative humidity to arrest further corrosion pitting. Coupons were subsequently fatigued to failure at 5 Hz, using a constant cyclic minimum-to-maximum stress ratio (*R*) of 0.1 and various maximum stress levels. After test specimen failure, coupon failure surfaces (which contained the failure crack front) were examined with a scanning electron microscope (SEM). The two-dimensional sections of each pit from which fatigue cracks emanated were recorded and used to define two-dimensional surfaces in

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

finite-element models. Hand sketches of two typical fatigue crack pits are shown in Fig. 11. Pit dimensions were used in subsequent finite-element analyses and crack growth predictions.

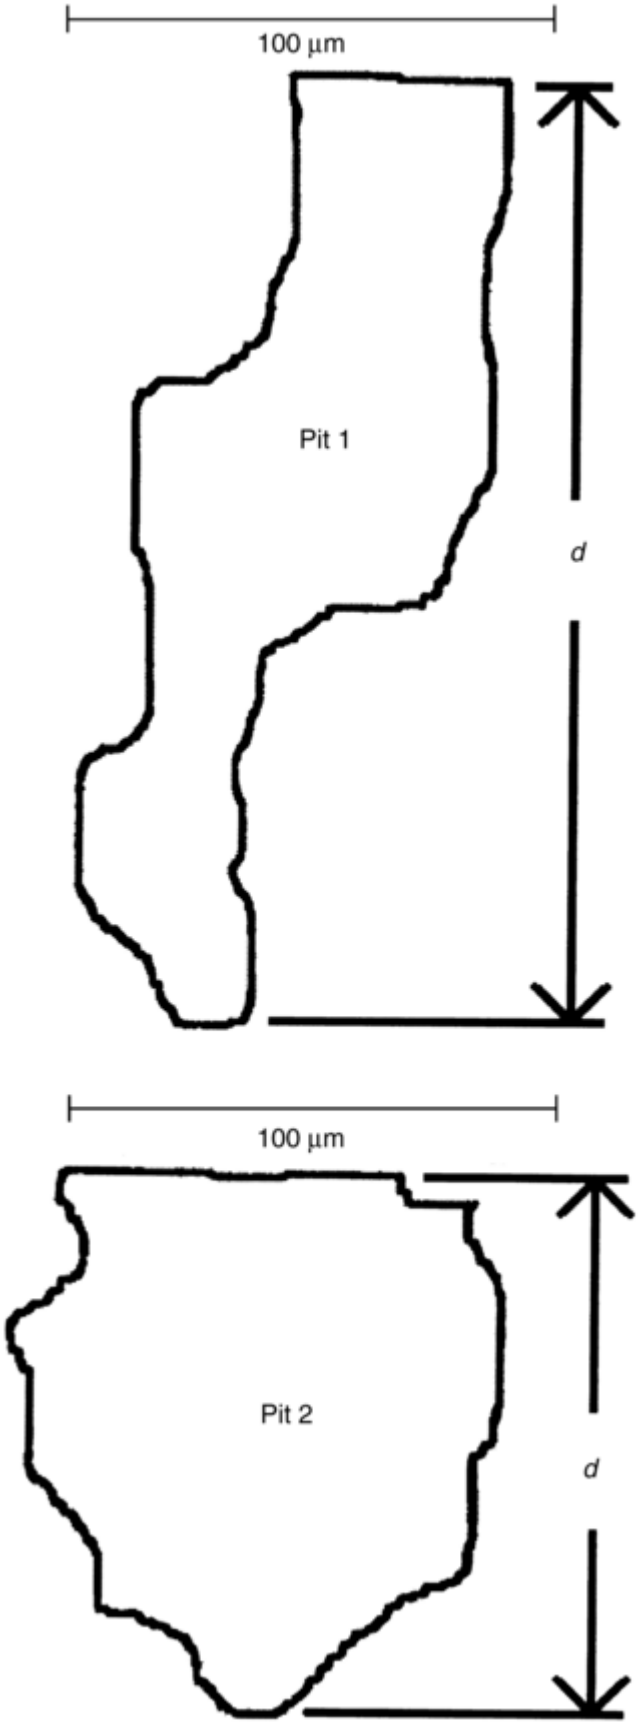

Fig. 11 Sketch of pit geometry, as received. Source: Ref 26

Correlation with Test Data. The stresses near actual corrosion pits sketched from SEM images of the postfracture were analyzed with the *p*-version finite-element method software, StressCheck. These pits were

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

fitted with cubic splines and located at the surface of a planar domain. A tension stress was applied so that the pits acted much as edge notches, with the highest stresses located at the bottom of the corrosion pits.

Figure 12 contains the results of the finite-element analyses for the two actual pits. The model referred to in this figure is the model of a pit as a crack; that is, for these pit geometries, the model is simply an edge crack of length equal to the pit depth d plus the crack at the bottom of the pit of length a. This is mechanically equivalent to the actual pit with a crack at the bottom of the pit. For instance, if the pit is 203 μm (0.008 in.) deep with a 51 μm (0.002 in.) crack at the bottom of the pit, the model is an edge crack of 254 μm (0.010 in.) in length. The effective crack length $a_{eff} = d + a$ is used to calculate the geometric factor, β:

$$\beta = \beta(a_{eff}/t) = \beta((d + a)/t) \quad \text{(Eq 1)}$$

The corresponding K_I is then obtained by multiplying β by the applied tensile stress, σ, and the square root of πa_{eff}, where a_{eff} is the effective crack length:

$$K_I = \beta(a_{eff}/t)\sigma\sqrt{\pi a_{eff}} \quad \text{(Eq 2)}$$

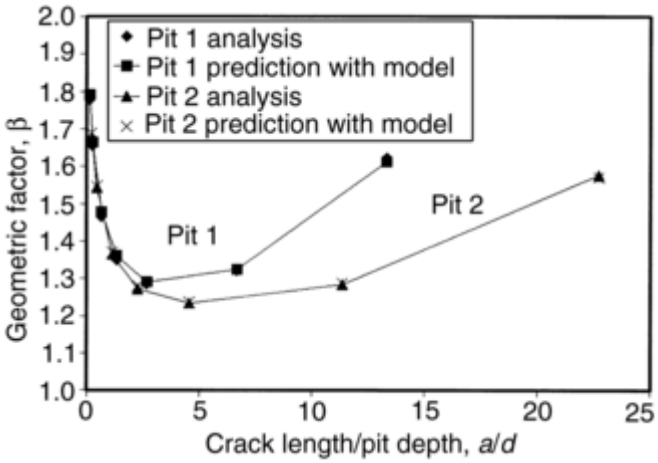

Fig. 12 Proposed pit-as-crack model compared with actual pit-plus-crack results. Finite-element method used to model the two pits of Fig. 11, with small cracks located at the bottom of pits ("Pit 1 analysis," "Pit 2 analysis") perpendicular to the applied tension stress (similar to the configurations shown in Fig. 5 and 6). The geometric factor, β, is the K_I normalized by the applied tension stress and the square root of πa, where a is the representative crack length. The "prediction with model" is the classical edge-crack-in-tension geometric factor, with the crack length defined as the pit depth added directly to the length of the small crack located at the bottom of the pit.

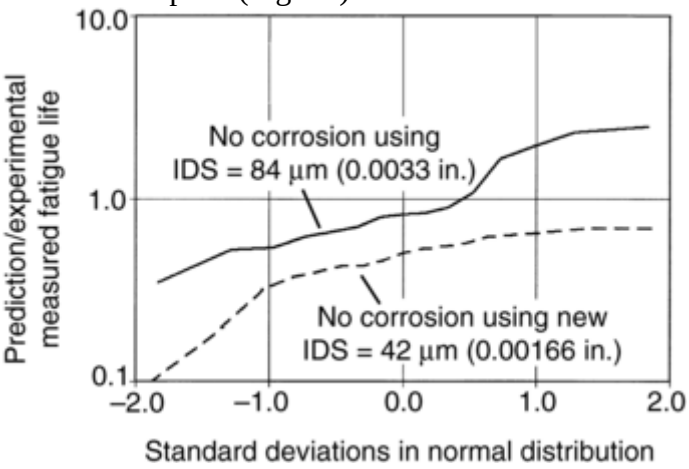
The simplified model of pit-as-crack was used in elementary crack growth analysis of an edge crack in AFGROW. Pristine (uncorroded) coupon test results (Fig. 13) were used to refine the crack growth rate curve, where the "Prediction," as labeled in Fig. 13, is actually a postdiction; that is, the best initial flaw size is calculated by back calculating the initial flaw size required to obtain the fatigue lives of the pristine coupons. The average of all initial flaw sizes for the pristine coupons was used in the prediction of the fatigue lives of the corroded coupons (Fig. 14).



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 13 Correlation of predicted fatigue lives with Aeronautical and Maritime Research Laboratory experimentally measured uncorroded fatigue lives. IDS, initial discontinuity state

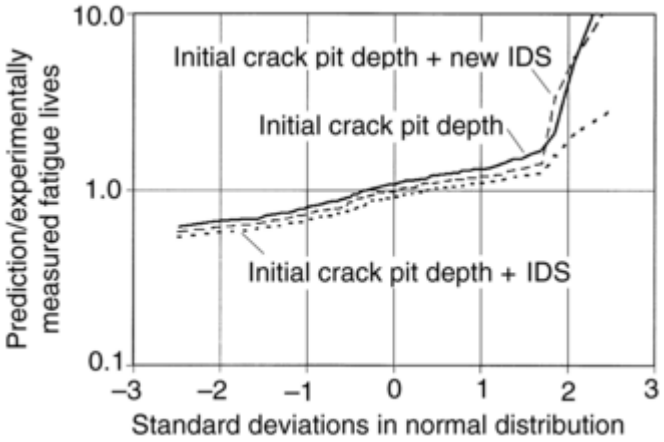


Fig. 14 Correlation of corrosion fatigue prediction (pit-as-crack) model and Aeronautical and Maritime Research Laboratory experimental corroded specimen results for approximately 80 corroded coupons. Pit depths measured postfracture used in the corrosion fatigue predictions, along with the initial discontinuity state (IDS) obtained from tuning the prediction model with Fig. 13 on corrosion fatigue lives. The new IDS equals 42 μm (0.00166 in).

These figures show predictions normalized by the actual measured fatigue lives, with the abscissa (horizontal axis) being the standard deviations in a normal distribution for each of the prediction groups, noncorroded and corroded. Ideally, the prediction/experimental curves would be horizontal and cross the zero (0.0) vertical standard deviation line at 1.0. A proprietary 7050-T7451 material crack growth rate curve (da/dN) was input into AFGROW. The pit depths, as measured by AMRL, defined the size of the initial crack length (i.e., pit depth).

Figure 13 shows the noncorroded specimen fatigue predictions. Note that the initial crack size, 84 μm (0.0033 in.), corresponding to a nominal IDS for this material, was chosen for the crack growth calculations. The new IDS was back calculated from the non-corroded AMRL experimental results procedure by calculating the initial flaw size needed to fail the pristine coupons at the measured fatigue lives; hence, this procedure results in a post-diction, not a prediction, because the fatigue lives are known and are used to tune the life predictions. The distribution of initial flaw sizes thus obtained is averaged; in this way, a much better value of the IDS for the as-manufactured 7050-T7451 can be obtained for subsequent corroded coupon life predictions. This tuned IDS used for the initial flaw size in the life predictions is the new IDS, 42 μm (0.00166 in.). Figure 13 demonstrates that the new IDS is closer to the ideal than the assumed IDS. The results could be improved by further tuning of the material crack growth rate curves (da/dN versus K_I) and a determination of 7050-T7451 IDS in order to capture the noncorroded (pristine) fatigue results more precisely.

Figure 14 shows the results of three groups of predictions: (a) the initial crack length is the pit depth, d; (b) the initial crack length is the IDS, 84 μm (0.0033 in.), plus the measured pit depth, d; and (c) the initial crack length is the new IDS, 42 μm (0.00166 in.), plus the measured pit depth, d. For each specimen, postfracture SEM images of the fracture faces were used to identify location and depth of the failure pit, that is, the pit with the crack that nucleated and eventually caused the specimen to fracture. These SEM- measured pit depths were used in the Fig. 14 corroded coupon predictions, along with the actual measured fatigue lives of the corroded coupons, which were not known; therefore, these corroded coupon analyses qualify as true predictions. For more than half of the specimens, the method using only the pit depth as the initial crack length overpredicted fatigue life (that is, predicted lives that were larger than measured fatigue lives and were therefore nonconservative), and the method using the pit depth plus the IDS as the initial crack length underpredicted fatigue lives (that is, predicted lives that were smaller than the measured lives and were therefore conservative). Predictions with the method using the pit depth plus the 42 μm (0.00166 in.) IDS as the initial crack length were right in the middle of these two methods, as expected, because the distribution of initial crack lengths used to begin the life predictions for this third group (initial crack length d + IDS = 42 μm, or 0.00166 in.) were

www.iran–mavad.com
مرجع مهندسی مواد و متالورژی

smaller than the first group (initial crack length *d*) and the second group (initial crack length *d* + IDS = 84 μm, or 0.0033 in.). Figures 13 and 14 indicate that the model of pit-as-crack is reasonable for this alloy.

Application of Models during Their Development

The framework just described can be used to examine the effects of age degradation on the service capability of structures in order to provide design/manufacturing optimization and to evaluate maintenance options. This

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

section describes the rationale and techniques needed to apply these age-based structural integrity processes to in-service structures in order to realize benefits throughout the full structural life cycle.

Maturity Levels and Use of Assessment

The demands for extended use of aging systems are providing new challenges to the various structural communities to ensure continued safety, readiness, and reduced costs of operating complex and expensive systems. Integrity can be built into new systems using the discussed framework; obviously, such is not the case for existing aging systems. For existing systems, the challenge is to maintain safety and readiness while keeping control of operating and maintenance costs.

It makes sense, from a safety and an economic perspective, to be proactive in managing the structural integrity impact of corrosion by using quantitative evaluations of real-time degradation processes in the design requirements for new systems. The result would be more corrosion- tolerant designs and more robust engineering processes that support the maintenance, inspection, repair, and life extension of structural systems.

The methods used to assist engineering disposition of corrosion found in-service can also be used during the design phase to evaluate the sensitivity of critical structure elements to the onset of corrosion. This evaluation can lead to improved corrosion-resistant structures and to more efficient inspection programs. In the same way that damage tolerance assessments can identify fracture-critical structures, corrosion-sensitivity analysis can identify corrosion-critical structures. Economic gains can then be realized by initial design changes and improved maintenance programs.

Significant progress has been made in technology related to corrosion and structural integrity. This includes a better understanding of basic material behavior, improvements in non-destructive inspection (NDI) corrosion detection, and the use of analytical tools for predicting residual strength and residual life. However, the benefits from this technology have not been fully realized. The state of this technology is mature enough to benefit industry but requires additional applications to advance and prove its potential. Improvements in new designs and solutions for aging-system problems require a strategic integration into the life-cycle management processes, from the original equipment manufacturer (OEM) designer, to the field or depot maintenance engineers, to fleet management personnel. Enhancing the framework also requires focused developmental programs to increase the capability of the analytic and experimental tools and to develop effective processes for corrosion measurement and classification. Integration of tools that incorporate age degradations directly into the existing structural integrity framework will result in the most efficient and expedient application of the new methods discussed here.

Assessments to address corrosion, stress-corrosion cracking (SCC), and age degradations can be implemented into any structural integrity program by applying many of the same rules and guidelines presently used for existing durability and damage tolerance assessment frameworks. For example, current analysis techniques use a spectrum of stress cycles; adapting this system to include age degradation would require the use of a spectrum of environmental-degradation cycles. Some examples of new terms that would come into use are minimum detectable corrosion limits, probability of detection for corrosion (PODC), initial corrosion assumptions, corrosion and other age-degradation failure modes and effects, MSCD, WSCD, and corroded residual strength (CR/S).

Design Phase. The goal of both the designer and the life-cycle manager should be to ensure the optimal performance of the aircraft or other system. The designer should evaluate the intended role and performance goals of the system, then formulate technical specifications to ensure that the system will meet those goals and also satisfy regulatory requirements. The life-cycle manager has several tools that can be used to modify the rate at which a system ages. For aircraft, these include repair and overhaul of the airframe at selected times to address time-related issues such as corrosion, aggressive fatigue-life- management programs that modify the rate of cyclic damage accumulation, midlife structural modification programs, operational- or performance-enhancing modification programs, and life-extension programs.

The responsibility for ensuring continued safety and readiness for the aging fleets lies primarily with the end users. Design decisions made, however, by the OEM heavily influence the operators' ability to maintain appropriate levels of safety and readiness in a cost-effective manner. Current structural integrity processes focus on use-related degradation, such as static strength, fatigue, and damage tolerance, but do not fully address real-time-related degradation phenomena, such as corrosion. There are cost benefits and safety benefits for

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

integrating consideration of real-time-based degradation mechanisms with the current structural integrity processes.
Modifications to the existing structural integrity processes are required to:

- Solve technical issues associated with actual use and effects of the field environment
- Consider maintenance practices and information from maintenance programs that were not included in the design criteria or in the in-service maintenance plans
- Provide end users with the appropriate technical information and engineering tools to effectively manage aging systems
- Ensure that all disciplines adequately interact during the design phase to address the issues of degradation of the systems in the field environment
- Incorporate recent advances in corrosion assessment and prediction technologies that are not included in conventional practices and procedures

Identification of a Critical Structure

Corrosion issues can influence the problem areas of a structural system in several fashions:

- Corrosion damage in critical structural elements can dramatically reduce the life of a component.
- Corrosion damage in structural elements can change a component status from non-critical to critical.
- Inspection programs, locations, methods, and intervals need to consider multiple damage modes, such as fatigue and corrosion, for which inspection methods are distinct.
- Corrosion damage is not just a cosmetic issue; it is also a safety issue.
- Corrosion has often led to cracking of major structural elements, at times significantly earlier than design predictions or expectations.

Some general categories are recommended to characterize the criticality of a structural component. A partial list of these key categories includes:

- Operational stress level
- Limit strength and residual strength
- Fail-safe aspects
- Load distribution characteristics
- Susceptibility to SCC
- Susceptibility to corrosion
- Susceptibility to accidental damage
- Inspectability
- Cost to repair or replace

The inclusion of corrosion and SCC within a structural integrity program forces design considerations of real-time degradation processes and their potential structural and life-cycle cost impacts. For efficiency, a means of assessing component criticality is required, similar to that used for identifying durability and fracture-critical components. As an example, a formal and systematic approach (Ref 27) leading to a documented criticality assessment was first used as part of a FAA certification and then subsequently used for several fighter aircraft assessments. The systematic process enabled identification and ranking of potentially critical elements of the structure, so that evaluations and inspections were performed and documented in a prioritized fashion.

Inspection Programs

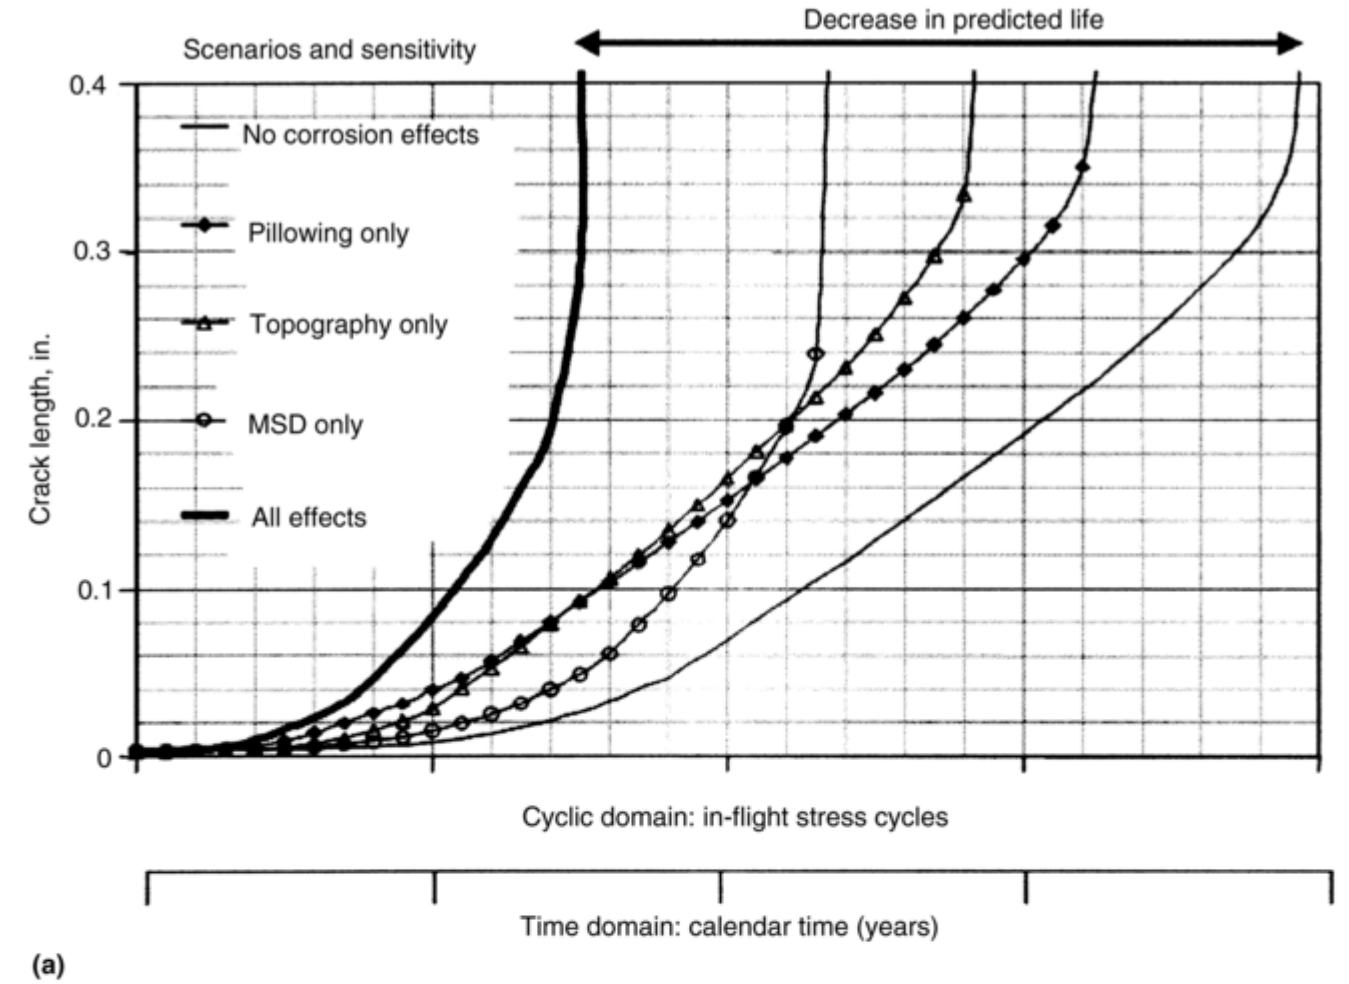
Products of a Predictive Model. The final product created by a life-assessment tool is a life curve (or remaining life curve), which quantifies the impact and effects of the age-degradation processes, as shown in Fig. 15(a) and (b). From Fig. 15(b), the relative sensitivities of potential maintenance and as-is conditions assist in making the proper cost-effective and safe maintenance decisions when linked with a cost model. For example, assume that the current level of NDI capabilities, the detection limit, is represented by the topmost horizontal line on Fig.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

15(b). Although the physical discontinuity or flaw existing today (the leftmost dot) could not be detected today (15 years after manufacture), the holistic life-assessment method allows the analyst to have some estimates of today's hidden discontinuity size as computed from the as-manufactured IDS. From this point, the analyst could use the results to evaluate several options while assuming a severe corrosion scenario:

- *Option 1:* do nothing, deferring action until the next mandated inspection interval
- *Option 2:* apply corrosion-preventive compounds (CPCs) that retard corrosion growth and therefore might allow a delay in further action for two intervals
- *Option 3:* apply a doubler or patch to reduce the operating stress level, allowing the structure to reach three inspection intervals with an adequate safety factor

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی



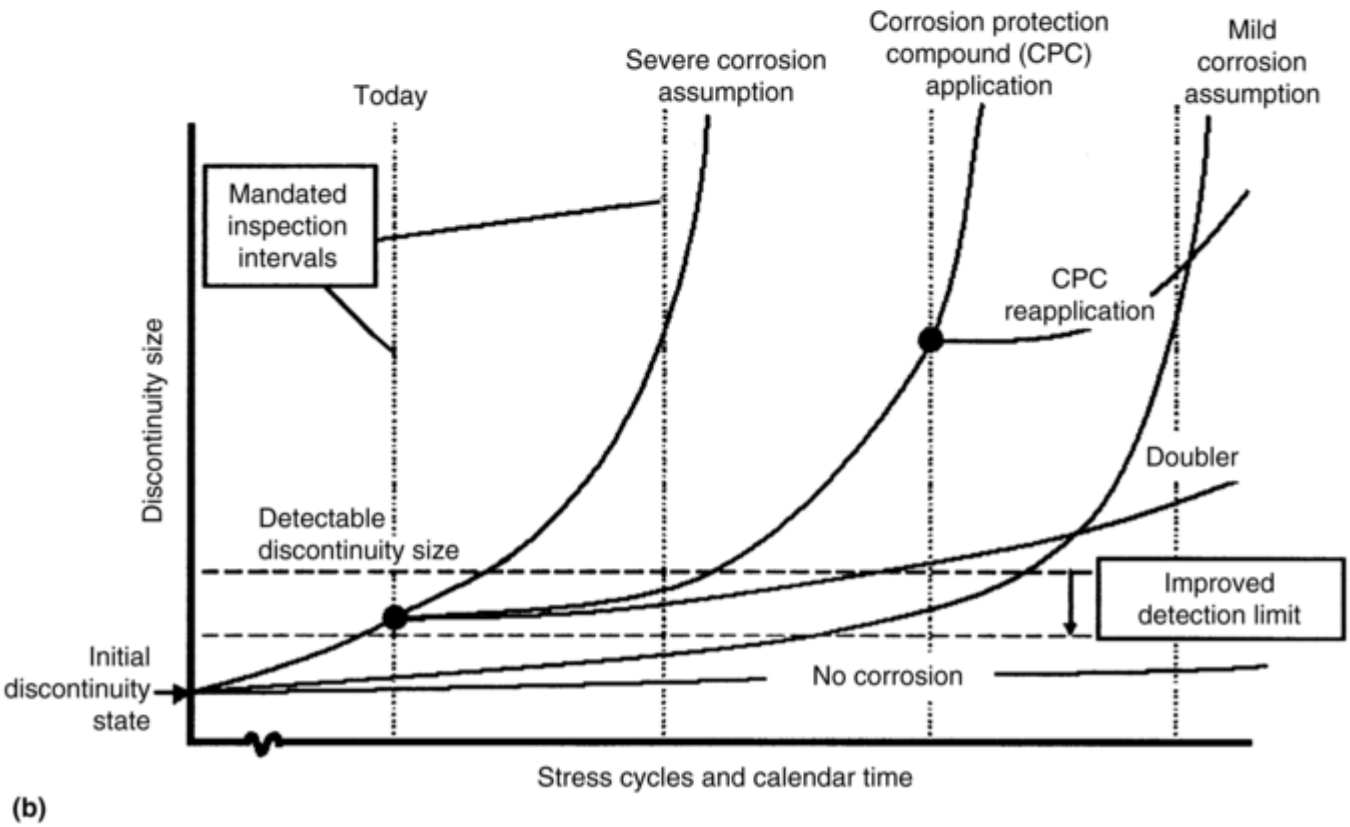


Fig. 15 Predictive models. (a) Crack growth as a function of time and duty. MSD, multisite damage. (b) Sensitivity scenarios allow cost-effective decision making. Decisions can be made and evaluated sooner with improved detection.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

These three options are shown as the three lines emanating from the leftmost dot in Fig. 15(b). Additional options could be made available to the structural maintenance manager, subject to changes in his present maintenance plan. Figure 15(b) shows how alternate inspections could be used. If the corrosion or actual damage state could be reliably detected and quantified more precisely (i.e., by detecting a smaller damage level via an improved NDI procedure or a supplemental NDI inspection) (Ref 28), then less expensive repairs could be devised, with a sufficient probability of achieving the structural lifetime goals. Maintenance records that document the details of prior and current inspections, combined with accurate historical-basing records, can be used to help establish confidence in the quantification of the as-built to current as- is conditions. Future inspection intervals can be determined based on future-basing assignments and the current applied maintenance actions, such as those described previously. The cost analysis accompanying this process would allow decisions that could optimize the direct maintenance while considering safety, readiness, and economic issues.

Economic Service Life and Fleet Management

Depending on the intended use and design requirements, in-service components may have considerable additional capability above and beyond the entire system design life or even beyond their own design life, especially if careful inspection and maintenance procedures have verified this. To assist in making a remain-in-service decision, it is important that a structural assessment determine the additional service-life capability of the component. For example, some automobiles may be kept running with extremely high mileage, but the cost of repairs, maintenance, quality of ride, and user inconvenience may result in available funds being better allocated toward a new automobile. At some point, the cost of maintenance no longer justifies continued service, and the structure has reached the particular operator's end of economic service life. The assessment methods discussed in this article are the tools for determining the economic life of the structure. Scenarios and repair options can be explored that consider both cyclic damage and age degradation. The additional capability, or lack thereof, can be analyzed in conjunction with cost of a repair or replacement or even the cost of continued inspection and monitoring, to determine the economics of continued service. The ability to estimate the economic service life and the remaining service life can be a powerful asset for many industries, allowing the user to maximize the return on investments in existing systems or reallocating investments to new equipment.

Implementation Process

An effective means of implementation of this framework may be to use the successful integrity process that has been established by the aircraft industry. The five tasks in the U.S.A.F. aircraft structural integrity process (Ref 29) provide an ideal format for integrating corrosion and sustained stress analyses into structural evaluations. Table 1 illustrates a modified version of the ASIP process, with additional items incorporated that emphasize the role of age-degradation effects, such as corrosion. Equally important to considering real-time degradation effects is the inclusion of life-cycle costs (LCC) as part of the design and support requirements. This implementation plan results in a minimal disruption of the current processes while defining necessary concepts as relative or parallel to existing concepts; for example, to complement damage tolerance assessments (DTAs), corrosion tolerance assessments (CTAs) would be introduced. The generic nature of the terminology and concepts lend themselves to adoption by other industries that are challenged with design and maintenance of new and existing structures in various environments.

Table 1 Existing structural integrity framework for aircraft

Corrosion degradation addressed by additions to activities in italic.

Task	Stage	Activities
I	Design information	Integrity master plan
		Structural design criteria; corrosion and SCC
		Damage tolerance and durability control plans
		Corrosion tolerance control plan
		Selection of materials and processes
		Material cost trade studies with corrosion and SCC
		Design service life and design usage
		Critical component and selection priority process definition
		Methodology and analysis review approval plan
II	Design analyses and development tests	Materials and joint allowables
		Loads, sonic, vibration, and flutter analysis
		Design service loads spectra
		Design chemical/thermal environment spectra
		Stress analysis
		Damage tolerance analysis
		Durability analysis
		Corrosion tolerance analysis
		LCC assessment
III	Component and full scale testing and demonstration	Static durability and damage tolerance tests
		Assembly process verification test with revisions and updates
		Analytical process verification test
		Flight and ground operations tests
		Sonic, flight vibrations, and flutter tests
		Interpretation and evaluation of test results
IV	Force management data package	Final design analyses
		Strength, durability and corrosion summaries
		Force structural maintenance plan
		DTA, CTA, and SCC summary
		Loads/environment spectra survey
		Aircraft tracking program
		Operational database. cracking, corrosion, repairs, and costs
		Corrosion protection verification
		Loads database, FEA, models, files, and geometry
V	Force management	Loads/environment spectra survey
		Aircraft tracking data
		Aircraft maintenance times
		Structural maintenance records
		Cost assessment process
		Repair tracking
		System feedback, lessons learned, and information

SCC, stress corrosion cracking; DTA, damage tolerance assessment; CTA, corrosion tolerance assessment; LCC, life-cycle cost; FEA, finite element analysis

Introduction

STUDIES of the cost of corrosion have been undertaken during the past several decades by a number of countries. These studies indicate, in general, that corrosion is very costly and has a major impact on the economies of industrial nations (Table 1) (Ref 1). The earliest U.S. study was reported in 1949 by H.H. Uhlig, who estimated the total cost of corrosion by summing materials and process costs related to corrosion control. The 1949 report was followed in the 1970s by a number of national studies in Japan, the United States, and the United Kingdom. The study by Japan conducted in 1977 followed the Uhlig methodology. In the United States, the Battelle National Bureau of Standards (NBS) study conducted in 1975 estimated the total direct cost of corrosion using an economic input/ output model. This model was later adopted by studies in two other nations, Australia in 1983 and Kuwait in 1995. In the United Kingdom, a study was conducted in 1970 using a method similar to the one used by Uhlig; however, in the U.K. study, a committee chaired by T.P. Hoar collected the data through interviews and surveys of targeted economic sectors. Table 1 summarizes the total corrosion costs and percentage of gross national product (GNP) of the respective economies. The table shows that the national costs of corrosion vary between 1.5 and 5.2%. The 1975 study by Battelle-NBS pointed out the severe corrosion impact on the U.S. economy. The estimate based on the Battelle-NBS study was that the cost of corrosion in the United States alone was approximately $70 billion/year, which was 4.2% of the GNP. A limited study in 1995, updating the 1975 figures, estimated the total cost of corrosion at approximately $300 billion. However, that study simply applied a multiplication factor to the 1975 cost that was equivalent to the GNP growth from 1975 to 1995.

Table 1 Results of studies estimating the cost of corrosion in various industrial nations

Country	Total annual corrosion cost	Percentage of GNP	Year
United States	$5.5 billion	2.1	1949
United Kingdom	£1.365 billion[(a)]	3.5	1970
Japan	$9.2 billion	1.8	1974
United States	$70 billion	4.2	1975
Australia	$2 billion	1.5	1982
Kuwait	$1 billion	5.2	1987
West Germany	$6 billion	3.0	1967
Finland	$54 million	…	1965
India	$320 million	…	1960

GNP, gross national product.
(a) Not reported in U.S. dollars

The previous national studies have formed the basis for much of the current thinking regarding the corrosion costs to the various national economies. Although the efforts of the previous national studies ranged from formal and extensive to informal and modest, all studies arrived at estimates of the total annual cost of corrosion that ranged from 1 to 5% of the GNP of each country.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The most recent U.S. cost study was conducted for the year 1998 by CC Technologies Laboratories, Inc. under the auspices of the U.S. Department of Transportation through the Transportation Equity Act for the 21st Century (passed by the U.S. Congress in 1998) in a cooperative effort with the U.S. Department of Transportation Federal Highway Administration (FHWA) (Ref 2). NACE International, The Corrosion Society, worked with Congressional representatives to secure $1 million in federal funding for the study. This article first describes the methodology used in this study and then reports the results and conclusions of the study.

Methodology

In the 1998 study, two methods were used to estimate the cost of corrosion to the United States:

- *Method 1:* The cost was determined by summing the costs for corrosion control methods and contract services.
- *Method 2:* The cost of corrosion was first determined for specific industry sectors and then extrapolated to calculate a national total corrosion cost.

Past studies have indicated that the second method is more likely to incorporate the majority of the corrosion-related costs, and the first method is likely to miss the significant cost of corrosion management, the cost for direct services related to the owner/operator, and the cost of loss of capital due to corrosion.

The costs of materials were obtained from various sources, such as the U.S. Department of Commerce Census Bureau, existing industrial surveys, trade organizations, industry groups, and individual companies. Data on corrosion control services, such as engineering services, research and testing, and education and training, were obtained primarily from trade organizations, educational institutions, and individual experts. These services included only contract services and not service personnel within the owner/operator companies.

Data collection for the sector-specific analyses differed significantly from sector to sector, depending on the availability of data and the form in which the data were available. In order to determine the annual corrosion costs for the reference year of 1998, data were obtained for various years in the last decade but mainly for the years 1996 to 1999. For many of the sectors, the information is public and could be obtained from government reports and other publicly available documents. Discussions with industry experts provided the basis of the industry sector data collection. Corrosion cost information from the private industry sectors was more difficult to obtain. This stemmed from the fact that either the information was not readily available or could not be

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

released because of company policies. In this case, information from publicly available industry records on operation and maintenance cost was obtained, and, with the assistance of industry experts, corrosion-related costs were estimated.

The industry sectors for corrosion cost analyses represented approximately 27% of the U.S. gross domestic product (GDP) and were divided among five sector categories: infrastructure, utilities, transportation, production and manufacturing, and government. The total cost of corrosion was estimated by determining the percentage of the GDP of those industry sectors for which direct corrosion costs were estimated and extrapolating these numbers to the total U.S. GDP. The direct cost used in this analysis was defined as the cost incurred by owners or operators of the structures, manufacturers of products, and suppliers of services.

The following elements were included in these costs:

- Cost of additional or more expensive material used to prevent corrosion damage
- Cost of labor attributed to corrosion management activities
- Cost of the equipment required because of corrosion-related activities
- Loss of revenue due to disruption in supply of product
- Cost of loss of reliability
- Cost of lost capital due to corrosion deterioration

For all industry sectors studied in this report, the direct corrosion costs were determined. For highway bridges, a life-cycle cost analysis was performed in which both the direct and indirect costs of corrosion were addressed. Indirect costs are incurred by individuals other than the owner or operator of the structure. Measuring and valuing indirect costs generally require complex assessments, and several different methods can be used to evaluate potential indirect costs. Owners or operators can be made to assume the costs through taxation, penalties, litigation, or payment for cleanup of spills. In such cases, these expenses become direct costs. In other cases, costs are assumed by the end user or the overall economy. In the case of highway bridges, indirect costs, such as traffic delays during bridge maintenance, repair, and rehabilitation, are more difficult to turn over to the owner or operator of the structure. Once assigned a dollar value, the indirect costs are included in the cost of corrosion management of the structure and treated the same way as all other costs.

Definitions

The following definitions were used in evaluating the cost of corrosion in the 1998 U.S. study (Ref 3):

annualized value.

Average cost of a corrosion control strategy over the entire service life of a structure.

benefit-cost analysis.

Analysis used to determine the net present value of options and the highest net benefit to society; also to determine the cost per unit of service.

corrosion management.

All activities throughout the service life of the structure that are performed to mitigate corrosion, to repair corrosion-induced damage, and to replace the structure, which has become unusable as a result of corrosion.

corrosion-related cash flow.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

All costs, direct and indirect, that are incurred due to corrosion throughout the entire life cycle of the structure.

current cost of corrosion.

The difference between the approach where no consideration is given to corrosion and corrosion control and the current corrosion control approach; calculated by life-cycle cost analysis and characterized by the annualized value.

direct costs.

Costs directly incurred by the owner or operator of the facility, plant, or structure.

gross domestic product (GDP).

The total value of all final goods and services produced in a country in a given year; equals total consumer, investment, and government spending, plus the value of exports minus the value of imports. Figure 1 shows the contribution of Bureau of Economic Analysis industry categories to the 1998 U.S. gross domestic product of $8.79 trillion.

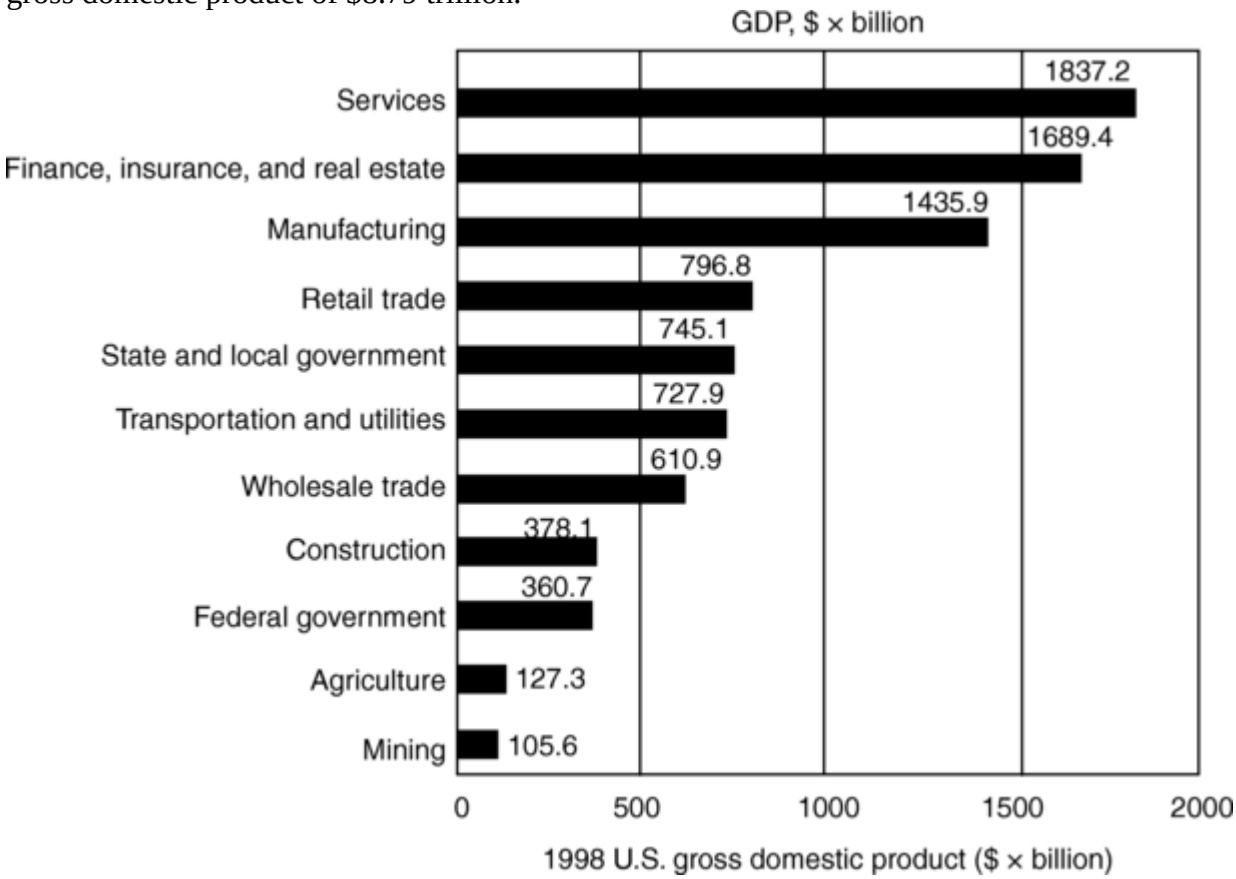

Fig. 1 Distribution of 1998 U.S. gross domestic product for Bureau of Economic Analysis industry categories

indirect costs.

Costs incurred by others, such as the public or society, and are not directly felt by the owner or operator.

life-cycle cost analysis.

A cost analysis that considers not only the cost of production but also the costs of use, service, and disposal or recycling; in the study, life-cycle cost analysis was used to determine the annualized values of options to provide a basis for comparing alternative corrosion control strategies.

maintenance.

An activity that maintains the level of service of a structure or facility.

present discounted value.

The value of future corrosion costs discounted for the cost of money and expressed in terms of present value.

repair.

Restoration of a damaged structure to its original or required service levels but does not eliminate the causes of corrosion.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

rehabilitation.

Restoration of a damaged structure to its original or required service level and corrects the deficiency that resulted in corrosion deterioration.

service life.

The required period of time a structure is designed to function.

Costs of Corrosion Control Methods and Services

As noted in the section “Methodology” in this article, the first method used in the 1998 study was to estimate the annual direct cost of corrosion in the United States by totaling the cost of corrosion control methods and services. The corrosion control methods that were considered include protective coatings, corrosion-resistant alloys, corrosion inhibitors, polymers, anodes, cathodic protection, and other corrosion control and monitoring equipment. Other contributors to the total annual direct cost that were reviewed in this report are contract services (i.e., nonowner/ operator services), corrosion research and development, and education and training.

Method 1 Results

The results for corrosion control methods and services are summarized in Table 2 and subsequently discussed in more detail.

Table 2 Summary of annual costs for corrosion control methods and services

Material and services	Range $ × billion	Average cost	
		$ × billion	**%**
Protective coatings			
Organic coatings	40.2–174.2	107.2	88.3
Metallic coatings	1.4	1.4	1.2
Metals and alloys	7.7	7.7	6.3
Corrosion inhibitors	1.1	1.1	0.9
Polymers	1.8	1.8	1.5
Anodic and cathodic protection	0.73–1.22	0.98	0.8
Services	1.2	1.2	1.0
Research and development	0.02	0.02	<0.1
Education and training	0.01	0.01	<0.1
Total	**$54.16–$188.65**	**$121.41**	**100%**

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Protective Coatings. Both organic and metallic coatings are used to provide protection against corrosion of metallic substrates. These metallic substrates, mostly carbon steel, corrode in the absence of the coating, resulting in the reduction of the service life of the steel part or component. The total annual cost for all organic and metallic protective coatings is $108.6 billion.

According to the U.S. Department of Commerce Census Bureau, the total amount of organic coating material sold in the United States in 1997 was 5.56×10^9 L (1.47×10^9 gal), at a cost of $16.56 billion. The total sales can be broken down into architectural coatings, product original equipment manufacturer (OEM) coatings, special-purpose coatings, and miscellaneous paint products. A portion of each of these was classified as corrosion coatings, at a total estimate of $6.7 billion. Raw material cost is only a portion of a total coating application project, ranging from 4 to 20% of the total cost of application. When applying these percentages to the raw materials cost, the total annual cost of coating application ranges from $33.5 billion to 167.5 billion (an average of $100.5 billion).

The most widely used metallic coating for corrosion protection is galvanizing, which involves the application of metallic zinc to carbon steel for corrosion control purposes. Hot dip galvanizing is the most common process, and, as the name implies, it consists of dipping the steel member into a bath of molten zinc. Information released by the U.S. Department of Commerce in 1998 stated that approximately 8.6×10^6 metric tons of hot dip galvanized steel and 2.8×10^6 metric tons of electrolytic galvanized steel were produced in 1997. The total market for metallizing and galvanizing in the United States is estimated at $1.4 billion per year. This figure is the total material costs of the metal coating and the cost of processing and does not include the cost of the carbon steel member being galvanized/metallized.

Corrosion-resistant alloys are used where corrosive conditions prohibit the use of carbon steels and protective coatings do not provide sufficient protection or are economically not feasible. Examples of these alloys include stainless steels, nickel-base alloys, and titanium alloys. The total 1998 consumption cost of the corrosion-resistant metals and alloys is estimated at $7.7 billion.

According to U.S. Census Bureau statistics, 2.5×10^6 metric tons of raw stainless steel were sold in the United States in 1997. With an estimated cost of $2.20/kg ($1/lb) for raw stainless steel, a total annual (1997) production cost of $5.5 billion was estimated. It was assumed that all production is for U.S. domestic consumption. The total consumption of stainless steel also includes imports, which account for more than 25% of the U.S. market. Thus, the total consumption of stainless steel can be estimated at $7.3 billion.

Where environments become particularly severe, nickel-base and titanium alloys are used. Nickel-base alloys are used extensively in the oil production, refinery, and chemical process industries, where conditions are severely corrosive. Furthermore, there is increased use of these alloys in other industries, where high temperatures and/or severe corrosive conditions exist. With the average price for nickel-base alloys at $13/kg ($6/lb) in 1998, the total sales value in the United States was estimated at $285 million.

The primary use of titanium alloys is in the aerospace and military industry, where the high strength-to-weight ratio and resistance to high temperatures are properties of interest. However, titanium and its alloys are also corrosion resistant to many environments and therefore have found application in oil production, refinery, chemical process, and pulp and paper industries. In 1998, it was estimated that 65% of titanium mill products were used for aerospace and 35% for nonaerospace applications. The total annual consumption price for titanium and titanium alloys for corrosion control applications is estimated at $150 million.

Corrosion Inhibitors. A corrosion inhibitor may be defined, in general terms, as a substance that, when added in a small concentration to an environment, effectively reduces the corrosion rate of a metal exposed to that environment. Inhibition is used within carbon steel pipes and vessels as an economic corrosion control alternative to stainless steels and alloys, coatings, or nonmetallic composites. A particular advantage of corrosion inhibition is that it often can be implemented or changed in situ without disrupting a process. The major industries using corrosion inhibitors are oil and gas exploration and production, petroleum refining, chemical manufacturing, heavy manufacturing, water treatment, and the product additive industries. The total consumption of corrosion inhibitors in the United States has doubled from approximately $600 million in 1982 to nearly $1.1 billion in 1998.

Engineering Plastics and Polymers. In 1996, the plastics industry accounted for $274.5 billion in shipments. It is difficult to estimate the fraction of plastics used for corrosion control, because, in many cases, plastics and composites are used for a combination of reasons, including corrosion control, light weight, economics, strength-to-weight ratio, and other unique properties. While corrosion control is a major market for many polymers, certain polymers are used mostly, if not exclusively, for corrosion control purposes. The significant

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

markets for corrosion control by polymers include composites (primarily glass-reinforced thermosetting resins), polyvinyl chloride pipe, polyethylene pipe, and fluoropolymers. The portion of polymers used for corrosion control is estimated at $1.8 billion.

Cathodic and Anodic Protection. The cost of cathodic and anodic protection of metallic structures subject to corrosion can be divided into the cost of materials and the cost of installation and operation. Industry data showed that the 1998 sales of hardware components totaled $146 million. The largest share of the cathodic protection market is taken up by sacrificial anodes at $60 million, of which magnesium has the greatest market share. Major markets for sacrificial anodes are the water heater market and the underground storage tank market. The cost of installation of the various cathodic protection components for underground structures varies significantly, depending on the location and the specific details of the construction. For 1998, the average total cost for installing cathodic protection systems was estimated at $0.98 billion (range: $0.73 billion to 1.22 billion). The total cost for replacing sacrificial anodes in water heaters and corrosion-related replacement of water heaters was estimated at $1.24 billion/year. Therefore, the total estimated cost for cathodic and anodic protection is $2.22 billion/year.

Corrosion Control Services. In the context of the study, services were defined as companies, organizations, and individuals that provide contract services for corrosion control purposes, while excluding corrosion-related activities that owners/operators may do in-house. By taking the NACE International membership as a basis, an estimate was made of the total number of engineers and scientists who provide corrosion control services. Based on a 16,000 membership in 1998 and the assumption that 25% provide contract corrosion control services, a total services cost of $1.2 billion was estimated.

Research and Development. Over the past few decades, less funding has been made available for corrosion-related research and development, which is significant in light of the costs of maintaining aging infrastructure. In fact, several government and corporate research laboratories have significantly reduced their corrosion research staff or have even closed down their research facilities. Moreover, less research and development funding has been available from either government or private sources. An estimate of an annual academic budget of $20 million was made, while no estimates were made for the cost of corporate corrosion-related research.

Education and Training. Corrosion-related education and training in the United States includes degree programs, certification programs, company in-house training, and general education and training. A few national universities offer courses in corrosion and corrosion control as part of their engineering curriculum. Professional organizations, such as NACE International and SSPC, The Society for Protective Coatings, offer courses and programs that range from basic corrosion training to certification of coating inspectors and cathodic protection specialists. NACE International offers the broadest range of courses and manages an extensive certification program. In 1998, NACE International held 172 courses with more than 3000 students, conducted multiple seminars, and offered publications, at a total cost of $8 million.

Method 1 Summary

A total annual direct cost of corrosion by summing the costs of corrosion control methods and services was estimated at $121 billion, which is 1.38% of the U.S. gross domestic product of $8.79 trillion in 1998. The largest portion (88.3%) of this cost is the organic coatings group, at $107.2 billion. Notably, the categories of research and development and education and training indicated unfavorably low numbers.

Costs of Corrosion Estimated by Industry Sector Analysis

In the second method used in the 1998 U.S. study, the cost of corrosion was first determined for specific industry sectors and then extrapolated to calculate a national total corrosion cost. The U.S. economy was divided into five sector categories and 26 sectors, as shown in Table 3. The cost of corrosion was estimated for each of the categories listed in Table 3. When summed, the total annual cost of corrosion for the industry sectors examined was $137.9 billion. The breakdown of these costs among the five sector categories is given in Fig. 2. Not all industries were examined in this study. The total economic impact on the U.S. economy of all sectors is greater than the $137.9 billion given here and was calculated in the study by extrapolation for sectors that were not researched. Details of the corrosion costs in the individual industry sectors are given subsequently.

Table 3 Industry sectors and sector categories for 1998 U.S. cost of corrosion study

Sector categories	Sectors
Infrastructure	Highway bridges

Infrastructure

The U.S. infrastructure and transportation system allows for a high level of mobility and freight activity for the nearly 270 million residents and 7 million business establishments. In 1997, more than 230 million motor vehicles, ships, airplanes, and railroad cars were used on 6.4×10^6 km (4×10^6 miles) of highways, railroads, airports, and waterways. Pipelines and storage tanks are part of the infrastructure as well. The annual direct cost of corrosion in the infrastructure category is estimated at $22.6 billion. Contributions to infrastructure corrosion costs are shown in Fig. 3.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

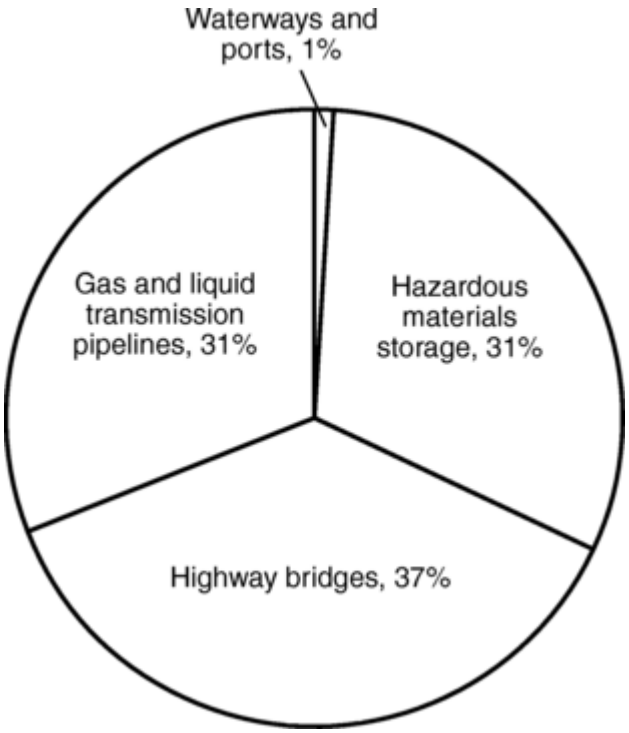

Fig. 3 Corrosion costs in infrastructure

Highway Bridges. There are 583,000 bridges in the United States (1998). Of this total, 200,000 bridges are steel, 235,000 are conventional reinforced concrete, 108,000 bridges are constructed using prestressed concrete, and the balance is made using other materials of construction. Approximately 15% of the bridges are structurally deficient, primarily due to corrosion of steel and steel reinforcement. The annual direct cost of corrosion for highway bridges is estimated at $8.3 billion, consisting of $3.8 billion to replace structurally deficient bridges over the next 10 years, $2.0 billion for maintenance and cost of capital for concrete bridge decks, $2.0 billion for maintenance and cost of capital for concrete substructures (minus decks), and $0.5 billion for maintenance painting of steel bridges.

Gas and Liquid Transmission Pipelines. There are more than 528,000 km (328,000 miles) of natural gas transmission and gathering pipelines, 119,000 km (74,000 miles) of crude oil transmission and gathering pipelines, and 132,000 km (82,000 miles) of hazardous liquid transmission pipelines. For all natural gas pipeline companies, the total investment in 1998 was $63.1 billion, from which total revenue of $13.6 billion was generated. For liquid pipeline companies, the investment was $30.2 billion, from which revenue of $6.9 billion was generated. At an estimated replacement cost of $643,800/km ($1,117,000/mile), the asset replacement value of the transmission pipeline system in the United States is $541 billion; therefore, a significant investment is at risk, with corrosion being the primary factor in controlling the life of the asset. The average annual corrosion-related cost is estimated at $7.0 billion, which can be divided into the cost of capital (38%), operation and maintenance (52%), and failures (10%).

Waterways and Ports. In the United States, 40,000 km (25,000 miles) of commercial navigable waterways serve 41 states, including all states east of the Mississippi River. Hundreds of locks facilitate travel along these waterways. In January 1999, 135 of the 276 locks had exceeded their 50 year design life. United States ports play an important role in connecting waterways, railroads, and highways. These ports include 1914 deepwater ports (seacoast and Great Lakes) and 1812 ports along inland waterways. Corrosion is typically found on piers and docks, bulkheads and retaining walls, mooring structures, and navigational aids. There is no formal tracking of corrosion costs for these structures. Based on figures obtained from the U.S. Army Corps of Engineers and the U.S. Coast Guard, an annual corrosion cost of $0.3 billion could be estimated. It should be noted that this is a low estimate, because the corrosion costs of harbor and other marine structures are not included.

Hazardous Materials Storage. The United States has approximately 8.5 million regulated and non-regulated aboveground storage tanks (ASTs) and underground storage tanks (USTs) for hazardous materials (HAZMAT). While these tanks represent a significant investment and good maintenance practices would be in the best interest of the owners, federal and state environmental regulators are concerned with the environmental impact

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

of spills from leaking tanks. The U.S. Environmental Protection Agency set a December 1998 deadline for UST owners to comply with requirements for corrosion control on all tanks, as well as overfill and spill protection. In case of noncompliance, tank owners face considerable costs related to cleanup and penalties. The total annual direct cost of corrosion for HAZMAT storage is $7.0 billion, broken down into $4.5 billion for ASTs and $2.5 billion for USTs.

Airports. The United States has the most extensive airport system in the world, which is essential to national transportation and the U.S. economy. According to 1999 Bureau of Transportation statistics data, there were 5324 public- use airports and 13,774 private-use airports in the United States. A typical airport infrastructure is complex, and components that might be subject to corrosion include the natural gas distribution system, jet fuel storage and distribution system, deicing storage and distribution system, vehicle fueling systems, natural gas feeders, dry fire lines, parking garages, and runway lighting. Generally, each of these systems is owned or operated by different organizations or companies; therefore, the impact of corrosion on an airport as a whole is not known or documented.

Railroads. In 1997, there were nine class I freight railroads (railroads with operating revenues of more than $256.4 million). These railroads accounted for 71% of the 274,399 km (170,508 miles) operated by the industry. There were 35 regional railroads (those with operating revenues between $40 million and 256.4 million and/or operating at least 560 km, or 350 miles, of railroad). The regional railroads operated 34,546 km (21,466 miles). Finally, there were 513 local railroads operating over 45,300 km (28,149 miles) of railroad. The elements that are subject to corrosion include metal members, such as rail and steel spikes; however, corrosion damage to railroad components is either limited or goes unreported. Hence, an accurate estimate of the corrosion cost could not be determined.

Utilities

Utilities supply gas, water, electricity, and telecommunications. All utility companies combined spent $42.3 billion on capital goods in 1998, broken down into $22.4 billion for structures and $19.9 billion for equipment. The total annual direct cost of corrosion in the utilities category is estimated to be $47.9 billion. Contributions to utility corrosion costs are shown in Fig. 4.

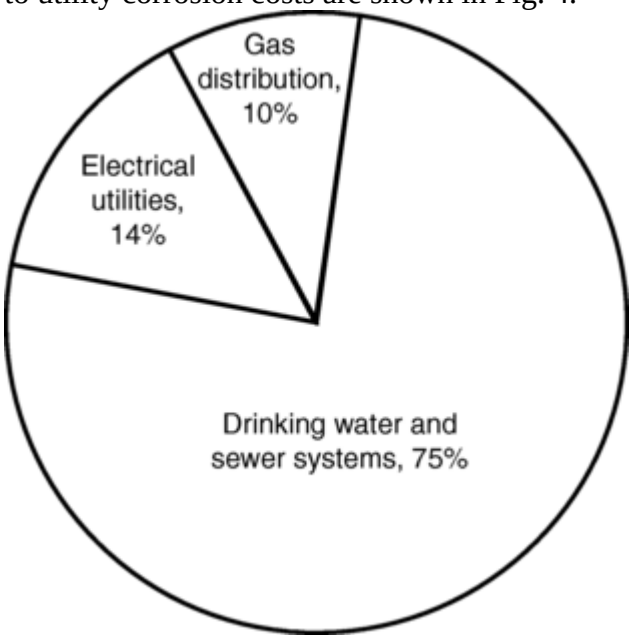

Fig. 4 Corrosion costs in utilities

Gas Distribution. The natural gas distribution system includes 2,785,000 km (1,730,000 miles) of relatively small-diameter, low-pressure piping, which is broken down into 1,739,000 km (1,080,000 miles) of distribution main and 1,046,000 km (650,000 miles) of services. There are approximately 55 million services in the distribution system. A large percentage of the mains (57%) and services (46%) are made of steel, cast iron, or copper, which are subject to corrosion. The total annual direct cost of corrosion was estimated at approximately $5.0 billion.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Drinking Water and Sewer Systems. According to the American Waterworks Association industry database, there are approximately 1,483,000 km (876,000 miles) of municipal water piping in the United States. This number is not exact, because most water utilities do not have complete records of their piping system. The sewer system consists of approximately 16,400 publicly owned treatment facilities that release some 155×10^6 m^3 (41×10^9 gal) of wastewater per day (1995). The total annual direct cost of corrosion for the drinking water and sewer systems of the nation was estimated at $36.0 billion. This cost consists of the cost of replacing aging infrastructure and the cost of unaccounted-for water through leaks, corrosion inhibitors, internal mortar linings, external coatings, and cathodic protection.

Electrical Utilities. In 1998, the electrical utilities industry provided a total amount of electricity of 3.24 trillion GWh, at a cost to consumers of $218 billion. Electrical generation plants can be divided into seven generic types: fossil fuel, nuclear, hydroelectric, cogeneration, geothermal, solar, and wind. The majority of electric power in the United States is generated by fossil fuel and nuclear supply systems. The total annual direct cost of corrosion in the electrical utilities industry in 1998 is estimated at $6.9 billion, with the largest amounts for nuclear power at $4.2 billion and fossil fuel at $1.9 billion, smaller amounts for hydraulic and other power at $0.15 billion, and transmission and distribution at $0.6 billion.

Telecommunications. The telecommunications infrastructure includes hardware, such as electronics, computers, and data transmitters, as well as equipment shelters and the towers used to mount antennas, transmitters, receivers, and television and telephone systems. According to the U.S. Census Bureau, the total value of shipments for communications equipment in 1999 was $84 billion. An important factor for corrosion cost is the additional cost of protecting towers and shelters, such as painting and galvanizing. In addition, corrosion of buried copper grounding beds and galvanic corrosion of the grounded steel structures contribute to the corrosion cost. For this sector, no corrosion cost was determined because of the lack of information on this rapidly changing industry. Many components are being replaced before physically failing, because their technology becomes obsolete in a short period of time.

Transportation

The transportation category includes vehicles and equipment, such as motor vehicles, aircraft, railroad cars, and hazardous materials transport, that make use of U.S. highways, waterways, railroads, and airports. The annual cost of corrosion in the transportation category is estimated at $29.7 billion. Contributions to transportation corrosion costs are shown in Fig. 5.

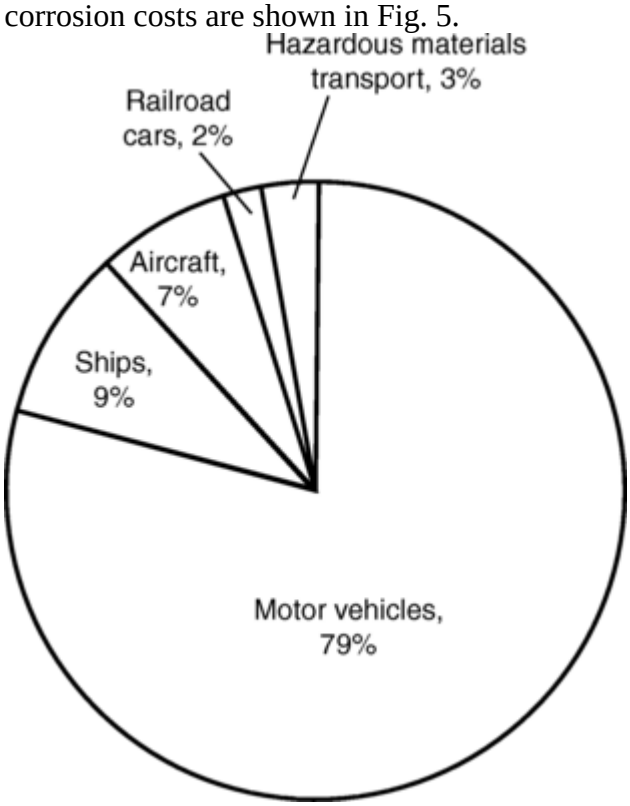

Fig. 5 Corrosion costs in transportation

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Motor Vehicles. United States consumers, businesses, and government organizations own more than 200 million registered motor vehicles. Assuming the average value of an automobile is $5000, the total investment Americans have made in motor vehicles can be estimated at $1 trillion. Since the 1980s, car manufacturers have increased the corrosion resistance of vehicles by using corrosion-resistant materials, employing better manufacturing processes, and designing corrosion-resistant vehicles. Although significant progress has been made, further improvement can be achieved in corrosion resistance of individual components. The total annual direct cost of corrosion is estimated at $23.4 billion, which is broken down into the following components: increased manufacturing costs due to corrosion engineering and the use of corrosion- resistant materials ($2.56 billion), repairs and maintenance necessitated by corrosion ($6.45 billion), and corrosion-related depreciation of vehicles ($14.46 billion).

Ships. The U.S. flag fleet consists of the Great Lakes, with 737 vessels at 100×10^9 ton-km (62×10^9 ton-miles); inland, with 33,668 vessels at 473×10^9 ton-km (294×10^9 ton-miles); ocean, with 7014 vessels at 563×10^9 ton-km (350×10^9 ton-miles); recreational, with 12.3 million boats; and cruise ships, with 122 boats serving North American ports (5.4 million passengers). The total annual direct cost of corrosion to the U.S. shipping industry is estimated at $2.7 billion. This cost is broken down into costs associated with new ship construction ($1.1 billion), maintenance and repairs ($0.8 billion), and corrosion-related downtime ($0.8 billion).

Aircraft. In 1998, the combined commercial aircraft fleet operated by U.S. airlines was more than 7000 airplanes. At the start of the jet age (1950s to 1960s), little or no attention was paid to corrosion and corrosion control. One of the concerns is the continued aging of the airplanes beyond the 20 year design life. Only the most recent designs (e.g., Boeing 777 and late-version 737) have incorporated significant improvements in corrosion prevention and control in design and manufacturing. The total annual direct cost of corrosion to the U.S. aircraft industry is estimated at $2.2 billion, which includes the cost of design and manufacturing ($0.2 billion), corrosion maintenance ($1.7 billion), and downtime ($0.3 billion).

Railroad Cars. In 1998, 1.3 million freight cars and 1962 passenger cars were operated in the United States. Covered hoppers (28%) and tanker cars (18%) make up the largest segment of the freight car fleet. The type of commodities transported range from coal (largest volume) to chemicals, motor vehicles, farm products, food products, and ores and minerals. Railroad cars suffer from both external and internal corrosion. The total annual direct cost of corrosion is estimated at $0.5 billion, broken down into external coatings ($0.25 billion) and internal coatings and linings ($0.25 billion).

Hazardous Materials Transport. According to the U.S. Department of Transportation, there are approximately 300 million hazardous materials shipments totaling more than 3.1×10^9 metric tons annually in the United States. Bulk transport over land includes shipping by tanker truck and rail car and by special containers on vehicles. Over water, ships loaded with specialized containers, tanks, and drums are used. In small quantities, hazardous materials require specially designed packaging for truck and air shipment. The total annual direct cost of corrosion for hazardous materials transport is more than $0.9 billion. The elements of the annual corrosion cost include the cost of transporting vehicles ($0.4 billion), specialized packaging ($0.5 billion), and the direct and indirect costs of accidental releases and corrosion-related transportation incidents.

Production and Manufacturing

This category includes industries that produce and manufacture products of crucial importance to the economy and the standard of living in the United States. These include oil production, mining, petroleum refining, chemical and pharmaceutical production, and agricultural and food production. The total annual direct cost of corrosion for production and manufacturing was estimated at $17.6 billion. Contributions to the production and manufacturing corrosion costs are shown in Fig. 6.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

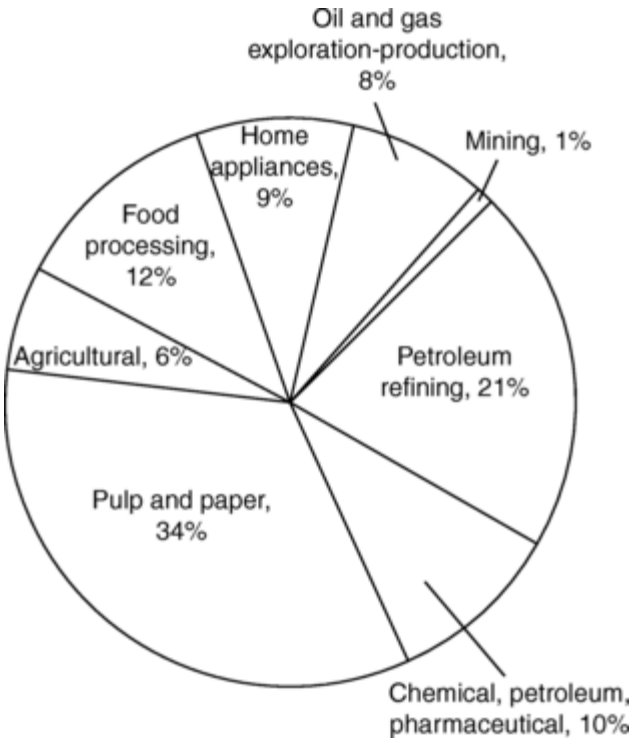

Fig. 6 Corrosion costs in production and manufacturing

Oil and Gas Exploration and Production. Domestic oil and gas production can be considered a stagnant industry, because most of the significant available onshore oil and gas reserves have been exploited. Oil production in the United States in 1998 consisted of 3.04×10^9 barrels. The significant recoverable reserves left to be discovered and produced are probably limited to less convenient locations, such as in deep water offshore, remote arctic locations, and difficult-to-manage reservoirs with unconsolidated sands. The total annual direct cost of corrosion in the U.S. oil and gas production industry is estimated at $1.4 billion, broken down into $0.6 billion for surface piping and facility costs, $0.5 billion in downhole tubing expenses, and $0.3 billion in capital expenditures related to corrosion.

Mining. In the mining industry, corrosion is not considered a significant problem. There is a consensus that the life-limiting factors for mining equipment are wear and mechanical damage rather than corrosion. Maintenance painting, however, is heavily relied on to prevent corrosion, with an annual estimated expenditure for the coal mining industry of $0.1 billion.

Petroleum Refining. The U.S. refineries represent approximately 23% of the petroleum production in the world, and the United States has the largest refining capacity in the world, with 163 refineries. In 1996, U.S. refineries supplied more than 18 million barrels/day of refined petroleum products. The total annual direct cost of corrosion is estimated at $3.7 billion. Of this total, maintenance-related expenses are estimated at $1.8 billion, vessel turnaround expenses at $1.4 billion, and fouling costs are approximately $0.5 billion annually.

Chemical, Petrochemical, and Pharmaceutical. The chemical industry includes those manufacturing facilities that produce bulk or specialty compounds by chemical reactions between organic and/or inorganic materials. The petrochemical industry includes those manufacturing facilities that create substances from raw hydrocarbon materials such as crude oil and natural gas. The pharmaceutical industry formulates, fabricates, and processes medicinal products from raw materials. The total annual direct cost of corrosion for this industry sector is estimated at $1.7 billion/year (8% of total capital expenditures). No calculation was made for the indirect costs of production outages or indirect costs related to catastrophic failures. The costs of operation and maintenance related to corrosion were not readily available; estimating these costs would require detailed study of data from individual companies.

Pulp and Paper. The $165 billion pulp, paper, and allied products industry supplies the United States with approximately 300 kg (660 lb) of paper per person per year. More than 300 pulp mills and more than 550 paper mills support its production. The total annual direct cost of corrosion is estimated at $6.0 billion, with the majority of this cost in the paper and paperboard industry, and is calculated as a fraction of the maintenance costs. No information was found to estimate the corrosion costs related to the loss of capital.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Agricultural operations produce livestock and crops. According to the National Agricultural Statistics Service, there are approximately 1.9 million farms in the United States. Based on the 1997 Farm Census, the total value of farm machinery and equipment is approximately $15 billion/year. The two main reasons for replacing machinery or equipment include upgrading old equipment and replacement because of wear and corrosion. Discussions with experts in this industrial sector resulted in an estimate of corrosion costs in the range of 5 to 10% of the value of all new equipment. Therefore, the total annual direct cost of corrosion in the agricultural production industry is estimated at $1.1 billion.

Food Processing. The food processing industry is one of the largest manufacturing industries in the United States, accounting for approximately 14% of the total U.S. manufacturing output. Sales for food processing companies totaled $265.5 billion in 1999. Because of food quality requirements, stainless steel is widely used. Assuming that the stainless steel consumption and cost in this industry are entirely attributed to corrosion, a total annual direct cost of corrosion is estimated at $2.1 billion. This cost includes stainless steel use for beverage production, food machinery, cutlery and utensils, commercial and restaurant equipment, and appliances. Also included are aluminum cans and the use of corrosion inhibitors.

Electronics. Corrosion in electronic components manifests itself in several ways, and computers, integrated circuits, and microchips are being exposed to a variety of environmental conditions. Corrosion in electronic components is insidious and cannot be readily detected; therefore, when corrosion failure occurs, it is often dismissed as just a failure, and the part or component is replaced. Particularly in the case of consumer electronics, devices become technologically obsolete long before corrosion-induced failures occur. However, in capital-intensive industries with significant investments in durable equipment with a considerable number of electronic components, such as the defense industry and the airline industry, there is a tendency to keep the equipment for longer periods, and corrosion is likely to become an issue. Although the cost of corrosion in the electronics sector could not be estimated, it has been suggested that a significant part of all electric component failures is caused by corrosion.

Home Appliances. The appliance industry is one of the largest consumer products industries. For practical purposes, two categories of appliances are distinguished: major home appliances and comfort-conditioning appliances. In 1999, 70.7 million major home appliances and 49.5 million comfort-conditioning appliances were sold in the United States, for a total of 120.2 million appliances. The cost of corrosion in home appliances includes the cost of purchasing replacement appliances because of premature failures due to corrosion. For water heaters alone, the replacement cost was estimated at $460 million/year, using a low estimate of 5% of replacement being corrosion related. The cost of internal corrosion protection for all appliances includes the use of sacrificial anodes ($780 million/year), corrosion-resistant materials (no cost estimate), and internal coatings (no cost estimate). The cost of external corrosion protection using coatings was estimated at $260 million/ year. Therefore, the estimated total annual direct cost of corrosion in home appliances is at least $1.5 billion.

Government

Federal, state, and local governments had a 1998 GDP of approximately $1.1 trillion ($360 billion federal, $745 billion state and local). While the government owns and operates significant assets under various departments, the U.S. Department of Defense was selected for analysis because of its significant impact on the U.S. economy. A second analyzed government sector is nuclear waste storage.

Defense. Corrosion of military equipment and facilities has been a significant and ongoing problem for many years. The corrosion-related problems are becoming more prominent as the acquisition of new equipment is decreasing and the reliability required of aging systems is increasing. The data provided by the military services (Army, Air Force, Navy, and Marine Corps) indicate that corrosion is potentially the number one cost driver in life-cycle costs. The total annual direct cost of corrosion incurred by the military services for systems and infrastructure is approximately $20 billion.

Nuclear Waste Storage. Nuclear wastes are generated from spent nuclear fuel, dismantled nuclear weapons, and products such as radiopharmaceuticals. The most important design item for the safe storage of nuclear waste is effective shielding of radiation. Corrosion is an important issue in the design of the casks used for permanent storage, which have a design life of several thousand years. A 1998 total life-cycle cost analysis by the U.S. Department of Energy for the permanent disposal of nuclear waste in Yucca Mountain, Nevada, estimated the total repository cost by the construction phase (2002) at $4.9 billion, with an average annual cost (from 1999 to 2116) of $205 million. Of this cost, $42.2 million is corrosion related.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Method 2 Summary

The cost of corrosion was estimated for the individual economic sectors discussed previously. The total cost due to the impact of corrosion for the analyzed sectors was $137.9 billion/year (Fig. 2, Table 4). Table 4 shows the costs of corrosion for each industry sector analyzed in the current study. The dollar values are rounded to the nearest $0.1 billion because of the uncertainty in the applied methods. The cost of $137.9 billion is believed to be a conservative estimate. In each sector, only the major corrosion costs were considered. In addition, even major costs were left out when no basis for an estimate was found; most notable were no operation and maintenance costs were included for the chemical, petrochemical, and pharmaceutical sector; no capital costs were included for the pulp and paper sector; no capital costs were included for the gas distribution sector; and replacement costs were considered for only water heaters in the home appliances sector. In most cases, conservative estimates were made when no basis was available; most notable was that only 5% of water heaters are replaced due to corrosion. Therefore, the total cost of corrosion is a conservative value and is likely higher than that presented in this study.

Table 4 Summary of industry sector direct corrosion costs analyzed in 1998 U.S. study

Category	Industry sectors	Estimated direct cost of corrosion per sector	
		$ × billion	**%[a]**
Infrastructure (16.4% of total)	Highway bridges	8.3	37
	Gas and liquid transmission pipelines	7.0	27
	Waterways and ports	0.3	1
	Hazardous materials storage	7.0	31
	Airports	[b]	[b]
	Railroads	[b]	[b]
	Subtotal	**$22.6**	**100%**
Utilities (34.7% of total)	Gas distribution	5.0	10
	Drinking water and sewer systems	36.0	75
	Electrical utilities	6.9	14
	Telecommunications	[b]	[b]
	Subtotal	**$47.9**	**100%**
Transportation (21.5% of total)	Motor vehicles	23.4	79
	Ships	2.7	9
	Aircraft	2.2	7
	Railroad cars	0.5	2
	Hazardous materials transport	0.9	3
	Subtotal	**$29.7**	**100%**
Production and manufacturing (12.8% of total)	Oil and gas exploration and production	1.4	8
	Mining	0.1	1
	Petroleum refining	3.7	21

	Subtotal	**$20.1**	**100%**
	Total	**$137.9**	

(a) Individual values do not add up to 100% because of rounding.
(b) Corrosion costs not determined

The data show that the highest corrosion costs are incurred by drinking water and sewer systems. The large value of $36.0 billion/year for both types of systems together is due to the extent of the water transmission and distribution network in the United States. The metal piping systems are aging and will require increased maintenance in the future. Large indirect costs are expected as well but were not quantified in the current study.

The second large corrosion cost ($23.4 billion/ year) was found in the motor vehicles sector. The corrosion impact consists of corrosion-related depreciation costs (62%), corrosion-resistant materials of construction (10%), and the cost of increased maintenance because of corrosion (28%). The indirect cost in this sector is expected to be large, especially because of the time users of motor vehicles lose when having to deal with car maintenance and repair.

The third large corrosion cost ($20 billion/ year) was observed in defense systems. Reliability and readiness are of crucial importance; therefore, military vehicles, aircraft, ships, weapons, and facilities must be continuously maintained. A determining factor in the defense sector is the readiness for operation under any circumstance and in corrosive environments such as seawater, swamps or wetlands, and in rain and mud.

Large corrosion costs were further found in the sectors for highway bridges ($8.3 billion/ year), gas and liquid transmission pipelines ($7.0 billion/year), electrical utilities ($6.9 billion/ year), pulp and paper ($6.0 billion/year) and gas distribution ($5.0 billion/year). Two factors were important for these sectors: the large number of units and the severely corrosive environments. The following lists specific concerns regarding corrosion for some of the sectors that have large corrosion costs:

- The national systems of highways require many bridges to be maintained. With the commonly used approach that bridges are constructed to have a design life, rather than being there forever, the burden to maintain, repair, and replace this infrastructure will continue to grow because of aging components.
- The network of transmission pipelines is quite large (779,000 km, or 484,000 miles) and transports potentially corrosive liquids and gas, which makes their operation sensitive to public opinion related to environmental spills and highly publicized ruptures. Although pipelines have proven to be the safest way to transport large quantities of product over long distances, preventing corrosion is a significant cost.
- The same argument regarding potential spills holds for the hazardous materials storage sector. Corrosion protection is a significant cost per tank for both underground and aboveground tanks. The total number of hazardous materials storage tanks in the United States is large—estimated at 8.5 million tanks.
- Electrical utilities have large corrosion costs due to the affected operation and maintenance costs, depreciation costs, and the cost of forced outages. The largest cost is found for nuclear-power-generated plants because of the higher inspection frequency in nuclear plants as compared with fossil-fueled plants.
- The pulp and paper industry uses corrosive media to make pulp from wood. Changes in process conditions over the last decades have had a significant impact on the materials used for construction. Paper quality and process reliability are driving spending in this sector.

The total cost of corrosion in the analyzed sectors of $137.9 billion/year was based on detailed analysis of industrial sectors, which are known to have significant corrosion impact. The sum of these sectors represented 27.55% of the GDP. Because not all economic sectors were examined, the sum of the estimated costs for the analyzed sectors does not represent the total cost of corrosion for the entire U.S. economy. Based on the procedure for extrapolation, which used the percentage of cost of corrosion for Bureau of Economic Analysis subcategories (see Fig. 1 for the primary categories), an estimated total direct cost of corrosion of $275.7 billion/year was calculated (Fig. 7).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

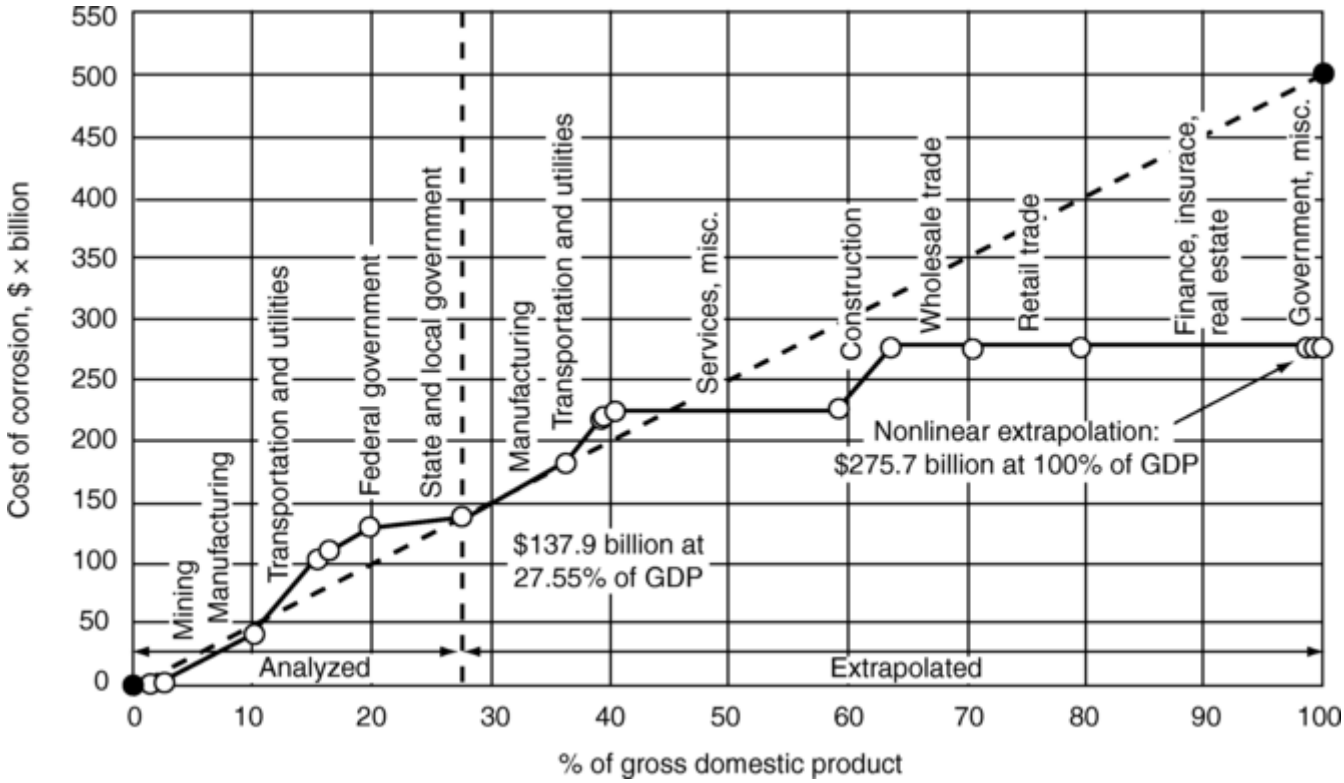

Fig. 7 Nonlinear extrapolation of cost of corrosion to entire U.S. economy

It must be noted that a straight, linear extrapolation of the costs is not recommended because of the expected lower overall corrosion impact in some of the nonanalyzed sectors (i.e., wholesale trade, retail trade, and finance, insurance, and real estate). If one would proceed with the linear extrapolation, the $137.9 billion for 27.55% of GDP would result in an estimate of total annual direct corrosion cost of $500.5 billion/year. In comparison, the nonlinear extrapolation in Fig. 7, based on the assumption that nonanalyzed sectors have different corrosion impact, shows a stepwise, cumulative calculation for total corrosion cost. The final estimate of direct corrosion costs is $275.7 billion/year.

Thus, the direct corrosion costs are 3.1% of the 1998 U.S. gross domestic product. Figure 8 shows graphically the impact of corrosion on the GDP of the nation. This estimate is considered a conservative estimate, because only well-documented costs were used. Other costs of corrosion were discussed in the study but were left out due to lack of documentation.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

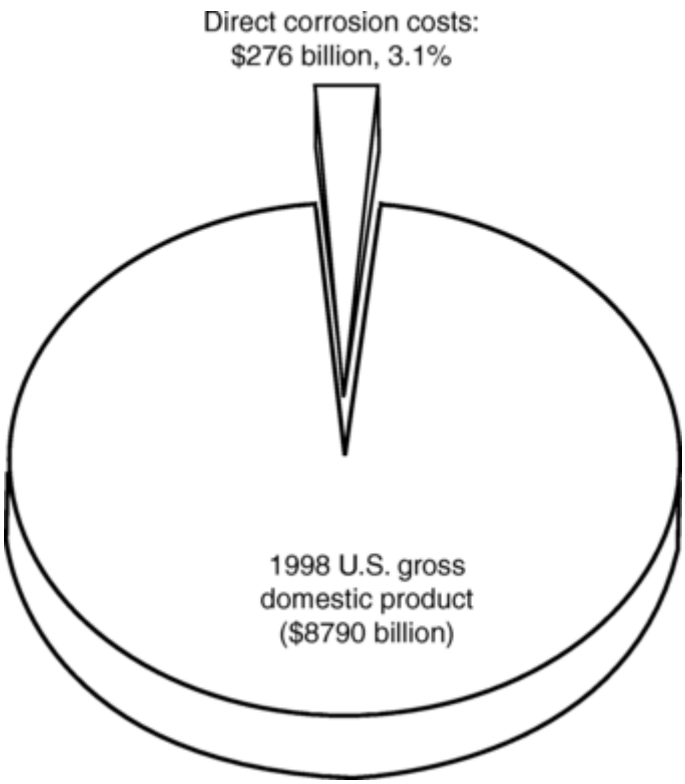

Fig. 8 Impact of corrosion on the U.S. economy

Direct corrosion costs were estimated based on direct costs to the owners or operators. The indirect costs incurred by those other than owners or operators were not included in the cost estimates. At 3.1% of the GDP, the cost of corrosion to the U.S. economy is already significant if only based on the direct cost of corrosion. However, the impact of corrosion can be significantly greater when indirect costs are included. Evidence of large indirect corrosion costs are lost productivity because of outages, delays, failures, and litigation; taxes and overhead on the cost of the corrosion portion of goods and services; and indirect costs of nonowner/operator activities. For example, an analysis of the corrosion cost for bridges indicated that the indirect costs due to traffic congestion and business disruption during repairs resulting in lost productivity can be 10 times or more than the direct bridge cost of corrosion. Analysis of the corrosion cost for electrical utilities indicated that the indirect costs (taxes and overhead costs to user) were 1.7 times the direct cost to the utility owner/operator. Averaged over the industry sectors, the assumption can be made that the indirect costs can be equal to, if not greater than, the direct costs. This would result in a total direct and indirect impact of corrosion of approximately $551.4 billion annually, or 6.3% of the GDP.

Conclusions Based on 1998 U.S. Study

The infrastructure of the nation is essential to the quality of life, industrial productivity, international competitiveness, and security. Everything depends on a functional, reliable, and safe infrastructure system, including food, water and energy needs, transportation for work, education and recreation, the production and

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

delivery of goods and services, communications, and the treatment and disposal of wastes. Each component of the national infrastructure, such as highways, airports, water supply, waste treatment, energy supply, and power generation, represents a complex system and large investments.

Corrosion is damage that results from the interaction of structures and materials with their environment. In some cases, corrosion damage is tolerable and perhaps only leads to somewhat higher maintenance costs and minimal losses; however, corrosion can result in catastrophic failures, with loss of life and disruption of essential services. In fact, corrosion is a primary cause of the degradation and a principal threat to the infrastructure of the nation. As documented in the 1998 U.S. Corrosion Cost Study, the direct costs of corrosion represent 3.1% of the U.S. gross domestic product, and the total costs to society can be twice that or greater. The infrastructure replacement cost is a major driver on the economic impact of corrosion and can still be greater if corrosion-preventive strategies are not properly employed. The opportunities for savings by improved corrosion control are presented in every industrial sector and can be significant.

The principal challenges in realizing the significant savings that result from improved corrosion control include an unfortunate lack of awareness of corrosion costs by the public and policymakers and a widely held misconception that nothing can be done about corrosion. The opportunities and the challenges for better corrosion control fall into two categories. First, there are technical issues for the realization of technological advances and the implementation of those advances. Second, there are nontechnical issues of perception regarding the policies and the practices used for improved corrosion control. In the 1998 U.S. Corrosion Cost Study, strategies for progress in corrosion control are presented for progress in both categories.

There is an increasing recognition and a growing shift in emphasis from the building of a new infrastructure to the preservation and extended use of an existing infrastructure. In Ref 4, the Federal Highway Administration indicated a shift in focus from constructing new highways to preserving and operating existing highways. Increased capacity, greater safety, and a longer life are desired from the existing infrastructure. The critical need for progress in preservation and extended use is also pertinent to the invisible infrastructure (i.e., those components of the infrastructure that are not recognized by the public and whose performance is taken for granted until a failure or loss of service occurs). This invisible infrastructure includes items such as water mains, gas and oil pipelines, power plants, and telecommunications systems.

The preservation and the extension of the useful life of an existing infrastructure is a great challenge because of the long service lives that are desired. The operating life of critical components of the infrastructure is often extended well beyond the original design service life. For example, the Brooklyn Bridge was constructed in 1883. Furthermore, some cast iron water mains that were constructed in the early 1900s remain in service today. These water mains continue to be a critical component for the municipal water supplies, even after nearly 100 years of use.

While the focus may recently have shifted from building a new infrastructure to the preservation and extended use of the existing infrastructure, the necessary changes in public attitudes, adjustments to the allocation of resources, changes to the industrial, government, and academic institutions, and revisions to policies, practices, and procedures have only just begun. The adjustments made to date do not adequately address the needs and opportunities. There are great opportunities for increased integrity, durability, and savings; however, both systemic and programmatic corrections are required so that these benefits can be realized. Barriers to progress and the effective implementation of improved corrosion control must be addressed.

Corrosion Prevention Strategies

The 1998 U.S. study showed that technological changes have provided many new ways to prevent corrosion and also showed the improved use of available corrosion management techniques. However, better corrosion management can be achieved using preventive strategies in nontechnical and technical areas. These preventive strategies include:

- Increase awareness of significant corrosion costs and potential cost savings
- Change the misconception that nothing can be done about corrosion
- Change policies, regulations, standards, and management practices to increase corrosion cost savings through sound corrosion management
- Improve education and training of staff in the recognition of corrosion control
- Implement advanced design practices for better corrosion management
- Develop advanced life prediction and performance assessment methods
- Improve corrosion technology through research, development, and implementation

While corrosion management has improved over the past several decades, the United States is still far from implementing optimal corrosion control practices. There are significant barriers to both the development of advanced technologies for corrosion control and the implementation of those technological advances. In order to realize the savings from reduced costs of corrosion, changes are required in three areas: the policy and management framework for effective corrosion control, the science and technology of corrosion control, and the technology transfer and implementation of effective corrosion control. The policy and management framework is crucial, because it governs the identification of priorities, the allocation of resources for technology development, and the operation of the system.

Incorporating the latest corrosion strategies requires changes in industry management and government policies as well as advances in science and technology. It is necessary to engage a larger constituency comprised of the primary stakeholders, government and industry leaders, the public, and consumers. A major challenge involves the dissemination of corrosion awareness and expertise that are currently scattered throughout government and industry organizations. In fact, there is no focal point for the effective development, articulation, and delivery of corrosion cost-savings programs.

Introduction

WHO IS A CORROSIONIST? A corrosion engineer, a corrosion technician, a corrosion scientist, a chemist, a physicist, an electrical engineer, a mechanical engineer, a coatings or plastics salesperson, a corrosion consultant, or a plant operator all may qualify for this title. The only requirement is a vocation that involves the understanding, evaluation, mitigation, or prevention of corrosion. The author first heard the term corrosionist used by Ted Kazmierczak, president of NACE International, 1998 to 1999, in his annual convention banquet address in San Diego, CA. He applied it to everyone in attendance, over a thousand people. And it seemed an appropriate and inclusive description of our collective interests.

“Tools for the Corrosionist” contains material not usually found in handbooks such as this. Corrosion is, however, an interdisciplinary subject, and corrosionists rely on many disciplines besides that central one that we identify with. The following articles are intended to help broaden the knowledge base of those concerned with the questions about corrosion and how to prevent or protect against it.

Statistics

Take, for example, statistics; corrosionists encounter statistical issues more often than most care to admit. The article “Statistics for the Corrosionist” presents an overview of statistical inference and addresses the most commonly used statistical tools and tests. It includes definitions and notational conventions, and a discussion of statistical hypotheses and selection of statistical tests. Illustrations are given of specific statistical tests and the concept of confidence limits. It concludes with a discussion of sampling issues, one- way analysis of variance, correlation, and simple regression analysis.

Instruments

The article “Applications of Modern Analytical Instruments in Corrosion” presents both in situ and ex situ analytical techniques successfully used to gain insight into the mechanisms of corrosion at a molecular and atomic level and for conducting failure analyses. The article explains the principles of various surface-sensitive techniques and the usefulness and limitations of these techniques. The techniques are divided into those that provide insight into surface topography and surface structure, and those that provide understanding of chemical nature and identity. No single analytical technique can answer all corrosion questions, but a suitable combination of techniques can provide much information about corrosion mechanisms. A clear understanding of corrosion mechanisms helps in identifying effective corrosion prevention techniques.

---

Additional Help

The article “Information Sources and Databases for the Corrosionist” provides some of the more important web sites and print media addressing corrosion and related topics. Lists are presented in five different areas: (a) societies and associations; (b) corrosion standards, specifications, and recommended practices; (c) sources of corrosion information; (d) corrosion databases and data compilations; and (e) other web resources. The lists are not inclusive but provide good starting points from which one can build.

Terminology and Presentation of Data

The article “Conventions and Definitions in Corrosion and Oxidation” describes some of the common conventions and definitions in corrosion and oxidation that can result in confusion and some degree of aggravation. The article is selective and modest in its goals and hopefully provides some clarity in the few areas addressed. These range from sign conventions, labeling conventions, definitions, and standard practices to conversions between different potential scales.

Introduction

THIS ARTICLE is an overview of basic statistical inference and reviews several of the most commonly used statistical tools and tests. It covers basic concepts but not in depth or detail, with the assumption that the reader already has at least some familiarity with these concepts and methods. For those interested in further reading, references to more thorough treatments are included. Also, the reader may wish to refer to the article “Statistical Interpretation of Corrosion Test Results” in this Volume.

Definitions, equations, and notational conventions that are used widely in statistical analysis are presented. The section on measurement provides a basic framework for the selection of a statistical test. While not the only consideration, the way that variables are measured is fundamental to the choice of a statistical test. The section “Statistical Hypothesis Testing” outlines the basic elements common to all statistical tests. Illustrations of specific statistical tests and the concept of confidence limits are introduced. An overview of sampling issues is provided, with guidance in both selecting a sampling method and determining the number of units to sample. One-way analysis of variance, correlation, and simple regression analysis are introduced and illustrated.

Statistical computations have become extremely easy to obtain. Most popular spreadsheet packages include statistical functions for most of the tests and other techniques described in this article. This article therefore emphasizes understanding underlying concepts as well as selection and interpretation of statistical tests and other tools. It should also be noted that, despite several references in this article to the use of published sampling distribution tables, with today's technology it is rarely necessary to look up a number in the appendix of a Handbook.

None of the information presented here is in any way new or original. Every effort has been made to acknowledge the original sources that were used to compile this article.

Definitions and Expressions

This section reviews definitions and formulas that are in wide use in statistical analysis. In addition to serving as a reference, this section is intended to establish definitions and conventions for the balance of the article.
Parameters Versus Estimates. A convention in statistical notation is to use Greek letters to represent parameters (true characteristics of a population or universe) and Roman letters to represent sample-based estimates of those parameters. Table 1 presents several of the most familiar concepts and their corresponding symbols.

Table 1 Symbols assigned to represent familiar statistical operations and quantities

	Operators	Variables	
		Parameters (universe)	**Estimates (sample)**
Mean	…	μ	$\overline{x}$, $\overline{X}$
Standard deviation	…	σ	*s*
Variance	…	σ^2	s^2
Standard error	…	$\sigma^2_{\bar{x}_i}$	$s/\sqrt{N-1}$
Summation	∑	…	…
Factorial	*n*!	…	…

Measures of central tendency are mean, median, and mode.
Mean is the arithmetic average. When *n* is the sample size and *N* is the population size:

$$\text{Sample mean:}\quad \overline{x} = \frac{\sum_{i=1}^{n} X_i}{n} \qquad \text{(Eq 1)}$$

$$\text{Population mean:}\quad \mu = \frac{\sum_{i=1}^{N} X_i}{N} \qquad \text{(Eq 2)}$$

Median is the midpoint, or the case separating equal numbers of larger and smaller values.
Mode is the most frequently occurring value.
Measures of dispersion include range, quartile deviation, variance, and standard deviation.
Range is the difference between highest and lowest values.
Quartile deviation is half the difference between upper and lower quartiles.
Variance is a means of quantifying the dispersion or scatter of the data or the total population. It is the second moment about the average.
Sample variance is represented by:

$$s^2 = \frac{\sum_{i=1}^{n} (X_i - \overline{x})^2}{n} \qquad \text{(Eq 3)}$$

Population variance is represented by:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\sigma^2 = \frac{\sum_{i=1}^{N}(X_i - \mu)^2}{N} \quad \text{(Eq 4)}$$

Standard deviation is the square root of the variance.
Sample standard deviation is:

$$s = \sqrt{\frac{\sum_{i=1}^{n}(X_i - \bar{x})^2}{n}} \quad \text{(Eq 5)}$$

Population standard deviation is:

$$\sigma = \sqrt{\frac{\sum_{i=1}^{N}(X_i - \mu)^2}{N}} \quad \text{(Eq 6)}$$

Other definitions and expressions that are useful in statistical analysis include standard error, binomial probability, and standard score.
Standard error (of the mean) is represented by:

$$\sigma_{\bar{x}} = \frac{\sigma}{\sqrt{N}} \quad \text{(Eq 7)}$$

Binomial probability is represented by:

$$P(r) = \frac{N!}{r!(N-r)!} \times p^r q^{N-r} \quad \text{(Eq 8)}$$

where N is the number of trials, r the number of successes, p the probability of success, and $q = 1 - p$.
Standard score is represented by:

$$Z = \frac{X - \bar{x}}{s} \quad \text{(Eq 9)}$$

where s is an estimate of the standard deviation obtained from a sample. Note that this transformation results in a variable with mean of 0 and standard deviation of 1. This has a number of useful applications, some of which are illustrated later in this article.

Measurement

Levels of Measurement. Measurement can be described as the process of assigning numbers to observations. The level of measurement is a critically important consideration in the selection of a statistical test. Scales of measurement can be classified according to a four-category typology developed by S.S. Stevens (Ref 1). The categories are nominal, ordinal, interval, and ratio.
A nominal scale consists of nothing more than a naming convention, or the assignment of a label to an attribute. Examples might be the numbers on ball players' uniforms or experimental test specimens made from copper, aluminum, steel, and glass.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

An ordinal scale, in contrast to a nominal scale, allows ordering of values in the scale but nothing else. An example of an ordinal scale is Moh's hardness scale, used in rock and mineral classification and identification (Ref 2).

An interval scale has all the properties of an ordinal scale but has the additional characteristic that scale integer values are separated by equal intervals (Ref 3). The condition that differentiates an interval scale from higher levels of measurement is that an interval scale has no meaningful or absolute zero point. Fahrenheit and Celsius temperature scales are examples of interval scales.

A ratio scale has all the attributes of an interval scale plus a meaningful zero point. Examples include absolute barometric pressure or Kelvin temperature.

Using Levels of Measurement in Test Selection. The choice of a statistical test depends heavily on the level of measurement for the variables involved in the test. In general, the test cannot involve computational operations that are not applicable for the scale type. For example, one cannot find the median (or a mean) for a nominal scale, because the scale values have no order. Consequently, only the mode (most frequent scale value) can be used to characterize central tendency of a nominal scale. Tests and other measures designed for nominal and ordinal scales are classified as nonparametric statistics. More generally, nonparametric statistics require fewer assumptions about level of measurement and/or about parameters of the underlying population (Ref 3).

Table 2 lists the correspondence between the level of measurement and the choice of a statistical test or other measure.

Table 2 Characteristics of the different levels of measurement scales

Levels-of-measurement scale	Descriptive statistics	Graphs	One- and two-variable statistical tests	Multivariate statistical tests
Nominal	Mode, frequency	Pie chart, bar graph	Binomial test, chi square	Log-linear models
Ordinal	Median, quartiles, percentiles	Pie chart, bar graph	Various non-parametric tests	Logistic regression, multinomial logit models
Interval	Mean, standard deviation, standard error	Histogram, scatter plot, line chart	Difference of means test, simple regression	Multiple regression
Ratio	Geometric mean, coefficient of variation	Histogram, scatter plot, line chart	Difference of means test, simple regression	Multiple regression
Mixed nominal and interval	…	…	One-way analysis of variance	N-way analysis of variance

Source: Adapted from Ref 3

Discrete and Continuous Variables. A second, related measurement issue involves whether a variable is discrete or continuous. A discrete variable can take only a finite number of values, but a continuous variable can take an infinite number of values (Ref 3). It is difficult, if not impossible, to come up with an example of a continuous, nominal scale. Ordinal, interval, and ratio scales may or may not be continuous.

Variables that are based on counts are discrete. Costs are technically discrete, because currency systems have a minimum unit, for example, the penny, that cannot be subdivided. From a practical standpoint, whenever a variable can take a large number of values relative to its range, it may be treated as continuous. However, when a variable has a relatively small number of possible values, special considerations apply in the selection of appropriate statistical techniques. Most generally, discrete variables can be addressed with nonparametric tests, and there are a number of other, more powerful options, depending on specific circumstances. Apart from nominal scales, this is most likely to be an issue for the statistical analysis of counts of rare events. An example might be traffic accidents, tabulated over a one-year period, at 100 residential street intersections.

Statistical Hypothesis Testing

The basis of a statistical test is that one can make a prediction about the range of possible outcomes of an experiment or other set of formal observations based on what is known or can readily be assumed about random events. One can then use that prediction to make a judgement about a specific outcome of an investigation, that is, whether or not the outcome occurred by chance.

Probability, Sampling Distributions, and the Normal Curve. Imagine a coin-tossing exercise in which a coin is tossed ten times, and the results (number of heads versus tails) are tallied. The probability of any particular outcome is given in Fig. 1. Note that the distribution in Fig. 1 could be approximated by repeating the coin-toss exercise a large number of times, and that the larger the number of repetitions of the exercise, the better the approximation. Figure 1 is an example of a *sampling distribution.* A sampling distribution associates probabilities with the possible outcomes of an experiment. In this case, the distribution is tailored to an experiment involving 10 trials and makes the assumption that the probability (*P*) of heads or tails is equal:

$$P(\text{heads}) = P(\text{tails}) = 0.5 \qquad \text{(Eq 10)}$$

On an informal basis, one can make a judgement about any one coin-tossing experiment, along the lines that 4, 5, or 6 heads should occur approximately two-thirds of the time and are not at all unusual. However, 0, 1, 9, or 10 heads are only expected in 2.2% of such experiments and should be regarded as unusual, if not suspicious.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

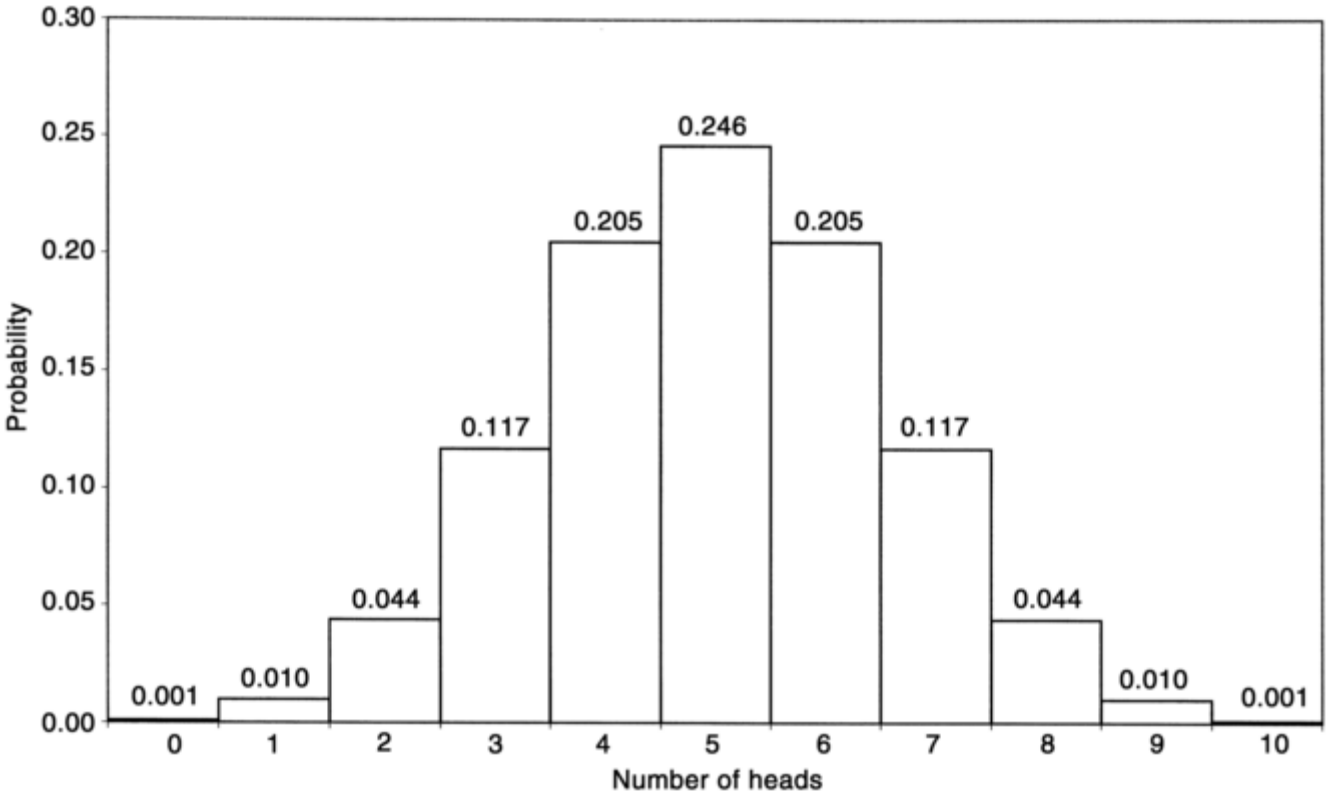

Fig. 1 Binomial distribution from a hypothetical coin-tossing experiment

Also, note that the shape of the distribution in Fig. 1 is beginning to approximate a bell-shaped curve and that if the coin-tossing exercise had been carried out in sets of say, 50 instead of 10, the resulting distribution would provide a crude, discrete approximation of the normal curve. The normal curve has a number of important properties. It is continuous, bell-shaped, and symmetrical. In its standard form, it has a mean $\mu = 0$ and standard deviation $\sigma = 1$. The tails of the curve approach but never reach zero. A normal curve can be generated with the following expression:

$$Y = \frac{1}{s\sqrt{2\pi}} e^{-(x-\bar{x})^2/2s^2} \qquad \text{(Eq 11)}$$

where Y is the height of the curve for any x. Another important attribute of the normal curve is that the area under it is unity. Also, 68.26% of the area falls within one standard deviation on both sides of the mean, and 95.46% within two standard deviations. Any statistics text includes a table of areas under the normal curve, for standard scores (see Eq 9).

Most statistical tests that are designed for variables measured using an interval and ratio scale use the normal distribution as a sampling distribution and consequently require an assumption that a sampling distribution generated from that universe would be normally distributed. This is rarely an issue for large samples, but it is an important assumption required for small samples.

Specifying Research and Null Hypotheses. From the previous discussion of coin-tossing experiments, it should be clear that some outcomes are more probable than others and that judgments can be made regarding most outcomes. Figure 1 suggests that an outcome of zero (or ten) heads in ten trials does not occur very often. If an outcome of ten heads were to occur, one might be inclined to question these assumptions about the experiment. In generating the sampling distribution in Fig. 1, it was assumed that the probably of heads or tails was 0.5 (Eq 10). However, there are potentially a number of explanations for an outcome that appears to defy probability. The coin itself could be biased. The person tossing the coin could be influencing the outcome, intentionally or inadvertently. There could be an unknown or unidentified external agent influencing the outcome.

In the context of a scientific experiment, the experimenter works with a research (alternative) hypothesis; for example, experimental coating *A* has a longer effective life than control coating *B*. However, in the design of an experiment, a variety of assumptions are required. For example, among other things, it is necessary to assume that materials used to prepare test samples are well within specifications for coatings *A* and *B*, that application of the coatings is comparable, and that environmental conditions affecting the test samples are truly equivalent.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The fact that an outcome fails to conform to expectations about probability does not tell us why the outcome occurred. Because of this, statistical inference is set up to test a *null hypothesis*, conventionally designated as H_0. In this example, an appropriate null hypothesis might be $\mu_A = \mu_B$, or that the mean effective life of coating *A* is no different from the mean effective life of coating *B*. The statistical test either rejects or fails to reject the null hypothesis. In this context, if the null hypothesis is not rejected, no conclusions are supported. The mean effective life of coating *A* could equal that of *B*, the sampling may not have been representative, or the test procedure may not have been sensitive to the difference. If the null hypothesis is rejected, the research (alternative) hypothesis remains and may be thought of as becoming more tenable but is not "proven." This is appropriate, because a statistical test requires more than one assumption, including the null hypothesis, and it is never certain which of the assumptions is incorrect. The null hypothesis could have been rejected, because the research hypothesis was true, but it could also have been due to a failure in the experimental setup, measurement error, or a variety of other causes.

Defining a Critical Region. Once a null hypothesis is stated, it is necessary to define a set of outcomes that entail rejection, called the critical region. Returning again to Fig. 1, one could arbitrarily define 0, 1, 9, and 10 heads to constitute the critical region, or the set of outcomes that would result in rejection of the null hypothesis, *P*(heads) = *P*(tails) = 0.5. The probability of rejecting the null hypothesis, if it is true, is 0.001 + 0.010 + 0.001 + 0.010 = 0.022. Fortunately, it is rarely necessary to generate a sampling distribution as in Fig. 1. A variety of applicable sampling distributions have been derived and are available, in tabular form, in the appendix of most statistics books.

Rejecting a true null hypothesis is known as a type I error. The probability of a type I error is α, 0.022 in the example just given, and is determined by the investigator through selection of the critical region. However, there is also a type II error, failing to reject a false null hypothesis, with a type II error rate designated by β. The double negative of the type II error, involved in the notion of failure to reject a false null hypothesis, refers to the power of the test. Table 3 is provided to help minimize potential confusion.

Table 3 Type I and type II errors in defining a critical region

Decision regarding H_0	H_0 is:	
	True	**False**
Reject H_0	Type I error α	Correct decision
Fail to reject H_0	Correct decision	Type II error β

Source: Adapted from Ref 4

A number of additional factors can influence β, but, in general, probabilities of α and β are inversely related. This is important for two reasons. First, an understanding of the risk of a type I error is essential in a number of important decisions leading up to a statistical test, including determining the required number of observations and selecting a test statistic. For any given α, there are a number of ways to reduce β. One is to increase the number of observations. Some statistical tests provide a smaller probability of a β error for a given α level. This test attribute is referred to as the *power* of a statistical test. More specifically, the power of a test is defined as 1 - β. In most cases, tests designed for the higher levels of measurement involving interval or ratio scales are more powerful than tests designed for nominal or ordinal scales. Assumptions also influence β. For example, in many cases, the ability to confidently predict direction relative to a central measure can be used to reduce β and gain statistical power by using what is referred to as a *directional*, or *one-tailed*, test.

A second major consideration comes into play primarily in applied research. There is an entrenched convention in basic research to use a critical region of α = 0.05 or smaller. In the context of basic research, smaller generally is better, to the extent that embracing false results is to be avoided at almost any cost. However, in applied science, both types of errors entail practical consequences. Costs of an error in one direction may greatly exceed those of an error in the other. For example, additional reinforcing steel in a reinforced concrete beam might increase construction cost by only 2% and prevent both premature and catastrophic structural failures. In this context, the two kinds of errors usually deserve more balanced consideration, and this may entail consideration of a larger α value. It should also be noted that the practice of pre- selecting any particular α level is falling out of favor, in preference for more straight-forward reporting of the probability (*p* value) associated with the test result and allowing users of the research to draw their own conclusions.

The Central Limit Theorem. Even though many known sampling distributions, including the normal, Student's *t*, χ^2, and *F* distributions, have been derived and tabulated, it is of some value to understand more about them.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Any sampling distribution could, in theory, be approximated empirically. To do so, one would simply replicate computation of the same statistic over a large number of samples of a given size. The resulting empirical distribution of the statistic converges with the sampling distribution as the number of replications approaches infinity. However, there are easier ways. For a sampling distribution of the mean, the central limit theorem states:

If repeated random samples of size *n* are drawn from any population having a mean μ and a variance σ^2, then as *n* becomes large, the sampling distribution of sample means approaches normality, with mean of μ and variance σ^2/N.

In other words, the "mean of means" converges with the universal mean. Second, the variance of the sampling distribution for the mean is given as σ^2/N. From this, it follows that the standard deviation of the sampling distribution of the mean is $\sigma/\sqrt{N}$, or the standard error (see Eq 7). A further, important implication of the central limit theorem is that whenever $N > 30$, the sampling distribution of the mean often approximates a normal distribution, even when the sampling universe or underlying population does not (Ref 5).

Simple Statistical Tests

A Simple Test Based on the Normal Curve. One commonly used test is based on the central limit theorem. It is called Student's *t*, Student being a pseudonym of its inventor, W.S. Gossett (Ref 6). Consider the following example:

Specifications for an industrial coating call for a minimum application thickness of 20 mil and an average application thickness of 30 mil. A coated surface is tested for coating thickness at 60 random locations over the surface. The coating exceeds the minimum 20 mil in every case. However, it remains to be determined whether the average thickness is 30 mil. Note that, in this case, direction is irrelevant, and the coating fails whether thicker or thinner than the specified 30 mils.

There are five key steps in carrying out a statistical test. These are (1) making assumptions, (2) selecting a test statistic, (3) defining the critical region, (4) computing the test statistic, and (5) making a decision.

Assumptions. There are many assumptions required in setting up this kind of test. However, among the key assumptions is that the sample of 60 locations is random. Also, if *n* were less than 30, it would be necessary to assume that *X*, the coating thickness over the surface, is normally distributed. These assumptions, along with a variety of other fairly obvious assumptions that the situation is as it has been described, constitute what are sometimes referred to as *model* assumptions.

A second category of assumptions are the *hypotheses*. In this case, the research hypothesis could be that the average application thickness is not 30 mils. The null hypothesis can be stated as $\mu = 30$. Note that while all assumptions present the same threat to validity of the results, only the null hypothesis is tested.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

For samples greater than 30, it is not as critical to make the model assumption that a variable is normally distributed because the central limit theorem implies that, for large samples, the sampling distribution of the mean from a nonnormal universe is often normal.

Selecting a Test Statistic. The test statistic is Student's *t*:

$$t = \frac{\bar{x} - \mu}{s/\sqrt{n-1}} \qquad \text{(Eq 12)}$$

where μ = 30, *n* = 60, and $\bar{x}$ and *s* can be computed directly from the sample data using Eq 1 and 3. At least two considerations apply to the selection of this particular test statistic. First, coating thickness is measured using a ratio scale, which means that a statistic based on the mean is applicable. Second, the sample is relatively small, and Student's *t* is designed for small samples.

Defining the Critical Region. The sampling distribution for Student's *t* depends on α and on degrees of freedom (*n* - 1). The limit of the critical region for Student's *t* at α = 0.05 and 59 degrees of freedom for a symmetric or two- tailed test is *t* > 2.000 or *t* < -2.000. A two- tailed test was specified, because the specification is nondirectional, that is, the coating can fail to meet the specification if the average thickness is either too thick or too thin.

The sampling distribution for Student's *t* is actually a family of distributions that resemble the normal distribution but are somewhat flatter, the relative flatness depending on the degrees of freedom. For samples exceeding *n* = 120, the distribution for *t* becomes normal. Thus, for small or large sample applications, this statistic is generally referred to as the *t* test.

Computing the Test Statistic. To compute the test statistic, first a sample mean ($\bar{x}$) of 29.5 mil and a standard deviation (*s*) of 1.9 mil must be computed. The test statistic *t* = (29.5 - 30)/ [(1.9)/$\sqrt{59}$] = −2.021.

Making a Decision. Because -2.021 < -2.000, the decision is to reject the null hypothesis, supporting the conclusion that the work fails to meet the specification. Note, however, that if the preselected α level had been 0.01, the critical region would have been *t* > 2.660 or *t* < -2.660, and the null hypothesis would not have been rejected. The *p* value associated with *t* > 2.021 is 0.046, only marginally less than 0.05. This illustrates the advantage of reporting *p* values in contrast to the practice of testing against pre-selected α criteria.

Other Issues Related to Student's *t*. Note the similarity between the definition of the standard error in Eq 7 and the denominator of Eq 12 defining Student's *t*. Note that using the estimate *s* instead of the parameter σ to estimate the standard error requires the quantity *n* - 1 to replace *N* in the denominator. A brief, clear explanation for this adjustment can be found in Ref 5. A longer but more intuitively appealing explanation can be obtained from Ref 7.

Two-Sample Tests. Note that in the preceding illustrations, μ is given or assumed. Consider a different situation, in which a series of test specimens is compared to a series of comparable control specimens. This simple experiment suggests the research hypothesis $\mu_1 \neq \mu_2$ and the null hypothesis, H_0, $\mu_1 = \mu_2$. This is referred to as a two-sample test. The statistical inference process is parallel to that described previously, except that instead of having one set of sample values and one assumed parameter, there are two sets of sample values. In general, the test seeks to determine whether the two sets of specimens could have been drawn randomly from the same universe. The test statistic, based on the difference between the samples, is:

$$t = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sigma_{\bar{x}_1 - \bar{x}_2}} = \frac{\bar{x}_1 - \bar{x}_2}{\sigma_{\bar{x}_1 - \bar{x}_2}} \qquad \text{(Eq 13)}$$

The simplification is possible, because the null hypothesis assumes $\mu_1 = \mu_2$. Note that what is being implied by this expression is not a sampling distribution of means but a sampling distribution of differences. The denominator for the expression in Eq 13 represents the standard error of that sampling distribution.

Computing the test statistic is straightforward, except that there are two ways to estimate the standard error: a pooled variance and a separate variance estimate. If it can be assumed that $\sigma_1 = \sigma_2$, then the pooled variance estimate can be obtained as:

$$\sigma_{\bar{x}_1 - \bar{x}_2} = \sqrt{\frac{n_1 s_1^2 + n_2 s_2^2}{n_1 + n_2 - 2}} \sqrt{\frac{n_1 + n_2}{n_1 n_2}} \qquad \text{(Eq 14)}$$

However, if it is assumed that $\sigma_1 \neq \sigma_2$, then the separate variance estimate can be obtained as:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\sigma_{\bar{x}_1-\bar{x}_2} = \sqrt{\frac{s_1^2}{n_1 - 1} + \frac{s_2^2}{n_2 - 1}} \qquad \text{(Eq 15)}$$

It should be noted that the test using the separate variance estimate is slightly less efficient than the test using the pooled variance estimate. It also should be noted that in cases where both samples are approximately equal, degrees of freedom = $n_1 + n_2 - 2$, but for unequal samples, there is a complex expression that is used to find degrees of freedom (Ref 7).

Confidence Limits

Sometimes, the goal of a statistical analysis is not to test a hypothesis but to evaluate an estimate by establishing upper and lower bounds. These bounds are called confidence limits or confidence intervals. The process of establishing confidence limits shares much with statistical hypothesis testing, but there are some key logical and procedural differences. Consider an example. Borings from a reinforced concrete structure are analyzed for chloride concentrations at different depths. The researcher is comfortable assuming that true chloride penetration is uniform at different surface coordinates over the zone of interest (at least for the sake of this illustration), but that there is measurement error in the data collection procedure. Consequently, borings are taken at 26 random locations. Specimens from each boring are captured at 6 mm (0.236 in.) increments to a depth of 100 mm (3.94 in.). The purpose of this investigation is to assess corrosion risk to the structure. More specifically, the goal is to determine whether chloride concentration is high enough to initiate corrosion at a 51 mm (2 in.) depth, the minimum cover for the reinforcing steel. In the sample, the average ($\bar{x}$) chloride concentration at a depth of 48 to 54 mm (1.89 to 2.13 in.) is 0.016%, and the standard deviation is 0.011%.

The first step in establishing a confidence interval is determining a confidence *level*, which is analogous to selection of a critical region in statistical hypothesis testing—that is, the risk one is willing to take of making an error. For example, a 95% confidence level corresponds to a critical region of $\alpha = 0.05$. In other words, with a 95% confidence level, the confidence limit is expected to contain the parameter in 95 and not to include it in the remaining 5 out of 100 samples.

Given a confidence level of 95%, the researcher can proceed to construct a confidence interval around $\bar{x}$. To do so, one works backward, starting with a table of areas under the normal curve, or in this case, because $n = 26$, from a table for the distribution of *t*. For 95% confidence (the same as $\alpha = 0.05$ for a two-tailed test) and $n - 1$ or 25 degrees of freedom, the table shows a value of 2.060. The confidence interval can now be constructed as:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$\bar{x} \pm 2.060 \frac{s}{\sqrt{n-1}} = 0.016 \pm 2.060 \frac{0.011}{\sqrt{25}} \quad \text{(Eq 16)}$$
$$= 0.016 \pm 0.00453$$

In other words, at a 95% confidence level, the true chloride concentration at a 48 to 54 mm (1.89 to 2.13 in.) depth is believed to be between 0.0114 and 0.0205%. Assuming the corrosion threshold is 0.02%, these results suggest that the structure could be at immediate risk of corrosion damage. For a more complete discussion of confidence intervals, see Ref 5 or 7.

Sampling Issues

In all of the applications of statistical inference discussed so far, there has been an underlying assumption that observations were selected randomly from a universe. In the interests of efficiency in presentation, this assumption has not been belabored until now. In plain language, the basis of statistical inference is that if chance alone determines the selection of observations, then chance alone also determines observed differences in the attributes of those observations. In practice, there are a number of ways to obtain what is known as a probability sample. The condition that defines a probability sample is that every element in a probability sample has a known probability of selection. For a discussion of the various approaches to probability sampling, see Ref 7.

Sampling and Randomization. Sometimes the goal of sampling is to make an inference from a sample to the universe from which the sample was drawn. Probably, the most familiar example is election polling. However, the general notion of random sampling also applies to random assignment in the context of an experiment. The former relates to establishing *external* validity for an inference from a sample to a larger universe or population. The latter relates to *internal* validity by establishing the basis for the inference that treatment and control specimens in an experiment are initially equivalent. Randomization in the design of experiments may have limited applicability in corrosion science. Randomization is most likely to be of value in situations where relatively large numbers of specimens can be included in the experiment, and/or there is variability in the specimens and relative uncertainty about variables that could affect the outcome of the experiment. Randomization is particularly effective in controlling unidentified or unknown confounding factors.

Determining Sample Size. The methods subsequently described focus on a sample drawn from a finite population but can readily be adapted to the context of randomization for an experiment. The determination of sample size is analogous to establishing a confidence interval in reverse. Consider Eq 17 and 18:

$$B = Z \frac{\sigma}{\sqrt{n}} \quad \text{(Eq 17)}$$

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$n = \left(Z \frac{\sigma}{B} \right)^2 = Z \frac{\sigma^2}{B^2} \quad \text{(Eq 18)}$$

where *B* represents the bound on the error, and *Z* represents the standard score on the normal curve associated with the desired level of confidence. In election polling and other surveys, *B* is usually referred to as the margin for error. Note that given *B*, one can solve for *n*, if a suitable estimate can be found for the standard deviation (σ). There are a number of strategies to obtain a value for σ. One is to look for a comparable data set from another study. A second is to conduct a small pilot study. A third is to substitute a worst case or make a bald assumption. The point here is that, in order to make a precise estimate of sample size, it is desirable to know something about the distribution of the variable in question.

To summarize, three pieces of information are needed to estimate sample size. The first is a tolerable error or an analogous goal for precision. The second is a confidence level to represent the acceptable risk of being wrong, typically 90, 95, or 99%. The third is an estimate for the standard deviation of the variable in question.

Sampling from a Finite Universe. Special sampling considerations apply whenever a sample is being drawn from a finite universe, and the sample represents a nontrivial fraction of the whole universe. There is, in fact, a correction that applies to variance estimates based on finite populations, such that:

$$\mathrm{Var}(\bar{x}) = \frac{N-n}{N} \times \frac{s^2}{n} \quad \text{(Eq 19)}$$

The quantity (*N* - *n*)/*N* is called the finite population correction (fpc). It should be obvious that the fpc becomes increasingly important as *n*/*N* increases. The fpc can be ignored whenever *n*/*N* does not exceed 5% (Ref 8).

Another important implication that can be drawn from Eq 19 is that whenever a sample is drawn from a large universe, the absolute sample size is primarily what determines error, while the size of the universe is irrelevant for practical purposes. This result may be counterintuitive for many people, but it can easily be verified that, other things being equal, a sample of 500 has virtually the same confidence interval when drawn from a universe of 100,000,000 as when drawn from a universe of 50,000.

Analysis of Variance

Analysis of variance is a specific technique developed in the early 1920s by the British statistician R.A. Fischer for application to agricultural experiments. The simplest case of analysis of variance involves one dependent variable, measured as an interval or ratio scale, and one independent variable, measured as a nominal or ordinal scale and having three or more categories or levels. In cases of an independent variable with two categories, analysis of variance reduces to a two-sample *t* test (see Eq 13).

Analysis of variance is based on the idea that the variance of a dependent variable can be partitioned into different components. In the simple case of one independent variable, these components are within and between

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

groups. More specifically, from Eq 3 and multiplying both sides by n, a new quantity, ns^2, called the sum of squares, is obtained:

$$ns^2 = \sum_{i=1}^{n} (X_i - \bar{x})^2 \qquad \text{(Eq 20)}$$

In order to proceed further, it is necessary to introduce some refinements in notation. Let X_{ij} represent the "*i*th" score in the "*j*th" category or subgroup. Subscript j ranges from 1 to k, and k is the number of categories of the independent variable. Subscript i ranges from 1 to n_1 within category 1, from 1 to n_2 in category 2, and from 1 to n_k for category k, where n_1, n_2, and n_k represent the number of cases within categories. Conditional, or within-category, means $\overline{X}_{\cdot 1}$, $\overline{X}_{\cdot 2}$, and $\overline{X}_{\cdot k}$ and the overall, or "grand," mean $\overline{X}_{\cdot\cdot}$ can also be described. Finally, to differentiate summation within and between categories, symbols $\sum_i$ and $\sum_j$ are used to represent summation over i and j, respectively. Partitioning of variance is illustrated in Eq 21:

$$\sum_i \sum_j (X_{ij} - \bar{X}_{\cdot\cdot})^2 = \sum_i \sum_j (X_{ij} - \bar{X}_{\cdot j})^2 + \sum_i \sum_j (\bar{X}_{\cdot j} - \bar{X}_{\cdot\cdot})^2 \qquad \text{(Eq 21)}$$

or the *total* sum of squares (TSS) equals the *within-groups*, or *residual*, sum of squares (WSS) plus the *between-groups* sum of squares (BSS) (Ref 7). Note further that the components can be rewritten from Eq 20 as:

$$\text{TSS:} \quad \sum_i \sum_j (X_{ij} - \bar{X}_{\cdot\cdot})^2 = ns^2 \qquad \text{(Eq 22)}$$

$$\text{WSS:} \quad \sum_i \sum_j (X_{ij} - \bar{X}_{\cdot j})^2 = n_1 s_1^2 + n_2 s_2^2 + \ldots . n_k s_k^2 \qquad \text{(Eq 23)}$$

$$\text{BSS:} \quad \sum_i \sum_j (\bar{X}_{\cdot j} - \bar{X}_{\cdot\cdot})^2 = ns^2 - \left(n_1 s_1^2 + n_2 s_2^2 + \ldots . n_k s_k^2\right) \qquad \text{(Eq 24)}$$

Note that BSS is found by subtracting WSS from TSS.

Consider Eq 24. If all the $\overline{X}_{\cdot j}$ conditional means equal the grand mean $\overline{X}_{\cdot\cdot}$, then BSS equals 0, and WSS equals TSS. Furthermore, the more the $\overline{X}_{\cdot j}$ differ, the larger the BSS and the smaller the WSS. Analysis of variance uses the ratio of BSS to WSS, adjusted for degrees of freedom, to compute a test statistic based on the F distribution:

$$F = \frac{\text{BSS}/(k-1)}{\text{WSS}/(n-k)} \qquad \text{(Eq 25)}$$

Example: Analysis of Variance in Coating Bond Strength Tests. A test bridge deck is treated with three different coatings, and pull tests are conducted to measure bond strength, with 20 tests completed for each coating. The critical region is set at the customary $\alpha = 0.05$. Analysis of variance is based on the F distribution. The distribution of F depends on degrees of freedom for both within- and between-groups estimates, and, in the case of $(k - 1) = 1$, $F = t^2$ and t can, in fact, be regarded as a special case of F (Ref 7). Consequently, tables constructed to find the critical region for F require three dimensions: one for $n - k$ degrees of freedom, one for $k - 1$ degrees of freedom, and one for α. Consequently, these tables are generally printed with each of several customary levels of α on a separate page. The lower limit of the critical region for F with $(n - k) = 57$, $(k - 1) = 2$, and $\alpha = 0.05$ is approximately 3.17.

Results show an overall average bond of $\overline{X}_{\cdot\cdot} = 203.5$ psi. However, for coating 1, the average is $\overline{X}_{\cdot 1} = 204.5$ psi, while for coatings 2 and 3, bond strengths are $\overline{X}_{\cdot 2} = 228.7$ psi and $\overline{X}_{\cdot 3} = 178.3$ psi, respectively. One approach to the analysis of these results would be to deal with the samples in pairs and to run three separate t tests on all possible differences of means: $\mu_1 = \mu_2$, $\mu_2 = \mu_3$, and $\mu_1 = \mu_3$. Analysis of variance allows tests of the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

form H_0: $\mu_1 = \mu_2 = \mu_3 = \ldots \mu_k$. The research hypothesis is that at least one mean is different. Analysis of variance, by simultaneously comparing all three means, is more efficient, because it uses all 60 observations. Also, and more important, running three separate *t* tests inflates the probability of rejecting at least one of three null hypotheses, just as drawing an ace from a deck of cards is more likely in three attempts than in one. In fact, the probability of rejecting one of three hypotheses at $\alpha = 0.05$ based on chance alone is 0.05 + 0.05 + 0.05 = 0.15.

Table 4 summarizes the results of the one-way analysis of variance. Note that the quantities labeled "Mean square" are obtained by dividing the sum of squares by the degrees of freedom and therefore may be viewed as variance estimates. From Eq 25, the *F* statistic is the ratio of the between-groups estimate to the within- groups estimate, which, in this case, gives a calculated *F* of 4.1048, which, being greater than 3.17, falls within the critical region. In other words, results support rejection of the null hypothesis and the conclusion that bond strengths of the three coatings are not equivalent. If *F* had fallen outside the critical region, it would have been untenable to infer any difference in bond strength among the three coatings.

Table 4 One-way analysis of variance of bond strength for three coatings

	Mean ($\bar{X}$)	*N*	Variance (S^2)
Coating 1	204.5	20	3000.89
Coating 2	228.7	20	2124.43
Coating 3	178.3	20	4162.43
Total	203.5	60	3421.76

Partition of variance sum of squares	Sum of squares	Degrees of freedom	Mean square	*F*
Between-groups (BSS)	25,416.3	2	12,708.15	
Within-groups (WSS)	176,467.3	57	3095.92	4.1048
Total (TSS)	201,883.6	59		

This discussion and example of analysis of variance deals with the simplest possible case. Analysis of variance can incorporate more than one categorical independent variable, and there exists a wide variety of specialized applications of analysis of variance to specific, complex experimental designs. Reference 7 provides a clear and accessible discussion of the extension of analysis of variance to two independent variables. More definitive and complete sources on analysis of variance are provided by Ref 9 and 10.

Correlation and Regression

Pearson's *r*. Previously in this article, consideration was given to statistical hypothesis testing. There is another class of statistical measures called measures of association. Correlations or measures of association measure dependence between two variables, or the ability to predict one variable from another. There are, in fact, many such measures designed for nominal and ordinal scales, and many of these are described in Ref 3 and 7. However, one particular measure of association, the Pearson product-moment coefficient, or Pearson's *r* (*r* represents the estimate; the symbol for the parameter is ρ), is probably the most widely recognized and used measure for two-interval or ratio scales. To begin a discussion of correlation, consider the expression for *covariance* in Eq 26:

$$\sigma_{x,y} = \frac{\sum_{i=1}^{n}(X_i - \mu_x)(Y_i - \mu_y)}{N} \qquad \text{(Eq 26)}$$

Note the similarity to Eq 3 and 4 for the variance, and that, while the variance is necessarily a positive quantity, the covariance can be either positive or negative. Also note that the covariance reaches a maximum (positive or negative) when *X* and *Y* are perfectly correlated, and that it approaches zero to the extent that there is no association between *X* and *Y*. However, covariance is of more theoretical than practical interest as a measure of association. However, a number of other important and useful measures are based on covariance. One of these is Pearson's *r*:

$$r = \frac{\sum_{i=1}^{n}(X_i - \bar{X})(Y_i - \bar{Y}) \Big/ n}{\sqrt{\left[\sum_{i=1}^{n}(X_i - \bar{X})^2 \Big/ n\right]\left[\sum_{i=1}^{n}(Y_i - \bar{Y})^2 \Big/ n\right]}} = \frac{\sum_{i=1}^{n}(X_i - \bar{X})(Y_i - \bar{Y})}{\sqrt{\left[\sum_{i=1}^{n}(X_i - \bar{X})^2\right]\left[\sum_{i=1}^{n}(Y_i - \bar{Y})^2\right]}} \qquad \text{(Eq 27)}$$

In other words, Pearson's *r* is the ratio of the covariance of *X* and *Y* to the product of the standard deviations of *X* and *Y* (Ref 7). Unlike the covariance, *r* has a range of -1 to +1.

Linear Regression Analysis. Figure 2 presents a scatter diagram. The variables in the scatter diagram are reflectivity measurements taken on reflective highway markers when new (*X*) and after weathering in service for one year (*Y*). As should be evident from the pattern, there is a fairly strong positive correlation of $r = 0.900$. In other words, the effects of weathering on reflectivity appear to be somewhat predictable. One expedient way to make that prediction is with linear regression analysis. Linear regression is based on the linear equation:

$$Y_i = \alpha + \beta X_i + \varepsilon_i \qquad \text{(Eq 28)}$$

where β is the slope of the line, α represents the *Y*-intercept, or the value of *Y* when $X = 0$, and ε_i represents an error or disturbance term. The regression line is fit to the data according to a specific criterion known as least squares. The regression line that minimizes the squared deviations of the observed values of *Y* from the values predicted for *Y* by the regression line satisfies the criterion of least squares (Ref 11). As it turns out, this criterion is met if *a* and *b* are obtained as in Eq 29 and 30:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$b = \frac{\sum_{i=1}^{n}(X_i - \bar{X})(Y_i - \bar{Y})}{\sum_{i=1}^{n}(X_i - \bar{X})^2} \quad \text{(Eq 29)}$$

$$a = \bar{Y} - b\bar{X} \quad \text{(Eq 30)}$$

where *a* and *b* are estimates for the parameters α and β. Regression analysis can be extended to cases involving more than one independent variable. There are also a variety of ways to model nonlinear associations using regression analysis. However, these topics are beyond the scope of this article, and the reader is referred to Ref 10 and 11 for more complete treatments of these and a variety of other extensions of simple regression analysis.

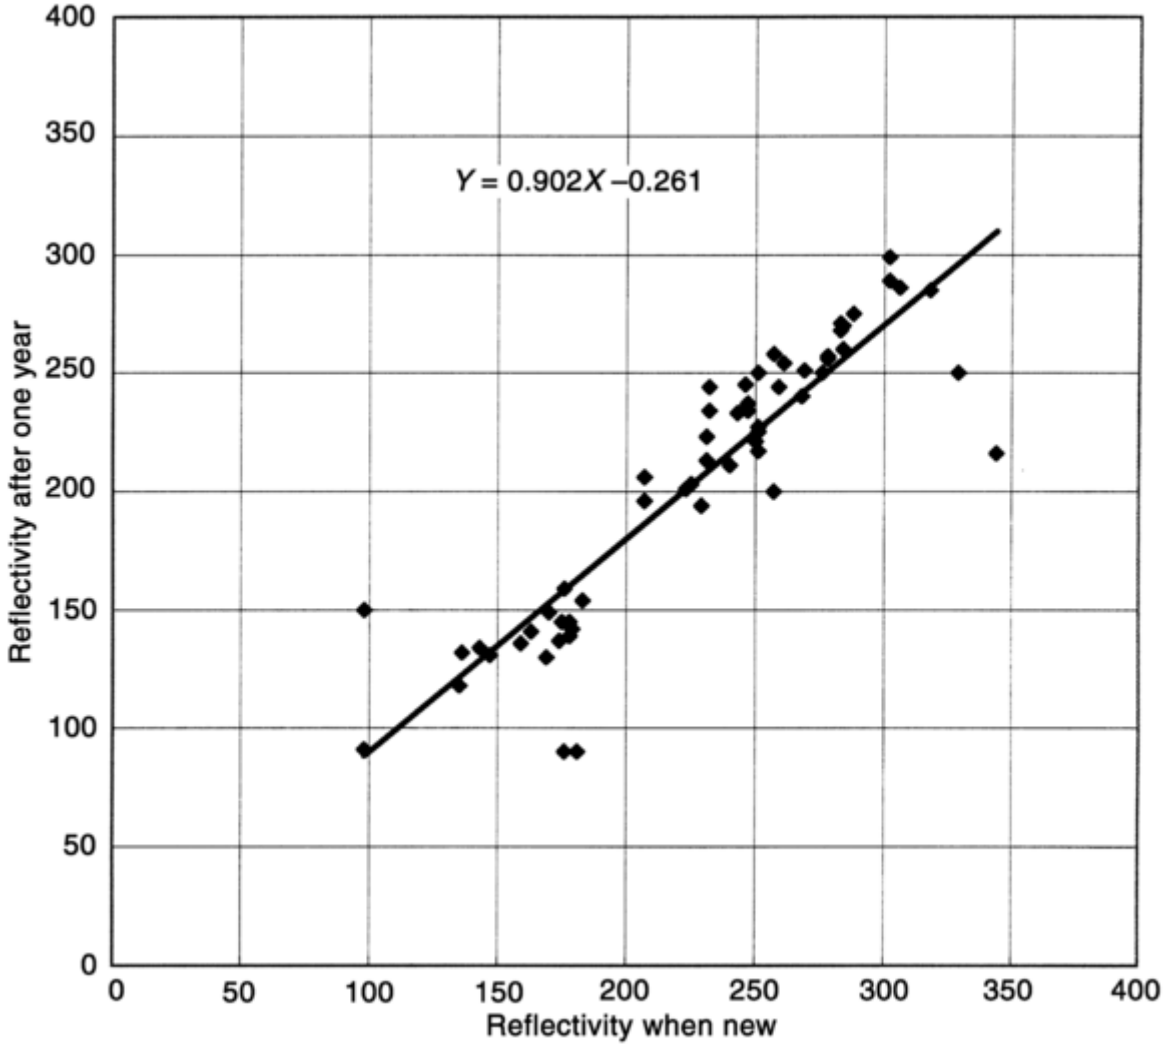

Fig. 2 Reflectivity of highway markers when new and after one year in service. Units for reflectivity are specific intensity (millicandela) per unit area.

Regression Analysis and Statistical Inference. Regression analysis can be used to predict one variable in terms of other variables, but the terms in the regression equation itself tell the researcher very little about the dependability of the prediction. Statistical tests are available to test for significance of the entire regression equation and also for the significance of *b*. It is also possible to place a confidence interval around the predictions of *Y* obtained from a regression analysis. Each type of statistical inference is discussed in turn. However, first, there are a number of assumptions required for regression analysis that deserve consideration.

To begin, there are specific assumptions relating to the disturbance term, ε. This term, also called the residual, represents measurement error in *Y* and specification error, or influences on *Y* not included in the regression equation. Regression assumes that ε has an expected value (mean) of 0, is approximately normally distributed,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

and that the independent (*X*) variable is measured without error. Note that the estimated residual always has a mean of 0, but the assumption refers to the parameter ε.

It is also necessary to assume that *X* and ε are statistically independent. Suppose that an unidentified third variable, *Q*, is the true source of influence on *Y*, but *Q* is also correlated with *X*. In that situation, *X* only appears to influence *Y* because of the influence of *Q* on both *X* and *Y*. This would be a case of violation of the assumed independence of *X* and ε. It should be noted, however, that an analogous assumption applies to all the statistical tests considered so far.

Regression analysis also assumes a multivariate normal distribution. In the case of two variables, a bivariate normal distribution could be represented graphically as an elliptical bell in three dimensions, to the extent that a normal distribution is represented by a bell curve. In other words, for each value of *Y*, the *X*s are distributed normally (Ref 7). Related to the assumption of a multivariate normal distribution is the assumption of *homoscedasticity*, which refers to the requirement that *Y* be not just normally distributed about each value of *X* but also that the variance of *Y* be consistent across values of *X*.

Given these assumptions, discussion can turn to statistical inference in the context of regression analysis. For the sake of brevity, this discussion is also limited to the case of regression with one independent variable.

In the case of simple regression with one independent variable, the test for the significance of β is identical to the test for the overall significance of the regression equation. The test parallels that for analysis of variance. Consider the following expression:

$$\sum_{i=1}^{n}\left(Y_i-\bar{Y}\right)^2=\sum_{i=1}^{n}\left(Y_i-\hat{Y}_i\right)^2+\sum_{i=1}^{n}\left(\hat{Y}_i-\bar{Y}\right)^2 \qquad \text{(Eq 31)}$$

where $\hat{Y}_i$ is the value predicted for Y_i from the regression equation. Note that the term to the left of the equals sign is the total sum of squares. The first term to the right represents the residual, or error, sum of squares and is analogous to within sum of squares in the context of analysis of variance. The final term is the sum of squares that is accounted for or "explained" by the regression equation and is directly analogous to between sum of squares. This term is often referred to as *explained*, *regression*, or *model* sum of squares. At this point, it should be evident that an *F* ratio can be obtained from these quantities, given the appropriate degrees of freedom. Also analogous to analysis of variance, degrees of freedom for the regression sum of squares is (*k* - 1) and for residual sum of squares (*n* - *k*), except that in this case, *k* represents the number of terms estimated for the regression equation, in this case, *a* and *b*, or 2. Table 5 works through a numeric example based on the reflectivity data in Fig. 2. Note that an *F* ratio of 246.6 is obtained, and the critical value for *F*, assuming 1 and 58 degrees of freedom and α = 0.05, is approximately 4.01, so the null hypothesis that the coefficient of determination P = 0 can be rejected.

Table 5 Regression analysis summary for the reflectivity problem in fig. 2

Number of cases (*N*)	**60**
Mean reflectivity when new (*X*)	229.33
Mean reflectivity after one year in service (*Y*)	206.52
Constant (*a*)	-0.261
Slope (*b*)	0.9016
Pearson's *r*	0.900
Pearson's r^2	0.810

Source	Sum of squares	Degrees of freedom	Mean square	*F*
Regression	154,328.31	1	154,328.31	246.61
Residual	36,296.67	58	625.81	
Total	190,624.98	59		

It is important to note that the foregoing test applies to the regression equation for both simple and multiple regression. However, it is applicable to the significance of β only in the limited case of regression with one independent variable. Another similar test is available for the significance of the individual estimates for the βs in multiple regression, but that is beyond the scope of this article.

Coefficient of Determination. In the case of multiple regression, there is a measure called the multiple correlation coefficient, or coefficient of determination, known as R^2. Note the use of the upper case "*R*" (upper

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

case rho, or P, to denote a parameter) to differentiate it from Pearson's *r*. R^2 is analogous and, in the two-variable case, equivalent to Pearson's r^2. Consider Eq 32:

$$R^2 = \frac{\sum_{i=1}^{n}\left(\hat{Y}_i - \bar{Y}\right)^2}{\sum_{i=1}^{n}\left(Y_i - \bar{Y}\right)^2} \qquad \text{(Eq 32)}$$

Referring back to Eq 31, R^2 is also the ratio regression/total sum of squares. The coefficient of determination is a useful summary measure, because it expresses the results of the regression equation in terms of proportionate reduction in error, or the proportion of variance in *Y* that is accounted for by the regression.

Introduction

THIS ARTICLE is an overview of the science and engineering of materials for corrosionists with limited knowledge in this field. The presentation is descriptive, not technical, and assumes a basic understanding and knowledge of science. To help with the understanding of materials, definitions and descriptions of many of the more commonly used materials terms are presented along with examples. Advanced information can be found in the Selected References. Materials terms are printed in *italics.* If not immediately provided, the definitions can be found in the glossary at the back of this Volume.

The first section in this article, "Classification of Materials," lists and defines the categories of materials and gives examples of commercial materials. In general, metals are versatile materials that can be modified easily to achieve specific properties. Polymers can be produced readily in complex near-net final shape, and they have high ductility and low strength. Ceramics tend to have high compressive strength and good resistance to oxidation and corrosion; ceramics also exhibit low electrical and thermal conductivity and are brittle.

The second section "Properties," discusses the more frequently cited, measured, and relevant physical properties of materials, such as phases, strength, conductivity, and wear. The more common methods used to determine these properties and the standard set of units used are presented.

The third section of this article, "Processing," describes methods used to fabricate materials into different products. It includes a summary table of materials and their properties.

The fourth and final section, "Material Design, Application, and Failure," addresses material design, materials applications, and materials failure analysis. A collection of representative materials and their properties and characteristics is tabulated.

Classification of Materials

Materials are defined as the elements, constituents, or substances of which something is composed or made. The study of materials can be divided into three overlapping fields:

- *Materials science,* concerned with the basic understanding and characterization of materials
- *Materials technology,* concerned with the development and processing of materials
- *Materials engineering,* concerned with the design and application of materials.

These fields have more commonalities than differences. While the materials scientist may be more concerned with developing fundamental theories, the technologist with applying those ideas to developing or improving

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

materials, and the engineer with taking these materials and building something from them, all three use common terminology.

Materials are either solids or fluids. Fluids (gases and liquids) are the principal agents of corrosion. The characteristics and properties of fluids, with the exception of glasses, are beyond the scope of this article and are not discussed. Solids have relatively fixed volumes and are able to support shear loads.

Engineered solids are the components of structures. The properties of the solid determine the design and construction of products. Processed solids can be divided into at least three categories: ceramics, metals, or organics. These categories are not exclusive and are roughly related to the type of bonding that holds the atoms together and their fundamental structural units as shown in Fig. 1 and described in Table 1. Ceramics have a large component of ionic bonds holding atoms together. The basic structural units of ceramics are molecules, which are rigid and can vary from 2 to 10 atoms in size. Organics have a large component of localized covalent bonds between atoms, and their basic structural units, again molecules, can vary from approximately 100 to more than 10,000 atoms. Organics are very flexible. Metals have a mutual sharing of electron bonding between all atoms. Their basic building unit is the single atom. In ionic bonding, one atom gives up its electrons to another atom; in covalent bonding, two atoms mutually share electrons. In metallic bonding, a large array of atoms give up individual ownership of their valence electrons, sharing them mutually.

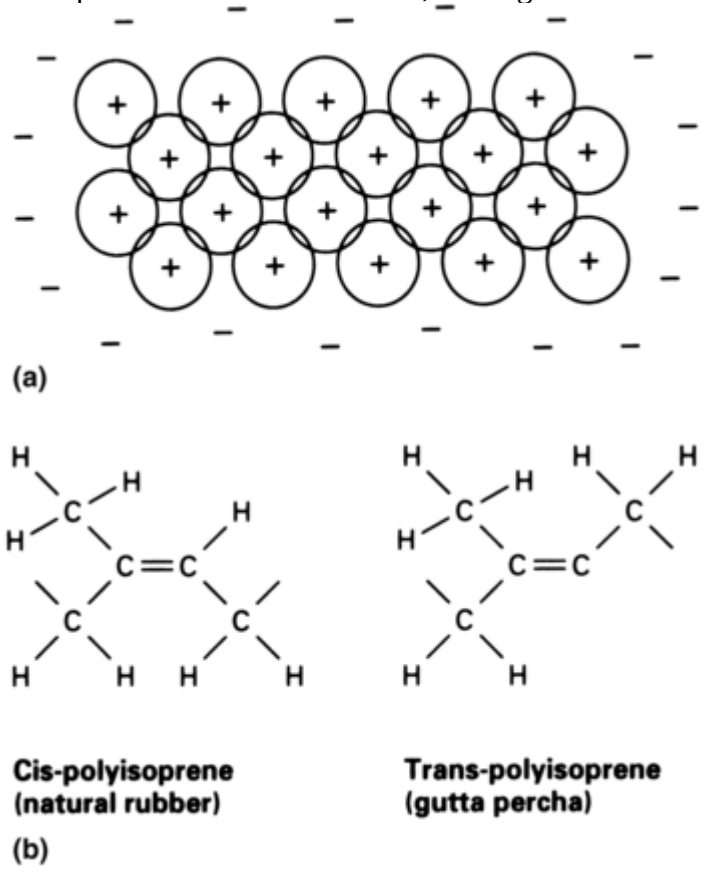

Fig. 1 Fundamental structural units of materials. (a) Metallic bond showing a cluster of cations (+) in a sea of electrons (-). (b) Geometric isomers of polyisoprene, typical of organics

Table 1 Material bonding Characteristics of solid materials

Type of solid material	Electronic bond	Fundamental unit
Metals	Shared between all atoms	Single atom
Ceramics	Ionic bonding between atoms	2 to 10 atoms in rigid structure
Organics	Covalent bond between two atoms	100 to over 10,000 atoms
Composites	Varies by constituents	Matrix and reinforcement

Many properties of solids are ultimately related to the interaction of atoms. Atomic interaction is explained by (a) electron interaction, which is best explained using quantum mechanics and (b) structural interaction, which

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

predominates as the number of atoms increases and can best be explained using Newtonian or continuum mechanics.

The three most widely used engineering materials are concrete, wood, and steel. These materials are from each of the materials categories: ceramics, organics, and metals, respectively. They are widely available, economical to produce, can be processed in a number of different ways to produce a great variety of products, and thus find a large number of applications. Each material has its own set of properties that make it best suited for particular applications. For example:

Application	Requirements	Example of material that meets most or all requirements
Dams	Large quantities of material able to withstand large compressive forces	Concrete
Home construction	Low cost, on-site processing, and renewable materials	Wood
Large cargo ships	High strength, flexibility, and corrosion resistance to a salt water environment	Steel

All materials have assets and limitations, such as availability, cost, strength, and corrosion resistance, which must be evaluated. Engineering guidelines and industry standards, as well as legal requirements, must be met when choosing a material for particular application. The materials information contained herein represents typical information and data. Consult the Selected References for more specific details or property values.

Ceramics are composed of carbide, oxide, nitride, sulfide, and/or silicate molecules. Examples include: SiC and Si_3N_4, used for cutting tools; SiO_2, the principal component in window glass, $2CaO{\cdot}SiO_2$, one of the principal components in cement; and $Al_2Si_2O_3\ (OH)_4$, clay used in making bricks. Ceramics are characterized by having good compressive strength and low tensile strength. The ionic nature of the interatomic bonds produces high rigidity (stiffness) and little ductility (elasticity). Ceramics are strong; once a crack starts, it grows rapidly, leading to immediate and rapid failure. The ionic bond is a high-energy bond, more stable than either a metallic or covalent bond, thus forming relatively stable molecules. Ceramics are generally more corrosion and oxidation resistant than either metals or organics. The nature of the ionic bond also limits the mobility of the electrons in the molecule, and ceramics thus have limited electrical and thermal conductivity and make good insulators.

Organics are composed of carbon-base materials. When carbon bonds covalently to other atoms such as other carbon atoms, nitrogen, oxygen, sulfur, and/or phosphorus, it can form extended one-dimensional chains (such as DNA molecules), two-dimensional (2D) arrays (graphite), or three-dimensional (3D) structures (diamond). Carbon atoms can share electrons or bond covalently up to four of its electrons with other atoms. As the degree of interlinking between carbon atoms increases, the structure becomes more rigid and the strength becomes greater, as shown in Fig. 2.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

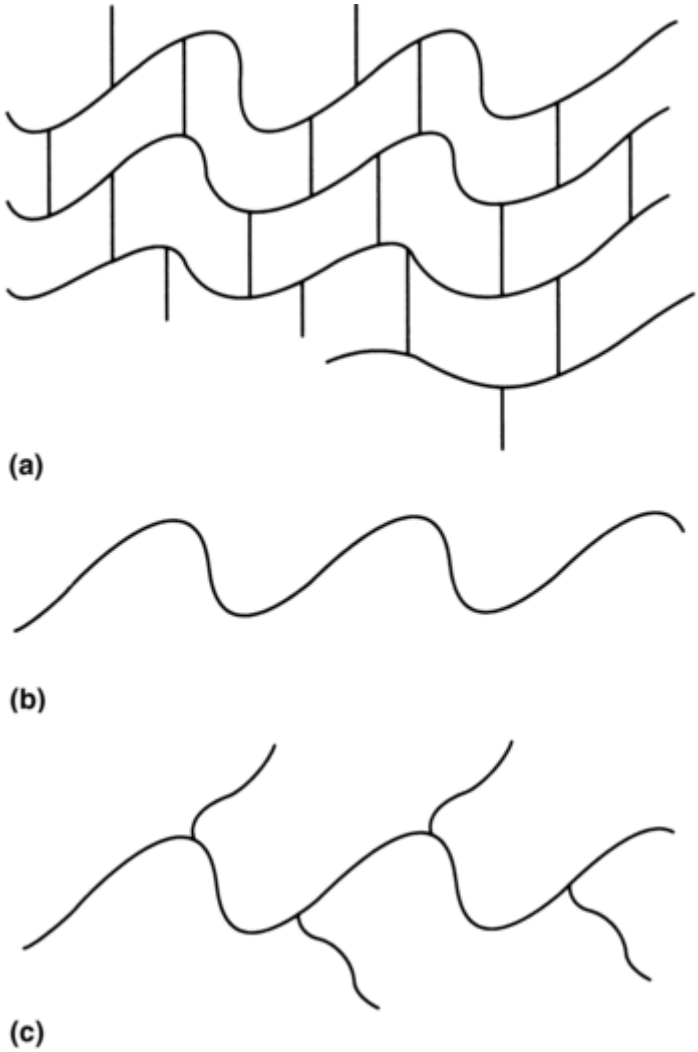

Fig. 2 (a) Simulated cross linked (networked or three-dimensional) structure. (b) Simulated linear polymer molecule. (c) Simulated structure of a branched polymer

Polymers are repeating chains of organic units (known as *mers* or *monomers*) that are covalently linked. Plastics are processed polymers and are categorized by how they are formed. *Thermoplastics* have very long chains that, when heated, readily flow past one another. However, as the temperature is reduced, the thermal energy of the molecule is reduced, and the interatomic motion and bonds become more restricted. The shape of the polymers thus becomes more rigid. As polymer length increases, the polymers can become ever more intertangled, resulting in a material of limited strength but great flexibility. Some plastics are able to stretch several hundred percent before failure. Reheating can reshape these plastics. Thermoplastics include natural rubber, nylon, polyvinyl chloride, polyesters, wood, silk, and cotton. *Thermosets* are polymers with multiple covalent links between polymer chains. The greater the number of links between the different chains, the more restrictive the movement of individual polymers, resulting in greater rigidity and higher strength. Heating cannot reshape these plastics once they are formed. Thermoset plastics include phenolics, polyesters, epoxies, urethanes, Bakelite, polyvinyl chloride (PVC), and polyethylene.

The localized nature of covalent bonds restricts the overall electron mobility in the polymer structure, resulting in high electrical resistivity and limited thermal conductivity. Organics generally have good corrosion resistance to mild acids and bases. However, solvents such as acetone attack organics, alcohol can dissolve polymer and interpolymer bonds, and ultraviolet radiation such as sunlight can break polymer bonds.

Metals are composed of those elements that readily share their electrons globally with other atoms. The elements that have this ability constitute the majority of the periodic table. The exceptions are the noble elements, the halides, carbon, nitrogen, oxygen, phosphorus, and sulfur. The metallic elements are able to form metallic compounds or alloys by combining with different metallic elements.

Metal atoms combine to form definite structural atomic arrangements or *lattices*, 3D crystal structures. Most metals have either face-centered cubic (fcc), hexagonal close packed (hcp), or body-centered cubic (bcc) unit

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

cells, as shown in Fig. 3. Metals with the fcc lattice structure have the highest ductility and lowest strength. The hcp metals have the highest strength and lowest ductility, and bcc metals are generally in between. When different metallic elements are mixed they can form a *solid solution* (random dispersion of atoms within a single phase), or they can: (a) form a different phase, (b) begin to segregate or cluster forming a second phase with separate or distinct composition and/or lattice, or (c) develop a very limited stoichiometric chemical relationship and form definite structure coordinated atomic configurations (producing *intermetallics* that have narrow chemical compositions). Because metallic electrons are able to move freely throughout the alloy, metals have good electrical and thermal conductivity.

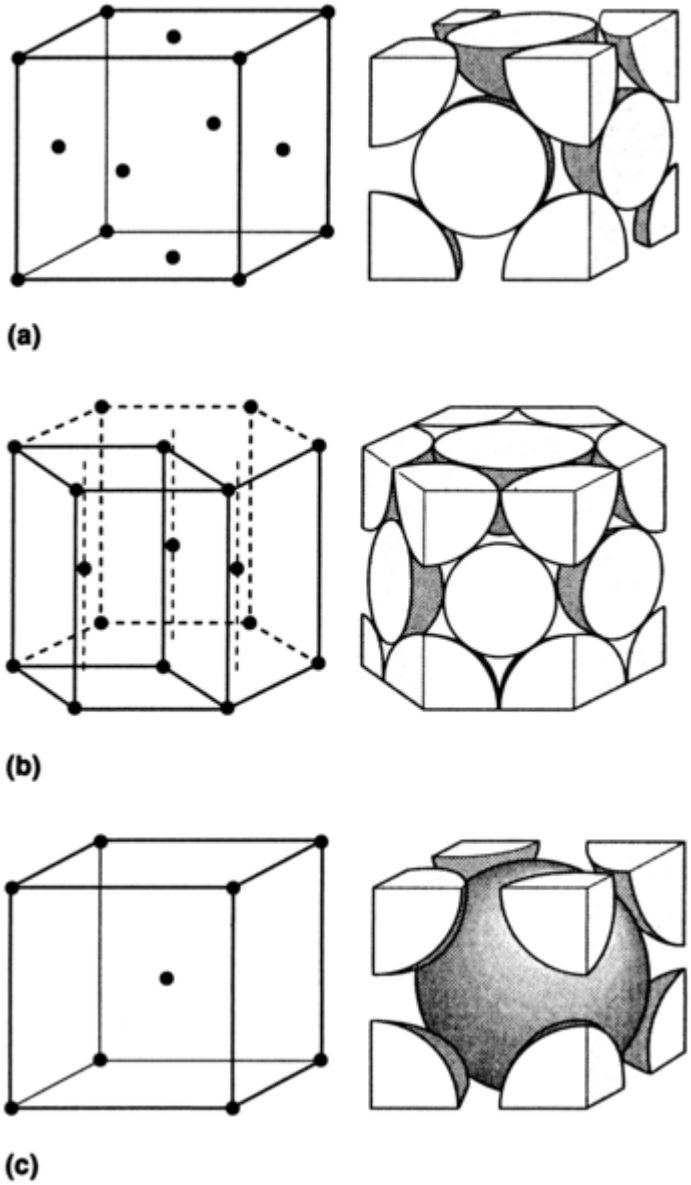

Fig. 3 Unit cells and atom positions for metal lattices. The positions of the atoms are shown as dots at the left of each pair of drawings, while the atoms themselves are shown close to their true effective size by spheres or portions of spheres at the right of each pair. (a) Face-centered cubic (fcc). (b) Hexagonal close-packed (hcp). (c) Body-centered cubic unit cells (bcc)

Semiconductors are materials that when pure are electrical insulators. For example, pure, single crystal silicon has a lattice structure similar to that of carbon diamond, is largely covalently bonded, and is an insulator. However, when minute quantities of impurities are present in the material (*doped*), the local electronic structure can be increased or depleted. This electron unbalance can greatly reduce the resistivity of the material, thus creating a semiconducting material.

Composites are combinations or mixtures of different phases or discrete materials. The range of composite possibilities is almost unlimited in composition and scale, as listed in Table 2. Composites are desirable because they are structures with properties of the individual components. For example, it is possible to increase the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

strength of metals while retaining much of the ductility of metal by incorporating and combining into the metal matrix very fine ceramic particles. Steel is a mixture of bcc iron with a dispersion of iron-carbide ceramic particles. Polymers can be strengthened with the addition of metallic wires (steel-belted automobile tires). Ceramics can be given some ductility by placing them in a metal matrix, for example, tungsten carbide coated cobalt cutting tools. Plywood is a composite in which the wood laminates are bonded by epoxy polymers. Strength properties of wood are highly directional. Laying-up the different layers of the plywood in different directions improves the overall directional strength of the final product. Care must be taken in designing and using composites. Just like the plywood, reinforced materials tend to be anisotropic their properties varying with direction. The choice of materials that results in improved composite properties in one application may possess undesirable properties in another application. For example, while the strength of a composite may be enhanced, the corrosion resistance may be decreased.

Table 2 Composite types

Type	Example, common name	Components and purpose
Metal-metal	Galvanized steel	Fe: bulk properties such as formability and strength Zn: surface coating for corrosion protection
	U.S. coin (penny)	Zn: structural material Cu: surface coating (modification)
Metal-organic	Painted steel structure	Fe: strength Paint: corrosion protection
	Electrical wires	Cu: electrical conductivity Organic: electrical insulator
Metal-ceramic	Cermet	Co: ductile binder WC: hard cutting component
	Reinforced concrete	Cement: binder, compressive strength Fe-rods: ductile, tensile strength
Organic-organic	Particle board	Wood: strength Epoxy: binder
Organic-ceramic	Fiberglass	Glass: strength Resin: binder
	Paper	Cellulose: structural material Clay: surface finish (modification)
Ceramic-ceramic	Concrete	Gravel: compressive strength Cement: binder
	Porcelain	Ceramic: structural material Glaze: surface finish (modification)

Properties

The *ASM Handbook* series is a good source of information about materials properties. The primary source of information for evaluating materials properties or materials testing is ASTM International (formerly the American Society for Testing of Materials), an organization devoted to establishing standardized procedures for all types of testing. The International Organization for Standards (ISO) promotes standardization and related activities worldwide. The work of the ISO results in international agreements that are published as International Standards. There are also regional standards such as the EN (Euronom) and other national standards organizations that are used to specify materials, materials testing, and quality.

Composition and phases are the most important materials properties. In principle, all other properties can be derived from knowledge of these two. The electronic interaction or bonding between the atoms can be determined from knowledge of the chemical elemental composition (the interatomic positions). Composition can be obtained from analytical chemistry (bulk chemical analysis), emission spectroscopy, x-ray fluorescence, and Auger spectroscopy. The measuring units for chemical composition are atom or mole fraction for scientists and weight percent for engineers. The structure of a material is its *atomic arrangement* and *lattice spacing.* From knowledge of the atomic placement and the increased complexity that arises as the number of atoms increases, there emerge new theories controlling material behavior. Structure can be determined using x-ray diffraction. Other methods include ultrahigh resolution electron microscopy and atomic microscopy. These methods are used to determine local (molecular structure), long- range order (lattice structure), the presence of local defect structure, or total disorder (amorphous structure). Most ceramic and metallic materials have an ordered structure whereas most organic materials and glasses have limited or no atomic order.

The size of the fundamental building component of a solid influences the resulting microstructure greatly, as shown in Fig. 4. The basic unit for most metals is the individual atom. Because the bonding is due to a global sharing of electrons, the atoms can be considered to have spherical symmetry and thus no orientation preference. The packing structure of metals is similar to the packing of tennis balls, in that atoms are stacked so that each is part of a repeating 3-D pattern. The *unit cell* is a coordinated set of atoms that form the 3D lattice that repeats by a simple translation. The basic unit for ceramics is the individual molecule, for example, SiO_2 (Fig. 4a). Molecules are a set of bonded atoms that have a rigid structure and a more complex geometry than single atoms. The bonding between the molecules is not as strong as the bonding within the molecule. The additional complexity associated with the molecular shape makes the unit structure more difficult to define than that for simple atoms. Many ceramics align readily into a lattice structure similar to that of metals with the individual metal atoms replaced with the ceramic molecules. However, rapid solidification or the presence of impurity molecules of different shape can result in a solid structure with limited local alignment of molecular unit cells, which, in the extreme, can result in amorphous or glass structures. The basic unit for organics is the polymer. Polymers have large complex atomic alignments, irregular geometry, and flexible molecules (Fig. 4b). Most organic solids have an amorphous or glass structure, as defined in Table 3.

Table 3 Characteristics descriptors of solids

Term	Description
Amorphous	Nonrepeating arrangement or alignment of fundamental building units
Crystalline	1, 2, or 3D alignment or repeating arrangement of fundamental building units
Phase	Region of space with uniform composition and uniform structure throughout
Single phase	Single-grain, uniform composition, same structural alignment throughout
Multiple grain	Structure composed of a number of single phase crystals
Grain boundary	Interface or boundary between two grains
Multiple phase	Multigrain structures composed of different phases
Precipitates	Second-phase smaller grains within large grains

Microstructure and *surface morphology* can be determined by optical and electron microscopy. Optical microscopy is typically used for 10 to 1000 times magnification. Numerous sample preparation and microscopic techniques have been developed for examination of flat polished surfaces to determine grain structure and, possibly, identify phases. Light or optical microscopy permits color to be observed and is used often to identify and differentiate microscopic features. Low magnification is used often for failure analysis to show the type of failure: intergranular or transgranular. With optical microscopy, the higher the magnification, the lower is the *depth of field* resolution, (focus in the vertical direction). Electron microscopy, especially scanning electron microscopy (SEM), has essentially an infinite depth of field and can magnify in excess of 100,000 times. Scanning electron microscopy is ideally suited for examination of surface features. Many SEMs are equipped with auxiliary features that allow for phase differentiation (secondary electron detection), atomic number differentiation (backscattered electron detection), quantitative and qualitative chemical analysis using energy dispersive spectroscopy (EDS), wavelength dispersive spectroscopy (WDS), and even rudimentary x-ray diffraction analysis (backscattered Kikuchi line analysis).

The *phase* of a material is defined as a region with homogenous atomic structure and chemistry; for example, amorphous silicate glass or a long-range repeating lattice of bcc iron. Many materials are composed of multiple phases (regions with different chemical composition and/ or different structures). The energy differences in phases may result in localized galvanic corrosion. Rarely does an entire piece of material maintain homogeneous structure. *Grains* (or crystals) are regions within a material that have both homogenous chemistry and atomic structure. *Precipitates* are small grains of different chemistry within a large grain. If the changes in homogeneity or local structure of the material are abrupt, the discontinuity results in the formation of a *grain boundary.* Grain boundaries may result from a change in the direction of atomic orientation, from difference in chemical composition, or from different phases being present. The abrupt property changes at a grain boundary are regions of energy higher than the energy level within the grain. This results in a more corrosion-prone region, a region along which diffusion is more rapid, and a region of higher stress.

In materials with a lattice structure, such as metals and ceramics, a line *dislocation* is another type of lattice structure that can be present. Dislocations are missing lines of atoms within grains and are important in understanding the plastic or ductile nature of a material and the increase in a material strength as it undergoes plastic deformation. Line dislocations are areas of higher localized stress.

Micrographs of surface morphology and microstructures are shown in Fig. 5.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

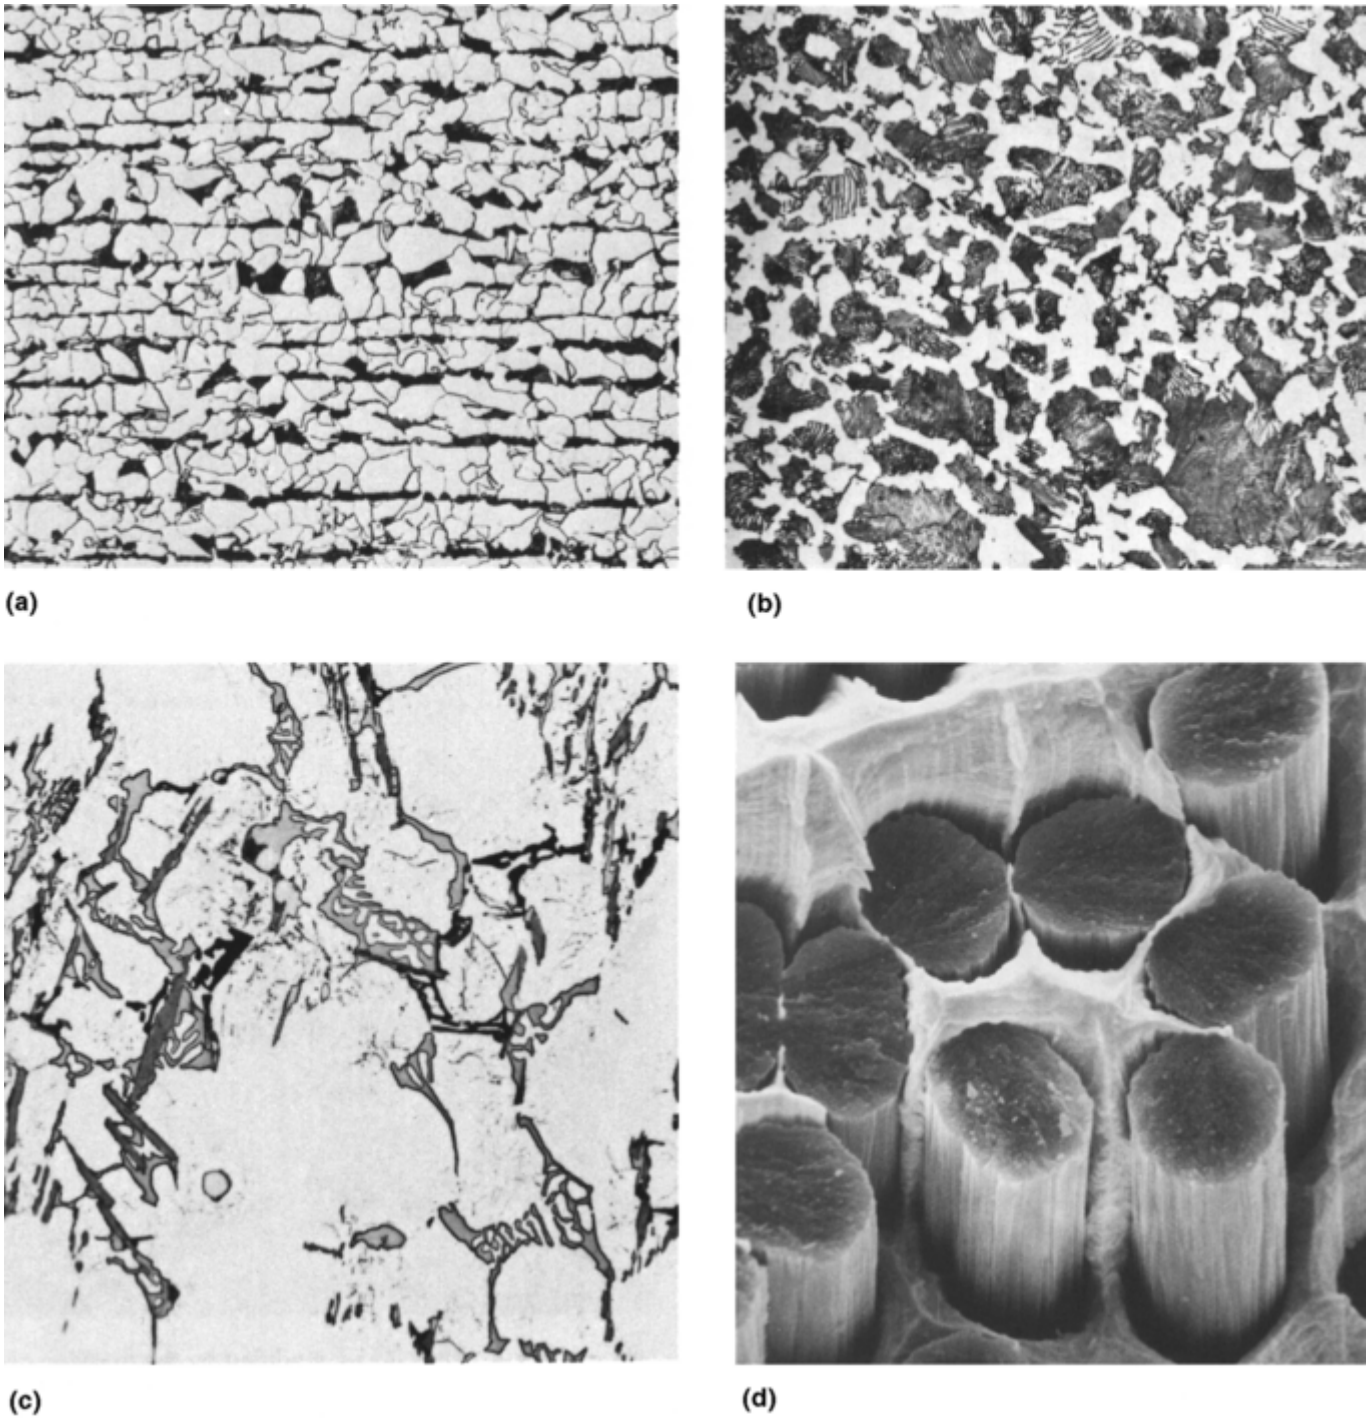

Fig. 5 Microstructure of materials. (a) High-strength low alloy steel (0.2% C) hot rolled. The structure is ferrite and pearlite. 4% picral, then 2% nital etchants were used. Magnification is approximately 200×. (b) 1045 steel sheet, 3 mm (0.13 inch) thick, normalized by austenitizing at 1095 °C (2000 °F) and cooling in air. Structure consists of pearlite (dark gray) and ferrite (light). Picral. 500× (c) Alloy 242-T571, permanent mold cast and artificially aged. Structure contains blades of $NiAl_3$ (dark gray) in the medium-gray Cu_3-$NiAl_6$ script. $CuAl_2$ particles (light) and scriptlike Mg_2Si (black) also are present. 0.5% HF. 250× (d) Graphite-silver copper composite (Thornel 300 fiber in 70Ag-30Cu eutectic matrix), unidirectional. Liquid-metal infiltration of fiber bundles followed by diffusion bonding. SEM of a failed tensile surface. The matrix shows good ductility, but the lack of matrix adhering of the fibers indicates low interfacial bond strength. 1860×

As particle or grain size decreases, the structure eventually reaches a size where the number of atoms associated with surface or grain boundary of a particle begins to approach the number of atoms within the particle or grain. Such materials are referred to as *nanomaterials* and are defined as materials having one or more structural dimensions between 1 and 100 nm (10^{-7} to 10^{-9} meters). To date, understanding nanomaterials properties has

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

required no new physics, and most properties of nanomaterials can be explained using either quantum mechanics or classical mechanics. Atoms or molecules at a surface have different environments surrounding them than do atoms and molecules in the interior of the particle or grain. Thus, surface effects— surface physics, chemistry, and mechanics, are important in understanding many of the phenomena associated with nanomaterials.

The relationships between composition, temperature, and phase often are presented in *phase diagrams.* These graphs describe the phases present as a function of the composition (most often wt%) on the abscissa and temperature as the ordinate. Equations have been derived from which the relative concentration of the different phases present as well as the composition of each phase present can be derived, given a temperature and an overall material chemical composition. Phase diagrams are derived for systems at thermodynamic equilibrium. Phase diagrams are generally limited to only two or three components because of the increase in complexity with increasing number of components, that is, atomic elements or molecules. Phase diagrams are extremely important in understanding the microstructure of a material and its properties. The iron–iron-carbide phase diagram (Fig. 6) describes carbon steels and is well known in the metals community.

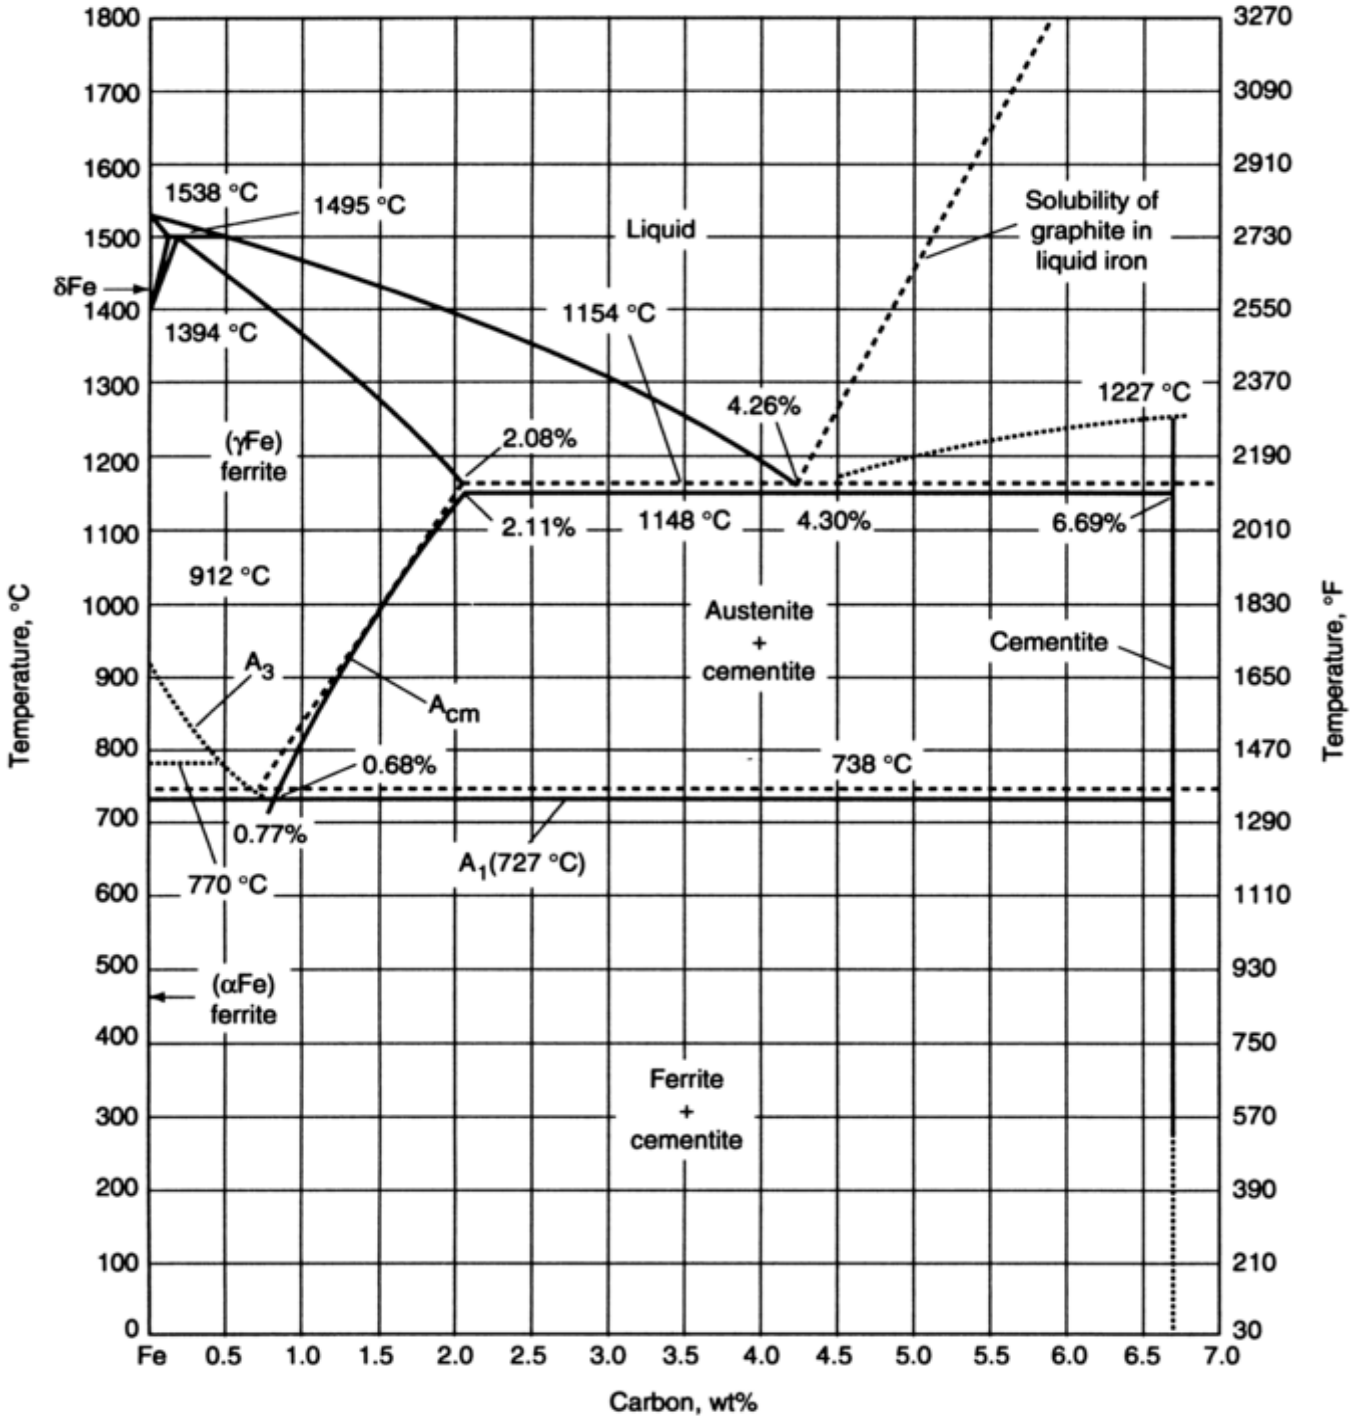

Fig. 6 Iron-carbon phase diagram

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Mechanical Properties. One of the more important and most often measured sets of materials properties is response to an applied load; the *strength* (ability of a material to support a load) and *ductility* (deformation under a load). A normalized response characteristic of the bulk material strength property defined as *stress* and symbolized as *s* or σ, the applied load divided by the cross section of a material, is measured in Pascals (Pa = newton/meter^2) or psi (pounds/ inch^2). The conversion is that 1 psi is approximately equal to 7000 Pa. A normalized material change in shape defined as *strain,* symbolized as *e* or ε, unitless, but with units sometimes given as length/length, is the change in length of a material divided by its original length, $\delta l/l$, or change in area over area, δarea/area. Engineers measure the stress-strain curve with respect to the original unstressed length or area, whereas scientists use the instantaneous length or area. During the initial phase of stress loading the material is *elastic*; that is, if the stress load is removed, the material returns to its original shape. During this elastic response, the stress-strain relationship is linear. The stiffness of a material, rigidity, or *modulus of elasticity, E,* is obtained by measuring the slope of the elastic stress-strain curve. Elastic modulus is measured using the same units as stress. Fig. 7(a) shows a typical stress-strain curve, and Fig. 7(b) shows typical curves for materials with different behaviors.

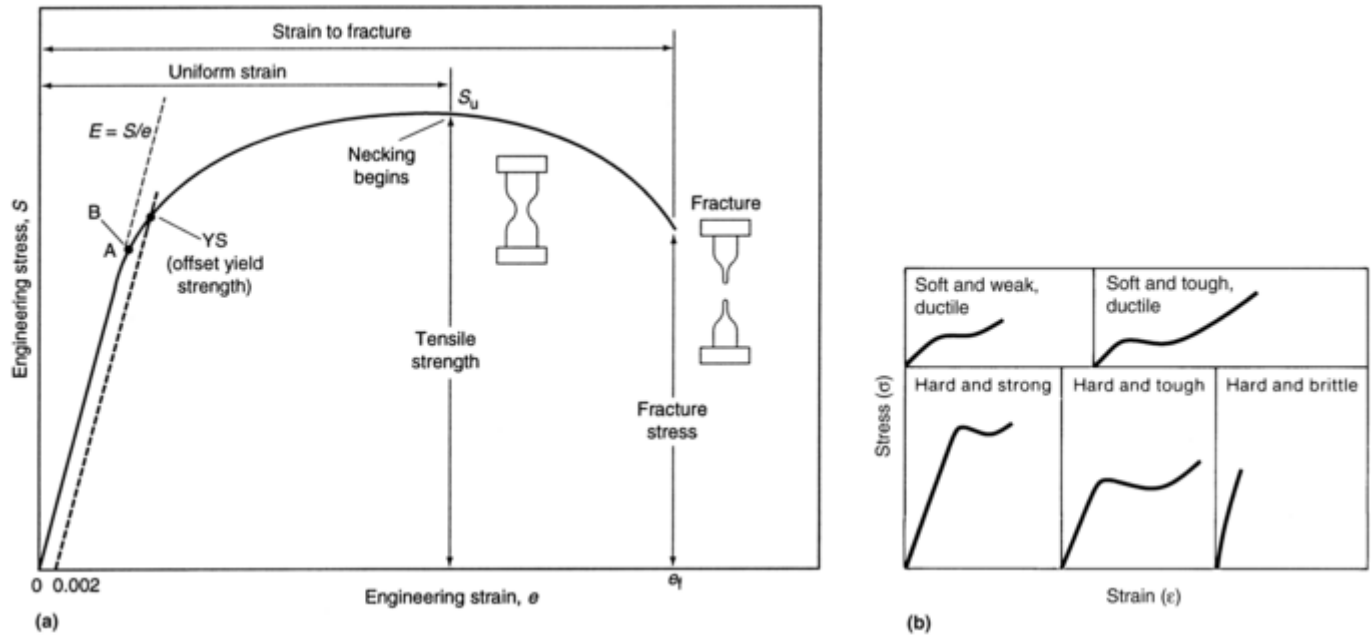

Fig. 7 Mechanical properties diagrams. (a) Typical stress-strain tensile curve (b) Typical stress-strain tensile curves for materials with different characteristics.

As the stress load increases, the material reaches a point at which it either breaks or fails, or yields and becomes plastic. *Plastic deformation* or *yielding* is defined as a permanent change in shape of a material in response to an applied load. After yielding, the change in strain per unit load increases. The stress at which the material becomes plastic is defined as the *yield stress,* σ_{ys}. Engineers normally design for loads less than σ_{ys}. Ceramics generally have very limited ductility, and the yield stress is often the failure stress. However, during fabrication, materials are often required to be deformed to a prescribed shape and thus must be loaded above the yield point. As the material undergoes plastic deformation, it becomes stronger due to (a) the generation and entanglement of dislocations within each grain in metals or (b) the alignment of polymer chains in organics. If the material is unloaded prior to failure, the material responds elastically from the point of maximum load. On reloading, the plastically deformed material will have a higher yield stress and is said to have undergone *work hardening.* The material can be returned to its original yield stress by heating (*recrystallization*). Deforming the material at elevated temperatures reduces the stress needed for deformation and eliminates the work hardening (*hot working*). In metals, regions of high tensile stress are anodic compared with regions of lower stress. A bent piece of tubing possesses higher residual tensile stresses on the outside of the bend.

Material response to load depends on the type of material, temperature, type of loading, previous loading, and the rate at which the load is applied. The most often cited stress-strain data are derived from *tensile tests.* In this test the response of a material to increasing pull or tensile stress is evaluated (normally at a strain rate of 0.02/s) at room temperature on samples with a typical sample-test length of approximately 5 cm (2 in.) and cross section diameter of approximately 1.25 cm (0.5 in.). Another commonly used stress-strain test is the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

compression test in which a cylinder is compacted. While metals have similar response to tensile and compression loads, ceramics generally have significantly higher compression strength than tensile strength and the strength values often are only reported for compression. Shear tests are also significant.

Strength of metals is strongly influenced by *grain size* (size of crystals). Strength increases as grain size decreases. The decrease in grain size is accompanied by an increased volume fraction of *grain boundaries.* The grain boundaries are high-energy regions that are capable of accelerated corrosion, which is the basis for etching for metallographic examination. Grain boundaries act as sinks for impurities, which can also accelerate corrosion. Elevated temperature processing encourages grain growth, thus reducing the volume percent of grain boundaries.

Another common measure of material response to a load is the hardness test, where the resistance of a material to a specific load using an indenter is measured. A number of different loads and indenter sizes, shapes, and materials have been adopted as standards. The area or depth of the indent is measured and reported as the Brinell, Rockwell, Knoop, or Vickers hardness number. In general, as the hardness of a material increases, so does its strength. An empirical relationship has been established between hardness and tensile strength.

In practice, many materials contain flaws or defects. Material imperfections can have serious consequences on the response of a material to a load by reducing the stress to fracture and/or changing the nature of the failure. Standards have been derived to measure the change in failure if surface cracks are present. *Fracture toughness* (symbolized by K_{Ic}, K_{IIc}, or K_{IIIc}, depending on load configuration) provides a relationship between catastrophic failure and the size of the surface crack. Fracture toughness is valid only for materials that undergo brittle rapid failure with little or no plastic component prior to failure; that is, only elastic deformation followed by failure (defined as *plane-strain failure*). For materials with a significant plastic component prior to failure (defined as *plane-stress failure*), the area under the elastic and plastic portion of the stress-strain curve, $\int \sigma \delta \varepsilon$, is the failure energy per unit volume. It is measured and defined as the *fracture energy*, (symbolized as J_{Ic}, J_{IIc}, or J_{IIIc}). In this type of failure, the advancing crack tip is often observed to have undergone plastic strain, and the sharpness of the crack tip is blunted and undergoes plastic deformation.

Other material strength measurements include the response of a material to long-term loading, dynamic or impact loading, and changing loads, as defined in Table 4. Materials at constant stress levels below the yield strength over extended periods of time exhibit permanent deformation or *creep* and fail at loads below those measured in tensile tests. This is especially true for plastics. Materials loaded at high strain rates; that is under dynamic or *impact loading*, generally have higher yield strength but less ductility prior to failure than that measured in tensile tests. Materials subjected to constantly changing cyclic loads also undergo plastic deformation over time at loads much less than the yield strength and will fail in *fatigue* after a number of cycles. Fatigue curves are typically called *S-N* curves (stress versus number of cycles). Since the long- term properties of materials are important in typical service applications, numerous handbooks provide tables with creep and fatigue data. Figure 8 shows a typical creep curve and a fatigue curve.

Table 4 Solid material mechanical properties

Material strength	Description
Creep	Material response of deformation over time to a constant load. Creep-rupture strength is the stress that will cause fracture in a given time.
Compressive	The maximum compressive stress a material can develop. Compressive stress results in deformation (shortening) in the direction of the applied force.
Tensile	The maximum load a material can support in response to a pulling force at a slow strain rate. The ultimate strength as contrasted to the yield strength
Shear	The maximum stress a solid can sustain when the force is tangential to the plane on which it acts. In metals the stress exists when parallel planes of metal crystals slide across each other. In plastics, layers of molecules slide across each other.
Impact	A measure of resiliency or toughness of a solid to a shock or very rapid strain rate. The amount of energy that can be absorbed without fracture
Fatigue	Material response leading to fracture to variation in stress (or strain) loading at less than the ultimate strength. Often cyclic loading

Thermal Properties. *Thermal conductivity* is the ability of a material to transmit heat. In most applications, thermal conductivity is the result of coordinated atomic or molecular movement (phonon wave) that is enhanced by long-range order. Metals possess higher thermal conductivity than ceramics, which are considered to be thermal insulators, while amorphous plastics are even better thermal insulators than ceramics. High thermal conductivity enhances the ability of a material to remove heat in applications such as metal-cooling fins on air-cooled engines for lawn mowers and motorcycles. Ceramics and plastics make good coffee cups because they do not readily transmit heat to the surrounding atmosphere or a person's hand.

Materials undergo *thermal expansion* as they are heated. Thermal expansion is the response of a material to an increase in individual, random atomic vibration. Increasing the internal energy of a material will cause the atoms or molecules to increase their vibration amplitude, increasing the distance between atoms. For materials that are packed closely, such as metals in a long- range lattice structure, the expansion is proportional to the change in thermal energy. The force a thermally expanded metal can exert is equal to the force it takes to expand it by the same amount. Ceramics and plastics have a more open structure resulting in a lower rate of thermal expansion than metals. Thermal expansion can induce compressive and tensile stresses within a component or assembly of components.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

When a material is subjected to rapid heating, the combined effects of thermal expansion and thermal conductivity may result in serious structural problems. Metals, because of their high thermal conductivity and good ductility, are not as affected by the thermal strain produced by the differential thermal expansion as ceramics. Ceramics have much lower thermal conductivity than metals, and thus experience a sharper thermal gradient that can produce greater thermal stress due to differences in thermal expansion over shorter distances. This results in surface spalling or cracking and compression (during rapid cooling) or tensile (during rapid heating) failure. Plastics also have low thermal conductivity, but their enhanced elasticity greatly reduces chances of failure due to thermal shock. However, their low thermal conductivity may cause localized heating and weakening during fatigue loading.

Diffusion is atomic or molecular movement within a material due to chemical gradients within the material. Processing materials at elevated temperatures and then cooling them rapidly before they can reach thermal equilibrium may result in compositional segregation, retention of unstable phases, retained thermal stresses, and so forth. Restoration of the system to thermodynamic equilibrium is accomplished by annealing. Many materials are processed in a manner that ensures the system is not in equilibrium. Most carbon steels have economic value because of their retention of the nonequilibrium Fe-Fe_3C microstructure. The room temperature Fe-C thermodynamic equilibrium state would be a gray cast iron—that is, pure iron in a bcc lattice and graphite microstructure.

Surface Interactions. Interactions at the solid surface with the environment can involve solid- gas interactions (oxidation), solid-liquid interactions (corrosion), and solid-solid interactions (wear). These interactions can be detrimental to the overall performance of the materials, as defined in Table 5.

Table 5 Characteristics of common material loss interactions on solid surfaces

Agent	Degradation	Description
Gas	Oxidation	Atmospheric reaction with solid surface to form solid or gaseous product
Liquid	Corrosion	Liquid reaction with solid surface to dissolve or form new surface phase
	Cavitation	Gas bubble implosion on solid surface in liquid media
Solid	Erosion	Solid or liquid impact on solid surface
	Abrasion	Solid scraping across solid surface

Oxidation is the chemical attack of gaseous elements (such as oxygen, sulfur, nitrogen, and chlorine) with metal surfaces. Most often the result of the interaction is the formation of a surface film that reduces or eliminates further solid- gas reaction. The type, density, thickness, and microstructure of the surface film depends on temperature, concentrations in the gas atmosphere, and thermodynamics of the reactions. The integrity and tenacity of the surface film to the metal surface depends on the difference in thermal properties, such as thermal expansion and thermal conductivity, as well as the difference in crystal lattice. *Spallation* is the flaking or chipping off of the surface film. Solid-gas interactions are normally evaluated by measuring the increase in material weight or the decrease in metal thickness due to development of the surface film with time. Thermodynamics of film compositions often are reported on a graph of temperature versus Gibb's free energy, *Ellingham diagrams.*

Aqueous corrosion is the chemical attack by liquids of metal surfaces. Note that prior to exposure to liquids, most metal surfaces are coated with a thin oxide surface due to prior interaction with the atmosphere. Corrosion reactions result in the dissolution of the material into the liquid. In some reactions, selective leaching or preferential removal of selected elements within the metal occurs. The corrosion reactions may also produce a protective film or precipitate on the metal surface and reduce the rate of metal-liquid interaction. The rate of metal removed from the surface depends on the diffusion rate of the dissolved metal from the surface, the kinetics of the reaction, and concentrations of the corroding element and temperature. Corrosion rates are determined by long-term immersion in solution where the corrosion rate is a measure of the material mass loss or by short-term evaluation using electrochemical tests where the corrosion rate (corrosion current) is measured as a function of material potential. Thermodynamics of corrosion reactions are plotted on Pourbaix diagrams that show the dominant state of the metal ion as a function of pH and potential (see the article “Potential versus pH (Pourbaix) Diagrams” in this Volume).

Wear is the physical removal of the surface of a material. *Erosive wear* is caused by solid or liquid particles impacting on the material surface. Cavitation erosion is caused by implosion of air bubbles formed on the surface of a solid as a result of rapid movement through a liquid (i.e., on a propeller of a ship). *Abrasive wear* is

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

caused by solid particles scraping across or impacting the material surface. Wear is extremely common and accounts for one-third to one-half of all equipment replacement in industry. Wear is a localized phenomenon, often the result of repeated events, and is characterized by chipping, plowing, or cutting away of the material at the surface. While individual event interactions can be almost innocuous, the cumulative effect over many events may remove a significant quantity of material and cause failure. Wear, like corrosion, is a complicated phenomenon and is influenced by a large number of factors. For example, erosion wear factors include hardness difference of the materials, relative speed, size, angle of impact, and morphology of the impacting particle and temperature.

The combination of wear and corrosion often has synergistic effects on the failure of a material. At elevated temperatures, abrasive wear can prevent the buildup of the tough, wear resistant, surface oxide layer, thus providing a continuously fresh surface for oxidation. In a liquid media, corrosion or erosion may remove a tough, protective surface film, exposing the less corrosion and erosion resistant metal to continuous attack.

Electrical, Magnetic, and Optical Properties. Electrical properties are related to the ease of moving electrons, ions, or charged molecules. This in turn is related to electron and atomic bonding and the material microstructure. Because metals share their valence electrons throughout the entire structure, there is little resistance to the ability of electrons to move. Conductivity is one of the distinguishing features of metals. Ceramics have ionic bonding, but the lattice structure does not allow for easy ionic movement. Thus ceramics are normally insulators. In organic compounds the covalent bonding between carbon atoms generally restricts the electron movement. An exception is graphite, which, because of the resonance between the interconnecting benzene rings, allows electrons to flow on a plane. Ionic and dipolar materials, while not providing good electrical conductivity, are used to store electrical energy by responding locally to electric fields that reorient their charge. This ability is utilized in capacitors and is a measure of the dielectric properties of the material. A change in shape or microstructure of a material due to an applied electric field is defined as the *Piezoelectric* effect. *Superconductivity* is the cooperative movement of a pair of electrons traveling through a lattice. This effect occurs readily at very low temperatures, from 0 to 70 K, when atomic vibrations are minimal.

Magnetic properties are related to the interaction between the inner or core electrons of atoms. Elements with the strongest magnetic properties are those in the center of row four of the periodic table (with an unfilled d-shell), row five (with an unfilled f-shell) and some of the rare earth elements. Magnetic molecules often are composed of iron-base spinel and sesquioxide compositions. *Hard* or *permanent magnets* are those materials that, once magnetized, readily retain their magnetic properties, for example, magnetic recording devices. *Soft magnets* are those materials that readily lose their magnetism, such as transformer cores.

Material response to electromagnetic energy, transmission, reflection, or absorption is a function of the material electron bonding and atomic microstructure and the wavelength of the radiation. The electrons in metals are bonded very loosely and react readily with electromagnetic fields (e.g., radio antennas). The dipole structure of ceramics and many polymers will respond to certain electromagnetic frequencies. Note that in microwave ovens, the electromagnetic frequency is chosen to resonate with the vibrational energy of water molecules and not with carbon bonds of polymers or most ceramic dipoles. Thus, food is heated selectively and not the plate. If the irradiating wavelength is less than that of the grain structure, grain boundaries will reflect the light. Light transmission is also affected by abrupt changes within a material. Thus, the amorphous structure of many polymers and ceramics will produce transparent materials. However, small changes in microstructure will result in local changes in light transmission. The local alignment of polymer chains, glazing, in response to stress, reduces the amorphous local microstructure and produces a translucent region.

Performance Maps. *Material performance maps* have been generated that relate material properties to environmental or engineering needs. (These are referred to often as *Ashby maps*). Generalized materials properties equations often can be separated into those variables that are intrinsic material properties and those variables that can be imposed upon the material by an external source. These equations present a theoretical or empirical model characterizing the response of a material. Often, as the external variable changes, a point is reached where the type or mode of material response changes; that is, the stress (external force)-strain (material response) changes with stress loading rates from creep to impact. Plots can be made using these equations with the material variable on one axis and the applied variables on the other axis. Boundaries can define regions or areas in which a range of material properties will respond in a similar manner to a range of imposed external conditions. Using these generic material performance maps, experimentally determined values for different materials can be derived. Often trends are observed between different types of materials or within a material

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

class that enables generalizations to be made where there may be no data to predict a material response to changing external forces. A typical Ashby map is shown in Fig. 9.

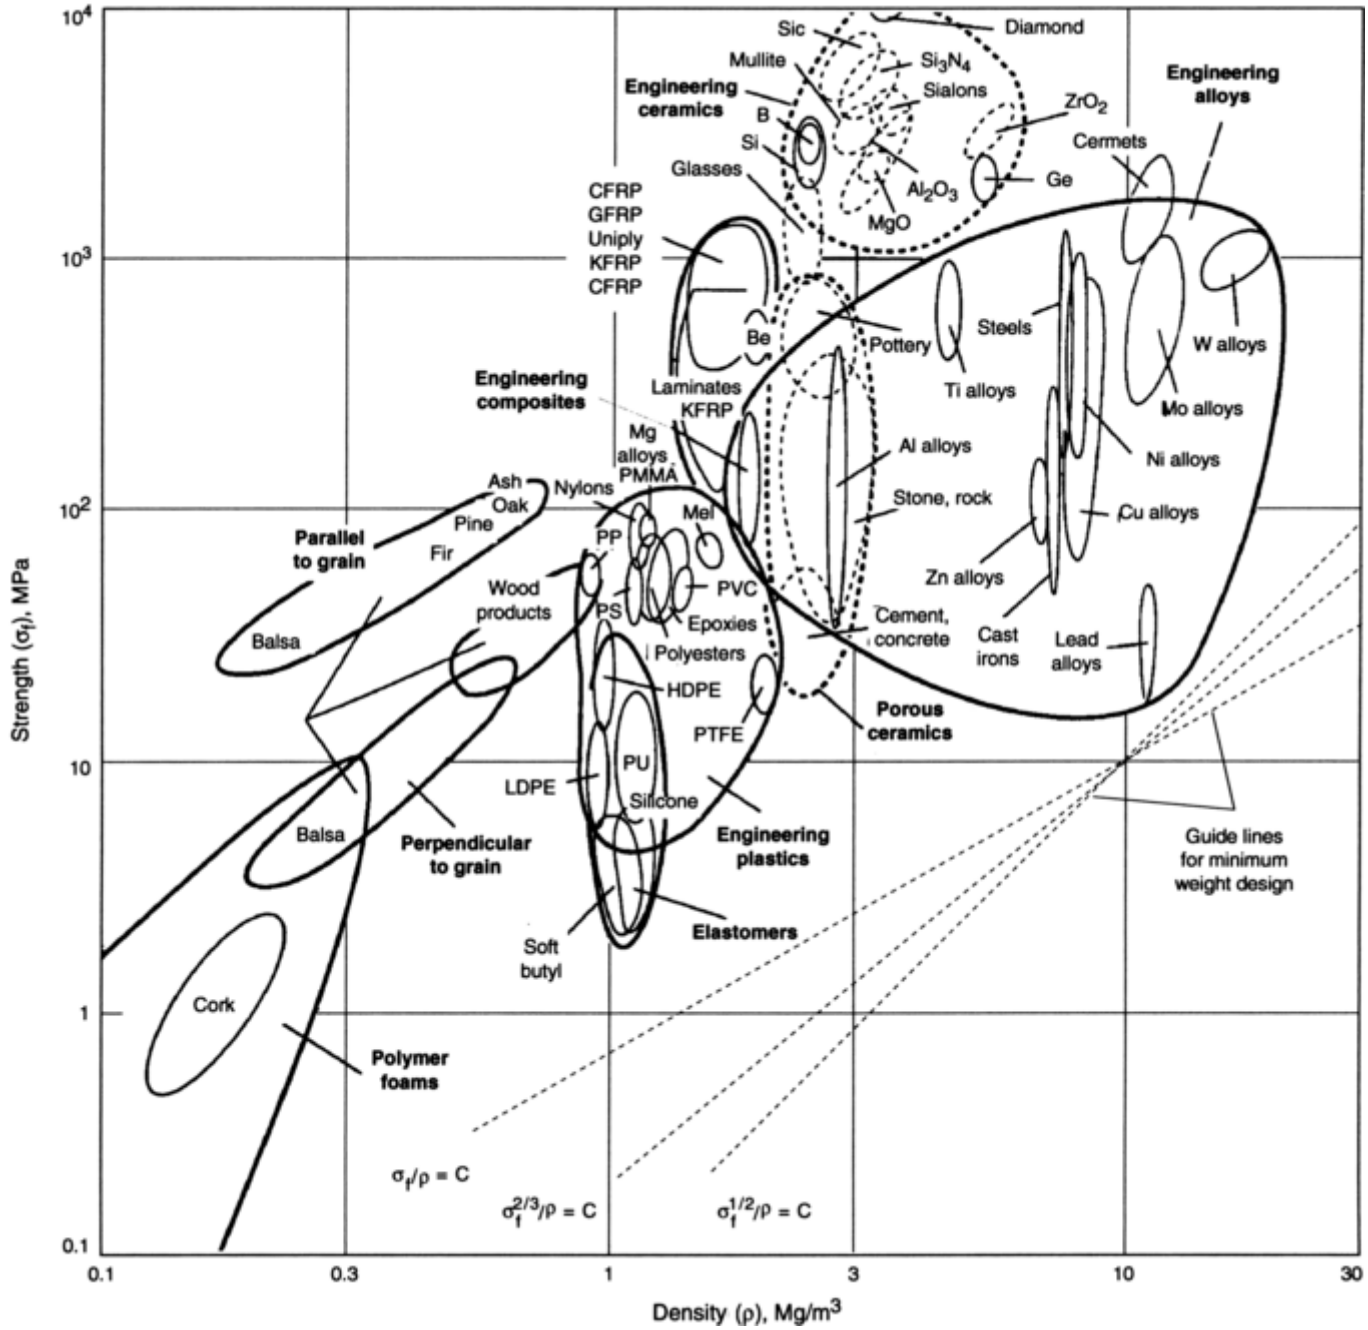

Fig. 9 Typical Ashby map. Strength, σ_f, plotted against density, ρ, for various engineered materials. Strength is yield strength for metals and polymers, compressive strength for ceramics, tear strength for elastomers, and tensile strength for composites. The guide lines of constant σ_f/ρ, $\sigma_f^{2/3}/\rho$, and $\sigma_f^{1/2}/\rho$ are used in minimum weight, yield-limited, design. Note: log scales are used to encompass the range of values.

Processing

Most materials do not come from nature ready for use. They must be refined, purified, alloyed, combined with other components, and shaped into a final product. The type of processing a material receives before application greatly affects the properties of the material and thus its applications. Representative mechanical and physical property values of materials from the different groups are found in Table 6.

Ceramics often are classified as being either low tech or high tech. Traditional or low-tech materials are those that are mined and, with little refinement, are ready for applications. Such materials include clays and silicates for bricks, pottery, concrete, and refractories. Advanced, or high-tech, ceramics are those with an application requiring a high degree of purity. Such materials include SiO_2 for semiconductors and TiO_2 for paints.

Most ceramics processing begins with powders. Because of their high melting points, many ceramic products are sintered-bonded powders. In *sintering,* the ceramic powders are blended with binders or other low melting ceramic powders or formed into a slurry. The new composition is formed into a near final shape, or green product, and heated for sufficient time so that the particles either surface diffusion bond together or the lower melting ceramic melts and forms a thin layer that holds the higher melting particles together. In many ceramic products the final composition has a fine structure porosity as high as 6 to 10%.

The ionic bonding of atoms in ceramics forms molecules that often have highly ordered localized structure. When these ceramics are cooled, they often do not go through a definite phase transition from liquid to solid. With decreasing temperature, the mobility of molecules becomes limited, and they may not be able to align themselves into a perfectly repeating lattice. The liquid viscosity continues to increase, eventually reaching a state where there is no molecular movement. This noncrystalline or amorphous structure is called *glass.* In commercial silica glasses, additives are placed in the SiO_2 to reduce long-range order present in quartz, lower the melting temperature, and increase the viscosity. The resulting ceramic alloy can be formed readily into a final shape that will be retained at room temperature.

By alloying, it is possible to reduce greatly the alloy melting point (T_m) beyond that of the individual elements or molecules. Commercial glass is made by alloying SiO_2 with $T_m \approx 1700$ °C (3100 °F) with Na_2O having $T_{dissoc} \approx 1300$ °C (2370 °F) and CaO, $T_m \approx 2600$ °C (4710 °F). The resulting softening, or melting, temperature can be as low as 800 °C (1470 °F). Similarly, low melting glazes (e.g., $CaO{\cdot}Al_2O_3{\cdot}2SiO_2$) are applied to the surface of ceramic green products (such as pottery and tableware) prior to firing so that, when heated, the glaze melts and forms a continuous, impermeable surface.

The difference in thermal conductivity and thermal expansion between ceramics and metals makes bonding between these materials very difficult and often requires a series of intermediate steps. Because of the somewhat open structure of ceramics at low temperatures, organic glues can be used to bond ceramics to other materials. Because ceramics have good resistance to oxidation, many being composed of oxides and having low thermal conductivity, often they are used as coatings or protective barriers on metals for high temperature applications. In the ceramic- metal composite, the ceramic component offers protection from the environment while the metal component provides the necessary strength and resistance to catastrophic failure.

Organics. The most common organic materials considered here are polymer-based plastics. These are long chain materials with carbon as their backbone. They are formed by reacting smaller size molecules called *mers* or *monomers* together to form *polymers. Plastics* are blends of polymers with different polymer lengths or with different polymer compositions. The structure of the polymer chains and length of the chains control many of the plastic properties. Monomers can be as simple as a two carbon molecule or can be very long carbon chains, which may contain small side chains. *Polymerization* is the reaction of individual similar monomers resulting in polymer of repeating similar units. In addition to reaction between similar mers, *copolymerization* occurs when the reaction is between different monomers. These reactions can be stimulated by temperature, by catalysts, or by reaction between the monomers themselves. Poly[chmerization and copolymerization are often incorporated into the final production step of plastic products.

Individual polymers interact by directly linking between the different polymer chains, by weak van der Waals bonding between atoms on different chains, or by mechanical interlocking of the polymer chains. Plastics generally have an amorphous microstructure; however, chains may be aligned partially during fabrication by drawing the polymers through dies. *Thermoset* plastics are formed in final shape by placing the polymers or combination of polymers in a final shape die and then stimulating the reaction that initiates the cross linking between polymers. *Thermoplastics* are formed most often into their final shape by high-pressure extrusion, often at elevated temperature.

Plastics often are joined by means of organic glues. These glues are organic polymer compounds designed to penetrate into the open, amorphous structure of plastics and break the bonds between polymer chains. When the glue dries or the glue polymer is stimulated to undergo a chemical reaction with itself and/or the material it has penetrated, the glued polymers become interlocked with polymer chains inside the surface of the softened polymers.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Metals. There are over 80 different elements that can form metals. Most of these elements can be combined with other metallic elements to form alloys. Very few metals can be found in nature with sufficient purity to be used directly. Metals often are derived from mined minerals, or ores, such as oxides, sulfides, and carbonates. Metal ores are refined or reduced to pure metal elements by a number of different reactions. Examples are:

$$Fe_2O_3 + 2C \rightarrow Fe + FeO + 2CO$$

$$FeO + C \rightarrow Fe + CO$$

$$TiO_2 + Cl_2 + C \rightarrow TiCl_4 + CO_2$$

$$TiCl_4 + 2Mg \rightarrow Ti + 2MgCl_2$$

$$PbS + O_2 \rightarrow Pb + SO_2$$

After refinement, the elemental metal can be further processed by combining different metals to form alloys: Fe + Cr + Ni yields stainless steel; Cu + Zn yields brass; Pb + Zn yields solder. Elements are alloyed to alter or augment specific properties—to increase corrosion resistance (i.e., Cr in stainless steel), to increase strength (i.e., Zn in brass), or to lower melting point (i.e., Pb in solder).

The microstructure of the final product is controlled by the metal chemistry and the fabrication steps. During solidification, if the cooling rate is rapid, there is insufficient time for the entire system to maintain thermal equilibrium. Initially at the solid-liquid interface, there is rapid grain nucleation producing a large number of small grains. The large difference in temperature enhances preferential grain growth in certain lattice directions, resulting in the solidification front limiting the number of grains that grow and producing elongated structures, *columnar grains,* or elongated treelike structures, *dendritic grains.* As the temperature gradient is reduced, the solidification front slows, and grain nucleation can again occur resulting in equiaxed grain structure in the interior of a casting.

During cold working, grains become flattened and elongated *platelet grains* in the rolling direction. Rapid cooling or reheating of a cold worked structure produces *equiaxed grains.* During the initial solidification of a metal, a high cooling rate may prevent the entire system from being in chemical equilibrium. Elemental segregation may result from different solubility levels at different temperatures and the inability of elements to diffuse rapidly through the solid to produce a uniform composition. Alloys often are held at elevated temperature after casting to allow sufficient time for atomic diffusion and to *normalize,* or homogenize, the composition throughout the microstructure.

After melting, the metal is cast into either near-net-final shape or into slabs or billets. Slabs and/or billets are processed further by either hot or cold working. In *hot working* a material is deformed at elevated temperatures where the yield strength is lower than at room temperature and the material does not work harden. During *cold working,* often done as a final processing step after several hot working operations, the material stores up elastic energy and its yield strength is increased. The energy can be reduced by a quick heat treatment (anneal) during which the elastic energy is dissipated and recrystallization occurs, resulting in new grain development or refinement and an overall material grain size reduction.

Because different elements can be combined readily to form alloys of different composition, a common means of joining alloys together is to weld them by melting their interface surface and allowing the molten material to form a new alloy during solidification. *Soldering* and *brazing* are forms of metallic glues. When applied, they are molten and the solder or braze wets (or reacts) with the metal surface, which can be thought of as a very thin weld zone. Fluxes are compounds that remove the surface metal oxide layer present on all metal surfaces and aid the solder or braze in bonding the metal surfaces.

Welding melts the metal surface and can generate several changes in the microstructure of metals. The resolidified region, melt zone, and the region adjacent to the melt zone, the heat- affected zone (HAZ) will often possess a different microstructure than that of the bulk material being joined. These zones can result in changes in material properties, most often mechanical and corrosion properties. The metal near a weld is annealed and is often a region of inhomogeneity.

Composites. The large range of possible structures and materials that are employed in composites (Table 2) is the result of a wide variety of processing techniques. Numerous techniques have been developed for creating particular composite structures, many of which are unique to a particular composite set of materials and microstructure. Examples include:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- *Surface processing* to improve surface hardness, enhance wear resistance, increase fatigue life, and/or improve corrosion-oxidation resistance. Techniques include laser processing, ion implanting, and shot and ball peening.
- *Surface coatings* to reduce surface interactions. Techniques include thermal spray (coating with metals and ceramics), painting (coating with organics), and vapor deposition and plating.
- *Coprocessing* to place a second phase in the interior of the structure. Techniques include coextrusion of polymers to form fiberglass, metal pipes, and layering of wood between organic glues to form plywood.
- *In situ processing* of materials in which a second phase is formed as part of the processing of the material. Techniques include heat treatment of metal alloys to form precipitates (often resulting in selected grain growth characteristics) and induction heating of polymers to form a different bonding structure in the interior than on the surface.

The field of composites is expanding rapidly with an ever-expanding array of processing techniques. Care must be taken, however, as processing of the composite may change the properties of the starting materials (e.g., thermal processing of metals may eliminate the cold work structure of metals). Thought must also be given to the long-term application for which the composite is designed. Long-term exposure at elevated temperature or thermal cycling may result in debonding between the composite phases if differences in thermal expansion and thermal conductivity are too great. These differences in thermal properties must be considered, along with mechanical stress concentrations, when joining different materials together. Long-term aging of composites may result also in diffusion of elements from one composite phase into the second, changing the properties of the composite materials or forming a unique phase at the two-phase interface, again changing the microstructure and overall properties of the composite.

Material Design, Application, and Failure

Materials currently are being chosen and composites designed to meet ever more demanding specifications. To ensure safe and economic designs and applications, industry, materials organizations, and government have established codes and regulations that materials are expected to meet before being placed in service. The codes or regulations require extensive testing before the material receives certification. These requirements are based on experience and knowledge learned over years of trial and error.

Material failure can occur because the wrong material was used, the material had a preexisting manufacturing defect, there was an engineering design flaw, abuse occurred and the material was degraded, or the design load limits were exceeded. With the development of better understanding of materials and their responses to different environments, the choice of a material for a particular application is no longer by chance or limited to past experience. Manufacturing techniques have improved significantly, and reproducibility and reliability of a consistent final product is realized by implementation of quality assurance programs. Engineering design has been improved greatly by computer design programs that allow for ever greater analysis. Current software programs can be used to understand the effect of environment and catastrophic events, to incorporate safety factors, to determine when safety checks should be performed, and to predict service lifetime before failure.

All products eventually fail or become no longer usable or obsolete. The service life of materials can be extended by proper maintenance and inspection. Proper material design and understanding can produce a product that performs safely for a specified time before it needs to be taken out or service; that is, before loss of function, catastrophic failure, and damage occurs. Most of the failures of today are not the result of a single

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

factor but result from a number of one-time events, none of which would cause failure by itself but when all are taken together, result in failure. The more common events that lead to failure are:

- Failure to note and report the occurrence of an unusual event (such as an overload of one type or another)
- The failure of inspection (either not performed or incomplete)
- Change of procedure or application
- Change of environment

The study of materials is a continuously evolving field. New demands are placing greater emphasis on new applications of old materials, on newer materials with better properties, and on greater understanding of both the fundamentals of material science and engineering design.

Introduction

CORROSION is a redox process at the metal- liquid or metal-air reactive interface. Identifying effective means to prevent corrosion requires an understanding of corrosion mechanisms under a variety of environmental conditions. However, unraveling corrosion mechanisms is not always a straightforward process. An understanding of the mechanistic details requires conducting experiments under simulated and controlled laboratory conditions. Ideally, it requires real time monitoring of the corrosion reactions under these conditions at a molecular or atomic level. To gain an insight into the mechanism of corrosion, both in situ (at the original location) and ex situ (away from the original location) techniques have been employed successfully over the last couple of decades (Ref 1). However, real time in situ experiments generally require controlled laboratory conditions. Several articles in the Section “Corrosion Testing and Evaluation” address controlled laboratory testing.

Alternatively, one can use ex situ analytical techniques that are capable of analyzing surfaces before and after the corrosion reaction, thus following the changes in metallurgy and chemistry at the interfaces under a given set of environmental conditions. This article reviews a variety of surface-sensitive ex situ analytical techniques that have been successfully used in understanding corrosion processes and identifying the nature of protective corrosion inhibitor films. The focus of this review is to explain the principles of various surface-sensitive techniques and the usefulness and limitations of these techniques (Ref 2, 3, 4, 5). To gain additional insight into the use of various surface-sensitive analytical techniques for applications in corrosion science, various examples from the recent literature are cited.

Strategy for Selecting Analytical Approaches

Various techniques can be used to analyze corrosion product samples removed from the surface and also small samples of the base metallurgy. However, this approach may require dissolving the sample in a suitable solvent system and then analyzing the solution. For such samples, one needs to be aware of the limitations during the sample preparation step. These limitations include the possibility of a change in the chemical nature of the corrosion product or incomplete sample transfer during sample preparation steps. This can result in revealing inaccurate or incomplete information about the chemical composition of the sample.

An ideal approach is to analyze surfaces and corrosion-product deposits by direct surface-sensitive analytical techniques when possible. It should be pointed out that no single analytical technique can answer all questions well; instead, a strategy involving the use of a suitable combination of analytical techniques is necessary to learn as much about the corrosion mechanism as possible. The Selected References cited here clearly demonstrate the importance of this strategy in corrosion science. A clear understanding of the mechanism of corrosion will help identify effective corrosion analysis and prevention techniques.

Modern analytical methods for analyzing surfaces for corrosion and corrosion inhibition processes as well as for failure analysis can be classified into two main categories: (a) surface structure and (b) chemical identity and composition. These categories are based strictly on the nature of the questions to be addressed, such as insight into surface topography or surface structure, or understanding the chemical nature and identity at a molecular and atomic level. Table 1 lists a broad spectrum of the surface-sensitive analytical techniques, the principles of respective techniques, and the information they reveal. These techniques are described in more detail under the section devoted to each analytical method.

Table 1 Surface sensitive analytical techniques, principles and applications

Analytical technique	Principle	Target information
Surface structure techniques		
Scanning electron microscopy (SEM)	Incident electron beam generates a secondary electron emission that is used to generate the surface image.	Microscopic imaging of the surface structure
Atomic force microscopy (AFM)	Microscopic force sensor (cantilever) is used to sense the force between a sharp tip and the sample surface as the sample is scanned to generate an image.	Imaging of insulated surface structure at atomic resolution
Scanning tunneling microscopy (STM)	Tunneling current is monitored as the probe tip is scanned over a surface of interest in the *x*-*y* plane to generate an image.	Imaging of conducting surface structure at atomic resolution
Optical microscopy	Reflected light is used to generate a magnified image.	Macroscopic surface structure details
Chemical identity and composition techniques		

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Energy dispersive x-ray spectroscopy (EDS)	Incident electron beam generates emission of x-rays characteristic of elements present at the surface.	Elemental identification of the surface species
Wavelength dispersive x-ray spectroscopy (WDS)	The principle is the same as that for EDS except the emitted x-rays are measured one wavelength at a time.	Elemental identification of the surface species with higher resolution and sensitivity than EDS
X-ray diffraction (XRD)	Diffraction of the incident x-ray beam from various plans of crystal lattice create a diffraction pattern characteristic of the sample.	Elemental and phase identity and composition of inorganic corrosion product
Auger electron spectroscopy (AES)	Incident electron beam initiates a multistep process to facilitate the ejection of an outer shell electron. The energy of this ejected electron is characteristic of the surface atoms.	Elemental identity and composition of the surface species and the depth profile
X-ray photoelectron spectroscopy (XPS) or ultraviolet photoelectron spectroscopy (UPS)	Incident x-rays or ultraviolet photons on the surface eject photoelectrons. The energy of the photoelectrons is characteristic of the surface atoms.	Elemental identity and composition of the surface species, the electronic structure, chemical bonding, and elemental depth profile
Ion scattering spectroscopy (ISS)	The energy of scattered primary ions from the surface allows identification of surface atoms.	Chemical composition of the surface films at atomic and a molecular level
Secondary ion mass spectrometry (SIMS)	Incident ion beam ejects the surface atoms as ions, and mass of these secondary ions is measured.	Chemical composition of the surface adsorbed species
Extended x-ray absorption fine structure (EXAFS)	The x-ray absorption generates the interference effects between emitted photoelectron waves and backscattering waves characteristic of the local structure.	Composition of adsorbed species, number, and separation distances of surface atoms
Fourier transform infrared absorption spectroscopy (FTIR)	The absorption of the infrared photons results in vibrational excitation that is characteristic of the surface molecules and the environment.	Vibrational structure of molecules and bonding interactions with the surface and the surroundings
Raman and surface enhanced Raman spectroscopy (Raman, SERS)	Energy shifts of the scattered photons are characteristic of the molecular identity.	Vibrational structure of adsorbed molecules on the surface

Surface-Structure Analysis

Examination of the surface structure pre- and post-corrosion can often reveal clues to the nature of the corrosion process, the role of the base metal, and the role of environmental conditions in the process. For

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

surface topographic details one may utilize microscopic techniques capable of revealing surface structure from the macroscopic level to the atomic level. These techniques include optical microscopy, scanning electron microscopy (SEM), atomic force microscopy (AFM), and scanning tunneling microscopy (STM) (Ref 6). Optical microscopes can magnify the surface structure to a certain magnification level. Higher magnification to micron levels requires the use of SEM, and for atomic and molecular level resolution, AFM or STM is required. While both AFM and STM are capable of revealing the structure at atomic and molecular levels, AFM is generally useful for electrically nonconducting surfaces and STM for conducting surfaces. When considering the use of SEM on organic surfaces, the analyst must foresee the possibility of thermal damage to the surface.

Determination of Chemical Composition

An understanding of the chemical identity of a metal surface before and after corrosion can reveal the mechanistic details of the corrosion reaction. The study may require analysis of the corrosion products or the corrosion inhibitor films after the corrosion reaction. Compositional analysis can also suggest the nature of the interaction between the metal surface and the aggressive species that led to the corrosion reaction or interaction of the corrosion inhibitor molecules for corrosion protection (Ref 7). A variety of analytical tools can be used to gain such information. Thus the analytical techniques for surface analysis can be divided into two classes, namely, (a) techniques used for the analysis of the metal surface and metal oxides and (b) those used for the analysis of the corrosion product and corrosion protective organic films.

Analysis of Metal Surfaces and Metal Oxides. The analysis of the metal samples to identify the chemical nature of the base metallurgy and the surface oxide films, including the protective passive film, can be accomplished by the use of various surface sensitive analytical techniques. These techniques include energy dispersive x-ray spectroscopy (EDS), wavelength dispersive x-ray spectroscopy (WDS), Auger electron spectroscopy (AES), x-ray photoelectron spectroscopy (XPS) also referred to as electron spectroscopy for chemical analysis (ESCA), ultraviolet photoelectron spectroscopy (UPS), ion scattering spectroscopy (ISS), secondary ion mass spectrometry (SIMS) and extended x-ray absorption fine structure (EXAFS). While x-ray diffraction (XRD) is not a surface technique, it is widely used for the analysis of metals, alloys, and the mineral contents and phase identifications of corrosion product.

Analysis of Corrosion Products and Protective Inhibitor Films. For the analysis of the corrosion product or protective films that are expected to be primarily inorganic in nature, EDS, AES, XPS, ISS, SIMS and EXAFS generally are suitable techniques. However, for corrosion inhibitor films that are primarily organic in nature, Fourier transform infrared (FTIR) spectroscopy, Raman or surface enhanced Raman spectroscopy (SERS), SIMS, ISS, and XPS are the most appropriate techniques. For routine analysis of the molecular nature of the film, FTIR is the most versatile and inexpensive nonvacuum technique. Even though Raman and SERS can also provide information regarding the molecular nature of the film, these techniques require a fair amount of additional instrumental sophistication and experience. The vacuum techniques SIMS, ISS, and XPS require expensive instrumentation and extensive experience. A number of private analytical service laboratories around the country offer these techniques.

Analytical Methods

In general, surface-sensitive techniques involve irradiation of the surface of interest with photons, x-rays, electrons, or an ion beam. The scattered, emitted, or reflected beam then carries with it information regarding the chemical identity of the surface atoms or molecules. An overview of commonly used surface-sensitive techniques for analysis of the surface, atomic, and molecular structures is given next.

Surface Topological Structure

Surface structural details can be examined by a variety of the analytical techniques with resolution ranging from the macroscopic level to the atomic and molecular level. These techniques are based on varied principles.

Optical Microscopy. A simple optical microscope can magnify the surface topological details to a level revealing critical details not visible to the naked eye. With the use of appropriate optics, the microscope utilizes optical reflections from a surface of interest to generate an image of the surface structure. However, it does not allow for the identification of the chemical nature of surface structures. The spatial resolution of this technique is limited to approximately 1 μm. This simple technique generally can be an important first step to survey the macroscopic surface details of a sample.

Scanning Electron Microscopy. In contrast to optical microscopy, which relies on photons, the SEM approach relies on an incident beam of electrons. Under ultrahigh vacuum an electron beam is focused on the surface of interest, and the secondary electrons emitted from the surface are used to generate the image of the surface structural details. The incident beam energy can be as high as 30 keV (1.15 kcal); however, the secondary emitted electrons have energy of a few tens of eV (cal). The images generated by the emitted electrons are sensitive to the orientation of the incident beam, the relative orientation of the detector, and the organic or inorganic chemical nature of the surface.

The spatial resolution is on the order of less than 100 nm (3.9×10^{-6} in.). SEM can magnify surface structures from 10 to 30,000 times. Care should be exercised in examining organic surface films or polymeric samples. These organic films can be thermally degraded by the high-energy incident electron beam. Thus, the lowest possible energy should be used for the incident electron beam. To improve the contrast, some surfaces may require gold, carbon, or palladium coating prior to SEM examination; however, here too thermal degradation must be a consideration. This technique has been used routinely for analyzing the surface structure, including the failure analysis of structures used in a broad range of applications (Ref 8, 9, 10, 11, 12, 13, 14). While SEM imaging relies on the emission of secondary electrons from the sample surface, another similar technique relies on the back-scattered incident electrons and is referred to as back-scattered electron imaging (BEI). In this technique the intensity of the back-scattered electrons depends on the atomic number of the elements present in the sample. The higher the atomic number of the elements present in the sample, the higher is the number of the back-scattered electrons. As a result, lower atomic number elements absorb more incident electrons and therefore appear dark in the micrographs. Similarly, higher atomic number elements scatter a larger number of the incident electrons, thereby making the micrograph bright. Thus on flat samples this technique can be

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

informative. In general this sensitivity of BEI to the atomic number can be used to make qualitative decisions about structure and compositions.

An extension of SEM is environmental scanning electron microscopy (E-SEM) where samples can be examined under relatively higher pressures than those involved in the traditional SEM (Ref 15). The pressure conditions allow for examination of the surface structure under atmospheres of water vapors, air, argon, nitrogen, or other gases or vapors. This allows for a dynamic characterization of the corrosion process and wetting, drying, melting, and crystallization processes. However, the instrumentation is not as common as that used for the traditional SEM.

Scanning Tunneling Microscopy (STM). In STM, a small bias voltage is applied between the probe tip and the sample, and the tunneling current is monitored as the probe is scanned in the *x-y* plane over the surface of interest. The probe tip is typically composed of platinum. The surface structure can be evaluated under a variety of environmental conditions such as ambient conditions, ultrahigh vacuum (UHV), air, cryogenic fluids, and liquid solutions. STM is capable of monitoring the surface structural details in situ, including the progression of pitting (Ref 16, 17, 18, 19, 20, 21). Samples can be conducting and semiconducting in nature.

Atomic force microscopy (AFM) is the counterpart to STM and is also used to examine surface structure (Ref 22, 23, 24, 25, 26). It utilizes a force sensor called a cantilever to sense the force between a sharp tip and the sample surface as the sample is scanned in the *x-y* direction. The signal is processed to generate the surface image. The AFM technique allows the examination of the surface structure of insulating substrates.

Atomic and Molecular Structure

Energy Dispersive X-Ray Spectroscopy (EDS). This technique is used in conjunction with a scanning electron microscope (SEM). During the SEM examination any surface structure of interest can be analyzed for elemental identity and elemental composition; the EDS technique can identify elements with atomic numbers greater than 5 (boron). The principle of the technique involves the analysis of the energy and the intensity of the emitted x-rays as the incident electron beam is focused on the surface of interest. The incident electron beam ejects an electron from an inner shell; an electron from a higher energy level then fills the vacancy generated by the ejected electron. The electron filling the vacant shell loses energy corresponding to the difference between the two energy levels involved in the form of x-rays. The energy of the emitted x-rays is characteristic of the elements involved (Fig. 1b).

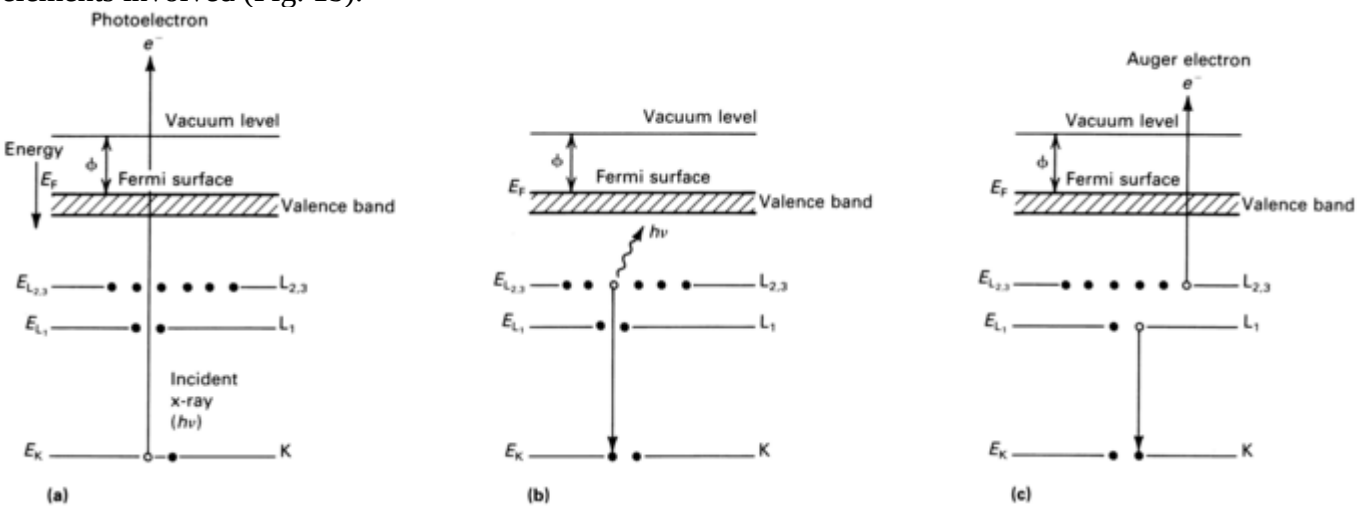

Fig. 1 Energy-level diagrams showing the electron transitions that form the basis for three techniques. (a) X-ray photoelectron spectroscopy (XPS). (b) X-ray analysis. (c) AES (Auger electron spectroscopy). φ, spectrometer work function

The instrument generates a spectrum of the relative intensity of the x-rays versus the energy of the x-rays, thereby allowing for the identification of various elements with atomic numbers greater than 5. The convenience of examining the structural details through SEM with the ability to focus on any structure of interest to gain information about the elemental identity of this structure becomes a powerful approach. The technique is available widely and relatively easy to use by trained professionals. With the use of known standards, the technique can be used for quantitative analysis of elements; however, it is commonly used for

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

qualitative examination of samples. Nevertheless, the EDS spectrum does reveal the relative concentration differences for various elements across the surface or between various samples compared. This technique is very useful for the analysis of surface contamination, corrosion products, preliminary identification of an alloy or surface coating, and phase identification (Ref 27, 28, 29, 30). The combination of SEM and EDS can also be used for failure analysis.

Wavelength dispersive x-ray spectroscopy (WDS) is another x-ray technique that can be used for the identification of the elemental composition of a sample of interest. In principle, WDS is a technique complementary to EDS. The main differences between these two techniques are that in EDS, the x-ray photons are evaluated for all energies at once and displayed against energy, and in WDS, x-ray photons are evaluated based on their wavelengths with a single wavelength measured at a time. Typically, WDS offers better resolution and sensitivity than EDS; however, the inherent nature of the slow measurement process makes this a slower technique than EDS. While not necessarily a surface technique, x-ray diffraction is widely used and is a valuable technique for determining mineral identities of surface films and corrosion products that are suitably thick.

Auger electron spectroscopy (AES) involves the use of an incident beam of electrons under ultrahigh vacuum (UHV) (Ref 31). The incident beam is focused on the surface of interest, and the energy of the emitted beam is analyzed. In AES spectroscopy the incident beam ejects an inner electron. Figure 1(c) illustrates the case of ejection of the core electron (K-shell). The vacancy created may be filled by an electron from a higher energy shell, in this case the L-shell. The energy corresponding to the difference of the K and L shells is then consumed in expelling an outer electron (Auger electron) from the atom (Fig. 1c).

Auger electrons have low energies, and therefore only electrons with sufficient energy originating from the surface or near the surface from a depth of approximately 0.8 to 2 nm (3.1 to 7.9 × 10^{-8} in.) can escape. Auger electron spectroscopy has been used for not only elemental identity of the surface but also for determining the depth profiles of elements such as the composition of oxide films including the passive films and organic corrosion inhibitor films (Ref 32, 33, 34, 35). Here again quantitative analysis can be conducted with the use of appropriate standards; however, use of a semiquantitative approach is more common.

X-ray photoelectron spectroscopy (XPS), also referred to as electron spectroscopy for chemical analysis (ESCA), is very similar to AES, except that an incident monochromatic x- ray beam is used and the energy of the photo- ejected electrons from the surface atoms or molecules is analyzed (Fig. 1a). These photo-ejected electrons from the surface carry information regarding the chemical identity and environment of the surface atoms and molecules. Therefore, the peak position of the photo-ejected electrons in the XPS spectrum depends on not only the atomic number but also the chemical environment of an atom or molecule. Thus, information regarding the functional groups adsorbed on the surface can be determined. Since the soft x-rays are less damaging, insulators with elements of atomic number greater than 4 (beryllium) can be analyzed to a depth of about 1 to 10 nm (3.9 × 10^{-8} to 3.9 × 10^{-7} in.). The technique can be used for quantitative analysis with the use of appropriate standards. X-ray photoelectron spectroscopy has been extensively used for the depth profiles of the elemental composition of surface films, both organic and inorganic in nature (Ref 36, 37, 38, 39, 40, 41, 42, 43). Such information allows for not only the chemical nature of the surface films but also the mechanistic details of the film forming processes.

Ion Scattering Spectroscopy. This technique involves scattering ions from the surface of interest. The measurement of the energy of the scattered ions allows for determining the chemical identity of the surface or the surface film (Ref 44, 45, 46, 47). The technique utilizes noble gas ions such as $^{3}He^{+}$, $^{4}He^{+}$, $^{20}Ne^{+}$, or $^{40}Ar^{+}$ at energies between 0.5 to 5.0 keV (1.91 × 10^{-2} to 1.91 × 10^{-1} kcal). Generally, a target ion mass less than the probe incident ion mass will not be detected. This technique has been used to examine surface adsorbed films, surface oxides, and corrosion inhibitors. The depth resolution can be at an atomic level. A major limitation for quantitative analysis with ISS is the neutralization of the scattered ions.

Secondary Ion Mass Spectrometry. The principle of this technique involves the use of an energetic incident ion beam to eject secondary ions from the surface of interest (Ref 48, 49, 50, 51). The ejected ions are analyzed by mass spectrometry to determine the chemical identity. The high yield of the secondary ions is a direct result of the high flux of the incident ion beam and the ionization probability. Thus, the depth profile of the elemental composition of the surface films can be easily monitored. The use of efficient ion collectors in the detection mode allows for good sensitivity. The SIMS technique has been used for analysis of surface adsorbed species, passive films, and surface contaminants. The depth resolution is at a molecular level. The analyses include surface oxides, hydroxides, and corrosion inhibitor chemistries. For organic corrosion inhibitor films, one must

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

be aware of the possibility of the surface charging. An advantage of this technique is that the detection of surface ions or clusters of ions allows for the identification of the molecular nature of the organic and inorganic protective films. This information provides an insight into the mechanistic details of the formation of the protective film.

Reflectance Fourier Transform Infrared Absorption Spectroscopy. Fourier transform infrared absorption spectroscopy (FTIR) relies on the vibrational excitation of the surface molecules (Ref 52). The infrared incident photons are absorbed by the appropriate functional groups adsorbed on a surface. The intensity of the reflected photons as a function of the energy of the photons results in a fingerprint spectrum of organic and some inorganic species. This allows for the identification of the chemical nature of the film at a molecular level (Ref 53, 54, 55, 56, 57, 58, 59).

This technique is primarily used for organic surface films; however, it can be used for some inorganic surface films as well. The technique is a relatively inexpensive approach for the analysis of relatively thick films of organic corrosion inhibitors or polymeric coatings on surfaces. However, extreme care should be taken in analyzing very thin films. FTIR can be used in ex situ and in situ modes. The ex situ mode allows for a relatively easy characterization of the surface films (Ref 60).

Attenuated total reflectance (ATR) is a sampling mode where the sample of interest is pressed against a flat window. Multiple infrared beam reflections from the surface of the film through the window carry the functional group information. Another sampling mode uses multiple reflections within the film (not the sampling window), such as crystalline materials, resulting in a diffuse reflectance infrared Fourier transform (DRIFT) spectrum. The DRIFT spectrum generally contains some specular reflectance that can potentially distort the spectral resolution. Attenuated total reflectance is the most commonly used sampling mode. The windows are generally composed of ZnSe, Si, or Ge. The ZnSe windows are attacked by strong acids, but Si and Ge are very inert. Each material has its own characteristic spectral operating range. Thus materials must be appropriately selected for the specific application of interest.

Raman and Surface Enhanced Raman Spectroscopy. Raman spectroscopy evaluates the shifts in the energy of the incident visible and ultraviolet photons at right angle to the incident beam. This measurement allows for the identification of the vibrational structure of the surface adsorbates, hence the molecular nature of the species (Ref 61, 62, 63, 64, 65, 66, 67, 68). The Raman scattering signal is generally weak; therefore an intense source of light such as a laser is needed for these measurements. The incident beam is typically an Ar^+ or a Kr^+ laser. For SERS the choice of the laser frequency that coincides with the electronic structure of the species of interest allows for thousand-fold signal enhancement. Thus SERS becomes an advantageous technique compared to Raman spectroscopy for some samples of interest. Surface enhanced Raman spectroscopy signal is typically observed for gold, copper, and silver. For SERS inactive steel, surfaces are typically coated with silver islands to make the surface SERS active. Both of the preceding techniques have been successfully used for examining the molecular nature of passive films and corrosion inhibitor films. Corrosion related Raman or SERS studies have been carried out on a broad range of alloys and protective corrosion inhibitor films in both in situ and ex situ modes (Ref 69, 70, 71, 72, 73, 74, 75, 76).

Raman spectroscopic technique also has some limitations that need to be considered for various samples of interest. For dark and colored samples, the high absorption coefficient of the incident visible light limits the strength of the scattered Raman signal. Although not common, in some instances any fluorescence signal can complicate the spectrum, thus making the measurements difficult. To improve the Raman signal, intense incident laser light is used, and it sometimes presents a challenge of thermal degradation of the sample of interest. Extreme care is thus needed in conducting experiments to avoid chemical compositional changes. In general, these limitations can be addressed by appropriate experimental precautions.

Extended X-Ray Absorption Fine Structure. X-ray absorption spectroscopy is used for a number of applications (Ref 77). This is primarily due to the availability of synchrotron radiation sources that can generate x-rays with intensities that are significantly higher than conventional x- ray sources. The absorption of x-rays by materials generally decreases as the energy of the incident x-ray beam is increased. However, when the energy of the x-ray reaches a threshold to promote a core electron to an unoccupied valence level or the continuum, absorption suddenly increases. The structure of this absorption edge is referred to as the x-ray absorption near edge structure (XANES). The energy of the x- ray edge corresponding to this absorption is characteristic of the individual elements, thus allowing for the identification of specific elements (Ref 78, 79, 80). Extending beyond the XANES region, from 100 to 1000 to 2000 eV (3.8 to 38.3 to 76.6 cal) above the edge are oscillations that are referred to as the extended x-ray absorption fine structure (EXAFS) (Ref 81, 82, 83, 84, 85,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

86, 87, 88, 89, 90, 91). The EXAFS results from the oscillatory modulation of the x-ray absorption cross section by the interference between the emitted photoelectron waves and the backscattered waves from neighboring atoms in the molecule. The EXAFS allows for determining the interatomic distances of the nearest neighbors of a given atom and therefore the molecular structure of the surface film. The technique can be used in situ and ex situ to monitor electrochemical reactions. The technique has been used successfully to evaluate the chemical nature of conversion coatings (Ref 92). This technique does require access to the synchrotron radiation source and sufficient theoretical and experimental experience.

More detailed descriptions of the principles and applications of these techniques are provided in *Materials Characterization,* Volume 10 of *ASM Handbook,* and in the section "Atomic Force Microscopy" in the article "Measurement of Surface Forces and Adhesion" in *Friction, Lubrication, and Wear Technology,* Volume 18 of *ASM Handbook.*

Introduction

REMARKABLE CHANGES in information technology have occurred since the 1987 edition of this Handbook was published. As a consequence, information and data that may not have been obtainable at that time are now routinely available by way of the World Wide Web. This article lists selected information sources and databases and the current (2003) way they are accessed. These lists were compiled from many other lists and from searches on the web. They represent the authors' choices of what are some of the more important corrosion sources on the web. They are not inclusive of all possible sites, which was not the authors' goal, but rather provide good starting points from which one can build.

The information in this article has a fairly high “vapor pressure,” and its permanence can be fairly tenuous. On the other hand, the Internet addresses for major sites are not as likely to change since they provide continuity for the user. Information is provided in five areas:

- Societies and associations addressing corrosion and related topics
- Corrosion standards, specifications, recommended practices, and related topics
- Sources of corrosion information
- Corrosion databases and data compilations
- Other web resources

These areas frame much of the material on the web that addresses corrosion and related topics and provide portals to even more material.

Societies and Associations

Many of the leading societies and associations addressing corrosion and related topics and having a broad membership are listed in Table 1 with their web address. An effort has been made to provide a geographic distribution of organizations as well. The International Corrosion Council maintains perhaps the most comprehensive record of corrosion institutions in a list titled “Sources of Corrosion Information” that covers 40 countries. The list was last updated in 1996.

Corrosion Standards, Specifications, Recommended Practices, and Related Topics

Standards, specifications, recommended practices, and test methods are essential to the organized progress of society and its goals. The standards organizations listed in Table 2 fall into three categories. The first have a mandate to provide standards across the breadth of society activities and are classified here as "broad spectrum." Included in their activities are standards that address corrosion and related topics. The second are more focused organizations that address a particular constituency or interest group—such as TAPPI, which is concerned with the pulp and paper industry, or ACI International, which is focused on the concrete industry—and that more prominently address corrosion and its impact on the organizations' members and activities. The third are the organizations devoted specifically to all aspects of corrosion, such as NACE International.

Table 2 Corrosion standards, specifications, recommended practices, and related topics

Source	Nature of standards	Web address
ACI International	Concrete, including corrosion	www.concrete.org/

Sources of Corrosion Information

The web provides many sources of information on corrosion, ranging from corrosion fundamentals, the forms of corrosion, and how corrosion is detected and measured, to the multitude of ways equipment and structures are protected from corrosion damage, and how society and the environment are protected from the consequences of corrosion damage. Selected sites are given in Table 3, representing a reasonably broad range of interests and providing portals to other sources of information. This list is, as they say, "only the tip of the iceberg," and the authors appreciate the fact that many readers have their own list of favorites.

Corrosion Databases and Data Compilations

Few situations in science and engineering exist where all the data needed are immediately available from direct experience. Corrosion— with the possible combinations of multiple materials, the multitude of corrosion agents in a variety of strengths over a range of temperatures, and other environmental factors—presents a daunting array of scenarios. Databases and data compilations represent the collective knowledge gleaned from a multitude of individual experiences. Databases and data compilations, supported by an understanding of fundamentals, move one toward goals with efficiency and economy in less-than-perfect situations; that is, most situations. The databases and data compilations listed in Table 4 provide fundamental information on a wide range of materials, their properties, their use and handling, and for evaluating their application. The data compilations are books that may or may not be available in electronic form. Their publishers are listed under contact information.

Corrosion and Electrochemical Cells

Anion. An anion is an ion that has a negative charge. An anion will move toward the anode in an electric field.
Anode. In an electrochemical cell, the anode is the electrode where oxidation takes place. See also the section “Cell Types and Conditions for Commercial and Industrial Processes” in this article.
Cathode. In an electrochemical cell, the cathode is the electrode where reduction takes place. See also the section Cell Types and Conditions for Commercial and Industrial Processes in this article.
Cation. A cation is an ion that has a positive charge. A cation will move toward the cathode in an electric field.
Corrosion. In its broadest sense, corrosion is the deterioration of a metallic or nonmetallic material by reaction with its environment involving processes other than strictly mechanical or thermal processes. Applied to metallic materials, corrosion is the deterioration of a material by chemical or electrochemical reactions between the material and its environment.
Corrosion Cell. A corrosion cell is typically a galvanic cell that results from a lack of homogeneity in a material or its environment. There are cases where a corrosion cell can be an electrolytic cell, for example, in stray current corrosion.
Corrosion Potential. The corrosion potential is the mixed electrode potential of a freely corroding material relative to a reference electrode, also called the open-circuit potential.
Current: Sign Convention. Anodic currents and current densities are positive, and cathodic currents and current densities are negative. This corresponds to the convention that current (referred to here as conventional current) is the flow of positive charge; electrons move in a direction that is counter to the flow of current. When displaying anodic and cathodic current or current density values on logarithmic coordinates, absolute values of the current or current density are used and the cathodic values are clearly indicated.
The direction of conventional current in an external circuit is defined by the cell type:

Cell type	Direction of conventional current
Reversible	No net current
Galvanic	From the cathode (+) to the anode (-)
Electrolytic	From the cathode (-) to the anode (+)
Corrosion	From the cathode (+) to the anode (-)

Current and Current Density: Symbol Conventions. *I* is commonly used to represent current, and *i* is commonly used to represent current density or flux. Some authors use *J* or *j* to represent current density. Subscripts may be added to these symbols to further distinguish them. For example a, c, or o may be used for anodic, cathodic, and exchange current, respectively.
The unit of *I* is the ampere (A), which is a base unit in the SI system or some multiple. Units of *i* are ampere per unit area, such as A/ m^2 (A/ft^2).
Dissociation. is the breakdown of dissolved compounds in a solvent into their charged constituents or components. These charged constituents or ions are the substances that carry charge through the solution. As a consequence of dissociation, the properties of acids, bases, and salts dissolved in water or other polar solvents are very different from those of the undissolved materials.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

To explain dissociation, Arrhenius theory states that an acid is a substance that produces hydrogen ions (H^+), and a base is a substance that produces hydroxide ions (OH^-) in water. Consequently, an acid solution contains an excess of hydrogen ions and a base an excess of hydroxide ions. The reactions that produce these ions are:

$$\text{acid: } HA \rightarrow H^+ + A^- \qquad \text{(Eq 1)}$$

$$\text{base: } catOH \rightarrow cat^+ + OH^- \qquad \text{(Eq 2)}$$

$$\text{salt: } catA \rightarrow cat^+ + A^- \qquad \text{(Eq 3)}$$

where A^- is an anion and cat^+ is a cation different from H^+.

In contrast, Brønsted-Lowry proton transfer theory states that an acid is a substance that dissociates to produce a proton and a base is a substance that accepts a proton:

$$\text{acid} \rightarrow \text{proton} + \text{base} \qquad \text{(Eq 4)}$$

$$HCl \rightarrow H^+ + Cl^- \qquad \text{(Eq 5)}$$

A proton (H^+) does not exist by itself in solution. Protons combine with water to form the hydrated hydrogen ion (H_3O^+), are known as the hydronium ion. Thus, Eq 5 becomes:

$$HCl + H_2O \rightarrow H_3O^+ + Cl^- \qquad \text{(Eq 6)}$$

Arrhenius theory applies to aqueous solutions. The Brønsted-Lowry proton transfer theory applies to all media. It is the more general and important theory, particularly when considering the chemistry of substances in solutions other than water. An example in aqueous solution is the salt ammonium chloride (NH_4Cl). Aqueous solutions of NH_4Cl are acidic. The Brønsted-Lowry explanation shows that the ammonium ion (NH_4^+) is a proton donor and:

$$NH_4^+ = H^+ + NH_3 \qquad \text{(Eq 7)}$$

According to Brønsted-Lowry theory, an acid such as H_2O, HCl, H_2S, HCN, and HNO_3 as well as cations and anions such as H_3O^+, NH_4^+, HS^-, HSO_4^-, and HCO_3^- can be electrically neutral. Bases do not need to contain OH^- and can be H_2O, NH_3, NH_2OH, CH_3NH_2, N_2H_4, OH^-, Cl^-, CN^-, CH_3COO^-, or $[Zn(H_2O)_3OH]^+$.

Electrochemical Cell. It is convenient to consider an electrochemical cell as consisting of two independent electrode or half-cell reactions. The anode supports an anodic reaction, and the cathode supports a cathodic reaction. Electrons carry charge through a metallic circuit (often an external circuit), and ions carry charge through the electrolyte.

Cell Types and Conditions for Commercial and Industrial Processes. Table 1 lists conditions that exist in different cell types and the commercial and industrial processes that correspond to these cell types. See the article “Introduction to Corrosion for Constructive Purposes” in this Volume for more information.

Table 1 Cell conditions for commercial and industrial electrode processes

Cell type	Cell potential	Net current	Polarity		Process
			Anode	**Cathode**	
Reversible	$e_{cell,rev}$	$I = 0$	-	+	…
Galvanic	$e_{cell} < e_{cell,rev}$	$I \neq 0$ (spontaneous)	-	+	Batteries, fuel cells
Electrolytic	$e_{cell} > e_{cell,rev}$	$I \neq 0$ (impressed current or applied potential)	+	-	Electrolytic polishing Electroplating Electrochemical machining Electrochemical refining
Corrosion	$e_{cell} \sim 0$	I_{corr} (spontaneous)	-	+	Corrosion Chemical-mechanical

Currents and Potentials at Electrodes in Different Cell Types. The currents and potentials at two reversible electrodes, copper and silver, are given in Table 2 as an example of the conditions that exist for different cell types. The electrode systems chosen are a copper electrode immersed in a copper sulfate solution at unit activity of Cu^{2+} and a silver electrode immersed in a silver nitrate solution at unit activity of Ag^{+}. This choice of electrodes (or half-cells) avoids the complexity that arises with many electrodes of commercial interest where oxides or other stable corrosion products form on the surface. It also avoids the complexity that arises with reactions involving chemical species from different redox systems, such as zinc in an aqueous solution where the reduction reaction can be the evolution of hydrogen or the reduction of dissolved oxygen. The solutions are connected by a porous barrier and are at a temperature of 25 °C (77 °F). See the article "Introduction to Corrosion for Constructive Purposes" in this Volume for more information.

Table 2 Electrical conditions at each electrode

Cell type	Electrode reactions		Cell potential	Electrode potentials, E_{SHE}	
	Cu	**Ag**		**Cu^{2+}/Cu**	**Ag^{+}/Ag**
Reversible	$I_a = I_c = I_o$	$I_a = I_c = I_o$	$e_{cell,rev}$ = 0.459 V	E^{o}_{Cu}= 0.340	E^{o}_{Ag}= 0.799
Galvanic	$I_a > I_c$	$I_a < I_c$	$e_{cell} < e_{cell,rev}$	$E > E^{o}_{Cu}$	$E < E^{o}_{Ag}$
Electrolytic	$I_a < I_c$	$I_a > I_c$	$e_{cell} > e_{cell,rev}$	$E < E^{o}_{Cu}$	$E > E^{o}_{Ag}$
Corrosion	$I_a > I_c$	$I_a < I_c$	$e_{cell} = 0$	$E > E^{o}_{Cu}$	$E < E^{o}_{Ag}$

I_a, current associated with the anodic reaction at the electrode; I_c, current associated with the cathodic reaction at the electrode; I_o, exchange current. E, the potential of the electrode with reference to the standard hydrogen electrode (SHE); e_{cell}, the potential between external connections to the cell

Electrode Potential: Temperature Coefficient Sign Convention. The thermal temperature coefficient is positive when an increase in temperature produces an increase in electrode potential; that is, the electrode potential shifts in the positive or more noble direction.

Electrode Potential: Measuring An Unknown Potential. In terms of measuring the potential of an electrode in an electrolyte, connect the reference electrode to the ground (negative) terminal of the measuring device (electrometer, multimeter, etc.) and the electrode of interest to the high (positive) terminal. A negative potential in this configuration means the unknown electrode potential is negative to the reference electrode and vice versa. The cell notation for this configuration (see *Electrode Reactions* and Cell Notation in this article) is:

reference electrode

‖ electrode reaction of interest (Eq 8)

A simple check of measuring device polarity is achieved with any battery. Connect the measuring device lead used for the reference electrode to the negative battery terminal. Connect the measuring device lead used for the electrode of interest to the positive battery terminal. The measuring device should show a positive potential. If it does not, the polarity switch of the measuring device should be moved to the positive position.

Electrode Reactions and Cell Notation. An electrochemical cell is composed of at least two half-cell reactions. An anodic reaction is:

$$A \rightarrow A^{n+} + ne^{-} \quad \text{(Eq 9)}$$

A cathodic reaction is:

$$C^{m+} + me^{-} \rightarrow C \quad \text{(Eq 10)}$$

to produce the net or overall cell reaction:

$$mA + nC^{m+} \rightarrow mA^{n+} + nC \quad \text{(Eq 11)}$$

The corresponding half-cell reactions are described by the following notation:
anodic reaction:

$$A|A^{n+}(aq, a_{An+}) \quad \text{(Eq 12a)}$$

cathodic reaction:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$C^{m+}(aq, a_{Cm+})|C$ (Eq 12b)

These half-cell reactions are combined as follows to denote the net cell reaction:

$A|A^{n+}(aq, a_{An+})||C^{m+}(aq, a_{Cm+})|C$ (Eq 13)

In this notation, the anode or oxidizing reaction is always on the left, and the cathode or reducing reaction is always on the right. Variations of this notation allow for a metallic electrode that does not react electrochemically, for dissolved gases, and for solid phases in equilibrium with the solution. The two vertical lines represent a cell where the liquid junction potential between two aqueous solutions (aq) has been eliminated or is assumed to be small. Liquid junction potentials are often small by comparison to the cell potential.

The cell potential for the net cell reaction (Eq 14), that is, the difference between the half-cell potentials for the cathode (right) and anode (left) reactions, is:

$e_{cell} = E_{right} - E_{left}$ (Eq 14)

where the potential on the right is half-cell (Eq 12bb) and the potential on the left is half-cell (Eq 12aa), and both are expressed as reduction potentials.

The electrochemical cell notation representing the measurement of the unknown potential of an electrode of interest with respect to the standard hydrogen electrode (SHE) is given by:

$$\mathrm{Pt, H_2}\,(f = 1)\,|\,\mathrm{H^+}\,(a = 1)$$
$$\|\,\text{electrode reaction of interest} \qquad \text{(Eq 15a)}$$

SHE||electrode reaction of interest (Eq 15b)

where $f = 1$ means the fugacity is one and $a = 1$ means unity activity.

Electrode Potential: Sign Convention. The electropositive direction of electrode potential implies an increasing oxidizing condition at the electrode. The electropositive direction is also known as the noble direction because the corrosion potentials of noble metals such as gold and platinum are more electropositive than those of more active base metals such as magnesium, zinc, and iron. The electronegative direction is associated with an increasing reducing condition at the electrode. The electronegative direction is also known as the active direction, because the corrosion potentials of active metals such as magnesium and zinc are substantially more electronegative than those of noble metals.

Half-cell electrode reactions written as reduction potentials follow this convention, adopted in 1953 by the International Union of Pure and Applied Chemistry, and yield positive potentials for more oxidizing conditions and negative potentials for more reducing conditions (Ref 1).

Electrolyte. An electrolyte is a nonmetallic electrical conductor where the current is carried by ions instead of electrons.

Exchange Current. The exchange current (I_o) is the common value of the anodic and cathodic currents when an electrode is at equilibrium with its environment

$I_o = I_a = -I_c$ (Eq 16)

Half-Cell Reactions. A half-cell reaction is the electrochemical reaction that describes charge transfer at an electrode and involves either a reduction or oxidation reaction.

Ion. An ion is an atomic or molecular particle having a net electric charge.

Reference Electrode Potentials: Values And Conversion Factors. Table 3 lists reduction electrode potentials for some common reference electrodes and the conversion factors to change measured potential values from that of the measuring electrode to the SHE (standard hydrogen electrode) and SCE (saturated calomel electrode) scales.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Table 3 Reference electrode potentials and conversion factors

Electrode	Potential at 25 °C (77 °F) V vs. SHE	Thermal temperature coefficient, mV/°C	Add the following value in volts to convert from measurements with the given reference electrode[(a)]:	
			To SHE scale	**To SCE scale**
(Pt)/H_2(*f* = 1)/H^+(*a* = 1), SHE	0.000	+0.87	0.000	-0.241
Ag/AgCl/1 *M* KCl	+0.235	+0.25	+0.235	-0.006
Ag/AgCl/0.6 *M* Cl^- (seawater)	+0.250	…	+0.250	+0.009
Ag/AgCl/0.1 *M* Cl^-	+0.288	+0.22	+0.288	+0.047
Hg/Hg_2Cl_2/sat KCl, SCE	+0.241	+0.22	+0.241	0.000
Hg/Hg_2Cl_2/1 *M* KCl	+0.280	+0.59	+0.280	+0.039
Hg/Hg_2Cl_2/0.1 *M* KCl	+0.334	+0.79	+0.334	+0.093
Cu/$CuSO_4$sat	+0.300	+0.90	+0.30	+0.06
Hg/$HgSO_4$	+0.616	…	+0.616	+0.375

(a) An electrode potential of 1.000 V vs. SCE would be 1.000 + 0.241 = 1.241 V vs. SHE. An electrode potential of -1.000 V vs. SCE would be -1.000 + 0.241 = -0.759 V vs. SHE.

Source: Ref 2

Overpotential is the current-producing potential difference between a nonequilibrium electrode potential and its corresponding equilibrium value for a definite electrode reaction, $\eta = E - E^o$ (Ref 3, Fig. 1). Overvoltage and overpotential are often used interchangeably (Ref 4).

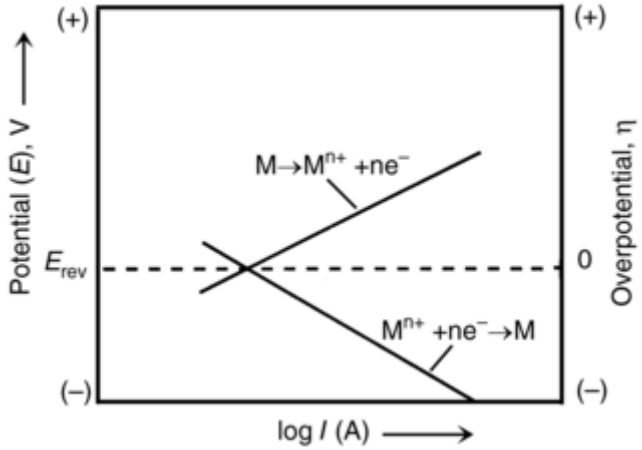

Fig. 1 Evans diagram showing the relationship between electrode potential and overpotential

Polarization is defined similarly to the overpotential; that is, the difference between the potentials of an electrode with and without current, $E - E^o$ (Ref 3, 4). The common forms of electrode polarization are activation polarization (η_{act}); concentration polarization (η_{conc}); and resistance polarization (η_r). Polarization is the sum of these contributions:

$$\eta = \eta_{act} + \eta_{conc} + \eta_r \qquad \text{(Eq 17)}$$

A term *overvoltage* (ε) has been defined similarly to overpotential to describe polarization (the current-voltage relationship) around the mixed potential (E_{corr}) for corrosion reactions (Ref 5); that is, $\varepsilon = E - E_{corr}$. The important distinction is that overpotential is related to the reversible potential of an electrode reaction, and *overvoltage* is related to the mixed potential of a corrosion reaction. Some of the confusion regarding polarization occurs because the term *overvoltage* can be used interchangeably with *overpotential* (Ref 4) or in the context of "overvoltage" (Ref 5).

مرجع مهندسی مواد و متالورژی

Polarization Data: Conventions for Displaying. On rectangular coordinates, positive values are plotted above the origin on the *y*-axis (ordinate axis) and to the right of the origin on the *x*-axis (abscissa axis). On logarithmic coordinates, increasing values are plotted from left to right on the *x*-axis and from bottom to top on the *y*-axis. Current or current density is plotted on the *x*- axis, and potential is plotted on the *y*-axis. Current or current density is plotted using either rectangular coordinates or logarithmic coordinates, depending on the range of current or current density values to be displayed. Absolute values of current or current density are used with logarithmic coordinates. Typically, current or current density values are plotted as amperes (A) or amperes per square meter (A/m^2). Potential is plotted using rectangular coordinates. Typically, potentials are converted to the SHE scale or the SCE scale and are plotted as volts (V) measured on this scale.

Cathodic Protection

Cathodic Protection (CP) is the reduction of corrosion by polarizing a structure to a sufficiently cathodic potential so that corrosion in the most anodic area(s) on the structure is/are reduced to an acceptably low level. Impressed-current CP (ICCP) protects the structure by making the structure the cathode (negative electrode) in an electrolytic cell consisting of an external source of direct current (dc) power and either a consumable or a nonconsumable anode (positive electrode) of material such as high-silicon cast iron, graphite, mixed metal oxide, or catalyzed titanium (Fig. 2a).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

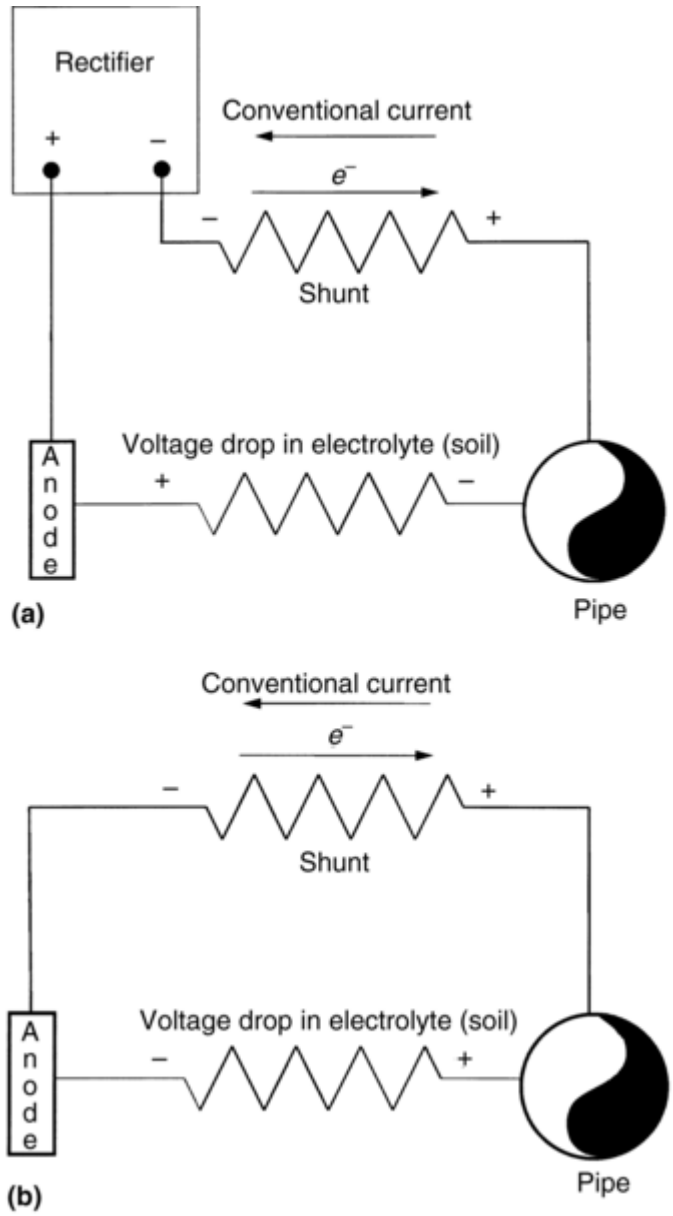

Fig. 2 Simplified layouts for cathodic protection systems. (a) Impressed current cathodic protection system (b) Galvanic or sacrificial cathodic protection system

Sacrificial CP (SACP)—also known as galvanic CP—protects the structure by coupling the structure to a consumable anode of a more active material such as zinc or magnesium (Fig. 2a).

An ICCP system is an electrolytic cell. A sacrificial CP system is a galvanic cell. Both systems polarize the structure to be protected in an electronegative direction. A properly designed CP system causes all areas of the protected structure to be made cathodic to the most anodic site on the structure before CP.

Cathodic Protection Testing Protocol. The working convention of many CP practitioners deviates from standard electrochemical convention. Two areas where this occurs are in current flow and meter configuration. “Conventional current” flows from positive to negative. This is opposite the flow of electrons. If one uses the flow of electrons as current flow and standard electrochemical convention in voltmeter connections for potential readings, some of the confusion in CP practice can be avoided.

Voltmeters used by early pipeline CP workers were analog and only read upscale. Potential surveyors for buried steel structures would almost always encounter readings that were negative with respect to a CSE (saturated copper-sulfate reference electrode). Given that the meters of the day read only up the scale, workers were in the habit of connecting the reference electrode to the positive terminal of the voltmeter and the structure to the negative and then adding the “-” in their heads. Also, by holding to the idea that “negative” always goes to the structure, it was thought that this practice helped to avoid problems with connecting ICCP systems backwards.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In time, the “upscale” meters were provided polarity switches, which were then followed by the autoranging/autopolarity digital meters of today. However, the old practice of connecting the CSE to the positive terminal of the voltmeter and the structure to the negative and changing the polarity by notation persists as of this printing in some sectors.

The practice of connecting the reference to the positive voltmeter terminal can lead to confusion in other areas. For example, SACP anodes are selected because they are more electronegative than the structure to be protected. The structure thus is positive with respect to the SACP anodes. In contrast, the rectifier positive terminal in ICCP is connected to the anodes while the negative terminal is connected to the structure. *In both cases, however, the flow of conventional current in the external circuit is away from the structure or, equivalently, the flow of electrons is towards the structure* (Fig. 2). It would be easy to think that, since the galvanic SACP anodes are electronegative to the structure while the ICCP anodes are electropositive, the current flow in the two CP systems is reversed. This is not true.

CP Protection Criteria. Early in the application of CP to pipeline protection, polished steel rods were used as “most anodic” references. The logic behind this approach was that if the pipe were polarized to the potential of the polished steel (zero volts between the pipe and rod), it would then be polarized to the level of most anodic sites. Reference electrodes, especially CSE, eventually displaced polished steel rods as the reference of choice. Likewise, standards were developed by organizations that defined protection criteria not only for buried pipelines but also for metals in other environments ranging from those submerged in seawater to those embedded in concrete. Four common criteria are used for unalloyed ferrous materials (Ref 6, 7):

- The *IR*-free (“instant off”) potential of buried materials must be more negative than -850 mV versus CSE.
- The “on potential” of buried materials is 300 mV more negative than the free corrosion potential in soil, similar to criterion 1.
- IR-free polarization of buried materials must be 100 mV more electronegative than the corrosion potential measured either by current interrupt or depolarization techniques.
- The protection current is sufficient to maintain the material at a condition that meets any of the above criteria in periodic testing.

CP Design: Area Basis for Current Densities. Current densities are employed in rule-of- thumb approaches to the design of cathodic protection systems. An assumption is made about the current density required to protect the structure. The selected density value (mA/m^2) is multiplied by the nominal surface area (m^2) of the structure in contact with the electrolyte to provide an estimate of the total required current. When a metal surface is new, there is a fairly good relationship between nominal surface area and the metal surface area in contact with the surrounding electrolyte. With age, the metal may corrode, roughness develops, and the actual metal surface area in contact with the electrolyte may increase to several times the “nominal” surface. In a similar fashion, when a metal to be protected is covered with a protective coating, the initial surface area in contact with the electrolyte is much less than the nominal surface area. With time, the coating will degrade and the surface area of the metal in contact with the electrolyte will increase.

Current densities also are important in the operation of CP anodes. In reinforced concrete, it is recommended (Ref 8) that the maximum sustained current density on the anode be less than 108 mA/m^2. In practice, some structure owners (Ref 9) operate their anodes at current densities as low as 2 mA/m^2.

Evans Diagram: Impressed Current CP (ICCP) in Neutral or Basic Environment. Figure 3(a) shows a plot of potential versus log current (Evans diagram) for an ICCP system in a neutral or basic environment. Only activation and concentration polarization are included in the structure corrosion kinetics. The structure anode reaction is the dissolution of iron; the structure cathode reaction is the reduction of oxygen. The intersection between the structure anodic polarization curve and the structure cathodic polarization curve determines the unprotected structure corrosion potential ($E_{corr,S}$) and the unprotected structure corrosion current ($I_{corr,S}$).

(c) Diagram for a galvanic or sacrificial CP system protecting a steel structure in an acidic environment using a consumable zinc anode.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Coupling the structure to a nonconsumable inert anode powered by a rectifier shifts the structure to a more electronegative potential ($E_{cp,S}$). This shift reduces the structure anodic current to $I_{cp,S}$, the corrosion current with cathodic protection. Because the cathodic reaction at the structure is diffusion limited and thus highly polarized, the current required by this shift in potential changes very little from $I_{corr,S}$.

The reaction at the inert anode is the oxidation of hydroxyl ions to form oxygen. As power is applied to the structure, the potential of the inert anode shifts in the electropositive direction to E_A, the potential of the inert anode at a current equal to $I_{corr,S}$. The ΔE shown, the *IR* drop in the solution, is a function of the partial current collecting on the structure ($I_{on,S}$) (equivalent to $I_{corr,S}$), and the electrolyte resistivity (R), in the vicinity of the reference electrode used to evaluate the system. Because of this *IR* drop, the structure appears to be polarized to $E_{on,S}$.

The rectifier output is given by $V = E_A - E_{on,S}$. When the current is interrupted, an IR free measurement of the structure potential is achieved after inductive artifacts have dissipated (typically ~0.5 seconds). This potential is the "instant off" potential and equivalent to $E_{cp,S}$. With the current off, the structure potential decays back toward $E_{corr,S}$. The value of this decay or depolarization over a period of time, typically 4 to 24 h, is a measure of how well the structure is protected by the application of CP. The reduction in the corrosion current is given by $\Delta I = I_{corr,S} - I_{cp,S}$.

In some situations, say deep well configurations, the environment surrounding the anodes may become acidic and reactions other than those shown may dominate. These reactions include gas generation, which if not vented, may greatly increase the electrical resistance at the anode.

Evans Diagram: Galvanic or Sacrificial Cathodic Protection (SACP) in Neutral or Basic Environment. Figure 3(b) shows an Evans diagram for SACP in a neutral or basic environment. The structure part of this diagram and the notation is the same as that used for the ICCP example. Only the anode has been changed, from an inert anode for ICCP to a consumable zinc anode for SACP. Again, only activation and concentration polarization are included in the structure corrosion kinetics. The structure anode reaction is the dissolution of iron; the structure cathode reaction is the reduction of oxygen. The intersection between the structure anodic polarization curve and the structure cathodic polarization curve determines the unprotected structure corrosion potential ($E_{corr,S}$) and the unprotected structure corrosion current ($I_{corr,S}$).

Coupling the structure to a consumable zinc anode shifts the structure to a more electronegative potential ($E_{cp,S}$). This shift reduces the structure anodic current to $I_{cp,S}$, the corrosion current with cathodic protection. Because the cathodic reaction at the structure is diffusion limited and highly polarized, the current required by this shift in potential changes very little from $I_{corr,S}$.

The reaction at the sacrificial anode is the oxidation of zinc to form zinc ions in solution. The potential of the zinc anode shifts in the electropositive direction to $E_{cp,S}$, the potential of the zinc anode at a current equal to $I_{corr,S}$. Just as in the case of ICCP, there is typically an *IR* potential drop between the structure and the zinc anode, and the structure and the zinc anode are at somewhat different potentials. However, for clarity, this has not been shown in Fig. 3(b).

As in the case of ICCP, when the current is interrupted, an *IR* free value of the structure potential, which is the "instant off potential" and equivalent to $E_{cp,S}$, is measured. With the current off, the structure potential decays back towards $E_{corr,S}$. The value of this decay or depolarization over a period of time, typically 4 to 24 h, is a measure of how well the structure is protected by the application of CP. The reduction in the corrosion current is given by $\Delta I = I_{corr,S} - I_{cp,S}$. Of course, these determinations cannot be made on SACP systems where the consumable anode and structure cannot be isolated from each other.

Evans Diagram: Galvanic or Sacrificial Cathodic Protection (SACP) in Acidic Environment. Figure 3(c) is an Evans diagram for SACP in an acidic environment using a consumable zinc anode. Note that both the zinc anode and the structure are polarized by the process as indicated by the dashed lines showing the combined reduction and oxidation rates. For clarity, similar details were not included in Fig. 3(a) and 3(b).

Only activation polarization is included in the structure corrosion kinetics. The structure anode reaction is the dissolution of iron; the structure cathode reaction is the reduction of hydrogen ions. The intersection between the structure anodic polarization curve and the structure cathodic polarization curve determines the unprotected structure corrosion potential ($E_{corr(Fe)}$) and the unprotected structure corrosion current ($I_{corr(Fe)}$).

Coupling the structure to a consumable zinc anode shifts the structure to a more electronegative potential ($E_{corr(couple)}$). This shift reduces the structure anodic current to $I_{cp(Fe)}$, the corrosion current with cathodic protection. Because the cathodic reaction at the structure is not diffusion limited, the current required by this shift in potentials increases substantially to $I_{corr(couple)}$, representing the increase in the cathodic current due to

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

hydrogen reduction on the zinc anode and the increase in the anodic current due to dissolution of the zinc anode.

The reaction at the consumable zinc anode is the oxidation zinc to form zinc ions in solution. The potential of the freely corroding zinc electrode in the acidic environment is $E_{corr(Zn)}$ and the corrosion current for the zinc at this potential is $I_{corr(Zn)}$. When the zinc anode is coupled with the structure, the potential shifts in the electropositive direction to $E_{corr(couple)}$. Just as in the case of ICCP, there is typically an *IR* potential drop between the structure and the zinc anode, and the structure and the zinc anode are at somewhat different potentials. However, for clarity, this has not been shown in Fig. 3(c).

As in the case of ICCP, when the current is interrupted, an *IR* free value of the structure potential is measured, which is the "instant off potential" and equivalent to $E_{corr(couple)}$. With the current off, the structure potential decays back towards $E_{corr(Fe)}$. The value of this decay or depolarization over a period of time, typically 4 to 24 h, is a measure of how well the structure is protected by the application of CP. The reduction in the corrosion current is given by $\Delta I = I_{corr(Fe)} - I_{cp(Fe)}$. Of course, these determinations cannot be made on SACP systems where the consumable anode and structure cannot be isolated from each other.

Electricity

Classifying Materials by Conductivity: Conductors (Metals), Semiconductors, and Insulators. Materials can be considered conductors (metals), semiconductors, and insulators. Metals are good conductors of electrons. An electric current flows under the influence of an electric or changing magnetic field in a metal. In insulators, there is no electric current flow under an electric field. In terms of the energy-band theory (Ref 10), insulators have completely full valence bands and cannot carry electrical current. Metals have partially filled valence bands and thus can carry current. In materials where the energy gap between the valence band and the band

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

immediately above it is small (less than about 2 eV at room temperature), electrons can be thermally excited from the valence band to the next band. This creates partially filled bands, and, thus, electrical current can flow. Such materials are semiconductors.

Electronic defects in nonstoichiometric semiconductors can be negative (electrons) or positive (holes) and are termed n-type and p-type semiconductors, respectively.

Conductivity. Conduction of electrical charge through an electrolyte results from the mobility of ions. Through a metal, conduction results from the mobility of electrons, and through a gas, conduction results from the mobility of gaseous ions and electrons. Conductivity, also called specific conductance, is a measure of these transport processes and a property of a homogeneous material. It is the inverse of resistivity and has the units of $(\Omega \cdot \text{length})^{-1}$ or S/ m. The siemens (S) is the conductance of a material such that one ampere current will flow with an applied potential of one volt; $S = 1/\Omega$

Electrochemical impedance (Z) is a complex number defined as:

$$Z(j\omega) = Z'(j\omega) + jZ''(j\omega) \qquad \text{(Eq 18)}$$

where Z' is the real or in-phase component of impedance; Z'' is the imaginary or out-of-phase component of impedance; $j^2 = -1$, and ω is the frequency in radian/s and $= 2\pi f$ where f is the frequency in Hertz (Hz). The impedance magnitude is $|Z|^2 = (Z')^2 + (Z'')^2$. The phase angle between the real and imaginary components of impedance is: $\theta = \arctan(Z''/Z')$. The admittance $Y = 1/Z = Y' + jY''$.

Impedance can be modeled in a linear constant parameter system as:

$$Z = R + jX \qquad \text{(Eq 19)}$$

where R is resistance; X is reactance $X = \omega L - 1/\omega C$; and L is inductance and C is capacitance.

Resistivity. Resistivity, also called specific resistance (ρ), is a property of a homogeneous material. It is computed from the resistance (R) of a volume of the material having unit length (l) and unit cross-sectional area (A). Its value is $\rho = RA/l$, and it has the units of $\Omega \cdot l$, such as $\Omega \cdot$ cm.

Oxidation

Crystal Structure. A crystal structure is the arrangement of atoms or ions in a regularly repeating pattern, such that the atoms or ions are located either on the points of a Bravais lattice or in a fixed relation to those points (Ref 11). A Bravais lattice is a set of points in space such that each point has identical surroundings. There are 14 possible arrangements or crystal structures (Table 4 and Fig. 4). The name of the crystal structure is a combination of the Bravais lattice and system; that is, body-centered cubic.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Table 4 Crystal structures

System	Bravais lattices	Shape	
		Axial lengths	**Angles**
Cubic	Simple Body-centered Face-centered	$a = b = c$	$\alpha = \beta = \gamma = 90°$
Tetragonal	Simple Body-centered	$a = b \neq c$	$\alpha = \beta = \gamma = 90°$
Orthorhombic	Simple Body-centered Base-centered Face-centered	$a \neq b \neq c$	$\alpha = \beta = \gamma = 90°$
Rhombohedral (or trigonal)	Simple	$a = b = c$	$\alpha = \beta = \gamma \neq 90°$
Hexagonal	Simple	$a = b \neq c$	$\alpha = \beta = 90°; \gamma = 120°$
Monoclinic	Simple Base-centered	$a \neq b \neq c$	$\alpha = \beta = 90°; \gamma \neq 90°$
Triclinic	Simple	$a \neq b \neq c$	$\alpha \neq \beta \neq \gamma \neq 90°$

Defect Structures: Kröger-Vink Notation. A notation used to describe point defects in inorganic compounds was developed by Kröger and Vink (Ref 12, 13, 14). In this system, the type of defect is indicated by a major symbol, and the site it occupies is indicated by a subscript. A superscript indicates the charge relative to a normal lattice, where ′ designates an effective negative charge, and · designates an effective positive charge. An x indicates a zero effective charge. Some examples are:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Designation	Meaning
$V_O^{2\cdot}$	Doubly charged oxygen vacancy
$Ni_{Cr}^{\cdot}$	Cr (+3) on a Ni(+2) site
O_O^x	Oxygen on an oxygen site (a normal anion)
M_M^x	Metal on a metal site (a normal cation)
$\mathbf{M_i}$	Metal interstitial
M_M'	Metal on a metal site with an extra electron
e'	Free electron (concentration of electrons ≡n)
$h^{\cdot}$	Electron hole (concentration of holes ≡p)

Defect Structures. Common point defect structures found in inorganic compounds are briefly described (Ref 15). Kröger-Vink notation is used to describe the defect equilibria.

Schottky defects are found in stoichiometric compounds and consist of equivalent concentrations of anion and cation defects. An example would be pairs of oxygen and metal vacancies:

$$O = V_O^{2\cdot} + V_M^{2\prime} \quad \text{(Eq 20)}$$

Frenkel defects are found in stoichiometric compounds and are formed when a metal ion on a regular cation site is moved to an interstitial site and leaves behind a vacancy. An example for singly charged interstitials and vacancies is:

$$M_M = M_i^{\cdot} + V_M' \quad \text{(Eq 21)}$$

Defects associated with oxygen-deficient or metal excess nonstoichiometric compounds can include extra oxygen vacancies or extra metal interstitials. An example of each is:

$$O_O = V_O^{2\cdot} + 2e' + \tfrac{1}{2}O_2 \quad \text{(Eq 22)}$$

$$O_O + M_M = M_i^{2\cdot} + 2e' + \tfrac{1}{2}O_2 \quad \text{(Eq 23)}$$

Defects associated with oxygen excess or metal-deficient nonstoichiometric compounds can include extra oxygen interstitials or extra metal vacancies. An example of each is:

$$\tfrac{1}{2}O_2 = O_i^x \quad \text{(Eq 24)}$$

$$\tfrac{1}{2}O_2 = O_O + V_M^{2\prime} + 2h^{\cdot} \quad \text{(Eq 25)}$$

Dopants can create a wide range of defects where the foreign atom takes the place of the metal cation in the normal lattice or as an interstitial.

Intrinsic ionization of electrons from the valence band to the conduction band create e' and $h^{\cdot}$ pairs. This typically occurs in stoichiometric compounds.

Parabolic Rate Equations. The oxidation of many metals at high temperatures can be described with parabolic kinetics. Often Wagner's oxidation theory is invoked to explain the behavior. It is worthwhile to note the assumptions used in Wagner's theory so that its limitations can be recognized when describing more complex systems (Ref 16, 17, 18, 19):

- Lattice diffusion of the reacting ions or atoms, or the transport of electrons through the dense compact scale, are rate determining.
- Lattice diffusion occurs through the migration of point defects. These defects migrate independently from each other.
- Reactions at the phase boundaries are rapid, and thermodynamic equilibria are established at the metal/oxide and oxide/oxygen interfaces.
- The driving force for the oxidation reaction is the free energy change that occurs on forming the oxide from the metal and gaseous oxygen. Thus a gradient in oxygen activity exists across the scale, with the activity at the metal/oxide interface determined from the metal/oxide equilibrium.
- Deviations from stoichiometry are small.
- O_2 solubility is negligible.
- Scales are thick enough to neglect charged surfaces.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The major deviations from the Wagner theory include easy diffusion paths, the formation of voids and porosity, and the effects of stresses in the scale.

Parabolic Rate Constant Evaluation: Use Δm^2 versus t (not Δm versus $t^{0.5}$). The kinetics of high-temperature corrosion experiments are often reported in terms of a parabolic rate law and a parabolic rate constant, k_p. One then has a choice to determine k_p from the slope of the experimental change in mass (Δm) and time (t) data plotted as either Δm versus $t^{0.5}$ or Δm^2 versus t. For the simplest form of the parabolic rate expression, $\Delta m^2 = k_p t$, the choice is immaterial. However, for most metallic materials, there is an initial transient period of fast kinetics that is best described by $(\Delta m - \Delta m_i)^2 = k_p(t - t_i)$. Pieraggi (Ref 20) has shown that systematic errors in determining k_p arise when there is this initial transient period and the slope of Δm versus $t^{0.5}$ is used instead of the slope of Δm^2 versus t.

Glossary of Terms

A

absorption.
A process in which fluid molecules are taken up by a liquid or solid and distributed throughout the body of that liquid or solid. Compare with adsorption.

accelerated corrosion test.
Method designed to approximate, in a short time, the deteriorating effect under normal long-term service conditions.

acicular ferrite.
A highly substructured nonequiaxed ferrite formed upon continuous cooling by a mixed diffusion and shear mode of transformation that begins at a temperature slightly higher than the transformation temperature range for upper bainite. It is distinguished from bainite in that it has a limited amount of carbon available; thus, there is only a small amount of carbide present.

acid.
A chemical substance that yields hydrogen ions (H^+) when dissolved in water; also a substance that dissociates to produce a proton (H^+) in any medium, that is, a proton donor. Compare with base.

acid embrittlement.
A form of hydrogen embrittlement that may be induced in some metals by acid.

acid rain.
Atmospheric precipitation with a pH below 5.6 to 5.7. Burning of fossil fuels for heat and power is the major factor in the generation of oxides of nitrogen and sulfur, which are converted into nitric and sulfuric acids in atmospheric moisture (fogs and precipitation). See also atmospheric corrosion.

acrylic.
Resin polymerized from acrylic acid, methacrylic acid, esters of these acids, or acrylonitrile.

activation.
The changing of a passive surface of a metal to a chemically active state. Contrast with passivation.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

active.

The negative direction of electrode potential. Also used to describe corrosion and its associated potential range when the electrode potential is more negative than adjacent potentials where the corrosion rate is depressed; that is, the passive region.

active metal.

A metal ready to corrode, or readily corroded.

active potential.

The potential of a corroding material.

activity.

A measure of the chemical potential of a substance, where the chemical potential is not equal to concentration, that allows mathematical relations equivalent to those for ideal systems to be used to correlate changes in experimentally measured quantities with changes in chemical potential.

activity (ion).

The ion concentration corrected for deviations from ideal behavior. Concentration multiplied by activity coefficient.

activity coefficient.

A characteristic of a quantity expressing the deviation of a solution from ideal thermodynamic behavior; often used in connection with electrolytes.

addition agent.

A substance added to a solution for the purpose of altering or controlling a process. Examples include wetting agents in acid pickling, brighteners or antipitting agents in plating solutions, and inhibitors.

adsorption.

The surface retention of solid, liquid, or gas molecules, atoms, or ions by a solid or liquid. Compare with absorption.

aeration.

(1) Exposing to the action of air. (2) Causing air to bubble through. (3) Introducing air into a solution by spraying, stirring, or a similar method. (4) Supplying or infusing with air, as in sand or soil.

aeration cell (oxygen cell).

See differential aeration cell.

age hardening.

Hardening by aging, usually after rapid cooling or cold working.

aging.

A change in the properties of certain metals and alloys that occurs at ambient or moderately elevated temperatures after hot working or a heat treatment (quench aging in ferrous alloys, natural or artificial aging in ferrous and nonferrous alloys) or after a cold- working operation (strain aging). The change in properties is often, but not always, due to a phase change (precipitation), but never involves a change in chemical composition of the metal or alloy. See also age hardening, artificial aging, natural aging, overaging, precipitation hardening, precipitation heat treatment, quench aging, and strain aging.

alclad.

Composite wrought product comprising an aluminum alloy core having on one or both surfaces a metallurgically bonded aluminum or aluminum alloy coating that is anodic to the core and thus electrochemically protects the core against corrosion.

alkali metal.

A metal in group IA of the periodic system—namely, lithium, sodium, potassium, rubidium, cesium, and francium. They form strongly alkaline hydroxides, hence the name.

alkaline.

(1) Having properties of an alkali. (2) Having a pH greater than 7.

alkaline cleaner.

A material blended from alkali hydroxides and such alkaline salts as borates, carbonates, phosphates, or silicates. The cleaning action may be enhanced by the addition of surface-active agents and special solvents.

alkyd.

Resin used in coatings. Reaction products of polyhydric alcohols and polybasic acids.

alkylation.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

(1) A chemical process in which an alkyl radical is introduced into an organic compound by substitution or addition. (2) A refinery process for chemically combining isoparaffin with olefin hydrocarbons.

alligatoring.

(1) Pronounced wide cracking over the entire surface of a coating having the appearance of alligator hide. (2) The longitudinal splitting of flat slabs in plane parallel to the rolled surface. Also called fish-mouthing.

alloy plating.

The codeposition of two or more metallic elements.

alpha ferrite.

See ferrite.

alpha iron.

The body-centered cubic form of pure iron, stable below 910 °C (1670 °F).

alternate-immersion test.

A corrosion test in which the specimens are intermittently exposed to a liquid medium at definite time intervals.

aluminizing.

Forming of an aluminum or aluminum alloy coating on a metal by hot dipping, hot spraying, or diffusion.

amalgam.

An alloy of mercury with one or more other metals.

ammeter.

An instrument for measuring the magnitude of electric current flow.

amorphous solid.

A rigid material whose structure lacks crystalline periodicity; that is, the pattern of its constituent atoms or molecules does not repeat periodically in three dimensions. See also metallic glass.

amphoteric.

A term applied to oxides and hydroxides that can act basic toward strong acids and acidic toward strong alkalis. Substances that can dissociate electrolytically to produce hydrogen or hydroxyl ions according to conditions.

anaerobic.

Free of air or uncombined oxygen.

anchorite.

A zinc-iron phosphate coating for iron and steel.

anion.

A negatively charged ion that migrates through the electrolyte toward the anode under the influence of a potential gradient. See also cation and ion.

annealing.

A generic term denoting a treatment, consisting of heating to and holding at a suitable temperature, followed by cooling at a suitable rate, used primarily to soften metallic materials, but also to simultaneously produce desired changes in other properties or in microstructure. The purpose of such changes may be, but is not confined to, improvement of machinability, facilitation of cold work, improvement of mechanical or electrical properties, and/or increase in stability of dimensions. When the term is used by itself, full annealing is implied. When applied only for the relief of stress, the process is properly called stress relieving or stress-relief annealing.

anode.

The electrode of an electrolyte cell at which oxidation occurs. Electrons flow away from the anode in the external circuit. It is usually at this electrode that corrosion occurs and metal ions enter solution. Contrast with cathode.

anode corrosion.

The dissolution of a metal acting as an anode.

anode corrosion efficiency.

The ratio of the actual corrosion (weight loss) of an anode to the theoretical corrosion (weight loss) calculated by Faraday's law from the quantity of electricity that has been generated by the anode during the corrosion.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

anode effect.
The effect produced by polarization of the anode in electrolysis. It is characterized by a sudden increase in voltage and corresponding decrease in amperage due to the anode becoming virtually separated from the electrolyte by a gas film.

anode efficiency.
The current efficiency at the anode.

anode film.
(1) The solution in immediate contact with the anode, especially if the concentration gradient is steep. (2) The outer layer of the anode itself.

anode polarization.
See polarization.

anodic cleaning.
Electrolytic cleaning in which the work is the anode. Also called reverse- current cleaning.

anodic coating.
A film or scale on a metal surface resulting from an electrolytic treatment at the anode.

anodic inhibitor.
A chemical substance or mixture that prevents or reduces the rate of the anodic or oxidation reaction. See also inhibitor.

anodic polarization.
The change of the electrode potential in the noble (positive) direction due to current flow. See also polarization.

anodic protection.
Imposing an external electrical potential to polarize a metal into the passive region where dissolution rates are low (applicable only to metals that show active- passive behavior). Contrast with cathodic protection.

anodic reaction.
Electrode reaction equivalent to a transfer of positive charge from an electronic to an ionic conductor. An anodic reaction is an oxidation process. A common example in corrosion is: $Me \rightarrow Me^{n+} + ne^{-}$.

anodizing.
Forming an anodic coating or conversion coating on a metal surface by anodic oxidation; frequently applied to aluminum.

anolyte.
The electrolyte adjacent to the anode in an electrolytic cell.

antifouling.
Intended to prevent fouling of underwater structures, such as the bottoms of ships.

antipitting agent.
An addition agent for electroplating solutions to prevent the formation of pits or large pores in the electrodeposit.

aqueous.
Pertaining to water; an aqueous solution is made by using water as a solvent.

artificial aging.
Aging above room temperature. See also aging. Compare with natural aging.

atmospheric corrosion.
The gradual degradation or alteration of a material by contact with substances present in the atmosphere, such as oxygen, moisture, acidic gases, acid precipitation, basic particulated, carbon dioxide, sulfur, and chlorine compounds. sulfur and chlorine compounds.

atomic weight.
A number assigned to each chemical element that specifies the average mass of its atoms. Because an element may consist of two or more isotopes having different masses, the atomic weight is the average of the masses of the naturally occurring isotopes proportional to their occurrence. The mean weight of the atom of an element in relation to $^{12}C = 12.000$.

austenite.
A solid solution of one or more elements in face-centered cubic iron. Unless otherwise designated (such as nickel austenite), the solute is generally assumed to be carbon.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

austenitizing.

Forming austenite by heating a ferrous alloy into the transformation range (partial austenitizing) or above the transformation range (complete austenitizing). When used without qualification, the term implies complete austenitizing.

auxiliary anode.

In electroplating, a supplementary anode positioned so as to raise the current density on a certain area of the cathode and thus obtain better distribution of plating.

auxiliary electrode.

An electrode commonly used in polarization studies to pass current to or from a test electrode. It is usually made from a noncorroding material; often called the counterelectrode.

B

backfill.

Material placed in a drilled hole to fill space around anodes, vent pipe, and buried components of a cathodic protection system.

bainite.

A metastable aggregate of ferrite and cementite resulting from the transformation of austenite at temperatures below the pearlite range but above M_s, the martensite start temperature. Bainite formed in the upper part of the bainite transformation range has a feathery appearance; bainite formed in the lower part of the range has an acicular appearance resembling that of tempered martensite.

banded structure.

A segregated structure consisting of alternating nearly parallel bands of different composition, typically aligned in the direction of primary hot working.

base.

A chemical substance that yields hydroxyl ions (OH^-) when dissolved in water; also, a proton receptor in any medium. Compare with acid.

base metal.

(1) The metal present in the largest proportion in an alloy; for example, brass is a copper-base alloy. (2) An active metal that readily oxidizes, or that dissolves to form ions. (3) The metal to be brazed, cut, soldered, or welded. (4) After welding, that part of the metal that was not melted.

beach marks.

Macroscopic progression marks on a fatigue fracture or stress-corrosion cracking surface that indicate successive positions of the advancing crack front. The classic appearance is of irregular elliptical or semielliptical rings, radiating outward from one or more origins. Beach marks (also known as clamshell marks or arrest marks) are typically found on service fractures where the part is loaded randomly, intermittently, or with periodic variations in mean stress or alternating stress. See also striation.

biaxial stress.

See principal stress (normal).

biological corrosion.

Deterioration of metals as a result of the metabolic activity of microorganisms. See also microbiologically influenced corrosion.

bipolar electrode.

An electrode in an electrolytic cell that is not mechanically connected to the power supply, but is so placed in the electrolyte, between the anode and cathode, that the part nearer the anode becomes cathodic and the part nearer the cathode becomes anodic. Also called intermediate electrode.

bituminous coating.

Coal tar or asphalt-base coating.

black liquor.

The liquid material remaining from pulpwood cooking in the soda or sulfate papermaking process.

black oxide.

A black finish on a metal produced by immersing it in hot oxidizing salts or salt solutions.

blister.

A raised area, often dome shaped, resulting from (1) loss of adhesion between a coating or deposit and the base metal or (2) delamination under the pressure of expanding gas trapped in a metal in a near-subsurface zone. Very small blisters may be called pinhead blisters or pepper blisters.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

blow down.

(1) Injection of air or water under high pressure through a tube to the anode area for the purpose of purging the annular space and possibly correcting high resistance caused by gas blocking. (2) In connection with boilers or cooling towers, the process of discharging a significant portion of the aqueous solution in order to remove accumulated salts, deposits, and other impurities.

blue brittleness.

Brittleness exhibited by some steels after being heated to a temperature within the range of about 200 to 370 °C (400 to 700 °F), particularly if the steel is worked at the elevated temperature.

blushing.

Whitening and loss of gloss of a usually organic coating caused by moisture. Also called blooming.

brackish water.

(1) Water having salinity values ranging from approximately 0.5 to 17 parts per thousand. (2) Water having less salt than seawater, but undrinkable.

breakdown potential (E_b)

The least noble potential where pitting or crevice corrosion, or both, will initiate and propagate. See also critical pitting potential.

brightener.

An agent or combination of agents added to an electroplating bath to produce a smooth, lustrous deposit.

brine.

Typically, water containing a higher concentration of dissolved salt than that of ordinary ocean water.

brittle fracture.

Separation of a solid accompanied by little or no macroscopic plastic deformation. Typically occurs by rapid crack propagation with less expenditure of energy than for ductile fracture.

burning.

(1) Permanently damaging a metal or alloy by heating to cause either incipient melting or intergranular oxidation. See also overheating. (2) In grinding, getting the work hot enough to cause discoloration or to change the microstructure by tempering or hardening.

C

calcareous coating or deposit.

A layer consisting of a mixture of calcium carbonate and magnesium hydroxide deposited on surfaces being cathodically protected because of the increased pH adjacent to the protected surface.

calomel electrode.

An electrode widely used as a reference electrode of known potential in electrometric measurement of acidity and alkalinity, corrosion studies, voltammetry, and measurement of the potentials of other electrodes. See also electrode potential, reference electrode, and saturated calomel electrode.

calorizing.

Imparting resistance to oxidation to an iron or steel surface by heating in aluminum powder at 800 to 1000 °C (1470 to 1830 °F).

carbonitriding.

A case hardening process in which a suitable ferrous material is heated above the lower transformation temperature in a gaseous atmosphere of such composition as to cause simultaneous absorption of carbon and nitrogen by the surface and, by diffusion, create a concentration gradient. The process is completed by cooling at a rate that produces the desired properties in the workpiece.

carburizing.

Absorption and diffusion of carbon into solid ferrous alloys by heating, to a temperature usually above Ac_3, in contact with a suitable carbonaceous material. A form of case hardening that produces a carbon gradient extending inward from the surface, enabling the surface layer to be hardened either by quenching directly from the carburizing temperature or by cooling to room temperature, then reaustenitizing and quenching.

case hardening.

A generic term covering several processes applicable to steel that change the chemical composition of the surface layer by absorption of carbon, nitrogen, or a mixture of the two and, by diffusion, create a concentration gradient. The outer portion, or case, is made substantially harder than the inner portion, or

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

core. The processes commonly used are carburizing and quench hardening; cyaniding; nitriding; and carbonitriding. The use of the applicable specific process name is preferred.

CASS test.

See *copper-accelerated salt-spray test.*

cathode.

The electrode of an electrolytic cell at which reduction occurs. Electrons flow toward the cathode in the external circuit. Typical cathodic processes are cations taking up electrons and being discharged, oxygen being reduced, and the reduction of an element or group of elements from a higher to a lower valence state. Contrast with anode.

cathode efficiency.

Current efficiency at the cathode.

cathode film.

The solution in immediate contact with the cathode during electrolysis.

cathodic cleaning.

Electrolytic cleaning in which the work is the cathode.

cathodic corrosion.

Corrosion resulting from a cathodic condition of a structure, usually caused by the reaction of an amphoteric metal with the alkaline products of electrolysis.

cathodic disbondment.

The destruction of adhesion between a coating and its substrate by the products of a cathodic reaction.

cathodic inhibitor.

A chemical substance or mixture that prevents or reduces the rate of the cathodic or reduction reaction.

cathodic pickling.

Electrolytic pickling in which the work is the cathode. See also pickling.

cathodic polarization.

The change of the electrode potential in the active (negative) direction due to current flow. See also polarization.

cathodic protection.

(1) Reduction of corrosion rate by shifting the potential of the electrode toward a less oxidizing potential with an externally applied voltage. (2) Partial or complete protection of a metal from corrosion by making it a cathode, using either a galvanic cell or an impressed current. Contrast with anodic protection.

cathodic reaction.

Electrode reaction equivalent to a transfer of negative charge from an electronic to an ionic conductor. A cathodic reaction is a reduction process. A common example in corrosion is: $Ox + ne^- \rightarrow Red$.

catholyte.

The electrolyte adjacent to the cathode of an electrolytic cell.

cation.

A positively charged ion that migrates through the electrolyte toward the cathode under the influence of a potential gradient. See also anion and ion.

caustic.

(1) Burning or corrosive. (2) A hydroxide of a light metal, such as sodium hydroxide or potassium hydroxide.

caustic dip.

A strongly alkaline solution into which metal is immersed for etching, for neutralizing acid, or for removing organic materials such as greases or paints.

caustic embrittlement or caustic cracking.

An obsolete historical term denoting a form of stress-corrosion cracking most frequently encountered in carbon steels or Fe-Cr-Ni alloys that are exposed to concentrated hydroxide solutions at temperatures of 200 to 250 °C (400 to 480 °F).

cavitation.

The formation and instantaneous collapse of numerous tiny voids or cavities within a liquid caused by rapid and intense pressure changes. Cavitation produced by ultrasonic radiation is sometimes used to

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

effect violent localized agitation. Cavitation caused by severe turbulent flow often leads to cavitation damage.

cavitation corrosion.

Material deterioration involving both corrosion and cavitation.

cavitation damage.

The degradation of a solid body resulting from its exposure to cavitation. This may include loss of the material, surface deformation, or changes in properties or appearance.

cavitation-erosion.

Progressive loss of the original material from a solid surface due to continuing exposure to cavitation.

cell.

Electrochemical system consisting of an anode and a cathode immersed in an electrolyte. The anode and cathode may be separate metals or dissimilar areas on the same metal. The cell includes the external circuit, which permits the flow of electrons from the anode to the cathode. See also electrochemical cell.

cementite.

A hard, brittle compound of iron and carbon, known chemically as iron carbide and having the approximate chemical formula Fe_3C. Characterized by an orthorhombic crystal structure. When it occurs as a phase in steel, the chemical composition will be altered by the presence of manganese and other carbide-forming elements.

chalking.

The development of loose, removable powder at the surface of an organic coating usually caused by weathering.

checking.

The development of slight breaks in a coating that do not penetrate to the underlying surface.

checks.

Numerous, very fine cracks in a coating or at the surface of a metal part. Checks may appear during processing or during service and are most often associated with thermal treatment or thermal cycling. Also called check marks, checking, or heat checks.

chelate.

(1) A molecular structure in which a heterocyclic ring can be formed by the unshared electrons of neighboring atoms. (2) A coordination compound in which a heterocyclic ring is formed by a metal bound to two atoms of the associated ligand. See also complexation.

chelating agent.

(1) An organic compound in which atoms form more than one coordinate bond with metals in solution. (2) A substance used in metalfinishing to control or eliminate certain metallic ions present in undesirable quantities.

chelation.

A chemical process involving formation of a heterocyclic ring compound that contains at least one metal cation or hydrogen ion in the ring.

chemical conversion coating.

A protective or decorative nonmetallic coating produced in situ by chemical reaction of a metal with a chosen environment. It is often used to prepare the surface prior to the application of an organic coating.

chemical potential.

In a thermodynamic system of several constituents, the rate of change of the Gibbs function of the system with respect to the change in the number of moles of a particular constituent.

chemical vapor deposition (CVD).

A coating process, similar to gas carburizing and carbonitriding, whereby a reactant atmosphere gas is fed into a processing chamber where it decomposes at the surface of the workpiece, liberating one material for either absorption by, or accumulation on, the workpiece. A second material is liberated in gas form and is removed from the processing chamber, along with excess atmosphere gas.

chemisorption.

The binding of an adsorbate to the surface of a solid by forces whose energy levels approximate those of a chemical bond. Contrast with physisorption.

chevron pattern.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

A fractographic pattern of radial marks (shear ledges) that look like nested letters “V”; sometimes called a herringbone pattern. Typically found on brittle fracture surfaces in structural parts whose widths are considerably greater than their thicknesses. The points of the chevrons can be traced back to the fracture origin.

chromadizing.

Improving paint adhesion on aluminum or aluminum alloys, mainly aircraft skins, by treatment with a solution of chromic acid. Also called chromodizing or chromatizing. Not to be confused with chromating or chromizing.

chromate treatment.

A treatment of metal in a solution of a hexavalent chromium compound to produce a conversion coating consisting of trivalent and hexavalent chromium compounds.

chromating.

Performing a chromate treatment.

chrome pickle.

(1) Producing a chromate conversion coating on magnesium for temporary protection or for a paint base. (2) The solution that produces the conversion coating.

chromizing.

A surface treatment at elevated temperature, generally carried out in pack, vapor, or salt bath, in which an alloy is formed by the inward diffusion of chromium into the base metal.

cladding.

(1) A layer of material, usually metallic, that is mechanically or metallurgically bonded to a substrate. Processes include roll cladding, welding, and explosive forming. (2) A relatively thick (>1 mm, or 0.04 in.) layer of material applied for the purpose of improved corrosion resistance or other properties.

clad metal.

A composite metal containing two or more layers that have been bonded together. The bonding may have been accomplished by corolling, coextrusion, welding, diffusion bonding, casting, heavy chemical deposition, or heavy electroplating.

cleavage.

Splitting (fracture) of a crystal on a crystallographic plane of low index.

cleavage fracture.

A fracture, usually of a polycrystalline metal, in which most of the grains have failed by cleavage, resulting in bright reflecting facets. It is associated with low-energy brittle fracture.

cold cracking.

A type of weld cracking that usually occurs below 205 °C (400 °F). Cracking may occur during or after cooling to room temperature, sometimes with a considerable time delay. Three factors combine to produce cold cracks: stress (for example, from thermal expansion and contraction), hydrogen (from hydrogen-containing welding consumables), and a susceptible microstructure (plate martensite is most susceptible to cracking, ferritic and bainitic structures least susceptible). See also hot cracking, lamellar tearing, and *stress- relief cracking.*

cold working.

Deforming metal plastically under conditions of temperature and strain rate that induce strain hardening. Usually, but not necessarily, conducted at room temperature. Contrast with hot working.

combined carbon.

The part of the total carbon in steel or cast iron that is present as other than free carbon.

complexation.

The formation of complex chemical species by the coordination of groups of atoms termed ligands to a central ion, commonly a metal ion. Generally, the ligand coordinates by providing a pair of electrons that forms an ionic or covalent bond to the central ion. See also chelate, coordination compound, and ligand.

compressive.

Pertaining to forces on a body or part of a body that tend to crush, or compress, the body.

compressive strength.

The maximum compressive stress a material is capable of developing. With a brittle material that fails in compression by fracturing, the compressive strength has a definite value. In the case of ductile,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

malleable, or semiviscous materials (which do not fail in compression by a shattering fracture), the value obtained for compressive strength is an arbitrary value dependent on the degree of distortion that is regarded as effective failure of the material.

compressive stress.

A stress that causes an elastic body to deform (shorten) in the direction of the applied load. Contrast with tensile stress.

concentration cell.

An electrochemical cell where the driving force is a difference in concentration of some component in the electrolyte. This difference leads to the formation of discrete cathode and anode sites.

concentration polarization.

That portion of the polarization of an electrode produced by concentration changes resulting from passage of current through the electrolyte.

conductivity.

The ratio of the electric current density to the electric field in a material. Also called electrical conductivity or specific conductance.

contact corrosion.

A term primarily used in Europe to describe galvanic corrosion between dissimilar metals.

contact plating.

A metal plating process wherein the plating current is provided by galvanic action between the work metal and a second metal, without the use of an external source of current.

contact potential.

The potential difference at the junction of two dissimilar substances.

continuity bond.

A metallic connection that provides electrical continuity between metal structures.

conversion coating.

A coating consisting of a compound formed from the surface metal by chemical or electrochemical treatments. Examples include chromate coatings on zinc, cadmium, magnesium, and aluminum, and oxide and phosphate coatings on steel. See also chromate treatment and phosphating.

coordination compound.

A compound with a central atom or ion bound to a group of ions or molecules surrounding it. Also called coordination complex. See also chelate, complexation, and ligand.

copper-accelerated salt-spray (CASS) test.

An accelerated corrosion test for some electrodeposits and for anodic coatings on aluminum.

corrodent.

A substance that will cause corrosion when brought in contact with a material. A corrosive agent.

corrodkote test.

An accelerated corrosion test for electrodeposits.

corrosion.

The chemical or electrochemical reaction between a material and its environment that produces a deterioration of the material and its properties.

corrosion effect.

A change in any part of the corrosion system caused by corrosion.

corrosion embrittlement.

The severe loss of ductility of a metal resulting from corrosive attack, usually intergranular and often not visually apparent.

corrosion-erosion.

See erosion-corrosion.

corrosion fatigue.

The process in which a metal fractures prematurely under conditions of simultaneous corrosion and repeated cyclic loading at lower stress levels or fewer cycles than would be required in the absence of the corrosive environment.

corrosion fatigue strength.

The maximum repeated stress that can be endured by metal without failure under definite conditions of corrosion and fatigue and for a specific number of stress cycles and a specified period of time.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

corrosion inhibitor.
See inhibitor.

corrosionist.
A person working in the field of corrosion; anyone working to prevent corrosion or protect against corrosion.

corrosion potential (E_{corr}).
The potential of a corroding surface in an electrolyte, relative to a reference electrode. Also called rest potential, open-circuit potential, or freely corroding potential.

corrosion product.
Substance formed as a result of corrosion.

corrosion protection.
Modification of a corrosion system so that corrosion damage is mitigated.

corrosion rate.
Corrosion effect on a metal per unit of time. The type of corrosion rate used depends on the technical system and on the type of corrosion effect. Thus, corrosion rate may be expressed as an increase in the depth of corrosion per unit of time (penetration rate, for example, mils/yr) or the mass of metal turned into corrosion products per unit area of surface per unit of time (weight loss, for example, $g/m^2/yr$). The corrosion effect may vary with time and may not be the same at all points of the corroding surface. Therefore, reports of corrosion rates should be accompanied by information on the type, time dependency, and location of the corrosion effect.

corrosion resistance.
Ability of a metal to withstand corrosion in a given corrosion system.

corrosion system.
System consisting of one or more metals and all parts of the environment that influence corrosion.

corrosivity.
Tendency of an environment to cause corrosion in a given corrosion system.

counterelectrode.
See auxiliary electrode.

couple.
See galvanic corrosion.

covering power.
The ability of a solution to give satisfactory plating at very low current densities, a condition that exists in recesses and pits. This term suggests an ability to cover, but not necessarily to build up, a uniform coating, whereas throwing power suggests the ability to obtain a coating of uniform thickness of an irregularly shaped object.

cracking (of coating).
Breaks in a coating that extend through to the substrate or underlying surface.

crazing.
A network of checks or cracks appearing on the surface.

creep.
Time-dependent strain occurring under stress. The creep strain occurring at a diminishing rate is called primary creep; that occurring at a minimum and almost constant rate, secondary creep; and that occurring at an accelerating rate, tertiary creep.

creep-rupture embrittlement.
Embrittlement under creep conditions of, for example, aluminum alloys and steels that results in abnormally low rupture ductility. In aluminum alloys, iron in amounts above the solubility limit is known to cause such embrittlement; in steels, the phenomenon is related to the amount of impurities (for example, phosphorus, sulfur, copper, arsenic, antimony, and tin) present. In either case, failure occurs by intergranular cracking of the embrittled material.

creep-rupture strength.
The stress that will cause fracture in a creep test at a given time in a specified constant environment. Also called stress-rupture strength.

crevice corrosion.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Localized corrosion of a metal surface at, or immediately adjacent to, an area that is shielded from full exposure to the environment because of close proximity between the metal and the surface of another material.

critical anodic current density.

The maximum anodic current density observed during anodic polarization in the active region for a metal or alloy electrode that exhibits active-passive behavior in an environment.

critical flaw size.

The size of a flaw (defect) in a structure that will cause failure at a particular stress level.

critical humidity.

The relative humidity above which the atmospheric corrosion rate of some metals increases sharply.

critical pitting potential (E_{cp}, E_p, E_{pp}).

The least noble potential at which pits nucleate and grow. It is dependent on the test method used. See also breakdown potential.

current (I).

The net transfer of electric charge (coulombs) per unit time. The unit of current, the ampere (A), is a base unit of the SI system. See also current density.

current density (i).

The current flowing to or from a unit area of an electrode surface. Expressed as ampere/meter^2 (A/m^2) in the SI system.

current efficiency.

The ratio of the electrochemical equivalent current density for a specific reaction to the total applied current density.

D

deactivation.

The process of prior removal of the active corrosive constituents, usually oxygen, from a corrosive liquid by controlled corrosion of expendable metal or by other chemical means, thereby making the liquid less corrosive.

dealloying.

The selective corrosion of one or more components of a solid solution alloy. Also called parting or selective leaching. See also dealuminification, decarburization, decobaltification, denickelification, dezincification, and graphitic corrosion.

dealuminification.

Selective leaching of aluminum, as from aluminum bronze. Also known as dealuminization.

decarburization.

Loss of carbon from the surface layer of a carbon-containing alloy due to reaction with one or more chemical substances in a medium that contacts the surface. See also dealloying.

decobaltification.

Corrosion in which cobalt is selectively leached from cobalt-base alloys, such as Stellite, or from cemented carbides. See also dealloying and selective leaching.

decomposition potential (or voltage).

The potential of a metal surface necessary to decompose the electrolyte in an electrochemical cell or component.

deep groundbed.

One or more anodes installed vertically at a nominal depth of 15 m (50 ft) or more below the earth's surface in a drilled hole for the purpose of supplying cathodic protection for an underground or submerged metallic structure. See also groundbed.

delta ferrite.

See ferrite.

dendrite.

A crystal that has a treelike branching pattern, being most evident in cast metals slowly cooled through the solidification range.

denickelification.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Corrosion in which nickel is selectively leached from nickel-containing alloys. Most commonly observed in copper- nickel alloys after extended service in fresh water. See also dealloying and selective leaching.

density (of gases).

The mass of a unit volume of gas at a stated temperature and pressure.

density (of solids and liquids).

The mass of unit volume of a material at a specified temperature.

deoxidizing.

(1) The removal of oxygen from molten metals by use of suitable deoxidizers. (2) Sometimes refers to the removal of undesirable elements other than oxygen by the introduction of elements or compounds that readily react with them. (3) In metalfinishing, the removal of oxide films from metal surfaces by chemical or electrochemical reaction.

depolarization.

A decrease in the polarization of an electrode

depolarizer.

A substance that produces depolarization.

deposit corrosion.

Corrosion occurring under or around a discontinuous deposit on a metallic surface. See also poultice corrosion.

descaling.

Removing the thick layer of oxides formed on some metals at elevated temperatures.

dewetting.

The withdrawal of molten solder or zinc from a surface that was previously wetted. If the solderable (or galvanizing) surface is not well protected during soldering (galvanizing), the intermetallic can oxidize and the dewetting phenomenon takes place.

dezincification.

Corrosion in which zinc is selectively leached from zinc-containing alloys. Most commonly found in copper-zinc alloys containing less than 85% Cu after extended service in water containing dissolved oxygen. See also dealloying and selective leaching.

dichromate treatment.

A chromate conversion coating produced on magnesium alloys in a boiling solution of sodium dichromate.

dielectric shield.

In a cathodic protection system, an electrically nonconductive material, such as a coating, plastic sheet, or pipe, that is placed between an anode and an adjacent cathode to avoid current wastage and to improve current distribution, usually on the cathode.

differential aeration cell.

An electrochemical cell, where the driving force is a difference in the dissolved air (oxygen) concentration in the electrolyte at one electrode compared with that at another electrode of the same material. See also concentration cell.

diffusion.

(1) Spreading of a constituent in a gas, liquid, or solid, tending to make the composition of all parts uniform. (2) The spontaneous movement of atoms or molecules to new sites within a material.

diffusion coating.

Any process whereby a base metal or alloy is either (1) coated with another metal or alloy and heated to a sufficient temperature in a suitable environment or (2) exposed to a gaseous or liquid medium containing the other metal or alloy, thus causing diffusion of the coating or of the other metal or alloy into the base metal with resultant changes in the composition and properties of its surface.

diffusion coefficient.

A factor of proportionality representing the amount of substance diffusing across a unit area through a unit concentration gradient in unit time.

diffusion-limited current density.

The current density, often referred to as limiting current density, that corresponds to the maximum mass transfer rate that a chemical species can sustain because of diffusion limitations.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

dimple rupture.

A fractographic term describing ductile fracture that occurs through the formation and coalescence of microvoids along the fracture path. The fracture surface of such a ductile fracture appears dimpled when observed at high magnification and usually is most clearly resolved when viewed in a scanning electron microscope.

disbondment.

The destruction of adhesion between a coating and the surface coated.

discontinuity.

Any interruption in the normal physical structure or configuration of a part, such as cracks, laps, seams, inclusions, or porosity. A discontinuity may or may not affect the usefulness of the part.

dislocation.

A linear imperfection in a crystalline array of atoms. Two basic types are recognized: (1) an edge dislocation corresponds to the row of mismatched atoms along the edge formed by an extra, partial plane of atoms within the body of a crystal; (2) a screw dislocation corresponds to the axis of a spiral structure in a crystal, characterized by a distortion that joins normally parallel planes together to form a continuous helical ramp (with a pitch of one interplanar distance) winding about the dislocation. Most prevalent is the so- called mixed dislocation, which is any combination of an edge dislocation and a screw dislocation.

double layer.

The interface between an electrode or a suspended particle and an electrolyte created by charge-charge interaction leading to an alignment of oppositely charged ions at the surface of the electrode or particle. The simplest model is represented by a parallel plate condensor.

drainage.

Conduction of electric current from an underground metallic structure by means of a metallic conductor. Forced drainage is that applied to underground metallic structures by means of an applied electromotive force or sacrificial anode. Natural drainage is that from an underground structure to a more negative (more anodic) structure, such as the negative bus of a trolley substation.

dry corrosion.

See gaseous corrosion.

drying oil.

An oil capable of conversion from a liquid to a solid by slow reaction with oxygen in the air.

ductile fracture.

Fracture characterized by tearing of metal accompanied by appreciable gross plastic deformation and expenditure of considerable energy. Contrast with brittle fracture.

ductility.

The ability of a material to deform plastically without fracturing, measured by elongation or reduction of area in a tensile test, by height of cupping in an Erichsen test, or by other means.

dummy cathode.

(1) A cathode, usually corrugated to give variable current densities, that is plated at low current densities to preferentially remove impurities from a plating solution. (2) A substitute cathode that is used during adjustment of operating conditions.

dummying.

Plating with dummy cathodes.

E

885 °F (475 °C) embrittlement.

Embrittlement of stainless steels upon extended exposure to temperatures between 400 and 510 °C (750 and 950 °F). Caused by fine, chromium-rich precipitates that segregate at grain boundaries; time at temperature directly influences the amount of segregation. Grain-boundary segregation of the chromium-rich precipitates increases strength and hardness, decreases ductility and toughness, and changes corrosion resistance. Can be reversed by heating above the precipitation range.

elastic deformation.

A change in dimensions directly proportional to and in phase with an increase or decrease in applied force.

elasticity.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The property of a material by virtue of which deformation caused by stress disappears upon removal of the stress. A perfectly elastic body completely recovers its original shape and dimensions after release of stress.

elastic limit.

The maximum stress that a material is capable of sustaining without any permanent strain (deformation) remaining upon complete release of the stress.

elastomer.

A natural or synthetic polymer, which at room temperature can be stretched repeatedly to at least twice its original length, and which after removal of the tensile load will immediately and forcibly return to approximately its original length.

electrical conductivity.

See conductivity.

electrical isolation.

The condition of being electrically separated from other metallic structures or the environment.

electrical resistivity.

The electrical resistance offered by a material to the flow of current, times the cross-sectional area of current flow and per unit length of current path; the reciprocal of the conductivity. Also called resistivity or specific resistance.

electrochemical admittance.

The inverse of electrochemical impedance.

electrochemical cell.

An electrochemical system consisting of an anode and a cathode in metallic contact and immersed in an electrolyte. The anode and cathode may be different metals or dissimilar areas on the same metal surface. See also cell.

electrochemical corrosion.

Corrosion that is accompanied by a flow of electrons between cathodic and anodic areas on metallic surfaces.

electrochemical equivalent.

The weight of an element or group of elements oxidized or reduced at 100% efficiency by the passage of a unit quantity of electricity. Usually expressed as gram-equivalents per coulomb.

electrochemical impedance.

The frequency-dependent complex-valued proportionality factor ($\Delta E/\Delta I$) between the applied potential or current and the response signal. This factor is the total opposition of an electrochemical system to the passage of charge. The value is inversely related to the corrosion rate under certain circumstances. Typical units are Ω or $\Omega \cdot cm^2$.

electrochemical machining.

Controlled metal removal by anodic dissolution. Direct current passes through a flowing conductive solution that separates the workpiece (anode) from the electrode tool (cathode).

electrochemical noise.

Fluctuations in potential or current, or both, originating from the uncontrolled variations in a corrosion process.

electrochemical potential.

The partial derivative of the total electrochemical free energy of a constituent with respect to the number of moles of this constituent where all factors are kept constant. It is analogous to the chemical potential of a constituent except that it includes the electric as well as chemical contributions to the free energy. The potential of an electrode in an electrolyte relative to a reference electrode.

electrochemical series.

A list of elements arranged according to their standard electrode potentials, with “noble” metals such as gold being positive and “active” metals such as zinc being negative.

electrode.

(1) An electronic conductor used to establish electrical contact with an electrolytic part of a circuit. (2) An electronic conductor in contact with an ionic conductor.

electrode polarization.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Change of electrode potential with respect to a reference value. Often the free corrosion potential is used as the reference value. The change may be caused, for example, by the application of an external electrical current or by the addition of an oxidant or reductant.

electrodeposition.

The deposition of a substance on an electrode by passing electric current through an electrolyte.

electrode potential.

The potential of an electrode in an electrolyte as measured against a reference electrode. The electrode potential does not include any resistance losses in potential in either the solution or external circuit. It represents the reversible work to move a unit charge from the electrode surface through the solution to the reference electrode.

electrode reaction.

Interfacial reaction equivalent to a transfer of charge between electronic and ionic conductors. See also anodic reaction and cathodic reaction.

electrogalvanizing.

The electroplating of zinc upon iron or steel.

electrokinetic potential.

This potential, sometimes called zeta potential, is a potential difference in the solution caused by residual, unbalanced charge distribution in the adjoining solution, producing a double layer. It differs from the electrode potential in that it occurs exclusively in the solution phase; that is, it represents the reversible work necessary to bring unit charge from infinity in the solution up to the interface in question but not through the interface.

electroless plating.

A process in which metal ions in a dilute aqueous solution are plated out on a substrate by means of autocatalytic chemical reduction.

electrolysis.

Production of chemical changes of the electrolyte by the passage of current through an electrochemical cell.

electrolyte.

(1) A chemical substance or mixture, usually liquid, containing ions that migrate in an electric field. (2) A chemical compound or mixture of compounds that when molten or in solution will conduct an electric current.

electrolytic cell.

An assembly, consisting of a vessel, electrodes, and an electrolyte, in which electrolysis can be carried out.

electrolytic cleaning.

A process of removing soil, scale, or corrosion products from a metal surface by subjecting it as an electrode to an electric current in an electrolytic bath.

electrolytic protection.

See cathodic protection.

electromotive force.

Electrical potential difference or voltage. This difference could be the result of two dissimilar electrodes in an electrolyte when electrochemical reactions occur. See also thermal electromotive force.

electromotive force series (emf series).

Same as electrochemical series.

electron flow.

A movement of electrons in an external circuit between an anode and cathode in a corrosion cell; current flow is in the opposite direction to the electron flow.

electroplating.

Electrodepositing a metal or alloy in an adherent form on an object serving as a cathode.

electropolishing.

A technique commonly used to prepare metallographic specimens, in which a high polish is produced by making the specimen the anode in an electrolytic cell, where preferential dissolution at high points smooths the surface.

electrotinning.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Electroplating tin on an object.

Ellingham diagram.

See free-energy diagram.

embrittlement.

The severe loss of ductility or toughness or both, of a material, usually a metal or alloy. Many forms of embrittlement can lead to brittle fracture. Many forms can occur during thermal treatment or elevated-temperature service (thermally induced embrittlement). Some of these forms of embrittlement, which affect steels, include blue brittleness, 885 °F (475 °C) embrittlement, quench-age embrittlement, sigma-phase embrittlement, strain-age embrittlement, temper embrittlement, tempered martensite embrittlement, and thermal embrittlement. In addition, steels and other metals and alloys can be embrittled by environmental conditions (environmentally assisted embrittlement). The forms of environmental embrittlement include acid embrittlement, caustic embrittlement, corrosion embrittlement, creep-rupture embrittlement, hydrogen embrittlement, liquid metal induced embrittlement, neutron embrittlement, solder embrittlement, solid metal induced embrittlement, and stress-corrosion cracking.

endurance limit.

The maximum stress that a material can withstand for an infinitely large number of fatigue cycles. See also fatigue strength.

enthalpy (*H*).

The sum of the internal energy of a system plus the product of the system volume multiplied by the pressure exerted on the system by its surroundings.

entropy (*S*).

The function of the state of a thermodynamic system whose change in any differential reversible process is equal to the heat absorbed by the system from its surroundings divided by the absolute temperature of the system.

environment.

The surroundings or conditions (physical, chemical, mechanical) in which a material exists.

environmental cracking.

Brittle fracture of a normally ductile material in which the corrosive effect of the environment is a causative factor. This general term includes corrosion fatigue, high-temperature hydrogen attack, hydrogen blistering, hydrogen embrittlement, liquid metal induced embrittlement, solid metal induced embrittlement, stress-corrosion cracking, and sulfide stress cracking. The following terms have been used in the past in connection with environment cracking, but are becoming obsolete: caustic embrittlement, delayed fracture, season cracking, static fatigue, stepwise cracking, sulfide corrosion cracking, and sulfide stress-corrosion cracking. See also embrittlement.

environmentally assisted embrittlement.

See embrittlement.

epoxy.

Resin formed by the reaction of bisphenol and epichlorohydrin.

equilibrium (reversible) potential.

The potential of an electrode in an electrolytic solution when the forward rate of a given reaction is exactly equal to the reverse rate. The equilibrium potential can only be defined with respect to a specific electrochemical reaction.

erosion.

Destruction of metals or other materials by the abrasive action of moving fluids, usually accelerated by the presence of solid particles or matter in suspension. When corrosion occurs simultaneously, the term erosion-corrosion is often used.

erosion-corrosion.

A material damage involving corrosion and erosion in the presence of a moving corrosive and erosive fluid, leading to the accelerated loss of material.

eutectic.

(1) An isothermal reversible reaction in which a liquid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as the number of components in

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

the system. (2) An alloy having the composition indicated by the eutectic point on an equilibrium diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectic reaction.

eutectoid.

(1) An isothermal reversible reaction in which a solid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as the number of components in the system. (2) An alloy having the composition indicated by the eutectoid point on an equilibrium diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectoid reaction.

exchange current.

When the electrode reactions reach equilibrium in a solution, the rate of anodic dissolution equals the rate of cathodic reduction. This rate is known as the exchange current.

exchange current density.

The exchange current expressed as a current density.

exfoliation.

Corrosion that proceeds laterally from the sites of initiation along planes parallel to the surface, generally at grain boundaries, forming corrosion products that force metal away from the body of the material, giving rise to a layered appearance.

external circuit.

The wires, connectors, measuring devices, current sources, etc., that are used to bring about or measure the desired electrical conditions within the test cell. It is this portion of the cell through which electrons travel.

F

failure.

A general term used to imply that a part in service (1) has become completely inoperable, (2) is still operable but is incapable of satisfactorily performing its intended function, or (3) has deteriorated seriously, to the point that it has become unreliable or unsafe for continued use.

false Brinelling.

Damage to a solid bearing surface characterized by indentations not caused by plastic deformation due to overload, but thought to be due to other causes such as fretting corrosion. Local spots appear when the protective coating on the metal is broken continually by repeated impacts, usually in the presence of corrosive agents. The term should be avoided when a more precise description is possible.

Faraday's constant (*F*).

The product of Avogadro's number times the charge on the electron. F is approximately 96,485 coulombs/ gram-equivalent.

Faraday's law.

(1) The amount of any substance dissolved or deposited in electrolysis is proportional to the total electric charge passed. (2) The amounts of different substances dissolved or deposited by the passage of the same electric charge are proportional to their equivalent weights.

fatigue.

The phenomenon leading to fracture under repeated or fluctuating stresses having a maximum value less than the tensile strength of the material. Fatigue fractures are progressive and grow under the action of the fluctuating stress.

fatigue crack growth rate (*da*/*dN*).

The rate of crack extension caused by constant-amplitude fatigue loading, expressed in terms of crack extension per cycle of load application.

fatigue life (*N*).

The number of cycles of stress that can be sustained prior to failure under a stated test condition.

fatigue limit.

The maximum stress that presumably leads to fatigue fracture in a specified number of stress cycles. If the stress is not completely reversed, the value of the mean stress, the minimum stress, or the stress ratio should also be stated. Compare with endurance limit.

fatigue strength.

The maximum stress that can be sustained for a specified number of cycles without failure, the stress being completely reversed within each cycle unless otherwise stated.

ferrite.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

(1) A solid solution of one or more elements in body-centered cubic iron. Unless otherwise designated (for instance, as chromium ferrite), the solute is generally assumed to be carbon. On some equilibrium diagrams, there are two ferrite regions separated by an austenite area. The lower area is alpha ferrite; the upper, delta ferrite. If there is no designation, alpha ferrite is assumed. (2) In the field of magnetics, substances having the general formula: $M^{2+}O \cdot M^{3+}2O_3$, the trivalent metal often being iron.

filiform corrosion.

Corrosion that occurs under some coatings in the form of randomly distributed threadlike filaments.

film.

A thin, not necessarily visible, layer of material.

fish eyes.

Areas on a steel fracture surface having a characteristic white, crystalline appearance.

flakes.

Short, discontinuous internal fissures in wrought metals attributed to stresses produced by localized transformation and decreased solubility of hydrogen during cooling after hot working. In a fracture surface, flakes appear as bright silvery areas; on an etched surface, they appear as short, discontinuous cracks. Also called shatter cracks or snowflakes.

flame spraying.

Thermal spraying in which a coating material is fed into an oxyfuel gas flame, where it is melted. Compressed gas may or may not be used to atomize the coating material and propel it onto a substrate.

foreign structure.

Any metallic structure that is not intended as part of a cathodic protection system of interest.

fouling.

An accumulation of deposits. This term includes accumulation and growth of marine organisms on a submerged metal surface and also includes the accumulation of deposits (usually inorganic) on heat exchanger tubing.

fouling organism.

Any aquatic organism with a sessile adult stage that attaches to and fouls underwater structures of ships.

fractography.

Descriptive treatment of fracture, especially in metals, with specific reference to photographs of the fracture surface. Macrofractography involves photographs at low magnification (<25×); microfractography, photographs at high magnification (>25×).

fracture mechanics.

A quantitative analysis for evaluating structural behavior in terms of applied stress, crack length, and specimen or machine component geometry. See also linear elastic fracture mechanics.

fracture toughness.

A generic term for measures or resistance to extension of a crack. The term is sometimes restricted to results of fracture mechanics tests, which are directly applicable in fracture control. However, the term commonly includes results from simple tests of notched or precracked specimens not based on fracture mechanics analysis. Results from tests of the latter type are often useful for fracture control, based on either service experience or empirical correlations with fracture mechanics tests. See also stress-intensity factor.

free carbon.

The part of the total carbon in steel or cast iron that is present in elemental form as graphite or temper carbon. Contrast with combined carbon.

free corrosion potential (E_{corr}).

Corrosion potential in the absence of net electrical current flowing to or from the metal surface. See also corrosion potential.

free energy.

See Gibbs free energy.

free-energy diagram.

A graph of the variation with concentration of the Gibbs free energy at constant pressure and temperature. Called Ellingham diagrams, or Richardson-Jeffes diagrams when nomographs are added.

free ferrite.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Ferrite that is formed directly from the decomposition of hypoeutectoid austenite during cooling, without the simultaneous formation of cementite. Also called proeutectoid ferrite.

free machining.

Pertains to the machining characteristics of an alloy to which one or more ingredients have been introduced to give small broken chips, lower power consumption, better surface finish, and longer tool life; among such additions are sulfur or lead to steel, lead to brass, lead and bismuth to aluminum, and sulfur or selenium to stainless steel.

free radical.

Any molecule or atom that possesses one unpaired electron. In chemical notation, a free radical is symbolized by a single dot (denoting the odd electron) to the right of the chemical symbol.

fretting.

A type of wear that occurs between tight-fitting surfaces subjected to cyclic relative motion of extremely small amplitude. Usually, fretting is accompanied by corrosion, especially of the very fine wear debris.

fretting corrosion.

The accelerated deterioration at the interface between contacting surfaces as the result of corrosion and slight oscillatory movement between the two surfaces.

fugacity.

A function used as an analog of the partial pressure in applying thermodynamics to real systems; at constant temperature it is proportional to the exponential of the ratio of the chemical potential of a constituent of a system divided by the product of the gas constant and the temperature, and it approaches the partial pressure as the total pressure of the gas approaches zero.

furan.

Resin formed from reactions involving furfuryl alcohol alone or in combination with other constituents.

G

galvanic anode.

A metal that, because of its relative position in the galvanic or electrochemical series, provides sacrificial protection to metals that are more noble in the series when coupled in an electrolyte.

galvanic cell.

A cell in which spontaneous chemical change is the source of electrical energy. It usually consists of two dissimilar conductors in contact with each other and with an electrolyte, or of two similar conductors in contact with each other and with dissimilar electrolytes.

galvanic corrosion.

Accelerated corrosion of a metal because of an electrical contact with a more noble metal or nonmetallic conductor in a corrosive electrolyte.

galvanic couple.

A pair of dissimilar conductors, commonly metals, in electrical contact. See also galvanic corrosion.

galvanic couple potential.

See mixed potential.

galvanic current.

The electric current that flows between metals or conductive nonmetals in a galvanic couple.

galvanic series.

A list of metals and alloys arranged according to their relative corrosion potentials in a given environment. Compare with electrochemical series.

galvanize.

To coat a metal surface with zinc using any of various processes.

galvanneal.

To produce a zinc-iron alloy coating on iron or steel by keeping the coating molten after hot dip galvanizing until the zinc alloys completely with the base metal.

galvanodynamic.

Referring to a technique where current, continuously varied at a selected rate, is applied to an electrode in an electrolyte.

galvanometer.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

An instrument for indicating or measuring a small electric current by means of a mechanical motion derived from electromagnetic or electrodynamic forces produced by the current.

galvanostaircase.

Referring to a galvanostep technique for polarizing an electrode in a series of constant current steps where the time duration and current increments or decrements are equal for each step.

galvanostatic.

A technique where an electrode is maintained at a constant current in an electrolyte.

galvanostep.

Refers to a technique in which an electrode is polarized in a series of current increments or decrements.

gamma iron.

The face-centered cubic form of pure iron, stable from 910 to 1400 °C (1670 to 2550 °F).

gaseous corrosion.

Corrosion with gases and vapors as the only corrosive agents and without any aqueous phase on the surface of the metal. Also called dry corrosion.

gel.

(1) A colloidal state comprised of interdispersed solid and liquid, in which the solid particles are themselves interconnected or interlaced in three dimensions. (2) A two-phase colloidal system consisting of a solid and a liquid in more solid form than a sol.

general corrosion.

See uniform corrosion.

Gibbs free energy.

The thermodynamic function $\Delta G = \Delta H - T\Delta S$ where H is enthalpy, T is absolute temperature, and S is entropy. Also called free energy, free enthalpy, or Gibbs function.

glass electrode.

A glass membrane electrode used to measure pH or hydrogen-ion activity.

grain.

An individual crystal in a polycrystalline metal or alloy; it may or may not contain twinned regions and subgrains.

grain boundary.

A narrow zone in a metal corresponding to the transition from one crystallographic orientation to another, thus separating one grain from another; the atoms in each grain are arranged in an orderly pattern.

grain-boundary corrosion.

Same as intergranular corrosion. See also interdendritic corrosion.

graphitic corrosion.

Deterioration of gray cast iron in which the metallic constituents are selectively leached or converted to corrosion products leaving the graphite intact. The term graphitization is commonly used to identify this form of corrosion, but is not recommended because of its use in metallurgy for the decomposition of carbide to graphite. See also dealloying and selective leaching.

graphitization.

A metallurgical term describing the formation of graphite in iron or steel, usually from decomposition of iron carbide at elevated temperatures. Not recommended as a term to describe graphitic corrosion.

green liquor.

The liquor resulting from dissolving molten smelt from the kraft recovery furnace in water. See also kraft process and smelt.

green rot.

A form of high-temperature attack on stainless steels, Ni-Cr alloys, and Ni-Cr-Fe alloys subjected to simultaneous oxidation and carburization. Basically, attack occurs first by precipitation of chromium as chromium carbide, then by oxidation of the carbide particles.

groundbed.

A buried item, such as junk steel or graphite rods, that serves as the anode for the cathodic protection of pipelines or other buried structures. See also deep groundbed.

H

half cell.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The electrode and associated electrode reaction comprising half of an electrochemical cell.

halogen.

Any of the elements of the halogen family, consisting of fluorine, chlorine, bromine, iodine, and astatine.

hard chromium.

Chromium plated for engineering rather than decorative applications.

hardenability.

The relative ability of a ferrous alloy to form martensite when quenched from a temperature above the upper critical temperature. Hardenability is commonly measured as the distance below a quenched surface at which the metal exhibits a specific hardness (50 HRC, for example) or a specific percentage of martensite in the microstructure.

hardfacing.

Depositing filler metal on a surface by welding, spraying, or braze welding to increase resistance to abrasion, erosion, wear, galling, impact, or cavitation damage.

hard water.

Water that contains certain salts, such as those of calcium or magnesium, which form insoluble deposits in boilers and form precipitates with soap.

heat-affected zone (HAZ).

That portion of the base metal that was not melted during brazing, cutting, or welding, but whose microstructure and mechanical properties were altered by the heat.

heat check.

A pattern of parallel surface cracks that are formed by alternate rapid heating and cooling of the extreme surface metal, sometimes found on forging dies and piercing punches. There may be two sets of parallel cracks, one set perpendicular to the other.

hematite.

(1) An iron mineral crystallizing in the rhombohedral system; the most important ore of iron. (2) An iron oxide, Fe_2O_3, corresponding to an iron content of approximately 70%.

high-temperature hydrogen attack.

A loss of strength and ductility of steel by high-temperature reaction of absorbed hydrogen with carbides in the steel resulting in decarburization and internal fissuring.

holidays.

Discontinuities in a coating (such as porosity, cracks, gaps, and similar flaws) that allow areas of base metal to be exposed to any corrosive environment that contacts the coated surface.

hot corrosion.

An accelerated corrosion of metal surfaces that results from the combined effect of oxidation and reactions with sulfur compounds and other contaminants, such as chlorides, to form a molten salt on a metal surface that fluxes, destroys, or disrupts the normal protective oxide. See also gaseous corrosion.

hot cracking.

Caused by the segregation at grain boundaries of low-melting constituents in the weld metal. This can result in grain-boundary tearing under thermal contraction stresses. This can be minimized by the use of low-impurity welding materials and proper joint design. Also called solidification cracking. See also cold cracking, lamellar tearing, and stress-relief cracking.

hot dip coating.

A metallic coating obtained by dipping the base metal into a molten metal.

hot shortness.

A tendency for some alloys to separate along grain boundaries when stressed or deformed at temperatures near the melting point. Caused by a low-melting constituent, often present only in minute amounts, that is segregated at grain boundaries.

hot working.

Deforming metal plastically at such a temperature and strain rate that recrystallization takes place simultaneously with the deformation, thus avoiding any strain hardening. Contrast with cold working.

humidity tests.

A corrosion test involving exposure of specimens at controlled levels of humidity and temperature. Contrast with salt-fog test.

www.iran_mavad.com

مرجع مهندسی مواد و متالورژی

hydrogen-assisted cracking (HAC).
See hydrogen embrittlement.

hydrogen-assisted stress-corrosion cracking (HSCC).
See hydrogen embrittlement.

hydrogen blistering.
The formation of blisters on or below a metal surface from excessive internal hydrogen pressure. Hydrogen may be formed during cleaning, plating, corrosion, and so forth.

hydrogen damage.
A general term for the embrittlement, cracking, blistering, and hydride formation that can occur when hydrogen is present in some metals.

hydrogen embrittlement.
A process resulting in a decrease in the toughness or ductility of a metal due to the presence of atomic hydrogen. Hydrogen embrittlement has been recognized classically as being of two types. The first, known as internal hydrogen embrittlement, occurs when the hydrogen enters molten metal, which becomes supersaturated with hydrogen immediately after solidification. The second type, environmental hydrogen embrittlement, results from hydrogen being absorbed by solid metals. This can occur during elevated-temperature thermal treatments and in service during electroplating, contact with maintenance chemicals, corrosion reactions, cathodic protection, and operating in high- pressure hydrogen. In the absence of residual stress or external loading, environmental hydrogen embrittlement is manifested in various forms, such as blistering, internal cracking, hydride formation, and reduced ductility. With a tensile stress or stress-intensity factor exceeding a specific threshold, the atomic hydrogen interacts with the metal to induce subcritical crack growth leading to fracture. In the absence of a corrosion reaction (polarized cathodically), the usual term used is hydrogen- assisted cracking (HAC) or hydrogen stress cracking (HSC). In the presence of active corrosion, usually at pits or crevices (polarized anodically), the cracking is generally called stress-corrosion cracking (SCC), but should more properly be called hydrogen-assisted stress-corrosion cracking (HSCC). Thus, HSC and electrochemically anodic SCC can operate separately or in combination (HSCC). In some metals, such as high-strength steels, the mechanism is believed to be all, or nearly all, HSC. The participating mechanism of HSC is not always recognized and may be evaluated under the generic heading of SCC.

hydrogen-induced cracking (HIC).
Same as hydrogen embrittlement.

hydrogen overvoltage.
Overvoltage associated with the liberation of hydrogen gas.

hydrogen stress cracking (HSC).
See hydrogen embrittlement.

hydrolysis.
(1) Decomposition or alteration of a chemical substance by water. (2) In aqueous solutions of electrolytes, the reactions of cations with water to produce a weak base or of anions to produce a weak acid.

hydrophilic.
Having an affinity for water. Contrast with hydrophobic.

hydrophobic.
Lacking an affinity for, repelling, or failing to absorb or adsorb water. Contrast with hydrophilic.

hygroscopic.
(1) Possessing a marked ability to accelerate the condensation of water vapor; applied to condensation nuclei composed of salts that yield aqueous solutions of a very low equilibrium vapor pressure compared with that of pure water at the same temperature. (2) Pertaining to a substance whose physical characteristics are appreciably altered by effects of water vapor. (3) Pertaining to water absorbed by dry soil minerals from the atmosphere; the amounts depend on the physicochemical character of the surfaces, and increase with rising relative humidity.

I

immersion plating.
Depositing a metallic coating on a metal immersed in a liquid solution, without the aid of an external electric current. Also called dip plating.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

immunity.
A state of resistance to corrosion or anodic dissolution of a metal caused by thermodynamic stability of the metal.

impingement corrosion.
A form of erosion-corrosion generally associated with the local impingement of a high-velocity, flowing fluid against a solid surface.

impressed current.
Direct current supplied by a device employing a power source external to the electrode system of a cathodic protection installation.

inclusions.
Particles of foreign material in a metallic matrix. The particles are usually compounds (such as oxides, sulfides, or silicates), but may be of any substance that is foreign to (and essentially insoluble in) the matrix.

incubation period.
A period prior to the detection of corrosion while the metal is in contact with a corrodent.

industrial atmosphere.
An atmosphere in an area of heavy industry with soot, fly ash, and sulfur compounds as the principal constituents.

inert anode.
An anode that is insoluble in the electrolyte under the conditions prevailing in the electrochemical cell.

inhibitor.
A chemical substance or combination of substances that, when present in the environment, prevents or reduces corrosion without significant reaction with the components of the environment.

inorganic.
Being or composed of matter other than hydrocarbons and their derivatives, or matter that is not of plant or animal origin. Contrast with organic.

inorganic zinc-rich paint.
Coating containing a zinc powder pigment in an inorganic vehicle.

intensiostatic.
See galvanostatic.

intercrystalline corrosion.
See intergranular corrosion.

intercrystalline cracking.
See intergranular cracking.

interdendritic corrosion.
Corrosive attack that progresses preferentially along interdendritic paths. This type of attack results from local differences in composition, such as coring commonly encountered in alloy castings.

intergranular.
Between crystals or grains. Also called intercrystalline. Contrast with transgranular.

intergranular corrosion.
Corrosion occurring preferentially at grain boundaries, usually with slight or negligible attack on the adjacent grains. Also called intercrystalline corrosion.

intergranular cracking.
Cracking or fracturing that occurs along the boundaries of grains or crystals in a polycrystalline aggregate. Also called intercrystalline cracking. Contrast with transgranular cracking.

intergranular fracture.
Brittle fracture of a metal in which the fracture is along the boundaries of grains or crystals that form the metal. Also called intercrystalline fracture. Contrast with transgranular fracture.

intergranular stress-corrosion cracking (IGSCC).
Stress-corrosion cracking in which the cracking occurs along grain boundaries.

intermediate electrode.
Same as bipolar electrode.

internal oxidation.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The formation of isolated particles of corrosion products beneath the metal surface. This occurs as the result of preferential oxidation of certain alloy constituents by inward diffusion of oxygen, nitrogen, sulfur, and so forth.

intumescence.

The swelling or bubbling of a coating usually because of heating (term currently used in space and fire protection applications).

ion.

An atom, or group of atoms, that has gained or lost one or more outer electrons and thus carries an electric charge. Positive ions, or cations, are deficient in outer electrons. Negative ions, or anions, have an excess of outer electrons.

ion exchange.

The reversible interchange of ions between a liquid and solid, with no substantial structural changes in the solid.

iron rot.

Deterioration of wood in contact with iron-base alloys.

irreversible.

Chemical reactions that proceed in a single direction and are not capable of reversal. See also reversible.

isocorrosion diagram.

A graph or chart that shows constant corrosion behavior with changing solution (environment) composition and temperature.

K

knife-line attack.

Intergranular corrosion of an alloy, usually stabilized stainless steel, along a line adjoining or in contact with a weld after heating into the sensitization temperature range.

kraft process.

A wood-pulping process in which sodium sulfate is used in the caustic soda pulp-digestion liquor. Also called kraft pulping or sulfate pulping.

kurtosis.

The extent to which a frequency distribution is concentrated about the mean or peaked. It is sometimes defined as the ratio of the fourth moment of the distribution to the square of the second moment.

L

lamellar corrosion.

See exfoliation.

lamellar tearing.

Occurs in the base metal adjacent to weldments due to high through- thickness strains introduced by weld metal shrinkage in highly restrained joints. Tearing occurs by decohesion and linking along the working direction of the base metal; cracks usually run roughly parallel to the fusion line and are steplike in appearance. Lamellar tearing can be minimized by designing joints to minimize weld shrinkage stresses and joint restraint. See also cold cracking, hot cracking, and stress-relief cracking.

Langelier saturation index.

An index calculated from total dissolved solids, calcium concentration, total alkalinity, pH, and solution temperature that shows the tendency of a water solution to precipitate or dissolve calcium carbonate.

ledeburite.

The eutectic of the iron-carbon system, the constituents of which are austenite and cementite. The austenite decomposes into ferrite and cementite on cooling below Ar_1, the temperature at which transformation of austenite to ferrite or ferrite plus cementite is completed during cooling.

ligand.

The molecule, ion, or group bound to the central atom in a chelate or a coordination compound.

limiting current density.

The maximum current density that can be used to obtain a desired electrode reaction without undue interference such as from polarization.

linear elastic fracture mechanics.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

A method of fracture analysis that can determine the stress (or load) required to induce fracture instability in a structure containing a cracklike flaw of known size and shape. See also fracture mechanics and stress-intensity factor.

lipophilic.

Having an affinity for oil. See also hydrophilic and hydrophobic.

liquid metal induced embrittlement (LMIE).

Catastrophic brittle failure of a normally ductile metal when in contact with a liquid metal and subsequently stressed in tension.

local action.

Corrosion due to the action of "local cells," that is, galvanic cells resulting from inhomogeneities between adjacent areas on a metal surface exposed to an electrolyte.

local cell.

A galvanic cell resulting from inhomogeneities between areas on a metal surface in an electrolyte. The inhomogeneities may be of physical or chemical nature in either the metal or its environment.

localized corrosion.

Corrosion at discrete sites, for example, crevice corrosion, pitting corrosion, and stress-corrosion cracking.

long-line current.

Current that flows through the earth from an anodic to a cathodic area of a continuous metallic structure. Usually used only where the areas are separated by considerable distance and where the current results from concentration-cell action.

luggin probe.

A small tube or capillary filled with electrolyte, terminating close to the metal surface under study. It is used to provide an ionically conducting path without diffusion between an electrode under study and a reference electrode and to reduce the potential (IR) drop in the potential measurement. Also called a Luggin-Haber capillary.

M

macroscopic.

Visible at magnifications to 25×.

macrostructure.

The structure of metals as revealed by macroscopic examination of the etched surface of a polished specimen.

magnetite.

Naturally occurring magnetic oxide of iron (Fe_3O_4).

martensite.

Generic term for microstructures formed by diffusionless phase transformation in which the parent and product phases have a specific crystallographic relationship. Characterized by an acicular pattern in the microstructure in both ferrous and nonferrous alloys. In alloys where the solute atoms occupy interstitial positions in the martensitic lattice (such as carbon in iron), the structure is hard and highly strained; but where the solute atoms occupy substitutional positions (such as nickel in iron), the martensite is soft and ductile. The amount of high-temperature phase that transforms to martensite on cooling depends to a large extent on the lowest temperature attained, there being a rather distinct beginning temperature (M_s) and a temperature at which the transformation is essentially complete (M_f).

mechanical plating.

Plating wherein fine metal powders are peened onto the work by tumbling or other means.

metal dusting.

Accelerated deterioration of metals in carbonaceous gases at elevated temperatures to form a dustlike corrosion product.

metallic glass.

An alloy having an amorphous or glassy structure. See also amorphous solid.

metallizing.

(1) The application of an electrically conductive metallic layer to the surface of nonconductors. (2) The application of metallic coatings by nonelectrolytic procedures such as spraying of molten metal and deposition from the vapor phase.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

microbial corrosion.
See biological corrosion.
microbiologically influenced corrosion (MIC).
Corrosion inhibited or accelerated by the presence or activity of microorganisms. Preferred term for the effect that microscopic organisms and their by-products have on electrochemical corrosion of metals and alloys. See also biological corrosion.
microscopic.
Visible at magnifications above 25×.
microstructure.
The structure of a prepared surface of a metal as revealed by a microscope at a magnification exceeding 25×.
mill scale.
The heavy oxide layer formed during hot fabrication or heat treatment of metals.
mischmetal.
A natural mixture of rare earth elements (atomic numbers 57–71) in metallic form. It contains about 50% Ce, the remainder being principally lanthanum and neodymium. Mischmetal is used as an alloying additive in ferrous alloy to scavenge sulfur, oxygen, and other impurities and in magnesium alloys to improve high-temperature strength.
mixed potential.
The potential of a material (or materials in a galvanic couple) when two or more electrochemical reactions are occurring. Also called galvanic couple potential.
moiety.
A portion of a molecule, generally complex, having a characteristic chemical property.
molal solution.
Concentration of a solution expressed in moles of solute divided by 1000 g of solvent.
molar solution.
Aqueous solution that contains 1 mole (gram-molecular weight) of solute in 1 L of the solution.
mole.
One mole is the mass numerically equal (in grams) to the molecular mass (weight) of a substance. It is the amount of substance in a system that contains as many elementary units (Avogadro's number, 6.02×10^{23}) as there are atoms of carbon in 0.012 kg of the pure nuclide ^{12}C; the elementary unit must be specified and may be an atom, molecule, ion, electron, photon, or even a specified group of such units.
molecular weight.
The sum of the atomic weights of the atoms in a molecule.
monomer.
A molecule, usually an organic compound, having the ability to join with a number of identical molecules to form a polymer.
N
natural aging.
Spontaneous aging of a supersaturated solid solution at room temperature. See also aging. Compare with artificial aging.
Nernst equation.
An equation that expresses the exact reversible potential of a cell in terms of the activities of products and reactants of the cell reactions.
Nernst layer, Nernst thickness.
The diffusion layer or the hypothetical thickness of this layer as given by the theory of Nernst. It is defined by: $i_d = nFD[(C_0 - C/\delta]$, where i_d is the diffusion-limited current density, D is the diffusion coefficient, C_0 is the concentration at the electrode surface, and δ is the Nernst thickness (0.5 mm in many cases of unstirred aqueous electrolytes).
neutron embrittlement.
Embrittlement resulting from bombardment with neutrons, usually encountered in metals that have been exposed to a neutron flux in the core of a reactor. In steels, neutron embrittlement is evidenced by a rise in the ductile-to-brittle transition temperature.
nitriding.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Introducing nitrogen into the surface layer of a solid ferrous alloy by holding at a suitable temperature (below Ac_1 for ferritic steels) in contact with a nitrogenous material, usually ammonia or molten cyanide of appropriate composition. Quenching is not required to produce a hard case.

nitrocarburizing.

Any of several processes in which both nitrogen and carbon are absorbed into the surface layers of a ferrous material at temperatures below the lower critical temperature and, by diffusion, create a concentration gradient. Performed primarily to provide an antiscuffing surface layer and to improve fatigue resistance. Compare with carbonitriding.

noble.

The positive direction of electrode potential, thus resembling noble metals such as gold and platinum.

noble metal.

(1) A metal whose potential is highly positive relative to the hydrogen electrode. (2) A metal with marked resistance to chemical reaction, particularly to oxidation and to solution by inorganic acids. The term as often used is synonymous with precious metal.

noble potential.

A potential more cathodic (positive) than the standard hydrogen potential.

normalizing.

Heating a ferrous alloy to a suitable temperature above the transformation range and then cooling in air to a temperature substantially below the transformation range.

normal solution.

An aqueous solution containing one gram equivalent of the active reagent in 1 L of the solution.

normal stress.

The stress component perpendicular to a plane on which forces act. Normal stress may be either tensile or compressive.

O

occluded cell.

An electrochemical cell created at a localized site on a metal surface that has been partially obstructed from the bulk environment.

open-circuit potential.

The potential of an electrode measured with respect to a reference electrode or another electrode when no current flows to or from it through an external circuit. See also corrosion potential.

organic.

Being or composed of hydrocarbons or their derivatives, or matter of plant or animal origin. Contrast with inorganic.

organic acid.

A chemical compound with one or more carboxyl radicals (COOH) in its structure; examples are butyric acid, $CH_3(CH_2)_2COOH$; maleic acid, HOOCCH- CHCOOH; and benzoic acid, C_6H_5COOH.

organic zinc-rich paint.

Coating containing zinc powder pigment and an organic resin.

overaging.

Aging under conditions of time and temperature greater than those required to obtain maximum change in a certain property, so that the property is altered in the direction of the initial value.

overheating.

Heating a metal or alloy to such a high temperature that its properties are impaired. When the original properties cannot be restored by further heat treating, by mechanical working, or by a combination of working and heat treating, the overheating is known as burning.

overvoltage.

The difference between the electrode potential when appreciable electrochemical reaction occurs and the reversible electrode potential.

oxidation.

(1) A reaction in which there is an increase in valence resulting from a loss of electrons. Contrast with reduction. (2) A corrosion reaction in which the corroded metal forms an oxide; usually applied to reaction with a gas containing elemental oxygen, such as air.

oxidized surface (on steel).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Surface having a thin, tightly adhering, oxidized skin (from straw to blue in color), extending in from the edge of a coil or sheet.

oxidizing agent.

A compound that causes oxidation, thereby itself being reduced.

oxygen concentration cell.

See differential aeration cell.

ozone.

A powerfully oxidizing allotropic form of the element oxygen. The ozone molecule contains three atoms (O_3). Ozone gas is decidedly blue, both liquid and solid ozone are an opaque blue-black color, similar to ink.

P

partial annealing.

An imprecise term used to denote a treatment given cold-worked material to reduce its strength to a controlled level or to effect stress relief. To be meaningful, the type of material, degree of cold work, and the time-temperature schedule must be stated.

parting.

See dealloying.

parts per billion.

A measure of proportion by weight, equivalent to one unit weight of a material per billion (10^9) unit weights of compound. One part per billion is equivalent to 0.001 μg/g or 1 μg/kg.

parts per million.

A measure of proportion by weight, equivalent to one unit weight of a material per million (10^6) unit weights of compound. One part per million is equivalent to 1 μg/g or 1 mg/kg.

passivation.

(1) A reduction of the anodic reaction rate of an electrode involved in corrosion. (2) The process in metal corrosion by which metals become passive. (3) The changing of a chemically active surface of a metal to a much less reactive state. Contrast with activation.

passivator.

A type of inhibitor that appreciably changes the potential of a metal to a more noble (positive) value.

passive.

(1) A metal corroding under the control of surface reaction product. (2) The state of the metal surface characterized by low corrosion rates in a potential region that is strongly oxidizing for the metal.

passive-active cell.

A corrosion cell in which the anode is a metal in the active state, and the cathode is the same metal in the passive state.

passivity.

A condition in which a piece of metal, because of an impervious covering of oxide or other compound, has a potential much more positive than that of the metal in the active state.

patina.

The coating, usually green, that forms on the surface of metals such as copper and copper alloys exposed to the atmosphere. Also used to describe the appearance of a weathered surface of any metal.

pearlite.

A metastable lamellar aggregate of ferrite and cementite resulting from the transformation of austenite at temperatures above the bainite range.

pH.

The negative logarithm of the hydrogen-ion activity; it denotes the degree of acidity or basicity of a solution. At 25 °C (77 °F), 7.0 is the neutral value. Decreasing values below 7.0 indicate increasing acidity; increasing values above 7.0 indicate increasing basicity.

phosphating.

Forming an adherent phosphate coating on a metal by immersion in a suitable aqueous phosphate solution. Also called phosphatizing. See also conversion coating.

physical vapor deposition (PVD).

A coating process whereby deposition species are transferred and deposited in the form of individual atoms or molecules. The most common PVD methods are sputtering and evaporation. Sputtering

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

involves the transport of a material from a source (target) to a substrate by means of bombardment of the target by gas ions accelerated through a high voltage in a vacuum chamber. In the evaporation process, the transport of a streaming vapor generated by melting and evaporating a coating material source bar by an electron beam in an evacuated chamber, coats the object.

physisorption.

The binding of an adsorbate to the surface of a solid by forces whose energy levels approximate those of condensation. Contrast with chemisorption.

pickle.

A solution or process used to loosen or remove corrosion products such as scale or tarnish.

pickling.

Removing surface oxides from metals by chemical or electrochemical reaction.

pitting.

Localized corrosion of a metal surface, confined to a point or small area, that takes the form of cavities.

pitting factor.

Ratio of the depth of the deepest pit resulting from corrosion divided by the average penetration as calculated from weight loss.

pitting potential.

See critical pitting potential.

plane strain.

The stress condition in linear elastic fracture mechanics in which there is zero strain in a direction normal to both the axis of applied tensile stress and the direction of crack growth (that is, parallel to the crack front); most nearly achieved in loading thick plates along a direction parallel to the plate surface. In plane strain, the plane of fracture instability is normal to the axis of the principal tensile stress.

plane stress.

The stress condition in linear elastic fracture mechanics in which the stress in the thickness direction is zero; most nearly achieved in loading very thin sheet along a direction parallel to the surface of the sheet. In plane stress, the plane of fracture instability is inclined 45° to the axis of the principal tensile stress.

plasma spraying.

A thermal spraying process in which the coating material is melted with heat from a plasma torch that generates a nontransferred arc; molten coating material is propelled against the base metal by the hot, ionized gas issuing from the torch.

plastic deformation.

The permanent (inelastic) distortion of metals under applied stresses that strain the material beyond its elastic limit.

plasticity.

The property that enables a material to undergo permanent deformation without rupture.

polarization.

(1) The change from the open-circuit electrode potential as the result of the passage of current. (2) A change in the potential of the electrodes in an electrolytic cell such that the potential of the anode becomes more noble, and that of the cathode more active, than their respective reversible potentials. Often accompanied by formation of a film on the electrode surface. See also overvoltage.

polarization admittance.

The reciprocal of polarization resistance (di/dE).

polarization curve.

A plot of current or current density versus electrode potential for a specific electrode-electrolyte combination.

polarization resistance.

The slope (dE/di) at the corrosion potential of a potential (E)/current density (i) curve. Also used to describe the method of measuring corrosion rate using this slope.

polyester.

Resin formed by condensation of polybasic and monobasic acids with polyhydric alcohols.

polymer.

A chain of organic molecules produced by the joining of primary units called monomers.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

potential.

Any of various functions from which intensity or velocity at any point in a field may be calculated. The driving influence of an electrochemical reaction. See also active potential, chemical potential, corrosion potential, critical pitting potential, decomposition potential, electrochemical potential, electrode potential, electrokinetic potential, equilibrium (reversible) potential, free corrosion potential, noble potential, open-circuit potential, protective potential, redox potential, and standard electrode potential.

potential-pH diagram.

See Pourbaix (potential-pH) diagram.

potentiodynamic (potentiokinetic).

The technique for varying the potential of an electrode in a continuous manner at a preset rate.

potentiostat.

An instrument for automatically maintaining an electrode in an electrolyte at a constant potential or controlled potentials with respect to a suitable reference electrode.

potentiostatic.

The technique for maintaining a constant electrode potential.

poultice corrosion.

A term used in the automotive industry to describe the corrosion of vehicle body parts due to the collection of road salts and debris on ledges and in pockets that are kept moist by weather and washing. Also called deposit corrosion or attack.

Pourbaix (potential-pH) diagram.

A plot of the redox potential of a corroding system versus the pH of the system, compiled using thermodynamic data and the Nernst equation. The diagram shows regions within which the metal itself or some of its compounds are stable and other regions where the metal corrodes.

powder metallurgy.

The art of producing metal powders and utilizing metal powders for production of massive materials and shaped objects.

precious metal.

One of the relatively scarce and valuable metals: gold, silver, and the platinum-group metals. See also noble metal.

precipitation hardening.

Hardening caused by the precipitation of a constituent from a supersaturated solid solution. See also age hardening and aging.

precipitation heat treatment.

Artificial aging in which a constituent precipitates from a supersaturated solid solution.

precracked specimen.

A specimen that is notched and subjected to alternating stresses until a crack has developed at the root of the notch.

primary current distribution.

The current distribution in an electrolytic cell that is free of polarization.

primary passive potential (passivation potential).

The potential corresponding to the maximum active current density (critical anodic current density) of an electrode that exhibits active-passive corrosion behavior.

primer.

The first coat of paint applied to a surface. Formulated to have good bonding and wetting characteristics; may or may not contain inhibiting pigments.

principal stress (normal).

The maximum or minimum value of the normal stress at a point in a plane considered with respect to all possible orientations of the considered plane. On such principal planes, the shear stress is zero. There are three principal stresses on three mutually perpendicular planes. The state of stress at a point may be (1) uniaxial, a state of stress in which two of the three principal stresses are zero, (2) biaxial, a state of stress in which only one of the three principal stresses is zero, and (3) triaxial, a state of stress in which none of the principal stresses is zero. Multiaxial stress refers to either biaxial or triaxial stress.

protection potential (E_{prot}, E_{pp}).

The least noble potential at which existing pits can either passivate or continue growing.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

protective potential.

The threshold value of the corrosion potential that has to be reached to enter a protective potential range.

protective potential range.

A range of corrosion potential values in which an acceptable corrosion resistance is achieved for a particular purpose.

Q

quench-age embrittlement.

Embrittlement of low-carbon steels resulting from precipitation of solute carbon at existing dislocations and from precipitation hardening of the steel caused by differences in the solid solubility of carbon in ferrite at different temperatures. Usually caused by rapid cooling of the steel from temperatures slightly below Ac_1 (the temperature at which austenite begins to form) and can be minimized by quenching from lower temperatures.

quench aging.

Aging induced by rapid cooling after solution heat treatment.

quench cracking.

Fracture of a metal during quenching from elevated temperature. Most frequently observed in hardened carbon steel, alloy steel, or tool steel parts of high hardness and low toughness. Cracks often emanate from fillets, holes, corners, or other stress raisers and result from high stresses due to the volume changes accompanying transformation to martensite.

quench hardening.

(1) Hardening suitable α-β alloys (most often certain copper or titanium alloys) by solution treating and quenching to develop a martensitelike structure. (2) In ferrous alloys, hardening by austenitizing and then cooling at a rate such that a substantial amount of austenite transforms to martensite.

quenching.

Rapid cooling of metals (often steels) from a suitable elevated temperature. This generally is accomplished by immersion in water, oil, polymer solution, or salt, although forced air is sometimes used.

R

radiation damage.

A general term for the alteration of properties of a material arising from exposure to ionizing radiation (penetrating radiation), such as x-rays, gamma rays, neutrons, heavy-particle radiation, or fission fragments in nuclear fuel material.

rare earth metal.

One of the group of 15 chemically similar metals with atomic numbers 57 through 71, commonly referred to as the lanthanides.

reactive metal.

A metal that readily combines with oxygen at elevated temperatures to form very stable oxides, for example, titanium, zirconium, and beryllium. May also become embrittled by the interstitial absorption of oxygen, hydrogen, and nitrogen.

recrystallization.

(1) Formation of a new, strain- free grain structure from that existing in cold- worked metal, usually accomplished by heating. (2) The change from one crystal structure to another, as occurs on heating or cooling through a critical temperature.

redox potential.

The potential of a reversible oxidation-reduction electrode measured with respect to a reference electrode in a given electrolyte.

reducing agent.

A compound that causes reduction, thereby itself becoming oxidized.

reduction.

A reaction in which there is a decrease in valence resulting from a gain in electrons. Contrast with oxidation.

reference electrode.

A nonpolarizable electrode with a known and highly reproducible potential used for potentiometric and voltammetric analyses, for example, the calomel electrode.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

refractory metal.

A metal having an extremely high melting point, for example, tungsten, molybdenum, tantalum, niobium, chromium, vanadium, and rhenium. In the broad sense, this term refers to metals having melting points above the range for iron, cobalt, and nickel.

relative humidity.

The ratio, expressed as a percentage, of the amount of water vapor present in a given volume of air at a given temperature to the amount required to saturate the air at that temperature.

residual stress.

Stresses that remain within a body as a result of plastic deformation.

resistance.

The opposition that a device or material offers to the flow of direct current, equal to the voltage drop across the element divided by the current through the element. Also called electrical resistance.

rest potential.

See corrosion potential and *open- circuit potential.*

reversible.

A chemical reaction that can proceed in either direction by a change in the system parameters (temperature, pressure, volume, concentration of reactants).

Reynold's number.

In fluid mechanics, a unitless number, N_R that characterizes the flow of liquids. $N_R = \nu \cdot d \cdot \rho/\mu$ where ν is the velocity of the liquid, d is the diameter of the liquid channel, ρ is the density of the liquid, and μ is the viscosity of the liquid. Generally, if N_R is less than 2000, the flow is characterized as laminar, with the molecules of the liquid tending to move in straight lines without turbulence.

riser.

(1) That section of pipeline extending from the ocean floor up the platform. Also, the vertical tube in a steam generator convection bank that circulates water and steam upward. (2) A reservoir of molten metal connected to a casting to provide additional metal to the casting, required as the result of shrinkage before and during solidification.

rust.

A visible corrosion product consisting of oxides and hydrated oxides of iron. Applied only to ferrous alloys. See also white rust.

S

sacrificial protection.

Reduction of corrosion of a metal in an electrolyte by galvanically coupling it to a more active (or anodic) metal; a form of cathodic protection.

salt-fog test.

An accelerated corrosion test in which specimens are exposed to a fine mist of a solution usually containing sodium chloride, but sometimes modified with other chemicals.

salt-spray test.

See salt-fog test.

saponification.

The alkaline hydrolysis of fats whereby a soap is formed; more generally, hydrolysis of an ester by an alkali with the formation of an alcohol and a salt of the acid portion.

saturated calomel electrode.

A reference electrode composed of mercury, mercurous chloride (calomel), and a saturated aqueous chloride solution.

scale.

A solid layer of corrosion products formed on a metal at high temperatures. In some countries the term is also used for deposits from supersaturated water.

scaling.

(1) The formation at high temperatures of thick corrosion product layers on a metal surface. (2) The deposition of water-insoluble constituents on a metal surface.

season cracking.

An obsolete historical term usually applied to stress-corrosion cracking of brass.

selective leaching.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Corrosion in which one element is preferentially removed from an alloy, leaving a residue (often porous) of the elements that are more resistant to the particular environment. Also called dealloying or parting. See also decarburization, decobaltification, denickelification, dezincification, and graphitic corrosion.

sensitization.

In austenitic stainless steels, the precipitation of chromium carbides, usually at grain boundaries, on exposure to temperatures of ~550 to 850 °C (~1000 to 1550 °F), leaving the grain boundaries depleted of chromium and therefore susceptible to preferential attack by a corroding (oxidizing) medium.

sensitizing heat treatment.

A heat treatment, whether accidental, intentional, or incidental (as during welding), that causes precipitation of constituents at grain boundaries, often causing the alloy to become susceptible to intergranular corrosion or intergranular stress-corrosion cracking. See also sensitization.

shear.

That type of force that causes or tends to cause two contiguous parts of the same body to slide relative to each other in a direction parallel to their plane of contact.

shear strength.

The stress required to produce fracture in the plane of cross section, the conditions of loading being such that the directions of force and of resistance are parallel and opposite, although their paths are offset a specified minimum amount. The maximum load divided by the original cross-sectional area of a section separated by shear.

SI.

International system of units, the modern metric system, defined in the document, *Le Système International d'Unités* (universally abbreviated SI).

sigma phase.

A hard, brittle, nonmagnetic intermediate phase with a tetragonal crystal structure, containing 30 atoms per unit cell, space group $P4_2/mnm$, occurring in many binary and ternary alloys of the transition elements. The composition of this phase in the various systems is not the same, and the phase usually exhibits a wide range in homogeneity. Alloying with a third transition element usually enlarges the field of homogeneity and extends it deep into the ternary section.

sigma-phase embrittlement.

Embrittlement of iron-chromium alloys (most notably austenitic stainless steels) caused by precipitation at grain boundaries of the hard, brittle intermetallic sigma phase during long periods of exposure to temperatures between ~560 and 980 °C (~1050 and 1800 °F). Sigma-phase embrittlement results in severe loss in toughness and ductility and can make the embrittled material susceptible to intergranular corrosion. See also sensitization.

slip.

Plastic deformation by the irreversible shear displacement (translation) of one part of a crystal relative to another in a definite crystallographic direction and usually on a specific crystallographic plane. Sometimes called glide.

slow-strain-rate technique.

An experimental technique for evaluating susceptibility to stress-corrosion cracking. It involves pulling the specimen to failure in uniaxial tension at a controlled slow strain rate while the specimen is in the test environment and examining the specimen for evidence of stress-corrosion cracking.

smelt.

Molten slag; in the pulp and paper industry, the cooking chemicals tapped from the recovery boiler as molten material and dissolved in the smelt tank as green liquor.

***S-N* diagram.**

A plot showing the relationship of stress, S, and the number of cycles, N, before fracture in fatigue testing.

soft water.

Water that is free of magnesium or calcium salts.

sol.

A colloidal suspension comprising discrete or separate solid particles suspended in a liquid. Differs from a solution, though one merges into the other. Compare with gel.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

solder embrittlement.
Reduction in mechanical properties of a metal as a result of local penetration of solder along grain boundaries.

sol-gel process.
An important ceramic and glass forming process in which a sol is converted to a gel by particle evaporation of the liquid phase and/or by neutralizing the electric charges on particles that cause them to repel each other. The gel is usually further processed (formed, dried, and fired).

solid metal induced embrittlement (SMIE).
The occurrence of embrittlement in a material below the melting point of the embrittling species. See also liquid metal induced embrittlement (LMIE).

solid solution.
A single, solid, homogeneous crystalline phase containing two or more chemical species.

solute.
The component of either a liquid or solid solution that is present to a lesser or minor extent; the component that is dissolved in the solvent.

solution.
In chemistry, a homogeneous dispersion of two or more kinds of molecular or ionic species. Solution may be composed of any combination of liquids, solids, or gases, but they are always a single phase.

solution heat treatment.
Heating an alloy to a suitable temperature, holding at that temperature long enough to cause one or more constituents to enter into solid solution, and then cooling rapidly enough to hold these constituents in solution.

solution potential.
Electrode potential where half-cell reaction involves only the metal electrode and its ion.

solvent.
The component of either a liquid or solid solution that is present to a greater or major extent; the component that dissolves the solute.

sour gas.
A gaseous environment containing hydrogen sulfide and carbon dioxide in hydrocarbon reservoirs. Prolonged exposure to sour gas can lead to hydrogen damage, sulfide stress cracking, and/or stress-corrosion cracking in ferrous alloys.

sour water.
Waste waters containing fetid materials, usually sulfur compounds.

spalling.
The spontaneous chipping, fragmentation, or separation of a surface or surface coating.

spheroidite.
An aggregate of iron or alloy carbides of essentially spherical shape dispersed throughout a matrix of ferrite.

sputtering.
A coating process whereby thermally emitted electrons collide with inert gas atoms, which accelerate toward and impact a negatively charged electrode that is a target of the coating material. The impacting ions dislodge atoms of the target material, which are in turn projected to and deposited on the substrate to form the coating.

stabilizing treatment.
(1) Before finishing to final dimensions, repeatedly heating a ferrous or nonferrous part to or slightly above its normal operating temperature and then cooling to room temperature to ensure dimensional stability in service. (2) Transforming retained austenite in quenched hardenable steels, usually by cold treatment. (3) Heating a solution- treated stabilized grade of an austenitic stainless steel to 870 to 900 °C (1600 to 1650 °F) to precipitate all carbon as TiC, NbC, or TaC so that sensitization is avoided on subsequent exposure to elevated temperature.

standard electrode potential.
The reversible potential for an electrode process when all products and reactions are at unit activity on a scale in which the potential for the standard hydrogen half-cell is zero.

strain.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The unit of change in the size or shape of a body due to force. Also known as nominal strain.

strain-age embrittlement.

A loss in ductility accompanied by an increase in hardness and strength that occurs when low-carbon steel (especially rimmed or capped steel) is aged following plastic deformation. The degree of embrittlement is a function of aging time and temperature, occurring in a matter of minutes at about 200 °C (400 °F), but requiring a few hours to a year at room temperature.

strain aging.

Aging induced by cold working.

strain hardening.

An increase in hardness and strength caused by plastic deformation at temperatures below the recrystallization range.

strain rate.

The time rate of straining for the usual tensile test. Strain as measured directly on the specimen gage length is used for determining strain rate. Because strain is dimensionless, the units of strain rate are reciprocal time.

stray current.

Current flowing underground or in soils along paths other than the intended circuit.

stray-current corrosion.

Corrosion resulting from direct current flow along paths other than the intended circuit.

stress.

The intensity of the internally distributed forces or components of forces that resist a change in the volume or shape of a material that is or has been subjected to external forces. Stress is expressed in force per unit area and is calculated on the basis of the original dimensions of the cross section of the specimen. Stress can be either direct (tension or compression) or shear. See also residual stress.

stress concentration factor (K_t).

A multiplying factor for applied stress that allows for the presence of a structural discontinuity such as a notch or hole; K_t equals the ratio of the greatest stress in the region of the discontinuity to the nominal stress for the entire section. Also called theoretical stress concentration factor.

stress-corrosion cracking (SCC).

A cracking process that requires the simultaneous action of a corrodent and sustained tensile stress. This excludes corrosion-reduced sections that fail by fast fracture. It also excludes intercrystalline or transcrystalline corrosion, which can disintegrate an alloy without applied or residual stress. Stress-corrosion cracking may occur in combination with hydrogen embrittlement.

stress-intensity factor.

A scaling factor, usually denoted by the K, used in linear elastic fracture mechanics to describe the intensification of applied stress at the tip of a crack of known size and shape. At the onset of rapid crack propagation in any structure containing a crack, the factor is called the critical stress- intensity factor, or the fracture toughness. Various subscripts are used to denote different loading conditions or fracture toughnesses.

***K_c*.**

Plane-stress fracture toughness. The value of stress intensity at which crack propagation becomes rapid in sections thinner than those in which plane-strain conditions prevail.

***K_I*.**

Stress-intensity factor for a loading condition that displaces the crack faces in a direction normal to the crack plane (also known as the opening mode of deformation).

***K_{Ic}*.**

Plane-strain fracture toughness. The minimum value of K_c for any given material and condition, which is attained when rapid crack propagation in the opening mode is governed by plane-strain conditions.

***K_{Id}*.**

Dynamic fracture toughness. The fracture toughness determined under dynamic loading conditions; it is used as an approximation of K_{Ic} for very tough materials.

***K_{ISCC}*.**

Threshold stress-intensity factor for stress-corrosion cracking. The critical plane-strain stress intensity at the onset of stress-corrosion cracking under specified conditions.

www.iran_mavad.com

مرجع مهندسی مواد و متالورژی

K_Q.

Provisional value for plane-strain fracture toughness.

K_{th}.

Threshold stress intensity for stress-corrosion cracking. The critical stress intensity at the onset of stress-corrosion cracking under specified conditions.

ΔK.

The range of the stress-intensity factor during a fatigue cycle, that is, K_{max} - K_{min}.

stress-raisers.

Changes in contour or discontinuities in structure that cause local increases in stress.

stress ratio (*A* or *R*).

The algebraic ratio of two specified stress values in a stress cycle. Two commonly used stress ratios are: (1) the ratio of the alternating stress amplitude to the mean stress, $A = S_a/S_m$; (2) the ratio of the minimum stress to the maximum stress, $R = S_{min}/ S_{max}$.

stress-relief cracking.

Occurs when susceptible alloys are subjected to thermal stress relief after welding to reduce residual stresses and improve toughness. Occurs only in metals that can precipitation harden during such elevated- temperature exposure; it usually occurs at stress raisers, is intergranular in nature, and is generally observed in the coarse-grained region of the weld heat-affected zone. Also called postweld heat treatment cracking. See also cold cracking, hot cracking, and lamellar tearing.

striation.

A fatigue fracture feature, often observed in electron micrographs, that indicates the position of the crack front after each succeeding cycle of stress. The distance between striations indicates the advance of the crack front across that crystal during one stress cycle, and a line normal to the striations indicates the direction of local crack propagation. See also beach marks.

subsurface corrosion.

See internal oxidation.

sulfidation.

The reaction of a metal or alloy with a sulfur-containing species to produce a sulfur compound that forms on or beneath the surface on the metal or alloy.

sulfide stress cracking.

Brittle failure by cracking under the combined action of tensile stress and corrosion in the presence of water and hydrogen sulfide. See also environmental cracking.

surface profile.

Anchor pattern on a surface produced by abrasive blasting or acid treatment.

surfactant.

A surface-active agent; usually an organic compound whose molecules contain a hydrophilic group at one end and a lipophilic group at the other.

T

Tafel line, Tafel slope, Tafel diagram.

When an electrode is polarized, it frequently will yield a current/potential relationship over a region that can be approximated by: $\eta = \pm B \log (i/ i_o)$, where η is the change in open-circuit potential, i is the current density, and B and i_o are constants. The constant B is also known as the Tafel slope. If this behavior is observed, a plot on semilogarithmic coordinates yields a straight line known as the Tafel line, and the overall diagram is termed a Tafel diagram.

tarnish.

Surface discoloration of a metal caused by formation of a thin film of corrosion product.

temper.

(1) In heat treatment, to reheat hardened steel or hardened cast iron to some temperature below the eutectoid temperature for the purpose of decreasing hardness and increasing toughness. The process is also sometimes applied to normalized steel. (2) In tool steels, temper is sometimes inadvisably used to denote carbon content. (3) In nonferrous alloys and in some ferrous alloys (steels that cannot be hardened by heat treatment), the hardness and strength produced by mechanical or thermal treatment, or both, and characterized by a certain structure, mechanical properties, or reduction of area during cold working.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

temper color.

A thin, tightly adhering oxide skin (only a few molecules thick) that forms when steel is tempered at a low temperature, or for a short time, in air or a mildly oxidizing atmosphere. The color, which ranges from straw to blue depending on the thickness of the oxide skin, varies with both tempering time and temperature.

tempered martensite embrittlement.

Embrittlement of ultrahigh-strength steels caused by tempering in the temperature range of 205 to 400 °C (400 to 750 °F); also called 350 °C or 500 °F embrittlement. Tempered martensite embrittlement is thought to result from the combined effects of cementite precipitation on prior-austenite grain boundaries or interlath boundaries and the segregation of impurities at prior-austenite grain boundaries.

temper embrittlement.

Embrittlement of alloy steels caused by holding within or cooling slowly through a temperature range just below the transformation range. Embrittlement is the result of the segregation at grain boundaries of impurities such as arsenic, antimony, phosphorus, and tin; it is usually manifested as an upward shift in ductile-to-brittle transition temperature. Temper embrittlement can be reversed by retempering above the critical temperature range, then cooling rapidly.

tensile strength.

In tensile testing, the ratio of maximum load to original cross-sectional area. Also called ultimate tensile strength.

tensile stress.

A stress that causes two parts of an elastic body, on either side of a typical stress plane, to pull apart. Contrast with compressive stress.

tension.

The force or load that produces elongation.

terne.

An alloy lead containing 3 to 15% Sn, used as a hot dip coating for steel sheet or plate. Terne coatings, which are smooth and dull in appearance, give the steel better corrosion resistance and enhance its ability to be formed, soldered, or painted.

thermal electromotive force.

The electromotive force generated in a circuit containing two dissimilar metals when one junction is at a temperature different from that of the other. See also electromotive force and thermocouple.

thermal embrittlement.

Intergranular fracture of maraging steels with decreased toughness resulting from improper processing after hot working. Occurs upon heating above 1095 °C (2000 °F) and then slow cooling through the temperature range of 815 to 980 °C (1500 to 1800 °F). Has been attributed to precipitation of titanium carbides and titanium carbonitrides at austenite grain boundaries during cooling through the critical temperature range.

thermally induced embrittlement.

See embrittlement.

thermal spraying.

A group of coating or welding processes in which finely divided metallic or nonmetallic materials are deposited in a molten or semimolten condition to form a coating. The coating material may be in the form of powder, ceramic rod, wire, or molten materials. See also flame spraying and plasma spraying.

thermocouple.

A device for measuring temperatures, consisting of lengths of two dissimilar metals or alloys that are electrically joined at one end and connected to a voltage-measuring instrument at the other end. When one junction is hotter than the other, a thermal electromotive force is produced that is roughly proportional to the difference in temperature between the hot and cold junctions.

thermogalvanic corrosion.

Corrosion resulting from an electrochemical cell caused by a thermal gradient.

threshold stress.

Threshold stress for stress-corrosion cracking. The critical gross section stress at the onset of stress-corrosion cracking under specified conditions.

throwing power.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

(1) The relationship between the current density at a point on a surface and its distance from the counterelectrode. The greater the ratio of the surface resistivity shown by the electrode reaction to the volume resistivity of the electrolyte, the better is the throwing power of the process. (2) The ability of a plating solution to produce a uniform metal distribution on an irregularly shaped cathode. Compare with covering power.

tinning.

Coating metal with a very thin layer of molten solder or brazing filler metal.

torsion.

A twisting deformation of a solid body about an axis in which lines that were initially parallel to the axis become helices.

torsional stress.

The shear stress on a transverse cross section resulting from a twisting action.

total carbon.

The sum of the free carbon and combined carbon (including carbon in solution) in a ferrous alloy.

toughness.

The ability of a metal to absorb energy and deform plastically before fracturing.

transcrystalline.

See transgranular.

transcrystalline cracking.

See transgranular cracking.

transference.

The movement of ions through the electrolyte associated with the passage of an electric current. Also called transport or migration.

transgranular.

Through or across crystals or grains. Also called intracrystalline or transcrystalline.

transgranular cracking.

Cracking or fracturing that occurs through or across a crystal or grain. Also called transcrystalline cracking. Contrast with intergranular cracking.

transgranular fracture.

Fracture through or across the crystals or grains of a metal. Also called transcrystalline fracture or intracrystalline fracture. Contrast with intergranular fracture.

transition metal.

A metal in which the available electron energy levels are occupied in such a way that the d-band contains less than its maximum number of ten electrons per atom, for example, iron, cobalt, nickel, and tungsten. The distinctive properties of the transition metals result from the incompletely filled d- levels.

transition temperature.

(1) An arbitrarily defined temperature that lies within the temperature range in which metal fracture characteristics (as usually determined by tests of notched specimens) change rapidly, such as from primarily fibrous (shear) to primarily crystalline (cleavage) fracture. (2) Sometimes used to denote an arbitrarily defined temperature within a range in which the ductility changes rapidly with temperature.

transpassive region.

The region of an anodic polarization curve, noble to and above the passive potential range, in which there is a significant increase in current density (increased metal dissolution) as the potential becomes more positive (noble).

transpassive state.

(1) State of anodically passivated metal characterized by a considerable increase of the corrosion current when the potential is increased. (2) The noble region of potential where an electrode exhibits a current density higher than the passive current density.

triaxial stress.

See principal stress (normal).

tuberculation.

The formation of localized corrosion products scattered over the surface in the form of knoblike mounds called tubercles.

U

مرجع مهندسی مواد و متالورژی

ultimate strength.
The maximum stress (tensile, compressive, or shear) a material can sustain without fracture, determined by dividing maximum load by the original cross-sectional area of the specimen. Also called nominal strength or maximum strength.

ultramicrotome.
An instrument for cutting very thin specimens for study with a microscope.

underfilm corrosion.
Corrosion that occurs under organic films in the form of randomly distributed threadlike filaments or spots. In many cases this is identical to filiform corrosion.

uniaxial stress.
See principal stress (normal).

uniform corrosion.
(1) A type of corrosion attack (deterioration) uniformly distributed over a metal surface. (2) Corrosion that proceeds at approximately the same rate over a metal surface. Also called general corrosion.

V

vacuum deposition.
Condensation of thin metal coatings on the cool surface of work in a vacuum.

valence.
A positive number that characterizes the combining power of an element for other elements, as measured by the number of bonds to other atoms that one atom of the given element forms upon chemical combination; hydrogen is assigned valence 1, and the valence is the number of hydrogen atoms, or their equivalent, with which an atom of the given element combines.

vapor deposition.
See chemical vapor deposition, physical vapor deposition, and sputtering.

vapor plating.
Deposition of a metal or compound on a heated surface by reduction or decomposition of a volatile compound at a temperature below the melting points of the deposit and the base material. The reduction is usually accomplished by a gaseous reducing agent such as hydrogen. The decomposition process may involve thermal dissociation or reaction with the base material. Occasionally used to designate deposition on cold surfaces by vacuum evaporation. See also vacuum deposition.

voids.
A term generally applied to paints to describe holidays, holes, and skips in a film. Also used to describe shrinkage in castings and welds.

W

wash primer.
A thin, inhibiting paint, usually chromate pigmented with a polyvinyl butyrate binder.

weld cracking.
Cracking that occurs in the weld metal. See also cold cracking, hot cracking, lamellar tearing, and stress-relief cracking.

weld decay.
A nonpreferred term for intergranular corrosion, usually of stainless steels or certain nickel-base alloys, that occurs as the result of sensitization in the heat-affected zone during the welding operation.

wetting.
A condition in which the interfacial tension between a liquid and a solid is such that the contact angle is 0 to 90°.

wetting agent.
A substance that reduces the surface tension of a liquid, thereby causing it to spread more readily on a solid surface.

white liquor.
Cooking liquor from the kraft pulping process produced by recausticizing green liquor with lime.

white rust.
Zinc oxide; the powdery corrosion product on zinc or zinc-coated surfaces.

work hardening.
Same as strain hardening.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

working electrode.
The test or specimen electrode in an electrochemical cell.

Y

yield.
Evidence of plastic deformation in structural materials. Also called plastic flow or creep.

yield point.
The first stress in a material, usually less than the maximum attainable stress, at which an increase in strain occurs without an increase in stress. Only certain metals—those that exhibit a localized, heterogeneous type of transition from elastic deformation to plastic deformation—produce a yield point. If there is a decrease in stress after yielding, a distinction may be made between upper and lower yield points. The load at which a sudden drop in the flow curve occurs is called the upper yield point. The constant load shown on the flow curve is the lower yield point.

yield strength.
The stress at which a material exhibits a specified deviation from proportionality of stress and strain. An offset of 0.2% is used for many metals.

yield stress.
The stress level in a material at or above the yield strength, but below the ultimate strength, that is, a stress in the plastic range.

Z

zeta potential.
See electrokinetic potential.
