Table 4 Corrosion rates of selected cast and wrought nickel alloys

Environment	Corrosion rate, mm/year					
	CW-12MW (cast)	**C-276 (wrought)**	**CW-2M (cast)**	**C-4 (wrought)**	**CX-2MW (cast)**	**C-22 (wrought)**
Sulfuric acid/ferric sulfate, boiling (ASTM G 28 Method A)	26.8	6.1	5	4.2	1.8	0.6
Mixed acid-oxidizing salt solution, boiling (ASTM G 28 Method B)	46.5	1.4	54.6	58.3	0.7	0.18
10% HCl, boiling	21.8	7.3	5.9	5.8	17.6	10.2
10% H_2SO_4, boiling	0.4	0.58	0.5	0.79	0.7	0.28
30% H_2SO_4, boiling	2	1.4	1.7	1.8	2.8	1.6
65% HNO_3, boiling	20.5	22.6	11.9	1.35	3	5.5
10% $FeCl_3$, boiling	43.2	0.1	96.6	6.8	4	0.02

Note: The cast alloys were annealed for 20 min at 1230 °C (2250 °F), followed by water quenching. Source: Ref 3

Conclusions

In the materials selection process for corrosion applications, the chemical composition of the alloy is generally the most important factor that an engineer considers. However, examples given in this article demonstrate that the metallurgical condition or microstructure of a particular nickel alloy is also a very important factor. For the same overall chemical composition, the corrosion rate of the same alloy can vary several orders of magnitude, depending on its particular microstructure. The most important metallurgical factors that need to be considered are second-phase precipitation by thermal instability and the presence of CW. The latter is especially important in cases where SCC may be expected.

Effects of Metallurgical Variables on Dealloying Corrosion

Sean G. Corcoran, Virginia Polytechnic Institute and State University

Introduction

DEALLOYING is a corrosion process in which one or more elements are selectively dissolved, leaving behind a porous residue of the remaining element(s). For example, in the silver- gold system, silver can be almost 100% removed in various acid electrolytes, leaving behind porous gold, as shown in Fig. 1. This bicontinuous metal-void structure is highly brittle in nature and has been linked to stress-corrosion cracking in many alloy systems (Ref 1, 2, 3, 4, 5, 6). The seasonal cracking of brass is perhaps the best recognized (Ref 7). Perhaps the first detailed investigation in the scientific literature on alloy corrosion was reported by Calvert and Johnson in 1866 (Ref 8) on copper-zinc alloys. Beyond its direct relevance to stress-corrosion cracking, interest in the dealloying phenomenon extends to the accelerated corrosion in aluminum alloy 2024-T3 (Unified Numbering System, or UNS, A92024) (Ref 9, 10) and the development of high-surface-area electrodes (Ref 11) and catalysts (Ref 12, 13).

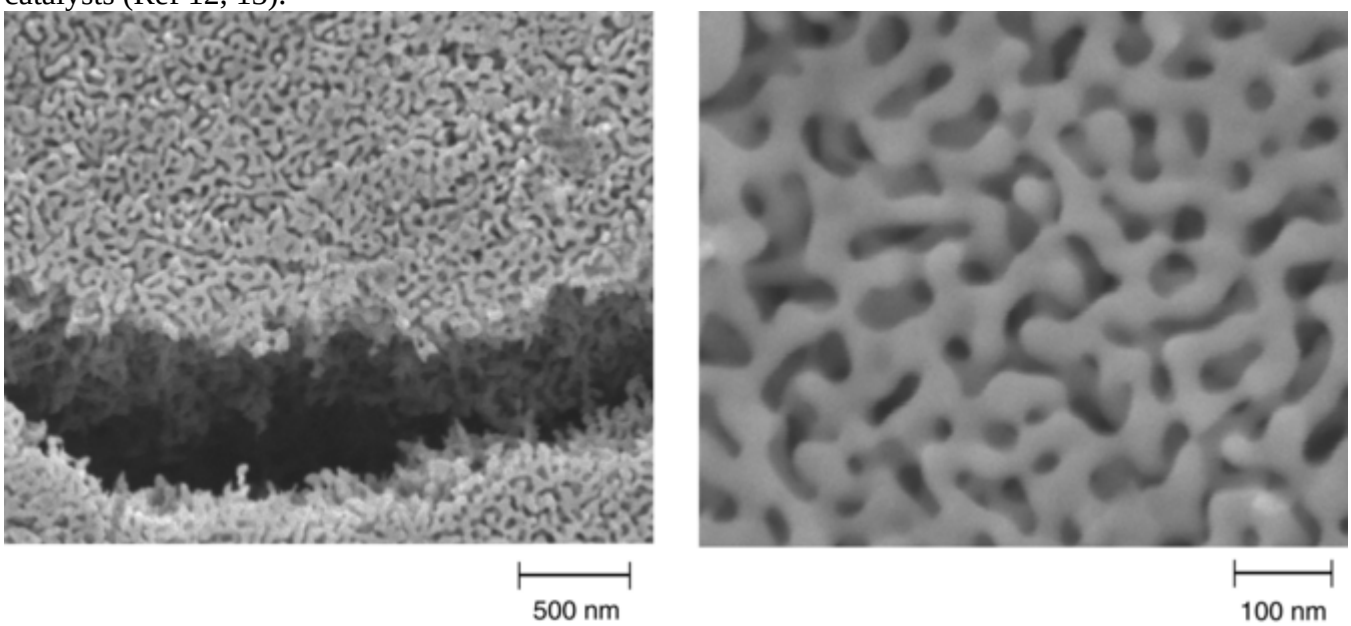

Fig. 1 Two micrographs at different magnifications of porous gold created by dealloying $Ag_{0.75}Au_{0.25}$ in 0.1 *M* $HClO_4$ at 650 mV saturated mercury-mercury sulfate (MSE). The sample was then heat treated at 250 °C (480 °F) for 30 min to coarsen the porosity.

Effects of Metallurgical Variables on Dealloying Corrosion

Sean G. Corcoran, Virginia Polytechnic Institute and State University

---

Dealloying in Aqueous Environments

Dealloying has been observed in a number of systems, and a few of these are discussed in this section. The alloy systems discussed here do not represent an exhaustive list but are chosen for their practical or historical significance. In fact, an exhaustive list could not be developed, because it is now known that dealloying can occur in nearly any system in which a large difference in equilibrium potential exists between the alloying components, and the fraction of the less noble constituent(s) is significantly high.

Dezincification. The dezincification of brass is the most well-studied dealloying system, receiving considerable attention after the observation of seasonal cracking of brass cartridge casings (Ref 7). In the 1920s, significant interest focused on the mechanism of brass dealloying with relevance to brass condensor tubes and other components used in seawater applications (Ref 7, 14, 15). Quoting early researchers (Ref 14), "… brass may

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

behave as an entity when corroded, and that the resulting copper is redeposited … will, in course of time, come to be regarded as correct, in spite of almost universal rejection at the present time." Presently, although the exact role of the redeposition mechanism is not fully understood, it is generally accepted that the dissolution of both copper and zinc and the subsequent redeposition of copper does occur during the corrosion of copper-zinc alloys in many electrolytic solutions. However, it should be pointed out that this condition is not necessary for dezincification to occur, although it surely enhances the rate (see the section "Mechanisms" in this article).

Brasses are immune to dealloying when the zinc compositon is less than approximately 15 at.%. For alloys with greater than 15% Zn, uniform dealloying has been observed in both marine and acidic freshwater environments, while plug (or local) dealloying is typically observed under deposits in seawater environments (Ref 7, 14, 15). Plug dealloying (Fig. 2) occurs spontaneously in 70:30 brass tubes after immersion in seawater at elevated temperatures for a few days and is associated with the formation of a white zinc-salt deposit. Dealloying has also been observed in ammonia-containing solutions (Ref 16, 17, 18), sodium nitrite solutions (Ref 19), and dilute acidic solutions (Ref 14, 15). The dealloying of β-brass (and also two-phase brass alloys) is particularly severe, owing to the high zinc composition of the β phase. In two-phase alloys, the β phase is attacked first, leaving behind a porous copper structure that can act as a cathode, driving the dealloying of the α phase. Dezincification is directly related to the stress-corrosion cracking of copper-zinc alloys (Ref 17).

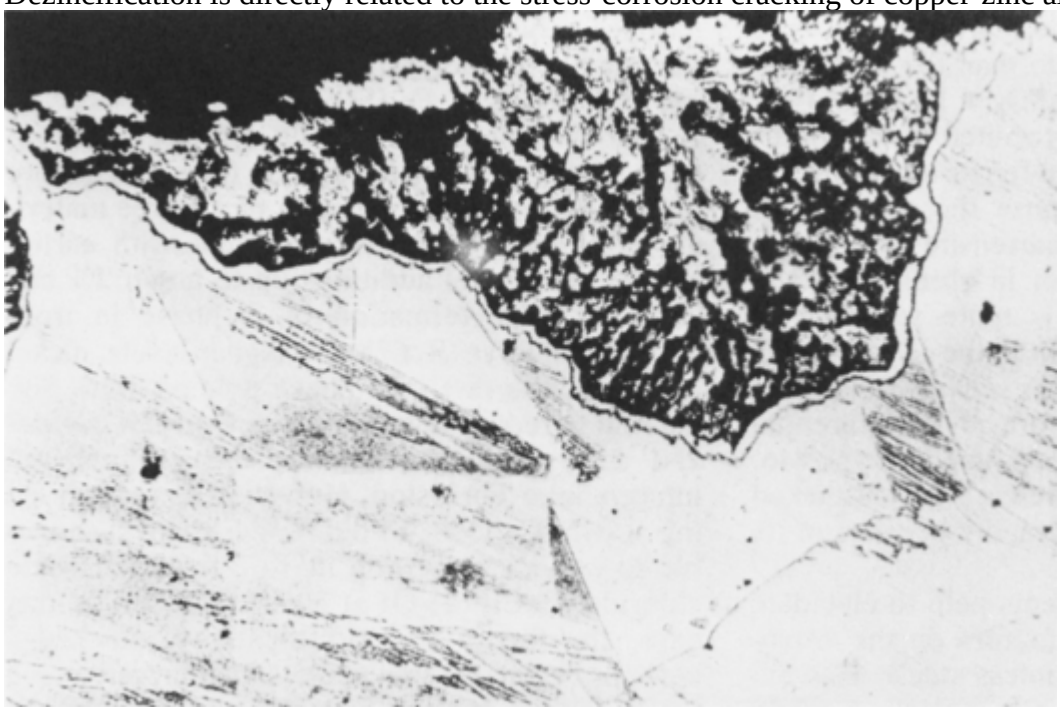

Fig. 2 Plug-type dezincification in an α-brass (70Cu-30Zn) exposed for 79 days in 1 *N* NaCl at room temperature. Note porous structure within the plug. Dark line surrounding the plug is an etching artifact. Total width shown is 0.56 mm (2.2 mils).

Dezincification of α-brass can be minimized by adding 1% Sn, as in admiralty brass (71Cu- 28Zn-1Sn, UNS C44400) and naval brass (60Cu-39Zn-1Sn, UNS C46400), and further inhibited by adding less than 0.1% of arsenic (Ref 20), antimony, or phosphorus. Uniform dealloying in admiralty brass is shown in Fig. 3.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

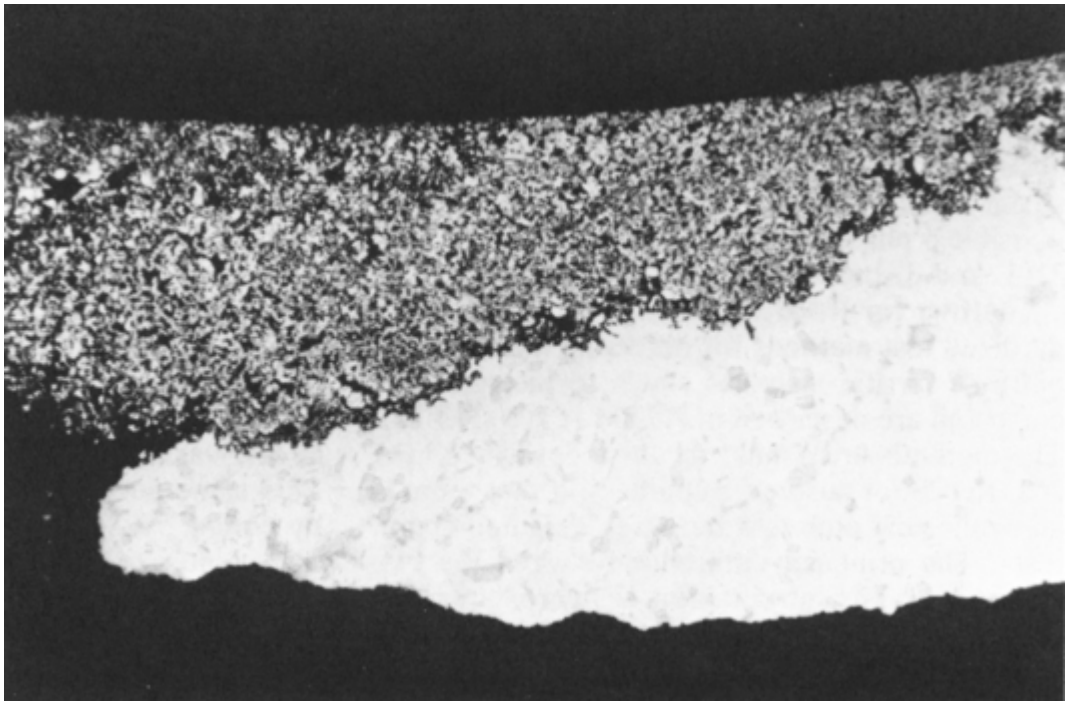

Fig. 3 Uniform-layer dezincification in an admiralty brass 19 mm ($\frac{3}{4}$ in.) diameter heat-exchanger tube. The top layer of the micrograph, which consists of porous, disintegrated particles of copper, was from the inner surface of the tube that was exposed to water at pH 8.0, 31 to 49 °C (87 to 120 °F), and 207 kPa (30 psi). Below the dezincified layer is the bright yellow, intact, admiralty brass outer tube wall. Width of figure is 2.5 mm (0.1 in.). Courtesy of James J. Dillon. Permission granted by Nalco Chemical Company, 1987

Graphitic Corrosion. Another major example of dealloying is graphitic corrosion that occurs in gray cast iron. Gray cast iron has a continuous graphite network in its microstructure that is cathodic to iron and remains behind as a weak, porous network as the iron is selectively removed from the alloy. Graphitic corrosion is observed on buried pipelines after many years of service. Examples of graphitic corrosion are shown in Fig. 4.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

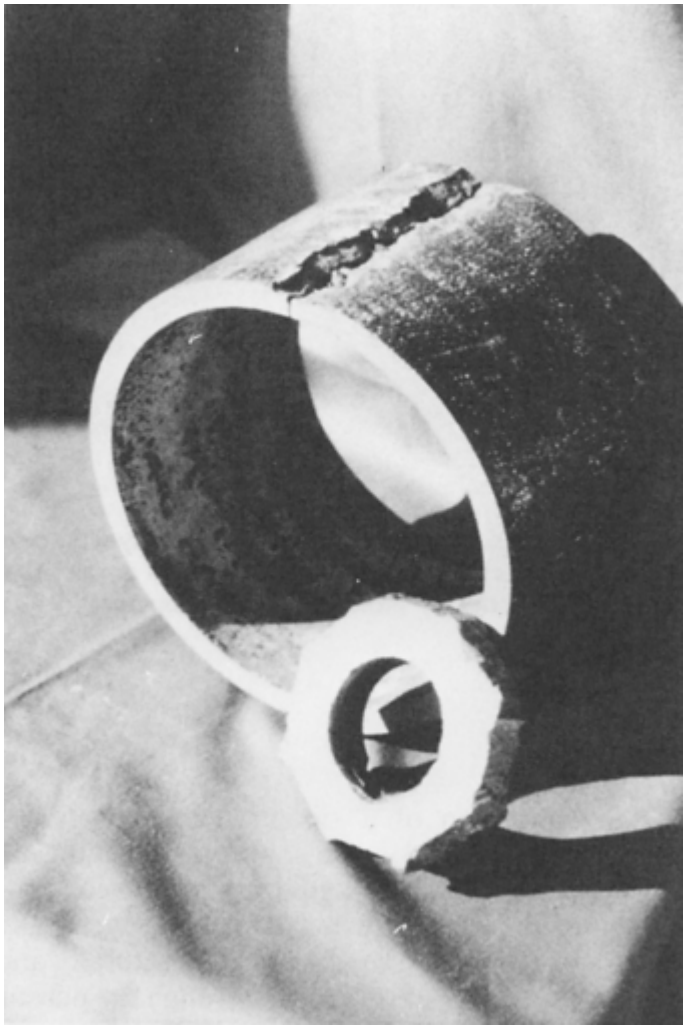

Fig. 4 A 200 mm (8 in.) diameter gray iron pipe that failed because of graphitic corrosion. The pipe was part of a subterranean fire control system. The external surface of the pipe was covered with soil; the internal surface was covered with water. Severe graphitic corrosion occurred along the bottom external surface where the pipe rested on the soil. The small-diameter piece in the foreground is a gray iron pump impeller on which the impeller vanes have disintegrated because of graphitic corrosion. Courtesy of Robert D. Port. Permission granted by Nalco Chemical Company, 1987

Dealuminification. Recent investigations have shown the importance of the dealloying of S-phase (Al_2CuMg) particles on the corrosion of aluminum aircraft alloys, specifically aluminum alloy 2024-T3 (Ref 9, 10). In 2024-T3, the S- phase particles represent approximately 60% of the particle population. These particles are of the order of 1 μm in diameter, with a separation of the order of 5 μm representing an area surface fraction of 3% (Ref 10). The selective removal of aluminum and magnesium from these particles leaves behind a porous copper particle that becomes the preferential site for oxygen reduction (Ref 9). Because the copper particles are small in size and separated over fairly large distances, they behave as microelectrodes and can support much higher oxygen reduction rates than might be expected (as high as 100 $\mu A/cm^2$ or 645 $\mu A/in.^2$) (Ref 9). These sites serve as the cathodes to drive the corrosion of the aluminum matrix, thus releasing more copper on the surface to act as cathodic sites, further driving the corrosion reaction.

Dealloying of Noble Metal Alloys. Dealloying has been observed in the silver-gold (Ref 21, 22, 23, 24, 25, 26, 27, 28), copper-gold (Ref 5, 29, 30, 31, 32, 33), copper-platinum (Ref 11), aluminum-platinum (Ref 34), aluminum-copper (Ref 13, 17, 35, 36, 37, 38), copper- zinc-aluminum (Ref 12, 39), copper-nickel (Ref 40, 41) and manganese-copper systems (Ref 37, 42, 43). The brittle nature of these films is shown in Fig. 5 for porous platinum. The silver-gold and copper-gold systems have been extensively investigated because they represent systems in which the dissolution-redeposition mechanism can be ruled out (see the section “Mechanisms” in this article); that is, gold does not undergo dissolution. The silver-gold system exists as a single-phase random solid solution for all alloy compositions, making this system a particularly well-behaved model system for

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

dealloying studies. Figures 6, 7, and 8 show one particularly comprehensive set of data for the silver-gold system in acid electrolyte. These results are subsequently discussed further.

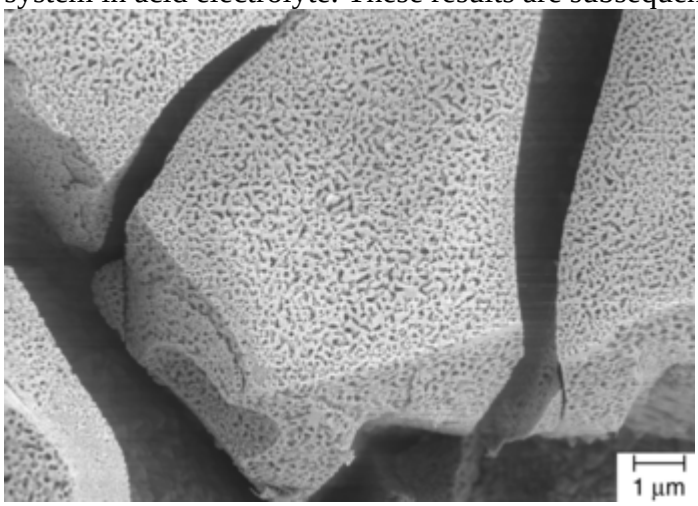

Fig. 5 Dealloyed $Cu_{0.75}Pt_{0.25}$ demonstrating the extreme brittle nature of these materials. The sample was heat treated at 650 °C (1200 °F) for 30 min following the dealloying to coarsen the porosity to a size scale easily observable in the electron microscope. The as-dealloyed structure consists of pores of 3 nm in diameter. Both intergranular and transgranular cracking are common in these materials.

Other Systems. In general, dealloying can occur in any system where a large difference exists in the equilibrium potentials of the alloy elements. A number of systems have been developed or investigated by various researchers in attempts at better understanding the dealloying process or in an interest to develop various porous metal structures. Of some of the more technologically relevant materials, evidence for dealloying has been reported in austenitic stainless steel and iron-nickel alloys in acidified chloride containing solutions (Ref 2, 46), reduction of titanium dioxide in molten calcium chloride (Ref 44, 45), and dissolution of copper-aluminum, and copper-zinc-aluminum alloy pellets in NaOH solutions to produce Raney (Grace Davison) metal particles (Ref 12, 13).

The Critical Potential

Figure 9 shows a schematic illustration of the current-potential behavior of a binary alloy undergoing selective dissolution as well as the corresponding dissolution of the individual pure elements. One way in which to quantify the susceptibility of an alloy to dealloying is to define its critical potential (Ref 4). The critical potential is the value of potential associated with the “knee” in the schematic curve of Fig. 9 (above this, potential dealloying proceeds). It is important to recognize that the critical potential is not very well defined; the dashed lines represent the ambiguity in defining the critical potential for this schematic curve. The position of this knee is dependent on the sweep rate, the prior history of the alloy surface, as well as the alloy composition and electrolyte composition.

Fig. 9 Schematic illustration of the current-potential behavior of elemental metal "A" and "B" dissolution and the corresponding "$A_pB_{(1-p)}$" alloy dissolution. The critical potential corresponds to that associated with the knee in the curve and is not sharply defined. The shape of the knee is affected by sweep rate as well as alloy and electrolyte composition. The dashed vertical lines indicate typical ambiguity in defining a critical potential.

Below the Critical Potential

Small but measurable currents (i) exist below the critical potential. These currents rapidly decay in time (t) following a power-law behavior, $i \alpha t^{-m}$, with m in the range of 0.5 to 1.0.

There have been two main opposing views for dealloying below the critical potential (Ref 47, 48) that represent the two limiting cases of the problem. Researchers (Ref 48) consider the evolution of concentration gradients near the surface as surface atoms of "A" that are dissolved into the electrolyte. Continued dissolution results from the diffusion of "A" atoms from the bulk of the alloy driven by the developing concentration gradient. Equating the kinetics of dissolution and diffusion, the researchers have developed analytical equations for the decaying current with time.

Other researchers (Ref 47) argue that, owing to curvature effects, "A" atoms located in terraces do not dissolve below the critical potential, and hence, dissolution initially begins at step edges and at a few large clusters of "A" atoms existing on the surface. The surface morphology evolves through the coalescence and diffusion of surface vacancies and vacancy clusters. Dissolution is supported when vacancy clusters contact "A" atoms in the surface layer or expose large clusters of "A" atoms in the second-layer terrace. The vacancy clusters grow with continued dissolution of "A" atoms, and, as a result, its overall diffusion decreases with time, resulting in a decreasing current. In situ scanning tunneling microscopy (STM) results support the mechanism of vacancy clustering and preferential attack at step edges (Ref 47, 49).

Morphology Above the Critical Potential

Initially, there was some debate on the morphology of porous dealloyed structures. It is now well recognized that these structures consist of bicontinuous metal-void phases, as shown in Fig. 1. The as-dealloyed structure consists of pore spacing on the nanometer scale and can be as small as 2 to 3 nm in, for example, the platinum-copper system (Ref 11). The structure can be coarsened to larger-length scales at elevated temperatures (Ref 50) (Fig. 5). Small-angle neutron scattering has been recently applied to the characterization of porous metals in both in situ and ex situ experiments (Ref 21, 51, 52). The researchers have found a dependence of the morphology on dealloying potential, electrolyte composition, halide additions to the electrolyte, alloy composition, temperature, and time.

Mechanisms

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

One of the fundamental questions regarding the formation of porous metals is the mechanism by which the selective dissolution process is maintained over more than a few atomic layers, leading to the three-dimensional porous structures shown in Fig. 1. Four possible mechanisms have been offered for the formation of porous metals:

- *The ionization-redeposition mechanism:* Both elements of the binary alloy dissolve, but the more noble element is redeposited (Ref 14).
- *The surface diffusion mechanism:* Only the less noble element is dissolved, and the remaining more noble element aggregates by surface diffusion (Ref 53).
- *The volume diffusion mechanism:* The less noble element is dissolved, but both atoms move in the solid phase by volume diffusion (Ref 54, 55).
- *The percolation model of selective dissolution:* The surface diffusion model was extended to account for preexisting interconnected paths of like elements in the binary alloy (Ref 56) and was later extended to include curvature effects on the dissolution potential (Ref 26, 57).

Before briefly reviewing the proposed mechanisms, it is useful to consider some features experimentally observed for dealloying systems. Any useful model of the dealloying process must be consistent with the experimentally observed behaviors.
There are common features associated with dealloying systems. They include:

- The electrochemical behavior consists of a dealloying critical potential above which the bicontinuous morphologies shown in Fig. 1 develop. The critical potential is dependent on the applied scan rate (Ref 26), electrolyte composition (Ref 26), presence of halides (Ref 58), temperature, and alloy composition (Ref 26, 58).
- The resultant pore morphologies are bicontinuous (Ref 52) and qualitatively resemble that of spinodally decomposed systems (Ref 52). They do not resemble (negative) dendritelike morphologies, as is expected for aggregation processes (Ref 59).
- The average pore spacing increases as the applied potential is decreased (Ref 21, 52), increases as the dealloying rate is decreased (Ref 60), and increases with an increase in the electrolyte temperature (Ref 60).
- Coarsening of the porosity occurs during the dealloying process and is potential dependent (Ref 52, 61). The pore size increases as $t^{0.25}$, consistent with surface diffusion coarsening (Ref 21, 51).
- Intermixing is observed at alloy surfaces during dealloying, which can result in the formation of low-composition phases or compositional variations in the dealloyed structure (Ref 33).
- An alloy compositional threshold exists, below which dealloying will not occur for a given alloy system (Ref 17, 56).
- Complete selectivity is obtained in certain binary alloy systems; for example, in the gold alloy and platinum alloy systems, only the alloying element is dissolved. For less noble systems, such as copper-zinc, both elements may undergo dissolution.

Ionization-Redeposition Mechanism for Selective Dissolution. One of the first mechanisms proposed for the dezincification of brass was the idea that both the copper and zinc dissolve into the electrolyte, followed by the redeposition of copper at more cathodic sites (Ref 14, 15). This model was thought to be necessary to explain how dealloying could be maintained over macroscopic depths. It is now clear that this mechanism is not a necessary condition for dealloying. For example, in the gold-silver system, only selective removal of silver occurs in 0.1 *M* $HClO_4$, because the gold can only undergo oxidation and not dissolution. This is also true for many other gold- and platinum-base systems. However, in the copper-zinc system, the dissolution of copper and zinc may occur simultaneously, although at different rates. In fact, during the production of Raney copper, researchers (Ref 13) measured a change in corrosion potential consistent with the ionization-redeposition mechanism. When present, this mechanism would result in accelerated dealloying kinetics and would be expected to affect overall pore size.
It is worth pointing out that, owing to curvature effects, the dissolution of copper may occur at values less than the standard equilibrium electrode potential. As the zinc is selectively dissolved, high-curvature copper regions develop. Considering the average initial radius of one of these regions to be of the order of 3 nm, then the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

change in the equilibrium potential for copper dissolution can be calculated using a Gibbs- Thomson relationship:

$$\Delta E \cong \frac{\gamma\Omega}{nq}\kappa \qquad \text{(Eq 1)}$$

where γ is the surface free energy, Ω is the atomic volume, n is the number of electrons tranferred per atom, q is the charge of an electron, and $\kappa = r^{-1}$, where r is the radius of the initial curvature of the bicontinuous dealloyed structure. For $\gamma = 1$ J/m^2, $\Omega = 1.6 \times 10^{-29}$ m^3, $n = 1$, $q = 1.602 \times 10^{-19}$ C, and $r = 3 \times 10^{-9}$ m, the equilibrium potential is decreased by 33 mV.

Volume Diffusion Model for Selective Dissolution. In this mechanism (Ref 54, 55, 62, 63), the less noble element in the alloy undergoes selective dissolution. The dissolution process is maintained beyond the first few monolayers by volume diffusion of both elements in the solid phase. The inherent problem with this mechanism is that, at room temperature, the rate of transport of the less noble element to the surface is not sufficient to support the dealloying current densities greater than 10 mA/cm^2 (64 mA/in.^{2}) observed experimentally. A mechanism was proposed (Ref 55) in an attempt to account for the requirement of unusually high volume diffusivities that would be necessary to support experimentally observed dealloying currents. The researchers proposed that as the alloy is subjected to the preferential removal of the less noble element, surface vacancies are created. These vacancies can be filled by either atoms on the surface, annihilation at step edges on the surface, coalescence into larger vacancy clusters, or by atoms from the lattice layer below. Taking the best-case scenario and allowing vacancies to only be filled by the lattice layer below, vacancies and divacancies are injected into the crystal volume below the surface. This would result in a buildup of excess vacancies beyond the thermodynamic equilibrium concentration and enhanced diffusion of the less noble element toward the surface and the more noble element away from the surface, owing to compositional gradients created by the selective removal process. This upper-bound calculation, based on a divacancy diffusion mechanism, can support currents as high as 0.2 mA/cm^2 (1.3 mA/in.^{2}), corresponding to a divacancy diffusivity of 10^{-12} cm^2/s (1.6×10^{-13} in.^{2}/s). Researchers (Ref 64) showed that if the dealloying process is rate limited by the volume diffusion of the less noble element to the electrolyte-alloy interface, a roughening instability is predicted. This instability is proposed as a mechanism to explain the highly porous morphologies observed in dealloyed systems.

There are several problems with the volume diffusion mechanism. In calculating an upper bound on the current, the researchers have had to use some extreme assumptions. For example, the mole fraction of divacancies needed to support a current of 0.2 mA/cm^2 (1.3 mA/in.^{2}) is 10^{-2}. This number is approximately 100 times larger than the equilibrium mole fraction of monovacancies at the melting point of a metal. Even with these assumptions, the value of 0.2 mA/cm^2 (1.3 mA/in.^{2}) is 10 to 100 times lower than experimentally measured dealloying currents. Further, the model does not seem to provide any basis for explaining experimentally observed compositional dependences of the dealloying current, critical compositional thresholds for dealloying, and the prediction of a critical potential.

The model also predicts that a surface-roughening instability occurs with the rate-limiting step in the metal phase. This instability is similar to that for aggregation processes (Ref 59) and should therefore lead to the formation of a (negative) dendritelike morphology rather than a bicontinuous structure, which exists for the dealloying process.

Researchers (Ref 37) pointed out that the dealloying rates for copper alloys (copper-aluminum, copper-manganese, and copper-zinc) do not fall in the same order as diffusion rates for the same alloys. For example, copper-manganese displays, by far, the fastest dealloying kinetics but the smallest diffusivity. Further, if one considers varying compositions in the copper-aluminum system, one finds 4 orders of magnitude increase in dealloying kinetics from the β′ to θ phase, while the diffusion coefficient actually decreases slightly. The volume diffusion mechanism is also fairly insensitive to alloy composition, while it is observed that the dealloying current densities increase several orders of magnitude as the aluminum composition in copper-aluminum is increased from 30 to 60%.

Surface Diffusion/Structural Rearrangement Model for Selective Dissolution. The surface diffusion model, or the surface disordering-reordering model (Ref 53), proposes that the less noble element is preferentially dissolved. The remaining more noble element is now in a highly disordered state and begins to reorder by surface diffusion and nucleation of islands of almost pure noble metal. The coalescence of these islands continues to expose fresh alloy surface where further dissolution will occur, leading to the formation of tunnels

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

and pits. Additions to the electrolyte of ions that would influence the surface diffusivity of the more noble metal would be expected to influence the dealloying process. Such observations have been observed experimentally; examples include potential-dependent coarsening of porosity (Ref 21, 61) and changes in the critical dealloying potential, owing to electrolyte impurity additions (Ref 58). However, the most common argument against this model is that the mechanism for sustained three-dimensional porosity development is not clear, and that the model predicts a nearly pure noble-metal dealloyed structure. The model, as originally formulated, would predict an enriching at the surface of the more noble element, eventually bringing an end to further dealloying. Calculations (Ref 53) do predict the formation of pits in the alloy surface but also predict the continual decreasing of the pit radius with time, at which time the dealloying process ceases. Much of these issues has been resolved by recognizing the importance of percolation concepts and curvature in dealloying and coarsening processes, as discussed in the next section.

A structural rearrangement of the more noble element, leaving behind a porous residue for the electrolyte to penetrate into the alloy, was also proposed (Ref 42) as an alternative to selective dissolution by volume diffusion. These researchers also recognized the fact that continuous paths of the less noble solute exist at high alloy concentrations (Ref 37). The solute can be easily removed along these paths, leaving behind the more noble element in high-energy configurations. The subsequent local rearrangement creates clusters and voids in the form of the bicontinuous morphologies. This structure then allows for penetration of electrolyte into the alloy for further dissolution and alleviates the problem of continuing dissolution through bulk transport of the solute to the surface. These ideas are central to the percolation model for selective dissolution developed later (Ref 56).

Percolation Model for Selective Dissolution. In many alloy systems, a sharp critical composition of the less noble element exists, below which dealloying does not occur (Ref 17). For the zinc-copper and aluminum-copper systems, the threshold is 18 ± 2 at.% for zinc and 14 ± 2 at.% for aluminum, respectively. These critical compositions are not consistent with the conventional views for a surface diffusion mechanism of dealloying. Motivated by the fact that these critical thresholds are very close to the site percolation thresholds for the face-centered cubic (fcc) lattice (19.8%) (Ref 65), researchers (Ref 56) developed the percolation model for selective dissolution. This model extends the surface diffusion model to include the importance of the atomic placement of atoms in the randomly packed alloy. The model predicts that, as a minimum requirement, a continuous connected cluster of the less noble atoms must exist in order for the selective dissolution process to be maintained for more than just the first few monolayers of the alloy. This percolating cluster of atoms provides a continuous active pathway for the corrosion process as well as a pathway for the electrolyte to penetrate the solid. As the dealloying process proceeds along these pathways, a highly porous network is created at the atomic scale. The structure immediately begins to coarsen by curvature-driven surface diffusion, which has been confirmed experimentally using impedance spectroscopy (Ref 61) and small-angle neutron experiments (Ref 21, 51, 52). The coarsening process enlarges the diameter of the pores, allowing further electrolyte into the alloy.

More recently, researchers (Ref 56, 57) analyzed the dealloying process in terms of a kinetic roughening instability occurring between curvature-dependent dissolution (roughening) and surface diffusion (smoothening). This analysis provides a basis for understanding critical compositions that do not fall close to the site percolation threshold. For example, the critical composition of silver in silver-gold is approximately 60%, which is substantially elevated from the fcc site percolation threshold of 19.8%. At the present time, this model is the most promising, in that it can qualitatively (and many times, quantitatively) explain the most common features associated with dealloying, including critical composition thresholds for dealloying, compositional dependence of the critical potential, and the formation of a bicontinuous dealloyed morphology.

Taking into account curvature effects, one can show from classical thermodynamics that the chemical-potential difference between a flat surface and a surface of curvature, κ, is given by $\Delta\mu = \gamma\Omega\kappa$, where γ is the isotropic solid-liquid interfacial free energy per unit area, and Ω is the atomic volume. As mentioned, the local equilibrium metal/metal-ion electrode potential is given by:

$$E = \bar{E} - \frac{\gamma\Omega\kappa}{nq} \qquad \text{(Eq 2)}$$

where $\bar{E}$ is the electrode potential for a flat surface, and κ is given by $\kappa = -\ddot{y}/(1 + \dot{y}^2)^{3/2}$, where the single dot and double dot represent derivatives with respect to position. Equation 2 demonstrates that as an electrode is

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

maintained at its equilibrium potential, $\bar{E}$, regions of positive curvature will tend to dissolve, and regions of negative curvature will tend to be deposition sites (ignoring any overpotentials necessary for these reactions).

The significance of the previous discussion is that, in contrast to elemental metal dissolution, regions of negative curvature must be created during alloy dissolution, owing to the selectivity of attack. This represents an additional energy that must be overcome by the dissolution process. The final form for the critical potential, $\eta(p)_{crit}$, following Ref 26, can then be written as:

$$\eta(p)_{crit} = E(p)_{crit} - \bar{E} = \frac{2}{\xi_a}\delta + \frac{2k_BT}{nq} \times \sinh^{-1}\left(\frac{\pi^2\gamma\Omega}{nq\delta}\frac{D_sN_s}{J_o}\frac{1}{\xi_a^2}\right) \quad \text{(Eq 3)}$$

where $\delta = \beta - (\gamma\Omega/nq)$, β is the variation in equilibrium potential of the alloy surface, owing to compositional fluctuations, γ is the solid-liquid interfacial energy, Ω is the atomic volume, n is the number of electrons transferred per atom, and q is the charge of an electron; ξ_a is the compositional length scale in the material, which can be taken as the percolation cluster size, $\xi_a = [(1 + p)a/1 - p]$, p is the fraction of dissolving species "A," and a is the near-neighbor distance in the lattice; $k_B$is the Boltzmann constant; T is the temperature; D_s is the surface diffusivity; N_s is the atom density on the surface; and J_0 is the exchange current density. For the silver-gold system, these variables take the values: $\Omega = 1.685 \times 10^{-29}$ m^3, $q = 1.602 \times 10^{-19}$ C, $n = 1$, $a = 2.880 \times 10^{-10}$ m, $k_B = 1.381 \times 10^{-23}$ J/K, $N_s = 1.395 \times 10^{19}$/m^2 for the [111] surface, $D_s = 2 \times 10^{-13}$ m^2/s, $T = 298$ K, and $\gamma \cong 1$ J/m^2. This leaves δ and J_0 as fitting parameters.

This equation has been tested for a series of silver-gold alloys as a function of alloy composition and electrolyte composition. The alloy composition varies the value of the percolation cluster size, ξ_a, in Eq 3, while the electrolyte composition varies the exchange current density, J_0. Figures 6 and 7 are the experimentally measured current density versus potential relationships as a function of alloy composition and electrolyte composition, respectively. The researchers defined the critical potential as the value of the potential at which the current reaches a value of 1 mA/cm^2 (6.5 mA/in.^{2}). Figure 8 summarizes this data for the electrolyte of various M $AgClO_4$ + 1 M $HClO_4$ and shows the fit to the data using Eq 3. The equation performs remarkably well at fitting the variation of the critical potential over a wide range of experimental variables for the silver-gold system and at generating reasonable values of the fitting parameters δ and J_o.

Corrosion of Carbon Steel Weldments

Revised by Stuart Bond, TWI Ltd., United Kingdom

Introduction

THE CORROSION BEHAVIOR of carbon steel weldments produced by fusion welding is dependent on a number of factors. Corrosion of carbon steel weldments can be due to metallurgical effects, such as preferential corrosion of the heat-affected zone (HAZ) or weld metal, or it can be associated with geometrical aspects, such as stress concentration at the weld toe, or creation of crevices due to joint design. Additionally, specific environmental conditions can induce localized corrosion such as temperature, conductivity of the corrosive fluid, or thickness of the liquid corrosive film in contact with the metal. In some cases, both metallurgical and geometric factors will influence behavior, such as in stress-corrosion cracking. Preferential weldment corrosion of carbon steels has been investigated since the 1950s, commencing with the problems on ice breakers, but the problem continues today in different applications.

This article describes issues related to corrosion of carbon steel weldments and remedial measures that have proven successful in specific cases; however, it is still difficult to predict whether attack will be concentrated on the HAZ, weld metal, or both areas in susceptible conditions. Care is also required in transfer of remedial measures to different applications because of the complexity of interacting factors that may lead to additional problems. Frequently, therefore, corrective measures need to be applied once a problem is identified, but laboratory testing is recommended for applications where preferential attack is anticipated.

Corrosion of Carbon Steel Weldments

Revised by Stuart Bond, TWI Ltd., United Kingdom

Influence of Weld Microstructure

Consideration must be given to the compositional effects of the base metal and welding consumable and to the different welding processes used. The base metal experiences temperatures ranging from ambient at a distance away from the weld to the melting point at the fusion boundary during welding. Therefore, metallurgical transformations occur across the weld metal and HAZ, and these microstructures can significantly alter the intrinsic corrosion rate of the steel. Fusion welding produces a weld metal that, due to the high cooling rate, is effectively a chill casting containing a high density of lattice defects and segregation of elements (Ref 1). A wide range of microstructures can be developed in a weldment based on cooling rates, and these microstructures are dependent on energy input, preheat, metal thickness (heat sink effects), weld bead size, and reheating effects due to multipass welding. As a result of their different peak temperatures, chemical compositions, and weld inclusions (oxides and sulfides), weld metal microstructures are usually significantly different from those of the HAZ and base metal. Similarly, corrosion behavior can also vary, but in cases where corrosion mitigation measures are correctly applied, for example, coating or cathodic protection or inhibition, these will normally be adequate to prevent preferential corrosion of carbon steel weldments.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Another important factor to note is that for a given composition, hardness levels will be lowest for high heat inputs, such as those produced by submerged arc weldments, and will be highest for low-energy weldments (with faster cooling rates) made by, for example, the shielded metal arc, gas tungsten arc, and metal inert-gas processes. Note that in comparing the heat input, it is necessary to account for the arc efficiency to compare processes. Depending on the welding conditions, weld metal microstructures generally tend to be fine grained with basic flux and somewhat coarser with acid or rutile (TiO_2) flux compositions.

Residual Stress

During welding, the base metal, HAZ, and underlying weld passes experience stresses due to thermal expansion and contraction. On solidification, high levels of residual stress, often close to the material yield stress, remain as a result of weld shrinkage. Stress-concentration effects as a result of geometrical discontinuities, such as weld reinforcement (excess weld metal) and lack of full weld penetration (dangerous because of the likelihood of crevice corrosion and the possibility of fatigue cracking), are also important because of the possibility of stress-corrosion cracking (SCC) in some environments.

Geometrical Factors

It should be recognized that excess root penetration can interrupt fluid flow close to the wall of a pipe in high-flow-rate operation, leading to impingement corrosion downstream of the weld. Alternatively, in low-velocity oil and gas systems where the water content is entrained in the bulk fluid, such excess penetration can cause flow disruption and water dropout, allowing pooling of water downstream of the weld, which can lead to increased corrosion of the weldment or adjacent base metal (Ref 2).

Preferential Heat Affected Zone Corrosion

A wide range of HAZ microstructures can be produced because, close to the fusion boundary, the HAZ transformation to austenite on heating will be followed on cooling by transformation to give either a ferrite-carbide microstructure or martensite, depending on material composition, peak temperature, and cooling rate. Farther from the weld, the material will be exposed to a lower peak temperature, so only partial reaustenization occurs, and those areas heated below the ferrite- to-austenite transformation temperature (Ac_1) will not be significantly affected, other than by some carbide coarsening and tempering. Despite these variations, in the majority of applications, there is little influence on the corrosion performance, and preferential HAZ corrosion is relatively rare. Where preferential HAZ attack has been reported, it is more common in carbon and carbon-manganese steels than in higher-alloy grades (Ref 1).

An example of preferential corrosion in the HAZ of a carbon steel weldment is shown in Fig. 1. This phenomenon has been observed in a wide range of aqueous environments, the common link being that the environments are fairly high in conductivity, while attack has usually, but not invariably, occurred at pH values below approximately 7 to 8.

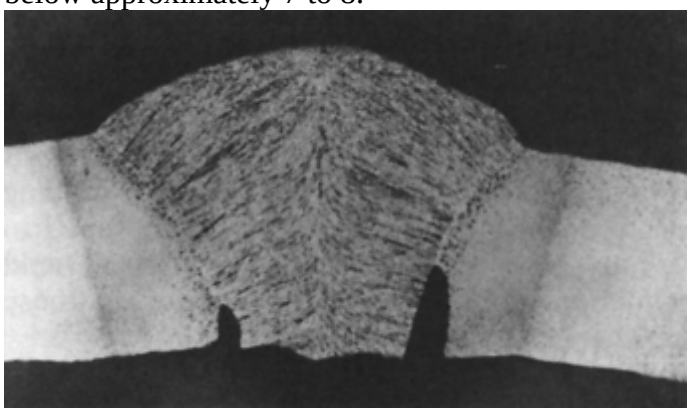

Fig. 1 Preferential corrosion in the heat affected zone of a carbon steel weldment after service in an aqueous environment. 5×. Source: Ref 3

Preferential HAZ corrosion in seawater was reported in the 1960s and attributed to the presence of low-temperature transformation products such as martensite, lower bainite, or retained austenite (Ref 4). Therefore, steel compositions favoring increased hardenability (e.g., increase in manganese content) may lead to increased localized corrosion, but microalloyed steels are not susceptible. *Tramline corrosion* is a term applied to preferential HAZ corrosion concentrated at the fusion boundaries and has been observed in acidic aqueous environments such as acid mine waters.

There is clearly a microstructural dependence, and studies on HAZs show corrosion to be appreciably more severe when the material composition and welding parameters are such that hardened structures are formed. It has been known for many years that hardened steel may corrode more rapidly in acid conditions than fully tempered material, apparently because local microcathodes on the hardened surface stimulate the cathodic hydrogen evolution reaction. The rate of corrosion is usually governed by the cathodic (reduction) rate, when other limiting factors are not present, and therefore, it is a factor in acidic environments but less so in neutral or alkaline conditions. On this basis, it is proposed that water treatments ensuring alkaline conditions should be less likely to induce HAZ corrosion, but even at a pH near 8, hydrogen ion (H^+) reduction can account for approximately 20% of the total corrosion current; pH values substantially above this level would be needed to suppress the effect completely. Furthermore, if such treatments may be useful to control preferential HAZ

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

corrosion when it has not been anticipated, it is considered to be more reliable to avoid the problem through design. Avoidance through selection of appropriate material or welding procedure, for example, to minimize hardness, is the preferred remedial approach, because postweld heat treatment (PWHT) may necessitate temperatures high enough for normalizing to gain full benefit, which is usually impractical (Ref 1).

In some oil and gas production environments, preferential weldment corrosion may lead to enhanced HAZ attack or weld metal corrosion. In the late 1980s, studies of the problems associated with preferential weldment corrosion in sweet oil and gas production systems were undertaken (Ref 5). In some cases, the HAZ was attacked, while in other cases, the weld metal was preferentially corroded. Where enhanced HAZ corrosion was observed, the composition was more influential than the microstructure; however, hardened transformed microstructures suffered increased corrosion. The postweld heat treatment at 590 °C (1100 °F) for stress relief was beneficial in reducing HAZ attack (Ref 2), despite the previous comments.

HAZ/Fusion Line Corrosion of Welded Line Pipe. There is a particular case of preferential weldment corrosion worth highlighting in respect to electric-resistance-welded/high-frequency-induction-welded (ERW/HFI) pipe, where attack of the seam weld HAZ/fusion line can occur in aqueous environments or when exposed to the water phase in a mixed-phase system due to flow conditions or water dropout at low points. This grooving corrosion has been attributed to inclusions within the pipe material being exposed at the pipe surface and modified by the weld thermal cycle (Ref 4). A normalizing heat treatment can reduce or prevent occurrence. However, the major remedial action is the selection of a cleaner alloyed steel (Ref 6). Corrosion is due to electrochemical potential differences (galvanic corrosion) between the HAZ/fusion line and the parent material, attributed to the unstable MnS inclusions produced during the welding cycle. It is highlighted that the potential difference may only be of the order of perhaps 30 to 70 mV, but the low surface area ratio of anode to cathode results in high corrosion rates (between 1 to 10 mm, or 0.04 to 0.4 in., per year). Mitigation against this form of corrosion was achieved through modified steel composition in the 1970s; the addition of copper plus reduced sulfur to minimize MnS formation and the addition of calcium, nickel, or titanium to stabilize the remaining sulfur eliminates the potential difference. Such corrosion has become less common in recent years, due to awareness of these issues and remedial measures.

Preferential Weld Metal Corrosion

The weld metal in a carbon-manganese steel may suffer preferential corrosion, but again, if quality corrosion mitigation is in place for the main structure, such as coating or cathodic protection, this preferential attack is also normally prevented. However, there are cases where coating failure or inefficient inhibition can then lead to localized corrosion.

It is probable that similar microstructural considerations also apply to the preferential corrosion of weld metal, but in this case, the situation is further complicated by the presence of deoxidation products, their type and number depending largely on the flux system employed. Consumable type plays a major role in determining weld metal corrosion rate, and the highest rates of metal loss are normally associated with shielded metal arc electrodes using a basic coating. In seawater, for example, the corrosion rate for a weld made using a basic-flux-coated consumable may be three times as high as for weld metal from a rutile-flux-coated consumable. Fewer data are available for submerged arc weld metals, but it would appear that they are intermediate between basic and rutile flux shielded metal arc electrodes and that a corrosion rate above that of the base steel can be expected. In many cases, the underlying cause of the problem is the electrochemical potential difference between the weld metal and the adjacent parent steel, as discussed subsequently.

Galvanic Corrosion

Some of the earliest problems of weld metal corrosion related to ships in arctic waters, where the action of ice abraded the paint to expose bare steel and damaged the anodes, thus rendering the cathodic protection system ineffective. In these cases, it was observed that enhanced corrosion of the weld metal was due to electrochemical potential differences between the weld metal and the base metal, such that the weld metal is anodic in the galvanic couple. Further detailed studies were undertaken in the late 1980s to assess more modern steels and welding consumables in arctic waters off Canada (Ref 7). Both HAZ and weld metal attack were observed, and the general conclusions were that for steels between 235 and 515 MPa (34 and 75 ksi) minimum yield strength, high manganese content (1.4%) in the parent steel resulted in enhanced preferential HAZ attack, but this could be reduced via increased heat input during welding. Generally, the rate of weld metal attack was dependent on the nickel and copper contents of the welding consumable and was less influenced by parent steel composition, although a steel with copper, nickel, and chromium additions led to a more noble parent steel, hence accelerating weld metal attack. It was noted that parent steel with low silicon content led to increased weld metal corrosion, supporting the earlier findings that silicon < 0.2% can be detrimental, but the opposite was observed for silicon in the weld metal.

It is highlighted that, as for the autogenous seam weld in ERW/HFI pipe, the difference in corrosion potential for the separated regions (parent steel, HAZ, and weld metal) may be only a few tens of millivolts, but due to

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

the low surface area ratio of anode to cathode in conductive solutions, the attack on the anodic weld metal or HAZ may be very high. Also, on-going corrosion of the parent steel will continue, and if this rate is unacceptable, mitigation or protection methods are required for the base material in addition to consideration of ways to control the enhanced localized attack at the weldments. Generally, such weld metal attack has occurred in high-conductivity media, and the measures described to ensure the weld metal is cathodic (more noble) relative to the base metal have been successful. However, this may not be successful in different environmental conditions.

Mitigation of Preferential Weldment Corrosion

Optimized process selection and welding procedures will assist in achieving good-quality welds, ensuring full weld penetration and minimizing excessive weld reinforcement; postweld dressing by grinding (a costly method) can be effective in minimizing the geometric effects.

A stress-relieving heat treatment may be effective in reducing residual stress (internal weld shrinkage stress) and metal hardness to safe levels in most cases of concern regarding environmentally assisted cracking (stress-corrosion cracking and sulfide stress cracking).

A PWHT stress relief has also been reported to be beneficial in reducing HAZ attack (Ref 1). However, in other cases, avoidance through selection of appropriate material or welding procedure is the preferred remedial approach, because PWHT may necessitate temperatures high enough for normalizing to gain full benefit, which is usually impractical (Ref 1).

Mitigation of preferential weld metal corrosion may be achieved in some cases via alloying additions to make the weld metal cathodic to the adjacent base metal. It must be noted that although the weld becomes cathodic to the base material, accelerated corrosion of the base metal is unlikely, because the anode-to-cathode surface area ratio becomes very high. However, care is required in extrapolating remedial measures proven in one environment, because they may not be efficient in different conditions. For example, the factors influencing such localized corrosion in sweet oil and gas environments are complex, and the use of nickel-containing weld metal for the root, successful in mitigating attack in seawater injection systems, has led to incidents of preferential attack in particular systems operated at temperatures of approximately 70 to 80 °C (160 to 175 °F) (Ref 8).

However, when introducing measures to avoid weld metal corrosion, care must be taken to avoid enhanced corrosion of the adjacent HAZ, due again to galvanic effects, particularly where the environment has relatively low conductivity, such as freshwater (Ref 4).

In summary, preferential weldment corrosion of carbon steels has been observed in diverse applications, from plate steels in the marine industry to pipe and process equipment, piping tankage, pressure vessels (Ref 9), and similar equipment in the oil and gas sectors. Some typical case histories are presented as follows, but mitigation in most cases requires an assessment of the particular environment and materials involved and will likely necessitate some testing to evaluate the performance in service.

Industrial Case Studies

In one case, premature weld failures were experienced in a 102 mm (4 in.) ASTM A53 pipe that was used to transfer a mixture of chlorinated hydrocarbons and water. During construction, the pipeline was fabricated with E7010-Al welding electrodes (see Table 1 for the compositions of all materials discussed in these examples). Initial weld failures and subsequent tests showed the following welding electrodes to be anodic to the A53, grade B, base metal: E7010-Al, E6010, E6013, E7010-G, and E8018-C2. Two nickel- base electrodes—Inco-Weld A (American Welding Society, or AWS, A5.11, class ENiCrFe-2) and Incoloy welding electrode 135—were tested; they were found to be cathodic to the base metal and to prevent rapid weld corrosion. The corrosion rates of these various galvanic couples are listed in Table 2.

Table 1 Compositions of carbon steel base metals and some filler metals subject to galvanic corrosion. See Tables 3 and 4 for corrosion rates of galvanic couples.

Another example is the failure of low-carbon steel welds in seawater service at 25 °C (75 °F). Fabrications involving ASTM A285, grade C, plate welded with E6013 electrodes usually start to fail in the weld after 6 to 18 months in seawater service at this temperature. Welds made with E7010 electrodes do not fail. Tests were conducted in seawater at 50 °C (120 °F) using A285, grade C, plate welded with E6010, E7010-Al, and E7010-G. It was determined that E7010-Al was the best electrode to use in seawater and that E6010 and E7010-G were not acceptable (although they were much better than E6013), because they were both anodic to the base metal. A zero resistance ammeter was used to determine whether the electrodes were anodic or cathodic to the base metal.

In another case, welds made from E7010-Al electrodes to join ASTM A285, grade C, base metal were found to be anodic to the base metal when exposed to raw brine, an alkaline-chloride (pH > 14) stream, and raw river water at 50 °C (120 °F). When E7010-G was exposed to the same environment, it was anodic to the base metal in raw brine and raw river water and was cathodic to ASTM A285, grade C, in the alkaline-chloride stream. When the base metal was changed to ASTM A53, grade B, and A106, grade B, it was found that E7010-Al weld metal was cathodic to both when exposed to raw brine at 50 °C (120 °F).

Finally, routine inspection of a column in which a mixture of hydrocarbons was water washed at 90 °C (195 °F) revealed that E7016 welds used in the original fabrication were corroding more rapidly than the ASTM A285, grade C, base metal. Corroded welds were ground to sound metal, and E7010-Al was used to replace the metal that was removed. Approximately 3 years later, during another routine inspection, it was discovered that the E7010-Al welds were being selectively attacked. Tests were conducted that showed E7010-Al and E7016 weld metals to be anodic to A285, grade C, while E7018 and E8018-C2 would be cathodic. Corrosion rates of these various galvanic couples are given in Table 3.

Table 3 Corrosion rates of galvanic couples of ASTM A285, grade C, base metal and various filler metals at 90 °C (195 °F) in water used to wash a hydrocarbon stream

Corrosion of Carbon Steel Weldments

Revised by Stuart Bond, TWI Ltd., United Kingdom

Stress-Corrosion Cracking

There is no doubt that residual welding stresses can contribute to SCC in specific environments in which such failure represents a hazard. This is the case for failure by both active path and hydrogen embrittlement mechanisms, and, in the latter case, failure may be especially likely at low-heat-input welds because of the enhanced susceptibility of the hardened structures inevitably formed. Most SCC studies of welds in carbon and carbon-manganese steels have evaluated resistance to hydrogen-induced SCC, especially under sour (H_2S) conditions prevalent to the oil and gas industry, which is commonly referred to as sulfide stress cracking (SSC). Although full definition of the effect of specific microstructural types has not been obtained, an overriding influence of hardness is evident (Fig. 2) and well accepted. The situation regarding active path cracking is less clear, but there are few, if any, cases in which SCC resistance increases at higher strength levels. On this basis, it is probable that soft, transformed microstructures around welds are preferable. In order that hard spots in the HAZ are not overlooked in weld procedure qualification, many standards now require the use of the Vickers hardness testing for welds, using 5 or 10 kg (e.g., ASTM E 92) loads, because the larger indenter used for Rockwell C measurements (often stipulated for parent material) will not identify such critical regions.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

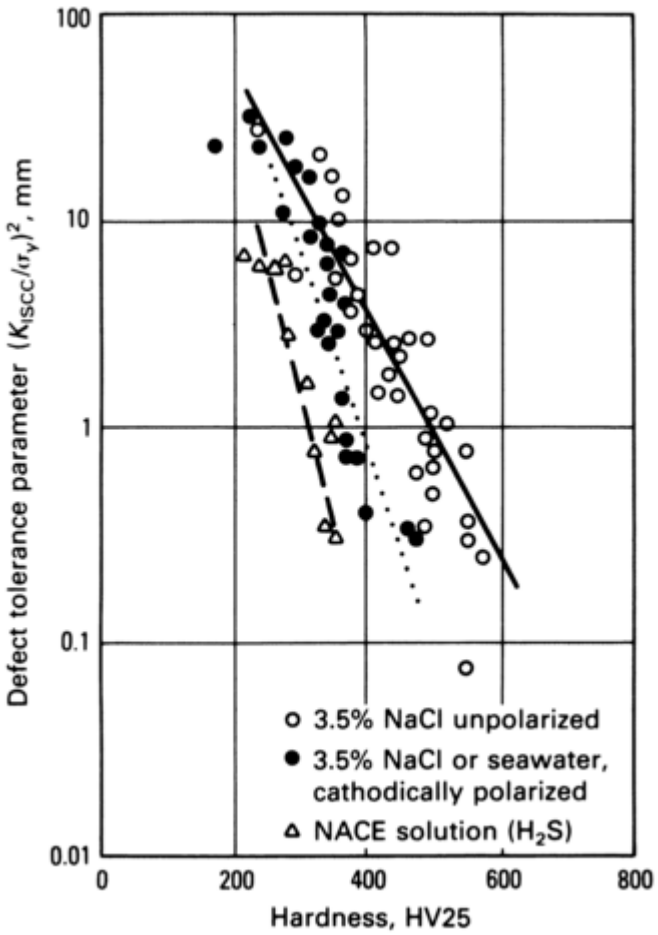

Fig. 2 Stress-corrosion cracking (SCC) defect tolerance parameter (K_{ISCC}/σ_y), where K_{ISCC} is the threshold SCC intensity factor and σ_y is yield stress versus hardness for carbon steel weldments in three environments. Data are derived from published tests on precracked specimens of various types of carbon steel base metals, heat-affected zones, and weld metals. SCC defect tolerance parameter is dependent on crack length; details are available in Ref 3. Source: Ref 3

Carbon and low-alloy steels are also known to fail by SCC when exposed to solutions containing nitrates (NO_3^-). Refrigeration systems using a 30% magnesium nitrate ($Mg(NO_3)_2$) brine solution, for example, are commonly contained in carbon steel. In this case, pH adjustment is important, as is temperature. Failures in the HAZ due to SCC have been reported when brine temperatures have exceeded 30 °C (90 °F) during shutdown periods. To avoid these failures, carbon steel is being replaced with type 304L stainless. Others have stress-relieved welded carbon steel systems and have operated successfully, although elevated-temperature excursions are discouraged.

SCC in Oil Refineries. Monoethanolamine (MEA) is an absorbent used to remove acid gases containing H_2S and CO_2 in oil refining operations. Recent failures in several refineries have shown that cracks can be parallel or normal to welds, depending on the orientation of principal tensile stresses. Cracking has been reported to be both transgranular and intergranular.

Before 1978, postweld stress relief of carbon steel weldments in MEA systems was performed only when the metal temperature of the equipment was expected to exceed 65 °C (150 °F) and the acid gas contained more than 80% CO_2 or when temperatures were expected to exceed 95 °C (200 °F) in any acid gas concentration.

Currently, any equipment containing MEA at any temperature and at any acid gas concentration is being postweld stress relieved. This is the result of surveys conducted by several refineries to define the extent of the SCC problem in this environment. These inspection programs showed that leaks were widespread and were found in vessels that ranged in age from 2 to 25 years. However, there were no reports of cracking in vessels that had been postweld stress relieved. In addition, it was found that all concentrations of MEA were involved and that MEA solutions were usually at relatively low temperatures (below 55 °C, or 130 °F). Equipment found to suffer from cracking included tanks, absorbers, carbon treater drums, skimming drums, and piping. The

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

following example of a metallurgical investigation conducted by one oil refinery illustrates the problem of SCC of carbon steel in amine service (Ref 10).

Leaking Carbon Steel Weldments in a Sulfur Recovery Unit. In December 1983, two leaks were discovered at a sulfur recovery unit. More specifically, the leaks were at pipe-to-elbow welds in a 152 mm (6 in.) diameter line operating in lean amine service at 50 °C (120 °F) and 2.9 MPa (425 psig). Thickness measurements indicated negligible loss of metal in the affected areas, and the leaks were clamped. In March 1984, 15 additional leaks were discovered, again at pipe-to-elbow welds of lean amine lines leading to two major refining units. The piping had been in service for approximately 8 years.

Investigation. Metallurgical examination of several of the welds revealed that leaking occurred at what appeared to be stress-corrosion cracks originating from the inside surface. Cracks were present in weld metal and base metal approximately 5 mm (0.2 in.) away from the weld, and they passed through the HAZ, as shown in Fig. 3. In other cases, stress-corrosion cracks also originated in the HAZ. The cracks typically ran parallel to the weld (Fig. 4).

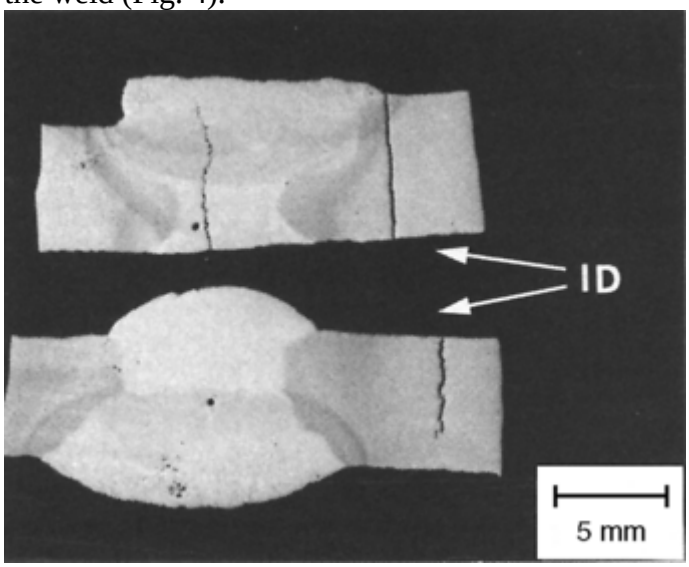

Fig. 3 Cross sections of pipe-to-elbow welds showing stress-corrosion cracks originating from the inside surface of the weld metal and the base metal. ID, inside diameter. Source: Ref 10

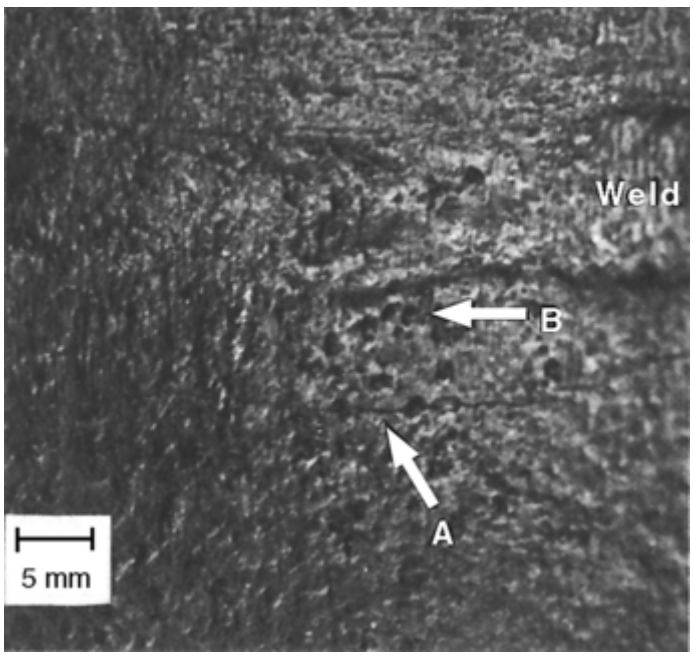

Fig. 4 Photograph of inside surface of a pipe showing 38 mm (1.5 in.) stress-corrosion crack (A) next to and parallel to a circumferential weld. Also shown are shallow corrosion pits (B). Source: Ref 10

مرجع مهندسی مواد و متالورژی

Brinell hardness values, obtained by conversion of Knoop microhardness readings, were 133 to 160 (pipe base metal), 160 to 230 (weld metal), 182 to 227 (HAZs), and 117 to 198 (elbow base metal). The pipe base metal had an equiaxed fine-grain microstructure typical of low-carbon steel, and the elbow base metal had a nonequiaxed microstructure typical of hot-finished fittings. Carbon contents ranged from 0.25 to 0.30% by weight. Cracking was intergranular, as shown in Fig. 5 and 6.

مرجع مهندسی مواد و متالورژی

The refinery operators immediately embarked on a program of visual inspection of all amine lines. As of June 1985, a total of 35 leaks in lean amine piping had been discovered. All leaks were at cracks in or around pipe-to-elbow welds, except for two leaks at welds that connected a tee and reducer, respectively. Piping size ranged from 76 to 305 mm (3 to 12 in.). Service temperature ranged from 40 to 60 °C (100 to 140 °F), with most leaks having occurred in lines carrying lean amine at 55 °C (130 °F). Pressures ranged from atmospheric to 2.9 MPa (425 psig), with most leaks having occurred between 2.8 and 2.9 MPa (400 and 425 psig). All piping had been in service for approximately 8 years, except two leaks at piping welds that had been in service for only 4 years.

As had been generally accepted industry practice, the specifications called for stress relieving or PWHT of piping and vessels in amine service at temperatures above 95 °C (200 °F). Therefore, it was highly unlikely that any of the leaking welds had received PWHT. Further metallurgical examination of leaking welds from various lines conclusively confirmed that the leaking originated at stress-corrosion cracks. No leaks were found in rich amine piping. The characteristics of the mode of fracture suggested that the failure mechanism was a form of caustic SCC.

It is interesting to note that other researchers also have metallographically examined numerous samples of similar cracks; their results can be summarized as follows:

- Cracks were essentially intergranular and were filled with gray oxide scale.
- Hardness of welds and HAZs was less than 200 HB.
- Cause of fracture was believed to be a form of caustic SCC.
- Cracking occurs whether or not MEA solutions contain corrosion inhibitors.

Preventive Measures. As a result of this particular investigation and others, all welds in equipment in MEA service are being inspected. Wet fluorescent magnetic-particle inspection after sandblasting to remove oxides and scale appears to be the most effective technique. Shear- wave ultrasonic (SWU) inspection has also been used for piping, but it does not always distinguish SCC and other defect indications, such as shrinkage cracks, slag inclusions, lack of fusion, or fatigue cracks. Nevertheless, SWU is considered helpful, because these other types of defects also can pose a threat to the structural integrity of the system in question. Inspection frequency is dependent on the critical nature of the particular equipment in question, and, most important, all welds in these systems are now being postweld stress relieved.

Corrosion of Welds in Carbon Steel Deaerator Tanks. Deaerator tanks, the vessels that control free oxygen and other dissolved gases to acceptable levels in boiler feedwater, are subject to a great deal of corrosion and cracking. Several years ago, there were numerous incidences of deaerator tank failures that resulted in injury to personnel and property damage losses. Since that time, organizations such as the National Board of Boiler and Pressure Vessel Inspectors and the Technical Association of the Pulp and Paper Industry have issued warnings to plant operators, and these warnings have resulted in the formation of inspection programs for evaluating the integrity of deaerator tanks. As a result, many operators have discovered serious cracking. The following example illustrates the problem (Ref 11).

Weld Cracking in Oil Refinery Deaerator Vessels. Two deaerator vessels with associated boiler feedwater storage tanks operated in similar service at a refinery. The vertical deaerator vessels were constructed of carbon steel (shell and dished heads), with trays, spray nozzles, and other internal components fabricated of type 410 stainless steel. Boiler feedwater was treated by sand filtration using pressure filters, followed by ion-exchange water softening. Hardness was controlled at less than 0.5 ppm calcium carbonate ($CaCO_3$). A strong cationic primary coagulant (amine) was used to aid the filtering of colloidal material. Treated water was blended with condensate containing 5 ppm of a filming amine corrosion inhibitor. Final chemistry of the feedwater was controlled to the concentration limits given in Table 4. Oxygen scavenging was ensured by the addition of catalyzed sodium bisulfite ($NaHSO_3$) to the storage tanks. Treated water entered the top of the tray section of the deaerators through five or six spray nozzles and was stored in the horizontal tanks below the deaerators.

Table 4 Concentration limits on deaerator feedwater

Control parameter	Concentration limit

Inspection Results. Deaerator vessel and storage tank A were inspected. All tray sections were removed from the deaerator. With the exception of the top head-to-shell weld in the deaerator, all internal welds were ground smooth and magnetic particle inspected. No cracks were found. Corrosion damage was limited to minor pitting of the bottom head in the deaerator vessel.

Inspection of deaerator vessel B revealed cracking at one weld. Tray sections were removed from the deaerator vessel, and shell welds were gritblasted. Except for the top head-to-shell weld in the deaerator, all internal welds in both B units were then ground smooth and magnetic particle inspected. Three transverse cracks were found at the bottom circumferential weld in the deaerator vessel. These were removed by grinding to a depth of 1.5 mm (0.06 in.).

Inspection of storage tank B revealed numerous cracks transverse to welds. With the shell constructed from three rings of plate, the longitudinal ring welds were located just below the water level. These longitudinal welds exhibited no detectable cracking. One circumferential crack was found above the working water level in the vessel. The remaining cracks were located at circumferential welds below the working water level. Numerous cracks transverse to circumferential welds were detected, but only one longitudinal crack was detected. All cracks were removed by grinding to a depth of 2 mm (0.08 in.).

Unlike deaerator vessel A, it was noted that none of the spray nozzles in deaerator vessel B was operational at the time of inspection. In addition, two valves had fallen to the bottom of the deaerator vessel. The bottom section of trays in deaerator vessel B had fallen to the bottom of the storage vessel. Corrosion damage in deaerator vessel B was limited to underdeposit pitting attack at circumferential welds in the bottom.

Metallurgical Analysis. A section was cut from a circumferential weld region in storage tank B. As shown in Fig. 7, the cracking was predominantly transverse to the weld. Chemical analysis was performed on samples cut from weld metal and base metal; the results are given in Table 5. The results show that the steel plate was not aluminum-or silicon-killed but was most likely a rimmed grade. Cross sections were cut perpendicular to both transverse and longitudinal cracks and were examined metallographically.

shows a longitudinal crack in a weld HAZ, with associated grain refinement. Cracking initiated from the bottom of a pit. The oxide associated with the major crack was extensive and contained numerous secondary cracks. Analysis of the oxide deposit within the crack by wavelength-dispersive spectroscopy revealed slightly less oxygen than an Fe_2O_3 standard. Therefore, it was assumed that the oxide deposit was a mixture of Fe_3O_4 and Fe_2O_3.

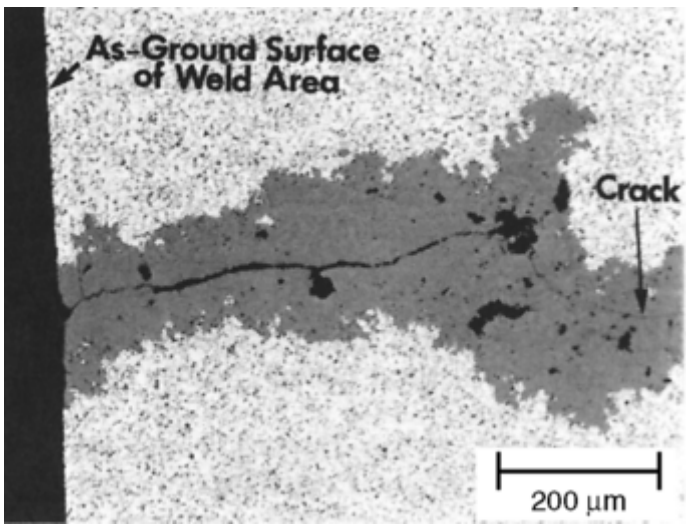

Fig. 9 Micrograph of a longitudinal crack in the heat affected zone of a weld from storage vessel B. Etched with nital. Source: Ref 11

Figure 10 shows a crack extending into base metal, transverse to the weld, with secondary cracking to the periphery of the oxidized region. It was clear that the oxide exhibited extensive internal cracking. Figure 10 also shows the entrainment of lamellar pearlite phase (dark) within the oxide corrosion product. In addition, the crack tips are blunt.

Discussion. The cracks described in this example are very similar to those found in many other investigations, despite a variety of deaerator vessel designs and operating conditions. Cracks typically display the following characteristics:

- Cracks occur most often in welds and HAZs but can also occur in the base metal.
- Cracks are generally transverse to the weld HAZ and occur both parallel and perpendicular to the hoop stress direction.
- The worst cracks appear to be located in circumferential and head-to-shell welds in horizontal vessel designs.
- Cracks are concentrated at, but not solely located within, the working water level in the vessel.
- Cracks are perpendicular to the vessel plate surface.
- Cracks are predominantly transgranular, with minor amounts of branching.
- Cracks are filled with iron oxide. Cracking of the oxide corrosion product is followed by progressive corrosion. The ferrite phase is selectively attacked, with retention of the pearlite phase within the oxide corrosion product.
- Cracks initiate from corrosion pits. Weld defects, however, can also become active sites for crack initiation.
- Crack tips are blunt.

Conclusions. These findings suggest that the failure mechanism is a combination of low-cycle corrosion fatigue and stress-induced corrosion. Extensive oxide formation relative to the depth of cracking is a key feature. The formation of oxide was associated with corrosion attack of the ferrite phase. The lamellar pearlite phase remained relatively intact and was contained within the oxide product. The oxide itself exhibited numerous cracks, allowing aqueous corrosion of fresh metal to occur at the oxide-metal interface. Mechanical or thermal stresses are most likely responsible for this network of cracks within the oxide product. The mechanism appears to be stress-assisted localized corrosion. Sharp, tight cracks were not found in fresh metal beyond the periphery of the oxide corrosion product. It therefore appears reasonable that cracking could have occurred subsequent to corrosion and within the brittle oxide.

Cracking at welds and HAZs suggests that residual weld shrinkage stresses play a major role. Welds in deaerator vessels typically have not been postweld stress relieved. It is not unusual to find residual welding stresses of yield strength magnitude. This problem can be aggravated by vessel design (high localized bending stresses around saddle supports that fluctuate with water level and are accelerated by operational upsets).

No fault was found with the steel plate chemical composition or with welding consumables. There was no evidence of embrittlement or caustic SCC (that is, no branched intergranular cracks).

Recommendations. All welds in deaerator vessels should be postweld stress relieved. Operational upsets should be avoided, and water chemistry must be maintained within acceptable limits. This is especially true with regard to water oxygen levels, which should be kept low to minimize pitting corrosion. Detailed assessment of the influence of welding on the occurrence of such cracking and mitigation methods is provided in Ref 3.

Corrosion of Stainless Steel Weldments

Introduction

STAINLESS STEELS are iron-base alloys that contain a minimum of approximately 11% Cr, the amount needed to prevent the formation of rust in unpolluted atmospheres (hence the designation *stainless*). Few stainless steels contain more than 30% Cr or less than 50% Fe. They achieve their stainless characteristics through the formation of an invisible and adherent chromium-rich oxide surface film. This oxide forms and heals itself in the presence of oxygen. Other elements added to improve particular characteristics include nickel,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

molybdenum, copper, titanium, aluminum, silicon, niobium, nitrogen, sulfur, and selenium. Carbon is normally present in amounts ranging from less than 0.03% to over 1.0% in certain martensitic grades.

Corrosion of Stainless Steel Weldments, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 301–316

Metallurgical Factors

Stainless steel base metals and thus the welding filler metals used with them are almost invariably chosen on the basis of adequate corrosion resistance for the intended application. This usually means that the welding filler metal must at least match (and sometimes overmatch) the contents of the base metal in terms of specific alloying elements, such as chromium, nickel, and molybdenum.

The cycle of heating and cooling that occurs during the welding process affects the microstructure and surface composition of welds and adjacent base metal. Consequently, the corrosion resistance of autogenous welds (welds made without the use of filler metals) and welds made with matching filler metal may be inferior to that of properly annealed base metal because of:

- Microsegregation
- Precipitation of secondary phases
- Formation of unmixed zones
- Recrystallization and grain growth in the weld heat-affected zone (HAZ)
- Volatilization of alloying elements from the molten weld pool
- Contamination of the solidifying weld pool

Corrosion resistance can usually be maintained in the welded condition by:

- Balancing alloy compositions to inhibit certain precipitation reactions
- Shielding molten and hot metal surfaces from reactive gases in the weld environment
- Removing chromium-enriched oxides and chromium-depleted base metal from thermally discolored (heat tinted) surfaces
- Choosing the proper welding parameters (Ref 1)

Weld Solidification. During the welding process, a number of important changes occur that can significantly affect the corrosion behavior of the weldment. Heat input and welder technique obviously play important roles. The way in which the weld solidifies is equally important to understanding how weldments may behave in corrosive environments (Ref 2).

A metallographic study has shown that welds solidify into various regions, as shown in Fig. 1. The composite region, or fusion zone, essentially consists of filler metal that has been diluted with material melted from the surrounding base metal. Next to the composite region is the unmixed zone where the base metal is melted and then quickly solidified to produce a composition similar to that of the base metal (Ref 4). For example, when type 304 stainless steel is welded using a filler metal with high chromium-nickel content, steep concentration gradients of chromium and nickel are found in the fusion zone, whereas the unmixed zone has a composition similar to the base metal (Fig. 2). The weld interface is the surface bounding the region within which complete melting occurred during welding, and it is evidenced by the presence of a cast structure. Beyond the weld interface is the partially melted zone, which is a region of the base metal within which the proportion melted ranges from 0 to 100%. Lastly, the true HAZ is that portion of the base metal within which microstructural change has occurred in the absence of melting. Although the various regions of a weldment shown in Fig. 1 are for a single-pass weld, similar solidification patterns and compositional differences can be expected to occur in underlying weld beads during multipass applications.

Corrosion of Stainless Steel Weldments, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 301–316

Corrosion of Austenitic Stainless Steel Weldments

The corrosion problems commonly associated with welding of austenitic stainless steels are related to precipitation effects and chemical segregation. These problems can be eliminated or minimized through control of base metal metallurgy, control of the welding practice, and selection of the proper filler metal.

Preferential Attack Associated with Weld Metal Precipitates. In austenitic stainless steels, the principal weld metal precipitates are δ-ferrite, σ-phase, and $M_{23}C_6$ carbides. Small amounts of M_6C carbide may also be present. Sigma phase is often used to describe a range of chromium- and molybdenum-rich precipitates, including χ and laves (η) phases. These phases may precipitate directly from weld metal, but they are most readily formed from weld metal δ- ferrite in molybdenum-containing austenitic stainless steels.

The δ-ferrite transforms into brittle intermetallic phases, such as σ and χ, at temperatures ranging from 500 to 850 °C (930 to 1560 °F) for σ and 650 to 950 °C (1200 to 1740 °F) for χ. The precipitation rate for σ and χ phases increases with the chromium and molybdenum contents. Continuous intergranular networks of a phase reduce the toughness, ductility, and corrosion resistance of austenitic stainless steels.

It is extremely difficult to discriminate between fine particles of σ and χ phases by using conventional optical metallographic techniques; hence the designation σ/χ phase. The use of more sophisticated analytical techniques to identify either phase conclusively is usually not justified when assessing corrosion properties, because the precipitation of either phase depletes the surrounding matrix of crucial alloying elements. Grain-boundary regions that are depleted in chromium and/or molybdenum are likely sites for attack in oxidizing and chlorine-bearing solutions. The damage caused by preferential corrosion of alloy-depleted regions ranges from the loss of entire grains (grain dropping) to shallow pitting at localized sites, depending on the distribution and morphology of the intermetallic precipitate particles at grain boundaries. Figure 3 shows two views of an austenitic stainless steel exhibiting intergranular corrosion. Figure 3(a) shows the surface of the sample. The grain structure is visible due to the attack, and some grains have fallen out (grain dropping). The cross-sectional view (Fig. 3b) shows the depth of penetration of the attack along the grain boundaries.

Because these precipitates are usually chromium- and molybdenum-rich, they are generally more corrosion resistant than the surrounding austenite. However, there are some exceptions to this rule.
Preferential attack associated with δ-ferrite and σ can be a problem when a weldment is being used close to the limit of corrosion resistance in environments represented by three types of acidic media:

- Mildly reducing (e.g., hydrochloric acid, HCl)
- Borderline active-passive (e.g., sulfuric acid, H_2SO_4)
- Highly oxidizing (e.g., nitric acid, HNO_3)

Acid cleaning of type 304 and 316 stainless steel black liquor evaporators in the pulp and paper industry with poorly inhibited HCl can lead to weld metal δ-ferrite attack (Fig. 4, 5). Attack is avoided by adequate inhibition (short cleaning times with sufficient inhibitor at low enough temperature) and by specification of full- finished welded tubing (in which the δ-ferrite networks within the weld metal structure are altered by cold work and a recrystallizing anneal). The latter condition can easily be verified with laboratory HCl testing, and such a test can be specified when ordering welded tubular products.

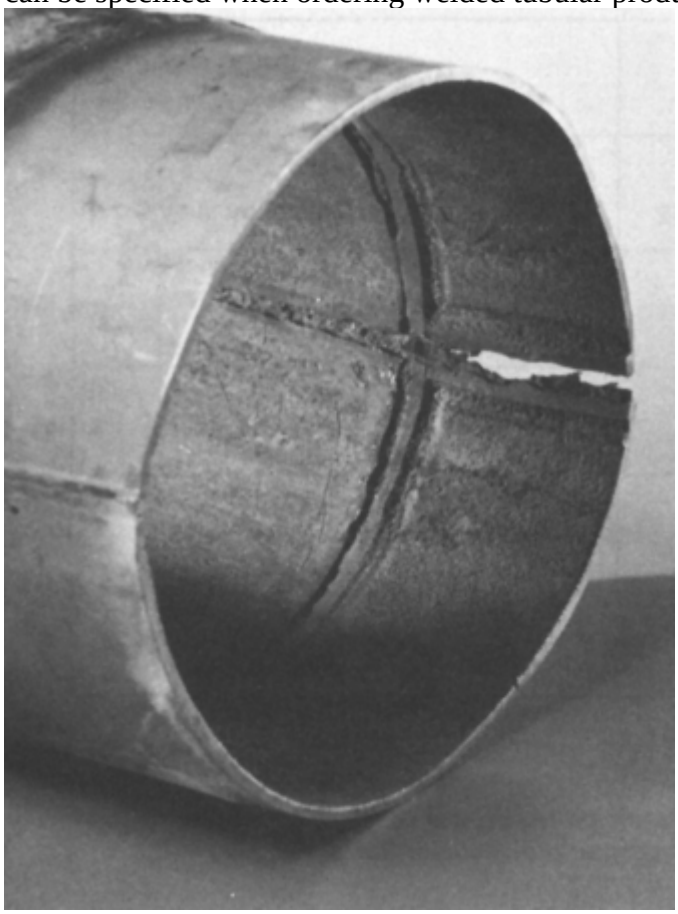

Fig. 4 Corroded type 316 stainless steel pipe from a black liquor evaporator. Two forms of attack are evident: preferential attack of the weld metal ferrite, suffered during HCl acid cleaning, and less severe attack in the sensitized HAZ center. Source: Ref 5

Electrolytically etched with 10% ammonium persulfate. 500×. Source: Ref 6

Sulfuric acid attack of a phase or of chromium- and molybdenum-depleted regions next to σ-phase precipitates is commonly reported. However, it is difficult to predict because the strong influence of tramp oxidizing agents, such as ferric (Fe^{3+}) or cupric (Cu^{2+}) ions, can inhibit preferential attack. Type 316L weld filler metal has been formulated with higher chromium and lower molybdenum to minimize σ- phase formation, and filler metals for more highly alloyed materials such as 904L (Fe-22Cr- 26Ni-4.5Mo) are balanced to avoid δ-ferrite precipitation and thus minimize σ-phase.

Highly oxidizing environments such as those found in bleach plants could conceivably attack δ-ferrite networks and σ phase. However, this mode of attack is not often a cause of failure, probably because free-corrosion potentials are generally lower (less oxidizing) than that required to initiate attack. Preferential attack of δ-ferrite in type 316L weld metal is most often reported after prolonged HNO_3 exposure, as in nuclear-fuel reprocessing or urea production. For these applications, a low corrosion rate in the Huey test (ASTM A 262, practice C) is specified (Ref 7).

Pitting Corrosion. Under moderately oxidizing conditions, such as a pulp and paper bleach plant, weld metal austenite may suffer preferential pitting in alloy-depleted regions. This attack is independent of any weld metal precipitation and is a consequence of microsegregation or coring in weld metal dendrites. Preferential pitting is more likely:

- In autogenous (no filler) gas-tungsten arc (GTA) welds (Fig. 6)
- In 4 to 6% Mo alloys (Table 1)
- When the recommended filler metal has the same composition as the base metal (Fig. 7)
- When higher-heat-input welding leaves a coarse microstructure with surface-lying dendrites (Fig. 8). Such a microstructure is avoided by use of a suitably alloyed filler metal (Fig. 7)

Avesta 254 SMO	Avesta P12, IN-112, Hastelloy alloy C-276

Even when suitable fillers are used, preferential pitting attack can still occur in an unmixed zone of weld metal. High-heat-input welding can leave bands of melted base metal close to the fusion line. The effect of these bands on corrosion resistance can be minimized by welding techniques that bury unmixed zones beneath the surface of the weldment.

When the wrong filler metal is used, pitting corrosion can readily occur in some environments. In the example shown in Fig. 9, the type 316L base metal was welded with a lower-alloy filler metal (type 308L). Tap water was the major environmental constituent contributing to crust formation on the weld joint. The type 316L base metal on either side of the joint was not affected.

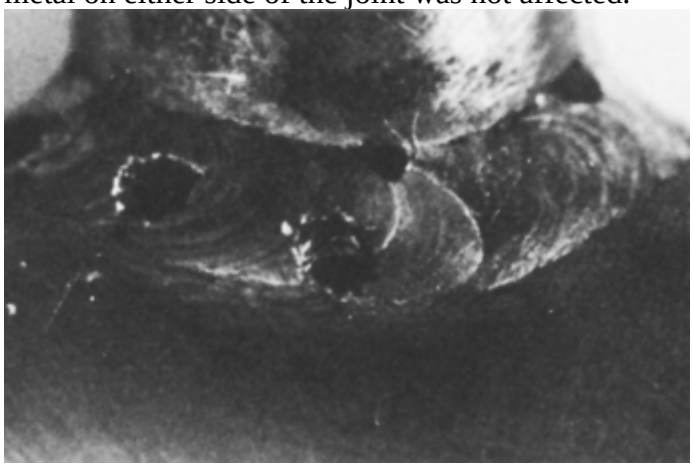

Fig. 9 Pitting of underalloyed (relative to the base metal) type 308L weld metal. The type 316L stainless steel base metal is unaffected. About 2.5×

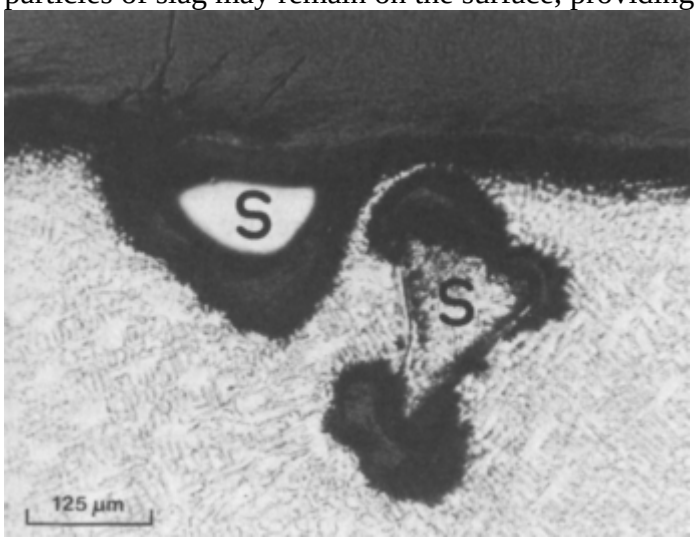
Crevice Corrosion. Defects such as residual welding flux and microfissures create weld metal crevices that are easily corroded, particularly in chloride-containing environments. Some flux formulations on coated shielded metal arc electrodes produce easily detached slags, and others give slags that are difficult to remove completely, even after grit blasting. Slags from rutile (titania- base) coatings are easily detached and give good bead shape. In contrast, slags from the basic- coated electrodes for out-of-position welding can be difficult to remove; small particles of slag may remain on the surface, providing an easy initiation site for crevice attack (Fig. 10).



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 10 Crevice corrosion under residual slag (S) in IN-135 weld metal after bleach plant exposure. Etched with glycergia. Source: Ref 5

Microfissures or their larger counterparts, hot cracks, also provide easy initiation sites for crevice attack, which will drastically reduce the corrosion resistance of a weldment in the bleach plant. Microfissures are caused by thermal contraction stresses during weld solidification and are a problem that plagues austenitic stainless steel fabrications. These weld metal cracks are more likely to form when phosphorus and sulfur levels are higher (i.e., >0.015% P and >0.015% S), with high-heat-input welding, and in austenitic weld metal in which the δ-ferrite content is low (<3%).

Small-scale microfissures are often invisible to the naked eye, and their existence can readily explain the unexpectedly poor pitting performance of one of a group of weldments made with filler metals of apparently similar general composition. The microfissure provides a crevice, which is easily corroded because stainless alloys are more susceptible to crevice corrosion than to pitting. However, microfissure-crevice corrosion is often mistakenly interpreted as self-initiated pitting (Fig. 11, 12).

Fig. 12 Section from the bleach plant test coupon in Fig. 11 showing crevice corrosion that has almost obliterated evidence of a microfissure. This form of attack is often mistakenly interpreted as self-initiating pitting; more often, crevice corrosion originates at a microfissure. Etched with glycergia. Source: Ref 5

Crevice corrosion sites can also occur at the beginning or end of weld passes, between weld passes, or under weld spatter areas. Weld spatter is most troublesome when it is loose or poorly adherent. A good example of this type of crevice condition is the type 304 stainless system shown in Fig. 13.

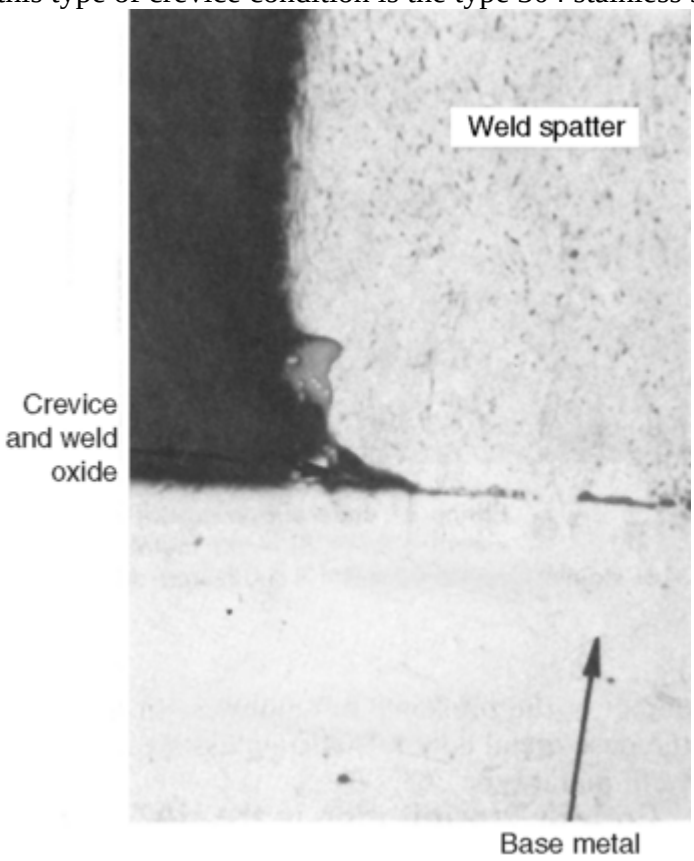

Fig. 13 Cross section of a weldment showing crevice corrosion under weld spatter. Oxides (light gray) have formed on the spatter and in the crevice between spatter and base metal.

Microfissure corrosion in austenitic stainless steel weldments containing 4 to 6% Mo is best avoided with the nickel-base Inconel 625, Inconel 112, or Avesta P12 filler metals, which are very resistant to crevice attack. Some stainless electrodes are suitable for welding 4% Mo steels, but they should be selected with low phosphorus and sulfur to avoid microfissure problems.

Hot tap water is not thought to be particularly aggressive; however, Fig. 14 shows what can happen to a weld that contains a lack-of-fusion defect in the presence of chlorides. In this case, the base metal is type 304 stainless steel, and the weld metal is type 308.

Sensitization. The best known weld-related corrosion problem in stainless steels is weld decay (sensitization) caused by carbide precipitation in the weld HAZ. Sensitization occurs in a zone subject to a critical thermal cycle in which chromium-rich carbides precipitate and in which chromium diffusion is much slower than that of carbon. The carbides are precipitated on grain boundaries that are consequently flanked by a thin chromium-depleted layer. This sensitized microstructure is much less corrosion resistant, because the chromium-depleted layer and the precipitate can be subject to preferential attack (Fig. 15, 16). In North America, sensitization is avoided by the use of low-carbon grades such as type 316L (0.03% C max) in place of sensitization-susceptible type 316 (0.08% C max). In Europe, it is more common to use 0.05% C (max) steels, which are still reasonably resistant to sensitization, particularly if they contain molybdenum and nitrogen; these elements appear to raise the tolerable level of carbon and/or heat input. However, low-carbon stainless steels carry a small cost premium and so are not universally specified.

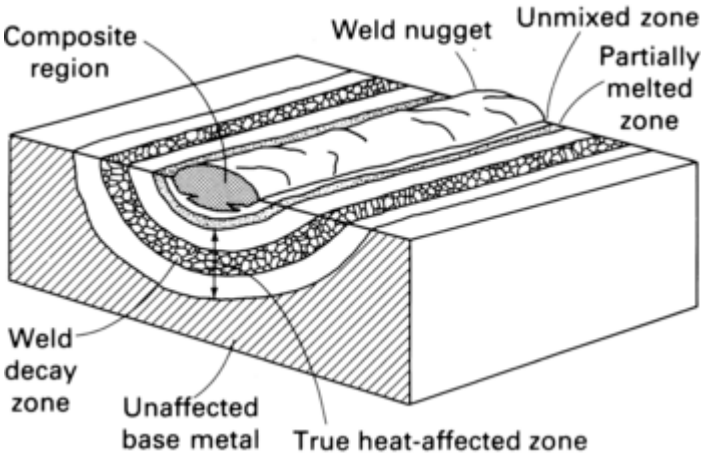

Fig. 15 Diagram of weld decay (sensitization) in an austenitic stainless steel weldment. Source: Ref 3

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

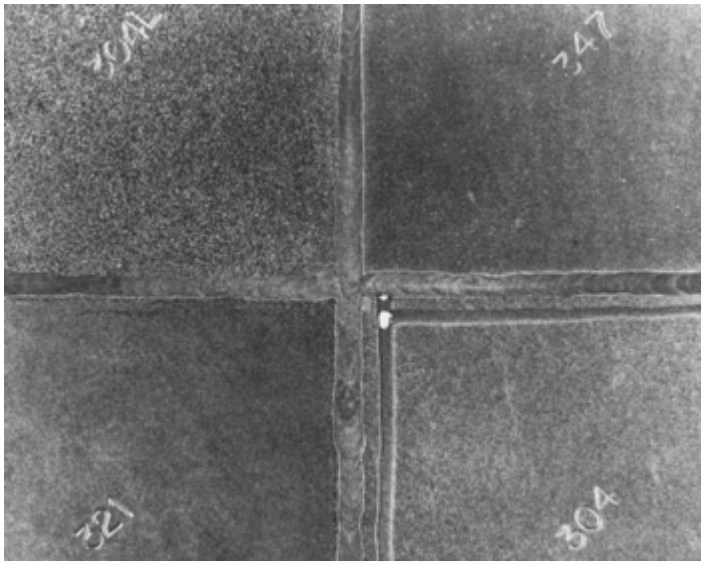

Fig. 16 Weld decay and methods for its prevention. The four different panels were joined by welding and then exposed to a hot solution of HNO_3/HF. Weld decay, such as that shown for the type 304 steel (bottom right), is prevented by reduction of the carbon content (type 304L, top left) or by stabilizing with titanium (type 321, bottom left) or niobium (type 347, top right). Source: Ref 2

Thiosulfate ($S_2O_3^{2-}$) pitting corrosion will readily occur in sensitized HAZs of type 304 weldments in paper machine white-water service (Fig. 17). This form of attack can be controlled by limiting sources of $S_2O_3^{2-}$ contamination; the principal one is the brightening agent sodium hyposulfite ($Na_2S_2O_4$). However, nonsensitized type 304 will also be attacked. Consequently, type 316L is the preferred grade of stainless steel that should be specified for paper machine service.

Fig. 17 Thiosulfate pitting in the HAZ of a type 304 stainless steel welded pipe after paper machine white-water service. Source: Ref 5

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

At higher solution temperatures, sensitized type 304 and type 316 are particularly susceptible to stress-corrosion cracking (SCC), whether caused by chlorides, sulfur compounds, or caustic. For example, type 304 or 316 kraft black liquor evaporators and white liquor tubing are subject to SCC in sensitized HAZs. In many cases cracking occurs after HCl acid cleaning. Although the initial crack path may be intergranular, subsequent propagation can have the characteristic branched appearance of transgranular chloride SCC. Intergranular SCC caused by sulfur compounds can also occur during the acid cleaning of sensitized stainless steels in kraft liquor systems.

Sigma Precipitation in HAZs. When the higher molybdenum alloys such as 904L, AL- 6XN, and 254SMO were first developed, one of the anticipated corrosion problems was attack of single-phase precipitates in weld HAZs. This form of attack has subsequently proved to be either superficial or nonexistent in most applications, probably because the compositions of the alloys have been skillfully formulated to minimize phase-related hot-rolling problems.

More recently, nitrogen has been added to molybdenum-bearing austenitic stainless steels to retard the precipitation of chromium- and molybdenum-rich intermetallic compounds (σ or χ phases). The incubation time for intermetallic precipitation reactions in Fe-Cr-Ni-Mo stainless alloys is significantly increased by raising the alloy nitrogen content. This has allowed the commercial production of thick plate sections that can be fabricated by multipass welding operations. In addition to suppressing the formation of deleterious phases, nitrogen, in cooperation with chromium and molybdenum, has a beneficial effect on localized corrosion resistance in oxidizing acid-chloride solutions.

Corrosion Associated with Postweld Cleaning. Postweld cleaning is often specified to remove the heat-tinted metal formed during welding. Recent work has shown that cleaning by stainless steel wire brushing can lower the corrosion resistance of a stainless steel weldment (Fig. 18). This is a particular problem in applications in which the base metal has marginal corrosion resistance. The effect may be caused by inadequate heat-tint removal, by the use of lower-alloy stainless steel brushes such as type 410 or 304, or by the redeposition of abraded metal or oxides.

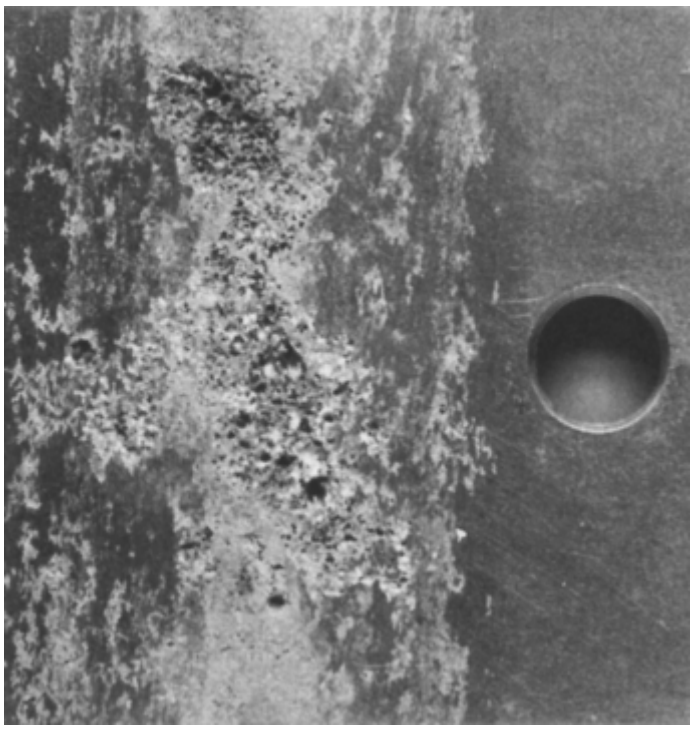

Fig. 18 Pitting corrosion associated with stainless steel wire brush cleaning on the back of a type 316L stainless steel test coupon after bleach plant exposure. Source: Ref 5

Any cleaning method may be impaired by contamination or by lack of control. Results of a study in bleach plants suggest that pickling and glass bead blasting can be more effective than stainless wire brushing and that brushing is more difficult to perform effectively in this case.

Corrosion Associated with Weld Backing Rings. Backing rings are sometimes used when welding pipe. In corrosion applications, it is important that the backing ring insert be consumed during the welding process to avoid a crevice. In the example shown in Fig. 19, the wrong type of backing ring was used, which left a crevice

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

after welding. The sample was taken from a leaking brine cooling coil used in the production of nitroglycerin. The cooling coils contained calcium chloride ($CaCl_2$) brine inhibited with chromates. Coils were made by butt welding sections of seamless type 304L stainless steel tubing. This failure was unusual because several forms of corrosion had been observed.

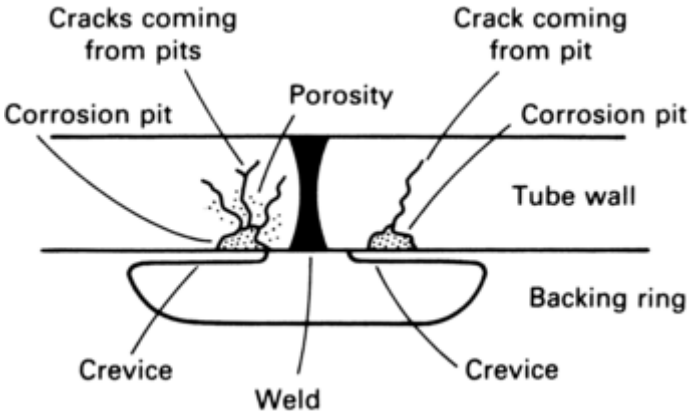

Fig. 19 Stainless steel nitrator cooling coil weld joint. Failure was caused by improper design of the backing ring, which was not consumed during welding and left a crevice. Source: Ref 8

A metallographic examination of a small trepanned sample revealed:

- *Microstructure:* The base metal and weld metal microstructures appeared satisfactory.
- *Pitting:* Irregular corrosion pits were seen on the inside tube surface at crevices formed by the tube and the backing ring adjacent to the tube butt weld. The deepest pits extended 0.1 to 0.2 mm (4 to 8 mils) into the 1.65 mm (0.065 in.) thick tube wall.
- *Cracking:* There were numerous brittle, branching transgranular cracks originating on the inside surface at the crevice under the backing ring.
- *Preferential weld corrosion:* Extensive preferential corrosion of the ferrite phase (vermicular morphology) in the tube weld had occurred and penetrated almost completely through the tube wall. Corrosion originated on the outside surface of the tube.

It was concluded that the preferential weld corrosion from the process side was the most probable cause of the actual leak in the nitrator coil. The preferential corrosion of ferrite in nitrating mixtures of HNO_3 and H_2SO_4 is well known. Whether this corrosion causes a serious problem depends on the amount of ferrite present in the weld. If the amount of ferrite is small and the particles are not interconnected, the overall corrosion rate is not much higher than that of a completely austenitic material. If the particles are interconnected, as in this case, there is a path for fairly rapid corrosion through the weld, causing failure to occur.

To minimize this problem, two possible solutions were considered. The first was to weld the coils with a filler metal that produces a fully austenitic deposit, and the second was to solution anneal at 1065 °C (1950 °F) after welding to dissolve most of the ferrite. It would also help to select stainless steel base metal by composition (e.g., high nickel, low chromium content) to minimize the production of ferrite during welding. Welding with a fully austenitic filler metal was considered to be the best approach.

Cracking on the brine side was caused by chloride SCC. The cracking probably did not happen during operation at 15 °C (60 °F) or lower. It is thought that the cracking most likely occurred while the coil was being decontaminated at 205 to 260 °C (400 to 500 °F) in preparation for weld repairing of the leak. Brine trapped in the crevice between the tube wall and the backing ring was boiled to dryness. Under these conditions, SCC would occur in a short time.

There probably were stress cracks behind all of the backing rings. Because the future life of this coil was questionable, a new coil was recommended.

The pitting corrosion caused by the brine was not considered to be as serious as it first appeared. If this had been the only corrosion (and the sample had been representative of the coil), the coil would not have failed for a considerable length of time. The decontamination process, which evaporated the trapped brine, produced some of the observed corrosion and made the pitting appear worse than it was before decontamination.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Because chromates are anodic inhibitors, they can also greatly increase the corrosion (usually by pitting) in the system if insufficient quantities are used. This might have occurred in the crevices in the nitrator coil butt welds, regardless of the bulk solution concentration. The best solution to this problem was to eliminate the crevices, that is, not to use backing rings.

Effects of GTA Weld Shielding Gas Composition. The chromium in a stainless steel has a strong chemical affinity for oxygen and carbon. Weld pools formed by electric arc processes must be shielded from the atmosphere to prevent slag formation and oxidation (Fig. 20), to maintain a stable arc, and to reduce contamination of the molten metal by the weld environment. Argon or argon plus helium gas mixtures are commonly used in GTA welding processes to create a barrier between the solidifying weld and the atmosphere. In other cases, nitrogen is commonly used as a backing gas to protect the backside of the root pass.

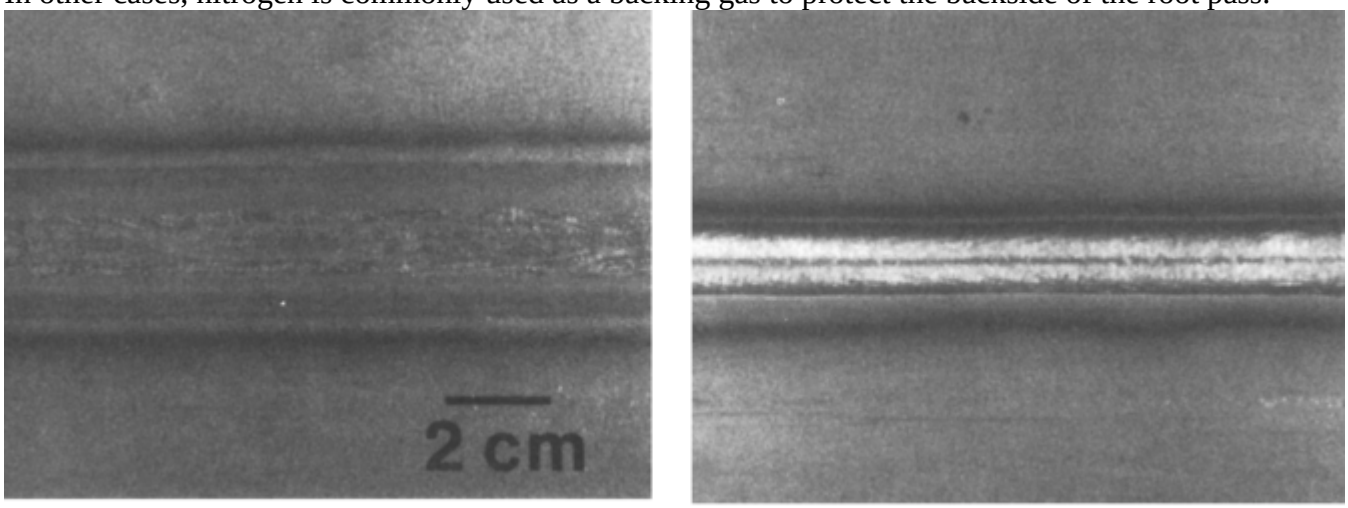

Fig. 20 Examples of properly shielded (a) and poorly shielded (b) autogenous gas tungsten arc welds in type 304 stainless steel strip. Source: Ref 8

The composition of a shielding gas can be modified to improve the microstructure and properties of GTA welds in austenitic stainless steels. More specifically, the use of argon mixed with small volumes of nitrogen (10 vol% N_2 or less) in a GTA welding process enhances the corrosion resistance of Fe-Cr-Ni-Mo-N stainless alloys in oxidizing acid chloride solutions (Fig. 21). In certain nonoxidizing solutions, argon-nitrogen shielding gas reduces the δ-ferrite content of weld metal and influences weld metal solidification behavior.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

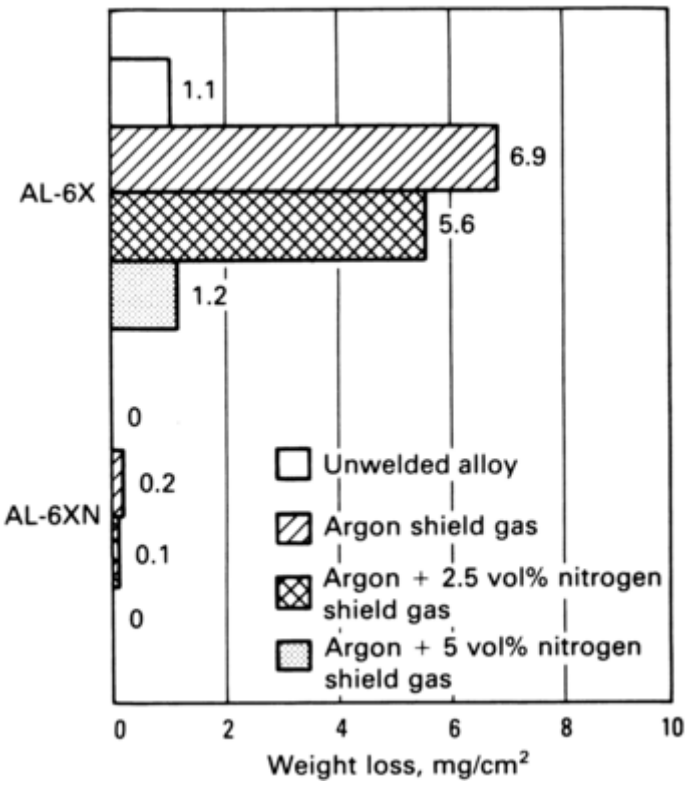

Fig. 21 Effect of gas tungsten arc weld shielding gas composition on the corrosion resistance of two austenitic stainless steels. Welded strip samples were tested according to ASTM G 48; test temperature was 35 °C (95 °F). Source: Ref 8

The nitrogen content of weld metal increases with the partial pressure of nitrogen in the GTA weld shielding gas. The increase in weld metal nitrogen content is greater when nitrogen is mixed with an oxidizing gas, such as carbon dioxide (CO_2), than with either a reducing (hydrogen) or a neutral (argon) gas. Porosity and concavity are observed in austenitic stainless steel weld metals when more than 10 vol% N is added to an argon shielding gas. Although solid-solution additions of nitrogen are not detrimental to the SCC resistance of unwelded molybdenum- containing austenitic stainless steels, an increased weld metal nitrogen content tends to increase susceptibility to SCC.

Effects of Heat-Tint Oxides on Corrosion Resistance. Under certain laboratory conditions, a mechanically stable chromium-enriched oxide layer can be formed on a stainless steel surface that enhances corrosion resistance. In contrast, the conditions created by arc-welding operations produce a scale composed of elements that have been selectively oxidized from the base metal. The region near the surface of an oxidized stainless steel is depleted in one or more of the elements that have reacted with the surrounding atmosphere to form the scale. The rate of oxidation for a stainless steel, and consequently the degree of depletion in the base metal, are independent of the alloy composition. They are controlled by diffusion through the oxide.

The oxidized, or heat-tinted, surface of a welded stainless steel consists of a heterogeneous oxide composed primarily of iron and chromium above a chromium-depleted layer of base metal. The properties of such a surface depend on:

- The time and temperature of the thermal exposure
- The composition of the atmosphere in contact with the hot metal surface
- The chemical composition of the base metal beneath the heat-tint oxide
- The physical condition of the surface (contamination, roughness, thermomechanical history) prior to heat tinting
- The adherence of the heat-tint oxide to the base metal

The defects, internal stresses, and composition of the heat-tint oxide make it a poor barrier to any corrosive media that might initiate localized corrosion in the chromium-depleted layer of base metal.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The severity of localized corrosion at heat- tinted regions exposed to oxidizing chloride solutions is directly related to the temperature of the hot metal surface during welding. A heat-tint oxide on an austenitic stainless steel exposed in air first becomes obvious at approximately 400 °C (750 °F). As the surface temperature is increased, differently colored oxides develop that appear to be superimposed on the oxides formed at lower temperatures. Table 2 shows the relationship between welding conditions and heat- tint color (Ref 9). Dark blue heat-tint oxides are the most susceptible to localized corrosion. Gas- shielded surfaces do not form the same distinctly colored oxides as surfaces exposed to air during welding, but gas-shielded surfaces can also be susceptible to preferential corrosion.

Table 2 Welding conditions and corrosion resistance of heat-tinted UNS S31726 stainless steel plate

Welding conditions[a]				Corrosion test results[b]		
Heat input		**Welding current, A**	**Centerline heat-tint color**	**Maximum pit depth**		**Number of pits on heat-tinted surface**
kJ/mm	**kJ/in.**			**mm**	**mils**	
0.3	7.525	50	None	0.1	4	2
0.59	15.050	100	Straw	0.7	28	10
0.89	22.576	150	Rose	0.8	31	50
1.19	30.101	200	Blue	0.7	28	>70
1.48	37.626	250	White	0.9	35	>70

(a) Single-pass autogenous bead-on-plate GTA welds were made to heat tint the root surface of 6.4 mm ($\frac{1}{4}$ in.) thick plate samples.
(b) Duplicate coupons, each with one 25 × 51 mm (1 × 2 in.) heat-tinted surface, were exposed to 10% $FeCl_3$ solutions at 50 °C (120 °F). The weld face and edges of each coupon were covered with a protective coating.

Whether a weld heat tint should be removed prior to service depends on the corrosion behavior of the given alloy when exposed to the particular environment in question. Preferential corrosion at heat-tinted regions is most likely to occur on an alloy that performs near the limit of its corrosion resistance in service, but certain solutions do not affect heat-tinted regions. Even when heat-tinted regions are suspected of being susceptible to accelerated corrosion in a particular environment, the following factors should be considered:

- The rate at which pits, once initiated in the chromium-depleted surface layer, will propagate through sound base metal
- The hazards associated with the penetration of a process unit due to localized corrosion
- The cost and effectiveness of an operation intended to repair a heat-tinted stainless steel surface

The corrosion resistance of heat-tinted regions can be restored in three stages. First, the heat- tint oxide and chromium-depleted layer are removed by grinding or wire brushing. Second, the abraded surface is cleaned with an acid solution or a pickling paste (a mixture of HNO_3 and HF suspended in an inert paste or gel) to remove any surface contamination and to promote the reformation of a passive film. Third, after a sufficient contact time, the acid cleaning solution or pickling paste is thoroughly rinsed with water, preferably demineralized or with a low chloride ion (Cl^-) content.

Grinding or wire brushing might not be sufficient to repair a heat-tinted region. Such abrading operations may only smear the heat-tint oxide and embed the residual scale into the surface, expose the chromium-depleted layer beneath the heat-tint oxide, and contaminate the surface with ferrous particles that were picked up by the grinding wheel or wire brush. A stainless steel surface should never be abraded with a wheel or brush that has been used on a carbon or low-alloy steel; wire brushes with bristles that are not made of a stainless steel of similar composition should also be avoided. Conversely, attempting to repair a heat-tinted region with only a pickling paste or acid solution can stain or even corrode the base metal if the solution is overly aggressive or is allowed to contact the surface for an extended time. If the acid is too weak, a chromium-depleted scale residue could remain on a surface, even if the chromium-depleted layer were completely removed by a grinding operation. Mechanically ground surfaces generally have inferior corrosion resistance compared to properly acid-pickled surfaces.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Unmixed Zones. All methods of welding stainless steel with a filler metal produce a weld fusion boundary consisting of base metal that has been melted but not mechanically mixed with filler metal and a partially melted zone in the base metal. The weld fusion boundary lies between a weld composite consisting of filler metal diluted by base metal and an HAZ in the base metal (Fig. 1). The width of the unmixed zone depends on the local thermal conditions along the weld fusion line. For a GTA welding process, the zone is narrowest at the weld face and widest near the middle of the weld thickness.

An unmixed zone has the composition of base metal but the microstructure of an autogenous weld. The microsegregation and precipitation phenomena characteristic of autogenous weldments decrease the corrosion resistance of an unmixed zone relative to the parent metal. Unmixed zones bordering welds made from overalloyed filler metals can be preferentially attacked when exposed on the weldment surface (Fig. 22). The potential for preferential attack of unmixed zones can be reduced by minimizing the heat input to the weld and/or by flowing molten filler metal over the surface of the unmixed zone to form a barrier to the service environment. Care must be taken in this latter operation to avoid cold laps and lack-of-fusion defects. In both cases, preferential attack is avoided as long as the surface of the unmixed zone lies beneath the exposed surface of the weldment.

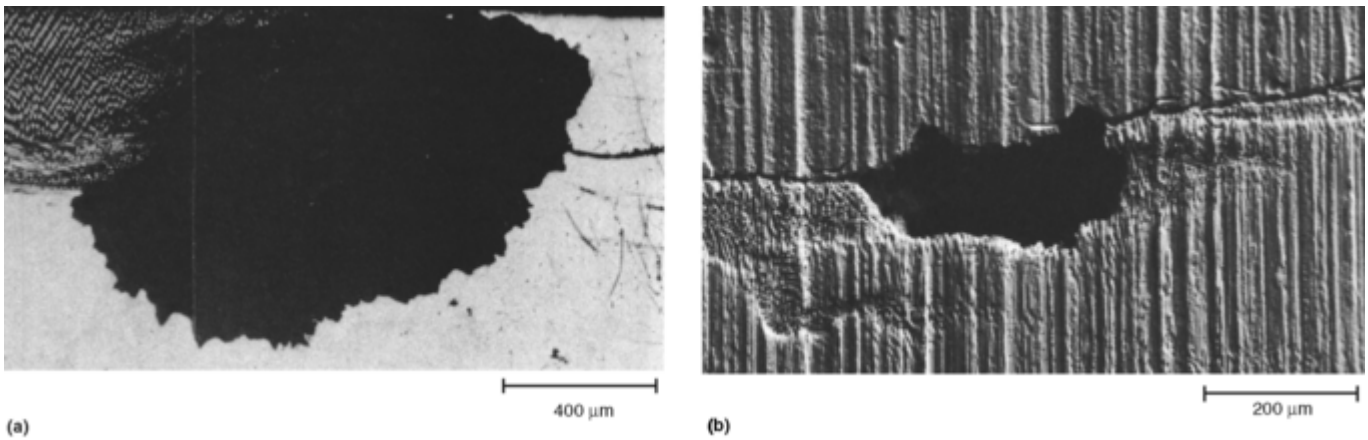

Fig. 22 Optical (a) and scanning electron (b) micrographs of pitting in the unmixed zone of Fe-Cr-Ni-Mo stainless steel plates that were gas tungsten arc welded with an overalloyed filler metal. The unmixed zones were preferentially attacked in an oxidizing acid chloride solution at elevated temperatures.

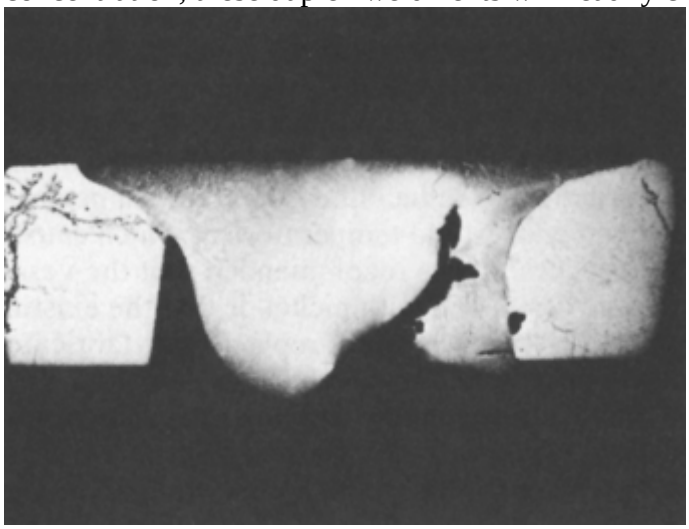
Chloride SCC. Welds in the 300-series austenitic stainless steels, with the exception of types 310 and 310Mo, contain a small amount of δ-ferrite (usually less than 10%) to prevent hot cracking during weld solidification. In hot, aqueous chloride environments, these duplex weldments generally show a marked resistance to cracking, while their counterparts crack readily (Fig. 23). The generally accepted explanation for this behavior is that the ferrite phase is resistant to chloride SCC and impedes crack propagation through the austenite phase. Electrochemical effects may also play a part; however, under sufficient tensile stress, temperature, and chloride concentration, these duplex weldments will readily crack. An example is shown in Fig. 24.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 23 Selective attack of a type 317L stainless steel weldment and chloride stress-corrosion cracking of the adjacent 317L base metal. The environment was a bleaching solution (7 g/L Cl_2) at 70 °C (160 °F).

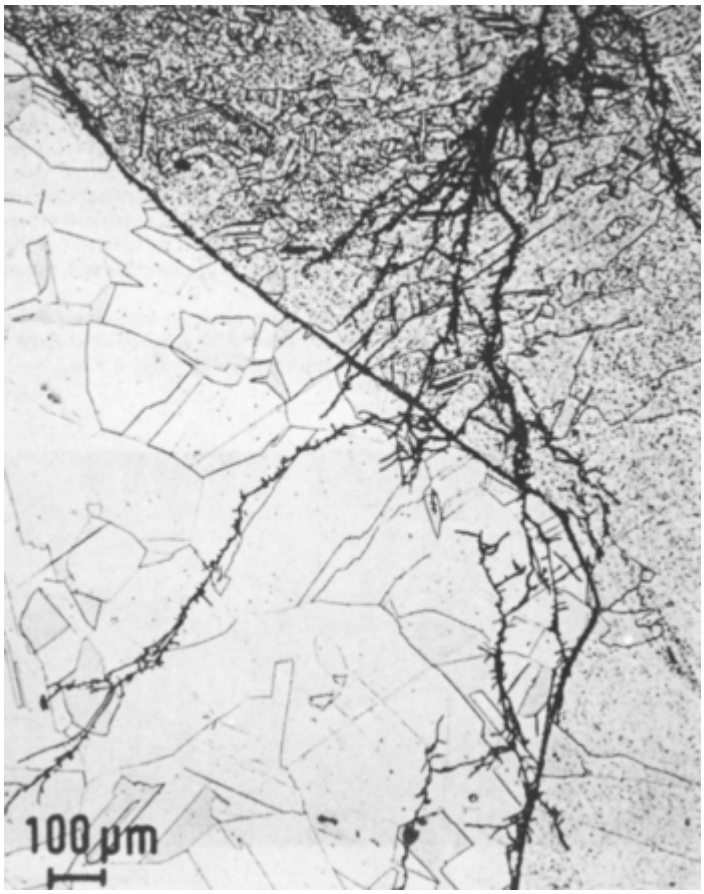


Fig. 24 Chloride stress-corrosion cracking of type 304 stainless steel base metal and type 308 weld metal in an aqueous chloride environment at 95 °C (200 °F). Cracks are branching and intergranular.

Caustic Embrittlement (Caustic SCC). Susceptibility of austenitic stainless steels to this form of corrosion usually becomes a problem when the caustic concentration exceeds approximately 25% and temperatures are above 100 °C (212 °F). Because welding is involved in most fabrications, the weld joint becomes the focus of attention because of potential stress-raiser effects and because of high residual shrinkage stresses. Cracking occurs most often in the weld HAZ.

In one case, a type 316L reactor vessel failed repeatedly by caustic SCC in which the process fluids contained 50% sodium hydroxide (NaOH) at 105 °C (220 °F). Failure was restricted to the weld HAZ adjacent to bracket attachment welds used to hold a steam coil. The stresses caused by the thermal expansion of the Nickel 200 steam coil at 1034 kPa (150 psig) aggravated the problem. Figure 25 shows the cracks in the weld HAZ to be branching and intergranular. Because it was not practical to reduce the operating temperature below the threshold temperature at which caustic SCC occurs, it was recommended that the vessel be weld overlayed with nickel or that the existing vessel be scrapped and a replacement fabricated from Nickel 200.

Microbiologically Influenced Corrosion (MIC). Microbiological corrosion in the process industries is most often found in three areas: cooling water systems, aqueous waste treatment, and groundwater left in new equipment or piping systems after testing. Nearly all confirmed cases of MIC have been accompanied by characteristic deposits. These are usually discrete mounds. Deposit color can also be an indication of the types of microorganisms that are active in the system. For example, iron bacteria deposits on stainless steel, such as those produced by *Gallionella,* are often reddish.

Investigators have shown that in almost all cases the environment causing the damage was a natural, essentially untreated water containing one or more culprit species of microbiological organisms. In the case of austenitic stainless steel weldments, corrosion generated by bacteria takes a distinctive form, that is, subsurface cavities with only minute pinhole penetration at the surface. The following case history illustrates these characteristics (Ref 10).

Example 1: Microbiological Corrosion of Butt Welds in Water Tanks. New production facilities at one plant site required austenitic stainless steels, primarily types 304L and 316L, for resistance to HNO_3 and organic acids and for maintaining product purity. The piping was shop fabricated, field erected, and then hydrostatically tested. All of the large (>190,000 L, or 25,000 gal) flat-bottom storage tanks were field erected and hydrostatically tested. During the early stages of construction, sodium-softened plant well water (also used for drinking) containing 200 ppm of chlorides was used for testing.

No attempts were made to drain the pipelines after testing. Tanks were drained, but then refilled to a depth of approximately 0.5 to 1 m (2 to 3 ft) for ballast because of a hurricane threat. The water was left in the tanks to evaporate.

The problem became evident when water was found dripping from butt welds in type 304L and 316L piping (nominal wall thickness 3.2 mm, or $\frac{1}{8}$ in.) approximately 1 and 4 months, respectively, after the hydrotest. Internal inspection showed pits in and adjacent to welds under reddish brown deposits. Tank manways were

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

uncovered, and similar conditions were found. As shown in Fig. 26, moundlike deposits were strung out along weld seams in the tank bottoms.

Fig. 26 Moundlike microbiological deposits along a weld seam in the bottom of a type 304L stainless steel tank after several months of exposure to well water at ambient temperature. Source: Ref 10

Figure 27 shows a closeup view of a typical deposit still wet with test water. The brilliantly colored deposit was slimy and gelatinous in appearance and to the touch, and it measured 75 to 100 mm (3 to 4 in.) in width. At one point during the investigation, a similar deposit on a weld that was covered with about 150 mm (6 in.) of water was thoroughly dispersed by hand. Twenty-four hours later, the deposit had returned in somewhat diminished form at exactly the same location.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

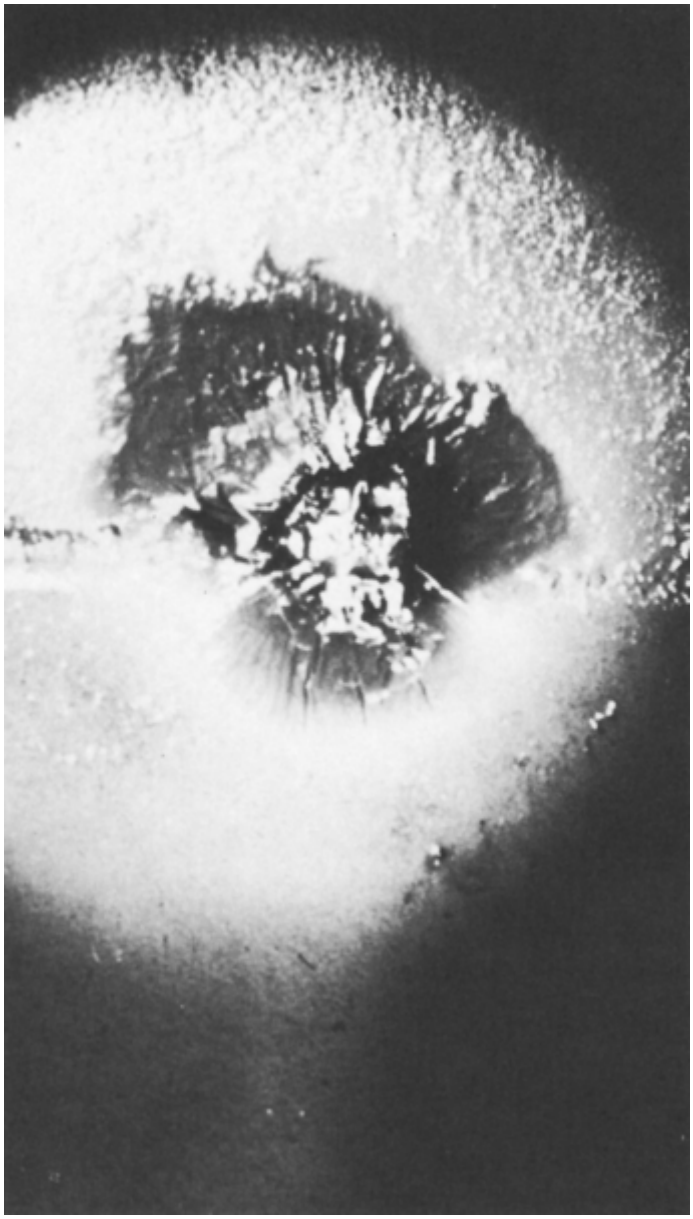

Fig. 27 Close-up of a wet deposit as shown in Fig. 26. Source: Ref 10

Figure 28 shows a nearly dry deposit. After wiping the deposit clean, a dark ring-shape stain outlining the deposit over the weld was noted (Fig. 29). There was, however, no evidence of pitting or other corrosion, even after light sanding with emery. Finally, probing with an icepick revealed a large, deep pit at the edge of the weld, as shown in Fig. 30. Figure 31, a radiograph of this weld seam, shows the large pit that nearly consumed the entire width of the weld bead, as well as several smaller pits. A cross section through a large pit in a 9.5 mm ($\frac{3}{8}$ in.) thick type 304L tank bottom is shown in Fig. 32.

interdendritic attack of base or weld metal. However, pitted welds in a type 316L tank showed preferential attack of the δ-ferrite stringers (Fig. 33).

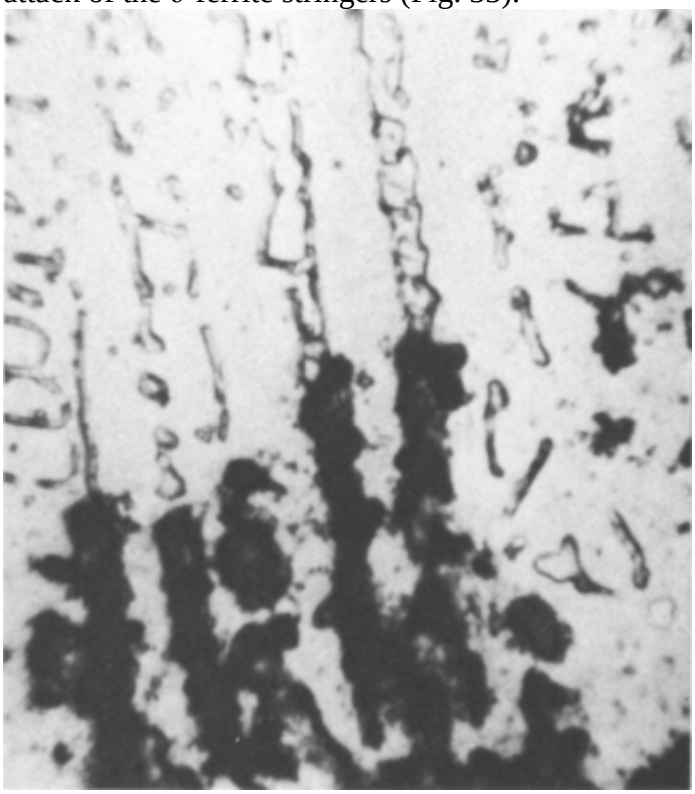

Fig. 33 Micrograph showing preferential attack of δ-ferrite stringers in type 316L stainless steel weld metal. 250×. Source: Ref 10

This type 316L tank was left full of hydrotest water for 1 month before draining. The bottom showed severe pitting under the typical reddish- brown deposits along welds. In addition, vertical rust-colored streaks (Fig. 34) were found above and below the sidewall horizontal welds, with deep pits at the edges of the welds associated with each streak (Fig. 35).

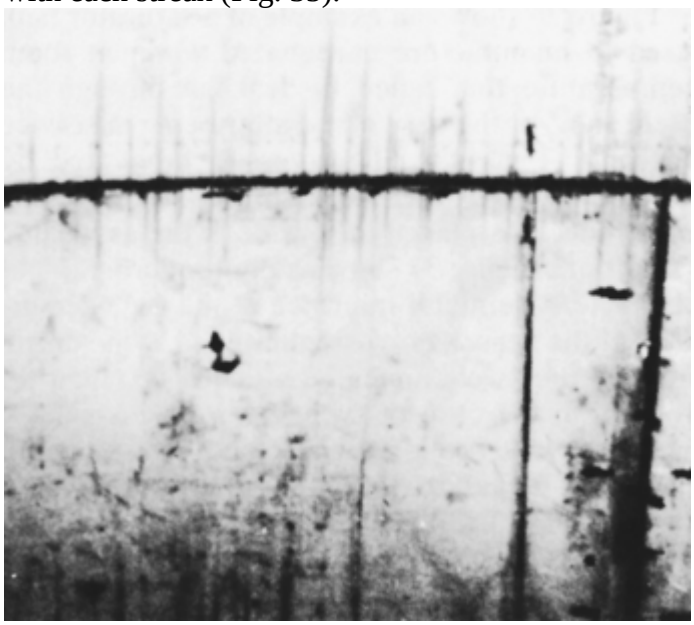

Fig. 34 Rust-colored streaks transverse to horizontal weld seams in the sidewall of a type 316L stainless steel tank. Source: Ref 10

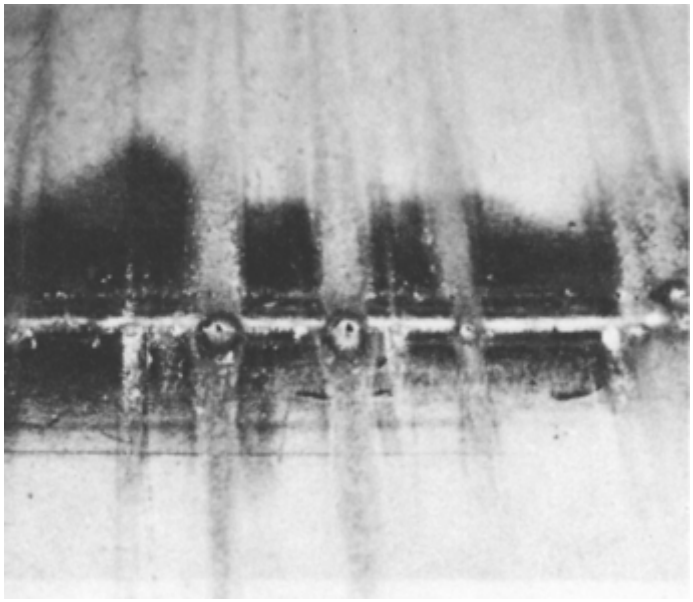

Fig. 35 Close-up of the rust-colored streaks shown in Fig. 34. Source: Ref 10

Analyses of the well water and the deposits showed high counts of iron bacteria (*Gallionella*) and iron-manganese bacteria (*Siderocapsa*). Both sulfate-reducing and sulfur-oxidizing bacteria were absent. The deposits also contained large amounts (thousands of parts per million) of iron, manganese, and chlorides.
As indicated, nearly all biodeposits and pits were found at the edges of, or very close to, weld seams. It is possible that the bacteria in stagnant well water were attracted by an electrochemical phenomenon or surface imperfections (oxide or slag inclusions, porosity, ripples, and so on) typically associated with welds. A sequence of events for the corrosion mechanism in this case might be:

1. Attraction and colonization of iron and iron- manganese bacteria at welds
2. Microbiological concentration of iron and manganese compounds, primarily chlorides, because Cl^- was the predominant anion in the well water
3. Microbiological oxidation to the corresponding ferric and manganic chlorides, which either singly or in combination are severe pitting corrodents of austenitic stainless steel
4. Penetration of the protective oxide films on the stainless steel surfaces that were already weakened by oxygen depletion under the biodeposits

All affected piping was replaced before the new facilities were placed in service. The tanks were repaired by sandblasting to uncover all pits, grinding out each pit to sound metal, and then welding with the appropriate stainless steel filler metal. Piping and tanks have been in corrosive service for about 19 years to date with very few leaks, indicating that the inspection, replacement, and repair program was effective.

Corrosion of Ferritic Stainless Steel Weldments

Conventional 400-series ferritic stainless steels such as types 430, 434, and 446 are susceptible to intergranular corrosion and to embrittlement in the as-welded condition. Corrosion in the weld area generally encompasses both the weld metal and weld HAZ. Early attempts to avoid some of these problems involved the use of austenitic stainless steel filler metals; however, failure by corrosion of the HAZ usually occurred even when exposure was to rather mild media for relatively short periods of time.

Figure 36 shows an example of a saturator tank used to manufacture carbonated water at room temperature that failed by leakage through the weld HAZ of the base metal after only 2 months of service. This vessel, fabricated by welding with a type 308 stainless steel welding electrode, was placed in service in the as-welded condition. Figure 37 shows a micrograph of the weld/base-metal interface at the outside surface of the vessel; corrosion initiated at the inside surface. Postweld annealing—at 785 °C (1450 °F) for 4 h in the case of type 430 stainless steel—restores weld area ductility and resistance to corrosion equal to that of the unwelded base metal.

To overcome some of these earlier difficulties and to improve weldability, several of the standard grade ferritic stainless steels have been modified. For example, type 405, containing nominally 11% Cr, is made with lower carbon and a small aluminum addition of 0.20% to restrict the formation of austenite at high temperature so that hardening is reduced during welding. For maximum ductility and corrosion resistance, however, postweld annealing is necessary. Recommendations for welding include either a 430- or a 309-type filler metal, the latter being used where increased weld ductility is desired.

Superferritic Stainless Steels. In the late 1960s and early 1970s, researchers recognized that a new generation of high Cr-Mo-Fe ferritic stainless steels, commonly referred to as *superferritics*, possess a desirable combination of good mechanical properties and resistance to general corrosion, pitting, and SCC. These properties make them attractive alternatives to the austenitic stainless steels commonly plagued by chloride SCC.

It was reasoned that the formation of martensite (as well as the need for preheat and postweld heat treatment) could be eliminated by controlling the interstitial element (carbon, oxygen, and nitrogen) content of these new ferritic alloys, either by ultrahigh purity or by stabilization with titanium or niobium. The welds would thus be corrosion resistant, tough, and ductile in the as-welded condition. To achieve these results, electron beam vacuum refining, vacuum and argon-oxygen decarburization, and vacuum induction melting processes were used. From this beginning, two basic ferritic alloy systems evolved:

- *Ultrahigh purity:* The (C + N) interstitial content is less than 150 ppm (Ref 12)
- *Intermediate purity:* The (C + N) interstitial content exceeds 150 ppm (Ref 12)

Chromium contents in these alloys generally range from 25 to 28% with ≥3% Mo (some alloys, however, contain less molybdenum). Nickel additions are also used with a maximum level of 4%. Although not usually mentioned in the alloy chemistry specifications, oxygen and hydrogen are also harmful, and these levels must be carefully restricted.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The unique as-welded properties of the superferritic stainless steels have been made possible by obtaining very low levels of impurities (including carbon, nitrogen, hydrogen, and oxygen, in the case of the alloys described as ultralow interstitials) and by obtaining a careful balance of niobium and/or titanium to match the carbon content in the case of the alloys with intermediate levels of interstitials. For these reasons, every precaution must be taken, and welding procedures that optimize gas shielding and cleanliness must be selected to avoid pickup of carbon, nitrogen, hydrogen, and oxygen.

To achieve maximum corrosion resistance, as well as maximum toughness and ductility, the GTA welding process with a matching filler metal is usually specified; however, dissimilar high-alloy weld metals have also been successfully used. In this case, the choice of dissimilar filler metal must ensure the integrity of the ferritic metal system. Regardless of which of the new generation of ferritic stainless steels is to be welded, the following precautions are considered essential:

- The joint groove and adjacent surfaces must be thoroughly degreased with a solvent, such as acetone, that does not leave a residue. This will prevent pickup of impurities, especially carbon, before welding. The filler metal must also be handled carefully to prevent it from picking up impurities. Solvent cleaning is also recommended. *Caution: Under certain conditions, when using solvents, a fire hazard or health hazard may exist.*
- A welding torch with a large nozzle inside diameter, such as 19 mm ($\frac{3}{4}$ in.), and a gas lens (inert gas calming screen) is necessary. Pure, welding-grade argon with a flow rate of 28 L/min (60 ft^3/h) is required for this size nozzle. In addition, the use of a trailing gas shield is beneficial, especially when welding heavy-gage materials. Use of these devices will drastically limit the pickup of nitrogen and oxygen during welding. Back gas shielding with argon is also essential. *Caution: Procedures for welding austenitic stainless steels often recommend the use of nitrogen backing gas. Nitrogen must not be used when welding ferritic stainless steels. Standard GTA welding procedures used to weld stainless steels are inadequate and therefore must be avoided.*
- Overheating and embrittlement by excessive grain growth in the weld and HAZ should be avoided by minimizing heat input. In multipass welds, overheating and embrittlement should be avoided by keeping the interpass temperature below 95 °C (200 °F).
- To avoid embrittlement further, preheating (except to remove moisture) or postweld heat treating should not be performed. Postweld heat treatment is used only with the conventional (less highly alloyed) ferritic stainless alloys.

The following example illustrates the results of not following proper procedures.

Example 2: Corrosion of Welds in a Ferritic Stainless Steel Wastewater Vaporizer. A nozzle in a wastewater vaporizer began leaking after approximately 3 years of service with acetic and formic acid wastewaters at 105 °C (225 °F) and 414 kPa (60 psig).

Investigation. The shell of the vessel was weld fabricated in 1972 from 6.4 mm ($\frac{1}{4}$ in.) E-Brite (UNS S44627, Fe-26Cr-1Mo+Nb) stainless steel plate. The shell measured 1.5 m (58 in.) in diameter and 8.5 m (28 ft) in length. Nondestructive examination included 100% radiography, dye-penetrant inspection, and hydrostatic testing of all E-Brite welds.

An internal inspection of the vessel revealed that portions of the circumferential and longitudinal seam welds, in addition to the leaking nozzle weld, displayed intergranular corrosion. At the point of leakage, there was a small intergranular crack. Figure 38 shows a typical example of a corroded weld. A transverse cross section through this weld will characteristically display intergranular corrosion with grains dropping out (Fig. 39). It was also noted that the HAZ next to the weld fusion line also experienced intergranular corrosion a couple of grains deep as a result of sensitization (Fig. 40).

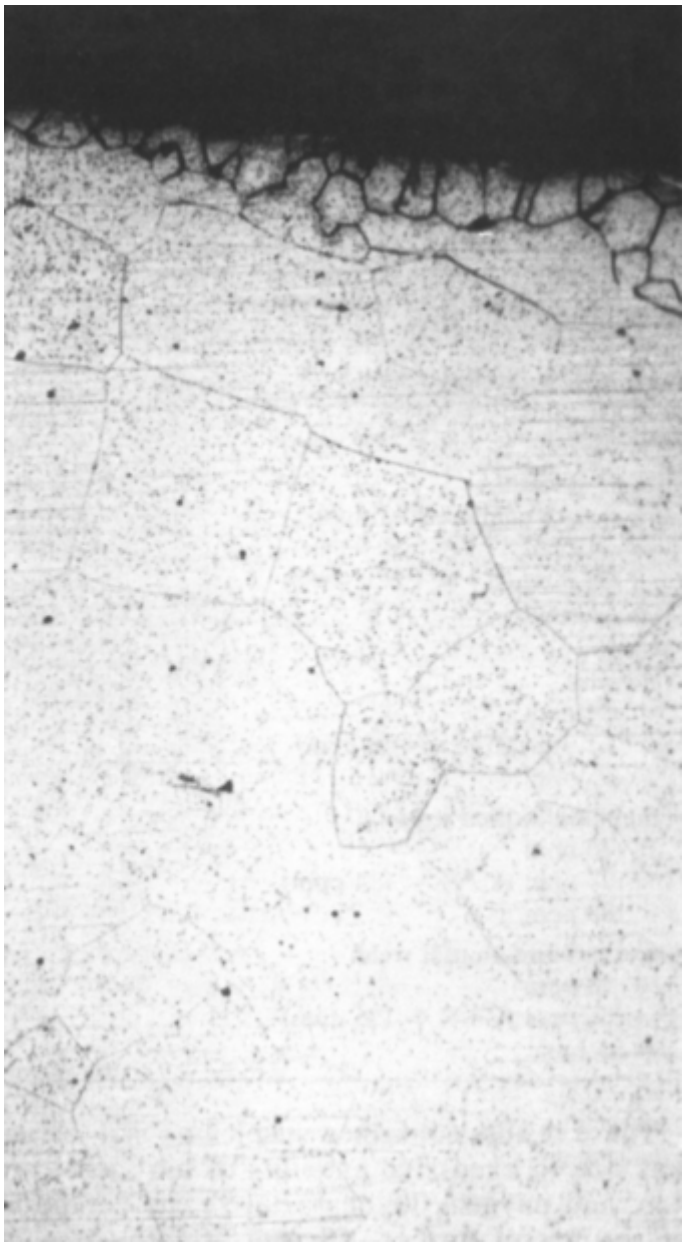

Fig. 40 Intergranular corrosion of the inside surface heat-affected zone of E-Brite stainless steel adjacent to the weld fusion line. Electrolytically etched with 10% oxalic acid. 100×

The evidence indicated weldment contamination; therefore, effort was directed at finding the levels of carbon, nitrogen, and oxygen in the various components present before and after welding. The averaged results were:

Base plate
C = 6 ppm
N = 108 ppm (C + N = 114 ppm)
O = 57 ppm
Corroded longitudinal weld
C = 133 ppm
N = 328 ppm (C + N = 461 ppm)
O = 262 ppm
Corroded circumferential weld
C = 34 ppm
N = 169 ppm (C + N = 203 ppm)

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

O = 225 ppm
Weld wire
C = 3 ppm
N = 53 ppm (C + N = 56 ppm)
O = 55 ppm
Sound longitudinal weld
C = 10 ppm
N = 124 ppm (C + N = 134 ppm)
O = 188 ppm
Sound circumferential weld
C = 20 ppm
N = 106 ppm (C + N = 126 ppm)
O = 85 ppm

These results confirmed suspicions that failure was due to excessive amounts of nitrogen, carbon, and oxygen. To characterize the condition of the vessel further, Charpy V-notch impact tests were run on the unaffected base metal, the HAZ, and the uncorroded (sound) weld metal. These tests showed the following ductile-to-brittle transition temperatures:

Specimen	Ductile-to-brittle transition temperature	
	°C	**°F**
Base metal	40 ± 3	105 ± 5
HAZ	85 ± 3	180 ± 5
Weld	5 ± 3	40 ± 5

Comparison of the interstitial levels of the corroded welds, sound welds, base metal, and filler wire suggested that insufficient joint preparation (carbon pickup) and faulty gas shielding were probably the main contributing factors that caused this weld corrosion failure. Discussions with the vendor uncovered two discrepancies. First, the welder was using a large, 19 mm ($\frac{3}{4}$ in.) inside diameter ceramic nozzle with a gas lens, but was flowing only 19 L/min (40 ft^3/h) of argon; this was the flow rate previously used with a 13 mm ($\frac{1}{2}$ in.) inside diameter gas lens nozzle. Second, a manifold system was used to distribute pure argon welding gas from a large liquid argon tank to various satellite welding stations in the welding shop. The exact cause for the carbon pickup was not determined.

Conclusions. Failure of the nozzle weld was the result of intergranular corrosion caused by the pickup of interstitial elements and subsequent precipitation of chromium carbides and nitrides. Carbon pickup was believed to have been caused by inadequate joint cleaning prior to welding. The increase in the weld nitrogen level was a direct result of inadequate argon gas shielding of the molten weld pool. Two areas of inadequate shielding were identified: improper gas flow rate for a 19 mm ($\frac{3}{4}$ in.) diam gas lens nozzle and contamination of the manifold gas system.

In order to preserve the structural integrity and corrosion performance of the more highly alloyed ferritic stainless steels, it is important to avoid the pickup of the interstitial elements carbon, nitrogen, oxygen, and hydrogen. In this particular case, the vendor used a flow rate intended for a smaller welding torch nozzle. The metal supplier recommended a flow rate of 23 to 38 L/ min (50 to 60 ft^3/min) of argon for a 19 mm ($\frac{3}{4}$ in.) gas lens nozzle. The gas lens collect body is an important and necessary part of the torch used to weld these alloys. Failure to use a gas lens will result in a flow condition that is turbulent enough to aspire air into the gas stream, thus contaminating the weld and destroying its mechanical and corrosion properties.

The manifold gas system also contributed to this failure. When this system is first used, it is necessary to purge the contents of the manifold of any air to avoid oxidation and contamination. When that is done, the system functions satisfactorily; however, when it is shut down overnight or for repairs, air reinfiltrates, and a source of contamination is reestablished. Manifold systems are never fully purged, and leaks are common.

The contaminated welds were removed, and the vessels were rewelded and put back into service. Some rework involved the use of covered electrodes of dissimilar composition. No problems have been reported to date.

Recommendations:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- To ensure proper joint cleaning, solvent washing and wiping with a clean lint-free cloth should be performed immediately before welding. The filler wire should be wiped with a clean cloth just prior to welding. *Caution: Solvents are generally flammable and can be toxic. Ventilation should be adequate. Cleaning should continue until cloths are free of any residues.*
- When GTA welding, a 19 mm ($\frac{3}{4}$ in.) diam ceramic nozzle with a gas lens collect body is recommended. An argon gas flow rate of 28 L/min (60 ft^3/min) is optimum. Smaller nozzles are not recommended. Argon back gas shielding is mandatory at a slight positive pressure to avoid disrupting the flow of the welding torch.
- The tip of the filler wire should be kept within the torch shielding gas envelope to avoid contamination and pickup of nitrogen and oxygen. (They embrittle the weld.) If the tip becomes contaminated, welding should be stopped, the contaminated weld area should be ground out, and the tip of the filler wire that has been oxidized should be snipped off before proceeding with welding.
- A manifold gas system should not be used to supply shielding and backing gas. Individual argon gas cylinders have been found to provide optimal performance. A weld button spot test should be performed to confirm the integrity of the argon cylinder and all hose connections. In this test, the weld button sample should be absolutely bright and shiny. Any cloudiness is an indication of contamination. It is necessary to check for leaks or to replace the cylinder.
- Corrosion resistance is not the only criterion when evaluating these new ferritic stainless steels. Welds must also be tough and ductile, and these factors must be considered when fabricating welds.

Lastly, dissimilar weld filler metals can be successfully used. To avoid premature failure, the dissimilar combination should be corrosion tested to ensure suitability for the intended service.

Corrosion of Duplex Stainless Steel Weldments

In the wrought condition, duplex stainless steels have microstructures consisting of a fairly even balance of austenite and ferrite. The new generation of duplex alloys, which have a composition centered around Fe-26Cr-6.5Ni-3.0Mo, are now being produced with low carbon and a nitrogen addition. These alloys are useful because of their good resistance to chloride SCC, pitting corrosion, and intergranular corrosion in the as-welded condition.

The distribution of austenite and ferrite in the weld and HAZ is known to affect the corrosion properties and the mechanical properties of duplex stainless steels. Figure 41 shows the effect of the ferrite-austenite balance on the pitting resistance of a duplex stainless steel. To achieve a satisfactory balance in properties, it is essential that both base metal and weld metal be of the proper composition. For example, without nickel enrichment in the filler rod, welds can be produced with ferrite levels in excess of 80%. Such microstructures have very poor

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

ductility and inferior corrosion resistance. For this reason, autogenous welding (without the addition of filler metal) is not recommended unless postweld solution annealing is performed, which is not always practical. To achieve a balanced weld microstructure, a low carbon content (~0.02%) and the addition of nitrogen (0.1 to 0.2%) should be specified for the base metal. Low carbon helps to minimize the effects of sensitization, and the nitrogen slows the precipitation kinetics associated with the segregation of chromium and molybdenum during the welding operation. Nitrogen also enhances the reformation of austenite in the HAZ and weld metal during cooling.

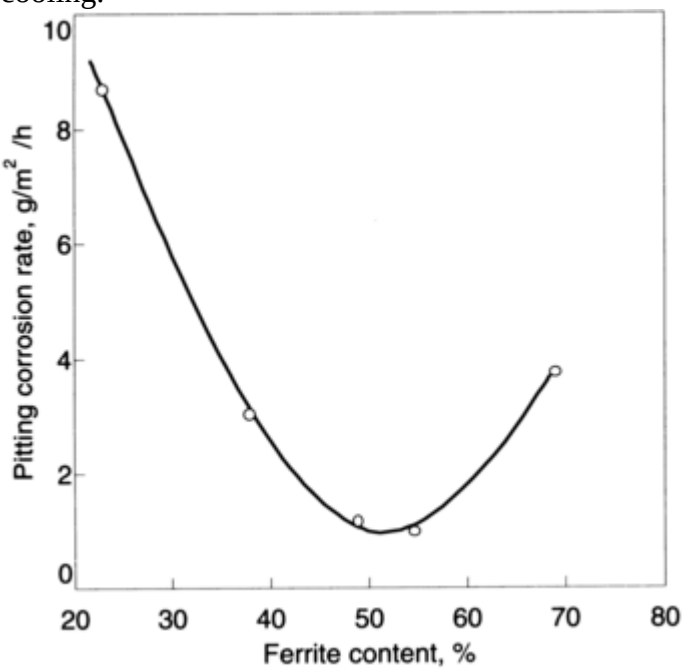

Fig. 41 Effect of ferrite-austenite balance on pitting resistance of Fe-22Cr-5.5Ni-3.0Mo-0.12N gas tungsten arc stainless steel welds. Source: Ref 13

Because these duplex alloys have been used in Europe for many years, guidelines relating to austenite-ferrite phase distribution are available. It has been shown that to ensure resistance to chloride SCC, welds should contain at least 25% ferrite. To maintain a good phase balance for corrosion resistance and mechanical properties (especially ductility and notch toughness) comparable to those of the base metal, the average ferrite content of the weld should not exceed 60%. This means using welding techniques that minimize weld dilution, especially in the root pass. Conditions that encourage mixing of the lower-nickel base metal with the weld metal reduce the overall nickel content. Weld metal with a lower nickel content will have a higher ferrite content, with reduced mechanical and corrosion properties. Once duplex base metal and welding consumables have been selected, it is then necessary to select joint designs and weld parameters that will produce welding heat inputs and cooling rates so as to produce a favorable balance of austenite and ferrite in the weld and HAZ.

Researchers have shown that the high-ferrite microstructures that develop during welding in lean (low-nickel) base metal and weld metal compositions can be altered by adjusting welding heat input and cooling rate. In these cases, a higher heat input that produces a slower cooling rate can be used to advantage by allowing more time for ferrite to transform to austenite. There are, however, some practical aspects to consider before applying higher heat inputs indiscriminately. For example, as heat input is increased, base metal dilution increases. As the amount of lower-nickel base metal in the weld increases, the overall nickel content of the deposit decreases. This increases the potential for more ferrite, with a resultant loss in impact toughness, ductility, and corrosion resistance. This would be another case for using an enriched filler metal containing more nickel than the base metal. Grain growth and the formation of embrittling phases are two other negative effects of high heat inputs. When there is uncertainty regarding the effect that welding conditions will have on corrosion performance and mechanical properties, a corrosion test is advisable.

The influence of different welding conditions on various material properties of alloy 2205 (UNS S31803, Fe-22Cr-5.5Ni-3.0Mo-0.15N) has been studied (Ref 14). Chemical compositions of test materials are given in Table 3, and the results of the investigation are detailed in the following sections.

Intergranular Corrosion. Despite the use of very high arc energies (0.5 to 6 kJ/mm, or 13 to 150 kJ/in.) in combination with multipass welding, the Strauss test (ASTM A 262, practice E) (Ref 7) failed to uncover any signs of sensitization after bending through 180°. The results of Huey tests (ASTM A 262, practice C) on submerged-arc welds showed that the corrosion rate increased slightly with arc energy in the studied range of 0.5 to 6.0 kJ/mm (13 to 150 kJ/in.). For comparison, the corrosion rate for parent metal typically varies between 0.15 and 1.0 mm/yr (6 and 40 mils/yr), depending on surface finish and heat treatment cycle.

Similar results were obtained in Huey tests of specimens from bead-on-tube welds produced by GTA welding. In this case, the corrosion rate had a tendency to increase slightly with arc energy up to 3 kJ/mm (75 kJ/in.).

Pitting tests were conducted in 10% ferric chloride ($FeCl_3$) at 25 and 30 °C (75 and 85 °F) in accordance with ASTM G 48 (Ref 15). Results of tests on submerged-arc test welds did not indicate any significant change in pitting resistance when the arc energy was increased from 1.5 to 6 kJ/mm (38 to 150 kJ/in.). Pitting occurred along the boundary between two adjacent weld beads. Attack was caused by slag entrapment in the weld; therefore, removal of slag is important.

Gas tungsten arc weld test specimens (arc energies from 0.5 to 3 kJ/mm, or 13 to 75 kJ/in.) showed a marked improvement in pitting resistance with increasing arc energy. In order for duplicate specimens to pass the $FeCl_3$ test at 30 °C (85 °F), 3 kJ/mm (75 kJ/in.) of arc energy was required. At 25 °C (75 °F), at least 2 kJ/mm (50 kJ/in.) was required to achieve immunity. Welds made autogenously (no nickel enrichment) were somewhat inferior; improvements were achieved by using higher arc energies.

For comparison with a different alloy, Fig. 42 shows the effect of heat input on the corrosion resistance of Ferralium alloy 255 (UNS S32550, Fe-25.5Cr-5.5Ni-3.0Mo-0.17N) welds made autogenously and tested on $FeCl_3$ at 15 °C (60 °F). Preferential corrosion of the ferrite phase is shown in Fig. 43. In a different test, Ferralium alloy 255 was welded autogenously and tested in a neutral chloride solution according to ASTM D 1141 (Ref 17) at 60 to 100 °C (140 to 212 °F). In this case, preferential attack of the austenite phase was observed. An example is shown in Fig. 44. Similar results would be expected for alloy 2205.

A study of the alloy 2205 weld microstructures (Ref 14) revealed why high arc energies were found to be beneficial to pitting resistance. Many investigations have indicated that the presence of chromium nitrides in the ferrite phase lowers the resistance to pitting of the weld metal and the HAZ in duplex stainless steels. In this study, both weld metal and HAZ produced by low arc energies contained an appreciable amount of chromium nitride (Cr_2N) (Fig. 45). The nitride precipitation vanished when an arc energy of 3 kJ/mm (75 kJ/in.) was used (Fig. 46).

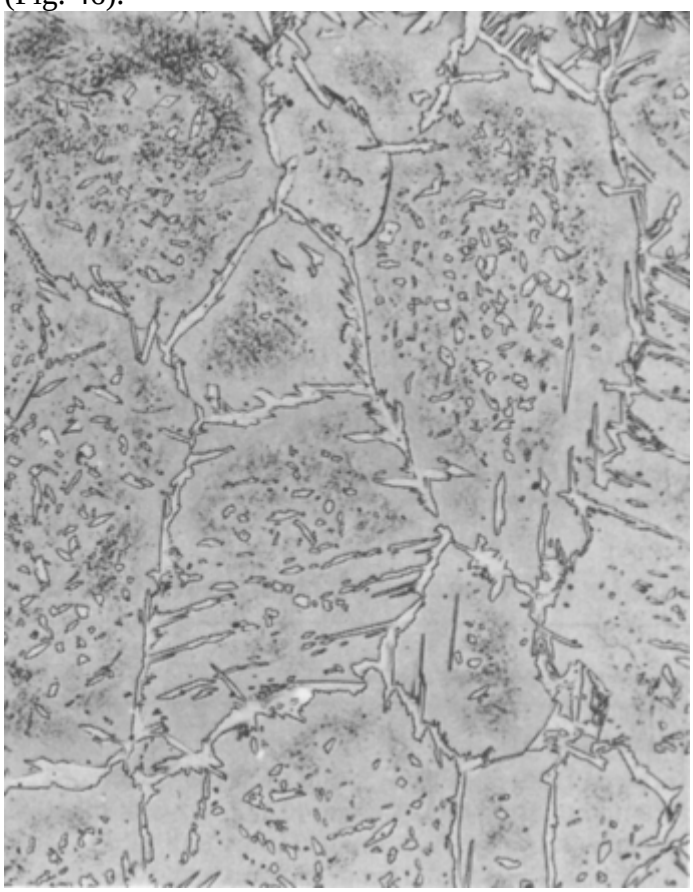

Fig. 45 Microstructure of bead-on-tube weld made by autogenous gas tungsten arc welding with an arc energy of 0.5 kJ/mm (13 kJ/in.). Note the abundance of chromium nitrides in the ferrite phase. See also Fig. 46. 200×. Source: Ref 14

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

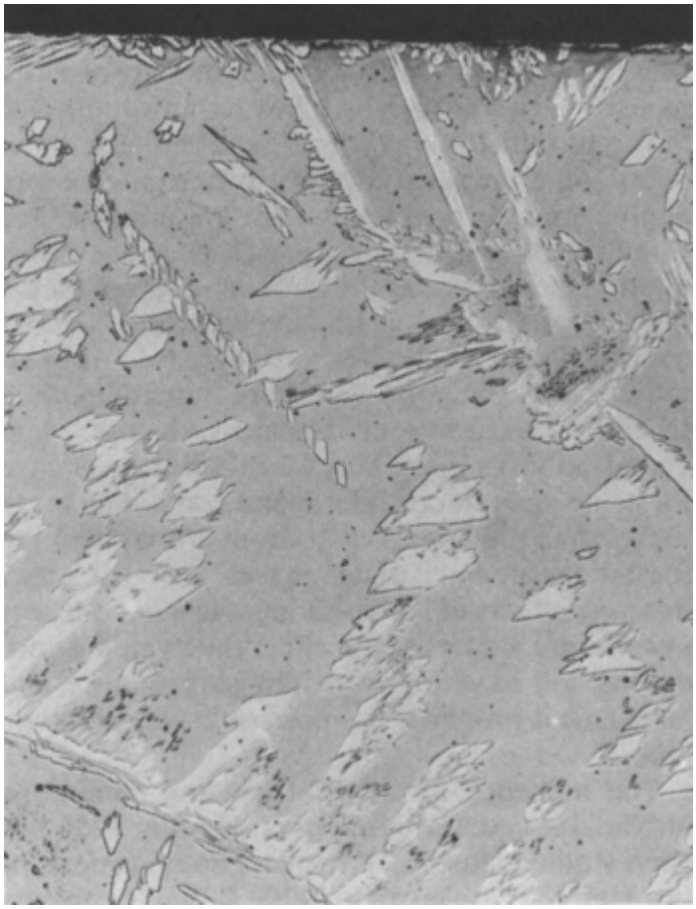

Fig. 46 Microstructure of bead-on-tube weld made by autogenous gas tungsten arc welding with an arc energy of 3 kJ/mm (76 kJ/in.). Virtually no chromium nitrides are present, which results in adequate pitting resistance. 200×. Source: Ref 14

The results of $FeCl_3$ tests on submerged-arc welds showed that all top weld surfaces passed the test at 30 °C (85 °F) without pitting attack, irrespective of arc energy in the range of 2 to 6 kJ/mm (50 to 150 kJ/in.). Surprisingly, the weld metal on the root side, which was the first to be deposited, did not pass the same test temperature.

The deteriorating effect of high arc energies on the pitting resistance of the weld metal on the root side was unexpected. Potentiostatic tests carried out in 3% sodium chloride (NaCl) at 400 mV versus saturated calomel electrode SCE confirmed these findings. Microexamination of the entire joint disclosed the presence of extremely fine austenite precipitates, particularly in the second weld bead (Fig. 47) but also in the first or root side bead. The higher the arc energy, the more austenite of this kind was present in the first two weld beads. Thus, nitrides give rise to negative effects on the pitting resistance, as do fine austenite precipitates that were presumably reformed at as low a temperature as approximately 800 °C (1470 °F).

The extremely fine austenite precipitate was formed as a result of reheating from the subsequent weld pass, which used an arc energy of 6 kJ/mm (150 kJ/in.). 1000×. Source: Ref 14

Therefore, the resistance of alloy 2205 to pitting corrosion is dependent on several factors. First, chromium nitride (Cr_2N) precipitation in the coarse ferrite grains upon rapid cooling from temperatures above about 1200 °C (2190 °F) causes the most severe impairment to pitting resistance. This statement is supported by a great number of $FeCl_3$ tests as well as by potentiostatic pitting tests. Generally, it seems difficult to avoid Cr_2N precipitation in welded joints completely, particularly in the HAZ, the structure of which can be controlled only by the weld thermal cycle. From this point of view, it appears advisable to employ as high an arc energy as practical in each weld pass. In this way, the cooling rate will be slower (but not slow enough to encounter 475 °C, or 885 °F, embrittlement), and the re- formation of austenite will clearly dominate over the precipitation of Cr_2N.

In addition, if there were no restriction on maximum interpass temperature, the heat produced by previous weld passes could be used to decrease the cooling rate further in the critical temperature range above about 1000 °C (1830 °F). Preliminary tests with preheated workpieces have shown the significance of temperature in suppressing Cr_2N precipitation. Currently, the maximum recommended interpass temperature for alloy 2205 is 150 °C (300 °F). This temperature limit does not appear to be critical, and it is suggested that this limit could be increased to 300 °C (570 °F). The maximum recommended interpass temperature for Ferralium alloy 255 is 200 °C (390 °F). Excessive grain growth as a result of too much heat input must also be considered to avoid loss of ductility and impact toughness.

Second, the fine austenite precipitates found in the reheated ferrite when high arc energies and multipass welding were combined are commonly referred to as γ_2 in the literature. The harmful influence of γ_2 on the pitting resistance has been noted with isothermally aged specimens, but as far as is known, it has never been observed in connection with welding. It is felt, however, that γ_2 is less detrimental to pitting than Cr_2N.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Moreover, γ_2 formation is believed to be beneficial to mechanical properties, such as impact strength and ductility.

A third factor that lowers pitting resistance is oxide scale. Where possible, all surface oxides should be removed by mechanical means or, preferably, by pickling. Root surfaces (in pipe), however, are generally inaccessible, and pitting resistance must rely on the protection from the backing gas during GTA welding. It is therefore advisable to follow the current recommendation for stainless steels, which is a maximum of 25 ppm oxygen in the root backing gas.

Stress-Corrosion Cracking. The SCC resistance of alloy 2205 in aerated, concentrated chloride solutions is very good. The effect of welding on the SCC resistance is negligible from a practical point of view. The threshold stress for various welds, as well as for unwelded parent metal in the calcium chloride ($CaCl_2$) test, is as high as 90% of the tensile strength at the testing temperature. This is far above all conceivable design limits.

Also, in environments containing both hydrogen sulfide (H_2S) and chlorides, the resistance of welds is almost as high as for the parent metal. In this type of environment, however, it is important to avoid too high a ferrite content in weld metal and the HAZ. For normal welding of joints, the resulting ferrite contents should not cause any problems. For weld repair situations, however, care should be taken so that extremely high ferrite contents (>75%) are avoided. To preserve the high degree of resistance to SCC, the ferrite content should not be less than 25% (Ref 18).

Another reason to avoid coarse weld microstructures (generated by excessive welding heat) is the resultant nonuniform plastic flow, which can locally increase stresses and induce preferential corrosion and cracking effects.

Use of High-Alloy Filler Metals. In critical pitting or crevice corrosion applications, the pitting resistance of the weld metal can be enhanced by the use of high Ni-Cr-Mo alloy filler metals. The corrosion resistance of such weldments in Ferralium alloy 255 is shown in Table 4. For the same weld technique, it can be seen that using high-alloy fillers does improve corrosion resistance. If high-alloy fillers are used, the weld metal will have better corrosion resistance than the HAZ and the fusion line. Therefore, again, proper selection of welding technique can improve the corrosion resistance of the weldments.

Corrosion of Nonferrous Alloy Weldments, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 317–321

Corrosion of Nonferrous Alloy Weldments

Introduction

IT IS NOT UNUSUAL to find that, although the wrought form of a metal or alloy is resistant to corrosion in a particular environment, the welded counterpart is not. Further, welds can be made with or without the addition of filler metal. However, there are also many instances in which the weld exhibits corrosion resistance superior to that of the unwelded base metal. There also are times when the weld behaves in an erratic manner, displaying both resistance and susceptibility to corrosive attack. Corrosion failures of welds occur in spite of the fact that the proper base metal and filler metal have been selected, industry codes and standards have been followed, and welds have been deposited that possess full weld penetration and have proper shape and contour.
It is sometimes difficult to determine why welds corrode; however, one or more of the following factors often are implicated:

- Weldment design
- Fabrication technique
- Welding practice
- Welding sequence
- Moisture contamination
- Organic or inorganic chemical species
- Oxide film and scale
- Weld slag and spatter
- Incomplete weld penetration or fusion
- Porosity
- Cracks (crevices)
- High residual stresses
- Improper choice of filler metal
- Final surface finish

This article describes some of the metallurgical factors that affect corrosion of weldments and then reviews considerations for selected nonferrous alloy systems: aluminum, titanium, tantalum, and nickel.

Corrosion of Nonferrous Alloy Weldments, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 317–321

Metallurgical Factors

The cycle of heating and cooling that occurs during the welding process affects the microstructure and surface composition of welds and adjacent base metal. Consequently, the corrosion resistance of autogenous welds (welds made without the addition of filler metals) and welds made with matching filler metal may be inferior to that of properly annealed base metal because of:

- Microsegregation

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- Precipitation of secondary phases
- Formation of unmixed zones
- Recrystallization and grain growth in the weld heat-affected zone (HAZ)
- Volatilization of alloying elements from the molten weld pool
- Contamination of the solidifying weld pool

Corrosion resistance can usually be maintained in the welded condition by balancing alloy compositions to inhibit certain precipitation reactions, by shielding molten and hot metal surfaces from reactive gases in the weld environment, by removing chromium-enriched oxides and chromium-depleted base metal from thermally discolored (heat tinted) surfaces, and by choosing the proper welding parameters (Ref 1).

Weld Solidification. During the welding process, a number of important changes occur that can significantly affect the corrosion behavior of the weldment. Heat input and welder technique obviously play important roles. The way in which the weld solidifies is equally important to understanding how weldments may behave in corrosive environments (Ref 2).

A metallographic study has shown that welds solidify into various regions, as illustrated in Fig. 1. The composite region, or weld nugget, consists of essentially filler metal that has been diluted with material melted from the surrounding base metal. Next to the composite region is the unmixed zone, a zone of base metal that melted and solidified during welding without experiencing mechanical mixing with the filler metal. The weld interface is the surface bounding the region within which complete melting was experienced during welding, and it is evidenced by the presence of a cast structure. Beyond the weld interface is the partially melted zone, which is a region of the base metal within which the proportion melted ranges from 0 to 100%. Lastly, the true HAZ is that portion of the base metal within which microstructural change has occurred in the absence of melting. Although the various regions of a weldment shown in Fig. 1 are for a single-pass weld, similar solidification patterns and compositional differences can be expected to occur in underlying weld beads during multipass applications.

Corrosion of Aluminum Alloy Weldments

Variations in microstructure across the weld and HAZ of aluminum weldments are known to produce susceptibility to corrosion in certain environments (Ref 4). These differences can be measured electrochemically and are an indication of the type of corrosion behavior that might be expected. Although some aluminum alloys can be autogenously welded, the use of a filler metal is preferred to avoid cracking during welding and to optimize corrosion resistance.

The variations in corrosion potential (equilibrium potential) across three welds are shown in Fig. 2 for alloys 5456, 2219, and 7039. These differences can lead to localized corrosion, as demonstrated by the corrosion of the HAZ of an as-welded structure of alloy 7005 shown in Fig. 3. In general, the welding procedure that puts the least amount of heat into the metal has the least influence on microstructure and the least chance of reducing the corrosion behavior of aluminum weldments.

Tables are available in the article “Welding of Aluminum Alloys” in *Welding, Brazing, and Soldering,* Volume 6 of *ASM Handbook,* that summarize filler alloy selection recommended for welding various combinations of base metal alloys to obtain maximum properties, including corrosion resistance. Care must be taken not to extrapolate the corrosion performance ratings indiscriminately. Corrosion behavior ratings generally pertain only to the particular environment tested, usually rated in continuous or alternate immersion in fresh or saltwater. For example, the highest corrosion rating (A) is listed for use of filler alloy 4043 to join 3003 alloy to 6061 alloy. In strong (99%) nitric acid (HNO_3) service, however, a weldment made with 4043 filler alloy would experience more rapid attack than a weldment made using 5556 filler metal. With certain alloys, particularly those of the heat treatable 7*xxx* series, thermal treatment after welding is sometimes used to obtain maximum corrosion resistance (Fig. 3) (Ref 5, 6, 7).

As with many other alloy systems, attention must be given to the threat of crevice corrosion under certain conditions. Strong (99%) HNO_3 is particularly aggressive toward weldments that are not made with full weld penetration. Although all of the welds shown in Fig. 4 appear to be in excellent condition when viewed from the outside surface, the first two welds (Fig. 4a and b), viewed from the inside, are severely corroded. The weld made using standard gas tungsten arc (GTA) welding practices with full weld penetration (Fig. 4c) is in good condition after 2 years of continuous service.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 4 Corrosion of three aluminum weldments in HNO_3 service. (a) and (b) Gas tungsten arc (GTA) and oxyacetylene welds, respectively, showing crevice corrosion on the inside surface. (c) Standard GTA weld with full penetration is resistant to crevice corrosion.

Researchers have shown that aluminum alloys, both welded and unwelded, have good resistance to uninhibited HNO_3 (both red and white) up to 50 °C (120 °F). Above this temperature, most aluminum alloys exhibit knife-line attack (a very thin region of corrosion) adjacent to the welds. Above 50 °C (120 °F), the depth of knife-line attack increases markedly with temperature. One exception was found in the case of a fusion-welded 1060 alloy in which no knife-line attack was observed even at temperatures as high as 70 °C (160 °F). In inhibited fuming HNO_3 containing at least 0.1% hydrofluoric acid (HF), no knife-line attack was observed for any commercial aluminum alloy or weldment even at 70 °C (160 °F).

More information on the welding of aluminum and aluminum alloys is available in the articles “Welding of Aluminum Alloys” and “Procedure Development and Practice Considerations for Resistance Welding” in *Welding, Brazing, and Soldering,* Volume 6 of *ASM Handbook.*

Corrosion of Titanium Alloy Weldments

Although titanium and its alloys are used chiefly for their desirable mechanical properties, among which the most notable is their high strength-to-weight ratio, another important characteristic of titanium and its alloys is their outstanding resistance to corrosion. Commercially pure (CP) titanium offers excellent corrosion resistance in most environments, except those media that contain fluoride ions. Titanium is more corrosion resistant than stainless steel in many industrial environments, and its use in the chemical process industry has been gradually increasing. Titanium exhibits excellent resistance to atmospheric corrosion in both marine and industrial environments.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Successful application of titanium and its alloys can be expected in mildly reducing to highly oxidizing environments in which protective oxide films spontaneously form and remain stable. Titanium and its alloys have been found to be largely immune to corrosion-related failure in most environments, although titanium alloys are generally less resistant to corrosion than CP titanium.

In unalloyed titanium and many titanium alloys, weld zones are just as resistant to corrosion as the base metal is. Other fabrication processes (such as bending or machining) also appear to have no influence on basic corrosion resistance.

Weldments and castings of CP grades and alpha-beta alloys such Ti-6Al-4V generally exhibit corrosion resistance similar to that of their unwelded, wrought counterparts. These titanium alloys contain so little alloy content and second phase that metallurgical instability and thermal response are not significant. Therefore, titanium weldments and associated HAZs generally do not experience corrosion limitations in welded components when normal passive conditions prevail for the base metal. However, under marginal or active conditions, for corrosion rates greater than or equal to 100 μm/year, weldments can experience accelerated corrosion attack relative to the base metal, depending on alloy composition. The increasing impurity (e.g., iron, sulfur, oxygen) content associated with the coarse, transformed beta microstructure of weldments appears to be a factor. Few published data are available concerning the corrosion resistance of titanium alloy weldments and castings other than Ti-6Al-4V, and limited information on other product forms has been reported.

Corrosion of Nonferrous Alloy Weldments, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 317–321

Corrosion of Nonferrous Alloy Weldments

Corrosion of Tantalum Alloy Weldments

Examination of equipment fabricated from tantalum that has been used in a wide variety of service conditions and environments generally shows that the weld, HAZ, and base metal display equal resistance to corrosion. This same resistance has also been demonstrated in laboratory corrosion tests conducted in a number of different acids and other environments. However, in applications for tantalum-lined equipment, contamination of the tantalum with iron from underlying backing material, usually carbon steel, can severely impair the corrosion resistance of tantalum. About the only known reagents that rapidly attack tantalum are fluorine; HF and acidic solutions containing fluoride; fuming sulfuric acid (H_2SO_4) (oleum), which contains free sulfur trioxide (SO_3); and alkaline solutions.

Oxygen Tolerance of Tantalum Weldments. Tantalum reacts with oxygen, nitrogen, and hydrogen at elevated temperatures. The absorption of these interstitial elements, often called a gettering reaction, produces a sharp reduction in ductility and can cause embrittlement. This impairment in ductility (and also in notch toughness, as manifested by an increase in ductile-to-brittle transition temperature) can be considered a form of corrosion. The other group Va refractory metals (niobium and vanadium) and the group IVa reactive metals (titanium, zirconium, and hafnium) can also suffer similar attack.

On the basis of chemical composition, the maximum oxygen tolerance for tantalum weldments appears to be approximately 400 to 550 ppm; for Tantaloy 63 (Ta-2.5W-0.15Nb) weldments, it is approximately 350 to 500 ppm. Although commercially pure tantalum exhibits a somewhat higher tolerance for oxygen (and total interstitial contamination) than Tantaloy 63, the latter material appears to have somewhat better resistance to oxidation; this tends to offset the advantage tantalum has of a higher allowable oxygen pickup before embrittlement occurs. It should be noted that these conclusions are based on the assumption that oxygen is distributed relatively uniformly throughout the cross section in all parts of the weldment. A locally high concentration, such as a high surface contamination of oxygen or nitrogen, could result in a severe loss in ductility and could possibly even produce embrittlement. Therefore, all handling, cleaning, and fabrication practices on tantalum and its alloys should avoid producing such surface contamination as well as gross contamination.

Corrosion of Nonferrous Alloy Weldments, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 317–321

Corrosion of Nickel and High-Nickel Alloy Weldments

The corrosion resistance of weldments is related to the microstructural and microchemical changes resulting from thermal cycling. The effects of welding on the corrosion resistance of nickel-base alloys are similar to the effects on the corrosion resistance of austenitic stainless steels, as described in the article “Corrosion of Stainless Steel Weldments” in this Volume. For example, sensitization due to carbide precipitation in the HAZ is a potential problem in both classes of alloys. However, in the case of nickel- base alloys, the high content of such alloying elements as chromium, molybdenum, tungsten, and niobium can result in the precipitation of other intermetallic phases, such as μ, σ, and η.

Therefore, this section is concerned with the characteristics of the various nickel-base alloys and the evolution of these alloys. The corrosion resistance of weldments is dictated not only by the HAZ but also by the weld metal itself. The effect of elemental segregation on weld metal corrosion must also be examined. The nickel-base alloys discussed in this section are the solid- solution alloys.

The nickel-molybdenum alloys, represented by Hastelloy alloys B (UNS N10001) and B-2 (UNS N10665), have been primarily used for their resistance to corrosion in nonoxidizing environments such as HCl. Hastelloy alloy B has been used since approximately 1929 and has suffered from one significant limitation: weld decay. The welded structure has shown high susceptibility to knife-line attack adjacent to the weld metal and to HAZ attack at some distance from the weld. The former has been attributed to the precipitation of molybdenum carbide (Mo_2C); the latter, to the formation of M_6C-type carbides. This necessitated postweld annealing, a serious shortcoming when large structures are involved. The knife-line attack on an alloy B weldment is shown in Fig. 5. Many approaches to this problem were attempted, including the addition of carbide-stabilizing elements, such as vanadium, titanium, zirconium, and tantalum, as well as the lowering of carbon.

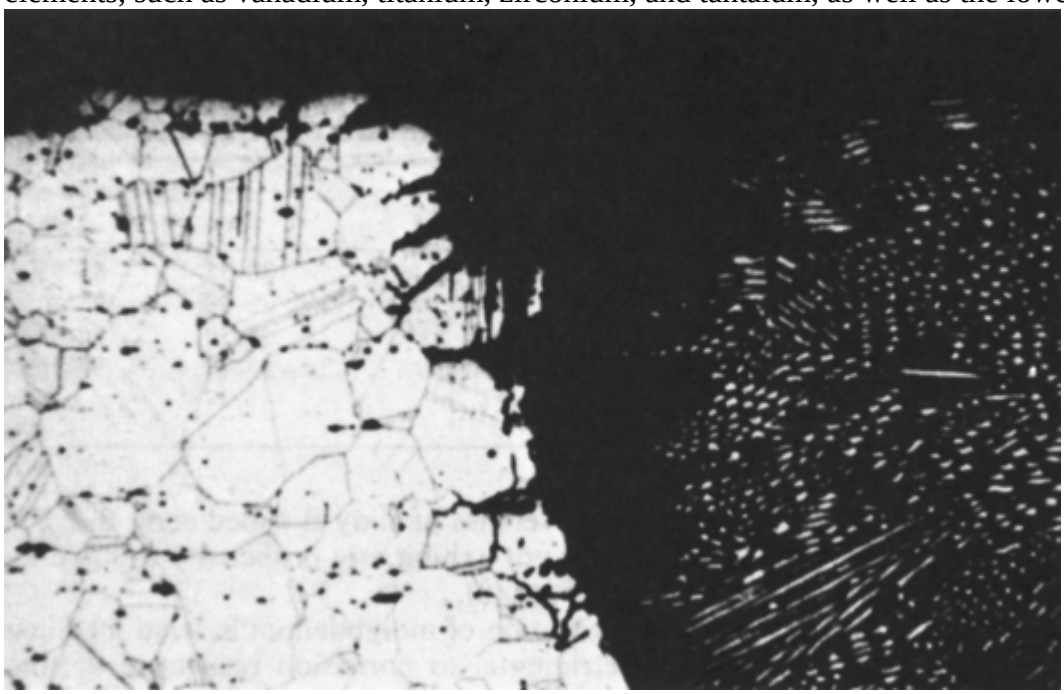

Fig. 5 Cross section of a Hastelloy alloy B weldment corroded after 16 days of exposure in boiling 20% HCl. 80×. Source: Ref 8

The addition of 1% V to an alloy B-type composition was first patented in 1959. The resultant commercial alloys—Corronel 220 and Hastelloy alloy B-282—were found to be superior to alloy B in resisting knife-line attack but were not immune to it. In fact, it was demonstrated that the addition of 2% V decreased the corrosion

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

resistance of the base metal in HCl solutions. During this time, improvements in melting techniques led to the development of a low-carbon low-iron version of alloy B called alloy B-2. This alloy did not exhibit any propensity to knife-line attack (Fig. 6).

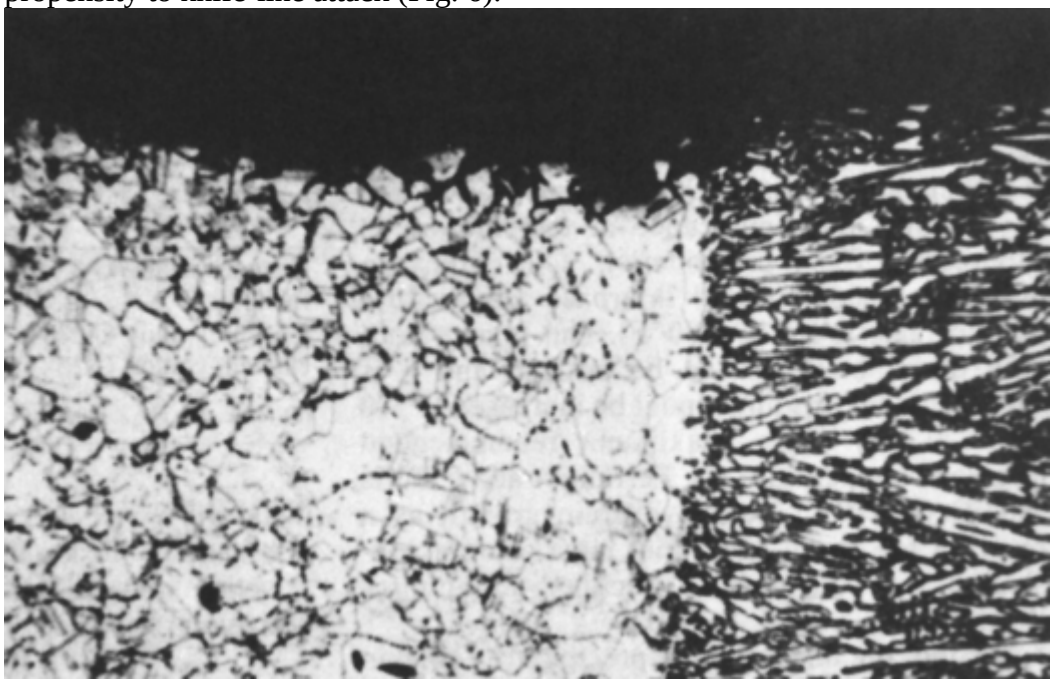

Fig. 6 Cross section of a Hastelloy alloy B-2 weldment after 16 days of exposure to boiling 20% HCl. 80×. Source: Ref 8

Segregation of molybdenum in weld metal can be detrimental to corrosion resistance in some environments. In the case of boiling HCl solutions, the weld metal does not corrode preferentially. However, in H_2SO_4 + HCl and H_2SO_4 + H_3PO_4 acid mixtures, preferential corrosion of as-welded alloy B-2 has been observed (Fig. 7). No knife-line or HAZ attack was noted in these tests. During solidification, the initial solid is poorer in molybdenum and therefore can corrode preferentially. This is shown in Fig. 7 for an autogenous GTA weld in alloy B-2. In such cases, postweld annealing at 1120 °C (2050 °F) is beneficial.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

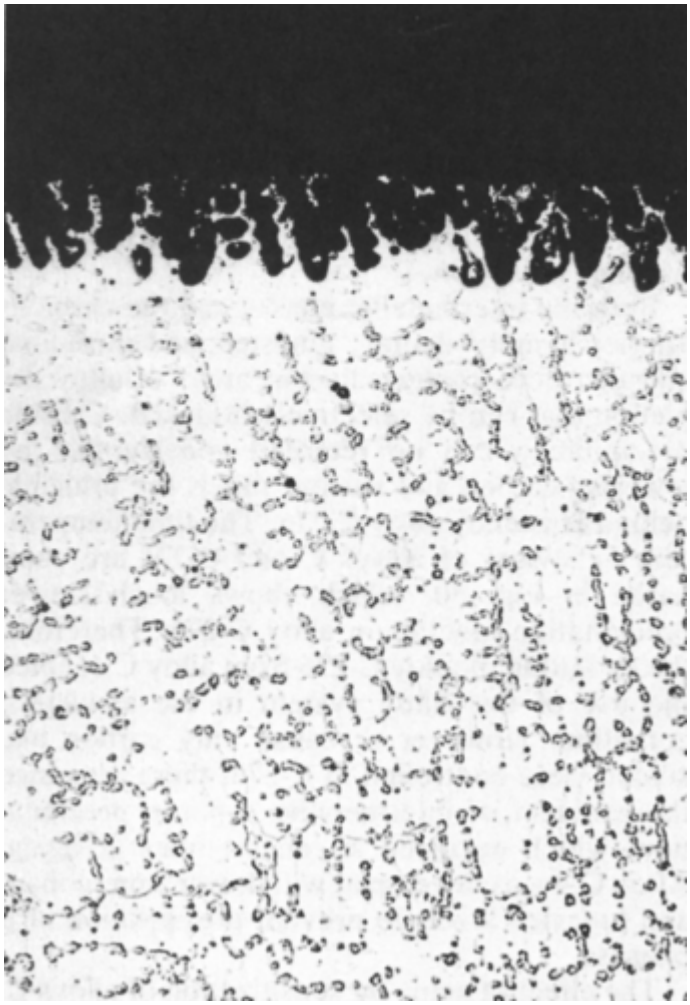

Fig. 7 Preferential corrosion of autogenous gas tungsten arc weld in Hastelloy alloy B-2 exposed to boiling 60% H_2SO_4 + 8% HCl

The nickel-chromium-molybdenum alloys represented by the Hastelloy C family of alloys and by Inconel 625 have also undergone evolution because of the need to improve the corrosion resistance of weldments. Hastelloy alloy C (UNS N10002), containing nominally 16% Cr, 16% Mo, 4% W, 0.04% C, and 0.5% Si, had been in use for some time but had required the use of postweld annealing to prevent preferential weld and HAZ attack. Many investigations were carried out on the nature of precipitates formed in alloy C, and two main types of precipitates were identified. The first is a Ni_7Mo_6 intermetallic phase called μ, and the second consists of carbides of the Mo_6C type. Other carbides of the $M_{23}C_6$ and M_2C were also reported. Another type, an ordered Ni_2Cr-type precipitate, occurs mainly at lower temperatures and after a long aging time; it is not of great concern from a welding viewpoint.

Both the intermetallic phases and the carbides are rich in molybdenum, tungsten, and chromium and therefore create adjacent areas of alloy depletion that can be selectively attacked. Carbide precipitation can be retarded considerably by lowering carbon and silicon; this is the principle behind Hastelloy alloy C-276. The time-temperature behaviors of alloys C and C-276 are compared in Fig. 8, which shows much slower precipitation kinetics in alloy C-276. Therefore, the evolution of alloy C-276 from alloy C enabled the use of this alloy system in the as- welded condition. However, because only carbon and silicon were controlled in C-276, there remained the problem of intermetallic μ-phase precipitation, which occurred at longer times of aging. Alloy C-4 was developed with lower iron, cobalt, and tungsten levels to prevent precipitation of μ phases.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

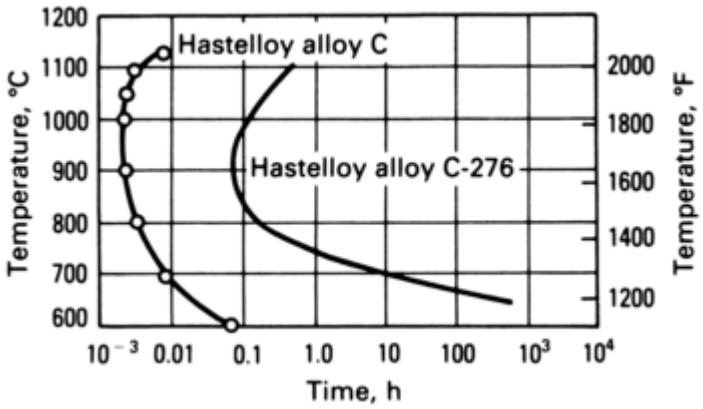

Fig. 8 Time-temperature transformation curves for Hastelloy alloys C and C-276. Intermetallics and carbide phases precipitate in the regions to the right of the curves. Source: Ref 9

The effect of aging on sensitization of alloys C, C-276, and C-4 is shown in Fig. 9. For alloy C, sensitization occurs in two temperature ranges (700 to 800 °C, or 1290 to 1470 °F, and 900 to 1100 °C, or 1650 to 2010 °F) corresponding to carbide and μ-phase precipitation, respectively. For alloy C-276, sensitization occurs essentially in the higher temperature region because of μ- phase precipitation. Also, the μ-phase precipitation kinetics in alloy C-276 are slow enough not to cause sensitization problems in many high-heat-input weldments; however, precipitation can occur in the HAZ of alloy C-276 welds (Fig. 10). Because C-4 has lower tungsten than C-276, it has lower pitting and crevice corrosion resistance, for which tungsten is beneficial. Therefore, an alternate solution to alloy C-4 was needed in which both corrosion resistance and thermal stability are preserved. Hastelloy alloy C-22 has demonstrated improved corrosion resistance and thermal stability.

مرجع مهندسی مواد و متالورژی

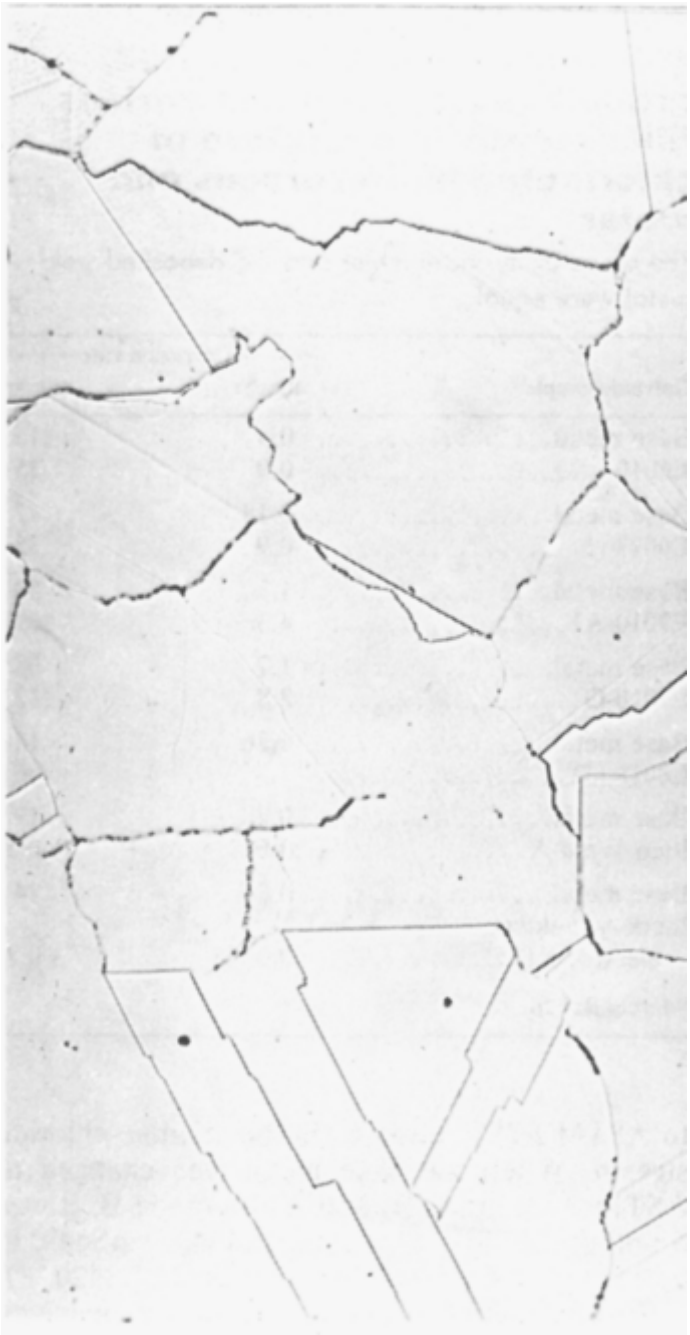

Fig. 10 Typical microstructure of the HAZ of a multipass submerged arc weld in Hastelloy alloy C-276. Source: Ref 11

Because of the low carbon content of alloy C- 22, the precipitation kinetics of carbides were slowed. Because alloy C-22 has lower molybdenum and tungsten levels than alloy C-276, μ- phase precipitation was also retarded.

From a weld HAZ point of view, this difference is reflected in lower grain-boundary precipitation even in a high-heat-input weld (Fig. 11). The HAZ microstructure of alloy C-4 was similar to this. This difference in the sensitization of the HAZ is also illustrated in Fig. 12, which shows that the HAZ and weld metal of alloy C-276 are attacked to a considerable extent in an oxidizing mixture of H_2SO_4 ferric sulfate ($Fe_2(SO_4)_3$), and other chemicals.

Introduction

MECHANICALLY ASSISTED DEGRADATION of metals is defined as any type of degradation that involves both a corrosion mechanism and a wear or fatigue mechanism. This article discusses five such forms of degradation: erosion, fretting, fretting fatigue, cavitation and water drop impingement, and corrosion fatigue. Only the mechanisms of these forms of degradation are discussed. The analyses of failures involving these mechanisms, as well as means of failure prevention, are detailed in *Failure Analysis and Prevention,* Volume 11 of *ASM Handbook.*

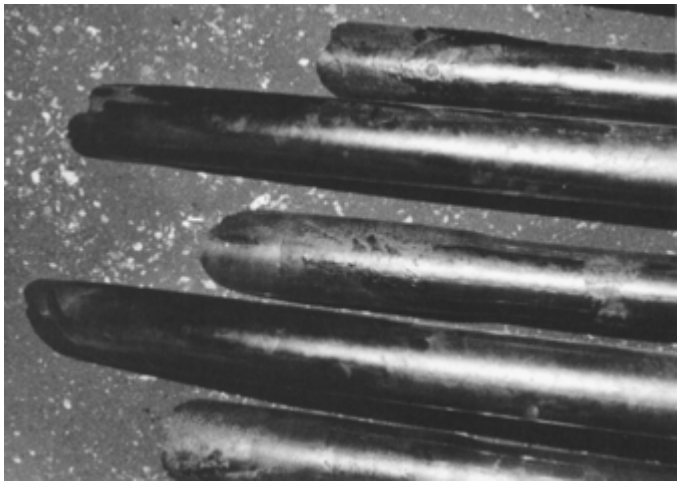
Erosion

Erosion can be defined as the removal of surface material by the action of numerous individual impacts of solid or liquid particles. Erosive wear should not be confused with abrasive or sliding wear, because the mechanisms of material removal, and therefore the materials selection criteria (though rudimentary), are different. In its mildest form, erosive wear manifests often as a light polishing of the upstream surfaces of components penetrating the flowstream, or of bends or other stream-deflecting structures. This is illustrated in Fig. 1, which shows carbon steel heat-transfer tubes in a fluidized-bed combustor. The tubes have been polished through the action of particles of sand impacting at a velocity of approximately 1.8 m/s (6 ft/s). The black appearance of these tubes is due to the oxide scale, which has been polished (that is, thinned) by the erosive action but not completely removed. In this case, metal wastage is probably a result of high-temperature corrosion assisted by erosion.



www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Fig. 1 Polishing of heat-transfer tubes from erosion by sand in a fluidized-bed combustor

Where the erosive action is more severe, any scales or deposits are removed, and the polished, eroded surface is base metal. Such surfaces on low-alloy steels are often very susceptible to rusting; therefore, swabbing the tubes with a damp cloth can give a useful indication of the erosion zones and patterns. Figure 2 shows such rusting on the underside of a tube from a different fluidized-bed combustor. This rusting indicates that erosion occurred in a uniform zone around the bottom of the tube, up to the 9 o'clock position.

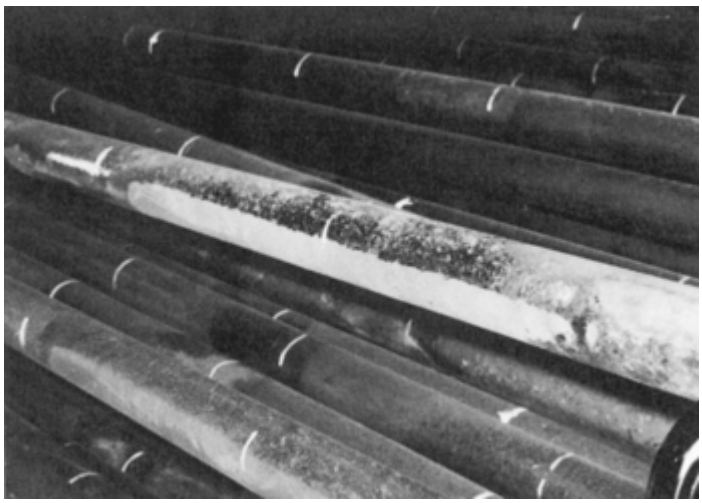


Fig. 2 Carbon steel heat-transfer tube from a fluidized bed that was damaged by erosion and subsequent rusting

Erosion attack can be quite localized, as shown by the polished zones on the tube supports from a steam boiler (Fig. 3). Localized fly ash-laden gas flow between the tube rows (supported on the lugs) eroded through the oxide scale and polished the metal surface beneath.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

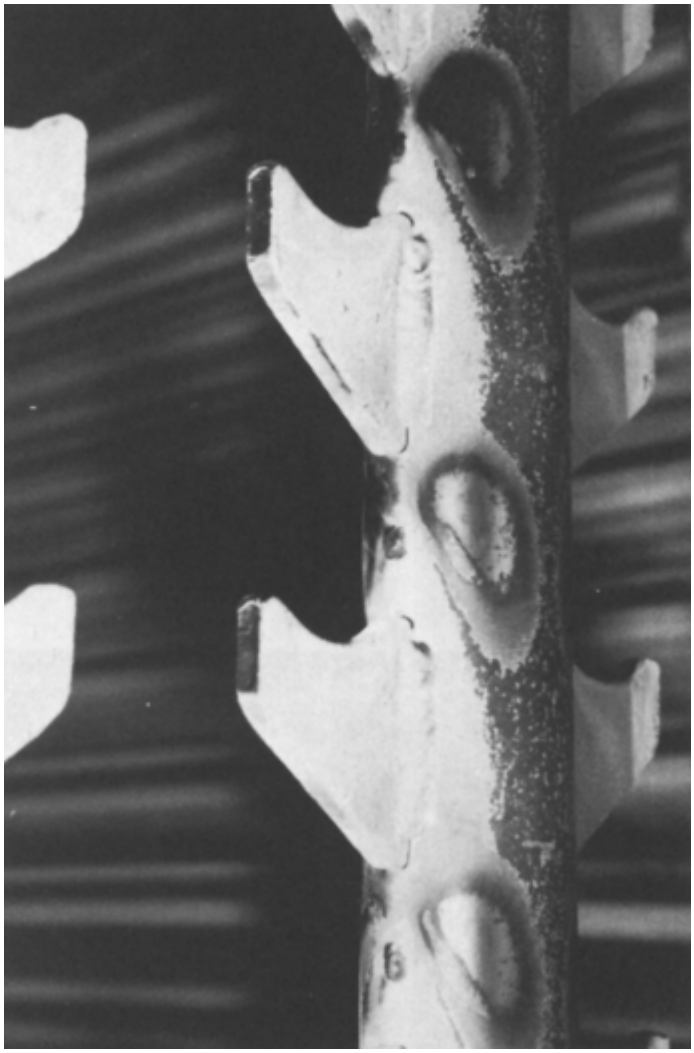

Fig. 3 Erosion of a tube support by ash-laden flue gas

In more severe cases, erosion can result in very rapid attack that quickly leads to thinning and penetration. Conditions that give rise to such rapid erosion usually involve high velocities, large amounts of entrained solid or liquid particles, and abrupt changes in direction of the fluid. These conditions can lead to segregation and concentration of the eroding particles. Examples of such rapid erosion are shown in Fig. 4, 5, 6.

Fig. 5 Eroded tube inserts from the inlet end of a fire-tube boiler. The inserts were eroded by particle-laden flue gas, which was forced to turn as it entered the boiler.

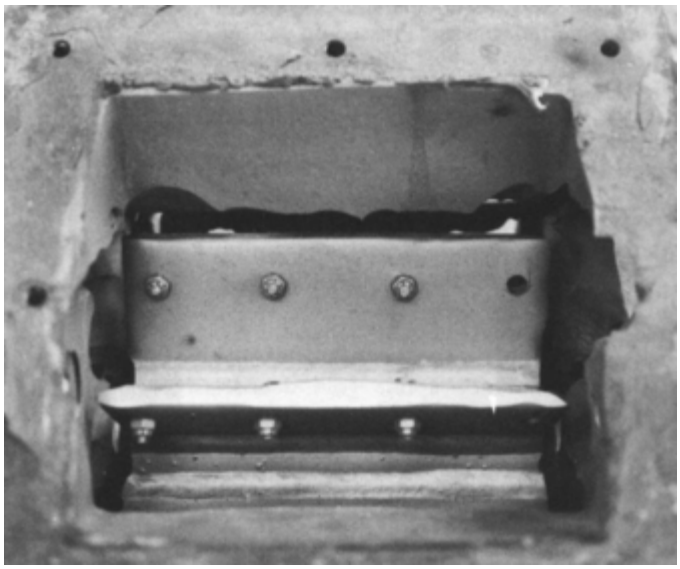

Fig. 6 Erosion of a rotary valve handling dust from a cyclone. The wear plates in the valve show some material loss, but the major damage is to the casing. Gaps between the casing and the valve allowed leakage of high-velocity air with entrained dust.

Erosion is thought typically to involve the action of a dilute dispersion of small solid (or liquid) particles entrained in a fluid jet, and it is from studies in this type of regime that most of the current understanding of erosion phenomena is derived. Strictly controlled laboratory studies of simplified systems or part processes in actual or simulated situations have provided a basis for the analysis of erosion damage produced under quite limiting circumstances: by the impacts of individual particles where particle motion is largely unconstrained in the approach to the target, during impact, and in rebounding from the target. There are many variables that can affect erosion. Important system variables are the relative velocities of the erodent and target; the angle of impact; the mass, size, size distribution, shape, hardness, and composition of the erodent particles; the number density of the particles in the conveying fluid or the frequency of impact; and the density and viscosity of the fluid.

The factors that affect the resistance of materials to erosion are difficult to define. Simple correlations of erosion rate have been attempted with target material hardness, melting temperature, elastic modulus, and so on, with some success for pure elements but less-than-universal application to steels and other alloys or ceramic materials. The relative importance of specific materials properties likely will change, depending on the predominating mechanisms of erosion, which in turn depend on any of the large number of systems variables and on the way in which the target material absorbs the energy of impact. For discrete impacts at a shallow angle to the target surface, it appears that the primary mode of material loss is through the displacement of material in the path of the erodent and the eventual loss of the displaced material by subsequent cutting or by fracture, if the material is embrittled.

This form of erosion can be equated to micromachining. The simple, elegant model discussed in Ref 1 and 2 and its refinements, relating erosion essentially to material hardness, has been found to predict erosion rates of approximately the right magnitude, even if the ability of the model to rank different alloys is sometimes poor. This model can be stated simply as:

$$\frac{\text{Erosion loss}}{\text{Quantity of impacting erodent}} = C \cdot F(\theta)\frac{\rho v^2}{\text{HV}}$$

where C is a system constant, $F(\theta)$ is a function of the angle of impact, ρ is the density of the erodent, v is the erodent velocity, and HV is the hardness of the target.

Other refinements to this model, as well as approaches to sophisticated models, have been proposed and are discussed fully in other reviews (Ref 3, 4, 5). In the later refinements (Ref 2) of this model, the velocity

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

dependence of erosion is increased from 2 to approximately 2.3. Nevertheless, the general relationship between erosive loss and erodent kinetic energy is not changed.

The functional relationship between erosion loss and the angle of impact is complex. For impacts at larger angles to the target surface, fluid flow considerations indicate that in most practical cases, the erodent particles actually strike the surface at a variety of shallower angles, depending on the size and velocity of the particles and the drag exerted on them by the conveying fluid. For impacts normal to the target surface, therefore, it is likely that only a small fraction of the particles actually impact at 90°. The forms of material loss involve surface displacement and cutting as well as modes that result from normal impacts. For most metallic materials, normal impacts result in indentation and local displacement of the surface by sharp particles, but less angular particles cause deformation and/or eventual fatigue, depending on the rate at which the deformation can be accommodated. Most ceramic materials suffer cracking from normal impacts; the form and extent of the cracking depend on the intensity of the impact (particle size, velocity, and shape) and on the structure of the ceramic.

Erosion models that describe erosion by deformation and fracture are based on elastic-plastic indentation fracture mechanics. The volume of the target surface removed following an individual impact usually is taken to be the volume enclosed by the radial and lateral cracks resulting from the impact. The depth of the lateral cracks can be related to the hardness of the target, while the length of the radial crack is a function of both hardness and toughness. The exact form of the relationship among erosion loss, hardness, and fracture toughness depends on assumed details of the geometry of the damage and mode of material removal. The predicted velocity dependence of erosion is usually approximately 3. Further discussion of these erosion models can be found in Ref 6 and 7.

In practice, erosive conditions cover a wide spectrum. In situations where the concentration of erodent particles is so great that the independent action of individual particles is unlikely, the form of damage may be more similar to scouring from particles embedded in a massive backing than that from discrete particle impacts. Rules derived for abrasive wear (see the article “Abrasive Wear” in *Friction, Lubrication, and Wear Technology*, Volume 18 of *ASM Handbook*) may then be more appropriate. In a large number of systems of practical importance, the density and viscosity of the carrier fluid are significantly different from those associated with airborne dilute phase erosion; therefore, the motion of the erodent particles before, during, and after impact may be quite different from that considered in most erosion models. The actual mechanisms of erosion, as well as the relationships with, for example, nominal angle of impact, may not correspond with those where air is the carrier fluid. Overall, at the present state of development, analytical relationships between systems and materials variables, as well as material loss through erosion, can be used only as a guide to the relative importance of the variables encountered. Testing under conditions that simulate accurately the situation under consideration is probably the best method of forming a basis for decision making. More information on failures caused by erosion is available in the article “Liquid Impact Erosion” in *Failure Analysis and Prevention*, Volume 11 of *ASM Handbook.*

Fretting Corrosion

Fretting corrosion is a combined wear and corrosion process in which material is removed from contacting surfaces when motion between the surfaces is restricted to very small amplitude oscillation (as low as 3 or 4 nm). Usually, the condition exists in machine components that are considered fixed and not expected to wear. Pressed-on wheels can often fret at the shaft/ wheel hole interface.

Oxidation is the most common element in the fretting process. In oxidizing systems, fine metal particles removed by adhesive wear are oxidized and trapped between the fretting surfaces. The oxides act like an abrasive (such as lapping rouge) and increase the rate of material removal. This type of fretting in ferrous alloys is recognized easily by the red material oozing from between the contacting surfaces.

Fretting can also persist in contacts where no corrosion exists. For example, gold fretting against gold produces fine gold debris. Fretting occurs in the vacuum of outer space.

A serious fretting problem that has injury potential is the loosening of wheels or flywheels from shafts or axles. Railroad car wheels, for example, are shrink fitted onto their axles. If the wheel loosens from running vibrations and comes off during operation of the train, it can cause derailment and has the potential of becoming a loose, rolling missile capable of penetrating nearby buildings.

Electrical connectors for low-current circuits are generally gold or gold-base alloys. Because of the high cost of gold, very thin electroplated gold coatings are used for contacts. Gold plate thicknesses as small as 0.25 μm (0.01 mil) are used. When electric contacts are subjected to vibrations of continual expansion and contraction from periodic thermal excursions, the small relative motion between the contacts produces fretting wear and the eventual removal of the gold plate. As the gold is removed, the substrate is subjected to atmospheric corrosion, and the contact resistance rises to intolerable levels. In addition, fretting debris becomes trapped between the surfaces and causes degraded conductivity. Fretting of electrical contacts is not anticipated in the design, and although it is common, it often comes as a surprise to the user. A typical progression of fretting damage induced between a solid gold rider on cobalt-gold-plated copper is shown in Fig. 7.

www.iran-mavad.com

Fretting corrosion has been a continuing problem in nuclear reactors. The condition is found on heat-exchanger tubes and on fuel elements. In both cases, long, flexible tubes are in contact with support surfaces and subjected to vibrations generated by fluid flow as the coolant flows around them. The supports for heat-exchanger tubes and fuel elements cannot be rigid because the tubes must be able to expand or contract under thermal excursions without binding (this is also true for any tube heat-exchanger system). Tube impact fretting caused by flow-induced tube vibrations can reduce wall thickness, requiring eventual replacement. Extensive experimentation has revealed that the interaction of tube support clearance, excitation force, and type of tube motion controls wear rates (Ref 9). Other mechanical parts susceptible to fretting damage include couplings, riveted and pin joints, surgical implants, rolling-contact bearings, and bridge bearings.

Factors Affecting the Severity of Fretting Corrosion

The following factors are known to influence the severity of fretting. If fretting conditions exist, fretting cannot be eliminated completely but can be reduced in severity.

Contact Load. As long as fretting amplitude is not reduced, fretting wear increases linearly with increasing load.

Amplitude. There appears to be no measurable amplitude below which fretting does not occur. However, if the contact conditions are such that deflection is only elastic, it is not likely that fretting damage occurs. Fretting wear loss increases with amplitude. The effect of amplitude can be linear, or there can be a threshold amplitude

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

above which rapid increase in wear occurs (Ref 10). The transition is not well established and probably depends on the geometry of the contact.

Frequency. When the fretting is measured in volume of material removed per unit sliding distance, there does not appear to be a frequency effect.

Number of Cycles. An incubation period occurs during which fretting wear is negligible (Ref 11). After the incubation period, a steady- state wear rate is observed. Figure 8 shows local cold welding on a fretted steel surface early in the fretting process (500 cycles). As the fretting continues, a more general surface roughening occurs, as shown in Fig. 9.

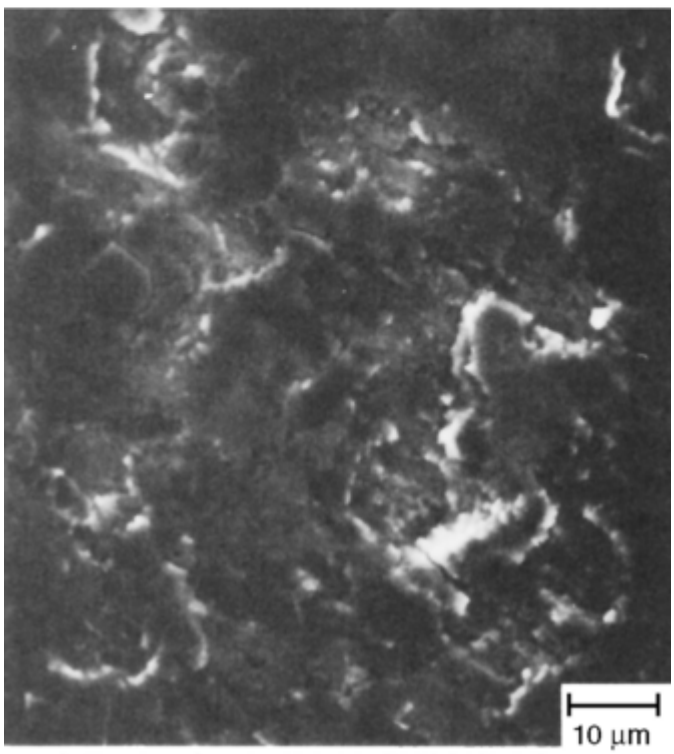
(a)



(b)

Fig. 9 Damage to Monel alloy after fretting in air at room temperature for (a) 1000 cycles and (b) 5×10^4 cycles. Courtesy of R.C. Bill, NASA Lewis Research Center

Relative Humidity. For materials that rust in air, fretting wear is higher in dry air than in saturated air. The effect of humidity is shown in Fig. 10 and 11. In dry air, both the iron and nickel produce debris that remains in the contact region. The debris separates the surfaces and reduces the contacts. As humidity is increased, the debris becomes more mobile, escaping the contact and allowing metal-to-metal contact, as shown in Fig. 10 and 11. Diffraction analysis of the debris from the iron surfaces shows it to be α-F_2O_3 (Ref 12).

Temperature. The effect of elevated temperature on fretting depends on the oxidation characteristics of the metals. If increased temperature encourages the growth of a protective, tough oxide layer that prevents metal-to-metal contact, the fretting rate is lower. Low-carbon steel tends to show a sudden decrease in fretting wear rate at approximately 200 °C (390 °F) (Ref 13). For titanium alloys, an increase in wear rate has been observed between 350 and 500 °C (660 and 930 °F), and a rapid decrease in wear has been observed above 550 °C (1020 °F) (Ref 12, 14). Even the difference between room-temperature wear and wear at 650 °C (1200 °F) is significant (Fig. 12, 13). Figure 12 shows the surface damage from room-temperature fretting, illustrating the inadequate protection afforded by the oxide. Figure 13 shows the effect of the tough, thick oxide layer formed at 650 °C (1200 °F), which protects the metal surface. It has been shown that superalloys behave similarly to titanium at elevated temperatures (Ref 15). A glassy layer of compacted oxide particles has been found on the fretted surface after high temperature. This layer reduces the fretting wear considerably. The formation of this glassy oxide layer has been linked to an increase of 130% in fretting fatigue strength of Inconel 718 (Ref 16).

Fretting Fatigue

Fretting decreases the fatigue life of parts operating under fatigue loading. Gas turbines experience this problem with clamped joints and shrink-fitted parts. These parts are subjected to high-frequency, low-amplitude vibrations, often in combination with bending fatigue stress states (Ref 17). The combined action of fretting and reversing bending stress causes accelerated crack initiation and an increase in the rate of crack propagation. The result is a decrease in the fatigue strength of a given alloy. The effect on 4130 steel is shown in Fig. 14. In this case, the fatigue strength of the alloy is reduced under fretting, and the sensitivity to load is increased. Fretting fatigue begins as a crack in the fretting scar zone. An example of a fretting fatigue crack is shown in Fig. 15. The crack is located at the boundary of the fretting scar. This is one attribute of fretting fatigue that identifies the origin of the fatigue. The fatigue crack, once initiated at the boundary of the fretted zone, propagates into the surface at an angle to the surface (Fig. 16). Other examples of the crack behavior are shown in Fig. 17 and 18. Wire rope can fail by fretting fatigue. As the rope flexes, wire strands rub against each other and produce fretting at the wire-wire contacts. If the fretting occurs in a zone that is also subject to cyclic fatigue stresses, failure occurs. An example of wire rope fretting fatigue is shown in Fig. 19 Note the lip in the detail micrograph in Fig. 20.

Recently, considerable attention has been given to fretting fatigue of aircraft turbine vanes. The fretting occurs in the dovetail joints that hold the vanes in the rotor disks. The problem occurs in the compressor section of the turbine. The vanes and disks are made of titanium alloy Ti-6Al-4V. It has been shown that fretting alone can produce surface cracks in the titanium components (Ref 19). An example of fretting-generated cracks in alloy Ti-6Al-4V is shown in Fig. 21. The figure is a micrograph from a sectioned as-fretted fatigue specimen prior to fatigue testing. Note that there are several cracks oriented at an angle to the surface and that cracks are filled with debris. Some branching crystallographic cracks (shown by the arrows) can be seen. The resulting fracture has a transgranular character. Deeper into the fracture, typical fatigue striations are often found. Fretting significantly reduces the fatigue strength of the blades and disks, requiring more frequent maintenance to ensure blade integrity.

Cavitation Erosion and Water Drop Impingement

Cavitation erosion occurs on metal surfaces in contact with a liquid. Pressure differentials in the fluid generate gas or vapor bubbles in the fluid. When these bubbles encounter a high-pressure zone, they collapse and cause explosive shocks to the surface. These surface shocks cause localized deformation and pitting. Cavitation pits eventually link up and cause a general roughening of the surface and material removal. Cavitation is similar to particle erosion in its damage. However, surface features formed by cavitation are different from those formed by particle erosion. Cavitation produces rounded microcraters in the surface, while particle erosion produces imprints of the impacting particles. Crater formation moves surface material to the edges of the craters, and these extrusions eventually break off, causing loss of material from the surface. The sharp pressure pulses caused by the collapsing bubbles are highly localized and can remove weak or soft portions of microstructural phases (for example, ferrite from pearlite) (Ref 20).

Scattered shallow dimples or depressions are the earliest evidence of cavitation erosion in ductile surfaces. This represents an incubation period before the actual loss of material. Damage is seen first in the weaker elements of the microstructure.

Material removal is different for soft materials and hard materials. Soft materials suffer local plastic deformation and penetration. Babbitt, for example, becomes pitted with steep-sided pits that group together in patterns reflecting the fluid dynamics. Hard materials experience localized microcracking and chipping from the pressure pulses. Brittle materials, such as glass and some plastics, appear to develop surface cracking at minute surface flaws.

In materials that depend on passivating films for corrosion protection, cavitation causes an apparent accelerated attack. In a corrosive medium, the cavitation removes the protective film, and corrosion weakens the material to the mechanical removal process. Figure 22 shows cavitation damage to an Alloy Casting Institute (ACI) CN-7M stainless steel impeller that was used to pump ammonium nitrate solution at 140 °C (280 °F). Hardfacing materials and cemented carbides react differently to cavitation than to abrasion (Ref 21). The carbides are selectively eroded from the Stellite (Stoody Deloro Stellite, Inc.) alloys, while cemented carbides suffer loss of the cobalt or nickel binder. Cavitation occurs in hydraulic equipment, fluid pump impellers, ship propellers, hydrodynamic bearings, fluid seals, inlets to heat-exchanger tubes, diesel engine wet cylinder liners, hydrofoils,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

liquid metal power plants, and steam turbines. Cavitation occurs in diesel engine main bearings and wrist pin bearings. Two sources have been identified in diesel bearings (Ref 22) downstream from bearings lubrication grooves and in engines subjected to rapid radial shaft movement. The reference suggests ways to design bearings to prevent cavitation.

Water drop impingement erosion is similar to cavitation in that it causes pitting of surfaces and may involve a cavitation mechanism. Two areas are most notable for water drop impingement: steam turbines and helicopter rotor blades. In turbines, condensation of steam produces droplets that are carried into the rotor blades, with consequent surface damage. Raindrop erosion on helicopter blades is the result of elastic compression waves produced by multiple impacts and their interaction; this action generates tensile stresses just below the surface and causes cracking.

Water drop impingement damage can appear to be somewhat different from cavitation damage in ductile materials. The cavities in the surface show a directionality that is related to the angle of attack of the drops.

Corrosion Fatigue

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Corrosion fatigue occurs in metals as a result of the combined action of a cyclic stress and a corrosive environment. Corrosion fatigue is dependent on the interactions among loading, environmental, and metallurgical factors. For a given material, the fatigue strength (or fatigue life at a given maximum stress value) generally decreases in the presence of an aggressive environment. The effect varies widely, depending primarily on the particular metal-environment combination. The environment may affect the probability of fatigue crack initiation, the fatigue crack growth rate, or both. Figure 23 shows an example of corrosion fatigue failure in a Ti-6Al- 4V alloy.

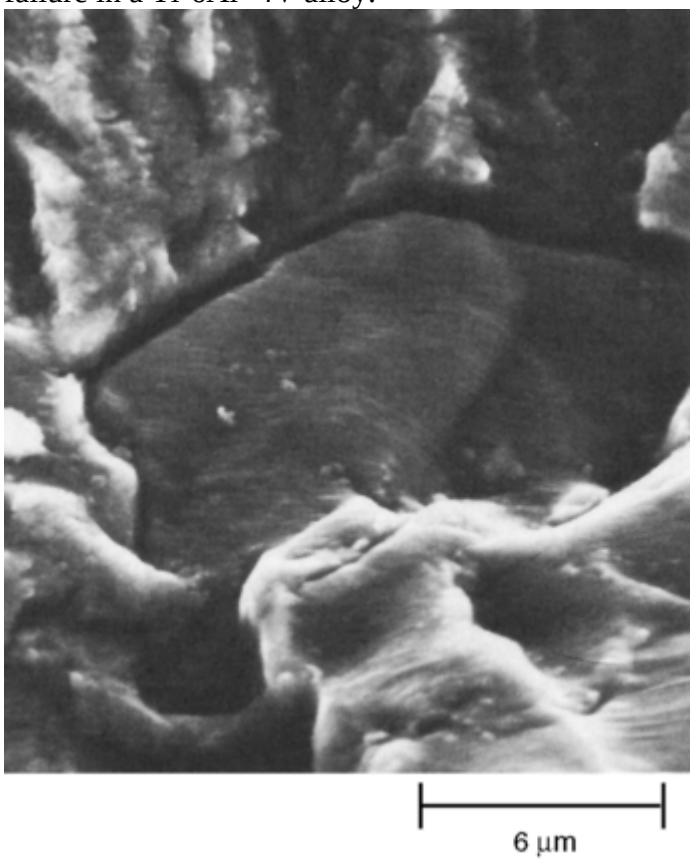

Fig. 23 Corrosion fatigue of a Ti-6Al-4V alloy tested in ambient air. Intergranular cracking and fatigue striations are evident on the fracture surface; the grain appears to have separated from the rest of the microstructure. Source: Ref 21

Corrosion Fatigue Crack Initiation. The influence of an aggressive environment on fatigue crack initiation of a material is illustrated in Fig. 24, which compares the smooth-specimen stress- life (*S-N*) curves obtained from inert and aggressive environments. Because as much as 95% of the structure life is spent on fatigue crack initiation, *S-N* curve comparison provides a good indication of the effect of environment on crack initiation. As shown in Fig. 24, an aggressive environment can promote crack initiation and can shorten the fatigue life of the structure. Corrosion fatigue cracks are always initiated at the surface, unless there are near-surface defects that act as stress concentration sites and facilitate subsurface crack initiation. Surface features at origins of corrosion fatigue cracks vary with the alloy and with specific environmental conditions. In carbon steels, cracks often originate at hemispherical corrosion pits and often contain significant amounts of corrosion products. The cracks are often transgranular and may exhibit a slight amount of branching. Surface pitting is not a prerequisite for corrosion fatigue cracking of carbon steels nor is the transgranular fracture path; corrosion fatigue cracks sometimes occur in the absence of pits and follow grain boundaries or prior-austenite grain boundaries.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

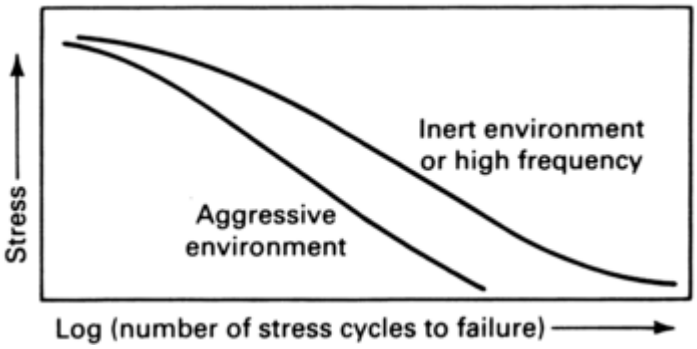

Fig. 24 Comparison of *S-N* curves for a material in an inert environment (top curve) and an aggressive environment (lower curve)

In aluminum alloys exposed to aqueous chloride solutions, corrosion fatigue cracks originate frequently at sites of pitting or intergranular corrosion. Initial crack propagation is normal to the axis of principal stress. This is contrary to the behavior of fatigue cracks initiated in dry air, where initial growth follows crystallographic planes. Initial corrosion fatigue cracking normal to the axis of principal stress also occurs in aluminum alloys exposed to humid air, but pitting is not a requisite for crack initiation.

Corrosion fatigue cracks in copper and various copper alloys initiate and propagate intergranularly. Corrosive environments have little additional effect on the fatigue life of pure copper over that observed in air, although they change the fatigue crack path from transgranular to intergranular. Copper-zinc and copper-aluminum alloys, however, exhibit a marked reduction in fatigue resistance, particularly in aqueous chloride solutions. This type of failure is difficult to distinguish from stress-corrosion cracking (SCC), except that it may occur in environments that normally do not cause failures under static stress, such as sodium chloride or sodium sulfate solutions.

Environmental effects can usually be identified by the presence of corrosion damage or corrosion products on fracture surfaces or within growing cracks. Corrosion products, however, may not always be present. For example, corrosion fatigue cracking of high-strength steel exposed to a hydrogen-producing gas, such as water vapor, may be difficult to differentiate from some other forms of hydrogen damage. At sufficiently high frequencies, the fracture surface features produced by corrosion fatigue crack initiation and propagation do not differ significantly from those produced by fatigue in nonaggressive environments.

Corrosion Fatigue Crack Propagation. Although corrosion fatigue phenomena are diverse, several variables are known to repeatedly influence crack growth rate:

- Stress-intensity range
- Load frequency
- Stress ratio
- Aqueous environment electrode potential
- Environment
- Metallurgical variables

Effects of such variables as temperature, load history and waveform, stress state, and environment composition are unique to specific materials and environments (Ref 23, 24, 25, 26, 27, 28, 29, 30, 31).

Stress-Intensity Range. For embrittling environments, crack growth generally increases with increasing stress intensity (ΔK); the precise dependence, however, varies markedly. Materials that are extremely environment-sensitive, such as ultrahigh-strength steel in distilled water (Fig. 25), are characterized by high growth rates that depend on ΔK to a reduced power. Time-dependent corrosion fatigue crack growth occurs mainly above the threshold stress intensity for static load cracking and is modeled through linear superposition of SCC and inert environment fatigue rates (Ref 31, 32).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

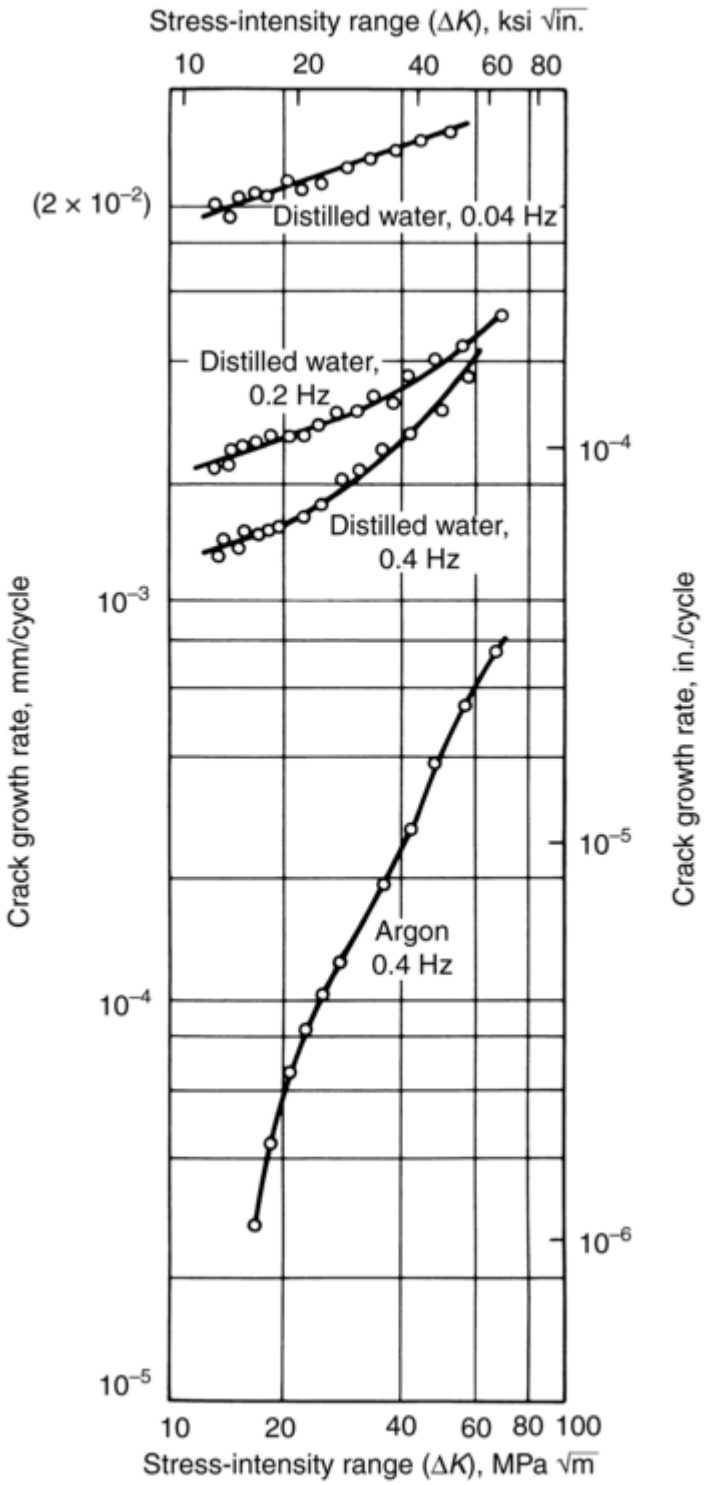

Fig. 25 Effect of stress-intensity range and loading frequency on corrosion fatigue crack growth in ultrahigh-strength 4340 steel exposed to distilled water at 23 °C (73 °F)

Frequency. Cyclic load frequency is the most important variable that influences corrosion fatigue for most material, environment, and stress- intensity conditions. The rate of brittle cracking above that produced in vacuum generally decreases with increasing frequency. Frequencies exist above which corrosion fatigue is eliminated. The dominance of frequency is related directly to the time dependence of the mass transport and chemical reaction steps required for brittle cracking. Basically, insufficient time is available for chemical embrittlement at rapid loading rates; damage is purely mechanical, equivalent to crack growth in vacuum.

Stress Ratio. Rates of corrosion fatigue crack propagation generally are enhanced by increased stress ratio, *R*, which is the ratio of the minimum stress to the maximum stress. Stress ratio has only a slight influence on fatigue crack growth rates in a benign environment.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Electrode potential, similar to loading frequency, strongly influences corrosion fatigue crack propagation rates in aqueous environments. Controlled changes in the potential of a specimen can result in either the complete elimination or the dramatic enhancement of brittle fatigue cracking. The precise influence depends on the mechanism of the environmental effect and on the anodic or cathodic magnitude of the applied potential.

Environment. Increasing the chemical activity of the environment—for example, by lowering the pH of a solution, by increasing the concentration of the corrosion species, or by increasing the pressure of a gaseous environment—generally decreases the resistance of a material to corrosion fatigue. Decreasing the chemical activity of the environment improves resistance to corrosion fatigue.

In aluminum alloys and high-strength steels, for example, corrosion fatigue behavior is related to the relative humidity or partial pressure of water vapor in the air. Corrosion fatigue crack growth rates for these materials generally increase with increasing water vapor pressure until a saturation condition is reached. Figure 26 shows the appearance of the fracture surfaces of an aluminum alloy fatigue tested in argon and in air with water vapor present. Temperature can have a significant effect on corrosion fatigue. The effect is complex and depends on temperature range and the particular material-environment combination in question, among other factors. The general tendency, however, is for fatigue crack growth rates to increase with increasing temperature.

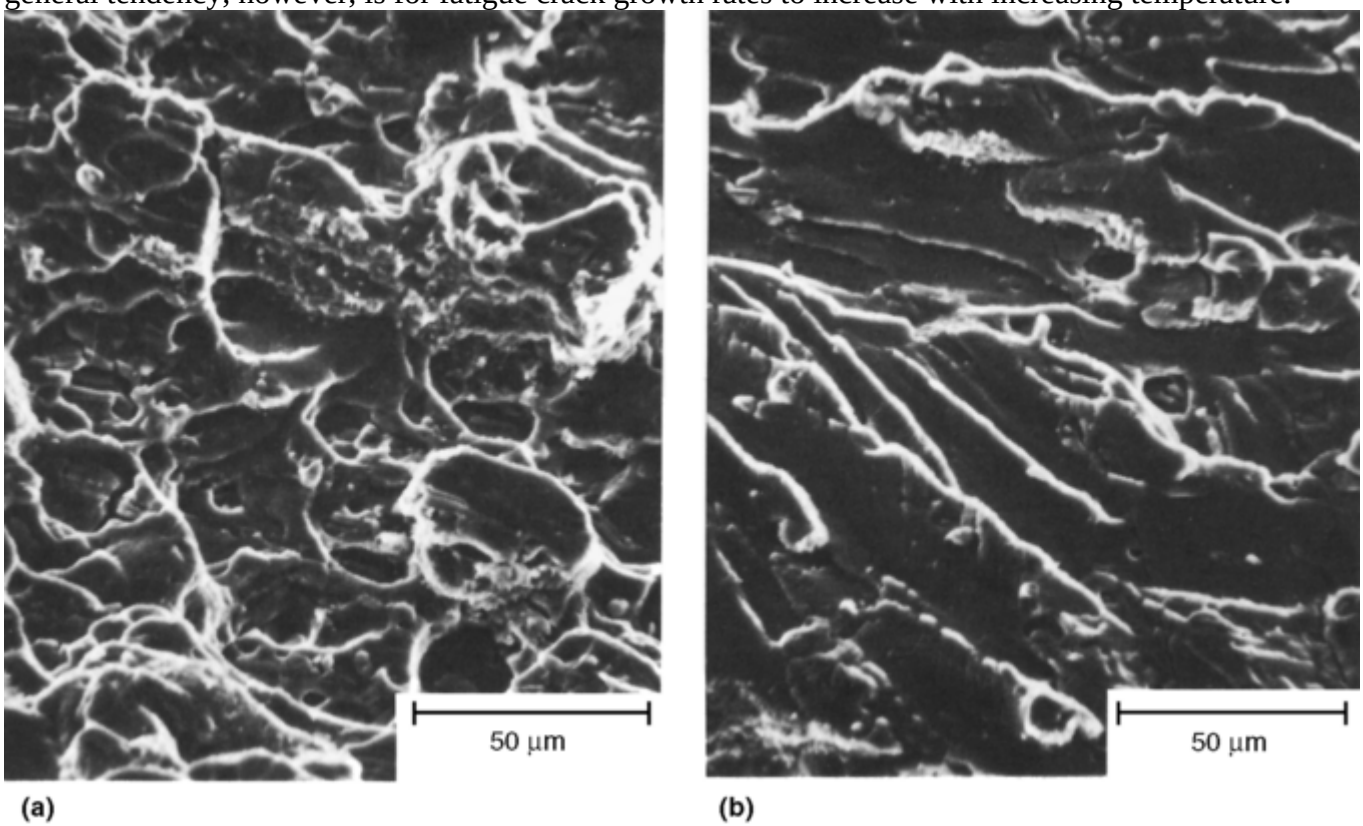

Fig. 26 Effect of water vapor on the fracture surface appearance of aluminum alloy 2219-T851 fatigue tested (a) in 0.101 MPa (1 atm) dry argon and (b) in 27 Pa (0.2 torr) water vapor. Testing conditions were the same except for frequency, which was 20 Hz in (a) and 5 Hz in (b). The magnifications, while too low to resolve fatigue striations clearly, indicate the general change in fracture morphology. Crack propagation was from left to right. Source: Ref 33

Other factors, including the metallurgical condition of the material (such as composition and heat treatment) and the loading mode (such as uniaxial), affect corrosion fatigue crack propagation. The article “Evaluating Corrosion Fatigue” in this Volume contains detailed information on testing methods and the use of fracture mechanics to predict corrosion fatigue behavior.

Relationship Between Corrosion Fatigue and SCC. The relationship between corrosion fatigue and two other environmental cracking mechanisms, SCC and hydrogen embrittlement, is shown in Fig. 27. Many investigations have attempted to link the mechanisms of corrosion fatigue and other environmental cracking processes (especially SCC); examples of these include Ref 35 to 38. There are, however, many unanswered questions about the mechanisms of these phenomena. Experimental evidence relating SCC and corrosion fatigue is presented in the article “Evaluating Corrosion Fatigue” in this Volume.

Introduction

WEAR AND CORROSION of slurry-handling equipment cause major maintenance problems, constituting a major cost for the mining and mineral processing industries. Wear and corrosion processes are complex—dependent on mechanical, physical, chemical, and electrochemical actions—not only on ferrous materials, but also on the minerals that come in contact with them. Collisions of mineral particles cause erosion of the surface and removal of corrosion resistant films, resulting in accelerated corrosion. Synergistic effects between erosion and corrosion have been extensively studied, leading to the formulation of the ASTM G 119, "Determining Synergism Between Wear and Corrosion" (Ref 1). Electroactive mineral particles, typically sulfide minerals, can galvanically couple with ferrous materials and further accelerate their corrosion. Conversely, the surface properties of mineral particles are altered and their beneficiation behaviors can be adversely affected. Wear is a critical issue in grinding mills and is also pertinent in sand pumps and slurry pipelines.

Grinding precedes concentration processes in the beneficiation of minerals. Rod mills and ball mills are used most widely in the mineral processing industry for grinding. As available mineral deposits become lower in grade, a finer grind for liberation is required. Power consumption per ton of concentrates produced increases, and the wear of balls used in fine grinding is increased in proportion to the increase in power consumption. The cost of grinding media wear often approaches or even exceeds the power cost of grinding (Ref 2, 3). In the United States, 28.5×10^9 kWh of electricity and 1 million tons of grinding media are used each year in grinding minerals, coal, and cement (Ref 4). Therefore, the reduction of wear of grinding media is just as important as the reduction in power consumption.

Within a ball mill, some of the balls are lifted, and falling balls impact among themselves. The rest of the balls are rolling against each other, causing abrasion of their surfaces. Both impact and abrasion lead to the grinding of mineral particles and the wear of grinding balls. The wear of grinding balls in wet grinding mills has been attributed to abrasion, corrosion, and impact, but their contributions to overall wear is not well established. Impact wear is an important problem in large operating mills, but it is not observed in laboratory ball mills. Abrasive wear also is claimed to become more important than corrosive wear in large industrial mills with much larger fall height (Ref 5).

The following three points are addressed from the results observed in laboratory ball mills:

- Relative significance of corrosion and abrasion
- Mechanism by which the galvanic interaction between grinding balls and mineral particles not only accelerates the ball wear but also adversely affects the flotation of minerals
- Guidelines for developing abrasion and corrosion resistant grinding media materials that are cost effective and do not adversely affect the flotation of minerals

Methods of Wear Measurements

Corrosive wear may be estimated from total wear if abrasive wear can be experimentally measured. For measurements of abrasive wear, the following four methods have been considered (Ref 6, 7, 8).

- In dry grinding, corrosion does not occur. However, the grinding mechanism is fundamentally different between dry and wet grinding. Wear in dry grinding cannot be used directly to represent abrasive wear in wet grinding. In wet grinding, ball surfaces are coated with slurries at all times, whereas in dry grinding, mineral particles do not stick to the surface of balls and the grinding proceeds mainly between mill walls and balls. As a result, the grinding efficiency is often quite low. When an ore contains some minerals with hydroxyl radicals, such as amphiboles and pyroxenes, the moisture released by grinding packs mineral particles around balls and the grinding process is in effect halted.
- Corrosion does not occur if an organic liquid with low electrical conductivity is used in place of water. The mechanism of grinding, however, appears to be different from that in water under seemingly identical conditions. Slurry rheology is thought to influence the grinding efficiency and wear.
- Corrosion may be suppressed by using corrosion inhibitors or by raising the pH. However, if the slurry is dispersed or flocculated by the addition of these reagents, ball wear is affected. Slurry rheology markedly influences wear behavior.
- A nitrogen atmosphere suppresses corrosion. As iron is an active metal, corrosion can occur even in a nitrogen atmosphere. However, the influence of corrosion is minimal and slurry rheology is not affected, so this is considered the most suitable method of estimating abrasive wear.

Several idealized methods have been used to investigate the effects of erosion/abrasion and corrosion in the wear of grinding balls, but it is difficult to correlate directly to plant practice. Marked ball wear tests are capable of providing test data close to practice (Ref 9). In this method, a sufficient number of marked balls are mixed with a regular charge of balls in a ball mill, and the weight decrease of the marked balls is measured after a certain time of grinding. In a laboratory scale, a 203 mm (8 in.) diameter porcelain mill charged with 126 balls of 25 mm (1 in.) diameter, of which about a dozen balls are marked, may be used (Ref 10, 11).
Ball wear data after dry and wet grinding using the marked ball wear test, plotted against grinding time, remain a straight line for well over 2 h, indicating that wear rates stayed constant over an extended period of time. The size distributions of the ground minerals, however, show that dry ground minerals are appreciably coarser than wet ground minerals (Ref 6, 7, 11). By determining the surface areas of the ground minerals using an air permeability method, ball wear is plotted against the surface-area increase by grinding (Fig. 1). In the figure, it is evident that wet grinding gives a notably larger surface-area increase than dry grinding. Such an observation

suggests that the mechanisms of dry and wet grinding are fundamentally different, and abrasive wear under dry grinding cannot represent the wear under wet grinding.

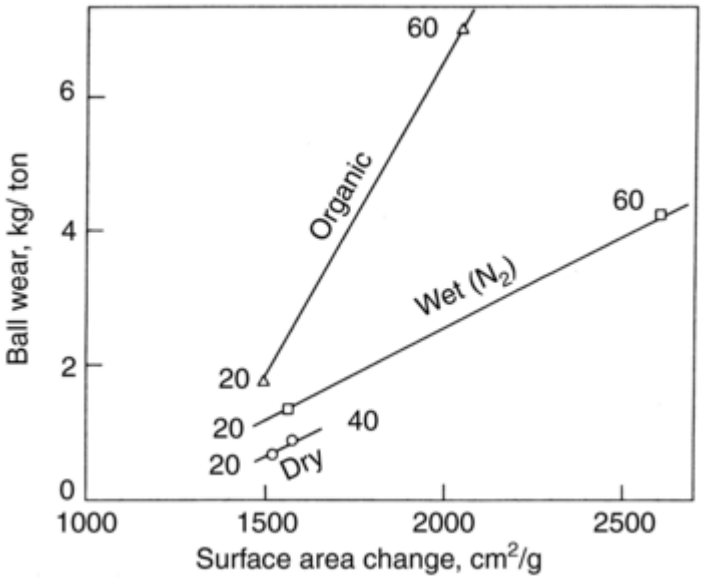

Fig. 1 Mild steel ball wear as a function of surface area change of ground magnetic taconite. On ends of plotted lines are the grinding times in minutes. Source Ref 6, 7, 10.

In Fig. 1, the results for organic liquid indicate that even though the wear rate is notably higher, the sample is not ground as fine as when water is used in grinding (Ref 11). Apparently, this wear behavior reflects the effect of slurry rheology on ball wear.

Model of Corrosive Wear

Corrosion of grinding balls may be classified into two types (Ref 6, 10). One type is called the differential abrasion cell (Fig. 2a), in which freshly abraded areas of the surface become anodes while unabraded areas become cathodes. Thus the corrosion reaction involves dissolution of iron by oxidation at freshly abraded areas and oxygen reduction at unabraded areas. Another type (Fig. 2b), involves galvanic interaction between electroactive minerals and balls. Sulfide minerals with high open circuit potentials become cathodes, while carbon steel balls become anodes. Corrosive wear by this galvanic interaction overshadows the corrosive wear by the differential abrasion cell.

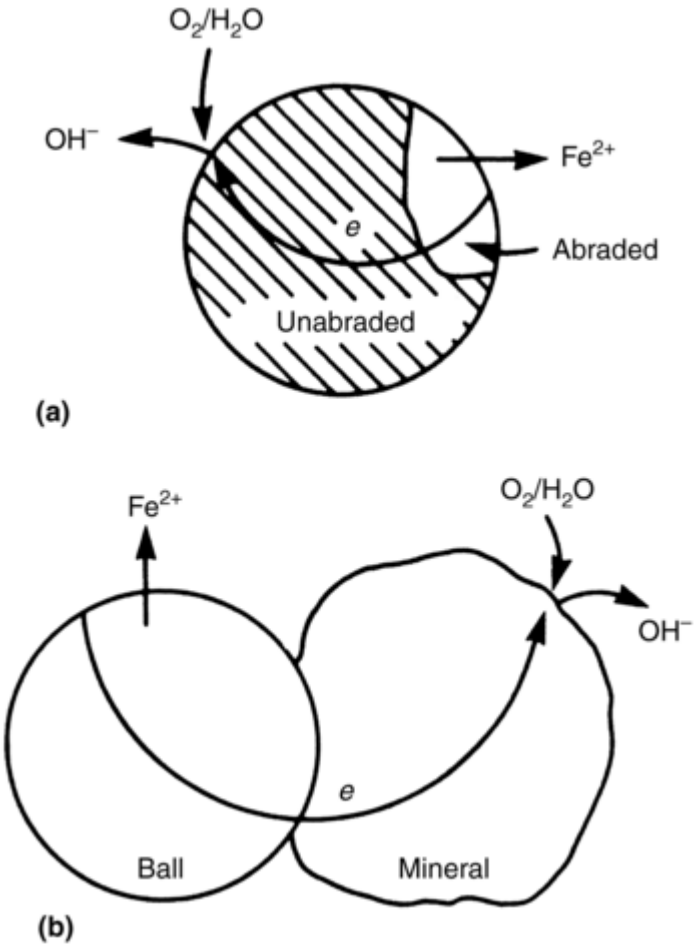

Fig. 2 Corrosion model for grinding balls in ore slurry in aqueous medium. (a) Differential abrasion cell. (b) Galvanic interaction cell. Source: Ref 6, 10

Figure 3 shows the effect of adding pyrrhotite (Fe_nS_{n+1}, typically Fe_7S_8) to a magnetic taconite ore ($\frac{1}{3}$ magnetite (Fe_3O_4), $\frac{2}{3}$siliceous gangue) and of mill atmosphere on ball wear. The results may be summarized as follows (Ref 12).

- In the absence of pyrrhotite, the effect of mill atmosphere is relatively minor.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- In the case of mild steel (MS) and high-carbon low-alloy (HCLA) steel, ball wear markedly increases with the addition of pyrrhotite under an oxygen atmosphere.
- Under a nitrogen atmosphere, ball wear is independent of pyrrhotite addition.
- With austenitic stainless steel (SS-A) balls, ball wear is virtually independent of mill atmosphere and also of the level of pyrrhotite addition.

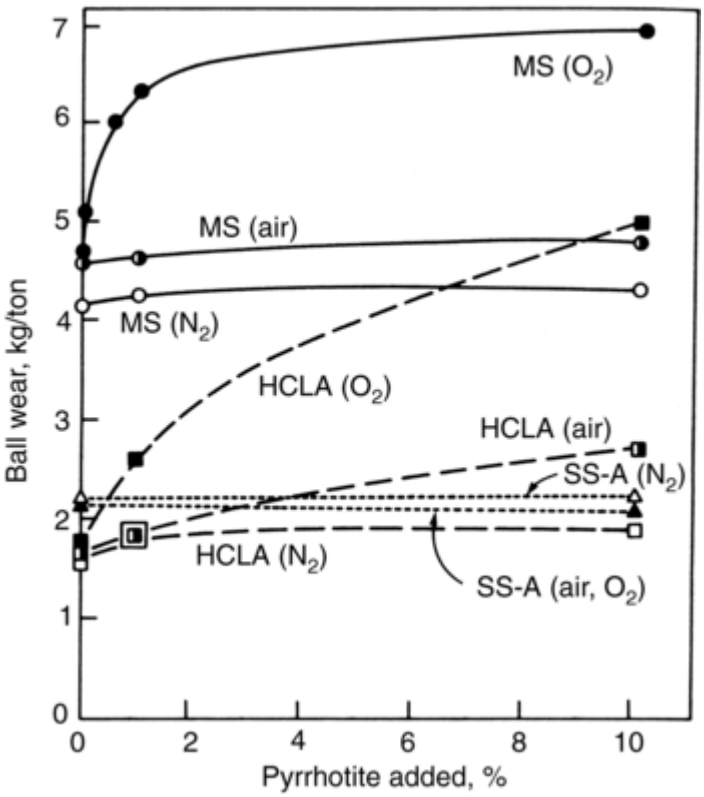

Fig. 3 Wear of mild steel (MS), high-carbon low-alloy steel (HCLA), and austenitic stainless steel (SS-A) balls as a function of pyrrhotite addition under different aeration conditions. Source: Ref 10

It is apparent that the wear of carbon steel balls is strongly influenced by the presence of pyrrhotite, particularly in mill atmospheres containing oxygen. Such an observation suggests that the wear under a nitrogen atmosphere is essentially due to abrasion, and the difference between the wear under an air or oxygen atmosphere and the wear under a nitrogen atmosphere represents corrosive wear.

Evidence in support of such an assumption may be provided by scanning electron microscope observations of the ball surfaces after grinding (Ref 6, 10, 11). Ball surfaces ground under a nitrogen atmosphere show numerous indentations with sharp ridges, suggesting that there is very little corrosion. Under an oxygen atmosphere, ridges become rounded and the appearance of corrosion becomes particularly severe in the presence of pyrrhotite.

Polarization Curve Measurements under Abrasion

Whether corrosive wear may be defined as the difference between wear under an air or oxygen atmosphere and wear under a nitrogen atmosphere can be examined by converting the weight losses to corrosion currents using Faraday's law and comparing with the corrosion currents obtained from electrochemical measurements under abrasive conditions in a slurry (Ref 8, 13).

Figure 4 shows an example of polarization curves of pyrrhotite (Fe_nS_{n+1}) and HCLA steel determined in a quartzite (SiO_2) slurry. According to corrosion theory, the intersection of the cathodic polarization curve of pyrrhotite and the anodic polarization curve of HCLA steel is the corrosion current. However, the total corrosion current between ground pyrrhotite and HCLA steel needs to be corrected for their respective surface areas. In this example, the surface area of the ground pyrrhotite was measured, and the polarization curve of pyrrhotite was drawn by taking the cathode/anode area ratio of 26.

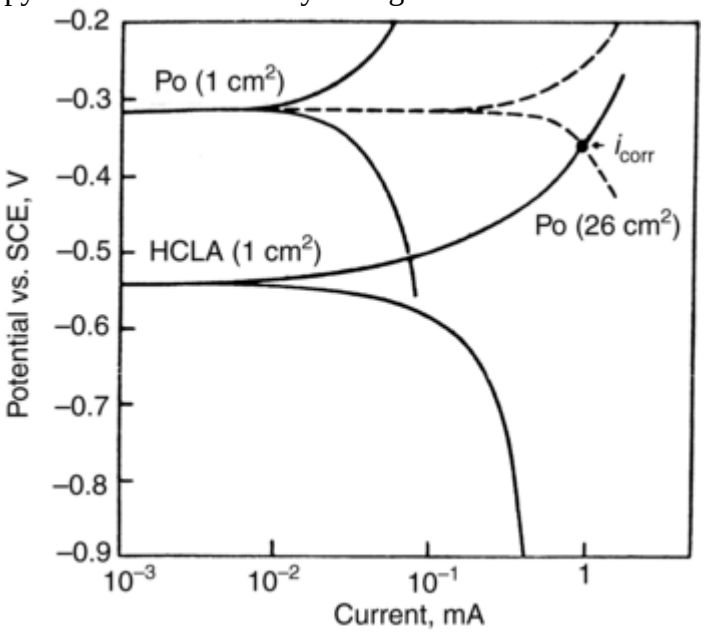

Fig. 4 Polarization curves. Estimation of corrosion current (i_{corr}) for the pyrrhotite (Po)-high-carbon low-alloy (HCLA) steel electrodes under abrasion in a quartzite slurry by adjusting to the surface area ratio of ground pyrrhotite and HCLA steel balls. SCE, saturated calomel electrode. Source: Ref 13

The corrosion current determined in this manner comes out to be 8 A/m^2 (0.74 A/ft^2) of ball surface. The total corrosion current is calculated to be 2.0 A for 126 balls of 25 mm (1 in.) diameter. This value agrees well with a value of 2.1 A estimated from the marked ball wear test data by using Faraday's law. This agreement demonstrates the role played by galvanic interaction in corrosive wear (Ref 8, 13).

Effect of Galvanic Interactions on Flotation

Thus far, the nature of reactions that occur at the surface of steel media in contact with pyrrhotite (Fe_nS_{n+1}) has been discussed. Now the manner in which the surfaces of pyrrhotite in contact with mild steel or stainless steel are affected by galvanic interaction is considered.

Figure 5 shows such an effect on pyrrhotite surfaces as manifested by its flotation behavior. The floatability of pyrrhotite left in air-exposed water in a glass beaker does not change with time. Pyrrhotite left in a stainless steel beaker does not show much change. However, the floatability of pyrrhotite contacted with a low-carbon steel crucible in air-exposed water notably decreases. When oxygen is bubbled into the water, the floatability is seen to decrease by an additional 15%. Conversely, when nitrogen is bubbled into the water, the floatability of pyrrhotite in contact with low-carbon steel is at the same level as pyrrhotite in contact with glass. Therefore, the galvanic interaction by contacting with low-carbon steel in the presence of oxygen adversely affects its floatability (Ref 14).

Aqueous Corrosion-Wear Interactions

Iwao Iwasaki, University of Minnesota Duluth

Mechanism of Electrochemical Interaction

Galvanic interaction between pyrrhotite and metallic iron leads to the formation of an iron hydroxide coating on the mineral by the reaction of hydroxyl ions released by the reduction of oxygen at the surface of a pyrrhotite cathode, and Fe^{2+} released from pyrrhotite (abbreviated as FeS). It interferes with the flotation as follows (Ref 14, 15):

$$\frac{1}{2}O_2 + H_2O + 2e^- = 2OH^- \quad \text{(Eq 1)}$$

$$FeS = Fe^{2+} + S^{2-}$$

$$S^{2-} \xrightarrow{+O_2} SO_4^{2-}$$

$$Fe^{2+} \xrightarrow{+O_2} Fe_2O(OH)_4 \text{ or } FeOOH \xrightarrow{} Fe(OH)SO_4 \quad \text{(Eq 2)}$$

At the steel anode, iron is oxidized and Fe^{2+} is released:

$$Fe = Fe^{2+} + 2e^- \quad \text{(Eq 3)}$$

This Fe^{2+} also becomes iron hydroxide, which coats the sulfide mineral surfaces and contributes to the interference with flotation. According to corrosion theory, the rates of oxidation reactions equal the rates of reduction reactions. Corrosive wear, therefore, should increase in proportion to the partial pressure of oxygen, and the hydroxide coating that forms on the pyrrhotite surface becomes heavier and seriously interferes with flotation. The presence of oxygen at the surface of pyrrhotite, a sign of the proposed mechanism, can be detected by Auger electron spectroscopy (Ref 15).

Thus, galvanic interaction affects not only the corrosive wear of grinding balls but also the flotation of pyrrhotite. A similar mechanism is reported on the flotation of galena (PbS) (Ref 16) arsenopyrite (FeAsS) (Ref 17), chalcopyrite ($CuFeS_2$) (Ref 18), and sphalerite (ZnS) (Ref 19).

Relative Significance of Corrosion and Abrasion in Wear

Table 1 shows an example of the results of laboratory marked ball wear tests for three types of steel balls in the wet grinding of magnetic taconite (Ref 6, 7). Ball wear is seen to increase with increasing oxygen partial pressure for mild steel and high-carbon low-alloy (HCLA) steel balls, and the increase is more pronounced when 10% by weight of pyrrhotite is added to the magnetic taconite. Assuming that wear under a nitrogen atmosphere approximates abrasive wear, the differences from wear in air and oxygen atmospheres represent corrosive wear. Table 2 shows percent corrosion in wear estimated in this manner.

Table 1 Grinding media wear in wet grinding of magnetic taconite in the absence and presence of pyrrhotite

	Mill atmosphere	Ball wear, mg per ball/h			
		Mild steel	**HCLA steel**	**Stainless steel**	
	Magnetic taconite	N_2	33.6 ± 0.4	13.0 ± 1.5	19.5 ± 0.1
Air		37.3 ± 0.7	13.8 ± 0.8	18.5 ± 0.1	
O_2		38.1 ± 0.5	14.2 ± 0.8	18.9 ± 0.9	
Magnetic taconite + 10% pyrrhotite	N_2	34.8 ± 0.4	15.1 ± 1.5	19.9 ± 0.3	
	Air	38.6 ± 0.5	21.7 ± 2.3	18.5 ± 1.1	
	O_2	55.5 ± 0.3	40.5 ± 3.5	18.7 ± 0.2	

HCLA, high-carbon low-alloy. Source: Ref 6, 7

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Table 2 Corrosion as a percent of total wear loss in taconite grinding

	Change in mill atmosphere	Corrosion in wear, %		
		Mild steel	**HCLA steel**	**Stainless steel**
Magnetic taconite	N_2 to air	10	6	(-5)
	N_2 to O_2	12	8	(-3)
Magnetic taconite +10% pyrrhotite	N_2 to air	10	30	(-7)
	N_2 to O_2	37	63	(-6)

HCLA, high-carbon low-alloy. Source: Ref 6, 7

Corrosion of mild steel and HCLA steel in the grinding of magnetic taconite is about 10%, and, therefore, abrasive wear is about 90%. In the case of stainless steel, the wear under air and oxygen atmospheres even decreases somewhat due to passivation.

When pyrrhotite (Fe_nS_{n+1}) is added to magnetic taconite, the wear of HCLA steel notably increases to approximately 30%. In the case of mild steel, the effect of pyrrhotite is relatively small. This is because mild steel is less abrasion resistant than HCLA steel and more abraded debris is generated. This is magnetically attracted to the surface of pyrrhotite and lowers the open circuit potential of the mineral, thereby lowering the galvanic interaction (Ref 13). Under an oxygen atmosphere, the corrosion of mild steel and high-carbon steel reached approximately 40 to 60%. This is because the metallic iron debris generated is oxidized and the open circuit potential of pyrrhotite increases and helps promote the galvanic interaction. In this case also, the wear of stainless steel decreased under an oxygen atmosphere, which suggests that the corrosion component in an abrasive environment may be controlled by a proper selection of alloy composition.

Galvanic Interactions in Multielectrode Systems

When complex sulfide ores are involved, multielectrode galvanic cells develop between minerals and grinding balls as well as among the minerals themselves. Figure 6 shows combination potentials and galvanic currents of a short- circuited pyrite (FeS_2), pyrrhotite (Fe_nS_{n+1}), and mild steel electrode under abrasion in a quartzite (SiO_2) slurry bubbled with oxygen (Ref 20). Pyrite, with a high open circuit potential, acts as the cathode on which oxygen reduction takes place. Pyrrhotite, with a lower open circuit potential, becomes an anode and dissolves. Such behavior suggests lower corrosion activity for mild steel when in contact with pyrite and pyrrhotite simultaneously than when in contact with pyrite alone.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

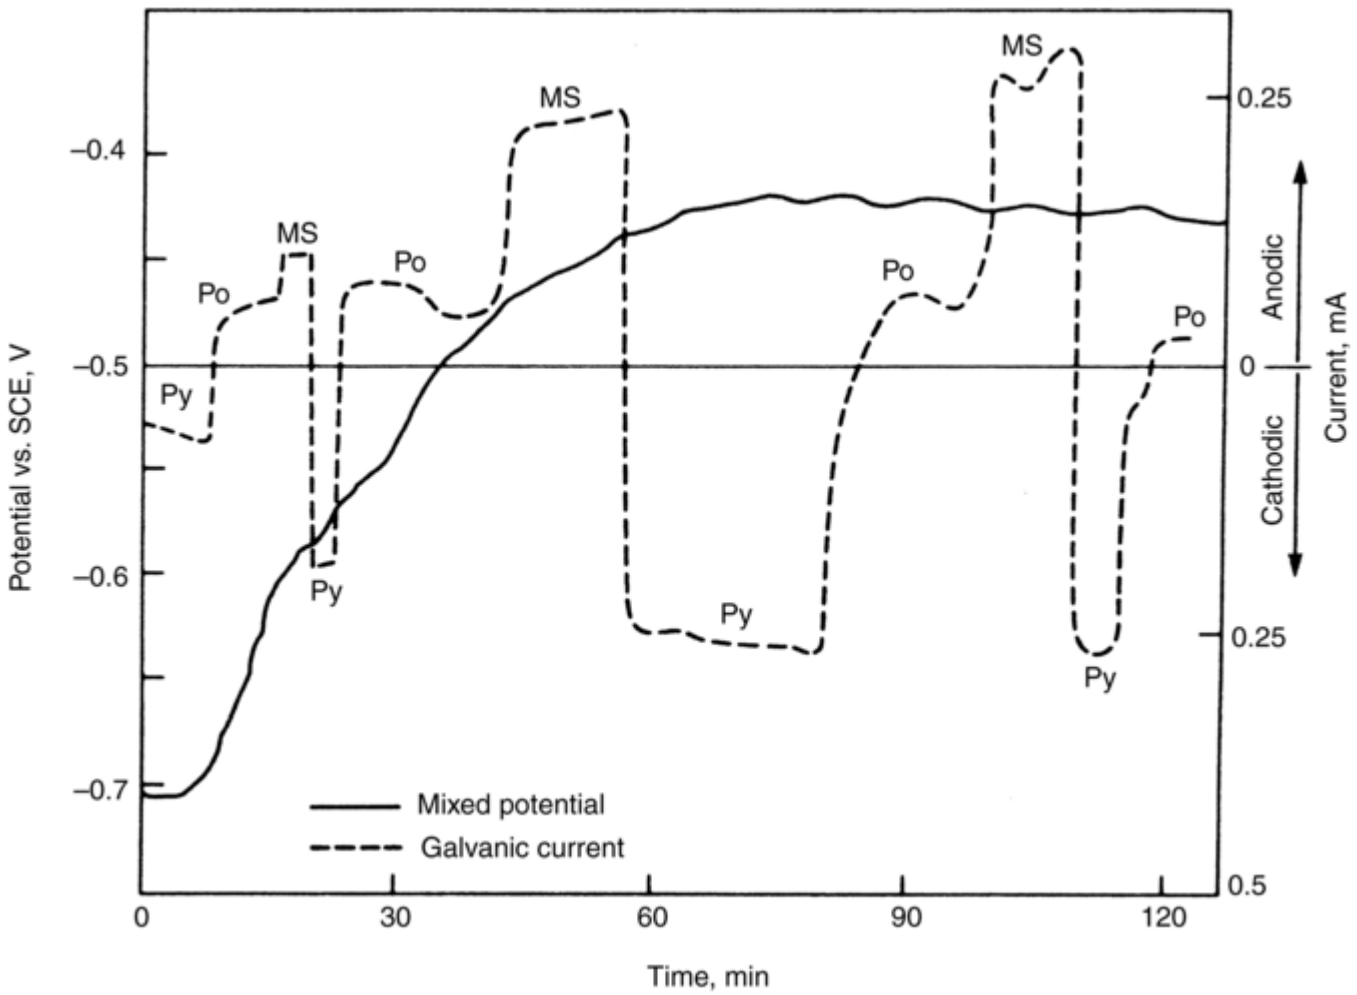

Fig. 6 Combination potentials and galvanic currents of a short-circuited pyrite-pyrrhotite-mild steel (MS) electrode under abrasion in a quartzite slurry in a 0.05 *M* sodium sulfate solution at neutral pH under oxygen atmosphere. Pyrrhotite, Po. Pyrite, Py. Source: Ref 20

Polarization curves of a pyrite, pyrrhotite, and mild steel combination are shown in Fig. 7. Point 1 represents the corrosion current for a pyrite- mild steel combination, and point 2 represents a pyrrhotite-mild steel combination. Point 3 represents a three-electrode combination involving pyrite, pyrrhotite, and mild steel. In Table 3, the results of marked ball wear tests and polarization measurements are compared. The table shows general agreement between the corrosion currents calculated from the marked ball wear tests and the corresponding corrosion currents determined from the polarization curves. Greater corrosion loss in the presence of pyrite with respect to corrosion loss in the presence of pyrrhotite can be understood by the nobler behavior developed by pyrite relative to pyrrhotite. The anodic behavior of the pyrrhotite electrode in the three-electrode system may also be understood by the smaller ball wear due to corrosion when both pyrrhotite and pyrite are present than when pyrite alone is present in the ore charge.

Case History on Material Selection for Grinding Balls

To minimize corrosion loss and the adverse effect on flotation, it is necessary to search for materials that form passive films rapidly on grinding ball surfaces.

Figure 8 shows the polarization curves of austenitic stainless steel (SS-A), martensitic stainless steel (SS-M) and HCLA steel under abrasion in a quartzite (SiO_2) slurry, bubbled with oxygen, as a function of rotating speed (Ref 22). Austenitic stainless steel at rest is fully covered with a passive film. As the rotational speed is increased, the current flow increases, indicating that more active surfaces are exposed. The electrode potential shifts toward negative or more active direction. Anode currents increase in the order SS-A, SS-M, and HCLA steel. In fact, the curves of HCLA steel show little dependence on rotational speed, suggesting that the HCLA steel surface forms essentially no effective passive film in a neutral solution.

Fig. 8 Polarization curves of (a) austenitic stainless steel (SS-A), (b) martensitic stainless steel (SS-M) and (c) high-carbon low alloy steel (HCLA) balls under abrasion in oxygenated quartzite slurries at different rotating speeds. Source: Ref 22

The results thus far indicate that HCLA steel is abrasion resistant but not corrosion resistant. Conversely, austenitic stainless steel is corrosion resistant but not abrasion resistant. Therefore, those materials that are as hard as HCLA steel and as corrosion resistant as austenitic stainless steel are desirable for grinding media application. High-chromium cast iron holds a possibility of combining both properties in a material. It is of interest what level of chromium imparts the electrochemical properties similar to those of austenitic stainless steel. Tests using a series of chromium-bearing cast iron balls having a Cr content ranging from 0 to 29% can provide such information. Polarization curves determined on this series of balls by changing the rotational speed under an oxygen atmosphere show that 0% Cr cast iron resembles HCLA steel, while those of 29% Cr cast iron resemble austenitic stainless steel (Ref 23).

Under a nitrogen atmosphere at a constant applied potential, anodic currents of chromium- bearing cast iron electrodes remain virtually independent of rotational speed, which suggests that very few passive films are formed. Hence, by extrapolating the anodic currents (measured as a function of rotational speed at a constant applied potential under an oxygen atmosphere) to that obtained under a nitrogen atmosphere, the anodic currents of fully active surfaces may be estimated. Here, there is no time to form a passive film at that rotational speed. Figure 9 shows the rates of passive film formation estimated from the rotational speed and the diameter of a ball used as the rotating electrode (Ref 24). The figure includes the results obtained on austenitic stainless steel (SS-A) in a similar manner along with those obtained on high-chromium cast iron (HCCl) balls containing 26 and 29% Cr. The rates of passive film formation are about 2 m/s (6.6 ft/s) and increase with increasing anodic potential. The rates of 29% Cr cast iron are similar to those of austenitic stainless steel (SS-A), but the rates of 26% Cr cast iron are somewhat lower. Therefore, high chromium cast iron can combine both hardness and corrosion resistance by rapid passive film formation.

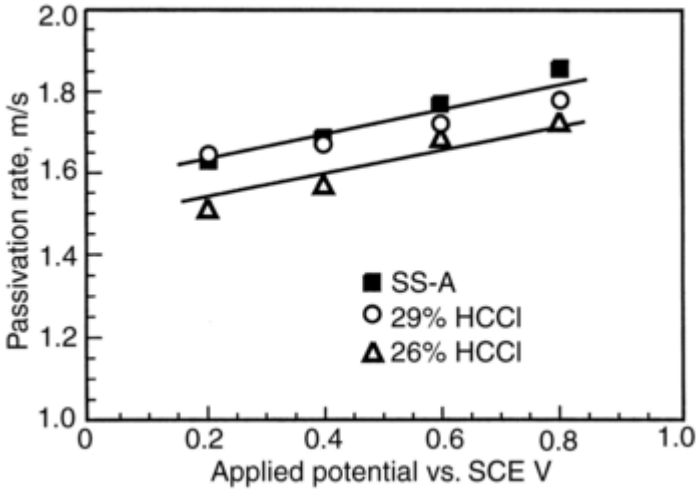

Fig. 9 Rates of passive film formation of austenitic stainless steel (SS-A) and high chromium cast iron (HCCI) balls in an oxygen atmosphere. Source: Ref 23

Wear Characteristics of Chromium-Bearing Cast Iron. Figure 10shows the wear data obtained for various cast iron balls under a nitrogen or oxygen atmosphere using artificial ore samples of quartzite (SiO_2) and quartzite mixed with either pyrrhotite (Fe_nS_{n+1}) or chalcopyrite ($CuFeS_2$). In a nitrogen atmosphere, the ball wear is essentially unaffected by the presence of sulfide minerals (Ref 23). A slight decrease in wear with increasing chromium content may be related to the abrasion resistance, which is governed by ball microstructure and carbide hardness.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

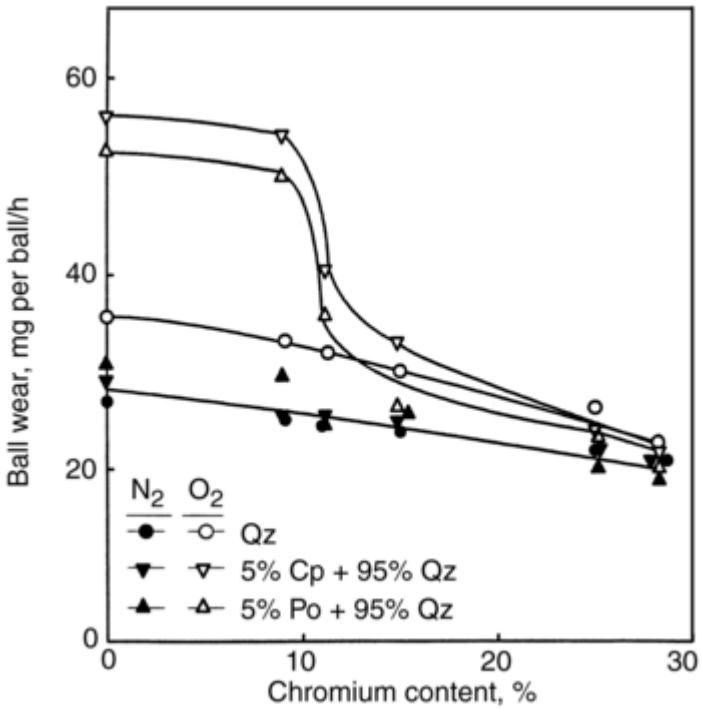

Fig. 10 The effect of chromium contents on the wear of ball materials in wet grinding of quartzite (Qz), quartzite with either 5% pyrrhotite (Po) or 5% chalcopyrite (Cp) slurries in the presence and absence of oxygen. Source: Ref 24

When a quartzite sample is ground in an oxygen atmosphere, ball wear increases. The difference between wear under nitrogen and oxygen atmospheres increases with decreasing chromium level. This difference can be attributed to corrosion due to differential abrasion cell, as discussed previously, and wear increases with a decreasing chromium level. In the presence of pyrrhotite and chalcopyrite, ball wear increases markedly in an oxygen atmosphere when ball chromium levels are below 10%. Apparently, there is a marked change in the nature of the passive film at low- and high-chromium contents. A transition in media wear is observed between 8.5% and 16% Cr.

Flotation of Samples Ground with Chromium-Bearing Cast Iron Balls. Figure 11 shows the flotation recoveries of pyrrhotite from a pyrrhotite-quartzite mixture, ground with various cast iron balls, as a function of collector addition (Ref 23). Potassium ethyl xanthate (KEX) is used as a collector for floating the sulfide mineral. The collector is adsorbed on pyrrhotite but not on quartzite. The collector-coated particles are attached to air bubbles, thereby leading to flotation separation. In a nitrogen atmosphere, the flotation of pyrrhotite, ground with cast iron balls containing less than 11% Cr, is minimal, even when an excessive amount of the collector is used. Although these results appear to contradict the results shown in Fig. 5, this behavior may be attributed to abraded debris generated in grinding. The abraded debris is magnetically attracted to the pyrrhotite surface, thereby lowering the open-circuit potential of pyrrhotite. Apparently, lowering of the potential prevented oxidation of the xanthate collector to dixanthogen, an effective form of the adsorbed collector for flotation.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

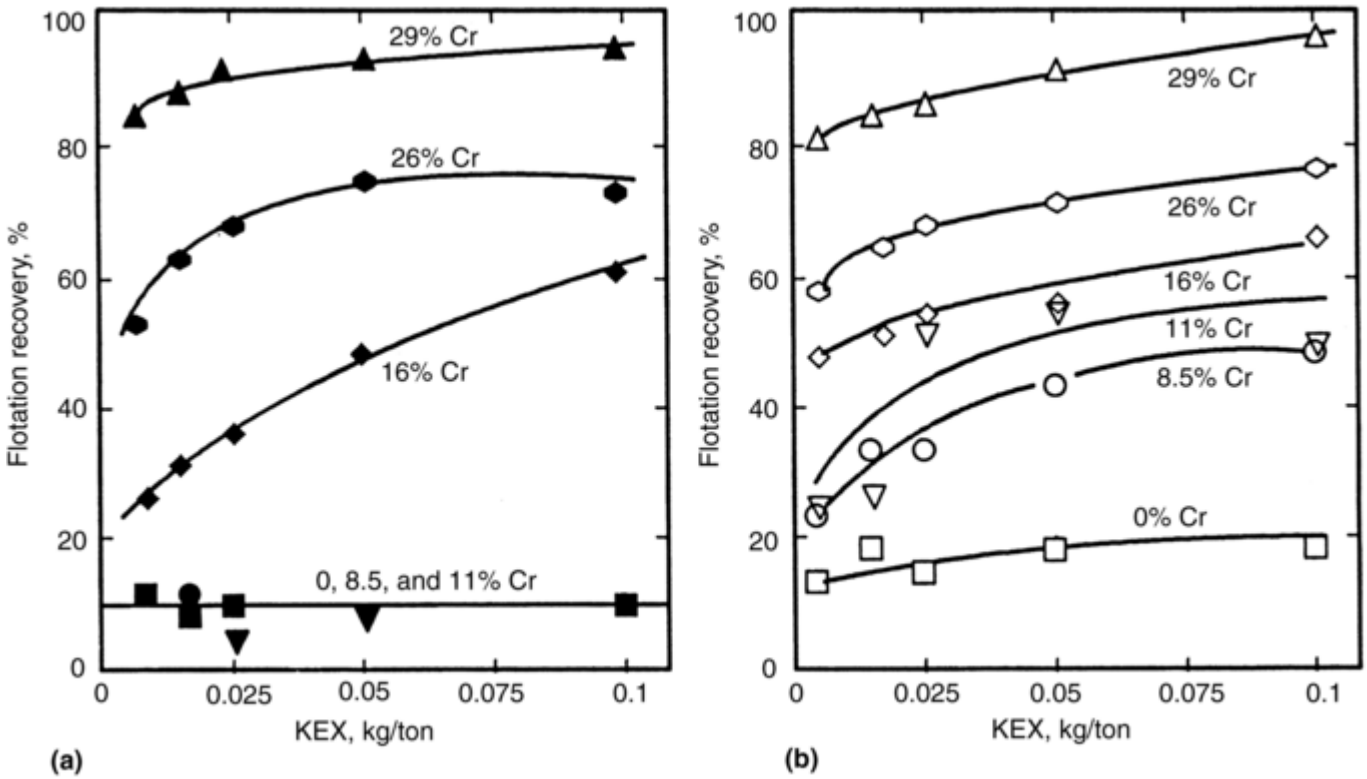

Fig. 11 Batch flotation results using potassium ethyl xanthate (KEX) on a quartzite with 5% pyrrhotite mixture ground with various cast iron ball materials under (a) nitrogen or (b) oxygen atmosphere. Source: Ref 24

Flotation results on the samples ground with 16 and 26% Cr balls show increasingly higher flotation recoveries and become less sensitive to the atmosphere in the grinding mill. Samples ground with 29% Cr balls give nearly full recoveries, even with a minimal addition of the collector. Formation of passive films raises the open circuit potentials of abraded debris, thereby relieving the adverse effect on the flotation of pyrrhotite by restoring its open-circuit potential.

Conclusions. Corrosion of ferrous materials is accelerated under abrasive conditions in slurries by the differential abrasion cell reactions. In the presence of sulfide minerals, corrosion is further accelerated by galvanic interaction. Sulfide mineral surfaces are also altered by contacting with ferrous materials, and their flotation recoveries are adversely affected. Flotation behaviors of pyrrhotite (Fe_nS_{n+1}) are complexly affected by abraded debris generated in grinding, which is magnetically attracted to pyrrhotite surfaces. This abraded debris alters the open circuit potential of pyrrhotite. Its mechanism may be clarified by studying the electrochemical behaviors under abrading conditions in a slurry medium.

Galvanic interaction phenomena play an important role in the wear of rods and balls in grinding, of slurry pipelines, and of sand pumps. In the case of grinding balls, high-chromium cast iron appears to be the material of choice because it is not only wear resistant but also does not adversely affect flotation.

Introduction

WEAR AND CORROSION are not easy to avoid in most industrial or manufacturing processes. Many industrial processes run at elevated temperatures, and pieces of equipment can become heated with use. Unfortunately, increased heat can exacerbate both wear and corrosion. In terms of wear, rising temperatures soften metals and make their surfaces easier to penetrate. A variety of wear mechanisms can operate including adhesive (or sliding), abrasive, erosive, and fretting. In terms of corrosion, thermal kinetics accelerate the chemical reactions that degrade material. Together, wear and corrosion can lead to high economic costs and productivity losses, as worn and/or corroded equipment requires increased repair and maintenance. The interactions between wear and corrosion in dry environments are addressed in this article.

Various industries experience increased maintenance costs as a result of oxidation-wear interactions. The power-generation industry is one such example. In coal-fired plants, the coal is pulverized in a highly abrasive process. Heated air, which accelerates corrosion, carries the coal fines through metal tubes to the burner units. The moving fines erode these metal pipes. At the end of the pipes, the fines are injected into the boiler through nozzles that themselves are eroded by the coal fines and oxidized as a result of the high temperatures. Products of combustion, waste silica, and exhaust gas can erode heat-exchange tubes in a boiler.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Burning biomass (Ref 1, 2) accelerates erosion-corrosion in power plants. Sliding wear can be a challenge on control valves (Ref 3) and hot drag chain conveyors. In coal-burning power plants, both in pulverized-coal and fluidized-bed (Ref 4) systems, high-temperature erosion-corrosion can occur on everything from boiler tubes and reheaters to the economizers.

Other industries also pay a heavy cost for wear-corrosion interactions. Crushing and grinding ores and minerals are sometimes done at elevated temperatures, which can lead to accelerated abrasive wear (Ref 5). Hot forming extrusion dies, hot drag chain conveyors for smelters and heat treaters, and continuous caster rolls can suffer from sliding wear (Ref 5). Cutting and machining metals at high speed can produce temperatures as high as 1000 °C (1800 °F), which leads to abrasive wear, adhesive wear, and corrosion (Ref 6). Cutting wood, particularly particleboard, can generate temperatures estimated as high as 800 to 1000 °C (1500 to 1800 °F) and cause wear and oxidation to the cutting tips (Ref 7). Other applications faced with wear- corrosion problems include: steam turbines, gas turbines, sliding electric contacts, internal combustion engines (cylinder liners, piston rings, valve seats, and valves), compressors, furnace parts, extrusion parts (dies), gas-cooled nuclear reactors, and brake rotors and drums.

A better understanding of how wear and corrosion interact in gaseous environments is necessary because together they can do more damage than either would do alone. The ability to decrease their synergistic impact can reduce significantly maintenance and replacement costs in a variety of manufacturing industries.

Mechanisms

The following sections discuss the mechanisms of wear and their interactions with gaseous corrosion. Further information on the mechanisms of gaseous corrosion is available in the article “Gaseous Corrosion Mechanisms” in this Volume.

Abrasive wear is the removal of material due to the relative motion of hard particles or protuberances against another surface. Although most research tends to focus on the wearing surface with the most potential for economic loss or gain, it should be noted that when two surfaces come into contact, wear can take place on both.

The rate at which a given surface abrades is dependent on the properties of the surfaces in contact, the presence of abrasives between them, the speed of contact, and the environmental conditions. In short, loss rates are not an inherent property of a given material. For example, a crusher grinding coal will not wear as quickly as an identical one grinding silicon carbide. A ball mill will see a different wear rate grinding coal than will a ball-and-race mill.

Abrasion is typically categorized according to types of contact and contact environment. Types of contact include two-body wear and three-body wear. Two-body wear occurs when an abrasive interacts with a single surface. Three-body wear occurs when an abrasive interacts with two surfaces or with a single surface and other particles. Two-body systems typically experience 10 to 1000 times as much loss as three-body systems for a given load and path length of wear. Contact environments (Fig. 1) are separated into open (or free) and closed (or constrained) contact. Blickensderfer (Ref 8) showed in several different tests that for a given load and wear path length, the wear rate is about the same for open and closed systems. However, the abrasive loss in closed systems will often appear higher than the abrasive loss in open systems. This can occur because closed systems tend to involve higher loads.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

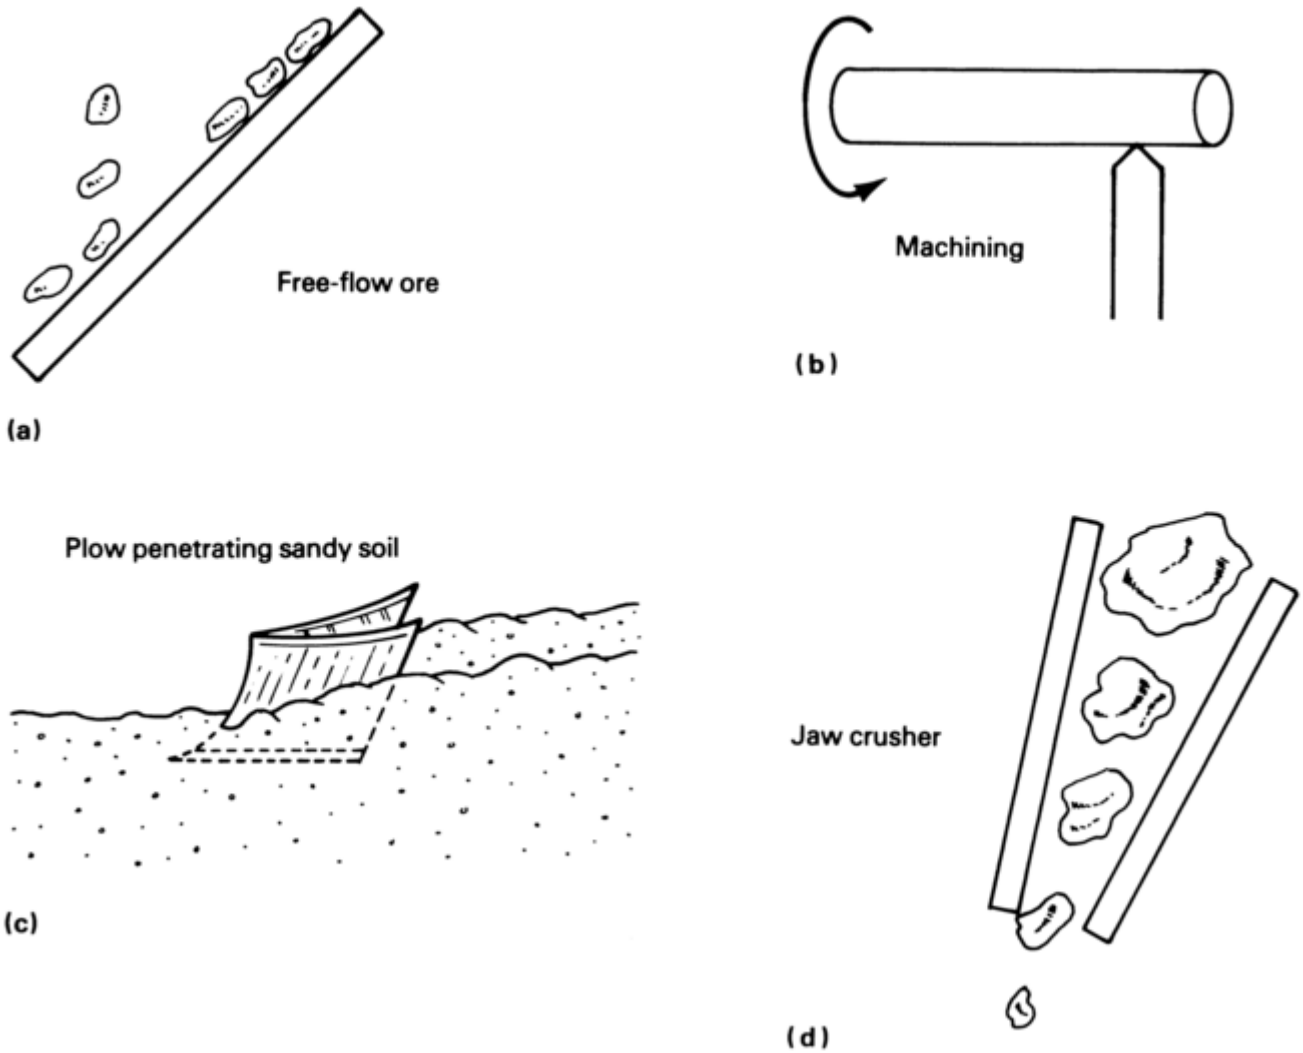

Fig. 1 Types of contact during abrasive wear. (a) Open two-body. (b) Closed two-body. (c) Open three-body. (d) Closed three-body

Abrasion can be divided further into low- stress, high-stress, and gouging classifications. Low-stress abrasion occurs when the abrasive remains relatively intact. High-stress abrasion exists when abrasive particles are being crushed (for example, in a ball mill where both the grinding balls and the abrasive material such as coal are worn down). In gouging, a relatively large abrasive surface cuts pieces off of another surface (for example, ore passing through a jaw crusher).

Several mechanisms have been proposed to explain how material is removed from a surface during abrasion. These mechanisms include fracture, fatigue, and melting. Due to the complexity of abrasion, no one mechanism completely accounts for all of the material loss.

Plowing is the process of displacing material from a groove to the sides. This occurs under light loads and does not result in any real material loss. However, the new surface created as a function of the material relocation is susceptible to loss through microfatigue. When the ratio of shear strength of the contact surface to the shear strength of the bulk rises to a high enough level—0.5 to 1.0—it is possible to develop a wedge on the front of an abrasive tip. In this case, the total amount of material displaced from the groove is greater than the material displaced to the sides. Wedge formation is still a fairly mild form of abrasive wear.

The most severe form of wear for a ductile material is cutting. During the cutting process, the abrasive tip removes chips from the second wear surface. This results mostly in material removal, as there is very little displaced material relative to the size of the groove. For every sharp abrasive particle there exists a critical angle that defines the difference between plowing and cutting. This angle is dependent on the material being abraded. The critical angles range from 45° for copper to 85° for aluminum (Ref 9, 10). Since all angles will be represented during abrasive wear, both cutting and plowing will be observed. Kato (Ref 11) and others have analyzed the effect of a rounded tip pushing through a surface. They found that the degree of penetration is

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

critical to the transition from plowing and wedge formation to cutting. When the degree of penetration, defined as depth of penetration divided by the contact area, exceeded about 0.2, cutting was the predominant mode of wear.

Archard's equation is commonly used to model abrasive wear (Ref 12):

$$W = k\frac{Ld}{H} \qquad \text{(Eq 1)}$$

This formula was derived for adhesive wear, but has also proven useful in measuring abrasive wear. *W* is the volume of material removed, *k* is a constant, *L* is load, *d* is distance traveled, and *H* is hardness of the material.

It is common to describe materials as having either good wear resistance or poor wear resistance. Wear resistance, *R*, is defined as the reciprocal of the wear volume:

$$R = \frac{1}{W} \qquad \text{(Eq 2)}$$

and the higher the value *R*, the better the wear resistance.

Brittle materials have an additional mode of abrasive wear, microfracture, which occurs when forces applied by the abrasive grain exceed the fracture toughness of a material. This is often the mode for wear removal of corrosive layers formed on the surface of metals.

Another mechanism of wear loss is thermally related processes such as the melting that can occur during a wear event. Loss via melting requires small, localized areas of strain-induced adiabatic heating. Research indicates that there can be enough temperature rise for dislocation recovery to take place near the abraded surface (Ref 13). The temperature rise can also contribute to the formation of a corrosion product layer.

It has been shown both experimentally and theoretically that the hardness of a material correlates with its abrasion rate. Extensive tests by Khruschov (Ref 14). documented an inverse relationship between abrasion rate and annealed hardness for pure metals (Fig. 2). Khruschov also tested steels of varying hardness and found an inverse linear relationship between wear and hardness, although the slope of the equation was different than that for pure metals.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

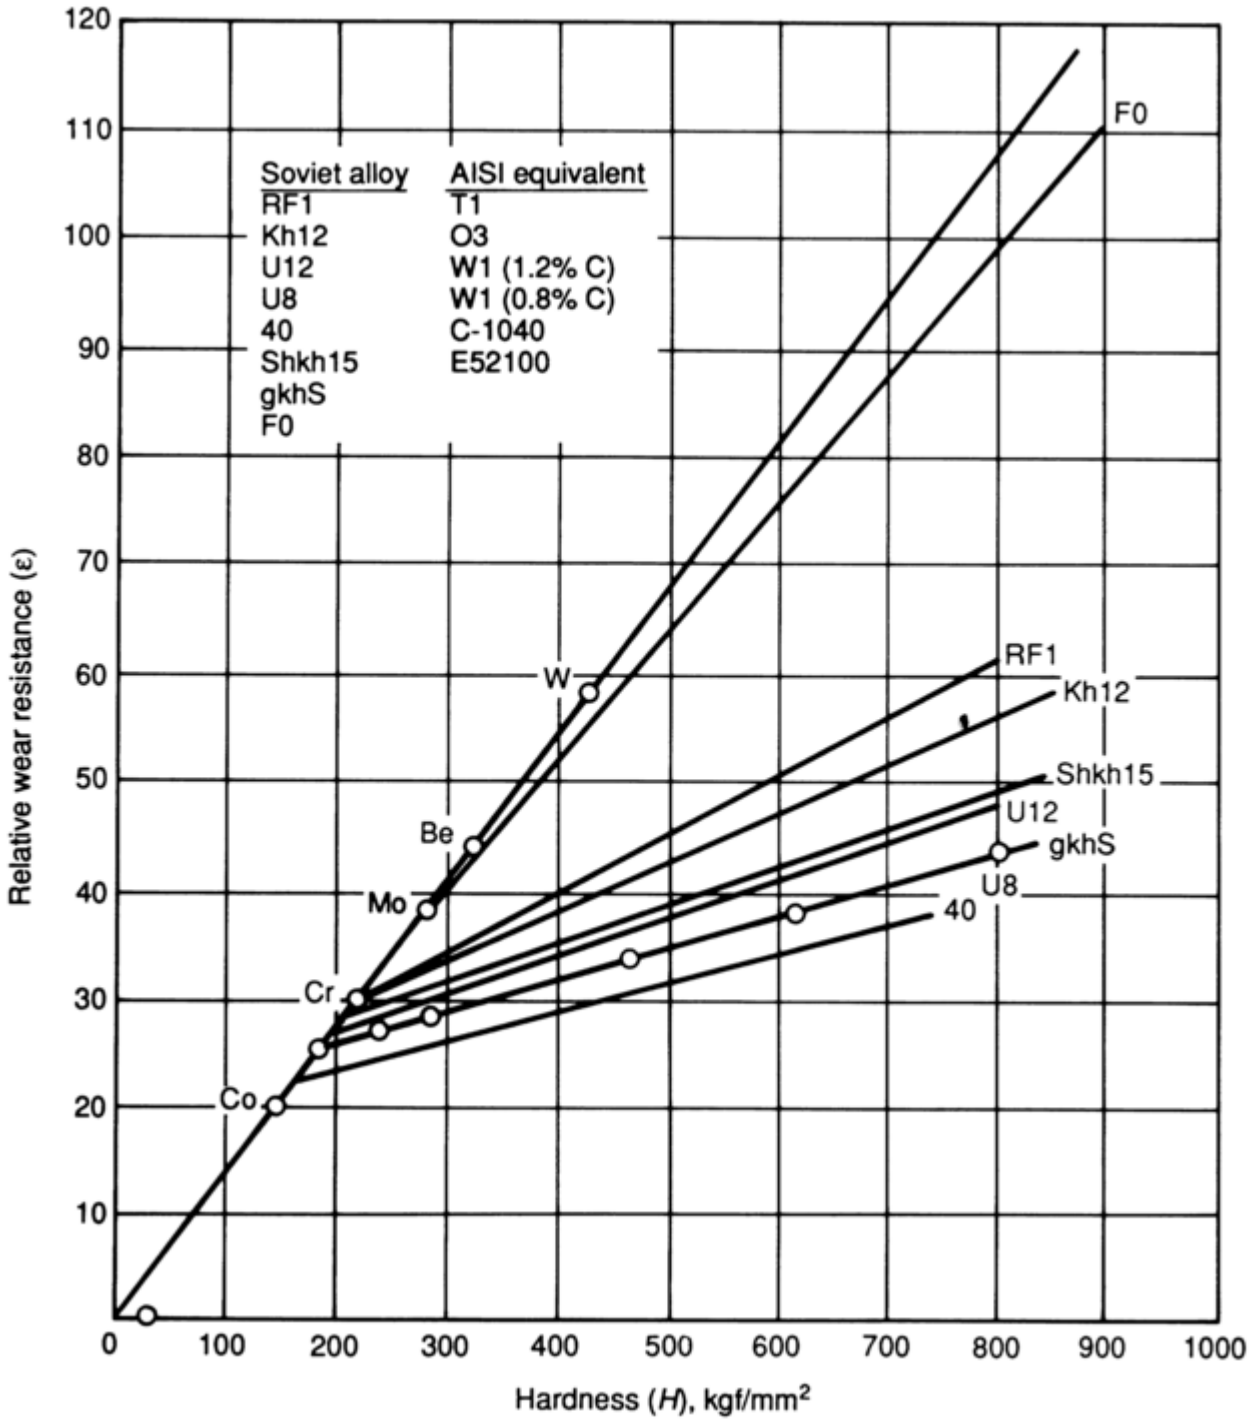

Fig. 2 Wear resistance versus hardness for pure metals and some steel alloys. Source: Ref 14

The hardness of abrasive particles is important to the rate of abrasive wear. As the hardness of the abrasive exceeds that of the wear material, the abrasive wear typically increases, as shown in Fig. 3.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

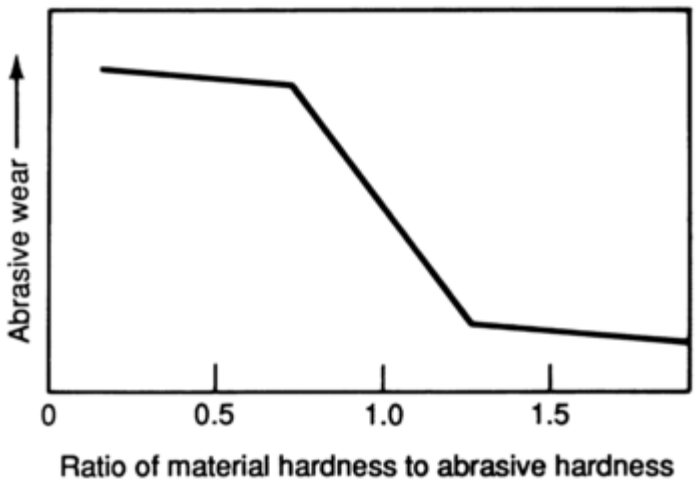

Fig. 3 Effect of abrasive hardness relative to material hardness on abrasive wear, showing the wear transition as wear surface becomes as hard as the abrasive

Elevated-temperature abrasion can produce what seems to be an unexpected result. Consider the case of a three-body abrasive-wear test on pure aluminum and copper (Ref 15). The copper abraded faster as the temperature increased to 400 °C (750 °F). At similar temperatures, the aluminum showed a slight decrease in abrasion. The increase for copper was attributed to an easily removed oxide coating. The decrease for aluminum was caused by a thin protective oxide film and abrasive particles embedded in the surface of the aluminum.

One common method of improving the abrasion resistance of a material is to add or form secondary-phase hard particles. Tungsten-carbide particles, with their high hardness (~2000 HV) and impressive toughness, are commonly added to steels to form materials more resistant to abrasion. In the tungsten-carbide/steel composite, the softer steel matrix is worn away, leaving the hard tungsten-carbide particles to protect the bulk material. This combination works best at temperatures below 700 °C (1300 °F).

Higher temperatures require other additives. Cr_3C_2 carbides are a good wear match for additions to nickel-base alloys. The combination is stable at higher temperatures. Above 800 °C (1500 °F) the carbides can actually work with other wear debris to form a protective glaze. Another hard particle that shows promise at high temperatures is TiC. Berns (Ref 16) has shown that in situ formed TiC particles, which are harder than Cr_3C_2, have promise for applications at 750 °C (1400 °F) in alloys with a NiCrAlSi matrix.

Erosive Wear. The mechanism of pure erosion, although extensively studied, is not fully understood. The impact of gases, liquids, solids, or a combination thereof onto a surface can result in erosive wear. The study of the erosion of ductile metals (Ref 17, 18, 19) is more advanced than that of brittle materials (Ref 20). Kosel (Ref 21) produced a review of solid-particle erosion on both ductile metals and brittle ceramics that includes corrosion effects. Additional sources (Ref 22) have attempted to bring more clarity to the field. Factors such as the rate of erosion, angle of impact, and velocity are all vitally important in predicting and reducing material loss.

In dry, elevated-temperature environments, erosion is usually a function of solid particles propelled by a gas stream. Erosion can be expected whenever there is a stream of entrained solids with a velocity above 1 m/s (2.2 mph). Thinning of the material subject to the gas stream can help identify damage caused by erosion. Other indications of erosion include localized changes in surface finish, or in some cases, the development of ripple patterns.

Erosion damage is sometimes mistaken for that of abrasion. Studying the wear environment is one way to differentiate between the two. Erosion occurs when particles rebound chaotically off of other surfaces; abrasion results from particles sliding along the surface. The wear on a boiler tube, for example, would be erosive due to the constant flow of airborne coal fines. The wear in a fluidized bed could be either abrasive or erosive, depending on the operating conditions.

Erosion in the absence of oxidation can be modeled in terms of three types of variables: material properties, impingement properties (such as flow variables), and particle properties. The material properties usually included in erosion models include strain-rate effects, hardness, and microstructure (Ref 23). Impingement properties include particle velocity (v), angle of incidence (α), and particle concentration. Particle properties include shape, size, hardness, and resistance to fracture.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Materials are typically described in terms of being brittle or ductile. This is based on the response of the material to the angle of incidence of the flow (Ref 23). Brittle materials such as glass or ceramics exhibit a maximum erosion rate at a 90° angle of incidence; the wear decreases as the angle of incidence decreases. Ductile materials, such as pure metals and low-alloy steels, have a maximum erosion rate at a low angle of incidence, usually 15 to 30°, as shown in Fig. 4).

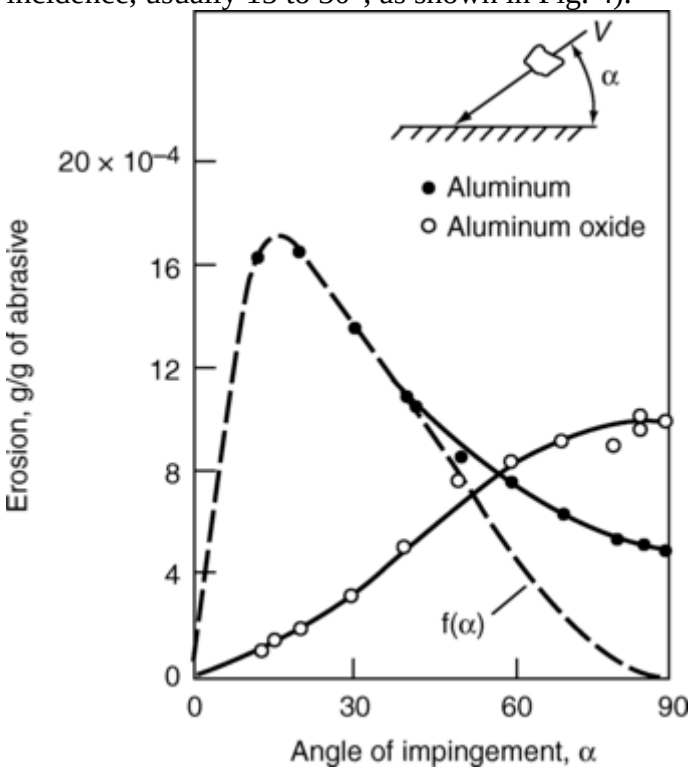

Fig. 4 Effect of angle of impingement on erosion rate for a ductile and brittle material, from Finnie (Ref 22). Note: aluminum oxide (Al_2O_3) data has been multiplied by 10 to better show the results. The line f(α) shows a projected model.

An oxidized metal can exhibit both brittle and ductile properties: the bulk metal can be ductile while its corrosion layer is brittle. In severe erosive conditions, the damage caused by an abrasive may penetrate through the brittle oxide layer and produce wear to the ductile base material. In the case of less-severe erosion conditions, the abrasive may remove the brittle oxide layer while having no impact on the ductile bulk material. In other instances, wear losses can include both the ductile bulk metal and semibrittle oxide layer. In this last case, the maximum erosion rate will be at an intermediate angle of incidence.

A fairly simple power-law model has been developed to equate erosion rate, *E*, with particle velocity:

$$E = kv^n \qquad \text{(Eq 3)}$$

where *k* is a constant and *n* is a velocity exponent that is dependent on material and erosion conditions. The value of *n* typically ranges from 2 to 2.5 for metals and 2.5 to 3 for ceramics.

The size of the abrasive particle seems to have little effect for particles larger that 100 μm. For particle sizes smaller than 100 μm the erosion rate decreases with particle size. There is very little erosion for particle sizes smaller than 5 to 10 μm.

The addition of oxidation to the erosion process leads to damage that is a function not only of material properties, but also of properties of the environment. The “Erosion by Liquid and Solid Impact” conferences have been a leading forum for research into the combined effects of oxidation and erosion (Ref 24, 25). While there may be some initial decrease in erosion as temperatures increase, pure erosion tends to increase as temperatures increase for both metals and ceramics. The combined erosion-corrosion process tends to show further increases in material loss at increasing temperatures. Most high-temperature alloys, designed for service below 850 °C (1560 °F), depend on a chrome oxide layer for protection against rapid oxidation. The ability of materials to resist further oxidation depends on a solid, nonporous adherent layer. Figure 5 shows the effect of erosion on a material forming a nonprotective brittle oxide, in this case Ti-6Al- 4V eroded at 700 °C (1300 °F) using 270 μm SiO_2 at a particle velocity of 20 m/s (45 mph). The dark areas are a thick oxide layer, and the

www.iran–mavad.com
مرجع مهندسی مواد و متالورژی

light areas have a thin oxide nonprotective layer, subject to continued oxidation and erosion. In this case, the erosion accelerates the corrosion by helping remove the brittle, oxidized surface. In contrast, Fig. 6 shows the erosion of a metal that forms a protective oxide layer, in this case type 310 stainless steel (UNS S31000) eroded using the same conditions. In this case, only small chips can be found in the protective layer. The surface also shows mechanical damage, such as small cracks and depressions, where the abrasive impacted the surface.

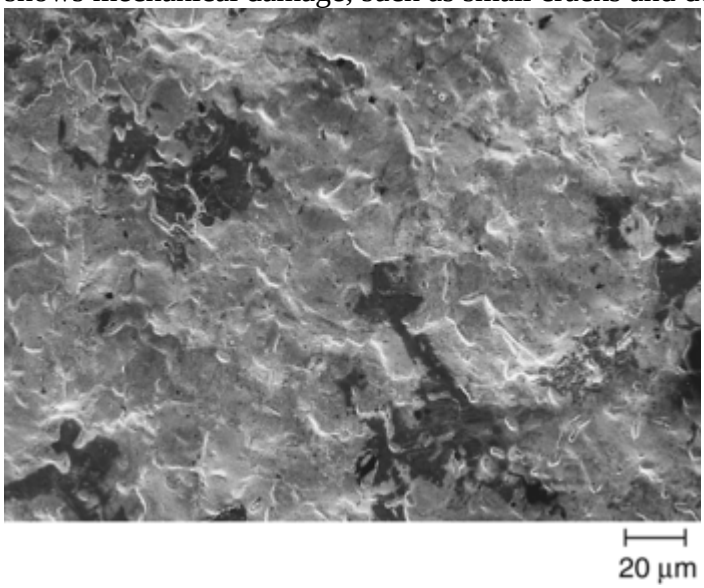

Fig. 5 Erosion on nonprotective oxide layer. Ti-6Al-4V sample eroded at 700 °C (1300 °F) in air using 270 µm SiO_2 abrasive at 20 m/s (45 mph)

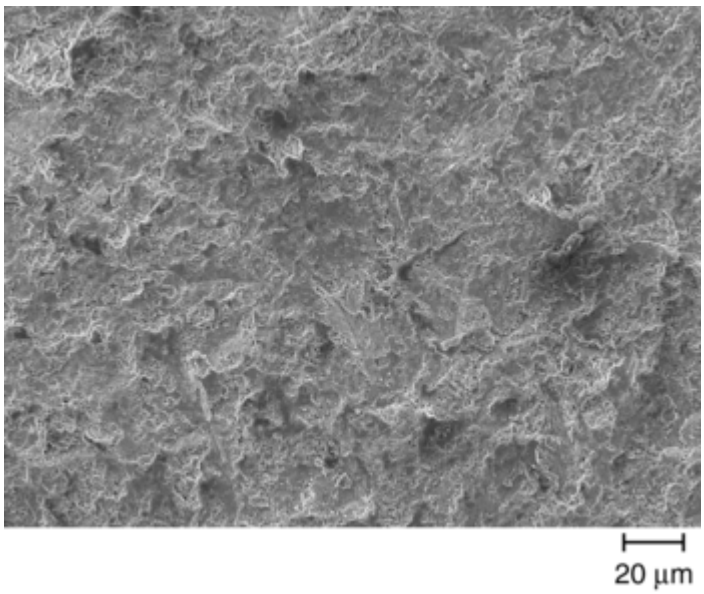

Fig. 6 Erosion on a protective oxide layer. Type 310 stainless steel (UNS S31000) sample eroded at 700 °C (1300 °F) in air using 270 µm SiO_2 abrasive at 20 m/s (45 mph)

Models of oxidation-enhanced erosion typically have several degradation regimes, depending on the temperature and the erodent energy (Ref 26). These can be classified by whether the scale thickness, ζ, maintains a constant thickness, ζ_{ss}, and if the removal rate is constant with respect to time. If the removal of the oxide is due to erosion alone, the removal rate can be represented as:

$$\frac{d\zeta}{dt} = -k' \qquad \text{(Eq 4)}$$

The scale thickness, ζ, often grows at a rate proportional to $t^{0.5}$, and this growth rate is called the parabolic rate. The oxide growth rate $d\zeta/dt$ is described by:

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$\frac{d\zeta}{dt} = \frac{k_p}{\zeta} \quad \text{(Eq 5)}$$

where k_p represents the parabolic rate constant.

If a continuous protective scale remains on the surface of the material during erosion-oxidation, then there is a parabolic rate constant $k_{o,e}$ that is a function of oxidation and erosion conditions. Further, if the oxide removal rate constant is represented by k', then the previous equation can be rewritten as:

$$\frac{d\zeta}{dt} = \frac{k_{o,e}}{\zeta} - k' \quad \text{(Eq 6)}$$

For the removal of a mix composite layer where the oxide removal rate is much faster than the parabolic rate, $k_{o,e}$, the rate will be dependent on time and the removal rate can be written as:

$$x = -k''t \quad \text{(Eq 7)}$$

Finally where no oxide layer forms, the loss will only be due to erosion of the metal. This removal rate will be dependent on time and can be written as:

$$x = -k'''t \quad \text{(Eq 8)}$$

Rishel (Ref 27) has illustrated the different oxidation/erosive regimes in Fig. 7. The regimes include, starting at the top moving by increasing erodent energy:

- Oxidation where the erodent has no effect. In this case if the removal rate constant, $k_{o,e}$, divided by ζ_{ss} is much greater than outer surface removal rate k', so the loss rate is dependent on the oxidation rate.
- Erosion enhanced oxidation, EEO, where the erodent damages the oxide layer and leads to faster oxidation. In this case there are three forms of EEO. In type I, the scaling rate is essentially unaffected by the erosion, so $k_{o,e} = k_p$. For type II, the erosion increases the rate of oxide-scale formation so $k_{o,e} > k_p$. For type III of EEO, the erosion causes spalling of the oxide scale, as seen in Fig. 5.
- The regime of oxidation-modified erosion, where the oxidation enhances the ability of the erodent to remove material. In this case, the total removal is a function of time.
- Bulk erosion, where the erodent energy is able to cut through the surface scale and remove the bulk material below the scale. In this case, the total removal is also just a function of time. Maps of these regimes have been produced to help illustrate the different mechanisms in operation (Ref 28).

In a study of stainless steels exposed to a combustion atmosphere from a propane-fired abrasive-jet machine at 975 °C, (1790 °F), Ives (Ref 29) found the velocity dependence of erosion rate, *E*, for a 90° impact of $v^{1.8}$. The tests were conducted using a commercial grade of SiC with the average particle size of ~135 μm. By comparison, the velocity dependence at room temperature was $v^{2.5}$. The results show the thickness loss decreased with increasing chromium content (Table 1). Aluminum additions had a beneficial effect under the conditions of excess fuel at 1000 °C (1800 °F) and a particle velocity of 55 m/s (180 ft/s, or 123 mph).

Table 1 Erosion-corrosion test results, using excess fuel at 1000 °C (1800 °F) and 55 m/s (123 mph) particle velocity of ~135 μm (5 mils) SiC abrasive

Erosion-corrosion maps have been developed in order to show the effects of different variables and to identify different degradation mechanisms (Ref 30). These maps should help the design engineer select materials and understand the mechanisms involved in erosion-corrosion at elevated temperatures (Ref 31).

Fretting Wear. Fretting is a form of wear that occurs between contacting surfaces subjected to cyclic relative motion of extremely small amplitude, usually in the range of 1 to 100 μm. This wear typically occurs on surfaces that are not intended to move in this manner, such as bearing mounts, hubs, and shafts. This is often considered a form of corrosion since usually the debris formed rapidly oxidizes.

The relative motion between the two surfaces causes fretting. The contact creates an abrasive wear on the oxide films on both surfaces, removing the passive layer while leaving oxide debris particles. These debris particles contribute to the wear process, increasing the wear as time passes. The passive layer on a fretting part is continuously restored and destroyed as new material is exposed to the atmosphere and oxidized. The destruction of the layer produces additional wear debris, which goes on to produce more corrosion and wear.

In steels, this debris layer can form a white etch-resistant layer, which is extremely hard and brittle (Fig. 8). This layer has been described as martensite.

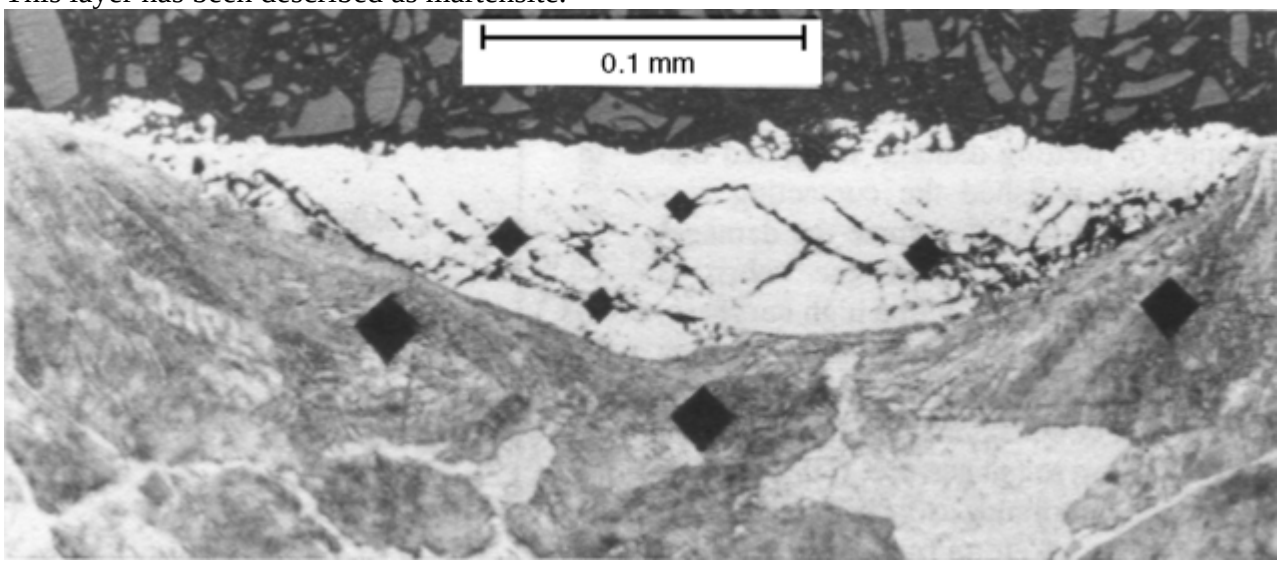

Fig. 8 Cross section of a white layer of martensite produced by fretting, after 105 fretting cycles and a contact stress of 40 MPa (5.8 ksi). Source: Ref 32

While not usually considered a major issue, fretting is known to occur at elevated temperatures. Examples of this are found in gas and steam turbines. Fretting at elevated temperatures can form low friction glazes (Ref 33), which will reduce the loss material.

Sliding Wear. Adhesive, oxidational, and sliding wear refers to the wear that takes place when one surface "slides" over another. This typically occurs in machining, unlubricated machinery, and material-handling operations. Machining is an example of the adhesive-wear process. At the tip of the cutting tool, the chip is separated from the bulk of the part. This chip may strike the tool further back. This can lead to both the dulling of the tip and crater wear further back. During high-speed machining tool temperatures can reach 1000 °C (1800 °F), which can cause oxidation of the tool surface. Typically, the self- formed oxide layer will be less resistant to adhesive wear than the bulk of the tool. As a consequence, wear damage accelerates as competition between the removal of the oxide film and the formation of fresh oxide occurs.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Oxidation has long been considered a fundamental aspect of sliding wear (Ref 34). Oxidation can occur at relatively low sliding velocities, in the range of 0.2 to 1 m/s (8 to 40 in./s) (Ref 35). Oxidation accelerates with increasing temperature and can lead to the formation of a protective layer under many conditions. These layers tend to be in the range of 3 to 4 μm thick and are quite beneficial in unlubricated conditions.

Measurement

The techniques of measuring wear and corrosion have resulted in the creation of many standard practices and specialized pieces of equipment. This Volume outlines many of the corrosion-measurement techniques, while

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Friction, Wear, and Lubrication, Vol 18, *ASM Handbook,* (Ref 36) outlines many of the wear-measurement techniques. Jet, whirling arm, and slinger tests have all been used successfully in the field of erosion. While the jet test (Ref 37) is most commonly used, there are definite advantages to the whirling-arm test. With the whirling-arm test, the impact velocity is well known, and an entire face of the specimen can be eroded, producing a more uniform surface. The machining test is the most commonly used high-temperature abrasive test, because the process of machining produces an elevated temperature. For slow abrasive elevated-temperature tests one of the most commonly used is a high- temperature ring-on-disk test.

Measurement of the interaction between corrosion and wear modes of damage is more difficult. One standard for measuring these interactions is ASTM G 119 (Ref 38). The scope of this standard is aqueous corrosion and wear, and applies to systems in liquid solutions or slurries. However, aspects of it can be adapted to dry corrosion and wear interactions as well.

The measurement of corrosion, wear, and corrosion/wear interactions is a multistep process. Each component of the interaction must be measured separately. The results may then be combined to create a complete picture of the damage process.

An example of this process is the measurement of the degradation on combustion walls in coal-fired boilers. First, one must fully understand the environment around the combustion walls. This would include knowing the temperature, gas chemistry, velocity of the gases, and the abrasive causing the erosion. After determining these details, the following tests might be used for measurements. First, an oxidation test should be performed in the combustion gas in the boiler. In this case, the gas should include the impurities (such as SO_2 and HCl) as well as the major gases, since they will greatly affect the scales formed. This measurement will show the loss rate due to the gaseous corrosion or oxidation process. An erosion test would be run, using an abrasive similar in both type and size to that found in the ash of the boiler. In the case of a coal-fired boiler, a quartz abrasive would probably best represent the abrasive found in the ash. The erosion test would need to be run in a neutral (nonoxidizing) atmosphere to block the effects of the corrosion. Elevated temperature would be necessary, since temperature alone has been shown to affect erosion rates. Different test velocities for the abrasive may be run to determine the sensitivity of the erosion rate to velocity. Finally, combined wear-corrosion tests would need to be run, fully simulating the boiler conditions. The synergistic effect can then be determined (after converting all the loss rates to a common unit such as surface recession rate in mm/day) by subtracting the individual corrosion and erosion results from the final combined test. The resulting number represents the degree to which oxidation-wear interactions increase the wear:

$$W_s = W_T - W_e - C \qquad \text{(Eq 9)}$$

where W_s is the erosion-corrosion synergy or interaction term, W_T is the total loss, W_e is the wear due to erosion, and C is the loss due to corrosion. The loss from erosion-corrosion interaction can then be divided by the total loss to get the percentage loss due to the interaction ($S_{e\text{-}c}$):

$$S_{e\text{-}c} = W_s/W_T \qquad \text{(Eq 10)}$$

Control

There is no definitive answer to the problem of wear, corrosion, and wear-corrosion interactions. In some environments, a trade-off between corrosion and wear can lead to a minimum of material loss. At intermediate temperatures, a corrosive layer can serve to protect the bulk material from wear (Ref 39). At high temperatures, over 800 °C (1500 °F), protective mixed-oxide layers can form, causing a decrease in the total loss rate.

Changing temperatures in manufacturing environments may have the potential to decrease material loss. Some abrasives grow softer with increased temperatures and thus decrease wear. Additional research needs to be done to determine if there are any manufacturing processes where this would be a viable solution.

In certain circumstances, changing the physical environment may offer potential for decreased wear and corrosion. Sulfur reacts with metals to form nonprotective coatings. Decreasing the sulfur compounds in a manufacturing environment, such as using a lower-sulfur coal, can thus reduce the material loss associated with both wear and corrosion.

Efforts have been made to identify advanced materials resistant to wear-corrosion (Ref 40). Coatings, for example, have been shown to offer viable wear-corrosion protection. This enables one to put high-alloy materials on the surface where they are most needed. In some cases, applying coatings to the base material can minimize material loss. There are six common coating techniques used for wear-corrosion control. Physical vapor disposition (PVD) produces a very thin (2–10 μm, or 0.08–0.4 mil) protective layer of a material that is vaporized and deposited. Chemical vapor deposition (CVD), which produces a 5 to 15 μm (0.2 to 0.6 mil) protective layer, is made by a gas-phase decomposition of a material onto a part. Flame spray uses a heated flame to partially melt a thin (0.25–0.6 mm, or 0.01–0.02 in.) coating, commonly a high- chrome alloy, and adhere it to the base material. Diffusion coating involves covering the surface to be treated with a mostly inert material such as alumina, and heating resulting in an interaction that creates a thin (0.25–0.3 mm, or 0.01–0.012 in.) protective layer. Weld overlays consist of a thicker (1–2 mm, or 0.04–0.08 in.) protective layer of higher-alloy metal welded over the base material. Thick (12–20 mm, or 0.47–0.79 in.) refractory coatings, such as silicon carbide base materials, can be bonded to a metallic base. Experience indicates that these all have useful applications, but overlays and refractory coatings may be the most resistant to severe erosion-corrosion.

Different environments require different solutions. In some instances, engineering changes to temperatures, equipment design, flow rates, and so forth, can minimize wear and corrosion. Lubrication, when it can be used, is a partial solution. Selecting advanced materials, such as ceramics or intermetallics, is another possible option.

There are three possibilities for reducing erosion-corrosion damage: (a) modify the erodent, (b) change the material, and (c) change the aerodynamics so the particle impacts are less damaging (Ref 41).

The more that is known about wear-corrosion interaction and the environmental specifics of a given manufacturing process, the more likely it is that solutions can be found to the wear-corrosion problem.

Introduction to Environmentally Induced Cracking

Bruce Craig, MetCorr

Introduction

THIS SUBSECTION was developed to introduce the fundamental aspects of environmentally induced cracking. It provides theoretical basis for further discussions on the evaluation, testing, and methods of protection against environmentally induced cracking found in the rest of this Volume. In the time between the publication of the first *ASM Handbook* on corrosion in 1987 and this publication, considerable work has been done in the area of environmentally induced cracking. However, little gain has been made on the theory of the various cracking mechanisms, and certainly the same is true for progress in modeling or quantitative methods to predict cracking induced by the environment. Thus, the information presented in the previous edition remains fresh today and provides a good starting point for a basic understanding of environmentally induced cracking. Where appropriate, the authors and reviewers of this subsection have updated or added information that brings this subsection up to the current state of the art. The efforts of the original authors are acknowledged at the end of each article.

Introduction to Environmentally Induced Cracking

Bruce Craig, MetCorr

Mechanisms That Induce Cracking

This subsection addresses the mechanisms of corrosion that produce cracking of metals and intermetallic compounds as a result of exposure to their environment. This cracking may take the form of relatively slow, stable crack extension with a predictable growth rate or, as is often the case, unpredictable catastrophic fracture. The subsection is divided into four articles (after this brief introduction). Each addresses a specific type of cracking or embrittlement phenomena: stress-corrosion cracking (SCC), hydrogen damage (frequently referred to as hydrogen embrittlement), liquid-metal embrittlement, and solid metal induced embrittlement. In general, these different phenomena show many similarities, and it would at first seem appropriate to propose an all-encompassing mechanism to account for these behaviors. For example, all of these phenomena generally are dependent on yield strength and applied stress. As both of these factors increase, resistance to SCC, hydrogen damage, liquid-metal embrittlement, and solid metal induced embrittlement decreases. However, as presented in the discussion of each of these phenomena, many differences between the various forms of environmentally induced cracking are encountered, and in fact, substantial differences are observed for behavior of metals and alloys within a specific form of cracking.

At this time, the understanding of each of these mechanisms of cracking is largely phenomenological. No satisfactory theory exists for any of these mechanisms that totally explains all behavior observed either under laboratory or field conditions. Although many theories that are specific to the behavior of certain alloy systems or environments, exist, none is universal enough to explain, for example, the diverse behavior of hydrogen

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

damage for systems that develop hydrides versus alloys of iron that do not form hydrides. There are many of these contradictory factors that impede the development of an all- encompassing theory.

Additionally, there has been a continuing controversy since the 1960s concerning the actual micromechanistic causes of SCC, which some investigators consider to be related to hydrogen damage and not strictly an active-path corrosion phenomenon. Although certain convincing data exist for a role of hydrogen in SCC of certain alloys, sufficient data are not available to generalize this concept.

As the understanding of these forms of cracking increases, the complexity of each also increases. For example, liquid-metal embrittlement has long been a recognized form of cracking induced by liquid metals. However, it has been shown that certain metals can become embrittlers below their melting point and that embrittlement by these metals becomes progressively worse as the temperature approaches the melting point. This behavior, although similar to liquid-metal embrittlement, is sufficiently different to warrant reclassifying it as ***solid metal induced embrittlement.*** Many of the environmentally induced fractures that were previously termed liquid-metal embrittlement are now considered solid metal induced embrittlement.

Because satisfactory mechanistic models have not been developed for any of these forms of environmental cracking, the prediction of environmentally assisted cracking is essentially nonexistent. However, the need for prediction of these types of failures is most important, because observable and measurable corrosion usually does not occur before or during crack initiation or propagation. When corrosion does occur, it is highly localized such as pitting or crevice attack and may be difficult to detect.

The field of environmentally assisted cracking is one of the most active in corrosion research, and it is continually changing. Therefore, the reader is encouraged to consult the most current literature for more detail on specific theories and alloy behavior. Toward this end, Selected References are given at the end of each article. Additional information also can be found in the articles “Evaluating Stress-Corrosion Cracking” and “Evaluating Hydrogen Embrittlement” in this Volume.

Stress-Corrosion Cracking

R.H. Jones, Battelle Pacific Northwest National Laboratory

Introduction

STRESS-CORROSION CRACKING (SCC) describes service failures in engineering materials that occur by slow environmentally induced crack propagation. The observed crack propagation is the result of the combined and synergistic interaction of mechanical stress and corrosion reactions. This is a simple definition of a complex subject, and, like most simplifications, it fails to identify the boundaries of the subject. As a result, before this problem can be discussed in detail, one must clearly define the type of loading involved, the types of materials involved, the types of environments that cause this type of crack propagation, and the nature of the interactions that result in this phenomenon. The term *stress-corrosion cracking* is used frequently to describe any type of environmentally induced or assisted crack propagation. However, in this discussion, the focus is on the normal usage of the term as defined subsequently.

One frequent misconception is that SCC is the result of stress concentration at corrosion-generated surface flaws (as quantified by the stress- intensity factor, K); when a critical value of stress concentration, K_{crit}, is reached, mechanical fracture results. Although stress concentration does occur at such flaws, these defects do not exceed the critical value required to cause mechanical fracture of the material in an inert environment ($K_{SCC} < K_{crit}$). Precorrosion followed by loading in an inert environment will not result in any observable crack propagation, while simultaneous environmental exposure and application of stress will cause time-dependent subcritical crack propagation. The term *synergy* was used to describe this process because the combined simultaneous interaction of mechanical and chemical forces results in crack propagation where neither factor

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

acting independently or alternately would result in the same effect. The exact nature of this interaction is the subject of numerous scientific investigations and is covered in the section “Crack Propagation Mechanisms” in this article.

The stresses required to cause SCC are small, usually below the macroscopic yield stress, and are tensile in nature. The stresses can be externally applied, but residual stresses often cause SCC failures. However, compressive residual stresses can be used to prevent this phenomenon. Static loading usually is considered to be responsible for SCC, while environmentally induced crack propagation due to cyclic loading is defined as *corrosion fatigue* (see the section “Corrosion Fatigue” in the article “Forms of Mechanically Assisted Degradation” in this Volume). The boundary between these two classes of phenomena is vague, and corrosion fatigue often is considered to be a subset of SCC. However, because the environments that cause corrosion fatigue and SCC are not always the same, these two should be considered separate phenomena.

The term *stress-corrosion cracking* usually is used to describe failures in metallic alloys. However, other classes of materials also exhibit delayed failure by environmentally induced crack propagation. Ceramics exhibit environmentally induced crack propagation (Ref 1), and polymeric materials frequently exhibit craze cracking as a result of the interaction of applied stress and environmental reactions (Ref 2, 3, 4, 5). Until recently, it was thought that pure metals were immune to SCC; however, it has been shown that pure metals are susceptible to SCC (Ref 6, 7). This discussion focuses on the SCC of metals and their alloys and is not concerned with stress- environment interactions in ceramics and polymers.

Environments that cause SCC are usually aqueous and can be condensed layers of moisture or bulk solutions. Typically, SCC of an alloy is the result of the presence of a specific chemical species in the environment. Thus, the SCC of copper alloys, traditionally referred to as *season cracking*, is virtually always due to the presence of ammonia in the environment, and chloride ions cause or exacerbate cracking in stainless steels and aluminum alloys. Also, an environment that causes SCC in one alloy may not cause SCC in another alloy. Changing the temperature, the degree of aeration, and/or the concentration of ionic species may change an innocuous environment into one that causes SCC failure. Also, an alloy may be immune in one heat treatment and susceptible in another. As a result, the list of all possible alloy-environment combinations that cause SCC is expanding continually, and the possibilities are virtually infinite. A partial listing of some of the more commonly observed alloy-environment combinations that result in SCC is given in Table 1.

Table 1 Alloy-environment systems exhibiting SCC

Alloy	Environment
Carbon steel	Hot nitrate, hydroxide, and carbonate/bicarbonate solutions
High-strength steels	Aqueous electrolytes, particularly when containing H_2S
Austenitic stainless steels	Hot, concentrated chloride solutions; chloride-contaminated steam
High-nickel alloys	High-purity steam
a-brass	Ammoniacal solutions
Aluminum alloys	Aqueous Cl^-, Br^-, and I^- solutions
Titanium alloys	Aqueous Cl^-, Br^-, and I^- solutions; organic liquids; N_2O_4
Magnesium alloys	Aqueous Cl^- solutions
Zirconium alloys	Aqueous Cl^- solutions; organic liquids; I_2 at 350 °C (660 °F)

In general, SCC is observed in alloy-environment combinations that result in the formation of a film on the metal surface. These films may be passivating layers, tarnish films, or dealloyed layers. In many cases, these films reduce the rate of general or uniform corrosion, making the alloy desirable for resistance to uniform corrosion in the environment. As a result, SCC is of greatest concern in the corrosion-resistant alloys exposed to aggressive aqueous environments. The exact role of the film in the SCC process is the subject of current research and is covered in the discussion “Crack Propagation Mechanisms” in this article. Table 2 lists some alloy-environment combinations and the films that may form at the crack tip.

The Phenomenon of SCC

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Stress-corrosion cracking is a delayed failure process. That is, cracks initiate and propagate at a slow rate from 10^{-9} to 10^{-6} m/s (4×10^{-7} to 4×10^{-4} in./s), until the stresses in the remaining ligament of metal exceed the fracture strength. The sequence of events involved in the SCC process usually is divided into three stages:

- Crack initiation and stage 1 propagation
- Stage 2 or steady-state crack propagation
- Stage 3 crack propagation or final failure

Distinction among these stages is difficult because the transition occurs in a continuous manner and the division is therefore arbitrary. To enhance the understanding of this process, these steps are discussed in the context of typical experimental techniques and results. Stress-corrosion cracking experiments can be classified into three different categories:

- Tests on statically loaded smooth samples
- Tests on statically loaded precracked samples
- Tests using slowly straining samples

More detailed information on these tests can be found in the article “Evaluating Stress-Corrosion Cracking” in this Volume.

Tests on statically loaded smooth samples usually are conducted at various fixed stress levels, and the time to failure of the sample in the environment is measured. Figure 1 illustrates the typical results obtained from this type of test. In Fig. 1, the logarithm of the measured time to failure, t_f, is plotted against the applied stress, $\sigma_{applied}$, and the time to failure can be seen to increase rapidly with decreasing stress; a threshold stress, σ_{th}, is determined where the time to failure approaches infinity. The total time to failure at a given stress consists of the time required for the formation of a crack (the incubation or initiation time, t_{in}, and the time of crack propagation, t_{cp}. These experiments can be used to determine the maximum stress that can be applied to avoid SCC failure, to determine an inspection interval to confirm the absence of SCC crack propagation, or to evaluate the influence of metallurgical and environmental changes on SCC. However, the actual time for the formation or initiation of cracks is strongly dependent on a wide variety of parameters, such as surface finish and prior history. If a cracklike flaw or a crevice is present in the material, then the time to initiate a crack may be reduced dramatically (Ref 8).

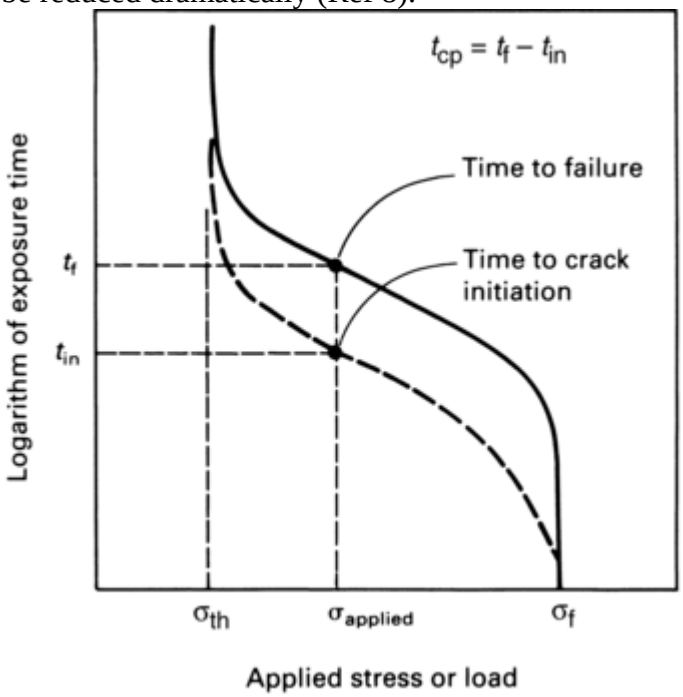

Fig. 1 Schematic of a typical time to failure as a function of initially applied stress for smooth sample stress-corrosion cracking tests

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Tests on statically loaded precracked samples usually are conducted with either a constant applied load or with a fixed crack opening displacement, and the actual rate or velocity of crack propagation, *da/dt*, is measured (Ref 9). The magnitude of the stress distribution at the crack tip (the mechanical driving force for crack propagation) is quantified by the stress intensity factor, *K*, for the specific crack and loading geometry. As a result, the crack propagation rate, *da/dt*, is plotted versus *K* as illustrated in Fig. 2. These tests can be configured such that *K* increases with crack length (constant applied load), decreases with increasing crack length (constant crack mouth opening displacement), or is approximately constant as the crack length changes (special tapered samples). Each type of test has its advantages and disadvantages. However, in service, most SCC failures occur under constant-load conditions such that the stress intensity increases as the crack propagates. As a result, it is usually assumed in SCC discussions that the stress intensity is increasing with increasing crack length.

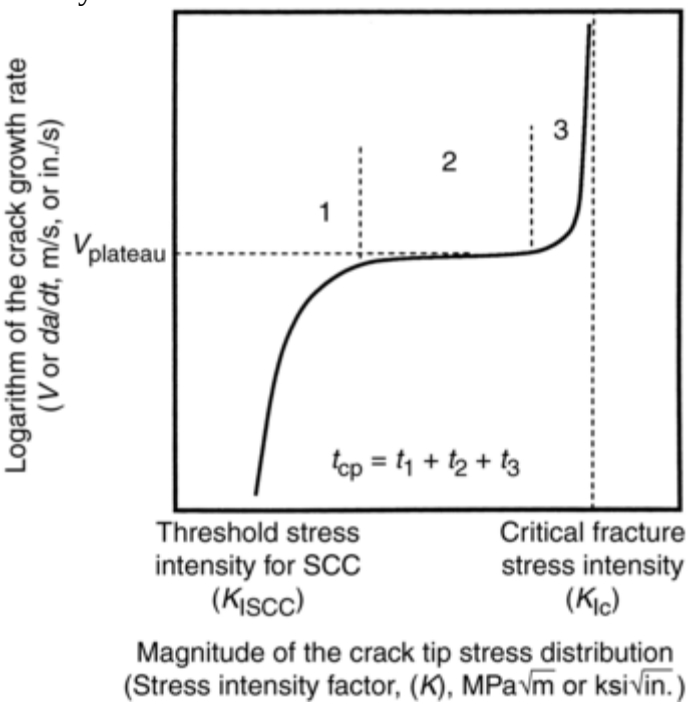

Fig. 2 Schematic of typical crack propagation rate as a function of crack tip stress-intensity behavior illustrating the regions of stages 1, 2, and 3 crack propagation, as well as identifying the plateau velocity and the threshold stress intensity

Typically, three regions of crack propagation rate versus stress-intensity level are found during crack propagation experiments. These regions are identified according to increasing stress-intensity factor as stage 1, 2, or 3 crack propagation (Fig. 2). No crack propagation is observed below some threshold stress-intensity level, K_{ISCC}. This threshold stress level is determined not only by the alloy but also by the environment and metallurgical condition of the alloy, and presumably, this level corresponds to the minimum required stress level for synergistic interaction with the environment. At low stress-intensity levels (stage 1), the crack propagation rate increases rapidly with the stress-intensity factor. At intermediate stress-intensity levels (stage 2), the crack propagation rate approaches some constant velocity that is virtually independent of the mechanical driving force. This plateau velocity, $V_{plateau}$, is characteristic of the alloy-environment combination and is the result of rate-limiting environmental processes such as mass transport of environmental species up the crack to the crack tip. In stage 3, the rate of crack propagation exceeds the plateau velocity as the stress-intensity level approaches the critical stress-intensity level for mechanical fracture in an inert environment, K_{Ic} (Ref 10).

Slow Strain Rate Testing. Stress-corrosion tests also can be conducted by slowly increasing the load or strain on either precracked or smooth samples. Usually, a tensile machine pulls a smooth sample that is exposed to the corrosive environment at a low cross head speed, 10^{-5} to 10^{-9} m/s. The strain to failure in the corrosive environment and the strain to failure in an inert environment can then be plotted against the strain rate, as shown in Fig. 3(a), or the ratio of these measurements can be plotted as shown in Fig. 3(b) for ductility. The ratio of other tensile property measurements, such as reduction in area and ultimate tensile strength, could also be plotted. These tests are known as *constant extension rates tests* (CERT), *slow strain rate tests*, or *straining electrode tests.* These tests are excellent for comparing the relative susceptibility of alloys to cracking in an

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

environment or for studying the influence of metallurgical variables on the susceptibility of an alloy. However, the application of this data to the prediction of actual in-service crack propagation rates is difficult and unreliable.

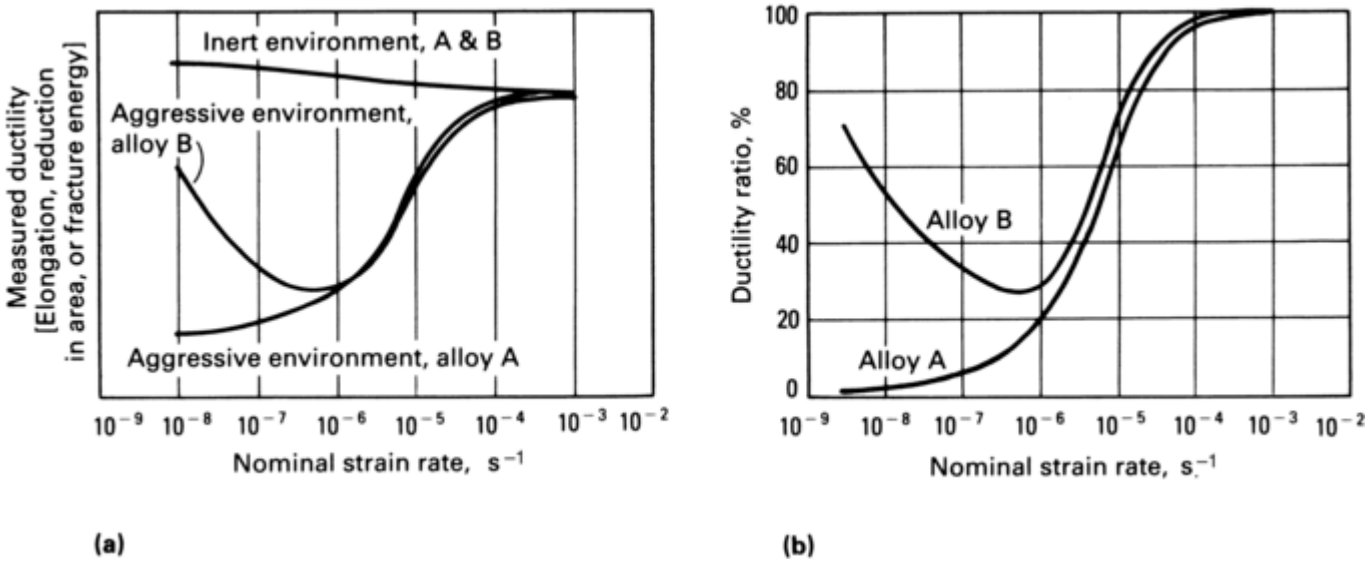

Fig. 3 Strain to failure plots resulting from slow strain rate testing. (a) Ductility of two alloys is measured by elongation, reduction in area, or fracture energy in the aggressive environment and an inert reference environment. The Phenomenon of SCC

Stress-corrosion cracking is a delayed failure process. That is, cracks initiate and propagate at a slow rate from 10^{-9} to 10^{-6} m/s (4×10^{-7} to 4×10^{-4} in./s), until the stresses in the remaining ligament of metal exceed the fracture strength. The sequence of events involved in the SCC process usually is divided into three stages:

- Crack initiation and stage 1 propagation
- Stage 2 or steady-state crack propagation
- Stage 3 crack propagation or final failure

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Distinction among these stages is difficult because the transition occurs in a continuous manner and the division is therefore arbitrary. To enhance the understanding of this process, these steps are discussed in the context of typical experimental techniques and results. Stress-corrosion cracking experiments can be classified into three different categories:

- Tests on statically loaded smooth samples
- Tests on statically loaded precracked samples
- Tests using slowly straining samples

More detailed information on these tests can be found in the article “Evaluating Stress-Corrosion Cracking” in this Volume.

Tests on statically loaded smooth samples usually are conducted at various fixed stress levels, and the time to failure of the sample in the environment is measured. Figure 1 illustrates the typical results obtained from this type of test. In Fig. 1, the logarithm of the measured time to failure, t_f, is plotted against the applied stress, $\sigma_{applied}$, and the time to failure can be seen to increase rapidly with decreasing stress; a threshold stress, σ_{th}, is determined where the time to failure approaches infinity. The total time to failure at a given stress consists of the time required for the formation of a crack (the incubation or initiation time, t_{in}, and the time of crack propagation, t_{cp}. These experiments can be used to determine the maximum stress that can be applied to avoid SCC failure, to determine an inspection interval to confirm the absence of SCC crack propagation, or to evaluate the influence of metallurgical and environmental changes on SCC. However, the actual time for the formation or initiation of cracks is strongly dependent on a wide variety of parameters, such as surface finish and prior history. If a cracklike flaw or a crevice is present in the material, then the time to initiate a crack may be reduced dramatically (Ref 8).

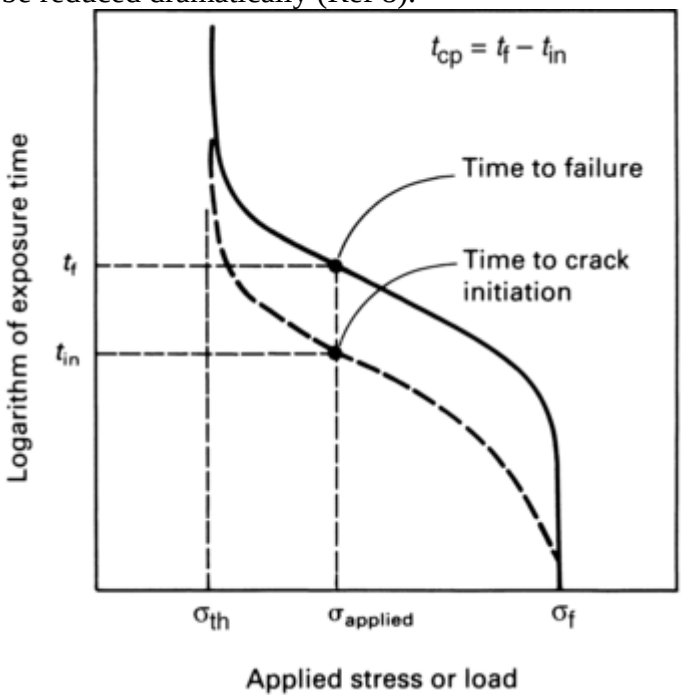

Fig. 1 Schematic of a typical time to failure as a function of initially applied stress for smooth sample stress-corrosion cracking tests

Tests on statically loaded precracked samples usually are conducted with either a constant applied load or with a fixed crack opening displacement, and the actual rate or velocity of crack propagation, *da/dt*, is measured (Ref 9). The magnitude of the stress distribution at the crack tip (the mechanical driving force for crack propagation) is quantified by the stress intensity factor, *K*, for the specific crack and loading geometry. As a result, the crack propagation rate, *da/dt*, is plotted versus *K* as illustrated in Fig. 2. These tests can be configured such that *K* increases with crack length (constant applied load), decreases with increasing crack length (constant crack mouth opening displacement), or is approximately constant as the crack length changes (special tapered samples). Each type of test has its advantages and disadvantages. However, in service, most SCC failures occur

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

under constant-load conditions such that the stress intensity increases as the crack propagates. As a result, it is usually assumed in SCC discussions that the stress intensity is increasing with increasing crack length.

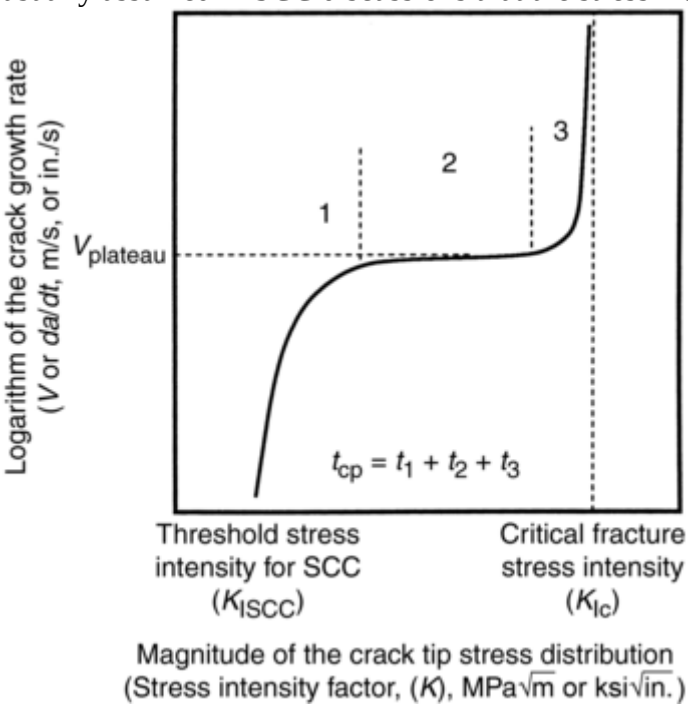

Fig. 2 Schematic of typical crack propagation rate as a function of crack tip stress-intensity behavior illustrating the regions of stages 1, 2, and 3 crack propagation, as well as identifying the plateau velocity and the threshold stress intensity

Typically, three regions of crack propagation rate versus stress-intensity level are found during crack propagation experiments. These regions are identified according to increasing stress-intensity factor as stage 1, 2, or 3 crack propagation (Fig. 2). No crack propagation is observed below some threshold stress-intensity level, K_{ISCC}. This threshold stress level is determined not only by the alloy but also by the environment and metallurgical condition of the alloy, and presumably, this level corresponds to the minimum required stress level for synergistic interaction with the environment. At low stress-intensity levels (stage 1), the crack propagation rate increases rapidly with the stress-intensity factor. At intermediate stress-intensity levels (stage 2), the crack propagation rate approaches some constant velocity that is virtually independent of the mechanical driving force. This plateau velocity, $V_{plateau}$, is characteristic of the alloy-environment combination and is the result of rate-limiting environmental processes such as mass transport of environmental species up the crack to the crack tip. In stage 3, the rate of crack propagation exceeds the plateau velocity as the stress-intensity level approaches the critical stress-intensity level for mechanical fracture in an inert environment, K_{Ic} (Ref 10).

Slow Strain Rate Testing. Stress-corrosion tests also can be conducted by slowly increasing the load or strain on either precracked or smooth samples. Usually, a tensile machine pulls a smooth sample that is exposed to the corrosive environment at a low cross head speed, 10^{-5} to 10^{-9} m/s. The strain to failure in the corrosive environment and the strain to failure in an inert environment can then be plotted against the strain rate, as shown in Fig. 3(a), or the ratio of these measurements can be plotted as shown in Fig. 3(b) for ductility. The ratio of other tensile property measurements, such as reduction in area and ultimate tensile strength, could also be plotted. These tests are known as *constant extension rates tests* (CERT), *slow strain rate tests*, or *straining electrode tests.* These tests are excellent for comparing the relative susceptibility of alloys to cracking in an environment or for studying the influence of metallurgical variables on the susceptibility of an alloy. However, the application of this data to the prediction of actual in-service crack propagation rates is difficult and unreliable.

Controlling Parameters

The mechanisms that have been proposed for SCC require that certain processes or events occur in sequence for sustained crack propagation to be possible. These requirements explain the plateau region in which the rate of crack propagation is independent of the applied mechanical stress. That is, a sequence of chemical reactions and processes is required, and the rate-limiting step in this sequence of events determines the limiting rate or plateau velocity of crack propagation (until mechanical overload fracture starts contributing to the fracture process in stage 3). Figure 4 illustrates a crack tip in which crack propagation results from reactions in metal ahead of the propagating crack. Close examination of Fig. 4 reveals that potential rate-determining steps include:

- Mass transport along the crack to the crack tip
- Reactions in the solution near the crack
- Surface adsorption at or near the crack tip
- Surface diffusion

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- Surface reactions
- Absorption into the bulk
- Bulk diffusion to the plastic zone ahead of the advancing crack
- Chemical reactions in the bulk
- The rate of interatomic bond rupture

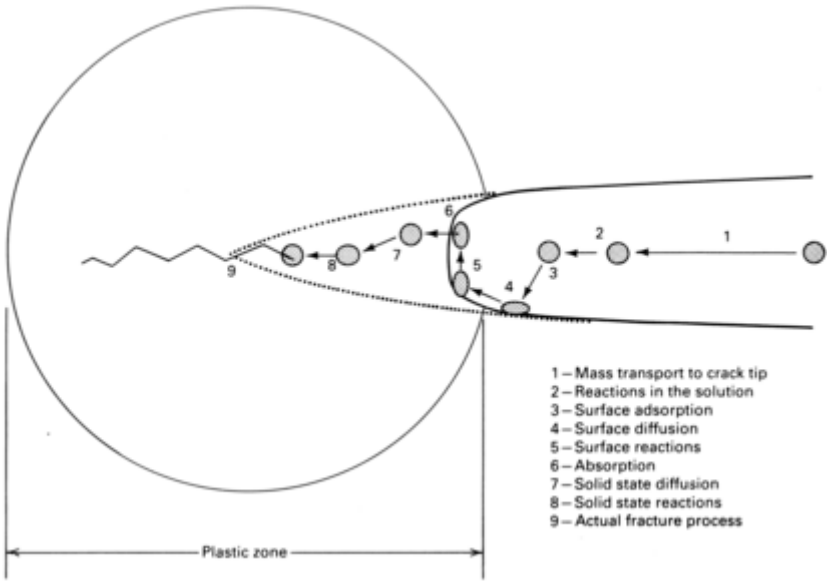

Fig. 4 Schematic of crack tip processes that may be the rate-determining step in environmentally assisted crack propagation

Changes in the environment that modify the rate-determining step will have a dramatic influence on the rate of crack propagation, while alterations to factors not involved in the rate-determining step or steps will have little influence, if any. However, significantly retarding the rate of any one of the required steps in the sequence could make that step the rate-determining step. In aqueous solutions, the rate of adsorption and surface reactions is usually very fast compared with the rate of mass transport along the crack to the crack tip. As a result, bulk transport into this region or reactions in this region frequently are believed to be responsible for determining the steady-state crack propagation rate or plateau velocity. In gaseous environments, surface reactions, surface diffusion, and adsorption may be rate limiting, as well as the rate of bulk transport to the crack tip (Ref 11, 12).

Several different environmental parameters are known to influence the rate of crack growth in aqueous solutions. These parameters include, but are not limited to:

- Temperature
- Pressure
- Solute species

- Solution viscosity
- Stirring or mixing

Altering any of these parameters may alter the rate of the rate-controlling steps, either accelerating or reducing the rate of crack propagation. Also, it may be possible to arrest or stimulate crack propagation by altering the rate of an environmental reaction. It is well known and generally accepted that the environment at occluded sites, such as a crack tip, can differ significantly from the bulk solution. If an alteration to the bulk environment allows the formation of a critical SCC environment at crack nuclei, then crack propagation will result. If the bulk environment cannot maintain this local crack tip environment, then crack propagation will stop. As a result, slight changes to the environment may have a dramatic influence on crack propagation, while dramatic changes may have only a slight influence.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In addition to these environmental parameters, stress-corrosion crack propagation rates are influenced by:

- The magnitude of the applied stress or the stress-intensity factor
- The stress state, which includes plane stress and plane strain
- The loading mode at the crack tip (tension or torsion, for example)
- Alloy composition, which includes nominal composition, exact composition (all constituents), and impurity or tramp element composition
- Metallurgical condition, which includes strength level, second phases present in the matrix and at the grain boundaries, composition of phases, grain size, grain-boundary segregation, and residual stresses
- Crack geometry, which includes length, width, and aspect ratio; and crack opening and crack tip closure

Important Fracture Features

Stress-corrosion cracks can initiate and propagate with little outside evidence of corrosion and no warning as catastrophic failure approaches. The cracks initiate frequently at surface flaws that are either preexisting or formed during service by corrosion, wear, or other processes. The cracks then grow with little macroscopic evidence of mechanical deformation in metals and alloys that are normally quite ductile. Crack propagation can be either intergranular or transgranular; sometimes, both types are observed on the same fracture surface. Crack openings and the deformation associated with crack propagation may be so small that the cracks virtually are invisible except in special nondestructive examinations. As the stress intensity increases, the plastic deformation associated with crack propagation increases, and the crack opening increases. When the final fracture region is approached, plastic deformation can be appreciable because corrosion-resistant alloys are frequently quite ductile. The features of stress-corrosion fracture surfaces are covered in greater detail in the article “Modes of Fracture” and the “Atlas of Fractographs” in *Fractography*, Volume 12 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Phenomenology of Crack Initiation Processes

Crack Initiation at Surface Discontinuities. Stress-corrosion cracking frequently initiates at preexisting or corrosion-induced surface features. These features may include grooves, laps, or burrs resulting from fabrication processes. Examples of such features are shown in Fig. 5; these features were produced during grinding in the preparation of a joint for welding. The feature shown in Fig. 5(a) is a lap, which subsequently recrystallized during welding and could now act as a crevice at which deleterious cations concentrate. The highly sensitized recrystallized material could also more readily become the site of crack initiation by intergranular corrosion. A cold-worked layer and surface burrs, shown in Fig. 5(b), can also assist crack initiation.

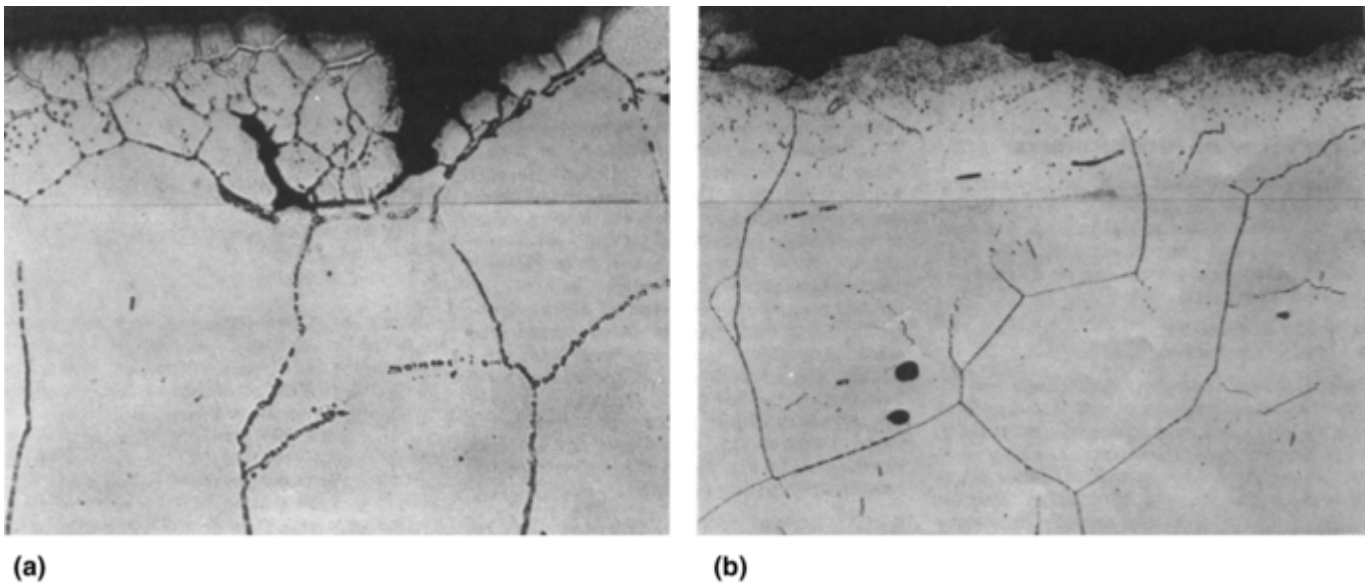

Fig. 5 Optical micrographs showing defects on the inner surface of type 304 stainless steel pipe near weld root (a) and near through crack (b). Both 670×

Crack Initiation at Corrosion Pits. Stress- corrosion cracks can also initiate at pits that form during exposure to the service environment (Fig. 6) or by prior cleaning operations, such as pickling of type 304 stainless steel before fabrication. Pits can form at inclusions that intersect the free surface or by a breakdown in the protective film. In electrochemical terms, pits form when the potential exceeds the pitting potential. It has been shown that the SCC potential and pitting potential were identical for steel in nitrite solutions (Ref 13).

The transition between pitting and cracking is dependent on the same parameters that control SCC—that is, the electrochemistry at the base of the pit, pit geometry, chemistry of the material, and stress or strain rate at the base of the pit. A detailed description of the relationship between these parameters and crack initiation has not been developed because of the difficulty in measuring crack initiation. Methods for measuring short surface cracks are under development but are limited to detecting cracks that are beyond the initiation stage. The pit geometry is important in determining the stress and strain rate at the base of the pit. Generally, the aspect ratio between the penetration and the lateral corrosion of a pit must be greater than approximately 10 before a pit acts as a crack initiation site. A penetration to lateral corrosion ratio of 1 corresponds to uniform corrosion, and a ratio of about 1000 is generally observed for a growing stress- corrosion crack. As in the case of a growing crack, the pit walls must exhibit some passive film-forming capability in order for the corrosion ratio to exceed 1. A change in the corrosive environment and potential within a pit may also be necessary for the pit to act as a crack initiator. Pits can act as occluded cells similar to cracks and crevices, although in general their volume is not as restricted. There are a number of examples in which stress-corrosion cracks initiated at the base of a pit by intergranular corrosion. In these circumstances, the grain-boundary chemistry and the pit chemistry were such that intergranular corrosion was favored. Crack propagation was also by intergranular SCC in these cases.

Although the local stresses and strain rates at the base of the pit play a role in SCC initiation, there are examples of preexisting pits that did not initiate stress-corrosion cracks. This observation has led to the conclusion that the electrochemistry of the pit is more important than the local stress or strain rate (Ref 13). A preexisting pit may not develop the same local electrochemistry as one grown during service because the development of a concentration cell depends on the presence of an actively corroding tip that establishes the anion and cation current flows. Similarly, an inability to reinitiate crack growth in samples in which active growth was occurring before the samples were removed from solution, rinsed, dried, and reinserted into solution also suggests that the local chemistry is very important.

Crack Initiation by Intergranular Corrosion or Slip Dissolution. Stress-corrosion crack initiation can also occur in the absence of pitting by intergranular corrosion or slip-dissolution processes. Intergranular corrosion-initiated SCC requires that the local grain-boundary chemistry differ from the bulk chemistry. This condition occurs in sensitized austenitic stainless steels or with the segregation of impurities such as phosphorus, sulfur, or silicon in a variety of materials. Slip-dissolution-initiated SCC results from local corrosion at emerging slip planes and occurs primarily in low stacking fault materials. The processes of crack initiation and propagation by the slip-dissolution process are in fact very similar.

Crack Initiation Mechanisms

Although the features causing SCC initiation, such as pits, fabrication defects, and intergranular corrosion, are observed and identified easily, there are few well-developed models of SCC initiation. This lack of models for crack initiation mechanisms is the result of several complicating factors. For example, the initiation of a crack is difficult to measure experimentally, even though it is not difficult to detect the location from which a growing crack has emanated. Furthermore, crack initiation has not been defined precisely, and it is difficult to determine at what point a pit is actually a crack and when intergranular corrosion becomes intergranular SCC. Also, the fracture mechanics concept of design assumes preexisting flaws in materials, although these may not be surface flaws that can become stress-corrosion cracks. It has been demonstrated that the corrosion fatigue threshold of 12% Cr steels and 2.0% NiCrMoV steels could be related to the minimum depth of surface pits, as shown in Fig. 7. Using a linear-elastic fracture mechanics approach and relating a pit to a half-elliptical surface crack, one researcher has shown that the critical pit dimension could be expressed by the following relationship (Ref 14):

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

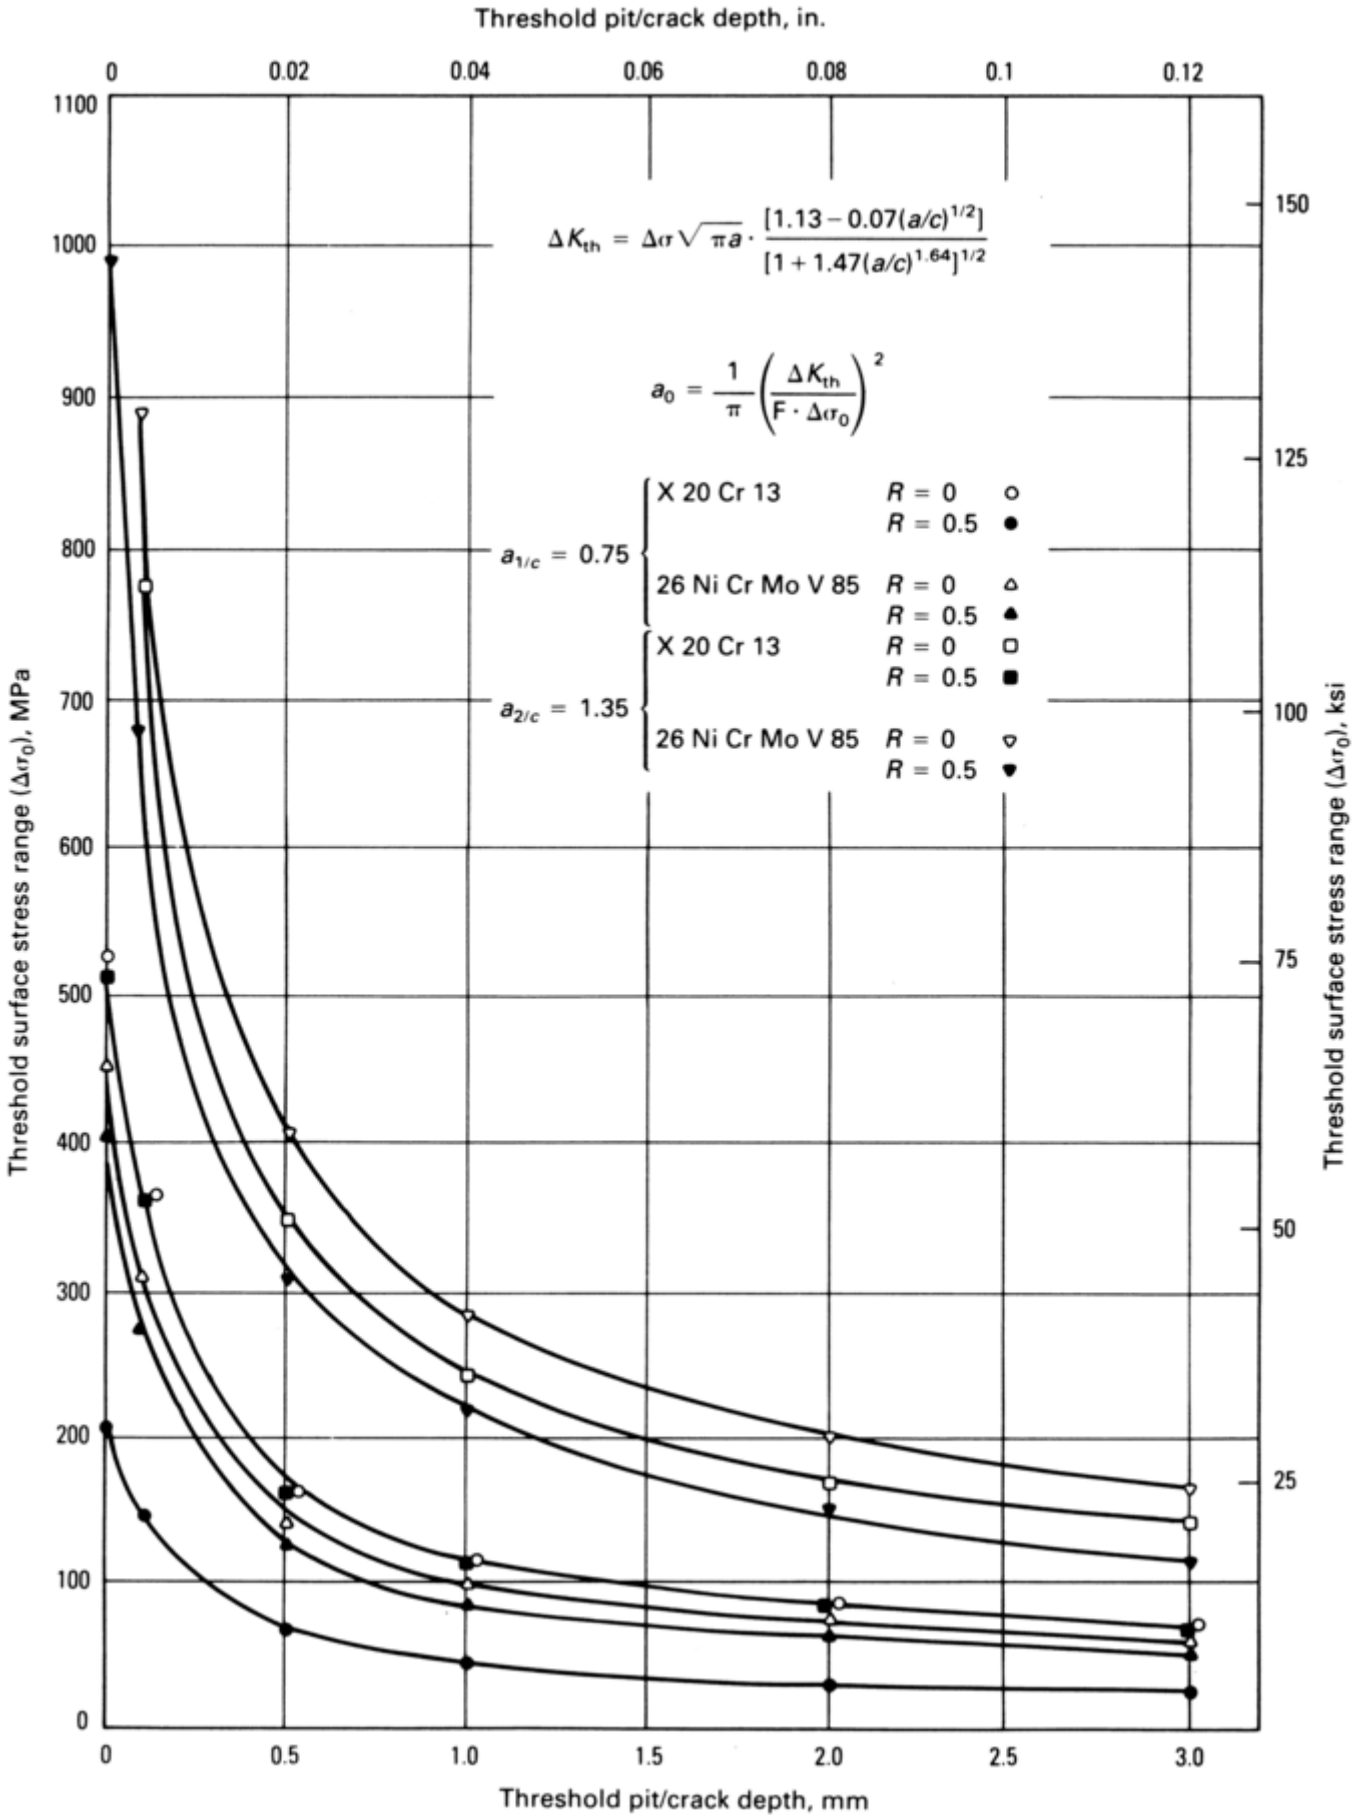

Fig. 7 Relationship between stress amplitude and minimum depth of surface defects for 12% Cr steel and a 2.0% NiCrMoV steel. Source: Ref 14

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

$$a_0 = \frac{1}{\pi}\left(\frac{\Delta K_{th}}{F\Delta\sigma_0}\right)^2 \qquad \text{(Eq 1)}$$

where ΔK_{th} is the corrosion fatigue threshold, F is a constant, and $\Delta\sigma_0$ is the alternating surface stress. A pit could be represented by a half-elliptical surface crack because it had intergranular corrosion at the base that caused the pit to have cracklike characteristics.

A model for stress-corrosion crack growth was developed from pits in brass tested in a non- tarnishing ammoniacal solution (Ref 15). The researchers evaluated the corrosion and stress aspects of a pit to develop a model for crack initiation. They assumed that the corrosion conditions in the base of the pit were essentially the same as those on a flat surface and that initiation required that a critical crack tip opening displacement be exceeded. Using linear-elastic fracture mechanics, the researchers developed the following relationship for the time to initiate a crack:

$$t_{inc} = \frac{(K_{ISCC})^2}{\pi B\left(\sigma^2 - \sigma_0^2\right)}\exp\left(\frac{-V_m}{V_0}\right) \qquad \text{(Eq 2)}$$

where K_{ISCC} is the stress-corrosion threshold for crack growth for brass in ammoniacal solution, σ is the applied stress, σ_0 is the stress needed to close the crack, B is a constant, $-V_m$ is the electrochemical potential of the sample, and V_0 is the reversible potential. However, the assumption that the pit corrosion conditions are equal to the flat surface conditions limits the applicability of this model, because generally it is accepted that the electrochemistry in a pit differs considerably from that of a flat surface. Also, this model does not describe explicitly the transition from a pit to a crack but treats a pit as a small crack in which the crack tip opening and crack depth are affected by corrosion.

The transition between intergranular corrosion and intergranular SCC was evaluated for nickel with segregated phosphorus and sulfur (Ref 16, 17). Because phosphorus and sulfur inhibit the formation of a passive film on nickel, it was expected that intergranular SCC would be similar in these two materials. It was observed, however, that only shallow intergranular corrosion to a depth of about 0.1 mm (0.004 in.) resulted in nickel in which sulfur was segregated to the grain boundary when tested at a strain rate of 10^{-6} s^{-1} in 1 *N* sulfuric acid (H_2SO_4). On the other hand, rapid intergranular SCC resulted in nickel in which phosphorus was segregated to the grain boundaries that was tested under similar conditions. Using crack tip chemistry modeling, it was shown that intergranular corrosion did not convert to a stress-corrosion crack in Ni+S because the sulfur remained on the crack walls, causing the electrolyte in the solution to become saturated and the crack tip corrosion rate to drop to zero. Starting from a flat surface, the corrosion current at the tip of the intergranular corrosion penetration was about 30 mA/cm^2 (195 mA/in.^{2}) and decreased to 0 at a depth of about 0.08 mm (0.003 in.), as shown in Fig. 8. A similar corrosion depth was measured for samples held at 900 mV for extended periods or for straining electrode samples, while for Ni+P a crack growth rate of 10^{-4} mm/s was measured. These results indicate the importance of electrochemistry in the base of a pit or an intergranular penetration and show that the occurrence of intergranular corrosion does not a priori indicate that intergranular SCC will follow.

Phenomenology of Crack Propagation Processes

Crack initiation and propagation are related but different processes; however, by definition, if a crack initiates, it will propagate. As indicated in the section “Crack Initiation Mechanisms” in this article, cracks may initiate at preexisting surface flaws if the necessary electrochemical, mechanical, and metallurgical conditions are met, or corrosion processes may create a surface flaw by pitting or localized corrosion. The conditions that create a pit or localized corrosion at chemical inhomogeneities such as grain boundaries, inclusions, second phases, and interphase boundaries are not necessarily the same as those needed for sustained crack growth. For example, the electrochemical conditions near the surface of a material are similar to the bulk electrolyte conditions; electrolyte conditions in a propagating crack generally differ from the bulk electrolyte. If the conditions at the tip of the growing pit or localized corrosion penetration cannot achieve the proper pH, potential, or chemistry, crack propagation may not proceed. Also, if the pit aspect ratio is not greater than a critical value, then the local stresses and strains resulting from a sustained sharp crack are not attained and crack growth cannot occur. Lastly, for stress-corrosion crack growth resulting from cathodic hydrogen, a short crack may have to initiate by an anodic dissolution process, while propagation depends on hydrogen activity.

Although there are conditions under which local corrosion or pitting may not result in crack propagation, more frequently they do lead to cracking. Three conditions cited often as requirements for sustained SCC are a susceptible material, a corrosive environment, and an adequate stress. The list of susceptible material conditions and corrosive environments that are known to cause SCC has been expanding steadily. For example, pure metals are known to crack when impurities are segregated to grain boundaries, nonsensitized stainless steels crack in high-purity water, and ferritic steels crack in environments other than nitrate and caustic solutions. Similarly, the details of the microstructure and microchemistry of a susceptible material, specific ions and chemistry, pH, potential, the corrosion rates of the local crack tip associated with a corrosive environment, and the crack tip stresses, strains, and strain rates associated with cracking are better known today than they were previously. Knowledge and understanding of the factors and mechanisms of stress corrosion are continuing to expand; however, a number of factors are well established. The phenomenological description of stress corrosion based on these known factors is presented in this section.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Environmental Factors

Environmental effects on SCC are summarized frequently simply by listing alloy-environment combinations in which SCC has been observed, such as that in Table 1. In recent years, the number of such combinations has increased. Added to this list is the observation of the transgranular SCC of copper, the intergranular SCC of pure metals such as iron and nickel, and the SCC of materials in high-purity water in the absence of specific anions. Stress-corrosion cracking of pure metals was thought to be impossible in early lists of material-environment combinations, but it is now realized that specific environment/metal reactions occur that allow crack advance. In the case of intergranular SCC of iron and nickel, this reaction occurs between the environment and impurities segregated to the grain boundaries (a condition that exists in many pure metals and engineering alloys).

This increase in known susceptible materials can be attributed to the use of new SCC tests, refined crack propagation monitoring equipment, improved electrochemical control equipment, and, perhaps most importantly, the increased research activity in this field over the last 20 to 30 years.

Expectations for material performance have increased also with time as materials are used in more aggressive environments under more demanding loading conditions. Lists such as that given in Table 1 can be useful in materials selection for a design involving corrosive environments because it can lead the materials engineer to seek more specific information on the materials and environments in question. However, such lists can also be misleading because service conditions may differ markedly from those in which the susceptibility listed in Table 1 was determined. Because SCC is dependent on bulk alloy chemistry, microstructure, microchemistry, loading parameters, and specific environmental factors such as oxidizing potential and pH, lists of the type given in Table 1 should be used only for a general overview of SCC.

A complete description of SCC must treat both the thermodynamic requirements and kinetic aspects of cracking. A knowledge of the thermodynamic conditions will help determine whether cracking is feasible; kinetic information describes the rate at which cracks propagate. There are thermodynamic requirements for both anodically assisted SCC (where crack propagation is dependent either directly or indirectly on the oxidation of metal atoms from the crack tip and their dissolution in the electrolyte) and for hydrogen-assisted crack growth resulting from the reduction of hydrogen ions at the crack tip.

Thermodynamics of SCC. The thermodynamic conditions for anodically assisted SCC are that dissolution or oxidation of the metal and its dissolution in the electrolyte must be thermodynamically possible and that a protective film, such as an oxide or salt, must be thermodynamically stable. The first condition becomes a requirement because, without oxidation, crack advance by dissolution would not result. That a process is controlled by anodic dissolution does not a priori indicate that the total crack extension is the sum of the total number of coulombs of charge exchanged at the crack tip. There are crack advance processes in which the crack advance is controlled by anodic dissolution but in which the total crack length is greater than can be accounted for by the total charge transfer. These processes are covered in the section “Crack Propagation Mechanisms” in this article. However, it is important to note that if the brittle crack advance process is initiated and controlled by anodic dissolution, the crack growth rate will be zero if the anodic current density is zero and will increase with increasing current density. This also holds true for crack advance resulting from brittle crack jump.

The thermodynamic requirement of simultaneous film formation and oxidation for stress- corrosion crack growth can be understood from the diagram shown in Fig. 9, in which the ratio of the corrosion currents from the walls relative to the crack tip is the critical parameter. This ratio must be substantially less than 1 for a crack to propagate; otherwise, the crack will blunt, or the crack tip solution will saturate. Crack initiation can also be controlled by this ratio because a pit with a high wall corrosion rate will broaden as fast or faster than it will penetrate, resulting in general corrosion rather than crack growth. It is believed generally that the activity of the crack walls relative to the crack tip is a consequence of greater dynamic strain at the tip than along the walls.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

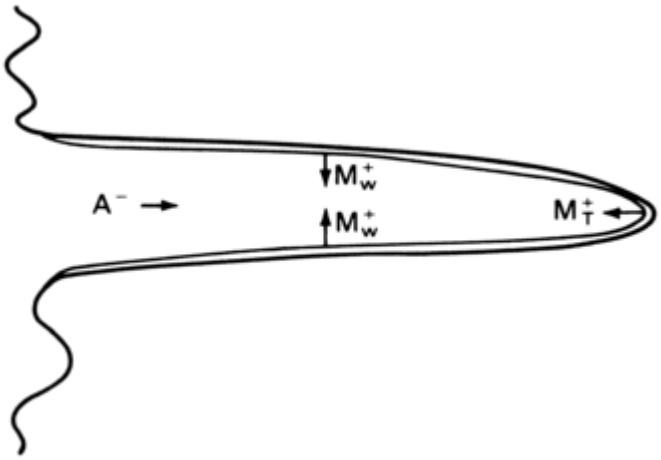

Fig. 9 Schematic of stress-corrosion crack showing important transport and corrosion reactions. A^- represents negatively charged anions migrating to the crack tip, M_w^+ represents metal ions entering the crack solution from the crack walls, and M_T^+ indicates metal ions entering the crack solution from the crack tip.

A thermodynamic requirement of simultaneous film formation and oxidation of the underlying material led to the identification of critical potentials for the presence or absence of SCC. An example of these critical potentials is shown in Fig. 10 for a passive film-forming material such as stainless steel. Zones 1 and 2 are those in which transgranular stress-corrosion crack growth is most likely to occur; intergranular stress-corrosion crack growth can occur over a wider range of potentials than these two zones can. Transgranular SCC occurs in zone 1 because the material is in transition from active corrosion to passive film formation such that the simultaneous conditions for film formation on the crack walls and corrosion at the crack tip are met. A similar condition exists in zone 2, with the added factor that these potentials are at or above the pitting potential so that cracks can initiate by pitting.

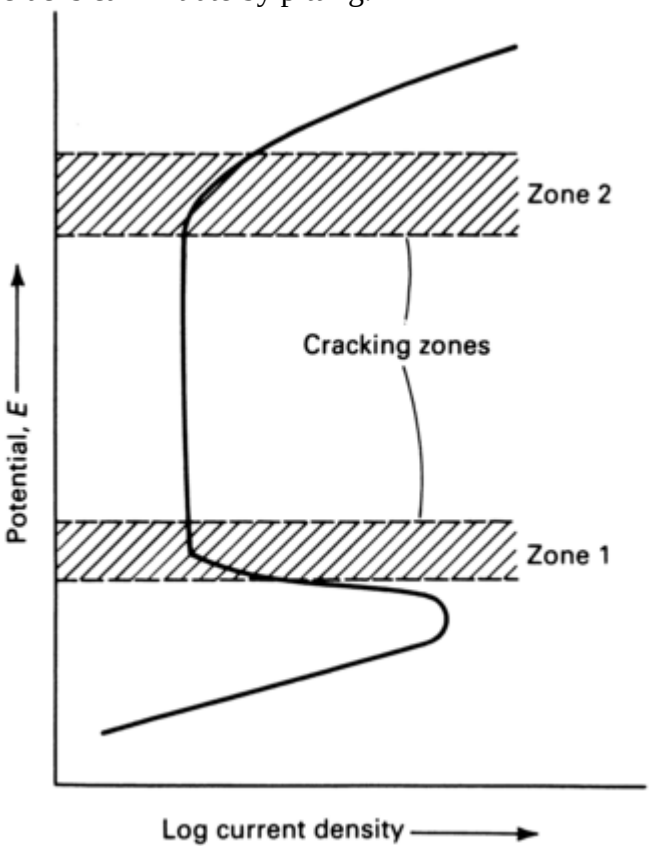

Fig. 10 Potentiokinetic polarization curve and electrode potential values at which stress-corrosion cracking appears

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Intergranular SCC occurs over a wider range of potentials than those shown for zones 1 and 2 because chemical inhomogeneities at the grain boundary produce a different electrochemical response relative to the bulk material. Therefore, passive crack walls and active crack tips can result over the potential range from zone 1 to zone 2.

Examples of the critical potentials for SCC are shown in Fig. 11 for several materials. Identification of critical potentials for SCC has led to the use of electrochemical methods for assessing stress-corrosion susceptibility. Zones 1 and 2 are identified by determining the electrochemical potential versus current curves, as shown in Fig. 10 and 11. The shapes of these curves determined at high and low sweep rates are also used to indicate potentials at which the simultaneous conditions of film formation and metal oxidation occur.

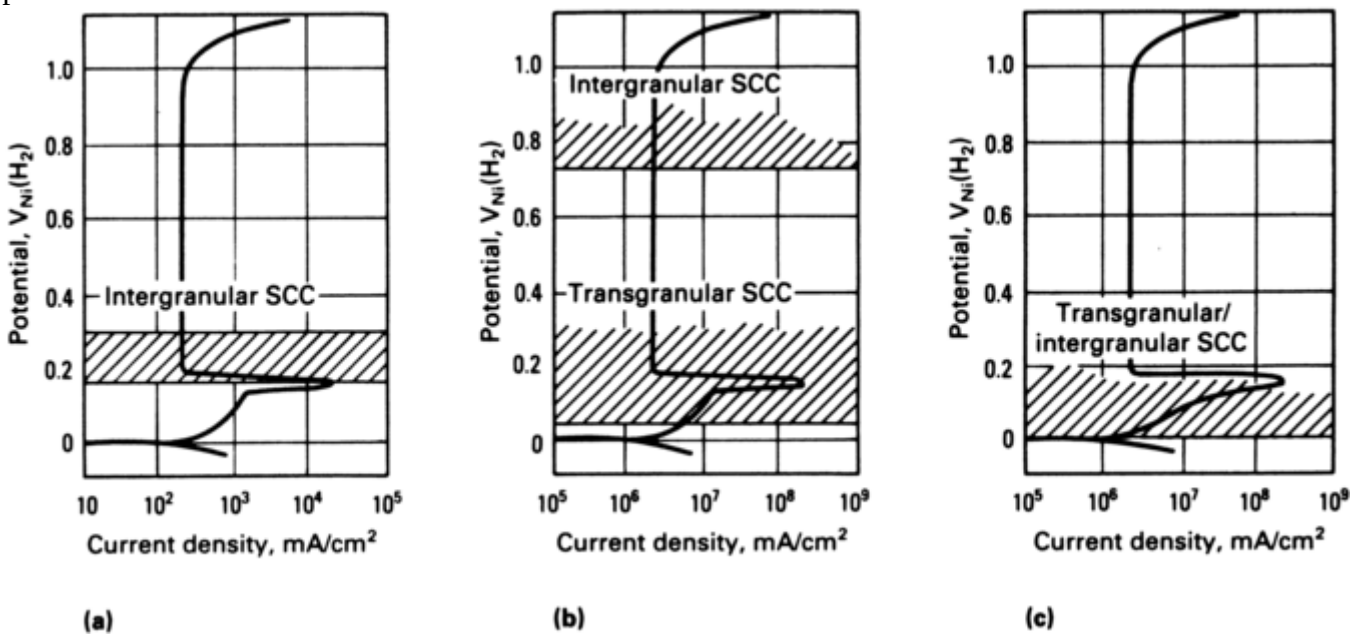

Fig. 11 Potentiokinetic polarization curve and electrode potential values at which intergranular and transgranular stress-corrosion cracking appear in a 10% NaOH solution at 288 °C (550 °F). (a) Alloy 600. (b) Alloy 800. (c) AISI type 304 stainless steel

Application of Potential-pH Diagrams. Critical potentials for SCC can also be related to potential-pH stability diagrams (Pourbaix diagrams) because these diagrams describe the conditions at which film formation and metal oxidation will occur. An example for carbon steel is given in Fig. 12, in which SCC is associated with potentials and pHs at which phosphate, carbonate, or magnetite films are thermodynamically stable while the species Fe^{2+} and $HFeO_2^-$ are metastable. A second example of the potential-pH regimes in which SCC occurs is given in Fig. 13 for a 70Cu-30Zn brass in a variety of solutions.

مرجع مهندسی مواد و متالورژی

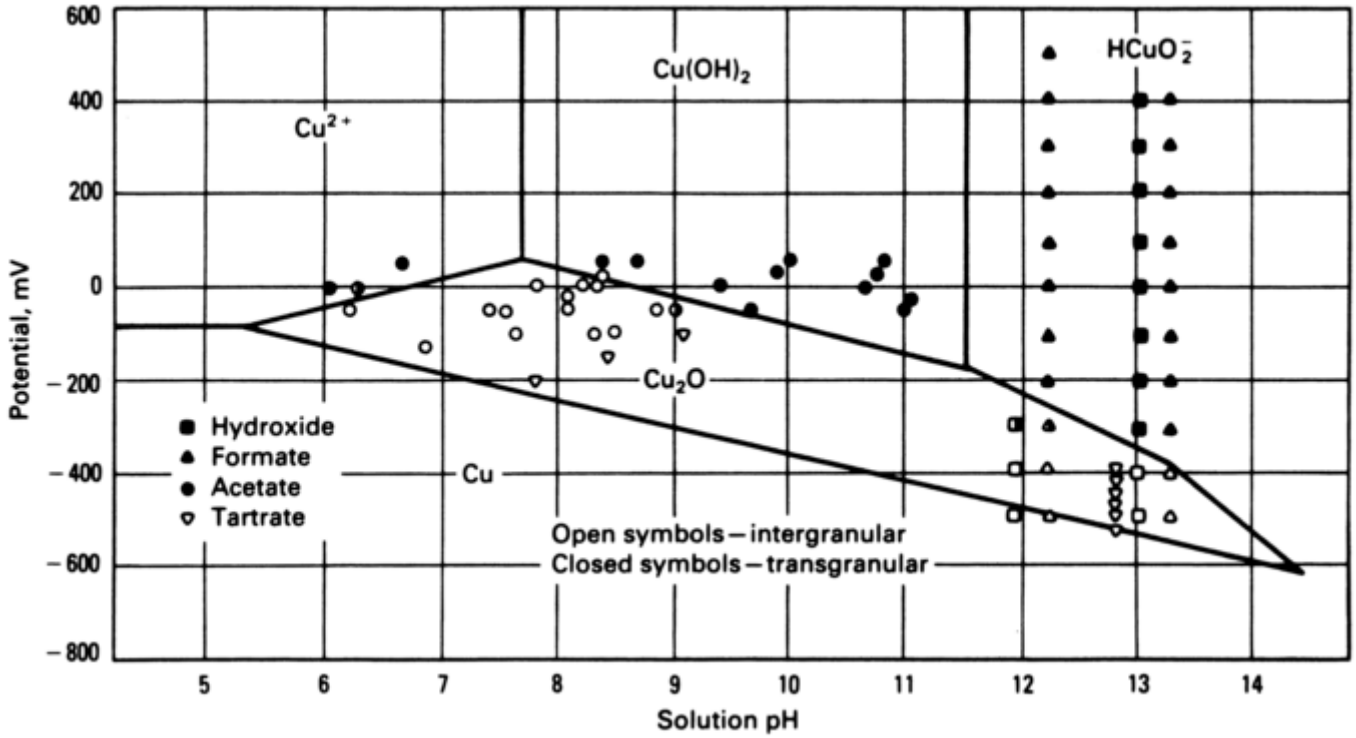

Fig. 13 Potential-pH diagram showing the domains of failure mode for 70Cu-30Ni brass in various solutions, together with the calculated positions of various boundaries relating to the domains of stability of different chemical species

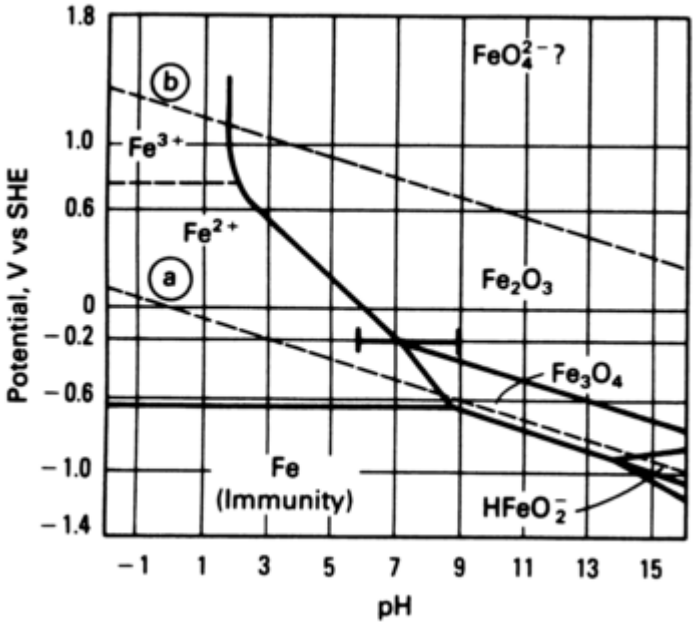
The effect of many environmental parameters, such as pH, oxygen concentration, and temperature, on the thermodynamic conditions for SCC can be related to their effect on the potential-pH diagrams (as shown in Fig. 12 and 13) or on the material potential relative to the various stability regions. Using the potential-pH diagram for iron in water at 25 °C (77 °F) shown in Fig. 14, the effects of changing the pH and oxygen concentration can be illustrated. A decrease in the pH from 9 to 6 at a potential of -0.2 V versus standard hydrogen electrode (SHE) shifts iron from a region of stability to one of active corrosion. Based on the thermodynamic criteria for simultaneous stability and active corrosion, the critical pH would be expected to be 7, with decreasing susceptibility at higher pHs because of increased film stability and at lower pHs because of decreased film stability and the increase of general corrosion. Changes in the oxygen concentration generally alter the electrode potential, with increasing oxygen concentration resulting in more oxidizing conditions. The effects of temperature on the potential-pH diagram must be determined for each temperature of interest as the regions of stability shift with temperature.



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 14 Potential-pH diagram (Pourbaix) for iron in water at 25 °C (77 °F). A decrease in pH from 9 to 6 at potential of -0.2 V, which shifts iron from a region of stability to one of active corrosion, is indicated by the solid bar.

For materials in which SCC occurs by a hydrogen-induced subcritical crack growth mechanism, the thermodynamic requirement for crack growth is governed by the hydrogen reduction line shown by dashed line *a* in Fig. 14. Hydrogen reduction on iron in water at 25 °C (77 °F) occurs at potentials below this line, but not above it. Therefore, the range of potentials at which hydrogen is available to cause crack growth increases and becomes more oxidizing with decreasing pH.

Application of potential-pH diagrams for identifying specific conditions at which SCC will occur is limited by a number of factors, such as the availability of these diagrams for complex solutions and for the temperatures of interest and the substantial deviation of the chemistry of a crevice or crack from the bulk solution chemistry. Also, the electrode potential at the crack tip can differ from that of the free surface of the material. These differences arise from the need for diffusion of metal ions away from the actively corroding crack tip, migration of anions into the crack, reactions along the crack walls, convection of the electrolyte in the crack, reactions along the crack walls, and, in some cases, by gas bubble formation that causes potential drops. Efforts to measure the local crack tip chemistry and potentials are restricted by crack sizes, which can be substantially smaller than 1 μm. Therefore, mathematical modeling of transport within cracks and the resulting crack tip chemistry, reactions, and potentials have been pursued actively in recent years. The results of measurements in simulated crevices and modeling have shown clearly that the crack tip chemistry can differ from the bulk conditions, but the specifics of these differences are not well known and depend on the material and environment being considered.

For example, based on evaluations by one researcher, the pH within cracks and crevices of structural steels in marine environments ranged from 4 to 11, of stainless steel from 0 to 3, of aluminum from 3 to 4, and of titanium from 1 to 2 (Ref 18). Shifts of up to 300 mV in the crack tip potential in the anodic direction were observed for cathodically polarized steel, while other researchers found only a small shift in the crack tip potential relative to the external potential under steady-state conditions (Ref 16) or a 300 mV shift in the cathodic direction when the crevice walls were active, reducing to a small shift when the walls passivated (Ref 19). Therefore, the critical potentials at which cracking may occur can differ from those given by the bulk equilibrium conditions used to determine the potential-pH diagrams. Although it is possible to determine the equilibrium conditions based on the crack tip conditions, the current knowledge of crack tip conditions is fragmentary at best. Other factors that limit the usefulness of the equilibrium potential-pH diagrams are the lack of available diagrams for specific materials and environments and the variable temperatures, chemistries, and potentials common in many industrial applications.

Kinetics of SCC. A knowledge of the thermodynamic conditions at which SCC can occur is insufficient without a corresponding understanding of the kinetics of crack growth because the life of a component may be adequate if the crack growth rate is sufficiently slow, even though SCC is thermodynamically possible. As in the thermodynamic conditions for SCC, environmental parameters such as potential, pH, oxygen concentration, temperature, and crack tip chemistry have a strong effect on the crack growth kinetics. The crack tip reactions and the rate-determining steps controlling the crack growth rate are specific to alloy-environment combinations; although a discussion of each system is beyond the scope of this section, some general observations are made. Also, the crack growth rate depends on the crack advance process even though it is controlled by electrochemical reactions.

Detailed descriptions of various crack growth mechanisms are given in the section “Crack Propagation Mechanisms” in this article by categorizing these mechanisms as either anodic dissolution or mechanical fracture models. For the case of a crack growing by anodic dissolution alone, the total crack advance is a function of the total charge transfer at the crack tip, while the crack velocity is a function of the crack tip current density. For a crack growing with mechanical fracture, the total crack advance exceeds the total charge transfer at the crack tip, but the crack velocity may still be controlled by the crack tip current density. A limiting velocity, *da/dt*, can be described for a crack advancing under pure anodic dissolution by the following Faradaic relationship:

$$\frac{da}{dt} = \frac{i_a M}{zF\rho} \qquad \text{(Eq 3)}$$

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

where i_a is the anodic current density of a bare surface, M is the atomic weight, z is the valence, F is Faraday's constant, and ρ is the material density. It has been shown (Ref 20) that this relationship (Eq 3) between the bare surface current density and the crack propagation rate is applicable to a wide variety of materials, as presented in Fig. 15. Equation 2 assumes that the crack tip is maintained in a bare condition, while the crack walls are relatively inactive. A bare crack tip and passive walls can result from the difference between the electrochemical conditions at the tip and other regions in the crack, a difference in the local chemistry of the material at the crack tip that causes the tip to be more active than the crack walls (such as at a sensitized or segregated grain boundary), or a crack tip strain rate that is sufficiently high to prevent the formation of a protective film.

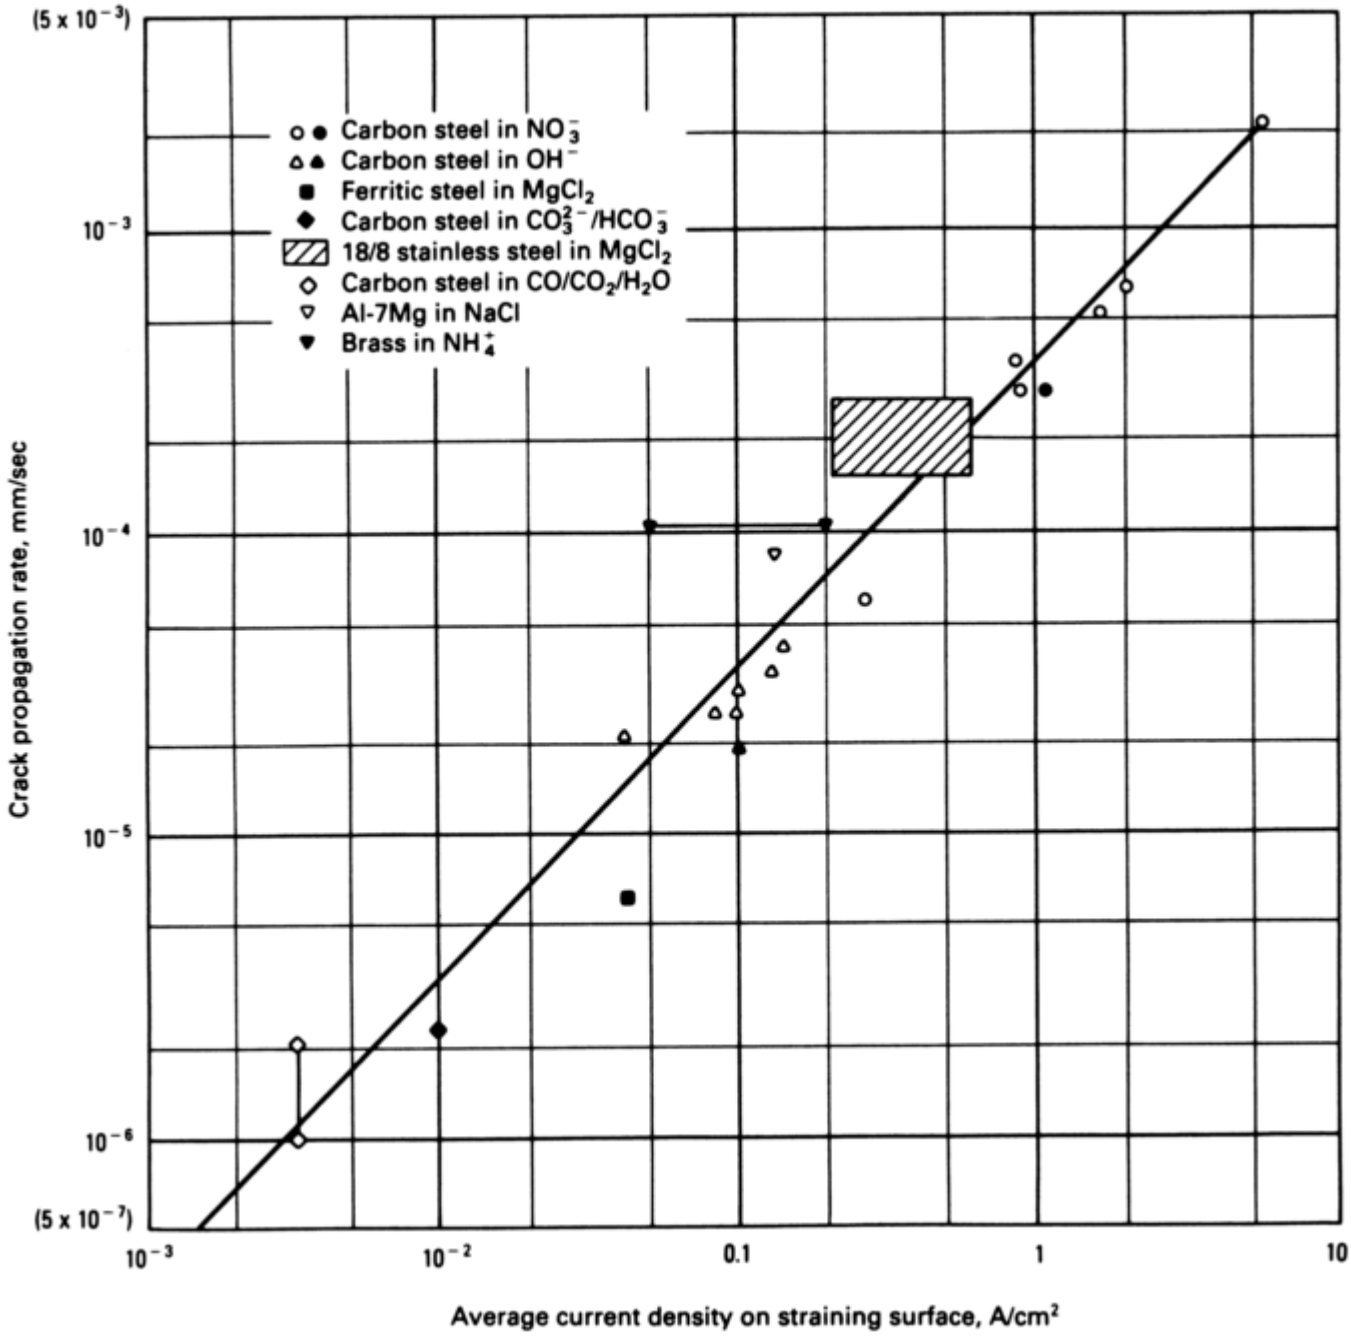


Fig. 15 Relationship between the average crack propagation rate and the oxidation (that is, dissolution and oxide growth) kinetics on a straining surface for several ductile alloy/aqueous environment systems

A number of factors can reduce the crack velocity below that given by Eq 3 and in Fig. 15. The most widely examined crack growth retardation process is that resulting from the crack tip being covered by a film for some fraction of time. The process of crack growth in the presence of a film at the crack tip has been described by several mechanisms, such as slip dissolution and passive film rupture, covered in the section “Crack Propagation Mechanisms” in this article. In general, the crack growth rate depends on the rate at which the film

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

is ruptured and reformed. The amount of corrosion that occurs between these two events has been used to describe the crack growth rate. This time period is determined by the crack tip strain rate, film fracture strain, repassivation rate of the surface, maximum corrosion rate while the tip is bare, and the corrosion rate decay with repassivation. Other factors that can reduce the crack growth rate below that given by Eq 3 are limits in the diffusion rate of species into and out of the crack tip, crack deflection away from the principal stress, and changes in the local material chemistry. Transport of species into and out of cracks is considered a major limitation to attaining the crack growth rate predicted by Eq 3. Factors such as the crack geometry or width, reactions or corrosion rate along the walls of the crack, diffusion rate of anions and cations, and metal salt solubility limits all contribute to transport-limited crack velocities.

A lack of clear knowledge about the specific conditions at the tip of a crack has limited the understanding of the role of specific species on crack growth rates. At this time, it is possible only to describe the effect of bulk electrolyte conditions on crack growth rate; the local conditions may vary significantly. However, knowledge of the local crack tip conditions is most important for understanding the mechanisms of cracking, although a knowledge of the external crack conditions is adequate for monitoring and controlling SCC. Using austenitic stainless steel as an example, the effects of electrochemical potential, oxygen content, and temperature are shown schematically in Fig. 16, 17, and 18. Similar relationships exist for other anion concentrations, such as halides and sulfur species, but the data base is not as well developed as the cases shown. It is important to note that these are not independent effects, because the effects of oxygen concentration and temperature are probably related to the potential. The details of this relationship are complex and are beyond the scope of this section.

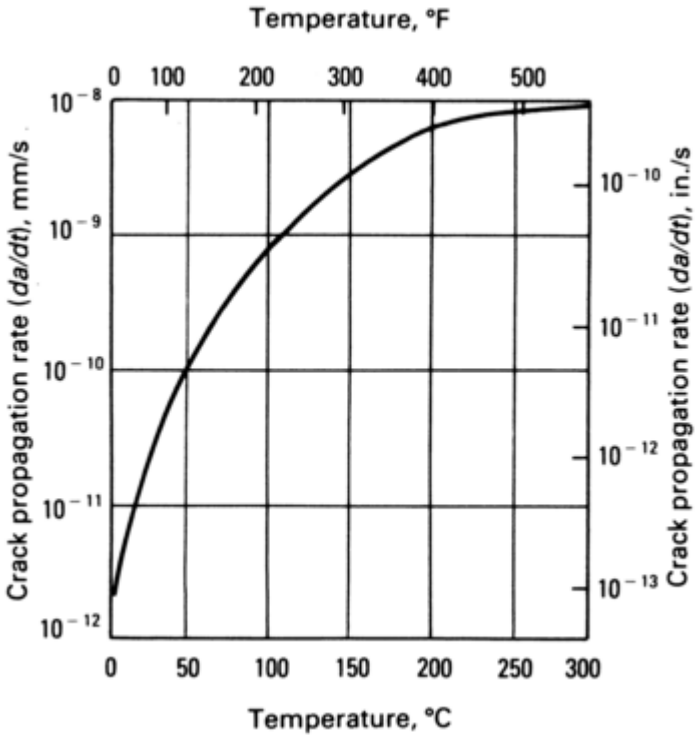

Fig. 18 Schematic of crack growth rate versus temperature for intergranular stress-corrosion cracking of type 304 stainless steel

A mechanical fracture process in SCC can produce crack velocities exceeding those given by Eq 3 by some magnification factor, which can be as large as 100. The mechanism of brittle fracture induced by SCC, which is covered in the section “Crack Propagation Mechanisms” in this article, is thought to involve the formation of a corrosion product at the crack tip in which a cleavage crack can initiate and propagate some depth into the ductile substrate. As mentioned earlier, this process would produce crack lengths that exceed those accounted for by the total charge transfer/metal oxidation process, but it would be dependent on the crack tip corrosion rate because the formation rate of the corrosion product would depend on the corrosion rate.

Early observations and proposals of this process have been made (Ref 21, 22, 23, 24, 25). A current list of materials in which SCC is thought to occur through a film-induced cleavage process as suggested in Ref 25 is given in Table 2, which shows a wide range of materials and environments. An attempt has been made to identify the corrosion product or layer that initiates the cleavage cracking process, but this identification must be considered speculative. The electrochemical conditions controlling the brittle SCC process have not been catalogued carefully; however, for many systems, the main issue is whether cracking can be described completely by anodic dissolution or whether a mechanical fracture process is involved. The greatest uncertainty involves the possibility of a transition between anodic and mechanical SCC processes that is affected by electrochemistry, material chemistry, or mechanics.

The electrochemical factors described in the previous paragraphs generally were drawn from examples of intergranular SCC, but many of the effects would be similar for brittle transgranular SCC. For example, the brittle transgranular crack growth rate follows closely the dependence of the anodic current density on potential. Whether there are critical potentials at which transgranular SCC may switch from a brittle mechanical fracture mode to a purely anodic dissolution mode is unknown. However, for many systems, the critical potentials describing SCC are valid control parameters even though the process associated with these critical potentials may be uncertain. For an anodic dissolution-controlled process, the critical potentials were associated with the need for an active tip and passive crack walls. These conditions are still necessary for a brittle SCC process because it is dependent on the anodic reaction to produce the corrosion reaction product. This product may be a film or a dealloyed layer, but the rate of formation and, therefore, the brittle crack growth rate are dependent on the crack tip current density.

Material Chemistry and Microstructure

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The relationship between material chemistry and microstructure and SCC is equally as complex as the relationship between the environment and SCC. Bulk alloy composition can affect passive film stability and phase distribution (for example, chromium in stainless steel), minor alloying elements can cause local changes in passive film-forming elements (for example, carbon in stainless steel causing sensitization), impurity elements can segregate to grain boundaries and cause local differences in the corrosion rate (for example, phosphorus in nickel or nickel-base alloys), and inclusions can cause local crack tip chemistry changes as the crack intersects them (for example, manganese sulfide in steel). In addition, alloys can undergo dealloying, which is thought to be a primary method by which brittle SCC initiates. The following summary is divided into intergranular and transgranular effects because some of the primary factors can be best described in this way; however, it is important to recognize that many of the material chemistry factors can affect both intergranular and transgranular cracking.

Intergranular Stress-Corrosion Cracking. Material chemistry and microstructure effects on intergranular SCC can generally be divided into two categories: grain-boundary precipitation and grain-boundary segregation. Grain-boundary precipitation effects include carbide precipitation in austenitic stainless steels and nickel-base alloys, which causes a depletion of chromium adjacent to the grain boundary and intermetallic precipitation in aluminum alloys, which are anodically active. Grain-boundary segregation of impurities such as phosphorus, sulfur, carbon, and silicon can produce a grain boundary that is up to 50% impurity within a 1 to 2 nm thick region. These impurities can alter the corrosion and mechanical properties of the grain boundary and can therefore cause cracking by anodic dissolution and perhaps mechanical fracture.

Grain-Boundary Precipitation in Stainless Steels. Chromium carbide precipitation in stainless steels occurs in the temperature range 500 to 850 °C (930 to 1560 °F), with the rate of precipitation controlled by chromium diffusion. For intermediate times, such as occurs with heat treating and welding, chromium depletion occurs adjacent to the grain boundary during chromium carbide growth. This depletion can be described by the minimum chromium concentration adjacent to the carbide and the width of the depleted zone. Minimum chromium concentrations of 8 to 10 at.% have been measured by analytical electron microscopy, while the width of the depleted zone has been measured to range from 10 nm to hundreds of nanometers. After times long enough for carbide growth to reach completion, the chromium profile is eliminated, and the chromium concentration returns to the bulk value.

The intergranular SCC of austenitic stainless steel depends primarily on the nature of the chromium-depleted zone, which is explained generally by the depletion of a passive film-forming element along a continuous path through the material. The stress-corrosion susceptibility and crack growth rate of austenitic stainless steel can be described by the degree of sensitization (DOS) as measured by corrosion tests such as the Strauss or electrochemical potentiokinetic reactivation (EPR) tests. Quantitative comparisons between susceptibility as measured by the presence or absence of intergranular SCC in an SCC test or the crack growth rate and the DOS or chromium depletion parameters have been successful in cases in which sufficient data have been available, but these correlations are limited to specific alloys, environments, and stress conditions. Semiquantitative comparisons in which intergranular SCC is predicted for DOS values greater than some critical value are less costly to obtain and have been used more extensively.

An example of the time/temperature/DOS curves at several carbon concentrations is shown in Fig. 19. The curves represent the conditions necessary for the development of a constant degree of sensitization, with the strong effect of bulk carbon concentration on the time needed to develop a sensitized microstructure. Therefore, the most common method for reducing the possibility of developing a sensitized microstructure is to reduce the carbon concentration or to control the thermal history of the material. Given that the material is sensitized, control of the environment and stress conditions can be used to reduce the crack propagation rate.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

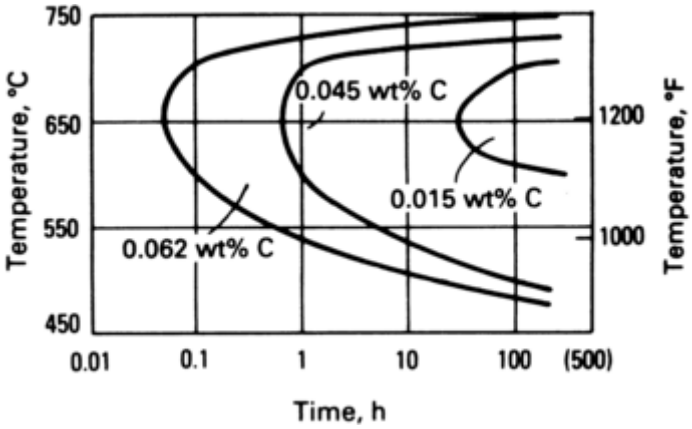

Fig. 19 Time/temperature/sensitization curves determined by EPR tests on type 304 stainless steel alloys of variable carbon contents

Clearly, chromium and carbon are the two most important elements involved in the development of sensitization; however, other elements can play a role. Molybdenum has an effect similar to that of chromium—incorporation into the carbides and depletion adjacent to the grain boundaries—although it is generally present in smaller concentrations (for example, in type 316 stainless steel) than chromium is. Nickel increases the activity of carbon in austenitic stainless steel; therefore, increases in nickel concentration can enhance sensitization for a given carbon concentration and thermal history. Manganese, silicon, and nitrogen have also been shown to affect sensitization, but the available data on these elements are comparatively sparse. Silicon has been shown to segregate to grain boundaries when present in sufficient quantities or by the nonequilibrium processes that occur when the material is irradiated with neutrons. The presence of silicon in the grain boundaries has been found to be deleterious in oxidizing environments.

Grain-Boundary Precipitation in Nickel Alloys. The cause of intergranular SCC in nickel- base alloys is more complex than it is in austenitic stainless steel. Chromium-carbide precipitation and chromium depletion occur in nickel-base alloys, such as alloy 600, as they do in austenitic stainless steels, but a clear connection between the presence of this microstructure and intergranular SCC has not been made. Carbon solubility is considerably lower and chromium diffusion is faster in nickel-base alloys than in austenitic stainless steels; therefore, the nose in the carbide precipitation or sensitization curves shown in Fig. 19 is shifted to shorter times and higher temperatures. Significant heat- to-heat variations in the chromium depletion of alloy 600 have been observed for a given heat treatment. This variation is attributed to the sensitivity of alloy 600 to carbon concentration and to the variability in mill-anneal heat treatment conditions. Chromium depletion is thought to accelerate cracking in oxygenated water but has not been identified as a controlling factor in deaerated water or caustic environments at 300 °C (570 °F). The rapid carbide precipitation kinetics in nickel-base alloys allows the development of a healed microstructure in which carbide growth is complete and the chromium profile is eliminated with relatively short heat treatment times.

Some significant differences between the intergranular SCC of nickel-base alloys and that of austenitic stainless steels include the positive effect of a semicontinuous distribution of carbides at the grain boundary in single-phase material and the galvanic couple between the γ' and γ phases in precipitation-hardened alloys. The beneficial effect of a semicontinuous distribution of carbides is thought to be related to dislocation generation from the carbides that results in a crack blunting or stress relaxation at the tip of a crack. The detrimental effect of the γ' phase is thought to result from a galvanic couple that polarizes the γ phase anodically relative to the γ' phase.

Grain-Boundary Precipitation in Aluminum Alloys. Aluminum alloys are also noted for the occurrence of intergranular SCC in aqueous environments, including sodium chloride (NaCl) solutions. The details of the intergranular SCC process in aluminum alloys are very complex and vary with alloy composition, but some features can be summarized. Grain-boundary precipitation has been identified as a contributing factor in the intergranular SCC in aluminum alloys; galvanic effects between the precipitates and matrix are considered to be important. In some cases, the precipitates are anodic, and in others, they are cathodic to the matrix. Peak- aged materials that give maximum hardnesses and microstructures in which slip bands are produced upon straining are considered to be vulnerable to SCC. Overaged structures are considered to be less susceptible. The mechanism of crack growth is thought to be a combination of local anodic dissolution and hydrogen

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

embrittlement. Whether crack extension is by anodic dissolution or by hydrogen embrittlement remains an open question; however, in aqueous solutions, the primary source of hydrogen is anodic dissolution.

Grain-Boundary Segregation in Aluminum Alloys. Grain-boundary enrichment of magnesium without precipitation of a magnesium-rich phase has been identified as a factor in the intergranular SCC of aluminum alloys (Ref 26, 27). This enrichment is associated with increased corrosion activity at the grain boundary and the possible formation of magnesium hydride (MgH) or enhanced hydrogen entry along the grain boundaries. Crack advance is thought to occur by discontinuous crack jumps (possibly nucleated by hydrides) and crack arrest after about 150 to 350 nm of advance, followed by repetition of this process.

Grain-Boundary Segregation in Ferrous and Nickel Alloys. Grain-boundary enrichment of impurities can contribute to the intergranular SCC of iron-base alloys, austenitic stainless steels, and nickel-base alloys. The extent of their effect depends on the electrochemical potential, the presence of other stress-corrosion processes such as chromium depletion, and their concentration in the grain boundary. The enrichment of impurities to grain boundaries by equilibrium segregation can be described by the enrichment ratio, as shown in Fig. 20 for a variety of impurity- alloy combinations (Ref 28). The enrichment ratio defines the upper bound to the grain-boundary concentration that will be achieved under equilibrium conditions, which can be very long times at low temperatures. It can be seen from Fig. 20 that enrichment ratios as high as 10^5 are possible for some impurities and that ratios greater than 10^2 are not uncommon. For the bulk impurity concentrations present in most engineering alloys, grain-boundary impurity concentrations of 10 to 20 at.% are possible. Therefore, an intergranular stress-corrosion crack can propagate along a grain boundary that has a composition vastly different from that of the bulk alloy.

Ferritic steels exhibit intergranular SCC in hot nitrate, caustic, carbonate, and a variety of other environments. The presence of intergranular SCC is dependent on the electrochemical potential because intergranular SCC is predominant at potentials in the active-passive transition. Early studies of this effect identified carbon segregation as the primary element of concern where the carbon atoms were said to provide suitable imperfection sites for adsorption of nitrate in an adsorption-induced crack growth mechanism (Ref 29). More recently, phosphorus segregation has been associated with the intergranular SCC of iron alloys in nitrate and caustic solutions (Ref 30, 31); grain-boundary concentrations as low as 2 to 3 at.% have been sufficient to alter the passivity of iron in hot nitrate solutions. A complexity of SCC in ferritic steels is the susceptibility of such steels to intergranular SCC and to hydrogen-induced subcritical crack growth. The temperatures and electrochemical potentials at which intergranular SCC and cathodic hydrogen-induced subcritical crack growth

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

occur generally are not the same. Stress corrosion tends to dominate at temperatures above about 50 °C (120 °F) and at potentials in the active-passive transition; hydrogen effects are predominant at temperatures below 50 °C (120 °F), at more cathodic potentials, and at lower pH values. Examples of the effect of sulfur and phosphorus on the tendency toward intergranular fracture are given in Fig. 21 and 22, from which it can be seen that sulfur was more effective than phosphorus in causing intergranular fracture of iron at cathodic potentials (Ref 32, 33). For the conditions of this test, a sulfur concentration of about 13 at.% was sufficient to change the fracture mode from transgranular to intergranular.

مرجع مهندسی مواد و متالورژی

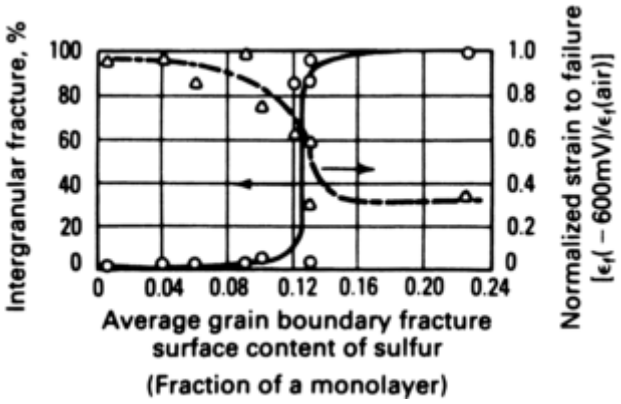

Fig. 22 Percent intergranular fracture and the normalized strain to failure plotted as a function of sulfur content at the grain boundary for straining electrode tests at a cathodic potential of -600 mV (SCE)

Grain-boundary impurity segregation of various impurities, including phosphorus, silicon, sulfur, and nitrogen, has been reported in austenitic stainless steels (Ref 34); however, no direct effect on intergranular SCC has been identified in high-temperature water. Phosphorus segregation has been shown to cause intergranular corrosion in highly oxidizing solutions, and impurity segregation of phosphorus and perhaps silicon has been suggested as a primary factor in irradiation-assisted SCC, which occurs in the oxidizing in-core environment of light water reactors (Ref 35). Phosphorus segregation apparently can contribute to the intergranular SCC of austenitic stainless steels in high-temperature water if the carbon concentration of the alloy is lower than 0.002%. At this low concentration, there is virtually no sensitization; therefore, the phosphorus segregation effect is observed.

Phosphorus is also the primary grain-boundary segregant in alloy 600 and has been shown to segregate by an equilibrium process (Ref 36). The grain-boundary composition versus temperature curves for alloy 600 and type 304 stainless steel are shown in Fig. 23, along with a calculated curve for equilibrium segregation in nickel (Ref 37). It can be seen that grain-boundary phosphorus concentrations to 15 at.% are possible. Grain-boundary segregation of sulfur, boron, nitrogen, and titanium also has been observed in alloy 600; however, a clear connection between the impurity segregation and intergranular SCC in nickel-base alloys has not been observed to date.

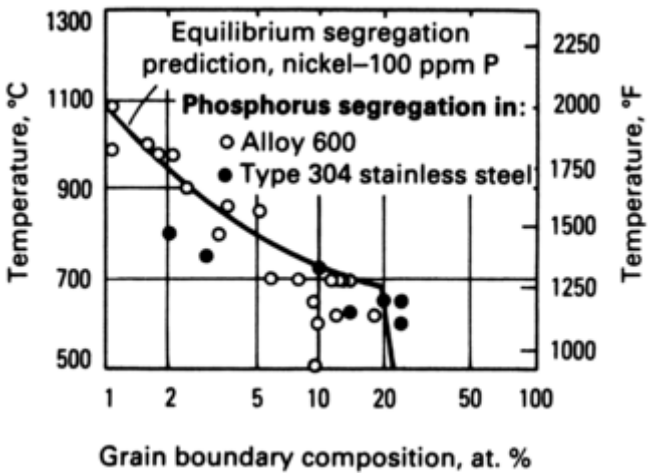

Fig. 23 Grain-boundary segregation measurements in Alloy 600 and type 304 stainless steel. Shown are auger electron spectroscopy measurements of phosphorus segregation in the two alloys as compared with model prediction for phosphorus segregation in nickel.

In contrast to the high-temperature water results for alloy 600, a clear effect of phosphorus segregation on the intergranular SCC of nickel was observed at oxidizing potentials in acidic solutions at 25 °C (77 °F) (Ref 18), as shown in Fig. 24. Intergranular SCC was observed at anodic potentials ranging from the active-passive transition to transpassive potentials in nickel with phosphorus-enriched grain boundaries but not sulfur-enriched grain boundaries. The role of phosphorus was identified with degradation of the passive film formed on nickel in acidic solutions. This example is a clear case of active- path corrosion; however, the cracking was clearly

www.iran–mavad.com
مرجع مهندسی مواد و متالورژی

stress dependent, as evidenced by a threshold stress intensity below which intergranular SCC did not occur and an alignment of cracks with the applied tensile stress. Because there were no grain-boundary carbides or chromium depletion in the nickel, these results illustrate the potential effect of impurities when other grain-boundary processes are absent. Therefore, it appears, as in the case of type 304 stainless steel cited earlier, that impurity segregation may induce intergranular SCC in the absence of carbides and chromium depletion.

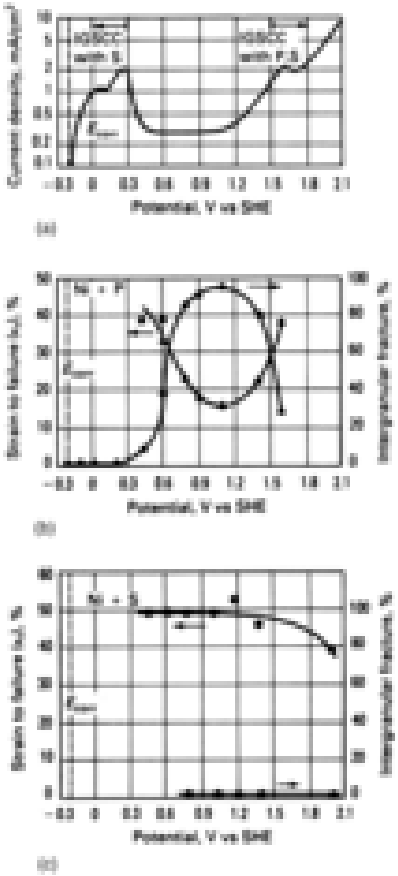

Fig. 24 Stress-corrosion cracking behavior of nickel with phosphorus and sulfur segregation. (a) Polarization curve for nickel in 1 *N* H_2SO_4 at 25 °C (77 °F). (b) Strain to failure and percent intergranular fracture for 26% phosphorus segregation at grain boundaries. (c) Strain to failure and percent intergranular fracture for 40% sulfur segregation at grain boundaries

Like ferritic materials, nickel-base alloys and austenitic stainless steels are susceptible to hydrogen-induced intergranular subcritical crack growth. Impurity segregation is thought to play a key role in this hydrogen-induced fracture, as the results for nickel shown in Fig. 25 illustrate. These results show the combined effect of sulfur segregation and cathodic hydrogen on the amount of intergranular fracture in nickel. For the conditions of these tests, a given amount of intergranular fracture resulted for different combinations of grain-boundary sulfur and hydrogen reduction rate. A decrease in the amount of sulfur could be compensated for by an increased hydrogen activity to give the same amount of intergranular fracture.

Transgranular Stress-Corrosion Cracking. Numerous metallurgical factors affect transgranular SCC, for example, crystal structure, anisotropy, grain size and shape, dislocation density and geometry, yield strength, composition, stacking fault energy, ordering, and phase composition. Some of these factors also affect intergranular SCC, as covered in the section “Intergranular Stress-Corrosion Cracking” in this article. Also, some of their effects on transgranular SCC are related to the corrosion behavior of the alloy, which can be understood from potential-pH diagrams or polarization curves. Because these effects are covered elsewhere, they are not discussed here. Similarly, yield strength effects are considered in the section “Mechanical Factors” in this article. Metallurgical factors in hydrogen-induced subcritical crack growth, such as crystal structure, hydride stability, and yield strength, are considered in the article “Hydrogen Damage” in this Volume. The effects of alloy composition on corrosion rate, hydrogen exchange current densities, and hydrogen absorption rates also influence the hydrogen-induced subcritical crack growth of materials in corrosive environments, but these are covered in the articles dealing with specific metals and alloys.

Alloying effects on slip planarity are a key metallurgical factor in transgranular SCC. Planar slip occurs in alloys with low stacking fault energy, alloys containing ordered phases, or alloys exhibiting short- or long-range ordering. The consequences of planar slip on transgranular SCC have been explained by the slip-dissolution model discussed in Ref 39. In this model, the passive film is ruptured by the emergence of a slip step. In high-chloride environments, evidence was presented that preferential corrosion occurred along the high dislocation density plane created by planar slip (Ref 40). A number of crack growth processes were suggested based on the planar slip localized corrosion process—for example, control of crack advance solely by anodic dissolution of the slip plane, brittle fracture of the corrosion product or tarnish film formed along the localized corrosion path, and the tunneling process by which corrosion along the slip plane branches out into tunnels accompanied by mechanical fracture of the remaining ligaments. The planar slip concept of transgranular SCC appears consistent with a number of observations, such as alloying and strain rate effects. Details of these mechanisms are presented in the section “Crack Propagation Mechanisms” in this article.

A significant difficulty associated with the slip-dissolution mechanism is the nature of the transgranular SCC fracture surfaces, which are generally not on the slip planes and have cleavage-like features. For example, for

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

admiralty brass tested in aqueous ammonia (NH_3) and Al- 5.5Zn-2.5Mg tested in aqueous NaCl, the primary fracture facets were (110) planes, while for stable austenitic stainless steel tested in aqueous magnesium chloride ($MgCl_2$) at 155 °C (310 °F), the primary facets were on (100) planes. There is also evidence that crack advance in brass occurs in a discontinuous manner (Ref 24). Several mechanisms for the development of a cleavage crack in ductile face-centered cubic (fcc) alloys have been presented, but a definite correlation has not emerged.

One concept that has received considerable attention is that proposed in Ref 25, in which a rapid crack advance that begins in a brittle film at the crack tip induces cleavage fracture of the ductile material ahead of the crack tip. The brittle films that are regarded as the initiating layers are given in Table 2. These include a dealloyed layer, oxide, nitride, carbide, or hydride. A dealloyed layer acting as a cleavage crack initiator is suggested for brass, copper-gold, and iron- chromium-nickel alloys. If this concept is supported by future research, the relative reactivity of the alloying elements will prove to be a key metallurgical factor in the transgranular SCC of materials. It has also been demonstrated that the dealloying rate of copper-aluminum and copper- zinc as a function of aluminum and zinc, respectively, corresponds to the crack growth rate in ammoniacal solution (Ref 25).

Mechanical Factors

There is more commonality in the mechanical aspects of stress corrosion between intergranular SCC and transgranular SCC and between various materials than there is in environmental and metallurgical aspects. As indicated earlier, many of the environmental or metallurgical factors are specific to a given material/environment combination such that a metallurgical factor may be significant in one environment, but not in another. Threshold stress intensities and stresses, the presence of a stress-independent crack growth regime, and a dependence of crack growth rate on strain rate are features common to a variety of environmentally induced crack growth processes and a variety of materials. Anodic and cathodic controlled processes show many of these common features.

The stress-intensity dependence of environmentally induced subcritical crack growth is shown schematically in Fig. 26, along with a relationship for the linear-elastic mode I stress intensity. The applied stress intensity is a function of the uniform stress and the crack length; therefore, for a constant-stress test, the stress intensity increases with increasing crack extension. For low-strength materials that form a significant plastic zone ahead of the crack, nonlinear fracture mechanics relationships must be used to calculate *K*. The subcritical crack growth behavior of many material/environment combinations is characterized by a threshold and by stages 1, 2, and 3 (see the article “Fracture Toughness and Fracture Mechanics” in *Mechanical Testing and Evaluation,* Volume 8 of *ASM Handbook,* for a detailed discussion of modes of crack formation).

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

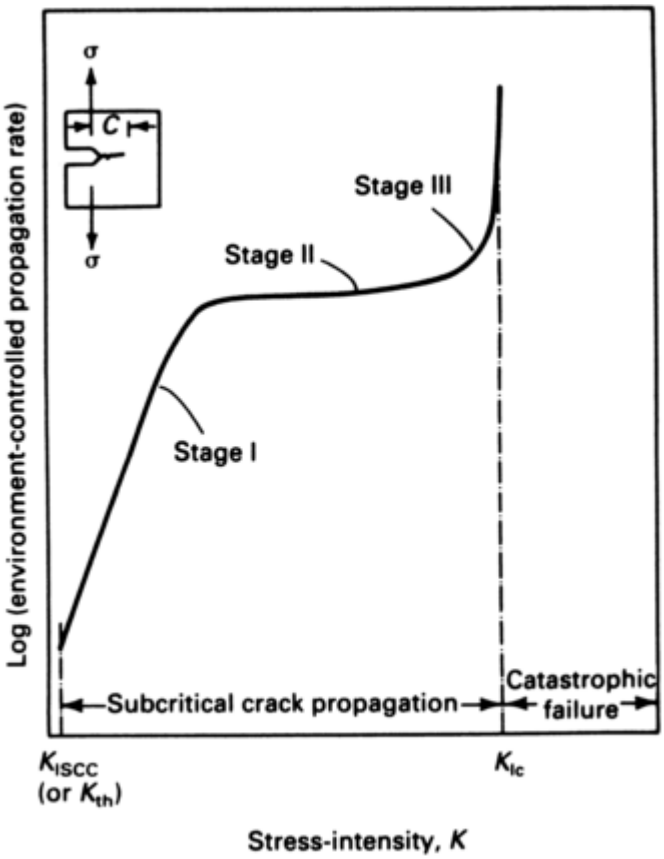

Fig. 26 Typical, subcritical crack propagation rate versus stress intensity relationship. Stress intensity, *K*, is defined as $K = A\sigma\sqrt{\pi C/B}$, where σ is the total tensile stress, *C* is the crack length, and A and B are geometrical constants.

In Fig. 26, the threshold is defined by the minimum detectable or reliably measured crack growth rate, while in some materials, stage 1 has a large *K* dependence such that a lower threshold does not result at lower crack velocities. There are a number of physical processes that can be associated with a threshold stress intensity, including a fracture strain for a passive film rupture mechanism, the critical resolved shear stress for the slip-dissolution mechanism, a fracture stress for a brittle film-induced cleavage mechanism, or a critical crack tip opening for transport of species in the crack. The threshold stress intensity generally is associated with the development of a plastic zone at the crack tip; however, calculations of crack tip strains are not very accurate, and experimental correlations between plastic zone development of K_{ISCC} have not been made.

Stage 1 subcritical crack growth is marked by a rapid increase in crack velocity with a small increase in *K*. Dependencies of crack velocity on stress intensity to the fourth power have been reported for a number of material/environment combinations. Changes in crack velocity of two orders of magnitude with small changes in *K* are not uncommon for the stage 1 regime. Few explanations for the *K* dependence of stage 1 have been put forth. One explanation is that in stage 1, the crack tip plastic strain rate is increasing rapidly with *K*, and another explanation is that the transport of species into and out of the crack increases rapidly with increasing crack volume in stage 1.

In metals tested in aqueous solutions, in transport of cations or anions in the crack electrolyte, or in passive film forming materials, the passive film rupture and repassivation rates are thought to be rate-limiting processes. Environmental parameters such as crack tip potential, corrosion rates, and pH also affect the stage 2 crack velocity so that in many systems the limiting velocity is a function of crack tip corrosion rate, strain rate, and transport rate. A steady-state crack transport calculation for intergranular SCC in nickel + phosphorus gave crack growth values within a factor of five of the measured stage 2 values (Ref 16). For transgranular SCC, there is increasing evidence that the crack velocity is a function of the corrosion rate, but that crack advance results from brittle crack jumps that exceed the depth of the corrosion reaction. In this case, the crack velocity may scale with the corrosion rate, but the crack length exceeds that determined from charge transfer.

Most stress-corrosion data have been obtained by using specimens loaded in a tensile mode in which the stress is perpendicular to the plane of the advancing crack; this condition is defined as mode 1 loading. In practice, a

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

component may have a complex loading mode such that torsion and shear components are present. The effect of mixed loading modes on SCC is therefore an important consideration in component design; however, very few SCC data exist for other than mode 1 loading. Some examples of SCC in modes 1 and 3 for aluminum in 3.5% NaCl and type 304 stainless steel in boiling $MgCl_2$ are shown in Fig. 27, in which it can be seen that mode 1 loading gives the lowest threshold stress or stress intensity. Also shown in Fig. 27(a) is a schematic of the test specimen used to perform mixed-mode SCC tests. In both cases, the researchers concluded that the lower thresholds and higher crack velocities in mode 1 tests of these materials indicate a hydrogen embrittlement component to SCC because hydrogen effects are more prominent under tensile loading conditions (Ref 41, 42). However, anodic stress- corrosion processes are also aided by the crack opening that results from mode 1 loading.

peak and aging; OA, overaged; UA, underaged. (b) Crack velocity versus stress intensity curves for stress-corrosion cracking of type 304 stainless steel in modes 1 and 3 in boiling $MgCl_2$

Stress-corrosion data are frequently given as applied stress versus time to failure, as shown in Fig. 28. These data are obtained with notched or unnotched specimens statically loaded in tension or bending. The threshold stress is sensitive to the environment, alloy composition, and structure and is not strictly a materials property. The threshold stress is related to the yield strength of the material, with thresholds generally being greater than one-half the yield strength, and in many cases, the threshold is a significant fraction (about 0.8) of the yield strength of the material. Therefore, most SCC tests performed with this technique are performed at values of about 80% or greater of the yield strength.

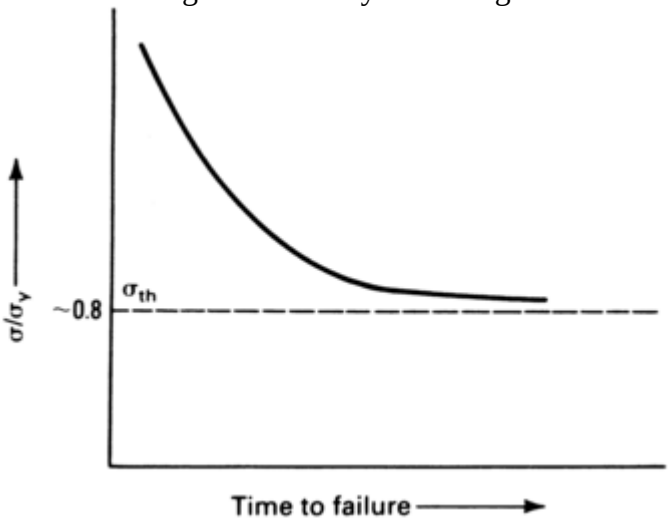

Fig. 28 Schematic diagram of time to failure versus applied stress, σ, normalized to the yield strength σ_y for stress corrosion

The data obtained with this method incorporate the stage 1, 2, and 3 regimes shown in Fig. 26 in addition to a crack initiation stage. Crack growth begins with the development of a pit or intergranular corrosion groove that raises the stress intensity to the K_{ISCC}. Because the stress is constant, the stress intensity increases with increasing crack length as given by the expression in Fig. 26 so that the crack progresses through stage 1 to stage 2 and ultimately to fracture in stage 3. Therefore, the failure time in a constant- stress test is dependent on the initiation rate, the value of the K_{ISCC}, the crack growth rate in stage 2, and the fracture toughness K_{Ic}. These test data are useful because they relate to the sequence that may occur in practice, but it is difficult to relate them to physical processes and rate-controlling steps. Crack growth rates are frequently estimated from constant-load tests based on the crack depth divided by the total test time. Crack velocities obtained in this manner are minimum values because the time for initiation is included so that instantaneous velocities will always be greater.

The threshold stress is perhaps the least complicated value obtained from constant-load tests. For film-forming materials, the threshold can be related to the film formation and rupture rate. Below the threshold stress, the film formation rate is sufficiently high to maintain the surface in a filmed condition; at higher stresses, the film rupture rate exceeds the reformation rate such that a pit or an intergranular corrosion groove can grow. For transgranular SCC initiated by a brittle corrosion film, the threshold stress could be related to the fracture stress of the film; however, this type of relationship has not been established for the brittle film-induced cleavage process.

Constant extension rate or slow strain rate tests have essentially replaced the use of the constant-stress test for stress-corrosion testing. This change has occurred because of the variability in times of failure with a constant-stress test and the long test times needed to define the stress threshold. Also, the concept that the crack growth rate is a function of the strain rate, as shown in Fig. 29 for intergranular type 304 stainless steel, has led to the use of a constant extension rate test. The CERT specimens will fail within a given period of time, thus eliminating specimens that do not fail because they are loaded to a stress below the threshold. The crack growth rates given in Fig. 29 are minimum values obtained from unnotched specimens, and the strain rate is the average applied rate. Clearly, once a crack develops, the crack tip strain rate will differ from the average

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

applied value. An example of the crack velocity as a function of the crack tip strain rate is given in Fig. 30 for intergranular SCC of a carbon-manganese steel tested in a carbonate solution. A threshold strain rate is evident in these results that is the same as a threshold stress intensity. A second threshold strain rate exists at high strain rates because mechanical fracture occurs before a crack can initiate and propagate to a measurable length. The two strain rate thresholds are illustrated in Fig. 31.

مرجع مهندسی مواد و متالورژی

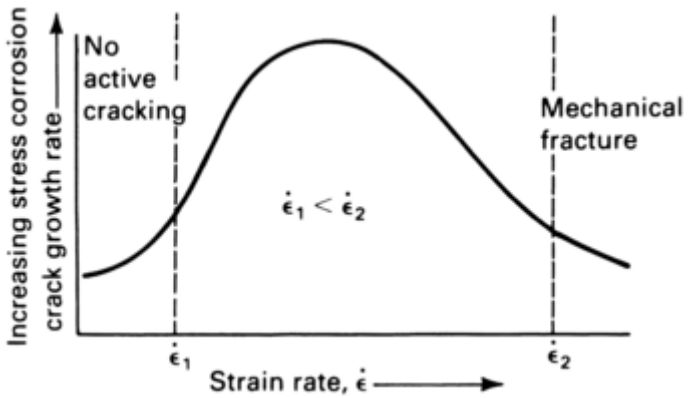

Fig. 31 Stress-corrosion crack growth as a function of the two strain rate thresholds, $\dot{\epsilon}_1$ and $\dot{\epsilon}_2$

It is important to distinguish between static and dynamic effects. For example, a sample could be plastically strained 10% and the load dropped to below the threshold stress before being immersed in a corrosive environment and SCC will not occur. However, a sample can be slowly strained 10% in a corrosive environment with the development of numerous cracks and perhaps even complete failure. Therefore, it is the dynamic strain and creation of fresh surface or dynamic fracture of a brittle film that is crucial to SCC. Corrosion current measurements corroborate these observations; the current density of a prestrained sample is usually very similar to an unstrained sample, while the current density measured during dynamic strain is considerably greater than that in the unstrained sample.

Stress-Corrosion Cracking

R.H. Jones, Battelle Pacific Northwest National Laboratory

Crack Propagation Mechanisms

As indicated in the previous discussion, it is unlikely that a single mechanism of SCC exists; instead, there are probably two or three different operative mechanisms. Many models have been proposed, but only the more

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

prominent are discussed. The proposed mechanisms for crack propagation fall into two basic classifications: those based on dissolution as the principal cause of crack propagation and those that involve mechanical fracture in the crack propagation process.

Dissolution Models

According to models of this type, the crack advances by preferential dissolution at the crack tip. A number of models have been proposed to account for this process. For example, preferential dissolution at the crack tip has been attributed to the formation of active paths in the material, stresses at the crack tip, and chemical-mechanical interactions (Ref 43, 44, 45, 46, 47, 48). However, research has essentially eliminated all but one model from serious consideration, and the debate has recently centered on the details of this model.

Film Rupture. The film rupture model, also referred to as the ***slip-dissolution model,*** assumes that the stress acts to open the crack and rupture the protective surface film. Two investigators, working independently, first postulated that localized plastic deformation at the crack tip ruptures the passivating film, exposing bare metal at the crack tip (Ref 49, 50). The freshly exposed bare metal then dissolves rapidly, resulting in crack extension. Some investigators (Ref 51, 52, 53) assume that once propagation starts, the crack tip remains bare because the rate of film rupture at the crack tip is greater than the rate of repassivation (Fig. 32a). Others (Ref 54, 55, 56, 57) assume that the crack tip repassivates completely and is ruptured periodically by the emergence of slip steps (Fig. 32b).

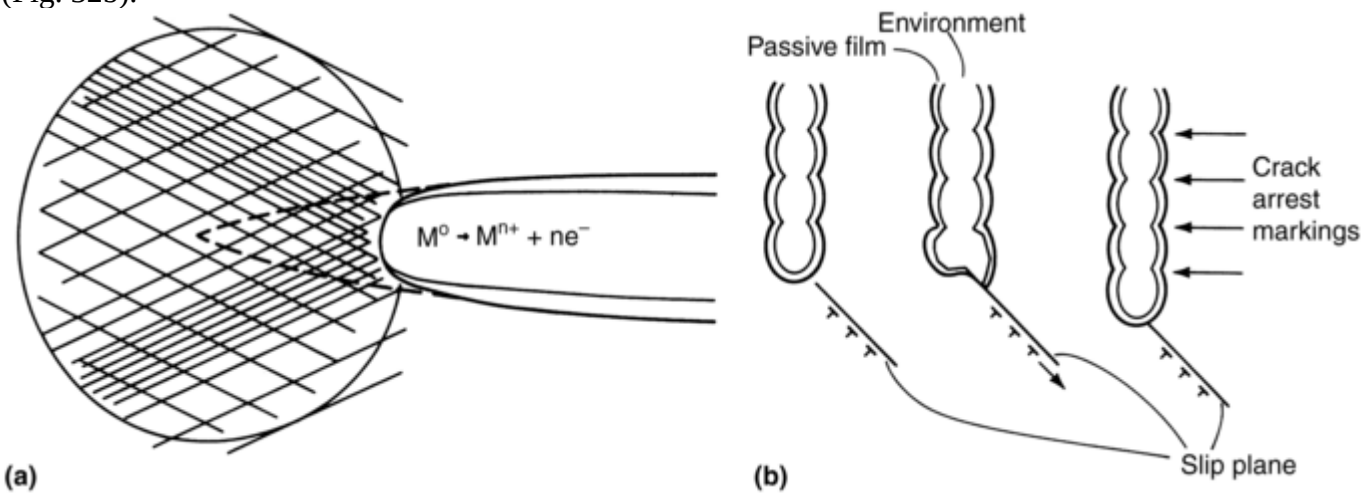

Fig. 32 Schematic representations of crack propagation by the film rupture model. (a) Ref 50. (b) Ref 56 and 57

Considerable evidence has been found to support these mechanistic models, and intergranular corrosion may be considered the low stress limiting case of this mechanism (Ref 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57). However, the observation of discontinuous cracking and crack arrest markings (discussed previously) is an indication that crack propagation can be, and frequently is, discontinuous. Also, transgranular SCC fracture surfaces are flat, crystallographically oriented, and match precisely on opposite sides of the fracture surface (indicating very little dissolution during crack advance). As a result, film rupture and dissolution are accepted as viable mechanisms of intergranular SCC in some systems, but generally are not accepted as mechanisms of transgranular SCC (Ref 58).

Mechanical Fracture Models

Mechanical fracture models originally assumed that stress concentration at the base of corrosion slots or pits increased to the point of ductile deformation and fracture (Ref 48). These early proposals assumed that the crack essentially propagated by dissolution and that the remaining ligaments then failed by mechanical fracture (ductile or brittle). A refinement of this approach has been proposed (Ref 40, 59); it is generally known as the *corrosion tunnel model.*

The Corrosion Tunnel Model. In this model, it is assumed that a fine array of small corrosion tunnels form at emerging slip steps. These tunnels grow in diameter and length until the stress in the remaining ligaments

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

causes ductile deformation and fracture. The crack thus propagates by alternating tunnel growth and ductile fracture (Fig. 33). Cracks propagating by this mechanism should result in grooved fracture surfaces with evidence of microvoid coalescence on the peaks, as illustrated in Fig. 33(a). This theory is not consistent with the common fractographic features discussed previously. As a result, it was suggested (Ref 60) that the application of a tensile stress results in a change in the morphology of the corrosion damage from tunnels to thin flat slots, as shown in Fig. 33(b). The formation of slots was observed below the dealloyed sponge layer on the {110} type planes in austenitic stainless steels, and it was found that the formation of these slots required the presence of a tensile stress. The width of the corrosion slots was found to approach atomic dimensions, and as a result, close correspondence of matching fracture surfaces would be expected. It was concluded that transgranular SCC can be explained in terms of the formation and mechanical separation of corrosion slots (Ref 60).

Adsorption-Enhanced Plasticity. Studies of liquid-metal embrittlement (LME), hydrogen embrittlement, and SCC have led to the conclusion that similar fracture processes occur in each case (Ref 61, 62, 63). Because chemisorption is common to all three, this process was concluded to be responsible for the environmentally induced crack propagation (Ref 61). Based on fractographic studies, it was concluded that cleavage fracture is not an atomically brittle process but occurs instead by alternate slip at the crack tip in conjunction with formation of very small voids ahead of the crack. It was also proposed that chemisorption of environmental species facilitated the nucleation of dislocations at the crack tip, promoting the shear processes responsible for brittle cleavagelike fracture (Ref 61, 62, 63). The origin of crack arrest markings by this mechanism is, however, uncertain. Nevertheless, this mechanism promises to explain many similarities among SCC, LME, and hydrogen embrittlement.

The Tarnish Rupture Model. This model was first proposed (Ref 64) to explain transgranular SCC but was later modified by other researchers (Ref 65, 66, 67) to explain intergranular SCC. In the original model (Ref 64), a brittle surface film forms on the metal that fractures under the applied stress. Fracture of the film exposes bare metal, which rapidly reacts with the environment to re-form the surface film. The crack propagates by alternating film growth and fracture, as shown in Fig. 34(a). This hypothesis was later modified to explain intergranular SCC based on the assumption that the oxide film penetrates along the grain boundary ahead of the crack tip, as shown in Fig. 34(b). Again, crack propagation consists of alternating periods of film growth and brittle film fracture. Film growth requires transport of species across the film and, as a result, the thickness of the film is limited in the absence of stress (Ref 67). This model predicts crack arrest markings on intergranular fracture surfaces and discontinuous acoustic emission during crack propagation that are not always observed during intergranular SCC. Also, it assumed penetration of the film into the grain boundary ahead of the crack tip, which may not be the case for all systems (Ref 68). At present, experimental results are insufficient to confirm or refute this model (Ref 66, 67).

The Film-Induced Cleavage Model. In 1959, the hypothesis was presented that dealloying and/or vacancy injection could induce brittle fracture (Ref 69). However, the exact nature of the interactions and how they could induce the observed crack propagation was not thoroughly evaluated. More recently, a model was developed based on the hypothesis that a surface film could induce cleavage fracture (Ref 70). This model assumes that:

- A thin surface film or layer forms on the surface
- A brittle crack initiates in this layer
- The brittle crack crosses the film/matrix interface with little loss in velocity
- Once in the ductile matrix, the brittle crack will continue to propagate
- This crack will eventually blunt and arrest, after which this process repeats itself

This model has the unique ability to explain the crack arrest markings, the cleavagelike facets on the fracture surface, and the discontinuous nature of crack propagation.

The hypothesis that a brittle crack will continue to propagate after it has entered the normally ductile matrix is a critical point. This allows a thin surface layer to induce brittle crack propagation over distances much greater than the film thickness. A critical examination of this hypothesis concluded that a brittle crack can propagate in a ductile matrix if the crack is sharp and is propagating at high velocities before entering the ductile matrix (Ref 71). A computer model was developed for this process, and it was concluded that a surface layer can initiate brittle fracture even if the layer is ductile (depending on lattice mismatch, etc.) (Ref 72). More research into surface films and brittle fracture is required before this model can be thoroughly evaluated.

Adsorption-Induced Brittle Fracture. This model, which was initially presented in Ref 46, is based on the hypothesis that adsorption of environmental species lowers the interatomic bond strength and the stress required for cleavage fracture. This model is frequently referred to as the stress-sorption model, and similar mechanisms have been proposed for hydrogen embrittlement and LME (Ref 73). This model predicts that cracks should propagate in a continuous manner at a rate determined by the arrival of the embrittling species at the crack tip. This model does not explain how the crack maintains an atomically sharp tip in a normally ductile material, because it does not include a provision for limiting deformation in the plastic zone. Also, the discontinuous nature of crack propagation is not explained by this model.

Hydrogen Embrittlement. Stress-corrosion cracking in some material/environment combinations can be a form of hydrogen-induced subcritical crack growth. Because the anodic reaction must have a corresponding cathodic reaction and because the reduction of hydrogen is frequently the cathodic reaction, hydrogen-induced subcritical crack growth can be the dominant stress-corrosion crack growth process in some materials. Many features of hydrogen-induced subcritical crack growth from cathodic hydrogen are very similar to those produced by gaseous or internal hydrogen. The mechanisms of hydrogen damage are discussed in the following section. However, a few features of hydrogen embrittlement from cathodic hydrogen that are different from other forms of hydrogen embrittlement are summarized.

Once hydrogen has been absorbed by a material, its effect, whether from a gaseous or cathodic source, is the same. This has been shown for a number of materials and a variety of properties. There are three primary differences between gaseous and cathodic hydrogen absorption processes. First, cathodic hydrogen adsorbs on the surface as atomic hydrogen (as reduced), while gaseous hydrogen adsorbs in the molecular form and must dissociate to form atomic hydrogen. Desorption of loosely bound molecular hydrogen is relatively easy, while the dissociation step can, in some cases, be the rate- determining step. Therefore, the desorption and absorption rates of gaseous and cathodic hydrogen may be substantially different for equal hydrogen activities. Second, the hydrogen activities produced by cathodic hydrogen can be quite large (thousands of psi) and are dependent on the anodic reaction rate, while gaseous hydrogen pressures are generally much lower. Lastly, the surface of the material at a crack tip may be substantially different under electrochemical corrosion conditions from that in the presence of gaseous hydrogen containing substantial quantities of other gases, such a O_2 and CO_2.

Hydrogen-induced crack growth as the dominant stress-corrosion mechanism has been suggested for ferritic steels, nickel-base alloys, titanium alloys, and aluminum alloys, although ferritic steels show the most evidence

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

of this mechanism. The effects of factors such as yield strength, impurity segregation, and temperature on the crack growth behavior of ferritic materials in aqueous environments all follow the trends of gaseous hydrogen embrittlement. For example, the crack growth rate of a 3% Ni steel as a function of temperature in water is shown in Fig. 35(a), while the crack growth rate of 4340 steel in gaseous hydrogen is shown in Fig. 35(b). The maximum crack growth rate occurs at about 20 °C (70 °F), with similar decreases at both higher and lower temperatures. However, anodic stress- corrosion processes become active at temperatures above 100 °C (212 °F) for the steel tested in water. Similar trends have been shown for impurity segregation effects on hydrogen-induced crack growth of materials where cathodic and gaseous hydrogen produce essentially similar results. Some of these results have been presented in the section “Material Chemistry and Microstructure” in this article.

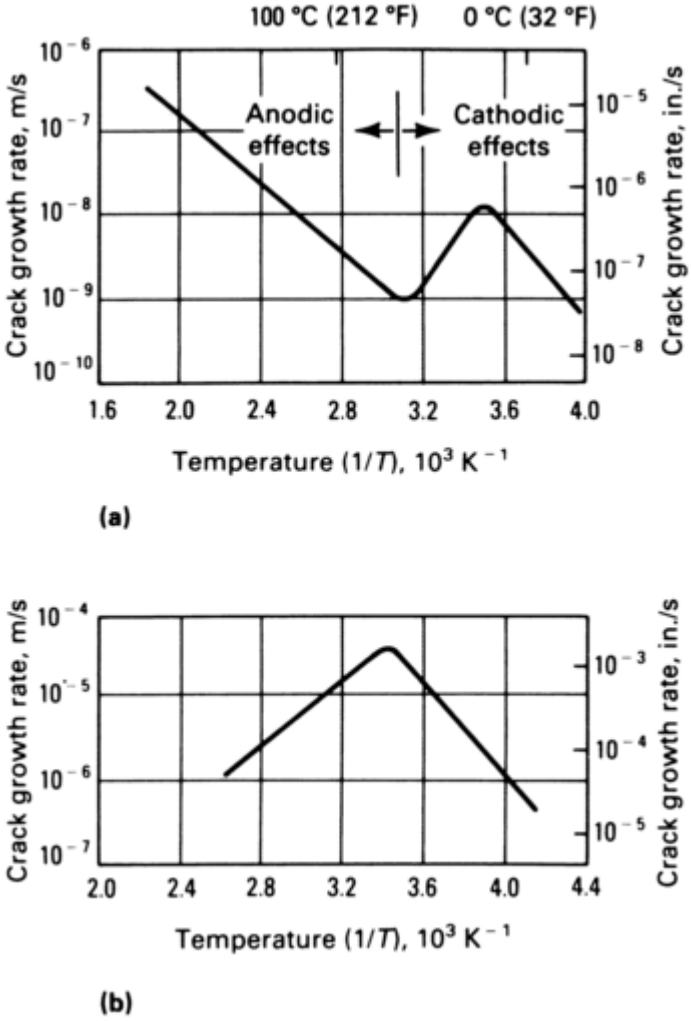

Fig. 35 Schematic of crack growth rate versus temperature for (a) 3% Ni steel in water (Ref 74) and (b) 4340 steel in gaseous hydrogen (Ref 75)

Specific mechanisms of cathodic hydrogen induced subcritical crack growth have not been developed because it has generally been sufficient merely to identify hydrogen as the cause for cracking. However, a mechanism was presented in which grain-boundary impurities act as hydrogen recombinant poisons and enhance the uptake of cathodic hydrogen (Ref 76). A schematic of this process is shown in Fig. 36, in which the tin and antimony that segregated to the grain boundaries of nickel enhance the hydrogen uptake kinetics. This mechanism does not propose a new mechanism by which hydrogen can cause cracking but merely proposes a mechanism by which impurity segregation can enhance hydrogen uptake. There may be circumstances in which such a mechanism could tip the balance between an anodically driven process and a cathodically driven process or could accelerate cracking to a value that is measurable or of practical significance. However, a review of the combined effects of impurity segregation and hydrogen embrittlement concluded that grain- boundary impurities behave the same with cathodic and gaseous hydrogen in that they enhance crack growth by a combined grain-boundary embrittlement processes but not by enhanced hydrogen uptake (Ref 77). It should be

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

noted, however, that a material with impurities such as sulfur, phosphorus, antimony, and tin segregated to their grain boundaries are more susceptible to all forms of hydrogen—cathodic, gaseous, or internal.

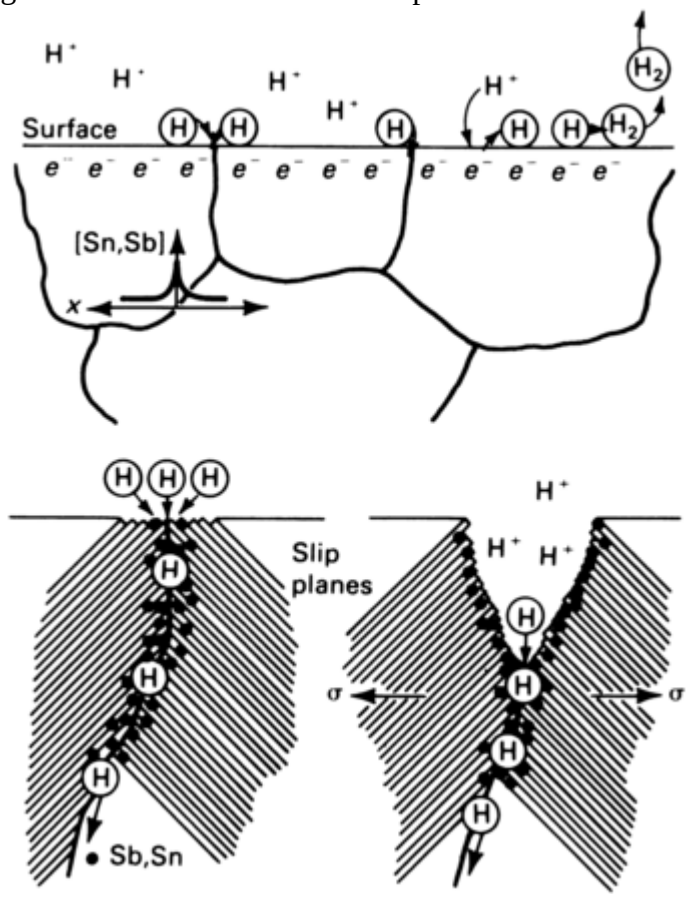

Fig. 36 Schematic showing effect of some impurities on mechanism by which intergranular embrittlement of nickel is presumed to occur at cathodic potentials

Stress-Corrosion Cracking

R.H. Jones, Battelle Pacific Northwest National Laboratory

Summary

Stress-corrosion cracking is a phenomenon in which time-dependent crack growth occurs when the necessary electrochemical, mechanical, and metallurgical conditions exist. Corrosion fatigue is a related process in which the load is cyclic in corrosion fatigue rather than static as in stress corrosion. When hydrogen is generated as a product of the corrosion reaction, crack growth can occur by a hydrogen embrittlement process in much the same way as if hydrogen were in the gaseous form. A common feature of each of these processes is the subcritical crack growth in which cracks grow from existing flaws or initiation sites and grow to a size at which catastrophic failure occurs. Catastrophic failure occurs because the combination of crack length and applied stress increases the stress intensity to the fracture toughness of the material. A second common feature of stress corrosion, corrosion fatigue, and hydrogen-induced crack growth is that these mechanisms do not require the entire component to become embrittled; the effect is localized to the crack tip region.

This article is intended to familiarize the reader with the phenomenological and mechanistic aspects of stress corrosion in order to enhance the use of other discussions in this Handbook on stress-corrosion evaluation and occurrence in specific industries and environments. The phenomenological description of crack initiation and propagation describes well-established experimental evidence and observations of stress corrosion, while the discussions on mechanisms describe the physical process involved in crack initiation and propagation. The physical processes involved in crack growth have received more evaluation and are better understood than the processes responsible for crack initiation. There is some phenomenological understanding of stress-corrosion crack initiation, but the detailed mechanistic information is not well known.

Stress-corrosion cracking occurs when certain critical conditions are achieved. These conditions include electrochemical, mechanical, and metallurgical factors that must exist simultaneously. A change in any one of these three factors is adequate for eliminating SCC; therefore, a clear knowledge of these critical factors is important in system design. The important electrochemical parameters include oxidizing potential, pH, impurity concentration, and temperature. The important mechanical parameters include stress, stress intensity, and strain rate. The important metallurgical factors include localized micro-chemistry (such as the depletion of passive

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

film forming elements or the enrichment of active corroding elements), bulk composition, deformation character, and yield strength.

There are a number of plausible mechanisms or physical processes that account for SCC. No single mechanism is adequate to describe stress corrosion in the variety of materials in which it has been observed. Stress-corrosion crack propagation mechanisms can be subdivided into dissolution and mechanical fracture models, with the mechanical fracture models further divided into ductile and brittle crack extension processes. Dissolution models include film-rupture and active-path processes, while ductile mechanical models include corrosion tunneling and adsorption-enhanced plasticity models. Brittle mechanical models include the tarnish rupture and film- induced cleavage models.

Hydrogen Damage

Bruce Craig, MetCorr

Introduction

HYDROGEN DAMAGE is a form of environmentally assisted failure that results most often from the combined action of hydrogen and residual or applied tensile stress. Hydrogen damage to specific alloys or groups of alloys manifests itself in many ways, such as cracking, blistering, hydride formation, and loss in tensile ductility. For many years, these failures have been collectively termed hydrogen embrittlement; this term persists even though it is improperly used to describe a multitude of failure modes involving hydrogen, several of which do not demonstrate the classical features of embrittlement (that is, reduced load-carrying capability or fracture below the yield strength). This section classifies the various forms of hydrogen damage, summarizes the various theories that seek to explain hydrogen damage, and reviews hydrogen degradation in specific ferrous and nonferrous alloys. Information on the effect of hydrogen on fracture characteristics is available in the article "Modes of Fracture" in *Fractography*, Volume 12 of *ASM Handbook*, formerly *Metals Handbook*, 9th ed.

Hydrogen Damage

Bruce Craig, MetCorr

Classification of Hydrogen Processes

The specific types of hydrogen damage have been categorized in order to enhance the understanding of the factors that affect this behavior in alloys and to provide a basis for development and analysis of theories regarding different hydrogen damage mechanisms (Ref 1). Table 1 presents one of these classifications schemes, describing the materials that are susceptible to the various forms of damage, the source of hydrogen, typical conditions for the occurrence of failure, and the initiation site. The mechanism for each of these failure modes is also described briefly. The first three classes are grouped together and designated hydrogen embrittlement because these are the failure modes that typically exemplify classical hydrogen embrittlement.

Hydrogen environment embrittlement occurs during the plastic deformation of alloys in contact with hydrogen-bearing gases or a corrosion reaction and is therefore strain-rate dependent. The degradation of the mechanical properties of ferritic steels, nickel-base alloys, titanium alloys, and metastable austenitic stainless steels is greatest when the strain rate is low and the hydrogen pressure and purity are high.

Hydrogen stress cracking, also referred to as hydrogen-induced cracking or static fatigue, is characterized by the brittle fracture of a normally ductile alloy under sustained load in the presence of hydrogen. Most often, fracture occurs at sustained loads below the yield strength of the material. This cracking mechanism depends on the hydrogen fugacity, strength level of the material, heat treatment/microstructure, applied stress, and temperature. For many steels, a threshold stress exists below which hydrogen stress cracking does not occur. This threshold is a function of the strength level of the steel and the specific hydrogen-bearing environment. Therefore, threshold stress or stress intensity for hydrogen stress cracking is not considered a material property. Generally, the threshold stress decreases as the yield strength and tensile strength of an alloy increase. Hydrogen stress cracking is associated with absorption of hydrogen and a delayed time to failure (incubation time), during which hydrogen diffuses into regions of high triaxial stress. Hydrogen stress cracking may promote one mode of fracture in an alloy rather than another form normally observed in benign environments. Thus, all modes of cracking have been observed in most commercial alloy systems; however, hydrogen stress cracking usually produces sharp, singular cracks in contrast to the extensive branching observed for stress-corrosion cracking (SCC). The catastrophic cracking of steels in hydrogen sulfide (H_2S) environments, referred to as sulfide stress cracking, is a special case of hydrogen stress cracking.

Loss in tensile ductility was one of the earliest recognized forms of hydrogen damage. Significant decreases in elongation and reduction in area are observed for steels, stainless steels, nickel-base alloys, aluminum alloys, and titanium alloys exposed to hydrogen. This mode of failure is most often observed in lower-strength alloys, and the extent of loss in tensile ductility is a function of hydrogen content of the material. Loss in tensile ductility behavior is strain-rate sensitive and becomes more pronounced as the strain-rate decreases.

Hydrogen attack is a high-temperature form of hydrogen damage that occurs in carbon and low-alloy steels exposed to high-pressure hydrogen at high temperatures for extended time. Hydrogen enters the steel and reacts with carbon either in solution or as carbides to form methane gas; this may result in the formation of cracks and fissures or may simply decarburize the steel, resulting in a loss in strength of the alloy. This form of damage is temperature dependent, with a threshold temperature of approximately 200 °C (400 °F).

Blistering occurs predominantly in low- strength alloys when atomic hydrogen diffuses to internal defects, such as laminations or nonmetallic inclusions, and then precipitates as molecular hydrogen (H_2). The pressure of molecular hydrogen can attain such high values that localized plastic deformation of the alloy occurs, forming a blister that often ruptures. Blisters are frequently found in low-strength steels that have been exposed to aggressive corrosive environments (such as H_2S) or cleaned by pickling.

Shatter cracks, flakes, and fisheyes are features common to hydrogen damage in forgings, weldments, and castings. They are attributed to hydrogen pickup during melting operations when the melt has a higher solubility for hydrogen than the solid alloy. During cooling from the melt, hydrogen diffuses to and precipitates in voids and discontinuities, producing the features that result from the decreased solubility of hydrogen in the solid metal. In many aspects, these features are comparable to blistering, and this could be considered a special case of that class.

Microperforation by high-pressure hydrogen occurs at extremely high pressures of hydrogen near room temperature. Microperforation occurs predominately in steels. This form of hydrogen damage manifests itself as a network of small fissures that allows permeation of the alloy by gases and liquids.

Degradation in flow properties in hydrogen environments has been found at ambient temperatures for iron and steel and at elevated temperature for several alloy systems. The steady- state creep rate under constant load has been observed to increase in the presence of hydrogen for some nickel-base alloys.

Hydride formation produces embrittlement in magnesium, tantalum, niobium, vanadium, uranium, thorium, zirconium, titanium, and their alloys, as well as many other less common metals and alloys. The degradation of mechanical properties and the cracking of these metals and their alloys are attributable to the precipitation of metal hydride phases. Hydrogen pickup often results from welding, heat treating, charging from corrosion processes, or during melting of the alloy. Hydride formation is enhanced for some metal-hydrogen systems by the application of stress—the so-called stress-induced hydride formation. Alloy systems that form hydrides are generally ductile at high, >300 K (80 °F), and low, <100 K(-280 °F), temperatures at which they fracture by ductile rupture. This temperature dependence is comparable to that observed for the hydrogen embrittlement of

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

ferrous and nickel alloys. Some of these alloys are also susceptible to failure in hydrogen by mechanisms other than hydriding. Some evidence exists that nickel and aluminum alloys may also form a highly unstable hydride that could contribute to hydrogen damage of these alloys; however, this possibility has not been confirmed.

Hydrogen Damage

Bruce Craig, MetCorr

Theories for Hydrogen Damage

As may be appreciated from the numerous classes of hydrogen damage, there are many explanations or theories for these various forms of degradation. The preeminent theories for hydrogen damage are based on pressure, surface adsorption, decohesion, enhanced plastic flow, hydrogen attack, and hydride formation. Although many other theories have been presented, most are variations on these basic models.

The pressure theory of hydrogen damage, or more specifically, hydrogen embrittlement, is one of the oldest models for hydrogen damage (Ref 2). This theory attributes hydrogen embrittlement to the diffusion of atomic hydrogen into the metal and its eventual accumulation at voids or other internal surfaces in the alloy, where it combines to form molecular hydrogen. As the concentration of hydrogen increases at these microstructural discontinuities, a high internal pressure is created that enhances void growth or initiates cracking. This model, although apparently reasonable for blistering and possibly appropriate for some aspects of loss in tensile ductility, does not explain many of the factors observed for classes of failure such as hydrogen stress cracking. However, it is a well-recognized phenomenon that charging hydrogen into steel or nickel alloys at high fugacity, either with high- pressure hydrogen gas or under extreme electrochemical charging, can create a significant density of voids and irreversible damage to the alloy consistent with a pressure-dependent model.

The surface adsorption theory suggests that hydrogen adsorbs on the free surfaces created adjacent to the crack tip, decreasing the surface free energy and thus the work of fracture (Ref 3). Reduction in the work of fracture would thus enhance crack propagation at stress levels below those typically experienced for a particular alloy in a benign environment. There are many arguments against this model. The principal criticism is that it greatly underestimates the work of fracture and does not account for the discontinuous crack growth that has been observed for hydrogen cracking.

Decohesion describes the effect of hydrogen on the cohesive force between atoms of the alloy matrix (Ref 4, 5, 6). Sufficiently high hydrogen concentrations that accumulate ahead of a crack tip are assumed to lower the maximum cohesive force between metal atoms such that the local maximum tensile stress perpendicular to the plane of the crack then becomes equivalent to or greater than the lattice cohesive force, and fracture results.

Enhanced plastic flow and instability are associated with hydrogen dislocation interactions and are primarily based on fractographic observations (Ref 7). This approach proposes that atomic hydrogen enhances dislocation motion (generally, screw dislocations) and the creation of dislocations at surfaces and/or crack tips, leading to softening of the material on a localized scale. Although this behavior has been observed in certain steels, hardening by hydrogen has also been found. Careful high-resolution electron microscopy of what appears to be brittle cleavage or intergranular fracture surfaces has revealed evidence of crack tip plasticity in support of this mechanism. Recently, it was proposed (Ref 8) that hydrogen may enhance plastic instability in the form of shear localization. Moreover, the coupling of shear-band propagation with the formation of microvoids at

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

second- phase particles that are intersected by these shear bands can produce significant reduction in the fracture toughness of an alloy, especially under mixed-mode loading.

Hydride formation is the degradation of Group Vb metals (niobium, vanadium, and tantalum) and zirconium, titanium, and magnesium in hydrogen environments by the formation of a brittle metal hydride at the crack tip. When sufficient hydrogen is available in the alloy, a metal hydride precipitates. Cracking of the hydride occurs, followed by crack arrest in the more ductile matrix or continued crack growth between hydrides by ductile rupture. Because hydride formation is enhanced by the application of stress, the stress field ahead of the crack tip may induce precipitation of additional hydrides that cleave. Thus, in some alloys, brittle crack propagation occurs by repeated precipitation of hydrides ahead of the crack tip, cleavage of these hydrides, precipitation of new hydrides, and so on until fracture is complete (Ref 9).

Hydrogen attack is one of the better understood mechanisms of hydrogen damage but is specific to a single class of damage by hydrogen at high temperature (Ref 10). Hydrogen attack may take two forms of damage: surface decarburization or internal decarburization. However, the mechanism is the same for both forms. At elevated temperatures, hydrogen diffuses into the steel or reacts at the surface with carbon in solid solution or that which has dissociated from carbides to form a hydrocarbon—typically methane. This chemical reaction is easily described thermodynamically, which sets this form of damage apart for the more complex forms of hydrogen damage. As expected, damage is dependent on temperature and hydrogen partial pressure. Surface decarburization occurs at temperatures above 540 °C (1000 °F) and internal decarburization at temperatures from 200 °C (400 °F) upward.

Hydrogen Trapping. Although numerous models exist, none adequately explains the behavior exhibited by alloys in different hydrogen-bearing systems. Until a universal theory is developed, one must rely on the phenomenological behavior between the more prominent alloy systems to understand hydrogen damage. One of the principal factors that determines the hydrogen damage susceptibility of ferrous alloys is a phenomenon referred to as trapping (Ref 11). Diffusion studies of iron and steels have shown an initial retardation in diffusion rate or lag time for hydrogen diffusion through these alloys before a steady-state diffusivity compatible with that expected theoretically is achieved. This lag time is generally considered to be related to the filling of traps by hydrogen. In fact, the apparent diffusivity of hydrogen in steels shows a precipitous decrease with increasing concentration of particles (traps), as shown in Fig. 1.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

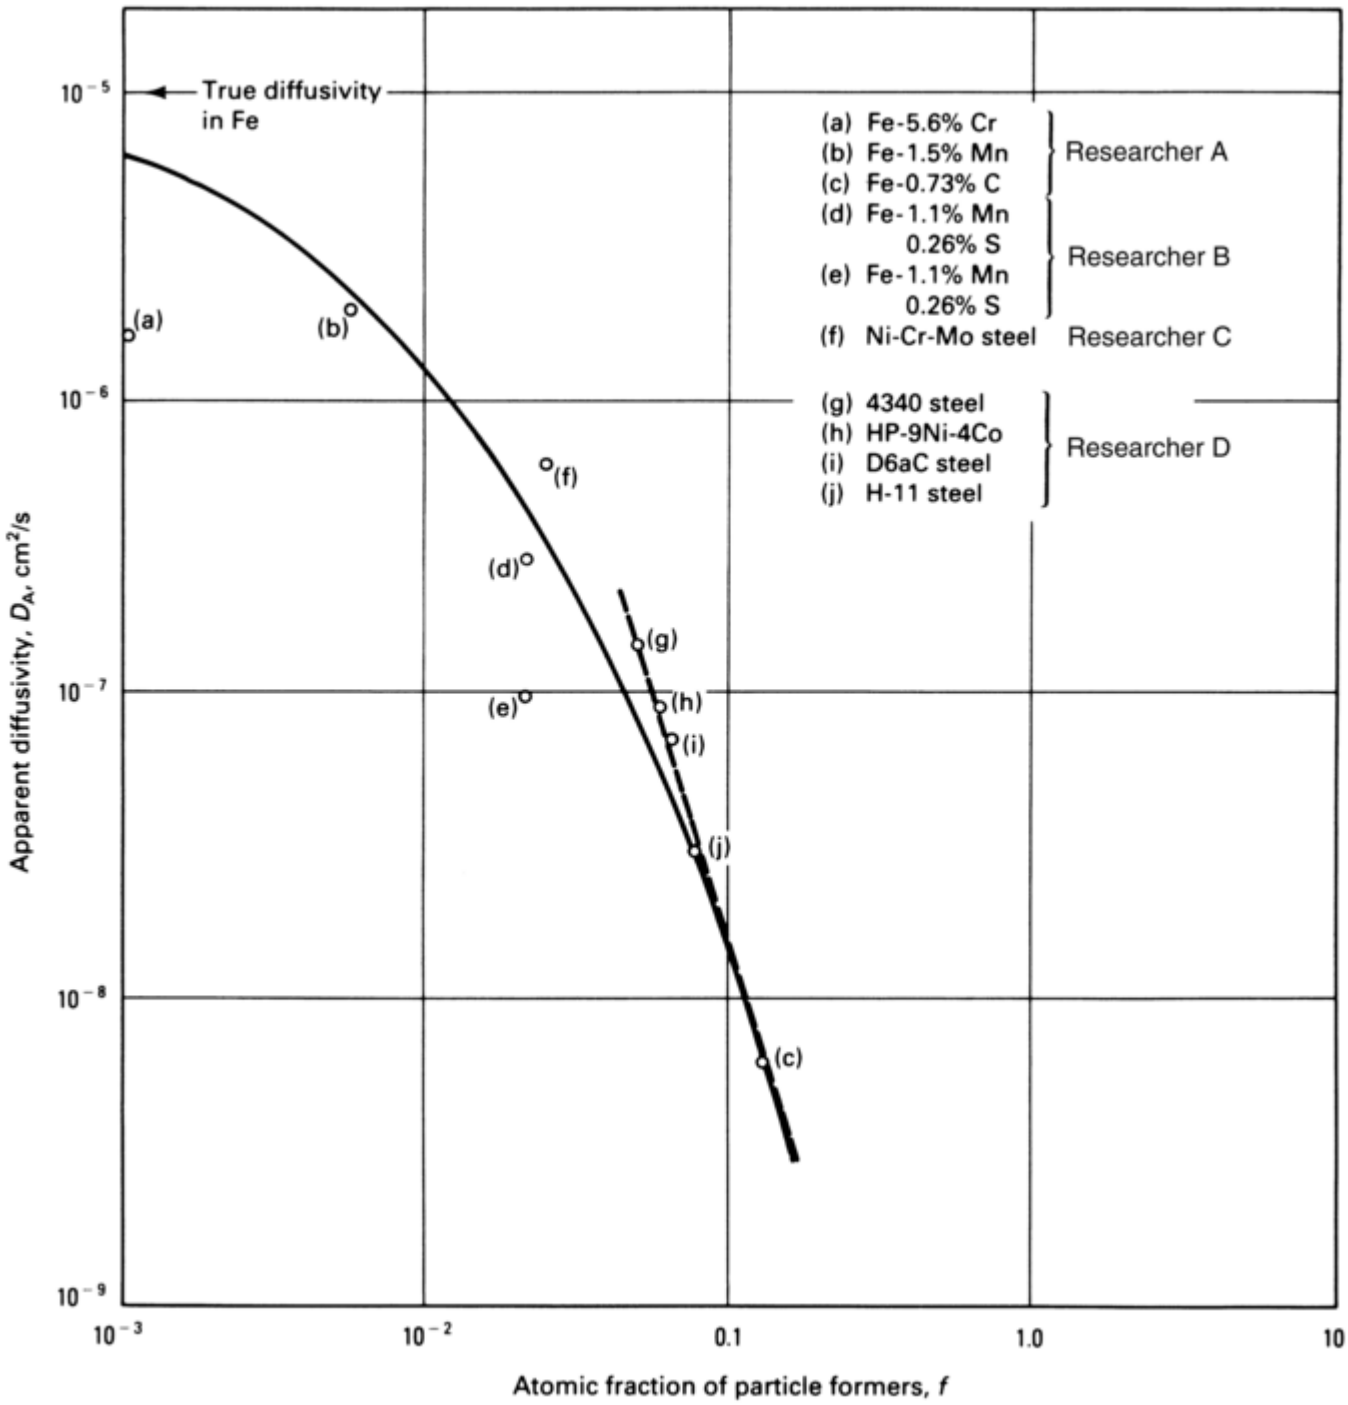

Fig. 1 Decrease in apparent hydrogen diffusivity with increased fraction of precipitate particles. Source: Ref 12

Hydrogen trapping may be considered the binding of hydrogen atoms to impurities, structural defects, or microstructural constituents in the alloy. Binding may be attributed to local electric fields and stress fields, temperature gradients, chemical potential gradients, or physical trapping. These hydrogen traps may be mobile (dislocations, stacking faults) or stationary (grain boundaries, carbide particles, individual solute atoms). They may also be reversible or irreversible traps. Short-duration trapping of hydrogen in which the occupancy time is limited is referred to as reversible. A long residency time for hydrogen characterized by a high binding energy is termed irreversible trapping. Table 2 presents a classification of hydrogen traps in steel. The concept and investigation of trapping have been developed primarily for steels; however, trapping may not be restricted to this system. Face- centered cubic (fcc) alloys show a similar trapping behavior, although at a somewhat reduced efficiency for trapping compared to steels.

Hydrogen Damage in Iron-Base Alloys

Pure Irons. Hydrogen damage may occur in relatively pure irons, such as Ferrovac E and other magnetically soft irons, producing either transgranular or intergranular fracture, depending on the heat treatment and the presence of impurities and solutes (carbon, oxygen, and nitrogen) at the grain boundaries. Hydrogen can also lower the yield strength and flow stress of high-purity iron at approximately room temperature or lead to hardening. Although the yield strength is reduced for impure iron, the flow stress may be increased under conditions of low hydrogen fugacity.

Ferrous Alloys. Many factors affect the behavior of ferrous alloys in hydrogen-bearing environments. Hydrogen concentration, temperature, heat treatment/microstructure, stress level (applied and yield stress), solution composition, and environment are the primary factors involved in determining susceptibility to hydrogen embrittlement. Figure 2 shows the effect of hydrogen concentration on the time to failure for a high-

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

strength steel. The longer the baking time, the lower the residual hydrogen in the steel matrix. In general, increasing the concentration of hydrogen in an alloy reduces time to failure and the stress level at which failure occurs.

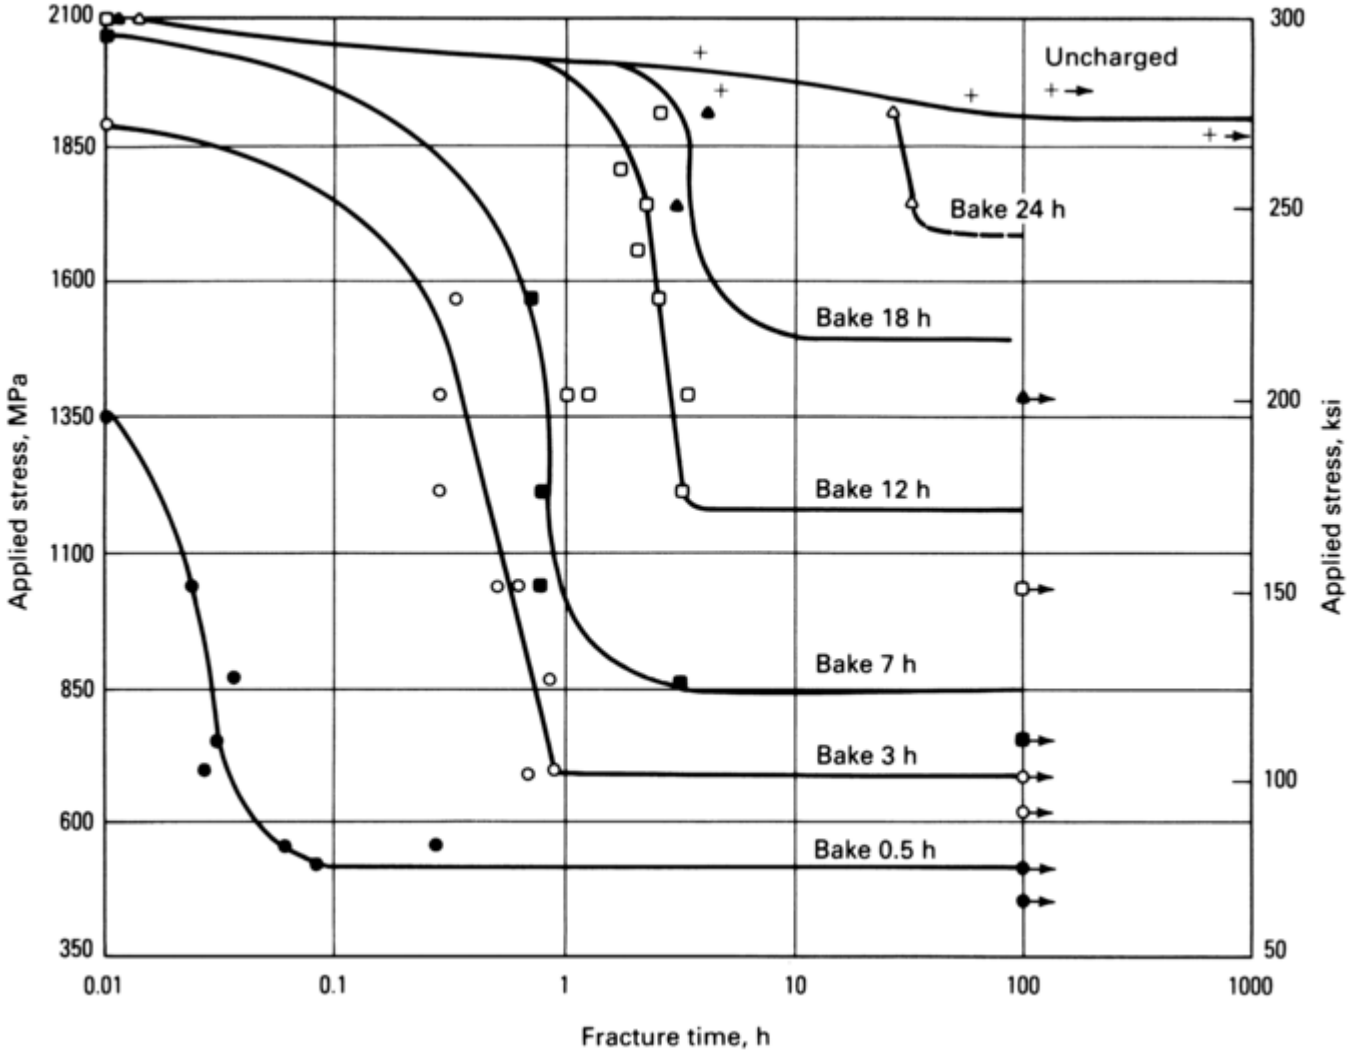

Fig. 2 Static fatigue curves for various hydrogen concentrations obtained by different baking times at 150 °C (300 °F). Sharp-notch high-strength steel specimens 1590 MPa (230 ksi); normal notch strength: 2070 MPa (300 ksi). Source: Ref 4

Hydrogen concentration in the alloy is a function of the fugacity or the approximate concentration of hydrogen at the surface exposed to the environment. Therefore, hydrogen embrittlement is controlled by the hydrogen gas pressure or pH of the environment as well as constituents within the environment that may accelerate or inhibit the entry of hydrogen into the alloy. Elements such as sulfur, phosphorus, antimony, tin, and arsenic and their compounds have been found to inhibit the hydrogen recombination reaction in aqueous solutions, thus increasing the charging of atomic hydrogen into the alloy. In contrast, small amounts of oxygen in gaseous hydrogen environments have demonstrated an inhibitive effect on crack growth of high- strength steels subject to hydrogen cracking.

Figure 3 shows the dependence of both the threshold stress intensity and the crack growth rate of high-strength American Iron and Steel Institute (AISI) 4130 (Unified Numbering System, or UNS, G41300) steel on hydrogen pressure. Increasing the hydrogen pressure reduces the threshold stress intensity for crack initiation and increases the crack growth rate for a specific stress-intensity value.

مرجع مهندسی مواد و متالورژی

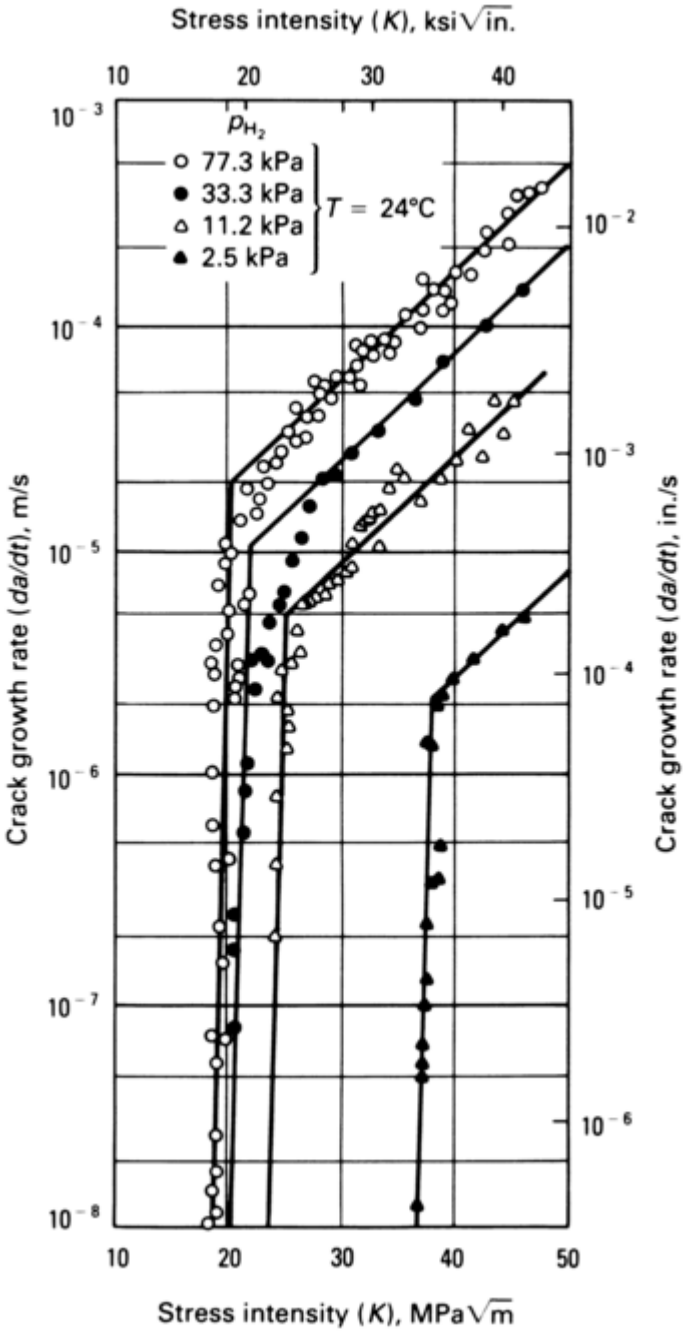

Fig. 3 The stress-intensity *K* dependence of crack growth rate da/dt at various hydrogen pressures at 24 °C (75 °F) for AISI 4340 steel. Source: Ref 14

Temperature also plays an important role in the hydrogen embrittlement of ferrous alloys. Embrittlement is most severe near room temperature (Ref 15) and becomes less severe or nonexistent at higher or lower temperatures (Fig. 4). At lower temperatures, the diffusivity of hydrogen is too sluggish to fill sufficient traps, but at high temperatures, hydrogen mobility is enhanced, and trapping is diminished. As can be seen in Fig. 4, embrittlement is also strongly strain-rate dependent. At high strain rates, fracture may proceed without the assistance of hydrogen, because the mobility of hydrogen is not sufficient to maintain a hydrogen atmosphere around moving dislocations.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

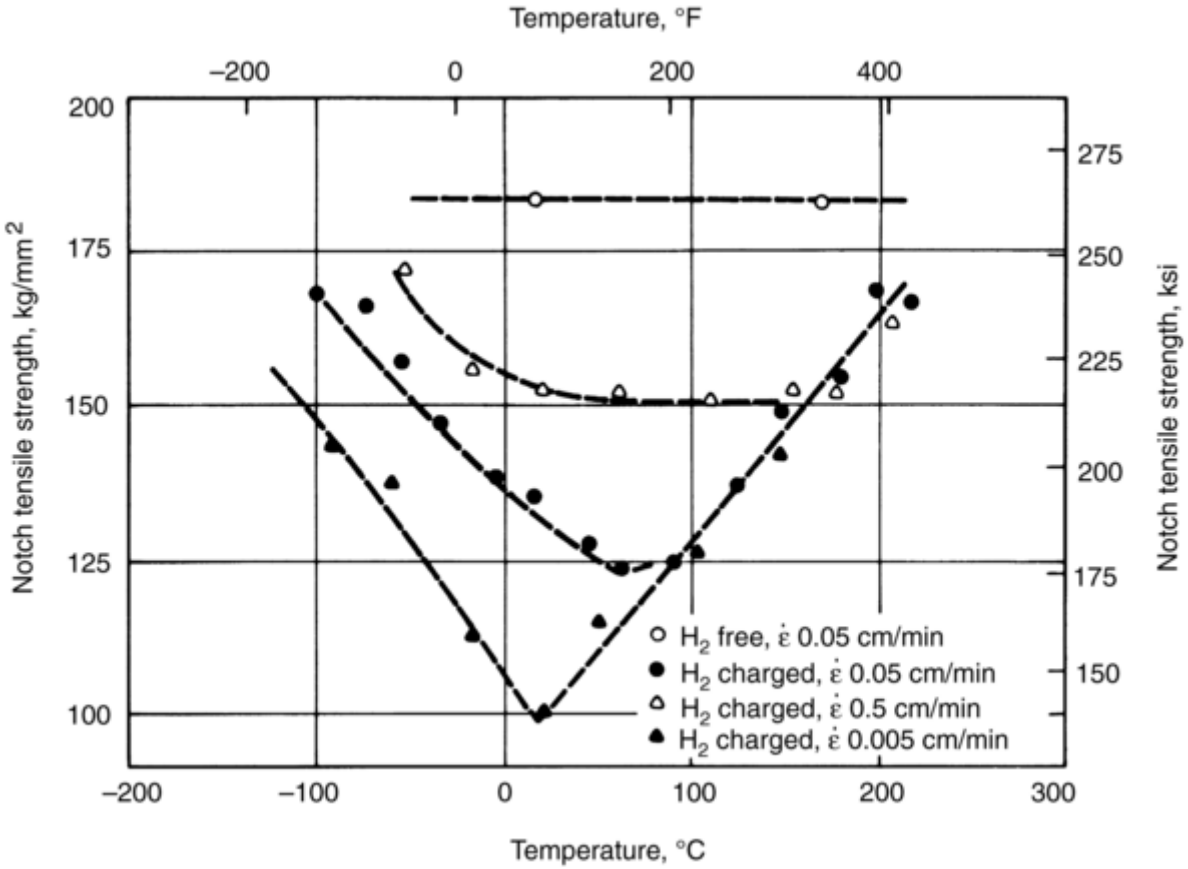

Fig. 4 Notch tensile strength of high-strength steel plotted against testing temperature for three strain rates (crosshead speeds, $\dot{\epsilon}$). Source: Ref 15

Figure 5 shows threshold stress intensity as a function of yield strength for a large number of steels in a variety of hydrogen-containing environments. It can be seen that the threshold stress intensity for crack growth generally decreases with increasing yield strength, regardless of environment, and that very high-strength steels are not usable in hydrogen environments. Threshold stress intensities and crack growth rates are a function of the specific hydrogen environments, with H_2S being one of the most severe environments (Fig. 6). At lower yield strengths, the mechanism for hydrogen-assisted failure apparently changes, and blistering becomes the more common feature of failure. The threshold stress intensities for high-strength steels subjected to hydrogen environments are significantly less than those thresholds measured under benign conditions. These lower thresholds lead to subcritical crack growth when compared to critical values expected from fracture mechanics. Therefore, it is common to designate these thresholds as K_{ISCC} or K_{IH}.

مرجع مهندسی مواد و متالورژی

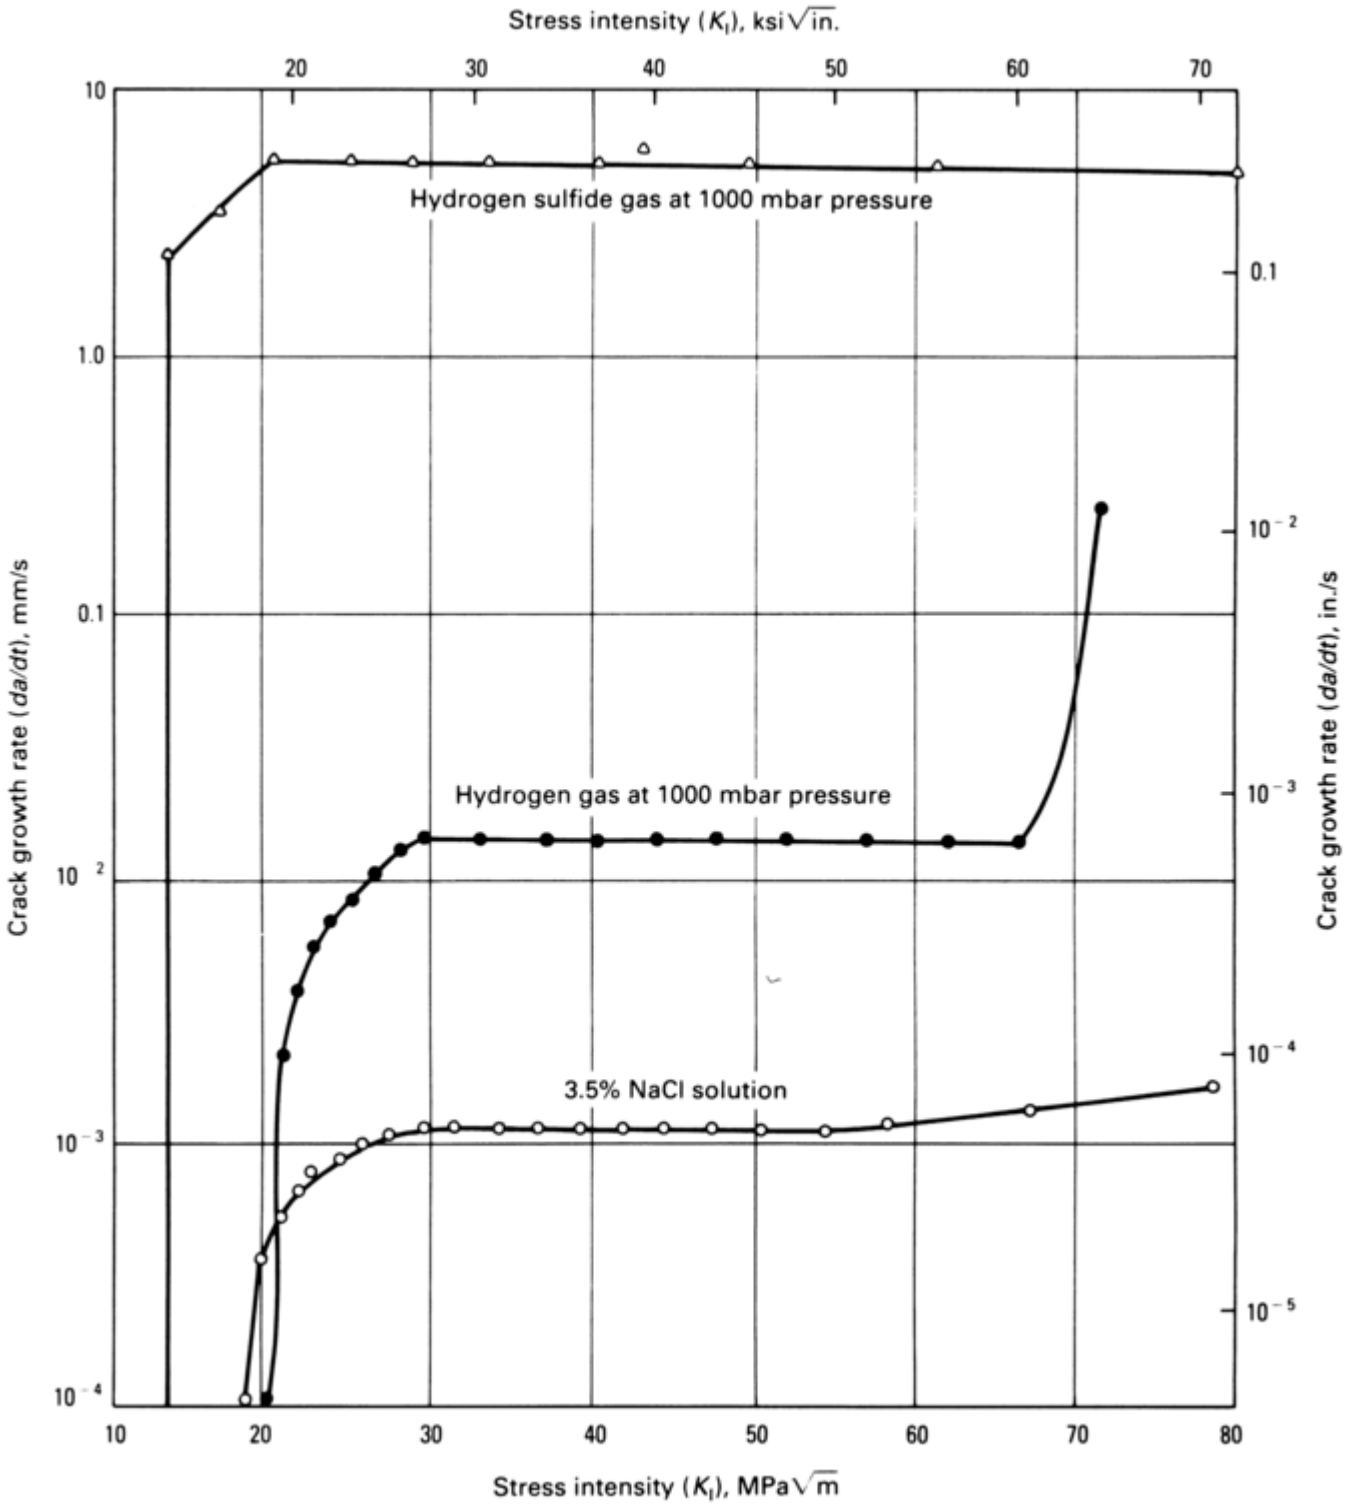

Fig. 6 Crack velocity as a function of stress intensity for a chromium-molybdenum-vanadium steel at 291 K (18 °C, or 64 °F). Source: Ref 17

In low-strength steels, 700 MPa (100 ksi) yield strength or less, hydrogen damage occurs predominately by loss in tensile ductility or blistering. For loss in tensile ductility, hydrogen promotes the formation and/or growth of voids by enhancing the decohesion of the matrix at carbide particle and inclusion interfaces.

At higher hydrogen fugacities and often in the absence of stress, blistering or a form of cracking also associated with inclusions—referred to as stepwise cracking, blister cracking, or hydrogen- induced cracking (HIC)—can occur. Stepwise cracking has been observed frequently in low- strength steels subjected to H_2S-containing environments in the absence of stress (Fig. 7). This type of cracking is not dependent on steel strength but is strictly a function of steel chemistry, processing, and the severity of the hydrogen environment (Ref 18). In H_2S environments, a cracking morphology has been observed in low-strength steels that combines the features of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

hydrogen stress cracking and HIC and has been designated stress-oriented hydrogen-induced cracking (SOHIC) (Ref 19). It is unfortunate that too often when investigators observe a new morphology of cracking, they establish a new name for the cracking regardless whether this is justified mechanistically. The result is that the literature is cluttered with many names for the same phenomenon.

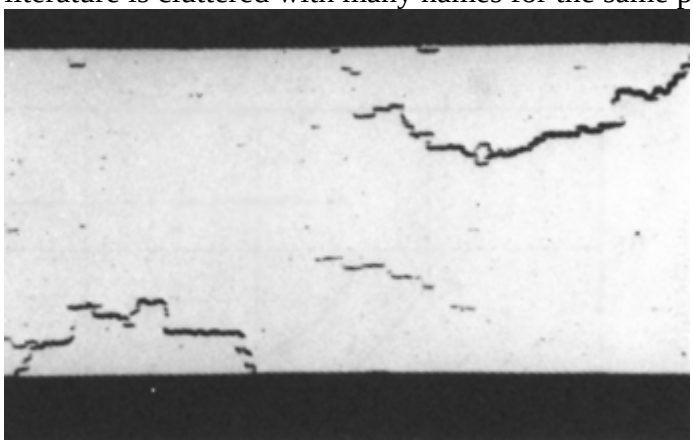

Fig. 7 Stepwise cracking of a low-strength pipeline steel exposed to H_2S. 6×

Fracture of low-strength steels in hydrogen environments may be characterized by ductile dimple rupture, tearing, cleavage, quasi-cleavage, and, less frequently under certain conditions, intergranular cracking. The article “Modes of Fracture” in *Fractography,* Volume 12 of *ASM Handbook,* formerly *Metals Handbook,* 9th ed., contains fractographs illustrating the effects of hydrogen on the fracture appearance of steels.

High-strength steels, those with yield strengths above 700 MPa (100 ksi), are prone to fracture either in an intergranular fashion or by quasi-cleavage, depending on the stress intensity. These steels commonly display an incubation time before fracture initiates under sustained loading, usually in association with regions of high triaxial stress. Because triaxial stresses are created at notch roots or under plane strain, fracture initiates internally in the steel. Intergranular fracture is promoted by the presence of impurity elements at prior-austenite or -ferrite grain boundaries. Elements such as phosphorus, sulfur, tin, antimony, and arsenic have been found to enhance the intergranular fracture of high- strength steels in hydrogen, and as expected, temper-embrittled steels are even more susceptible to hydrogen stress cracking than steels that are not embrittled.

Metallurgical structure can have a profound effect on the resistance of steels to hydrogen embrittlement. When compared at equivalent strength levels, a quenched-and-tempered fine- grain microstructure is more resistant to cracking than a normalized or bainitic steel. However, this is also dependent to a large extent on the strength level at which this comparison is made. In general, the most resistant microstructure is a highly tempered martensitic structure with equiaxed ferrite grains and spheroidized carbides evenly distributed throughout the matrix. Because microstructure is dependent on heat treatment and composition, these factors are not easily separated and must be considered together. There is also a grain size effect that produces enhanced resistance to hydrogen with decreasing prior- austenite grain size (Fig. 8). However, if the grain size is significantly larger than the plastic zone size, the reverse may be true.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

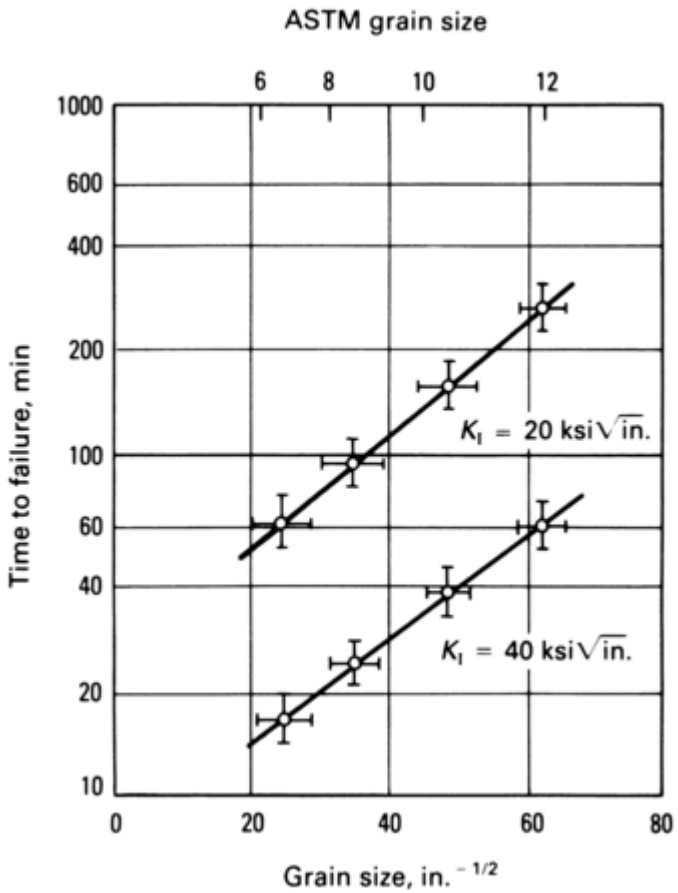

Fig. 8 Illustration of how a refinement in grain size improves resistance to hydrogen failure as measured by the time to failure of two strengths of AISI 4340 steels. Source: Ref 20

The role of alloying elements is quite complex and not easily distinguished from the effects of heat treatment, microstructure, and strength level. Depending on the microstructure and strength level, a specific alloying element may or may not contribute to the hydrogen embrittlement resistance of an alloy or may even increase susceptibility to cracking. The concentration of the alloying element is also a factor in the behavior of alloys in hydrogen. Molybdenum, for example, is beneficial in reducing susceptibility to sulfide stress cracking, a form of hydrogen stress cracking, in AISI 4130 steels up to approximately 0.75 wt%. However, beyond this concentration, a separate Mo_2C phase precipitates in the alloy after tempering at above 500 °C (930 °F), significantly reducing resistance to sulfide stress cracking.

In general, elements such as carbon, phosphorus, sulfur, manganese, and chromium impart greater susceptibility to hydrogen embrittlement in low-alloy steels. However, large increases in such elements as chromium, nickel, and molybdenum in order to produce stainless steels alter the crystal structure, microstructure, and subsequently the heat treatment requirements and therefore the hydrogen embrittlement behavior of this group of ferrous alloys.

Stainless Steels The response of stainless steels to hydrogen-bearing environments is basically related to their strength level. Ferritic stainless steels have excellent resistance to hydrogen embrittlement because of their low strength and enhanced ductility. However, if the ferritic stainless steels are cold worked, they may become susceptible to cracking in hydrogen environments. Similarly, austenitic stainless steels are highly resistant to hydrogen cracking in the annealed or lightly cold-worked condition but can become quite susceptible when heavily cold worked. This increased susceptibility to hydrogen cracking due to increasing yield strength from cold working is similar to the dependence of carbon and low-alloy steel on strength. Decreased resistance to hydrogen for highly cold- worked austenitic stainless steels is largely attributed to the deformation-induced formation of martensite. For those austenitic stainless steels having a very stable austenite phase and high yield strength, such as 21Cr-6Ni-9Mn (UNS S21900), susceptibility is considered to be solely a function of yield strength, similar to the body- centered cubic (bcc) low-alloy steel behavior.

Other factors that may affect the susceptibility of austenitic stainless steels to hydrogen damage are the possible formation of metastable hydride phase that would produce a hydride-based fracture path and the interaction of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

hydrogen with stacking faults to reduce stacking fault energy in the austenite, leading to planar slip and brittle fracture. The degree of participation of any of these factors has not been established.

Just as a similarity exists between austenitic stainless steels and low-alloy steels at the high- strength end of the spectrum, the lower-strength austenitics behave in the same manner as the low-alloy steels in hydrogen by a reduction in ductility. Figure 9 shows the loss in reduction in area for several austenitic stainless steels in high-pressure hydrogen. It is apparent that a wide variation in hydrogen damage exists between these various austenitic alloys. Type 304L (UNS S30403) is the most susceptible to loss in tensile ductility, and the stable austenitic alloys, such as 15Cr-25Ni (UNS S66286), are almost unaffected. As observed in carbon and low-alloy steels, there is a temperature effect (~0 °C, or 32 °F) involved with the ductility loss in austenitic stainless steels, although it is somewhat lower than the room-temperature dependence observed for low-alloy steels.

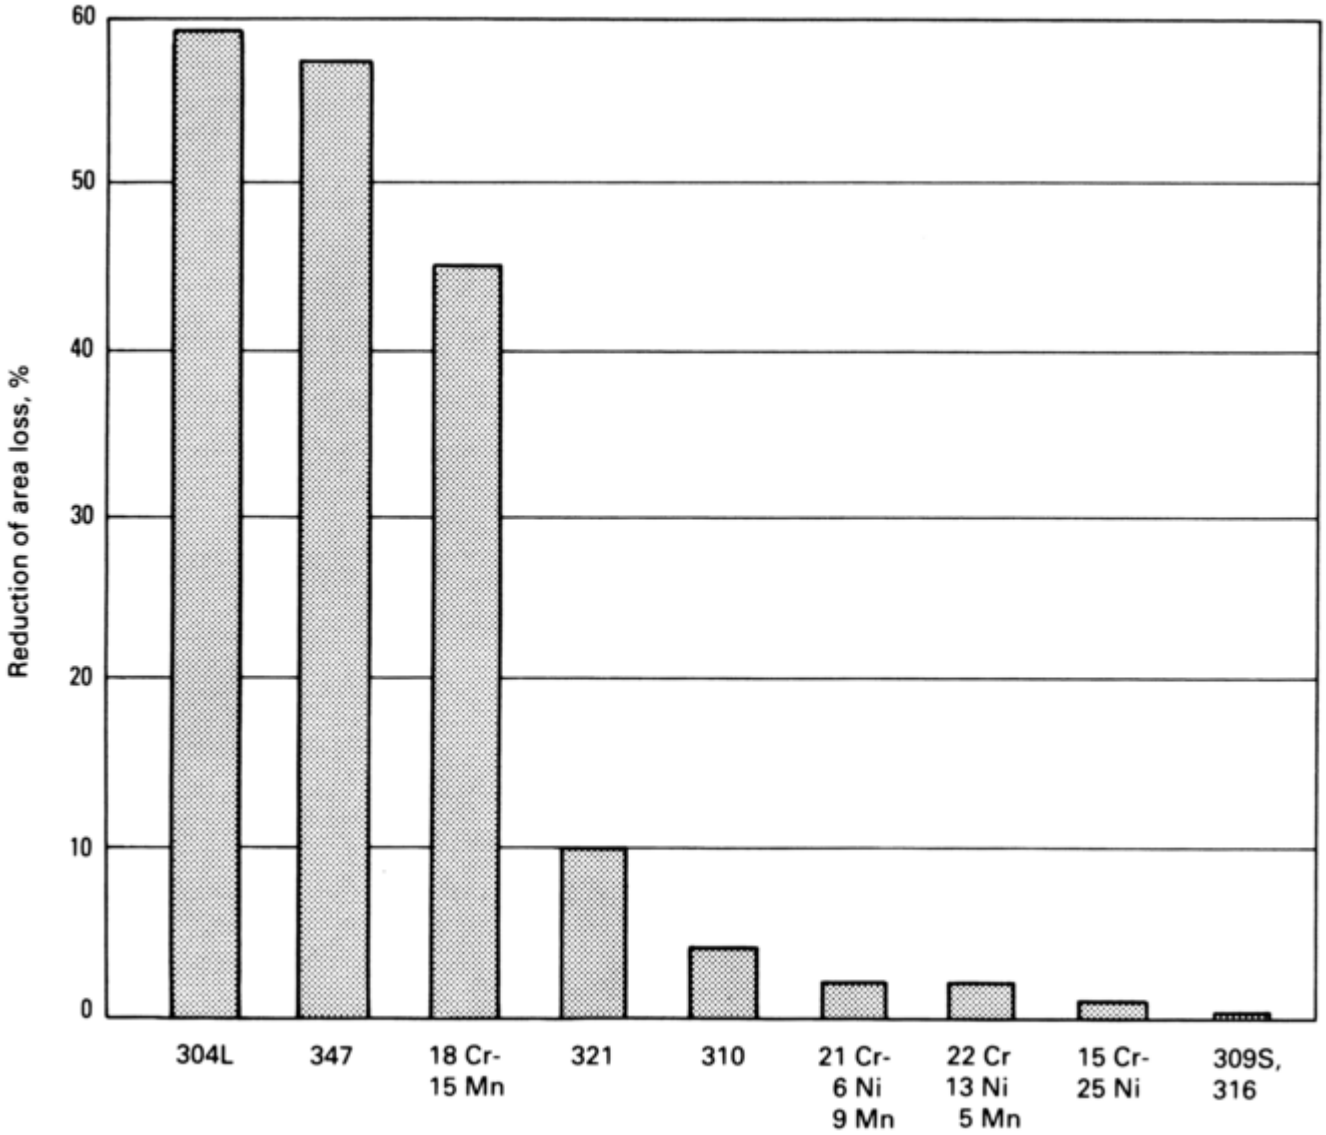

Fig. 9 Ductility loss for several austenitic stainless steels in high-pressure hydrogen. Source: Ref 21

Duplex stainless steels represent an interesting type of behavior in hydrogen as a result of their two-phase structure of ferrite and austenite. Because the solubilities and diffusivities of hydrogen are quite different between the austenite and ferrite phases, the response of the overall duplex alloy is significantly different than either a ferritic or austenitic stainless steel. Reference 22 compiles much of the data in the literature regarding the measured hydrogen diffusion coefficient in duplex stainless steels, as shown in Fig. 10. As could be expected, there is a large degree of scatter in these data as a result of factors such as the relative ferrite-to-austenite ratio, the grain- boundary areas, the volume fraction of precipitates, and so on.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

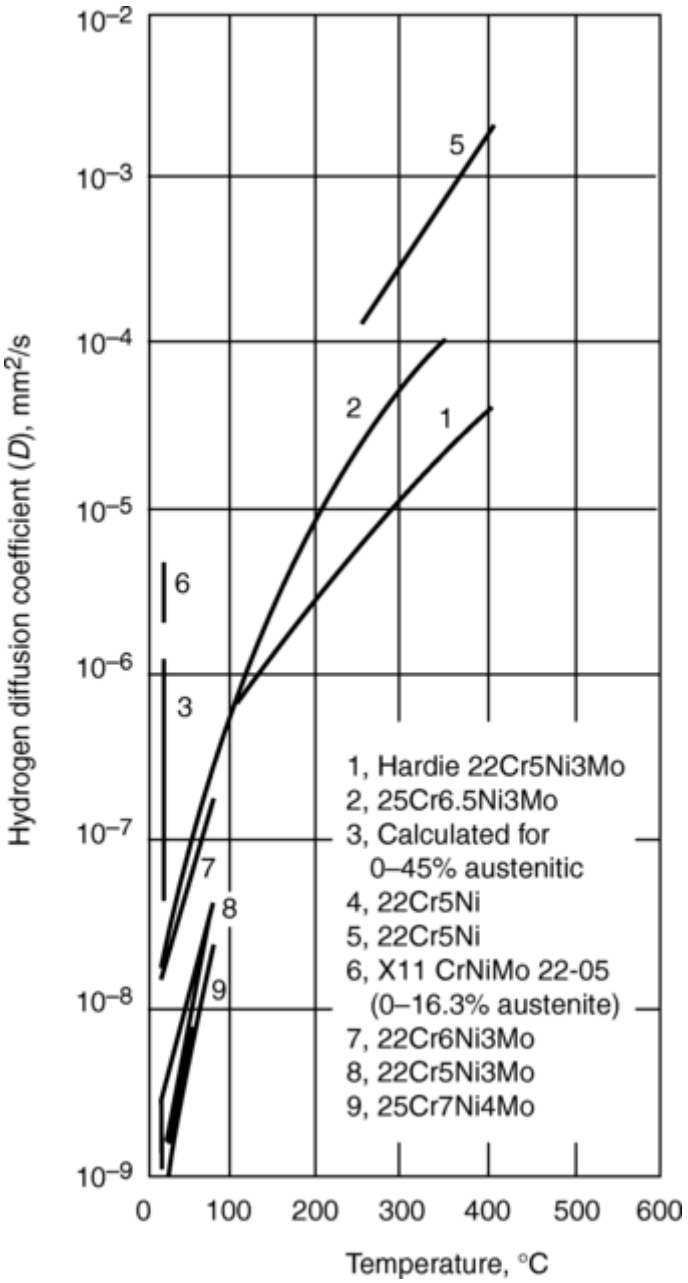

Fig. 10 Published values of hydrogen diffusion coefficients in duplex stainless steels. Data sources are identified in Ref 22. Curves 4 and 5 are from the same source. Curves 8 and 9 are from the same source: Ref 22

A theoretical analysis for hydrogen transport in these two-phase alloys (Ref 23) showed that the effective diffusivity of hydrogen in duplex stainless steels was reduced by a factor of approximately 400 compared to a fully ferritic steel, and that trapping at the ferrite-austenite interface was the most significant factor in explaining this reduced diffusivity of hydrogen in duplex stainless steels relative to ferritic steels. The behavior of hydrogen in duplex stainless steels is very complex, because a change in the ferrite- to-austenite ratio not only alters the relative interface area but also changes the volume fraction of each phase, thereby increasing the solubility and diffusivity of hydrogen in the alloy as a whole.

It is apparent that there are many similarities in behavior between stainless steels and carbon and low-alloy steels in hydrogen. Similarly, the martensitic and precipitation-hardening stainless steels exhibit the same dependence on strength level and microstructure as observed in low-alloy steels. Martensitic and precipitation-hardening stainless steels are extremely susceptible to hydrogen embrittlement with increasing yield strength. Figure 11 compares several grades of precipitation-hardening stainless steel with type 410 martensitic stainless steel tested in an aqueous environment saturated with H_2S. The numbers adjacent to each data point represent the tempering or aging treatment. Generally, the same trend of decreasing time to failure with increasing yield strength is observed as for low- alloy steels. The poor performance of the type 410 martensitic stainless steel

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

compared to precipitation-hardening stainless steels is typical of the behavior of most martensitic stainless steels, which also compare poorly with low-alloy steels at the same strength level. Even the newer family of martensitic stainless steels, recently introduced as Super 13 Cr, have relatively poor resistance to cracking in hydrogen-bearing environments. Figure 12 shows the regions of hydrogen-assisted cracking (HAC) and those that are not (no HAC) for a steel containing approximately 15% Cr, 4% Ni, and 1.5% Mo. Note that the hydrogen-generating power of the solution, given by the combination of pH and H_2S concentration, defines the boundary of cracking (Ref 25).

مرجع مهندسی مواد و متالورژی

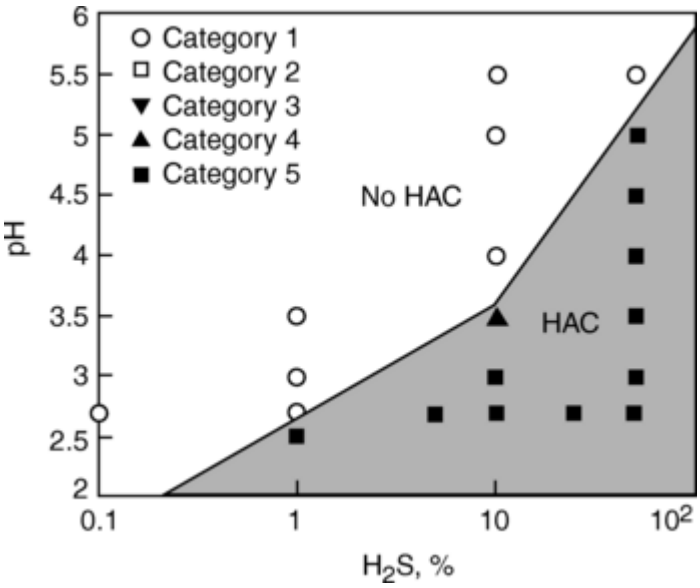

Fig. 12 The H_2S-pH tolerance of low-carbon martensitic stainless steel tested by the slow strain-rate technique. HAC, hydrogen-assisted cracking. Source: Ref 25

Ultrahigh-strength, >1400 MPa (200 ksi), martensitic stainless steels, low-alloy steels, and maraging steels are extremely susceptible to cracking in hydrogen environments, including aqueous solutions containing NaCl. Although chlorides are the primary cause of SCC in many alloy systems, it is generally accepted that the mechanism of cracking in ultrahigh-strength steels is related to hydrogen embrittlement.

Figure 13 compares the crack growth rate of AISI 4340 in several environments against grade 250 maraging steel. The maraging steel has much better resistance to crack propagation in 3.5% NaCl than 4340 and displays a high threshold stress intensity for crack propagation. For maraging steels, there is evidence that peak-aged condition or slight overaging may improve resistance to hydrogen embrittlement, but underaging is detrimental to resistance.

مرجع مهندسی مواد و متالورژی

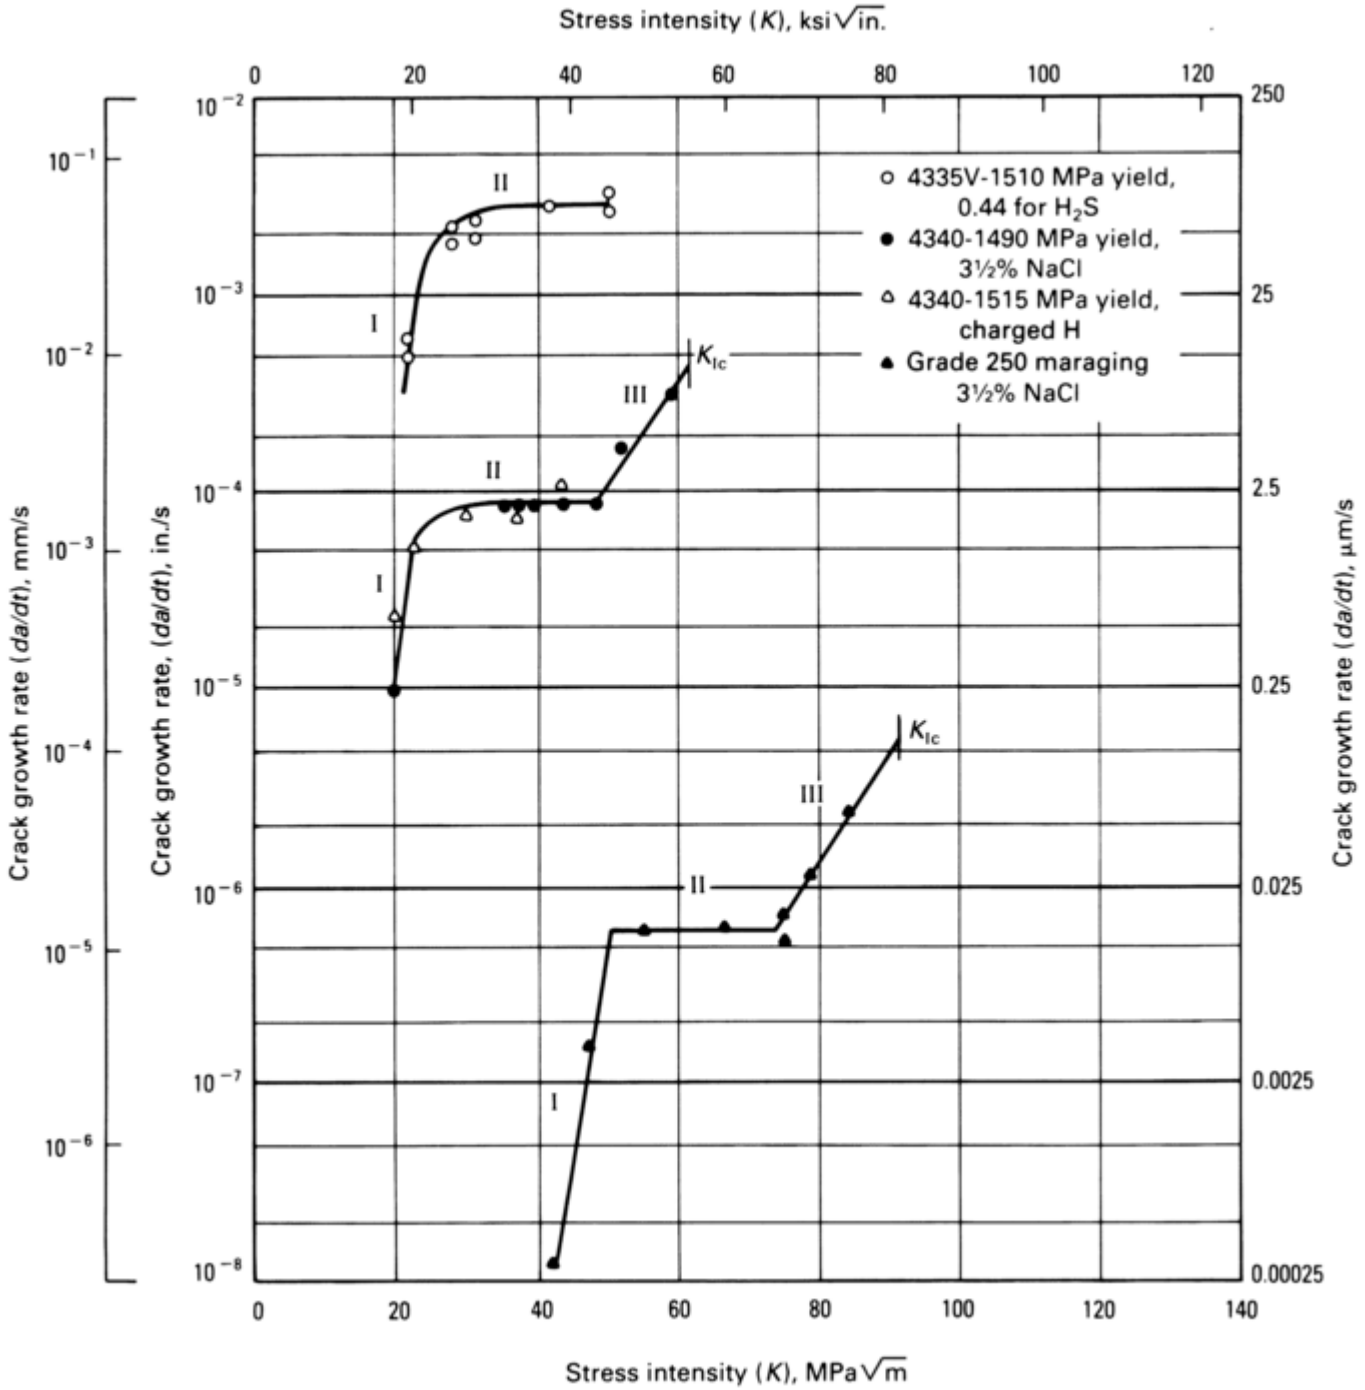

Fig. 13 Effect of material, environment, and stress-intensity level on crack growth. Source: Ref 12

Hydrogen attack is strictly a high-temperature form of hydrogen damage that primarily affects ferritic steels. Hydrogen attack is dependent on time, temperature, and hydrogen pressure. After a certain incubation time, a diminution of properties occurs with the onset of decarburization and cracking (Fig. 14). Resistance of steels to hydrogen attack is related to the stability of the carbides, and as such, the addition of carbide- stabilizing elements such as vanadium, titanium, niobium, and molybdenum enhance the resistance to this form of hydrogen damage.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Chromium-molybdenum steels have been found to be the most resistant to hydrogen attack for the cost involved; therefore, a great deal of industrial experience has been gained with these alloys. Much of this experience has been compiled and plotted to provide a guideline for steel selection as a function of temperature and hydrogen partial pressure and is presented as a series of curves often referred to as a Nelson diagram (Ref 26). As more experience is gathered on the use of these steels in hydrogen, this series of curves is periodically updated by the American Petroleum Institute.

Nickel Alloys

Nickel and its alloys are susceptible to hydrogen damage in both aqueous and gaseous hydrogen environments. The same factors that affect hydrogen embrittlement susceptibility in ferrous alloys are also prevalent in nickel alloys, although to a lesser degree. In general, fcc metals, because of their greater ease of slip and reduced solute diffusivities as compared to bcc materials, are less susceptible to hydrogen damage. As with ferrous alloys, hydrogen in nickel and its alloys may introduce intergranular, transgranular, or quasi-cleavage cracking, and although the macroscopic features appear to be brittle, on a microscopic scale there is a high degree of local plasticity, suggesting that hydrogen enhances flow at the crack tip. Figure 15 shows the reduction in ductility associated with hydrogen charging a 72Ni-28Fe alloy as a function of strain rate. Almost identical behavior was observed for unalloyed nickel.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

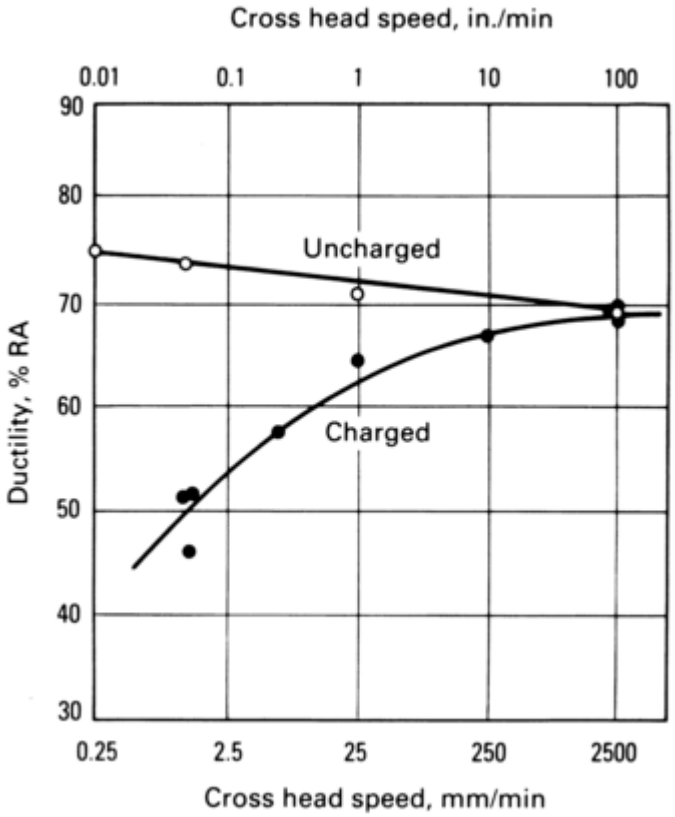

Fig. 15 Ductility at fracture as a function of strain rate in a hydrogen-charged and uncharged 72Ni-28Fe alloy. RA, reduction in area. Source: Ref 4

Alloys based on the ternary Fe-Ni-Cr system (Incoloy) and Inconel alloys show reductions in ductility when charged with hydrogen, depending on the specific thermomechanical treatments performed on the alloy. Generally, these alloys are more resistant to hydrogen stress cracking in the cold-worked and unaged condition as compared to the cold-worked and aged condition. Age-hardenable alloys show the least resistance to hydrogen when aged to their peak or near- peak strength. Stabilization treatments followed by aging reduce the resistance of these alloys as compared to direct aging. Increased cold work also produces a loss in tensile ductility. Hydrogen stress cracking of these alloys may also occur, rather than a loss in tensile ductility, when they possess high yield strengths or are under high hydrogen fugacity. The nickel-copper alloys (Monels) have also been found to be susceptible to hydrogen embrittlement, with increasing strength obtained by cold working or aging.

Figure 16 is a good comparison of the effect of hydrogen on the threshold cracking behavior of several stainless steels and nickel alloys (Ref 27). It is interesting to note that there is not an obvious distinction between single-phase alloy resistance and that of multiphase alloys. For example, the single-phase alloy 625 performs much the same as the precipitation-hardening alloy 718. Likewise, the single-phase alloy 310 is not significantly different from the age-hardening alloy A286. The significant reductions in the threshold stress-intensity factor (K_{th}) for types 301 and 304 are attributable to the strain-induced transformation to martensite in these alloys.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

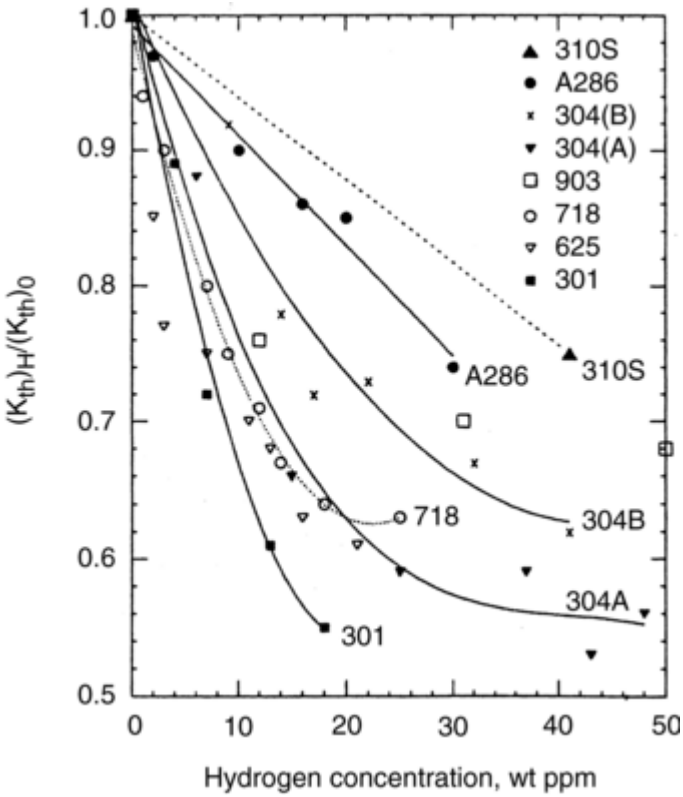

Fig. 16 Effect of hydrogen on the threshold stress intensity for crack propagation, normalized against the hydrogen-free values. Ref 27

Several nickel-base alloys are resistant to hydrogen stress cracking when cold worked to yield strengths in excess of 1240 MPa (180 ksi). However, when these alloys (Hastelloy alloy C- 276, Hastelloy alloy C-4, and Inconel alloy 625) are aged at low temperature, their resistance to hydrogen cracking is considerably diminished. This behavior is attributed to the segregation of phosphorus and sulfur to grain boundaries, which provide low-energy fracture paths (much the same as occurs in high-strength steels), or to an ordering reaction of the form $Ni_2(Cr, Mo)$. Figure 17 presents data that relate the reduction in area loss to ordering for the ordering alloy Ni_2Cr charged with hydrogen.

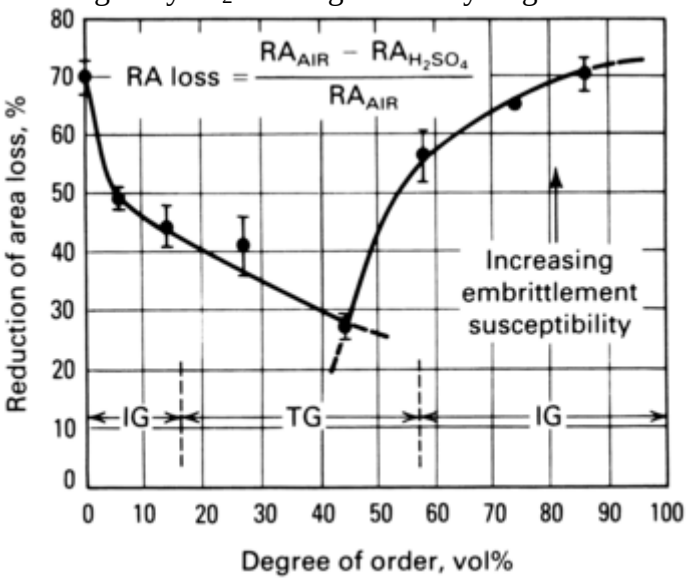

Fig. 17 Effect of the degree of order on the embrittlement susceptibility of Ni_2Cr. Regions of intergranular (IG) and ductile transgranular fracture (TG) are shown. RA, reduction of area. Source: Ref 28

Aluminum Alloys

Only recently has it been determined that hydrogen embrittles aluminum. For many years, all environmental cracking of aluminum and its alloys was represented as SCC; however, testing in specific hydrogen environments has revealed the susceptibility of aluminum to hydrogen damage. Hydrogen damage in aluminum alloys may take the form of intergranular or transgranular cracking or blistering. Blistering is most often associated with the melting or heat treatment of aluminum, where reaction with water vapor produces hydrogen. Blistering due to hydrogen is frequently associated with grain-boundary precipitates or the formation of small voids. Blister formation in aluminum is different from that in ferrous alloys in that it is more common to form a multitude of near-surface voids that coalesce to produce a large blister.

In a manner similar to the mechanism in iron- base alloys, hydrogen diffuses into the aluminum lattice and collects at internal defects. This occurs most frequently during annealing or solution treating in air furnaces prior to age hardening.

Dry hydrogen gas is not detrimental to aluminum alloys; however, with the addition of water vapor, subcritical crack growth increases dramatically (Fig. 18). The threshold stress intensity for cracking of aluminum also decreases significantly in the presence of humid hydrogen gas at ambient temperature (Fig. 19).

مرجع مهندسی مواد و متالورژی

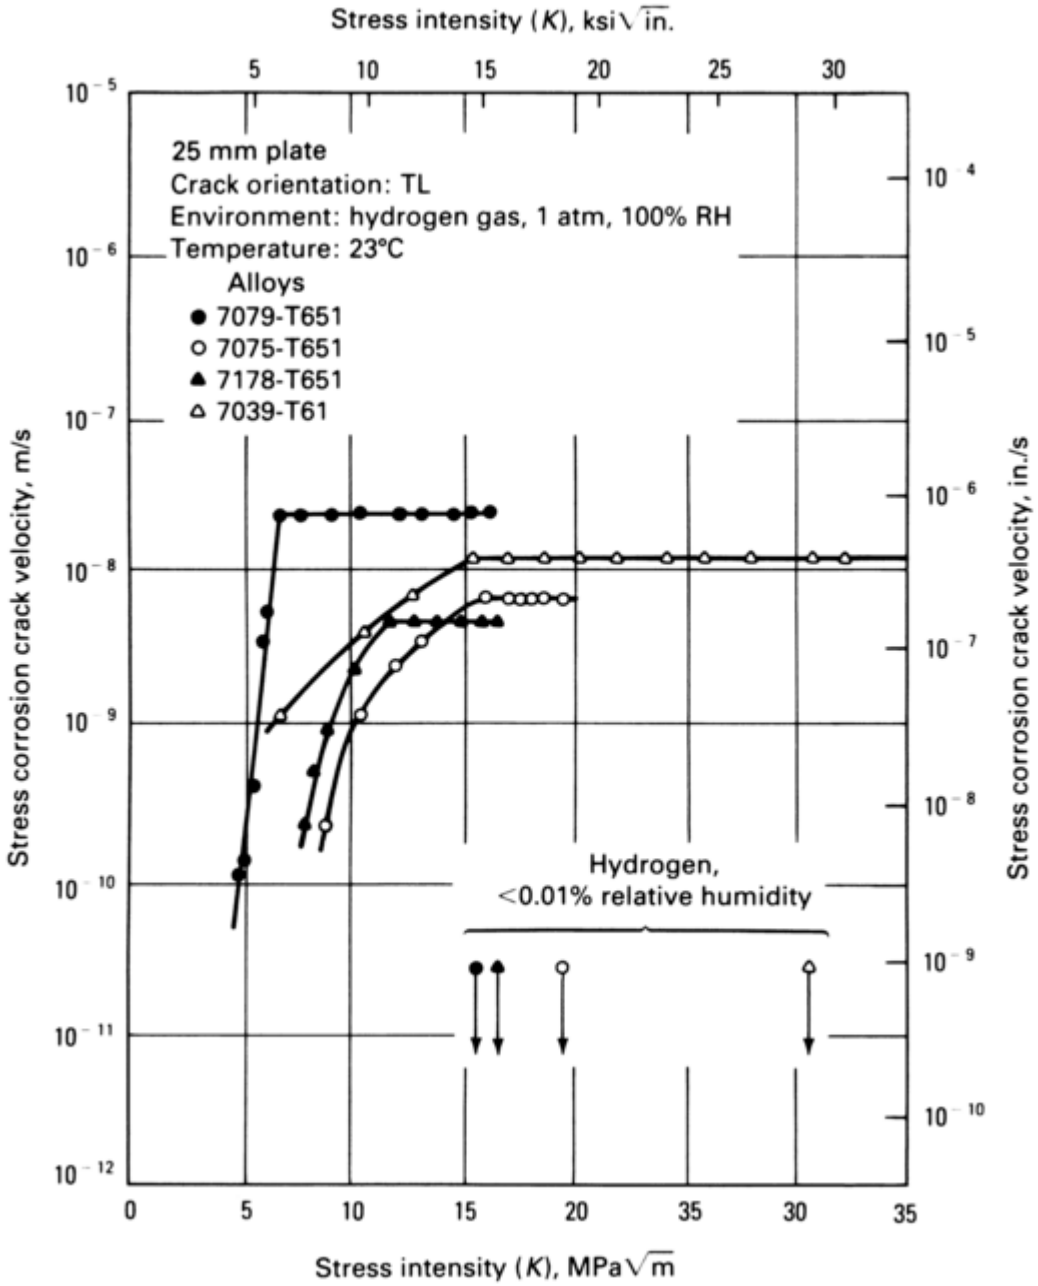

Fig. 19 Crack velocity of four high-strength aluminum alloys plotted as a function of crack-tip stress intensity in moist and dry hydrogen gas. Source: Ref 29

Crack growth in aluminum in hydrogen is also a function of hydrogen permeability, as in the iron-and nickel-base alloys. Hydrogen permeation and the crack growth rate are a function of potential, increasing with more negative potentials, as expected for hydrogen embrittlement behavior. Similarly, the ductility of aluminum alloys in hydrogen is temperature dependent, displaying a minimum in reduction in area below 0 °C (32 °F); this is similar to other fcc alloys (Ref 29).

Most of the work on hydrogen embrittlement of aluminum alloys has been on the 7000 series (Al-Zn-Mg); therefore, the full extent of hydrogen damage in aluminum alloys has not been determined or the mechanisms established. Some evidence for a metastable aluminum hydride has been found that would explain the brittle intergranular fracture of aluminum-zinc-magnesium alloys in water vapor. However, the instability of the hydride is such that is has been difficult to evaluate. Another explanation for intergranular fracture of these alloys is preferential decohesion of grain boundaries containing segregated magnesium. Overaging of these alloys increases their resistance to hydrogen embrittlement in much the same way as for highly tempered martensitic steels.

Copper Alloys

A common form of hydrogen damage in copper has been known for years as steam embrittlement and is observed only when copper contains oxygen. Hydrogen entering the metal reacts with oxygen either in solid solution or at oxide inclusions to form water. At temperatures above the critical temperature for water, steam forms, and the pressure generated is sufficient to produce microcavity formation and cracking. The equation for reaction with cuprous oxide particles is $Cu_2O + 2H = 2Cu + H_2O(g)$. The circumstances under which this form of hydrogen damage occurs are typically related to the annealing of copper in a hydrogen atmosphere. At lower temperatures, steam is not generated and therefore does not create the problem. Although the use of oxygen-free copper essentially eliminates susceptibility to steam embrittlement, the heavy cold working of oxygen-free copper can result in grain-boundary void formation when hydrogen is introduced.

Compared to the ferrous and nickel alloys, relatively little work has been performed specific to the hydrogen embrittlement of copper-base alloys. There is some indication that age-hardenable alloys such as beryllium-copper are susceptible to embrittlement under severe charging conditions, producing a loss in tensile ductility. A systematic study of these alloys remains to be performed.

Titanium Alloys

Titanium and its alloys suffer hydrogen damage primarily by hydride-phase formation. Pure α-titanium is relatively unaffected by small concentrations (<200 ppm) of hydrogen; however, above this content, the impact toughness is impaired. The purity of the α-titanium is important to its behavior in hydrogen. Commercially pure titanium is much more sensitive to hydrogen than pure titanium is. The amount of hydrogen necessary to induce ductile-to-brittle transition behavior in commercially pure titanium is one- half the amount needed in pure titanium.

Loss in impact toughness also occurs in α/β- titanium and β-titanium alloys and is sometimes referred to as impact embrittlement. This hydrogen damage at high strain rates is the result of hydrides that precipitate after the high-temperature exposure of titanium to hydrogen.

Another mode of failure for titanium alloys in hydrogen predominates under slow strain-rate loading. Figure 20 shows the strain-rate behavior for an α/β alloy. As the strain rate increases, the effect of hydrogen is lost. As in steels, the reduction in area and the elongation of titanium alloys are diminished in hydrogen.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

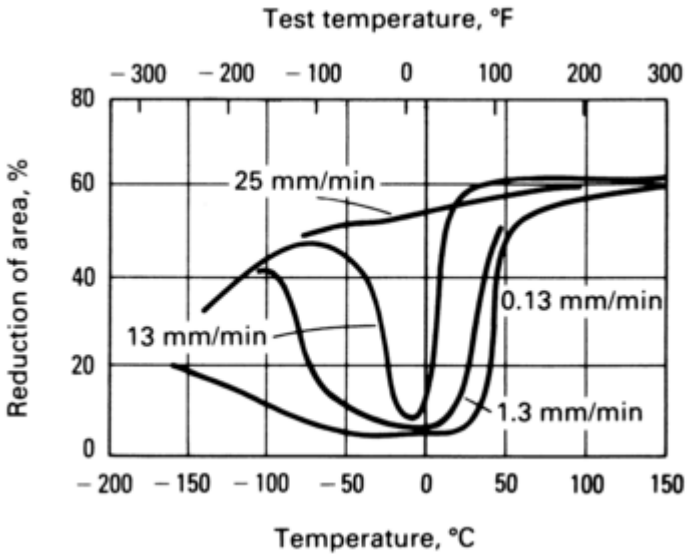

Fig. 20 Effects of hydrogen content (375 ppm), strain rate, and temperature on the tensile ductility of typical α/β-titanium alloy unnotched tensile specimens. Source: Ref 30

Both types of failure for titanium alloys in hydrogen are attributed to hydride-phase precipitation. The low strain-rate embrittlement is related to hydride formation caused by strain- enhanced precipitation, but embrittlement under impact is caused by hydride-phase formation after fabrication or heat treatment. Unlike many hydride-forming systems, titanium forms a stable hydride, but the kinetics of precipitation are slow compared to the Group Vb metals. Therefore, embrittlement is more prone to occur at low strain rates at which precipitation can proceed at a rate that is sufficient to provide a brittle crack path.

Because hydrogen solubility increases with temperature for these alloys, hydride embrittlement typically decreases as the temperature increases. Additionally, at higher temperatures, the hydride may become more ductile, reducing brittle crack initiation. As expected, the threshold stress intensity for crack propagation is also a function of the hydrogen content decreasing with increasing hydrogen.

The role of microstructure in the hydrogen damage of titanium is quite complex and is not fully understood. However, it has been determined that under slow strain rates, the α/β alloys fail by intergranular separation along boundaries but that completely α-alloys fracture by transgranular cleavage. Embrittlement is not as severe in α/β alloys with a continuous equiaxed α matrix as for those alloys with a continuous acicular β-matrix (Ref 31). However, this behavior is a function of hydrogen pressure and may be reversed at lower pressures (Ref 32).

Zirconium Alloys

Zirconium and its alloys suffer hydrogen damage by hydride precipitation, especially in the presence of notches or at low temperatures in smooth specimens. Failure occurs by cracking of the brittle, precipitated hydride phase during straining. These fractured hydrides may then accelerate fracture by ductile microvoid formation and coalescence, primarily enhancing the latter. Similar to titanium, zirconium alloys precipitate stable hydrides. Depending on the hydrogen content of the alloy, one of two stable or one metastable hydride(s) may precipitate. The two stable zirconium hydrides are δ-hydride (fcc) and ε- hydride (face-centered tetragonal, or fct). The metastable gamma-hydride also has a fct structure (Ref 33).

As in other alloy systems, the tensile ductility generally diminishes with increasing hydrogen content (Fig. 21). Similarly, the hydrogen embrittlement of these alloys is dependent on stress state, becoming more pronounced as the stress state moves from uniaxial to biaxial to triaxial tension. For example, the local stress state ahead of a sharp notch can produce a region of biaxial or triaxial stress, thus increasing the susceptibility to hydrogen embrittlement.

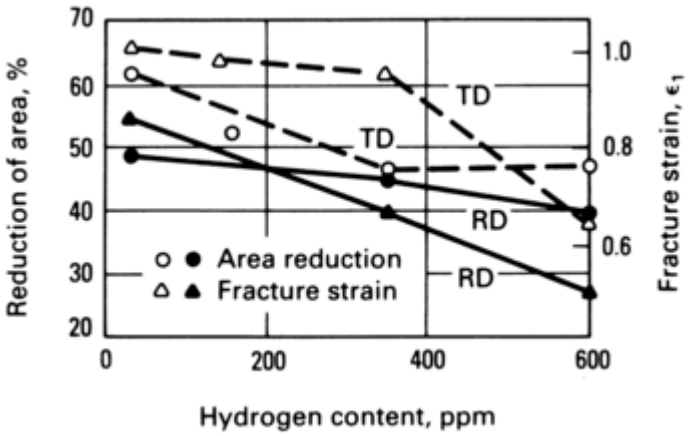

Fig. 21 Influence of hydrogen on the reduction of area at fracture and the true strain at fracture for Zircaloy-2. TD transverse direction; RD, rolling direction. Source: Ref 34

The embrittlement by zirconium hydride formation is a strong function of temperature, because increasing the temperature reduces the volume fraction of hydride due to the increased solid solubility of hydrogen with temperature. Ductile-to-brittle transition behavior has been observed in hydrided zirconium alloys, and the transition temperature has been found to be a function of hydrogen content, increasing with hydrogen concentration (Fig. 22).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

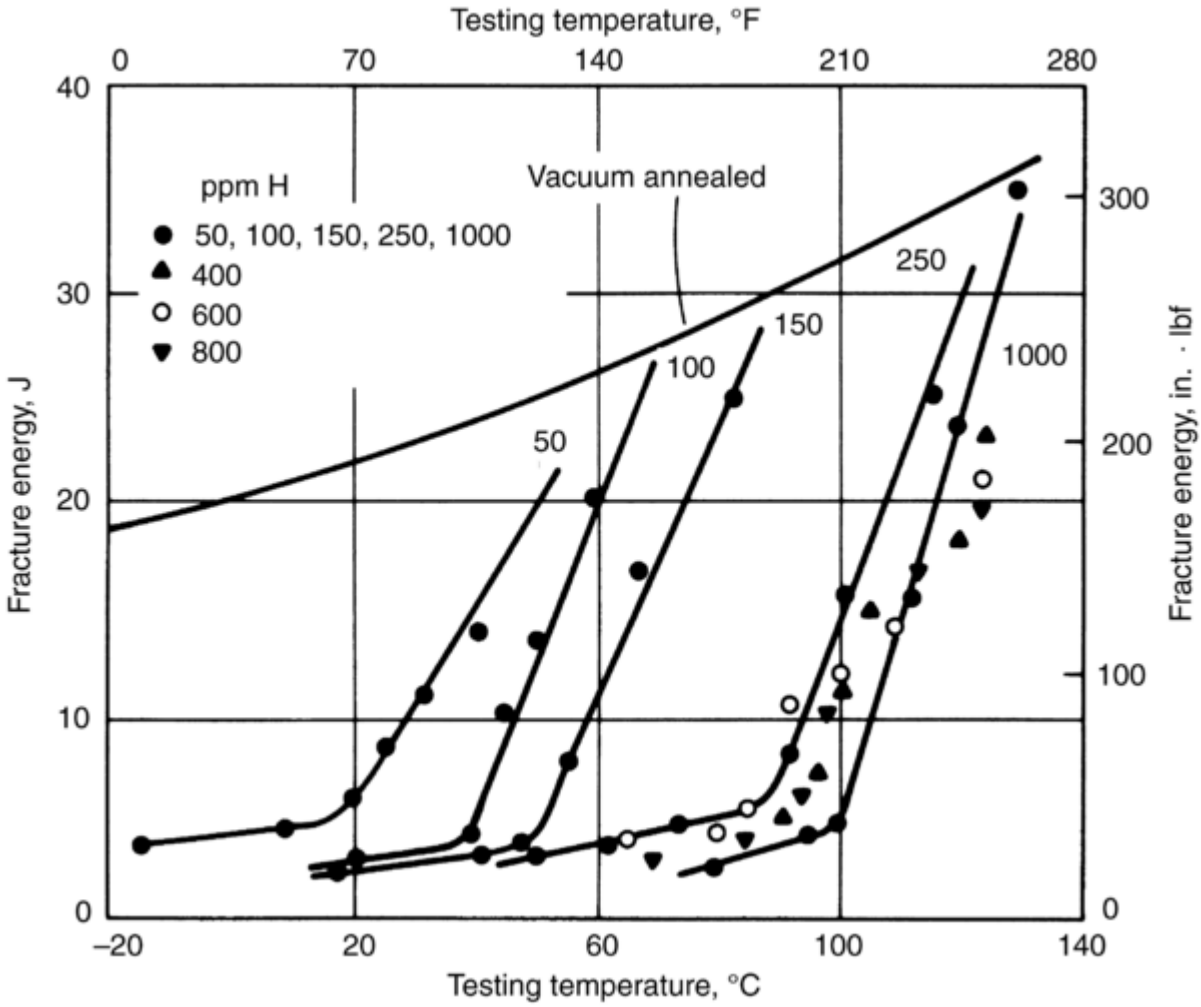

Fig. 22 Ductile-to-brittle transitions in hydrided zirconium. Source: Ref 35

Hydride distribution and morphology are other important factors in the extent of hydrogen damage in zirconium alloys. Because the brittle hydride phase provides an easy crack path for fracture, the distribution and morphology of this phase in relation to the sense of the applied tensile stress determine the degree of embrittlement. The shape and distribution of the hydrides are dependent on heat treatment prior to precipitation and cooling rate during precipitation. Rapid cooling produces a more uniform dispersion of hydrides, while slow cooling enhances the grain- boundary precipitation of the hydride platelets. Toughness is not as dramatically affected in the former case as in the latter.

Vanadium, Niobium, Tantalum, and Their Alloys

These metals and alloys are all embrittled by hydrogen—primarily by hydride-phase formation; however, unlike titanium and zirconium alloys, these systems do not form a stable hydride. The introduction of hydrogen into unalloyed vanadium, niobium, and tantalum increases the yield strength of these metals and creates ductile-to-brittle transition behavior (Fig. 23).

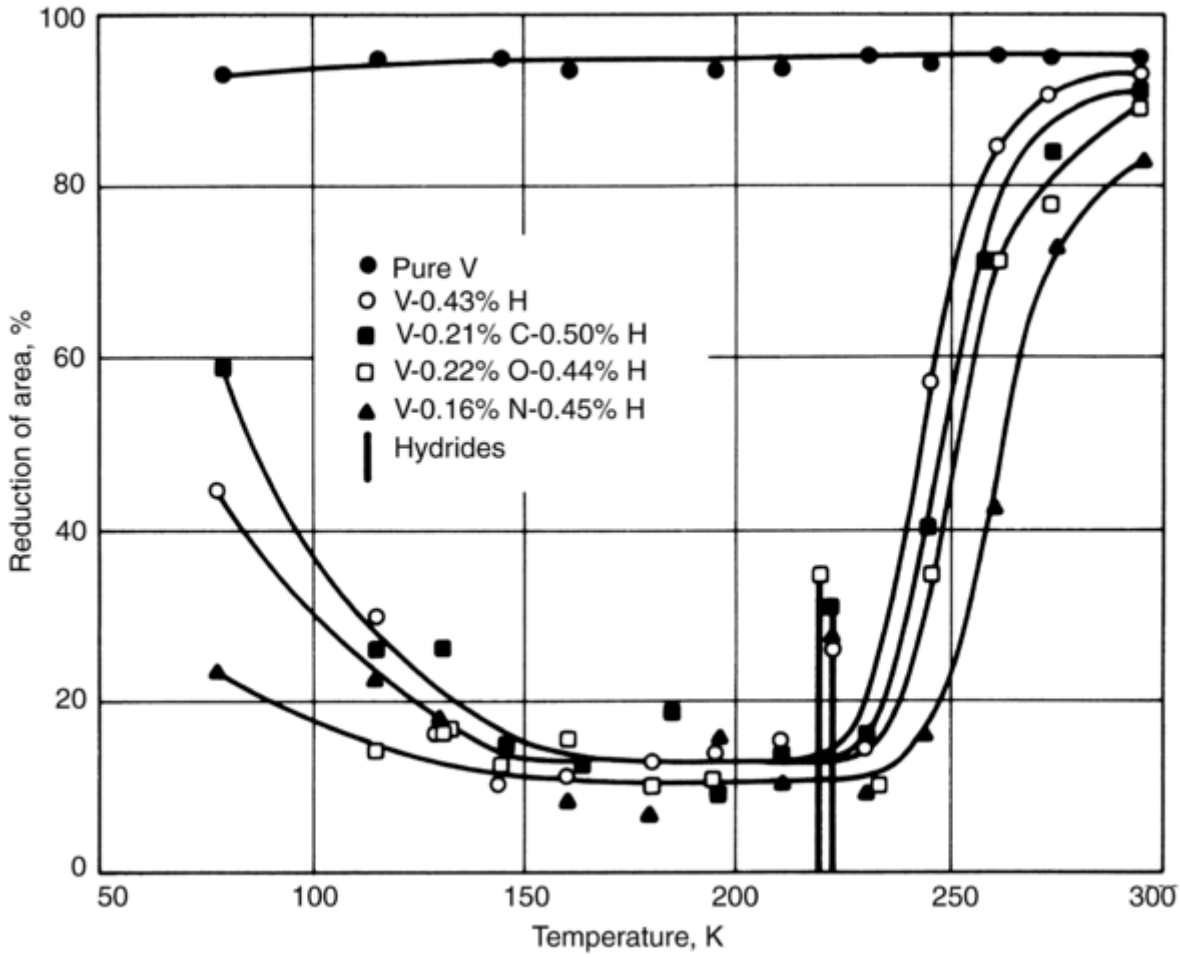

Fig. 23 Effect of hydrogen and combined carbon, nitrogen, or oxygen and hydrogen on the temperature dependence of ductility in vanadium. Source: Ref 36

Many of these alloy systems display ductile- to-brittle transition behavior in the presence of hydrogen in much the same manner as that described for zirconium and titanium. However, these alloys have been found to exhibit grain- boundary cracking when low levels of hydrogen are present in solid solution below the terminal solid-solubility limit. In fact, all of the hydride- forming systems exhibit hydrogen damage from solute hydrogen at low concentrations of hydrogen at which hydrides are not expected to precipitate. Although fracture transition is correlated with hydride formation in vanadium, other systems, such a niobium, zirconium, titanium, and tantalum, display more classical hydrogen embrittlement without a corresponding hydride- phase precipitation (Ref 33, 36).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Once the hydrogen content exceeds terminal solid solubility, damage may proceed by hydride precipitate formation. Below this solubility limit, the relative resistance to cracking or loss in tensile ductility is largely a function of the hydrogen concentration and alloying elements (Fig. 24). However, the terminal solid solubility for a particular metal-hydrogen system that forms hydrides is an extremely strong function of stress, so that reference to stress-free equilibrium phase diagrams for predicting hydride-phase behavior may be inaccurate (Ref 38).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

There are many other metals and alloys that form hydrides (for example, thorium, uranium, and beryllium), but far less is known about these systems. Therefore, a great deal of investigation into the metal-hydrogen interactions in many alloy systems remains to be done, especially considering the trend in new materials for advanced technologies.

Intermetallic Compounds

Since the late 1980s, there has been a significant effort to understand the behavior of intermetallic compounds when exposed to hydrogen- bearing environments. An excellent review of the subject is presented in Ref 39. Table 3, taken from that review, indicates that essentially all of the intermetallic compounds are embrittled by hydrogen.

Table 3 Intermetallic compounds embrittled by moisture or hydrogen at ambient temperature

Alloy	Agent	Crystal structure[(a)]
Ni_3(Al,Ti) single crystal	Moisture	$L1_2$

مرجع مهندسی مواد و متالورژی

This hydrogen embrittlement occurs either by contact with hydrogen-containing environments or from direct hydrogen charging. Even exposure to moisture can induce hydrogen damage in some of these compounds. Moreover, many of these alloys are compromised by hydrogen regardless of whether they are in the ordered or disordered condition. Just as with conventional metallic alloys, intermetallic compounds that fail from hydrogen damage can demonstrate intergranular and transgranular cracking, cleavage, and formation of brittle hydrides. Likewise, factors such as composition, microstructure, temperature, and strain rate are important to these alloys and their behavior in hydrogen, as they are in metallic alloys.

Liquid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Introduction

LIQUID METAL INDUCED EMBRITTLEMENT (LMIE), also known as liquid metal embrittlement, is the reduction of the fracture resistance of a solid material during exposure to a liquid metal. References in the literature to liquid metal embrittlement were first made over 100 years ago (Ref 1). Commonly, LMIE is described as the catastrophic brittle failure of a normally ductile metal when coated with a thin film of a liquid metal and subsequently stressed in tension. The fracture mode typically changes from a ductile to a brittle intergranular or brittle transgranular (cleavage) mode; however, there is no change in the yield and flow behavior of the solid metal. As shown in Fig. 1, embrittlement manifests itself as a reduction in fracture stress, strain, or both. Fracture can occur well below the yield stress of the solid. The stress required to propagate a sharp crack or a flaw is significantly lower than that necessary to initiate a crack in the liquid metal environment. In most cases, the initiation or the propagation of cracks appears to occur instantaneously, with the fracture propagating through the entire test specimen. The velocity of crack or fracture propagation can be as large as 10 to 100 cm/s (4 to 40 in./s) (Ref 2, 3, 4, 5).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

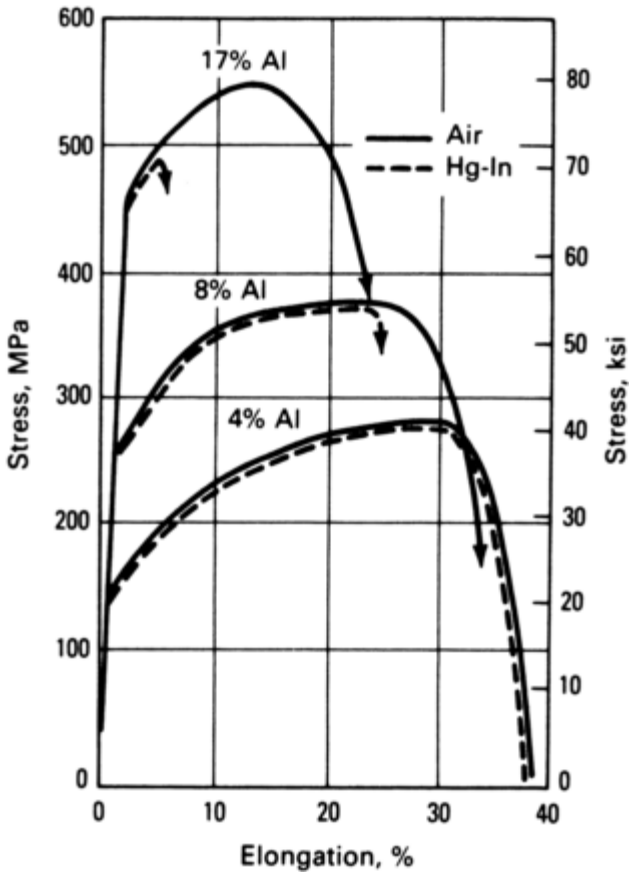

Fig. 1 Effects of environment on the yield stress and strain-hardening rate on various iron-aluminum alloys tested in air and mercury-indium solutions

Examination of LMIE fracture surfaces shows complete coverage by the liquid metal. Liquid metal is in intimate contact with the solid and is usually difficult to remove. The fracture mode becomes apparent when special techniques are used to remove the liquid (Ref 6). It should be emphasized that gross amounts of liquid are not necessary; even micrograms of liquid lead can cause LMIE in 75 mm (3 in.) thick steel tubes (Fig. 2). In fact, one monolayer is sufficient to cause LMIE (Ref 7). The fracture is usually brittle intergranular, with little indication of crack branching or striation to indicate slow crack propagation.

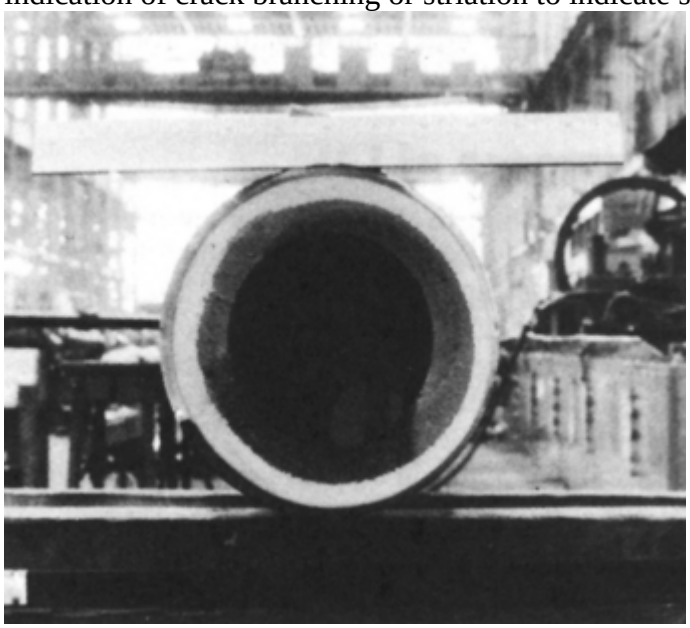

Fig. 2 Liquid lead induced brittle fracture of a 75 mm (3 in.) section of a 4340 steel pressure vessel tube

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The presence of liquid at the moving crack tip appears necessary for fast fracture. However, in high-strength brittle metals, a crack initiated in the presence of liquid may propagate in a brittle manner in the absence of liquid. In low-strength metals, a transition may occur from brittle-to- ductile failure under similar circumstances. Although far less frequent than brittle fracture, embrittlement can also occur by a ductile dimpled rupture mode in certain steels, copper alloys, and aluminum alloys. The embrittlement then manifests itself as the degradation of the fracture properties of the solid metal. Fracture is not limited to polycrystalline metals and the presence of grain boundaries. Embrittlement of amorphous alloys (Ref 8, 9) and single crystals (Ref 10, 11) has been observed. Single crystals of zinc and cadmium exhibited brittle cleavage fracture as a result of LMIE (Fig. 3). These are but a few of the manifestations of LMIE.

Fig. 3 Cleavage fracture of cadmium monocrystals at 25 °C (75 °F) following a coating with Hg-60In (at.%) solution

Embrittlement is not a corrosion, dissolution, or diffusion-controlled intergranular penetration process but is considered to be a special case of brittle fracture that occurs in the absence of an inert environment and at low temperatures. Time- and temperature-dependent processes are not considered to be responsible for the occurrence of LMIE. Also, in most cases of LMIE, little or no penetration of liquid metal into the solid metal is observed. The embrittlement of the solid metal coated with liquid metal or immersed in the liquid does not depend on the time of exposure to the liquid metal before testing (Fig. 4) or on whether the liquid is pure or presaturated with the solid. Usually, one of the prerequisites is that the solid has little or no solubility in the liquid and forms no intermetallic compound to constitute an embrittlement couple (Ref 12). However, exceptions to this empirical rule have been noted (Ref 72).

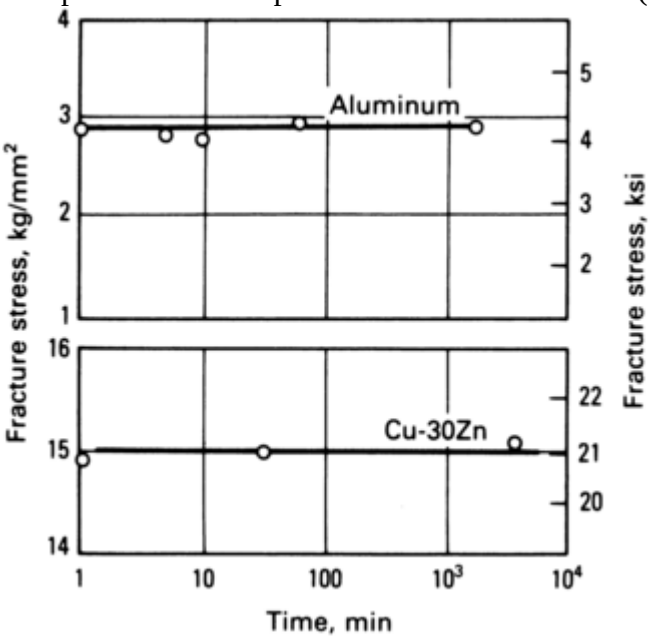

Fig. 4 Fracture stress of polycrystalline aluminum and Cu-30Zn brass as a function of exposure to liquid mercury before testing in this environment

An increase in test temperature usually decreases embrittlement, which leads to a brittle- to-ductile transition. Severe embrittlement occurs near the freezing temperature of the liquid. In fact, in iron lead, iron indium (Fig.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

5), and many other metallic couples, embrittlement occurs below the melting temperature of the liquid. This phenomenon is called solid metal induced embrittlement (SMIE) of metals and is described in the following article in this Section. Gaseous metal embrittlement, not discussed here, has been noted as well.

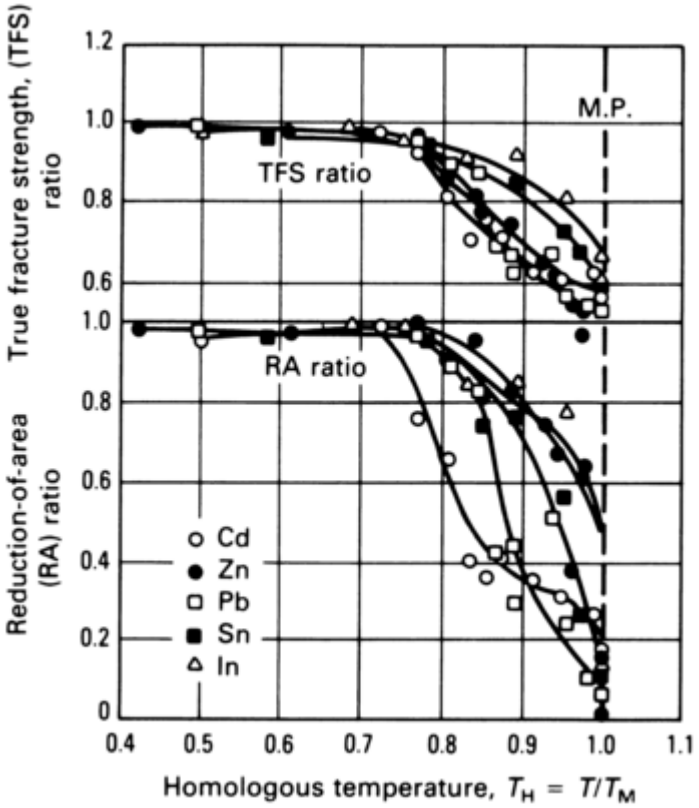

Fig. 5 Embrittlement of 4140 steel by various metals below their melting point. Comparison of normalized true fracture strength (TFS) ratio and the reduction-of-area (RA) ratio as a function of homologous temperature, T_H, where T and T_M are the test and the melting temperature of the embrittling metal, respectively. M.P., melting point. Source: Ref 13

The occurrence of LMIE is not a laboratory curiosity. Such failures have been observed in metals and alloys in the following industrial applications and processes:

- Small amounts of alloying elements, such as lead and tellurium, added to steel to improve machinability may lead to embrittlement (Fig. 6). Internally leaded steels have cracked at lead inclusions. For example, leaded steel gears have cracked during induction-hardening heat treatments, and warm punching of leaded steel shafts has resulted in unexpected fracture during the forming operation.
- Cadmium-plated titanium and steels are embrittled during high-temperature service by molten cadmium.
- Indium, used as a high-vacuum seal in steel chambers, has caused cracking during bakeout operations.
- Zircaloy tubes used in nuclear reactors have been cracked by both solid and liquid cadmium.
- Although infrequent, LMIE also occurs in petrochemical plants and in the steel industry during heat treatment, hot rolling, brazing, soldering, and welding (Ref 14, 15, 16, 17) operations.
- Embrittlement of steel occurs by electroplated or dipped cadmium, zinc, or tin—all of which provide corrosion resistance.
- In liquid metal cooled reactors, liquid lithium can cause LMIE in metals.

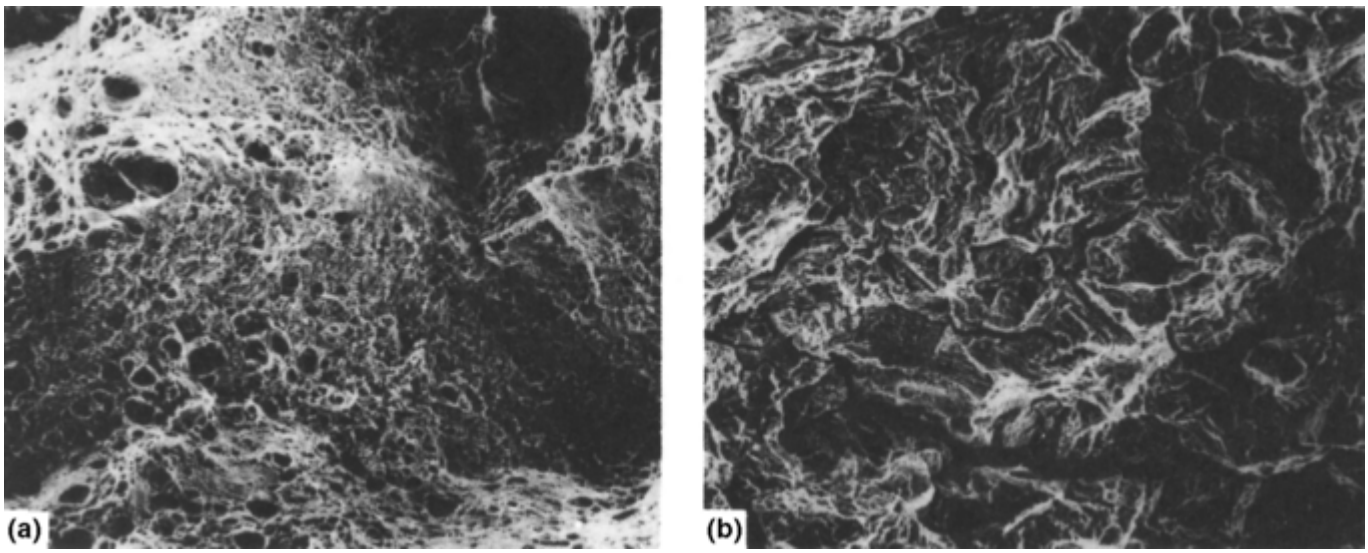

Fig. 6 Influence of lead on the fracture morphology of a 4340 steel. (a) Ductile failure after testing in argon at 370 °C (700 °F). (b) The same steel tested in liquid lead at 370 °C (700 °F) showing brittle intergranular fracture

As would be expected of embrittlement, the fracture is typically associated with a significant loss of macroscopic ductility. The fracture mode is often largely intergranular, although transgranular brittle fracture (cleavage) can occur. Intergranular (IG) fractures may also reveal dimples associated with the ductile mechanism of microvoid coalescence along the grain boundaries. This is referred to as dimpled intergranular (or intercrystalline) fracture.

Fracture surfaces from LMIE are easily distinguishable from those due to stress-corrosion cracking (SCC), and more details on the failure analysis of LMIE fractures are described in the article “Liquid Metal and Solid Metal Induced Embrittlement” in *ASM Handbook,* Volume 11 (2002), *Failure Analysis and Prevention.* The embrittlement is severe, and the propagation of fracture is typically very fast in the case of LMIE as compared to that in SCC. Thus, the predominant occurrence of brittle fracture surfaces, fast or catastrophic fracture, significant loss in ductility and strength/fracture toughness, and the presence of liquid at the tip of the propagating crack are some of the characteristics that may be used to distinguish LMIE from other environmentally induced failures. Detailed information on the mechanisms of LMIE and the susceptibility of specific metals and alloys to liquid metal induced failures can be found in Ref 8 and 18, 19, 20, 21, 22, 23, 24, 25, 26.

Liquid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Mechanisms of Embrittlement

Several mechanisms have been proposed to explain LMIE, including stress-assisted dissolution of the solid at the crack tip, reduction in the surface energy of the solid by the liquid metal, and adsorption-enhanced plasticity. It has been suggested that embrittlement is associated with liquid metal adsorption-induced localized reduction in the strength of the atomic bonds at the crack tip or at the surface of the solid metal at sites of stress concentrations.

With this possibility in mind, consider the crack shown in Fig. 7. Crack propagation occurs by the breaking of A-A_0 bonds at the crack tip and, subsequently, the breaking of similar bonds at the propagating crack tip by the chemisorbed liquid metal atom B. (A vapor phase from a solid in a solid-solid metal embrittlement couple or an elemental gas, such as hydrogen, may also provide the embrittling atom B.) Next, assume that liquid metal atom B at the crack tip reduces the cohesive strength of A-A_0 bonds. The chemisorption process presumably occurs spontaneously or only after the A-A_0 bonds have been strained to some critical value. In any event, electronic rearrangement occurs because of adsorption, which weakens the bonds at the crack tip. The crack propagates when the applied stress is increased, so that it exceeds the reduced breaking strength of A-A_0 bonds. The liquid metal atom becomes stably chemisorbed on the freshly created surfaces. The surface diffusion of the liquid metal atoms over the chemisorbed liquid metal atoms feeds the advancing crack tip, thus propagating the crack at reduced stress and causing complete failure of the specimen.

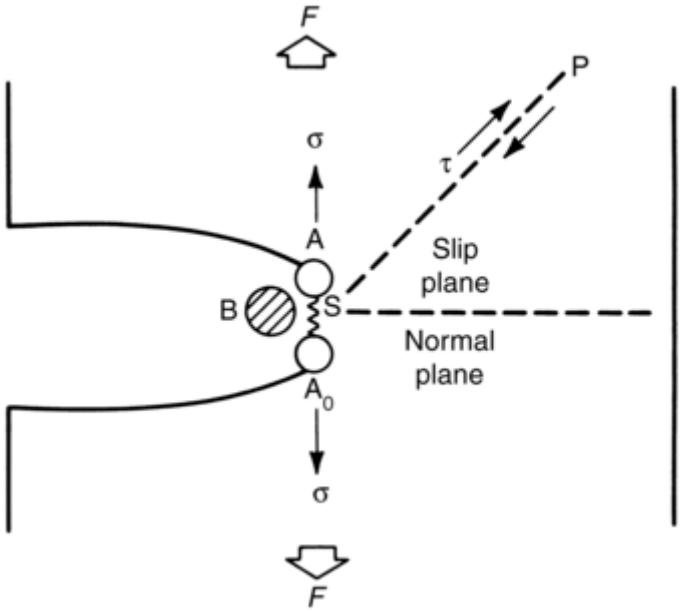

Fig. 7 Schematic illustrating displacement of atoms at the crack tip. The bond A-A_0 constitutes the crack tip, and B is the liquid metal atom.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

In the previously mentioned mechanism, it is assumed that tensile decohesion is predominantly responsible for the occurrence of embrittlement, although both tensile as well as shear decohesion can occur. Embrittlement can also occur by the adsorption-induced reductions in the shear strength of the atomic bonds at the crack tip. The reduced shear strength facilitates nucleation of dislocations or slip at low stresses at or near the crack tip. Localized plasticity can result in void nucleation at precipitates, inclusions, or at other discontinuities (such as subboundaries in a single grain). The voids may grow and thus result in a rupture (i.e., an IG fracture) with the appearance of dimples on the fracture surfaces. The localized increased plasticity results in an overall reduction in the strain at failure as compared to that in the absence of liquid metal, thus causing embrittlement. For embrittlement due to reduced shear cohesion, lower strain at failure or subcritical crack growth by linkage of voids is the measure of LMIE.

A schematic representation of the previously mentioned process is given in Fig. 8, and supporting fractographic evidence is given for high- strength steel (Fig. 9a) and beryllium-copper alloys (Fig. 9b) broken in liquid metal environments. Conversely, Fig. 9(c–e) and Fig. 10 provide strong support for the reduced tensile cohesion mechanism.

Fig. 10 Optical micrograph (a) and scanning electron micrograph (b) showing a cleavage fracture surface produced by cracking a zinc single crystal in liquid mercury

Most often, LMIE induces a brittle IG or cleavage fracture mode at reduced tensile stresses and thus supports the tensile decohesion mode. However, the dimpled IG fracture by LMIE should be considered an embrittling process in a failure analysis in which the reduction in the mechanical parameters at fracture is the measure of embrittlement. Although LMIE can occur by either a brittle or a ductile microscopic mechanism; both degrade the fracture properties of the solid metal. In addition, macroscopic fracture features may be a combination of macroscale ductile fracture (by microvoid coalescence) truncated by LMIE fracture from a transgranular brittle mechanism (cleavage) or IG mechanisms.

Liquid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Role of Liquid in Crack Propagation

In the mechanism of embrittlement described previously, it was implied that once a crack is nucleated, subsequent crack propagation occurs mechanically with liquid absent at the crack tip or occurs by the continuous presence of the liquid metal atoms at the propagating crack tip caused by the surface diffusion of liquid metal atoms over chemisorbed liquid metal atoms. The role of liquid in embrittlement should be investigated by measuring the crack growth rate as a function of temperature and stress intensity. The velocity of crack propagation, or crack growth rate, in SCC has been extensively investigated. However, such investigations in liquid metal are limited (Ref 2, 3, 4, 5, 6, 27, 28, 29). Figure 11 shows that the velocity of crack growth in brass in liquid mercury was at least 2 orders of magnitude higher than that in an inert environment. The crack propagation activation energy for brass in liquid mercury is only 3 to 5 kcal/mol (Fig. 12). This corresponds to diffusion of liquid mercury over mercury adsorbed on brass. The very high velocities of crack propagation and very low activation energies are considered to be distinguishing features from similar investigations in SCC environments in the same metals. Such characteristics can be used to differentiate liquid metal induced crack propagation from stress- corrosion or hydrogen damage.

Liquid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Occurrence of LMIE

Susceptibility to LMIE is unique to specific solid metal/liquid metal systems. For example, liquid gallium embrittles aluminum but not magnesium, and liquid mercury embrittles zinc but not cadmium. The equilibrium phase diagrams of most embrittlement couples show that they form binary systems with little or no solid solubility. Also, they form immiscible liquids in the liquid state, and they usually do not form intermetallic compounds. This is an empirical observation, valid for many embrittlement couples, although exceptions have been reported.

The most critical and mandatory condition for LMIE is that the liquid should be in intimate contact with the surface of the solid to initiate embrittlement and should subsequently be present at the tip of the propagating crack to cause brittle failure. Even a thin oxide film several angstroms thick may prevent interaction between the solid and the liquid so that embrittlement is not observed. Thus, conditions that promote intimate contact and enhanced wetting of the liquid by the solid, such as freshly created surfaces by plastic deformation in a liquid environment, breaking of oxide films, or other such factors, lead to LMIE of the solid. Indeed, investigators have used chemical (Ref 4, 30) and mechanical (Ref 2, 6, 31) depassivation techniques in order to achieve reliable wetting of specimens for testing.

The severity of embrittlement is not necessarily related to just the previously mentioned criteria and conditions, but it is related to the chemical nature of the embrittling species. For example, zinc can be embrittled more by liquid gallium than by mercury. In addition, the severity of embrittlement is related to the properties of the solid and depends on such factors as strength, alloying elements, grain size, and strain rate. The severity or occurrence or nonoccurrence of embrittlement depends on the type of test and whether the solid contains stress concentrators, such as preexisting cracks or flaws, or is smooth and free of stress raisers. By increasing the possibilities of maintaining high stress concentrations, the susceptibility of the solid to LMIE is also increased.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

For example, smooth specimens of low-alloy low-strength steel are not embrittled by liquid lead, but the same steel containing a fatigue precrack is severely embrittled by liquid lead. Therefore, uniaxial tension tests provide a nonconservative assessment of LMIE susceptibility, and the use of fracture mechanics specimens and test techniques (Ref 2, 3, 4, 5, 6, 27, 28, 29, 32) is preferable. Note that fracture mechanics testing of specimens in liquid metal environments is much more challenging than uniaxial tension testing, due to difficulties with crack tip wetting, crack growth measurement, and data interpretation.

Certain other prerequisites must be fulfilled before fracture can initiate in a solid. For a ductile metal without a precrack, these are tensile stress, plastic deformation, and the presence of a stable obstacle to slip serving as a stress concentrator. This obstacle can be preexisting (for example, a grain boundary) or can be created during deformation (for example, a twin or kink band).

In addition, there should be an adequate supply of liquid metal to adsorb at the obstacle and subsequently at the propagating crack tip. Plastic deformation or yielding may mean localized deformation in few grains rather than general yielding of the solid metal. If a specimen contains a preexisting crack, then adsorption of the liquid at the crack tip and some tensile stress are necessary to propagate a crack. If the solid is notch brittle, LMIE can occur at reduced stress. In order for LMIE to occur, there must be an embrittler at the crack tip. However, once a crack is initiated, it may propagate further in a ductile or brittle manner in the absence of the liquid, depending on the constraints at the crack tip. Brittle fracture may occur after some ductile fracture in an inert environment. The changing constraint conditions may enable brittle crack propagation after the embrittler is exhausted, but only if, under the crack tip conditions, the material is intrinsically brittle. Thus, it may not be necessary for the liquid to be present during the entire process of crack propagation. The occurrence of LMIE in an embrittlement couple requires good wetting of the surface of the solid by the liquid, the presence of sufficient stress concentration to initiate or propagate a crack in liquid, and possible concurrence with the empirical observations mentioned previously.

Liquid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Effects of Metallurgical, Mechanical, and Physical Factors

It has been shown that the prerequisites for liquid metal induced brittle fracture are the same as those for brittle fracture in an inert environment at low temperatures, that is, the need for plastic flow. Sufficient stress intensity and adsorption of liquid metal are necessary to initiate and/or propagate a crack. From the investigations reported for many embrittlement couples, including classic zinc-mercury couples, it has been concluded that adsorption-induced embrittlement can be regarded as a special case of brittle fracture that normally occurs in brittle materials at low temperatures in an inert environment. (Ductile fracture can also result by the adsorption-induced reductions in the shear strength of the atomic bonds at the crack tip.) Thus, the effects of yield stress, grain size, strain rate, temperature, and so on in a liquid metal environment follow trends similar to those noted for metals tested in an inert environment. The effects of a variety of metallurgical factors on LMIE can be found in (Ref 8).

Effects of Grain Size. The grain size dependence of fracture stress has been investigated for zinc mercury, cadmium gallium, brass and copper alloys in mercury, and low-carbon steel in lithium. In these and other instances, the fracture stress varied linearly with the reciprocal of the square root of grain size and followed the well- known Cottrell-Petch relationship of grain size dependence on fracture stress (Ref 8).

For the zinc-mercury couple shown in Fig. 13, fracture is nucleation controlled in region I, whereas in region II it is propagation controlled. Nucleation-controlled embrittlement implies the occurrence of unstable crack propagation; that is, once a crack is initiated, it propagates to failure in the presence or absence of the liquid metal at the crack tip. In propagation-controlled failure, stable crack propagation occurs such that microcracks are formed at some low stress in a liquid metal environment, but the microcracks propagate to failure only when a higher stress is reached. Thus, in propagation-controlled failure, unpropagated microcracks may be found beside the main fracture, and complete fracture of the specimen occurs only in the presence of liquid metal. The reverse is observed when fracture is initiation-controlled.

مرجع مهندسی مواد و متالورژی

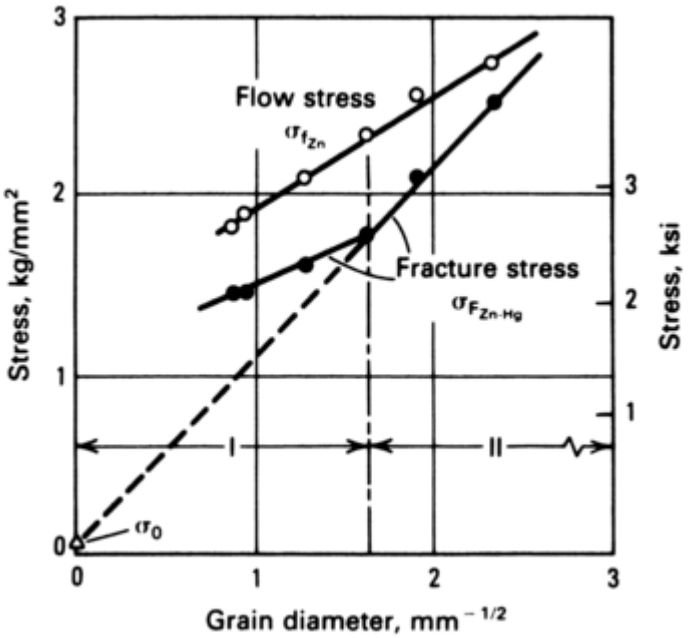

Fig. 13 Effect of grain size on LMIE. Variation of the flow stress of amalgamated zinc polycrystalline specimens, σ_{fZn}, and fracture stress of amalgamated zinc specimens, $\sigma_{FZn\text{-}Hg}$, as a function of grain size at 298 K

Effects of Temperature and Strain Rate. Liquid metal induced embrittlement occurs at the melting point of liquid metal. There are quite a few instances in which embrittlement occurs below the melting point of liquid by SMIE. In some instances, an embrittlement maximum is seen at intermediate temperatures (Ref 5, 11, 30, 33, 34, 35, 36, 37, 38, 39). In other cases, the susceptibility to embrittlement may remain essentially unchanged with temperature. At a sufficiently high test temperature, a brittle-to-ductile transition occurs when embrittlement ceases and ductility is restored to the solid. Such transitions do not occur at a sharply defined temperature and are not predictable on a theoretical basis or in terms of diffusion, dissolution, or other such embrittlement processes. It is generally accepted that a significant increase in temperature counteracts the inherent propensity for fracture in the embrittling liquid metal environment.

In smooth steel specimens tested in liquid lead, brittle-to-ductile transition occurs at approximately 510 °C (950 °F), 335 °C (600 °F) above the melting point of lead. In fracture-mechanics specimens of similar steel containing sharp notches tested in liquid lead, the transition occurs at approximately 650 °C (1200 °F), which is 140 °C (250 °F) higher than that for smooth specimens. Transition temperature in this case depends on the presence or absence of a stress raiser in the specimen and on the type of test method used. It should also be noted that this effect is probably related not just to stress concentration but also to constraint effects on the apparent flow stress of the material at the crack tip. This also promotes brittle behavior. Such brittle-to-ductile transitions also have been reported for zinc-mercury, aluminum-mercury, brass-mercury, titanium-cadmium, steel-lead, and steel-lead-antimony solution embrittlement couples.

Transition temperature also varies with strain rate and grain size in a manner similar to metals tested in an inert environment; that is, an increase in strain rate and a decrease in grain size increase the transition temperature. The effects of grain size on transition temperature have been reported for aluminum in Hg-3Sn solutions and brass-mercury embrittlement couples. The effects of strain rate on transition temperature have been reported for cadmium-gallium, zinc-mercury, aluminum-mercury, zinc-indium, brass- mercury, and titanium-cadmium embrittlement couples. Changes in the strain rate by orders of magnitude are usually required to change the transition temperature by 50 to 100 °C (90 to 180 °F). For example, in the titanium-cadmium couple, a change of approximately 60 °C (110 °F) occurs with a change of one to two orders of magnitude in the strain rate and corresponds to a comparable increase in yield stress with the strain rate. The effects of strain rate appear to be related to the increase in the yield stress. This corresponds to an increase in the embrittlement susceptibility and a decrease in the brittle-to- ductile transition temperature.

Effects of Stress. Static fatigue or delayed- failure tests are conducted to study the effects of time-dependent processes, such as diffusion penetration of the grain boundary, as the cause of embrittlement. Also, such tests are performed because they simulate service conditions of constant stress in an embrittling environment as a

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

function of time and assist in the failure analysis. Time-to-failure depends on the notch sensitivity of the alloy, and embrittlement may be independent of time-to-failure in notch-insensitive alloys. Conversely, the time-to-failure may be very sensitive to the stress level in other alloys. In notch-sensitive zinc tested in mercury, for example, complete failure can occur instantly at a stress slightly higher than a threshold stress.

These kinds of results indicate that time-dependent diffusion penetration or dissolution processes are not always dominant factors in LMIE. In isolated instances, grain-boundary penetration by the liquid has been the cause of embrittlement. For example, under no applied load (unstressed but with internal residual stress still possible), aluminum or commercial aluminum alloys disintegrate into individual grains when contacted with liquid gallium. Liquid antimony embrittles steel, and embrittlement increases with temperature; thus, diffusional processes cause antimony to embrittle steel. Liquid copper and liquid lithium embrittle steel in a similar manner (Fig. 14). However, in these cases, both diffusional and classic LMIE have been observed. Such behavior can be differentiated by the temperature dependence, by the susceptibility to embrittlement, or by embrittlement occurring in solid metal environments.

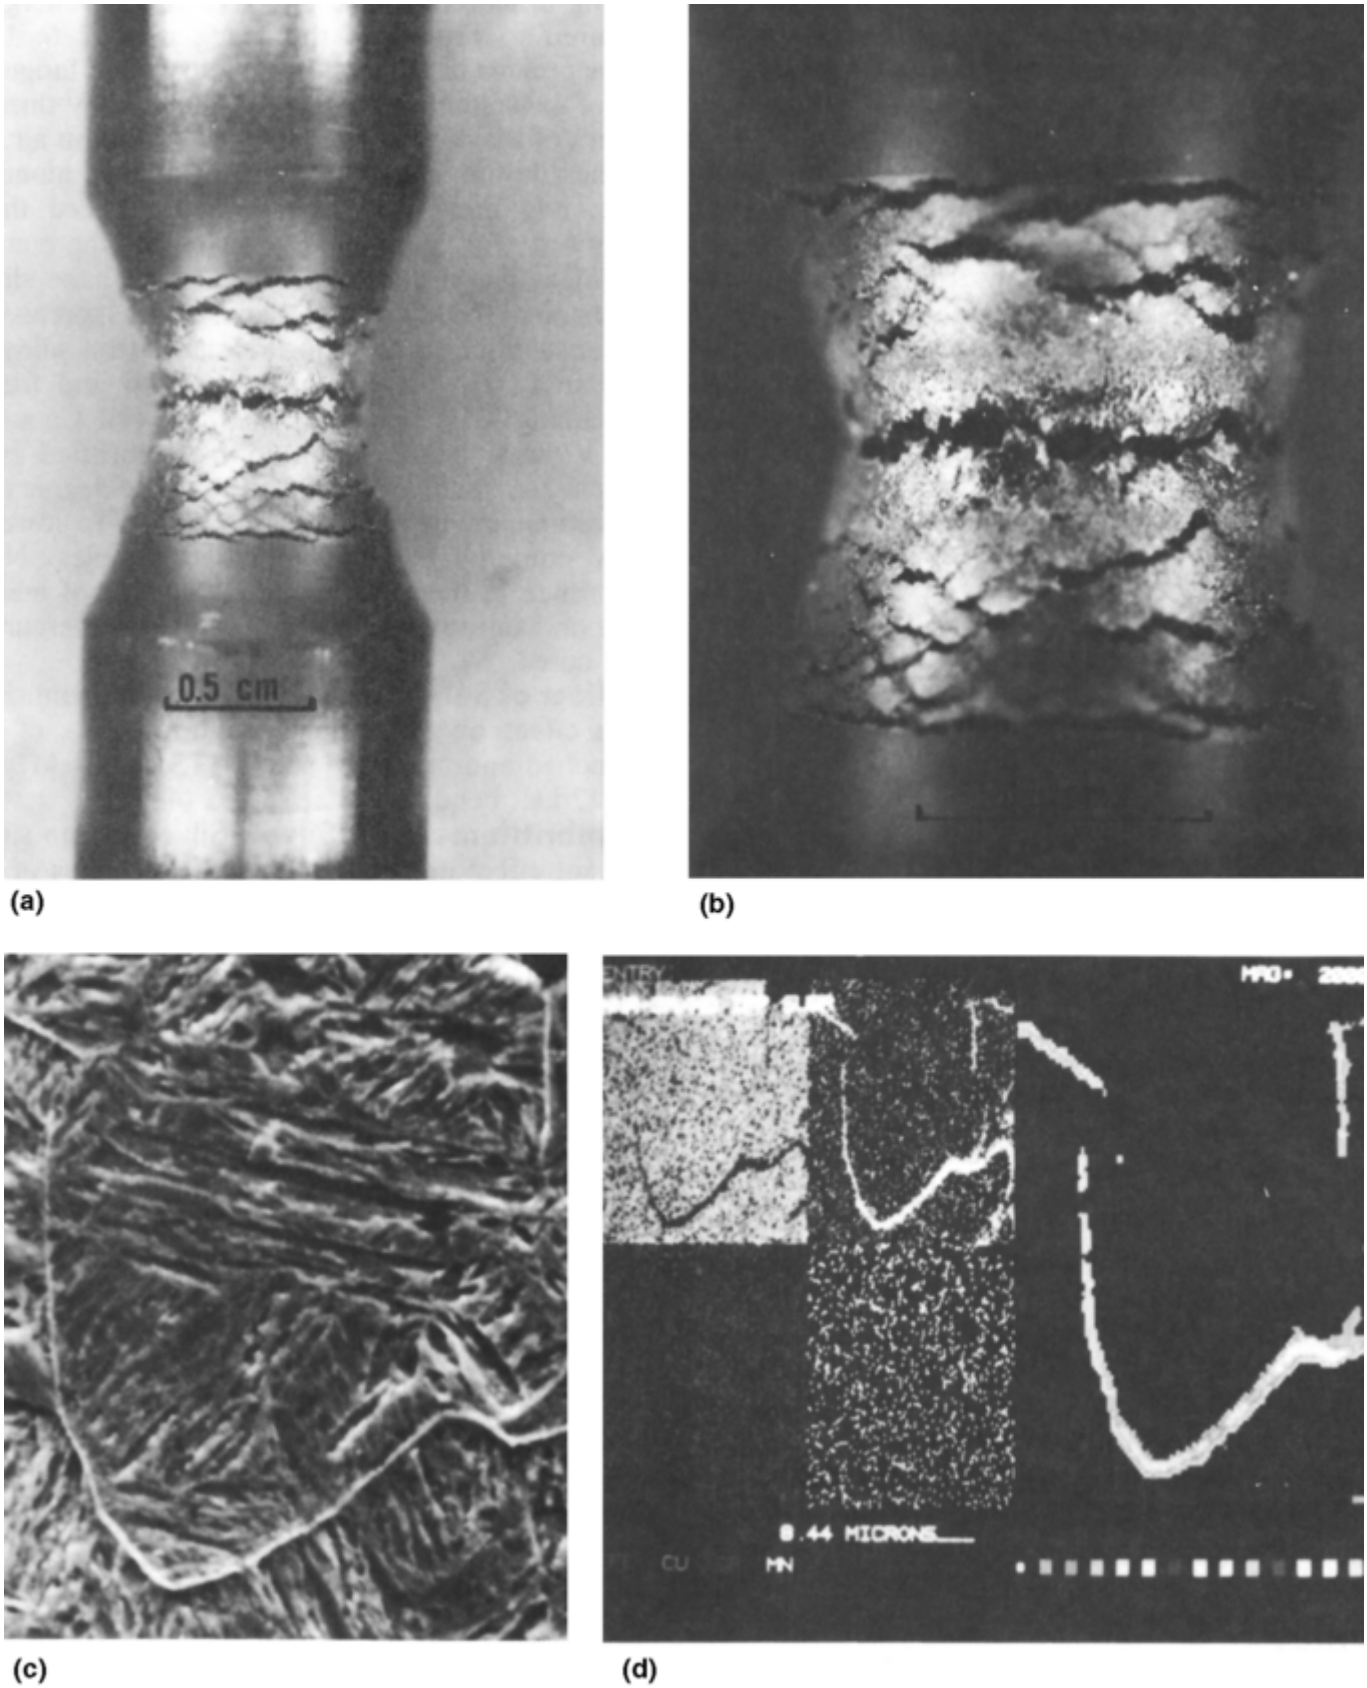

Fig. 14 Copper-induced LMIE of 4340 steel. (a) and (b) Copper-plated specimen that was pulled at 1100 °C (2010 °F) in a Gleeble hot tensile machine showing liquid copper embrittlement of steel. (c) Scanning electron micrograph of the pulled specimen. 1600×. (d) Computer-processed x-ray map showing the presence of copper in prior-austenite grain boundaries

Inert Carriers and LMIE. In some cases, investigation of the embrittlement behavior of a potential solid-liquid metal couple is not possible. The reason is that the solid metal at temperatures just above the melting temperature of the liquid metal is either too ductile to initiate and propagate a brittle crack or the solid is

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

excessively soluble in the liquid metal. It is possible, however, that a solid metal can be embrittled by a liquid metal of high melting point by dissolving it in an inert-carrier liquid metal of a lower melting point. Thus, the embrittling species is effectively in a liquid state at some temperature far below its melting point. In addition, it provides a means of investigating the variation in the degree of embrittlement induced in a solid metal as a function of the concentration and as a function of the chemical nature of the several active liquid metal species dissolved separately in a common inert-carrier liquid metal.

For example, mercury does not embrittle cadmium, but indium may embrittle cadmium (melting point: 325 °C, or 617 °F). However, cadmium is quite ductile at 156 °C (313 °F), the melting temperature of indium. Mercury dissolves up to 70% indium at room temperature. The indium in the mercury-indium solution at room temperature embrittles cadmium (Fig. 15). In fact, cadmium single crystals, which are ductile even at liquid helium temperature, can be embrittled by indium and cleaved in indium- mercury solutions (Fig. 3). Another example of embrittlement by inert carriers is that of Zircaloy nuclear fuel claddings used in liquid metal cooled nuclear reactors. In liquid cesium, Zircaloy claddings fail in a ductile manner; in cesium saturated with cadmium, Zircaloy is subject to brittle fracture (Ref 40).

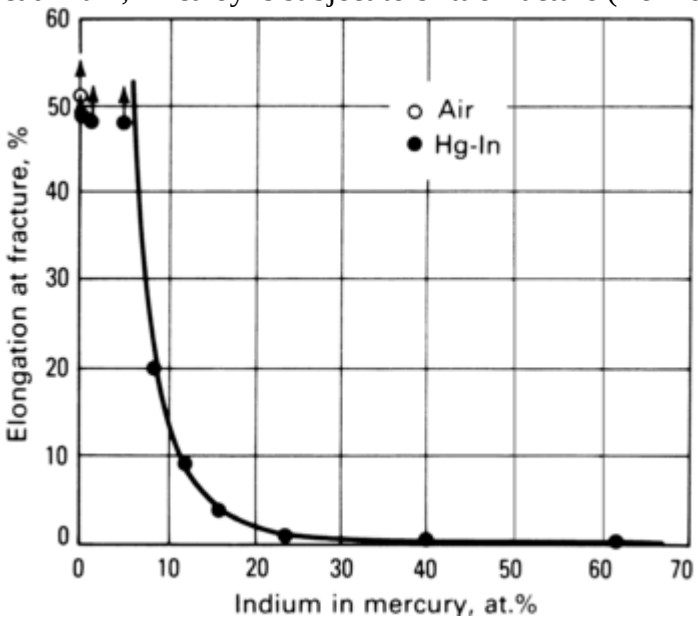

Fig. 15 Variation in ductility of polycrystalline cadmium as a function of indium content of mercury-indium surface coatings. Specimens were tested at 25 °C (75 °F) in air and in mercury-indium solution.

The concept of inert-carrier LMIE is useful in failure analysis where LMIE has occurred in a liquid solution—for example, solder rather than a pure liquid metal. The susceptibility of various species in the solder in causing LMIE can be investigated by incorporating each species in an inert liquid. This may suggest a means of preventing embrittlement by replacing the most potent embrittling agent with a nonembrittling species.

Fatigue in Liquid Metal Environments

Most studies of LMIE have been concerned with the effects of tensile loading on fracture. Investigations of fatigue behavior (Ref 2, 4, 5, 6, 8, 25, 27, 41, 42, 72) are important, because this test condition is more severe than other test conditions, including the tensile testing of metals. Thus, a solid tested in fatigue may become embrittled, but the same solid tested in tension may not exhibit embrittlement. This may be because at the high stress level corresponding to yield stress, which is a prerequisite for the occurrence of embrittlement in tough metals, the solid may be sufficiently ductile to prevent initiation of a crack in the liquid. Another explanation is that fatigue generates and maintains a sharper crack tip that gives rise to a greater stress intensity. Another explanation is that cyclic stress is more efficient at crack tip wetting than tensile stress (Ref 6).

For example, smooth specimens of high-purity chromium-molybdenum low-alloy steel with yield stress of approximately 690 MPa (100 ksi) are not embrittled by liquid lead, but the same steel specimens containing a fatigue precrack are severely embrittled by liquid lead. The fatigue life in liquid lead is reduced to 25% of that in an inert argon environment. Crack propagation in a liquid metal environment under fatigue and tensile loading can be significantly different. The stress intensity at failure of 7.7 MPa$\sqrt{m}$ (7 ksi $\sqrt{\text{in.}}$) for a 4340 steel specimen containing a fatigue precrack tested in cyclic fatigue in liquid lead was 5 times lower than that for the same specimen tested in tension in static fatigue and was 20 times lower than that in an inert argon environment. Furthermore, the 7.7 MPa$\sqrt{m}$ (7 ksi$\sqrt{\text{in.}}$) stress intensity was the same whether the specimen had a machined notch (0.13 mm, or 0.005 in., root radius) or a fatigue precrack at the root of the notch; that is, embrittlement was independent of root radius. These results indicate that embrittlement is very severe, and even blunt cracks can propagate to failure. Similar results have also been reported for the same steel tested in liquid mercury.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

These results clearly indicate that fatigue testing of a notched or a fatigue precracked specimen provides the most severe test condition and therefore causes maximum susceptibility to embrittlement in a given liquid metal environment. To determine whether a solid is susceptible to LMIE in a particular liquid, it is advisable to test the solid metal with a stress raiser or a notch in a tension-tension fatigue test.

Liquid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Decrease or Elimination of LMIE Susceptibility

The decohesion mechanism of embrittlement is related to electron interactions, where by electron redistribution between the solid and the liquid metal atoms reduces cohesion and thus induces embrittlement. Such

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

interactions at the electron level are the inherent properties of the interacting atoms and are therefore difficult or impossible to change in order to reduce the susceptibility to LMIE.

One possibility is to introduce impurity atoms in the grain boundary that have more affinity for sharing electrons with the liquid metal atoms than for sharing electrons with the solid metal atoms. For example, phosphorus additions to Monel segregate to the grain boundaries and reduce the embrittlement of Monel by liquid mercury. Additions of lanthanides to internally leaded steels reduce lead embrittlement of steel. Another alternative is to electroplate or clad the solid surface with a metal as a barrier between the embrittling solid-liquid metal couple, making sure that the barrier metal is not embrittled by the liquid metal.

Another possibility is that a ceramic or a covalent material coating on the solid surface can inhibit embrittlement. Apparently, only materials with metallic bonding are susceptible to LMIE. The severity of embrittlement could be reduced by decreasing the yield stress of the solid below the stress required to initiate a crack or by cladding with a high-purity metal of the alloy that is embrittled but that has a very low yield stress. Thus, Zircaloy, which is clad with a high-purity zirconium, becomes immune to embrittlement by cadmium. The obvious possibility is to replace embrittling liquid metals or solutions by nonembrittling metals or solutions.

Liquid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Embrittlement of Nonferrous Metals and Alloys

Zinc. Mercury, indium, gallium, and Pb-20Sn solder embrittle zinc. Mercury decreases the fracture stress of pure zinc by 50% and dilute zinc alloys (0.2 at.% Cu or Ag) by 5 times that in an inert environment. The fracture propagation energy for a crack in zinc single crystals in mercury is 60%, and in gallium it is 40% of that in air. Zinc is embrittled more severely by gallium than by indium or mercury.

Aluminum. Mercury embrittles both pure and alloyed aluminum. (Ref 2, 4, 5, 43). The tensile stress is decreased by some 20%. The fatigue life of 7075 aluminum alloy is reduced in mercury, and brittle-to-ductile transition occurs at 200 °C (390 °F). Additions of gallium and cadmium to mercury increase the embrittlement of aluminum. Delayed failure by LMIE occurs in mercury. Dewetting of aluminum by mercury has been found to inhibit embrittlement. The possible cause of dewetting is the dissolution of aluminum by mercury, the oxidation of fine aluminum particles by air, and the formation of aluminum oxide at the aluminum-mercury interface.

The aluminum-gallium system has been well studied (Ref 2, 6, 11, 44, 45, 46, 47, 48, 49, 50). As little as 1 MPa$\sqrt{m}$ (1 ksi$\sqrt{\text{in}}$.) can yield failure (Ref 3, 6). In some cases, gallium in contact with aluminum disintegrates aluminum alloys into individual grains in the absence of applied stress. Therefore, grain-boundary penetration of gallium is sometimes used to separate grains and to study topographical features and orientations of grains in aluminum.

Aluminum alloys are embrittled by tin-zinc and lead-tin alloys. The embrittlement susceptibility is related to heat treatment and the strength level of the alloy. There is some uncertainty about whether zinc embrittles aluminum. However, indium severely embrittles aluminum. Alkali metals, sodium, and lithium are known to embrittle aluminum. Aluminum alloys containing either lead, cadmium, or bismuth (Ref 33) inclusions embrittle aluminum when impact tested near the melting point of these inclusions. The severity of embrittlement increases from lead to cadmium to bismuth.

Copper. Mercury embrittles copper (Ref 41), and the severity of embrittlement increases when copper is alloyed with aluminum and zinc. Antimony, cadmium, lead, tin (Ref 51), and thallium are also reported to embrittle copper. Mercury embrittlement of brass is a classic example of LMIE. Embrittlement occurs in both tension and fatigue and varies with grain size and strain rate. Mercury embrittlement of brass and copper alloys

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

has been extensively investigated. Lead and tin inclusions in brass cause severe embrittlement when tested near the melting point of these inclusions. Lithium reduces the rupture stress and elongation at failure of solid copper. Sodium is reported to embrittle copper; however, cesium does not. The embrittling effects of bismuth for copper and their alloys are well documented. Gallium embrittles copper at temperatures ranging from 25 to 240 °C (75 to 465 °F) (Ref 7, 27, 36, 52). Gallium also embrittles single crystals of copper. Indium embrittles copper at 156 to 250 °C (313 to 480 °F).

Other Nonferrous Materials. Tantalum and titanium alloys are embrittled by mercury and by Hg-3Zn solution. Refractory metals and alloys, specifically W-25Re, molybdenum, and Ta-10W, are susceptible to LMIE when in contact with molten Pu-1Ga. Cadmium and lead are not embrittled by mercury. However, indium dissolved in mercury embrittles both polycrystalline and single-crystal cadmium (Fig. 3). The embrittlement of titanium and its alloys by both liquid and solid cadmium is well recognized by the aircraft industry. Cadmium-plated fasteners of both titanium and steel are known to fail prematurely below the melting point of cadmium. Cadmium- plated steel bolts have good stress-corrosion resistance, but cadmium is known to crack steel. Therefore, such bolts are not recommended for use. Zinc is reported to embrittle magnesium and titanium alloys. Silver, gold, and their alloys are embrittled by both mercury and gallium. Nickel and nickel alloys are embrittled by mercury (Ref 10, 53, 54), cadmium (Ref 55), bismuth (Ref 39), lithium (Ref 54), and sodium (Ref 54). Nickel is severely embrittled by cadmium dissolved in cesium. The fracture mode is brittle IG with bright grain-boundary fracture.

Embrittlement of Zircaloy by mercury (Ref 32, 56), calcium, strontium, zinc, cesium cadmium (Ref 57, 58), cadmium (Ref 40, 58), and iodine has been reported. Failure of Zircaloy tubes used as cladding material for nuclear fuel rods has been suspected to result from nuclear- interaction reaction products, such as iodine and cadmium carried by liquid cesium, which is used as a coolant in the reactor. Systematic investigation in the laboratory has shown that cadmium, both in the solid and the liquid state or as a carrier species dissolved in liquid cesium, causes severe LMIE and SMIE of zirconium and Zircaloy-2.

Liquid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Embrittlement of Ferrous Metals and Alloys

Embrittlement by Aluminum. Tensile and stress-rupture tests have been conducted on steels in molten aluminum at 690 °C (1275 °F). For short-term tensile tests, a reduced breaking stress and reduction of area were found as compared to the values in air. In the stress-rupture tests, the time to failure was dependent on the applied stress.

Embrittlement by Antimony. American Iron and Steel Institute (AISI) 4340 steel tested in fatigue in liquid Pb-35Sb at 540 °C (1000 °F) and in antimony at 675 °C (1250 °F) was very severely embrittled (Ref 30). The embrittlement in lead antimony occurred 165 to 220 °C (300 to 400 °F) higher than that observed for high-purity lead. Small additions of antimony (~5 wt%) to lead had no effect on embrittlement when tested in fatigue, although 0.002 to 0.2% Sb additions have caused a significant increase in the embrittlement of smooth AISI 4140 steel specimens tested in tension. Embrittlement by antimony increases with temperature and is thought to occur by the grain-boundary diffusion of antimony in steel.

Embrittlement by Bismuth. On testing in liquid bismuth at 300 °C (570 °F), no embrittlement was noted in bend tests on a quenched-and-tempered steel. No intercrystalline attack was noted on the low-carbon steel after stress-rupture time- to-failure testing.

Embrittlement by Cadmium. In several studies of the embrittlement of AISI 4340 steel, embrittlement occurred at 260 to 322 °C (500 to 612 °F) but not at 204 °C (399 °F) for high- strength steel. Cracks were observed in samples loaded to 90% of their yield stress at 204 °C (399 °F). The threshold stress required for cracking decreases with an increase in temperature. Cracking at 204 °C (399 °F) was strongly dependent on the strength level of the steel, and embrittlement was not observed for strength levels less than 1240 MPa (180 ksi). Delayed failure occurs in cadmium-plated high-strength steels (AISI 4340, 4140, 4130, and an 18% Ni maraging steel). Failures were observed at 232 °C (450 °F), which is approximately 90 °C (160 °F) below the melting point of cadmium. Static failure limits of 10 and 60% of the room-temperature notch strength have been reported for electroplated and vacuum-deposited cadmium, respectively, at 300 °C (570 °F). A discontinuous crack propagation mode was observed, consisting of a series of crack propagation steps separated by periods of no apparent growth. This slow crack growth region was characterized by cracks along the prior-austenite grain boundaries. Once the cracks reached a critical size, a catastrophic failure occurred that was characterized by a transgranular ductile fracture. An AISI 4130 steel exposed to cadmium has also been reported to fail at 316 °C (601 °F) (Ref 55).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Embrittlement of high-strength steels occurs when they are stress-rupture tested in liquid and solid cadmium. Cadmium produces a progressive decrease in the reduction of area at fracture of AISI 4140 steel over the temperature range of 170 to 321 °C (338 to 610 °F). Cadmium was identified as a more potent solid metal embrittling agent than lead, tin, zinc, or indium.

It has been reported that 304 stainless steel is immune to LMIE in cadmium and cadmium aluminum over a wide range of temperature and strain rate (Ref 59).

Embrittlement by Copper. The embrittlement of low-carbon steel by copper plate occurred at 900 °C (1650 °F) during a slow-bend test. The embrittling effects of the copper plate exceeded those encountered with brazing alloys. Similar observations have been made for plain carbon steels, silicon steels, and chromium steels at 1000 to 1200 °C (1800 to 2190 °F). Iron-36 Ni (Ref 35), 304 stainless steel (Ref 15, 17), and 316 stainless steel (Ref 17) also have been shown to be embrittled by copper.

The surface cracking produced during the hot working of some steels at 1100 to 1300 °C (2010 to 2370 °F) also has several characteristics of LMIE. It is promoted by surface enrichment of copper and other elements during oxidation and subsequent penetration along the prior-austenite grain boundaries. Elements such as nickel, molybdenum, tin, and arsenic that affect the melting point of copper or its solubility in austenite also influence embrittlement. A ductility trough has also been noted, with no cracking produced at temperatures above 1200 °C (2190 °F). Steel plated with copper and pulse heated to the melting point of copper in milliseconds was embrittled by both liquid and solid copper. Hot tensile testing in a Gleeble testing machine at high strain rates produced severe cracking in AISI 4340 steel by both the liquid and solid copper.

Embrittlement by Gallium. The alloy Fe-3Si is severely embrittled by gallium, as are the solid solutions of iron, AISI 4340 steel (Ref 6), and 316L stainless steel (Ref 72).

Embrittlement by Indium. Indium embrittles pure iron and carbon steels. Embrittlement depends on both the strength level and the microstructure. Pure iron was embrittled only at temperatures above 310 °C (590 °F), appreciably above the melting point of indium. However, other steels, such as AISI 4140 (ultimate tensile strength of 1379 MPa, or 200 ksi), were embrittled by both solid and liquid indium. Surface cracks were detected at temperatures below the melting temperature of indium. This was interpreted as a local manifestation of the underlying embrittlement mechanism, and it was assumed that the cracks must reach a critical size before the gross mechanical properties are affected.

Embrittlement by Lead. The influence of lead on the embrittlement of steel has been extensively investigated (Ref 30, 38, 39, 60, 61, 62) and has been found to be sensitive to both composition and metallurgical effects. The studies fall into two major classifications:

- Liquid metal induced embrittlement due to contact with an external source of liquid lead
- Internal LMIE in which the lead is present internally as inclusions or a minor second phase, as in leaded steels

Both external and internal lead-induced embrittlement exhibit similar characteristics, but for the purpose of simplicity, each is treated individually.

Liquid Metal Induced Embrittlement Due to External Lead. When exposed to pure lead, AISI 4145 and 4140 steels exhibit classic LMIE, as shown by substantial decreases in both the reduction of area and the elongation at fracture. The fracture stress and the reduction of area decreased at temperatures considerably below the melting point of lead and varied continuously through the melting point, suggesting that the same embrittlement mechanism is operative for both solid and liquid metal environments.

Additions of zinc, antimony, tin, bismuth, and copper increase the embrittling potency of lead. Additions of up to 9% Sn, 2% Sb, or 0.5% Zn to lead increased the embrittlement of AISI 4145 steel. In some cases, the embrittlement and failure occurred before the ultimate tensile strength (UTS) was reached. The extent of embrittlement increases with increasing impurity content. No correlation was observed between the degree of embrittlement and wettability. The lead-tin alloys readily wetted steels, but the more embrittling lead-antimony alloys did not.

Liquid Metal Induced Embrittlement Due to Internal Lead. Leaded steels are economically attractive, because lead increases the machining speed and the lifetime of the cutting tools. The first systematic investigation of embrittlement of leaded steels was reported in 1968 by Mostovoy and Breyer. Embrittlement characteristics similar to those promoted by external lead were observed. The degradation in the ductility began at approximately 120 °C (215 °F) below the melting point of lead, with the embrittlement trough present from 230

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

to 454 °C (446 to 849 °F). This was followed by a reversion to ductile behavior at approximately 480 °C (895 °F).

The severity of the embrittlement and the brittle-to-ductile transition temperature, T_R, have been shown to be dependent on the strength level of the steel, with the degree of embrittlement and T_R increasing with strength level. In these studies, IG fracture was produced, which was propagation controlled at low temperatures and nucleation controlled at high temperatures. The degree of embrittlement was critically dependent on the lead composition, and the influence of trace impurities completely masked any variations due to different carbon and alloy compositions of the steel. Lead embrittlement of a steel compressor disk was induced by bulk lead contents of 0.14 and 6.22 wt%. The lead is associated with the nonmetallic inclusions, and on yielding, microcracks form at the weak inclusion-matrix interface, releasing a source of embrittling agent to the crack tip that aids subsequent propagation. An electron microprobe analysis of the nonmetallic inclusions identified the presence of zinc, antimony, tin, bismuth, and arsenic. With the exception of arsenic, all these trace impurities have been shown to have a significant effect on the external LMIE of steel.

The two most promising methods of suppressing LMIE are the control of sulfide composition and morphology and the cold working of the steel. The addition of rare earth elements to the steel melt modifies the sulfide morphology and composition and can eliminate LMIE.

Embrittlement by Lithium. Exposure of AISI 4340 steel to lithium at 200 °C (390 °F) resulted in static fatigue, with the time to failure depending on the applied stress. A decreasing fracture stress and elongation to fracture were noted with increasing UTS of variously treated steels, and catastrophic failure occurred for those steels with tensile strengths exceeding 1034 MPa (150 ksi). The tensile ductility of low-carbon steel at 200 °C (390 °F) was drastically reduced in lithium, with IG failure after 2 to 3% elongation, but there was no effect on the yield stress or the initial work-hardening behavior. The fracture stress was shown to be a linear function of $d^{-1/2}$, where d is the average grain diameter, in accordance with the Petch relationship.

Embrittlement by Mercury. A variety of studies have examined the steel-mercury system (Ref 5, 9, 63, 64). It has been shown that mercury embrittlement is crack nucleation controlled and can be induced in low-carbon steel samples by the introduction of local stress raisers. The fracture toughness of a notched 1Cr-0.2 Mo steel was significantly decreased on testing in mercury. The effective surface energy required to propagate the crack was 12 to 16 times greater in air than in mercury. The fatigue life of AISI 4340 steel in mercury is reduced by 3 orders of magnitude as compared to that in air.

The addition of solutes (cobalt, silicon, aluminum, and nickel) to iron, which reduced the propensity for cross slip by decreasing the number of active slip systems and changed the slip mechanism from wavy to planar glide, increased the susceptibility to embrittlement. Iron alloys containing 2% Si, 4% Al, or 8% Ni and iron containing 20% V or iron containing 49% Co and 2% V have been shown to be embrittled by mercury in unnotched tensile tests. The degree of embrittlement behavior was extended to lower alloy contents by using notched samples. No difference in the embrittlement potency of mercury or a saturated solution of indium in mercury was noted.

Effect of Selenium. Selenium had no embrittling effect on the mechanical properties of a quenched-and-tempered steel (UTS ~1460 MPa, or 212 ksi) bend tested at 250 °C (480 °F).

Embrittlement by Silver. Silver had no significant effect on the mechanical properties of a range of plain carbon steels, silicon steels, and chromium steels tested by bending at 1000 to 1200 °C (1830 to 2190 °F). However, a silver- base filler metal containing 45% Ag, 25% Cd, and 15% Sn has been reported to embrittle A- 286 heat-resistant steel in static load tests above and below 580 °C (1076 °F), the melting point of the alloy.

Effect of Sodium. Unnotched tensile properties of low-carbon steel remained the same when tested in air and in sodium at 150 and 250 °C (300 and 480 °F). Similarly, Armco iron (Armco Inc.), low-carbon steel, and type 316 steel were not embrittled by sodium at 150 to 1600 °C (300 to 2910 °F). Sodium containing nonmetallic impurities was shown to be more aggressive than sodium alone for bainitic, martensitic, tempered martensitic, and ferritic/pearlitic steels (Ref 34, 65).

Embrittlement by Solders and Bearing Metals. A wide range of steels are susceptible to embrittlement and intercrystalline penetration by molten solders and bearing metals at temperatures under 450 °C (840 °F). Tensile tests have revealed embrittlement as a reduction in ductility. The embrittlement increased with grain size and strength level of the steel, except for temper-embrittled steels.

The tensile strength and ductility of carbon steel containing 0.13% C were decreased on exposure to the molten solders and bearing alloys. The embrittlement was concomitant with a change to a brittle IG fracture mode and penetration along prior-austenite grain boundaries. Ductile failure was observed with samples tested in air or in

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

the liquid metal at temperatures exceeding 450 °C (840 °F). No intercrystalline penetration of solder was noted in carbon steels containing 0.77 and 0.14% C at 950 °C (1740 °F).

It has been reported that solder embrittles steel more than Woods metal (a bismuth-base fusible alloy containing lead and tin), particularly if it contains 4% Zn. The bearing metals produced embrittlement similar to the solder-containing 4% Zn alloy.

Embrittlement by Tellurium. Tellurium-associated embrittlement has been reported for carbon and alloy steels. Hot shortness occurs in AISI 12L14 + Te steel, with the most pronounced loss in ductility between 810 and 1150 °C (1490 and 2100 °F), embrittlement being most severe at 980 °C (1795 °F). The embrittlement has been shown to occur by the formation of a lead-telluride film at the grain boundary, which melts at 923 °C (1693 °F). The mechanical test data and the examination of fracture surfaces by Auger electron spectroscopy and scanning electron microscopy indicated LMIE of steel by the lead-telluride compound. The embrittlement of austenitic stainless steel by tellurium and tellurium-cesium mixtures has been well documented (Ref 42, 66, 67, 68, 69, 70, 71).

Effect of Thallium. Thallium had no embrittling effects on the mechanical properties of a quenched-and-tempered steel (UTS ~1460 MPa, or 212 ksi) tested in bending at 325 °C (615 °F).

Embrittlement by Tin. The embrittling effect of tin has been observed in a range of austenitic and nickel-chromium steels, the degree of embrittlement increasing with strength level. Embrittlement depends on the presence of a tensile stress and is associated with intercrystalline penetration.

The embrittlement by solid tin occurs at approximately 120 °C (215 °F) below its melting point. The fracture surfaces exhibited an initial brittle zone perpendicular to the tensile axis that followed the prior-austenite grain boundaries. Layers of intermetallic compound present at the steel-tin interface did not impede the embrittlement process. Embrittlement has been observed in delayed-failure tests down to 218 °C (424 °F) (14 °C, or 25 °F, below the melting point of tin); however, in tensile tests, embrittlement by solid tin was effective at temperatures as low as 132 °C (270 °F), which is 100 °C (180 °F) below melting point.

An AISI 3340 steel doped with 500 ppm of phosphorus, arsenic, and tin has been tested in the presence of tin while in the segregated (temper embrittled) and the unsegregated states. Temper-embrittled steels were found to be more susceptible to embrittlement than steel heat treated to a nontempered state.

A lower fatigue limit and lifetime at stresses below the fatigue limit for low-carbon steel and for 18-8 stainless steel have been noted when tested in tin at 300 °C (570 °F). The exposure time to the tin before testing had no influence on the fatigue life of the steel.

Embrittlement of Austenitic Steels by Zinc. Two main types of interaction of zinc and austenitic stainless steel have been observed. Type I relates to the effects on unstressed material in which liquid metal penetration/erosion is the major controlling factor, and type II relates to stressed materials in which classic LMIE is observed.

Type I Embrittlement. Zinc slowly erodes unstressed 18-8 austenitic stainless steel at 419 to 570 °C (786 to 1058 °F) and penetrates the steel, with the formation of an intermetallic β nickel- zinc compound at 570 to 750 °C (1060 to 1380 °F). At higher temperatures, penetration along the grain boundaries occurs, with a subsequent diffusion of nickel into the zinc-rich zone. This results in a nickel-exposed zone adjacent to the grain boundaries, reducing the stability of the γ phase and causing it to transform to an α-ferrite; the associated volume change of the $\gamma \rightarrow \alpha$ transformation produces an internal stress that facilitates fracture along the grain boundaries. Similar behavior has been observed in an unstressed 316C stainless steel held 30 min at 750 °C (1380 °F), in which penetration occurred to a depth of 1 mm (0.04 in.), and in an unstressed type 321 steel held 2 h at 515 °C (960 °F), in which a penetration of 0.127 mm (0.005 in.) was observed.

Type II embrittlement occurs in stainless steel above 750 °C (1380 °F) and is characterized by an extremely fast rate of crack propagation that is several orders of magnitude greater than that of type I, with cracks propagating perpendicular to the applied stress. In laboratory tests, an incubation period was observed before the propagation of type II cracks, suggesting that they may be nucleated by type I cracks formed during the initial contact with zinc.

At 800 °C (1470 °F), a stressed type 316C stainless steel failed catastrophically when coated with zinc. Cracking was produced at a stress of 57 MPa (8 ksi) at 830 °C (1525 °F) and 127 MPa (18 ksi) at 720 °C (1330 °F), but failure was not observed at a stress of 16 MPa (2 ksi) at 1050 °C (1920 °F).

Liquid metal induced embrittlement may be produced by the welding of austenitic steels in the presence of zinc or zinc-base paints (Ref 16). Intercrystalline cracking has been observed in the heat-affected zone in areas heated from 800 to 1150 °C (1470 to 2100 °F), and electron microprobe analysis has been used to identify the

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

grain-boundary enrichment of nickel and zinc, together with the formation of a low-melting nickel-zinc compound. The embrittlement of sheet samples of austenitic steel coated with zinc dust dye and zinc chromate primer occurs at stresses of the order of 20 MPa (3 ksi).

Embrittlement of Ferritic Steels by Zinc. Embrittlement of ferritic steels and Armco iron by molten zinc has been reported in the temperature range of 400 to 620 °C (750 to 1150 °F). Long exposures and intercrystalline attack were needed to cause a reduction in the elongation to fracture; an iron-zinc intermetallic layer was formed that inhibited embrittlement until the layer was ruptured. High-alloy ferritic steels exhibit embrittlement by zinc at temperatures above 750 °C (1380 °F).

Delayed failure occurs in steel in contact with solid zinc at 400 °C (750 °F), which is 19 °C (34 °F) below the melting point of zinc. The slow crack growth region is characterized by intergranular mode of cracking.

Exposing AISI 4140 steel to solid zinc results in a decrease in the reduction of area and in fracture stress at 265 °C (510 °F), with no significant changes in the other mechanical properties. The tensile fracture initially propagates intergranularly, with the final failure occurring by shear. Liquid zinc embrittles 4140 steel at 431 °C (808 °F), and it has been shown that zinc is present at the crack tip.

Figure 16 shows a compilation of liquid metal embrittling and nonembrittling couples based on the theoretical calculations of the solubility parameter and the reduction in the fracture surface energy. The embrittlement curve is separated by brittle and ductile fracture. A concise summary of embrittlement couples is provided in Table 1. Both pure and alloyed solids are listed. References 8, 20, 22, 23, 24, and 26 are review articles that discuss embrittlement couples, some of which are not covered in Table 1.

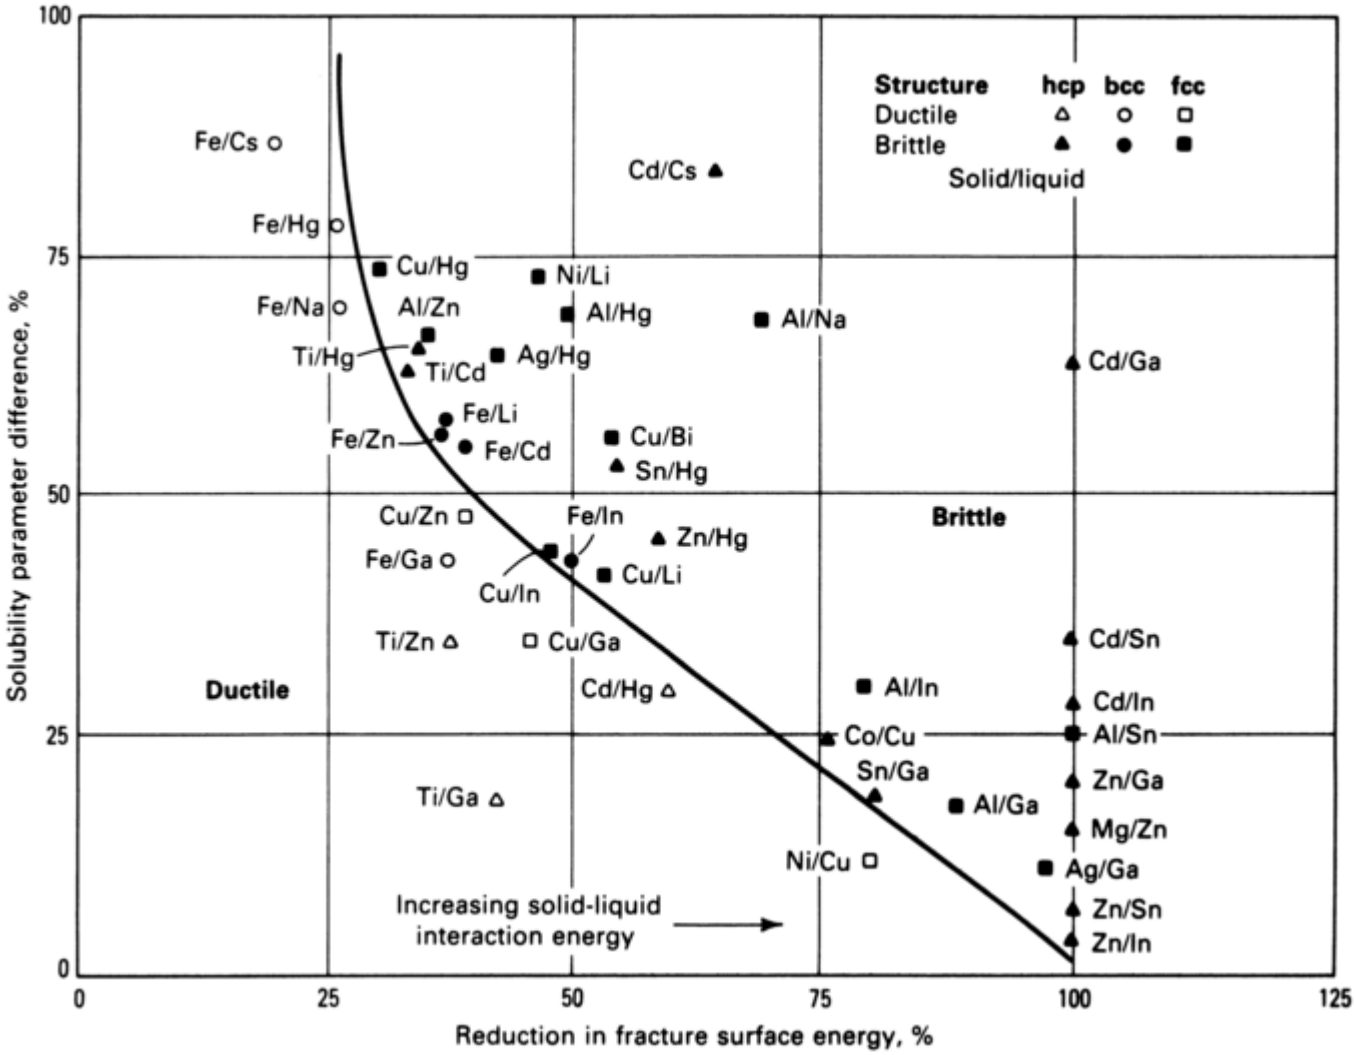

Fig. 16 Calculated reduction in the fracture surface energy relating to solubility parameter for many solid-liquid embrittlement couples. Note that the curve separates embrittlement couples from nonembrittled solid-liquid metal couples. hcp, hexagonal close-packed; bcc, body-centered cubic; fcc, face-centered cubic

Solid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Introduction

EMBRITTLEMENT that occurs below the melting point, T_m, of the embrittling species is known as solid metal induced embrittlement (SMIE) of metals. The severity of embrittlement increases with temperature (Ref 1), with a sharp and significant increase in severity at the T_m of the embrittling agent. Above T_m, embrittlement has all the characteristics of liquid metal induced embrittlement (LMIE), as described in the previous article in this Section.

Although SMIE of metals has not been mentioned or recognized as an embrittlement phenomenon in industrial processes, many instances of loss in ductility, strength, and brittle fracture of metals and alloys have been reported for electroplated metals and coatings or inclusions of low-melting metals below their T_m (Ref 2). Delayed failure of cadmium-plated high-strength steel has been observed below the T_m of cadmium (Ref 3, 4). Accordingly, cadmium-plated steel bolts, despite their excellent resistance to corrosion, are not recommended for use above 230 °C (450 °F). Notched tensile specimens of various steels are embrittled by solid cadmium. Solid cadmium, silver, and gold embrittle titanium. Leaded steels are embrittled by solid lead, with considerable loss in ductility below the T_m of lead; this phenomenon accounts for numerous elevated-temperature failures of leaded steels, such as radial cracking of gear teeth during induction-hardening heat treatment, fracture of steel shafts during straightening at elevated temperature, and heat treatment failure of jet engine compressor disks. Liquid and solid cadmium metal environments, as well as cadmium dissolved in inert nonembrittling coolant liquid, serve to embrittle the Zircaloy-2 nuclear fuel cladding tubes used in nuclear reactors (Ref 5). Inconel vacuum seals are cracked by solid indium. These reports of brittle failure clearly indicate the importance of SMIE in industrial processes.

Solid metal induced embrittlement was first recognized and investigated in the mid-1960s and early 1970s by studying the delayed failure of steels and titanium in a solid cadmium environment (Ref 6, 7, 8). Results of these studies are shown in Fig. 1 and 2. A systematic investigation of SMIE (Ref 9) of steel by a number of solid metal embrittling species found that solid metal as an external environment can cause embrittlement and for steels represents a generalized phenomenon of embrittlement (see Fig. 3 in the article, “Liquid Metal Induced Embrittlement”).

Solid metal induced embrittlement can also occur when the embrittling solid is an internal environment, that is, present in the solid as an inclusion (Ref 9). It has been clearly demonstrated that internally leaded steel is embrittled below the T_m of the lead inclusion of steel (Ref 9).

Brittle fracture in LMIE and SMIE is of significant scientific interest, because the embrittling species are in the vicinity of or at the tip of the crack and are not transported by dislocations or by slip due to plastic deformation into the solid, as is hydrogen in the hydrogen embrittlement of steels. Also, embrittling species are less likely to be influenced by the effects of grain- boundary impurities, such as antimony, phosphorus, and tin, which cause significant effects on the severity of hydrogen and temper embrittlement of metals. Investigations of SMIE and LMIE, therefore, can be interpreted less ambiguously than similar effects in other environments, such as hydrogen and temper embrittlement of metals. Thus, solid-liquid environmental effects provide a unique opportunity to study embrittlement mechanisms in a simple and direct manner under controlled conditions.

It is conceivable that a common mechanism may underlie solid, liquid, and gas phase induced embrittlement (Ref 10, 11, 12, 13, 14). The interactions at the solid-environment interface and the transport of the embrittling species to the crack tip may characterize a specific embrittlement phenomenon. A study of SMIE and LMIE may provide insights into the mechanisms of hydrogen and temper embrittlement. It is apparent that the phenomenon of SMIE is of both industrial and scientific importance. A review of the investigations of the occurrence and mechanisms of SMIE follows. See also the brief review paper by Lynch (Ref 1).

Solid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Characteristics of SMIE

To date, SMIE has been observed only in those couples in which LMIE occurs, suggesting that LMIE is a prerequisite for the occurrence of SMIE. Solid metal induced embrittlement may occur in the absence of LMIE if a brittle crack cannot be initiated at the T_m of the embrittling agent. A recent compilation of SMIE couples is given in Tables 1 and 2, which show that all solid metal embrittling agents are also known to cause LMIE.

Table 1 Occurrence of SMIE in steels

Solid metal induced embrittlement (SMIE) and liquid metal induced embrittlement (LMIE) are strikingly similar phenomena. The prerequisites for SMIE are the same as those for LMIE: intimate contact between the solid and the embrittling agent, the presence of tensile stress, crack nucleation at the solid/embrittling agent interface from a barrier (such as a grain boundary), and the presence of embrittling species at the propagating crack tip. Also, metallurgical factors that increase brittleness in metals, such as grain size, strain rate, increases in yield strength, solute strengthening, and the presence of notches or stress raisers, all appear to increase embrittlement. The susceptibility to SMIE is stress and temperature sensitive and does not occur below a specific threshold value. Embrittlement by delayed failure is also observed for both LMIE and SMIE (Table 3).

Some differences between LMIE and SMIE exist. Multiple cracks are formed in SMIE; in LMIE, a single crack usually propagates to failure. The fracture in SMIE is propagation controlled. However, crack propagation rates are at least 2 to 3 orders of magnitude slower than in LMIE. Brittle intergranular fracture changes to ductile shear because of the inability of the embrittling agent to keep up with the propagating crack tip. Incubation periods have been reported, indicating that the crack nucleation process may not be the same as in LMIE (Ref 15, 16, 17). Nucleation and propagation are two separate stages of fracture in SMIE.

These differences may arise because of the rate of reaction or interactions at the metal/embrittling agent interface and because the transport properties of solid and liquid metal embrittling agents are of significantly different magnitudes. It has been suggested that reductions in the cohesive strength of atomic bonds at the tip are responsible for both SMIE and LMIE (Ref 2, 15, 16, 18, 19). However, transport of the embrittling agent is the rate-controlling factor in SMIE. Another possibility is that stress-assisted penetration of the embrittling agent in the grain boundaries initiates cracking, but surface self- diffusion of the embrittling species similar to that proposed for LMIE controls crack propagation.

Solid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Investigations of SMIE

The first investigations of delayed failure were reported in cadmium-, zinc-, and indium-plated tensile specimens of 4340, 4130, 4140, and 18% Ni maraging steel in the temperature range of 200 to 300 °C (390 to 570 °F), as shown in Fig. 4 and 5. The results indicated that 4340 was the most susceptible and that 18% Ni maraging steel was the least susceptible alloy to cadmium embrittlement. The activation energy for steel-cadmium embrittlement was 39 kcal/mol (Fig. 3), which corresponded to diffusion of cadmium in the grain boundary. A thin, plated layer of nickel or copper has been reported to act as a barrier to the embrittling agent and to prevent SMIE of steel (Ref 3). Solid indium is reported to embrittle steels (Ref 16, 17), and an incubation period exists for crack nucleation.

Embrittlement of different steels in lead was investigated as both an external and internal (leaded steel) environment; SMIE was conclusively demonstrated to be a reproducible effect (Ref 2, 9). It was also demonstrated that SMIE is an extension of LMIE (Ref 2, 16). Internally leaded high-strength steels are susceptible to severe embrittlement in the range of the T_m of lead, and this embrittlement is a manifestation of LMIE. However, it was found that the onset of embrittlement occurs some 95 °C (200 °F) below the T_m of lead (330 °C, or 625 °F) and is continuous up to the T_m with no discontinuity or anomalies in the variation of the embrittlement with temperature (Ref 2). At the T_m of lead, a sharp increase occurs in the severity of embrittlement, and ductile-to-brittle transition occurs in the temperature range of 370 to 450 °C (700 to 840 °F). The same behavior was noted for pure lead as an external environment soldered onto 4140 steel, and such embrittlement has also been observed for surface coatings of zinc, lead, cadmium, tin, and indium on steel (Ref 2). Embrittlement manifests itself as a reduction in tensile ductility over a range of temperatures extending from approximately three-quarters of the absolute T_m of the embrittling agent up to the T_m (Ref 9). It has been shown that the embrittlement is caused by the growth of stable subcritical intergranular cracks and that crack propagation is the controlling factor in embrittlement (Ref 2, 16). This indicated that transport of embrittling agents to the crack tip was either by vapor phase or by surface or volume diffusion. In this study, the vapor pressure of the embrittling species at T_m varied widely and ranged from 20 to 6×10^{-36} Pa (1.5×10^{-1} to 4.5×10^{-38} torr) (Table 4). However, the crack propagation times for all embrittling agents were similar. The estimated values of the diffusion coefficients ranged in the vicinity of 10^{-4} to 10^{-6} cm^2/s (6.5×10^{-4} to 6.5×10^{-6} $in.^2/s$). These values are comparable to surface or self-diffusion of embrittling agent over embrittling agent and suggest that diffusion, not vapor transport, is the rate-controlling process.

There have been few studies of the SMIE of nonferrous alloys. A small amount of lead impurity has been shown to be detrimental to the failure resistance of an aluminum-magnesium- silicon alloy (Ref 20). Aluminum 7075 is embrittled by solid indium (Ref 21). A titanium alloy was shown to be susceptible to SMIE by cadmium, silver, and gold (Ref 22).

Solid Metal Induced Embrittlement

Revised by David G. Kolman, Los Alamos National Laboratory

Delayed Failure and Mechanism of SMIE

If a metal in contact with the embrittling species is loaded to a stress that is lower than that for fracture and is tested at various temperatures, then either the environment-induced fracture initiates and propagates instantaneously, as in a zinc-mercury LMIE couple, or delayed failure or static fatigue is observed. Examples of these two types of fracture processes are given in Table 3. Investigations of delayed failure provide an opportunity to separate crack nucleation from crack propagation and, specifically, to evaluate the transport-related role of the embrittling species. Solid metal induced embrittlement is a propagation-controlled fracture

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

process, and the time, temperature, and stress dependence of embrittlement presents an opportunity to study the kinetics of the cracking process.

The most critically investigated embrittlement system is 4140 steel embrittled by solid and liquid indium. Measurement of the decrease in electrical potential has been used to monitor crack initiation and propagation and to investigate the effects of temperature and stress level on delayed failure in 4140 steel by liquid and solid indium (Ref 15). The effects of temperature and stress level on the initiation time (incubation period for crack initiation) for both SMIE and LMIE are given in Fig. 6. The activation energy of the crack initiation process is approximately 37 kcal/mol and is essentially independent of the applied stress level. The activation energy represents the energy for stress-aided self-diffusion of both liquid and solid indium in the grain boundaries of the steel. Thus, crack initiation in both SMIE and LMIE occurs first by the adsorption of the embrittling agent at the site of crack initiation.

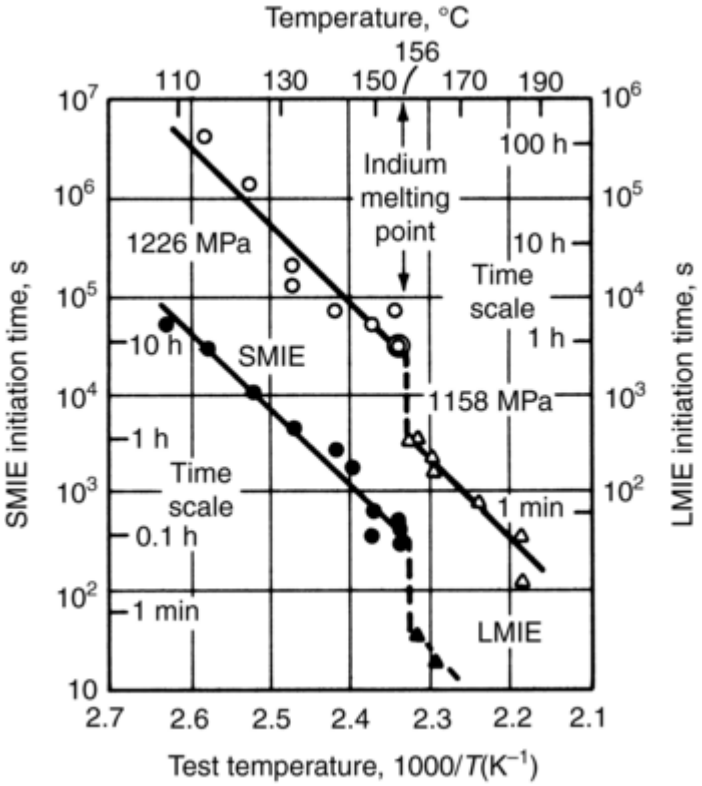

Fig. 6 Initiation time versus temperature in SMIE and LMIE of 4140 steel exposed to indium at two stress levels. Source: Ref 16

However, because of the presence of an incubation period, the rate-controlling process is stress-aided diffusion penetration of the base- metal grain boundaries. Such penetration reduces the stress necessary to initiate a crack, causing embrittlement of the base metal. On this basis, it is difficult to explain embrittlement of single crystals, which do not contain grain boundaries. Thus, rather than stress-aided diffusion penetration along grain boundaries, the embrittling species may reduce cohesion of atoms at the grain boundaries in accord with the reduction-in-cohesion mechanism. This mechanism would also explain SMIE of single crystals. Crack propagation time as a function of temperature and stress level for both SMIE and LMIE of steel by indium is plotted in Fig. 7. The activation energy for crack propagation for this couple was 5.6 kcal/mol, which represents the energy for self-diffusion of indium over indium. Thus, propagation is controlled by the diffusion of indium over several multilayers of indium adsorbed on the crack surface or by the so-called waterfall mechanism of embrittlement. This mechanism is a variation of that proposed and discussed in detail as the reduction-in-cohesion mechanism for LMIE.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

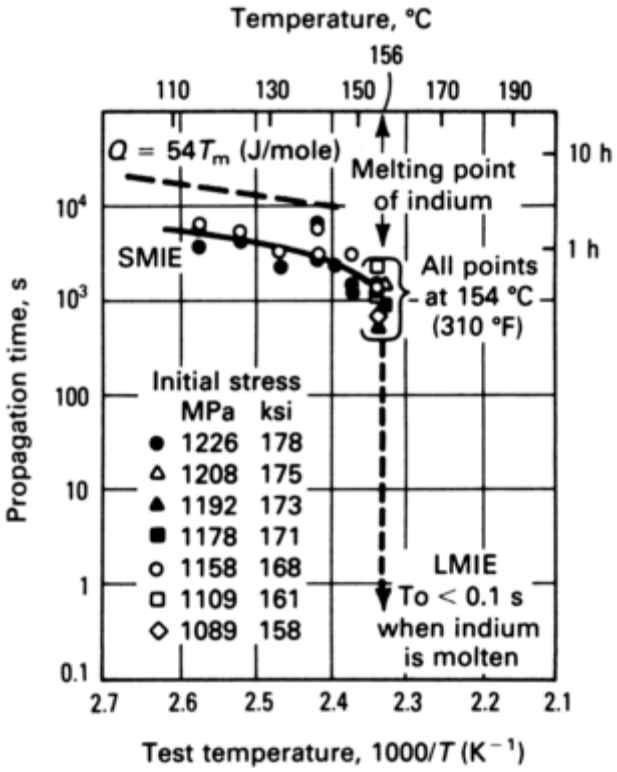

Fig. 7 Propagation time versus temperature for 4140 steel exposed to indium at various temperatures and stress levels. Note the occurrence of SMIE and LMIE and little dependence on stress level of test. Source: Ref 16

Adsorption of the embrittling agent at the solid surface is followed by the rate-controlling step of stress-aided diffusion of the embrittling agent in the grain boundary of the base metal. The embrittling agent reduces cohesion of the grain-boundary base-metal atoms, thus initiating a crack at a lower stress than that observed for the alloy in the absence of the embrittling species, resulting in embrittlement. Crack propagation occurs by multilayer self-diffusion of the embrittling species. These processes are valid for both LMIE and SMIE in the steel-indium embrittlement couple. It is clear that SMIE is similar to LMIE except that SMIE is a slower, embrittling agent transport-limited process. In this regard, the study of SMIE is important in eliminating the possibility in LMIE that a crack, once nucleated, may propagate in a brittle manner in the absence of the embrittling species at the tip of the crack. Solid metal induced embrittlement has only recently been recognized, and further research is needed concerning the effects of metallurgical, mechanical, and chemical parameters on embrittlement. However, it is clear that SMIE must be recognized as yet another phenomenon of environmentally induced embrittlement.

Microbiologically Influenced Corrosion

Stephen C. Dexter, University of Delaware

Introduction

A GREAT VARIETY of microscopic organisms (microorganisms) are present in virtually all natural aqueous environments, such as bays, estuaries, harbors, coastal and open ocean seawaters, as well as rivers, streams, lakes, and ponds. The same could be said for all manner of aqueous industrial fluids and waste waters. These organisms include many species of bacteria, algae, and fungi. In all of these environments, the tendency is for microorganisms present in the water to attach to and grow on the immersed surfaces of structural materials, resulting in the formation of a biological film, or biofilm. Larger, macroscopic organisms, such as the well-known barnacles and mussels, are also present in many environments. The presence of such macroorganisms can result in a heavy encrustation of hard-shelled fouling organisms on structures in coastal seawater. There is a voluminous amount of literature on the formation of biofilms and their adverse effects (Ref 1, 2, 3, 4, 5). The emphasis of this article on microbiologically influenced corrosion (MIC) is on the effects of the microscopic organisms and the by-products they produce on the electrochemical corrosion of metals.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The biofilms that form on the surface of structural metals and alloys immersed in aqueous environments have the capability to influence the corrosion of those metals and alloys. This influence derives from the ability of the organisms to change the environmental variables such as pH, oxidizing power, velocity of flow, and concentration of chemical species at the metal surface. Thus, the value of a given parameter at the metal-water interface within the biofilm may be quite different from that in the bulk electrolyte away from the interface. The result can be the initiation of corrosion under conditions in which there would be none in the absence of the film, a change in the mode of corrosion (that is, from uniform to localized), or an increase or decrease in the corrosion rate, as shown in Fig. 1 (Ref 6). It is important to note, however, that the presence of a biofilm does not necessarily mean that there will always be a significant effect on corrosion.

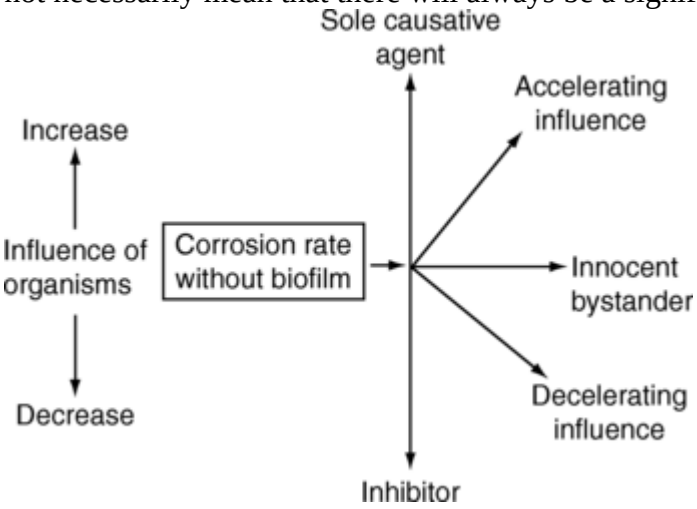

Fig. 1 Schematic showing that the influence microorganisms can have on corrosion ranges from sole causative agent to inhibitor. The most usual influence, however, is to change the mode of corrosion from general to localized and increase the rate of penetration. Source: Ref 6

Most of the documented cases in which biological organisms are the sole cause of, or an accelerating factor in, corrosion involve localized forms of attack. One reason for this is that organisms usually do not form in a continuous film on the metal surface. Additional information on biofilms can be found in the section “Community Structure and Formation of Biofilms” in this article. The large fouling organisms in marine environments settle as individuals, and it is often a period of months or even years before a complete cover is built up. A scatter of individual barnacles on a stainless steel surface creates oxygen concentration cells. The portion of the metal surface covered by the barnacle shell is shielded from dissolved oxygen in the water and thus becomes the anode through mechanisms described in the Section “Fundamentals of Corrosion” in this Volume. The result is crevice corrosion under the base of the barnacles, as shown in Fig. 2. A similar effect can take place on aluminum and, to a lesser extent, on structural steel. There is some evidence that the attack begins only after the animal dies (Ref 7).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

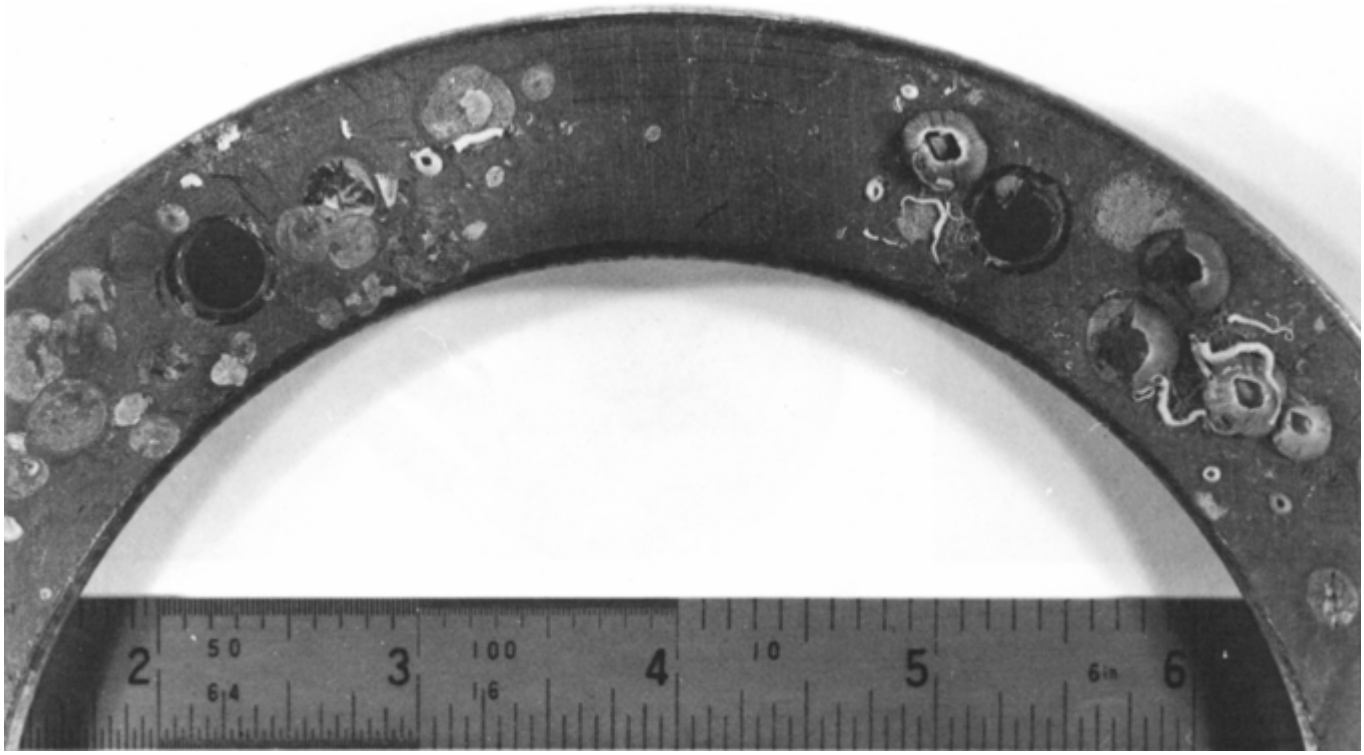

Fig. 2 Corrosion under a scatter of individual barnacles on a stainless steel surface

Microscopic organisms also tend to settle nonuniformly on metal surfaces. In some cases, they form discrete colonies; in other cases, they form biofilms with nominally complete coverage of the immersed surface. In the latter case, however, the distribution of organisms within the biofilm is usually extremely heterogeneous, leading to sharp chemical gradients both along the metal surface and perpendicular to it.

The purpose of this article is to consider in general the characteristics of organisms that allow them to interact with corrosion processes, the mechanisms by which organisms can influence the occurrence or rate of corrosion, and the types of corrosion most often influenced by microbes. In addition, the industries most often reported as being affected by microbiological corrosion are listed, along with the organisms usually implicated in the attack. The types of attack that have most commonly been documented are illustrated by generalized case histories for different classes of alloys. Cases that are still in the research stage or cases in which evidence for a primary role of the biofilm is not convincing are not covered. Sources of further information on MIC are listed in the Selected References and References at the end of this article.

Microbiologically Influenced Corrosion

Stephen C. Dexter, University of Delaware

General Characteristics of Microbes

The organisms that are known to have an important impact on corrosion are mostly microorganisms such as bacteria, algae, and fungi (yeasts and molds). In this section, the general characteristics of the microorganisms that facilitate their influence on the electrochemistry of corrosion are discussed (Ref 8, 9, 10, 11).

Physical Characteristics. Microorganisms range in length from 0.1 to over 5 μm (some filamentous forms can be several hundred micrometers long) and up to approximately 3 μm in width. Many of them are motile; that is, they can "swim" to a favorable, or away from an unfavorable, environment. Because of their small size, they can reproduce themselves in a short time. Under favorable conditions, some bacteria can double in number every 20 min or less. Thus, a single bacterium can produce a mass of over one million microorganisms in less than 7 h.

In addition to rapid reproduction, the bacteria as a group can survive wide ranges of temperature (-10 to >100 °C, or 15 to >212 °F), pH (~0 to 10.5), dissolved oxygen concentration (0 to saturation), pressure (vacuum to >31 MPa, or 4500 psi), and salinity (tolerances vary from the parts per billion range to approximately 30% salt). Despite these wide ranges of tolerance for the microorganisms as a whole, most individual species have much narrower ranges. Most bacteria that have been implicated in corrosion grow best at temperatures of 15 to 45 °C (60 to 115 °F) and a pH of 6 to 8. Oxygen requirements vary widely with species. Microbes may be obligate aerobes (require oxygen for growth), microaerophilic (require minute levels of oxygen for growth), facultative anaerobes (grow with or without oxygen), or obligate anaerobes (grow only in the complete absence of oxygen).

Some microbes can produce spores that are resistant to a variety of environmental extremes, such as drying, freezing, and boiling. Spores have been known to survive for hundreds of years under arctic conditions and then to germinate and grow when conditions become favorable. Many microbes can adapt quickly to a wide variety of compounds as food sources. This gives them high survivability under changing environmental conditions.

Metabolic Characteristics. Many of the microorganisms implicated in corrosion are able to have an influence on the electrochemical reactions involved by virtue of chemical compounds consumed and the products produced during the course of their metabolism. A large percentage of them can form extracellular polymeric materials termed simply *polymer*, or *slime*. The slime is involved in attaching the organisms to the surface, trapping and concentrating nutrients for the microbes to use as food, and often, in shielding the organisms from the toxic effect of biocides. The slime film can influence corrosion by trapping or complexing heavy-metal ions near the surface. It can also act as a diffusion barrier for chemical species migrating to or from a metal surface, thus changing the chemical concentrations and pH at and near the solid-liquid interface where the corrosion takes place.

Some species of microbes can produce organic acids, such as formic and succinic, or mineral acids, such as H_2SO_4. These chemicals are corrosive to many metals. One series of bacteria is involved in metabolizing nitrogen compounds. As a group, they can reduce nitrates (NO^{-3}) (often used as corrosion inhibitors) to nitrogen (N_2) gas. Others can convert nitrates to nitrite, or vice versa, or they can break it down to form ammonia (NH_3). Still other series of bacteria are involved in the transformation of sulfur compounds (Fig. 3). They can oxidize sulfur or sulfides to sulfates (SO_4^{2-}) (or H_2SO_4), or they can reduce sulfates to sulfides, often producing corrosive H_2S as an end product.

مرجع مهندسی مواد و متالورژی

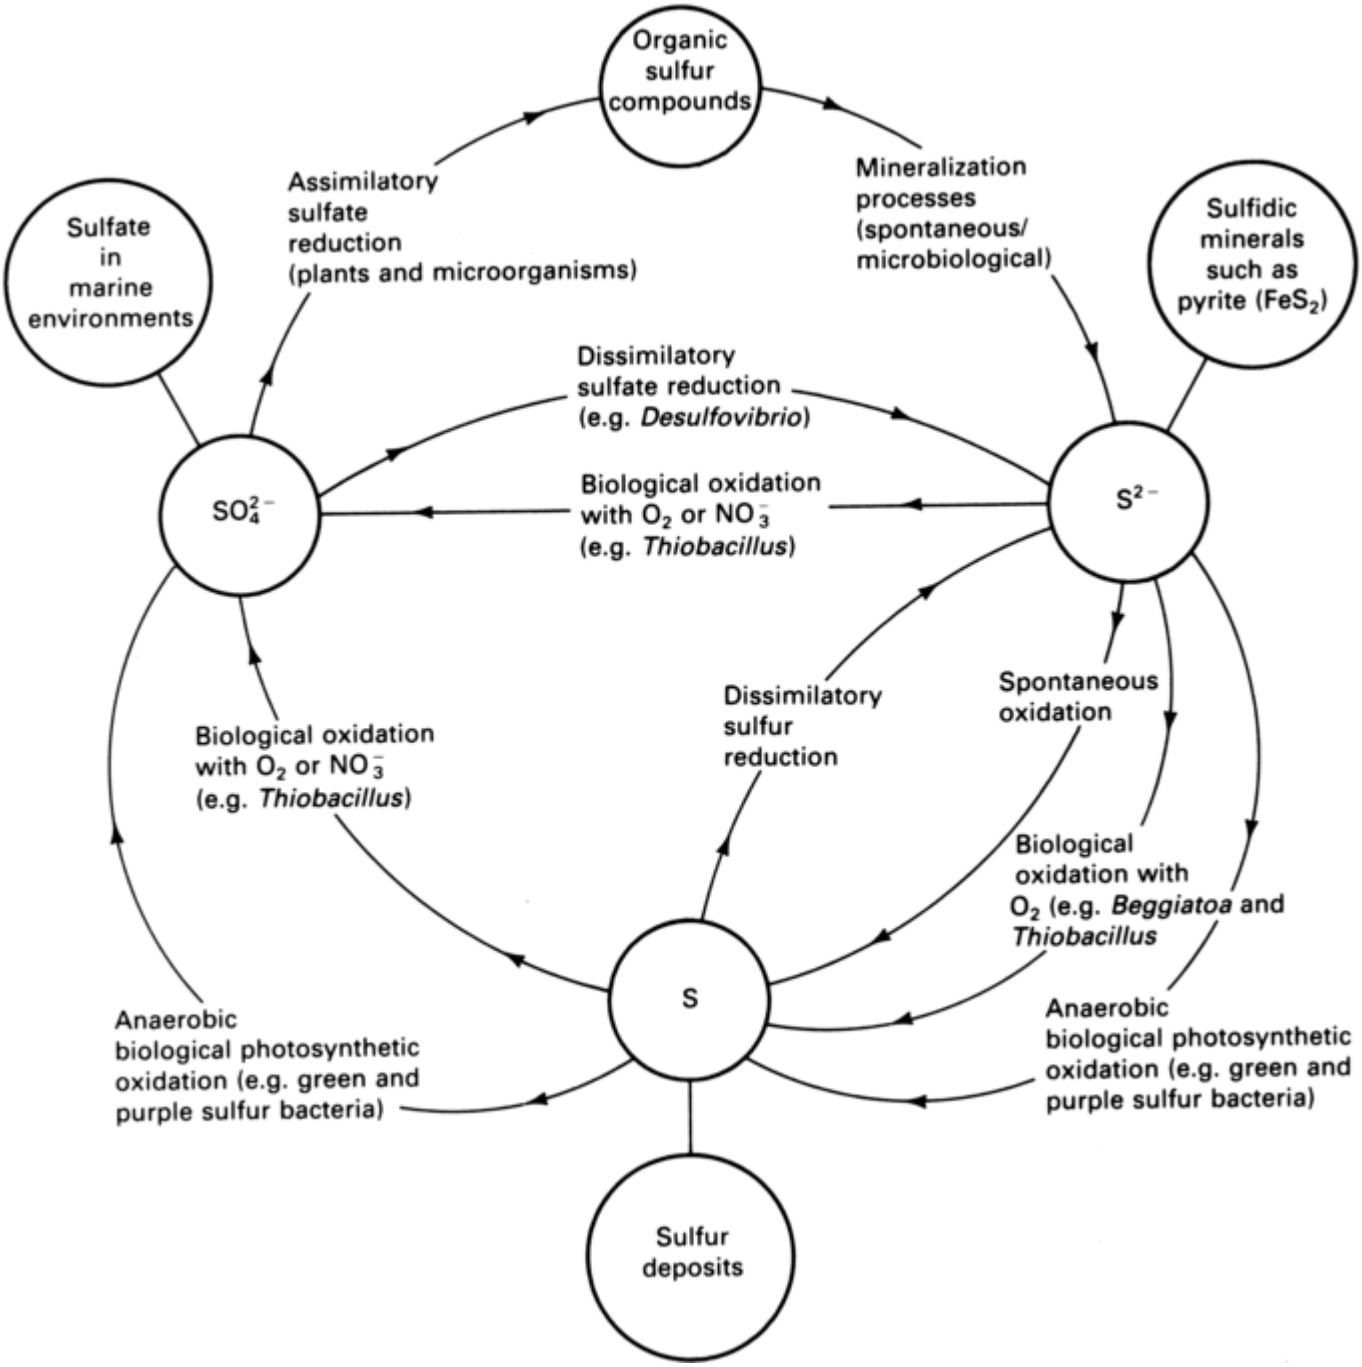

Fig. 3 The sulfur cycle showing the role of bacteria in oxidizing elemental sulfur to sulfate (SO_4^{2-}) and in reducing sulfate to sulfide (S^{2-}). Source: Ref 12

Organisms that have a fermentative type of metabolism produce carbon dioxide (CO_2) and hydrogen (H_2). Other microbes can use CO_2 and H_2 as sources of carbon and energy, respectively. Numerous species of bacteria and algae either produce or use oxygen. It is rare that a corrosion process does not depend on the concentration of at least one of these three dissolved gasses. Finally, some bacteria are capable of being directly involved in the oxidation or reduction of metal ions, particularly iron and manganese. Such bacteria can shift the chemical equilibrium between Fe, Fe^{2+}, and Fe^{3+}, which often influences the corrosion rate.

Organisms Involved in MIC Corrosion

A select number of organisms are repeatedly reported as causing corrosion in environments in which there would be none without them, or accelerating corrosion, or changing a relatively slow rate of general corrosion into one with rapid localized penetration of the metal. These organisms are listed in Table 1.

Table 1 Microorganisms most commonly implicated in biological corrosion

Genus or species	pH range	Temperature range		Oxygen requirement	Metals affected	Action
		°C	°F			
Bacteria						
***Desulfovibrio* (best known: *D. desulfuricans*)**	4–8	10–40	50–105	Anaerobic	Iron and steel, stainless steels, aluminum, zinc, copper alloys	Use hydrogen in reducing SO_4^{2-} to S^{2-} and H_2S; promote formation of sulfide films
***Desulfotomaculum* (best known: *D. nigrificans*, also known as *Clostridium*)**	6–8	10–40 (some at 45–75)	50–105 (some at 115–165)	Anaerobic	Iron and steel, stainless steels	Reduce SO_4^{2-} to S^{2-} and H_2S (spore formers)
Desulfomonas	…	10–40	50–105	Anaerobic	Iron and steel	Reduce SO_4^{2-} to S^{2-} and H_2S
Acidithiobacillus thiooxidans	0.5–8	10–40	50–105	Aerobic	Iron and steel, copper alloys, concrete	Oxidizes sulfur and sulfides to form H_2SO_4; damages protective coatings

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Acidithiobacillus ferrooxidans	1–7	10–40	50–105	Aerobic	Iron and steel	Oxidizes ferrous (Fe^{2+}) to ferric (Fe^{3+})
Gallionella	7–10	20–40	70–105	Aerobic	Iron and steel, stainless steels	Oxidizes ferrous to ferric ions and manganous to manganic ions; promotes tubercule formation
Siderocapsa* Type species: *S. treubii	Unknown	Unknown	Unknown	Low oxygen	Iron and carbon steel	Oxidizes iron
Leptothrix	6.5–9	10–35	50–95	Aerobic	Iron and steel	Oxidizes ferrous to ferric ions and manganous to manganic ions
Sphaerotilus	7–10	20–40	70–105	Aerobic	Iron and steel, stainless steels	Oxidizes ferrous to ferric ions and manganous to manganic ions; promotes tubercule formation
S. natans	…	…	…	…	Aluminum alloys	…
Pseudomonas	4–9	20–40	70–105	Aerobic	Iron and steel, stainless steels	Some strains can reduce Fe^{3+} to Fe^{2+}
P. aeruginosa	4–8	20–40	70–105	Aerobic	Aluminum alloys	…
Fungi						
Cladosporium resinae	3–7	10–45 (best at 30–35)	50–115 (best at 85–95)	…	Aluminum alloys	Produces organic acids in metabolizing certain fuel constituents

Formation of Biofilms

Community Structure and Formation of Microbial Biofilms. The ability of an organism to survive on a surface and to influence corrosion is often related to associations between that organism and those of other species. The bacteria implicated in corrosion may begin their lives on a metal surface as a scatter of individual cells, as shown in Fig. 4(a). As the biofilm matures, however, the organisms are usually found as individuals or in

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

colonies embedded in the matrix of a semicontinuous and highly heterogeneous biofilm (Fig. 4 b,c). It is in this latter configuration that there is the most potential for survival and growth of the organisms capable of influencing corrosion.

Fig. 4 Various forms of bacterial film that can influence corrosion. (a) Scatter of individual cells. 6050×. (b) Semicontinuous film of bacteria in slime. 3150×. (c) Bacterial cells in a colony. 2700×

Immersion of any solid surface in a natural aqueous environment, such as seawater or fresh water from lakes, rivers, streams, and ponds, initiates a continuous and dynamic process, beginning with adsorption of nonliving, dissolved organic material and continuing through the formation of bacterial and algal slime films. The process of colonization begins immediately on immersion with the adsorption of a nonliving organic conditioning film. This conditioning film is nearly complete within the first 2 h of immersion, at which time the initially colonizing bacteria begin to attach in substantial numbers. The bacterial, or primary, slime film develops over a period of 24 to 72 h in most natural waters, depending on the temperature, although further changes in the film can often be observed over more than a 2 month period.

The physical structure of the biofilm is heterogeneous, starting with a thin base layer of organisms embedded in extracellular polymeric substances. Depending on the velocity of fluid flow, that base layer may be anywhere from 10 to 100 μm in thickness, and it may cover from less than 20% to more than 90% of the metal surface. On top of the base film is a columnar, or cauliflower-like, structure extending out into the bulk fluid. Between and around the columnar entities is a network of microchannels through which water may flow (Ref 13, 14, 15), as shown in Fig. 5. Microscopic observations (Ref 15) indicate that such a biofilm may contain diverse microbial populations, including coccoidal, rod- shaped, chain-forming, and filamentous microorganisms (Fig. 6, 7, 8).

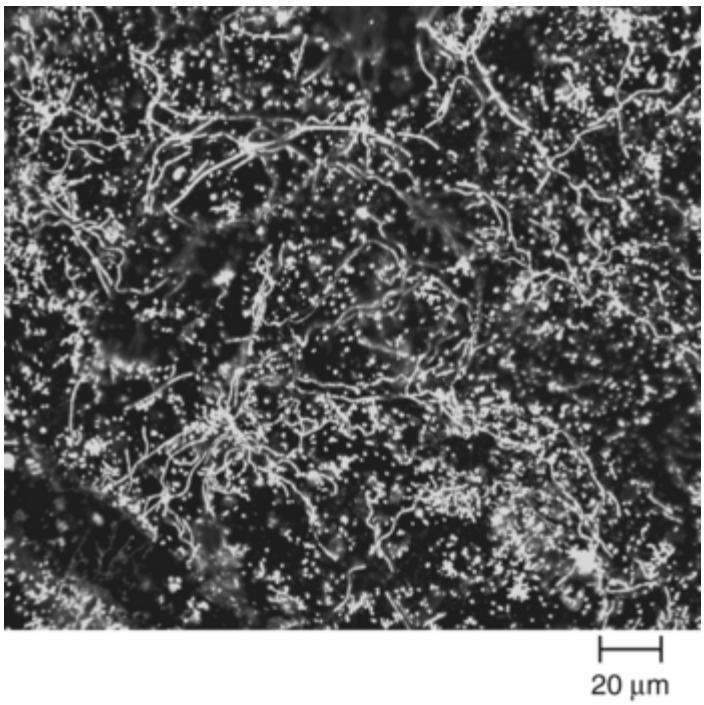

Fig. 8 Filamentous and coccoidal microorganisms observed on a UNS S20910 (Nitronic 50) alloy surface immersed in natural seawater for 42 days. Source: Ref 16

Mature biofilms in most aqueous environments including seawater are composed of microorganisms, the by-products of their metabolism, trapped detrital materials, and corrosion products. In the outer portions of the biofilm, aerobic heterotrophic bacteria consume oxygen and produce metabolites useful to other organisms residing nearby and beneath them in the biofilm. This produces favorable microenvironments for anaerobic microorganisms to grow in a synergistic community on an immersed metal surface (Ref 17, 18, 19, 20). For example, the sulfate- reducing bacteria (SRB) are implicated in the corrosion of iron-base alloys in a variety of environments (Ref 10, 12, 17, 21). The traditional view is that most SRB are obligate anaerobes, yet they are

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

known to accelerate corrosion in aerated environments. This becomes possible when the aerobic organisms in the outer portions of the columnar structure create an anaerobic microenvironment with the organic acids and nutrients necessary for growth of the SRB close to the metal surface (Fig. 9). Thus, the organisms influencing corrosion can often flourish at the corrosion site by associating with other organisms in a microbial colony or consortium, even when the bulk environment is not conducive to their growth. This traditional view is currently being challenged by recent research showing many SRB are microaerophillic and able to function under low oxygen conditions at any depth of the biofilm.

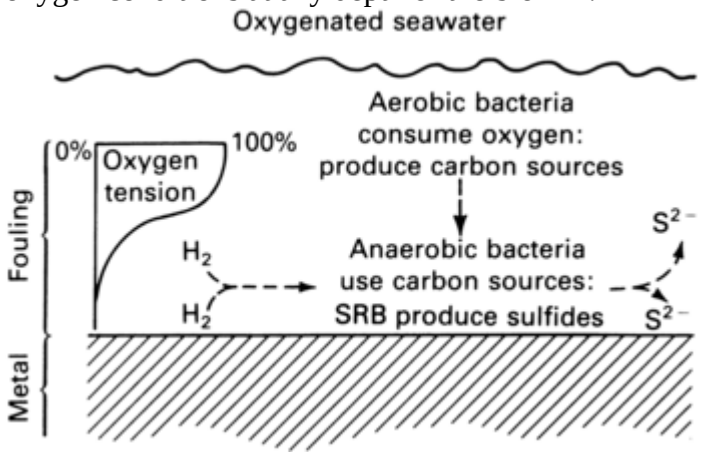

Fig. 9 Variations through the thickness of a bacterial film. Aerobic organisms near the outer surface of the film consume oxygen and create a suitable habitat for the sulfate-reducing bacteria (SRB) at the metal surface. Source: Ref 17

It should be noted that the dynamics of fluid flow past the metal surface can alter the form of the biofilm or even prevent its formation. This can result in acceleration or deceleration of corrosion, depending on the role of the biofilm. See the section “Corrosion Inhibition by Bacteria” in this article for additional information on inhibitive effects.

Formation of Macrofouling Films. In addition to the microbial biofilms discussed previously, natural seawater typical of coastal oceanic and estuarine environments worldwide supports the settlement and growth of a great variety of macroscopic plants and animals. In such marine environments, the fouling film, which starts with the formation of a microbial biofilm, often becomes dominated by the growth of the macroscopic organisms within weeks to months of immersion. The exact process of colonization is complex, depending on location, temperature, climate, and the nature of the surface being colonized. Additional information on the formation of macrofouling films is available (Ref 1, 2, 3, 4, 5).

A heavy encrustation of biofouling organisms on structural steel immersed in seawater often decreases the corrosion rate of the steel, as long as the cover of organisms remains complete and relatively uniform. The heavy fouling layer acts as a barrier film in limiting the amount of dissolved oxygen reaching the metal surface. A layer of hard-shelled organisms, such as barnacles or mussels, on steel in the splash zone (just above the high-tide level) also shields the metal from the damaging effect of wave action. It should be emphasized that these beneficial effects on general corrosion occur under a complete fouling layer. If coverage is incomplete, as shown in Fig. 10, the fouling film is then more likely to cause the initiation of localized corrosion by creating oxygen concentration cells. The beneficial effects may also be lost if the fouling film leads to a high activity of SRB at the metal surface. A heavy encrustation of these macroorganisms also can have a number of undesirable physical effects on marine structures. The fouling layer increases both weight and hydrodynamic drag on the structure. Interference with the functioning of moving parts also may occur.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

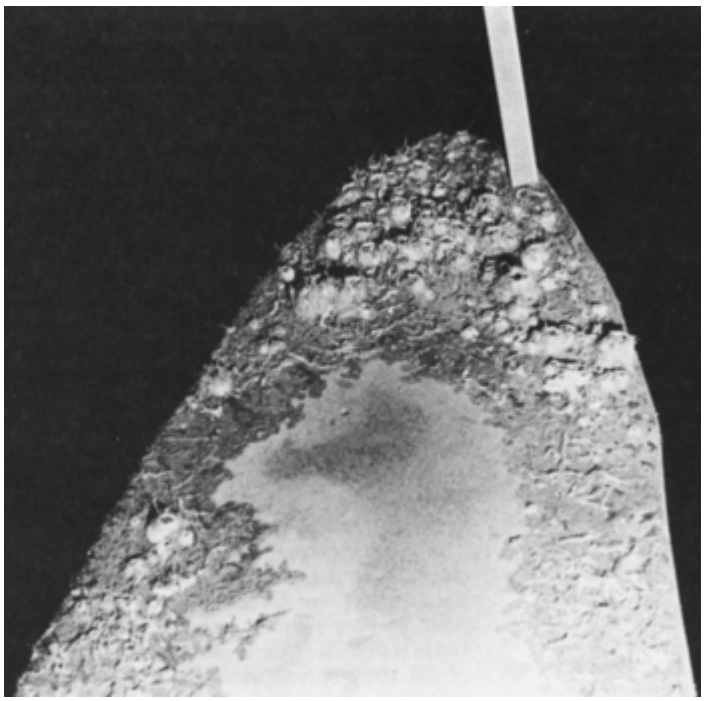

Fig. 10 Barnacles attached to the periphery of a high-strength steel rudder, which had originally been coated with an antifouling paint. During use, the paint around the edges had been removed by mechanical action, thus allowing the attachment of barnacles. Partial coverage of such macroorganisms can lead to localized corrosion. Complete coverage can sometimes provide a barrier film and limit corrosion. Courtesy of B. Little, Naval Ocean Research and Development Activity, Department of the Navy

As documented in the following sections, the influence of biofilms on the rate at which corrosion propagates can range from acceleration to inhibition. In a few well-documented situations, the organisms are the sole cause of corrosion, while in other cases, they may be innocent bystanders, having little to no effect. The challenge from the corrosion engineering perspective is to determine when the influence of the organisms is important enough that effective corrosion control cannot be achieved without specifically addressing the microbial effect.

Microbiologically Influenced Corrosion

Stephen C. Dexter, University of Delaware

General Mechanisms by Which Biological Organisms Influence Corrosion

The presence of a biological film on a corroding metal surface does not introduce some new type of corrosion, but it may influence the occurrence and/or the rate of all currently known types of corrosion. The net effect of both micro- and macrobiofouling film formation on corrosion is variable. The most usual effect of both types of fouling is to make corrosion of the metal substratum more localized than it would be in water with the same bulk chemistry but without microorganisms. This effect is a consequence of the heterogeneity of the biofilm, which in turn leads to an increase in the variability of the chemical environment from place to place along the metal surface.

Microbial biofilms change the chemistry at the metal-liquid interface in a number of ways that have an important bearing on corrosion. As the biofilm grows, the bacteria in the film produce a number of by-products. Among these are organic acids, hydrogen sulfide, and protein-rich polymeric materials commonly known as *slime.* The first effect of the composite film of bacteria and associated polymer is to create a diffusion barrier between the metal-liquid interface and the bulk seawater. The barrier itself is over 90% water, so it does not truly isolate the interface. Instead, it supports strong concentration gradients, both parallel and perpendicular to the metal surface (Ref 22). Thus, the water chemistry at the interface may be different from that in the bulk water, although the two are closely coupled through diffusive processes. These biological influences can be divided into four general categories:

- Production of organic and inorganic acids as metabolic by-products

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- Production of sulfides under oxygen-free (anaerobic) conditions
- Introduction of new redox reactions
- Production of oxygen or chemical concentration cells

Acid Production. The sulfur-oxidizing bacteria can produce up to approximately 10% H_2SO_4. This mineral acid, with its accompanying low pH, is highly corrosive to many metals, ceramics, and concrete. Other species of bacteria produce organic acids (e.g., acetic, citric, succinic, lactic) that are corrosive to metal surfaces (Ref 5). The acids produced by these organisms can also contribute to corrosion by aiding the breakdown of coatings systems. Alternatively, other organisms that have no direct influence on corrosion may be involved in the breakdown of coatings. The breakdown products are then sometimes usable as food by the acid-producing bacteria, ultimately leading to accelerated corrosion of the underlying metal. Organic acids produced by fungi were identified as the cause of pitting failures in painted carbon steel holds on a bulk carrier and aluminum fuel storage tanks (Ref 5). Acid production is discussed further in the section “Concrete” in this article.

Bacterial action on decaying organic matter in the slime film can also result in the production of ammonia and sulfides. Ammonia causes stress-corrosion cracking of copper alloys (Ref 23), and sulfides have been implicated in accelerated localized and/or uniform corrosion of both copper alloys and steels (Ref 5).

Anaerobic Sulfide Production. The most thoroughly documented case in which microbes are known to cause corrosion is that of iron and steel under anaerobic conditions in the presence of SRB. Based on electrochemistry, deaerated soils of near-neutral pH are not expected to be corrosive to iron and steel. However, if the soil contains SRB and a source of sulfates, rapid corrosion has been found to occur.

The classical mechanism originally proposed for this corrosion involved the removal of atomic hydrogen from the metal surface by the bacteria using the enzyme hydrogenase (Ref 24). The removed hydrogen was then supposedly used by the bacteria in the reduction of sulfates to sulfides. The following set of equations was proposed to explain this mechanism:

$Fe \rightarrow 4Fe^{2+} + 8e^{-}$ Anodic reaction (Eq 1)

$8H_2O \rightarrow 8H^{+} + 8OH^{-}$
Dissociation of water (Eq 2)

$8H^{+} + 8e^{-} \rightarrow 8H$ Cathodic reaction (Eq 3)

$SO_4^{2-} + 8H \xrightarrow{SRB} S^{2-} + 4H_2O$
Cathodic depolarization (Eq 4)

$Fe^{2+} + S^{2-} \rightarrow FeS$ Corrosion product (Eq 5)

$3Fe^{2+} + 6OH^{-} \rightarrow 3Fe(OH)_2$
Corrosion product (Eq 6)

Without SRB, the mechanism would stop after Eq 3, when the surface became covered by a monolayer of hydrogen. According to the theory, this hydrogen is stripped off by the bacteria, a process known as *cathodic depolarization;* this process allows corrosion to continue. It is now recognized that this original mechanism, although it undoubtedly plays an important role, does not represent the entire process (Fig. 11). It has been shown that the iron sulfide (FeS) film produced is protective if continuous, but that it causes galvanic corrosion of the bare iron underneath if defective. The bacteria thus transform a benign environment into an aggressive one in which steel corrodes quite rapidly. Other corrosive substances, such as H_2S, can also be produced. The SRB also have been identified as contributors to the corrosion of stainless, copper, and aluminum alloys (Ref 5, 12, 21).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

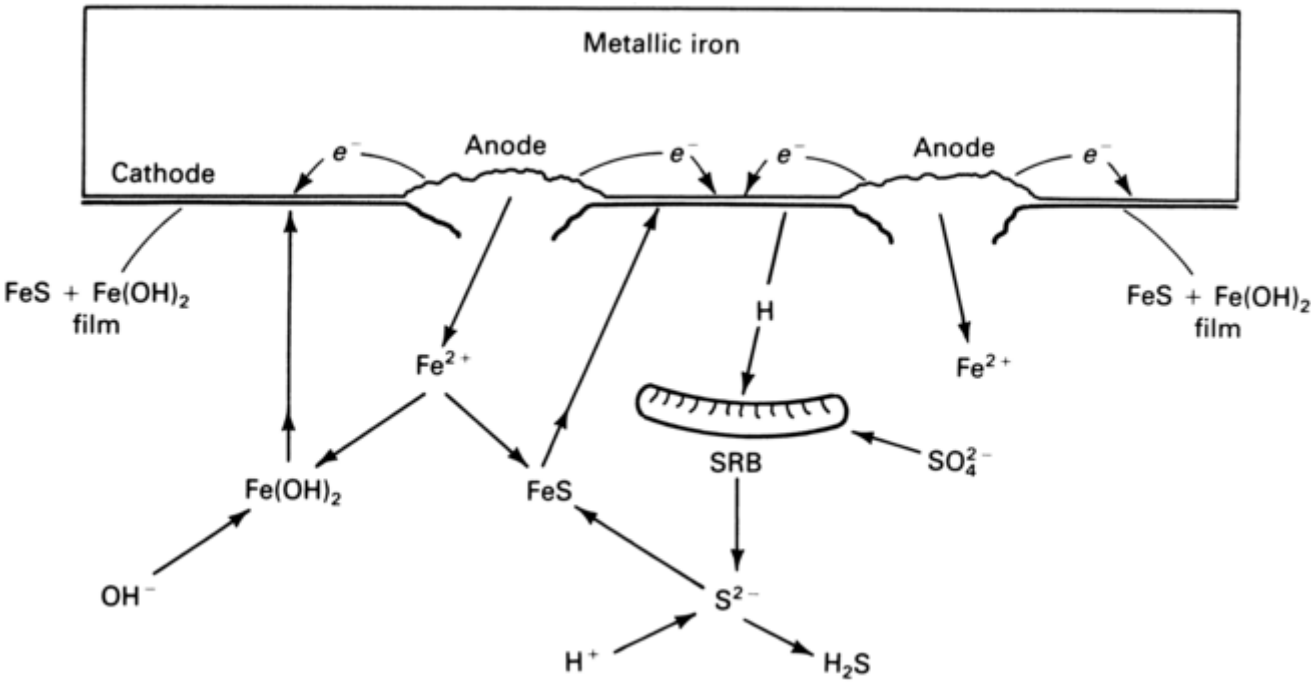

Fig. 11 Schematic of the anaerobic corrosion of iron and steel showing the action of sulfate-reducing bacteria (SRB) in removing hydrogen from the surface to form FeS and H_2S

Introduction of New Redox Reactions. Biofilms are able to accumulate ions, such as the heavy metals manganese and iron, in concentrations far above those in the surrounding bulk water. For example, the concentration of dissolved Mn^{2+} is in the nanomolar range in Lower Delaware Bay seawater (Ref 25). Within a biofilm grown on a passive alloy in that same seawater, the concentration is in the micromolar range (Ref 21), and the total manganese is in the millimolar range (Ref 25). The presence of these compounds makes new redox reactions available to the corrosion process, particularly to the cathodic reaction.

To use manganese again as an example, the following reactions have been proposed for the acceleration of corrosion reactions by manganese redox cycling within biofilms. Linhardt (Ref 26) originally proposed the two-electron transfer reduction of MnO_2 directly to Mn^{2+}. The one-electron transfer reduction of MnO_2 to solid MnOOH is discussed in Ref 27:

$$MnOOH + 3H^+ + e^- \rightarrow Mn^{2+} + 2H_2O \quad \text{(Eq 7)}$$

Or by disproportionation:

$$2MnOOH + 2H^+ \rightarrow MnO_2 + Mn^{2+} + 2H_2O \quad \text{(Eq 8)}$$

It was concluded that disproportionation of the solid MnOOH by Eq 8 was unlikely, because the free energy of formation was positive under the test conditions, and that reduction by Eq 7 would allow for reoxidation in the presence of manganese-oxidizing bacteria to keep the redox cycle going.

Alternately, the reduction of MnO_2 via a soluble Mn^{3+} intermediate is (Ref 25):

$$4H^+ + MnO_2 + 1e^- \rightarrow Mn^{3+} + 2H_2O \quad \text{(Eq 9)}$$

$$2H_2O + 2Mn^{3+} \rightarrow MnO_2 + Mn^{2+} + 4H^+ \quad \text{(Eq 10)}$$

$$2H_2O + Mn^{2+} + O_2 \rightarrow Mn^{3+} + 4OH^- + 1e^- \quad \text{(Eq 11)}$$

Equation 9 describes the one-electron reduction of MnO_2 to a soluble Mn^{3+} species, which is metastable and disproportionates quickly to Mn^{4+} and Mn^{2+} in seawater (Eq 10) unless complexed by strong organic ligands (Ref 25). These reactions explain the production of MnO_2 and Mn^{2+} in the absence of dissolved oxygen. If oxygen is present, it can reoxidize Mn^{2+} back to Mn^{3+} (Eq 11), where Eq 10 can occur again. If oxygen is not present, Mn^{3+} disproportionation alone can still account for the results, because MnO_2 can never be fully depleted. This manganese redox cycle can include both inorganic and biological processes.

Oxygen and Chemical Concentration Cells. Any biofilm that does not provide for complete, uniform coverage of the entire immersed surface of a metal or alloy has the potential to form concentration cells. Two chemical

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

species, oxygen and hydrogen, that are often implicated (or even rate controlling) in corrosion are also important in the metabolism of the bacteria. A given bacterial slime film can be a source or a sink for either oxygen or hydrogen. Moreover, these films are rarely continuous. Usually, they provide only spotty coverage of the metal surface. Thus, they are capable of inducing oxygen (or other chemical) concentration cells. In aerated environments, areas of the metal surface between the columnar structures of the biofilm may be in contact with oxygenated electrolyte. These areas with relatively high oxygen concentrations within the biofilm are cathodic relative to areas with less oxygen. Beneath a microbial colony, oxygen is depleted as it is used by the organisms in their metabolism. Oxygen from the bulk electrolyte is unable to replenish those areas because of a combination of effects. First, oxygen migration through the film is slowed by the diffusion barrier effect, and second, oxygen that does penetrate the film is immediately used by the microbial metabolism. Formation of such a corrosion cell, as shown in Fig. 12, causes a pit to form at the anodic area under the bacterial colony.

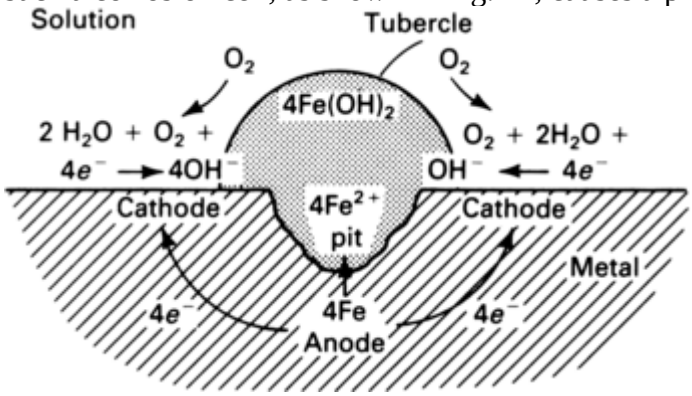

Fig. 12 Schematic of pit initiation and tubercle formation due to an oxygen concentration cell under a biological deposit. Source: Ref 21

As the pit grows, iron dissolves according to the anodic reaction:

$$Fe \rightarrow Fe^{2+} + 2e^- \qquad \text{(Eq 12)}$$

The cathodic reaction is reduction of dissolved oxygen outside the pit to form OH^- according to:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \qquad \text{(Eq 13)}$$

The insoluble ferrous hydroxide corrosion product forms by the reaction:

$$3Fe^{2+} + 6OH^- \rightarrow 3Fe(OH)_2 \qquad \text{(Eq 14)}$$

Corrosion products mingle with polymer from the bacterial film to form a corrosion tubercule, which itself may cause a problem with obstruction of fluid flow in piping systems. In addition, if the previously mentioned process takes place in the presence of bacteria capable of oxidizing ferrous ions to ferric ions, the corrosion rate is accelerated, because the ferrous ions are removed from solution as soon as they are produced. This depolarizes the anode and accelerates corrosion of iron under the deposit. The ferric ions form ferric hydroxide ($Fe(OH)_3$), which contributes to the rapid growth of the tubercule. This process has been responsible for corrosion and plugging of iron water pipes.

If chlorides are present in the system, the pH of the electrolyte trapped inside the tubercule may become very acid by the autocatalytic process of metal hydrolysis similar to that described in the articles “Evaluating Pitting Corrosion ” and “Evaluating Crevice Corrosion” in this Volume. Chloride ions from the environment combine with ferric ions produced by corrosion in the presence of the bacteria to form a highly corrosive, acidic ferric chloride solution inside the tubercule. This has been responsible for severe pitting of stainless steel piping systems, as described in the section “MIC of Passive Alloys” in this article.

Another example of a chemical concentration cell is that between manganese- and sulfide-rich areas. Whenever microbial sulfate reduction and manganese deposition occur simultaneously within biofilms, then a differential potential cell is likely to form at the metal surface. The microbially mediated manganese redox cycle drives the metal open-circuit potential in the noble direction, whereas bacterial sulfide production drives it in the active direction. Thus, when a manganese-oxidizing microcolony and an SRB microcolony form at different sites on the same metal surface, a differential potential cell may be created. The area under sulfide species becomes anodic, while the area under manganese species becomes cathodic. Localized corrosion is likely to initiate at the metal surface as a result of the differential potential cell.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The cathodic site would be expected to form where manganese had accumulated and manganese-oxidizing microorganisms were active. The dominant cathodic reaction at this site would involve the reduction of Mn(III) or Mn(IV) complexes to Mn(II), according to a reaction of the type:

$$\text{Mn(III) complex} + e^- \rightarrow \text{Mn(II) complex} \qquad \text{(Eq 15)}$$

Conversely, the anode should form where SRB reside at the metal surface, leading to a neutral pH reaction such as:

$$HS^- + Fe \rightarrow FeS + H^+ + 2e^- \qquad \text{(Eq 16)}$$

The potential difference between these sulfide and Mn(III) or MnO_2 areas of the surface is larger than 500 mV (Ref 16). In comparison, differential aeration cells are quite weak. Even for an oxygen concentration differential of 10^4 between the aerated and deaerated areas, the potential difference is only approximately 60 mV.

In all of the previous examples, the biofilm is able to change the chemistry of the electrolyte substantially at the water-metal interface. Thus, the initiation of corrosion as well as the corrosion rate may depend more on the details of the electrolyte chemistry at the interface, including its heterogeneity, than it does on the ambient bulk water chemistry.

Industries Affected

The various industries that have been affected by microbiological corrosion problems are listed in Table 2. References to problems in the chemical-processing, nuclear power, oil field (both onshore and offshore), and underground pipeline industries are most common in the published literature. This does not necessarily mean that these industries are more prone to problems of this type than other industries. It does mean that these industries have been quick to recognize the biological causes of some of their corrosion problems, to take steps to solve these problems, and to make the results public. More recently, biological corrosion represents a growing challenge to the fire protection industry.

Table 2 Industries affected by microbiologically influenced corrosion

Industry or structure	Problem areas
Chemical processing	Stainless steel tanks, pipelines, and flanged joints, particularly in welded areas after hydrotesting with natural river or well waters
Power generation: nuclear, hydro, fossil fuel, and geothermal	Carbon and stainless steel piping and tanks; copper-nickel, stainless, brass, and aluminum-bronze cooling water pipes and tubes, especially during construction, hydrotest, and outage periods
Onshore and offshore oil and gas	Mothballed and waterflood systems; oil- and gas-handling systems, particularly in those environments soured by sulfate-reducing-bacteria (SRB)-produced sulfides
Underground pipeline	Water-saturated clay-type soils of near-neutral pH with decaying organic matter and a source of SRB
Water treatment	Heat exchangers and piping
Sewage handling and treatment	Concrete and reinforced-concrete structures
Highway maintenance	Culvert piping
Buildings and stoneworks	Ancient and modern limestones, marbles, sandstones, granites, and mortars
Pulp and paper	Raw, process, and cooling water systems; paper machine headboxes and suction rolls
Hydraulic systems	Increased corrosivity of hydraulic oils with entrained water; fouling and corrosion of filters
Fire protection systems	Pinhole leaks in piping systems; plugging of piping and sprinkler heads
Aviation	Aluminum integral wing tanks and fuel storage tanks
Metalworking	Increased wear from breakdown of machining oils and emulsions

The frequency of literature reports of microbiological corrosion problems in these industries also does not mean that corrosion is accelerated everywhere microorganisms are present. Many bacteria existing in natural and man-made environments do not cause or accelerate corrosion. Bacteria may exist at the corrosion site only because the electrochemistry of corrosion creates a favorable environment for their growth.

Microbiologically Influenced Corrosion of Various Materials

This section describes microbiologically influenced corrosion (MIC) of irons and steels, passive alloys (austenitic stainless steels), aluminum alloys, copper alloys, and composites.

Biological Corrosion of Irons and Steels

A large number of case histories involving the microbial acceleration of the localized corrosion of iron and steel have been presented in the literature. These are far too numerous to list in this article. An excellent introduction to the literature can be gained by referring to Ref 8, 9, 10, 11, 12, 21, 28, 29, 30, 31).

Anaerobic Corrosion. The corrosive action of the SRB from the genera *Desulfovibrio, Desulfotomaculum,* and *Desulfomonas* in anaerobic environments is well known. The morphology of attack is almost always localized and often looks very similar to the pitting shown for cast iron in Fig. 13.

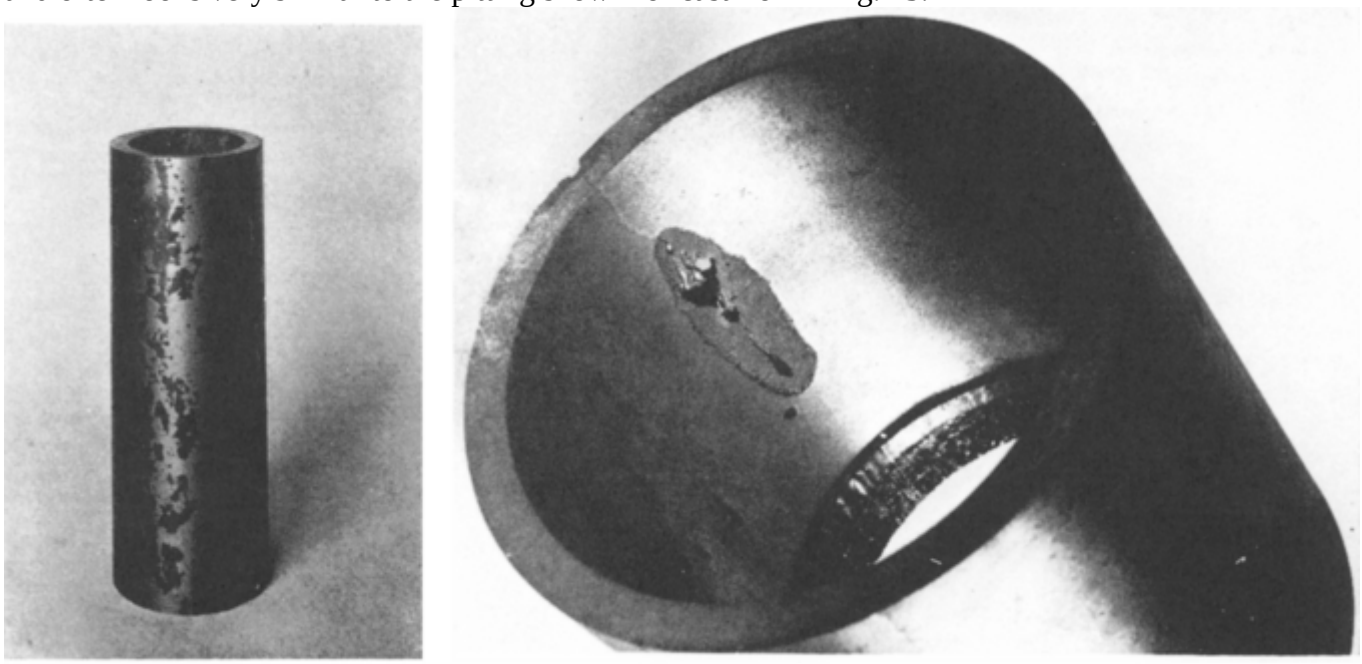

Fig. 13 Anaerobic biological corrosion of cast iron. (a) Cast iron pipe section exhibiting external pitting caused by bacteria. (b) Cast iron pipe showing penetration by bacteria-induced pitting corrosion. Source: Ref 10

In the early decades of this century, it was generally believed that the SRB could influence the corrosion of steel only in totally anaerobic environments such as deaerated soils and marine sediments. Recently, it has been recognized that anaerobic corrosion by SRB can take place in nominally aerated environments. In these latter cases, anaerobic microenvironments can exist under biodeposits of aerobic organisms, in crevices built into the structure, and at flaws in various types of coating systems. The most corrosive environments are often those in which alternate aerobic-anaerobic conditions exist because of the action of variable flow hydrodynamics or periodic mechanical action.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The anaerobic corrosion of iron and steel has been identified in such diverse environments as waterlogged soils of near-neutral pH; bottom muds of rivers, lakes, marshes, and estuaries (especially when these contain decaying organic material as a source of sulfates for the SRB); under marine fouling deposits and in various other offshore industrial environments (Ref 32); under nodules or tubercules in natural freshwaters and recirculating cooling waters; and under disbonded areas of pipeline coatings.

Unexpectedly rapid localized corrosion of steel bulkheads in marine harbor environments and of the ship hull plating of several tankers has been documented (Ref 33). In each case, the localized attack was found beneath macrofouling layers. The biofilm at and around the corrosion sites was populated with a rich consortium of aerobic and anaerobic microorganisms, and the SRB population was elevated by several orders of magnitude above that in the biofilm remote from the corrosion sites. These observations, coupled with the occurrence of corrosion rates too high to be explained by the usual metallurgical and electrochemical mechanisms, are the classic signs of biocorrosion.

A considerable amount of work has been done to assess the relative aggressiveness of various soils and sediments. The work in soils prior to 1970 is reviewed in Ref 34. Factors such as the presence or absence of SRB, soil resistivity, and water content were considered. It was discovered that SRB activity correlated well with soil redox potential, E_h, on the normal hydrogen scale (NHE), a variable that is much easier to measure than numbers of SRB. Aggressive soils tended to have mean resistivities of less than 2000 ohm · cm and a mean redox potential more negative than 400 mV on the NHE corrected to pH 7. Soils that were borderline based on these two tests tended to be aggressive if their water content was over 20%. With regard to redox potential alone, soil corrosivity varied, as shown in Table 3 (Ref 34).

Table 3 Dependence of soil corrosivity on redox potential

Soil E_h (NHE), mV	Corrosivity
<100	Severe
100–200	Moderate
200–400	Slight
>400	Noncorrosive

E_h, redox potential; NHE, normal hydrogen scale

Other attempts to assess the risk of corrosion by SRB have been sporadic. One investigation attempted to assess the severity of the SRB hazard on the inside of submarine pipelines carrying North Sea crude oil by measuring both the numbers of SRB present in the oil and the activity (or vigor of growth) of the organisms (Ref 35). The risk was assessed as extreme if both the numbers of organisms and their activity were rated high, and the risk was considered to be minimal if both were rated low.

Efforts to solve the anaerobic iron and steel corrosion problem, as outlined in Ref 34, include:

- Replacing the iron or steel with noncorrodible materials, such as fiberglass, polyvinyl chloride, polyethylene, and concrete
- Creating a nonaggressive environment around the steel by backfilling with gravel or clay-free sand to encourage good drainage (that is, oxygenating to suppress SRB), making the environment alkaline, or using biocides (in closed industrial systems)
- Using cathodic protection. Potentials of -0.95 V versus $Cu/CuSO_4$ (or even more negative) are often required. At these potentials, the risk of hydrogen cracking or blistering should be assessed.
- Use of various barrier coatings, sometimes including corrosion inhibitors and/or biocides

Aerobic Corrosion. Corrosion of iron and steel under oxygenated conditions generally involves the formation of acidic metabolites. The aerobic sulfur-oxidizing bacteria *Thiobacillus* can create an environment of up to approximately 10% H_2SO_4, thus encouraging rapid corrosion. Other organisms produce organic acids with similar results. This corrosion can be localized or general, depending on the distribution of organisms and metabolic products. If all the bacterial activity is concentrated at a break or delamination in a coating material, the corrosion is likely to be highly localized. If, on the other hand, the metabolic products are spread over the surface, the corrosion may be general, as has been reported for carbon steel tendon wires used to prestress a concrete vessel in a nuclear power plant (Ref 9). In this case, the wires were coated with a hygroscopic grease

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

prior to installation. A study to determine the cause of corrosion concluded that the wires, shown in Fig. 14, were corroded by formic and acetic acids excreted by bacteria in breaking down the grease.

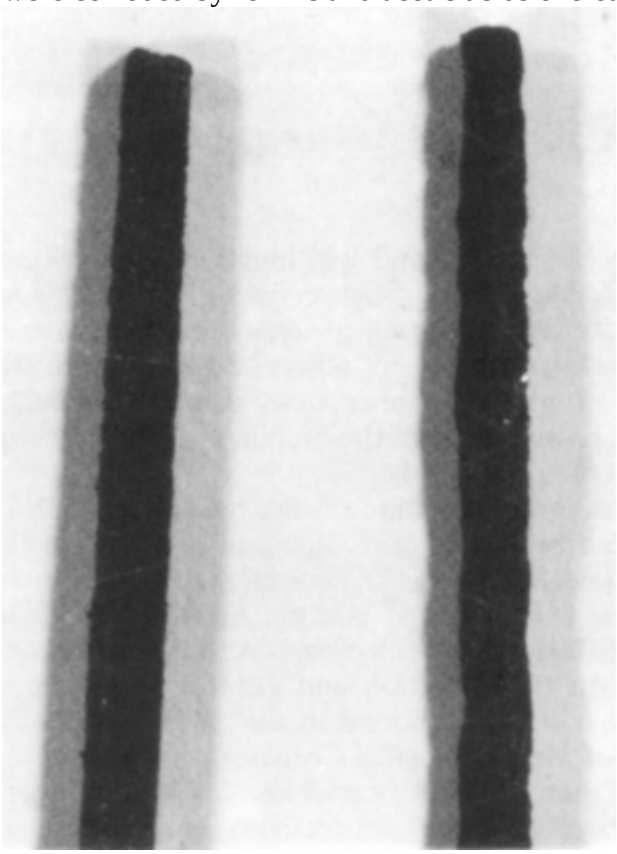

Fig. 14 Carbon steel wires from a prestressing tendon of a nuclear power plant showing the damage resulting from the formation of organic acids in the tendon due to the breakdown of grease by the bacteria present in the tendon. Source: Ref 9

Other cases of aerobic corrosion of iron and steel begin with the creation of oxygen concentration cells by deposits of slime-forming bacteria. Such corrosion is often accelerated by the iron-oxidizing bacteria in the formation of tubercules.

MIC of Passive Alloys

There are three general sets of conditions under which localized biological corrosion of austenitic stainless steel occurs (Fig. 15). These are illustrated by two generalized case histories. Typical examples of microbiologically induced localized corrosion of stainless steel are shown in Fig. 16.

Du Pont de Nemours & Co., Inc.

Hydrotest or Outage Conditions. As originally reported in Ref 36, a new production facility required type 304L and 316L austenitic stainless steels for resistance to nitric and organic acids. All of the piping and flat-bottomed storage tanks were field erected and hydrostatically tested. The hydrotest water was plant well water containing 20 ppm chlorides and was sodium softened.

The pipelines were not drained after testing. The tanks were drained but were then refilled for ballast because of a hurricane threat. Two to four months after hydrotesting, water was found dripping from butt welds in the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

nominally 3 mm ($\frac{1}{8}$ in.) wall piping. Internal inspection revealed numerous pits in and adjacent to welds under reddish-brown deposits in both piping and tanks. On cleaning off the deposit, the researchers found a large stained area with a pit opening. Metallographic sectioning showed a large subsurface cavity with only a small opening to the surface. Pitted welds in a type 316L tank showed some evidence of preferential attack of the delta- ferrite stringers, as shown in Fig. 17. It is not yet known exactly why such attack often concentrates at the weld line. Work by many investigators to characterize this phenomenon has been reviewed (see Borenstein, p 168–171 in "Selected References"). It is not always clear whether biological colonization precedes or follows the initiation of localized corrosion. What is clear is that once corrosion and biodeposits are both established, the attack proceeds more rapidly than would be expected due to electrochemical effects alone.

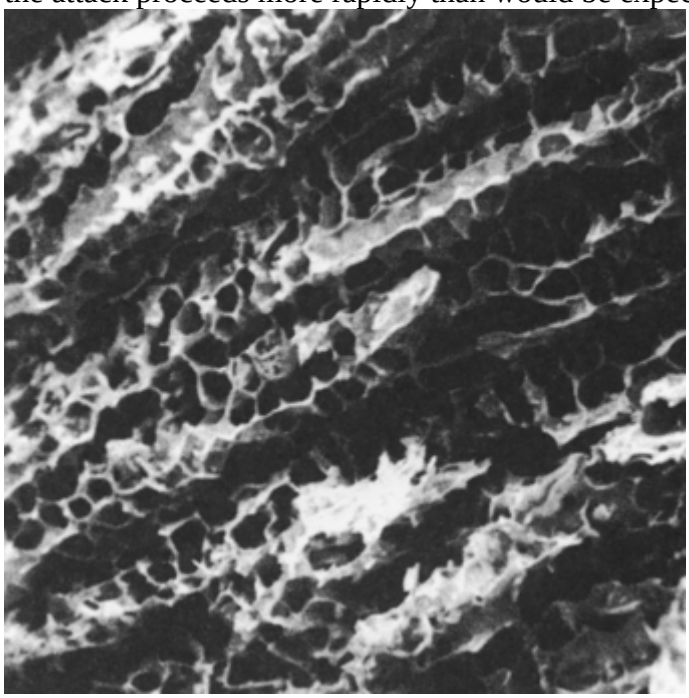

Fig. 17 Scanning electron micrograph showing matrix remaining after preferential corrosion of the δ-ferrite phase in a type 316 stainless steel. 300×. Courtesy of J.G. Stoecker, Monsanto Company

Well water and deposits both showed high counts of the iron bacteria *Gallionella* and the iron-manganese bacteria *Siderocapsa.* Deposits also contained thousands of parts per million of iron, manganese, and chlorides. Sulfate-reducing and sulfur-oxidizing bacteria were not present in either water or deposits. The proposed mechanism for the attack involves:

- Original colonization by the iron and manganese bacteria at the weld seams to create an oxygen concentration cell. Several investigators have confirmed that microorganisms are attracted to any site on a metallic surface having enhanced electrochemical activity, whether or not stable corrosion has initiated (Ref 37, 38).
- Dissolution of ferrous and manganous ions under the deposits
- Attraction of chloride ions as the most abundant anion to maintain charge neutrality
- Oxidation of the ferrous and manganous ions to ferric and manganic by the bacteria to form a highly corrosive acidic chloride solution in the developing pit

Many failures of this type have been reported in the chemical-processing industries in new equipment after hydrotesting but prior to commissioning in service. Similar failures have been reported in older equipment in both the chemical-processing and nuclear power industries when untreated well or river water was allowed to remain stagnant in the equipment during outage periods. Occasionally, the pitting is accompanied by what appear to be chloride stress-corrosion cracks under the deposits (Ref 9, 29). Examples of transgranular cracks in a type 304 stainless steel tank are shown in Fig. 18.

Crevice or Gasket Conditions. A different set of conditions has led to the localized corrosion of asbestos-gasketed flanged joints in a type 304 stainless steel piping system (Ref 40). Inspection of the system after approximately 3 years of service in river water revealed severe crevice corrosion in and near the flanged and gasketed joints. The corrosion sites were covered by voluminous tan-to-brown, slimy biodeposits, as shown in Fig. 19(a). Under the deposits were broad, open pits with bright, active surfaces (Fig. 19b). The surfaces under the gasket material and adjacent to the corroded areas were covered with black deposits, which emitted H_2S gas when treated with HCl.

Numerous other similar deposits were dislodged in opening the joint. (b) Closeup of gouging-type corrosion under deposits shown in (a) after cleaning to remove black corrosion products. Source: Ref 40

The biological deposits were high in iron, silt- and slime-forming bacteria, and iron bacteria but not chloride, manganese, and sulfur compounds. Sulfate-reducing bacteria were found only in the black deposits. These bacteria had survived continuous chlorination (0.5 to 1.0 ppm residual), caustic adjustment of pH to 6.5 to 7.5, and continuous additions of a polyacrylate dispersant and a nonoxidizing biocide (quarternary amine plus tris tributyl tin oxide) (Ref 40).

The suspected mechanism involves:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- Colonization by slime-forming bacteria at low-velocity sites near gasketed joints
- Trapping of suspended solids rich in iron by the growing biodeposit, thus creating an environment conducive to growth of the filamentous iron bacteria
- Rapid depletion of oxygen in the crevice area by a combination of biological and electrochemical mechanisms (Ref 41), creating an environment for the SRB
- Breakdown of passivity by a combination of oxygen depletion and SRB activity, causing localized corrosion

Standard approved methods for controlling the biological corrosion of stainless alloys are currently being developed. Some general guidelines for avoiding problems in hydrotesting, however, are given in Ref 36. These guidelines are summarized as follows. First, demineralized water or high-purity steam condensate is used for the test water. The equipment should be drained and dried as soon as possible after testing. Second, if a natural freshwater must be used, it should be filtered and chlorinated, and the equipment should be blown or mopped dry within 3 to 5 days after testing.

Effects in the Marine Environment. The idea that natural seawater, with its full complement of organisms, is more corrosive than artificial seawater often has appeared in the corrosion literature. Many papers have been published since the late 1980s in documentation of this phenomenon. The material is organized into three categories giving the effects on:

- Open-circuit (OCP) and pitting potentials
- Initiation of localized corrosion
- Corrosion propagation

Effect of Biofilms on OCP and Pitting Potentials. During the past 15 years, many investigators from all over the world have documented the tendancy for biofilms to cause a noble shift in the OCP of passive alloys (Ref 42, 43, 44, 45, 46, 47, 48). The alloys tested include but are not limited to Unified Numbering System (UNS) S30400, S30403, S31600, S31603, S31703, S31803, N08904, N08367, S44660, S20910, S44735, N10276, and R50250. To a first approximation, the amount of ennoblement was independent of alloy composition as long as the alloy had an *n*-type semiconducting passive film. It has been shown that the noble shift in OCP for passive alloys with *p*- type passive films, such as alloy N06455 (C4), took place more slowly with a smaller total shift than alloys such as N08367 (6XN) with an *n*- type passive film (Ref 49).

Ennoblement of the OCP occurred in fresh, brackish, and seawaters as long as corrosion initiation did not interfere. The rate of ennoblement was slower in fresh water than in seawater, but the amount of ennoblement was inversely related to the salinity of the electrolyte (Ref 50). The most noble potentials reached were also highest and most consistent in freshwater. Thus, it was concluded that ennoblement of the OCP decreased the salinity level below which a given alloy should be resistant to localized corrosion initiation (Ref 50). Theoretically, this information could be used to decide the upper salinity limits for application of any given alloy. In practice, however, this is impractical for two reasons. First, there are seasonal and tidal salinity fluctuations in any natural estuarine environment. Second, complex industrial equipment, such as heat exchangers, that are often fabricated from passive alloys may themselves create salinity gradients due to variations in temperature and flow rate.

Research showed that the critical potential for pit initiation (E_{cpp}) on an open surface and the breakdown potential for initiation of localized corrosion (E_b) at occluded sites or the air-water interface are also affected by formation of biofilms (Ref 51). For alloy S30400, the average E_{cpp} of samples with biofilms (425 ± 24 mV saturated calomel electrode, or SCE) was 95 mV higher than that of the bare samples (330 ± 35 mV). This result is not surprising, because bacteria produce nitrates and sulfates. Further, many bacteria accumulate large amounts of inorganic phosphate in the form of granules of polyphosphate. When these bacteria die, those phosphates are released into the biofilm. Na_2SO_4 and $NaNO_3$ (concentrations as low as 0.0125 *M*) are known to be pitting inhibitors for stainless steels. For alloy S31600, the E_{cpp} values of the biofilmed samples (500 mV) were not much different than the bare metal samples (480 ± 17 mV). The reason for this is unknown, but it is possible that the inhibitor concentration produced in the biofilm was not high enough to affect the higher E_{cpp} for S31600.

The breakdown potential data for alloy S30400 showed that E_b increased from 60 mV for the bare sample to 260 ± 20 mV for those with biofilms. For alloy S31600, E_b increased a smaller amount, from 300 mV for the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

bare sample to 390 ± 14 mV for those with biofilms. These values agreed favorably with the observation that corrosion at the air-water interface was observed for S30400 and S31600 after the corrosion potential reached potentials of 250 and 350 mV SCE, respectively. These data strongly suggest that critical pitting and breakdown potentials should be measured on samples with natural biofilms when the application involves exposure to waters from which they form.

Initiation of Pitting and Crevice Corrosion. Tests on crevice-corrosion samples of passive alloys S30400 and S31600 revealed that crevice initiation times were reduced when natural marine biofilms were allowed to form on the exposed external cathode surface (Ref 46, 52, 53, 54). Even though there was a lot of variability in the data, it was concluded from the tests that ennoblement of the OCP in the presence of natural biofilms usually caused the alloy to reach its breakdown potential for crevice initiation faster than when the test was repeated under control conditions without the biofilm.

Propagation of Crevice Corrosion. Many investigators have used potentiodynamic polarization curves to show that cathodic kinetics are increased during biofilm formation on passive alloy surfaces (Ref 46, 55, 56, 57). Tests have shown that this increase in kinetics results in higher propagation rates for crevice corrosion (Ref 52, 53, 54). Crevice propagation rates after initiation were enhanced significantly and consistently. Crevice propagation current densities were increased by 1 to 3 orders of magnitude versus the control for alloys S30400, S31603, S31725, and N08904. The effect was also reflected in greater weight loss as well as higher maximum and average depths of attack on test alloys with biofilms on the exterior cathode surface versus the control.

Effect of Biofilms on Galvanic Corrosion. The increase in cathodic kinetics due to the action of biofilms on passive alloy surfaces also can increase the propagation rate of galvanic corrosion. Researchers tested galvanic corrosion of copper, steel 3003, aluminum, and zinc anodes coupled to cathode panels of passive alloy N08367 (Ref 58). In one series of tests, natural marine microbial biofilms were allowed to form on the cathode surface. On the control tests, the action of the biofilm was prevented. Corrosion of the copper, steel, and aluminum anodes was significantly higher when connected to cathodes on which the biofilm was allowed to grow naturally. The largest effect was noted for the copper anodes. As shown in Fig. 20, the galvanic current for copper corrosion, as measured with a zero resistance ammeter, was 2 to 3 decades higher for copper couples with biofilms on the cathode than for the corresponding control couples. Weight loss values for the copper anodes were also significantly higher when coupled to cathodes with biofilms than on control coupons.

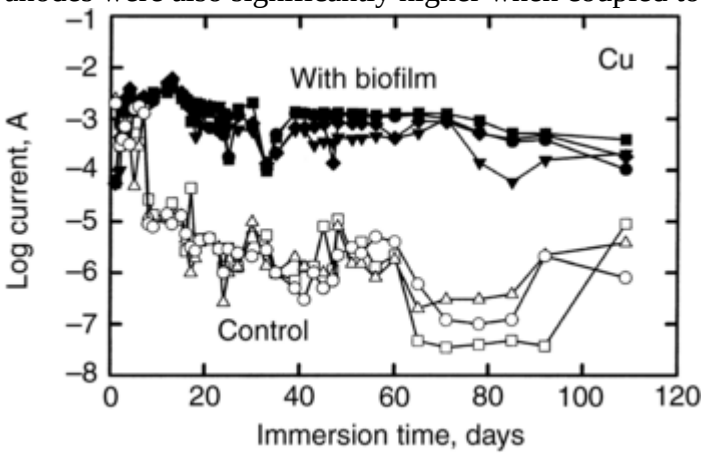

Fig. 20 Corrosion currents for galvanic couples of UNS C1100 copper anodes versus UNS N08367 stainless steel cathodes with and without (control) the influence of natural marine microbial biofilms. Source: Ref 58

Similar results were found for the steel and aluminum anodes. Average corrosion currents and weight losses were 5 to 8 times higher for the steel and aluminum anodes when biofilms were allowed to grow on the cathode surface than for the control without the biofilm. The galvanic currents measured for aluminum are shown in Fig. 21, and the aluminum anodes themselves are shown in Fig. 22.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

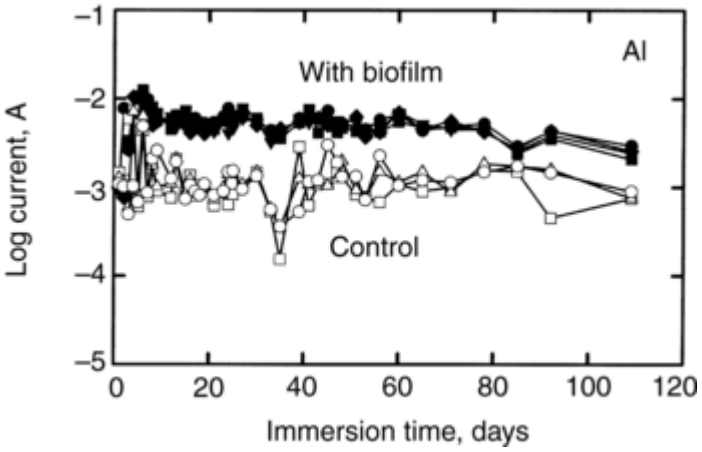

Fig. 21 Corrosion currents for galvanic couples of UNS A93003 aluminum alloy anodes versus UNS N08367 stainless steel cathodes with and without (control) the influence of natural marine microbial biofilms. Source: Ref 58

In contrast, the corrosion currents and weight loss values for all zinc couples, both with and without biofilms on the cathode, fell within the same scatter band. The reason why biofilms had no effect on galvanic corrosion of zinc anodes was not determined. It was speculated, however, that the zinc anodes generated a high enough pH at the cathode surface to interfere with the action of microorganisms within the biofilm.

MIC of Aluminum

Pitting corrosion of integral wing aluminum fuel tanks in aircraft that use kerosene-based fuels has been a problem since the 1950s (Ref 59). The fuel becomes contaminated with water by vapor condensation during

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

variable-temperature flight conditions. Attack occurs under microbial deposits in the water phase and at the fuel-water interface. The organisms grow either in continuous mats or sludges, as shown in Fig. 23, or in volcano-like tubercules with gas bubbling from the center, as shown schematically in Fig. 24.

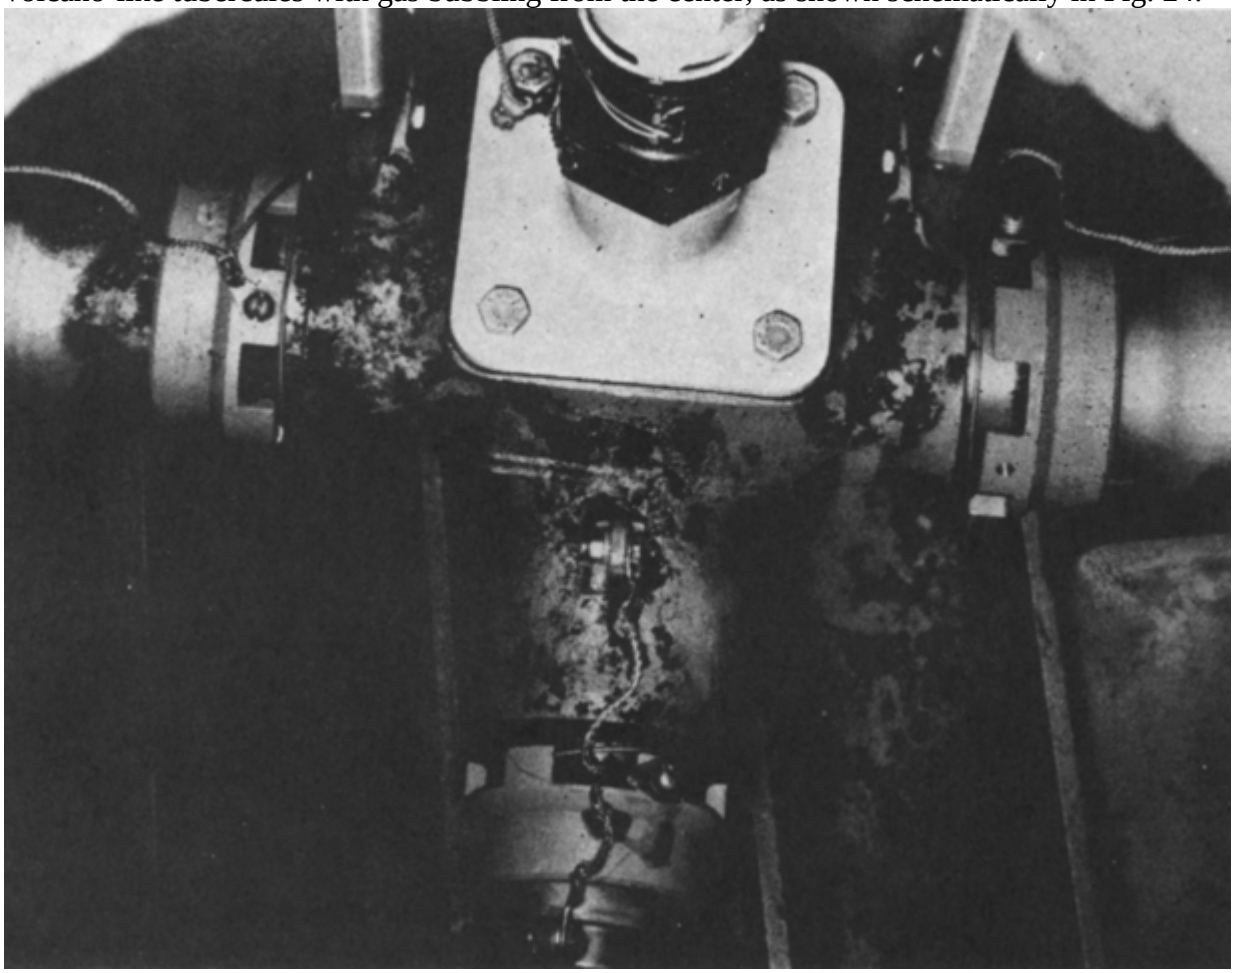

Fig. 23 Microbial growth in the integral fuel tanks of jet aircraft. Source: Ref 10

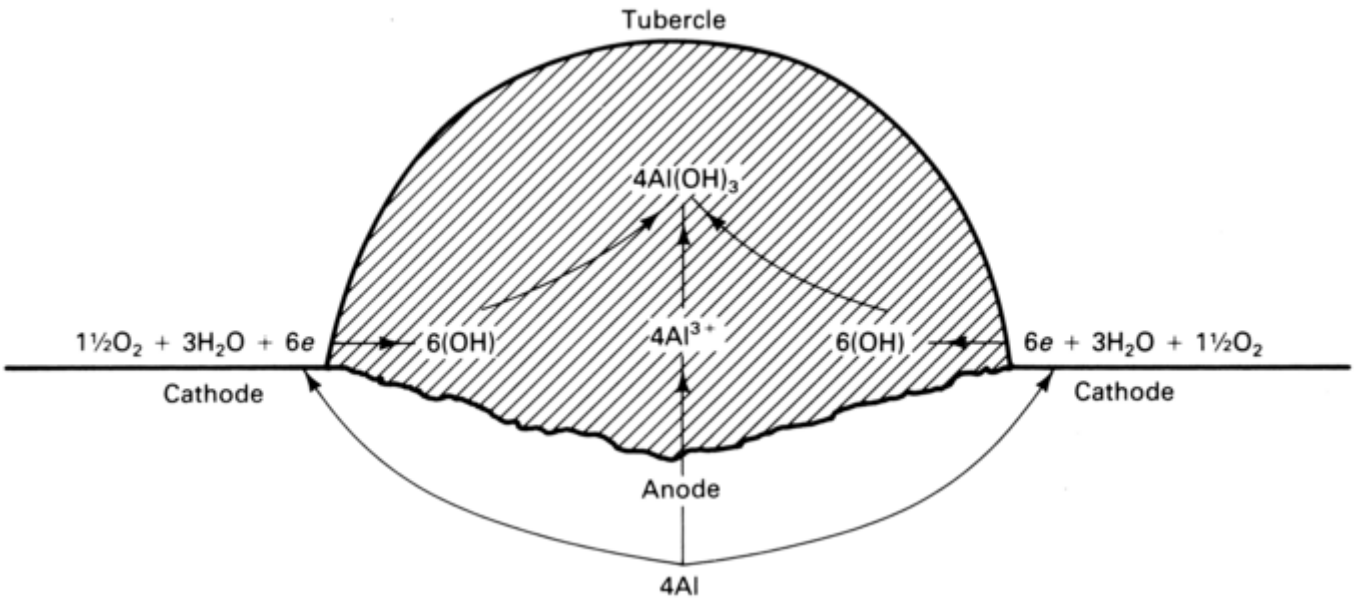

Fig. 24 Schematic of tubercle formed by bacteria on an aluminum alloy surface. Source: The Electrochemical Society

The organisms commonly held responsible are *Pseudomonas, Cladosporium,* and *Desulfovibrio.* These are often suspected of working together in causing the attack. *Cladosporium resinae* is usually the principal

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

organism involved; it produces a variety of organic acids (pH 3 to 4 or lower) and metabolizes certain fuel constituents. These organisms may also act in concert with the slime-forming *Pseudomonads* to produce oxygen concentration cells under the deposit. Active SRB have sometimes been identified at the base of such deposits. Control of this type of attack has usually focused on a combination of reducing the water content in fuel tanks; coating, inspecting, and cleaning fuel tank interiors; and using biocides and fuel additives. More information can be found in Ref 8 and 59.

MIC of Copper and Nickel Alloys

The well known toxicity of cuprous ions toward living organisms does not mean that the copper-base alloys are immune to biological effects in corrosion. It does mean, however, that only those organisms having a high tolerance for copper are likely to have a substantial effect. Thiobacillus thiooxidans, for example, can withstand copper concentrations as high as 2%. Localized corrosion of copper alloys by SRB in estuarine environments has been documented in published reports (Ref 60, 61). Cases of MIC of Cu-10Ni, Admiralty brass (Cu-30Zn-15Sn), and aluminum brass (Cu-20Zn-2Al) at electric generating facilities using fresh or brackish cooling waters also have been documented (Ref 62, 63, 64). Most of the reported cases of microbial corrosion of copper alloys are caused by the production of such corrosive substances as CO_2, H_2S, NH_3, and organic or inorganic acids (Ref 5, 23). Bacterial extracellular polymers play a role in the corrosion of copper alloys in freshwater distribution systems (Ref 65, 66).

Laboratory and field studies have been designed to evaluate corrosion in welds and heat- affected zones in Cu-Ni seawater piping systems exposed to estuarine and sea waters (Ref 61). It was demonstrated that welds provide unique environments for the colonization of SRB with the subsequent production of sulfides that affect the weld seam surface, the adjacent flow zone, and the downstream surface of the heat-affected zone. Exposure of sulfide-derived surfaces to fresh, aerated seawater resulted in rapid spalling on the downstream side of weld seams. The bared surfaces became anodic to the sulfide- coated weld root, accelerating corrosion.

Copper-nickel tubes from the fan coolers in a nuclear power plant were found to have pitting corrosion under bacterial deposits (Fig. 25). Slime-forming bacteria acting in concert with iron- and manganese-oxiding bacteria were responsible for the deposits.

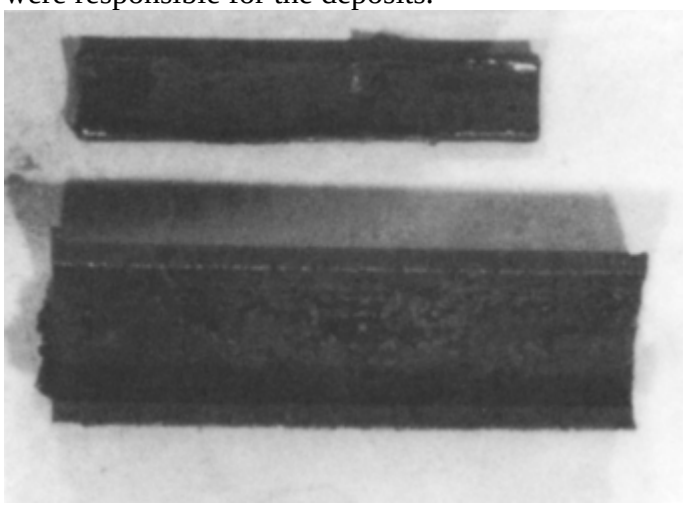

Fig. 25 Pitting corrosion in 90Cu-10Ni tubes from a fan cooler in a nuclear power plant. Pits are located under the small deposits associated with the deposition of iron and manganese by bacteria. Source: Ref 9

Monel 400 (66.5% Ni, 31.5% Cu, and 1.25% Fe) tubing was severely pitted after exposure to marine and estuarine waters containing SRB (Ref 67). Localized corrosion was attributed to a combination of differential aeration cells, a large cathode-to-anode area ratio, concentration of chlorides, development of acidity within the pits, and the specific reactions of the base metals with sulfides produced by the SRB. Chlorine and sulfur reacted selectively with the iron and nickel in the alloy, leaving a copper-rich, spongy pit interior (selective dealloying). Monel 400 (UNS N04400) was found to be highly susceptible to MIC attack in Arabian Gulf seawater by SRB (Ref 68). The SRB attack was in the form of circular cavities where an intergranular mode of corrosion took place and was accompanied by selective leaching of nickel and iron.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In another case, Monel heat-exchanger tubes were found to have severe pitting corrosion (Fig. 26) under discrete deposits rich in iron, copper, manganese, and silicon, with some nickel (Ref 9). Associated with the deposit were slime-forming bacteria, along with iron- and manganese- oxidizing bacteria. Several million SRB were found within each pit under the deposit. It was thought that the deposit-forming organisms created an environment conducive to growth of SRB, which then accelerated corrosion by the production of H_2S.

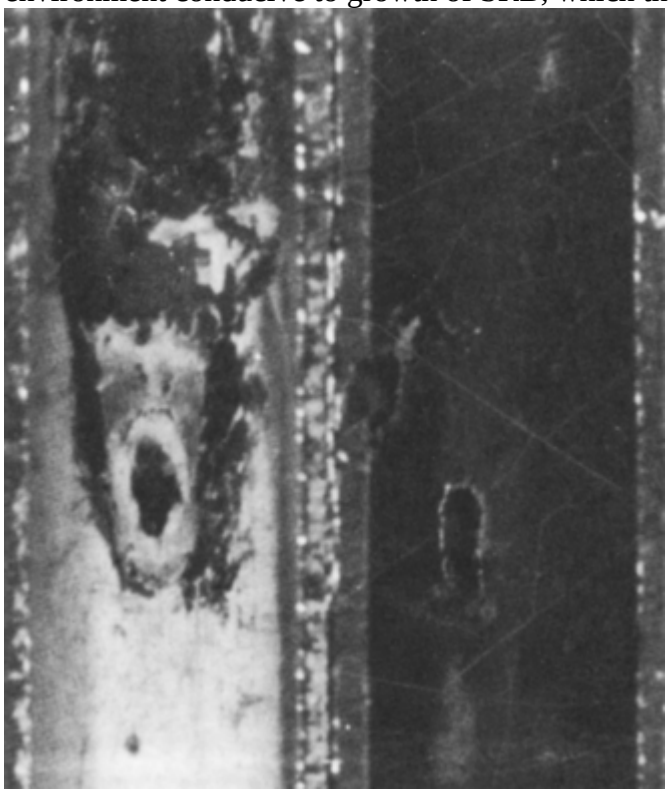

Fig. 26 Pitting corrosion in Monel tubes from a heat exchanger. Each pit was originally covered by a discrete deposit containing large numbers of SRB. Source: Ref 9

It is quite common to have bacterial slime films on the interior of copper alloy heat-exchanger and condenser tubing. Usually, these films are a problem only with heat transfer as long as the organisms are living. When they die, however, organic decomposition produces sulfides, which are notoriously corrosive to copper alloys. Occasionally, NH_3-induced stress-corrosion cracking has been directly attributed to microbial NH_3 production.

Biodeterioration of Nonmetallics, Composites, and Coatings

In addition to influencing the corrosion of metals and alloys, microorganisms have long been known for their ability to participate in the biodeterioration of wood, concrete, stone, polymers, asphalt, and various minerals (Ref 11). More recently, cases have been documented for the biodeterioration by bacteria and/or fungi of architectural building materials, stoneworks, fiber-reinforced composites, polymeric coatings, and concrete (Ref 69).

Building Materials and Stoneworks. As summarized in Ref 70, microbiological activity plays an important role in the overall process of deterioration for a variety of building materials. Weathering by rain, wind, freeze-thaw, and the ultraviolet component of sunlight begin to break down the surface and provide microorganisms with organic and inorganic nutrients. Biodeterioration then proceeds by the processes of staining, patina formation, pitting, etching, disaggregation, and exfoliation. Prevention measures under outdoor conditions include the application of biocides and other formulations based on a combination of silicones and biocides. Control of environmental variables, such as humidity, temperature, and light, also is used under some indoor conditions to minimize degradation.

The same types of processes are active in the biodeterioration of cultural heritage stoneworks at many locations worldwide (Ref 71). The attack is generally the result of interactions between microorganisms (bacteria, algae, fungi), macroorganisms (lichens and mosses), and physico-chemical mechanisms, including atmospheric pollution.

مرجع مهندسی مواد و متالورژی

Composite Materials. It was reported that the glass fibers used in fiber-reinforced polyester (FRP) lost all rigidity when exposed to SRB for 90 days, although the glass itself and the epoxy and vinyl resin materials were not attacked (Ref 72, 73). Some attack on graphite fibers by soil bacteria (Ref 74) has been reported. A 10% loss in strength of a carbon-fiber-reinforced epoxy resin composite has been reported on exposure to SRB. It has also been shown that fungi can cause degradation of carbon-reinforced epoxies and other FRP due to *hyphae* penetration of the resin material (Ref 75).

Coatings. Many types of polymeric coatings can be subject to biodegradation. The attack is usually caused by acids or enzymes produced by bacteria or fungi. This often results in selective attack on one or more specific components of a coating system, with consequent increase in porosity and water or other ion transport through the coating and the formation of blisters, breaches, and disbonded areas. Many of these effects have recently been reviewed (Ref 72). It has been noted that the microbes responsible for damage to coatings may or may not be involved in corrosion initiation under the damaged coating (Ref 76). The electrochemical impedance and electrochemical noise techniques have been used for studying microbial deterioration of coatings (Ref 77, 78, 79). Blisters and delaminations in the coatings were usually associated with microorganisms in both natural marine and laboratory exposures. It was not clear, however, whether those organisms played any role in corrosion initiation under the coating. As already noted earlier in this article, both marine and freshwater microbes can be attracted to iron corrosion products or even sites of heightened electrochemical activity without necessarily being implicated in corrosion initiation. The mere observation that microbial attachment and corrosion occur at a common location on a metal surface is not enough evidence to assign cause and effect (Ref 80, 81).

Concrete can be damaged by the acids, sulfates, ammonium, and other materials produced by microorganisms. Perhaps the most prevalent concrete application in which significant biodeterioration problems have been encountered is municipal wastewater collection and treatment systems. Researchers have studied such systems in which the bacterially mediated sulfur cycle (Fig. 3) plays the major role (Ref 82, 83). In the anaerobic environment of the sewage itself, SRB convert sulfates to sulfides, causing hydrogen sulfide (H_2S) to be released into the aerobic environment near the top of the sewer pipe. The H_2S is in turn oxidized to sulfuric acid by the sulfur-oxidizing bacteria *Thiobacillus.* Bacterial acid production caused the pH in the vicinity of the sewer pipe crown to reach values as low as 2.0, resulting in acid attack on the concrete (Ref 82).

Steel reinforcing bar in concrete corrodes readily in such environments, once exposed by sufficient deterioration of the concrete. Even in the absence of acid attack on the concrete, it has been shown (Ref 84) that H_2S production by SRB can cause corrosion of the rebar in reinforced-concrete structures. If the H_2S is able to permeate the concrete, the normally passive iron oxide film on the rebar in the high-pH pore- water environment of the concrete is converted to a non-protective iron sulfide film.

Microbiologically Influenced Corrosion

Stephen C. Dexter, University of Delaware

Testing for Microbiologically Influenced Corrosion

Electrochemical corrosion and biological film formation have often been treated as separate events. However, the presence of microorganisms on a metal surface, even in the early stages of biofilm formation, can change the chemistry at the interface where corrosion reactions take place. Thus, the biological effect can be substantial, and it can take place simultaneously with the electrochemical reactions. Testing for microbiologically influenced corrosion (MIC) is used to determine if the microbes are the cause of specific types of corrosion failures or if the microbes in a given environment result in an unacceptably high corrosion rate for a given alloy.

Just as there is no unique microbiological environment, there also is no uniquely definitive test for MIC. The question has often been asked: How can I determine whether the corrosion in my system is MIC or not? The question itself can be misleading. The presence of microorganisms in the environment at a corrosion site does

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

not introduce some new form of corrosion. Rather, the organisms are capable of enhancing all known types of corrosion. The real question is: Are the organisms present in my system having a strong enough influence on corrosion that no corrosion control program can be successful without specifically controlling the organisms? In order to prove that the organisms present were the sole cause of corrosion, one would have to show first that the organisms can reproduce the attack when introduced into a sterile system, and second, that the effect does not happen when the organisms are absent from an otherwise identical environment. There are only a few well-documented situations in which this is the case. In most cases, the organisms present exert an accelerating influence on corrosion, hence the name Microbiologically Influenced Corrosion.

No specific standards have been written for MIC testing (Ref 6). Four types of evidence— metallurgical, microbiological, chemical, and electrochemical—are generally used to determine if the influence of the organisms is important enough that it must be addressed for a corrosion control program to be successful.

Metallurgical Evidence. The metallurgical history of the alloy in use is important, as is the morphology of the corrosive attack. Some types of MIC are recognizable, in part, by the pattern of corrosion on the surface, as detailed elsewhere (Ref 85, 86). The distribution and morphology of the corrosive attack should be recorded photographically.

Microbiological Evidence. Even though no direct correlation can be made between numbers of organisms or their distribution along the surface of the metal and the probability of MIC, this information is important. Moreover, the data must be gathered while the corrosion site is still wet. If, as is often the case, the corroded component is removed from the system, discarded, and allowed to dry before it is examined, much of the important information is lost. It is important to photographically record the initial appearance of the corrosion site in color as soon as possible, so that the organisms are still alive. Sampling of biological materials and corrosion products must be done using proper procedures, which are well described elsewhere (Ref 86, 87).

Chemical Evidence. As much chemical information as possible should be gathered about the electrolytic environment and the microorganisms themselves. Particular attention should be given to recording the chemistry of the liquid phase and its variability, both spatially and with time in relation to the observed corrosive attack. Any localized inputs of chemicals or pollutants not normally present in the environment should be noted.

Detailed chemical information should also be gathered for the corrosion products and any biological mounds that may be present at or near the corrosion site. This information should include the color, texture, odor, and distribution of the materials as well as their organic and inorganic chemistries. Detailed procedures for doing this have also been published (Ref 86).

Electrochemical Evidence. Virtually all electrochemical tests described elsewhere in this Volume have proven useful within certain limitations for MIC testing. The procedures for performing such tests and interpreting the data in cases where MIC is suspected have been given in several prior publications (Ref 86, 87, 88, 89). Further information on MIC testing may be found in Ref 11, 86, and 90.

Microbiologically Influenced Corrosion

Stephen C. Dexter, University of Delaware

Prevention of MIC

Much has been written over the past decade about prevention and control of biological corrosion. The purpose of this section is not a comprehensive review of the subject but rather to describe the general approaches taken and to point the reader to the literature for additional information.

The most effective general approach to biocorrosion control starts with the notion that it is easier to prevent biocorrosion problems than it is to fix them. The most important step in prevention is to start with a clean system and to keep it clean (Ref 11). The first encounter of a system with a biocorrosive electrolyte is often in the process of hydrostatic testing immediately after fabrication. Hydrotesting of fabricated stainless steel structures has often been done with untreated fresh well waters. Such waters may contain microorganisms, such as *gallionella,* which have been noted for causing corrosion. The use of biocides (see subsequent information) in the hydrotest water or complete drainage and drying of the structure after hydrotesting is necessary to avoid problems. Additional information about biocorrosion of weldments and during hydrotesting can be found in the section “MIC of Passive Alloys” in this article.

Subsequent to placing any structure in service under possible biocorrosion-conducive conditions, a successful biocorrosion prevention program should feature keeping the metallic surfaces of the system clean as the major priority. The reason this has been stressed by so many authors is that it is much easier to control microorganisms that are dispersed in the liquid phase than it is after they have settled on the surface in the form of a biofilm.

The general approaches to maintaining a system free of biocorrosion problems vary with the materials of construction, environment, economics, and duty cycle of the equipment. The most common approaches involve the use of coatings, cathodic protection, and biocides.

Cathodic protection is usually used together with coatings in order to decrease the cost of the applied current. (See the article “Cathodic Protection” in this Volume.) Coatings themselves can be subject to biodeterioration, as discussed previously. Cathodic protection can be of benefit for the prevention of some forms of biocorrosion. The cathodic current may be applied by means of sacrificial anodes or other direct-current power supply (e.g., solar cells) or by an external alternating-current power supply and rectifier system. In either case, the applied current opposes the naturally occurring corrosion current regardless of whether that current is influenced by biological processes. Only a few interactions between cathodic protection and biofilms have been documented in the literature.

The application of a cathodic current changes the pH at the metal surface, making it more basic due to the production of hydroxyl ions from the reduction of oxygen. An increase in pH above 9 to 10 is considered detrimental to many marine microorganisms (Ref 91). In the biocorrosion literature, cathodic currents are

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

known to both inhibit the growth of general aerobic microorganisms and stimulate the growth of SRB in anaerobic regions of metal surfaces (Ref 92, 93).

The increase in pH at the metal surface due to cathodic protection also decreases the solubility of calcium and magnesium salts in seawater, resulting in the precipitation of calcareous deposits. There is some evidence (Ref 94) that preexisting biofilms tend to make calcareous deposition more uniform. Theoretically, this could make the calcareous deposit more protective, and the biofilm could enhance cathodic protection. This possible benefit of a biofilm to cathodic protection must be balanced against the tendency of cathodic currents to stimulate the growth of SRB, which would be detrimental. Marine biofilms also have been shown to increase or decrease the effectiveness of cathodic protection, depending on the applied current density (Ref 95).

Two further examples serve to illustrate the detrimental effects biofilm formation can have on cathodic protection. First, it is generally recognized that biofilms increase the cathodic kinetics of stainless steel cathodes (Ref 46, 55, 56, 57, 58). In the North Sea offshore industry, where sacrificial iron anodes are used to cathodically protect stainless steel from localized corrosion, the enhanced cathodic kinetics due to biofilm growth on the stainless steel result in a higher-than-expected consumption of the anodes. Second, in the presence of SRB biofilms on stainless steel in seawater, cathodic protection is sometimes unable to prevent localized corrosion initiation even at very active cathodic potentials (Ref 96). Thus, in spite of some possible beneficial effects, the bulk of the evidence indicates that biofilm formation is detrimental to the process and economics of cathodic protection.

Biocides in Closed Systems. For many years, various chemicals with biocidal action have been widely used to control biofilm formation in closed systems, such as heat exchangers, cooling towers, and storage tanks. Such chemicals work by killing or disrupting the reproductive cycle of the target organisms. Biocides in very low concentrations are often sufficient to kill organisms suspended in the liquid phase (i.e., in the planktonic state). Once the organisms attach to a solid surface and form a biofilm, however, much higher concentrations of the biocide are needed to control them. There are two reasons for this effect. First, the extracellular polymeric substance materials secreted by the organisms in the biofilm are able to bind the biocidal entities and shield the organisms from their action. Second, microorganisms in the biofilm may become resistant to the biocide used (Ref 97). Thus, the biocides and corrosion inhibitors that are so often used together to control biocorrosion work best in a system that is kept clean.

The three main ways that biocides work are as enzyme poisons or protein denaturants, oxidizing agents, and surface-active agents (Ref 98). The enzyme poisons tend to act against specific groups of microbes. For example, bisthiocyanates are effective against all organisms having iron-containing cytochromes. These are suitable for incorporation into some coatings. Other compounds within this group are the isothiazolones, which react with the thiol groups in proteins, and the aldehydes, such as formaldehyde, which act on both proteins and lipopolysaccharides in the bacterial cell wall.

The oxidizing biocides are probably the most widely used in practice. These include chlorine, hypochlorite, chlorine dioxide, bromine, and ozone. Chlorine has been widely used in the water treatment industry for many decades. Recently, however, it has been coming under regulatory pressure, and its use is being limited. Moreover, this class of biocides has the ability to raise the OCP of passive alloys sufficiently to initiate localized corrosion in some cases, if used to excess. Ozone is coming into increasing use as a biocide in cooling water systems (Ref 99). It has the advantage over chlorination in that lower dosages are required to prevent biofilm formation or to remove existing biofilms (Ref 100).

The surface-active agents, such as the quaternary ammonium compounds (quats), work by targeting the surface structure of individual microbial cells, causing them to be damaged with eventual lysis. The hydrophobic and hydrophilic portions of the biocide molecules allow them to penetrate the lipid-containing cell wall of the microbes. An excellent table showing the advantages and disadvantages of the biocides most commonly used in the water treatment industry can be found in Ref 11 and 101. For additional information on the range of biocides available, the recommended selection criteria, and procedures for application, the reader is referred to Ref 10 and 102 to 104.

Monitoring for MIC. Any well-conceived and effective biocorrosion mitigation program needs to include monitoring as a periodic or continual means of assessing whether program goals are being achieved. This is especially true in industrial water-handling systems with known susceptibility to biocorrosion, such as cooling water and injection water systems, heat exchangers, wastewater treatment facilities, storage tanks, piping systems, and all manner of power plants, including those based on fossil fuels, hydroelectric, and nuclear.

Monitoring systems originally configured for use in programs to control scaling and inorganic corrosion do not necessarily provide the information needed to maintain control of biofouling and biocorrosion. Initial attempts to extend abiotic corrosion monitoring into the biocorrosion arena were geared toward assessing the number of microbes per unit volume of water sampled from the system. This data were combined with electrochemical corrosion measurements, using electrical resistance or polarization resistance probes sometimes together with weight loss measurements from sample coupons. The problem with this approach is that numbers of planktonic organisms in the water do not correlate well with the organisms present in biofilms on the metal surface where the corrosion actually takes place. The combined data indicate that something is happening to corrosion in the system but do not usually give sufficient information for control of either biofouling or biocorrosion.
An effective monitoring scheme for controlling both biofouling and biocorrosion should include the generation of as many of the following types of data as possible:

- Sessile bacterial counts of the organisms in the biofilm on the metal surface done by either conventional biological techniques (Ref 86) or optical microscopy
- Direct observation of the community structure of the biofilm. This can be done on metal coupons made from the same alloy used for the system. Several types of probe systems are commercially available for holding and inserting such coupons into the system (Ref 105, 106, 107, 108). Imaging of the organisms in the biofilm can be done by scanning electron microscopy, environmental scanning electron microscopy, epifluorescence optical microscopy, or confocal laser scanning microscopy.
- Identification of the microorganisms found in both the process water and on the metal surface. Methods for doing this are reviewed in some detail in Ref 86.
- Surface analysis to obtain chemical information on corrosion products and biofilms
- Evaluation of the morphology of the corrosive attack on the metal surface after removal of biological and corrosion product deposits. Conventional macrophotography as well as low-power stereomicroscopy, optical microscopy, metallography, and scanning electron microscopy may all be helpful in this regard.
- Electrochemical corrosion measurements from electrical resistance or polarization-resistance-type probes, as described elsewhere in this Volume
- Water quality and redox potential measurements
- Other types of information specific to each operational system, including duty cycle and downtime information, concentrations and timing for addition of biocides and other chemical inputs, local sources and nature of pollutants, and so on

Recent developments in biocorrosion monitoring have been reviewed (Ref 11, 109), including a detailed description of two case histories: one in a chemical industry cooling water system and the other for an oilfield water injection system in which the previously mentioned approach has been used successfully. In addition to the types of data discussed previously, several new on-line fouling and corrosion sensor systems have been developed (Ref 110, 111, 112, 113, 114). These systems use the interactions between biofouling and the electrochemistry of corrosion to generate data of interest in biocorrosion monitoring and control.

Microbiologically Influenced Corrosion

Stephen C. Dexter, University of Delaware

Corrosion Inhibition by Bacteria

As was shown in Fig. 1, the influence of microorganisms may not always be to cause or accelerate corrosion. There is also the possibility that they may be able to inhibit corrosion. Any such inhibitory effect occurs in the same type of complex and heterogeneous environment in which biocorrosion takes place. Thus, the same general biofilm formation processes that have been described earlier in this article as being important to biocorrosion also are in operation during corrosion inhibition. This is an important point to consider if one is

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

contemplating including a biological component to a corrosion control program. The objective of corrosion control strategies is usually to create a uniformly noncorrosive condition at the metal surface that can be maintained in that state with a minimum of effort and expense. Thus, the same highly variable and heterogeneous processes that lead to corrosion under a living biofilm work counter to the objective of corrosion control. Biofilms are not inherently uniform and stable. This may partially explain why some organisms found in biofilms can inhibit general corrosion, while other organisms in the same biofilm can cause localized corrosion. Moreover, the same organisms reported to cause MIC under one set of conditions can be protective under another. It has been noted that some strains of *Pseudomonas* increase the corrosion rate of iron and nickel (Ref 115), while under other conditions, they can have a protective effect (Ref 116).

Nevertheless, inhibition of corrosion by the action of microorganisms is an exciting new topic that is now being developed. The topic has recently been reviewed (Ref 11). At least in theory, microbial inhibition of corrosion could work in several ways, including:

- Forming or stabilizing protective films on the metal surface. This could include bacterial mediation of sulfide species at iron surfaces (Ref 11) and the stabilization of protective films on copper (Ref 117) and copper-nickel alloys (Ref 118).
- Decreasing the corrosiveness of the electrolyte. Just as microorganisms can create aggressive conditions by the formation of corrosive metabolites, they also can create benign conditions, for example, by decreasing the dissolved oxygen concentration (Ref 119) or changing the pH, as long as a uniform effect can be achieved.
- Altering or neutralizing corrosive substances. Organic compounds related to biofilm formation have been reported to decrease hydrogen embrittlement and cracking by hindering the dissolution, dissociation, and adsorption of hydrogen (Ref 120).

The concept of using regenerative biofilms for corrosion control in aluminum, brass, and steel systems is actively under investigation by several investigators (Ref 121, 122, 123, 124, 125, 126). It must be emphasized, however, that the process of corrosion control by bacteria is highly complex. As of the date of this publication, it cannot be predicted and controlled (Ref 127). Thus, considerable further research is required before this process can be used successfully as a reliable industrial corrosion control technique.

Introduction to Corrosion Testing and Evaluation

Bernard S. Covino, Jr., Albany Research Center, U.S. Department of Energy

Introduction

"CORROSION TESTING AND EVALUATION" contains information on the how, why, and where of corrosion testing. There are step- by-step instructions for techniques, examples of actual test data, hints to help in interpretation, references, and selected references for further information. Because corrosion testing and evaluation is such an integral part of the job of all corrosion engineers, scientists, and technicians, this Section presents a uniform view of state-of- the-art corrosion testing and evaluation procedures that are currently being used by corrosionists.

There are many good reasons for having a uniform source of corrosion testing and evaluation procedures. Uniformity of testing and evaluation ensures that the worldwide corrosion community will speak the same language to its customers. Uniformity can be viewed as a form of quality control of the product that corrosionists present to their clients. On the other hand, active members of the corrosion community will always push the envelope to develop new corrosion testing techniques and ways of interpreting corrosion data. The challenge is to create and achieve acceptance and agreement for the new techniques that will become basic tools for future corrosionists.

The "Corrosion Testing and Evaluation" Section consists of five subsections: "Planning Corrosion Tests and Evaluating Results," "Laboratory Corrosion Testing," "Simulated Service Corrosion Testing," "In-Service Techniques for Damage Detection and Monitoring," and "Evaluating Forms of Corrosion." The articles in this Section have been extensively updated, plus there is more than 30% totally new material.

Planning Corrosion Tests and Evaluating Results

This subsection contains vital information for the corrosionist. Properly designed and planned experiments can reduce the number of experiments and produce data that are subjected to statistical analysis. Statistically significant data can then be used to develop mechanistic- and knowledge-based models that are used, for example, as critical elements in life cycle management of equipment and structures.

Laboratory Corrosion Testing

Laboratory procedures are used to screen metals and alloys for further testing and to develop data helpful to understanding corrosion processes. Immersion testing is the most frequently conducted procedure for evaluating corrosion resistance. However, when more information than corrosion rate is needed or accelerated testing is required, electrochemical techniques are often considered. Many electrochemical techniques are available, and their use has been made easier by the incorporation of computer software and hardware. Accelerated testing of materials is often conducted in salt spray, fog, and light exposure cabinets. Techniques for conducting microbiologically influenced corrosion tests are presented with an increased emphasis in this subsection.

Simulated Service Corrosion Testing

Simulated service testing produces corrosion data with reliability second only to in-service exposures. This subsection considers corrosion testing techniques for three common environments: atmosphere, water, and soil. Changes in atmospheric corrosion testing are being driven by the need for more mechanistic and predictive information and by the development of corrosivity maps. Some of this predictive capability requires the determination of a mass balance for the corrosion reaction and the determination of the effect of atmospheric constituents on corrosion through the measurement of runoff water chemistry. Testing in waters is a mature science, and most applicable techniques are covered by NACE and ASTM standards. As in aqueous environments, immersion testing by using buried coupons is the most widely used practice for underground or soil corrosion tests.

In-Service Techniques for Damage Detection and Monitoring

This subsection addresses corrosion and corrosivity sensing techniques that can be used in situ in addition to ex situ techniques for detecting corrosion. Direct testing of coupons is used frequently to monitor in-service corrosion because of the simplicity and accuracy of the technique. Electrochemical techniques such as linear polarization resistance and electrochemical noise have moved from the laboratory to the processing plant and beyond to help with the detection of general and localized corrosion. Electrical and inductive resistance probes are frequently used to measure general corrosion rates. Ex situ techniques, such as ultrasonic thickness measurements, work from the outside of the vessel. Emerging techniques, such as microwave and guided wave ultrasonic methods can be configured to detect corrosion under coatings or to measure the moisture content of the interior of structures. Infrared imaging is typically used to detect the presence of corrosion under a coating.

Evaluating Forms of Corrosion

The articles in this subsection address the wide variety of corrosion phenomena experienced in the laboratory, in simulated service testing, and in in-service testing: uniform, pitting, crevice, galvanic, intergranular, exfoliation, cavitation, impingement, gaseous, and microbiologically influenced corrosion. Stress-corrosion cracking, hydrogen embrittlement, and erosion corrosion also are covered. This subsection describes specific tests and their interpretation for all of the aforementioned forms of corrosion. Substantial information is included on specialized test techniques not addressed in the subsections “Laboratory Corrosion Testing” or “Simulated Service Corrosion Testing,” for forms of corrosion such as stress-corrosion cracking, corrosion fatigue, and hydrogen embrittlement.

Designing, Planning, and Preparing Corrosion Tests

P.R. Roberge, Royal Military College of Canada

Introduction

THE CORROSION BEHAVIOR of a given material depends on the environment and the conditions of exposure as well as the condition of the test material. The most reliable predictor of performance is service experience, followed closely by field testing, because both are based on the actual environment and its complex variations. Part of the testing philosophy involves whether the test is intended to reproduce a certain environment accurately or whether it is more advisable to use a corrosive environment that represents a worst-case situation. In either case, the corrosion investigator must do everything possible to make the test reproducible by documenting and exercising explicit control over environmental factors such as concentration of reactants and contaminants, solution pH, temperature, aeration, velocity, impingement, and bacteriological effects.

Corrosion behavior is often the result of complicated interactions between the conditions of a metallic surface and the adjacent environment to which it is exposed. Therefore, there is no universal corrosion test for all purposes. Many investigators have traditionally avoided the use of statistical techniques because the added reliability did not seem to offset the effort and time required to become familiar with the methodology or to perform the calculations. Most often, the results must be interpreted in terms of relative rankings. Such interpretations can be subjective and depend much on the judgment of the investigator. Therefore, it is advisable, when planning a corrosion-testing program, to select the testing conditions carefully in order to produce ranking parameters with minimal influence from testing conditions while rich in engineering significance.

P.R. Roberge, Designing, Planning, and Preparing Corrosion Tests, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 420–424

Test Objectives and Conditions

Properly conducted corrosion tests can mean the savings of important assets. They are the means of avoiding the use of a metal under unsuitable conditions or of using a more expensive material than is required. Corrosion tests also help in the development of new alloys that perform more inexpensively, more efficiently, longer, or more safely than the alloys currently in use. Corrosion testing programs can be simple and completed in a few minutes or hours, or they can be complex, requiring the combined work of a number of investigators over a period of years. Preliminary time and effort spent considering metallurgical factors, environmental variations, statistical treatment, and the interpretation of accelerated test results are often the most useful part of the test procedures. Typical corrosion test objectives include:

- Determining the best material to fill a need (material selection)
- Predicting the probable service life of a product or structure

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- Evaluating the new commercial alloys and processes
- Assisting with development of materials with improved resistance to corrosion
- Conducting lot-release and acceptance tests to determine whether material meets specifications (quality control)
- Evaluating environmental variations and controls (inhibitors)
- Determining the most economical means of reducing corrosion (evaulate prevention methods)
- Studying corrosion mechanisms

Metal Composition and Metallurgical Condition. If commercial alloys are to be tested, the preferred procedure is to obtain mill-fabricated material representative of current production. If possible, a fabrication history should be obtained listing the major fabricating steps, together with an accurate analysis of the metal composition. Metallographic examination may also be necessary to ensure that the material is in a proper metallurgical condition. When nonstandard alloys or metallurgical treatments are to be evaluated, it may be economically impractical to have them fabricated with large production equipment. In such cases, laboratory casts or heats can be made in small quantities. Although this is a valid procedure for initial tests, a promising alloy candidate should be evaluated several times by using specimens from quantities of material large enough to be representative of typical production runs before it is produced commercially. Several production lots must be evaluated because promising results from a single lot of material are often not reproduced on subsequent fabrication runs.

Another preliminary decision is the form of metal to be tested. Metals are available in two basic forms: cast and wrought (worked). These two forms should not be interchanged in testing. The various methods of casting (such as die, permanent mold, and sand mold) and the various methods of working wrought products (drawing, extruding, forging, rolling) will affect grain structure and homogeneity, which consequently can affect corrosion resistance. The metal procured for the test should be, as nearly as possible, the type that will be used in the intended application.

Preparation of Test Specimens. The sampling of test materials and the preparation of test specimens are important variables in corrosion testing, because corrosion behavior can be significantly influenced by variations in metallurgical structure and the condition of the metal surface. These factors are especially pertinent when various forms of localized corrosion are under evaluation in complex alloys. The uniformity of the randomly chosen metal sample population should be verified as part of the plan for preparation of the test specimens. Problems resulting from lack of uniformity are less likely to be encountered with pure metals and homogeneous alloys.

The primary consideration should be the use of test specimens that are truly representative of the specified material, that is, alloy, metallurgical condition, and product form, rather than specimens that are the most expedient for the investigation. For example, it might seem advantageous to obtain flat, uniform disk specimens by machining slices from an extruded rod rather than by shearing or stamping test coupons from rolled sheet (and avoiding residual stresses in the sheared edges). However, the corrosion behavior of the end-grain surfaces of the machined disks could be different from that of the rolled surface of the sheet product.

Surface preparation by various machining or polishing methods and various chemical treatments can be a source of considerable variation in test results and must be controlled. In some cases, it may be desired to evaluate the metal in the mill-finished condition, although this approach will generally result in the greatest variability. As a general rule, corrosion-testing standards contain specific recommendations regarding appropriate surface treatments, depending on the metal alloy system. Judicious use of proper or standardized surface treatments will reduce variability in corrosion test results.

Assessment of Corrosion Damage. Appropriate methods of measuring degradation of metallic materials depend on the form of corrosion being observed. For example, the age-old method of measuring corrosion by determining weight loss and calculating average corrosion rates, which is adequate for metals that corrode uniformly, is not a realistic measure of localized forms of corrosion, such as pitting and intergranular attack. A serious consideration in the corrosion testing of metals is the use of suitable controls, both for the metal and for the test environment. With some materials, certain characteristics used for assessing corrosion damage will change with time, even in the absence of corrosion. In such cases, a set of control specimens must be provided for each period of corrosion testing. This set is then evaluated at the same time as the corroded specimens. Some alloys, for example, gradually change in strength over long periods of time at room temperature, and the strength of most metals is affected by time at elevated temperatures.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Another required control is a method of determining whether the corrosive medium maintains the intended degree of corrosivity. When an alloy is tested repeatedly by the same method, as in quality-control tests, the investigator may be sufficiently experienced to know whether the visual appearance and resultant data are of the order expected. This is often not the case with new alloys or products because their corrosion performance is unpredictable. The usual procedure is to expose a well-established previously tested alloy as a control to determine whether the results are consistent with past experience. If they are, the new alloy is considered to have received a valid exposure. However, if the effects of corrosion on the well-known alloy are not typical, the investigator is alerted to the possibility of an error in test environment and the necessity for a rerun of the test after corrective measures have been made.

Reliability of Corrosion Test Results. Corrosion rate results should be used with caution. Corrosion engineers frequently take the results of relatively short-term one-period exposure tests, divide the weight loss (or pit depth) of the metal by the time of exposure, and from this determine a constant rate of corrosion for the particular metal-environment combination. Such early one-point average rates are valid only when materials corrode linearly with time; however, this is the exception rather than the rule for metals in natural environments. The effect of film formation on the surface varies the corrosion rate with time in a large majority of cases. The creation of a film of corrosion product often shields the metal substrate from the corrosive environment, with a resulting decrease in corrosion rate. In this case, the projection of corrosion rates before a film has formed will be unduly pessimistic.

At best, the precision of corrosion test results leaves something to be desired because of the relative complexity of corrosion systems. This is particularly true when evaluating forms of localized corrosion, which can be related often to heterogeneous microstructures in the test material. As progress is being made in the standardization of corrosion test methods, more attention is being directed toward providing potential users of the methods with information to help them assess in general terms its usefulness in proposed applications. The American Society for Testing and Materials (ASTM) recently made it mandatory that statements on the precision (reproducibility) and bias (systematic error) be included in every standard for a test method. If this information is not currently available to the corrosion investigator, it should added as a requirement to the test plan.

Designing, Planning, and Preparing Corrosion Tests

P.R. Roberge, Royal Military College of Canada

Design of Experiments

A strategy for planning research known as design of experiments was first introduced in the early 1920s when a scientist at a small agricultural research station in England, Sir Ronald Fisher, showed how one could conduct valid experiments in the presence of many naturally fluctuating conditions such as temperature, soil condition, and rainfall. The design principles that he developed for agricultural experiments have been successfully adapted to industrial and military applications since the 1940s.

Experimental design is an iterative process of analyzing test results in a systematic way to create, verify, and perfect models that can in turn serve to plan more efficient and less costly test programs. Applied to a corrosion problem, such a process can combine modern scientific principles with an appreciation of the mechanisms of degradation of the material being studied. Experimental design is an accepted methodology that can help to make the transition between simple but practical empirical models to the most sophisticated multiparameter mechanistic models.

The role of experimental design in acquiring the knowledge of a process (Fig. 1) emphasizes the iterative aspect of the process leading to the creation of realistic models. As expressed in this figure, the selection of an experimental strategy should precede and influence data acquisition. It is indeed difficult, if not impossible, to

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

retrofit experiments to satisfy the statistical considerations necessary for the construction of valid models. Any time spent in preparing a test program is a good investment. The most important consideration, at the initial planning stages, should be to integrate the available information in order to limit future setbacks. Table 1 expands on each of the elements in Fig. 1 by indicating many of the questions that should be asked at the three stages of a statistical design loop for acquiring knowledge of a process. See Ref 1 for a detailed description of the experimental design process.

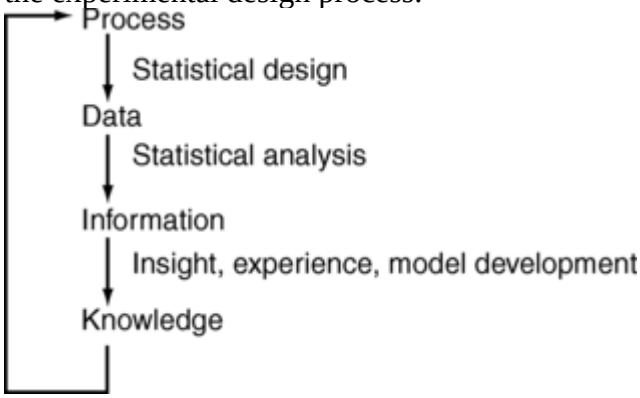

Fig. 1 Statistical design loop for acquiring knowledge of a process

Table 1 Elements of the iterative process for experimental design

Process step/Category	Question
Statistical design	
Process definition	What are the relevant material and environmental factors?
	What is the domain or operating envelope to be investigated?
	What is the expected outcome?
Preliminary questions	What are the experimental constraints?
	What systematic errors are expected?
	Should the trials be randomized?
	Is there an estimate for the experimental errors?
	Should all factors be investigated at once?
	Should there be a central point measurement?
Optimizing design	How many factors must be considered?
	Are interactions between factors expected?
	Should the design be complete or fractional?
	What is the most logical order of experiments?
Data—analysis of results	
Critical analysis	Are some results suspect (outliers)?
	Were the factor levels well set?
	Calculate the effects of the factors using statistical parameters.
	Check for ambiguities.
Follow-up	Should the experimental domain be modified?[(a)]
	Is a complementary test design required?[(a)]
	Is the chosen mathematical model appropriate?[(a)]
Information-model development	
Model development	Will complementary designs be encompassed?
	Are complementary trials required?
	Are new factors addressed?
	Can the operating envelope be expanded?
	Is a new model more suitable?
	Is the mathematical model optimized?

مرجع مهندسی مواد و متالورژی

(a) If all three answers are “no,” the experiment can be stopped. If one is “yes,” the experimentation should continue.

It is believed that the systematic design of experiments can (Ref 2):

- Save time and money: fewer experiments are required per firm conclusion.
- Simplify data handling: data are digested in a readily reusable form.
- Establish better correlations: variables and their effects are isolated.
- Provide greater accuracy: the estimation of errors is cornerstone to statistical design.

While some of the factors leading to corrosion damage can be reproduced relatively easily by creating a situation favorable to their occurrence, other factors depend entirely on the development of local defects that often become visible only after long and highly variable periods of exposure. When an experiment or test is planned, many factors have to be considered. Some of the standard considerations for the design of a test program include (Ref 3):

- How should the results be interpreted?
- How can the information be integrated with earlier or other tests?
- How many specimens are available?
- What is the production schedule (batch, sequential)?
- How many factors control the behavior of the specimen?
- How many factors are to be included in the tests?
- Which of these factors interact and which have negligible interaction?
- What type of data is to be measured?
- Is the sample homogeneous?
- How representative is the sample?
- Are the tests destructive?
- How expensive are the tests and/or specimens?
- How much control is there over testing?
- How difficult would it be to compensate for human errors in the planning?

Out of all these questions and interrogations, a test protocol should be developed to transform the corrosion test design into a set of reliable and reproducible measurements that achieve the goals and objectives of the test. The test protocol can simply be a guide or “road map” to the collection of raw or uninterpreted measurements defining the methods and standards used. When measurements must meet legal, regulatory, or customer requirements, the test protocol may be codified into a quality assurance plan. The test protocol typically specifies criteria for precision, accuracy, completeness, representativeness, and comparability of the corrosion and related measurements. The test protocol can address sampling and analytical procedures, calibration procedures and standards, data reduction and processing methods, data validation, data reporting, and even data audits (Ref 4).

Experiment Design Strategies. Properly designed and executed experiments will generate more precise data while using substantially fewer experimental runs than alternative approaches. They will lead to results that can be interpreted using relatively simple statistical techniques, in contrast to the information gathered in observational studies, which can be exceedingly difficult to interpret. Corrosion scientists and engineers usually work with either controlled or uncontrolled experiments. Properly designed controlled experiments are much more amenable to statistical analysis of variance than are properly designed uncontrolled experiments (Ref 5).

Controlled Factorial Experiments. In controlled experiments, levels of independent variables are controlled, and the dependent variables showing the progress of a corrosion attack are measured with proper means. The framework of factors and subfactors presented in Table 1 of the article “Statistical Interpretation of Corrosion Test Results” in this Volume is an exhaustive list of the independent variables to control in a planned corrosion experiment. The results of an expert opinion poll highlighting the most important factors involved in various forms of corrosion failures presented in Table 2 of the same article could help shorten the list of actual variables of significance in given situations.

Each controlled variable with more than one controlled level is considered a factor in such experiments. The main advantage of a factorial design experiment is that interaction as well as direct effects can be studied with

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

less replication than several one-way analyses of variances. An example of an interaction effect is a change of slope of a corrosion-rate/relative-humidity curve with a change in temperature. Researchers use two-level factorial experiments to determine which variables or factors cause direct synergistic effects on the measured parameter. Each new factor introduced, however, doubles the number of test conditions. Thus, the need to include a large number of factors in a complete experimental design often results in an impractical number of test conditions. To circumvent this problem, statisticians can design fractional experiments that produce nearly all the information needed by confounding some possible effects such as higher-order interactions (Ref 5).

This efficiency is often lost when interactions exist. In the field of corrosion research, it is difficult to find combinations of three or more significant variables that will not produce at least one interaction. Sometimes interaction effects are more important than the separate variable effects. A particular example of such interactions in a corrosion situation is the occurrence of stress-corrosion cracking (SCC), which clearly involves three factors:

- Susceptibility of the material to SCC
- The presence of a corrosive environment conducive to SCC
- The presence of sustained stresses

Stress-corrosion cracking will not occur if any one of the three conditions is absent. Because interactions can be important, the factorial design determines what interactions occur and the magnitude of their effect. The two-level factorial design is excellent to use when several variables could affect the test outcome. This design determines what variables, combination of variables, or both, could have a significant effect on the results. In practice, all variables or factors that could possibly affect the test outcome should be included. If n is the number of variables, 2^n is the number of cases or conditions in the two- level factorial design. Replication of some of the conditions is necessary to establish an error variance (Ref 4). One disadvantage of two-level factorial designs is that the size of the study increases by a factor of two for each additional factor. For example, with eight factors, 2^8 or 256 runs would theoretically be necessary. Fortunately, because three-factor and higher-order interactions are rarely important, such intensive efforts are seldom required.

For most purposes, it is only necessary to evaluate the main effects of each variable and the two-factor interactions, which can be done with only a fraction of the runs in a full-factorial design. Such designs are called resolution V designs. If there are some two-factor interactions that are known to be impossible, one can further reduce the number of runs by using resolution IV designs.

Design resolution is defined in terms of which effects are unconfounded with which other effects. One ordinarily seeks fractional factorial experiments that have main effects (s = 1) and low-order interactions (say those involving s = 2 or 3 factors) unconfounded with other main effects and low-order interactions-equivalently, in which they are confounded only with high- order interactions.

The resolution of a design is usually denoted by uppercase Roman numerals (e.g. III, IV, V). A design in which main effects are not confounded with other main effects but are confounded with two-factor and higher-order interactions is a resolution-III design. Such a design is of resolution III because effects containing s = 1 factor are unconfounded with effects containing less than R - s = 3 - 1 = 2 factors. The only effects containing less than s = 2 factors are other main effects.

In a resolution-IV design, main effects are unconfounded with effects involving less than R - s = 4 - 1 = 3 factors, i.e., main effects and two-factor interactions. Two-factor interactions (s = 2) are unconfounded with effects involving less than R - s = 2 factors, i.e., main effects (s = 1). There are some two-factor interactions confounded with other two-factor interactions in R IV designs.

A design of resolution V has main effects and two-factor interactions (s = 1, 2) unconfounded with one another. Some main effects are confounded with four-factor and higher-order interactions. Some two-factor interactions are confounded with three-factor and higher-order interactions.

A good compromise for complex situations is to employ what is called a screening design technique to identify the most dominant factors, often with the intent to conduct a more extensive and systematic investigation (Ref 6). An important application of screening experiments is also to perform ruggedness tests that, once completed, will permit the control or limitation of environmental factors or test conditions that can easily influence a test program (Ref 7). There are, of course, many subtleties in designing experiments that may intimidate a person with limited familiarity of statistics. Fortunately, however, there are a number of software systems that will guide a user in a friendly manner through the process of designing experiments.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Uncontrolled Experiments. In the real world, materials are seldom exposed to controlled environments. In uncontrolled experiments such as atmospheric exposures, uncontrolled independent variables such as temperature and relative humidity are measured along with the dependent corrosion results. A properly designed uncontrolled experiment is one that considers all the possible effects of uncontrolled variables. The knowledge of physical and chemical processes is most valuable in this respect. If an important variable is missed, all the other data become less meaningful (Ref 5).

For proper subsequent analysis, uncontrolled experiments require the collection of considerable data. As an example, if one were to collect ten sets of data involving nine uncontrolled variables and the measured corrosion results, a total of 100 data points would have been collected for further analysis. If all the variables were included in that analysis, a perfect mathematical fit could be obtained; however, this fit would be both physically and statistically meaningless. The experimental design does not consider the possibility of nonlinear effects, interaction effects, or error effects. One approach to ensure that enough data sets are collected is to count all the physically and chemically (not mathematically) possible direct and interaction effects of the measured variables and multiply by 4 or 5 to account for possible nonlinearity and error (Ref 5).

Blocking. The more widely used statistical techniques typically assume that “independent” variables are not associated with each other and that their levels are fixed and have no measurement error. These assumptions are seldom true in practice. Often the independent variables studied as possible corrosion contributors are subject to measurement error and may have effects on each other as well as on corrosion performance. Too few or poor measurements of independent variables can result in an inability to show statistical association when an actual cause-effect relationship exits. The more data collected on the independent variables, the greater the probability that good relationships between these variables and corrosion performance can be established (Ref 4). It is well recognized that the planning activities that precede the actual test runs are critical to the successful resolution of the experimenter's problem. In planning an experiment, it is necessary to limit any bias that may be introduced by the experimental units or experimental conditions. Strategies such as randomization and blocking can be used to minimize the effect of nuisance or noise elements.

In some production processes, units are produced in natural “chunks” or blocks. Blocking can be used to prevent experimental results from being influenced by variations from batch to batch, machine to machine, day to day, or shift to shift. For example, when the process being investigated can only produce a fraction of the samples required for all runs in a planned experiment, it may be necessary to break up the experiment into blocks. However, it is not desired to run positive settings of all factors in one block, and all negative settings in the other. Otherwise, any incidental differences between blocks would systematically affect all estimates of the main effects of the factors of interest. Rather, it is advisable to distribute the runs over the blocks so that any differences between blocks (i.e., the blocking factor) do not bias the results for the factor effects of interest. This is accomplished by treating the blocking factor as another factor in the design. Consequently, another interaction effect is lost to the blocking factor, and the resultant design is of lower resolution. However, these designs often have the advantage of being statistically more powerful because they allow estimating and controlling the variability in the production process that is due to differences between blocks.

Examples of Experimental Designs Applied to Corrosion Testing

Example 1: Selection of a Cast Superalloy. In this study, a series of cast nickel-base γ/γ′ superalloys were systematically varied at selected levels of cobalt, chromium, molybdenum, tantalum, and aluminum and the alloys weight change performance was monitored (Ref 8). A full-factorial central experimental design was used, making up five sets of star points to completely map the response of these alloys. For five elemental variables, 43 alloy compositions were required. The results analyzed by regression analysis led to a complete second-degree equation describing the total variability of the alloy performance.

Example 2: Improved Cosmetic Corrosion Test. Within the efforts of the American Iron and Steel Institute's (AISI) Task Force on Automotive Corrosion, a design of experiments program was initiated. The aim of this program was to study the effects of a number of carefully selected test parameters on the performance of automotive steel sheet products subjected to a cyclic corrosion test and to “on-vehicle” tests (Ref 9). A review of the literature guided the initial selection of the seven test variables considered of major importance to corrosion performance of automotive steel. Triplicate 100 by 150 mm (4 by 6 in.) panels were exposed to eight test runs designed according to a Plackett-Burman partial factorial design. The results of these tests were to be used as a guide to develop an improved test procedure.

Example 3: Container Material for Nuclear Waste Disposal. In this project, a two-level factorial design was adopted to map the effects of five environmental factors (Cl^-, SO^{2-}_4, NO^-_3, F^-, and temperature) on a candidate material for containers in the Yucca Mountain repository site (Ref 10). The trial order was randomized before testing and a five-factor interaction was used to block the experiments, in terms of two different potentiostats used in the study, in order to verify the instrumental variability. A complete response surface of alloy 825 resistance to localized corrosion, estimated by cyclic polarization, was produced as a function of environmental variables.

Example 4: Managing Water Chemistry. Experimental design was also used to study mild steel corrosion in water containing various scaling agents and the addition of an organophosphorus inhibitor (Ref 11). The corrosion rates were measured in laboratory experiments with linear polarization. Mathematical models were generated relating the corrosion behavior to solution flow rate and the concentrations of Ca^{2+}, Cl^-, HCO^-_3, and the organic inhibitor. Two models were developed in this study: the first described the corrosion rates of mild steel and the second the scaling tendencies of the water. These models were then validated with pilot cooling tower experiments.

Example 5: Corrosivity in Complex Environments. Experimental design techniques were also used to develop models for understanding the effects of complex environments on materials considered for the operation of different processes such as wood pyrolysis (Ref 12), gas desulfurization (Ref 13), and continuous digesters (Ref 14). In these studies, it was demonstrated that designed experiments are essential to reduce the complexity of the environments (solution variables, constraints, etc.) to a manageable level. When properly done, the results of such studies can be used to predict the corrosion performance of alloys as a function of solution composition.

Statistical Interpretation of Corrosion Test Results

P.R. Roberge, Royal Military College of Canada

Introduction

IMPORTANT ASPECTS of any corrosion investigation are the credibility of the test results and user acceptance of the test methodology. When commercially competitive materials are evaluated or when corrosion tests are used for materials acceptance, the testing techniques come under close scrutiny and quick criticism in the marketplace. Public safety and producer liability are potent considerations in decisions involving materials selection and the determination of safe environments. A significant degree of confidence is justified only after an accumulation of sufficient experience in correlating test data with actual performance behavior under known conditions.

Statistical Interpretation of Corrosion Test Results

P.R. Roberge, Royal Military College of Canada

Complexity of Test Conditions

Corrosion test results often show more scatter than many other types of tests because of a variety of factors, an important one being the effect on corrosion rates due to minor impurities in the materials themselves or in the testing environments (Ref 1). This intrinsic complexity has made the transformation of corrosion testing results into usable real-life functions for service applications a difficult task, because testing often results in the generation of unreliable data (Ref 2). The accuracy of data against testing time and number of factors, presented in Fig. 1, illustrates the relative difficulties associated with reproducing industrially realistic corrosion problems.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

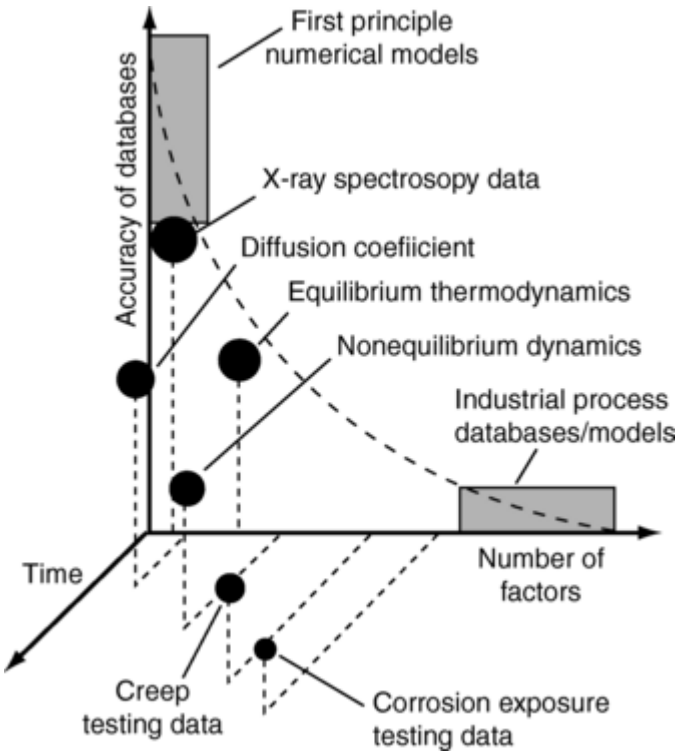

Fig. 1 Time and environment dependency of databases and models. Source: Ref 2

In the development of laboratory corrosion tests for alloy evaluation, for example, it is necessary to determine the dominant corrosion factors. Preferred practice is to design a test to represent a severe condition for the corrosion system involved, thus reducing the time for effects to be observed. One of the dominant factors is then chosen to be the rank-ordering factor. Study of alloy response as a function of this factor provides a means for comparing the corrosion resistance of different alloys. Following is a partial list of factors that have been used for evaluating the susceptibility of alloys to stress-corrosion cracking (Ref 3):

- Time to failure under constant load conditions
- Time to failure under constant strain conditions
- Threshold stress for failure
- Threshold stress for failure/yield strength
- Threshold strain for failure
- Threshold stress intensity
- Strain for 50% probability of failure
- Crack growth rate
- Time to failure (slow strain rate test)
- Loss of ductility (slow strain rate test)
- Fracture appearance (slow strain rate test)
- Work to failure (slow strain rate test)
- Critical strain rate

Mechanistic Aspects

Developments in accelerated testing should be based on modern scientific principles and incorporate an appreciation of the mechanisms of service degradation of the metal being studied. In the course of carrying out a failure analysis, the analyst must consider a broad spectrum of possibilities or reasons for the failure occurrence. A large number of factors, frequently uncorrelated, have to be considered to determine the cause of the original failure. If the failure can be duplicated under controlled simulated service conditions, much can be learned about the initial reasons for its occurrence (Ref 4). Many considerations impact the validity and accuracy of information gathered from laboratory testing programs, however. In principle, accelerated life tests and performance degradation tests serve various purposes, ranging from quality control to measuring the reliability of manufactured products (Ref 5).

Acceleration Considerations. The continuous salt spray practice (Ref 6), for example, which was designed originally to test coatings on metals, has been used widely to evaluate the resistance of metals to corrosion in marine service or on exposed shore locations (Ref 7, 8). Extensive experience has shown that, although salt spray tests yield results somewhat similar to those in marine exposure, they do not reproduce all the factors causing corrosion in marine service. Reviews on this subject indicated that the salt spray test cannot realistically be used, for example, for parts with complicated shapes, because salt spray particles fall in vertical patterns, creating a strong orientation dependency (Ref 9, 10). Another major inadequacy of the test is the variable sensitivity of different metallic materials to the ions present in various service environments.

Many other cabinet tests have been developed to determine the corrosion performance of materials intended for use in natural atmospheres; see the article “Cabinet Testing” in this Volume. A series of ASTM International standards have been developed, for example, to relate different variations of creating and controlling fog and humidity in cabinets for corrosion testing of a broad spectrum of products. These products range from decorative electrodeposited coatings to the evaluation of the corrosivity of solder fluxes for copper tubing systems. The basic humidity test is most commonly used to evaluate the corrosivity of materials or the effects of residual contaminants. Cyclic humidity tests are conducted to simulate exposure to high humidity and heat typical of tropical environments.

More complex tests are based on controlled amounts of corrosive gases added to humidity to replicate more severe environments. Some of these tests are designed to reveal and amplify certain characteristics of a material by using very high concentrations of corrosive gases. Some amplify the presence of pores in gold or palladium coatings (Ref 11, 12). The moist SO_2 test is intended to produce corrosion in a form resembling that in industrial environments (Ref 13). A very sophisticated variation of these tests is the flowing of mixed gas test. Pollutants such as chlorine, hydrogen sulfide, and nitrogen dioxide are measured to a parts-per-billion precision in a chamber at controlled temperature and humidity (Ref 14). This test is particularly adapted to the needs of the electronics industry.

Framework of Factors. An increasingly accepted methodology consists of correlating the results obtained with these tests with actual service performance to verify that the corrosion mechanisms have indeed followed the same paths. Modern surface analysis techniques have been found to be quite useful to ascertain that the corrosion products have the same morphologies and crystallographic structures typically found on equipment

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

used in service. An interesting point of view is that all engineering materials are reactive chemicals and that the strength of materials depends on the extent to which environments influence the reactivity and subsequent degradation of these engineering materials (Ref 15). This concept was the subject of a major review with respect to stress-corrosion cracking (SCC), but the rationale behind the effort is universal and can be extended to all corrosion processes. The general framework consisted of the six factors presented in Table 1 (Ref 16). These factors represent independent variables affecting the intensity of SCC, with a number of subfactors, as shown in Table 1.

Table 1 Factors and subfactors controlling the occurrence of a stress-corrosion cracking failure

Factor	Subfactors and contributing elements
Material	Chemical composition of alloy
	Crystal structure
	Grain-boundary composition
	Surface condition
Environment	
Chemical definition	Type, chemistry, concentration, phase, conductivity of corrodent
Circumstance	Velocity of fluid, thin layer in equilibrium with relative humidity, cyclic wetting and drying, heat transfer, boiling, wear and fretting, deposits
Temperature	At metal surface exposed to environment
	Temperature fluctuation
Stress	
Stress definition	Mean stress, maximum stress, minimum stress, constant load, constant strain, strain rate, plane stress, plane strain, modes of deformation (I, II, III), biaxial, cyclic frequency, wave shape
Sources of stress	Intentional, residual, produced by reacted products, thermal cycling
Geometry	Discontinuities as stress intensifiers
	Creation of galvanic potentials
	Heterogeneous chemicals in crevices
	Gravitational settling of solids
	Restricted geometry, with heat transfer leading to concentration effects
	Orientation vs. environment
Time	Change in grain-boundary chemistry
	Change in structure
	Change in surface deposits, chemistry, or heat-transfer resistance
	Development of surface defects, pitting, or erosion
	Development of occluded geometry
	Relaxation of stress

Types of Corrosion Damage. A generally accepted classification scheme of corrosion damage is based on the appearance of a corrosion attack. The term *form* of corrosion generally is attributed to Ref 17. The eight basic forms of corrosion were considered, slightly expanded, and divided into three groups, based on their ease of identification (Ref 18):

Group 1: readily identifiable by ordinary visual examination	**Uniform corrosion** **Pitting** **Crevice corrosion** **Galvanic corrosion**
Group 2: may require supplementary means of examination	Erosion Cavitation Fretting Intergranular
Group 3: verification is usually required by microscopy	Exfoliation Dealloying Stress-corrosion cracking Corrosion fatigue

Many tests have been designed specifically to reveal the susceptibility of materials to one or more of these corrosion forms. However, the mechanisms behind a corrosion attack are controlled by factors similar to those listed in Table 1. Because there are actually no known studies specifically linking these two different frameworks, it was decided to carry out a survey following principles of knowledge engineering. Fifteen recognized corrosion experts completed an opinion poll concerning the main subfactors and the common forms of corrosion. Responses were then analyzed to determine the importance of factors in Table 1 to commonly accepted forms of corrosion failure (Table 2). A more detailed analysis of the responses obtained for pitting corrosion is shown as box-and-whisker plots in Fig. 2. (In a box-and-whisker plot, the whiskers represent the complete range of values. The median, also called the second quartile, is the vertical line within the box. The median of the lower part of the data is calculated. This is the first quartile, and it locates the left side of the box. Likewise, the median of the remaining upper part of the data is calculated. This is the third quartile, and it locates the right side of the box.) In Table 3, the responses are ranked in decreasing order of the median and sharpness of the responses (inverse of the breadth of the whiskers).

(a) Presence of one suspect outlier

Such a simple survey reveals the lack of consensus that exists currently on the importance of many of the subfactors causing corrosion damage. Some of the ambiguities are probably due to the high level of context sensitivity that is a fundamental character of failure analysis. Pitting corrosion, which was selected here as an example, may assume different shapes. Pitting corrosion can produce pits with their mouth open (uncovered) or covered with a semipermeable membrane of corrosion products. Pits can be either hemispherical or cup-shaped. In some cases, they are flat walled, revealing the crystal structure of the metal, or they may have a completely irregular shape (Ref 19). In some instances, pits can be very damaging even at the micrometer level, while in other cases an inspector would only get nervous upon the appearance of pits at the macroscopic level.

Statistical Interpretation of Corrosion Test Results

P.R. Roberge, Royal Military College of Canada

Probabilistic Aspects

The concept of probability distribution was first applied in a corrosion context in the 1930s (Ref 20, 21). A landmark paper (Ref 21) described a simple arrangement of metallic coupons subdivided in a multitude of small squares by masking with paraffin (Fig. 3). From this arrangement, the influence of 16 basic variables on the probability and relative velocity of corrosion attack was estimated. The probabilistic behavior of corrosion

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

processes has since been described to fall under one of several basic probability distributions, as indicated in Table 4 (Ref 22). The following descriptions highlight the main characteristics of some of these distributions.

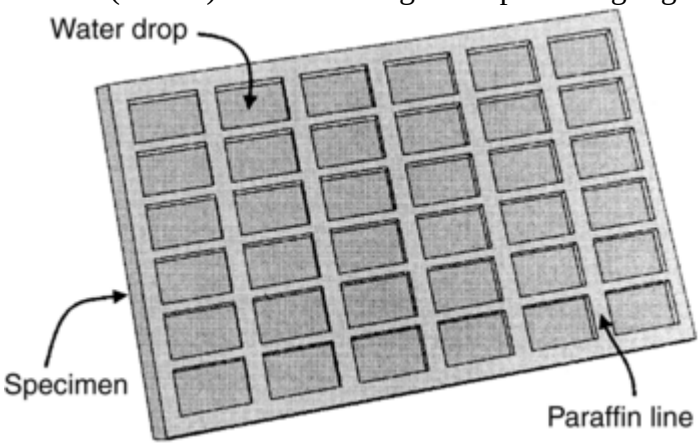

Fig. 3 Schematic representation of the test specimen used in the experiment to demonstrate the probabilistic nature of corrosion phenomena

Table 4 Main probability distributions observed in corrosion testing

Probability distribution	Corrosion phenomenon
Normal	Pitting potential
Log normal	Stress-corrosion cracking (SCC) failure time
Poisson	Two-dimensional distribution of pits
Exponential	Pit induction time SCC and hydrogen embrittlement failure time
Extreme value	Maximum pit depth SCC failure time Fatigue crack depth

Source: Ref 22

Normal Distribution. The normal probability distribution function has the familiar symmetrical bell shape and is the basis for the most common statistical techniques of experimental design and data analysis. A sample of test results of mass loss, mass gain, thickness loss, corrosion potential, corrosion rate, and pitting area may have a normal distribution. The following equations describe the normal probability distribution function, $f(x)$, and the cumulative normal probability function, $F(x)$:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] \quad \text{(Eq 1)}$$

$$F(x) = \int f(x)dx = \frac{1}{\sigma\sqrt{2\pi}} \int \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] dx \quad \text{(Eq 2)}$$

where μ is the mean, σ is the standard deviation, and x is the measured variable.

Log-Normal Distribution. In some cases, assuming a log-normal distribution can produce a more fitting analysis of the results. A log-normal distribution is simply data that have a normal distribution after they are converted to logarithms. The data can then be analyzed using normal statistical techniques. Some types of corrosion data that have been shown to be distributed in log-normal functions are weight loss, thickness loss,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

time to initial stress-corrosion cracks, time to SCC failures, and polarization currents in the Tafel slope range. Some indicators that a process is best described by log-normal distribution are (Ref 23):

- Data values that physically cannot be negative
- Normal standard deviations that are proportional to arithmetic means
- Arithmetic means that are consistently greater than median values
- Dependent parameters whose logarithms are proportional to the values of independent parameters

The following equations describe the log-normal probability distribution function, $f(x)$, and the cumulative log-normal probability function, $F(x)$:

$$f(x) = \frac{1}{\sigma' x\sqrt{2\pi}} \exp\left[-\frac{(\ln x - \mu')^2}{2\sigma'^2}\right] \quad \text{(Eq 3)}$$

$$F(x) = \int f(x)\,dx$$

$$= \frac{1}{\sigma'\sqrt{2\pi}} \int \frac{1}{x} \exp\left[-\frac{(\ln x - \mu')^2}{2\sigma'^2}\right] dx \quad \text{(Eq 4)}$$

where μ' is the mean, σ' is the standard deviation of data in logarithm form, and x is the measured variable.

Exponential distribution is widely used in reliability analysis. It is the simplest probability distribution because it is characterized by one parameter, a constant hazard rate (λ), which, in terms of frequency of occurrence, translates into a rapid decay from high initial values. Metastable pitting on stainless steels or on other noble alloys has often been characterized by such distribution. The electrochemical noise amplitude of singular events generated by corrosion processes has been shown to decay following an exponential distribution (Ref 24). The following equations describe the exponential probability distribution function, $f(x)$, and the cumulative exponential probability function, $F(x)$:

$$f(x) = \lambda \exp(-\lambda x) \quad \text{(Eq 5)}$$

$$F(x) = \int f(x)\,dx = 1 - \exp(-\lambda x) \quad \text{(Eq 6)}$$

where λ is the constant hazard rate, and x is the measured variable.

Poisson Distribution. Typically, a Poisson random variable is a count of the number of events that occur in a certain time interval or spatial area. The Poisson distribution is usually considered when the random or stochastic phenomena being observed occur on relatively rare occasions. Stable pit generation on stainless steel has been found to follow such a probability distribution (Ref 22). The following equations describe the Poisson probability distribution function, $f(x)$, and the cumulative Poisson probability function, $F(x)$:

$$f(x) = \frac{\lambda^x \exp(-\lambda)}{x!} \quad \text{(Eq 7)}$$

$$F(x) = \int f(x)\,dx = \sum_{i=0}^{x} \frac{\lambda^i \exp(-\lambda)}{i!} \quad \text{(Eq 8)}$$

where λ is the shape parameter defined by the number of events in a time-given interval, and x is the measured variable.

Extreme-Value Distribution. The depths of deepest pits on specimens, the times to first leaks in pipe lengths, the times to first SCC failures, and the number of cycles to first corrosion fatigue failures are, by definition, extreme values. The depth of the deepest pit on a specimen is the upper tail of the distribution of depths of all pits on that specimen (Ref 23). Engineers concerned with soil corrosion and underground steel piping are aware that the maximum pit depth found on a buried structure is somehow related to the percentage of the structure inspected. Finding the deepest actual pit requires a detailed inspection of the whole structure. As the area of the structure inspected decreases, so does the probability of finding the deepest actual pit. A number of statistical transformations have been proposed to quantify the distributions in pitting variables. Gumbel is given the credit

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

for the original development of extreme-value statistics (EVS) for the characterization of pit-depth distribution (Ref 25).

The EVS procedure is to measure maximum pit depths on several replicate specimens that have pitted, then arrange the pit-depth values in order of increasing rank. The Gumbel or extreme-value cumulative probability function is shown in Eq 9, where λ and α are the location and scale parameters, respectively. This probability function can be used to characterize the data set and estimate the extreme pit depth that possibly can affect the system from which the data was initially produced:

$$F(x) = \exp\left(-\exp\left[-\frac{x-\lambda}{\alpha}\right]\right) \quad \text{(Eq 9)}$$

In reality, there are three types of extreme- value probability functions (Ref 26):

- *Type 1:* exp(-exp[-*x*]), or the Gumbel distribution
- *Type 2:* exp(-x^{-k}), or the Cauchy distribution
- *Type 3:* exp(-[ω - *x*]^{k}), or the Weibull distribution

where *x* is a random variable, and *k* and ω are constants.

A goodness-of-fit test is required to verify which of these three distributions best fits a specific data set. The chi square test, or Kolmogorov-Simirnov test, has been used often for this purpose. A simpler graphical procedure is also possible using a generalized extreme-value distribution with a shape factor dependent on the type of distribution. There are two expressions for the generalized extreme-value cumulative probability function, that is, when $kx \leq (\alpha + \lambda k)$ and $k \neq 0$:

$$F(x) = \exp\left(-1 - k\frac{x-\lambda}{\alpha}\right)^{1/k} \quad \text{(Eq 10)}$$

and when $x \geq \lambda$ and $k = 0$:

$$F(x) = \exp\left(-\exp -\frac{x-\lambda}{\alpha}\right) \quad \text{(Eq 11)}$$

Some examples of corrosion situations have been reported where extreme-value distribution proved to be an adequate representation of the problems being addressed (Ref 27):

- For underground piping in a cathodic protection feasibility study
- For the evaluation of a gas distribution system and power plant condenser tubing
- During the assessment of stainless steel tube leaks
- The assessment of copper-nickel tube pitting performance

In another study, data from water injection pipeline systems and from the published literature were used to simulate the sample functions of pit growth on metal surfaces (Ref 28). The conclusions of that study were:

- Maximum pit depths were adequately characterized by extreme-value distribution.
- Corrosion rates for water injection systems could be modeled by a Gaussian distribution.
- An exponential pipeline leak growth model was appropriate for all operation regimes.

Statistical Analysis

Most physical and chemical measurements, performed under nominally identical conditions, yield differing data. The results of corrosion tests are no exception. Sometimes, the difference between values is less than measurement precision and cannot be detected. At other times, the difference approaches the magnitude of the values. This variability can diminish greatly the confidence in using corrosion test data to predict lifetime or long-term corrosion behavior. The consequences are that structures must be overdesigned, or unexpected failures can occur if variability is not addressed adequately during corrosion testing. The most effective way to address variability is to use the appropriate number of replicate samples for each test performed (Ref 29). Some of the statistical concepts to produce effective test programs are:

- Population, sample, and replication
- Best estimate of variance and standard deviation
- Confidence limits for the mean
- Simple linear regression
- Multiple regression analysis and analysis of variance
- Covariance of independent variables
- A long list of secondary topics that are the fabric of statistical analysis

Most of the modern spreadsheet programs can now do complex regression analysis and often even provide information on the analytical processes themselves.
In this Volume, the article "Statistics for the Corrosionist" provides information on some of these concepts.

Introduction

RECORDING CORROSION INFORMATION presents multiple difficulties, ranging from the basic lack of details in failure analyses to the inherent complexity of the variables involved. The complexities associated with corrosion damage information are compounded by a general lack of standard schemes to represent materials in their operational environments. Data gathered in controlled laboratory environments can usually be obtained with more precision, and for such data, standards have been developed to streamline the exchange of information between organizations. For scientists and engineers developing materials, models have become an essential benchmarking element for the selection and life prediction associated with the introduction of new materials or processes. For systems managers, the corrosion performance or underperformance of materials has a very different meaning. In the context of life-cycle management, corrosion is only one element of the whole, and the main difficulty with corrosion information is its presentation at the system management level.

One of the principal goals of scientific discovery is the development of a theory, a coherent body of knowledge that can be used to provide explanations and predictions for a specific domain of knowledge. Theory development is a complex process involving three principal activities: theory formation, theory revision, and paradigm shift. A theory is first proposed from a collection of known observations. It then goes through a series of revisions aimed at reducing the shortcomings of the initial model. The initial theory can thus evolve into one that can provide sophisticated predictions, but such a theory can also become much more complex and difficult to use. In such cases, the problems can be partly eliminated by a paradigm shift, that is, a revolutionary change that involves a conceptual reorganization of the theory (Ref 1).

The Venn diagrams of Fig. 1 illustrate the three stages of a theory revision (Ref 2). In the first stage of theory revision (Fig. 1a), an anomaly is noted, a new observation that is not explained by the current model. In a subsequent stage (Fig. 1b), the old theory is reduced to its most basic or fundamental expression before it finally serves as the basis of a new theory formulation (Fig. 1c). Corrosion models have similarly evolved over the relatively short history of corrosion science and engineering. Modern understanding of corrosion phenomena and control of corrosion damages was greatly accelerated when the thermodynamic and kinetic behaviors of metallic materials were made explicit in what became known, respectively, as potential-pH diagrams and mixed-potential diagrams. These two fundamental models, which were both established in the 1940s, have become the basis of many models developed in an evolutionary fashion since then.

Mechanistic Models

Mechanistic models of corrosion processes have been developed to incorporate a range of chemical and electrochemical reactions with the complex interactions of diffusion and migration details. Some specific situations lend themselves to the development of useful mechanistic models to account for the main features governing corrosion processes. These models are most naturally expressed in terms of differential equations or in other nonexplicit forms of mathematics. However, modern developments in computing facilities and in mathematical theories of nonlinear and chaotic behaviors have made it possible to cope with relatively complex problems. A mechanistic model has the following advantages (Ref 3):

- It contributes to our understanding of the phenomenon under study.
- It usually provides a better basis for extrapolation.
- It tends to be parsimonious, that is, frugal in the use of parameters, and it provides better estimates of the system response.

The multidisciplinary nature of corrosion science is reflected in the multitude of approaches that have been proposed to explain and model fundamental corrosion processes. The following list illustrates some scientific disciplines, with examples of modeling efforts one can find in the literature:

- *Surface science:* atomistic model of passive films
- *Physical chemistry:* adsorption behavior of corrosion inhibitors
- *Quantum mechanics:* design tools for organic inhibitors
- *Solid-state physics:* scaling properties associated with hot corrosion
- *Water chemistry:* control model of inhibitors and antiscaling agents
- *Boundary-element mathematics:* cathodic protection

When the mechanisms underlying corrosion processes are not understood sufficiently well or are too complicated to allow an exact model to be built from theory, empirical models have proven to be quite useful. The degree of complexity of an empirical model can seldom be assessed in the initial phase of model development. A pragmatic model development approach is to start with a limited set of variables and increase its complexity as required by growing evidence and the need for increased confidence in the results.

Basic Principles of Mechanistic Models

Rates of general corrosion in aqueous environments depend on a multitude of factors, such as the chemistry of the aqueous solution, concentrations of components, temperature, presence of nonaqueous phases, hydrodynamic conditions, and metallurgical factors. Therefore, it is desirable to rationalize and predict the effects of these factors using mechanistic models.

Pourbaix Model. The first comprehensive model that summarized many of the basic variables underlying a corrosion situation became known as potential-pH (*E*-pH) diagrams, also called predominance or Pourbaix diagrams, which have been adopted universally since their introduction in late 1940s. These diagrams have repeatedly been proven an elegant way to represent the thermodynamic stability of chemical species in given aqueous environments. The *E*- pH diagrams are typically plotted for various equilibria on normal Cartesian coordinates, with potential, *E*, as the ordinate (*y*-axis) and pH as the abscissa (*x*-axis) (Ref 4).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Pourbaix diagrams have proven to be a convenient way to summarize a situation in terms of its thermodynamics and to provide a useful means of predicting electrochemical and chemical processes that could potentially occur in certain conditions of pressure, temperature, and chemical makeup. The following example illustrates potential corrosion damage to steel in water flowing through the radiators and pipes of an hydronic system (Ref 5). Given a pH range of 6.5 to 8 for mains water and the *E*-pH diagram in Fig. 2, it is apparent that minimal corrosion damage is to be expected if the corrosion potential remains below -0.65 V (standard hydrogen electrode) (Ref 6). While *E*-pH diagrams were initially designed for relatively simple situations involving pure metals and pure water at a single temperature, the availability of computing power and basic thermodynamic information has permitted the development of these diagrams for increasingly complex situations, such as interaction associated with multielement systems (Ref 7).

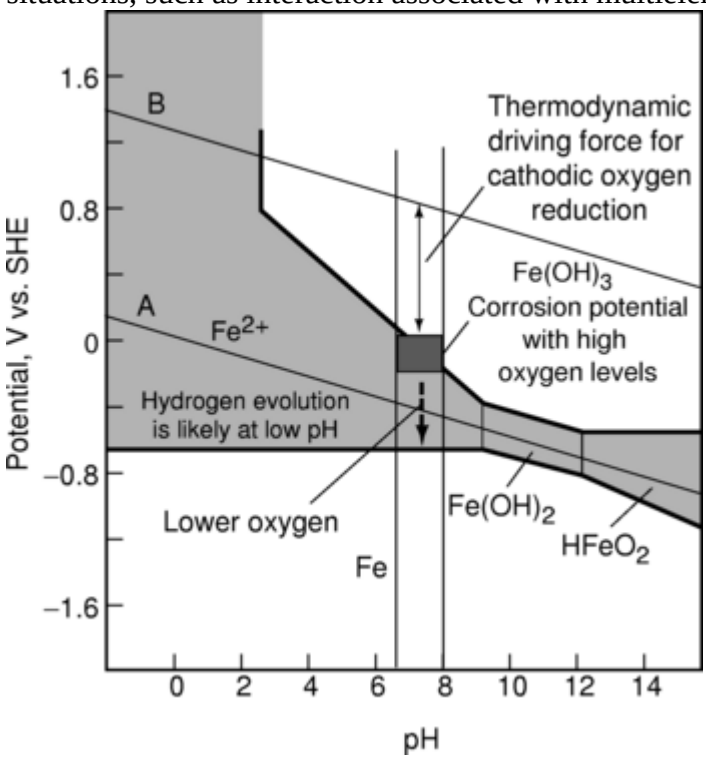

Fig. 2 Potential-pH diagram of iron in water at 25 °C (77 °F) highlighting the corrosion processes in the hydronic pH range. SHE, standard hydrogen electrode

Polarization Curves. The use of polarization curves for the study of corrosion reactions can be traced back to the 1930s (Ref 8). However, the representation of the mixed potential behavior is often associated with Professor Evans, who has popularized this representation of corrosion polarization measurements (Ref 9). These diagrams have become a reflection of our understanding of the corrosion basics in the most complex chemistries, as is illustrated in the following example.

Anodic protection of a kraft liquor tank was first successfully realized at the end of 1984, and the success of this system resulted in many commercial installations. Unfortunately, unexpectedly high corrosion rates were reported at localized areas in several of the tanks, even though the remainder of the surfaces corroded at rates less than 0.13 mm/yr (0.005 in./yr) (Ref 10). Most of the problems experienced have been attributed to incomplete understanding of the electrochemistry of carbon steel in these liquors and the coexistence of active and passive areas, which had not been addressed properly in earlier control strategies. An elegant yet simple model of passivation in caustic sulfide was developed to explain the role of sulfide in the process (Ref 11). According to the research, after the initial nucleation of Fe_3O_4, sulfide is incorporated as substitutional ions into the Fe_3O_4 spinel lattice, forming a nonprotective compound, $(Fe_3O_4)_{-x}S_x$, where x was predicted to be approximately 0.19 at the peak of the active-passive transition. Because passivation cannot occur until the sulfide in the film is completely removed by oxidation, high current densities are required to force this reaction. However, once devoid of sulfide, the film can remain stable if the potential is kept more positive than the Flade potential corresponding to the reduction reaction of oxidized sulfur species, such as $S_2O_3^{2-}$ and S_2^{2-} (Ref 10).

Figure 3 depicts one anodic and four cathodic idealized polarization curves, including the possible intersection points (Ref 6). The number and location of the intersection points creates four types of behavior, namely,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

monostable (active), bistable, astable, and monostable (passive). A potentiodynamic curve of each of these types of behavior is shown, respectively, in Fig. 4(a–d). Astable behavior occurs infrequently, because it requires a single anodic-cathodic intersection on the negative resistance portion of the anodic curve. This is an unstable operating condition, resulting in continuous oscillations between active and passive potentials. Various alloys in elevated-temperature sulfuric acid are known to exhibit such behavior (Ref 10).

Modeling the Efficiency of Corrosion Inhibitors

A mechanistic model has been developed for simulating the rates of general corrosion of selected metals in aqueous solutions. The model predictions have been verified for a number of systems that include corrosion inhibitors (Ref 12), carbon steel and stainless steel CO_2/H_2S corrosion (Ref 13), and systems containing concentrated brines (Ref 14). In all cases, good agreement with experimental data has been obtained. An assessment of the requirements to produce such an extensive model has indicated that the model should (Ref 12):

- Use a comprehensive thermodynamic model to compute the speciation and activities of species in the aqueous solution
- Use models for calculating transport properties, which are necessary to predict mass- transfer effects
- Represent the partial cathodic and anodic processes on the metal surface
- Reproduce the active-passive transition and the effect of active ions on passivity
- Reproduce experimental corrosion rates using parameters calibrated on the basis of a limited amount of data
- Be implemented in an easy-to-use program

The model presently contains a thermophysical module that provides comprehensive speciation calculations and an electrochemical module to predict the partial reduction and oxidation processes on the surface of the metal.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Thermophysical Module. This part of the model combines information about standard- state properties of all species of interest with a formulation for the excess Gibbs energy, which accounts for solution nonideality. The thermodynamic model is used to predict the concentrations and activities of both ionic and neutral species in multicomponent systems that may contain an aqueous phase, any number of solid phases, and, if necessary, a vapor and a nonaqueous liquid phase. The activities of individual species are further used in the electrochemical model. After completing speciation calculations, the thermophysical module computes several properties of the solution, including pH, density, electrical conductivity, viscosity, and diffusivity. The calculations included in this module have been described in detail elsewhere (Ref 15).

Electrochemical Module. The parameters of the electrochemical model have been determined by using a large number of experimental polarization and corrosion rate data. In particular, the parameters for the proton reduction, water reduction, oxygen reduction, and iron oxidation processes were determined from relevant data on the corrosion of iron and mild steel in various mineral acids, bases, and saline solutions. The parameters that represent the effect of several inhibiting ions have been calibrated using polarization data or experimental corrosion rate data that relate the corrosion inhibition to the solution concentration (Ref 12). Because the model contains empirical parameters obtained from experimental data, the quality of model predictions depends on the data on which the parameters are based. This is a common feature of all semiempirical models. The partial electrochemical processes are then combined into a total predicted polarization curve by applying the mixed-potential theory, which states that, in a freely corroding situation, the total cathodic current, i_c, is equal to the total anodic current, i_a:

$$\sum i_{c,i} = \sum i_{a,j} \qquad \text{(Eq 1)}$$

where $i_{c,i}$ and $i_{a,j}$ denote the i-th cathodic and j- th anodic process. Once the corrosion potential is obtained by solving Eq 1, the corrosion current density is also computed. The model is implemented in two steps:

1. It calculates the speciation and thermodynamic properties. At the end of the speciation calculations, it also computes the transport properties that are necessary for modeling mass-transfer effects.
2. Then, the program uses the previously obtained speciation and transport properties to calculate the partial anodic and cathodic processes that are possible in the system. Finally, the partial electrochemical processes are combined, and the corrosion rate and potential are calculated using the mixed-potential theory.

The electrochemical module is capable of reproducing the active-passive transition and the effect of solution species on passivity. In order to simulate the effect of active ions on the passive current density, the electrochemical module relies on an approach developed for studying the chemical dissolution kinetics of oxides in aqueous media. Surface reactions between the passive oxide layer and the ions present in solution are considered in the development of a mathematical relationship between the activities of these aggressive or inhibitive ions and the passive-anodic current density.

Applications of the Model. To verify the performance of the model, corrosion rates have been calculated for carbon steel exposed to aerated water in the presence of several inhibitors. Figure 5 shows the dependence of the calculated corrosion rate on the concentration of three inhibitors; that is, monobasic phosphate (Fig. 5a), silicate (Fig. 5b), and chromate ions (Fig. 5c). In all cases, a fairly sharp transition to passive behavior is observed as the concentration of the inhibitor exceeds a certain threshold value. This threshold value is very low for chromates and substantially higher for phosphates and silicates. It is noteworthy that the model represents the experimental corrosion rates with very good accuracy. The presence of inhibitive ions counteracts the effect of halide ions and limits the current density. In this way, the model simultaneously takes into account the ions that promote the dissolution of the passive film and those that inhibit its dissolution.

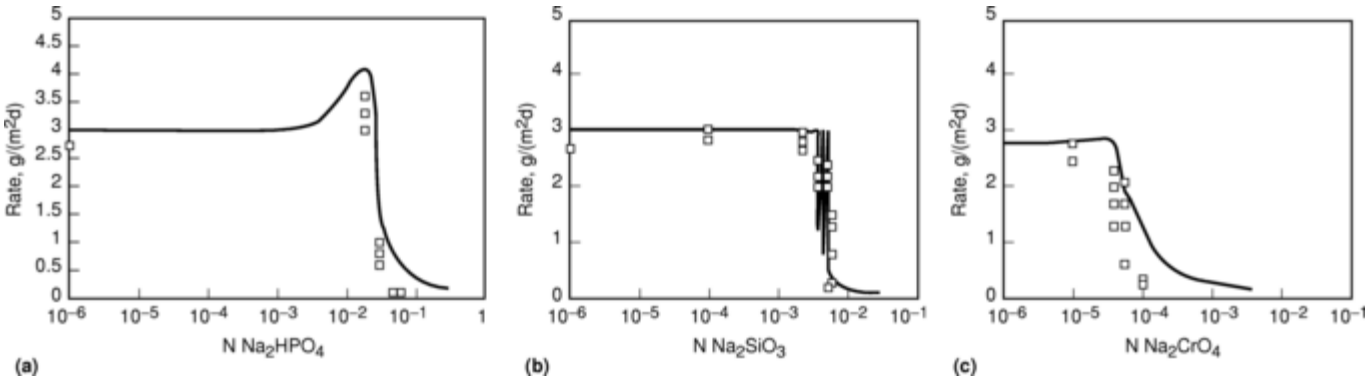

Fig. 5 Effect of various inhibitors on the corrosion rate of carbon steel in aerated water at 25 °C (77 °F). (a) HPO_4^{2-} ions. (b) SiO_3^{2-} ions. (c) CrO_4^{2-} ions. Line generated from electrochemical model and test data (squares) are given.

Figure 6, which shows the calculated current density versus potential relationships for three concentrations of silicate ions, illustrates how the model reproduces the competitive behavior between the local cathodic and anodic processes that are taken into account in the analysis. The dominant cathodic process, the reduction of oxygen, in this example, proceeds under mass- transfer control, as shown by the vertical portion of the oxygen reduction line. The iron oxidation process shows an active-passive transition, which is strongly influenced by the presence of inhibitors. Without silicate ions (Fig. 6a), the oxygen reduction line intersects the iron oxidation line in the range of active dissolution of iron. Correspondingly, the corrosion potential is low, and the corrosion rate is substantial.

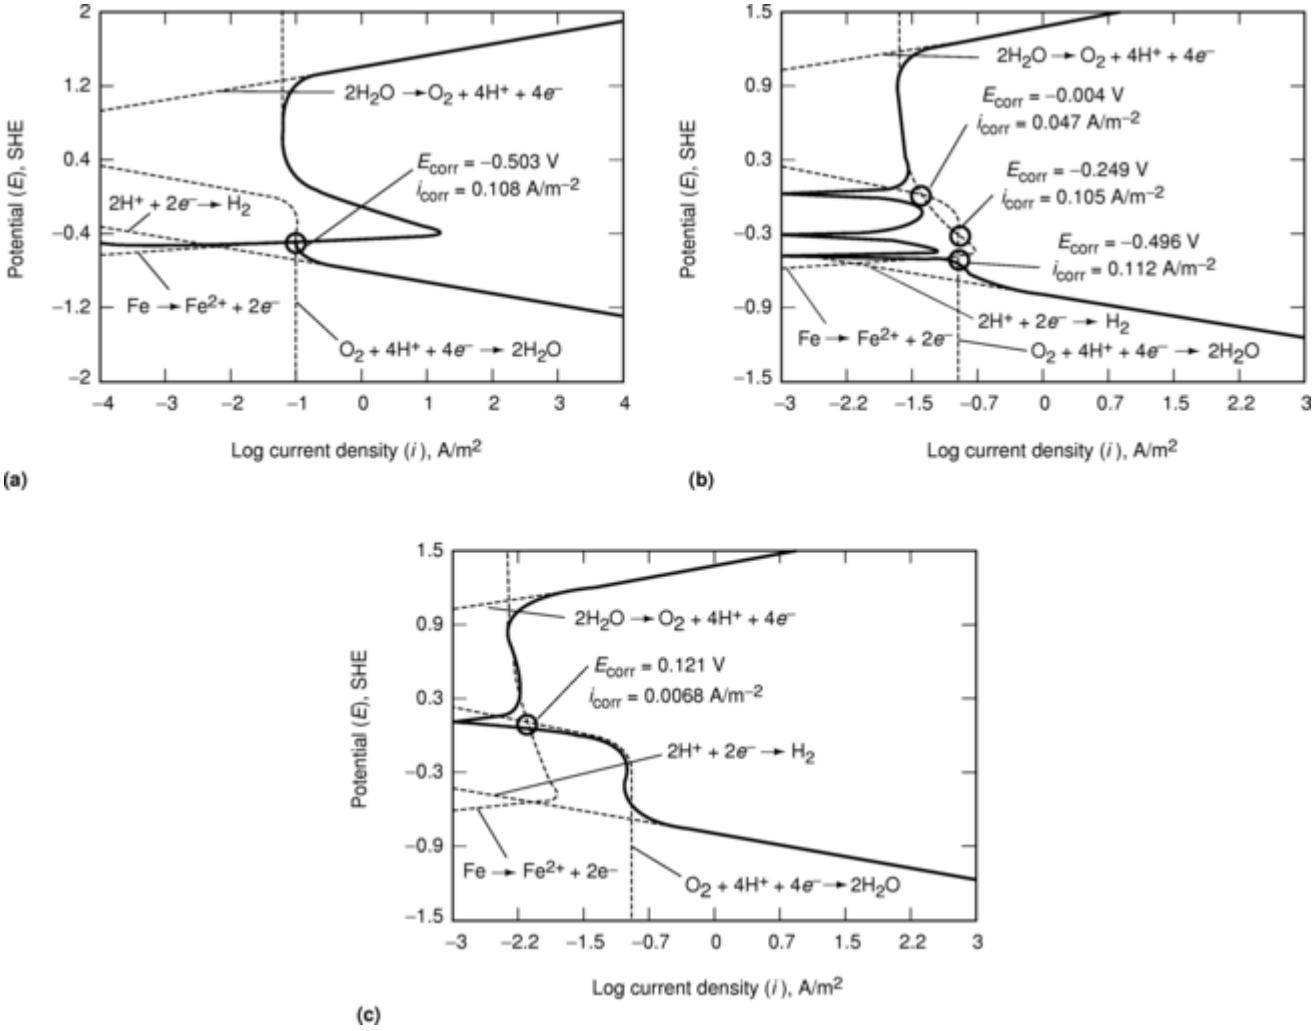

Fig. 6 Predicted current density/potential relationships, including partial anodic and cathodic processes, for carbon steel in aerated water with (a) no Na_2SiO_3, (b) 0.0014 *m* Na_2SiO_3, and (c) 0.008 *m* Na_2SiO_3. SHE, standard hydrogen electrode; E_{corr}, corrosion potential; i_{corr}, corrosion current

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

With a substantial concentration of silicate ions (Fig. 6c), both the passive current density and the critical current density are substantially reduced. Subsequently, the oxygen reduction line intersects the iron oxidation line within the passive range. The corrosion potential is substantially increased, and the corrosion rate is reduced. For intermediate concentrations of silicate ions (Fig. 6b), the shape of the predicted iron oxidation line is such that three mixed potentials are possible. This results in multiple steady states, and the system may oscillate between corrosion in the active and passive states. The electrochemical model was found to be particularly suitable for studying the synergistic effects of mixtures of inhibitors, such as mixtures of molybdate and nitrite inhibitors.

The ion association model has been in use by major water treatment companies since the early 1970s. Saturation indexes used routinely by water treatment chemists provide a measure of the thermodynamic driving force for a scalant to form; however, these indexes do not incorporate the capacity of the water for continued scaling. The water concentrations of various substances in dissolved, colloidal, or suspended forms are typically low but can vary considerably. Water can have a high saturation level with no visible scale formation. The driving force might be present, but there is insufficient mass for gross precipitation. Simple indexes include:

- Langelier saturation index (LSI)
- Ryznar stability index
- Stiff-Davis saturation index
- Oddo-Tomson index for calcium carbonate

Indexes have also been developed for other common scales, such as calcium sulfate and calcium phosphate. All these indexes provide an indicator of scale potential but lack accuracy, principally because they ignore the reduced availability of ions such as calcium, which is affected by association with sulfate, and other ions (Ref 16). This binding, or reduced availability of the reactants, decreases the effective ion activity product for a saturation level calculation. The most efficient method for modeling the speciation of a water is to proceed through numerous computer iterations for (Ref 17):

- The verification of electroneutrality via a cation-anion balance, and balancing with an appropriate ion (e.g., sodium or potassium for cation-deficient waters; sulfate, chloride, or nitrate for anion-deficient waters)
- Estimation of ionic strength, calculating and correcting activity coefficients and dissociation constants for temperature and correcting alkalinity for noncarbonate alkalinity
- Iterative calculation of the distribution of species in the water from dissociation constants. A partial listing of these ion pairs is given in Table 1.
- Verification of mass balance and adjusting ion concentrations to agree with analytical values
- Repetition of the process until corrections are insignificant
- Calculation of saturation levels based on the free concentrations of ions estimated, using the ion association model (ion pairing)

Table 1 Example ion pairs used to estimate free ion concentrations

Aluminum = (Al^{3+}) + $(Al(OH)^{2+})$ + $(Al(OH)_2^+)$ + $(Al(OH)_4^-)$ + (AlF^{2+}) + (AlF_2^+) + (AlF_3) + (AlF_4^-) + $(AlSO_4^+)$ + $(Al(SO_4)_2^-)$
Barium = (Ba^{2+}) + $(BaSO_4)$ + $(BaHCO_3^+)$ + $(BaCO_3)$ + $(Ba(OH)^+)$
Calcium = (Ca^{2+}) + $(CaSO_4)$ + $(CaHCO_3^+)$ + $(CaCO_3)$ + $(Ca(OH)^+)$ + $(CaHPO_4)$ + $(CaPO_4^-)$ + $(CaH_2PO_4^+)$
Iron = (Fe^{2+}) + (Fe^{3+}) + $(Fe(OH)^+)$ + $(Fe(OH)^{2+})$ + $(Fe(OH)_3^-)$ + (FeHPO4+) + $(FeHPO_4)$ + $(FeCl^{2+})$ + $(FeCl_2^+)$ + $(FeCl_3)$ + $(FeSO_4)$ + $(FeSO_4^+)$ + $(FeH_2PO_4^+)$ + $(Fe(OH)_2^+)$ + $(Fe(OH)_3)$ + $(Fe(OH)_4^-)$ + $(Fe(OH)_2)$ + $(FeH_2PO_4^{2+})$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Magnesium = (Mg^{2+}) + $(MgSO_4)$ + $(MgHCO_3^+)$ + $(MgCO_3)$ + $(Mg(OH)^+)$ + $(MgHPO_4)$ + $(MgPO_4^-)$ + $(MgH_2PO_4^+)$ + (MgF^+)
Potassium = (K^+) + (KSO_4^-) + $(KHPO_4^-)$ + (KCl)
Sodium = (Na^+) + $(NaSO_4^-)$ + (Na_2SO_4) + $(NaHCO_3)$ + $(NaCO_3^-)$ + (Na_2CO_3) + (NaCl) + $(NaHPO_4^-)$
Strontium = (Sr^{2+}) + $(SrSO_4)$ + $(SrHCO_3^+)$ + $(SrCO_3)$ + $(Sr(OH)^+)$

The use of ion pairing to estimate the concentrations of free species overcomes several of the major shortcomings of traditional indexes. Ion pairing takes into account the association that can occur between ions at concentrations far from infinite dilution, effectively reducing their availability in solution. Calcium, for example, may be paired with sulfate, bicarbonate, carbonate, phosphate, and other species. Bound ions are not readily available for scale formation. When indexes are used to establish operating limits, such as maximum concentration ratio or maximum pH, the differences between the use of indexes calculated using ion pairing can have some serious economic significance. For example, experience on a system with high total dissolved solids (TDS) water may be translated to a system operating with a lower TDS water. The high indexes that were found acceptable in the high TDS water may be unrealistic when translated to a water where ion pairing is less significant in reducing the apparent driving force for scale formation. Table 2 summarizes the impact of TDS on LSI when calculated using total analytical values for calcium and alkalinity and when calculated using the free calcium and carbonate concentrations calculated using an ion association model. Indexes based on ion association models provide a common denominator for comparing results between systems. For example, the calcite saturation level calculated using free calcium and carbonate concentrations has been used successfully as the basis for developing models that describe the minimum effective scale inhibitor dosage that maintains clean heat-transfer surfaces (Ref 18). The following example illustrates how silica, a very common compound, can greatly influence the fragile equilibria involved in cooling water and how this can be revealed with the use of a commercial software system (Ref 17).

Table 2 Impact of ion pairing on the Langelier scaling index (LSI)

Water type	Ion pairing	LSI		TDS impact on LSI
		Low TDS	**High TDS**	
High chloride	No pairing	2.25	1.89	-0.36
	With pairing	1.98	1.58	-0.40
High sulfate	No pairing	2.24	1.81	-0.43
	With pairing	1.93	1.07	-0.86

TDS, total dissolved solids

Guidelines for the upper silica operating limits have been well defined in water treatment practice and have evolved with treatment programs. In the days of acid chromate cooling system treatment, an upper limit of 150 ppm silica as SiO_2 was common. The limit increased to 180 ppm with the advent of alkaline treatments and pH control limits up to 9.0. Silica control levels approaching or exceeding 200 ppm as SiO_2 have been reported for the current high-pH, high-alkalinity, all-organic treatment programs, where pH is allowed to equilibrate at 9.0 or higher (Ref 19).

The evolution of silica control limits can be readily understood by reviewing the silica solubility profile. As depicted in Fig. 7, amorphous silica solubility increases with increasing pH. Silica solubility also increases with increasing temperature. In the pH range of 6.0 to 8.0 and temperature range of 20 to 30 °C (68 to 86 °F), cooling water is saturated with amorphous silica when the concentration reaches 100 ppm as SiO_2 (20 °C, or 68 °F) or 135 ppm (30 °C, or 86 °F). These concentrations correspond to a saturation level of 1.0. The traditional silica limit for this pH range has been 150 ppm as SiO_2. As outlined in Table 3, at pH 7.6, a limit of 150 ppm corresponds roughly to a saturation level of 1.4 at 20 °C (68 °F) and 1.1 at 30 °C (86 °F).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

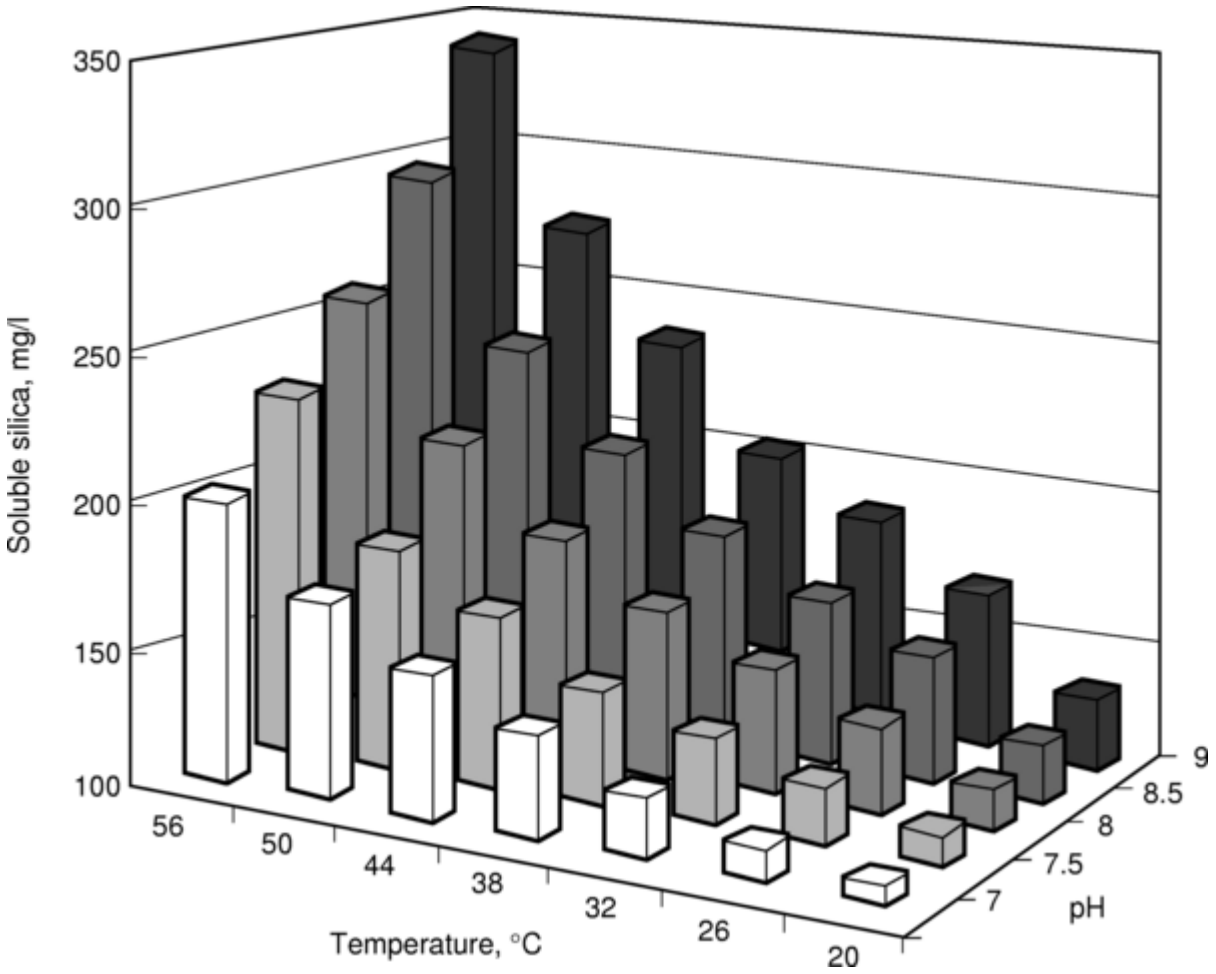

Fig. 7 Solubility of amorphous silica as a function of temperature and pH

Table 3 Silica limits for three treatment schemes

pH level	Temperature		Silica level, ppm	Saturation level limit
	°C	**°F**		
Low (6.0)	20	68	130	1.2
	30	86	150	1.1
Moderate (7.6)	20	68	150	1.4
	30	86	150	1.1
High (8.9)	20	68	>180	1.5
	30	86	>180	1.3

At the upper end of the cooling water pH range (9.0), silica solubility increases to 115 ppm (20 °C, or 68 °F) and 140 ppm (30 °C, or 86 °F). A control limit of 180 ppm corresponds to saturation levels of 1.5 and 1.3, respectively. In systems where concentration ratio is limited by silica solubility, it is recommended that the concentration ratio limit be reestablished seasonally based on amorphous silica saturation level or whenever significant temperature changes occur (Ref 19).

Boundary-Element Modeling

Early predictions of corrosion rates and estimates of adequate cathodic protection (CP) have traditionally been based on case studies and sample exposure tests. Applying these techniques to real structures usually involves extrapolations, use of large safety factors, and ongoing corrections and maintenance of the system. In the late 1960s, the finite-element method was applied to the problem by discretization of the electrolytically conductive environment with a mesh (Ref 20). The mathematical solution is found at the intersection points, or nodes, of the mesh. The solution is numerical, because an approximate form of Laplace's equation governs variations of the solution between adjacent nodes. However, creating a finite-element mesh can be an extremely tedious and

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

time-consuming process. Even when the mesh-generation process is automated, it is difficult to perform a simulation when there are large geometry scale differences in the model, which is exactly the case found in most corrosion control problems where anodes are small compared with the size of the structure and the problem areas are most likely in corners and areas of complex geometry.

In the late 1970s, boundary-element (BE) methods became available. As the name implies, this numerical method requires mesh elements to be created but now only on the boundary (or surfaces) of the object to be modeled (Fig. 8). The main advantages of boundary elements for impressed current cathodic protection (ICCP) analysis are (Ref 20):

- Meshes are now only on the surface; hence, only two-dimensional elements are required. Mesh generators can be used with confidence, and models can be constructed extremely quickly and inexpensively once the geometry is defined.
- Models can be created with fine detail of key or complex areas while course modeling the remaining structure or large volume of electrolyte.
- Boundary-element methods are very effective and accurate for modeling large or infinite domains, as is the case for CP analysis.

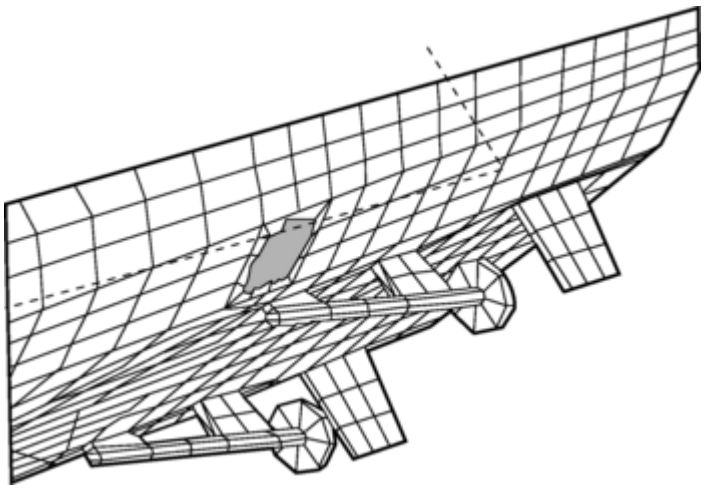

Fig. 8 Boundary-element model of the wetted surface of the propeller section of a ship showing the dark anode area in contrast with the protected cathodic surface

The design goal of an ICCP system is to produce an evenly distributed protection potential on the structure as well as to reduce the power consumption of the anodes to a minimum. The available design variables are the number of anodes, their location, and the location of the reference cells. The constraints on the design are the values of the potential on the structure. In order to provide adequate protection, the potential must be less than a specified value, for example, -800 mV. In order to prevent overprotection, the potential must be greater than a specified value, for example, -900 mV. By combining an automatic optimization procedure with the BE model of the ICCP system, an optimal solution can be obtained. The equation governing electrochemical corrosion for the wetted surface of a ship hull is (Ref 21):

$$k\nabla^2\Phi = 0 \qquad \text{(Eq 2)}$$

where Φ is the potential, k is the conductivity of the electrolyte, and ∇^2 is the symbol for a Laplacian operator, a second-order, multidimensional, partial differential equation.

Equation 2 is valid if the electrolyte is homogeneous, there are no electrical sources or sinks, and the system is electroneutral. A shipboard ICCP system can be modeled in such a way to meet these conditions. Seawater is often represented as a uniform mixture of multiple components. Current source points and exposed metal can be represented by boundary conditions, eliminating the need to include sources and sinks in the model. Electroneutrality maintains charge equilibrium for the ship, surrounding water, and ICCP system. The solution space for the problem defined by Eq 2 used in the BE approach is the surface, Γ, which bounds the domain, Ω, as defined by:

$$\Gamma = \Gamma_A + \Gamma_C + \Gamma_I \qquad \text{(Eq 3)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

where Γ_A is the anodic surface, Γ_C is the cathodic surface, and Γ_I is the insulated surface.
The surface, Γ, must be continuous, but all sections of one surface type do not have to be contiguous. An ICCP system consists of the surfaces to be protected, the anodes, the reference cells, and the power supply. Anodes are defined by maintaining the potential at a constant value, Φ_A:

$$\Phi(x, y) = \Phi_A \quad \text{(Eq 4)}$$

defining the current density as a constant, q_A, on a surface:

$$\frac{\partial \Phi(x, y)}{\partial n(x, y)} = q_A \quad \text{(Eq 5)}$$

where $\Phi(x, y)$ is the electrical potential at the point (x, y), and $n(x, y)$ is the normal to the surface at the point (x, y). Reference cells are defined as specific points on the hull where the mathematical solution is obtained.
It has been demonstrated that BE modeling can accurately predict experimental results. A major issue for accurate predictions is the availability of detailed polarization data. However, the lack of availability of accurate polarization data for a particular design condition does not eliminate all advantages associated with BE modeling. Reasonable polarization data can be used to obtain potential maps that identify good and bad regions of protection. Boundary-element methods also can be used to evaluate the effect of a single parameter on system performance. In this way, basic understanding of electrochemical corrosion and parameter interactions can be obtained. Several parametric studies have been completed to date (Ref 21):

- Damage levels in the propeller area
- Seawater conductivity
- Finite paint resistance
- Influence of stray current source on system performance

It is possible to design experiments that would account for the majority, if not all, of the factors that influence polarization response for the materials involved in ICCP. However, this approach quickly leads to impracticably large experimental programs. There are two processes for ICCP system design that rely on BEs but eliminate the need for a high degree of accuracy in polarization response. One proposed method defines the polarization response as an unknown to be solved in the BE process (Ref 21). Sensors provide potential information at specific locations. An inverse problem is defined in which the potential map of the ship hull is defined from the measured data and assumptions of behavior in the regions between sensor points. The solution, obtained through a series of BE evaluations, is the polarization data. Discrete areas of damage can be located based on differences in calculated potentials and measured values at the sensor locations. Once the polarization response is determined for a given ship geometry and service condition, anode strengths and power requirements can be readily obtained.
Combined Boundary Element and Physical Scale. The second proposed approach is a hybrid design combining BE and physical scale (PS) modeling techniques (Ref 21). In the first stage, BE modeling is used to develop best estimates of the layout of an ICCP system. Anode locations, anode numbers, reference cell locations, and reference cell numbers are factors that can be varied using computational analyses. The polarization response used in this phase does not have to duplicate service conditions but only has to be a reasonable approximation. The second stage of the ICCP design uses PS modeling. In PS modeling, the structural dimensions and the conductivity of the electrolyte are scaled by the same factor (Ref 22). In this process, the scaled model and the full-sized structure maintain identical current density values at points, identical potential differences at points, identical polarization potentials at the anode and cathode, and an identical potential drop across the electrolyte. The use of a best-estimate design eliminates multiple cycles of PS modeling. This approach enables the designer to exploit the advantages of both BE and PS modeling approaches.

Alloy Selection System for Elevated Temperatures

The task of providing reliable information on corrosion of metals and alloys in high-temperature gases is difficult, due to the diversity of corrosive environments and the lack of standardization for corrosion data. The Alloy Selection System for Elevated Temperatures (ASSET) information system is being developed to address many of these difficulties. The present system contains information on approximately 80 commercial alloys,

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

4900 corrosion data measurements, and over six million exposure hours. Data compilation in this interactive model has been organized to allow prediction of sound metal thickness losses by several corrosion mechanisms at high temperatures as functions of gas composition, temperature, time, and alloy type (Ref 23, 24). The equations, which correlate the corrosion measurements with exposure conditions and the data, are stored in databases. The corrosion mechanisms for which corrosion predictions can be made are:

- Sulfidation
- Sulfidation/oxidation
- Isothermal oxidation
- Carburization

The program stores the corrosion measurements, exposure conditions, and corrosion mechanisms and predicts alloy corrosion by accessing the stored data for that alloy and determining the parameters of the rate equation. A different equation is used for each corrosion mechanism. The software uses the alloy composition and the corrosive environment information to calculate the stable corrosion products and the equilibrium gas composition for a given combination of alloy and exposure conditions. The computations use the ChemSage program from FACT, a Gibbs free energy minimization program (Ref 25). Some of the potential solution or mixed corrosion product phases considered are MO, M_3O_4, M_2O_3, MS, M_2S_4, M_3C, $M_{23}C_6$, and M_7C_3, where M represents a combination of iron, nickel, and chromium in the compound.

The thermodynamic solution behaviors of the solid austenitic and ferritic alloys are also considered. Thermochemical characteristics such as the partial pressures $p_{O_2}$and $p_{S_2}$and the carbon activity of the environment, which help determine corrosion product stabilities, are also provided by the calculation. The software assists identification of the likely corrosion mechanism by knowing the stable corrosion products at the corrosion product/corrosive gas interface, the alloy in question, and the partial pressures, $p_{O_2}$and p_{S_2}. Different alloys in the same exposure conditions may exhibit different stable corrosion products and different corrosion mechanisms. In the absence of experimental data for the specific conditions of interest, predictions made by using this approach may be the best available for the corrosion mechanisms that are incorporated into the system, in comparison with those made using the traditional methods of literature review and data analysis. Examples of the accuracy using the ASSET system are shown in Fig. 9. They show how large amounts of corrosion data can be well correlated. The correlations are quite good for three decades of variation in corrosion penetration for several alloys and corrosion mechanisms, considering the uncertainty associated with these types of data.

Predicting the Life of Nuclear Waste Containers

In the United States and Canada, the regulations pertaining to the geologic disposal of high- level nuclear waste require that the radionucleides remain substantially contained within the waste package for 300 to 1000 years after permanent closure of the repository. The current concept of a waste package involves the insertion of spent fuel bundles inside a container that is then placed in a deep borehole, either vertically or horizontally, with a small air gap between the container and the borehole. For vitrified wastes, a pour canister inside the outer container acts as an additional barrier, making the successful performance of the container material crucial to fulfilling the containment requirements over long periods of time.

Providing that no failures occur as a result of mechanical effects, the main factor limiting survival of these containers is expected to be corrosion in the groundwater to which they would be exposed. Two general classes of container materials have been studied internationally: corrosion-allowance and corrosion-resistant materials. Corrosion-allowance materials possess a measurable general corrosion rate but are not susceptible to localized corrosion. By contrast, corrosion-resistant materials are expected to have very low general corrosion rates because of the presence of a protective surface oxide film. However, they may be susceptible to localized corrosion damage. A model developed to predict the failure of grade 2 titanium has considered two major corrosion modes (Ref 26):

- Failure by crevice corrosion
- Failure by hydrogen-induced cracking (HIC)

In this predictive model, a small number of containers are assumed to be defective and to fail within 50 years of emplacement. Each modeling parameter is assigned a range of values, resulting in a distribution of corrosion rates and failure times. The crevice corrosion rate is assumed to be solely dependent on properties of the material and the temperature of the vault. Crevice corrosion is also assumed to initiate rapidly on all containers and subsequently propagate without repassivation. Failure by HIC is assumed to be inevitable once a container temperature falls below 30 °C (86 °F). However, the concentration of atomic hydrogen to render a container susceptible to HIC would occur only very slowly and might even be negligible if that container had never been subject to crevice corrosion.

Figure 10 illustrates the thin-shell packed-particulate design chosen as a reference container for this study. The mathematical procedure to combine various probability functions and arrive at a failure probability of a hot container due to crevice corrosion at a certain temperature is illustrated in Fig. 11. The failure rate due to HIC in this model is arbitrarily assumed to have a triangular distribution in order to simplify the calculations and knowing that HIC is only a predicted marginal failure mode in the considered burial conditions. On the basis of these assumptions and the subsequent calculations, it was predicted that 96.7% of all containers would fail by crevice corrosion and the remaining by HIC. However, only 0.137% of the total number of containers was predicted to fail before 1000 years (0.1% by crevice corrosion and 0.037% by HIC), with the earliest failure after 300 years (Ref 26). For a view of nickel alloys in similar applications, see the article “Effects of Metallurgical Variables on the Corrosion of High-Nickel Alloys” in this Volume.

Pitting Corrosion Fatigue (PCF) Models

The phases of life of a structure have been classified as follows (Ref 27):

- *Phase 1:* nucleation or formation of damage by a specific physical or corrosion damage process. Corrosion and other processes may act alone to create the damage.
- *Phase 2:* microstructurally dominated crack linkup and propagation
- *Phase 3:* crack propagation in the regime where various fracture mechanics methods may be applied, both for analysis and material characterization
- *Phase 4:* final instability of the system

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Figure 12 illustrates these degradation processes, with the portion of life on the abscissa and the corresponding growth in discontinuity size plotted schematically on the ordinate. In a first model to estimate the number of fatigue cycles for a pit to reach the critical pit depth to nucleate a mode I crack, it was proposed that pit growth rate theory applied to data obtained with fatigue crack growth experiments in a corrosive environment would be sufficient. Using this model, the pit-to-crack transition length and cycles to failure for various stresses could be determined. However, there are many unknowns for the analysis of real components to estimate accurately the fatigue life under PCF conditions (Ref 27). Once critical-sized pits are formed, it is necessary to estimate the time or cycles for the pits to reach a critical condition or critical depth to nucleate fatigue cracks from those pits. Pit-to- crack transition length under various stresses using the stress-intensity threshold value from fatigue crack growth experiments can be estimated in a two-step process (Ref 27):

1. Pit-to-crack transition analysis
2. Estimation of fatigue cycles to failure

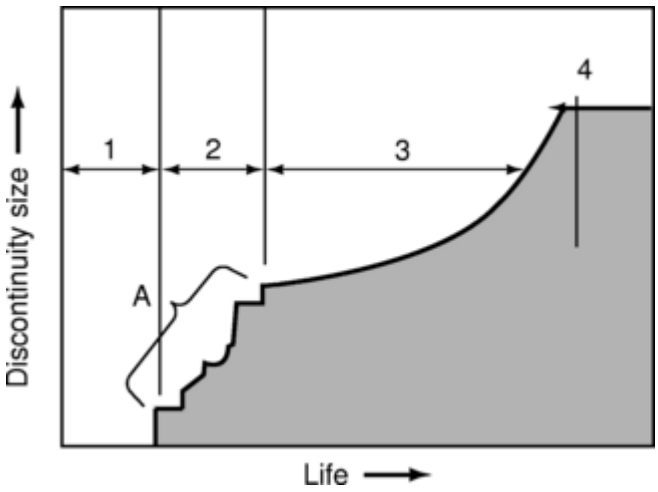

Fig. 12 Four phases involved in the degradation process of in-service components, where "A" corresponds to the first detectable crack, and the crack length progression steps correspond to (1) nucleation, (2) phase steps due to local anisotropy, (3) stress-dominated crack growth, and (4) crack to fracture. Source: Ref 27

The pit-to-crack transition analysis is first performed to determine the critical size of a pit in terms of pit depth that would transition to a crack (not necessarily a mode I crack) for different stresses. The stress values that could be used in the calculation are the estimated maximum applied stress that the component would be subjected to and the ultimate stress for the material in question. The PCF model can be used to determine the critical pit depth (Ref 27):

$$K_{sf} = 1.1\sigma\sqrt{\pi(a/Q)} \qquad \text{(Eq 6)}$$

where, K_{sf} is the stress-intensity factor for a surface discontinuity (MPa/m$^{0.5}$), σ is the applied stress (MPa), a is the size of the pit in terms of pit depth (μm or m), and Q is the dimensionless shape parameter.
In this calculation, it can be assumed that K_{sf} is equal to "short" crack stress-intensity threshold (ΔK_{scth}) for the material. It is recommended that the value of ΔK_{scth} be used, because the pit- to-crack transition first would result in a non- mode I crack, that is, in the short crack region. It is important to note that there is no standard value for the ΔK_{scth} in the short crack region for a particular material, because there is no standard test method to measure the fatigue crack growth rates in this regime. Therefore, this value can either be determined from conducting short fatigue crack growth experiments or determined from literature for a specific material. The shape parameter, Q, for a surface crack can be assumed, depending on the pit morphology. For different stress levels, ranging from the estimated applied stress for the component to the ultimate stress of the material, the critical pit depth, a, that would enable the transition of the pit to a short crack can be determined. The resultant value of a can be compared with the measured depth of the pit from the failure analysis of a similar component, if there is any. Moreover, the calculated value of a can be correlated to the experimentally generated pit growth rate curve to estimate the phase 1 life. A model has been proposed to estimate allowable stresses based on the

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

allowable stress-intensity threshold (Ref 28). This model is expressed in Eq 7, where the allowable stress, $\Delta\sigma_{all}$, at which the particular component can be operated is determined from the allowable stress-intensity threshold, ΔK_{all}, which itself is determined from corrosion fatigue experiments. The maximum pit depth, h_{max}, in Eq 7 is measured from corrosion pit growth rate experiments for a given machine-material-environment system:

$$\Delta\sigma_{all} = \frac{\Delta K_{all}}{F\sqrt{\pi h_{max}}} \qquad \text{(Eq 7)}$$

where, ΔK_{all} can be determined from a fatique crack growth rate, da/dN, versus stress-intensity factor, ΔK, plot for a material; h_{max} is the maximum pit depth; and F is a geometric factor. The total cycles to failure under corrosion fatigue conditions can subsequently be estimated using the well-known Paris equation:

$$da/dN = C\Delta K^n \qquad \text{(Eq 8)}$$

where, da/dN is the rate of crack growth per cycle (m/cycle), C and n are empirical parameters, and ΔK is the stress-intensity range (MPa $\cdot$ $m^{0.5}$)

The accuracy of the estimation can be improved if fatigue crack growth rate data under realistic corrosive environments are used in calculating the total cycles to failure. As well, the data on the effect of prior corrosion on the fatigue crack propagation also can help in getting more accurate estimation. The reader is referred to Ref 27 for a detailed example of the applicability of the PCF model in estimating the fatigue life of a real component.

Risk-Based Models

Some of the issues involved in deciding on a cost-effective solution for combating corrosion are generic to sound system management. Others are specifically related to the impact of corrosion damage on system integrity and operating costs. Risk assessments can be designed to answer many questions. Some have risk hierarchies with a limited number of variables to produce a quick screening of high-risk system components. Others consider the impact of a multitude of variables in their overall assessment. The danger in using too few variables is that the analysis becomes more qualitative than quantitative, approaching more of the fundamental indexing method. Similarly, when considering a large number of variables, the potential exists for diluting the impact of rare-occurrence events among the myriad of other potential problems. Therefore, the development and fine-tuning of the risk algorithm to ensure that potentially dangerous conditions are properly identified is the most critical step in any risk analysis program (Ref 29).

Basic Principles of Risk Management

Traditional risk management has been based on regulatory code compliance issues, and the decision to perform maintenance has been left up to a limited number of people, drawing off of their own experience and the limited amount of information they can access. Risk-based models use a systematic and structured approach based on the consequences of failure. As such, they represent a shift away from time-based tasks and emphasize the functional importance of system components and their failure/maintenance history. The following examples illustrate how these considerations are put into practice and integrated into efficient management systems.

Corrosion-Based Design (CBD) Applied to a Steam Generator. More industrial equipment is being designed or forced to perform for durations for which the environmental effects have never been seriously considered. An objective of the CBD method is to provide a framework within which materials and design disciplines can communicate effectively. The basic principles for conducting CBD are (Ref 30):

- All engineering materials are simply reactive chemicals that, in some environments, dissolve as rapidly as table salt in hot water. The surprise is never that materials fail; the surprise should be that these reactive materials work.
- Materials fail in the environments that are specifically adjacent to the surface and not in the bulk environment. These local environments are greatly influenced by prior history of exposure, flow, buildup of deposits, and local cells.
- What appears to be imponderable complexity in corrosion can be handled and bounded by explicit consideration of specific possible environments and modes of corrosion that can occur.

The CBD approach to predicting performance is a series of knowledge-elicitation steps that require detailed consideration on a multitude of topics. The two most important of these steps are shown in Fig. 13 and 14, which describe, respectively, the environment and the material definitions. Each of the numbers in brackets in Fig. 13 identifies an explicit action that needs to be considered in the step of environmental definition. The endpoint of the process is an input to a location-for-analysis (LA) matrix, whose locations in a steam generator are indicated in Fig. 15. A brief explanation of the individual elements in Fig. 13 follows:

1. Nominal chemistry refers to the bulk chemistry. For components exposed to ordinary air atmospheres, the major elements mean humid air. The minor elements refer to industrial contaminants, such as SO_2 and NO_2.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

2. Prior chemistry history refers to exposures to environmental species that might still reside on the surfaces or inside crevices.
3. System sources refer to those environments that do not come directly from a component but from outside.
4. Physical features include occluded geometries, flow, and long-range electrochemical cells.
5. Transformations refer, for example, to microbial actions that can change relatively innocuous chemicals, such as sulfates, into very corrosive sulfide species that accelerate hydrogen entry and increase corrosion rates.
6. Concentration refers to accumulations much greater than that in the bulk environment due to various actions of wetting and drawing, evaporation, potential gradients, and crevice actions that prevent dilution.
7. Inhibition refers to actions taken to minimize corrosive actions. This usually involves additions of oxygen scavengers or species that interfere directly with anodic or cathodic reactions.

Defining materials characterizes those aspects that affect the modes of corrosion. A brief explanation of the individual elements in Fig. 14 follows:

1. Major nominal alloy composition includes those species added in relatively large concentrations, such as the iron, chromium, nickel, and molybdenum in type 316 stainless steel.
2. Minor nominal alloy composition includes species such as sulfur, nitrogen, phosphorus, silicon, and manganese usually found in steels, or the oxygen and nitrogen usually found in titanium.
3. Impurities include species such as arsenic, selenium, and similar elements that contribute to temper brittleness, or to excess oxygen and nitrogen picked up during welding of titanium.
4. Processing includes fabrication to shape, with associated times and temperatures of hot deformation and heat treatments, cold deformation to size, welding, machining, and grinding.
5. Structure includes single and multiple phases, anisotropy, second phases, and grain size.
6. Embrittlement includes grain-boundary composition and the formation of phases that embrittle, such as sigma phases in iron-chromium-base alloys.
7. Surface includes surface machining, surface stresses that result from thermal gradients, grinding, shot peening, and impurities absorbed at the surface.
8. Mechanical includes the mechanical properties of tensile strength, ductility, and toughness.

A Fault Tree for the Risk Assessment of Gas Pipeline. A fault tree is a diagrammatic representation of the relationship between component-level failures and a system-level undesired event. A fault tree depicts how component-level failures propagate through the system to cause a system-level failure. The component-level failures are called the terminal events, primary events, or basic events of the fault tree. The system-level undesired event is called the top event of the fault tree. Figure 16 presents the most commonly used logic symbols and gates for the construction of fault trees (Ref 31). Fault tree analysis (FTA) is a very efficient method for reviewing and analytically examining a process or piece of equipment in its details to emphasize the lower-level fault occurrences that directly or indirectly contribute to a major fault or undesired event. By performing a FTA from lower-level failure mechanisms, a global overview of the system is achieved. Once completed, the fault tree allows the risk engineer to fully evaluate the safety or reliability of a system by altering the various lower-level attributes of the tree. Through this type of modeling, a number of variables may be visualized in a cost-effective manner.

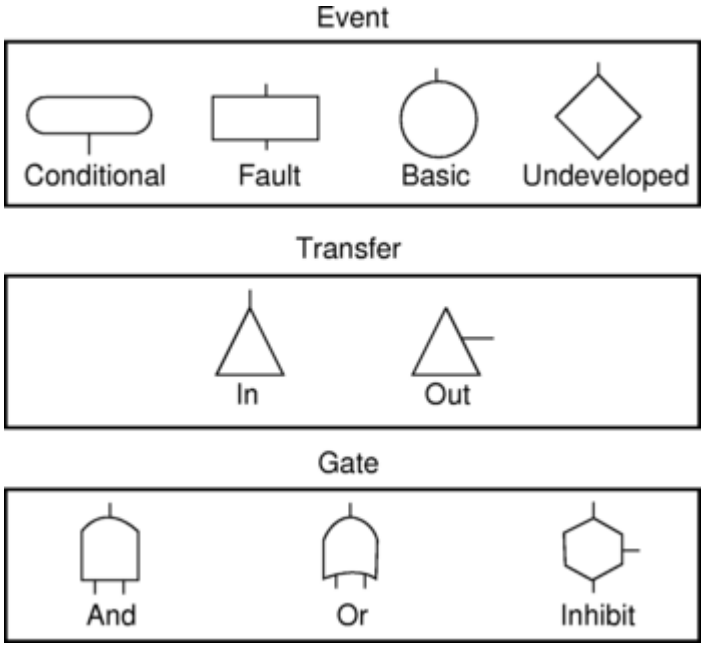

Fig. 16 Fault tree symbols for gates, transfers, and events

Figure 17 illustrates how Nova Corporation adopted FTA for the risk assessment of uniform corrosion on its 18,000 km (11,000 mile) gas pipeline network (Ref 32). The Nova rupture- risk FTA was normally performed for the review and analytical examination of systems or equipment to emphasize the lower-level fault occurrences, and the results of the FTA calculations were regularly validated with inspection results. These results also served to schedule maintenance operations, conduct surveys, and plan research and development efforts. Each element of each branch in Fig. 17 contains numeric probability information related to technical and historical data for each segment of the complete pipeline network. In some cases, it is simpler to assume some probability values for an entire system. The probabilities of operating at maximum permitted pressure and the presence of electrolyte were both set at value unity in Fig. 17, therefore forcing the focus on worst-case scenarios. Other, more verifiable variables can be fully developed, as is shown in Fig. 18 for two basic events describing the probable impact of a cathodic protection deficiency on the pipeline network.

Maintenance Steering Group (MSG) System Applied to Aircraft. The aircraft industry and its controlling agencies have developed, over the past few decades, a comprehensive system to represent potential failures of aircraft components, the maintenance steering group (MSG). The first generation of formal air carrier maintenance programs was based on the belief that each part on an aircraft required periodic overhaul. As experience was gained, it became apparent that some components did not require as much attention as others, and new methods of maintenance control were developed. Condition monitoring was thus introduced in the decision logic of the initial MSG document (MSG-1) and was applied to Boeing 747 aircraft.

After several alterations to the system, industry and regulatory authorities began working together in 1991 to provide additional enhancements to MSG-3. As a result of these efforts, revision 2 was submitted to the Federal Aviation Administration (FAA) in September 1993 and was accepted a few weeks later (Ref 33). One particularly interesting addition in this revision is a procedure for incorporating corrosion damage in the MSG logic. The environmental deterioration analysis (EDA) involves the evaluation of the structure against probable exposure to adverse environments. The evaluation of deterioration is based on a series of steps supported by reference materials containing baseline data expressing the susceptibility of structural materials to various types of environmental damage, and it produces inputs for the structure maintenance program.

The MSG-3 (revision 2) structures analysis begins by developing a complete breakdown of the aircraft systems to the component level. All structural items are then either classified as structure-significant items (SSIs) or other structure. An item is classified as a SSI depending on consideration of consequences of failure and likelihood of failures as well as material, protection, and probable exposure to corrosive environments. All SSIs are then listed and categorized as damage-tolerant or safe-life items, to which life limits are assigned (Ref 34). Accidental damage, environmental deterioration, corrosion prevention and control, and fatigue damage evaluation are then performed for these SSIs, following the logic diagram illustrated in Fig. 19. Once the MSG-3 structure analysis is completed, each element of the structural analysis diagram (Fig. 19) can be expanded right to the individual components and associated inspection and maintenance tasks. The logic of the EDA,

مرجع مهندسی مواد و متالورژی

illustrated in Fig. 20, requires the input of a multitude of parameters, such as component part number, location, material composition, and protective coating, that can be actuated in practical templates.

Corrosion Index for Pipeline Risk Evaluation. The third example of comprehensive models is the pipeline risk assessment methodology, described in detail in (Ref 35). The methodology is based on subjective risk assessment, a method particularly well adapted to situations where knowledge is incomplete and judgments are based on opinions, experience, and other nonquantifiable resources. The technique used for quantifying risk factors is a hybrid of several methods, allowing the user to confide in scores obtained by combining statistical failure data with operator experience. The subjective scoring system allows the assessment of the pipeline risk picture in two general parts:

- A detailed itemization and relative weighting of all reasonably foreseeable events that may lead to the failure of a pipeline are carried out. The itemization is further broken down into the four indexes illustrated in Fig. 21, corresponding to typical categories of pipeline accident failures. By considering each item in each index, an expert evaluator arrives at a numerical value for that index. The four index values are then summed to obtain the total index value.
- A detailed analysis is made of potential consequences of each failure, considering product characteristics, pipeline operating conditions, and line location.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

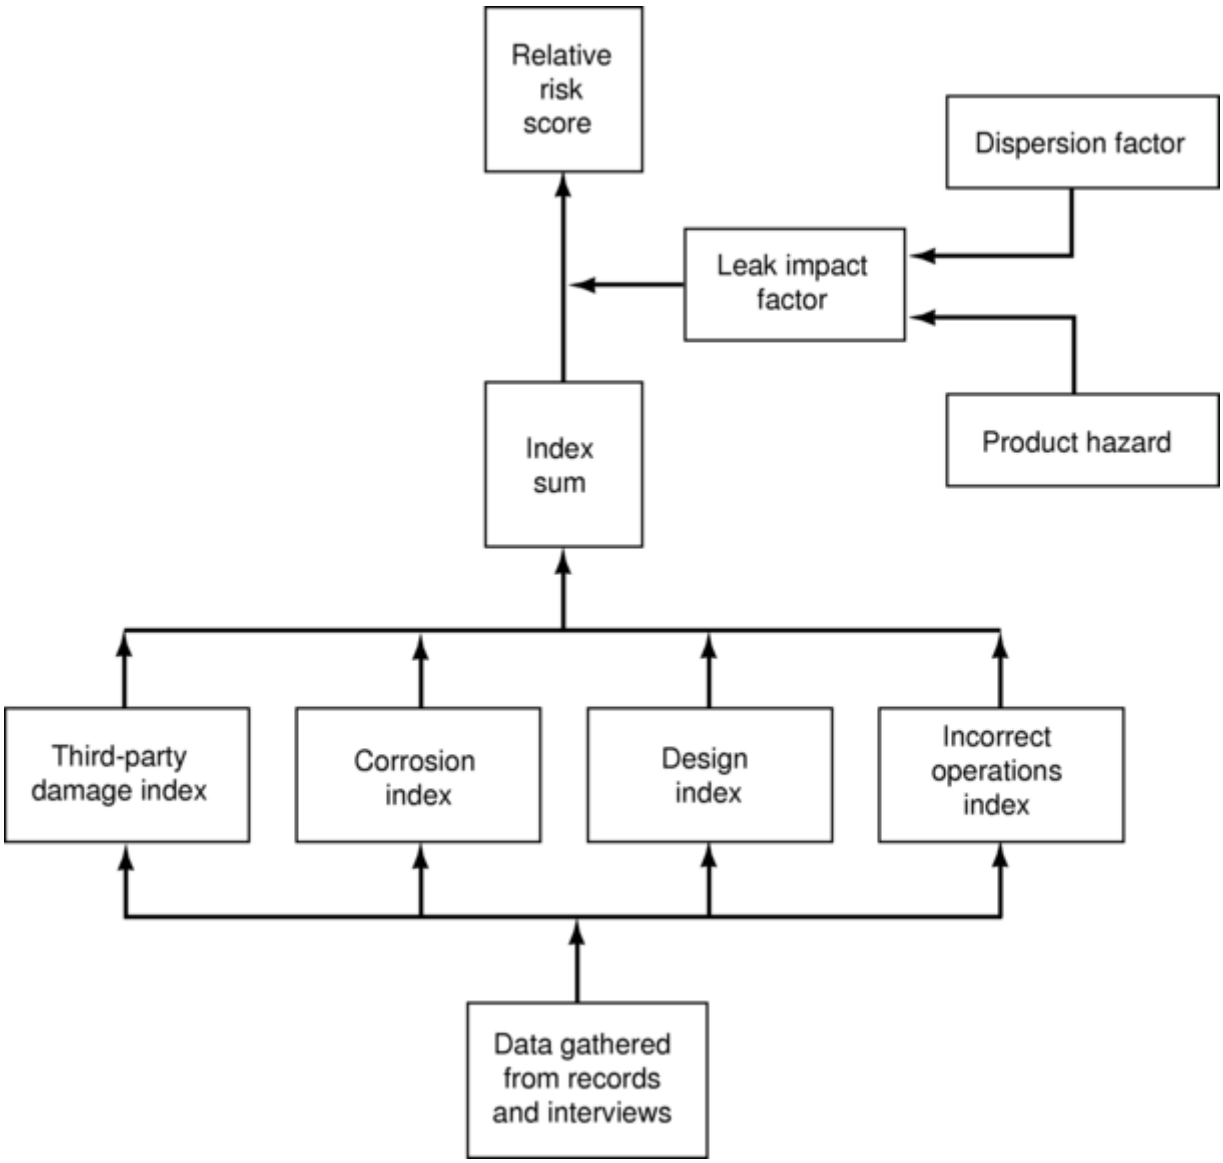

Fig. 21 Pipeline risk assessment model

The risk of a pipeline failure caused by corrosion, directly or indirectly, is probably the most common hazard associated with steel pipelines. The corrosion index was organized into three categories to reflect three types of environment to which pipelines are typically exposed, that is, atmospheric corrosion, soil corrosion, and internal corrosion. Table 5 contains the elements contributing to each type of environment and the suggested weighting factors. Building the risk assessment tool requires the following four steps:

1. *Sectioning:* dividing a system into smaller sections. The size of each section should reflect practical considerations of operation, maintenance, and cost of data gathering versus the benefit of increased accuracy.
2. *Customizing:* deciding on a list of risk contributors and risk reducers and their relative importance
3. *Data gathering:* building the database by completing an expert evaluation for each section of the system
4. *Maintenance:* identifying when and how risk factors can change and updating these factors accordingly

Knowledge Models

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The adequate transfer and reuse of information involves the development of information- processing strategies that can become quite complex. Humans are accustomed to working with imprecise information. They naturally accept vague use of language, making continuous interpretations of the information they receive based on context. Ambiguity can cause problems. However, if the scope for ambiguity is provided, a question and answer clarifies the matter. For a machine to carry out the same tasks, unambiguous language must be defined. This, of course, is the first event in the creation of a traditional programming language, such as FORTRAN, PASCAL or C. The structuring of knowledge inevitably requires the definition of terms, statements of relationships between them, and elimination of ambiguity. Despite this, modern mathematics has devised techniques that do allow for imprecise or error-containing information, and, by means of fuzzy logic, some computers can now cope with such situations (Ref 36). Some of the artificial intelligence tools that have been developed in support of corrosion control and protection are reviewed in the following sections.

Basic Principles of Knowledge Models

From a practical point of view, all models of expertise have their place and possess special features designed to represent specific types of knowledge. Knowledge engineering research has produced a wide range of models of expertise, which have been classified into five major classes (Ref 37):

- *Heuristic models:* offer a symbolic, or representational, description of expertise that is seen as a combination of facts and heuristics. A rule-based or heuristic system would be an excellent choice, for example, when the hierarchy between facts and decisions is well established.
- *Deep models:* suggest that experts use a variety of deep knowledge structures represented differently from heuristic rules. Deep models of expertise are said to better represent the expert functions at each level of the expertise model hierarchy.
- *Implicit models:* offer a representational description with a particular emphasis on the implicitness or explicitness of knowledge. Implicit models have become increasingly popular, with the development of artificial neural networks.
- *Competence models:* are representation independent and principally distinguish between domain and task knowledge. The focus of competence models is usually on the strategy of a problem-solving process. These models provide an extension of a functional rule-based system from which the heuristic knowledge was extracted to generate an explicit knowledge-level description of a specialist's expertise (Ref 37).
- *Distributed models:* can be compared to negotiation schemes. The tools implementing this approach are still on the research bench, because many aspects of fuzzy systems development for fuzzification and defuzzification remain both attractive and mysterious to apply (Ref 36).

Expert Systems. During the 1970s, research in expert systems (ES) was mostly a laboratory curiosity. The research focus then was really centered on developing ways of representing and reasoning about knowledge in a computer and much less on designing actual systems (Ref 38). In 1985, approximately 50 systems were deployed and reported, but the success of some of these captured the attention of many organizations and individuals. The corrosion community reacted with interest to the advent of these new information-processing technologies by establishing programs to foster and encourage the introduction of ES in the workplace. While some of these programs were relatively modest, others were quite ambitious and important both in scope and in funding. The advantages and limitations of using ES technology were analyzed in great detail in one of the first reported efforts on combating corrosion with ES (Ref 39). The stress-corrosion cracking (SCC) ES (SCCES) had been created to calculate the risk of various factors involved in SCC, such as crack initiation, when the user supplied evidence. The main goal of this effort was to support the decision process of “general” materials engineers. The system would initially play the role of a consultant, but it was anticipated that SCCES had the potential to become:

- An intelligent checklist
- A trainer
- An expert sharpener
- A communication medium

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

- A demonstration vehicle

The transfer of corrosion expertise into ES has been realized in a multitude of projects. The NACE International Conference Proceedings, for example, regularly contain papers that illustrate the continuous interest in the application of knowledge engineering to corrosion. Unfortunately, many systems reported in the literature have never been commercialized. This has resulted in a lack of impartial and practical information concerning the performance and accuracy of these systems. It is indeed very difficult to believe everything that is said in a paper or, even more so, when the information is some form of publicity. To remedy this situation, the European Federation of Corrosion (EFC) and the Materials Technology Institute (MTI) have performed two surveys, between 1988 and l990, requesting recognized developers of ES in corrosion-related areas to provide very specific information concerning the availability, scope, and performance of their systems (Ref 40). A review of the information presented in these reports was summarized (Ref 41), and other developments in expert systems for corrosion prevention and control were reported subsequently (Ref 42).

Neural Networks. A modeling neural network essentially acts as a mapping operator or a transfer function, taking inputs normally fed to a process and computing its predicted output values (Ref 36). Because the input-output mapping can be either static or dynamic, the technology can be applied to a broad range of applications, being particularly efficient with real-time operations. However, neural networks are also well adapted to perform other implicit expert functions, such as pattern recognition and classification.

An artificial neural network (ANN) is a network of many very simple processors or neurons (Fig. 22), each possibility having a small amount of local memory. The interaction of the neurons in the network is roughly based on the principles of neural science. Unidirectional channels that carry numeric data based on the weights of connections connect these neurons, which operate only on their local data and on the inputs they receive via the connections. Most neural networks have some sort of training rule. The training algorithm adjusts the weights on the basis of presented patterns. In other words, neural networks “learn” from examples. Artificial neural networks excel particularly at problems where pattern recognition is important and precise computational answers are not required. When ANNs inputs and/or outputs contain evolved parameters, their computational precision and extrapolation ability significantly increases and can even outperform more traditional modeling techniques. Some applications of ANN to corrosion problems are briefly described below.

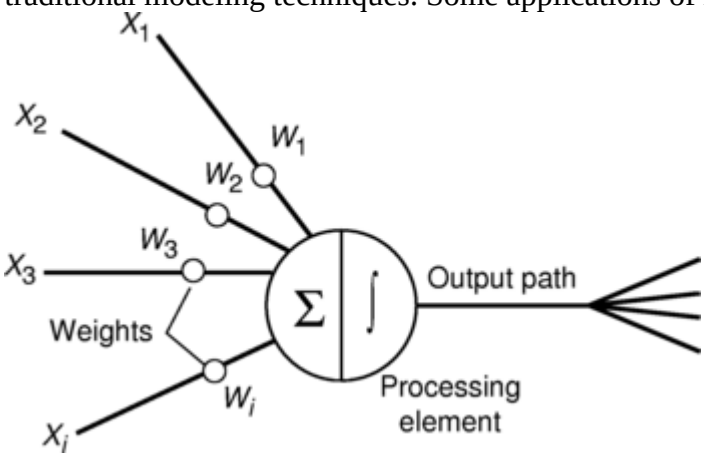

Fig. 22 Schematic of a single processor or neuron in an artificial neural network

Predicting the SCC Risk of Stainless Steels. The risk of encountering a SCC situation was functionalized in terms of the main environment variables (Ref 43). Case histories reflecting the influence of temperature, chloride concentration, and oxygen concentration have been analyzed by means of a back-propagation network. Three neural networks were developed. One was created to reveal the temperature and chloride concentration dependency (Fig. 23) and another to expose the combined effect of oxygen and chloride content in the environment. The third ANN was trained to explore the combined effect of all three parameters. During this project, ANNs were found to outperform traditional mathematical regression techniques, where the functions have to be specified before performing the analysis.

Corrosion Prediction from Polarization Scans. An ANN was put to the task of recognizing certain relationships in potentiodynamic polarization scans in order to predict the occurrence of general or localized corrosion, such as pitting and crevice (Ref 44). The initial data inputs were derived by carefully examining a number of polarization scans for a number of systems and recording those features that were used for the predictions. Table 6 lists the initial inputs used and how the features were digitized for computer input. The variables shown were chosen because they were thought to be the most significant in relation to the predictions (Table 6). The final ANN proved to be able to make appropriate predictions using scans outside the initial training set. The resulting ANN was embedded in an ES to facilitate the input of data and the interpretation of the numerical output of the ANN.

Table 6 Data inputs and outputs for predicting corrosion out of polarization scans with an artificial neural network

Parameter	Value of feature
Input	
Repassivation potential	E_{prot} - E_{corr}
Pitting potential	E_{pit} - E_{corr}
Hysteresis	+1 = Positive
	0 = None
	-1 = Negative

	0 = No

E_{prot}, repassivation (or protection) potential; E_{corr}, corrosion potential; E_{pit}, pitting potential; $E_{A\ to\ C}$, anodic to cathodic potential

Predicting the Degradation of Nonmetallic Lining Materials. An ANN was trained to recognize the pattern between results from a sequential immersion test for nonmetallic materials and the behavior of the same material in field applications (Ref 45). Eighty-nine cases were used for the supervised training of the network. Another 17 cases were held back for testing of the trained network. An effort was made to ensure that both sets had experimental data taken from the same test but using different samples. Appropriate choice of features enabled the ANN to mimic the expert with reasonable accuracy. The successful development of this ANN was another indication that ANNs could seriously aid in projecting laboratory results into field predictions.

Validation and Extrapolation of Electrochemical Impedance Data. The ANN developed in this project had three independent input vectors: frequency, pH, and the applied potential (Ref 46). The ANN was designed to learn from the invisible or hidden information at high and low frequencies and to predict in a lower frequency range than that used for training. Eight sets of impedance data acquired on nickel electrodes in phosphate solutions were used for this project. Five sets were used for training the ANN and three for its testing. The ANN proved to be a powerful technique for generating diagnostics at these conditions.

Modeling CO_2 Corrosion. A CO_2 corrosion worst-case model based on an ANN approach was developed and the model validated against a large experimental database (Ref 47). An experimental database was used to train and test the ANN. It consisted initially of six elemental descriptors (temperature, partial CO_2 pressure, ferrous and bicarbonate ion concentrations, pH, and flow velocity) and one output, that is, the corrosion rate. The system demonstrated superior interpolation performance compared to two well-known semiempirical models. The ANN model also demonstrated extrapolation capabilities comparable to a purely mechanistic electrochemical CO_2 corrosion model.

Pitting of Aluminum in Natural Waters. The development and testing of an ANN model for the prediction of pitting of aluminum alloy A91100 was demonstrated in the context of nuclear waste storage (Ref 48). The U.S. Department of Energy Savannah River site for the extended storage of aluminum-clad spent nuclear fuel, where most of this waste is stored in large water basins, is fully equipped with corrosion control programs. Vigilant monitoring and regulation of water chemistry has reduced the occurrence of pitting to essentially zero. Trained ANN models, based on the configuration described in Fig. 24, were used to predict pit depths for periods up to 1 year. Because the supply waters contained species not included in the training data of these models, correlation between predicted and actual pit depth deteriorated for longer time periods.

Electrochemical Methods of Corrosion Testing

Florian Mansfeld, University of Southern California

Introduction

DURING CORROSION, at least two electrochemical reactions, an oxidation and a reduction reaction, occur at a metal-electrolyte interface. Because corrosion is due to an electrochemical mechanism, it is clear that electrochemical techniques can be used to study corrosion reactions and mechanisms. This article reviews the fundamentals of electrochemical corrosion test methods, preparations for electrochemical polarization experiments, and the various electrochemical techniques available for laboratory studies of corrosion phenomena.

F. Mansfeld, Electrochemical Methods of Corrosion Testing, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 446–462

Electrochemical Methods of Corrosion Testing

Florian Mansfeld, University of Southern California

Fundamentals

The basis of all electrochemical techniques lies in the principle of mixed-potential theory, which was clearly established in a classic paper published in 1938 (Ref 1). It was demonstrated that uniform corrosion occurs when anodic and cathodic reactions take place in constant change of location and time of the individual processes. In this concept, it is not necessary to postulate the presence of local anodes and cathodes for corrosion to occur. Nevertheless, in later years it has often been stated that corrosion occurs when local anodes and cathodes have been established, despite the obvious fact that, in this case, uniform corrosion is not possible.

The corrosion potential, E_{corr}, or open-circuit potential (OCP), is a mixed potential; that is, it is the unique potential at which the rates of the anodic and cathodic reaction are exactly equal. The rate of the anodic or the cathodic reaction at E_{corr} equals the corrosion rate. Because the rates of these two reactions are independent of each other, it is possible to inhibit corrosion by reducing the rate of only one of the two reactions by using, for example, anodic or cathodic corrosion inhibitors. Cathodic protection in which the material to be protected is polarized cathodically in order to reduce the rate of the anodic metal dissolution reaction is another example. The concept of mixed-potential theory and its application in corrosion science and technology has been discussed in many textbooks (Ref 2, 3).

The use of mixed-potential theory for the monitoring of corrosion rates was also demonstrated by showing that the slope of a potential versus current density plot at E_{corr} can be used to determine the corrosion rate (Ref 1). Today, this technique is referred to as the polarization- resistance technique or, less precisely, as the linear polarization technique (Ref 4). From this research, it also becomes clear that corrosion current densities, i_{corr}, can be obtained from the analysis of anodic and cathodic polarization curves, which is often referred to as Tafel extrapolation (Ref 2, 3). This concept has been developed further (Ref 4, 5). In addition, mechanistic information can be obtained by analysis of the Tafel slopes that have characteristic values, depending on the nature of the rate-determining step in the corrosion mechanism (Ref 2, 4).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

A large number of electrochemical techniques are available for laboratory studies of various corrosion phenomena as well as for corrosion monitoring (Ref 6, 7, 8, 9, 10). The National Association of Corrosion Engineers (NACE) series, *Corrosion Testing Made Easy*, contains several volumes that deal with the use of electrochemical methods (Ref 11, 12, 13). The advice given previously (Ref 14)—"Don't be afraid of electrochemical techniques, but use them with care"— applies for laboratory studies. Often, electrochemical techniques are considered to be overly complicated. However, recent developments by the manufacturers of hardware and software have made the use of these techniques quite simple. Most equipment contains software that enables the user to carry out an electrochemical test in a straightforward manner. Of course, interpretation of the results of such tests remains up to the user. Often, only the experimental results are presented; sometimes, the results of very simple measurements, such as E_{corr}, have been overinterpreted. It has to be remembered that electrochemical tests indicate that corrosion has happened but do not contain information concerning the cause of corrosion. Therefore, statements that certain electrochemical techniques such as the electrochemical noise (ECN) technique "offers unique capabilities that should allow quantification of microbial effects on corrosion," and "ECN offers promise in identifying microbiologically influenced corrosion" (Ref 15) should be viewed with caution.

Electrochemical techniques available for laboratory studies of corrosion phenomena are summarized in Table 1. These techniques range from those in which no external signal is applied, such as E_{corr} and electrochemical noise analysis (ENA), to those in which only a small potential or current perturbation is applied, such as polarization resistance, R_p, and electrochemical impedance spectroscopy (EIS); to those in which the applied potential or current is varied over a wide range, such as anodic and cathodic polarization curves and pitting scans.

Table 1 Electrochemical corrosion testing techniques

Category	Test method
No applied signal	Open circuit or corrosion potential
	Dissimilar metal corrosion (galvanic corrosion)
	Electrochemical noise analysis
Small-signal polarization	Polarization resistance (linear polarization)
	Electrochemical impedance spectroscopy
Large-signal polarization	Potentiostatic and galvanostatic polarization
	Potentiodynamic and galvanodynamic polarization
Scanning electrode techniques	Potential scans
	Current scans
	Electrochemical impedance spectroscopy scans
Miscellaneous tests	Hydrogen permeation
	Anodized aluminum corrosion test
	Electrolytic corrosion test
	Paint adhesion on a scribed surface
	Impedance test for anodized aluminumodized
	Critical pitting temperature

The galvanic current flowing between two dissimilar metals can be monitored using a zero- resistance ammeter (ZRA). Diffusion of atomic hydrogen into metals, such as steel, that can cause failure can be evaluated with the electrochemical permeation method. Scanning electrode techniques can be used to determine the location of anodes and cathodes on electrodes. It has to be recognized that very simple techniques, such as those in which no external signal is applied, usually provide much less quantitative information concerning corrosion mechanisms than those in which a carefully controlled signal is applied to the system under investigation and the response of the system is analyzed. An example for this kind of approach is EIS, in which the frequency of the applied signal is used as an additional variable. ASTM Committee G-1 has published standard practices for most of the techniques listed in Table 1, describing the experimental approach and giving examples for the use of these methods.

Electrochemical Methods of Corrosion Testing

Florian Mansfeld, University of Southern California

Preparing an Electrochemical Polarization Experiment

For the performance of most electrochemical tests discussed here, a potentiostat and an electrochemical cell are required. Open-circuit-potential measurements may be performed using only a high-input impedance voltmeter, while galvanic current and ECN measurements may be carried out using a ZRA instead of a potentiostat, as

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

discussed subsequently. The features and requirements of the instrumentation needed for an electrochemical test are discussed in brief. A more detailed description can be found in Ref 12.
The basic instrumentation needed for the electrochemical tests includes:

- Test or working electrode (WE)
- One or more counter electrodes (CE)
- Reference electrode (RE)
- Test cell
- Potentiostat
- Voltmeters for monitoring of potential and current (optional)
- Recording devices (strip chart or *x-y* recorders)
- Computer with software program and plotter (replacing the voltmeter and recording devices) (optional)
- Gas tank with nitrogen, argon, or another gas to deaerate the solution (optional)
- Thermostat with a constant temperature bath or heating mantle (optional)

In a potentiostatic experiment, the applied potential, E_{appl}, is maintained between the RE and WE. The WE is at virtual ground. Therefore, the sign of the potential displayed on the potentiostat is sometimes that of the RE to ground and opposite the potential of the WE. This fact, unfortunately, often leads to confusion concerning the sign of the measured potential. The instruction manual of the potentiostat to be used should be consulted regarding this point. The current flows between CE and WE and is usually displayed with the correct sign (positive for an anodic current). A simple test can be carried out using a zinc WE, which has a very negative E_{corr} versus any common RE, and for which a negative (cathodic) current is recorded when a potential $E < E_{corr}$ is applied.
The minimum requirements for a potentiostatic test are a test cell with WE, RE, CE, a potentiostat, and a recording device (Ref 11, 12). Potential and current can be monitored using voltmeters, although this is also possible with the built-in instruments in the potentiostat. In most current applications of polarization techniques, the experiment is carried out using software that is either supplied by the instrument manufacturer or is available from other commercial sources. This method is a very convenient practice that allows storage of many experimental data that can later be analyzed with appropriate analysis software.
Test or Working Electrode. The WE can be of various shapes, such as a cylinder or a flat disk. Often, the availability of a material as rod or sheet determines the shape of the electrode. When a cylinder is used, it has to be considered that edge effects can play a role due to different current distribution along the WE surface. The metallurgical properties may also be different for the sides and the bottom of the cylinder. Fewer problems occur with a flat disk, especially when care is taken that crevice corrosion does not occur. Not much attention is usually paid to the size of the electrode, with 1 cm^2 (0.2 $in.^2$) being a common test area. However, a much larger size is useful when very small currents have to be measured, while much smaller electrodes are useful when very large currents flow in the system. The error due to the ohmic drop between WE and RE is less when small electrodes are used.
The WE is connected to an electrode holder to which the lead to the potentiostat is attached. Details of the construction of electrode holders appear in Ref 11 and 12 and are not repeated here. It is important that only glass, synthetic fluorine-containing resin, or other nonmetallic materials are immersed as part of the electrode holder. Figure 1 shows electrode holders with a cylinder electrode (Fig. 1a) or a sheet electrode (Fig. 1b).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

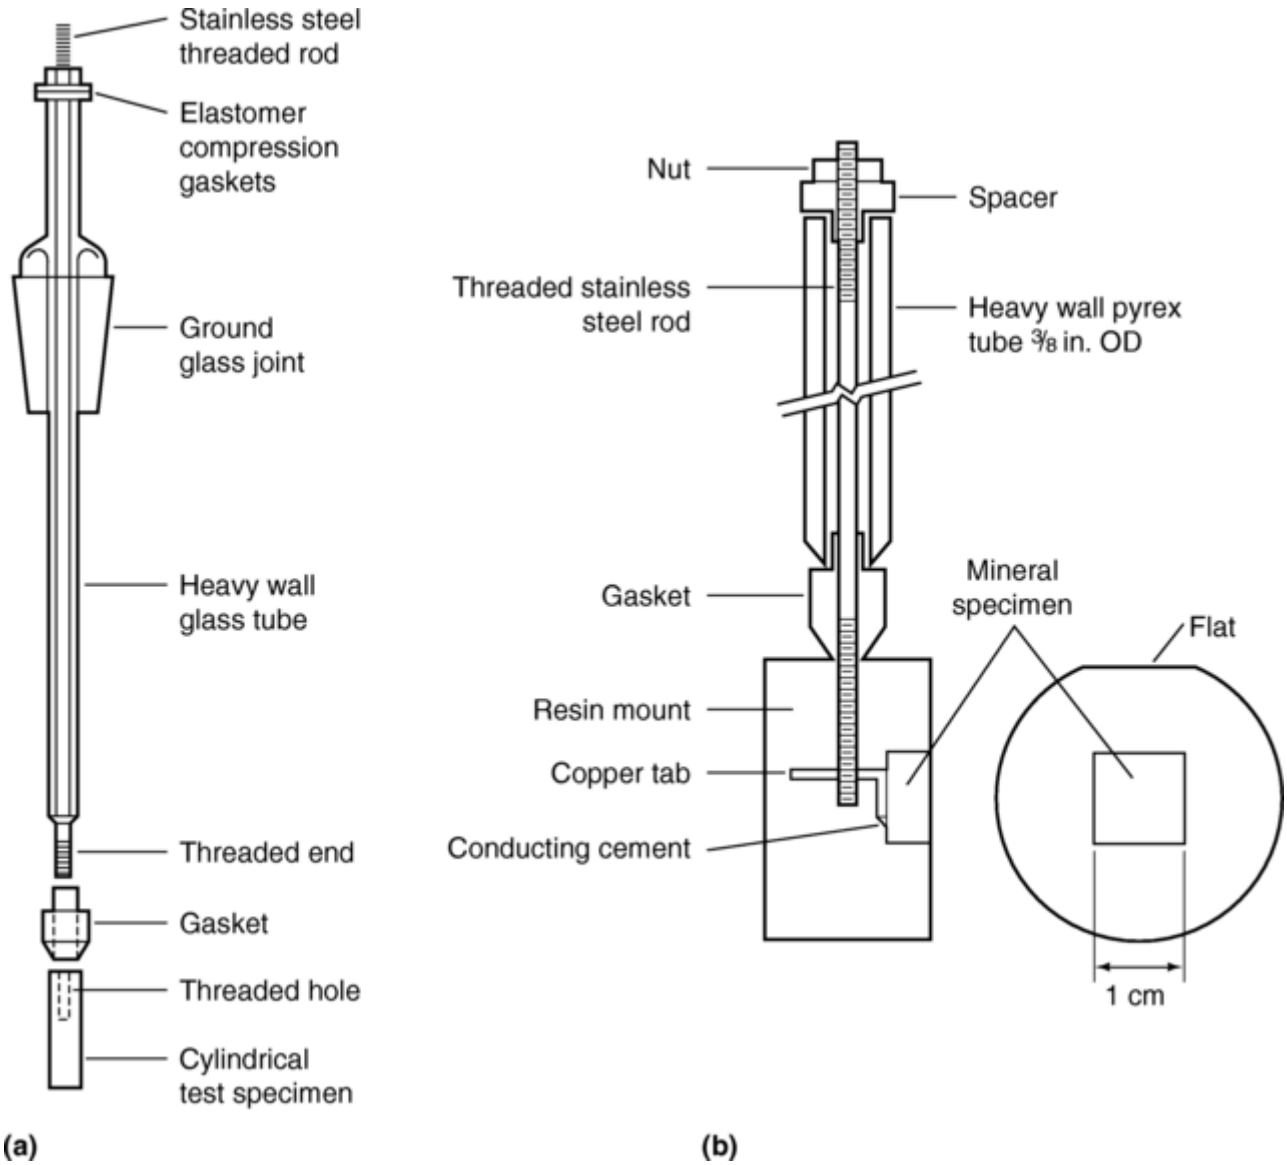

Fig. 1 Test electrodes and electrode holders. (a) Cylindrical electrodes. (b) Flat disk or sheet electrodes. OD, outside diameter

In neutral, aerated solutions, the cathodic reaction (reduction of oxygen) is usually under mass transport control. In this case, the electrochemical experiment should be carried out under controlled hydrodynamic conditions that can be achieved through the use of a rotating disk electrode (Fig. 2a) or a rotating cylinder electrode (RCE) (Fig. 2b). The RCE is preferred for corrosion studies because it provides very good current distribution. Polarization curves may be obtained at a constant rotation speed or as a function of rotation speed in studies where information concerning the details of the diffusion- controlled reduction reaction is required.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

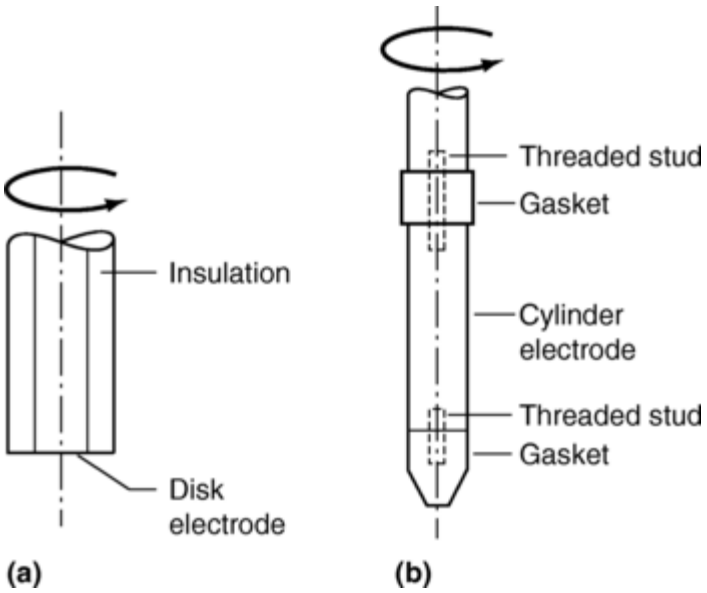

Fig. 2 Test electrodes. (a) Rotating disk electrodes. (b) Rotating cylinder electrodes

Counter Electrode. The choice of the CE is dictated by the requirement that the CE should be of good conductivity and should not dissolve as a result of current flow. Platinum is used in most experiments. Because it is desirable to use CEs that are much larger than the WE in order to reduce the current density at the CE and avoid contamination by reaction products of the electrolyte, less expensive materials, such as graphite, stainless steel, or titanium alloys, are often used as CEs. For the same reason, the CE should be placed in a separate compartment with a glass frit to the main cell. However, this precautionary measure is often neglected.

Reference Electrode. The saturated calomel electrode (SCE) is the most common RE used in studies of corrosion reactions, due to its stability and commercial availability. Care must be taken to avoid contamination of the test electrolyte by leakage of chloride ions from a SCE when tests are carried out in chloride ion-free test solutions. A mercury/mercurous sulfate electrode may be used when chloride ion contamination is not acceptable. Other REs are the Ag/AgCl and the Cu/ $CuSO_4$ electrodes. A luggin capillary is used to minimize the ohmic drop between WE and RE (Ref 11, 12).

A number of REs should be kept in the laboratory, with one RE being set aside as a calibration standard or the master RE, which is not used in actual potential tests. All other REs should be checked against this master RE before use by measuring the potential difference between the two electrodes, using a high-input impedance voltmeter. The potential difference should be less than 2 to 3 mV. Electrodes still showing a large potential difference after this procedure should be reconditioned or discarded.

Test Cell. The design of the test cell can be quite complicated for studies in deaerated solutions with constant temperature control, or very simple in tests with oxygenated solutions at room temperature. Three-compartment cells are often used in the first case, while an open beaker often gives satisfactory results in the second case. For larger sheet electrodes, such as those used in the evaluation of polymer coatings or anodic films (Ref 16), the simple cell with the flat sample exposed horizontally, as shown in Fig. 3, has been used by many authors. The Avesta cell has the advantage that its cell design allows crevice corrosion, which might be a problem with most other cell designs, to be avoided during the test. Important points to consider in assembly of a test cell are the correct placement of the luggin capillary for minimization of the ohmic drop and the CEs for satisfactory current distribution. Deaeration of the test solution is carried out by bubbling nitrogen gas or argon through the test cell for a sufficient time.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

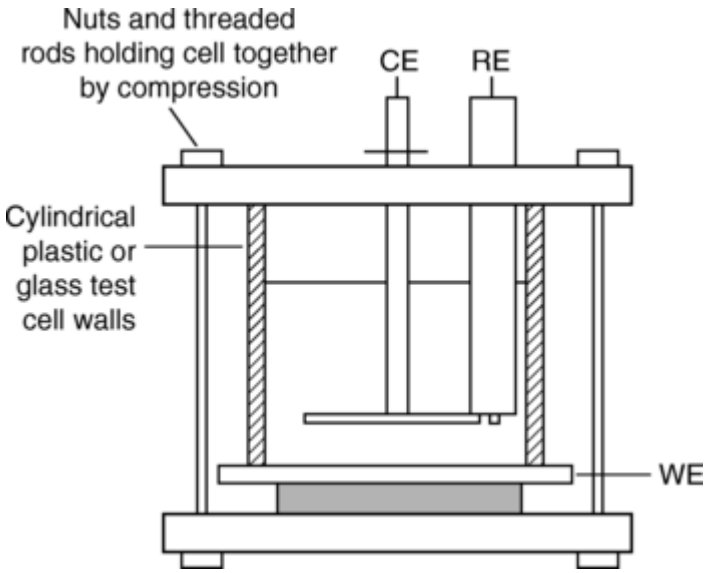

Fig. 3 Test cell for flat sheet electrodes. CE, counter electrode; RE, reference electrode; WE, working electrode

Potentiostat. A number of different potentiostats are available from different manufacturers. These instruments can be very sophisticated, allowing the recording of a number of electrochemical tests under computer control, or quite simple, with only the basic features in a low-cost model. Some newer instruments, using appropriate software, allow simultaneous recording of several experiments.

The main requirements of a potentiostat have been discussed elsewhere in detail (Ref 11, 12). The available range of E_{appl} should be at least ±2 V, and the current capability should be ±1 A. A larger range of E_{appl} may be required for some tests, such as the pitting of titanium alloys. The maximum cell voltage should be approximately 60 V. Outputs should be provided for monitoring of potential and current. For the latter purpose, the current should be provided as a voltage versus ground, which is important for recording of the current on a strip chart or *x-y* recorder. The positive feedback or the current interrupter technique can be used for elimination of the ohmic drop, which can be significant in studies in low-conductivity media such as very dilute solutions and nonaqueous media (Ref 17, 18). The possibility of conducting the experiment under computer control is highly desirable, especially for more complicated tests such as the potentiodynamic tests described subsequently.

Voltmeters. The values of potential and current usually are displayed on the front panel of the potentiostat. Often, only one of these parameters can be read at a given time. Therefore, it is sometimes convenient to observe both values on separate voltmeters, especially when meters with a digital display are used. If current-time (*I-t*) or potential-current (*E-I*) curves are recorded, the use of digital voltmeters is useful to ensure that these curves are recorded correctly.

If it is desired to determine the potential of an electrode directly with a voltmeter rather than from the potential output of the potentiostat, a high-input impedance voltmeter has to be used to prevent current flow and polarization of WE and RE due to the potential measurement. The potential can be recorded on a strip chart recorder using the output of such a voltmeter. In this case, the input impedance of the recorder is not important. However, direct connection of a recorder to the RE and WE should be avoided, because the input impedance of most recorders is quite low.

Recording Devices. For tests in which the current, *I*, is monitored at a fixed value of E_{appl} as a function of time, *t*, a strip chart recorder is needed for the recording of the *I-t* curve. In this case, the current output, which is provided in the potentiostat as a voltage versus ground, is connected to the recorder, with the appropriate settings of the current range on the potentiostat and the voltage range on the recorder.

For tests in which a number of potential steps are applied, increasing in the anodic or cathodic direction, a strip chart or an *x-y* recorder can be used for the recording of the *I-t* curve. In the latter case, the current output is connected to the *y*-axis, and the *x*-axis is set to a time scale that is appropriate for the time used for each potential step.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

If a computerized system is used, recording devices are not needed. One of the advantages of the use of proper software is the fact that the electrochemical data are displayed on the screen as they are collected, which allows the researcher to stop an experiment that obviously is not running properly.

Computer with Software Program and Plotter. It is convenient and time saving to use a software program to record polarization data. Most commercial software programs contain a number of typical electrochemical tests, such as potentiostatic, potentiodynamic, galvanostatic polarization, and other tests, such as the measurement of the galvanic current, the electrochemical impedance, or ECN. The user can input the particular parameters that are desired for use in the test. Usually, default values are included in the program, which allows the running of a test with only a few inputs provided by the user.

For a potentiostatic test of type 1 (explained later in this article), the inputs are the applied potential, E_{appl}, and the time for which the potential is applied. Additional inputs depend on the particular software program to be used. The *I-t* curve is displayed on the computer screen with a current scale that has been selected by the program. After the test is completed, the *I-t* curve can be plotted after reformatting of the two axes into more convenient scales. In a galvanostatic test, a constant current, *I*, is applied for a certain time, and the *E-t* curve is monitored.

The potentiostatic test of type 2 (detailed later) requires additional inputs, such as the starting potential and the final potential as well as step height and length. Sometimes, for cleaning or other purposes, the test electrode is held at a preconditioning potential for a certain period before the test is started.

Figure 4 shows a typical arrangement for the application of electrochemical techniques in laboratory studies. The potentiostat connected to the test cell is controlled by a computer with suitable software; the experimental data can be printed out on the printer and/or displayed later, using software designed for analysis of the results of a given electrochemical test (Ref 11, 12).

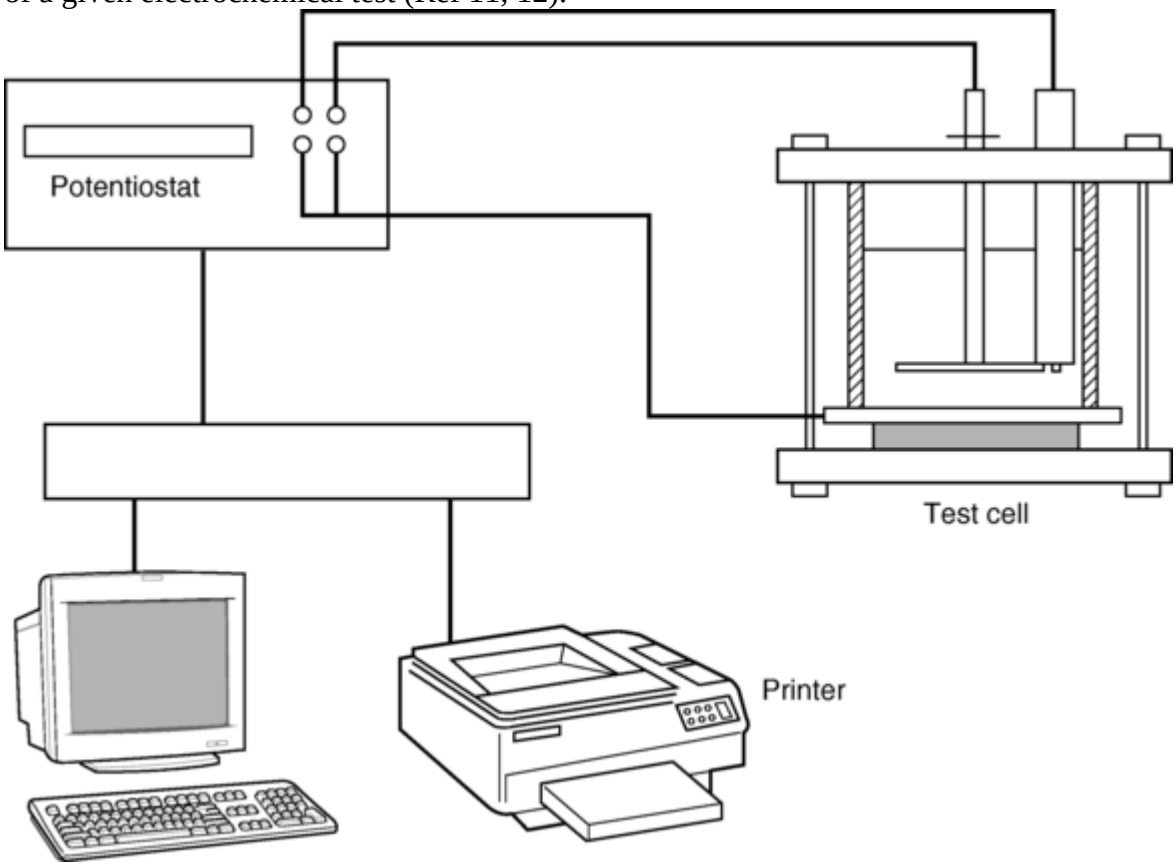

Fig. 4 Experimental arrangement for application of electrochemical techniques in laboratory tests

Thermostat. For studies that require carefully controlled temperatures, the test cell is placed in a constant-temperature bath, or a heating/cooling jacket is placed around the test cell.

Electrochemical Methods of Corrosion Testing

Florian Mansfeld, University of Southern California

No-Applied-Signal Tests

In measurements of OCP or E_{corr}, the galvanic current flowing between two dissimilar metals and ECN, no external electrochemical signal is applied. In one approach to the measurement of ECN data, the galvanic current flowing between two electrodes of the same material maintained at zero potential and the potential of this couple versus a stable RE are recorded simultaneously.

Open-Circuit or Corrosion Potential. Measurement of E_{corr} is the easiest electrochemical test to perform, but it provides the least amount of mechanistic information. Measurement of E_{corr} requires a stable reference electrode, such as a SCE, a high-impedance voltmeter, and, in most cases, a suitable recording device. Corrosion potential can be determined also by observing the digital display on the potentiostat, monitored by recording the potential output value from the potentiostat on a strip chart recorder as a function of exposure time or, if a suitable software program is used, by plotting the potential- time curve stored on a disk on a printer after the test is finished.

Open-circuit potential often increases with time for passive samples as passivity improves, and OCP often decreases when localized corrosion begins.

The time dependence of E_{corr} has been monitored by many groups investigating the effects of biofilm formation on localized corrosion of stainless steels in natural seawater (Ref 19). Most published data show a rapid ennoblement of E_{corr} (i.e., a shift to more positive values) during the first days of exposure.

The corrosion potential was monitored for Al 2024, mild steel, and cartridge brass during exposure to abiotic artificial seawater (AS) and to AS containing *Shewanella algae* or *Shewanella ana* (Ref 20). For Al 2024 (Fig. 5a) and brass (Fig. 5b), E_{corr} decreased in the presence of bacteria, while for mild steel (Fig. 5c), an increase of E_{corr} was observed. After exposure for 7 days to AS containing *S. ana,* kanamycin was added to kill the bacteria, and E_{corr} changed to the values observed in the abiotic AS for Al 2024 and brass but not for mild steel (Fig. 5). Electrochemical impedance spectroscopy was used to determine the corrosion mechanism of these systems in more detail (Ref 20).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

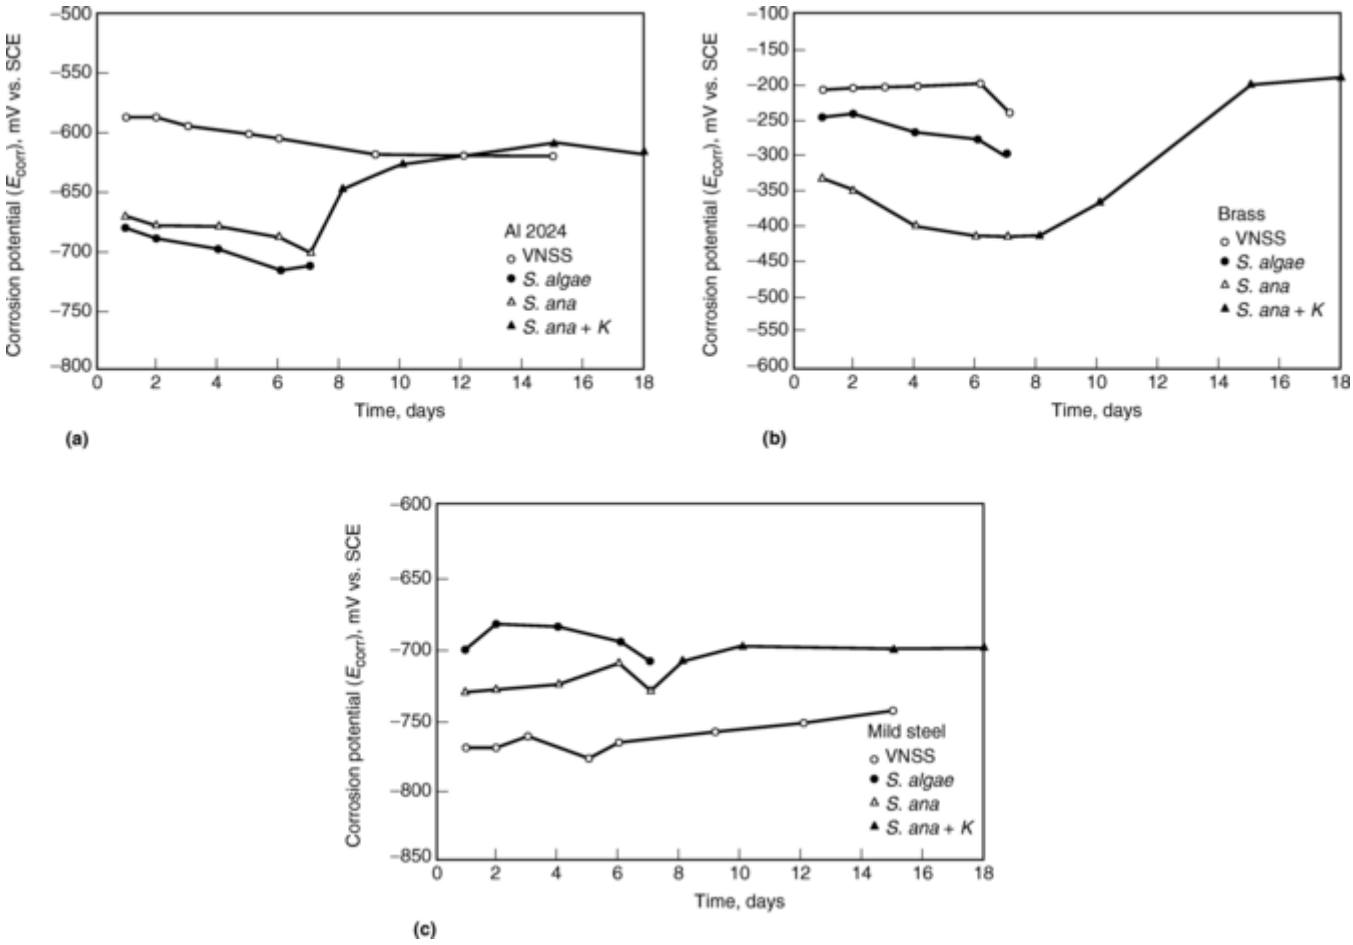

Fig. 5 Time dependence of corrosion potential (E_{corr}) for (a) Al 2024, (b) brass, and (c) mild steel exposed to artificial seawater with or without bacteria. VNSS, Väätänen nine salts solution. *K*, kanamycin. Source: Ref 20

The main problem with the use of E_{corr} measurements is overinterpretation. Based on information obtained with E_{corr} alone, it is not possible to determine whether corrosion rates have increased or decreased. Some authors have interpreted shifts of E_{corr} in the negative direction as a reduction of the rate of cathodic reaction or an increase of the rate of the anodic reactions. These are the two simplest possibilities that can be expected to lead to the observed result. However, without additional data, such as measurement of the polarization resistance (R_p), no valid mechanistic conclusions can be drawn.

Dissimilar Metal Corrosion (Galvanic Corrosion). Short-circuit currents between dissimilar metals or metals exposed to electrolytes of different composition need to be measured by means of a ZRA, because the introduction of a milliammeter with an internal resistance, R_i, in a low-resistance circuit may alter the total current by producing a potential difference, IR_i, between the two electrodes. The ZRA based on operational amplifiers, which was introduced in 1970 by Lauer and Mansfeld (Ref 21) for corrosion studies (Fig. 6), applies 0 mV potential difference between the two electrodes in the galvanic couple. The potential of the couple should be measured versus a RE in order to obtain additional information concerning the corrosion mechanism. A potentiostat can be used as a ZRA by setting the applied potential to 0 mV. The galvanic current is monitored as the current output of the potentiostat.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

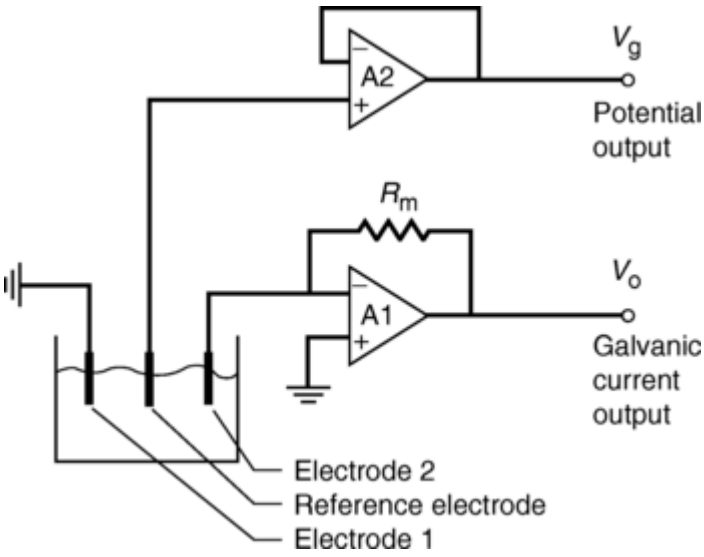

Fig. 6 Instrumental arrangement for continuous measurement of the galvanic current and potential. A1 and A2 represent operational amplifiers. R_m, measuring resistor; V_g, galvanic voltage; V_o, output voltage. Source: Ref 22

In using a ZRA based on operational amplifiers, one electrode is connected to the grounded input (Fig. 6). The galvanic current, I_g, needed to maintain 0 mV between the two electrodes is monitored as the output voltage $V_o = I_g R_m$, where R_m is the measuring resistor. The measuring resistor can be varied to maintain V_o in a convenient range, that is, 0 to 1 V. The potential V_g of the galvanic couple is measured with the voltage follower (A2 in Fig. 6), which determines the potential of the RE versus ground. Both V_o and V_g can be recorded on strip chart recorders or other devices. The advantage of the design in Fig. 6 is its low cost, which allows construction of several devices and monitoring of multiple test cells at the same time. Operational amplifiers can also be used to construct inexpensive and versatile potentiostats, as discussed elsewhere (Ref 22).

The galvanic current is a measure of the increase of the corrosion current of the anode due to the coupling to the cathode and does not allow calculation of the corrosion rate of either electrode (Ref 23). Simultaneous measurements of the galvanic current and the potential of the coupled electrodes using a RE allow determination of the changes of the kinetics of the corrosion reactions with exposure time. It has to be recognized that the magnitude of the measured galvanic current depends on the area ratio of anode and cathode, A^c to A^a. If this ratio is not 1, then the measured galvanic current, I_g, has to be normalized to determine the galvanic current densities, $i_g^a = I_g/A^a$ and $i_g^c = I_g/A^c$, which have different numerical values (Ref 24).

Detailed studies have been conducted on the galvanic corrosion of aluminum alloys coupled to a number of materials (Ref 25, 26). Figure 7 shows the time dependence of the galvanic current, I_g, (Fig. 7a) and the potential, E_g, (Fig. 7b) of different galvanic couples versus a SCE (Ref 25). Galvanic current flowing between Al 2024 and a dissimilar metal decreased in the sequence copper > 304 stainless steel > Ti-6Al-4V, indicating that copper acted as an efficient cathode, while the titanium did not cause significant galvanic corrosion of Al 2024. For couples involving cadmium or zinc, Al 2024 was protected cathodically (Fig. 7a). Except for the couple involving zinc, E_g remained close to E_{corr} of Al 2024 (Fig. 7b). Similar results were obtained for Al 7075 (Fig. 7). A ZRA has been used to evaluate the effect of dichromate additions on the galvanic corrosion of a brass-steel couple in aerated 20% NaCl (Ref 27).

Electrochemical Noise Analysis (ENA). Electrochemical noise data can be obtained as fluctuations of E_{corr}; as fluctuations of the potential, E, at an applied current, I; or as fluctuations of I at an applied E. Recently, it has

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

become common practice—at least in laboratory studies—to measure potential and current fluctuations simultaneously, as shown in Fig. 8 (Ref 28, 29, 30, 31). In this approach, two electrodes of the same material are coupled through a ZRA. Current fluctuations are measured using the ZRA, while the potential fluctuations are measured with a high-impedance voltmeter between the two coupled electrodes and an RE, which could be a stable RE, such as an SCE, or a third electrode of the same material as the two test electrodes (Ref 28, 29). The latter approach is commonly used in corrosion monitoring. A review of different methods for collection of ECN data can be found in Ref 32.

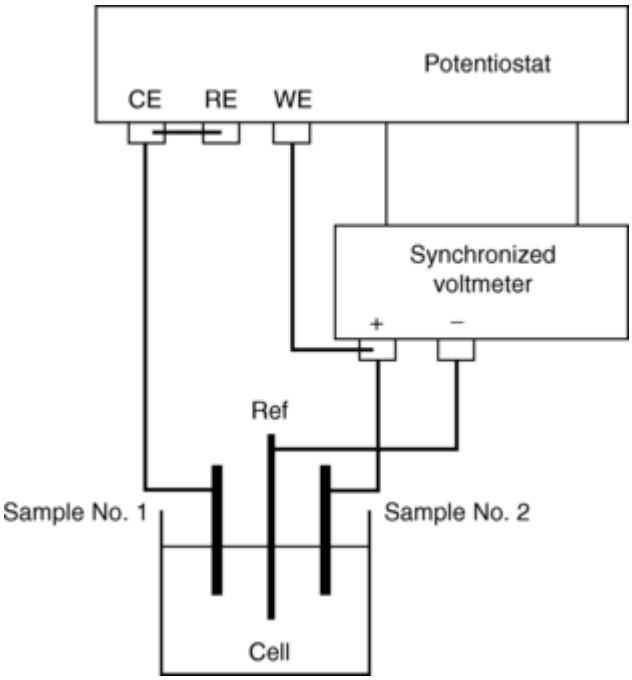

Fig. 8 Experimental arrangement for simultaneous collection of potential and current fluctuations. Source: Ref 30

Simultaneous collection of potential and current ECN data allows ENA in the time and the frequency domains. Various methods of data analysis have been discussed in detail (Ref 30, 31, 33, 34, 35). The parameters commonly determined in these analyses are listed in Table 2. Figure 9 shows experimental potential, V, (Fig. 9a) and current, I, (Fig. 9b) fluctuations for mild steel exposed to aerated 0.5 N NaCl as well as the power spectral density (PSD) plots for these data (Fig. 9c, d) (Ref 36). The drift in the raw experimental data that causes erroneous PSD slopes was removed using a linear method (Ref 36). From the PSD plots for potential and current fluctuations, the spectral noise or noise impedance plot (R_{sn}) (Fig. 9e) can be determined as the ratio of the fast Fourier transform of potential and current fluctuations, or the square root of the ratio of the potential and current PSD plots. Good agreement was observed between the impedance spectra and the spectral noise plots (Ref 36). Analysis of ECN data in the time domain results in values of the mean potential, E_{coup}, and the mean current, I_{coup}, of the coupled electrodes. In addition, the standard deviations σV and σI of the potential and current fluctuations, respectively, and the noise resistance $R_n = \sigma V/\sigma I$ are obtained. The localization index LI = $\sigma I/I_{rms}$, where I_{rms} is the root mean square value of the current fluctuations, can also be determined (Ref 32, 37). The suggestion that LI can be used to determine the prevailing corrosion mechanism should be viewed with great caution (Ref 35, 37).

(c) Power spectral density (PSD) plot from voltage data. (d) Power Spectral density plot from current data. (e) Spectral noise impedance, R_{sn}, derived from PSD. Source Ref 36

It has been assumed often that R_n is equal to R_p; however, it has been shown for passive systems, such as stainless steel or titanium alloys exposed to neutral media, that R_n was several orders of magnitude lower than R_p (Ref 35, 38). Similar results were reported for polymer- coated steel. In fact, for epoxy-polyamide- coated steel, no relationship between R_n and any properties of the coated steel sample could be found (Ref 29, 30, 31). Moreover, R_n was found to depend on bandwidth Δf of the noise measurement (Ref 30). In general, R_n is close to R_p only in those cases where the impedance is independent of frequency within Δf (Ref 30). Skewness and kurtosis of the ECN data can be used for a more detailed analysis of the ECN data. High kurtosis values are considered to be indicative of localized corrosion. Drift of ECN data can affect the slopes of PSD plots (Ref 39). It has been shown how to correct derived parameters such as σV, σI, and R_n for the effects of drift (Ref 36). A description of the background and application of the ECN technique, including detailed descriptions of the measurement procedure and different approaches to the analysis of ECN data, is available in Ref 13.

Electrochemical Methods of Corrosion Testing

Florian Mansfeld, University of Southern California

Small-Signal Polarization Tests

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

In measurements of the polarization resistance and electrochemical impedance spectra, only a small electrochemical signal is applied in order to ensure that the system under investigation remains linear. This requirement also ensures that these measurements are nondestructive and therefore can be repeated many times on the same system.

Polarization-Resistance Method. Thorough reviews of background and application of the polarization-resistance technique for measuring corrosion currents are found in Ref 4 and 40. The polarization resistance (R_p) defined as:

$$R_p = (dE/di)_{E_{corr}} \qquad \text{(Eq 1)}$$

is determined as the slope of a polarization curve at E_{corr}, where $i = 0$. Usually, potentiodynamic polarization curves collected in close vicinity of E_{corr} are used for this purpose. ASTM G 59, "Standard Practice for Conducting Potentiodynamic Polarization-Resistance Measurements," deals with experimental procedures for determining R_p according to Eq 1. This method describes an experimental procedure for polarization-resistance measurements that allows an investigator to calibrate equipment and test methods. Figure 10 shows standard polarization curves for type 430 stainless steel in 1.0 *N* H_2SO_4, deaerated with hydrogen, at 30 °C (85 °F). Experimental polarization curves must fall within curves 2 and 3; otherwise, experimental problems have occurred.

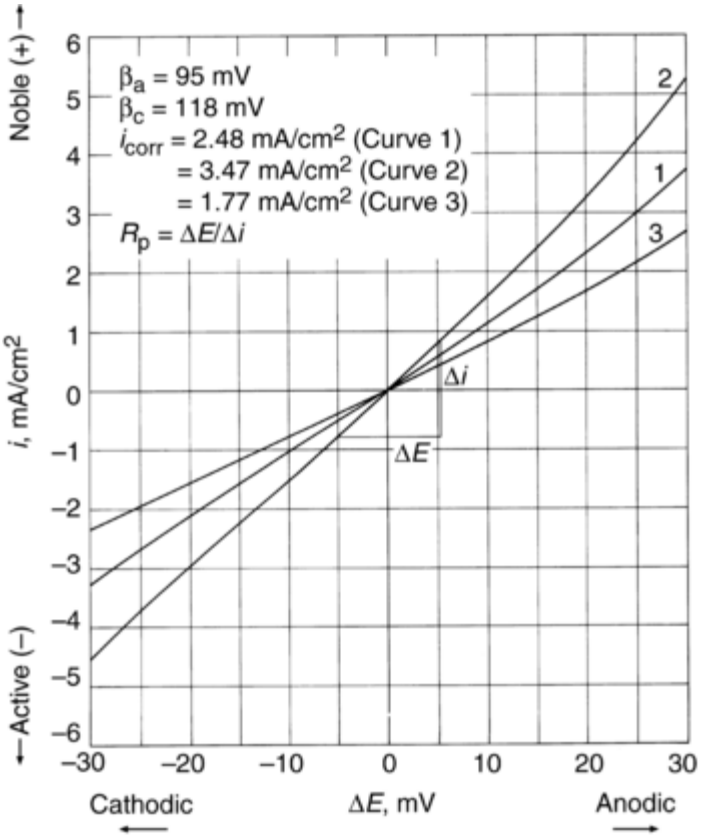

Fig. 10 Standard potentiodynamic polarization curves in the vicinity of E_{corr} for type 430 stainless steel in 1 *N* H_2SO_4, 30 °C (85 °F). Source: ASTM G 59

Applications of the R_p technique as a nondestructive method for monitoring corrosion rates have been discussed in detail in review articles (Ref 4, 40). The main advantage of the R_p technique over periodic weight-loss measurements is the possibility of continuously monitoring instantaneous corrosion rates of a metal exposed to a corrosive environment.

Polarization resistance can be converted to i_{corr} using the Stern-Geary equation:

$$i_{corr} = B/R_p \qquad \text{(Eq 2)}$$

where B is a parameter calculated using the Tafel slopes:

$$B = \beta_a\beta_c/2.3(\beta_a + \beta_c) \qquad \text{(Eq 3)}$$

where β_a and β_c are the anodic and cathodic Tafel slopes, respectively.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In order to obtain quantitative values of i_{corr} from experimental R_p data, B has to be known for the same experimental conditions. For qualitative estimates, a constant value of B between 13 and 26 mV often is used. Corrosion rates can be obtained from i_{corr} using Faraday's law.

In determining R_p values from polarization curves, scan rate and ohmic drop effects have to be considered. Experimental polarization curves can change with increasing scan rate. In general, R_p is underestimated (and corrosion rates overestimated) when scan rates are too high. Polarization resistance is overestimated (and corrosion rates underestimated) when the uncompensated resistance (R_s) is not considered, because the experimental value of R_p ($R_{p,exp}$) contains a contribution from R_s:

$$R_{p,exp} = R_p + R_s \qquad \text{(Eq 4)}$$

The contribution from R_s can be eliminated during the measurement by using positive feedback or current interrupter techniques or by subtracting R_s from $R_{p,exp}$ as calculated from analysis of the polarization curve. Uncompensated resistance can be determined by applying a constant current pulse, I_{appl}, and observing the potential response on an oscilloscope (Fig. 11). The initial sharp rise of the potential $E = I_{appl}R_s$ due to ohmic drop is followed by a slower increase due to double-layer charging. Thus, $R_s = E/I_{appl}$.

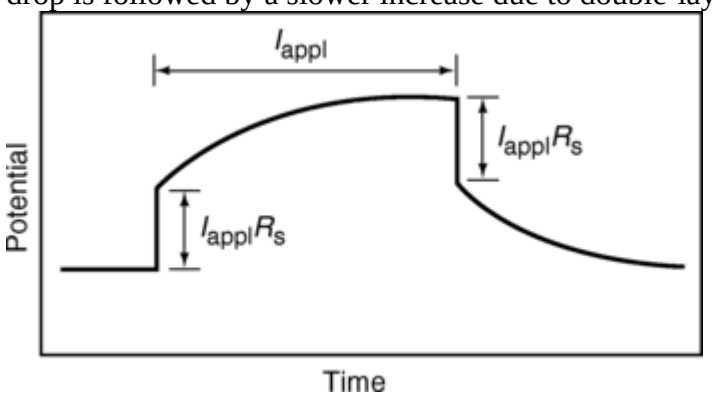

Fig. 11 Potential pulse method for determining the uncompensated resistance, R_s

The error $e = R_s/R_p$ due to the uncompensated resistance can have similar values for a system with high corrosion rates in a solution of high conductivity and for a system with low corrosion rates in a solution of low conductivity. Therefore, ohmic drop effects can be important in all systems. Experimentally, it has been observed that the largest errors due to the uncompensated resistance occur for systems with high corrosion rates and low conductivity, such as steel in acid/ alcohol mixtures.

The linear polarization technique is a variation of the polarization-resistance technique and forms the basis of commercial corrosion-rate monitors. In this approach, it is assumed that polarization curves are linear in the vicinity of E_{corr} ($E_{corr} \pm 10$ mV). In this case, R'_p is defined as:

$$R'_p = \Delta E/i \qquad \text{(Eq 5)}$$

where $\Delta E = E_{appl} - E_{corr}$, and i is the current density measured at the applied potential, E. Because ΔE is constant, i_{corr} is proportional to the measured current density, i:

$$i_{corr} = k \cdot i \qquad \text{(Eq 6)}$$

where k is treated as a system constant.

In commercial instruments, positive and negative values of ΔE are applied, and the average value of i is used to determine the corrosion rate. The assumption that the polarization curve is linear with ΔE has been discussed, and the limitation of the technique has to be considered in each application (Ref 4, 40). Several commercial devices are available, and automatic ohmic drop compensation is available in some instruments.

Electrochemical impedance spectroscopy (EIS) data are recorded as a function of frequency of an applied alternating current (ac) signal at a fixed working point (E, i) of a polarization curve. In corrosion studies, this working point is often E_{corr} ($E = E_{corr}$, $i = 0$). Usually, a very large frequency range has to be investigated to obtain the complete impedance spectrum. In most corrosion studies, this frequency range extends from 100 kHz, the upper limit of commonly used frequency response analyzers (FRAs), to 1 mHz. Measurements at lower frequencies are very time consuming. Impedance data usually are determined with a three-electrode system, although it is also possible to use a two-electrode system in which both electrodes are of the same material. In this case, the EIS data are collected at $E = 0$ V. A potentiostat is used to apply the potential at

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

which the data are to be collected. The FRA is programmed to apply a series of sine waves of constant amplitude, small enough to remain in the linear potential region, and varying the frequency. Impedance data are determined by the FRA at each frequency and stored in its memory. Because a very large number of data points have to be collected, displayed, and analyzed, it is essential to use adequate software for these purposes. Such software is available from all major manufacturers of FRAs.

Information obtained with EIS differs from that determined with the other techniques previously described, because the corrosion system is analyzed at a fixed potential (or current). Properties of the system at this potential can then be determined through analysis of the frequency dependence of the impedance. One of the advantages of EIS is that only very small signals are applied, making it a nondestructive technique. In many cases, EIS data have shown that existing models for corrosion systems based on results of studies with direct-current (dc) techniques were too simplistic.

Experimental impedance spectra can be displayed using linear coordinates in complex plane plots in which the negative value of the imaginary impedance ($-Z''$) is plotted versus the real part (Z'). For a simple circuit consisting of a parallel combination of resistance, R_p, and capacitance, C_{dl}, with R_s in series (Fig. 12a), such a plot results in a semicircle (Fig. 12b). This approach neglects the fact that the impedance often changes over many orders of magnitude, and that the frequency dependence of the impedance cannot be recognized in complex plane plots. The preferred format for display of EIS data is therefore the Bode plot (Fig. 12c, d), in which log $|Z|$ and the phase angle (Φ) are plotted versus the logarithm of the frequency (f) of the applied signal, with $|Z|$ being the modulus of the impedance. In Fig. 12, the curves for $\alpha = 1$ refer to ideal capacitive behavior, while the curves for $\alpha = 0.9$ are typical for the often-observed deviations from ideal behavior. The constant phase element concept is often used in such cases. ASTM G 106, "Standard Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements," describes an experimental procedure that may be used to check the instrumentation and technique for collection and presentation of EIS data. Reference impedance plots in both complex plane and Bode format are included for a dummy cell and for stainless steel type 430 in a solution containing 0.005 *M* sulfuric acid (H_2SO_4) and 0.495 *M* sodium sulfate (Na_2SO_4).

(c) Bode plot of the base 10 log of the magnitude of the impedance against the log of the frequency. The range of the impedance is between R_s and $R_s + R_p$. (d) Bode plot of the negative phase angle versus the log of the frequency

In order to perform a quantitative analysis of EIS data, it is necessary to use an appropriate equivalent circuit that describes accurately the physical properties of the system under investigation. Equivalent circuits for polymer-coated metals, anodized aluminum alloys, and localized corrosion of aluminum alloys have been described in the literature (Ref 41). The ANALEIS software contains modules that were designed for the analysis of EIS data for these systems (Ref 41).

The most successful application of EIS has probably been in the analysis of the properties of protective polymer coatings and their changes during exposure to corrosive environments (Ref 42, 43). Impedance spectra for polymer-coated metals exposed to corrosive media can be analyzed with the software module COATFIT, which is based on the equivalent circuit shown in Fig. 13(a). In this equivalent circuit, C_c is the capacitance of the coating, which depends on its dielectric constant, ε, and its thickness, d:

$$C_c = \varepsilon\varepsilon_o A/d \qquad \text{(Eq 7)}$$

where ε_o is the dielectric constant of vacuum, and A is the exposed area. The variable R_{po} has been called the pore resistance, because it is considered to be due to the formation of ionically conducting paths in the polymer (Ref 44, 45). The variable R_p is the polarization resistance of the area at the polymer coating/metal interface at which corrosion occurs, and C_{dl} is the corresponding capacitance. An increase of C_c with time can be related to water uptake by the coating (Ref 43). The rate at which R_{po} decreases with increasing exposure time has been used to rank the efficiency of different pretreatments for steel in providing corrosion protection by a polybutadiene coating (Ref 44, 45). The changes of C_{dl} can be used to estimate the corroding delaminated area, A_{corr}, (Ref 46) and to calculate the specific polarization resistance $R^o_{po} = R_{po}A_{corr}(\text{ohmcm}^2)$, from which an estimate of the corrosion rate of the delaminated area can be made. Figure 13(b) shows a comparison of experimental and fitted impedance spectra for polymer-coated Mg AZ31 that had been exposed to 0.5 *N* NaCl. Excellent agreement of the experimental and fitted data was observed. The use of EIS for lifetime prediction of organic coatings on steel is described in Ref 47. Damage functions based on the experimental values of A_{corr} have been determined and can be used for lifetime prediction of polymer-coated steel exposed to natural seawater for several years (Ref 48).

(b) Comparison of an experimental and fitted impedance spectra for polymer-coated Mg AZ31 exposed to 0.5 *N* NaCl. (b) C_c, 5.129 pF; C_{dl}, 99.69 pF; R_{po}, 357.1 Ω; R_s, 3Ω; R_p, 102.1 kΩ. Source: Ref 41

Impedance spectra for anodized aluminum alloys can be analyzed with the module ANODAL (Ref 41). The analysis is based on the equivalent circuit in Fig. 14(a), where C_{po} is the capacitance of the outer porous layer, R_{po} is the resistance of the sealed pores, and C_b and R_b are the capacitance and resistance of the inner barrier layer, respectively (Ref 16, 49, 50, 51). Analysis of impedance spectra for a large number of anodized and sealed aluminum alloys has shown that the spectra fall into a narrow scatter band if the same anodizing and sealing procedures are followed. Electrochemical impedance spectroscopy has been recommended therefore as

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

a quality-control test for anodized and sealed aluminum alloys (Ref 16). It should be noted that for unsealed or dichromate sealed samples, R_{po} is very low. Therefore, C_{po} does not appear in the measured spectrum in these two cases (Ref 51).

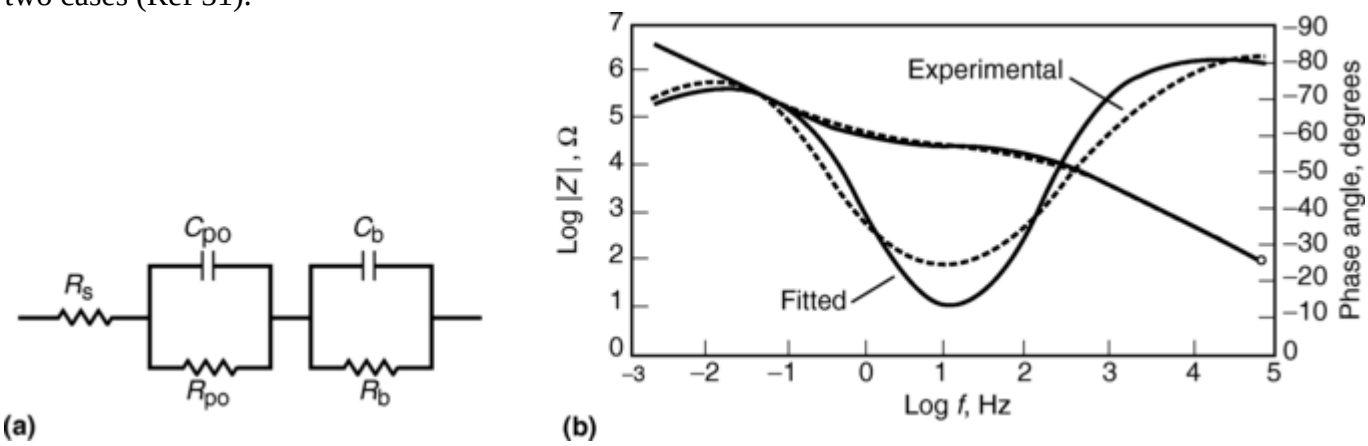

Fig. 14 (a) Equivalent circuit for anodized aluminum alloys. (b) Comparison of experimental and fitted spectra for Al 6061 (sulfuric acid anodized and hot water sealed) exposed to 0.5 *N* NaCl. C_{po}, 56.87 pF; C_b, 0.37 μF; R_{po}, 28.83 kΩ; R_b, 26.62 MΩ; R_s, 1Ω. Source: Ref 41

Figure 14(b) shows the result of a fit of experimental data for sulfuric-acid-anodized and hot-water-sealed Al 6061 that had been exposed to 0.5 *N* NaCl. Good agreement between the measured and fitted spectra was observed at the highest and lowest frequencies. However, significant deviations occurred in the frequency range between 1000 and 0.1 Hz. For a modified equivalent circuit in which R_{po} was replaced by a transmission line impedance $Z_{po} = K(j\omega)^n$ (Fig. 15a), excellent agreement between the experimental and fitted data was obtained (Fig. 15b). From the fitted values of C_b and C_{po}, the thickness of the barrier and the porous layer can be obtained. For the fit parameters in Fig. 15(b), a barrier layer thickness of 250 Å was calculated. The calculated thickness of 21 μm for the porous layer agreed very well with that obtained by observation in the scanning electron microscopy of the cross section of the anodized sample (Ref 41).

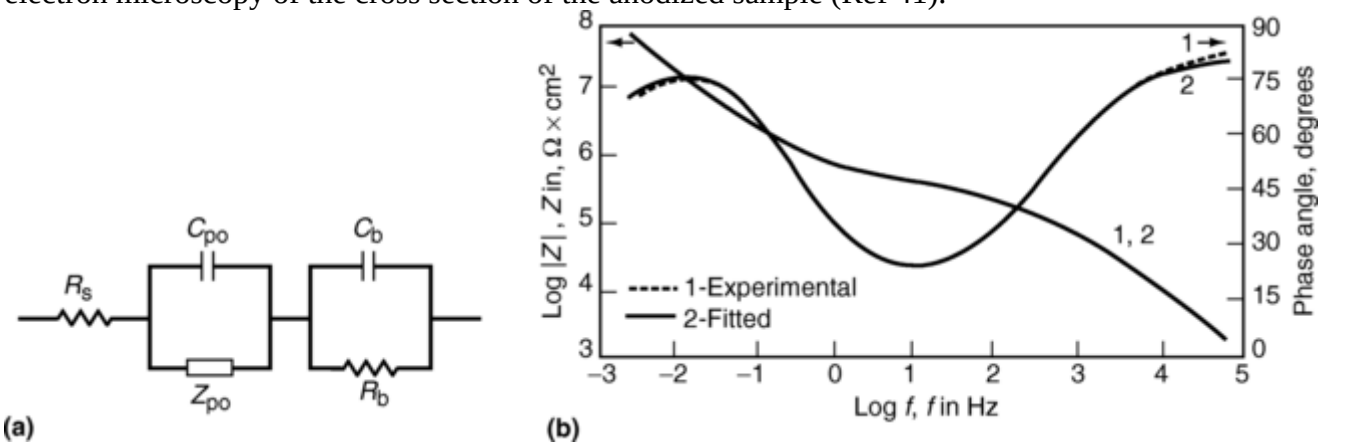

Fig. 15 (a) Modified equivalent circuit for anodized aluminum alloys. (b) Comparison of experimental and fitted spectra for Al 6061 (sulfuric acid anodized and hot water sealed) exposed to 0.5 *N* NaCl. Source: Ref 41

The experimental impedance spectra for aluminum alloys exposed to solutions containing chloride ions show characteristic changes when pits initiate and grow (Ref 52, 53, 54, 55). The spectra can be explained by the equivalent circuit in Fig. 16, where R_p and C_p are the polarization resistance and capacitance, respectively, of the passive surface; R_{pit} and C_{pit} are the corresponding values for the growing pits; $W = (K/F)(j\omega)^n$ is a transmission line impedance; and F is the area fraction at which pits have initiated. Figure 17 gives a comparison of experimental and fitted impedance spectra for Al 6061 after 24 h exposure to 0.5 *N* NaCl. As explained elsewhere (Ref 56), it is possible to obtain F from the time dependence of C_{pit}, which allows determination of the pitted area, A_{pit}, which can be used to normalize R_{pit} and obtain the specific pit polarization

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

resistance, R^{o}_{pit}. As a result of this procedure, it is possible to determine relative pit growth rates, the time dependence of which can be expressed as:

$$\log\left(1/R^{o}_{pit}\right) = a + b\log\left(t - t_{o}\right) \quad \text{(Eq 8)}$$

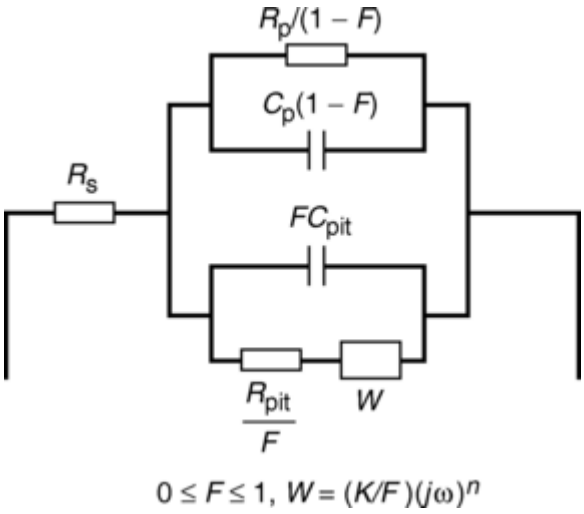

Fig. 16 Equivalent circuit for the impedance of aluminum alloys for which pits have been initiated. Source: Ref 41

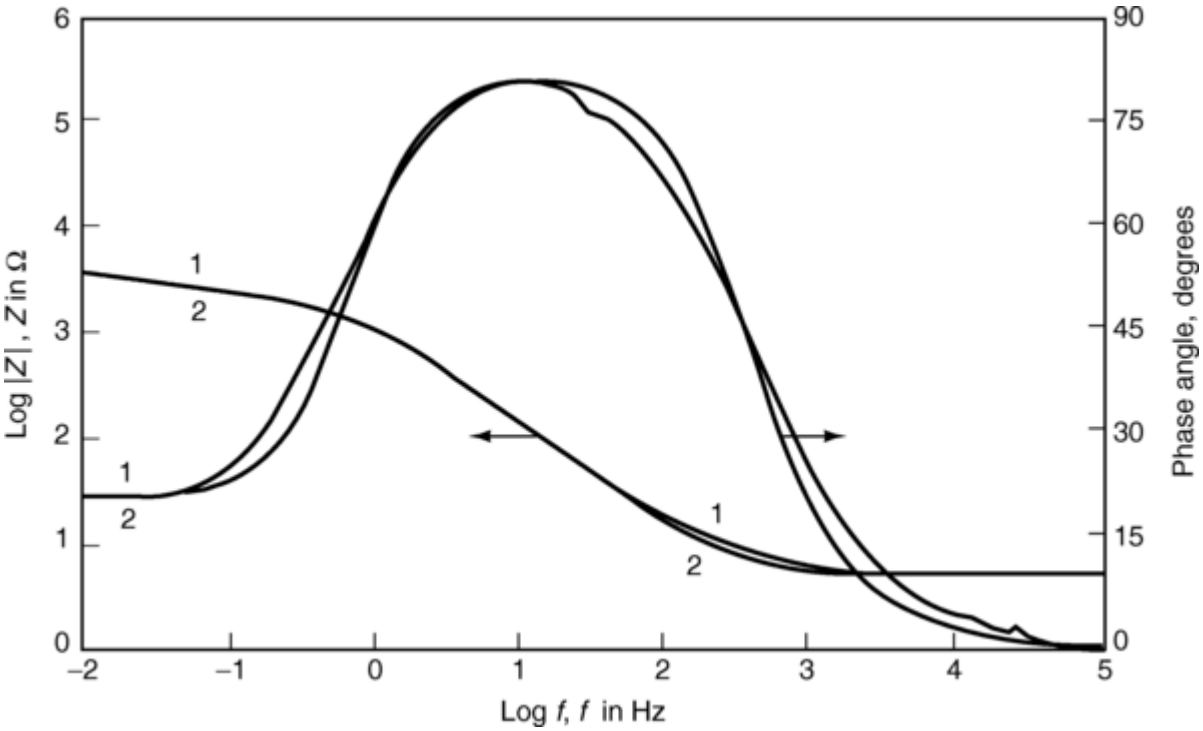

Fig. 17 Comparison of experimental (curve 1) and fitted (curve 2) impedance spectra for Al 6061 after 24 h exposure to 0.5 *N* NaCl. Source: Ref 41

The time dependence of $\log\left(1/R^{o}_{pit}\right)$ for Al 7075 that had been passivated in 1000 ppm $CeCl_3$ (Ref 55) in Fig. 18 agrees with the time law in Eq 8.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

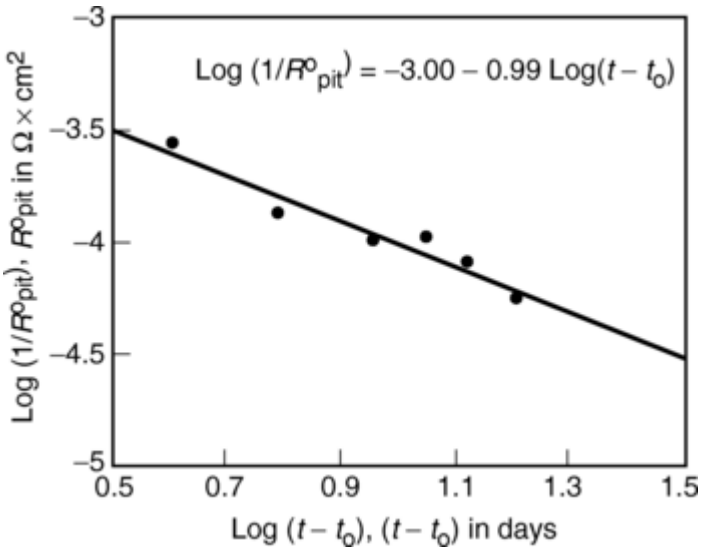

Fig. 18 Time dependence of R^o_{pit} for Al 7075 (passivated in $CeCl_3$) during exposure to 0.5 *N* NaCl. Source: Ref 41

Electrochemical impedance spectroscopy data have often been used only to determine R_p, which is defined as the limit of the real part of the impedance for $f = 0$ (Ref 41):

$$R_p = \lim_{f \to 0} Z'(f) - R_s \qquad \text{(Eq 9)}$$

In this case, all other important information contained in the impedance spectrum is ignored. Nevertheless, the nondestructive nature of EIS makes it an ideal tool for monitoring the corrosion behavior over extended time periods.

In Fig. 19(a), R_p values obtained for Al 2024 exposed to artificial seawater (AS) containing *S. algae* or *S. ana* are plotted as a function of exposure time, while the corresponding results for brass and mild steel are plotted in Fig. 19(b) and (c), respectively (Ref 20). For Al 2024 exposed to sterile AS, pitting was observed, and therefore, R^o_{pit} obtained by fitting of the experimental spectra to the equivalent circuit in Fig. 16 is shown in Fig. 19(a). Similar very high R^o_p values were obtained for Al 2024 in the presence of *S. algae* or *S. ana*, indicative of passive behavior. When kanamycin was added to the AS containing *S. ana* after 7 days, R_p did not change immediately (Fig. 19a). After 15 days, pitting was observed. These changes of R_p are different from those of E_{corr} in Fig. 5(a), where E_{corr} increased very shortly after addition of kanamycin. For brass, *S. algae* produced only a small increase of R^o_p, while a much larger effect was found for *S. ana* (Fig. 19b). As observed for Al 2024 (Fig. 19a), R^o_p did not change for several days after addition of kanamycin (Fig. 19b), while E_{corr} changed almost immediately (Fig. 5b). The changes of R^o_p due to the addition of the two different bacteria were quite similar for mild steel, and, as observed for Al 2024 and brass, R^o_p did not decrease to the levels observed in sterile AS for several days (Fig. 19c).

Electrochemical Methods of Corrosion Testing

Florian Mansfeld, University of Southern California

Large-Signal Polarization Tests

In large-signal polarization tests, the applied potential is varied over a wide range, using either a series of applied potential steps or a change of potential at a constant rate. It is also possible to use a series of current steps or a constantly changing current; however, these techniques are less popular. Because polarization over a wide potential range might cause irreversible changes of the sample surface properties, it is not possible, in most cases, to repeat a large-signal polarization test on the same sample.

Potentiostatic Techniques. There are two types of potentiostatic techniques:

- *Type 1:* recording of the current as a function of time at a constant applied potential, E_{appl}
- *Type 2:* recording of the steady-state current as a function of E_{appl}

The data obtained in the type 1 test provide information about the time dependence of the rate of an electrochemical reaction at a given potential. The data collected with the type 2 test can be used to construct a polarization curve, which usually is plotted as E_{appl} versus the logarithm of the measured current density, *i*. Polarization curves also can be obtained by the potentiodynamic technique. Because the instrumentation and experimental procedures are quite similar for both techniques (Ref 11, 12), much of the discussion presented in this section is also valid for the following section. ASTM G 5, "Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements," is a classic document that has been used for many years in many countries. This test method describes experimental procedures for checking one's experimental technique and instrumentation. If followed, using ASTM-provided type 430 stainless steel in 1.0 *N* H_2SO_4, the method provides repeatable polarization curves that reproduce the curves shown in ASTM G 5. If discrepancies are found, the experiment has not been performed correctly, there might be problems with the test cell, and/ or the equipment might not function properly.

A complete polarization curve consists of a cathodic part and an anodic part. The cathodic portion of the polarization curve contains information concerning the kinetics of the reduction reaction(s) occurring for a particular system. Depending on the solution composition, a mass- transport-controlled region can be reached at more negative potentials, at which the reaction rate (the measured current density) depends only on the solution composition and the hydrodynamic conditions. The particular features of the anodic part of the polarization curve depend strongly on the metal-electrolyte system. Usually, a charge-transfer-controlled region occurs at potentials close to E_{corr}. So-called passive metals show an active-passive transition followed by a passive region and the region of oxygen evolution at the highest applied potentials. For those metals, which are susceptible to localized corrosion, a large increase of the current occurs in the passive region when the pitting potential, E_{pit}, has been exceeded. ASTM G 3, "Standard Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing," provides conventions for reporting and displaying electrochemical data and contains theoretical and experimental polarization curves.

In general, only qualitative information, such as changes in the polarization characteristics in the passive region or changes of E_{pit} due to the presence of inhibitors or alloying, is extracted from a full polarization curve. However, it is possible to determine from such curves quantitative information that is related to the kinetics of the corrosion reactions and the corrosion rate.

The relationship between the applied potential, E_{appl}, and the measured current density, *i*, in the Tafel region is given by (Ref 2, 3):

$$E_{appl} = E_{corr} + \beta_a \log (i/i_{corr}) \qquad \text{(Eq 10)}$$

for the anodic polarization curve and:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$E_{appl} = E_{corr} - \beta_c \log (i/i_{corr})$ (Eq 11)

for the cathodic polarization curve.

In Eq 10 and 11, the anodic Tafel slope, β_a, and the cathodic Tafel slope, β_c, are positive numbers. Plots of E_{appl} versus log i are called Tafel plots. The corrosion current density, i_{corr}, can be determined according to Eq 10 and 11 by extrapolation of the Tafel lines to $E_{appl} = E_{corr}$, where $i = i_{corr}$ (Fig. 20). This method of obtaining corrosion current density is called the Tafel extrapolation method. It is also possible to determine i_{corr} from either the anodic or the cathodic Tafel plot or from the intersection of both plots. It is advantageous to use computer software to record polarization curves and analyze the experimental data in terms of parameters such as β_a, β_c, and i_{corr}. From the numerical values of β_a and β_c, conclusions concerning the rate- determining step in the reaction mechanism can be made (Ref 2, 3, 4). From i_{corr}, the corrosion rate can be calculated using Faraday's law. ASTM G 102, “Standard Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements,” provides guidance in converting the results of electrochemical measurements to rates of uniform corrosion.

مرجع مهندسی مواد و متالورژی

An equivalent circuit for a three-electrode cell is shown in Fig. 21, where R_p is the polarization resistance of the test electrode; C is its capacitance; R_s is the resistance of the electrolyte between the surface of the test electrode and the tip of the Luggin capillary, which houses the reference electrode; and R_c is the resistance of the electrolyte between the test electrode and the counter electrode. The applied potential, E_{appl}, appears across R_p + R_s and therefore always includes an ohmic drop, IR_s, where I is the current flowing as a result of polarization. This ohmic drop is an error in the measurement, because the potential E_{appl} set at the potentiostat differs from the true electrode potential E by IR_s. This fact has to be recognized in all polarization experiments. In many cases, where electrolytes with reasonable conductivity are used and IR_s is small compared to E_{appl}, this error can be neglected. In other cases, it can be eliminated by the positive feedback or current interrupter techniques (Ref 17, 18) that are available in most modern potentiostats.

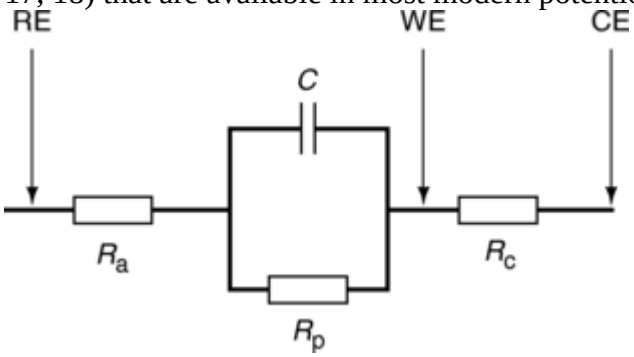

Fig. 21 Dummy cell for testing of potentiostat

Experimental Procedure for Potentiostatic Test Type 1. The experimental procedures for the two types of potentiostatic tests are described using the same types of electrodes and test cells. They differ insofar as type 2 involves the application of a series of potential steps. This requires changes of E_{appl} by hand, periodic adjustment of the sensitivity of the current-measuring device in the potentiostat, and sometimes, adjustment of the current scale of the recorder also. The procedure is greatly simplified if appropriate software is used and the experiment is carried out under computer control.

When the test cell has been assembled, the electrodes can be connected to the potentiostat. In most cases, E_{corr} is monitored before starting the potentiostatic test. When E_{corr} has reached a reasonable stable value, the potential can be applied and the corresponding current measured.

Often, a series of potential steps is applied to the same test electrode. This is the case in a test in which the pitting potential, E_{pit}, is determined as the potential at which the anodic current keeps increasing rather than decreasing after application of the potential step, as it would in the case for $E < E_{pit}$.

When the experiment is performed under computer control, the control parameters, such as the value of E_{appl} and the length of the potential step, have to be entered. Additional parameters related to the current measurement, such as the number of data points per second, might have to be entered. The experiment is performed then as programmed, and the current-time plot is displayed on the computer screen. After reformatting of the data, a printout of the *I-t* curve is obtained.

Experimental Procedure for Potentiostatic Test Type 2. The test is started by applying the first potential, which might be 10 to 50 mV more positive than E_{corr} if an anodic polarization curve is measured. After the current, which is recorded continuously throughout the test on a strip-chart recorder, has reached a steady-state value or after a predetermined time has elapsed, E_{appl} is increased to the next value, and the current is recorded. As increasing values of E_{appl} are used, it may become necessary to switch to less sensitive current scales. After the current at the final value of E_{appl} has been recorded, the polarization curve (E_{appl} versus log i) can be plotted using the final values of the current, I, at each potential and converting it into current density, i. Figure 22 shows the typical standard potentiostatic anodic polarization plot for type 430 stainless steel in 1.0 N H_2SO_4 at 30 °C (85 °F). Polarization curves performed according to ASTM G 5 with the standard ASTM sample have to fall within the scatter band shown in Fig. 22. Slightly different curves have been obtained with a new lot of samples introduced in recent years. Deviations from these standard plots point to deficiencies in the experimental technique, problems with the test cell, the equipment, and/or the operator.

Potentiodynamic Techniques. Potentiodynamic polarization curves can be obtained as a single sweep, that is, E_{appl} is increased at a constant scan rate, $s = dE_{appl}/dt$, between a starting potential, E_s, which often is E_{corr} or possibly below, and a final potential, E_f. Sometimes the scan is reversed when E_f or a preset maximum current density is reached, and stopped when the previous E_{corr} or a new value of E_{corr} is reached. Great care has to be taken in choosing an appropriate value of the scan rate (Ref 57). In general, less distortion of the true polarization curve occurs at the lowest scan rates. In ASTM G 5, a scan rate of 600 mV/h is recommended. Figure 23 shows the effects of varying scan rate on the shape of the anodic polarization curves for type 430 stainless steel in 1.0 *N* H_2SO_4 (Ref 14). Scan rates were increased from curve 1 to curve 4.

Single Sweeps. Anodic and cathodic polarization curves are usually determined at constant scan rate in a single sweep between two preset potentials, E_s and E_f. ASTM G 3 gives examples of polarization curves determined in this manner. Figure 24 shows the typical standard potentiodynamic anodic polarization plot for type 430 stainless steel in 1.0 *N* H_2SO_4 at 30 °C (85 °F). Anodic potentiodynamic polarization curves performed according to ASTM G 5 with the standard ASTM sample have to fall within the scatterband shown in Fig. 24. Slightly different curves have been obtained with a new lot of samples introduced in recent years. Deviations from these standard plots point to deficiencies in the experimental technique or problems with the test cell, the equipment, and/or the operator.

The results obtained by E_{corr} measurements and EIS suggest that the mechanism of microbiologically influenced corrosion inhibition (MICI) observed in the presence of *Shewanella algae* or *ana* is different for Al 2024 (Fig. 5a and 19a) and brass (Fig. 5b and 19b) on the one hand and mild steel (Fig. 5c and 19c) on the other. For Al 2024 and brass, the reduction of corrosion rates was accompanied by a shift of E_{corr} to more negative values, suggesting that MICI is due to a decrease of the rate of oxygen reduction in the presence of the biofilm. The increase of E_{corr} with a decrease of corrosion rates observed for mild steel can be explained only by a simultaneous decrease of the rates of the anodic and cathodic reactions. The former is assumed to be due to an increase of the Fe^{2+} concentration in the solution due to reduction of Fe^{3+} by *Shewanella*, leading to an increase of reversible potential, E_0, of the Fe/Fe^{2+} reaction, as discussed in Ref 58. This mechanism is shown schematically in Fig. 25, where it is assumed that the anodic reaction is under charge transfer control, while the cathodic reaction is under charge transfer control at low polarization and under mass- transport control at higher polarization. In the presence of the biofilm, the limiting current density, i_L, for oxygen reduction for Al 2024 and brass is decreased, but the rate of the anodic reaction remains unchanged. As a consequence, E_{corr} decreases from point 1 in Fig. 25 to point 2, and $i_L = i_{corr}$ decreases to i'_L. For mild steel, the rate of both reactions is decreased, and E_{corr} changes from point 1 to point 3, while i_L decreases to i'_L (Fig. 25).

The assumptions leading to the proposed mechanism have been confirmed by recording of potentiodynamic polarization curves after exposure to Väätänen nine salts solution (VNSS, pH 7.5) containing *Shewanella algae* for 7 days (Ref 20). For Al 2024 (Fig. 26) and brass (Fig. 27), a significant reduction of the rate of the cathodic reaction was observed, while for mild steel (Fig. 28), the rate of both reactions was reduced.

Pitting Scans. Pitting scans are carried out to determine E_{pit} and sometimes also the protection potential, E_{prot}. ASTM G 61, "Standard Test Method for Conducting Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Base Alloys," gives a procedure for conducting cyclic potentiodynamic polarization measurements to determine relative susceptibility to localized corrosion in the form of pitting or crevice corrosion. An indication of the susceptibility to localized corrosion is given by the potential, E_{pit}, at which the anodic current increases rapidly from the low values in the passive region. The more noble E_{pit} with respect to E_{corr}, the less susceptible is the alloy to initiation of localized corrosion (Ref 3, 11, 12). Figure 29 shows representative cyclic potentiodynamic polarization curves for type 304 stainless steel, which is susceptible to pitting and has a value of E_{pit} close to 0 mV versus SCE, and alloy C-276, which is immune to localized corrosion. The area under the curve for the forward and reverse scan for a susceptible alloy is a qualitative measure of corrosion damage due to pit growth. The difference between pitting and protection potentials is also used for this purpose.

Evaluation of Alloy Sensitization. The electrochemical potentiokinetic reactivation (EPR) method, based on the original work found in Ref 59, has been developed for laboratory and field determination of the degree of sensitization of stainless steels (Ref 60, 61). The method is described in ASTM G 108, "Standard Test Method for Electrochemical Reactivation (EPR) for Detecting Sensitization of AISI Type 304 and 304L Stainless Steel." It also has been used successfully to evaluate sensitization of other stainless steels and nickel alloys. The EPR test is carried out using a reactivation potentiodynamic sweep from the passive region back to the active region, stopping at E_{corr}. The sweep is carried out in H_2SO_4 containing potassium thiocyanate (KSCN), which serves to activate the chromium- depleted grain boundaries. The current peak observed during the reactivation scan increases with the degree of sensitization. The charge Q passed is a measure of the degree of sensitization and can be used to determine a sensitization number, P_a, after normalization with the grain- boundary area. A modification of the EPR method is the double-loop electrokinetic repassivation test that involves a potentiodynamic scan from E_{corr} to the passive range, followed immediately by reverse polarization back to E_{corr} (Ref 62, 63). In this method, the degree of sensitization is determined by the ratio I_r/I_a of the maximum current generated in the reverse scan compared to that in the initial anodic scan. Figure 30 illustrates the principle of these two methods.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

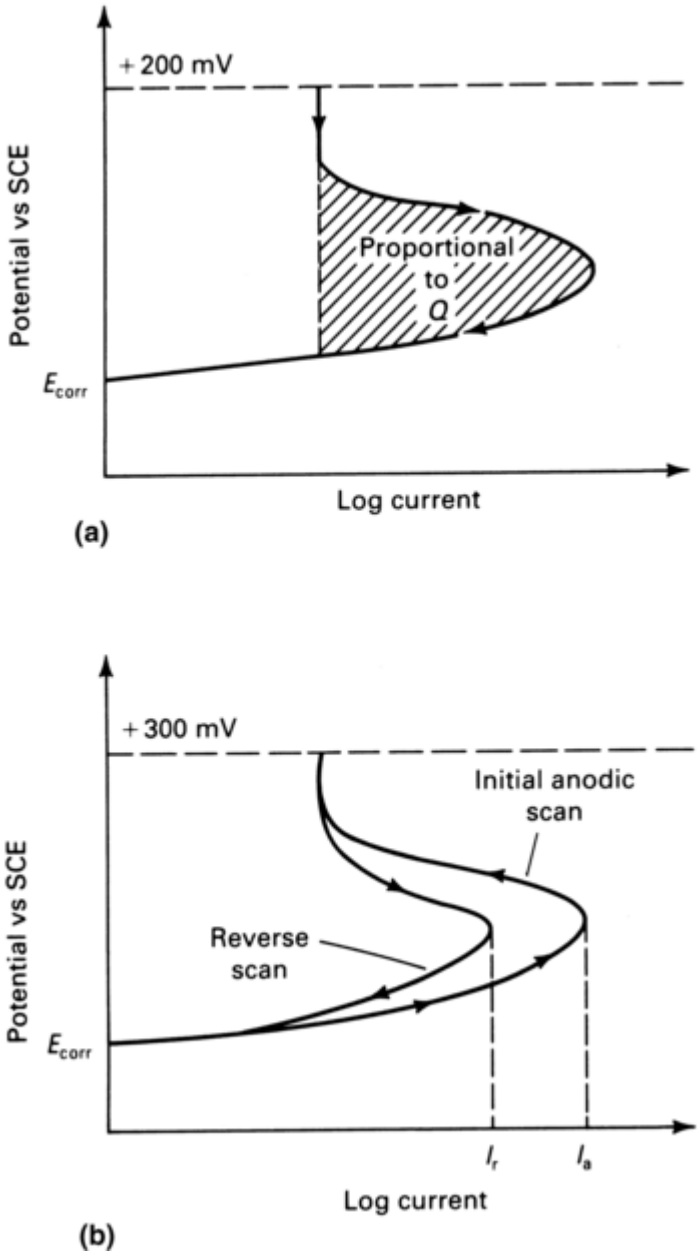

Fig. 30 Schematic potentiodynamic polarization curves for two methods for determination of the degree of sensitization. (a) Clarke et al method (Ref 61). (b) Akashi et al method (Ref 62)

Polarization curves obtained in the vicinity of E_{corr} can be analyzed by fitting of the experimental data to the equation that relates potential, E, and current density, i (Ref 2, 3):

$$i = i_{corr}\left[\exp\left\{2.3(E - E_{corr})/\beta_a\right\} - \exp\left\{2.3(E_{corr} - E)/\beta_c\right\}\right] \quad \text{(Eq 12)}$$

The polarization curves usually are obtained in the potentiodynamic mode. The results of the fit consist of experimental values of i_{corr}, β_a, and β_c. Several software programs have been described for carrying out this fit (Ref 64). Most potentiostat manufacturers supply software for this procedure. Because only a small polarization range /E - E_{corr}/ is applied (usually ±30 mV or less), this approach to obtain corrosion rates and Tafel slopes in the non-Tafel region is nondestructive and can be applied repeatedly without the danger of changing the properties of the surface under investigation. It is noted that the experimental approach is similar to that used in the determination of the polarization resistance, R_p. However, the kinetic data are obtained directly from the analysis of the measured polarization curve.

Galvanostatic and galvanodynamic techniques are used less commonly than the potentiostatic and potentiodynamic techniques described previously. In galvanostatic techniques, a constant current is applied, and

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

the potential is monitored as a function of time. It is also possible to record an entire polarization curve in the galvanostatic mode. A limitation of this approach for passive metals is that the passive region cannot be investigated. ASTM G 100, "Standard Test Method for Conducting Cyclic Galvanostaircase Polarization," describes a method for determining E_{pit} for aluminum alloys, using a variation of the galvanostatic technique.

Scanning Electrode Techniques

The local distribution of anodic and cathodic sites can be evaluated using a number of electrochemical tests, such as the scanning reference electrode (SRET), the scanning vibrating electrode (SVET), local electrochemical impedance spectroscopy (LEIS), and the scanning Kelvin probe (SKP). While SRET and SVET allow measurements of the local corrosion currents, SKP provides a record of the surface potential distribution. The application of these techniques in electrochemistry and corrosion technology has recently been reviewed (Ref 65). A review of the early applications of scanning electrode techniques is found in Ref 8.

The SRET has been used mainly for investigation of local corrosion processes, such as pitting and crevice corrosion (Ref 8). The application of the SRET technique to localized corrosion phenomena is reviewed in Ref 66. More recently, SRET has also been used for the evaluation of delamination of organic coatings (Ref 67). The SRET technique is based on a microprobe that is capable of detecting local variations of the electrochemical properties of a metal surface with high lateral resolution. An optimized SRET has been used to evaluate the performance of several clear coatings, with good correlation between SRET signals and permeability as well as wet adhesion of these coatings (Ref 68).

The SVET offers a rapid method for monitoring the progress of corrosion of many metals and alloys exposed to corrosive solutions. The SVET technique has been shown to be a powerful tool for evaluating the efficiency of a variety of potential corrosion inhibitors as well as the determination of the current distribution in the vicinity of defects on polymer-coated metal surfaces (Ref 65, 69). It has also been used for determining the heterogeneous characteristics of consortia of bacteria and their possible influences on metallic substrates leading to microbiologically influenced corrosion (Ref 70).

The SKP. While SRET and SVET have to be used in immersion, the SKP is normally operated in (moist) air (Ref 71, 72). The SKP measures the Volta potential difference between a vibrating microreference electrode and the metallic surface under investigation. The corrosion potential can be derived from the Volta potential difference using a suitable calibration technique. One of the main advantages of the SKP technique is its nondestructive nature, while one disadvantage could be the fact that only potentials can be monitored. The SKP has been mainly applied to the study of polymer-coated metal surfaces, because it allows the detection of distinct potential differences between delaminated and intact areas (Ref 73). The SKP technique has been used to monitor the progress of filiform corrosion on a painted aluminum panel (Ref 65).

The SKP has been used to map the potential distribution under small drops of electrolyte in the classic Evans drop experiment (Ref 74, 75). Small drops of NaCl were placed on carbon steel, galvanized steel, stainless steel, and an aluminum alloy. In the absence of chromate, local anodes and cathodes were established in a short time. When dichromate was added to NaCl, very uniform potential distribution was found for stainless steel and Al 2024. The main driving force for the development of local anodes was considered to arise from oxygen reduction in very thin films of electrolyte surrounding the NaCl drop (Ref 74). The SKP technique has also been applied to the study of atmospheric corrosion processes (Ref 76).

Miscellaneous Techniques

A number of electrochemical techniques have been developed that allow evaluation of processes such as hydrogen embrittlement, especially of steels, or the susceptibility of metal and alloys to localized corrosion, such as pitting. Certain standard laboratory tests, such as the anodized aluminum corrosion test, the impedance test for anodized aluminum, the electrolytic corrosion test, as well as the paint adhesion on a scribed surface (PASS) test, are used mainly as quality-control tests.

Hydrogen Permeation Technique. The Devanathan-Stachurski method can be used to study parameters associated with the hydrogen embrittlement tendencies of metals and alloys (Ref 77). This method is described in ASTM G 148, “Standard Practice for Evaluation of Hydrogen Uptake, Permeation, and Transport in Metals by an Electrochemical Technique.” The technique involves placing a thin metal foil between two electrochemical cells—a hydrogen charging cell and a hydrogen oxidation cell (Fig. 31). Hydrogen is generated on the side of the metal foil facing the charging cell by application of a sufficiently negative potential. For characterization of the hydrogen transport in the bulk of the material under investigation, galvanostatic charging is preferred. The hydrogen that diffuses through the foil is oxidized on the side of the foil that faces the oxidation cell. The potential of the foil is controlled at a sufficiently positive potential to ensure that the kinetics of the oxidation of hydrogen atoms are limited by the flux of hydrogen atoms. The total oxidation current is monitored as a function of time. It is the sum of the hydrogen oxidation current, which is the permeation current, and the background current due to dissolution of the metal foil. The latter needs to be kept small by choosing a proper electrolyte in the oxidation cell. For ferrous materials, an alkaline solution, such as 0.1 *M* NaOH, is used to ensure passive behavior.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

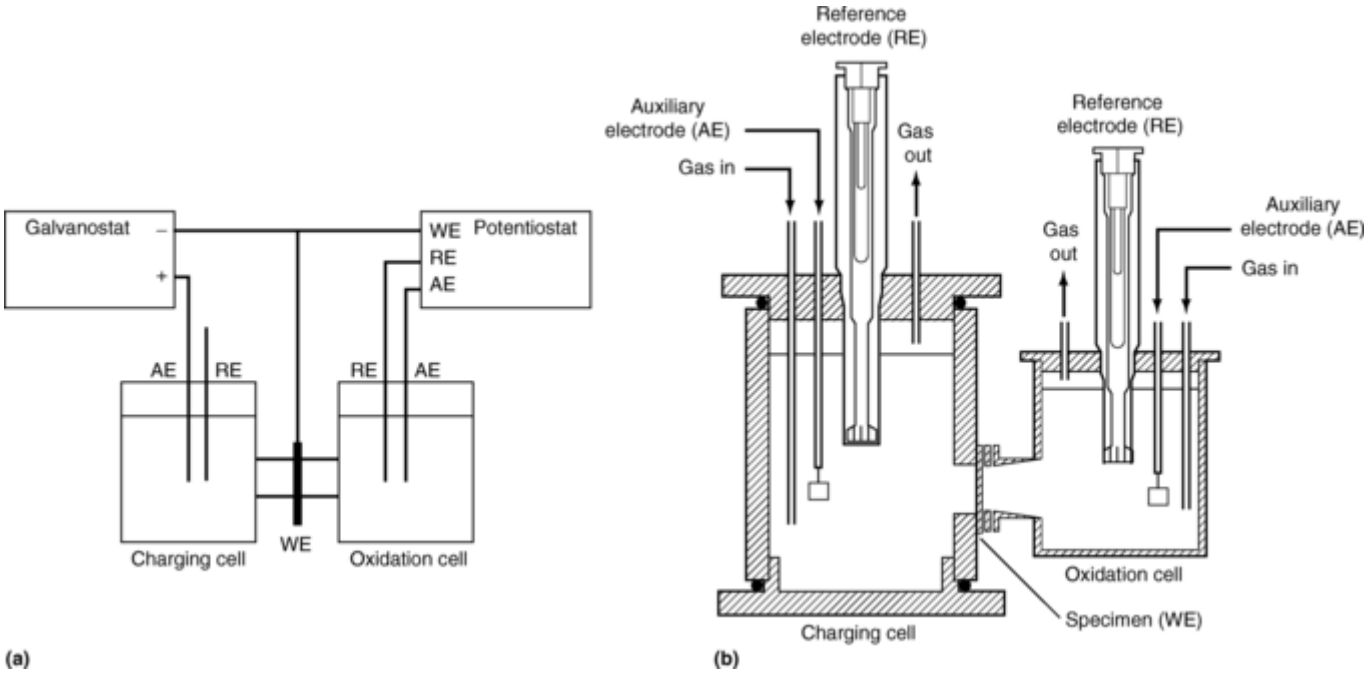

Fig. 31 Electrochemical hydrogen permeation cell assembly and measuring apparatus. (a) Schematic. (b) Polytetrafluoroethylene (PTFE) hydrogen permeation cell. Source: ASTM G 148

For a known foil thickness, L, the steady-state permeation current, J_{ss}, gives information concerning the subsurface concentration, C_H, at the charging surface:

$$J_{ss} = C_H D_l / L \qquad \text{(Eq 13)}$$

where D_l is the lattice diffusion coefficient of hydrogen. ASTM G 148 gives a detailed description of the procedure for the analysis of the results of electrochemical hydrogen permeation results obtained from steady-state permeation current measurements or from permeation transient measurements.

The barnacle electrode assembly allows determination of the amount of mobile hydrogen atoms in a metallic structure that had been exposed previously to an aqueous or gaseous environment. In this case, only the hydrogen oxidation cell is used (Ref 78, 79).

Standard Laboratory Tests. Numerous ac and dc electrochemical methods have been used to study the performance and quality of protective coatings, including passive films on metallic substrates, and to evaluate the effectiveness of various surface pretreatments. Several of these methods are discussed subsequently.

The Anodized Aluminum Corrosion Test. The Ford anodized aluminum corrosion test (FACT) (Ref 80) involves cathodic polarization of the anodized aluminum surface by using a small, cylindrical, glass clamp-on cell and a special 5% NaCl solution containing cupric chloride ($CuCl_2$) acidified with acetic acid. A large voltage is applied across the cell by using a platinum auxiliary electrode. The alkaline conditions created by the cathodic polarization promote dissolution at small defects in the anodized aluminum surface. As the coating resistance is decreased, more current begins to flow, and the voltage decreases. The cell voltage (auxiliary electrode to test specimen voltage) is monitored for 3 min, and the parameter “cell voltage multiplied by time” is recorded. ASTM B 538, “Standard Method of FACT (Ford Anodized Aluminum Corrosion Test) Testing,” describes the method in greater detail.

A similar test, known as the cathodic breakdown test, involves cathodic polarization to -1.6 versus SCE for a period of 3 min in acidified NaCl. The test was designed for anodized aluminum alloys, because the alkaline conditions created by the large applied currents promote the formation of corroding spots at defects in the anodized film.

The Electrolytic Corrosion Test. This test was designed for electrodeposits of, principally, nickel and chromium on less noble metals, such as zinc or steel (Ref 81). Special solutions are used, and the metal is polarized to +0.3 V versus SCE. The metal is taken through cycles of 1 min anodic polarization and 2 min unpolarized condition. An indicator solution is then used to detect the presence of pits that penetrate to the substrate. Each exposure cycle is assumed to simulate one year of exposure under atmospheric corrosion conditions. ASTM B 627, “Standard Method for Electrolytic Corrosion Testing (EC Test),” describes the method in greater detail.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The PASS test involves cathodic polarization of a small portion of a painted metal. The area exposed contains a scribed line that exposes a line of underlying bare metal. The sample is cathodically polarized for 15 min in 5% NaCl. At the end of this period, the amount of delaminated coating is determined using an adhesive-tape pulling procedure.

The Impedance Test for Anodized Aluminum. ASTM B 457, "Standard Method for Measurement of the Impedance of Anodic Coatings on Aluminum," is used to study the efficiency of the sealing process for anodized aluminum alloys (Ref 82, 83). In this sense, the test is similar to the FACT test, except that this method uses a 1 V_{rms}, 1 kHz signal source from an impedance bridge to determine the impedance of sealed, anodized aluminum. The impedance of the sealed, anodized aluminum alloy is determined in kΩ. The test area is defined with a portable cell, and a platinum or stainless steel auxiliary electrode is typically used. The sample is immersed in 3.5% NaCl. In contrast to the methods discussed previously, this quality-control test is essentially nondestructive and does not accelerate the corrosion process.

The Critical Pitting Temperature. The susceptibility of a material to pitting is usually evaluated based on the pitting potential, E_{pit}, that can be determined using a potentiostatic or potentiodynamic (pitting scan) technique. An alternative approach is based on the critical pitting temperature (CPT) that is described in ASTM G 150, "Standard Test Method for Electrochemical Critical Temperature Testing of Stainless Steels." The CPT is defined as the lowest temperature at which stable pit propagation occurs. The test method determines the potential-independent critical pitting temperature using a potentiostatic technique with a temperature scan. A specific sample holder is recommended that eliminates the occurrence of crevice corrosion. The test sample is exposed to a 1*M* NaCl solution that is initially maintained at 0 °C. The solution is then heated at a rate of 1 °C/min. The sample is polarized to a potential above the E_{pit} range during the entire temperature scan. The current is monitored during the temperature scan, and the CPT is defined as the temperature at which the current density exceeds 100 μA/ cm^2. The occurrence of pitting is confirmed visually after the test. The standard parameters recommended in ASTM G 150 are suitable for determining the CPT of austenitic stainless steels and other related alloys.

Immersion Testing

Te-Lin Yau, Te-Lin Yau Consultancy

Introduction

IMMERSION TESTING is the most frequently conducted test for evaluating the corrosion of metals in aqueous solutions. It appears simple: Totally immerse a test specimen in a corrosive solution for a period of time and then remove the specimen for examination. It is sometimes referred to as a "quick and dirty" test. However, a number of factors must be considered to achieve specific goals and to ensure adequate reproducibility of test results. The actual conditions of the test are usually determined by the nature of the problem at hand, the ingenuity of the investigator, and the budget of the test program. The following information is presented as a guide, so that some of the pitfalls of such testing may be avoided.

The methods and procedures described include basic factors that must be considered in sophisticated test procedures as well as in simple tests. Primary consensus standards for immersion corrosion testing of metals have been developed by ASTM International and NACE International. Applicable ASTM standards are given in Ref 1 to 9. The NACE method is given in Ref 10.

For proper planning of the test and interpretation of the test results, the specific influences of the following variables must be considered: solution composition, temperature, aeration, volume, velocity, and waterline effects; specimen surface preparation; method of immersion of specimens; duration of test; and method of cleaning specimens at the conclusion of the exposure.

In most cases, immersion tests are conducted to determine the corrosion rates of metals in a given environment. However, by employing specifically designed specimens and/or environments, immersion tests can also be conducted to evaluate the resistance of the metal to pitting, crevice corrosion, galvanic corrosion, hydrogen embrittlement, erosion, and stress-corrosion cracking. Sections of this Volume devoted to these topics have details on the specific testing methods.

Immersion Testing

Te-Lin Yau, Te-Lin Yau Consultancy

Total Immersion

Composition of Solution. Test solutions can be: (a) accurately prepared by combining chemicals according to the specifications of the Committee on Analytical Reagents of the American Chemical Society with distilled water, (b) naturally occurring solutions, or (c) samples of plant process solutions. The composition of the test solutions should be controlled to the fullest extent possible. They should be described as completely and accurately as possible in the test report. It helps to include information such as color, pH, and specific gravity before and after the test.

Evaporation losses can be controlled by a constant level device or by frequent addition of appropriate solution to maintain the original volume within ±1%. The use of a reflux condenser ordinarily, but not always, precludes the necessity of adding to the original kettle charge. Certain chemicals are too volatile to be quickly condensed.

The composition of the test solution sometimes changes as a result of catalytic decomposition or by reaction with the test specimens. For example, hydrogen peroxide may catalytically decompose, and hydrofluoric acid is quickly consumed by reacting with reactive metals such as titanium and zirconium. These changes should be determined if possible. Where required, the exhausted constituents should be added or a fresh solution provided during the course of the test. If problems are suspected, the composition of the test solutions should be checked by analysis at the end of the test to determine the extent of change in composition that took place from evaporation or reactions.

Corrosion products from the specimen may influence the corrosion rate of the metal or the corrosion rate of different metals exposed at the same time. For example, the accumulation of cupric ions in the testing of copper alloys in intermediate strength of sulfuric acid accelerates the corrosion of copper alloys, as compared to the rates that are found if the corrosion products are continually removed. Cupric ions may also exhibit a passivating effect on stainless steel specimens exposed at the same time. It is generally advisable to expose only the same type of alloys in the testing apparatus. Alloys in the same group may be quite different in chemical compositions. For example, there are copper-containing stainless steels, such as some of the precipitation-hardening and duplex stainless steels, and there are copper-free stainless steels.

Temperature of Solution. Temperature is a critical factor in corrosion. Accordingly, the temperature of the test solution and, if different, the temperature of the test specimen must be known. In many cases, corrosion increases rapidly with temperature. The corrosion of type 303 stainless steel by 65% nitric acid is shown in Table 1 (Ref 10). Corrosion increases from a low rate of less than 0.5 mm/yr (20 mils/yr) to over 100 mm/yr (4000 mils/yr) as a result of increasing the temperature 65 °C (120 °F). For some corrosion systems, the thermal effect is more complex. For example, the corrosion rate of Monel alloy in air- saturated sulfuric acid solutions increases sharply with rising temperature to a maximum at 80 °C (175 °F) and then decreases with a further increase in temperature. This is because of the decrease in dissolved oxygen in sulfuric acid, as indicated in Fig. 1 (Ref 11, 12).

Table 1 Effect of temperature on corrosion of type 303 stainless steel by 65% HNO_3

Temperature		Corrosion rate	
°C	**°F**	**mm/yr**	**mils/yr**
Up to 120	250	<0.5	<20
125	260	2.5	100
135	280	5.0	200
160	320	12.5	500
165	330	25	1000

185	370	125	5000

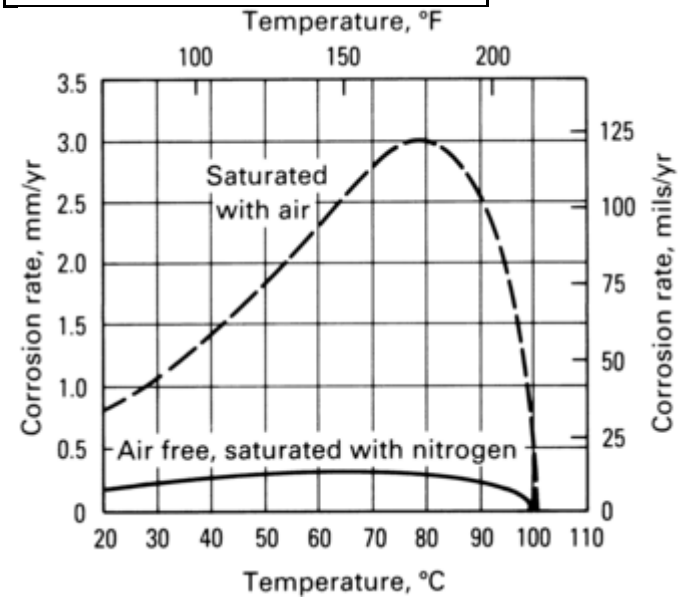

Fig. 1 Effect of temperature on the corrosion of Monel in 5 to 6% sulfuric acid. Solution velocity: 4.7 to 5 m/min (15.5 to 16.5 ft/min). Source: Ref 11, 12

Laboratory tests are often conducted in controlled-temperature water or oil baths. The temperature of the corroding solution should be controlled within ±1 °C (±1.8 °F) and must be stated in the report of test results.

If no specific temperature, such as a boiling point, is required or if a temperature range is to be investigated, the selected temperatures used in the test, as well as their respective durations, must be reported. Tests at ambient temperature should be conducted at the highest temperature anticipated. The variation in temperature should be reported also.

Accelerated corrosion tests often are conducted at temperatures above proposed operating temperatures in order to decrease the time of testing. Because the effect of temperature on corrosion rates may be great, there is a danger that economic, yet suitable materials may be eliminated. Also, as shown in the Monel example, if the temperature-corrosion-rate relation is nonlinear, an extrapolation of results based on increased temperature could lead to erroneous conclusions.

A common error involves the assumption that the environment temperature is the corroding temperature. This is particularly true in the case of materials for heating surfaces. The average temperature of the liquid in the tank may be 65 °C (150 °F), but the corroding or surface temperature of the steam heating coil is considerably higher. Therefore, tests conducted at 65 °C (150 °F) may provide erroneous results. Surface temperatures can often be estimated by considering heat-transfer coefficients.

Results of corrosion tests have shown that dissolution of borosilicate glass vessels in distilled water at temperatures above 60 °C (140 °F) lowers the corrosion rate of low-carbon steel significantly. Test apparatus has been designed that is capable of precise control and measurement of temperature (Ref 13).

Aeration of Solution. Aeration, or the presence of dissolved oxygen in a liquid environment, can influence corrosion rates profoundly. Accordingly, this factor should be considered carefully in a corrosion test program. In general, some metals and alloys are attacked more rapidly in the presence of oxygen, but others may show better corrosion resistance. Although this discussion is concerned primarily with the oxidizing effects of aeration, these effects could also be produced by other oxidizing agents. Figure 2 shows a generalized picture of several materials in different environments (Ref 14).

Fig. 2 Effect of solution oxidizing capacity on corrosion rates of various metal-solution combinations. Source: Ref 14

Figure 1 shows the effect of aeration and deaeration on Monel. An interesting feature is the rapid decrease in corrosion as the temperature approaches the boiling point. The rates at the boiling points are essentially the same under the two conditions of test. The reason for this behavior is that the solubility of oxygen in boiling water or dilute aqueous solutions is practically nil. This feature is of interest from the practical standpoint, because a test at the boiling point is more convenient to conduct than one at an arbitrary temperature, such as 80 °C (175 °F), because the temperature is easily controlled and is reproducible. The operator might expect more severe results by running the test at the boiling point, but the actual results may be just the opposite.

Unless specified, the solution should not be aerated. Most tests related to process equipment should be conducted with the natural atmosphere inherent in the process, such as the vapors of the boiling liquid. If aeration is used, the specimens should not be located in the direct air stream from the sparger (perforated tube or pipe). Extraneous effects can be encountered if the air stream impinges on the specimens.

The simplest and most widely used aeration method consists of bubbling air through the solution. The solution is assumed then to be saturated with air. In most applications being simulated in the test, air is involved; therefore, air is used in the test. If air is not bubbled through the solution, the aeration effect depends on the air present in the solution at the start of the test and on its rate of removal or escape, if any. Air can also be absorbed from the atmosphere over the solution.

If oxygen saturation of the test solution is desired, this test can best be achieved by sparging with oxygen. Appropriate precautions should be taken when oxygen-rich gases are used, because many materials burn violently in pure oxygen. For other degrees of aeration, the solution should be sparged with synthetic mixtures of air or oxygen with an inert gas.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

If complete exclusion of dissolved oxygen is necessary, specific techniques, such as prior heating of the solution and sparging with an inert gas (usually nitrogen), are required. A liquid atmospheric seal is often used on the test vessel to prevent air ingress.

Volume of Solution. The volume of the test solution should be large enough to avoid any appreciable change in its corrosivity during the test through exhaustion of corrosive constituents or by accumulation of corrosion products that may affect further corrosion. Typical minimum volume recommendations are solution-to-specimen area ratios of 200 L/m^2 of specimen surface when detecting susceptibility to intergranular attack of austenitic stainless steel (Ref 7) and 100 L/m^2 of specimen surface when evaluating the exfoliation corrosion susceptibility of 5*xxx* aluminum alloys (Ref 9).

When the objective of the test is to determine the effect of a metal alloy on the characteristics of the test solution (for example, to determine the effects of metals on dyes or the catalytic decomposition of hydrogen peroxide), it is desirable to reproduce the ratio of solution volume to exposed metal surface area that exists in practice. The actual time of contact of the metal with the solution must also be taken into account. Any necessary distortion of the test conditions must be considered when interpreting results.

Solution Velocity. The effect of velocity is not usually determined in normal laboratory tests, although specific tests have been designed for this purpose (Ref 11, 15, 16). However, for the sake of reproducibility, some velocity control is desirable. Tests at the boiling point should be conducted with the least heat input to avoid excessive turbulence and bubble impingement. In tests conducted below boiling point, thermal convection is generally the only source of liquid velocity. In test solutions with high viscosities, supplemental controlled stirring is needed to assure uniform conditions.

Method of Supporting Specimens. The supporting device and container should not be affected by or cause contamination of the test solution. The method of supporting specimens varies with the apparatus used for conducting the test, but supports should be designed to insulate the specimens from each other physically and electrically and to insulate the specimens from any metallic container or supporting device used within the apparatus.

The shape and form of the specimen support should ensure free contact of the specimen with the corroding solution, the liquid-vapor line, or the vapor phase (Fig. 3). If clad alloys are exposed, special procedures, such as coating of edges, are required to ensure that only the cladding is exposed, unless the purpose is to test the ability of the cladding to protect cut edges. Alternatively, a clad sample can be attached to an opening in a T-pipe so that only the clad surface is exposed to the test solution. Common supports include glass or ceramic rods, glass saddles, glass hooks, fluorocarbon plastic strings, and various insulated or coated metallic supports.

Source: Ref 7

In aqueous solutions under one atmosphere of air or oxygen pressure, it is desirable to position all specimens so that the oxygen supply is similar. This is especially important with corrosion systems in which the corrosion rate may be fairly high, such as for iron and steel in neutral salt solutions. In such tests, totally immersed specimens at a depth of less than 20 mm (0.8 in.) had markedly higher corrosion rates, but with deeper immersion, the rate was lower and variations in depth were unimportant (Ref 17). More detailed discussion of the factors that can affect corrosion behavior in immersion tests can be found in Ref 11.

Autoclave Tests

In order to improve conversion rate and yield, elevated temperature and pressure are employed in modern chemical technologies. Consequently, it is important to conduct corrosion tests at such elevated temperature and pressure. Autoclaves are often used for this type of test. They need to be manufactured in conformance with the American Society for Mechanical Engineers, or similar industry standards worldwide, and government regulations governing unfired pressure vessels. As shown in Fig. 4, the autoclave is fitted with devices for safety as well as measurement and control of pressure and temperature. The autoclave body should be made of a material that is compatible with the intended test environments. Structural materials include stainless steels, nickel-base alloys, titanium, zirconium, tantalum, and polytetrafluoroethylene-lined materials. Autoclaves are available in many sizes and types, ranging from hundreds of milliliters to several liters. They may be static, stirred, or refreshed. For refreshed autoclaves, there are additional devices, such as a high-pressure, constant-volume pump; a preheater; a back-pressure controller; and an overpressure protection system.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

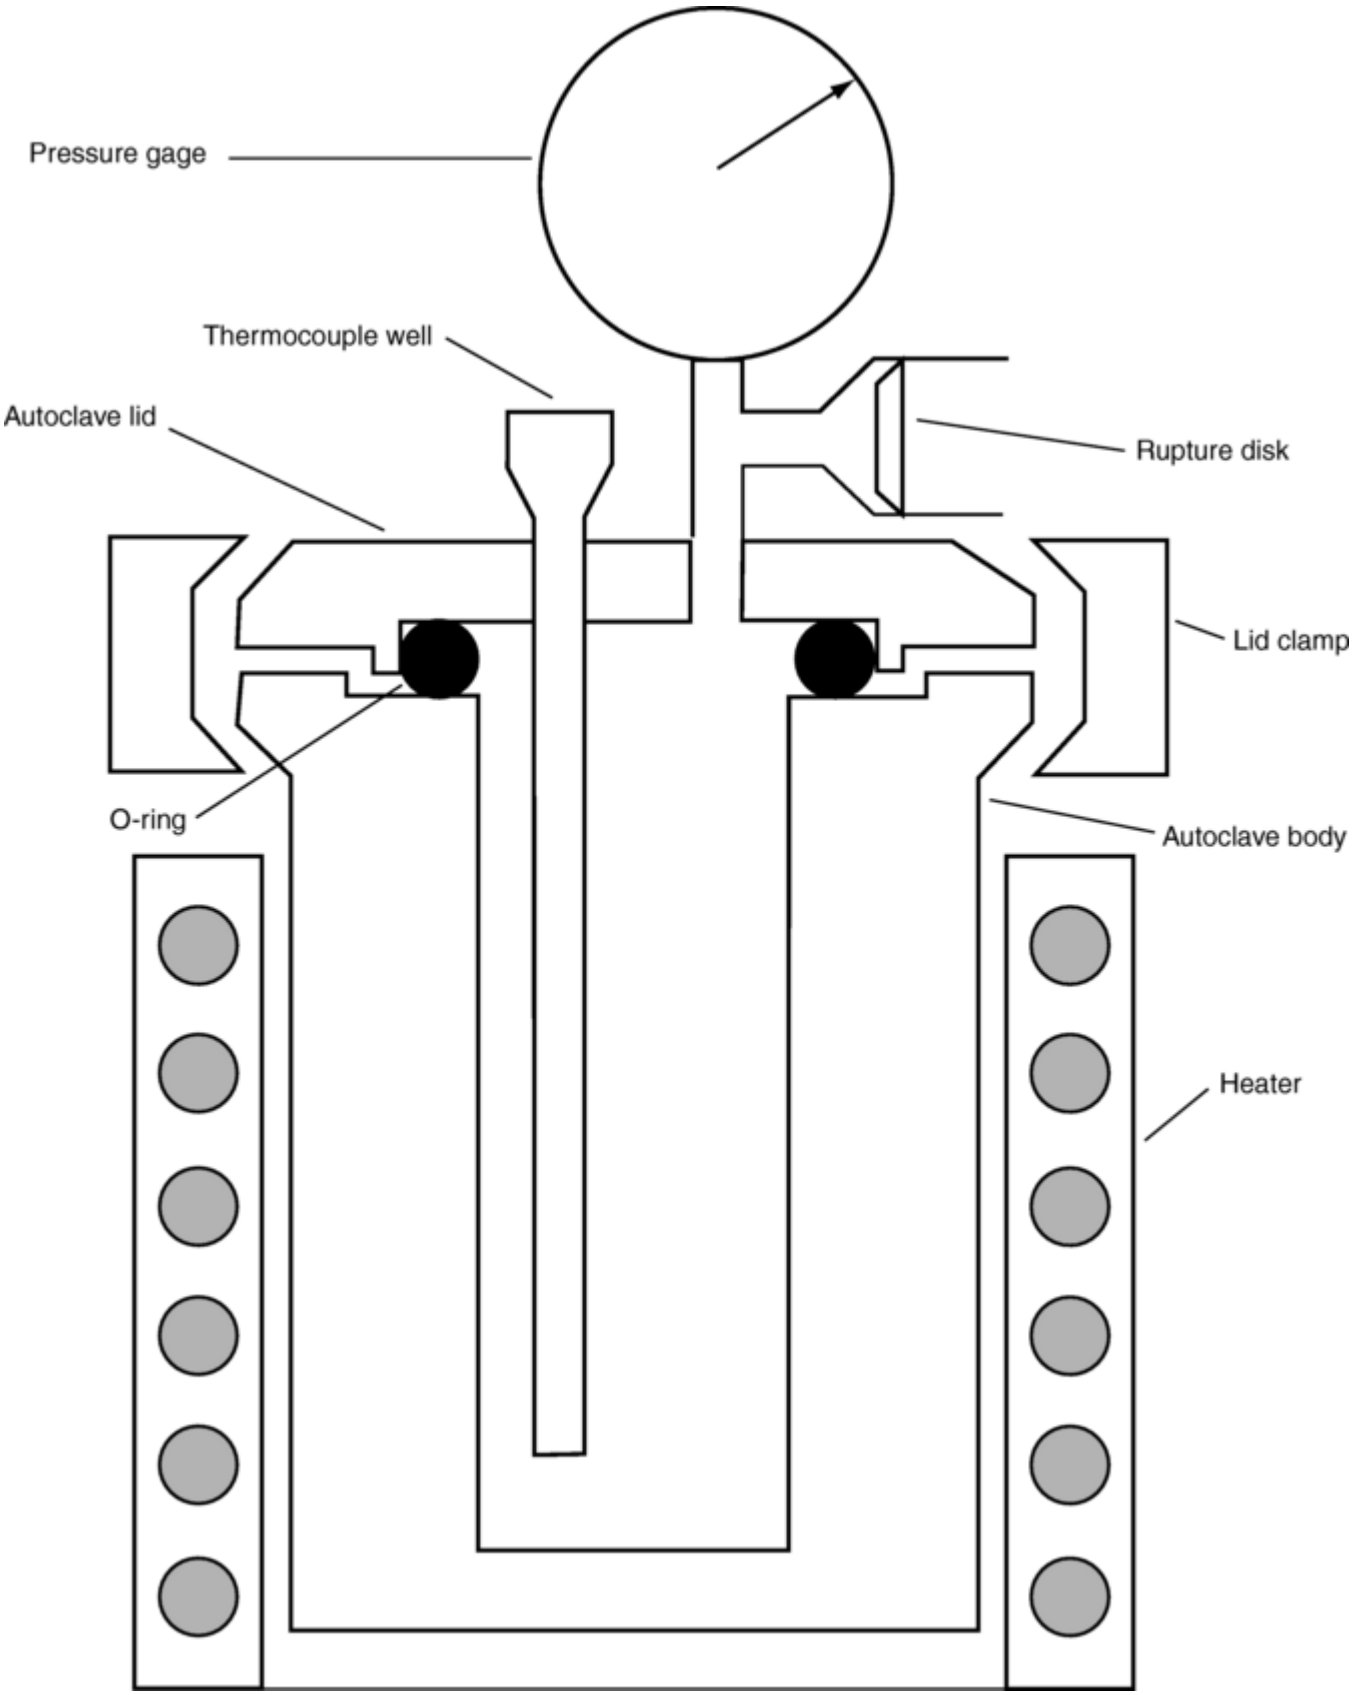

Fig. 4 An autoclave drawing showing common components

Temperature stability is a critical requirement in conducting autoclave tests. Temperature may fluctuate due to the heater, the control thermocouple, the heating rate, changes in external conditions, the degree of insulation, and the corrosion of specimens. The temperature measurement and recording systems should be calibrated to a specified accuracy at an established interval, such as every six months, to an accuracy of ±2.8 °C (±5 °F). Also, it is desirable to establish a vertical thermal profile for the autoclave, for example, every six months or whenever the heater or the control thermocouple is adjusted or replaced. Pressure affects the corrosion of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

certain alloys under certain conditions. To accurately record the pressure, and for safety, the pressure gage should be calibrated.

Proper cleaning methods should be established for new autoclaves and for autoclaves after each test. Both chemical and mechanical methods should be considered, based on structural materials and test environments.

Because the autoclave body is often an alloy, the body itself is regarded as a test specimen. It may be difficult to follow the recommended minimum solution-volume-to-specimen area ratio, because this is dictated by the geometry of the autoclave. Still, the ratio should be as large as possible, and the test solution should be changed as frequently as practical.

A method for autoclave testing zirconium and hafnium in water or steam is given in Ref 18.

Partial Immersion to Vapor Phase

Laboratory tests under conditions of partial immersion and vapor phase are of practical importance, because such conditions are commonly found in service. Tests conducted in three locations in a resin flask, as shown in Fig. 3, can be used to determine the relative susceptibility of a material to localized corrosion at the liquid line and in the vapor phase. Partial-immersion conditions provide a very suitable accelerated test for such metals as aluminum alloys and others that develop concentrated attack at the liquid line (or splash zone in certain equipment). In certain alloy-environment systems, the vapor phase is more corrosive than the liquid phase.

Immersion Testing

Te-Lin Yau, Te-Lin Yau Consultancy

Intermittent Immersion

The term *intermittent immersion* refers to alternate immersion and emersion in a liquid corrodent. The conditions are of practical importance, because they simulate the effects of the rise and fall of tidal waters and the movements of corrosive liquids in chemical plants. Also, they may provide a relatively rapid test for the effect of aqueous solutions, because a thin film of the solution, frequently renewed and almost saturated with oxygen, can be maintained on the test specimen during most of the period of exposure, even when the shape of the specimen is complex. Reference 11 contains a detailed discussion of the rather considerable research that has been done on various alternate immersion cycles and drying conditions for tests of metallic materials.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

To simulate cyclic service conditions, the specimens should be dry before reimmersion, because this has an important effect on the protective character of films on the metal. For maximum corrosion, this drying should be done slowly, so that the film of the corrodent on the metal can be allowed the maximum time to act during immersion. In the interest of reproducibility, it is desirable to control the humidity and temperature of the atmosphere in order to ensure a constant rate of drying in successive cycles. When more thorough drying of the specimen is desired, forced-air circulation or radiant heating can be used to accelerate the drying. Artificial heating adds to the complexity of the test conditions, however, and may reduce the reproducibility of the test if it is not very carefully controlled.

Alternate Immersion in 3.5% NaCl. This test has gained widespread acceptance, particularly in the United States, and is described in ASTM G 44 (Ref 19). This practice uses a 1 h cycle that includes a 10 min period of immersion in an aqueous solution of 3.5% NaCl or a substitute ocean water (without heavy metals), followed by a 50 min emersion period. This 1 h cycle is continued 24 h/day for the test duration required for the particular test material. Aluminum and steel alloys are typically exposed from 10 to 90 days or longer, depending on the resistance of the alloy to corrosion by saltwater. Although this alternate-immersion test is considered to be an accelerated test representative of certain natural conditions (particularly marine environments), it is not intended to relate to specialized chemical environments.

Air circulation is an important consideration, because it affects the rate at which specimens dry and the loss of water by evaporation from the salt solution. The most important consideration consists of achieving moderate specimen drying conditions. Because various testing facilities use different immersion apparatuses and room sizes, individual experimentation is necessary to achieve adequate circulation. A mild circulation of air is recommended.

Specimen Drying. As with air circulation, no fixed procedure has been established and probably cannot be, unless a standardized immersion apparatus and test chamber are adopted. The objective, however, is to ensure that all specimens dry slowly during the 50 min emersion period. Because they all drain differently, specimens with different accrued corrosion films dry at different rates. New specimens with little accumulated corrosion products become dry in approximately 15 min, but other specimens with an accumulation of corrosion product and salt should be allowed approximately 40 min to dry.

Apparatus. The usual methods of immersion involve:

- Placing specimens on a movable rack that is periodically lowered into a stationary tank containing the solution (Fig. 5)
- Placing specimens on a hexagonal, semisubmerged Ferris wheel arrangement that rotates 60° every 10 min and thus passes the specimens through a stationary tank of solution
- Placing specimens in a stationary tray open to the atmosphere and having the solution moved by air pressure, nonmetallic pump, or gravity drain from a reservoir to the tray

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

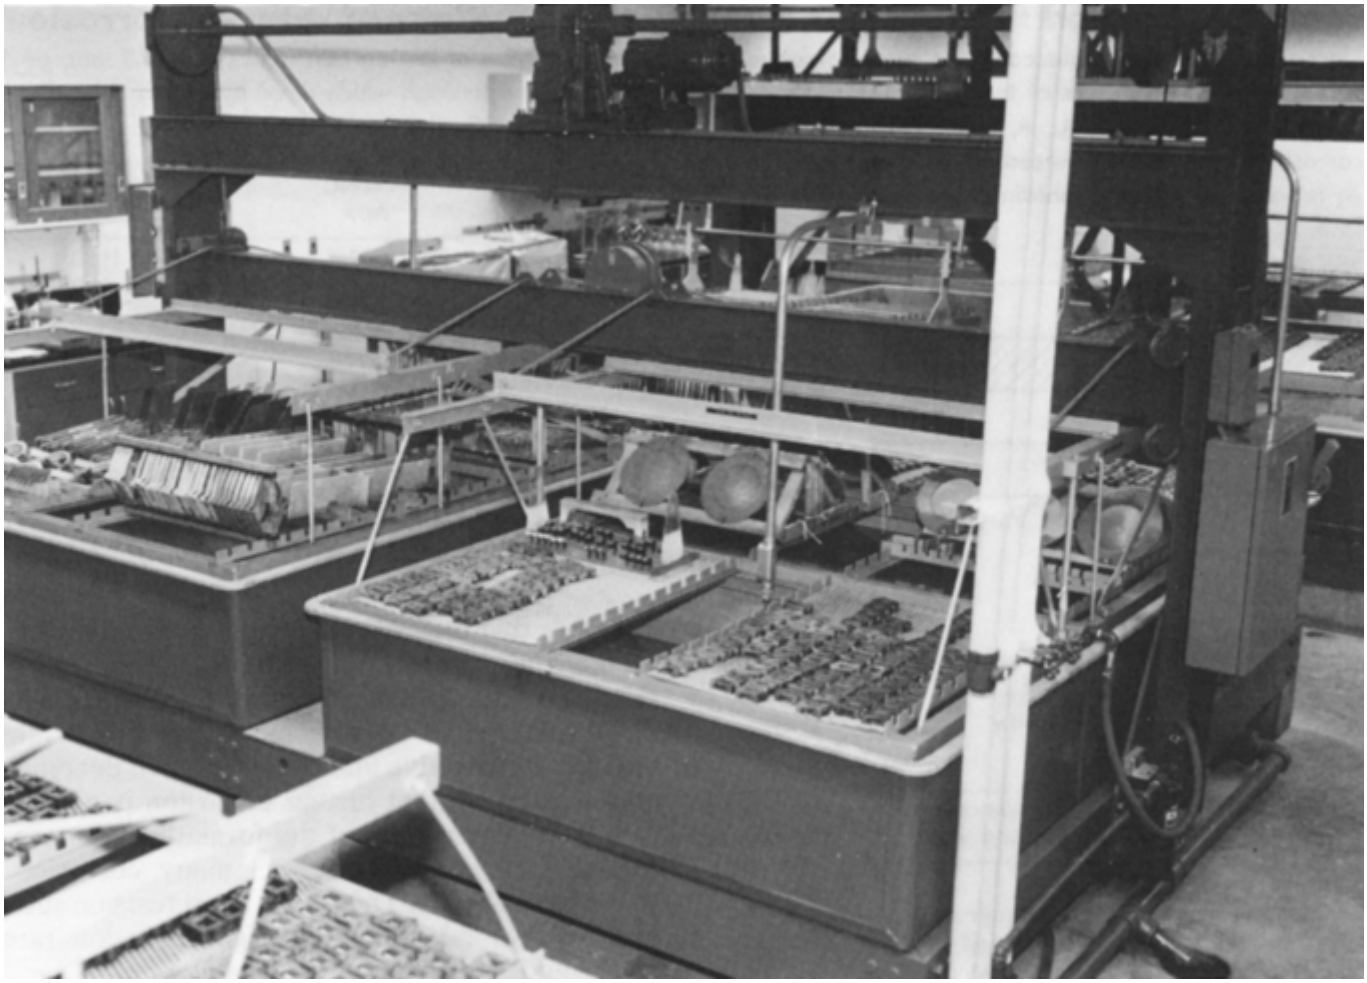

Fig. 5 Lift-type alternate-immersion apparatus. Courtesy of the Aluminum Company of America

Rate of Immersion. The rate of immersion and removal of the specimens from the solution should be as rapid as possible without jarring them. For purposes of standardization, an arbitrary limit is adopted, such that no more than 2 min elapse from the time the first portion of any specimen is covered or uncovered by solution.

Materials of construction that contact the salt solution are such that they are not affected by the corrodent to an extent that they can cause contamination of the solution and change its corrosiveness. Use of inert plastics or glass is recommended, where feasible. Metallic materials of construction should be selected from alloys that are recommended for marine use and are of the same general type as the metals being tested. Preferably, all metal parts should be protected with a suitable corrosion-resistant coating.

Specimen holders should be designed to electrically insulate the specimens from each other and from any other bare metal. When this is not possible, as with certain stressing bolts or jigs, the bare metal contacting the specimen should be isolated from the corrodent by a suitable coating. Protective coatings should be of a type that do not leach inhibiting or accelerating ions or protective oils over the noncoated portions of the specimen. Coatings containing chromates should be avoided. They should not obstruct airflow over the specimens, which retards the drying rate.

Solution Conditions. The salt solution is prepared by dissolving 3.5 ± 0.1 parts by weight of NaCl in 96.5 parts of water. The NaCl conforms to the specifications of the Committee on the Analytical Reagents of the American Chemical Society. Distilled or deionized water is used for compliance with the purity requirements of ASTM D 1193, type IV, reagent water (Ref 20).

When tests are to be made in substitute ocean water, it is prepared without heavy metals, in accordance with ASTM D 1141 (Ref 21). An advantage of the substitute ocean water in the case of stress-corrosion tests of certain high-strength aluminum alloys is that it causes less severe pitting than the 3.5% NaCl solution. It may be preferred in certain other cases, because the test results do (or are thought to) relate better to real marine environments.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Temperature. A freshly prepared solution should be allowed to come within 3 °C (5.4 °F) of the specified air temperature before being used. Thereafter, no control is required on the solution temperature. Instead, the air temperature is controlled, and the solution is allowed to reach temperature equilibrium.
Minimum Volume. The volume of the test solution should be large enough to avoid any appreciable change in its corrosiveness through exhaustion of corrosive constituents or through the accumulation of corrosion products or other constituents that might significantly affect further corrosion. A recommended arbitrary minimum ratio between the volume of the test solution and the surface area of the specimen(s) (including any uncoated accessories) is 320 L/m^2 (7.9 gal/ ft^2 or 206 mL/in^2).
Air Conditions. The air temperature is maintained at 27 ± 1 °C (80 ± 2 °F). The relative humidity is controlled at 45 ± 6%.

Immersion Testing

Te-Lin Yau, Te-Lin Yau Consultancy

Specimen Preparation and Duration of Tests

The type, size, and shape of specimens vary with the purpose of the test, the nature of the test materials, and the apparatus used. Standard practices for preparing, cleaning, and evaluating corrosion test specimens are provided in ASTM G 1 (Ref 4). Corrosion is a surface phenomenon. Surface condition of specimens is critical in determining the outcome of tests. It is essential to know the quality of specimens (Ref 22). The knowledge of this effect is important in specifying surface finish for equipment. Surface condition of as-fabricated equipment is preferred in many tests. It can be rough with embedded impurities or smooth with post-fabrication cleaning.
Proper selection of appropriate lengths of exposure is important for any corrosion test, and misleading results may be obtained if the time factor is not considered. An excellent technique for investigating changes in corrosion rate with length of exposure is described in Ref 7, 10, and 14.
Planned interval tests involve the accumulated effects of corrosion at several times under a given set of conditions as well as the initial rate of corrosion of fresh metal, the more or less instantaneous corrosion rate of metal after long exposure, and the initial corrosion rate of fresh metal during the same period of time as the latter. The rates, or damage per unit time interval of one day, are shown in the diagram in Table 2 as A_1, A_2, and B, respectively. The exposure over several days is indicated as A_t and A_{t+1}. It would be desirable to have duplicate specimens for each interval. Further time extensions of the test should be made with similar added specimens and interval spacing if no changes occurred in the corrosion rate of the metal or the corrosiveness of the liquid during the first selection of test duration.

Table 2 Planned interval test

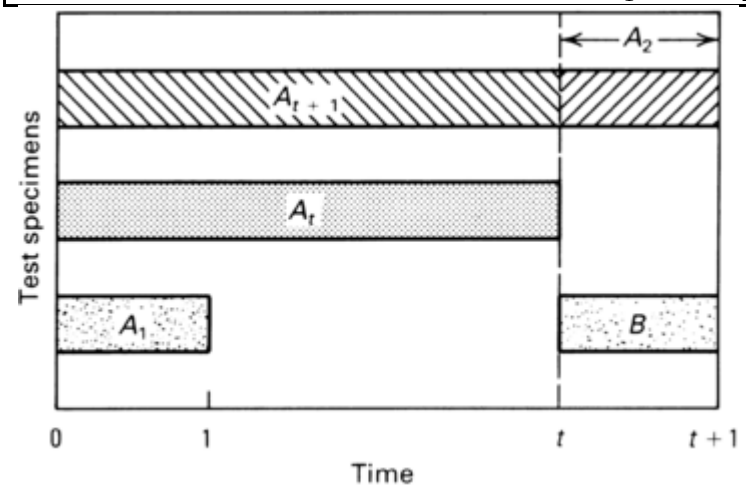
www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Identical specimens are placed in the same corrosive liquid; imposed conditions of test are constant for the entire time ($t + 1$); A_1, A_t, A_{t+1}, B, represent the corrosion damage experienced by each test specimen; A_2 is a calculated value obtained by subtracting A_t from A_{t+1}.

Corrosivity	Observed weight changes during corrosion testing	Criteria
Liquid corrosiveness	Unchanged	$A_1 = B$
	Decreased	$B < A_1$
	Increased	$A_1 < B$
Metal corrodibility	Unchanged	$A_2 = B$
	Decreased	$A_2 < B$
	Increased	$B < A_2$

Combinations of situations

Liquid corrosiveness	**Metal corrodibility**	**Criteria**
Unchanged	Unchanged	$A_1 = A_2 = B$
Unchanged	Decreased	$A_2 < A_1 = B$
Unchanged	Increased	$A_1 = B < A_2$
Decreased	Unchanged	$A_2 = B < A_1$
Decreased	Decreased	$A_2 < B < A_1$
Decreased	Increased	$A_1 > B < A_2$
Increased	Unchanged	$A_1 < A_2 = B$
Increased	Decreased	$A_1 < B > A_2$
Increased	Increased	$A_1 < B < A_2$



Comparison for corrosion damage A_1 on fresh metal in the time interval from 0 to 1 with corrosion damage B on fresh metal for the unit time interval from t to $t + 1$ shows the magnitude and direction of change in the corrosivity of the liquid that may have occurred during the total time of the test. Correspondingly, comparison of A_2 with B, where A_2 is the corrosion damage calculated by subtracting A_t from A_{t+1}, shows the magnitude and direction of change in corrodibility of the metal specimen during the test. These comparisons can be taken as criteria for the changes and are tabulated in Table 2. Also given in Table 2 are the criteria for all possible combinations of changes in the corrosivity of the liquid and corrodibility of the metal. The additional information obtained on occurrences in the course of the test justifies the additional effort involved. Table 3 lists the data obtained from a planned interval test of a carbon steel specimen in an aluminum chloride ($AlCl_3$)/antimony trichloride ($SbCl_3$) solution.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Table 3 Planned interval corrosion test

Duplicate strips of low-carbon steel (19 × 75 mm, or $\frac{3}{4}$ × 3 in.) were immersed in 200 mL of 10% $AlCl_3$-90% $SbCl_3$ mixture through which dried hydrogen chloride gas was slowly bubbled at atmospheric pressure. Temperature: 90 °C (195 °F)

Value	Interval, days	Weight loss, mg	Penetration		Apparent corrosion rate	
			µm	**mils**	**mm/yr**	**mils/yr**
A_1	0–1	1080	42.9	1.69	15.7	620
A_t	0–3	1430	56.9	2.24	6.8	270
A_{t+1}	0–4	1460	58.2	2.29	5.3	210
B	3–4	70	2.8	0.11	1.02	40
A_2	Calculated 3–4	30	1.3	0.05	0.46	18

Analysis: $A_2 < B < A_1$, or 0.05 < 0.11 < 1.69. Conclusions: Liquid markedly decreased in corrosiveness during the test, and the formation of a partially protective scale on the steel was indicated; that is, metal became less corrodible.

The causes for the changes in corrosion rate as a function of time are not given by the planned interval test criteria. The corrosivity of the liquid may decrease as a result of corrosion during the course of a test because of the reduction in concentration of the corrosive agent, the depletion of a corrosive contaminant, the formation of inhibiting products, or other metal-catalyzed changes in the liquid. The corrosivity of the liquid may increase because of the formation of autocatalytic products, the destruction of corrosion-inhibiting substances, or other catalyzed changes in the liquid. Changes in the corrosiveness of the liquid may also arise from changes in composition that would occur under the test conditions, even in the absence of metal. To determine if the latter effect occurs, an identical test is run without test strips for the total time, *t*. Test strips are then added, and the test is continued for the unit time interval. Comparison with A_1 of corrosion damage from this test shows if the corrosive character of the liquid changes significantly in the absence of metal.

The corrodibility of the metal in a test may decrease as a function of time because of the formation of protective scale or the removal of a less resistant surface layer of metal. Metal corrodibility may increase because of the formation of corrosion-accelerating scale or the removal of a more resistant surface layer of metal. Indications of the causes of changes in corrosion rate can often be obtained from close observation of tests and corroded specimens as well as from special supplementary tests designed to reveal effects that may be involved.

Changes in liquid corrosiveness are not a factor in most plant tests that consist of once- through runs or where large ratios of solution volume to specimen area are involved. If the effect of corrosion on the mechanical properties of the metal or alloy is under consideration, a set of unexposed specimens is needed for comparison purposes.

Lengthy corrosion tests are generally not necessary to obtain accurate corrosion rates from materials that undergo severe corrosion. However, there are cases in which this assumption is not valid. For example, lead exposed to sulfuric acid initially corrodes at an extremely high rate while building a protective film; the rates then decrease considerably, so that further corrosion is negligible. The phenomenon of the formation of a protective film is observed with many corrosion-resistant materials. Therefore, short tests on such materials would indicate a high corrosion rate and would be completely misleading.

Short-term tests can also give misleading results on alloys that form passive films, such as stainless steels. With borderline conditions, a prolonged test may be needed to permit the breakdown of the passive film and the subsequent more rapid attack. Consequently, tests conducted for long periods are considerably more realistic than those conducted for short durations. This statement must be qualified by stating that corrosion should not proceed to the point at which the original specimen size or the exposed area is drastically reduced or the metal is perforated.

If anticipated corrosion rates are moderate or low, the following equation gives the suggested tests duration:

$$\text{Hours} = 50/(\text{corrosion rate in mm/yr})$$

$$\text{Hours} = 2000/(\text{corrosion rate in mils/yr})$$

For example, where the corrosion rate is 10 mils/yr (0.25 mm/yr), the test should run for at least 200 h. This method of estimating test duration is useful as an aid in deciding, after a test has been made, whether or not it is desirable to repeat the test for a longer period.

Cleaning Corrosion Test Specimens

After corrosion testing, specimens should be properly cleaned to remove bulky deposits and corrosion products but not the metals. This must be done as soon as possible, so that the measured corrosion time interval is accurate. Corrosion may be continuing under the damp corrosion products until they are removed. Various mechanical, electrolytic, and chemical cleaning methods have been developed to clean different metals and alloys (Ref 4).

Calculation of Corrosion Rate

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The average corrosion rate may be obtained as follows:

$$\text{Corrosion rate} = (K \times W)/(A \times T \times D)$$

where K is a constant, T is the time of exposure in hours to the nearest 0.01 h, A is the area in cm^2 to the nearest 0.01 cm^2, W is the mass loss in grams to the nearest 1 mg, and D is the density in g/cm^3.

Several units are used to express corrosion rates. Using the previously mentioned units for T, A, W, and D, the corrosion rate can be calculated in a variety of units, with the following appropriate value of K:

Corrosion rate units desired	Constant, K
Mils per year (mils/yr)	3.45×10^6
Inches per year (in./yr)	3.45×10^3
Millimeters per year (mm/yr)	8.76×10^4
Micrometers per year (µm/yr)	8.76×10^7
Milligrams per square decimeter per day (mdd)	$2.40 \times 10^6 \times D$

Adapted from Ref 4

When expressing corrosion rates in years, the corrosionist must keep in mind the underlying assumption that the corrosion rate is uniform. When based on test data measured in hours, the extrapolation to years may not be valid. Also, by measuring the weight loss, an average loss of thickness is calculated. This may not be the most relevant characteristic.

Reporting the Data

The importance of reporting all data as completely as possible cannot be overemphasized. Expansion of the testing program in the future or correlating the results with tests of other investigators is possible only if all pertinent information is properly recorded, so the veracity of the data can be assured. The following checklist is a recommended guide for items that should be included in a standard report of immersion tests:

- Name of personnel and laboratory involved
- Date
- Identification of specimen material and number
- Form and metallurgical conditions of specimens (composition, quality grade)
- Cite standard methods employed (industry, government, or laboratory standards and guides)
- Treatment used to prepare specimens
- Visual-appearance remarks of each specimen before and after the corrosion testing
- Weights and dimensions of specimens before and after the corrosion testing
- Corrosive media and concentration (and any changes during test)
- Volume of test solution
- The color, pH, and specific gravity of the test solution before and after the corrosion testing
- Temperature (maximum, minimum, and average)

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

- Aeration (describe conditions or technique)
- Agitation (describe conditions or technique)
- Type of apparatus used for test. Include identification of measuring devices for auditing calibrations in accordance with established laboratory procedure.
- Duration of each test
- Number of specimens of each material tested, and whether specimens were tested separately or which specimens were tested in the same container
- Method used to clean specimens after exposure, and the extent of any error expected by this treatment. Use of a documented standard method is desirable.
- Evaluation of attack if other than general, such as crevice corrosion under support rod, pit depth and distribution, and results of microscopic examination or bend tests
- Corrosion rates for each specimen
- Minor occurrences or deviations from the proposed test program often can have significant effects and should be reported, if known.

Introduction

SALT SPRAY (FOG) TESTS have been used for over 100 years as accelerated tests for determining both the corrodibility of nonferrous and ferrous metals and the degree of protection afforded by both inorganic and organic coatings on metallic base (Ref 1).

The tests are utilized most often to compare the relative performance of metals and coatings to a known and retained standard for quality control purposes. The tests can be an indicator of the consistency of a production process and/or materials utilized. There has been extensive discussion of the salt fog test since its inception because of the reproducibility variances and the questionable correlation of results as related to actual “in-service” performance. This can be a result of the misapplication of the salt fog test with the expectation that the test atmosphere simulates a particular environment or service condition. Salt spray tests were not intended for this purpose, except in rare instances where corroborating data has been obtained to support such application. The test actually represents the application of a standardized amount of corrosive activity for comparing the relative performance of materials and/or coatings.

Many revisions and improvements to the salt spray test procedures, salt spray test chambers, and apparatus have been made over the years. A significant amount of the contributions result from efforts of ASTM International; The National Institute of Standards and Technology (NIST, formerly known as the U.S. National Bureau of Standards); other governmental agencies (including all branches of the U.S. Military); industry trade associations (such as The Society of Automotive Engineers; NACE International; SSPC: The Society for Protective Coatings, formerly The Steel Structures Painting Council); major automobile manufacturing companies and their suppliers, and various test equipment manufacturers. Some improvements have included the establishment of required test specifications, along with tolerance limits for test variables, which help

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

produce more reliably reproducible and meaningful test results. Even with the newly revised test procedures and modern designs of salt spray test equipment, there are still test procedures, support information, variables, and specifications of the tests that need to be examined for inclusion or evolved to improve the test standards.

Cabinet Testing

Raymund Singleton, The Singleton Corporation

Applications and Use of Salt Spray (Fog) Testing

The salt spray type test has received its widest acceptance as a tool for evaluating the uniformity of thickness and degree of porosity of metallic and nonmetallic protective coatings. It has served this purpose with a great deal of success. The test is useful for evaluating different lots of the same product once a standard level of performance has been established. It is especially helpful as a screening test for revealing a particularly inferior coating. In recent years, certain cyclic acidified salt spray tests have been used to test the resistance of aluminum alloys to exfoliation corrosion. The salt spray test is, also, considered very useful as an accelerated laboratory corrosion test that attempts to simulate the effects of marine atmospheres on different metals, with or without protective coatings.

The most commonly used and accepted salt spray test methods in the United States and much of the rest of the world are the methods outlined in ASTM Standards B 117, B 368, and G 85 (Ref 2, 3, 4). U.S. Government agencies, professional associations, trade associations and groups, many industry groups, and automotive manufacturers and suppliers have established their own salt spray standards and procedures, but in the interest of utilizing existing successful technology, many of these standards largely conform to the details of the ASTM tests. Representative of these similar salt spray tests are GM 4298/Salt Fog and Mil Standard 810E, method 509.3. In addition, some international standards of similar type are DIN 50018 and ISO 9227, which includes salt fog, acetic-acid and copper accelerated salt spray (CASS) procedures.

It is important to note that it is possible to perform widely utilized humidity corrosion test standard procedures of similar type and operation to the “salt-fog” tests in the same type test apparatus when properly equipped. The humidity tests, however, use deionized water as the only corrosive agent and do not include a “salt- type,” corrosion-accelerator electrolyte in the test solution. Examples of domestic and international “humidity” corrosion tests are ASTM D 1735 (humidity-fog type)(Ref 5), ASTM D 2247 (100% condensing humidity) (Ref 6), GM 4465 (humidity-fog type), and ASTM G 60 (cyclic humidity) (Ref 7). See Table 1.

There are two basic types of salt-spray/fog corrosion tests—"static" condition tests and "cyclic" condition tests. In tests classified as static type, the conditions and atmosphere are constant throughout the duration of the test exposure. Thus the test temperature, fog-density (as determined by condensate-collection rate), electrolyte solution pH, and specific gravity are all to remain constant within tolerance limits. Many organizations conducting static condition tests operate the equipment 24 hours a day, 7 days a week. After test specimens are placed into the test apparatus, they remain until they are subjected to the total duration time specified for each particular specimen. Each is then removed for study and analysis.

As with most endeavors, the field of corrosion testing is evolving. Current efforts are to design tests that correlate more closely, or simulate more realistically, actual environmental exposure and service conditions. With this in mind, most newer tests are cyclic. Cyclic tests subject specimens to a repeated sequence of timed, different-atmosphere steps until a predetermined time of exposure, or number of cycles, is achieved. A complete set of steps, before repetition of the sequence begins, makes up a cycle. These steps in each cycle usually incorporate (a) different temperatures (ambient, elevated, plus some lower than ambient); (b) varying levels of relative humidity (RH) from lower than 20 to 100% (that produce dry-off to saturated atmosphere conditions); and (c) various corrosive agents/pollutants/electrolytes (that can include any of a variety of different salts and gases to produce accelerated corrosion effects in the presence of moisture).

Some examples of the various exposure zone conditions used as steps in the cyclic tests are salt fog with and without compressed air humidification; humidity fog with and without compressed air humidification; controlled humidity, dry stage, ambient, specification-ambient with temperature and humidity control; and soak with maintained temperature, purge, solution spray, immersion, and dwell (no activity).

Representative of established standard cyclic salt spray (fog) type corrosion tests by industry and international groups are SAE J-2334, DIN 50018/SO2, GM 9540P, Ford APGE and CCT I, II, III, and IV from the Japanese automotive industry. (see Table 1 for a synopsis of test details for some of the tests). Using the SAE J-2334, GM 9540P, and CCT IV as examples, notice the similarity in Table 1 between these procedures and the common atmospheric conditions specified for some of their steps in the designated cycles.

Static Atmosphere Condition Salt Spray (Fog) Tests

Salt Spray (Fog) Tests. ASTM B 117 is the most commonly used salt spray test for evaluating inorganic and organic coatings, especially where such tests are a part of material or product specifications. ASTM B 117 includes: DIN 50021-SS, GM 4298, and ISO 9227 (see Table 1).

There is quite a bit of commonality between the salt spray (fog) test and most of the other tests mentioned in this article as far as ingredients, specifications, apparatus, and procedures. As a result the salt spray (fog) test provides the best basis for the study of the other tests.

The ASTM B 117 test, when properly applied and performed, should yield a “standardized” amount and type of corrosive activity for comparison purposes. The test is not intended to correlate to any particular service environment or exposure condition unless long-term exposure data for a particular material or coating are available for comparison purposes. A criticism of the test as not being typically equivalent to “outdoor” exposure usually results when the procedure is misapplied or relied on to produce correlating results for which it was never intended.

The ASTM B 117 test consists of atomizing a specified sodium chloride aqueous solution to create a corrosive fog atmosphere in an enclosed chamber under controlled temperature. The use of ASTM D 1193, type IV reagent grade water is specified for makeup of the salt solution. Type IV reagent water must meet the following criteria: (a) pH in the range of 5 to 8 prior to use for testing purposes; (b) maximum electrical conductivity = 5.0 μs/cm at 298 K or 25 °C (77 °F); and (c) minimum electrical resistivity = 0.2 MΩ · cm at 298 K or 25 °C (77 °F). Limits for content of separate sodium and chloride in the type IV specification may be ignored because each would be insignificant once the sodium chloride salt was added. Other similar tests also use deionized (DI) water.

The aqueous test solution consists of 95% by weight of reagent water and 5% by weight of sodium chloride (NaCl), which contains not more than 0.1% by weight of sodium iodide, 0.3% by weight of total impurities, and 200 ppm total solids. In addition, the test solution needs to be substantially free (the operative term) of nickel and copper. This solution is representative for many “typical” fog type corrosion test procedures.

The salt used for many of these tests is a food grade sodium chloride with no anticaking agents. The use of food grade is specified because it produces scientifically valid results and is readily available.

Conditioned, humidified, and heated compressed air is used to atomize this solution to create the necessary corrosive fog atmosphere in the test chamber. When all specified test conditions are met, the resulting pH reading determined from the collected condensed-fog solution after atomization should be in the range of 6.5 to 7.2. The condensed-fog solution should be collected at a rate of 1 to 2 mL per collector (minimum of two collectors in the exposure zone) per hour of continuous operation. This verification of the density of the fog atmosphere helps establish the standardized test conditions. The temperature is maintained at 35 + 1.1 or -1.7 °C (95 + 2 or -3 °F) within the exposure zone of the closed salt spray chamber throughout the duration of the test. The duration of this test can range from 8 to 3000 h depending on the product or type of coating being tested.

The Acetic Acid-Salt Spray (Fog) Test. ASTM G 85, Annex A1, is also used for testing inorganic and organic coatings but is particularly applicable to the testing of decorative nickel- chromium or copper-nickel-chromium plating and cadmium plating on steel or zinc die castings. This test is usually used for the evaluation of the consistency of product quality (Ref 4).

As in the ASTM B 117 salt spray (fog) test, a 5% by weight of sodium chloride (NaCl) solution is used, but the solution is adjusted to a pH range of 3.1 to 3.3 by the addition of acetic acid. Note that the pH specification is for the solution obtained from the fog condensate collection devices after atomization. The temperature of the

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

salt spray chamber exposure zone is controlled to maintain 35 + 1.1 or -1.7 °C (95 + 2 or -3 °F) within the exposure zone of the closed chamber throughout the duration of the test.
This test can be as brief as 16 h, although it normally ranges from 144 to more than 240 h.
The copper-accelerated acetic acid-salt spray (fog) test or CASS test, ASTM B 368, (Ref 3), is primarily used for the relatively rapid testing of decorative copper-nickel-chromium or nickel-chromium plating on steel and zinc die castings. It is also useful in the testing of anodized, chromated, or phosphated aluminum. A 5% by weight of sodium chloride (NaCl) solution is used, with the addition of 1 g of copper II chloride ($CuCl_2 \cdot 2H_2O$) added to each 3.8 L of salt solution. The solution is then adjusted to a pH range of 3.1 to 3.3 by adding acetic acid. The exposure zone temperature of the CASS chamber is controlled to maintain 49 + 1.1 or -1.7 °C (120 + 2 or -3 °F) throughout the duration of the test, which ranges from 6 to 720 h.

Cyclic and Other Atmosphere Condition Salt Spray (Fog) Tests

Many other cyclic salt spray (fog) test procedures have been developed in order to more closely approximate a specific application, service condition, or environment. Some of these are grouped as the ASTM G 85 "Modified Salt Spray (Fog) Testing" procedures. There are 5 Annexes of the G 85 standard: A1, the acetic acid salt spray (fog) test (a static condition test as mentioned in the previous section); A2, the cyclic acidified salt spray (fog) test; A3, the acidified synthetic seawater spray (fog) test; A4, the salt spray (fog)/sulfur dioxide (SO_2) test; and A5, the dilute electrolyte cyclic fog/dry test. Another test of significance is the ASTM moist sulfur dioxide (SO_2) test (ASTM G 87).
The cyclic acidified salt spray (fog) test (ASTM G 85, Annex 2) and the acidified synthetic sea water spray (fog) test (ASTM G 85, Annex 3) are each used, in part, for production control of exfoliation-resistant heat treatments for various aluminum alloys (Ref 8). The salt spray (fog)/SO_2 test (ASTM G 85, Annex 4) (Ref 9) is often used to test for the exfoliation corrosion resistance of various aluminum alloys and a wide range of nonferrous and ferrous materials and coatings, both inorganic and organic, when exposed to an SO_2-laden salt spray (fog) atmosphere. These conditions are encountered, for example, in shipboard and nearshore marine environments. As more of these, and other, cyclic-type tests are introduced and utilized, the development and implementation of capably sophisticated testing chambers and equipment will occur concurrently. Much newer equipment incorporates automatic functions to perform cyclic tests while largely unattended.
Some of the more widely used cyclic corrosion tests are for the automotive industry. However, their versatility and applicability have been demonstrated to the extent that their use is not limited to that industry. Some of these tests were developed to measure the cosmetic effects of corrosion of automotive painted, or coated, steel surfaces. Their success at evaluating the performance of these finishes by relative rank has led to wider use. Representative examples of these tests include (a) GM 9540 P, originating with General Motors yet used widely in addition by others including the U.S. Military; (b) SAE J2334, originating with the Society of Automotive

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Engineers, and (c) CCT IV, originating with the Japanese automotive industry, yet containing many aspects in common with the two aforementioned cyclic test procedures. Note from Table 1 the similarities in exposure atmospheres and conditions between these tests.
Another popular cyclic corrosion test is the ASTM G 85 Annex 5 (Ref 10). It is used primarily to test paints for industrial maintenance coatings and architectural finishes.
The cyclic nature of the last group of tests simulates the effects of the changing nature of outdoor and in-service environmental conditions.

Combining Weathering (Light Exposure Apparatus) and Salt Spray (Fog) Type Corrosion Tests

An interesting practice that has proven useful in materials evaluation and research is the capability to study the degradation effects produced through the combination of accelerated weathering and corrosion testing procedures. This allows materials and coatings to be subjected to more complex accelerated effects. The following information indicates the significant differences in each type test used in the combined procedure.
Accelerated weathering testing generally attacks the coating material with various types of light exposures (from ultraviolet to infrared), along with heat, moisture, pollutant, and microbial attack to cause degradation and physical property changes to or within the coating or material. This type of procedure is often used to test nonmetallic polymer materials (Ref 11). Accelerated corrosion testing in this type testing, conversely, is usually used to examine the ability of a coating to protect a substrate by attacking the substrate material. Corrosion testing is often used to test metallic materials and coatings on metallic materials.
The combination of these two test types, where applicable, is very useful in the investigation of materials performance. A convenient, representative example of this type combined test standard is the ASTM D 5894, the UV condensation/salt spray (fog)-dry exposure test. The test comprises alternating one week of ASTM D 4587, UV-condensation exposure, and one week of ASTM G 85 Annex 5, salt-fog/dry exposure, to a predetermined total number of cycles. A complete cycle is made up of one week of each type test for a total of two weeks per cycle.

Test Specimen Procedures for Salt Spray (Fog) Corrosion Tests

Corrosion test specimens for these tests include ferrous and non-ferrous metals in possible combinations with organic and inorganic coatings of various formulations, properties, and production and application methods. Test specimens are representative of items used in architectural, industrial, electrical and electronic, hardware, appliance, transportation, military, aerospace, marine, and other industrial applications. There are specific standardized procedures to be used for selecting, preparing, handling, cleaning, and storing test specimens prior to corrosion testing and after the tests have been completed. ASTM standards are a good starting point due to their wide use and acceptance. Industry specific standards for test specimen procedures often reference the ASTM standards as a basis.

A widely used document is ASTM G 1, “Standard Practice for Preparing, Cleaning and Evaluating Corrosion Test Specimens.” This standard, as the title implies, provides good general information for those aspects of corrosion test specimen procedures for both pretest and posttest needs. Other standards, described in more detail subsequently, furnish examples of typically encountered aspects.

Cabinet Testing

Raymund Singleton, The Singleton Corporation

Pretest Specimen Preparation for Salt Spray Corrosion Tests

ASTM D 609, Practice for Preparation of Cold-Rolled Steel Panels for Testing Paint, Varnish, Conversion Coatings and Related Coating Products (Ref 12), describes several cleaning procedures used prior to testing. These cleaning methods include vapor degreasing, solvent brushing, solvent wiping, and alkaline cleaning:

- *Procedure A, conversion coatings:* Preparation of test panels consists of one or more steps of cleaning, rinsing, or conditioning prior to the application of the coating. Additional water rinsing is required after the conversion coating is applied. Force air dry immediately after rinsing.
- *Procedure B, vapor degreasing:* Suspend panels in vapor-phase type degreaser using 1,1,1-trichloroethane. Prewipe with a clean, lintless cloth saturated with mineral spirits to remove solid particulate matter.
- *Procedure C, solvent brushing:* Power-brush scrub with mineral spirits. Dry at 52 to 93 °C (125 to 200 °F) before use or storage.
- *Procedure D, solvent wiping:* Remove all soluble and loosely adhering soil by rubbing the panel with a clean, lintless cloth wet with mineral spirits. Dry at 52 to 93 °C (125 to 200 °F) before use or storage.
- *Procedure E, alkaline cleaning:* Clean panels with alkaline solution by spray or immersion. One or more steps may be required. Force dry immediately after rinsing.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

ASTM D 609 also provides information for materials and supplies. In addition, storing and handling methods are covered, such as the use of lint-free gloves when necessary, handling panels only by their edges, wrapping cleaned panels in paper treated with a corrosion inhibitor, and placement in a sealable plastic bag or envelope.

ASTM D 1654, Standard Test Method for Evaluation of Painted or Coated Specimens Subjected to Corrosive Environments furnishes information on both pretest and posttest procedures (Ref 13). This test method provides information necessary for test specimens. Pretreatment procedures include details on scribing, a deliberate simulation of coating failure, where applicable. Scribing is used to simulate the failure observed when coated products are subjected to abrasion or accidental damage and then exposed to corrosive influences.

The scribe tool consists of a “straight shank tungsten-carbide tip, lathe cutting tool (ANSI B94.50, Style E) or carbide tipped pencil type tool.” The apparatus for scribing also includes a straight-edge guide “of sufficient length and rigidity to guide the scribing tool in a straight line” (Ref 13). The scribe lines are often applied to test specimen panels by holding the tool at approximately 45 degrees from vertical and pulling along the straight edge guide to produce a uniform V-cut through the coating on the test piece. Scribe marks are applied to the surface of the test piece in vertical, diagonal, intersecting, or cross-hatch patterns. The uniformity in width and depth of the scribe mark is of great importance to the final test results.

Post-test operations for previously painted or coated specimens subjected to accelerated corrosion tests include their subsequent evaluation in respect to corrosion, blistering associated with corrosion, loss of adhesion at the scribe mark, or other coating failure. After testing it is necessary to clean the tested pieces and remove any loose coatings and corrosion products. A rigid spatula type scraping tool, a dull knife, or a similar instrument without sharp edges, is used for this purpose along with a compressed air source and air gun. The air gun should have necessary protective guards and be capable of delivering air at 10 ft^3/min at 80 psi. A scale or rule with 1 mm divisions is used to mark uniform increments along the scribed line. The extent of coating failure is then measured perpendicularly from the center of the scribe at each of the marks, either to one side or both sides of the scribe. The information from individual data points and averages are then entered into reports for further examination, processing, and analysis.

ASTM D 1654 covers preliminary treatment of scribed or unscribed test specimens. The standard provides information on the protection for cut edges with wax, tape, or other means. Posttest procedures prior to evaluation of test results detail cleaning methods such as rinsing, compressed air removal of corrosion products, and scraping and towel-drying or compressed-air drying. Directions for evaluation of the general surface condition, recording of data such as the percent of failed area, and the evaluation of unprotected edges are present also.

Post-Test Procedures for Test Specimen Evaluation. The ASTM D 1654 Standard directs the use of ASTM D 610 for evaluating the degree of rusting on painted steel surfaces and ASTM D 714 for evaluating the degree of blistering of paints. These two standards are representative of the type of evaluation and reporting necessary for some types of observed corrosion test results and provide examples of standardized rating methods for corrosion test results.

The ASTM D 610 Standard Test Method for Evaluating Degree of Rusting on Painted Steel Surfaces (Ref 14) includes a numerical evaluation scale to enable convenient rating of observed corrosion on tested pieces as follows:

Scale	Description
10	No rusting or <0.01% of surface rusted
9	Minute rusting <0.03% of surface rusted
8	Few isolated rust spots <0.1% of surface rusted
7	<0.3% of surface rusted
6	Extensive rust spots but <1% of surface
5	Rusting to the extent of 3% of surface rusted
4	Rusting to extent of 10% of surface rusted
3	Approximately $\frac{1}{6}$of surface rusted
2	Approximately $\frac{1}{3}$of surface rusted
1	Approximately $\frac{1}{2}$of surface rusted
0	Approximately 100% of surface rusted

Pictorial reference images are also included to aid evaluation.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

ASTM D 714, Standard Test Method for Evaluating Degree of Blistering of Paints (Ref 15) is similar to ASTM D 610 in that a numeric code is given for reporting type, size, and frequency of blistering as a result of testing. Reference photographic images are included to aid the evaluation. ASTM D 714 suggests the use of certain recommended descriptive terms, such as *medium, few,* and so forth in standardized reporting format. The photographic reference images illustrating blistering are to be used in conjunction with the following numeric reporting scale:

Size	Description
10	No blistering
8	Smallest size easily seen by unaided eye
6, 4, 2	Progressively larger sizes

Descriptive terms for frequency are dense, medium dense, medium, and few. Quantitative physical descriptions should include (by actual count):

- Size distribution by unit area
- Frequency of occurrence per unit area
- Pattern of distribution over surface

Descriptions of the shape of the blisters should include terms such as *small clusters* or *large patches.*
ASTM G 46, “Guide for Examination and Evaluation of Pitting Corrosion” (Ref 16) aids in evaluating this type of corrosion. Standards are included as references for reporting results.
After examinations, evaluations and interpretations of test results are performed, the information needs to be communicated. Industry- wide standardized report forms are generally used. There are, instead, many more specific, even proprietary, report forms designated by individual organizations, groups, and specific industries for particular materials and coatings. As a guide, some generalized information and categories recorded are listed subsequently.
Two areas of interest are the test environmental conditions produced in the exposure zone and test results observed on the tested specimens. Pertinent information to record for each follows:

Exposure data:

- Test identification/designation
- Type of salt and water used
- Exposure zone temperature
- Daily records of fog collection
- Volume of salt solution condensate collected (mL/h per 80 cm^2 collector)
- Salt concentration (% NaCl in H_2O) or specific gravity of collected condensed salt solution at 35 °C
- pH of collected solution

Test specimen data and observed results:

- Complete description of material/coating tested, including substrate used where appropriate
- Part identification/code/number/drawing reference
- Type of specimen
- Part dimensions
- Method of preparation/cleaning (before and after testing). Report cleaning standard identification number (example: ASTM D 609).
- Method of supporting or suspending test specimen in chamber
- Description of edge protection
- Exposure period (start and end times and dates of exposure)
- Interruptions in exposure: cause and length of time
- Results of all inspections

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In addition to other formats, reporting of results can be enhanced with the inclusion of chart recorder output, photographs of the tested piece/ material illustrating corrosion effects, and digital scans (preferably color) of the surface of the tested piece/material illustrating corrosion effects.

Salt Spray Test Chamber Apparatus

Salt spray cabinets are available from many manufacturers and range in size from extremely small bench-top cabinets to large walk-in and drive-in types. The ISO salt spray (fog) test specification (ISO 9227) indicates a minimum chamber size of 0.2 m^3 (8 ft^3) interior volume with a recommended minimum volume of 0.4 m^3 (16 ft^3). It has been found that small bench-top models are usually not practical since it can be difficult to obtain and control an adequate, uniform corrosive atmosphere. This is, in part, because of the small confined area used to produce the necessary homogeneous atmosphere. Larger walk-in or drive-in types (Fig. 1) are produced and are able to generate required test atmosphere specifications throughout the larger exposure zone.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

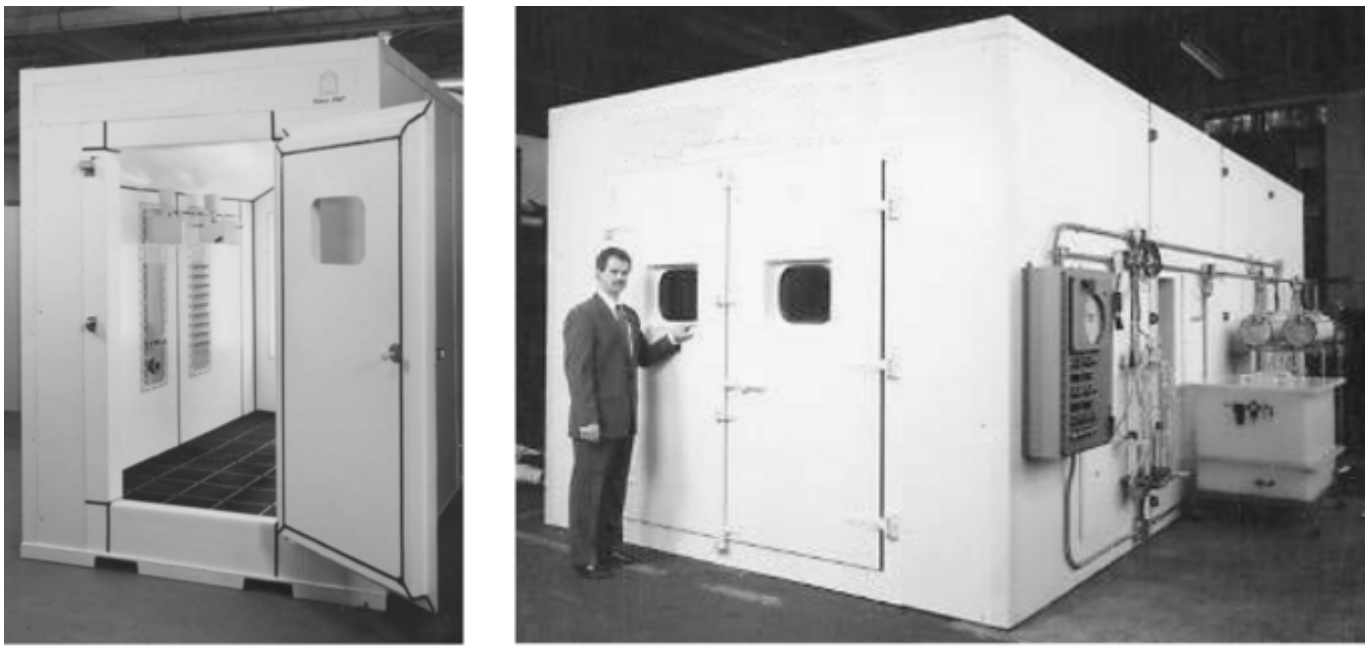

Fig. 1 Large test chambers. (a) Walk-in type. (b) Drive-in type

The most commonly used type of corrosion test chamber is the top-opening type (Fig. 2), which can range in size from 0.25 to 4.5 m^3 (9 to 160 ft^3) and larger. It should be large enough to hold the required number of parts adequately without overcrowding. Make sure also that adequate space is allowed for the size (length, width, and height) in required testing position, as well as the number of necessary test pieces.

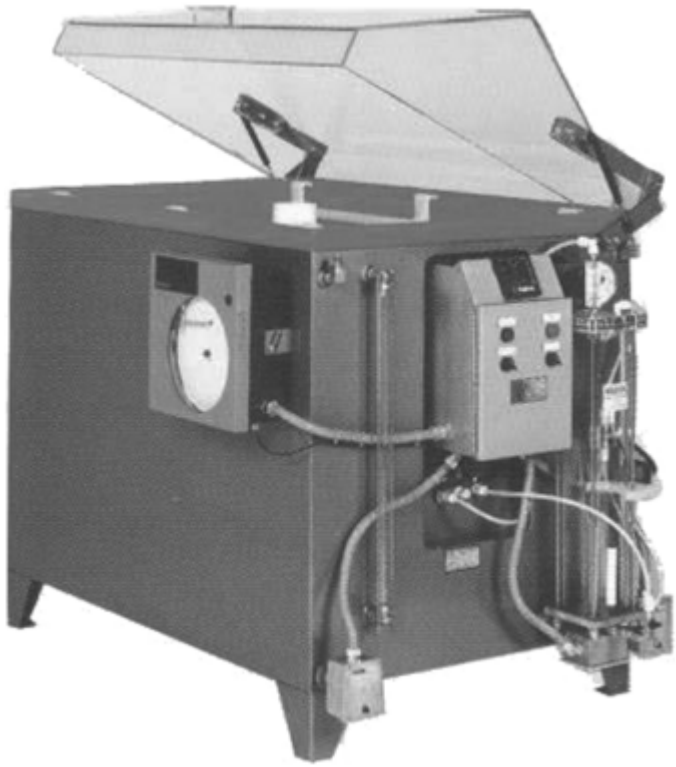

Fig. 2 A commonly used open-top corrosion test chamber

Most corrosion test chambers are constructed of plastic (fabricated or molded), fiberglass (usually molded) (Fig. 3), or, more commonly, of steel with a plastic-lined interior (exposure zone) surface. It is important that all test chambers have no exposed metals or corrodible materials in the interior (exposure zone) testing area.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 3 A corrosion test chamber constructed of molded fiberglass

Major components of a corrosion test chamber consist of the components shown in Fig. 4 and described as follows:

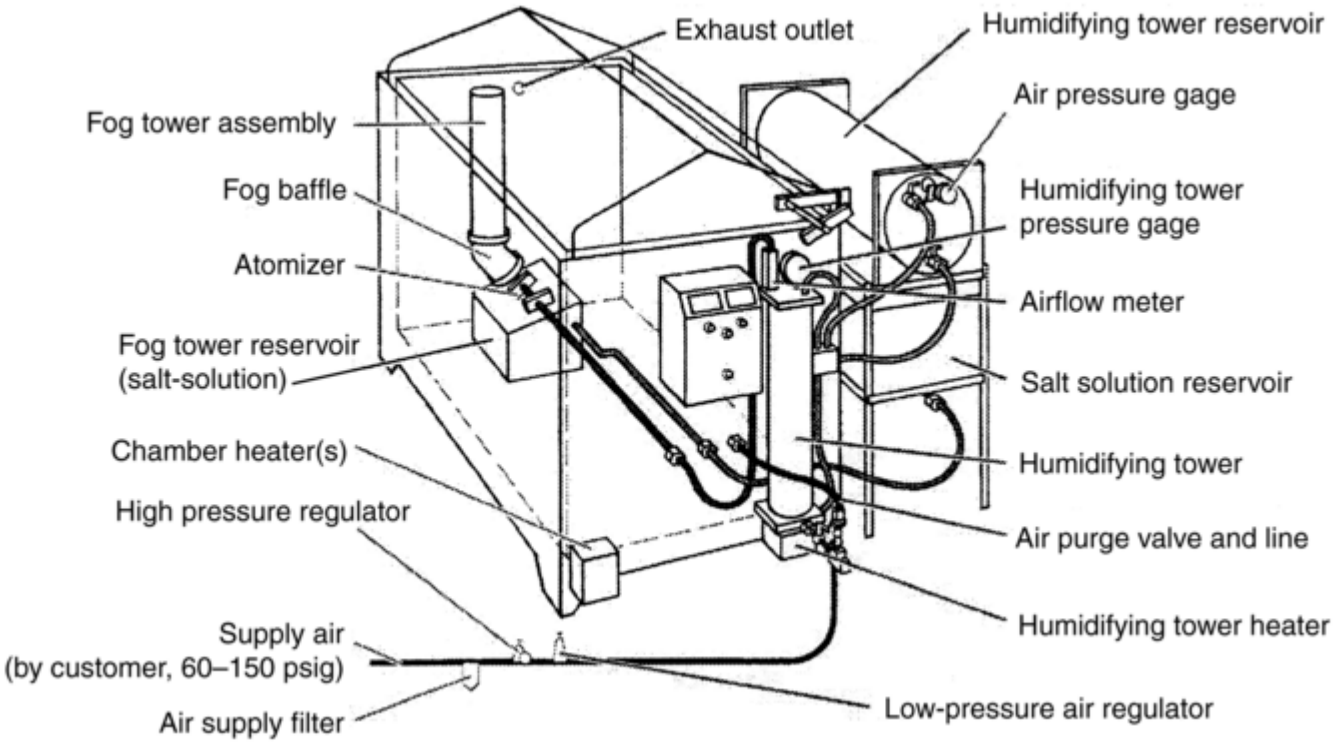

Fig. 4 A diagram of a standard salt-fog corrosion test chamber shows key components of the environment conditioning and control systems.

Compressed-air conditioning apparatus. Usually in the form of a tower, the conditioning apparatus is for heating and humidification (saturation) of the compressed-air supply. Since compressed-air is needed to atomize the salt (electrolyte) solution into the corrosive fog, it must be properly conditioned and controlled to promote uniformity and consistency of test results. To help accomplish this, the tower(s) must be equipped with suitable automatic controls to maintain (a) required temperature and (b) DI water-solution level. An uninterrupted supply of DI water is also necessary for the humidification process. The supply can take the form of (a) an automatic pressurized DI water supply system or (b) a refillable, DI water supply reservoir with

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

automatic level controls. The tower apparatus should properly condition the compressed air used to atomize the salt solution into a corrosive fog.
Exposure-zone heating apparatus. Along with suitable controls, the exposure-zone heating apparatus will properly maintain required chamber temperature(s). The controls should include temperature displays that indicate both (a) the humidifying (saturation) tower temperature and (b) the wet and dry bulb exposure zone temperatures (in order that RH may be determined for the tests).
A continuously available supply of salt (electrolyte) solution. Usually the salt-solution supply is from a reservoir system. It is necessary that an internal (exposure zone) reservoir be included in order that the salt solution can be preheated to meet the requirement that the solution be atomized at the test temperature. For this reason, the solution supply system requires automatic level controls.
Plastic atomizing nozzle(s). Usually such nozzles are mounted in a fog-generation tower(s) apparatus with adequate internal baffling to prevent direct impingement of the spray on the test pieces. The number of fog generation units (usually towers) required is dependent on the creation of enough fog density and uniformity, to produce 1 to 2 mL (for most test fog cycles) of fog condensate per hour of operation in each collection device (usually a plastic 100 mL graduated cylinder with an 80 cm^2 funnel mounted on top).
Specimen (test piece) supports are generally of inert material and can include fiberglass angle bars, plastic or wood bars, trays with angled slots or special mounting provisions, mesh tray panels of polypropylene, for example, and fishing line to tie or suspend test pieces (Fig. 5).

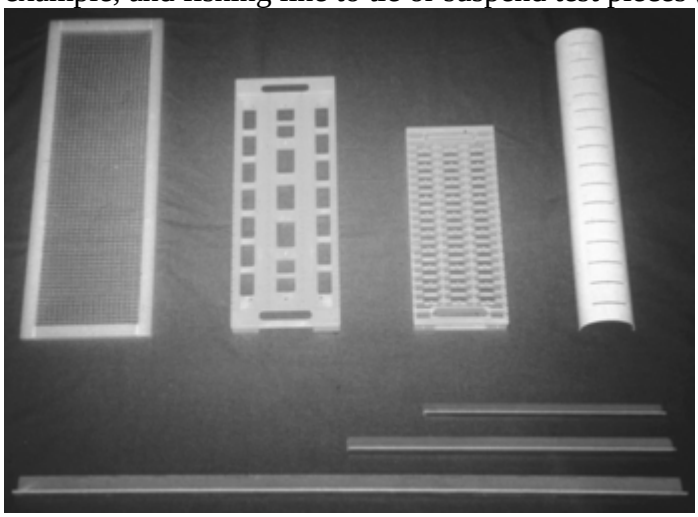

Fig. 5 Specimen supports used within test chambers. Trays, bar, and slotted fixtures are made of materials such as fiberglass and polypropylene that are inert in the test environment.

The dominant surface (principal surface of interest) of the test piece is generally mounted 15 to 30 degrees from the vertical. Sometimes the designation is either vertical or 6 degrees from vertical. Location, position, orientation, and fixturing of test specimens should be decided prior to the commencement of any testing. A good practice is to orient the dominant surface of the test piece(s) parallel with the principal direction of flow (the direction from the fog generation unit to the chamber exhaust) to reduce variability resulting from other orientations.
Another suggestion is to visually divide the exposure zone into at least four horizontal zones and locate the test pieces in each of the four zones for one quarter of the total test time. This procedure should maximize the repeatability of test results by assuring each test specimen receives uniform exposure.
Test specimens and collecting devices should be located no closer than 10 cm (4 in.) from the walls of the exposure zone. A separation of 20 cm (8 in.) should set apart the collecting device from the fog-generation (atomizing) tower(s). This allows the fog atmosphere to circulate evenly about all test specimen surfaces.
The top orifice of the collecting device should be located at the mean or average (vertical) height of the subject test pieces in the exposure zone. Leave adequate spacing (no less than 2.5 cm, or 1 in., is recommended) between adjacent average- or larger-sized, test specimens for proper flow of fog atmosphere to all surfaces. Do not position test pieces above others where dripping onto lower pieces would cause unpredictable or nonuniform patterns of corrosion and unrealistic results.
A bottom drain for the exposure zone should be provided in order to continuously dispose of the accumulating condensed fog. Some chamber drain systems are equipped with a trap that allows continuous draining while

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

maintaining approximately 2.5 cm (1 in.) of condensed solution in the bottom of the chamber. This is referred to as a “wet bottom” condition. The advantage is that the higher RH values necessary for proper fog collection are more easily achieved. The “wet bottom” condition is, however, not desirable for “dry off” cyclic test steps. For those situations, automatic, or manual valves are operated during those steps to allow the bottom to drain completely.

An exhaust system for the exposure zone vents the unit and eliminates the corrosive fog from entering the ambient atmosphere.

Temperature recording device(s) and/or data- logging software automatically reports test conditions on a continuous basis for record verification and auditing purposes.

In addition to including the previously mentioned features, most cyclic-capable corrosion test chambers incorporate computers and programmable logic controls (PLC) that allow the cyclic test sequences to be performed automatically without the need for an attendant.

Test chambers with computer (PLC or PC) control can include the ability to furnish controlled RH atmospheres. This ability is very useful for cyclic corrosion testing procedures that subject test specimens to a designated sequence of changed environmental conditions for more realistic test results. Computer controlled test chambers also may include the ability for automatic data logging and output for reporting purposes of test conditions. Data obtained can be used for real-time display in graph format or manipulated in spreadsheet-type software for use in reports.

Some corrosion test chambers equipped with computer control can be operated over a local area network (LAN) for remote monitoring and control of the tests. Operators of test chambers of this type can observe current test condition and data information, and they can change tests, adjust test set-point parameters remotely, and operate several test chambers from one PC.

Introduction

CORROSION resulting from the presence and activities of microbes on metals and metal alloys is generally referred to as microbiologically influenced corrosion (MIC). Microbiologically mediated reactions can alter both rates and types of electrochemical reactions, but do not result in a unique manifestation of corrosion. Rather, MIC can produce a broad range of outcomes from severe localized corrosion to significant reductions in corrosion rate (Ref 1). Pitting, crevice corrosion, differential aeration cells, metal concentration cells, selective dealloying, enhanced erosion, and enhanced galvanic corrosion can result from MIC. Most MIC studies have focused on bacterial involvement; however, other single-celled organisms—such as fungi, yeast, and diatoms—can influence corrosion processes. Numerous test kits are available for culturing microorganisms known to influence corrosion. However, accurate diagnosis of MIC requires a combination of microbiological, surface analytical, and electrochemical techniques. Because microorganisms are ubiquitous and can be attracted to both anodic (Ref 2) and cathodic (Ref 3) sites, spatial relationships between microorganisms and corrosion products are not sufficient on their own to be interpreted as MIC. The following section describes biofilm formation and structure, microbial processes influencing corrosion, and electrochemical techniques used to study and monitor MIC.

Biofilm Formation

Cells attach to wet solid surfaces and produce a biofilm consisting of a matrix of polymeric substances and cells in microcolonies (Ref 4, 5, 6, 7, 8). Biofilm formation consists of a sequence of steps (Fig. 1) and begins with adsorption of macromolecules (proteins, polysaccharides, and humic acids) and smaller molecules (fatty acids, lipids) on solid surfaces. Adsorbed molecules or conditioning films alter physiochemical characteristics of the water/surface interface, including hydrophobicity and surface charge.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

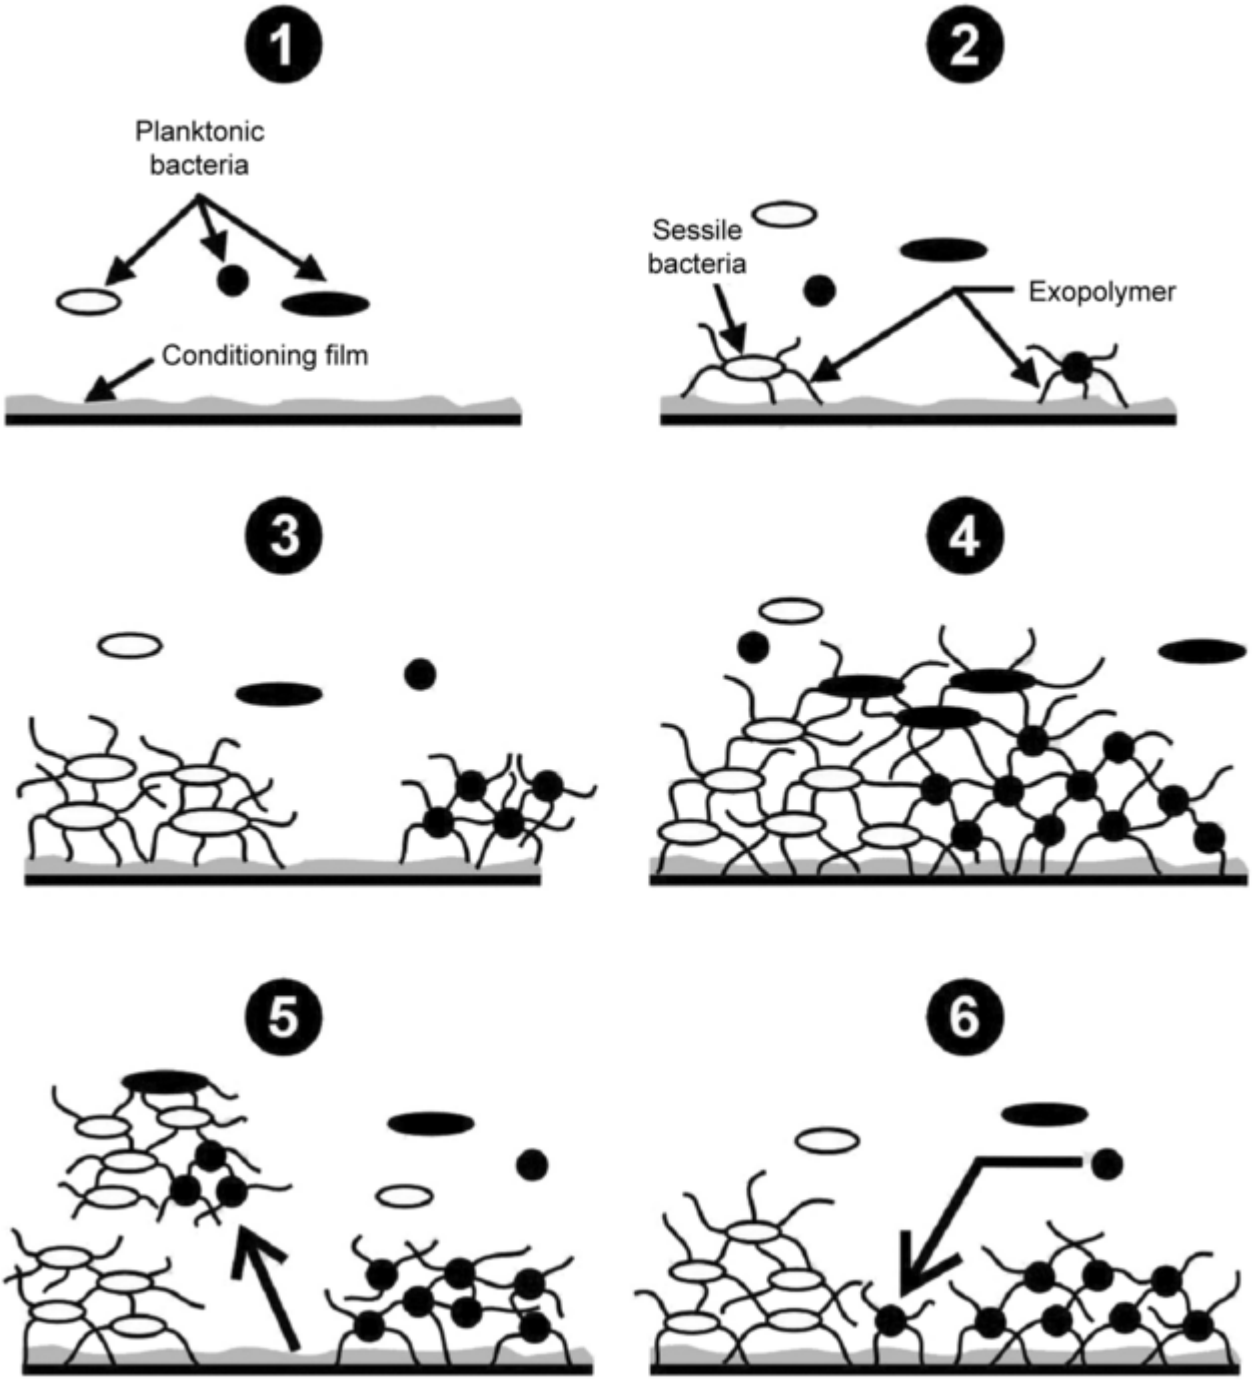

Fig. 1 Conceptual illustration of heterogeneous biofilm structure. (1) Initial attachment to substratum. (2) Synthesis of extracellular polymeric substances to establish more secure association with substratum. (3) Bacterial replication on the substratum and microcolony formation. (4) Formation of mature biofilm. (5) Sloughing and detachment of portions of biofilm. (6) Recolonization of areas of substratum exposed by sloughing events. Courtesy of the Center for Biofilm Engineering at Montana State University, Bozeman; Illustrator, P. Dirckx

Hydrodynamics play a major role in controlling the rate of microbial colonization during initial stages of biofilm formation. Transport of microorganisms to an interface and subsequent attachment are mediated by: diffusive transport due to Brownian motion, convective transport due to liquid flow, and active movement of motile bacteria near the interface. The influence of convective transport exceeds the other two mechanisms by several orders of magnitude. Once a microbial cell is in contact with a surface it may or may not adhere. The ratio of adhering cells to the total number of cells transported to an interface depends on substratum properties (including charge density), physiological state of the microbes, hydrodynamics, and nutritional signals from the environment. For many bacteria, attachment requires cell-surface appendages (fimbriae, pili) or adhesive substances (Ref 6, 7).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Immediately after attachment, microorganisms initiate production of adhesive substances, predominantly exopolysaccharides (Ref 7), collectively known as extracellular polymeric substances (EPS), that provide the biofilm matrix. Extracellular polymeric substances bridge microbial cells with the substratum and permit negatively charged bacteria to adhere to both negatively and positively charged surfaces.

Biofilm formation proceeds with division of cells and recruitment of planktonic cells to form a complicated architectural structure and ends with detachment of individual cells and aggregates (Fig. 1) (Ref 9, 10). The architectural structure is typically composed of pillar- and mushroom-shaped cell clusters separated by water channels that allow nutrients in and waste products out (see Fig. 2 in the article “Microbiologically Influenced Corrosion” in this Volume). Biofilm accumulation at surfaces is a self-perpetuating and continuous process. Initial colonization increases surface irregularity and promotes recruitment of additional free-swimming cells, promoting further surface irregularity. Each species in a biofilm has its own growth parameters, and there appear to be spatial distributions of growth (Ref 11). Development of specialized multicellular biofilm structures can involve cell-to-cell signaling (quorum sensing) among cells in close proximity (Ref 12, 13). Detachment includes two processes: sloughing and erosion. Sloughing is the process in which large pieces of biofilm are removed, exposing the underlying surface. Reasons for biofilm sloughing are not well understood. Biofilm erosion is the continuous removal of single cells or small groups of cells from the biofilm and is driven by shear stress at the biofilm/fluid interface. An increase in shear stress increases erosion rate and decreases biofilm accumulation rate. Empirical observations indicate that erosion rate is related to flow velocity, biofilm thickness, density, and tertiary structure (Ref 14).

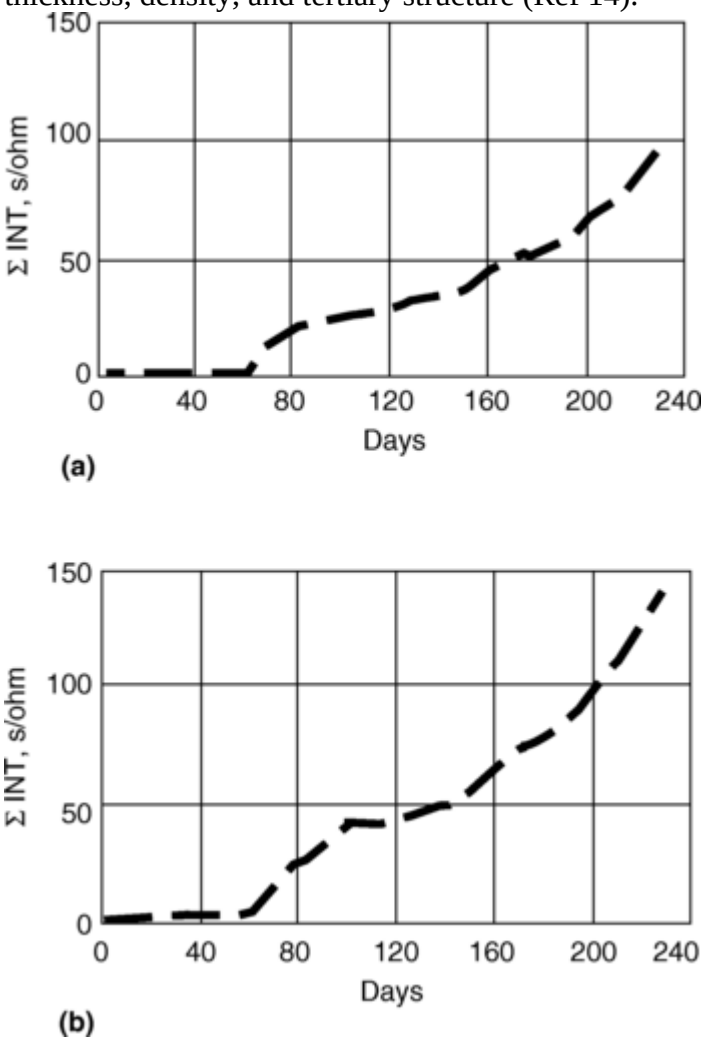

Fig. 2 Cumulative corrosion loss, ΣINT, for mild steel sensors embedded in concrete and exposed in a sewer bypass. (a) Control sample. (b) Flushed sample

Biofilms are capable of maintaining environments at biofilm/surface interfaces that are radically different from the bulk fluid in terms of pH, dissolved oxygen, and other organic and inorganic species. In some cases, these interfacial conditions could not be maintained in the bulk medium at room temperature near atmospheric

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

pressure. The consequence is that microorganisms within biofilms facilitate reactions that are not predicted by thermodynamic arguments based on the chemistry of the bulk medium.

Mechanisms

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The most serious MIC takes place in the presence of microbial consortia where many types of microorganisms are present within the structure of the biofilm. These include sulfate-reducing bacteria (SRB), metal-oxidizing and metal-reducing bacteria (MRB), acid-producing and slime-producing bacteria, hydrogen-consuming and hydrogen-producing bacteria, and metal-depositing bacteria, plus other forms of aerobic and anaerobic microbes (Fig. 3).

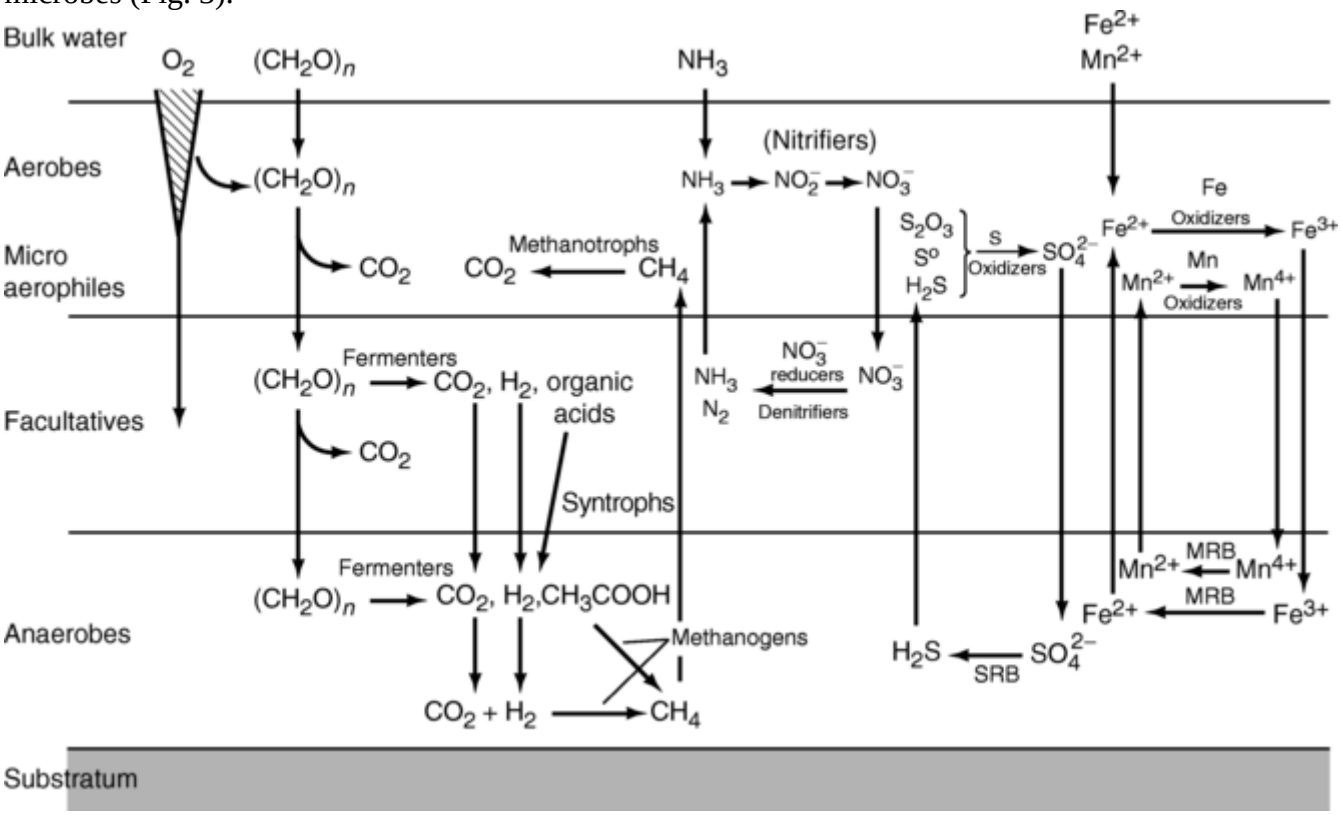

Fig. 3 Possible reactions that can occur in a biofilm

Sulfate-reducing bacteria are a phylogenetically diverse group of anaerobic bacteria found in natural and industrial environments. Sulfate- reducing bacteria use sulfate as the terminal electron acceptor during respiration and produce hydrogen sulfide. When the aerobic respiration rate within a biofilm is greater than the oxygen diffusion rate, the metal/biofilm interface can become anaerobic and provide a niche for SRB. The critical biofilm thickness required to produce anaerobic conditions depends on availability of oxygen and the respiration rates of organisms in the biofilm. The corrosion rate of iron and copper alloys in the presence of hydrogen sulfide is accelerated by the formation of iron sulfide minerals that stimulate the cathodic reaction.

Some microorganisms couple manganese and iron oxidation and reduction reactions to cell growth and metabolism of organic carbon. Manganese oxide deposited by microorganisms on stainless and mild steel alters the electrochemical properties pertaining to open-circuit potential or corrosion potential (E_{corr}) (Ref 15, 16). Iron-oxidizing bacteria produce tubercles of iron oxides and hydroxides creating oxygen-concentration cells that initiate a series of events that individually or collectively are very corrosive. Other microorganisms promote corrosion of iron and its alloys through dissimilatory metal reduction reactions that lead to the dissolution of protective iron oxide/hydroxide films on the metal surface. Passive layers are either lost or replaced by less stable films that allow further corrosion (Ref 17).

Bacteria and fungi produce a wide variety of organic acids (e.g., acetic, formic, lactic, succinic) as by-products of metabolism that are capable of initiating or accelerating corrosion (Ref 18, 19). Mineral acids, such as sulfuric, produced by some bacteria are very corrosive. The EPS may also control interfacial chemistry at a metal/ biofilm interface and thereby affect the rate of metal dissolution. Extracellular polymeric substances are also implicated in increased resistance of cells to biocides and other antimicrobial compounds (Ref 20, 21).

Inhibition of general corrosion by biofilms has been reported for mild steel, copper, aluminum, and stainless steels (Ref 22, 23, 24, 25, 26, 27). The mechanisms most frequently cited for the inhibition are:

- Formation of a diffusion barrier to corrosion products that stifles metal dissolution

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

- Consumption of oxygen by respiring aerobic microorganisms within the biofilm causing a diminution of that reactant at the metal surface
- Production of metabolic products that act as corrosion inhibitors (e.g., siderophores) or specific antibiotics that prevent proliferation of corrosion-causing organisms (e.g., SRB)
- Formation of passive layers that are unique to the presence of microorganisms

Electrochemical Techniques

Electrochemical techniques used to study MIC include those in which no external signal is applied (redox potential, E_{corr}, electrochemical noise, or ECN), those in which only a small potential or current perturbation is applied (polarization resistance, electrochemical impedance spectroscopy), and those in which the potential is scanned over a wide range (anodic and cathodic polarization curves, pitting scans). Galvanic current flowing between biotic and abiotic cells has also been measured using a dual-cell technique (also called “biological battery”). Current and potential mapping have been used to locate anodic and cathodic sites, and microsensors have been applied to determine concentration profiles in biofilms. Background for the most widely used electrochemical techniques and examples of applications to MIC are presented in the following sections.

Open-circuit or corrosion potential measurements require a stable reference electrode— usually assumed to be unaffected by biofilm formation—and a high-impedance voltmeter. E_{corr} values are difficult to interpret, especially when related to MIC (Ref 28). Despite this limitation, probably no other phenomenon has fascinated those studying MIC more than ennoblement, that is, the increase of E_{corr} due to formation of a biofilm on a metal surface.

Ennoblement has been observed mainly for stainless steels exposed to natural seawater (Fig. 4) (Ref 29, 30, 31, 32, 33, 34). Explanations for microbially influenced ennoblement include microbial production of hydrogen peroxide, corrosion inhibitors, extracellular substances, organometallic complexes, enzymes, and changes of cathodic properties of stainless steels as a result of microbial activity. Early explanations used thermodynamic arguments suggesting that the reversible potential (E^o) of the oxygen electrode increased in the presence of biofilms due to either an increase in partial pressure of oxygen or a decrease of surface pH. Since E^o increases only very slightly with an increase of oxygen pressure and since it is unlikely that acidification would increase passivity, those explanations were rejected.

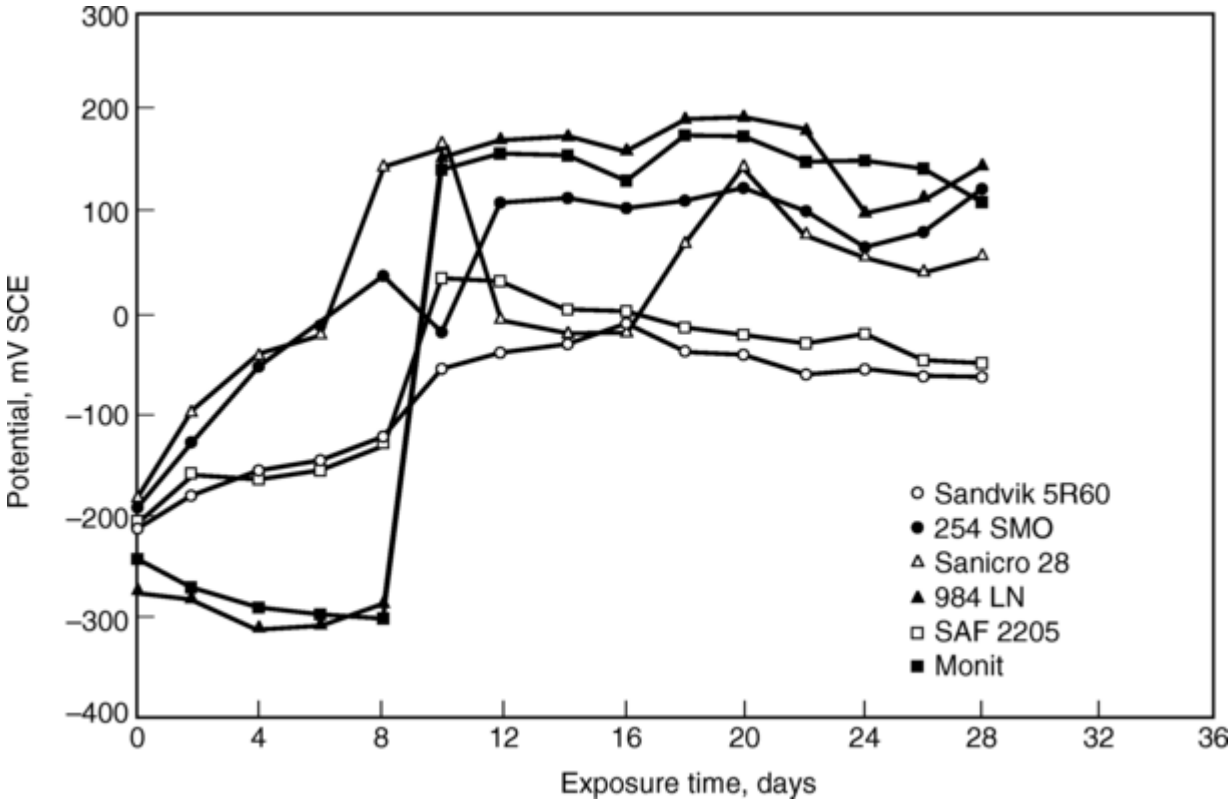

Fig. 4 Potential measured on freely exposed specimens in natural seawater at a velocity of 0.5 m/s. SCE, saturated calomel electrode

Results by Linhardt (Ref 35, 36), Olesen et al. (Ref 15, 16), and Dickinson et al. (Ref 37, 38) demonstrated ennoblement of stainless steels in river waters due to microbial deposition of MnO_2. Linhardt found large amounts of manganese minerals (mainly MnOOH and MnO_2) on severely pitted turbine runner blades in a hydroelectric plant and suggested that pitting was due to biomineralized manganese oxides. Von Rege et al. reported severe pitting around welds in type 316 stainless steel pipes used to pump cooling water from the Rhine River (Ref 39). He reported that the failure mechanism involved iron- and manganese-oxidizing bacteria causing ennoblement and pitting. Linhardt (Ref 36) concluded that ennoblement was due to the formation of MnO_2 according to:

$$Mn^{2+} + 2H_2O \rightarrow MnO_2 + 4H^+ + 2e^- \quad \text{(Eq 1)}$$

Pitting occurred as a result of galvanic interaction between areas covered by manganese oxides acting as cathodes and bare stainless steel surfaces serving as anodes. Dickinson et al. (Ref 37, 38) observed an increase of E_{corr} from -150 mV to +350 mV versus saturated calomel electrode (SCE) for 316L stainless steel exposed to a fresh water creek over a 30 day period. The authors concluded that ennoblement was due to microbial deposition of manganese oxides.

The polarization resistance technique can be used to continuously monitor instantaneous corrosion rate of a metal or alloy exposed to a corrosive environment. Mansfeld (Ref 40) and more recently Scully (Ref 41) reviewed the background and use of polarization resistance (R_p) for measurement of corrosion currents. See the section “Polarization Resistance Method” in the article “Electrochemical Methods of Corrosion Testing” in this Volume for more details. R_p is defined as the slope of a potential (E) versus current density (i) curve at E_{corr}, where $i = 0$:

$$R_p = \left(\frac{dE}{di}\right)_{i=0} = 0 \quad \text{(Eq 2)}$$

Corrosion current density (i_{corr}) is calculated from R_p by:

$$i_{corr} = B/R_p \quad \text{(Eq 3)}$$

where

$$B = \beta_a\beta_c/2.303(\beta_a + \beta_c) \quad \text{(Eq 4)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The exact calculation of i_{corr} for a given time requires simultaneous measurements of R_p and anodic (β_a) and cathodic (β_c) Tafel slopes (Ref 42).

A simplification of the polarization resistance technique is the linear polarization technique in which it is assumed that the relationship between E and i is linear in a narrow range around E_{corr}. Usually only two points (E, i) are measured and B is assumed to have a constant value of about 20 mV. This approach is used in field tests and forms the basis of commercial corrosion rate monitors.

Keresztes et al. (Ref 43) studied the effect of *Desulfovibrio desulfuricans* on anaerobic corrosion of mild steel and brass using linear polarization and atomic force microscopy. The influence of biocides—*N*-hydroxy-methyl-glycine (GLY) and *N*-hydroxy-methylphenyl-alanine (PHE)—on corrosion rates was determined (Fig. 5). Corrosion rates for mild steel were lower in the presence of GLY. For brass, both biocides reduced corrosion rates compared to those observed for the sterile solution. The authors used these data in combination with results from polarization curves to obtain mechanistic information on the influence of biocides on MIC of mild steel and brass.

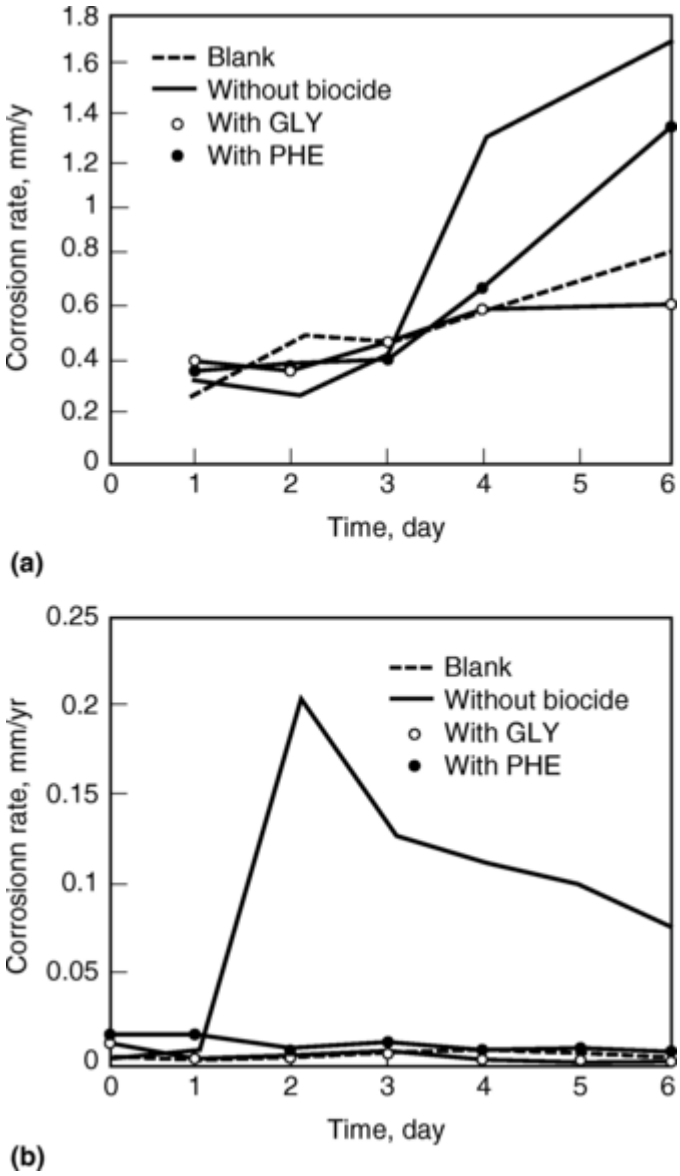

Fig. 5 Corrosion rate in the culture of *Desulfovibrio desulfuricans* for specimens with and without biocide treatment. (a) Mild steel. (b) Brass. GLY, *N*-hydroxy-methyl-glycine; PHE, *N*-hydroxy-methylphenyl-alanine

Mansfeld et al. (Ref 44) used linear polarization to determine R_p for mild steel sensors embedded in concrete exposed to a sewer environment. One concrete sample was periodically flushed with sewage to remove sulfuric acid (H_2SO_4) produced by sulfur-oxidizing bacteria. Another sample was used as a control. A data- logging system collected R_p at 10 min intervals simultaneously for the two corrosion sensors and two pH electrodes

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

placed at the concrete surface. Figure 2 shows the cumulative corrosion loss, ΣINT, obtained by integration of the $1/R_p$ versus time curves as:

$$\Sigma INT = \int \frac{1}{R_p} dt \qquad \text{(Eq 5)}$$

A qualitative measure of the corrosion rate can be obtained from the slope of the curves in Fig. 2. ΣINT is given in units of s/Ω. Because of uncompensated ohmic resistance and lack of precise values for Tafel slopes, data in Fig. 2 should be viewed as a qualitative measure of changes in corrosion rates. Corrosion losses remained low during the first two months followed by a large increase for both the flushed sample and the control sample. Increased corrosion rates of the embedded steel electrodes occurred when surface pH reached values of 1 or less due to accumulation of H_2SO_4. Total corrosion loss determined from integrated R_p data was less for the control sample than for the flushed sample.

Large signal polarization is applied to obtain potentiostatic or potentiodynamic polarization curves, as well as pitting scans. Polarization curves can be used to determine i_{corr} by Tafel extrapolation, while mass-transport-related phenomena can be evaluated based on the limiting current density (i_{lim}) Mechanistic information can be obtained from experimental values of β_a and β_c. In metal/electrolyte systems for which an active-passive transition occurs, the passive properties can be evaluated based on the critical potential (E_{crit}) and critical current density for passivation (i_{crit}), and the passive current density (i_{pass}). Pitting scans are used to determine pitting potential (E_{pit}) and protection potential (E_{prot}). A disadvantage of large-signal polarization is its destructive nature, that is, the irreversible changes of surface properties due to application of large anodic or cathodic potentials. Polarization curves are usually obtained for sterile solutions and solutions containing microorganisms (Ref 43) (Fig. 6).

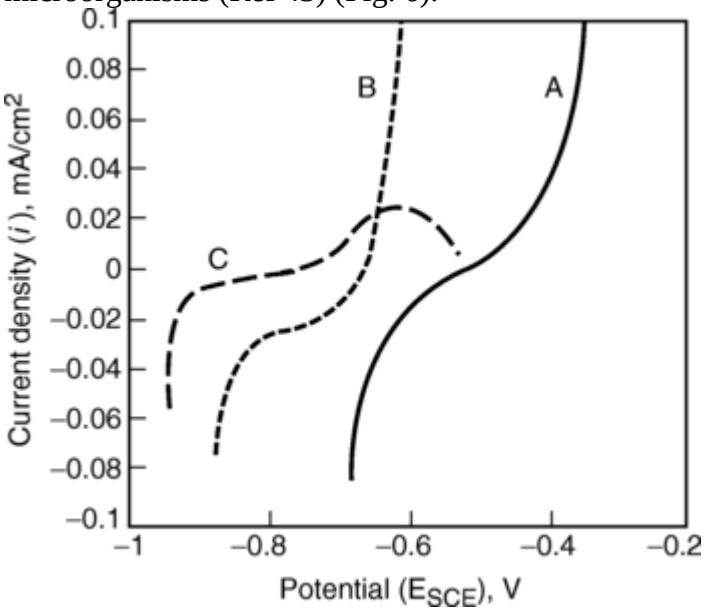

Fig. 6 Polarization curves measured on mild steel in the solution of biogenic and chemical sulfide. A, blank; B, biogenic sulfide; C, chemical sulfide

Electrochemical impedance spectroscopy (EIS) has been used in mechanistic studies of MIC (Ref 28). This development has been made possible in part by the availability of equipment that optimizes data collection in a wide range of frequencies and impedance values. In addition, software is available for fitting experimental data to appropriate equivalent circuits. The impact of microorganisms on corrosion protection of mild steel by polymer coatings was evaluated by Mansfeld and coworkers using EIS and electrochemical noise (ECN) to monitor coating degradation during exposure to natural seawater for periods up three years (Ref 45, 46). Figure 7 gives an example for impedance spectra over a seven-month period for a four coatings (thickness ≈ 200 μm). Impedance spectra show a gradual decrease of the impedance modulus $|Z|$ with time for all coatings except for an all-epoxy-polyamide system (Fig. 7d). Electrochemical impedance spectroscopy data for polymer coated steel are usually fit to the equivalent circuit shown in Fig. 8(a), where C_c is the coating capacitance, R_{po} is the pore resistance, C_{dl} is the capacitance of the delaminated area (A_d) and R_p is the corresponding polarization

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

resistance. Spectra for thick coatings should be fit to the open-boundary finite-length diffusion (OFLD) model (Fig. 8b) (Ref 46) in which C_c is replaced by a constant-phase element (CPE). The OFLD element is given by:

$$Z_{OFLD} = \frac{\tanh\left(B(j\omega)^{1/2}\right)}{Y_o(j\omega)^{1/2}} \qquad \text{(Eq 6)}$$

where $B = l/(D)^{1/2}$ is the characteristic diffusion parameter, l is the diffusion length, D is the diffusion coefficient, ω is angular frequency ($\omega = 2\pi f$), and $Y_o = (\sigma(2)^{1/2})^{-1}$. For infinite values of l this model becomes the Randles circuit, in which the Warburg impedance (Z_w) is in series with R_p and is given by:

$$Z_w = \sigma(1 - j)\omega^{-1/2} \qquad \text{(Eq 7)}$$

where σ is the Warburg coefficient.

Deterioration of protective coating properties can be followed by determination of A_d estimated from experimental values of R_{po}, C_{dl}, or R_p (Ref 47). In corrosion monitoring it is often not necessary to obtain a full analysis of all impedance spectra, and a simpler approach such as the break-point frequency (f_b) method can be used. A_d can be estimated from f_b, defined as:

$$f_b = \left(2\pi R_{po} C_c\right)^{-1} = A_d \left(2\pi R^{\circ}_{po} C_c\right)^{-1} = \Delta\left(2\pi R^{\circ}_{po} C^{\circ}_c\right)^{-1} \quad \text{(Eq 8)}$$

where R^{o}_{po} is the specific pore resistance (ohm · cm^2) and C^{o}_{c} is the specific coating capacitance (F/cm^2). The damage function, Δ, is equal to A_d/ A_t where A_t is the total exposed area. Figure 9 gives a comparison of Δ values calculated based on Eq 8. The f_b data were converted into Δ values using the results of visual observation according to ASTM D 610 after about 110 days. Excellent agreement was observed between electrochemical and visual data for the remainder of the exposure period.

Fig. 9 Time dependence of damage function, Δ, based on electrochemical data and visual data for exposure to natural and artificial seawater

Electrochemical impedance spectroscopy has been used to evaluate genetically engineered bacteria as alternatives to biocides as inhibitors for MIC (Ref 26). Trandem et al. (Ref 27) used reciprocal polarization resistance ($1/R_p$) to compare corrosion rates of steel samples with and without engineered organisms (Fig. 10) tested in standard service water and service water inoculated with bacteria. Their data indicate that the engineered bacteria significantly reduced the corrosion rate of mild steel.

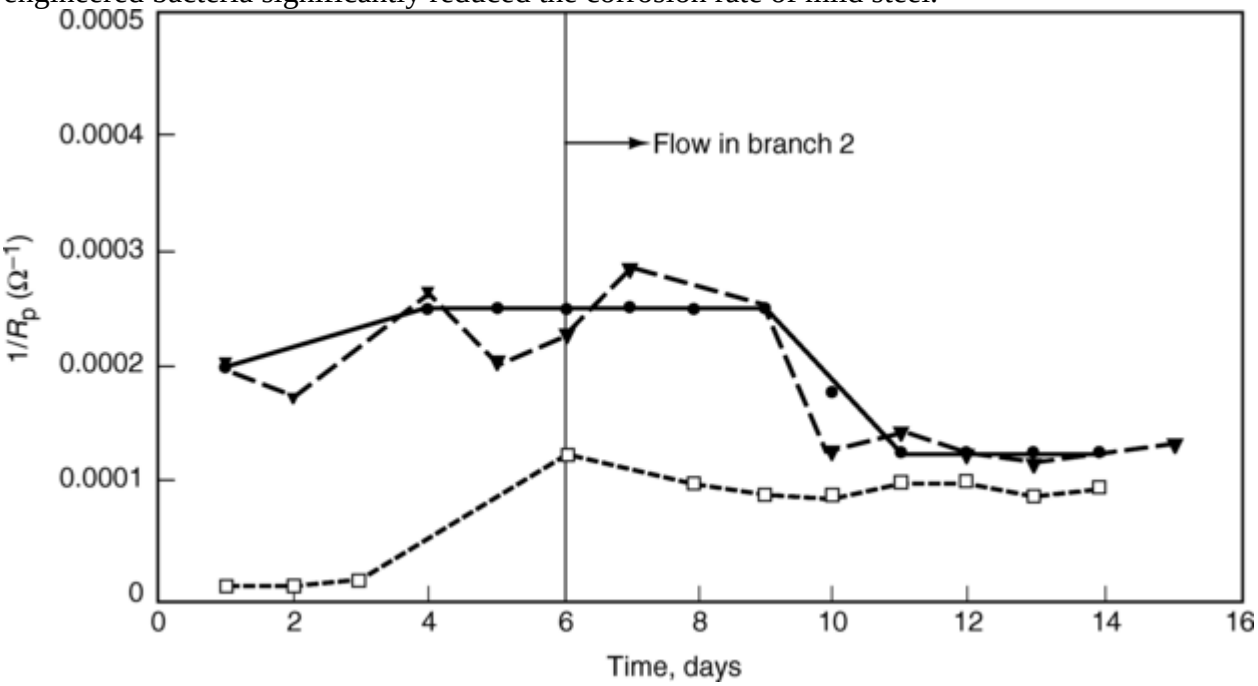

Fig. 10 Comparison of relative corrosion rates ($1/R_P$) for mild steel samples exposed to service water conditions (circle), to engineered bacteria with flow (inverted triangle), and to engineered bacteria without flow (square)

Electrochemical noise (ECN) can be studied as fluctuations of E_{corr}, as fluctuations of potential (E) at an applied current (I) or as the fluctuations of I at an applied E. In laboratory studies, it is possible to measure potential and current fluctuations simultaneously (Ref 49). In this approach, two electrodes of the same materials are coupled through a zero resistance ammeter (ZRA). Current fluctuations are measured using a ZRA, while the potential fluctuations are measured with a high-impedance voltmeter between the two coupled electrodes and a stable reference electrode. The reference electrode can be a SCE, or a third electrode of the same material as the two test electrodes. The latter approach is used commonly in corrosion monitoring. Eden reviewed methods for data collection (Ref 48).

Simultaneous collection of potential and current data allows analysis in time and frequency domains. Bertocci et al. (Ref 50, 51) and Mansfeld et al. (Ref 52) discussed methods of data analysis for this technique in detail. Experimental potential and current fluctuations for polymer-coated steel samples exposed to artificial seawater for 780 days are shown in Fig. 11(a) and (b), respectively, while the corresponding power spectral density (PSD) plots are shown in Fig. 11(c) and (d). The spectral noise plot— also called noise impedance plot—shown in Fig. 11(e) contains the impedance spectrum determined in an independent measurement. Figure 11(e) demonstrates excellent agreement between the two different types of electrochemical measurements.

Analysis of ECN data in the time domain results in values of the mean potential (E_{coup}) and the mean current (I_{coup}) of coupled electrodes. In addition, standard deviations of potential (σV) and current fluctuations (σI), and the noise resistance $R_n = \sigma V/\sigma I$ are obtained. The spectral noise resistance (R^o_{sn}) is defined as the direct-current (dc) limit of the spectral noise plot (Ref 53). The localization index (LI) = $\sigma I/I_{rms}$, where I_{rms} is the root-mean-square value of the current fluctuations, can also be determined (Ref 48). The suggestion that LI can be used to determine the prevailing corrosion mechanism should be viewed with caution (Ref 52).

It is often assumed that R_n is equal to R_p; however, it has been shown for passive systems such as stainless steel or titanium alloys exposed to neutral media that R_n was several orders of magnitude lower than R_p (Ref 52). Similar results were reported for polymer-coated steel. In fact, no relationship between R_n and any properties of the coated steel sample could be found for the epoxy-polyamide-coated steel sample in Fig. 11 (Ref 49).

The main application of ECN data has been in corrosion monitoring. Mansfeld et al. used ECN for remote on-line monitoring of carbon steel electrodes in a test loop of a surge water tank at a gas storage field (Fig. 12). R_n values were compared to corrosion rates obtained from weight loss of the electrodes used for the ECN measurements. R_n (Fig. 12c) and ΣINT (Fig. 12d) values were prepared for one of 19 three- electrode steel probes. ΣINT was converted to total weight loss (grams) as indicated in Fig. 12(d). The weight loss increased sharply in the first two weeks of exposure of fresh steel probes and then leveled off (Fig. 12d). Fairly good agreement between corrosion rates obtained by ENA (CR_{INT}) and weight loss (MCR) was observed as demonstrated in Fig. 12(e). The solid line in this figure was obtained by regression analysis. Results suggest that R_n can serve as useful measure of corrosion rate for systems exhibiting fairly high corrosion rates.

(c) Noise resistance, R_n. (d) Cumulative corrosion loss, ΣINT. (e) CR_{INT} values for 19 noise probes compared with mean corrosion rates (MCR) determined from weight loss

Little et al. used EIS and ENA to examine spatial relationships between marine bacteria and localized corrosion on polymer-coated steel (Ref 54). Samples containing intentional defects in polymer coatings were exposed for 30 days in artificial and natural seawater with and without attached zinc coupons providing cathodic protection

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

to the exposed areas. R_n and R_{sn}^{o} increased with time for all cathodically protected samples. Electrochemical impedance spectroscopy suggested that increases were due to the formation of calcareous deposits in the defects. Surface analysis showed that very few bacteria were present in the defects of cathodically protected samples, while large amounts of bacteria were found in corrosion layers of the freely corroding samples.

Microsensors. Lee and de Beer (Ref 55) described ideal microsensors as having small tip diameters to prevent distortion of the local environment, small sensor surfaces for optimal spatial resolution, low noise levels, stable signal as well as high selectivity and strength to resist breakage. Lewandowski used microelectrodes to determine the oxygen concentration around a microcolony (Ref 56, 57) (Fig. 13). The microcolony was anoxic in the middle, but oxygen was detected at the bottom demonstrating transport via channels and voids.

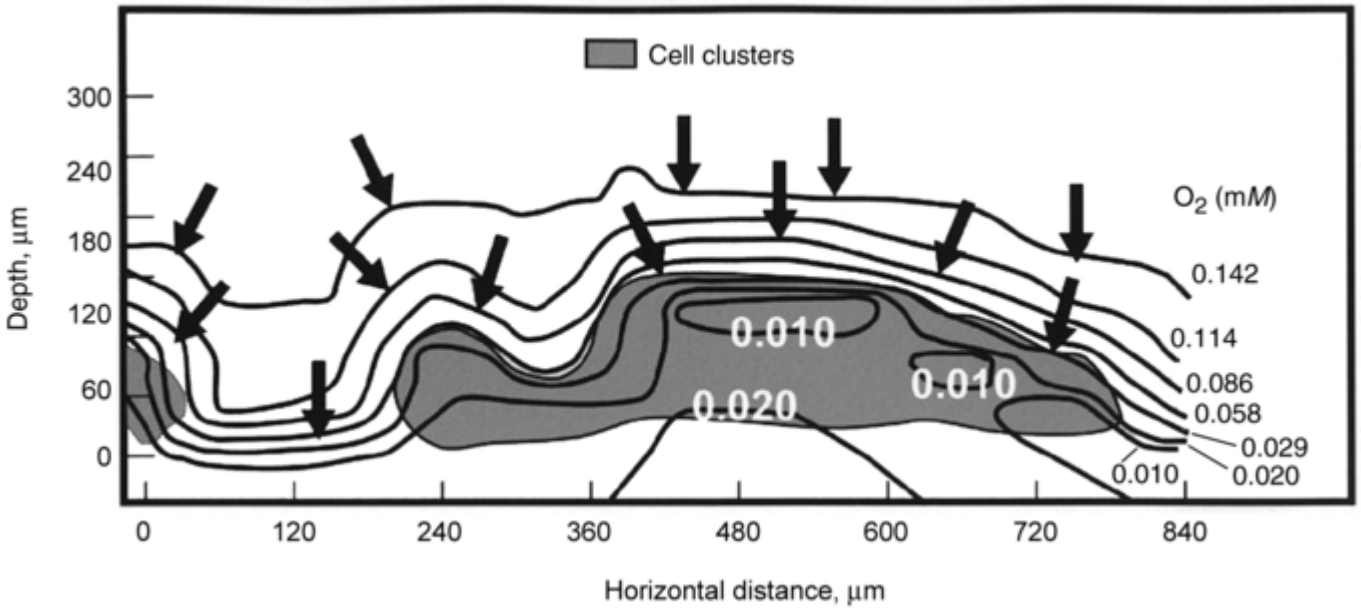

Fig. 13 Oxygen-concentration profiles around a colony of respiring aerobic organisms in an oxygenated environment. Continuous lines are isolines of equal oxygen concentration, while arrows indicate the direction of oxygen fluxes, always perpendicular to the active surface.

Dickinson et al. (Ref 58) used microelectrodes to measure dissolved oxygen and H_2O_2, and local E_{corr} values within biofilm on stainless steel surfaces exposed to river water. Ennoblement was not caused by elevated levels of dissolved oxidants. Measurements at various heights above the substratum and at numerous sites over the coupon surface showed H_2O_2 concentrations to be less than 2 µM. No significant variation in E_{corr} for the stainless steel microelectrode was detected at any site. Dissolved oxygen profiles in the same regions showed saturation levels at all sites.

Scanning vibrating electrode microscopy (SVEM) can provide a sensitive means of locating local anodic and cathodic currents using a vibrating microreference electrode and potential distributions associated with corrosion. Franklin et al. (Ref 2) used autoradiography of bacterial incorporated ^{14}C acetate to locate bacterial metabolic activity and SVEM to locate anodic and cathodic currents on colonized steel surface (Fig. 14). They demonstrated that pit propagation in carbon steel exposed to a phosphate-containing electrolyte required either stagnant conditions or microbial colonization of anodic regions. In sterile, continuously aerated medium, pits initiated and repassivated, while in the absence of aeration, pits initiated and propagated. Pit propagation was observed in continuously aerated medium inoculated with a heterotrophic bacterium. Sites of anodic activity coincided with sites of bacterial activity. Results suggest that bacteria may preferentially attach to the corrosion products formed over pits. Biofilms over anodic sites may create stagnant conditions within corrosion pits that result in pit propagation.

Simulated Service Testing in the Atmosphere

Stephen D. Cramer and Steven A. Matthes, Albany Research Center, U.S. Department of Energy

Introduction

SIMULATED SERVICE TESTING is the most reliable predictor of corrosion behavior short of in-plant tests and actual service experience. Simulated service testing includes exposures of structural components and test specimens in outdoor environments that are representative of many general service situations. These so-called natural environments include exposures to the atmosphere, waters, and soil. They include the full spectrum of chemical, biological, meteorological, geological, and physical influences. Test materials are subjected to the cyclic effects of the weather, the complex chemistry of the atmosphere, the biochemical responses of water and soil, and the dynamic effects of the atmosphere and waters that cannot be realistically duplicated in the laboratory. This type of testing is important for objectives such as materials selection, predicting the probable service life of a product or structure, evaluating new commercial alloys and processes, and calibrating laboratory corrosion tests.

Atmospheric Corrosion

Corrosion or degradation of materials in the atmosphere occurs as the result of natural forces augmented by man-made (or anthropogenic) impacts. The degree of degradation varies for different materials and is influenced by a number of environmental factors. Many of these factors are natural in origin, such as meteorology (or climate), air chemistry, and seasonal and diurnal cycles, but some have man-made origins as well as natural origins. These include sulfur oxides, nitrogen oxides, hydrochloric acid, carbon dioxide, hydrocarbons, and particulate matter produced as fossil fuel and other organic material combustion products. They combine in a complex mix of chemical and physical processes that deliver reactive chemical species to exposed surfaces in wet and dry deposition processes that affect the corrosion or degradation of these surfaces (Ref 1).

While most atmospheric-corrosion studies focus on the growth of a protective corrosion product on metal surfaces, there is increasing interest in metal-environment interactions (weathering) related to wet and dry deposition that facilitate the loss of protective corrosion product and therefore affect the long-term performance or service life of metals (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14). These interactions lead to the formation of nonprotective, soluble minerals within the corrosion product layer that, in outdoor exposures, are typically removed in precipitation runoff (Ref 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20). These interactions can accelerate atmospheric-corrosion processes and, by virtue of the removal of metal ions in precipitation runoff, can affect soil and water quality (Ref 14, 15, 16, 17, 18, 19, 20). Of particular interest in this regard is acid deposition or acid rain, which can accelerate corrosion damage of some widely used structural materials, including galvanized steel, zinc, copper, limestone, and marble (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14).

Over the years, considerable attention has been devoted to the weathering of building materials. Observations of materials corrosion performance in the atmosphere have ranged from those made on existing structures to carefully designed atmospheric exposure programs. These data represent an excellent base for understanding the behavior of materials in the atmosphere. However, much of the existing data suffer from two primary difficulties. First, many testing programs have been limited to characterizing a material for a specific application. This has resulted in variations in experimental designs, such that the results of one testing program cannot be compared unambiguously to the results of others. Second, and more seriously, test programs have generally been conducted without comprehensive environmental monitoring and characterization. This prevents the establishment of cause-and-effect relationships for atmospheric- corrosion phenomena and has precluded the establishment of a baseline understanding of the atmospheric environmental characteristics for which a considerable materials degradation database exists. The monitoring of relevant environmental parameters in association with controlled atmospheric exposures of materials is necessary to assess the impact of atmospheric variables on materials.

Simulated Service Testing in the Atmosphere

Stephen D. Cramer and Steven A. Matthes, Albany Research Center, U.S. Department of Energy

Types of Atmospheres

Before materials or materials data can be evaluated, the important atmospheric variables at the test site must be identified and then recorded during the exposure period. The variability of atmospheric-corrosion severity has been well documented (Ref 21, 22, 23). One way to address this is to characterize atmospheric exposures as occurring in rural, urban, industrial, or marine environments, or a combination of these. These designations reflect the level of chemical pollutants that are typical in the test environment. Table 1 lists typical rates for the deposition of SO_x and Cl^- on metal surfaces exposed to these environments (Ref 24).

Table 1 Typical activity ranges of SO_x and Cl^- measured in various atmospheres

These are average activity ranges measured over a 20–25 month period.

Type of atmosphere	mg $SO_x/dm^2/d$	mg $Cl^-/m^2/d$
Industrial	0.5–2	nil
Urban	0.5–4	nil
Rural (semi)	nil–2	nil
Marine	nil–0.5	25–150

Source: Ref 24

A rural atmosphere is normally classified as one that does not contain significant chemical pollutants but does contain organic and inorganic dusts. Its principal corrodents are moisture, oxygen, and carbon dioxide. Arid or tropical atmospheres are special cases of the rural environment because of their extremely low or high relative humidities (Ref 25). The rural atmosphere is generally the least corrosive of the atmospheric exposures encountered.

An urban atmosphere is similar to the rural environment in that it is thought to be away from sources of industrial pollution. Materials exposed to an urban atmosphere are subjected to the normal precipitation patterns and typical urban contaminants of SO_x and NO_x emitted by motor vehicles and the combustion of home fuels. However, pollution levels in urban atmospheres may, in fact, be similar to those in industrial atmospheres because of long-range transport of pollutants (Ref 1).

An industrial atmosphere is typically identified with heavy industrial manufacturing facilities. These atmospheres can contain significant concentrations of sulfur oxides, nitrogen oxides, chlorides, phosphates,

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

particulates, and other industrial emissions. These emissions can combine with precipitation or dew to form fairly corrosive solutions on metal surfaces.

A marine atmosphere is laden with fine particles of sea salt carried by the winds and deposited on materials. The marine atmosphere is usually one of the more corrosive atmospheric environments. It has been shown that the amount of salt (chlorides) in the marine environment decreases with increasing distance inland from the ocean and is greatly influenced by wind speed and direction (Ref 26).

Because long-range transport of pollutants can blur distinctions in atmospheric corrosivity (aggressivity) based on regional geography (rural, urban, industrial, marine), distinctions based on atmospheric chemistry may be more useful for predicting corrosion performance. The International Organization for Standardization (ISO) characterizes environments in ISO 9223 based on the level of pollutants in the environment (Ref 27, 28, 29). The pollutants measured are sulfur dioxide and chloride. Their concentration is determined by their deposition rate on standard surfaces. Deposition rates define four ranges of pollutant concentration, providing sixteen levels of corrosivity with which to characterize the performance of metals in the atmosphere. Field exposures of standard metals (carbon steel, zinc, copper, and aluminum) have been conducted to, in effect, calibrate the level of corrosion performance expected by exposure in each corrosivity category. Corrosion damage to the standard metals is ranked in five levels. A key factor determining corrosion performance in the corrosivity categories is the presence of moisture, characterized by the time of wetness (TOW).

Continuous air monitoring goes beyond discrete corrosivity categories to define atmospheric chemistry in terms of instantaneous or average measures of pollutant concentrations (sulfur and nitrogen oxides, hydrochloric acid, hydrocarbons, carbon dioxide, particulates) and environmental variables (temperature, wind speed and direction, relative humidity, precipitation rate and chemistry, solar radiation) (Ref 1, 9, 10, 11, 12, 13). While monitoring these variables can be expensive, it is often possible to co-locate atmospheric exposure test panels at or near local or regional monitoring sites that provide some or all of the needed information. This greatly enhances the usefulness of the resulting corrosion data for interpreting environmental effects and for modeling corrosion performance.

Indoor environments differ substantially from outdoor environments, with, in most cases, substantially lower levels of moisture, less dramatic variations in relative humidity and temperature, slower air movement, and complex air chemistry affected by a wide variety of sources and sinks for chemical species that can influence indoor corrosion (Ref 30). Indoor corrosion rates are typically lower than those outdoors and do not affect the structural integrity of most materials. They can, however, influence the performance of electronic devices and alter the surface of cultural artifacts.

Relative Corrosivity

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Several programs have been conducted to assess the relative corrosivity of the environment at specific geographic locations over a finite period of time (Ref 24, 31, 32, 33). The use of calibration specimens to measure corrosivity can be traced to J.C. Hudson (Ref 32), who established the ranking of ten different environments based on the corrosion of wrought iron (Table 2). Table 3 summarizes additional site comparisons for the atmospheric-corrosion performance of steel and zinc (Ref 34).

Table 2 Relative corrosivity of atmospheres at different locations measured using wrought iron

Location	Type of atmosphere	Average weight loss of iron specimens in 1 year, mg/cm^2	Relative corrosivity
Khartoum, Sudan	Dry island (arid)	0.08	1
Singapore	Tropical/marine	0.69	9
State College, PA	Rural	1.90	25
Panama Canal Zone	Tropical/marine	2.28	31
Kure Beach, NC (250 m, or 800 ft, lot)	Marine	2.93	38
Kearny, NJ	Industrial	3.92	52
Pittsburgh, PA	Industrial	4.88	65
Frodingham, U.K.	Industrial	7.50	100
Daytona Beach, FL	Marine	10.34	138
Kure Beach, NC (25 m, or 80 ft, lot)	Marine	35.68	475

Source: Ref 32

Table 3 Measured atmospheric-corrosion rates for steel and zinc

Site	Location	Type of atmosphere	Relative corrosivity	
			Steel	**Zinc**
1	Normal Wells, Northwest Territory	Rural	0.02	0.2
2	Saskatoon, Saskatchewan	Rural	0.2	0.2
9	State College, PA[(a)]	Rural	1.0	1.0
17	Pittsburgh, PA (roof)	Industrial	1.8	1.5
18	London (Battersea), U.K.	Industrial	2.0	1.2
27	Bayonne, NJ	Industrial	3.4	3.1
28	Kure Beach, NC (250 m, or 800 ft, site)	Marine	3.6	1.9
31	London (Stratford), U.K.	Industrial	6.5	4.8
33	Point Reyes, CA	Marine	9.5	2.0
37	Kure Beach, NC (25 m, or 80 ft, site)	Marine	33.0	6.4

(a) The average weight losses on two 100 × 150 mm (4 × 6 in.) specimens after 1 year of bold exposure at the indicated site were used to calculate the relative corrosivity of the site. The losses in the rural atmosphere at State College, PA, were taken as unity, and the relative corrosiveness at each of the other sites is given in this table as a fraction or a multiple of unity. Environmental Factors

Methods have been developed for measuring many of the factors that affect atmospheric corrosion (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 24, 27, 28, 29, 30). Atmospheric chemistry, precipitation and particulate chemistry, meteorology, wet and dry deposition, precipitation runoff, and their variation with time can be determined continuously and by discrete measurements. Measurements can be site specific, regional, and global. Measurements can be instantaneous, short-time averages, daily, weekly, or annual. Identifying the important factors and interactions between factors that affect atmospheric corrosion is a challenging task. Often, annual average values of the important factors will suffice for environmental characterization. Environmental factors that should be considered for measurement include, but are not limited to, those listed in Table 4.

Table 4 Environmental parameters often considered as influences on the atmospheric degradation of materials

Category	Parameters
Wet deposition	pH
	Conductivity
	Cations: calcium (Ca^{2+}), magnesium (Mg^{2+}), sodium (Na^{+}), potassium (K^{+}), ammonium (NH_4^+), and hydrogen (H^{+})
	Anions: sulfates (SO_4^{2-}), nitrates (NO_3^-), and chlorides (Cl^{-})
Dry deposition	Sulfur dioxide (SO_2)
	Nitrogen dioxide (NO_2)
	Nitric acid (HNO_3)
	Ammonia (NH_3)
	Particulate matter, sulfates, nitrates
Meteorology	Ozone
	Wind speed
	Wind direction
	Relative humidity (dewpoint)
	Temperature
	Solar radiation
	Rainfall volume and intensity
Others	Test specimen surface temperature
	Time of wetness

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Note: Time of wetness and the quantity of SO_2 and chloride are the most important variables in determining atmospheric corrosion. Such factors as hydrogen sulfide, nitrogen compounds, and other specific pollutants may be significant at specific sites if sources of these pollutants are located nearby.

Conducting Atmospheric-Corrosion Tests

The type of data or information required from the atmospheric-corrosion test dictates the specifics of the test program. For example, the test purpose could be to evaluate the general corrosion behavior of a material, the resistance to solar radiation, coating discoloration, pitting, galvanic effects, loss of strength, or the impact of environmental factors. The information to be obtained must be established in the planning stages of the work.

Materials To Be Exposed. Atmospheric-corrosion studies are generally carried out for periods of months and even years to measure environmental effects and to establish long-term performance. Therefore, it is important to select standard or reference materials (referred to as control specimens) that will be exposed alongside of the test materials, alloys, or coatings of interest. Control materials with a prior performance record in the exposure environment are extremely important for comparison purposes and for monitoring site corrosivity. The ISO recommends low-copper steel, commercial-purity aluminum, commercial-purity zinc, and commercial-purity copper as reference metals; they are representative of the engineering materials most widely used in indoor and outdoor exposures. They also have known performance records in various environments and documented corrosion behaviors when exposed to different atmospheric constituents and chemistries. With daily, seasonal, and long-term changes in air chemistry, precipitation chemistry, and meteorology, site corrosivity can change, and the use of reference materials provides a basis for quantifying these changes.

The number of replicate samples used depends on the exposure period and the number of scheduled sample removals. For visual observations, two samples for each environment are usually sufficient. More samples will

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

be needed for periodic removals. Samples that have been removed and cleaned should never be reexposed as part of the same test.

Atmospheric Specimens. ASTM International, NACE International, and ISO provide guidelines for sample design, preparation, exposure, postexposure cleaning, and evaluation (Table 5). These guidelines include standard sample designs for flat panels, stress corrosion, and other types of atmospheric-corrosion samples (Ref 35) (Table 6), such as the ISO wire helix sample (Fig. 1).

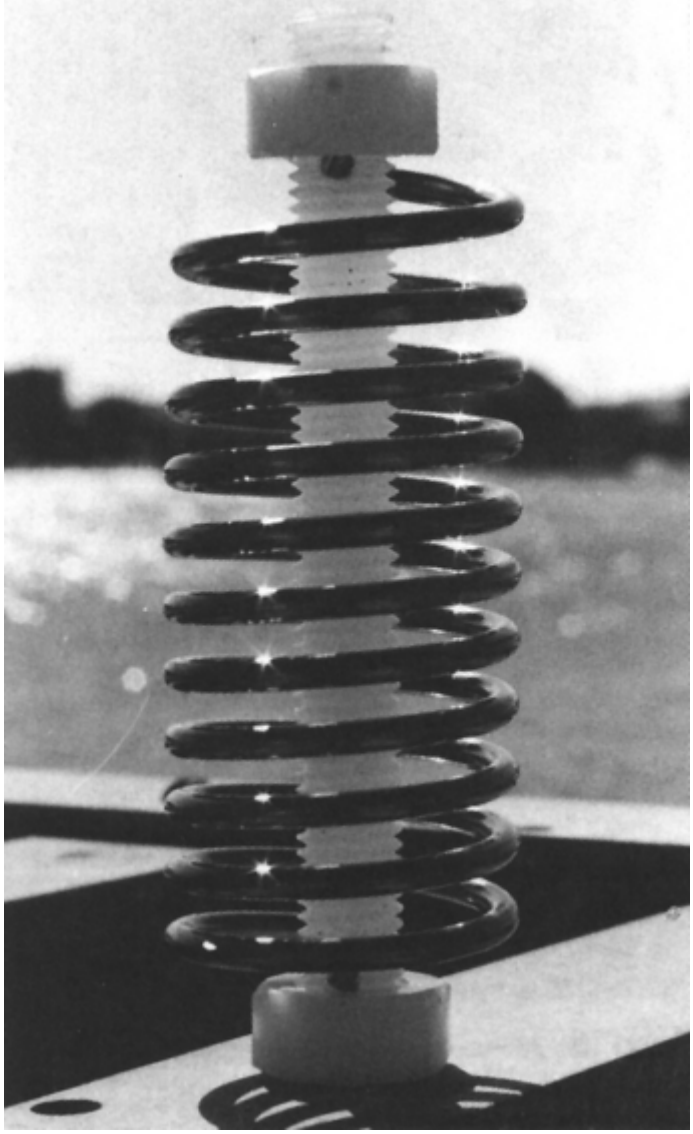
مرجع مهندسی مواد و متالورژی

Stress corrosion		
U-bend	ASTM G 30 (Ref 37)	3 mm × 15 mm × 130 mm × 32 mm diam (0.12 in. × 0.6 in. × 5 in. × 1.25 in. diam)
Bent beam	ASTM G 39 (Ref 38)	3 point: 1 mm × 5 mm × 65 mm span (0.04 in. × 0.2 in. × 2.5 in. span); 2 point: 25 mm wide × 180 mm span (1 in. wide × 7 in. span)
C-ring	ASTM G 38 (Ref 39)	12 mm wide × 25 mm diam (0.5 in. wide × 1 in. diam)
Direct tension	ASTM G 49 (Ref 40)	Specimen size depends primarily on the dimensions of the product to be tested.
Welded	ASTM G 58 (Ref 41)	The thickness and size of the test specimen should represent the actual structural member.
Galvanic		
Disk	B-3 (Ref 42)	36 mm diam × 1.6 mm (1.4 in. diam × 0.06 in.), 33.5 mm diam × 1.6 mm (1.3 in. diam × 0.06 in.), 30 mm diam × 1.6 mm (1.2 in. diam × 0.06 in.), 25 mm diam × 1.6 mm (1 in. diam × 0.06 in.)
Plate	ISO/TC 156/WG3/N11 (Ref 43)	90 mm × 150 mm × 2 mm (3.5 in. × 6 in. × 0.08 in.), 70 mm × 25 mm × 2 mm (2.75 in. × 1 in. × 0.08 in.), 45 mm × 90 mm × 2 mm (1.8 in. × 3.5 in. × 0.08 in.), 25 mm × 70 mm × 2 mm (1 in. × 2.75 in. × 0.08 in.)
Open helix (metallic wire)	ISO/TC 156/WG4/N131 (Ref 44)	Wires with a diameter of 2–3 mm (0.08–0.12 in.) and 1000 mm (40 in.) long rolled into helix and attached to polyamide or metallic holder. See Fig. 1.

(a) The appropriate ASTM International or International Organization for Standardization (ISO) document should be consulted before selecting a specimen size. Source: Ref 35



www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Fig. 1 International Organization for Standardization wire helix specimen

A suitable means of sample identification should be used. Stamped code numbers can be used for the more corrosion-resistant materials but will be lost on the more corrodible materials, such as steel. For these materials, drilled holes or side notches according to a number template can be used. A plastic tag affixed through a drilled hole with a nonmetallic tie has also been successfully used. In all cases, the method of identification of the sample should not bias the corrosion evaluation. It is also good practice to map the samples on the exposure rack; that is, draw, sketch, or list according to exposure the identity of each sample on the rack in case the codes or tags corrode away or are lost. Among the more important steps in atmospheric-corrosion testing is the documentation of results and observations for future reference and application. This reporting can take the form of internal company reports, technical papers, or presentations. In all cases, the objectives of the work, the exposure details, and the conclusions drawn from the analysis of the corrosion results should be documented. The chain of custody of this information and associated records is crucial to the completion of long-term exposure tests.

Exposure Guidelines. Atmospheric-corrosion samples are normally exposed on a test rack similar to that shown in Fig. 2. The rack is then attached to a frame or stand (ASTM G 50 or ISO DP8565). Sample sizes are normally 100 by 150 mm (4 by 6 in.) in these racks but can be any size necessary to properly evaluate the performance of the exposed material. For example, large panels (Fig. 3) and stress-corrosion cracking (SCC) U-bend samples (Fig. 4) are used in sizes and configurations necessary for the tests and environments of interest.

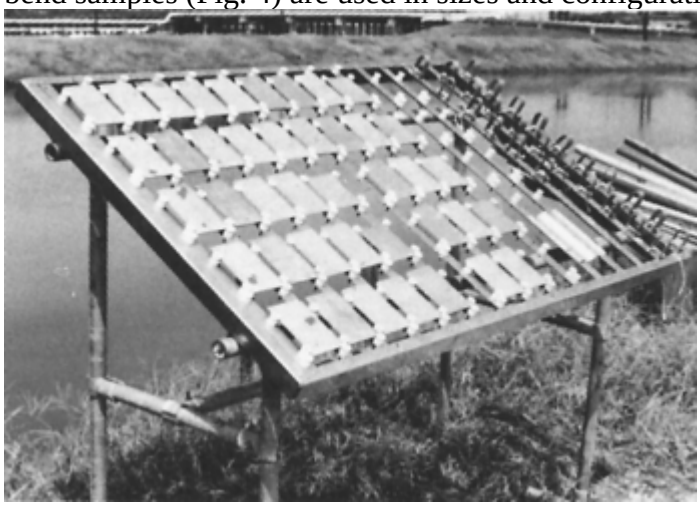


Fig. 2 Atmospheric-corrosion test rack

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

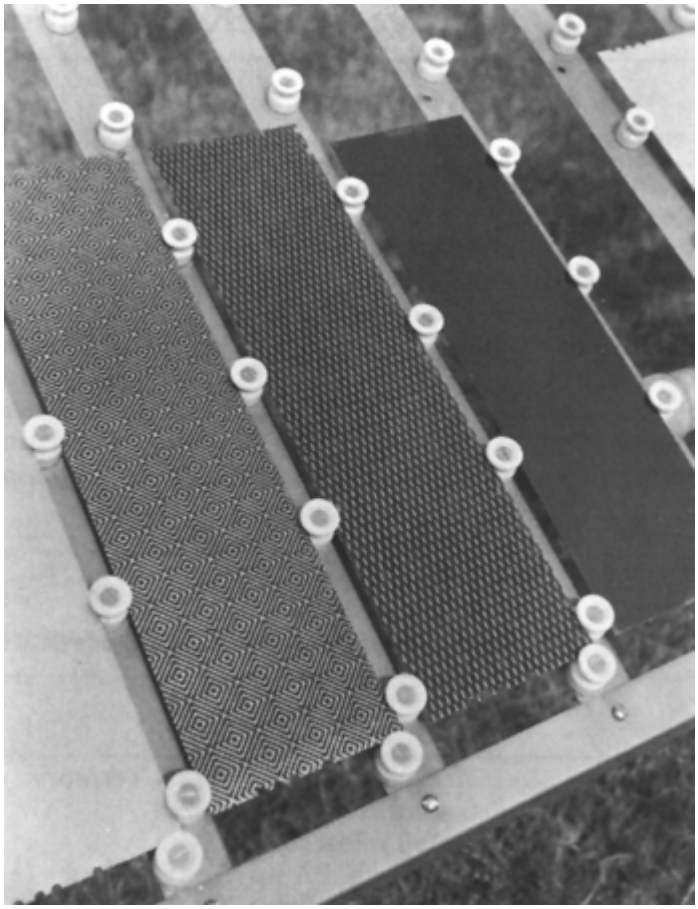

Fig. 3 Large atmospheric-corrosion test panels

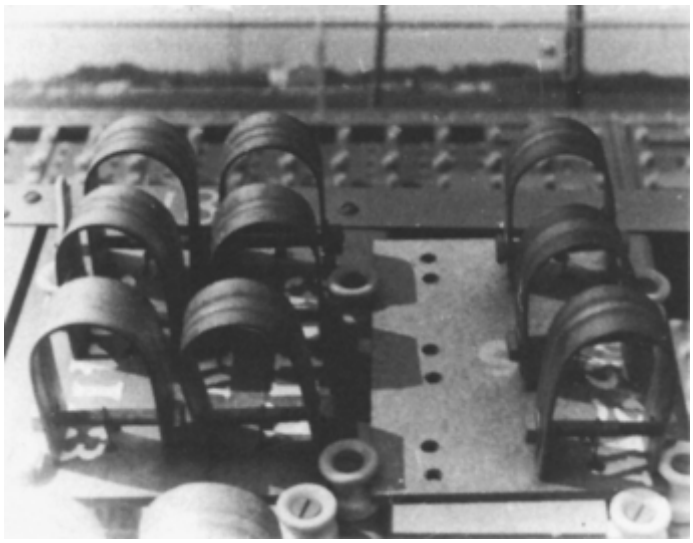

Fig. 4 U-bend specimens used for atmospheric-corrosion testing

For special situations, the exposure rack can be streamlined for small areas or for specialized exposures by using a corrosion spool rack similar to that shown in Fig. 5. In all cases, unless the objective of the exposure is to determine galvanic effects, the specimens should be electrically isolated from each other and from the exposure rack by nonconductive materials, such as porcelain or plastic insulators similar to those visible in Fig. 1, Fig. 2, Fig. 3, Fig. 4, Fig. 5.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

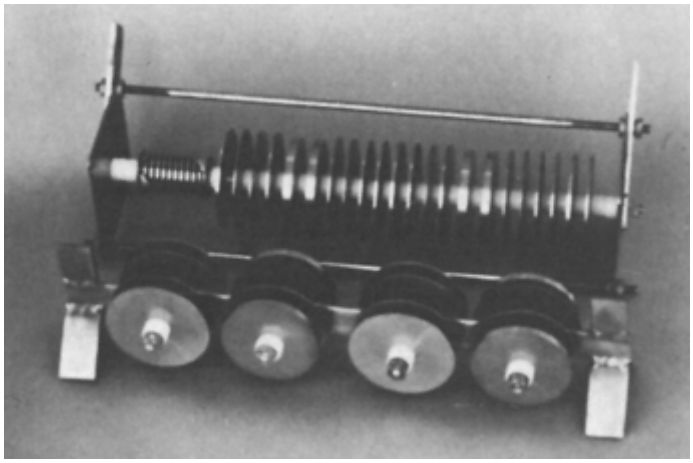

Fig. 5 Atmospheric-corrosion spool rack

The convention used for atmospheric-corrosion sample orientation is as follows: samples exposed in the northern hemisphere normally face south toward the sun; samples exposed in the southern hemisphere normally face north. It is also common practice to expose samples facing the most corrosive direction if the exposure site is close to a pollutant point source, such as sea coast, a fossil energy power plant, or the plume of pollutants downwind from an industrial site or even a city. ASTM G 50 recommends that samples be exposed on an angle 30° to the horizon (in Europe this angle is 45°). If maximum exposure to sunlight is desired, the specimens should be exposed at an angle to the horizon equal to the latitude of the site.

In order to fully characterize the effect of the environment on the corrosion process and to quantify the release of corrosion products into soils and groundwater, precipitation runoff may be studied (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20). Precipitation runoff is the precipitation containing dissolved corrosion products and environmental species that drain from a metal surface. Figure 6 shows a site where both atmospheric-corrosion and precipitation runoff measurements are made to provide a more complete characterization of the competing processes of corrosion film growth and corrosion film dissolution that accompany the corrosion process. Mass loss panels, typically one-sided with the downward side masked off to prevent corrosion, are exposed on an atmospheric-corrosion test rack such as that shown in Fig. 2. Precipitation is collected in a wet/dry collector. The collector is activated by a sensor that uncovers the bucket and collects precipitation during a rain event, then covers the bucket and seals it to prevent evaporation losses when the event stops. The sensor is heated so that the collection bucket remains open only as long as precipitation continues to wet the sensor. The collected precipitation provides a measure of precipitation rate, rain intensity, the wet deposition rate, and the chemistry of incident precipitation. The precipitation runoff panels are large, one-sided metal panels of the same materials as the mass loss panels and sit in a tray that collects and funnels all precipitation draining from the panel surface into runoff collection containers. The difference between the chemistry of the incident precipitation and the precipitation runoff is a measure of the rate that soluble corrosion product is removed from the panel surface. This difference in chemistry also gives a measure of the rate that environmental species such as sulfur and nitrogen oxides, chloride ion, ammonia, and particulate matter are dry deposited on the panel surface.

مرجع مهندسی مواد و متالورژی

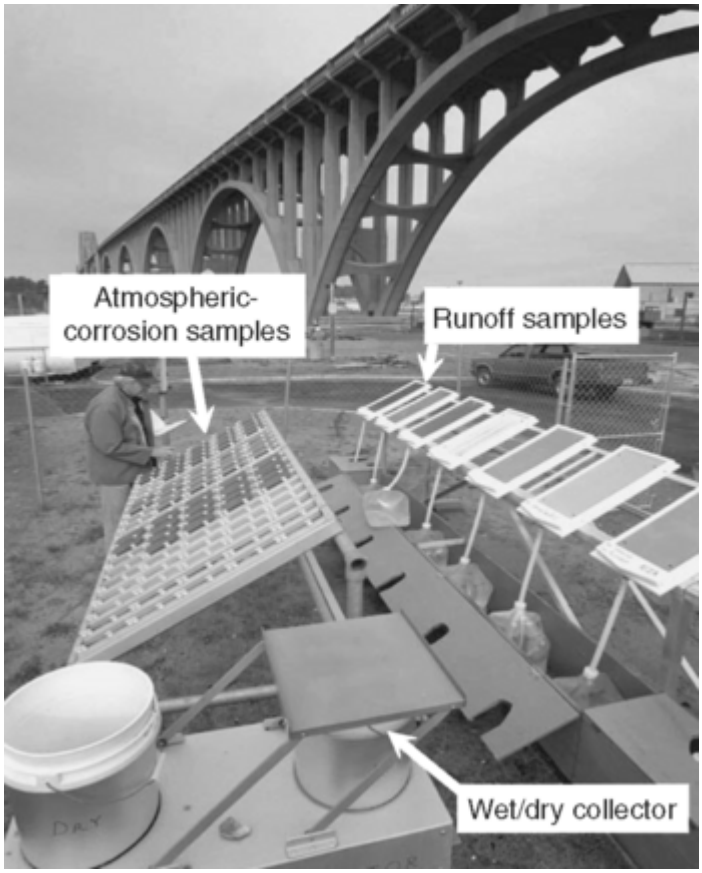

Fig. 6 Marine atmospheric-corrosion and precipitation runoff test site at Newport, OR

Evaluating Corrosion Panels and Precipitation Runoff. Exposed atmospheric-corrosion panels are evaluated in a variety of ways (Ref 45, 46, 47), beginning with a visual examination and progressing to other forms of analysis (Table 7). Coated samples are evaluated for undercutting of the coating, blistering, loss of surface finish, and protection of the substrate. Uncoated samples are evaluated for uniform corrosion, localized corrosion (pitting, crevice corrosion, SCC), or galvanic corrosion. Mass loss is quantified by chemical removal of corrosion product from the panel surface (something that was not done when atmospheric-corrosion studies were first attempted in the early 20th century) and determining the change in mass of the panel after exposure. The corrosion film is characterized by a variety of analytical techniques, such as wet chemistry, optical microscopy, scanning electron microscopy, x-ray fluorescence spectroscopy, x- ray diffraction, x-ray photoelectron spectroscopy, Auger electron spectroscopy, and other techniques. Precipitation and precipitation runoff chemistry is quantified by well-known wet chemical analytical techniques.

Table 7 Evaluation techniques for atmospheric-corrosion specimens

Technique	Value
Photographic documentation	Photographs of the specimens before and after cleaning give a permanent record of the performance of the material in the particular atmosphere.
Corrosion product analysis and surface deposits	Atmospheric-corrosion specimens usually have the corrosion product and airborne deposits on the surface at the time of removal. This adds a wealth of information to the observed behavior of the material.
Mass loss	For uniform corrosion, this is simple and can be converted to corrosion rate as $g/m^2/d$, mils per year, etc.
Pitting and localized corrosion	Yields information on the susceptibility of a material to localized attack. Pitting corrosion is often reported as average or maximum depth of attack and is usually measured with a dial depth gage or vernier microscope. Where possible, pitting data should be treated statistically with recognized methods covered in various standards. Weight loss data should not be used indiscriminately to calculate corrosion rates

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

	where the primary form of corrosion is localized.
Rust or rust stain	Data reveal the propensity of a material to rust and the degree of rust staining. Also, through cleaning procedures, it can be determined if the original appearance was retained.
Tensile test and other physical tests	Can often yield information on the atmospheric effect on the strength of materials, cracking behavior, etc.
Appearance	Effect of environment on appearance, color retention, etc.

Analyzing Atmospheric-Corrosion Tests

One of the principal goals of atmospheric-corrosion measurements is to have sufficient data to estimate the service life of the part being evaluated. Uniform corrosion is one of the most widely studied corrosion processes in atmospheric corrosion. In a mass balance for a metal surface in a bold, skyward exposure at any time, t, the total or cumulative corrosion loss, $M_T(t)$, is equal to the total metal present in the corrosion film, $M_F(t)$, plus the cumulative amount of metal in soluble corrosion product washed from the surface in precipitation runoff, $M_P(t)$; that is:

$$M_T(t) = M_F(t) + M_P(t) \quad \text{(Eq 1)}$$

The time derivative of this equation is:

$$dM_T(t)/dt = dM_F(t)/dt + dM_P(t)/dt \quad \text{(Eq 2)}$$

where $dM_T(t)/dt$ is the instantaneous corrosion rate, $dM_F(t)/dt$ is the rate of metal accumulation contributing to protective corrosion film growth, and $dM_P(t)/dt$ is the rate of metal loss from the corrosion film in precipitation runoff.

For materials such as nickel, steel, and stainless steel, the corrosion products are insoluble or not very soluble in precipitation, and the precipitation runoff loss rate is typically 0. Materials such as zinc, galvanized steel, copper, and aluminum have corrosion products soluble in precipitation. For these materials, if the atmospheric exposure is relatively short and corrosion film growth is the dominant process, the precipitation runoff loss rate is also effectively 0. Under these conditions, if the corrosion rate is assumed to be inversely proportional to the corrosion film thickness raised to some power n, that is:

$$dM_T(t)/dt \propto 1/M_F(t)^n \quad \text{(Eq 3)}$$

integration of Eq 2 (with $M_F(t) = M_T(t)$) gives the well-known power model (Ref 48) describing the time variation of corrosion in the absence of precipitation runoff losses:

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

$$M_T(t) = a_o t^{1/(n+1)} \quad \text{(Eq 4)}$$

where a_o is a proportionality constant. When $n = 0$, the corrosion kinetics are linear, and the corrosion film is essentially non-protective; when $n = 1$, the corrosion kinetics are parabolic, and the corrosion film is protective. Data for a number of alloy steels exposed in a wide range of environments give n values ranging from 0 to roughly 2, or a little higher (Ref 48). Of course, expressed differently, Eq 4 is the bilogarithmic law for atmospheric corrosion:

$$\log M_T(t) = \log a_o + [1/(n + 1)] \log t \quad \text{(Eq 5)}$$

In other words, in the absence of precipitation runoff losses, the total corrosion plotted versus exposure time on logarithmic coordinates is a straight line with a slope of $[1/(n + 1)]$. Values of the slope generally fall in the range from 1 for $n = 0$ to $\frac{1}{3}$ for $n = 2$.

Equation 2 can also be integrated for conditions when soluble corrosion product is washed from the metal surface, that is, the precipitation runoff loss rate is nonzero, $dM_P(t)/dt > 0$. Independent measurements for metals such as zinc and copper (Ref 2, 3, 4, 6, 12, 13) that have corrosion products soluble in precipitation show that the cumulative precipitation runoff loss, $M_P(t)$, is essentially linear with respect to time, regardless of daily and seasonal variations in meteorology and air chemistry (Fig. 7). In other words, the precipitation runoff loss rate, $dM_P(t)/dt$, can be treated as a constant for a given geographic location or exposure site. Substituting Eq 3 with $n = 1$ into Eq 2 and integrating gives:

$$M_T(t) = (\alpha/\beta)[1 - \exp\{-\beta M_T(t)/\alpha\}] + \beta t \quad \text{(Eq 6)}$$

where β is the precipitation runoff loss rate, and α is a constant related to properties of the corrosion film.

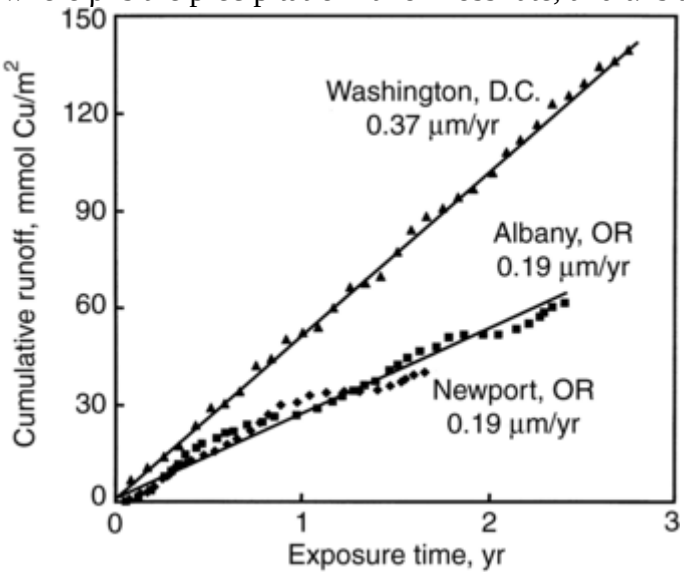

Fig. 7 Cumulative copper precipitation runoff losses at marine unpolluted and polluted sites as a function of exposure time

This empirical model describes the time variation of the total corrosion loss when the precipitation runoff loss rate is nonzero. It describes conditions where there is competition between corrosion film growth and corrosion film dissolution and removal in precipitation runoff. The precipitation runoff loss rate, β, describes the influence of environmental factors on corrosion film stability. The constant α describes the effect of intrinsic properties of minerals in the corrosion film on corrosion film stability. The ratio of the two terms, (α/β), describes the balance between the tendency for protective corrosion film growth and the environmental factors producing corrosion product losses in precipitation runoff. Equation 6 reduces to the parabolic form of Eq 4 in the limit where the precipitation runoff loss rate is 0.

With sufficient environmental data and limited geochemical modeling, contributions of environmental processes to the precipitation runoff rate can be estimated. This has been done for zinc (Ref 12) and copper (Ref 13) exposed in a polluted urban environment, a marine environment, and a rural environment. Figure 8 shows four contributions to copper corrosion in the polluted urban environment: (a) a strong acid contribution from wet deposition representing the effect of acid rain, (b) a weak acid contribution in wet deposition representing the effect of the carbon dioxide/bicarbonate/carbonate equilibia, (c) a dry deposition contribution representing

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

acid gases (sulfur dioxide, nitric acid, hydrochloric acid) and perhaps modified by the deposition of basic particulates, and (d) a precipitation of brochantite, $CuSO_4 \cdot 3Cu(OH)_2$, within the corrosion film as a result of weathering of the corrosion film. These contributions add together stoichiometrically to give the curve for the cumulative precipitation runoff loss, $M_P(t) = t\beta$.

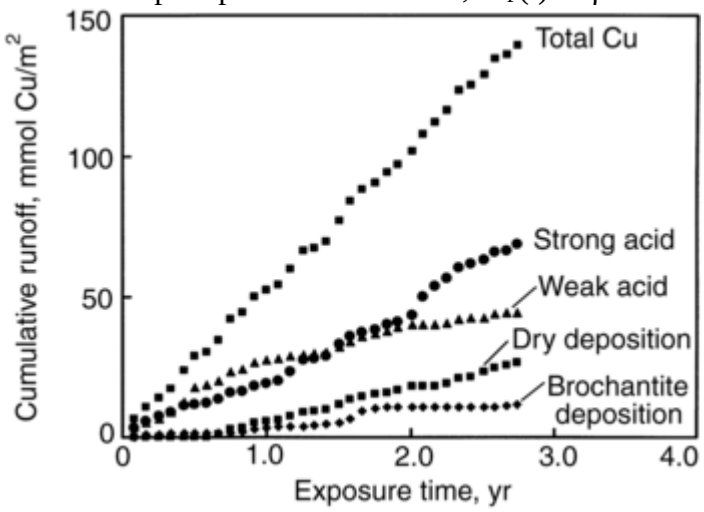

Fig. 8 Dry deposition, strong acid, weak acid, and brochantite deposition contributions to cumulative copper precipitation runoff loss as determined by geochemical modeling for the polluted Washington, D.C. site

Very long-term corrosion data that include both mass loss and corrosion film thickness and chemistry are not often available to test Eq 6. Data were available for a 100 year old copper roof in Stockholm, Sweden (Ref 5). Values of α and β were estimated, knowing that the ratio of the two values was equal to the steady-state thickness of the corrosion film. For an effective corrosion film thickness of 15.5 μm, the best estimates of the two values were (Ref 13) α = 13.9 μm^2/year and β = 0.9 μm/year. The resulting curves for cumulative precipitation runoff loss, total corrosion mass loss, and the patina thickness are shown in Fig. 9 (Ref 13). This figure illustrates that corrosion film growth is the dominant process during the early exposure period. However, in long exposures, such as the 100 year old copper roof, a large fraction of the corrosion mass loss simply maintains the patina thickness so as to balance precipitation runoff losses. Of course, this is the result expected from Eq 2 for steady-state conditions where film growth has ceased, that is, $dM_F(t)/dt = 0$. In that case, the corrosion rate equals exactly the precipitation runoff loss rate.

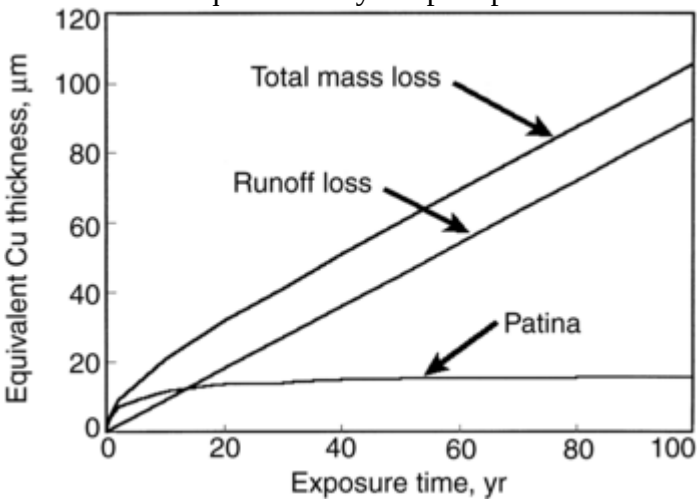

Fig. 9 Cumulative corrosion mass loss, corrosion film growth (patina), and precipitation runoff loss for a 100 year old copper roof exposed in Stockholm, Sweden

Finally, the parameters in Eq 6, α and β, can be used to define a dimensionless corrosion equation, that is:

$$M_T(t^*)^* = [1 - \exp\{-M_T(t^*)^*\}] + t^* \qquad \text{(Eq 7)}$$

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

where $M_T(t^*)^* = M_T(t)\beta/\alpha$, dimensionless cumulative corrosion loss; $t^* = t\beta^2/\alpha$, dimensionless time; $M_{F,S} = \alpha/\beta$, the steady-state corrosion film or patina thickness; $t_c = \alpha/\beta^2$, a characteristic time (17.2 years for the example of the 100 year old copper roof).

The dimensionless corrosion equation gives the curve shown in Fig. 10 as a function of time (Ref 13). Early in the corrosion process, the corrosion kinetics are parabolic, and the slope of the curve is $\frac{1}{2}$. As the corrosion film matures and the corrosion process approaches steady state, the corrosion kinetics transition from parabolic kinetics to linear kinetics, and the slope changes from $\frac{1}{2}$ to 1. In the framework of the dimensionless equation, short and long exposures are relative terms defined by the balance of environmental factors (β) and factors related to the mineralogy of the corrosion film (α).

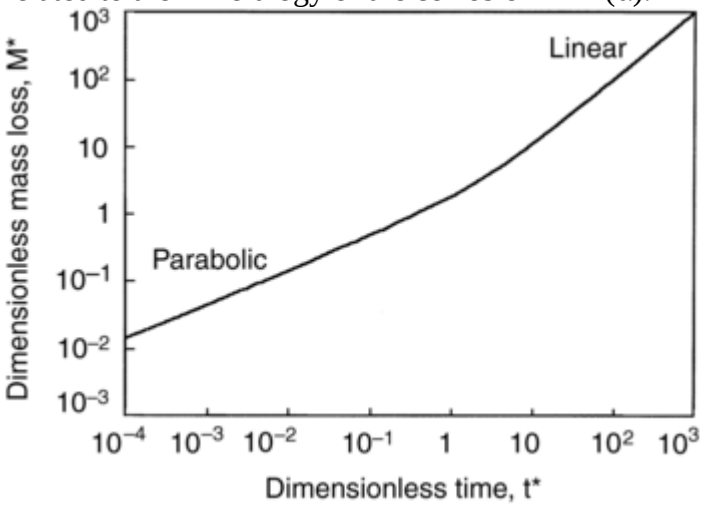

Fig. 10 Dimensionless empirical model for atmospheric corrosion with precipitation runoff losses showing effect of exposure time on cumulative mass loss and corrosion kinetics

Simulated Service Testing in Water

Introduction

SIMULATED SERVICE TESTING is the most reliable predictor of corrosion behavior short of actual service experience. This includes exposures of either structural components or test specimens in environments that are representative of many general service situations. Test materials are subjected to the cyclic effects of the weather, geographical influences, and bacteriological factors that cannot be realistically duplicated in the laboratory.

This type of testing is important for such objectives as materials selection, predicting the probable service life of a product or structure, evaluating new commercial alloys and processes, and calibrating laboratory corrosion tests. The type of information sought determines the selection of test specimens and the methods of assessing the corrosion effects.

As an environment in which corrosion occurs, water can be categorized as treated or natural. Regardless of the original intent for which a test has been developed, application can be extended to include any use. For example, ASTM G 78 (described in Table 1) is a guide for crevice corrosion testing of iron- and nickel-base alloys in seawater. The crevice assembly described could be installed on any alloy type in any environment if crevices are being studied. Only when quality control or acceptance stipulates a particular test method is there no room for departure. Some test methods involve the insertion of coupons or test panels into a conduit, with the environment at actual velocity and aeration. Other test methods involve the insertion of a test section into the flow line, especially if wall effects might be important. Still other tests require immersion of specimens in relatively open bodies of water.

Table 1 ASTM International and NACE methods for testing waters and materials in waters

Designation	Title	Description
ASTM standards		
D 1293	Standard Test Methods for pH of Water	These methods cover the determination of pH by electrometric measurement, using the glass electrode as the sensor. Two procedures are discussed. Method A covers the precise laboratory measurement of pH in water with the use of at least two of seven standard reference buffer solutions for equipment standardization. Method B concerns the routine or continuous measurement of pH in the laboratory and the measurement of pH under various continuous process conditions.
D 1498	Standard Practice for Oxidation-Reduction Potential of Water	This practice covers the apparatus and procedure for the electrometric measurement of oxidation-reduction potential in water.
D 2688	Standard Test Methods for Corrosivity of Water in the Absence of Heat Transfer (Weight Loss Methods)	These methods cover the determination of the corrosivity of water by evaluating pitting and by measuring the weight loss of metallic specimens. Additional information can be found in the articles “Pitting Corrosion” and “Evaluating Pitting Corrosion” in this Volume.
E 645	Standard Test Method for Efficacy of Microbiocides Used in Cooling Systems	This method covers the effect of bactericides and fungicides in controlling microbial growth in cooling water by using water collected from operational cooling water systems. Additional information can be found in the articles “Microbiologically Influenced Corrosion” and “Evaluating Microbiologically Influenced Corrosion” in this Volume.
G 52	Standard Practice for Exposing and Evaluating Metals and Alloys in Surface Seawater	This practice covers conditions for exposure of metals and alloys to surface seawater and presents the general procedures that should be followed in conducting seawater exposure tests so that meaningful comparisons can be made for different locations.
G 78	Standard Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments	This guide provides information for conducting crevice corrosion tests and identifies factors that may affect results and influence conclusions. These procedures can be used to identify the conditions that will most likely result in crevice corrosion and to provide a basis for assessing the relative resistance of various alloys to crevice corrosion under certain specified conditions. Additional information on crevice corrosion can be found in the articles “Crevice Corrosion” and “Evaluating Crevice Corrosion” in this Volume.
NACE standards		
TM 0174	Laboratory Methods for the Evaluation of Protective Coatings Used as Lining Materials in Immersion Service	This standard gives guidelines to assist manufacturers and users of protective coatings in selecting materials by providing standard test methods for evaluating protective coatings used as linings for immersion service. Two test methods are discussed for the evaluation of protective coatings on any substrate, such as steel, copper, or aluminum, so that both the factors of chemical resistance and permeability can be considered.
RP 0775	Preparation and Installation of Corrosion Coupons and Interpretation of Test Data in Oil	This standard emphasizes the use of uniform industry-proven methods to monitor corrosion in oil production systems. Procedures for preparing, analyzing, and installing

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Production Practice	corrosion coupons are also outlined.

Tests used as criteria for acceptance and/or quality control may require a very specific water chemistry and values of such factors as hardness, pH, aeration, temperature, alkalinity, and specific dissolved ion concentrations. It is usually valuable to monitor some of these factors in testing any water because compositions and contaminants change with time as sources (well, river, estuary, storm drains) and climatic conditions (wind direction, temperature, acid rain) vary. A variation in the mixture of sources might change test results significantly. It is important to be aware of the factors that can affect test results when interpreting those results.

Unless galvanic action is being investigated (and it probably should be in most cases), specimens of differing alloy composition or thermomechanical treatment should be electrically isolated or insulated from each other and from the support framework. The factors that require consideration in water supplies are discussed in Ref 1, 2, 3, 4, 5. Many standardized and nonstandardized tests, methods, and practices are discussed in Ref 6, 7, 8, 9, 10. The ASTM International and NACE International standards that are directly or indirectly applicable to simulated service corrosion testing in water are listed and described in Table 1.

Test Method Selection and Precautions

It is necessary to exercise sound judgment when selecting suitable testing procedures. For example, the results of static-immersion tests or alternate-immersion tests bear little relationship to pipelines flowing full within an operating plant. Test coupons inserted into an operating process line, or at least into a laboratory test loop using

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

process fluids at operating temperatures and velocities, will produce results that agree much better with actual plant experience. Because corrosion is often accelerated at metal/ liquid/vapor interfaces, these interfaces should be duplicated in the testing procedure if they are present in the plant or should be omitted from the testing if they are not an actual factor.

Simulated Service Corrosion Testing in Water, *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, *ASM Handbook*, ASM International, 2003, p 495–496

Test Specimens

Specimen geometry, ratio of environment solution volume to exposed specimen area, or other shape and area factors should be as similar as possible to true plant conditions. Exposed, cut specimen edges, which are often attacked more rapidly than other parts, should be examined and discounted if edges are not exposed in plant equipment. Similarly, stamped specimen identification characters may suffer increased rates of attack or may be sites of stress-assisted or accelerated corrosion.

Virtually every specimen size has been used in immersion testing. Popular laboratory test specimen sizes range from 1 cm^2 (0.15 $in.^2$) of exposed surface to 25 × 100 mm (1 × 4 in.), both of which are used frequently, to 100 × 150 mm (4 × 6 in.). In-plant and seawater tests sometimes involve specimens measuring 150 × 250 mm (6 × 10 in.) or larger. When weldments or projections are of concern, either the weldment or the projection should be incorporated into the specimen. Entire components are seldom tested in the laboratory but may be installed in pilot plant or works scale operations (pumps, condensers, heat exchangers).

Simulated Service Testing in Water

Effect of Water Variables

To date, no compilation of relative rankings of alloy types in various aqueous environments is available. However, for iron-base alloys, the corrosion rate is relatively uniform in most waters, whether they are of high or low purity. The rate seems to vary more with aeration, that is, from less than 0.05 mm/yr (<2 mils/yr) in deaerated water to more than 1.25 mm/yr (>50 mils/ yr) in aerated water. In tap, brackish, or seawater, pitting tends to occur. In tap water and seawater, yellow brass tends to dezincify (especially when conditions are near stagnation), although corrosion rates are less than 0.05 mm/yr (<2 mils/yr) and more than 0.5 mm/yr (>20 mils/yr) for tap water and seawater, respectively. Detailed information on dezincification can be found in the article “Effects of Metallurgical Variables on Dealloying Corrosion” in this Volume.

There are no definite rules concerning the effect of flow rates, temperatures, and/or pH on the corrosion of alloys in water systems, although in waters free of passivators (including dissolved oxygen), increasing flow rates tend to erode any protective corrosion films that may have formed. Corrosion rates of most alloys over the pH range of 4 to 10 show little effect of pH. Outside this range, that is, 0 to 4 and 10 to 14, the environment cannot technically be considered water, except for some highly unusual acid rain cases. Increasing temperatures sometimes precipitate protective salts, such as calcium carbonate, which decrease corrosion rates in normal-to-hard waters.

Very pure or very soft waters are often excellent solvents for metallic ions, such as copper. If these waters are used to prepare laboratory solutions for test purposes, dissolved copper from copper water lines can deposit or

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

plate out on more active metal surfaces. In the case of aluminum alloys, this deposited copper can greatly accelerate corrosion immediately adjacent to the copper. The effect of dissolved copper ion on localized corrosion of aluminum is cited in ASTM Standards G 4, section 4.5 (Ref 11); G 52, section 6.2 (Ref 12); and G 71, section 4.2.1 (Ref 13). Similar effects of lesser intensity have been observed on most active metals.

Temperature differentials between points in a flow system can produce accelerated attack due to differences in ionic activity. Although this attack usually occurs at the point of higher temperature, protective scales occasionally precipitate on the high-temperature surface, with attack occurring at the cooler sites. In any system involving differential temperature, the investigator should be aware of this possible behavior.

Another temperature effect in open, aqueous systems is the decreasing solubility of gases, particularly oxygen, with increasing temperature. This effect reduces the cathodic action, or more exactly that portion due to oxygen reduction, and thus decreases the amount of anodic reaction that occurs.

Similarly, the solubility of air and oxygen in saline solutions decreases with increasing concentration of salt, but the solution conductivity increases with the dissolved salt concentration. The two effects combine in oxygen reduction cathodic systems to produce increasing corrosion rates up to about 3.5 wt% sodium chloride (NaCl) solutions and decreasing corrosion rates above that value. This particular effect is not observed in freshwater systems.

Natural waters, depending on the source, may contain variable concentrations of dissolved carbonates. These are principally calcium, magnesium, and/or sodium, with the solubility controlled by both the partial pressure of carbon dioxide and the solubility product of calcium carbonate as it varies with alkalinity and temperature. Deposition of a thin continuous film of carbonate can protect the underlying metal where a lack of the same would allow attack. On the other hand, a film that is too thick impedes heat transfer and can lead to reduced flow and ultimately to possible tube burn-out. Carbonate scaling, measurement through the Langelier Index, and controlling treatments are discussed in Ref 14.

Introduction

TEST METHODS for evaluating the durability of a metal in soil are described in this article. Specimen design, preparation, burial, and retrieval techniques are discussed. The type of information sought during soil-induced corrosion evaluation controls the design configuration and the nature of the corrosion measurements. Consideration of these factors during the planning stage will help the corrosion engineer obtain a maximum amount of information with a minimum number of problems.

The corrosion of metals in soils, which is also called underground corrosion, can be divided into two broad categories: corrosion in undisturbed soils and corrosion in disturbed soils. Corrosion in undisturbed soil is always low, regardless of soil conditions, and is limited only by the availability of the oxygen necessary for the cathodic reaction. Steel piles driven into soil fall under this category and therefore undergo limited corrosive attack. Corrosion of metals in disturbed soils is strongly affected by soil conditions. Soil electrical resistivity, mineral composition, dissolved salts, moisture content, total acidity or alkalinity (pH), redox potentials, microbiological activity, and concentration of oxygen play important roles in determining whether metal corrosion is a serious problem in soils (Table 1). Other, secondary factors are also important but are more difficult to define. Thus, simply testing metals and alloys in a variable pH solution or in aerated or deaerated solutions will not accurately simulate the conditions in soil (Ref 2).

Table 1 Numerical corrosivity scale

Point system for predicting soil corrosivity according to American Water Works Association C 105

Soil parameter	Value	Assigned points
Resistivity, Ω · cm	<700	10
	700–1000	8
	1000–1200	5
	1200–1500	2
	1500–2000	1
	>2000	0
pH	0–2	5
	2–4	3
	4–6.5	0
	6.5–7.5	0
	7.5–8.5	0
	>8.5	3

	50–100	3.5
	0–50	4
	<0	5
Sulfides	Positive	3.5
	Trace	2
	Negative	0
Moisture	Poor drainage, continuously wet	2
	Fair drainage, generally moist	1
	Good drainage, generally dry	0

When points in the American Water Works Association scale equal 10 or higher, protective measures have been recommended for cast iron alloys. Source: Ref 1

Any metal buried by backfilling is in a disturbed soil and is subject to corrosion attack, depending on the characteristics of the soil. Most metals in soil are exposed to disturbed-soil conditions. Because it is the more common of the two, only the disturbed-soil condition is discussed.

Soil Characteristics

Soil is a complex, dynamic environment that changes continuously and seasonally, both chemically and physically. Precipitation, plants, and animals all have their effects on the environment, but perhaps a greater effect results from human activities of building structures, roads, electric power lines, underground utilities, landfills, farming, snow removal with salts, and so on. Characterizing a soil for its corrosivity is difficult at best. However, certain empirically derived facts are known to affect the corrosivity of soils.

Soil electrical resistivity is recognized as an important parameter in underground corrosion (Ref 3). Ions from dissolved salts and minerals must migrate through the electrolyte in a soil to supply the metal surface with the electron donors or acceptors necessary for the corrosion reaction to proceed. Soil resistivity is a measure of the concentration of these ions and how easily they move through the soil environment (Ref 4). A high soil resistivity suggests a low corrosion rate, because the rate of ion diffusion is low. The nature of the ion species is also critical. Chlorides, for example, are known to enhance the breakdown of the protective oxide on some metals (Ref 5). Copper ions accelerate the attack on aluminum (Ref 6). Sulfates can provide oxidizers for microbiological corrosion (Ref 7). Other salts, such as carbonates, can affect the pH of the soil. Thus, the corrosivity of a soil can be strongly affected by the presence of certain chemical species, and a soil that is corrosive for one metal may not be corrosive for another metal. Table 2 shows the generally adopted corrosion severity ratings based on soil resistivity (Ref 8).

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Table 2 Corrosivity ratings based on soil resistivity

Soil resistivity, Ω · cm	Corrosivity rating
>20,000	Essentially noncorrosive
10,000–20,000	Mildly corrosive
5,000–10,000	Moderately corrosive
3,000–5,000	Corrosive
1,000–3,000	Highly corrosive
<1,000	Extremely corrosive

pH. The acidity or the alkalinity of most soils is stable because of the buffering action of the soluble minerals available. However, soils across the United States, for example, can differ in pH from 5 to 10. This pH range has a small effect on general and pitting corrosion attack but has a large effect on the susceptibility of ferrous alloys to hydrogen embrittlement (Ref 9). Furthermore, some metals, such as zinc, copper, and aluminum, are amphoteric and can undergo corrosive attack at high and low pH values; by definition, these metals may be susceptible to attack in acid and alkaline soils (Ref 6). These effects on the corrosion process make it desirable to measure the pH of the soil at a test site (Ref 10).

Soil texture is dependent on the proportions of sand, silt, and clay mineral particles making up a soil. Clay, having the finest particle size and minimum pore volume between particles, tends to reduce the movement of air and water through the soil and can therefore develop conditions of poor aeration when wet. Sand has the largest particle size and promotes increased aeration and distribution of moisture. Soil texture is important as an influence on the diffusivity of soluble salts and gases. Internal drainage describes the water- retention properties of a soil and is related to soil texture. Internal drainage also is affected by the height of the water table and thus whether the soil is in a saturated or unsaturated condition. Soil texture and drainage also influence the movement of corrosion products within the soil environment and how corrosion products may change as they are transported away from the metal.

The ways in which soil resistivity, pH, and soil composition interact to determine soil corrosivity are not well understood despite extensive amounts of data that have been collected over the years (Ref 3, 11, 12). Soil temperature has been found to have a strong effect on soil resistivity and oxygen solubility. Because these are opposing effects competing to control the corrosion process, their cumulative effect on metal corrosion in soil is minimized (Ref 9). Clearly, many factors affect soil corrosivity, and their interrelationship is complex.

Test Approach

Although soil characteristics give some indication of the corrosivity of a soil environment, the optimal test of metals is to bury specimens in the soil of interest. The concept is simple, but there are some important considerations. For example, the type of data sought and the data objectives will determine the design of specimens and the test procedure. Will the data be used as an analog for underground utilities or structures, or will they be used in models to determine long- term containment failure and contaminant transport into the soil environment? Interest in metal corrosion in soils extends to long-term stability of critical underground infrastructure, such as water, gas, oil, and waste pipelines and telephone and electric power distribution cables. Another even more pressing environmental issue concerns the long-term underground containment of legacy and newly generated hazardous chemical and nuclear wastes—wastes requiring isolation and containment for hundreds or even thousands of years.

In addition to buried specimens of metals, provision must be made for electrochemical corrosion measurements and for environmental measurements during the burial period. Periodic retrieval of specimens of an alloy requires that identical sets be buried, one set per retrieval. Each set must have statistically significant numbers of each alloy represented. It is necessary to mark the specimens for future identification and to mark the location of the specimens at the site. The importance of maintaining permanent, clear, detailed records cannot be overemphasized. These records become increasingly important for long-term burial periods where personnel and organizations may change. Loss of records can directly impact the uncertainties in the corrosion rate measurements.

Specimen Preparation

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

The type of data needed usually determines the design of the specimen. If corrosion of pipe is under consideration, then pipe material should be used. To minimize internal corrosion effects, the ends can be sealed with caps. Corrosion of a tank container suggests the use of sheet or plate material for testing. If welds are expected, then welded material should be included. If dissimilar metals will be in contact, then galvanically coupled materials are required. Stressed U-bend or C-ring specimens, for example, are necessary for stress-corrosion or hydrogen embrittlement studies. Control specimens should also be included. Control specimens could be uncoated metals when the effect of coatings is being evaluated. Similarly, unstressed specimens should be included when stressed specimens are being studied. Archived samples of the alloys being studied (not exposed in the test environment but kept in a protected environment such as a desiccant chamber) should be kept for comparative purposes.

Before cleaning and weighing, the specimen is marked for proper identification by stamping or notching the specimen. In the case of a brittle metal, chemical or laser etching of an identification mark is preferred. In addition to this identification on the specimen, a secondary identification method should be used. One method is to attach plastic tags to the specimen in case corrosion is sufficiently severe to destroy the identification markings. Because these tags are often lost during retrieval or transportation, they should not be the primary marking system. Another method for identification is placement of the specimen. Both the placement position and the location of the trench can be used to identify the specimen, as long as the installation records are maintained. Where retrievals are planned on a periodic basis, duplicate specimens must be provided, and each must have its own unique identification mark.

Electrical contact to a specimen is required when electrochemical measurements are made during the burial period. This contact can be achieved with a 14-gage (~1.9 mm, or 0.075 in., diameter) insulated metal conductor that extends above ground and is soldered or bolted to the specimen. Solder can be removed after retrieval and before reweighing by heating the joint and wiping away the solder, but this is possible only with high-melting-point metal specimens, such as ferrous alloys. To avoid galvanic attack of the specimen or the conductor during burial, the joint must be coated. Electrical conductors to both electrodes of a galvanic couple allow galvanic currents to be measured.

Another real-time measurement to consider for corrosion rate comparison is the use of electrical resistance probes made from the alloys being tested. Electrical resistance probes have one element exposed to the test environment while another element is sealed and protected from corrosion in an epoxy or plastic sheath. This allows a comparison of electrical resistance between the two elements. Sensitivity of the probe depends on the element configuration and thickness. Periodic measurements are made over the course of the test to determine corrosion rate.

Specimen Burial

A technique frequently used for shallow burial is to dig a trench up to 1.22 m (4 ft) deep that is long enough to allow placement of the specimens approximately 300 mm (12 in.) apart along its length (Fig. 1). For burial of specimens deeper than 1.22 m (4 ft), a large-diameter hole can be drilled. In deeper burials, caution should be used to ensure worker safety and cave-in protection (Fig. 2). If specimens are to be retrieved periodically, for example, after 1, 2, or 4 years exposure, then all specimens of a given retrieval increment should be grouped together; that is, all specimens to be recovered at the end of 1 year are grouped separately from those that are to be retrieved at the end of 2 years, and so on.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

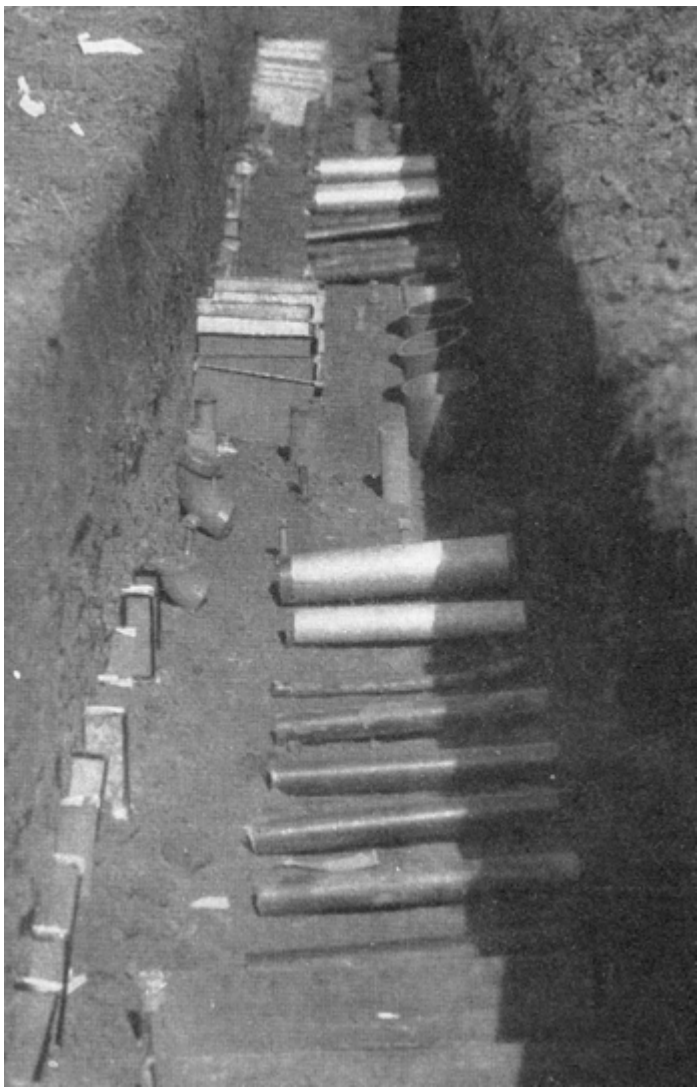

Fig. 1 Metal specimens in trench. Typical of underground corrosion studies, metal samples of sheet metal, pipes, and pipe fixtures are arranged in a shallow trench.

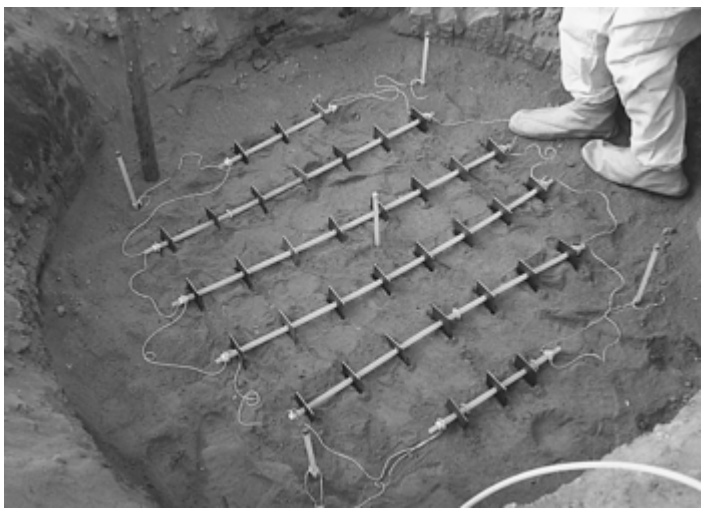

Fig. 2 Metal specimens in augured drill hole. Metal samples are arranged on inert rods arranged as an array in the hole. The rods are tethered to location rods with nylon cords. Other instrumentation, such as a pipe for moisture monitoring and a tube for soil gas sampling, are also pictured. Depths may vary, depending on the requirements of the underground corrosion to be investigated.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

To facilitate retrieval of the specimens, it is useful to tie a small-diameter (3 mm, or 0.12 in.) nylon rope (or other nonconductive material) to each specimen in a retrieval group. Thus, when one specimen is found, digging can proceed by following the rope until all of the specimens are recovered. Wood posts can be used to mark the location of the ends of a group of specimens, and the rope can be tied to these posts. Where posts cannot be used, metal markers buried just below the surface of the ground are used to mark the location of the specimens. These markers can then be located with a metal detector. It is useful to have a clearly visible surface marker that identifies the site and an individual or company that can be contacted for further information about the test.

An accurate map of the area identifying the exact location of all specimens is mandatory. Global positioning system (GPS) coordinates can be used to identify the location of the specimens and markers on installation and again at the time of specimen retrieval. The GPS elevation data also can provide the depth of specimens in relationship to the elevation of the soil surface. This GPS data should be recorded on the specimen map of the test site. Although describing the details of burial and recovery may seem mundane, important data can be lost in long-term exposure tests because such information was not properly recorded and maintained.

Electrical conductors attached to the specimens, including those from installed probes, must be carefully and permanently marked for identification at the surface end of the conductor. These conductors can then be attached to contact points on the wood posts or secured through a stand-up pipe with a weather-protective instrument/terminal enclosure (Fig. 3).

Corrosion Measurements

Engineers are usually interested in obtaining data on the corrosion rate of a metal in soil, and this requires knowledge of mass loss and length of exposure. However, rate of pit growth may be the more important measurement if the material is to be used in construction of a fluid container or a pipeline. For some metals and

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

alloys, stress- corrosion cracking or hydrogen embrittlement may more likely be the mode of failure. Other aspects related to corrosion may also need to be examined, such as microbiological influences and transport of corrosion products away from the specimens and into the surrounding environment.

Uniform Corrosion. Gravimetric mass loss is the reference by which all mass loss measurements are judged when evaluating the uniform or general corrosive attack of a metal in soil. Gravimetric mass-loss determinations involve weighing the specimen before the exposure period and then reweighing it after retrieval. When properly carried out, the mass loss represents the average rate at which the metal is consumed by corrosion. This technique generally requires long exposures (years) so that the mass loss is measurable and significant. Specimens of 1000 g or less should be weighed to an accuracy of 0.5 mg. Sample size may be limited by the capacity of the balance available. An excellent source of information on preparing, cleaning, and evaluating specimens is ASTM G 1 (Ref 13).

If data are obtained through periodic retrievals, little can be learned about corrosion losses between retrieval times. One method of obtaining continuous corrosion rate data is to use electrical measurements that take advantage of the electrochemical nature of underground corrosion. Another method is to employ real-time electrical resistance corrosion probes.

In the polarization resistance technique, the potential of a metallic specimen is changed by 10 mV or less, and the amount of current applied to make this change is measured (Ref 14). Three electrodes are usually used: the working electrode (the metal of interest), the reference electrode (used to measure the potential of the working electrode), and the counterelectrode (used to apply current to the working electrode). Figure 4 illustrates the configuration of the three electrodes for a typical measurement in soil. The effects of the potential (*I*R) drop between the reference electrode and working electrode, an error that arises when measuring a potential in the presence of current (*I*) flowing through a resistive medium (R), must be considered (Ref 15). Details of this polarization technique are described in the article “Electrochemical Methods of Corrosion Testing” in this Volume.

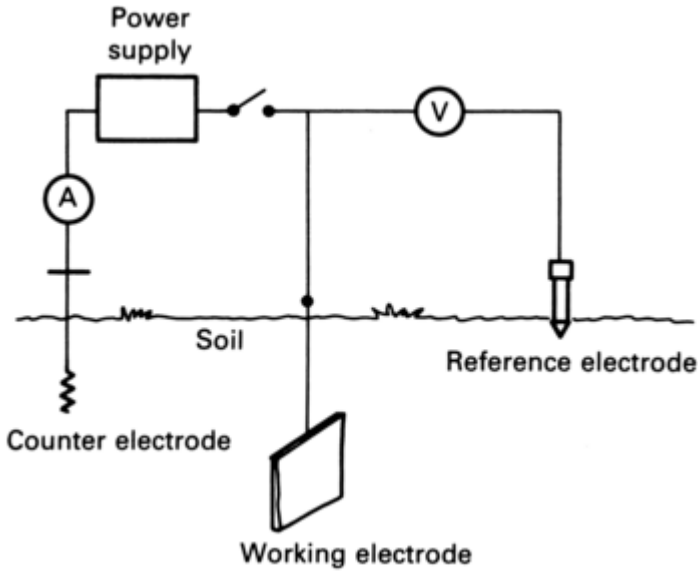

Fig. 4 Configuration of electrodes used in a polarization measurement of metals in soil

Pitting corrosion is typically measured after retrieval of the specimens, as described in ASTM G 46 (Ref 16). Large, shallow pits can be easily measured with pit micrometers. A narrow, deep pit is more difficult to measure, because a pit micrometer cannot be used. Scanning vertical interferometry is a method to precisely measure even small-diameter pits nondestructively. Another accurate but time-consuming method is to cross section the specimen and use an optical means to measure the pit. A micrometer stage on a low-power microscope is useful for this type of measurement.

Whichever method is used, the objective is to measure the deepest pits. By measuring the maximum pit depth of duplicate specimens over a period of time, a rate of maximum pit growth can be obtained. The distribution of the pits (percentage of surface pitted) may also be of interest. Time-to-perforation data can be obtained by designing a specimen that is pressurized with air. This pressure is then monitored over a period of time until failure is indicated by a pressure decrease (Ref 17). It is important to design the system so that the specimen being tested fails before the monitoring lines fail.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Stress-Corrosion Cracking and Hydrogen Embrittlement. Preparation of stressed specimens for underground performance studies is more time-consuming, because the specimen must be properly stressed before burial. Fixtures or bolts attached to the specimen must be nonmetallic, electrically insulated from the specimen, or coated to avoid galvanic effects. When hydrogen embrittlement specimens are cathodically charged by a sacrificial anode, it may be useful to monitor the current between the two electrodes and the electrical potential of the couple versus a reference electrode (Ref 18).

Time-to-failure data can be obtained by attaching a hollow tensile specimen to a stressing ring (Fig. 5) and monitoring the change in strain or diameter of the ring. Stress is applied to the tensile specimen by turning the stressing nuts so that the stressing ring is elastically deformed. The stressed tensile specimen is then embedded in the soil, with the stressing ring extending above ground (Fig. 5). This and other special designs can provide failure data before retrieval. Retrieval of the specimen soon after failure is important to prevent subsequent destruction of the failure surface by general corrosion attack. Examination of this surface can provide information on the mode of failure.

Specimen Retrieval

When the specimens are buried as described here, the retrieval process should proceed smoothly. The initial surface digging can be carried out with power equipment, but the final few centimeters of soil must be removed by careful hand shoveling to reduce the possibility of specimen damage, loss of corrosion products, or loss of identification labels. Corrosion product at or near the specimen surface needs to be collected once the specimen location is determined. The spatial distribution of corrosion product relative to the specimen will provide information on migration or transport of corrosion product in the surrounding soil. Microbial sampling of the specimens should be done immediately after retrieval for best results. A preliminary examination of specimens and a photographic record during the retrieval can be very useful. The preliminary examination helps identify changes that may occur in the time between excavation and final specimen examination in a laboratory.

Conclusions

Corrosion of metals in undisturbed soil is typically very low and is independent of soil characteristics. However, corrosion in disturbed soil is strongly influenced by the soil environment. Because determining soil corrosivity through soil characterization is difficult, and because data on specific alloys are needed, it is necessary to conduct underground corrosion studies. Information on the durability of metals in soil can be obtained by using physical and electrochemical measurements.

Gravimetric measurements and electrochemical polarization measurements provide information on deterioration due to uniform corrosion. Pit depth measurements and surface monitoring of pressurized vessels provide data that can be used to determine metal perforation rates. The susceptibility of metals to hydrogen embrittlement and stress-corrosion cracking can also be determined by physical measurements at the soil surface or by periodic retrieval of stressed specimens. Monitoring the potential and the galvanic current of cathodically charged stressed specimens can reveal the susceptibility of an alloy to hydrogen embrittlement.

Specimen design depends on the type of data sought. It is essential to mark burial specimens properly, to map burial sites, and to maintain permanent records. A reliable chain of custody of the records is particularly important in long-term exposure tests.

Introduction

BECAUSE OF THE MAGNITUDE of the corrosion problem, its economic impact, and human safety factors, new methods for detecting and monitoring corrosion are being developed. Past efforts have resulted in new methods being used in the field or being tested for possible field use. The possibility of a "smart coating" that could detect corrosion, inhibit corrosion, and facilitate the repair of corroded areas is an industry goal. Wireless technology has resulted in the possible implantation of sensors that can be interrogated from remote locations and thus monitor areas that were previously inaccessible except by detailed examination and disassembly of the structure.

While the standard techniques of coupon evaluation for field studies of corrosive conditions are still valuable, they may be inconvenient, labor intensive, or too slow to monitor the corrosion process. Resistance and hydrogen probes monitor on-line corrosion in reactor cooling waters, oil pipelines, and refineries (Ref 1, 2). The location and monitoring of these probes are critical for obtaining meaningful data. NACE Standard, RP0189-95 discusses such methods for on- line monitoring of cooling waters (Ref 2). Figure 1 shows an on-line monitoring system. Parameters such as pH, temperature, conductivity, and corrosion currents are monitored. Other parameters, including heat-transfer rates across piping, water-flow rate, pressure-drop changes, and biofilm sensors, as well as electrochemical and optical sensors are reviewed in this article. This article covers some standard techniques, but also reviews some of the new methods that have been developed. At the time of publication, some of these newer methods were being field tested, while others were in development.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

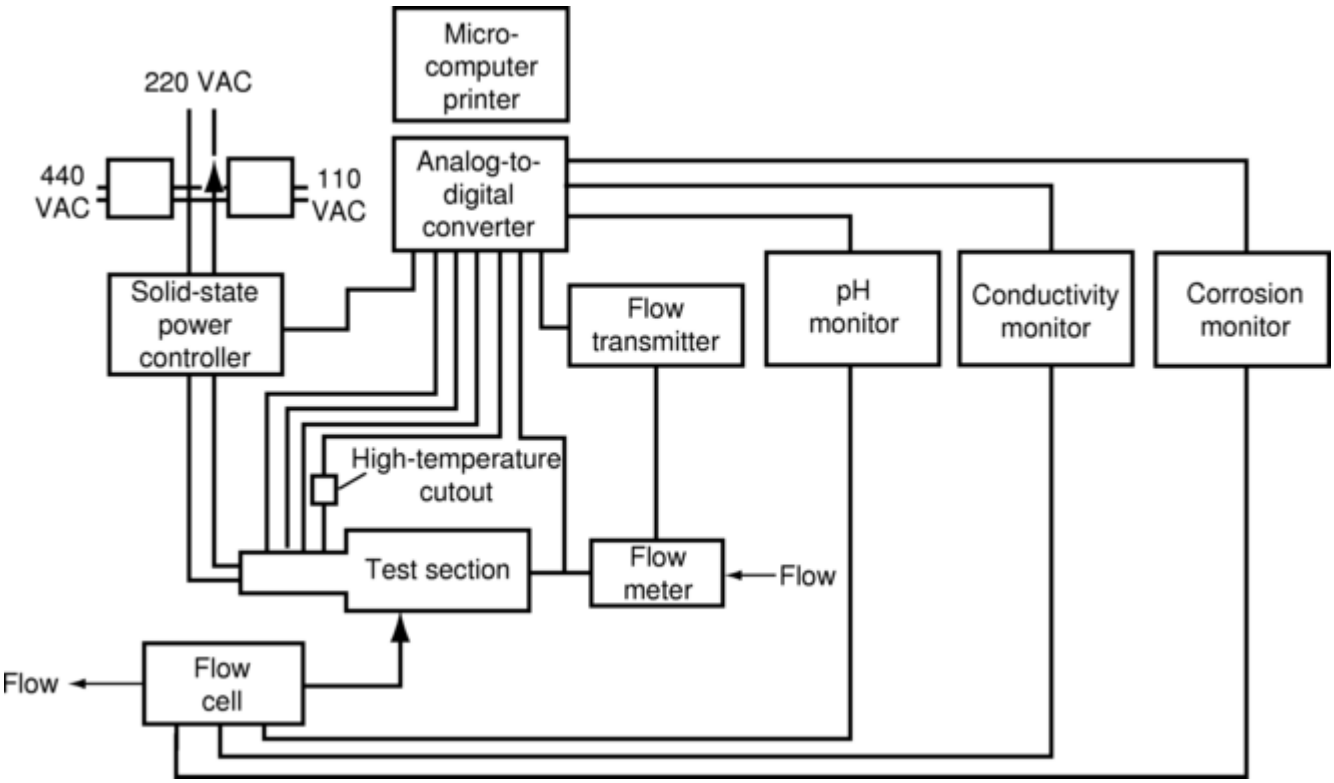

Fig. 1 Integrated on-line monitor

The most promising newer techniques are detailed in subsequent articles in this Handbook. In general, these techniques fall into such categories as electrochemical methods, electromagnetic or sound wave methods, and fiber-optic technology, along with visible, ultraviolet or infrared light, and some unique methods utilizing reflected and amplified light to look at surface topography, triboluminescent sensing, thermography, and the superconducting quantum interference device (SQUID). Reports describing these methods are included in NACE Symposia on corrosion monitoring (CORROSION/1994, Ref 3; CORROSION/1997, Ref 4; and CORROSION/2000, Ref 5). Agarwala and Ahmad (Ref 6) give detailed references to many of the corrosion-monitoring techniques mentioned in this article. For the management of corrosion data, Roberge and Tullmin show how to monitor corrosion in aging systems for maintenance and repair issues (Ref 7, 8).

Electrochemical Methods

Polarization resistance measurement has been used to detect crevice corrosion under O-rings and at the ends of pipe. Crevice corrosion measured visually correlates well with polarization resistance (Ref 9). Embeddable microinstruments can measure resistance and other corrosive parameters and transmit data from remote locations (Ref 10). Figure 2 shows a 4 by 6 mm (0.16 by 0.24 in.) microinstrument, which includes potentiostat, zero-resistance ammeter (ZRA), analog-to-digital and the reverse (A/D- D/A) converters, and three on-chip electrodes. Results from the microinstruments to measure polarization resistance indicated good correlation to results from conventional instrumentation. Further development of microinstruments will include potentiometric measurements controlled by microprocessor. The microinstrument can be incorporated in on-line testing systems by attaching them to actual parts of interest.

Corrosion potential and cathodic protection current monitoring was used to determine the extent of coating damage inside large ship tanks (Ref 11). This technique, combined with a camera on the probe for visual information, provided a convenient method to monitor corrosion damage to wastewater collection and ship ballast tanks. Access of the probe was through normal hatches in these ship tanks and off-the-shelf equipment was utilized. When the electromotive force (emf) or anodic current was monitored, limits could be established by correlating corrosion damage to that shown on the video camera. Software enhancements of the video recordings also produced images highlighting the corrosion damage itself. Figure 3 indicates the probe assembly inserted through the hatch with zinc anodes, reference electrodes, and associated data logger. Figure 4 indicates the acceptable levels for the potential to monitor corrosion; similar figures could have been developed in the work for monitoring the zinc electrode anodic current (Ref 11).

مرجع مهندسی مواد و متالورژی

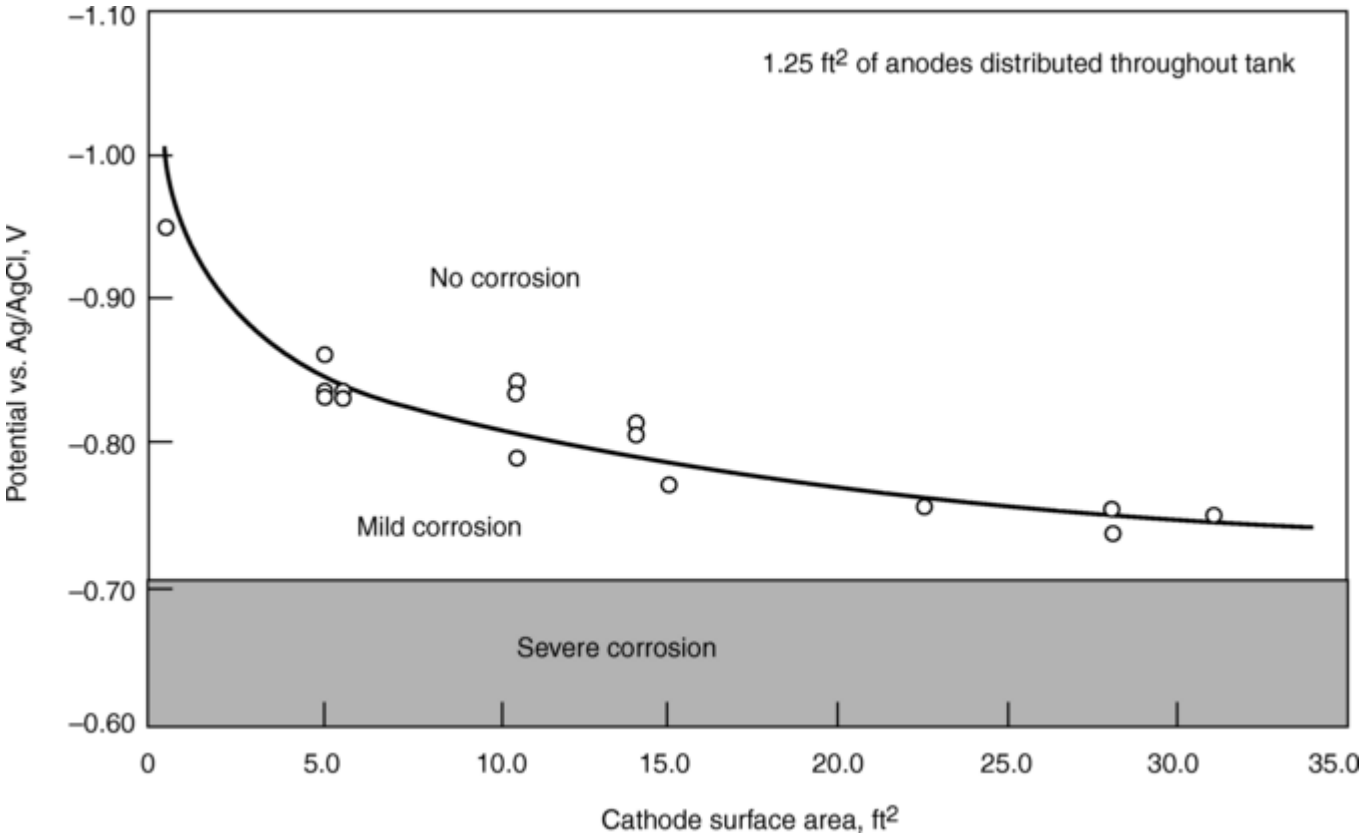

Fig. 4 Potential versus surface area of cathode with areas marked for no corrosion, mild corrosion, and serious corrosion

Electrochemical impedance measuring systems have been developed with implantable electrodes to monitor in situ corrosion of surfaces and interfaces (Ref 12). Figure 5 shows the information obtained from this implantable type of system at low frequency. Electrochemical noise (ECN) measurement has been used for corrosivity assessment. Interpretation of the results of ECN was difficult (Ref 13, 14). With advances in software, transform programs, and enhancement techniques, patterns of ECN are being correlated with the different types of corrosion.

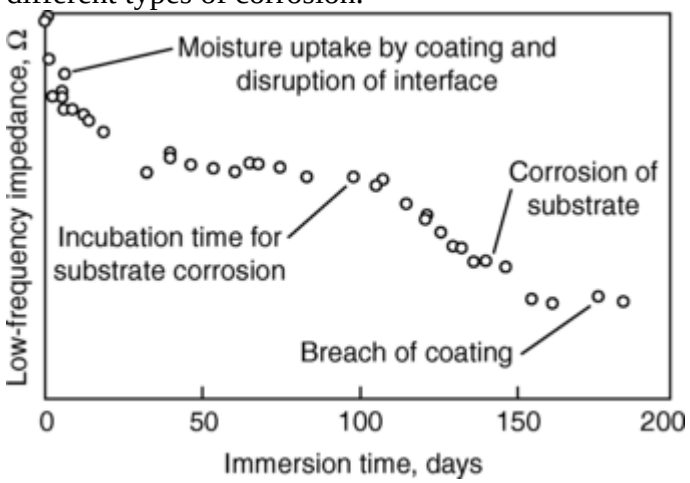

Fig. 5 Low-frequency impedance as a function of sample exposure time for immersed epoxy-coated aluminum. Three stages of coating degradation shown are moisture absorption, incubation, and substrate corrosion.

Voltammetric microelectrodes have been developed to measure corrosivity parameters such as metal ions, pH, sulfide ions, and oxygen (Ref 15, 16, 17, 18, 19). Figure 6 is an example of a microelectrode system that fits inside a standard rivet fastener. These measurements are indirect and very localized, but the possibility of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

several outputs that can then be correlated to corrosion is possible and may become more reliable with the multiple signal outputs.

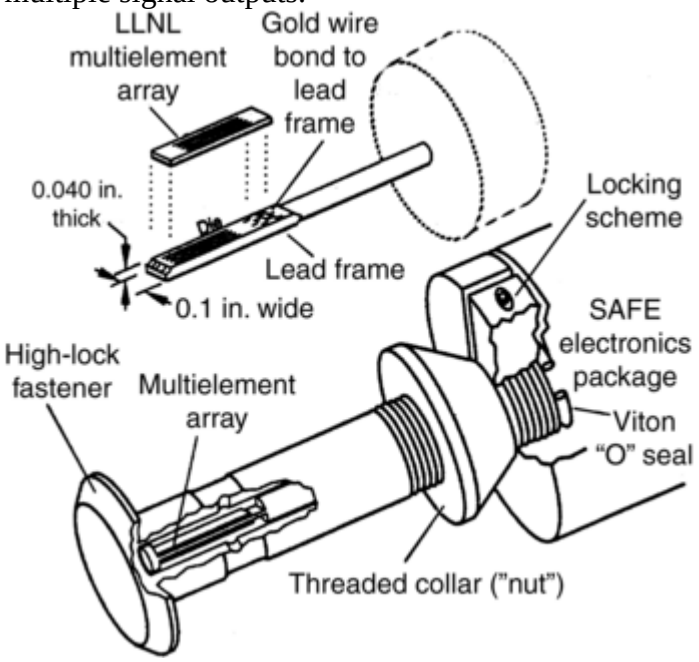

Fig. 6 Microelectrode array fitted into a rivet fastener

Coulometric measurements on a macroscale using copper cup, glass beads, and steel screens (Ref 19) or on a microscale with implantable bimetallic thin-film galvanic sensors (Ref 20, 21, 22, 23) have been developed and tested. The latter stand- alone, microthin film coulometer, called intelligent corrosivity sensor (ICS), is presently being validated to monitor hidden corrosion conditions inside aircraft using a wireless concept (Ref 20, 21, 22). The ICS measures galvanic current produced by the thin-film bimetallic elements, collects and stores data in its memory chip, and downloads data when queried through a radio frequency (RF) data-gathering transceiver (DGT) or transponder to a laptop computer. Figure 7 shows a composite picture of ICS components.

Fig. 7 The hardware components of intelligent corrosivity sensor (ICS). The schematic below thin-film sensor shows the sensing element with interdigitated metallic strips.

Figure 8(a) shows how sensors can be mounted in the most corrosion-prone interior of a P-3 aircraft. The technique measures corrosivity of the localized environment and is stand- alone for up to three years during military deployment. The data download is done through the DGT when desired or on the availability of the aircraft. The software is used to develop a real-time profile of current and then to transform it into coulombs to indicate corrosion rate as total possible corrosion damage with period of exposure, as shown in Fig. 8(b). This is finally used to develop a corrosion index for determining repair and maintenance calls.

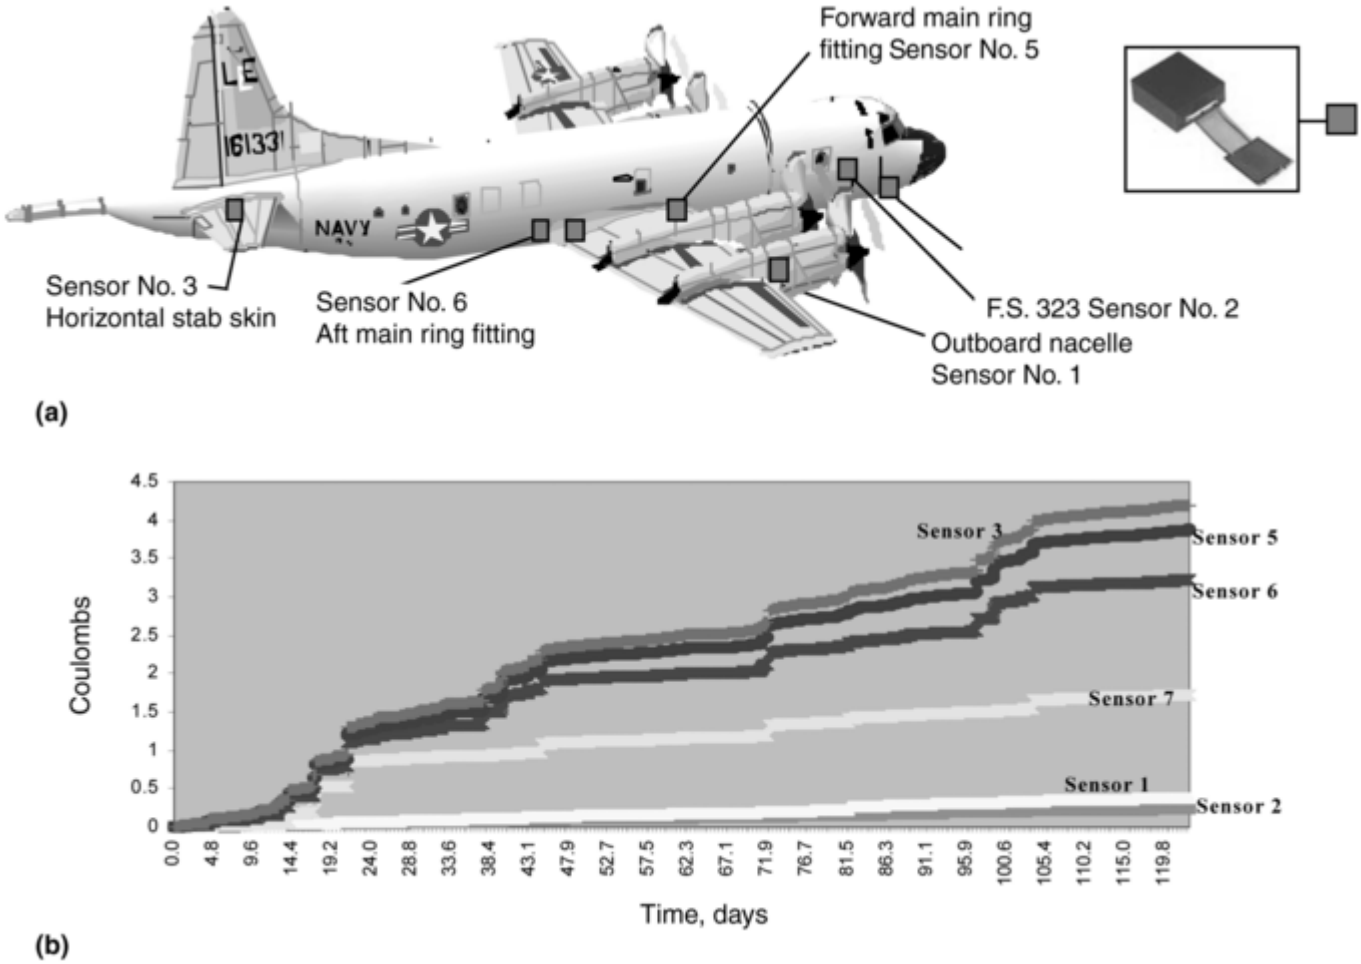

Fig. 8 Corrosion data recording on an aircraft. (a) Sensor locations. (b) Coulombs versus deployment time of data downloaded from each ICS (shown as square blocks mounted on P-3 aircraft) during service

Hidden corrosion damage detection has been the most difficult task where teardown inspection is cost prohibitive. In the past, nondestructive inspection (NDI) was at best 60% accurate. In the last decade, significant technical advancements have led to breakthroughs in the use of NDI techniques. The new microwave, ultrasonic, and acoustic techniques are finding much greater applications for monitoring hidden corrosion and cracks. For instance, a microwave corrosion detector (MCD) can scan and locate corrosion underneath paint using microwave sources and analyzing the reflected wave to determine the integrity of the coating/substrate interface (Ref 23). It is based on the principle that the energy of the reflected radar wave is different in corroded areas compared to a reference or noncorroded surface. The concept was derived from a police radar gun. Figure 9 shows the latest version of a MCD, which has been used for scanning surface corrosion under coatings.

Fig. 9 A handheld microwave corrosion detector (MCD) scanner

A typical eddy-current system measures the impedance of a very small area of a structure within its reach. In the presence of crack/corrosion damage, the eddy currents are interrupted, causing a change in the complex impedance of the test area in that location. Often this change or blip in the impedance spectra is skewed and becomes indeterminate when there are multilayers present. The new developments in this technology have made eddy current a better tool to find corrosion in multilayer aircraft structures (Ref 24) and in reinforced and prestressed concrete structures (Ref 25).

Acoustical monitoring of concrete bridges and pipelines with computer software analysis and remote sensing has been successfully used in identifying localized areas of deterioration (Ref 26). An array of acoustical sensors embedded/ installed on large structures such as bridges or buildings can be monitored from remote locations, detecting large cracks or other acoustical events and alerting personnel to inspect those sites.

Until recently, ultrasonics was the least used method because of the complex nature of the waves and noise signals generated during its application. The new developments in signal processing and the hardware and software designs of ultrasonic guided wave methods have made it possible to sense defects in inaccessible areas under coatings or in joints on aircraft structures (Ref 27, 28). Alloy wall thinning, microcracking, and debonding effects can be seen with this method as demonstrated on helicopter and fixed- wing aircraft surfaces. Figure 10 shows an example of lap splice inspection and detection of poor bonding in the splice joint. Recently, the use of piezoelectric films has miniaturized the transducers that produce ultrasonics; this makes the method more useful as a leave-in-place device for long-term monitoring of corrosion-assisted damage.

Optical and Fiber-Optic Sensing

The change in optical properties of aluminum- clad fiber-optic probes as the aluminum corrodes has been tested at Boeing for monitoring hidden areas of aircraft for corrosion (Ref 29, 30). This method is adaptable to remote sensing and can be installed in new installations and on aging aircraft during maintenance in the corrosion-susceptible areas.

Uses of pigments that change color upon evolution of hydrogen have been tested as indicators of metal oxidation at a nearby site (Ref 31). These pigments could be incorporated into paint coatings to detect corrosion. A fiber-optic strain sensor has been used to detect changes in a metal surface due to corrosion, cracking, or joint failure (Ref 32, 33). Changes in pH can also be detected with fiber-optic probes (Ref 34). During corrosion of surfaces, the pH can increase or decrease in different areas.

Fluorescence Methods

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Fluorescence utilizes an excitation light source of a given wavelength and then measures the corresponding emission of fluorescence light at a lower wavelength. The light source can be ultraviolet, visible, or infrared light. The development of fiber-optic fluorescence in the red and infrared regions is a new approach to corrosion detection as only few natural materials fluoresce in the infrared (Ref 35). The fluorescence can detect pH changes as well as changes in concentration of specific analytes (metal ions, oxygen, carbon dioxide, etc.). Thus, fluorescent techniques have been developed that are sensitive to small-concentration species and are very selective. The methods of detection can also be varied from direct measurement of fluorescence emission to determine the ratio of emission at two wavelengths and even fluorescence lifetime measurements following the decay of emitted light after a pulse of excitation light. For corrosion detection, fluorescence can be used to monitor redox changes, pH changes, or the buildup of corrosion products (adsorption-type indicators) on selected surfaces.

The application of fluorescence methods to scan large areas for corrosion has been investigated by Agarwala and Johnson (Ref 36, 37, 38). The concept is based on the specificity of incorporated indicator material in a paint/coating that changes its fluorescent property when it either oxidizes or interacts with corrosion products. On many surfaces, corrosion is not easily seen because of surface coatings, limited access locations, or difficulty in inspecting large areas thoroughly. The incorporation of fluorophore into a coating would change its fluorescent properties during localized corrosion and could greatly enhance corrosion detection, providing economic and safety benefits. Large surfaces such as those on an aircraft could be scanned with an ultraviolet (UV) source, and the fluorescence could be monitored visually or with a recorder to note areas where corrosion may have occurred. These areas could then be checked in detail with other techniques if necessary. Figure 11 illustrates this method of scanning.

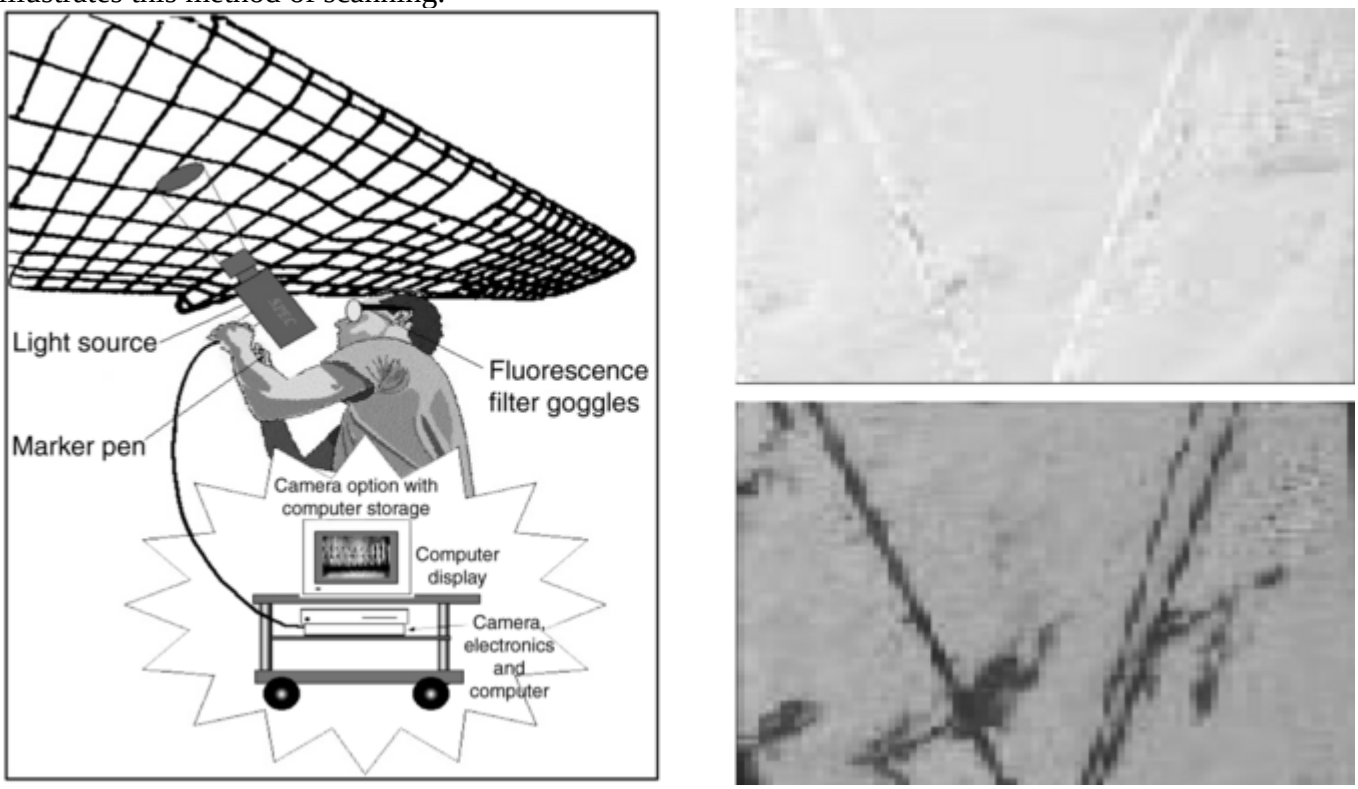

Fig. 11 Large-area scanning system for corrosion under coating using ultraviolet (UV) light source. Left: a camera option to visually inspect and record corrosion suspect areas on an aircraft wing. Right: a close-up picture of a panel showing corrosion under the coating. Fluorescence under UV is quite obvious as compared to the one in visible light.

Fluorophores such as fluorescein, oxine, and morin have been tested for this type of application. Fluorescein is highly fluorescent in high pH conditions and also in the oxidized state. Figure 12 shows the behavior of fluorescein when formulated in an epoxy and applied on an aluminum panel. Figure 12(a) shows the difference in fluorescence as the degree of corrosion increases. This painted panel was exposed to salt-spray conditions of varying degree to cause corrosion. Figure 12(b) shows the fluorescent spectra with high emissions for fluorescein in a broad range of 525 to 555 nm wavelengths.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

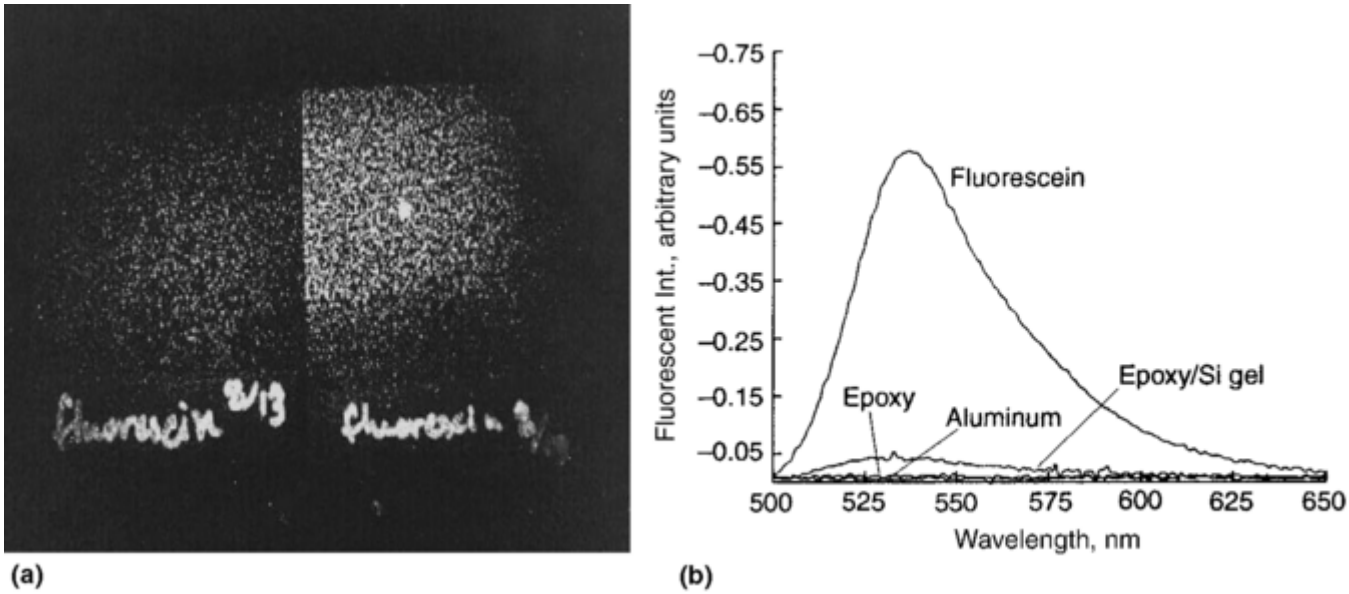

Fig. 12 The result of fluorescein test as indicator of corrosion. (a) Variance in fluorescence under ultraviolet light with varying degree of corrosion. (b) A broad range high emission for fluorescein

Oxine is an adsorption-type indicator, and when it adsorbs to aluminum oxide it fluoresces. The aluminum oxide must be in a granular state from localized corrosion and not the tight layer type that is present on all aluminum surfaces. Oxine has been shown to fluoresce more on a painted but nonchromated surface than on a chromate conversion coated 7075-T6 aluminum alloy. Morin is a complexing agent that binds to aluminum ions and becomes fluorescent. This fluorescence is an indication of the oxidation of aluminum on a surface.

There are also temperature-sensitive fluorophores that change color with temperature so that they can monitor small changes in surface temperature. They can monitor chemical reactions due to corrosion under the surface, or, with thermal imaging, they can sense temperature differences when the surface is subjected to a transient from a heat source.

Other Corrosion-Detection Methods

The Diffracto Sight, or D-Sight, is an optical method that uses a charge-coupled device (CCD) camera and a white light source. It measures reflected light from a low incident angle light on surfaces (Ref 39, 40). The reflected light is amplified by the collection method, and the resulting image magnifies surface topology so that pillowing (corrosion products) around rivets and other surface changes can easily be seen. Figure 13 indicates the difference seen by this method in a heavily corroded area and a noncorroded area.

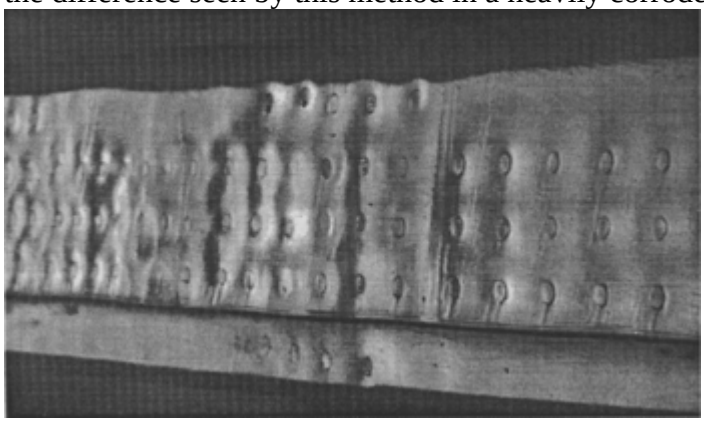

Fig. 13 The results of using Diffracto Sight (D-Sight) method in examining areas with heavy corrosion

Triboluminescent damage sensors detect the light emitted by materials upon fracturing (Ref 41). This is being looked at for detection of cracks and fretting/fatigue damage. Thermography senses thermal gradients from a surface after flashing it with a heat source (Ref 42). The thermal patterns will be different for areas with corrosion products, delaminations, and cracks compared to the noncorroded surface. Figure 14(a) shows a thermography setup for either reflection or transmission. Figure 14(b) is a thermograph of a lap joint showing hot spots and possible corrosion around two of the fastener areas.

Fig. 14 Infrared thermography. (a) Standard setup of heat lamps, sample, and infrared detector for reflectance (left) or transmission mode (right). (b) A thermograph of a lap joint showing two hot spots at fasteners indicating possible corrosion products

The superconducting quantum interference device (SQUID) magnetometer can image changes in the magnetic fields of a surface caused by corrosion (Ref 43, 44). The setup for this method is shown in Fig. 15. In this novel approach, actual corrosion currents are detected. So far, this device can be used only in the laboratory and on conveniently sized surfaces. Even at this early stage, it could certainly identify problem areas that are more susceptible to corrosion (types of lap joints, fasteners, etc.) and should be monitored more carefully on larger surfaces.

Data Management and Expert System

Management of data collected by various methods is key to a successful corrosion prevention and control program. A good record of corrosion types, locations, and repair history is essential for determining trends and patterns of corrosion, according to Colavita et al. (Ref 45). Problems can be identified and prioritized. Of course, this would require creating a systematic approach to develop a good diagnostic solution for repair and maintenance. Handsy and coworkers (Ref 46, 47, 48) used this concept to develop a general-purpose statistical database management system for inspection, data collection, and analysis of military vehicles. Their Corrosion Expert System (CES) was designed to act as an intelligent assistant to a vehicle designer (Ref 48). Figure 16 shows the architecture used by CES. It is a hybrid rule-based production system and Bayesian network composed of seven parts:

- A hybrid production system composed of a long-term memory containing a knowledge base of rules formulated with the help of human experts through the knowledge acquisition facility; a working memory containing a global database of facts or evidence used by the rules; an agenda containing a prioritized list of rules created by the inference engine, whose patterns are satisfied by facts or objects in working; an inference engine that decides which rules are satisfied by the facts or objects, prioritizes the satisfied rules, and executes the rules with the highest priority; and a Bayesian network propagating uncertainty in the rules
- Computer-aided design/computer-aided engineering (CAD/CAE) system interface for converting geometry
- Geometry analyzer that uses a separate rule- based production system to determine some geometry-related facts such as the galvanic potential of the materials, area ratio, presence of crevices, poultice entrapment, and drainage
- Explanation facility for the expert system to explain its reasoning to the user
- Knowledge acquisition facility for automatically entering new knowledge into the system in the future
- An advisory system that utilizes information from the system explanation facility and the geometry analyzer in a separate rule-based production system to formulate proposed actions the user can take to avoid corrosion
- User interface for communication with the expert system, specifically, a Java-based graphical user interface (GUI)

Simulation and Modeling

Predictive modeling and simulation offer an economic and efficient way to investigate the appropriate procedures for incorporating the mechanisms of corrosion prevention into military hardware systems design and operation. This area addresses model development, model implementation, system simulation, visualization, and more. This includes, but is not limited to, performing failure modes and effects analysis, reliability modeling and analysis, fault-tree analysis for reliability and safety operations, man- machine models,

www.iran-mavad.com

maintainability modeling and analysis, life-cycle predictions, behavioral projections, virtual-reality models, and safety-impact analysis for normal and abnormal environments. The Aircraft Structural Integrity Program (ASIP) of U.S. Air Force is perhaps the first effort based on this concept (Ref 49).

Introduction

A VARIETY OF ELECTROCHEMICAL TECHNIQUES are used to detect and monitor material deterioration in service or in the field. Static or direct current (dc), potential or current measurements, are well established in a number of applications, including buried pipelines and storage tanks. Electrochemical impedance spectroscopy (EIS) and electrochemical noise (ECN) measurements are more common in the laboratory but are also finding applications in the field, especially for inspection of coatings.

Direct Current Electrochemical Techniques

The most commonly used electrochemical technique in corrosion detection of buried or immersed structures is to measure the corrosion potential or open-circuit potential of the corroding metal against a reference electrode and follow its variation with time. In general, if the corrosion potential of a buried pipeline falls to more active values, then corrosion is developing, but a shift in the positive or noble direction indicates a stifling of corrosion through passivation or the formation of insoluble protective corrosion products. For example, newly laid insulated steel pipelines may have an average potential in excess of -0.8 V with respect to a copper/copper sulfate reference electrode, whereas old corroded steel pipes may have an average potential in the order of -0.2 V (Ref 1). In this case, the old pipe with the less negative voltage, though corroded, is corroding at a slower rate.

The copper/copper sulfate half cell is commonly used as a reference electrode for underground metals—that is, those in contact with soil or concrete (Ref 2). Differences in potential values along the pipeline mean that galvanic currents are flowing through the soil between the anodic and cathodic points on the pipe. If all the pipe-to-soil potentials along the pipe were of equal value or if infinite circuit resistances existed, galvanic currents could not flow and the pipelines would not corrode. These ideal conditions do not exist. The rate of corrosion will depend on the magnitude of the galvanic currents flowing.

In addition to the corrosion information that the pipe-to-soil potential technique provides, potential surveys over various parts of the pipeline may determine such effects as current distribution, induced currents, and stray-current pickup. This information can be used to design a suitable corrosion protection system to prevent further pipeline degradation. In Fig. 1 (Ref 3), three reading locations are shown for a pipe-to-soil potential survey on

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

an insulated pipeline. If no corrosion were occurring, each potential reading would be essentially the same. However, because these measurements are affected by corrosion currents flowing to or from the pipe due to voltage drops in the soil in the immediate vicinity of the pipeline, pipeline corrosion is reflected in the voltage measurements.

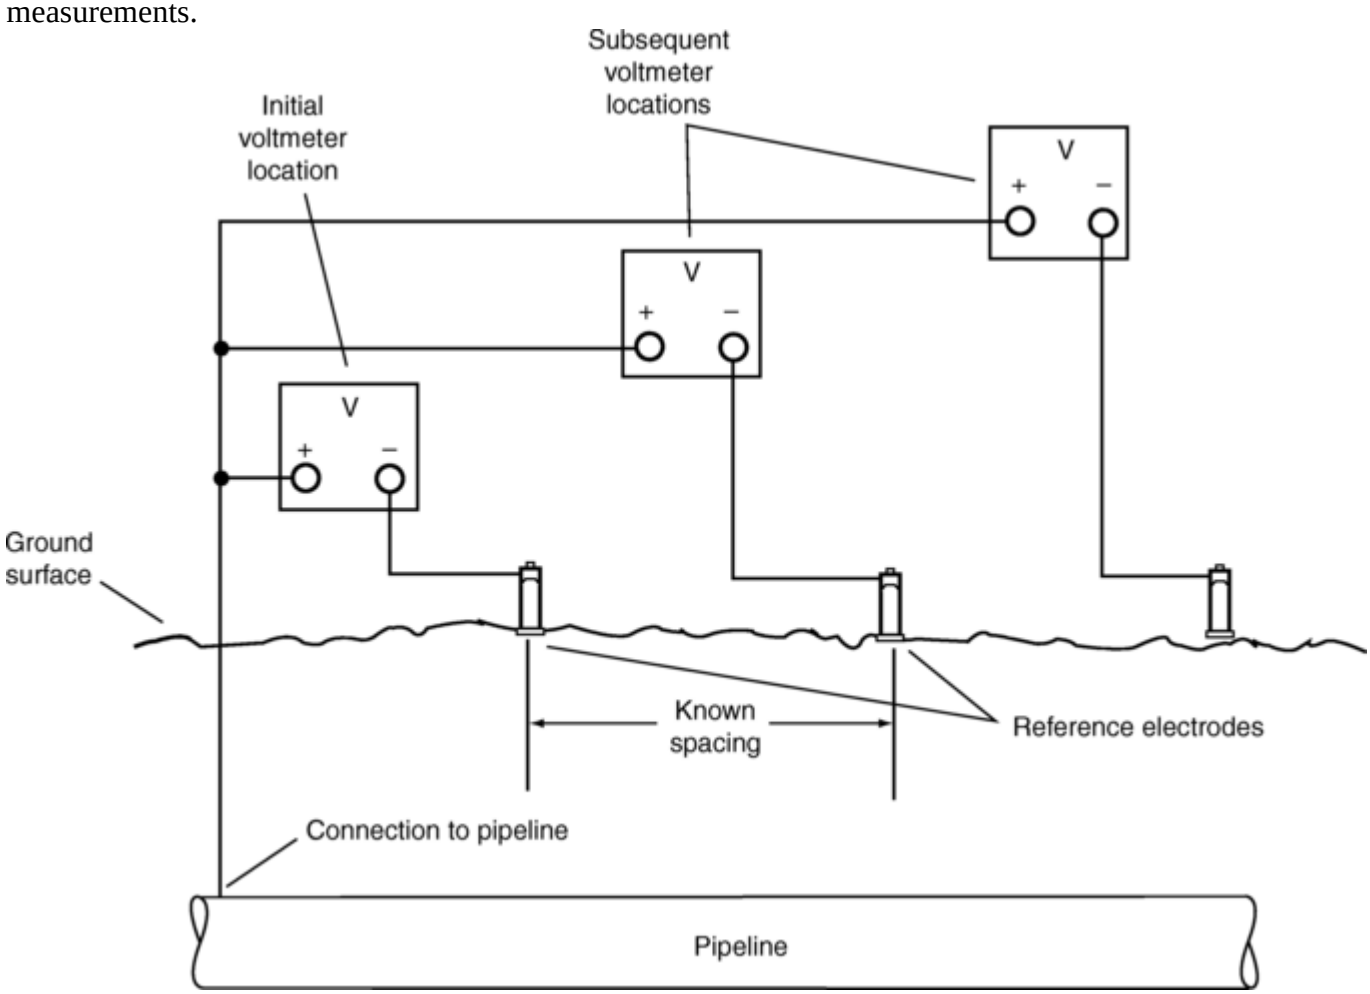

Fig. 1 Principle of pipe-to-soil potential survey

Figure 2 shows data from an actual field survey (Ref 3). Peaks in the plot (the most negative values) indicate locations to be suspected as corroding areas. Material variations that create peaks in the plots can be analyzed and corrosion rates developed with the aid of supporting electrochemical techniques such as EIS. These electrochemical techniques allow determination and correlation of the types of corrosion occurring.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

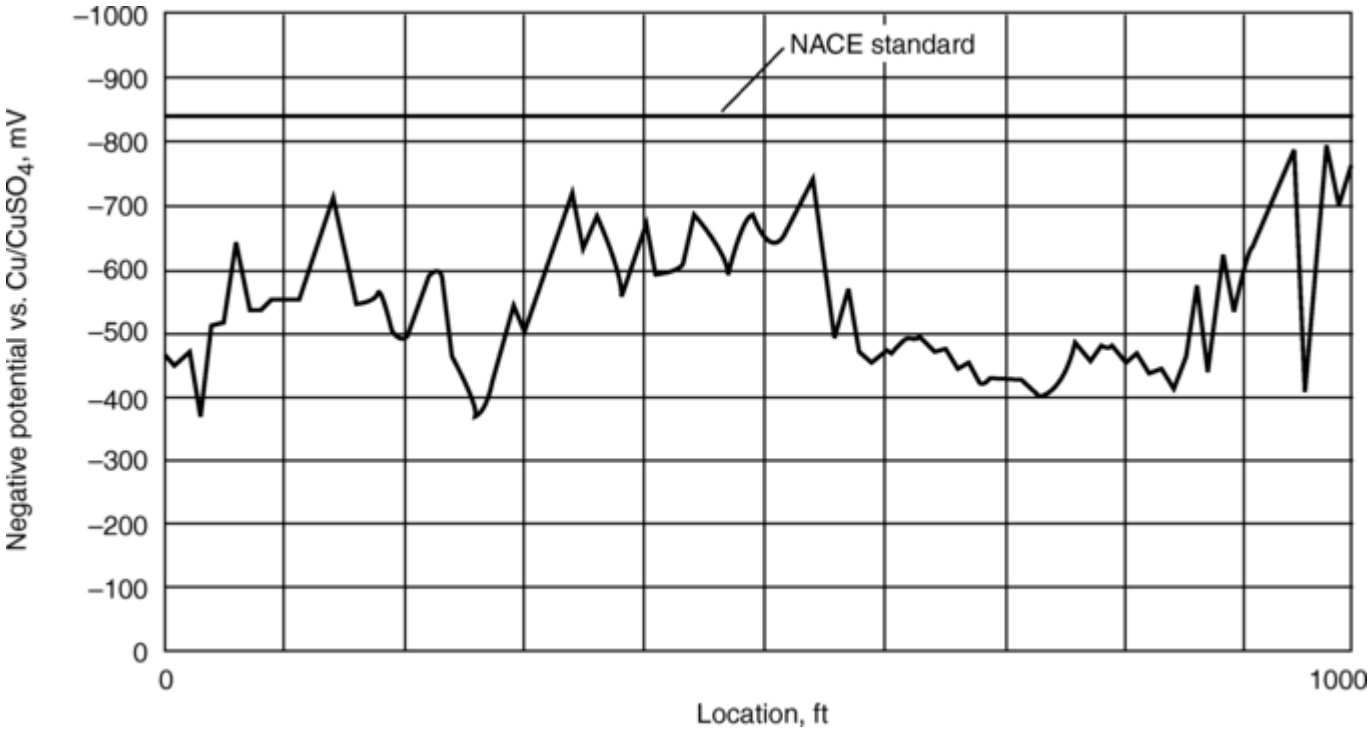

Fig. 2 Pipe-to-soil potential measurements.

If it is not possible to make direct electrical contact with the pipeline, then a closely matched pair of copper/copper sulfate electrodes can be used (Fig. 3) (Ref 1). This procedure can identify the location on the pipeline from which the corrosion current is coming—that is, top, side, or bottom.

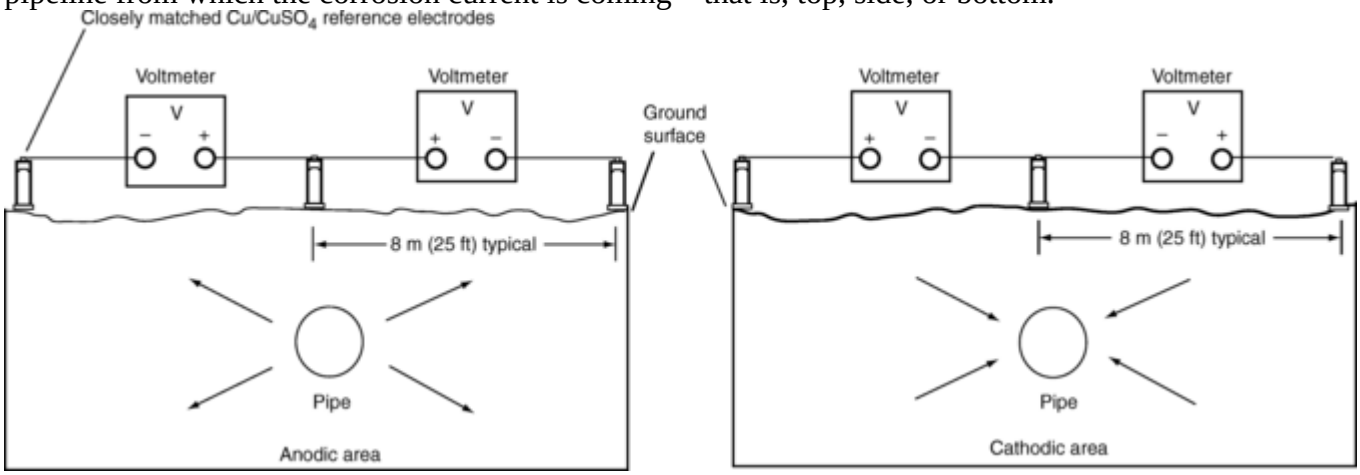

Fig. 3 Pipe-to-soil potential survey using two electrodes. The volt meter with electrodes is moved to take measurements on both sides of the pipe are as shown for anodic and cathodic areas.

For exposed insulated pipelines, prevention of moisture intrusion to the exterior wall will prevent corrosion. To detect moisture intrusion, a small conductivity probe can be pushed through the insulation to the outer surface of the pipe. By monitoring the local conductivity as a function of insulation depth, the amount and location of moisture can be determined. If sufficient moisture is present, potential measurements can be taken to assess the extent of corrosion, similar to those for buried pipelines. Additionally, small specific ion electrodes can detect the presence of different ions and thus help determine the degree of material degradation.

Electrochemical Impedance Spectroscopy

Electrochemical impedance spectroscopy, also known as ac impedance, involves applying a small alternating current voltage between the working electrode (specimen) and a counter electrode and measuring the current that is induced between the specimen and a reference electrode (Ref 4, 5, 6, 7, 8, 9, 10, 11). Both the magnitude and phase of the current relative to the voltage are measured, and a complex impedance is calculated. This measurement is repeated over a wide range of frequencies like 0.01 to 10,000 Hz. Corrosion and degradation of both bare and coated metals can be investigated. This technique is especially suited for coated metals because the coating acts as a capacitor and is amenable to ac but not to dc techniques.

It is common to model the impedance spectrum as an equivalent circuit. The equivalent circuit shown in Fig. 4 is very popular in describing a coating with defects. The left-most resistance and capacitance (RC) circuit represents the coating while the right-most RC circuit represents the interface. Initially, the coating resistance is very high so that the impedance spectrum is dominated by the coating capacitance. This is illustrated by the "good" spectrum of solid symbols in Fig. 5. In this Bode magnitude representation, the impedance has a slope of -1 and a high value, typically 10^8 to 10^{10} Ω, at low frequencies. The phase angle is close to -90° over most of the frequency range. As a coating degrades, moisture penetrates and allows conductance, so the coating resistance decreases. The impedance at low frequencies decreases by one or more orders of magnitude and becomes independent of frequency. In the phase angle plots, the phase is close to zero (purely resistive) at low frequencies and drops to near -90° (purely capacitive) at high frequencies. The "bad" spectrum of open symbols in Fig. 5 is an indication of a degrading coated metal. Once enough moisture reaches the interface, the metal can start to corrode. The interface circuit parameters will reflect this corrosion, and a second time constant can often be detected in the spectrum.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

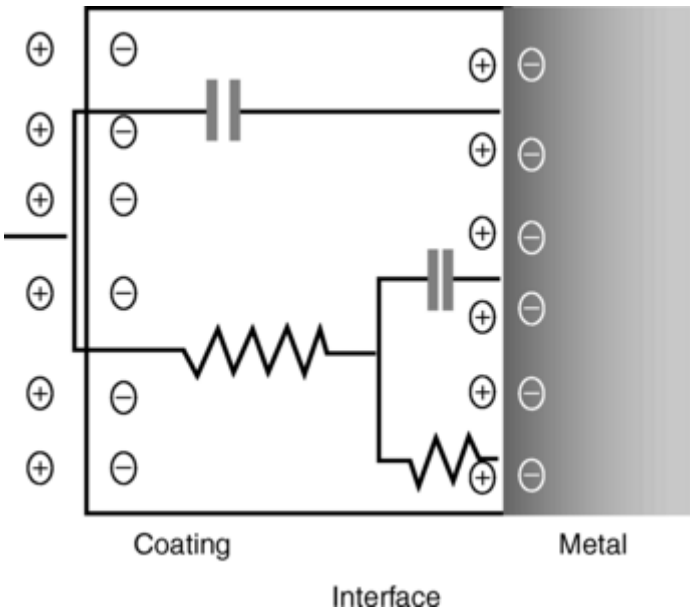

Fig. 4 Equivalent circuit for a defective coating

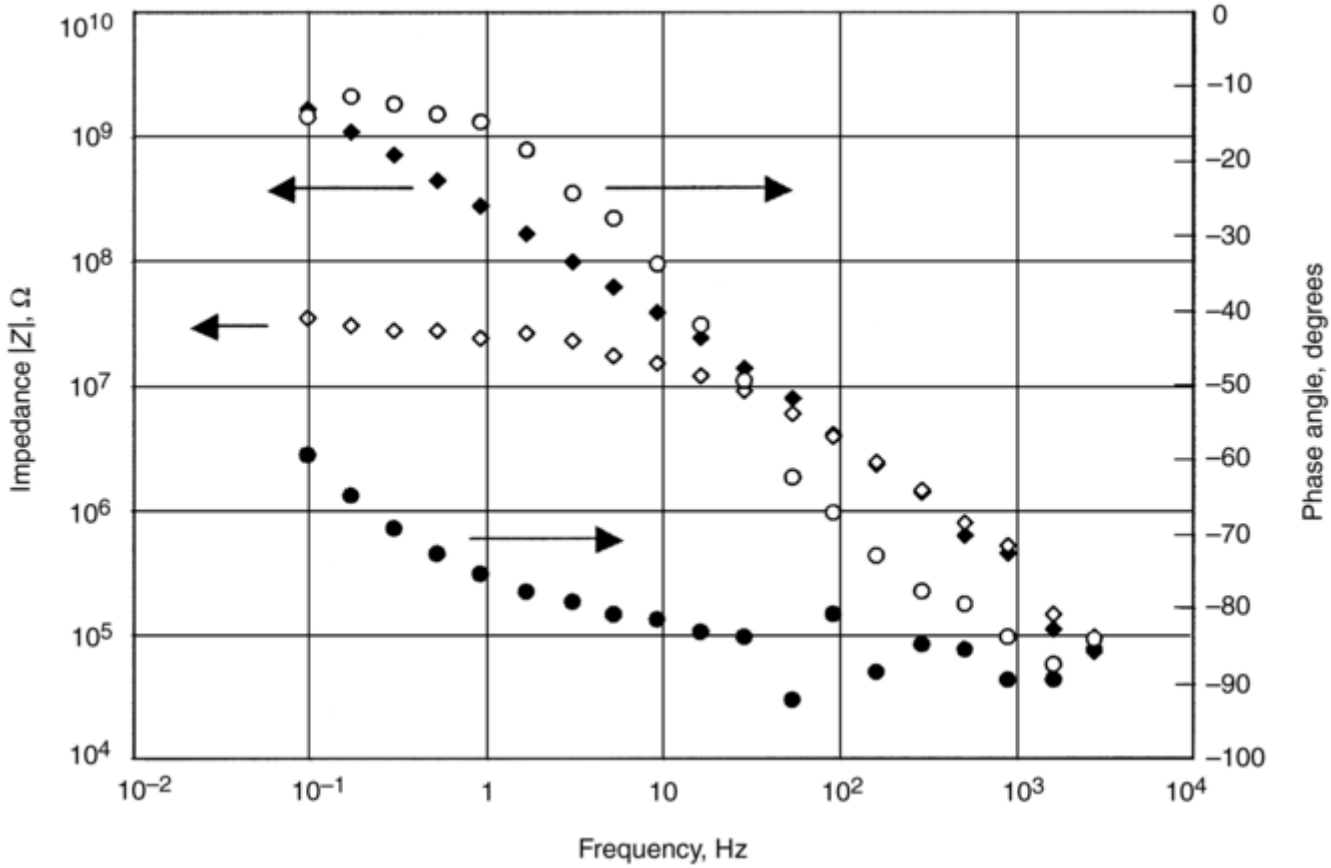

Fig. 5 Bode format for magnitude of impedance (diamonds) and phase angle (circles). A good coating is plotted with solid symbols, and a bad coating is indicated by the plots with open symbols.

The changes detected by EIS are well in advance of any visual signs of corrosion, such as, rust or blistering, so that EIS can be used to predict coating performance.

Good correlation has been reported between EIS measurements and long-term coating performance during immersion in different electrolytes (Ref 8, 12, 13, 14). This predictive capability is illustrated in Fig. 6. A variety of different coatings and substrates were prepared with a wide range of protective qualities and subjected to a cyclic laboratory corrosion test that automotive manufacturers have found predictive of service performance of materials. The time for the low-frequency impedance of the coating to decrease to 10^7 Ω

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

correlated very well to the amount of rust or corrosion on the panels at the end of the 100 cycle (5 month) test. Although there were no visible signs of corrosion on the panels at the time that the impedance had decreased to 10^7 Ω, that time value was predictive of the effectiveness of the coating (Ref 15, 16). Similar measurements have shown that the 100-cycle test could be shortened by up to 40% without loss of information (Ref 15, 16, 17).

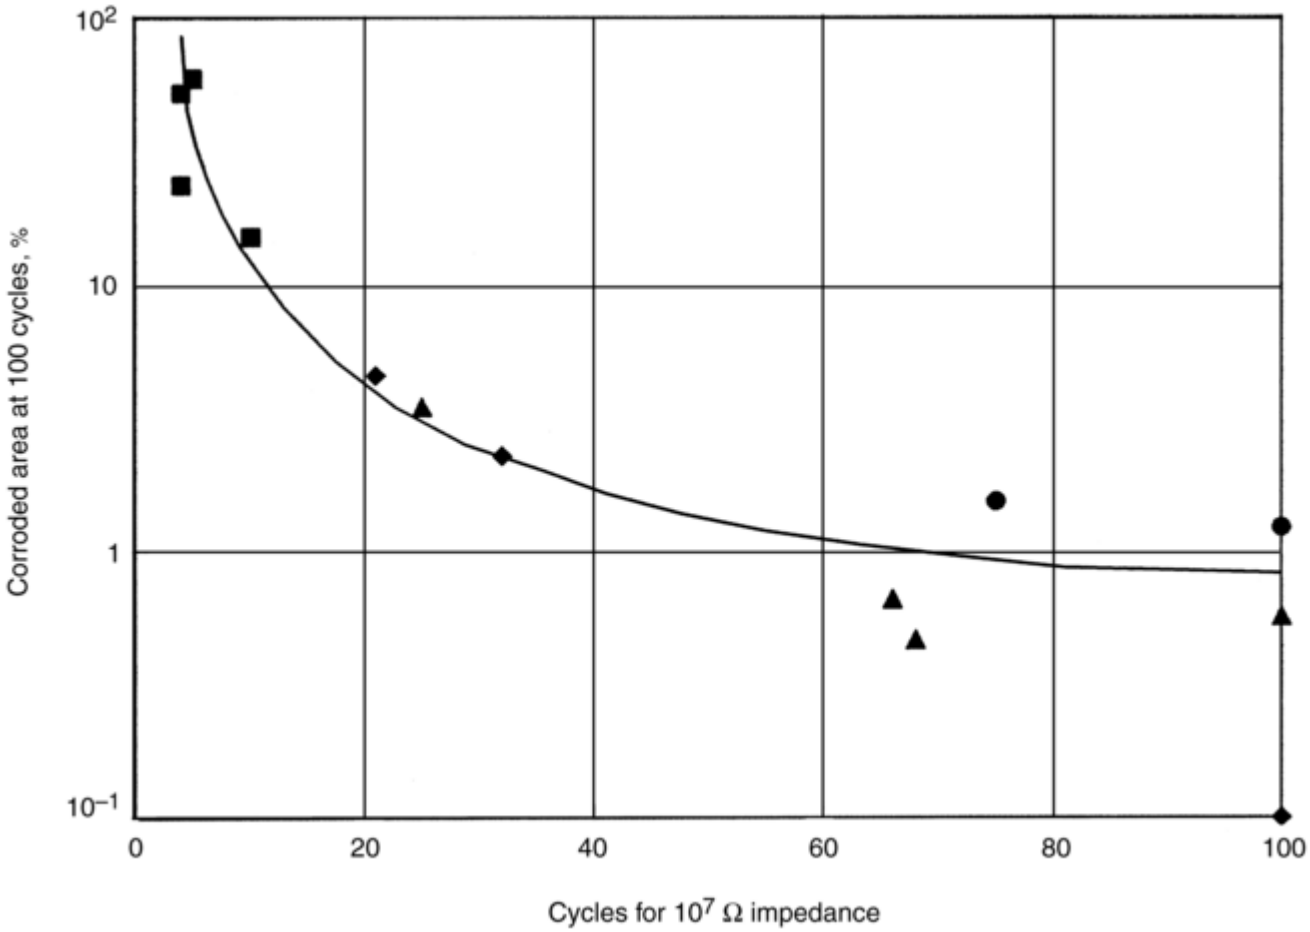

Fig. 6 Correlation of corroded area at end of cyclic laboratory corrosion test with the time for the low-frequency impedance to decrease to 10^7 Ω. The different symbols represent different substrate materials.

Traditionally, EIS has been primarily a laboratory tool for several reasons. The electronics (potentiostats) needed to perform the measurements were bench-top size and inconvenient to take into the field. Furthermore, the specimens had to be immersed into an electrolyte along with the counter and reference electrodes. This process required small specimens. Recent developments have ameliorated these limitations. Portable electronics that can easily be taken into the field are available. Alternative means of inspecting large structures have also been introduced to expand the types of systems that can be examined by EIS. The first of these is a clamp-on electrochemical cell (essentially a bottomless beaker with an O-ring seal at the bottom) (Fig. 7, left) that can be attached to a flat, horizontal surface of a large structure (Ref 18, 19, 20). In a few cases, clamp-on cells containing sponges, gels, or similar materials impregnated with electrolyte have proven satisfactory and have eased the flat, horizontal surface requirement. The other approach is the use of in-situ corrosion sensors (Ref 15, 16, 21), either sensors of conductive paint that are applied directly to the surface of interest for long-term monitoring or handheld sensors that are pressed against the surface during measurement (Fig. 7, right). These sensors require no externally applied electrolyte and can be used on structures of any shape and size under ambient or accelerated laboratory conditions.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

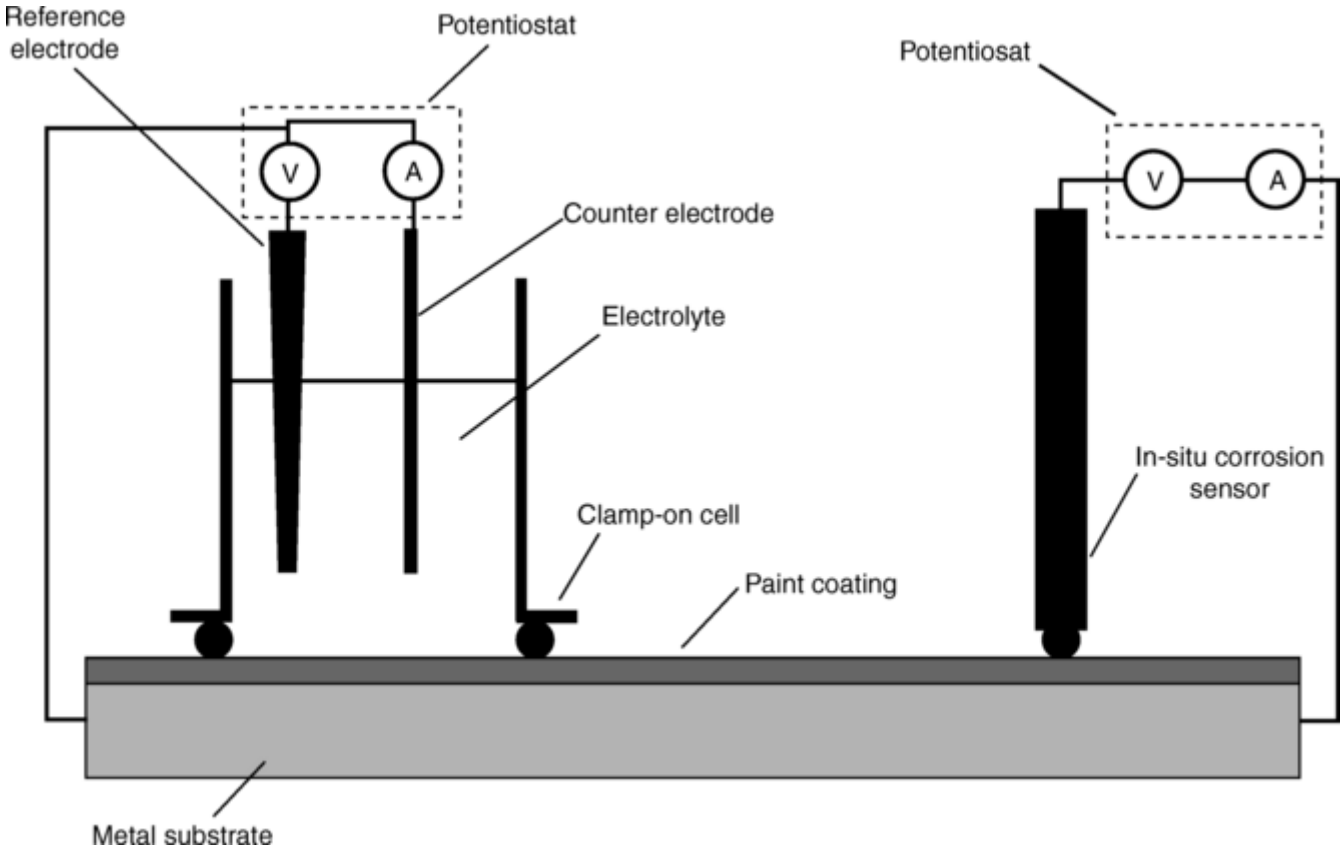

Fig. 7 Left: schematic representation of a clamp-on cell with O-ring seal that allows conventional EIS to be performed on areas of large structures. Right: schematic representation of in-situ corrosion sensor, which allows EIS to be performed under ambient conditions without electrolyte.

The ability to take measurements under arbitrary conditions enables EIS to become part of a condition-based maintenance (CBM) protocol or to directly and qualitatively compare coating degradation in different environments. This allows accelerated testing to be validated more readily than relying on visual comparison of specimens once extensive corrosion has occurred. This comparison is illustrated in Fig. 8. A series of coatings were subjected to salt fog (ASTM B 117), a cyclic laboratory accelerated test, and exposure on the beach at Kennedy Space Center (Ref 17). No correlation was seen between the beach exposure and salt fog; in fact, the correlation coefficient was -0.04, indicating a nearly random relationship. In contrast, the cyclic test exhibited a correlation coefficient of 0.97 with beach exposure. Although the relevance of salt fog testing to field exposures has long been questioned (Ref 22, 23, 24, 25, 26), the comparisons have generally involved visual observations, weight loss measurements, analyses of corrosion products, or other semiquantitative or late-stage measurements.

Electrochemical Techniques for In-Service Corrosion Monitoring

Guy D. Davis and Chester M. Dacres, DACCO SCI, INC.; Lorrie A. Krebs, Anderson Materials Evaluation, Inc.

Electrochemical Noise

Tracking the perturbations in current and potential caused by random corrosion events is the focus of the electrochemical noise (ECN) method. Techniques include monitoring the changing potential of a corroding surface relative to a selected reference electrode, monitoring the current fluctuations between nominally identical electrodes in a corrosive environment, and comparing current and potential noise in order to determine electrochemical noise resistance or impedance. Refer to “Electrochemical Methods of Corrosion Testing” in this Volume for further details. For nearly two decades these methodologies have been practiced as a means of detecting and observing corrosion phenomena such as general corrosion, cavitation and erosion corrosion, crevice and pitting corrosion, coating degradation, microbiologically induced corrosion, stress-corrosion cracking, and inhibition (Ref 27, 28). The application of this technique for continuous in-plant corrosion monitoring has become more popular in recent years.

The earliest studies in electrochemical noise and its relationship to corrosion are attributed to Iverson (Ref 29), who examined potential transients associated with corroding metals and alloys. Many researchers have

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

subsequently studied the applicability of electrochemical noise measurement to the evaluation of corrosion rates and identification of corrosion mechanisms. Typically, current fluctuations are measured by connecting two identical electrodes through a zero-resistance ammeter (ZRA) (Ref 30). Variations in potential can be monitored by introducing a third electrode, either another nominally identical electrode or a standard reference electrode. Potential fluctuations may also be monitored by using two electrodes identical to, but electrically isolated from, the pair used for current measurement. These arrangements constitute the two-, three-, and four-electrode systems encountered in electrochemical noise measurement.

Statistical interpretation of current and potential fluctuation data may be employed to determine R_n, the noise resistance (Ref 27, 31). For example, the ratio of the standard deviations of the potential and current over a fixed time frame can be used to define R_n. R_n has been shown to be an indicator of the onset of localized corrosion, as well as to have an inverse relationship to corrosion rate.

Alternatively, a frequency domain analysis such as fast Fourier transform (FFT) or maximum entropy method (MEM) may be employed. The FFT analysis is better suited to long-term data where several transforms can be averaged, while MEM analysis is preferable for single data sets (Ref 27). The power spectral densities that result from frequency domain transforms may be used to calculate the spectral noise resistance (R_{sn}) as a function of frequency, or noise impedance. It has been shown experimentally that the frequency domain transform methods produce more quantitatively reliable results than statistical data analysis (Ref 31, 32). Statistical analysis methods may be useful when qualitative results are considered adequate (Ref 33).

Electrochemical noise techniques have been developed for on-line monitoring in a variety of industries, including power generation, nuclear waste containment, and water supply (potable and heating/cooling) (Ref 28, 34). The corrosion behavior of several metals and alloys has been characterized by the electrochemical noise technique in a variety of environments, and results have compared well with those characterized by more traditional techniques (Ref 28, 33, and 35). However, certain factors, including electrode asymmetry (material differences, bias voltages, coatings) and the influence of instrumental noise, may affect results and must be considered when employing electrochemical noise measurement as a monitoring tool (Ref 36, 37, 38).

Corrosion Monitoring Techniques

P.R. Roberge and R.D. Klassen, Royal Military College of Canada

Introduction

CORROSION MONITORING has become important in the operation of modern industrial plants and in the use and maintenance of expensive assets such as bridges and aircraft. Engineering and maintenance personnel need to be aware of both the cumulative damage caused by corrosion and the rate of the deterioration, because the costs associated with corrosion problems can be huge and the risks devastating. (See the article “Direct Costs of Corrosion in the United States” in this Volume). The term *on-line monitoring,* as used in this context, includes electrochemically based techniques for evaluating the progress or rate of corrosion. Nondestructive approaches for monitoring metal thickness are covered in the articles “Corrosion Monitoring Using Microwave and Guided Wave Nondestructive Evaluation” and “Corrosion Monitoring for Industrial Processes” in this Section.

On-Line Corrosion Monitoring Techniques

Corrosion monitoring techniques can be divided into two categories, direct and indirect. Direct techniques measure parameters that are directly associated with the corrosion processes. These include coupons, electrical resistance (ER) and inductive resistance, linear polarization resistance (LPR), electrochemical impedance spectroscopy (EIS), zero-resistance ammetry (ZRA), electrochemical noise (ECN) and self- linear polarization resistance (SLPR). Indirect techniques measure parameters that are indirectly related to the rate of corrosion, such as monitoring the corrosion potential and the use of hydrogen probes. Further details on the corrosion potential, EIS, and ECN techniques are given in the article “Electrochemical Techniques for In-Service Corrosion Monitoring” in this Volume.

There are differences in the quality of information obtained between different corrosion monitoring techniques. Some techniques provide information on the average corrosion rate only (ER, LPR, and EIS), while other techniques can additionally provide information on the type of corrosive attack (ECN and SLPR). References 1, 2, 3, 4, 5 give reviews of on-line corrosion monitoring for process-plant control. A broad review of corrosion engineering is presented elsewhere (Ref 6).

---

Direct Techniques

Corrosion Coupons. A simple and inexpensive method of corrosion monitoring involves the exposure and subsequent evaluation of actual metal specimens or “coupons.” Small specimens are exposed to the environment of interest for a specific period of time and subsequently removed for weight-loss measurement and more detailed examination. ASTM G 4 (Ref 7) was designed to provide guidance for this type of testing, and Ref 8 gives additional details. Two disadvantages of this approach are that a long exposure period is required and only cumulative information is provided. Coupons are also commonly used to monitor the effectiveness of cathodic protection measures in buried pipelines. In this application the mass loss is not measured, but coupons are examined to determine the corrosion state of the exterior pipe wall.

Electrical and Inductive Resistance. Electrical resistance (ER) probes are specially designed corrosion coupons with electrical connections. The corrosion rate of the exposed element is calculated from a measurement of electrical resistance rather than mass loss. These measurements are made by installing a device fabricated from the material in question, such as a wire, in such a way that its electrical resistance can be measured. Resistance is a strong function of temperature and therefore must be accounted for with simultaneous temperature measurement. As corrosion processes reduce the metallic cross section of the exposed element, the electrical resistance increases with exposure time. The corrosion rate is obtained by taking the slope of a series of measurements made over a period of time. Generally, the sensitivity of ER probes is insufficient to qualify for real-time corrosion measurements because transients of short duration go undetected.

The inductive resistance probe is a recently introduced derivative of ER (Ref 6). The reduction in the thickness of a sensing element is measured by changes in the inductive resistance of a coil embedded in the sensor. Sensing elements with high magnetic permeability intensify the magnetic field around the coil; therefore, thickness changes affect the inductive resistance of the coil. The decrease in response time, or sensitivity, has been claimed to be several orders of magnitude higher than it is with comparable ER probes. Both techniques should be applied only to nonpitting environments.

Linear Polarization Resistance. The technique of LPR provides an estimate of the corrosion rate based on the Stern-Geary equation (Ref 9). The theory behind the technique is that the corrosion rate of a metal, in the

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

absence of diffusional resistances, is inversely proportional to the *polarization resistance*; that is, the slope of the potential/current response curve near the corrosion potential. The equation and Tafel plots are found in the article “Electrochemical Methods of Corrosion Testing” in this Volume. The proportionality factor, *B*, is a function of the anodic and cathodic Tafel slopes, which depend on temperature and the chemical species and concentration in the electrolyte. An external power supply gradually polarizes the specimen about 10 mV on both sides of the corrosion potential. The slope between the induced potential and the resulting current is interpreted as the polarization resistance. The time required for each resistance determination is a matter of minutes. Thus, this type of probe can provide corrosion rate feedback information with sufficient speed that it can be used in process control schemes.
The limitations to this approach include:

- A requirement that the electrolyte has a sufficiently high conductivity
- The vessel wall or pipe must be penetrated.
- The use of a stable reference electrode.

The latter limitation is usually not restrictive since three electrodes of the same material provides satisfactory service in most industrial applications. Even though the applied sensor perturbation is small, repeated application over a long period can lead to “artificial” surface damage. In addition, these systems cannot provide information on localized corrosion, such as pitting and stress-corrosion cracking (SCC).
An algorithm for evaluating the suitability of the ER versus LPR probes is shown in Fig. 1 (Ref 10). If the electrolyte is nonconductive, then ER is recommended over LPR. If the product of estimated corrosion rate and resistivity is less than 25 kΩ · cm · mil/year, then a two-electrode LPR probe is recommended. If the above product is greater than 250 kΩ · cm · mil/year, then a three-electrode LPR probe is recommended. (The kΩ · cm · mil/year units are those used in the original algorithm.) For intermediate values of the above product, an ER probe is recommended.

Source: Ref 10

Electrochemical Impedance Spectroscopy. In principle, the same type of probe used for linear polarization resistance measurements can be used for electrochemical impedance measurements. In order to characterize certain features of corrosion behavior in detail, measurements throughout the entire frequency range are required; that is, from 0.1 Hz to 100 kHz. This approach permits the separation of the electrolyte resistance, the corrosion reaction resistance, and mass-transfer resistances. Therefore this approach is viable for highly resistive electrolytes such as steam condensate. Although EIS is usually considered to measure uniform corrosion only, the pit depth has been found to correlate to a fitted model element, the constant phase angle (Ref 11).

Zero-Resistance Ammetry. In zero-resistance ammetry (ZRA), galvanic currents are usually measured between dissimilar materials with the current being proportional to the corrosion rate of the corroding element. The electronic circuitry for this task is simple and inexpensive (Ref 12). The dissimilarities between the sensor elements may be related to different compositions, heat treatments, stress levels, or surface conditions. As per

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

the Stern-Geary approximation, the measured or galvanic current is proportional to the corrosion current, the anodic and cathodic potential differences with E_{corr} and the Tafel slopes for the anodic and cathodic processes. Under conditions where the latter four factors are constant, the galvanic current is consistently proportional to the corrosion current.

Electrochemical Noise. In this technique, fluctuations in potential and current between freely corroding electrodes are measured. Because of the small scale of these fluctuations of interest (in many cases <1 μV and <1 nA), sensitive instrumentation is required. A measurement frequency of 1 or 2 Hz usually suffices. For simultaneous measurement of electrochemical potential and current noise, a three-electrode sensor is required. The current is measured between two of the sensor elements with a zero- resistance circuit, and the potential is measured between the third element and the other two elements, which are at the same nominal potential. For industrial corrosion monitoring purposes, each element is usually constructed from the same material.

While measurement of electrochemical noise (EN) is straightforward, data analysis can be complex. Such analysis is usually directed at distinguishing the different forms of corrosion, quantifying the noise signals, and processing the vast number of accumulated data points into a summarized format. Data processing approaches can involve both time-domain and frequency spectral analysis. A resistance parameter that is considered to be a polarization resistance and therefore a measure of the corrosion rate can be obtained from each approach (Ref 13); that is, noise resistance from the time domain and spectral noise resistance from the frequency domain.

Self-Linear Polarization Resistance. An alternate technique for extracting a polarization resistance from EN measurements in the time domain is self-linear polarization resistance (SLPR). Blocks of potential and current measurements are independently detrended and then plotted against each other. The slope of detrended potential versus detrended current is interpreted as a polarization resistance. It is understood that this treatment of EN data reveals perturbations from E_{corr} that are initiated by localized corrosion events. Comparison of mass loss and LPR measurements indicates that SLPR provides a better estimate of polarization resistance than noise resistance or spectral noise resistance Ref 14.

Indirect Techniques

Corrosion Potential. Measurement of corrosion potential is a relatively simple concept, and the underlying principle is widely used for monitoring the corrosion state of reinforcing steel in concrete and buried pipelines under cathodic protection. This approach can also be valuable in cases where an alloy could show both active and passive corrosion behavior in a given process stream. For example, stainless steels can provide excellent service as long as they remain passive. However, if an upset occurs that would introduce either chlorides or reducing agents into the process stream, stainless alloys may become active and exhibit excessive corrosion rates. Corrosion potential measurements can indicate the transition from passive to active corrosion.

The success of corrosion potential measurements depends on the long-term stability of a reference electrode. Such electrodes have been developed for continuous pH monitoring of process streams, and their application for measuring corrosion potentials is straightforward. However, temperature, pressure, electrolyte composition, pH, and other variables can limit the applications of these electrodes for corrosion-monitoring service. Also, while the technique may indicate changes in corrosion behavior over time, it does not provide any indication of corrosion rates.

Hydrogen Probes. The concept of the hydrogen probe is based on the fact that one of the cathodic reaction products in nonoxidizing acidic systems is hydrogen. The hydrogen atoms thus generated diffuse through the vessel wall and are liberated at the exterior surface. In one variation, a hydrogen probe contains a piece of palladium foil applied to the exterior surface and serving as both collector and catalyst for the subsequent oxidation of the hydrogen (Ref 15). This method is in practice limited to steel, which has a high hydrogen diffusivity and low solubility of hydrogen. This approach has another variation that consists of simply attaching a chamber to the exterior of the pipe and monitoring hydrogen liberation through increasing pressure of hydrogen gas (Ref 5).

Generic guidelines relating the measured hydrogen flux and actual damage (thickness loss, cracking, blistering) have not been established. This approach is also limited to systems in which the temperature outside of the pipe is moderate and the diffusion rate of hydrogen is high. Gas pipeline service is the most common application. In this case, corrosion can occur when hydrogen sulfide, water, and sometimes carbon dioxide (CO_2) are present.

Corrosion Monitoring Techniques

P.R. Roberge and R.D. Klassen, Royal Military College of Canada

System Considerations

In the selection of a corrosion monitoring method, a variety of factors should be considered. First, everyone concerned with the corrosion monitoring program should understand the purpose of the test. The costs and reliability of the methods under consideration should be understood. In many cases, it is desirable to include more than one method in order to provide more confidence in the information generated. Another question of importance is whether there is access to the process streams and equipment in question. If access is available, methods that involve probes or coupons become more feasible. Otherwise, nondestructive methods may be required.

An important factor in the selection of monitoring methods is the response time required to obtain the desired information from the method. Coupon methods and techniques that require plant shutdown tend to be relatively slow in generating information. On the other hand, equipment that measures instantaneous corrosion rates can provide fast results. A final consideration is one of safety. In an operating plant, equipment failure can lead to a leak, which can result in loss of product, a hazard potential, and possible shutdown of the plant. It is important for the monitoring apparatus to minimize the possibility of such an incident (Ref 16).

Probe Location

A principal part of any corrosion-monitoring program is deciding where to locate the corrosion monitoring devices. Because corrosion will probably not occur uniformly throughout a region of interest, it is desirable to find sites at which the highest corrosion rates will be experienced.

Example 1: Corrosion Monitoring of a Distillation Column. The problems involved in developing corrosion monitoring programs for a plant are illustrated in the example of a distillation column. The most logical points for corrosion monitoring in a distillation column are the feed point, the overhead product receiver, and the reboiler or bottoms product line. These points are the locations at which the highest and lowest temperatures are encountered, as well as the points at which the most and least volatile products are concentrated. However, these points are usually not the locations of the most severe corrosion. The species causing corrosion will often concentrate at an intermediate point in the column because of chemical reactions within the column. Therefore, if there is a possibility of concentrating a corrosive species within the distillation column, several monitoring points are required throughout the column for the corrosion monitoring program to be comprehensive. A monitoring program can be restricted to the most corrosive location within the column once this area has been identified. Another problem with distillation columns is that the liquid on trays tends to be frothy. This creates difficulties for electrochemical methods. One solution to this problem is to install bypass loops that remove liquid from the column, pass it over the corrosion-monitoring probes, and then reinject it at a lower point in the column. This practice avoids the problem of foam and froth and provides a more controlled flow rate over the corrosion monitoring equipment. Use of a bypass loop also allows removal of liquid samples at times of high corrosion rates for further analysis.

Example 2: Corrosion Monitoring of Piping with High-Velocity Gas Streams. High-velocity gas streams in pipes may cause problems with conventional monitoring systems. In this case, the presence of an aqueous phase is usually restricted to a thin layer on the surface of the pipe. A probe that protrudes into the pipe may miss the liquid layer that is present only close to the pipe wall. A flush-mounted surface probe can be used in such cases.

Example 3: Probe Location in Storage Tanks. Probe location is also critical in storage tanks containing nonaqueous liquids. The most corrosive location in these tanks may be at the liquid level if the liquid in the tank has a density exceeding that of water. In this case, the corrosion-monitoring probe should be mounted on a floating platform. In this way, the probe can detect the presence of a corrosive aqueous phase. However, when

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

the liquid stored in the tank is less dense than the water, the corrosion-monitoring device should probably be positioned at the bottom of the tank.

Leakage. Where vessel and piping walls must be penetrated in order to install probes, the potential for leaks exists. Leaks can cause hazards and can shut down operating plants. The corrosion monitoring system must be installed such that leaks from the probe can be handled with minimal interruption (Ref 17).

Installation Techniques

Coupons. A slip-in rack is designed to be inserted and removed from equipment that is in operation. A retractable coupon holder makes this type of rack especially useful (See Fig. 3 in the article “Corrosion Monitoring for Industrial Processes” in this Volume). The slip-in rack requires a gate valve and a suitable-sized nozzle to serve as a retraction chamber. A rod-shaped coupon holder is contained in the retraction chamber, which is flanged to the gate valve. The other end of the retraction chamber contains a packing gland through which the coupon holder passes. Coupons are mounted on the rod in the retracted position. The chamber is bolted to the gate valve, which is then opened to allow the coupons to be slid into the process stream. The sequence is reversed to remove the test coupons. Other appliances for installing coupons are the spool (birdcage) rack, the insert rack, and the slip-in rack (Ref 3, 4).

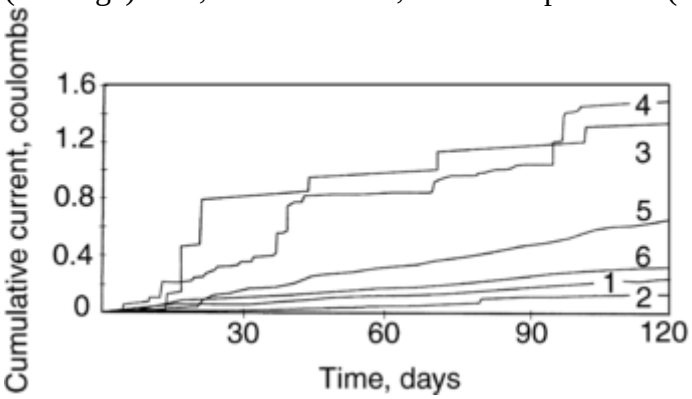

Fig. 2 Cumulative current, in coulombs, from the zero-resistance ammetry (ZRA) sensors at various location on the aircraft shown in Fig. 5. Source: Ref 17

Electrical Resistance Probe. A schematic of an electrical resistance probe is shown as Fig. 4 in the article “Corrosion Monitoring for Industrial Processes” in this Volume. The wire is fabricated from the material of concern in such a way that its electrical resistance or inductance can be measured. A temperature-compensating element of the same material is usually incorporated such that it is shielded from the corrosive environment but close to the same temperature environment as the exposed element.

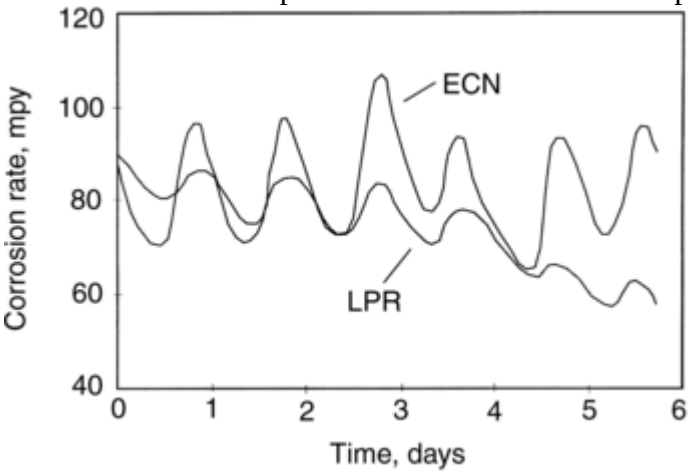

Fig. 3 Smoothed corrosion rates from electrochemical noise (ECN) and linear polarization resistance (LPR) measurements from the same probe within an oil/water separation plant. The oscillations correlated with daily operations of a vacuum truck. Source: Ref 18

مرجع مهندسی مواد و متالورژی

Linear Polarization Resistance Probe. A schematic of a three-electrode linear polarization resistance probe is shown in Fig. 5(a) in the article “Corrosion Monitoring for Industrial Processes” in this Volume. The probe elements are constructed from the material of interest, similar to an ER probe. One method of exposing the probe elements in a process pipe is through a pipe tee, as shown in Fig. 5(c) in the article “Corrosion Monitoring for Industrial Processes” in this Volume.

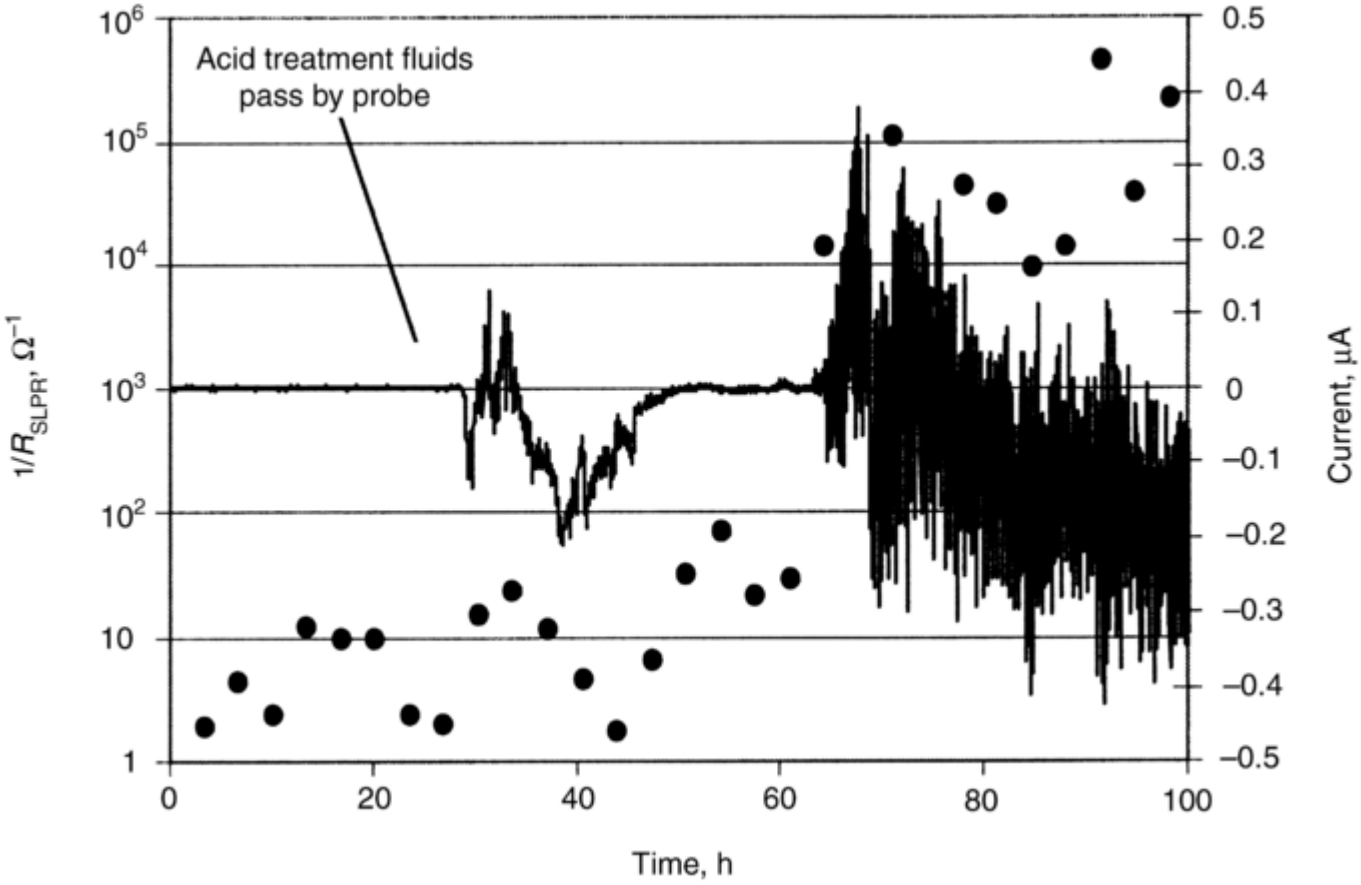

Fig. 4 Electrochemical noise data current (solid line) and $1/R_{SLPR}$ (dots) from a probe monitoring acid treatment fluids entering the Simonette battery. Source: Ref 21

Hydrogen Probe. A schematic of a hydrogen probe on the outside of a pipe is shown in Fig. 7 in the article “Corrosion Monitoring for Industrial Processes” in this Volume. The interface between the outside of the pipe wall and electrolyte is a foil of palladium. The foil is permeable to hydrogen gas escaping through the container wall and catalyzes its oxidation under an applied potential. The electrolyte is 90% sulfuric acid, and the counter electrodes for the oxidation reaction are stainless steel rods. The current that is required to oxidize the hydrogen is proportional to the corrosion rate of the interior of the vessel.

Wiring. A primary difficulty with corrosion- monitoring equipment is the need to install wires from the probes to the control room or to data storage systems. The cost of wiring usually exceeds the cost of probes and electronic instruments. In addition, wiring systems are often sources of problems due to breakage, moisture entry, and connection difficulties. Emerging wireless systems have great potential for enabling corrosion monitoring sensors to be more effectively deployed.

Corrosion Management

In-line corrosion monitoring requires skill in interpretation and reporting since important economic decisions are often based on the test results (Ref 17). Although there are a number of standards that provide guidelines for certain procedures, there is no standard that is comprehensive. To plan an appropriate test program, the investigator must know or have good advice on both the chemistry and the mechanics of the processes involved; that is, the investigator must understand the entire corrosion system. It is important to prepare detailed records of what was done as part of the experiment, and it is also important to document any unplanned changes that occur in the process stream or the equipment during the investigation. Without valid interpretation and

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

effective (timely) reporting, the price of the work can be significantly greater than the cost of time and materials. However, the consequences of corrosion failures go beyond these additional costs. Also involved are personal safety risks and liability, hazard potentials, decreased product quality, and pollution problems. Several technical and personnel requirements for the success of a corrosion monitoring program are given in Ref 16.

Examples of On-Line Corrosion Monitoring

In addition to the previous examples dealing with probe locations, the following examples illustrate various monitoring techniques.

Example 4: Smart Reinforced Concrete Structures. In the civil engineering and construction industry, corrosion measurements are usually limited to periodic inspections. While such measurements can be misleading, it is at times difficult to make a persuasive argument for continuous measurements, in view of the fact that rebar corrosion often only manifests after decades of service life. As a result of advances in corrosion monitoring technology and selected on-line monitoring studies that have demonstrated the highly time-dependent nature of rebar corrosion damage, continuous measurements may gradually find increasing application. Furthermore, the concept of smart reinforced concrete structures is gaining momentum through the utilization of a variety of diagnostic sensing systems. The integration of corrosion monitoring technology and information on the location of the damage appears to be a logical evolution (Ref 6).

The simplest electrochemical rebar corrosion monitoring technique is measurement of the corrosion potential. A measurement procedure and data interpretation procedure are described in ASTM C 876. The basis of this technique is that the corrosion potential of the rebar will shift in the negative direction if the surface changes

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

from the passive to the actively corroding state. A simplified interpretation of the potential readings is presented in Table 1.

Table 1 Significance of rebar corrosion potential values

Potential (volts vs. SCE), V	Significance
V > -0.20	Greater than 90% probability that no corrosion is occurring
-0.35 ≤ V ≤ -0.20	Uncertainty regarding corrosion activity
V < -0.35	Greater than 90% probability that corrosion is occurring

SCE, saturated calomel electrode. Source: ASTM C 876

Apart from its simplicity, a major advantage of this technique is that large areas of concrete can be mapped with the use of mechanized devices. This approach is typically followed on civil engineering structures such as bridge decks, for which potential "contour" maps are produced to highlight problem areas. The potential measurements are usually performed with the reference electrode at the concrete surface and an electrical connection to the rebar. However, the results obtained with this technique are only qualitative, without any information on actual corrosion rates. Highly negative rebar corrosion values are not always indicative of high corrosion rates, as the unavailability of oxygen may stifle the cathodic reaction. Also, interpreting the potential readings from epoxy-coated rebar is even more problematic.

Example 5: Atmospheric Corrosion in Aircraft. While corrosion inspection is mandated and nondestructive testing of aircraft are widely practiced, corrosion monitoring activity is only beginning to emerge, led by efforts in the military aircraft domain. In recent years, prototype corrosion monitoring systems have been installed on operational aircraft in the United States, Canada, Australia, the United Kingdom and South Africa. Several systems are in the laboratory and ground-level research and testing phases. The interest in aircraft corrosion monitoring activities is related to three potential application areas: reducing unnecessary inspections, optimizing certain preventative maintenance schedules and evaluating materials performance under actual operating conditions. The first application area arises from the fact that many corrosion-prone areas of an aircraft are difficult to access and costly to inspect. Typically, these areas are inspected on fixed schedules, regardless of whether corrosion has taken place or not on a particular aircraft. Unnecessary physical inspections could be delayed if there was a full understanding of when and where corrosion occurred (Ref 17).

A zero-resistance ammeter (ZRA)-based sensor for monitoring corrosive conditions for aircraft as well as other equipment was developed (Ref 18). It consisted of a novel thin film device (interdigitized bimetallic strips on a Kapton (E.I. DuPont de Nemours and Co.) polyimide film), which was galvanically coupled or short circuited through a ZRA and interfaced to a miniature data acquisition system. In most applications the active element was cadmium and the inert metal was gold. An underlying assumption is that atmospheric conditions that cause cadmium to corrode will also cause aluminum to corrode. In one trial, six sensors were installed in the interior of an aircraft as shown in Fig. 5 (Ref 19). These locations were (1) outboard vacelle, (2) fuselage near the nose, (3) within the horizontal stabilizer, (4) forward main ring fitting, (5) aft main ring fitting, and (6) heat exchanger. The cumulative current, expressed in coulombs over a three-month exposure period, is shown in Fig. 2 for each location. The results illustrate that locations on the same aircraft exposed to the same weather and outside environmental factors experience widely different degrees of atmospheric corrosivity. Sensors of this type can become a basis for condition-based maintenance of aircraft hardware in the future.

Fig. 5 Schematic of an aircraft showing locations where zero-resistance ammetry (ZRA) corrosivity sensors were placed. Source: Ref 17

Example 6: Electrochemical Noise Probes in Chemical Plants. Five probes with five elements each were installed at an oil/water separation facility (Ref 20). Each probe was designed to measure the corrosion rate by both LPR and ECN. Bridging between the elements by sludge and iron sulfide was a problem that was addressed by regular cleaning of the probe elements. Figure 3 shows variations in the corrosion rates, which were averaged over 5 min intervals and then smoothed. The oscillations were attributed to the effects of vacuum loading truck operations that occurred daily. These variations would not have been observable from corrosion coupon data, which give an integrated or cumulative view of corrosion damage.

Another example of field tests with ECN probes was described by Ref 21. One ECN probe was placed in a flow line between the well and processing plant. In order to reduce scaling problems, the well was treated with 3 m^3 (106 ft^2) of crude oil containing 15% hydrochloric acid combined with 13% xylene. Figure 4 shows the raw electrochemical current and $1/R_{SLPR}$ (analyzed by the SLPR method presented earlier, Ref 14) from the probe in the flow line just before and just after the line was "pigged." The data indicates that fluctuations in the current and a large jump in corrosion rate ($1/R_{SLPR}$) did not occur until about 30 h after the oil/acid/xylene mixture had passed by.

Introduction

LOCALIZED CORROSION, in the form of pitting and crevice corrosion, once initiated, can propagate rapidly and either result in component failure or trigger other modes of failures, such as stress-corrosion cracking. Because localized corrosion is isolated to certain areas and often has small lateral dimensions compared with its depth, detection methods that measure response over a large surface area, such as the widely used electrical resistance and linear polarization methods (Ref 1, 2, 3, 4, 5, 6), are not sufficiently sensitive. Development of suitable on-line monitoring tools for localized corrosion has been a challenge to researchers, plant engineers, and operators. The nature of localized corrosion must be understood to develop monitoring tools.

Monitoring of Localized Corrosion

Lietai Yang and Narasi Sridhar, Southwest Research Institute

Initiation of Localized Corrosion

A number of factors influence the initiation of localized corrosion:

- Presence of a critical concentration of an aggressive species (e.g., chloride) or inhibiting species (e.g., nitrate)
- Sufficiently high corrosion potential caused by the presence of oxidizing agents
- Sufficiently high temperature
- Stagnant regions
- Surface and microstructural heterogeneities (e.g., manganese sulfide inclusions)
- Microbial activity

While the early stages of localized corrosion processes are still not completely understood (Ref 7, 8, 9), the stable growth of localized corrosion has long been established to be a process where the dissolution sites (anodic sites) are separated spatially from the sites where oxidants in the environment are reduced (cathodic sites), with the electronic current flowing through the metal to couple these two processes. Therefore, many of the electrochemical techniques for studying localized corrosion processes rely on monitoring the current flow between these two sites (Ref 10). Some of these electrochemical methods have been adopted for on-line monitoring of localized corrosion. Nonelectrochemical methods also have been used for on-line monitoring of localized corrosion in recent years. The following section describes some of the methods that have been used or have the potential to be used for on-line, real-time monitoring of localized corrosion.

Electrochemical Noise Method

The electrochemical noise (ECN) measurement technique (Ref 11) uses three electrodes comprising two normally identical working electrodes (electrodes 1 and 2) and a reference electrode (or, alternatively, a pseudoreference electrode manufactured from the same material as the working electrodes). Electrodes 1 and 2 are coupled through a zero resistance ammeter (ZRA), and the output from the current coupling is connected to an electrochemical current noise- monitoring device. Electrode 1 and the reference electrode are connected to an electrochemical potential-monitoring apparatus. This potential- monitoring device measures the electrochemical potential noise between the reference or pseudo- reference electrode and the coupled electrodes (electrodes 1 and 2). Both the electrochemical current noise and the electrochemical potential noise are connected to a signal processor, usually a personal computer.

Corrosion processes are stochastic in nature. The electrochemical reactions occurring at corroding surfaces generate low-frequency (<1 Hz) and low-amplitude random fluctuations (noise) of current (1 nA to 10 μA) and potential (0.1 μV to 10 mV) signals. The measurement and analysis of such noise signals provide useful information on the corrosion processes, including the type of corrosion and time of corrosion initiation (Ref 12, 13). The analyses of the electrochemical noise data usually are performed in the time and frequency domains. The pattern of the noise signals usually is used to evaluate the corrosion activity. Because automated pattern recognition requires sophisticated computer programming, statistical single parameters derived from the noise signals, such as mean potential, mean coupling current, standard deviations of the voltage and the current (or root mean square from an analog instrument), and noise resistance often are used as corrosion indicators for on-line applications (Ref 11, 14, 15, 16). In addition, pit index (Ref 15) and Kurtosis current (Ref 17) are used to evaluate the pitting activity.

The ECN method has many advantages in detecting localized corrosion. It is essentially non- perturbing. Measurements are carried out either at or close to the corrosion potential. It may have a mechanistic link to the stochastic nature of the localized corrosion-initiation processes and relies on the measurement of non-steady-state responses typical of early stages of localized corrosion. However, the measurement is not quantitative for localized corrosion rates and has not been reproducible in all cases. The pitting index, which is the ratio of the standard deviation of the current noise to the root mean square of the coupling current, has been shown not to correlate with the onset of pitting (Ref 18, 19). Furthermore, the noise signal between two identical electrodes is not highly sensitive to localized corrosion events in systems containing powerful redox agents (Ref 18).

Galvanically Coupled Differential Flow Cell

The galvanically coupled differential flow cell (Ref 20, 21, 22, 23, 24) employs essentially a slow-moving (relative to solution) electrode and a fast-moving electrode, both being made of identical corrodible metals and coupled together through a ZRA, as shown in Fig. 1. In Fig. 1, a valve and two flow meters are used to regulate the flow rates through the two cells so that the slow-moving electrode is exposed to a slow-moving liquid, and the fast-moving electrode is exposed to a fast-moving liquid. The area ratio of the fast- moving electrode to the-slow moving electrode is in the range of 20:1 to 200:1. Because of the differences between the flow pattern on the surfaces and the geometries of the two electrodes, the slow-moving electrode acts as an anode and the fast-

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

moving electrode acts as a cathode in a localized corrosion environment. Thus, a current flows between the two electrodes. The localized corrosion rate (LCR) is calculated according to:

$$LCR = 11.7 \cdot I/A_{se} + GCR \quad \text{(Eq 1)}$$

where LCR is in μm/yr; 11.7 is a conversion factor for carbon steel; I is the ZRA reading in μA; A_{se} is the surface area of the slow-moving electrode, measured in cm^2; and GCR is the general corrosion rate in μm/yr. The general corrosion rate can be obtained from the slow-moving electrode by decoupling it from the fast-moving electrode and connecting it to a linear polarization resistance corrosion monitor. Usually, the contribution from the general corrosion rate is negligibly low.

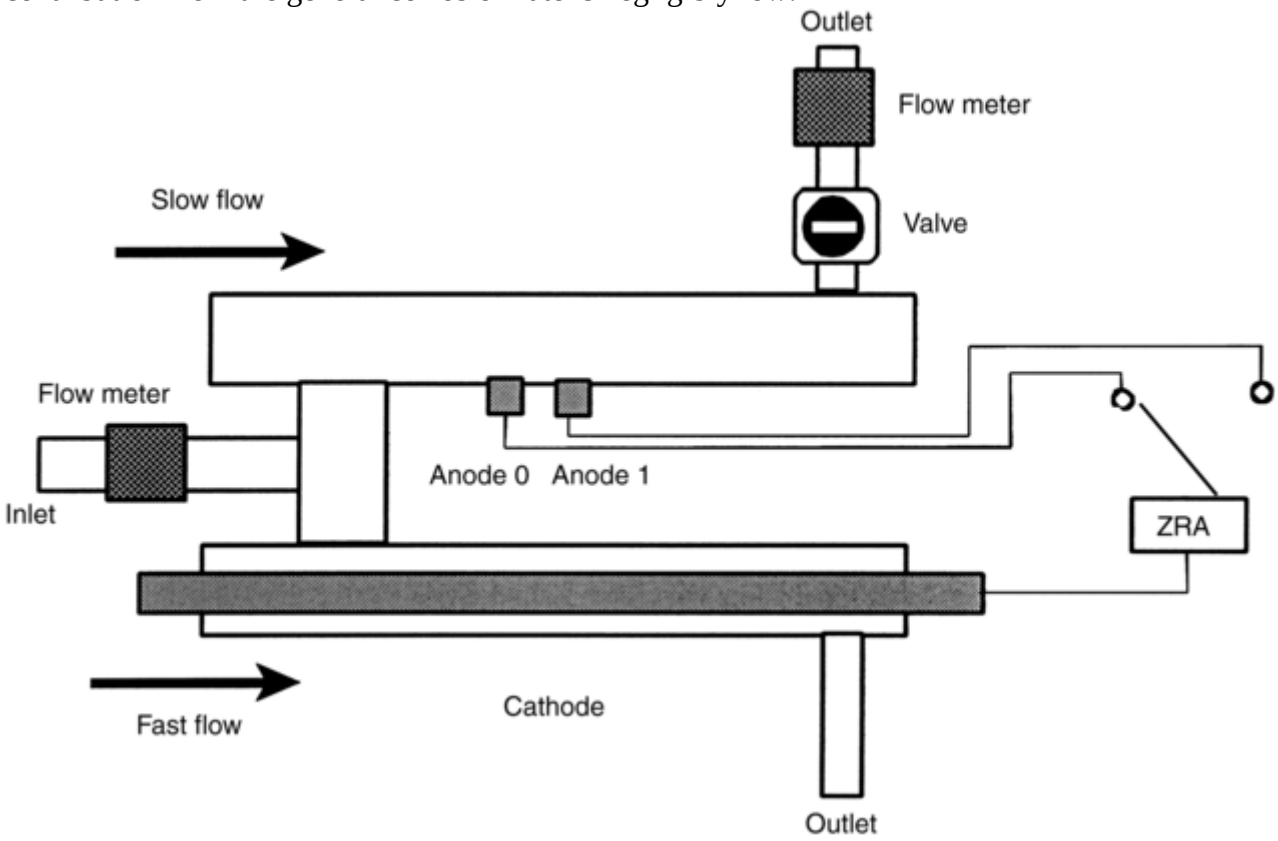

Fig. 1 Differential flow cell sensor for localized corrosion. Valve adjusts relative flow rates. Anode 0 and anode 1 are redundant, and zero resistance ammeter (ZRA) can be switched to either anode. Adapted from Ref 24, with permission from the National Association of Corrosion Engineers (NACE) International

This method has been tested for localized corrosion monitoring in cooling water systems (Ref 20, 21, 23, 24). The measurement conducted in a cooling water system of an integrated plastics plant (Ref 23) shows that the sensor responded to upset or nonideal operating conditions and the dosing of inhibitors. It was shown to be a useful tool in optimizing treatment performance and identifying upset conditions at the plant as well as providing field verification of the effectiveness of a new treatment program in reducing the localized corrosion rate of carbon steel. However, this method relies on the forced movement of the electrodes (or the solution), and the current between the slow-moving anode and the fast- moving cathode may not represent the true corrosion current flowing from a corroding site to a noncorroding site of a metal under localized corrosion conditions. Furthermore, localized corrosion, for example, pitting, usually focuses on an area that is significantly smaller than the large, slow-moving electrode (0.3 to 0.5 cm^2, or 0.05 to 0.08 $in.^2$) for the differential flow cell (Ref 20, 21, 22, 23, 24). It may not be reliable to predict a localized corrosion rate based on the current measured from a large surface area. The sensor has not been widely used either in laboratories or in the field.

Galvanically Coupled Crevice Cell

The galvanically coupled crevice cell has been used to study the crevice corrosion of stainless steel materials in seawater (Ref 25, 26, 27, 28). Figure 2 shows the schematic diagram of a coupled crevice cell system (Ref 27). In Fig. 2, there are three creviced stainless steel specimens and a large, noncreviced specimen that is similar to the creviced specimens in composition. Each of the three creviced specimens is coupled independently to the large, noncreviced specimen through a resistor. The crevice corrosion taking place in the crevices drives the electrode potential of the creviced specimen more negative (or anodic) than the large, noncreviced specimen (cathode). This process produces a coupled current from the large, non-creviced specimen to the creviced specimen. The coupled current is measured from its associated resistor and used to indicate the degree of crevice corrosion. The reference electrode in Fig. 2 is used to measure the potential of the coupled electrodes.

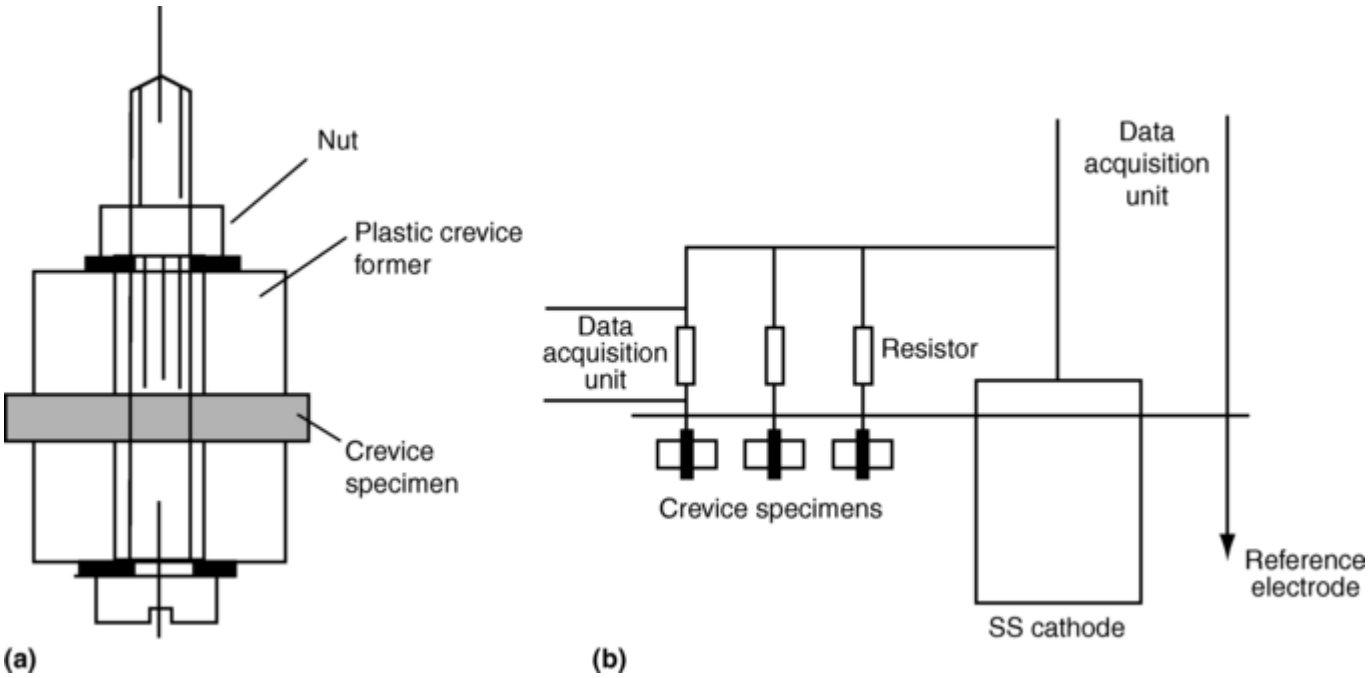

Fig. 2 Crevice cell system. (a) Cross section of crevice assembly. (b) Schematic diagram of crevice assemblies galvanically coupled to stainless steel (SS) cathode. Source: Ref 27, with permission from NACE International

Figure 3 shows typical results obtained with the crevice cell system (Ref 27). The measurement was conducted in a seawater test loop at 15 °C (59 °F), under which condition the specimen normally is not subject to crevice corrosion. The purpose of this measurement was to study the effect of temporary upset conditions on crevice corrosion of a welded stainless steel (UNS S31254) in seawater. Prior to the start of the measurement in Fig. 3, the crevice specimens were aged temporarily at high temperatures and high electrochemical potentials to initiate crevice corrosion. Figure 3 shows that the corrosion attack continued to propagate at 15 °C (59 °F) for 10 to 20 days before repassivation took place.

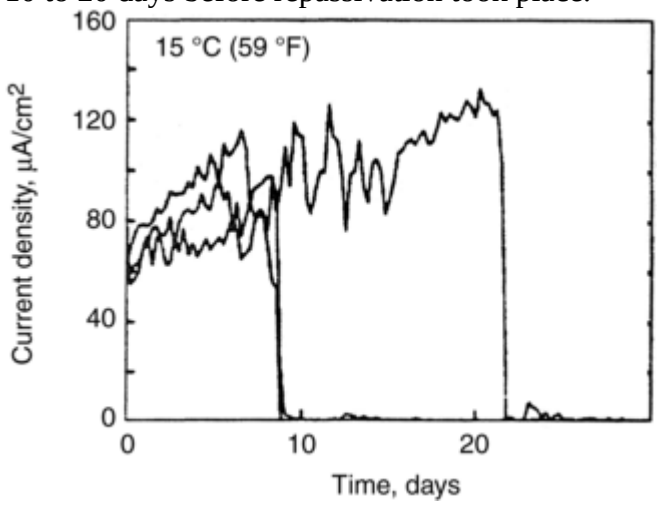

Fig. 3 Galvanic current densities of three creviced specimens of welded stainless steel (UNS S31254) and a cathode as a function of time in seawater at 15 °C (59 °F). This illustrates that repassivation occurs in approximately 10 to 20 days. Source: Ref 27, with permission from NACE International

This technique requires only straightforward voltage measurements and yet is capable of detecting the onset of localized corrosion under service conditions. Depending on the accuracy and resolution of the voltage-monitoring instrument, it may be able to detect localized corrosion in the early stages of degradation. The disadvantage of this method is that it cannot be used to determine the true rate of localized corrosion, due to the large surface area of the crevice (5.5 cm^2, or 0.85 $in.^2$). On-line application of this sensor remains to be demonstrated in the field.

Galvanically Coupled Crevice Cell

The galvanically coupled crevice cell has been used to study the crevice corrosion of stainless steel materials in seawater (Ref 25, 26, 27, 28). Figure 2 shows the schematic diagram of a coupled crevice cell system (Ref 27). In Fig. 2, there are three creviced stainless steel specimens and a large, noncreviced specimen that is similar to the creviced specimens in composition. Each of the three creviced specimens is coupled independently to the large, noncreviced specimen through a resistor. The crevice corrosion taking place in the crevices drives the electrode potential of the creviced specimen more negative (or anodic) than the large, noncreviced specimen (cathode). This process produces a coupled current from the large, non-creviced specimen to the creviced specimen. The coupled current is measured from its associated resistor and used to indicate the degree of crevice corrosion. The reference electrode in Fig. 2 is used to measure the potential of the coupled electrodes.

Electrochemical Biofilm Activity Sensor

Microbially induced localized penetration of materials can occur due to a combination of microbially mediated electrochemical reactions, local generation of deleterious species, and geometrical restrictions produced by the biofilm. Through-wall penetration of piping and heat exchanger tubing at rates 10 to 1000 times more rapid than typical general corrosion rates can result (Ref 41). Figure 7 shows the schematic diagram of a sensor (Ref 41, 42, 43, 44, 45) developed to monitor localized corrosion due to microbiological activity.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

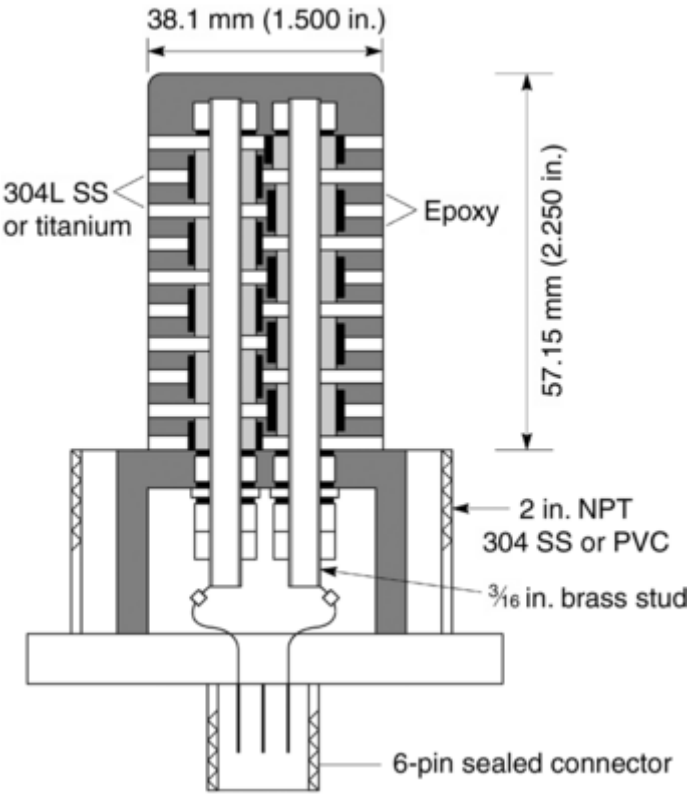

Fig. 7 Electrochemical biofilm activity monitoring probe. Probe is cylindrical, 38.1 mm (1.500 in.) in diameter, and 57.15 mm (2.250 in.) high. SS, stainless steel; NPT, American National Standard Taper Pipe Thread; PVC, polyvinyl chloride. Source: Ref 41, with permission from NACE International

The sensor consists of a stack of identical stainless steel discs (other passive metals, such as titanium, have also been used successfully) configured as a right-circular cylinder. The discs are divided into two groups, with each being connected to a brass stud to form an electrode. The electrodes are electrically isolated from each other and from the body of the probe, using an epoxy resin. One electrode (set of discs) is polarized relative to the other for a short period of time each day. The externally applied potential creates different local conditions on the stainless steel electrodes, conditions that cause different microbiological colonies to become established on the positive and negative electrodes. This polarization cycle produces slightly modified environments on the discs that are conducive to biofilm formation. Tracking the daily applied current and noting significant changes in that current provides one method to detect the onset of biofilm formation. The difference in the magnitude of the applied current from the baseline (i.e., the applied current when no biofilm is present) provides a measure of the localized corrosion due to biofilm activity. The generated current, the current that flows between the two electrodes when no external potential is applied, provides an additional, and often more sensitive, indicator of the effect of biofilm activity. In general, the onset of biofilm formation is signaled by an abrupt change in the generated current from the typical baseline value that is always very near zero. The magnitude of the deviation of the generated current from its baseline value provides a quantitative measure of the effect of biofilm activity on corrosion. It has been demonstrated in field measurements (Ref 41) that the biofilm activity sensor offers the system operator real-time information on the condition of microbiological fouling in the system so that injections of biocides or other mitigation activities can be based on measured effects of biofilm activity on a surface. However, its application in the field has been limited, and the reproducibility of the sensor remains to be seen.

Nonelectrochemical Methods

The electric field mapping technique (Ref 46) measures metal loss over a pipeline surface. An array of permanently installed pick-up wires is positioned around the outside of a pipe. A current is fed through a selected section of the pipe and an electric potential map is derived to correlate the change in wall thickness.
This method has the ability to monitor the localized corrosion of an actual component as it occurs. It gives the corrosion depth, pit size, and the actual location of the damage. It is also nonintrusive and non-perturbing to the corrosion metal-electrolyte interface or to the corrosion environment. The disadvantage of this method includes the requirement of special multichannel hardware and the associated software for data collection and data analysis. It also requires the installation of a large number of miniature electrodes on a small surface area of a pipe or equipment to obtain the high resolution for localized corrosion monitoring.
Magnetic Field Detection. Although not an ideal on-line detection tool, another nonelectrochemical technique that has been used to detect localized corrosion is the superconducting quantum interference device (SQUID) (Ref 47), which is a highly sensitive magnetic field detector that can detect fields less than approximately 2×10^{-8} of the terrestrial magnetic field. Originally, SQUID was developed using conventional superconducting materials and required cooling by liquid helium to 4 K. However, with the advent of ceramic superconductors, SQUIDs operating at liquid nitrogen temperature (77 K) are commercially available. The technique relies on sensitively detecting the magnetic fields generated by the currents at the anodic and cathodic areas during localized corrosion. The spatial separation of the anodic and cathodic areas aids in the detection of localized corrosion sites. The technique has been demonstrated for aluminum alloys used in aircraft systems (Ref 47). The advantages of this technique include its ability to detect corrosion without contacting the corroding metal; the potential for identifying corrosion on hidden surfaces, such as lap joints; and to develop some idea of the rate of corrosion. The disadvantages of the technique include its inability to be used on ferromagnetic metals or where ferromagnetic metals are in proximity, such as steel rivets on aluminum, and its inability to be used as a real-time monitor.

Conclusions

On-line monitoring of localized corrosion is still a challenge to researchers, plant engineers, and operators. The ECN method has been the most extensively studied method for localized corrosion monitoring. It may provide useful information on localized corrosion, including initiation and propagation. However, the results have not been reproducible in all cases. The differential flow cell and crevice cell methods may be used as qualitative but not quantitative sensors for localized corrosion, because the surface areas of the electrodes are significantly larger than the areas of localized attacks. The coupled multielectrode sensor offers promise as a localized corrosion sensor. However, it is a newly emerging technology, and its performance as a localized corrosion sensor remains to be judged by future work. Nonelectrochemical techniques that rely on electric or magnetic field detection are also being used in specific applications, such as underwater pipelines and aircraft lap joints.

Introduction

ACTIVE INFRARED (IR) THERMOGRAPHY continues to gain acceptance as a nondestructive evaluation (NDE) tool for both in-service and manufacturing applications. For example, pulse thermography is the preferred method for in-service inspection of core cracks in E2-C propellers at Cherry Point Naval Depot and for inspection of metallic honeycomb structures during manufacturing at BF Goodrich Aerospace. This technique compares favorably to point-by-point nondestructive inspection (NDI) techniques such as eddy-current and ultrasonic methods. Positive aspects of IR pulse thermography include:

- Images of a relatively large area can be produced, which makes it a fast inspection technique (Ref 1).
- It is partially insensitive to curved surfaces (Ref 2).
- Images are easy to interpret, and it does not have liftoff effects.
- It has a wide range of material applicability: metals, composites, ceramics, and coatings.
- It is very easy to use as it does not require a couplant.
- Analytical and numerical models (Ref 3, 4, 5) together with computing speed and storage capacity have been steadily increasing.
- Cost of computers and IR cameras have been decreasing.

Infrared Thermography Equipment

There are three key components that are required to perform active thermography: an excitation source, a thermographic camera, and a computer with software that controls the instrumentation, acquires data, and displays the results. The challenge of active thermography is to match the thermal excitation source to the material and defect type being inspected. Some of the most common thermal excitation sources include:

- Arc lamps for detection of delaminations in composites and generalized corrosion in metals
- Hot air guns for detecting disbondments in weakly conducting materials
- Microwave sources for detection of trapped water in dielectric media
- More recently, ultrasonic welder guns for detection of cracks in materials

All of these thermal excitation techniques produce relative “hot spots” or large thermal contrasts on the specimen surface when there is a defect within the material. With the aid of the IR camera and associated equipment, the inspector makes a permanent record of these hot spots.
Figure 1 shows a laboratory setup of a pulse thermographic system with two arc lamps and an IR camera in between them. In a typical pulse thermographic experiment arrangement, the arc lamps are positioned as close as possible to the samples being inspected so as to deposit as much energy as possible over the sample's surface. The lamps are arranged to produce a uniform heating zone over the samples. The IR camera is situated to best capture images of the surface of the sample. Power to the lamps is provided by a capacitor bank that is charged to full capacity, typically 10 kJ. Just before discharging the capacitor through the arc lamps, the IR camera is triggered to start acquiring thermal images of the sample surface for background subtraction purposes. Usually ten frames suffice. After a few frames have been acquired with the sample at room temperature, the capacitor bank is discharged and the radiant energy produced by the lamps is deposited over the surface of the sample.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

The radiant pulse deposition time (τ_{dep}) should be made short enough so that only the surface of the sample increases in temperature initially, while the bulk of the sample remains at room temperature. Typically, the minimum τ_{dep} is approximately 5 ms. In general, the thermal excitation source should be capable of depositing the energy on the surface of the sample in a time comparable to or shorter than the lateral diffusion time (τ_{lat}) of the material being imaged. If τ_{dep} were much longer than the τ_{lat}, the resulting contrast temperature would be significantly lower than otherwise. Table 1 provides typical values of the normal and lateral diffusion times for an aluminum panel with two thickness values and with flat bottom holes of different radii to simulate defects.

Table 1 Infrared imaging time constants for a 7075 T6 aluminum sheet

(a) Based on $\rho c/k = 1.8$ s/cm^2

The pulse thermographic process can be described as follows. As soon as the radiant energy is deposited on the surface of the sample, it starts to diffuse into the bulk sample. Regions in the sample with delaminations, debonding, or corrosion will offer greater resistance to the flow of energy than regions with no defects. As a result, hot spots—or regions with large thermal contrast—will develop on the surface of the sample. These hot spots will be recorded by the IR camera system, which has been acquiring data throughout the experiment. It is the analysis of these hot spots that will allow the inspector to detect damage.

Figure 1(b) shows a portable version of the pulse thermographic system described previously. In this case, the IR camera and the arc lamp are integrated together in the same casing and situated on top of the tripod. The data-acquisition system and the capacitor bank are located on the adjacent dolly. The capacitor bank used in this system is significantly smaller than the one used in the laboratory to make the entire unit more portable. Typically, 2 to 3 kJ of energy storage is available in the portable unit compared to 10 kJ in the laboratory system. To compensate for the lower amount of energy and a potential drop in sensitivity, the inspection area is made proportionally smaller in order to maintain a similar energy density over the surface of the sample.

Thermographic Process

Simple models have been developed (Ref 6, 7, 8) describing the pulse thermographic process. They all are characterized by three distinctive phases:

- The energy-deposition phase characterized by the duration of the heat pulse
- The contrast-formation phase characterized by the diffusion of the surface thermal energy into the bulk of the material
- The contrast dissipation phase characterized by the lateral dissipation of energy

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Each phase is characterized by a specific time constant τ_{dep}, τ_{nor}, and τ_{lat}, as shown in Fig. 2. In the limit of short pulse duration ($\tau_{dep} \ll \tau_{nor}$), the following simple relation characterizes the thermal contrast in terms of the parameters shown in Fig. 2:

$$\Delta T_{max} = \frac{Q}{\rho c}\left(\frac{1}{d} - \frac{1}{t}\right) \cdot \left(\frac{\tau_{lat}}{\tau_{nor}}\right)^{\left\{1/\left[1-(\tau_{lat}/\tau_{nor})\right]\right\}}$$

where ΔT_{max} is the peak thermal contrast developed on a sample with a defect; $Q = J \cdot \tau_{dep}$, where Q is the amount of energy deposited on the surface of the sample per unit area, J is energy flux per unit area and time, and τ_{dep} is deposition time; ρc is the product of the density and specific heat of the material; d is the distance from the defect to the surface of the material; t is the thickness of the sample; R is the radius of defect; $\tau_{nor} = \rho c/k(d(t - d)/t)^2$ is the normal diffusion time; $\tau_{lat} = \rho c/k(R^2/2)$ is the lateral diffusion time; and k is thermal conductivity. For nonisotropic materials, k in the normal and lateral directions will have different values.

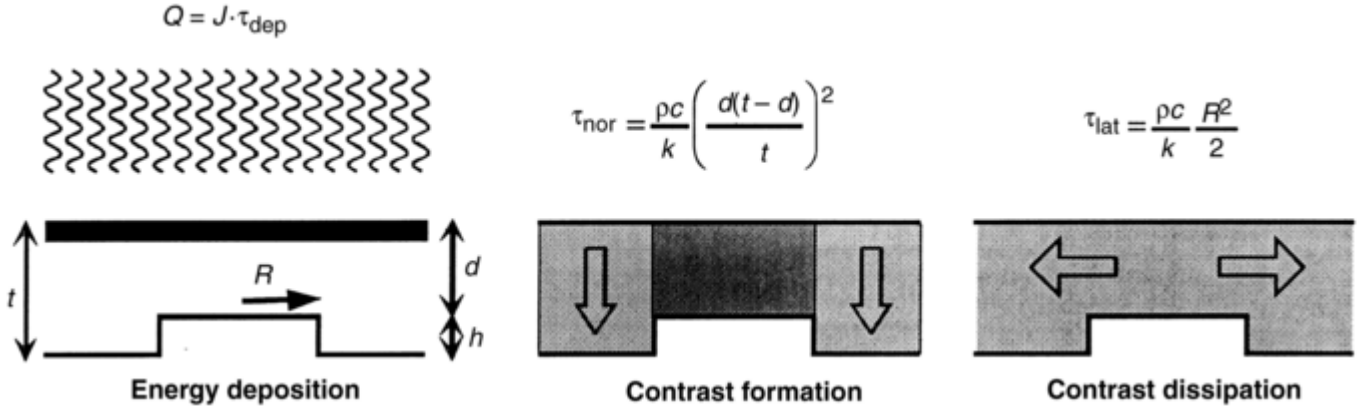

Fig. 2 The three phases characteristic of the pulse thermographic process and their respective characteristic time constant (a) deposition τ_{dep}; (b) contrast formation, τ_{nor}; (c) contrast dissipating, τ_{lat}. The key parameters characterizing the specimen and defect are: thickness, *t*; depth to defect, *d*; height of defect, *h*; radius of defect, *R*. Formulas are explained in the text.

These phases are not separated in time; rather, they all start at the same time. As soon as energy starts to be deposited over the surface of a panel, the energy will also start to diffuse into the panel. If there is a discontinuity in the panel, energy will begin to accumulate over the discontinuity and a thermal contrast will start forming. As soon as a contrast starts forming, it will also start dissipating laterally. All processes take place simultaneously. Depending on their relative duration, the contrast will be larger or smaller. The condition necessary to maximize the contrast temperature when a fixed amount of energy, Q, is deposited on the surface of a panel is obtained when:

$$\tau_{dep} \leq \tau_{nor} < \tau_{lat}$$

In other words, to maximize the amount of contrast formed one needs to deposit the energy in a time shorter than or comparable to the contrast formation time, which is largely controlled by the normal diffusion time constant. After this time, the lateral diffusion effects take hold and the contrast will not reach its maximum potential. For an isotropic material, the relation $\tau_{nor} < \tau_{lat}$ is equivalent to having the size of the defect (R) larger than the thickness of the plate; that is, $2R > t$. In this limit, the quantity

$$\left(\frac{\tau_{lat}}{\tau_{nor}}\right)^{\left\{1/\left[1-(\tau_{lat}/\tau_{nor})\right]\right\}}$$

approaches 1, and the thermal contrast approaches a very simple relation $\Delta T = Q/\rho c(1/d - 1/t)$. This relationship has been observed and reported in many scientific papers.

Imaging Results

The detection sensitivity of the pulse thermographic process, like ΔT_{max}, depends on the amount of energy deposited on the surface of the panel, the deposition time (Q, τ_{dep}), the size and depth of the flaw and thickness of the panel (R, d, t) (Ref 9). In general terms, the sensitivity increases linearly with the amount of energy, Q, and decreases inversely to the distance of the defect from the surface, d. Other factors that will significantly affect the sensitivity of the technique are edge effects, fasteners with different thermal conductivity than the base metal, and variations of an adhesive layer thickness in multilayered structures. Presently, the resolution achieved with the state-of-the-art system is about 3% thickness loss in laboratory environments inspecting flat panels and about 15 to 20% thickness loss under realistic field conditions inspecting structural components.

Pulse thermographic methods work best when inspecting materials with defects that are parallel to the surface such as disbondments, delaminations, and generalized corrosion because they disrupt the flow of energy very effectively. When the defect is perpendicular to the surface of the sample, such as with many types of cracks, pulse thermography does not work since disruption to the energy flow is minimal. Other thermographic methods are being developed for these types of defects such as line-scanning thermography and, more recently, sonic thermography.

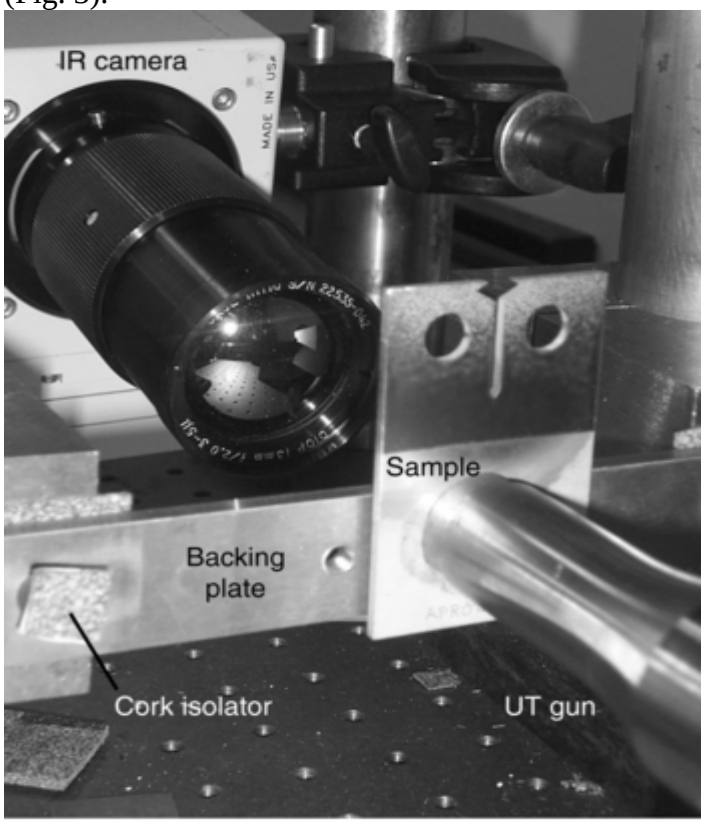
Sonic Thermography for Crack Detection

www.iran-mavad.com

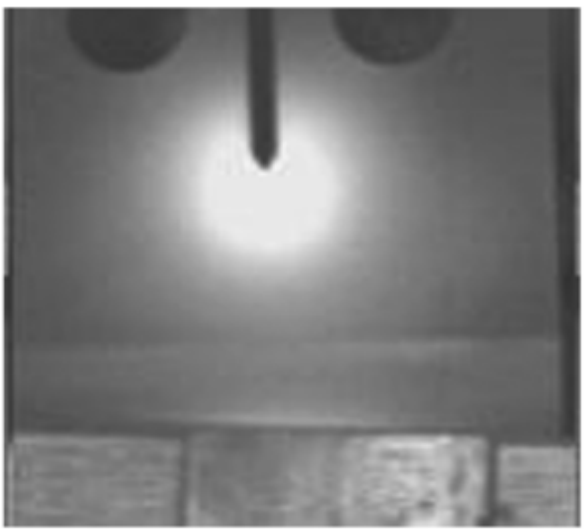
مرجع مهندسی مواد و متالورژی

Original work on sonic thermography started in the late 1970s with studies on the interaction between high-power ultrasonic sources and materials (Ref 10). It was found accidentally that when a cracked specimen was insonified with a high-power ultrasonic gun, cracks would be excited in such a way that they were easily detected with a thermal camera. Recent work in sonic thermography or thermosonics (Ref 11, 12) has demonstrated that this technique can also be applied to detect other forms of damage in materials, such as delamination in composites or corrosion in aluminum.

In the thermosonic method, a burst of high- power ultrasonic energy is applied to a sample. The energy quickly floods all corners of the sample. If a crack is present anywhere on the sample, energy will dissipate very effectively from it, creating a region of elevated temperature that can be imaged effectively with an IR camera (Fig. 3).



(a)



(b)

Fig. 3 Sonic thermography arrangement. (a) Ultrasonic (UT) gun energizes sample. Cork insulators mechanically isolate samples from the backing plate. Infrared (IR) camera captures images. (b) Thermograph from IR camera detects a crack at the root of the slot.

مرجع مهندسی مواد و متالورژی

This mode of coupling energy to a sample is much more effective than the one used in the pulse thermographic method. In the pulse thermographic method, energy must be deposited uniformly over the entire surface of the sample being inspected, but it is only the energy that falls over the defective area that contributes to the thermographic signal. The remainder of the incident energy contributes to the background temperature, thereby reducing the maximum possible thermal contrast, since the thermal contrast is obtained by subtracting the background temperature from the temperature of the hot spot. In the thermosonic method, energy is coupled to the sample being inspected with an ultrasonic (UT) gun in contact with the sample at one point of its surface. The energy then quickly spreads to all corners of the sample, with the amplitude of vibration building up in the sample while the UT gun is on. If there is a crack present in the sample, vibrational energy will start dissipating through it. The dissipation mechanism is not completely understood, but it is believed to be related to rubbing or clapping of the facing surfaces of the crack. The net effect of this dissipation is that the area surrounding the crack will heat up, thereby allowing for its detection. This is a very effective use of the interrogation energy, since most of it is consumed in generating the thermosonic signal.

An analogy to detecting a crack by using the thermosonic process is finding a hole on a bicycle tire by using an air pressure gun. The analogy can be explained as follows. To find a hole in a tire, one applies air pressure through one point on the surface of the tire. The air quickly fills the entire volume of the tire and the pressure keeps building up in the tire while the pump remains on. If there is a small hole in the tire, air will leak through it, generating a small sound, thereby allowing for its detection. If there are several holes in the tire, each one will leak air, allowing for their detection. The higher the pressure in the tire, the stronger the sound produced by the hole. Continuing with the analogy, we know that a minimum amount of air pressure is required to detect a hole in a tire. Very small holes are effectively closed due to the elastic properties of rubber, and a minimum amount of air pressure is required to force air through the hole. Likewise in thermosonic experiments, a minimum amount of energy is required to excite cracks. This should be expected since closed cracks, such as hairline fatigue cracks that are almost invisible to the naked eye, would require a minimum amount of vibration amplitude to overcome the frictional forces produced by the mating surfaces. Evidence of this phenomena has been observed in laboratory experiments.

Figure 3 shows the experimental setup used by the author. A 1000 W power supply (not shown in the figure) was used, and the excitation frequency was 20 kHz. It would be desirable to have a system where the frequency of the UT gun could be adjusted depending on the particular characteristics of the sample and defect being inspected. Unfortunately, a recent search found all high-power commercial units had a fixed excitation frequency. This is because these units are engineered to achieve maximum amplitude displacements at the tip of the gun by stacking up a series of precisely cut piezoelectric crystals operating at the same resonant frequency. A steel horn (Fig. 3) is used in the UT gun to enhance the amplitude of vibration.

During a standard experiment, the controller is set to maximum power with pulse duration adjusted according to the experimental requirements, but limited to no more than 0.5 s because of hardware constraints. In fact, the longer the excitation, the stronger the thermosonic signal will be (Ref 13).

The UT gun was mounted on a platform to impede it from sliding over the surface of the sample and damaging the surface, while providing good load control via a pneumatic regulator. The load applied to the gun against the sample determines the amount of energy that couples into the sample and thereby determines the amplitude of the thermosonic signal. It was found in experiments that the thermosonic signal increased linearly with the applied load. Conservation of energy dictates that at some higher load value the thermosonic signal will saturate, but the available load capacity of 45 lb was far from saturation. As high loads tend to scourge the surface of the sample, a scientist at Wayne State University placed a thin coupling agent (a thin foil of copper) between the UT gun and the sample to minimize surface damage while maintaining good mechanical coupling. The appropriate choice of the coupling agent will determine if this technique is truly nondestructive and how much energy couples into the part being inspected. The infrared camera used in all the experiments discussed in this paper was a Radiance HS camera with a frame rate adjusted to capture thermal images at a rate of 120 frames/s.

Mechanical isolation of the sample is required in order to obtain an optimal thermosonic signal. If the sample being inspected rested directly over a backing plate of similar acoustic impedance or if the mechanical isolation between the sample and the backing plate was not significant, then the thermosonic signal would be minimal or not existing at all. This lack of thermosonic signal is understandable because the ultrasonic energy would leak out of the sample through the backing plate. Using the bicycle tire analogy, trying to detect a small fatigue crack in a sample in direct contact with a backing plate would correspond to trying to detect a small pinhole on

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

the tire when there was a large open gap in the tire. Air pressure would not be able to build in the tire due to the presence of the open gap in the tire. Similarly, good thermosonic signals are obtained when a piece of cork is placed between the sample and the backing plate to produce good mechanical isolation (Fig. 3) (Ref 13).

In practice, complete isolation, while desirable, is difficult to achieve. This does not mean that thermosonics is limited to the inspection of well-isolated components. As long as the energy leakage to the surrounding area is small compared to the energy required to excite a crack, thermosonics will be useful as an NDE technique.

There is still considerable experimental work and development to be done before thermosonics becomes a user-friendly NDE technique. The thermographic imaging techniques presented in this article and other techniques currently being developed are expanding the use of thermography into areas not previously considered.

Corrosion Monitoring Using Microwave and Guided Wave Nondestructive Evaluation

Alan V. Bray, Systems and Materials Research Consultancy (SMRC)

Introduction

TWO INTERESTING TECHNIQUES for finding hidden corrosion are emerging as viable in-service nondestructive evaluation (NDE) tools: microwave NDE and guided wave (GW) ultrasonic NDE methods. The in-service inspection scenario is complicated by the fact that corrosion is often hidden, and expensive disassembly can be required to complete an inspection. Microwave and GW NDE techniques have promise as methods that minimize disassembly in many common corrosion detection problems. Both methods are capable of detecting corrosion damage, cracks, and other defect types in inaccessible areas.

The most common corrosion-detection application of microwave NDE is inspecting under a coating or appliqué for corrosion. This corrosion detection is based on the physics of the way in which microwaves interact with the materials of the coating and the sublayers of corrosion. Paint, appliqués, and corrosion byproducts are all dielectric materials, and each influences a microwave signal differently. In addition, the damage caused by corrosion can change the distance from the coated surface to the base metal, and this change in height is also detectable. Aircraft coatings are critical targets because corrosion under a coating can ultimately result in loss of airframe integrity. Non-corrosion-related applications include inspection of composites and detection of moisture in nonconducting structures.

The NDE by GW differs from other ultrasonic methods in two distinct ways: GW evaluation is typically conducted at lower frequencies—often under 1 MHz, and GW signals travel long distances. Thus an area can be inspected from a significant distance. Some GW methods are aimed at detecting corrosion wastage from as far away as 20 m (65 ft) from a GW sensor array. Applications include inspection of insulated pipe runs while only removing a small portion of the insulation, and inspection of structures such as beams from a fixed set of GW sensors.

Like many NDE techniques, microwave and guided wave ultrasonic methods can be valuable tools for detecting hidden corrosion when used properly and interpreted with care. Much of the current research in applying these NDE methods to modern inspection problems centers on developing systems that are insensitive to errors and false alarms, and this often means systems that are specific to a given inspection scenario. As an example, a guided wave inspection system for insulated piping would be quite different than one used for detecting the presence of wing icing. Similarly, microwave NDE systems for detecting corrosion under coatings are configured differently than for moisture detection within a nonconducting structure like a honeycomb panel or a sandwich panel. Many of the basic system tools remain unchanged, but sensor configurations, frequency ranges, and analysis techniques can differ dramatically from one application to the next.

Corrosion Monitoring Using Microwave and Guided Wave Nondestructive Evaluation

Alan V. Bray, Systems and Materials Research Consultancy (SMRC)

Microwave NDE Devices

Microwave transmitters provide the incident energy for an inspection. The most commonly used transmitters for corrosion detection are actually transceivers; diodes in the transmitter receive the reflected signal. The incident and reflected signals are separated in the device, and the reflected signals are then analyzed for evidence of corrosion. The presence of corrosion attenuates the received signal, as do changes in the distance from the metal substrate caused by wastage. A key to microwave NDE device design is keeping the sensor at a fixed distance from the inspection surface in order to avoid misinterpreting changes in standoff distance from actual corrosion features. The mechanical design, coupled with electronic processing of the reflected signal, are crucial in minimizing false alarms.

Open-ended waveguides are used often as microwave corrosion NDE sensors, although open- ended coaxial sensors (Ref 3) and strip-line antennae (Ref 4) have also successfully detected defects under coatings. Open ended rectangular waveguide sensors typically operate in the X- band (8 to 12.5 GHz) or K-band (12.5 to 40 GHz) frequency range. Corrosion detection sensitivity is dependent on frequency and standoff distance. Emerging microwave NDE tools for inspecting under coatings include small programmable logic devices that aid in distinguishing good and bad operating conditions (e.g., conditions that would lead to false alarms or missed detections).

Microwave devices sense the dielectric change that results when corrosion products are present under the coating. The amount/degree of corrosion has an influence that can also be sensed by the device. A heavily corroded area will attenuate the signal output more than a lightly corroded area will. Device displays can include a range of corrosion severity based on the extent of change in the returned signal. Defining the amount or degree of corrosion at the threshold of detection is difficult since it is defined by the corrosion itself. Some groups have used standard exposure methods such as ASTM G 34 specimens to define the lower detection limits in terms of hours of exposure under a defined regimen of corrosion (Ref 5).

Inspections with a microwave NDE device can be done with standard scanning systems, but handheld scanning is also possible. Any microwave scanning mechanism must be designed with altitude (standoff) distance and cant angle sensitivity in mind. Robust systems include logic to eliminate drastic changes that could be changes in altitude. As an example, the radius of curvature of the inspection surface can cause inaccuracies if the altitude control system has a wide enough footprint so that the distance to the sensor changes significantly with radius of curvature of the part.

Principles of Operation. Microwave NDE techniques depend on the interaction of incident microwave energy with a material or structure. This interaction involves the effect of the material on the electric and magnetic fields generated by the microwave device. Changes in the conductivity, permittivity, and permeability of the inspected material relative to its surroundings are sensed in these field changes, as well as changes in substrate morphology.

Figure 1 illustrates that the damage caused by corrosion of the substrate and the corrosion product itself both result in a change in the received signal. The bottom sketch portrays change caused by a change in the distance to the substrate, the top attenuation of the signal caused by the presence of corrosion products. Clearly, most detections are some combination of the two extremes. Corrosion products are typically dielectric materials, such as metal oxides—for example, iron and aluminum oxides. The dielectric nature of a material is described mathematically by its permittivity and loss factor, the real and imaginary components of the dielectric characteristic. Microwave NDE techniques for detecting corrosion under paints and appliqués exploit the contrast in the dielectric characteristics of corrosion versus that of the coating as well as the changes in substrate characteristics that indicate corrosion damage such as pitting and wastage.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

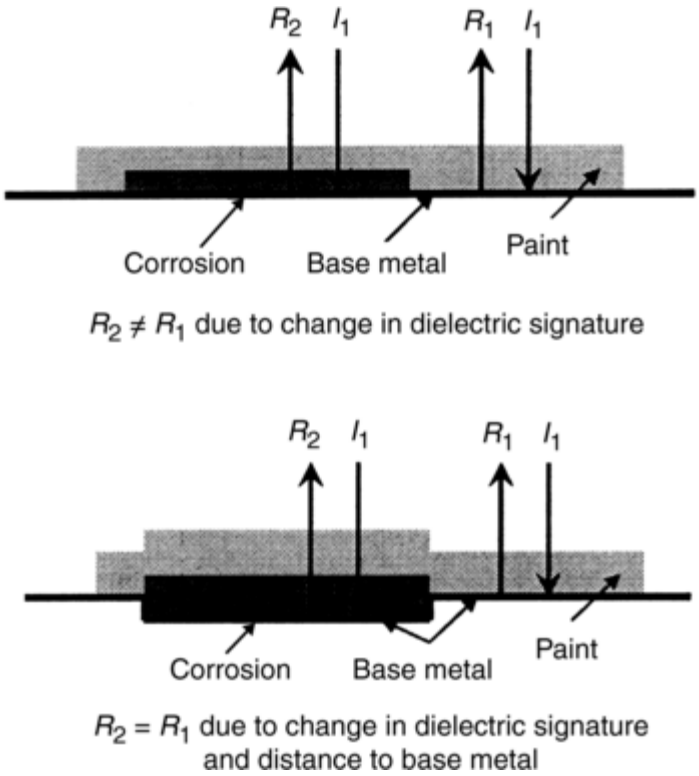

Fig. 1 The same incident signal (I_1) yields differing reflected signals (R_1 and R_2). R_1 is the return from an undamaged area, the base-line measurement. On the top, the change from R_1 to R_2 is due to the dielectric nature of the corrosion product. On the bottom the change is due to a combination of the dielectric change and a change in the transmission length.

In the microwave sensor, a three-port circulator or similar element is used to separate the incident and reflected signals. The drive signal for the microwave source is typically a continuous wave transmitter. These are low-power devices, typically under 0.5 mW; however, shielding the operator from stray microwave radiation is considered a good safety practice. Corrosion can be detected as an attenuation of the received signal relative to that for a noncorroded state.

Detecting Hidden Corrosion. Since microwaves are reflected by metals, they are not useful in inspecting under metal structures such as lap joints. Their primary use as a corrosion NDE tool is in inspecting under paints and appliqués applied to metallic substrates. Microwave NDE methods can be used to inspect deep into the material matrix of nonconducting structures such as fiberglass composites (e.g., Ref 6) for delaminations, voids, and the presence of moisture.

When scanning over a painted surface, corrosion products under the paint cause a change in the electromagnetic energy reflected back to the microwave device. It is this change that is then used to indicate the presence of corrosion (Ref 7). Microwaves are very sensitive to the presence of moisture, and this feature can be both a hindrance and a boon in NDE. Surfaces that are wet cannot be inspected without drying, yet the ability to find trapped moisture can be a valuable asset in some applications. Another scanning issue is inspection in corners and tight spots. The mechanical design used to maintain standoff control is rarely small enough to get into these tight spaces, yet these areas are a high priority in NDE because of their potential for corrosion. Special heads can be fitted to the wave guide of the device to maintain standoff control in corners, but it is difficult to include all the possible corner configurations in a single NDE device kit. In operations where the inspection geometry is constant from one unit to the next, such as inspection of a single aircraft type, a special set of heads can be developed to cover the various corners and tight spots.

In-service inspections can be done with a handheld device, and the power consumption is low enough for battery operation. Scanning speeds on a uniform surface such as an aircraft skin are surprisingly fast and are only limited by the electronic processing time. Scanning is typically done in a quick search mode that looks for any indication of degradation, and then the indicated area is inspected more carefully to ensure that it is not a false alarm and to get a rough determination of the severity and size of the corroded area.

Typical Applications. Microwave corrosion NDE applications that concentrate on inspection of the metallic substrate under coatings include shipboard painted or laminated structures (Ref 8), painted and appliquéd

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

aircraft skins (Ref 5), coated bridge structures (Ref 9), or any other metal component under a coating that would otherwise be difficult to inspect without removing the coating. Microwave sensors used for corrosion NDE are most often single-point devices. Focused microwave sensors have been successfully used in other applications such as inspection of fiber-reinforced plastic (FRP) jacketed concrete structures (Ref 10). Arrays of microwave sensors for inspecting large areas such as aircraft skins have potential applications, but sensor control (standoff and cant angle) can become problematic.

A spot microwave NDE sensor is a relatively simple device, and inspection rates are fast compared with those for most other NDE techniques. The reason for this is that there is very little integration time required to make a corrosion/no- corrosion decision. Scan speeds of 0.3 to 0.6 m/ s (1 to 2 ft/sec) have been reported, which is roughly the hand speed of moving a paint brush. A microwave NDE device with a 12 mm (0.5 in.) aperture can easily cover over 20 to 40 m^2 (200 to 400 ft^2) in an hour in the hands of a trained operator. Operator displays can be as simple as looking at a string of light-emitting diodes, hearing an audible alarm, or watching a meter. Even with modern digital logic built in, it is still important that an operator be able to discern the difference between changes in sensor altitude caused by rivets or seams, and changes due to corrosion. The low cost of microwave NDE sensors is attractive, but as with any NDE procedure, training is essential to ensure reliable corrosion detection.

Corrosion Monitoring Using Microwave and Guided Wave Nondestructive Evaluation

Alan V. Bray, Systems and Materials Research Consultancy (SMRC)

Guided Wave Ultrasonic Devices

Guided wave ultrasonic NDE methods have a loose microwave analog—the wave guide. Guided waves are generated by first flooding a structure with acoustic energy. This energy is reflected from the boundaries of the structure with small changes in frequency, and these signals constructively combine to form wave packets that travel within structure much like a wave guide. Some wave packets, or modes, can travel long distances without significant attenuation once they are formed (Ref 11), and these are the richest modes for detecting corrosion wastage. Figure 2 illustrates the manner in which GW modes are formed in a structure. There are many variations on the basic elements of GW systems of NDE; these include a wide range of frequency selection, drive pulse shapes, sensor arrays, and electronic display systems.

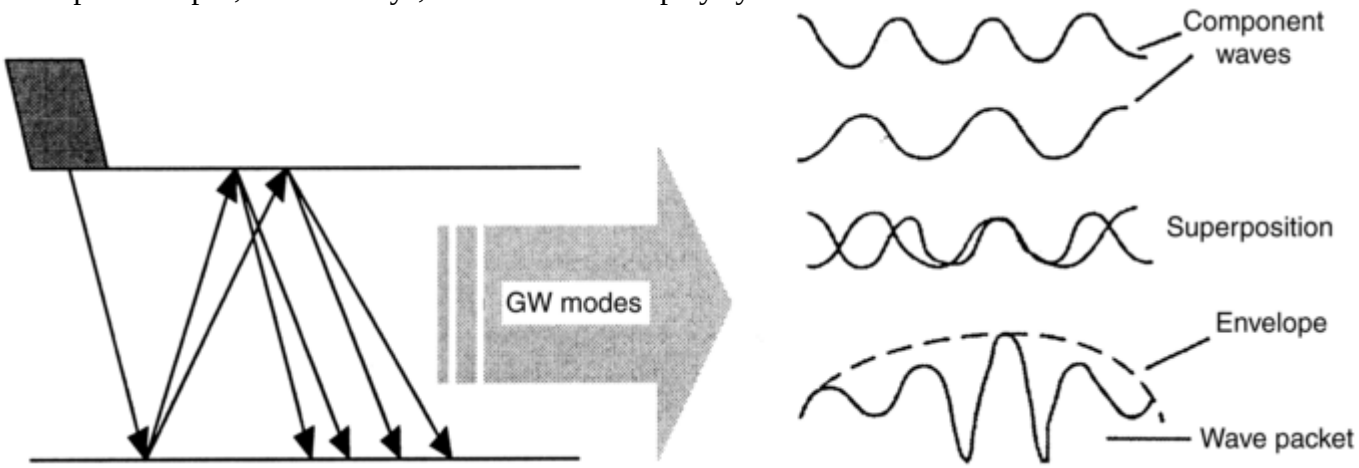

Fig. 2 The formation of a guided wave within a structure is shown on the left. Superposition of the component waves create the wave packet within the carrier envelope.

Guided waves are useful in inspection scenarios where an item is covered or encased. Examples include insulated piping, sandwiched structures such as lap joints, encapsulated pressure vessel walls, and applications such as wing icing where a guided wave is generated in the wing skin (Ref 12) and the presence of ice shows up as a change in the return signal. Guided wave NDE systematic “noise” sources include mode- coupling phenomena, array pattern dropouts or blind spots, and operator training and interpretation.

Principles of Operation. Most GW ultrasonic sensors are piezoelectric transducers in either crystalline or piezo-composite format. Guided wave transducers are driven by high- voltage (on the order of 1000 V in some applications) tone burst electronics. Detection of corrosion damage is done in pulse-echo or through-transmission modes, the latter requiring a separate receiving sensor or array. Common displays include amplitude versus time of arrival for a given frequency range. Each mode travels at a different speed, but in most inspections the frequency range is narrow enough that the time scale can be recalibrated in distance from the transducer.

Guided wave ultrasonic NDE sensors can be classified into two major designs—those that are in contact with the inspection surface and those that use standoff sensors such as electromagnetic acoustic transducers (EMATs) or laser generated/ received sound (Ref 13). Contact sensors can be used in such applications as insulated piping systems, but a section of the insulation must be removed from the transmitter and receiver sites. Electromagnetic acoustic transducers and laser devices can insert and receive sound through porous coatings up to the limiting distance for the device.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

In many guided wave applications, arrays of GW sensors are driven in phase or with programmed delays for activating sensors in the array. The advantages of an array include larger cross-sectional coverage, increased distances of inspection, and the ability to tune the signal using array delay times to increase the probability of detecting corroded or cracked areas.

Detecting Hidden Corrosion. Pipe or pressure vessel wall thinning due to corrosion is a classic GW target. As the GW packets strike a thinned area, mode changes are induced that can be detected as changes in frequency content and time delay. Time delay changes result since each mode travels at a unique velocity. Mode diagrams of phase velocity versus $f \times d$, the product of frequency (f) and the dimension (d) of the "waveguide." In a pipe inspection, d is the pipe wall thickness. These mode diagrams in the frequency region of interest are an important tool in understanding inspection results. Tone burst systems are typically built on a personnel computer platform, and many of the analysis functions are programmed into the system.

The smallest defects that are detectable with NDE systems by GW method depend on the application. In pipe inspection scenarios, the lower defect limit is usually characterized as 5 to 7% of the cross-sectional area of the pipe wall (Ref 14). Since the distance of the defect from the transducer is known, it is a simple matter to pinpoint the defect location with a tape measure. This makes it an excellent tool for quickly scanning large lengths of pipe, tubing, and hidden aircraft structures to identify and locate in-service corrosion problems that can then be examined in detail with more conventional ultrasonic methods.

Typical Applications. Guided wave ultrasonic applications encompass a wide range of customized scenarios for corrosion and crack NDE. Monitoring existing structures with an array of guided wave leave-in-place (LIP) sensors is a relatively new technique (Ref 15). Small GW sensors are placed in the vicinity of a critical high stress region, and initial measurements record the state of the part at that point in time. As the part is used in service the "array" that was formed by the LIP sensors can be interrogated and compared to the initial state. This is a particularly pertinent technique for parts that have a history of failure under stress. Leave-in-place sensors for monitoring existing structures operate in the 200 KHz region. The sensors are relatively inexpensive, and they can be left in place for years.

As frequencies drop to accommodate larger structures, the GW sensor size naturally increases. In applications requiring a lower frequency approach, the sensor array is commonly moved from site to site and operated in pulse- echo mode. Trend analysis of inspection results is possible, but care must be taken to record the original array positions if time/frequency scans are to be compared over time. The pipe inspection application is an example of a low frequency GW NDE application employing this approach (Ref 16).

Corrosion Monitoring for Industrial Processes

Sheldon W. Dean, Dean Corrosion Technology, Inc.

Introduction

IN-SERVICE MONITORING of industrial manufacturing operations is the type of service- corrosion testing that presents the greatest challenge and for which there is a great need. In such operations, the expense of corrosion problems can be huge and the risks devastating. These expenses are summarized in the article "Direct Costs of Corrosion in the United States" in this Volume. The detailed report to the United States Congress is available (Ref 1). Corrosion monitoring has become an important aspect of the design and operation of modern industrial plants because it is one of several techniques that can be used to keep track of the degradation processes that may be occurring in an industrial operation. The most widely used application of in-service monitoring is to identify the occurrence of corrosive conditions that may be caused by unknown circumstances, such as a new catalyst that promotes corrosive chemicals formation, or a feed stock that may contain corrosive

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

impurities from time to time. In such circumstances, in-line monitoring can be an important tool to maintaining safe operation. Because of the high cost of installing in-line monitoring systems, and the need for regular maintenance, these systems are seldom used in well-behaved operations. In these cases, periodic inspections suffice to meet both the regulatory and management needs for a safe operation. However, in situations such as oil and gas production, where substantial variations in process fluids may occur in a relatively short time, the value of on-line monitoring is higher and can be essential to long- term safety and reliability.
This article, therefore, focuses on methods of monitoring corrosion in industrial plants. The term *monitoring,* as used in this context, includes any technique for evaluating the progress or rate of corrosion.

Selecting a Corrosion-Monitoring Method

A large variety of techniques are available for corrosion monitoring in plant corrosion tests, and much has been written on the subject (Ref 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12). The most widely used and simplest method of corrosion monitoring involves the exposure and evaluation of the actual test coupons (specimens). ASTM G 4 was developed to provide guidance for this type of testing (Ref 13). Additional detailed information on procedures from practical experience is given in Ref 10. Extensive overviews of some electrochemical methods of corrosion monitoring in industrial plants are given in Ref 7 and 8. ASTM G 96 (Ref 14) provides detailed information on the use of electrical and electrochemical monitoring methods. However, in view of the growing number of methods available, the selection of corrosion-monitoring methods may be somewhat arbitrary.
In the selection of a corrosion-monitoring method, a variety of factors should be considered. First, the purpose of the test should be understood by everyone concerned with the corrosion-monitoring program. The cost and applicability of the methods under consideration should be known, and it is important to consider the reliability of the method selected. In many cases, it is desirable to include more than one method in order to provide more confidence in the information generated.
Another key question is what type of access to the process streams and equipment is available. If access is available, methods that involve probes or coupons become more feasible. Otherwise, nondestructive methods may be required. An important factor in the selection of monitoring methods is the response time required to obtain the desired information from the method. Coupon methods and techniques that require plant shutdown for installation and retrieval of specimens tend to be relatively slow in generating information. On the other hand, equipment that measures instantaneous corrosion rates can provide rapid results, but often with a reduction in accuracy. A most important consideration is safety. In an operating plant, equipment failure can lead to a leak, which can result in loss of product, a hazard potential, and possible shutdown of the plant. It is important for the monitoring apparatus to be designed to minimize the possibility of such an incident and to have a plan in place to safely deal with any leak that might develop.

Direct Testing of Coupons

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Although they are not intended to replace laboratory tests, plant coupon tests usually are designed to monitor the damage rate occurring on existing equipment, to evaluate alternative materials of construction, and sometimes to determine the effects of process conditions that cannot be reproduced in the laboratory.

Advantages of Coupon Testing (Ref 10). Plant coupon testing provides several specific advantages over laboratory coupon testing. A large number of materials can be exposed simultaneously and can be ranked in actual process streams with actual process conditions. Testing can be used to monitor the corrosivity of process streams. The coupons can be designed for specific forms of corrosion, but the exposure time is usually determined by the plant operation.

Large Number of Coupons. Because many coupons can be exposed simultaneously, they can be tested in duplicate or triplicate (to measure scatter), and they can be fabricated to simulate such conditions as welding, residual stresses, or crevices. These variations can provide the engineer with increased confidence in selecting materials for new equipment, maintenance, or repair.

Actual process streams reveal the synergistic effects of combinations of chemicals or contaminants. In addition, the possibility is remote that the corrosion of specific coupons contaminates the process and affects the corrosion resistance of other coupons. However, one potential source of error that must be checked is contamination of the process stream by the corrosion of the existing equipment.

For example, in a hypothetical case, the equipment is fabricated from a nickel-base alloy, and the process is a reducing acid. Contamination of the process by nickel ions may result in an apparent improvement in the corrosion resistance of titanium test coupons. If the existing equipment is then replaced with titanium, based on these misleading test results, it may corrode rapidly without the beneficial effect of the nickel ions.

Monitoring of Inhibitor Programs. Coupons often are used to monitor inhibitor programs in, for example, water treatment or refinery overhead streams. With retractable coupon holders, the coupons can be extracted from the process without having to shut down in order to determine the corrosion rate.

Long Exposure Times. Some forms of localized corrosion, such as crevice corrosion, pitting, and stress-corrosion cracking (SCC), require time to initiate. To increase confidence in the test results, coupons can be exposed for as long as necessary to ensure that the initiation time has been exceeded.

Coupon design can be selected to test for specific forms of corrosion. Coupons can be designed to detect such phenomena as crevice corrosion, pitting, and dealloying corrosion. For example, some pulp mill bleach plant washer drums are protected electrochemically to mitigate crevice corrosion. Specifically designed crevice-corrosion test coupons are used to monitor the effectiveness of the electrochemical protection program. These coupons are removed periodically from the equipment and examined for evidence of crevice corrosion.

Disadvantages of Coupon Testing (Ref 10). Coupon testing has four main limitations:

- Coupon testing cannot be used to detect rapid changes in the corrosivity of a process.
- Localized corrosion cannot be guaranteed to initiate before the coupons are removed— even with extended test durations.
- Corrosion rate calculated from coupons may not reflect the corrosion of the plant equipment because of factors such as multiphase flow, where the aqueous phase is much more corrosive than the organic or vapor phase, or turbulence from mixers, elbows, valves, pumps, and other items that accelerate the corrosion in a specific location in the equipment removed from where the coupons were exposed.
- Coupons may be misleading in situations where the corrosion rate varies significantly over time because of unrealized process factors.

Contamination of the process fluid is an issue that must be addressed in the food, medical, and electronic equipment manufacturing industries, if coupons are introduced.

Rapid Changes in Corrosivity. The corrosion rate calculated from a coupon is an average over a specific period of time. Therefore, field coupon testing cannot detect process upsets as they occur. For real-time monitoring, electrochemical methods, such as the polarization-resistance technique, may be more appropriate (see the section “Polarization-Resistance Measurement” in this article).

Corrosion Rates of Coupons Compared with That of Equipment. The corrosion rate of plant equipment seldom equals that calculated on a matching test coupon because it is almost impossible to duplicate the equipment exposure with a coupon exposure. However, coupons are very helpful in many situations because they provide a clear view of the corrosion damage with information on the development of deposits, films, and localized

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

attack. In addition, coupon testing is probably the least complicated type of in-service testing and, consequently, requires the least operator skill.

Corrosion Forms Not Detected. The principal limitation of coupon testing is the simulation of erosion-corrosion and heat-transfer effects. Careful placement of the coupons in the process equipment can slightly offset these weaknesses.

Erosion-corrosion is related to process turbulence, and process turbulence is often a function of equipment design. Because coupons tend to shield one another from the effects of process turbulence, field coupon testing is not reliable as a method of simulating erosion-corrosion.

For heat-transfer effects, specially designed coupons are required that simulate effects such as those found in heating elements or condenser tubes. Coupons range in design from thermowell-shaped devices to sample tubes in a test heat exchanger. Thermowell-shaped devices are heated or cooled on the inside and project into the process stream (Ref 13). Heat-transfer tests can also be conducted in the laboratory. In this environment, the coupon forms part of the wall of the test vessel and can therefore be heated or cooled from one side. Because of the cost involved, heat-transfer coupon tests are usually carried out on only one (or perhaps two) alloys that have been selected from a larger group.

Coupon Options (Ref 10). The design of the coupon is an important part of any plant corrosion-testing program. Proper selection of the coupon shape, surface finish, metallurgical condition, and geometry allows evaluation of specific forms of corrosion.

Uniform Corrosion Coupons. The most common coupon shape for the evaluation of uniform corrosion is rectangular. Circular shapes are also used. Rectangular coupons are the most common because most alloys are available in plate or sheet form. Other shapes are used when there are restrictions on available product forms or when a specific material condition is required. Coupon identification must be legible and permanent. The simplest, and preferred, method of identification is stencil stamping.

Coupon finish represents a significant contribution to the overall cost. The least expensive finish that is consistent with the test requirements should be selected. For example, an inexpensive surface finish is acceptable where carbon steel coupons are used routinely to monitor additions of inhibitor in water treatment programs. This may be achieved by punching or shearing, followed by glass bead blasting. On the other hand, when it is necessary to rank alloys in a process environment, the coupons must be finished with ground or machined parallel edges and sanded faces.

A wide variety of coupon finishes are available, including:

- Mill finish
- Glass bead blasted
- Sandblasted
- Steel shotblasted
- Abrasive cloth or paper sanded
- Machined
- Electrolytically polished

Ideally, the surface finish of the coupon should match the finish of the equipment. This match is very difficult to achieve for several reasons. For example, there is the difference in surface finish between different mill product forms and even between different heats of the same metal or alloy. In addition, there can be wide variation among mill scale and surface deposits from processing operations. The principal requirement of testing is to assess the corrosion resistance of the test alloy in the condition that would be used in actual equipment.

Abrasive cloth or paper sanding is the most common practice of surface preparation. Sanding removes such surface deposits as mill scale and such defects as scratches or pits. A 120-grit finish, which is standard, can be produced easily without specialized equipment. Metallurgical changes that are heat induced, such as the sensitization of stainless steels or nickel-base alloys, can be prevented by keeping the coupon cool through wet sanding with progressively finer abrasives.

Clean polishing belts should be used to avoid contamination of the coupon surface. For example, a belt that has been used to polish a brass coupon should not be used to polish an aluminum coupon.

The corrosion resistance of some alloys can be enhanced by a special surface condition, for example, the oxide films that are formed on titanium or zirconium. For these alloys, conditioning of the coupons would take place

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

after mechanical surface preparation. However, some films that form during mill processing or chemical exposure actually reduce corrosion resistance. Certain forms of iron sulfide on carbon steel are examples of these types of films. The coupons must be specially treated in such cases.

Coupons that are cut by punching or shearing have cold-worked edges. The effects of cold work extend back from the cut edge a distance equal to the material thickness. These affected areas can be removed by grinding or machining. Cold-worked edges may affect the corrosion rate in some cases, and the residual stresses it induces may cause SCC in some materials. Extensive edge preparation can be a major contributor to the cost of the coupon.

Galvanic-Corrosion Coupons. Pairs of test coupons are coupled electrically to study the effects of galvanic corrosion. The relative areas exposed usually vary from 1:1 to 10:1 or greater. The area ratios should be reversed for complete assessment, that is, 10:1 and 1:10. This reversal may not be necessary when a specific effect is being studied, for example, simulation of the galvanic corrosion of dissimilar-metal fasteners in column trays.

A major concern with electrically coupled coupons is maintaining electrical continuity for the entire exposure period. Corrosion product films can wedge mechanically joined coupons apart, thereby eliminating the electrical contact and any galvanic corrosion effect. ASTM G 71 (Ref 15) provides valuable information on galvanic corrosion testing in both field and laboratory environments.

With metals that can become embrittled by hydrogen absorption—for example, titanium, zirconium, tantalum, and hardenable steels—the cathodic (protected) member of the galvanic couple may be subject to the greater damage. However, the typical mass-loss measurements would not reveal such damage.

Crevice-Corrosion Coupons. Equipment crevices, such as weld backing rings, tube-tubesheet joints, or flanged connections, are common sites for localized corrosion in the process environment. Many metals perform differently in crevices as opposed to unshielded areas. Behavior is dependent on several factors. These factors include how strongly oxygen reduction (cathode depolarization) controls the cathode reaction or how the crevice alters the bulk process chemistry by lowering the pH or concentrating aggressive species.

The most imaginative form of coupon-corrosion testing is the simulation of crevice corrosion (Ref 16). The various techniques that can be used for crevice-corrosion testing include rubber bands, spot-welded lap joints, and wire wrapped around threaded bolts. Each crevice test creates a particular crevice geometry between specific materials and has a particular anode/cathode area ratio. Thus, no crevice-corrosion test is universally applicable (see the article “Evaluating Crevice Corrosion” in this Volume).

The two most widely used crevice geometries in field coupon testing employ insulating spacers to separate and electrically insulate the coupons. Spacers are usually either flat washers or multiple-crevice washers. Either type of spacer can be made of materials ranging from hard ceramics to soft thermoplastic resins (Ref 17).

ASTM G 78 (Ref 17) and G 48 (Ref 18) provide valuable information on crevice corrosion specimen design and should be consulted before attempting a crevice-corrosion test.

Stress-Corrosion Coupons. Typical sources of sustained tensile stress that cause SCC of equipment in service are the residual stresses resulting from forming and welding operations and the assembly stresses associated with interference-fitted parts, especially in the case of tapered, threaded connections. Therefore, the most suitable coupons for plant tests are the self-stressed bending and residual-stress specimens described in the article “Evaluating Stress-Corrosion Cracking” in this Volume. Convenient coupons are the cup impression, U-bend (Ref 19), C-ring (Ref 20), tuning fork, and welded panel (Ref 21). The method of stressing for all of these coupons results in decreasing load as cracks form and begin to propagate. Therefore, complete fracture is seldom observed, and careful examination is required to detect cracking.

Welded Coupons. Because welding is a principal method of fabricating equipment, the use of welded coupons is often desirable. Aside from the effects of residual stresses, the primary concern is the behavior of the weld bead and the heat-affected zone (HAZ). In some alloys, the HAZ becomes sensitized to severe intergranular (sometimes called knife-line) attack, and in certain other alloys, the HAZ is anodic to the parent metal. When possible, it is more realistic to remove welded coupons from production-sized weldments than to weld the small coupons. Because the thermal conditions in both the weld metal and the HAZ are a function of the number of weld passes, the metal thickness, the weld position, and the welding technique, it is not usually considered good practice to use welded coupons to assess the possibility of sensitization from welding. It is generally better to carry out a sensitizing heat treatment on an unwelded coupon before it is tested and then look for evidence of intergranular corrosion or cracking.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Sensitized Metal. Sensitization is a metallurgical change that occurs when certain austenitic stainless steels, ferritic stainless steels, nickel- base alloys, and other alloys are heated under specific conditions. This results in the precipitation of carbides or other intermetallic phases at grain boundaries, which reduces corrosion resistance. Any heat-inducing process (for example, stress relief of weldments) may cause sensitization, which is time and temperature dependent. There is a specific temperature range over which each particular alloy sensitizes rapidly. Sensitization leads to intergranular corrosion in specific environments.

Welding is the most common cause of sensitization. However, welded coupons may not exhibit sensitization because they may be given insufficient weld passes (compared with actual process equipment). As a result, they spend insufficient time in the sensitizing temperature range, and susceptibility to intergranular corrosion may not be detected.

An appropriate sensitizing heat treatment guarantees that any corrosion susceptibility induced by welding or heat treatment is detected. The optimal temperature and time ranges for sensitization vary for different alloys. For example, 30 min at 650 °C (1200 °F) is usually sufficient to sensitize American Iron and Steel Institute (AISI) type 316 stainless steel.

Some of the corrosion-resistant aluminum- magnesium (5000-series) alloys containing 3 to 6% Mg are also subject to sensitization when heated at temperatures in the range of 65 to 175 °C (150 to 350 °F). Reference 22 describes a test method for susceptibility to this phenomenon. The effective time and temperature conditions depend on the alloy content and metallurgical condition (Ref 23).

The advantage of using sensitized coupons is that, if corrosion occurs, they indicate a potential problem. The user is thus obliged to consider how the equipment will be welded and heat treated and to determine whether high-temperature excursions will occur during operation.

Test Rack Design. It may be possible to expose corrosion coupons in stagnant or slowly flowing conditions by simply hanging them on an insulated wire or plastic cord, but this procedure is generally inadequate. Instead, specimen holders and test racks are usually used to support and insulate the coupons. These racks must hold coupons firmly in place to prevent mechanical damage and metal loss from causes other than corrosion. They must also electrically isolate the coupons from contact with each other and from the vessel itself to prevent unintentional electrochemical interactions. The basic types of racks are discussed briefly as follows. They are described in detail in Ref 2, 5, 10, and 12.

Spool (Birdcage) Rack. A typical spool rack is useful in open vessels, such as reactors and tanks, for which access to the spool is readily achieved (Fig. 1). It has the advantage that a relatively large number of coupons can be accommodated.

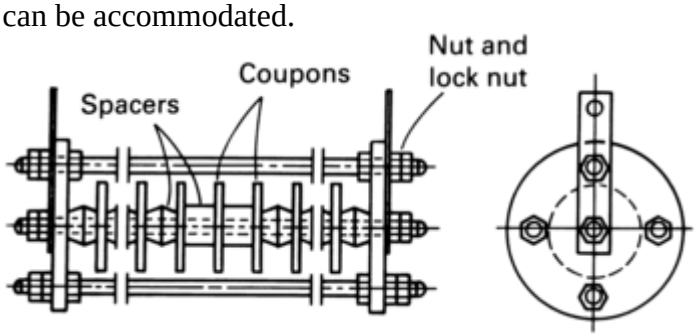

Fig. 1 Illustration of typical spool-type coupon rack. Source: Ref 13

The insert rack is convenient for use in pipes or other units that have flanged connections that allow easy access to the system. For larger-diameter pipes or nozzles, a dutchman-type rack can be used. Such a rack consists of a suitable spool-type piece with the coupons mounted crosswise on a bar (Fig. 2). In both cases, the equipment must be shut down during installation and removal of the racks, or a by-pass line added to the system that allows the process fluid to be routed around the specimens while they are being inserted or removed. It is very important to have good-quality shut-off valves and drain and flush provisions if a bypass is to be used.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

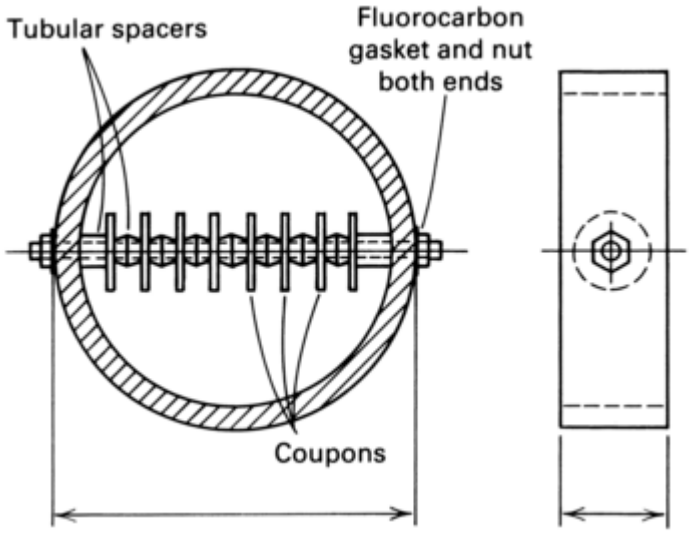

Fig. 2 Illustration of typical dutchman coupon rack. Source: Ref 13

A slip-in rack is designed to be inserted into and removed from equipment that is in operation. A retractable coupon holder makes this type of rack especially useful (Fig. 3). The slip-in rack requires a full-port gate valve and a suitable- sized nozzle to serve as a retraction chamber. A rod-shaped coupon holder is contained in the retraction chamber, which is flanged to the gate valve. The other end of the retraction chamber contains a packing gland through which the coupon holder passes. Coupons are mounted on the rod in the extended position and are then drawn into the retraction chamber. The chamber is bolted to the gate valve, which is then opened to allow the coupons to be slid into the process stream. The sequence is reversed to remove the test coupons. It is essential that the rod or handle be equipped with a restraining chain or other device to prevent the blowout of the specimen holder when retracting the specimens when the system is under pressure. Drain and flush ports are desirable additions to deal with the process fluid that is present in the retraction chamber before the specimens are removed. These ports are also useful to eliminate intrusion of air into the process fluid during insertion of the coupons.

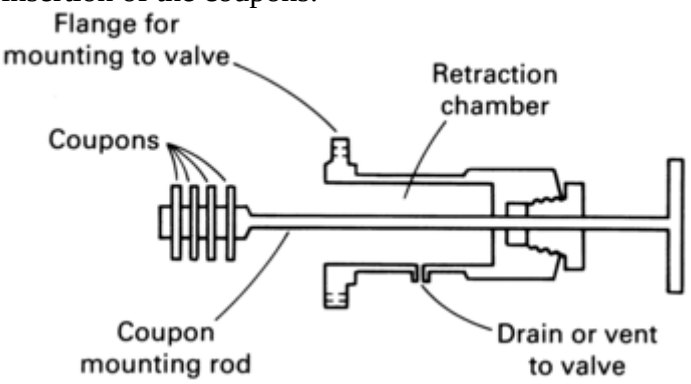

Fig. 3 Illustration of retractable coupon holder. Source: Ref 10

Coupon Cleaning and Evaluation. The test coupons should be cleaned as soon as possible after removal from the test. The procedures for cleaning and weighing, which depend on the test material and the extent of corrosion, are described in Ref 4, 10, and 24. These methods are overviewed in the article “Statistical Interpretation of Corrosion Test Results” in this Volume.

Examination of the coupons after cleaning and weighing reveals the forms of corrosion that may be expected in equipment made of the coupon material. Because the coupons used for calculating corrosion rates are usually small, they should be examined very carefully for signs of localized corrosion effects that could invalidate the mass- loss data. Coupons are examined with the unaided eye and then at increasing magnifications, up to 30 to 50×, with a binocular microscope. The scanning electron microscope is an extremely useful tool for detecting superficial localized effects.

In some cases, coupons must be bent and/or sectioned and metallographically examined to reveal certain types of corrosion damage. There are special localized corrosion effects that could not only jeopardize determination

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

of realistic corrosion rates but also signal other serious types of behavior. These effects include edge attack, crevice corrosion, stress corrosion near stenciled identification numbers, pitting, selective corrosion (such as dealloying), knife-line attack, blistering, intergranular corrosion, embrittlement, and erosion-corrosion. In addition to the various corrosion effects, there may be inadvertent mechanical or galvanic corrosion damage. Techniques for evaluating specific forms of corrosion are described in various articles in this Section.

Electrical-Resistance Probes

Electrical-resistance probes (Fig. 4) are specially designed corrosion coupons; see ASTM G 96, method A (Ref 14). Their corrosion rate is calculated from measurement of electrical resistance rather than mass loss. These measurements are made by installing a wire or other device fabricated from the material in question in such a way that its electrical resistance can be conveniently measured. Corrosion reduces the cross section of the exposed element; therefore, its electrical resistance increases with exposure time, if corrosion is taking place. A temperature- compensating element should be incorporated in such a probe because the resistance of the probe is also influenced by the temperature.

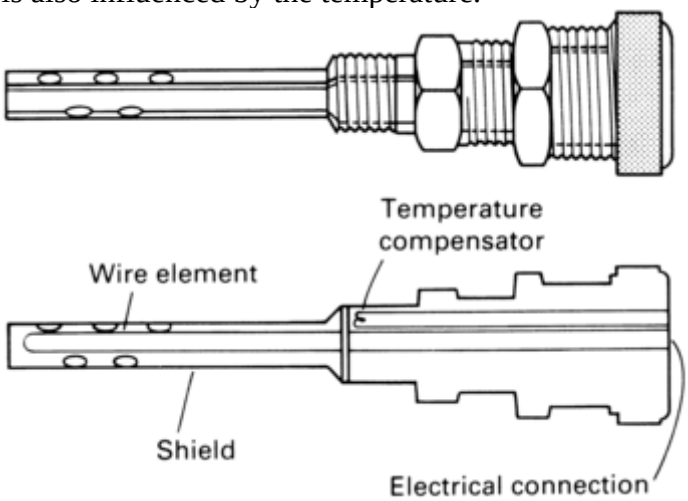

Fig. 4 Electrical-resistance probe. Source: Ref 7

When installing the probe, if galvanic corrosion is a concern, the probe should be tested for electrical isolation with adjacent metallic materials.

Electrical-resistance probes measure the remaining average metal thickness. To obtain the corrosion rate, a series of measurements are made over a period of time, and the results are plotted as a function of exposure time. The corrosion rate can be determined from the slope of the resulting plot.

There are several advantages to this approach. Because probes are relatively small, they can be installed easily. To determine the metal remaining, the probe can be wired directly to a control room location or to a portable resistance bridge at the probe location. For systems that are wired directly to control rooms, a computer system can be used to obtain the data and to reduce the results to corrosion rate values. Commercial electrical-resistance equipment is available. Use of electrical-resistance probes does not depend on the environment; there are two reasons for this. First, only the remaining metal is measured, and second, the conductivity of the corrosive environment is usually inconsequential. This is not true in, for example, molten salts or liquid metals;

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

the high conductivity of the environment in such systems precludes the use of electrical-resistance probes. Thus, no problems exist in measuring corrosion that occurs in liquid or vapor streams. Electrical-resistance probes are used in various applications, such as monitoring the corrosivity of cooling water systems (Ref 14).
However, there are some disadvantages to this approach. Vessel and piping walls must be penetrated in order to install the probes; such penetration results in the potential for leaks. It is expensive to direct wire the probe to a control room location, and such work must be carried out with care to avoid spurious signals and errors. On the other hand, it is time consuming and sometimes impossible to take measurements at the probe site with a portable bridge. The temperature-compensation device reacts slowly, and it can be a source of error if the temperature varies when the measurement is taken. Corrosion- rate measurements obtained in short periods of time can be inaccurate, because the method measures only the remaining metal, not the rate of attack; thus, the errors involved in estimating small differences between large numbers make this method inaccurate. This method provides no practical information on localized attack.
It is also very important to select the correct type of probe for the application. Cylindrical probes or wires may not detect corrosion of a pipe wall from a thin film of liquid on the pipe wall resulting from annular two-phase flow. A flush-mounted probe must be used in this case. Another major problem is finding leak-tight insulators that have sufficient corrosion resistance to the process fluids encountered. In some cases, it has been necessary to weld a nozzle with a flange over the external connection so that the area could be closed tightly if a leak developed during operation.

Ultrasonic Thickness Measurements

Ultrasonic thickness measurements can be used to monitor corrosion rates in situ. Ultrasonic thickness measurements involve placement of a transducer against the exterior of the vessel in question. The transducer produces an ultrasonic signal. This signal passes through the vessel wall, bounces off the interior surface, and returns to the transducer. The thickness is calculated by using the time that elapses between emission of the signal and its subsequent reception, along with the velocity of sound in the material. To obtain a corrosion rate, a series of measurements must be made over a time interval, and the metal loss per unit time must be determined.
One advantage of this method is that it is not necessary to penetrate the vessel to make the measurements. In addition, the results are obtained in terms of thickness. Small, handheld probes and reading devices are available for making these measurements and are relatively easy to use.
There are also several disadvantages. Ideally, a bare metal surface free of paint, thermal insulation, and corrosion products must be exposed. A coupling agent, such as grease, petroleum jelly, or oil, must be used so that the signal can pass from the probe into the metal and return. Problems may arise when vessel walls are at

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

high or low temperatures. Serious problems may exist in equipment that has a metallurgically bonded internal lining, because it is not obvious from which surface the returning signal originates.
Despite these drawbacks, the ultrasonic thickness approach is widely practiced where it is necessary to evaluate vessel life and suitability for further service. It must be kept in mind, however, that depending on the type of transducer used, the ultrasonic thickness method can overestimate metal thickness when the remaining thickness is under approximately 1.3 mm (0.05 in.).

Measurement of Corrosion Potentials

The use of corrosion-potential measurements for in-service corrosion monitoring is not as widespread as the use of polarization resistance. However, this approach can be valuable in some cases, particularly where an alloy could show both active and passive corrosion behavior in a given process stream. For example, stainless steels

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

can provide excellent service, as long as they remain passive. However, if an upset occurs that would introduce either chlorides or reducing agents into the process stream, stainless alloys may become active and may exhibit excessive corrosion rates. Corrosion-potential measurements would indicate the development of active corrosion, and they may be coupled with polarization-resistance measurements as additional confirmation of high corrosion rates (Ref 8).

The success of corrosion-potential measurements depends on the long-term stable performance of a standard reference electrode. Such electrodes have been developed for continuous pH monitoring of process streams, and their application for measuring corrosion potentials is straightforward. However, the conditions of temperature, pressure, electrolyte composition, pH, and other possible variables can limit the applications of these electrodes for corrosion-monitoring service.

Alternating Current Impedance Measurements

Alternating current (ac) impedance-polarizing techniques are being increasingly used in electrochemical evaluation. In principle, the same probe elements used for polarization-resistance measurements can be used for ac impedance studies. As shown in Fig. 6, the ac impedance approach permits the separation and independent analysis of the resistive and capacitive elements of the electrochemical corrosion reaction (Ref 26). The method is particularly useful for high- resistivity electrolytes, such as steam condensate. In these cases, polarization-resistance measurements provide readings that are erroneously low, because the bulk resistance of the electrochemical cell adds to the measured resistance. This problem is minimized with the ac approach. ASTM G 96 (Ref 14) provides a very comprehensive discussion of this problem and gives practical guidance on dealing with it.

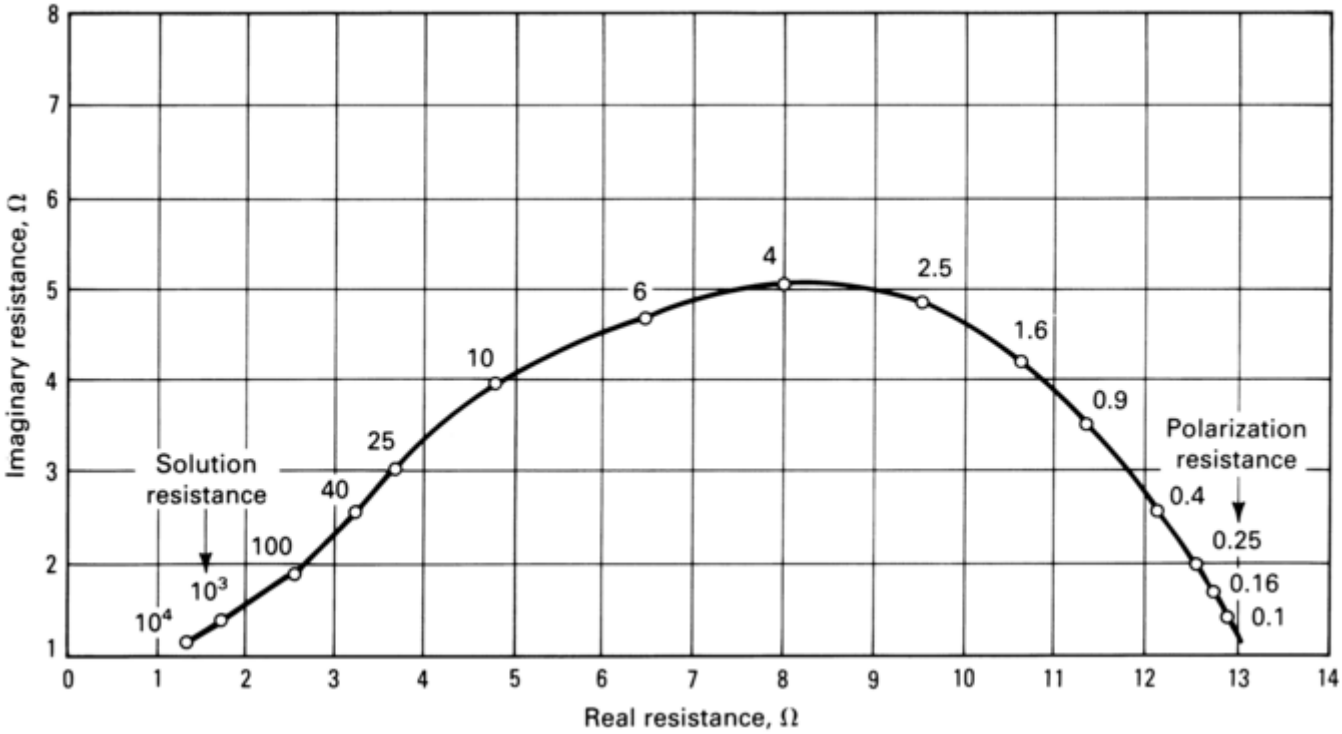

Fig. 6 Typical plot of ac impedance data in terms of real and imaginary resistance. The numbers on the curve indicate the frequency in hertz. Source: Ref 7

A sophisticated ac frequency generator and analyzer system is necessary to obtain results such as those shown in Fig. 6. Some investigators have suggested using only two frequencies to characterize ac impedance behavior (Ref 27). Although this minimizes the number of measurements, it does not reveal the details of the behavior. It is necessary to be familiar with the approach in order to interpret the results of ac impedance studies. The specimen designs used in commercial polarization-resistance probes have not been optimized for ac analysis. For this reason, a full frequency-response curve is desirable in order to verify that the behavior can be analyzed by conventional techniques, although it may take several hours to obtain a complete frequency-response curve. Thus, more development is necessary before the ac impedance technique achieves widespread acceptance for in-service corrosion monitoring. Another drawback is that the Stearn-Geary constant (Ref 25) or Tafel slopes must be known in order to convert ac impedance data into corrosion-rate information.

Electrochemical Noise

Electrochemical noise refers to the natural fluctuations of either current or potential of a corroding specimen (Ref 28). If a specimen is electrically isolated and allowed to corrode, there are fluctuations of the corrosion potential as the corrosion proceeds. Likewise, if a corroding specimen is held at constant potential, fluctuations occur in the current required to maintain that potential. In one type of setup, three identical specimens are exposed to the environment. The potential between one of the specimens and the other two is monitored, while the current between the other two is also monitored by a zero- resistance ammeter. These signals are subsequently analyzed to obtain a standard deviation of the current noise and a standard deviation of the potential noise. The ratio of the potential standard deviation to the current standard deviation is believed to be equal to the polarization resistance, and this can then be converted to a corrosion rate through the Stearn-Geary relationship (Ref 25).

This approach has appealed to some investigators, because it does not involve any external polarization of the specimens and does not require the use of reference electrodes. Localized corrosion produces unique noise signals, and this has attracted attention because it gives this approach a chance of detecting these forms of corrosion while they are initiating. Pitting, for example, has been characterized by the ratio of the current standard deviation to the average corrosion current. Other analyses of the noise characteristics have been proposed but not universally accepted.

Hydrogen Probe

The concept of the hydrogen probe is based on the fact that one of the cathodic reaction products in nonoxidizing acidic systems is hydrogen. The hydrogen atoms thus generated diffuse through the thickness of the vessel and are liberated at the exterior surface. A hydrogen probe—in one variation, the probe is a piece of palladium foil—is applied to the exterior surface. The probe serves as collector and catalyst for the subsequent oxidation of the hydrogen (Ref 26). The cell is attached to the palladium foil. The current employed in the oxidation reaction is supplied by a stainless steel working electrode (Fig. 7). The electrolyte is 90% sulfuric acid. The current that is required to oxidize the hydrogen is measured; it is directly proportional to the corrosion rate of the interior of the vessel.

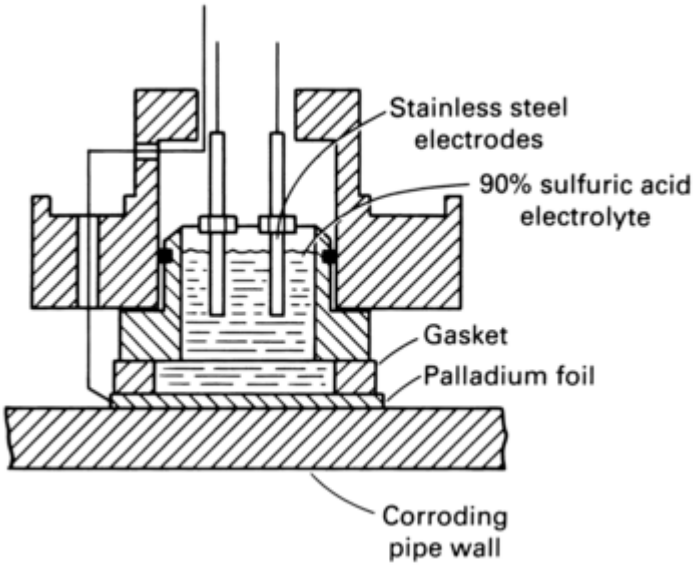

Fig. 7 Design of palladium foil hydrogen patch probe. Source: Ref 27

Hydrogen-probe analysis measures the corrosion rate, unlike ultrasonic thickness measurements and other techniques that measure remaining wall thickness. However, hydrogen-probe analysis is limited to systems in which the temperature is close to ambient and the diffusion rate of hydrogen is high. Gas pipeline service is the most common application. In this case, corrosion can occur when hydrogen sulfide, water, and sometimes carbon dioxide (CO_2) are present. This approach has another variation that consists of simply attaching a chamber to the exterior of the pipe and monitoring hydrogen liberation through increasing pressure (Ref 2).

One advantage of exterior hydrogen monitoring is that it does not require penetration of the pipe wall in order to obtain the corrosion rate. It is assumed in this method that all of the hydrogen liberated in the corrosion reaction diffuses through the steel vessel wall instead of being liberated as hydrogen gas at the surface, and this is true when hydrogen recombination poisons, such as hydrogen sulfide (H_2S), are present. Commercial devices are available for corrosion monitoring by this technique, although it is questionable whether such devices could be positioned and allowed to operate unattended for extended periods of time. In addition, these units have all of the problems associated with any electrochemical measuring device, namely the need for complex electronic equipment and wiring and the need for operators and installers with a sensitivity to the requirements of such equipment. Also, this method is, in practice, limited to steel, which has a high hydrogen diffusivity and low solubility of hydrogen.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Exterior hydrogen monitoring does not supply a quantitative measurement of hydrogen damage. However, it does provide a means of measuring the relative severity of corrosion damage and of evaluating the effects of process changes on the severity of corrosion.

Analysis of Process Streams

Another useful in-service corrosion-monitoring technique is analysis of the process streams for the presence of corrosion products. This straight-forward approach usually does not require the installation of specialized equipment. For example, process streams from the bottom of the distillation column can be routinely sampled, and atomic absorption analysis techniques can be used to determine such heavy metals as iron, nickel, and chromium at very low levels. The concentration of such impurities is then directly proportional to the corrosion rate multiplied by the area of metal corroding, if the only source of metal ions is corrosion, and if the corrosion products are not precipitating. One problem is that the corroding area may not be known with certainty; therefore, the results are relative. However, they do help to determine whether conditions have improved.

Sentry Holes

In this monitoring technique, small sentry holes are drilled into the outside of a vessel or pipe at areas that are considered to be particularly susceptible to corrosion. The holes are drilled to the pressure-design thickness. Thus, when corrosion has almost consumed the corrosion allowance, the appearance of a small leak indicates that action must be taken to prevent a major failure. Sentry holes may be threaded or may have nipples attached

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

to facilitate plugging. Nondestructive testing is frequently performed in the area near the leak to determine the extent of the damage before repair or shutdown.
These holes are required in reinforcing pads applied to support nozzles in pressure vessels. In these cases, leakage from the hole signals corrosion or cracking of the nozzle weld and is an important safety feature of the design.

Side-Stream (Bypass) Loops

It is sometimes advantageous to operate a side-stream loop to determine the effect of chemical process changes without making these changes in the entire process system. This provides the advantage of an in-service corrosion test with product streams, yet permits evaluation of the effects of additives, inhibitors, and other changes in the environment without affecting the main process stream.
In the simplest case, a side stream from a major piece of equipment is run through a small tank or a widened section of the line in order to permit changes in the product stream and insertion of corrosion-monitoring devices. In such a case, the effluent from the side stream is usually discarded. In a more complicated installation, the entire cycle of the operation may be duplicated on a small scale using a portion of the mainstream. Obviously, a more sophisticated side-stream apparatus can approach the complexity and the expense of a pilot plant.

Strategies in Corrosion Monitoring

Monitoring Locations. A principal part of any corrosion-monitoring program is deciding where to locate the corrosion-monitoring devices. Because corrosion will probably not occur uniformly throughout the plant, it is desirable in any corrosion-monitoring program to find sites at which the highest corrosion rates will be experienced.
The problems involved in developing corrosion-monitoring programs for a plant are illustrated in the example of a distillation column. The most logical points for corrosion monitoring in a distillation column are the feed point, the overhead product receiver, and the reboiler or bottoms product line. These points are the locations at which the highest and lowest temperatures are encountered, as well as the points at which the most and least volatile products are concentrated. However, these points are usually not the locations of the most severe corrosion.
The species causing the corrosion often concentrates at an intermediate point in the column because of chemical changes within the column. Therefore, if there is a possibility of concentrating a corrosive species within the distillation column, several monitoring points would be required throughout the column for the corrosion-

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

monitoring program to be comprehensive (Fig. 8). A monitoring program can be restricted to the most corrosive location within the column, once this area has been identified (Ref 29).

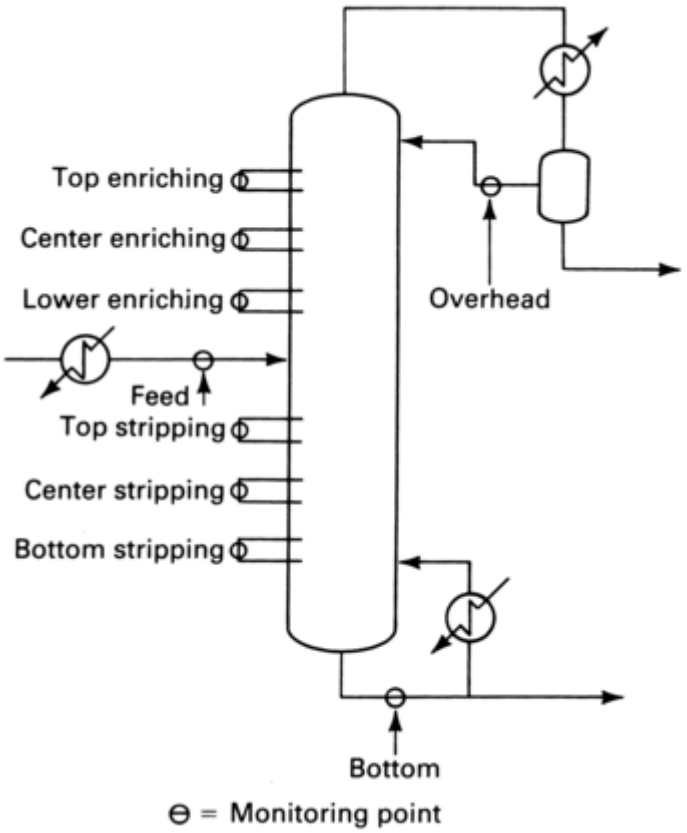

Fig. 8 Distillation column showing preferred locations of monitoring probes or other devices. Source: Ref 7

Another problem with distillation columns is that the liquid on trays tends to be frothy. This creates difficulties for electrochemical methods. One solution to this problem is to install bypass loops that remove liquid from the column, pass it over the corrosion-monitoring probes, and reinject it at a lower point in the column (Ref 2). This practice avoids the problem of foam and froth and provides a more controlled flow rate over the corrosion-monitoring equipment. Use of a bypass loop also allows removal of liquid samples at times of high corrosion rates (Fig. 9).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

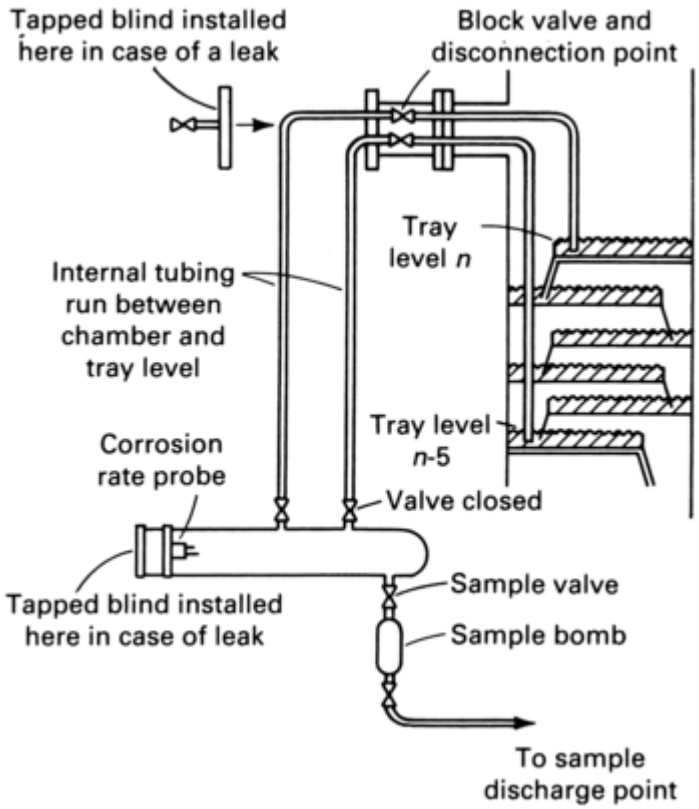

Fig. 9 Use of a side-stream (bypass) loop to monitor corrosion in a distillation column. Source: Ref 7

The process stream can be sampled in locations other than distillation columns. A sample tap can be helpful in conjunction with polarization-resistance devices. The alarm on polarization-resistance monitoring equipment can be used to signal the need to remove samples. This is particularly desirable in the case of pilot plant operation, in which wide variations in processing conditions are encountered. It is also helpful in plants that produce different products in the same equipment.

High-velocity gas streams in pipes may cause problems with conventional monitoring systems. In this case, the presence of an aqueous phase is usually restricted to a thin layer on the surface of the pipe. This condition is known as annular flow. A probe that protrudes into the pipe may miss the liquid layer that is present only close to the pipe wall. A flush-mounted surface probe can be used in such cases. This probe permits the measurement of polarization resistance in order to estimate the corrosion rate of the pipe wall (Ref 30).

Probe location is also critical in storage tanks containing nonaqueous liquids. The most corrosive location in these tanks may be at the liquid level, if the liquid in the tank has a density exceeding that of water. In this case, the corrosion- monitoring probe should be mounted on a floating platform. In this way, the probe can detect the presence of a corrosive aqueous phase. However, when the liquid stored in the tank is less dense than the water, the corrosion-monitoring device should probably be positioned at the bottom of the tank.

Ultrasonic Thickness Data Analysis. Ultrasonic thickness measurements are often obtained during turnaround periods when the plant is not operating. A well-designed program provides a series of thickness measurements at specified locations throughout the plant. Assuming that the original thickness of a vessel was constant, a diagram similar to that shown in Fig. 10 can be drawn. Figure 10 shows the inverse relationship between the average corrosion rate and the remaining thickness. It is then possible to estimate the remaining life of the vessel from the maximum corrosion rate and the remaining corrosion allowance. In cases in which corrosion rate varies randomly, the highest corrosion rate and the smallest remaining thickness can be estimated by using statistical analysis. This approach provides a rational method of estimating remaining life when faced with a quantity of thickness readings from an ultrasonic thickness survey.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

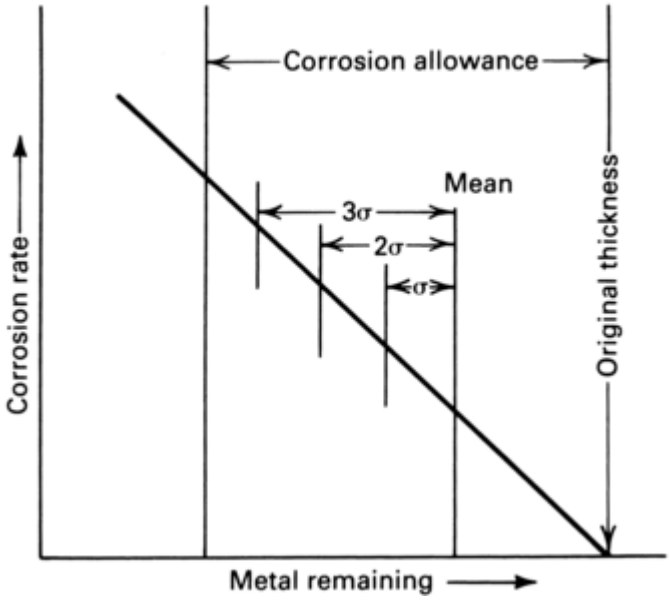

Fig. 10 Typical plot of metal thickness remaining versus calculated corrosion rate obtained from ultrasonic thickness data. Statistical analysis can be used to estimate the remaining corrosion allowance in terms of standard deviation σ. Source: Ref 7

Redundancy is also important in designing corrosion-monitoring programs. The use of at least two different types of corrosion-monitoring devices at any location is often desirable. For example, the use of an electrical-resistance probe with a polarization-resistance probe allows measurement of both instantaneous corrosion rates and an average corrosion rate. The data thus obtained can be correlated, and this is very helpful in identifying spurious or inaccurate readings.

In another approach, the polarization-resistance probe is weighed before and after the test in order to correlate mass loss with the average corrosion rate that the probe suffered. There is reason to expect that the electrochemical value is in error if the average corrosion rate and the mass loss of the probe do not agree. Also, to obtain time-average corrosion-rate values, independent coupons can be installed together with polarization-resistance probes.

A variety of corrosion-monitoring approaches must be used when designing pilot or demonstration plants. Coupon tests can be very helpful in selecting optimal materials for processes based on pilot-plant experience. Polarization-resistance monitoring is very useful for determining whether certain processing conditions cause corrosive situations to develop. Because the corrosion mechanisms are often not well understood, and because the result of erroneous information can be serious overdesign or exposure to unexpected hazards, redundancy in the design of such monitoring systems is important in pilot plants.

Other Issues. A primary difficulty with corrosion-monitoring equipment is the need to install wires from the probes to the control room or to the instruments and data-storage systems. Hardwire systems are usually more expensive than the probes and electronic instruments. In addition, wiring systems are often sources of problems due to breakage, moisture entry, and connection difficulties. One option is the use of devices to transform the data to coded citizens' band (CB) radio signals. These small, battery- operated units can be installed at probe locations, and they provide the desired information to the base station on command. The base station would be located in the control room. Acceptance of this approach may increase as such systems become more available and more reliable.

The problem of leaks is another important issue in corrosion-monitoring systems. Leaks can cause hazards and can shut down operating plants. The corrosion-monitoring system must be installed such that leaks from the probe can be handled with minimal interruption. A device that penetrates the wall of the vessel may leak; therefore, it is essential to have contingency plans for dealing with leaks before the devices are installed.

A related problem concerns packing glands on pressure vessels that have removable devices. The pressure within a system exerts a force on any removable device. Therefore, it is important to prevent the device from being blown out, which might injure personnel attempting to remove the device or would expose such personnel to the fluid within the vessel. For this reason, restraining rods, chains, and flush and drain ports must be used.

Interpretation and Reporting

In-service monitoring, more than any other type of corrosion testing, requires the utmost skill in interpretation and reporting. Important economic decisions are often based on the test results. Although there are a number of standards that provide guidelines for certain procedures, there is no standard that is comprehensive. To plan an appropriate test program, the investigator must know or have good advice on both the chemistry and the mechanics of the processes involved; that is, the investigator must understand the entire corrosion system. There must be a strong emphasis on the strategy of the program and a searching analysis of the test results. It is important to prepare detailed records of what was done as part of the experiment, and it is also important to document any unplanned changes that occur in the process stream or the equipment during the investigation. Without a valid interpretation and effective (timely) reporting, the price of the work can be significantly greater than the cost of time and materials. However, the consequences of corrosion failures go beyond additional costs. Also involved are personal safety risks (and liability), hazard potentials, process reliability, and product quality and pollution problems.

Evaluating Uniform Corrosion

Revised by Bopinder Phull, Consultant

Introduction

UNIFORM CORROSION refers to attack on an exposed metal surface that results in homogeneous thickness loss. In other words, the metal loss is spread evenly over the surface rather than being localized as, for example, pitting or stress- corrosion cracking. Uniform corrosion is also known as general corrosion. Practical examples of uniform or general corrosion include dissolution of iron or zinc in dilute sulfuric acid, aluminum in sodium hydroxide solution, bare or galvanized steel in atmospheric environments, and so on. In terms of electrochemistry, the metal undergoing uniform corrosion can be regarded as a single electrode, which supports anodic and cathodic reactions concurrently. Furthermore, the anodic and cathodic sites can be considered as local with respect to each other, approximately equal in area, and fluctuating randomly in a stochastic manner over the metal surface. Corrosion occurs by local cell action, that is, metal dissolution of the anodic sites due to oxidation (electron loss), driven by charge-transfer reduction reaction(s) at the adjacent cathodic sites (electron consumption). Uniform corrosion can be mitigated by materials selection, coatings, inhibitors, cathodic protection, and in specific cases anodic protection. Another practical means of addressing uniform corrosion in many practical applications is to build in a corrosion allowance at the design stage. The most appropriate corrosion control method will depend on specific metal-environment considerations, application criticality, and economics.

Testing for uniform corrosion and its evaluation are relatively simple. Appropriate test specimens (also often referred to as corrosion coupons) are exposed to the environment of interest, and the metal loss is determined after a prescribed period by, for example, mass loss or measurement of thickness change. Convenience, practicality, safety considerations, and economics will typically dictate whether testing is performed in the laboratory and/or in actual service conditions. Laboratory testing usually consists of small specimens immersed in relatively small volumes of simulated or actual service environments. The advantage of this type of testing is that the tests can be controlled closely; thus, unintentional disturbances that could occur during in-plant tests can be avoided. These tests are usually designed to simulate expected service conditions. It should be recognized that the objective of testing is to determine the type and extent of corrosion incurred. There is no advance assurance that the test specimens will undergo uniform corrosion.

Service tests (field, in-plant, or on-line tests) involve placing test samples in actual service conditions for evaluation. The test specimens need to be mounted securely and are usually electrically isolated from each other and plant equipment to preclude galvanic interactions— unless the objective of the test is to investigate such effects. The advantage of service testing is that the test specimens are exposed to the actual service environment. However, in-plant testing is also fraught with limitations. For instance, it may be difficult to subject the test specimens to the same flow, pressure, or heat-transfer conditions as the actual plant equipment, such as in piping, pumps, valves, and condensers. Although techniques are available commercially for on-line

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

insertion and retrieval of test specimens, that is, without plant shutdown, they are not used routinely in all industries because of cost.

Evaluating Uniform Corrosion

Revised by Bopinder Phull, Consultant

Mass-Loss Tests

For engineering applications, uniform corrosion rates are reported as loss of metal thickness per unit time. Corrosion rates are often calculated from mass-loss data. Mass loss is the difference between the original mass of the specimen and the mass after a prescribed or known exposure period. Before determining the mass loss after exposure, it is important to clean the specimens properly to remove corrosion product adhering to the surface. After cleaning, it is essential to examine the test specimens visually. Calculation of corrosion rates from mass-loss data will yield meaningful results for use in design only if the specimens have suffered uniform attack. Conversely, computation of corrosion rates from mass loss for specimens that have predominately incurred localized corrosion will give erroneous information to the designer or end-user.

It may be possible to measure the thickness changes in the test specimens or equipment directly, for example, by using calipers, micrometers, or ultrasonic gages. Ultrasonic thickness measurements are particularly suited to scheduled inspection of actual plant equipment such as piping, vessels, tanks, pump casings, and valve bodies. Uniform corrosion rates are usually expressed as thickness loss per unit time, for example, micrometers/year (μm/y), millimeters per year (mm/y), and mils per year (mpy; where 1 mil = 25.4 μm).

Specimen Preparation. The first step in testing is the selection and preparation of suitable test specimens. Clear and complete documentation of the test material is very important. This should include the chemical composition as well as the metallurgical condition of the specimens. The specimens are usually saw-cut from larger stock and the surfaces and edges ground and deburred. It is important to minimize introduction of stresses or metallurgical transformations (e.g., due to overheating) during specimen preparation. Laser cutting, while rapid and convenient, may introduce microstructural changes that make the heat-affected areas, for example, specimen edges or mounting holes, more or less prone to corrosion, depending on the material and test environment. Each sample should be clearly identified before testing. This is commonly done with identification codes that are stenciled (stamped or engraved) on the specimens. Stamped codes introduce stresses where cracking can occur in susceptible materials. Similarly, codes made by laser stenciling or electrical discharge machining (EDM) may increase corrosion propensity of associated areas. It is important to prepare a map sheet so that test specimens can still be identified even if the identification codes are obliterated by corrosion during the test.

The size and shape of the test specimens are often specified in such a manner as to make them easy to handle and allow for ease of surface preparation, cleaning, and weighing. Specimens 1.6 to 6.4 mm ($\frac{1}{16}$ to $\frac{1}{4}$ in.) thick and a few inches square are not uncommon. While it may be desirable to protect specimen edges for some materials, this is not always practical in corrosion tests. Before exposure to the corrosive medium, the test specimen surface needs to be prepared and cleaned. The surface can be ground, grit or glass-bead blasted, or pickled. Ideally, the surface finish of the test specimen should be the same as that of the metal or alloy in service. Unfortunately, this is not always possible because of the variations in surface condition produced during fabrication. However, surface preparation of the test specimens ensures a standard surface condition during testing. Usually, sufficient material is removed to reach the bulk composition/ structure of the metal or alloy; that is, surface- depleted or -enriched layers nonrepresentative of bulk material are removed, unless influence of these variables is part of the investigation. After surface preparation, the specimens are degreased with a solvent such as acetone, dried, weighed, and either immediately exposed to the test medium or stored in a desiccator until test commencement. For most laboratory tests, specimens should ideally be weighed to a

www.iran_mavad.com

مرجع مهندسی مواد و متالورژی

precision of ±0.1 mg. Ideally, specimens with a large surface-area-to-volume ratio are preferred for accurate mass-loss determination, especially when the expected corrosion rate is low. Practical guidelines for preparing, cleaning, and evaluating corrosion test specimens are provided in ASTM G 1 (Ref 1).

Test Methods. The method and apparatus used to expose the test specimens to the test environment are very important and should meet the following guidelines:

- The corrosive medium should have easy access to the test specimens.
- The specimens should be well supported.
- The specimens should be electrically insulated from all other metals in the system.
- The specimens should be completely immersed, unless other effects are being studied.
- The specimens should be readily accessible.

Practical guidelines for laboratory immersion corrosion testing of metals are provided in ASTM G 31 (Ref 2) and NACE International TM0169-2000 (Ref 3).

It is important to plan the experimental technique so that the test specimens are removed and the mass loss determined after appropriate exposure duration. The corrosion rate may initially increase or decrease and eventually become constant with time. Exposure of many replicate specimens is usually necessary with the mass- loss test method to determine corrosion rate variations as a function of time. The following very rough rule of thumb suggested for test duration (in hours) is cited in Refs 2 and 3:

$$\text{Test duration(hours)} = 2000/(\text{expected corrosion rate in mpy}) \quad \text{(Eq 1)}$$

In addition to the sequential removal of specimens with time, a planned interval testing schedule can be used to obtain more information on the initial corrosion rates and on accumulated effects (see ASTM G 31, Ref 2). Planned interval testing involves exposing identical specimens to the test solution at various intervals during the test. By evaluating the results, initial corrosion rates and changes in solution corrosivity can be determined. Planned interval testing is an excellent example of good experimental planning. References 2 and 3 also include recommendations for minimum solution volume to use in the test per unit surface area of exposed specimen (e.g., 20 mL/cm^2, or 125 mL/in^2). This is to avoid depletion of corrodents and hence significant changes in solution corrosivity during the test.

Test Variables. Important variables that must be addressed during experimental planning include gases, temperature, solution volume and flow, and exposure time. The presence of dissolved gases, for example, O_2, CO_2, H_2S, SO_2, and so on, in the test solution can have a dramatic effect on the rate of corrosion. Dissolved gases are usually supplied by bubbling them through the solution. Running the test under pressure or partial vacuum will alter the dissolved gas concentration. If degassing is required, purified nitrogen or argon can be bubbled through the solution to displace dissolved gases.

The influence of temperature can be complicated in that it affects gas solubility, pH, corrosion product formation, and other parameters. Therefore, the temperature of the test should be monitored and controlled as necessary during the corrosion test.

The flow velocity of the solution also plays an important role in determining the corrosion rates. Corrosion rates may increase or decrease as the fluid velocity near the sample is increased. In any case, flow characteristics that represent the condition in service should be established during testing. This is often not a simple task, because the hydrodynamic conditions in service and their effect on the corrosion rate can be complex. Rotating disks and cylinders and jet-impingement apparati have been used to study corrosion rates under controlled hydrodynamic conditions (Ref 4, 5, 6, 7).

The type of exposure is also important in test design; total, partial, or intermittent exposure can change the mode and rate of corrosion. For immersion testing, all test specimens should be immersed at approximately the same depth in the test environment. Partially immersed samples can be used to study waterline corrosion. Samples can also be tested in the vapor phase.

Posttest Sample Cleaning, Data Acquisition, and Reporting. After the test specimens are removed from the exposure environment, they are cleaned to remove any corrosion products. The corrosion products must be removed with minimal additional corrosion of the test specimens. Sometimes, the corrosion products are not removed, and the mass gain is used to calculate corrosion rate. In principle, this approach has some appeal, because the specimen can be returned to the test after weighing (i.e., without removing corrosion products).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

However, it assumes that all of the corrosion products formed from the inception of the test remain on the surface and that their stoichiometry is well known. Mass-gain testing has been used in high- temperature oxidation, gaseous, and atmospheric environments. However, the more common method is to remove the corrosion products by a combination of careful chemical and mechanical cleaning before determining mass loss. Detailed procedures and solutions for cleaning specimens after exposure are given in ASTM G 1 (Ref 1), including how to make corrections for mass loss incurred during cleaning.

It is essential to examine the test specimens visually to verify or characterize the type of corrosion attack suffered. This can generally be done with the unaided eye and does not usually require the aid of a microscope. If corrosion is uniform, the corrosion rate can be calculated from the mass-loss data as follows:

$$\text{Corrosion rate} = (K \times W)/(A \times t \times \rho) \qquad \text{(Eq 2)}$$

where K is a constant, W is mass loss, A is exposed specimen area, t is exposure time, and ρ is material density. Table 1 shows the various corrosion rate units and corresponding values of the constant K in Eq 2 when W is in grams, A is in cm^2, t is in hours, and ρ is in g/cm^3 (Ref 1, 2). ASTM G 1 also contains material density data for common metals and alloys. It must be reiterated that corrosion rates that reflect material-thinning rates should not be calculated from mass-loss data when corrosion attack is primarily localized, because they will lead to erroneous interpretation and conclusions. For example, calculation of corrosion rate from mass-loss data alone may indicate a negligible uniform corrosion rate for a given material, whereas, in reality, the subject test specimen may have been completely perforated by a few small-diameter pits. In other words, the low uniform corrosion rate would provide a false sense of confidence in the corrosion performance that would be contradicted by unexpected failure in service (e.g., heat-exchanger tubing). In the case of uniform and nonuniform corrosion, units such as $g/m^2 \cdot h$ or mdd (see Table 1) can be used for making relative comparisons of corrosion performance, for example, evaluation of solution corrosivity or determining efficacy of corrosion mitigation methods. However, the data should not be converted to thinning rates (e.g., mpy or mm/y) unless the corrosion is confirmed to be uniform.

Table 1 Values for constant *K* in the corrosion rate equation (Eq 2)

Corrosion rate units desired	Constant *K* in corrosion rate equation
Mils per year (mpy)	3.45×10^6
Inches per year (ipy)	3.45×10^3
Micrometers per year (μm/y)	8.76×10^7
Millimeters per year (mm/y)	8.76×10^4
Grams per square meter per hour ($g/m^2 \cdot h$)	$1 \times 10^4 \times \rho$
Milligrams per square decimeter per day (mdd)	$2.40 \times 10^6 \times \rho$

ρ is material density in g/cm^3.

Other Test and Evaluation Methods

If visual appearance indicates uniform corrosion on the test specimens, then periodic analysis for dissolved or insoluble corrosion products may be used to calculate corrosion rate (Ref 9). This is generally most meaningful for closed systems; that is, the test solution is not refreshed. This approach assumes that all of the corroded metal enters the test solution does not remain on the surfaces of the test specimens as corrosion product. For an alloy, it is assumed that its constituent elements enter the solution stoichiometrically. For material-environment combinations where hydrogen is evolved as a by-product, the hydrogen can be collected during the test, using a gas burette. Again, if corrosion is uniform, it may be possible to calculate the corrosion rate from the volume of hydrogen evolved, provided the correlation between metal loss and amount of gas liberated is known (Ref 9, 10).

If corrosion attack is uniform, useful estimates of corrosion rates can be obtained from electrochemical techniques such as linear polarization resistance (LPR). This technique is described in ASTM G 59 (Ref 11). Basically, a small voltage is applied between two small, identical electrodes made from the material of interest. The electrodes are usually incorporated in a probe, which is immersed in the environment. The current associated with the small voltage perturbation is measured. Polarization resistance is the ratio of applied voltage to the resultant current density and is inversely related to the corrosion rate via a Stern and Geary constant. This technique requires immersion of the probe in an aqueous (preferably conductive) medium. The LPR technique lends itself readily to monitoring uniform corrosion in laboratory tests or in-plant applications (Ref 12). Instrumentation ranges from portable, single-channel, hand-held units to multichannel systems installed in control rooms.

Another technique for monitoring uniform corrosion is the electrical resistance (ER) method. The change in the electrical resistance of a sensing element (e.g., wire, strip, or foil) made from the material of interest and exposed to the environment is monitored with a Kelvin- Wheatstone bridge as a function of time. The sensing element is usually incorporated into a suitable probe. The sensing element thins due to corrosion, with a corresponding increase in its electrical resistance. The corrosion rate is directly related to the slope of the curve from plotting resistance change versus time. A major attribute of the ER technique is that, unlike the LPR technique, it does not require an aqueous or conductive medium. Monitoring equipment for laboratory and on-line corrosion tests using the electrical resistance technique is available commercially (Ref 12).

Evaluating Pitting Corrosion

Revised by Bopinder Phull, Consultant

Introduction

PITTING is a form of localized corrosion that is often a concern in applications involving passivating metals and alloys in aggressive environments. Pitting can also occur in nonpassivating alloys with protective coatings or in certain heterogeneous corrosive media. It is a very damaging form of corrosion that is not readily evaluated by the methods used for characterizing metal loss caused by uniform corrosion. It should be recognized that accelerated laboratory test methods allow ranking of relative susceptibility or resistance to pitting corrosion but typically do not provide reliable predictions of time to failure in actual service environments.

Test Methods

ASTM G 48 gives procedures for determining the pitting (and crevice) corrosion resistance of stainless steels and related alloys when exposed to an oxidizing chloride environment, namely, 6% ferric chloride ($FeCl_3$) at 22 ± 2 or 50 ± 2 °C (70 ± 3.5 or 120 ± 3.5 °F) (Ref 1). Method A is a 72 h total-immersion test of small coupons that is designed to determine the relative pitting resistance of stainless steels and nickel-base chromium-bearing alloys. Method B is a crevice test under the same exposure conditions, and it can be used to determine both the pitting and crevice corrosion resistance of these alloys. These tests can be used for determining the effects of alloying additions, heat treatments, and surface finishes on pitting and crevice corrosion resistance. Methods A and B are designed to cause breakdown of type 304 stainless steel at room temperature. Methods C and D are used to determine the critical temperature to cause initiation of pitting and crevice corrosion, respectively, in 6% $FeCl_3$ + 1% HCl solution. In each of these methods, the use of $FeCl_3$ solution is justified on the basis that a similar electrolyte chemistry develops within the pits in susceptible ferrous alloys exposed to chloride-containing service environments. As a result, these tests can give misleading results for alloys intended for chloride-free service environments.

ASTM F 746 describes a procedure to determine the resistance to pitting or crevice corrosion of passive metals and alloys from which surgical implants will be produced (Ref 2). This is an electrochemical potentiostatic screening test that is used to rank surgical implant alloys in order of their resistance to localized corrosion in a 0.9% NaCl solution at 37 ± 1 °C (98.6 ± 1.8 °F) (average human body temperature). Using a potentiostat, an anodic potential is applied to a small test specimen in an effort to initiate localized corrosion; the current is then monitored as a function of time at a constant potential. With this method, alloys are ranked in terms of the critical potential for pitting; the more electropositive (more noble) this critical potential is, the more resistant the alloy is to passive film breakdown and to localized corrosion. The method was intentionally designed to cause breakdown of at least one alloy (type 316L stainless steel) that is currently considered acceptable for

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

surgical implant use. Those alloys that suffer pitting or crevice corrosion during more severe portions of the test do not necessarily suffer localized corrosion when placed within the human body as a surgical implant.

ASTM G 61 is an electrochemical test method for conducting cyclic potentiodynamic polarization measurements to determine susceptibility to localized corrosion (Ref 3) of iron-, nickel-, and cobalt-base alloys in chloride environments. A small test specimen is polarized using a potentiostat, a counter electrode, and a reference electrode. Commencing at the free (or open circuit) corrosion potential, a polarization curve is generated by scanning the potential of the test specimen in the anodic direction. (The potential versus log current density plot is usually recorded automatically.) The scan is reversed at some preset criterion (potential or current density). Breakdown potential for pitting, repassivation (protection) potential, and hysteresis behavior (difference between forward and reverse anodic scans) data are acquired from the polarization curve and used to compare the pitting (or crevice) corrosion resistance of test materials. Several different methods for determining the protection potential have been compared (Ref 4).

The general interpretation of the results is that pits initiate and grow at potentials more noble than the breakdown (pitting) potential of the passive film. In service environments, this can happen when the corrosion potential shifts sufficiently in the electropositive direction, for example, due to the influence of oxidizing species such as O_2, Fe^{3+}, OCl^-, and so on. At potentials more active or electronegative than the repassivation (protection) potential, pit initiation and growth are stifled. It should be noted that breakdown potential, repassivation potential, and hysteresis behavior are not material properties; they are empirical values, which are influenced by experimental technique and procedure. Nevertheless, they are useful in ranking alloy performance when nominally the same test procedure is followed. Criticisms of such tests for predicting long-term corrosion behavior are discussed in Ref 5, 6, 7.

ASTM G 100 gives a procedure for conducting cyclic galvanostaircase polarization (GSCP) to determine relative susceptibility to pitting (and crevice) corrosion of alloys (Ref 8). In this method, the current is increased and decreased and the potential is monitored. For some materials, specifically aluminum alloy 3003-H14 (UNS A93003), this method gives a more reproducible protection potential value compared to potentiodynamic methods such as ASTM G 61.

Although polarization test techniques such as ASTM G 61 or G 100 are used primarily in the laboratory, they can also be used successfully in the field. However, the risk of ground (earth) loops, which can affect measurement capabilities and hence results, is greater for in-plant (field) applications because of the possibility of the large electrical and magnetic fields often associated with industrial equipment. A common ground-loop problem can be circumvented by using a potentiostat that has a floating working (test) electrode terminal instead of a grounded one. Because of the large applied potentials used in these tests, the test specimens are usually irreversibly affected, at least in electrochemical terms. Thus, they are not considered as on-line techniques for routine monitoring of localized corrosion. There are on-line techniques (Ref 9), such as electrochemical linear polarization resistance (LPR) and electrical resistance (ER), but they are more suited to monitoring uniform rather than localized corrosion.

Electrochemical noise (EN) is a relatively new technique that is finding increasing use alongside the more traditional electrochemical methods, both in research and the field. Electrochemical potential noise (EPN) involves monitoring small shifts (typically μV to mV range) in the corrosion potential of a test electrode with respect to a suitable reference electrode. Initiation of pits is usually characterized by distinct shifts in potential; repassivation is indicated by potential recovery. Quantitative information on corrosion rate is given by electrochemical current noise (ECN) measurements in which the micro-galvanic current between two nominally identical test specimens made from the material of interest is monitored. References 10, 11, 12 provide additional information on EN techniques.

Evaluating Pitting Corrosion

Revised by Bopinder Phull, Consultant

Examination of Pits

ASTM G 46 provides guidance for the identification and examination of pits and evaluating the extent of pitting corrosion (Ref 13). It is important to be able to determine the extent of pitting, either in service applications or in laboratory tests for ranking alloy performance. The following is a summary of the procedures described in detail in Ref 13. Additional guidelines can be found in Ref 14.

Identification and Examination of Pits

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Visual examination of the corroded surface can be performed with the unaided eye or a low- power microscope. The corroded surface is usually photographed, and the size, shape, and density of the pits determined (Fig. 1, 2).

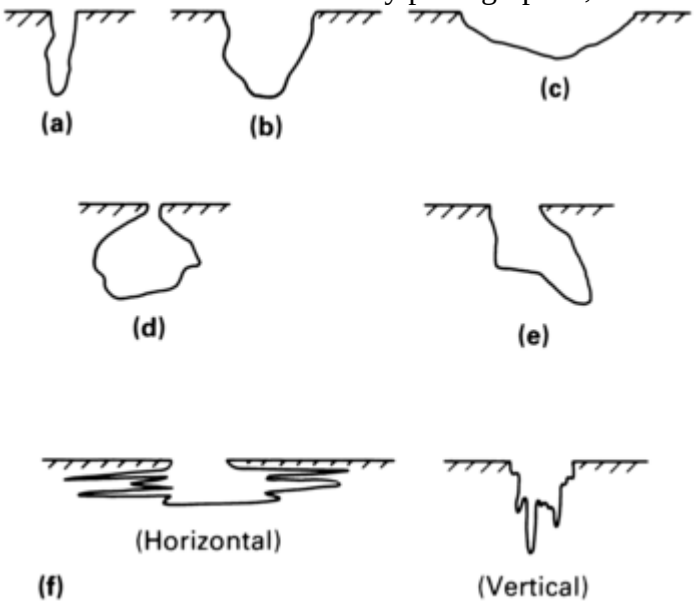

Fig. 1 Variations in the cross-sectional shape of pits. (a) Narrow and deep. (b) Elliptical. (c) Wide and shallow. (d) Subsurface. (e) Undercutting. (f) Shapes determined by microstructural orientation. Source: Ref 13

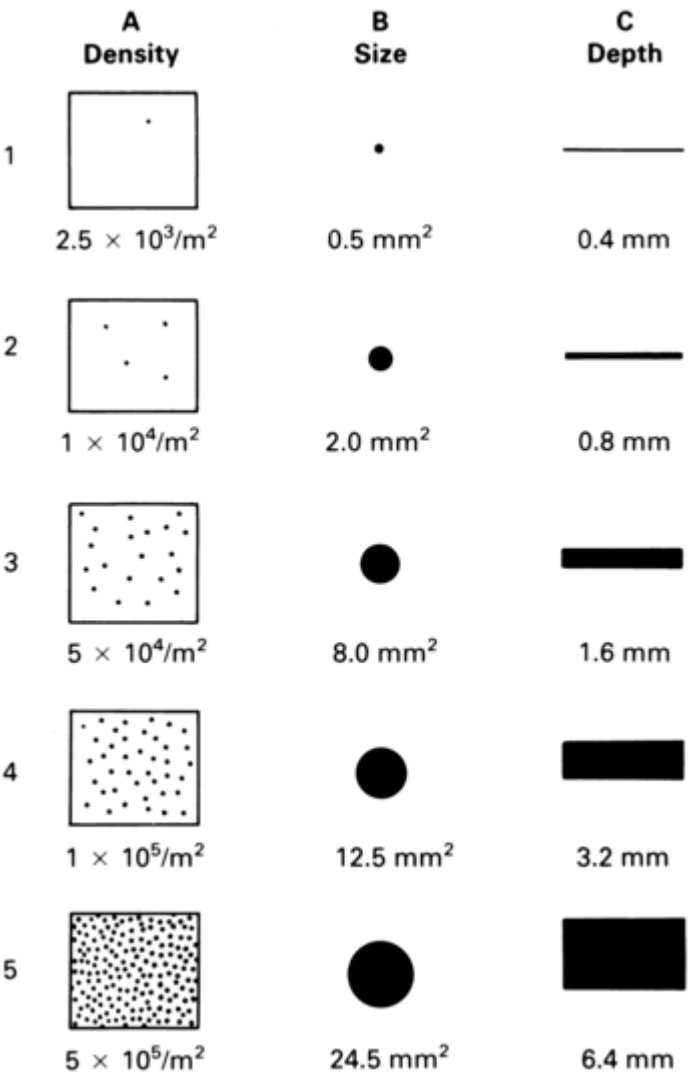

Fig. 2 Standard rating chart for pits. Source: Ref 13

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Metallographic examination can be used to determine whether there is a correlation between pits and microstructure and whether the cavities are true pits or the result of another mechanism, such as intergranular corrosion or dealloying.

Nondestructive Inspection. Reference 13 outlines procedures for the nondestructive evaluation of pitted specimens. These include radiographic, electromagnetic, ultrasonic, and dye- penetrant inspection. These methods can be used to locate pits and to provide some information on their size, but they generally cannot detect small pits or differentiate between pits and other types of surface defects.

Extent of Pitting

Mass loss is generally not a good indication of the extent of pitting unless uniform corrosion is slight and pitting is fairly severe. If there is significant uniform corrosion, the contribution of pitting to total mass loss is small. Mass loss should not be ignored in every case, however. For example, measurement of mass loss, along with visual comparison of pitted surfaces, may be sufficient to rank the relative resistance of alloys in laboratory tests.

Pit depth measurement is generally a better indicator of the extent of localized attack than mass loss. Pit depth measurement can be accomplished by several methods, including metallographic examination, machining, use of a micrometer or depth gage, and microscopic measurements. In the microscopic method, a metallurgical microscope is focused on the lip of the pit and then on the bottom of the pit. The difference between the initial and final readings on the fine-focusing knob or stage vernier is the pit depth.

Evaluating Pitting Corrosion

Revised by Bopinder Phull, Consultant

Evaluation of Pitting

Pitting can be described in several ways. Reference 13 includes procedures for the use of standard charts, metal penetration, statistical analysis, and loss in mechanical properties to quantify the severity of pitting damage. More than one of these methods can be used. In fact, it is often found that no single method is sufficient by itself.

Standard charts such as shown in Fig. 2 can be used to rate pits in terms of density, size, and depth. Columns A and B in Fig. 2 are used to rate the density (that is, the number of pits per unit area on the specimen surface) and the average size of the pits, respectively. Column C rates the average depth of attack. An example of a rating using Fig. 2 might be A-3, B-2, C-3; this rating indicates a density of 5×10^4 pits/m^2, an average pit size of 2.0 mm^2, and an average pit depth of 1.6 mm.

Such charts facilitate communication among those who are familiar with the standard ratings and offer a simple means of storing data for comparison with other test results. However, it can be tedious and time-consuming to

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

measure all of the pits, and the time spent doing so is usually not justified, because maximum values (especially pit depths) are often more significant than average values.

Metal Penetration. In this method, the deepest pits are measured and metal penetration is expressed in terms of the maximum pit depth, an average of, for example, the ten deepest pits, or both. Metal penetration is especially significant when the metal is intended for service as an enclosure for gas or liquid and when a hole could result in loss of fluid.

Metal penetration can also be expressed in terms of a pitting factor, which is the ratio of the deepest metal penetration to the average metal penetration (determined from mass loss):

$$\text{Pitting factor} = \frac{\text{Deepest metal penetration}}{\text{Average metal penetration}} \qquad \text{(Eq 1)}$$

A pitting factor of 1 represents uniform corrosion. The larger the number, the greater the pit depth penetration. The pitting factor cannot be used when pitting or general corrosion is slight, because values of 0 or infinity are obtained in such situations, respectively.

The application of statistics to the analysis of corrosion data is covered in detail in ASTM G 16 (Ref 15). The subject is discussed briefly in Ref 13 to show how statistics can be used in the evaluation of pitting data.

The probability that pitting will initiate on a metal surface depends on a number of factors, including the pitting tendency of the metal, the corrosivity of the solution, the specimen area, and the duration of exposure. A pitting probability test can be used to determine the susceptibility of metals to pitting. However, this test will not provide information about the rate of propagation, and the results are applicable only to the conditions of exposure. Pitting probability P is expressed as a percentage and requires exposure of a number of specimens to a particular set of conditions (Ref 16, 17):

$$P = \frac{N_p}{N} \times 100 \qquad \text{(Eq 2)}$$

where N_p is the number of specimens that pit, and N is the total number of specimens.

The relationship between pit depth and area or time of exposure may vary with such factors as the environment and the metal exposed. Equations 3 and 4 are examples of the relationships that have been found to apply under certain exposure conditions. Equation 3 is the relationship between maximum pit depth D and the area A of a pipeline exposed to soil (Ref 18, 19, 20):

$$D = bA^a \qquad \text{(Eq 3)}$$

where a and b are constants (each > 0) derived from the slope and the y-intercept of a straight line obtained when the logarithm of the maximum or mean pit depth for successively increasing exposed areas on the pipeline are plotted against the logarithm of the corresponding pipeline areas. The dependence on exposed area is attributed to the increased chance for the deepest pit to be found when the size of the sample of pits is increased by an increase in the area of corroded surface.

There is a common but highly mistaken tendency to divide measured pit depth by exposure time to compute a pitting rate, for example, mils per year, millimeters per year, and so on. Unless independently corroborated by good data, this approach can be misleading and potentially hazardous in predicting time to failure by pitting corrosion. The maximum pit depth D of aluminum exposed to various waters was found to vary as the cube root of time t, as shown in Eq 4 (Ref 16, 21):

$$D = Kt^{1/3} \qquad \text{(Eq 4)}$$

where K is a constant that is dependent on the composition of the water and the alloy. Equation 4 has been found to apply to several aluminum alloys exposed to different waters.

Extreme value probability statistics (Ref 22, 23) have been successfully applied to estimate the maximum pit depth on a large area of material based on examination of only a small portion of that area (Ref 14, 16, 21). The procedure consists of measuring maximum pit depths on several replicate specimens and then arranging the pit depth values in order of increasing rank. A plotting position for each order of ranking is obtained by substitution in the relation $M/(n + 1)$, where M is the order of ranking of the specimen in question, and n is the total number of specimens or values. For example, the plotting position for the second value out of 10 would be $2/(10 + 1) = 0.1818$. These values are plotted on the ordinate of extreme value probability paper versus corresponding maximum pit depths. A straight line indicates that extreme value statistics are applicable.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Extrapolation of the straight line can be used to determine the probability that a specific pit depth will occur or the number of observations that must be made to find a particular pit depth.

Loss in Mechanical Properties. If pitting is the predominant form of corrosion and if the density of pitting is relatively high, the change in a mechanical property relative to unexposed control specimens can be used to characterize degree of pitting. The typical properties considered for this purpose are tensile strength, elongation, fatigue strength, impact resistance, and burst pressure (Ref 24, 25).

The precautions that must be taken in the application of these mechanical test procedures are covered in most standard methods. However, it must be stressed that the exposed and unexposed specimens should replicate each other as closely as possible. Therefore, consideration should be given to such factors as specimen size, edge effects, direction of rolling, and surface finish.

Representative specimens of the metal are exposed to the same conditions except for the corrosive environment. The mechanical properties of the exposed and unexposed specimens are measured after the exposure, and the difference between the two results is attributed to corrosion damage.

Some of these methods are better suited to the evaluation of other forms of localized corrosion, such as intergranular or stress corrosion. Therefore, their limitations must be considered. The often erratic nature of pitting and the location of pits on the specimen can affect results. In some cases, the change in mechanical properties due to pitting may be too small to provide meaningful results. Perhaps one of the most difficult problems is to separate the effects due to pitting from those caused by other forms of corrosion.

Introduction

CREVICE CORROSION is a form of localized corrosion that affects many alloys that normally exhibit passive behavior. Stainless steels, particularly those with little or no molybdenum, are especially prone to crevice corrosion. In neutral and acidic chloride-containing environments, some higher-alloyed stainless-type materials and related nickel-base alloys may also be susceptible to crevice attack. Although other materials, such as aluminum alloys, copper alloys, and titanium alloys, may also be susceptible to crevice-related corrosion, testing and test development have primarily focused on assessing the behavior of the stainless-type alloys. Much of this attention has been directed toward identification and development of more resistant alloys for marine applications and in certain process industries, such as pulp and paper. Over the years, diverse crevice corrosion testing methodologies have evolved and continue to find significant utility in simple immersion studies, electrochemical testing, and the development of mathematical modeling. This article discusses a number of the more frequently used crevice corrosion testing and evaluation procedures. It is recognized, however, that other techniques may exist and that their merits should be examined, especially in the context of the intended application.

Aspects of Crevice Corrosion Testing

Because crevices are real space dimensions between mating materials, use of the term *artificial* crevice test is discouraged in favor of descriptors that identify the crevice former as naturally occurring (for example, a barnacle) or man-made (for example, a washer). Man-made crevice formers can be either a metal or nonmetal and recreate the geometry of some fabricated crevices. Man-made crevice formers may or may not reproduce all conditions found in service, particularly those that are naturally occurring.

Crevice corrosion tests are based on two accepted phases of crevice corrosion: initiation and propagation. Initiation refers to the breakdown of passivity and propagation or penetration as the actual occurrence of crevice corrosion. Under some conditions, breakdown may be followed by repassivation without any outward evidence of attack. For a given alloy-environment combination, the occurrence of crevice corrosion is highly dependent on the crevice geometry. Tighter crevices are more conducive to promoting initiation, but this factor may affect

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

the propagation behavior of materials in different ways (Ref 1). Environmental factors may affect the rate of crevice corrosion propagation. Although natural and synthetic seawater, for example, will both initiate crevice corrosion on type 316 (Unified Numbering System, or UNS, S31600) and many other stainless alloys, propagation in the two environments is often quite different (Ref 2). The overall size of the specimen in relation to the crevice (cathode-to-anode) surface area can also affect propagation behavior. Regardless of the purpose of crevice corrosion testing, the investigator should be aware that these and many other factors can affect test results.

Depending on availability, natural or actual process environments may be used in laboratory immersion tests. This provides a convenient opportunity to study, for example, the effects of temperature, crevice geometry, and other factors such as surface finish. Crevice corrosion tests can be conducted at marine corrosion test sites and at laboratories associated with chemical-processing facilities.

Guidelines for Crevice Corrosion Testing

Laboratory crevice corrosion screening tests play a valuable role in the ultimate use of stainless steels in corrosive environments. Laboratory immersion tests and electrochemical studies are important tools for investigating the effects of alloy content, surface preparation, and environmental variables. However, test results should be used judiciously so as not to limit materials that may otherwise not meet contrived conditions selected to accelerate test results. ASTM G 78 provides guidance for conducting crevice corrosion tests on stainless steels and related nickel-base alloys in seawater and other chloride-containing environments (Ref 3). While its origins grew out of attempts to standardize the use of multiple- crevice assemblies, described later in this article, this guide does not promote any particular crevice former but advises the reader to be aware that crevice corrosion test results can be affected by a number of interrelated factors. In particular, crevice geometry and specimen preparation are very important aspects of testing. This standard provides guidance in the conduct of tests for flat and cylindrical specimens as well as those having irregular surfaces, such as weldments. It also reviews evaluation and reporting considerations. Importantly, Ref 3 points out that the occurrence or absence of crevice corrosion in a given test is no assurance that it will not occur under other test conditions. This is especially true if the design fails to consider those factors that may affect initiation and/or propagation behavior.

Specific Crevice Corrosion Tests

In-Plant and Field Testing. A considerable amount of crevice corrosion data has been obtained from in-plant and field test rack exposures of candidate alloys in various process streams and other industrial environments.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

ASTM G 4 (Ref 4) provides guidance on specimen preparation, test rack assembly, and exposure considerations. Simple tetrafluoroethylene (TFE) fluorocarbon sleeves and washers, intended primarily as electrical insulating spacers between candidate alloy specimens, have proved to be effective crevice formers. Likewise, metal-to- metal configurations have also been used. Test results for square, rectangular, and circular spool disk specimens have identified the occurrence of crevice corrosion and the extent of penetration incurred during the exposure period. Although these and other tests lack definition with regard to actual times to initiation and rates of propagation, they are nonetheless quite effective in screening materials for further consideration. Some test racks are spring loaded, while others are not. It is generally recognized that rapid and severe attack on some specimens in a test assembly may influence crevice tightness on others in the same assembly.

One area in which test rack exposures have been extensively used is the pulp and paper industry. For example, Ref 5 discusses results from bleach plant exposure in which crevice corrosion susceptibility was identified for 24 of the 26 alloys tested. However, the crevices found in bleach plant equipment may be less severe than those on the test specimens. This is supported by the observation that some materials that exhibited less than 0.4 to 0.46 mm (15 to 18 mils) of crevice penetration in a 3 month test actually performed satisfactorily in service for up to 20 years.

Ferric Chloride Crevice Corrosion Tests. Ferric chloride tests involve exposure to a highly oxidizing acid chloride environment. The pH of the standard 6% $FeCl_3$ solution, according to ASTM G 48 (Ref 6), is approximately 1.2. This is less than the pH of the critical crevice solution, which can cause a breakdown of passivity for UNS S30400 and S31600 stainless steels. Critical crevice solution compositions for these alloys with respect to pH and chloride concentration have been identified as pH 2.0 at 1.5 *M* Cl^- and pH 1.7 at 3.5 *M* Cl^-, respectively (Ref 7, 8). Use of $FeCl_3$ eliminates the time factor for development of the aggressive crevice solution from the neutral pH of, for example, a chloride- containing natural water. The crevice prevents oxygen from maintaining the passive film. The combination of low pH and high Cl^- lowers the breakdown or critical potential for pitting in the crevice, while ferric ions (Fe^{3+}) maintain the potential of the alloy in the critical region that supports the cathodic reaction outside the crevice.

More resistant alloys do not exhibit a breakdown potential in the domain associated with Fe^{3+} reduction at ambient temperature. In some cases, the Fe^{3+} serves as a chemical potentiostat and holds the corrosion potential well within the passive region in the absence of oxygen. Increasing the $FeCl_3$ solution temperature to 50 °C (120 °F), for example, promotes breakdown and allows for ranking of more resistant alloys. Figure 1 shows schematically the polarization characteristics for stainless steels exposed to $FeCl_3$.

ASTM and Materials Technology Institute (MTI) Test Methods. Both ASTM G 48 (method B) and MTI-2 (Ref 9) used a simple 6% ferric chloride solution prepared with $FeCl_3 \cdot 6H_2O$ and distilled water solutions. Both are intended for short-term testing within ambient and elevated- temperature ranges. In the G 48 (method B) procedure, crevices are formed by the placement of a polytetrafluoroethylene (PTFE) cylindrical block on each side of the test specimen and securing them in place with rubber bands. Tests at 22 ± 2 °C (72 ± 3.5 °F) are conducted for 72 h. Crevices in the MTI-2 method are created by the application of two modified multiple-crevice assemblies (serrated PTFE washers), each having 12 plateaus or contact sites. An assembly torque of 0.28 N · m (2.5 in. · lbf) was prescribed for tests of 24 h duration. The MTI-2 method calls for a series of tests so as to define a critical crevice temperature (CCT) within 2.5 °C (4.5 °F) increments. A CCT was one that produced at least a 0.025 mm (0.001 in.) deep attack at one or more of the available crevice sites.

There are currently two ASTM methods available for CCT testing: one intended primarily for nickel-base and chromium-containing alloys, G 48 (method D), and one for stainless steels, G 48 (method F). Corresponding standardized pitting tests appear under designations G 48 (methods A, C, and E). Both G 48 (methods D and F) use the serrated washer device mentioned previously. Method D specifies the original MTI-2 torque of 0.28 N · m (2.5 in. · lbf), while method E specifies a higher torque of 1.58 N · m (14 in. · lbf). Currently, the recommended test durations are 12 and 24 h, respectively. Both methods D and F use an acidified (1% HCl) solution of ferric chloride (6% $FeCl_2$), intended to provide stable pH conditions during elevated-temperature testing.

During modification of the original MTI-2 method, ASTM subcommittee G-01.05 adopted two alloy-chemistry-based equations useful in identifying a starting test temperature for the respective methods. Both G 48 (methods D and F) are intended to identify a CCT within the 0 to 85 °C (32 to 185 °F) range by the use of

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

fresh specimens for each exposure. If crevice corrosion is observed at the initial test temperature, methods D and F advise lowering the temperature for the next test by 5 °C (9 °F) and repeating the test. If no attack is found after the initial tests, the temperature is raised by 10 °C (18 °F) and a new specimen exposed. The process is repeated, as needed, until the CCT is identified. The criterion for crevice corrosion in these methods is a measured attack depth of ≥0.025 mm (0.001 in.).

Precision and bias statements exist for ASTM G 48 (methods D and F). For the purpose of alloy ranking, specimens tested by all three methods (B, D, and F) can be evaluated by mass loss, number of sites attacked, and the range of penetrations incurred. The user is cautioned that surface preparation can influence test results. Testing in ferric chloride solution with fresh specimens for each temperature increment resulted in lower CCT values than when the same specimen was reused without resurfacing (Ref 10). ASTM G 48 has been used for alloy development purposes as well as for quality control. Generally, acceptable criteria are established by agreement between alloy producer and the purchaser.

The value of CCT ranking for service life prediction remains limited. Some correlation has been reported for CCT and specific seawater test data (Ref 11, 12), but it does not take into account the effect of crevice geometry and the interrelationship with the natural environment. Although increasing temperature (for example, from 25 to 50 °C, or 77 to 120 °F) of the $FeCl_3$ solution is certainly detrimental, the same is not necessarily true with respect to crevice corrosion in seawater where bulk oxygen concentration decreases with increasing temperature (due to inverse solubility), and biological activity may increase initially but decreases drastically above a threshold temperature (Ref 13).

Sodium Chloride Crevice Corrosion Test. Materials Technology Institute method MTI-4 (Ref 9) involves testing in chloride solutions at eight concentrations, ranging from 0.1 to 3.0% NaCl, to establish a minimum (critical) Cl^- concentration that results in crevice corrosion at room temperature (20 to 24 °C, or 68 to 75 °F). Specimen requirements, crevice assembly procedure, and evaluation technique for the MTI-4 method are identical to those used in the MTI-2 method. The recommended test period for the MTI-4 method, however, is 1000 h, and suggested controls are UNS S30400 and S31600 stainless steel.

Both methods are acceptable screening tools and are well suited for alloy development purposes. However, extension of either method beyond its intended scope may be misleading. In the case of MTI-4, for example, deviations in crevice geometry from that of the serrated washer could significantly alter resistance to a given bulk Cl^- concentration. Tighter and/or larger crevices could promote initiation at lower Cl^- levels (Ref 14). Use of the serrated washer identified earlier, for example, has produced crevice initiation at Cl^- levels as low as 100 to 300 mg/L in a matter of a few days when assembled at an initial torque of 8.5 N · m (75 in. · lbf) (Ref 15). Metal-to-metal crevice sites can sometimes promote more rapid initiation and at lower Cl^- levels in comparison to nonmetal-to- metal crevices of comparable geometry (Ref 16).

Evaluating Crevice Corrosion

R.M. Kain, Consultant

Multiple-Crevice Assembly Testing

The multiple-crevice assembly (MCA) technique was originally introduced in the mid- 1970s as a rapid and economical screening tool for establishing resistance to crevice corrosion in natural seawater (Ref 17). Testing was specifically intended to be severe enough to produce some indication of alloy susceptibility or resistance instead of relying on other factors, such as fouling and seasonal variation in temperature. It was also desirable that the MCA demonstrate recognized differences in alloy capabilities, such as those between UNS S30400 and S31600 stainless steels, as well as the exceptional degree of performance expected of highly corrosion-resistant alloys. Unlike some other popular crevice corrosion tests, the MCA test relied solely on naturally occurring processes and required neither outside electrochemical nor chemical stimulation.

It was argued that because crevice corrosion appeared to be random in its occurrence, the creation of a number of identical crevice sites on a given set of specimens would provide a basis for statistical analysis. Therefore, the MCA design and the use of the probability-of-attack concept gained appeal (Ref 18). Early concerns with geometrical factors primarily addressed the size of the specimen in terms of boldly exposed area (cathode) to shielded or crevice area (anode) (Ref 17). Subsequent research, especially through mathematical modeling (Ref 1, 14, 16), showed that the occurrence of crevice corrosion was dependent on a number of interrelated factors, while the probability concept suggested only a material (i.e., alloy) property. Because crevice geometry factors, such as crevice tightness, could be overriding considerations (Ref 19, 20), proponents and users of the MCA

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

generally abandoned the probability concept in describing the occurrence of crevice corrosion. However, as evidenced by the number of investigations reported in the literature (for example, see Ref 21, 22, 23, 24), the MCA technique remained popular, because it enabled the investigator to report results in terms of initiation and propagation. For example, resistance to initiation could be expressed as the number of crevice sites or the percentage of sites exhibiting attack in a given test period. Because attack, when it occurs, is located at specific sites (Fig. 2), penetration measurements could be made at each site and reported as a maximum depth. This can be accomplished by using an appropriate dial depth gage or focusing microscope. Results have been reported as a range of these maximum values or their average value. Table 1, for example, gives data describing the effect of molybdenum content on both initiation and propagation resistance for a series of controlled-chemistry heats of a nickel- base alloy containing 30% Cr. Multiple-crevice test results have been reported in bar graph form as mean values plus and minus one standard deviation of the percentage of sites initiated and maximum depth of attack (Ref 25).

Reference 26, which was prepared under a grant from the National Institute of Standards and Technology (NIST), provides a critical review on the significance and use of MCAs for testing in natural seawater. The report traces the development and changes in design and application of the acetal resin device shown in Fig. 2. Included in Ref 26 are results of an ASTM International subcommittee G-01.09 round-robin test aimed at standardization of the MCA test procedure. Triplicate specimens of four different alloys, with wet-ground (120-grit SiC) surfaces and MCAs tightened to an initial torque of 8.5 N · m (75 in. · lbf), were exposed for 30 days

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

in natural seawater. Of the eight participants with access to natural seawater, seven were located on the U.S. east coast at latitudes ranging from Key West, FL, to New England. The eighth test location was the California coast. All except two test sites provided some degree of seawater filtration; three were unable to provide temperature control. As expected, some differences in seawater chemistry (for example, chloride and dissolved oxygen) and ambient temperatures were reported.

Although the purpose of these tests was to determine the reproducibility of results for different classes of materials, the test alloys were also ranked for corrosion susceptibility. None of the participants reported any incidence of crevice corrosion for nickel alloy C-276 (UNS N10276), which contains ~15% Mo. On the other hand, at least one specimen of alloy G (UNS N06007), which contains ~6% Mo, initiated attack at all eight test locations. Overall, the actual number of crevice sites attacked and the range and maximum depth of penetration for UNS N06007 were both found to be quite minimal. For UNS S30400 and S31600 stainless steels, however, crevice corrosion occurred on all specimens except for one UNS S31600. In general, identification of alloy susceptibility was quite reproducible. However, in terms of the actual number of sites that initiated crevice corrosion, much variability was observed, particularly with respect to test location and participant.

Because of the variability in the round-robin test results, a second set of tests with five participants was conducted at one location. The test was restricted to UNS S30400 and S31600 stainless steels. Actual assembly and conduct of the test were performed by individuals with different degrees of experience in MCA testing. All of the tests were conducted at the same time in natural seawater at 25 ± 2 °C (77 ± 3.5 °F). The results of these tests are shown in Fig. 3. Overall, the degree of variability is consistent with that observed from data provided from the original round-robin testing at different test locations. In addition, penetrations measured for the two stainless steels in the latter round-robin test were comparable to those in the original.

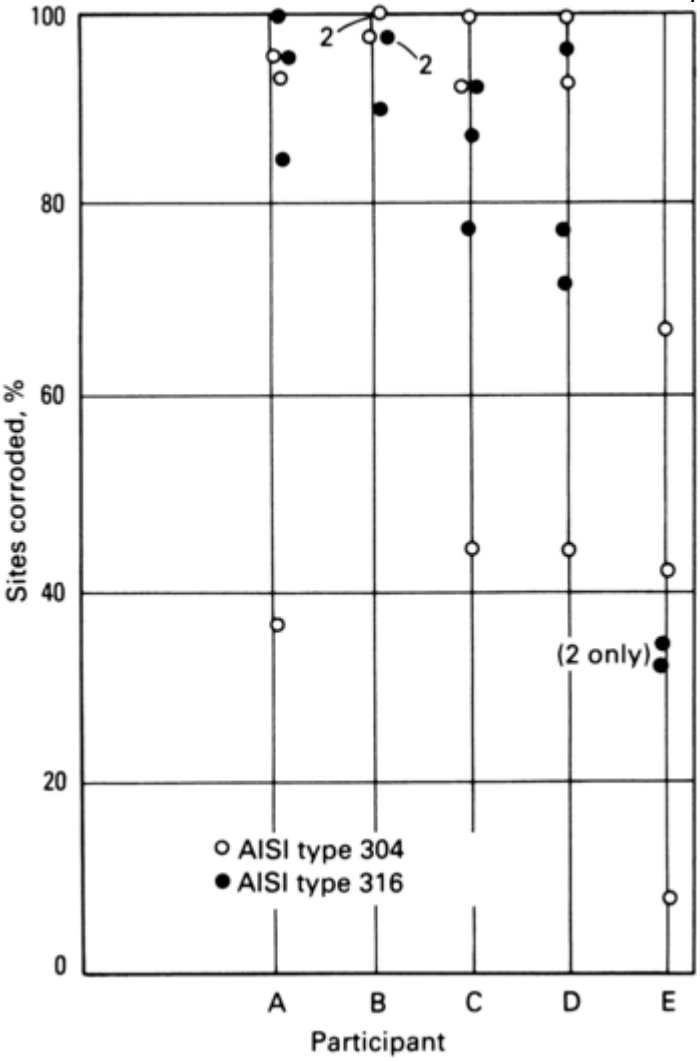

Fig. 3 Multiple-crevice assembly round-robin results from 30 day test conducted simultaneously at one ASTM International selected seawater site. AISI, American Iron and Steel Institute

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

In another series of 30 day comparative tests (Ref 27), 13 participants used MCAs in round- robin testing of UNS S30400 in 3.5% NaCl at 30 °C (85 °F). Crevice assembly design and initial torque were the same as in the ASTM International committee G-01.09 round-robin test. Again, considerable variability was evident from one participant to another. Crevice sites that exhibited initiation out of 120 available crevice sites ranged from 20 to 86%. Although some exceptions were noted, a number of individual participants reported good reproducibility among replicate specimens. Compared to attack in natural seawater, penetrations in 3.5% NaCl tests did not exceed 0.23 mm (9 mils). Average penetrations for triplicate specimens varied by only a few hundredths of a millimeter.

The degree of variability described previously is likely to be encountered in any type of crevice corrosion test. When conducted in a conscientious manner, MCA tests can generate meaningful results for ranking of alloys and identifying the effects of other exposure variables. The MCA test cannot and should not be used to predict alloy performance under other conditions.

Another test series involved exposure of several grades of stainless steel in different to pulp- bleaching environments. Testing was performed in accordance with a procedure developed by NACE International T-5H-6 task group ("Test Methods for Measuring Crevice Corrosion Rates"). Multiple exposures involved the use of a Rulon (Saint-Gobain Performance Plastics) crevice device similar to that shown in Fig. 2 but with somewhat larger plateaus. Participants used specimens of a given size, and the assemblies were torqued to prescribed levels. Because only a few crevice sites initiated, and reproducibility was poor, it was concluded that the method was not useful in warm (up to 82 °C, or 180 °F), low- pH (1 to 5), low-chloride (50 to 2000 ppm) environments. However, these conditions actually fit well with the premise that a range of tight crevice gaps exists for each type of assembly. Mathematical modeling has shown an interrelationship between bulk chloride level and crevice gap (Ref 14). For the relatively small depth of a MCA site and the low-level chlorides present in the bleach plant, only the tightest of sites should be expected to initiate crevice corrosion.

Evaluating Crevice Corrosion

R.M. Kain, Consultant

Continuous Crevice Formers

Perspex Crevice Assemblies. While MCAs were being used extensively in the 1980s to investigate crevice corrosion in marine and paper mill environments, another type of device was developed as a research tool. The Perspex crevice assembly (PCA) was initially devised and used to provide immersion test verification data for the development of mathematical models of crevice corrosion (Ref 7). Perspex is a British trade name (Imperial Chemical Industries, UK) for a hard plastic, polymethyl methacrylate (PMMA). This material and related plastics, such as Plexiglas (ATOFINA Chemicals, Inc.), can be machined as a continuous-type crevice former with depth dimensions that are intentionally varied. The design shown in Fig. 4 was prepared with bored holes that enabled access of the test medium to the inside diameter (ID), creating an effective crevice depth equivalent to one-half the PCA annular dimension. The most common- size PCAs reported in the literature are those measuring 40 mm outside diameter (OD) by 20 mm ID (1.6 by 0.8 in.) and a smaller version measuring 30 mm OD by 20 mm ID (1.2 by 0.8 in.) (Ref 3, 28). Because of the translucent nature of the acrylic plastic, the earliest stages of crevice corrosion development can be detected in situ. This led to greater accuracy in reporting times to initiation and the extent of measured propagation.

Perspex crevice assemblies have been used extensively in comparing alloy performance and in tests to investigate variations in Cl^- and SO_4^{2-} levels in simulated natural waters, crevice geometry, test temperature, alloy surface conditions, and cathode-to-anode area ratio (Ref 28, 29, 30, 31, 32).

Perspex crevice assemblies have been used in the smooth, polished, ground, and machine- grooved condition to vary the severity of the geometry formed at a particular assembly torque, usually 2.8 N · m (25 in. · lbf). In some tests, crevice conditions were made even more severe by introducing a deformable insert (plastic tape) between the hard plastic and the test metal surface. Effects of the previously mentioned variations on alloy performance in natural seawater are reported in Ref 31 and 32. Results for several alloys that have diverse chemistries are shown in Table 2.

For the most part, PCAs have been assembled with simple nut, bolt, and washer assemblies of a corrosion-resistant material such as UNS N10276 or titanium Gr-2 (UNS R50400). As described, for example, in Ref 19, precision washers have also been used to ensure a constant pressure.

At least one investigation (Ref 33) has employed continuous washers of the 30 mm OD by 20 mm ID (1.2 by 0.8 in.) design but fashioned from other polymers, including PTFE, Rulon, and fiber-impregnated PTFE. In these tests, the crevice formers were made without access holes and thus had a nominal crevice depth of 5.0 mm (0.2 in.) as contrasted with the 2.5 mm (0.1 in.) depth inherent with the original PCA. Unlike the translucent, polished acrylic plastic, PCAs made from the previously mentioned materials do not permit detection of the early stages of crevice corrosion initiation.

Gaskets. Over the years, gaskets have been a perennial source of crevice corrosion at flanged surfaces and other mounting sites where a nonmetallic was used for sealing or for electrical isolation purposes. In early seawater tests, for example, crevice corrosion often developed beneath Bakelite (Georgia Pacific Corp.) insulators used to mount specimens on test racks.

As reported in Ref 34, PTFE and cloth fiber- filled rubber gaskets were used in an extensive U.S. Navy program to evaluate candidate valve materials for seawater service. Materials considered for valve body applications were tested with grooved surfaces and the fiber-filled rubber gaskets. Other material considered for valve trim hardware was tested in the surface-ground condition with PTFE gaskets. In both tests, the respective metal surface roughness was quantified. Both types of gasket were ~50 mm OD by 13 mm ID (2 by 0.5 in.) and held in place on both sides of the 100 mm by 150 mm (4 by 6 in.) testpieces, as shown in Fig. 5. Tables 3 and 4 summarize the results of a 6 month test conducted in filtered seawater at 25 ± 5 °C (77 ± 9 °F).

The effect of gasket material on the crevice corrosion resistance of cast (UNS J92800) and wrought (UNS S31600) stainless steel was investigated in seawater and a less aggressive Cl^-- and SO_4^{2-} -containing water (Ref 35). Identification of 11 gasket materials (plus PCA controls) and seawater test results for J92800 flanges are provided in Table 5. In seawater, the propensity for attack favored crevices formed with nitrile and PTFE-type gaskets. The nominal cathode-to- crevice area ratio in the tests was smaller than in many of the other crevice corrosion tests cited here.

Irregular Surfaces. The use of rigid crevice formers with deformable inserts, for example, PCAs and gasket assemblies, can generally produce tight crevices on metals with irregular surfaces associated with coarse grinding, machining, and heavy acid pickling. However, these types of devices are generally not applicable to testing autogenous welds, raised weld beads, or unfinished weld overlays. Some success has been achieved by using O-rings or rods (Ref 36) made of deformable polymers. In each case, some type of holder or retainer is needed to position and secure the crevice former over the desired section of weldment. This may be achieved by bolting through a hole drilled in the test specimen or by using a clamping device.

Another, more adaptable method involves the use of an epoxy-type coating. Reference 37 describes the application of an epoxy coating to assess the crevice corrosion behavior of weld metal and adjacent heat-affected zones on cruciform-shaped specimens in seawater. Reference 37 discusses the repeatability aspects of the testing performed on UNS S31603, S20910, and N08367. Elsewhere, a paint marking pen was successfully used to create crevice conditions and assess the performance of seal-welded tube- to-tube sheet assemblies fabricated with unidentified stainless steel components (Ref 38). Figure 6 shows before-and-after views of a tested section. The use of dried plastic from a felt tip pen to produce crevice sites is discussed in Ref 39. Some of the attributes described for this technique include a constant critical geometry, no need for fixturing, a crevice area that can be varied, and simple specimens having concave, convex, or uneven surfaces.

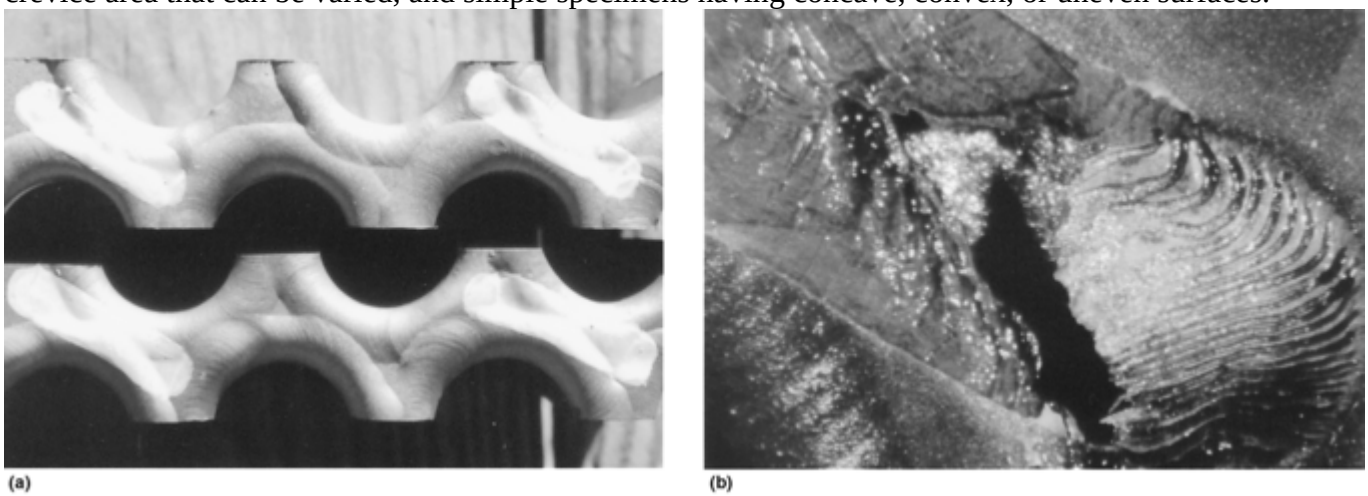

Fig. 6 Example of the use of paint marker (a) to create crevice site on irregular weld surface and (b) resulting attack after exposure to seawater. Courtesy of the LaQue Center for Corrosion Technology, Inc.

There appears to be some similarity in the undulated pattern of attack found beneath coatings (see Fig. 6b) and that associated with heat tint on as-welded stainless steel exposed to seawater and other chloride-containing solutions.

Evaluating Crevice Corrosion

R.M. Kain, Consultant

Evaluating Cylindrical Materials and Products

It is often desirable to evaluate the crevice corrosion resistance of product forms other than flat sheet and plate. Crevice corrosion testing of rod and barstock as well as alloy tubing and pipe can be accomplished by the use of devices that can produce a crevice on the OD of the test material. Such devices exist as off-the-shelf fittings or other products that can be cut and adapted to meet test needs. Among those available are wood collars, O-rings, ferrule and sleeve-type compression fittings, polyvinyl chloride (PVC) compression fittings with internal rubber glands, various flexible hose products, snap-type hose clamps, packing materials, and epoxy coatings.

The selection of an appropriate crevice former should take into account the purpose of the tests, for example, direct one-on-one alloy evaluations, assessing environmental variables, or evaluating product performance under conditions likely to be found in service. The selection depends heavily on the size (OD) of the product being tested and the available size of the crevice- forming material. The fact that rod and barstock can be machined to specific dimensions gives the investigator some control over the test design. In contrast, the testing of tubular products may be dictated by the available mill-produced OD and whether the products are formed to English or metric dimensions. The combination of product form and selected crevice device can accurately reproduce or closely approximate the crevice geometries found in some service applications.

O-Rings. The simplest method of crevice corrosion testing of cylindrical specimens, including tubulars, is by the application of O-rings (PTFE, rubber, Viton [DuPont Dow Elastomers] or other polymer). The crevice can be made more or less severe by varying the size of the O-ring with respect to the OD of the alloy product. It should be recognized that excessive stretching of an O-ring may alter its width and, accordingly, the depth of the crevice formed. O-rings of different thicknesses allow the crevice depth to be varied. One advantage of O-rings is that they do not require tightening and thus eliminate a source of variation found in some other types of devices. However, O-rings should not be overstretched.

Another advantage of O-rings is that results from simple immersion tests can be correlated with electrochemical tests, such as ASTM F 764 (Ref 40), that use a rod-shaped electrode with an O-ring crevice former. A disadvantage is that the crevice depth is limited. The shallow depth of an O-ring is less likely to promote attack of more highly alloyed stainless steels and nickel-base alloys that otherwise may be more susceptible with deeper crevices, for example, with gasket or washer-type crevice formers. As a rule, deep- tight crevices are considered to be more severe than shallow-loose crevices.

Wood Collars. Collars fashioned from water- resistant redwood (but not copper-chromium- arsenate-treated lumber) have been used to assess the relative resistance of stainless alloy shaft stock to crevice corrosion in seawater (Ref 41). In this case, the redwood was drilled to provide holes of the same diameter as the OD of the barstock tested. The lumber was then split to provide two half-bracelets and further cut into the shape of collars analogous to a penal stock. The collars were positioned over a length of barstock material and tightly secured with corrosion-resistant fasteners. The crevice depth can be intentionally changed by varying the lumber thickness. The cathode-to-anode (crevice) area ratio can be varied by varying the bar length or by adding multiple collars.

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

Packing Material. Packing glands are sites where crevice corrosion could occur, for example, on boat and pump shafts. Reference 42 details a method for comparing the effect of different types of packing materials on the crevice corrosion resistance of stainless steel shafting under static and dynamic conditions. In brief, the packing material was cut into lengths approximately one-half the circumference of the test material. The lengths of packing were freely shaped to form a collar or gland around the test-piece and held tightly in place within a retainer fashioned from a PVC fitting. Some internal machining of the fitting may be required to ensure a tight fit of the packing around the testpiece.

Sleeve Assemblies. The use of sleeves (Fig. 7) produced from polymer and rubber tubing or from hose and applied to the OD of cylindrical specimens allows crevices of varying tightness and depth to be formed. Under simple immersion conditions, these nonmetallic sleeves can be used alone, without the need for additional clamping. For direct alloy comparisons, the OD of all test specimens should be the same, so that crevice tightness is not a variable.

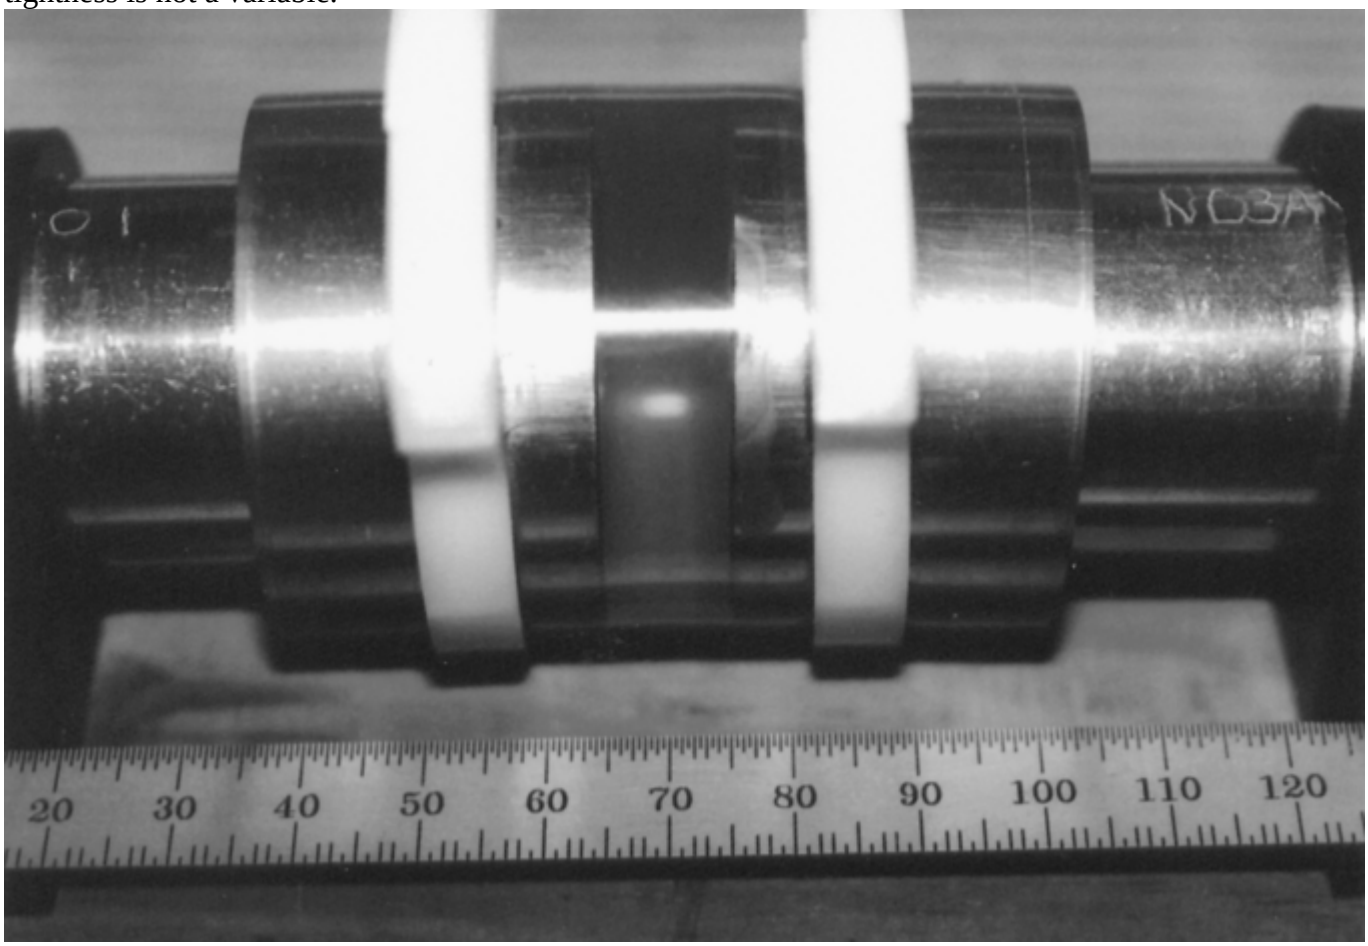

Fig. 7 Translucent vinyl sleeve assembly applied to pipe or tube outside diameter for crevice corrosion testing under static or dynamic flow conditions. Courtesy of the LaQue Center for Corrosion Technology, Inc.

The vinyl sleeve test method offers several advantages. These include ease of preparation, ability to produce tight crevices, and the translucent nature, which facilitates detection of crevice corrosion initiation at the earliest stages.

A number of investigations (Ref 43, 44, 45, 46, 47, 48) have used vinyl sleeves (Tygon tubing, Saint-Gobain Performance Plastics) and/or rubber hose to test alloy tube and pipe sections under dynamic conditions. In those tests, seawater (treated and untreated) flowed through a series of alloy tubes or pipes connected by the vinyl sleeves. In dynamic tests, it is essential that the sleeves be clamped to the specimens to prevent separation due to line pressure. The spacing between specimens should be minimal to prevent any bulging of the sleeve that could vary crevice geometry. In tests of this design, the wetted interior pipe surface (ID) serves as the cathode and the shielded portion of the pipe OD as the crevice (anode).

Ideally, all tubular specimens should be of the same size and schedule. However, this is not always possible. Reference 45 describes one seawater crevice corrosion test program that examined the performance of a series

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

of high-alloy stainless steel produced to English and metric dimensions. In these tests, the IDs of the vinyl sleeves either matched or were smaller than the ODs of the tubular test specimens. Testing proceeded with the understanding that the severity of the crevices was different. In Table 6, those specimens tested with the tightest fit were identified as severe (S) and those with matching ID/ ODs as moderately severe (MS). The differences in seawater velocity associated with each specimen ID dimension are also noted in Table 6.

(b) Maximum depth (0.57 mm, or 0.022 in.) found on UNS S31703 tube; all others ≤0.22 mm (0.0087 in.). Source: Ref 45

Large-Diameter Pipe. Testing the crevice corrosion resistance of large-diameter pipe (e.g., 250 mm, or 10 in.) creates challenges for the investigator. In a previously unreported case (Ref 49), large-diameter pipes prepared by different metallurgical processes were tested in seawater in lengths measuring approximately 750 mm (30 in.). Equally spaced holes were drilled along the length of the pipe at 0°, 90°, 180°, and 270°. To accommodate the inner and outer curvature of the pipes, sections of 25.4 mm diameter by 6.4 mm (1 by 0.25 in.) wall vinyl tubing were split and punched into 25.4 mm (1 in.) OD diameter disks with a 6.4 mm (0.25 in.) center hole. To create the desired crevice on the OD and ID of the test pipe, these disks were then mated with the ID and OD of the pipe at the location of the drilled holes and bolted in place with micarta retainers. The resulting conditions produced crevice corrosion of alloy UNS N06625 within 60 days and revealed no significant effect of the metallurgical processes that were investigated.

Compression Fittings. A disadvantage of vinyl sleeves is their cost relative to that of other crevice formers, particularly when testing larger, for example, >25.4 mm (1 in.), alloy tubulars. One option is to use inexpensive PVC compression fittings with internal rubber glands. The width of the gland increases with the pipe size of the fitting. Some variability in crevice geometry may result during assembly and tightening of the compression nuts on either end. Selection of this type of crevice-forming device, while economical, sacrifices the ability for early in situ detection of crevice attack available with the translucent vinyl sleeve device. However, if the attack is significant, corrosion products may become evident at the compression nut/tube interface. References 50 and 51 cite results of two seawater test programs aimed at examining benefits of surface treatment to enhance the crevice corrosion resistance of stainless steel and nickel-base alloy UNS N06625. In another test program (Ref 52), the effects of alternating flow and stagnant seawater conditions on the behavior of 90/10 copper-nickel (UNS C71500) and alloy- 400 (UNS N04400) were investigated with this type of crevice former. Elsewhere, the behavior of stainless alloy tubing fitted with PVC compression fittings was investigated in aerated, deaerated, and sulfide-containing seawater (Ref 52).

Other types of readily available but more costly compression fittings containing internal ferrules and sleeves have also been used. One test program (Ref 53) used UNS S31600 stainless steel compression fittings to test the resistance of two versions of a 6Mo-containing stainless steel in a tube-to-tubesheet simulation. Nylon compression fittings of this type have also been used to compare alloy resistance to natural and chlorinated

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

seawater (Ref 43). Results were compared with those from concurrent tests with vinyl sleeves and those made from Buna-N (E.I. Dupont) tubing.

The ferrule-and-sleeve devices actually create at least three different crevice geometries within an assembly: a shallow-tight one beneath the ferrule, a deeper-tight crevice at the sleeve, and a considerably deeper but less tight crevice between the tube wall and fitting annulus. Depending on alloy sensitivity, attack may occur at all locations or only at one or both of the tighter crevice sites.

Due to their opaqueness and need for tightening, the ferrule-and-sleeve-type devices share the same limitations as the PVC/rubber gland devices. On the other hand, some versions are available in both English and metric unit dimensions and are therefore suitable for testing tubular and other cylindrical products.

Metal-to-Metal Assemblies. Reference 52 describes metal-to-metal crevice corrosion testing of stainless steel tubulars fitted with compression fittings. A test simulating a tube-to-tube support sheet (Fig. 8) configuration with 0.13 mm (0.005 in.) clearance was reported in Ref 45. While both tubes and plate comprising UNS S30400 stainless steel were attacked within 60 days, no attack of AL-6XN (UNS N08367) tubes or mating tube support plates of UNS S31603 or alloy 2507 (UNS S37250) occurred.

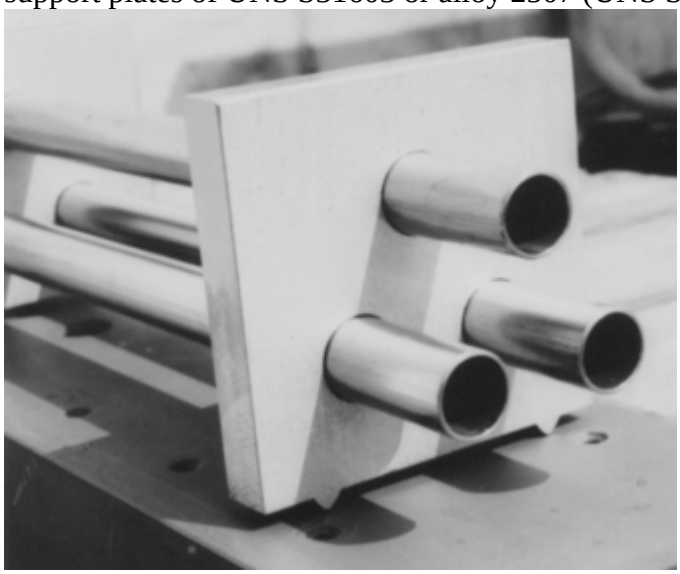

Fig. 8 Example of mixed-metal crevice assembly intended to mimic actual tube and tube support plate conditions (described in Ref 45). Courtesy of the LaQue Center for Corrosion Technology, Inc.

Coatings, such as a marine-grade epoxy, have been used to create crevice conditions on both cylindrical and flat specimens (Ref 37, 54, 55). This is a relatively inexpensive approach for testing of tubulars of all sizes under simple immersion conditions. The coating can be applied to as-produced and prepared tubular surfaces (Ref 54). Anode-to-cathode area ratio effects can be investigated by varying the percentage of tube surface area coated (Fig. 9). In general, the interface between the coating (edge) and the bare metal serves as the crevice mouth and from which corrosion product inevitably appears if the material is susceptible. Once initiated, the attack may continue further inward beneath the coating, progressively disbonding it.

Assessing Corrosion Damage on Cylindrical Specimens. As with flat-panel-type specimens, cylindrical and tubular specimens can be evaluated by their resistance to initiation and propagation. Initial resistance can be reported according to the observed times to visible attack as well as the number or percent of crevice sites attacked. Depending on the size of the specimens, it may be possible to determine mass loss. In addition, affected crevice area and the depth of attack (penetration) can be determined. Affected area can be measured (or estimated) by placing a transparent grid over the crevice site and counting the number of area units (e.g., millimeters squared). Measuring the depth of attack for a cylindrical specimen can be more challenging than for a flat specimen. One method entails placing the cylindrical specimen in a lathe and rotating the specimen manually. A dial depth gage mounted on the traversing tool post is then used to measure depth of attack along the circumference and axis of the specimen. For example, depth of attack can be measured along a line at various degrees of rotation, for example, every 15°, 30°, or 45°.

Component Testing

In some cases, it may be possible to test manufactured components or assemblies and assess their resistance to crevice corrosion. These may comprise nonmetal-to-metal or metal-to-metal joints. In the latter case, like-metal or dissimilar- metal couples may be involved. Testing of flanges with gaskets or O-rings and fasteners are common examples. In an unpublished test (Ref 56), a number of highly torqued like-metal and dissimilar-metal nut, bolt, and washer assemblies were tested by alternate immersion in seawater for 25 weeks. Fasteners comprising all UNS N06625 components exhibited some evidence of crevice attack at mated nut-to-washer, bolthead-to-washer, washer-to-washer, nut-to- bolthead and nut-to-bolt-thread surfaces. When NiCu alloy UNS N04400 washers were substituted for UNS N06625, no attack on the latter occurred, due to galvanic protection (sacrificial corrosion) provided by the NiCu alloy. In another case using UNS N06625 washers in an otherwise all-titanium assembly, attack of the nickel-base alloy was limited to the mated washer surfaces. No attack was found at the titanium-to-UNS N06625 crevice sites created at bolt-head and nut locations. In a metal-to-metal configuration, hydrolysis reactions involving corrosion products from both surfaces in a crevice can contribute to changes in the crevice electrolyte chemistry, leading to breakdown of passivity (Ref 7). Only the UNS N06625 surface in the preceding example would be a contributor of pH-lowering chromium ions.
Reference 57 describes seawater testing of alloy 686 (UNS N08686) bolting securely fastened to large plates of UNS N06625. Specimens were exposed with and without cathodic protection from zinc anodes.

Electrochemical Tests

ASTM Standard Methods. ASTM G 61 is recommended primarily for investigating localized corrosion on iron-, nickel-, or cobalt-base alloys (Ref 58). Crevices are formed on a 16 mm (0.63 in.) diameter disk test electrode by a TFE- fluorocarbon gasket/mounting assembly. Other gasket materials can also be used. The test electrode

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

is the anodic member of a polarization cell containing a deaerated 3.5% NaCl solution. After a 1 h period of free corrosion, the test specimen electrode potential is scanned in the noble direction at a rate of 0.6 V/h. Current density and potential are continuously plotted. On reaching an anodic current density of 5 mA/cm^2, the scan direction is reversed and the scan continued back to its original potential. Susceptibility to crevice corrosion is identified by the occurrence of positive hysteresis during the reverse scan. Relative alloy resistance can be established by comparing the forward and reverse scan potential-current domains with UNS N10276 and S30400 stainless steel standards. ASTM G 61 provides standard polarization plots for comparison and equipment performance verification. Some degree of variability is expected. Several factors may affect results, most notably the actual time between specimen preparation and exposure as well as the degree of tightness used in assembling the test electrode holder.

Nonstandard variations of ASTM G 61, such as the use of different electrode assemblies and/ or polarization scan rates, may significantly affect the measured response (Ref 59). Some correlations have been made between cyclic polarization tests performed according to ASTM G 61 and immersion crevice tests in seawater (Ref 60). For the most part, cyclic polarization tests are able to differentiate between highly alloyed, resistant materials (for example, the high-molybdenum nickel-base alloys UNS N06625 and N10276) and lower-alloy materials (for example, 300-series stainless steel). Correlation for alloys with intermediate compositions may be more difficult, because they exhibit resistance to a broader range of environments (that is, Cl^- concentration and crevice geometry) than the 300- series stainless steels but less than that for nickel-base chromium plus high-molybdenum alloys.

Previously mentioned ASTM F 746 describes procedures for evaluating the pitting and crevice corrosion resistance of metallic surgical implant materials (Ref 40). Testing is again limited to making relative rankings of performance. The procedure calls for the use of a cylindrical electrode with crevices formed by a mounting compression gasket and an intentional crevice-forming collar. Corrosion is induced by a polarization step to +0.8 V versus a saturated calomel reference electrode (SCE). Provisions are established for current monitoring and subsequent potential-time increments. The test is designed to produce corrosion for a control electrode of UNS S31600 stainless steel. Alloys can be compared relative to breakdown, propagation, and repassivation tendencies.

Other Potentiostatic and Potentiodynamic Polarization Tests. A potentiostatic test procedure (Ref 61) identifies alloy crevice corrosion resistance according to an established critical crevice temperature (CCT). Tests have been conducted in neutral NaCl solution and synthetic seawater under constant applied potentials, for example, +600 mV versus SCE. In this automated test, the equipment is programmed to increase the solution temperature in 5 °C (9 °F) increments until a specific critical current level is reached in a given period, for example, 15 to 20 min.

Test results obtained with the previously mentioned method using MCAs are summarized in Table 7 (Ref 62). Also given in Table 7 is a CCT ranking determined in 72 h $FeCl_3$ tests performed according to ASTM G 48 (rubber band test) and another ranking based on the total number of crevice corrosion sites initiated in 30 day natural seawater MCA tests. The three procedures gave the same ranking merit for only 3 of the 12 test materials, numbers 1, 2, and 6. In several cases, two procedures provided the same ranking for a given alloy. In the Santron test, the noble potential is intended to mimic the redox potential of $FeCl_3$. In natural seawater, such potentials would never be achieved without chemical stimulation. In the absence of crevice corrosion, nickel-base chromium-molybdenum alloys as well as some stainless steels have achieved potentials in the +300 to +400 mV range versus SCE in ambient temperature seawater (Ref 55, 63, 64).

Potentiodynamic polarization tests for crevice-free electrodes in a series of increasingly aggressive simulated crevice solutions have been used to rank alloys according to a criterion associated with anodic peak current density (Ref 7). Such information has been used in mathematical modeling to identify the localized environment or critical crevice solution (CCS) that can cause breakdown of passivity and the conditions leading up to it (Ref 28, 30). In addition, as shown in Fig. 10, a plot of log current versus pH has been used to characterize propagation resistance for several cast alloys (Ref 65). Alloy propagation behavior can be ranked according to the slope of the log *i*/pH plot. For the previously mentioned tests, the electrode and its wire lead connection are potted with a thermosetting resin. After curing, the electrode surface is ground, then wiped with a coat of resin to fill gaps, and reground or polished prior to testing.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

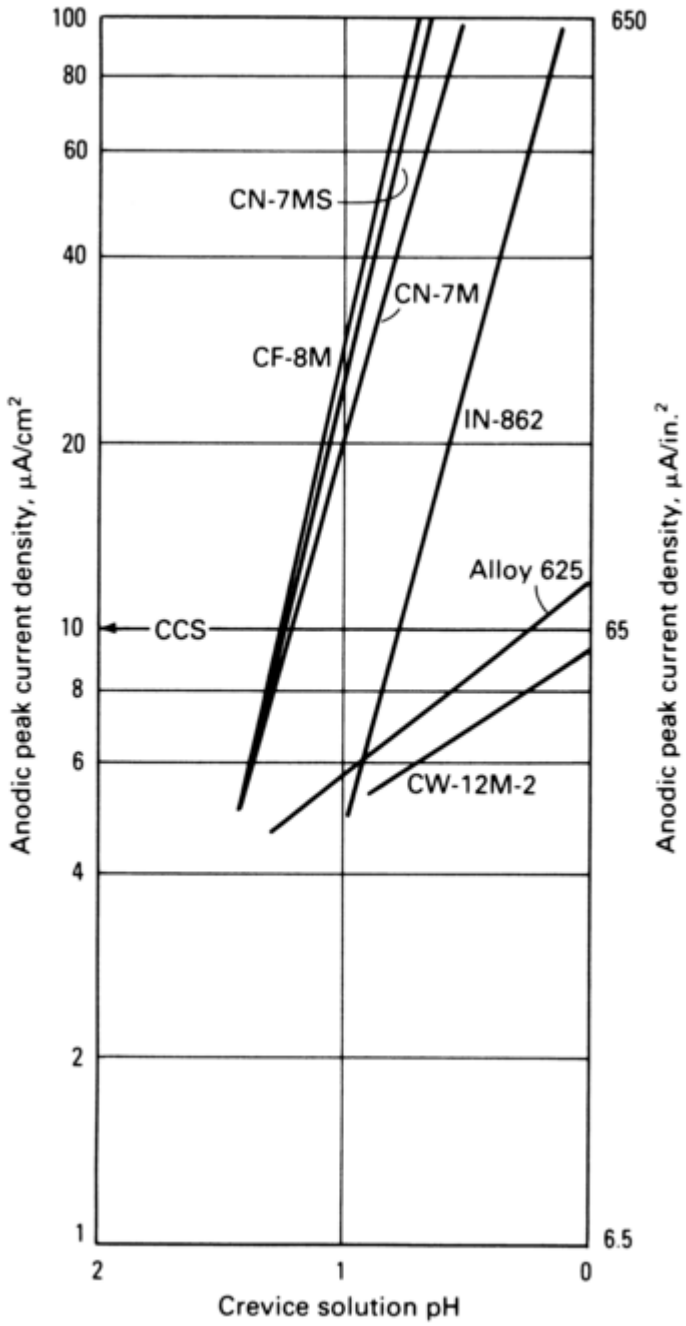

Fig. 10 Plot of anodic peak current density versus simulated crevice solution pH used to determine the composition (pH) of the critical crevice solution (CCS) according to the 10 μA/cm^2 (64.5 μA/in.^{2}) criterion. Source: Ref 8

While not intended for the previously mentioned purpose, ASTM G 150 (Ref 66) may also have some utility in CCS identification. ASTM G 150 was developed to produce a crevice-free electrode for the study of critical pitting temperature. While a crevice gap is present between the test electrode and its holder, this space is continuously flushed with purified water to prevent the buildup of aggressive H^+ and Cl^- ions that would otherwise contribute to breakdown of passivity and lead to crevice attack.

Remote Crevice Assemblies. An electrochemical procedure requiring no stimulation other than that provided by the bulk environment/alloy reaction has been described in the literature. Techniques have been identified as either remote crevice or remote cathode tests (Ref 44, 65, 67, 68). Remote crevice assembly tests involve the physical separation but electrical connection of a small anode or crevice member and a larger cathodic member. Both are exposed in the bulk environment. Current between the two members can be monitored through a zero-resistance ammeter. The technique is quite capable of accurately identifying the time to initiation and subsequent propagation.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

Unlike other techniques, this procedure is able to separate the initiation and propagation phases of crevice corrosion. This capability is summarized by the plot of corrosion current normalized for initiation time in Fig. 11. Results show good reproducibility in both the trend of increasing current once initiation has occurred as well as the magnitude of current. The total charge (coulombs) is a measure of propagation, which is directly proportional to mass loss due to crevice corrosion.

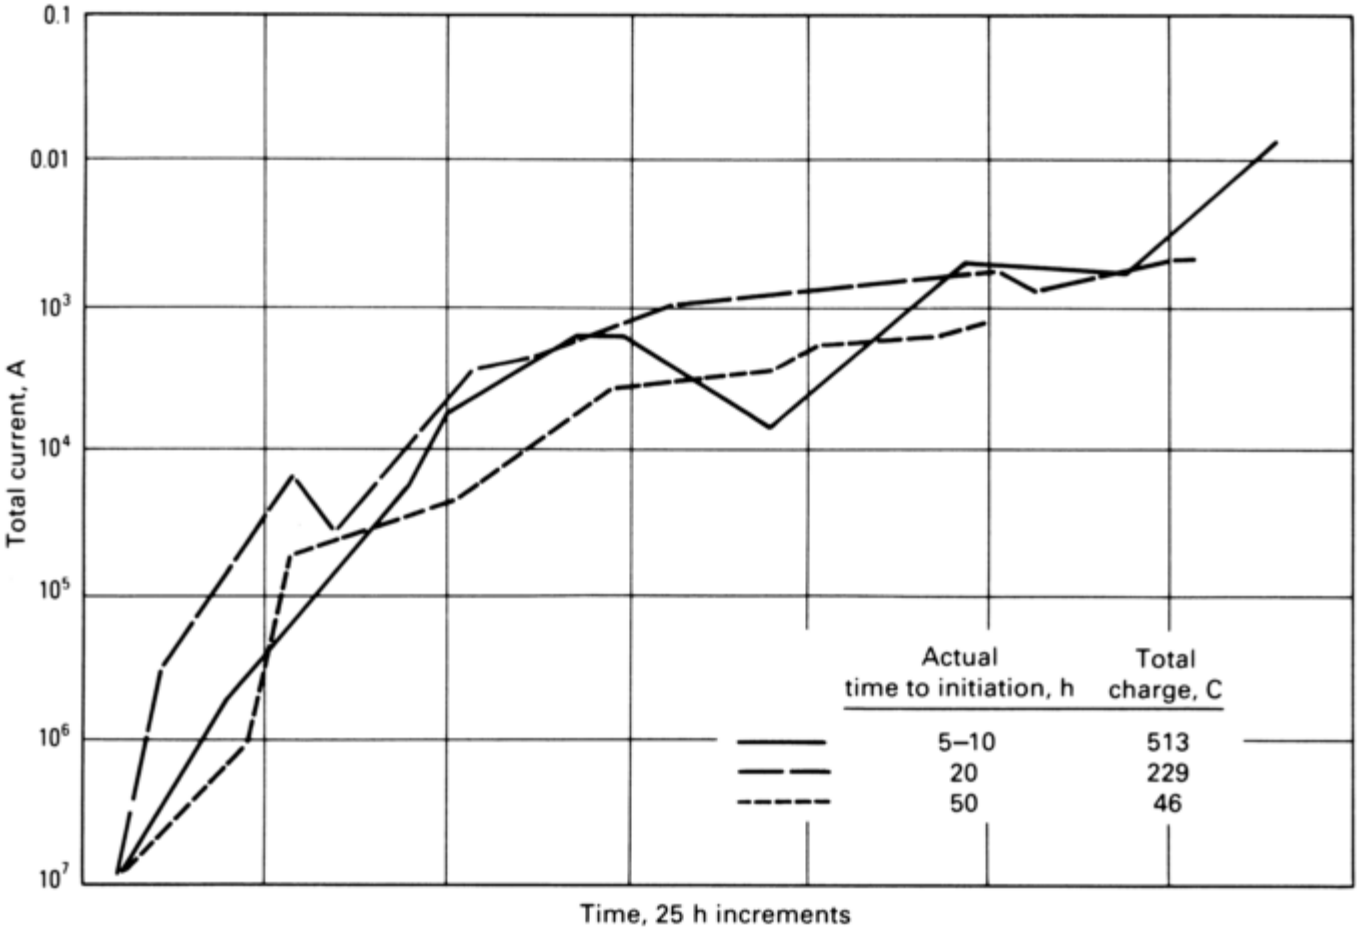

Fig. 11 Comparison of crevice corrosion propagation currents for UNS S31603 stainless steel remote crevice assemblies after normalizing initiation times. Source: Ref 2

Other Electrochemical Techniques. Other specialized tests have been developed, with varying degrees of success. One test involves the use of compartmentalized cells with anode and cathode members exposed to actual or simulated environments (Ref 69). Such tests have been used to evaluate the effects of changes in solution chemistry and surface area ratios. In addition, a vibrating electrode technique has been used to map variations in current density above a creviced stainless steel specimen of known crevice geometry (Ref 70). Such tests are more expensive and perhaps more conducive to mechanistic studies rather than for routinely characterizing alloy resistance to crevice corrosion. A number of electrochemical techniques that may be considered for crevice corrosion testing are reviewed in Ref 71 and 72.

Evaluating Crevice Corrosion

R.M. Kain, Consultant

Mathematical Modeling

Mathematical models have been developed to serve as research and predictive tools describing the many interrelated factors known to influence crevice corrosion behavior in chloride-containing environments (Ref 7, 73, 74). Model development is heavily dependent on input from laboratory confirmation tests using some of the evaluation methods described in this article. The PCA test, for example, was used extensively in support of the Sutton-Oldfield model (Ref 7, 16) and its subsequent refinements (Ref 73). In addition, results from potentiodynamic polarization tests were used to model passive current and CCS chemistries (Ref 16).

Figure 12 shows a sample model output describing the influence of crevice geometry on initiation behavior of UNS S31803 stainless steel (Ref 73). Figure 13 shows a sample model prediction of expected resistance for UNS S31600 in various chloride- and sulfate-containing waters (Ref 73).

Evaluating Galvanic Corrosion

Harvey P. Hack, Northrop Grumman Corporation

Introduction

GALVANIC CORROSION, although listed as one of the forms of corrosion, should instead be considered a type of corrosion mechanism, because galvanic effects can accelerate any of the other forms of corrosion. Any of the tests used for the more conventional forms of corrosion, therefore, such as uniform attack, pitting, or stress corrosion, can be used with modifications to determine galvanic-corrosion effects. The modifications can be as simple as connecting a second metal to the system or as complex as necessary to evaluate the appropriate parameters. A change in the method of data interpretation is often all that is needed to convert conventional test methods into galvanic-corrosion tests.

This article discusses component, model, electrochemical, and specimen tests.

Component Testing

Component testing is an especially useful technique for galvanic corrosion prediction. The materials in a system are often selected primarily for reasons other than galvanic compatibility. In complex components, such as valves or pumps, many different materials can be used in a geometric configuration that is extremely difficult to model. In more complicated cases, even the most basic prediction, such as which materials will suffer increased corrosion due to galvanic effects, may not be possible from simple laboratory tests. Therefore, component testing becomes the best method for predicting galvanic corrosion behavior in complex systems.

Conducting component tests for galvanic corrosion is similar to conducting component tests for any other type of corrosion. The same care must be taken to ensure that the materials, the operation of the component, and the environment are similar to those in service. However, one important difference with regard to galvanic corrosion is the relationship between the component being tested and the other elements of the system. It would, for example, be a waste of effort to expose a complicated piece of machinery in order to look for galvanic corrosion when the whole device is cathodically protected as a result of being attached to a protected structure. Alternatively, incorrect results would be obtained for the exposure of an isolated bronze mixed-material valve when the ultimate use is in a piping system made of a more noble metal that could accelerate the corrosion of the entire valve galvanically. When outside interactions of this type are possible, the interacting materials must be made part of the corrosion system by exposing the appropriate surface area of those materials electrically connected to, and in the same electrolyte as, the component being tested.

The principal advantages of component testing are the ease of interpretation of results and the lack of scaling or modeling uncertainties. The disadvantages include the high cost and the need for extremely sensitive measures of corrosion damage to obtain results within reasonable time periods.

Modeling

Even when the galvanic behavior of panels of the materials of interest is known, the geometrical arrangement of these materials may make galvanic-corrosion prediction difficult because of the effects of solution (electrolyte) resistance on the corrosion rates. An example of this is a heat-exchanger tube in a tubesheet. Assuming the tube to be anodic to the tubesheet, areas of the tube near the tubesheet will have low solution resistance to the cathode and will corrode rapidly, but areas away from the tubesheet will have a large solution resistance to the cathodic metal and will therefore corrode more slowly. In the reverse case, in which the tubesheet is anodic to the tube, the areas of the cathodic tube near the tubesheet will drive the galvanic corrosion of the tubesheet much more than distant areas will.

Computer Modeling. Geometrical effects can be modeled in computers by using such techniques as finite elements, boundary elements, and finite differences. The best computer models solve a version of the Laplace

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

equation for the electrolyte surrounding the corroding materials and use the polarization behavior of the material in question as boundary conditions at the metal/ electrolyte interface. The analysis is similar to the heat flow analysis, with potential analogous to temperature, current analogous to heat flux, and the polarization boundary condition analogous to a special nonlinear type of temperature- dependent convective flux.

The only data this type of model requires are the geometry, electrolyte conductivity, and polarization characteristics of the materials involved. The program generates potentials and current densities as a function of location, either of which can be related back to corrosion rate. The nonlinear boundary conditions make this type of computer modeling difficult to perform unless sufficient computing power is available. Computer modeling provides an excellent predictive tool for geometrical effects; however, it is still seen as less satisfying than physical scale- model exposures.

Physical scale modeling must model the solution resistance effects and the relative effects of polarization resistance and solution resistance to obtain accurate geometrical predictive capability. When solution resistance is important, the best type of scale modeling is the scaled conductivity exposure. In this type of exposure, the model is reduced in size by some factor from the original. To maintain proper potential and current distribution scaling, the electrolyte conductivity must also be reduced by the same factor. Any resistive coatings such as paints must also have their conductivity scaled similarly. In the case of paints, this can be accomplished by applying a thinner layer, reduced by the same scaling factor used for size, than the thickness used in practice.

For example, a one-tenth-scale model of a heat exchanger designed to operate in seawater with a conductivity of 4 S/cm should be placed in seawater diluted to a conductivity of 0.4 S/cm. In this case, the observed potential and current distributions will be the same between the model and the full-scale heat exchanger. For physical scale modeling, measurements that can be taken include potential distribution by the use of a movable reference electrode, corrosion depth as a function of location, and, if the model design permits, current to different parts of the structure and mass loss of certain model components.

Although less expensive than full-scale component testing, physical scale modeling has many of the disadvantages of component testing. In addition, a great inaccuracy in conductivity scaling stems from the fact that the polarization resistance of the materials in the system of interest is often a function of solution conductivity. Thus, changing solution conductivity may influence polarization resistance sufficiently to make the results of the model inaccurate. There is no experimental way to avoid this shortcoming.

Laboratory Testing

Laboratory tests fall into two categories: electrochemical tests in which the data are analyzed and reported in a way that assists galvanic-corrosion predictions and specimen exposures that may or may not be electrochemically monitored.

Electrochemical Tests

The use of electrochemical techniques to predict galvanic corrosion is summarized in Ref 1. The details that relate to testing techniques are discussed in the following paragraphs.

Galvanic Series. When the only information needed is which of the materials in the system are possible candidates for galvanically accelerated corrosion and which will be unaffected or protected, the information from a galvanic series in the appropriate medium is useful. Such a series is a list of freely corroding potentials of the materials of interest in the environment of interest arranged in order of potential (Fig. 1). The galvanic series is easy to use and is often all that is required to answer a simple galvanic-corrosion question. The

www.iran-mavad.com

مرجع مهندسی مواد و متالورژی

material with the most negative, or anodic, corrosion potential has a tendency to suffer accelerated corrosion when electrically connected to a material with a more positive, or noble, potential. The disadvantages include:

- No information is available on the rate of corrosion.
- Active-passive metals may display two widely differing potentials.
- Small changes in electrolyte can change the potentials significantly.
- Potentials may be time dependent.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

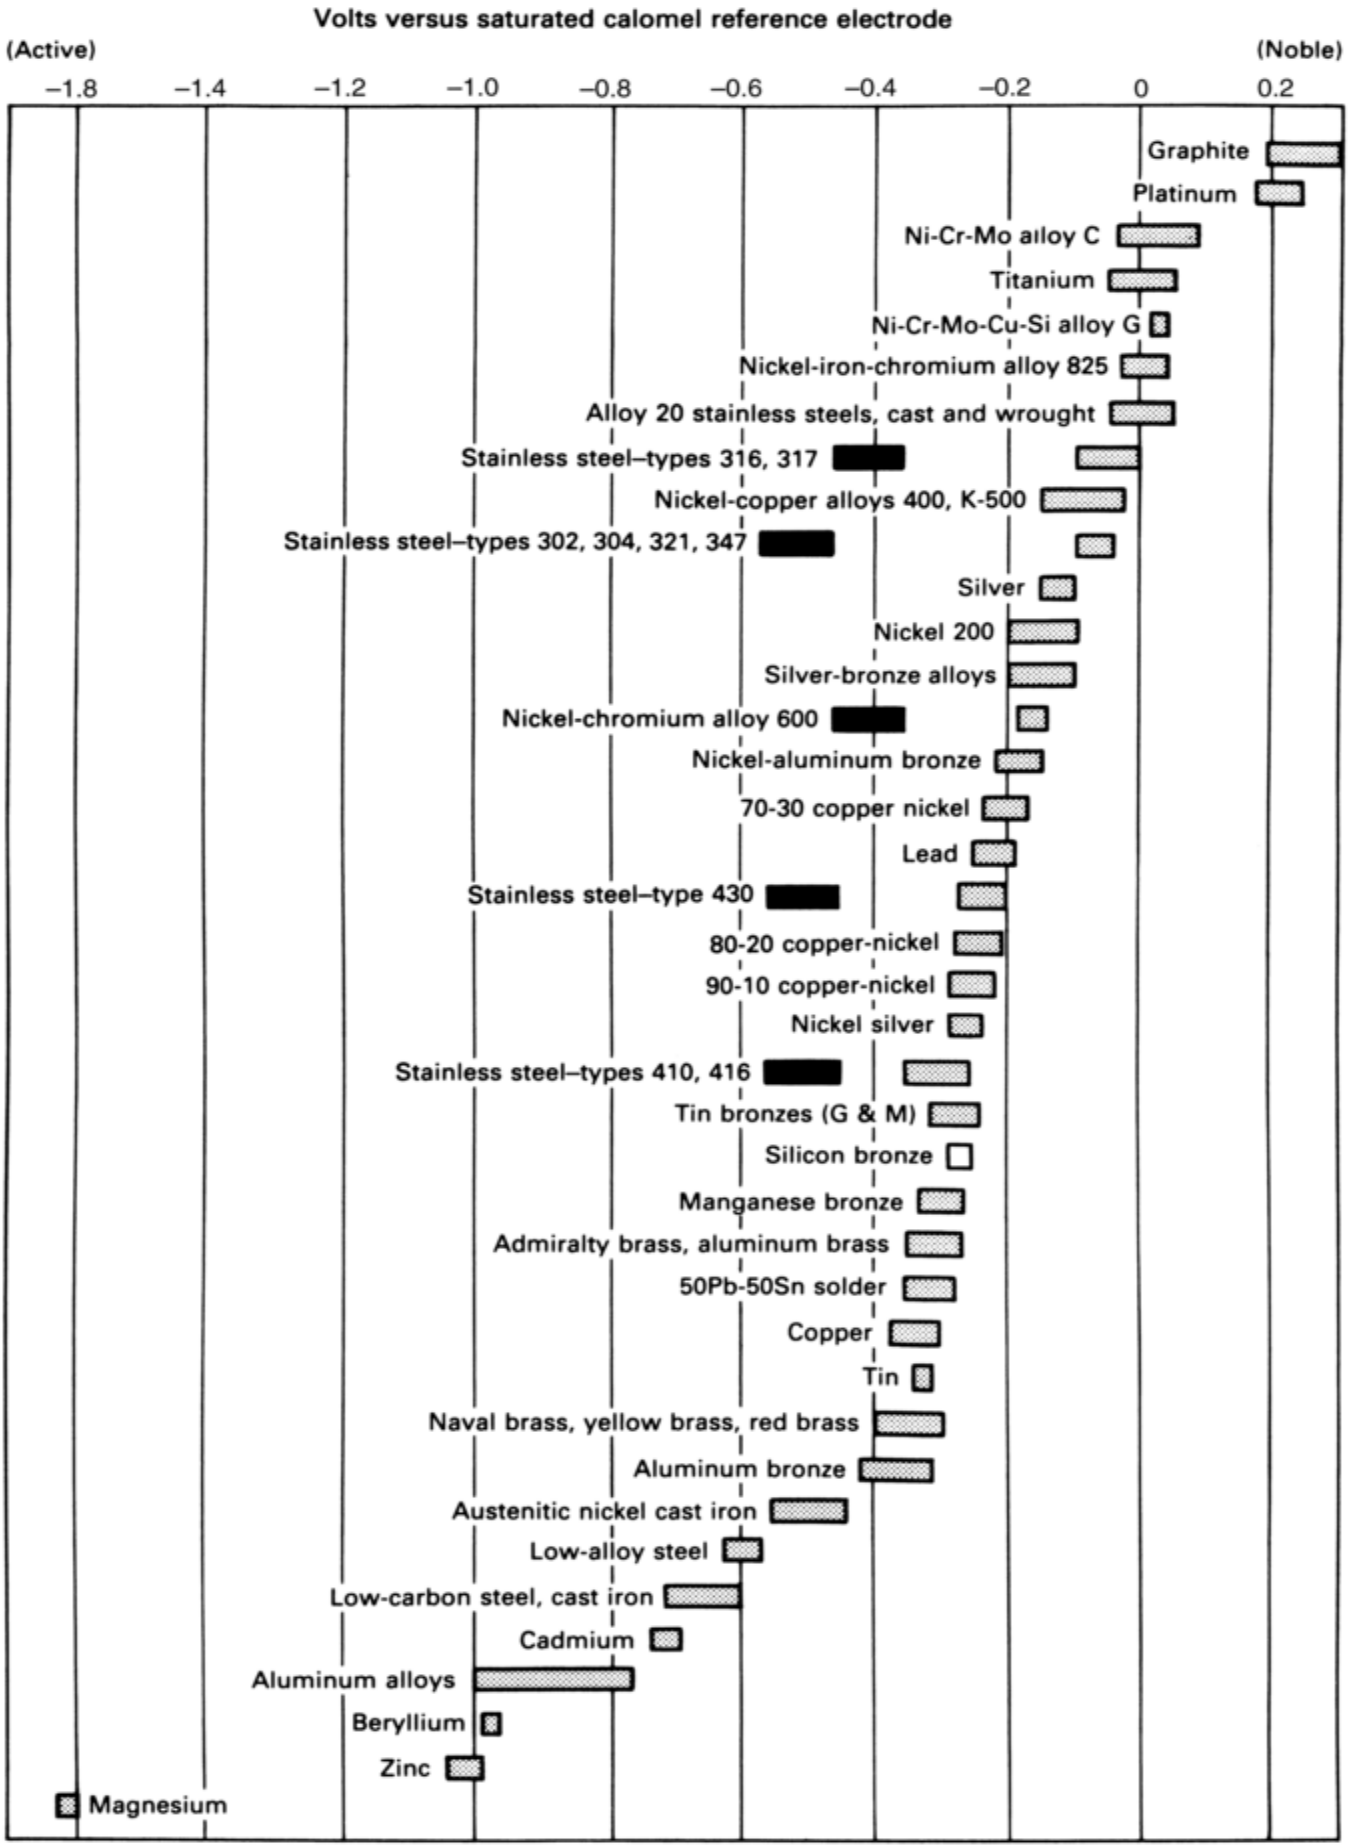

Fig. 1 Galvanic series for seawater. Dark boxes indicate active behavior of active-passive alloys.

www.iran_mavad.com
مرجع مهندسی مواد و متالورژی

Creating a galvanic series is a matter of measuring the corrosion potential of various materials of interest in the electrolyte of interest against a reference electrode half-cell, such as saturated calomel. This procedure is described in Ref 2. The details of such factors as meter resistance, reference cell selection, and measurement duration are also addressed in Ref 2. There is little difference from a normal reading of corrosion potential except for the measurement duration and the creation of a list ordered by potential.

To prepare a galvanic series that will be valid for the materials and environment of interest in service, all of the factors that affect the potential of those materials in that environment must be accounted for. These factors include material composition, heat treatment, surface preparation (mill scale, coatings surface finish, etc.), environmental composition (trace contaminants, dissolved gases, etc.), temperature, and flow rate. One important effect is exposure time, particularly on materials that form corrosion product layers. All of the precautions and warnings regarding the generation and use of a galvanic series are given in Ref 2.

Polarization Curves. More useful information on the rate of galvanic corrosion can be obtained by investigating the polarization behavior of the materials involved. This can be done by generating stepped potential or potentiodynamic polarization curves or by obtaining potentiostatic information on polarization behavior. The objective is to obtain a good indication of the amount of current required to hold each material at a given potential. Because all materials in the galvanic system must be at the same potential in systems with low solution resistivity, such as seawater, and because the sum of all currents flowing between the materials must equal 0 by Kirchoff's Law, the coupled potential of all materials and the galvanic currents flowing can be uniquely determined for the system. Faraday's Law can then be used to relate the corrosion rate to the galvanic current if the resulting potential of the anodic materials is well away from their corrosion potential, or the corrosion rate can be found as a function of potential by independent measurement.

Potentiodynamic polarization curves are generated by connecting the specimen of interest to a scanning potentiostat. This device applies whatever current is necessary between the specimen and a counterelectrode to maintain that specimen at a given potential versus a reference electrode half-cell placed near the specimen. The current required is plotted as a function of potential over a range that begins at the corrosion potential and proceeds in the direction (anodic or cathodic) required by that material. Such curves would be generated for each material of interest in the system. Additional information on the method for generating these curves is available in the article “Electrochemical Methods of Corrosion Testing” in this Volume and in Ref 3. The scan rate for potential must be chosen such that sufficient time is allowed for completion of electrical charging at the interface.

Potentiodynamic polarization is particularly effective for materials with time-independent polarization behavior. It is fast, relatively easy, and gives a reasonable, quantitative prediction of corrosion rates in many systems. However, potentiostatic techniques are preferred for time-dependent polarization. To establish polarization characteristics for time-dependent polarization, a series of specimens is used, each held to one of a series of constant potentials with a potentiostat while the current required is monitored as a function of time. After the current has stabilized or after a preselected time period has elapsed, the current at each potential is recorded. Testing of each specimen results in the generation of one potential/current data pair, which gives a point on the polarization curve for that material. The data are then interpolated to trace out the full curve. This technique is very accurate for time- dependent polarization but is expensive and time consuming. The individual specimens can be weighed before and after testing to determine corrosion rate as a function of potential, thus enabling the errors from using Faraday's Law to be easily corrected.

The process of predicting galvanic corrosion from polarization behavior can be illustrated by the example of a steel-copper system. Steel has the more negative corrosion potential and will therefore suffer increased corrosion on coupling to copper, but the amount of this corrosion must be predicted from polarization curves. If the polarization of each material is plotted as the absolute value of the log of current density versus potential and if the current density axis of each of these curves is multiplied by the wetted surface area of that material in the service application, then the result will be a plot of the total anodic current for steel and the total cathodic current for copper in this application as a function of potential (Fig. 2).

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

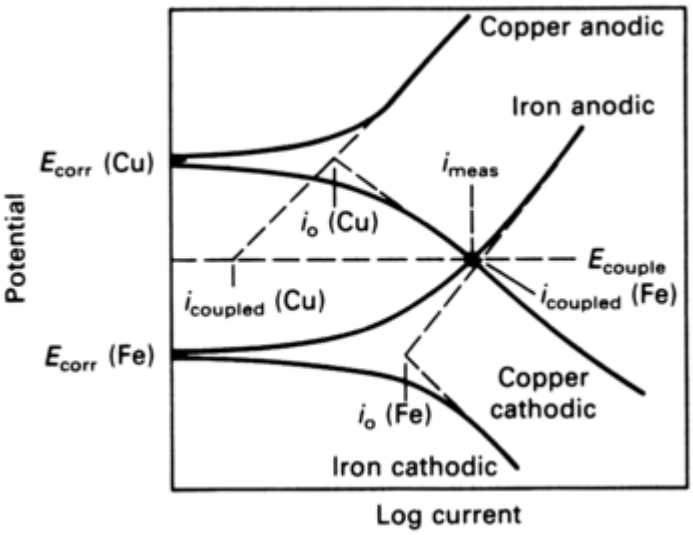

Fig. 2 Prediction of coupled potential and galvanic current from polarization diagrams. *i*, current; i_o, exchange current; E_{corr}, corrosion potential

Furthermore, when the two metals are electrically connected, the anodic current to the steel must be supplied by the copper; that is, the algebraic sum of the anodic and cathodic currents must equal 0. If the polarization curves for the two materials, normalized for surface area as described previously, are plotted together, this current condition is satisfied where the two curves intersect. This point of intersection allows for the prediction of the coupled potential of the materials and the galvanic current flowing between them from the intersection point. This procedure works if there is no significant electrolyte resistance between the two metals; otherwise, this resistance must be taken into account as described in Ref 4.

Specimen Exposures

Specimens for galvanic-corrosion testing include panels, wires, pieces of actual components, and other configurations of the materials of interest that are exposed in a process stream, a simulated service environment, or the actual environment. Specimens of the materials of interest are usually exposed in the same ratios of wetted or exposed areas as in the service application. The different materials are either placed in physical contact to provide electrical connection or are wired together such that the current between the materials can be monitored, usually as a function of time. Seldom can the effects of electrolyte resistance be included in this type of test, and the resistance is usually kept extremely low by appropriate relative placement of the materials.

Immersion. There are virtually no standardized tests for galvanic corrosion under immersion conditions, partly because the type of information needed, the extent of modeling of the service situation, and the type of system studied vary widely. This makes development of a standard test difficult. However, some general guidelines for galvanic-corrosion specimen testing in liquid electrolytes are given in Ref 5.

Immersion testing always involves an electrical connection between at least two dissimilar metals. This is usually accomplished with a wire, as in Fig. 3, although threaded mounting rods such as the assembly shown in Fig. 4 have also been used successfully for electrical connection. Soldered or brazed connections have the best electrical integrity.

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

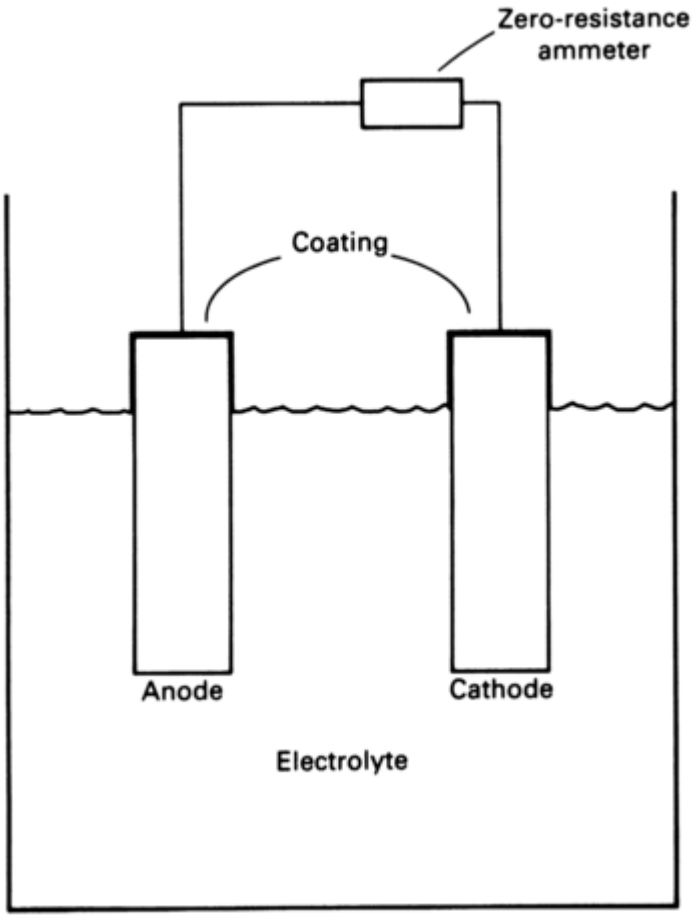

Fig. 3 Typical galvanic-corrosion immersion test setup using wire connections

www.iran-mavad.com
مرجع مهندسی مواد و متالورژی

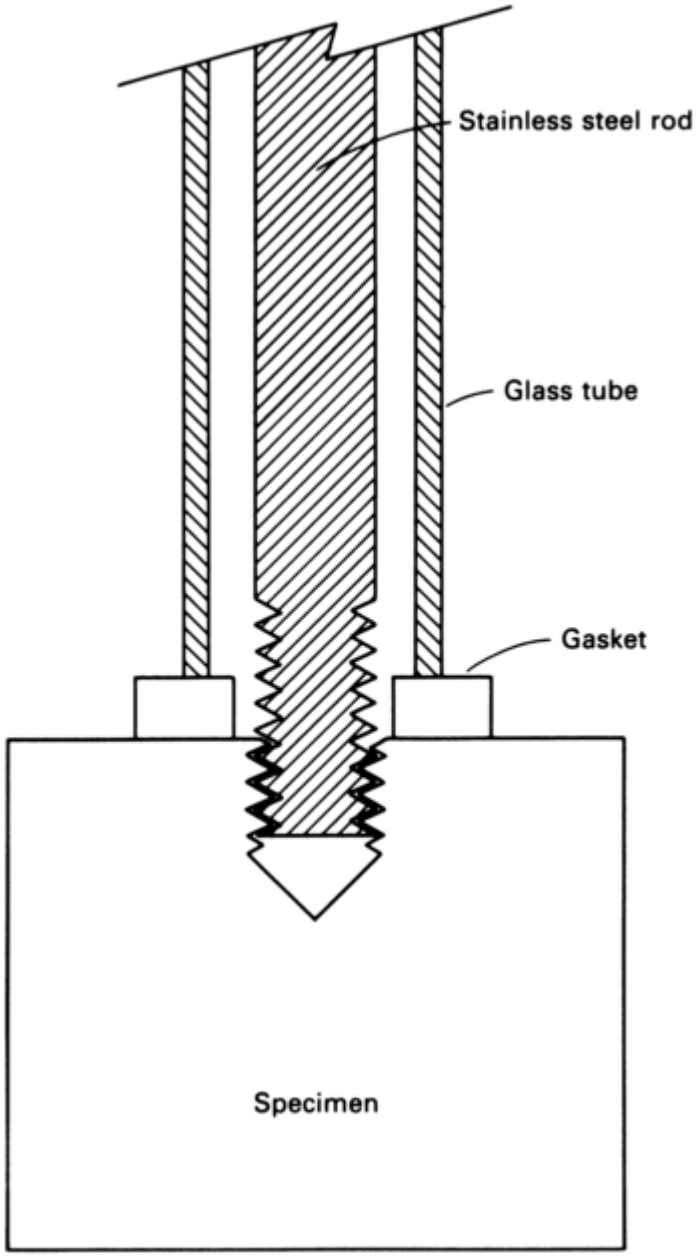

Fig. 4 Typical galvanic-corrosion test specimen using a threaded rod for mounting and electrical connection

The electrolyte must be excluded from the contact area by applying a sealant, such as silicone or epoxy; by keeping the joint area out of the electrolyte by partial immersion of the specimen, in which case a waterline area is created; or by use of a tube and gasket or O-ring seal, in the case of a threaded mounting rod. Mounting the specimen in a specially formulated epoxy has been found to be effective in minimizing crevice corrosion while maintaining a dry electrical connection. However, selection of the best epoxy formulation is difficult. Care must be taken that the sealant or gasket material is stable in the electrolyte being studied.

Almost any sealing procedure will create a potential area for crevice corrosion; thus, it is very difficult to study galvanic behavior independent of crevice-corrosion behavior. Control specimens may be run with similar crevices and no electrical connection, but because the reproducibility of crevice-corrosion behavior is not good, data scatter will be large. Under some circumstances, the galvanic effect of importance may be the acceleration of crevice-corrosion attack.
