**ASM HANDBOOK®**

**VOLUME  
19**

**FATIGUE AND  
FRACTURE**

*Fatigue and Fracture* was published in 1996 as Volume 19 of *ASM Handbook*. The Volume was prepared under the direction of the ASM International Handbook Committee.

## Foreword

The publication of this Volume marks the first time that the *ASM Handbook* series has dealt with fatigue and fracture as a distinct topic. Society members and engineers involved in the research, development, application, and analysis of engineering materials have had a long-standing interest and involvement with fatigue and fracture problems, and this reference book is intended to provide practical and comprehensive coverage of all aspects of these subjects.

Publication of *Fatigue and Fracture* also marks over 50 years of continuing progress in the development and application of modern fracture mechanics. Numerous Society members have been actively involved in this progress, which is typified by the seminal work of George Irwin ("Fracture Dynamics," *Fracturing of Metals*, ASM, 1948). Since that time period, fracture mechanics has become a vital engineering discipline that has been integrally involved in helping to prevent the failure of essentially all types of engineered structures.

Likewise, fatigue and crack growth have also become of primary importance to the development and use of advanced structural materials, and this Volume addresses the wide range of fundamental, as well as practical, issues involved with these disciplines.

We believe that our readers will find this Handbook useful, instructive, and informative at all levels. We also are especially grateful to the authors and reviewers who have made this work possible through their generous commitments of time and technical expertise. To these contributors we offer our special thanks.

William E. Quist

President, ASM International

Michael J. DeHaemer

Managing Director, ASM International

## Preface

This volume of the *ASM Handbook* series, *Fatigue and Fracture*, marks the first separate Handbook on an important engineering topic of long-standing and continuing interest for both materials and mechanical engineers at many levels. Fatigue and fracture, like other forms of material degradation such as corrosion and wear, are common engineering concerns that often limit the life of engineering materials. This perhaps is illustrated best by the "Directory of Examples of Failure Analysis" contained in Volume 10 of the 8th Edition *Metals Handbook*. Over a third of all examples listed in

that directory are fatigue failures, and well over half of all failures are related to fatigue, brittle fracture, or environmentally-assisted crack growth.

The title *Fatigue and Fracture* also represents the decision to include fracture mechanics as an integral part in characterizing and understanding not only ultimate fracture but also "subcritical" crack growth processes such as fatigue. The development and application of fracture mechanics has steadily progressed over the last 50 years and is a field of long-standing interest and involvement by ASM members. This perhaps is best typified by the seminal work of George Irwin in *Fracturing of Metals* (ASM, 1948), which is considered by many as the one of the key beginnings of modern fracture mechanics based from the foundations established by Griffith at the start of this century.

This Handbook has been designed as a resource for basic concepts, alloy property data, and the testing and analysis methods used to characterize the fatigue and fracture behavior of structural materials. The overall intent is to provide coverage for three types of readers: i) metallurgists and materials engineers who need general guidelines on the practical implications of fatigue and fracture in the selection, analysis or application structural materials; ii) mechanical engineers who need information on the relative performance and the mechanistic basis of fatigue and fracture resistance in materials; and iii) experts seeking advanced coverage on the scientific and engineering models of fatigue and fracture.

Major emphasis is placed on providing a multipurpose reference book for both materials and mechanical engineers with varying levels of expertise. For example, several articles address the basic concepts for making estimates of fatigue life, which is often necessary when data are not available for a particular alloy condition, product configuration, or stress conditions. This is further complemented with detailed coverage of fatigue and fracture properties of ferrous, nonferrous, and nonmetallic structural materials. Additional attention also is given to the statistical aspects of fatigue data, the planning and evaluation of fatigue tests, and the characterization of fatigue mechanisms and crack growth.

Fracture mechanics is also thoroughly covered in Section 4, from basic concepts to detailed applications for damage tolerance, life assessment, and failure analysis. The basic principles of fracture mechanics are introduced with a minimum of mathematics, followed by practical introductions on the fracture resistance of structural materials and the current methods and requirements for fracture toughness testing. Three authoritative articles further discuss the use of fracture mechanics in fracture control, damage tolerance analysis, and the determination of residual strength in metallic structures. Emphasis is placed on linear-elastic fracture mechanics, although the significance of elastic-plastic fracture mechanics is adequately addressed in these key articles.

Further coverage is devoted to practical applications and examples of fracture control in weldments, process piping, aircraft systems, failure analysis, and more advanced topics such as high-temperature crack growth and thermo-mechanical fatigue. Extensive fatigue and fracture property data are provided in Sections 5 through 7, and the Appendices include a detailed compilation of fatigue strength parameters and an updated summary of commonly used stress-intensity factors.

Once again, completion of this challenging project under the auspices of the Handbook Committee is made possible by the time and patience of authors who have contributed their work. Their efforts are greatly appreciated along with the guidance from reviewers and the Editorial Review Board.

S. Lampman

Technical Editor

## General Information

### Officers and Trustees of ASM International (1995-1996)

#### Officers

- **WILLIAM E. QUIST** PRESIDENT AND TRUSTEE BOEING COMMERCIAL AIRPLANE GROUP
- **GEORGE KRAUSS** VICE PRESIDENT AND TRUSTEE COLORADO SCHOOL OF MINES

- **MICHAEL J. DEHAEMER** SECRETARY AND MANAGING DIRECTOR ASM INTERNATIONAL
- **THOMAS F. MCCARDLE** TREASURER KOLENE CORPORATION
- **JOHN V. ANDREWS** IMMEDIATE PAST PRESIDENT ALLVAC

#### Trustees

- **AZIZ I. ASPHAHANI** CARUS CHEMICAL COMPANY
- **NICHOLAS F. FIORE** CARPENTER TECHNOLOGY CORPORATION
- **MERTON C. FLEMINGS** MASSACHUSETTS INSTITUTE OF TECHNOLOGY

## Staff

ASM International staff who contributed to the development of the Volume included Steven R. Lampman, Technical Editor; Grace M. Davidson, Manager of Handbook Production; Faith Reidenbach, Chief Copy Editor; Randall L. Boring, Production Coordinator; Amy Hammel, Editorial Assistant; and Scott D. Henry, Manager of Handbook Development. Editorial assistance was provided by Nikki DiMatteo, Kathleen S. Dragolich, Kelly Ferjutz, Heather Lampman, Kathleen Mills, and Mary Jane Riddlebaugh. The Volume was prepared under the direction of William W. Scott, Jr., Director of Technical Publications.

## Conversion to Electronic Files

*ASM Handbook*, Volume 19, *Fatigue and Fracture* was converted to electronic files in 1998. The conversion was based on the Second printing (1997). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Marlene Seuffert, Gayle Kalman, Scott Henry, Robert Braddock, Alexandra Hoskins, and Erika Baxter. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

## Industrial Significance of Fatigue Problems

David W. Hoepfner, Department of Mechanical Engineering, The University of Utah

---

### Introduction

THE DISCOVERY of fatigue occurred in the 1800s when several investigators in Europe observed that bridge and railroad components were cracking when subjected to repeated loading. As the century progressed and the use of metals expanded with the increasing use of machines, more and more failures of components subjected to repeated loads were recorded. By the mid 1800s A. Wohler (Ref 1) had proposed a method by which the failure of components from repeated loads could be mitigated, and in some cases eliminated. This method resulted in the stress-life response diagram approach and the component test model approach to fatigue design.

Undoubtedly, earlier failures from repeated loads had resulted in failures of components such as clay pipes, concrete structures, and wood structures, but the requirement for more machines made from metallic components in the late 1800s stimulated the need to develop design procedures that would prevent failures from repeated loads of all types of equipment. This activity was intensive from the mid-1800s and is still underway today. Even though much progress has been made, developing design procedures to prevent failure from the application of repeated loads is still a daunting task. It involves the interplay of several fields of knowledge, namely materials engineering, manufacturing engineering, structural analysis (including loads, stress, strain, and fracture mechanics analysis), nondestructive inspection and evaluation, reliability engineering, testing technology, field repair and maintenance, and holistic design procedures. All of these must be placed in a consistent design activity that may be referred to as a fatigue design policy. Obviously, if other time-related failure modes occur concomitantly with repeated loads and interact synergistically, then the task becomes even more challenging. Inasmuch as humans always desire to use more goods and place more demands on the things we can design and produce, the challenge of fatigue is always going to be with us.

Until the early part of the 1900s, not a great deal was known about the physical basis of fatigue. However, with the advent of an increased understanding of materials, which accelerated in the early 1900s, a great deal of knowledge has been developed about repeated load effects on engineering materials. The procedures that have evolved to deal with repeated loads in design can be reduced to four:

- The stress-life approach
- The strain-life approach
- The fatigue-crack propagation approach (part of a larger design activity that has become known as the damage-tolerant approach)
- The component test model approach

### What is Fatigue?

*Fatigue* is a technical term that elicits a degree of curiosity. When citizens read or hear in their media of another fatigue failure, they wonder whether this has something to do with getting tired or "fatigued" as they know it. Such is not the case.

One way to explain fatigue is to refer to the ASTM standard definitions on fatigue, contained in ASTM E 1150. It is difficult, if not impossible, to carry on intelligent conversations if discussions on fatigue do not use a set of standard definitions such as E 1150. Within E 1150, there are over 75 terms defined, including the term *fatigue*: "fatigue (Note 1): the *process of progressive localized permanent structural change* occurring in a material subjected to conditions that produce *fluctuating stresses and strains* at some *point or points* and that may culminate in *cracks or complete fracture* after a sufficient number of fluctuations (Note 2). Note 1--In glass technology static tests of considerable duration are

called 'static fatigue' tests, a type of test generally designated as stress-rupture. Note 2--Fluctuations may occur both in load and with time (frequency) as in the case of 'random vibration'." (Ref 2).

The words in italics (emphasis added) are viewed as key words in the definition. These words are important perspectives on the phenomenon of fatigue:

- Process
- Progressive
- Localized
- Permanent structural change
- Fluctuating stresses and strains
- Point or points
- Cracks or complete fracture

The idea that fatigue is a *process* is critical to dealing with it in design and to the characterization of materials as part of design. In fact, this idea is so critical that the entire conceptual view of fatigue is affected by it! Another critical idea is the idea of *fluctuating stresses and strains*. The need to have fluctuating (repeated or cyclic) stresses acting under either constant amplitude or variable amplitude is critical to fatigue. When a failure is analyzed and attributed to fatigue, the only thing known at that point is that the loads (the stresses/strains) were fluctuating. Nothing is necessarily known about the *nucleation* of damage that forms the origin of fatigue cracks.

## Design for Fatigue Prevention

In design for fatigue and damage tolerance, one of two initial assumptions is often made about the state of the material. Both of these are related to the need to invoke continuum mechanics to make the stress/strain/fracture mechanics analysis tractable:

- The material is an ideal homogeneous, continuous, isotropic continuum that is free of defects or flaws.
- The material is an ideal homogeneous, isotropic continuum but contains an ideal cracklike discontinuity that may or may not be considered a defect or flaw, depending on the entire design approach.

The former assumption leads to either the stress-life or strain-life fatigue design approach. These approaches are typically used to design for finite life or "infinite life." Under both assumptions, the material is considered to be free of defects, except insofar as the sampling procedure used to select material test specimens may "capture" the probable "defects" when the specimen locations are selected for fatigue tests. This often has proved to be an unreliable approach and has led, at least in part, to the damage-tolerant approach.

Another possible difficulty with these assumptions is that inspectability and detectability are not inherent parts of the original design approach. Rather, past and current experience guide field maintenance and inspection procedures, if and when they are considered.

The damage-tolerant approach is used to deal with the possibility that a crack-like discontinuity (or multiple ones) will escape detection in either the initial product release or field inspection practices. Therefore, it couples directly to nondestructive inspection (NDI) and evaluation (NDE). In addition, the potential for initiation of crack propagation must be considered an integral part of the design process, and the subcritical crack growth characteristics under monotonic, sustained, and cyclic loads must be incorporated in the design. The final instability parameter, such as plane strain

fracture toughness ( $K_{Ic}$ ), also must be incorporated in design. The damage-tolerant approach is based on the ability to track the damage throughout the entire life cycle of the component/system. It therefore requires extensive knowledge of the above issues, and it also requires that fracture (or damage) mechanics models be available to assist in the evaluation of potential behavior. As well, material characterization procedures are needed to ensure that valid evaluation of the required material "property" or response characteristic is made. NDI must be performed to ensure that probability-of-detection determinations are made for the NDI procedure(s) to be used. This approach has proved to be reliable, especially for safety-critical components.

The above approaches often are used in a complementary sense in fatigue design. The details of all three approaches are discussed in this Volume.

The *fatigue process* has proved to be very difficult to study. Nonetheless, extensive progress on understanding the phases of fatigue has been made in the last 100 years or so. It now is generally agreed that four distinct phases of fatigue may occur (Ref 3, 4):

- Nucleation
- Structurally dependent crack propagation (often called the "short crack" or "small crack" phase)
- Crack propagation that is characterizable by either linear elastic fracture mechanics, elastic-plastic fracture mechanics, or fully plastic fracture mechanics
- Final instability

Each of these phases is an extremely complex process (or may involve several processes) in and of itself. For example, the nucleation of "fatigue" cracks is extremely difficult to study, and even "pure fatigue" mechanisms can be very dependent on the intrinsic makeup of the material. Obviously, when one decides to pursue the nucleation of cracks in a material, one has already either assumed that the material is crack-free or has proved it! The assumption is the easier path and the one most often taken. When extraneous influences are involved in nucleation, such as temperature effects (e.g., creep), corrosion of all types, or fretting, the problem of modeling the damage is formidable. In recent years, more research has been done on the latter issues, and models for this phase of life are beginning to emerge.

## Industrial Significance

There is little doubt that fatigue plays a significant role in all industrial design applications. Many components are subjected to some form of fluctuating stress/strain, and thus fatigue potentially plays a role in all such cases. However, it is still imperative that all designs consider those aspects of nucleation processes other than fatigue that may act to nucleate cracks that could propagate under the influence of cyclic loads. The intrinsic state of the material and all potential sources of cracks must also be evaluated.

Nonetheless, fatigue is a significant and often a critical factor in the testing, analysis, and design of engineering materials for machines, structures, aircraft, and power plants. An important engineering advance of this century is also the transfer of the multi-stage fatigue process from the field to the laboratory. In order to study, explain, and qualify component designs, or to conduct failure analyses, a key engineering step is often the simulation of the problem in the laboratory. Any simulation is, of course, a compromise of what is practical to quantify, but the study of the multi-stage fatigue process has been greatly advanced by the combined methods of strain-control testing and the development fracture mechanics of fatigue crack growth rates. This combined approach (Fig. 1) is a key advance that allows better

understanding and simulation of both crack nucleation in regions of localized strain and the subsequent crack growth mechanisms outside the plastic zone. This integration of fatigue and fracture mechanics has had important implications in many industrial applications for mechanical and materials engineering.

## Fracture and Structure

C. Quinton Bowles, University of Missouri-Columbia/Kansas City

---

## Introduction

IT IS DIFFICULT to identify exactly when the problems of failure of structural and mechanical equipment became of critical importance; however, it is clear that failures that cause loss of life have occurred for over 100 years (Ref 1, 2). Throughout the 1800s bridges fell and pressure vessels blew up, and in the late 1800s railroad accidents in the United Kingdom were continually reported as "The most serious railroad accident of the week"! Those in the United States also

have heard the hair-raising stories of the Liberty ships built during World War II. Of 4694 ships considered in the final investigation, 24 sustained complete fracture of the strength deck, and 12 ships were either lost or broke in two. In this case, the need for tougher structural steel was even more critical because welded construction was used in shipbuilding instead of riveted plate. In riveted plate construction, a running crack must reinitiate every time it runs out of a plate. In contrast, a continuous path is available for brittle cracking in a welded structure, which is why low notch toughness is a more critical factor for long brittle cracks in welded ships.

Similar long brittle cracks are less likely or rare in riveted ships, which were predominant prior to welded construction. Nonetheless, even riveted ships have provided historical examples of long brittle fracture due, in part, from low toughness. In early 1995, for example, the material world was given the answer to an old question, "*What was the ultimate cause of the sinking of the Titanic?*" True, the ship hit an iceberg, but it now seems clear that because of brittle steel, "high in sulfur content even for its time" (Ref 3), an impact which would clearly have caused damage, perhaps would not have resulted in the ultimate separation of the Titanic in two pieces where it was found in 1985 by oceanographer Bob Ballard. During the undersea survey of the sunken vessel with Soviet Mir submersibles, a small piece of plate was retrieved from 12,612 feet below the ocean's surface. Examination by spectroscopy revealed a high sulfur content, and a Charpy impact test revealed the very brittle nature of the steel (Ref 3). However, there was some concern that the high sulfur content was, in some way, the result of eighty years on the ocean floor at 6,000 psi pressures. Subsequently, the son of a 1911 shipyard worker remembered a rivet hole plug which his father had saved as a memento of his work on the Titanic. Analysis of the plug revealed the same level of sulfur exhibited by the plate from the ocean floor. In the years following the loss of the Titanic metallurgists have become well aware of the detrimental effect of high sulfur content on fracture.

There are numerous other historical examples where material toughness was inadequate for design. The failures of cast iron rail steel for engine loads in the 1800s is one example. A large body of scientific folklore has arisen to explain structural material failures, almost certainly caused by a lack of tools to investigate the failures. The author was recently startled to read an article on the building of the Saint Lawrence seaway that described the effect of temperature on equipment: "The crawler pads of shovels and bulldozers subject to stress cracked and crumbled. Drive chains flew apart, cables snapped and fuel lines iced up. . . *And anything made of metal, especially cast metal, was liable to crystallize and break into pieces* (Ref 4). It is difficult to realize that there still exists a concept of metal crystallization as a result of deformation that in turn leads to failure. Clearly, the development of fluorescence and diffraction x-ray analysis, transmission and scanning electron microscopes, high-quality optical microscopy, and numerous other analytical instruments in the last 75 years has allowed further development of dislocation theory and clarification of the mechanisms of deformation and fracture at the atomic level.

During the postwar period, predictive models for fracture control also were pursued at the engineering level from the work of Griffith, Orowan, and Irwin. Since the paper of Griffith in 1920 (Ref 5, 6) and the extensions of his basic theory by Irwin (Ref 7) and others, we have come to realize that the design of structures and machines can no longer under all conditions be based on the elastic limit or yield strength. Griffith's basic theory is applicable to all fractures in which the energy required to make the new surfaces can be supplied from the store of energy available as potential energy, in the form of elastic strain energy. The elastic strain energy per unit of volume varies with the square of the stress, and hence increases rapidly with increases in the stress level. One does not need to go to very high stress levels to store enough energy to drive a crack, even though this crack can be accompanied by considerable plastic deformation, and hence consume considerable energy. Thus, self-sustaining cracks can propagate at fairly low stress levels, a phenomenon that is briefly reviewed in this article along with the microstructural factors that influence toughness.

## Fracture Behavior

In most structural failures, final fracture is usually abrupt after some sort of material or design flaw (such as a material defect, improper condition, or poor design detail) that is aggravated by a crack growth process that causes the crack to reach a critical size for final fracture. The cracking process occurs slowly over the service life from various crack growth mechanisms such as fatigue, stress-corrosion cracking, creep, and hydrogen-induced cracking. Each of these cracking mechanisms has certain characteristic features that are used in failure analysis to determine the cause of cracking or crack growth.

In contrast, the final fracture is usually abrupt and occurs from cleavage, rupture, or intergranular fracture (which may involve a combination of rupture and cleavage). Fracture mechanisms also are termed "ductile," although these terms must be defined on either a macroscopic or microscopic level. This distinction is important, because a fracture may be termed "brittle" from an engineering (macroscopic) perspective, while the underlying metallurgical (microscopic) mechanism could be termed either ductile or brittle. For metallurgists, cleavage is often referred to as brittle fracture and dimple rupture is considered ductile fracture. However, these terms must be used with caution, because many service failures occur by dimple rupture, even though most of these failures undergo very little overall (macroscopic) plastic deformation from an engineering point of view.

The majority of structural failures are of the more worrisome type, brittle fracture, and these almost invariably initiate at defects, notches, or discontinuities. Cracks resulting from machining, quenching, fatigue, hydrogen embrittlement, liquid-metal embrittlement, or stress corrosion also lead to brittle fracture. In fact, the single most prevalent initiator of brittle fracture is the fatigue crack, which conservatively accounts for at least 50% of all brittle fractures in manufactured products by one account (Ref 8).

In contrast, service failure by macroscopic ductile failure is relatively infrequent (although the microscopic mechanisms of ductile fracture can ultimately lead to macroscopic brittle fracture). Typically, macroscopic ductile fracture occurs from overloads as a result of the part having been underdesigned (a term that includes the selection and heat treatment of the materials) for a specific set of service conditions, improperly fabricated, or fabricated from defective materials. Ductile fracture may also be the result of the part having been abused (that is, subjected to conditions of load and environment that exceeded those of the intended use).

This section briefly introduces the macroscopic and microscopic basis of understanding and modeling fracture resistance, while other articles in this Volume expand upon the microscopic and macroscopic basis of fatigue and fracture in engineering research and practice. More detailed information on the mechanisms of ductile and brittle fracture is given in the article "Micromechanisms of Monotonic and Cyclic Crack Growth" in this Volume.

**Griffith Theory and the Specific Work of Fracture.** The origins of modern fracture mechanics for engineering practice may be traced to Griffith (Ref 5, 6), who established an energy-release-rate criterion for brittle materials. Observations of the fracture strength of glass rods had shown that the longer the rod, the lower the strength. Thus the idea of a distribution of flaw sizes evolved, and it was discovered that the longer the rod, the larger the chance of finding a large natural flaw. This physical insight led to an instability criterion that considered the energy released in a solid at the time a flaw grew catastrophically under an applied stress.

From the theory of elasticity comes the concept that the strain energy contained in an elastic body per unit volume is simply the area under the stress-strain curve, or:

$$U_0 = \frac{\sigma^2}{2E} \quad (\text{EQ 1})$$

where  $\sigma$  is the applied stress and  $E$  is Young's modulus. However, there is a reduction (that is, a release) of energy in an elastic body containing a flaw or a crack because of the inability of the unloaded crack surfaces to support a load. We shall assume that the volume of material whose energy is released is the area of an elliptical region around the crack (as shown in Fig. 1) times the plate thickness,  $B$ ; the volume is  $\pi(2a) \cdot (a)B$ . This is based on the area of an ellipse being  $\pi$

$r_a r_b$ , where  $r_a$  and  $r_b$  are the major and minor radii of the ellipse. Then, the total energy released from the body due to the crack is the energy per unit volume times the volume, which is:

$$U = \pi(2a) (a)B \frac{\sigma^2}{2E} = \frac{\pi\sigma^2 a^2 B}{E} \quad (\text{EQ 2})$$

**Fig. 1** Schematic illustration of the concept of energy release around a center crack in a loaded plate

In ideally brittle solids, the released energy can be offset only by the surface energy absorbed, which is:

$$W = (2AB) (2\gamma_s) = 4AB\gamma_s \quad (\text{EQ 3})$$

where  $2aB$  is the area of the crack and  $2\gamma_s$  is twice the surface energy per unit area (because there are two crack surfaces).

Griffith's energy-balance criterion, in the simplest sense, is that crack growth will occur when the amount of energy released due to an increment of crack advance is larger than the amount of energy absorbed:

$$\frac{dU}{da} \geq \frac{dW}{da} \quad (\text{EQ 4})$$

Performing the derivatives indicated in Eq 4 and rearranging gives the Griffith criterion for crack growth:

$$\sigma\sqrt{\pi a} = \sqrt{2E\gamma_s} \quad (\text{EQ 5})$$

Fracture theory was built upon this criterion in the early 1940s by considering that the critical strain energy release rate,  $G_c$ , required for crack growth was equal to twice an effective surface energy,  $\gamma_{\text{eff}}$ :

$$G_c = 2\gamma_{\text{EFF}} \quad (\text{EQ 6})$$

This  $\gamma_{\text{eff}}$  is predominantly the plastic energy absorption around the crack tip, with only a small part due to the surface energy of the crack surfaces. Then, with the development of complex variable and numerical techniques to define the stress fields near cracks, this energy view was supplemented by stress concepts (i.e., the stress-intensity factor,  $K$ , and a critical value of  $K$  for crack growth,  $K_c$ ). Replacing  $\gamma_s$  with  $\gamma_{\text{eff}}$  in Eq 5 and noting that the energy and stress concepts are essentially identical (that is,  $K = \sqrt{EG}$ ) gives:

$$K_c = \sqrt{EG_c} = \sigma\sqrt{\pi a} \quad (\text{EQ 7})$$

which is the crack-growth-criterion equivalent of Eq 1. Thus,  $K_c$  is the critical value of  $K$  that, when it is exceeded by a combination of applied stress and crack length, will lead to crack growth. For thick-plate plane-strain conditions, this critical value became known as the plane-strain fracture toughness,  $K_{Ic}$ , and any combination of applied stress and crack length that exceeds this value could produce unstable crack growth, as indicated schematically in Fig. 2(a) (linear-elastic). This forms the basis for understanding the relation between flaw size and fracture stress, which can be significantly lower than yield strengths, depending on crack length and geometry (Fig. 3).

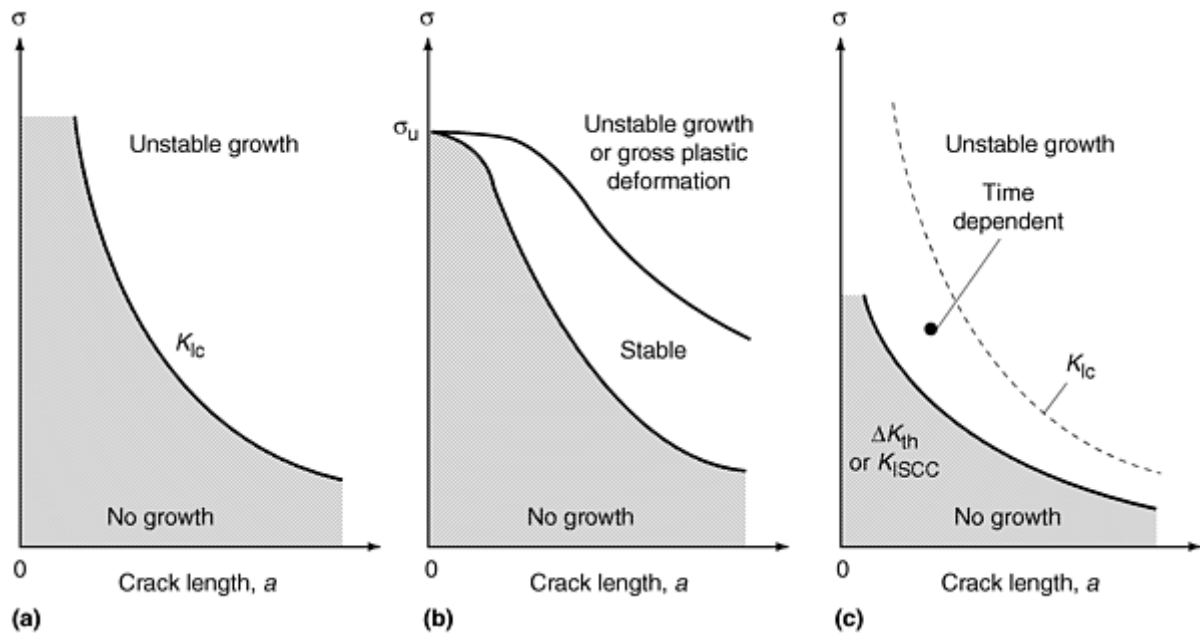

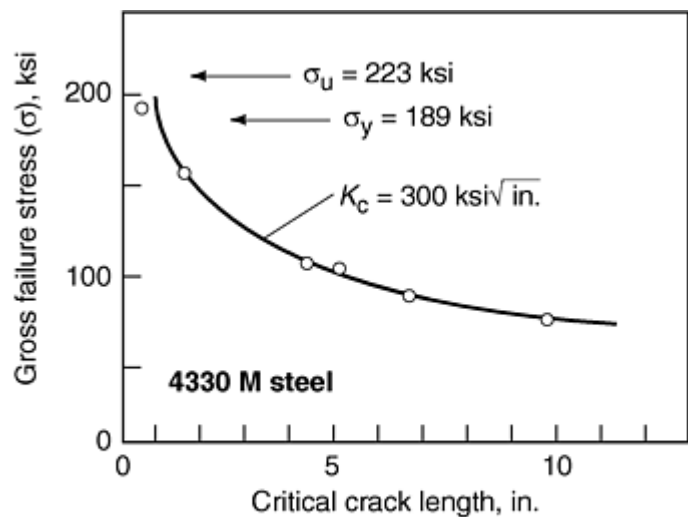

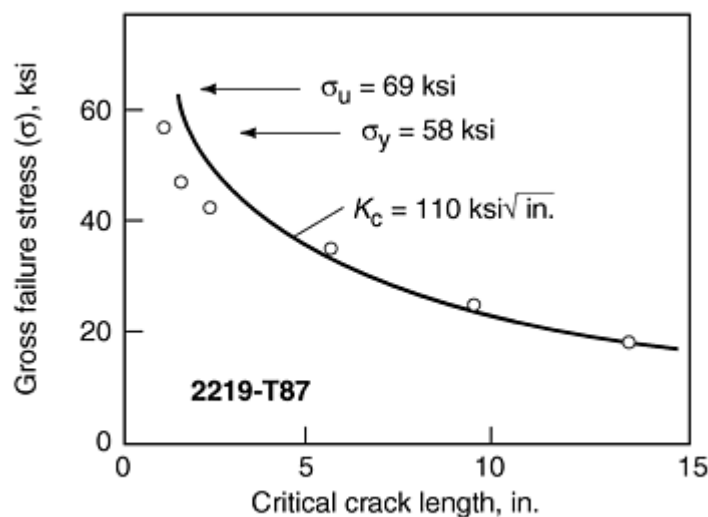

Fig. 2 Relationships between stress and crack length, showing regions and types of crack growth. (a) Linear-elastic. (b) Elastic-plastic. (c) Subcritical

(a)

(b)

**Fig. 3** Influence of crack length on gross failure stress for center-cracked plate. (a) Steel plate, 36 in. wide, 0.14 in. thick, room temperature, 4330 M steel, longitudinal direction. (b) Aluminum plate, 24 in. wide, 0.1 in. thick, room temperature, 2219-T87 aluminum alloy, longitudinal direction. Source: Ref 9

In work with tougher, lower-strength materials, it was later noted that stable slow crack growth could occur even though accompanied by considerable plastic deformation. Such phenomena led to the nonlinear  $J$ -integral and  $R$ -curve concepts, which can be used to predict the onset of stable slow crack growth and final instability under elastic-plastic conditions, as noted in Fig. 2(b). Finally, the fracture mechanics approach was applied to characterize subcritical crack growth phenomena where time-dependent slow crack growth,  $da/dt$ , or cyclic crack growth,  $da/dN$ , may be induced by special environments or fatigue loading. For combinations of stress and crack length above some environmental threshold,  $K_{Isc}$ , or fatigue threshold,  $\Delta K_{th}$ , subcritical growth occurs, as indicated in Fig. 2(c). These concepts form the macroscopic model of fracture for practical engineering use at the component level.

**Microscopic Factors in Fracture.** Although planar discontinuities (cracks) are the dominant defect in fracture, dislocation theory has been another avenue of research. Quite early in the study of materials and their failure, attempts were made to calculate the theoretical strength of crystals, but of all the possibilities perhaps that of Frenkel (Ref 10) for estimating the theoretical shear strength is most common. Theoretical (or "ideal") shear strength can be related to ductile fracture, because the shearing-off mechanism that is basic to shear lip formation in a tensile test and to the final shearing mode ("internal necking") occurs during void coalescence. However, for cleavage (brittle fracture, which is by far the most worrisome type of fracture), the corresponding ideal strength is the ideal tensile strength first estimated by Orowan in 1949 and described by Kelly in Ref 11.

The estimate of Frenkel considers two rows of atoms that shear past one another. The spacing between rows is  $a_r$  and the spacing between atoms in the slip direction is  $a_0$ . The shear stress is  $\sigma$  and is considered to be sinusoidal. The well-known result is:

$$\sigma = B/A(\mu/2\pi) \text{ SIN}(2\pi X/B) \quad (\text{EQ 8})$$

where  $\mu$  = shear modulus. The maximum value, which is also the point at which the lattice is mechanically unstable and slip occurs, is  $\sigma = b/a(\mu/2\pi)$ . Because  $a \approx b$ , the theoretical shear strength is  $\sigma_{\text{theo}} \approx \mu/2\pi$ , which is several orders of magnitude greater than the value usually observed for soft crystals. There have been numerous variations and improvements to Eq 8 in an effort to improve predictions of material strength, but the result remains essentially the same. Unfortunately, the strength of a given material predicted by theoretical calculations is much larger than the observed strength. The question is "why?" Certainly it is important that slip in crystals occurs well below the ultimate stress and that slip occurs by the movement of dislocations, as postulated by Taylor (Ref 12), Orowan (Ref 13), and Polanyi (Ref 14). But these observations do not completely answer the question, and we are led to search for other reasons for weakness.

In looking for points of weakness, we begin by noting that pure metals by definition contain no alloying constituents (and may be single crystals or polycrystalline), while structurally useful materials generally contain alloying constituents for strengthening and may be precipitation hardening, such as many of the aluminum alloys, but may also contain larger second-phase particles. Structural metals may also contain multiple phases, such as the ferrous alloys do, and have grain boundary phases as well as phases within the grain interior. A method that has been used to classify materials as to their mode of failure is that of structure. Shown below are some material properties and their effect on fracture behavior (Ref 15):

Physical property	Increasing tendency for brittle fracture
Electron bond	Metallic $\rightarrow$ Ionic $\rightarrow$ Covalent
Crystal structure	Close-packed crystals $\rightarrow$ Low-symmetry crystals
Degree of order	Random solid $\rightarrow$ Short-range order $\rightarrow$ Long-range order solution

For the different classes of materials, crystal structure is of fundamental importance because it influences or determines the competition between flow and fracture. For example, polycrystals of copper are invariably ductile, while magnesium polycrystals are relatively brittle. Magnesium has a close-packed hexagonal crystal structure, with parameters of  $a = 3.202 \text{ \AA}$ ,  $c = 5.199 \text{ \AA}$ , and  $c/a = 1.624$  (which is very close to the ratio of 1.633 obtained by piling spheres in the same arrangement). This structure is basic to much of the physical metallurgy of magnesium and magnesium alloys. At room temperature, slip occurs mainly on (0001)  $\langle 11\bar{2}0 \rangle$ , with a small amount sometimes seen on pyramidal planes such as  $(10\bar{1}1) \langle 11\bar{2}0 \rangle$ . As the temperature is raised, pyramidal slip becomes easier and more prevalent. However, note that the slip directions, whether associated with basal or the pyramidal planes, are coplanar with (0001), a general observation for all observed slip in magnesium and magnesium alloys. Therefore, it is impossible for a polycrystalline piece of magnesium to deform without cracking unless deformation mechanisms other than slip are available. These mechanisms are twinning, banding, and grain-boundary deformation.

At the microstructural level, fracture in engineering alloys can occur by a transgranular (through the grains) or an intergranular (along the grain boundaries) fracture path. However, regardless of the fracture path, there are essentially only four principal fracture modes:

- Ductile fracture from microvoid coalescence
- Brittle fracture from cleavage, intergranular fracture, and crazing (in the case of polymers)
- Fatigue
- Decohesive rupture

These basic fracture modes are discussed in more detail in the article "Micromechanisms of Monotonic and Cyclic Crack Growth" in this Volume (with somewhat more emphasis on cleavage than in this article). Cleavage is perhaps more related to the rapidity of fracturing, as suggested by Irwin's classic paper (Ref 7).

Four major types of failure modes have also been extensively discussed in the literature. A list of classes and the associated modes of failure is shown below (Ref 16):

#### Dimpled rupture (microvoid coalescence):

- Ductile fracture
- Overload fracture

#### Ductile striation formation

- Fatigue cracking (subcritical growth)

#### Cleavage or quasicleavage

- Brittle fracture
- Premature or overload failure
- Quasicleavage from hydrogen embrittlement

#### Intergranular failure

- Grain boundary embrittlement (by segregation or precipitation)
- Subcritical growth under sustained load (stress-corrosion cracking or hydrogen embrittlement)

A study of these fracture classes normally requires use of the scanning electron microscope or the preparation of replicas that may be examined in the transmission electron microscope. In some instances it is possible to examine cracked inclusions and second-phase particles using thin foil transmission electron microscopy. An example of this latter behavior can be found in the work of Broek (Ref 17). Optical microscopy can also be of use for examining large inclusion particles.

## Precipitation-Hardening Alloys

Precipitation-hardening alloys, such as those of aluminum, can be expected to have dispersed fine precipitates that may range from spherical to platelet, depending on the alloy (Fig. 4a, b). The precipitates may be extremely small and primarily produce lattice strain, such as the case of Guinier-Preston zones, or they may be somewhat larger but still have coherent boundaries with the matrix, as in the case of peak-aged alloys, or be in the overaged condition, which usually results in incoherent boundaries. Precipitates are generally impediments to dislocation motion and therefore tend to raise both the yield strength and the ultimate strength.

**Fig. 4** (a) Platelet formation in a 2xxx-series aluminum alloy that was solution heat treated, quenched, cold rolled 6%, and aged 12 h at 190 °C. (b) Spheroidal precipitates in a 7xxx-series aluminum alloy. Larger precipitates are seen in the subgrain boundary as well as around the dispersoid particle. Source: *Aluminum: Properties and Physical Metallurgy*, J.E. Hatch, Ed., American Society for Metals, 1984, p 101, 191

Problems begin to arise when laboratory alloys are scaled to commercial production levels. Levels of alloy additions are more difficult to control, and the purity of starting materials can be almost impossible to maintain. As a result, in addition to precipitates there may be larger second-phase particles in the grain interior or the grain boundary (Fig. 4a, b). These particles, which are also called constituent particles, are assumed to be directly related to dimple rupture and are usually observed in the bottom of the dimple in fractographs. Finally, there may be denuded zones at grain boundaries that are devoid of precipitates and constituent particles (Fig. 4a, 5a, 5b). These denuded zones may also exist around second-phase particles.

**Fig. 5** (a) Precipitate-free zones or denuded zones at a grain boundary in a 6xxx-series alloy. (b) Similar denuded regions around dispersoid or constituent particles in a 7xxx-series alloy. Source: *Aluminum: Properties and Physical Metallurgy*, J.E. Hatch, Ed., American Society for Metals, 1984, p 102

It is certainly possible to consider failure as occurring during tensile overload and general tensile yield. However, we are also interested in failure resulting from an initial fatigue crack that is formed by cyclic loading, followed by crack growth and then final failure. These failures generally result in a more localized plastic deformation behavior that is governed by linear elastic fracture mechanics. With this scenario in mind, Grosskreutz and Shaw (Ref 18), Bowles and Schijve (Ref 19), and McEvily and Boettner (Ref 20), among others, have shown that fatigue cracks generally initiate at larger inclusions that are still larger than the usual second-phase particle. An example of this behavior is shown in Fig. 6. As critical crack lengths are approached, dimple rupture begins. Numerous examples of dimple rupture have been published, but Broek (Ref 17, 21) was probably the first to demonstrate clearly that void formation begins at the matrix-precipitate or matrix-constituent particle interface and is followed by a linking of other dimples by a mechanism of interface separation leading to final fracture.

**Fig. 6** Two examples of cracks initiated at inclusions. In figure (a) the crack clearly initiated at a void occurring in a cracked inclusion cluster. In figure (b) the crack appears to have initiated from the side of the inclusion. Cracks were observed after 150,000 cycles. Material was 2024-T3.

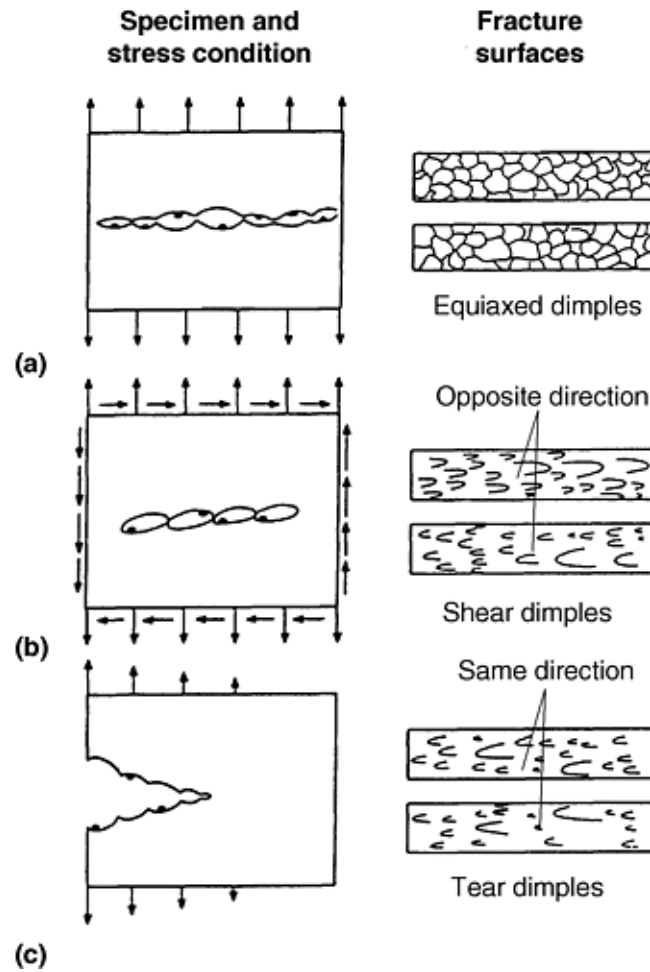

Although fatigue crack initiation in commercial alloys begins at the inclusion-matrix interface, it has been demonstrated that many larger particles are broken during fabrication processes such as forging or plate rolling, or the final stretching that may be part of the heat treatment process. Larger particles can also be broken under tensile loading (Ref 16, 22). Broek (Ref 17) has also observed by means of thin foil electron microscopy that long slender particles probably fracture, whereas smaller, more spherical particles form voids at the particle-matrix interface (Fig. 7). In either case these particles are clearly a potential source of void formation.

**Fig. 7** Transmission electron micrograph of thin foil of an aluminum alloy. Fractured elongated dispersoids can be clearly seen, along with one or two possible interface separations that led to voids. Courtesy of Martinus Nijhoff Publishers. Source: Ref 21

Numerous authors have devised schematic diagrams depicting void formation and coalescence. One of the more descriptive schematic diagrams, developed by Broek (Ref 21), is reproduced in Fig. 8. In general the progression is believed to begin with the formation of small voids at the particle-matrix interface, or perhaps the fracture of some particles at low stress levels. As stresses begin to increase, voids grow and ultimately begin to link. The stress distributions shown in Fig. 8 determine the type of dimples that can be expected, and they can be of considerable value to the failure analyst when it is necessary to determine the loading that caused a particular failure. A fractograph of classic dimple fracture in an aluminum alloy, with small particles clearly visible in the bottom of the voids, is shown in Fig. 9. A study of matching fracture surfaces, also carried out by Broek, showed that the particle is always left in the bottom of one half of the dimple.

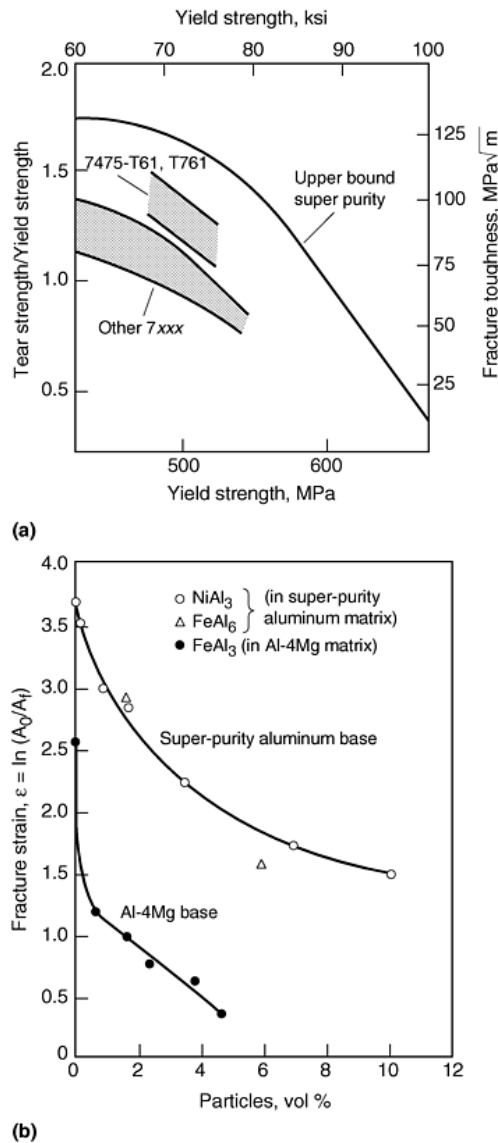

**Fig. 8** Different dimple geometries to be expected from three possible loading conditions. The dimple geometry can be valuable to the failure analyst in determining the loading conditions present at the time of failure. Courtesy of Martinus Nijhoff Publishers. Source: Ref 21

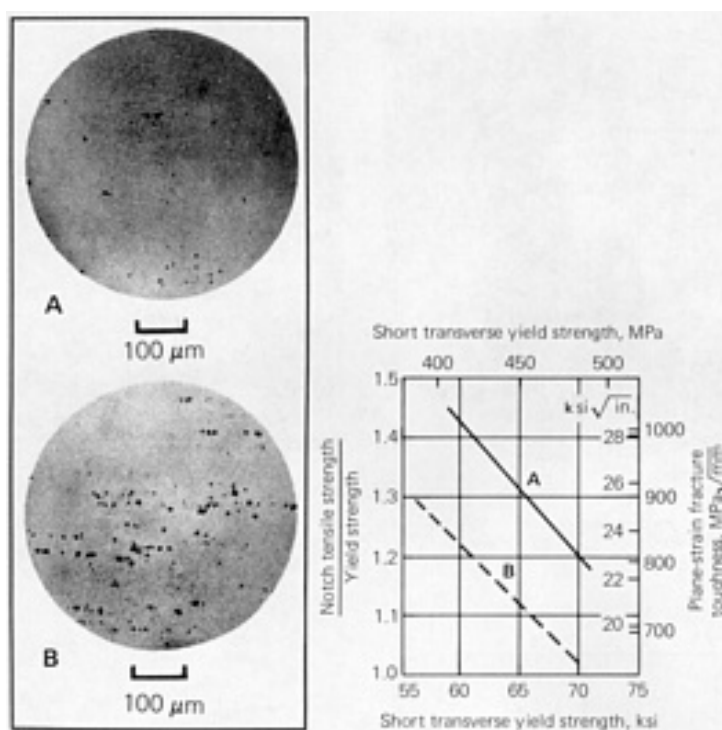

**Fig. 9** Fractograph taken from 2024-Al fracture surface replica. Arrows identify small constituent particles at the bottom of dimples that are the origin of the fracture process. Courtesy of Martinus Nijhoff Publishers. Source: Ref 21

The larger constituent particles in aluminum alloys are generally intermetallic compounds and are relatively insoluble  $\text{AlCu}_2\text{Fe}$ ,  $\text{Mg}_2\text{Si}$ , and  $(\text{Fe},\text{Mn})\text{Al}_6$ . Somewhat more soluble particles, such as  $\text{CuAl}_2$  and  $\text{CuAl}_2\text{Mg}$ , can also be found.

However, it is virtually impossible to eliminate these particles by any usual heat treatment once they have formed. A reduced fracture toughness in aluminum alloys can be attributed to the presence of these particles (Ref 23, 24), and a change in toughness of  $10$  to  $15 \text{ MPa}\sqrt{\text{m}}$  has been observed when efforts have been directed at improving alloy cleanliness by removing copper, chromium, silicon, and iron from commercial alloys. Further evidence of the detrimental role of particles is given in Fig. 10(a), which shows the decrease of fracture strain with increase of volume percent of micron-size intermetallic particles for a super-purity aluminum matrix and an Al-4Mg matrix. By contrast, Fig. 10(b) demonstrates the effect of high-purity 7050 sheet material compared to that of 7475 and other 7xxx-series aluminum alloys. Clearly, tear strength and fracture toughness are improved by increasing purity. Finally, Fig. 11 demonstrates the effect of removing constituent particles on the fracture toughness of 7050 aluminum plate.

**Fig. 10** (a) The decrease in fracture strain with increase of volume percent of micron-size intermetallic particles for a super-purity aluminum matrix and an Al-4Mg matrix. (b) A comparison of high-purity 7050 aluminum sheet, 7475 sheet, and a 7xxx-series aluminum alloy. Tear strength and fracture toughness are clearly better for the super-purity alloy. ## Ferrous Alloys

**Effect of Second-Phase Particles.** Certain fundamental characteristics of fracture that are observed in aluminum alloys are also observed in the fracture of ferrous alloys. For example, the presence of particles such as the sulfide inclusions shown in Fig. 12 results in the typical inclusion-matrix interface failure and the formation of voids, including the possible

brittle fracture of the inclusion itself. Either the interface failure or the particle fracture leads to void formation and the linking of voids to give ultimate failure with the usual mechanism of dimple rupture. Still another failure mode prevalent in pearlitic steels is the initial brittle fracture of  $\text{Fe}_3\text{C}$  lamella. These fractures open under continued loading and form voids that can link up to result in larger voids, which in turn further link to give final failure. An example of this type of initial failure, shown in Fig. 13, is taken from the work of Roland (Ref 25), who was examining several possible high-toughness experimental alloys suitable for railroad wheels. Finally, it is not unusual to find fracture surfaces with dimples having small particles at the bottom that have clearly been the sites of initial void formation. In Fig. 14 the resulfurized AISI 4130 had higher strength and lower toughness, while the spheroidized low-sulfur AISI 4130 showed lower strength and higher toughness. Note also that the void geometry of the spheroidized steel is completely different than that of the resulfurized steel. However, ultimate failure was still the result of the linking of voids in both cases.

**Fig. 12** Areas from two different fracture surfaces. The fractures are clearly ductile, with varying sizes of dimples and distinct particles in the bottom of the larger dimples. In the upper right-hand corner of (a), the particle is clearly fractured. The material was a low-carbon steel (0.52% C, 0.90% Mn, 0.38% Cr, 0.32% Si) that was being considered for railroad wheels. Source: Ref 19

**Fig. 13** Optical photograph of polished surface of a highly strained sample of experimental 0.65% C wheel steel. Initial fractures of iron carbide lamella are indicated by the arrow. The fractured lamella result in voids that link up to form a continuous fracture. Source: Ref 19

(c) Low-sulfur AISI 4130 steel that had been spheroidized to 600 MPa. In all three photographs, particles can be found in the dimples. Source: *Metals Handbook*, 9th ed., Vol 8

It is well known that hypoeutectoid steels (those with less than 0.8% C) generally have a proeutectoid grain boundary ferrite that may be continuous or segregated, depending on the composition, and is present in addition to the usual pearlite. Grain boundary ferrite is thought to contribute to crack arrest due to the energy expended in blunting a propagating crack because of the ductile nature of ferrite. Observation of this crack arrest mechanism has been reported by Bouse et al. (Ref 26) and Fowler and Tetelman (Ref 27). A crack blunting model based on the presence of grain boundary ferrite was developed by Fowler and Tetelman (Ref 27) and is shown in Fig. 15. In contrast to the proeutectoid ferrite found in hypoeutectoid steels, grain boundary carbide resulting from proeutectoid  $Fe_3C$  in hypereutectoid steels may also lead to crack arrest. It is very hard and serves as an impediment to crack propagation because of the energy expended in fracturing the hard carbide. However, the iron carbide would also be expected to fail in a brittle manner, and once failed it might lead to lower overall material toughness because of its brittle nature.

**Fig. 15** A crack-blunting mechanism resulting from crack propagation into grain boundary ferrite in proeutectoid alloys. Courtesy of American Society for Testing and Materials

In addition to the pearlite colonies and grain boundary ferrite or carbide found in plain carbon steels, there are a variety of second-phase particles in alloy steels, as well as the usual inclusions that are visible in the optical microscope. A considerable body of literature has examined the effect of particle size and particle distribution on the fracture properties of alloy steels. For example, an empirical relationship relating the effect of particle size to fracture has been given by Priest (Ref 28) for a Ni-Cr-Mo-V steel with 0.45% C:

$$K_{IC} = 23 \text{ MPa} \sqrt{\text{m}} + 7(\sigma^* - \sigma_{YS})(\lambda)^{\frac{1}{2}} \quad \text{(EQ 9)}$$

where  $\sigma^* = 2000 \text{ MPa}$  (290 ksi),  $\sigma_{ys}$  is the material yield strength (in MPa) and  $\lambda$  is the average particle spacing between inclusions (in mm). Figure 16 shows that Eq 9 fits the experimental data for large variations in particle spacing as well as for three different test temperatures. In all cases reported, a dimpled rupture surface was the microstructural failure mode.

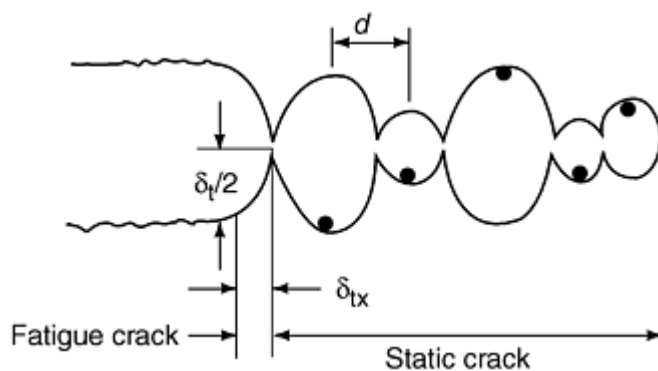

**Fig. 16** Plot of Eq 1 from Priest (Ref 28), demonstrating the relationship between constituent particle spacing, material yield stress, and fracture toughness (Ref 15). Experimental data points are for the 0.45C-Ni-Cr-Mo-V steel. Source: Ref 16

Schwalbe (Ref 29) has suggested a model as shown in Fig. 17, whereby the crack-tip opening displacement,  $\delta_t$ , is related to the distance between voids,  $d$ . Schwalbe assumes that constancy of volume and plane-strain conditions cause crack advance because of negative strain in the  $x$ -direction. The large plastic strains also are responsible for fracture of inclusions (or boundary separation at the inclusion-matrix interface), which leads to void formation. Because the dimple size roughly corresponds to  $d$ , one can write:

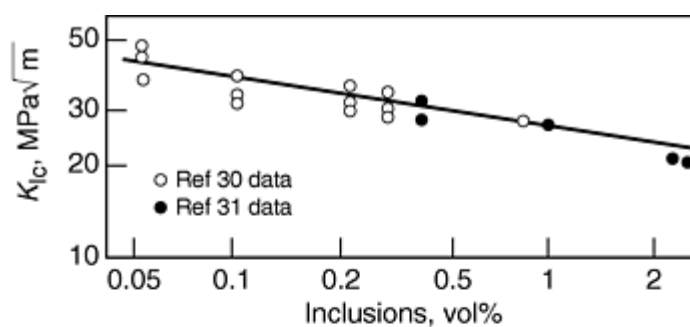

$$\text{Crack tip opening displacement} = \delta_t \quad (\text{EQ 10})$$

$$\delta_T = D \quad (\text{EQ 11})$$

Thus, the more closely spaced the inclusions (and by inference, the larger the density of particles), the smaller the crack-tip opening displacement and the sooner void coalescence with the crack tip begins. Assuming that the onset of instability is related to void coalescence with the crack tip, then an increase in  $K_{Ic}$  should be expected with an increase in  $d$ . The relationship between volume fraction of inclusions in aluminum and  $K_{Ic}$  is shown in Fig. 18(a), and Fig. 16(b), which shows the effect of sulfur content on the fracture properties of 0.45C-Ni-Cr-Mo steels (Ref 32). In Fig. 18(b) the embrittling effect of sulfur results from the dimple formation at sulfides. Finally, note that  $d$  in Eq 10 and  $\lambda$  in Eq 9 are essentially equivalent.

**Fig. 17** Model of static crack advance after Schwalbe (Ref 29). The crack-tip opening displacement is equal to the dimple spacing or inclusion spacing.

**Fig. 18** (a) Fracture toughness of some aluminum alloys vs. volume fraction of inclusions. (b) Fracture toughness of 0.45C-Ni-Cr-Mo steels as a function of sulfur content and tensile strength

Similar relationships are discussed by Hahn (Ref 33), who has examined the relationships between particle size, particle spacing, and the results of tensile tests, Charpy V-notch impact tests (CVN), and fracture toughness ( $K_{Ic}$ ) results. Hahn's results seem to show that the important variable is the size of the stressed volume. Thus, CVN samples, which have a

larger stressed volume in front of a somewhat blunt notch, tend to be more strongly influenced by the particle size in the stressed volume, whereas  $K_{Ic}$  samples, which have a much smaller stressed volume at the tip of a fatigue crack, typically give results that are more dependent on the particle spacing in the volume in front of the crack tip. Hahn also advances the interesting hypothesis that the differing dependencies of CVN and  $K_{Ic}$  tests explain the lack of an all-inclusive, single equation that is able to correlate CVN and  $K_{Ic}$  results for all steels. An example of noncorrelating CVN and  $K_{Ic}$  toughness measurements is shown in Table 1.

**Table 1 Example of noncorrelating Charpy V-notch (CVN) and  $K_{Ic}$  toughness measurements of AISI 4340 steel**

Condition <sup>(a)</sup>	CVN energy, J	$K_{Ic}$ , MPa $\sqrt{m}$	$K_{Iid}$ , MPa $\sqrt{m}$
A	6.6	70	52
B	9.5	34	33

Source: Ref 34

(a) Condition A--1 h at 1200 °C, salt quench to 870 °C, 1 h at 870 °C, oil quench to room temperature,  $\sigma_0 = 1592$  MPa.  
Condition B--1 h at 870 °C, oil quench to room temperature,  $\sigma_0 = 1592$ .

**Effect of Matrix.** Although void formation and the role of second-phase particles and small inclusions are important, it is well known that properties of the matrix may also have an important influence on fracture toughness behavior. For example, Rice (Ref 35) has shown that an increase in matrix strength results in an increase in plastic zone normal stress, such that:

$$\sigma_Y = \sigma_Y (1 + \pi/2) \quad (\text{EQ 12})$$

where  $\sigma_y$  is the stress normal to the crack path and  $\sigma_Y$  is the material yield strength. Thus, higher yield strengths result in smaller particles, contributing to dimple formation that in turn results in a smaller average effective inclusion spacing. Similar observations were found by Psioda and Low (Ref 36) during a study of maraging steels. Generally, any change that increases yield strength (such as lower temperature, high deformation rate, or heat treatment) results in a decrease in  $K_{Ic}$ . Of course, microstructural changes (such as change in particle size as a result of heat treatment) negates this statement. Pellissier (Ref 37) concludes that a fine, homogeneous distribution of particles of intermetallic compounds results in a high fracture toughness, whereas in martensitic steels the higher carbide content due to high carbon is detrimental to toughness. It should also be noted that Eq 12 is for an elastic perfectly plastic material and that with strain hardening, substantial increases in  $\sigma_y$  can develop.

Numerous workers have examined high-strength steels such as AISI 4340 and AISI 4130. Low tempering temperatures led to a carbide film at the martensite lath boundaries and thus led to low toughness for 4340, according to Wei (Ref 38), whereas Parker (Ref 39) suggests that fracture toughness in the as-quenched condition of AISI 4340 and similar steels is determined by precipitation at prior-austenite grain boundaries.

## Titanium Alloys

The titanium alloys are somewhat unique in that they can exist in the alpha (face-centered cubic), beta (body-centered cubic), or alpha + beta condition, depending on the alloy composition and heat treatment. However, in any case, interface weaknesses between the phases tend to lead to failure. For example, Gerberich and Baker (Ref 40) have shown that a change from an equiaxed alpha to a platelet alpha structure gives an increase in  $K_{Ic}$  of approximately 25%, with 5% or less change in yield strength and ultimate strength. The authors concluded that the properties changed because of the change in fracture path that resulted from the change in microstructure. The authors also noted that an increase in oxygen content tended to cause embrittlement of the alpha phase, with a subsequent decrease in toughness. In another paper, Gerberich (Ref 16) reiterates the importance of both composition and microstructural effects on the toughness of Ti-6Al-4V. For example, he points out that the alpha platelets in the alpha + beta Widmanstätten matrix may be either detrimental or beneficial, depending on the oxygen content. However, there apparently is no processing route that provides a toughness greater than  $55 \text{ MPa} \sqrt{\text{m}}$  for yield strengths greater than about 1080 MPa.

Finally, an experimental alpha + beta alloy was studied where the strength was held constant in both the equiaxed alpha and transformed microstructural conditions. For equiaxed alpha, toughness increased with beta grain boundary area per unit volume. In the transformed condition, toughness increased with an increase in the percentage of primary alpha. Table 2 gives the relationship between  $K_{Ic}$  and the fraction of transformed structure for Ti-6Al-4V.

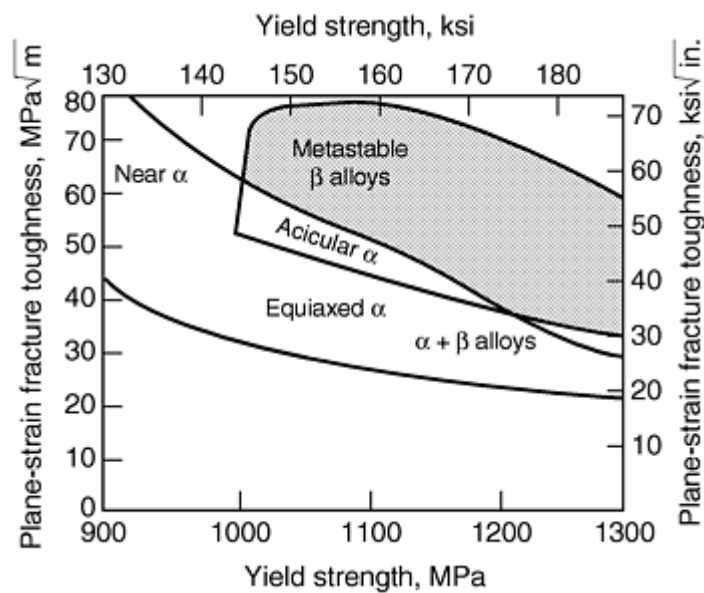

**Table 2 Relation between  $K_{Ic}$  and fraction of transformed structure Ti-6Al-4V**

Heat treat temperature		Fraction of transformed structure, %	$K_{Ic}$	
°C	°F		MPa $\sqrt{\text{m}}$	ksi $\sqrt{\text{in.}}$
1050	1920	100	69.0	<b>63</b>
950	1740	70	61.5	<b>56</b>
850	1560	20	46.5	<b>42</b>
<b>750</b>	<b>1380</b>	<b>10</b>	<b>39.5</b>	<b>36</b>

Harrigan (Ref 41) has examined the effect of microstructures on the fracture properties of titanium alloys and concludes that variations in microstructures can result in large scatter of experimental results. This is suggested by Fig. 19, where no correlation is evident between toughness and yield strength. Still another representation of the relationship between microstructure and toughness for titanium alloys was given by Rosenfield and McEvily (Ref 42), who conclude that toughness depends on the size, shape, and distribution of the phases that are present (Fig. 20). Metastable beta alloys appear to have the highest toughness, while alpha + beta alloys are generally less tough.

## Fatigue Properties in Engineering

D.W. Cameron, Allegany, NY, and D.W. Hoepfner, Department of Mechanical Engineering, University of Utah

---

## Introduction

FATIGUE PROPERTIES are an integral part of materials comparison activities and offer information for structural life estimation in many engineering applications. They are a critical element in the path relating the materials of construction to the components and must take into account as many influences as possible to reflect the actual product situation. In application, fatigue is a detail analysis, trying to assess what will occur at a particular location of a component or assembly under cyclic loading.

The topic of fatigue properties is very broad and is typically based on testing coupons. To be applicable, determined properties must support one of the fatigue design philosophies that may be applied to the part. In this article the three general approaches to fatigue design are stated, with discussion of their respective attributes, and their individual property requirements are described. The intent here is not to present a comprehensive catalog of properties; that would take many volumes this size. Instead, the purpose is to provide the basic insights necessary to examine those properties that can be found, review some of the common presentation formats, and recognize their inherent characteristics. It is important to review information critically for any use, to know when a direct "apples to apples" comparison can be made, and potentially to know how to manipulate some of the data to put it on equal footing with information gathered from diverse sources. The susceptibility of mechanical properties to variation through microstructural manipulation and structural consideration can be substantial.

The importance of testing in property generation is reviewed briefly, and material, property, and structure relations are discussed. Three sections then cover properties specific to each of the major design approaches: stress-life, strain-life, and fracture mechanics. The individual sections offer selected examples of properties that reflect some detail of each approach.

Although life estimation is not the subject of this article, it is obvious that this is one of the main uses of the "properties" development. Basically, data on test coupons are only good at estimating the life of test coupons; other structures may not be as amenable to estimation. A life estimation within a factor of 2 would be exceptional, and perhaps one within an order of magnitude would not be considered too outrageous, depending on the quality of information, appropriateness of technique, and "property" data. The substantial amount of scatter in results is one of the contributing features to these difficulties. Certainly verification of life estimations should be considered an important activity to confirm the calculations.

For the sake of brevity, we limit our discussion to constant-amplitude loading. Often, variable-amplitude loading is necessary to correctly replicate structural situations. It is essential to understand that variable-amplitude loading can produce different rankings than constant-amplitude results. Another concession to brevity is that within the fracture mechanics area, only plane-strain considerations are included. Among other critical aspects not covered specifically here are: crack nucleation models and the basic physics of this process and as well as that of crack extension; the extremely important extrinsic factor of environment on both 'initiation' and propagation characteristics; and other phenomenon such as fretting discussed in more detail elsewhere in this Volume.

## Fatigue Design Philosophies

To be usable in anything other than a comparative sense, fatigue properties must be consistent with one of three general fatigue design philosophies. Each of these has a concomitant design methodology and one or more means of representing testing data that provide the 'properties' of interest. These are:

Design philosophy	Design methodology	Principal testing data description
Safe-life, infinite-life	Stress-life	$S-N$
Safe-life, finite-life	Strain-life	$\epsilon-N$
<b>Damage tolerant</b>	<b>Fracture mechanics</b>	$da/dN - \Delta K$

These "lifing" or assessment techniques correspond to the historical development and evolution of fatigue technology over the past 150 to 200 years.

The safe-life, infinite-life philosophy is the oldest of the approaches to fatigue. Examples of attempts to understanding fatigue by means of properties, determinations, and representations that relate to this method include August Wöhler's work on railroad axles in Germany in the mid-1800s (Ref 1). The design method is stress-life, and a general property representation would be  $S-N$  (stress vs. log number of cycles to failure). Failure in  $S-N$  testing is typically defined by total separation of the sample.

General applicability of the stress-life method is restricted to circumstances where continuum, "no cracks" assumptions can be applied. However, some design guidelines for weldments (which inherently contain discontinuities) offer what amount to residual life and runout determinations for a variety of process and joint types that generally follow the safe-life, infinite-life approach (Ref 2). The advantages of this method are simplicity and ease of application, and it can offer some initial perspective on a given situation. It is best applied in or near the elastic range, addressing constant-amplitude loading situations in what has been called the long-life (hence infinite-life) regime.

The stress-life approach seems best applied to components that look like the test samples and are approximately the same size (this satisfies the similitude associated with the use of total separation as a failure criterion). Much of the technology in application of this approach is based on ferrous metals, especially steels. Other materials may not respond in a similar manner. Given the extensive history of the stress-life method, substantial property data are available, but beware of the testing conditions employed in producing older data.

Through the 1940s and 1950s, mechanical designs pushed to further extremes in advanced machinery, resulting in higher loads and stresses and thus moving into the plastic regime of material behavior and a more explicit consideration of finite-lived components. For these conditions, the description of local events in terms of strain made more sense and resulted in the development of assessment techniques that used strain as a determining quantity. The general data (property) presentation is in terms of  $\epsilon-N$  (log strain vs. log number of cycles or number of reversals to failure). The failure criterion for samples is usually the detection of a "small" crack in the sample or some equivalent measure related to a substantive change in load-deflection response, although failure may also be defined by separation.

Employment of strain is a consistent extension of the stress-life approach. As with the safe-life, infinite-life approach, the strain-based safe-life, finite-life philosophy relies on the "no cracks" restriction of continuous media. While considerably more complicated, this technique offers advantages: it includes plastic response, addresses finite-lived situations on a sounder technical basis, can be more readily generalized to different geometries, has greater adaptability to variable-amplitude situations, and can account for a variety of other effects. The strain-life method is better suited to handling a

greater diversity of materials (e.g., it is independent of assuming steel-like response for modification factors). Because it does not necessarily attempt to relate to total failure (separation) of the part, but can rely on what has become known as "initiation" for defining failure, it has a substantial advantage over the stress-life method. Difficulties in applying the method arise because it is more complex, is more computationally intensive, and has more complicated property descriptions. In addition, because this method does not have as extensive a history, "properties" may not be as readily available.

The ability to generate and model both  $S-N$  and  $\epsilon-N$  data effectively is clearly very important. Three good sources for increasing the understanding of this are ASTM STP 91A (Ref 3), ASTM STP 588 (Ref 4), and Ref 5. Specifications covering the individual areas are indicated below.

From a design standpoint, there are some circumstances where inspection is not a regularly employed practice, impractical, unfeasible, or occasionally physically impossible. These situations are prime candidates for the application of the safe-life techniques when coupled with the appropriate technologies to demonstrate the likelihood of failure to be sufficiently remote.

The notable connection between the two techniques described above is the necessary assumption of continuity (i.e., "no cracks"). Many components, assemblies, and structures, however, have crack-like discontinuities induced during service or repair or as a result of primary or secondary processing, fabrication, or manufacturing. It is abundantly clear that in many instances, parts containing such discontinuities do continue to bear load and can operate safely for extended periods of time. Developments from the 1960s and before have produced the third design philosophy, damage tolerant. It is intended expressly to address the issue of "cracked" components.

In the case where a crack is present, an alternative controlling quantity is employed. Typically this is the mode I stress-intensity range at the crack tip ( $\Delta K_I$ ), determined as a function of crack location, orientation, and size within the geometry of the part. This fracture mechanics parameter is then related to the potential for crack extension under the imposed cyclic loads for either subcritical growth or the initiation of unstable fracture of the part. It is markedly different from the other two approaches. Property descriptions for the crack extension under cyclic loading are typically  $da/dN - \Delta K_I$  curves (log crack growth rate vs. log stress-intensity range).

The advantage of the damage tolerant design philosophy is obviously the ability to treat cracked objects in a direct and appropriate fashion. The previous methods only allow for the immediate removal of cracked structure. Use of the stress-intensity values and appropriate data (properties) allows the number of cycles of crack growth over a range of crack sizes to be estimated and fracture to be predicted. The clear tie of crack size, orientation, and geometry to nondestructive evaluation (NDE) is also a plus. Disadvantages are: possibly computationally intensive stress-intensity factor determinations, greater complexity in development and modeling of property data, and the necessity to perform numerical integration to determine crack growth. In addition, the predicted lives are considerably influenced by the initial crack size used in the calculation, requiring quantitative development of probability of detection for each type of NDE technique employed. Related to the initial crack size consideration is the inability of this approach to model effectively that the component was actually suitable for modeling as a continuum, which eliminates the so-called "initiation" portion of the part life.

## Considerations in Conducting Tests

Having properties implies testing of materials to make such determinations. Even approximations of properties assume some model of behavior, and initially testing was employed to provide that information. Thus, testing per se warrants some discussion.

The principal question to be asked when considering testing is whether or not the desired information will be produced by the testing. This is reflected directly in the "properties" that will result. Fatigue testing can vary from a few preliminary tests to elaborate, sophisticated programs. In support of deriving the necessary data in the best manner, the principal author identifies three critical aspects of testing programs as the three E's of testing: efficacy, efficiency, and economy. These are certainly not unique to fatigue. They are stated in order of importance and are interpreted as follows:

- *Efficacy*: The testing *must* tell you what you want to know and provide it to the required confidence level. It must be physically capable of generating the desired information, and it must be designed to discriminate to the degree necessary to sort out the details or subtleties of response that is required. (It is sometimes the task of testing to determine whether any difference can be distinguished.) This may call for extensive experimental design up front, and statistical examination of data. Established and consistent test procedures are always a requirement.
- *Efficiency*: The testing should be scheduled, consistent with maintaining efficacy, to generate the greatest amount of usable/desired information as early as possible in the test program.
- *Economy*: Testing should proceed in the most economical manner without compromising efficacy, while meeting the desired information generation levels as well as possible.

Both efficiency and economy are necessarily subservient to efficacy. A substantial amount of work may have to be done before testing begins, to maximize the likelihood of success. If test program manipulations are to be done, they must be done only to balance efficiency/economy issues. If the testing proceeds without the ability to generate the necessary information (e.g., effectively identify subtleties), or if it is altered midstream with the same result, the integrity of the program is breached and there is little or no justification to run or continue the tests (at least according to the original intent of the project). Explicit consideration of the statistical nature of fatigue data should always be part of a testing program.

---

## Assessing Fatigue Characteristics

**Supporting Information and What to Look for in Fatigue "Properties" Data.** The ability to assess properties information is one of the critical points in deciding if the data found are applicable and usable. Testing should have been done to a stated, set procedure or standard, and all information germane to the testing and resulting data should have been recorded. With the multitude of influential variables, obviously this list can get quite long, but without it the relative value of the information cannot be determined. Dogs and horses have pedigrees, so do data.

For example, in trying to find fatigue properties of rather heavy 7075-T6 aluminum alloy forging, a fatigue curve is found that indicates it is for this alloy and condition. The plot indicates a single line drawn on  $S_{\max}$  versus  $\log N$  coordinates, and that's all. What use is it? There is no other description provided. Recommendation: ignore it, or call the originator for clarification. Use of the data would be risky, because there is not sufficient information present to make a defensible assessment. Many necessary pieces of data are simply missing. A partial list might be:

- What were the coupon size and geometry?
- Was there a stress concentration?
- What was the temperature?
- Was an environment other than lab air employed?
- What was the specimen orientation in the original material?
- Does the line represent minimum, mean, or median response?
- How many samples were tested?
- What was the scatter?
- If the plot is based on constant-amplitude data, what were the frequency and waveform?
- Was testing performed using variable-amplitude loading? What spectrum?
- What was the failure criterion?

- If there were runouts, how were they handled and represented?
- If the data found describe a thin sheet response, it is the wrong data.
- If the product form is correct, but the plot represents testing done at  $R = 0.3$  and fully reversed data are required, the plot may be helpful, but it is not what is desired.

Material chemistry; product form, condition, and strength level; coupon geometry, size, orientation, and preparation; testing equipment, procedures, parameters, failure criterion, and number of samples; data treatment; and sequence of testing are just some of the contributing and possibly controlling features represented by the single line on the graph. An example of what should be considered important as supporting facts can be found in ASTM E 468-90, "Presentation of Constant Amplitude Fatigue Test Results for Metallic Materials" (Ref 6). It provides guidelines for presenting information other than just final data.

Finding, characterizing, and critical review are clearly extremely challenging parts of attempting to apply materials properties data, with critical designs requiring the most stringent consideration. In some cases this is extremely difficult: necessary data may be sparse, proprietary, and/or poorly documented and very careful use of any information the only choice available. Different criterion, however, apply to the use of property descriptions as examples, representative of *potential* responses for purposes of demonstration and illustration (as they are employed here). While full documentation is still desirable, the use of information in this context only requires that the data be judged an adequately sound depiction of the archetypal behavior.

As in all disciplines, the definition and standardization of both terms and nomenclature are extremely important. A survey of different books, articles, and other literature sources indicates that the fatigue community is no exception to maintaining consistency in this area. The reader is directed to ASTM E 1150-87 (1993), "Standard Definitions of Terms Relating to Fatigue" (Ref 7), for terminology. The authors have attempted to adhere to those definitions.

One point should be made very clear: to establish the nature of any constant-amplitude fatigue data, two dynamic variables *must* be stated, or as a poor second, implied by the nature of the testing. Many dynamic variables apply to constant-amplitude loads:  $P_{\max}$ ,  $P_{\min}$ ,  $P_m$ ,  $P_a$ , and  $\Delta P$ , which indicate load maximum, minimum, mean, amplitude, and range, respectively. Two load ratio quantities are also frequently encountered:  $R$  and  $A$ , defined as  $P_{\min}/P_{\max}$  and  $P_a/P_m$ , respectively. Note that  $P$ , as load, is used in a generic sense here, with other possibilities including  $S_a$ , alternating stress;  $\epsilon_m$ , mean strain;  $\Delta K_I$ , stress-intensity range; and so on. These dynamic variables are related such that if any two are known, all the others can be determined, but two *must* be known.

As an example, if a series of tests are conducted at a constant  $R$  value ( $S_{\min}/S_{\max}$ ), and the alternating stress is used as the other independent dynamic variable, an  $S-N$  curve for that situation can be produced and all dynamic variables can be determined. If only one variable is given (e.g.,  $S_a$  or  $S_{\max}$ ), there is insufficient information to tell what the test conditions were and the data are virtually useless.

## Material-Property-Structure Interrelations

It is important to discriminate between fatigue "properties" and structural fatigue response within the context of this article. The term *fatigue properties* is used to describe the response of a test coupon, with all the necessary standardization and other work that this implies. This point is then used to determine the "properties" content of the rest of the article. While test coupons are indeed mini-structures, they are frequently items of geometric convenience, designed for the exigencies of testing, prepared especially for the investigation, and idealized for specific testing or influence determinations. Their relation to any specific structure can be very remote.

A few comments on what ends up as the *material* for a structure should also be made. First is a composition, essentially the basic chemistry of an alloy or the specific components of a composite. Producing the structure may require a few or many steps beyond this chemistry/components combination. Primary processing plays an important role. As examples, an investment cast superalloy blade will have different characteristics depending on whether it is made using an equiaxed, directionally solidified, or single-crystal process; and fiber-reinforced composites clearly have numerous wrap/lay configurations that can influence their response. Subsequent thermal treatment for an alloy, or curing conditions for a composite, also contribute to the end product. Many metallic alloys, far from being the uniform homogenous materials often envisioned, are carefully orchestrated arrangements of microconstituents designed to provide specific property balances from these in situ composites.

Effects of scale in the production of a material can have controlling effects. Examples are graphite size in gray iron, transformation characteristics of steels or titanium alloys in heavy sections, mechanical working in forgings and extrusions, distributions of fibers in chopped-fiber reinforced polymer parts, and phase and discontinuity distribution in ceramics. Further considerations might include machining processes, plating, shot-peening, adhesive bonding, welding, and a myriad of other influences that confound what initially appears to be the desired, rather straightforward association between the material content and structure. This is coupled with the geometric requirements of shape necessary to provide the geometry of the structure. Indeed, it is equally true that the material defines the structure and the structure defines the material.

A small shaft simply loaded in rotating bending may behave quite like specimens tested in a similar manner. On the other hand, a composite wing, built up from multiple parts joined by adhesives and mechanical fasteners, should not be expected to behave in the same manner as a small simple-configuration test coupon of skin material. Attributes of the material, coupon, or structure, along with testing conditions, contribute to the structure-sensitive mechanical behavior identified here as fatigue properties. These have been aptly categorized by Hoepfner (Ref 8) as intrinsic and extrinsic factors, and substantial progress has been made in understanding and controlling both. Design of the materials covers the intrinsic characteristics (e.g., composition, grain size, cleanliness level, layup geometry, and cure cycle). Mechanical design for a specific application addresses the extrinsic influences of the scale, geometry, stress state, loading rates, environment, etc. Both material design and mechanical design play synergistic, substantial, and possibly determining roles in controlling the structural response to cyclic loads.

Does this eliminate the importance of testing and property determinations? Certainly not, but it does increase awareness of the limitations of testing and suggests that they at least be recognized and included in actual structural assessments.

The three following sections provide examples of property determinations from each of the three major groups ( $S-N$ ,  $\epsilon-N$ , and  $da/dN$ ). Each example demonstrates the general and/or specific aspects of the information within the context of the design philosophy it supports. Where examples of data are offered, the reader should regard the information as indicative only of the specific material/process/product combination involved.

## Infinite-Life Criterion ( $S-N$ Curves)

Safe-life design based on the infinite-life criterion reflects the classic approach to fatigue. It was initially developed through the 1800s and early 1900s because the industrial revolution's increasingly complex machinery produced dynamic loads that created an increasing number of failures. The safe-life, infinite-life design philosophy was the first to address this need.

As stated earlier, the stress-life or  $S-N$  approach is principally one of a safe-life, infinite-life regime. It is generally categorized as a "high cycle fatigue" methodology, with most considerations based on maintaining elastic behavior in the sample/components/assemblies examined. The "no cracks" requirement is in place, although all test results inherently include the influence of the discontinuity population present in the samples.

This methodology is one where the influence of steel seems virtually overwhelming, despite the fact that substantial work has been done on other alloys and materials. There are many reasons for this, including the place of steel as the predominant metallic structural material of the century: in land transportation, in power generation, and in construction. The "infinite-life" aspect of this approach is related to the asymptotic behavior of steels, many of which display a fatigue limit or "endurance" limit at a high number of cycles (typically  $>10^6$ ) under benign environmental conditions. Most other materials do not exhibit this response, instead displaying a continuously decreasing stress-life response, even at a great number of cycles ( $10^6$  to  $10^9$ ), which is more correctly described by a fatigue strength at a given number of cycles. Figure 1 shows a schematic comparison of these two characteristic results. Many machine design texts cover this method to varying degrees (Ref 9, 10, 11, 12, 13, 14).

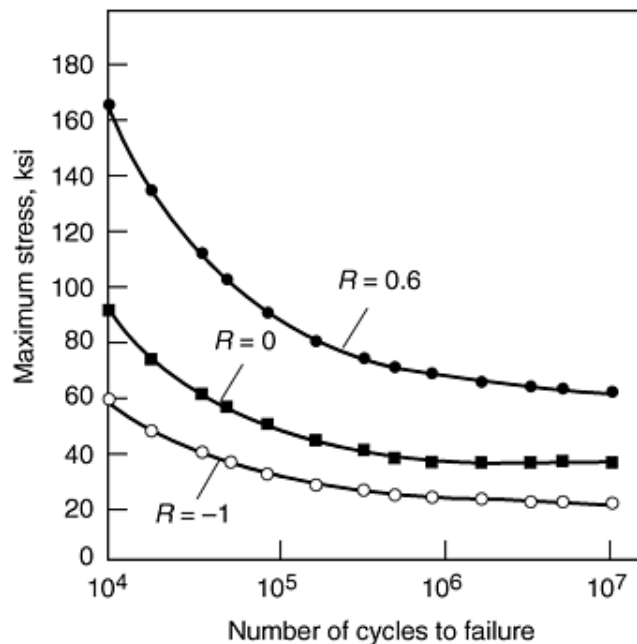

**Fig. 1** Schematic  $S-N$  representation of materials having fatigue limit behavior (asymptotically leveling off) and those displaying a fatigue strength response (continuously decreasing characteristics)

What about the  $S-N$  data presentation? Stress is the controlling quantity in this method. The most typical formats for the data are to plot the log number of cycles to failure (sample separation) versus either stress amplitude ( $S_a$ ), maximum stress ( $S_{max}$ ), or perhaps stress range ( $\Delta S$ ) (Ref 15). Remember that one other dynamic variable needs to be specified for the data to make sense. Figures 2(a) and 2(b) provide plots for three constant- $R$  value tests ( $R$  is the second dynamic variable). Note the apparent reversal of the effect of  $R$ , although the data are identical. Clearly, while the analytical result must be identical regardless of which graphic means is employed, the visual influence in interpretation varies with the method of presentation.

(a)

(b)

**Fig. 2** The influence of method of  $S-N$  data presentation on the perceived effect of  $R$  value. (a) Stress amplitude vs.  $N$ . (b) Maximum stress vs.  $N$

Many applications of this technique require estimations of initial properties and provision for approximating other effects. Overall influences of various conditions (e.g., heat treatment, surface finish, and surface treatment) were determined using substantial empiricism: test and report results. Consequently, much of the challenge was met by testing coupons/components with variations in processing to establish some guidelines for the effect of each such alteration (i.e., see Ref 16). Thus, various correction factors were developed for a variety of conditions, including load type, stress concentration, surface finish, and size. The influences of these intrinsic and extrinsic effects on the properties are typically accounted for by graphics (e.g., Fig. 3), tabular presentations, or mathematical expressions. Reference 18 is an excellent example of this approach, presented in the form of a standard.

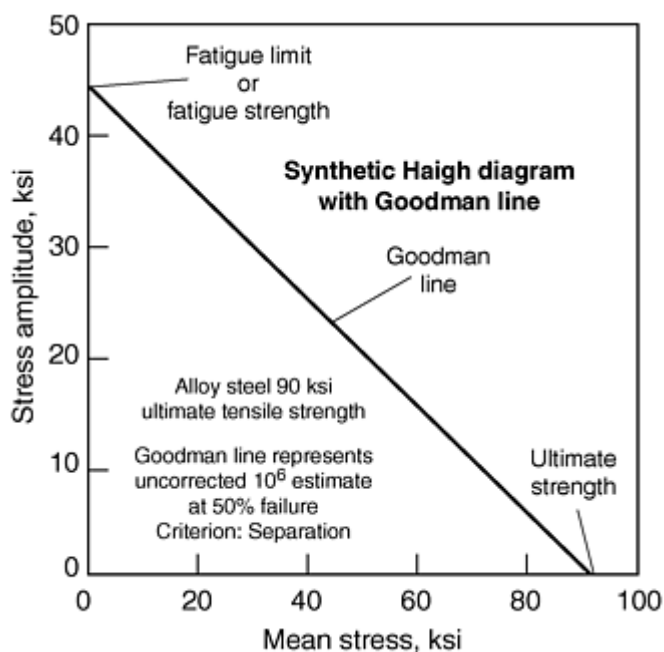

**Fig. 3** A plot of reduction factor for use in estimating the effect of surface finish on the  $S-N$  fatigue limit of steel parts. Source: Ref 17

Mean stress influences are very important, and each design approach must consider them. According to Bannantine et al. (Ref 13), the archetypal mean ( $S_m$ ) versus amplitude ( $S_a$ ) presentation format for displaying mean stress effects in the safe-life, infinite-life regime was originally proposed by Haigh (Ref 19). The Haigh diagram can be a plot of real data, but it requires an enormous amount of information for substantiation. A slightly more involved, but also more useful, means of showing the same information incorporates the Haigh diagram with  $S_{max}$  and  $S_{min}$  axes to produce a constant-life diagram. Examples of these are provided below.

For general consideration of mean stress effects, various models of the mean-amplitude response have been proposed. A commonly encountered representation is the Goodman line, although several other models are possible (e.g., Gerber and Soderberg). The conventional plot associated with this problem is produced using the Haigh diagram, with the Goodman line connecting the ultimate strength on  $S_m$ , and the fatigue limit, corrected fatigue limit, or fatigue strength on  $S_a$ . This line then defines the boundary of combined mean-amplitude pairs for anticipated safe-life response. The Goodman relation is linear and can be readily adapted to a variety of manipulations.

In many cases Haigh or constant-life diagrams are simply constructs, using the Goodman representation as a means of approximating actual response through the model of the behavior. For materials that do not have a fatigue limit, or for finite-life estimates of materials that do, the fatigue strength at a given number of cycles can be substituted for the intercept on the stress-amplitude axis. Examples of the Haigh and constant-life diagrams are provided in Fig. 4 and 5. Figure 5 is of interest also because of its construction in terms of a percentage of ultimate tensile strength for the strength ranges included.

**Fig. 4** A synthetically generated Haigh diagram based on typically employed approximations for the axes intercepts and using the Goodman line to establish the acceptable envelope for safe-life, infinite-life combinations

**Fig. 5** A constant-life diagram for alloy steels that provides combined axes for more ready interpretation. Note the presence of safe-life, finite-life lines on this spot. This diagram is for average test data for axial loading of polished specimens of AISI 4340 steel (ultimate tensile strength, UTS, 125 to 180 ksi) and is applicable to other steels (e.g., AISI 2330, 4130, 8630). Source: Ref 20

What are some other examples of metallic response to cyclic loading in this regime? First, consider the behavior of an aluminum alloy 2219-T85 in Fig. 6, consistent with current MIL-HDBK-5 presentations, showing a  $S_{max}$  versus  $\log N$  plot with the supporting data shown. Figure 7 shows the constant-life diagram for Ti-6Al-4V, solution treated and aged, from another MIL-HDBK-5 case: it includes both notched and unnotched behavior, and constant-life lines for various finite-life situations.

**Fig. 6** Best-fit  $S/N$  curves for notched,  $K_t = 2.0$ , 2219-T851 aluminum alloy plate, longitudinal direction. This is a typical  $S-N$  diagram from MIL-HDBK-5D showing the fitted curve as the actual data that support the diagram. This is the currently required approach for representing this type of information in that handbook. Source: Ref 21

**Fig. 7** Typical constant-life diagram for solution-treated and aged Ti-6Al-4V alloy plate at room temperature, longitudinal direction. Notched and smooth behavior are indicated in this constant-life diagram in addition to the finite-life lines. The influence notches is one of the critical effects on the fatigue of component details. Source: Ref 22

Plastics and polymeric composites are interesting materials for the variety of responses they can present under mechanical loading, with dynamic excitation being no exception. The nature of hydrocarbon bonding results in substantially more hysteresis losses under cyclic loading and a greater susceptibility to frequency effects. An example of *S-N*-type results for a variety of materials is provided in Fig. 8 (which is missing one dynamic variable). Also, different specifications are used for fatigue testing of plastics (e.g., Ref 24). The plastics industry also employs tests to determine a "static" fatigue response, which is a sustained load test similar to a stress-rupture or creep test of metallic materials.

**Fig. 8** Typical fatigue-strength curves for several polymers (30 Hz test frequency). Source: Ref 23

In application, this method is in its simplest form for steels in a benign environment. The task is to compare the  $S_a$  determined in the part to a  $S_a$  versus  $N$  curve at the necessary  $R$  value. If the operational  $S_a$  is less than the fatigue limit, then an acceptable safe-life, infinite-life situation exists (for whatever reliability was implied). In a slightly more complex scenario, the  $S_m$ ,  $S_a$  pair operating in a component is compared to the appropriately determined Goodman line on a Haigh diagram with two possible results: results on or under the Goodman line indicate an acceptable safe-life, infinite-life situation; or while results above the Goodman line indicate a finite-life situation that can be managed if the general boundary conditions of the method are not heavily abused.

Difficulties occur in multiaxial stress states (discussed in a separate article elsewhere in this Volume) because of the difficulty in identifying an appropriate "stress." The assumption of the failure criterion associated with separation can be problematic in disparate coupon-structure situations. While cumulative damage can be accounted for using this technique, there is no means of including load sequence effects in variable-amplitude loading (which are known to be important).

The stress-life technique offers a variety of advantages. Its extension using strain as a controlling quantity is a natural progression of technology.

## Finite-Life Criterion ( $\epsilon$ - $N$ Curves)

With more advanced and highly loaded components, it became obvious that stress-based techniques alone would not be sufficient to handle the full range of problems that needed to be addressed using continuum assumptions. The occurrence of plasticity, for example, and the accompanying lack of proportionality between stress and strain in this regime led to the use of strain as a controlling quantity. This was an evolutionary, not revolutionary, change in technology.

Strain-life is the general approach employed for continuum response in the safe-life, finite-life regime. It is primarily intended to address the "low-cycle" fatigue area (e.g., from approximately  $10^2$  to  $10^6$  cycles). The basic approaches and modeling, however, also make it amenable to the treatment of the "long-life" regime for materials that do not show a fatigue limit. The use of a consistent quantity, strain, in dealing with both, rather arbitrarily described "high-" and "low-cycle" fatigue ranges, has considerable advantages.

Work in this area was underway in the 1950s (Ref 25, 26). Cyclic thermal cracking problems contributed some of the stimulus for investigation, but the primary driving forces seem to have come from the power generation, gas turbine, and reactor communities. While the general approaches have remained consistent since that time, other outgrowths have offered variations on the theme (Ref 27, 28, 29). A simple summary of the strain-life approach can be found in Ref 30.

From a properties standpoint, the representations of strain-life data are similar to those for stress-life data. Rather than  $S$ - $N$ , there are now  $\epsilon$ - $N$  plots, with a log-log format being most common. The curve represents a series of points, each associated with an individual test result. The vertical axis can have different strain quantities plotted, however. While total strain amplitude seems to be the most common quantity presented, total strain range, plastic strain range, or other determined strain measures can also be found. In  $\epsilon$ - $N$  tests the strain can be monitored either axially or diametrically (watch for this possible variable). Again, be aware of the type of presentation, and consider critically what the independent variable is. Also, look for the necessary two dynamic load quantities to define the testing conditions and the specific failure criterion employed.

For data generation to support the  $\epsilon$ - $N$  method, there are standards by which testing is conducted (e.g., Ref 31, which includes suggestions for the information to be recorded with the results). According to Ref 31, any of the following may be used as the failure criterion: separation, modulus ratio, microcracking ("initiation"), or percentage of maximum load drop.

Testing for strain-life data is not as straightforward as the simple load-controlled (stress-controlled)  $S$ - $N$  testing. Monitoring and controlling using strain requires continuous extensometer capability. In addition, the developments of the technique may make it necessary to determine certain other characteristics associated with either monotonic or cyclic behavior. The combined output of the extensometer and load cell provides the displacement-load trace from which the hysteresis loop is formed. After several to several hundred strain excursions, the hysteresis loop typically stabilizes. This stabilized loop is shown in Fig. 9, which indicates the partitioning of the response into elastic and plastic portions. A stabilized loop of this type is formed during every constant-amplitude test and should be recorded as part of test procedures.

**Fig. 9** Stress-strain hysteresis in a constant-amplitude strain-controlled fatigue test. Source: Ref 32

Any given stabilized hysteresis loop represents only one of many such loops that would result from conducting the series of tests that are required to develop an  $\varepsilon$ - $N$  curve. The sequential connection of the vertices of these loops (e.g. point B of Fig. 9) conducted at different strain levels from what is known as the cyclic stress-strain curve. Some of the parameters used in developing the response models for strain-life technology are derived from the cyclic stress-strain curve. Later sections deal with this topic more extensively and additional material on this important subject can be found in the references provided here.

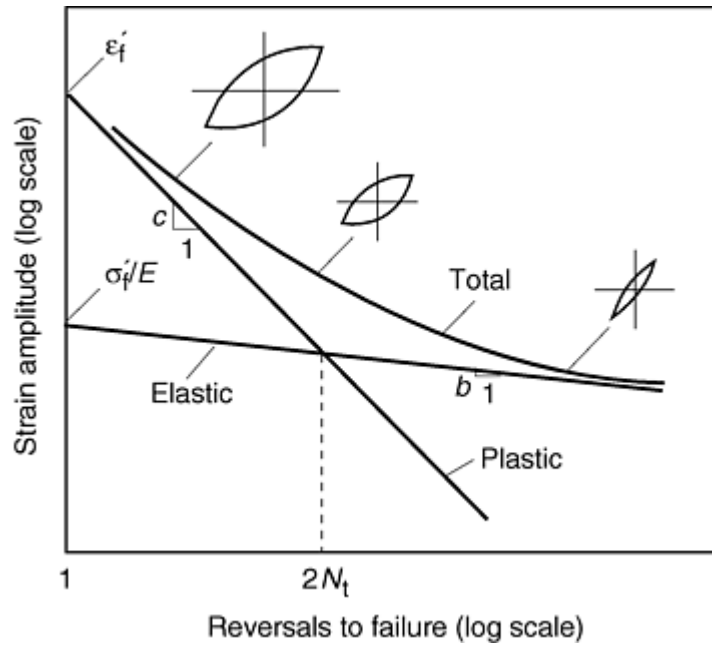

In some cases, strain control is discontinued after loop stabilization and the test proceeds under load control (usually used on long-life samples). If the failure criterion is other than separation or load drop, other monitoring/inspection capabilities may also be required. With one sample per data point and several to many samples to generate an entire curve, replicate tests are important to gauge both mean behavior and scatter.

Modeling of the  $\varepsilon$ - $N$  curve currently employs the separated elastic and plastic strain contributions described above. The total strain amplitude,  $\Delta\varepsilon/2$ , is considered as follows (note the use of half the range for strain amplitude, instead of  $\varepsilon$ ):

$$\begin{aligned} \Delta\varepsilon/2 &= \Delta\varepsilon_E/2 + \Delta\varepsilon_P/2 \\ &= (\sigma'_F/E) \cdot (2N_F)^b + \varepsilon'_F \cdot (2N_F)^c \end{aligned} \quad \text{(EQ 1)}$$

where  $\Delta\varepsilon/2$  is the total strain amplitude,  $\varepsilon_e/2$  is the elastic strain amplitude,  $\varepsilon_p/2$  is the plastic strain amplitude,  $\sigma'_f$  is the fatigue strength coefficient,  $b$  is the fatigue strength exponent,  $\varepsilon'_f$  is the fatigue ductility coefficient,  $c$  is the fatigue ductility exponent, and  $2N_f$  is the number of reversals to failure (2 reversals = 1 cycle).

A graphical representation of this modeling practice is shown in Fig. 10 (Ref 33). The coefficients and exponents either represent determined cyclic characteristics or can be approximated from monotonic tests. Further appreciation of these terms, means of approximating the necessary coefficients, and the variety of related technology can be gained in either Bannantine (Ref 13) or Conway (Ref 5). The use of approximations can result in synthetic or constructed  $\varepsilon$ - $N$  plots that contain no real data, similar to the creation of  $S$ - $N$  curves or Goodman lines and should be acknowledged as such.

**Fig. 10** Representation of total strain amplitude vs. number of reversals to failure, including elastic and plastic portions as well as the combined curve  $N_t$ , transition life from plastic (low-cycle) regime to the elastic (high-cycle) regime

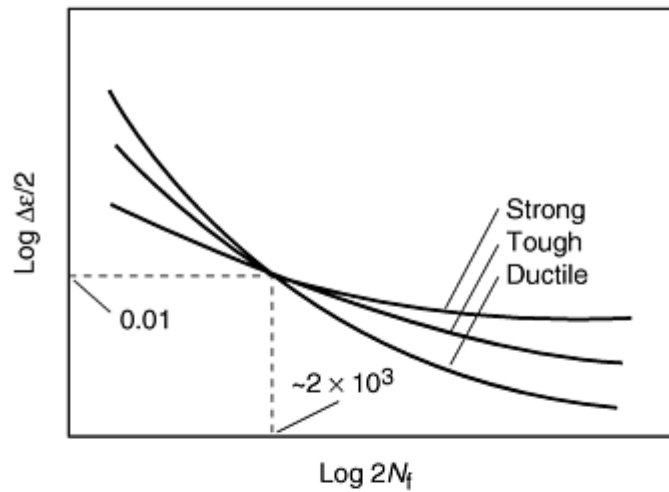

The use of the number of reversals to failure as opposed to the number of cycles to failure seems to be an artifact of early developments in the field. The relationship is simple: a cycle consists of two reversals. There appears to be no argument for its retention in the context of the strain-life expression, but it has become a working part of this technological "package." Note that a reversal need not imply fully reversed loading ( $R = -1$ ), but may only indicate a change in direction in load.

As with all methods, there must be a mechanism for treating mean stresses, while mean strain effects are apparently considered negligible (Ref 34). One of the factors that are readily implemented in the strain-life expression is a Morrow-type correction factor in the elastic term of Eq 1:

$$\frac{\Delta \epsilon / 2}{\epsilon'_F} = \left[ \frac{\sigma'_F - \sigma_0}{E} \right] \cdot (2N_F)^B + \epsilon'_F \cdot (2N_F)^C \quad \text{(EQ 2)}$$

where  $\sigma_0$  is the mean stress (as determined from the hysteresis loop developed at the detail, not the mean elastic stress). The convenience of the mathematical representation is readily evident here, and the inclusion of this term generally follows the actual data. Although it requires the mean stress from the hysteresis loop (a supplementary determination or calculation), this is a complete expression. In practice, the application would require the estimation of the strain amplitude and resulting mean stress at the detail, then an iterative solution for the number of reversals to failure,  $2N_f$ .

The important steps, though, are to review properties and offer examples of the various behaviors. Figure 11 shows generalizations of the response of metallic materials to strain-controlled testing. The terms *strong*, *tough*, and *ductile* are general descriptors of the response.

(a)

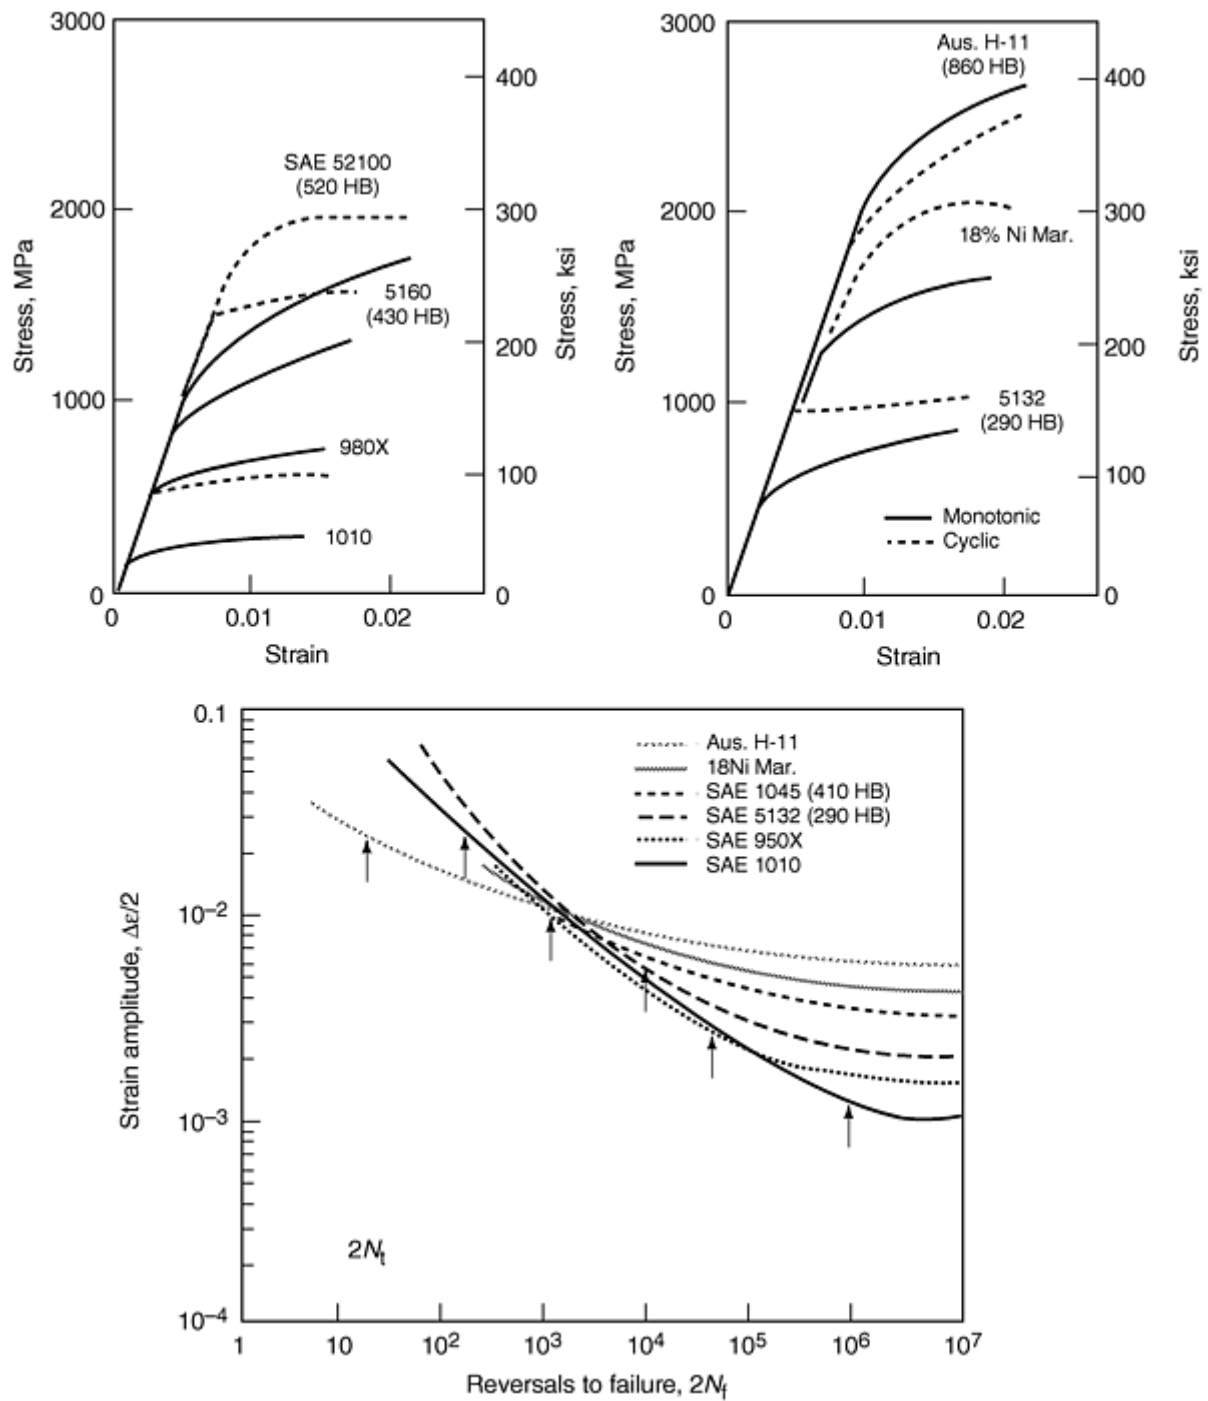

(b)

**Fig. 11** Schematic representation of the cyclic strain resistance of idealized metals. Response to the strain-controlled testing has resulted in several generalizations of material behavior, which this figure displays in two different formats for a better appreciation of the descriptions. Source: Ref 35

Because most examples of these data are quite similar, only a selected few are reviewed here.

Figures 12 and 13 offer composite plots of several steels and aluminum alloys. Note that these plots use strain amplitude on the ordinate; there was no second dynamic variable or failure criterion provided. The display of monotonic and cyclic response of the materials produces an interesting plot. It is instructive to reflect on the generalization of Fig. 11 as it is represented in Fig. 12 and 13.

**Fig. 12** Examples of the fatigue response of several steels, including their monotonic and cyclic strain-stress curves and their  $\epsilon$ - $N$  response. Source: Ref 36

**Fig. 13** Fatigue behavior of several aluminum alloys. Aluminum alloys are readily characterized using the strain-controlled methods. The general lack of a fatigue limit in these materials is well represented by the  $\epsilon$ - $N$  method. Source: Ref 37

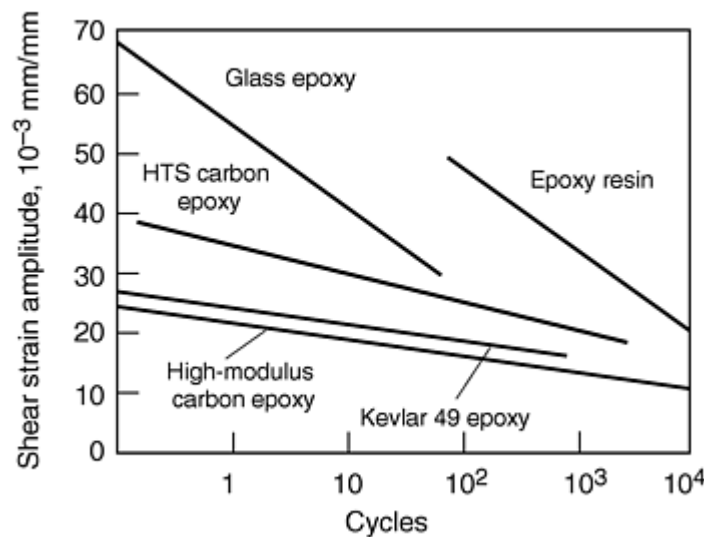

The "low-cycle fatigue" characterization of nickel-base superalloys is an area of considerable interest for various high-temperature applications. Several alloys are shown in Fig. 14, which represents the responses at 850 °C. This plot utilizes total strain range, no  $R$  or  $A$  value or failure criterion was specified. At elevated temperatures, wave-form, frequency, holdtime, and other effects may be more evident, and occasionally material instabilities may contribute to the response. Creep-fatigue interactions can alter an assumed "simple" fatigue situation to a considerable degree. Plastics and composites also can be approached in this manner (Fig. 15). Orientation effects can dominate this response, and loading must be carefully considered. Two strain-life plots show varying responses in fiber-reinforced composites in Fig. 15.

**Fig. 14** Low-cycle fatigue curves for superalloys at 850 °C (1560 °F). Superalloys used under high-load, high-temperature situations are frequently characterized in the safe-life, finite-life regime. This comparison at 850 °C (1560 °F) shows that different alloys can be "better" depending on the specific life desired for the coupon. Source: Ref 38

(a)

(b)

**Fig. 15** Fatigue strain-life data. (a) For unidirectional carbon-fiber composites with the same high-strain in different epoxy matrices. (b) Torsional shear strain-cycle diagram for various  $0^\circ$  fiber-reinforced composites. Source: Ref 39

A distinct advantage of the strain-life method is its ability to deal with variable-amplitude loading through improved cumulative "damage" assessment. Cyclic plasticity responses are accounted for, and load sequence effects are reflected in the analysis and results, one area where the concepts of reversals and the development of closed loops remains important. In addition, advanced methods have been developed to address elevated-temperature situations where creep and fatigue are active simultaneously.

Multiaxial loads as well as in- and out-of-phase loading remain a problem and have not yet been addressed successfully in a general sense. Each situation should be reviewed carefully for possible interactions, and situation-specific testing may be required. More detailed coverage is provided in the article "Multiaxial Fatigue Strength" in this Volume.

Application of the strain-life method in its simplest form is to compare the total strain amplitude ( $\Delta\varepsilon/2$ ) at a detail of the part to a  $\varepsilon$ - $N$  curve having the necessary mean strain (stress) effects included. The assumption here is that the detail on the part, perhaps in a high-constraint area, will respond identically to a specimen that is inherently a smooth bar in plane

stress, albeit at the same strain level. The life, of course, corresponds to the intercept of the strain level and the  $\epsilon-N$  curve. In many instances, no actual visual comparison is done; instead, the determination is readily done through calculation using the mathematical model of the  $\epsilon-N$  curve. The result is typically a safe-life, finite-life estimate, consistent with the reliability and failure criterion of the model.

## Damage Tolerant Criterion ( $da/dN$ vs. $\Delta K$ )

The  $S-N$  and  $\epsilon-N$  techniques are usually appropriate for situations where a component or structure can be considered a continuum (i.e., those meeting the 'no cracks' assumption). In the event of a crack-like discontinuity, however, they offer no support. The mandate is either to "attempt to remove the crack" or "remove the parts." The fact that components with "cracks" may continue to bear load is generally unaddressable using either  $S-N$  or  $\epsilon-N$  methods (except through residual life testing).

So what has made these two techniques no longer usable? One point is the inability of the controlling quantities to make sense of the presence of a crack. A brief review of basic elasticity calculations shows that both stress and strain become astronomical at a discontinuity such as a crack, far exceeding any recognized property levels that might offer some sort of limitation. Even invoking plasticity still leaves inordinately large numbers or, conversely, extremely low tolerable loads. An alternative concept and controlling quantity must be used.

That quantity is *stress intensity*, a characterization and quantification of the stress field at the crack tip. It is fundamental to linear elastic fracture mechanics. It recognizes the singularity of stress at the tip and provides a tractable controlling quantity and measurable material property. (Note: The stress intensity as used here is *not* the same as the stress intensity identified with the ASME Boiler and Pressure vessel calculations, which use this term to define the difference between the maximum and minimum principal stresses.)

The development of fracture mechanics has roots in the early 1920s and has developed considerably since the late 1940s and early 1950s. Examples of applicable texts are Ref 40 and 41.

A very basic expression for the stress intensity is its determination for a semi-infinite center-cracked panel having a through-thickness crack of length  $2a$  in a uniform stress field that is operating normal to the opening faces of the crack. The resulting stress intensity is as follows (Ref 42):

$$K_I = \sigma \cdot (\pi a)^{0.5} \quad (\text{EQ 3})$$

where  $\sigma$  is the far field stress responsible for opening mode loading (mode I) and  $a$  is the crack depth in from the edge of the plate. This formula allows an immediate appreciation of the combined influence of stress and crack length common to all stress intensity determinations. Specifically, stress intensity depends directly, but not singularly, on stress, and secondly it depends on crack length.

In a more general format, stress intensities might be expressed as:

$$K_I = \sigma \cdot Y \cdot (\pi A)^{0.5} \quad (\text{EQ 4})$$

where  $Y$  is a geometric factor allowing the representation of other geometries. For example, the correction for finite width ( $W$ ) of Eq 3 is (Ref 43):

$$K_I = \sigma \cdot \{\text{SEC}[\pi(A/W)]\}^{0.5} \cdot (\pi A)^{0.5} \quad (\text{EQ 5})$$

In addition, many geometries (geo), including test specimens, do not readily lend themselves to stress determinations, but the applied loads (forces) are known, so the stress intensity would take the form:

$$K_I = P \cdot (\text{GEO}) \cdot F(A/W) \quad (\text{EQ 6})$$

From a philosophical standpoint, a stress can never be applied, but a load can. Stress is always a resultant and determined quantity; it is not measurable. It is a mathematical device that has some very useful characteristics and provides a wealth of interpretations and insights, especially in reflecting an areal rationalized force (load) path through the structure. Structures and materials, however, only experience loads (mechanical, thermal, chemical, etc.) and respond with strains and displacements.

In some cases, however, where complexity precludes a simple "stress" approach, analytical techniques do allow the calculation of stress intensity factors under the imposed loads.

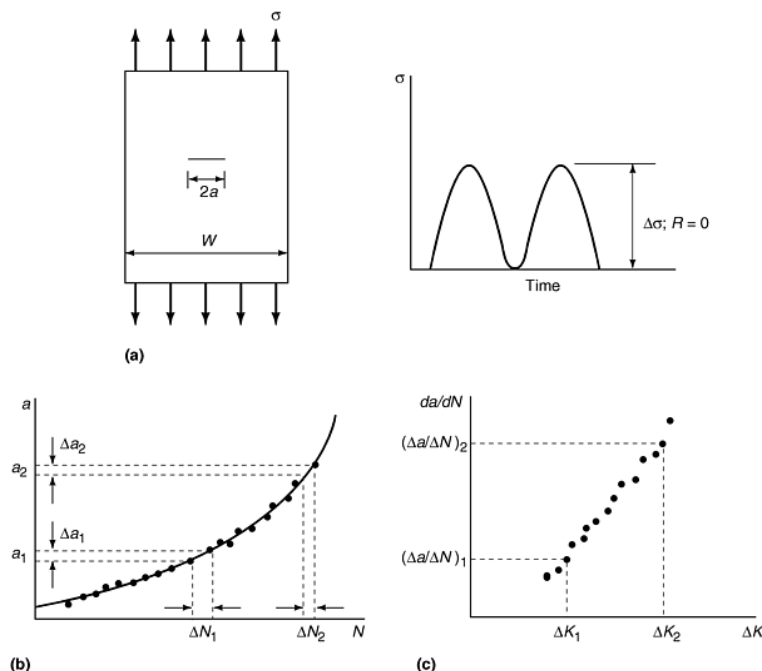

The connection of stress intensity,  $K_I$ , as a controlling quantity for fracture is a direct consequence of a physical model for linear elastic fracture under plane-strain conditions. Its limit is  $K_{Ic}$ , the critical plane-strain fracture toughness. The use of the stress intensity range,  $\Delta K_I$ , as a controlling quantity for crack extension under cyclic loading is simply by correlation. The ability of the stress intensity to reflect crack-tip conditions remains mathematically correct, but the correlation of  $\Delta K_I$  to crack growth is a successful application by repeated demonstration. By altering Eq 3 using  $\Delta\sigma$  instead of  $\sigma$ ,  $\Delta K_I$  results:

$$\Delta K_I = \Delta\sigma \cdot (\pi a)^{0.5} \quad (\text{EQ 7})$$

The stress intensity range to a certain extent simply reflects an extension of the stress-based practices. However, the testing to support fracture mechanics-based fatigue data is done differently than in the  $S-N$  or  $\epsilon-N$  methods because of the necessity to monitor crack growth. Crack growth testing is performed on samples with established  $K_I$  versus  $a$  characteristics. Under the controlled load specified using two dynamic variables, the crack length is measured at successive intervals to determine the extension over the last increment of cycles. Crack length measurement can be done visually or by mechanical or electronic interrogation of the sample using established techniques that allow for automation of the process.

The immediate results from the testing then are not  $da/dN$ , but  $a$  versus  $N$ . Subsequent manipulation of the  $a-N$  data set using numerical differentiation provides  $da/dN$  versus  $a$ . Coupling this latter data with a stress intensity expression ( $K_I$  as a function of load and crack length) for the specific sample results in the final desired plot of  $da/dN$  versus  $\Delta K_I$ . This process is shown schematically in Fig. 16. Details of this procedure can be found in Ref 45. The  $da/dN$  versus  $\Delta K_I$  curve

has a sigmoidal shape, and a full data set covers crack growth rates that range from threshold to separation. It is important to note that this data represents only "long crack" behavior; that is, the cracks are substantially greater in size than any controlling microstructural unit (e.g., grain size) and typically exceed several millimeters in length. A second important assumption is that of a plane-strain stress state; therefore, a plane-stress descriptor is not required.

**Fig. 16** Schematic representation of the specimen, data, and modeling process for generating fatigue crack growth rate ( $da/dN - \Delta K$ ) data. (a) Specimen and loading. (b) Measured data. (c) Rate data. Source: Ref 44

A real test of modeled  $da/dN$  vs.  $\Delta K_I$  expressions is whether, under reintegration, the original  $a-N$  data will be reproduced. This type of review should be consistently employed to assess the integrity of the modeling process.

The generation of  $da/dN$  versus  $\Delta K_I$  data is obviously considerably more involved than either  $S-N$  or  $\epsilon-N$  testing. It does have the advantage, however, of producing multiple data points from a given test.

Figure 17 reflects interesting features at each extreme of the  $da/dN$  vs.  $\Delta K_I$  curve. First, at the upper limit of  $\Delta K_I$ , it reaches the point of instability and the crack growth rates become extremely large as fracture is approached. The second point of interest is the lower end of the  $\Delta K_I$  range where crack growth rates essentially decrease to zero; this is identified as the fatigue crack growth threshold,  $\Delta K_{I, th}$ .

**Fig. 17** Entire  $da/dN$  vs.  $\Delta K$  plot for A533 steel showing asymptotic behavior at either end of the curve and a relatively linear portion in the center. Yield strength 470 MPa (70 ksi). Test conditions:  $R = 0.10$ ; ambient room air, 24 °C (75 °F). Source: Ref 46

The existence of threshold behavior at low  $\Delta K_I$  values is analogous, in some senses, to the fatigue limit of some ferrous materials in  $S-N$  response. If, with the appropriate  $R$  ratio, the stress intensity range is below the threshold value,  $<\Delta K_{I,th}$ , cracks will not extend under the applied load(s). Thus, an assessment of nonpropagating crack(s) can be made under the appropriate circumstances.

A reflection on failure criterion is appropriate here. Much as  $K_I$  is a quantity for assessing the point of initiation of propagation of unstable fracture,  $\Delta K_{I,th}$  functions as the limit for the initiation of crack propagation (for "long" cracks) under cyclic loading. Above  $\Delta K_{I,th}$  and below instability, the criterion for subcritical extension is satisfied and the rate is as determined by the curve.

Modeling of the central portion of the  $da/dN$  versus  $\Delta K_I$  curve is frequently done using the Paris equation:

$$DA/DN = C (\Delta K_I)^N \quad \text{(EQ 8)}$$

This is a very simple exponential relation that can readily be curve fit to the desired portion of the data (see Fig. 18, where one of the data sets is modeled as indicated).

**Fig. 18** An example of the use of a Paris relation to model the linear portion of a crack growth rate curve. Effect of stress ratio on the fatigue crack propagation rate in a 140 ksi yield strength martensitic steel. Source: Ref 47

Stress or load ratio (mean stress) effects exist in crack propagation data as well. The influence is that increasing  $R$  ( $R = K_{\min}/K_{\max}$ ) decreases both the threshold value at the low end and the instability characteristic at the upper end of the  $da/dN$  versus  $\Delta K_I$  curve. Examples of this are provided in Fig. 19 and 20.

**Fig. 19** The influence of  $R$  value on the fatigue crack growth characteristics of a steel. Fatigue crack propagation properties of JIS SS41 steel. Source: Ref 48

**Fig. 20**  $R$  value effects on threshold and fracture instability behavior of 300M steel. Source: Ref 49

Microstructural features must influence fatigue crack growth characteristics as well as all other properties. An example of this is provided in Fig. 21, which shows the compound influence of both gamma prime and grain sizes on fatigue crack propagation in Waspaloy.

**Fig. 21** Effect of grain size on fatigue crack growth of Waspaloy superalloy. Source: Ref 50

Plastics also can be analyzed using this technique. Figure 22 shows a variety of materials that are displayed in the conventional form. Many polymeric materials exhibit substantial frequency effects, and this should be considered in the generation of data.

**Fig. 22** Fatigue crack propagation behavior of various polymers. Source: Ref 51

In application, use of  $da/dN$  versus  $\Delta K_I$  is completely different than either the  $S-N$  or  $\varepsilon-N$  continuum method. Instead of providing an immediate life estimate in association with a given stress or strain combination and a test coupon's modeled failure criterion, a more complicated determination is required. Using the  $a$  versus  $\Delta K_I$  relation in the part, the applied loads are employed to assess crack extension over incremental changes in length, and they are continuously summed to reflect the total increase. In essence, this is the regeneration of the  $a-N$  curve for the specific part. Crack growth can be assessed until fracture (achieving a critical crack size) or some other intermediate point.

It is common in several industries to use the above technique to determine intervals between directed inspections to ensure structural integrity. This ability to formulate inspection schedules that maximize the likelihood of detecting an extending discontinuity prior to it becoming critical is one of the principal advantages of the damage tolerant approach. Even using this technique, a crack, once discovered, cannot necessarily be left in place. Removal or structural modification may be the only acceptable alternative (e.g. airframes). In other instances, the predictive aspects of the technique can justify continued operation of equipment under full or derated conditions while waiting for programmed replacement parts or with a stated finite-life limit for the unit (supplemental inspections may be required). Probabilistic methods can be used to produce a quantified risk assessment for these situations.

Extreme caution is advised regarding units, especially for  $da/dN$  expressions, where conversions among units can be very confusing because of the mathematical relationships involved. Multiaxiality in this instance is reflected in complex loading modes (e.g., combinations of modes I, II, and III). In a very general sense, the cracks tend to extend in directions that are normal to maximum principal stresses.

## Alloy Design for Fatigue and Fracture

Stephen D. Antolovich, Washington State University

---

## Introduction

FRACTURE MECHANICS is a very powerful tool for predicting the loads and crack lengths at which fracture can occur. Broken down to its essential form, it allows an engineer to predict the onset of fracture if the following information is available:

- Load/crack geometry (usually available from NDI)
- A formula for the so-called stress-intensity parameter,  $K$ , for the load/crack geometry of interest (the result of

sophisticated mathematical analysis but available in handbooks, such as Ref 1)

- The numerical value of the fracture toughness (generally denoted  $K_{Ic}$ ), which is determined experimentally through well-defined procedures (Ref 2)
- For fatigue crack propagation, knowledge of the crack growth rate as a function of the stress-intensity parameter

With this information and the use of fracture mechanic methods (as briefly described in the next section for monotonic and fatigue fracture), it is possible to compute the life without any consideration of those processes that determine the values of the fracture toughness or the crack growth rates. Such procedures as are outlined below are obviously of great value in carrying out engineering calculations for existing or contemplated components. However, in some instances the properties are insufficient to meet the engineering requirements. In such cases it is necessary to consider alternate materials or, in some instances, to develop alternate heat treatments and compositions that yield properties that allow the requirements to be met. Clearly in these instances it is important to have a clear understanding of the basic processes that affect toughness and fatigue so that effective changes can be made.

Another reason for understanding basic processes is that conditions can change. For example, if an alloy is selected for intended service at 298 K with no impact loading and the temperatures change to 250 K and impact loading occurs, what will the effect of these changes be on the fracture properties of the material that has been selected? Is there perhaps another material that is more forgiving in terms of temperature and loading changes? These questions must be addressed if materials are to be put into service (or developed) with confidence. In this context, the goals of this article are:

- To review the basic processes of fracture and fatigue
- To show how these processes occur in materials of engineering interest, such as iron-, aluminum-, titanium-, and nickel-base alloys
- To provide a reference of practical data for engineering alloys and to describe typical applications

## Fracture Mechanic Methods

**Fracture Mechanics in Monotonic Loading.** In many applications there may be a pre-existing flaw that results from processing or from fabrication. Typically such flaws can result from welding, riveting, machining, or, in some cases, inherent material defects that may be considered to be "flaw-like." It is important to know whether the part can operate at the intended stresses given a particular flaw size. Of course, it may be possible in some instances to derate the operating stress to a level that is safe given the flaw that exists. In either case, an analysis can be carried out to determine if the component can be safely used. As an example of the way in which fracture mechanics is used to predict the onset of fracture, consider the following example (Ref 3):

**Maximum Stress to Fracture.** Suppose that the fracture toughness of a titanium alloy has been determined to be 44 MPa  $\sqrt{m}$  and a penny-shaped crack of diameter 1.6 cm (0.016 m) has been located in a thick plate that is to be used in uniaxial tension. If we assume plane-strain conditions and a material yield stress of 900 MPa (130 ksi), then the maximum allowable stress without fracture is calculated as follows.

**Solution:** The stress-intensity parameter formula for a penny-shaped crack is given by:

$$K = 2\sigma \left( \frac{a}{\pi} \right)^{1/2} \quad (\text{EQ 1})$$

where  $a$  is the crack radius and  $\sigma$  is the applied stress. At fracture, the applied stress intensity is equal to the plane-strain fracture toughness:  $K = K_{Ic}$ . Rearranging Eq 1 and substituting appropriate values gives:

$$\sigma = K/2[\pi/A]^{1/2} = 44/2[\pi/0.008]^{1/2} \quad (\text{EQ 2})$$

$$\sigma_F = 436 \text{ MPA}$$

Thus, fracture will occur well below the yield stress of the material. This calculation shows that there is no guarantee that fracture will not occur simply because the nominal applied stresses are below the yield stress.

**Fracture Mechanics in Fatigue Loading.** In the preceding example it is assumed that there is a pre-existing crack and that the only item of interest is the maximum load that can be applied without failure. While such a situation is certainly important, the more usual situation is that there is a pre-existing crack and cyclically applied loads are present whose magnitude is below that which would cause immediate fracture. In this case, the repeated application of a load (such that  $K < K_{Ic}$ ) causes the crack to grow, slowly at first but more rapidly as the crack increases in length. The question now is how many cycles can be applied before the crack becomes so long that complete separation occurs? In order to determine the number of cycles, the crack growth rate as a function of the stress intensity parameter is required. This is usually available for materials of engineering interest in the form:

$$\frac{da}{dN} = f(\Delta K) \quad (\text{EQ 3})$$

where  $N$  is the number of cycles and  $\Delta K = K_{\max} - K_{\min}$ . In this equation,  $\Delta K$  is known as the *stress-intensity parameter range*. The stress-intensity parameter range characterizes the cyclic stresses and strains ahead of the crack tip and uniquely characterizes the crack growth rate through a relationship such as Eq 3. Perhaps one of the simplest, yet most widely used forms of Eq 3 is the Paris equation, which is used to describe crack growth behavior over a fairly broad range of  $\Delta K$ . Equation 3 then takes on the specific form:

$$\frac{da}{dN} = C(\Delta K)^n \quad (\text{EQ 4})$$

where  $C$  and  $n$  are material parameters that depend on temperature, frequency, and load ratio.

The cyclic life is computed by integration of the crack growth rate equation or by numerical integration of crack growth rate data. This is illustrated in a straightforward way by integration of the Paris equation, as shown below.

**Estimation of Fatigue Life Using Paris Equation.** The crack growth rate of 7075-T6 Al is given by:

$$\frac{da}{dN} = 5 \times 10^{-10} (\Delta K)^4$$

where  $\Delta K$  is given in units of  $\text{ksi}\sqrt{\text{in.}}$  and  $da/dN$  is given in units of  $\text{in./cycle}$ . Assume that a part contains a center crack that is 0.20 in. long. The stresses vary from 0 to 30 ksi and the fracture toughness is  $25 \text{ ksi}\sqrt{\text{in.}}$ . The life of the part is computed as follows.

**Solution:** For this geometry, the stress-intensity parameter is given by:

$$K = \sigma\sqrt{\pi a}$$

$$\Delta K = \Delta\sigma\sqrt{\pi a}$$

Using the information given in the problem statement and the above expression, the crack growth rate is given by:

$$\frac{da}{dN} = 5 \times 10^{-10} \times 30^4 \times \pi^2 \times a^2$$

$$= 4 \times 10^{-3} a^2$$

This equation can be integrated from the initial condition of  $N = 0$  and  $a = a_0 = 0.10$  in. to the final condition of  $N = N_f$  and  $a = a_f$ . The final crack length  $a_f$  is the crack length at which fracture occurs, and it corresponds to the condition  $K_{\max} = K_{Ic}$ . Here  $K_{\max}$  corresponds to the value of  $K$  at the maximum stress. Integrating and rearranging terms gives the following expression:

$$N_f = 250 \int_{a_0}^{a_f} \frac{da}{a^2}$$

Integration of the right-hand side of the equation gives:

$$N_f = 250 \left[ \frac{1}{a_0} - \frac{1}{a_f} \right]$$

The only remaining problem is to compute the crack length at failure. As mentioned above,  $a_f$  depends on the fracture toughness. For the geometry being considered, this is given by:

$$a_f = \frac{1}{\pi} \left( \frac{K_{Ic}}{\sigma} \right)^2 = \left( \frac{25}{30} \right)^2 = 0.22 \text{ in. (5.6 mm)}$$

Substituting into the expression for life, we have:

$$N_f = 250 \left( \frac{1}{0.1} - \frac{1}{0.22} \right) = 1363$$

The part is thus expected to last slightly over 1300 cycles.

## Monotonic Fracture

As pointed out in the preceding section, fracture below the yield stress can occur if there are sufficiently large pre-existing flaws. There are different mechanisms by which such fracture can occur, and these mechanisms depend, to some extent, on the material being considered. In this section, a brief overview of the mechanisms and some related models are given for appropriate classes of materials. More detailed information on fracture mechanisms is given in the article "Micromechanisms of Monotonic and Cyclic Crack Growth" in this Volume.

In general, fracture toughness can be viewed as a property that depends on both strength and ductility, modified by the complex stress states that occur within the plastic zone and that trigger certain failure processes. Fracture properties are improved by fine grain sizes, low volume fractions of inclusions that are widely spaced, and special microstructural features (e.g., transformation-induced plasticity in steels, TRIP), and the mechanisms for crack deflection that exist in Al-Li alloys and certain morphologies of titanium alloys. These microstructural factors are briefly reviewed in this section as well.

While for a given system the toughness usually decreases with increasing strength, there are wide variations, and it is frequently possible to manipulate the microstructure and/or chemistry in order to increase the toughness while at the same time maintaining acceptable strength levels. Reducing the grain size of most alloys results in both an increase in toughness and an increase in strength. Thus, grain size control has been a popular mechanism for obtaining desirable combinations of mechanical properties.

**Processing Effects on Toughness.** Most alloys used in engineering applications must be processed in some way before they can be used. Processing frequently involves mechanical working at intermediate and high temperatures. Hot working can produce highly directional grain structures (e.g., in aluminum alloys) and a significant degree of texturing (e.g., in titanium alloys). The fracture toughness is affected by both of these types of directionality, and it is customary to see fracture toughness values tabulated in terms of the orientation relative to the principal direction of working. Generally, the fracture toughness will be high for orientations in which the grains are elongated normal to the crack plane (e.g., L-S, L-T) and proportionally lower for crack planes parallel to the elongated grain direction (e.g., S-T, S-L).

Of course, other processing steps also have a large effect on the fracture toughness. For example, if a material is produced by a powder metallurgy technique, there is the possibility of prior-particle boundary (PPB) contamination with gaseous species such as oxygen. The absorbed gases can weaken the interfaces of the compacted and sintered material through an effect on the interatomic bonding or through formation of gas bubbles in the material.

Basically, all processing will have an effect on the microstructure, chemistry, or dislocation substructure, which will in turn affect the fracture toughness.

**Fabrication Effects on Toughness.** Once processed and heat treated, materials must somehow be fabricated to produce a final component. Fabrication frequently involves material removal steps and joining steps, both of which affect the performance of the manufactured component. For example, both machining and welding may be involved.

Machining usually is not a source of reduced fracture toughness (although, as we will see below, it can have a significant effect on fatigue behavior). However, under some circumstances inappropriate machining may damage the surface of a semibrittle material sufficiently that fracture occurs below the net section yield. Materials that are used in applications where wear resistance is of primary concern are susceptible to such a situation, because they are generally very hard in order to improve the wear properties.

Welding often gives rise to fracture problems. In steels, there is always the possibility of developing an untempered martensitic structure or a severe stress pattern that causes microcracks. For example, in welding of ground vehicle frames, weld cracks may occur. The propensity toward crack formation is increased if alloy steels are welded or if thick sections are used. Not only can welding cause microcracking, but it also has the effect of radically altering the microstructure in ways that usually result in lower fracture toughnesses. This can be a result of segregation within the weld solidification structure or the development of coarse grains, to name but two such effects. It is interesting, however, to note that in  $\alpha/\beta$  titanium alloys, welding of fairly thick sections results in rapid cooling and the formation of a transformed microstructure that, as we have seen, is actually beneficial for the fracture toughness. Weighed against this beneficial structure is the fact that interstitials can be absorbed during the weld process; the benefits of a desirable structure may be negated by an increased interstitial content.

However desirable a microstructure may be, processing and fabrication methods affect the fracture toughness and may degrade toughness properties. We will see in the following sections that these considerations are even more important for fatigue properties.

---

## Fracture Mechanisms and Models

It is important to define the term *fracture toughness* and how fracture toughness relates, in a general way, to mechanical and microstructural parameters. Toughness may be thought of as the amount of energy that is absorbed when the crack advances one unit of area. In other words, it is the energy absorbed per unit area of crack advance. As such, it has the same units as the results of a Charpy test (i.e., force  $\times$  length/length<sup>2</sup>). In fracture mechanics, this value is denoted by the symbol  $G_{IC}$ . This definition of toughness is particularly attractive to materials developers because it focuses on the crack-tip processes. However, it has become customary to report toughness in terms of the critical value of the stress-intensity parameter at which fracture occurs. As seen above, this is denoted by the symbol  $K_{IC}$  and is called the plane-strain fracture toughness. There is a simple, well-known relationship between these two parameters:

$$G_{IC} = K_{IC}^2/E \quad (\text{EQ 5})$$

where  $E$  is Young's modulus. This means that it is a simple matter to go from an energy representation (i.e.,  $G$ ) to a stress-intensity representation (i.e.,  $K$ ). In general, the fracture toughness can be computed by calculating all of the energy

absorbed in bringing the crack-tip elements to the point of fracture and dividing by the amount of crack extension associated with this critical event. While simple in concept, there are significant problems in implementing such computations, including knowledge of the stress/strain fields ahead of the crack tip in the plastic zone and, of course, the criterion for crack extension. A simple guide for relating the fracture toughness to the mechanical properties based on these concepts is (Ref 4):

$$K_{IC} = N (E\sigma_{YS}E_F)^{\frac{1}{2}} \quad \text{(EQ 6)}$$

where  $n$  is the strain hardening exponent,  $\sigma_{ys}$  is the yield strength, and  $e_f$  is the fracture strain.

Equation 6 and variants thereof provide some guidance for understanding the effects of microstructure on the fracture toughness of many engineering materials.

**Cleavage** is a mechanism whereby in the ideal case, crack extension occurs by breaking of bonds across an atomic plane. In principle, little energy is absorbed in this case and materials tend to behave in a brittle manner. Of course, one must add the caveat that the toughness or brittleness of a material is determined by the total energy that is absorbed, not by the mechanism. We shall see a case in which cleavage is the final failure mechanism but the material is overall very tough. Cleavage occurs frequently in steels and in titanium alloys and is discussed below in more detail. Cleavage cracking is illustrated schematically in Fig. 1. Factors that affect the fracture toughness of materials that fracture by cleavage are the size, strength, and distribution of the cleavage nuclei (i.e., carbide particles in steels) and the cleavage facet size and orientation.

**Fig. 1** Cleavage crack formation. Bands are broken across the idealized crack plane.

**Microvoid Coalescence.** In many materials, particles (which may be intentional or unintentional) are found within a ductile matrix. These particles act as initiators of fracture. This initiation can be the result of interface decohesion, fracture of the particle, or a combination. In steels, such fracture occurs above the ductile/brittle transition temperature (DBTT) and may involve both inclusions and small, dispersed carbides. In aluminum alloys, this is the predominant fracture mode at all temperatures and is frequently initiated by large constituent particles, followed by void formation and growth around other particles. A schematic model for microvoid coalescence is shown in Fig. 2. In materials that fail by microvoid coalescence, important factors affecting the fracture toughness are the mechanical properties of the particles, the properties of the particle/matrix interface, the size and distribution of the particles, and the plastic properties of the matrix.

**Fig. 2** Schematic of microvoid coherence

**Boundary Decohesion.** In many materials, failure along grain boundaries (or prior-grain boundaries) is an important mode of fracture. This fracture mode will occur when the boundary is the "weak link" in the microstructure, which occurs under the following conditions:

- The grain interiors do not deform, but the cleavage strength is higher than the boundary strength (typical of some ceramics).
- The boundary has been weakened by segregation of a damaging species (typical of phosphorus segregation to boundaries in steel).
- The boundary is strong, but brittle particles have nucleated on the boundaries and provide both crack initiators and an easy fracture path (typical of the formation of MnS on prior-austenite boundaries in steel).
- The boundary is strong but is attacked by an external species in the application environment. This situation is similar to the second condition in this list, but it is time dependent because the damaging species must diffuse into the material ahead of the crack tip (typical of stress-corrosion cracking).

Grain boundary cracking is illustrated in Fig. 3. Clearly it can be influenced by chemistry as well as by heat treatments that control the distribution of boundary particles. For example, a continuous brittle boundary film could be disastrous, whereas a heat treatment that produces discrete boundary particles would increase the toughness.

**Fig. 3** Schematic of grain boundary cracking

**Phase Changes during Deformation.** In some materials (e.g., steels, ceramics, titanium alloys) it is possible to have a phase change ahead of the crack tip during loading such that additional energy is absorbed and the material is effectively toughened. The classical example of this is in TRIP steels. Here a metastable austenite transforms to martensite as the crack propagates. Even though the martensite is significantly more brittle than the austenite that it replaces, it transforms along planes of maximum shear, and the invariant shear associated with the transformation represents an additional deformation mode that absorbs energy. In many cases the TRIP process results in materials that are significantly tougher than those with similar properties but do not transform during crack extension. These ideas have been described quantitatively and verified experimentally (Ref 5). They have also been successfully applied to materials in which there are multiple toughening mechanisms (Ref 6). The process is illustrated in Fig. 4. Factors that influence toughness with such a mechanism are the invariant shear as well as the mechanical properties of the initial and final phases. In ceramics (Ref 3) (and to a lesser extent in metals) there is also a significant volume change (e.g., in zirconia) when the transformation occurs and compressive stress fields are generated ahead of the crack tip, which reduces the driving force for crack extension. This is shown schematically in Fig. 5.

**Fig. 4** (a) Martensite formation in the center of a specimen of steel 1 that was reduced 45% at 460 °C and fractured at room temperature. The crack has extended approximately 60 mils beyond the fatigue crack. (b) Schematic of the above process

**Fig. 5** Toughening mechanism for ceramics: residual compression at the crack tip. Selected regions of a microstructure are induced to expand in the vicinity of the crack tip such that a local state of compression counteracts the externally applied tensile stress.

## Fracture in Steels

Because steels are used in many microstructural conditions, this section is limited to a few examples. The subject is treated in more detail later in this Volume. This section provides an overview of some of the major microstructural considerations in carbon and alloy steels that affect the fracture toughness, such as the ferrite grain size for low-temperature fracture, the prior-austenite grain size, the size, spacing, and character of inclusions, and phase transformations, if any.

For fracture of a mild steel at low temperatures, it is reasonable to assume that fracture will occur when the conditions at the crack tip are such that the plastic constraint factor (pcf) elevates the yield stress to a level equivalent to the fracture stress. This simple idea may be expressed by the condition:

$$\text{PCF} \cdot \sigma_{\text{YS}} = \sigma_{\text{F}} \quad (\text{EQ 7})$$

It is well known that both the yield stress and the fracture stress increase with decreasing grain size. It is also known that the pcf increases with  $K_{\text{IC}}$  and decreases with  $\sigma_{\text{ys}}$ . This can be understood by considering the case in which the fracture toughness is low and the yield strength is high. In this case the low fracture toughness doesn't allow crack tip stresses to build up to sufficiently high values to exert significant constraint.

These ideas have been combined (Ref 7) to yield an equation of the form:

$$K_{\text{IC}} = A + BD^{-\frac{1}{2}} \quad (\text{EQ 8})$$

The values of  $A$  and  $B$  would be expected to correspond to the particular steel being considered and whether the correlation is being made with the ferrite grain size or the austenite grain size. Graphs showing the effects of the austenite grain size are shown in Fig. 6 (Ref 8), where it can be seen that for a wide range of temperatures the form of Eq 8 is followed.

**Fig. 6** Relationship of fracture toughness to inverse square root of grain size. Dependence of fracture toughness on prior-austenite grain size at four temperatures. Source: Ref 8

Steels frequently contain inclusions, and these inclusions, in conjunction with other precipitates that might be present, have a major influence on the fracture toughness of steels. For example, MnS is frequently present, and for a given size of inclusion, it is known that the toughness increases with decreasing volume fraction of MnS. This is equivalent to saying that the toughness increases with increasing spacing of the inclusions for a given inclusion size. Physically, this is quite understandable, because as the crack is loaded, the crack-tip opening displacement (Eq 6) will not be able to reach its maximum value, due to cracking/decohesion of the inclusion, and link up with the crack tip. In fact  $K_{Ic}$  would be expected to vary directly with the square root of the inclusion spacing. It would also be expected that at a given inclusion spacing, the fracture toughness would increase with increasing strength of the inclusion/matrix interface above the yield strength. This variation is shown for a 0.45C-Ni-Cr-Mo-V steel (similar to 4340) in Fig. 7 for a wide range of conditions (Ref 9). The correlation follows an equation of the form:

$$K_{Ic} = A + (\sigma^* - \sigma_{YS}) \cdot \lambda^{\frac{1}{2}} \quad (\text{EQ 9})$$

where  $A$  is a material-dependent constant,  $\sigma^*$  is a fitting constant related to the strength of the inclusion/matrix interface, and  $\lambda$  is the spacing of the inclusions.

**Fig. 7**  $K_{Ic}$  for a martensitic 0.45C-Ni-Cr-Mo-V steel as a function of inclusion spacing and yield strength. Source: Ref 9

In Eq 9 it should be noted that the relationship is strictly valid only for inclusions of a particular size. If the volume fraction is held constant and the size of the inclusions is increased, it is easier to nucleate voids at the inclusion/matrix interface and the toughness will be lowered at a given spacing. This is accounted for in the term  $\sigma^*$ , which decreases with increasing size. It is clear from this equation and the data of Fig. 7 that it is very important to control the inclusion character (size and volume fraction) in order to increase the fracture toughness. It should also be noted that there should be a "cutoff" to the behavior seen in Fig. 7, because if all inclusions were removed, the fracture toughness would reach some limiting value that is characteristic of the material being considered.

Other inclusions also play a role. For example, in quenched-and-tempered steels the incoherent carbide particles are rather large, and Low (Ref 10) has suggested that the toughness of these steels is limited by the formation of a "void sheet" between the inclusion voids associated with decohesion between the carbides and the matrix. Void sheet nucleation is shown in Fig. 8 (Ref 11). Nucleation of this void sheet will have the effect of limiting the fracture toughness, because the

energy absorption process associated with growth of the larger voids to the point of impingement will be interrupted and early linkup will occur. When such mechanisms operate it is usual to see both large and small voids on the fracture surface, such as is seen in Fig. 9 for a 250-grade maraging steel (Ref 12). The nucleation of the void sheet is easier the larger the particles. This mechanism explains the relatively high fracture toughness of maraging steels, which contain extremely fine strengthening precipitates compared to the carbides in common quenched-and-tempered steels.

**Fig. 8** Effect of particles on fracture toughness. Source: Ref 11

**Fig. 9** An SEM view of the surface of the tensile-test fracture in 18% Ni, grade 300 maraging steel, showing a portion of the central zone of the fracture, close to the origin. The surface here is composed of equiaxed dimples of two sizes. The large dimples probably formed at Ti(C,N) particles; all the dimples were caused by particles of some sort. Source: Ref 12

As mentioned above, high toughness levels can be attained when austenite transforms to martensite at the crack tip. When this occurs a significant amount of energy may be absorbed. The energy absorption ahead of the crack tip is given by (Ref 5):

$$\Delta U^{A \rightarrow M} = (\sigma_M \cdot \varepsilon_{IS} / \sqrt{3}) \cdot V_{PZ} \cdot V_{FM} \quad (\text{EQ 10})$$

where  $\sigma_M$  is the stress at which martensite forms,  $\varepsilon_{IS}$  is the invariant shear associated with martensite formation,  $V_{PZ}$  is the volume of plastic zone (Ref 13), and  $V_{FM}$  is the volume fraction of martensite in the plastic zone. Equation 10 has been used to obtain an expression for the fracture toughness. Without going into the details, the energy absorption is increased for a large plastic zone that contains a large amount of martensite. It is also increased for relatively high stress levels of

martensite formation and large shear strains associated with the transformation. Figure 10 illustrates the incremental toughness due to martensite formation (Ref 5).

## Aluminum Alloy Fracture Toughness

Aluminum alloys are widely used in the aerospace industry for airframes and in other applications that require a good combination of strength and light weight. They generally consist of a face-centered cubic (fcc) solid solution matrix with various complex precipitate particles. While the physical metallurgy of these alloys is not reviewed here, it is important to note that they generally contain very small, coherent precipitates that are responsible in large measure for the observed

strength of these alloys. In addition, other particles are present that usually have a negative effect on the fracture toughness. Some of these particles are rather large and are referred to as "constituent" particles. There are also intermediate-sized particles that cannot be resolutioned on heat treating. Because of the microstructure, a duplex distribution of dimples is usually seen on the fracture surface, and the normal fracture mode is by the formation and coalescence of microvoids, with "void sheet" formation being an important aspect of fracture in these alloys. This fracture mode is very similar to that discussed above for steels, and many of the conclusions drawn apply also to aluminum alloys.

The fracture toughness of the traditional aluminum alloys shows, as do most materials, a general decrease in toughness with increases in yield strength (Fig. 11) (Ref 14). As the strength increases, the strain-hardening exponent generally decreases and void sheet nucleation occurs more easily, thus limiting the crack-tip opening displacement. These effects then account for the decreased fracture toughness.

**Fig. 11**  $K_{Ic}$  measurements on specimens from plate 25 to 38 mm (1.0 to 1.5 in.) thick. Source: Ref 14

While the strength generally causes a decrease in the toughness, the effects of the large constituent particles should not be overlooked. At any given strength level the toughness of the  $2xxx$  and  $7xxx$  alloys, for example, can be increased through careful control of the insoluble constituent particles that contain iron and/or silicon, such as  $Al_7Cu_2Fe$ ,  $Mg_2Si$ , and  $(Fe,Mn)Al_2$ . These particles are quite large (i.e., in excess of  $1 \mu m$ ) and nucleate voids. The toughness can be controlled through control of those elements that effectively increase the spacing of such particles. This results in an increase in the toughness, similar to what was observed for steels (Fig. 8). The efficacy of Fe + Si control is illustrated in Fig. 12 for a series of aluminum alloys of differing orientation (Ref 15). Reducing the Fe + Si content improves the toughness of both the  $2xxx$  and  $7xxx$  alloys.

**Fig. 12** Fracture toughness comparisons of aluminum alloys 2024, 2124, 7075 and 7475. Source: Ref 15

Another class of alloys is Al-Li alloys, which contain lithium to form coherent  $Al_3Li$  precipitates. These precipitates are based on the  $L1_2$  structure (i.e., ordered "fcc" with lithium atoms at the cube edges and aluminum atoms at the face centers) and are fully coherent with the matrix. In this regard they are similar to the  $\gamma'$  precipitates found in nickel-base superalloys. These alloys are strong and light and have a significantly higher modulus than the conventional alloys used in the aerospace industry.

The principal problem with Al-Li alloys is that a significant degree of segregation attends their fabrication, and during mechanical processing (e.g., rolling) the interdendritically segregated regions are rolled out into sheets such that the transverse properties are very low. The corresponding fracture toughness is shown in Fig. 13. Note that for both alloys the fracture toughness depends on the orientation to some extent. In Fig. 13 the first letter refers to the load direction and the second to the expected direction of crack propagation. Thus in both the S-L and S-T orientations, the crack propagates on a plane parallel to that formed by the strong segregation and would be expected to be relatively low. Indeed, other data for which fracture toughness is available shows that the fracture toughness of 8090 in the L-T direction is approximately double that of the S-L and S-T orientations (Ref 16). Based on that result, fracture toughness in excess of  $30 \text{ MPa}\sqrt{\text{m}}$  would be expected and indeed have been measured. The reason for the increased toughness in that orientation for 8090 (and indeed for most other wrought aluminum alloys) is that the precipitate sheets (and associated precipitate free zones PFZ's) promote debonding ahead of the crack tip. This debonding tends to both relax the constraint and blunt the crack, giving rise to an apparent fracture toughness increase. Such boundaries have been studied in maraging steel composites (Ref 17), where phenomenal increases in fracture toughness have been observed. The low short transverse properties of the Al-Li alloys are a significant barrier to wide application of these materials, despite their promise.

## Titanium Alloy Fracture Toughness

Titanium is light and strong, with a relatively high melting point and good resistance to both oxidation and attack by chlorides. As a result, it is an attractive alloy for use in aerospace applications such as fan disks. The most widely used alloy is Ti-6Al-4V, which is discussed elsewhere in this Volume.

There are three major groups of titanium, depending on the amount of  $\alpha$  (hexagonal close-packed phase) and  $\beta$  (body-centered cubic phase) constituents in the microstructure:

- $\alpha$  alloys such as Ti-6Al-2Sn-4Zr-2Mo
- $\alpha + \beta$  alloys such as Ti-6Al-4V
- $\beta$  alloys such as Ti-10V-2Fe-3Al

The  $\alpha$  alloys and the  $\alpha + \beta$  alloys have similar structure-property relations, as described below, while  $\beta$  alloys are more distinct and are discussed separately. No single  $\beta$  alloy has the same broad applicability as Ti-6Al-4V, although the near- $\beta$  alloy Ti-10V-2Fe-3Al is an important alloy for aerospace structures. In general, retained  $\beta$  alloys are used for workability, corrosion resistance, and the ability to heat treat larger section sizes in which  $\beta$  has been retained. Beta alloys also tend to have higher density and lower elastic modulus values than  $\alpha$  alloys.

## Alpha and Alpha-Beta Alloys

Fracture toughness can be varied within a nominal titanium alloy by as much as a multiple of two or three by manipulating alloy chemistry, microstructure, and texture. Some tradeoffs of other desired properties may be necessary to achieve high fracture toughness. There are significant differences among titanium alloys, but there is also appreciable overlap in their properties. Table 1 gives examples of typical plane-strain fracture toughness ranges for  $\alpha$ - $\beta$  titanium alloys. From these data it is apparent that the basic alloy chemistry affects the relationship between strength and toughness. From Table 1 it is also evident that transformed microstructures may greatly enhance toughness while only slightly reducing strength.

**TABLE 1 TYPICAL FRACTURE TOUGHNESS OF HIGH-STRENGTH TITANIUM ALLOYS**

Source: Ref 24

Within the permissible range of chemistry for a specific titanium alloy and grade, oxygen is the most important variable insofar as its effect on toughness is concerned. This is readily shown by the data of Ferguson and Berryman (Ref 18), who reported strength and  $K_{IC}$  values for specimens of  $\alpha$ - $\beta$  processed and recrystallization annealed Ti-6Al-4V. Regression analysis of their data shows that for each 0.01% increase in oxygen, toughness is reduced by about 3.7 MPa  $\sqrt{m}$  (3.4 ksi  $\sqrt{in}$ ). Whether this is a direct effect or an indirect effect, in the sense that oxygen increases strength and the strength increase reduces  $K_{IC}$ , remains to be determined. Multiple regression analysis of the Ferguson and Berryman data, where both oxygen content and tensile strength are assumed to be independent variables, shows that tensile strength is the dominant variable (the residual effect of oxygen does not reach statistical significance). This implies that, if oxygen affects  $K_{IC}$ , it does so through its strengthening effect. The solid solution strengthening effect of oxygen is further complicated by the fact that oxygen tends to promote the formation of  $Ti_3Al$ .

As might be expected, hydrogen also has an effect on toughness. The work of Meyn (Ref 19) shows that very low hydrogen contents (less than about 40 ppm) enhance toughness. This effect is particularly dramatic with hydrogen contents below 10 ppm. Table 2 illustrates the essential results for Ti-6Al-4V at two different oxygen levels.

**Table 2 Effect of hydrogen content on room-temperature  $K_{IC}$  in alloy Ti-6Al-4V after furnace cooling from 927 °C (1700 °F)**

50	96	<b>87</b>

(a) Specimens were tested in accord with ASTM E 399 but were loaded rapidly (total testing time = 10 s).

**Effects of Microstructure.** Improvements in  $K_{Ic}$  can be obtained by providing either of two basic types of microstructures: (a) transformed structures, or structures transformed as much as possible, because such structures provide tortuous crack paths; and (b) equiaxed structures composed mainly of regrowth  $\alpha$  that have both low dislocation densities and low concentrations of aluminum and oxygen (the so-called "recrystallization annealed" structures). It is not yet known (in 1995) whether or not combinations of these two types of structures would further enhance  $K_{Ic}$  values.

Transformed structures appear to be tough primarily because fractures in such structures must proceed along tortuous, many-faceted crack paths. According to the work of Hall and Hammond (Ref 20),  $K_{Ic}$  is proportional to the fraction of transformed microstructure in alloy Ti-6Al-4V (see Table 3). These authors, however, propose that it is strain-induced transformation of the retained laths of  $\beta$  phase that leads to enhanced fracture toughness. Evidently, their idea is that this TRIP mechanism enhances "ductility" in front of each crack tip. However, in comparing  $\beta$  alloys deformed by either slip or TRIP mechanisms, Wardlaw et al. (Ref 21) could find no advantage in ductility for the TRIP alloys. Curtis and Spurr (Ref 22) suggested that it is primarily the  $\alpha$  platelet size and efficient dispersion of the  $\beta$  phase that enhance toughness. In any event, most direct evidence indicates that crack tortuosity is an important variable affecting  $K_{Ic}$ .

**Table 3 Relationship between  $K_{Ic}$  and fraction of transformed structure in alloy Ti-6Al-4V**

(a) Heated for 1 h at indicated temperature and then air cooled.

(b) Values in parentheses calculated from linear least-squares expression relating percent transformation to  $K_{Ic}$ .

**Effects of Environment.** Effects of temperature on toughness are usually less abrupt for titanium than for common low-alloy steel. For example, Tobler (Ref 23) reported a gradual  $K_{Ic}$  transition temperature between -196 and -143 °C (-320 and -215 °F) for recrystallization annealed Ti-6Al-4V extra-low interstitial (ELI). For temperatures at and above -143 °C (-215 °F), his  $K_{Ic}$  values were typically about 90 MPa  $\sqrt{m}$  (82 ksi  $\sqrt{in.}$ ). At -196 °C (-320 °F), his values were typically 60 to 65 MPa  $\sqrt{m}$  (55 to 60 ksi  $\sqrt{in.}$ ). The loss is about 30%. The early conclusion by Christian and Hurlich (Ref 24) that Ti-6Al-4V ELI may be used to cryogenic temperatures thus has some justification. The same may not be true of standard-grade Ti-6Al-4V.

**Texture Effects.** Titanium alloys, like most other practical engineering alloys, are very dependent on the texture. In the hot working operations that generally attend the fabrication of titanium alloys, all of the c directions from grain to grain tend to be parallel. Thus, different plastic responses will be elicited, depending on the direction of crack propagation. The effects of direction on toughness are illustrated for a Ti-6Al-2Sn-4Zr-6Mo plate in Table 4 (Ref 25). Similar trends are observed for Ti-6Al-4V alloys.

**TABLE 4 EFFECT OF TEST DIRECTION ON MECHANICAL PROPERTIES OF TEXTURED TI-6AL-2SN-4ZR-6MO PLATE**

## Beta Alloys

Beta titanium alloys, which include both near- $\beta$  alloys and  $\beta$ -rich  $\alpha$ - $\beta$  alloys such as Ti-10V-2Fe-3Al, can be heat treated to a wide range of strength levels and can be tailored to strength-toughness combinations for specific applications. That is, moderate strength with high toughness or high strength with moderate toughness can be achieved. This is generally not possible for other types of titanium alloys because they cannot be heat treated over a very wide range. At moderate strength levels, say 965 MPa (140 ksi) and above, the fracture toughness of the  $\beta$  alloys can be processed to achieve higher values than for the other types ( $\alpha$  and  $\alpha$ - $\beta$  alloys).

To accomplish these higher toughnesses, however, the processing window is tighter than that normally used for the other alloy types. For the less highly  $\beta$ -stabilized alloys, such as Ti-10V-2Fe-3Al, Ti-17, and  $\beta$ -CEZ, the thermomechanical process is critical to the properties combinations achieved, because this has a strong influence on the final microstructure and the resultant tensile strength and fracture toughnesses that may be achieved.

This is somewhat less important in the more highly  $\beta$ -stabilized alloys such as Ti-3Al-8V-6Cr-4Mo-4Zr ( $\beta$ -C) and Ti-15V-3Cr-3Al-3Sn. In these the final microstructure, precipitated  $\alpha$ , is so fine that microstructural manipulation through thermomechanical processing is not as effective. In these cases the aging heat treatments--sequence and temperature--are more critical. The key is to obtain a uniform precipitation. This may be obtained by a low-high aging sequence, or, with residual cold or warm work, possibly a high-low aging sequence. When highly alloyed  $\beta$  alloys, such as  $\beta$ -C, are cold worked prior to aging, high strength can be obtained with good ductility because cold work induces finer and more uniform precipitation.

The thermomechanical processing must, however, be controlled to provide a uniform microstructure throughout the cross-section of the material and, in conjunction with the heat treatment, avoid the occurrence of extensive grain boundary  $\alpha$  or a precipitate-free zone near the grain boundaries. Some characteristic mechanical properties of  $\beta$  alloys are given in Table 5. Comparison of Table 5 with Table 1 indicates that the  $\beta$  alloys have a higher fracture toughness at higher yield strength than the  $\alpha$ - $\beta$  alloys.

**TABLE 5 TYPICAL MECHANICAL PROPERTIES OF SELECTED BETA ALLOYS**

## Fatigue Crack Propagation

This section briefly reviews fatigue crack propagation (FCP) behavior in some major structural alloy families, with emphasis on general microstructural factors. Like fracture toughness, FCP behavior is subject to microstructural control. In some instances, however, improvements in the fracture toughness may produce a structure in which the FCP properties are degraded and vice versa. For example, decreasing the grain size generally leads to improvements in the fracture toughness but can degrade both the fatigue threshold,  $\Delta K_{th}$ , and the FCP rate at high  $\Delta K$  levels. In other instances, most notably for titanium alloys, a microstructure that leads to improvements in  $K_{Ic}$  also produces improved FCP properties. These structure-property relations can be important factors in meeting design-critical properties.

This section begins with a brief review of FCP mechanisms and models. While it is not the goal of this section to make a complete review of models of FCP, it is nonetheless of use to briefly examine the physical basis of FCP and to indicate a few models that have been proposed to understand FCP behavior in engineering alloys. It is also of use to briefly discuss empirical models that have been used to correlate FCP behavior with extrinsic variables. Fatigue crack growth in major structural alloy families is then discussed.

---

## FCP Mechanisms and Models

**Damage Accumulation at Crack Tip.** An intuitively appealing model of FCP is to imagine that the high stresses and strains at the crack tip produce reversed plastic deformation and damage. As a result of this damage the crack advances a certain distance, which is essentially defined by the microstructure. This distance could be related to the grain size, to the cell size for materials in which cells are formed, or to other microstructural features. Several models based on these ideas have been reviewed in detail elsewhere (Ref 26). One model of this type that has been proposed (Ref 27) predicts a crack growth rate as follows:

$$DA/DN = C/(\sigma_{YS}\epsilon_{FE})^{1/\beta} \cdot (1/L)^{1/\beta-1} \cdot \Delta K^{2/\beta} \quad \text{(EQ 11)}$$

where  $C$  is a constant,  $\epsilon_f$  is the fracture strain of cyclically deformed material,  $\beta$  is the Coffin-Manson exponent, and  $l$  is the process zone size. This model predicts that the FCP rate should decrease with increasing process zone size, which for many materials would be expected to be the grain size. Such a dependence is indeed observed for many materials. It furthermore predicts that the Paris exponent (discussed below) should be simply related to the Coffin-Manson exponent for low-cycle fatigue (LCF). This is also observed. Thus, one mechanism for improving FCP behavior would be to increase the grain size of alloys of interest, especially for alloys that exhibit planar glide and for which the primary obstacles are the grain boundaries. There is extensive experimental evidence that such an approach is indeed very effective for many materials (Ref 26).

**Reduced Crack Growth Rate by Crack Tip Interference (Roughness-Induced Closure).** Somewhat related to the above discussion is the notion that if the fracture surface is very "rough," then the opposite faces of the crack tip will come into premature contact with one another during unloading. Thus, during FCP, the nominal stress-intensity range  $\Delta K_{nom}$  is reduced to  $\Delta K_{eff}$  and the crack growth rate is correspondingly reduced. The point at which contact of opposite faces occurs is used in computing the minimum  $K$  level in the  $\Delta K_{eff}$  expression. Because  $\Delta K$  has been reduced, the crack growth rate is also correspondingly reduced. While these concepts make sense physically in certain situations, their applicability depends sensitively on the elastic/plastic properties of the material being considered and the geometry of the fracture surface. Furthermore, these ideas, while appealing, are very difficult to implement in an engineering application, because it is not usually possible to measure the closure load. The utility of this insight appears to be qualitative in nature, predicting that rough fracture surfaces should exhibit low FCP rates. However, rough fracture surfaces are associated with large-grained planar slip materials, and it is difficult to see how the roughness arguments can be separated from those discussed previously. A more detailed discussion of these ideas is found elsewhere (Ref 28, 29, 30). Additional information on crack closure is in the article "Micromechanisms of Monotonic and Cyclic Crack Growth" in this Volume.

**Phenomenological Models for FCP.** The best-known empirical equation for correlating the FCP rate is the Paris equation (Eq 4). While it is now recognized that this equation is an oversimplification of a very complex phenomenon, Paris was the first to recognize that FCP could be correlated with a global parameter that describes the stresses and strains in the vicinity of the crack tip (Ref 31). The Paris equation accurately represents the behavior of many materials in the mid- $\Delta K$  range, which is of significant engineering interest. This equation does not recognize the effects of load ratio ( $P_{min}/P_{max}$ ), the existence of a threshold  $\Delta K_{th}$ , or very high acceleration of the FCP rate as the stress intensity approaches the fracture toughness of the material.

Fatigue crack propagation has been extensively characterized experimentally. The primary objective of such studies is to develop data that can be used to predict the life of a component given the stress state and the crack geometry. For analytical convenience, models have been developed to correlate the data. Typical of these models is the hyperbolic sine (Ref 32):

$$\text{LOG}(DA/DN) = C_1 \text{SINH} \{C_2 \text{LOG} \Delta K + C_3\} + C_4 \quad (\text{EQ 12})$$

where  $C_1$  is a material constant and the other constants are functions of load ratio, temperature, and frequency. The constants can be determined by a regression analysis. This model and other similar models are symmetric about an inflection point and this property is not always in consonance with actual behavior. A model developed for use in the electric power industry, which allows for a more general fit of the data (Ref 33) is given by:

$$\frac{1}{da/dN} = \frac{A_1}{(\Delta K)^{n_1}} + \frac{A_2}{(\Delta K)^{n_2}} + \frac{A_2}{(K_c(1-R))^{n_2}} \quad (\text{EQ 13})$$

where the various constants and exponents are fitting parameters and  $R$  is the load ratio. Temperature and frequency effects are easily accommodated in the fitting parameters. At values of the crack growth rate that are relatively high (e.g.,  $da/dN > 2.5 \times 10^{-5}$  mm/cycle), data are well represented by the familiar Paris equation.

Another simple equation, known as the Forman equation, has found wide application in correlating FCP data for aluminum alloys (Ref 34):

$$\frac{da}{dN} = \frac{C\Delta K^n}{(1-R)K_c - \Delta K} \quad (\text{EQ 14})$$

It must be emphasized that the real utility of these representations lies in data correlation and life calculations. It is not possible to use such equations to gain insight into the mechanisms associated with the FCP process or to design new alloys for increased fatigue resistance.

## Nickel-Base Alloys

Nickel-base alloys generally consist of coherent  $\gamma'$  precipitates in an fcc matrix. Typically there will also be grain boundary carbides in polycrystalline alloys. These are present, especially in cast forms used in turbine blade applications, to limit grain boundary sliding at high temperatures, and they also usually limit the conventional fracture toughness to rather low values. However, fracture toughness is not a design-critical parameter for most of these applications, and the low fracture toughness levels are not a particular concern as compared to creep and LCF. On the other hand, alloys that are designed for use in turbine disks usually exhibit significantly higher fracture toughness values and do not contain significant amounts of carbides. A very widely used disk material is In 718, which is strengthened primarily by fine, coherent  $\gamma''$  precipitates in an fcc matrix. The fracture toughness of In 718 depends on factors such as grain size and inclusions, much like some of the systems mentioned previously. The fracture toughness and other mechanical properties of In 718 are shown in Table 6 (Ref 35). We see that the fracture toughness is substantial over a very wide range of temperatures.

The FCP of nickel-base superalloys has been extensively reviewed (Ref 36, 37) and is considered in detail in this book. Thus only some of the major features of FCP in these systems are discussed below. These alloys are used in many fatigue-critical applications in jet engines, and much of their development has been made with the goal of improving fatigue properties.

**FCP in Conventionally Processed Alloys.** In an extensive study of FCP in commercial alloys it was shown that the FCP rate tended to decrease with increasing strength, as predicted by Eq 11. However, these commercial alloys differed in many ways and were not particularly suitable for consistent comparisons. It was also shown in this study, as well as in other studies (Ref 39, 40, 41, 42), that increasing the grain size in a given system also had the effect of decreasing the crack growth rate, again consistent with Eq 11.

One of these studies (Ref 41) demonstrated the effects of slip mode and microstructure using Waspaloy, an alloy that has been widely used in the jet engine industry as a disk material. Heat treatments resulted in coarse and fine-grained specimens (ASTM 3 and 9). For each grain size, further heat treatments resulted in precipitate sizes of either 8 or 90 nm. Based on well-known physical metallurgy principles, the most planar slip would then occur for specimens containing small precipitates and coarse grains, while the least planar slip would occur for the fine-grained specimens containing large particles. The other microstructures would be expected to have deformation modes intermediate between these.

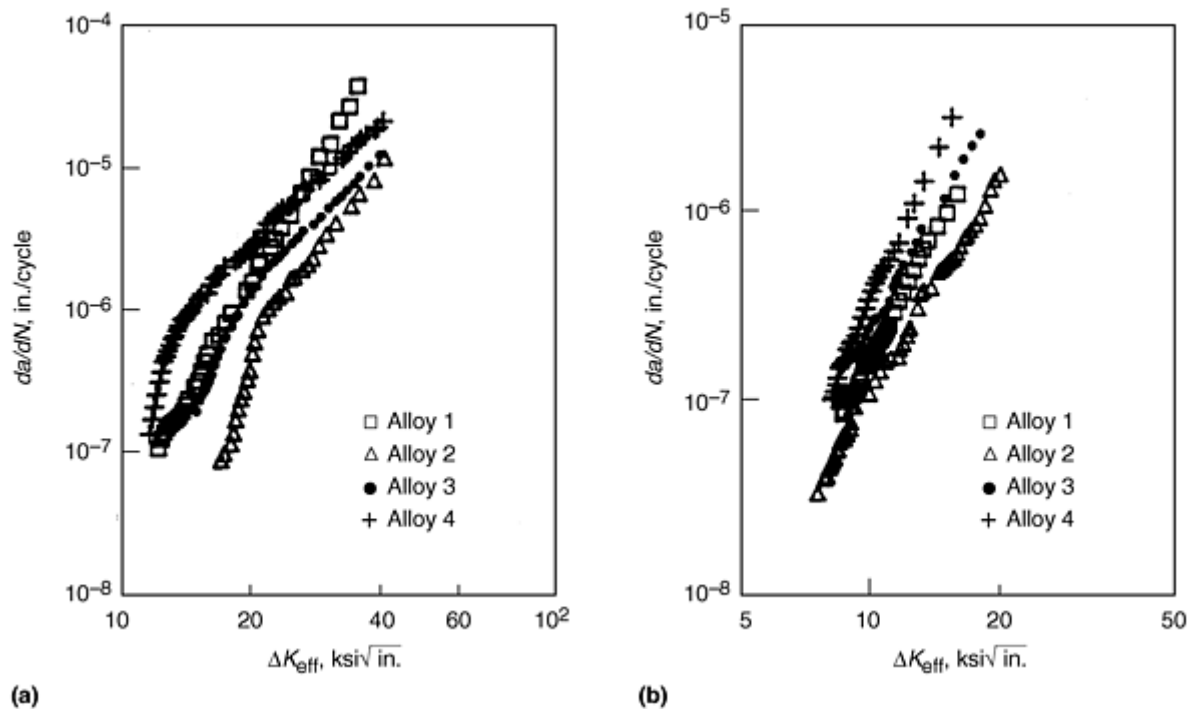

The results of FCP experiments are shown in Fig. 14. These results make it quite clear that microstructures that showed the most planar slip also had the most crystallographic or "rough" surfaces and the lowest crack growth rates. Similar results were also obtained for In 718 (Ref 43). In this study, heat treatments were used to produce four combinations of grain size (250 vs. 25  $\mu\text{m}$ ) and precipitate size (150 vs. 20 nm diameter disks). Independent of precipitate size, the FCP rate was lowest for the larger grain sizes. The effect of precipitate size was more complicated and is discussed in more detail in the articles on fcp of nickel-base alloys. Testing was also done at a very high load ratio ( $R = 0.75$ ) to attempt to assess the contribution of roughness-induced closure on lowering the FCP rates. While increasing the  $R$ -ratio did increase the FCP rate for all microstructures, the relative ranking of the FCP rates associated with the different microstructures remained unchanged from the tests that were carried out at  $R = 0.05$ . These results strongly suggest that differences in closure mechanisms (roughness-induced, oxide-induced) were not responsible for the observed behavior and that intrinsic microstructural features and slip mode parameters play at least as important a role in influencing the FCP behavior as does closure.

**Fig. 14** Composite plot of Waspaloy fatigue crack propagation data. GS, grain size

This is not to imply that closure may not be important in other systems, and in fact it has been shown in some systems that differences in FCP rates do disappear when testing is done at high  $R$  ratios (Ref 44). A detailed study of the effects of slip mode has been carried out on model nickel-base alloys (Ref 45). The results again indicate that the lowest FCP rates occur for materials that exhibit planar reversible glide. The results are shown in Fig. 15.

**Fig. 15** Fatigue crack propagation response of small  $\gamma'$  materials. (a) Results plotted vs.  $\Delta K_{eff}$ , thus accounting for crack closure. (b) Material response at  $R = 0.8$

**FCP in Single-Crystal Alloys.** At present, single crystalline nickel-base alloys are not used in turbine components that are FCP-critical. However, there is current interest in introducing such requirements into military engines, and some FCP studies have been conducted.

Fatigue crack propagation in the single-crystal alloy designated as N4 has been characterized over a range of temperatures from 25 °C to 1000 °C (Ref 46). The crack propagation direction was [110] and the loading direction was [001]. At room temperature, crack propagation was crystallographic, with cracking occurring primarily on {111} planes with some instances of cracking on {100} planes (Fig. 16). The preferred crack plane was the one having the highest linear combination of resolved shear stress on the slip system (i.e., on the slip plane in the Burgers vector direction) and normal stress across the slip plane. These criteria for multiaxial failure were motivated by the fact that the shear stresses cause dislocation motion, cause corresponding damage in the form of dislocation debris, and consequently weaken the slip plane. The normal stress is required for final separation. The FCP rates appeared to separate into two groups, depending on temperature (Fig. 17). Above 925 °C (1700 °F), FCP rates increased dramatically and the fracture planes were macroscopically normal to the loading axis, except for the initial amount of crack extension, which was on a plane inclined to the load axis.

**Fig. 16** Crystallographic cracking along the  $\{111\}$  and  $\{100\}$  planes of the single-crystal nickel-base alloy designated as N4. Note the less crystallographic nature of the fracture on (001). Source: Ref 46

**Fig. 17** The effect of temperature on crack growth rates ( $R = 0.1$ ). At  $T \leq 927$  °C, the crack growth rates in the Paris regime are similar. At the two higher temperatures, the growth rates are an order of magnitude larger than at the lower temperatures.

The anisotropic nature of single crystals renders a straightforward application of fracture mechanics problematic. These issues were addressed in a recent study (Ref 47). Using a finite element approach to determine the stresses ahead of the crack tip, and taking into account elastic anisotropy, it was demonstrated that the features on the fracture surface

depended on the critical combinations of normal and shear stress as well as temperature, with environment also playing an important role. At higher temperatures and in areas where the normal stresses were high, cracking was macroscopically on {100} planes. Closer examination revealed that  $\gamma'$  particles were present on the surface and that cracking was limited to the channels between the  $\gamma'$  precipitates. This can be understood in terms of the morphology and temperature dependence of the hardness of  $\gamma'$ . It is well known that  $\gamma'$  become harder with increasing temperature up to about 800-900 °C (1470-1650 °F), depending on the system. Thus, there is a tendency for dislocations to be confined to the regions between the precipitates, and even though deformation in the matrix between the precipitates probably occurs on the {111} planes, the heavily damaged regions are macroscopically parallel to {100} and final fracture would occur in these areas, assisted, naturally, by environmental interactions. Similar results were obtained for Mar-M002 crystals tested with a [001] load axis at 25, 600, and 850 °C (Ref 48). Crack propagation was in the [100], [210], and [110] directions.

In another study of FCP in nickel-base alloys (Ref 49), Mar-M200 was tested under various loading and crack propagation directions. It was found that cracking occurred on {111} planes, with the preferred plane(s) being the one(s) that had the highest and/or second highest resolved shear stress in the direction of potential Burgers vectors on the slip plane. There was considerable crack branching, and the fracture surfaces were macroscopically "rough," defined by various combinations of {111} planes. When crack branching and surface roughness were taken into account, it was possible to correlate the crack growth rate with the effective stress-intensity parameter. The effective stress-intensity parameter takes into account the fact that there may be modes I, II, and III present in a single crystal that is nominally loaded in mode I. Physically, the effective stress-intensity parameter relates to the elastic strain energy driving the crack and may be defined mathematically as:

$$\Delta K_{\text{eff}} = \left[ \Delta K_I^2 + \frac{C_2}{C_1} \Delta K_{II}^2 + \frac{C_3}{C_1} \Delta K_{III}^2 \right] \quad (\text{EQ 15})$$

where  $\Delta K_I$ ,  $K_{II}$ , and  $K_{III}$  are mode I, II, and III stress-intensity parameters and  $C_1$ ,  $C_2$ , and  $C_3$  are constants related to the elastic anisotropy of the material and loading direction. Acceptable correlations of the data were obtained using  $\Delta K_{\text{eff}}$ . Those orientations for which crack deviation and closure were minimized showed the most rapid crack growth rates.

**Environmental Factors.** Because nickel-base alloys are used at temperatures as high as 1125 °C (2050 °F) in air environments, the environment becomes a significant factor in influencing FCP behavior. Fatigue crack propagation in nickel-base alloys has been shown to be very sensitive to both oxygen (Ref 36) and hydrogen (Ref 50). The effect of oxygen has been demonstrated to depend on an interplay between two factors: embrittlement due to oxygen diffusion (detrimental) and increased closure due to oxide formation (beneficial). As temperature is increased, the FCP rate first decreases (closure effect) and then increases very rapidly due to the oxygen ingress and embrittlement of the crack-tip region (Ref 36). When an activation energy analysis was carried out on the FCP behavior of René 95, it was shown that an activation energy of about 30 kcal/mol represented the process quite well. This number is in reasonable agreement with the activation energy for diffusion of oxygen in nickel. The environment also has the effect of changing the fracture surface morphology, which can cloud the effects of the environment. In a study using model nickel-base alloys (Ref 51), testing in air and testing in vacuum at elevated temperatures revealed similar crack growth rates. However, in air the fracture surface exhibited crystallographic facets and was macroscopically rough. In vacuum, the surface was smooth. When tests were carried out on a single specimen, first in air and then in vacuum, the crack growth rate decreased significantly in vacuum, leading to the conclusion that the environment was in fact playing a critical role even at temperatures where obvious oxide films were not formed. These results are shown in Fig. 18.

**Fig. 18** Vacuum and air/vacuum/air fatigue crack propagation tests. Results for alloy II-S at 427 °C and  $R = 0.1$ . Environmental and closure effects can be separated.

## FCP of Steels

Steels are microstructurally and compositionally complex, so this section is limited to an overview of some of the principal features of FCP behavior of steels.

**Near-Threshold Crack Growth.** The form of the  $da/dN$  versus  $\Delta K$  curves for steels (indeed for all materials) follows the form predicted by Eq 12. That is, at relatively low values of  $\Delta K$ , the crack growth rate will go to zero at some value of  $\Delta K$ , which is customarily defined as  $\Delta K_{th}$ . In the near-threshold regime, the effects of load ratio are significant. As the load ratio is increased,  $\Delta K_{th}$  decreases according to an equation of the form:

$$\Delta K_{TH} = C(1 - 0.85R) \quad (\text{EQ 16})$$

Thus, increases in  $R$  have a pronounced effect on the threshold. The value of the constant  $C$  will depend on the composition and heat treatment being considered. However, for many steels the following values for  $C$  have been determined (Ref 52):

$$\begin{aligned} C &= 6.4 \text{ FOR } R \geq 0.1 \\ C &= 5.5 \text{ FOR } R < 0.1 \end{aligned} \quad (\text{EQ 17})$$

where  $K$  is in  $\text{ksi}\sqrt{\text{in}}$ . Because the threshold regime is where good design and inspection would place the operating conditions, small changes in  $R$  would lead to huge changes in the FCP rate and corresponding decreases in the fatigue life. It is in the threshold regime that the most significant effects of microstructure are observed. As was the case for the nickel-base alloys considered previously, increasing the grain size (in this case the ferrite grain size) has the effect of increasing the threshold. This can be understood in terms of basic fracture mechanics. For example, it might be hypothesized that crack propagation could occur only if the plane-strain reversed plastic zone is on the order of the grain size (Ref 7). However, we know that the fatigue zone size is given by the approximate equation:

$$R_p = (\Delta K / \sigma_{YS})^2 / (24\pi) \quad (\text{EQ 18})$$

Substituting the grain size  $d$  for the plastic zone size and  $\Delta K_{th}$  for  $\Delta K$  gives the following result:

$$\Delta K_{TH} = 6.14\sigma_{YS} \cdot D^{\frac{1}{2}} \quad (\text{EQ 19})$$

where  $K$  is in  $\text{ksi}\sqrt{\text{in}}$ . The predictions of Eq 20 are actually followed for low-carbon and low-alloy steels (Ref 7). If Eq 16 and 19 are combined, we can describe the effects of grain size, yield strength, and  $R$ -ratio:

$$\Delta K_{TH} = 6.14\sigma_{YS} \cdot D^{\frac{1}{2}} \cdot (1 - 0.85R) \quad (\text{EQ 20})$$

An extensive compendium of threshold and FCP data for mild steels, alloy steels, stainless steels, aluminum alloys, titanium alloys, and nickel-base alloys is available (Ref 52). All data are evaluated in terms of validity, and structural information (e.g., grain size, heat treatment) is provided where available. The interested reader is referred to this work for further information.

**Stress-Ratio Effects at Intermediate Crack Growth Rates.** At higher levels of  $\Delta K$ , the crack growth rate follows Eq 4 very closely with little effect of  $R$ -ratio. Thus, it would be unduly conservative to use the Forman equation (Eq 14), which overemphasizes the effect of  $R$ -ratio in steels. In the Paris law regime, the upper-bound FCP rates of common steels may be described by the following equations (Ref 53):

$$DA/DN = 0.66 \times 10^{-8} (\Delta K)^{2.25} \quad \text{(EQ 21)}$$

$$\begin{aligned} & \text{(Martensitic steels)} \\ da/dN &= 3.6 \times 10^{-10} (\Delta K)^{3.0} \quad \text{(EQ 22)} \\ & \text{(Ferrite/pearlite steels)} \end{aligned}$$

As was the case for the nickel-base alloys, the effects of temperature and environment are complex, depending on composition, microstructure, and the aggressive species in the environment. In general, ferritic steels will exhibit higher crack growth rates at temperatures below the onset of severe microcleavage. At higher temperatures, many steels are susceptible to oxidation, which accelerates the FCP rates. Cr-Mo steels are typical of those that are subject to a strong environmental effect. A more detailed description of FCP in steels is provided in the chapter on steels.

## Aluminum-Alloy FCP

Aluminum alloys find wide application in fatigue-critical structures, especially in the aerospace industry, where they are used throughout airframes (skins, spars, bulk heads, etc.). As expected, there is considerable detailed knowledge of the FCP behavior of these materials. In addition, due to the continuing push for lighter, stronger structures, new alloys are being introduced, of which the most promising appear to be the Al-Li alloys, which are lighter than conventional alloys and have a higher modulus of elasticity. The key features of most aluminum alloys are grain size, precipitates, dispersoids, and constituent particles.

Aluminum alloys are fairly sensitive to mean stress effects, so Eq 14 can be used with reasonable success for correlating FCP data of most aluminum alloys. However, it should be remembered that the main purpose of such equations is to put data in a format that can be readily integrated, and equations like Eq 12 and 13 can provide better fits because of their increased number of experimentally determined parameters. Indeed, if life analysis is the sole objective, then numerical integration of the data can be performed directly without fitting it to *any* model. Use of Eq 14 is demonstrated in the data shown in Fig. 19 for 7075-T6 Al in various tempers (Ref 54).

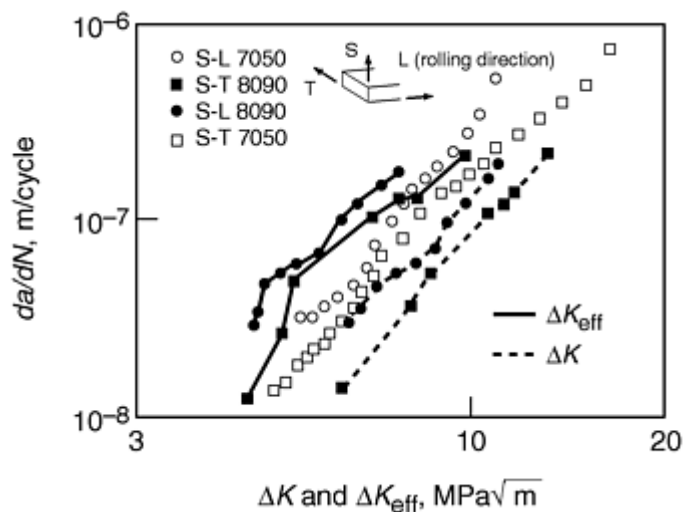

**Fig. 19** Effect of  $R$  on fatigue crack growth rates in aluminum alloy 7075-T6. Source: Ref 54

As with most wrought forms, fatigue behavior of aluminum alloys can have significant directionality effects, especially in the threshold regime, as shown in Fig. 20 for 7050-T7452 hand forgings tested at room temperature in moist air (Ref 55). This can be understood quite easily in terms of the grain structure of wrought forms. In the L-T orientation the crack is free to propagate intergranularly in the intermetallic-dominated regions. As a result, the fracture surface would be expected to be quite flat with little or no closure. This effect means that the crack would "feel" the full stress-intensity range. On the other hand, in the S-T direction the crack could not propagate between the grains very effectively. In essence it would be retarded by the grains and could propagate only slightly in the narrow intergranular regions. Furthermore, the crack surface would be rougher, giving rise to an enhanced closure effect. Thus, at any nominal  $\Delta K$  level,  $\Delta K_{\text{eff}}$  would be much lower and the driving force for crack propagation would be reduced. As the stress intensity reaches the Paris law regime, the effects of orientation are reduced, as has been pointed out elsewhere (Ref 56). The effects of orientation and closure were investigated in the S-L and S-T orientations for a 7050-T7452 alloy and an 8090 Al-Li alloy. The results are shown in Fig. 21 for  $R = 0.1$  (Ref 57). In this study, the 7050 showed minimal closure in these orientations, while the 8090 showed significant closure. It should be noted that in these experiments, extraordinary care was taken to ensure that true closure levels were being measured, as recommended and detailed elsewhere (Ref 58). In this way all artifacts of the closure measurement (which are in fact quite common) were eliminated or reduced to insignificance.

**Fig. 20** Fatigue crack propagation data for 7050-T7452 hand forgings. Source: Ref 55

**Fig. 21** Effect of crack closure:  $da/dN$  vs.  $\Delta K_{eff}$  for 8090-T852 material compared with  $da/dN$  vs.  $\Delta K_{app}$  for 8090 and 7050-T7452. Source: Ref 57

It can be seen that when closure is not accounted for, the FCP rates of the Al-Li alloys appear to be superior. However, when closure is taken into account, the effective value of  $\Delta K$  is decreased at the same level of  $da/dN$ . Thus the  $da/dN$  versus  $\Delta K$  curves for the 8090 shift to lie *above* those of the 7050. These results make it very clear that the reason for the observed superior FCP properties of the Al-Li alloys is primarily due to crack closure. It is important to understand this, because at higher  $R$  levels, closure effects would be eliminated (or at least significantly reduced) and the FCP properties of the 7050 would be expected to be superior.

The effect of the various types of particles found in conventional aluminum alloys has been characterized (Ref 59). As might be expected, the larger constituent particles begin to play a role at the higher  $\Delta K$  levels, where normal rupture modes become important. The precipitates influence the FCP behavior at the lowest  $\Delta K$  levels, while the dispersoid particles, which have the effect of controlling the grain size, have an effect at slightly higher  $\Delta K$  levels. These ideas are summarized in Fig. 22.

**Fig. 22** Comparison of typical particle sizes in aluminum alloys with crack advance per cycle on fatigue loading

It is interesting to note that the relative ranking of aluminum alloys in constant-amplitude FCP is not preserved in variable-amplitude or peak overload FCP environments. This is related to the effects that overloads have on debonding large particles and the subsequent reduced constraint during lower- $\Delta K$  cycling. This is illustrated in Fig. 23 for three levels of yield strength (Ref 60). At the lower  $\Delta K$  levels, the higher-yield-strength material exhibits the highest FCP rate, with the lower-strength material showing the lowest FCP rate. As the base  $\Delta K$  level increases, the overloads are higher and the large constituent particles in the higher-strength material crack locally and reduce the constraint, thereby lowering the FCP rate during subsequent cycling at the base  $\Delta K$  levels. When the base  $\Delta K$  level increases to the highest levels, there is significant crack advance per cycle in the high-strength material, corresponding to its lower fracture toughness, and the relative ordering of the alloys goes back to what is seen in constant-amplitude cycling. These ideas would also apply to a given class of alloys with differences in the constituent particle size and density. It can easily be envisioned that alloys with a higher density of large particles will show decreased crack growth rates under tension-dominated spectrum loading.

**Fig. 23** Schematic effect of yield strength (peak and overaged tempers) on fatigue crack growth rate under spectrum loading. Source: Ref 60

The effects of the strengthening precipitates would be expected to play an important role in the FCP behavior of aluminum alloys because they influence, in a profound manner, the basic slip characteristics, which as we have seen

influence the crack propagation behavior. However, great care must be taken in the interpretation of test results, because the complexity of these alloys means that several potentially competing mechanisms may operate simultaneously. These ideas are discussed more fully in the section on aluminum alloys.

Aluminum alloys are used in environments that can be very aggressive. Saline environments would be typical, for example, of aircraft on carriers or of aircraft operating in warm, coastal areas such as Hawaii or California. The effects of composition, orientation, and environment are illustrated in Fig. 24 (Ref 57). In this figure, FCP curves have been integrated based on data that was generated for air and saline solution environments. The assumed geometry was a wide edge-cracked plate subjected to a remote stress of 50 MPa. The crack sizes and stresses are representative of what would be expected for military aircraft under normal inspections and operating conditions. The integrated life results show spectacular differences for different environments, discernible differences for different orientations, and modest differences for different alloys.

## Titanium-Alloy FCP

Titanium alloys, like the other systems that we have discussed so far, have FCP properties that are sensitive to chemical composition, microstructure, environment, and loading variables. In general, titanium alloys, like most others, exhibit three regimes of behavior: a near-threshold regime (low  $\Delta K$  values), a Paris law regime (intermediate  $\Delta K$  levels), and a regime where normal rupture modes dominate as  $K_{Ic}$  is approached (high  $\Delta K$  levels). The effects of these variables on FCP are complex, and only major trends will be discussed here.

The effect of the  $R$  ratio on FCP for many alloys is as predicted by Eq 14. The  $R$  ratio effect is largest at low and high values of  $\Delta K$  and somewhat reduced for the intermediate values, as has been pointed out elsewhere (Ref 61). The fit of the data to Forman's equation is well illustrated for the near- $\alpha$  T-6242 alloy tested at two  $R$  ratios (Fig. 25) (Ref 62). As predicted by the form of Eq 14, the FCP rate is higher for the higher  $R$  ratio.

**Fig. 25** Comparison of fatigue crack propagation data from Forman's equation and experimental results at room temperature,  $R = 0.02$  and  $R = 0.5$ . Source: Ref 62

Interstitial oxygen is known to embrittle the  $\alpha$  phase in  $\alpha$ - $\beta$  alloys, and this effect would also be expected in the FCP behavior of these alloys to the extent that the FCP behavior is influenced by those factors which influence  $K_{Ic}$ . Figure 26 shows that for a Ti-6Al-4V alloy, the crack growth rate is higher the higher the oxygen content (Ref 63). Of course, the precise composition of titanium alloys has a significant effect on FCP. For example, depending on the composition, some alloys may be more prone to texturing than others. Although this is not a direct compositional effect, texturing does have a significant influence, and in this regard it may be considered a composition-related effect.

**Fig. 26** Variation of fatigue crack propagation rate with yield strength,  $K_{Ic}$ , and other variables for annealed Ti-6Al-4V forgings.  $R = 0.02$ ; 10 Hz; air, argon, and JP4 environments pooled; average of six tests per trend line. Source: Ref 63

Microstructural factors are very important in influencing the FCP rates of titanium alloys, and it has been demonstrated that the FCP rate may be changed an order of magnitude depending on the microstructure, especially at low values of  $\Delta K$ . As has been pointed out elsewhere (Ref 61), FCP properties generally track trends in  $K_{Ic}$ . FCP properties are generally quite desirable for transformed structures and for microstructures produced by recrystallization anneals. The effect of microstructure is shown in Fig. 27 (Ref 64). Part of the improvement in the transformed structures is surely related to the meandering nature of the crack and the increased closure levels associated with such a crack surface. In fact, it has been shown that the FCP rate decreases with the size of the Widmanstätten  $\alpha$  packet size (Ref 65). Some authors have attributed the reduced crack growth rates to a longer crack path. However, this effect is rather small and can account for at most a factor of 2 compared to the order-of-magnitude changes in FCP rates that occur.

**Fig. 27** Effect of heat treatment on fatigue crack growth rate of alloy Ti-6Al-4V. Source: Ref 64

Titanium alloys are fairly resistant to the effects of environment, except at fairly high temperatures. However, it has been established through a very detailed analysis of experimental data that in a 3  $\frac{1}{2}$  % NaCl solution, the rates of crack extension (fatigue and static loading) can be associated with an activation energy very close to that of hydrogen in titanium (Ref 66). This effect is in agreement with the results of other investigators who have found that hydrogen plays a significant role in embrittling titanium alloys and causing higher rates of crack extension.

The fatigue behavior of titanium alloys is very sensitive to the environment and in general corresponds with well-understood principles of fracture mechanics. There is consequently great opportunity for controlling the fatigue behavior through heat treatment and compositional control to achieve desired goals.

## Specific Design for Improved Fatigue Resistance

While the details of improving the FCP properties depend on the class of materials being considered, some general principles appear to be valid for the alloy systems considered here. For example, while microstructural effects are observed in all regimes, they are most pronounced in the near-threshold regime. Larger grain sizes generally tend to produce lower FCP rates, either through lowering the average plastic strain at the tip of a propagating crack or (in some sense equivalently) through producing a rougher fracture surface and increased closure levels. In systems with simple microstructures and well-defined slip mechanisms (e.g., nickel-base superalloys), control of the precipitate size also provides a means for controlling FCP. In general, the degree of slip reversibility will depend on the size of the precipitates, and the size of the precipitate can be adjusted to promote increased reversibility. Of course this can also be put in the context of closure, because reversible slip, as we have seen, also produces a fracture surface with considerable surface roughness.

Introduction

FRACTURE is the complete separation of a material that occurs when a crack reaches a critical size and impairs strength below the service load. The final fracture is usually abrupt, but it is generally preceded by a cracking process that occurs slowly over the service life from various crack growth mechanisms (e.g., see Fig. 1) such as fatigue, stress-corrosion cracking, creep, and hydrogen-induced cracking. Each of these cracking mechanisms has certain characteristic features that are used in failure analysis to determine the cause of cracking or crack growth.

FIG. 1 CRACK PROPAGATION MECHANISMS: (A) CLEAVAGE CRACK PROPAGATION. (B) DIMPLE FRACTURE DUE TO COARSE PARTICLES. (C) DIMPLE FRACTURE DUE TO FINE PARTICLES. (D) DIMPLE FRACTURE DUE TO COARSE AND FINE PARTICLES. (E) INTERGRANULAR CRACK PROPAGATION DUE TO GRAIN BOUNDARY

PRECIPITATES. (F) INTERGRANULAR CRACK PROPAGATION DUE TO A HARD PHASE GRAIN BOUNDARY FILM. (G) CRACK PROPAGATION MECHANISMS WHEN A SOFT PHASE GRAIN BOUNDARY FILM IS PRESENT. (H) CRACK PROPAGATION BY SLIP PLANE/SLIP PLANE INTERSECTION. (I) CRACK PROPAGATION BY SLIP PLANE/GRAIN BOUNDARY INTERSECTION. (J) CRACK PROPAGATION SOLELY BY PLASTIC BLUNTING.

The purpose of this article is to provide a brief description of the different types of micromechanisms of monotonic and cyclic fracture. General information on what material variables have the most beneficial effect on resistance to failure will be presented. Each micromechanism may have a particular manifestation in a given material system, but there are general features of each micromechanism that are common to all relevant systems. In this article, the micromechanisms are divided into monotonic and cyclic mechanisms. This distinction is somewhat artificial in that one can observe evidence of "monotonic" micromechanisms on fracture surfaces that failed under cyclic loading. Also, the effect of environment on the micromechanism is considered as a variable that may change the micromechanism under a given loading condition rather than a unique type of fracture. Polymer fracture and fatigue crack growth occur by micromechanisms that are not observed for monolithic crystalline materials. Therefore, polymer failure will be discussed separately in each section. The failure of fiber-reinforced composite materials also has unique aspects and is covered in a separate volume, *Engineered Materials Handbook, Volume 1, Composites* (ASM International, 1987).

### Types of Fracture

The classification of fractures has been approached in many different ways. In general, fracture modes can be classified into four general categories, based on the appearance of fracture surfaces: dimple rupture, cleavage, fatigue, or decohesive rupture (or intergranular fracture from crack growth mechanisms such as creep or stress corrosion) (Ref 1). This classification is viable, because each mode has a characteristic fracture surface appearance and an underlying mechanism for crack growth. However, it is also useful to make a distinction between progressive crack growth mechanisms and abrupt or "instantaneous" fracture, as noted above. This general distinction is shown in Table 1 with distinguishing features of various fracture modes.

**TABLE 1 FRACTURE MODE IDENTIFICATION CHART**

(A) FRACTOGRAPHERS OFTEN REFER TO "OVERLOAD FRACTURE" AS A WAY TO DISTINGUISH THE FAILURE FROM FATIGUE OR STRESS-CORROSION CRACK GROWTH. HOWEVER, A TRUE OVERLOAD FAILURE IS RARE. INDICATION OF OVERLOAD FRACTURE MAY JUST INDICATE AN UNDETECTED CRACK OR DEFECT LEADING TO FRACTURE.

(B) EDS, ENERGY-DISPERSIVE SPECTROSCOPY.

Confusion arises when fractures are classified as either ductile or brittle, because correct usage of these terms depends on whether one is referring to a fracture micromechanism or the macroscopic work of fracture. For example, if an unnotched tensile sample of a ductile alloy is pulled to fracture, overall plastic deformation will occur and thus the fracture is ductile. However, if a notched sample is loaded, then plastic deformation can be restricted to the notched area, in which case the overall plastic deformation may be substantially reduced (relative to the percent elongation of the unnotched sample). In this sense, most fractures from an engineering perspective are termed brittle, because plastic deformation is restricted to the notched section or cracked area where fracture failures occur.

Yet even though the fracture can be classified as brittle when plastic deformation is confined to the fracture path, the micromechanism of fracture may be ductile. In fact, many fractures occur by a ductile micromechanism, even though the macroscopic fracture is termed brittle with little or no overall plastic deformation or macroscopic work. In this sense, the terms *brittle* and *ductile fracture* are most clearly defined in a macroscopic context. Most components are designed with stresses in the elastic range, when a crack propagates from a flaw, only a relatively small volume of material plastically deforms and absorbs energy. Because the energy to cause fracture is "small" compared to that expected from a ductile fracture, the failure is often described as a brittle fracture. This characterization is often applied even if the micromechanism of material separation involves plastic flow and would otherwise be considered a ductile micromechanism.

Ductile fractures are characterized by tearing of metal accompanied by appreciable gross plastic deformation and expenditure of considerable energy. Ductile tensile fractures in most materials have a gray, fibrous appearance and are classified on a macroscopic scale as either flat-face (square) or shear-face (slant-shear) fractures.

Brittle fractures are characterized by rapid crack propagation with less expenditure of energy than in ductile fractures and without appreciable gross plastic deformation. Brittle tensile fractures are of the flat-face type, and are produced under plane-strain conditions with little or no necking (Fig. 2).

**FIG. 2** TYPICAL CONSTRAINT CONDITIONS FOR PLANE-STRAIN AND PLANE-STRESS FRACTURE IN A TENSILE BAR. (A) LOW-STRESS, THICK-PLATE, THIN-CYLINDER, NO-CONTRACTION PLANE-STRAIN. (B) LOW-STRESS, THIN PLATE, FREE-CONTRACTION PLANE-STRESS. (C) HIGH-STRESS, THICK-PLATE, THICK-CYLINDER, FREE-CONTRACTION PLANE-STRESS. STRESSES AND STRAINS ARE HIGH AT THE CRACK TIP, AND THE HIGH STRAINS IN THE X- AND Y-DIRECTIONS AT A CRACK TIP INDUCE A CONTRACTION IN THE Z-DIRECTION. IF THE CONTRACTION (PLASTIC) ZONE IS LONG AND THIN, CONTRACTION IS PREVENTED BY THE SURROUNDING MATERIAL, WHICH THUS CONSTRAINS THE CONTRACTION AND EXERTS A STRESS IN THE Z-DIRECTION SO AS TO KEEP  $\epsilon_0 = 0$  SUCH THAT  $\epsilon_z = (\sigma_z/E) - [\nu(\sigma_x + (\sigma_y)/E] = 0$  OR  $\sigma_z = \nu(\sigma_x + \sigma_y)$ , WHERE  $\nu$  IS POISSON'S RATIO. IF PLASTICITY OCCURS, THE VALUE OF  $\nu$  APPROACHES 0.5. THE ABOVE IS FOR PLAIN-STRAIN. FOR PLANE-STRESS, CONTRACTION IS UNHINDERED, IN WHICH CASE  $\epsilon_z = -\nu[(\sigma_x + \sigma_y)/E]$

$\gamma)/E]$  AND  $\sigma_z = 0$ .

**Fracture Micromechanisms.** The micromechanisms of fracture can be defined as ductile and brittle fracture, provided that the terms are clearly distinguished from the geometric and mechanical constraints that distinguish brittle and ductile fracture on a component or structural level. Nonetheless, ductile fracture is clearly associated with dimpled rupture, while brittle fracture mechanisms produce the well-known fracture features of:

- TRANSGRANULAR CLEAVAGE OR QUASICLEAVAGE
- INTERGRANULAR SEPARATION
- FEATURES ON TRANSGRANULAR FACETS, SUCH AS RIVER MARKS, HERRINGBONE PATTERNS, OR TONGUES
- CRAZING (IN POLYMERS)

In this context, the micromechanisms of fracture can be appropriately defined as ductile or brittle, depending on whether or not the micromechanisms *require* plastic flow for material separation. A crystalline material can separate by a combination of two micromechanisms: plastic flow and physical separation of atomic planes. While separation of atomic planes generally requires a high stress, the energy absorbed to create the two surfaces is very small from an engineering standpoint. Fracture micromechanisms that occur primarily by separation of atomic planes are described as brittle. Fracture by plastic flow takes on the order of  $10^6$  times as much energy as fracture by separation of atomic planes. The atomic surface energy of pure metals is in the range of 0.1 to 10 J/m<sup>2</sup> (Ref 2, 3), and the  $J_{Ic}$ , a measure of surface energy, is in the range of  $10^4$  to  $10^6$  J/m<sup>2</sup> for typical engineering materials (Ref 4). Fracture micromechanisms that occur with a significant amount of plastic flow are generally termed ductile.

**Fracture Micromechanism Maps.** Putting the distinction between brittle and ductile fracture mechanisms in a broader perspective, Ashby et al. (Ref 5) and Ghandi and Ashby (Ref 6) constructed a series of deformation mechanism maps for crystalline materials. Several of these maps are shown in Fig. 3 (Ref 7). They classified brittle fractures into three distinct types: modes I, II, and III. (These are different from the three modes of crack growth: mode I, opening; mode II, in-plane shear; and mode III, anti-plane shear.) Mode I brittle fractures originate from flaws or cracks in the structure and occur at lower normalized stresses. Little or no plastic deformation occurs. In contrast, microscopic yielding occurs before and during mode II brittle fractures, but the plastic strains are not significant. Mode II and mode III brittle fractures occur in materials in which the flaws or inclusions are smaller than the relevant microstructural unit, usually the grain size. During mode III brittle fracture, macroscopic yielding occurs before fracture. As the material deforms, the capacity for further deformation is exhausted and the material fractures by a brittle micromechanism. In all cases, the fracture path can be transgranular (cleavage) or intergranular. The three brittle fracture mechanisms are schematically shown in Fig. 4, along with stress-strain curves for each mode and for ductile fracture. While high-temperature fracture may absorb a significant amount of energy, the inelastic deformation is strongly rate dependent, in contrast to that for low-temperature fracture, and is therefore classified as a distinct mechanism. Most low-temperature fracture is brittle (Table 2). Constraint (Fig. 2a) can also effect abrupt, brittle-like fracture in plane-strain conditions.

**TABLE 2 CHARACTERISTICS OF THE VARIOUS LOW-TEMPERATURE FRACTURE MODES**

FRACTURE PRECEDED	FRACTURE NUCLEATION	INITIAL CRACK PROPAGATION	FINAL CRACK PROPAGATION	FRACTURE MODE BY MACROSCOPIC YIELDING
MODE I BRITTLE FRACTURE	BY PRESENCE OF PRE-EXISTING FLAWS	NONE	BY CLEAVAGE OR INTERGRANULAR FRACTURE WITH LIMITED CRACK-TIP PLASTICITY	NO
MODE II BRITTLE FRACTURE	BY MICROSCOPIC YIELDING AT YIELD STRENGTH	TO SOMETHING ON THE ORDER OF THE SIZE OF A GRAIN	BY CLEAVAGE OR INTERGRANULAR FRACTURE WITH LIMITED CRACK-TIP PLASTICITY. FOR BCC TRANSITION	NO

			METALS, IMMEDIATELY FOLLOWING YIELDING, BECAUSE $\sigma_Y > \sigma_F$ .	
MODE III BRITTLE FRACTURE	BY MICROSCOPIC YIELDING AT YIELD STRENGTH	TO SOMETHING ON THE ORDER OF THE SIZE OF A GRAIN; BECAUSE $\sigma_Y < \sigma_F$ , MULTIPLE MICROCRACKING IS FOUND	<ul style="list-style-type: none"> <li>• BY CLEAVAGE BETWEEN MICROCRACKS OR BY INTERGRANULAR FRACTURE BETWEEN MICROCRACKS.</li> <li>• EXTENSIVE CRACK-TIP PLASTICITY.</li> <li>• SOME FIBROUS TEARING AT THE HIGHEST TEMPERATURES OF MODE III FRACTURE.</li> </ul>	LIMITED

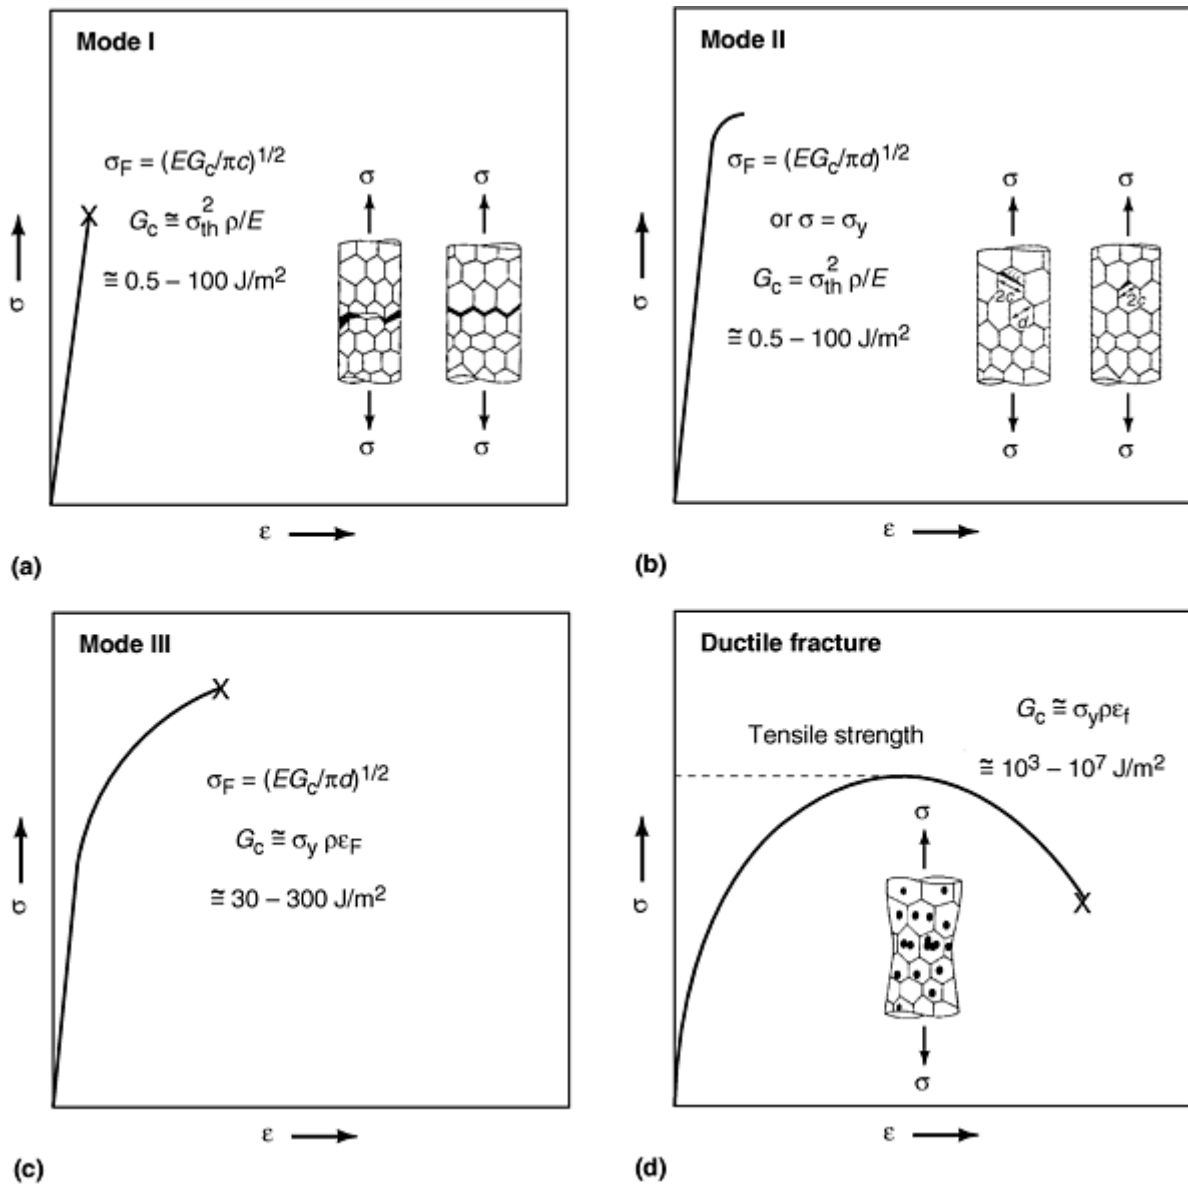

FIG. 4 SCHEMATIC OF STRESS-STRAIN CURVES OF BRITTLE AND DUCTILE FRACTURE ( $G_c$  = CRITICAL STRAIN ENERGY RATE). (A) MODE I BRITTLE FRACTURE OCCURS WITHOUT PLASTIC DEFORMATION, EXCEPT PERHAPS TO A LIMITED DEGREE IN THE MATERIAL ADJACENT TO THE CRACK TIP. MODE I FRACTURE MAY PROPAGATE TRANSGRANULARLY OR INTERGRANULARLY BRITTLE INTERGRANULAR FRACTURE, BIF. (B) MODE II BRITTLE FRACTURE IS PRECEDED BY MICROSCOPIC, BUT NOT MICROSCOPIC, PLASTIC DEFORMATION. INDEED, PLASTIC DEFORMATION NUCLEATES CRACKS THAT MAY PROPAGATE BY CLEAVAGE OR IN AN INTERGRANULAR MODE (AS SHOWN SCHEMATICALLY). (C) MACROSCOPIC DEFORMATION TAKES PLACE BEFORE FRACTURE BY MODE III BRITTLE FRACTURE. A LIMITED REDUCTION IN AREA IS OBTAINED IN A TENSILE TEST, BUT FRACTURE PROPAGATION BY CLEAVAGE OR BIF TAKES PLACE PRIOR TO NECKING. (D) DUCTILE TENSILE FRACTURE PROPAGATION IS PRECEDED BY NECKING. MICROSCOPIC VOIDS FORM THROUGHOUT THE MATERIAL, AND SUBSEQUENTLY GROW AND COALESCE BY MEANS OF PLASTIC DEFORMATION PROCESSES. VOIDS ARE NUCLEATED FREQUENTLY AT INCLUSIONS BUT MAY ALSO BE FORMED IN REGIONS OF INTENSE, HETEROGENEOUS SLIP. VOID LINKUP IS RESTRICTED TO THE NECKED REGION OF THE TENSILE SAMPLE. SOURCE: REF 7

Face-centered cubic (fcc) metals are unique in that they do not exhibit any brittle modes of fracture. (Iridium and rhodium are the exceptions to this statement.) As seen in the fracture mechanism maps, body-centered cubic (bcc) metals and hexagonal close-packed (hcp) metals undergo a transition from mode III brittle fracture to ductile fracture. For bcc metals,

this transition is related to the strong temperature and rate dependence of the flow stress. At low temperatures, the flow stress is above the stress required to nucleate voids, which then propagate by cleavage or intergranular fracture (both of which are discussed in the following sections). For hcp metals, the limited number of slip systems active at low temperatures prevents significant plastic deformation, and the metal fractures in a brittle manner. At higher homologous temperatures, secondary slip systems are activated, enabling the macroscopic plasticity required for ductile fracture.

Alkali halides, refractory oxides, and covalently bound materials exhibit only brittle modes of fracture and high-temperature fracture. For alkali halides (e.g., NaCl), the stress to initiate plastic flow can be less than the stress to initiate a void and cause mode II or mode III brittle fracture, but (as for hcp metals at low temperatures) the limited number of slip systems prevents the distribution of plastic strain necessary for ductile behavior. Refractory oxides (e.g., MgO and Al<sub>2</sub>O<sub>3</sub>) have stronger bonding (mixed ionic, covalent) than the ionically bonded alkali halides. Accordingly, the flow stress is much higher than the stress to initiate voids, and ductile fracture is not observed. The same is true for covalently bound materials (e.g., Si, SiC, Si<sub>3</sub>N<sub>4</sub>).

Polymeric materials and blends can be classified into modes of brittle fracture similar to those for metals, alkali halides, ceramics, and covalently bound materials, although the time-dependent nature of polymeric deformation suggests classification as a high-temperature fracture. Ductile fracture is also observed for polymers. A stress-strain curve for a polymer that exhibits ductility is schematically represented in Fig. 3. Large, inhomogeneous plastic strain occurs prior to ductile fracture of polymers.

## Micromechanisms of Monotonic Fracture

Within the general context of the previous discussions on fracture modes, this section presents generic descriptions of monotonic fracture micromechanisms. For fcc, hcp, and bcc metals, the ductile micromechanism of fracture is microvoid coalescence. The brittle micromechanisms of fracture are cleavage, intergranular fracture, and crazing (for polymeric materials). Some evidence of the first three micromechanisms can be observed on fracture surfaces of many structural metals. However, every attempt is usually made to encourage the occurrence of microvoid coalescence, because it absorbs the most energy during fracture.

**Microvoid Coalescence.** The only "low-temperature" ductile micromechanism of monotonic fracture (Table 2) is microvoid coalescence. Another term used to describe this mode is dimpled rupture. While it is a ductile micromechanism, the presence of microvoid coalescence on a fracture surface does not guarantee that the fracture absorbed a significant amount of energy. There are a number of situations where dimpled rupture is observed for

embrittled materials. Also, dimpled fracture surfaces are observed when voids form on grain boundaries during high-temperature deformation.

Figure 5 is a scanning electron micrograph of a steel fracture surface in which the material failed by microvoid coalescence. Voids initiate at second-phase particles or inclusions either by particle-matrix decohesion, cracking of the particle, or a combination. Upon continued plastic deformation, the voids grow and cause fracture when they impinge on one another. Microvoid coalescence is also observed in polymers. Broek (Ref 8) has shown that the dimple diameter and the inclusion spacing correlate quite well in aluminum alloys, as shown in Fig. 6.

**FIG. 6 CORRESPONDENCE OF THE DIMPLE SIZE TO THE INCLUSION SPACING IN SEVERAL ALUMINUM ALLOYS. THIS PROVIDES STRONG EVIDENCE THAT MICROVOIDS ARE NUCLEATED AT INCLUSIONS. NUMBERS REPRESENT ALUMINUM ALLOY DESIGNATIONS; ELLIPSES INDICATE SCATTER. SOURCE: REF 8**

The sequence of fracture is void initiation, void growth, and finally coalescence. Accordingly, the effect of microstructural variables on each step has been studied in detail. Two reviews provide summaries of both experimental studies and analytical models of microvoid coalescence (Ref 9, 10). These two articles summarize two to three decades of the study of fracture and are gateways to the vast literature on the subject. Several textbooks also provide useful and more detailed summaries of the phenomenon of microvoid coalescence (Ref 7, 11, 12). The following paragraphs briefly summarize the important observations.

Void initiation or nucleation occurs by particle-matrix decohesion or particle cracking. Particle-matrix decohesion can be negatively affected by interfacial segregation of trace elements. Smaller particles require a greater plastic strain for void initiation. In some materials, a critical strain defines void initiation; in others, void initiation is more closely correlated with stress level. In some systems, the void-initiating particles are damaged by the initial hot or cold forming process, so void initiation by cracking occurs at low stresses.

For systems containing large volume fractions of particles, the stress fields around the particles interact in such a way as to minimize the effect of particle size on initiation. The void initiation process is affected by the state of stress. Figure 7 compares  $Al_2O_3$  particle-reinforced 6061 aluminum alloy tensile specimens fractured in tension with 300 MPa hydrostatic compression to a specimen fractured at atmospheric pressure. The increased reduction of area in the specimen fractured at high pressure was attributed, in part, to suppression of void initiation (Ref 13). Accordingly, a hydrostatic tensile stress (such as that present at a crack tip) would tend to enhance void initiation.

**FIG. 7 EFFECT OF ATMOSPHERIC PRESSURE ON FRACTURE OF A DISCONTINUOUSLY REINFORCED ALUMINUM METAL-MATRIX COMPOSITE. FRACTURED TENSILE SPECIMENS AT (A) 0.1 MPA AND (B) 300 MPA AND RESPECTIVE FRACTURE SURFACES. THE INCREASED REDUCTION OF AREA IN THE HIGH-PRESSURE FRACTURE IS ATTRIBUTED TO SUPPRESSION OF VOID INITIATION AND GROWTH.**

Void growth, which is strongly affected by microstructure, is thought to absorb most of the work of fracture. Void growth can occur by plastic flow of the matrix or by linkup of smaller voids surrounding the large initial void. Triaxial stresses, such as those occurring at a notch, accelerate void growth and tend to encourage the formation of spherical dimples. Anything that short-circuits the void growth process will degrade the fracture resistance. Conversely, any microstructural feature that inhibits or interferes with void growth will enhance fracture resistance.

Void coalescence occurs by several mechanisms. The voids can grow until the remaining ligament ruptures. Void impingement absorbs the most energy. Voids can also coalesce by shear rupture. Because the volume of material that absorbs energy is more restricted, shear rupture is thought to absorb less energy. Void coalescence can also occur by linkup of smaller voids formed at smaller particles along bands of shear between large voids. This phenomenon, termed void sheet coalescence, degrades the fracture toughness. The classic micrograph, showing void sheet formation between two larger voids formed at sulfide inclusions in 4340 steel, is shown in Fig. 8.

**FIG. 8 LARGE VOIDS IN AISI 4340 LINKED BY NARROW VOID SHEETS CONSISTING OF SMALL MICROVOIDS. (A) SECTION THROUGH THE NECKED REGION OF A 4340 STEEL SPECIMEN SHOWING THE FORMATION OF A VOIDS SHEET BETWEEN TWO VOIDS FORMED AT LARGER INCLUSIONS. (B) SCHEMATIC OF NUCLEATION AT SMALLER PARTICLES ALONG THE DEFORMATION BANDS.**

The anisotropy of fracture toughness in wrought metals is attributed to the anisotropic distribution and shape of void-initiating particles that result from forming operations. The effect of the shape and distribution of the inclusions is clearly exhibited on the fracture surfaces. Shape control of sulfide inclusions in steel is a well-known method to improve the short-transverse fracture toughness.

Crack growth by microvoid coalescence exhibits a zig-zag pattern in cross section, as shown by Fig. 9 and 10. The reason for this morphology is that the plastic strain at a crack tip is maximum at an angle  $45^\circ$  from the macroscopic plane of growth (Ref 15). Void initiation and growth are thought to be controlled by plastic strain. When the specimen or component is thick with respect to the plastic zone radius, the crack is in a state of plane strain and the crack plane is perpendicular to the maximum principal stress. The dimples are elongated in the same direction on opposing sides of the fracture surface. When the component is thin with respect to the plastic zone radius, the fracture surface is inclined at approximately  $45^\circ$  to the principal stress and is in a state of plane stress. The inclined fracture surfaces are loaded in shear, and the dimples are elongated in opposite directions on opposing sides of the fracture surface.

**FIG. 9 DUCTILE CRACK GROWTH IN A  $45^\circ$  ZIG-ZAG PATTERN. THE PLANE OF MAXIMUM STRAIN IS  $45^\circ$  FROM**

THE MACROSCOPIC GROWTH DIRECTION, WHICH CAUSES MICROVOIDS TO GROW IN A ZIG-ZAG PATTERN.

FIG. 10 DUCTILE CRACK GROWTH IN A HIGH-STRENGTH LOW-ALLOY STEEL (A710). THE ZIG-ZAG CRACK GROWTH RESULTS FROM VOID INITIATION AND GROWTH ON THE PLANE OF MAXIMUM STRAIN, AS ILLUSTRATED IN FIG. 9.

**Cleavage.** Cleavage fracture is a transgranular, low-energy fracture that occurs primarily by separation of atomic bonds on low-index atomic planes. Because cleavage occurs along well-defined crystallographic planes within each grain, a cleavage fracture will change directions when it crosses grain or subgrain boundaries (Fig. 11). Engineering materials contain second-phase constituents; therefore, true featureless cleavage is difficult to obtain, even within a single grain. Transition of the crack from one grain to another and interaction with tilt/twist boundaries generate characteristic river lines (Fig. 12). In hcp metals, a feature called a cleavage tongue is caused when the crystallographic crack interacts with small twins (Ref 16). Although cleavage fracture occurs by separation of atomic bonds, the river lines are tear ridges that form by plastic deformation and absorb energy. The difference between the calculated thermodynamic surface energy,  $14 \text{ J/m}^2$ , and the experimentally measured energy,  $23 \text{ J/m}^2$ , to form a cleavage crack in Fe-4Si has been attributed in part to the energy absorbed by tear ridge formation and crack reinitiation at grain boundaries (Ref 17, 18). The energy to reinitiate the crack on crossing grain boundaries is one reason that toughness increases with a decrease in grain size.

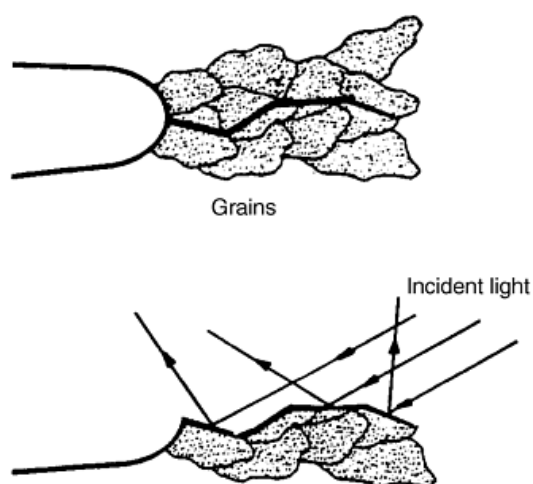

FIG. 11 SCHEMATIC OF CLEAVAGE THROUGH GRAINS AT A BLUNT CRACK TIP. EACH FACET THROUGH A GRAIN IS FLAT AND SO PROVIDES A HIGHLY REFLECTIVE SURFACE.

**FIG. 12 EFFECT OF TWIST BOUNDARY ON CLEAVAGE DECORATION. (A) FRACTURE MODELS SHOWING A TWIST BOUNDARY AND THE NEW CLEAVAGE STEPS THAT DEVELOP AS THE PROPAGATING CRACK CROSSES A TWIST BOUNDARY. FEATHER MARKS EXIST BETWEEN STEPS.**

Cleavage fracture occurs in materials that exhibit little or no capacity for plastic deformation (covalently bound materials, alkali halides, refractory oxides) as well as materials that exhibit significant plastic deformation (bcc and hcp metals). In materials with limited capacity for plastic deformation, it is not too surprising that the mechanism of fracture is by separation of atomic bonds. However, the cleavage fracture of bcc and hcp metals has perplexed and fascinated researchers for decades. The focus has been the ductile-to-brittle transition in steels because of its obvious technological significance.

Cleavage fracture in steels has been difficult to explain because the crack tip stress is below the theoretical fracture stress. Due to crack-tip blunting and redistribution of stresses due to yielding, the crack-tip stress is typically no more than 3 to 4 times the yield stress. Considering a range of yield strength from 400 to 1000 MPa, this indicates that crack-tip stresses are 4000 MPa at best. This is sufficiently below the theoretical fracture stress ( $E/\pi \sim 70,000$  MPa for iron) to cause fracture that one must invoke some other mechanism to explain the brittle fracture. In steels, the most commonly accepted explanation is that carbides fracture ahead of the crack tip, producing sharp, Griffith-type cracks that have crack-tip stresses equal to the theoretical fracture stress (Ref 19). The carbides fracture due to stresses from dislocation pileups. The key to this mechanism is that the crack remains sharp. Cleavage cracks in iron can arrest at grain boundaries if the crack blunts or if the local stresses are below that required for continued growth.

In the oft-quoted Ritchie, Knott and Rice (RKR) model (Ref 20), it is proposed that the crack-tip stress must exceed the stress required to propagate the crack from the carbide over a critical distance before the crack will propagate. It is suggested that this distance is one to two grain diameters. Subsequent researchers have proposed various statistical arguments to explain the grain size dependence, the thickness dependence, and the scatter in fracture strength values (Ref 21, 22, 23). While these are all generally based on a weakest link argument, considerable progress has been made in understanding cleavage fracture in steels.

Cleavage fracture is also observed for metals and ceramics in conditions of stress-corrosion cracking and hydrogen-assisted cracking. In fact, fcc austenitic stainless steel, which normally fails by microvoid coalescence, will exhibit stress-corrosion crack growth by transgranular cleavage in certain aqueous solutions (e.g., NaCl solutions). The simplistic explanation of stress-corrosion cleavage crack growth is that the corrosive environment acts to break the crack-tip bonds and thereby lowers the apparent thermodynamic surface energy. The phenomenon is considerably more complicated, and the reader is referred to Ref 24 for recent literature on stress-corrosion cracking.

**Intergranular fracture** is always associated with low toughness and low ductility and is therefore an undesirable fracture mode. The fracture surface is faceted and is often characterized as being similar to rock candy. The explanation is simply that the grain boundaries are usually stronger than the interior, but when they are not, the grain boundary is the failure path. Some of the causes of intergranular fracture are:

- INTRINSIC WEAKNESS OF THE GRAIN BOUNDARIES
- PRECIPITATION OF A BRITTLE PHASE OR SEGREGATION OF AN EMBRITTLING ELEMENT ON THE GRAIN BOUNDARY
- EMBRITTLEMENT OF THE GRAIN BOUNDARY BY HYDROGEN OR OTHER AGGRESSIVE ENVIRONMENTS
- INTERGRANULAR CORROSION

Thompson and Knott (Ref 17) provide a brief description of current theories of intergranular fracture. The theories either focus on the reason for intrinsic grain boundary weakness or on the effect of segregation of embrittling elements.

**Crazing of Polymers.** Above the glass temperature, amorphous polymers generally fail by rupture that may be assisted by void initiation. The usage of amorphous polymers above the glass temperature is generally not for structural purposes, and therefore fracture is not a significant problem. Nylon is a crystalline polymer used for structural applications and the glass transition temperature is 55 °C. Polymer failure above the glass temperature is quite ductile. Below the glass temperature, both amorphous and crystalline polymers can fail by propagation of crazes. An individual craze is similar in appearance to a crack, except that bundles of polymer chains form fibrils that bridge the boundaries of the craze. The density of the craze is significantly less than that of the parent matrix. The schematic in Fig. 13 shows side and top views of a craze. The craze is a preferred fracture path. Material separation typically occurs at the craze-matrix interface. This can occur in patches or bands (Fig. 14). Fibril failure is sometimes observed.

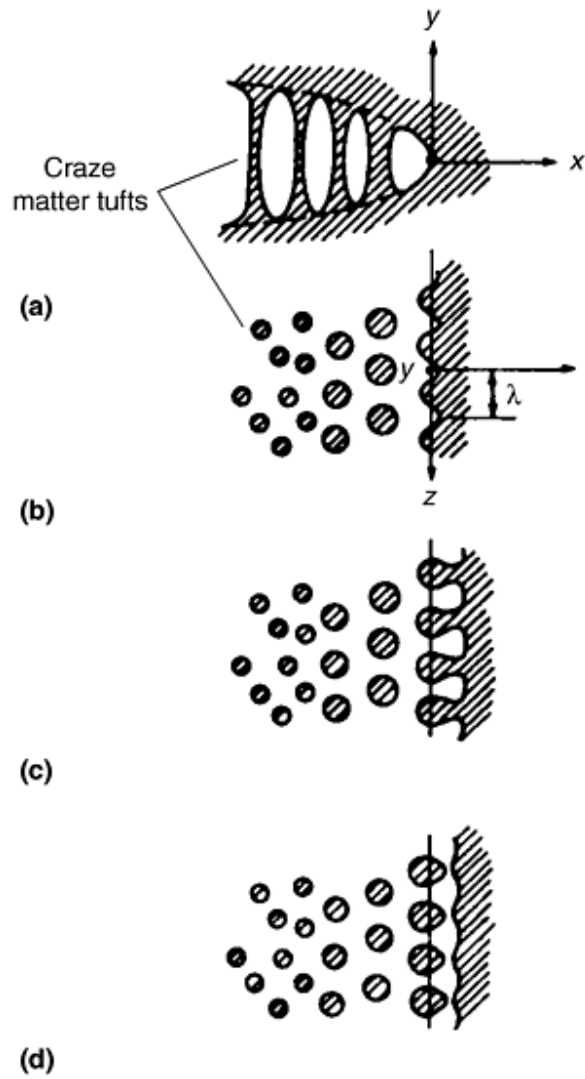

FIG. 13 SCHEMATIC OF CRAZE FORMATION. (A) OUTLINE OF A CRAZE TIP. (B) CROSS SECTION IN THE CRAZE PLANE ACROSS CRAZE MATTER TUFTS. (C,D) ADVANCE OF THE CRAZE FRONT BY A COMPLETED PERIOD OF INTERFACE CONVOLUTION

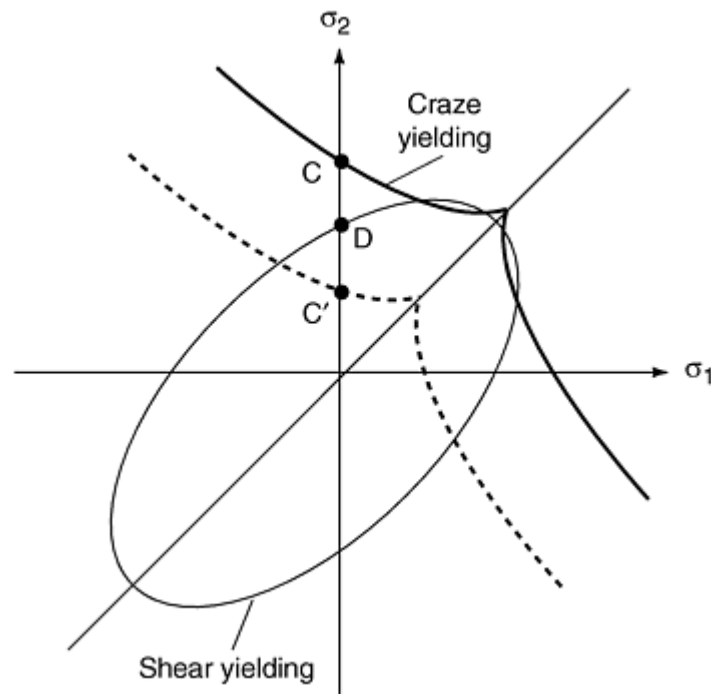

FIG. 14 CRAZE FRACTURE SURFACE (A) PATCH MORPHOLOGY AND (B) BAND MORPHOLOGY

Failure of amorphous polymers below the glass temperature,  $T_g$ , is often incorrectly associated with brittle fracture behavior. This is because failure by propagation of a single craze does not absorb much energy. The brittle tensile failure of polymethylmethacrylate (PMMA,  $T_g \sim 105^\circ\text{C}$ ) at room temperature typically occurs by craze propagation. However, polycarbonate, an amorphous polymer with  $T_g \sim 145^\circ\text{C}$ , exhibits considerable ductility (one application is "bulletproof" glass). The explanation for this effect is that amorphous polymers can yield by craze formation and/or shear yielding. The yield surfaces for crazing and shear yielding under biaxial stress is depicted in Fig. 15. When a polymer yields by shear band formation, prior to craze formation, fracture is suppressed until the ability of the matrix to form shear bands is exhausted. Then, fracture will occur by propagation of a craze. When craze formation is favored over shear band formation, the polymer initiates a craze that typically propagates to failure.

**FIG. 15 SHEAR AND YIELD LOCI UNDER BIAxIAL STRESSES. ONLY SHEAR YIELDING IS OBSERVED FOR BIAxIAL COMPRESSIVE STRESSES ( $\sigma_1, \sigma_2 < 0$ ). POINTS C AND D ARE THE UNIAXIAL TENSILE STRESSES REQUIRED FOR CRAZING AND SHEAR YIELDING, RESPECTIVELY. APPLICATION OF A HYDROSTATIC STRESS MOVES THE CRAZE YIELD LOCUS AWAY FROM THE ORIGIN. THE DASHED LINE SHOWS THE CRAZE YIELD LOCUS FOR LOWER HYDROSTATIC PRESSURE WITH C' LOWER THAN D. A TENSILE TRIAXIAL STRESS WOULD MOVE THE CRAZE LOCUS CLOSER TO THE ORIGIN**

It is interesting, however, to note that the plane-strain fracture toughness of PMMA and polycarbonate are comparable. For PMMA,  $K_c = 0.9$  to  $1.4 \text{ MPa}\sqrt{m}$ ; for polycarbonate,  $K_c = 1.0$  to  $2.6 \text{ MPa}\sqrt{m}$  (Ref 25). This is in contrast to the tensile ductility of 5% for PMMA and 130% for polycarbonate (Ref 26). The Izod impact toughness is  $0.5 \text{ ft} \cdot \text{ft} \cdot \text{lb/in.}$  for PMMA and  $16 \text{ ft} \cdot \text{ft} \cdot \text{lb/in.}$  for polycarbonate. Clearly, the competition between shear band formation and craze formation has a major impact on the toughness, but the testing methods may yield conflicting results. The tendency for craze formation is enhanced by a hydrostatic tensile stress (Ref 27). Presumably, the triaxial tensile stress at the tip of a sharp crack in a fracture toughness test favors craze formation, resulting in lower apparent fracture toughness. The blunt notch of an Izod impact test would have a lower triaxial tensile stress and would tend to favor shear band formation in polycarbonate.

Polymers that yield by craze formation can be toughened by distribution of micrometer-sized (or less) rubber particles in the brittle matrix. The rubber particles act as stress concentrators that initiate and ultimately blunt crazes. In addition, because the particles are widely distributed, they encourage the formation of a dense network of crazes that absorbs a considerable amount of energy. Also, the compliance of the crazed material is greater than that of the glassy matrix, so the stress concentration at the crack tip is reduced.

References 28, 29, 30 provide additional details on polymeric fracture.

### Micromechanisms of Monotonic and Cyclic Crack Growth

Todd S. Gross, University of New Hampshire; Steven Lampman, ASM International

---

### Cyclic Crack Growth

Crack growth during uniaxial cyclic deformation occurs by initiation of a microcrack that propagates on a plane close to that for maximum shear. This is termed a stage I fatigue crack. As the crack extends, it rotates from the plane of maximum shear to the plane normal to the principal stress and is then termed a stage II fatigue crack. This transition is shown in Fig. 16. This section focuses first on the factors influencing the initiation of fatigue cracks, then on the micromechanisms and the effects of microstructure and environment on long fatigue crack growth.

**FIG. 16 CROSS SECTION THROUGH A CRACK THAT INITIATES ON THE MAXIMUM SHEAR PLANE AND GROWS AS A STAGE I FATIGUE CRACK UNTIL IT ROTATES NORMAL TO THE MAXIMUM TENSILE STRESS RANGE AND BECOMES A STAGE II FATIGUE CRACK. SOURCE: REF 31**

Fatigue of uncracked metals is traditionally divided into low-cycle and high-cycle fatigue. The transition is usually associated with about 1000 to 2000 cycles to failure. Low-cycle fatigue involves bulk plasticity, whereas deformation in high-cycle fatigue is primarily elastic. The micromechanisms of crack growth at stresses in the low-cycle fatigue region are quite similar to monotonic crack growth. This discussion is restricted to crack growth rates less than approximately 1  $\mu\text{m}$  per cycle, which corresponds to the high-cycle fatigue region.

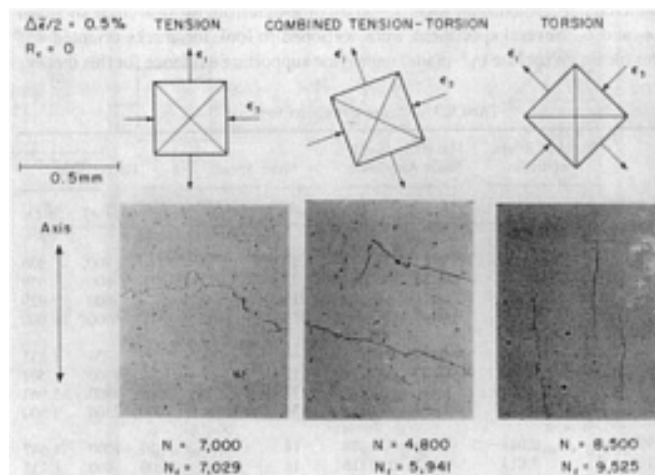

## Fatigue Crack Initiation

In single-phase, flaw-free, fcc metals, crack initiation is associated with persistent slip bands. As the dislocations exit the surface and possibly try to re-enter, the surface roughens. A protrusion that is composed of intrusions and extrusions forms at the intersection of the persistent slip band and the surface. The surface roughening and protrusion further localize the stresses and cyclic plastic strain until a microcrack initiates in the persistent slip band (Ref 32). If the environment is completely benign, the surfaces of the cracks can reweld thereby retarding the formation of a crack. Rewelding is strongly inhibited by oxidation of the intrusion-extrusion surfaces if they are exposed to an oxidizing environment (Ref 32).

Environment also has an effect on slip morphology and crack initiation in bcc metals (Ref 33). Samples of vacuum-arc remelted iron fatigued in high vacuum exhibit generalized surface rumpling, and the cracks initiate exclusively on the grain boundaries. The same samples fatigued in air exhibit well-defined slip lines, and cracks grow along the slip lines (Ref 33). Presumably, the reversibility of surface slip is inhibited in oxygen-containing environments, leading to concentration of slip and crack initiation. The presence of water vapor has been shown to cause grain boundary sliding and microvoid formation on boundaries (Ref 33).

In commercial alloys, fatigue crack initiation occurs at any feature that concentrates the local stress and plastic strain. Some of these features are voids, inclusions, twin boundaries, grain boundaries, stronger second phases, and notches. Crack initiation at voids occurs at the persistent slip bands emanating from the void. Crack initiation at inclusions can occur in a similar manner to that for voids, because a void can be considered an inclusion with an elastic modulus of zero. Sometimes inclusions are already cracked as a result of thermomechanical processing, and crack propagation occurs from the cracked inclusion. Sometimes the inclusion is cracked from the stress concentration resulting from blocking the persistent slip band. The inclusion can also debond from the matrix, and subsequent crack propagation will be similar to that from a void.

Crack initiation under multiaxial loading can be quite complex. Usually, but not always, the crack initiates on the plane of maximum shear (Ref 34). Figure 17 shows how the plane of crack initiation corresponds to the plane of maximum shear for several combinations of axial and torsional loading on a hollow tube. In contrast to axial loading, shear cracks under torsional loading can propagate to significant lengths before rotating to the plane of maximum principal stress range. The higher the stress range, the longer the duration of shear crack growth. The article "Multiaxial Fatigue Strength" in this Volume discusses fatigue under multiaxial loading in greater detail.

**FIG. 17 CRACK DIRECTIONS UNDER VARIOUS BIAxIAL LOAD TYPES. THE CRACK DIRECTIONS CORRESPOND TO THE PLANE OF MAXIMUM SHEAR FOR DIFFERENT COMBINATIONS OF IN-PHASE TENSION-TORSION LOADING. THE MATERIAL IS INCONEL 718 ( $R = 0$ , 0.5% STRAIN AMPLITUDE). SOURCE: REF 34**

The crack size at the transition from a microcrack to a macrocrack is usually associated with some microstructural unit (e.g., grain size or inclusion spacing). More importantly, it is associated with rotation of the crack from the plane of maximum shear strain range to that of maximum tensile stress range. Another descriptor used to describe cracks is short cracks versus long cracks. One of the central assumptions of linear elastic fracture mechanics is that the crack length is "large" with respect to the extent of the process zone at the crack tip and with respect to the extent of the stress concentration. Short cracks do not meet this condition and are discussed in the article "Behavior of Small Fatigue Cracks" in this Volume.

Because a significant portion of the high-cycle fatigue lifetime includes the initiation and growth of microcracks, many investigators have conducted studies of the growth of short cracks. In some of those studies, a long crack is shortened by removing material up to a short distance from the crack tip. In others, crack initiation from an artificial notch is studied. Yet another approach is to observe crack initiation and growth for a large number of cracks in a fixed area on a specimen. All three techniques have demonstrated that the rate of crack growth is discontinuous and is often greater than that extrapolated from "long" crack data. It is also a common observation that the crack-tip displacements exhibit both shear and opening displacements (Ref 35).

## Fatigue Crack Growth Mechanisms

**Stage I Growth.** Fatigue crack initiation and growth during stage I occurs principally by slip-plane cracking. A typical stage I fatigue fracture is shown in Fig. 19. Stage I fatigue fracture surfaces are faceted, often resemble cleavage, and generally do not exhibit regularly spaced fatigue striations. Stage I fatigue is normally observed on high-cycle, low-stress fractures and is frequently absent in low-cycle, high-stress fatigue.

**FIG. 18 SCHEMATIC COMPARING CRACK ORIENTATIONS FOR TESTING IN DRY NITROGEN AND (HUMID) LABORATORY AIR. STAGE I CRACK GROWTH IS ENHANCED IN THE INERT ENVIRONMENT. SOURCE: REF 36**

The tendency toward stage I crack propagation is strongly affected by anything that concentrates slip and by environments that affect slip reversibility (Ref 36, 37). Repeated cutting and disordering of coherent precipitates is suggested to lead to concentrated slip for age hardened aluminum alloys. Figure 18 shows that stage I fatigue crack growth occurs in dry nitrogen at any frequency whereas stage II fatigue crack growth is observed at low frequencies in laboratory air. The oxidation of the fresh surface prevents the slip reversibility required for stage I fatigue crack growth. Many titanium and aluminum alloys are known to exhibit highly localized, concentrated slip and therefore to have a tendency toward stage I crack propagation. Conversely, microstructure that tends to homogenize slip (e.g., incoherent, closely spaced dispersoids or fine grains) will suppress the tendency for cracks to propagate by stage I, shear crack growth.

**FIG. 19 CLEAVAGELIKE, CRYSTALLOGRAPHIC ORIENTED STAGE I FATIGUE FRACTURE IN A CAST NI-14CR-4.5MO-1TI-6AL-1.5FE-2.0(NB+TA) ALLOY**

In polycrystalline materials, the tendency toward localized strain is affected by the size of the crack-tip cyclic plastic zone relative to the grain or microstructural feature size (Ref 38). If the grain or microstructural packet is much bigger than the cyclic plastic zone, it is possible to have an extended, localized slip band for subsequent crack extension. The crack extends on the most favorably oriented plane in a given grain. Because the grains in a polycrystalline metal will have many different orientations, the macroscopic crack will have a zig-zag appearance. When the cyclic plastic zone is on the order of or bigger than the relevant microstructural unit, the tendency toward slip band cracking is suppressed and the crack becomes nearly planar.

**Stage II Crack Growth and Fatigue Striations.** The largest portion of a fatigue fracture consists of stage II crack growth, which generally occurs by transgranular fracture and is more influenced by the magnitude of the alternating stress than by the mean stress or microstructure. Fatigue fractures generated during stage II fatigue may exhibit crack marks known as fatigue striations (Fig. 20), which are a visual record of the position of the fatigue crack front during crack propagation through the material.

**FIG. 20 UNIFORMLY DISTRIBUTED FATIGUE STRIATIONS IN AN ALUMINUM 2024-T3 ALLOY. (A) TEAR RIDGE AND INCLUSION (OUTLINED BY RECTANGLE). (B) HIGHER-MAGNIFICATION VIEW OF THE REGION OUTLINED BY THE RECTANGLE IN (A), SHOWING THE CONTINUITY OF THE FRACTURE PATH THROUGH AND AROUND THE INCLUSION**

During stage II fatigue, the crack often propagates on multiple plateaus that are at different elevations with respect to one another (Fig. 21). A plateau that has a concave surface curvature exhibits a convex contour on the mating fracture face (Ref 39). The plateaus are joined either by tear ridges or walls that contain fatigue striations. Fatigue striations often bow out in the direction of crack propagation and generally tend to align perpendicular to the principal (macroscopic) crack propagation direction. However, variations in local stresses and microstructure can change the orientation of the plane of fracture and alter the direction of striation alignment.

FIG. 21 SCHEMATIC ILLUSTRATING FATIGUE STRIATIONS ON PLATEAUS

Large second-phase particles and inclusions in a metal can change the local crack growth rate and resulting fatigue striation spacing. When a fatigue crack approaches such a particle, it is briefly retarded if the particle remains intact or is accelerated if the particle cleaves. In both cases, however, the crack growth rate is changed only in the immediate vicinity of the particle and therefore does not significantly affect the total crack growth rate. However, for low-cycle, high-stress fatigue, the relatively large plastic zone at the crack tip can cause cleavage and matrix separation at the particles at a significant distance ahead of the advancing fatigue crack. In effect, the cleaved or matrix-separated particles behave as cracks or voids that promote a tear or shear fracture between themselves and the fatigue crack, thus significantly advancing the crack front. Relatively small, individual particles have no significant effect on striation spacing (Fig. 20b).

The distinct, periodic markings sometimes observed on fatigue fracture surfaces are known as "tire tracks," because they often resemble the tracks left by the tread pattern of a tire (Fig. 22). These rows of parallel markings are the result of a particle or a protrusion on one fatigue fracture surface being successively impressed into the surface of the mating half of the fracture during the closing portion of the fatigue cycle (Ref 39, 40). Tire tracks are more common for the tension-compression than the tension-tension type of fatigue loading. The direction of the tire tracks and the change in spacing of the indentations within the track can indicate the type of displacement that occurred during the fracturing process, such as lateral movement from shear or torsional loading. The presence of tire tracks on a fracture surface that exhibits no fatigue striations may indicate that the fracture occurred by low-cycle, high-stress fatigue.

FIG. 22 TIRE TRACKS ON THE FATIGUE FRACTURE SURFACE OF A QUENCHED-AND-TEMPERED AISI 4140 STEEL. TEM REPLICA. (COURTESY OF I. LE MAY, METALLURGICAL CONSULTING SERVICES LTD.)

**Fatigue Crack Growth Rates and Striation Spacings.** Fatigue striations provide very useful mechanistic information on fatigue crack growth, and a striation spacing and formation mechanisms. The spacing of fatigue striations provides important evidence for understanding the fatigue crack growth process, not because the spacing necessarily reveals much about the process itself, but because striations constitute unambiguous, quantitative evidence of the *average increment* by which a fatigue crack advances.

Typically, one striation forms on each loading cycle, and it is clear from early experiments that one striation often evidences an increment of crack growth and arrest. More recent observations, by numerous investigators, have shown that one striation does not necessarily correspond to one cycle; tens to thousands of cycles may be required to obtain one striation (Ref 41). Data for both results appear to be correct, and many of the differences found have been due to studying different parts of the crack growth rate curve. Early work examined relatively large crack growth rates ( $>10^{-6}$  m/cycle), where striation spacing approximately equals the crack growth rate. Later studies have emphasized lower growth rates where striation spacing is larger than crack growth rate.

In the near-threshold (stage I) regime, striation spacing can exceed crack growth rates by orders of magnitude (Ref 41). Based on a large amount of information collected for numerous materials, Grinberg (Ref 42) was the first to recognize the important fact that the minimum striation spacing observed, regardless of material, is approximately 0.1  $\mu\text{m}$ . This has been found to be true for aluminum and its alloys; magnesium, nickel, and titanium alloys; and many steels. For cases in which the striation spacing increases with  $\Delta K$ , the minimum spacing occurs near  $\Delta K_{\text{th}}$ , or if data were not obtained at such low stress intensities, values obtained at higher  $\Delta K$  extrapolate to  $\sim 0.1 \mu\text{m}$  at the threshold. The fact that striation spacing and crack growth rate diverge with decreasing  $\Delta K$ , and that the minimum striation spacing is approximately constant for all materials, may have significant mechanistic implications, which are explored in Ref 41.

For a stage II fatigue crack propagating under conditions of reasonably constant cyclic loading frequency and advancing within the nominal range of  $10^{-5}$  to  $10^{-3}$  mm/cycle, the Paris relation of crack growth rate ( $da/dN = C(\Delta K)^m$ ) is applicable. If a fatigue striation is produced on each loading cycle,  $da/dN$  represents the striation spacing. The Paris equation does not adequately describe stage I or stage III fatigue crack growth rates; it tends to overestimate stage I and often underestimates stage III growth rates.

Stage III is the terminal propagation phase of a fatigue crack in which the striation-forming mode is progressively displaced by the static fracture modes, such as dimpled rupture or cleavage. The rate of crack growth increases during stage III until the fatigue crack becomes unstable and the part fails. Because the crack propagation is increasingly dominated by the static fracture modes, striation formation per cycle is expected to be intermittent.

The profile of the fatigue fracture can vary, depending on the material and state of stress. Materials that exhibit fairly well-developed striations display a sawtooth-type profile (Fig. 23a) with valley-to-valley or groove-to-groove matching (Ref 40). Low compressive stresses at the crack tip favor the sawtooth profile; however, high compressive stresses promote the groove-type fatigue profile, as shown in Fig. 23(c) (Ref 43, 44). Jagged, poorly formed, distorted, and unevenly spaced striations (Fig. 23b), sometimes termed quasi-striations (Ref 40), show no symmetrical matching profiles. Even distinct sawtooth and groove-type fatigue surfaces may not show symmetrical matching. The local microscopic plane of a fatigue crack often deviates from the normal to the principal stress. Consequently, one of the fracture surfaces will be deformed more by repetitive cyclic slip than its matching counterpart (Ref 39). Thus, one fracture surface may show well-developed striations while its counterpart exhibits shallow, poorly formed striations.

**FIG. 23 SAWTOOTH AND GROOVE-TYPE (TYPE B) FATIGUE FRACTURE PROFILES OF A SINGLE FRACTURE (TOP) AND MATCHING FRACTURE SURFACE (BOTTOM). ARROWS SHOW CRACK PROPAGATION DIRECTION. (A) DISTINCT SAWTOOTH PROFILE (ALUMINUM ALLOY). (B) POORLY FORMED SAWTOOTH PROFILE (STEEL). (C) GROOVE-TYPE PROFILE (ALUMINUM ALLOY). IT SHOULD BE NOTED THAT MATCHING SURFACES CAN BE EITHER SELF-SIMILAR OR OF THE OPPOSITE TYPE. MUGHRABI ET AL. (REF 43) DISCUSS FIVE DIFFERENT SHAPES OF STRIATIONS FORMED IN AIR. MUCH MORE IRREGULAR AND POORLY FORMED PERIODIC MARKINGS HAVE BEEN FOUND ON FRACTURE SURFACES FORMED BY FATIGUE CRACK GROWTH IN VACUUM. STRIATIONS FORMED IN A VACUUM TEND TO BE ROUNDED BUT CLOSER TO TYPE A THAN TYPE B. SOURCE: REF 1, 41**

Under normal conditions, each striation is the result of one load cycle and marks the position of the fatigue crack front at the time the striation was formed. However, when there is a sudden decrease in the applied load, the crack can temporarily stop propagating, and no striations are formed. The crack resumes propagation only after a certain number of

cycles are applied at the lower stress (Ref 40, 45). This phenomenon of crack arrest is believed to be due to the presence of a residual compressive stress field within the crack-tip plastic zone produced after the last high-stress fatigue cycle (Ref 40, 45).

Fatigue crack propagation and therefore striation spacing can be affected by a number of variables, such as loading conditions, strength of the material, microstructure, and the environment (e.g., temperature and the presence of corrosive or embrittling gases and fluids). Considering only the loading conditions--which would include the mean stress, the alternating stress, and the cyclic frequency--the magnitude of the alternating stress ( $\sigma_{\max} - \sigma_{\min}$ ) has the greatest effect on striation spacing. Increasing the magnitude of the alternating stress produces an increase in the striation spacing. While rising, the mean stress can also increase the striation spacing; this increase is not as great as one for a numerically equivalent increase in the alternating stress. Within reasonable limits, the cyclic frequency has the least effect on striation spacing. In some cases, fatigue striation spacing can change significantly over a very short distance. This is due in part to changes in local stress conditions as the crack propagates on an inclined surface.

**Mechanisms of Fatigue Striation Formation.** Fatigue striations are found frequently on the fracture surfaces of aluminum alloys cycled in moist air, while for other alloys, striations are not always found. It is not clear in many instances why fatigue striations do not form, but it is a subject that has attracted considerable investigation. However, even if striations are not observed, the absence of fatigue striations does not mean that the basic mechanism by which cracks advance has been changed. This fact is illustrated by several examples in Ref 41. A lack of striations on a fatigue fracture surface may be due also to their having been obscured by crack-closure-induced rubbing of the fracture surfaces, as caused by mode II sliding. The debris caused by this process, reported by many investigators, is particularly prevalent when thick oxides form on newly exposed fracture surfaces.

The mechanism of striation formation generally is a two-step process as a result of crack-tip blunting on the rising portion of the load, followed by resharpening as the load is released. The model of this mechanism is based on slip at the crack tip, although slip may not occur precisely at the crack tip due to the presence of lattice or microstructural imperfections (Ref 46, 47, 48). If stress is concentrated at a fatigue crack, plastic deformation (slip) will be confined to a small region at the tip of the crack while the remainder of the material is subjected to elastic strain. As shown in Fig. 24(a), the crack opens on the rising-tension portion of the load cycle by slip on alternating slip planes. As slip proceeds, the crack tip blunts, but it is resharpened by partial slip reversal during the declining-load portion of the fatigue cycle. This results in a compressive stress at the crack tip due to the relaxation of the residual elastic tensile stresses induced in the uncracked portion of the material during the rising load cycle (Fig. 24b). The closing crack does not reweld, because the new slip surfaces created during the crack-opening displacement are instantly oxidized, which makes complete slip reversal unlikely. Some fracture surfaces containing widely spaced fatigue striations exhibit slip traces on the leading edges of the striation and relatively smooth trailing edges, as predicted by the model (Fig. 24). Not all fatigue striations, however, exhibit distinct slip traces, as suggested by Fig. 24, which is a simplified representation of the fatigue process.

**FIG. 24 MECHANISM OF FATIGUE CRACK PROPAGATION BY ALTERNATE SLIP AT THE CRACK TIP. SKETCHES ARE SIMPLIFIED TO CLARIFY THE BASIC CONCEPTS. (A) CRACK OPENING AND CRACK-TIP BLUNTING BY SLIP ON ALTERNATE SLIP PLANES WITH INCREASING TENSILE STRESS. (B) CRACK CLOSURE AND CRACK-TIP RESHARPENING BY PARTIAL SLIP REVERSAL ON ALTERNATE SLIP PLANES WITH INCREASING COMPRESSIVE STRESS**

Striations are more commonly observed in air than in vacuum. The essential absence of striations on fatigue fracture surfaces of metals tested in vacuum tends to support the assumption that oxidation reduces slip reversal during crack closure, which results in the formation of striations. The lack of oxidation in hard vacuum promotes a more complete slip reversal, which results in a smooth and relatively featureless fatigue fracture surface. For fatigue crack growth in a vacuum, evidence points to a two-step process that begins with crack-tip blunting followed by a step evidencing less plasticity (Ref 41). The crack-tip blunting is accompanied first by the generation of numerous dislocations. As the crack advances, many of these dislocations do not return to the crack tip, but remain nearby and are detected in the transmission electron microscopy foils as a tangle of dislocations (Ref 41). The second step in striation formation is related to breakdown along a slip line, which forms during the crack blunting step. Formation and fracture of the slip line evidently leaves few dislocations behind, which might be construed as brittle materials behavior (Ref 41).

In air, striation formation is also a two-step process, although the sequence of effects may depend on type A or type B striation (Fig. 23), as reported in Ref 41 from results of Nix and Flower (Ref 49). Nix and Flower state that a band of deformation accompanies the leading edge of the type A striation. But for the type B striation, the opposite is true, with the first part of the striation being caused by cleavage, followed by crack-tip blunting and dislocation generation. As such the type of striation that forms may depend on the combination of cleavage, dictated by the local tensile stress, followed by shear, controlled by the local shear stress, and the detailed profile developed depends on the orientation of the cleavage plane and the slip systems to the tensile and shear stresses.

**Fatigue Crack Growth in Duplex Microstructures.** Duplex microstructures (such as in dual-phase steels,  $\alpha$ - $\beta$  titanium alloys, or metal-matrix composites) can have unique fatigue crack growth features, depending on whether the soft phase is continuous or whether the hard phase is continuous. A series of classic experiments were performed (Ref 50, 51) in which these two types of microstructures were obtained with martensite and ferrite. In both structures, crack initiation occurred at the ferrite-martensite interface. In the continuous ferrite microstructure, the crack deviated to avoid the martensite, leading to a more tortuous, rougher fracture surface. The crack path in the continuous martensite structure was flatter than the continuous ferrite, and the crack grew in the martensite, although the crack occasionally deviated by interaction with large ferrite grains. The crack growth rate was slower in the continuous martensite microstructure. While the crack path was rougher in the continuous ferrite structure, the continuous martensite structure exhibited higher closure loads, which is opposite to what one would expect from roughness-induced crack closure. It has been proposed that there is a semicohesive zone behind the crack tip (Fig. 25) in which ligaments of unfractured material limit the driving force for crack extension (Ref 52). Perhaps ductile ferrite ligaments in the continuous martensite structure caused the crack faces to come into contact at a higher load and exhibit a greater degree of crack closure. The fatigue fracture surfaces often have cleaved and ductile regions in duplex microstructures such as  $\alpha$ - $\beta$  titanium (e.g., Ref 53) or metal-matrix composites.

**FIG. 25 SCHEMATIC OF SEMICOHESIVE ZONE BEHIND THE CRACK TIP. SOURCE: REF 52**

**Cyclic Crack Growth in Polymers.** The low thermal conductivity of polymers can cause hysteretic heating during fatigue cycling (Ref 54). This greatly complicates the prediction of fatigue behavior and lifetime. The elastic modulus can decrease one to three orders of magnitude for amorphous polymers as they are heated above the glass temperature. Also, the amount of viscoelastic deformation will become prominent above the glass temperature. Therefore, the fatigue response of a given polymer will depend on frequency, thermal mass of the component, and the proximity of ambient temperature to the glass temperature. The data from  $S$ - $N$  curves may or may not accurately represent component behavior, because  $S$ - $N$  curves are usually obtained on (thermally) small samples at frequencies between 5 and 100 Hz. A large component may experience a greater temperature rise than the fatigue specimens and a small component may experience less heating. One should use data from fatigue lifetime curves with some caution.

Surprisingly little has been published on the factors influencing fatigue crack initiation in polymers. The primary focus is on fatigue crack growth. Polymer fatigue fracture surfaces often have the classic beach marks or clam shell markings. As with metals, while the macroscopic features represent the positions of the crack front, the spacing of the prominent parallel features more closely corresponds to the spacing between high-load cycles. At higher magnification, fatigue fracture surfaces may be featureless, have patches of striations, have long bands of striations, exhibit a patchy rumpled surface, or have a combination of the above with microvoid coalescence. These features can be related to the mechanisms of crack extension.

Patches of striations can be observed where the striation spacing corresponds to the macroscopic growth rate (Ref 54, 55). This is only observed for crack growth rates in excess of  $\sim 0.1 \mu\text{m}$  per cycle. The striations can have fine features oriented parallel to the crack growth direction, which are tear ridges connecting crack fronts on different levels. The surface can also have fine features parallel to the striations. The mechanism of crack growth is similar to that for metals, where the

crack tip blunts by homogeneous inelastic flow on the rising part of the load cycle. The crack then resharpens as the load is released.

Striation-like features have also been observed in which the spacing is many times the macroscopic crack growth rate (Ref 54, 55). These features, termed discontinuous growth bands, are formed by crack extension along a craze that extends from the crack tip, as seen in Fig. 26. The crack grows by progressive breakdown of the craze. The fibrils in the craze are drawn out of the uncrazed matrix and may undergo orientation hardening. At some point, the load-carrying capacity of the fibrils is exceeded and the crack propagates across the craze. Crack growth can be accompanied by audible clicks and pops. At this point, a new craze is initiated and the process repeats itself.

**FIG. 26 CRAZE EMANATING FROM A FATIGUE CRACK TIP IN AMORPHOUS NYLON. A DISCONTINUOUS GROWTH BAND WILL FORM AS THE CRACK PROPAGATES THROUGH THE CRAZE. UNDER POLARIZED LIGHT, 560 $\times$ . SOURCE: REF 56**

In amorphous polymers, a single craze will emanate from the crack tip, as can be seen in Fig. 26. Because the single craze is nearly planar, a discontinuous growth band can laterally extend all the way across a typical crack growth specimen. The lateral extent of the striation-like feature may be one way to determine whether it is a true striation or a discontinuous growth band. In crystalline polymers, crazes may emanate on several levels, as can be seen in the microtomed sections through a crack in nylon in Fig. 27. A patch-like morphology results as tear ridges form when the different levels link up (Ref 56).

**FIG. 27 MICROTOMED CROSS SECTION SHOWING MULTIPLE CRAZES EMANATING FROM A FATIGUE CRACK IN CRYSTALLINE NYLON. SOURCE: REF 56**

As for monotonic fracture, there is competition between the two mechanisms of yielding, crazing and shear banding. At the tip of a plane-strain crack, the stress field has a strong hydrostatic tensile component that favors formation of crazes. For plane-stress cracks, the large shear component stress field and reduced hydrostatic tensile component has been shown to favor shear banding (Ref 57). Shear banding may also be promoted by the introduction of rubber particles and other

second phases. In both cases, anything that promotes shear banding will increase the size of the damage zone and thereby increase the work of fatigue crack growth.

### Fatigue Crack Closure

Since 1970 (Ref 58, 59) premature crack closure during unloading has been considered important in the evaluation of the crack tip driving force necessary to quantify fatigue crack growth data. Fatigue crack closure is an important effect because it alters the relationship between the applied stress-intensity factor (calculated from applied stress and crack length) and that actually experienced by the crack tip. In linear elastic fracture mechanics under maximum and minimum loading, the  $K_I$  fields ahead of the fatigue crack tip uniquely define the rate of fatigue crack propagation. However, with the discovery of crack closure by Elber (Ref 58, 59), it is now known that crack growth rates are influenced not only by the conditions ahead of the crack tip, but also by the nature of crack face contact behind the crack tip during unloading. Elber suggested that a zone of residual tensile deformation occurs in the wake of a fatigue crack tip, which thus reduces crack opening displacements and causes contact between faces in the wake of the crack tip.

Crack closure reduces the applied stress-intensity amplitude,  $\Delta K_{apl}$ , by a factor related to the stress intensity at which closure occurs,  $K_{cl}$ . The magnitude of  $K_{cl}$ , which is generally measured by observing the change in the compliance at the point of closure, depends on material, microstructure, environment, and loading conditions. The effective stress-intensity factor amplitude at the crack tip,  $\Delta K_{eff}$ , is given by

$$\Delta K_{EFF} = K_{MAX} - K_{CL} < \Delta K_{APL}, \text{ IF } K_{CL} > K_{MIN} = \Delta K_{APL} = K_{MAX} - K_{MIN}, \text{ IF } K_{CL} \leq K_{MIN}$$

where  $K_{max}$  and  $K_{min}$  are the stress intensities at maximum and minimum loads, respectively. For tests involving high  $R$  ratios ( $K_{max}/K_{min}$ ) i.e., for  $R > 0.6$  to  $0.7$ ,  $K_{min} > K_{cl}$ , there is little or no crack closure (Ref 60) and the effective driving force is equal to the applied driving force.

Fatigue crack closure is not completely understood, but it is a factor in the retardation of crack growth rates. Under constant-amplitude loading, the applied stress-intensity factor range is decreased by crack closure, which thus has the effect of retarding crack growth rates. In addition, with the suggestion of wake effects by Elber, the importance of prior history is also a factor in the possible retardation or acceleration of fatigue crack growth rates. While crack closure has become a major concern in fatigue crack growth which cannot be easily predicted or measured, its effect is considered significant, particularly for near-threshold crack growth at low  $R$  ratios. Crack closure is considered primarily responsible for several fatigue crack growth phenomena, such as the effects of the following:

- $R$  RATIO ON FATIGUE CRACK THRESHOLDS,  $\Delta K_{TH}$ , AND ON FATIGUE CRACK GROWTH RATES,  $DA/DN$

- VACUUM, AIR, HUMIDITY, HYDROGEN, AND CORROSIVE ENVIRONMENTS
- MICROSTRUCTURE THAT CONTRIBUTES TO CRACK PATH TORTUOSITY
- RETARDATION DUE TO OVERLOADS, UNDERLOADS, AND THERMAL HISTORY
- ACCELERATION OF SHORT CRACKS

**Mechanisms of Fatigue Crack Closure.** Although a considerable amount of research has been devoted to the study of closure for the last two decades, the mechanisms and effects of closure are only partially understood, and in some cases they are controversial. This section only briefly reviews possible mechanisms, while the next section discusses predictive models of closure effects.

Fatigue crack closure may be caused by several different phenomena (Fig. 28):

- THE PLASTIC DEFORMATION OF MATERIAL IN THE REGION NEAR TO THE CRACK TIP (BOTH AHEAD AND BEHIND)
- CRACK SURFACE ROUGHNESS
- THE GROWTH OF OXIDES WITHIN THE CRACK, USUALLY CAUSED BY INTERACTION OF THE MATERIAL WITH THE ENVIRONMENT IN WHICH THE CRACK IS BEING GROWN

Other closure mechanisms include viscous-fluid induced closure and transformation-induced closure.

**FIG. 28** SCHEMATIC ILLUSTRATION OF THREE MECHANISMS THAT PROMOTE RETARDATION OF FATIGUE CRACK GROWTH IN CONSTANT-AMPLITUDE FATIGUE. (A) PLASTICITY-INDUCED CRACK CLOSURE. (B) OXIDE-INDUCED CRACK CLOSURE. (C) ROUGHNESS-INDUCED CRACK CLOSURE. OTHER MECHANISMS INCLUDE FLUID-INDUCED CRACK CLOSURE, TRANSFORMATION-INDUCED CRACK CLOSURE, CRACK DEFLECTION, CRACK BRIDGING BY FIBERS, CRACK BRIDGING (TRAPPING) BY PARTICLES, CRACK SHIELDING BY MICROCRACKS, AND CRACK SHIELDING BY DISLOCATIONS. SOURCE: REF 64

Oxide-induced closure is perhaps the best understood and least controversial of these closure mechanisms, even though actual observation of a crack volume filled with oxides or a corrosion product has not been documented extensively. Oxide-induced closure has been an effective concept when measuring load-ratio effects on threshold stress-intensity ranges ( $\Delta K_{th}$ ) for fatigue crack growth in corrosive and inert environments. In general, fatigue crack growth rates typically are lower in an inert environment and a vacuum (than in air or other corrosive environment). In the near-threshold (low  $\Delta K$ ) regime, however, crack growth rates at lower  $R$  ratios are higher in an inert environment as opposed to air or wet environments (see, for example, Fig. 29a, Ref 61). This effect is rationalized by the concept of crack closure, whereby oxide deposits promote premature contact of the fracture surfaces during unloading, thereby reducing the effective stress intensity at the crack tip ( $K_{eff} = K_{max} - K_{cl}$ ). This concept is further demonstrated by considering the effect of load ratio ( $R$ ) on the threshold  $\Delta K_{th}$  in dry and wet environments (Fig. 30). At lower load ratios ( $R < 0.5$ ), the oxides on the fracture surface promote earlier closure, thereby increasing  $K_{cl}$  and reducing  $K_{eff}$ . As load ratio is increased, the threshold stress-intensity ranges in air and wet environments decrease below that of in dry helium, because premature closure during unloading is less pronounced at higher load ratios. Therefore, load-ratio effects on  $\Delta K_{th}$  in corrosive environments is a key demonstration of crack-closure concepts, although efforts have been made to explain this phenomena without invoking closure (see "New Concepts for Fatigue Thresholds" at the end of this article).

**Asperity (or Surface-Roughness)-Induced Closure.** Fatigue crack closure is often attributed to crack-wake surface roughness, and many studies have addressed this potential closure-effect on fatigue crack growth rates. Several examples of roughness-induced closure effects are described in the article "Fatigue Crack Thresholds" in this Volume. Additional references of other examples are listed in the "Selected References" at the end of this article.

However, direct demonstration of roughness-induced closure is less definitive than oxide-induced closure. *Partial crack closure* can occur *locally* at asperities, but their effects are nominal on the crack-tip stress field (Ref 62). Load ratio effects on  $\Delta K_{th}$  (Ref 67) also indicate that roughness-induced closure is less significant than oxide-induced closure. Therefore, even if surface roughness is a cause of crack closure, its effect on crack growth may be less critical unless more definitive work is done.

One review (Ref 41) even suggests that roughness is not a factor in closure and that all closure can be described as a plasticity effect. It does seem evident, however, that closure occurs when asperities come into contact behind the crack tip and wedge open the crack at loads above the minimum load,  $P_{min}$  (see Gray et al, Horng and Fine, Baker and Mayers, Minakawa and McEvily, and Suresh and Ritchie in "Selected References" ). This closure effect is more likely at low stress ratios in the near-threshold regime due to lower crack opening displacements.

**Closure from Plastic Deformation.** Plastic deformation of material just ahead of the crack tip can cause closure when residual tensile strains are left in the material behind the advancing crack front. Material elements just ahead of the crack tip are elongated by strain concentration at the tip, and this deformation may not be fully reversed when the element

breaks as it passes into the wake of the crack. On unloading, the crack surfaces of these "stretched" elements may touch before minimum load is reached, thereby resulting in closure.

In terms of plasticity effects, some success has been obtained by estimating the mode I value of  $\Delta K_{th}$  using the simple concept that crack growth at threshold will only occur if dislocations are emitted from the crack tip (Ref 63). Using the equations of elasticity, the following expression is easily derived for large cracks:

$$\Delta K_{TH} = \sigma_Y \sqrt{2pr_s} \quad (\text{EQ 1})$$

where  $\sigma_y$  is the yield stress and  $r_s$  is the distance dislocations move through the material before being stopped. This equation assumes that a slip line occurs at the crack tip, and that dislocations are emitted and move  $r_s$ , with  $\sigma_y$  being the stress at the end of the slip line. The problem with using the above equation to predict  $\Delta K_{th}$  is that it is difficult to determine  $r_s$ . The most success using this concept was obtained for particulate-reinforced composites where  $r_s$  was controlled by the size and volume fraction of silicon carbide (Ref 64). This concept seems to hold promise as a method for computing  $\Delta K_{th}$ , but it has not been proven and remains a hypothesis to be further tested.

Like roughness-induced closure, a definitive consensus has not been reached on the significance (and perhaps existence) of plasticity-induced closure, despite an overwhelming amount of published literature on its measurement and implications (see "Selected References: Plasticity-Induced Closure" at the end of this article for a limited bibliography). Plasticity-induced closure is considered dominant at higher  $\Delta K$  levels (i.e., in the Paris regime), based on the observation that the Elber closure ratio ( $U = \Delta K_{eff}/\Delta K$ ) decreases rapidly as the threshold is approached. However, the ability of plasticity-induced closure in accounting for  $R$  ratio effects on FCG rates at high  $\Delta K$  levels has been questioned by some (T. Shih and R. Wei, *Engr. Frac. Mech.*, Vol 6, 1974, p 19-32). In the low- $\Delta K$  threshold regime, interpretation of closure effects from possible plasticity effects is complicated by possible roughness- or oxide-induced closure.

Using basic concepts from dislocation theory, Vasudevan et al suggest that crack-tip plasticity cannot contribute to crack closure because crack opening displacements are always greater than crack closing displacements (Ref 62, 65). The experimental basis of this position is based on limited fatigue threshold data, as a function of load ratio  $R$  in vacuum (Fig. 31). If there is any plasticity-induced closure, it should manifest more readily in a material tested in vacuum, wherein closure contributions from oxidation or corrosion are absent. Figure 31 shows that  $\Delta K_{th}$  is essentially independent of load ratio  $R$ . Since  $K_{max} = \Delta K/(1 - R)$ , which increases nonlinearly with  $R$ , the contribution from plasticity-induced closure should be particularly apparent at large values of  $R$ . The observed independence of  $\Delta K_{th}$  on  $R$  suggests that crack closure due to plasticity is either nonexistent or insignificant (Ref 62).

FIG. 31 APPARENT LACK OF CLOSURE DUE TO INDEPENDENCE OF  $\Delta K_{TH}$  VERSUS LOAD RATIO IN A VACUUM. SOURCE: REF 62

**Oxide-Induced Crack Closure.** The mechanism of oxide-induced crack closure evolved as a consequence of attempts to rationalize apparent anomalies in the effects of environment on near-threshold fatigue crack growth in steels and aluminum alloys, as previously noted. Another classic example of this has been demonstrated by Suresh and Ritchie (Ref

66) for a martensitic  $2\frac{1}{4}$ Cr-1Mo steel in moist laboratory air and in dehumidified, ultra-high-purity hydrogen and helium (138 kPa) at  $R = 0.05$  and  $0.75$ . The near-threshold crack propagation in both the dry gaseous environments are up to two orders of magnitude higher, and the  $\Delta K_{th}$  is about 50% lower, than in air at the lower  $R$  ratio (Ref 66).

The mechanism of this near-threshold behavior can be explained in terms of oxide-induced closure. During the propagation of a fatigue crack, the presence of a moist atmosphere leads to oxidation of the freshly formed fracture surfaces. At low amplitudes of cyclic crack-tip opening displacements (i.e., at near-threshold  $\Delta K$  levels and low  $R$  ratios), the possibility of repeated crack face contact during tensile fatigue is enhanced as a consequence of locally mixed-mode crack opening and closure. In contrast, at high  $R$  ratios, the possibility of crack face contact is minimized because of the larger crack-tip opening displacements. Likewise, at high  $\Delta K$  levels, the rate of crack advance is generally too rapid to allow oxide buildup at any  $R$  value.

**Models of Fatigue Crack Closure.** Fatigue crack closure is not fully understood, but the mechanisms mentioned above have been proposed over the years for various alloys. Other mechanisms that impede constant-amplitude fatigue crack growth are also of interest in composites and nonmetallic materials such as ceramics. These mechanisms include crack deflection, crack bridging or trapping, and crack shielding due to microcracking, phase transformations, or dislocations. These processes are briefly discussed in the article "Fatigue of Brittle Materials" in this Volume.

Predictive modeling of closure mechanisms is a formidable task. Closure is influenced by several variables, such as microstructure,  $\Delta K$  magnitude, crack size, environment, variations in load amplitude,  $R$  ratio, and temperature. However, Eq 1 is a tentative basis for considering plasticity effects, even though closure probably results from a combination of crack-tip plasticity and wedging open of the crack along its wake. Models that consider both crack wake stretch and plastic zone residual stress include that of Newman (Ref 67), strip yield models (Ref 68, 69) and finite element models (Ref 67, 70).

Oxide-induced closure is also a very complicated process that cannot be predicted in all instances. However, Suresh provides a simple analogy for a qualitative estimate of oxide-induced effects on the near-threshold "driving force" ( $K$ ) (Ref 60). Consider a rigid wedge of constant thickness  $d_0$  inside a linear elastic fatigue crack. If the wedge extends all along the length of the fatigue crack and its edge terminates at a distance  $2l$  behind the crack tip, then closure occurs during unloading of a stress-intensity factor of:

$$K_{cl} = \frac{d_0 E}{4\sqrt{\pi l} (1 - \nu^2)}$$

where  $E$  and  $\nu$  are the Young's modulus and the Poisson's ratio of the cracking material, respectively. Taking typical values of  $l = 0.2 \mu\text{m}$  and  $d_0 = 0.2 \mu\text{m}$  from experiments on lower-strength steels, it is found that  $K_{cl} \approx 2.3 \text{ MPa} \sqrt{m}$ . This estimate of the closure  $K$  due to wedge contact, although too simplistic to account for all the effects associated with the complex process of oxide-induced closure, provides a justification for the experimentally observed differences in the  $\Delta K_{th}$  values of  $2\frac{1}{4}$ Cr-1Mo steels in dry and moist environments at low load ratios documented in Ref 66.

**New Concepts for Fatigue Thresholds.** Despite an overwhelming amount of publications on crack closure measurements and its implications, a unanimous view of its significance on crack growth has not been reached based on some critical re-examination of crack closure concepts (Ref 62, 65). This re-examination has led to a two-parameter analysis of fatigue crack growth based on a critical stress-intensity ( $\Delta K_{th}^*$ ) and critical maximum stress intensity ( $K_{max}^*$ ). The two loading driving force parameters have to be satisfied simultaneously for a crack to advance, a concept that is independent of the crack-closure phenomena. Such a description gives an intrinsic description of fatigue that can be related to microstructure, slip modes, and environment. The concepts also suggest, that for a complete fatigue description, it is necessary to get a systematic set of data at various load ratios and crack growth rates. Details of the mechanistic descriptions on the fatigue behavior are given in Ref 62, 65, and 71-73. An overall classification scheme of fatigue crack growth rates is also given in Ref 74 based on this two-parameter method. With the two parameters  $\Delta K_{th}^*$  and  $K_{max}^*$ , the entire fatigue data of  $\Delta K_{th}$  vs  $R$  dependence can be fully explained without invoking closure.

For example, this description is shown in Fig. 32(a) for alloy Ti-6Al-4V. At low  $R$ , fatigue is  $K_{max}$  controlled, meaning that  $\Delta K_{th}$  increases with decreasing  $R$  to meet the  $K_{max}^*$ . Similarly, at high  $R$  values, fatigue is  $\Delta K_{th}$  controlled and  $K_{max}$  then increases to meet the  $\Delta K_{th}^*$ . Both these critical parameters can be determined by plotting  $\Delta K_{th}$  vs  $K_{max}$  (as in Fig.

32b). This plot provides the interrelation between the two driving force parameters defining the regimes where  $\Delta K_{th}^*$  provides the minimum cyclic amplitude required to establish a characteristic fatigue damage, and  $K_{max}^*$  provides the critical stress required to break open the crack-tip bonds in the fatigue damaged region. Figure 32(b) provides a plot showing the interdependence of these two parameters to ensure the conditions necessary for fatigue crack growth. These two critical parameters are dependent on the microstructure, slip mode, and crack tip environment; for example, with an increasing aggressiveness of the crack tip environment (oxygen, hydrogen, water vapor, or NaCl) the role of  $K_{max}^*$  becomes increasingly important than  $\Delta K_{th}^*$ , since the environment affects the crack tip bonds more than the fatigue damage zone ahead of the crack tip. The two parametric description is applicable at all crack growth rates starting from the near threshold region. Details on this topic are given in Ref 71, 72, 73.

## Fatigue Failure in Metals\*

Morris E. Fine and Yip-Wah Chung, R.R. McCormick School of Engineering & Applied Science, Department of Materials Science & Engineering, Northwestern University

---

## Introduction

FATIGUE is the progressive, localized, and permanent structural change that occurs in a material subjected to repeated or fluctuating strains at nominal stresses that have maximum values less than (and often much less than) the static yield strength of the material. Fatigue may culminate into cracks and cause fracture after a sufficient number of fluctuations. Fatigue damage is caused by the simultaneous action of cyclic stress, tensile stress, and plastic strain. If any one of these three is not present, a fatigue crack will not initiate and propagate. The plastic strain resulting from cyclic stress initiates the crack; the tensile stress promotes crack growth (propagation). Although compressive stresses will not cause fatigue, compressive loads may result in local tensile stresses. Microscopic plastic strains also can be present at low levels of stress where the strain might otherwise appear to be totally elastic.

During fatigue failure in a metal free of cracklike flaws, microcracks form, coalesce, or grow to macrocracks that propagate until the fracture toughness of the material is exceeded and final fracture occurs. Under usual loading conditions, fatigue cracks initiate near or at singularities that lie on or just below the surface, such as scratches, sharp changes in cross section, pits, inclusions, or embrittled grain boundaries.

Microcracks may be initially present due to welding, heat treatment, or mechanical forming. Even in a flaw-free metal with a highly polished surface and no stress concentrators, a fatigue crack may form. If the alternating stress amplitude is high enough, plastic deformation (i.e., long-range dislocation motion) takes place, leading to slip steps on the surface. Continued cycling leads to the initiation of one or more fatigue cracks. Alternately, the dislocations may pile up against an obstacle, such as an inclusion or grain boundary, and form a slip band, a cracked particle, decohesion between particle and matrix, or decohesion along the grain boundary.

The initial cracks are very small. Their size is not known well because it is difficult to determine when a slip band or other deformation feature becomes a crack. Certainly, however, cracks as small as a fraction of a micron can be observed using modern metallographic tools such as the scanning electron microscope or scanning tunneling microscope. The microcracks then grow or link up to form one or more macrocracks, which in turn grow until the fracture toughness is exceeded.

The fatigue failure process thus can be divided into five stages:

1. CYCLIC PLASTIC DEFORMATION PRIOR TO FATIGUE CRACK INITIATION
2. INITIATION OF ONE OR MORE MICROCRACKS

3. PROPAGATION OR COALESCENCE OF MICROCRACKS TO FORM ONE OR MORE MICROCRACKS
4. PROPAGATION OF ONE OR MORE MACROCRACKS
5. FINAL FAILURE

These stages in the process of fatigue failure are complicated and are influenced by many factors. This introductory article summarizes some fundamental aspects of the first four stages, prior to the fifth stage of final failure. Further coverage on both crack initiation and crack propagation is given in more detail in subsequent articles in this Volume. In particular, other articles in this section provide detailed information on the fundamental and applied aspects of fatigue crack propagation. Nonetheless, this article briefly considers crack propagation with particular emphasis on the measurement and relation of plastic work with fatigue crack propagation. This article refers primarily to ambient air or an inert environment.

The variability in fatigue behavior in similar specimens or parts is well known. This is true for cycles to failure, cycles to crack initiation, microcrack propagation rate, and macrocrack propagation rate. A fatigue database should include this variability, as well as a clear description of the specimen or part geometry, surface finish, microstructure, and stress state. The design engineer needs to know about such variability in order to predict probability of failure for a given design. Often reported data do not contain sufficient information about variations in fatigue properties to be useful in a database used for design engineers. Also  $S-N_f$  or  $\epsilon_p-N_f$  curves of smooth (unnotched) specimens are often presented. Macrofatigue crack propagation rates are also presented as smoothed curves based on averaged data points; even when data points are plotted, they represent a trailing average of three to seven points. A fatigue crack does not propagate at a uniformly increasing rate, but frequently slows down or speeds up due to local conditions along the crack front. Real-world spectrum loading further complicates matters.

As the resolution of inspection instruments has increased, the portion of the fatigue lifetime ascribed to fatigue crack "initiation" has decreased. For practical purposes, it is useful to define the "initiation stage" as that portion of the fatigue lifetime before a crack is detectable by usual nondestructive evaluation techniques. This is typically  $\frac{1}{2}$  to 1 mm. Initiation of such an "engineering" crack represents the preponderance of the fatigue lifetime, except in the regime of very low cycles to failure. After formation of such an engineering crack, the remaining fatigue lifetime is usually relatively short. Thus, the design engineer can design with more precision, utilizing cycles to formation of a small crack combined with crack propagation to failure, than with cycles to failure alone or with propagation rates of macrofatigue cracks alone. More data that include statistical variations on formation of small cracks in a form useful to the design engineer are needed.

## Cyclic Deformation Prior to Fatigue Crack Initiation

As previously mentioned, even if no stress risers, notches, or inclusions are present, small microcracks may initiate due to a sufficiently high alternating plastic strain amplitude. When a dislocation emerges at the surface, a slip step of one Burgers vector is created. During perfect reversed loading on the same slip plane, this step is canceled; however, slip occurs on many planes, and the reversal is never perfect. Accumulation of slip steps in a local region leads to severe roughening of the surface. Thus, resistance to fatigue failure is greater for alloys that are not subject to severe localization of plastic strain.

Sometimes features called extrusions and intrusions clearly form on the surface. A simple mechanism, described by Cottrell and Hull (Ref 1), for forming an intrusion-extrusion pair is illustrated in Fig. 1. Sequential slip on two intersecting slip planes is imagined to occur. In the first half-cycle, first one slip system and then the other is imagined to operate, producing indentation (Fig. 1c). Alternately, a protrusion would form if the dislocations have Burgers vectors of opposite sign. During the second half-cycle, the first slip system and then the second is imagined to operate again, giving rise to an intrusion and extrusion pair (Fig. 1e).

**FIG. 1 COTTRELL-HULL MODEL FOR FORMATION OF INTRUSIONS AND EXTRUSIONS. OPERATION OF TWO INTERSECTING SLIP SYSTEMS IS ASSUMED TO OCCUR IN THE SEQUENCE SHOWN.**

It is not believed that intrusions and extrusions form exactly by the Cottrell-Hull mechanism, but this mechanism serves to illustrate the type of process that must be operative. Laird and Duquette (Ref 2) pointed out that intrusion-extrusion pairs have been observed when there is only one operative slip system, and it is not clear whether intrusions and extrusions are always paired (Ref 3). Neumann (Ref 4) postulated that an intrusion or extrusion may form by a dislocation avalanche along parallel neighboring slip planes containing dislocation pileups of opposite sign.

The term "persistent slip band" was introduced by Thompson et al. (Ref 5). They examined polished surfaces of copper and nickel after various amounts of cyclic deformation and observed many slip bands. Although most were removed easily by electropolishing, some required extensive electropolishing for removal; when the samples were retested, slip bands formed again in these places. The authors called such slip bands "persistent." Persistent slip bands in copper have a ladderlike dislocation structure (Ref 3, 6, 7). Ungrouped veins or braids of dislocations occur in the surrounding matrix. The ladderlike structure has a lower flow stress than the surrounding matrix, so very extensive plastic deformation occurs in the persistent slip bands. Lukas and Klesnil (Ref 8) considered that stacking-fault energy and the attendant ease of cross-slip would play a role in formation of the ladderlike structure, and they thus studied 15 and 31% Zn brasses. The stacking-fault energy is progressively reduced and ease of cross-slip is progressively decreased as zinc is added to copper. The ladderlike structure was found in 15% Zn brass but not in 31% Zn brass. Kuhlmann-Wilsdorf and Laird (Ref 9) have presented an extensive discussion of dislocation models for forming persistent slip bands and attendant surface roughness. Their results are shown in Fig. 2. The persistent slip band protruded slightly from the surface by 0.3  $\mu\text{m}$ , but there were sharp hills and valleys of up to 5  $\mu\text{m}$  in the band.

**FIG. 2 APPROXIMATE PROFILE OF SURFACE AT A PERSISTENT SLIP BAND IN COPPER DETERMINED FROM AN INTERFEROGRAM. THE COPPER SINGLE CRYSTAL WAS CYCLED OVER THE PLASTIC STRAIN RANGE 0.0025 FOR 30,000 CYCLES. SOURCE: REF 7**

In polycrystalline specimens of copper, the ladderlike structure and the persistent slip bands are thought to form only near the surface (except in gears and railroad rails, where compressive contact stress dominates). Although the ladderlike structure does not form in all metals, even in 31% Zn brass coarse surface relief is formed from an aggregation of fine slip lines (Ref 8).

The term "persistent slip band" has probably been used somewhat loosely to mean any coarse slip band. Nevertheless, plastic deformation in slip bands produces regions of intense surface roughness, and this is quite general for all metals. Coarse slip bands or plastic strain localization occurs more readily as a result of cyclic deformation than during monotonic deformation. Localized regions of surface roughness occur because certain regions are softer or have become softer than others. For example, the soft regions may be less work hardened, or work softening may have occurred, as from unpinning of dislocations in iron.

During cyclic plastic deformation, cyclic hardening or cyclic softening may occur. Much has been written on this subject (Ref 10, 11). Annealed single-phase alloys usually cyclically harden, while cold-worked alloys cyclically soften. Alloys with coherent precipitates, such as  $\gamma'$  ( $\text{Ni}_3\text{Al}$ )-type precipitates in nickel-base alloys, show intense cyclic hardening (Fig. 3) (Ref 12). In binary aluminum-copper containing Guinier-Preston zones, intense hardening is followed by softening (Ref 13). Introducing a dispersed second phase to distribute the plastic deformation more uniformly eliminates the softening (Fig. 4) (Ref 14). Commercial aluminum-base alloys contain dispersoids for grain refinement, but these dispersoids also act to eliminate cyclic softening.

**FIG. 3 MAXIMUM COMPRESSIVE STRESS,  $\Delta\epsilon/2$ , VERSUS CYCLES AT A CONSTANT STRAIN AMPLITUDE OF  $\Delta\epsilon/2$**

= 0.75% FOR OVERAGED NI-14AL (AT.%). SOURCE: REF 12

**Fig. 4** Stress amplitude,  $\Delta\sigma/2$ , versus reversals,  $2n$ , at constant strain amplitude,  $\Delta\varepsilon/2$ , in binary aluminum-base copper alloys and in 2024 aluminum alloy aged at room temperature. The Al-3.6Cu alloy shows cyclic softening at large  $n$ . This is reduced in the Al-6.3Cu alloy at low strain amplitude. This alloy has 5 to 10  $\mu\text{m}$   $\theta$  dispersoids to reduce strain localization. In alloy 2024, which has manganese to form  $\text{MnAl}_6$  dispersoid particles approximately 0.5  $\mu\text{m}$  in diameter, the cyclic softening is absent. The precipitous drop in  $\Delta\sigma/2$  is due to cracking. Source: ref 14

The cyclic behavior of quenched-and-tempered steels is particularly interesting. As-quenched steels cyclically harden, whereas quenched-and-tempered steels soften by as much as 40% (Ref 15). Monotonic and cyclic stress-strain curves for 4140 steel quenched and then tempered at 400 °C (750 °F) are shown in Fig. 5 (Ref 15); a large amount of softening is evident. This softening is due largely to a change in dislocation structure with cycling (Ref 15). Even though the steel has been tempered at 400 °C (750 °F), many dislocations remain from the martensite transformation. Cyclic straining reduces the dislocation density, and the remaining dislocations form cell walls. Figure 6 shows a comparison of the structure before and after tempering. Coherent precipitates result in cyclic hardening; therefore, addition of precipitates such as Ni<sub>3</sub>Al to quenched-and-tempered steels counteracts cyclic softening (Fig. 7) (Ref 16).

**FIG. 5 MONOTONIC AND CYCLIC STRESS-STRAIN CURVES FOR 4140 STEEL TEMPERED AT 400 °C (750 °F). LARGE CYCLIC SOFTENING IS OBSERVED. THE CYCLIC STRESS-STRAIN CURVE WAS OBTAINED BY THE INCREMENTAL STRAIN TECHNIQUE. SOURCE: REF 15**

**FIG. 6 TRANSMISSION ELECTRON MICROSCOPY STRUCTURES OF 4140 STEEL TEMPERED AT 400 °C (750 °F) BEFORE (A) AND AFTER (B) CYCLING AT  $\Delta\epsilon/2 = 2.5\%$ . THERE HAS BEEN A LARGE REDUCTION IN DISLOCATION DENSITY. SOURCE: REF 15**

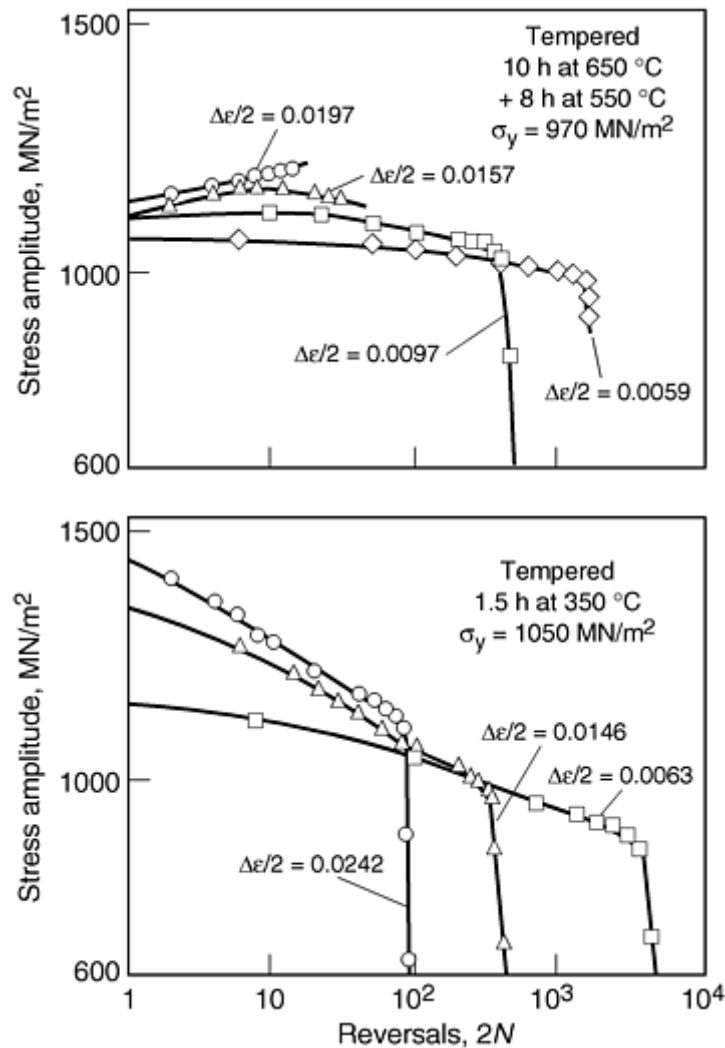

FIG. 7 STRESS AMPLITUDE,  $\Delta\sigma/2$ , IN FE-0.3C-4NI-1AL-1CU STEEL VERSUS REVERSALS,  $2N$ , FOR VARIOUS STRAIN AMPLITUDES,  $\Delta\epsilon/2$ . DATA FOR TWO TREATMENTS ARE SHOWN. AFTER TEMPERING 1.5 H AT 350 °C (660 °F), ONLY  $\text{Fe}_3\text{C}$  IS PRESENT AND MUCH CYCLIC SOFTENING IS OBSERVED. WHEN TEMPERED 10 H AT 650 °C (1200 °F) PLUS 8 H AT 550 °C (1020 °F), COHERENT NiAl AND COPPER PRECIPITATES ARE PRESENT. THERE IS VERY LITTLE CYCLIC SOFTENING FOR THIS TREATMENT. THE CYCLES TO FATIGUE CRACK INITIATION IN A NOTCHED SPECIMEN WERE MORE THAN TEN TIMES GREATER FOR THE LATTER TREATMENT AT A NOMINAL STRESS AMPLITUDE OF 196 MN/M<sup>2</sup>. SOURCE: REF 16

### Initiation of Microcracks

Initiation of fatigue cracks has been observed to occur along slip bands, in grain boundaries, in second-phase particles, and in inclusion or second-phase interfaces with the matrix phase. The mode of fatigue crack initiation depends on which occurs most easily. If weak, brittle precipitates are present, then they will probably play a dominant role. Slip is discontinuous across grain boundaries, and many slip systems must be active to keep the grains from pulling apart. Therefore, grain boundaries are particularly susceptible to fatigue crack initiation.

In the authors' opinion, the sequence of events and modes of initiation of fatigue cracks occur as follows. During cyclic plastic deformation, dislocations either emerge at the surface of the metal or pile up against obstacles. If the dislocations continuously emerge at the surface rather than pile-up against obstacles, then slip bands that eventually become cracks appear in the central portions of the grains, where the flow stress is lower. As expected, resistance to slip-band initiation in the central portion of a grain decreases with increasing grain size, following the Hall-Petch relation. A slip-band crack in the central portion of a grain in 2124 aluminum alloy aged at room temperature is shown in Fig. 8 (Ref 17).

**FIG. 8 SLIP-BAND CRACK IN CENTRAL PORTION OF GRAIN IN 2124-T4 ALUMINUM ALLOY. THIS OCCURRED AFTER 240 CYCLES AT A NOMINAL STRESS OF 87 MN/M<sup>2</sup> IN A POLISHED NOTCH WITH AN ELASTIC STRESS-CONCENTRATION FACTOR OF 4.4. THE STRESS-CONCENTRATION FACTOR, TAKING PLASTICITY INTO CONSIDERATION, WAS 2.6. SOURCE: REF 17**

Many types of obstacles can cause dislocation pile-ups during cycling, including grain boundaries, inclusions, oxide films, and domain boundaries. Dislocation pile-ups result in an increase in elastic strain energy. When the strain energy density exceeds twice the surface free energy, a condition of instability occurs that energetically favors the initiation of microcracks. This can lead to a slip-band crack in the matrix, decohesion along a grain boundary, or cracking of a second-phase particle that may lie in the matrix or grain boundary. If the grain-boundary regions in a precipitation-hardened alloy are free of precipitates (i.e., precipitate-free zones), then plastic flow at low plastic strains may be concentrated in these regions and initiate fatigue cracks. Even if an isolated second-phase particle cracks, it must spread into the matrix for initiation of a fatigue crack to occur. Thus, not all cracked inclusions initiate fatigue cracks. All of these types of cracks have been observed.

Figure 9 depicts how paired dislocation pile-ups might give rise to an intrusion or extrusion by an avalanche (Ref 18). Here an oxide on the surface is imagined to be the obstacle, but other obstacles would have similar effects. A slip band that is thought to be cracked and that may have formed in this way in a high-strength, low-alloy (HSLA) steel is shown in Fig. 10 (Ref 19). A slip-band crack emanating from an inclusion is shown in Fig. 11 (Ref 17). It appeared very suddenly.

**FIG. 9 PAIRED DISLOCATION PILE-UPS (FROM SOURCES NOT SHOWN) AGAINST OBSTACLE ON METAL SURFACE ARE IMAGINED TO GROW WITH CYCLIC STRAINING UNTIL THEY REACH A CRITICAL SIZE. AN AVALANCHE THEN OCCURS, PRODUCING AN INTRUSION OR EXTRUSION, DEPENDING ON THE DISLOCATION SIGN. SOURCE: REF 18**

**FIG. 11** SLIP-BAND CRACK IN POLISHED NOTCH EMANATING FROM AL<sub>7</sub>Cu<sub>2</sub>Fe INCLUSION IN 2024-T4 ALUMINUM ALLOY AFTER 12,000 CYCLES. CRACK APPEARED SUDDENLY. OTHER CRACKS ARE ALSO VISIBLE. NOMINAL STRESS WAS 84 MN/M<sup>2</sup>. SEE FIG. 8 FOR STRESS-CONCENTRATION FACTOR. SOURCE: REF 17

The mode by which inclusions aid in fatigue crack initiation, as already stated, may be for the inclusion to crack first and then extend into the matrix. As shown by Morris (Ref 20), this is the case for 2219-T851 aluminum alloy. Chang et al. (Ref 21) modeled this process. Particle size determines whether cracking of the particle from a dislocation pile-up or advance of the fatigue crack into the matrix is rate controlling. Advance of the fatigue crack into the matrix was predicted to be rate controlling for large particles.

Eid and Thomason (Ref 22) showed that in a quenched-and-tempered medium-carbon molybdenum alloy steel containing Al<sub>2</sub>O<sub>3</sub> inclusions up to 25 μm in diameter, there was debonding between the particles and the matrix as well as cracking of the particles, both initiating fatigue cracks. Their stress field analysis pointed out the importance of the ratio of Young's modulus in the particle to that of the matrix. A ratio greater than 1:1, which is the case for Al<sub>2</sub>O<sub>3</sub> in iron, results in large tensile stress concentrations at the polar points of the particles. Neither MnS inclusions nor Fe<sub>3</sub>C particles, whose moduli are smaller than that of iron, were sources of fatigue cracks in the same alloy. In a high-strength aluminum alloy prepared by hot working of pressed powder compacts, Al<sub>2</sub>O<sub>3</sub> particles, which have approximately ten times the modulus of the matrix, may be the origin of fatigue crack initiation in grain boundaries (Ref 23).

Inclusion size also plays a role, at least in 2024-T4 aluminum alloy. Kung and Fine (Ref 17) determined that the probability for an Al<sub>2</sub>CuMg or Al<sub>7</sub>Cu<sub>2</sub>Fe constituent particle to initiate a slip-band crack decreases rapidly as its size decreases below 7 μm.

Whether cyclic hardening or softening occurs probably has only a minor effect on the fatigue limit, because the plastic strain amplitude corresponding to the fatigue limit is quite small. The severity of the surface disturbance or the size of the dislocation pile-up produced by cyclic loading depends on the plastic strain amplitude in the localized region where the fatigue cracks form, which in turn depends on the yield stress. It is well known that the fatigue limit is not a definite fraction of the yield stress for all metals and alloys. Two additional factors are important: the degree of strain localization and the critical localized plastic strain to initiate the crack.

The plastic strain amplitude over the gage length, the quantity usually measured in a monotonic or cyclic stress-strain curve, may be made up taking the two extremes of a small number of severe local plastic strains or a large number of small plastic strains. The latter case is much better for fatigue resistance, which benefits from any reduction in strain localization. The chromium present in commercial 7075 aluminum alloy forms Cr<sub>2</sub>Mg<sub>3</sub>Al<sub>18</sub> dispersed particles approximately 0.5 μm in size. Hornbogen and Lütjering (Ref 24) showed that these dispersoid particles inhibit the formation of coarse slip bands and improve the fatigue limit by approximately one-third. A similar result was obtained in 2024-type alloys (Ref 25). The precipitate-free zones near grain boundaries, often present in precipitation-hardened alloys aged at elevated temperatures, are also regions of strain localization. Thermomechanical processing that produces jagged grain boundaries improves fatigue resistance (Ref 26).

The local critical plastic strain to initiate a crack is related to notch sensitivity. If a material is highly notch sensitive, then only a small surface intrusion or extrusion is needed to initiate fatigue cracking. Notch sensitivity is often considered to increase with yield strength, but this is not a general rule. Other factors are also related to notch sensitivity. For example,

removal of large iron- and silicon-containing inclusions in aluminum alloys improves the fatigue limit (Ref 27). It is also well known that removal of inclusions in steels improves the fatigue limit. The local plastic strain necessary for crack initiation has been little studied. This would appear to be a very worthwhile field for research, both to develop fatigue-resistant alloys and to help theoreticians model fatigue crack initiation.

Recently, Mura et al. (Ref 28, 29) adopted a free-energy approach to derive basic equations governing initiation of microcracks. They modeled the fatigue deformation process as one of injecting dislocations along slip bands impinging onto certain obstacles. The buildup of local plastic strain and hence strain energy eventually leads to energy instability that results in the initiation of microcracks. Mura et al. showed that the fatigue limit is directly proportional to the friction stress and that environmental sensitivity is related to the degree of slip reversibility.

## Propagation and Coalescence of Microcracks

A fatigue crack must be a certain length before it can be observed; thus, some microcrack growth has always occurred before the measured cycles to "initiation" reported in the literature. The values will depend on the resolving power of the measuring instrument used. Mura et al. (Ref 28, 29) showed that the size of just-initiated cracks is on the order of 0.1  $\mu\text{m}$  or less. Therefore, in order to track the evolution of microcracks from initiation, one must use instruments with resolution better than 0.1  $\mu\text{m}$ . Recently, scanning tunneling microscopy has been used successfully to track the initiation of microcracks during fatigue deformation of silver single crystals (Ref 30). In order to minimize tip artifacts, the tip must be sharp with a small opening angle. Also, imaging conditions must be chosen to minimize tip-induced surface damage. Atomic force microscopy can also be used, with the same precautions.

As a consequence of stress or plastic strain cycling above the fatigue limit, the initial microcracks grow or coalesce until a macrocrack may be reasonably defined as larger than a number of grain cross sections in an area, with smaller cracks being defined as microcracks. In single crystals, a 500  $\mu\text{m}$  crack diameter may be a reasonable dividing line.

It is not certain to what extent microcracks form in materials cycled below the fatigue limit and then stop growing. This is another subject that requires study. Microcracks that have formed may not grow further for a number of reasons. For example, a fatigue crack may initiate within an inclusion, but could be stopped by the interface because, as suggested by Chang et al. (Ref 21), the stress required to extend the crack into the matrix is larger than that required to initiate the crack in the inclusion. Fatigue cracks that are isolated in inclusions are often observed, for example, in  $\text{Al}_7\text{Cu}_2\text{Fe}$  inclusions in aluminum alloys (Ref 17). In two-phase alloys or composites, microcracks may form in a noncontinuous phase but be unable to propagate into the continuous phase. The stress-concentration factor falls off with distance from a notch, hole, scratch, pit, or other flaw. Thus, a crack that forms near or at flaws may stop growing at a nominal stress amplitude just below the fatigue limit. It is now well known that microcrack growth is impeded by grain boundaries (Ref 17, 31).

Based on reviews beginning with Ewing and Humfrey (Ref 32), as well as research at Northwestern University, the number of microcracks that form during fatigue depends on stress or plastic strain amplitude. At high amplitudes, many cracks form, and coalescence across grain boundaries is the dominant mode of microcrack growth. At low stresses, growth of individual microcracks is more important. At the endurance limit, the macrocrack is expected to form most often from a single source. The basic mechanism for micro- or macrofatigue crack propagation in metals is by plastic deformation, except perhaps when there is very extreme grain-boundary embrittlement. A small crack often propagates initially along a crystallographic plane (Forsythe's stage I) (Ref 33). The resistance to microcrack propagation offered by grain boundaries arises because plastic deformation is discontinuous across grain boundaries. In a precipitation-hardened high-strength aluminum alloy made by forging or extruding a pressure-sintered powdered compact, the cracks initiate in the grain boundary, but the propagation mode quickly changes to transgranular (Ref 23).

A significant fraction of the fatigue lifetime is taken up by propagation of microfatigue cracks. Building microcrack stoppers into the microstructure is feasible and should be investigated more fully.

## Growth of Macrocracks

Once a macrocrack a few millimeters or more in length has formed, the stress-intensity range,  $\Delta K$ , of linear fracture mechanics becomes the rate-controlling parameter under the condition that only small-scale yielding occurs at the tip of

the crack. Here  $\Delta K$  is  $\Delta\sigma\sqrt{af(g)}$ , where  $\Delta\sigma$  is  $\sigma_{\max} - \sigma_{\min}$ , the maximum nominal stress minus the minimum nominal stress;  $a$  is the crack length; and  $f(g)$  is a function of specimen geometry, loading conditions, and the ratio of crack length to specimen width,  $a/w$ . Formulas for  $f(g)$  have been derived for a wide variety of conditions and are tabulated in a number of texts.

Fatigue crack propagation rates are typically plotted as log-log graphs of  $da/dN$  versus  $\Delta K$  (Fig. 12). Fatigue crack growth behavior is characterized by three regimes (Fig. 12), which may include the region where the scale of yielding at the crack tip is no longer necessarily small. Full discussion of crack growth behavior and analysis is provided elsewhere in this Volume. However, brief descriptions of the three regimes are provided below:

- REGION I: THRESHOLD AND NEAR-THRESHOLD REGION WHERE  $DA/DN$  DECREASES RAPIDLY WITH DECREASE IN  $\Delta K$  TO A THRESHOLD VALUE ( $\Delta K_0$  OR  $\Delta K_{TH}$ )
- REGION II: MIDREGION WHERE THE PARIS RELATION (REF 34) HOLDS:

$$DA/DN = C (\Delta K)^N \text{ WHERE } C \text{ AND } N \text{ ARE CONSTANTS} \quad (\text{EQ 1})$$

- REGION III: HIGH-RATE REGION WHERE THE MAXIMUM STRESS INTENSITY,  $K_{MAX}$ , APPROACHES THE CRITICAL STRESS INTENSITY FOR STATIC FAILURE,  $K_C$

FIG. 12 SCHEMATIC PLOT OF FATIGUE CRACK PROPAGATION RATE,  $DA/DN$ , VERSUS STRESS-INTENSITY RANGE,  $\Delta K$ , ON A LOG-LOG SCALE. SEE TEXT FOR DISCUSSION OF REGIONS I TO III.

Region III will not be discussed. By the time region III has been reached, the fatigue crack is moving so rapidly that for practical purposes a failure has already occurred.

These three regions are modeled mathematically by the McEvily-Forman empirical equation (Ref 35):

$$da/dN = C' \left( \Delta K^2 - \Delta K_0^2 \right) \frac{(1 + \Delta K)}{(K_c - K_{\max})} \quad (\text{EQ 2})$$

In this equation, the exponent 2 replaces  $n$  in the Paris relation. As shall be discussed later, while an  $n$  of 2 is observed in some materials, a value closer to 4 is more common (Ref 36). Equation 2 should be modified to allow for a variable exponent on  $\Delta K$ .

**Threshold and Near-Threshold Growth of Macrocracks.** Considering region I first, macrocracks will not grow at all values of  $\Delta K$ ; a threshold stress-intensity range,  $\Delta K_0$ , is thought to exist below which the crack does not propagate. The rate  $da/dN$  increases rapidly as  $\Delta K$  increases from  $\Delta K_0$ , merging into the Paris relation region. The values of  $\Delta K_0$  and the near-threshold behavior established for cracks a few millimeters or more in length do not hold for shorter cracks. They may propagate at  $\Delta K$  values smaller than  $\Delta K_0$ .

Crack closure is another factor that influences near-threshold behavior. The concept of crack closure was first put forth by Elber (Ref 37). When  $\Delta K$  is relatively large, plastic stretching of the material at the crack tip imposes a compressive stress on the reverse loading, causing the crack to close prior to the tensile stress becoming zero. Elber defined an effective stress-intensity range,  $\Delta K_{\text{eff}} = \Delta K - \Delta K_{\text{closure}}$ . Near-threshold plastic stretching is not thought to be important, because the maximum stress intensity is small; however, there are other sources of crack closure, such as oxide bridging of the crack and mixed shear-tensile mode (Ref 38). If the crack propagates partly in a shear mode and partly in a tensile mode, the crack surface is rough and the rough surfaces on each side of the crack face become displaced to each other as the crack propagates. Therefore, the surfaces in the wake touch before the minimum or zero stress is reached. This has been quantitatively related to  $\Delta K_{\text{closure}}$  (Ref 39, 40). Also, the increase in  $\Delta K_0$  with grain size has been shown to be almost completely due to closure effects; the variation of  $\Delta K_{0,\text{eff}}$  is either very small or nonexistent (Ref 41). Further, the crack closure stress depends on specimen geometry being larger for a side notch specimen than for a center notch specimen, due to the larger bending moment at the crack tip in the former (Ref 42). The bending moment is even larger for a compact tension specimen.

Short cracks (i.e., less than 1 to 2 mm long) are commonly observed to propagate differently than long cracks. This is at least partly due to crack closure increasing with crack length. For 100 to 1000  $\mu\text{m}$  cracks in VAN 80 steel loaded above  $\Delta K_0$ , a large variation from long crack data was observed. However, when  $da/dN$  was plotted versus  $\Delta K_{\text{eff}}$  in the 3 to 10  $\text{MPa}\sqrt{\text{m}}$  range, the data for many specimens fell into a small scatterband with the long crack data (Ref 43).

Short cracks are also observed to propagate at  $\Delta K$  values below  $\Delta K_0$ . Of course, when the cracks are in the microcrack range, the  $\Delta K$  values at a given stress range are very small, yet microcracks grow sporadically, as already discussed. Thus, fracture-mechanics-based estimates are not valid. From an engineering point of view, the fatigue process can be divided into an "initiation" stage, which continues to first detection of a crack by nondestructive inspection, and a crack propagation stage. The practical detectable crack size limit is usually about 1 mm, and this takes up most of the lifetime. Therefore, the traditional  $S-N_f$  curve or the newer  $\Delta\epsilon_p$  versus  $N_f$  curve is still often the most practical design basis, provided that the statistics of the variation in  $N_f$  (the cycles to failure) as a function of  $S$  (the applied stress range) are known. Corrections for mean stress effects are, of course, routinely made.

**Paris Relation Region of Fatigue Crack Propagation Rate.** Many theoretical studies have resulted in equations of the form of the Paris relation (Eq 1). Based on the concept that plastic work must be provided to advance the crack, the following can be derived (Ref 44):

$$\frac{da}{dN} = A \frac{(\Delta K)^n}{\mu \sigma_y^2 U} \quad (\text{EQ 3})$$

where  $A$  and  $n$  are dimensionless constants,  $\mu$  is the shear modulus,  $\sigma$  is an appropriate yield stress, and  $U$  is the plastic work required to advance the crack by a unit area.

The Weertman (Ref 45) general theory predicts  $n$  values of 2 or 4 as two limiting approximations. For  $n < 4$ ,  $U$  was predicted to be a function of  $\Delta K$  such that:

$$U = \beta(\Delta K)^{4-N} \quad (\text{EQ 4})$$

where  $\beta$  is the proportionality constant. When  $n$  is 4,  $U$  is independent of  $\Delta K$ , but when  $n$  is 2,  $U$  is proportional to  $\Delta K^2$ .

Experimentally determined values of  $n$  range from 2 to 8. Fatigue crack propagation rate data compiled by Frost et al. (Ref 46) for 14 alloys gave an average value of  $n$  of 3.94 with a standard deviation of  $\pm 0.86$ . For eight alloys (four aluminum alloys, three steels, and one nickel alloy), Izumi et al. (Ref 36, 47) observed  $n = 3.7 \pm 0.5$ . There are alloys, however, where  $n$  is close to 2 (Ref 35) that were not included in these compilations. Values of  $n$  greater than 4 may be due to inclusion of a portion of regions I or III in the data range analyzed.

In order to test Eq 3, Ikeda et al. (Ref 47) devised a method for measuring  $U$ . Foil strain gages, 200 by 210  $\mu\text{m}$ , were strategically cemented ahead of the fatigue crack. Holding  $\Delta K$  constant by reducing  $\Delta\sigma$  as the crack lengthened, the nominal stress/local strain curves were measured in these gages as the fatigue crack approached. Figure 13 shows typical results, where  $X$  is defined as the distance from the center of the gage to the crack tip along the crack plane and  $Y$  is defined as the distance from the center of the gage to the crack plane. A series of nominal stress/local strain curves of decreasing  $X$  for two different  $Y$  values are shown. The initial curves A and G do not close; however, the subsequent curves close to a first approximation, forming loops. The nonclosure represents permanent strain, which is negligibly small after the first cycle. The curves have been arbitrarily shifted to the right on the strain axis to set them apart. When the gages are far from the crack tip, the hysteresis loop width is too small to be shown on the scale of the figure (curves B and H). Curve D shows slight hysteresis, which increases with decrease of  $X$  (loops E, F, I, and J). When the crack enters the gage, it is broken. When  $Y$  is large, the crack bypasses the gage (e.g., loop K).

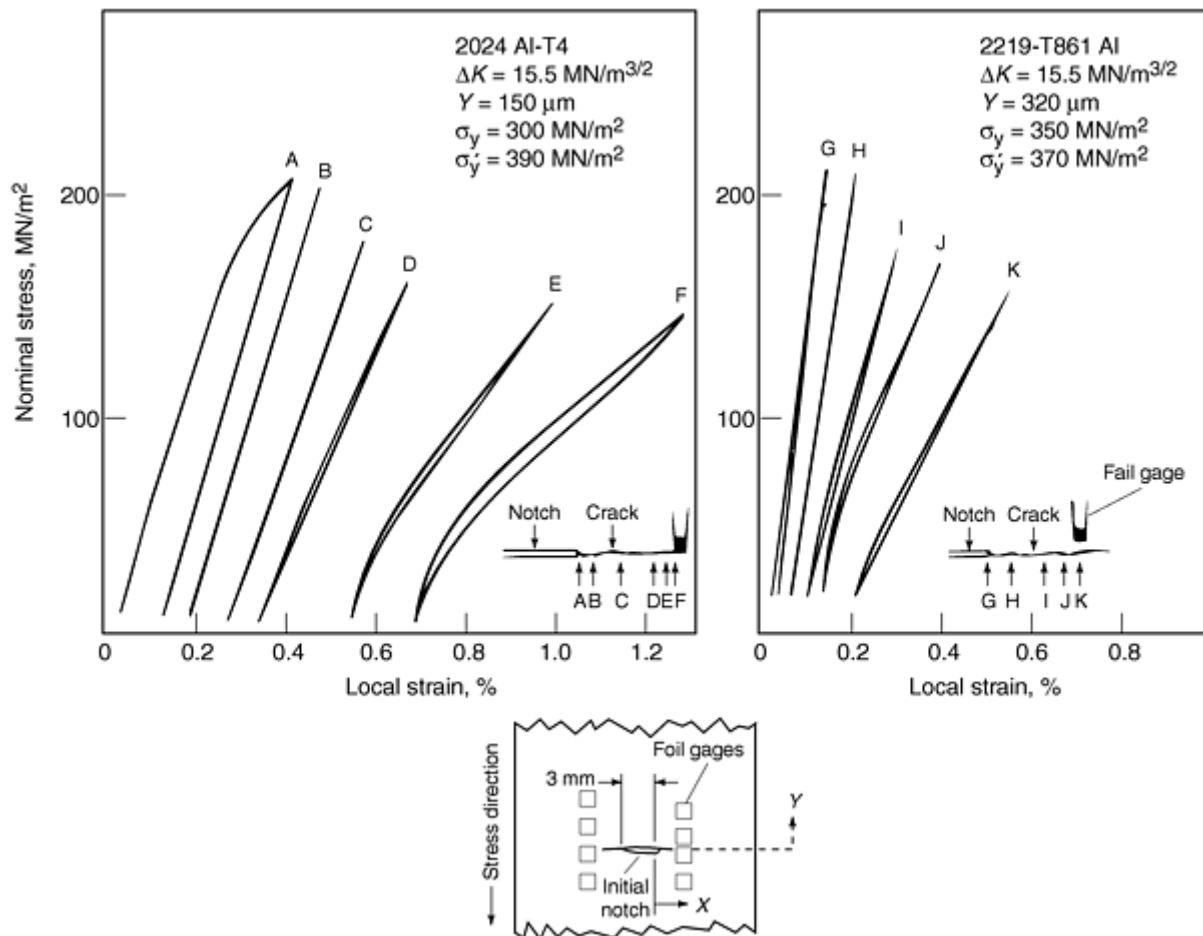

FIG. 13 TYPICAL NOMINAL STRESS/LOCAL STRAIN CURVES VERSUS DISTANCES FROM CRACK TIP DETERMINED USING 200  $\mu\text{m}$  FOIL STRAIN GAGES. THE DISTANCES A-F AND G-K ARE APPROXIMATELY 2 MM. CENTER NOTCH IS 3 MM LONG AND 0.2 MM WIDE.  $R$  WAS 0.05. SOURCE: REF 36

For determination of  $U$ , local stress rather than nominal stress is needed. This was determined from the stress-strain hysteresis loops for unnotched specimens using the strain amplitudes determined with the foil strain gages.

The plastic work  $U$  is made up of two parts, hysteretic  $U_h$  and permanent  $U_p$ . The latter was measured in several alloys and found to be less than 1% of  $U$ . Since the major part of  $U$  is hysteretic, the areas of the loops are of primary interest.

From the local stress/local strain hysteresis loops, the local plastic work per unit area of crack advance for the coordinates in the plastic zones  $X$  and  $Y$ ,  $U_{XY}$ , was determined:

$$U_{XY} = \frac{\int_{\epsilon_1}^{\epsilon_2} \sigma_u d\epsilon - \int_{\epsilon_1}^{\epsilon_2} \sigma_l d\epsilon}{da/dN} \quad (\text{EQ 5})$$

where  $\sigma_u$  and  $\sigma_l$  refer to local stresses in the upper and lower curves, respectively, of the hysteresis loop. The experiment is done at constant  $\Delta K$ , so according to fracture mechanics a constant plastic zone advances with the crack. Thus, a contour map of  $U_{XY}$  in the plastic zone can be drawn, as shown in Fig. 14 for HY 80 and HY 130 pressure vessel steels (Ref 48). The plastic zones are butterfly-wing shaped, in keeping with the maximum shear stress being  $45^\circ$  from the loading direction and the crack plane. The plastic zone size increases with decreasing yield stress. The plastic work was obtained by integrating over the plastic zone:

$$U = \iint U_{XY} dX dY \quad (\text{EQ 6})$$

In order to obtain  $U_{XY}$  closer than  $100 \mu\text{m}$  to the crack tip (Ref 49),  $U_{XY}$  for a constant small  $Y$  was extrapolated to small  $X$  on a log-log scale and, following the solution proposed by Rice (Ref 50) for a mode III crack (the present case is mode I, i.e., tensile stress normal to crack face), the contour lines were assumed to be circles touching the crack tip and symmetrical to the crack tip. Using this method of extrapolation,  $U$  is finite because  $X$  approaches zero faster than  $U_{XY}$  approaches infinity. The contribution to  $U$  from closer than  $1 \mu\text{m}$  to the crack tip is negligible.

FIG. 14 CONTOUR MAPS OF PLASTIC ZONES AT  $\Delta K$  OF  $20 \text{ MPa}\sqrt{m}$  IN PRESSURE VESSEL STEELS HY 80 (0.16% C, 3% NI, 1.5% CR, AND 0.4% MO, TEMPERED 1 H AT  $700^\circ\text{C}$ , OR  $1290^\circ\text{F}$ ) AND HY 130 (0.10% C, 3% NI, 0.5% CR, 0.45% MO, AND 0.10% V, TEMPERED 1 H AT  $600^\circ\text{C}$ , OR  $1110^\circ\text{F}$ ). THE CONTOUR LINES ARE LINES OF EQUAL LOCAL PLASTIC WORK,  $U_{xy}$ , IN UNITS OF  $10^{11} \text{ J/m}^4$  AS INDICATED BY THE NUMBERS. SOURCE: REF 48

Davidson and Lankford (Ref 51) devised a different method for measuring  $U$  utilizing electron channeling to measure the cell size in 0.05% C steel versus distance from the crack. The hysteresis loop areas were then obtained from a calibration of cell size versus loop area determined on unnotched specimens. Liaw et al. (Ref 49) compared the contributions to  $U$  from closer than  $100 \mu\text{m}$  to the crack tip in the same low-carbon steel as determined by both techniques. The agreement was very good, with the two values in agreement to within 15%.

The results of measurements of  $U$  for alloys with  $n$  ranging from 3 to 4.6 are given in Table 1 along with other pertinent data and values of  $A$ . This set of data is discussed in another paper by Liaw et al. (Ref 55). The mean value of the "constant"  $A$  in Eq 3 is  $2.9 \times 10^{-3}$ , with a standard deviation of  $\pm 1.1 \times 10^{-3}$ . The theoretical treatment of Mura and Villman (Ref 56) obtained  $2 \times 10^{-3}$  for  $A$ , which is close to the mean experimental value. In Table 1, yield stress varies from 42 to 868 MPa, shear modulus ( $\mu$ ) varies from 26 to 84 GPa,  $da/dN$  varies from  $0.16 \times 10^{-8}$  to  $32 \times 10^{-8} \text{ m/cycle}$ ,  $\Delta K$  varies from 2.5 to  $20 \text{ MPa}\sqrt{m}$ , and  $U$  varies from 0.5 to  $53 \times 10^{-5} \text{ J/m}^2$ . When the individual data are inserted into Eq 3, a "constant"  $A$  emerges with a relatively small standard deviation. It should, of course, be recognized that data are included for alloys ranging in  $n$  from 3 to 4.6, that the 0.2% offset cyclic yield stress may not strictly be the correct yield stress for Eq 3, and that there are errors in measurement of  $U$  (Ref 36, 47). The latter two factors lead to errors in  $A$ .

(A) COMPOSITIONS GIVEN IN WEIGHT PERCENT

Dependence of measured  $U$  on  $\Delta K$  will be considered next. As already mentioned, when  $n$  is 4,  $U$  is expected to be independent of  $\Delta K$ . This was investigated in a steel (Ref 47) and several aluminum alloys (Ref 36), as shown in Table 1. The variation observed is considered to be within experimental error. When  $n$  is less than 4,  $\Delta K$  is theoretically expected to be a function of  $U$ , with Eq 3 still holding. Noteworthy among  $n$  values near 2 reported in the literature is the analysis of martensitic steels by Barsom (Ref 57), where  $n = 2.25$  fit a large set of data.

Recently, Kwun and Fine (Ref 48) observed  $n$  of 2.3 in MA 87 powder metallurgy aluminum-base alloy containing 6.5 wt% Zn, 2.5 wt% Mg, 1.5 wt% Cu, and 0.4 wt% Co aged 25 h at 120 °C (250 °F) followed by 4 h at 163 °C (325 °F). It was decided to measure  $U$  at two different values of  $\Delta K$ , 10 and 17 MPa  $\sqrt{m}$ , to check Eq 4. The resulting values of  $U$  were 1.7 and 4.3  $\times 10^4$  J/m<sup>2</sup>. Substituting into Eq 3 gave  $A$  values of 2.2 and 2.3  $\times 10^{-3}$ , which are close to the mean value of Table 1. Taking  $U$  proportional to  $(\Delta K)^{1.7}$ , the predicted ratio of  $U$  for the two  $\Delta K$  values is 2.5, which is the observed ratio.

It has thus been proved that the plastic work per unit area of fatigue crack propagation,  $U$ , is an important material parameter, along with yield stress, for controlling the rate of fatigue crack propagation. At a constant  $\Delta K$ ,  $da/dN$  varies inversely as  $\mu U(\sigma_y)^2$ . For alloys of the same major component,  $\mu$  varies little with alloying, and the product  $U(\sigma_y)^2$  is controlling.

Many experimental studies have observed that increasing yield strength in an alloy system, such as by changing the tempering temperature in steels, changes  $da/dN$  at constant  $\Delta K$  relatively little. This can be understood by  $U$  and  $\sigma_y$  changing in opposite directions. Because  $U$  depends in part on the size of the plastic zone, decrease in  $U$  with increase in alloy strength is not unexpected, and most of the data in Table 1 bear this out. Of all the alloys studied, annealed 0.05 wt% C steel has the highest  $U$ , but  $\partial a/\partial N$  (at constant  $\Delta K$ ) is high because  $\sigma_y$  is low. A similar conclusion is reached for 99.99+ aluminum. Fortunately, there are exceptions to the rule that  $U$  is inversely related to  $(\sigma_y)^2$ . The niobium-alloyed steel when quenched and tempered at 400 °C (750 °F) has a very high  $U$  for its yield strength and a correspondingly low

fatigue crack propagation rate. The binary Al-6.3Cu alloy (aged at room temperature to form Guinier-Preston zones) also has a high value of  $U$  for aluminum alloys.

Preventing strain localization is certainly important for increasing  $U$ . If the plastic deformation is localized in the plastic zone, then small  $U$  is expected. The Al-6.3Cu alloy has excess copper, which forms 5 to 10  $\mu\text{m}$  spherical  $\text{CuAl}_2$  particles dispersed uniformly in the matrix. These prevent strain localization, which is characteristic of an alloy containing only Guinier-Preston zones.

Even enhancement of the fatigue crack propagation rate by a corrosive environment can be understood by its effect on  $U$ . Davidson and Lankford (Ref 51) measured fatigue crack propagation rate and  $U$  in dry and moist air. The faster rate in moist air was accompanied by a reduction in  $U$ .

### Appendix: Scanning Probe Microscopy of Fatigue

Scanning probe microscopy refers to a class of surface diagnostic techniques that operate by scanning a fine probe across a specimen surface. The first such instrument is the topographiner developed by Young in the early 70s (Ref 58), followed by the now well-known scanning tunneling microscope. The scanning tunneling microscope (STM) was invented by Rohrer and Binnig of IBM's Zurich Research Laboratory in Switzerland in 1982 (Ref 59). One of the most interesting aspects of this new microscopy technique is its ability to perform high resolution imaging of surfaces over hundreds of microns, and that such high resolution is achieved in vacuum, air and liquid environments, thus making this a convenient technique for use in various branches of physical and biological sciences, including the study of fatigue-induced surface deformation.

#### Principle of STM Imaging

Consider a sharp conducting tip brought to within one nm of a specimen surface (see Fig. 15). Typically, a bias of 0.01-1 volt is applied between the tip and the specimen. Under these conditions, the tip-surface spacing ( $s$ ) is sufficiently small that electrons can tunnel from the tip to the specimen. As a result, a current ( $i$ ) flows across this gap which can be shown to vary with  $s$  as follows:

$$I \propto \text{EXP}(-10.25\sqrt{\phi} s) \quad (\text{EQ 7})$$

where  $\phi$  is the effective work function in eV (3-4 eV for most systems) and  $s$  is in nm. One can see that if the tip-surface spacing is increased (decreased) by 0.1 nm, the tunneling current will decrease (increase) by about a factor ten for an effective work function of 4 eV.

FIG. 15 ELECTRON TUNNELING FROM PROBE TIP TO SPECIMEN SURFACE

One can then exploit this sensitive dependence of the tunneling current  $i$  on the tip-surface spacing for topographic imaging as follows. In scanning the tip horizontally across the specimen, any change in the tip-surface spacing results in a large change in the tunneling current  $i$ . One can use some feedback mechanism to move the tip up or down to maintain a constant tunneling current. According to the above equation, this implies that one is maintaining a constant tip-surface spacing (assuming constant  $\phi$ ). In other words, the up-and-down motion of the tip traces out the topography of the

surface, analogous to the conventional technique of stylus profilometry, except that the tip never touches the surface in STM. This is known as constant current imaging, the most common imaging mode used in scanning tunneling microscopy.

Because of the proximity of the tip to the surface and the nature of tunneling, the tunneling electron beam diameter can be very small. For a tunneling junction with work function of 4 eV, the full-width at half-maximum is approximately equal to  $0.2 \sqrt{z}$  (Ref 60), where  $z$  is the sum of  $R$ , the local radius of curvature of the tip and  $s$ , the tip-surface spacing in nm. For example, for  $R = 0.2$  nm, and  $s = 0.5$  nm, the electron beam diameter is on the order of 0.2 nm. This implies that the tunneling current is self-focused into a region with atomic dimensions. Scanning tunneling microscopy has been demonstrated to yield atomic resolution in many cases.

## Experimental Aspects

**Coarse Motion Control.** In order to bring the tip to within tunneling range, one must move the tip over macroscopic distances (hundreds of microns) with precision  $\sim 100$  nm. Two schemes are commonly used. One involves the use of piezoelectric inchworms. Another one is based on purely mechanical means. For example, consider a conventional 80-pitch screw, i.e., the screw advances by one inch (2.54 cm) after 80 turns. This translates into a motion advance of about 880 nm for one degree of screw rotation. Using a cantilever beam with mechanical advantage of 10, one can achieve a precision of 88 nm for one degree of screw rotation.

**Fine Motion Control.** The precision required for tip positioning relative to the specimen surface during image acquisition has to be better than 0.1 nm. This is achieved by piezoelectric positioners. Piezoelectric materials expand or contract upon the application of an electric field. Lead zirconium titanate (PZT) is the material of choice in the STM community. Most STMs are designed with response ranging from 1-300 nm/volt. Since voltages can be controlled and monitored in the submillivolt level easily, subnanometer control can be readily attained.

Two types of STM scanners are being used. In one design, three-axis scanning is accomplished using three separate pieces of piezoelectric bars held together in an orthogonal arrangement. In another design, a single piezoelectric tube with four separately biased quadrants provides the capability of three-axis scanning (Ref 61). The major advantage of the tube scanner is its improved rigidity.

**Tip Preparation.** Two tip materials are widely used, viz. tungsten and platinum alloys (e.g., Pt-Ir and Pt-Rh). Tungsten is strong and can be fabricated into a sharp tip easily, but it tends to oxidize rapidly in air. On the other hand, Pt alloys are stable in air, but they may not survive occasional tip crashes on surfaces. Several methods can be used to create sharp tips of these materials. These include electropolishing, cutting and grinding, momentary application of a high bias voltage (a few volts), or simply waiting for a few minutes after achieving tunneling. In order to image rough surfaces with minimal distortion as one normally encounters in fatigue studies, sharp tips with large aspect ratios should be used. For further details, see Ref 62.

**Vibration Isolation.** Most STMs are supported using damped springs, air tables or stacked stainless steel plates separated by viton dampers. The goal in all these designs is to keep the tip-surface spacing immune to external vibration. The general design is that one should support the STM on a soft platform and design a microscope with high rigidity.

**Data Acquisition and Analysis.** In a typical experiment, a bias of 0.01-1 volt is applied between the tip and the specimen. The tunneling current so obtained is then compared with a preset value (typically 1-10 nA). The error signal then drives a feedback circuit whose output is used to control a fast high voltage operational amplifier which feeds voltage to the Z electrode of the scanner (which moves the tip perpendicular to the surface). At the same time, raster-scanning is accomplished by using two computer-controlled digital-to-analog converters to control the output of two high voltage operational amplifiers feeding voltages to the X and Y electrodes of the scanner. At each step, the Z voltage required to maintain a constant tunneling current is read by the computer via an analog-to-digital converter (either through AC coupling or potential dividers). This Z voltage, as discussed earlier, corresponds to the surface height at the XY location. This information can then be displayed in real time as gray level images on a video monitor or stored as two-dimensional integer arrays which can later be retrieved for further processing.

## Atomic Force Microscopy

In scanning tunneling microscopy, the tip-surface spacing is sensed by the tunneling current. This sensing technique does not work well for highly resistive materials. An alternative scheme to sense the tip-surface spacing is by measuring the

force of interaction between the tip and the specimen surface (Ref 63). This is the basis of atomic force microscopy. The tip is normally part of a small wire or microfabricated cantilever. The force of interaction between the tip and the surface results in a deflection of the cantilever. In most modern designs, the cantilever deflection is sensed either by detecting the reflection of a light beam from the back of the cantilever or by optical interferometry. Other operational aspects of AFM (i.e., motion control, vibration isolation, etc.) are identical to STM. By operating under small loads ( $\sim nN$ ), most surfaces can be imaged with high resolution without damage. One important strength of AFM is its ability to obtain images from insulator surfaces. In addition, one can modify an atomic force microscope to study friction and surface mechanical properties on the nanometer scale. For further details, see Ref 63.

### Limitations of Scanning Probe Microscopy

One limitation of scanning probe microscopy is the small range of piezoelectric scanners ( $\sim 100$  microns). This limitation is solved in most modern designs by incorporation of an optical microscope, which serves to search for the region of interest. The probe can then be positioned over this region for a close-up view. Another limitation is tip geometry. With the exception of atomically smooth surfaces, images obtained from all other surfaces are due to the convolution of the actual surface topography and the tip geometry, an important consideration in applying scanning probe techniques in fatigue studies (Ref 64). Unfortunately, mathematical deconvolution cannot recover the original topography even if the tip geometry is exactly known. The only practical solution is to image with the sharpest possible tip with large aspect ratio.

## Cyclic Stress-Strain Response and Microstructure

Hans-Jürgen Christ, Universität-GH-Siegen

---

## Introduction

FATIGUE has been known for more than 150 years (Ref 1, 2, 3), especially for metallic materials that exhibit a lower strength under cyclic loading conditions compared to static load. For more than a century, common engineering practice has been to characterize the fatigue resistance of materials against cyclic loading by means of Wöhler curves or so-called *S-N* plots. Wöhler (Ref 4), who studied the cyclic strength of steel railroad axes and various other structural parts, was solely interested in the fatigue limit, which is the threshold stress amplitude below which fatigue failure will not occur, even for a very large number of cycles. For many decades it was a mystery as to why the stress level of the fatigue limit often occurs not only below the rupture strength but even below the yield stress.

For many years, and especially since the work of Coffin (Ref 5) and Manson (Ref 6), it has been known and well-accepted that fatigue failure has to be attributed to repeated cyclic plastic straining. The stress amplitudes leading to fatigue failure are in most cases too small to cause "macro-yielding," but they are at least large enough to give rise to cyclic "microplastic" strains that are measurable and of the order of  $10^{-5}$  to  $10^{-4}$  at the fatigue limit. Consequently, fatigue fracture has to be considered as a result of repeated plastic straining, where the plastic-strain amplitude rather than the stress amplitude represents the decisive loading parameter. Thus, fundamental studies on the nature of fatigue damage must be based on well-designed cyclic deformation experiments in combination with a detailed evaluation of the

microstructural changes that occur during cyclic deformation. The dislocations, their interaction among themselves and with second-phase particles, grain boundaries, and so on, and their behavior in cyclic strain localization play an important role. Even localized events during fatigue, such as crack initiation and crack propagation, which lead to what is commonly referred to as fatigue damage, can be considered a consequence of bulk microstructural changes that normally occur relatively early in fatigue life.

Figure 1 (Ref 7) tries to separate the single processes that finally lead to fatigue failure according to the chronological order of their occurrence. Although this scheme represents a very simplified description of the real situation, it applies to the behavior of many metallic materials under cyclic loading conditions and allows us to define the term *cyclic stress-strain behavior* (or *cyclic deformation behavior*). According to Fig. 1, this expression means the area of fatigue that comprises all aspects that deal with the global mechanical and microstructural response of a material to cyclic loading, without giving much consideration to damage processes, which are mostly localized. Nevertheless, it should be emphasized that fatigue damage usually evolves from microstructural changes as a consequence of cyclic plastic deformation, and that the study of the cyclic stress-strain response and its correlation with microstructure leads to a better understanding of the early stages of the fatigue failure process.

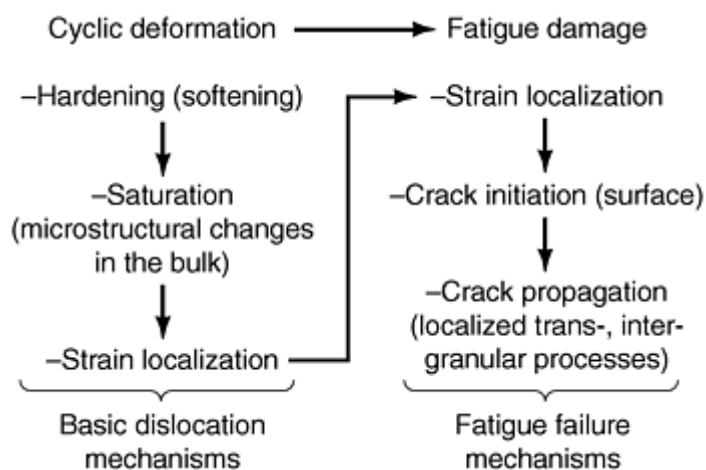

FIG. 1 THE SEQUENCE OF PROCESSES DURING FATIGUE OF METALLIC MATERIALS. SOURCE: REF 7

This article, which is restricted to the cyclic stress-strain behavior of metallic materials addresses the microstructural processes that take place during plastic deformation. Cyclic-stress-strain response is discussed on the basis of microstructure, because microstructural processes underlie and influence the examination, interpretation, and understanding of the macroscopic behavior.

From an engineering point of view, it might appear somewhat unsatisfactory and disappointing that no direct answers can be deduced from the cyclic stress-strain behavior to the important question of cyclic life and its assessment. Therefore, it appears necessary to indicate that many methods, especially the more advanced methods, used for cyclic lifetime prediction in engineering practice are based on knowledge of the cyclic deformation behavior of the material considered. Even in simple phenomenological approaches, most damage parameters contain a combination of stress amplitude and strain (or plastic-strain) amplitude (e.g., Ref 8). As an example of more sophisticated concepts for cyclic lifetime assessment, the methods based on the cyclic  $J$ -integral,  $\Delta J$ , can be cited. The transfer of the  $J$ -integral of elastic-plastic fracture mechanics as a parameter to characterize the situation at the crack tip under monotonic straining (Ref 9, 10) to cyclic loading (Ref 11) has been shown to be successful in numerous studies (e.g., Ref 12, 13, 14). The value of  $\Delta J$  that actually describes fatigue crack propagation is usually determined by evaluating the stress-strain hysteresis loop, which is the fundamental diagram to represent the cyclic stress-strain response. Moreover, the application of  $J$  to cyclic loading demands a certain kind of cyclic stress-strain behavior (commonly termed Masing behavior). This behavior, which is considered in more detail below, should normally be checked first, before  $\Delta J$  is used.

This article is constructed in such a way that the level of difficulty increases from section to section. The following section gives a plain phenomenological and general description of the cyclic stress-strain response. Then, the microstructural aspects of cyclic deformation are described, taking into account the role of the dislocation slip character and the type of crystal lattice. Examples illustrate the effect of deformation-induced phase transformations on cyclic

deformation behavior. The interaction of dislocations and strengthening second-phase particles is subsequently discussed briefly. Most materials used for engineering applications are optimized regarding their mechanical properties by means of a thermal and/or mechanical pretreatment, so the effect of a mechanical history is considered in a separate section. Finally, in the last section, a simple method for modeling the cyclic stress-strain response is introduced.

## Cyclic Stress-Strain Response and Microstructure

Hans-Jürgen Christ, Universität-GH-Siegen

---

### The Mechanical Stress-Strain Response

**The Hysteresis Loop.** In order to obtain reproducible and unambiguous results, laboratory studies of cyclic stress-strain response are mostly conducted using unnotched samples of high surface quality (i.e., mechanically or electrochemically polished). A sufficient cylindrical gage length allows a precise determination of the uniform axial strain  $\epsilon$  by means of a suitable extensometer. Servohydraulic test systems, normally used for cyclic loading experiments, can be run in closed-loop stress and strain control, respectively, as the standard control modes. The fatigue damage and the dislocation motion and rearrangement are determined by the plastic strain amplitude involved, so in some studies the control of the plastic strain is preferred (Ref 15).

The basic information on the cyclic stress-strain behavior of a material is provided in the form of the stress-strain hysteresis loop. In contrast to monotonic loading, cyclic deformation does not lead to a unique relationship between stress  $\sigma$  and strain  $\epsilon$ , but rather to a hysteresis loop for each loading cycle. Figure 2 illustrates the way in which the courses of  $\epsilon$  versus time  $t$  and  $\sigma$  versus  $t$  are combined. The example considered represents a fatigue experiment in which the test system forces the sample to follow a triangular signal of the plastic strain  $\epsilon_{pl}$ . Total strain consists of plastic strain and elastic strain  $\epsilon_{el}$ :

$$\varepsilon = \varepsilon_{PL} + \varepsilon_{EL} \quad (\text{EQ 1})$$

The elastic strain can be calculated from stress via Hooke's law, so the plastic strain can be determined easily and continuously if the stress is measured. This allows the use of the plastic strain signal as feedback signal in the closed loop of a testing system:

$$\varepsilon_{pl} = \varepsilon - \frac{\sigma}{E} \quad (\text{EQ 2})$$

where  $E$  is Young's modulus.

FIG. 2 MECHANICAL HYSTERESIS LOOP, CONSTRUCTED FROM THE COURSES OF  $\sigma$  AND  $\varepsilon(\varepsilon_{pl})$  VS. TIME.

In addition to the hysteresis loop in the form of  $\sigma$  versus  $\varepsilon$ , Fig. 2 also contains the loop as a plot of  $\sigma$  versus  $\varepsilon_{pl}$ . According to Eq 2, the representations are equivalent and can easily be converted one into the other. The representation against  $\varepsilon_{pl}$  is advantageous if the portion of elastic strain in total strain is high and the hysteresis loop resembles an elastic line in the plot of  $\sigma$  versus  $\varepsilon$ .

In principle, the hysteresis loop depends not only on the material, but also on the load frequency and control mode (strain or stress control). The hysteresis loop represents the microscopical deformation processes occurring during a load cycle in an integral form.

Some important quantities can be taken directly from the hysteresis loop (Fig. 3). The unloading after the load reversal point in tension, which is described by the coordinates  $\varepsilon_{max}$  and  $\sigma_{max}$  for maximum strain and stress, occurs with a slope of the tangent that represents the value of Young's modulus. This holds true also for the unloading in compression after having passed the minimum ( $\varepsilon_{min}$ ,  $\sigma_{min}$ ). The stress range  $\Delta\sigma$  follows from:

$$\Delta\sigma = \sigma_{MAX} - \sigma_{MIN} \quad (\text{EQ 3})$$

and the strain range  $\Delta\varepsilon$  can analogously be obtained by:

$$\Delta\varepsilon = \varepsilon_{\text{MAX}} - \varepsilon_{\text{MIN}} \quad (\text{EQ 4})$$

The corresponding amplitudes of stress and strain are determined as the half ranges.

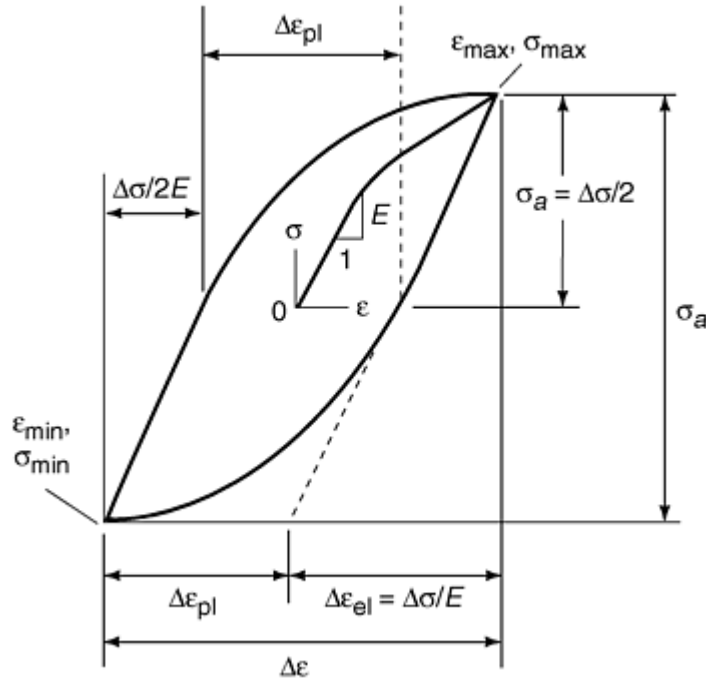

FIG. 3 PRIMARY QUANTITIES OF THE HYSTERESIS LOOP

The plastic strain range  $\Delta\varepsilon_{pl}$  is equal to the distance between the points of intersection of the hysteresis loop and the strain axis (Fig. 2). Depending on the material, a more or less pronounced back-deformation may occur during unloading, which gives rise to a difference between  $\Delta\varepsilon_{pl}$  and  $\varepsilon_{\text{max}} - \varepsilon_{\text{min}}$ . This difference is sometimes attributed to a "reversible plastic strain," an expression that itself seems contradictory.

Figure 3 depicts symmetrical tension-compression loading with a mean stress  $\sigma_m = (\sigma_{\text{max}} + \sigma_{\text{min}})/2 \approx 0$  and a mean strain  $\varepsilon_m = (\varepsilon_{\text{max}} + \varepsilon_{\text{min}})/2 \approx 0$ .

**Transient cyclic deformation behavior** (such as cyclic hardening or softening) refers to a continuous change in the cyclic strength that may occur throughout a test or at least in the first stage of cyclic deformation. Schematic examples of cyclic hardening (Fig. 4a) and cyclic softening (Fig. 4b) (Ref 16) show the stress course and the hysteresis loop shape from a symmetrical total-stress-controlled test performed applying a triangular demand signal with constant amplitude. Cyclic hardening leads to an increase in the stress amplitude, and consequently the hysteresis loop becomes larger. Cyclic softening has the opposite effect: a decrease of  $\Delta\sigma/2$  and a reduction of the size of the hysteresis loop. The type of transient behavior is mainly determined by the pretreatment of the material tested. It is plausible that, for instance, heavy cold working prior to cyclic loading could cause subsequent cyclic softening, whereas a recrystallization treatment could give rise to cyclic hardening. Furthermore, deformation-induced microstructural changes may also be the reason for transient deformation behavior.

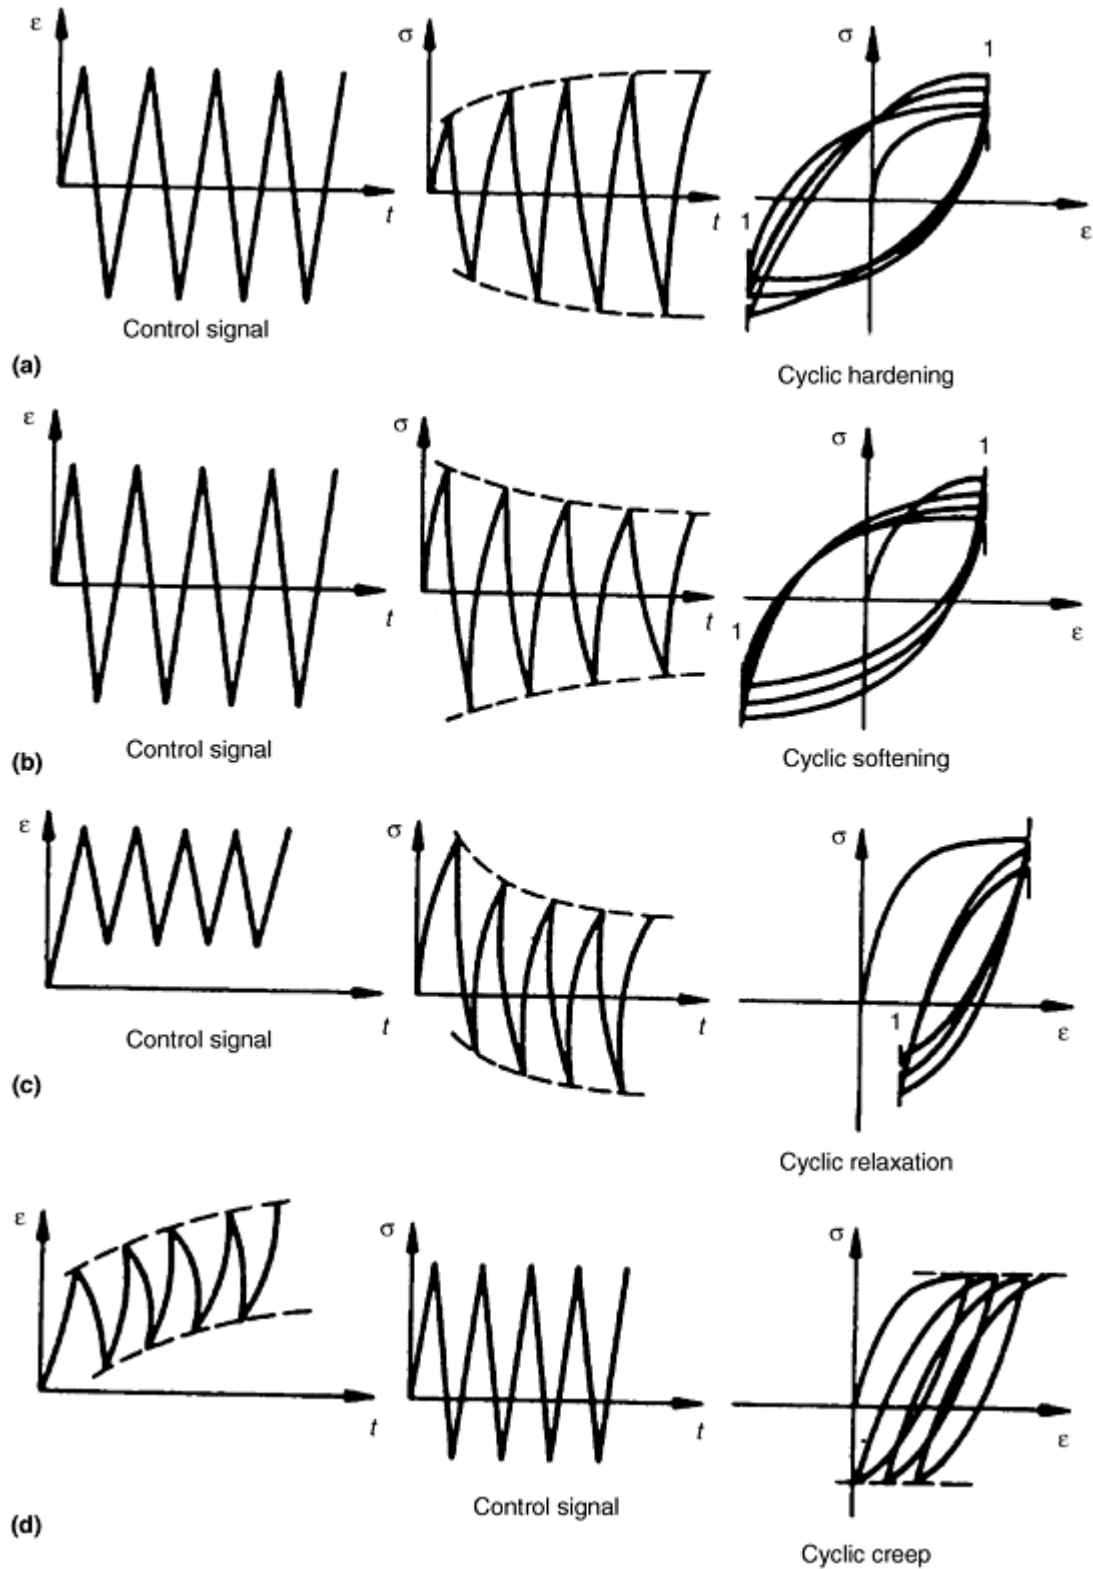

FIG. 4 SCHEMATIC REPRESENTATION OF TRANSIENT CYCLIC DEFORMATION PROCESSES. SOURCE: REF 16

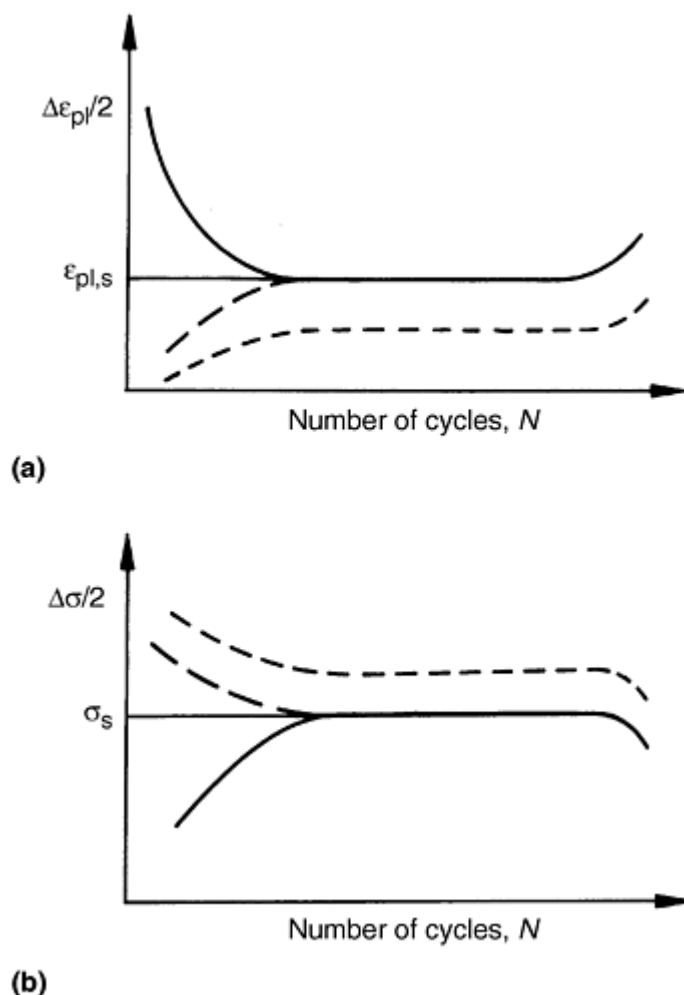

It is typical of asymmetrical cyclic deformation that transient processes take place that tend to reduce asymmetry. Figure 4(c) depicts the situation in a strain-controlled test in which a mean strain is superimposed. As a consequence, a mean stress arises that slowly diminishes. This process is termed cyclic relaxation. If the test is performed under stress control and a mean stress is applied, the material may show cyclic creep. The mean strain increases continuously, leading to a steady shift of the hysteresis loop to the right.

**Cyclic Saturation.** Transient effects are often neglected in the description of the cyclic stress-strain behavior due to their very strong dependence on material, testing condition, and mechanical history. A general formalism for a mathematical treatment of the transient cyclic deformation behavior is not known and probably does not exist. Data collections in handbooks usually provide an approximate representation of the cyclic deformation behavior by referring only to the stabilized deformation condition, which is usually termed the cyclic saturation state.

In Fig. 5, two different types of cyclic deformation curves are shown. Figure 5(a) refers to the case where the stress amplitude  $\Delta\sigma/2$  is held constant during the test. The cyclic deformation response of the material is therefore plotted in the form of the course of the plastic-strain amplitude  $\Delta\varepsilon_{pl}/2$  versus the number of cycles  $N$ . In a plastic-strain-controlled test (where  $\Delta\varepsilon_{pl}/2$  is constant), the stress amplitude exhibits characteristic changes (Fig. 5b). If tests with considerably different numbers of cycles to fracture  $N_f$  are to be compared, instead of  $N$ , often the cumulative plastic strain  $\varepsilon_{pl,cum}$  is used:

$$\varepsilon_{PL,CUM} = 2 N \Delta\varepsilon_{PL} \quad (\text{EQ 5})$$

The value of  $\varepsilon_{pl,cum}$  represents the total plastic strain that the sample undergoes during cyclic deformation. The final value at failure far exceeds the sustainable plastic strains of monotonic loading (typical values: monotonic loading 50%, cyclic loading 10.000%).

**FIG. 5 SCHEMATIC REPRESENTATION OF CYCLIC DEFORMATION CURVES FOR TESTS WHERE (A)  $\Delta\sigma/2$  IS CONSTANT AND (B)  $\Delta\varepsilon_{pl}/2$  IS CONSTANT**

Many metallic materials show a cyclic deformation curve of the type shown in Fig. 5, which can be separated into three stages. At the beginning cyclic deformation causes a cyclic hardening or a cyclic softening, as described in the previous

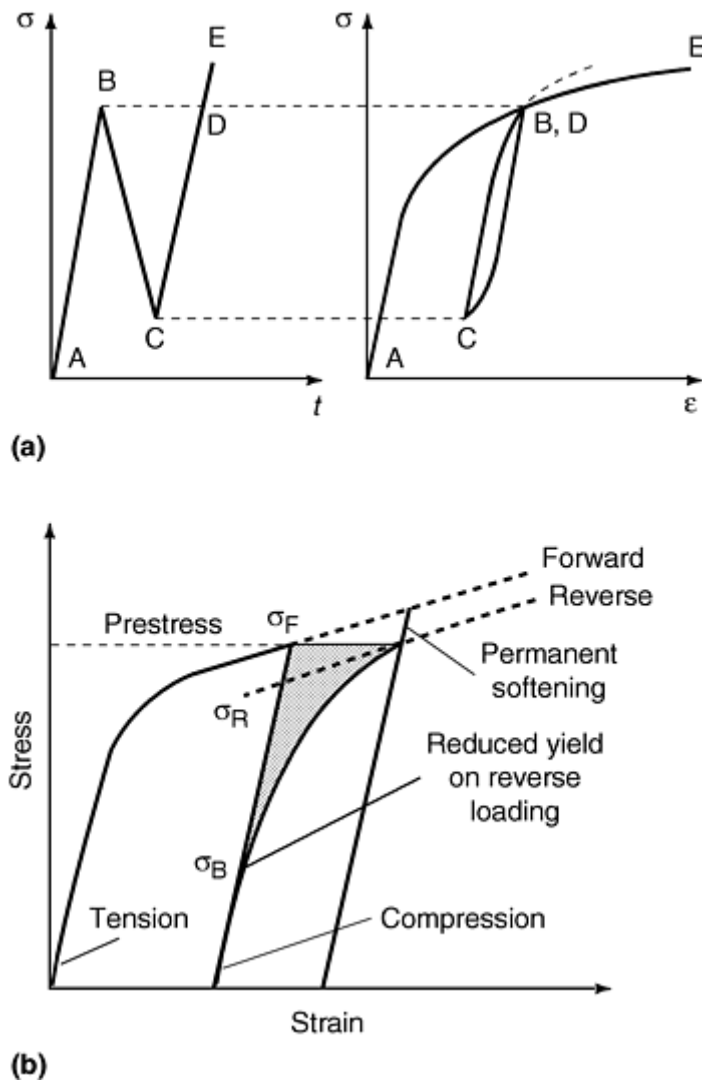

section. Cyclic hardening means that the plastic-strain amplitude decreases (solid line in Fig. 5a) and the stress amplitude increases (solid line in Fig. 5b). In the case of cyclic softening, the reverse changes take place (short dashed lines).

After this initial stage, a second region often follows in which  $\Delta\varepsilon_{pl}/2$  and  $\Delta\sigma/2$  are approximately constant. In this region a quasisteady condition exists. The prefix "quasi" is necessary to indicate that only the amplitude is constant, while the material is still continuously deformed along the hysteresis loop. The values of  $\Delta\varepsilon_{pl}/2$  and  $\Delta\sigma/2$  in this region of cyclic saturation ( $\varepsilon_{pl,s}$  and  $\sigma_s$ , respectively) are of great importance, because frequently the stabilized behavior occupies a major part of fatigue life. For this reason, it is permissible to use the steady-state amplitudes  $\varepsilon_{pl,s}$  and  $\sigma_s$  as rough mean values for an estimate of the "average behavior" during fatigue life. The stabilized conditions established in various tests with different loading amplitudes are used to define the cyclic stress-strain (CSS) curve (Ref 17).

In the third region of the cyclic deformation curve, the cyclic stress-strain behavior is affected by the propagation of a fatigue crack. In this region the crack size is already in the same range as the specimen dimensions, so the determined values of stress and strain are no longer of physical validity.

If the material has suffered mechanical deformation, it must not be taken for granted that the same stabilized condition will be established as on a deformation-free sample. This is illustrated in Fig. 5 by the long dashed lines, which define history-dependent behavior. In contrast, if the transient cyclic deformation merges into the plateau of an initially annealed sample (short dashed lines), the cyclic deformation is considered to be history-independent.

**Memory of Prior Deformation.** A phenomenon that might seem astonishing at first, but that provides some fundamental insights on important microstructural processes, is the "memory" of materials of their prior load history. If, as schematically shown in Fig. 6(a), a material is deformed in tension into the plastic region up to point B, and subsequently unloaded down to point C, a plastic back-deformation will take place if the unloading is sufficiently large. The fact, whether point C is connected with positive (tensile) or negative (compressive) stress, is therefore not the main criterion for plastic back deformation to take place.

**FIG. 6 SCHEMATIC OF: (A) MEMORY OF A PRIOR DEFORMATION AND (B) BAUSCHINGER EFFECT WITH SOFTENING EXAGGERATED FOR CLARITY. THE HYSTERESIS LOOP IN (B) SHOWS THAT ON UNLOADING, PLASTIC DEFORMATION BEGINS AT A LOWER BACKWARD STRESS,  $\sigma_B$ , THAN REACHED IN THE FORWARD DIRECTION,  $\sigma_F$ . THE INITIAL ROUNDED PORTION OF THE REVERSE CURVE IS DUE TO SHORT-RANGE EFFECTS OF WEAK OBSTACLES, AND THE DOWNWARD DISPLACEMENT OF THE SUBSEQUENT REGION IS RELATED TO THE BACK STRESS. SOURCE: REF 18, 19**

Since the work of Bauschinger (Ref 20) more than a century ago, it has been known that the elastic limit after plastic deformation in one direction will be reduced if the loading direction is reversed (Fig. 6b) The Bauschinger effect is a basis for describing the reversibility of deformation, as shown graphically in Fig. 6(b). Its magnitude depends on a variety of factors, including amount of prestrain, deformation mode, and microstructure. Although the Bauschinger effect is an attractive parameter to describe deformation reversibility quantitatively, and thus to describe fatigue resistance, it should be remembered that it is a bulk phenomenon, whereas fatigue is a local process. Therefore, although small inhomogeneities in the material may not measurably affect the Bauschinger effect, fatigue life may be drastically lowered.

The memory of mechanical history leads to the observation that a new increase of the stress, which exceeds the first maximum level B, does not give the smooth stress-strain path plotted as the dashed curve in Fig. 6(a) (starting from D). Rather, at D, where the stress level of the former maximum B is reached, the material proceeds along the initial predeformation  $\sigma$ - $\epsilon$  path (the strain path A-E without the interruption BCD). The small hysteresis loop (BCD) is "forgotten." The ability of a material to maintain  $\sigma$ - $\epsilon$  behavior along the original A-E path after BCD cycling is a feature which causes understanding problems if the deformation is considered to be uniformly distributed, as discussed below.

In the case of cyclic deformation with varying amplitude, the memory effect ensures a consistent continuation when stress-strain paths are interrupted by small cycles. The original  $\sigma$ - $\epsilon$  cycle continues as soon as the interrupting cycles are closed. If an interrupting cycle is again interrupted by another cycle, and so on, the memory is termed "second order," "third order," and so on. In Fig. 7, for example, an experimentally determined stress-strain path is represented that has been observed on polycrystalline copper, a relatively soft and ductile metallic material. The specimen had been cycled at  $\Delta\epsilon_{pl}/2 = 1 \cdot 10^{-3}$  for 25,000 cycles into the region of cyclic saturation. Figure 7 exhibits three large hysteresis loops, the second of which has been interrupted by five small unloadings in tension and compression, respectively. It is due to the memory effect that the enclosing loop (No. 2) is almost identical to the stabilized hysteresis loops (No. 1 and 3). The interruptions do not affect the size and the shape of the following loop (No. 3), so the cyclic stabilized state is maintained. However, in contrast to the schematic representation in Fig. 6, the transition from the small hysteresis loop back to the enveloping loop takes place smoothly, without a kink. Transient processes, those described above, can gradually remove the memory. If, for example, in Fig. 7 one of the small plastic strain cycles in tension were constantly applied, a mean stress relaxation would gradually eliminate the influence of the enclosing hysteresis loop. Nevertheless, it is very important to take the memory effect into account if the cyclic stress-strain behavior under variable-amplitude loading is considered. This knowledge has led to the development of appropriate methods for cycle counting (e.g., range pair method or rainflow method, Ref 21).

FIG. 7 EXPERIMENTALLY DETERMINED STRESS-STRAIN PATH MEASURED ON POLYCRYSTALLINE COPPER

**Memory Effect and the 1:2 Rule.** The term *cyclic neutralization* denotes an experimental technique whereby the stress-strain origin in a cyclic deformation test can be found. For this purpose, starting from a (stabilized) hysteresis loop, the stress or strain amplitude is continuously reduced in small increments down to zero. This method is helpful in order to check whether a clip gage extensometer has slipped, because then a strain signal different from zero exists at zero load in the cyclic neutralized state.

If the cyclic neutralization doesn't take too many loading cycles, the microstructure of the material remains almost unchanged in its saturation condition. Therefore, if the original amplitude is again applied, immediately after the initial half cycle the stabilized hysteresis loop is expected to be established. Normally this initial half cycle after cyclic neutralization differs strongly from the monotonic stress-strain curve (first loading curve) because of microstructural changes that have taken place during cyclic loading. Materials that do not undergo such changes are scarce and are called cyclically neutral (in other words, the first and the initial loading curves coincide).

It has been shown frequently (e.g., Ref 22, 23) that the initial half cycle is approximately identical to the ascending branch of the stabilized hysteresis loop if the branch is related to the load reversal point (in compression) and multiplied with a scale factor of  $1/2$ . An example is given in Fig. 8, which was obtained on polycrystalline copper. The coordinates used are called relative coordinates  $\sigma_r$ ,  $\epsilon_r$ , and  $\epsilon_{pl,r}$ .

$$\sigma_R = \sigma - \sigma_{MIN} \quad (EQ 6)$$

$$\epsilon_R = \epsilon - \epsilon_{\text{MIN}} \quad (\text{EQ 7})$$

$$\epsilon_{\text{PL,R}} = \epsilon_{\text{PL}} - \epsilon_{\text{PL,MIN}} \quad (\text{EQ 8})$$

This simple relation between the hysteresis loop branch and the initial half cycle was first reported by Morrow (Ref 17) and is termed the 1:2 rule or Masing hypothesis. It is shown in the last section of this article that this rule can easily be understood on the basis of Masing's simple multicomponent model. Moreover, an identical relation exists between the CSS curve and the hysteresis loop branch, indicating that the CSS curve equals the initial half cycle.

FIG. 8 COMPARISON OF THE INITIAL HALF CYCLE (MULTIPLIED BY A FACTOR OF 2) AFTER CYCLIC NEUTRALIZATION WITH THE ASCENDING BRANCH OF A STABILIZED HYSTERESIS LOOP IN RELATIVE COORDINATES, MEASURED ON POLYCRYSTALLINE COPPER

## Cyclic Stress-Strain Response and Microstructure

Hans-Jürgen Christ, Universität-GH-Siegen

---

### Microstructural Aspects of Cyclic Loading

The underlying microstructural processes for the above-described cyclic mechanical behavior of metallic materials is a highly complex topic covered in an enormous number of publications. Therefore, a reasonable restriction is necessary.

The emphasis in this section is on single-phase materials tested in initially soft, dislocation-poor conditions resulting from a prior heat treatment. The aspects of a mechanical pretreatment and the strengthening effect of a second phase are dealt with in the subsequent sections "Cyclic Deformation in Structural Alloys" and "Variables and Modeling," respectively, in this article.

### Dislocation Arrangement of Cyclic Saturation

**Factors Determining the Slip Character of a Material.** The slip character of a material is a basic parameter that determines the type of dislocation arrangement formed during cyclic loading and therefore also the cyclic stress-strain response. The term slip character describes the tendency of a material to form a three-dimensional dislocation arrangement. The two extreme cases of slip character are represented by materials that show on the one hand a pure planar dislocation slip and on the other hand a pure wavy dislocation slip. Some examples for typical microstructures illustrating the consequences of different slip characters, are summarized below.

When the cyclic stress-strain behavior of a material is estimated, it would be helpful if "slip character" could be quantified from independent materials data. The factors determining the slip character of a material are a subject of continuing research. Gerold and Karnthaler (Ref 24) describe the origin of planar slip in face-centered cubic (fcc) alloys, emphasizing the role of short-range order in slip planarity. Another paper (Ref 25) discusses several factors, including short-range order and a quantitative basis for distinguishing wavy and planar slip. References 24 and 25 are mainly complementary, although Ref 25 does demonstrate that two of the conclusions in Ref 24 are inconsistent with the evidence. The most important factor promoting planarity of slip is a high friction stress, irrespective of its cause. There is good evidence of a role for interstitial solutes in promoting slip planarity, which clearly does not involve short-range order.

The early studies on the influence of loading amplitude on dislocation arrangement were almost exclusively carried out on copper, Cu-Al alloys, and  $\alpha$ -brass (Cu-Zn) (e.g., Ref 26, 27, 28, 29, 30, 31). The stacking fault energy of copper ( $\approx 40$  mJ/m<sup>2</sup>, e.g., Ref 32) decreases with increasing concentration of alloying element. Because  $\alpha$ -brass and Cu-Al alloys of higher aluminum content exhibit planar slip character, the idea seems to be reasonable that the stacking fault energy might be the decisive quantity for the ease of forming a three-dimensional dislocation arrangement. This idea is based on the assumption that the stacking fault energy determines the possibility of cross slip of screw dislocations.

**Cross Slip in Pure Metals.** As a brief review, if a fcc crystal structure is considered, gliding of a dislocation leads to a shift of a {111} plane in the  $\langle 110 \rangle$  direction. The atomic arrangement of the fcc lattice can be envisioned to result from simply stacking close-packed {111} planes in a stacking sequence of ABCABC. This is illustrated in Fig. 9, in which the atoms of layer A are drawn and the positions of the atoms of layers B and C are marked. If a dislocation of the Burgers vector  $\mathbf{b}_1 = \langle 110 \rangle$  glides on plane A, the atoms of plane B will reach again B positions. Therefore, the atomic arrangement in front of and behind the gliding dislocation is undisturbed. It can clearly be seen in Fig. 9 that the movement of a B atom along  $\mathbf{b}_1$  is unfavorable compared to the path following  $\mathbf{b}_2$  to a C position and then  $\mathbf{b}_3$  to the final

B position. This zigzag course is possible if the dislocation with the Burgers vector  $\mathbf{b}_1$  dissociates into two partial dislocations with the Burgers vectors  $\mathbf{b}_2$  and  $\mathbf{b}_3$  according to the reaction:

$$\mathbf{B}_1 \rightarrow \mathbf{B}_2 + \mathbf{B}_3 \quad (\text{EQ 9})$$

or in the notation of Miller's indices:

$$\frac{1}{2} \langle 110 \rangle \rightarrow \frac{1}{6} \langle 211 \rangle + \frac{1}{6} \langle 12\bar{1} \rangle \quad (\text{EQ 10})$$

As the elastic energy per unit length of a dislocation is proportional to  $G\mathbf{b}^2$ , where  $G$  denotes the shear modulus, this dissociation is connected with an energy reduction ( $\mathbf{b}_1^2 < \mathbf{b}_2^2 + \mathbf{b}_3^2$ ), and hence it is favorable.

FIG. 9 PART OF A  $\{111\}$  PLANE OF THE FCC CRYSTAL LATTICE, SHOWING THE POSITIONS OF THE ATOMS OF THE TWO NEXT PLANES STACKED ABOVE (B AND C)

The elastic interaction of the partial dislocations leads to a repulsion that is balanced by the energy of the stacking fault existing between the partial dislocations. The stacking fault (e.g., B atoms in C positions) is a disturbance of the perfect lattice, and the energy increase per unit area defines the stacking fault energy  $\gamma_{\text{SF}}$ . From a simple consideration of force equilibrium, it follows that the width of splitting up (the distance between corresponding partial dislocations) can be calculated by means of the expression

$$d = \frac{G\mathbf{b}^2}{4\pi\gamma_{\text{SF}}} \quad (\text{EQ 11})$$

Therefore,  $\gamma_{\text{SF}}$  can be determined if  $d$  is measured (e.g., by means of high-resolution transmission electron microscopy, TEM, or by applying the weak-beam technique in TEM, see Ref 32). The value of  $\gamma_{\text{SF}}$  depends very sensitively on alloy composition (Ref 33) and increases in almost all fcc metals and alloys with increasing temperature.

The link between the slip character and the stacking fault energy is given by the following reasoning. A three-dimensional arrangement of dislocations demands that dislocations can leave their slip plane. Screw dislocations can do so simply by

cross slip. If, however, a screw dislocation has dissociated into partial dislocations, a recombination of these partial dislocations leading back to a complete dislocation must first take place, because the character of partial dislocations does not allow them to cross slip. It is obvious that force is required to push the partial dislocations against each other for recombination and that recombination as a prerequisite for cross slip is easier, if the dissociation width is small, that is, if  $\gamma_{SF}$  is high (see Eq 11). According to this reasoning, wavy slip character is to be expected if the value of the stacking fault energy is high, whereas in materials with low stacking fault energy, planar slip should prevail.

If the type of dislocation arrangement established in reality under cyclic loading conditions is compared with this expectation, it is found that the correlation with  $\gamma_{SF}$  works for pure metals at best, but the agreement is poor for alloys. Therefore, different approaches need to be used to describe the physical origin of the slip character in alloys.

**Slip Character in Alloys.** As previously noted, Hong and Laird (Ref 25) have treated in a semiquantitative model the role of the dislocation friction stress and the structure of the stacking fault, in order to explain the influence of the content of alloying elements on the slip character. The basic idea is that friction effects impede the recombination of partial dislocations and are the main reason for planar slip. The resultant equation expresses that in addition to a low value of  $\gamma_{SF}$ , a high atomic misfit, a high shear modulus, and a high concentration of solved foreign atoms favor planarity of slip.

According to Gerold and Karnthaler (Ref 24) it is essential for the slip character that a short-range order exists (confirmed by Wolf et al. in Ref 34). The metals and alloys considered in Ref 24 (mostly taken from Ref 35) can be classified into two groups. One group contains the materials free of short-range order, which all show wavy slip, whereas the other materials exhibit planar slip and short-range order phenomena are present.

The basic idea is depicted in Fig. 10. If in a slip plane a first dislocation is moving, the short-range order that might exist will be destroyed. Because the short-range order is energetically favorable, a locally higher stress is required to move this first dislocation (e.g., provided by a dislocation pile-up). Once the short-range order has been destroyed, the following dislocations, which might be emitted from a dislocation source S, can move quite easily. Therefore, there is no need to activate new slip planes, and the plastic deformation is confined to individual planes (slip localization).

**FIG. 10 SCHEMATIC REPRESENTATION OF A CROSS SLIP PROCESS OF SEVERAL DISLOCATIONS AT AN OBSTACLE (X), IF (A) PLANAR SLIP OR (B) WAVY SLIP PREVAILS. SOURCE: REF 24**

According to this idea, planar slip character does not mean that cross slip does not take place, or takes place only rarely. Rather, the course of cross slip is different, as shown in Fig. 10. In the case of wavy slip, the dislocations cross slip independently of each other on individual slip planes (e.g., due to the presence of an obstacle) and continue to move in the

initial direction on numerous planes (Fig. 10b). This process occurs as a combined movement of a whole group of dislocations in a short-range ordered material. Therefore, the dislocations remain localized in certain planes, giving rise to an overall planar dislocation arrangement.

**Loading Amplitude, Slip Character, and Dislocation Arrangement.** The results of various studies on fcc metals and alloys are summarized in Fig. 11. The different types of dislocation arrangements are mapped as a function of the number of cycles to fracture (abscissa) and the slip character of the material (ordinate). The value of  $N_f$  depends on the loading amplitude, in the sense that, for example, a high plastic-strain range corresponds to a low cycle number to fracture, and vice versa. It is assumed that a state of cyclic saturation is established (i.e., the dislocation arrangement included in Fig. 11 is that of stabilized cyclic deformation behavior).

**FIG. 11 DISLOCATION ARRANGEMENT IN CYCLICALLY DEFORMED FCC METALS AS A FUNCTION OF SLIP CHARACTER AND NUMBER OF CYCLES TO FRACTURE. SOURCE: REF 27, 28**

The representation in Fig. 11 was introduced in 1968 by Feltner and Laird (Ref 27), who used a three-dimensional plot with the homologous temperature  $T/T_m$  ( $T_m$  denotes the melting temperature) as the third axis. Because the temperature range studied was relatively small ( $T/T_m < 0.25$ ), the influence of temperature can be neglected in this temperature interval. However, for certain materials, such as copper (Ref 36) or aluminum (Ref 37), representations have been developed that show a pronounced effect of temperature, mainly because with increasing temperature, recovery processes gain importance and may lead to an instability of low-temperature dislocation arrangements.

Figure 11, which has been confirmed quantitatively by Lukáš and Klesnil (Ref 28), roughly classifies materials into those showing wavy slip and those showing planar slip. The dislocation arrangement in cyclic saturation of wavy-slip metals depends very strongly on the loading amplitude. At low amplitudes (high values of  $N_f$ ), arrangements of edge dislocation dipoles are found that form mainly due to single slip. Dislocations agglomerate to so-called bundles or veins, which are separated from each other by regions of low dislocation density (channels). Embedded in this matrix, persistent slip bands (PSB) can form. At higher amplitudes, multiple slip takes place and gives rise to labyrinth and cell structures.

In planar-slip metals and alloys, the dislocation motion is confined to the slip plane. Planar arrangements form, mainly consisting of edge dislocations that occupy a slip plane and line up parallel to each other. Secondary slip contributes to cyclic deformation at high amplitudes, although secondary slip also seems important for PSB formation, even at low amplitudes.

In the following sections the characteristic dislocation arrangements of cyclically deformed metals and alloys are treated in more detail according to slip character (wavy and planar) and crystal lattice structure (fcc and body-centered cubic, bcc).

## Cyclic Stress-Strain Response and Microstructure

Hans-Jürgen Christ, Universität-GH-Siegen

---

### fcc Metals with Wavy Slip

Most studies on materials showing wavy dislocation slip were performed on copper as a model material. This should not be considered a serious restriction of the general validity of the results, as comparative studies show (e.g., on nickel or austenitic stainless steel). Numerous important results can be obtained on single crystals because of the possibility of adjusting simple and exactly defined conditions regarding slip geometry and resolved shear stress. The transfer of these findings to polycrystals has often proved to be key to developing insight into the processes taking place under complex conditions. Therefore, a brief description of the behavior of single crystals is given first.

### Cyclic Stress-Strain of Single Crystals

**Dislocation Arrangement in Saturation.** The dislocation arrangement established in cyclic saturation of fully reversed fatigue experiments under fixed amplitudes of resolved plastic shear strain,  $\gamma_{ap}$ , can be discussed on the basis of the CSS curve of single crystals (Fig. 12), which represents the saturation value of the resolved shear stress,  $\tau_s$ , versus  $\gamma_{ap}$ . Figure 12 refers to copper, but very similar curves have been found for other wavy-slip fcc metal alloys (see Ref 39 for more details).

**FIG. 12 CYCLIC STRESS-STRAIN CURVE OF MONOCRYSTALLINE COPPER ORIENTED FOR SINGLE SLIP. SOURCE: REF 38**

In Fig. 12, three distinct regions, marked A, B, and C, can be distinguished. At very low amplitudes of plastic shear ( $\gamma_{ap} < 6 \times 10^{-5}$ ), the shear stress amplitude increases with increasing  $\gamma_{ap}$  (region A). A plateau denoted region B follows, where the saturation stress is independent of the plastic strain (plateau stress). If the plastic shear strain amplitude exceeds  $7.5 \times 10^{-3}$ , region C is reached, where again an increase of  $\tau_s$  with  $\gamma_{ap}$  occurs.

The shape of the CSS curve is relatively insensitive to the orientation of the single crystal. In most orientations,  $\tau_s$  values agree with those represented in Fig. 12. In cases where the load axis is oriented in such a way that two or more slip systems are equivalent, a basically different behavior results (e.g., Ref 40, 41, 42). The grains in polycrystalline materials sometimes behave like single crystals oriented for single slip, but textures favoring multislip orientation are common and can have large effects.

**Region A.** At low values of  $\gamma_{ap}$ , the cyclic hardening of well-annealed single crystals is almost entirely due to the accumulation of primary dislocations. The dislocations have mainly edge character and form dipoles that agglomerate to bundles. The saturation condition is characterized by an equilibrium between these dislocation-rich bundles and their relatively dislocation-poor surrounding. Figure 13 tries to give a three-dimensional image of the dislocation arrangement in region A. The top area shows the position of the dislocations in the slip plane (111), whereas the area at the right side represents a  $(1\bar{2}1)$  plane that is perpendicular to the slip plane and contains the Burgers vector  $[\bar{1}01]$  of the primary slip system. The portion of screw dislocations in the bundles is small. With increasing saturation stress the volume fraction of the bundles is enhanced up to about 50% at the transition to region B; the bundles become so-called veins. These veins are separated by dislocation-poor channels that are oriented parallel to the veins, (i.e., with their long axis parallel to the dislocation line of primary edge dislocations).

**FIG. 13** THREE-DIMENSIONAL IMAGE OF THE SATURATION DISLOCATION ARRANGEMENT OF MONOCRYSTALLINE COPPER AT  $\gamma_{AP} = 2.6 \times 10^{-5}$  (REGION A). SOURCE: REF 43

**Region B.** Under region A conditions, only fine slip markings are observed on the surface of the sample and the number of cycles to fracture is almost infinite. In contrast, a slip concentration process characterizes the behavior in region B and limits fatigue life. As soon as the plastic shear strain amplitude exceeds the limit of  $\gamma_{ap} = 6 \times 10^{-5}$ , PSBs are formed, regions of localized slip in which plastic deformation is much larger than the overall deformation of the crystal. The volume fraction of PSBs increases in region B with increasing  $\gamma_{ap}$ , starting from 0% at the boundary to region A, up to about 100% at the beginning of region C. The local shear strain amplitude of a PSB and the surrounding matrix, respectively, can be seen as the values of  $\gamma_{ap}$  that limit region B in Fig. 12. This documents that a PSB deforms about 100 times more than the matrix. The heterogeneous deformation within the plateau of the CSS curve can be described by Winter's rule of mixtures (Ref 44):

$$\gamma_{AP} = F_{PSB} \cdot \gamma_{AP,PSB} + (1 - F_{PSB})\gamma_{AP,M} \quad (\text{EQ 12})$$

where  $f_{PSB}$  is the volume fraction of PSBs,  $\gamma_{ap,PSB}$  is the local plastic shear strain amplitude acting in a PSB, and  $\gamma_{ap,M}$  is the plastic shear strain amplitude of the matrix.  $\gamma_{ap,PSB}$  has to be interpreted as an average value, because the deformation amplitude varies from PSB to PSB and also within a PSB, as shown, for instance, by means of interferometric surface observations (Ref 45). Nevertheless, Eq 12 explains reasonably and in accord with the experimental results why  $\tau_s$  is constant in region B, if one assumes that  $\gamma_{ap,PSB}$  and  $\gamma_{ap,M}$  are fixed amplitudes and  $f_{PSB}$  changes linearly with  $\gamma_{ap}$ .

Figure 14 shows the typical ladder-like structure of PSBs in a  $(1\bar{2}1)$  plane. The "rungs" of this ladder consist of edge dislocations (more precisely of dislocation dipoles). Between the rungs there are channels with low dislocation density.

**FIG. 14 THREE-DIMENSIONAL IMAGE OF THE DISLOCATION ARRANGEMENT OF CYCLIC SATURATION OF MONOCRYSTALLINE COPPER AT  $\gamma_{AP} = 1.5 \times 10^{-3}$  (REGION B). SOURCE: REF 46**

PSBs are embedded in a matrix structure whose dislocation arrangement depends on the value of  $\gamma_{ap}$  applied. In the low-amplitude part of region B, the matrix consists of a bundle/vein structure in which single slip prevails (as in the PSBs), whereas secondary slip gains importance at high amplitudes, leading to an arrangement that resembles a labyrinth structure (Ref 47).

The plateau value of  $\tau_s$  is reported to be 28 MPa for copper single crystals (Ref 38). Similar values of  $\tau_s/G$  ( $\approx 6.5 \times 10^{-4}$ ) are obtained for other fcc metals (Ref 46). However,  $\tau_s$  (and hence also the surface and dislocation structure) is affected by the testing mode that is used to produce PSBs (e.g., Ref 48, 49, 50). Furthermore, the test temperature plays an important role, in the sense that  $\tau_s$  depends strongly on temperature (e.g., Ref 51), PSBs cannot exist at high temperatures, and extended wall structures are found instead of PSBs at low temperatures (e.g., Ref 52).

PSBs deform in region B at a constant stress amplitude. An increase of  $\gamma_{ap}$  leads to an increase of the volume fraction of PSBs, which is connected with a brief rise of the shear stress amplitude until the plateau value is established again. According to Blochwitz and Veit (Ref 53), who tried to determine the "true CSS curves" of PSB and matrix, respectively, the plateau value of the plastic shear amplitude of the matrix can be considered as that value at which the corresponding stress amplitude in the matrix equals the nucleation stress of PSBs. Therefore, an increase of  $\gamma_{ap}$  triggers an increase of the PSB volume fraction at constant  $\tau_s$ , whereas a decrease of  $\gamma_{ap}$  leads to a reduction in  $\tau_s$ , as a result of a smaller local deformation amplitude in the PSB at a volume fraction that is unchanged (at least for the first moment).

By means of a mathematical estimate of the dislocation multiplication and annihilation processes occurring within a PSB (Ref 54, 55) and by in situ cyclic deformation experiments performed in TEM (Ref 56, 57), it could be shown that both the walls and the dislocation-poor channels take part in plastic deformation. The main mechanism of the macroyielding of the PSB (local shear strain amplitude of about 1%) is that edge dislocations bow out from the walls, traverse the channels, and penetrate partially into the opposite wall. This leads to the existence of screw dislocation segments that glide along the channels (Fig. 15), increasing the length of the edge-dislocation part.

**FIG. 15 SCHEMATIC REPRESENTATION OF THE DISLOCATION ARRANGEMENTS IN (A) A MATRIX STRUCTURE AND (B) A PERSISTENT SLIP BAND. SOURCE: REF 58**

Screw dislocations can annihilate if their distance is smaller than the so-called annihilation distance. The edge dislocations are incorporated into the walls and are partially annihilated. Altogether a highly dynamic process of dislocation formation and annihilation results, so that after about every 50 cycles all dislocations are renewed, as can be shown by a rough estimate (Ref 59). A micrograph of the screw dislocations spanning the channels (Fig. 16) shows only about 10% of the screw dislocations, which are produced in one cycle and glide between the walls. It should be noted that plastic yielding of the hard walls is a consequence of the requirement of compatible deformation.

**FIG. 16 TEM MICROGRAPH OF THE WALL STRUCTURE OF A PERSISTENT SLIP BAND UNDER LOAD, IN THE SECTION PARALLEL TO THE SLIP PLANE. SOURCE: REF 46**

In the matrix structure (Fig. 15a), the local plastic deformation is small. Therefore, this deformation can be provided by a quasireversible to-and-fro bowing of the screw dislocations in the channels, essentially by elastic polarization of the hard veins (e.g., Ref 60, 61), and maybe the isolated occurrence of dipole flip-flop (i.e., two edge dislocations forming a dipole change from one stable  $45^\circ$  position to the other).

The importance of PSBs for fatigue is a consequence of their high localized plastic deformation. It has been demonstrated in numerous studies that PSBs form through the bulk of the single crystal and mark their egress at the specimen surface. These slip lines at the surface (which are parallel to the primary glide plane, about 1 to 2  $\mu\text{m}$  high, and show a rough

topography) have been given the attribute "persistent" by Thompson et al. (Ref 62), because they reappear at the same sites during continued cycling, even after a thin layer of surface containing these bands has been removed by electropolishing.

PSBs are considered to be responsible for crack initiation. The interrelation of fatigue damage and the effect of PSBs at the surface has been proven by Thompson et al. (Ref 62) in an experiment that has been repeated quite often. The cyclic lifetime of a sample can be extended if a surface layer is removed by electrochemical polishing.

The crack initiation in single crystals takes place at extrusions (e.g., Ref 63, 64, 65, 66, 67, 68, 69, 70, 71), which probably form primarily as a consequence of a high concentration of point defects arising from the dislocation annihilation processes in the PSBs. Polycrystals are prone to surface grain boundary cracking at low strain amplitudes, which is a result of the interaction of PSBs with grain boundaries (e.g., Ref 72, 73, 74, 75, 76, 77, 78, 79) or twin boundaries (e.g., Ref 19).

**Region C.** If the plastic shear amplitude exceeds a critical value ( $7.5 \times 10^{-3}$  for copper), secondary slip gains importance, leading to a dislocation cell structure. Figure 17 gives an impression of the resultant dislocation arrangement. Long cells are formed, the geometry of which resembles the wall structure of the PSBs. However, the typical ladder structure of PSBs is not observed. In addition to primary dislocations, secondary ones are present in the walls, so these walls are sometimes termed secondary walls (Ref 80). The long shape of cells in Fig. 17 is only one type of appearance; equiaxed cells are often observed, especially at high amplitudes. The plastic deformation takes place in a homogeneous manner; that is no slip localization exists.

**FIG. 17 THREE-DIMENSIONAL IMAGE OF THE DISLOCATION ARRANGEMENT OF MONOCRYSTALLINE COPPER IN CYCLIC SATURATION AT  $\gamma_{AP} = 1.45 \times 10^{-2}$ . SOURCE: REF 43**

**Development of dislocation arrangements** in single-crystal fcc metals with wavy slip is discussed below for constant amplitude and for ramp loading.

**Behavior at Constant Amplitude.** The description given above deals with the situation where the dislocation structure has reached a steady state (cyclic saturation). Detailed TEM observations of the development of the dislocation arrangement with number of loading cycles have been carried out, for example by Hancock and Grobkeutz (Ref 81) at an amplitude in region C and by Basinski et al. (Ref 82) at low values of  $\gamma_{ap}$ , leading to basically identical results.

In contrast to monotonic loading, there is no rotation of the slip system with respect to the loading axes. Therefore, the primary slip system remains the most highly stressed. After only a few cycles the dislocations are heterogeneously distributed in the material. Bundles form that are oriented perpendicular to the primary Burgers vector with their long axis, and parallel to the dislocation lines of edge dislocations. The bundles consist mainly of edge dislocations, indicating that screw dislocations can annihilate by cross slip. The edge dislocations interact with each other, forming dipoles or

multipoles over a large part of their length. At high plastic-shear amplitude after only about 100 cycles, a dislocation arrangement is formed that resembles a cell structure with appreciable contribution of secondary dislocations.

From these observations it can be concluded that the formation of bundles is a consequence of mutual trapping of primary edge dislocations. The bundles and veins are obstacles to further plastic deformation because they partially impede dislocation motion on the primary slip system. The dislocation density within the veins and the number of veins per unit volume both increase with cycle number, giving rise to a pronounced cyclic hardening. The dislocation multiplication is considered to occur according to a Frank-Read mechanism, a bowing out of dislocations into the areas adjacent to the veins.

The mean dislocation spacing in the veins is relatively small ( $\approx 30$  nm) and can be related to the so-called trapping distance of the edge dislocations. As a consequence of the approximately equal number of positive and negative edge dislocations, the average Burgers vector of the veins is close to zero. Thus, no long-range internal stresses are produced. This is an important distinction between monotonic and cyclic hardening of fcc single crystals at low amplitudes of imposed strains. It should be noted here that hardening under monotonic loading occurs much faster than that under cyclic loading, if as a basis of such a comparison the cumulative plastic strain of cyclic deformation is assumed to be analogous to monotonic plastic strain.

As hardening proceeds, the dislocation arrangement develops perpendicular to the primary slip plane, and at high loading amplitudes a labyrinth or cell structure is finally formed as a consequence of an increased contribution of secondary slip.

In spite of numerous models proposed in the literature, there is no fully satisfactory explanation of the establishment of characteristic dislocation arrangements in fatigue. In various works related to this issue, the emerging structures are treated as low-energy dislocation structures (e.g., Ref 43, 83, 84). Attempts have also been made to develop analytical models of continuous concentration fields of dislocations in fatigued crystals (Ref 85, 86). In this approach, the to-and-fro motion of dislocations under cyclic stress is modeled as a diffusion phenomenon, which is treated mathematically by means of a formalism similar to that developed by Cahn and Hillert for spinodal decomposition. A third viewpoint is based on the theory on self-organization of dissipative structures (nonequilibrium systems, Ref 87). Taking into account the high dynamics of the dislocation reactions and rearrangements, the last-mentioned approach seems to be most promising.

Even the formation of the geometrically highly regular PSBs, albeit fundamentally significant, has remained a poorly understood phenomenon (e.g., Ref 88). Noting that the transformation to PSBs starts from a vein structure, some investigators believe that the instability of the vein structure relative to the dislocation arrangement found in PSBs is the main point. According to Kuhlmann-Wilsdorf and Laird (Ref 89), a critical value of the dislocation density in the veins needs to be reached in order to trigger the PSB formation.

A quantitative description of the formation of dislocation structures within veins and PSBs can potentially be obtained from calculations of the equilibrium positions of finite populations of dislocations. The basis for most of the models is the Taylor-Nabarro lattice (Ref 90, 91), which consists of a regular arrangement of parallel edge dislocations extending to infinity. It has been shown by Neumann (Ref 92, 93) that in diamond-shaped sections of the Taylor-Nabarro lattice, the application of a stress results in the emergence of dipolar walls of dislocations from the polarization of the initial regular distribution. The initial configuration begins to decompose into walls only if a certain critical value of the shear stress is exceeded. Moreover, it could be shown that the wall structure is more stable than the vein structure.

**Instabilities During Ramp Loading.** If single crystals are subjected to a steadily increasing stress amplitude (ramp loading), the resultant strain amplitude shows a somewhat surprising and unusual behavior in the form of perfectly periodic strain maxima (Fig. 18), which were termed strain bursts by Neumann (Ref 94). Strain bursts have been observed in single crystals of copper, aluminum, magnesium, and zinc and of Cu-Al (Ref 94, 95).

**FIG. 18 STRAIN BURSTS OBSERVED IN A COPPER SINGLE CRYSTAL SUBJECTED TO RAMP LOADING AT 90K.**  
SOURCE: REF 39, 94

The microstructural processes that are responsible for the occurrence of these maxima in strain amplitudes (Ref 92, 96) provide an insight into the basic mechanisms of cyclic hardening, so a brief description seems to be appropriate here. As mentioned above, cyclic loading leads to a hardening that is due to the dislocation multiplication and mutual trapping of dislocations. As a consequence, one would expect a progressively reducing  $\gamma_{ap}$  if loading takes place at constant shear stress amplitude. This effect continues until the mean free path for dislocation motion is smaller than their mean spacing. Therefore, the plastic strain is accommodated mainly by a polarization of the dipoles in the bundles and dipole flip-flop. If the stress amplitude is slowly raised, dislocations of dipoles of smaller cohesion are separated, leading to an avalanche of free dislocations. This process can be observed macroscopically in the occurrence of a strain burst. After a while, the released dislocations are trapped again, and the cycle repeats.

This mechanism is also expected to occur during cyclic loading at constant amplitude. However, no strain bursts are found, because they do not occur in a "coherent" manner but rather are local events that take place asynchronously and lead at most to a slightly oscillating course of the shear stress amplitude  $\tau_a$ .

### Cyclic Stress-Strain Behavior of Polycrystals (fcc, Wavy Slip)

The next step is whether the basic information on the fatigue mechanisms of single crystals is also applicable to polycrystalline materials (e.g., Ref 80, 97, 98, 99, 100, 101, 102), which are closer to actual technical alloys for structural use. Because the presence of precipitates, impurities, inclusions, and additional phases gives rise to a CSS response that may significantly deviate from that described for single crystals, single-phase polycrystalline metals and alloys are considered first.

It is obvious that the existence of grains of different orientation that form a solid unit and have to deform in a compatible manner leads to a wide spectrum of the resolved shear stress for the dislocation motion. Therefore, it is not to be expected that only one of the characteristic dislocation arrangements observed in single crystals will become established. When the stabilized microstructure of polycrystalline copper is compared to that of copper single crystals, first of all a distinction between surface grains and grains in the interior is necessary (e.g., Ref 103). PSBs are connected with high local plastic deformation, which is hard to realize in grains located in the interior of a material. It has been documented in various studies (e.g., Ref 97, 99, 100, 101, 103, 104, 105, 106) that PSBs are also formed in the interior of a material, but that their number is much smaller than in the surface grains (about 10% smaller). As with single crystals, three plastic-strain amplitude regions can be distinguished by means of prevailing dislocation arrangement. At low amplitudes, loose veins are formed; in an intermediate range, veins with PSBs are observed; and at sufficiently high values of  $\Delta\epsilon_{pl}/2$ , cells prevail. Comparing the boundaries of these regions with those of the regions A, B, and C of the single-crystal deformation, it becomes evident that as a direct consequence of compatibility constraints, the single-slip dislocation arrangements are restricted to relatively low plastic-strain amplitudes. That means that the cell structure expands its region of dominance drastically in polycrystals ( $\Delta\epsilon_{pl}/2 > 6 \times 10^{-4}$  for copper).

Different dislocation arrangements may exist not only in different grains of a polycrystalline material, but also within a single grain providing the physical basis for the development of a "composite-grain" model (Ref 107). This is illustrated by the TEM micrograph shown in Fig. 19. In the upper part, the ladder-like structure of PSBs embedded in a bundle/vein structure can be seen, whereas the lower part shows a kind of labyrinth structure. If a higher amplitude is applied, mainly cells with long or equiaxed shape form. Beside these cells, labyrinth structures can be found that exhibit misorientations leading to differences in brightness (Fig. 20).

**FIG. 19** DIFFERENT DISLOCATION ARRANGEMENTS WITHIN A SINGLE GRAIN OF COPPER.  $\Delta\varepsilon_{pL}/2 = 5 \times 10^{-4}$ ,  $N \approx 10^5$ . SOURCE: REF 101

**FIG. 20** LABYRINTH/CELL STRUCTURE WITH MARKED MISORIENTATION.  $\Delta\varepsilon_{pL}/2 = 2 \times 10^{-3}$ ,  $N \approx 10^4$ . SOURCE: REF 101

Whether the CSS curves of single crystals and polycrystals are (in certain regions) related to each other depends strongly on the orientation factor  $M$  used to convert the loading quantities:

$$\frac{\Delta\sigma}{2} = M \cdot \tau_a \quad (\text{EQ 13})$$

$$\frac{\Delta\varepsilon_{pl}}{2} = \frac{\gamma_{ap}}{M} \quad (\text{EQ 14})$$

The well-known Taylor factor,  $M = 3.06$ , is based on the assumption of multiple slip in all grains, whereas the Sachs factor,  $M = 2.24$ , is reasonable if single slip exists even in the mostly stressed grains. The maximum value of the locally effective shear stress results from the reciprocal Schmid factor,  $M = 2$ , which demands that both slip plane and slip direction be ideally oriented (i.e.,  $45^\circ$  with respect to stress axis).

Whether the CSS curve of polycrystalline copper exhibits a plateau analogous to the behavior of single crystals has been discussed in the literature very inconsistently. Systematic studies on the effect of grain size (e.g., Ref 108, 109, 110, 111, 112, 113) have shown that in tests where  $\Delta\varepsilon_{pl}/2$  is constant and the grains are small or medium, no plateau exists. Small horizontal regions in the CSS curves of polycrystals (e.g., Ref 42, 102, 114) either are due to a special testing mode or are a consequence of very large grains. In the case of copper, at large grain sizes a "hard" annealing texture affects the CSS behavior and leads to a "reversed" grain size effect (i.e., lower saturation stress amplitude for smaller-grained material) (e.g., Ref 111), whereas nickel shows a normal grain size effect (Ref 115).

At low values of  $\Delta\varepsilon_{pl}/2$ , the CSS curves of copper single crystals and polycrystals coincide if the Sachs orientation factor is applied (Ref 80, 97). This is easily understood, because single slip prevails in the low-amplitude region. However, with increasing values of  $\Delta\varepsilon_{pl}/2$ , secondary slip starts early in polycrystals. This gives rise to high stress amplitudes, which correspond to region C of single crystals at much higher shear strain amplitudes. Hence, the application of the Taylor factor leads to a reasonable "average" transformation of single-crystal to polycrystal data (Ref 116).

In view of the fatigue cracks that result from the action of PSBs, it is interesting that the lower limit of the existence of PSBs in polycrystals can be estimated by using the Sachs or the Schmid factor to convert single-crystal data (i.e., the transition from region A to region B).

In the case of wavy-slip material, the characteristic dimensions of the dislocation arrangement are in unique relation to the loading amplitude. At sufficiently high amplitudes the mean diameter of the cells,  $d_c$ , existing in cyclic saturation serves as a geometric quantity. In 1966, Pratt showed in experiments at room temperature (Ref 117) and at the temperature of liquid nitrogen (Ref 118) that the saturation stress amplitude of polycrystalline copper is inversely proportional to  $d_c$ . Since then, this finding has been confirmed for many other metals and alloys (e.g. Ref 119, 120, 121).

Figure 21 represents this relation in the form:

$$\frac{\sigma_s - \sigma_F}{E} \propto \frac{b}{d_c} \quad (\text{EQ 15})$$

where  $\sigma_F$  denotes the stress that must be exceeded to overcome the friction of the dislocations in the crystal lattice (friction stress) and  $b$  is the length of the Burgers vector. The values of  $b$  and  $E$  are used in Eq 15 to apply this relation to different materials and temperatures.

FIG. 21 RELATION BETWEEN CELL DIAMETER AND NORMALIZED SATURATION STRESS AMPLITUDE. SOURCE: REF 121

Figure 21 shows some results of monotonic tests. This indicates that Eq 15 is not restricted to cyclic loading only. However, the establishment of an equiaxed cell structure under monotonic loading normally requires large plastic strains or high temperatures (e.g., Ref 122).

At small values of  $\Delta\epsilon_{pl}/2$ , the mean cell diameter cannot be used as the characteristic quantity of the dislocation structure, because cells do not form or exist in a few grains only. Then a relation similar to Eq 15 holds under single-slip conditions, if the width of the channels in the bundle/vein structure and the distance between the walls in the PSBs are used instead of  $d_c$  (e.g., Ref 123, 124, 125).

### Secondary Cyclic Hardening (fcc, Wavy Slip)

Cyclic deformation of a metallic material starting from a dislocation-poor (annealed) condition gives rise to a hardening that merges into cyclic saturation. As mentioned above repeatedly, the dislocation arrangement of saturation condition is considered to be in a quasisteady state; that is, no changes can be observed with cycle number. As a consequence, the CSS response (hysteresis loop shape and dimensions) remains constant.

A more detailed analysis of the deformation behavior indicates that a state of cyclic saturation does not exist in the strict sense. During cyclic saturation, minor microstructural processes take place that lead to a gradual change of the dislocation structure. If this change is observable by an increase of  $\Delta\sigma/2$  in the cyclic hardening curve, a "secondary cyclic hardening" occurs. Its existence depends mainly on whether this rise (starting from  $\sigma_s$ ) begins earlier than fatigue failure occurs.

Figure 22 shows two cyclic deformation curves of polycrystalline copper measured at  $\Delta\epsilon_{pl}/2 = 5 \times 10^{-4}$ . The curves were obtained in air and vacuum, respectively. Because the crack formation occurs normally at the surface and is affected by the surrounding environment, tests in vacuum lead to prolonged cyclic life and may give the opportunity to observe processes that take place at cycle numbers above  $N_f$  in air. The lifetime extension in Fig. 22 approximately corresponds to a factor of 10. The course of the curves is identical up to the number of cycles to fracture in air. Various studies on the development of dislocation arrangement and the degree of surface coverage with PSBs have proved that the environment has no influence, provided that samples are compared that have been cyclically loaded up to the same cycle number in air and in vacuum (e.g., Ref 100, 101, 106, 126, 127, 128).

**FIG. 22 CYCLIC DEFORMATION CURVE OF POLYCRYSTALLINE COPPER (MEAN GRAIN SIZE 55  $\mu\text{M}$ ) IN AIR AND IN VACUUM. SOURCE: REF 106**

The increased cyclic lifetime in vacuum in Fig. 22 enables the detection of secondary cyclic hardening, which means that after the plateau (corresponding to cyclic saturation) the stress amplitude steadily increases again. At the amplitude considered in Fig. 22, the drop of  $\Delta\sigma/2$  in air, which occurs shortly before failure due to crack propagation, coincides with the beginning of secondary hardening (observable in vacuum). At higher amplitude, secondary hardening can also be found in air, because the stress amplitude starts to rise at cycle numbers less than  $N_f$  in air.

The microstructural processes responsible for secondary cyclic hardening have been studied best on single crystals (Ref 126, 127). When a single crystal is deformed in region B of the CSS curve (Fig. 12), the primary ladder structure of the PSBs hardens by a gradual increase of the density of secondary dislocations. Contrast experiments in TEM have documented that secondary dislocations are preferentially pinned at the boundary between PSBs and matrix. The local shear strain amplitude is continuously decreased and the PSBs are gradually transformed into a cell structure. The hardening of PSBs forces the formation of new PSBs in the matrix. This leads to increasing coverage of the surface with PSBs. The process continues until the specimen fails or a cell structure exists throughout the whole volume.

Secondary cyclic hardening is responsible for a passivation of PSBs, which can be found if a test is interrupted at certain numbers of cycles and a surface layer is removed each time by polishing. Some formerly active PSBs no longer form slip traces at the surface, but additional new PSBs are initiated. This process may give the appearance of slip homogenization in vacuum (compared to air) if failed samples are studied, but it is simply a consequence of the different cyclic life in air and vacuum (Ref 106, 126, 127, 128, 129).

The microstructural processes that take place in polycrystals are basically identical to those discussed thus far, but they are hard to quantify due to the heterogeneity of the dislocation arrangement. It is typical of specimens that have undergone secondary cyclic hardening that a cell structure prevails and that almost no matrix structure exists, whereas in specimens that were cyclically loaded up to a cycle number before the onset of secondary hardening, a high portion of single-slip arrangements can be found. This observation is in accord with studies on alloys (Ref 130, 131) in which secondary hardening was observed only when "transformable" dislocation structures (Ref 131) were completely converted into "nontransformable" arrangements.

The description given above indicates that the term *cyclic saturation* must be used with care. Obviously, even during cyclic deformation in the saturation state, a continuous small deviation from a steady-state deformation process exists, leading under certain circumstances to a hardening by means of a cumulative process. This behavior can be understood if the dynamic equilibrium between dislocation multiplication and annihilation is considered, which is required for a steady-state cyclic deformation. The primary dislocations quickly reach a high density during initial hardening, so that a dynamic equilibrium can be established. In comparison, the formation of secondary dislocations at low plastic-strain amplitudes is a slow process, and the secondary dislocation density is too low to cause steady-state conditions.

## Cyclic Stress-Strain Response and Microstructure

Hans-Jürgen Christ, Universität-GH-Siegen

---

## fcc Metals With Planar Slip

The idea that planar slip results from the presence of short-range order seems to be at least a promising starting point for a necessary improvement of the classical textbook statement that planar dislocation slip takes place in materials of low stacking-fault energy (due to a reduced ability of screw dislocations to cross slip).

As a rule of thumb, the cyclic deformation behavior of alloys is similar to that of the base metal in a relatively wide range of composition. Only at high concentrations of alloying elements do significant deviations exist. Typical planar-slip materials are Cu-Al alloys, Cu-Zn ( $\alpha$ -brass, e.g., Ref 132) and some austenitic stainless steels at low amplitudes (e.g., Ref 133).

Very fundamental studies on the microstructural development in planar-slip materials were conducted by Feltner and Laird (Ref 27, 31), who compared copper with a Cu-Al alloy of 7.5% Al. In a planar-slip alloy, dislocations are localized in discrete bands between which relatively dislocation-poor regions exist. These bands form parallel to the primary slip plane and contain mainly parallel edge dislocations of the primary slip system. If the plastic-strain amplitude is raised, the dislocation density increases and the distance between the bands decreases. Even at very high values of  $\Delta\varepsilon_{pl}/2$  (corresponding to  $N_f < 10^4$ ), no cell formation can be observed.

The alloy system Cu-Zn ( $\alpha$ -brass) was studied by Lukáš and Klesnil in the early 1970s (Ref 28, 29, 30), who applied loading amplitudes to single crystals that corresponded to numbers of cycles to fracture in the range between  $4 \times 10^4$  and  $4 \times 10^6$ . Whereas  $\alpha$ -brass containing 15% Zn showed a behavior very similar to that of pure copper, brass with 31% Zn exhibited planar-slip behavior. TEM micrographs of foils cut parallel to the primary slip plane showed long segments of primary dislocations predominantly of edge character (Fig. 23). In  $(1\bar{2}1)$  sections (i.e., perpendicular to the slip plane and parallel to the slip direction of the primary slip system), the localization of the dislocations in single active slip planes was visible. In contrast to copper, there were no detectable differences between regions near the surface and those in the interior of the material.

**FIG. 23 DISLOCATION ARRANGEMENT IN A SECTION PARALLEL TO (111) OF A 69CU-31ZN ALLOY ( $\alpha$ -BRASS). SOURCE: REF 29**

Since these first systematic works, the alloy system Cu-Al has been the subject of investigations in many studies (e.g., Ref 134, 135, 136). Many efforts have been made to adjust the slip character specifically by means of the aluminum content. Regarding the short-range order as a possible origin of planar-slip behavior, Abel et al. (Ref 134, 136) observed that strain bursts occur in alloys with an aluminum content higher than 7%. These maxima of slip differ from those shown in Fig. 18, in that they are not formed during ramp loading but at constant amplitude and are less pronounced in the cyclic deformation curve. As a possible interpretation, strain bursts can be considered to occur as a result of a local destruction of short-range order by gliding dislocations. This leads to a softening of individual slip planes along which dislocations emitted from an active dislocation source can glide easily. As a consequence, the appearance of new slip bands/lines at the surface is connected with the occurrence of these strain bursts and changes in the shape of the hysteresis loop.

In newer studies on Cu-16Al (Ref 137, 138, 139), these fluctuations in the cyclic deformation curve were confirmed in single crystals as well as in polycrystals. The results obtained on single crystals indicate a (small) plateau in the CSS curve, which might result from a strain localization in slip bands (analogous to the behavior of wavy-slip single crystals). However, due to the slow cyclic hardening typical of planar slip, it is questionable whether a stabilized condition can be reached at all and whether therefore only approximately constant values of  $\Delta\sigma/2$  at only a few amplitudes of plastic strain can be interpreted as a plateau of cyclic saturation.

The plastic deformation is almost completely localized in small bands, as proven by interferometric surface observations (Ref 137). These bands are termed persistent Lüders bands (PLB). The dislocation arrangement in a PLB is shown schematically in Fig. 24 and differs fundamentally from that in a PSB (Fig. 15b). PLBs are about 3 to 5  $\mu\text{m}$  thick and are oriented parallel to the slip plane. They consist of neighboring planes that are fully packed with dislocations. In addition, secondary dislocations exist which cut the groups of primary dislocations while gliding on their slip planes. The local dislocation density within a PLB varies strongly.

FIG. 24 SCHEMATIC REPRESENTATION OF DISLOCATION ARRANGEMENT IN A PERSISTENT LÜDERS BAND. SOURCE: REF 43

Due to the lack of systematic studies of different planar-slip alloy systems, it is not known whether the formation of PLBs is a specific feature of the Cu-Al system or a general property of planar-slip materials. However, observations in the Cu-Zn (brass) system (Ref 140) document a considerable parallelism.

### bcc Metals and Alloys

**Influence of Temperature and Strain Rate.** The aforementioned fatigue mechanisms seem to have good applicability to hexagonal close-packed (hcp) materials (e.g., Ref 141, 142) and to almost all technical bcc alloys (e.g., Ref 143). Therefore, the following discussion refers to differences and particularities in the cyclic deformation behavior and in the basic dislocation processes of the bcc crystal structure with respect to fcc metals and alloys. The conditions under which a deviant behavior exists need to be considered carefully (more detailed information is given in Ref 46 and 144).

The mechanical properties of pure bcc metals depend very strongly on temperature and strain rate and are sensitive to small amounts of interstitial impurities (such as carbon, nitrogen, and oxygen). In Fig. 25, a schematic representation of the temperature dependence of the flow stress,  $\tau_f$ , is shown. According to Seeger (Ref 145),  $\tau_f$  consists of a thermal component,  $\tau^*$ , and an athermal component,  $\tau_G$ :

$$\tau_F = \tau_G + \tau^*(\dot{\epsilon}_{PL}, T) \quad (\text{EQ 16})$$

**FIG. 25** DEPENDENCE OF FLOW STRESS ON TEMPERATURE AND STRAIN RATE IN THE CASE OF BCC CRYSTAL STRUCTURE. SOURCE: REF 144, 145

As indicated in Eq 16,  $\tau^*$  depends on temperature and plastic strain rate,  $\dot{\epsilon}_{pl}$ , and is essentially a consequence of the extended core structure of the screw dislocations, which has a threefold symmetry and is the reason for a large pseudo-Peierls stress. Therefore,  $\tau^*$  is caused mainly by lattice friction stress for screw dislocations, whereas in the fcc structure  $\tau^*$  is determined by the dislocation/dislocation interaction. The gliding of the screw dislocations occurs by thermal activation, giving rise to the strong temperature dependence of  $\tau^*$ .

The athermal stress component  $\tau_G$  is usually considered to be connected with the dislocation density,  $\rho$ :

$$\tau_G = \alpha G B \sqrt{\rho} \quad (\text{EQ 17})$$

where  $\alpha$  is a geometric constant ( $\alpha \approx 0.1 \dots 0.4$ ) that depends on the dislocation arrangement. The origin on  $\tau_G$  is the elastic interaction of dislocations during deformation.

An increase in  $\dot{\epsilon}_{pl}$  has basically the same effect as a decrease in temperature, and vice versa. The transition temperature  $T_0$  (Fig. 25), which defines the boundary between the high-temperature and the low-temperature behavior, is shifted to higher temperatures if the deformation rate increases.

A very illustrative example, in which the flow stress of  $\alpha$ -Fe is affected by a change of the plastic strain rate, has been given by Mughrabi (Ref 15, 146). Figure 26 shows the course of the (controlled) plastic strain signal used in this study. Based on the triangular course of  $\epsilon_{pl}$  in Fig. 26(a), which keeps the (absolute) value of  $\dot{\epsilon}_{pl}$  constant during the test, the strain rate is changed within each cycle. For this purpose the slope of the demand signal is increased or decreased shortly before the reversal points are reached. As a result, one restricts the changed plastic strain rate  $\dot{\epsilon}_{pl,2}$  to a small time interval around the load reversals, whereas during the main part of the cycle,  $\dot{\epsilon}_{pl,1}$  continues to exist.

FIG. 26 CHANGES OF PLASTIC STRAIN RATE WITHIN EACH CYCLE. SOURCE: REF 146

The resultant change in the shape of the hysteresis loop can be seen in Fig. 27. According to Fig. 25, an increase of  $\dot{\epsilon}_{pl}$  leads to an increase of the stress, and vice versa. The shape of the hysteresis loop in the part of the cycle where  $\dot{\epsilon}_{pl}$  remains unchanged is not affected, indicating that the very short intervals with changed values of  $\dot{\epsilon}_{pl}$  do not alter the dislocation arrangement. Therefore, this testing method is an elegant way to determine the dependence of  $\tau^*$  on  $\dot{\epsilon}_{pl}$  (and  $T$ ) without changing  $\tau_G$  at the same time (Ref 147).

**FIG. 27** HYSTERESIS LOOPS WITH CHANGES OF  $\dot{\epsilon}_{pl}$ , OBTAINED ON HIGH-PURITY POLYCRYSTALLINE  $\alpha$ -FE. SOURCE: REF 15

The marked temperature dependence of the peak stress in Fig. 27 is due to the fact that cyclic deformation has been carried out in the low-temperature region of Fig. 25. This is a consequence of the rather high strain rate usually applied in a typical fatigue test (e.g.,  $\dot{\epsilon} \approx 10^{-2} \times s^{-1}$ ). Under this condition, the temperature  $T_0$  is shifted to values above room temperature. In other words, the cyclic deformation behavior of pure bcc metals is governed essentially by the low-temperature deformation mode. This mode is characterized by a large difference in the relative mobilities of screw and nonscrew (edge) dislocations. As a consequence of the pseudo-Peierls stress for the screw dislocations, their mobility is very limited.

A sufficiently small plastic-strain amplitude can be accommodated by a quasi-reversible to-and-fro displacement of the more mobile non-screw segments while the screw segments are only stretched and do not move. In this region of cyclic microyielding, no microstructural changes take place and no cyclic hardening is noticeable. The CSS curve reflects this behavior by exhibiting a small plateau at low plastic-strain amplitudes.

If the material is subjected to an intermediate or high plastic-strain amplitude, the lack of mobile (primary) dislocations causes early secondary (multiple) glide. The more mobile edge dislocations draw out long screw dislocations. If the temperature is not too low, these screw dislocations are at least sufficiently mobile to interact and form cell structures. Consequently, there is a high tendency to form a cell structure at relatively small (compared to fcc metals) plastic-strain amplitudes.

If the screw dislocations are forced to glide in this low-temperature, high-amplitude regime, the threefold symmetry of the core structure leads to an asymmetric slip in tension and compression. In other words, slip occurs on different planes during tension and compression in each fatigue cycle, leading to a change in shape. In the case of a single crystal, an initially circular cross section becomes elliptical (Ref 148, 149, 150, 151). The shape changes also play an important role

in the fatigue failure of bcc polycrystals. In contrast to the constrained grains in the interior, the surface grains can develop shape changes due to asymmetric slip rather freely. A surface roughness results, with the periodicity of the grain structure leading to incompatibilities and stress concentrations at the grain boundaries. These stress concentrations give rise to crack initiation at these loci, along with a remarkable tendency to the development of intergranular cracks.

The behavior of bcc metals in the high-temperature regime (i.e., high temperature and/or low strain rate) is quite similar to that of fcc metals. From an engineering point of view, it is important to note that small amounts of interstitial atoms enhance this tendency. Obviously, the effect of interstitials on the mobility of edge dislocations leads to a kind of balancing of the velocities of edge and screw dislocations. Under these circumstances (i.e., high-temperature behavior), PSBs have been observed that appear as dislocation-poor channels embedded in a matrix of veins (Ref 46, 144). PSBs are also known to form in both the surface and interior grains of polycrystalline low-carbon steels (Ref 152).

In summary, the cyclic deformation behavior of technical bcc metals and alloys is mostly very similar to that of wavy-slip fcc materials.

**Dynamic Lüders Band Propagation.** In any discussion of the CSS behavior of bcc metals and alloys, the phenomenon of dynamic Lüders band propagation must be considered, because it clearly relates the macroscopic deformation behavior to processes occurring on the atomic scale. It is well known that a large number of structural alloys exhibit discontinuous yielding in monotonic straining. This is typical for bcc metals containing interstitial atoms and showing distinguished upper and lower yield stresses in the monotonic stress-strain curve. Normalized low-carbon steels are probably the most important alloy system in this context.

The occurrence of Lüders band propagation under cyclic loading conditions depends very strongly on the testing mode applied. In the case of plastic strain control, the sample is forced to plastically deform up to the amplitude value of the control signal during the first quarter of the first cycle (where a quarter cycle is the same as a tensile test with Lüders band propagation). After the first or first few cycles, a homogeneous plastic deformation of the gage length prevails. The situation is even more definite if in a stress-controlled test a stress amplitude higher than the yield point is applied. Then, in order to reach this stress amplitude, the whole region of Lüders strain must be passed through completely within the first load increase up to the stress amplitude.

From a technical point of view, the case is far more interesting when the stress amplitude is lower than the yield point. In Fig. 28, the cyclic deformation curves obtained in a study on a normalized steel containing 0.45% C (with yield point between 420-440 MPa) are represented in a plot of the plastic-strain amplitude versus the number of cycles for different stress amplitudes. It can be seen that during the first cycles the material behaves almost purely elastically ( $\Delta\varepsilon_{pl}/2 \approx 0$ ). After a certain cycle number, which depends on the stress amplitude applied, plastic deformation begins. The cyclic softening leads to a marked increase of  $\Delta\varepsilon_{pl}/2$ , which occurs earlier at high stress amplitudes. After deformation passes through a maximum of  $\Delta\varepsilon_{pl}/2$ , a continuous cyclic hardening follows.

FIG. 28 CYCLIC DEFORMATION CURVES OF A NORMALIZED STEEL CONTAINING 0.45% C AT VARIOUS STRESS AMPLITUDES. SOURCE: REF 153

The course of the curves depicted in Fig. 28, which is typical of normalized low-alloy steels under stress control (e.g., Ref 154, 155), can be described quantitatively on the basis of the microstructural processes in reasonable agreement with the experimental observations (Ref 156, 157). Qualitatively, the shape of the curve can be explained as follows. During the first half cycle, a small number of dislocations are unpinned in individual isolated grains. This process is repeated during the following cycles and leads to an increase of the number of mobile dislocations. Hence, the material is in a plastically inhomogeneous condition, because besides the plastically deforming grains there are those that behave essentially elastically. The steady increase of the volume fraction of regions containing mobile dislocations leads to an increase in  $\Delta \epsilon_{pl}/2$ . In these regions, the processes taking place are typical of the cyclic deformation of wavy-slip materials (i.e., dislocation multiplication and the formation of a heterogeneous dislocation arrangement). The resultant local cyclic hardening dominates when its effect is no longer overcompensated by the formation of new plastically deformable regions. The maximum in the cyclic deformation curve corresponds in a reasonable approximation to the condition in which for the first time the whole gage length undergoes plastic deformation.

## Cyclic Stress-Strain Response and Microstructure

Hans-Jürgen Christ, Universität-GH-Siegen

---

## Cyclic Deformation in Structural Alloys

The role of microstructure in the cyclic deformation of structural alloys depends, to a large extent, on the operative strengthening mechanism. For example, ferrite-pearlite structural steels are (at least) two-phase materials because they contain pearlite ( $\alpha$ -Fe + Fe<sub>3</sub>C). Nevertheless, carbon steels can be treated as "quasi-single-phase," because plastic deformation processes are almost completely restricted to the ferritic grains up to a carbon content of about 0.45% (Ref 154). In this case, the second phase does not have a pronounced effect on deformation mechanisms. In contrast, age-hardenable alloys are very dependent on a second phase for increased strength. The effect of strengthening particles on the cyclic deformation is addressed briefly in this section after discussion of deformation-induced phase transformation. Selected examples, which illustrate marked phase transformations caused by cyclic plastic deformation, are described for some metastable alloy systems that are prone to phase transformations. The mechanisms depend very strongly on the particular material, and therefore a comprehensive discussion is far beyond the scope of this article. Nonetheless, the two examples below provide some insight into phase transformation effects on the CSS response.

## Deformation-Induced Transformations

**Austenitic Strainless Steels.** Phase transformations during cycling have been studied particularly carefully in steels where austenite-martensite transformations occur. Cyclic-deformation-induced martensitic transformation is beneficial in high-strength TRIP (transformation-induced plasticity) steels and in lower-strength metastable austenitic stainless steels, depending on the testing mode and the amplitude. The following example describes deformation-induced martensite formation in an austenitic stainless steel.

At sufficiently low temperatures (below the martensite start temperature,  $M_S$ ) a spontaneous martensitic transformation takes place. This temperature limit can be raised by means of elastic stresses or plastic deformation, which induce an additional driving force. The threshold temperature for deformation-induced transformation is termed  $M_d$ .

Figure 29 shows the stress-strain path of the first 30 cycles of an austenitic stainless steel deformed under plastic-strain control with  $\Delta\epsilon_{pl}/2 = 1.26 \times 10^{-2}$ . The test was carried out at 103 K in order to promote martensite formation. The stress amplitude increased strongly, whereas the hardening rate decreased slowly. The maximum stress amplitude was reached after about 40 cycles. The marked cyclic hardening was mainly due to deformation-induced martensitic transformation of austenite, which has been investigated in several steels of the 300 series (Ref 159, 160, 161, 162, 163, 164, 165, 166, 167).

FIG. 29 STRESS-STRAIN PATH OF THE FIRST 30 CYCLES AT 103 K OF A METASTABLE AUSTENITIC STAINLESS STEEL UNDER PLASTIC-STRAIN CONTROL ( $\Delta\epsilon_{PL}/2 = 1.26 \times 10^{-2}$ ). SOURCE: REF 158

The formation of  $\alpha'$ -martensite can occur directly from austenite or via the intermediate phase  $\epsilon$ -martensite. The transformation starts if a threshold value of the plastic-strain amplitude is exceeded and a certain cumulative "incubation" plastic strain (which increases with decreasing amplitude) is reached. In the case of the alloy corresponding to Fig. 29, it could be shown unambiguously that the martensite forms as a result of cyclic plastic deformation (i.e., deformation-induced and not stress-induced), because quenching (even down to the temperature of liquid helium) and purely elastic cyclic loading did not trigger austenite transformation.

The increase of  $\Delta\sigma/2$  shown in Fig. 29 can be attributed directly to an increase in the volume fraction of martensite, as shown by independent measurements of the martensite content. The negative mean stress  $\sigma_m$  that develops during cycling stems from the volume expansion (the martensite formation is connected with a volume expansion of about 2%). It is interesting to note that by means of an optimized low-temperature cyclic predeformation, the residual room-temperature fatigue life can be improved by a factor of almost 2.

**Commercial Age-Hardened Aluminum Alloy.** Figure 30 shows various cyclic deformation curves obtained on an aluminum alloy in three different conditions (Ref 168). The material studied is a commercial age-hardenable aluminum alloy (corresponding to aluminum alloy 7022) that was heat treated prior to fatigue testing in three different ways: to obtain a precipitate-free condition, a peak-aged precipitation structure, and an overaged condition. Surprisingly enough, in the initially precipitate-free condition the stress amplitude increased drastically during cyclic deformation and exceeded even the corresponding values of the peak-aged condition after sufficiently high cumulative plastic strain. The gain in strength took place at the expense of cyclic lifetime.

**FIG. 30 CYCLIC DEFORMATION CURVES OF THREE CONDITIONS OF AN AL-ZN-MG-0.5CU ALLOY AT VARIOUS VALUES  $\Delta\epsilon_{pl}/2$ . SOURCE: REF 168**

An interpretation of the mechanical behavior can be given on the basis of corresponding TEM studies. In Fig. 31(a), the microstructure of the quenched condition is shown as it exists prior to cyclic deformation. Particles of the hardening second phase are not detectable. Only the relatively large dispersoids are present, because they cannot be dissolved during the solution annealing. The reason for the tremendous increase of  $\Delta\sigma/2$  during cycling becomes evident in Fig. 31(b). Even at the lowest value of  $\Delta\epsilon_{pl}/2$  used, very small and uniformly distributed precipitates are formed that interact very strongly with the moving dislocations. The TEM micrographs indicate that particle cutting is the most important deformation mechanism. The deformation-induced precipitation is more pronounced with higher values of  $\Delta\epsilon_{pl}/2$ . Similar cyclic-induced precipitation processes have been reported to occur in other aluminum alloys (e.g., Ref 169, 170).

### Cyclic Stress-Strain Response and Microstructure

Hans-Jürgen Christ, Universität-GH-Siegen

---

### Effect of Second-Phase Particles

Precipitation hardening is an important and commonly used method to raise the strength of alloys. The particles of a second phase act as obstacles to the dislocation motion and markedly influence the dislocation arrangement compared to the precipitate-free situation. The large number of precipitation-hardening alloy systems and the broad range of possible dislocation-particle interactions make a general and uniform summary beyond the scope of this article. Therefore, this section focuses on the underlying mechanisms and tries to illustrate the main effects in selected alloy systems. More detailed information can be found in numerous review articles (e.g., Ref 171, 172, 173).

The most important parameters determining particle-dislocation interaction are the size and distance of the precipitates. If the strengthening particles are coherent, small, and close-spaced, they are cut by dislocations as a result of the resolved shear stress. This process is typical of underaged alloys. Overaging leads to a relatively large particle diameter (in combination with a large mean particle distance in the slip plane) at which dislocation motion between the obstacles by the Orowan mechanism (bowing out of the dislocations and finally forming Orowan dislocation loops around the precipitates) is favored. The same is true if the particles are incoherent (e.g., dispersoids).

## Single-Crystal Alloys

**Shearable Precipitates.** Systematic studies of the effect of particle strengthening on fatigue behavior have been carried out, especially in the systems Al-Cu (e.g., Ref 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187) and Cu-Co (e.g., Ref 188, 189, 190, 191, 192). Al-Cu alloys are very well suited to these investigations, because the precipitation behavior, the sequence of the phases forming, and the resultant effects on monotonic properties are well known (e.g., Ref 193). Furthermore, in Cu-Co a condition of solid solution can be established as a reference state that exhibits the dislocation arrangement of copper reasonably well.

If particle-strengthened single crystals are subjected to a cyclic deformation at constant plastic-shear amplitude, first a cyclic hardening up to a maximum of the shear stress amplitude is found, followed by a marked softening. This behavior is observed in a wide range of  $\gamma_{ap}$  values. A state of cyclic saturation is not established in air (but is sometimes found in vacuum as a consequence of an extended lifetime), so that a CSS curve cannot be determined according to its definition. Following a suggestion of Wilhelm (Ref 194), a pseudo-CSS curve can be constructed, taking the maximum values of  $\tau_a$  instead of the saturation values  $\tau_s$  for those plastic shear strain amplitudes at which no cyclic saturation is reached.

Figure 32 shows the corresponding representation for Al-3.8Cu. Analogous to the CSS curve of copper (Fig. 12), three regions A, B, and C can be distinguished, and region B defines a marked plateau. Whereas in region A a state of cyclic saturation is reached, in region B the above-mentioned pronounced maximum in the cyclic deformation curve is observed. Therefore, the values of  $\tau_a$  represented are essentially higher than the true saturation stress amplitudes. The reason for the plateau stress lies in the tremendous change in the dislocation arrangement that takes place during the initial phase of hardening, shortly before the maximum of  $\tau_a$  is reached. PSBs are formed which, however, differs essentially from those observed in pure metals and single-phase alloys. These PSBs are very thin ( $<0.1 \mu\text{m}$ ), and they can carry large local plastic strains of 30 to 60% (Ref 181). The volume fraction of PSBs increases with increasing  $\gamma_{ap}$  in region B, but a value of 100% is never reached. In contrast to single-phase wavy-slip materials, no cell structures are formed in region C. Rather, PSBs exist in different intersecting slip systems.

FIG. 32 PSEUDO-CSS CURVE OF AL-3.8CU SINGLE CRYSTALS CONTAINING SHEARABLE PRECIPITATES. SOURCE: REF 179

The pronounced cyclic softening (in region B), which is undesirable in technical applications, is caused by the destruction of the strengthening effect of the particles within the PSBs as a result of particle shearing. If the precipitates are not ordered, as is the case in Cu-Co, the repeated cutting of the particles by the to-and-fro motion of dislocations may ultimately lead to a complete redissolution when the particles become too small to be stable. This random chopping-up process has been reproduced by computer simulation (e.g., Ref 195). The dislocation slip character can be considered wavy. This is also confirmed by the width of the PSBs formed (about  $0.1 \mu\text{m}$ ).

Especially the ordered  $\gamma'$  precipitates in superalloys suffer shearing by planar slip bands that consist of only one or few slip planes (e.g., Ref 196). These planar bands result from a local softening along active slip planes, which itself is a consequence of a reduction in strength of the sheared particles due to the loss of order.

In Al-Cu, Laird et al. (Ref 180, 176) did not find destruction of the particles within the PBSs. The contrast provided by the slip bands in TEM could be attributed to an orientation difference between PSBs and the surrounding matrix. By slightly tilting the sample in the microscope, the precipitates in the PSBs could be detected again. This observation led to the interpretation that the loss of order within the  $\theta''$  particles is responsible for softening. However, in other aluminum alloys a redissolution of the ordered precipitates within the PSBs has been proven to occur (e.g., Ref 197).

Cyclic plastic deformation can also strongly affect the kinetics of precipitation and the coarsening processes, due to the high point defect concentrations connected with dislocation reactions. Therefore, processes such as overaging or Ostwald ripening may occur in an accelerated manner, especially if areas of strain localization exist. In many aluminum alloys, aging processes take place at room temperature, leading to a particle size distribution that is a strong function of time and affects the CSS response.

**Non-shearable Particles.** With increasing overaging, cyclic hardening with subsequent softening ceases, and a cyclic saturation state is established. In this case, the CSS behavior depends much more strongly on the crystal orientation than in the situation when shearable particles are present (Ref 183). The strain is not localized, because the relatively coarse precipitates reduce the slip length and prevent the formation of PSBs. Therefore, a plateau in the CSS curve is not observed. Furthermore, cyclic softening, which must be considered a consequence of strain localization, does not occur.

At small and moderate strain amplitudes, the dislocation arrangement in Al-Cu consists of dipolar walls that are formed mainly from primary dislocations and are located at the broad sides of the  $\theta'$  plates. With increasing amplitude the portion of secondary dislocations in the networks surrounding the  $\theta'$  plates increases. The  $\theta'$  plates form the basic skeleton of the dislocation arrangement.

Because cutting of particles does not take place, the precipitation structure is quite stable during cyclic loading. As a consequence, changes in test frequency or test interruptions have only minor influence on the CSS behavior (e.g., Ref 184, 185).

## Pure Polycrystals

The results obtained on precipitation-hardened single crystals can be transferred to polycrystals provided that these materials are pure (i.e., that they contain only elements necessary to form the hardening second phase). In addition to the orientation differences between the grains of a polycrystal, the grain boundaries themselves influence the deformation behavior, because the precipitation conditions in the vicinity of grain boundaries can be different from those in the matrix.

In Fig. 33, cyclic deformation curves are depicted that were measured on Al-4Cu polycrystals by Calabrese and Laird (Ref 176, 177, 178) using three different precipitation states. In the case of shearable coherent  $\theta''$  particles (Fig. 33a), a curve is found that exhibits a maximum and resembles that of the corresponding single crystals. The initial hardening is attributed to an increase of the friction stress due to the coherent stress fields of the precipitates, the formation of anti-phase boundaries during cutting, and mainly the occurring dislocation accumulation. Even before the stress maximum is reached, slip bands are visible on the surface that are formed first in favorably oriented grains. These surface bands correspond to the deformation bands (PSBs) that could be found in the grain interior by means of TEM. The cyclic softening can (in the case of Al-Cu) be traced back to the disordering of the ordered precipitates due to the repeated cutting by dislocations within the PSBs.

(b)

(c)

FIG. 33 CYCLIC DEFORMATION CURVES OF POLYCRYSTALLINE AL-4CU IN DIFFERENT CONDITIONS. (A)  $\theta''$ . (B) FINE  $\theta'$ . (C) COARSE  $\theta'$ . SOURCE: REF 176, 177, 178

The cyclic deformation curves of the conditions with nonshearable particles (Fig. 33b, c) are fundamentally different. At small values of  $\Delta\epsilon_{pl}/2$ , cyclic saturation occurs almost immediately; at high values it occurs after few cycles. Monotonic and CSS curves are approximately identical, indicating the stability of the precipitation condition and the dominant role of the precipitates regarding the deformation behavior. This is confirmed by the results of accompanying TEM studies. The particles are the dominant obstacles to dislocation motion as long as the amplitude is not too high. Dislocations are preferentially located at the phase boundary particle/matrix. The plastic strain can be accomplished by the slip of only a few dislocations between the particles, because the "mean cell size" is determined by the small distance between the precipitates.

If a high loading amplitude is applied to a material with relatively large particle distance, a real cell formation can occur. In other words, additional dislocation walls form between the precipitates. The saturation stress amplitude is determined by the same mechanisms that prevail in single-phase alloys. Dislocations bow out from the cell walls, cross the dislocation-poor cell interior, and react with the opposite wall. Therefore, the deformation behavior of the dislocation cell structure gains importance with increasing  $\Delta\epsilon_{pl}/2$ .

The question of whether there is a plateau in the CSS curve of polycrystals containing shearable particles, as found in the pseudo-CSS curve of corresponding single crystals (Fig. 32), was checked in a study on Al-Cu with three different grain sizes (0.15, 0.32, and 1 mm) (Ref 182). Only the coarsest grain structure led to a very small plateau. With decreasing grain size, the behavior deviated more and more from that of single crystals, in accordance with the expectations based on the observations on single-phase materials.

Grain boundaries can be of significance for the distribution of precipitates, leading to a modification of the particle population. Usually relatively coarse particles precipitate on grain boundaries, whereas in the vicinity of grain boundaries, precipitate-free zones may exist. These areas are mechanically softer than the grain interior, so that localized deformation is promoted. A preferential crack initiation at these locations may result.

## Commercial Alloys

In more complex, commercial structural alloys, the fatigue properties (including both resistance against crack initiation and crack propagation) are a function of not only the precipitation condition but also the whole microstructure. For example, the effect of two microstructural features (shearable precipitates and precipitate-free zones) on fatigue resistance are summarized in Table 1. The effect of specific microstructural features on the fatigue properties depends on the degree of plastic-strain localization, which is primarily determined by the slip length and degree of age hardening. Because extensive age hardening and corresponding high yield strength are desirable in commercial alloys, emphasis often is placed on improving the fatigue life by reducing the slip length (reducing grain size, for example). Intermetallic inclusions, however, have mostly a negative influence. They are too large to affect the stress-strain behavior. Rather, they can cause cracks and therefore determine the cyclic lifetime.

**TABLE 1 EFFECT OF MICROSTRUCTURAL MODIFICATIONS ON THE FATIGUE RESISTANCE OF ALLOYS**

ALIGNMENT OF GRAIN BOUNDARIES	NO EFFECT	IMPROVES

Source: Ref 198

The relationship between microstructure and cyclic plastic-deformation behavior is known to be complex, especially for high-strength commercial alloys. It is clear, however, that any microstructural feature that causes an inhomogeneous distribution of plastic strain will have a deleterious effect on fatigue life. In general, a material that cyclically hardens will restrict cyclic plastic deformation, which is a desired effect. However, under strain control, the imposed strain in conjunction with the loss of ductility associated with the higher cyclic strength can lead to a poor low-cycle fatigue life.

The concept of reversible deformation also may not be applicable in complex, commercial alloys. As described above, slip reversibility is a desirable property for fatigue resistance. Planar-slip alloys, with fine, narrow slip bands, are more resistant to fatigue than wavy-slip materials, in which coarse slip bands lead to early crack initiation. Planar slip increases the reversibility of deformation and thus improves the fatigue resistance for some low-stacking-fault-energy materials. However, in commercial alloys strengthened by dislocation substructures, precipitates, and carbides, planar slip can cause softening in the slip bands, resulting in strain localization. Consequently, slip reversibility may have little or no meaning in complex, engineering-type materials (Ref 198).

**Structural aluminum alloys** contain various alloying elements that are added, for example, to adjust the proper grain size or to improve the corrosion resistance. Typically the following types of precipitated phases can be found (Ref 172):

- THE MAIN STRENGTHENING SECOND PHASE IS PRECIPITATED IN THE FORM OF FINELY

DISTRIBUTED PARTICLES. THIS PHASE IS IN MOST CASES ORDERED AND COHERENT. THE SHAPE OF THE PARTICLES DEPENDS ON THE ALLOY SYSTEM; PARTICLES MAY BE SPHERICAL, PLATE-SHAPED, OR NEEDLE-SHAPED. NORMALLY THE DISTRIBUTION OF THESE PARTICLES IS UNIFORM, EXCEPT THAT PRECIPITATE-FREE ZONES FORM AT GRAIN BOUNDARIES.

- DISPERSOIDS ARE FORMED DURING COOLING-DOWN IN THE SOLID STATE, AND THEY CAN HARDLY BE DISSOLVED DURING THE HEAT TREATMENT THAT IS NECESSARY TO ADJUST THE PROPER MICROSTRUCTURE. THE MAIN ROLE OF THE DISPERSOIDS IS TO KEEP THE GRAIN SIZE SMALL BY AVOIDING RECRYSTALLIZATION AFTER FORMING AT HIGH TEMPERATURES.
- INTERMETALLIC INCLUSIONS GROW UP TO SEVERAL MICRONS. THEY ARE MOSTLY FORMED DUE TO IRON AND SILICON IMPURITIES IN ALUMINUM.

Besides the strengthening particles of the second phase, the dispersoids are important for the CSS behavior of technical alloys. Because they cannot be cut by the dislocations, they tend to prevent slip localization. This manifests itself by the lack of a pronounced softening region in the cyclic deformation curve (e.g., Ref 173). Cyclic lifetime is essentially prolonged, compared to that of pure alloys, as a result of the effect of dispersoids. A full discussion of the fatigue and fracture resistance of structural aluminum alloys is contained in the article "Selecting Aluminum Alloys to Resist Failure by Fracture" in this Volume.

## Cyclic Stress-Strain Response and Microstructure

Hans-Jürgen Christ, Universität-GH-Siegen

---

## Variables and Modeling

Cyclic stress-strain behavior and its relation with microstructure can be complex, because almost every structural alloy undergoes thermomechanical treatment prior to service. In order to classify the reactions of a material to predeformation or thermomechanical treatments, the terms *history dependence* and *history independence* are commonly applied. A history-independent CSS behavior means that after a transition stage a saturation condition is reached that is exactly the same as the saturation state established in a nonpredeformed (well-annealed) sample. Accordingly, a history-dependent material never reaches the saturation state of the corresponding annealed specimen, even after extended cycling.

---

## Cyclic Stress-Strain Response and Microstructure

Hans-Jürgen Christ, Universität-GH-Siegen

---

## Effect of Predeformation

**Set-Up and Control Effects.** The effect of predeformation on the CSS behavior is complicated by the fact that the application of a particular start-up procedure (e.g., frequency and/or choice of control mode) may affect the saturation state via the dislocation arrangement established (Ref 199, 200). As an example, the plateau stress amplitude of copper single crystals varies between 24 and 33 MPa, depending on how saturation is reached (Ref 48).

This influence on the CSS response occurs because of the different transient deformation behavior under different testing modes. Usually an initially annealed sample first undergoes cyclic hardening before the cyclic saturation state is reached. If plastic-strain control is applied,  $\Delta\varepsilon_{pl}/2$  is held constant during the test and cyclic hardening is moderate, because during the first few cycles the maximum (minimum) in plastic strain can be reached quite easily (i.e., at low load). Stress control, however, can force the sample in the first cycles (soft condition) to plastically deform tremendously in order to accomplish the given stress amplitude. Therefore, it seems reasonable to treat these first cycles as a special type of predeformation. As a consequence, somewhat different microstructural processes (e.g., a higher portion of secondary slip) can occur that give rise to an altered stabilized behavior.

Systematic studies on single-phase materials show (e.g., Ref 201) that the CSS curve, which represents the stabilized condition as a function of amplitude, does not depend on the control mode applied during single-step fatigue testing if the material exhibits wavy slip and the amplitude of testing is not too low. Especially in the case of planar-slip materials, appreciable deviation can be observed in the high-cycle fatigue range (i.e., at low amplitudes).

**Effect of Deformation History on Cyclic Deformation.** In order to characterize the history dependence of cyclic deformation behavior, mostly either a monotonic predeformation (e.g., Ref 202, 203, 204, 205, 206) or a reduction of the cross section by means of swaging (e.g., Ref 26, 31, 207, 208) is applied. These types of predeformation lead to a high flow stress, so that a cyclic softening occurs during the subsequent cyclic deformation.

Differences between wavy-slip and planar-slip materials are again important. Materials showing wavy dislocation slip exhibit a history-independent CSS curve at sufficiently high amplitudes of the plastic strain ( $\Delta\varepsilon_{pl}/2 \geq 5 \times 10^{-4}$  in the case of polycrystalline copper). In this region, the dislocation arrangements found after cyclic loading in specimens that were annealed prior to cycling are identical to those of predeformed samples. However, in the low-amplitude region, cold-worked and annealed samples do not show identical stress amplitude values in cyclic saturation established in tests where  $\Delta\varepsilon_{pl}/2$  is constant. Here, the dislocation arrangement resulting from predeformation is not completely changed to the low-amplitude fatigue configuration (Fig. 11), because the tensile deformation (or swaging) leads to a dislocation cell structure that cannot be converted into the single-slip structures typical of wavy-slip materials at low amplitudes.

In materials showing planar dislocation glide, the CSS curve is strongly influenced by predeformation in both the high-amplitude and the low-amplitude regions. In contrast to the mechanical behavior, the microstructure is not markedly affected and shows planar dislocation arrays located on distinct glide planes independent of the prehistory suffered.

The above results have been only partially confirmed by newer and probably more sensitive measurements (Ref 209, 210). Figure 34 shows cyclic deformation curves of  $\alpha$ -brass (planar slip) observed after monotonic predeformation in tension up to certain strains and after swaging down to a reduction in diameter of 27%. The behavior of the reference condition (annealed) is represented as a dotted line. In spite of the relatively high plastic strain range of  $5 \times 10^{-3}$  applied during cyclic loading, a history-dependent behavior is present, because the saturation stress amplitude depends strongly on the degree of predeformation. This is in accordance with the observations reported above (e.g., Ref 26, 31).

**FIG. 34** CYCLIC DEFORMATION CURVE OF  $\alpha$ -BRASS AT  $\Delta\varepsilon_{pl} = 5 \times 10^{-3}$  AS A FUNCTION OF THE DEGREE OF MONOTONIC (TENSILE) PREDEFORMATION. SOURCE: REF 209

However, deviations from the "literature behavior" are found in the case of wavy-slip materials. Figure 35 depicts the CSS curves determined on polycrystalline copper samples with and without prestraining. The saturation stress amplitude is raised with increasing degree of predeformation. Swaging, which corresponds to a tensile prestrain of about 87%, gives rise to the highest increase of  $\sigma_s$ . Figure 35 indicates that the influence of predeformation decreases with increasing plastic-strain amplitude, but that it does not cease to exist even at very high  $\Delta\varepsilon_{pl}/2$  values.

FIG. 35 CYCLIC STRESS-STRAIN CURVES OF ANNEALED AND PRESTRAINED COPPER SPECIMENS. SOURCE: REF 210

From these observations it can be concluded that the CSS behavior is generally history-dependent. Therefore, any assumption of history independence must be considered as a specific technical limit, such that the deviation between the saturation state of annealed samples and that of predeformed samples does not exceed a given limit in each situation. Nevertheless, wavy-slip materials generally are less history dependent than planar-slip materials. The behavior of particle-strengthened alloys lies somewhere between these extreme cases. If cyclic deformation is mainly controlled by the dislocation/particle interaction (e.g., in top-aged condition) and particle cutting takes place, a planar-slip-type behavior can be expected. If, on the contrary, dislocation/dislocation interactions prevail due to large particle size, wavy-slip-type behavior may exist.

**Effect of Amplitude Changes.** As a consequence of the relationship between dislocation arrangements formed during cyclic loading and those formed during monotonic loading (e.g., Fig. 21), cyclic predeformation can be considered a special case of (repeatedly) monotonic prestraining in some respects. Again, the combination of wavy-slip behavior with high plastic-strain amplitude can be understood most easily. Under these conditions, a change from one constant value of  $\Delta\epsilon_p/2$  to another leads to a more or less reversible adaptation of the dislocation cell structure. For example, if  $\Delta\epsilon_p/2$  is decreased, a rearrangement of the dislocations is possible in such a way that the dislocation cell size increases to the value that would have been established if the cyclic predeformation had not have been applied (e.g., Ref 26, 202). This rearrangement, which leads to the saturation microstructure of the initially annealed condition, can of course not (completely) take place if a change leaves the high-amplitude range by leading to an amplitude in the low-amplitude range in which single-slip prevails. Then the cell structure is preserved, and normally the stress-strain response differs from that of non-predeformed samples. This agrees with the assumption that cell structures are relatively stable dislocation configurations. However, some indications are given in the literature that under certain conditions a transformation of cells into single-slip arrangements might be possible (e.g., Ref 211).

In the case of planar-slip materials, an effect of the cyclic predeformation always applies, which is still not understood microstructurally. Usually this effect is more pronounced if the loading amplitude is lowered than if the amplitude is increased.

Sometimes multiple-step tests are applied in order to determine the CSS curve of a material in a sample-saving manner. From the discussion so far, it can be deduced that single-step tests are to be preferred for this purpose. If multiple-step

tests are unavoidable, the tests should at least be carried out with step-wise increasing amplitude, small steps, and ample cycling at each step.

**Incremental Step Test.** A technique that has been proposed as a time-saving method to determine the CSS curve with one sample is the incremental step test (IST) (Ref 212, 213). In each block the amplitude is first increased linearly with time up to a maximum amplitude, then decreased to zero (or a minimum amplitude value). This loading sequence (block) is applied repeatedly until a stabilized behavior is established. Then the CSS curve is obtained simply by connecting the load reversal points in the stress-strain course. From previous discussion, it appears very doubtful that this test procedure gives a CSS curve identical to that determined in single-step tests at different amplitudes. As described above, each amplitude leads to a characteristic dislocation distribution and arrangement that cannot be expected to exist at each single cycle of the IST.

In fact, it can be shown (Ref 214, 215) that a high number of blocks are required to attain a state of saturation or at least approximate saturation. In this state, where no further changes in the mechanical stress-strain response are appreciable, the microstructure is stabilized (i.e., it remains not only unchanged from block to block, but, more important, it is also independent of the immediately acting amplitude). A comparison of this microstructure with those existing in saturation of single-step tests documents that the IST leads to the same dislocation arrangement that is established in a single-step test at an amplitude slightly lower than the maximum amplitude used in the IST. In other words, the microstructural effect of the IST can be described by an "effective" amplitude, and therefore the CSS behavior on the IST differs from that of single-step tests, because it does not take into account the amplitude-dependent dislocation arrangement. However, this behavior at constant microstructure is of interest from an engineering point of view, because under service conditions, if the loading amplitude changes sufficiently fast and often, a similar behavior may exist.

## Cyclic Stress-Strain Response and Microstructure

Hans-Jürgen Christ, Universität-GH-Siegen

---

### Modeling of the CSS

In concluding this article, a very brief description of a basic concept used to model the CSS response on a physical basis is given. Numerous approaches have been reported, mostly either starting from a description of the individual dislocation behavior or based on plain numerical relations without appreciable physical foundation. However, a more reasonable and promising starting point for a microstructure-related description is provided by so-called multicomponent models.

Cyclic deformation (i.e., the macroscopic behavior) is mostly connected with the formation of a heterogeneous dislocation distribution (Fig. 13, 14, 16, 17, 19, 20). Independent of the details of the dislocation arrangements (the microscopic scale), dislocation-rich and dislocation-poor areas are formed within a few cycles due to bifurcation of the dislocation density (e.g., cell wall and cell interior). It is easily understood that different dislocation densities should lead to different yield stresses. Therefore, on a mesoscopic scale a local variation of the (microscopic) yield stress is to be expected. Consequently, even a single-phase single-crystalline material should be treated like a composite consisting of local areas of different stress-strain behavior (Ref 55, 58, 216, 217). Then, the macroscopic behavior is composed of the behavior of all elements. The relations that determine how the elements are combined result from the assumptions applied to describe the geometric arrangement of the elements.

In order to illustrate the basic idea and the main features of such a multicomponent model, let us consider the parallel arrangement of ideally elastic-plastic elements, which was proposed by G. Masing in 1923 (Ref 218, 219). For the sake of simplicity, only two elements should exist, which have a local yield strength of  $\sigma_{1f}$  and  $\sigma_{2f}$ , respectively, and occupy an area fraction of 50% each. Figure 36 shows the stress-strain path of this two-element model during one cycle, starting from the deformation-free condition. As a consequence of the parallel arrangement, each element undergoes the same strain as the composite. Furthermore, the stress acting on the composite can easily be obtained graphically from the  $\sigma$ - $\epsilon$  courses of the individual elements, because it is the arithmetic mean due to the identical area fractions of the elements.

**FIG. 36 STRESS-STRAIN PATH OF A TWO-ELEMENT COMPOSITE ASSUMING PARALLEL ARRANGEMENT AND IDEALLY ELASTIC-PLASTIC BEHAVIOR. SOURCE: REF 220**

Starting from the deformation-free condition in point A, a purely elastic deformation occurs until the "weakest" element reaches its yield strength (point B). Further stress increase shows a slope  $E/2$ , because element 1 no longer contributes to the stress increase. As soon as the yield stress of element 2 is reached (point C), the composite deforms ideally plastically (without hardening). A load reversal (point D) leads first to an elastic back-deformation until, at point F, the plastic deformation of element 1 begins, and the cycle repeats.

In spite of the simplicity of this two-component model, some important consequences that arise from the "composite idea" can be deduced:

- IN THE MACROSCOPICALLY STRESS-FREE CONDITION (POINT E), INTERNAL STRESSES EXIST. THE WEAKER ELEMENT CONTAINS A COMPRESSIVE STRESS, WHEREAS IN THE STRONGER ELEMENT A TENSILE STRESS IS ACTING (E.G., REF 221).
- AS A CONSEQUENCE OF THE COMPRESSIVE INTERNAL STRESS IN THE WEAKER ELEMENT AT  $\sigma=0$ , PLASTIC DEFORMATION AFTER A PRIOR LOAD REVERSAL (POINT D) BEGINS AT A REDUCED MACROSCOPIC YIELD STRESS (IN ABSOLUTE VALUES, POINT F). THIS BEHAVIOR IS COMMONLY TERMED THE BAUSCHINGER EFFECT (FIG. 6B).
- IF THE MONOTONIC STRESS-STRAIN CURVE IS SPREAD BY A SCALE FACTOR OF 2, THE CURVE EQUALS THE BRANCH OF THE HYSTERESIS LOOP (REPRESENTED IN RELATIVE COORDINATES). THIS 1:2 RULE WAS INTRODUCED ABOVE AS A TYPICAL FEATURE OF CSS BEHAVIOR.
- THE MEMORY OF A PRIOR LOAD HISTORY IS IMPLICITLY CONTAINED IN THIS MODEL (THE INTERESTED READER IS INVITED TO "CONSTRUCT" THE  $\sigma$ - $\epsilon$  PATH AFTER A LOAD REVERSAL BETWEEN POINT F AND POINT G). A PRIOR LOAD HISTORY IS STORED IN THE FORM OF THE INTERNAL STRESS DISTRIBUTION (MEMORY OF THE MATERIAL).

Obviously, a two-element model is not suitable for precise reproduction and prediction of the stress-strain behavior. More advanced models (e.g., Ref 222, 223, 224, 225, 226, 227, 228) use a statistical mathematical treatment in which an infinite number of elements is considered and the distribution of the yield stresses is described by a distribution density function. This does not affect the basic consequences of the composite idea as listed above.

Figure 37 shows the result of such a calculation, with small cycles interrupting a large cycle. The calculation is based exclusively on the stress levels of the reversal points and their sequence. The memory of a prior load history is "automatically" taken into account.

**FIG. 37** CALCULATED STRESS-STRAIN PATH FOR VARIABLE-AMPLITUDE CONDITION SHOWING THE MEMORY OF PRIOR LOAD HISTORY. SOURCE: REF 220, 228

In order to give an impression of the quality of prediction, Fig. 38 compares the calculated stress-strain path with that measured on copper in a (half block of an) incremental step test. The only input function for the calculation is the distribution density function of the elementary yield stresses, which has been obtained unambiguously from one ascending branch of the hysteresis loop measured in a single-step test at the effective amplitude. The excellent agreement of measured and calculated data is due to very careful consideration of the microstructural aspects of CSS behavior in terms of the application of a multicomponent model and the correct value of the effective amplitude.

FIG. 38 COMPARISON OF CALCULATED AND EXPERIMENTALLY DETERMINED STRESS-STRAIN COURSES OF A HALF BLOCK OF AN INCREMENTAL STEP TEST ON COPPER. SOURCE: REF 220, 228

### Introduction

THE FATIGUE PROCESS can be roughly divided into four stages: cyclic hardening/softening, crack nucleation, crack propagation, and overload (fracture). In flaw-free materials a significant fraction of the total lifetime is spent before the first detectable microcracks appear. At low amplitudes the nucleation stage can occupy the majority of the lifetime. At high amplitudes nucleation is usually accomplished within a small fraction of the fatigue life. Another fraction of the lifetime is needed for propagation of the microstructurally small cracks (cracks small compared to microstructural size scales) to reach the size of the physically small cracks (i.e., cracks of the size  $\leq 0.5-1$  mm). Again, this fraction can be quite high at low amplitudes. Propagation of physically small cracks and macrocracks can be quantitatively described by means of fracture mechanics. On the other hand, there is no generally accepted quantitative description of the nucleation process, and there is no widely applicable description of the propagation of microstructurally small cracks. Thus, any numerical analysis of these stages in the fatigue process must be preceded by deeper understanding of the physical mechanisms.

**Role of Surface Conditions in Fatigue.** It is well established that the fatigue process is very sensitive to surface state and is influenced by the surface finish and surface treatment. The reason is that fatigue cracks in most cases nucleate from free surfaces of cyclically loaded metals. This has been repeatedly demonstrated impressively by the observation that when a specimen is fatigued for a substantial fraction of its fatigue life and its surface is then removed by electropolishing, the specimen in a subsequent test exhibits a fatigue life as long as that of a virgin specimen (Ref 1).

Crack nucleation, as well as the whole fatigue process, is controlled by the cyclic plastic deformation. Therefore, it can be expected that cracks nucleate at positions where cyclic plastic deformation is higher than average. There are basically two reasons why the cyclic plastic deformation is higher just at the surface: concentration of plastic deformation due to higher stresses near the surface; and lower degree of constraint of the near-surface volumes of cyclically loaded material.

In complex engineering components, higher surface stresses result from either notches or bending and twisting, both of which lead to stress gradients with the highest stress on the surface. Even in nominally uniformly stressed parts, a small degree of eccentricity in the axial load is practically unavoidable, again leading to small bending or twisting moments and consequently to higher surface stresses in the surface layer. Besides these macroscopic sources of stress concentration on the surface, there are also microscopic stress concentrators, which are effective even under conditions of ideal uniaxial loading. The stress level at the surface is sensitive to surface topography, and the surface is never perfectly smooth. For example, very fine grinding produces grooves with depths of the order of  $0.1 \mu\text{m}$ , which very locally can increase the stress by about 10%. Fortunately, the surface finish often produces a thin plastically deformed surface layer with compressive residual stress, which may balance or even overbalance the detrimental effect of microscopic stress concentration on the resulting life.

A further type of microscopic stress concentrator is the surface step produced by dislocations leaving the metal during plastic deformation. The cycling itself can produce localized stress concentration at the surface. Second-phase particles, such as inclusions and precipitates, have elastic properties different from those of the matrix and generally also serve as stress concentrators. Argon (Ref 2) showed very instructively that the effect of second-phase particles at the free surface is higher than in the interior. Figure 1, taken from his paper, compares the stress-concentration ( $K_t$ ) and the stress-intensity ( $K_I$ ) factors for idealized shapes of particles of zero modulus at the surface and in the interior. The first case is that of a spherical particle. For equal biaxial stress,  $K_t = 2.23$  was found for a hemispherical depression in the surface of a semi-infinite body (for Poisson constant  $\nu = \frac{1}{4}$ ). This is about 7% higher than for the corresponding case of a spherical cavity ( $K_t = 2.09$  for  $\nu = \frac{1}{4}$ ) (Ref 3). The second example is the sharp, penny-shaped crack in the interior and the sharp crack of the same cross-sectional dimensions in plane-strain. The stress-intensity factor for the plane-strain crack is higher by a factor  $\sqrt{p/2}$ . The third example is the sharp plane-strain crack and the sharp plane-strain half-crack on a surface. The stress-intensity factor for the surface crack is higher by 12%. Although the comparison in Fig. 1 does not correspond perfectly to the real situation (because it assumes zero modulus and idealized shape), the predictions clearly indicate that inclusions at the surface should produce a higher stress concentration than inclusions in the interior.

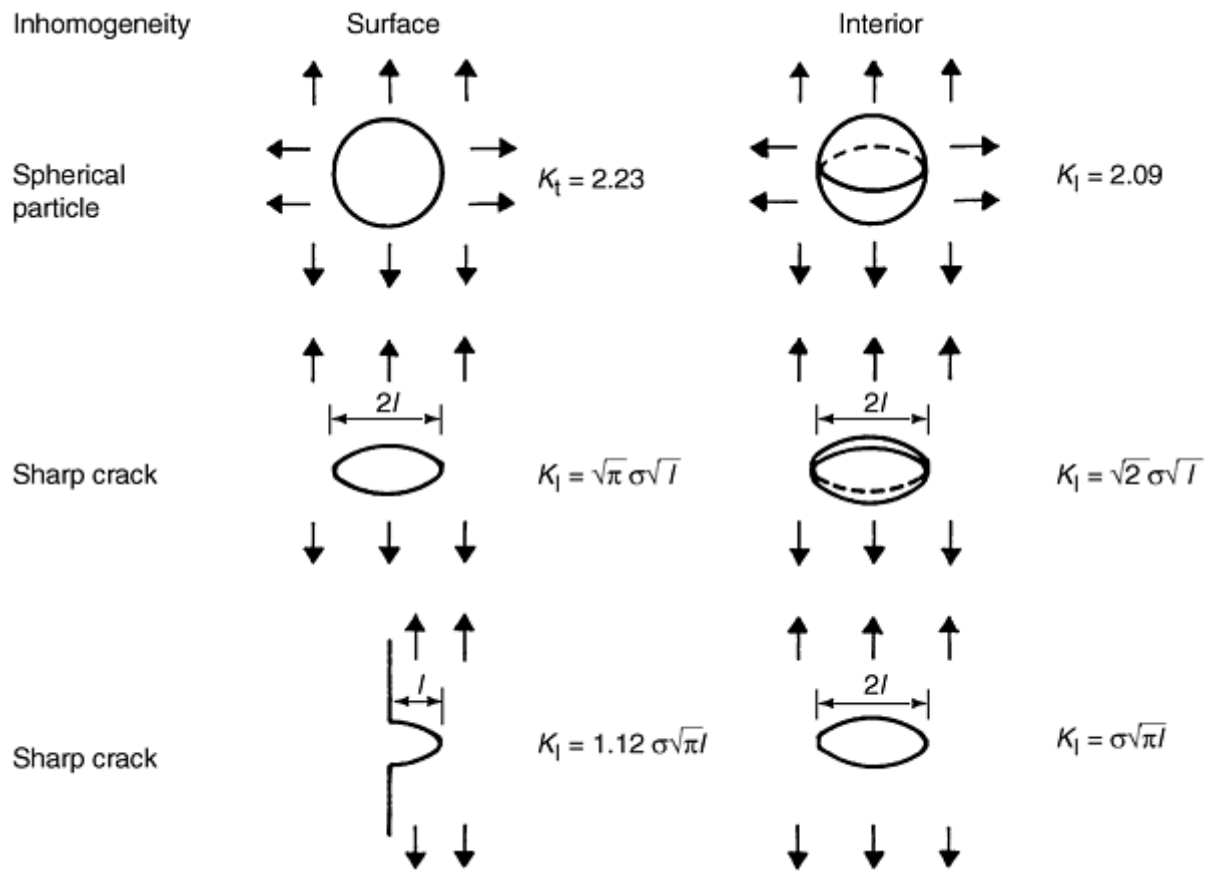

FIG. 1 COMPARISON OF STRESS-CONCENTRATION ( $K_T$ ) AND STRESS-INTENSITY ( $K_I$ ) FACTORS FOR INHOMOGENEITIES OF THE SAME TYPE ON THE SURFACE AND IN THE INTERIOR

Higher cyclic plastic deformation at or near the surface is higher, also due to the reduced constraint associated with deformation within the surface layer. This can be best explained in the case of a polycrystalline metal. In the bulk material, each interior grain is under constraints imposed by neighboring grains. Surface grains have a lower number of neighboring grains than interior grains and, consequently, the constraint is relaxed. In less constrained surface grains, single slip is more easily accommodated than in strongly constrained bulk grains, in which multiple slip may be more necessary (Ref 1). Experimentally it has been found by measuring local plasticity in individual surface grains (Ref 4) that the local surface strains can exceed the average strain of the specimen by orders of magnitude (Ref 5).

### Sites of Crack Initiation

Significant experimental observations performed by either light or electron microscopy have shown that in homogeneous materials, microcracks always originate at free surfaces (Ref 6). In macroscopically inhomogeneous materials, such as surface hardened steels, cracks often start below the surface where constraint effects induce high triaxial stresses. For the same plastic strain amplitude in the surface layer, a much higher stress is required in comparison to the softer matrix. This is why the microcracks can originate at the interface between the hard layer and the soft matrix. In engineering components, cracks may start from internal defects, where cracks nucleate at internal surfaces or interfaces.

Direct observations of surfaces have shown that there are three types of nucleation sites:

- *NUCLEATION AT FATIGUE SLIP BANDS IS PERHAPS THE MOST FREQUENT TYPE. ITS NATURE IS SLIP CONCENTRATION WITHIN THE GRAINS.*
- *NUCLEATION AT GRAIN BOUNDARIES IS TYPICAL FOR HIGH-STRAIN FATIGUE, ESPECIALLY AT HIGHER TEMPERATURES.*
- *NUCLEATION AT SURFACE INCLUSIONS IS TYPICAL FOR ALLOYS CONTAINING LARGE ENOUGH PARTICLES.*

Common to all three types of nucleation is local plastic strain concentration at or near the surface. Nucleation in the fatigue slip bands is a basic type of nucleation, not only because this is the most frequent case, but mainly because the cyclic slip processes and formation of fatigue slips bands often precede nucleation at grain boundaries (Ref 7, 8) or at surface inclusions. From this point of view, nucleation at inclusions can be understood as cyclic slip localization (Ref 9) due to the stress-concentrating effect of the inclusion. See the section "Easy-Cross-Slip Metals (Low-Amplitude Cycling)" in this article. Nucleation at inclusions can lead either to decohesion of the inclusion-matrix interface or to cracking of the inclusion. Both of these microcracks have been observed experimentally (Ref 10).

There is strong evidence that nucleation at grain boundaries is also conditioned by the cyclic slip processes. Kim and Laird (Ref 11) concluded that the nature of cross-slip within grains, and the compatibility of slip at grain boundaries, are the most important factors in defining crack sites. Mughrabi et al. (Ref 12) showed that nucleation at grain boundaries occurs at sites where persistent slip bands (PSBs) impinge, and they formulated a dislocation model of this kind of crack initiation.

This article emphasizes nucleation at fatigue slip bands. A typical example of the development of fatigue slip bands with an increasing number of loading cycles is shown for polycrystalline copper in Fig. 2. The intensity and number of fatigue slip bands increase with the number of strain cycles, and the surface exhibits a more marked notch-peak topography. The overall appearance of the fatigue slip bands depends mainly on the stress or strain amplitude and on the slip character of the material. Wavy-slip materials are typified by lower numbers of intense bands, sometimes irregular and wavy. Under similar testing conditions, planar-slip materials exhibit higher numbers of less intense, highly regular bands lying exactly along the slip planes.

**FIG. 2 EVOLUTION OF FATIGUE SLIP BANDS DURING CYCLING OF COPPER. (A)  $N = 5 \times 10^3$  (B)  $N = 10^4$  (C)  $N = 10^5$  CYCLES. PUSH-PULL SYMMETRICAL LOADING ( $R = -1$ ) WITH LOW STRESS AMPLITUDES. NUMBER OF CYCLES TO FRACTURE,  $N_f = 1.2 \times 10^6$  CYCLES**

The initial appearance of fatigue slip bands typically coincides with the end of the macroscopic hardening/softening. The first microcracks are detectable within the bands later during cycling. Figure 3 shows fatigue slip bands with short microcracks in copper. In this replica micrograph, the microcracks cast a shadow. The typical length of microcracks at first detection is of the order of 0.1 to 1.0  $\mu\text{m}$ , depending on the material and the experimental technique.

**FIG. 3 REPLICA MICROGRAPH OF THE FIRST MICROCRACKS IN FATIGUE SLIP BANDS ON THE SURFACE OF CYCLED COPPER. SAME LOADING AS IN FIG. 2; REPLICA STRIPPED OFF AT  $N = 10^5$  CYCLES**

A large number of microcracks usually form during the first 20 to 40% of the total fatigue life. With continued cyclic loading, some of the nucleated microcracks grow, and practically no new ones are nucleated. This is shown in Fig. 4 which shows the measured crack density versus number of load cycles for an Al-Cu-Mg alloy (Ref 10). In this case, the microcracks emanate from cracked or debonded intermetallic particles, and their shapes are approximately semicircular. After the microcracks nucleate, the density undergoes only minor changes. The slight increase in microcrack density by the end of the lifetime is due to the formation of new microcracks in the plastic zone of the propagating macrocracks.

FIG. 4 DENSITY OF MICROCRACKS FOR TWO STRESS AMPLITUDES ( $\sigma_a$ ) IN AL-CU MG ALLOY.  $N$ , NUMBER OF CYCLES;  $N_f$ , NUMBER OF CYCLES TO FRACTURE. AXIAL LOAD,  $R = -1$

Crack nucleation usually takes place after saturation of the bulk mechanical properties. In the interior of metals cycled at low stress or strain amplitudes, the dislocation processes are reversible at this stage. The intensification of fatigue slip bands on the surface and the formation of microcracks show that the dislocation processes in the surface layer are irreversible.

### Relation of Dislocation Structures and Surface Relief

To understand the process of nucleation, it is necessary to understand the dislocation processes in the surface layer. Perhaps the most substantial part of our current understanding of crack nucleation comes from direct electron microscopy observations of dislocation structures in surface layer after cyclic loading. There have been numerous experimental observations of near-surface dislocation structures in single-phase materials and those behaving like single-phase materials. It is now well established that in single crystals, there are no substantial differences between dislocation structures in the surface layer and in the interior of a crystal.

On the other hand, there are clear differences in polycrystals. This point was a matter of controversy in the literature for many years. The pioneering work of Hirsch et al. from 1959 (Ref 13) showed virtually no difference between near-surface structures and the structure typical of the whole volume, in a polycrystalline austenitic steel with low stacking-fault energy. Segall et al. (Ref 14) in 1961 came to the same conclusion for copper, aluminum, nickel, and gold, which have high stacking-fault energies. A few years later, considerable differences between near-surface and interior structures were unequivocally proved for low-carbon steel (Ref 15) and copper (Ref 16). More specifically, it was found that PSBs in the surface grains exhibit a structure that differs from the structure in the surrounding matrix and interior grains. Near-surface structures were studied in a variety of polycrystalline materials, but the controversy in the literature continued. While the earlier papers (Ref 15, 16) indicated that PSBs are formed only in surface grains, later papers also showed PSBs in interior grains (Ref 17, 18, 19). Systematic investigations (Ref 1, 20, 21) proved that this is a difference of quantitative nature: PSBs occur much less frequently in interior grains than in surface grains. The reason might lie in the fact that the cyclic plastic deformation of surface grains is less constrained than the cyclic plastic deformation of interior grains.

In summary, there is no difference between surface and interior grains as to the types of dislocation structures produced during cycling. Besides the difference in the quantity of the PSBs in wavy-slip materials, there is a minor difference between surface and interior dislocation structures in both single crystals and polycrystals: the dislocation density in the volumes near the surface is somewhat lower than the dislocation density in the interior of the cycled specimens (Ref 22, 23, 24). The lower dislocation densities near the surface is an effect from the so-called "mirror" or "image" forces at the surface, which attract dislocations to the free surface. This certainly contributes to surface relief formation (Ref 24).

The principal result of all investigations is that the types of near-surface structures depend, exactly in the same way as interior structures depend, on two parameters: the difficulty of cross-slip and the stress or strain amplitude. The difficulty of cross-slip is governed by the stacking-fault energy and to a lower extent by short range order and the yield strength (Ref 25, 26, 27). In a simplified sense, the ease of cross-slip can be identified with the stacking-fault energy, which can be expressed (contrary to other parameters affecting the cross-slip) quantitatively. Figure 5 correlates the types of dislocation structures observed in FCC alloys with stacking-fault energy,  $\gamma$ , and loading history, expressed here as number of cycles to fracture. For example, dislocation cells develop in high stacking-fault energy materials when subjected to high stress amplitudes (that is, low number of cycles to failure), while persistent slip bands are observed in the same material at low stress amplitudes (high number of cycles to failure). The following detailed description of the near-surface structures is given according to the regions in Fig. 5 (Ref 28).

FIG. 5 SUMMARY OF NEAR-SURFACE DISLOCATION STRUCTURES AS A FUNCTION OF AMPLITUDE (EXPRESSED HERE THROUGH NUMBER OF CYCLES TO FRACTURE,  $N_f$ ) AND STACKING-FAULT ENERGY,  $\gamma$ . THIS SUMMARY COVERS MATERIALS THAT WERE WELL ANNEALED BEFORE CYCLING.

**Easy-Cross-Slip Metals (Low-Amplitude Cycling).** The dislocation structures and corresponding surface relief described below are typical for both fcc metals with high stacking-fault energies, cycled at any strain rate and at almost any temperature, and body-centered cubic (bcc) metals, cycled at low strain rates and moderate temperatures (Ref 29, 30). Fatigue slip bands, which lie along the intersection lines of the surface with the active slip plane, develop on the surface provided the specimen was cycled far enough in saturation. The dislocation structure just beneath the surface intrusions and extrusions, and in their nearest vicinity, differs considerably from the dislocation structure in the surrounding area and in the interior of the specimen. Examples are presented in Fig. 6, 7, 8, and 9. The crystallographic planes and directions are explained in Fig. 10.

FIG. 10 NOTATION OF CRYSTALLOGRAPHIC PLANES AND DIRECTIONS

Figure 6 is an electron micrograph obtained by "method-of-one-side" thin foils from the surface grain of a low-carbon steel cycled in push-pull loading at a frequency of 83 Hz (Ref 15). Figure 7 is an electron micrograph taken from the

surface replica of the same specimen (but not of the same grain). In Fig. 6, there are well-developed bands with a dislocation structure (very dense dislocation patches indicated by arrow "A") which is different from the structure of the observed surrounding matrix (inexpressive cell structure, arrow "B"). In Fig. 7, a complicated surface relief can be seen. There is probably a one-to-one relation between the zones of specific dislocation structures beneath the surface (Fig. 6) and the fatigue slip bands on the surface consisting of extrusions and intrusions (Fig. 7).

Figure 8 (Ref 31) presents dislocation structure as observed a few microns below the  $(1\bar{2}1)$  surface of a cycled single crystal of copper (see the schematic drawing of the specimen in Fig. 10). As mentioned above, there is no substantial difference between near-surface and interior dislocation structures in single crystals. Thus, the same structure can be observed in the center of the crystal. Two distinctly different structures can be seen here. The structure of the fatigue slip band, lying along the  $[\bar{1}01]$  crystallographic direction, resembles here three irregular ladders, while the surrounding matrix structure is one of perpendicularly cut veins.

Figure 9 is a transmission electron micrograph obtained in the following way: After cycling, the specimen (not the same one used for Fig. 8) was electroplated. The foils parallel to the  $(1\bar{2}1)$  plane (see Fig. 10) were then prepared from the interface of the specimen with the electrodeposited layer. In such foils it is possible to see simultaneously the dislocation structure and the corresponding surface relief. Here the broad zone of ladder-like structure lying along the trace of the primary slip plane ends on the specimen surface in a strong extrusion. The structure surrounding this zone is the typical interior structure (perpendicularly cut veins).

The differences in dislocation structures within bands and in the surrounding matrix cause the difference in etching response. Even before electron microscopy methods were applied to the study of structures in fatigued metals, it was established that polishing a few microns from a surface could cover fatigue slip bands, which then can become visible again after etching. That is why these fatigue slip bands were termed PSBs, persistent slip bands.

In the light of current knowledge, the PSB can be defined as a zone that fulfills three conditions: there is a cyclic strain localization in this zone; its dislocation structure differs from that in the surrounding matrix; and the zone ends on the specimen surface in intrusions and extrusions. The structure shown in Fig. 8 and 9 represents the section  $(1\bar{2}1)$  perpendicular to the slip plane (111) and containing the slip direction  $[\bar{1}01]$ ; that is, the PSB structure is here seen from the profile. In the section parallel to the primary slip plane, the structure associated with the PSBs can be described as a series of dislocation walls or "hedges" with a  $[\bar{1}01]$  normal, extended tens of microns in the  $[1\bar{2}1]$  direction.

The PSB structure is not always of this type; it is often formed by completely closed cells. Thus there are two types of PSBs: ladder-like PSBs consisting of parallel walls perpendicular to the primary slip direction; and cell-like PSBs consisting of fully closed cells. The ladder structure is typical for new PSBs, while the cell structure is typical for old PSBs (Ref 32, 33). This change in dislocation structure within the PSBs during cycling is responsible for the slow secondary hardening after saturation is reached (Ref 33, 34). In other words, the PSBs become hardened by secondary dislocations, and thus they continue to deform, but at a reduced local strain amplitude.

The distance between walls in ladder-like PSBs (the mean distance between the centers of neighboring walls) is highly regular. For example, in copper single crystals cycled at room temperature, the distance is 1.4  $\mu\text{m}$ . This ladder spacing depends strongly on temperature, both in single crystals (Ref 35, 36, 37) and in polycrystals (Ref 21). The lower the temperature, the smaller the ladder spacing. There is an inverse proportionality between the ladder spacing and the saturation stress amplitude.

The highly regular dislocation structures presented in Fig. 8 and 9 are typical for the "well-behaved" materials like copper. In more complicated materials the degree of dislocation structure regularity is lower. See, for example, the PSB in low-carbon steel presented in Fig. 6. It does not change anything on the above given definition of the PSB.

Despite some minor discrepancies between experimental results concerning the details of PSB structure, there is agreement on the following points (Ref 28, 38, 39):

- PSBS LIE ALONG THE SLIP PLANE, AND THEIR STRUCTURE IS DIFFERENT FROM THE SURROUNDING MATRIX.
- THERE ARE CERTAIN STRESS AND STRAIN REQUIREMENTS FOR PSB FORMATION. PSBS HAVE NEVER BEEN OBSERVED BELOW A THRESHOLD VALUE OF THE PLASTIC STRAIN AMPLITUDE. THIS THRESHOLD IS TYPICALLY OF THE ORDER OF  $10^{-5}$ . FOR SOME

MATERIALS IT IS SLIGHTLY HIGHER, BUT IT DOES NOT EXCEED  $2 \times 10^{-4}$ . THE CORRESPONDING THRESHOLD VALUES OF THE STRESS AMPLITUDE DEPEND VERY STRONGLY ON THE MATERIAL, IN CONTRAST TO THE PLASTIC STRAIN AMPLITUDE. THESE TWO VALUES (THRESHOLDS OF THE STRESS AND STRAIN) ARE CONNECTED DIRECTLY THROUGH THE CYCLIC STRESS-STRAIN CURVE.

- IN POLYCRYSTALLINE MATERIALS, PSBS ARE CONFINED MAINLY TO THE SURFACE GRAINS. IN SINGLE CRYSTALS, THEIR VOLUME FRACTION INCREASES WITH BOTH THE NUMBER OF CYCLES AND THE LOADING AMPLITUDE. AFTER A SUFFICIENTLY HIGH NUMBER OF LOADING CYCLES, THE ENTIRE CRYSTAL IS FILLED WITH PSBS.
- THE PLASTIC STRAIN AMPLITUDE IN PSBS IS HIGHER THAN IN THE MATRIX. FOR EXAMPLE, FROM THE CYCLIC STRESS-STRAIN CURVE FOR COPPER SINGLE CRYSTAL (REF 29), IT CAN BE DEDUCED THAT THE SHEAR PLASTIC STRAIN AMPLITUDE IN THE PSBS IS ABOUT  $7.5 \times 10^{-3}$  (END OF THE PLATEAU), WHILE ITS MATRIX VALUE IS ONLY ABOUT  $6 \times 10^{-5}$  (BEGINNING OF THE PLATEAU). THUS, THE LOCAL PLASTIC STRAIN AMPLITUDE IN THE PSBS IS HIGHER BY A FACTOR OF ABOUT 100 THAN THE PLASTIC STRAIN AMPLITUDE IN THE SURROUNDING MATRIX.

In the region of easy-cross-slip metals cycled at low amplitudes, the surface relief is two-stage: (1) a fine slip, with traces observed on the surface between the PSBs (Ref 16, 40, 41); and (2) a coarse slip, that is, PSBs with strong extrusions and intrusions. Fine slip lines are formed during fatigue hardening, and coarse slip markings (i.e., PSBs) appear on the surface at saturation. The PSBs cannot be detected metallographically on the specimen surface right from the onset of cycling, but rather only at the end of hardening/softening process when the interior structure is already formed. Therefore, PSBs are probably formed by transferring the matrix structure into the PSB structure. This process certainly requires cross-slip, and that is probably why no PSBs are formed in very difficult-cross-slip materials.

Some experimental findings show that the interior dislocation structure is on the boundary of stability. Basinski et al. (Ref 41) observed that during the early stages of fatigue of copper single crystals cycled with constant plastic strain amplitude, a very slight increase in strain amplitude resulted in quick formation of intensive slip markings on the surface. Neumann (Ref 42) cycled single crystals with linearly increasing stress amplitude. The plastic strain amplitude showed very strong maxima during testing; these peaks have been called strain bursts since that time. Holzwarth and Essmann (Ref 43) used transmission electron microscopy to prove the transformation of matrix structure into PSB structure on copper single crystals. All these results have shown that matrix structure is not stable with respect to slight variations of stress or strain amplitude.

The formation of PSBs can be approximated as follows: During the early stages of cycling, the interior structure is formed, and simultaneously fine slip lines appear on the specimen surface because dislocations are escaping to the free surface. Near the surface, the stress conditions are a little different from those at greater depths, because of the factors discussed above. Therefore, at or near the surface, the stress in localized places can exceed average. Because of the instability of the interior structure, described above, the dislocation structure in such places must respond to the increased stress. In easy-cross-slip materials, this response can be very quick (in a few loading cycles), and it results in the formation of a new type of structure, the PSB structure. The cyclic plastic strain within these PSBs leads to formation of surface intrusions and extrusions, which in turn give rise to stress concentration and thus enhance the process of PSBs broadening and growing to greater depths. A model for this cyclic plastic strain, based on the idea of low-energy dislocation configurations, has been proposed by Kuhlmann-Wilsdorf and Laird (Ref 44).

**Prenucleation Stage Prior to Microcrack Nucleation.** To give a concise picture of the prenucleation stage, the outline of the kinetics of PSB formation must be complemented by a more detailed explanation of the processes that lead to the formation of the surface relief. Several models have been proposed to explain the formation of surface extrusions and intrusions due to the processes within the PSBs. These models are based on the slip processes, on the formation and migration of point defects, or on a combination of both.

It seems plausible to correlate the formation of surface intrusions and extrusions with the processes within the whole PSB, not with processes taking place near the surface only (as some earlier models proposed). A qualitative model accounting for these phenomena in terms of slip processes was best formulated by Finney and Laird (Ref 45). In the interior of the specimen, primary-edge dislocation segments bow out from the walls comprising the PSB structure until they become incorporated in the opposite wall. As this is taking place, the stress imbalance causes a segment in the opposite wall to

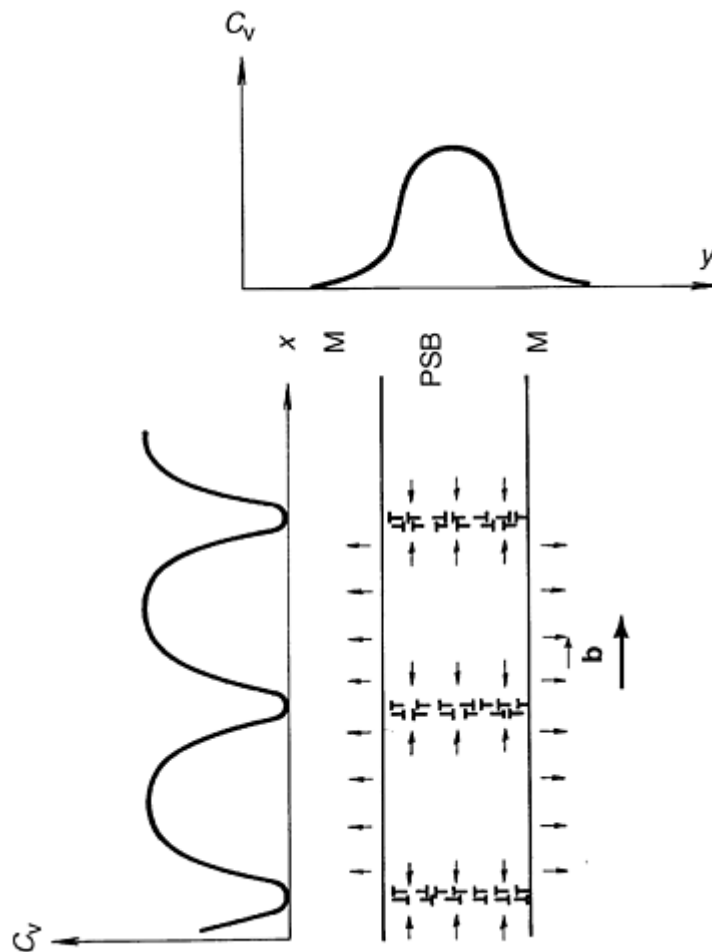

become active, producing a cascading effect that channels numerous dislocations down the PSB. Upon reverse loading, the same or similar segments travel in the opposite direction, and by this means reversibility occurs. However, the segments that emerge at the surface are not completely reversible. Thus, the formation of surface intrusions and extrusions is due to dislocation motion within the whole PSB.

The model by Essmann et al. (Ref 46) is based on the role of vacancies and their agglomerates, produced by nonconservative jog dragging and opposite-edge dislocation annihilation. These vacancies lead to the deposition of edge dislocations at the PSB-matrix interfaces, as shown in Fig. 11(a). These interface dislocations correspond to a multipolar array built up of interstitial-type dipoles. The number of atoms contained in the extra atomic planes is equivalent to the number of vacancies that prevail in the PSBs. Under the action of the applied stress, interface dislocations glide out of the crystal at A and A' during the tensile phases of cycling and at B and B' during the compressive phases, respectively. This process leads to the formation of extrusions on both sides of the PSBs, as shown in Fig. 11(b). This extrusion does not remain smooth; the random irreversible slip leads to the development of surface roughness.

**FIG. 11 MODEL BY ESSMANN ET AL. (REF 46) FOR FORMATION OF EXTRUSIONS. (A) ARRANGEMENT OF INTERFACE DISLOCATIONS CORRESPONDING TO AN INTERSTITIAL-TYPE DISLOCATION-DIPOLE LAYER. (B) EXTRUSIONS FORMED BY EMERGENCE OF INTERFACE DISLOCATIONS. B, BURGERS VECTOR; M, MATRIX; PSB, PERSISTENT SLIP BAND**

A model by Polák (Ref 47) specifies the flux of vacancies in the PSBs (Fig. 12). Vacancies are formed both in the walls and in the channel areas between the walls in the PSBs. The densities of dislocations in the walls and in the channels differ considerably. Because edge dislocations serve as sinks for vacancies, the excess vacancy concentration also differs. The excess vacancy concentration and vacancy fluxes are shown in Fig. 12. The flux of vacancies in one direction is equivalent to the flow of atoms in the opposite direction. This results in the accumulation of mass in two directions perpendicular to the direction of flow. Thus, the material is extruded from the crystal along the channels and is intruded into the crystal along the walls.

**FIG. 12 MODEL BY POLÁK (REF 47) FOR SURFACE RELIEF FORMATION. A SINGLE PERSISTENT SLIP BAND IS SHOWN WITH VACANCY CONCENTRATIONS IN THE X- AND Y-DIRECTIONS (VACANCY FLUXES ARE DENOTED BY ARROWS). B, BURGERS VECTOR;  $C_v$ , VACANCY CONCENTRATION; M, MATRIX; PSB, PERSISTENT SLIP BAND**

The models of surface relief formation based on vacancies imply temperature dependence of PSB profile geometry on the mobility of vacancies. Basinski and Basinski (Ref 48, 49) observed formation of expressive surface relief over the PSBs also at temperatures where vacancies are immobile. The existence of immobile vacancies limits the applicability of vacancy-based models to the temperature range where vacancies can migrate. In summary, the formation of the surface relief connected with the PSBs results both from the slip processes and from the production and migration of point defects.

The coarse slip markings on the surface are not always related to the zones of specific dislocation structure that differ from the structure of the surrounding matrix. For example, Bretschneider et al. (Ref 50) found no characteristic arrangements of dislocations that could be correlated with the extrusions on the surface of nickel single crystals cycled at low amplitudes at 77 K. Thus, zones with specific dislocation structures are not prerequisites for the formation of surface coarse slip bands and for subsequent microcrack nucleation.

**Easy-Cross-Slip Metals (High-Amplitude Cycling).** High-amplitude cycling of easy-cross-slip materials has been found to form the cell structure both in the interior and the surface layer of specimens (Ref 28). No clear differences have been found between interior and near-surface cell structures. On the other hand, the finer parameters of the cell structure in the surface layer, such as disorientation and the Burgers vectors of dislocations in the walls, have never been measured. Therefore, differences between interior and near-surface cell structure in these finer parameters is a remaining question.

Figure 13 (Ref 28) shows the surface relief and the underlying dislocation structure in a copper single crystal cycled by a high strain amplitude. The foil parallel to the  $(1\bar{2}1)$  plane (see Fig. 10) was prepared by the method of "electroplated samples" described above (see text to Fig. 9). Very marked surface relief can be seen; the surface extrusions and intrusions can be described as valleys and hills that lie predominantly along the intersection lines of the slip plane with the surface of the specimen. As in the previous case, formation of the notch-peak topography must be related to the collective motion of dislocations within the whole layer of cells lying along the slip plane. Again, the basic mechanism probably lies in bowing-out dislocation segments from cell walls that reach the nearest wall and cause an avalanche along the whole layer of cells. On reverse load, the process is repeated in the opposite direction, but the surface steps produced by dislocations emerging at the surface are not completely reversible, again because of cross slip. Contrary to the low-amplitude case, the interaction of slip activity of different systems must be taken into account in future detailed explanations.

**FIG. 13 SURFACE RELIEF MICROCRACKS AND DISLOCATION STRUCTURE IN SURFACE LAYER. SECTION PERPENDICULAR TO THE SPECIMEN SURFACE AND THE PRIMARY SLIP PLANE IN COPPER SINGLE CRYSTAL. D, ELECTRODEPOSITED LAYER; S, SPECIMEN; M, MICROCRACKS**

Figure 13 also shows the first microcracks (denoted M) that start from sharp surface intrusions. In both high-amplitude and low-amplitude cases, the first microcracks are connected with sharp intrusions. The microcracks shown in Fig. 13 follow the trace of the primary slip plane, which proves that they lie along the primary slip plane.

**Difficult-Cross-Slip Metals.** In the case of materials with very low stacking-fault energies, interior and near-surface structures were similar and described as planar arrays of dislocations. However, near-surface structure differs from interior structure in a minor way: the dislocation density is lower by a factor of 2 to 3 (Ref 22).

An example of the planar array of dislocations is shown in Fig. 14 (Ref 52). The foil was taken from the interior of a Cu-22Zn single crystal cycled at a low strain amplitude; the notation of the crystallographic planes and directions is shown in Fig. 10. The dislocations on the active primary slip planes  $(111)$  appear as thin bands in this  $(1\bar{2}1)$  section. The dislocation density within some of these bands obviously exceeds the dislocation density in the others. Cycling at higher amplitudes results in a higher number of these dense bands (Ref 22). The same type of dislocation structure was found in polycrystalline planar slip alloys after cycling (Ref 53, 54, 55, 56). Laird et al. (Ref 23, 57, 58, 59, 60) call the slabs of activated primary slip planes (the dense bands in Fig. 14) "persistent Lüder's bands" (PLBs). These bands are assumed to represent zones of localized cyclic slip. Contrary to the PSBs in wavy-slip metals, PLBs are not permanent and do not represent zones of dislocation structure that are distinctly different from surrounding matrix. PLBs are not stable; the localized strain moves around the gage length, and the active life of the slip band is short.

**FIG. 14 DISLOCATION STRUCTURE IN CU-22WT%ZN SINGLE CRYSTALS**

One example of the near-surface planar-slip structure is shown in Fig. 15, a TEM section of a Cu-31Zn single crystal (Ref 28). The sample was electroplated after cycling, and the foil was prepared in such a way that it contains the interface between the specimen and the  $(hkl)$  surface (see Fig. 10). The roughness profile on the specimen surface can be seen simultaneously with the underlying dislocation structure. The relation between the hill-and-valley surface topography and the slabs of the planar arrays of dislocations is obvious.

**FIG. 15 SURFACE RELIEF AND UNDERLYING DISLOCATION STRUCTURE IN A SECTION PERPENDICULAR TO THE SPECIMEN SURFACE AND THE PRIMARY SLIP PLANE IN  $\alpha$ -BRASS SINGLE CRYSTAL (CU-31WT%ZN). D, ELECTRODEPOSITED LAYER; S, SPECIMEN**

The surface morphology in planar-slip alloys is different from that in wavy-slip metals. The surface slip relief in wavy-slip metals is related to the slip activity of PSBs. In many cases a one-to-one correspondence between a ladder-like PSB and a coarse slip band on the surface can be proved (see Fig. 9). In planar-slip crystals, a more or less regular hill-and-valley surface morphology is often found after a sufficiently high number of loading cycles. This, together with the fact that PLBs do not represent zones of distinctly different dislocation structures, leads to the conclusion that surface relief forms because homogeneous cyclic slip takes place simultaneously and with the same intensity over the whole gage length.

A quantitative approach to the homogeneous type of surface roughness formation, based on computer simulation of random slip and on slip irreversibility at the surface (Ref 12), led to reasonable agreement with the experimentally observed surface roughness profile of the type shown in Fig. 15.

Careful experiments performed by Hong and Laird (Ref 23, 59, 61) on Cu-16at.%Al crystals offer a different interpretation of the kinetics of surface morphology formation. Hong and Laird found that the fraction of the gage length occupied by slip bands (in the sense of surface markings) increases with an increasing number of cycles, so that surface relief is not formed simultaneously over the whole gage length. Most important is that the active slip bands repeatedly move around the gage length (i.e., the slip bands can cease their activity and be reactivated again). In fact, the final result of this process is also a regular and rather homogeneous hill-and-valley surface morphology. The cracks are observed after the whole gage length becomes completely filled with slip bands (Ref 60). This confirms again that the prerequisites for microcrack nucleation are a sufficient notch-peak topography, hardening at nucleation sites, and local concentration of cyclic plastic deformation. The way that these necessary conditions are achieved seems to be of less importance.

## Fatigue Crack Nucleation and Microstructure

Petr Lukáš, Institute of Physics of Materials, Academy of Sciences of the Czech Republic

---

### Damage in Nucleation Stage

Microcrack nucleation is always preceded by cyclic slip localization. The magnitude of the local cyclic plastic strain amplitude is a key parameter governing crack nucleation. The fatigue damage in the prenucleation stage is related to the local cyclic plastic strain, but this fact is of almost no practical use, because the local cyclic plastic strain amplitude at the nucleation sites cannot be measured. Microcracks start from the surface intrusions (i.e., from surface micronotches formed by cyclic plastic deformation). The other, related possibility in polycrystals is grain-boundary nucleation due to the interaction of PSBs with the grain boundaries, which also leads to the formation of surface micronotches. Crack nucleation on the PSBs and in the grain boundaries often occurs concurrently. The relative density of these two nucleation sites depends on the amplitude and the environment (Ref 67).

As mentioned above, a number of experiments have shown that removal of the surface layer prior to nucleation considerably increases fatigue life. Electropolishing removes the surface roughness produced by cyclic plastic deformation, but it does not change the dislocation structure. Experiments of this type have led to the conclusion that the surface layer as a whole, and the surface stress raisers especially, are the principal sources of fatigue damage. More

specifically, the damage can be related primarily to the sharpness and density of the surface notches and, to a lesser extent, to the state of the dislocation structure surrounding them.

The term *fatigue damage* can be defined precisely during the stage of stable crack propagation (i.e., stage II). At this stage, fatigue damage is proportional to crack length. To define fatigue damage during nucleation (stage I), it would be necessary to find a quantitative characteristic of the acuity of the surface relief. Generally, the expressiveness of the surface relief (i.e., the height of extrusions and the depth of intrusions) increases with the number of cycles (Ref 69, 70) and with increasing local plastic strain amplitude in the nucleation sites. It seems plausible that this local plastic strain amplitude increases with increasing overall plastic strain amplitude, and thus that fatigue damage in the prenucleation stage is an increasing function of the plastic strain amplitude and the number of cycles. Irrespective of the mechanism of microcrack initiation, the first microcracks in flaw-free materials nucleate simultaneously in many places on the surface. Thus, the initiation process should be understood as a formation of the whole system of microcracks, not as an isolated event concerning just one nucleation site. The interaction of the particular microcrack with the surrounding system of other microcracks cannot be generally neglected.

For all materials, the population and size distribution of microcracks are strong functions of the stress or strain amplitude and the number of cycles (Ref 10, 62, 63, 64). Moreover, these quantities depend strongly on the type of material. We shall discuss here two examples: an Al-Cu-Mg alloy exhibiting a relatively low microcrack density (Fig. 4); and  $\alpha$ -iron exhibiting a high density of microcracks (Fig. 16). The degree of mutual interaction among the microcracks varies accordingly.

**FIG. 16 MICROCRACK DENSITY IN DEPENDENCE ON RELATIVE NUMBER OF CYCLES IN  $\alpha$ -IRON FOR TWO STRAIN AMPLITUDES.  $\epsilon_a$ , STRAIN AMPLITUDE;  $N$ , NUMBER OF CYCLES;  $N_f$ , NUMBER OF CYCLES TO FRACTURE**

Figure 4 shows the dependence of microcrack density on the relative number of cycles in an Al-Cu-Mg alloy for two stress amplitudes (Ref 10), both greater than the endurance limit. A high number of microcracks are formed during the first 20 to 30% of total fatigue life. With continued cycling, some of the nucleated microcracks grow, and practically no new ones are nucleated. In addition, the microcracks do not coalesce and the microcrack density does not decrease. Thus the mutual interaction is weak. The microcracks emanate from cracked or debonded intermetallic particles, and their shape is roughly semicircular. After the whole family of microcracks nucleated, their density undergoes only minor change. The same holds for the size of these microcracks. The mean depth of the microcracks is about 6  $\mu\text{m}$  for the lower amplitude and about 9  $\mu\text{m}$  for the higher amplitude. This implies that only a few microcracks can grow after they have reached a critical size, which is obviously strongly stress dependent.

Figure 16 shows the effect of strain amplitude and number of cycles on the density of microcracks for  $\alpha$ -iron (Ref 63). There are two clear differences from Al-Cu-Mg alloy: the density of microcracks in  $\alpha$ -iron is considerably higher (for comparable fatigue lives); and the density increases with the number of cycles, reaches a maximum, and then decreases. The average crack length on the surface corresponding to the maxima is about 20  $\mu\text{m}$  for the lower amplitude and about 80  $\mu\text{m}$  for the higher amplitude. The curves prior to  $N/N_f = 0.5$  represent a continuing nucleation of new microcracks. At the beginning portion of fatigue life (at low values of cycles,  $N$ ), microcracks nucleate and grow independently. With increased  $N$ , additional microcracks nucleate and existing cracks grow. With crack growth eventually there are interactions between microcracks, the local stress is relieved, and microcrack nucleation ceases. For  $N/N_f > 0.5$ , crack growth and coalescence dominate and the total number of cracks decrease. The subsequent coalescence of the microcracks is the reason for the decrease in microcrack density.

The strain redistribution due to microcrack growth was considered by Ma and Laird (Ref 65) to determine the behavior of the whole system of nucleated microcracks. The strain redistribution leads to the result that shallower cracks stop growing, while a few deeper ones grow faster and become the fatal cracks. This suggests that once the microcrack mean spacing reaches a certain critical value, the fatigue life preceding macrocrack propagation must be close to exhaustion.

Figures 4 and 16 concern the population of freshly nucleated microcracks at stress or strain levels above the fatigue limit. There is now enough experimental evidence to show that microcracks are nucleated and propagated up to the critical size, even at stress or strain levels at or slightly below the fatigue limit. At stress levels at or below the fatigue limit, propagation of nucleated microcracks stops. This is in contrast to stress levels above the fatigue limit, where some microcracks continue to propagate. Thus, the fatigue limit can be understood as the stress (or strain) level that represents the threshold for propagation of critical microcracks. At the fatigue limit, the largest microcrack of the whole population is more important than the mean value of the overall population of microcrack sizes.

The extent of damage due to an array of microcracks depends primarily on the mean spacing between the microcracks. For large mean spacing (i.e., mutual interaction of microcracks is insignificant), the damage can be best defined as the crack length of the dominant crack. This interpretation can probably be applied to all materials subjected to cycling at levels near the fatigue limit. For higher stress or strain levels, this definition can be used only for materials with low microcrack density, such as Al-Cu-Mg (see Fig. 4). Otherwise, in high stress or strain amplitude cycling, the microcrack density should be used as the basis for the definition of damage. For example, Hua and Socie (Ref 66) defined the damage as weighted crack density, taking into account the fact that cracks forming late in the life should not be as damaging as cracks that form earlier.

## Fatigue Crack Nucleation and Microstructure

Petr Lukáš, Institute of Physics of Materials, Academy of Sciences of the Czech Republic

---

## Mechanisms of Microcrack Nucleation

A large number of models have been proposed for nucleation of microcracks. In light of the experimental results considered above, it is clear that the proposed mechanisms may operate only in nucleation sites (i.e., at the root of intrusions in fatigue slip bands, in the vicinity of an inclusion, or near grain boundaries).

In order to model crack nucleation, the difference between sharp intrusions and the microcracks must be defined. For example, on the basis of experimental data obtained mainly on copper single crystals, Neumann states (Ref 68) that "intrusion formation and crack nucleation are two different processes." Basinski and Basinski conclude (Ref 69), also on the basis of experimental observation of cycled copper single crystals, that intrusions continue to grow with an increasing number of cycles, so that near to failure there is a large population of cracks. The different observations with respect to the transition between intrusions and microcracks leads to different models. Some of the models consider the process of crack nucleation to be indistinguishable from the process of intrusion formation. Other models distinguish intrusions from microcracks, and they require qualitatively different processes for intrusion formation and microcrack formation. None of the proposed models can be experimentally verified to the full extent, so all are more or less hypothetical.

The proposed mechanisms of microcrack nucleation can be roughly divided into five groups, described below. The basis for the division here is the mechanism of the critical event leading to a loss of cohesion, i.e. to the microcrack formation. All of the models have merits and have been justified by experimental findings. None of them has been worked out quantitatively, which would make it possible to express the influence of both external and internal parameters on the rate of nucleation.

**Models That Do Not Distinguish between Intrusions and Microcracks.** In some models, microcrack formation is identical with continuous growth of intrusions. Growth may occur by repeated slip on one or more slip systems. The basic idea for the one-slip system is the relative motion of parallel "cards" (Fig. 17). Wood (Ref 71) assumes that intrusions act as a stress raiser and promote further slip just in the "notch root." May (Ref 72) showed theoretically on the basis of statistical formalism that with continued cycling, progressively deeper intrusions would result from random slip. Lin et al. (Ref 73, 74) calculated the relative motion of two non-neighboring "cards" or slices. They showed that the local plastic shear strain in both slices (one positive and the other negative) can reach very high values within a relatively short number of cycles. These large plastic strains cause the continuous "squeezing out" or "sucking in" of the layer between the slices. In other words, in the second case we get a continuously deepening intrusion.

FIG. 17 MODEL OF CARD SLIP IN FATIGUE SLIP BAND

The model by Lynch (Ref 75), also using the idea of soft layers being extruded or intruded during cycling, yields a similar result: the fatigue cracks initiate and grow by a mechanism of intrusion that occurs when soft layers are "sucked in." A modern version of the models based on intrusions is represented by computer simulations of random irreversible slip. The model by Rosenbloom and Laird (Ref 76) operates by determining the number of active slip planes during each half cycle, randomly choosing the corresponding number of slip planes, and then randomly distributing the slip among those slip planes after ensuring that each chosen slip plane has received at least one increment of slip. Crack nucleation, defined as an intrusion of 4 mm depth, occurred in good agreement with the observed number of cycles.

Neumann (Ref 42) proposed a model for the formation of cracks by coarse slip on alternating parallel slip planes (Fig. 18). In this model the crack develops from coarse slip steps. In tension (Fig. 18a), slip plane 1 is activated; excess dislocations of one sign remain on this slip plane. The slip step that is produced acts as a stress raiser, which also helps to activate slip plane 2 under the same tensile load. This leads to the configuration shown in Fig. 18(b) and to excess dislocations of one sign on plane 2. During the next compression, excess dislocations on slip planes 1 and 2 run back, leading to the configuration shown in Fig. 18(c). It is assumed that at A in Fig. 18(c) the surfaces are not "rewelded" but rather only touch macroscopically. Thus, A in Fig. 18(c) already represents a crack nucleus. Repetition of this process takes place on further glide planes of the same slip systems, leading to continuous increase of microcrack length. Note that in this model, the crack nucleation is on an average plane which is perpendicular to the maximum tensile stress as opposed to parallel to the shear plane as in the case of intrusion formation.

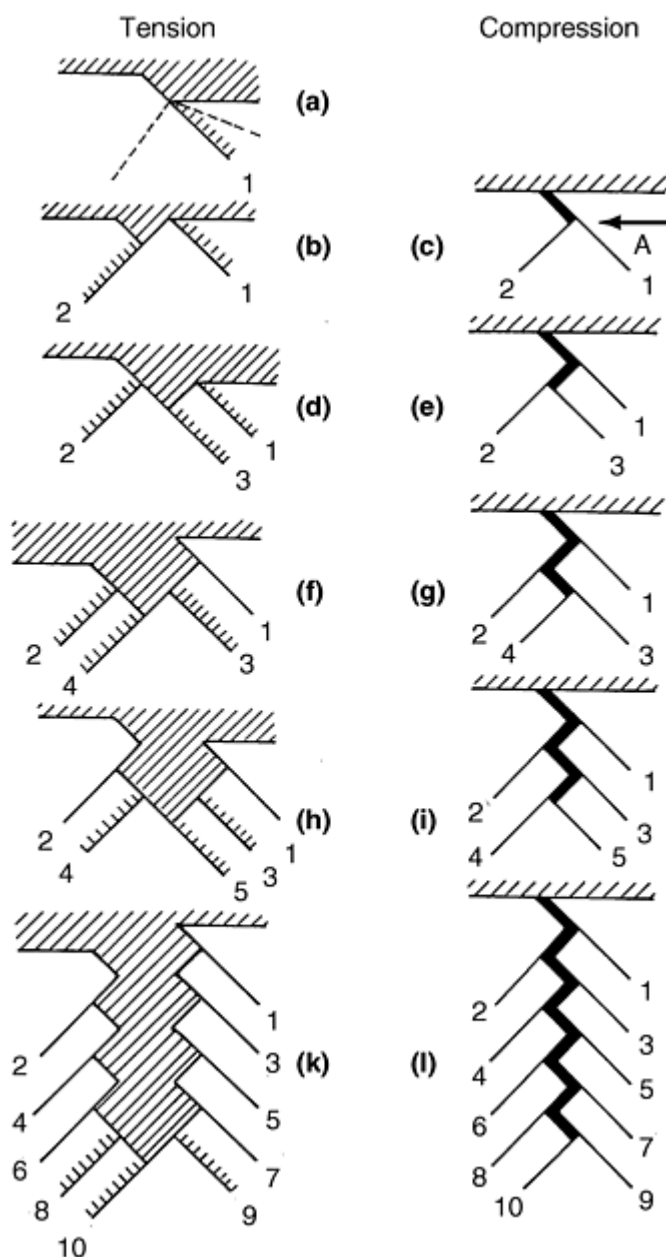

FIG. 18 NEUMANN'S MODEL OF CRACK NUCLEATION. IN PART (C), A REPRESENTS A CRACK NUCLEUS. SOURCE: REF 42

Harvey et al. (Ref 77) proposed a model based on slip band spacing, slip height displacement, and cumulative plastic strain. The quantitative treatment is based on two assumptions: that surface displacements are crack-like and that crack-tip displacement controls nucleation. The number of cycles to crack initiation is the number of cycles necessary to reach a

certain critical displacement. The model predicts that the number of cycles to nucleate a crack increases with a decrease in grain size, an observation which is consistent with experimental results (see, e.g., Ref 78).

**Crack Nucleation based on Critical Conditions for Local Brittle Fracture.** The concept of local brittle fracture distinguishes clearly between intrusions and cracks. A trivial example is the cracking of a brittle second-phase particle at the site of a stress concentration due to fatigue notch-peak topography.

There is quite a high probability that the critical conditions for local brittle fracture can be reached also in very ductile materials like copper. Figure 13 shows microcracks starting from the surface intrusions. The appearance of the microcracks distinguishes them clearly from intrusions. Thus the mechanism of continuous growth of intrusions does not come into question. Much more acceptable is the explanation that the stress concentration and the stress triaxiality due to the intrusions reach their critical values at or ahead of the tips of the intrusions. The dislocations cannot anymore relax the local stress concentration and the microcracks are formed by local brittle fracture. The role of dislocations in this type of microcrack formation is thus only indirect, through the building up of the surface relief and the hardening of the crystal around the intrusions.

**Condensation of Vacancies (Ref 82).** Cyclic deformation produces a higher number of vacancies than monotonic loading. This may be due mainly to the to-and-fro motion of dislocations with jogs. As PSBs exhibit higher plastic strain amplitude, it is probable that the vacancies generated could condense to form voids, thus nucleating a crack. This model implicitly requires diffusion of vacancies, which is strongly temperature dependent. There are papers which show that the fatigue processes (crack nucleation and propagation) take place even at cryogenic temperatures (Ref 35), that is, temperatures where practically no diffusion is possible. This limits the applicability of the vacancy model to high temperatures, where creep phenomena and diffusion play critical roles.

**Loss of Coherency across a Slip Plane due to Accumulation of Defects.** The basic idea of loss-of-coherency models is the formation of dislocation configurations in critical sites, which leads to local increases in stress or energy sufficient to destroy crystal coherency in small regions (of the order of nanometers and less).

Fujita (Ref 79) showed theoretically that a dislocation dipole with a small separation of the two components of the dipole may lead to crack nucleation via annihilation. His model is shown in Fig. 19. On two parallel slip planes, the pileup configurations of opposite signs are formed during cycling, where  $h$  is the separation of the planes. The calculation shows that as a function of  $h$ , one of two events can happen: for  $h > 1$  nm, the two sets of pileups pass each other; or for  $h < 1$  nm, the leading dislocations annihilate, even though they do not lie in the same slip plane. By this process a small area with destroyed coherency is formed. If not only the leading dislocations annihilate, but also  $n$  dislocations from each pileup (Fig. 19b), then coherency is lost in a region of length  $n\mathbf{b}$  (where  $\mathbf{b}$  is the Burgers vector) and height  $h$ , and a microcrack is formed. This mechanism can operate when each pileup consists of at least a few tens of dislocations.

FIG. 19 FUJITA'S MODEL OF CRACK NUCLEATION. SEE TEXT FOR DEFINITIONS OF SYMBOLS. SOURCE: REF 79

The model of Oding (Ref 80) is based on the assumption that the multipole dislocation configuration of the type shown in Fig. 20 is built up during cycling. The distances among the particular dislocations continuously decrease with increasing number of cycles. The elastic energy, having its peak values at points  $b_1$  to  $b_4$ , increases with decreasing distances among the dislocations. After these distances reach the values shown in Fig. 20, the peak values of the elastic energy are comparable with the latent melting heat. This is considered by Oding to be equivalent to the destruction of the coherency at the critical points. The area with lost coherency is, in turn, identical with the microcrack. The formation of the dislocation configuration in Fig. 20 again requires high local stress concentration. One of its sources, also in the model of Fujita, is a set of pileup dislocations, but a sharp surface micronotch could, in principle, also produce the required stress.

FIG. 20 ODING'S MODEL OF CRACK NUCLEATION.  $B$ , BURGERS VECTOR. SOURCE REF 80

Dislocation configurations of the type shown in Fig. 19 have never been observed in cycled metals, and therefore the mechanism by Fujita in its original formulation is not applicable. However, its more sophisticated modifications by Mura (Ref 81) seems quite realistic. Mura considers two adjacent planes where positive and negative dislocations are accumulated. The dislocation dipoles are increased by each cycle of loading. Thus, the elastic strain energy increases with the number of cycles. Mura has shown that there exists a critical number of cycles beyond which the dislocation dipole accumulation becomes energetically unstable. The dislocation dipoles are annihilated to form a microvoid (crack).

**Nucleation of Cracks in Grain Boundaries.** Basically, two kinds of models for nucleation in grain boundaries have been proposed, one based on plastic instability (Ref 83) and one that takes into account the interaction of slip within the grain with the grain boundary (Ref 11, 12).

The first kind of model assumes a very high degree of homogenous cyclic plastic strain across the whole surface layer of surface grains. Because the boundary hinders plastic deformation (the displacement perpendicular to the surface is negligible at the boundary), the plastic instability can occur on a microscale in such a way that the depth of a crease at a

grain boundary deepens with an increasing number of cycles, until the strain concentration of the crease becomes so large that it constitutes a microcrack.

From models based on slip band interaction with grain boundaries, the model by Mughrabi et al. (Ref 12) is worked out in a semiquantitative way. This model represents an extension of the model by Essmann et al. (Fig. 11) (Ref 46), proposed for the growth of surface extrusions above PSBs in single crystals. In polycrystals, the interaction between the PSB and the grain boundary leads to a stress concentration that can ultimately cause a decohesion along the grain boundary.

In fcc metals, twin boundaries have often been found to be nucleation sites (Ref 84, 85). Twin boundaries can promote microcrack nucleation in two ways: PSBs form preferentially in highly stressed region near the twin boundary; and in the stress concentrations, twinning dislocations move along the boundary, which is effectively equivalent to a motion of the twin boundary. The region over which the boundary moves undergoes a high cyclic strain that promotes nucleation.

## Fatigue Crack Nucleation and Microstructure

Petr Lukáš, Institute of Physics of Materials, Academy of Sciences of the Czech Republic

---

## End of the Nucleation Stage

Several interpretations have been used to define the end of the nucleation stage, all of which are based on a characteristic crack size and spacing. Each interpretation of them has its experimental justification. From the section "Damage in the Nucleation Stage" in this article, it does not seem plausible to relate the end of nucleation with the appearance of the first detectable microcracks. The transition from nucleation to propagation is rather the transition from the system of microcracks governed by cyclic plastic strain to crack propagation governed by fracture mechanics.

In cases in which there is substantial interaction among microcracks, the idea of a critical degree of strain relaxation, discussed above (Ref 65), is a good basis for the definition of the end of the nucleation process. When a critical degree of mean microcrack spacing is reached by crack multiplication, strain relaxation effectively hinders nucleation of new microcracks, and the strain redistribution accelerates stage II crack growth. Nevertheless, it is difficult to formulate this definition quantitatively.

Vašek and Polák (Ref 63) adopted a similar point of view. They assumed every nucleated microcrack leads to strain relaxation in its vicinity. The total area of the surface, at which the strain is relaxed below the value needed for nucleation, increases with an increasing number and size of microcracks. When the number and size of microcracks reach critical values, no new nucleation is possible, and further material degradation is caused by growth of the largest cracks. Vašek and Polák identify the number of cycles that correspond to the maximum of microcrack density in Fig. 16 with the transition from the nucleation stage to the crack propagation stage. The corresponding representative microcrack length strongly depends on strain amplitude, being considerably lower for the low amplitude (20  $\mu\text{m}$ ) than for the high amplitude (80  $\mu\text{m}$ ). The fraction of cycles spent in the nucleation stage is independent of the strain amplitude, namely about 50% of the total life. This contradicts the generally accepted view that the nucleation process at high amplitudes is completed within a negligible fraction of total life. Thus the assumption that the end of nucleation is given by the position of the maximum in Fig. 16 is obviously not correct. It is probably another characteristic of the family of nucleated microcracks, which characterizes the end of nucleation stage.

A long period of cycling at stress equal to or slightly lower than the fatigue limit produces nonpropagating microcracks with a size comparable to the grain size (Ref 86, 87). It follows that the fatigue limit is the threshold for small cracks that nucleated (at the same stress level), grew to a critical size, and then ceased to grow (Ref 88). The existence of such a critical crack size implies another possible definition for the end of the nucleation stage: as the number of loading cycles needed to produce a crack of a critical size.

The short crack threshold can be conveniently described by means of the Kitagawa-Takahashi plot (Ref 89), which relates the short threshold stress amplitude with crack size (Fig. 21). The Kitagawa-Takahashi plot introduces a "demarcation line" below, which the cracks cannot propagate. This threshold presentation in terms of the threshold stress amplitude automatically involves the fact that the highest possible short crack threshold stress amplitude is the fatigue limit of smooth specimens. Figure 21 (Ref 90) is an experimentally determined Kitagawa-Takahashi diagram for two  $R$ -ratios. Up to a critical size, the cracks are nondamaging. This critical size is about 0.1 mm for both the  $R$ -ratios, which corresponds approximately to the prior-austenite grain size. The threshold stress amplitudes at the horizontal parts of the curves (i.e., the threshold stresses for cracks up to the critical size) are identical with the independently determined fatigue limits.

FIG. 21 KITAGAWA-TAKAHASHI DIAGRAM FOR NATURAL SURFACE CRACKS IN LOW-CARBON STEEL AT STRESS RATIOS OF  $R = -1$  AND  $R = 0$

Many years ago, French (Ref 91) proposed the "critical-damage curve." The determination of this damage curve, also called French's curve for a material of known  $S-N$  curve, can be performed by the following procedure. A specimen is cycled at a chosen stress level for a chosen number of cycles; then the stress is decreased to the level of fatigue limit and the cycling is continued. If the specimen fractures after a (high) number of further cycles, the original stress level lies above French's curve. If the specimen does not fracture, even after a high number of cycles, the original stress level lies below French's curve. A repetition of this procedure for a number of specimens enables the investigator to locate the position of French's curve quite exactly.

An example of the experimentally determined French's curve is presented in Fig. 22 (Ref 92). In agreement with the definition of French's curve, each specimen was cycled for a chosen number of cycles at a chosen stress level. The stress level was then decreased to the fatigue limit and the cycling was continued. Points marked by upward arrows denote specimens that fractured; points marked by downward arrows denote specimens that did not fracture during the course of  $10^7$  loading cycles. Experimentally, it was found for low-carbon steel that at French's curve the PSBs contain cracks extending from grain boundary to grain boundary, in some cases even across two or three grains. This is independent of the stress level. Thus, French's curve represents the curve of constant crack size. It is important that the crack size corresponding to French's curve (Fig. 22) be roughly equal to the critical crack size determined from the Kitagawa-Takahashi diagram (Fig. 21).

FIG. 22 S/N CURVE AND FRENCH'S CURVE FOR LOW-CARBON STEEL

In summary, two concepts can be used to define the end of the nucleation stage. One is based on the relaxation of strain around microcracks, and the other is based on the size of the largest crack that cannot propagate below the fatigue limit. The latter definition gives considerably larger cracks at the end of nucleation than the former definition. In a way, the transition from microstructurally small cracks to physically small cracks is well compatible with the latter definition. At present, there is no physically sound basis for a particular choice of definition of the end of the nucleation stage.

### Factors That Influence Crack Nucleation

There is no clearcut demarcation between nucleation and early-stage propagation, so it is difficult to define the end of the nucleation stage (see the previous section). For practical purposes, however, such a definition is often necessary. The only possibility is either a convention based on the density of microcracks and their depth and length along the surface, or a convention based on the dimensions of the largest crack. Let us denote the number of loading cycles necessary to complete the nucleation stage as  $N_0$  (for an arbitrarily chosen definition of the end of nucleation) and the number of cycles to fracture as  $N_f$ . Then the ratio  $N_0/N_f$  is a measure of the length of the nucleation stage in terms of the relative fatigue life.

The relative number of cycles  $N_0/N_f$  depends mainly on the amplitude and asymmetry of cycling, the shape of the specimen or engineering component, the material parameters, the environment, the temperature, and the surface layer.

**Cycling Amplitude and Asymmetry.** The value of  $N_0/N_f$  decreases with increasing amplitude. In the low-amplitude region,  $N_0$  can represent a significant percent of the total fatigue life. For very high amplitudes, the nucleation is very quick,  $N_0$  is negligible with respect to  $N_f$ , and essentially the whole fatigue life is spent in crack propagation. Nucleation is also strongly influenced by the stress cycle asymmetry. For example, in an extreme case of repeated compression, no cracks at all were found on the surface of cycled single crystals of copper (Ref 93).

**Specimen Shape.** Notches generally significantly reduce the value of  $N_0/N_f$ . For very sharp notches and especially for crack defects, the nucleation stage is almost completely missing and the whole fatigue life is given by the crack propagation stage.

**Environment** has a strong effect on crack initiation (Ref 94). Ample experimental data show that the fatigue life of all materials tested in vacuum is considerably longer than the fatigue life in any other environment. A part of the increase in fatigue life in vacuum is due to the fact that the growth rate of cracks (especially of small cracks) is smaller in vacuum than in air or other environment. Another substantial part of this increase is due to the inhibited crack initiation. For example, crack initiation in copper single crystals tested in vacuum has been found to be 1 to 2 orders of magnitude slower than that in air (Ref 68). This can be explained by rewelding of newly formed slip steps on slip reversion in vacuum. In air, every slip step is covered by adsorbed atoms or molecules from the environment. After slip reversion, this adsorption layer prevents annihilation of the newly formed surface of the slip step.

**Temperature** decreases lead to an increase in  $N_0/N_f$  for stress-cycled metals exhibiting crack nucleation in fatigue slip bands. For materials in which cracks nucleate at surface inclusions, the decrease in temperature should result in a decrease in  $N_0/N_f$ . At higher temperatures, nucleation in slip bands may be by nucleation at grain boundaries.

**The surface layer** has a very strong effect on fatigue life. The nature of this strong dependence lies mainly in the influence on crack nucleation. Surface treatment of any type leads to one or more of these effects:

**Surface Roughness.** The surface topography, especially surface scratches, act as stress concentrators and thus shorten the nucleation stage.

**Residual Stresses.** Macroscopic residual stresses can be detected on the surface after almost all types of surface treatment. Tensile residual stresses are detrimental (they enhance nucleation), whereas compressive residual stresses are beneficial (they inhibit nucleation). The essence of the explanation lies in the superposition of the external stress with the residual stress: the higher the tensile mean stress, the lower the number of cycles necessary for nucleation. This is justified by the above-mentioned experimental result that cracks do not nucleate in the compressive stress cycle.

**Phase and Chemical Composition.** The effect of phase and chemical composition either is deliberate (as in surface quenching, carbonitriding, coating, ion implantation, laser hardening, etc.) or occurs as a side effect of heat treatment (e.g., decarburization of the surface layer). The phase and chemical composition may influence the nucleation both beneficially and detrimentally, depending on the resistance of the surface layer to cyclic plastic deformation.

**Work hardening of the surface layer** inevitably occurs as a result of machining and finishing the surface simultaneously, due to the occurrence of residual stress. Cyclic loading removes or reduces work hardening during fatigue softening.

**A corrosive environment** generally shortens the nucleation stage. The effect of gaseous environments on fatigue crack initiation is a controversial subject. If there is any influence at all, it is probably not strong. However, aqueous environments have been found to significantly shorten the nucleation stage, perhaps without exception. Theories explaining this strong effect can be divided into the following categories:

- **PITTING:** LOCAL ETCHING, EITHER SELECTIVELY AT PLACES OF HIGHER SLIP ACTIVITY (I.E., AT FATIGUE SLIP BANDS) OR NONSELECTIVELY AT ANY PLACE ON THE SURFACE, PRODUCES PITS THAT ACT AS STRESS RAISERS. PROBABLY MORE IMPORTANT IS THE PITTING OR PREFERENTIAL DISSOLUTION AT AREAS OF HIGHER SLIP ACTIVITY, WHERE SLIGHT DIFFERENCES IN ELECTROCHEMICAL POTENTIAL INSIDE AND OUTSIDE SLIP BANDS ENHANCE THE PROCESS OF STRESS RAISER FORMATION.
- **DESTRUCTION OF PROTECTIVE OXIDE FILMS:** THE SURFACE OF A METAL EXPOSED TO AN AQUEOUS ENVIRONMENT IS COVERED BY A THIN OXIDE FILM THAT IS CATHODIC WITH RESPECT TO THE METAL. SLIP PROCESSES CAN EASILY DESTROY THE OXIDE FILM LOCALLY, ESPECIALLY IN PLACES OF HIGH SLIP ACTIVITY, AT THE FATIGUE SLIP BANDS. THE ELECTROCHEMICAL CELL (THE SMALL ANODIC REGION AT THE SITE OF OXIDE LAYER DESTRUCTION) FORMED AS A RESULT CAN THEN VERY EFFECTIVELY SPEED UP LOCAL DISSOLUTION AT THE SLIP BAND AND THUS PRODUCE MICRONOTCHES.
- **REDUCTION OF SURFACE ENERGY BY ADSORPTION:** THE DECREASE IN SURFACE ENERGY BY AN ADSORBING SPECIES IN AN AQUEOUS ENVIRONMENT FACILITATES THE PROCESS OF SURFACE SLIP FORMATION. THUS, THE FORMATION OF FATIGUE SLIP BANDS AND, CONSEQUENTLY, NUCLEATION ARE EASIER.

Common to all of these explanations is the idea that a corrosive environment promotes slip activity in the surface layer of cycled metal. The mechanism of microcrack nucleation is probably the same as in the absence of environment.

## Fatigue Crack Nucleation and Microstructure

Petr Lukáš, Institute of Physics of Materials, Academy of Sciences of the Czech Republic

---

## Summary

A basic understanding of the fatigue process on a submicroscopical level is important in safe design against fatigue. Fatigue crack nucleation is perhaps the most difficult stage of the fatigue process to study. This is due mainly to the fact that the microcrack nucleation is a highly localized event taking place in a very small part of the total volume. At present, the sites of microcrack nucleation are relatively well known both in the model materials and in the engineering materials. The basic features of the microscopic mechanisms of the nucleation are partly understood on the qualitative level. No quantitative description of the nucleation mechanisms covering explicit expressions for all critical parameters is available.

Thus it is not surprising that the present-day research on the mechanisms of fatigue crack nucleation aims to the quantification of the knowledge gathered over years.

The aim of this article is to give an overview on the fatigue crack nucleation from the point of view of the material microstructure and its evolution during cycling. The article describes the sites of microcrack nucleation at the free surfaces, discusses the relation of dislocation structures and surface relief and offers a review of the current mechanisms of crack nucleation. Moreover the meaning of the "damage" of material due to crack nucleation, the extent (in terms of the number of cycles) of the nucleation stage and the factors influencing crack nucleation are covered. The experimental findings discussed in the article concern mainly relatively simple model materials. Further data on crack nucleation in complicated engineering materials can be found in the "Selected References List of Crack Nucleation in Structural Alloys."

## Fatigue Crack Growth under Variable-Amplitude Loading

J. Schijve, Delft University of Technology

---

### Introduction

FATIGUE is a practical problem for all kinds of structures subjected to a spectrum of many load cycles under normal service utilization conditions. A single load application need not be harmful, but a repetition of many load cycles can initiate a fatigue crack. The crack will grow until collapse of the structure, unless it is found by inspection. The variety of practical fatigue problems is large because of the many types of structures, materials, load spectra, and other design variables.

Fatigue failures can have significant consequences in practice, which can be highly undesirable for reasons of economy. Fatigue failures in expensive structures built in small numbers are practically unacceptable. Another important argument is safety. Disastrous fatigue failures occurred in the past with fatalities, serious damage to the environment, and liability problems afterwards. As a consequence, the concept of *designing against fatigue* has attracted much attention from industry, research institutes, universities, and the authorities responsible for safety regulations to protect society against fatal accidents. The economic and social impact of fatigue failures will not be discussed here, but designing against fatigue obviously is a matter of concern. It encompasses various design options, and needless to say, experience and engineering judgment are essential. Fatigue predictions are then necessary to quantify the fatigue problem in terms of fatigue life and crack growth.

A general survey of a fatigue prediction scenario is given in Fig. 1. It illustrates that design includes choosing among various options (first column). The second column includes data on material fatigue properties and calculations, basically stress analysis problems. The third column includes information on the fatigue loads in service, the dynamic response of the structure, and the environment. All aspects of the input information have to be used for predictions on fatigue life and crack growth. A pertinent question then is: Do we have reliable prediction models? If so, do we obtain accurate indications of the fatigue behavior of a structure in service? Is it desirable to verify the predictions by fatigue experiments? If that is necessary, how are we going to simulate the reality of service conditions in a fatigue test? An evaluation of these questions requires a fundamental understanding of the fatigue mechanisms occurring in structural materials under conditions applicable to the real structure.

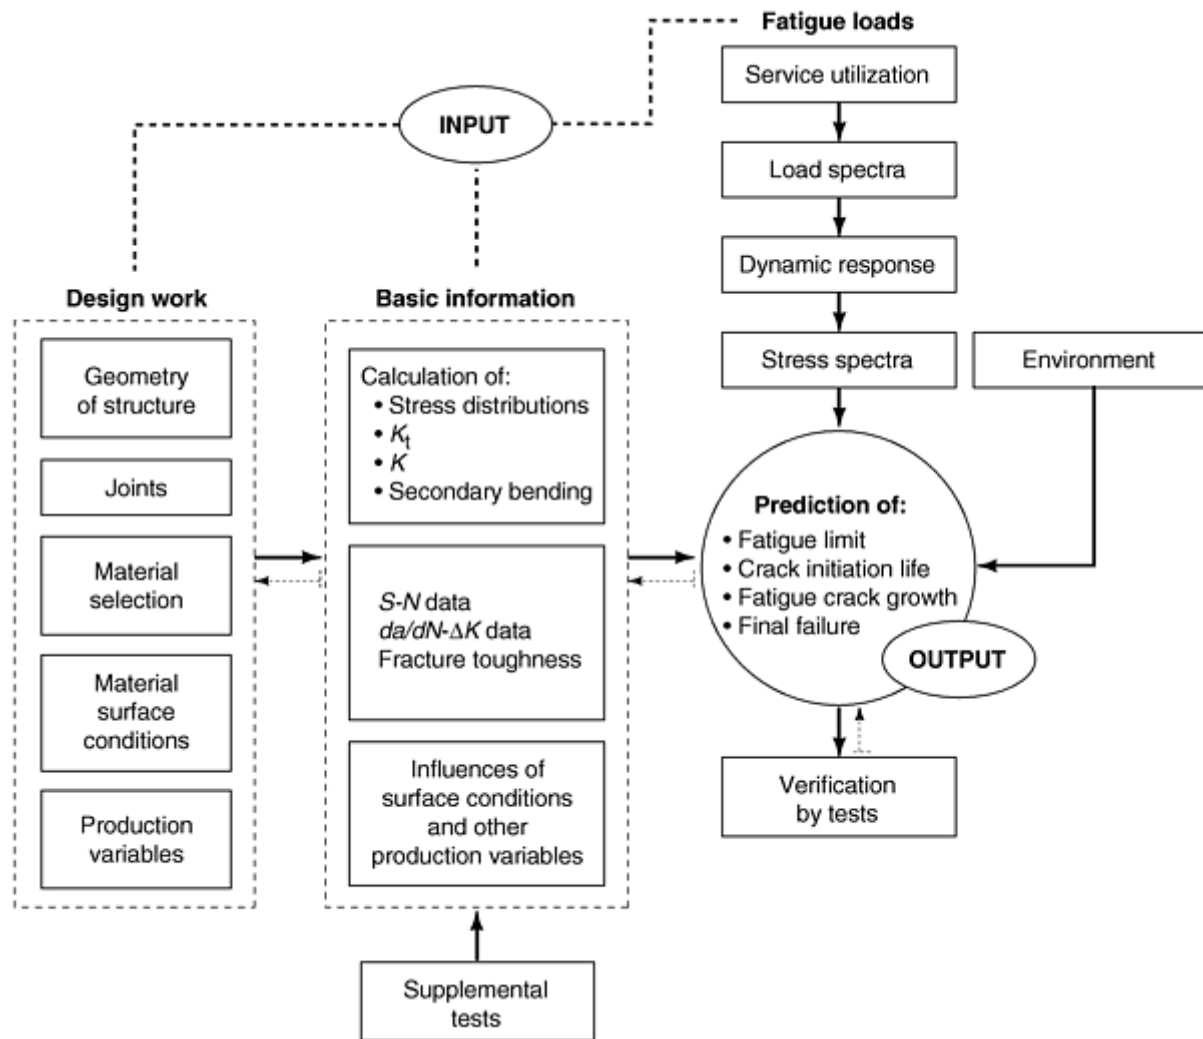

FIG. 1 DIAGRAM OF THE FATIGUE PREDICTION PROBLEM IN PRACTICAL APPLICATIONS. DOTTED ARROWS INDICATE FEEDBACK.

This paper summarizes fatigue phenomena in metallic materials, discusses fatigue under variable-amplitude (VA) loading, where the emphasis is on crack growth, and presents prediction models. Its aim is to survey the state of the art. It should be useful for further research, but at the same time, it should indicate possibilities and limitations of fatigue predictions in a practical engineering environment.

## Fatigue Crack Growth under Variable-Amplitude Loading

J. Schijve, Delft University of Technology

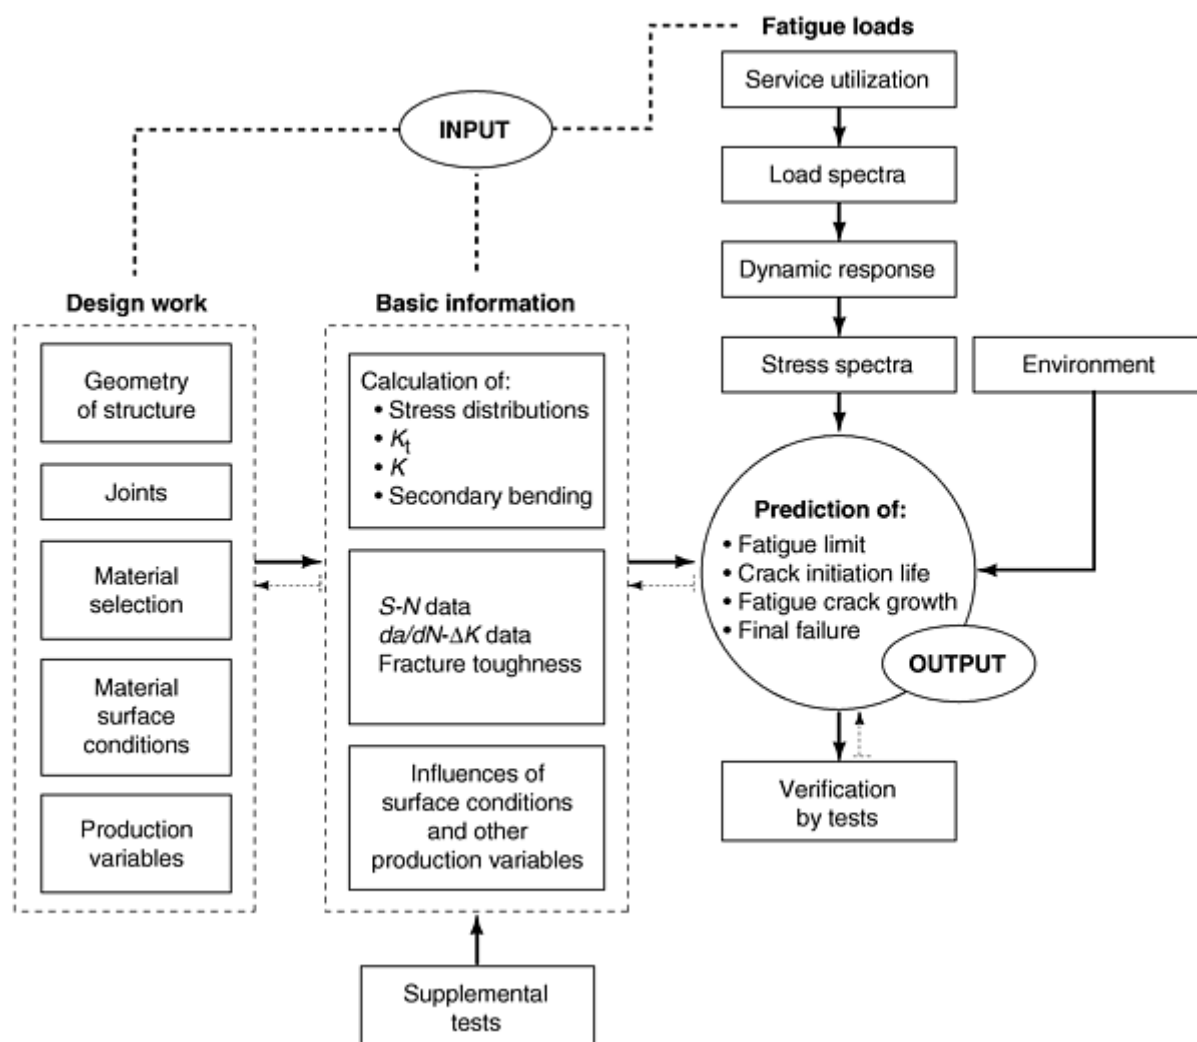

### Introduction

FATIGUE is a practical problem for all kinds of structures subjected to a spectrum of many load cycles under normal service utilization conditions. A single load application need not be harmful, but a repetition of many load cycles can initiate a fatigue crack. The crack will grow until collapse of the structure, unless it is found by inspection. The variety of practical fatigue problems is large because of the many types of structures, materials, load spectra, and other design variables.

Fatigue failures can have significant consequences in practice, which can be highly undesirable for reasons of economy. Fatigue failures in expensive structures built in small numbers are practically unacceptable. Another important argument

is safety. Disastrous fatigue failures occurred in the past with fatalities, serious damage to the environment, and liability problems afterwards. As a consequence, the concept of *designing against fatigue* has attracted much attention from industry, research institutes, universities, and the authorities responsible for safety regulations to protect society against fatal accidents. The economic and social impact of fatigue failures will not be discussed here, but designing against fatigue obviously is a matter of concern. It encompasses various design options, and needless to say, experience and engineering judgment are essential. Fatigue predictions are then necessary to quantify the fatigue problem in terms of fatigue life and crack growth.

A general survey of a fatigue prediction scenario is given in Fig. 1. It illustrates that design includes choosing among various options (first column). The second column includes data on material fatigue properties and calculations, basically stress analysis problems. The third column includes information on the fatigue loads in service, the dynamic response of the structure, and the environment. All aspects of the input information have to be used for predictions on fatigue life and crack growth. A pertinent question then is: Do we have reliable prediction models? If so, do we obtain accurate indications of the fatigue behavior of a structure in service? Is it desirable to verify the predictions by fatigue experiments? If that is necessary, how are we going to simulate the reality of service conditions in a fatigue test? An evaluation of these questions requires a fundamental understanding of the fatigue mechanisms occurring in structural materials under conditions applicable to the real structure.

**FIG. 1** DIAGRAM OF THE FATIGUE PREDICTION PROBLEM IN PRACTICAL APPLICATIONS. DOTTED ARROWS INDICATE FEEDBACK.

This paper summarizes fatigue phenomena in metallic materials, discusses fatigue under variable-amplitude (VA) loading, where the emphasis is on crack growth, and presents prediction models. Its aim is to survey the state of the art. It

should be useful for further research, but at the same time, it should indicate possibilities and limitations of fatigue predictions in a practical engineering environment.

### Fatigue Phenomena in Metallic Materials

It is useful to consider the fatigue life as consisting of two periods:

- *THE CRACK INITIATION PERIOD*, INCLUDING CRACK NUCLEATION AND MICROCRACK GROWTH
- *THE CRACK GROWTH PERIOD*, COVERING THE GROWTH OF A VISIBLE CRACK (FIG. 2)

There is an obvious question of defining the transition from the initiation period to the crack growth period, but that will be addressed later.

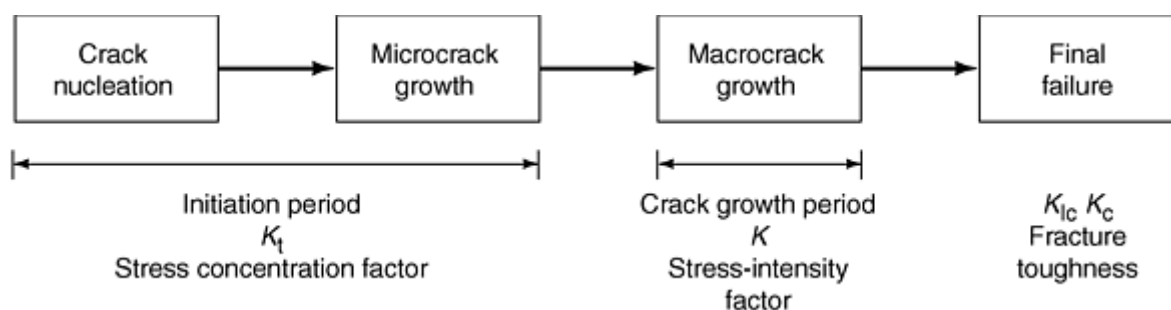

FIG. 2 DIFFERENT PHASES OF FATIGUE LIFE AND RELEVANT FACTORS

In a fatigue curve ( $S$ - $N$  curve, Wöhler curve), the fatigue life ( $N$ ) until failure is plotted as a function of the stress amplitude ( $S_a$ ). Such curves apply to so-called constant-amplitude (CA) loading, that is, cyclic loading with a constant amplitude, but also a constant mean load. Quite often the fatigue curve turns out to be approximately linear in a double logarithmic plot (see Fig. 3, the Basquin relation). However, there are two cutoffs (i.e., two horizontal asymptotes). The upper one is associated with static failure, because the maximum load of the fatigue cycle exceeds the static strength. The lower one is usually referred to as the fatigue limit ( $S_f$ ). For amplitudes below the fatigue limit, failure no longer occurs, even after a very high number of cycles. The fatigue limit is often defined as the stress amplitude for which the fatigue life becomes infinite, or as the maximum stress amplitude for which failure does not occur. A better definition is that the fatigue limit is the minimum stress amplitude that can still nucleate a crack that grows until failure. It does not imply that a microcrack cannot be initiated below the fatigue limit, but it does not grow into macrocracks. Apparently, the microcrack is arrested at some microstructural barrier.

FIG. 3 S-N CURVE WITH EXTRAPOLATIONS BELOW THE FATIGUE LIMIT

**Cyclic Plasticity, Microcrack Initiation, and Microcrack Growth.** Fatigue cracks generally start at the material surface, for practical and fundamental reasons:

- PRACTICAL REASONS: HIGHER STRESS LEVEL,  $K_T$  ALWAYS  $>1$ ; AND SECONDLY SURFACE ROUGHNESS AND OTHER SMALL-SCALE STRESS CONCENTRATIONS
- FUNDAMENTAL REASONS: LOWER RESTRAINT ON CYCLIC PLASTICITY, AND IN ADDITION ENVIRONMENTAL EFFECTS

Of course there are notorious exceptions, such as subsurface crack nucleations associated with inside material defects, inhomogeneous residual stress distributions, and a more fatigue-resistant material structure at the surface (shot peened surface layer, nitriding, etc.). The fundamental reasons are given more attention below, because they are significant for considering threshold problems and the relevance of applications of fracture mechanics to fatigue, also in relation to VA loading.

Grains at the material surface are not supported by other grains at one side (i.e., the side of the environment). As a consequence, cyclic slip can occur more easily than it does inside the material, where slip is more restrained by the surrounding material. Because of the lower restraint on slip in a surface grain, it can occur at a lower stress level. It is one of the reasons why crack nucleation generally starts in surface grains, or slightly subsurface (e.g., at an inclusion). There are different theories on microcrack nucleation, which will not be surveyed here. They explain how cyclic slip in just a few cycles can lead to a physical microcrack at the surface. In several materials the initial microcrack is growing in a slipband. The microshear stress concentration in a slip band depends on the crystal lattice orientations and grain shapes. Due to slip during uploading, the reversed shear stress during unloading will again be high in the same slip band. Cyclic slip and the initial microcrack growth will thus concentrate in slip bands. Cyclic slip is not a reversible phenomenon (if it were, material fatigue would not be a problem), partly because of strain hardening, but also because of the environmental interaction with slip steps and cracked material. In air it implies strongly adhering oxide monolayers. Aggressive environments promote the initiation of microcracks in cyclic slip bands.

As long as the size of the microcrack is still on the order of a single grain, there is a microcrack in an elastically anisotropic material with a crystalline structure and a number of different slip systems. The microcrack causes an inhomogeneous stress distribution on a microlevel, with a stress concentration at the tip of the microcrack. If that activates more than one slip system, the microcrack growth direction can deviate from the initial slip band orientation. Cracks then tend to grow perpendicular to the loading direction (Fig. 4). Microcrack growth depends on the material structure, crystallography, possible slip systems, the ease of cross-slip (stacking fault energy), the grain lattice orientation

(texture), and the grain size. As a result, crack nucleation and the first microcrack growth cannot be expected to be similar phenomena for different materials. As an example, Al alloys usually have small grains, the elastic anisotropy is low, and cross-slip is relatively easy. For Ni alloys, grains can be large, the elastic anisotropy is much larger, and cross-slip is relatively difficult.

FIG. 4 CROSS SECTION OF A MICROCRACK

In general, a large number of grains at the material surface are nominally loaded to the same cyclic stress level, even if we consider a notched specimen. An obvious question then is why microcracks are not nucleated in all grains. Actually, if the strain amplitude at the surface is large, microscopic investigations have shown that there will be a high number of microcracks in Al alloys (Ref 1, 2, 3). Due to the low elastic anisotropy of aluminum, the stress level from grain to grain does not change much, and as a consequence, there will be many grains with a high local stress level. Microcracks can coalesce after some growth and continue to grow as a single crack. Macroscopic fractography usually shows only one or a few dominant fatigue crack nuclei. The number of visible nuclei depends on the fatigue load. At a stress level close to the fatigue limit, only one crack nucleus is observed. This appears to be logical, because the fatigue limit is a threshold stress level. Only one crack nucleus will be successful in growing until final failure. Statisticians call it the *weakest link* in the material.

Because microcrack growth depends on cyclic plasticity, barriers to slip can imply a threshold for crack growth. This has indeed been observed. Illustrative results were published by Blom et al. (Ref 4) for an aluminum alloy (Fig. 5). The crack rate decreases when the crack tip approaches a grain boundary. After passing a third grain boundary, the microcrack continues to grow with a steadily increasing crack growth rate. Reinitiation in a second (subsurface) grain has been shown by fractographic work of Lankford (Ref 5). In low-carbon steel it has been shown that pearlite colonies considerably hamper fast microcrack growth in the ferrite matrix (Ref 6). In the literature there are several observations on initially inhomogeneous microcrack growth, starting with a relatively high crack rate, which is slowed down or even stopped by material structural barriers. Suresh (Ref 7) introduced the term *microstructurally short cracks* for this behavior.

FIG. 5 GRAIN BOUNDARY (GB) EFFECT ON MICROCRACK GROWTH IN AN AL ALLOY. SOURCE: REF 4

If the growth rate of microcracks is plotted as a function of  $\Delta K$  together with results of large cracks, a confusing picture can result (Fig. 6). The apparent paradox is that large macrocracks do not grow if  $\Delta K < \Delta K_{th}$ , whereas microcracks in surface grains can grow in a low- $\Delta K$  regime. It appears to be a paradox, but as pointed out above, cyclic slip can occur relatively easily close to the material surface. It allows an initially fast development of a microcrack at the surface. Also, a microcrack initiated at a subsurface inclusion can attain an initially high crack rate during breakthrough to the material surface (Fig. 7). Moreover, it should be realized that  $\Delta K$  for a microcrack at the material surface is a nominally calculated  $\Delta K$ . It is not necessarily a meaningful concept for small microcracks. Basically, the stress-intensity factor is meaningful for a crack in a homogeneous material for the stress distribution in close proximity to the crack tip, as long as the plastic zone is very small compared to the crack length. These conditions are simply not satisfied for microcracks with a size of 1 or 2 grain diameters. The literature on small cracks and crack growth at  $\Delta K$  values below  $\Delta K_{th}$  is rather extensive (Ref 10, 11).

FIG. 6 GROWTH RATES OF SMALL AND LARGE CRACKS PLOTTED TOGETHER AS A FUNCTION OF  $\Delta K$ . CA, CONSTANT AMPLITUDE. SOURCE: REPLOTTED IN REF 8 FROM AGARD REPORT NO. 732, 1988

FIG. 7 SUBSURFACE CRACK NUCLEATION AT INCLUSION, ERRONEOUSLY SUGGESTING INITIAL FAST CRACK GROWTH. SOURCE: REF 9

The crack front of larger cracks passes through a number of grains, as schematically shown in Fig. 8. Because the crack front must remain a coherent crack front, the crack cannot grow in each grain in an arbitrary direction and at any growth rate independent of crack growth in adjacent grains. This coherence prevents significant gradients of the crack growth rate along the crack front. As soon as the number of grains along the crack front becomes sufficiently large, the local crack growth rate can be considered to be well approximated by local averages. Crack growth will occur as a more or less continuous process. The crack front can be approximated by a simple continuous line (e.g., semielliptical curve). How fast the crack will grow depends on the crack-growth resistance of the material, which then is considered to be a bulk property of the material. (The fatigue crack growth resistance for the long transverse direction can differ from the resistance for the short transverse direction.) The applicability of fracture mechanics may become relevant as soon as the crack extension of a fatigue crack nucleus is controlled by the balance between the crack driving force along the crack front and the material crack growth resistance.

FIG. 8 TOP VIEW OF CRACK WITH CRACK FRONT THROUGH MANY GRAINS

The previous discussion leads to two important conclusions:

- MICROCRACK INITIATION IS A SURFACE PHENOMENON
- CONTINUED CRACK GROWTH IS CONTROLLED BY BULK PROPERTIES OF THE MATERIAL

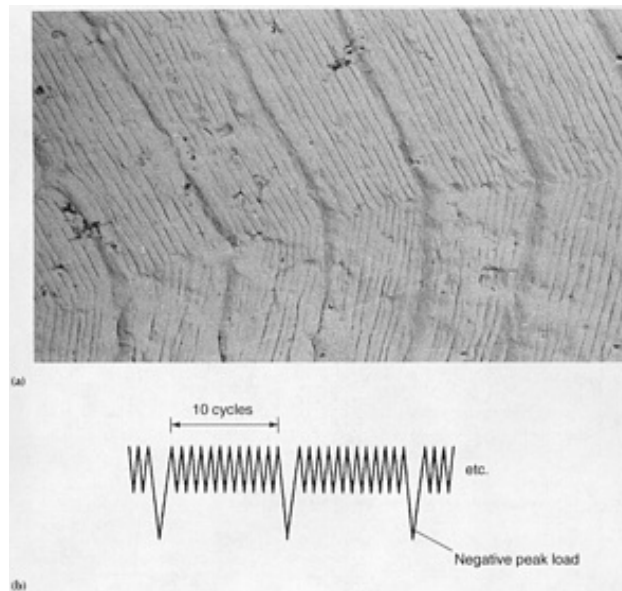

The microcrack initiation life time primarily depends on the surface conditions of the material. It thus can be sensitive to a large scatter if the surface conditions do not represent a constant surface quality. Continued crack growth occurs away from the material surface; it does not depend on the material surface quality. As a consequence, it does not exhibit the large sensitivity to scatter of crack initiation. The previous discussion also implies that the applicability of fracture mechanics to small microcracks is questionable, but that it can be a useful tool for describing macrocrack growth.

**Growth of Macrofatigue Cracks.** In this article, fatigue cracks are referred to as macrocracks if crack growth has become a regular growth process along the entire crack front. Macrocracks can still be rather small, and they are not necessarily visible cracks. According to this definition, the transition from the microcrack growth period to the macrocrack growth period depends on the type of material. It can occur in an Al alloy at a short crack length (100 to 200  $\mu\text{m}$ ) (Ref 12), whereas in certain Ni alloys the transition may occur at a much longer crack length. In any event, the transition will not be a very sharply defined crack length. The transition crack length is a function of material structure and structural dimensions.

A characteristic observation on the growth of macrocracks is the occurrence of striations on the fatigue fracture surface (Fig. 9). The correlation between the cyclic load (10 small cycles + 1 larger cycle, repeated) and the striation pattern strongly suggests that crack extension occurs in every cycle. The striations are supposed to be remainders of microplastic deformations, but the mechanism need not be the same for all materials. Moreover, striations are not observed in all materials, at least not equally clearly. The visibility of striations also depends on the severity of the load cycle. Furthermore, microscopic fractography of a macrocrack has shown that the crack front is not a simple straight line and that the crack tip is not necessarily a very sharp crack. New information on the geometry of the crack front in aluminum alloys became available when Bowles (Ref 13, 14) carried out vacuum infiltration experiments. A plastic casting of the crack tip with the crack front was obtained and could be observed in the SEM (Fig. 10). There are interesting observations to be made in this figure:

- THE CRACK FRONT IS NOT A STRAIGHT LINE.
- THE CRACK TIP IS ROUNDED.
- STRIATIONS APPEAR ON THE UPPER AND THE LOWER SIDE OF THE CRACK TIP CASTING (I.E., STRIATIONS FROM BOTH SIDES OF THE FATIGUE CRACK APPEAR IN ONE PICTURE).

These observations were made for visible macrocracks. Apparently, the geometry of the macrocrack on a microscopic level does not agree with the classical concept of a crack in elementary fracture mechanics (perfectly flat, straight, or elliptical crack front). However, for these cracks, fracture mechanics applications have been proven to be possible.

**FIG. 10 PLASTIC CASTING OF FATIGUE CRACK IN 2024-T3. NOTE THE STRIATIONS, WAVY CRACK FRONT, AND ROUNDED CRACK TIP. SOURCE: REF 13**

The observation of cycle-by-cycle crack extension has stimulated various prediction models on fatigue crack growth. It is a basic concept for models on crack growth under VA loading. Another important concept used in these models is crack closure. Plasticity-induced crack closure was discovered by Elber (Ref 15, 16) in 1968. It implies that fatigue cracks can be fully or partly closed while the material is still under tension. It occurs as a consequence of plastic deformation left in the wake of the crack along the crack flanks. The plastic deformation remains from crack-tip plasticity of previous load cycles. As long as the crack tip is still closed, there is no stress singularity at the physical crack tip. During cycling, the crack opening stress level,  $S_{op}$ , can be between  $S_{min}$  and  $S_{max}$ . The crack tip is fully open if  $S \geq S_{op}$ . Elber defined an effective stress range  $\Delta S_{eff} = S_{max} - S_{op}$ , and similarly an effective  $\Delta K$  value by:

$$\Delta K_{EFF} = \beta \Delta S_{EFF} \sqrt{pa} \quad (\text{EQ 1})$$

where  $\beta$  is the geometry correction factor. According to Elber:

$$\Delta K_{EFF}/\Delta K = U(R) \quad (\text{EQ 2})$$

where  $U(R)$  is a function of the stress ratio  $R = S_{min}/S_{max}$ . Several  $U(R)$  relations have been proposed in the literature (Ref 17), partly based on fatigue tests results, and for another part supported by finite-element calculations. It turned out that empirical  $U(R)$  relations could describe the effect of the  $R$ -ratio on crack growth under CA loading by using  $\Delta K_{eff}$ . Plasticity-induced crack closure has significantly contributed to our understanding of fatigue crack growth under VA loading. Other mechanisms for crack closure have been proposed in the literature, such as roughness-induced crack closure (Ref 18), but they are not considered here for the problem of VA loading.

The literature on VA fatigue investigations has steadily increased through the years and is extensive now. Many test programs were carried out to check the famous Miner rule ( $\sum n/N = 1$ ), which Miner published in 1945 (Ref 19). The rule was published earlier by Pålmgren in 1924 (Ref 20). Another noteworthy publication came from Langer in 1937 (Ref 21). He divided the fatigue life into an initiation period and a crack growth period, then postulated that  $\sum n/N = 1$  is valid for each of the two periods, where  $N$  had to be  $N_{initiation}$  and  $N_{crack\ growth\ life}$  for the two periods, respectively. Langer did not tell how  $N_{initiation}$  had to be obtained.

Numerous test series found that the Miner rule was unreliable.  $\sum n/N$  values much smaller and much larger than one were obtained. In spite of this negative result, a certain understanding of fatigue damage accumulation emerged. Illustrative results are summarized in this article.

## VA Load Sequences

The increased complexity of load histories applied in VA fatigue tests became possible by the development of modern fatigue machines (closed-loop computerized load control). A survey of different types of fatigue tests is given in Table 1, which illustrates the increasing complexity of load histories. It also indicates that the number of variables is large, even for simple tests, as will be shown by the test results. Examples of test load sequences are presented in Fig. 11 and 12 for

simple and more complex load sequences, respectively. The most simple but elementary sequences are A1, A2, B1, and B2 (Fig. 11). These sequences are labeled as Hi-Lo and Lo-Hi (Hi-Lo if a high-amplitude block of cycles is followed by a low one, and Lo-Hi for the reversed sequence).

SOURCE: REF 22

The program test was introduced by Gassner in 1939 (Ref 23) as a first attempt to simulate a VA load spectrum in a test (Fig. 12a). At that time, fatigue machines could not yet simulate more realistic load sequences. The Lo-Hi-Lo sequence of the program test was replaced later by a randomized sequence (Fig. 12b; see, e.g., Ref 24). However, in each block the number of cycles is still large. In general, such a test cannot be considered a realistic simulation of a service load history.

Many loads in service have a random character, although there are different types of randomness. A structure with a predominant resonance frequency response is quite often vibrating in a narrow random mode (Fig. 12c). If resonance is less significant, the load history can be a broad-band random load (Fig. 12d). These sequences can now be applied in fatigue tests.

For aircraft it was recognized in the 1950s that the service load history is a mixture of *random loads* and *deterministic loads* (non-random loads, e.g., ground-air-ground transition loads or maneuvers). Initially both types of loads were applied in fatigue tests, with the random loads reduced to one or two amplitudes (Fig. 12e) for reasons of simplicity. This reduction was done by a Miner calculation, with the aim being that the CA cycles of the test should have the same fatigue damage as the random spectrum. Unfortunately, the Miner rule is fully unreliable for this purpose. In tests on aircraft structures and components, as well as on other types of structures, it is now recognized that a realistic simulation of the service load sequence is essential to obtain a similar fatigue damage accumulation (Fig. 12f). Although it looks quite simple to adopt a simulation of service load histories as a basis for realistic fatigue tests, actually, there are a few inherent problems:

- **THE SERVICE LOAD HISTORY MUST BE KNOWN. BY SO-CALLED MISSION ANALYSIS (REF 25), DETERMINISTIC FATIGUE LOADS MAY BE OBTAINED. RANDOM LOADS, HOWEVER, IN THE BEST CASE ARE KNOWN BY STATISTICAL DISTRIBUTION FUNCTIONS ONLY.**

The sequence of random loads is by nature unknown. Fortunately, techniques for measuring fatigue loads in service have developed considerably. Equipment for that purpose is commercially available, the size is small and it can sample load histories for a long time as standalone equipment (Ref 26). If we wish, we can be well informed about loads in service by relatively easy measurement programs.

- **A FATIGUE TEST WITH A SERVICE SIMULATION LOAD HISTORY IS IN THEORY VALID ONLY FOR THE LOAD HISTORY APPLIED IN THE TEST. LOAD HISTORIES ADOPTED IN SUCH TESTS ARE USUALLY SELECTED TO BE CONSERVATIVE IN ORDER TO COVER SEVERE SERVICE.**
- **A WELL-KNOWN AND EASILY RECOGNIZED PROBLEM OF SERVICE SIMULATION FATIGUE TESTS IS THAT THEY MUST BE COMPLETED IN A LIMITED TIME PERIOD. AS A CONSEQUENCE, THE SERVICE SIMULATION FATIGUE TEST IS AN ACCELERATED FATIGUE TEST. IF THERE ARE TIME-DEPENDENT EFFECTS IN FATIGUE, WE HAVE A PROBLEM. THE CLASSICAL ONE IS FATIGUE IN A CORROSIVE ENVIRONMENT. THIS OBVIOUSLY APPLIES TO WELDED OFFSHORE STRUCTURES IN SALT WATER. FOR AIRCRAFT STRUCTURES THE SITUATION IS LESS DRAMATIC, AS BRIEFLY REPORTED BELOW.**

Figure 13 shows the principle of a flight simulation fatigue test for problems related to the tension skin structure of an aircraft wing. In Fig. 13(a), the top curve shows the deterministic load, which can be obtained by calculation. The bottom curve shows the superposition of two types of random loads, turbulence (gust loads) and taxiing loads. At cruising altitude, gust loads are generally negligible. During landing and takeoff taxiing, loads occur as a result of runway roughness. Turbulence is a matter of weather conditions, so gust severity is different from flight to flight. It is usual to simulate some eight to ten different weather conditions in a flight simulation fatigue test. A sample load record is shown in Fig. 14 (Ref 28). In view of the time scale (flight duration in service in terms of hours), such a load profile cannot be used in a fatigue test. Acceleration occurs by leaving out the time that the load does not vary. Small taxiing loads, if they may be supposed to be nondamaging, are also omitted. Finally, in a fatigue test the load variations are applied at a higher loading rate than in service. As a consequence, a simulated flight in a full-scale test occurs in a few minutes, while it occurs in a laboratory fatigue test on specimens at a rate on the order of 10 flights per minute.

**FIG. 14 SAMPLES OF A LOAD HISTORY APPLIED IN FLIGHT SIMULATION TESTS ACCORDING TO THE FOKKER F-28 WING LOAD SPECTRUM. SOURCE: REF 28**

It now can be questioned whether such accelerated tests can still give reliable information. The time scale has been considerably modified. Actually, what is left is the simulation of going from peak load to peak load, from maximum to minimum to maximum, and so on. For the process as related to microplasticity, these load turning points are indeed the decisive events. However, if time-dependent effects (and thus frequency-dependent effects) on fatigue crack extension are significant, the compression of the time scale should have an influence on the test result. For fatigue of Al alloys in air and in other gaseous environments the water vapor content (absolute humidity) has a significant influence on fatigue (Ref 29, 30, 31), whereas oxygen is not important. Under normal humidity, cyclic loads with frequencies of about 10 Hz and lower give the same maximum environmental contribution to fatigue crack growth. However, an experimental proof is not easy. Flight simulation tests have been carried out on 2024-T3 and 7075-T6 sheet specimens with test frequencies of 10 Hz, 1 Hz, and 0.1 Hz (Ref 32). Especially the latter frequency leads to very long testing times. The results have confirmed that the same crack growth rates are found for the three frequencies. This limited experimental verification indicates that time-dependent effects may not be significant, because under both low- and high-frequency load histories, there is sufficient time for the same environmental damage contribution to crack growth.

The situation can be quite different for other materials and other environments. As an example, for fatigue of steel in salt water, a systematic frequency effect was clearly observed long ago (Ref 33). A detrimental salt water effect has also been found in random-load fatigue tests on steel for off-shore structures tested under a sea wave spectrum (Ref 34). For accurate predictions this is a rather unpleasant problem, which is pragmatically solved by applying empirical life reduction factors.

In the last two decades, several standardized service-simulation load histories have been developed. A survey is given in Table 2. The load spectra are supposed to be characteristic for the structures mentioned in the table. The sequences of loads in these standardized load histories are fully defined in a numerical format. The load scale can still be selected. A

major problem in arriving at some of the standards was the omission of numerous small cycles. If these cycles were included, tests with some standardized sequences could still take a very long time. The main goal of the standardized load histories is the application in general fatigue research programs, where specific variables are studied (usually comparative tests in view of material selection, joint design, surface treatments, etc.).

### **Results of Simple VA Fatigue Tests**

**Crack Initiation Life.** VA tests results strictly on the crack initiation period are rare. However, numerous VA test series until failure have been carried out on unnotched specimens and simple notched specimens. In such specimens the crack growth period is relatively short, and the total fatigue life thus gives approximate information on the initiation period.

Test results for the VA load sequences B1, B2, and B3 (sequences in Fig. 11) are presented in Fig. 15 (Ref 37). The most noticeable results are obtained for the notched specimens. In the Hi-Lo sequence,  $\Sigma n/N$  is much larger than 1. The cycles at the high amplitude in the first block increase the fatigue life at the low amplitude in the second block approximately five times. This large effect is considered to be due to residual compressive stress at the notch root introduced by the first block of cycles.

FIG. 15 SEQUENCE EFFECTS IN UNNOTCHED AND NOTCHED SPECIMENS OF 2024-T3. SOURCE: REF 37

Another illustrative example, the load sequence A1 (Hi-Lo), is presented in Fig. 16 (Ref 38). It shows results of 2024-T3 Al alloy specimens notched by two holes and tested at zero mean stress. Plastic deformation occurs at the root of the notches. The first block of cycles is followed by a block with a much lower amplitude. However, there is a small but essential difference between the two load programs in Fig. 16(b) and 16(c). In Fig. 16(b), the transition from the first block to the second block occurs after a positive peak load of the high-load cycles, whereas in Fig. 16(c) it occurs after a negative load cycle of the first block. In Fig. 16(b) the last positive peak load leaves a residual compressive stress field at the root of the notch, which is favorable for fatigue in the second block. In Fig. 16(c) the last negative peak load leaves a residual tensile stress field at the notch root, which is unfavorable for fatigue in the second block. As a result, the fatigue life in Fig. 16(b) is significantly longer than predicted by the Miner rule, whereas in Fig. 16(c) it is (slightly) shorter than the Miner prediction. In the latter case there is a kind of damage accelerating effect. After the first block, small cracks must have been present in both types of tests, but the crack length was still much smaller than the hole radius. As a consequence, the plastic deformation was still largely controlled by the geometry of the notch. It does affect the initial growth of a small crack.

**FIG. 16 HI-LO TESTS ON NOTCHED AL ALLOY SPECIMENS. NOTE THE EFFECTS OF COMPRESSIVE OR TENSILE RESIDUAL STRESS AT THE NOTCH ROOT. (A) TWO-HOLE SPECIMEN. (B)  $\Sigma N/N = 2.04$  (C)  $\Sigma N/N = 0.90$ . SOURCE: REF 38**

Similar indications of the effect of residual stresses at the root of notches were obtained by Heywood (Ref 39) in tests with high preloads (C1 in Fig. 11). Figure 17 shows results obtained for a variety of notched elements. The magnitude of the preload along the vertical axis is presented as the ratio of the preload stress and the 0.1% yield stress. The horizontal axis of the figure gives the life improvement factor (i.e., the ratio of the fatigue life after preloading and the life without preloading). The results clearly demonstrate the large and favorable effect of a positive preload, which induces favorable compressive residual stresses. Fatigue lives were increased up to more than 100×. The smaller number of tests with a negative preload (compression) confirm that the tensile residual stresses do reduce the fatigue life, and this effect can be large.

**FIG. 17 EFFECT OF POSITIVE AND NEGATIVE PRELOADS ON THE FATIGUE LIFE OF NOTCHED ELEMENTS. SOURCE: REF 39**

These tests were carried out after the Comet accidents. Part of the Comet fuselage had been fatigue tested before the accidents, which gave a life until cracking on the order of 15 times the life in service until the accidents. However, that part of the fuselage had been statically tested until the ultimate design load before the fatigue test. Due to this high preload, a highly unconservative test result was unfortunately obtained (Ref 40).

Heywood's results were confirmed by Boissonat in tests on notched specimens and joints (Al alloys, Ti alloy, and low-alloy steel) (Ref 41). Boissonat also observed that a periodical repeating of a high load was much more effective than a single preload.

**Crack Growth and Overload (OL) Cycles.** Simple load sequences have also been adopted in many test series on macrocrack growth (e.g., Ref 42). Figure 18 shows crack growth curves as recorded under CA loading and under CA loading interrupted by a single OL cycle applied at  $a = 10$  mm. The OL cycle starting with the minimum peak, followed by the maximum peak (+/- OL cycle) caused a very large retardation of the fatigue crack growth. The maximum peak load caused a large plastic zone at the crack tip, which left compressive residual stresses in this zone. That will retard subsequent crack growth when a crack grows through this zone. The explanation can also be formulated in terms of the plasticity-induced crack closure phenomenon (Elber mechanism). Due to the plastic deformation of the OL, more crack closure will occur after the OL has been applied.  $S_{op}$  is increased and  $\Delta S_{eff}$  is reduced.

**FIG. 18 EFFECT OF TWO DIFFERENT OVERLOAD CYCLES ON FATIGUE CRACK GROWTH IN 2024-T3. BASELINE CYCLE:  $S_A = 25$  MPa,  $S_M = 80$  MPa. OVERLOAD CYCLE:  $S_A = 120$  MPa. CA, CONSTANT AMPLITUDE. SOURCE: REF 43**

In the experiments with the reversed OL cycle (+/- OL cycle), a relatively small crack growth delay was observed. The positive peak load again produced a large crack-tip plastic zone. However, the positive peak load was followed by a negative peak load. That will lead to significant reversed plastic deformation, also because the crack was opened and blunted by the preceding positive peak load. The remaining tensile plastic strain was considerably reduced, and the remaining residual stress field was much less intensive. As a consequence, there was less crack closure and a modest crack growth delay was found.

It is easily recognized that macrocracks are closed under a compression load, but due to plasticity in the wake of the crack, that occurs already at a positive load. Because a closed crack is no longer a stress raiser, large negative plastic strains cannot be introduced. This is a fundamental difference with the hole-notched specimen of Fig. 16. If a notched specimen (e.g., with an open hole) is subjected to a high compressive load, there can be significant plastic strains in compression with tensile residual stresses at the root of the notch as a result. That will have a considerable effect on subsequent microcrack growth in that region. The difference between the behavior of notches and cracks has consequences for prediction models on the crack initiation period and the crack growth period under VA loading.

Some elementary tests on crack closure before and after an OL have been carried out (Ref 44). Crack closure measurements were made during a CA test ( $R = 0.67$ ) with an OL as shown in Fig. 19. The delay caused by the OL can easily be observed from the crack growth curve. The crack closure measurements carried out before the application of the OL indicated  $S_{op} \sim 62$  MPa. Directly after the OL the  $S_{op}$  level was reduced to about 45 MPa. Because the OL opens the crack by crack-tip plasticity, such a trend should be expected. Crack closure measurements made after the OL application indicated  $S_{op}$  values above  $S_{min}$  of the CA cycles. However,  $S_{op}$  decreased later below  $S_{min}$ . At the moment that  $S_{op} = S_{min}$ , the crack growth delay had finished. This should also be expected because crack closure no longer occurred during the CA cycles at  $R = 0.67$ . Of course, it must be admitted that accurate crack closure measurements are difficult, but the trend of Fig. 19 is considered to be correct.

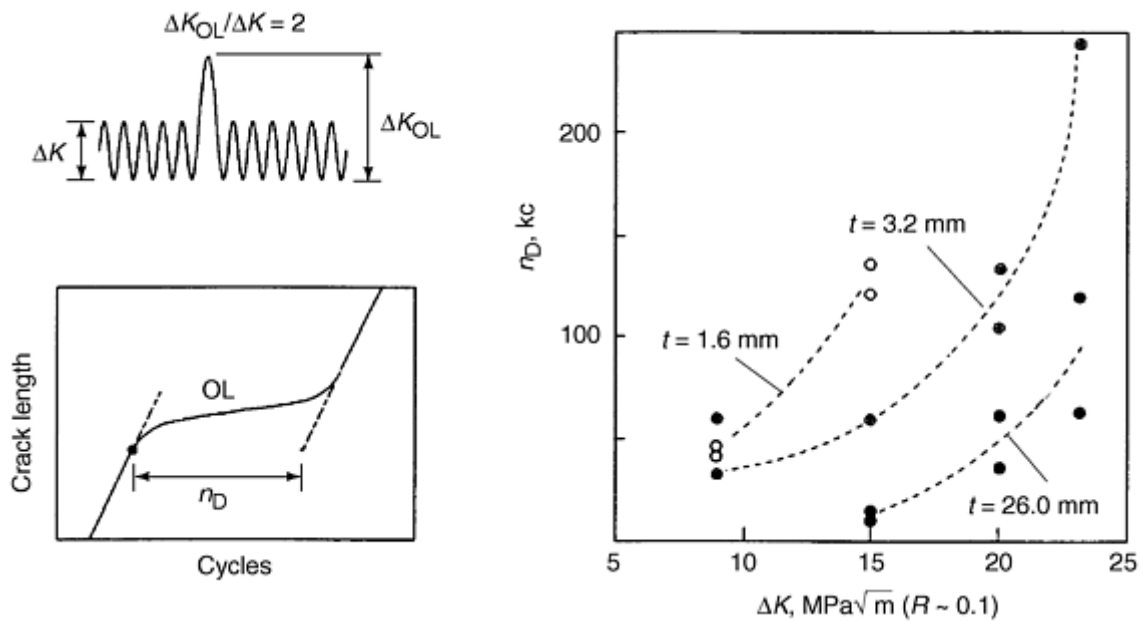

FIG. 19 CRACK GROWTH DELAY AFTER AN OVERLOAD AND THE INFLUENCE ON  $S_{op}$  IN 2024-T3 SHEET. SOURCE: REF 44

Crack growth retardation after an OL is generally related to the size of the plastic zone, because crack closure results from the crack-tip plasticity induced by the OL. Unfortunately, the size of the plastic zone is different for plane strain and for plane stress. In a thin sheet the state of stress at the crack tip is predominantly plane stress, whereas in a thick plate it is predominantly plane strain. It then should be expected that the retardation effects are different for fatigue cracks in thin sheets and thick plates. This is very nicely confirmed by results of Mills and Hertzberg (Ref 45) in Fig. 20. They carried out constant- $\Delta K$  tests and found a constant crack growth rate,  $da/dN$ , as expected. The OL cycle then systematically reduced the crack growth during a delay period, after which the growth rate returned to its original constant value. The delay period ( $n_D$  cycles) can then be defined in a simple way (see the inset figure in Fig. 20). Two trends are obvious from the test results: the delay period is larger for thinner materials (larger plastic zone), and the delay period increases at higher stress intensities (also larger plastic zones). Both trends agree with the effect of the plastic zone size on crack growth delay.

**FIG. 20 EFFECT OF MATERIAL THICKNESS ON CRACK GROWTH DELAY DUE TO AN OVERLOAD CYCLE IN CONSTANT- $\Delta K$  TESTS IN 2024-T3 SOURCE: REF 45**

Another instructive example, shown in Fig. 21, has been obtained by Petrak (Ref 46) for an alloy steel. The material was heat treated to three different yield stress levels. Petrak also carried out constant- $\Delta K$  tests, but he introduced periodic OL cycles after each 20,000 cycles. In tests without peak loads, the crack growth rate was larger if the steel was heat treated to a higher yield stress. The periodic OL cycles reduced the crack growth rate. The reduction was large for a low-yield-stress material (larger plastic zone) and much smaller for the high-yield-stress material (small plastic zone).

**FIG. 21 EFFECT OF MATERIAL YIELD STRESS ON CRACK GROWTH RETARDATION BY OVERLOAD CYCLES IN HP-9NI-4CO-30C (0.34C-7.5NI-1.1CR-1.1MO-4.5CO).  $T = 9$  MM. HEAT TREATED TO THREE DIFFERENT STRESS LEVELS (675, 1235, AND 1400 MPa). SOURCE: REF 46**

**Crack Growth and OL Blocks, Multiple OLs and Delayed Retardation.** As discussed above, one OL cycle can considerably delay crack growth. However, it has also been observed that more OL cycles give a larger delay. Illustrative results for a carbon steel are presented in Fig. 22. Dahl and Roth (Ref 47) also carried out constant- $\Delta K$  tests and adopted the same delay period definition as Mills and Hertzberg. The test results show that the delay period is larger for higher OLs. However, it is noteworthy that larger numbers of OL cycles systematically increased the delay period. The latter trend may be explained by considering that crack extension occurs during the OL cycles. More OL cycles then will leave more plastic deformation in the wake of the crack behind the crack tip. This is a simple explanation based on the Elber crack closure mechanism.

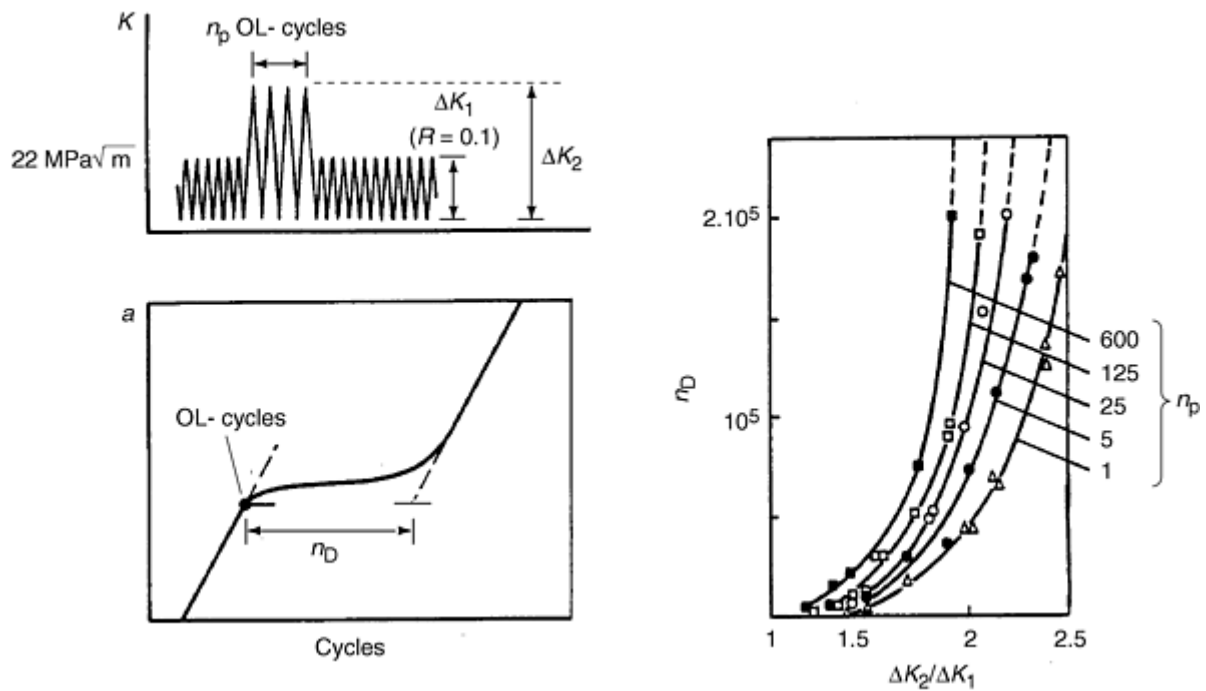

FIG. 22 THE INFLUENCE OF THE NUMBER OF OVERLOAD CYCLES ON THE CRACK GROWTH DELAY PERIOD. TESTS ON COMPACT-TENSION SPECIMENS IN 0.2C STEEL. SOURCE: REF 47

In Fig. 22 the effect of a block of OL cycles is illustrated. A related problem was investigated by Mills and Hertzberg (Ref 48). They considered the effect of two OL cycles in constant- $\Delta K$  tests, with a certain number of cycles between the two OLs as a variable (Fig. 23). The second OL cycle can be applied at the moment that the crack growth retardation of the first one is still effective. The results indicate that the delay of the second OL cycle is dependent on the interval between the two OLs (see the lower graph in Fig. 23). According to Mills and Hertzberg, the maximum interaction between the two single OLs is obtained when the crack growth increment between the overloads is about 25% of the plastic zone of the first OL. This multiple OL effect was introduced by de Koning in his CORPUS model, discussed below. The multiple OL effect has recently been confirmed by Tür and Vardar (Ref 49). They applied periodic OLs in CA crack growth tests, with the number of CA cycles ( $n_{CA}$ ) between the OLs as a variable. Initially the retardation increased for increasing  $n_{CA}$ , but for a larger  $n_{CA}$  it decreased again.

FIG. 23 CRACK GROWTH DELAY AFTER TWO OVERLOAD CYCLES AS AFFECTED BY THE NUMBER OF CYCLES BETWEEN THE OVERLOADS. SOURCE: REF 48

**Delayed retardation** has been observed by several research workers. The more reliable indications should come from observations on striation spacings. Delayed retardation implies that the maximum reduction of the crack growth rate does not occur immediately after the OLs. It requires some crack growth before  $da/dN$  has reached its minimum (Fig. 24a). Illustrative results have been obtained by Ling and Schijve (Ref 50) in tests with periodic blocks of overload cycles (type B3 in Fig. 11). In tests with more low-amplitude cycles (100 as compared to 50), delayed crack growth occurred in the same way, but the crack rate could be reduced for a longer time to a lower level (Fig. 24). It apparently requires some crack growth into the plastic zone of the OL cycles to give the maximum increase of  $S_{op}$  (and the minimum  $\Delta K_{eff}$ ). In Fig. 24 that point had not yet been reached.

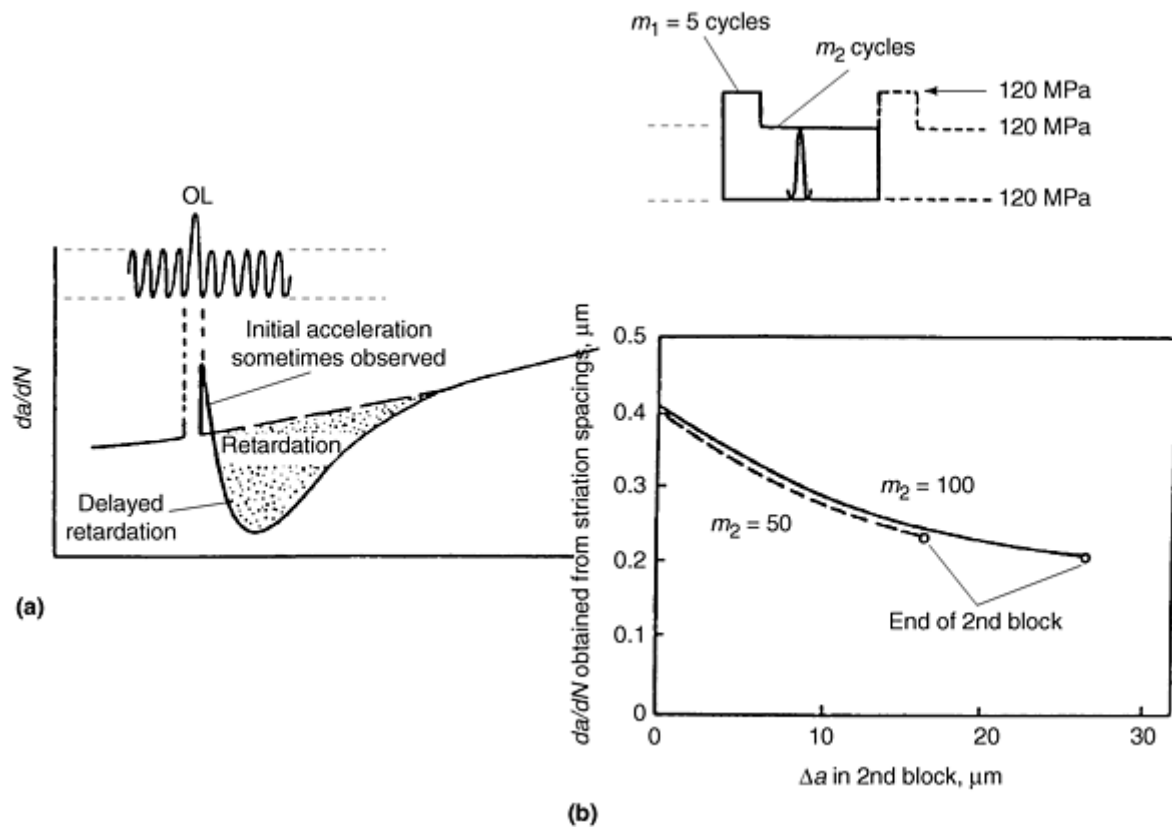

FIG. 24 DELAYED RETARDATION AFTER OVERLOAD AND AFTER A BLOCK OF HIGH-AMPLITUDE CYCLES. (A) OVERLOAD EFFECT. (B) DELAYED RETARDATION. SOURCE: REF 50

**Incompatible Crack Front Orientation under VA Loading.** Shear lips are well known for Al alloys, but they have been observed for several other materials as well (Ref 51, 52, 53). When the crack growth rate increases (CA loading assumed), the shear lip width also increases (Fig. 25, 26). It can lead to a full transition from a tensile-mode crack to a shear-mode crack, depending on the material thickness and the stress cycle (Ref 53). Under VA loading the transition can easily imply incompatible crack front orientations, a topic rarely covered in the literature. A simple example is shown on the two fracture surfaces in Fig. 26 (Ref 43). The central cracks in both specimens were already fully in the shear mode under high CA loading when a batch of low-amplitude cycles was introduced. It caused a narrow bright band on the fracture surface (arrows in Fig. 26). The normal fracture mode of the low-amplitude cycles in CA loading at that crack length is the tensile mode (with minute shear lips). This is not compatible with the existing shear mode. There was indeed a tendency to grow again in the tensile mode, which gave the band a stepped appearance. The growth rates in the bands of the two specimens were 2.5 and 8 times lower than observed in normal CA tests at the same crack length. The incompatibility caused a strong retardation effect.

FIG. 25 FATIGUE CRACK GROWTH WITH SHEAR LIPS

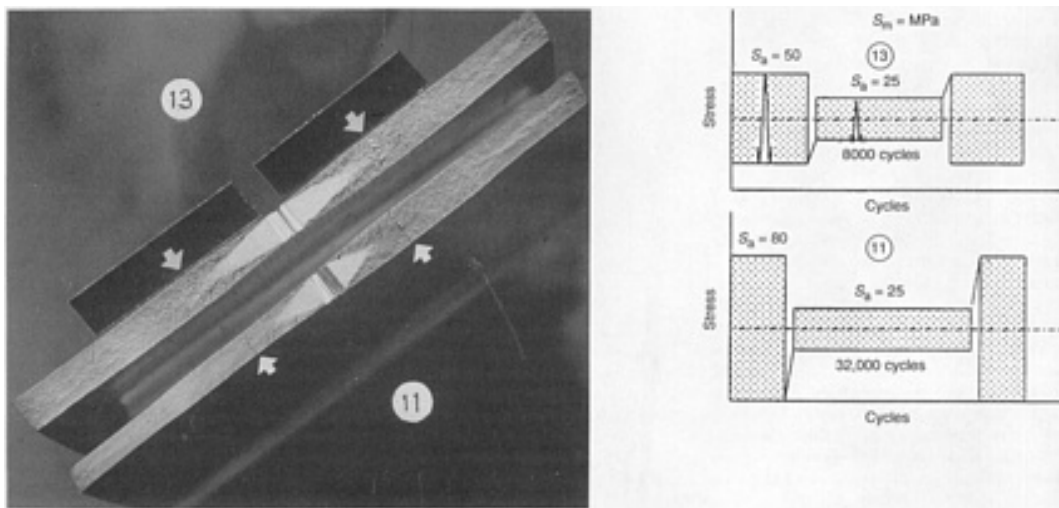

FIG. 26 INCOMPATIBLE CRACK FRONT ORIENTATION, WHICH OCCURS IF LOW-AMPLITUDE CYCLES ARE APPLIED WHEN THE CRACK FRONT IS ALREADY IN THE SHEAR MODE. SOURCE: REF 43

The reverse case is perhaps more relevant, that is, when high-amplitude cycles occur between many low-amplitude cycles. The fracture surface then can be largely in the tensile mode, whereas the failure mode corresponding to the nominal  $\Delta K$  cycle of the high-amplitude cycle in a CA test may be the shear mode. In elementary tests (Ref 43) such cycles produced dark bands on the fracture surface and a growth rate far in excess of the corresponding CA results. In this case the incompatible crack front caused an accelerated crack growth. It is interesting to note that five high-amplitude cycles produced approximately the same band width as a single high-amplitude cycle. In other words, the major contribution came from the first cycle.

**Crack Growth Retardation by Crack Closure and/or Residual Stress in Crack-Tip Plastic Zone.** Dahl and Roth (Ref 47) have raised the question whether crack growth delay after an OL is due only to crack closure, or whether there is also an effect of the residual compressive stress in the plastic zone ahead of the crack tip. The question turns up from time to time in discussions. In this respect, interesting experiments were carried out in 1970 by Blazewicz (Ref 54). He made ball impressions on 2024-T3 sheet specimens before the crack growth test was started (Fig. 27). As a result there was a zone between the impressions with residual compressive stresses, which delayed the crack growth. The delay was small during the growth through the zone between the impressions, but it was significant at a later stage. It simply suggests that

the crack growth retardation should be explained by crack closure only. In terms of crack growth mechanisms, it appears logical that the crack must be opened before crack extension can start. The efficiency of creating a crack length increment ( $\Delta a$ ) depends on the plasticity right at the crack tip (the fracture process zone), not on residual stresses ahead of the crack tip. The residual stress in the crack-tip plastic zone can have an indirect effect on the cyclic plasticity at the crack tip, but opening the crack tip is the decisive mechanism to have crack extension.

FIG. 27 CRACK GROWTH RETARDATION BY RESIDUAL STRESS IN THE WAKE OF THE CRACK. SOURCE: REF 54

Blazewicz also made saw cuts along a fatigue crack and removed part of the plastically deformed material in the wake of the crack. That eliminated crack closure, and crack growth retardation was effectively removed. This observation also confirms the significance of the crack closure contribution to crack growth retardation, rather than residual stresses in the crack-tip plastic zone.

Crack closure has also been removed by heat treatments after OLs (Ref 55, 56), and crack growth retardation is thus eliminated.

**More Crack Closure at the Material Surface.** At the surface of a material the crack tip is loaded under plane-stress conditions. Depending on the material thickness, the state of stress at mid-thickness approaches plane-strain conditions. The plastic zone size under plane stress is significantly larger than under plane strain. Irwin plastic zone size estimates are  $r_p = 1/(\alpha\pi)(K/S_{0.2})^2$ , with  $\sigma=1$  for plane stress and  $\sigma=3$  for plane strain. It thus should be expected that crack closure will be more significant near the material surface and will occur to a lesser degree at mid-thickness. This is confirmed by finite-element calculations (Ref 57), but there is also experimental confirmation (Ref 58). McEvily (Ref 59) studied crack growth after an OL in Al alloy specimens (6061), which gave a significant crack growth delay. He then reduced the thickness of the specimen immediately after the OL and observed a much smaller crack growth delay. Similarly, Ewalds and Furnee (Ref 60) measured a lower  $S_{op}$  after removal of surface layers. In the VA crack growth prediction models discussed below, an averaged  $S_{op}$  (averaged over the material thickness) is generally adopted.

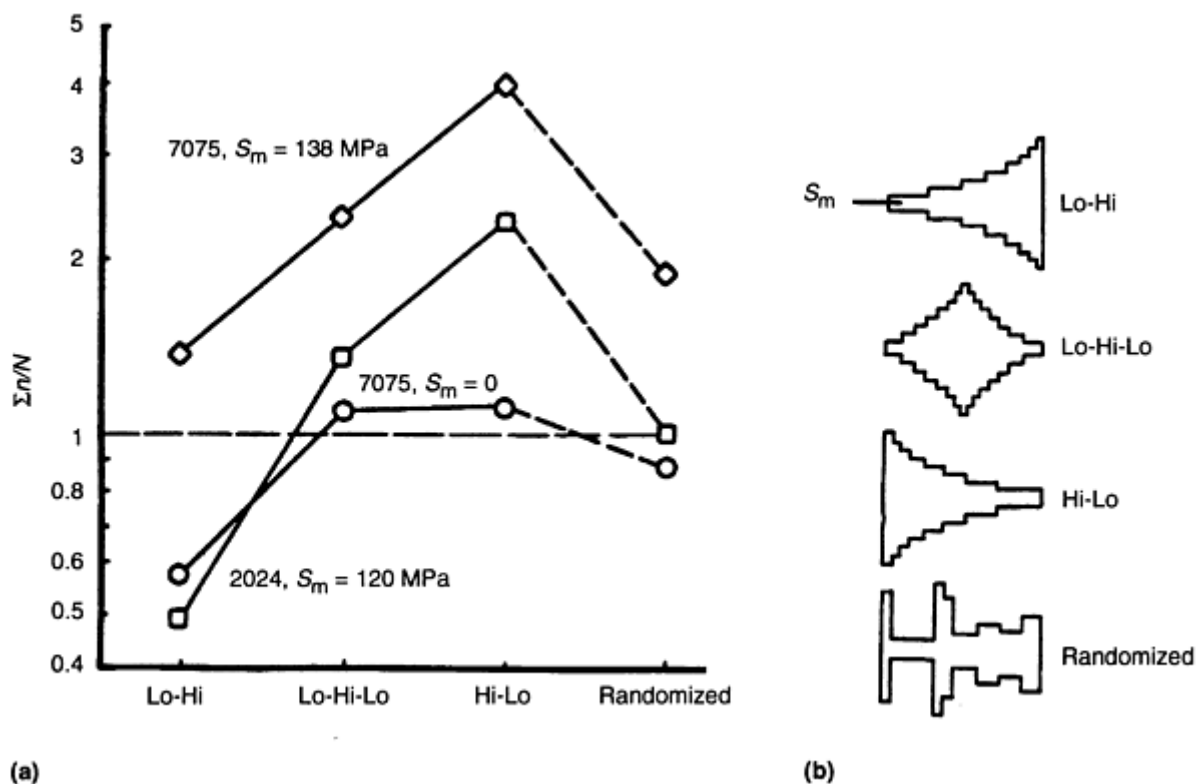

**Interaction Effects.** The observations discussed above are referred to as *interaction effects*. Interaction effects imply that fatigue damage accumulation in a certain load cycle is affected by fatigue in the preceding load cycles of a different magnitude. In other words, a fatigue cycle will affect damage accumulation in subsequent load cycles. As an example, the crack extension in the OL cycle in Fig. 18, although too small to be visible in the graph, was larger than expected without interaction effects. It implies that  $\Delta a$  in the OL cycle was longer than it would have been in a CA test with OL cycles only. The large crack growth retardations induced by OL cycles are a prominent illustration of interaction effects.

## Results of More Complex VA Fatigue Tests

**Crack Initiation Life.** As previously noted, few results on the crack initiation life are available, but data for notched specimens may be representative, assuming that the crack growth period is relatively short. The total life then gives an approximate indication of the crack initiation life. In the past, large numbers of tests were carried out to check the validity of the Miner rule. An enormous scatter of  $\Sigma n/N$  at failure was observed, which amply confirmed that the Miner rule is far from accurate. Surveys can be found in Ref 61 and 62. Schütz (Ref 61) reports values of  $\Sigma n/N$  in the range of 0.1 to 3.0, which implies that significant interactions must have occurred. In terms of the arguments discussed above, it can be understood that low  $\Sigma n/N$  values are to be expected for unnotched specimens and for  $S_m = 0$ . Large  $\Sigma n/N$  values are possible for  $S_m > 0$  and notched specimens in view of introducing favorable compressive residual stresses. Some illustrative data are presented below.

Results of a NASA investigation (Ref 24) on edge-notched specimens are presented in Fig. 28. Program tests were carried out with three different sequences, and a randomized sequence was also adopted. The number of cycles in one period was 30,000 to 100,000, while the number of cycles for the eight amplitudes varied from 1 to 82,000 in one block. Two  $S_m$  levels were used for 7075-T6 specimens ( $S_m = 0$  and  $S_m = 138$  MPa). The fatigue lives ( $\Sigma n/N$  values) at the positive  $S_m$  are about two to four times larger than for  $S_m = 0$ . It confirms the effect of favorable residual stresses at the notch root mentioned above. The results in Fig. 28 further show a most significant sequence effect. The effect should be attributed to variations of the residual stress at the notch root, but it is not a simple question to suggest how the variation did occur in detail.

**FIG. 28 THE EFFECT OF THE AMPLITUDE BLOCK SEQUENCE ON THE FATIGUE LIFE IN PROGRAM FATIGUE TESTS. (A) TESTS ON EDGE-NOTCHED AL ALLOY SPECIMENS.  $K_T = 4$ . (B) BLOCK SEQUENCE IN ONE PERIOD. SOURCE: REF 24**

Another example is given in Fig. 29, test results of flight simulation tests. In such tests it is a rather delicate problem to decide whether rarely occurring but very severe fatigue loads with a high amplitude should be included. Such loads can extend the fatigue life considerably, as amply demonstrated in many investigations, surveyed in Ref 27. Unfortunately, the life enhancement of such loads may give unconservative fatigue life results. As a consequence, truncation of high load amplitudes (also called clipping) must be considered (Fig. 30). Test results for three different truncation levels are presented in Fig. 29, both for the crack initiation life (until a 2 mm crack) and for the crack growth life. The maximum  $S_a$  level (truncation level) did systematically affect the crack initiation life (i.e., there were longer fatigue lives if some cycles of the spectrum with a higher  $S_{max}$  were introduced). That leads to more favorable residual stresses. A similar trend was

found for the crack growth period, but it is noteworthy that the effect on the crack growth period is significantly larger (Fig. 29).

### Fatigue Prediction Models for VA Loading

In general, prediction models published in the literature employ basic material fatigue data as a reference. Such data can be fatigue limits,  $S-N$  data, fatigue diagrams, crack growth data, and the fracture toughness for final failure. The data are obtained with simple specimens, unnotched specimens for the fatigue data, and simple precracked specimens (center-cracked tension or compact-type specimens) for the fatigue crack growth data. The fatigue load on the specimens should also be of a "fundamental simplicity" (i.e., a cyclic load with a sinusoidal wave shape and a constant  $S_a$  and  $S_m$ ). The data are supposed to be characteristic fatigue properties of a material, characterizing the fatigue resistance or the fatigue crack growth resistance. These properties are used as the material data in predictions on fatigue under VA load histories. They emphasize that fatigue is thought to be primarily a material problem.

The prediction models in principle adopt a *similarity approach* (also called *similitude*): similar stress cycles or similar strain cycles should give the same fatigue damage. Also, similar  $\Delta K_{\text{eff}}$  cycles should give similar crack length increments. This approach implies that fatigue data for the most simple conditions are extrapolated to more realistic engineering conditions. The fatigue model is the frame of the extrapolation procedures, but the extrapolation steps can be quite large. As a consequence, prediction models require empirical verifications. However, to judge the reliability of models, a physical understanding of a model is essential. Because problems involved with crack initiation and crack growth are different, models will be discussed in two categories: models for the crack initiation period and models for fatigue crack growth.

### Prediction of Crack Initiation under VA Loading

In the literature, prediction models are rarely presented as models for the crack initiation period. However, several models simply ignore fatigue crack growth. The predicted fatigue life then is the fatigue life until failure. If the macrocrack growth period is relatively short, the total life until failure is mainly covered by the fatigue crack initiation period. Under such conditions, we may consider the perspectives of prediction models for the initiation period under VA loading. The literature covers two approaches: fracture mechanics applied to the initial microcrack growth and models based on stress or strain histories, disregarding microcrack growth.

Fracture mechanics applied to the crack initiation period involves some fundamental problems:

- CRACK GROWTH LIFE PREDICTIONS BASED ON FRACTURE MECHANICS CONCEPTS CANNOT START FROM ZERO CRACK LENGTH, BECAUSE THEN THERE WILL BE NO CRACK GROWTH. THEY THUS MUST START FROM SOME INITIAL CRACK LENGTH. THE SIZE OF THE INITIAL CRACK LENGTH,  $A_0$ , MAY BE ASSOCIATED WITH SOME INITIAL STRUCTURAL DEFECT, SUCH AS AN INCLUSION. UNFORTUNATELY, THE PREDICTED CRACK GROWTH LIFE IS VERY SENSITIVE TO THE SIZE OF SUCH AN INITIAL DEFECT. BECAUSE OF THE SMALL SIZE,  $K$ -VALUES ARE SMALL AND PREDICTED CRACK GROWTH RATES ARE VERY LOW. AS A CONSEQUENCE, A LARGE PART OF THE FATIGUE LIFE IS COVERED BY THE INITIAL GROWTH OF A SMALL CRACK. DIFFERENT INITIAL SIZES, SAY 10  $\mu\text{m}$  AND 100  $\mu\text{m}$ , CAN IMPLY A LARGE DIFFERENCE OF THE PREDICTED LIFE (REF 78). THE CHOICE OF  $A_0$  THUS HAS A LARGE EFFECT ON THE PREDICTION RESULT.
- AS DISCUSSED BEFORE, FRACTURE MECHANICS CONCEPTS HAVE A LIMITED RELEVANCE TO MICROSTRUCTURALLY SHORT CRACKS. PROBABLY ALL ALLOYS OFFER THE BEST CONDITIONS FOR PREDICTIONS OF VERY SHORT CRACK LENGTHS. IN GENERAL, IT IS STILL HARD TO BELIEVE THAT MICROCRACK GROWTH PREDICTION CAN BE MADE WITH SOME REASONABLE ACCURACY FOR VA LOADING. FOR MANY LOAD HISTORIES IN TABLE 2, AGARD REPORTS R-732 AND R-767 SHOW OVERWHELMING RESULTS IN SMALL-CRACK GROWTH PREDICTION. HOWEVER,

SURFACE EFFECTS ARE VERY IMPORTANT AND MUST BE CONSIDERED IN FUTURE APPLICATIONS OF "SMALL-CRACK THEORY."

- A THIRD PROBLEM IS A VERY PRACTICAL ONE. IT WAS CONCLUDED ABOVE THAT CRACK INITIATION IS A SURFACE PHENOMENON. AS A CONSEQUENCE, THE CRACK INITIATION LIFE IS SENSITIVE TO VARIOUS SURFACE CONDITIONS.

### Environmental factors

Crack initiation life is influenced by several factors such as those listed in Table 4. The influence of these factors on fatigue can be large, and several of the effects are not easily accounted for in a strictly rational way. It must then be admitted that fracture mechanics predictions of crack initiation life are quite limited.

**TABLE 4 FACTORS INFLUENCING CRACK INITIATION LIFE**

**The Miner Approach.** Miner published his famous rule ( $\sum n/N = 1$ ) 50 years ago. Initially many test were carried out to check the validity of the rule, which was rather frustrating in view of the discrepancies between test results and Miner predictions. Some simple arguments can easily prove why the rule cannot be correct:

- IF A SMALL FATIGUE CRACK IS INITIATED BY LOAD CYCLES WITH  $S_A > S_F$  (WHERE  $S_F$  = FATIGUE LIMIT), LOAD CYCLES WITH  $S_A < S_F$  CAN PROPAGATE THE CRACK AND THUS CONTRIBUTE TO FATIGUE DAMAGE. ACCORDING TO THE MINER RULE, THAT SHOULD NOT BE TRUE BECAUSE  $N = \infty$  FOR  $S_A < S_F$ .
- IN A NOTCHED ELEMENT, PLASTIC DEFORMATION AT THE NOTCH ROOT CAN BE INDUCED BY A HIGH  $S_{MAX}$ . IT INTRODUCES RESIDUAL STRESSES THAT AFFECT THE FATIGUE DAMAGE CONTRIBUTION OF LATER CYCLES WITH A LOWER  $S_{MAX}$  (SEE FIG. 15, 16). THIS INTERACTION IS NOT RECOGNIZED BY THE MINER RULE.
- THE MINER RULE IMPLIES THAT FATIGUE DAMAGE IS FULLY DESCRIBED BY A SINGLE PARAMETER,  $\sum n/N$ , WHICH CAN VARY BETWEEN 0 (VIRGIN SPECIMEN) AND 1 (FINAL FAILURE). FINAL FAILURE SHOULD ALWAYS STAND FOR THE SAME AMOUNT OF DAMAGE. HOWEVER, A HIGH  $S_{MAX}$  LEADS TO FAILURE AT A SMALL CRACK LENGTH, WHEREAS A LOW  $S_{MAX}$  REQUIRES A MUCH LARGER CRACK (I.E., A DIFFERENT AMOUNT OF DAMAGE). THE MINER RULE PRESUMES THAT AN S-N CURVE IS A LINE OF

## CONSTANT DAMAGE, AND THAT IS SIMPLY NOT TRUE.

In a certain way, the first objection (damage contributions of cycles with  $S_a < S_f$ ) can be complied with by extrapolating the  $S-N$  curve below the fatigue limit (see Fig. 3). Fatigue cycles below the fatigue limit then contribute to fatigue damage. This might appear to be a reasonable approach, but it does not imply that accurate predictions will be obtained. The second objection was related to notch root plasticity and the introduction of favorable or unfavorable residual stresses as a consequence. Quite often, fatigue critical elements carry a positive mean stress. That is one of the reasons why they can become fatigue-critical. The probability of introducing residual stresses by the VA load history depends on the shape of the load spectrum. However, in general, favorable residual stresses are more likely if the load spectrum is associated with a positive mean stress. Although the Miner rule does not account for residual stress variations, it thus may be thought that ignoring the residual stresses should not necessarily lead to unconservative life predictions. It must be realized, however, that the predictions cannot be accurate. A rough estimate is the best result to be obtained. Another significant argument for this conclusion is that the prediction also depends on the reliability of the  $S-N$  curve to be used.

A warning must be made here: the Miner rule is fully unreliable for comparing the severity of different load spectra. As a simple illustration, compare a load spectrum to a modification of that spectrum obtained by adding a small number of high-load cycles. According to the Miner rule the addition should lead to somewhat shorter fatigue lives, whereas in general it leads to significant fatigue life improvements.

**The Strain History Prediction Model.** Plastic deformation at the root of a notch is not accounted for in the Miner rule. In low-cycle VA fatigue, however, plastic deformation at the root of a notch can occur in every cycle. This has led to fatigue predictions based on the strain history at the notch root (Ref 79, 80). This approach was stimulated by two developments. Low-cycle fatigue experiments under constant-strain amplitudes have indicated an approximately linear relation between  $\log \Delta \epsilon$  and  $\log N$  (the Coffin-Manson relation). Secondly, predictions of the plastic strain at a notch root could be made by adopting an analytical relation of Neuber (Ref 81) between  $K\sigma$  and  $K\epsilon$  (concentration factors for stress and strain, respectively), that is,  $K\sigma \cdot K\epsilon = K_t^2$ . The relation was derived for a prismatic notch loaded in shear (mode III), but it was assumed to be valid for notches loaded in tension as well. In order to solve the strain at the notch, the cyclic stress strain curve was adopted as a second equation.

Figure 41 schematically shows the procedures to be used for calculation of the strain history at the notch under VA loading and for the subsequent life prediction. The prediction model has recently been discussed in detail by Dowling (Ref 82). The main steps are mentioned here in order to show the advantages and weaknesses of the approach. Additional information on the strain-life method (including the use of total-strain-life and mean-stress rules commonly used for life prediction) is also provided in the article "Fundamentals of Modern Fatigue Analysis for Design" in this Volume.

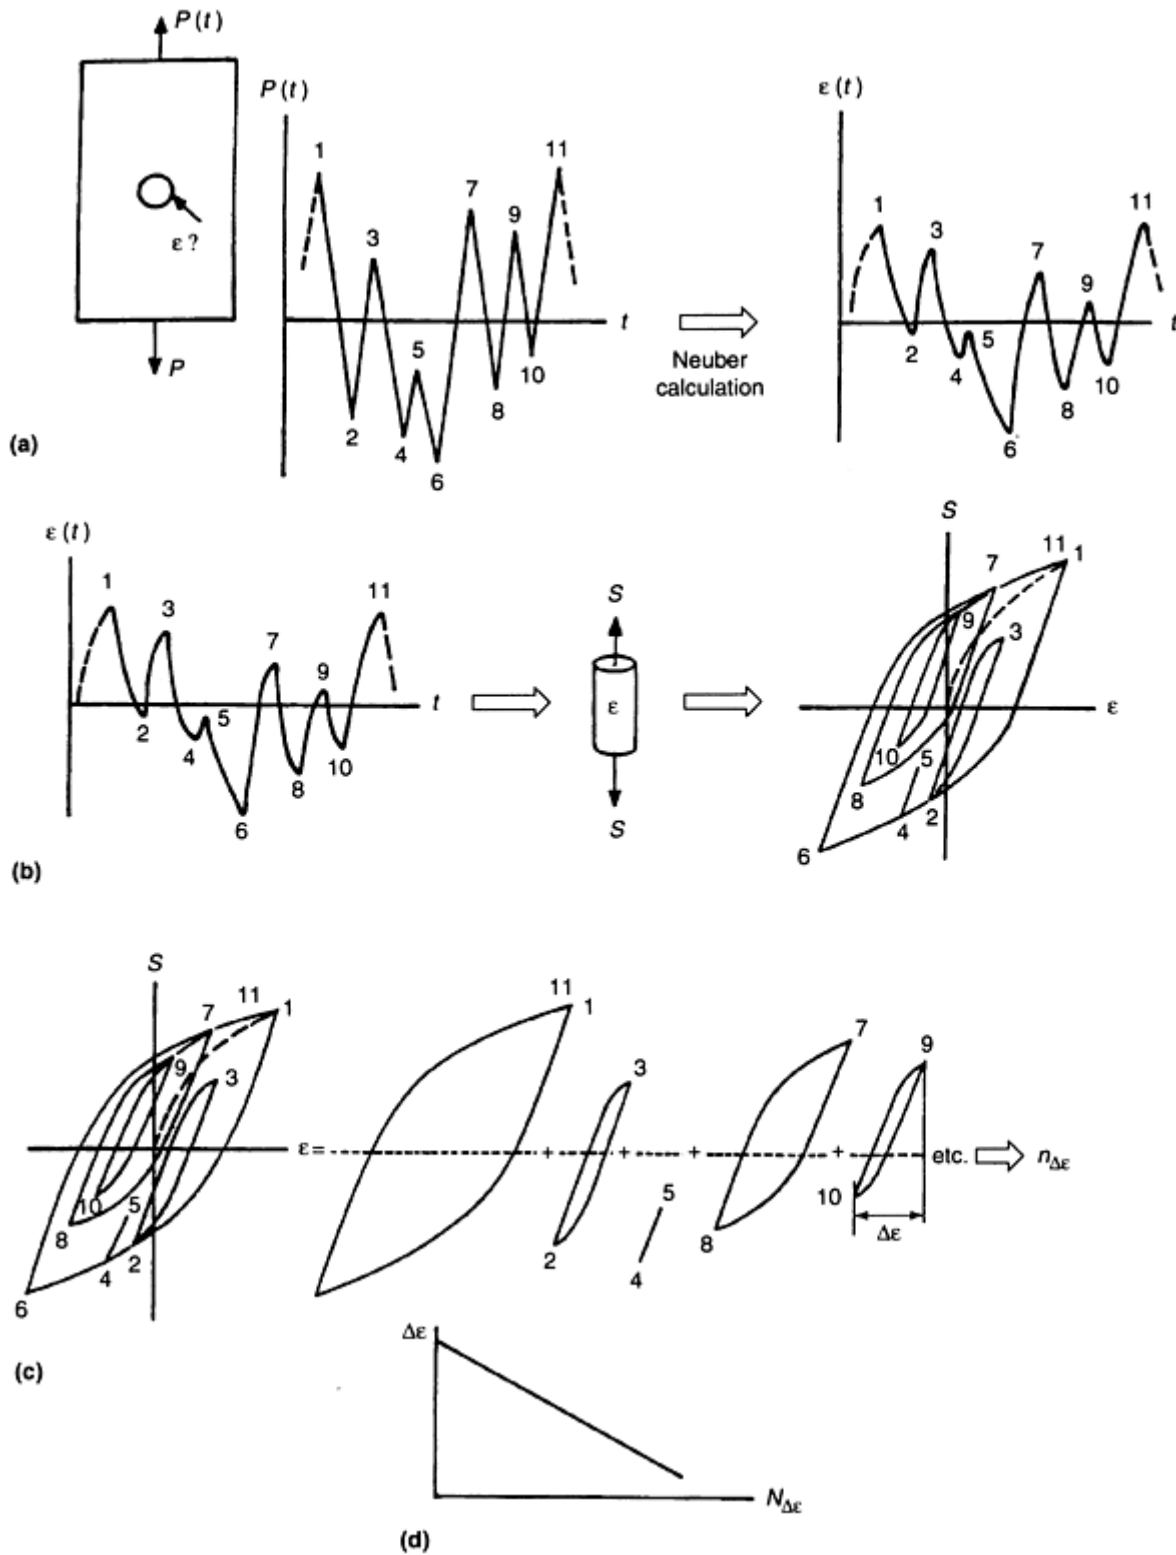

FIG. 41 PRINCIPLES OF THE STRAIN-BASED LIFE PREDICTION MODEL. FAILURE CRITERION:  $\sum(N_{\Delta\epsilon}/M_{\Delta\epsilon}) = 1$  (SEE PARTS C AND D). (A) LOAD HISTORY (LEFT GRAPH) AND STRAIN HISTORY (RIGHT GRAPH). (B) MATERIAL RESPONSE. (C) CYCLES AS CLOSED LOOPS. (D) MATERIAL FATIGUE RESISTANCE. SOURCE: REF 80

In the first step (Fig. 41a), the strain history  $\epsilon(t)$  is derived from the load history  $P(t)$  by employing the Neuber postulate and the cyclic stress-strain curve. In the second step (Fig. 41b), the  $\sigma$ - $\epsilon$  response of the material (at the root of the notch) is derived from  $\epsilon(t)$ . This derivation presumes a certain plastic hysteresis behavior based on the material memory for previous plastic deformation. In the third step (Fig. 41c), the cyclic hysteresis history is decomposed into closed

hysteresis loops. Each loop represents a full strain cycle. In the last step (Fig. 41d), the  $\Delta\varepsilon-N\Delta\varepsilon$  curve (adjusted for mean stress with a mean stress rule) is used as the material property characterizing the material resistance against low-cycle fatigue. The Miner rule is then adopted as the failure criterion.

The material properties required for the strain-history model are the cyclic stress-strain curve and the Coffin-Manson relation. Both types of data are considered to be unique for a material. This is an advantage over the stress-based  $S-N$  fatigue data, which depend on mean stress and surface quality. The surface quality is much less important for low-cycle fatigue, because the plastic strains are larger and as such depend on the material bulk behavior. It might be said that low-cycle fatigue is no longer a surface phenomenon as it is for high-cycle fatigue. At the same time, limitations of the strain-history model are easily recognized. The failure criterion is again the Miner rule, for which physical arguments can hardly be mentioned. Secondly, crack initiation and crack growth are fully ignored. Moreover, the model is restricted to notched elements, for which a theoretical stress concentration factor has a realistic meaning. As a consequence, application to joints is generally impossible. It was emphasized by Dowling (Ref 82) that the merits of the model should be looked for in low-cycle VA problems. Actually verification experiments are still rather limited.

There is a noteworthy comment to be made on the decomposition in Fig. 41(c). The individual cycles obtained are the same as the cycles obtained with the rainflow count method. This implies that this counting method finds some justification in the material memory for previous plastic deformation.

## Prediction of Crack Growth under VA Loading

The literature on prediction models for fatigue crack growth under VA loading is extensive. Observations on crack growth retardation after OLs and the occurrence of crack closure have stimulated the development of several prediction models on crack growth under VA loading. Most literature sources on prediction models give verification test data of crack growth in Al alloy sheet and plate material, mainly because VA loading and fatigue crack growth are important for aircraft structures. Acceleration and retardation must also both be considered. Predictive models that do not address acceleration do not appear effective (Chang and Hudson in ASTM STP 748).

**Simple Approach to Crack Growth under VA Loading (Noninteraction).** The most simple VA load sequence consists of two blocks of load cycles, where the second block is continued until a final crack length  $a = a_f$  is reached (Fig. 42a). The sequence may be Hi-Lo (as in Fig. 42a) or Lo-Hi. The simplest prediction model is obtained if all possible interaction effects are ignored. Crack growth then follows the growth curve applicable to the load cycle in the first block (Fig. 42b). After the stress level is changed, crack growth continues along the curve valid for the load cycle of the second block. There is a simple noninteraction transition from one crack growth curve to the other one. The predicted life is  $N_p = n_1 + n_2$ .

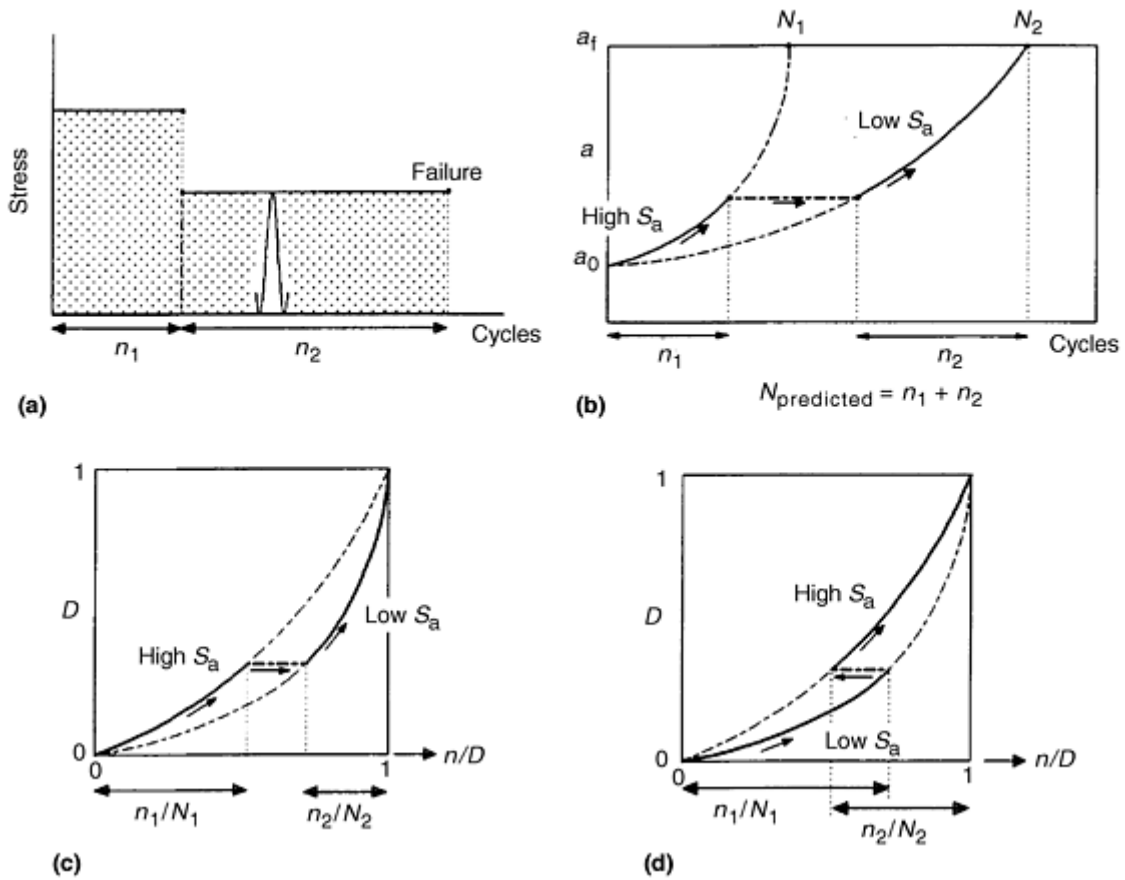

FIG. 42 NONINTERACTION FATIGUE CRACK GROWTH AND FATIGUE DAMAGE IN HI-LO AND LO-HI TESTS.  $D = (A - A_0) / (A_f - A_0)$ . (A) HI-LO. (B) HI-LO.  $N_{\text{PREDICTED}} = N_1 + N_2$ . (C) HI-LO.  $\Sigma n/N < 1$ . (D) LO-HI.  $\Sigma n/N > 1$ .

The two curves in Fig. 42(b) can also be presented as a function of  $n/N$ . The beginning and the end of the two curves then coincide at  $n/N = 0$  and  $n/N = 1$ , respectively. The fatigue damage,  $D$ , represented by the crack length  $a$  in Fig. 42(b), is converted to the crack increment  $(a - a_0)$  relative to the total crack increment to be covered  $(a_f - a_0)$ . It is a kind of damage parameter defined by:

$$D = \frac{a - a_0}{a_f - a_0} \quad (\text{EQ 3})$$

where  $D$  varies from 0 ( $a = a_0$ ) to 1 ( $a = a_f$ ). Considering crack growth along the two curves in Fig. 42(c), it is obvious that it leads to  $\Sigma n/N < 1$ . For the reversed block sequence (Lo-Hi), it leads to  $\Sigma n/N > 1$  (Fig. 42d). This suggests that there is a sequence effect, although interaction effects are disregarded.

An elementary statement can now be made (Ref 83): If fatigue damage is fully characterized by a single damage parameter, interaction effects are impossible. The reverse statement can also be made: If interaction effects do occur, fatigue damage cannot be fully described by one single damage parameter.

There is another interesting observation. If the two curves in Fig. 42(c) and 42(d) coincide, crack growth leads straightforwardly to  $\Sigma n/N = 1$ . More generally, if the same damage curves apply to any cyclic stress level, and if interaction effects do not occur, then the Miner rule is valid for any load sequence (Ref 83). In other words, if a damage function can be written as:

$$D = f\left(\frac{n}{N}\right) \quad (\text{EQ 4})$$

which is valid for any cyclic stress level, it leads to the Miner rule, independent of the shape of the function. (As discussed in Ref 83, the function  $f(n/N)$  should be a monotonously increasing function in order that  $D$  has a unique value for any  $n/N$ .) According to Miner,  $f(n/N)$  is a linear function, but nonlinear functions have been proposed in the literature (e.g., Ref 84).

**Interaction Models for Prediction of Fatigue Crack Growth under VA Loading.** The most well-known prediction models for fatigue crack growth under VA can be characterized by whether crack closure is involved and whether that is done in an empirical way or by calculation. Three categories are listed in Table 5.

**TABLE 5 THREE CATEGORIES OF CRACK GROWTH PREDICTION MODELS**

<b>TYPE OF MODEL</b>	<b>CRACK CLOSURE USED?</b>	<b>CRACK CLOSURE RELATION</b>
<b>YIELD ZONE MODELS</b>	<b>NO</b>	<b>...</b>
<b>CRACK CLOSURE MODELS</b>	<b>YES</b>	<b>EMPIRICAL</b>
<b>STRIP YIELD MODELS</b>	<b>YES</b>	<b>CALCULATED</b>

The models were developed in the order shown in the table. It was thought that the crack closure models were an improvement of the more primitive yield zone models, and strip yield models were considered superior to the initial crack closure models. As stated above, the models were primarily verified for through-cracks in Al alloy sheet and plate specimens, but experiments on other materials were done. In all models, plastic zone sizes are significant, whereas relaxation of residual stress and plastic shakedown are not included. It appears that the models are considered applicable for high-strength alloys with a limited ductility. Actually, these materials are the most fatigue-critical materials. Due to its special yielding behavior and its high ductility, mild steel is a class of materials of its own. However, fatigue crack growth in low-carbon steel under VA loading is becoming an increasingly relevant problem in welded structures.

**Yield Zone Models.** The models of Willenborg et al. (Ref 85) and Wheeler (Ref 86) were proposed to explain crack growth delays caused by OLs. The models consider the plastic zone sizes indicated in Fig. 43, but the concepts are different. In both models it was recognized that new plastic zones are created inside the large plastic zone of the OL. Moreover, the possibility was considered that these new plastic zones could be large enough to grow outside the OL plastic zone.

FIG. 43 PLASTIC ZONE SIZE CONCEPTS IN THE MODELS OF WILLENBORG (REF 85) AND WHEELER (REF 86)

The Willenborg model starts from a strange assumption that the delay is due to a reduction of  $K_{max}$  instead of a reduction of  $\Delta K_{eff}$ . This is physically incorrect. Crack closure in the model is supposed to occur only if  $K_{min} < 0$ . From a mechanistic point of view, the Willenborg model does not agree with the present understanding of crack closure. Wheeler introduced a retardation factor  $\beta$ , defined by:

$$\left(\frac{da}{dN}\right)_{VA} = \beta \cdot \left(\frac{da}{dN}\right)_{CA, \text{ same } K \text{ cycle}} \quad (\text{EQ 5})$$

The factor  $\beta$  is supposed to be a power function of the ratio  $r_{pi}/\lambda_i$ :

$$\beta = (R_{p,i}/\lambda)^m \quad (\text{EQ 6})$$

The empirical "constant"  $m$  is not a material constant, because it depends on the type of the VA load history. Both models can predict crack growth retardation only ( $\beta < 1$ ), not acceleration. After an OL the maximum retardation occurs immediately. Delayed retardation is not predicted. A more extensive summary is given in Ref 87.

Modifications of the two models have been proposed in the literature, which leads to more empirical constants. Crack closure, however, is not included. As a consequence, the models lack a background in sufficient agreement with the present understanding.

**Crack Closure Models for Predicting Crack Growth under VA Loading.** The crack closure models are based on the phenomenon of plasticity-induced crack closure. The Elber crack closure concept is used (i.e., there is an  $S_{op}$  in each cycle and the effective stress range is  $\Delta S_{eff} = S_{max} - S_{op}$ ). A cycle-by-cycle variation of  $S_{op}$  has to be predicted (Fig. 44). The cycle-minus-by-cycle calculations then follow apparently simple equations:

$$A = A_0 + \sum \Delta A_i \quad (\text{EQ 7})$$

$$\Delta A_i = (DA/DN)_i = F(\Delta K_{EFF,i}) \quad (\text{EQ 8})$$

$$\Delta K_{EFF,i} = C_i (S_{MAX,i} - S_{OP,i}) \sqrt{\pi a_i} \quad (\text{EQ 9})$$

FIG. 44 VARIABLE-AMPLITUDE LOAD WITH CYCLE-BY-CYCLE VARIATION OF  $S_{OP}$

The crack extension  $\Delta a_i$  in cycle  $i$  is supposed to be a function of  $\Delta K_{eff}$  in that cycle, while  $\Delta K_{eff,i}$  is a function of  $S_{max,i}$  and the predicted  $S_{op,i}$  for cycle  $i$ . The geometry factor  $C_i$  depends on the crack size,  $a_i$ . The crack opening stress level  $S_{op,i}$  depends on the previous load history, but  $S_{max,i}$  is part of the imposed load history (i.e., input data). In the models to be discussed below, the Paris relation is used for Eq 8:

$$DA/DN = C \Delta K_{eff}^m \quad (\text{EQ 10})$$

Another relation (e.g., interpolation in a table) can also be used.

Four models are briefly discussed below:

- THE ONERA MODEL (REF 88)
- THE CORPUS MODEL (REF 73)
- THE MODIFIED CORPUS MODEL (REF 87)
- THE PREFFAS MODEL (REF 89)

The models were developed primarily for applications to flight simulation load histories. They all calculate a variation of  $S_{op}$  during the flight simulation load history. The variation depends on the previous load history. It implies that information characteristic of the previous load history must be stored in a memory. The characteristic information is associated with the larger positive and negative peak loads. These loads either have introduced significant plastic zones for the determination of  $S_{op}$  or have reduced  $S_{op}$ , respectively. There are also significant differences between the models, which will not be discussed here in detail. The PREFFAS model is the simplest; the CORPUS model is the most detailed and also presents the most explicit picture about crack closure between the crack flanks. The differences between the models are associated with the assumptions made for the plane-strain/plane-stress transition during crack growth, the calculation of the plastic zone sizes, the empirical equations for calculating  $S_{op}$  (Elber-type relations), the decay of  $S_{op}$  during crack growth, the multiple OL effect, and in general the method of deriving  $S_{op}$  from the previous load history.

An analysis and comparison of the models has been made by Padmadinata (Ref 87) with extensive verifications, primarily for realistic flight simulation load histories and test results of two Al alloys, 2024-T3 and 7075-T6. However, simplified flight simulation tests were also included. As an example, comparative results for a realistic load spectrum are presented in Fig. 45. The test variables include the stress level, characterized by the mean stress in flight ( $S_{mf}$ ), the gust spectrum severity, and the downward severity of the ground load during landing. Noninteraction predictions are also shown in this figure. Unfortunately, this is not always done in model verifications, but differences between noninteraction predictions

and predictions of improved models are part of the motivation for the new models. Moreover, these differences indicate whether significant interaction effects have occurred in the test. The results in Fig. 45 clearly show that the noninteraction predictions did systematically underestimate the crack growth life in the tests to a large extent. The test life on the average was 5.3 times longer. The predictions of all models were significantly superior to the noninteraction prediction. Some comments on the results can be made:

- THE PREFFAS MODEL DOES NOT PREDICT ANY EFFECT OF THE GROUND STRESS LEVEL. THAT IS A CONSEQUENCE OF CLIPPING NEGATIVE LOADS IN THIS MODEL TO ZERO.
- THE PREDICTIONS OF THE CORPUS MODEL AND THE ONERA MODEL ARE FAIRLY CLOSE TO THE TEST RESULTS. THE TEST RESULTS INDICATE A SIGNIFICANT REDUCTION OF THE CRACK GROWTH LIFE FOR A MORE SEVERE GROUND STRESS LEVEL. THIS TREND IS NOT ALWAYS PREDICTED BY THE CORPUS MODEL, ESPECIALLY IF THE GUST SPECTRUM IS MORE SEVERE. THE MAXIMUM DOWNWARD GUST LOAD OCCURS ONLY ONCE IN A LARGE NUMBER OF FLIGHTS (2500 FLIGHTS IN FIG. 45). HOWEVER, THE GROUND LOAD OCCURS IN EVERY FLIGHT. IN CORPUS ITS EFFECT IS SMALL IF THE MOST NEGATIVE GUST IS MORE SEVERE DOWNWARD. THAT OVERRULES THE GROUND STRESS LEVEL. THIS WAS THE REASON THAT THE CORPUS MODEL WAS MODIFIED. THE MODIFIED MODEL IS STILL LARGELY THE SAME AS THE ORIGINAL, BUT DUE TO A MODIFIED MEMORY EFFECT FOR DOWNWARD LOADS THE MODIFIED CORPUS MODEL GIVES A BETTER PREDICTION FOR THE ABOVE-MENTIONED CONDITIONS (REF 87, 90).

FIG. 45 COMPARISON BETWEEN TEST RESULTS AND PREDICTIONS OF FATIGUE CRACK GROWTH LIFE UNDER FLIGHT SIMULATION LOADING IN 2024-T3 ( $T = 2$  MM). S, SEVERE; N NORMAL; L, LIGHT. SOURCE: REF 87

It may now be asked if all observations listed in Table 3 are covered to some extent by the basic assumptions on which the crack closure models are based. It then turns out that:

- CRACK GROWTH RETARDATION AFTER OLS IS PREDICTED, BUT DELAYED RETARDATION IS NOT. THE RETARDATION STARTS IMMEDIATELY AFTER THE

## OVERLOAD.

- PLANE-STRAIN/PLANE-STRESS TRANSITION IS INCLUDED IN THE CORPUS AND ONERA MODELS, ALTHOUGH NOT IN THE SAME WAY. IT LEADS TO A THICKNESS EFFECT, BUT VARIATIONS ALONG THE CRACK FRONT ARE AVERAGED OUT. THE TRANSITION IS NOT INCLUDED IN THE PREFFAS MODEL, BUT THE MODEL REQUIRES EMPIRICAL DATA FOR THE OL EFFECT REPRESENTATIVE OF THE THICKNESS CONSIDERED.
- MULTIPLE OL EFFECTS DO OCCUR ACCORDING TO THE CORPUS AND THE ONERA MODELS, ALTHOUGH THEY ARE NOT MODELED IN THE SAME WAY. THE CORPUS MODEL PREDICTS AN INCREASING  $S_{OP}$  DURING STATIONARY FLIGHT SIMULATION LOADING, WHICH IS NECESSARY TO PREDICT THE INITIALLY DECREASING CRACK GROWTH RATE (FIG. 35).
- THE DIFFERENT CRACK GROWTH MECHANISMS FOR PRIMARY AND SECONDARY CRACK-TIP PLASTIC ZONES ARE NOT INCLUDED.
- INCOMPATIBLE CRACK FRONT ORIENTATIONS AND RELATED PHENOMENA ARE NOT COVERED.

Some comments should be made here on the verification of models. In Fig. 45 a comparison is made between predicted and experimental crack growth lives. This is a primitive comparison, and if the crack growth lives do agree, a disagreement between crack growth curves is still possible (Fig. 46). In Fig. 46(a) the agreement between  $N_{\text{predicted}}$  and  $N_{\text{test}}$  is satisfactory, but that is not true for the crack growth curves or for the crack growth rate development during the crack growth lives. Even if the predicted and the measured crack growth curves do match quite well, that is not necessarily true for the crack rate in small batches of individual cycles. This question has been studied for crack growth under flight simulation loading (Ref 87, 91). The crack extension in the more severe flights has been determined by fractographic analysis. As shown by the results in Fig. 47 (Ref 91), the crack extension in the more severe flights was considerably larger than predicted by the modified CORPUS model, although the agreement for the macroscopic crack growth curve was quite good. This is not strange, because the number of the most severe flights in a flight simulation test is small. Incorrect predictions for the severe flights thus have a minor effect on the general behavior. There are two possible explanations for the discrepancy for the severe flights: the larger  $\Delta a$  for primary plastic deformation (Fig. 37) and incompatible crack front orientation. The discrepancy indicates that the model is not reliable in all details. A real verification of a prediction model also requires a comparison on a microscopic level. Without such observations delayed retardation cannot really be documented.

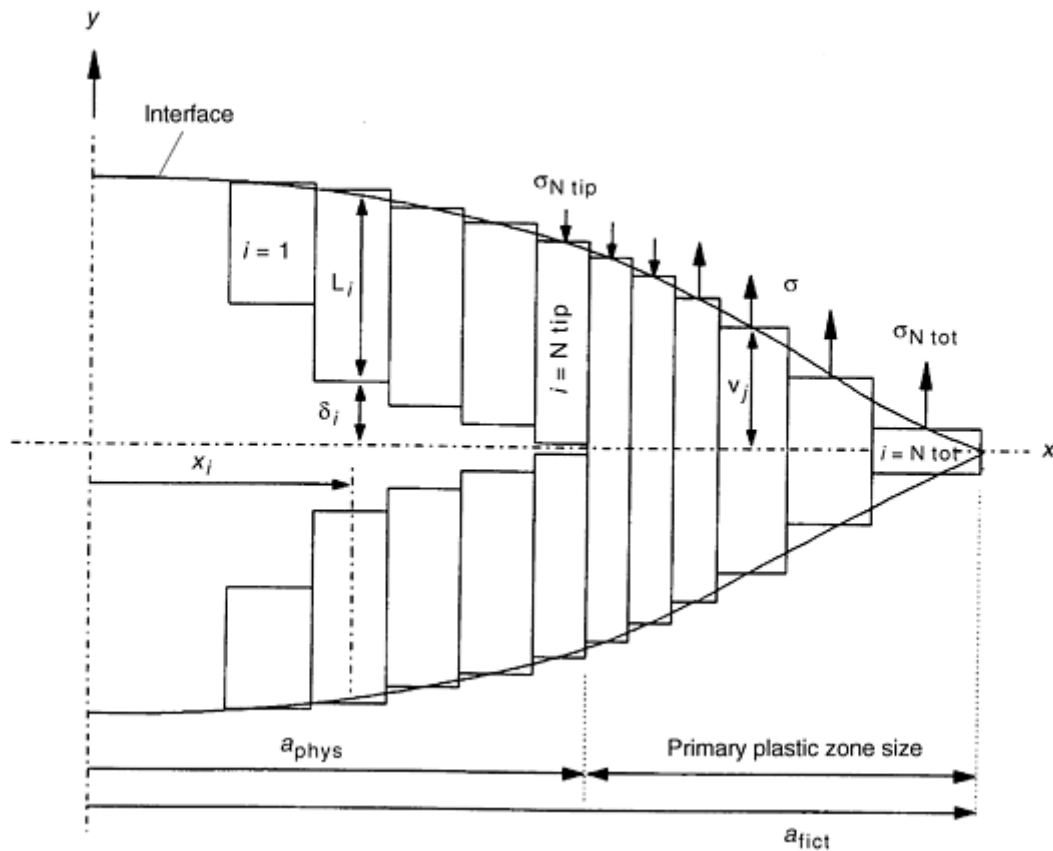

FIG. 47  $\Delta A$  IN THE MOST SEVERE FLIGHTS OF A FLIGHT SIMULATION TEST IN 2024-T3 ( $T = 2$  MM).  $\Delta A$  IS LARGER THAN THE CRACK LENGTH INCREMENTS PREDICTED BY THE MODIFIED CORPUS MODEL. SOURCE: REF 91

**Strip Yield Models.** The empirical crack closure models discussed above are based on the occurrence of crack closure in the wake of the crack. Assumptions are made to account for crack closure under VA loading, but plastic deformation in the wake of the crack is not calculated. This was done in some finite-element modeling studies (Ref 92, 93), which confirmed the occurrence of crack closure and simple interaction effects in qualitative agreement with empirical observations. Such calculations cannot be made for many cycles, so the Dugdale model was adopted and extended to arrive at a crack growth model that leaves plastic deformation in the wake of the crack. This type of work was started by Fühling and Seeger (Ref 94, 95). In the Dugdale plastic zone model, plastic deformation occurs in a thin strip with a rigid perfectly plastic material behavior. Because the crack grows into the plastic zone, a plastic wake field is created, which can induce crack closure at positive stress levels.

Quantitative strip yield models have been proposed by Dill et al. (Ref 96, 97), Newman (Ref 98), DeKoning et al. (Ref 99), and Wang and Blom (Ref 100). The models are rather complex, which is a consequence of the nonlinear material behavior and the changing geometry (crack closure and crack opening). Reversed plastic deformation in the wake field can occur when the crack is closed and locally under compression. Iterative solution procedures are to be used, which require significant computer capacity for a cycle-by-cycle calculation. They also require a number of plastic elements in the plastic zone and in the wake of the crack (Fig. 48). Newman has introduced local averages of  $S_{op}$  to avoid excessive computer time. Plane-strain/plane-stress transitions are included by changing the yield stress used in the Dugdale model. This has led to a so-called plastic constraint factor  $\alpha$ , developed by Newman and defined by him as the ratio of normal stresses in the plastic zone to the flow stress under tension. A separate  $\alpha$  factor is defined by Newman for compression. DeKoning's interpretation of Newman's  $\alpha$  factor is the ratio between the yield stress in tension and the yield stress in compression. Several predictions are reported for both simple tests with overload/underload cycles and flight simulation tests. In general, good agreement is reported.

**FIG. 48 A STRIP YIELD MODEL WITH DISCRETE PLASTICALLY STRETCHED PARTS AHEAD OF THE PHYSICAL CRACK TIP AND IN THE WAKE OF THE CRACK. SOURCE: REP 101**

The models cannot be discussed here in any detail. However, in comparison to the crack closure models, the improvements appear to be that:

- EMPIRICAL EQUATIONS FOR CRACK CLOSURE LEVELS ARE REPLACED BY THE CALCULATION OF  $S_{OP}$  AS A FUNCTION OF THE HISTORY OF PREVIOUS PLASTIC DEFORMATIONS. ELBER'S ASSUMPTION THAT  $U(R)$  IS INDEPENDENT OF THE CRACK LENGTH IS NO LONGER NECESSARY.
- DELAYED RETARDATION IS PREDICTED (REF 101).
- IN THE STRIP YIELD MODEL OF DE KONING, THE CONCEPT OF PRIMARY AND SECONDARY PLASTIC ZONES IS INTRODUCED, WHICH ACCOUNTS FOR LARGE  $\Delta A$  VALUES OF PEAK LOADS (PREDICTION VERIFICATION IN REF 99).
- MULTIPLE OL EFFECTS ARE PREDICTED BY THE STRIP YIELD MODEL IF THE MODELING IS SUFFICIENTLY REFINED (SEE ASTM STP 761, 1982, FOR EXAMPLE).
- THE PLANE-STRAIN/PLANE-STRESS TRANSITION IS STILL COVERED BY ASSUMPTIONS.
- INCOMPATIBLE CRACK FRONT INTERACTIONS ARE NOT COVERED.

Strip yield models are superior to the crack closure models because the physical concept has been improved. In general terms, the calculation of the crack driving force,  $\Delta K_{eff}$ , is based on calculations of the history of the plastic deformations in the crack-tip zone and in the wake of the crack. However, it still may be questioned whether the models are sufficiently realistic from a mechanistic point of view (Table 3) in order to arrive at accurate predictions. There is a lot of verification work to be done.

## Fatigue Crack Growth under Variable-Amplitude Loading

J. Schijve, Delft University of Technology

---

## Engineering Applications

As a result of many experimental investigations, we have obtained a reasonably detailed picture about fatigue in metallic materials under variable amplitude loading. The understanding should lead us to the question whether it is possible to aim at accurate and reliable prediction models for engineering purposes. That is a problem schematically surveyed in Fig. 1 about designing against fatigue. The alternative to making predictions is to carry out experiments for specific fatigue questions when they arise. Unfortunately, testing is not always possible. Moreover, it is not at all easy to accomplish experimental fatigue conditions that will give a relevant answer to our question. In many cases Miner calculations are made as a first life estimate, but as discussed above, they can lead to conservative estimates if a realistic  $S-N$  curve is extrapolated below the fatigue limit. Also, a noninteraction fatigue crack growth prediction can certainly lead to a conservative prediction (although even then it is a recommended practice to extrapolate the  $da/dN-\Delta K$  relation below  $\Delta K_{th}$ ), but for macrocracks the noninteraction approach might well lead to *overconservative* predictions. In other words, there are still good arguments to continue our efforts for improved fatigue prediction methods. An extensive verification of a new model must be recommended to cover all possible conditions associated with engineering applications. The physical understanding to see whether a model is feasible is necessary, but verification of the accuracy is essential in order to be confident that the application can be justified. More comments on practical aspects of Fig. 1 are made in Ref 102.

A final comment should be made on types of material. As stated above, most information on fatigue under VA loading has been obtained in research on aircraft materials. However, mild steel is abundantly used in many welded structures, and fatigue and crack growth are highly relevant issues for this type of material. Mild steel differs from many high-strength structural materials because of its own characteristic plastic yielding behavior. Plastic zone shapes are different for mild steel and high-strength alloys. For mild steel, Dugdale (Ref 103) observed that the shape is a narrow slit in line with the crack. The Dugdale concept for calculating the plastic zone shape for mild steel has been adopted in the VA strip yield models. Ironically, the plastic zone shape observed in high-strength alloys agrees better with the butterfly shape that is obtained in elastic-plastic finite-element calculations.

## Fatigue Crack Thresholds

A.J. McEvily, University of Connecticut

---

## Introduction

THE FATIGUE CRACK THRESHOLD is a function of a number of variables, including the material, the test conditions, the  $R$ -ratio, and the environment. ASTM E 647 defines the fatigue crack growth threshold,  $\Delta K_{th}$ , as that asymptotic value of  $\Delta K$  at which  $da/dN$  approaches zero. For most materials an operational, although arbitrary, definition of  $\Delta K_{th}$  is given as that  $\Delta K$  which corresponds to a fatigue crack growth rate of  $10^{-10}$  m/cycle.

Figure 1 (Ref 1) depicts the form of the  $da/dN$  versus  $\Delta K$  plot, where  $a$  is the crack length,  $N$  is the number of cycles, and  $\Delta K$  is the range of the stress-intensity factor in a loading cycle. The curve shown is bounded by two limits, the upper limit being the fracture toughness of the material and the lower limit being the threshold.

**FIG. 1 SCHEMATIC ILLUSTRATION OF THE DIFFERENT REGIMES OF STABLE FATIGUE CRACK PROPAGATION. SOURCE: REF 1**

It is appropriate to review some background information before dealing specifically with the topic of thresholds. For example, although the subject of fatigue has been investigated since the mid-nineteenth century, attention was not focused on the fatigue crack growth aspect of the fatigue process until the 1950s. Several events occurred in this latter period that led to increased interest in concern about fatigue crack growth. One of these was the investigation of the crashes of the Comet jet-aircraft, which raised awareness of the importance of fatigue crack growth. A second development was the emergence of the field of fracture mechanics, which permitted the quantitative analysis of fatigue crack growth. The third major development was the advent of the transmission electron microscope and a bit later the scanning electron microscope, which permitted detailed analysis of the fractographic features associated with fatigue crack growth.

Some of the early studies that relate to what we now refer to as the threshold were carried out by Frost and Dugdale (Ref 2). They observed that under certain loading conditions, nonpropagating cracks formed at notch roots, and Fig. 2 is an example of the type of plot they developed. The plot shows three regions. In one region, the stress amplitude was sufficient to result in complete fracture. In a second region, where the stress amplitude was smaller than the endurance limit divided by  $K_T$ , the theoretical stress concentration factor, no cracks formed. In a third region, nonpropagating cracks formed. These cracks exhibited a decreasing rate of growth with increase in crack length before reaching a growth rate of zero, over many millions of cycles, at a crack length of the order of a millimeter.

FIG. 2 FROST AND DUGDALE PLOT OF NOMINAL ALTERNATING STRESS VERSUS  $K_T$  FOR REVERSED DIRECT STRESS MILD STEEL SPECIMENS HAVING NOTCHES 5 MM DEEP. SOURCE: REF 2

Frost (Ref 3) also determined an empirical relationship between crack length and the stress necessary for crack growth. Notched test specimens were cycled to introduce fatigue cracks, then reprofiled to remove the notches. The specimens were then stress relieved to minimize any residual stresses introduced during the precracking. The fatigue-cracked specimens were then subjected to fully reversed cycling, and the subsequent fatigue crack growth behavior was noted. Tests in which a crack did not grow were continued for at least  $50 \times 10^6$  cycles. The fatigue limit for cracked specimens is shown in Fig. 3 as a function of crack length for copper plates. Frost observed that the equation  $\sigma_a^3 a = C$ , where  $\sigma_a$  is the stress amplitude,  $a$  is the crack length, and  $C$  is a constant, described the fatigue limit for such precracked specimens. At the shortest fatigue crack lengths, the plain fatigue strength is plotted as an upper limit to the stress amplitude, an indication that Frost realized that there was a transition from crack length control of the fatigue limit to material control in the very short crack length region. Further mention of this transition is made below. Fatigue-limit data of this nature were later analyzed by Frost et al. (Ref 4) in terms of the fracture mechanics parameter  $\Delta K$ , with  $\Delta K$  taken to be equal to  $1.1 \times \sigma_a (\pi a)^{1/2}$ . Table 1 gives both the constant  $C$  as well as the corresponding  $\Delta K_{th}$  values. The  $\Delta K_{th}$  values decrease with decrease in crack length, and this may be associated with crack closure, as discussed below.

Frost and Greenan (Ref 5) also determined the critical stress for growth of a fatigue crack as a function of  $R$ , where  $R$  is the ratio of the minimum to maximum stress in a loading cycle. Table 2 gives their results. As  $R$  increases, the value of  $\Delta K_{th}$  decreases.

(A) HEAT TREATED AFTER FATIGUE CRACKING: 1 H AT 820 °C, AIR COOLED, 3 H AT 480 °C

Paris et al. (Ref 6) were the first to determine the threshold value,  $\Delta K_{th}$ , at crack growth rates of the order of  $2.5 \times 10^{-11}$  m/cycle. Paris was concerned about the situation where existing material flaws are small and lightly stressed but are subjected to a large number of cycles over a lifetime. It was therefore of interest to examine slow rates of growth of fatigue cracks as well as the secondary variables that may affect these rates, such as mean stress, environment, and temperature. In these studies, compact tension specimens and a load shedding technique were used to approach threshold. Figure 4 shows the results for an A533 B-1 steel tested at  $R = 0.1$ .

**FIG. 4 PARIS DATA FOR FATIGUE CRACK PROPAGATION OF ASTM A533 B-1 STEEL,  $R = 0.10$ , AMBIENT ROOM AIR, 75 °F. SOURCE: REF 6**

Interest in fatigue testing at low fatigue crack growth rates grew during the 1970s to the extent that an international symposium on fatigue thresholds was held in Stockholm in 1981. This was followed in 1983 by a second symposium on fatigue crack growth threshold concepts. Since that time, research has increased considerably.

Two other developments have played an important role in explaining fatigue crack behavior at the threshold level. One of these is crack closure, a phenomenon discovered by Elber (Ref 7). The other development is modelling of short crack behavior.

**Crack closure** can occur during the unloading portion of a fatigue cycle and is defined as the contacting of the opposing surfaces of a crack before the minimum of the loading cycle is reached. The crack opening load is that particular load level during the loading portion of a cycle at which the crack surfaces become fully separated. Usually the crack opening process is viewed in a continuum sense as an unzipping process, in which contact between the opposing crack surfaces is first lost at some distance behind the crack tip, then progressively closer to the crack tip until all contact is lost at the opening level. Only that portion of a loading cycle above the opening level is considered to be effective in propagating the fatigue crack (i.e.,  $\Delta K_{\text{eff}} = K_{\text{max}} - K_{\text{op}}$ ). The rate of fatigue crack growth then becomes a function of  $\Delta K_{\text{eff}}$ , provided that the nature of the cracking process at the crack tip is similar (i.e., we are not comparing branched cracks with nonbranched cracks). ASTM STP 982 provides a comprehensive review of this subject.

To illustrate the importance of crack closure on the propagation or nonpropagation of fatigue cracks, consider the results obtained by Pippan with Armco iron (Ref 8). He prepared specimens that contained slightly blunted, closure-free long cracks. These specimens were then cyclically loaded at various  $R$  values that included compression-compression cycling. Pippan observed that the initial fatigue crack growth rate was independent of the  $R$  value and was a function only of  $\Delta K$ , which initially was identical to  $\Delta K_{\text{eff}}$  because of the closure-free starting condition. As roughness-induced closure developed, the rate of crack growth decreased with decrease in  $\Delta K_{\text{eff}}$  and became sensitive to the  $R$  value, with crack arrest occurring under compression-compression loading. The conditions of loading, as well as  $K_{\text{op}}$ , are shown in Fig. 5. For each test the corresponding  $R$  and  $\Delta K$  values are indicated in parentheses. Cracks became nonpropagating if the  $K_{\text{max}}$  value did not exceed  $\Delta K_{\text{th}}$ . Further, the fact that the initial rate was independent of  $R$  implies that the cracks were initially closing only at  $K_{\text{min}}$ , even for compression-compression loading. This means that even if  $K_{\text{min}}$  is in compression, its value is initially significant in defining  $\Delta K_{\text{eff}}$ . The observed behavior can be analyzed with the aid of the following constitutive relation:

$$\frac{da}{dN} = A(\Delta K_{\text{eff}} - \Delta K_{\text{eff(th)}})^2 \quad (\text{EQ 1})$$

To allow for the development of crack closure with crack advance, Eq 1 becomes:

$$\frac{da}{dN} = A[(K_{\text{max}} - K_{\text{min}}) - (1 - e^{-k\lambda})(K_{\text{opmax}} - K_{\text{min}}) - \Delta K_{\text{eff(th)}}]^2 \quad (\text{EQ 2})$$

For Armco iron, the value of  $A$  is  $1.8 \times 10^{-10} (\text{MPa})^{-2}$ ,  $\lambda$  is the length of the crack that develops from the blunted crack, and  $k$  is a parameter that relates to the rate of crack closure development in the wake of the new crack. For Armco iron it has a value of  $2 \text{ mm}^{-1}$  with  $\lambda$  measured in millimeters. Figure 6 compares the experimental results with the predicted results based upon Eq 2, and the agreement is quite good, illustrating the importance of crack closure in interpreting some fatigue crack growth phenomena. Other constitutive relations involving the threshold level have been proposed. For example, Ohta et al. (Ref 9) have used the nonlinear equation  $da/dN = C[(\Delta K)^m - (\Delta K_{\text{th}})^m]$  to fit  $da/dN$  versus  $\Delta K$  data by a regression method to evaluate the 99% confidence intervals. Experimental results on fatigue crack propagation properties of welded joints in several low-alloy steels (SM50B, HT80, SB42, and SPV50) were compared by using these confidence intervals.

FIG. 5 PIPPAN LOADING CONDITIONS WITH THE VARIATION OF  $K_{TH}$  AND  $K_{OP}$  AS A FUNCTION OF  $K_{MIN}$  IN ARMCO IRON. THE VERTICAL LINES INDICATE THE RANGE OF  $\Delta K$  USED BY PIPPAN (REF 8) AT EACH  $R$  VALUE.

(a)

(b)

FIG. 6 PIPPAN DATA FOR FATIGUE CRACK GROWTH RATE AS A FUNCTION OF CRACK LENGTH AND  $R$  IN ARMCO IRON. SOLID LINES REPRESENT THE EXPERIMENTAL FINDINGS OF PIPPAN (REF 8). DASHED LINES ARE PREDICTED VALUES (A. MCEVILY AND Z. YANG, *MET. TRANS.*, VOL 22A, 1991, P 1079). (A)  $\Delta K = 16 \text{ MPA}\sqrt{m}$ . (B)  $\Delta K = \text{MPA}\sqrt{m}$

The types of closure mechanisms include plasticity-induced, roughness-induced, oxide-induced, and fretting-debris-induced. The type of closure mechanism can vary with test condition and material. For example, if an overload is applied near threshold, plasticity-induced closure in the plane-stress, surface regions of a specimen may be important (Ref 10). More often, roughness-induced closure accompanied by differing degrees of wear in various materials is the important type of closure at threshold. Increasing fracture surface roughness tends to correlate with lower fatigue crack growth rates, and this has been related to variations in the extent of crack closure (Ref 11).

There is also an influence of the  $R$  level on the extent of roughness. For example, at  $R = -1$ , lower thresholds are found than at small positive  $R$  values. This is due to the development of smoother crack surfaces due to the compressive loads and consequently less roughness-induced crack closure (Ref 12). It has been noted by Ohta et al. (Ref 13) that the fracture

surface appearance can differ significantly at a given growth rate as a function of the  $R$  value. Blom (Ref 12) found, in studies of near-threshold fatigue crack growth and crack closure in 17-4 PH steel and 2024-T3 aluminum alloy, evidence for oxide-induced closure at room temperature. It was definitely a contributing factor to the closure level of steels at elevated temperature (Ref 14). Kobayashi et al. (Ref 15) found that crack closure resulting from fretting oxide debris is of particular importance to the near-threshold characteristics of A508-3 steel.

The fracture surface appearance near threshold differs from that in the mid-range of crack growth rates where mode I growth dominates and where in ductile materials the fatigue striations typical of a fatigue crack can be found. In the near-threshold range, mode II growth is often found to dominate (Ref 16), and Fig. 7 (Ref 17) emphasizes this point.

FIG. 7 SCHEMATIC ILLUSTRATION OF MODE I AND II FATIGUE CRACK GROWTH PROCESSES

An analysis of fatigue crack closure caused by asperities using a modified Dugdale model developed by Newman (Ref 18) has been presented by Nakamura and Kobayashi (Ref 19). This analysis involved the rigidity of the asperities, the asperity length, the asperity thickness, and the distance from the crack tip. However, despite the overwhelming amount of data relating to crack closure, a unanimous view as to its significance has not as yet been reached (see, e.g., Ref 20).

**Short-Fatigue-Crack Behavior.** In 1973, Pearson (Fig. 8) drew attention to the fact that short fatigue cracks could grow at stress intensity levels below the threshold level for macroscopic cracks, a process referred to as anomalous fatigue crack growth behavior. Such behavior is now better understood. For example, it has been shown with respect to Fig. 2 that cracks that are initially closure free can propagate below  $\Delta K_{th}$ . Such behavior clearly demonstrates that use of the macroscopic threshold level as a design criterion to guard against the growth of fatigue cracks is not applicable in the realm of short fatigue cracks. In fact, as a crack under consideration is made smaller and smaller, there is a transition from linear elastic fracture mechanics (LEFM) treatment of long cracks at threshold to endurance-limit-dominated behavior of short cracks, as shown by Kitagawa and Takahashi for a steel of 725 MPa yield strength tested under  $R = 0$  conditions. When the surface crack length,  $2a$ , is larger than 0.5 mm, then a simple conventional fracture mechanics law can be applied to calculate the threshold condition, (i.e.,  $\Delta K_{th}$  is constant). However, below a surface crack length of 0.5 mm, the threshold stress range departs gradually from its macroscopic value, and as  $2a$  decreases,  $\Delta\sigma_{th}$  asymptotically approaches a constant stress range level that is approximately equal to the fatigue limit of unnotched smooth specimens of this material. The type of diagram depicting this situation, shown in Fig. 9, is referred to as a Kitagawa diagram.

FIG. 9 KITAGAWA PLOT OF THE EFFECT OF CRACK LENGTH ON THE THRESHOLD STRESS RANGE FOR FATIGUE CRACK GROWTH. SOURCE: *2ND INTL. ON MECH. BEHAVIOR OF MATERIALS*, ASM, 1976, 627-631

Morris and James (Ref 21), in an investigation of the growth threshold for short cracks, observed that the stochastic growth rate variations found experimentally were attributable to crack closure and to the reduced stress intensity that accompanied irregularities in the crack path. More information on this topic is in the next article "Behavior of Small Fatigue Cracks" in this Volume.

A comprehensive review of threshold data has been provided by Taylor (Ref 22). Liaw (Ref 23) reviewed the effects of microstructure, environment, loading condition, and crack size on near-threshold fatigue crack growth rate and concluded that the crack closure concept led to the correlation of much fatigue crack growth data. Beevers et al. (Ref 24) have discussed crack closure in relation to  $\Delta K_{th}$ , and Beevers and Carlson (Ref 25) have considered the significant factors controlling fatigue thresholds. In many instances the fatigue cracks are initiated at small defects that originate from microstructural or fabrication flaws. The development of these small defects involves, in many instances, stress intensities near the threshold regime and fatigue crack growth rates in the range of  $10^{-8}$  to  $10^{-13}$  m/cycle. Because most of the "lifetime" is spent in this low growth rate regime, variables such as microstructure, stress state, and environment have an appreciable influence on  $\Delta K_{th}$ .

## Test Techniques

In order to establish a valid threshold value experimentally, it is necessary to reduce gradually the applied stress-intensity factor range. ASTM 647 recommends that the rate of load shedding with increasing crack length should be gradual enough to: (a) preclude anomalous data resulting from reductions in the stress-intensity factor and concomitant transient growth rates; and (b) allow the establishment of about five  $da/dN$ ,  $\Delta K$  data points of approximately equal spacing per decade of crack growth rate. These requirements can be met by limiting the normalized  $K$ -gradient,  $C = (1/K)(dK/da)$ , to a value equal to or greater than  $-0.08 \text{ mm}^{-1}$ . The ASTM procedure further recommends that the load ratio,  $R$ , and  $C$  be maintained constant during  $K$ -decreasing testing. A procedure for standardizing crack closure levels has been proposed by Donald (Ref 26).

The following procedure, given in ASTM 647, provides an operational definition of the threshold stress-intensity factor range for fatigue crack growth,  $\Delta K_{th}$ , that is consistent with the general definition. Determine the best-fit straight line from a linear regression plot of  $\log da/dN$  versus  $\log \Delta K$  using a minimum of five  $da/dN$ ,  $\Delta K$  data points of approximately equal spacing between  $10^{-9}$  and  $10^{-10}$  m/cycle. Calculate the  $\Delta K$  value that corresponds to a growth rate of  $10^{-10}$  m/cycle using the fitted line. This value of  $\Delta K$  is defined as  $\Delta K_{th}$  according to the operational definition of this test method. The requirements for obtaining economic fatigue crack growth data in the threshold regime in inert, gaseous, elevated-temperature, and aqueous environments can be facilitated by the development of remote crack growth monitoring techniques (Ref 27).

Some investigators have checked on the effect of the rate of load shedding on the threshold level. In one case it was reported that for type 316 stainless steel in air at 24 °C, load shedding rates greater than the maximum rate recommended in the ASTM test procedure were found to have no substantial effect on the threshold behavior. At very low  $\Delta K$  levels, crack growth rates were apparently dependent on environmental effects and the degree of plastic constraint (Ref 28). However, it has also been noted that a rapid load reduction can increase the threshold by 10 to 100% in the aluminum alloy 2024, and that after a rapid decrease in vacuum the crack may begin to propagate again after  $5 \times 10^7$  cycles (Ref 29).

A number of investigators have developed other modes of load shedding, in the attempt to avoid crack closure during the load shedding process, by testing at effectively high  $R$  values where closure is not a factor, or by maintaining  $K_{max}$  constant and gradually decreasing  $\Delta K$  so that the  $R$  value continually shifts to a higher value as load is shed. The threshold determined by such procedures, being free of closure, is designated  $\Delta K_{eff}$ , a conservative lower bound to long crack threshold values. One such method, designated " $P_{max}$  constant,  $\Delta K$  decreasing" was introduced to avoid the closure effect in fatigue crack growth testing near the threshold region. It was useful in investigating the effect of the environment, because it allowed a direct evaluation of  $da/dN$  versus  $\Delta K_{eff}$  relations (Ref 30). The  $K_{max}$  constant, decreasing  $\Delta K$  method

has been used to determine the threshold level in liquid helium (Ref 31).  $\Delta K$ -decreasing threshold fatigue crack propagation data under conditions of constant maximum stress intensity ( $K_{\max}$ ) has been generated by Herman et al. (Ref 32), by Ohta et al. (Ref 33), and by Matsuoka et al. (Ref 34). The influence of test variables on  $\Delta K_{th}$  has been discussed by Priddle (Ref 35), and Ref 36 provides a comparison of test methods for the determination of  $\Delta K_{th}$  in titanium at elevated temperature.

In addition, crack initiation and growth under cyclic compression has been demonstrated to be a useful method for quickly obtaining estimates of fatigue crack growth thresholds while minimizing some of the uncertainties inherent in the conventional (load shedding) procedures (Ref 37).

Even under closure-free conditions, some uncertainties remain. For example, a hysteresis effect on the value of  $\Delta K_{th}$  has been observed for near-threshold fatigue crack propagation behavior of a high-strength steel investigated in laboratory air under closure-free conditions ( $R = 0.7$ ). Also, the  $\Delta K$  curves obtained on the same specimen during the  $\Delta K$ -decreasing and the  $\Delta K$ -increasing tests may not be identical in the threshold regime (Ref 38).

Other test procedures relating to threshold behavior have also been used. For example, under narrow-band random loading, the threshold for fatigue crack growth may be lower than that observed under sinusoidal loading. It has been suggested that small, regular overloads under random loading help to keep the crack faces apart, and thereby prevent closure and assist in crack growth (Ref 39). On the other hand, in tests carried out in salt water environments, multiple overloads produced a much larger increase in  $\Delta K_{th}$  than a single overload (Ref 40). The effect of underload cycles on the reduction of the threshold level of a structural steel has also been investigated (Ref 41). Debris in salt water solutions has been shown to significantly affect the near-threshold growth through its influence on crack closure and the transport processes occurring at the crack tip (Ref 42). Also, under fretting conditions the threshold for S45C steel fell to the critical threshold value of the order of  $1 \text{ MPa} \sqrt{m}$  (Ref 43).

Specialized techniques relating to the threshold studies have also been employed. For example, by using thermometrical techniques, the crack opening load and the stress distribution during crack growth near the threshold value can be determined (Ref 44). Ultrasonics has been used to investigate the degree of contact of asperities during crack closure, and the existence of a threshold has been related to crack closure (Ref 45).

Ultrasonic fatigue testing involves cyclic stressing of material at frequencies typically in the range of 15 to 25 kHz. The major advantage of using ultrasonic fatigue is its ability to provide near-threshold data within a reasonable length of time. High-frequency testing also provides rapid evaluation of the high-cycle fatigue limit of engineering materials as described in the article "Ultrasonic Fatigue Testing" in Volume 8 of *ASM Handbook*, formerly 9th edition *Metals Handbook*.

Some of the values of  $\Delta K_{th}$  and the corresponding minimum crack growth rate are presented in Table 3 for several pure metal and alloy systems, from threshold testing at ultrasonic frequencies. The minimum crack growth rates obtained at ultrasonic frequency are decades below the value of one lattice parameter per cycle. At these low crack growth rates and  $\Delta K$  values, the crack tip plastic size is extremely small.

(A) INCLUDING COMPARISON WITH LOW-FREQUENCY TEST DATA.

Acoustic emission also has potential for determining threshold levels (Ref 46). Testing at 20 KHz has been employed to reduce total test time, and crack growth rates between  $10^{-12} < da/dN < 10^{-9}$  m/cycle have been measured (Ref 47).

## Aluminum Alloy Crack Growth Thresholds

Figure 10(a) shows the  $\Delta K_{th}$  values for three aluminum alloys as a function of the load ratio,  $R$ , and environment: laboratory air (50% relative humidity) versus vacuum ( $10^{-5}$  torr). Figure 10(b) shows the same data after correction for crack closure (i.e.,  $\Delta K_{eff(th)}$ ). Figure 10 shows that the dependence of the threshold value on  $R$  is about the same in air as in vacuum, and that  $\Delta K_{eff(th)}$  is within experimental error independent of  $R$ . Threshold data obtained in air in other investigations generally show a similar  $R$  dependency, whereas the threshold data obtained in vacuum may not. For example, Lafarie-Frenot and Gasc (Ref 48) found little effect of  $R$  in vacuum on  $\Delta K_{th}$  or  $\Delta K_{eff(th)}$ , which means that the extent of closure above  $K_{min}$  had to be the same at  $R = 0.5$  as at  $R = 0.1$ , which is unexpected. Beevers (Ref 49) has found the threshold level determined in vacuum to be independent of  $R$  for high-strength aluminum alloys and En24 steel; however, no closure data were obtained. It is usually found that alloys exhibit a higher  $\Delta K_{eff(th)}$  in vacuum as compared to air, but in at least one case the reverse has been reported. Jono (Ref 50) observed that fatigue cracks in aluminum alloys grew in vacuum below the  $\Delta K_{eff(th)}$  for crack growth in air. He attributed this circumstance to the ease of deformation of aluminum in vacuum. A review of the near-threshold fatigue crack growth behavior of 7xxx and 2xxx alloys has been given by Vasudevan and Bretz (Ref 51).

FIG. 10  $\Delta K_{TH}$  AND  $\Delta K_{EFF(TH)}$  DATA ON THREE ALUMINUM ALLOYS. SOURCE: M. RENAULD, UNIVERSITY OF CONNECTICUT

Bretz et al. (Ref 52) determined the effects of grain size and stress ratio on fatigue crack growth in wrought P/M 7091 aluminum alloy and found that increasing the grain size by thermomechanical processing can significantly increase near-threshold fatigue crack growth resistance. A factor of 2 increase in  $\Delta K_{th}$  with grain size was measured at both  $R$  ratios. Bretz et al. concluded that crack closure alone was not responsible for grain size effects on fatigue behavior at a particular  $R$  ratio, but that crack tip deviation was an important mechanism by which near-threshold fatigue crack growth rates were reduced as grain size increased.

The influences of load ratio,  $R$  (at values of -2, -1, 0, 0.33, 0.5, and 0.7), and crack closure on fatigue crack growth thresholds in 2024-T3 aluminum alloy have been investigated by Phillips (Ref 53). He found that values of  $\Delta K_{th}$  varied significantly with  $R$ , whereas values of  $\Delta K_{eff(th)}$  did not. The influence of load ratio on fatigue crack growth in 7090-T6 and IN9021-T4 P/M aluminum alloys was examined by Minakawa et al. (Ref 54). A principal difference between these two alloys was grain size, which was  $<1 \mu\text{m}$  for the alloy IN9021 and  $>5 \mu\text{m}$  for the alloy 7090. Crack closure was observed in the 7090 alloy, and there was also a dependency of the threshold level on  $R$  (Fig. 11). No closure was found in the fine-grained IN 9021 alloy, nor was there any dependency of  $\Delta K_{th}$  on  $R$  (Fig. 12). Such results support a  $\Delta K_{eff(th)}$  interpretation of the effect of  $R$  on the threshold level.

FIG. 12 FATIGUE-CRACK GROWTH RATE AT VARIOUS  $R$  RATIOS AS A FUNCTION OF  $\Delta K$  FOR THE P/M

Park and Fine (Ref 51) studied the near-threshold fracture characteristics of an Al-3%Mg alloy ( $\sigma_y = 52 \text{ MPa}$ ) and found that the shear-mode areal fraction of the fracture surface increased in dry argon as the threshold was approached, with the increase greater at  $R = 0.05$  than at  $R = 0.5$ . The mechanism for crack closure at low load ratio appeared to be surface roughness coupled with shear mode displacements. (In Al-Zn-Mg single crystals, crystallographic cracks propagated in vacuum near threshold, even as  $K_{\text{eff}}$  approached zero and mode II was dominant (Ref 55)). Park and Fine also observed that the roughness of the fracture surface decreased as the threshold was approached, and that the roughness also decreased with decrease in  $R$ . Such results suggest that crack-surface wear was responsible for the reduction in roughness. This wear, due to rubbing of the mating fracture surfaces, increased with closure level near the threshold, where an increasingly large number of cycles is required to advance the crack a given increment.

Wanhill (Ref 56) compared the low-stress-intensity fatigue crack growth of 2024 aluminum alloy in the naturally aged T3 and T351 conditions. Particular attention was paid to crack growth curve transitions in the near-threshold regime. These transitions corresponded to monotonic or cyclic plane-strain plastic zone dimensions becoming equal to characteristic microstructural dimensions, and changes in fracture surface topography were also associated with the transitions.

Harrison and Martin (Ref 57) studied the effect of dispersoids on near-threshold fatigue crack propagation in an Al-Zn-Mg alloy and found that manganese-bearing dispersoids lowered  $\Delta K_{\text{th}}$ . They proposed that manganese-bearing dispersoids homogenized the dislocation distribution, which reduced the tendency for slip reversibility. Zinc-bearing dispersoids did not homogenize slip, and their effect was to raise  $\Delta K_{\text{th}}$  without changing the predominantly intergranular fracture mode. It was suggested that the action of zinc-bearing dispersoids was to reduce hydrogen embrittlement. Near-threshold fatigue crack propagation and crack closure in Al-Mg-Si alloys with varying manganese concentrations have also been investigated by Scheffel and Detert (Ref 58).

Manganese dispersoids were also found to have a deleterious effect on near-threshold fatigue crack growth in 2134 type alloys by Jata et al. (Ref 59). They tested the alloy in the under- and overaged conditions as a function of manganese additions ranging from 0 to 1.02 wt%. The additions of manganese resulted in a continuous decrease of the nominal threshold in both conditions, with the effect more pronounced in the overaged condition. Crack deflections, closure, and fractography suggested that roughness-induced crack closure was dominant in all alloys. The fractographic evidence also suggested that large manganese particles contributed to local microcrack acceleration, resulting in an intrinsic lowering of the fatigue thresholds and faster crack propagation rates as compared to a similarly overaged 2124 alloy.

Venkateswara et al. (Ref 60) have observed that overaging the Al-Li alloy 2090 led to a decrease in strength and toughness, principally through the formation of platelike copper-rich grain boundary precipitates and associated copper-depleted and  $\delta'$  precipitate-free zones. This overaging also was found to result in increased fatigue crack growth rates, except near-threshold rates. Such behavior was related to a diminished role of crack-tip shielding during crack extension in overaged microstructures, resulting from less crack deflection and lower roughness-induced crack closure levels because of the more linear crack paths.

Yoder et al. (Ref 61), in a study of the Al-Li alloy 2090 at  $R = 0.1$  in ambient air, observed that the fracture surface exhibited an extraordinary tortuosity, with considerable oxide debris attributable to fretting giving rise to a macroscopically blackish appearance. Associated with this tortuosity, the fracture surface exhibited asperities of unusual height, comprised of adjacent pairs of slip-band facets. This height was a consequence of an extraordinary textural intensity and an uncommon propensity for a planar slip mode in Al-Li alloys. Thus, individual, well-defined slip-band facets were formed that could traverse multiple grains at a time to give asperities of unusual height, which gave rise to high closure levels at stress-intensity ranges much above near-threshold values. Moreover, it was shown that the characteristic included angle between an adjacent pair of slip-band facets that comprise an individual asperity was a consequence of the texture.

Welch and Picard (Ref 62) observed an effect of texture on fatigue crack propagation in aluminum alloy 7075. Their results showed a small but distinct variation in crack propagation rates for the three orientations, with the effect somewhat more marked near the fatigue threshold.

In the Al-Li alloy Lital-A, Anandan et al. (Ref 63) observed a rough sawtooth-type fracture in both plate and sheet material. The material exhibited a higher  $\Delta K_{\text{th}}$  and lower fracture toughness than 2024, and the stress ratio effect was pronounced over the entire growth rate range.

Fatigue crack propagation behavior has been examined in a commercial 12.7 mm thick plate of Al-Cu-Li-Zr alloy 2090 by Yu and Ritchie (Ref 64) with specific emphasis on the effect of single compression overload cycles. Based on low- $R$ -value experiments on cracks arrested at  $\Delta K_{th}$ , it was found that crack growth at  $\Delta K_{th}$  could be promoted through the application of periodic compression cycles of magnitude two times the peak tensile load. Similar to 2124 and 7150 aluminum alloys, such compression-induced crack growth at the threshold decelerated progressively until the crack rearrested, consistent with the reduction and subsequent regeneration of crack closure. The compressive loads required to cause such behavior, however, are far smaller in the 2090 alloy. Such diminished resistance of Al-Li alloys to compression cycles was discussed in terms of their enhanced "extrinsic" crack growth resistance from crack path deflection and resultant crack closure, and the reduction in the closure from the compaction of fracture surface asperities by moderate compressive stresses.

Venkateswara et al. (Ref 65) found that artificial aging of commercial Al-Li alloys to peak strength had a mixed influence on the long crack resistance. Although behavior at higher growth rates was relatively unaffected, in 2091, the nominal  $\Delta K_{th}$  values were increased by 17%, whereas in 8090 and 8091 they were decreased by 16 to 17%. Aging to peak strength also resulted in a decrease in  $\Delta K_{eff(th)}$ . For three Al-Cu-Li-Mg-Ag alloys (Weldalite 049, X2095, and MD 345) (Ref 66), the threshold level increased with increasing strength.

Tintillier et al. (Ref 67) showed that for the 8090 alloy, alloying with lithium produced a significant improvement of the near-threshold crack growth resistance as compared to that of 2024-T351 and 7075-T651. This improvement was considered to be a consequence of the planar slip mechanism observed in the  $\delta'$  hardened matrix, which resulted in substantial roughness-induced closure effects. The influences of load ratio and texture were shown to be mainly related to crack closure and the propagation behavior was rationalized in terms of the effective stress-intensity factor range  $\Delta K_{eff}$  for given environmental and aging conditions. The influence of environment was discussed in terms of water vapor embrittlement.

Good crack growth resistance in Al-Li, Al-Li-Zr, and 8090 alloys has been observed by Xiao and Bompard (Ref 68), with  $\Delta K_{th}$  higher than  $9 \text{ MPa} \sqrt{m}$ . High closure levels were due to crack propagation into persistent slip bands or grain boundaries. Expressed in terms of  $\Delta K_{eff}$ , the resistance of the alloys was comparable to that of other aluminum alloys.

At 150 °C, the threshold for 8090 has been found to be lower than at room temperature (Ref 69). Increases in slip homogenization, coarsening, and precipitate-free zone formation were associated with decrease.

## Steel Crack Growth Thresholds

Figure 13 is a plot of  $\Delta K_{th}$  and  $\Delta K_{eff(th)}$  as a function of yield strength for a number of steels.  $\Delta K_{th}$  decreases with increase in yield strength, indicating that the extent of roughness decreases with refinement in grain size and microstructure as strength increases. On the other hand, the value of  $\Delta K_{eff(th)}$  remains fairly constant.

FIG. 13 THRESHOLD AS A FUNCTION OF YIELD STRENGTH  $\Delta K_{TH}$  AT  $R = 0-0.05$  VS. YIELD STRENGTH FOR VARIOUS TYPES OF STEELS. SOLID SYMBOLS INDICATE  $\Delta K_{EFF}$  AT THRESHOLD. THE LINE IS OBTAINED BY THE LEAST SQUARE METHOD ( $\Delta K_{TH} = -4.0 \times 10^{-3} \sigma_y + 10.7$ ). SOURCE: K. MINAKAWA AND A. MCEVILY, IN *FATIGUE THRESHOLDS*, VOL 1, EMAS, 1982, P 373

A comparison of the crack opening and fatigue crack growth characteristics of three tempered martensitic steels (a modified 4135, 2.25Cr-1Mo, and a modified 9Cr-1Mo) in ambient air and in vacuum ( $3 \times 10^{-5}$  torr) at  $R = 0.05$  was made by Zhu et al. (Ref 70). It was found that in vacuum, roughness-induced closure was responsible for closure in the near-threshold region and that the level of closure was independent of  $\Delta K$ . The presence of oxygen in the ambient environment (50% relative humidity) increased the overall closure level by as much as 50% in the case of 4135 and 2.25Cr-1Mo steels, but it did not contribute to closure in the case of the 9Cr-1Mo steel (Fig. 14). The level of roughness-induced closure increased with increase in tempering temperature, but  $\Delta K_{eff(th)}$  was fairly independent of tempering temperature (Fig. 15), being about  $4 \text{ MPa} \sqrt{m}$  in vacuum and  $2.8 \text{ MPa} \sqrt{m}$  in air. Clearly the environment as well as closure played a role in reducing  $\Delta K_{eff(th)}$ . It was also concluded that rewelding was not responsible for the high threshold levels found in vacuum, because the opening levels in vacuum were never higher than those observed in air. Oxide film rupture as well as hydrogen embrittlement were deemed to be responsible for the increased rate of fatigue crack growth in air over that observed in vacuum.

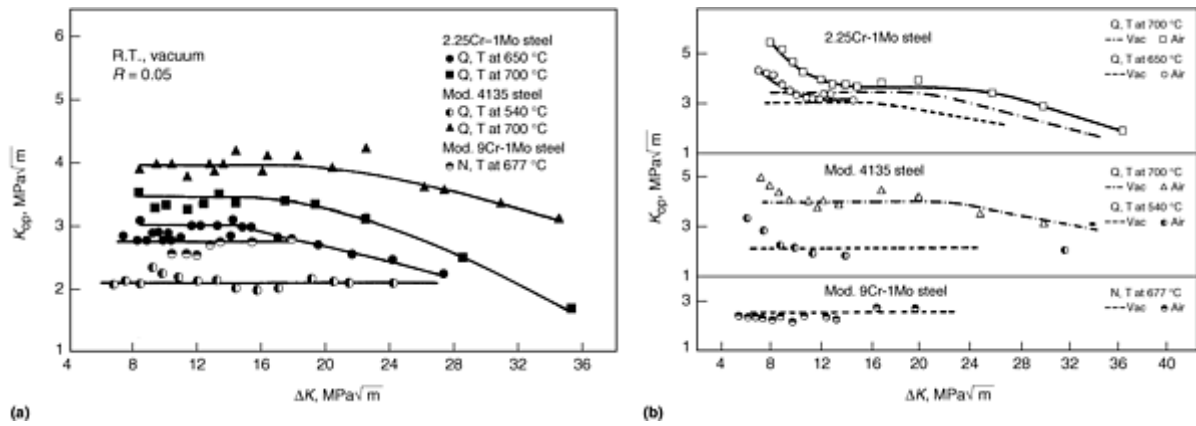

FIG. 14 CRACK CLOSURE IN AIR AND IN VACUUM. (A)  $K_{OP}$  LEVEL AS A FUNCTION OF  $\Delta K$  IN VACUUM FOR 4135 AND 2.25CR-1 MO STEELS. FIG. 15 EFFECT OF TEMPERING ON FATIGUE CRACK GROWTH RATE AS A FUNCTION OF THE RANGE OF THE EFFECTIVE STRESS-INTENSITY FACTOR,  $\Delta K_{EFF}$ . SOURCE: REF 70

A study of the effect of tempering temperature on near-threshold fatigue crack behavior in quenched and tempered 4140 steel (Ref 71) indicated that as the yield strength increased (lower tempering temperature), the crack growth rate increased at a given  $\Delta K$ , and  $\Delta K_{th}$  decreased from 9.5 MPa  $\sqrt{m}$  (700 °C temper) to 2.8 MPa  $\sqrt{m}$  (200 °C temper) (Ref 72). Another study of the influence of carbon content and tempering temperature on  $\Delta K_{th}$  of a low-alloy steel showed that while a tempering treatment increased  $\Delta K_{th}$ , increasing the carbon content from 0.13 to 0.8% significantly decreased the  $\Delta K_{th}$  value by more than 100%. The threshold stress-intensity level could be expressed as  $\Delta K_{th} = 8.74 - 3.42 \times 10^{-3} (\sigma_y) \text{ MPa} \sqrt{m}$ .

Yu et al. (Ref 73) determined  $\Delta K_{th}$  and crack opening levels for a 1010 steel. As the stress ratio and the magnitude of the compressive peak stress were increased,  $\Delta K_{th}$  decreased linearly.  $\Delta K_{th}$  also decreased linearly as the yield strength was increased by cold rolling, and severe cold rolling decreased the opening stress in the near-threshold region to near zero. Crack opening measurements showed that the measured threshold was composed of two parts: an intrinsic threshold stress intensity range,  $\Delta K_{eff(th)}$ , and an opening stress intensity,  $K_{op}$ . Whereas  $K_{op}$  decreased with increasing magnitude of the compressive peak stress,  $\Delta K_{eff(th)}$  was not significantly affected. In a constant-amplitude, load-controlled test, the ratio of  $K_{op}$  to  $K_{max}$  decreased as the maximum stress intensity (crack length) increased, and when the net stress approached the yield strength of the material, no crack closure could be observed. A similar study was carried out by Yu and Topper with 1045 steel (Ref 74). The effect of crack closure on the near-threshold behavior of structural steels has also been studied (Ref 75).

An investigation into the micromechanics of fatigue crack growth in the near-threshold region of a high-strength steel (Fe-0.32C-1.2Si-1.1Mn-0.97Cr-0.22Ti) under three different temper levels has been made (Ref 76). Tempering at high temperatures resulted in a strong dependence of  $\Delta K_{th}$  on the prior austenitic grain size by the virtue of strong interaction between the crack-tip plastic zone and prior austenitic grain boundaries. Tempering at a low temperature resulted in a high-strength, high-strain-hardening microstructure and a weak dependence of  $\Delta K_{th}$  on the prior austenitic grain size.

Bulloch (Ref 77) observed for granular bainitic microstructures of differing carbon contents that the  $\Delta K_{th}$  values markedly decreased with increasing area fraction martensite, and that a 0.3% C steel at area fraction martensite values approaching 0.4 exhibited  $\Delta K_{th}$  values that were below those for a 0.13% C steel. The influence of  $R$  ratio and microstructure on the threshold fatigue crack growth characteristics of spheroidal graphite cast irons has been investigated by Bulloch and Bulloch (Ref 78). A study by Bulloch (Ref 79) of the effect of material segregation on the near-threshold fatigue crack propagation characteristics of a low-alloy pressure vessel steel in various environments showed that with the exception of high  $R$  ratio air results, segregation effects had little effect on the fatigue crack growth characteristics in air, argon, or vacuum environments.

Fatigue thresholds of isothermally transformed cast steel and nodular cast iron were determined by Zhou et al. (Ref 80). Cu-Mo nodular cast iron exhibited the lowest  $\Delta K_{th}$ , and silicon cast steel and plain nodular iron and superior  $\Delta K_{th}$  values together with adequate mechanical properties. Another study (Ref 81) showed that the fracture surface roughness was greater in as-cast material than in heat-treated material.

Reference 82 shows that for 300-series stainless steels, with the exception of 310S and 304HN, the influence of specimen thickness on  $\Delta K_{th}$  was large at 300 K. On the other hand, the influence was relatively small on  $\Delta K_{eff(th)}$  at 300 K or on  $\Delta K_{th}$  and  $\Delta K_{eff(th)}$  at 4 K. The influence of load ratio was greater on  $\Delta K_{th}$  than on  $\Delta K_{eff(th)}$  at both 300 and 4 K. The influence of yield strength on  $\Delta K_{th}$  at 4 K was relatively small.  $\Delta K_{th}$  and  $\Delta K_{eff(th)}$  values at 4 K for 310S, a stable stainless steel, was 1.7 to 1.8 times greater than for 300-series metastable stainless steel, excluding 304HN. This phenomenon is believed to be mainly due to the nonexistence of the  $\alpha'$  martensitic transformation.

The influence of  $R$  ratio and orientation on  $\Delta K_{th}$  in a low-alloy free-machining (0.31% S) steel was studied by Cadman et al. (Ref 83). They found that the effects of  $R$  were dependent on the orientation of the crack with respect to the rolling direction. For both the orientations considered, an increase in the  $R$  ratio not only decreased the threshold values but also led to marked changes in the fracture appearance.

Residual stresses can affect the threshold level, as indicated by a study of laser surface hardening on fatigue crack growth rate in AISI-4130 steel (Ref 84). Residual compressive stresses retarded the crack growth rate near  $\Delta K_{th}$ , but this beneficial effect disappeared as the  $\Delta K$  value increased.

The near-threshold fatigue crack growth behavior of a ferrite/martensite dual-phase steel with different volume fractions of martensite was investigated in laboratory air at  $R$  values of 0 and 0.5 (Ref 85). The volume fraction of martensite had a significant effect on the fatigue threshold. The threshold value of the dual-phase steel first increased and then decreased as the martensite content increased, with a maximum at a volume fraction of approximately 35% martensite.

A study of the influence of prestrain and aging on near-threshold fatigue crack propagation in as-rolled and heat-treated dual-phase steels (Ref 86) revealed that  $\Delta K_{th}$  increased with increasing grain size and decreasing yield stress. A combination of 10% prestraining with aging at 175 °C for 30 min showed almost no effect on the threshold level of as-rolled dual-phase steel but decreased that of heat-treated dual-phase steels more than 37%. This difference in behavior was suggested to result from the differences in grain size and volume fraction of martensite in these two kinds of dual-phase steels.

The role of crack-tip shielding in retarding fatigue crack growth has been examined (Ref 87) in ferritic-martensitic duplex microstructures, with the objective of achieving maximum resistance to fatigue through crack deflection and resultant crack closure.  $\Delta K_{th}$  values were 100% higher than in normalized structures, (i.e., greater than  $20 \text{ MPa}\sqrt{m}$ ), the highest thresholds reported for a metallic alloy at that time. Duplex as well as ferritic and austenitic single-phase materials have been tested (Ref 88). Ferritic specimens exhibited the highest  $\Delta K_{th}$  levels, while austenite had the lowest. Prestraining by 8% led to a significant drop in the threshold level for all materials, while the crack closure level decreased solely in the single-phase austenitic and ferritic materials.

The near-threshold properties of a ferritic/austenitic stainless steel were studied (Ref 89). Cold rolling of the originally hot-rolled, banded microstructure increased  $\Delta K_{th}$  by 25%. A further increase in  $\Delta K_{th}$  of the same order was caused by annealing the cold-rolled structure for 120 h at  $475 \text{ }^\circ\text{C}$ , resulting in the spinodal decomposition of the ferritic phase.  $\Delta K_{th}$  was also raised by high-temperature annealing, which broke up the banded structure. These improvements were caused by an increase in the closure level,  $K_{cl}$ , and also in  $\Delta K_{eff(th)}$ . The results were interpreted in terms of changes in the fracture surface topography and the flow properties.

The near-threshold fatigue crack growth behavior at elevated temperatures is a matter of interest. A study by Nakamura et al. (Ref 90) involved 2.25Cr-1Mo, 9Cr-1Mo, and 9Cr-2Mo steels as influenced by both temperature and environment. At  $538 \text{ }^\circ\text{C}$ , crack closure in vacuum in these alloys was not detected, and the  $da/dN$  results for all three alloys at  $R$  values of 0.05 and 0.5 fell along a single curve (Fig. 16). When the change in modulus with temperature was accounted for, the in-vacuum results for the 9Cr steels at both room temperature and  $538 \text{ }^\circ\text{C}$  fell along a single line. However, in air at  $538 \text{ }^\circ\text{C}$ , the  $\Delta K_{th}$  level was above that in vacuum (Fig. 17), due to the effects of oxidation-induced closure, and a sharp break appeared in the  $da/dN$  plot just above threshold due to oxide rupture at the crack tip.

FIG. 16 FATIGUE CRACK GROWTH RATE AS A FUNCTION OF  $\Delta K$  FOR MOD. 9CR-1MO, 9CR-2MO, 2MO, AND 2.25CR-1MO STEELS IN VACUUM AT  $538 \text{ }^\circ\text{C}$ . SOURCE: REF 90

**FIG. 17 FATIGUE CRACK GROWTH RATE AS A FUNCTION OF  $\Delta K$  FOR 9CR-2MO STEEL IN AIR AND VACUUM AT 20 °C, AND IN VACUUM AT 538 °C. SOURCE: REF 90**

The effect of crack surface oxidation on near-threshold fatigue crack growth characteristics and crack closure has been investigated at elevated temperatures (80 to 350 °C) in an A508-3 steel (Ref 91).  $\Delta K_{th}$  decreased with increasing temperature up to 100 °C and increased thereafter. Oxidation of the crack surfaces had an important role on the near-threshold characteristics. Below 150 °C, a thin oxide layer formed that prevented the formation of fretting oxide debris during crack growth. At 288 and 350 °C, a thick oxide layer formed that induced crack closure.

The near-threshold fatigue crack growth properties at elevated temperature for 1Cr-1Mo-0.25V steel and 12Cr stainless steel were investigated by Matsuoka et al. (Ref 92). Fatigue tests were conducted at 0.5, 5, and 50 Hz, in a manner designed to avoid crack closure. The effective value of threshold stress-intensity range increased with increasing temperature and with decreasing frequency for the Cr-Mo-V steel, whereas the effective threshold stress-intensity range was independent of temperature and frequency in the case of the more oxidation-resistant SUS403 steel. The observed threshold levels and crack growth behavior were closely related to the oxidation process of the bare surface formed at the crack tip during each loading cycle.

Nishikawa et al. (Ref 93) investigated the near-threshold fatigue crack growth and crack closure behavior in SS41, SM41A, and SUS304 steels and A2218-T6 aluminum alloy at temperatures up to 500 °C. The fatigue threshold increased with increasing test temperature in all the steels tested, while it decreased in 2218-T6 alloy. Oxide-induced crack closure played an important role in the increase of  $\Delta K_{th}$  at elevated temperatures in SM41A but played a less important role in SS41 and SUS304. It was concluded that oxide products on the fracture surface enhance crack closure only when the crack-tip opening displacement at threshold remains small at elevated temperatures.  $\Delta K_{th}$  for type 304 stainless steel at 650 °C was lower than that at 550 °C (Ref 94).

Near-threshold fatigue crack propagation (FCP) behavior was studied in an 18Cr-Nb stabilized ferritic stainless steel (Ref 95) as a function of elevated temperature. Crack closure measurements were obtained from room temperature to 700 °C. At a stress ratio of 0.1, increasing the test temperature from room temperature to 500 °C resulted in an increase of the growth rates in the midrange growth regime and a sharply defined threshold at a  $\Delta K$  level higher than the room-temperature threshold, giving rise to a crossover type of behavior of a type similar to that shown in Fig. 14. A constant- $K_{max}$  increasing  $R$ -ratio (CKIR) test procedure was utilized at room temperature and at 500 °C in an attempt to identify near-threshold FCP data in the absence of crack closure. The type of crossover behavior identified with constant  $R$  ratio

tests at room temperature and 500 °C was also observed in the CKIR tests, an indication that at low  $\Delta K$  levels, even at high  $R$  ratios, oxidation-induced closure may still be effective as a shielding mechanism.

The effect of  $R$  ratio on near-threshold fatigue crack growth in a stainless steel and a metallic glass has been studied by Alpas et al. (Ref 96).

### Titanium Alloy Crack Growth Thresholds

There have been a number of investigations of the effect of microstructure and load ratio on  $\Delta K_{th}$  in titanium alloys, for example, Ref 97. Fatigue threshold levels have been determined for  $\alpha_2 + \beta$  forged Ti-24Al-11Nb (Ref 98). Both roughness-induced and phase-transformation-induced types of crack closure were studied in the metastable  $\beta$  alloy Ti-10V-2Fe-3Al (Ref 99). Such crack-tip shielding mechanisms can provide a means of increasing the fatigue threshold. The near-threshold behavior of P/M Ti-6Al-4V has been determined using a high-frequency test method (20 KHz) at room temperature for crack growth rates between  $10^{-12}$  and  $10^{-9}$  m/cycle (Ref 47). It has been reported for Ti-6Al-4V with a Widmanstätten colony microstructure that two transitions during fatigue crack growth can occur at  $\Delta K$  values where the cyclic and monotonic plastic zones become equal to the  $\alpha$  lath size. Data were obtained on near-threshold fatigue crack growth behavior and crack closure for this microstructure (Ref 100).

Near-threshold fatigue crack growth behavior of Ti-6Al-4V alloy was investigated as a function of Widmanstätten microstructure with emphasis on the effect of colony size on  $\Delta K_{th}$  and  $\Delta K_{eff(th)}$  (Ref 101). It was found that crack growth rates were strongly affected by microstructural sizes such as colony size and  $\alpha$  lath size. The microstructural units controlling crack growth in fast-cooled aligned microstructures were colonies, whereas they were  $\alpha$  laths in relatively slow-cooled ones. This distinction was brought about by the thick continuous interplatelet  $\beta$  phase present in slowly cooled structures. In rapidly cooled structures, thin discontinuous  $\beta$  phase appears to be ineffective in arresting cracks. The crack growth rates and the magnitudes of  $\Delta K_{th}$  and  $\Delta K_{eff(th)}$  were correlated with the controlling microstructural units, with crack closure levels being dependent on colony size. It has also been determined that for high  $\Delta K_{th}$  values at low  $R$  in Ti-6Al-4V, the best microstructural condition is a coarse lamellar structure with high (0.2%) oxygen content, age-hardened at 500 °C (Ref 102).

The fatigue crack growth rates of small surface cracks have received much attention in the last several years, because it has been observed that small cracks can propagate not only much faster than long cracks under nominally identical  $\Delta K$  values, but also well below the  $\Delta K_{th}$  values of long cracks (Ref 103). One study was made to determine the effect of microstructural parameters on propagation of small surface cracks in two representative titanium alloys (Ti-8.6Al and Ti-6Al-4V). It was concluded that aside from the absence of significant crack closure in the early stages of growth of small surface cracks, there must be other contributing factors, because the threshold value of long cracks were significantly higher than that of small cracks, even after the long crack data was corrected for closure. It was also found that the ranking of different microstructures with respect to the resistance to crack growth of small surface cracks could be the reverse of that of long through-cracks. Smaller grains and finer phase dimensions led to lower growth rates of small surface cracks, while for long through-cracks these parameters exhibited an opposite effect.

The influence of crack closure and load history on near-threshold crack growth behavior in surface flaws has been studied in Ti-6Al-6Mo-4Zr-2Sn (Ref 104). Four types of loading histories were used to reach a threshold condition. Results from all four test types indicated that a single value of  $\Delta K_{eff(th)}$  was obtained that was independent of stress ratio,  $R$ , or load history. Crack growth rate data in the near-threshold regime, on the other hand, appeared to have a dependence on  $R$ , even when  $\Delta K_{eff}$  was used as a correlating parameter. In another study of the propagation of small surface cracks in titanium alloys in vacuum and in laboratory air, it was also found that small semielliptical surface cracks propagated faster and below the near-threshold stress-intensity factors of long through-cracks (Ref 105).

A study of the effect of an in situ phase transformation on  $\Delta K_{th}$  in Ti-Ni shape-memory alloys has shown that the value of  $\Delta K_{th}$  can vary from 5.4 MPa  $\sqrt{m}$  in a stable austenitic microstructure, to 1.6 MPa  $\sqrt{m}$  in an unstable (reversible) austenitic microstructure (Ref 106).

A number of papers have dealt with near-threshold fatigue crack growth phenomena at elevated temperature in titanium alloys (see, e.g., Ref 107). Crack closure data at moderately elevated temperatures have been obtained for several structural alloys, including Ti-6Al-4V alloy, Inconel 600, and A2218-T6 Al alloy, and the effects of crack closure as well as negative  $R$  values on crack propagation have been discussed (Ref 108). In a study of fatigue crack growth behavior of Ti-6Al-4V at 300 °C in high vacuum, it was observed that near the threshold, a crystallographic stage I type of crack

propagation occurred, and that the transition from the stage I to stage II type of propagation was sensitive to loading conditions and temperature (Ref 109).

The effect of stress ratio on the near-threshold fatigue crack growth behavior of Ti-8Al-1Mo-1V has been studied at 24 and 26 °C in laboratory air (Ref 110). The effects of stress ratio at a constant temperature could be explained in terms of crack closure and  $\Delta K_{\text{eff}}$ . However, crack closure did not account for the effects of temperature at a fixed stress ratio of 0.1, because higher near-threshold crack growth rates were observed at 260 °C than at 24 °C when the data were plotted as a function of  $\Delta K_{\text{eff}}$ . This difference in crack growth rate was believed to be attributable to significant crack front branching and secondary cracking.

### Nickel-Base Alloys

In a study of the near-threshold behavior of nickel-base superalloys (Ref 111), the crack closure level was a function of  $\Delta K$ . The existence of  $\Delta K$ -dependent closure in nickel-base superalloys resulted in microstructurally sensitive crack growth rates, even at high  $R$  ratios. This behavior is in contrast to that of steels and titanium alloys, for which crack closure levels are often found to be  $\Delta K$  independent, and for which an increase in the  $R$  ratio has a larger influence on near-threshold crack growth than on region II crack growth.

**Single-Crystal Superalloy.** In single crystals of the nickel-base superalloy Udimet 720, Reed and King found that stage I growth occurred along slip planes of maximum resolved shear stress giving rise to faceted fatigue fracture surfaces. Short crack growth behavior was observed in that the crack growth rates were higher than for short cracks in polycrystals, an indication that grain boundaries in the polycrystals retarded fatigue crack growth. The threshold level for the single crystals at  $R = 0.5$  was about  $3 \text{ MPa} \sqrt{m}$  as compared to about  $6 \text{ MPa} \sqrt{m}$  for polycrystalline material. In polycrystals an  $R$ -effect was observed which was attributed to surface roughness associated with small-scale faceted growth. Additional results implied that crack closure played a role in single crack growth crystals as well.

**Plasma-Sprayed Alloy.** In a porous, plasma-sprayed 80Ni-20Cr alloy it was found that there was little or no effect of the  $R$  ratio on  $\Delta K_{th}$ . This finding was attributed to the material's fine grain size of the material as well as to regions of porosity (Ref 111).

### Metal Matrix Composites/Intermetallics

This section briefly reviews results for fiber-reinforced, whisker-reinforced, and particulate-reinforced metal-matrix alloys. In addition, reference will be made to ARALL, a composite of aluminum sheets reinforced with layers of aramid fibers.

Results for a number of aluminum alloys reinforced with SiC particulate ( $\text{SiC}_p$ ) have shown the threshold for  $R = 0.1$  to be in the range  $2.5$  to  $4.7 \text{ MPa} \sqrt{m}$  (Ref 112). In 6061 with 15 vol%  $\text{SiC}_p$  there was a 50% increase in the threshold level as a result of increased closure and crack deflection. In 2024 reinforced with  $\text{SiC}_p$ , an increase in the crack closure level

led to a higher threshold (Ref 113). The addition of SiC to 6061 led to a decrease in the threshold range due to a decrease in grain size associated with the reinforcement (Ref 114). Davidson (Ref 115) found that reinforcing an Al-4Mg alloy with SiC led to an increase in  $\Delta K_{th}$  but also resulted in higher growth rates above the threshold level. On the other hand, a 6061/SiC<sub>p</sub> composite was found to be superior to the 6061 matrix alloy over the whole range of  $\Delta K$  values studied, including  $\Delta K_{th}$ . Because the grain size and microhardness were identical in the two materials, it was concluded that the superiority of the composite was solely due to the SiC particles. Detailed crack profile analysis showed that the crack was deflected by the particles, leading to higher crack closure, which resulted in slower crack growth rates (Ref 116).

In 2024, both SiC<sub>p</sub> and SiC whiskers (SiC<sub>w</sub>) raised the threshold level (Ref 117). Some of this improvement resulted from roughness-induced closure, which develops as the crack meanders to avoid particles, as in a cast aluminum alloy composite reinforced with 15% alumina (Ref 118). It has also been reported that coarser distributions of SiC were more effective in raising the threshold level in SiC/Al alloys (Ref 119). However, Shang and Ritchie (Ref 120) found that whereas a coarse-particle distribution resulted in higher  $\Delta K_{th}$  values at low  $R$  ratios, fine particles gave higher threshold values at high  $R$  ratios. Such behavior was analyzed in terms of the interaction of SiC<sub>p</sub> with the crack path, both in terms of the promotion of roughness-induced crack closure at low  $R$  ratios and the trapping of the crack by particles at high  $R$  ratios. Consideration of the latter mechanism yielded the limiting requirement for the intrinsic threshold condition in these materials that the maximum plastic zone size must exceed the effective mean particle size. This implies that for near-threshold crack advance, the tensile stress in the matrix must exceed the yield strength of the material beyond the particle. It was also noted that as  $\Delta K$  levels increased from near-threshold levels, there was a gradual transition of fracture mode, with a high incidence of reinforcement particle/matrix decohesion at low  $\Delta K$  and a predominance of particle cracking at higher  $\Delta K$  levels (Ref 121).

High-strength 2025 aluminum alloy reinforced with SiC<sub>w</sub> also showed an improvement in  $\Delta K_{th}$  (Ref 122). Stretching after quenching to relieve residual stresses in 8090 aluminum alloy reinforced with SiC<sub>w</sub> resulted in a decrease in threshold as well as a decrease in closure due to the elimination of compressive stress on stretching (Ref 123). In a SiC<sub>w</sub>-reinforced aluminum alloy, short fatigue cracks were observed to grow at  $\Delta K$  levels below the threshold for long cracks. The fatigue crack growth characteristics (with emphasis on  $\Delta K_{th}$ , considered to be one of the most important fracture mechanical properties for ensuring the composite structural integrity) were investigated for a whisker-reinforced high-strength aluminum alloy, continuous fiber-reinforced aluminum, and composites with titanium alloy matrices (Ref 124). In a study of the cyclic crack growth behavior of extrusions of TiC<sub>p</sub>-reinforced P/M Ti-6Al-4V metal-matrix composites,  $\Delta K_{th}$  was typically below 10 MPa  $\sqrt{m}$  (Ref 125).

For long fatigue cracks, both roughness and crack deflection have been observed to reduce the driving force (Ref 126). The presence of alumina fibers in squeeze cast 6061 aluminum alloy resulted in higher closure levels and a significant increase in  $\Delta K_{th}$  (Ref 127). The near-threshold transverse fatigue crack growth characteristics of unidirectionally continuous-fiber-reinforced metals have been discussed by Hirano (Ref 128).

Fatigue cracks have been grown in five-layer aluminum alloy 2024-T8-aramid fiber laminate composite ARALL-4 over the range of cyclic stress-intensity factors ( $\Delta K$ ) from 3.5 to 91 MPa  $\sqrt{m}$ .  $\Delta K_{th}$  was about the same as for unreinforced aluminum alloys, and the extent of crack closure depended on the crack length, with fiber bridging influencing the results (Ref 129). In ARALL the threshold level has also been found to increase with crack length, and this behavior has been attributed to fiber bridging (Ref 130).

Fatigue-crack propagation along ceramic/metal interfaces at  $10^9$  m/cycle has also been investigated (Ref 131).

**Crack Growth Thresholds in Gamma Titanium Aluminide.** Davidson and Campbell have found that  $\Delta K_{th}$  for fatigue crack growth through the  $\gamma + \alpha_2$  lamellar microstructure of an alloy based on TiAl was lower at 25 °C than at 800 °C, and the lamellar microstructure was found to have a strong influence on crack tip behavior (Ref 132).

## Fatigue Crack Thresholds

A.J. McEvily, University of Connecticut

---

### Effect of Environment on $\Delta K_{th}$

At room temperature, the ambient environment generally has a deleterious effect on  $\Delta K_{th}$ . For example, in high-frequency (20 kHz) testing of 2024-T3 aluminum alloys,  $\Delta K_{th}$  determined at  $10^{-13}$  m/cycle was found to be 2.1 MPa  $\sqrt{m}$  in moist air, whereas in vacuum it was 3.3 MPa  $\sqrt{m}$ . The decrease was attributed to hydrogen embrittlement (Ref 133). A large number of factors are involved in dealing with the effects of the environment. For example, Vosikovsky et al. (Ref 134) considered the influence of sea water temperature on corrosion fatigue crack growth in structural steels. Often hydrogen embrittlement is considered to be a factor, and it has been found (Ref 135) that both external and internal hydrogen can play similar roles in the degradation of  $\Delta K_{th}$  in high-strength steels.

Pao et al. have studied the influences of yield strength and microstructure on environmentally assisted fatigue crack growth in 7075 and 7050 high-strength aluminum alloys. The influences were analyzed on the basis of a model for transport-controlled fatigue crack growth that incorporated metallurgical, mechanical, and environmental variables. The model was based on the assumption that when the crack driving force is below that of the stress-corrosion cracking threshold, the rate of fatigue crack growth in a deleterious environment is the sum of the rate of fatigue crack growth in an inert environment plus a corrosion fatigue component (Ref 136).

Piasecik and Gangloff (Ref 137) have investigated the effect of gaseous environments on fatigue crack propagation in the Al-Li-Cu alloy 2090 in a peak-aged condition. For the moderate  $\Delta K$ /low  $R$  regime as well as the low  $\Delta K$ /high  $R$  regime, crack growth rates decreased and  $\Delta K_{th}$  increased when the environment was changed from purified water vapor to moist air, helium, or oxygen. The gaseous environmental effects were pronounced near threshold and were not closure dominated. The deleterious effect of low levels of H<sub>2</sub>O (ppm) supports a hydrogen embrittlement mechanism and suggests that molecular-transport-controlled cracking, established for high  $\Delta K$ /low  $R$ , is modified near threshold. Localized crack-tip reaction sites or high  $R$  crack opening shape may enable the strong environmental effect at low levels of  $\Delta K$ . The similarity of crack growth in helium and oxygen ruled out the contribution of surface films to fatigue damage in alloy 2090. In a comparison of 2090 and 7075, both alloys exhibited similar environmental trends, but the Al-Li-Cu alloy was more resistant to intrinsic corrosion fatigue crack growth. Another study found that 2090 exhibited the lowest threshold in salt water, a somewhat higher threshold in air, and the highest in vacuum (Ref 138).

It has also been found (Ref 139) that Al-Li alloys exhibit environmental fatigue crack growth characteristics similar to those of the conventional 2000-series alloys and are more resistant to environmental fatigue than 7000-series alloys. The superior fatigue crack growth behavior of Al-Li alloys 2090, 2091, 8090, and 8091 was related to crack closure caused by a tortuous crack path morphology and crack surface corrosion products. At high  $R$  and reduced closure, the chemical environmental effects were pronounced, resulting in accelerated near-threshold  $da/dN$  values. The "chemically small crack" effect observed in other alloy systems was not pronounced in Al-Li alloys. Modeling of environmental fatigue in Al-Li-Cu alloys related accelerated fatigue crack growth in moist air and salt water to hydrogen embrittlement.

For steam turbine rotor steels (Ref 140), pure water at 160 °C reduced the fatigue strength by about 25% compared to the value in air at room temperature. Fatigue crack propagation rates in water at 100 °C were higher than at 160 °C and were about three times higher than in air at room temperature. A deaerated water environment reduced  $\Delta K_{th}$  by approximately 20%.

An increase in  $\Delta K_{th}$  in sea water was observed by Todd et al. (Ref 141) for ASTM A710 steel cathodically protected at an applied potential of -1.0 V. This increase was not attributable to calcareous deposit formation, but rather appeared to be a result of hydrogen embrittlement. Such embrittlement led to the development of metal wedges in the crack wake that contributed to a new mechanism of crack closure.

The effect of laboratory air, dry hydrogen, and dry helium gaseous environments on the fatigue crack propagation behavior of low-alloy 4340 steel has been investigated (Ref 142). Below an  $R$  value of 0.5,  $\Delta K_{th}$  in the air environment was larger than in the dry environments.  $\Delta K_{th}$  in wet hydrogen was between the values in air and dry environments. At a high load ratio of 0.8, however,  $\Delta K_{th}$  was insensitive to test environment. It was concluded that oxide-induced crack closure governed the kinetics of gaseous-environment, near-threshold crack propagation behavior. However, thick oxide deposits in wet hydrogen did not cause high levels of crack closure.

Near-threshold fatigue crack growth of HY80 (Q1N) alloy steel was investigated in air and in a vacuum by James and Knott (Ref 143). The applied stress ratio affected crack growth rates in air but had little effect on rates in the vacuum environment. Additional studies have been carried out by Kendall and Knott (Ref 144).

The effects of moisture on the fatigue crack growth behavior of a low-alloy 2Ni-Cr-Mo-V rotor steel near threshold were investigated by Smith (Ref 145). At  $R = 0.14$ , the growth rates in moist air were much lower than in dry air. This difference was associated with the formation of oxides on the fracture surface, with moisture modifying the type and extent of oxidation observed. Observations of the transient crack growth following environmental changes suggested that fracture surface oxides within approximately 0.3 mm of the crack tip exerted a strong retarding influence on crack growth, although oxides up to at least 3 mm from the tip may also have had some retarding effect.

In a study at high frequency of the near-threshold behavior of stage I corrosion fatigue of an austenitic stainless steel (316L), Fong and Tromans (Ref 146) found that at high anodic potentials with good mixing between the crack solution and bulk solution, crack retardation and arrest effects due to surface-roughness-induced closure were minimized by electrochemical erosion.

In a study of the environmental influence on the near-threshold behavior of a high-strength steel, it was concluded (Ref 147) that fatigue crack growth rates measured in ambient air depend on three processes: intrinsic fatigue crack propagation as observed in vacuum; adsorption of water vapor molecules on freshly created rupture surfaces, which enhances crack propagation; and a subsequent step of hydrogen-assisted cracking. A reduction of sea water temperature from room temperature to 0 °C decreased the fatigue crack growth rates at free corrosion potential by a factor of almost 2. At -1.04 V, the plugging of cracks by calcareous deposits reduced the effective stress-intensity range and increased the apparent  $\Delta K_{th}$  level.

Esaklul and Gerberich (Ref 148) observed that the presence of internal hydrogen through cathodic charging had a substantial influence on the near-threshold fatigue behavior of a high-strength, low-alloy steel with an as-received yield strength of 365 MPa. The results of fatigue crack propagation tests indicated higher crack propagation rates and lower threshold stress intensities in the presence of internal hydrogen. These effects were dependent on strength,  $R$  ratio, and test temperature. The enhancement in the crack propagation process was more severe at higher strength levels and at higher mean stresses.

Under freely corroding conditions,  $\Delta K_{eff(th)}$  values in 3% sodium chloride (NaCl) aqueous solution were found by Matsuoka et al. (Ref 149) to be lower than in air for all of the structural-grade steels investigated. In particular,  $\Delta K_{eff(th)}$  values for carbon and high-strength steels were almost equal to a theoretical  $\Delta K_{eff(th)}$  value of approximately  $1 \text{ MPa} \sqrt{m}$ , calculated on the basis of the dislocation emission from the crack tip.

The effects of free corrosion and cathodic protection on fatigue crack growth in structural steel (BS4360-50D) in synthetic sea water were studied by Bardal (Ref 150). At an  $R$  value of 0.5, free corrosion in sea water led to higher crack growth rates and a lower threshold value than in air, while cathodic protection had the opposite effect.

Komai (Ref 151) has found that due to a corrosion-product-induced wedge effect, crack growth rates in HT55 steel (tensile strength 580 MPa) were significantly reduced in NaCl solution, with  $\Delta K_{th}$  greater than in air. In corrosion-resistant stainless steel SUS304, the corrosion-product-induced wedge effect diminished. In the absence of closure, two factors were considered to increase the growth rate: a suppression of reversed slip by water molecule adsorption, and in the case of SUS304, the hydrogen embrittlement of the stress-induced martensite formed at the crack tip.

For Ti-10V-2Fe-3Al tested in vacuum as well as in 3.5% NaCl solution, it was found that the corrosive environment led to near- $\Delta K_{th}$  values of 2 to 3 MPa  $\sqrt{m}$ , compared to 4 to 5 MPa  $\sqrt{m}$  in vacuum (Ref 152).

Environment/mechanical interaction processes and hydrogen embrittlement of titanium alloys (IMI115, IMI130, IMI155) have been investigated (Ref 153). While interstitial hydrogen was found to have little effect, a significant increase in the resistance to fatigue crack propagation was observed with increasing interstitial oxygen content. In contrast, when hydrogen was present in the form of hydride precipitates, crack growth rate was significantly increased, particularly in the threshold and high- $\Delta K$  regions of the  $da/dN$  versus  $\Delta K$  curve. The results showed that crack propagation in the matrix containing hydrides occurred mainly through the hydride/matrix interface without any significant hydride cracking.

In a determination of  $\Delta K_{th}$  at cryogenic temperatures for aluminum alloys (2024, 2124, Al-3Mg), copper, steels (304, Fe-4.0Si, Fe-0.1C-9Ni, Fe-0.15C-4Mn), nickel alloy (Inconel 706), and titanium alloy (Ti-30Mo), it was observed that resistance to near-threshold fatigue crack propagation generally improved with decreasing temperature. Although crack closure could account for the influence of load ratio on low-temperature near-threshold crack propagation behavior, it alone could not account for the temperature effect (Ref 154). It is possible that the absence of any deleterious environmental effect also played a role.

Additional aspects of the interaction of microstructure and environment in the near-threshold range have been discussed by Petit (Ref 155) and Bailon et al. (Ref 156). There is also information available on the effect of overloads on the corrosion fatigue crack growth behavior of low-alloy steel in the threshold region in 3.5% NaCl solution (Ref 157).

### Welds

Investigations of the effect on  $\Delta K_{th}$  of the tensile residual stresses in steels resulting from welding have shown that such stresses lower  $\Delta K_{th}$  (Ref 158, 159). When these tensile residual stresses were high,  $\Delta K_{th}$  became equal to  $\Delta K_{eff(th)}$  as a lower limit and was no longer a function of  $R$ . In a study of near-threshold fatigue crack propagation in welded joints under random loading, Ohta et al. (Ref 160) found that for specimens of HT80 steel in which tensile residual stresses were present at the crack tips,  $da/dN$  could be estimated from constant-amplitude tests, assuming a linear cumulative damage law. In Ref 161 it was found that MIG welding yielded higher values of  $\Delta K_{th}$  than shielded metal arc welding, and that  $\Delta K_{th}$  was highest when the fatigue crack propagated through the weldment.

**Modes II and III.** Otsuka et al. (Ref 162) have shown that  $\Delta K_{IIth}$  values for mode II growth in the heat-affected zone of the aluminum alloy 7N01-T4 and in 2017-T3 and -T4 base metal were quite low, about  $1 \text{ MPa } \sqrt{m}$ . They noted that for other materials,  $\Delta K_{IIth}$  values fell between 6 and  $10 \text{ MPa } \sqrt{m}$ .

A comparison of fatigue crack propagation in modes I and III has been provided by Ritchie (Ref 163), and Ref 164 discusses near-threshold fatigue crack growth in steels under mixed mode II and III loading. In a study of the fatigue crack direction and threshold behavior of a medium-strength structural steel under mixed mode I and III loading, the experimental fatigue crack growth threshold data were close to a lower-bound failure envelope, based on the premise that the event controlling failure is the propagation of mode I branch cracks (Ref 165). It has also been observed (Ref 166) that mode I thresholds shifted toward higher values when mode III superimposed loads were increased, with this increase more pronounced for  $R = -1$  than for  $R = 0$  and  $0.5$ . Roughness-induced crack closure was assumed to be the main closure mechanism in explaining this result. It has also been concluded that a crack cannot grow by mode III shear without the presence of a mode II component (Ref 167), and Ref 163 considers whether or not there is a fatigue threshold for mode III crack growth.

## Fatigue Crack Thresholds

A.J. McEvily, University of Connecticut

---

## Modeling Threshold Behavior

One of the fundamental considerations regarding near-threshold fatigue crack growth is whether or not a fatigue crack, in the absence of environmental effects, can advance an increment per cycle somewhere along the crack front. Opinions on this point differ. For example, it has been observed (Ref 168) for a ferritic steel that for over four orders of magnitude in near-threshold region fatigue crack propagation rates, the striation spacing was independent of the  $\Delta K$ , which might imply that the number of cycles necessary to form one striation was greater than one. On the other hand, the observed striation spacing happened to be equal to the dislocation cell size, and an apparent striation may have been created where a crack, growing at a spacing per cycle too small to be resolved, crossed the cell boundary. No such striation-like markings were observed in aluminum alloy in which no cell substructure formed (Ref 169).

The threshold itself can be considered the dividing line between the propagation and nonpropagation of a fatigue crack, and a number of proposals for the threshold condition have been put forth. Among these are the emission of dislocations from the crack tip (Ref 170) and the blockage of slip from the crack tip by some barrier such as a grain boundary or more resistant phase. Radon and Guerra-Rosa (Ref 171) have developed a model for the threshold based on the tensile and cyclic properties of the material. McClintock in 1963 proposed that crack growth could occur when the local strain or accumulated damage at the crack tip reached a critical value. Such proposals are purely mechanical in nature, whereas in tests in air the effects of the environment are always superimposed. In some mechanical models, propagation is a go no-go situation, whereas when environmental effects are present, corrosion may continuously reduce the threshold, much as it reduces the long-life portion of the  $S/N$  curve. Another aspect of the environment is that it may introduce a discontinuity into the growth process, particularly near threshold, if the development of a critical extent of corrosion takes time rather than cycles to be accomplished. Also, because there is a transition from the LFM  $\Delta K_{th}$  value to the endurance limit with decreasing crack size, it is to be expected that some of the factors that govern the endurance limit also affect the threshold level. In fact, the existence of a lower limit for fatigue crack growth was postulated by McEvily and Illg in 1956. They proposed that  $K_N S_{net} = EL$ , where  $K_N$  is the stress-concentration factor for a fatigue crack, computed according to Neuber's procedures for a crack tip of effective radius of the order of 0.05 mm;  $S_{net}$  is the net section stress; and EL is the endurance limit. The term  $K_N S_{net}$  is directly related to the stress-intensity factor, and the equation can provide a smooth transition of the type observed by Kitagawa and Takahashi in the small crack regime between the endurance limit and the macroscopic threshold level (Fig. 9).

Use of a strain-intensity factor ( $K/E$ ) for crack growth near threshold resulted in a narrow scatter band in high- $R$  tests where closure was absent (Ref 172).

In considering the models for the threshold condition, it is clear that Young's modulus is an important parameter (Ref 172). Other mechanical properties play a much smaller role on the relationship between the rate of crack growth and  $\Delta K_{eff}$ . On the other hand, grain size does affect  $\Delta K_{th}$ , because it influences the degree of roughness and hence the level of closure at low  $R$  values. The effect of grain size on  $\Delta K_{th}$  is principally due to a larger degree of crack deflection in coarse-grained structures and the accompanying high levels of crack closure as a consequence of zig-zag crack growth (Ref 173). A theoretical model (Ref 174) for the effects of grain size on the magnitude of roughness-induced crack closure at  $\Delta K_{th}$  considered a crack propagating incrementally along planar slip bands and being deflected at grain boundaries to create an

idealized zig-zag crack path. The effective slip band length was taken to be equal to the grain size. It was assumed that the dislocations emitted from the crack tip upon loading to form the pile-up were completely irreversible to produce a combined mode I and II displacement at the crack tip. The magnitude of  $\Delta K_{clth}$  can then be expressed in terms of slip length or grain size, macroscopic yield stress, critical resolved shear stress, and the angle between slip plane and crack plane (Ref 175).

Taira et al. (Ref 176) proposed a micromechanistic model for the fatigue limit to relate a Petch-type dependence of the fatigue limit on grain size. A model for the threshold condition was developed that involved a microscopic stress-intensity factor at the tip of a crack blocked at a grain boundary. Fatigue crack propagation depended on whether or not a slipband near the crack tip propagated into an adjacent grain. Tanaka and Nakai (Ref 177) extended this model to include the development of crack closure with crack length in considering the mechanics of the threshold for the growth of small cracks. Fatigue crack growth at near-threshold rates has also been modeled using microstructurally-controlled micromechanical crack tip parameters (Ref 178). The model is based on the concept of crack opening by means of local slip lines whose length and dislocation density are controlled by the alloy microstructure.

Gerberich et al. (Ref 179) considered dislocation cell networks important features in cyclic strain hardening and crack-tip advance in Fe-4Si. Near-threshold fatigue crack behavior was considered, together with evidence of crack-tip interactions with dislocation cells, and a computer simulation of slip band pile-ups interacting with an idealized cell network was developed. A threshold model was derived that included the flow stress, cell size, test frequency, and strain rate sensitivity.

In pearlitic steels it has been shown and related to a theoretical model (Ref 173) that while the interlamellar spacing explicitly controls the yield strength, a similar effect on  $\Delta K_{th}$  cannot be expected. On the other hand, the pearlitic colony size was shown to strongly influence  $\Delta K_{th}$  and  $K_{clth}$  through the deflection and retardation of cracks at colony boundaries. An increase in  $\Delta K_{th}$  and  $K_{clth}$  with colony size was found. Further,  $\Delta K_{eff(th)}$  was found to be insensitive to colony size and interlamellar spacing.

Mura and Weertman (Ref 180) reviewed the dislocation models that have been applied to the near-threshold stress intensity factor region. They concluded that because of the sparseness of existing theory, this region of the fatigue crack growth curve is as yet not well understood.

## Thresholds in Design

Figure 18 is an example of a modified Kitagawa diagram, where  $c$  is the length of the crack-initiating notch and  $l$  is the crack length measured from the notch. The modification consists of plotting both the  $\Delta K_{\text{eff(th)}}$  (line B) and the  $\Delta K_{\text{th}}$  (line A) conditions for long cracks. It is clear that with respect to the initiation and growth of fatigue cracks from flaws or notches,  $\Delta K_{\text{eff(th)}}$  is a much more significant parameter than  $\Delta K_{\text{th}}$ . Lines C, D, and E indicate the stress amplitude required to maintain a fatigue crack growth rate of  $10^{-11}$  m/cycle as crack closure develops in the wake of a newly formed fatigue crack. If cracks are initiated at notches at stress amplitudes between the dashed horizontal line and the maximum value of curves C or D, nonpropagating cracks will develop, as has been observed by El Haddad et al. (Ref 181). The shaded area indicates the region on this diagram where crack arrest due to the development of crack closure is predicted to occur. Below an initial notch depth of the order of  $10 \mu\text{m}$ , the material is insensitive to the presence of cracks and the endurance limit is the dominant parameter. If one wanted to design a notched component so as to avoid any fatigue crack growth, then depending on the initial notch or flaw size, the allowable stress amplitude would have to fall within the indicated area of "no propagation." However, a number of factors can shrink this area in service: corrosion, surface damage, the endurance limit, and the threshold value. The selection of a material of higher strength to improve the endurance limit would most likely result in a decrease in  $\Delta K_{\text{th}}$  but not in  $\Delta K_{\text{eff(th)}}$ , so that there should be some expansion of the no-propagation region. An increase in  $R$  value over that shown here for  $R = -1$  conditions should lead to a decrease in the endurance limit and hence a decrease in the no-propagation region. At high  $R$  values,  $\Delta K_{\text{eff(th)}}$  and  $\Delta K_{\text{th}}$  would merge, and the nonpropagation of fatigue cracks should not be observed because closure would be absent.

**FIG. 18 MODIFIED KITAGAWA PLOT FOR THE INFLUENCE OF CRACK CLOSURE ON THE STRESS REQUIRED TO PROPAGATE FATIGUE CRACKS AS A FUNCTION OF NOTCH OR FLAW SIZE. SOURCE: *FRACTURE* (WELLS AND LANDES, ED.), AIME, 1984, P 215-234**

It can also be noted from Fig. 18 that fatigue notch sensitivity is related to crack closure, in that higher stress amplitudes are required for crack propagation from small notches than from large notches of the same geometrical shape.

Figure 19, based on Fig. 18, shows the crack and no-propagation regions as a function of the initial stress-concentration factor. This figure is of the same type as that originally developed by Frost and Dugdale (Fig. 2) and provides a rationale, based on crack closure, for their observations.

FIG. 19 MODIFIED FROST PLOT OF ARREST CONDITIONS AS A FUNCTION OF INITIAL NOTCH SIZE AND  $K_T$ . SHADED AREAS INDICATE REGIONS IN WHICH FATIGUE CRACKS WILL FORM AND THEN BECOME NONPROPAGATING. FOR A GIVEN INITIAL NOTCH SIZE, CRACKS WILL NOT FORM BELOW THE LEVEL OF THE CORRESPONDING SHADED AREA. SOURCE: *SCRIPTA MET.*, VOL 18, 1984, P 71

In a meaningful analysis of near-threshold fatigue crack growth behavior in service, a number of complicating factors may also have to be considered. For example, Koterazawa (Ref 182) has observed that crack propagation rates were accelerated by more than 100 times in some cases by understressing below the threshold, with this effect more pronounced in low-strength materials. It has also been observed (Ref 183) that a very small number of cycles of overstress, applied intermittently during a very large number of cycles of understress below threshold, caused significant acceleration in crack growth rate as compared to steady cyclic stress in moist air, dry air, and nitrogen. It has also been observed (Ref 184) that prolonged in-service exposure of a rotor steel at elevated temperature led to a decrease in  $\Delta K_{th}$  due to the precipitation of carbides in the material. Geary and King (Ref 185) have demonstrated that residual stresses can also exert a strong influence on near-threshold fatigue crack behavior.

As indicated above, in design the effect of notches may have to be considered. Lukáš et al. (Ref 186) have examined the limiting case of nondamaging notches in fatigue, and Ogura et al. (Ref 187) have dealt with the threshold behavior of small fatigue cracks at notches in type 304 stainless steel, with nonpropagation occurring when the value of  $\Delta K_{eff}$  reached its threshold level.

The practical significance of the fatigue crack growth threshold condition has also been discussed in relation to engineering design considerations by, for example, Austen and Walker (Ref 188), who considered corrosion fatigue crack growth and lifetime predictions for offshore environments. Harrison has written on damage-tolerant design (Ref 189), and Brook (Ref 190) has assessed the significance of the threshold as a design parameter. In a study of the influence of orientation on the fatigue strength of Ni-Cr-Mo-V steels, Nix and Lindley (Ref 191) used LEFM to calculate  $\Delta K_{th}$  values for fatigue crack growth from inclusions.

## Introduction

FATIGUE CRACKS are small for a significant fraction of the total life of some engineering components and structures. The growth behavior of these small cracks is sometimes significantly different from what would be expected based on conventional (i.e., large-crack) fatigue crack growth (FCG) rate test data and standard FCG design and analysis techniques discussed elsewhere in this Volume. Small fatigue cracks are sometimes observed to grow faster than corresponding large cracks at the same nominal value of the cyclic crack driving force,  $\Delta K$ . Small cracks have also been observed to grow at non-negligible rates when the nominal applied  $\Delta K$  is less than the threshold value,  $\Delta K_{th}$ , determined from traditional large-crack test methods. Therefore, a structural life assessment based on large-crack analysis methods can be nonconservative if the life is dominated by small-crack growth. In contrast to large-crack growth rates, which generally increase with increasing  $\Delta K$ , small-crack growth rates are sometimes observed to increase, decrease, or remain constant with increasing  $\Delta K$ . A variety of typical small-crack growth rate behaviors are illustrated schematically in Fig. 1.

**FIG. 1 TYPICAL SMALL-CRACK GROWTH RATE BEHAVIORS, IN COMPARISON TO TYPICAL LARGE-CRACK BEHAVIOR**

The fundamental reason for this disagreement between measured large-crack and small-crack growth rate data is often a lack of similitude. Although nominal calculated  $\Delta K$  values for large and small cracks may be the same, the actual driving force for crack growth may be different due to the effects of localized plasticity, crack closure, microstructural influences on crack-tip strain, or localized crack-tip chemistry. In some cases, the basic continuum mechanics assumptions of material homogeneity and small-scale yielding may be violated for small-crack analysis.

Small-crack behavior is a complex subject, due to the variety of factors that may affect small cracks and the variety of microstructures used in engineering structures. Many different researchers have published small-crack data and offered various explanations and models to rationalize these data, and apparent disagreements are not uncommon in the literature. This article is a general introduction to the subject of small cracks that attempts to provide an organizational framework for published data and to summarize the most current understandings of the phenomena. The serious student should consult more extensive review articles (Ref 1, 2, 3) and collections of small-crack papers (Ref 4, 5, 6, 7) for further details and references.

In this article, different types of small cracks are carefully defined, and different factors that influence small-crack behavior are identified. Appropriate analysis techniques, including both rigorous scientific and practical engineering treatments, are briefly described. Important materials data issues are addressed, including increased scatter in small-crack data and recommended small-crack test methods. Applications where small cracks may be particularly important are highlighted.

## Acknowledgements

### Types of Small Cracks

All small cracks are not the same. Different mechanisms are responsible for different types of "small-crack" effects in different settings. Criteria that properly characterize small-crack behavior in one situation may be entirely inappropriate in another situation. It is critical, therefore, to understand the different types of small cracks before selecting suitable analytical treatments. This article considers three types of small cracks: microstructurally small, mechanically small, and chemically small.

One note on nomenclature is needed at the outset. The terms "small crack" and "short crack" both appear in the literature, and sometimes the two appear to be used interchangeably. In recent years, however, the two terms have acquired distinct meanings among many researchers. In the U.S. research community, the currently accepted definition for a "small" crack requires that all physical dimensions (in particular, both the length and depth of a surface crack) are small in comparison to the relevant length scale. The relevant length scale, and hence the specific physical dimensions, vary with the particular material, geometry, and loading of interest. In contrast, a crack is defined as being "short" when only one physical dimension (typically, the length of a through-crack) is small in comparison to the length scale. These definitions are illustrated in Fig. 2. However, it should be noted that this distinction has not always been observed in the literature, and that some current authors (especially in Europe) employ the terms with nearly reverse meanings. Whatever the usage, the reader should carefully observe which type of "little" crack is the subject of a given application. Some of the different implications of short versus small cracks are discussed later in the article.

FIG. 2 SCHEMATIC OF "SMALL" AND "SHORT" CRACKS, INCLUDING RELATIONSHIP TO MICROSTRUCTURE

## Microstructurally Small Cracks

A crack is generally considered to be "microstructurally small" when all crack dimensions are small in comparison to characteristic microstructural dimensions. The relevant microstructural feature that defines this scaling may change from material to material, but the most common microstructural scale is the grain size. The small crack and its crack-tip plastic zone may be embedded completely within a single grain, or the crack size may be on the order of a few grain diameters.

Typical crack growth data for microstructurally small cracks are shown for a 7075 aluminum alloy in Fig. 3, along with traditional large-crack data for the same material (Ref 8). Note that small-crack growth can occur at nominal  $\Delta K$  values below the large-crack threshold. Small-crack growth rates are often faster than would be predicted by the extrapolated large-crack Paris equation (the dashed line in Fig. 3), and the apparent Paris slope for the small-crack data can be smaller than for the large-crack data. Crack arrest (momentary or permanent) can occur at these low  $\Delta K$  values, and this arrest is often observed to occur when the crack size,  $a$ , is on the order of the grain size (GS) (i.e., when the crack tip encounters a grain boundary). However, not all small cracks arrest or even slow down at these microstructural barriers. As the crack continues to grow, the small-crack  $da/dN$  data often merge with large-crack data.

**FIG. 3** TYPICAL FATIGUE CRACK GROWTH DATA FOR MICROSTRUCTURALLY SMALL CRACKS AND LARGE CRACKS. SOURCE: REF 8

Why do microstructurally small cracks behave this way? Several factors are involved, all related to the loss of microstructural and mechanical similitude (Ref 9, 10). When the crack-tip cyclic plastic zone size,  $r_p^c$ , (and sometimes the crack itself) is embedded within the predominant microstructural unit (e.g., a single grain), the crack-tip plastic strain range is determined by the properties of individual grains and not by the continuum aggregate. The growth rate acceleration of small cracks embedded within a single surface grain is primarily due to enhancement of the local plastic

strain range that results from a lower yield stress for optimum slip in the surface grains. This microplastic behavior also causes (and, in turn, is affected by) changes in crack closure behavior.

As a small crack approaches a grain boundary, the fatigue crack may accelerate, decelerate, or even arrest, depending on whether or not slip propagates into the contiguous grain. The transmission of slip across a grain boundary in turn depends on the grain orientation, the activities of secondary and cross slip, and the planarity of slip. The transition of the small crack from one grain to another may require a change in the crack path, which may also influence crack closure. The resulting crack growth behavior is therefore very sensitive to the crystallographic orientation and properties of individual grains located within the cyclic plastic zone. As the crack grows, the number of grains interrogated by the crack-tip plastic zone increases, and the statistically averaged material properties become smoother.

However, it is important to note that the fundamental mechanism of crack growth is often the same for small and large cracks in the near-threshold regime. In both cases, FCG occurs as an intermittent process involving strain range accumulation and incremental crack extension, followed by a waiting period during which plastic strain range reaccumulates at the crack tip. Fatigue striations of equivalent spacing have been observed on the fracture surfaces of both large and small fatigue cracks tested under equivalent nominal  $\Delta K$  ranges, as shown in Fig. 3 for 7075 aluminum alloy. The essential difference between large and small cracks is that the number of fatigue cycles per striation is less for small cracks, due to differences in the local crack driving force.

Other factors may also influence microstructurally small cracks. In some cases, small cracks are stage I shear cracks oriented along preferred crystallographic directions, which exhibit different resistance to crack advance. Microstructurally induced changes in crack path can influence the development of crack closure due to crack surface roughness. In addition, many microstructurally small cracks grow under relatively large applied stresses, which further magnifies near-tip plasticity effects.

How can the behavior of microstructurally small cracks be modeled or predicted analytically? Many different approaches have been developed, ranging from detailed scientific models to simplified engineering treatments. However, no single approach has demonstrated widespread applicability. The fundamental problem is that the customary linear elastic fracture mechanics (LEFM) parameter  $\Delta K$  is, strictly speaking, an invalid representation of the crack driving force in the presence of enhanced near-tip plasticity and microstructural inhomogeneity. Unfortunately, no obvious alternative to  $\Delta K$  has been widely accepted as a correlating parameter for microstructural small-flaw growth. In view of the widespread use of  $\Delta K$  for large-crack analysis, many researchers and engineers have attempted to describe microstructurally small crack growth in terms of some modified  $\Delta K$ .

At one extreme, complex micromechanical models attempt to address directly the changes in the local crack driving force and the local microstructure. For example, some models are based on a modified Dugdale crack in an idealized microstructure with microplastic grains and grain boundaries (e.g., Ref 9). The nominal  $\Delta K$  may be modified by influence functions that explicitly describe the effects of microplastic/macroplastic yield strength, large-scale yielding at the crack tip, and crack closure. More general phenomenological models motivated by detailed experimental measurements of near-tip strains and displacements employ an "equivalent"  $\Delta K$  incorporating a plastic component and a closure-modified elastic component.

Simpler mechanical treatments have also been proposed to address FCG behavior in the microstructurally small crack regime. The attractive simplicity of these models is that they avoid dealing directly with complex microstructural issues. Small-crack acceleration effects are incorporated through simple modifications to mechanical parameters in the expression for the crack driving force. El Haddad (Ref 11), for example, replaced the actual crack length  $a$  by an effective length  $(a + a_0)$  to calculate  $\Delta K$ , which enhances the predicted crack growth when  $a$  is very small. A more sophisticated approach has been developed by Newman (Ref 12). The Newman model is based on computed changes in plasticity-induced crack closure for small cracks growing out of initiation sites simulated as micronotches. Newman has shown reasonably good success in predicting small-crack growth rates and total fatigue lives for several different materials, but it should be remembered that the simple mechanical treatments do not address the most fundamental causes of the microstructurally small crack effect. Hence, the generality of the models cannot be ensured.

Simpler, more empirical engineering approaches may be useful for some practical applications in which it is not possible or practical to address changes in the driving force explicitly. Stochastic treatments that acknowledge the inherent uncertainties associated with microstructurally small crack growth address this uncertainty through appropriate statistical techniques. Formulation and calibration of these techniques may require extensive analysis of statistical-quality small-crack data, which is a limitation. Variability of small-crack data is discussed further below. Conservative bounding approaches that simply draw some upper bound to the crack growth data in the defined small-crack regime, or fitting

approaches that perform regression on small-crack data to generate a new set of Paris equation constants, are also possible. These engineering treatments may be a useful means of avoiding detailed analysis, especially when small-crack data are available for materials and load histories representative of service conditions.

Based on these observations and models, several practical suggestions can be offered to predict growth rates for microstructurally small cracks. In general, it appears that the large-crack Paris equation can be extrapolated downward at least to some microstructural limit, neglecting the large-crack threshold. Some treatment of nominal plasticity and crack closure effects on the crack driving force (discussed at more length in the next section) may be useful to improve agreement with large-crack data. However, it must be emphasized that some nonconservatism may remain if the true local microstructural effects have not been addressed. Guidance for addressing these effects can be obtained from various scientific approaches, although practical considerations may dictate the use of more general engineering approaches.

## Mechanically Small Cracks

A crack is generally considered to be "mechanically small" when all crack dimensions are small compared to characteristic mechanical dimensions. The relevant mechanical feature is typically a zone of plastic deformation, such as the crack-tip plastic zone or a region of plasticity at some mechanical discontinuity (e.g., a notch). The crack may be fully embedded in the plastic zone, or the plastic zone size may simply be a large fraction of the crack size, as illustrated by Fig. 4. As discussed below, many microstructurally small cracks are also mechanically small, but our focus in this section is on mechanically small cracks that are microstructurally large. The "short" crack, as defined above, also behaves in the same manner as the mechanically small crack. The crack front of a short crack interrogates many different grains and hence is not subject to strong microstructural effects.

FIG. 4 SCHEMATIC OF RELATIONSHIP BETWEEN MECHANICALLY SMALL CRACKS AND PLASTIC ZONES

Typical crack growth data for mechanically small cracks in unnotched configurations are shown in Fig. 5 for a high-strength, low-alloy (HSLA) steel (Ref 13). Note again that small-crack growth can occur below the large-crack threshold. The slope of the Paris equation often appears to be roughly the same for small- and large-crack data, but the small-crack data sometimes fall above the large-crack trend line when expressed in terms of nominal  $\Delta K$ .

**FIG. 5 TYPICAL FATIGUE CRACK GROWTH DATA FOR MECHANICALLY SMALL CRACKS AND LARGE CRACKS. SOURCE: REF 13**

Small or short cracks growing in notch fields can exhibit a characteristic "fish-hook" growth behavior, as illustrated in Fig. 6 (Ref 14). Here small-crack growth rates are much faster than for comparable large cracks when the cracks are extremely small in comparison to the notch dimensions. These small-crack growth rates can actually decrease with increasing crack growth and then eventually merge with large-crack data.

FIG. 6 TYPICAL FATIGUE CRACK GROWTH DATA FOR SHORT CRACKS AT NOTCHES. SOURCE: REF 14

Why do mechanically small cracks grow in this manner? The primary motivation appears to be that local stresses are significantly larger than those encountered under typical small-scale yielding (SSY) conditions, especially at near-threshold values of  $\Delta K$ . These local stresses may have been elevated by the presence of a stress concentration, or they may simply be large nominal stresses in uniform geometries. These large local stresses significantly enhance crack-tip plasticity, which in turn enhances the crack driving force, either directly through violations of  $K$ -dominance, indirectly through changes in plasticity-induced crack closure, or both. The appropriate analytical treatment of the mechanically small crack, then, primarily involves appropriate treatments of the elastic-plastic crack driving force and crack closure.

The nominal elastic formulation of  $\Delta K$  gradually becomes less accurate as a measure of the crack driving force as the applied stresses become a larger fraction of the yield stress. Under intermediate-scale yielding (ISY), when  $\sigma_{\max}/\sigma_{ys}$  exceeds about 0.7, a first-order plastic correction to  $\Delta K$  may be useful (Ref 15). This correction may be based on the complete Dugdale formulation for the  $J$ -integral, expressed in terms of  $K$ , or it may be based on an effective crack size, defined as the sum of the actual crack size and the plastic zone radius. However, in most cases this first-order correction will change the magnitude of  $\Delta K$  by no more than 10 to 20%. In the large-scale yielding (LSY) regime, when the nominal plastic strain range becomes non-negligible (typically, when the total stress range approaches twice the cyclic yield strength), it will generally be necessary to replace  $\Delta K$  entirely with some alternative elastic-plastic fracture mechanics (EPFM) parameter (Ref 16), such as a complete  $\Delta J$  formulation.

Plasticity-induced crack closure also becomes increasingly significant outside the small-scale yielding regime. Crack opening stresses are a function of the ratio of maximum stress to yield stress, the ratio of minimum to maximum stress ( $R$ ), and the stress state. Changes in closure behavior are most pronounced for large maximum stresses, low  $R$ , and plane stress (typical conditions for mechanically small cracks). Simple closed-form equations based on modified-Dugdale closure models are available to predict normalized crack opening stress as a function of maximum stress, stress ratio, and a constraint factor (Ref 17). Changes in closure behavior are also significant for crack growth at notches, and simple models are available to predict these changes.

If appropriate revisions to the crack driving force based on plasticity and crack closure considerations are carried out, the growth rates of mechanically small cracks can often be predicted successfully by extrapolating the large-crack Paris

equation and neglecting the large-crack threshold. This implies that if plastic corrections to  $\Delta K$  are relatively minor, and if the closure behavior of the small crack does not differ significantly from that of the large cracks used to derive the Paris equation, the small-crack growth rates may be essentially the same as for the large cracks at the same nominal  $\Delta K$ . It is not entirely clear under what conditions the large crack threshold will be observed by the small cracks, and in the absence of contradicting data, it is probably prudent to neglect the threshold for all mechanically small cracks. If a complete crack closure analysis is not possible or practical, it may be sufficient to predict the growth rates of mechanically small cracks using closure-free (high-stress-ratio) large-crack data (Ref 18).

As noted above, the regimes of mechanically small and microstructurally small cracks can overlap. A more complete organizational scheme for large and small cracks from both microstructural and mechanical perspectives is given in Table 1 (Ref 19). The "microstructurally small" crack discussed earlier in this article is often both microstructurally and mechanically small, although it is also possible to have a crack that is microstructurally small and mechanically large. This can be true of cracks in very large-grained materials, or cracks in single crystals, although single crystals do not exhibit all aspects of small-crack behavior due, in part, to the homogeneity of the microstructure. The traditional "mechanically small" (or "short") crack discussed in this article is typically microstructurally large. Traditional large cracks are both microstructurally and mechanically large.

**TABLE 1 CLASSIFICATION OF CRACK SIZE ACCORDING TO MECHANICAL AND MICROSTRUCTURAL INFLUENCES**

MICROSTRUCTURAL SIZE	MECHANICAL SIZE	
		<b>LARGE</b> $A/R_p > 4-20$ (SSY)
<b>LARGE:</b> ( $A/M > 5-10$ ) AND ( $R_p/M \geq 1$ )	MECHANICALLY AND MICROSTRUCTURALLY LARGE (LEFM VALID)	<b>MECHANICALLY SMALL/MICROSTRUCTURALLY LARGE (MAY NEED EPFM)</b>
<b>SMALL:</b> ( $A/M < 5-10$ ) AND ( $R_p/M \sim 1$ )	MECHANICALLY LARGE/MICROSTRUCTURALLY SMALL	<b>MECHANICALLY AND MICROSTRUCTURALLY SMALL (INELASTIC, ANISOTROPIC, STOCHASTIC)</b>

(A) A, CRACK SIZE;  $R_p$ , CRACK-TIP PLASTIC ZONE SIZE; M, MICROSTRUCTURAL UNIT SIZE; SSY, SMALL-SCALE YIELDING; ISY, INTERMEDIATE-SCALE YIELDING; LSY, LARGE-SCALE YIELDING; LEFM, LINEAR ELASTIC FRACTURE MECHANICS; EPFM, ELASTIC-PLASTIC FRACTURE MECHANICS

### Size Criteria for Small Cracks

Table 1 also includes some suggestions for approximate size criteria based on comparisons of the crack dimensions with either the crack-tip plastic zone size,  $r_p$ , or the microstructural unit size,  $M$ . Cracks are generally considered to be microstructurally small when their size is less than 5 to 10 times the microstructural unit size (typically the grain size). Alternatively, a crack may be microstructurally small when the plastic zone size is roughly less than or equal to the microstructural unit size. A crack often behaves in a mechanically small manner when the ratio of crack size to crack-tip plastic zone size is less than 4 to 20. Here the lower limit corresponds roughly to an applied maximum stress that is about 70% of the yield strength. It should be recognized, however, that these operational definitions of the transition crack size are rough approximations. The actual transition will likely be more gradual than distinct, and identification of the proper criterion is less clear when cracks are both microstructurally and mechanically small.

Another approach to identification of the small-crack regime is based on the relationship between the crack growth threshold and the fatigue limit shown in Fig. 7. From an initiation perspective, failure of a specimen without a preexisting crack should occur only if the applied stress range is greater than the fatigue limit,  $\Delta S_e$  (although it should be noted that microstructurally small crack growth can sometimes occur at applied stresses below the fatigue limit). From a fracture mechanics perspective, crack growth should occur only if the applied stress-intensity factor range,  $\Delta K = F \Delta \sigma \sqrt{pa}$ , is greater than the threshold value,  $\Delta K_{th}$ , which is the region above the sloping line. Therefore, the utility of  $\Delta K_{th}$  as a "material property" appears to be limited to cracks of lengths greater than that given by the intersection of the two lines ( $a_0$ ). For many materials,  $a_0$  appears to give a rough approximation of the crack size below which microstructural small-crack effects become potentially significant. However,  $a_0$  may underestimate the importance of small-crack effects when

crack closure or localized chemistry effects are dominant. Note that the construction of Fig. 7 also indicates that the effective threshold decreases with crack size for cracks smaller than  $a_0$ .

FIG. 7 DIAGRAM FOR ESTIMATING  $A_0$

### Chemically Small Cracks

Experiments on a variety of ferritic and martensitic steels in aqueous chloride environments have shown that under corrosion-fatigue conditions, small cracks can grow significantly faster than large cracks at comparable  $\Delta K$  values (Ref 20). This phenomenon is believed to result from the influence of crack size on the occluded chemistry that develops at the tip of fatigue cracks. The specific mechanism responsible for this "chemical crack size effect" is believed to be the enhanced production of embrittling hydrogen within small cracks, resulting from a crack size dependence of one or more factors that control the evolution of the crack-tip environment: convective mixing, ionic diffusion, or surface electrochemical reactions (Ref 21). This mechanism is distinctly different from that responsible for the enhanced rate of crack growth in microstructurally or mechanically small fatigue cracks. However, the enhanced crack-tip plasticity associated with microstructurally or mechanically small cracks could further stimulate the electrochemical reactions through the creation of additional fresh and highly reactive surfaces at the crack tip.

The chemical crack size effect is clearly illustrated by the data of Gangloff (Ref 20) for 4130 steel in an aqueous NaCl environment (see Fig. 8). Note that corrosion-fatigue crack growth rates from small surface cracks (0.1 to 1 mm deep), as well as short through-thickness edge cracks (0.1 to 3 mm), are appreciably faster than corrosion-fatigue crack growth rates from large through-thickness cracks (25 to 40 mm) in standard compact tension specimens. It is also interesting to note that the corrosion-fatigue crack growth rates for small surface cracks decrease with increasing applied stress (at a given  $\Delta K$ ). This trend is opposite to the dependence of applied stress on crack growth rates in mechanically small fatigue cracks. Moreover, all of the corrosion-fatigue crack growth rates in NaCl are enhanced compared to those in a moist laboratory air environment, even though the latter were generated with both small and large cracks. Thus, in relation to the fatigue small-crack effect, the chemical small-crack effect is of potentially greater importance, because it can occur over a much larger range of crack sizes (up to 3 mm).

FIG. 8 TYPICAL CORROSION-FATIGUE CRACK GROWTH DATA FOR CHEMICALLY SMALL CRACKS AND LARGE CRACKS. SOURCE: REF 20

Not all materials exhibit a chemically small crack effect, and the complexity of the important electrochemical mechanisms makes it difficult, if not impossible, to predict a priori the existence or quantitative extent of this effect in a given application. Changes in alloy and solution chemistry, electrode potential, oxygen concentration, applied stress and stress ratio, and the specific rate-controlling process in the electrochemical reaction can all influence crack growth rates. In general, experimental data for specific material-geometry-load-chemistry combinations are needed to characterize chemically small crack effects.

## Small-Crack Test Methods

Analytical treatments of small-crack growth rate behavior often attempt to derive predictions of small-crack growth rates from large-crack data, which is more commonly available. In some applications, however, this approach will clearly not be adequate (e.g., for some microstructurally small cracks), and it may be necessary to obtain direct experimental evidence for small-crack behavior. Unfortunately, small-crack growth rates cannot usually be measured with the standard test procedures developed for large cracks. Small-crack tests usually require different specimen geometries and different specimen preparation techniques, different crack length measurement techniques and equipment, and different data analysis techniques.

Guidelines for small-crack test methods are now available in appendix X3 to ASTM E 647-95 (Ref 22). This appendix does not prescribe complete, detailed test procedures. Instead, it provides general guidance on the selection of appropriate experimental and analytical techniques and identifies aspects of the testing process that are of particular importance when fatigue cracks are small. A brief summary of these recommendations is provided here for completeness.

Several well-established experimental techniques are available for measuring the size of small fatigue cracks, and hence deducing their growth rates. These techniques include replication, photomicroscopy, potential difference, ultrasonic, laser interferometry, and scanning electron microscopy. Some of these techniques, such as replication and photomicroscopy, are amenable to routine use, while others require significant expertise and expenditures. Each technique has unique strengths and limitations, and different techniques are optimum for different circumstances. All are useful for measuring the growth of fatigue cracks on the order of 50  $\mu\text{m}$  and greater, and some are applicable to even smaller cracks. Detailed descriptions of each technique are collected in Ref 7.

The study of small cracks requires detection of crack initiation and growth while physical crack sizes are extremely small, and this requirement influences specimen design. Today the preferred and most widely used technique is to promote the initiation of naturally small surface or corner cracks in rectangular or cylindrical specimens, rather than growing a large crack and then machining away material in the crack wake to leave a small crack. Early crack detection can be facilitated by using specimens with extremely small artificial flaws or very mild stress concentrations, but the completely natural initiation of a small crack at a location chosen entirely by the crack itself is sometimes preferred. Near-surface residual stresses and surface roughness induced by specimen fabrication can artificially influence small-crack growth behavior and should be eliminated or minimized prior to testing. However, the growth rates of small surface cracks in engineering components can be influenced by residual stress fields arising from fabrication of the component, so residual stresses should be considered when the laboratory data are applied.

Many small surface cracks develop shapes that are approximately semielliptical, and the standard  $K$  solutions for these geometries can be applied during data analysis. However, variations in the crack shape can be a source of scatter in growth rate data, especially for microstructurally small cracks, and some confirmation of crack shape is desirable. Interactions between closely spaced multiple cracks that affect growth rates are more likely to occur in the small-crack regime and must be addressed. Special attention must be given to the minimum interval between successive crack length measurements,  $\Delta a$ . Closely spaced measurements are often needed to capture key crack-microstructure interactions, but measurement error can significantly influence variations in  $da/dN$  for extremely small  $\Delta a$  values.

## Scatter in Small-Crack Growth Rate Data

Small-crack data often exhibit much more scatter in  $da/dN$  than large-crack data, sometimes several orders of magnitude at a single  $\Delta K$  value (see Fig. 3, 5). Of course, this leads to greater uncertainty in life calculations, especially when the small-crack regime dominates the total life. Analytical approaches based on simple upper bounds to the small-crack regime may be unacceptably overconservative.

This apparent variability can arise from several different sources. Some true variability is due to stochastic microstructural effects. Local resistance to crack growth will vary with local differences in grain orientation, microplastic yield strength, and grain boundary effects, and these can be especially significant when the crack driving force is small (on the same order as the material resistance to crack growth). A small crack embedded in a preferentially oriented microstructure may grow very rapidly, while a similar crack in a contrasting microstructure might arrest completely. Larger cracks simultaneously interrogate many grains and microstructural features along the crack front, and hence there is a smoother average resistance to crack advance.

On the other hand, some apparent variability in  $da/dN$  is more artificial and hence will not have a significant impact on variability in total life. Measurement errors become significant when the crack growth increment becomes small relative to the measurement resolution. Other apparent variability can be attributed to mathematical averaging effects. The normal point-to-point variability in growth rates due to local microstructural variations is effectively averaged out for most large cracks, because the crack travels a relatively long distance (through many different microstructural features) during the measurement interval. But because the small crack usually travels only a short distance during the measurement interval, this normal variability has a more dramatic impact on calculated  $da/dN$ . Large cracks could exhibit a similar increase in apparent variability if they, too, were measured at much shorter  $\Delta a$  intervals.

The appropriate treatment for small-crack scatter depends, at least in part, on the origin of the scatter. Some scatter that is only apparent can be effectively reduced with improvements in the measurement precision or in the analytical schemes used to process the raw crack growth data, including data filtering and modified incremental polynomial techniques (Ref 22). However, other forms of scatter may require a formal stochastic treatment of the data. Many stochastic FCG models are available in the literature. Unfortunately, many of these models require extensive data of high statistical quality, which is often difficult (expensive) to obtain for small cracks. Other stochastic FCG models designed for practical engineering applications, such as the lognormal random variable model, require fewer data and simpler calculations. However, these models are often not able to address the effects of crack size on scatter.

### **Applications Where Small Cracks Are Important**

Small-crack behavior is not an important issue for applications in which initial defects are large and fatigue cracks of interest are also large, such as welded civil engineering structures. In addition, small cracks are generally not significant for many traditional mechanical and aeronautical engineering design/analysis applications based on damage tolerance concepts, because the initial flaw size (based on conventional nondestructive evaluation inspection limits) is usually beyond the small-crack regime. However, damage tolerance methods are sometimes applied to more highly stressed structures where tolerable flaw sizes are much smaller and nondestructive evaluation requirements are stricter. Small-crack behavior can be very important in these applications, which historically have been treated with safe-life methods based on bulk damage strain-life or stress-life analyses. Note that the total life in many strain-life applications is often dominated by the growth of small cracks, especially in the low-cycle fatigue (LCF) regime where crack formation occurs very early in life and final crack sizes are still relatively small. Therefore, the damage growth process in LCF, which is often treated as an "initiation" problem, is often actually a small-crack growth process. Small-crack analysis techniques may provide valuable new insights into some difficult LCF lifting problems. Small-crack phenomena, especially small-crack arrest, are thought by some to be the key to high-cycle fatigue (HCF) behavior, including the fatigue limit, but a practical treatment of HCF based on small cracks is not yet available. The relative contributions of crack nucleation and small crack growth for total HCF life are not yet well understood. Small cracks can also be important for fracture mechanics-based durability assessments in which an equivalent initial flaw size (EIFS) is back-calculated from some economic total life. This EIFS is often well within the small-flaw regime.

### **Discussion/Summary**

Small-crack behavior was first documented in the mid-1970s, extensively investigated in the 1980s, and remains an active research topic. The problem is now well enough understood to facilitate some standardization of concepts, test methods, and analysis techniques, but small-crack technology is not yet routinely applied in industrial practice. At this writing, no general-purpose computer codes for fatigue crack growth (FCG) analysis are available that explicitly address small-crack behavior. Furthermore, several important problems remain unresolved. For example, some small-crack effects appear to be accentuated under variable-amplitude loading, but load history effects have not been adequately characterized. In addition, as noted earlier, it is not yet clear if small cracks exhibit a well-defined threshold or nonpropagation condition; if so, how this might be related to the large-crack threshold; or when small cracks observe the large-crack threshold. Nevertheless, the current understandings about when and why small-crack effects occur, how to characterize them experimentally, and how to treat them analytically are adequate to provide significant improvements in the quality of structural integrity assessments.

## Effect of Crack Shape on Fatigue Crack Growth

K.S. Ravichandran, The University of Utah

---

## Introduction

FRACTURES in engineering applications (Ref 1) occur mostly from surface or internal three-dimensional cracks, which generally propagate in all directions and often have irregular shapes. Such shapes may not strictly have an elliptical or circular geometry, although such an approximation is often practiced in research investigations and engineering analyses. This may introduce errors in growth data and the estimated fatigue life, but it also raises several parallel questions. First, what are the factors that make the three-dimensional cracks grow with irregular shapes? Second, how can we describe the growth behavior of regular and irregular cracks exhibiting a continuous change in shape from initiation to failure? Third, how can we predict the growth of these cracks in fatigue leading to unstable fracture?

Recent studies on the effects of crack shape on the behavior of surface and embedded cracks have resolved these issues to some extent. These studies have also clarified several important factors that influence the three-dimensional crack growth behavior, including, for example, loading mode, residual stress, microstructure, and material anisotropy. Additionally, methods have been developed to calculate stress-intensity factors (SIFs) of arbitrarily shaped flaws and to predict failure from these cracks. This article summarizes the aspects of crack shape and irregularity that are relevant to fatigue and fracture of surface cracks. The issues covered are the basic nature of regular surface cracks; variables that influence the shape of surface cracks, such as grain size, residual stresses, texture, loading mode, environment, and crack coalescence; techniques for monitoring crack shape development; methods for calculating SIFs for arbitrarily shaped flaws; and simple approaches to predicting failure or threshold for crack growth from arbitrarily shaped flaws and notches.

### Nature of Three-Dimensional Surface Cracks

Two terms pertain to the three-dimensional aspects of surface cracks: the crack shape (semicircular, semielliptical, square, triangular, etc.) and the crack aspect ratio ( $a/c$ , the ratio of half surface length to the distance of maximum depth point in crack front, from surface) (Fig. 1). The two terms are somewhat related: the former provides a qualitative description of crack geometry, whereas the latter is a quantitative measure of depth in relation to the length at surface, irrespective of geometry.

FIG. 1 THE GEOMETRY OF SURFACE CRACKS

The straight crack fronts of through cracks, as in standard fracture mechanics specimens, allow the characterization of fatigue fracture in terms of two-dimensional fracture mechanics formulations. On the other hand, an elliptical surface crack requires two parameters to describe the fracture process. The surface crack length ( $2c$ ) and the depth ( $a$ ) are required to adequately describe the stress-intensity factor,  $K$ , along the crack front (Fig. 1).

Irwin (Ref 2) formulated the SIF of a semi-elliptical surface crack in an infinite plate, subjected to an applied stress,  $\sigma$ , as:

$$K = \frac{\sigma\sqrt{\pi a}}{\phi} \left[ \left( \frac{a}{c} \right)^2 \cos^2 \phi + \sin^2 \phi \right] \quad (\text{EQ 1})$$

where the elliptic integral  $\phi$  is given by:

$$\phi = \int_0^{\pi/2} \left[ \sin^2 \phi + \left( \frac{a}{c} \right)^2 \cos^2 \phi \right]^{1/2}$$

In Eq 1,  $\phi$  is the parametric angle (Fig. 1) of the point of interest on the crack front. The ratio  $a/c$  is referred to as the "aspect ratio" of the crack and is often used to describe the semicircular ( $a/c = 1$ ), shallow ( $a/c < 1$ ), and deep ( $a/c > 1$ ) crack morphologies found in engineering components. Equation 1 is useful only for surface cracks in infinite bodies. However, employing detailed finite element analysis, Newman and Raju (Ref 3) modified surface crack formulae for wider practical use by incorporating the specimen thickness ( $t$ ) and width ( $2w$ ). The Newman-Raju formula for surface cracks is given by:

$$K = \sigma\sqrt{a} F G F\phi F_w \quad (\text{EQ 2})$$

where:

$$F = \left[ M_1 + M_2 \left( \frac{a}{t} \right)^2 + M_3 \left( \frac{a}{t} \right)^4 \right] \sqrt{\frac{\pi}{Q}}$$

$$f_w = \sqrt{\sec \left( \frac{\pi c}{2w} \sqrt{\frac{a}{t}} \right)}$$

In the above equations, for  $a/c \cdot 1$ :

$$M_1 = 1.13 - 0.09 \left( \frac{a}{c} \right)$$

$$M_2 = -0.54 + \frac{0.89}{0.2 + \left( \frac{a}{c} \right)}$$

$$M_3 = 0.5 - \frac{1}{0.65 + \left( \frac{a}{c} \right)} + 14 \left( 1 - \frac{a}{c} \right)^{24}$$

$$g = 1 + \left[ 0.1 + 0.35 \left( \frac{a}{t} \right)^2 \right] (1 - \sin \phi)^2$$

$$f_\phi = \left[ \left( \frac{a}{c} \right)^2 \cos^2 \phi + \sin^2 \phi \right]^{1/4}$$

$$Q = 1 + 1.464 \left( \frac{a}{c} \right)^{1.65}$$

and for  $a/c > 1$ :

$$M_1 = \sqrt{\frac{c}{a}} \left( 1 + 0.04 \frac{c}{a} \right)$$

$$M_2 = 0.2 \left( \frac{c}{a} \right)^4$$

$$M_3 = -0.11 \left( \frac{c}{a} \right)^4$$

$$g = 1 + \left[ 0.1 + 0.35 \left( \frac{c}{a} \right) \left( \frac{a}{t} \right)^2 \right] (1 - \sin \phi)^2$$

$$f_\phi = \left[ \left( \frac{c}{a} \right)^2 \sin^2 \phi + \cos^2 \phi \right]^{1/4}$$

$$Q = 1 + 1.464 \left( \frac{c}{a} \right)^{1.65}$$

It is noted that Eq 2 is only for pure tensile loading with an aspect ratio ( $a/c$ ) between 0.2 and 2.0 and for  $a/t < 0.8$ . The SIF equations for loading and crack conditions are in Ref 3. The SIF in Eq 2 varies with location along the crack front as a function of surface length and crack depth, for a given specimen size. The SIF values at different points along the crack front are nearly the same for a crack of  $a/c = 0.85$ , and this shape is often termed *equilibrium crack shape* or *semielliptical crack*. Surface cracks in relatively brittle materials grow with this shape in the presence of uniform stress and homogeneous material characteristics along the crack front. In relatively ductile materials, plastic deformation occurs at

tips at the surface, due to a lower degree of constraint. This retards the growth of surface tips, causing the equilibrium shape to be nearly semicircular ( $a/c = 1$ ), even though the  $K$  at the surface tip ( $K_c$ ) is about 8% higher than that at the depth position ( $K_a$ ). Hereafter, the term *equilibrium crack shape* means either semielliptical or semicircular, depending on the material.

The SIF distribution changes significantly when there is a deviation from the equilibrium crack shape, depending on whether the crack is shallow ( $a/c < 1$ ) or deep ( $a/c > 1$ ). The distribution becomes very complex if the crack shape is irregular, deviating far from the elliptical geometry. The nature of SIF variations in an elliptical crack can be visualized from Fig. 2, in which the SIFs at the surface ( $\phi = 0$ ),  $K_c$ , and at the maximum point at depth ( $\phi = 90$ ),  $K_a$ , are plotted as a function of  $a/c$ . When the crack is shallow, the SIF at depth is higher than at the surface tip ( $K_a > K_c$ ). The situation is reversed for the deep crack ( $K_c > K_a$ ). Hence, for example, initially shallow and initially deep cracks grow at depth and surface positions, respectively, in order to make the SIF uniform all around the crack front. Similarly, in irregularly shaped cracks, irrespective of their geometric shape, crack growth at locations of high  $K$  occur to move the shape to equilibrium. Although crack growth is dictated by the requirement to maintain equilibrium shape, in practice, surface cracks often maintain irregular shapes due to nonuniformity in structural stress distribution as well as material and microstructural inhomogeneities. These factors are discussed in the following sections.

FIG. 2 THE VARIATION OF STRESS-INTENSITY FACTOR (SIF) AT THE SURFACE ( $K_c$ ) AND AT THE DEPTH ( $K_a$ ) WITH THE ASPECT RATIO OF THE SURFACE CRACK

## Effect of Crack Shape on Fatigue Crack Growth

K.S. Ravichandran, The University of Utah

---

### Variables That Influence Crack Shape

**Mechanical Variables.** The principal factors that affect the variation in crack shape or aspect ratio are the nature of stress distribution in the crack plane and residual stresses induced by surface damage, machining, shot peening, and coating.

In the absence of residual stresses, the variation of crack aspect ratio as the crack grows through a plate of rectangular cross-section depends on whether the remote loading is tension or bending in nature. Additionally, the initial crack aspect ratio influences the aspect ratio during growth. For purely tensile loading, the  $a/c$  will tend to reach a value of 0.85 after sufficient crack growth from a crack with arbitrary initial aspect ratio. At large crack sizes, when the crack front at the depth approaches the specimen back surface, there is a tendency for the cracks to become shallow. This is due to the fact that even in nominally tensile loading, the bending component becomes significant at small net section sizes, due to specimen rotation with respect to the loading axis. The variation in  $a/c$  is illustrated in Fig. 3(a) for different materials with varying initial aspect ratios. The aspect ratio variation can be described by (Ref 4):

$$\frac{da}{dc} = \left\{ \sqrt{\frac{a}{c}} \left[ 1 + 0.3182 \left( \frac{a}{t} \right)^2 \right] \right\}^{-n} \quad (\text{EQ 3})$$

where  $n$  is the exponent in the Paris law for stage II fatigue crack growth:

$$\frac{da}{dN} = C \Delta K^n \quad (\text{EQ 4})$$

where  $C$  is a material constant. From Eq 3,  $a/c$  can be determined at any stage during fatigue crack growth using Runge-Kutta numerical technique if the initial aspect ratio,  $a_0/c_0$ , and  $a_0/t$  are known.

(a)

(b)

FIG. 3 THE NATURE OF CRACK ASPECT RATIO VARIATION IN (A) TENSION AND (B) BENDING FOR VARIOUS STARTING CRACK SHAPES, IN THE ABSENCE OF RESIDUAL STRESSES AND MICROSTRUCTURAL INFLUENCES

On the other hand, in bending,  $a/c$  changes continuously, even for the cracks starting with  $a/c = 1$ , due to the variation of stress in the through-the-thickness direction. As the crack grows, a shallow shape is preferred, because the tensile stress at the depth point is lower than that at the surface, leading to different local  $K$  values at the tips in these locations. Cracks with arbitrary initial shapes also follow this trend eventually, after some growth. The variation in aspect ratio in bending

is illustrated in Fig. 3(b) for different materials with varying initial aspect ratios. The rate of change of  $a/c$  in this case is given by:

$$\frac{da}{dc} = \left\{ \frac{\sqrt{\frac{a}{c} \left[ 1 + 0.3182 \left( \frac{a}{t} \right)^2 \right]} H_1}{H_2} \right\}^{-n} \quad (\text{EQ 5})$$

where:

$$H_1 = 1 - 0.34 \left( \frac{a}{t} \right) - 0.11 \left( \frac{a}{c} \right) \left( \frac{a}{t} \right)$$

$$H_2 = 1 - \left[ 1.22 + 0.12 \left( \frac{a}{c} \right) \right] \left( \frac{a}{t} \right) + \left[ 0.55 - 1.05 \left( \frac{a}{c} \right)^{0.75} + 0.47 \left( \frac{a}{c} \right)^{1.5} \right] \left( \frac{a}{t} \right)^2$$

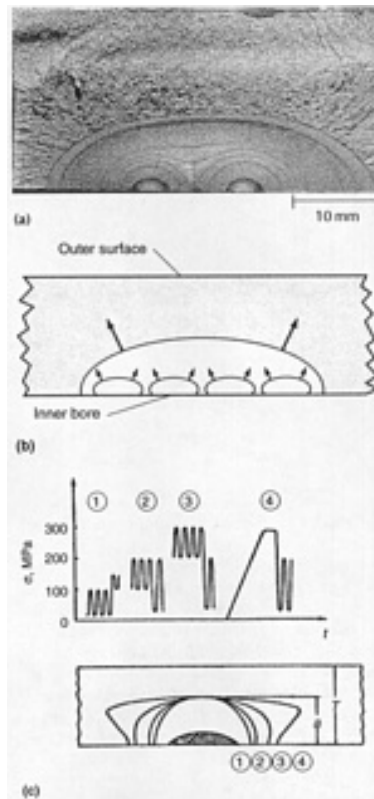

In Fig. 3(a) and 3(b), the solid lines are the predictions from Eq 3 and 5, respectively, and they are often referred to as preferred propagation paths (PPP). In practice, the initial crack shape depends on the geometry of discontinuities, including notches introduced during component fabrication, cracks forming from inclusions, and so on. Hence, knowing the initial aspect ratio,  $a_0/c_0$ , of these defects, the aspect ratio at any stage in fatigue life can be determined numerically from Eq 3 and 5. This is of considerable use in predictions of fatigue failure.

The nature of development of crack shape or aspect ratio is also influenced by stress states other than that due to applied loading. One example is the residual stress introduced by surface modification processes, such as shot peening, surface hardening, and coating. The variation in the shape of surface cracks during fatigue after shot peening (Ref 5) is shown in Fig. 4, along with the data for unpeened material, for 7010 high-strength aluminum alloy. While the unpeened alloy maintained nearly the equilibrium shape ( $a/c = 0.85$ ), the shot-peened alloy showed shallow crack shape ( $a/c = 0.5$ ) during growth. After shot peening, the growth rate of the surface crack tips was higher than that at the depth. Shot peening of the alloy produced a highly deformed layer at the surface. Due to extensive plastic deformation in the direction normal to the shot-peened surface, the width of grains in this direction was smaller than in other directions. The grains had a layered microstructure. As a result, propagation was difficult normal to these grain layers into the specimen, relative to that in the surface direction. The shallow crack shape also reflects this difficulty, indicating that it is easier for the crack to grow in the surface direction than in the depth direction.

**FIG. 4 THE TRENDS IN ASPECT RATIOS OF SURFACE CRACKS IN 7010 ALUMINUM ALLOY, BEFORE AND AFTER SHOT PEENING**

Other factors influence the development of crack shape in surface cracks. Unique circumstances such as crack coalescence can cause a sudden change in aspect ratio (Ref 6). As shown in Fig. 5(a), when two semicircular cracks propagating in the same plane touch each other, the combined crack has a lower aspect ratio ( $a/c < 1$ ), and the crack propagation in surface temporarily ceases. In conventionally manufactured components, residual stresses are invariably present. In autofretagged gun tubes (Ref 7), small cracks, initially pinned from growing in the surface direction, coalesce to larger ones with shallow shape, often resulting in a far more complex shape (Fig. 5b). These shapes are not generally semielliptical, so some inaccuracy is expected when using the known SIF formulas for elliptical cracks. Therefore, alternate methods are required to estimate the SIFs for these cracks.

**FIG. 5 THE NATURE OF CRACK SHAPE DEVELOPMENT DURING (A) THE COALESCENCE OF TWO SEMICIRCULAR CRACKS, (B) THE COALESCENCE OF MULTIPLE CRACKS IN AUTOFRETTAGED GUN TUBES, AND (C) THE APPLICATION OF VARYING MEAN STRESS FATIGUE LOADING**

Changes in load spectrum, either due to change in mean stress or stress ratio,  $R$ , or a change in loading mode, can cause a change in the shape of the crack (Ref 8). Figure 5(c) shows how the change in  $R$  alters the crack front for a surface crack in a plate under tensile loading. It was suggested that the constraint loss in surface changed the size of the plastic zone through which the crack should enter the body. This in turn led to unusual crack shapes, as shown in the figure. Additionally, the resulting stress redistribution influenced the crack shape.

The variations in surface crack aspect ratio, or the PPP, also depend on the environment (Ref 9). Figure 6 shows the effect of environment and stress ratio on the change in  $a/c$  of surface cracks in HY80 steel. For crack growth in air, the aspect ratios were generally lower at  $R = 0.7$  than  $R = 0.2$ , similar to the effect of load spectrum on crack shape, indicated above. However, the effect was not seen for vacuum or saltwater environments. Additionally, the crack aspect ratios in these environments are similar. The reason for this different behavior is not well understood, but the data clearly suggest that the effect of environment on crack shape development can be significant and should be considered in surface crack analyses.

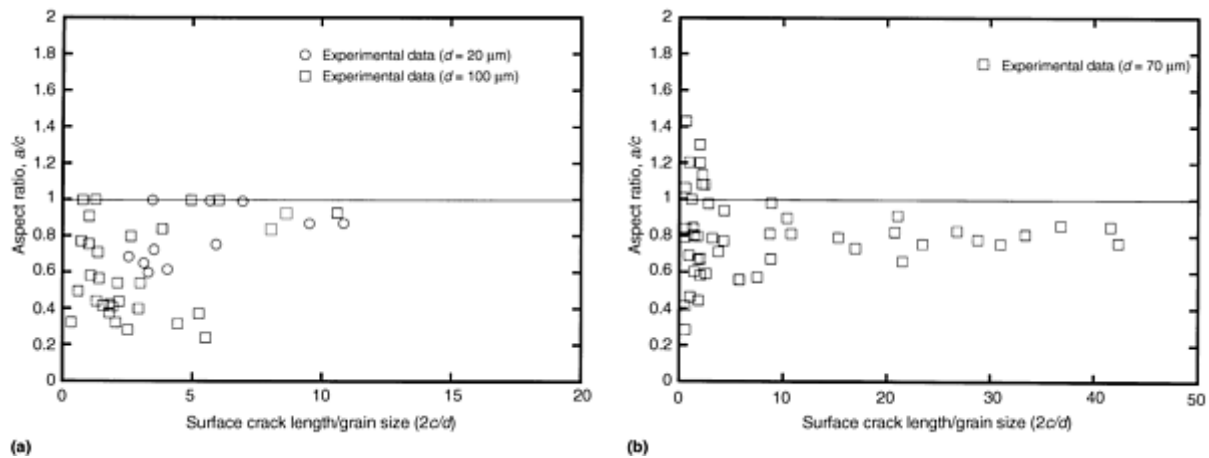

FIG. 6 THE EFFECT OF ENVIRONMENT ON CRACK SHAPE DEVELOPMENT

**Microstructural Variables.** Many microstructural parameters, including grain boundaries, crystallographic orientation/texture, and inclusions, influence the development of crack shape in surface cracks. Despite its importance to microstructure control and fatigue life prediction in general, this subject has received little attention in research, let alone in fatigue life prediction. One of the principal reasons is that microstructure-induced effects occur at very small sizes, making measurement and interpretation difficult. Until recently, nondestructive evaluation procedures in engineering emphasized a lower detectable crack size limit of about 1 mm. At this size, the microstructure-induced effects on crack shape are generally small. However, in high-performance applications, high-strength and inherently anisotropic materials are being used increasingly often, leading to a decrease in the limiting crack size at which unstable failure may occur. Therefore, consideration should be given to microstructural effects on small cracks, in the size range in which microstructural effects are significant.

The shape of inclusions, for example in steel, influences the crack shape at very early stages of fatigue, affecting the fatigue life (Ref 10, 11). This influence is significant on the initial values of crack aspect ratio. As the crack grows away from the inclusion, equilibrium semielliptical shape is reached, provided that factors such as residual stress and microstructural effects are absent.

The most significant microstructural factors that have a documented influence on crack shape development are grain size and texture. It is to be noted that microstructural effects on crack shape are yet to be fully understood. However, certain experimental data are included here for the reader, to caution the use of surface crack equations at small crack sizes, as well as to appreciate the relevance of microstructure in crack shape variations. The effect of grain size on crack shape is dominant at small crack sizes of the order of a few grain diameters. Figures 7(a) and 7(b) illustrate  $a/c$  values determined by serial electropolishing (Ref 12) and by heat tinting (Ref 13), respectively. Both data sets consist of measurements from cracks grown to different sizes in several specimens. The fluctuations in crack aspect ratio are significant, especially at small crack sizes of the order of a few grain diameters. At large crack sizes, the aspect ratios converge to nearly equilibrium crack shape ( $a/c = 0.85$ ).

**FIG. 7 MICROSTRUCTURE (GRAIN SIZE) INDUCED CRACK ASPECT RATIO VARIATIONS IN (A) TI-8AL ALLOY AND (B) STAINLESS STEEL**

The reasons for the grain-induced aspect ratio variations are beginning to be understood (Ref 14). At small crack sizes, the crystallographic orientations of grains influence the crack extension. Perturbations in the crack front occur at locations where the grains ahead of the crack are favorably oriented for cleavage or slip. The crack front is arrested at locations having grains not so oriented. The isolated crack front perturbations are significant at crack sizes of the order of a few times the grain size. These perturbations significantly alter the shape as well as the distribution of SIF along the crack front. As a result, there are wide variations in crack shape and SIF distribution. When the crack grows to a larger size, of the order of several times the grain diameter, the same perturbations become less significant in relation to the size of the crack. Hence, the changes in overall shape and the  $K$  distribution along the crack front are less severe. With continued crack growth, the crack approaches the equilibrium crack shape. Therefore, microstructure-induced crack shape variations are limited to few grain diameters, typically of the order of ten times the grain size (Ref 14). This limit can change with a material, but it appears to be linked to the ratio of crack size to grain size. Grain-induced crack shape variations are also significant in materials such as beta-processed titanium alloy, in which cracks of the order of 1 mm are known (Ref 15) to exhibit irregular crack shapes due to the coarse colony microstructure.

Texture or grain shape can influence the shape of the surface crack during fatigue crack growth, especially in rolled and extruded materials such as aluminum alloys. This is because the resistance to crack growth is different in the longitudinal, transverse, and short-transverse directions of a rolled plate, leading to different rates of crack front advance in different directions under the same applied stress range. Hence, nonequilibrium crack shapes occur, either shallow or deep configurations (Ref 16), depending on the relative crack growth resistance at the surface direction compared to that at the depth direction. Figures 8(a) and 8(b) illustrate the crack shapes as observed on fracture surfaces in different orientations of a 7010 aluminum alloy. The effect of texture or orientation is more significant in the case of Al-Li alloys (Ref 5), in which shallow crack configuration is seen even in the absence of shot peening (Fig. 8c).

### Effect of Crack Shape on Fatigue Crack Growth

K.S. Ravichandran, The University of Utah

---

### Measurement and Analysis

Measurement of crack shapes or aspect ratios during fatigue crack growth can be performed by a number of techniques. Most common are application of high mean stress and low- $\Delta K$  loading periodically during the regular cyclic loading to mark the crack front, heating the specimen with the crack in air at 300 to 700 °C (for most steels and titanium alloys) for

1 or 2 h to color the crack surfaces by oxidation (heat tinting), and using dye penetrants or inks to mark the crack front. However, these techniques provide useful information only after specimen fracture. In many instances, a knowledge of the shape of the crack before fracture is required in order to assess the criticality of the structure.

To this end, a method has recently been developed (Ref 17) to continuously track the changes in shape or aspect ratio of the crack during fatigue crack growth, using advanced measurement techniques. The method relies on the measurements of instantaneous crack compliance and surface crack length. A laser interferometric displacement measurement system is used to accurately measure the crack compliance. A photographic camera or replication is used to continuously record the surface crack length at the same time as the compliance measurement. The compliance of a surface crack is a function of surface length and its depth (alternatively, aspect ratio), so the aspect ratio can be estimated if the compliance and the surface length are known. The relationship between the compliance ( $2U/\sigma$ , where  $2U$  is the crack-mouth opening displacement due to a stress,  $\sigma$ , on the specimen), the surface crack length, and the aspect ratio is given by:

$$\frac{2U}{\sigma} = 1.6 \frac{\sqrt{8}}{\sqrt{\pi E}} c (1 - \nu^2) \lambda F f_w g \quad (\text{EQ 6})$$

where the parameters  $F$  and  $f_w$  are the same as in Eq 2. For  $a/c < 1$ ,  $M_1$ ,  $M_2$ , and  $M_3$  are the same as in Eq 2 for  $a/c < 1$ , and:

$$\lambda = \frac{a}{c}$$

$$g = 1 + \left[ 0.1 + 0.35 \left( \frac{a}{t} \right)^2 \right]$$

For  $a/c > 1$ ,  $M_1$ ,  $M_2$ , and  $M_3$  are the same as in Eq 2 for  $a/c > 1$ , and:

$$\lambda = \sqrt{\frac{a}{c}}$$

$$g = 1 + \left[ 0.1 + 0.35 \left( \frac{c}{a} \right) \left( \frac{a}{t} \right)^2 \right]$$

In Eq 6,  $E$  is the tensile modulus, and  $\nu$  is Poisson's ratio. The validity of Eq 6 is restricted to  $0.2 < a/c < 2.0$ .

The method presented above was evaluated for the growth of surface cracks initially having shapes different from the equilibrium shape. A shallow notch ( $a/c = 0.1$ ) and a deep notch ( $a/c = 2.5$ ) were introduced in tensile specimens made out of a near  $\alpha$ -titanium alloy. Surface cracks are known to exhibit semicircular ( $a/c = 1$ ) shapes in this material (Ref 18). Therefore, cracks initiating from these starter notches are expected to grow with continuous changes in crack aspect ratio, eventually converging to a semicircular crack at crack lengths that are large compared to notch dimensions. Figure 9(a) and 9(b) illustrate the fracture surfaces, heat tinted before fracture to reveal the final crack shape. The initial notch geometries are also visible. The crack aspect ratios estimated by the present technique are given in Fig. 10, along with the changes in aspect ratio predicted using the SIF equations. The good agreement between the measured and predicted data suggests that this approach is accurate and reliable.

FIG. 9 SHAPES OF SURFACE CRACKS, REVEALED BY HEAT TINTING BEFORE SPECIMEN FRACTURE. THE CRACKS WERE GROWN FROM (A) SHALLOW AND (B) DEEP NOTCHES

FIG. 10 COMPARISON OF THE EXPERIMENTALLY MEASURED ASPECT RATIOS WITH THE PREDICTED TREND DURING FATIGUE CRACK GROWTH FROM INITIALLY SHALLOW AND DEEP NOTCHES

The difficulties associated with this approach are the cost of instrumentation, set-up time, and the experimental care required. At present, this technique is limited to laboratory investigations. However, extension of this technique to complicated geometries or actual components in service is possible by replacing the laser interferometric system with simpler techniques, such as using a strain gage or miniature linear variable differential transformer to measure crack opening displacements. In this approach, it is also implied that the surface cracks have elliptical geometry, because the compliance relationship (Eq 6) was deduced from the Newman-Raju formula for elliptical cracks. However, reasonably

accurate measurements of average crack aspect ratio have been made (Ref 19, 20) by approximating irregular cracks to elliptical shapes in a titanium aluminide alloy. Figure 11 illustrates some of the crack shapes at the end of fatigue tests in Ti-24Al-11Nb alloy. The measured aspect ratios reasonably agreed with those measured from fracture surface after heat tinting (Ref 20). Hence, the described technique can provide good estimates of aspect ratios of regular surface cracks, as well as those having limited irregularity in shape, continuously during their growth in fatigue.

FIG. 11 CRACK SHAPES OBSERVED IN A TITANIUM ALUMINIDE ALLOY, REVEALED BY HEAT TINTING

**Estimation of SIF for Arbitrarily Shaped Cracks.** Analytical solutions for straight, circular, and elliptical cracks are readily available, owing to their simplicity of geometry. On the other hand, irregular cracks seldom have simple solutions due to their complex geometry. Often, the finite element method must be applied in order to determine the distribution of SIF (or stress concentration factor, in the case of a pore/cavity). Because of crack irregularity, fatigue crack growth often occurs at points of maximum stress intensity, leading to continuous change in the irregularity of the crack front. Under these circumstances, the finite element method calculations must be repeated to trace the change in crack shape and/or to allow for the loading spectrum. However, this is not practical, due to the cost and time involved.

Based on weight function technique in fracture mechanics, Oore and Burns (Ref 21) developed a simple procedure to calculate the mode I stress-intensity factor at any point along the front of an irregular flat crack embedded in an infinite solid and subjected to an arbitrary normal stress field. The stress-intensity factor,  $K_Q$ , at any point  $Q'$  on the crack front (Fig. 12) is given by:

$$K_{Q'} = \iint_A W_{QQ'} q_Q dA_Q \quad (\text{EQ 7})$$

where  $q_Q$  is the opening force intensity (pressure) acting at point  $Q$  over the area  $dA_Q$  and  $W_{QQ'}$  is the weight function. If  $W_{QQ'}$  is known for each point on the crack surface,  $K_{Q'}$  can be calculated for any distribution of pressure on the crack

surface. For a circular crack the weight function is readily available (Ref 22). From this, Oore and Burns recognized that the form of weight function depends on the inverse of the square of the distance ( $l_{QQ'}$ ) from the load point (Q) to the point of interest (Q'), the geometry of the crack front, and the location of the load point Q in crack geometry. They arrived at the weight function for an irregular crack as:

$$W_{QQ'} = \frac{\sqrt{2}}{\left[ \pi l_{QQ'}^2 \sqrt{\int_S \frac{dS}{\rho_Q^2}} \right]} \quad (\text{EQ 8})$$

where the integral over the crack front,  $S$ , captures the irregularity of the crack front and its effect on SIF at different locations, and the variable  $\rho_Q$  is the distance from the point load at Q to each infinitesimal portion,  $dS$ , of the crack front. Using Eq 7, SIFs can be calculated by simple numerical methods. Equation 7 is a general expression for SIF and is suitable for any shape of the embedded crack. Its application to the prediction of crack front advance of irregular cracks during fatigue crack growth yielded consistent results (Ref 21). Although Eq 7 is applicable to embedded cracks, a modification to surface cracks appears to be possible (Ref 23) by incorporating a magnification factor for the specimen geometry. Hence, this approach can be of significant use in analyzing the growth behavior of arbitrarily shaped flaws, such as those found in weldments, during fatigue.

FIG. 12 AN IRREGULAR CRACK EMBEDDED IN AN INFINITE SOLID SUBJECTED TO A POINT FORCE

**Methods of Failure Prediction for Arbitrarily Shaped Flaws.** Application of fracture mechanics methods to the prediction of failure from through cracks is simple and straightforward, because only crack length in one direction is involved. On the other hand, for surface and embedded cracks with arbitrary shapes, both the size and shape are important. This is because changes in length in any direction can change the projected area of the defect on the plane perpendicular to the principal loading direction, thereby altering the load-bearing cross-sectional area. This would naturally affect the SIF or stress concentration in the vicinity of the crack or cavity, respectively. An appropriate methodology is therefore required to take into account the irregularity of the crack/defect in predictions of failure.

Cracks and cavities encountered in most applications are irregular, far from the circular or elliptical geometries assumed in standard fracture mechanics solutions. Murakami et al. (Ref 24, 25) have developed simple approaches to extend fracture mechanics to irregularly shaped cracks as well as defects of varying geometry. The key to this approach is the observation that the maximum SIF along the crack front is proportional to the square root of crack area. In the case of notches or cavities, the area projected onto the plane normal to the loading direction is considered the crack area. This

approach brings cracks and defects of varying geometries to a common base, since the square root of the area and the square root of the projected area, which are dimensionally equivalent to length, are considered for cracks and notches, respectively. Figure 13 shows the normalized maximum SIF as a function of the crack area for several crack geometries having aspect ratios (ratio of major axis to minor axis) restricted to  $\leq 5$  (Ref 24).

**FIG. 13 THE UNIQUENESS IN THE VARIATION OF MAXIMUM STRESS-INTENSITY FACTOR OF IRREGULAR CRACKS WITH THE SQUARE ROOT OF THE AREA, FOR VARIOUS CRACK GEOMETRIES**

On this basis, the threshold for the nonpropagation of defects of various geometries can be represented (Ref 25) as a function of the square root of the area, as shown in Fig. 14. The increase in  $\Delta K_{th}$  with the square root of the area, is due to the increase in threshold with crack size in the short-crack regime of through cracks, an effect arising from crack closure. For several metals, including carbon steels, aluminum alloys, brass, and stainless steel, it has been found that:

$$\Delta K_{TH} = 0.0033(HV + 120) (\sqrt{\text{area}})^{\frac{1}{3}} \quad \text{(EQ 9)}$$

where HV is Vickers hardness. It has been found that Eq 9 is within 10% of the experimentally observed threshold data of the materials studied and is applicable to cracks of varying size and geometry. The only restriction is the defect or crack aspect ratio ( $a/b$ , where  $a$  and  $b$  are the major and minor dimensions of the projected area of the crack or defect) should not exceed 5, since the approximation of the square root of the area becomes inaccurate for  $a/b > 5$ . It is evident that this equation is a simple and useful tool to predict the failure of components in engineering practice.

FIG. 14 RELATIONSHIP BETWEEN  $\Delta K_{TH}$  AND THE SQUARE ROOT OF THE AREA, FOR VARIOUS DEFECTS AND CRACKS. LETTERS CORRESPONDING TO THE MATERIALS ARE GIVEN IN TABLE 1.

TABLE 1 MATERIALS IN FIG. 14

MATERIAL	HV	DEFECT

Cracks and cavities with irregular shapes initiate cracks from the location of maximum stress concentration. These cracks propagate to the extent that the projected area of the crack, onto the plane perpendicular to stress, becomes close to a circle. This is the condition of uniform stress intensity or concentration around the crack or cavity. Such crack propagation behavior was observed (Ref 24) in rotating bending fatigue tests of steel specimens having starter notches of various geometries, as well as in steels containing irregularly shaped inclusions. It was then deduced that it is the nonpropagation condition of cracks, not the initiation of cracks at the point of maximum stress concentration, that determines the fatigue limit. On this basis, Murakami et al. correlated the fatigue limit of specimens containing variously shaped notches to the square root of the area, projected onto the plane normal to applied stress:

$$\sigma_a^n \sqrt{\text{area}} = C \quad (\text{EQ 10})$$

in which  $\sigma_a$  is the fatigue limit at  $R = -1$  of a specimen containing a defect of the square root of the area, irrespective of its shape, and  $n$  and  $C$  are material constants. This approach is generally limited to notches with  $a/b < 5$ . For several metals, including aluminum alloy, brass, stainless steel, and quenched and tempered martensitic steels, a practically useful correlation has been produced (Ref 25) from a large set of experimental data:

$$\sigma_a = 1.43 \frac{(HV + 120)}{(\sqrt{\text{area}})^{1/6}} \quad (\text{EQ 11})$$

It has been found that Eq 11 is within 10% of the experimentally observed fatigue limits of specimens having cracks and notches of varying geometry. Hence, this relationship is useful to predict the effect of defects and notches on the fatigue limit of components in service.

The problem of irregularity of crack front is of foremost importance in common metallurgical situations such as weldments, carburized and surface-hardened materials, and components with notches. Further work is clearly needed to advance the understanding generated to date and to apply it more widely in engineering practice.

## Fatigue Crack Growth Testing

Ashok Saxena and Christopher L. Muhlstein, Georgia Institute of Technology

---

### Introduction

FATIGUE is generally understood to be a process dominated by cyclic plastic deformation, such that fatigue damage can occur at stresses below the monotonic yield strength. The process of fatigue cracking generally begins from locations where there are discontinuities or where plastic strain accumulates preferentially in the form of slip bands. In most situations, fatigue failures initiate in regions of stress concentration such as sharp notches, nonmetallic inclusions, or at preexisting crack-like defects. Where failures occur at sharp notches or other stress raisers, cracks first initiate and then propagate to critical size, at which time sudden failure occurs. The fatigue life consists of crack initiation as well as crack propagation. On the other hand, when fatigue failures are caused by large inclusions or pre-existing crack-like defects, the entire life consists of crack propagation. Such situations are commonly encountered in service failures. A typical example of such a failure in a railroad track is shown in Fig. 1. The light area in the photograph is the region of fatigue crack growth, and the surrounding darker area is the region of fast fracture. The dark spot within the light area is the origin of the failure, which is a pre-existing defect due to a hydrogen flake.

FIG. 1 FATIGUE FAILURE OF A RAILROAD TRACK

Testing of smooth or notched specimens generally characterizes the overall fatigue life of a specimen material. This type of testing, however, does not distinguish between fatigue crack initiation life and fatigue crack propagation life. With this approach, preexisting flaws or crack-like defects, which would reduce or eliminate the crack initiation portion of the fatigue life, cannot be adequately addressed. Therefore, testing and characterization of fatigue crack growth is used extensively to predict the rate at which subcritical cracks grow due to fatigue loading. For components that are subjected to cyclic loading, this capability is essential for life prediction, for recommending a definite accept/reject criterion during nondestructive inspection, and for calculating in-service inspection intervals for continued safe operation.

## Fracture Mechanics in Fatigue

Linear elastic fracture mechanics is an analytical procedure that relates the magnitude and distribution of stress in the vicinity of a crack tip to the nominal stress applied to the structure; to the size, shape, and orientation of the crack or crack-like imperfection; and to the crack growth and fracture resistance of the material. The procedure is based on the analysis of stress-field equations, which show that the elastic stress field in the region of a crack tip can be described by a single parameter,  $K$ , called the stress-intensity factor. This same procedure is also used to characterize fatigue crack growth rates ( $da/dN$ ) in terms of the cyclic stress-intensity range parameter ( $\Delta K$ ).

When a component or a specimen containing a crack is subjected to cyclic loading, the crack length ( $a$ ) increases with the number of fatigue cycles,  $N$ , if the load amplitude ( $\Delta P$ ), load ratio ( $R$ ), and cyclic frequency ( $\nu$ ), are held constant. The crack growth rate,  $da/dN$ , increases as the crack length increases during a given test. The  $da/dN$  is also higher at any given crack length for tests conducted at higher load amplitudes. Thus, the following functional relationship can be derived from these observations:

$$\left(\frac{da}{dN}\right)_{R,\nu} = f(\Delta P, a) \quad (\text{EQ 1})$$

where the function  $f$  is dependent on the geometry of the specimen, the crack length, the loading configuration, and the cyclic load range. This general relation is simplified with the use of the  $\Delta K$  parameter as summarized below.

**Correlation between  $da/dN$  and  $\Delta K$ .** In 1963, Paris and Erdogan (Ref 1) published an analysis consisting of considerable fatigue crack growth rate (FCGR) data and demonstrated that a correlation exists between  $da/dN$  and the cyclic stress intensity parameter,  $\Delta K$ . They argued that  $\Delta K$  characterizes the magnitude of the fatigue stresses in the crack-tip region; hence, it should characterize the crack growth rate. Such a proposition is in obvious agreement with the functional relationships of Eq 1. The parameter  $\Delta K$  accounts for the magnitude of the load range ( $\Delta P$ ) as well as the crack length and geometry. A number of later studies (Ref 2) have confirmed the findings of Paris and Erdogan. The data for intermediate FCGR values can be represented by the following simple mathematical relationship, commonly known as the Paris equation:

$$\frac{da}{dN} = C(\Delta K)^n \quad (\text{EQ 2})$$

where  $C$  and  $n$  are constants that can be obtained from the intercept and slope, respectively, of the linear  $\log da/dN$  versus  $\log \Delta K$  plot. This representation of FCGR is a useful model for midrange FCGR values (Fig. 2).

FIG. 2 FATIGUE CRACK GROWTH REGIMES VERSUS  $\Delta K$

It has been shown that specimen thickness has no significant effect on the FCGR behavior (Ref 3), although that is not always the case. The ability of  $\Delta K$  to account for so many variables has tremendous significance in the application of the data. Thus, the FCGR behavior expressed as  $da/dN$  versus  $\Delta K$  can be regarded as a fundamental material property analogous to the yield and ultimate tensile strength, plane strain fracture toughness,  $K_{Ic}$ , etc. From the knowledge of this property, prediction of the crack length versus cycles behavior of any component using that material and containing a preexisting crack or crack-like defect can be obtained, as long as the fatigue stresses in the component are known and a  $K$  expression for the crack/load configuration is available.

**Crack-Tip Plasticity during Fatigue.** The cyclic stress-intensity parameter,  $\Delta K$ , is based on linear elastic fracture mechanics, and characterizes only the elastic stress field beyond the plastic zone. However, fatigue is a process dominated by cyclic plastic deformation. Even when fatigue damage occurs at stresses below the monotonic yield strength, the process of fatigue cracking begins from locations where there are discontinuities, such as nonmetallic inclusions, or from surfaces where plastic strain accumulates preferentially in the form of slip bands (Ref 4). Therefore, a brief explanation is given why  $\Delta K$  can characterize fatigue crack growth behavior.

When a cracked body is subjected to cyclic loading, a monotonic plastic zone develops at the crack tip during the first loading cycle. If predominantly linear elastic conditions are maintained during loading, as are necessary for  $\Delta K$  to be a valid crack-tip parameter, compressive stress develops within this plastic zone during unloading because the elastic forces in the overall body tend to restore its original shape (Ref 2). The magnitude of the maximum compressive stress increases as the crack tip is approached. In a small region within the monotonic plastic zone, the maximum compressive stress exceeds the yield strength, resulting in plastic flow in compression. This small region of reversing plastic flow is called the cyclic plastic zone. A simple estimate of the size of this zone was made by Paris (Ref 2) and Rice (Ref 5) for nonhardening materials by substituting  $2\sigma_{ys}$  in place of  $\sigma_{ys}$  in the expression for monotonic plastic zone size and by replacing  $K$  with  $\Delta K$ :

$$r_{cp} = \frac{1}{\pi} \left( \frac{\Delta K}{2\sigma_{ys}} \right)^2 \quad (\text{EQ 3})$$

where  $r_{cp}$  is the cyclic plastic zone size under plane-stress conditions. For materials that undergo cyclic hardening or softening, a first-order estimate of the fatigue plastic zone size can be obtained by replacing  $\sigma_{ys}$  with the cyclic yield strength ( $\sigma_{cys}$ ) in Eq 3.

**General Crack Growth Behavior.** When crack growth rates over six to seven decades are plotted against  $\Delta K$ , the behavior is no longer a straight line on a log-log plot. Results of FCGR tests for nearly all metallic structural materials have shown that the  $da/dN$  versus  $\Delta K$  curves have three distinct regions. The behavior in region I (Fig. 2) exhibits a fatigue crack growth threshold,  $\Delta K_{th}$ , which corresponds to the stress-intensity factor range below which cracks do not propagate. Equation 2 is applicable in the midrange of  $da/dN$  values for FCGR (region II in Fig. 2). Typically, the validity of Eq 2 is limited over a range of two to four decades for midrange crack growth rates. Testing and material factors that affect crack growth behavior in regions I, II, and III of Fig. 2 are discussed in more detail in the article "Fatigue Failure in Metals" in this Volume.

At high  $\Delta K$  values, region III, the  $K_{max}$  approaches the critical  $K$  for instability,  $K_c$ , and the crack growth rate accelerates. In some cases  $K_c$  may be equal to  $K_{Ic}$ , but this cannot be generalized because the FCGR specimens or even actual components may not always satisfy size requirements for valid linear elastic plane-strain conditions. In some materials there is also an effect of prior fatiguing on the  $K$  value at which instability occurs (Ref 6). In such cases,  $K_c$  will not be equal to the  $K_{Ic}$  of the material.

At low  $\Delta K$  values (region I in Fig. 2), the crack growth rate decreases rapidly with decreasing  $\Delta K$ , and ultimately  $\Delta K$  approaches a threshold value,  $\Delta K_{th}$ , when the crack growth rate approaches zero. In high-cycle fatigue applications,  $\Delta K_{th}$  is an important design parameter. The above definition of  $\Delta K_{th}$  is an idealized definition; for practical usage it is important to define its value unambiguously. An operational value of  $\Delta K_{th}$  is frequently defined as the  $\Delta K$  value at a  $da/dN$  of  $10^{-10}$  m/cycle (Ref 7).

**FCGR under Elastic-Plastic Conditions.** There are applications when fatigue crack growth occurs under conditions of gross plastic deformation, or at least under conditions for which dominant linear elasticity cannot be ensured. As a crack tip parameter,  $\Delta K$  breaks down under these conditions and can no longer be expected to uniquely characterize FCGR

behavior. Dowling and Begley have defined a cyclic  $J$ -integral,  $\Delta J$ , which is determined utilizing the loading portion of the load-displacement diagram during cyclic loading (Ref 8, 9).

Metals and alloys can be assumed to deform according to the cyclic stress-strain law given by:

$$\Delta \varepsilon = \frac{\Delta \sigma}{E} + D' \left( \frac{\Delta \sigma}{2\sigma_{cys}} \right)^{m'} \quad (\text{EQ 4})$$

where  $\Delta \varepsilon$  is the cyclic strain range,  $\Delta \sigma$  is the cyclic stress range,  $E$  is the elastic modulus, and  $D'$  and  $m'$  are empirically determined material constants. The value of  $\Delta J$  for such materials can be defined by (Ref 10):

$$\Delta J = \int_{\Gamma} (\Delta W) dy - \Delta T_i \left( \frac{\partial \Delta u_i}{\partial x} \right) ds \quad (\text{EQ 5})$$

The term  $\Delta J$  in Eq 5 is a path-independent integral along any given path  $\Gamma$  which originates at the lower crack surface and ends on the upper crack surface traversing along the contour in a counterclockwise direction. The definition of  $\Delta J$  is written as a direct analogy to Rice's  $J$ -integral (Ref 11) used extensively in characterizing fracture under monotonic loading conditions. The term  $\Delta W$  in Eq 5 is as follows:

$$\Delta W = \int_0^{\Delta \varepsilon_{ij}} \Delta \sigma_{ij} D(\Delta \varepsilon_{ij}) \quad (\text{EQ 6})$$

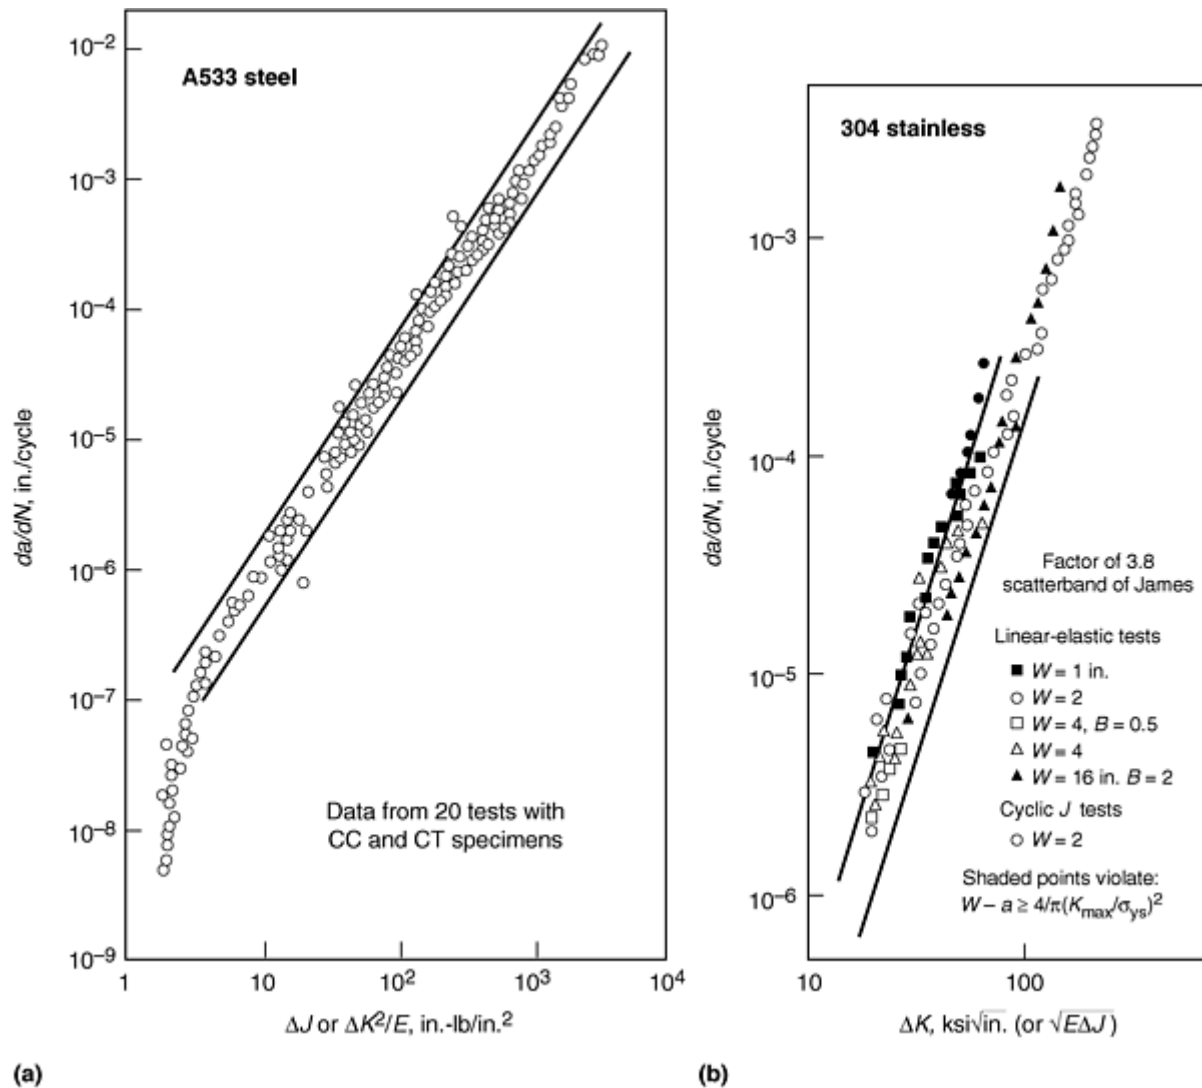

Other terms in Eqs 5 and 6 are:

- $\Delta T_i$  IS THE RANGE OF THE TRACTION VECTOR
- $\Delta U_i$  IS THE RANGE OF DISPLACEMENT
- $\Delta \sigma_{ij}$  AND  $\Delta \varepsilon_{ij}$  ARE THE RANGES OF THE STRESS AND STRAIN, RESPECTIVELY
- $DS$  IS AN ELEMENT ALONG THE CONTOUR  $\Gamma$

All range quantities are calculated by subtracting the values at minimum load from the corresponding values at maximum load. When  $\Delta J$  is defined in the above manner, its value characterizes the crack-tip stress and strain ranges according to the Hutchinson (Ref 12) and Rice and Rosengren (Ref 13) relationships. It must also be noted that for linear elastic conditions, Eq 5 will yield the following relationship:

$$\Delta J = \frac{\Delta K^2}{E} \quad (\text{EQ 7})$$

From the above relationship, the data from linear elastic tests and elastic-plastic or fully plastic tests can be combined into a single plot of  $da/dN$  with  $\Delta K$  or  $\sqrt{E\Delta J}$ . Similarly, the data can be correlated with  $\Delta K^2/E$  or  $\Delta J$ . Figure 3 shows the FCGR data for A533 and for 304 stainless steel in this manner (Ref 9, 14). These data were developed on specimens of two geometries and more notably on specimens with varying sizes within those geometries. Thus, small specimens exhibited considerable plasticity, and the large specimens were under dominantly elastic conditions. Despite the enormous differences in the scales of plasticity among the various tests, the FCGR data lay in a single scatter band.

**FIG. 3 FATIGUE CRACK GROWTH RATE OBTAINED UNDER LINEAR ELASTIC AND ELASTIC-PLASTIC CONDITIONS IN A533 STEEL (A) AND 304 STAINLESS STEEL (B). CC, CENTER-CRACKED; CT, COMPACT-TYPE. SOURCE: REF 9, 14**

**Crack Closure.** The concept of crack closure was first introduced by Elber (Ref 15, 16) as an effect from a zone of residual deformation that is left in the wake of a growing fatigue crack. According to this concept, crack surfaces at the crack tip might stay closed during a portion of the fatigue cycle due to compressive residual stress acting at the crack tip. Elber further postulated that this portion of the loading cycle is ineffective in growing the fatigue crack and that thus the corresponding load should be subtracted from the applied  $\Delta P$  to determine the effective value of  $\Delta K$ .

Figure 4 shows a series of schematic sketches that show the stress and strain distributions at the crack tip at maximum and minimum load. At the maximum load, *A*, all the load is borne by the uncracked ligament because cracks are unable to transmit the load. At the minimum load, *B*, there are compressive stresses to the left of the crack tip because of the contact between opposing crack surfaces within the zone of residual plastic deformation. This causes the effective stiffness of the cracked body to change, which manifests itself in the load-displacement diagram. Thus, the crack closure load can be defined as the load at which this change in stiffness occurs.

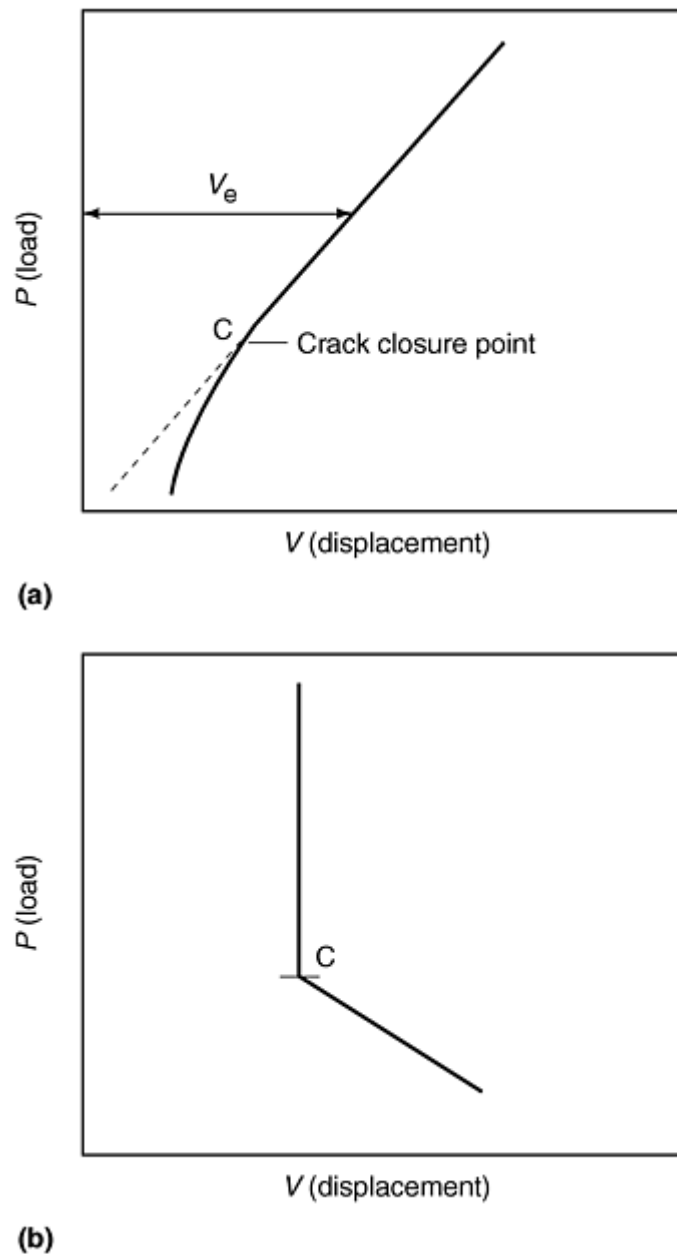

FIG. 4 SCHEMATIC REPRESENTATION OF THE CRACK-TIP CONDITIONS DURING CRACK CLOSURE

Figure 5(a) shows a schematic load-deflection diagram and the crack closure point. Figure 5(b) plots only the deviation between the total deflection and the linearly predicted deflection, thus highlighting the crack closure point.

**FIG. 5 LOAD VERSUS DISPLACEMENT DIAGRAMS. (A) DIAGRAM SHOWING A CHANGE IN STIFFNESS AT THE CRACK CLOSURE POINT. (B) A PLOT OF TOTAL DEFLECTION MINUS THE ELASTICITY CALCULATED DEFLECTION AMPLIFIED TO HIGHLIGHT CRACK CLOSURE.  $V_e$ , ELASTIC DISPLACEMENT**

The importance of crack closure varies with the crack growth regime, crack tip material-microstructure interactions, and the extent of plasticity. Crack closure is more significant in the near-threshold regime (region I) than in region II. Materials in which the crack path is such that rougher crack surfaces are produced usually exhibit enhanced crack closure levels. The crack closure levels can also increase with plasticity. For example, during fatigue crack growth in the elastic-plastic regime, crack closure levels take on added significance (Ref 8, 9).

## Fatigue Crack Growth Testing

Ashok Saxena and Christopher L. Muhlstein, Georgia Institute of Technology

---

## Test Methods and Procedures

American Society for Testing and Materials Standard E647 (Ref 7) is the accepted guideline for fatigue crack growth testing and is applicable to a wide variety of materials and growth rates.

FCGR testing consists of several steps, beginning with selecting the specimen size, geometry, and crack length measurement technique. When planning the tests, the investigator must have an understanding of the application of FCGR data. Testing is often performed in laboratory air at room temperature; however, any gaseous or liquid environment and temperature of interest may be used to determine the effect of temperature, corrosion, or other chemical reaction on cyclic loading (see the article "Corrosion Fatigue Testing" in this Volume and the appendix "High-Temperature Fatigue Crack Growth Testing" at the end of this article). Cyclic loading also may involve various waveforms for constant-amplitude loading, spectrum loading, or random loading.

In addition, many of the conventions used in plane-strain fracture toughness testing (ASTM E-399, Ref 17) are also used in FCGR testing. For tension-tension fatigue loading, the  $K_{Ic}$  loading fixtures frequently can be used. For this type of loading, both the maximum and minimum loads are tensile, and the load ratio,  $R = P_{\min}/P_{\max}$ , is in the range  $0 < R < 1$ . A ratio of  $R = 0.1$  is commonly used for developing data for comparative purposes.

**Cyclic Crack Growth Rate Testing in the Threshold Regime.** Cyclic crack growth rate testing in the low-growth regime (region I in Fig. 2) complicates acquisition of valid and consistent data, because the crack growth behavior becomes more sensitive to the material, environment, and testing procedures in this regime. Within this regime, the fatigue mechanisms of the material that slow the crack growth rates are more significant (see the article "Fatigue Crack Thresholds" in this Volume).

It is extremely expensive to obtain a true definition of  $\Delta K_{th}$ , and in some materials a true threshold may be nonexistent. Generally, designers are more interested in the fatigue crack growth rates in the near-threshold regime, such as the  $\Delta K$  that corresponds to a fatigue crack growth rate of  $10^{-8}$  to  $10^{-10}$  m/cycle ( $3.9 \times 10^{-7}$  to  $10^{-9}$  in./cycle). Because the duration

of the tests increases greatly for each additional decade of near-threshold data ( $10^{-8}$  to  $10^{-9}$  to  $10^{-10}$ , etc., m/cycle), the precise design requirements should be determined in advance of the test. Although the methods of conducting fatigue crack threshold testing may differ, ASTM Standard E- 647 addresses these requirements.

In all areas of crack growth rate testing, the resolution capability of the crack measuring technique should be known; however, this becomes considerably more important in the threshold regime. The smallest amount of crack length resolution as possible is desired, because the rate of decreasing applied loads (load shedding) is dependent on how easily the crack length can be measured. The minimum amount of change in crack growth that is measured should be ten times the crack length measurement precision. It is also recommended that for noncontinuous load shedding testing, where  $[(P_{\max 1} - P_{\max 2})/P_{\max 1}] > 0.02$ , the reduction in the maximum load should not exceed 10% of the previous maximum load, and the minimum crack extension between load sheds should be at least 0.50 mm (0.02 in.).

In selecting a specimen, the resolution capability of the crack measuring device and the  $K$ -gradient (the rate at which  $K$  is increased or decreased) in the specimen should be known to ensure that the test can be conducted appropriately. If the measuring device is not sufficient, the threshold crack growth rate may not be achieved before the specimen is separated in two. To avoid such problems, a plot of the control of the stress intensity ( $K$  versus  $a$ ) should be generated before selection of the specimen.

When a new crack-length measuring device is introduced, a new type of material is used, or any other factor is different from that used in previous testing, the  $K$ -decreasing portion of the test should be followed with a constant load amplitude ( $K$ -increasing) to provide a comparison between the two methods. Once a consistency is demonstrated, constant-load amplitude testing in the low crack growth rate regime is not necessary under similar conditions.

## Fatigue Crack Growth Testing

Ashok Saxena and Christopher L. Muhlstein, Georgia Institute of Technology

---

## Specimen Selection and Preparation

The two most widely used types of specimens are the middle-crack tension, M(T), and the compact-type, C(T), specimen (see Fig. 6 and 7). However, any specimen configuration with a known stress-intensity factor solution can be used in fatigue crack growth testing, assuming that the appropriate equipment is available for controlling the test and measuring the crack dimensions.

**Center-cracked tension specimens  $\Delta K$ :**

$$\Delta K = \frac{\Delta P}{B} \sqrt{\frac{\pi \alpha}{2W}} \sec \frac{\pi \alpha}{2}$$

where  $\alpha = \frac{2a}{W}$  ; expression valid for  $\frac{2a}{W} < 0.95$

**FIG. 6 STANDARD CENTER-CRACKED TENSION (MIDDLE-TENSION) SPECIMEN AND  $\Delta K$  SOLUTION. SPECIMEN WIDTH ( $W$ ) ·75 MM (3 IN.).  $2A_n$ , MACHINED NOTCH;  $A$ , CRACK LENGTH;  $B$ , SPECIMEN THICKNESS**

**Compact-type specimens  $\Delta K$  value:**

$$\Delta K = \frac{\Delta P (2 + \alpha)}{B \sqrt{W} (1 - \alpha)^{3/2}} (0.886 +$$

$$4.64\alpha - 13.32\alpha^2 + 14.72\alpha^3 - 5.6\alpha^4), \text{ where}$$

$$\alpha = \frac{a}{W} ; \text{ expression valid for } \frac{a}{W} \geq 0.2$$

**FIG. 7 STANDARD COMPACT-TYPE SPECIMEN AND  $\Delta K$  VALUE (PER ASTM E 647). ALLOWABLE THICKNESS:  $W/20 \cdot B \cdot W/4$ . MINIMUM DIMENSIONS.  $W = 25 \text{ MM (1.0 IN.)}$  AND MACHINED NOTCH SIZE ( $A_N$ ) =  $0.20W$**

Specimens used in FCGR testing may be grouped into three categories: pin-loaded (Fig. 6, 7), bend-loaded (Fig. 8a) and wedge-gripped specimens (Fig. 8b, c, d). Precisely machined specimens are essential, and ASTM E 647 specifies the recommended tolerances and  $K$ -calibrations for compact-type C(T) and middle-tension M(T) geometries. Single-edge bend SE(B), arc-shaped A(T), and disk-shaped compact DC(T) specimen geometries and their  $K$ -calibrations are discussed in ASTM E 399. Comparable tolerances should be specified for "nonstandard" specimens. The selection of an appropriate geometry requires consideration of material availability and raw form, desired loading condition, and equipment limitations.

FIG. 8 ALTERNATIVE CRACK GROWTH SPECIMEN GEOMETRIES. (A) SINGLE-EDGE-CRACK BENDING SPECIMEN. (B) DOUBLE-EDGE CRACK TENSION SPECIMEN. (C) SINGLE-EDGE-CRACK TENSION SPECIMEN. (D) SURFACE-CRACK TENSION SPECIMEN

**Crack Length and Specimen Size.** The applicable range of the stress-intensity solution of a specimen configuration is very important. Many stress-intensity expressions are valid only over a range of the ratio of crack length to specimen width ( $a/W$ ). For example, the expression given in Fig. 7 for the compact-type specimen is valid for  $a/W > 0.2$ ; the expression for the center-cracked tension specimen (Fig. 7) is valid for  $2a/W < 0.95$ . The use of stress-intensity expressions outside their applicable crack-length region can produce significant errors in data.

The size of the specimen must also be appropriate. To follow the rules of linear elastic fracture mechanics, the specimen must be predominantly elastic. However, unlike the requirements for plane-strain fracture toughness testing, the stresses at the crack tip do not have to be maintained in a plane-strain state. The stress state is considered to be a controlled test variable. The material characteristics, specimen size, crack length, and applied load will dictate whether the specimen is predominantly elastic. Because the loading modes of different specimens vary significantly, each specimen geometry must be considered separately.

For the center-cracked tension specimen, the following is required:

$$W - 2a \geq \frac{1.25P_{\max}}{B\sigma_{ys}} \quad (\text{EQ 8})$$

where  $W - 2a$  is the uncracked ligament of the specimen (see Fig. 6) and  $\sigma_{ys}$  is the 0.2% offset yield strength at the temperature corresponding to the FCGR data. For the compact-type specimen, the following is required:

$$W - a \geq \frac{4}{\pi} \left( \frac{K_{\max}}{\sigma_{ys}} \right)^2 \quad (\text{EQ 9})$$

where  $W - a$  is the uncracked ligament (see Fig. 7). For the compact-type specimen, the size requirement in Eq 9 limits the monotonic plastic zone in a plane-stress state to approximately 25% of the uncracked ligament. For both Eq 8 and 9, ASTM E 647 recommends the use of the monotonic yield strength. The size requirements in Eq 8 and 9 are appropriate for low-strain hardening materials ( $\sigma_u/\sigma_{ys} \cdot 1.3$ ), where  $\sigma_u$  is the ultimate tensile strength of the material. For higher-strain-hardening materials, Eq 8 and 9 may be too restrictive. In such cases, the criteria may be relaxed by replacing the yield strength,  $\sigma_{ys}$ , with the effective yield strength,  $\sigma_F$ :

$$\sigma_F = \frac{(\sigma_{ys} + \sigma_u)}{2} \quad (\text{EQ 10})$$

**Specimen Thickness.** While fatigue crack growth rates have been shown to be relatively insensitive to stress state (i.e., plane-stress versus plane-strain, Ref 3), there are some practical limitations on specimen thickness. ASTM E 647 recommends that generally compact-type specimen thickness ( $B$ ) range between 5 and 25% of width ( $W/20 \leq B \leq W/4$ ). Middle-tension specimens may have thicknesses up to 12% of width ( $\leq W/8$ ). For center-cracked tension specimens, thickness should not exceed 25% of width. When other specimen geometries are used, similar ranges for the thicknesses should be employed.

Although specimen thickness can vary significantly, the amount of crack curvature in the specimen will increase as the thickness increases. Because stress-intensity solutions are based on a straight through-crack, a significant amount of curvature, if not properly accounted for, can lead to an error in the data. Crack-curvature correction calculations are detailed in ASTM E 647. The minimum allowable thickness depends on the gripping method used; however, the bending strains should not exceed 5% of the nominal strain in the specimen.

**Material Form and Microstructure Considerations.** The material and its microstructure play an important role in the selection of an appropriate specimen geometry. Materials with anisotropic microstructures due to processing such as rolling or forging may show large variations in fatigue crack growth rates in different directions (Ref 18). If the experimental crack growth rate data are to be used for life estimates, the orientation of the specimen should be selected to represent loading orientations expected in service.

In order to eliminate grain size effects, it is usually recommended that the specimen thickness ( $B$ ) be greater than 30 grain diameters (Ref 19, 20). In some cases, such as in large-grain ( $\sim 3$  mm) lamellar  $\gamma$ - $\alpha_2$  Ti-Al intermetallic or  $\alpha$ - $\beta$  titanium alloys, the required specimen sizes would be prohibitively expensive, test loads would be very high, and the component dimensions would probably be less than 30 times the grain size. In such cases, testing should be performed on thickness representative of the component. Curvature of the crack front and side-to-side variation in crack length due to excessive thickness can also be a problem in thick specimens, as discussed below.

**Loading Considerations.** The desired loading conditions play an important role in the specimen geometry and size selection process. Loading considerations include load ratio,  $R$ , residual stresses,  $K$ -gradients, and maintaining small-scale yielding (SSY). All specimen geometries are well suited for tension-tension ( $R > 0$ ) testing. However, tests that call for negative  $R$  (i.e., those with minimum loads of less than 0) are restricted to symmetric, wedge-grip loaded specimens such as the middle-tension specimens. This is due to questions about the crack-tip stress field under compressive loads (Ref 7) and difficulties moving through zero load with pin-loaded specimens.

Residual stresses in the material also have a marked effect on FCGR. Depending on the orientation of the residual stresses, specimen dimensions or geometries should be altered. Residual stresses through the thickness of the specimen (i.e., perpendicular to the direction of crack growth) may accelerate or retard crack growth. When these stresses are not uniform, the ASTM E 647 recommends a reduction of the thickness-to-width ratio ( $B/W$ ).

The rate at which  $K$  increases as the crack extends at a constant-load amplitude is given by the geometry function  $f(a/W)$  and may be a consideration when selecting the most appropriate specimen geometry. Figure 9 shows the effect of

geometry on the  $K$ -gradient through a variety of specimen geometries. Specimens with shallower  $K$ -gradients are preferable for brittle materials, while the opposite is true for ductile materials.

FIG. 9  $K$ -GRADIENTS FOR A NUMBER OF FATIGUE CRACK GROWTH SPECIMENS. SOURCE: REF 7, 17

**Equipment Considerations.** Specimen size and geometry can also be influenced by laboratory equipment such as the loadframe, loadcell, existing loading fixtures, testing environment, and even the crack length measurement apparatus. To minimize cost, specimen sizes and geometries should be selected to use existing clevises, pins, and other hardware.

Most modern mechanical testing laboratories exclusively use electroservohydraulic loadframes for FCGR investigations. Current controls and data acquisition technology have hydraulic load-frames more versatile than the electromechanical systems used in previous years. When selecting a specimen geometry and size, one must be aware of the load capacity of the actuator and load-frame. Loads that are too high cannot be applied, and those that are too low cannot be controlled with the required accuracy ( $\pm 2\%$ ). In addition, the load cell to be used during testing must be able to measure the maximum applied load and resolve the lowest expected amplitudes, as specified in ASTM E 4.

When testing in environments, specimens fit inside ovens, furnaces, or other chambers with ample space left for clevises, cantilever beam clip gages, and other hardware. Special notch geometries or knife edge attachment locations are often necessary for attaching clipgages or other types of extensometers for nonvisual crack length measurements using compliance techniques.

**Notch and Specimen Preparation.** The method by which a notch is machined depends on the specimen material and the desired notch root radius ( $\rho$ ). Sawcutting is the easiest method but is generally acceptable only for aluminum alloys. For a notch root radius of  $\rho \cdot 0.25$  mm (0.010 in.) in aluminum alloys, milling or broaching is required. A similar notch root radius in low- and medium-strength steels can be produced by grinding. For high-strength steel alloys, nickel-base superalloys, and titanium alloys, electrical discharge machining may be necessary to produce a notch root radius of  $\rho \cdot 0.25$  mm (0.010 in.).

The specimen is polished to allow measurement of the crack during the precracking and testing phases of the experiment. Many specimens can be polished using standard metallography practices. In some cases, etching of the polished surface may provide better contrast for viewing of the crack. If the specimen is too large or small to be handled, then hand grinders, finishing sanders, or handheld drills can be used with pieces of polishing cloth to locally apply the abrasive and create a satisfactory viewing surface. These techniques are quick and easy to apply, and they are often used when visual measurements are made only during precracking and subsequent measurements are made by automated techniques such as electric potential or compliance.

**Precracking.** The  $K$ -calibration functions found in ASTM E 647 and E 399 are valid for sharp cracks within the range of crack length specified. Consequently, before testing begins a sharp fatigue crack that is long enough to avoid the effects of the machined notch must be present in the specimen ( $0.1B$ , or  $0.1H$ , or 1 mm [0.040 in.], whichever is greatest). The

process that generates this crack is termed precracking. In general, loads for precracking should be selected such that the  $K_{\max}$  at the end of precracking does not exceed levels expected at the start of a test.

For most metals, precracking is a relatively simple process that can be performed under load or displacement control conditions. Moderate growth rates ( $1 \times 10^{-5}$  m/cycle) can be selected by estimating the necessary  $\Delta K$  from growth curves in the literature. Precracking of a specimen prior to testing is conducted at stress intensities sufficient to cause a crack to initiate from the starter notch and propagate to a length that will eliminate the effect of the notch. To decrease the amount of time needed for precracking to occur, common practice is to initiate the precracking at a load above that which will be used during testing and to subsequently reduce the load.

Load generally is reduced uniformly to avoid transient (load-sequence) effects. Crack growth can be arrested above the threshold stress-intensity value due to formation of the increased plastic zone ahead of the tip of the advancing crack. Therefore, the step size of the load during precracking should be minimized. Under these circumstances, the loads should be shed no faster than 20% (per increment of crack extension, as discussed below) from the previous load increment (Ref 7). This will eliminate load-sequence effects on growth rates. As the crack approaches the final desired size, this percentage can be decreased.

The amount of crack extension between each load decrease must also be controlled. If the step is too small, the influence of the plastic zone ahead of the crack may still be present. To avoid transient (load-sequence) effects in the test data, as discussed above, the load range in each step should be applied over a crack-length increment of at least  $(3\pi) (K'_{\max}/\sigma_{ys})^2$ , where  $K'_{\max}$  is the terminal value of  $K_{\max}$  from the previous load step. This requirement ensures that the crack extension between load sheds is at least three plastic zone diameters.

The influence of the machined starter notch must be eliminated so that the crack tip conditions are stable. For compact-type and center-cracked tension specimens, this requires that the final precrack be at least 10% of the thickness of the specimen or equivalent to the height of the starter notch, whichever is greater (Ref 7).

Two additional considerations regarding crack shape are the amount of crack variation from the front and back sides of the specimen and the amount of out-of-plane cracking. Due to microstructural changes through the specimen thickness, residual stresses (particularly in weldments), or misalignment of the specimen in the grips, the crack may grow unevenly on the two surfaces. If any two crack length measurements vary by more than  $0.025W$  or by more than  $0.25B$  (whichever is less), the precracking operation was not suitable and test results will not be valid. If a fatigue precrack departs more than  $\pm 5^\circ$  from the plane of symmetry, the specimen is not suitable for subsequent testing.

**Precracking of Brittle Materials.** Brittle materials such as intermetallics and ceramics can be very difficult to precrack. It is not uncommon to initiate a flaw that immediately propagates to failure. This is due, in part, to the increasing  $K$ -gradient found in FCGR specimens and the relatively narrow range of  $\Delta K$  for stable crack growth.

To improve the chances of successful precracking of brittle materials, chevron notches are advised. Chevron-notched specimens (Fig. 10) are used for determining the fracture toughness of brittle materials that are difficult to fatigue precrack. Chevron notches generate decreasing  $K$ -gradients at the start of precracking and may be machined as part of the specimen, or they may be added just prior to testing using a thin diamond wafering blade. The maximum slope of the chevron notch should be  $45^\circ$ . Precracking of brittle materials should be performed under displacement control conditions, so that as the crack extends, the load and the applied  $K$  decrease. Lastly, the loads should be increased slowly from low levels due to the stochastic nature of crack initiation in these materials. If initiation is especially difficult, compressive overloads may assist the process. It is also helpful to monitor the initiation process with a method other than optical observation. Electric potential techniques (bulk and foil) and back face strain compliance techniques are very effective.

FIG. 10 SCHEMATIC OF CHEVRON NOTCHES IN FRACTURE MECHANICS SPECIMENS. THE SHADED AREA (B) IS THE CRACK AREA.

Once precracking has been completed, an accurate optical measurement of the initial crack length,  $a_0$ , must be made on both sides of the specimen to within 0.10 mm (0.004 in.) or  $0.002W$  (whichever is greatest), or to within 0.25 mm (0.01 in.) for specimens where  $W > 127$  mm (5 in.). If the crack lengths on the two surfaces differ by more than  $0.25B$ , then the test will not be valid, because  $K$ -calibration functions presume the existence of a straight crack front. Middle-tension specimens further require that both halves of the precrack be the same length to within  $0.025W$ . In addition, ASTM E 647 requires that cracks lie on the centerline such that the crack is no more than  $\pm 20^\circ$  from a centerline over a distance  $0.1W$ . Once the precrack has been measured and side-to-side variation and distance from centerline have been established, testing may begin. Additional information on fatigue testing of brittle materials is in "Fatigue of Brittle Materials" in this Volume.

**Gripping of the specimen** must be done in a manner that does not violate the stress-intensity solution requirements. For example, in a single-edge notched specimen, it is possible to produce a grip that permits rotation in the loading of the specimen, or it is possible to produce a rigid grip. Each of these requires a different stress-intensity solution. In grips that are permitted to rotate, such as the compact-type specimen grip, the pin and hole clearances must be designed to minimize friction. It is also advisable to consider lateral movement above and below the grips.

When appropriate, the use of a lubricant is recommended to reduce friction. In thick samples, the amount of bending in the pins should be minimized. Finally, the alignment of the system should be checked carefully to avoid undesirable bending stresses, which generally cause uneven cracking. Alignment can be easily checked using a strain gage specimen of a geometry similar to that used in the test program. Generally, bending strains should not exceed 5% of the nominal strain to be used in the test program.

Gripping arrangements for compact-type and center-cracked tension specimens are described in ASTM E 64 (Ref 7). For a center-cracked tension specimen less than 75 mm (3 in.) in width, a single pin grip is generally suitable. Wider specimens generally require additional pins, friction gripping, or some other method to provide sufficient strength in the specimen and grip to prohibit failure at undesirable locations, such as in the grips.

## Fatigue Crack Growth Testing

Ashok Saxena and Christopher L. Muhlstein, Georgia Institute of Technology

---

## Crack Length Measurement

Precise measurements of fatigue crack extension are crucial for the determination of reliable crack growth rates. ASTM E 647 requires a minimum resolution of 0.1 mm (0.004 in.) in crack length measurement. Crack extension measurements are recommended at intervals that are 10 times the minimum required resolution.

Various crack measurement techniques have been applied, including optical (visual and photographic), ultrasonic, acoustic emission, electrical (eddy current and resistance), and compliance (displacement and back face strain gages) methods. Optical, compliance, and electric potential difference are the most common laboratory techniques, and their merits and limitations are reviewed in detail in the following sections. Other references are listed in "Selected References" at the end of this article and in the article "Detection and Monitoring of Fatigue Cracks" in this Volume.

## Optical Crack Measurement

Monitoring of fatigue crack length as a function of cycles is most commonly conducted visually by observing the crack at the specimen surfaces with a traveling low-power microscope at a magnification of 20 to 50 ×. Crack-length measurements are made at intervals such that a nearly even distribution of  $da/dN$  versus  $\Delta K$  is achieved. The minimum amount of extension between readings is commonly about 0.25 mm (0.010 in.).

For planar specimens, the crack length is measured on one or both surfaces, depending on the section thickness. For example ASTM E 647 (Ref 7) specifies a  $B/W$  value of 0.15 as the limit; measurements on only one side are sufficient if  $B/W < 0.15$ .

Through-thickness variations in crack length must be considered and corrected for if too severe. Typical behavior is for the crack length to lead at the midplane (crack tunneling). Because this cannot be observed in situ by visual monitoring, post-test observations must be made. Rough alignment of the traveling microscope can be easily achieved by shining a pen light through the eyepiece on the crack-tip region. To ensure accurate crack measurements, obliquely incident light on a well-polished specimen surface is an effective means of highlighting fine cracks. High-intensity strobe lights with adjustable function generators are used to allow "motion free" viewing of cracks during high-frequency tests. The development of extra-long focal length optics has added new functionality to optical techniques. These microscopes allow the in situ observation and image analysis of crack-tip processes while keeping the instruments a reasonable distance (>381 mm, or 15 in.) from the specimen and other testing hardware.

To account for through-thickness crack-length variation, ASTM E 647 recommends measuring the crack length at five points along the crack front contour and averaging the five readings. If the average of the five points exceeds the surface length by more than 5%, the average length is used in computing the growth rate and  $K$ .

The optical technique is straightforward and, if the specimen is carefully polished and does not oxidize during the test, produces accurate results. However, the process is time consuming, subjective, and can be automated only with complicated and expensive video-digitizing equipment. In addition, many fatigue crack growth rate tests are conducted in simulated-service environments that obscure direct observation of the crack. The trend toward laboratory automation has resulted in the development of indirect methods of determining crack extension, such as specimen compliance and electric potential monitoring.

## Compliance Method

Under linear elastic conditions for a given crack size, the displacement,  $v$ , across the load points or at any other locations across the crack surfaces is directly proportional to the applied load ( $P$ ). The compliance,  $C$ , of the specimen is defined as

$$C = \frac{v}{P} \quad (\text{EQ 11})$$

The relationship between dimensionless compliance,  $BEC$ , where  $B$  is the thickness and  $E$  is the elastic modulus, and the dimensionless crack size,  $a/W$ , where  $W$  is the specimen width, is unique for a given specimen geometry (Ref 21). Thus:

$$BEC = f\left(\frac{a}{W}\right) \quad (\text{EQ 12})$$

The inverse relationship (Ref 21) between crack size and compliance can be written as  $a/W = q(u)$  where  $u = [1 + BEC]^{0.5}$ . This relationship may be determined numerically using finite element techniques or by experiment. ASTM E 647 also specifies these relationships for compact-type and middle-tension specimens.

The compliance of an elastically strained specimen (expressed as the quotient of the displacement,  $v$ , and the tensile load,  $P$ , per Eq 11) is determined by measuring the displacement along, or parallel to, the load line. Figure 11 illustrates that the more deeply a specimen is cracked, the greater the amount of  $v$  measured for a specific value of tensile load. Additional information on the calculation of compliance and the method can be found in the "Selected References" listed at the end of this article.

FIG. 11 SCHEMATIC OF THE RELATIONSHIP BETWEEN COMPLIANCE AND CRACK LENGTH. (A)  $C(A_0) = V_0/P$ . (B)  $C(A_1) = V_1/P$

**Instrumentation.** The displacement usually is measured across the crack mouth opening using cantilever beam clip gages, optical (laser and white light) extensometry, or back face strain gages. Linear variable differential transducers have been used, but hysteresis in their response can sometimes be a problem. Each of these techniques has its own advantages and may be used to continuously monitor crack length. An additional benefit of compliance techniques is that the same signal can be used for determining crack closure, as discussed below.

Cantilever beam clip gages based on resistive and capacitance strain gage technology are well suited for elevated (<370 °C) and high-temperature tests (up to 1200 °C), respectively. Deflection of the arms is measured by the output of the strain gages mounted on the clip gage arms. Extensometer and transducer design theory is well established in the

literature (Ref 17, 22). Attachment of clip gages to the specimen is achieved through integral, machined knife edges or by knife edge blocks bolted to the front face of the specimen across the crack plane.

Optical extensometry techniques include those based on fiber optics and laser technology. There are two main types of optical extensometry used in compliance measurement. The first are advanced laser systems that track the motion of spots projected on the specimen. In this case the transmitter and receiver are located on the same side of the specimen. A second group of extensometers measure the width of the notch using a transmitter and receiver on opposite sides of the specimen. Laser and white light systems based on these principles are available commercially. Optical systems may have restrictions on their frequency response. Like optical crack length measurement techniques, most optical extensometry techniques are difficult to use when testing at elevated temperatures or in environmental chambers.

An electrical resistance strain gage mounted opposite the notch on the back face of the fatigue specimen is termed a back face strain (BFS) gage. Just as with the clip gage, the load-strain signal from the BFS gage may be used to determine the crack length in the specimen. While conventional strain gages are limited to elevated temperatures (<370 °C) in gaseous or aqueous environments, they have the advantage of directly measuring strain without the application of a force. The direct measurement of strain eliminates frequency limitations associated with clip gages at the expense of having no geometric amplification of the strains or the sensitivity benefits of a four active leg Wheatstone bridge (Ref 22). BFS is especially useful for nonmetallic materials where integral knife edges and tapped holes for knife edge blocks are difficult to machine.

The required sensitivity of the systems depends on specimen geometry and sizes. In general, noise-free, amplified output on the order of 1 V direct current (dc) per 1 mm (0.04 in.) of deflection is satisfactory. Similarly, for the load range applied to the specimen, an approximately 1 V dc change in signal from the load cell is required for accurate calculation of the compliance.

**Attachment of Displacement Measurement Hardware.** One of the most important factors affecting the accuracy of crack-opening displacement measurements is the manner in which the displacement transducer is attached to the test sample. Transducers for measuring the crack-opening displacement commonly consist of cantilevered arms affixed across the crack. When the crack is opened, deflections either in the arms, or in a flexure attached to the arms, induces measurable strains, which are ultimately converted to displacements.

To prevent slipping of the gage during testing, the gage must have an adequate, well-documented clamping force (~2500 g). This force must be added to the mean tensile load applied to the specimen by the gage during data analysis. For thin or small specimens, this gage-induced mean load may be high enough to preclude testing at the desired load levels. Even with high clamping forces, there will be a limitation on the maximum testing frequency for the gage due to the excitation of resonant modes in the gage or inadequate clamping force. If necessary, higher frequencies can be achieved by bolting the clip gage to the specimen.

The transducer can be bolted across the crack opening at the point of testing, or it can be attached to the specimen through hardened knife-edge pivots that are mechanically or adhesively affixed to the specimen. The transducer can also be affixed via knife-edge contacts that are machined into the test sample. For elevated-temperature testing, feed-rod systems are frequently used.

The bolt-on system of attaching the transducer to the test specimen (Fig. 12) is capable of reacting to high acceleration loads. These result from higher-frequency dynamic testing when the rocking moment generated by the mass of the transducer is carried to the bolt-on attachment through the transducer frame. This attachment system is preferred when a transducer has high mass or an effective mass center that is located a great distance from the specimen contact pads.

**FIG. 12 BOLT-ON ATTACHMENT OF CRACK-OPENING DISPLACEMENT TRANSDUCER TO FATIGUE TEST SPECIMEN**

The bolt-on system also provides accurate crack-opening displacement measurements on specimens tested under environments that are not conducive to the use of knife edges, such as elevated-temperature or corrosive environments. In addition, the bolt-on attachment system allows the use of stiffer cabling without disturbing the measurement. For example, a displacement transducer with relatively rigid stainless steel-jacketed cabling can be used to make measurements in pressurized high-temperature water/steam environments.

Hardened knife-edge pivot contacts (Fig. 13) provide a measurement system with minimal sliding action; the knife edge rocks in a hardened seat in the transducer arm. This allows measurements to be made with very low hysteresis levels. Contact and seat ramp angles can be designed for optimal tradeoffs between static and dynamic measurement accuracy, dynamic stability, and contact durability. Male knife-edge contact replacements are relatively low in cost, and various configurations are available, such as three-point contact, line contact, large radius, and small radius.

**FIG. 13 BOLT-ON HARDENED KNIFE-EDGE ATTACHMENT OF CRACK-OPENING DISPLACEMENT TRANSDUCER**

## TO FATIGUE TEST SPECIMEN

Knife-edge contacts that are machined into the test sample (Fig. 14) eliminate the possibility of knife-edge screws loosening, which results in slippage and hysteresis. The compressed initial gage length can be machined to the required tolerance.

FIG. 14 ATTACHMENT OF CRACK-OPENING DISPLACEMENT TRANSDUCER TO SPECIMEN BY MACHINED KNIFE-EDGE CONTACTS

**Computing Normalized Compliance.** When measuring the compliance of a fatigue specimen, the usual practice is to compute a normalized compliance ( $EBv/P$ ). This normalized compliance is plotted against a normalized crack length,  $a/W$ . For standard geometries, such as a compact-type specimen, this relationship has the form shown in Fig. 15. Thus, from the measured compliance, a crack length can be obtained from the known analytical relationships as shown in Fig. 15 (Ref 21). Note that when the crack is short ( $a/W \sim 0.2$  to  $0.4$ ), the compliance is less sensitive to changes in crack length than when the crack length is long ( $a/W > 0.5$ ). Thus, the sensitivity of the compliance method is significantly improved for the longer crack lengths, both because of this relationship and because the amount of crack mouth opening and the resulting displacement gage signal are larger. The amount of displacement or crack mouth opening that is measured is a strong function of the location of the line of measurement of the gage with respect to the load line, which is the reference point for crack extension. The farther away from the crack tip the measurement can be made, the more displacement that will be incurred, and the sensitivity of the method will be improved proportionately.

FIG. 15 COMPARISON OF PREDICTED AND EXPERIMENTAL COMPLIANCE FOR A COMPACT-TYPE FATIGUE SPECIMEN

**Data Acquisition and Processing.** The signals from the load cell and displacement gage must be obtained simultaneously in order for this method to work to its best advantage. In the most direct case, the two signals can be fed to an  $x$ - $y$  recorder, with the load applied to the  $y$ -axis and displacement to the  $x$ -axis. At various intervals during the test, a trace of the two signals can be made. If the test is being conducted at a reasonably high frequency ( $>1$  Hz), then the frequency will have to be reduced so that the slow rate of the recorder can keep up with the changing voltage. This is not a problem if a transient recorder is used and the results from the two channels (load and displacement) are co-plotted. The slopes of the recorder traces can be measured, multiplied by suitable calibration factors, and used in the compliance to crack length relationship.

A more sophisticated method is to use a computerized data acquisition system to obtain load displacement data. These systems are usually faster and thus can accept data from rather high-frequency waveforms. In addition, software can be developed to perform the calculations involved in processing the compliance data to crack length. Software to perform fatigue crack growth rate measurements is generally available from manufacturers, but most researchers write their own data acquisition packages, perhaps using some of the manufacturer-supplied subroutines that are specific to the hardware involved.

Additionally, data should be taken between about 10 and 90% of the load range. Eliminating the top and bottom fractions of the load range avoids problems of crack closure (at loads approaching zero) or incipient plasticity (near the load maximum, at longer crack lengths). The sets of load-displacement pairs are fitted to a straight line, the slope of which is used in the compliance expression.

### Electric Potential Difference Method

The electrical potential, or potential drop, technique has gained increasingly wide acceptance in fracture research as one of the most accurate and efficient methods for monitoring the initiation and propagation of cracks. This method relies on the fact that there will be a disturbance in the electrical potential field about any discontinuity in a current-carrying body, the magnitude of the disturbance depending on the size and shape of the discontinuity.

For the application of crack growth monitoring, the electric potential method entails passing a constant current (maintained constant by external means) through a cracked test specimen and measuring the change in electrical potential across the crack as it propagates. With increasing crack length, the uncracked cross-sectional area of the test piece decreases, its electrical resistance increases, and thus the potential difference between two points spanning the crack rises. By monitoring this potential increase,  $V_a$ , and comparing it with some referencing potential,  $V_0$ , the ratio of crack length to width,  $a/W$ , can be determined through the use of the relevant calibration curve for the particular test piece geometry concerned. The crack length is expressed as a function of the normalized potential ( $V/V_0$ ) and the initial crack length ( $a_0$ ) (Fig. 16).

FIG. 16 POTENTIAL RESPONSE FOR A COMPACT-TYPE SPECIMEN

Accuracy of electrical potential measurements of crack length may be limited by a number of factors, including the electrical stability and resolution of the potential measurement system, electrical contact between crack surfaces where the fracture morphology is rough or where significant crack closure effects are present, and changes in electrical resistivity with plastic deformation. Another key factor is the determination of calibration curves relating changes in potential across the crack ( $V_a$ ) to crack length ( $a$ ). In most instances, experimental calibration curves have been obtained by measuring the electrical potential difference: across the machined slots of increasing length in a single test piece; across a growing fatigue crack, where the length of the crack at each point of measurement is marked on the fracture surface by a single overhead cycle or by a change in mean stress; across a growing fatigue crack in thin specimens where the length of the crack is measured by surface observation.

Other experimental calibrations have been achieved using an electrical analog of the test piece, where the specimen design is duplicated, usually with increased dimensions for better accuracy, using graphitized analog paper or thin aluminum foil, and where the crack length can be increased simply by cutting with a razor blade. Such calibration procedures, however, are relatively inaccurate, particularly at short crack lengths, and are tedious to perform. Furthermore, where measurements of crack initiation and early growth are required ahead of short cracks or notches of varying acuity, such procedures demand a new experimental calibration to be obtained for each notch geometry.

Electric potential response may be determined empirically (Ref 23, 24, 25) or using numerical methods such as finite element or conformal mapping techniques (Ref 26, 27, 28, 29, 30). Johnson's analytical solution of the middle-tension geometry is widely used in experimental work due to its flexibility (Ref 28):

$$a = \frac{W}{\pi} \cos^{-1} \left[ \frac{\cosh\left(\frac{\pi}{W} \times Y_0\right)}{\cosh\left[\frac{V}{V_0} \times \cosh^{-1}\left[\frac{\cosh\left(\frac{\pi}{W} \times Y_0\right)}{\cos\left(\frac{\pi}{W} \times a_r\right)}\right]\right]} \right] \quad (\text{EQ 13})$$

for  $0 \leq 2\frac{a}{W} \leq 1$

where  $a$  is the crack size,  $a_r$  is the reference crack size from other method,  $W$  is the specimen width,  $V$  is the measured electric potential difference,  $V_r$  is the measured voltage corresponding to  $a_r$ , and  $Y_0$  is the voltage measurement lead spacing from crack plane. With minor modifications, Eq 13 can be applied to edge-cracked geometries by treating them as half of a middle-tension geometry. Third or higher-order polynomial expressions with coefficients obtained from regression analysis can be used to describe the potential response of the specimens when simplified expressions are required or Eq 13 does not apply.

The electric potential technique may be used with alternating current (ac) or dc power supplies. Alternating current systems have lower power requirements and do not suffer from the thermally induced potentials that plague dc systems. On the other hand, dc systems are widely used because of their relative simplicity. Consequently, this discussion of typical experimental setups is restricted to dc systems.

The main component of a dc electric potential system is a power supply. The operating parameters for such a system are applied currents from 5 to 50 A and output voltages from 0.1 to 50 mV. Power supplies must be stable to 1 part in  $10^4$  or better, and nano- or microvoltmeters with a resolution of 0.05 to 0.5  $\mu\text{V}$  are used (Ref 7). It is crucial that all dc potential measurement equipment (e.g., power supplies, voltage meters, etc.) and the loadframe itself be properly grounded. Before a power supply or nearby electromagnetic field (EMF) source (e.g., induction heater) is faulted for poor performance of the electric potential technique, researchers are reminded to check that all equipment is properly grounded. In some cases, EMF shielding may be required.

High-resolution, stable, properly grounded equipment does not guarantee reliable performance and high resolution for the dc potential difference technique. Proper selection and use of current and potential leads are essential. High-current (welding) cable is ideal for current input leads, which are usually bolted to the specimen. To reduce noise, the potential leads should be firmly attached to the specimen, shielded, and twisted together. To ensure that current will pass through the specimen, the ratio of the loadtrain resistance to that of the specimen must be on the order of  $10^4$ . If this cannot be achieved, the specimen must be electrically isolated using nonconducting (e.g., alumina) pins and washers or sleeves. The current applied to the specimen should be large enough to produce a measurable potential. Table 1 lists typical current and output voltages for compact-type (CT) specimens of steel, aluminum, and titanium. Excessive current ( $>10$  A) can cause heating of the specimen and should be avoided. Potential leads should be made from fine wire of the same material as the specimen to reduce thermally induced EMF. Potential measurement leads and equipment should be kept away from EMF sources such as transformers to further reduce noise.

**TABLE 1 TYPICAL EPD VOLTAGES AS MEASURED ON A STANDARD COMPACT-TYPE SPECIMEN**

ALUMINUM	0.1	300
STEEL	0.6	50

TITANIUM	3.5	9
----------	-----	---

Based on  $a/W = 0.22$ ,  $B = 7.7$  mm, and  $W = 50$  mm. Lead geometry per Ref 7 and direct current of 10 A

Crack tip processes such as fatigue crack closure (see the section "Crack Closure" in this article) can reduce the potential of the specimen as the crack faces come together, effectively shortening the crack. This is especially a problem when testing materials that do not form protective, nonconducting oxide layers in the environment of interest. The solution to this problem is to measure the potential output at the peak load. In addition to crack closure, crack-tip plasticity and distributed damage such as microcracking must be considered. Large plastic zones such as those encountered under elastic-plastic conditions disturb the equipotential lines much like the crack (Ref 31). Distributed damage processes can also complicate measurements by making it difficult to define a continuous crack. Hence, optical measurements of the crack should be made to ensure that the electric potential difference technique provides a realistic representation of crack length. Changes in the electrical properties of the material can also limit the effectiveness of dc potential systems.

Changes in conductivity can complicate electric potential measurements. When high-conductivity materials such as aluminum are tested, temperature fluctuations of  $\pm 1$  °C will cause a change in potential on the order of a few  $\mu\text{V}$  due to the temperature dependence of conductivity, and this change may vary with time. This can limit the crack extension resolution. Environmental chambers are useful with high-conductivity materials, even when testing at room temperature.

The primary difficulty with the dc electric potential technique is the junction potentials created at points of current and potential lead attachment. When dissimilar materials are in contact, a potential is generated due to the thermocouple effect, and it may be of the same order of magnitude as the potential generated by the specimen. This thermally induced potential, also known as the thermal voltage, may not be constant. Consequently, care must be taken to separate changes in potential due to fluctuations in thermal voltage from changes due to crack extension. This is especially important when measuring the slow growth rates found in the near-threshold regime.

There are three common approaches to accounting for the thermal voltage. The first method is to periodically turn off the power supply, note the value of thermal voltage, and subtract it from the output of the specimen with the current applied. This approach is acceptable for manually run tests, but it is not very useful when a continuous signal is required for computer-controlled tests. One alternative to manual measurement of the thermal voltage is to apply a current to an uncracked specimen with no applied load in the same environment as the test specimen in the "reference potential" technique. The tendency of the thermal voltage to drift should be the same in both the cracked and uncracked specimens. The drift can then be monitored, and the thermal voltage simply becomes an offset. Attempts have been made to apply the reference potential technique to a single specimen by measuring potentials in areas of the specimen that are "insensitive" to crack extension. The development of high-current-capacity solid-state switches has made the use of fully reversed electric potential drop systems a third method for dealing with thermal voltages. If the direction of current flow is periodically reversed, the thermal voltage, which has a fixed polarity, will shift the maximum and minimum output potentials but will not influence the range or amplitude of the signal. Thus, the amplitude of the output potential can be used to determine the length of the crack.

The electric potential technique may also be applied to nonconducting specimens with the use of conducting thin foils. The foils are applied prior to testing, and they crack with the underlying specimen. Current is applied to the foil instead of to the specimen, and the calibrated response of the foil may be used to monitor the growth of the crack. This technique may be used for room- and elevated-temperature tests, provided that the foil accurately reflects the growth of the crack. Polymer-backed gages sold under the trade name KrakGage require special hardware for mounting and use and may be used with conducting or nonconducting specimens. It is also possible to vapor deposit gages directly to nonconducting specimens or to nonconducting oxide films on conducting or nonconducting (e.g., SiC) materials. The drawback of electric potential foils is the tendency for cracks with small opening displacements to "tunnel" under the gage. This crack extension without breaking the foil will lead to inaccurate growth rates.

**Optimization Parameters.** In any specimen geometry, there are numerous locations for both the current input leads and the potential measurement probes. Optimization of the technique involves finding the best locations, considering accuracy, sensitivity, reproducibility, and magnitude of output (measurability).

In practice, the accuracy of the electrical potential technique may be limited by several factors, such as the electrical stability and resolution of the potential measurement system, crack front curvature, electrical contact between crack surfaces where the fracture morphology is particularly rough or where significant crack closure effects are present, and changes in electrical resistivity with plastic deformation, temperature variations, or both.

Reproducibility refers to inaccuracies produced by small errors in positioning the potential measurement leads. Such leads are generally fine wires that are spot welded or screwed to the specimen, and accurate positioning is typically no better than within 0.5 mm (0.02 in.). To maximize reproducibility, these leads should be placed in an area where the calibration curve is relatively insensitive to small changes in position--that is, where  $dV/dx$  and  $dV/dy$  are small, where  $x$  and  $y$  are position coordinates-- with the origin at the midpoint of the specimens. This consideration is often at variance with sensitivity considerations for measuring small changes in crack length.

To optimize measurability (i.e., signal-to-noise ratios), current input and potential measurement lead locations are chosen to maximize the absolute magnitude of the output voltage signal  $V_a$ . As output voltages are generally at the microvolt level and because of the high electrical conductivity of metals, a practical means of achieving measurability is simply to increase the input current. However, there is a limit to this increase, because when the current is too large (typically exceeding 30 A in a 12.7 mm, or 0.5 in., thick *1T* steel compact-type specimen), appreciable specimen heating can result from contact resistance at current input positions.

Studies have shown that there must be a compromise between the sensitivity, reproducibility, and magnitude of the output signal when using electric potential techniques. In the case of compact-type specimens, it has been shown that potential leads are best placed on the notched side of the specimen, as close to the mouth as possible, as recommended by the ASTM E 647. When using nonstandard geometries, the reader is encouraged to use the above references to ensure a sound basis for lead placement.

## Fatigue Crack Growth Testing

Ashok Saxena and Christopher L. Muhlstein, Georgia Institute of Technology

---

## Loading Methods

The goal of a fatigue crack growth rate test is to generate a record of crack length ( $a$ ) versus number of cycles ( $N$ ) under specified loading conditions. This information can be generated by applying cyclic varying loads of specified amplitude and frequency.

The frequency of the test should, when possible, be kept constant. However, it may be necessary to reduce the frequency of a test in order to make crack length measurements. Frequency effects are usually not observed in metals in laboratory air at room temperature over the range of typical testing frequencies (1 to 100 Hz). Although higher-frequency tests finish more quickly, specimen and loadtrain stiffness, as well as load range, impose a practical limit on the maximum testing frequency. Steel specimens that are 50 mm wide can be run on a typical 90 kN (20 kilo pounds) capacity loadframe at 25 to 50 Hz. If compliance methods are being used to control the test or monitor crack extensions, the frequency response of the clip gage and recording instruments may limit the maximum frequency for testing.

The waveform to be used during a test is usually a sine or sawtooth (ramp) shape. Both waveforms will generate similar data at room temperature in benign environments. However, sine waveforms are easier for servohydraulic systems to control. Ramp waveforms should be used when elevated-temperature FCGR and creep-fatigue interaction are of interest (see the section "High-Temperature Fatigue Crack Growth Testing" in this article) or when testing in aqueous environments (Ref 32).

Five types of FCGR tests are used in laboratories today. How the specimen is loaded defines the type of growth rate test. Different types of tests are often conducted in series to confirm growth rates and to use as much of the specimen as possible. To avoid load sequence effects, tests conducted in series should adhere to the same guidelines specified for precracking.

The simplest test type is one in which the load amplitude is kept constant and the applied  $\Delta K$  increases as the crack extends. The simplicity of the test is its advantage. However, this test is essentially impractical for crack growth rates below  $1 \times 10^{-8}$  (m/cycle). In a second type of test, loads are shed manually at increments of 10% or less. Although cumbersome because they require constant attention, these tests allow the generation of data for slower crack growth in a more time-efficient manner than the constant-load-amplitude test. The prevalence of personal computers and modern controls technology in today's laboratories has popularized the remaining three types of so-called "continuous loadshedding" or " $K$ -controlled" experiments.

**Continuous loadshedding** tests are those in which loads are shed at steps of 2% or less for a predetermined increment of crack extension. During these tests the crack length is continuously monitored by electric potential, compliance, or another suitable technique. Loads are shed or increased according to the following relation proposed by Saxena et al. (Ref 33):

$$\Delta K = \Delta K_0 \text{ EXP } [C(A - A_0)] \quad (\text{EQ 14})$$

where  $\Delta K$  is the applied range of  $\Delta K$ ,  $\Delta K_0$  is the initial range of  $\Delta K$ ,  $a$  is the current crack length,  $a_0$  is the crack length at the beginning of the test, and  $c$  is the normalized  $K$ -gradient. The normalized  $K$ -gradient is defined as:

$$c = \frac{1}{K} \left( \frac{dK}{da} \right) [L^{-1}] \quad (\text{EQ 15})$$

The use of Eq 14 for changing fatigue loads is ideally suited for personal computers, and it allows testing under  $K$ -controlled conditions. If the normalized  $K$ -gradient is less than zero, the applied  $\Delta K$  will be decreased as the crack extends. These are termed  $K$ -decreasing tests. Conversely,  $c > 0$  will lead to increasing  $\Delta K$  as the crack extends.

The appropriate value of  $c$  for a decreasing  $\Delta K$  test is that which avoids the anomalous growth rates caused by shedding loads too quickly. Investigators have determined that  $c = 0.08 \text{ mm}^{-1}$  ( $-2 \text{ in.}^{-1}$ ) is an appropriate value for decreasing  $\Delta K$  tests on most metals (Ref 34). This value of  $c$  was derived to eliminate load-interaction effects caused by crack-tip plasticity in metals. The same value of  $c$  for a  $K$ -decreasing test in intermetallics and ceramics is recommended because it ensures that sufficient data can be obtained over the narrow range of stable crack growth, even though plastic zones are considerably smaller or nonexistent in these materials (Ref 35, 36).

Increasing  $\Delta K$  tests (i.e.,  $c > 0$ ) are usually conducted after a decreasing test to confirm the growth rates measured during the previous  $K$ -decreasing portion of the test. Increasing  $\Delta K$  tests may, if necessary, be conducted with larger normalized  $K$ -gradients. It is important to note that during an increasing  $\Delta K$  test, loads may have to be decreased as the crack extends, which could lead to difficulties with control. Hence, it is preferable to use the simple constant amplitude instead of a controlled increasing  $\Delta K$  test.

The first type of continuous loadshedding test is where the load ratio ( $R$ ) is held constant. Constant- $R$  tests generate the same type of information as constant-amplitude tests. Low- and high- $R$  ( $R = 0.1$  and  $0.5$ , respectively) tests are usually conducted for comparison purposes.

Another type of  $K$ -controlled test is a constant- $K_{\max}$  test, which is essentially a variable- $R$  test. When  $K_{\max}$  is held constant as the crack extends,  $R$  will vary as shown schematically in Fig. 17. Once again, the value of  $\Delta K$  to be applied to the specimens is dictated by Eq 14. The advantage of this test is that it quickly establishes the role of  $R$  on crack growth rate. For decreasing  $\Delta K$  in constant- $K_{\max}$  tests with negative  $c$ , the lower crack growth rates are at very high values of  $R$ . The behavior of threshold cracks under these conditions has been used as a measure of "closure free" fatigue crack growth, reflecting the "intrinsic resistance" of the material to fatigue (Ref 37).

FIG. 17 CONSTANT  $K_{\max}$  TEST LOAD RATIO

The last type of continuous loadshedding fatigue test is a constant- $K_{\text{mean}}$  test. Much like the constant- $K_{\max}$  test, a constant- $K_{\text{mean}}$  test can be used as a comparison with constant  $K_{\max}$  to help establish the role of  $K_{\text{mean}}$  versus  $K_{\max}$  on fatigue crack growth rates. Constant- $K_{\max}$  and  $K_{\text{mean}}$  tests have been popular in the testing of brittle materials where definitive mechanisms for crack advance have yet to be established.

Once testing is complete, the final crack in the specimen should be measured optically on both sides of the specimen. This will be compared to the terminal crack length predicted by other measurement techniques in the analysis of the investigation.

**Electromechanical Fatigue Testing Systems.** The primary function of electromechanical fatigue testers is to apply millions of cycles to a test piece at oscillating loads up to 220 kN (50,000 lbf) to investigate fatigue life, or the number of cycles to failure under controlled cyclic loading conditions. Variables associated with fatigue-life tests are frequency of loading and unloading amplitude of loading (maximum and minimum loads), and control capabilities. The fundamental data output requirement is the number of cycles to failure, as defined by the application.

A variety of electromechanical fatigue testers have been developed for different applications. Forced-displacement, forced-vibration, rotational-bending, resonance, and servomechanical systems are discussed in this article and are compared in Table 2. Other specialized electromechanical systems are available to perform specific tasks.

**TABLE 2 COMPARISON OF ELECTROMECHANICAL FATIGUE SYSTEMS**

DISADVANTAGES	<b>NO LOAD CONTROL, VERY LIMITED APPLICATIONS (SOFT SAMPLES)</b>	<b>FIXED FREQUENCY, LIMITED CONTROL (OPEN-LOOP)</b>	<b>ROTATIONAL BENDING ONLY, LIMITED APPLICATIONS</b>	<b>OPERATING FREQUENCY DIRECTLY PROPORTIONAL TO SAMPLE STIFFNESS</b>	<b>LOW FREQUENCY ONLY</b>

Servo-hydraulic testing machines are particularly well suited for providing the control capabilities required for fatigue testing. Extreme demands for sensitivity, resolution, stability, and reliability are imposed by fatigue evaluations. Displacements may have to be controlled (often for many days) to within a few microns, and forces can range from 100 kN to just a few newtons. This wide range of performance can be obtained with servomechanisms in general and, in particular, with the modular concept of servo-hydraulic systems.

Usually, the problem of selecting the appropriate system is simply a matter of optimizing the various components to form a system best suited to the given testing application. With any type of control system, the objective is to obtain an output that relates as closely as possible to the programmed input. In a fatigue testing system, it may be desired to vary the force on a specimen in a sinusoidal manner, at a frequency of 1 Hz over a force range of 0 to 100 kN (0 to 22,000 lbf). The only practical means to accomplish this with precision is through the use of a negative-feedback closed-loop system.

## Fatigue Crack Growth Testing

Ashok Saxena and Christopher L. Muhlstein, Georgia Institute of Technology

## Analysis of Crack Growth Data

The two major aspects of FCGR test analysis are to ensure suitability of the test data and to calculate growth rates from the data. In addition to growth rate calculations, analysis also may require the calculation of fatigue crack closure levels and the characterization of fracture surface and metallographic features as discussed in this section. Combining the results from all of these areas is necessary to develop an understanding of the FCGR behavior of the material. Finally, the reliability of "real time" analysis by personal computers must be verified, and the sophisticated tests performed in today's laboratories must undergo some degree of analysis. Hence, it is essential that computer-controlled tests generate records of  $a$  versus  $N$  as well as FCGR.

**Validity of the Test Data.** The first step is to ensure the validity of the test data and make corrections to the crack length, if necessary. Crack measurement intervals are recommended in ASTM E 647 according to specimen type. For compact-type specimens:

$$\Delta a \leq 0.04 W \text{ for } 0.25 \leq \frac{a}{W} \leq 0.40$$

$$\Delta a \leq 0.02 W \text{ for } 0.40 \leq \frac{a}{W} \leq 0.60$$

$$\Delta a \leq 0.01 W \text{ for } \frac{a}{W} \geq 0.60$$

For center-cracked tension specimens:

$$\Delta a \leq 0.03 W \text{ for } \frac{a}{W} < 0.60$$

$$\Delta a \leq 0.03 W \text{ for } \frac{a}{W} > 0.60$$

At the end of the test, the final crack length is measured on both sides of the specimen. A comparison between optical measurements and the final predicted crack length by any non-optical techniques used should be made. Differences between the measured crack lengths should be corrected using a linear relationship. In other words, the error between the final measured and predicted crack size is linearly distributed over the crack extension range. If periodic optical measurements were made during the test, other more appropriate correction procedures can be used.

Thicker specimens should be fractured after testing to determine the degree of crack front curvature. Cooling the specimen to liquid nitrogen temperatures allows the brittle fracture of most metallic materials and reveals a clear demarcation between the fatigued and fractured portions of the specimen. Five evenly spaced measurements of crack length should be made across the crack front. The average length should then be used as the final crack length, and the corrections should be applied using this value instead of the surface measurements.

**Crack Growth Rate Calculation.** A number of different numerical techniques have been used to calculate crack growth rates from the set of  $(a_i, N_i)$  data points of a given crack growth rate test (Table 3). The secant and incremental polynomial methods are the most widely used. When the data are processed to a final smoothed  $da/dN = f(\Delta K)$  format, these methods provide approximately equivalent results. However, the scatter of individual  $da/dN$  values about the average depends greatly on the data reduction method.

**TABLE 3 METHODS FOR CALCULATING CRACK GROWTH RATES**

### INCREMENTAL POLYNOMIAL METHOD

A LEAST-SQUARES, SECOND-ORDER POLYNOMIAL IS OBTAINED FOR SUCCESSIVE SETS OF  $(2K + 1)$  DATA POINTS:

$$\hat{a}_i = b_0 + b_1 \left( \frac{N_i - C_1}{C_2} \right) + b_2 \left( \frac{N_i - C_1}{C_2} \right)^2$$

WHERE  $C_1 = (N_{I+K} + N_{I-K})/2$  AND  $C_2 = (N_{I+K} - N_{I-K})/2$  ARE CENTERING AND SCALING CONSTANTS, RESPECTIVELY, THAT ARE INTRODUCED TO PREVENT NUMERICAL PROBLEMS IN OBTAINING THE LEAST SQUARES FIT. THE CRACK GROWTH RATE AT  $\hat{a}_i$ , THE PREDICTED CENTRAL CRACK LENGTH AT  $N_i$ , IS GIVEN BY THE DERIVATIVE:

$$\left. \frac{da}{dN} \right|_{\hat{a}_i} = \frac{b_1}{C_2} + 2b_2 \frac{(N_i - C_1)}{C_2}$$

TYPICAL VALUES OF  $K$  ARE 1, 2, OR 3, RESULTING IN THE SECOND-ORDER POLYNOMIAL BEING ESTIMATED ON THE BASIS OF 3, 5, OR 7 SUCCESSIVE DATA POINTS. THE ESTIMATED CRACK GROWTH RATE FUNCTION LOSES  $K$  DATA POINTS AT EACH END. LESS APPARENT SCATTER IS OBTAINED FOR LARGER  $K$  VALUES.

### SECANT METHOD

IN THE SECANT METHOD FOR DIFFERENTIATING THE  $A$  VERSUS  $N$  DATA, THE AVERAGE CRACK EXTENSION PER CYCLE IS CALCULATED FOR EACH PAIR OF DATA POINTS, AND  $\Delta K$  IS CALCULATED AT THE MIDPOINT OF THE CRACK LENGTHS:

$$\left. \frac{da}{dN} \right|_{\hat{a}_i} = \frac{a_{i+1} - a_i}{N_{i+1} - N_i}$$

$$\hat{a}_i = \frac{a_{i+1} + a_i}{2}$$

THIS METHOD IS SIMPLE BUT EXHIBITS THE MOST SCATTER IN  $DA/DN$  VALUES.

### THE MODIFIED DIFFERENCE METHODS

THESE METHODS ARE FINITE DIFFERENCE TECHNIQUES FOR ESTIMATING THE DERIVATIVE AT THE MIDPOINT OF A DATA SET. THESE METHODS USE NUMERICAL DERIVATIVES. THE FORMULA FOR ESTIMATING THE DERIVATIVE AT THE MIDPOINT  $A_i$ , OF THREE SUCCESSIVE DATA POINTS IS GIVEN BY:

$$\left. \frac{da}{dN} \right|_{a_i} = \frac{a_i - a_{i-1}}{N_i - N_{i-1}} + \left[ \frac{N_i - N_{i-1}}{N_{i+1} - N_{i-1}} \right]$$

$$\left[ \frac{a_{i+1} - a_i}{N_{i+1} - N_i} - \frac{a_i - a_{i-1}}{N_i - N_{i-1}} \right]$$

The **secant method** fits a line between adjacent data points. The slope of the line is the crack growth rate,  $da/dN$ . The load at the average crack length of the interval is used to calculate the corresponding  $\Delta K$ . It is not uncommon to collect data points more closely spaced than the 0.25 mm (0.010 in.) minimum crack extension for growth rate calculations. When more data are available, a straight line through the multiple data points can be fitted by regression analysis to calculate crack growth rates. A 50% overlap between data sets used for calculating successive crack growth rates can considerably reduce scatter in the processed data. This method is termed the *modified secant method*.

The **polynomial method** uses the derivative of a second-order polynomial fitted to a fixed number of data points (often five or seven). The growth rate and  $\Delta K$  level are calculated for the average value of crack length in the interval. This method tends to provide data with less scatter than the secant method. In practice, there are no systematic differences in the  $da/dN$  versus  $\Delta K$  trends if the same data are processed by these different techniques (Ref 38). In fact, little difference is observed between the data processed by the modified secant method and the polynomial method.

**Variability.** Although the apparent variability in the resulting  $da/dN$  value depends on the calculation method, none of the methods introduces a significant bias to an overall mean trend curve. Figure 18(b) plots  $da/dN$  versus  $\Delta K$ , as calculated from the data of Fig. 18(a) using the secant, incremental polynomial, and five-point modified difference methods. Because methods of analyzing and interpreting the scatter in  $da/dN$  are not currently available, the simpler techniques--i.e., the secant and incremental polynomial methods--are often chosen.

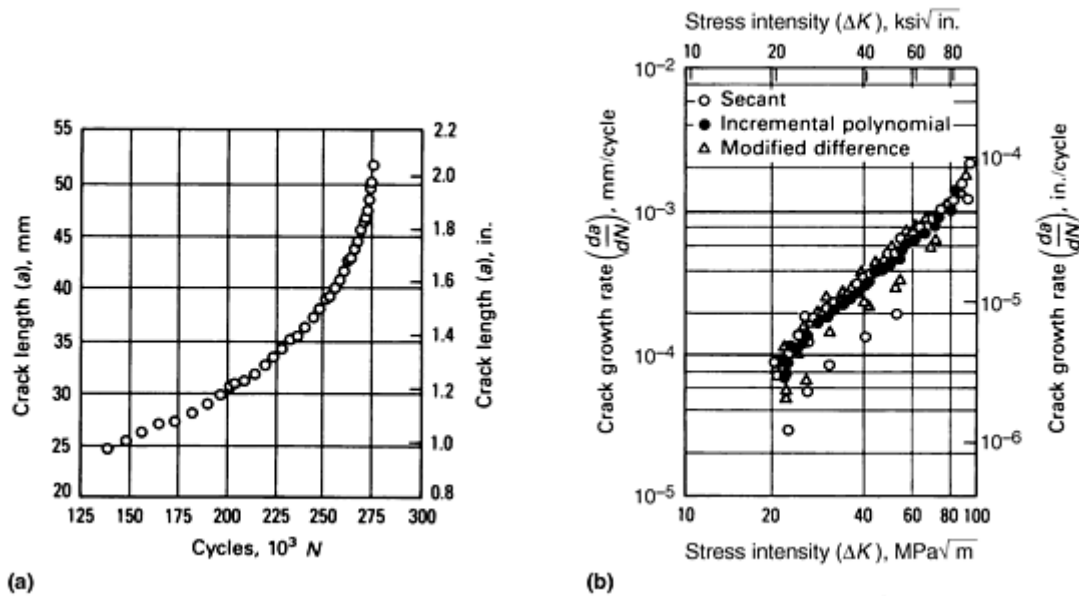

FIG. 18 COMPARISON OF  $DA/DN$  CALCULATION METHODS. (A) CRACK LENGTH TEST DATA. (B) PLOT OF CALCULATED  $DA/DN$  RATES FROM THE DATA IN (A). SOURCE: *METALS HANDBOOK*, 9TH ED., VOL 8, P 679-680

**Crack Closure Analysis.** The determination of the fatigue crack closure load is a subject of vigorous debate. Visual inspection of compliance curves can be used to estimate closure levels. However, the method is subjective and not well suited for large amounts of data. ASTM task groups have explored the use of the compliance offset and correlation method for closure analysis (Ref 39). In the compliance offset method, crack closure levels are determined by finding the point that deviates from the linear portion (i.e., is offset) by a set amount (usually 1, 2, 4, or 8%). The correlation method

determines the closure level by mathematically representing the "strength" of the linear relationship between load and displacement/strain along the curve. To confirm that the methods are applied correctly, one is encouraged to test algorithms with hypothetical, bilinear compliance curves, for which both methods should yield identical results.

The compliance offset method is generally applied using a computer, because the calculations do not lend themselves to the use of spreadsheets. The procedure is as follows:

1. COLLECT DIGITIZED STRAIN/DISPLACEMENT AND LOAD DATA FOR A COMPLETE LOAD CYCLE. THE DATA SAMPLING RATE SHOULD BE HIGH ENOUGH TO ENSURE THAT AT LEAST ONE DATA PAIR (DISPLACEMENT AND LOAD) IS TAKEN IN EVERY 2% INTERVAL OF THE CYCLIC LOAD RANGE.
2. STARTING WITH THE FIRST DATA SAMPLE BELOW MAXIMUM LOAD ON THE UNLOADING CURVE, FIT A LEAST-SQUARES STRAIGHT LINE TO A SEGMENT OF THE CURVE SPANNING APPROXIMATELY THE UPPERMOST 25% OF THE CYCLIC LOAD RANGE. THE SLOPE OF THIS LINE IS THE COMPLIANCE VALUE THAT CORRESPONDS TO THE FULLY OPEN CRACK CONFIGURATION.
3. STARTING WITH THE FIRST DATA SAMPLE BELOW MAXIMUM LOAD ON THE LOADING CURVE, FIT LEAST-SQUARES STRAIGHT LINES TO SEGMENTS OF THE CURVE THAT SPAN APPROXIMATELY 10% OF THE CYCLIC LOAD RANGE AND THAT OVERLAP EACH OTHER BY APPROXIMATELY 5% OF THE RANGE. STORE THE COMPLIANCE (SLOPE) AND THE CORRESPONDING MEAN LOAD FOR EACH SEGMENT IN A VERTICAL ARRAY WITH THE HIGHEST LOAD LOCATION AT THE TOP.
4. REPLACE THE COMPLIANCE STORED IN EACH LOCATION IN THE ARRAY WITH THE CORRESPONDING COMPLIANCE OFFSET, WHICH IS COMPUTED AS A PERCENTAGE OF THE "OPEN CRACK" COMPLIANCE AND IS GIVEN BY:

Compliance offset

$$= \frac{(\text{"Open crack" compliance} - \text{compliance})(100)}{\text{"Open crack" compliance}} \quad (\text{EQ 16})$$

5. IDENTIFY THE HIGHEST LOAD LOCATION IN THE ARRAY WHICH HAS A COMPLIANCE OFFSET GREATER THAN THE SELECTED OFFSET CRITERION, AND FOR WHICH ALL ARRAY LOCATIONS BELOW IT HAVE COMPLIANCE OFFSETS GREATER THAN THE OFFSET CRITERION.
6. STARTING AT THE ARRAY LOCATION IDENTIFIED IN STEP 5, IDENTIFY THE NEAREST, HIGHER LOAD LOCATION WHICH HAS A COMPLIANCE OFFSET LESS THAN THE SELECTED OFFSET CRITERION, AND FOR WHICH ALL ARRAY LOCATIONS ABOVE IT HAVE COMPLIANCE OFFSETS LESS THAN THE OFFSET CRITERION.
7. DETERMINE THE OPENING LOAD CORRESPONDING TO THE SELECTED OFFSET CRITERION BY LINEAR INTERPOLATION BETWEEN THE TWO (COMPLIANCE OFFSET, LOAD) POINTS IDENTIFIED IN STEPS 5 AND 6 (REF 39).

An alternative to the offset method is the correlation coefficient method. The correlation coefficient,  $r$ , is defined as (Ref 39):

$$r = \frac{n \sum (x_i y_i) - \sum x_i \sum y_i}{[(n \sum x_i^2 - (\sum x_i)^2)(n \sum y_i^2 - (\sum y_i)^2)]^{1/2}} \quad (\text{EQ 17})$$

where  $x_i$  are individual load data samples,  $y_i$  are individual displacement data samples,  $n$  is the number of data pairs, and  $\sum$  denotes the summation from  $i = 1$  to  $n$ . The closure level is defined as the load at which the correlation coefficient has the highest value. In contrast to the offset method, in which different levels of offset can be selected, there is only one criterion in this method. Both methods generate similar closure levels for the same data. However, issues of data quality

are currently the biggest problem for consistent experimental closure analysis. Methods to characterize data quality are presently being explored.

**Fracture Surface Characterizations.** Cracked specimens are also useful for establishing modes of crack advance and other interactions of the crack with the microstructure. Scanning electron microscopy is used to characterize the fracture surface. Care should be taken to establish the level of  $\Delta K$  associated with the image of the fracture surface. This is especially important when working with brittle materials where inspection of the surface does not reveal an obvious difference in fracture surface morphology between the fatigued material and post-test fracture.

Portions are often removed from the interior of the specimen and mounted for metallographic preparation. "Crack profiles" can be useful for illustrating the interaction of the crack with the microstructure. There can be marked differences in how cracks interact with microstructures, especially in cases where crack closure and distributed damage are important.

## Appendix: High-Temperature Fatigue Crack Growth Testing

David C. Maxwell, University of Dayton; Theodore Nicholas, Wright-Patterson Air Force Base

The concepts and procedures for fatigue crack growth testing at room or ambient temperature, described in this article, are generally applicable to elevated-temperature conditions. In this appendix, some of the features that are unique to testing and measurement at high temperatures are reviewed. In particular, methods for heating and controlling temperature are discussed briefly. Other aspects related to instrumentation, measurement, and test techniques are also highlighted. While there are no well-established standards for elevated-temperature crack growth testing, one standard testing procedure has been recommended recently based on a cooperative study using 304 stainless steel (Ref 40). While documentation on methods employed in elevated-temperature crack growth testing are scattered widely in the open literature, conferences devoted to this particular subject contain many papers that provide details of individual investigations (see, e.g., Ref 41).

**Specimen Design.** In general, the specimens used in room-temperature testing are equally applicable for high-temperature testing. In fact, in making comparisons of crack growth rates as a function of temperature, it is considered good practice to retain the same test specimen geometry at all temperatures tested.

An exception to this is the specialized case of testing under thermomechanical fatigue (TMF) crack growth conditions. Here, the temperature as well as the load is cycled. In order to control the cyclic temperature on the specimen, effective means of both heating and cooling the specimen must be employed. This usually requires either a thin planar specimen or a thin-walled tube, both of which minimize the thermal mass and allow for more rapid heating or cooling and better control of temperature gradients. Information on some of the techniques that have been employed for TMF can be found in conference proceedings such as those of ASTM (Ref 42, 43), ASME (Ref 44), or the International Conferences on Fatigue and Fatigue Thresholds (Ref 45, 46).

Another aspect of TMF crack growth that is almost unique to this type of test is the use of strain control as the mode of load application, similar to that used in low-cycle fatigue. A brief discussion of the problems and limitations of the use of strain control in elevated-temperature or TMF crack growth testing can be found in Ref 47.

The final consideration in TMF crack growth testing is the ability to heat and cool the specimen, or the access of heat and cooling air to the specimen. For example, clevises used on compact-type specimens tend to shield the specimen from the heating or cooling source and make it difficult to control the temperature cycle. Therefore, other geometries, such as middle-tension geometries, are generally used for this type of test.

**Specimen Gripping.** There are two main considerations in gripping specimens at high temperature. The first is the possible introduction of friction at any type of pin joint. Whereas friction can be minimized at room temperature through lubrication or careful surface finishing, these methods are less effective at elevated temperatures. Special high-temperature lubricants or oxidation-resistant materials for pins and clevises are methods for minimizing the development of friction in pin joints. Rigid fixtures and grips, on the other hand, do not require such considerations.

The second aspect of gripping at high temperatures is the possible loss of friction due to mismatches in the coefficient of thermal expansion of grips and specimens. Calculations or experimental evaluations should be made to ensure that the load-carrying capacity of the gripping system does not degrade due to differential thermal expansions so that slippage might occur.

Further, it should be demonstrated that excessive clamping stresses do not develop such that the specimen is crushed or the grips fail. This aspect of high-temperature testing is only applicable to cases where "hot" grips are used, such as when the grips and specimens are both contained within a furnace. Cold grips, on the other hand, produce high-temperature gradients along the length of the specimen and make it more difficult to maintain a constant temperature over the gage length or the crack growth region of the specimen.

**Heating Methods.** There are several methods available for heating specimens and maintaining a constant and uniform temperature during elevated-temperature crack growth testing. One of the more common methods is to use a commercially available or homemade furnace and power controllers that produce one or more zones of uniform, controlled temperature. Temperature control is achieved from thermocouple feedback, either from within the chamber, where the air temperature is being controlled, or from thermocouples directly attached to the specimen at one or more locations. In either case, temperature control with commercial units is generally accurate and reliable and can be considered to be a mature, state-of-the-art technology.

A second method of heating specimens is through the use of induction heaters, where the specimen is heated by alternating currents produced by an electromagnetic field (EMF) generated by the inductance coil surrounding the test specimen. Shielding of the specimen by grips may cause nonuniform temperature distribution. Therefore, single-edge-tension specimen geometries are generally preferred. The number and spacing of the coils, though calculated from formulas provided with such apparatus, is determined most often from trial and error and usually requires a certain amount of experience for optimum performance. Feedback is provided from one or more thermocouples attached to the specimen, and uniformity of temperature must be checked with some type of temperature mapping system such as multiple thermocouples on a dummy specimen.

Another method of heating used in several laboratories is the use of radiant energy from quartz lamps mounted in reflective and cooled housings. Each lamp focuses its energy over a limited portion of the test specimen, so multiple lamps, multiple thermocouples, and good thermal conductivity across the specimen all lead to more uniform temperature fields. A description of the technique of quartz lamp heating can be found in Hartman (Ref 48).

The last common method of specimen heating is direct resistance heating. Here, a current is passed directly through the specimen from one end to another. The test apparatus must be electrically insulated from the input and output leads. Uniform gage length specimens are better adapted to this method of heating than highly nonuniform ones; that is, a middle-tension specimen would be a much better candidate than a compact-type specimen. Because of the high current passing through the specimen, no conducting leads can be attached to the specimen that would provide an alternative path for the current. Thus, temperature measurement from thermocouples attached directly to the specimen and electric potential crack growth measurements cannot be made with this type of heating. Similarly, extensometry that attaches directly to the specimen must use nonconducting elements.

**Temperature Measurement.** The science of the measurement of temperature, known as pyrometry, dates back to before World War II. Books on the subject of pyrometry in general (Ref 49), or optical pyrometry in particular (Ref 50) were published in 1941 and provide detailed descriptions of the theory and the methods used in that era. The basic principles have not changed. The most common method for temperature measurement is through the use of thermocouples, or thermoelectric pyrometer, directly attached to the specimen. A thermocouple is made by welding two dissimilar wires together at one end. A change in temperature will generate an EMF which can be recorded on an instrument attached to the other end of the wires. These provide a real-time, continuous record of temperatures at a given point on a specimen, and they are commonly used for temperature control feedback as well as direct temperature measurement.

Another commonly used method of measuring temperature is through the use of commercially available infrared detectors, which sense the radiation emitted from a sample and convert the frequency of the radiation to temperature after appropriate calibration. The theory and methods of optical pyrometry are documented in numerous places (see, e.g., Ref 51 and 52). The emissivity of the test material whose temperature is being measured is the quantity that is used as the basis of the measurement. Emissivity is the ratio between total radiant energy per square centimeter per second between the specimen being measured and a black body at the same temperature. Thus, as the emissivity of a material decreases from 1, the apparent temperature as measured by an optical pyrometer will deviate from the actual temperature by a greater amount.

The emissivity of a heated specimen will always be less than 1, and the apparent temperature will therefore be less than the desired test temperature. Emissivity can be influenced by surface roughness, the spectral transmission of any windows between the test specimen and the measuring instrument, and the chemical changes of the specimen surface due to oxidation or other environmental degradation. All these issues should be addressed when using optical pyrometry. Commercial units are widely available for this type of measurement and usually come with detailed instructions.

**Crack Length Measurements.** Electric potential drop is a common method of crack length determination, both at room temperature and at elevated temperatures. The major consideration for elevated-temperature testing is to ensure that temperature fields are uniform and constant between the potential drop leads. Changes in temperature can result in a false indication of crack length changes. The error is due to the resistivity change in the material due to a change in temperature, and this change, in turn, is dependent on the resistivity characteristics of the material. For the direct current potential drop (DCPD) method, a 3 °C (5.5 °F) change in temperature in an aluminum alloy can result in a 1% change in the DCPD signal, whereas for the same change in resistivity, Inconel 718 would require a 100 °C (180 °F) change in temperature (Ref 53). The electric potential drop method of crack length measurement, used commonly in both room- and elevated-temperature isothermal crack growth testing, has also been applied to TMF testing (Ref 54). As with any other technique, modifications and improvements are continually being developed and documented in the literature, as in the work of Shin et al. (Ref 55), where modification to the dc potential drop system is reported.

**Compliance methods** are equally valid at elevated temperatures as at room temperature, provided that some simple considerations are addressed. Nonconstant thermal gradients must be avoided, because any change in the dimensions of any part of a mechanical extensometer can result in a change in electrical output. The gage portion, which is normally attached to the specimen through special high-temperature extension arms or feed rods, is usually shielded from the specimen (Fig. 19) and cooled with either blowing air or circulating water. Whatever the setup, the gage should reach thermal equilibrium and stability before measurements are made, in order to avoid false indications due to thermal transients.

**FIG. 19 FEED-ROD ATTACHMENT FOR HIGH-TEMPERATURES TESTS. FEED RODS ARE MADE OF QUARTZ FOR TESTS UP TO 1000 °C OR CERAMICS FOR TESTS AT HIGHER TEMPERATURES.**

**Optical methods** are less widely used today than years ago because of the availability of automated methods for crack length measurement. Optical methods, such as use of a traveling microscope, are useful for reference measurements and are equally valid at room or elevated temperature. At elevated temperature, however, the resolution of crack length may be reduced because of deterioration of the surface of the specimen through oxidation. When specialized optical methods such as laser interferometry are used, the deterioration of the specimen surface over time should be considered so that the optical information is still available with sufficient resolution.

**Special Methods.** Other specialized techniques see occasional application in high-temperature crack growth testing. For example, crack growth over prolonged periods of time has been measured using real-time holographic interferometry (Ref 56). Compact-tension specimens were tested under sustained load at 120 °C (250 °F) for 860 h, and crack-opening displacement (COD) was monitored. The COD measurements had to be converted to crack lengths using an elastic-plastic finite-element analysis code and clip gage COD measurements on a reference sample.

**Validity of  $K$  Solutions.** The reduction of crack length versus  $N$  data to a  $da/dN-\Delta K$  curve depends on having a  $K$  solution for the specimen geometry being used. Stress-intensity solutions are widely available, or can be easily generated, for almost any specimen geometry used in laboratory testing. These solutions, however, are based on the assumption of a homogeneous material and do not take into account any thermal gradients or thermal stresses that may arise in elevated-temperature crack growth testing. For cases where the specimen and grips are at a uniformly high temperature, such as within a furnace, there is no problem. For cases where the temperature is nonuniform, such as with inductance or quartz lamp heating with cooled grips, temperature gradients are developed along the axis of the specimen. These gradients, in turn, may result in thermal stresses that produce thermal  $K$ -values that alter the isothermal  $K$  solution for a given specimen. These thermal  $K$ -values, therefore, must be taken into account in the  $K$  analysis of the particular crack geometry.

Ohta et al. (Ref 57) found that crack growth rate data at 300 °C (570 °F) in a middle-tension specimen matched room-temperature data in a low-alloy ferritic steel (SB46) only when the parabolic temperature gradient that existed along the specimen was taken into account using finite element analysis, which was confirmed with experimental measurements. Coker et al. (Ref 58) conducted a finite element analysis of a single-edge crack specimen with thermal gradients between the plane of the crack and the room-temperature grips. For their specific geometry and temperature profile, stress-intensity factors due to thermal stresses were below  $2 \text{ MPa}\sqrt{m}$  for  $a/W \cdot 0.8$ . While these values are small, near-threshold tests involving very small values of  $\Delta K$  could be substantially influenced by thermal stresses. It is important, therefore, to have calculations or estimates of thermal-stress-induced values that have nonuniform temperature profiles. Unfortunately, there are very few papers in the literature where this particular problem is addressed. Nonetheless, this can be an

important consideration in high-temperature testing, particularly when testing in the near-threshold regime or when thermal gradients are severe.

Thermal gradients and effective values of  $K$  resulting from direct resistance heating are discussed by Cunningham and Griffin (Ref 59). Their analysis shows when direct resistance heating becomes important during the cyclic conditions of thermal fatigue. The results indicate that stress intensities resulting from thermal gradients due to direct resistance heating are generally small except when thermal cycling frequencies are high. The thermal gradients and resultant  $K$ -values resulting from thermal cycling are reported in a subsequent publication (Ref 60). There, it is shown that for high thermal frequencies, significant magnitudes of  $K$  can be developed at the crack tip due to the thermal transients. For those involved in TMF crack growth testing, this information should be considered when determining the stress intensity at the crack tip.

### Introduction

CORROSION FATIGUE refers to the phenomenon of cracking in materials under the combined actions of fatigue (or cyclic) loading and a corrosive (or deleterious) environment (gaseous or aqueous). This phenomenon is known to occur in many engineering alloys over a broad range of environments and has been recognized as an important cause for failure of engineering structures. Characterization and understanding of corrosion fatigue kinetics and mechanisms are essential to service life prediction, fracture control, and the development of fatigue-resistant alloys. The primary characteristics of corrosion fatigue crack growth are that the crack growth rates can be substantially higher in the corrosive environment than those obtained in a benign environment (such as in vacuum) and that crack growth rates can be dependent upon a large number of chemical and electrochemical variables not present in a benign environment.

Several corrosion fatigue mechanisms have been proposed to explain the enhanced crack growth rates with varying degrees of success. The generalized corrosion fatigue cracking mechanism involves the single or mutual occurrence of hydrogen-induced cracking and/or anodic dissolution at the crack tip. There appears currently to be at least four possible mechanisms of anodic dissolution:

- SLIP-DISSOLUTION
- BRITTLE FILM-RUPTURE
- CORROSION-TUNNELING
- SELECTIVE-DISSOLUTION (DEALLOYING)

Hydrogen embrittlement appears to be divided into five types of mechanisms:

- DECOHESION
- PRESSURE
- ADSORPTION
- DEFORMATION
- BRITTLE HYDRIDE

The balance between various phenomena is very difficult to sort out. Many researchers think that dissolution and hydrogen-induced cracking processes are competitive, so that only one of them makes the major contribution to cracking and the lesser process can be ignored. However, both processes (dissolution and hydrogen evolution) can occur simultaneously at the crack tips over ranges of potential that have been measured or that are suspected to occur. If the processes were independent and were really competitive, it would only be necessary to determine which process is faster. The anodic and cathodic processes are, however, interdependent, and they may operate simultaneously or sequentially. Another general type of mechanism is the surface energy reduction mechanism, and it will be described later in this article.

In addition to the various mechanisms of corrosion fatigue, there also are many mechanical, metallurgical, and environmental variables that affect fatigue crack growth rates. These variables are discussed in more detail following a brief review of the corrosion fatigue mechanisms associated with hydrogen-assisted cracking (hydrogen embrittlement) and anodic dissolution. Another common environment-assisted cracking phenomenon is stress-corrosion cracking where susceptible materials fail under the conjointed action of corrosion environment and a sustained load. In many engineering alloy/environment systems, because the fatigue process can efficiently rupture the protective surface oxide films and facilitate access to corrosive environments and produce new metal surfaces, threshold stress intensities for cracking to occur are often lower under corrosion fatigue conditions than under a static stress-corrosion cracking condition.

Depending on the stress level and the cyclic frequency, the crack growth rates may be high under both stress-corrosion and corrosion fatigue. However the underlying mechanisms for both corrosion fatigue and stress-corrosion cracking may very well be the same, as the only difference between these two phenomena is the mode of loading (cyclic vs. sustained). Stress-corrosion cracking is covered elsewhere in this Volume.

### Hydrogen-Assisted Cracking

In corrosion fatigue, hydrogen (either atomic or protonic) is generated by the reaction of environmental species such as gaseous hydrogen, water vapor, water, and so forth, with the newly cracked material at the crack tip. This hydrogen is absorbed at the metal surface and then transported by diffusion or dislocation sweeping mechanisms into the highly stressed region (plastic zone) at the crack tip, where it causes localized damage and increases the fatigue crack growth rate. Figure 1 illustrates schematically various processes that might be involved in corrosion fatigue crack growth of ferrous alloys by a hydrogen-assisted cracking mechanism. The processes or steps shown in Fig. 1 are sequential, and the rate of corrosion fatigue crack growth is controlled by the slowest process in this sequence. Additionally, in some cases, hydrogen can enter the material during fabrication without an aggressive external environment. Several hydrogen-assisted cracking mechanisms have been proposed to explain how hydrogen enhances corrosion fatigue crack growth rates. Because of the complex nature of corrosion fatigue phenomenon, it is not likely that a unified hydrogen-assisted cracking mechanism can be assumed to account for all alloy/environment systems. Rather, the actual hydrogen-assisted cracking mechanism may depend on the specific alloy/environment combination. Several principal hydrogen-assisted cracking mechanisms are briefly discussed below.

FIG. 1 VARIOUS SEQUENTIAL PROCESSES INVOLVED IN CORROSION FATIGUE CRACK GROWTH IN ALLOYS EXPOSED TO AGGRESSIVE ENVIRONMENTS. SOURCE: REF 1

**Pressure Mechanism.** Many of the earlier observations of hydrogen embrittlement were associated with the formation of high-pressure hydrogen gas bubbles in internal voids and microcracks. These hydrogen bubbles may form when the alloy is exposed to a high-hydrogen-fugacity environment such as high-pressure hydrogen gas or an extreme cathodic

charging condition. The atomic hydrogen derived from metal-environment surface reactions diffuses to crack-tip microstructural heterogeneities such as voids and microcracks, recombines to the molecular form, and builds up a very large internal pressure. For example, the hydrogen pressure under cathodic charging conditions can be as large as  $10^5$  atm. This high pressure obviously will exert an additional stress and thus will increase the crack-tip driving force and result in a higher crack propagation rate.

Except in the high-hydrogen-fugacity environment, the pressure mechanism is not generally adequate for explaining the phenomenon of alloys cracking in less severe environments (most corrosion fatigue of engineering alloys). For instance, high-strength ferrous alloys exhibit significantly higher corrosion fatigue crack growth rates in gaseous hydrogen environments with pressure considerably less than 1 atm when compared with those obtained in vacuum. These observations suggest that, from a thermodynamic consideration, the hydrogen pressure developed in internal voids in the crack-tip region should not exceed the external hydrogen pressure of 1 atm. Thus, it would be difficult to reconcile these results with the classic pressure mechanism.

**The lattice decohesion mechanism** postulates that hydrogen as a solute decreases the cohesive bonding forces between metal atoms. Crack growth occurs when the local tensile elastic stress in the crack-tip region exceeds the hydrogen-weakened interatomic cohesive strength. It is also suggested that hydrogen migrates to regions of maximum triaxial stresses under stress-assisted diffusion, and the magnitude of cohesive force reduction depends on the local hydrogen concentration. An accumulation of hydrogen is also preferred along grain or second-phase boundaries. This mechanism, though attractive because of its simplicity, is difficult to prove on the atomic scale.

**The surface adsorption mechanism** proposes that strongly adsorbed hydrogen at the surface serves to lower the surface energy of the metal, and if the classic theory of the Griffith criteria for crack propagation is adopted, facilitates crack extension and increases the crack growth rate. The surface adsorption mechanism and the lattice decohesion mechanism are closely linked. While the adsorption mechanism suggests that adsorbed hydrogen reduces the surface energy needed for crack extension, the lattice decohesion mechanism proposes that hydrogen lowers the atomic bonding strength at the crack tip. The end results of these two mechanisms are the same in that the critical crack-tip drive force required for advancing the crack is reduced by the presence of hydrogen.

One of the major deficiencies in the surface adsorption mechanism is centered on the generally large amount of plastic deformation energy that accompanies crack growth. The plastic deformation energy is usually much larger than the relatively small surface energy (about 1000 to 1). Thus, even a large reduction in surface energy due to hydrogen adsorption should not markedly affect the fracture stress. Another discrepancy is that other environmental species, such as oxygen and nitrogen, also strongly adsorb to the clean metal surfaces and have the potential to reduce surface energy to a greater extent than hydrogen. Yet, neither oxygen nor nitrogen accelerates crack growth rates like hydrogen does.

**Hydride Mechanism.** Many metals that are susceptible to environmentally assisted cracking are also known to form stable or metastable hydrides. Hydrides have been reported to form in titanium, nickel, niobium, vanadium, zirconium, and so forth. These hydrides are often brittle and in alloy/environment systems where hydride precipitation is feasible, crack propagation is assisted by either cracking through the hydrides or along the hydride-matrix interfaces. Because of the volume expansion that occurs upon formation of metal hydrides, high tensile stress at the crack-tip region would promote the formation of stress-assisted hydrides. In alloys that form stable hydrides, hydride formation is a plausible mechanism for corrosion fatigue cracking. In alloys that form either metastable hydrides, such as AlH, or unstable hydrides, such as FeH, the evidence that links hydrides directly to fracture are lacking and the applicability of the hydride mechanism to these alloys is thus debatable.

**Hydrogen-Enhanced Plasticity Mechanism.** In contrast to previous hydrogen-assisted cracking mechanisms that suggest hydrogen "embrittles" the material and thus reduces the driving force required for crack extension, the hydrogen-enhanced plasticity mechanism proposes that hydrogen assists the processes of plastic flow by making dislocations move at reduced stresses or by easing the generation of dislocations at the crack tip. By recognizing that the three major categories of fracture paths, namely microvoid coalescence, cleavage, and intergranular cracking, which are observed in benign environments, are also produced in environmentally assisted cracking, it is argued that hydrogen in the lattice merely assists these fracture processes. This mechanism has received some experimental support recently in that, using environmental cell transmission electron microscopy, hydrogen is seen to enhance the dislocation mobility in nickel by reducing the activation enthalpy for dislocation motion.

### Anodic Dissolution

Commonly referred to as anodic dissolution, active path dissolution, slip dissolution, strain/stress-enhanced dissolution, and surface film rupture/metal dissolution, this mechanism maintains that crack growth rates are enhanced by anodic dissolution along susceptible paths such as grain boundaries or crack-tip strained metal that are anodic relative to the surrounding matrix. In corrosion fatigue cracking, the anodic dissolution mechanism depends on the rupture of the protective film at the crack tip by the fatigue process and the subsequent repassivation of the newly exposed fresh metal surface. Corrosion fatigue crack growth rates will be controlled by the bare surface anodic dissolution rate, the rate of repassivation, the rate of oxide film rupture, the mass transport rate of reactant to the dissolving surface, and the flux of solvated metal cations away from the surface. The repassivation rate is critical in that it must be rapid enough to avoid extensive and widespread dissolution, which leads to crack-tip blunting and pit formation rather than sharp and directional crack advance, but slow enough to allow significant dissolution at the crack tip.

The dynamic nature of the anodic dissolution and repassivation processes is schematically illustrated in Fig. 2. Under fatigue loading, a slip step forms at the crack tip and ruptures the protective surface film (Fig. 2B). The freshly created surface reacts with the environment and partly dissolves until the crack-tip region is completely repassivated and the protective surface film is repaired (Fig. 2C and 2D). These processes repeat themselves when a slip step again ruptures the protective film and exposes more bare surface.

FIG. 2 SEQUENCE OF EVENTS OCCURRING AT THE CRACK TIP. SOURCE: REF 2

Anodic dissolution can be reduced or controlled by cathodic protection techniques, which are commonly used to increase the cracking resistance of alloys in marine environments. This phenomenon is consistent with the anodic dissolution mechanism in that it indicates an anodic process controlling the cracking. Cathodic protection will reduce the corrosion fatigue crack growth rate by promoting repassivation, reducing the dissolution rate, and facilitating film repair.

While the anodic dissolution mechanism is often used to explain corrosion fatigue cracking of alloys exposed in deleterious aqueous environments, it is difficult to apply this mechanism to corrosion fatigue of alloys in gaseous environments (such as water vapor, hydrogen, or hydrogen sulfide) or in deaerated distilled water where the

electrochemical reaction necessary for dissolution at the crack tip is unattainable. Also, the phenomenon of partial reversibility of preexposure by heat treatment is inconsistent with the anodic dissolution mechanism.

Anodic dissolution also fails to account for several phenomenological observations, especially the fractographic features of steels. The brittlelike appearance of fatigue fracture surfaces, including fan-shaped features emanating from manganese sulfide inclusions in steels and brittle striations on the fans, are difficult to reconcile with the lateral dissolution velocity concept that is an integral part of the anodic dissolution mechanism description (Ref 3). The hydrogen-assisted cracking mechanism has the advantage that it can account for the fractographic features in steels, but it is difficult to quantify the hydrogen effect.

Another concern is that the dissolution mechanism cannot account for the observed threshold behavior and frequency dependence of fatigue crack growth rates in steels without invoking a strong competitive process. For low load ratios ( $R \sim 0.1$  to  $0.2$ ), it has been demonstrated that very long cyclic periods produce little or no environmental assistance (Ref 4), while for very high load ratios ( $R \sim 0.8$  to  $0.9$ ), the maximum in growth rate enhancement comes at high frequencies, up to about 10 or 20 Hz (Ref 5). On its own, anodic dissolution would predict a continuing increase in growth rates for increasing cyclic periods. Advocates of the dissolution mechanism usually invoke creep and crack blunting arguments to help handle the low frequency problem.

---

## Surface Energy Reduction Mechanism

This mechanism is similar to the hydrogen surface adsorption mechanism discussed previously in that the species (other than hydrogen) that are strongly adsorbed at the surfaces serve to lower the surface energy required for the formation of a crack and thus increase corrosion fatigue crack growth rates. The surface energy reduction mechanism is also difficult to reconcile with the problems that hinder the acceptance of the hydrogen adsorption mechanism.

## Variables Affecting Corrosion Fatigue

In corrosion fatigue crack growth analysis, the mechanical driving force is normally characterized in terms of the fracture mechanics parameters such as the crack-tip stress-intensity factor,  $K$ , or stress-intensity-factor range,  $\Delta K$ . The assumptions, utility, and restrictions of this approach are discussed in detail elsewhere in this Handbook. Two of the following three interrelated loading variables are commonly used for characterizing corrosion fatigue crack growth: maximum stress-intensity factor,  $K_{\max}$ ; stress-intensity-factor range,  $\Delta K$  ( $\Delta K = K_{\max} - K_{\min}$ ); and stress ratio, or load ratio,  $R$  ( $R = K_{\min}/K_{\max}$ ), where  $K_{\min}$  is the minimum stress-intensity factor in a load cycle.

Many variables can influence corrosion fatigue crack growth. Many of the significant variables have been examined, and the results are available in a number of review papers. The influences of some of the variables on the corrosion fatigue crack growth are described briefly in the following sections. Some of these variables include, along with the aforementioned loading variables:

## MECHANICAL VARIABLES

- FATIGUE LOAD FREQUENCY
- FATIGUE LOAD RATIO
- FATIGUE LOAD WAVEFORM
- MAXIMUM STRESS-INTENSITY FACTOR AND STRESS-INTENSITY-FACTOR RANGE
- LOAD INTERACTIONS IN VARIABLE AMPLITUDE LOADING (OVER/UNDER/SPECTRUM LOAD)
- RESIDUAL STRESS

## GEOMETRICAL VARIABLES

- CRACK SIZE
- CRACK GEOMETRY
- SPECIMEN THICKNESS (PLANE STRAIN VERSUS PLANE STRESS)

## METALLURGICAL VARIABLES

- ALLOY COMPOSITION
- MICROSTRUCTURE AND CRYSTAL STRUCTURE
- HEAT TREATMENT
- GRAIN BOUNDARY STRUCTURE
- GRAIN SHAPE AND SIZE
- TEXTURE
- DISTRIBUTION OF ALLOY ELEMENTS AND IMPURITIES
- DEFORMATION MODE (SLIP CHARACTER, TWINING, CLEAVAGE)
- MECHANICAL PROPERTIES (STRENGTH, TOUGHNESS, ETC.)

## ENVIRONMENTAL VARIABLES

- TYPE OF ENVIRONMENTS (GASEOUS OR LIQUID)
- PARTIAL PRESSURE OF DAMAGING SPECIES IN GASEOUS ENVIRONMENTS
- CONCENTRATION OF DAMAGING SPECIES IN AQUEOUS OR OTHER LIQUID ENVIRONMENTS
- TEMPERATURE
- PH
- ELECTROCHEMICAL POTENTIAL
- VISCOSITY OF THE ENVIRONMENT

**Effect of Fatigue Load Frequency.** An example of the frequency effect is shown in Fig. 3 (Ref 6) for an AISI 4340 steel in a water vapor environment (585 Pa). Data for tests in argon are also included in Fig. 3 for comparison. These data cover  $\Delta K$  from 15 to 40  $\text{MPa}\sqrt{\text{m}}$  at a load ratio,  $R$ , of 0.1 and the corresponding  $K_{\text{max}}$  values are below the apparent  $K_{\text{Isc}}$  (approximately 55  $\text{MPa}\sqrt{\text{m}}$  for this water vapor pressure. Figure 3 clearly shows that the environmental effect is much more pronounced at lower cyclic frequencies than that at higher frequencies as the fatigue crack growth rates at 0.1 Hz are more than an order of magnitude higher than those obtained at 10 Hz. As shown in Fig. 4, the environment-induced increase, which is represented by the value  $(C - C_0)$ , is found to be linearly proportional to the "time-at-load" or period (the inverse of cyclic-load frequency). Fractographic examination of the fracture surfaces also indicated that, at lower frequencies, where the environmental effect was significant, the fracture path in water vapor was primarily intergranular along the prior austenite grain boundaries, similar to those observed in hydrogen and in water under sustained load conditions. At higher test frequencies, the fracture path was primarily transgranular with respect to the prior austenite grains and resembled paths in specimens tested in inert argon environment.

**FIG. 3 ROOM-TEMPERATURE FATIGUE CRACK GROWTH KINETICS OF AISI 4340 STEEL IN DEHUMIDIFIED ARGON AND IN WATER VAPOR (585 PA) AT  $R = 0.1$  SOURCE: REF 6**

**FIG. 4 ENVIRONMENT-DEPENDENT COMPONENT OF FATIGUE CRACK GROWTH PARAMETER AS A FUNCTION OF CYCLIC LOAD PERIOD FOR AISI STEEL IN 585 PA WATER VAPOR AT ROOM TEMPERATURE. SOURCE: REF 6**

Fatigue crack growth kinetics shown in Fig. 3 are steady-state rates corresponding to a particular cyclic load frequency. If the cyclic load frequency is abruptly changed during fatigue test, a region of transient growth may develop. Figure 5 shows fatigue data obtained at 0.1, 1, and 10 Hz under the same maximum and minimum loads. A region of transient growth is evident following each change in cyclic load frequency, before steady-state growth rate related to the new cyclic load frequency is established. For example, decreasing the test frequency from 10 to 0.1 Hz did not produce an immediate change in crack growth rate to its expected steady-state value. Instead, it resulted in a gradual change that extended over crack growth increments of the order of 0.1 cm. Similarly, an increase in frequency produced a gradual decrease in growth rate to its steady-state value. The extent of crack growth required to establish steady-state growth and the size of the transition zone appeared to depend on the magnitude of the frequency change and on the crack length (or  $\Delta K$ , for constant load-amplitude fatigue). Because there is no influence of frequency on fatigue crack growth in argon over this range of frequencies, the observed transient phenomenon must result from interactions with the environment.

FIG. 5 CRACK GROWTH RATE RESPONSE FROM CHANGES IN CYCLIC LOAD FREQUENCY. SOURCE: REF 6

The above examples of the frequency effect are consistent with the hydrogen-assisted cracking mechanisms. Because condensation is not expected at such low water vapor pressure, it would be difficult to apply the anodic dissolution mechanism. Also, the anodic dissolution mechanism cannot explain adequately the observed transient responses during frequency cycling.

Titanium alloys exhibit an unusual frequency dependency of corrosion fatigue crack growth in salt-water environments. This frequency dependence is illustrated in Fig. 6 by data on a Ti-6Al-4V alloy tested in 0.6 M NaCl solution. The crack growth rates increased with decreasing frequency and reached a maximum that depended on  $\Delta K$ , and then decreased to rates that are comparable to those observed in vacuum or other inert environments. Further analyses also suggested that, at higher frequencies, corrosion fatigue crack growth rates were inversely proportional to the square root of frequency. This dependence, coupled with the surface reactivity of titanium, is consistent with hydrogen-diffusion-controlled crack growth and suggests a hydride formation mechanism. The abrupt decrease in crack growth rates at the lower frequencies is attributed to the difficulty of hydride formation at the substantially lower strain rates associated with the lower cyclic frequencies.

FIG. 6 INFLUENCE OF FREQUENCY ON FATIGUE CRACK GROWTH IN A TI-6AL-4V ALLOY EXPOSED TO 0.6 M NaCl SOLUTION AT ROOM TEMPERATURE AND  $R = 0.1$ . SOURCE: REF 7

**Effect of Environment (Water Vapor Pressure).** Figure 7 shows the effect of water vapor pressure on the fatigue crack growth kinetics of 2219-T851 aluminum alloy at three  $\Delta K$  levels, along with data from a reference dehumidified argon environment. As shown in Fig. 7, at the cyclic frequency of 5 Hz, the rate of fatigue crack growth is unaffected by water vapor until a threshold pressure is reached. The rates then increase and reach a maximum within an order of magnitude increase in vapor pressure from this threshold. The maximum fatigue crack growth rate at each  $\Delta K$  is equal to that obtained in air, distilled water, and 3.5% NaCl solution. This observed crack growth response as a function of water vapor pressure is similar to the water vapor/aluminum alloy surface reaction kinetics and is consistent with the transport limited model. These results strongly suggest that, instead of an anodic dissolution mechanism, the hydrogen produced by the surface reactions is responsible for the enhancement in fatigue crack growth.

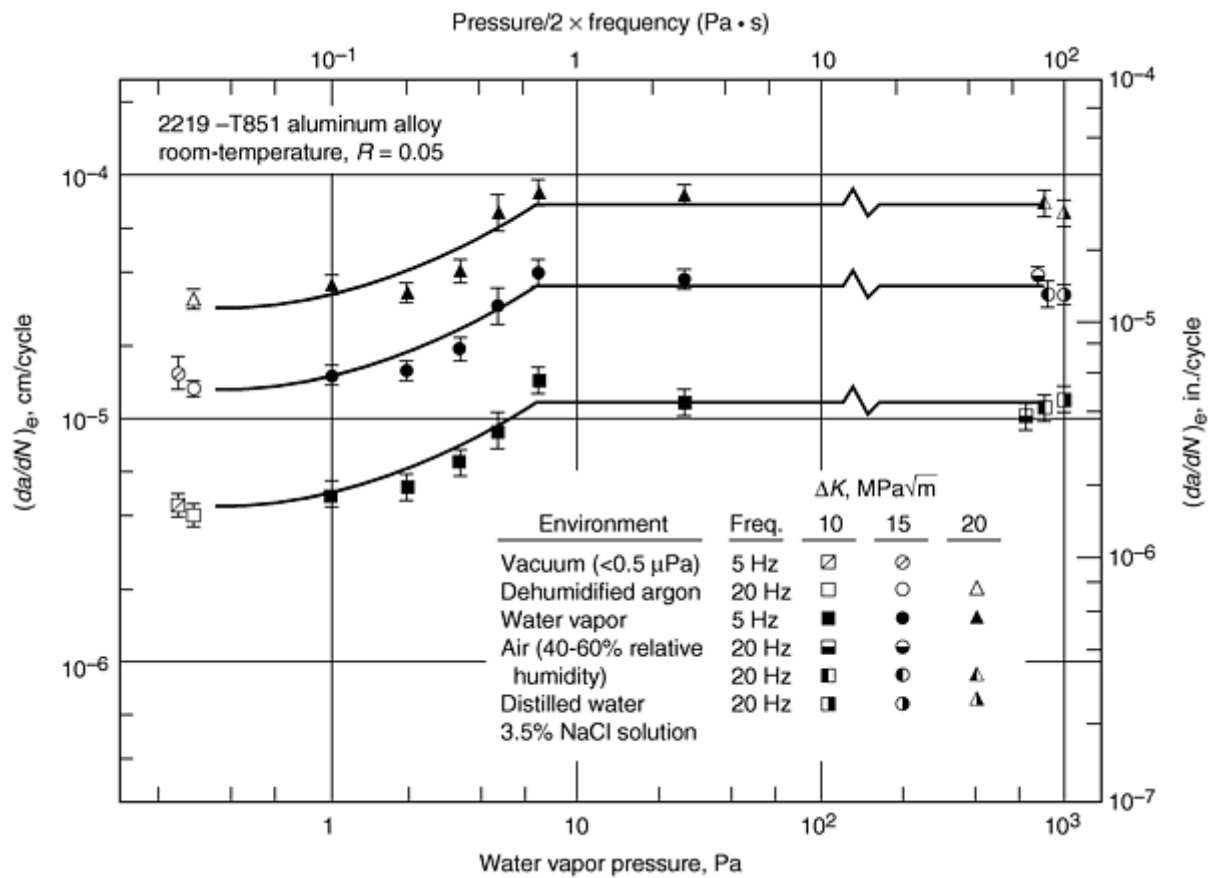

FIG. 7 INFLUENCE OF WATER VAPOR PRESSURE ON FATIGUE CRACK GROWTH RATES IN 2219-T851 ALUMINUM ALLOY AT ROOM TEMPERATURE. SOURCE: REF 8

**Effect of Grain Size.** The influence of grain size on the corrosion-fatigue crack growth behavior of an alloy depends on the fracture mode of that particular alloy in the environment. In a benign environment, such as in a vacuum, the fatigue crack propagates generally along transgranular slip bands and the crack growth rates usually decrease with increasing grain size. Examples of this grain size effect are shown in Fig. 8 and Ti-8.6Al and in Fig. 9 for Al-5.7Zn-2.5Mg-1.5Cu. In both cases, the fatigue crack growth rates of coarser-grain alloys are substantially lower than those for finer-grain alloys. This grain size effect in the benign environment can be explained by the concept of reversed slip of dislocations within the plastic zone ahead of the crack tip or by increased closure induced by interference between irregular mating crack surfaces during unloading.

FIG. 8 EFFECT OF GRAIN SIZE ON THE FATIGUE CRACK GROWTH RATES OF TI-8.6AL IN VACUUM AND 3.5% NaCl SOLUTION. SOURCE: REF 9

FIG. 9 EFFECT OF GRAIN SIZE ON THE FATIGUE CRACK GROWTH RATES OF AL-5.7ZN-2.5MG-1.5CU IN VACUUM AND 3.5% NaCl SOLUTION. SOURCE: REF 9

In aggressive environments, the grain size effect will either still be present or greatly diminish, depending on how the fracture mode of the alloy is affected by the environment. For the Ti-8.6Al alloy, the fracture mode in salt-water environments for both small- and larger-grain alloys is primarily transgranular slip-band cracking, similar to that in vacuum environments. As shown in Fig. 8, the corrosion fatigue crack growth rates of large-grain alloys are significantly lower than those of small-grain alloys. The slip reversal concept discussed previously can be applied to explain the observed grain size dependency of the corrosion fatigue crack growth behavior in Ti-8.6Al.

However, for Al-5.7Zn-2.5Mg-1.5Cu in a salt-water environment, the grain size dependence of corrosion fatigue crack growth rates almost disappears, as shown in Fig. 9. Fractographic analyses indicated that the fracture path in salt water changed to intergranular at low  $\Delta K$ . At higher  $\Delta K$ , the transgranular fracture surfaces for both small- and large-grain alloys are relatively flat as several slip systems are activated and cross slips become possible. These changes in the

fracture mode, particularly the change to intergranular separation, would explain the lack of grain size dependence for corrosion fatigue crack growth rates.

The effect of stress ratio on corrosion fatigue crack growth rates depends on the alloy/environment system. In general, higher stress ratios will result in higher corrosion fatigue crack growth rates and lower corrosion fatigue crack growth thresholds. An example of the stress-ratio effect is shown in Fig. 10 for MF-80 HSLA steel in a salt-water environment. The corrosion fatigue crack growth rates of MF-80 HSLA steel in 3.5% NaCl solution at  $R = 0.67$  are about two times higher than the rates obtained at  $R = 0.10$  at similar stress-intensity levels.

FIG. 10 EFFECT OF LOAD RATIO ON THE CORROSION FATIGUE CRACK GROWTH RATES OF MF-80 HSLA IN 3.5% NaCl SOLUTION. SOURCE: REF 10

A special case of corrosion fatigue cracking is "ripple load" cracking. "Ripple loading" refers to a loading profile where relatively small amplitude cyclic loads are superimposed on a large sustained load. A typical ripple load profile is schematically shown in Fig. 11 where the stress ratio often exceeds  $R = 0.90$ . The significance of ripple load cracking is its relation to stress-corrosion cracking (SCC), where the applied load is assumed to be constant. However, in the real world, structures rarely experience a constant load condition, but are far more apt to see a combination of very small amplitude cyclic loads and a large constant load. A typical example is offshore platform structures. Under ripple loading conditions, if a structure is designed solely based on the SCC threshold without considering the possibility of ripple loads, cracking or fracture may occur prematurely.

FIG. 11 RIPPLE LOAD PROFILE

Ripple load cracking has been approached successfully as high stress ratio corrosion fatigue. An example of the ripple load effect is shown in Fig. 12 for 5Ni-Cr-Mo-V steel in a 3.5% NaCl solution. As shown in Fig. 12, at  $R = 0.90$  (representing ripple loads with a cyclic amplitude equal to 5% of the sustained load), cracking can occur by a corrosion fatigue mechanism under ripple loading at stress intensities as much as 60% lower than the static SCC threshold ( $K_{Isc}$ ) and the ripple load cracking threshold ( $K_{IRLC}$ , which is defined as  $\Delta K_{th}/(1 - R)$ ) is less than half of the  $K_{Isc}$ .

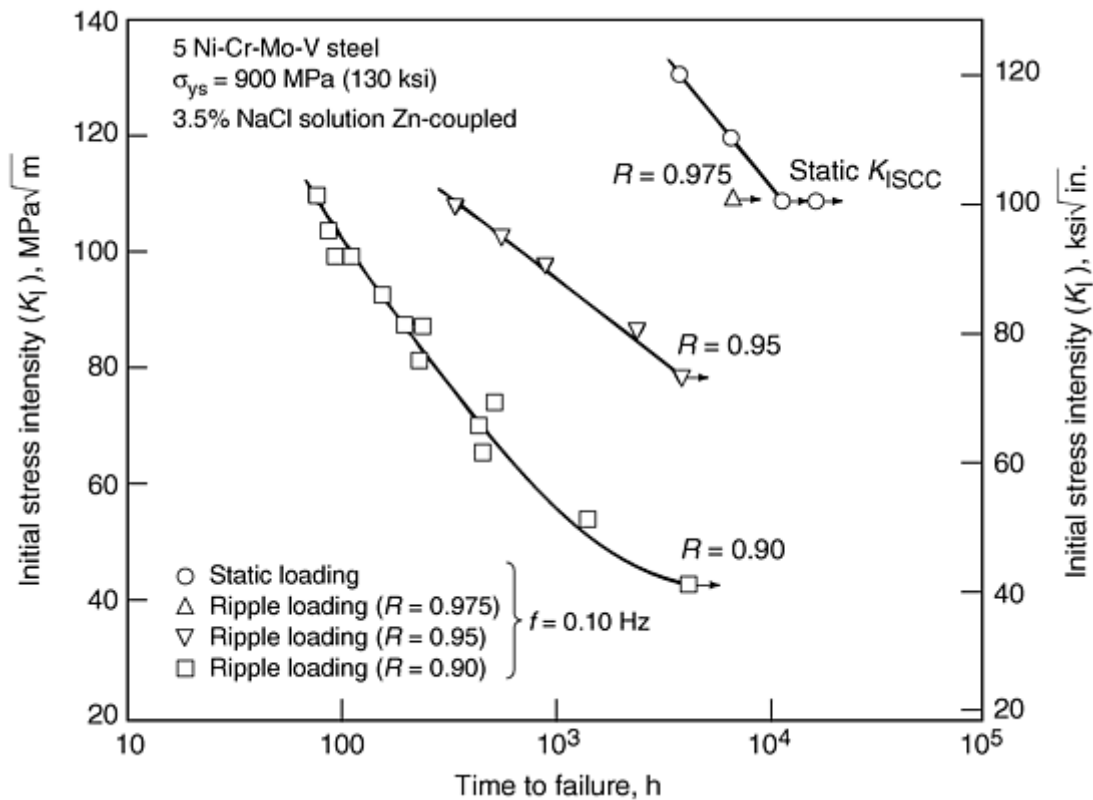

FIG. 12 RIPPLE-LOAD CRACKING OF 5NI-CR-MO-V STEEL IN A 3.5% NAACL SOLUTION. SOURCE: REF 11

It is significant to note that the ripple effect depends strongly on the size or amplitude of the ripple loads. As the fatigue crack growth threshold,  $\Delta K_{th}$ , varies with the stress ratio,  $R$ , the ripple load cracking threshold correspondingly varies with  $R$ . Thus, while a material may exhibit substantial ripple load degradation with larger amplitude ripple loading, the same material may show less or even no ripple load degradation if the existing ripples are smaller. Such ripple size effect is shown in Fig. 12 for 5Ni-Cr-Mo-V steel under SCC and ripple load conditions in a 3.5% aqueous NaCl solution. For the 5Ni-Cr-Mo-V steel, a static  $K_{I,SCC}$  was established at  $110 \text{ MPa}\sqrt{\text{m}}$ . As shown in Fig. 12, a 1.25% ripple loading (corresponding to  $R = 0.975$ ) did not cause any degradation and the apparent cracking threshold equaled the static  $K_{I,SCC}$ . However, as the amplitude of the ripples was increased to 2.5% (corresponding to  $R = 0.95$ ) and 5% (corresponding to  $R = 0.90$ ) of the sustained load, ripple loading significantly reduced the values of time to failure and the apparent cracking threshold. For instance, at the initial stress intensity of  $90 \text{ MPa}\sqrt{\text{m}}$ , which is well below the  $K_{I,SCC}$  of  $110 \text{ MPa}\sqrt{\text{m}}$ , SCC failure will not occur under static loading. However, when small ripple loads with amplitude equal to 2.5% of the static load were added, the test specimen failed in about 1600 h. For a 5% ripple loading, the failure time was further reduced to only 180 h.

Not all materials, however, appear susceptible to the ripple load effect. While materials that exhibit greater SCC resistance under static load conditions, such as 5Ni-Cr-Mo-V steel, are susceptible to ripple load degradation, materials that are less SCC resistant may exhibit little or no ripple load degradation. An example is shown in Fig. 13 for a SCC-susceptible AISI 4340 steel in a 3.5% NaCl solution. As shown in Fig. 13, the SCC threshold, determined from long-term static tests, was established at  $33 \text{ MPa}\sqrt{\text{m}}$ . The two 5% ripple loading tests (corresponding to  $R = 0.90$ ) produced results that fell directly on the static SCC time-to-failure curve. That is, even under a fairly large 5% ripple loading, AISI 4340 steel does not exhibit any ripple load effect. It is also safe to predict, based on the experience with 5Ni-Cr-Mo-V steel, that AISI 4340 steel is not likely to demonstrate any ripple load degradation if the size of the ripple is smaller than 5% of the sustained load.

FIG. 13 RIPPLED-LOAD CRACKING OF AISI 4340 STEEL IN A 3.5% NaCl SOLUTION. SOURCE: REF 11

**Effect of Waveform.** While cyclic load waveform has little effect on the fatigue crack growth rates in benign environments, available data indicate that corrosion fatigue crack growth rates in aggressive environments may be highly dependent on the shape of the cyclic load waveform. This waveform effect is illustrated in Fig. 14 and 15 for 15Ni-5Cr-3Mo steel in ambient air and in a 3% NaCl solution, respectively. As shown in Fig. 14, fatigue crack growth rates in ambient air are identical and the applied cyclic load waveform has no effect on the fatigue crack growth rates.

FIG. 14 EFFECT OF CYCLIC LOAD WAVEFORM ON THE FATIGUE CRACK GROWTH RATES OF 16NI-5CR-3MO STEEL IN AMBIENT AIR. SOURCE: REF 12

FIG. 15 EFFECT OF CYCLIC LOAD WAVEFORM ON THE CORROSION FATIGUE CRACK GROWTH RATES OF 15NI-

The nature of the cyclic load waveform can significantly affect the corrosion fatigue crack growth rates in aggressive environments. As shown in Fig. 15, corrosion fatigue crack growth rates in 3% NaCl solution under both square and negative sawtooth waveforms, which have very short rising load periods, are identical and are statistically equal to the fatigue crack growth rates in ambient air. That is, no environment-enhanced effect is observed with the square and negative sawtooth waveforms.

On the other hand, environment-enhanced effects on fatigue crack growth rates can be substantial if the cyclic waveform consists of a significant period of rising load. As shown in Fig. 15, the corrosion fatigue crack growth rates of 15Ni-5Cr-3Mo steel in 3% NaCl solution under sinusoidal, triangular, and positive sawtooth waveforms, which all have long rising load periods, are identical and are about three times higher than the fatigue crack growth rates under square and negative sawtooth waveforms in the same 3% NaCl environment and in air. It has been suggested that the environmental enhancement of fatigue crack growth is caused primarily by the interaction between the environment and the steel during the rising load portion of each loading cycle. The longer the load rise time during each load cycle, the greater the influence of an aggressive environment. In the case of the square cyclic waveform that has a very short rising load period, the aggressive environment has little effect on the fatigue crack growth rates.

**Effect of Temperature.** Because temperature may influence the environment/metal surface reactions as well as the many transport processes listed in Fig. 1, temperature can be expected to affect corrosion fatigue crack growth rates. In many environment/alloy systems, corrosion fatigue crack growth rates increase with increasing temperature. That is, the corrosion fatigue cracking process is thermally activated. If the activation energy for corrosion fatigue cracking can be measured, then the rate-limiting process and possibly the mechanism of cracking may be determined.

An example of the temperature effect is shown in Fig. 16 for a metastable austenitic steel (composition in wt%: 0.27C-0.43Mn-0.09Si-11.95Cr-1.90Mo-7.96Ni) in distilled water. As shown in Fig. 16, as the temperature increases, the corrosion fatigue crack growth rates also increase. The activation energy for corrosion fatigue crack growth has an averaged value of 35.2 kJ/mol. This activation energy is very close to the activation energy ( $36 \pm 14$  kJ/mol) of water vapor reaction with AISI 4340 steel surface (Ref 14). The good agreement between the activation energy for corrosion fatigue crack growth and the activation energy for water vapor/steel surface reaction kinetics suggests that the surface reaction is the rate limiting process for crack growth and the hydrogen produced during the surface reaction is responsible for the embrittlement of this austenitic steel fatigued in distilled water.

FIG. 16 EFFECT OF TEMPERATURE ON THE CORROSION FATIGUE CRACK GROWTH RATE OF A METASTABLE AUSTENITIC STEEL IN DISTILLED WATER. SOURCE: REF 13

Corrosion fatigue is a function of the chemistry of the environment/material system, the microstructure, and the applied loading conditions. Because environmental susceptibility is a complex phenomenon occurring at the atomic/molecular level, it is difficult to predict or verify using specific models or tests. For the present, it is necessary to characterize materials using appropriate real time loading profiles in the service environment to ensure adequate service lives. Obviously, given the widely varying nature of growth behaviors under such loading/environment conditions, variations in the environmental and loading parameters must be considered to ensure that the worst case conditions are captured in the life verification tests.

### Corrosion Fatigue Testing

Peter L. Andresen, GE Corporate Research & Development

---

### Introduction

ENVIRONMENTAL EFFECTS play a dominant role in fatigue behavior, as illustrated in fatigue crack growth of laboratory test specimens (Fig. 1) and the general fatigue life behavior of engineering component applications (Fig. 2, 3). Many environments can produce a profound increase in crack growth rates, including seemingly innocuous environments such as high-purity water, laboratory air, and very low partial pressures of oxygen, hydrogen, or water vapor. A general review of these underlying mechanisms of environmental effects on fatigue crack growth is provided in the article "Mechanisms of Corrosion Fatigue" in this Volume.

The objective of this article is to introduce fundamental aspects of environmental crack advance in general, and corrosion fatigue in particular, and then discuss critical experimental issues associated with corrosion fatigue testing. Insufficient emphasis is often given to environmental effects, despite their influence on fatigue. Attention to testing detail is required because of the greater number of critical variables and their interactions. Whereas fatigue crack propagation studies in inert environments may evaluate only a few primary test variables, and require control to be maintained over less than a

dozen significant parameters (alloy composition, heat treatment, etc.), the number of variables and control parameters in environmentally assisted cracking investigations is typically multiplied by 3 to 10 times (Fig. 4).

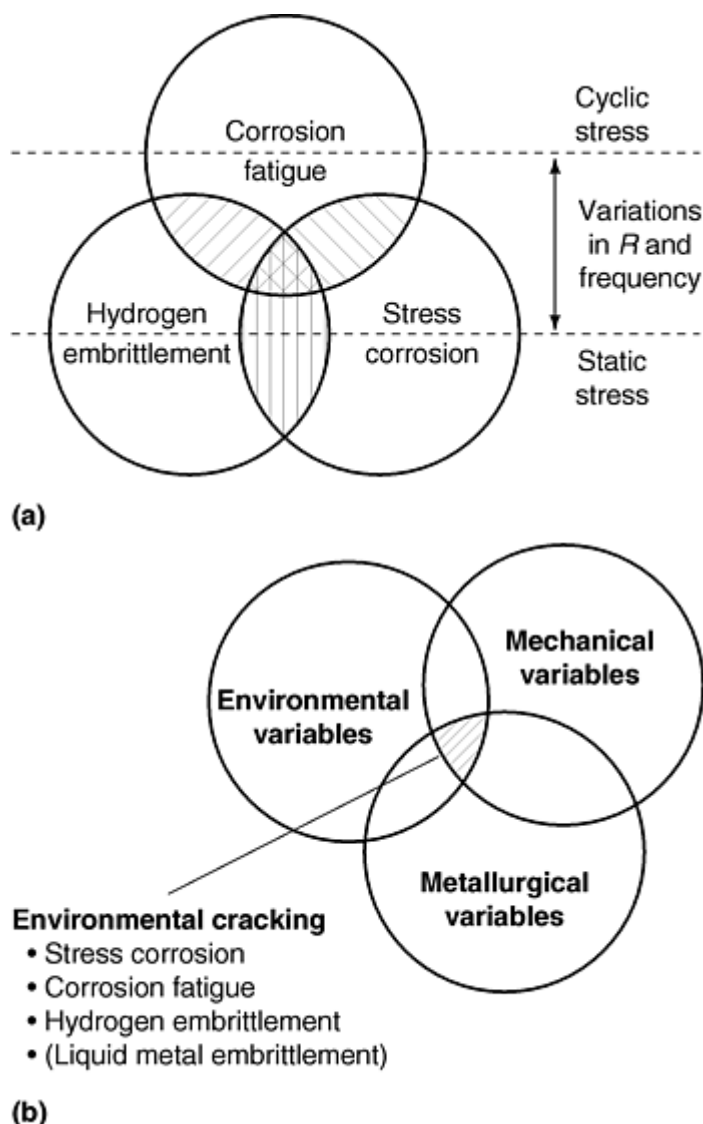

FIG. 4 GENERAL INTERRELATIONSHIPS ASSOCIATED WITH ENVIRONMENTALLY ASSISTED CRACKING, WHICH CAN ENCOMPASS CRACK GROWTH RATES OF MORE THAN 10 MM/S TO LESS THAN  $10^{-10}$  MM/S. (A) VENN DIAGRAM OF MECHANISMS. (B) VENN DIAGRAM OF VARIABLES LISTED IN TABLE 1

TABLE 1 MATERIAL, MECHANICAL, AND ENVIRONMENTAL VARIABLES OF ENVIRONMENTALLY ASSISTED CRACKING

#### METALLURGICAL VARIABLES

- ALLOY COMPOSITION
- DISTRIBUTION OF ALLOYING ELEMENTS AND IMPURITIES
- MICROSTRUCTURE AND CRYSTAL STRUCTURE
- HEAT TREATMENT
- MECHANICAL WORKING
- PREFERRED ORIENTATION OF GRAINS AND GRAIN BOUNDARIES (TEXTURE)
- MECHANICAL PROPERTIES (STRENGTH, FRACTURE TOUGHNESS, ETC.)

## ENVIRONMENTAL VARIABLES

- TEMPERATURE
- TYPES OF ENVIRONMENTS: GASEOUS, LIQUID, LIQUID METAL, ETC.
- PARTIAL PRESSURE OF DAMAGING SPECIES IN GASEOUS ENVIRONMENTS
- CONCENTRATION OF DAMAGING SPECIES IN AQUEOUS OR OTHER LIQUID ENVIRONMENTS
- ELECTRICAL POTENTIAL
- PH
- VISCOSITY OF THE ENVIRONMENT
- COATINGS, INHIBITORS, ETC.

## MECHANICAL VARIABLES

- MAXIMUM STRESS OR STRESS-INTENSITY FACTOR,  $\sigma_{MAX}$  OR  $K_{MAX}$
- CYCLIC STRESS OR STRESS-INTENSITY RANGE,  $\Delta\sigma$  OR  $\Delta K$
- STRESS RATIO ( $R$ )
- CYCLIC LOADING FREQUENCY
- CYCLIC LOAD WAVEFORM (CONSTANT-AMPLITUDE LOADING)
- LOAD INTERACTIONS IN VARIABLE-AMPLITUDE LOADING
- STATE OF STRESS
- RESIDUAL STRESS
- CRACK SIZE AND SHAPE, AND THEIR RELATION TO COMPONENT SIZE AND GEOMETRY

In this article, the primary emphasis is on corrosion fatigue testing of steel in high-temperature water. However, the Appendix at the end of this article provides details for corrosion fatigue testing in other aggressive environments. A brief collection of corrosion fatigue data for selected nonferrous alloys is also included in the Appendix. Further information on corrosion fatigue of specific alloys is covered in separate articles in this Volume.

## Corrosion Fatigue Testing

Peter L. Andresen, GE Corporate Research & Development

---

## Environmentally Assisted Cracking

Because corrosion fatigue is just one part of the complex phenomenon known as environmentally assisted cracking (Fig. 4), a brief review of some fundamentals is useful. Not all aspects of environmentally assisted crack advance are identical in all cracking systems, but many interactions between mechanical loading and environmental exposure are common across the spectrum of loading conditions and materials.

In broad terms, the phenomenon of environmentally assisted cracking can encompass relevant crack propagation rates of more than  $10^1$  mm/s to less than  $10^{-10}$  mm/s depending on:

- *ENVIRONMENT*, INCLUDING LOW- AND HIGH-TEMPERATURE AQUEOUS SOLUTIONS, LOW- AND HIGH-TEMPERATURE GAS, STEAM, ORGANICS, LIQUID METALS, AND SO ON.
- *LOAD CONDITION*, SUCH AS STATIC AND MONOTONICALLY INCREASING LOADING (*STRESS-CORROSION CRACKING*) AND CYCLING LOADING (*CORROSION FATIGUE*). IN MOST SYSTEMS, LOADING VARIATIONS REPRESENT A COMPLETE CONTINUUM IN RESPONSE, WHICH IS NOT SURPRISING GIVEN THAT DISTINCTIONS ARE NECESSARILY BLURRY WHEN CONSIDERING RIPPLE (I.E., LOW-AMPLITUDE) LOADING, LONG HOLD TIME BEHAVIOR, AND SO ON.

Thus, the choice between the terms *stress-corrosion cracking* and *corrosion fatigue* is often arbitrary. They can refer to the same underlying degradation phenomenon.

- *MATERIAL*, RANGING FROM METALS AND ALLOYS TO GLASSES, PLASTICS, COMPOSITES, CERAMICS, AND SO ON. MATERIALS SUCH AS VERY PURE METALS, WHICH WERE ONCE CONSIDERED UNSUSCEPTIBLE TO ENVIRONMENTALLY ASSISTED CRACKING, HAVE USUALLY, ON MORE DETAILED INVESTIGATION, BEEN SHOWN TO BE SUSCEPTIBLE.

More examples of these variables are given in Table 1.

Because of the large contribution of environment to crack advance, attention to experimental detail is greatly rewarded. Unless the multidisciplinary nature of these studies is recognized however, most efforts will produce seriously misleading results or outright confusion, which is perhaps most responsible for the slow progress in quantifying and understanding environmental cracking. Familiarity with chemical and physical metallurgy, mechanics, chemistry, electrochemistry, and corrosion also is generally considered essential.

**Environmental Factors during Crack Advancement.** In simple terms and from a thermodynamic perspective, almost all engineering materials are highly reactive in most environments, consistent with the observation that, with rare exceptions, metals are found in nature in their oxidized state. Thus, the use of most engineering materials relies on the presence of a kinetic surface barrier (passivity) to reduce the oxidation rate to manageable proportions. When passivity is disturbed (e.g., by local strains in the underlying material), the reaction (oxidation) rate of the exposed metal is generally very high ( $>1$  A/cm<sup>2</sup>, Fig. 5) as the protective film is reformed (as repassivation occurs).

**FIG. 5 OXIDATION CURRENT DENSITY VS. TIME FOLLOWING RUPTURE OF THE PROTECTIVE OXIDE ON A STAINLESS STEEL WIRE BY RAPID STRAINING IN HOT WATER. A HIGH-PEAK (BARE-SURFACE) CURRENT DENSITY (GENERALLY  $\cdot 1$  A/CM<sup>2</sup>, CORRESPONDING TO RAPID METAL DISSOLUTION) IS FOLLOWED BY REPASSIVATION AS THE PROTECTIVE FILM RE-FORMS. SOURCE: REF 6**

In aqueous environments, oxidation reactions can have several repercussions, including the formation of atomic hydrogen from chemical reactions (e.g.,  $2\text{Fe} + 3\text{H}_2\text{O} \rightarrow \text{Fe}_2\text{O}_3 + 6\text{H}$ ) or electrochemical reactions (e.g.,  $2\text{H}^+ + 2\text{e}^- \rightarrow 2\text{H}^0 \rightarrow \text{H}_2$ ), and shifts in pH from localization of specific reactions (e.g., differential aeration crevice cells). Thus, many environmental effects on crack advance are associated with the direct loss (oxidation/dissolution) of metal (known as the *slip oxidation mechanism*); the formation, absorption, and transport of hydrogen (*hydrogen embrittlement*); and other corrosion- or repassivation-related phenomena. An example of the latter is *film-induced cleavage*, whereby cracks that form in a brittle surface layer propagate in the ductile underlying metal. Such brittle layers can form by selective corrosion and dealloying, or by the formation of a brittle, coherent film (Ref 7).

The role of deformation is often of paramount, fundamental importance, because it defines the periodicity of rupture of the protective oxide. For a growing crack, the *crack-tip strain rate* can be associated with reversed slip during cyclic loading, thermal or irradiation creep, or any "crack advance" process (e.g., corrosion) that redistributes the stress/strain fields in front of a crack and produces dislocation motion.

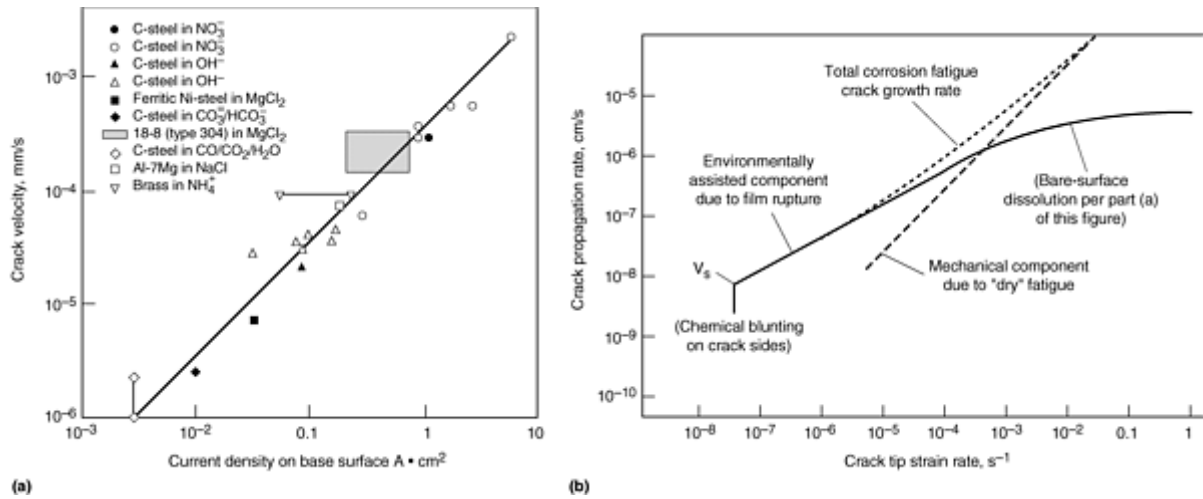

In some alloy environment systems (e.g., carbon steels in carbonate/bicarbonate solutions, stainless steel in high-temperature water), the maximum environmental contribution can be predicted by measuring the dissolution rate on a bare (e.g., scratched or rapidly strained) metal surface (Fig. 6). A large environmental component of crack advance thus may occur with increasing cyclic amplitude or frequency, although this can be misleading because:

- THE INERT FATIGUE CRACK GROWTH RATE ALSO INCREASES, AND EVENTUALLY BECOMES DOMINANT. THUS THE ENVIRONMENTAL ENHANCEMENT (I.E., THE PERCENTAGE INCREASE ABOVE THE INERT BASELINE RATE) ALSO DECREASES, WHICH

CAN LEAD, FOR EXAMPLE, TO TRANSITIONS FROM INTERGRANULAR CRACKING TO THE TRANSGRANULAR MORPHOLOGY CHARACTERISTIC OF INERT FATIGUE.

- WITH DECREASING CYCLIC AMPLITUDE/FREQUENCY, THE ENVIRONMENTAL CONTRIBUTION TO CRACKING CAN BEGIN TO DOMINATE, AND THE TRADITIONAL PARIS LAW DEPENDENCE (E.G.,  $\Delta K^4$ ) CAN SHIFT SUBSTANTIALLY (E.G., TO  $\Delta K^2$ ), RESULTING IN A GREATLY REDUCED SENSITIVITY TO CYCLIC AMPLITUDE OR FREQUENCY (FIG. 7, 8).

**FIG. 6 THE RELATIONSHIP BETWEEN (A) THE BARE-SURFACE CURRENT DENSITY AND (B) THE MAXIMUM ENVIRONMENTALLY ASSISTED CRACK GROWTH RATE FOR VARIOUS MATERIAL/ENVIRONMENT SYSTEMS. (A) FATIGUE CRACK GROWTH OF A533B AND A508 LOW-ALLOY STEELS WITH 0.01-0.25% S TESTED IN DEAERATED HIGH-TEMPERATURE WATER AT 0.0167 HZ AND  $R = 0.7$ . THE NOMINAL  $\Delta K^4$  DEPENDENCY OF CRACK GROWTH RATE IN INERT ENVIRONMENTS CAN VARY SUBSTANTIALLY IN THE ENVIRONMENT. SOURCE: REF 8, 9. (B) EFFECT OF STRESS RATIO ON CORROSION FATIGUE CRACK PROPAGATION IN A533B AND A508 CARBON STEELS EXPOSED TO PRESSURIZED HIGH-PURITY WATER. TEMPERATURE 288 °C (550 °F), FREQUENCY 0.017 HZ. AVERAGE BEHAVIOR IN AIR IS REPRESENTED BY THE DASHED LINE LABELED "DRY." SOURCE: REF 10**

**FIG. 8 CORROSION FATIGUE CRACK GROWTH RATES FOR A533B LOW-ALLOY STEEL (ASME GRADE SA533B-1, 0.025% S) IN 288 °C PURE WATER. ENVIRONMENTAL ENHANCEMENT IS NOT UNIFORM BUT REACHES A MAXIMUM UNDER INTERMEDIATE  $\Delta K$ ,  $R$ , AND FREQUENCY CONDITIONS. SOURCE: REF 8, 9**

The interactions that give rise to corrosion fatigue can be quite complex and sometimes non-intuitive. For example, in low-alloy and carbon steels in high-temperature water (Fig. 8), a very large environmental enhancement occurs at intermediate  $\Delta K$  or frequency conditions. At higher cyclic amplitudes or frequencies, the total crack growth rate becomes dominated by the inert fatigue crack growth rate. As cyclic amplitude or frequency is decreased, the environmental component is more pronounced, and the crack growth rate response follows a shallower  $\Delta K$ /frequency dependency. With further decreases in cyclic amplitude or frequency, a dramatic decrease in crack growth rate is observed, and the subsequent response parallels the inert fatigue response. This complex behavior is associated with the ability to sustain an aggressive crack chemistry; in these steels, MnS inclusions dissolve and create a sulfur-rich crack chemistry. As the cyclic amplitude or frequency is decreased, eventually the rate of intersection of new MnS inclusions slows to the point that insufficient MnS dissolution occurs and a critical chemistry (for a large environmental enhancement) is not sustained. Complicating factors include the very high sensitivity to relatively low dissolved-sulfur concentrations ("high-sulfur" behavior is observed above about 1 ppm sulfur) and the large role of dissolved oxygen/corrosion potential (which concentrates sulfur anions in the crack), flow rate (which can flush out the aggressive crack chemistry), and nonuniform distribution of MnS inclusions (Ref 8, 11).

**Concepts and Role of Environmentally Assisted Crack Growth.** Historically, the progression in the understanding of metal failure has shifted from addressing simple overload and buckling, to addressing repeated application of lesser loads (fatigue), then to addressing environmental effects on cracking. While the role of environment has long been acknowledged, the design and life evaluation codes (e.g., the ASME Boiler and Pressure Vessel Codes) are based largely on a mechanical engineering perspective and may ignore or average, rather than distinguish and quantify, the following:

- TIME DEPENDENT (VS. CYCLE DEPENDENT) ENVIRONMENTAL CRACK GROWTH
- THE CONTINUUM IN LOADING FROM CORROSION FATIGUE TO STRESS-CORROSION CRACKING
- THE SPECTRUM OF ENVIRONMENTAL CONDITIONS
- VARIATIONS IN MATERIAL MICROSTRUCTURE (E.G., SENSITIZATION)

This historical emphasis on mechanical quantification to the exclusion of environmental and material effects can provide either overly conservative predictions, which penalize systems designed for and/or operated under improved conditions, or non-conservative predictions (i.e., creating risk of failure by environmental cracking). Other factors that are unaccounted for include "anomalies" associated with chemically short cracks, metallurgically small cracks, crack-tip shielding (closure), transient crack growth, and net section stresses above the yield strength. These factors are either proscribed in the design, left to the discretion of the engineer, or incorporated (by conservatism) into the code.

Another aspect of corrosion fatigue, of importance both to laboratory studies and component life evaluation, is the difficulty in conceptually or experimentally distinguishing crack initiation from propagation. Many scientists and engineers consider crack initiation to be phenomenologically distinct from crack advance. However, in most instances there is little evidence to support this view, and any "initiation phase" is merely associated with crack detection capability. Thus "initiation" can span the range from complete failure, to 25% load drop in strain-controlled tests, to readily observable in visual examination, to subgrain size. All of these definitions of crack initiation are arbitrary. In many cases the processes that control propagation of long cracks also control very short crack behavior, although there are also instances where crack propagation occurs from localized corrosion (e.g., pitting or grain boundary attack), fracture of inclusions, and so on, where the processes controlling initiation differ from those that control propagation. In some systems, very small environmentally assisted cracks (e.g.,  $\sim 20 \mu\text{m}$ ) have been shown to behave exactly the same as long cracks (e.g.,  $>1 \text{ mm}$ ) (Ref 12). Clearly the traditional distinctions and delineations associated with "crack initiation" need to be carefully examined.

Similar concerns exist for the traditional concepts of an environmental fatigue threshold ( $\Delta K_{\text{th}}$ ) and a threshold stress intensity for (constant-load) stress-corrosion cracking ( $K_{\text{Isc}}$ ). It has long been known that the nominal (applied) cyclic amplitude ( $\Delta K$ ) can be attenuated at the crack tip by crack closure (crack-tip shielding) (Ref 13), which can be attributed to a variety of phenomena that promote premature contact of the crack flanks, including fracture surface roughness, oxide growth on the walls of the crack, plasticity or phase transformation in the crack wake, and high-viscosity fluids. While usually affecting the behavior primarily at low load ratios ( $P_{\text{max}}/P_{\text{min}}$ ), under conditions where copious oxide forms in the crack (e.g., high-temperature water), closure can also occur at high load ratio (Ref 14). The significance of closure is very large, making it difficult to determine whether a "real" (intrinsic) threshold crack tip  $\Delta K_{\text{th}}^{\text{ct}}$  exists; closure can shift the observed threshold from less than  $2 \text{ MPa}\sqrt{m}$  to more than  $15 \text{ MPa}\sqrt{m}$  (ASTM STP 982, *Mechanics of Fatigue Crack Closure*, 1988).

The role of environment can add substantial complexity by increasing crack growth rates, for example, while perhaps also increasing closure effects, which increases  $\Delta K_{\text{th}}$ . However, the observed  $\Delta K_{\text{th}}$  cannot be considered a constant, given the large effect of environment on oxide formation, oxide solubility (in aqueous systems) (Ref 14), and calcareous deposits (e.g., from sea water) (Ref 15).

These concerns become greater when considering threshold stress intensity for stress-corrosion cracking ( $K_{\text{Isc}}$ ). No such closure mechanism can be invoked because closure limits the effective *cyclic* amplitude at the crack tip, precisely by maintaining a closure-induced "tare" load at the crack tip. Thus, the maximum load cannot be decreased, and in some instances it may be increased from oxide wedging forces. The origin and significance of  $K_{\text{Isc}}$  is controversial, with broad agreement that it is very dependent on test technique (and most test variables) and is rarely, if ever, thermodynamic in origin. In many engineering systems, cracks are observed to grow at stress intensities dramatically lower than the observed  $K_{\text{Isc}}$  in laboratory data. There is also increasing awareness that there is a subtle, delicate, and complex interdependence between sustained dynamic strain at the crack tip (which locally disrupts passivity) and the crack

advance process itself. Once crack advance stalls, corrosion or small environmental, thermal, or loading fluctuations may be required to reinitiate crack advance.

Fully integrated approaches to mechanistic understanding and life prediction of environmentally assisted cracking are being developed for a variety of systems (Ref 16, 17). Some of these (Ref 18) are specifically designed to address the shortcomings of the traditional codes that address only cyclic-based crack growth (not time-dependent crack growth) and fail to address the continuum in the environmental and material responses, crack initiation, the fundamental role of passivity in most alloy/environment systems, and so on.

## Corrosion Fatigue Testing

Peter L. Andresen, GE Corporate Research & Development

---

### General Test Methods

Laboratory fatigue tests can be classified as crack initiation or crack propagation. In crack initiation testing, specimens or parts are subjected to the number of stress (or strain-controlled) cycles required for a fatigue crack to initiate and to subsequently grow large enough to produce failure. In crack propagation testing, fracture mechanics methods are used to determine the crack growth rates of preexisting cracks under cyclic loading. Both methods can be used in a benign environment, or by the combined effects of cyclic stresses and an aggressive environment (corrosion fatigue), as described below. A general review of corrosion fatigue testing is also provided in Ref 19 for these two general methods.

**Fatigue Life (Crack Initiation) Testing.** In general, fatigue life testing is stress controlled (SN) or strain controlled ( $\epsilon$ -N). The test specimens (Fig. 9) are described primarily by the mode of loading, such as:

- DIRECT (AXIAL) STRESS
- PLANE BENDING
- ROTATING BEAM
- ALTERNATING TORSION
- COMBINED STRESS

FIG. 9 TYPICAL FATIGUE LIFE TEST SPECIMENS. (A) TORSIONAL SPECIMEN. (B) ROTATING CANTILEVER BEAM SPECIMEN. (C) ROTATING BEAM SPECIMEN. (D) PLATE SPECIMEN FOR CANTILEVER REVERSE BENDING. (E) AXIAL LOADING SPECIMEN. THE DESIGN AND TYPE OF SPECIMEN USED DEPEND ON THE FATIGUE TESTING MACHINE USED AND THE OBJECTIVE OF THE FATIGUE STUDY. THE TEST SECTION IN THE SPECIMEN IS REDUCED IN CROSS SECTION TO PREVENT FAILURE IN THE GRIP ENDS AND SHOULD BE PROPORTIONED TO USE THE UPPER RANGES OF THE LOAD CAPACITY OF THE FATIGUE MACHINE (I.E., AVOIDING VERY LOW LOAD

## AMPLITUDES WHERE SENSITIVITY AND RESPONSE OF THE SYSTEM ARE DECREASED).

Testing machines are defined by several classifications: (a) the controlled test parameter (load, deflection, strain, twist, torque, etc.); (b) the design characteristics of the machine (direct stress, plane bending, rotating beam, etc.) used to conduct the specimen test; or (c) the operating characteristics of the machine (electromechanical, servohydraulic, electromagnetic, etc.). Machines range from simple devices that consist of a cam run against a plane cantilever beam specimen in constant-deflection bending to complex servohydraulic machines that conduct computer-controlled spectrum load tests.

High-cycle corrosion fatigue tests (performed in the range of  $10^5$  to  $10^9$  cycles to failure) are typically done at a relatively high frequency of 25 to 100 Hz to conserve time. Multiple, inexpensive rotating-bend machines are often dedicated to these experiments. Low-cycle corrosion fatigue tests (in the regime where plastic strain,  $\epsilon_p$ , dominates) follow from the ASTM standard for low-cycle fatigue testing in air (ASTM E 606) with further technical information provided in Ref 19 and 20.

For aqueous media, the typical cell for corrosion fatigue life testing includes an environmental chamber of glass or plastic that contains the electrolyte. The specimen is gripped outside of the test solution to preclude galvanic effects. The chamber is sealed to the specimen, and solution can be circulated through the environmental cell. The setup should include reference electrodes and counter electrodes to enable specimen (working electrode) polarization with standard potentiostatic procedures. Care should be taken to uniformly polarize the specimen, to account for voltage drop effects, and to isolate counter electrode reaction products. If potential is controlled, control of the oxygen content of the solution may not be necessary (Ref 19), although highly deaerated solutions are considered prudent.

Environmental containment for high-cycle and low-cycle corrosion fatigue life testing is similar, but the overall setup for low-cycle (strain-controlled) testing is more complicated because gage displacement must be measured. For strain-controlled fatigue life testing in simple aqueous environments, diametral or axial displacement is measured by a contacting but galvanically insulated extensometer, perhaps employing pointed glass or ceramic arms extending from an extensometer body located outside of the solution. Hermetically sealed extensometers or linear-variable-differential transducers can be submerged in many electrolytes over a range of temperatures and pressures. Alternately, the specimen can be gripped in a horizontally mounted test machine and be half-submerged in the electrolyte with the extensometer contacting the dry side of the gauge (Ref 20). For simple and aggressive environments, grip displacement can be measured external to the cell-contained solution, such as for high-temperature water in a pressurized autoclave (Ref 21, 22). It is necessary to conduct low-cycle fatigue tests in air (at temperature), with an extensometer mounted directly on the specimen gauge, to relate grip displacement and specimen strain (Ref 19).

**Fracture Mechanics ( $da/dN$ ) versus  $\Delta K$  Approach to Corrosion Fatigue.** While there is still a strong reliance on smooth-specimen, low- and high-cycle fatigue testing, which is designed to characterize stress or strain amplitude vs. cycles to failure, there is an increasing emphasis on characterizing crack propagation using a fracture mechanics approach. This results from the ambiguities associated with defining or identifying crack "initiation" (addressed above), as well as increasingly successful efforts to unify the two approaches by predicting "initiation" and short crack behavior from a thorough understanding of crack propagation. The advantage of this approach is that corrosion fatigue crack growth ( $da/dN$  vs.  $\Delta K$ ) data from laboratory testing is in many cases (though not all, as described below) useable in stress-intensity solutions for practical prediction of component life. For example, Fig. 10 illustrates the predicted 85-year life of a welded pipe based on week-long laboratory measurements of  $da/dN$  versus  $\Delta K$  for steel in an oil environment.

**FIG. 10 PREDICTED FATIGUE CRACK EXTENSION FROM A WELD TOE CRACK IN AN API 5LX52 CARBON STEEL PIPELINE CARRYING HYDROGEN-SULFIDE-CONTAMINATED OIL. TEMPERATURE 23 °C (73 °F). SOURCE: REF 23**

Fracture mechanics is based on the concept of similitude, wherein the stress-intensity factor ( $K$ ) defines the near-tip driving forces for crack growth and thus is able to characterize crack growth for different geometries and loads. Crack growth rate data also are important to fundamental studies of corrosion fatigue mechanisms. The fracture mechanics approach isolates crack propagation from initiation and in terms of a precise near-tip mechanical driving force,  $\Delta K$ . Crack growth rates are related directly to the kinetics of mass transport and chemical reaction that constitute embrittlement. As shown in Fig. 11, prediction of the effect of loading frequency on crack growth rate in salt water (normalized to vacuum) identifies important rate-limiting crack tip electrochemical reactions. Modeling and measurements in Fig. 11 provide a sound basis for extrapolating short-term laboratory data to predict long-term component cracking.

FIG. 11 MODELED EFFECT OF LOADING FREQUENCY ON CORROSION FATIGUE CRACK GROWTH IN ALLOY STEELS IN AN AQUEOUS CHLORIDE SOLUTION. THE DETERMINATION OF THE NORMALIZED CRACK GROWTH RATE AND THE TIME CONSTANTS,  $\tau_0$ , FROM THE MODEL CAN BE FOUND IN REF 24.

However, the fracture mechanics approach to corrosion fatigue can be compromised by various factors. In addition to the complications arising from crack-tip plasticity (which may affect the assumption of linear, elastic conditions for  $K$ ) and crack closure effects (which can be accounted for if  $\Delta K_{eff}$  is known), environmental effects can complicate the requirement of similitude. This is not surprising, because stress intensity is designed to provide only a mechanical description of similitude, which cannot be expected to account for the interaction of chemical and mechanical contributions. Examples of loss of similitude from environmental effects would include any case where a different crack chemistry (or, more generally, chemical contribution to crack advance) develops in small versus deep cracks (where mass transport can vary substantially), or three-sided open cracks (e.g., compact-type specimens) versus 1-side open (thumbnail cracks) (where convection can have a dramatically different effect) (Ref 25).

Another disadvantage of the fracture mechanics approach is that it may not provide a meaningful description of crack "nucleation," especially in cases where cracks are observed to nucleate by processes (e.g., pitting, and corrosion or cracking at inclusions) that are unrelated to crack advance.

**Importance of Environmental Definition and Control.** The nature and variations of the environment are dominating factors in environmental cracking, and all environments must be considered damaging compared to vacuum or "laboratory air" until proven otherwise. Figure 1(a) shows that, compared to vacuum, the crack propagation rate of a high-strength steel is 4 times higher in moist air, 100 times higher in sodium chloride solutions, and 1000 times higher in gaseous hydrogen. Environmental cracking kinetics tend to be controlled by chemical reaction and transport rates, and much less so by metallurgical variables. For example, the moist air data vary by less than 3 times for a wide range of yield strengths (300 to 2100 MPa) and microstructures (pearlitic, martensitic, and bainitic). The large differences in crack growth rate at constant  $\Delta K$  correlate with a shift from ductile (reversed slip) transgranular fatigue cracking in vacuum, to brittle intergranular and transgranular cleavage micromechanisms in aggressive environments.

Another example of environmental effects is shown in Fig. 7, 8, and 12 for a low-alloy steel of medium sulfur content tested in high-temperature water, where a very large environmental enhancement in crack growth rate is observed under specific conditions. Figures 7 and 8 highlight the important observation that the environment enhancement is not uniform, for example across the entire range of loading conditions. Indeed, the environmental enhancement tends to decrease at very high loading rates (e.g., at high frequency and  $\Delta K$  values), and it may also decrease at very low loading rates. Figure 12 shows the importance of the specific test conditions. Tests at high flow rates on three-side-open compact-type specimens caused the aggressive crack chemistry to be flushed out, resulting in lower crack growth rates.

FIG. 12 THE EFFECT OF SOLUTION FLOW RATE ON THE CORROSION FATIGUE CRACK GROWTH RATE OF A MEDIUM-SULFUR, LOW-ALLOY STEEL TESTED IN DEAERATED 288 °C (550 °F) WATER. TESTS AT HIGH FLOW RATE ON THE 3-SIDE-OPEN COMPACT-TYPE SPECIMENS PERMIT THE AGGRESSIVE CRACK CHEMISTRY TO BE FLUSHED OUT, REDUCING THE CRACK GROWTH RATES. SOURCE: REF 8, 9

## Corrosion Fatigue Testing

Peter L. Andresen, GE Corporate Research & Development

---

## Key Test Variables

The specific types and influence rankings of experimental variables in corrosion fatigue can vary markedly with specific alloy/environment systems. However, the following factors are crucial in most investigations of corrosion fatigue:

- STRESS INTENSITY AMPLITUDE ( $\Delta K$ ) OR STRESS AMPLITUDE ( $\Delta\sigma$ )
- LOADING FREQUENCY ( $V$ )
- LOAD RATIO ( $R = P_{\text{MIN}}/P_{\text{MAX}}$  OR  $K_{\text{MIN}}/K_{\text{MAX}}$ )
- CHEMICAL CONCENTRATION AND CONTAMINANTS (E.G., FOR AQUEOUS ENVIRONMENTS: IONIC SPECIES; PH; AND DISSOLVED SPECIES/GASES, SUCH AS OXYGEN, HYDROGEN, AND COPPER ION, THAT INFLUENCE THE CORROSION POTENTIAL)
- ALLOY MICROSTRUCTURE; YIELD STRENGTH; AND OFTEN INHOMOGENEITIES, SUCH AS MNS AND OTHER INCLUSIONS AND SECOND PHASES, GRAIN BOUNDARY ENRICHMENT OR DEPLETION, ETC.

Other variables, such as load waveform, load history, and test temperature may also contribute, but they vary substantially in importance from system to system. Electrode potential should be monitored and, if appropriate, maintained constant during corrosion fatigue experimentation. Often, apparent effects of variables such as solution dissolved oxygen content, flow rate, ion concentration, and alloy composition on corrosion fatigue are traceable to changing electrode potential.

**Stress Intensity Amplitude ( $\Delta K$ ).** While environmental crack growth rates increase with increasing  $\Delta K$ , the specific dependency varies greatly. In some environments, the effect of environment is merely to offset the observed crack growth rate by some fixed factor above the inert rate (e.g., Fig. 1(a) for moist air vs. vacuum; Fig. 7(a), 12 for low-alloy steel in high-temperature water). However, there is often a profound shift in the dependence of  $\Delta K$ , typically producing a reduced  $\Delta K$  dependence in aggressive environments, at least in the intermediate region where power law behavior is observed. It is always important to examine the entire relevant  $\Delta K$  regime, not assuming the observed enhancement at a specific  $\Delta K$ .

Environments do not always enhance the crack growth rate. The most common origins of crack retardation are associated with increased crack closure and crack blunting. Crack closure is most often increased by thicker oxides and perhaps the rougher (i.e., intergranular, with secondary cracks) fracture surface (Ref 13, 14). Crack blunting results from aggressive environments that result in inadequate passivity. If the flanks of the crack are not adequately passive, then the crack tip will not remain sharp. This has been observed in low-alloy and carbon steels in hot water (Fig. 13) and in other systems.

**FIG. 13 CYCLE-BASED CORROSION FATIGUE CRACK GROWTH RATES VS. TIME FOR AN SA333-GRADE 6 ASME CARBON STEEL TESTED IN 97 °C WATER. AT 0.1 PPM DISSOLVED OXYGEN, THE CORROSION RATE IS LOW, THE CRACK TIP REMAINS SHARP, AND CRACKING IS SUSTAINED. AT 1.5 PPM DISSOLVED OXYGEN, CONSIDERABLE CORROSION OCCURS, THE CRACK TIP BECOMES BLUNTED, AND THE CRACK GROWTH RATE DECAYS. SOURCE: REF 26**

Shifts in  $\Delta K$ ,  $K_{max}$ , or load ratio during testing should be made very gradually, preferably continuously (e.g., under computer control). Changes in  $K$  should be limited to less than 10%, preferably much less. Any large change in growth rate should be confirmed using increments of <1%. Data may differ for rising  $K$  versus  $K$ -shedding conditions. Crack increments should be sufficient to provide statistically significant crack growth rates (e.g., >10 times above the crack length resolution) and should account for effects of plastic zone size under prior conditions during  $K$ -shedding. Shifts in frequency and hold time are not as restrictive, although changes greater than 3 to 10 times can lead to anomalous results.

The presence of an environment can also shift the dependence on stress amplitude ( $\Delta\sigma$ ) or plastic strain amplitude ( $\Delta\varepsilon$ ), not only by decreasing the stress at which a certain cyclic life can be attained, but also by eliminating the stress amplitude threshold altogether (Fig. 2). This, and increased scatter in the data, can lead to differences in estimating environmental effects at different stress amplitudes (Fig. 3). Note also that there is a consistent trend versus time in which the "bounding" curves are periodically shifted lower and to the left in Fig. 3.

**Loading Frequency ( $\nu$ ).** Because the environment induces a significant time-dependent response, environment enhancement can vary markedly with loading frequency. At high frequency it is common for the environmental enhancement to be substantially eliminated because of inadequate time available for associated chemical reaction and mass transport kinetics.

Transitions in significant environmental enhancement are often apparent when plotting crack growth rate versus frequency or hold time. For example, in Fig. 11 at frequencies below about 0.1 Hz, time-dependent processes completely dominate and there is no effect of loading frequency (i.e., crack growth is not controlled by cycling and would be high at constant load). In contrast, above about 0.1 Hz there is little time dependency, and growth rates are proportional to frequency.

Strong frequency effects are observed in most corrosion fatigue systems. In high-temperature water (Fig. 14), behavior similar to that in Fig. 11 exists, although it is plotted versus loading period or hold time (Ref 6) rather than frequency. Predictive modeling has been quite successful in accounting for the transition between cycle- and time-dependent behavior as a function of corrosion potential, water purity, and degree of sensitization of the stainless steel (Ref 6, 18).

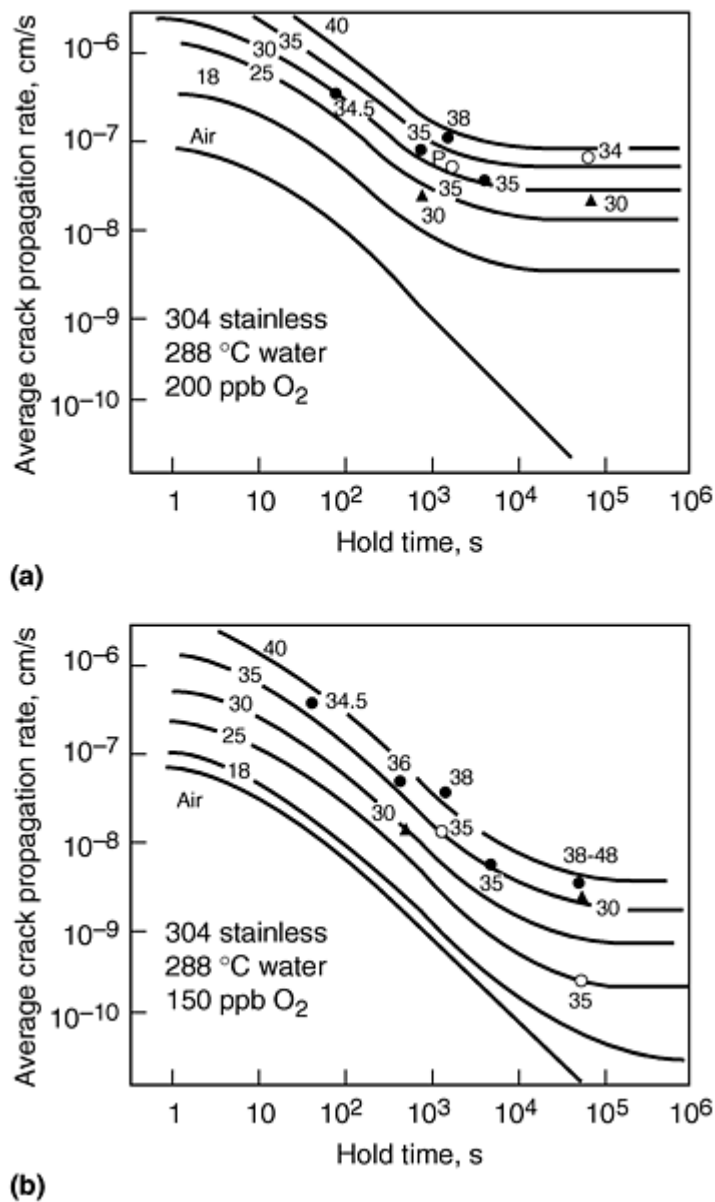

FIG. 14 COMPARISON OF OBSERVED (DATA) AND PREDICTED (CURVES) CRACK GROWTH RATES FOR SENSITIZED TYPE 304 STAINLESS STEEL IN 288 °C WATER. THUMBNAIL CRACK SPECIMENS WERE LOADED USING TRAPEZOIDAL LOADING PATTERNS OF VARYING HOLD TIME AT THE MAXIMUM STRESS INTENSITY WITH NET SECTION STRESSES ABOVE YIELD. THEORETICAL RELATIONS FOR VARIOUS NET SECTION STRESSES (IN KSI) AS NOTED BY NUMBERS.  $K(\text{MAX}) = 16.5 \text{ MPa}\sqrt{m}$  (15 KSI  $\sqrt{in}$ );  $R = 0.1$ ; LOADING RISE AND FALL TIMES OF 5S;  $E(\text{CORR}) = +125 \text{ MV}(\text{SHE})$ ; AND  $0.1 \mu\text{S}/\text{CM}$ . (A) IN 200 PPB DISSOLVED OXYGEN. (B) IN 150 PPB DISSOLVED HYDROGEN. SOURCE: REF 6

**Load Ratio ( $R$ ).** At higher load ratios ( $P_{\min}/P_{\max}$ ), corrosion fatigue crack growth rates are usually higher than in inert environments. This can be viewed as a mean stress effect, and the greater environmental enhancement can be considered to result from the expected increase in contribution of time-dependent crack advance that would occur even under static load conditions. Figure 15 shows the effect of load ratio in low-alloy steel tested in high-temperature water at 0.017 Hz. The increased  $K_{\max}$  associated with testing at  $R = 0.7$  (e.g.,  $K_{\max} = 66.7 \text{ MPa}\sqrt{m}$  for  $\Delta K = 20 \text{ MPa}\sqrt{m}$ ) compared to 0.2 ( $K_{\max} = 25 \text{ MPa}\sqrt{m}$ ) is substantial, and it is consistent with an increase in crack-tip strain rate and thereby an increase in

the frequency of rupture of the protective oxide film and high growth rates. As expected, the effect of load ratio is frequency dependent. Also, if plotted versus  $K_{max}$  rather than  $\Delta K$ , higher crack growth rates should always result with decreasing load ratio.

**FIG. 15 CORROSION FATIGUE CRACK GROWTH RATES PLOTTED FOR MEDIUM-SULFUR A533B AND A508-2 LOW-ALLOY STEELS AND WELDMENTS IN 288 °C DEAERATED (PRESSURIZED WATER REACTOR PRIMARY) WATER. DATA SHOW A STRONGER ENVIRONMENTAL EFFECT AT  $R = 0.7$  THAN AT  $R = 0.2$ . SOURCE: REF 8, 9**

**Test Environment and Chemical Contaminants.** Besides the obvious concern of primary species (such as NaCl concentration for salt water) in corrosion fatigue, small amounts of contaminants are also a key variable. A striking example (Ref 27) of an environmental-purity effect is illustrated in Fig. 16 for gaseous hydrogen embrittlement of a low-strength carbon steel. Relative to vacuum, crack growth is accelerated by factors of 3 and 25 for moist air and highly purified low-pressure hydrogen gas, respectively. Small additions of oxygen to the hydrogen environment essentially eliminate the brittle corrosion fatigue component to crack growth, consistent with a trend first reported by Johnson (Ref 28). Similar effects have been reported for carbon monoxide and unsaturated hydrocarbon contamination of otherwise pure hydrogen environments. In aqueous environments, the effects of bulk ionic concentration and pH are often quite pronounced (especially in unbuffered systems), although dissolved oxidants are often of greater consequence (e.g., dissolved oxygen, hydrogen peroxide, and copper and iron ions), as are contaminants (e.g., dissolved sulfur, chloride, lead, mercury).

FIG. 16 EFFECT OF OXYGEN (O<sub>2</sub>) CONTAMINATION ON GASEOUS HYDROGEN EMBRITTLEMENT OF A LOW-STRENGTH AISI/SAE 1020 CARBON STEEL. FREQUENCY 1 HZ. SOURCE: REF 27

The primary role of oxidizing and reducing species, especially dissolved oxygen and hydrogen, is in shifting the corrosion potential. Some species, such as nitrate, may also directly influence crack chemistry and, if reduced to ammonia, can be directly responsible for environmental enhancement (e.g., of brasses). In many cracking systems, the role of oxidants (elevated corrosion potential) is an indirect one, because inside the crack the oxidants are generally fully consumed and the corrosion potential is low (Ref 25). In such systems, the role of oxidants is to create a potential gradient, usually near the crack mouth, that causes anions (e.g., Cl<sup>-</sup>) to concentrate in the crack and causes the pH to shift.

Oxidants increase the corrosion potential in aqueous environments, which can have very pronounced effects on environmental enhancement. This can occur at exceedingly low concentrations; in high-temperature water, crack growth rates can increase by orders of magnitude merely from the presence of parts-per-billion levels of dissolved oxygen in water (Fig. 17, 18); this is also evident in Fig. 14). Similar enhancements are observed for small concentrations of aqueous impurities (e.g., <10 ppb of sulfate or chloride) or MnS inclusions in low-alloy and carbon steels, which dissolve within the crack to form sulfides. This usually is associated with the formation of a differential aeration cell by complete oxygen consumption within the crack (Fig. 19). Thus, even very small cracks usually advance under deaerated conditions, and the gradient in corrosion potential that is formed from crack mouth to crack tip causes an increase in anion concentration and a shift in pH in the crack. The shift is often acidic, but not necessarily so, because it requires the presence of non-OH<sup>-</sup> anions to balance the acidity (H<sup>+</sup>). Thus, if only OH<sup>-</sup> is present (e.g., from NaOH), the pH shift can only be in the alkaline direction.

FIG. 17 THE EFFECT OF DISSOLVED OXYGEN ON THE CORROSION POTENTIAL OF TYPE 304 STAINLESS STEEL IN 274 °C HIGH-PURITY WATER. IMPORTANT EFFECTS ON CORROSION POTENTIAL AND CRACK GROWTH RATE (FIG. 18) OCCUR AT PPB LEVELS OF DISSOLVED OXYGEN, A SMALL FRACTION OF THE OXYGEN-SATURATED VALUE OF  $\approx 42$  PPM AT STANDARD TEMPERATURE AND PRESSURE. SOURCE: REF 6

FIG. 18 COMPARISON OF OBSERVED (DATA) AND PREDICTED (CURVES) CRACK GROWTH RATE RESPONSE OF SENSITIZED TYPE 304 STAINLESS STEEL IN 288 °C WATER. CIRCLED DATA POINTS REPRESENT MEASURED CORROSION POTENTIALS AND CRACK GROWTH RATES UNDER IRRADIATED WATER CHEMISTRY CONDITIONS. SOURCE: REF 6, 18

**FIG. 19 SCHEMATIC OF CRACK SHOWING THE DIFFERENTIAL AERATION MACROCELL THAT ESTABLISHES THE CRACK-TIP CHEMISTRY AND THE LOCAL MICROCELL THAT IS ASSOCIATED WITH METAL DISSOLUTION AND CRACK ADVANCE. BECAUSE THE DIFFERENTIAL AERATION MACROCELL IS NOT ESSENTIAL TO ELEVATED CRACK GROWTH RATES, SOME COUPLING OF THE CURRENTS ASSOCIATED WITH THESE TWO CELLS MAY OCCUR, BUT THIS IS UNNECESSARY. SOURCE: REF 25**

Potentiostats can be used to control the specimen potential, although their use (which rarely directly simulates the real situation) can provide misleading data. Primary concerns are associated with:

- **VOLTAGE DROP IN SOLUTION:** THE REFERENCE ELECTRODE READING MAY BE BIASED BY THE POTENTIAL DISTRIBUTION IN THE SOLUTION ASSOCIATED WITH PASSAGE OF IONIC CURRENT.
- **FAILURE TO POLARIZE THE CRACK TIP:** EVEN IN HIGHLY CONDUCTIVE SOLUTIONS, THE CRACK-TIP POTENTIAL IS RARELY SIGNIFICANTLY AFFECTED BY EXTERNAL POLARIZATION, AND THEREFORE CRACK ADVANCE DOES NOT OCCUR AT THE POTENTIAL THAT IS CONTROLLED ON THE SPECIMEN SURFACE.
- **A REVERSAL OF SURFACE REACTIONS AND SHIFTS IN LOCAL PH:** IN SOLUTIONS CONTAINING OXYGEN, THE REACTION ON THE EXTERNAL SURFACE IS CATHODIC, AND INSIDE THE CRACK, ANODIC REACTIONS OCCUR. WITH A POTENTIOSTAT, AS THE SPECIMEN IS POLARIZED TO MORE POSITIVE POTENTIALS, IT BECOMES MORE ANODIC AND CAUSING OXIDATION REACTIONS TO BECOME PREDOMINANTLY ON THE METAL SURFACE, WHICH CAN ALTER THE LOCAL PH. CATHODIC REACTIONS OCCUR PREDOMINANTLY ON THE RELATIVELY REMOTE COUNTER ELECTRODE.

To accurately measure potentials, commercial or custom-built reference electrodes are used. Both to measure potentials accurately and to prevent galvanic coupling, it is desirable to electrically isolate the specimen from the linkage and surrounding metal surfaces. If the environment is not very conducting or the potentials of surrounding metal surfaces are not too different from the specimen, electrical isolation may not be critical. However, it is then necessary to place the reference electrode *much closer* to the test specimen than to other (electrically connected) metal surfaces.

Other concerns for the environment include:

- SPECIMEN AND GRIP DESIGN (E.G., TO AVOID FAILURE AT CREVICES BY MINIMIZING STRESS IN CREVICED REGIONS)
- PROPER DESIGN OF ENVIRONMENTAL CELLS (E.G., TO AVOID CONTAMINATION FROM LEACHANTS FROM OR DIFFUSION OF OXYGEN THROUGH PLASTICS)
- MAINTENANCE OF PROPER CHEMISTRY, WHICH OFTEN REQUIRES REFRESHED/FLOWING SYSTEMS FOR CONTROLLING THE CHEMISTRY IN GASES OR LIQUIDS
- PROPER STABILITY AND MEASUREMENT OF TEMPERATURE (NEAR THE SPECIMEN)
- PROPER AND THOROUGH MONITORING/RECORDING OF ALL RELEVANT CHEMICAL AND ELECTROCHEMICAL PARAMETERS

**Metallurgical Variables.** Microstructure and alloy strength influence fatigue crack propagation in embrittling gases and liquids. In general, brittle corrosion fatigue cracking is accentuated by:

- IMPURITY (E.G., PHOSPHORUS OR SULFUR) SEGREGATION AT GRAIN BOUNDARIES
- SOLUTE DEPLETION OR SENSITIZATION (E.G., CHROMIUM) ABOUT GRAIN BOUNDARIES
- PLANAR DEFORMATION ASSOCIATED WITH ORDERING OR PEAK AGED COHERENT PRECIPITATES
- INCREASED YIELD STRENGTH OR HARDNESS
- LARGE INCLUSIONS (E.G., MNS)

The effects of alloy composition, grain size, and microstructure (e.g., bainitic vs. martensitic steel) vary with environment and brittle cracking mechanism. Laboratory experiments are necessary to establish specific trends. For example, sulfide (MnS) inclusions have already been discussed in connection with accelerated environmental cracking of low-alloy and carbon steels in hot water (Fig. 7, 8, 12, 15).

Yield strength plays a large role in environmental cracking, which has been attributed both to enhanced crack-tip strain rate as well as to complete shifts in the crack advance mechanism. The importance of hydrogen embrittlement in higher-strength materials has been confirmed by experiments in gaseous hydrogen. Its direct role in environmental crack advance is considered to be limited to about 150 °C in iron- and nickel-base alloys, although it may have an indirect role at higher temperatures.

Similar effects have been observed for bulk or surface cold work, which raises the yield strength. Thus, machining and surface treatments such as shot peening can significantly affect cracking. Shot peening and related treatments that produce surface compressive stresses can be very beneficial, provided that cracks do not exist (or form) and that tensile stresses do not exceed them. If sufficient strain occurs, transgranular cracks often nucleate in the surface-hardened region.

Other important microstructure factors include gamma prime or delta phases on grain boundaries of nickel alloys, martensite formation in steels, carbide formation (sensitization) in stainless steel and nickel alloys, and inhomogeneities (e.g., MnS and nonmetallic inclusions). These often have an even larger role in corrosion fatigue than under inert conditions, and a uniform microstructure or distribution of inhomogeneities can rarely be assumed.

**Crack Closure Effects.** Premature crack surface contact during unloading, or "crack closure," can greatly reduce rates of fatigue crack propagation. The true (or effective) crack-tip driving force is reduced below the applied  $\Delta K$  because of the reduced crack-tip displacement range. Closure phenomena are produced by a variety of mechanisms and are particularly

relevant to fatigue crack propagation in the near-threshold regime, after large load excursions, or for corrosive environments.

Two mechanisms of crack closure are relevant to corrosion fatigue. Rough intergranular crack surfaces (typical of environmental embrittlement) promote crack closure, because uniaxially loaded cracks open in a complex three-dimensional mode, thus allowing for surface interactions and load transfer. Roughness-induced closure is most relevant to corrosion fatigue at low  $\Delta K$  and at stress-ratio levels where absolute crack opening displacements (0.5 to 3  $\mu\text{m}$ ) are less than fractured grain heights (5 to 50  $\mu\text{m}$ ).

Alternately, crack closing is impeded by dense corrosion products within the fatigue crack. For mildly oxidizing environments, such as moist air, this closure mechanism is relevant at low stress-intensity levels and contributes to the formation of a "threshold," as described by Suresh and Ritchie (*Inter. Metals Review*, Vol 29, 1984, p 445-476).

For corrosive bulk environments or localized crack solutions, cracking at high  $\Delta K$  values may be retarded below the growth rates observed for air or vacuum due to corrosion product formation within the crack. The engineering significance of beneficial crack closure influences depends on the stability of the corrosion product during complex tension-compression loading and fluid conditions.

The complexity of predicting environmentally enhanced cracking is emphasized by data contained in Fig. 20 for a 2.25Cr-1Mo steel (ASTM A542, class 3) stressed in hydrogen at 23 °C (73 °F). At high  $\Delta K$  levels and low loading frequencies, cracking is accelerated in hydrogen compared to moist air, due to classic hydrogen embrittlement. For low stress intensities, cracking is also enhanced by hydrogen exposure; however, the effect is not due to chemical embrittlement because of the rapid loading frequencies. Oxides form on crack surfaces through a fretting mechanism during cycling in air. Crack growth rates are reduced by oxide-induced closure. Thus crack growth at low frequencies may increase by embrittlement but decrease from increased oxide formation and closure.

FIG. 20 CORROSION FATIGUE IN 2.25CR-1MO PRESSURE-VESSEL STEEL IN HYDROGEN DUE TO HYDROGEN EMBRITTLEMENT AT HIGH  $\Delta K$  AND TO REDUCED OXIDE-INDUCED CLOSURE AT LOW  $\Delta K$ . STRESS RATION =

## Corrosion Fatigue Crack Growth Test Methods

Standard methods of fatigue crack growth (as defined in ASTM E 647 and described in the article "Fatigue Crack Growth Testing" in this Volume) are generally applicable to corrosion fatigue crack growth tests. ASTM E 647 (1991) also

contains an appendix specific to crack growth in marine environments. Procedures for other corrosion fatigue environments are not standardized, but various methods have evolved. Some general aspects of corrosion fatigue crack growth are described below, and additional background is provided in Ref 19.

Three problem areas are relevant to corrosion fatigue experimentation. The environment must be contained about the cracked specimen without affecting loading, crack monitoring, or specimen-environment composition. Parameters such as environmental purity, composition, temperature, and electrode potential must be monitored and controlled frequently.

Secondly, the deleterious effect of low cyclic frequency dictates that crack growth rates must be measured at low (often <0.2 Hz) frequencies, which lead to long test times, often from several days to weeks. Load-control and crack-monitoring electronics and environment composition must be stable throughout long-term testing.

Thirdly, crack length must also be measured for calculations of stress intensity and crack growth rate. Optical methods are often precluded by the environment and test chamber. Indirect methods, based on specimen compliance or electrical potential difference, have been applied successfully to monitor crack growth in a wide variety of hostile environments and are described in more detail below. Experimental and analytical requirements, however, are complex for indirect crack monitoring.

**Test Specimens.** Finally, specimen geometry and size requirements for  $\Delta K$ -based crack propagation data, which are scaleable to components through similitude, have not been established completely for subcritical crack growth. In-plane yielding must be limited to the crack tip by guaranteeing that the net section stress is below yield and that the maximum plastic zone size, defined as  $\sim 0.2 (K_{\max}/\sigma_{ys})^2$ , is much less (e.g., 10- to 50-fold) than the uncracked ligament. Specimen thickness, as it influences the degree of plane-strain constraint, and crack size, as it influences the chemical driving force, may affect corrosion fatigue crack speeds. Currently, such effects are unpredictable; specimen thickness and crack geometry must be treated as variables.

Corrosion fatigue testing often is performed at low cyclic frequencies. Consequently, multiple test stations are desirable. For this reason and for general economy, compact tension specimens are frequently used. Such specimens minimize the applied load required to achieve a given crack tip stress intensity, thus permitting the use of low load capacity and less expensive test machines.

In corrosion fatigue, the electrochemistry within the crack is mass transport dependent and can vary with crack depth, and possibly also with specimen geometry and with accessibility of solution in the through-thickness direction via the crack sides. These factors can influence crack growth rates despite the constancy of the range of the stress-intensity factor. The application of fracture mechanics to corrosion fatigue must therefore be considered carefully, because in some circumstances the basic concepts may be invalid. In reports of test data, information regarding crack depth should be quoted or be deducible from the data. An alternative is to determine crack depth and  $\Delta K$  as independent variables to verify that  $\Delta K$  is an adequate characterizing parameter for the rate of crack growth.

In applying load to specimens in a test cell, cell friction must not affect load in sealed systems. This is generally not a significant factor in most ambient-temperature applications, however. Insulation between specimens and grips, pin assemblies, and so forth is essential to avoid galvanic effects, but greases should not be used.

## Electrode Potential

Monitoring and reporting the electrode potential during corrosion fatigue experiments is important. The potential should be measured using a reference electrode located in the bulk solution adjacent to the specimen. When impressed currents are applied to the specimen, measurement should be made adjacent to the surface using a Luggin capillary to minimize the potential drop between the reference electrode and the metal surface, the magnitude of which will depend on the solution conductivity and flow of current.

Selection of a reference electrode depends on the particular application, but those most commonly used in laboratory room-temperature tests are the saturated calomel electrode and the silver/silver chloride electrode. For some solutions in which contamination with chloride is undesirable, use of a mercury/mercurous sulfate reference electrode is an option. Contamination can be reduced by using commercially available double-junction electrodes, in which the outer jacket is filled with test solution.

In quoting measured potentials, the potential should be referred to a standard scale such as the standard hydrogen electrode (SHE) or the saturated calomel electrode (SCE) at 25 °C (75 °F). In tests remote from 25 °C (75 °F), allowance must be made for the fact that the half cell potential of the reference electrode varies with temperature. A high-impedance meter ( $>10^{12} \Omega$ ), such as an electrometer or a pH meter, should be used for monitoring potential, although periodic (short-term) measurements can usually be successfully performed using digital voltmeters whose input impedance is  $\geq 10^9$  ohms (usually limited  $\cdot 2V$  full scale dc ranges).

Near room temperature, it generally is possible to use commercial reference electrodes such as calomel and silver chloride electrodes; some electrode designs permit use near boiling. Designs that place the reference electrode in a separate chamber at a different temperature than the test solution are complicated by formation of a thermal junction potential in the electrolyte, the magnitude of which may be large (over 0.1 V).

At temperatures over boiling, a custom reference electrode generally is necessary. Most investigators use internal or external silver/silver chloride reference electrodes. For internal electrodes, the silver chloride reaction occurs at the test temperature. For external electrodes, the silver chloride reaction occurs at room temperature, but system pressure is applied (so no streaming potentials form), with a temperature gradient occurring in the potassium chloride electrolyte as it enters the autoclave. A porous junction in the autoclave isolates the potassium chloride electrolyte from the autoclave solution. This thermal junction potential has been well characterized over a range of temperatures and potassium chloride concentrations (*Electrochem. Society*, Vol 126, 1979, p 908).

Potentials should be reported on the standard hydrogen electrode (SHE) scale, particularly for elevated-temperature tests, for which the conversion factors to  $V_{(SHE)}$  are not widely known. However, when comparing results as a function of temperature, it may be helpful to eliminate the contribution of the standard hydrogen cell, because like other reactions, it has a potential that varies with temperature. It is by convention that the standard hydrogen cell is 0 V at any temperature; relative to the standard hydrogen reaction at 25 °C (75 °F), the potential of the standard hydrogen reaction is about 0.021 V at 50 °C (120 °F), 0.057 V at 100 °C (212 °F), 0.086 V at 150 °C (300 °F), and about 0.105 V between 210 and 300 °C (410 and 570 °F).

Application of imposed potential using a potentiostat requires electrical isolation of the specimen. In some cases, it may be difficult to insulate the specimen from the loading linkage; instead, the linkage must be insulated from the autoclave, and the measured current flow cannot be attributed only to reactions at the specimen. Ground loops present perpetual problems, because most potentiostats are designed to hold the specimen at ground (or virtual ground). With necessary mechanical and plumbing connections, the autoclave is usually connected to ground; thus, the specimen is effectively connected to the autoclave. The problem is compounded if the autoclave is used as the counter electrode, because the ground loop shorts out the potentiostat. Options include thorough electrical isolation of the autoclave from ground and use of a fully floating potentiostat.

Attachment of a lead to the specimen to permit measurement or application of potential can be a challenge in aggressive environments. Recommendations include use of wire that is either identical to the specimen or a very noble metal, such as platinum. Attachment using a weld bead (e.g., by gas-tungsten arc welding) usually is superior to spot welding. Covering the lead wire with heat-shrink Teflon and, at low test temperatures, covering the weld with an organic "stopoff" coating helps maintain a good connection and minimizes the effects of the wire (via galvanic coupling or its contribution to the measured current). Another technique involves the use of a commercially available plasma-sprayed insulating coating, which can also be used in high-temperature water.

Errors in the potential applied by a potentiostat can occur in solutions of low conductivity. These  $iR$  drops, which result from current flow between the counter electrode and working electrode in the high-resistance solution, are detected by the reference electrode and summed with the electrode potential of the specimen. Electronic compensation is possible, but not straightforward in most high-resistivity media. Partial compensation is possible by placing the reference electrode near the specimen, although for small specimens the measured potential becomes very sensitive to electrode positioning. A rough estimate of the possible error can be made by multiplying the resistivity of the solution (preferably determined by measuring the alternating current (ac) flowing between the counter electrode and working electrode when a known 1000 Hz ac voltage is applied) by the potentiostat current that flows during a test.

## Monitoring Crack Length

The electrical potential technique and the compliance method (discussed elsewhere in this Volume) are frequently used to monitor fatigue crack growth in solution and in gaseous environments. Visual methods generally are not practical; often, the crack and the test specimen are obscured by the test chamber, or a microscope with a long focal length is needed.

The electrical potential technique is preferred over the compliance method for use inside an environmental test chamber, because the compliance gage may outgas and is a potential source of test environment contamination. Its use in a corrosive environment is also unsuitable. The electric potential technique, however, is noncontaminating and can be used in most environments.

Use of the compliance method is generally limited to compact tension (CT, or compact type) and wedge-opening load specimens. It is not used for center-cracked tension specimens because of limitations in sensitivity and accuracy. The electrical potential technique can be readily applied to all three specimen types. The principal drawback of the electrical potential technique is that the specimen must be electrically conductive; thus, it cannot be applied directly to specimens made of nonelectrically conducting materials, such as polymer-based composites and ceramics. In addition, electrical shorting across the crack surfaces may affect its measurement accuracy, particularly for tests in vacuum. Both the electrical potential and compliance techniques can be readily interfaced with a computer for real-time control of the experiment and for online data acquisition and reduction.

**Potential Drop Method.** The most common and sensitive in situ crack monitoring technique is reversing direct current (dc) potential drop, which typically applies a constant current to a specimen and measures the changes in potential across the specimen as the crack grows. The current is reversed between readings to eliminate thermoelectric effects, amplifier offsets, and so on. A digital voltmeter is recommended, preferably with an integration time of more than one power line cycle. Hundreds or thousands of readings are often averaged to reduce noise and improve the sensitivity. Some investigators use a "reference probe" pair, whose potential is as insensitive as possible to crack growth, to normalize any changes in current or temperature (which changes the resistivity of metals). Usually, solving the problem at its origin (i.e., using very stable constant current sources; using high-quality, well-tuned digital temperature controllers; and ensuring stable room temperature) works better.

In the environment, there are several special considerations. Solution conductivity can be a major issue; an extreme example is the inability to use potential drop in liquid metal environments. Some deviations in crack length versus measured potential response can also occur in highly conducting environments (e.g., aqueous solutions), and it must be recognized that the crack chemistry can be substantially more conductive and at different pH than the bulk solution. However, despite the small distance between the upper and lower crack flanks, the role of ionic (e.g., aqueous) conductivity is not large compared to that of metal conductivity, because aqueous conductivities are typically measured in  $10^{-1}$  to  $10^{-6}$  S/cm (S, or Siemen, is  $\Omega^{-1}$ ), whereas metal conductivities are typically between  $10^5$  and  $10^6$  S/cm. Thus, errors associated with aqueous environments are relatively small, although not always ignorable.

Another concern relates to inaccuracies in indicated crack length because of a nonuniform crack front or because of metal contact along the crack flank during the fatigue cycle. In both cases, an abnormal fraction of the dc current "shorts" through the uncracked metal ligament in the wake of the nominal crack front, and the measured potential and indicated crack length is strongly affected. For example, if the crack front moves forward in a 25 mm compact-type specimen by 3 mm in all locations except along one narrow, rectangular ligament that is only 1 mm wide, the indicated crack advance by potential drop can be very small (i.e., dramatically less than the area average of crack advance). Nonuniform crack fronts are much more common when the environmental contribution to crack advance is high, and static loading (stress-corrosion cracking) is generally much worse than dynamic loading (e.g., corrosion fatigue). Certain microstructures, such as weld metal, can be quite susceptible to accelerated or retarded crack advance in localized regions (i.e., along certain weld dendrites). The "unzipping" of the final metal ligament can lead to anomalously high "apparent" crack growth rates over certain testing periods.

In many instances, the importance of metal contact from the upper to lower crack flank surface during the fatigue cycle is low because of the formation of surface oxides of very limited electrical conductivity. However, in vacuum, hydrogen, or sufficiently reducing aqueous conditions (e.g., nickel-base alloys in hot water containing sufficient dissolved hydrogen), little or no oxide forms, and contact and shorting of dc current occurs during the unloading cycle. In these cases, either a different crack monitoring technique should be used, or potential drop measurements should only be made at maximum load. Even so, making environmental conditions more reducing (e.g., increasing the hydrogen fugacity in high-temperature water testing of nickel-base alloys) can lead to an indicated decrease in crack length by potential drop because of the change in the insulating characteristic of the oxides.

Other concerns for dc potential drop include electrochemical effects, particularly polarization. If a well-designed, ground isolated power supply is used, then all of the dc current that leaves the "+" terminal must return on the "-" terminal, and direct polarization of the specimen is not possible. In most cases, there is little basis for concern for the electrochemical effects of using dc potential drop, although, for example, the small potential difference between the crack flanks could have some influence in tight cracks in conductive solutions. This potential difference is very small near the crack tip, so it is more likely to influence, for example, dissolution of MnS inclusions at some distance toward the crack mouth, where the potential difference across the crack flanks is higher. While the potential difference between the upper and lower surfaces of the crack is small (typically 100  $\mu\text{V}$  in many potential drop implementations), the gradient can be relatively large because of the small separation of the crack faces. The importance of this issue can be quantified by establishing a steady-state crack growth rate and disconnecting the potential drop system for a period of time, then reconnecting it to evaluate its effect (or by comparing a duplicate experiment using an extensometer to monitor the crack growth rate).

Electrochemical effects can also result from improperly insulated dc current leads. Because significant current is passed through leads that are often relatively small, the potential drop in the current leads can be large (e.g.,  $>1\text{ V}$ ). If the current leads are not continuously insulated through the entire solution right up to the location where they are spot welded onto the specimen, there is an opportunity for crosstalk with closely adjacent potential leads (where the signal is typically 100  $\mu\text{V}$ ). Additionally, biasing of the specimen can occur if the current leads are not continuously insulated through the system seals. Any ionic communication in the tight-fitting seal area permits leakage to the metal (e.g., autoclave), and a circuit is established. The current leads act like a 1 V battery that is shared across two resistors, one representing the water resistivity in the seal and one representing the water resistivity between the specimen and the autoclave. This can cause some polarization of the specimen in conductive solutions, or voltage ( $iR$ ) drop in low-conductivity solutions. In the latter case, even though no substantial polarization occurs, reference electrodes that are located between the specimen and the autoclave "see" the voltage drop, and the apparent (measured) corrosion potential can be observed to fluctuate as the direction of the dc current is reversed. This represents a good check of the integrity of the dc potential drop system and wire insulation.

Finally, there is a potential concern for self-heating of the specimen by the applied dc current. While this is not a problem in aqueous environments or at common current densities, there have been cases where high current densities coupled with air or vacuum exposure resulted in significant self-heating.

High-quality implementations of dc potential drop are consistently able to achieve a crack length resolution on 1T compact-type specimens of about 1  $\mu\text{m}$ , and an overall accuracy of  $<5\%$  on the overall increment in crack advance. Current and potential leads can be insulated using Teflon tubing for test temperatures up to 300  $^{\circ}\text{C}$ ; above 300  $^{\circ}\text{C}$ , zirconia is generally used. The relationship between measured potential and crack length varies with specimen geometry and placement of the current and potential leads (see the article "Fatigue Crack Growth Testing" in this Volume). Because of this sensitivity to lead placement, it is best to avoid detaching and reattaching leads on specimens (e.g., specimens that are only periodically measured for crack length such as those for in-reactor exposures).

**Compliance Method and Other Cracking Monitoring Methods.** The next most common crack following technique is mechanical compliance, which relies on the relationship between crack mouth opening displacement and load during an unload/reload cycle). Resolution is typically limited by the strain gage or proximity sensors (e.g., eddy current or capacitance) that must monitor crack opening displacement in the (high-temperature water) environment. See the article "Fatigue Crack Growth Testing" in this Volume.

Another method is the ac potential drop technique, which relies on the "skin" (surface) effect of high-frequency current in metals. The advantage of the skin effect for detecting crack nucleation is generally more than offset by the higher noise (poorer noise rejection) of the ac measurement, even with sophisticated lock-in amplifiers, although improved instrumentation is closing the gap. Other crack following techniques include burst detection by monitoring pressurized tubes, periodic ultrasonic or eddy current scans to detect small cracks, and periodic interruption and inspection.

In aqueous environments, electrochemical noise can be used as a semiquantitative crack monitoring technique. This technique measures the small variations in corrosion potential and/or corrosion current as cracks (or other corrosion phenomena, such as pitting) nucleate and grow. This technique is good at discriminating the early stages of crack initiation. However, the correlation between crack depth (or number of cracks) and the electrochemical noise signal is at best semiquantitative, because: (a) the noise signal intensity decreases with increasing crack depth, increasing distance between sensors, and the location of cracking on the specimen surface (especially in low-conductivity solutions); and (b) noise from multiple small cracks cannot be distinguished from noise from longer cracks.

## Post-Test Analysis

**Parametric Measurement, Computer Automation, and Data Analysis.** Most aspects of experimental procedure are basic to all types of fatigue testing (see the article "Fatigue Crack Growth Testing" in this Volume). In environments, there are numerous additional parameters to control and measure (e.g., those related to partial pressures of gases, ionic species, pH, corrosion potential, temperature, etc.). These are ideally measured on a "continuous" basis and included as part of the computer data record, and they generally substantially expand the size and complexity of the data acquisition requirements.

Additionally, data analysis should recognize the time-dependent character of environmentally assisted cracking (or high-temperature creep-fatigue interactions). Fatigue processes are historically viewed as (purely) cycle-dependent processes, and this approach must be broadened to avoid missing (or misinterpreting) environmental enhancement. It is particularly important to factor this into experimental design, so that experiments include an evaluation over a wide range of loading frequencies and/or hold times. By contrast, the assumption that the greatest environmental enhancement occurs at very low frequency/long hold time can also be erroneous, because of the role of dissolving species in the crack (e.g., MnS dissolution in low-alloy and carbon steels, which can require continuing exposure of new MnS inclusions to maintain the sulfur-rich crack-tip chemistry). Thus, corrosion fatigue testing requires recognition that:

- IT IS IMPORTANT TO ACHIEVE A STEADY-STATE CRACK GROWTH RATE AT EACH TEST CONDITION, WHICH REQUIRES ACHIEVING A STEADY-STATE SURFACE CONDITION AND CRACK CHEMISTRY. THE POTENTIALLY LARGE ROLE OF NONUNIFORM DISTRIBUTION OF INHOMOGENEITIES MUST ALSO BE RECOGNIZED.
- TIME DEPENDENCY IS VERY IMPORTANT, AND THEREFORE THE ROLE OF MEAN/MAXIMUM STRESS AND FREQUENCY/HOLD TIME CAN BE VERY LARGE.
- UNEXPECTED INCREASES IN CRACK GROWTH RATE CAN OCCUR AT SPECIFIC LOADING CONDITIONS (E.G., ASSOCIATED WITH ACHIEVING CRITICAL CRACK CHEMISTRY). SOME SYSTEMS ALSO EXHIBIT HYSTERESIS (E.G., IN FREQUENCY, WHEREBY HIGH CRACK GROWTH RATES CAN BE SUSTAINED TO LOW FREQUENCY, BUT ONCE A LOW GROWTH RATE IS OBTAINED, THE FREQUENCY MAY HAVE TO BE INCREASED TO HIGH VALUES BEFORE A RETURN TO "HIGH" GROWTH RATES IS OBSERVED). THIS BEHAVIOR IS OFTEN CHARACTERISTIC OF ANY SYSTEM WHERE THERE IS A STRONG INTERACTION BETWEEN THE CRACK CHEMISTRY AND GROWTH RATE.

**Calculation of Crack Growth Rate.** Crack growth rate is calculated from crack length versus cycle number ( $da/dN$ ) data. The data for crack growth rate determination should be chosen to eliminate transient effects, which may be caused by changes in stress-intensity range level, test frequency or waveform, or gas partial pressure or temperature. The crack length increment for transient behavior can be estimated from the plastic zone size,  $R_p$ :

$$R_p = \frac{1}{3\pi} \left( \frac{\Delta K}{\sigma_{ys}} \right)^2$$

where  $\Delta K$  is the stress-intensity factor range and  $\sigma_{ys}$  is the yield strength.

Crack length data should not be used for crack growth rate determination until the crack has propagated a distance of at least twice the plastic zone size. Crack growth rate can be calculated by the secant and incremental methods, which are described in the article "Fatigue Crack Growth Testing" in this Volume and in ASTM E 647.

**Analysis of the fracture surface** is crucial to ensure accuracy of the crack monitoring technique, to identify branching and out-of-plane cracking, and to determine crack morphology. Because pits can act as nucleation sites for cracking in solutions containing chloride, possible interaction between pitting and fatigue behavior should also be examined. Accurate determination of crack growth on a cycle or time basis requires an understanding of the resolution of the monitoring technique under the actual test conditions.

Fracture surfaces of fatigue-fractured test specimens usually are examined by scanning electron microscopy to determine the fracture path and the fracture mode of the test material in relation to its microstructure. Such information may be valuable in identifying the fracture mechanism in certain environment and material combinations and may be used to

assess the severity of the deleterious environment and to aid in analyzing service failures. Fatigue in inert environments (including vacuum) generally produces different fracture modes or fracture paths than does fatigue in deleterious environments. Good qualitative agreement between the observed fracture modes and fatigue crack growth kinetics can be expected. In some cases, excellent quantitative correlation between fracture surface morphology and fatigue crack growth kinetics has been reported.

## Appendix: Crack Growth Test Methods for Specific Environments\*

The preceding article provides an overview of corrosion fatigue testing, with particular emphasis on corrosion fatigue crack growth of steels in high-temperature water. This appendix briefly reviews test methods for other environments and gives a brief summary of environmental effects on fatigue of selected nonferrous alloys. Environmentally assisted fracture of specific alloys is covered elsewhere in this Volume.

### Vacuum and Gases at Room Temperature

One of the most critical considerations for fatigue tests in vacuum and gaseous environments is the maintenance of the purity of (and the reduction and measurement of the impurity level in) the test environment. As mentioned above, small amounts of contaminants (impurities) in the test environment can lead to fatigue crack growth rates that are not representative of the resistance of the material to fatigue crack growth in that environment.

A clean environmental test chamber that provides a very low background pressure and quantifiable impurity levels (below  $10^{-7}$  to  $10^{-6}$  Pa, or  $7.5 \times 10^{-10}$  to  $7.5 \times 10^{-9}$  torr) is essential, even if the tests are to be carried out in gaseous environments at relatively high pressures (i.e., above the background).

**Environment Containment.** An all-metal environmental test chamber with mechanical-force feedthroughs is preferred for the study of environmentally assisted fatigue crack growth in vacuum and gaseous environments. Stainless steels are suitable materials for the environmental test chamber, with copper used as the gasketing material. The test chamber usually is equipped with a glass viewport that enables the operator to visually monitor the progress of the experiment.

With adequate pumping, the background pressure in the clean test chamber is usually below  $10^{-6}$  Pa ( $7.5 \times 10^{-9}$  torr). Maintaining an ultraclean test system is important, because a small amount of impurities can either significantly reduce or accelerate the fatigue crack growth rate, depending on the material and the types of impurities.

To achieve a low background pressure, the test chamber frequently is baked out (with the test specimen in place) at a temperature above ambient (60 to 400 °C, or 140 to 750 °F) to remove adsorbed and absorbed gases on the chamber wall. The bakeout temperature should be considerably below the tempering or aging temperature of the test material to ensure that the microstructure and the mechanical properties of the test material are not altered by the bakeout process. For example, the first-step artificial aging temperature for high-strength 7050-T7451 aluminum alloy is 121 °C (250 °F). The bakeout temperature for the test chamber is thus normally kept below 80 °C (175 °F).

**Environment.** Only high-purity, laboratory-grade gases should be used. Additional purification and dehumidification of the gas is recommended by passing it through a molecular-sieve purifier and a cold trap (-196 °C, or -321 °F) before allowing the gas to enter the test chamber. Gas pressure in the environmental test chamber is usually controlled by admitting the gas through a variable-leak valve.

If the test environment contains a toxic gas (such as hydrogen sulfide) or a combustible gas (such as hydrogen or methane), a protective hood with negative suction pressure should be used to enclose the test chamber or the entire test system. The test chamber should be purged thoroughly with an inert gas, such as argon or nitrogen, before it is reopened to the atmosphere.

If water vapor is used as the test environment, it can be drawn through the variable-leak valve from a high-purity reservoir that is attached to the test chamber. Deionized distilled water in the reservoir should be purified further by subjecting it to repeated freezing/pumping/thawing cycles to remove residual dissolved gases in the water (*Surface Science*, Vol 64, 1977, p 617).

Certain gases can decompose or react with containment vessels over time. For example, hydrogen sulfide can react with a stainless steel container to produce hydrogen. Provision must be made to remove the product gases before the test gas is admitted into the test chamber.

Finally, if the environment consists of mixed gases, the gas at the lowest partial pressure should be admitted first. If premixed gases are used, they must be thoroughly mixed in the supply reservoir to minimize stratification.

If test conditions such as gas pressure, test frequency, or applied load are changed during fatigue testing, a transient period may occur before the material assumes the steady-state fatigue crack growth rate that corresponds to the new test condition. The duration of this transient period depends on several variables, including the type of material, the test environment, and the magnitude of the change in test conditions.

## **High-Temperature Vacuum and Oxidizing Gases**

Fatigue testing in elevated-temperature vacuum and oxidizing environments requires a carefully designed vacuum test chamber. The chamber must keep the test specimen in a vacuum or oxidizing gas environment, allowing forces to be applied to the specimen, a means to measure crack length, and a method of applying and controlling the specimen temperature.

Variables that can affect fatigue crack growth rate at high temperature are time and rate dependent or structure dependent. Examples of time- and rate-dependent variables are oxidation and creep (Fig. 21). Structure-dependent variables include phase transformations, nucleation and growth of new and existing phases, and grain growth. When fatigue crack growth rate test data are reported for these environments, test temperature, vacuum pressure, partial pressure of oxidizing gas, waveform type, waveform frequency, and stress ratio must be reported. Additional information on high-temperature fatigue crack growth testing is given in the article "Fatigue Crack Growth Testing" in this Volume.

FIG. 21 HIGH-TEMPERATURE FATIGUE CRACK GROWTH OF TWO NICKEL-BASE SUPERALLOYS. (A) HASTELLOY X AT 760 °C (1400 °F) WITH  $R = 0.05$ . (B) NASA 11B-7 AT 650 °C (1200 °F) WITH  $R = 0.05$ .

**Environment Chambers.** Materials used in the test chamber should be selected to minimize outgassing in vacuum. For example, many plastic materials contain plasticizers, which slowly outgas in vacuum. These types of materials limit the ultimate vacuum obtainable. Stainless steel is suitable for the manufacture of the main test chamber. Components in the chamber should be designed for fast outgassing. When threaded components are used in the test chamber, channels should be machined in the threads to allow paths for fast outgassing.

For vacuum levels of  $6.5 \times 10^{-5}$  Pa ( $5 \times 10^{-7}$  torr), O-rings provide sufficient sealing; for higher vacuum levels, copper gaskets should be used. Electricity, water, radiofrequency, and the thermocouple can be input into the chamber using standard vacuum feedthroughs.

**Specimen Heating and Temperature Control.** Induction heating is the only suitable method to heat test specimens in vacuum and oxidizing environments. Radiofrequency generators with frequencies of 200 to 500 kHz are used for induction heating of test specimens. The induction coils should be made of copper and have no insulating coating. When oxidizing gases are introduced into the test chamber, a certain pressure range exists at which the gases will be ionized between the specimen and induction coils. In this pressure range, it is impossible to heat the specimen, because the radio frequency field arcs and shuts off the radiofrequency generator. To continue testing, the gas pressure must be either increased or decreased.

Two types of temperature controllers that are suitable for induction heating are thermocouple and infrared controllers. Each controller type has advantages and disadvantages. Infrared temperature controllers measure and control temperature from the spectral energy density emitted from the test specimen over a certain wavelength range. These measurements are noncontacting but require a clear optical path from the sensor head to the test specimen. Infrared temperature controllers have a minimum temperature measurement capability of approximately 350 °C (660 °F). Two-color infrared controllers eliminate errors due to transmission loss and emissivity changes, but they have a minimum temperature measuring capability of 700 °C (1290 °F).

Thermocouple temperature controllers are also used in vacuum test chambers. A variety of thermocouple types can be used, depending on the temperature range and the required durability of the thermocouple. For example, American National Standards Institute type S and type K thermocouple temperature ranges overlap, but for long-term tests of more than one week, type S thermocouples are preferred because they are more oxidation resistant. This would not be a consideration in a high-vacuum environment. Thin thermocouple wire less than 0.25 mm (0.01 in.) in diameter must be used to eliminate inductive heating of the thermocouple wire. With some temperature controllers, it is necessary to filter out radiofrequency noise in the thermocouple with a passive inductor/capacitor-type filter.

**Test Specimens.** Because high-temperature vacuum requires specimen heating by induction, many of the standard fracture mechanics test specimens cannot be used. Center-cracked tension and single-edge notched specimens are commonly used, because it is relatively easy to maintain the specimen gage section at uniform temperature with induction heating. When tests are conducted at high vacuum levels or low oxidizing gas partial pressures, specimen thickness may affect crack growth rate, because transport of the oxidizing gas to the crack tip may be the rate-limiting factor.

## **Aqueous Solutions at Ambient Temperature**

Fatigue studies in aqueous solutions at ambient temperatures present fewer problems experimentally than many of the other environments considered in this article. Nevertheless, it is often the case that the most frequent problem in determining the validity of corrosion fatigue data lies with the control and monitoring of the bulk water chemistry and the monitoring and recording of the electrochemical potential.

**Environment Containment.** Glass and plastics are suitable materials for environmental test chambers and ancillary pipework for aqueous solutions at ambient temperatures. At elevated temperatures (>60 °C, or 140 °F), however, dissolution of silicates from glassware can inhibit corrosion. Dissolution of plasticizers from certain plastics (e.g., polypropylene) is also a concern. Flexible plastics, such as twin-pack casting silicone rubber, have proved to be useful in the vicinity of the fatigue specimen.

A corrosion fatigue test cell that avoids the need for a water-tight seal at the specimen is shown in Fig. 22. Normal specimen movement and any sudden fracture event can be accommodated without catastrophic consequences. Highly effective seals between plastic and metal surfaces can be made with silicone rubber caulking compounds, if necessary, although sufficient time must be allowed for escape of the acetic acid solvent base.

**FIG. 22 TYPICAL CORROSION FATIGUE TEST CELL. MAINTENANCE OF THE EQUILIBRIUM OXYGEN CONCENTRATION IS ENSURED BY CASCADING THE SOLUTION IN THE CIRCULATION RIG.**

Fatigue specimens of passive metals such as aluminum, titanium, and stainless steel may be subject to crevice corrosion under the caulking compound unless a primer and epoxy paint coat are applied initially to the metal surface. Gasket seals using O-rings, for example, can also form a satisfactory seal, but generally are more expensive to engineer and can also be subject to crevice corrosion in some configurations. The decision to circulate the environment depends on the application and the extent of any problems in controlling water chemistry.

**Water Chemistry.** The prevailing water chemistry and the electrode potential of the material in its environment in the field are essential factors in any simulation experiment. Accelerated fatigue cracking can occur in a number of environments, including seawater, salt water/salt spray, and body fluids. These must be reproduced as closely as possible in the laboratory, although limitations are necessarily imposed in simulating aspects of complex environments, such as the biological activity of seawater.

The importance of reproducing the service environment as closely as possible is illustrated by comparing the behavior of metals in sodium chloride and in seawater. The buffering action of seawater associated with dissolved bicarbonate/carbonate can result in the formation of calcareous scale under cathodic protection, which can precipitate in cracks and influence the cyclic crack opening and closing, thus affecting crack growth rates. Substitute ocean water, as described in ASTM D 1141, usually is a satisfactory substitute for seawater, but some differences have been observed in relation to the rate of calcareous scale formation and the rate of corrosion fatigue growth.

Laboratory solutions should be prepared using the purest chemicals available in distilled or deionized water. Concentrations at the level of parts per million can have profound effects on electrochemistry and corrosion.

Several variables must be measured and controlled when simulating an aqueous environment: solution purity, composition, temperature, pH, dissolved oxygen content, and the flow (circulation) rate of the solution.

### **Acidified Chloride**

Investigations performed in acidified chloride, particularly at high temperature, pose unique problems. These include not only experimental barriers, such as suitable containment and seal materials and sensitivity to low-level oxidizing species, but also interpretational complexities, such as the effects of pitting and crevice processes on enhancement or retardation (by blunting) of crack initiation and growth. Care must be exercised in designing and conducting experiments to ensure personnel and equipment safety and to ensure proper simulation, control, and monitoring of environmental parameters.

**Below 100 °C (212 °F).** Materials and techniques for solution containment depend on the test temperature regime. Below the boiling point in solutions containing dissolved oxygen, a primary design concern is to prevent leaks that can damage equipment. A horizontal loading frame helps ensure that sensitive components are not readily damaged by leaks. Additionally, some specimen configurations (such as compact tension) permit the loading linkage to be placed above the solution, simplifying the choice of materials and seal designs.

Testing in deaerated solutions may require careful selection of materials, depending on the sensitivity of the test to low oxygen concentration. For example, the clear, flexible tubing often used in laboratories is very permeable to oxygen. Additionally, some plastics degrade in acidic environments.

**Above 100 °C (212 °F),** the propensity for pitting and crevice attack increases, the internal pressure rises, the design strength of some materials (e.g., titanium) begins to decrease, and good seal design (particularly for sliding seals) is crucial. Pitting and crevice potential studies show that the resistance of iron- and nickel-base alloys in environments containing chloride decrease from room temperature to about 200 °C (390 °F).

The best approach for selecting pressure boundary materials is to combine published data with recommendations from autoclave manufacturers and metals producers. No assumptions should be made regarding the performance of materials with varying environment. For example, commercial-purity titanium, which is often used in neutral and acidified chloride environments, performs very poorly in acidified chloride under reducing conditions, in acidified environments containing sulfate, and in caustic environments at high temperature. Addition of a small amount (0.2%) of palladium (grade 7) greatly improves resistance in acidified environments that contain sulfate.

**Above 200 °C (390 °F),** materials selection is particularly difficult. In general, for acidified chlorides, commercial-purity titanium is favored under oxidizing conditions (containing oxygen, iron ion, or copper ion), while zirconium (for example, UNS R60702) is favored for reducing environments. Zirconium alloys are highly intolerant of fluoride. In some cases, high-strength materials, such as Ti-6Al-4V or the Hastelloy C series alloys, are required, although there is generally a loss in corrosion resistance. Liners of Teflon or tantalum are options in some instances.

Because of its effect on the autoclave and test results, control of the oxidizing nature of the environment is often critical. In addition to oxidizing species, such as oxygen, iron ions, and copper ions, care in the use of externally applied potential is required. The autoclave may be polarized into a harmful regime if ground loops exist, or if it is used as the counterelectrode. A similar result can occur if the autoclave contacts a dissimilar metal.

Because of the rate and extent of expansion on leakage, hot pressurized water poses a serious safety hazard. Each autoclave must have a pressure-relief device attached to it, preferably in a fashion that does not permit bypassing or isolation. Selection of the pressure-relief device must account for the pressure, environment (often gold-coated elements are used in rupture disks), and temperature at which the device actually operates. Additionally, autoclaves, particularly when used in aggressive environments, must be examined regularly for damage resulting from pitting, crevice attack, general corrosion, hydriding, and so forth.

Pressure testing coupled with dimensional checks must also be performed. Manufacturers offer this service and will usually provide the test details. Test pressure and dimensional tolerances are a function of autoclave design, material, and temperature of use. Leaks may also occur in tubing and in valves, which are often difficult to inspect or test. Leaks almost always develop slowly. Nevertheless, a relatively rapid, controlled method for depressurizing the system should be included in the system design.

For some applications, inexpensive miniature autoclaves can be custom fabricated. The small internal volume of these devices is an advantage if a leak occurs in the system.

## Liquid Metal Environments

Liquid metals (sodium, potassium, and lithium, for example) are frequently used in heat-transport applications at elevated temperatures. Such applications include liquid-metal-cooled nuclear reactors, first-wall coolant for fusion devices, and heat-transport systems in solar collectors. These applications often involve cyclic temperature and/or pressure fluctuations, as well as other sources of cyclic stresses. For this reason, knowledge of the fatigue crack propagation behavior of structural alloys in the liquid metal environments is sometimes necessary.

Generally, liquid metals react (in some cases, quite violently) with air and/or water vapor; therefore, testing systems must be designed to exclude both air and water. Three basic designs have been developed to expose the specimen (or crack region of a specimen) to the liquid metal environment, while excluding air, water, and other contaminants.

The simplest method uses a sealed environmental chamber attached to the specimen that completely surrounds the notch and crack extension plane in a compact-type specimen. The small environmental chamber contains the liquid metal but does not extend to the region of the loading holes; hence, the loading pins, clevis grips, and remainder of the load train are not subjected to the liquid metal environment.

Relative motion across the notch and crack area is accommodated by bellows. This type of system has the advantages of simplicity and low cost. The main disadvantage is that the liquid metal is static; hence, the characteristics of large heat transport systems (e.g., mass transport due to nonisothermal operation) cannot be studied.

The second type of system, a circulating loop, is much more costly to build and operate, but it can be used to study potential effects on fatigue crack propagation such as mass transport, which occurs during carburizing, decarburizing, and dissolution of alloying elements. A third type of system consists of an open crucible (containing the test specimen immersed in static liquid metal) that is located within an inert gas cell or glovebox. This type of system is relatively inexpensive to build and operate, but it has the greatest potential for exposure to air and other contaminants.

Austenitic stainless steels generally have been used in the construction of current systems, and their use has been satisfactory. System designers should consider, however, that under some conditions mechanical properties (tensile, stress rupture, etc.) can be influenced by long-term exposure to liquid metals.

Typical results for fatigue crack propagation behavior of austenitic stainless steels in a liquid sodium environment are documented in Ref 29 and 30. In most cases, fatigue crack propagation rates are lower in sodium environments than in elevated-temperature air environments. The relatively benign nature of sodium environments also leaves the fracture faces in excellent condition for viewing with optical microscopes, scanning electron microscopes, or transmission electron microscopes.

## **Steam or Boiling Water with Contaminants**

Corrosive environments, such as steam or boiling water with contaminants, come in contact with many structural components. To assess the structural integrity of machine hardware, testing in the environments of concern is essential. Fatigue crack growth testing in corrosive environments requires special care because of the presence of corrosive mediums and testing complexity.

**Environment Containment.** Special designs are required to accommodate fatigue crack growth testing in steam or boiling water with contaminants. If the environmental pressure and temperature are moderate, for example at a pressure of 500 kPa (72.5 psi) and a temperature of 100 °C (212 °F), simple stainless steel O-ring sealed chambers can be clamped to each side of the specimen in which cracking will occur. If necessary, the test environment can be circulated through the chamber at a controlled flow rate.

If the environmental pressure and temperature are high, for example in steam at a pressure of 7.2 MPa (1040 psi) and a temperature of 288 °C (550 °F), a chamber that encloses the test specimens must be constructed. Composition of the test environment must be carefully analyzed before and after the experiment, given the variety of possible chemical effects on crack growth rates. (See Fig. 23 and 24 as examples for selected alloys.)

(a)

(b)

FIG. 24 EFFECT OF PH ON NEAR-THRESHOLD FATIGUE CRACK GROWTH RATES OF (A) TYPE 403 STAINLESS AND (B) TI-6AL-4V. ENVIRONMENT: 0.1 G NaCl + 0.1 G Na<sub>2</sub>SO<sub>4</sub> (G/100 ML H<sub>2</sub>O) IN BOILING WATER (100 °C, OR 212 °F). STRESS RATIO = 0.8

**Dissolved Oxygen.** Control and measurement of dissolved oxygen levels in the steam environment are of prime importance, because oxygen can affect fatigue crack propagation rate properties. Oxygen content can be controlled by bubbling argon or nitrogen through the water reservoir, or by maintaining a hydrogen overpressure. Oxygen content can be measured by using a colorimetric technique or by using oxygen analyzers that can continuously monitor oxygen in the parts per billion range.

## Detection and Monitoring of Fatigue Cracks

S. Shanmugham and P.K. Liaw, Department of Materials Science and Engineering, University of Tennessee

---

### Introduction

MEASUREMENT OR DETECTION of fatigue cracks and damage can, in general terms, be classified into the following two application areas: laboratory methods and field service assessment methods. Specific techniques for these two areas of application are summarized in Table 1. Several techniques are available to detect crack initiation and measure crack size for laboratory and field applications.

**TABLE 1 APPLICATIONS OF THE METHODS AVAILABLE FOR DETECTING FATIGUE CRACKS**

<b>METHOD</b>	<b>APPLICATION</b>
OPTICAL	<b>DETECTING FATIGUE CRACKS IN THE LABORATORY</b>
COMPLIANCE	<b>DETECTING FATIGUE CRACKS IN THE LABORATORY</b>
ELECTRIC POTENTIAL/KRAK GAGE	<b>DETECTING FATIGUE CRACKS IN THE LABORATORY AND DURING SERVICE</b>
GEL ELECTRODE IMAGING	<b>DETECTING FATIGUE CRACKS IN THE LABORATORY</b>
LIQUID PENETRANT	<b>INSPECTING STRUCTURAL COMPONENTS IN THE LABORATORY AND DURING SERVICE</b>
MAGNETIC PROPERTY	<b>DETECTING FATIGUE DAMAGE IN THE LABORATORY AND INSPECTING STRUCTURAL COMPONENTS DURING SERVICE</b>
POSITRON ANNIHILATION	<b>RESIDUAL LIFE ESTIMATION AND FATIGUE DAMAGE IN THE LABORATORY</b>
ACOUSTIC EMISSION	<b>LABORATORY AND IN-FIELD TESTING</b>
ULTRASONICS	<b>LABORATORY AND IN-FIELD TESTING</b>
EDDY CURRENT	<b>LABORATORY AND IN-FIELD TESTING</b>
INFRARED	<b>LABORATORY AND IN-FIELD TESTING</b>

SCANNING ACOUSTIC MICROSCOPE	<b>DETECTING FATIGUE CRACK INITIATION</b>
X-RAY DIFFRACTION	<b>DETECTING FATIGUE DAMAGE AND RESIDUAL STRESSES IN THE LABORATORY</b>

This article describes and compares the test techniques listed in Table 1. An attempt is made to include methods that are available for monitoring crack initiation and crack growth. Some methods (such as x-ray diffraction) for obtaining information on fatigue damage in test specimens are also included. The fatigue damage can be considered as the progressive development of a crack from the submicroscopic phases of cyclic slip and crack initiation, followed by the macroscopic crack propagation stage, to final fracture. These three stages are important in determining the fatigue life of structural components. In many cases, crack initiation can, however, be the dominant event for life analyses and design considerations, such as the applications of  $S$  (applied stress) versus  $N$  (fatigue-life cycle) curves. Furthermore, crack initiation is the precursor of fatigue failure. If the early stage of crack initiation can be detected and the mechanisms of crack initiation can be better understood, fatigue failure may be prevented.

Each method in Table 1 is summarized in the following sections along with a brief discussion of principles underlying each method. When selecting a method for fatigue crack detection or monitoring, oftentimes the sensitivity or crack size resolution plays a dominant role in the selection. The resolution of crack detection methods can range from 0.1  $\mu\text{m}$  to 0.5 mm as summarized in Table 2. The resolution depends on the specific technique, component geometry, surface condition, physical accessibility, and phenomenon responsible for crack initiation. While selecting a technique for crack detection, the sensitivity or crack size resolution plays a dominant role. For a higher crack size resolution requirement, the choice should be a method having greater sensitivity.

**TABLE 2 SUMMARY OF THE CRACK DETECTION SENSITIVITY OF THE METHODS AVAILABLE FOR DETECTING FATIGUE CRACKS**

<b>METHOD</b>	<b>CRACK DETECTION SENSITIVITY, MM</b>
<b>GAMMA RADIOGRAPHY</b>	<b>2% OF THE COMPONENT THICKNESS</b>
<b>MAGNETIC PARTICLE</b>	<b>0.5</b>
<b>KRAK GAGE</b>	<b>0.25</b>
<b>ACOUSTIC EMISSION</b>	<b>0.1</b>

Techniques listed in Table 1 can be used for either lab or field use, with some suitable for both. For example, the eddy current technique is used as an inspection tool and as a laboratory tool. Generally, one technique may not satisfy all requirements, and hence, a combination of two or more techniques may be utilized. For example, one may utilize the compliance technique for measuring the crack initiation and propagation behavior, and the mechanisms involved in the fatigue process could be examined using the scanning electron microscope.

Table 3 is a collection of sample testing and material parameters from several investigations (Ref 1, 2, 3, 4, 5, 6, 7) including loading type, specimen type, material, environment, crack initiation site, crack detection method, and sensitivity. For example, loading condition could be bending, axial, reverse bending, tension, and mode II loadings. Specimen types could be plate, welded plate, cylindrical bar, compact-type (CT) specimen, blunt-notched specimen, and three-point bend bar. Test environments have been air, water, vacuum, hydrogen, helium, and oxygen.

**TABLE 3 TESTING PARAMETERS ADOPTED BY SOME FATIGUE RESEARCHERS**

LOADING TYPE	SPECIMEN TYPE	MATERIAL	ENVIRONMENT	CRACK DETECTION METHOD	SENSITIVITY, MM	REF
REVERSE BENDING	PLATE	ALPHA IRON	AIR AND VACUUM	SCANNING ELECTRON MICROSCOPY REPLICA	0.001	1
AXIAL	PLATE	ALPHA IRON	AIR	TRANSMISSION ELECTRON MICROSCOPY REPLICA	0.0001	2

### Crack Measurement for Specimen Testing

Laboratory methods for developing fatigue life ( $S-N$  or  $\epsilon-N$ ) and crack growth ( $da/dN$  versus  $\Delta K$ ) are described elsewhere in this Volume and in Ref 10. General aspects of  $S-N$  or  $\epsilon-N$  testing are discussed in this Volume in the article "Corrosion Fatigue Testing," while crack growth testing and crack monitoring techniques are described in detail in the article "Fatigue Crack Growth Testing." Nonetheless, this section briefly summarizes the key methods for detecting and monitoring fatigue cracks in laboratory specimen testing as reference information prior to discussions of methods suitable for field or service life assessment.

**Optical methods** are often used to characterize fatigue crack growth, and numerous investigators have utilized this technique. Monitoring crack length is usually done by a traveling microscope, and the crack on the specimen surface is observed usually at a magnification of 20 to 50 $\times$ . The crack length is measured as a function of cycles at intervals so as to obtain an even distribution of  $da/dN$  versus  $\Delta K$ . Traveling microscopes usually have a repeatability of 0.01 mm, and the interval between measurements is typically about 0.25 mm. To aid in crack-length measurements, scribe marks are often applied on specimens.

Surface characteristics of a metal object at two different times in its fatigue life can be correlated when coherent optical techniques are employed as shown by Marom and Mueller (Ref 11). They reported that the degree of correlation prevalent between these two states may be used for detecting the onset of fatigue failure and the subsequent formation of fatigue cracks. A stroboscopic light source arrangement to observe specimens during fatigue testing has been reported (Ref 10). Cracks can be detected with good sensitivity provided the light is triggered at the time of the maximum tensile stress, and the specimen observation is conducted at moderate magnification.

The optical technique is simple and inexpensive, and calibration is not required (Ref 12). Accurate measurements can be performed provided corrosion or oxidation products are not formed during testing. Crack length is usually underestimated with this method. This technique has the following limitations:

- IT IS TIME CONSUMING.
- AUTOMATION IS EXPENSIVE.
- THE SPECIMEN MUST BE ACCESSIBLE DURING THE TESTING.

**The compliance method** is based on the principle that when a specimen is loaded, a change in the strain and displacement of the specimen will occur. These strains and displacements are altered by the length of the initiated crack. Crack length can be estimated from remote strain and displacement measurements. However, each specimen/crack geometry requires separate calibration that can be either experimental or theoretical. The methods used to measure changes in compliance include crack-opening displacement (COD), back-face strain, and crack-tip strain measurements (Ref 12 and 13).

The compliance method typically has a crack-length detection sensitivity of 10  $\mu\text{m}$ , and more detailed discussions on the use of the method in specimen testing is contained in the article "Fatigue Crack Growth Testing" in this Volume. Duggan and Proctor (Ref 14) also have provided a good review of crack-length measurements from specimen compliance changes. Compliance-crack-length relationships has been given for most of the common fatigue crack growth specimen configurations (Ref 15, 16). The compliance method enables crack growth measurements with accuracies similar to optical and electrical methods in the case of long cracks and high crack growth rates (Ref 13). The strain gage method is more suitable than the crack-opening displacement measurement in high-frequency fatigue tests. The unloading elastic compliance method is applicable for both short and long crack measurements

Each compliance method has its own merits and demerits. For example, the COD method is less expensive, the specimen need not be visually accessible, and it provides an average crack-length figure. However, separate calibration tests are required in some cases. Richards (Ref 12) also has summarized the advantages and limitations of the various compliance techniques, such as COD, back-face strain, and crack-tip strain measurements as described below.

The COD method has the following advantages: it can be used from nonaggressive to aggressive environments and for various geometry configurations that behave in an elastic manner; its costs range from low in room-temperature air tests to moderately expensive in high-temperature aggressive environments; it can be used as a remote method and is easily automated; and it produces an average crack-length figure where crack-front curvature occurs. The COD technique, however, has its limitations: separate calibration tests are warranted in some instances, and it is used for specimens where time-dependent, time-independent, and reversed-plasticity effects are small.

The back-face strain method has the following advantages (Ref 12): cost ranges from low in room-temperature tests to moderately expensive in high-temperature tests, remote method, easy automation, and crack length increases of 10  $\mu\text{m}$  can be resolved. However, this technique could be used only for specimens where time-dependent, time-independent, and reversed plasticity effects are small.

The crack tip strain measurement is applicable to various specimen geometries and detects crack initiation even in a large-scale plasticity condition. However, it cannot be used for large specimens where the surface behavior is not identical with the crack growth in the interior.

**Electric Potential Measurement.** The existence of a crack or defect in an electrical field can introduce a perturbation which, if measured, can be interpreted in terms of crack size and shape. The electric field can be produced by means of direct potential or alternating potential. In this method, a constant current is passed through a cracked test specimen, and the change in the electric potential across the crack, as the crack propagates, is monitored and measured. When the crack length increases, the uncracked cross-sectional area of the specimen decreases and the electrical resistance increases. This is reflected as an increase in the potential difference between two points across the crack. The calibration curves are established by monitoring this potential increase against a reference potential and plotting it as a function of crack length to specimen width ratio. The electrical potential crack monitoring technique is discussed in detail in the article "Fatigue Crack Growth Testing" in this Volume, but a brief description of the direct potential (with a Krak gage technique) and alternating current (ac) methods are summarized below.

In general, electric potential methods can be used for detecting crack initiation as well as for measuring the propagation rate in the laboratory. If proper calibration is established, this method can be used for predicting residual life as well. This can be used for room-temperature applications as well as high-temperature applications. Typically, the crack-detection sensitivity of this method ranges from 0.1 to 0.5 mm. For the Krak Gage technique, the crack detection sensitivity is around 0.25 mm. Richards (Ref 12) and Watt (Ref 17) have summarized the relative advantages and disadvantages of dc (direct potential) and ac potential difference methods, as described below.

**The direct potential (DP) method** uses the changing potential distribution around a growing crack when a constant direct current is passed through the specimen. This is usually monitored by measuring the potential difference between two probes, which are placed on either side of the crack. The technique relies on the relationship between the crack length and the measured potential, which can be determined either by empirical or theoretical means. The basic equipment for the DP method consists of a source of constant dc current and a means of measuring the potential differences that are produced across the crack plane.

The direct potential technique is simple, robust, and of relatively low cost. It is amenable to automation and for long-term high-temperature testing but is well established for only certain specimen geometries. Theoretical relationships are limited, and hence the potential difference and crack-length relationship needs to be established through calibration tests. Furthermore, the method has the limitation of not distinguishing between the crack extension and external dimensional changes of the specimen that would typically occur during general yielding and is not suitable for large specimens. The possible interference of electrochemical conditions near the crack tip cause some uncertainty in corrosion fatigue and stress-corrosion studies. For the DP method, the sensitivity level has been reported from 0.1 to 0.5 mm based on a review of the measurements documented in Ref 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28.

The Krak Gage technique utilizes an indirect dc potential measurement method, and Liaw et al. have utilized this gage for fatigue studies (Ref 29, 30, 31). Krak Gage is a registered tradename of Hartrun Corporation (Chaska, MN) and is a bondable, thin, electrically insulated metal foil of certain dimensions photoetched from a constantan alloy. The gage

backing is made of a flexible epoxy-phenolic matrix that provides the desired insulation and bonding surface area similar to the technology of foil-type strain gages. Conventional and well-established foil strain-gage installation methods can be applied to the bonding and installation of such a gage to test samples. The gage is bonded to the specimen under investigation such that when a crack is initiated in the material, it will also propagate in the bonded Krak Gage.

A constant current source of the order of 100 mA is used to excite the low-resistance gage, as shown in Fig. 1. A propagating crack produces a large change in the resistance of the gage and yields a sufficient dc output, proportional to crack length, of 0 to 100 mV for the full-scale rating of the gage. The output voltage of the gage is further amplified to a 10 V dc full scale and is shown in Fig. 1(b). The precision in the geometry of the gage determines the accuracy and the linear relationship between the output voltage and the crack length. A typical length of the gage equals 20 mm and yields a crack-detection sensitivity of 0.25 mm. The potential generated is further amplified and displayed on a digital voltmeter. Furthermore, analog outputs are provided to readily interface with all conventional recording instrumentation, data acquisition systems, and computers for fully automated crack detection.

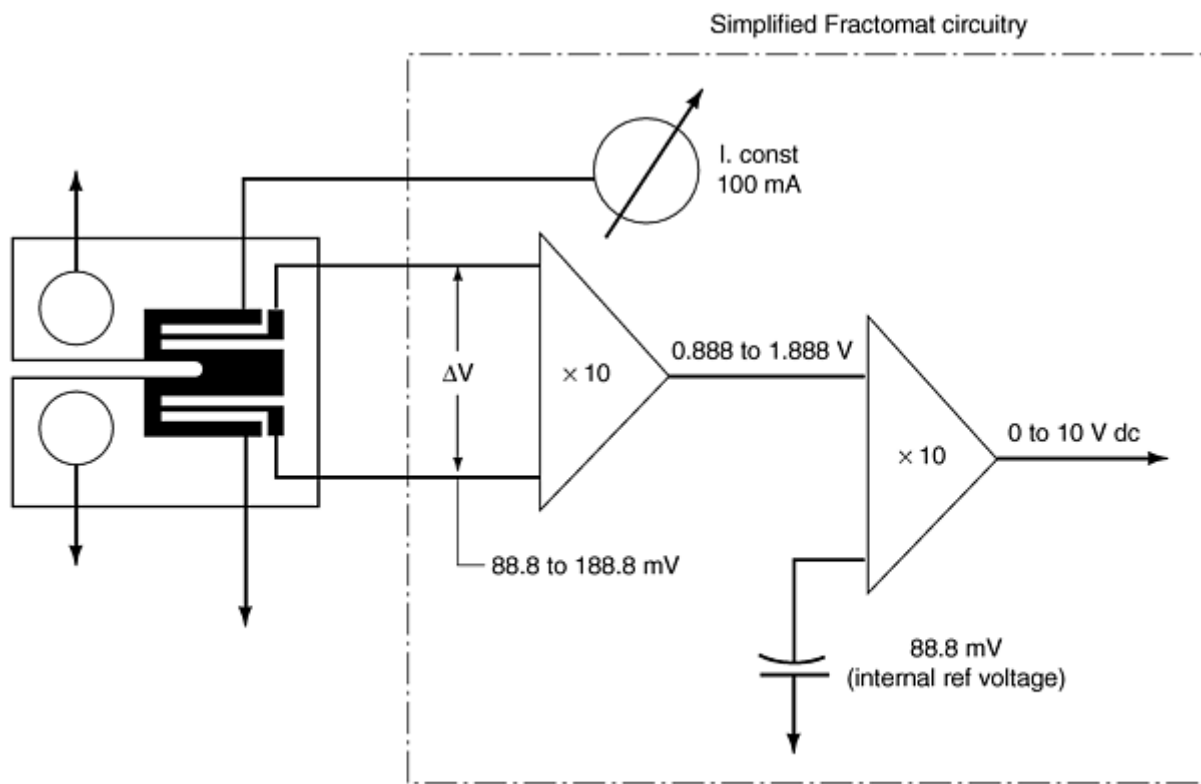

FIG. 1 SCHEMATIC OF THE KRAK GAGE TECHNIQUE. (A) CONSTANT CURRENT CIRCUITRY. (B) OUTPUT VOLTAGE AMPLIFICATION CIRCUITRY. SOURCE: REF 29

The ac electric potential method involves an ac source connected to the specimen such that the current flows perpendicularly to the crack. The ac field is typically limited to the thin skin at the metal surface and hence is effective in measuring crack dimensions at or near the specimen surface compared to the dc method. For the ac technique, the following crack-depth equation is applicable:

$$D = (V/V_0 - 1)D/2 \quad (\text{EQ 1})$$

where  $d$  is the crack depth,  $v$  is the measured electric potential,  $v_0$  is the initial electric potential, and  $D$  is the separation distance of the output leads for measuring the potential.

The ac electric potential method is applicable to all test geometries, involves simple calibration procedures, and has no specimen-size dependence. This technique can be easily automated and has high sensitivity suitable for large-specimen testing and for surface-crack detection in specimens and structures. Similar to the dc method, the ac method produces average crack length values and accommodates relaxation from linear elastic behavior. However, the ac method is relatively expensive, connection wires need to be carefully placed, electrical insulation of specimens are required, and long-term stability is difficult to achieve. Erroneous crack-length measurements can occur due to bridging of crack surfaces by corrosion products in both dc and ac methods.

Wei and Brazill (Ref 32) utilized an ac potential method for monitoring fatigue crack growth rates in an ASTM A 542 steel and reported that fatigue crack growth rates could be determined within  $\pm 20\%$ . Their setup comprised an excitation circuit that supplied a constant ac current to the system and a measurement circuit that detected the ac potential drop across the system.

For the CT specimen geometry, Wei and Brazill (Ref 32) established the relationship between the normalized ac potential and the crack length through a calibration test in which data pairs of crack length and potential were recorded during fatigue. The calibration crack length was taken as the five-point average of posttest measurements on the fracture surface obtained at the specimen side surface, quarter points, and midpoint. They normalized the potential measurements with respect to the initial potential of the uncracked specimen and obtained a calibration curve of crack length versus normalized ac potential for three specimens (Fig. 2). Also shown in Fig. 2 is the calibration data obtained for two specimens utilizing a dc system, and the curves were fitted using a third-order polynomial. The accuracy of the ac crack-length measurement method was reported to be better than 1% for crack lengths from 20 to 45 mm. The ac system had a resolution better than 0.01 mm for a 20 nV resolution in the electric potential at an operating current of 1 A.

FIG. 2 CALIBRATION CURVE FOR AC AND DC POTENTIAL SYSTEMS. SOURCE: REF 32

**Gel Electrode Imaging Methods.** Gel electrode imaging is capable of detecting fatigue crack initiation. It is simple and possesses good sensitivity. Typically, the crack detection sensitivity of this method is of the order of  $30 \mu\text{m}$ . This technique uses a hand-held probe for detecting and imaging short fatigue cracks in metallic components subjected to cyclic loading (Ref 33). The only precondition is that the metal surface be coated with a thin anodic film before fatigue testing. It can be used to follow the fatigue damage process without the need for dismantling the test fixture. Fatigue

cracks as small as 0.01 mm can be easily imaged and provides discrimination of features, such as machining marks, scratches, or notches.

The gel electrode imaging method is based upon a redox printing technique developed by Klein (Ref 34). Klein soaked a filter paper in an electrolyte containing potassium iodide, starch, and agar gel and squeezed it between the specimen and a metal cathode. On application of an electric potential, the potassium iodide is anodically oxidized to release iodine ions that react with the starch to form a black adsorption complex. This usually occurs at conductive flaws in the surface oxide film on the metal at the interface between the electrolyte and the positively polarized specimen. Klein mapped the distribution of high conductivity defective areas in anodic oxide films on several valve metals.

Baxter (Ref 35) modified Klein's method and imaged fatigue cracks in 6061-T6 aluminum. He used a liquid drop electrode with a surface skin of dehydrated gel and pressed it against the specimen. During fatigue damage imaging, the current flows preferentially to thinner surface oxide regions that form during fatigue of the underlying metal. A thick layer of the surface oxide on the specimen is grown prior to the fatigue test, and during fatigue loading the thick oxide film develops microcracks exposing fresh metal surfaces. These regions rapidly reoxidize but only to a very thin layer, thus providing sites of high conductivity during subsequent imaging.

Baxter printed the image on the gel tip and photographed it immediately in order to prevent the deterioration of the image that occurs at room temperature within a few hours. The current during imaging was recorded on a Nicolet digital oscilloscope and was then displayed on a recorder. The total charge flow was obtained by measuring the area under the curve. Figure 3 shows the experimental setup for developing image and recording current flow.

**FIG. 3 SCHEMATIC OF EXPERIMENTAL ARRANGEMENT FOR DEVELOPING IMAGE AND RECORDING CURRENT FLOW. SOURCE: REF 35**

The sensitivity and spatial resolution attainable by this method is determined by the amount of charge flow, which depends on the duration of the voltage pulse. The data obtained during imaging of virgin cracks with 10 and 25 ms pulses are shown in Fig. 4. The charge flow in the absence of a fatigue crack is indicated in the figure, and the data extrapolation indicate that fatigue cracks as small as 60 μm can be detected with a 10 ms pulse. The result corresponded well with the microscopic examination.

### Liquid Penetrant Method

The liquid penetrant method involves the penetration of liquid to flow into the minute surface openings through capillary action (Ref 36). The test surface is covered with a penetrating liquid, then the excess liquid is removed after a particular period of time and a developing agent is then applied to the surface. A powder film is formed after drying of the developing agent, and it draws the liquid to the surface from the crack.

The liquid penetrant method provides only crack length information, and cracks of the order of 1  $\mu\text{m}$  can be detected. Typically, the crack detection sensitivity ranges from 0.025 to 0.25 mm. However, the crack depth information cannot be obtained by this technique. The sensitivity level of the method depends on the surface condition, crack morphology, and physical access to the components. The sensitivity spectrum of this method ranges from fine, tight cracks to broad, shallow, and open cracks. Using this method, only crack-length information can be obtained and cracks of the order of 1  $\mu\text{m}$  in width can be detected. For field applications, the crack detection sensitivity ranges from 0.025 to 0.25 mm provided that the surface is clean, polished, and an appropriate penetrant is selected.

The liquid penetrant technique is simple, applicable to nonmagnetic and magnetic materials, and possesses higher sensitivity than the magnetic particle method. However, only surface imperfections can be detected, and in components having high surface roughness or porosity, this method cannot be successfully employed.

The liquid penetrant method is classified into four methods: water washable, postemulsifiable lipophilic, solvent removable, and postemulsifiable hydrophilic. The latter terms indicate the type of media that are required to remove the excess penetrant from the surface. For example, solvent removable requires a solvent, while water washable mandates a water spray. These methods are discussed in detail in *ASM Handbook*, Volume 17, *Nondestructive Evaluation and Quality Control*.

### Magnetic Techniques

Magnetic techniques are primarily used as inspection techniques for detecting fatigue cracks in structural components, and in particular, the magnetic particle method is widely used. However, these methods can be employed only for magnetic materials. Magnetic methods provide ways of following how the magnetic properties of materials change as a function of various factors, such as microstructure, heat treatment, chemical composition, and mechanical condition. The crack detection sensitivity of the magnetic method is of the order of 0.076 mm.

Structure-sensitive magnetic properties, such as coercivity, remanence, permeability, susceptibility, and hysteresis loss, are intimately related to the microscale of domain sizes and orientations, and hence their measurements can be used to infer the microstructural state of the steel (Ref 8). Fatigue damage is associated with changes in dislocation density and dislocation structure, and thus could be measured by magnetic techniques. The different magnetic methods could be used for the measurement of fatigue damage and they are described below.

**Magnetic Barkhausen Effect.** The Barkhausen effect (Ref 37) consists of discontinuous changes in the flux density known as Barkhausen jumps. These jumps are due to sudden irreversible motion of magnetic domain walls when they break away from pinning sites because of changes in the magnetic field  $H$ . By placing a search coil in the vicinity of the specimen undergoing a change in magnetization, a series of transient pulses of electromotive force will be induced across it and could be measured individually by counting and amplitude sorting or as a root mean square (rms) signal, as a function of magnetic field or as a scalar rms value (Ref 8).

Karjalainen and Moilanen (Ref 38, 39) investigated the effects of plastic deformation and fatigue on the magnetic Barkhausen effect. They utilized a surface coil placed between two magnetizing pole pieces operating at 50 Hz and measured the root-mean-square Barkhausen signal with respect to an applied stress axis from the mild steel tensile sample in both parallel,  $B_p$ , and perpendicular,  $B_t$ , directions. The authors observed drastic changes in the Barkhausen signals occurring only after 5% of the fatigue life and suggested that the life of components could be determined using this technique.

**Magnetoacoustic Emission.** Magnetoacoustic emission (MAE) is caused by microscopic changes in strain due to magnetostriction when the discontinuous irreversible domain wall motion of the non-180° domain wall occurs (Ref 40). It arises when ferromagnetic steels are subjected to a time-dependent field. A piezoelectric transducer bonded to the specimen could measure acoustic emissions, and the amplitude of MAE depends on the magnetostriction coefficient, frequency, and amplitude of the driving field. Because the stress alters the magnetocrystalline anisotropy, MAE should also change with the applied stress.

The MAE technique is of recent origin and not well developed but is sensitive to fatigue damage. Ono and Shibata (Ref 41) investigated several carbon steels, A533-B steel, and pure iron, using MAE. The magnetic field was alternated at 60 Hz, and the maximum field was 25.5 kA/m rms. They used two acoustic emission transducers of different resonant frequencies and measured rms voltages at two frequency ranges. Also, the maximum applied stress level was 350 MPa in tension. They observed that the 1020 steel showed the highest acoustic emission response among the materials tested. They also reported that residual stress levels can be determined by monitoring the ratio of the outputs of the two acoustic emission transducers for a given material condition.

**Magnetic Particle Method.** When a ferromagnetic material is magnetized, magnetic discontinuities that lie in a direction generally transverse to the magnetic field will set up leakage fields. The presence of this leakage field, and hence the crack or discontinuity can be detected by the application of finely divided magnetic particles over the surface, which tend to gather and are held by the leakage field. Thus, an outline of the discontinuity and its location, size, shape, and extent could be obtained from the magnetically held collection of particles. More details about this method are given in *ASM Handbook*, Volume 17, *Nondestructive Evaluation and Quality Control*.

Magnetic particles are available in a variety of highly visible colors or as a fluorescent substance visible under a black light. Crack detection resolution depends on the type of magnetic particles applied. The magnetic particle accumulation could be used to ascertain crack length, but no useful information about crack depth is generated. It is used as an inspection technique for detecting cracks in structural components during service, and cracks with a major dimension of 0.5 mm can be detected (Ref 36).

**Magnetic Flux Leakage.** When a ferromagnetic material is magnetized, magnetic discontinuities, such as microcracks, voids, inclusions, and local stresses, give rise to magnetic flux leakage. The magnetic flux leakage could be measured utilizing a magnetometer, and the field components could be measured in three directions (perpendicular and parallel to the flaw and normal to the surface).

Barton (Ref 42) monitored fatigue damage during stress cycling of SAE 4140 steel specimens using a high-frequency vibrating magnetic probe (60 kHz). He used various tensile and compressive stress levels and reported that fatigue damage signals were detected in the steel tubes well before gross crack development. Fatigue cracks were easily detected using this method, and he reported that the cracks could be detected with an accuracy of  $\pm 0.25$  mm. Barton established a functional relationship between signal buildup and fatigue damage so that fatigue life could be predicted with good accuracy. The crack detection sensitivity of this method can be of the order of 0.076 mm (Ref 9).

**Magnoscope.** Jiles et al. (Ref 43) reported a portable inspection device that could be used for nondestructive evaluation of the mechanical condition of steel structures and components outside the laboratory. They showed the dependence of magnetic properties of four identical samples of rail steel as a function of number of fatigue cycles. Jiles et al. followed the changes in remanence and coercivity of the rail steel samples with expended fatigue life. He observed that the coercivity and remanence reduced drastically as the material approached failure. Thus, by measuring coercivity and remanence, one would be able to predict the remaining fatigue life.

## Detection and Monitoring of Fatigue Cracks

S. Shanmugham and P.K. Liaw, Department of Materials Science and Engineering, University of Tennessee

---

## Positron Annihilation

Positron annihilation is a nondestructive method that may be utilized for predicting fatigue life. It involves injecting of positrons from a radioactive source and measuring positron lifetime as a function of fatigue cycles. It can provide a basic understanding of what stage the material is subjected to in terms of its total life.

The positron-annihilation method obtains information about the state of imperfection of the solid based on the principle that when a positron is injected into a material, it annihilates with an electron within a few hundred picoseconds (Ref 8). During this process, it emits annihilation radiation in the form of two gamma rays that travel in opposite directions. The

average behavior of a large number of positrons are usually determined, and the precision of the measurement has a direct dependence on the square root of the measurement duration.

By measuring the positron lifetime in a solid, the state of imperfection of the solid can be deduced (Ref 44). The defects in crystals, such as dislocation or vacancy, serve as trapping sites for positrons. Hence, trapped positrons survive on an average longer than an untrapped positron. Untrapped positrons, on the other hand, annihilate with an electron in a more perfect region of the lattice. Thus, by measuring the average positron lifetime, the state of crystalline perfection can be ascertained with high sensitivity.

In a similar manner, the state of imperfection of the solid can be deduced by measuring the Doppler broadening of the energies of gamma rays emitted during the annihilation events (Ref 44). Defect trap sites are deprived of higher energy core electrons, and hence a trapped positron has a higher probability of annihilating with a lower energy conduction electron. This trend is reflected as a narrowing of the energy distribution about the value of 511 keV. If the electron-positron center of the mass was stationary, then 511 keV would be the gamma ray energy. Thus, the Doppler energy shift from the 511 keV can be considered to be due to the energy of the electron involved in the annihilation process.

Fatigue damage increases defect concentration, such as dislocation and vacancies, in the test specimen and hence can be estimated from positron annihilation measurements. The fraction of positrons trapped at the defect sites increases with increase in fatigue damage, and hence saturation can occur at high damage levels. In order for positrons to be useful for actual applications, there has to be a reasonable balance between the trapping and annihilation processes (Ref 8). The existence of such balance and whether fatigue life could be monitored successfully using positron lifetime measurements can be determined only by empirical methods.

In high-cycle fatigue testing, it typically takes several fatigue cycles before fatigue damage can be observed in a test specimen (Ref 8). With the inception of fatigue damage, a rapid buildup of damage occurs with sustained fatigue cycling. This damage can be easily followed using positron lifetime measurements since the positron response increases with increase in fatigue damage. This process continues and beyond a particular damage level, the positron response either flattens or increases very slowly.

The positron mean lifetime measurements are conducted by sandwiching the positron source between two flat-faced portions of the test specimen with the two scintillator detectors positioned on the opposite sides of the sandwich (Ref 8). A  $^{22}\text{Na}$  source emits a 1.37 MeV marker gamma ray along with the positron at the same time. By measuring the time lag between the arrival of the marker gamma ray and of one of the annihilation gamma rays in the scintillators, the individual positron lifetime in the sample is established.

The Doppler broadening measurements are typically conducted using a Ge(Li) detector, multichannel analyzer, and digital stabilizer (Ref 44) and has a resolution of 1.24 keV full width half maximum at the total count rate of 14 kHz. The changes in the spectrum of the annihilation photon energies are described using a shape factor. The shape factor represents the sum of counts in a peak region divided by the total counts in two wing regions.

Lynn and Byrne (Ref 45) investigated AISI 4340 steels of Rockwell hardness levels (27 and 51 HRC) using cantilever bending fatigue cycles with a maximum stress of two-thirds of their corresponding yield stresses. Figure 5 summarizes their measurements. The mean positron lifetime decreased during fatigue for 51-HRC steel, and this was due to cyclic fatigue softening. However, fatigue hardening of the soft 27-HRC samples resulted in increasing the mean positron lifetime. The positron lifetime was 119 ps initially, and increased to 165 ps at fracture, thus indicating an increase in the number of defects. Also, the decrease in slope occurred at about 20% of the total fatigue life.

**FIG. 5 MEAN POSITRON LIFETIME IN PICOSECONDS VERSUS NUMBER OF FATIGUE CYCLES FOR 4340 STEEL OF INITIAL HARDNESSES. 27 AND 51 HRC. SOURCE: REF 45**

Alexopoulos and Byrne (Ref 46) conducted x-ray line broadening and positron lifetime measurements on 4340 steel with hardness of 30 HRC. In order to provide a better explanation and understanding for the increase in the positron lifetime with cyclic fatigue of soft steels, they made measurements at much smaller fatigue intervals. They observed that the mean positron lifetime increased to a maximum in the vicinity of  $10^4$  cycles, and subsequently, instead of failure, there was an interesting undulation in the positron mean lifetime. This undulation persisted till fracture at about 73,000 cycles, and the more frequent interruptions and reapplications of fatigue cycling seem to have considerably increased the fatigue life by a factor of about 7. They called this process "coaxing." The x-ray measurements did not give any indications of corresponding changes in particle size. This trend indicates that the positrons did respond to structural changes that do not influence the x-ray particle size. Byrne (Ref 44) did an excellent review paper on positron studies of the annealing of the cold-worked state of different materials.

Duffin and Byrne (Ref 47) utilized positron Doppler broadening measurements to detect changes in trapping mechanisms in steels. They cycled 1020 steel at an alternating stress of  $\pm 606.7$  MPa (much below the yield stress of 1110 MPa) in cantilever bending in a thermomechanically produced condition arrived at by: 75% cold rolling, up-quenching to 751.5 °C for 1 min followed by a brine quench. The Doppler peak to wings parameter was plotted as a function of fatigue cycles, and the variation reflected an increasing degree of damage during cycling. An excellent review of the application of positron annihilation techniques for defect characterization was done by Granatelli and Lynn (Ref 48).

### Acoustic Emission Techniques

Acoustic emissions allow the capability of determining fatigue crack initiation and following the crack propagation as the crack generates elastic waves in the material. Acoustic emissions occur as a result of the release of elastic strain energy that accompanies crack extension and other processes involving atomic rearrangement in materials (Ref 49). These elastic waves can be detected by the use of sensitive transducers that are located at the surface of the sample. These piezoelectric transducers normally operate in the range of 20 kHz to 1 MHz.

Acoustic emissions can produce transducer outputs that can vary over many orders of magnitude from less than 10  $\mu\text{V}$  to more than 1 V. Usually, most emissions produce outputs toward the lower end of this range, and hence processing equipment is used. The initial preamplification of the acoustic emission signals involves a gain of 20, 40, or 60 dB. Band-pass filtration is then used, commonly over the range of 100 to 300 kHz, for removing much of the mechanical and electrical background noise before final amplification. This is followed by main amplifiers with gain levels. There are various methods by which the amplified acoustic emission signals can be analyzed. The different methods yield different information about the source responsible for the emissions. They include: ring-down counting, event counting, energy measurements, amplitude measurements, and frequency analyses. A good summary of the analyzing methods, and a review of the literature is provided by Lindley and McIntyre (Ref 50).

Acoustic emission monitoring has been used in the laboratory to study various crack propagation mechanisms including fatigue, corrosion fatigue, stress corrosion, hydrogen embrittlement, and ductile tearing. It could also be useful for predicting the residual fatigue life in specimens, if properly calibrated. The crack detection sensitivity of this method is of the order of 0.1 mm. Examples are given below.

Morton and coworkers (Ref 51, 52) studied the high-cycle fatigue behavior of 2024-T851 aluminum and correlated the peak load acoustic emission rate,  $N'$ , with the crack growth rate,  $da/dN$ , and the applied stress-intensity factor range,  $\Delta K$  (Fig. 6).

FIG. 6 CRACK GROWTH RATE AND  $\Delta K$  VERSUS ACOUSTIC EMISSION COUNT RATE FOR 2024-T851 ALUMINUM ALLOY. SOURCE: REF 51

Houssyn-Emam and Bassim (Ref 7) utilized an acoustic emission technique to monitor the onset of crack initiation and to follow the fatigue damage process in low-cycle fatigue of AISI 4340 steel. They plotted total counts against the number of cycles and divided it into three regimes. The first stage is the initial softening that results in a high acoustic emission activity. The second stage corresponds to a quasi-stable stage during which there is relatively little activity. This is followed by a further increase in the acoustic activity that accompanies the onset of crack initiation and crack propagation to failure.

### Ultrasonic Methods

Ultrasonic techniques involve transmitting pulses of elastic waves into the specimen from an ultrasonic probe held on the surfaces of the specimen (Ref 53). It is used for following crack propagation as an in-field or a laboratory technique. The crack detection sensitivity of this technique is around 50  $\mu\text{m}$ .

Ultrasonic techniques are widely used for the detection and sizing of fatigue cracks and monitoring the crack growth both in the laboratory and field. Ultrasonic methods fall into one of the following groups depending on the way the crack size is determined (Ref 53):

- THOSE METHODS THAT CALIBRATE THE ULTRASONIC SIGNAL AMPLITUDE DIRECTLY IN TERMS OF CRACK SIZE
- THOSE TECHNIQUES IN WHICH TRANSMITTING AND/OR RECEIVING PROBES ARE DISPLACED OVER THE SPECIMEN SURFACE TO LOCATE THE CRACK TIP AT A PARTICULAR POSITION WITHIN THE ULTRASONIC BEAM
- THOSE METHODS THAT MEASURE CRACK SIZE BY THE TIME OF FLIGHT OF PULSES FROM THE TRANSMITTER TO RECEIVER VIA THE CRACK TIP, IRRESPECTIVE OF THE PULSE AMPLITUDE

Ultrasonic measurements comprise two stages. The first stage involves obtaining the signal from the crack, and the second stage involves the interpretation of this signal to estimate crack size and shape. In order to obtain a signal, the most commonly used equipment is the piezoelectric probe and commercial flaw detector, and it is shown in Fig. 7. The wavepackets of ultrasound are transmitted into the specimen, and the scattered pulses are then received at the probe. These pulses are then reconverted to electric signals and are displayed on an oscilloscope screen as a function of time of flight.

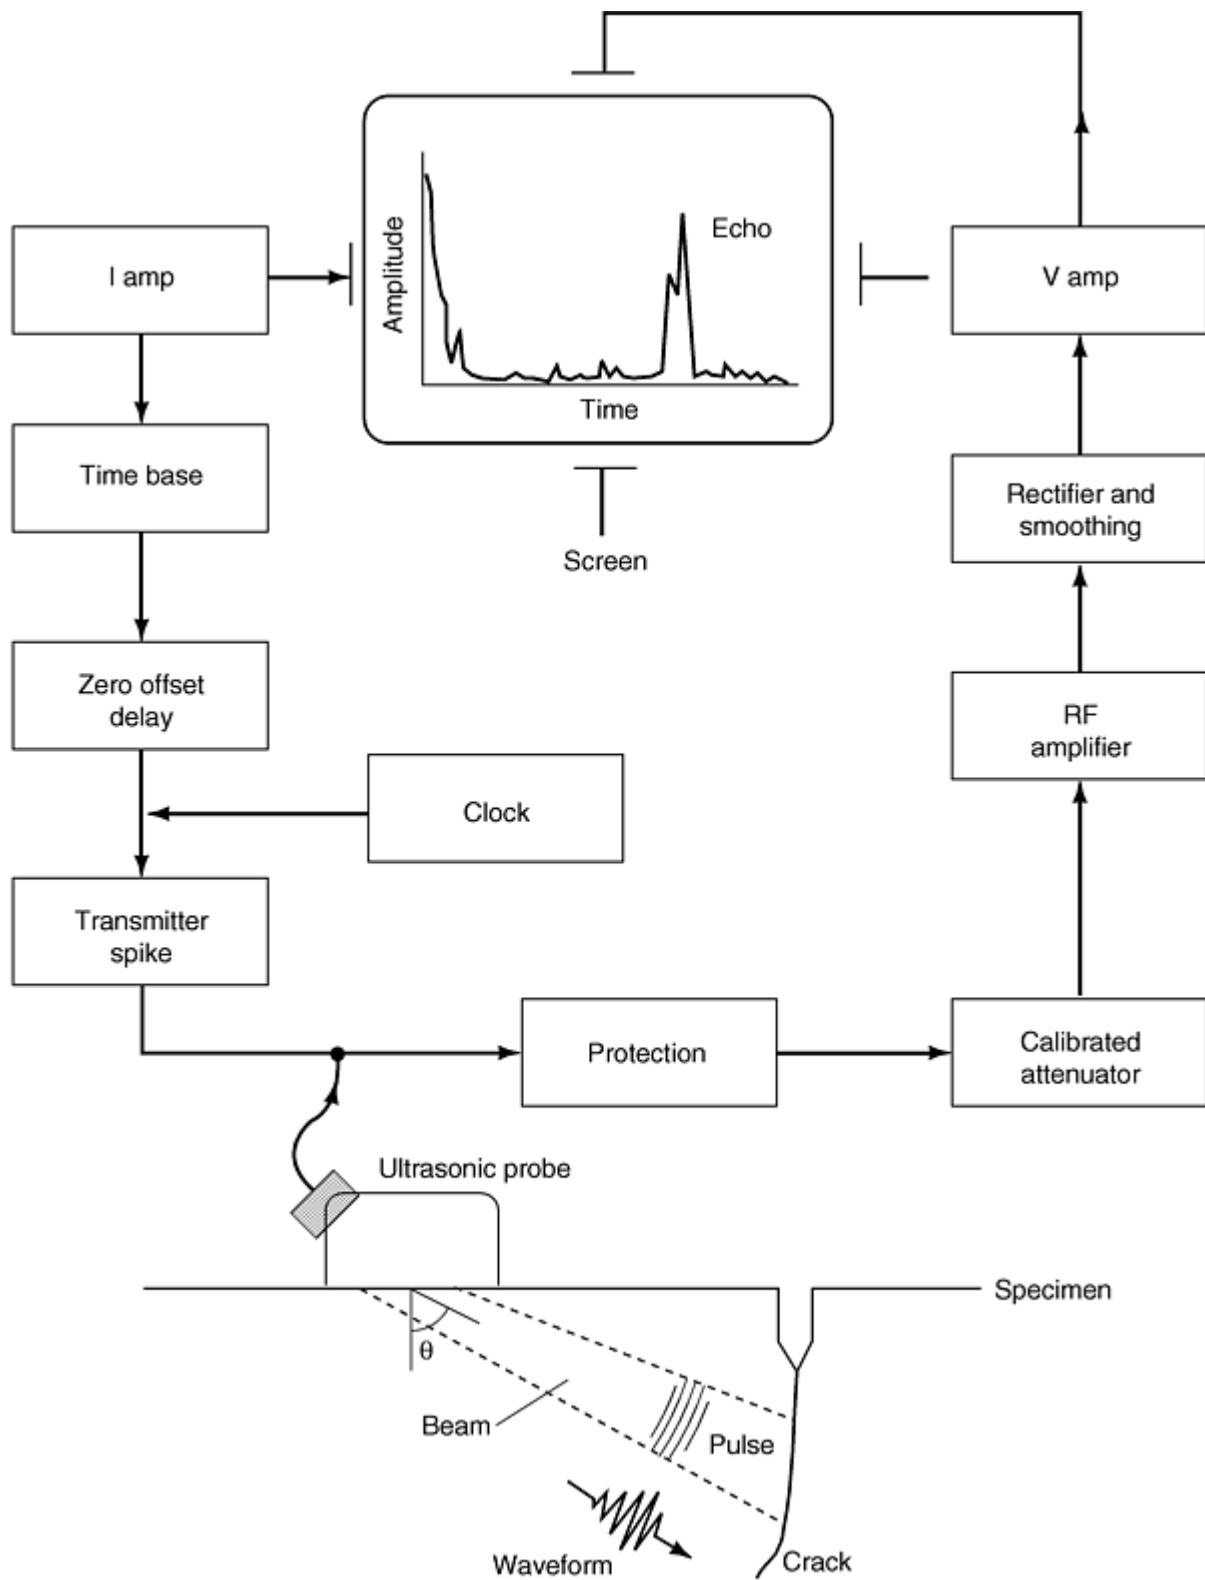

FIG. 7 BLOCK DIAGRAM OF AN ULTRASONIC PROBE AND FLAW DETECTOR. SOURCE: REF 53

**Ultrasonic Amplitude Calibration Methods.** In this method, a fixed transmitting probe is used to beam pulses onto a crack, and a fixed receiver is used to receive the signal (Ref 53). The receiver can be located either in the shadow of the crack or positioned so as to receive the specular reflection from the crack face. The amplitude calibration methods use specimens containing known cracks to calibrate either the drop in directly transmitted signals or the amplitude of specular

echoes against crack size. If the ultrasonic coupling of the probes and the morphology and orientation of the cracks are reproducible, then accurate results could be obtained.

Lumb et al. (Ref 54) utilized a compression beam to monitor through-thickness growth of fatigue and ductile cracks initiating at shallow surface notches or natural cracks at the toes of the welds. They established the ultrasonic signal versus crack depth calibration curve using milled slots and checked against part-through fatigue cracks from interrupted tests. They reported that growth increments of 0.025 mm can be easily detected and larger amounts of growth measured to  $\pm 0.25$  mm.

Defebvre and Pouliquen (Ref 55) monitored fatigue tests using surface waves. They observed a sudden increase in the attenuation at about 60,000 cycles of a steel sample and related it to the onset of microcracking. They monitored a total of 170,000 cycles and the crack had propagated to 30% of the width of the specimen during this time.

Recently, Resch and Karpur (Ref 56) utilized a surface acoustic wave technique to detect the initiation of surface microcracks in highly stressed regions of hourglass-shaped 2024-T6 alloy aluminum specimens during fatigue cycling. They used contacting wave transducers to excite the incident waves and to detect the reflected wave signals. They demonstrated the effectiveness of a split spectrum processing algorithm to separate specular reflections of isolated cracks from nonspecular reflections of microstructural features.

Joshi (Ref 57) utilized an ultrasonic attenuation technique to monitor continuously precrack damage and crack propagation in polycrystalline aluminum and steel specimens subjected to cyclic loading. He reported that the measurement of change in ultrasonic attenuation prior to the onset of the stage II crack propagation proved useful in explaining the rate of crack propagation. Also, the specimens that undergo higher precrack damage showed shorter postcrack percent lives.

**Probe Displacement Method on Compact Specimens.** Clark (Ref 58) developed an equipment that utilized the specularly reflected signal from the crack for use in a wedge-opening load (WOL) fracture-toughness specimen. They used a fixed 10 mm diam, 10 MHz normal compression probe in pulse-echo to observe the increase in echo as the fatigue crack grows. They moved the probe along the surfaces of specimens containing long fatigue cracks to establish the calibration curve of growth against echo amplitude. The accuracy of this method was found to be about  $\pm 0.1$  mm using beach-marked cracks in steel and aluminum. However, the maximum amount of crack that can be monitored without transducer movement was only 2.5 mm because of the saturation characteristics of the associated instrumentation.

Subsequently, Clark and Ceschini introduced a motor drive to increment the probe's position along the specimen (Ref 59). They used a conventional ultrasonic flaw detector in conjunction with a reflectoscope. Using this method, the position of the transducer on the specimen surface can be related to the extent of crack growth by transducer movement such that a constant flaw signal is maintained from the tip of the propagating crack. This arrangement permitted the crack tip always to be kept near the center of the beam. Their setup is shown schematically in Fig. 8.

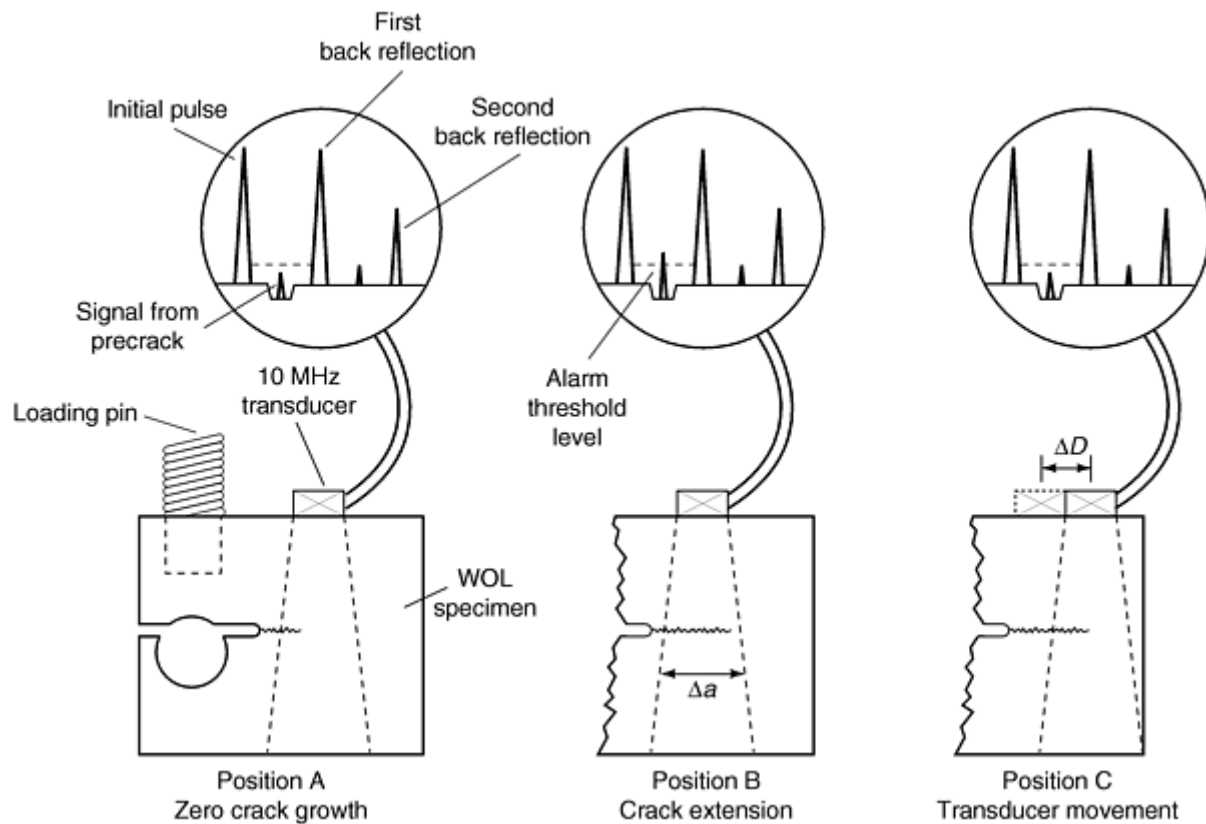

FIG. 8 CLARK AND CESCHINI'S ULTRASONIC SETUP. SOURCE: REF 59

First, a 25 mm sweep to peak second back reflection signal was generated through the uncracked portion of the specimen by adjusting the ultrasonic instrumentation. Then the transducer was positioned on the specimen so as to obtain a 5 mm sweep to peak signal from the fatigue precrack tip (Fig. 8, position A). The position A corresponds to the zero crack growth transducer location. This serves as a reference for subsequent crack growth measurements. With an increase in crack length, the flaw signal amplitude increases (Fig. 8, position B) due to the increase in the reflecting area of the crack within the scanning beam. The transducer is then moved to position C in the direction of crack growth till the flaw signal is similar to that of position A. Thus, the transducer movement distance is equivalent to the crack growth increment. By recording the transducer location versus time or cycles, one could deduce the crack growth rate. Using this method, a crack-length measurement sensitivity of  $\pm 0.25$  mm was reported.

**Time of Flight Measuring Techniques.** These methods detect and measure the flight time of the ultrasonic pulse diffracted from the crack tip (Ref 60). If the path taken from the transmitter to the receiver via the crack tip is known, one can calculate the position of the tip and hence the crack length.

The probe arrangement for measuring surface cracks along with the electronics is shown in Fig. 9 (Ref 53). Most of the beam that is incident on the crack is either reflected or passed directly on, but a small portion is diffracted. This diffracted signal reaches the receiver. If the transmitted rays emerge effectively from a point on the specimen surface, and the diffracted rays are received at another point, then the time of the flight,  $t$ , to the crack depth,  $a$ , is related by the equation

$$A = [(CT/2)^2 - H^2]^{\frac{1}{2}} \quad \text{(EQ 2)}$$

where  $c$  is the velocity of sound, and  $h$  is the horizontal distance of the receiver from the crack.

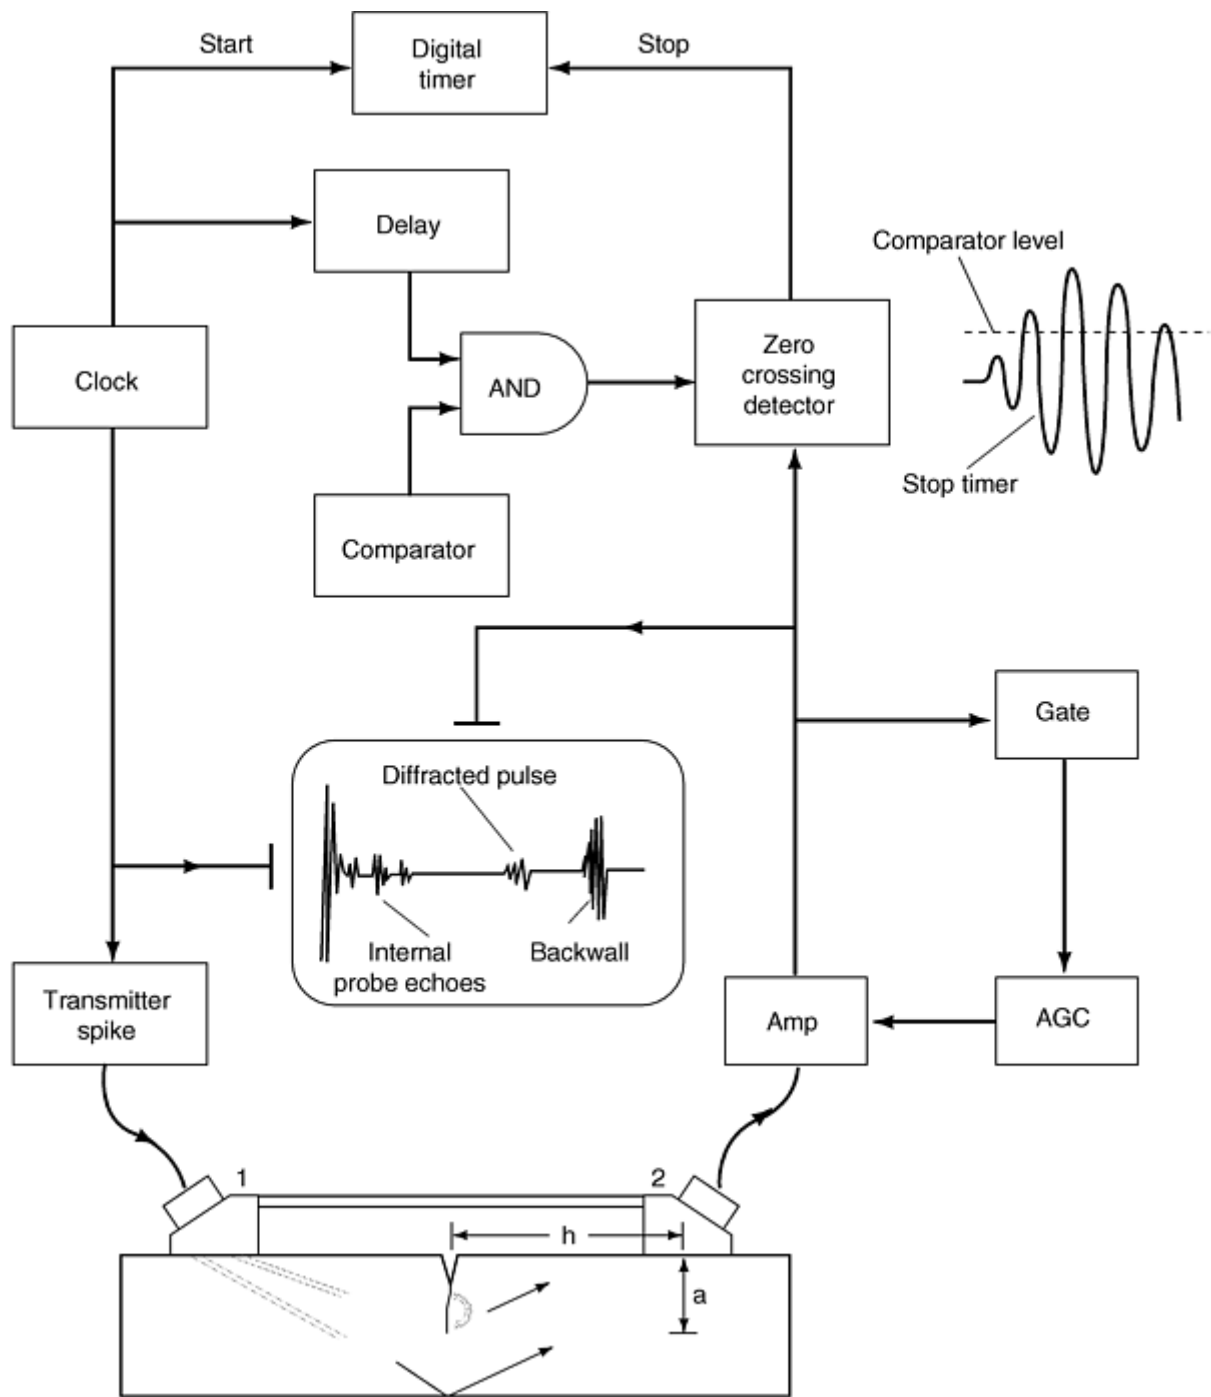

FIG. 9 SCHEMATIC MEASURING THE TIME OF FLIGHT OF A DIFFRACTED WAVE. SOURCE: REF 53

The surface crack measurements by timing the diffracted pulses is accurate since the time of flight can be measured precisely to nanoseconds level. Mudge and Whitaker (Ref 61) have measured fatigue precracks in wide plate tests and the onset of ductile tearing in crack-opening displacement specimens. They reported errors in measuring fatigue crack depth within  $\pm 0.2$  mm.

Silk (Ref 60) pointed out that both surface and subsurface defects can be evaluated using the ultrasonic method. Richards (Ref 12) summarized the relative merits and demerits of the ultrasonic methods for fatigue crack growth monitoring. The merits of this method include: Embedded cracks and crack profiles can be easily measured, it can be easily automated, both metals and nonmetals can be studied, and it accommodates relaxation from linear-elastic behavior. However, the ultrasonic methods have the following limitations: They are neither suited for small specimens nor are they well developed for high-temperature studies, and they are expensive.

## Detection and Monitoring of Fatigue Cracks

S. Shanmugham and P.K. Liaw, Department of Materials Science and Engineering, University of Tennessee

---

## Eddy Current Techniques

The eddy current method is essentially a combination of a local resistance measuring technique and a magnetic method. Typically, the crack-length as well as the crack-depth information can be easily obtained using this method. It is widely used in the aerospace industry and also for laboratory applications. The crack detection sensitivity of this technique is around 0.1 mm.

The eddy current method is essentially a variation of the alternating current electric potential method. The connection between the specimen and the measuring system is done by electromagnetic induction instead of connecting wires (Ref 9, 62). In this method, an alternating current is passed through a coil adjacent to the sample surface, which contains crack initiation sites or cracks. An alternating magnetic field is created, and this induces eddy current in the sample. The eddy currents result in a secondary current, which adds vectorially to the exciting field, and the combined field can then be detected by a secondary coil. However, for crack detection, the variation in the complex impedance of the driving coil is usually determined.

The eddy current method uses a range of frequency from several hundred Hz to several MHz depending upon the type of application. Eddy current excitation is usually on a small, local scale, and hence a traveling probe is commonly employed to scan the whole surface of the test specimens and to detect small defects. Because there are no direct electrical connections to the specimen, the specimen insulation from the test machine is usually not required.

Portable eddy current instruments are available, and they exhibit phase and/or amplitude changes in the eddy currents induced in the presence of a crack. The amplitude or phase variation can then provide estimates of crack length or depth, respectively, and typically for a short crack, crack length or depth is obtained from amplitude or phase variation. The crack length or crack depth is usually several times the eddy current skin depth,  $S$ , and is given by the equation

$$S = (\mu \mu_0 \sigma \pi F)^{-0.5} \quad (\text{EQ 3})$$

where  $\mu$  is the permeability of the material,  $\mu_0$  is that of the free space permeability,  $\sigma$  is the metal conductivity, and  $f$  is the frequency. In eddy current measurements, there is always a compromise between high sensitivity at high frequencies and the ability to monitor deeper cracks at lower frequencies.

The eddy current method depends on the change in the inductance of a search coil in the vicinity of a conducting test specimen caused by the generation of electrical currents in the test specimen when it is subjected to a time-varying magnetic field. It can be used for the crack detection because the defects interrupt the flow of the eddy currents generated in the material. This is reflected in a different complex impedance of the eddy current pick-up coil when it is positioned over the flaw in comparison to the signal generated over an undamaged region of the material.

An eddy current system employed for continuous crack monitoring has been reported (Ref 10). In this system, the probe is enclosed in a nylon sheath and is positioned at a fixed distance (0.25 mm) from the sheet surface in order to prevent any damage of the probe when the specimen fractures into two pieces. On the occurrence of a crack, the eddy current off-null signal is used to drive the linear servomotor horizontally to the right. The probe is then moved physically to the right, and when it reaches the crack tip the off-null signal drops to zero and the servomotor movement is stopped. Thus, the high-response actuator system is locked onto the tip of the crack. This system is capable of measuring increments in crack growth of less than 0.25 mm. The eddy current method is simple and amenable to automation. However, it is expensive and produces only surface measurements (Ref 12).

## Detection and Monitoring of Fatigue Cracks

S. Shanmugham and P.K. Liaw, Department of Materials Science and Engineering, University of Tennessee

---

## Infrared Techniques

Infrared techniques allow detection of fatigue damage from remote locations. It also can be used for predicting the residual fatigue life of components in service. Infrared techniques have been investigated for their potential to detect fatigue damage since the mid-1970s. They can be classified into passive, mechanically activated, or radiation activated (Ref 8). In the passive technique, the heat produced by spontaneous strain release is monitored, and in the case of the mechanically activated method, the rise in temperature around stress concentrations is monitored when the material is subjected to cyclic loading. In the radiation-activated technique, heat is applied to the material and the subsequent heat flow is observed over a period of time. The infrared technique has the following features: Functions in real-time, is nondestructive, and can be used for remote measurements.

Huang et al. (Ref 63) used an infrared-sensing method for monitoring fatigue processes in stainless steels and superalloys during a revolving-bending fatigue test. They used an infrared radiometer to record the temperature changes of the center part of the specimen. They reported an exponential relationship between the temperature rise and stress increment of the fatigue fracture. The rate of increase in the initial temperature for materials with high ductility during high-stress fatigue testing could be related to the life of the fatigue fracture. On the basis of their experiments, they concluded that the

infrared technique could be used for monitoring the sudden fracture due to overloading as well as for predicting fatigue life.

## Detection and Monitoring of Fatigue Cracks

S. Shanmugham and P.K. Liaw, Department of Materials Science and Engineering, University of Tennessee

---

## Exoelectrons

Exoelectron methods can be used to predict residual fatigue life as well as to follow crack propagation. However, it has limited sensitivity for detecting fatigue cracks. The photoelectron emission from a metal may be enhanced by plastic deformation of the surface (Ref 64). This effect is commonly known as exoelectron emission. Exoelectrons can be produced by unidirectional tensile deformation from slip steps. As a slip step emerges from a brittle natural surface oxide, cracks open to reveal the fresh metal surface of the slip step. These surfaces have a lower photoelectric work function than the surrounding oxide-coated surface and result in enhanced emission.

Baxter investigated the fatigue behavior of a 1018 steel sheet stock in a reverse-bending constant-amplitude mode using the exoelectron approach (Ref 64). The specimen was mounted in a vacuum chamber, and a small spot (~70  $\mu\text{m}$  diam) of ultraviolet radiation was used to scan along its gage length. The light source utilized was a 1 kW mercury arch lamp with a Corning 9-54 filter. The ultraviolet spectral range of interest stability was monitored by diverting the beam through an interference filter, and the transmitted radiation was measured using an RCA 1P28 photomultiplier. The electrons emitted from the sample were accelerated up to 500 eV and were detected by an electron multiplier. Baxter recorded the emission rate as a function of the position of the light spot. Five parallel paths separated by ~300  $\mu\text{m}$  were scanned to provide a more complete and representative picture of the exoelectron emission generated during fatigue.

Baxter demonstrated that the exoelectrons emitted are associated with the accumulation of fatigue damage but are also influenced by pressure. For example, exposure to higher pressures of air results in decreased exoelectron emission. He interrupted the fatigue cycling at 800 cycles and exposed the sample to air at atmospheric pressure for 1 h, thereby eliminating the three emission peaks. On resumption of the fatigue cycling, the emission peaks reappeared, grew rapidly, and followed an apparent extension of the original growth curve which clearly shows the significance of the surface oxide (Fig. 10). With the accumulation of fatigue deformation, the brittle surface oxide cracks open and reveal a fresh metal surface of a lower work function ( $\Delta j \sim 1$  eV) that emits exoelectrons. The location of final failure always corresponded to the largest exoelectron peak.

**FIG. 10 GROWTH OF THREE EXOELECTRON PEAKS WITH CONTINUED FATIGUE CYCLING. TEST INTERRUPTED AT 800 CYCLES AND SPECIMEN EXPOSED TO AIR AT ATMOSPHERIC PRESSURE FOR 1 H. FATIGUE CYCLING THEN RESUMED UNDER VACUUM. SOURCE: REF 64**

Samples after being fatigued at different strain amplitudes were compared to produce a range of fatigue lives from 27,400 to 942,000 cycles. The normalized exoelectron emission intensity (at 2%) was plotted against the number of fatigue cycles normalized with respect to the number of cycles of failure. The parallel growth curves revealed that the increase of localized exoelectron emission is a very systematic, reproducible, and continuous process, particularly in the range of  $\sim$  0.7% to 7% of life. Based on his results, Baxter concluded that the intensity of the localized exoelectron emission is a measure of the localized accumulation of fatigue damage. Also, the growth of the emission is not only a function of the number of fatigue cycles at a given strain level but is related to the total accumulated fraction of life. In order to facilitate the extraction of the number of fatigue cycles remaining before failure from the exoelectron emission measurement, he developed a procedure for normalizing the emission intensity. Based on this new procedure, he showed that when the maximum intensity of localized exoelectron emission is 10 times the initial background intensity, the sample is between 0.8 to 3% of its ultimate fatigue life.

## Gamma Radiography

The gamma radiography technique is an in-field technique, and the crack detection sensitivity is typically around 2% of the component thickness. It uses penetrating radiation emitted by an isotope source, such as  $^{60}\text{Co}$  or  $^{192}\text{Ir}$ , on a structural component (Ref 9). This penetrating radiation is either transmitted or attenuated by the component under investigation. Fatigue cracks having major dimensions parallel to the radiation represents regions lacking attenuative material, and the difference can be easily imaged on a radiographic film.

Gamma radiography is typically an in-field application technique, and its use is restricted to dense or thick metallic materials. Crack detection sensitivity of this method is typically 2% of the thickness of the component. Crack length also can be measured with a sensitivity level that depends on component geometry, crack morphology, and accessibility to the component (Ref 36). Another method similar to gamma radiography is x-ray radiography, which is primarily used for laboratory applications.

## Microscopy Methods

Microscopic techniques allow us the capability of understanding the mechanisms involved in fatigue crack initiation and propagation. It is the most widely used technique for characterizing the fatigue damage. It has very high sensitivity for crack detection and can be used for following crack propagation. This feature provides us insights not only in microstructural changes, but also in compositional changes. Crack detection sensitivity of the scanning electron microscopy (SEM) and the transmission electron microscopy (TEM) methods are 1 and 0.1  $\mu\text{m}$ , respectively. Optical

techniques serve the same purpose as that of the microscopic techniques but with a lower sensitivity. Atomic force microscopy (AFM), scanning tunneling microscopy (STM), and scanning acoustic microscopy (SAM) are relatively new techniques. They can provide much better insights into the crack nucleation process than any of the other techniques. However, they have to be nurtured and involve elaborate specimen preparation.

**Electron Microscopy.** Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) are often used to follow fatigue crack initiation and growth behavior to identify the mechanisms involved. The fatigue process can be divided into four stages based on the structural changes that take place when a metal is subjected to cyclic stress as described in the article "Fatigue Failure in Metals" in this Volume and Ref 65:

- *CRACK INITIATION:* THIS REPRESENTS THE EARLY DEVELOPMENT OF FATIGUE DAMAGE.
- *SLIP-BAND CRACK GROWTH:* DURING THIS STAGE, THE DEEPENING OF THE INITIAL CRACK ON PLANES OF HIGH SHEAR STRESS TAKES PLACE AND IS REFERRED TO AS STAGE I CRACK GROWTH.
- *CRACK GROWTH ON PLANES OF HIGH TENSILE STRESS:* THE CRACK GROWS IN A DIRECTION NORMAL TO THE MAXIMUM TENSILE STRESS AND IS REFERRED TO AS STAGE II CRACK GROWTH.
- *FINAL DUCTILE FRACTURE:* THE CRACK REACHES A LENGTH AT WHICH THE REMAINING CROSS SECTION DOES NOT HAVE THE ABILITY TO SUPPORT THE APPLIED LOAD.

For steel alloys subjected to fatigue testing in air or inert environments, the crack can initiate from persistent slip bands, extrusions/intrusions, grain boundaries, inclusions, and porosity (Ref 9). During fatigue testing, the dislocations can move to the specimen surface and form fine lines. These lines are called persistent slip bands. The stage I crack propagates initially along these slip bands, and the fracture surface of stage I fractures are typically featureless. In contrast, the stage II crack propagation fracture surface is marked by a pattern of ripples or fatigue fracture striations.

Three approaches of following fatigue damage using SEM are replication, direct, and in situ techniques. In the replication method using SEM, cellulose acetate films softened with acetone are typically used to replicate the specimen surface for detecting crack initiation (Ref 9). Usually, the replicas are taken at a predetermined number of fatigue cycles to detect crack initiation processes. The replicas are placed or rolled onto the fatigued specimens. The specimen should be under tensile loading as replication proceeds. The above procedure enables the opening of the cracks and the better penetration of the replication material into the potential cracking area. Following acetone evaporation, the acetate films are removed from the specimens to develop replicas.

The replicas are typically coated with gold in a vacuum evaporator. Replicas represent a negative image of the actual surface as the replicas are typically based on the one-stage technique. Hence, small fatigue cracks on the specimen surface appear as protrusions whereas extrusions on the surface appear as valleys in the micrographs. The crack-length detection sensitivity is typically 1  $\mu\text{m}$ . A two-stage replica technique is also available (Ref 66).

In the two-stage replication method, a layer of solder approximately 0.3  $\mu\text{m}$  is vapor deposited on the cellulose acetate, and subsequently a mount of epoxy adhesive containing a set screw is applied to enable the peeling of the solder film. Thus, in this technique, positive impressions of the actual test specimens are obtained. The resolution of crack size detection is typically 0.1  $\mu\text{m}$ .

The replication techniques enable the microstructural evolution of fatigue cracks to be examined easily at the same site on the specimen as a function of the number of fatigue cycles and provides detailed and direct information of small fatigue cracks.

In the direct method, the fatigued specimens are periodically removed from the test machine and inspected for evaluating crack initiation process using SEM. In some instances, a multiple specimen technique is used for studying crack initiation. Each specimen can be fatigued for a given number of cycles and removed from the test machine for SEM examination. This method is expensive and time consuming compared with the replication technique. In the in situ technique, the fatigue machine is installed in the SEM, and the test specimens are fatigued as well as inspected in the SEM (Ref 67, 68,

69, 70). This method is effective and convenient for investigating crack initiation, and the detection sensitivity is typically  $1 \mu\text{m}$ .

Two-stage replicas are prepared for TEM examination (Ref 9). Replicas are taken from the fatigued specimens and coated with a thin layer of metal, such as gold. Then, the replicas are generally coated with amorphous carbon to develop the two-stage replicas. Typical crack detection sensitivity is  $0.1 \mu\text{m}$ .

Davidson and Lankford (Ref 71) have provided a comprehensive review of fatigue crack growth in metals and alloys and discuss in detail the origin of striations and crack growth. The spacing of fatigue striations provides important evidence for understanding the fatigue crack growth process. This is because striations provide unambiguous, quantitative evidence of the increment by which a fatigue crack advances. Grinberg (Ref 72) examined the fatigue behavior of annealed iron in moist air. Figure 11 illustrates the fatigue crack growth behavior compared with the average number of cycles required for single striation formation, and the striation spacing was found to be much greater than  $da/dN$  (Ref 72).

FIG. 11 CRACK GROWTH RATE AND STRIATION SPACING FOR AN ANNEALED IRON TESTED IN MOIST AIR. SOURCE: REF 72

**Scanning Tunneling Microscope (STM).** The STM is a recent innovation and is capable of resolving surface features down to the atomic level. The STM works on the principle of development of tunneling current (Ref 73). A tunneling current is developed when an electrode is placed close to the specimen surface at a distance of 0.5 to 1.0 nm away from the surface. By maintaining a constant tunneling current, as the probe moves across the specimen, it pops up when there is a protrusion on the surface. It moves down when it comes across a cavity, and the up-and-down motions are recorded by the computer. The topographical data thus gathered provide a sensitive image of the specimen surface.

The STM has a sharp conducting tip that traces the surface contours with atomic resolution, and the tip is moved in three dimensions by means of an  $x, y, z$  piezoelectric translator (Ref 74). With the piezoelectric element calibrated to move 1 nm for a 1 V application, the tip will move over approximately three atoms for an incremental potential of 1 V. The voltage applied to the  $z$ -piezo element governs the distance between the surface of the specimen and the tip. The voltage is determined by a feedback circuit that also measures and controls a small electric current. This current is due to the electrons tunneling between the tip and the sample and is affected by the bias voltage applied to the tip. The tunneling current is maintained constant by the feedback circuit, which modulates the voltage to the  $z$ -piezo, as the  $x$ -piezo moves the tip across the specimen surface.

The amplitude of the tunneling current is very sensitive to the gap distance between the tip and the specimen surface. For example, as the distance between the tip and the surface changes by 0.1 nm, the tunneling current value changes by a

multiple of 2 or greater. This tunneling current sensitivity enables divulging of height differences along the contours to be better than 0.01 of an atomic diameter. However, the lateral resolution along the contours is governed by the radius of curvature of the tip. In a single scan, the voltage applied to the z-piezo is recorded as a function of the voltage applied to the x-piezo. Thus, a complete image is an assembly of multiple scans, with each displaced from the preceding scan by a small shift in the y direction, to form a raster pattern. By virtue of computer-aided image processing, the data can be presented as images that provide topographical information either as a gray level, illuminated filled surfaces, or multicolored elevation maps.

Recently, Venkataraman et al. (Ref 6) used STM to study fatigue crack initiation of silver single crystals oriented for a single slip. They reported that the slip bands could easily be captured using STM, and the fatigue process has a definite crack nucleation stage. An STM image of a just-nucleated crack found within a slip band of a specimen fatigued to crack initiation at 180 K in He-15%O<sub>2</sub> was also captured. Subsequently, Sriram et al. (Ref 75) demonstrated the effect of oxygen partial pressure on fatigue crack initiation in silver single crystals and captured the nucleation process using STM.

Sriram et al. (Ref 76) investigated the role of surface chemistry in the initiation of fatigue cracks for silver single crystals. They conducted fatigue tests in an oxygen environment up to crack initiation on pure silver specimens. The STM can be easily utilized for observing shallow cracks with the lateral resolution restricted by the geometry of the tip. However, the STM can be used only for conducting surfaces. By using STM, the cracks were identified that satisfied the following criteria:

- THEY WERE INVARIABLY ASSOCIATED WITH SLIP BANDS.
- THEY WERE PIT- OR ARROWHEAD-SHAPED AND USUALLY 1 μM IN LENGTH ALONG THE SLIP BANDS AND 0.1 μM DEEP.
- THE CRACKS APPEARED ONLY AFTER A CERTAIN NUMBER OF CYCLES IN COMPARISON WITH INTRUSIONS OR EXTRUSIONS.

**Atomic Force Microscope (AFM).** The AFM is a recent invention that produces images that are much closer to simple topographs and can image nonconducting surfaces (Ref 74, 77). The AFM is a combination of the principles of the scanning tunneling microscope and the stylus profilometer.

The AFM operates by measuring the forces between the specimen and the probe. These forces are determined by the nature of the sample, the operating distance between the probe and the sample, the geometry of the probe, and the contaminants present on the specimen surface. The two important properties of the AFM cantilever are spring constant and resonant frequency. The spring constant governs the force between the probe and the specimen when they are close to each other; the spring constant is defined by the material used to build the cantilever. If the cantilever is moved from its equilibrium position and released, it will vibrate at a resonant frequency. This frequency is determined by the cantilever material, dimensions of the cantilever, and the forces acting on the probe.

The AFM records interatomic forces between the apex of a tip and atoms in a sample as the tip is moved over the surface of the sample (Ref 74). During this process, it senses the repulsive forces between the tip and the sample with the tip actually touching the sample. The tip is very sharp, and the tracking force used is small, and the tip traces over individual atoms without damaging the surface of the sample. In this mode of operation, the AFM cantilever is weak with a very low spring constant.

Another mode in which the AFM can be operated involves being sensitive to the attractive forces between the tip and the sample. A feedback system is used in order to prevent the tip from touching and damaging the sample. Also, the resolution attained in this mode of operation is at the expense of decreased lateral resolution.

Recently, Gerberich (Ref 78) used AFM to study fatigued titanium samples. He reported that it can be used to capture images of the surface where fatigue cracks normally initiate, and the slip upset can be directly measured to angstrom accuracy.

**Scanning Acoustic Microscope (SAM).** The SAM is based on the principle that an acoustic lens having good focusing properties on axis can be used to focus acoustic waves onto a spot on a specimen and receive the acoustic energy from the spot (see *ASM Handbook, Volume 17, Nondestructive Evaluation and Quality Control*). By scanning the lens over the specimen systematically, and by sending the intensity of the reflected signal to a synchronous display, a scanned image is

built up. Fatigue crack images of an Al-20%Si plain bearing alloy that failed in fatigue have been recorded using SAM (Ref 9).

## X-Ray Diffraction

X-ray diffraction can be used for determining the compositional changes, strain changes, and residual stress evaluation during fatigue process. Hence, by utilizing this technique the processes occurring during fatigue damage can be understood. The macroscopic and microscopic properties of materials subjected to fatigue cycling have been studied using XRD techniques by measuring the position and shape of diffraction profiles (Ref 8). The XRD method is widely used for the qualitative and quantitative analysis of samples, precise determination of lattice constants, crystallite size, and lattice strains from line broadening, investigation of preferred orientation and texture, stress measurements, and radial distribution studies of noncrystalline materials.

The phenomenon of XRD by crystals is due to the scattering process in which x-rays are scattered by the electrons of the atoms without change in wavelength (Ref 79). Monochromatic x-rays are usually obtained by the electron bombardment of targets of metallic elements, such as chromium, iron, cobalt, or copper. A diffracted beam will be produced by such scattering only when certain geometrical conditions are satisfied. These geometrical conditions are provided by Bragg's law or the Laue equations. Thus, the resultant diffraction pattern of a crystal that contains both the positions and intensities of the diffraction pattern is a physical property of the substance. Diffraction patterns obtained this way can be

recorded by a Debye-Scherrer method, parafocusing technique (powder diffractometer), or a monochromatic pinhole approach. Among the three available methods, the powder diffractometer is the most sensitive.

Diffraction theory predicts that the lines of the powder pattern obtained from a polycrystalline specimen will be exceedingly sharp, if the specimen consists of sufficiently large and strain-free crystallites. Hence, the profile analysis method could be used for assessing fatigue damage, and the broadness of the diffraction line is related to the microscopic structure of polycrystalline materials (Ref 8). The shape and breadth of the profile are determined both by the mean crystallite size or distribution of sizes, and the particular imperfections prevailing in the crystal lattice. Precise diffraction profiles of the material under investigation are usually obtained from the powder diffractometer. Then, by utilizing either Fourier transformation or the iterative method of successive foldings, the line broadening is separated into two components related to microstrain and particle size, from which the dislocation density can be calculated.

The residual stress determined by XRD is a macroscopic parameter, and it represents the mean value of microscopic lattice distortions in a surface layer, which is few square millimeters in area and of thickness equal to the depth of penetration of the x-rays (Ref 8). When a polycrystalline piece of metal is deformed elastically such that the strain is uniform over relatively large distances, the lattice plane spacings in the constituent grains change from their stress-free value to some new value. The new lattice plane spacing value corresponds to the magnitude of the applied stress. This uniform macrostrain results in a shift of the diffraction lines to new  $2\theta$  positions. This stress is calculated from precise measurements of the peak shifts of diffraction profiles caused by changes in the interplanar spacing from the equilibrium value. The lattice strain is calculated by employing the double-exposure method, which measures the changes in lattice dimensions in two or more directions in the surface layer. Once the strain is determined, the stress can be determined by a calculation involving the mechanically measured elastic constants of the material or by a calibration procedure involving the measurement of the strains produced by known stresses.

Alexopoulos and Byrne (Ref 80) investigated the fatigue behavior of hard and soft copper using x-ray line broadening and positron annihilation lifetime measurements. The cold-rolled copper was annealed for 1 h at 93.3 °C and had a yield stress of 186.3 MN/m<sup>2</sup>. The fatigue testing was conducted at a maximum cyclic stress of 1.5 times the yield stress. The mean positron lifetime and x-ray particle size variation with cycles were determined. They observed that the mean positron lifetime decreased after about 55,000 cycles, and then increased after about 80,000 cycles. In the same fatigue range, the x-ray particle size first increased and then decreased. They explained that the increase in the x-ray particle size is expected because of the occurrence of cyclic softening. In the same study, they did mean positron lifetime and x-ray particle size measurements on cold-rolled copper annealed at 399 °C for 1 h at a maximum cyclic stress of 1.3 times the yield stress. The mean positron lifetime initially increased, then decreased, and again increased prior to fracture. The x-ray particle size measurements followed exactly an opposite behavior. This behavior results from the fact that the present sample initially fatigue hardened and then fatigue softened.

## Detection and Monitoring of Fatigue Cracks

S. Shanmugham and P.K. Liaw, Department of Materials Science and Engineering, University of Tennessee

---

## In-Field Application

The following techniques are capable of inspecting components in service for fatigue cracks: magnetic methods, liquid penetrant, eddy current, electric potential, acoustic emission, ultrasonics, radiography, and infrared. Most of the above techniques are also utilized for nondestructive evaluation of components during fabrication as well as manufacturing to

detect cracks (not necessarily fatigue cracks). For example, weld defects can be detected by radiography, ultrasonics, magnetic particle, or liquid penetrant method (Ref 81). Hence, in the following paragraphs, in-field applications of each of the above methods for crack detection are summarized.

The magnetic particle method is applicable only to magnetic materials. It is used for inspecting cracks in steel tubular products, pressure vessels, weldments, castings, and forgings. The field applications of other magnetic methods, such as magnetic Barkhausen, magnetoacoustic emissions, and magnetic flux leakage, are well detailed in the article "Magnetic Field Testing" in *ASM Handbook*, Volume 17, *Nondestructive Evaluation and Quality Control*. These methods have been used to detect cracks or flaws in ferromagnetic tubular products (such as gas pipelines, down hole casing, and other steel piping), helicopter rotor blade D-spars, gear teeth, artillery projectiles, drill pipe, collars, steel ropes, and cables, and steel reinforcement in concrete beams. The liquid penetrant method is applicable for both magnetic and nonmagnetic materials. It is used for inspecting cracks in nonmagnetic ferrous tubular products, boilers, pressure vessels, weldments, brazed assemblies, castings, and forgings.

The eddy current method has been used for detecting surface cracks in aircraft structures and engines since the late 1950's (Ref 82). Reference 82 provides a historical development of eddy current testing in aircraft maintenance. The article "Eddy Current Inspection" in *ASM Handbook*, Volume 17, *Nondestructive Evaluation and Quality Control* includes several examples of inspections of aircraft structural and engine components using the eddy current technique. The eddy current method is also used for inspecting tubular products, bars, billets, castings, boilers, pressure vessels, weldments, and forgings. The electric potential method is used for monitoring the crack initiation and propagation behavior in steam turbine components and pipes.

The acoustic emission method is widely used for structural testing of aircraft, spacecraft, bridges, bucket trucks, buildings, dams, military vehicles, pressure vessels, tubular products, rotating machinery, weldments, storage tanks, and other structures. The article "Acoustic Emission Inspection" in *ASM Handbook*, Volume 17, *Nondestructive Evaluation and Quality Control* gives an example of fatigue crack detection in jumbo tube trailers, which transport large volumes of industrial gases at a pressure of about 18.2 MPa. Ultrasonic methods are used for detecting defects in tubular products, bars, boilers, pressure vessels, machine components, weldments, forgings, and castings. The detection of in-service fatigue cracks in machine components has been reported in the article "Ultrasonic Inspection" in *ASM Handbook*, Volume 17.

Radiography methods are used to detect flaws in weldments, pressure vessels, and boilers. In-service radiographic inspection of boilers and pressure vessels is outlined in the article "Boilers and Pressure Vessels" in *ASM Handbook*, Volume 17, *Nondestructive Evaluation and Quality Control*. This article also compares the merits and demerits of the techniques discussed above for nondestructive evaluation of pressure vessels and boilers.

Infra-red techniques are utilized for detecting fatigue cracks in the metallic skin of aircraft and missile structures, and the details are presented in Ref 83.

### Introduction

FATIGUE CRACK INITIATION is an important aspect of materials performance in design, and this introductory article summarizes some fundamental concepts and procedures for fatigue life prediction of relatively homogeneous, wrought metals when a major portion of total life is exhausted in crack initiation. Life prediction based on fatigue crack growth involves the concepts of fracture mechanics and is discussed elsewhere in this Volume. Cast and composite materials also are discussed elsewhere in this Volume.

The basic concepts and methods discussed in this article include:

- CYCLIC STRESS-STRAIN MECHANICAL BEHAVIOR
- STRAIN-LIFE BEHAVIOR
- EFFECTS OF MEAN STRESS AND GEOMETRIC NOTCHES
- LOCAL STRESS-STRAIN AND CUMULATIVE FATIGUE DAMAGE ANALYSIS

Several examples are also given as a way to illustrate the use of strain-based fatigue analysis in the early design stages of components. These methods can reduce costly design alterations (particularly in materials selection) and prototype testing, but by no means imply the elimination of component testing (particularly in the case of "critical" components). The techniques and concepts described in this article are best suited to material selection for specific strain-time histories and comparison of design "A" to design "B" on a relative life improvement basis. They should be employed as early in the design stage as possible in order to circumvent costly prototype development and testing programs.

The strain-life approach is effective in characterizing the fatigue behavior of materials because it accounts for plastic strain, which is a fundamental cause of fatigue crack initiation. Constitutive equations between strain and life are therefore useful because materials are metastable under cyclic loads. Understanding of cyclic strain-strain behavior is necessary for fatigue design.

To predict the crack-initiation life of actual components, the following techniques (with an understanding of strain-life behavior) need to be considered:

1. MEAN STRESS EFFECTS NEED TO BE ACCOUNTED FOR BY MODIFICATION OF THE STRAIN-LIFE EQUATION
2. SIZE EFFECTS OF GEOMETRIC NOTCHES NEED TO BE CONSIDERED
3. PROCEDURES NEED TO RELATE REMOTELY MEASURED STRESSES AND STRAINS TO THE STRESSES AND STRAINS AT A NOTCH ROOT WHERE PLASTICITY DOMINATES

By combining the above "analytical tools" with an adequate cycle-counting technique that accrues closed hysteresis loops (for example, rainflow or range pair), a means is available to predict fatigue-initiation life of real components or parts.

Explanation of these topics is aimed primarily as a primer on the basic concepts and methods for predicting fatigue crack initiation lifetimes. It should be noted, however, that the techniques outlined in this article are not "the only" or "the best" way to approach an engineering solution to materials selection or the lifetime prediction of materials in design. Other techniques and more complex materials such as composites are therefore covered in a multitude of books, journal articles, and conference proceedings. The major driving forces in development and dissemination of fatigue analysis techniques are the Fatigue Design and Evaluation Committee of the Society of Automotive Engineers (SAE FD&E) and the E 08 Committee on Fatigue and Fracture Mechanics of the American Society for Testing and Materials (ASTM). The SAE FD&E has published its second *Fatigue Design Handbook*, AE10, 1988, and has furthered these general principles to include multiaxial fatigue with the publication of *Multiaxial Fatigue*, AE 14, 1989. The ASTM has numerous Special

Technical Publications (STP's) germane to this topic but the most directly applicable are *Advances in Fatigue Life-time Predictive Techniques*, Vol 1, STP 1122, 1992 and Vol 2, STP 1211, 1993, *Low Cycle Fatigue*, STP 942, 1988 and *Low-Cycle Fatigue and Life Predictions*, STP 770, 1982.

## Acknowledgements

This article was adapted from the article "Fundamentals of Modern Fatigue Analysis for Design" in *Fatigue and Microstructure*, ASM, 1979.

This paper has drawn heavily from the course notes of Professor (Emeritus) Jo Dean Morrow, Department of Theoretical and Applied Mechanics, University of Illinois; and Dr. R.W. Landgraf, Virginia Polytechnic Institute. The former was my thesis advisor, the latter a colleague while I worked for Ford Motor Co., Scientific Research Staff. Both are long time friends and colleagues and to both I owe an eternal debt of gratitude. Much of the information given herein was originally presented as an introductory seminar to sponsors of the Fracture Control Program, College of Engineering, University of Illinois at Urbana-Champaign and was published as FCP Report No. 26 in 1976. A later version of similar notes published under the same program at the University of Illinois expanding these concepts and including fatigue crack propagation methodologies for life predictions was written by J.A. Bannantine, J.J. Comer and J.L. Handrock, and titled *Fundamentals of Metal Fatigue Analysis*, 1987.

## Historical Development

The failure of a metal because of repeated loads was first documented by Albert (circa 1838) (Ref 1). Since that time, considerable attention has been paid to the deformation behavior of metals under a variety of loading conditions. Initially, possibly because of Wöhler (circa 1860) (Ref 2), the fatigue resistance of metals was investigated by conducting rotating-bending experiments; the results were reported as the now familiar  $S$ -log  $N$  (stress-log cycles to failure) curve, from which the concept of an "endurance limit" (a stress limit below which failure of metal *should* never occur) finds its origin.

We now know that fatigue of metal is the result of to-and-fro slip, or plastic deformation, particularly at a local level. In earlier attempts to describe the fatigue resistance of metals, the rotating-bending stress ( $S$ ) was calculated by the familiar elasticity relationship:

$$S = MC/I \quad (\text{EQ 1})$$

where  $M$  is the applied bending moment to the specimen;  $c$  is the distance from neutral axis to the surface of the specimen; and  $I$  is the cross-sectional moment of inertia or second moment of area of the specimen. It would seem that these earlier attempts are, at least, questionable because there was no account for plastic deformation.

This article contains an overview of the strain-based, as opposed to stress-based, criterion of material behavior and fatigue analysis. Attention is focused on failure of metals caused by repeated or cyclic loading. *Cyclic stress-strain* behavior of metals is described to illustrate the inadequacy of the monotonic or tensile stress-strain curve in accounting for material instabilities caused by cyclic deformations. The concept of the strain-life curve, that does account for plastic deformation, is also illustrated. Next, the local stress-strain approach to fatigue analysis is explained--an approach in which attention is focused on critical locations in a structure where failure is most likely to occur. Finally, a cyclic-plasticity analysis is described for a strain-time history such as that expected in an actual component history. All these concepts are then combined in an attempt to predict the design life of engineering structures, and several examples are used for illustration.

Failure of metals because of repeated loads became a recognized engineering problem with the advent of rotating or reciprocating machinery during the Industrial Revolution of the early 1800s. Metals that were known to be ductile were observed to fail in what appeared on their fracture surfaces to be a "brittle" manner--at what were considered to be "safe" load levels. Since that time, the fatigue problem has plagued engineers. Today it accounts for the vast majority of service failures in ground, air and sea vehicles as well as in many electronic components.

Considerable effort has been expended to determine the nature of the fatigue-damage problem and to find relatively simple methods for coping with it in design. This problem has been investigated from a number of differing viewpoints, or observation levels, as illustrated in Fig. 1. Studies have ranged from dislocation mechanism to phenomenological material behavior to full-scale structural analyses. Many investigators have made pioneering contributions to our present understanding of the fatigue process. For example:

- 1838--ALBERT IN GERMANY: FAILURE BECAUSE OF REPEATED LOADS FIRST DOCUMENTED
- 1839--PONCELET IN FRANCE: INTRODUCES TERM *FATIGUE*
- 1849--INSTITUTE OF MECHANICAL ENGINEERS IN ENGLAND: "CRYSTALLIZATION" THEORY OF METAL FATIGUE DEBATED
- 1860--WÖHLER: FIRST SYSTEMATIC INVESTIGATION OF FATIGUE BEHAVIOR OF RAILROAD AXLES; ROTATING-BENDING TEST; *S-N* CURVE; CONCEPT OF "ENDURANCE LIMIT"
- 1864--FAIRBAIRN: FIRST EXPERIMENTS OF EFFECTS OF REPEATED LOADS
- 1886--BAUSCHINGER: NOTES CHANGE IN "ELASTIC LIMIT" CAUSED BY REVERSED LOADING OR CYCLING; STRESS-STRAIN HYSTERESIS LOOP
- 1903--EWING AND HUMFREY: MICROSCOPIC STUDY DISPROVES OLD "CRYSTALLIZATION" THEORY; FAILURE DEFORMATION TAKES PLACE BY SLIP SIMILAR TO MONOTONIC DEFORMATION
- 1910--BAIRSTOW: INVESTIGATES CHANGES IN STRESS-STRAIN RESPONSE DURING CYCLING; HYSTERESIS LOOP MEASURED; MULTIPLE-STEP TESTS; CONCEPTS OF CYCLIC HARDENING AND SOFTENING
- 1955--COFFIN AND MANSON (WORKING INDEPENDENTLY): THERMAL CYCLING, LOW-CYCLE FATIGUE, PLASTIC-STRAIN CONSIDERATIONS
- 1965--MORROW: CYCLIC PLASTICITY, LOCAL STRESS-STRAIN APPROACH, CUMULATIVE DAMAGE, LIFE PREDICTION TECHNIQUES

**Stress-Strain Behavior of Materials**

The engineering stress-strain behavior of materials is usually determined from a monotonic tension test on smooth specimens with a cylindrical gage section (shown schematically in Fig. 2). "Specimens" as used throughout this paper are axially loaded cylindrical samples with a gage length-to-diameter ratio of approximately two ( $l_0/d_0 \approx 2$ ). Many designs are shown in Ref 3 and ASTM E606-92. For such a test specimen:

$$S = \text{ENGINEERING STRESS} = P/A_0 \quad (\text{EQ 2})$$

$$e = \text{engineering strain} = \frac{l - l_0}{l_0} = \frac{\Delta l}{l_0} \quad (\text{EQ 3})$$

where  $P$  is the applied load;  $A_0$  is the original area;  $l_0$  is the original length; and  $l$  is the instantaneous length.

FIG. 2 ORIGINAL (A) AND INSTANTANEOUS (B) CYLINDRICAL SECTION OF TENSION-TEST SPECIMEN

However, because of changes in cross-sectional area during deformation, the true stress,  $\sigma$ , which is greater than the engineering stress in tension (conversely, less in compression), is defined as:

$$\sigma = \text{TRUE STRESS} = P/A \quad (\text{EQ 4})$$

where  $A$  is the instantaneous area.

Similarly, in tension, true strain,  $\epsilon$ , is less than engineering strain (up to necking). Ludwik (circa 1909) defined true or natural strain, based on the instantaneous gage length,  $l$ , as:

$$\epsilon = \text{true strain} = \int_{l_0}^l \left( \frac{dl}{l} \right) = \ln \frac{l}{l_0} \quad (\text{EQ 5})$$

The use of true stress and true strain merely changes the appearance of the monotonic tension stress-strain curve, as illustrated for a typical low-carbon steel in Fig. 3, and provides an advantage in that it lends itself readily to mathematic description as will be shown subsequently.

FIG. 3 ENGINEERING AND TRUE STRESS-STRAIN CURVES

The engineering stress and strain may be related to true stress and strain from the following equation for strain:

$$L = L_0 + \Delta L \quad (\text{EQ 6})$$

Combining Eq 5 and 6:

$$\epsilon = \ln \left[ \frac{l_0 + \Delta l}{l_0} \right] = \ln \left[ 1 + \frac{\Delta l}{l_0} \right] \quad (\text{EQ 7})$$

From Eq 3, then:

$$\epsilon = \text{LN} (1 + E) \quad (\text{EQ 8})$$

Note that this relationship is *valid only up to the point of necking* of the specimen during the tension test (that is, when the strain is uniform throughout the gage length of the specimen). It should be noted also that the deviation between the engineering and true strain becomes significant at an engineering strain of approximately 10% [that is,  $\epsilon = \ln (1 + 0.1 = 0.0953)$ ]. Since the volume of the metal changes by less than 1/1000 during large plastic strains, it is convenient to assume constant volume. Therefore:

$$A_0 L_0 = AL = \text{CONSTANT} \quad (\text{EQ 9})$$

or

$$\frac{A_0}{A} = \frac{l}{l_0} \quad (\text{EQ 10})$$

So that:

$$\epsilon = \ln\left(\frac{l}{l_0}\right) = \ln\left(\frac{A_0}{A}\right) = 2 \ln\left(\frac{d_0}{d}\right) \quad (\text{EQ 11})$$

where  $d_0$  is the original diameter and  $d$  is the instantaneous diameter. To relate true stress,  $\sigma$ , to engineering stress,  $S$ , from Eq 2, we have  $P = SA_0$ ; and from Eq 3,  $P = SA$ . Therefore:

$$\sigma = S\left(\frac{A_0}{A}\right) \quad (\text{EQ 12})$$

Up to the inception of necking in the specimen, by combining Eq 8 and 11:

$$\epsilon = \ln(1 + e) = \ln\left(\frac{A_0}{A}\right) \quad (\text{EQ 13})$$

or:

$$\left(\frac{A_0}{A}\right) = (1 + e) \quad (\text{EQ 14})$$

Thus:

$$\sigma = S(1 + E) \quad (\text{EQ 15})$$

Again, note that this relationship is valid *only up to the point of necking* in the specimens during a monotonic tension test.

The total true strain in a tension test may be separated conveniently into two components, as illustrated in Fig. 4: (1) the linear elastic, or that portion of strain that is recovered upon unloading,  $\epsilon_e$ ; and (2) the nonlinear plastic strain, that cannot be recovered on unloading,  $\epsilon_p$ . Mathematically, this concept is expressed by the equation:

$$\epsilon = \epsilon_E + \epsilon_P \quad (\text{EQ 16})$$

at any point,  $P$ , on the true stress-strain curve.

FIG. 4 ILLUSTRATION OF TOTAL STRAIN COMPONENTS

For most metals, a logarithmic plot of true stress versus true plastic strain is a straight line, as shown in Fig. 5. It may be expressed by the power law equation:

$$\sigma = K(\epsilon_p)^n \quad (\text{EQ 17})$$

or:

$$\epsilon_p = \left( \frac{\sigma}{K} \right)^{1/n} \quad (\text{EQ 18})$$

where  $K$  is the strength coefficient (intercept on a  $\log \sigma$  vs.  $\log \epsilon_p$  plot at  $\epsilon_p = 1$ ) and  $n$  is the strain-hardening exponent (slope).

FIG. 5 TRUE STRESS VERSUS PLASTIC STRAIN (LOG-LOG COORDINATES)

At the point of fracture, two other quantities, true fracture strength and ductility (shown in Fig. 3), are also quite important. True fracture strength is the true stress at final fracture:

$$\sigma_f = \frac{P_f}{A_f} \quad (\text{EQ 19})$$

where  $A_f$  is the area at fracture generally determined from measurements of the averaged minimum diameter on the failed halves of the specimen with an optical comparator at several positions on the necked ligaments. If the material has "sufficient" ductility, a Bridgeman correction factor should be employed to augment the stress due to the triaxiality in the necked section (Ref 4). Likewise, true fracture ductility is the true strain at final fracture:

$$\epsilon_f = \ln \left( \frac{A_0}{A_f} \right) = 2 \ln \left( \frac{d_0}{d_f} \right) = \ln \left( \frac{1}{1 - RA} \right) \quad (\text{EQ 20})$$

where the reduction in area  $RA = (A_0 - A_f)/A_0$ .

Substituting  $\sigma_f$  and  $\epsilon_f$  into Eq 17:

$$\sigma_F = K(\epsilon_F)^N \quad (\text{EQ 21})$$

or  $K = \sigma_f / \epsilon_f^N$ . Combining Eq 21 and 17:

$$\epsilon_p = \left( \frac{\sigma / \sigma_f}{\epsilon_f^N} \right)^{1/n} = \left( \frac{\sigma \epsilon_f^N}{\sigma_f} \right)^{1/n} = \epsilon_f \left( \frac{\sigma}{\sigma_f} \right)^{1/n} \quad (\text{EQ 22})$$

Since the elastic strain is defined by:

$$\epsilon_E = \sigma / E \quad (\text{EQ 23})$$

we may now express the total strain ( $\epsilon = \epsilon_e + \epsilon_p$ ) as:

$$\epsilon = \frac{\sigma}{E} + \epsilon_f \left( \frac{\sigma}{\sigma_f} \right)^{1/n} \quad \text{(EQ 24)}$$

Summary of Monotonic Stress-Strain Relationships:

- ENGINEERING STRESS:  $S = P/A_0$  EQ 2
- ENGINEERING STRAIN:  $E = \Delta L/L_0$  EQ 3
- TRUE STRESS:  $\sigma = P/A$  EQ 4
- TRUE STRAIN:  $\epsilon = \ln(L/L_0) = \ln(A_0/A) = 2 \ln(D_0/D)$  EQ 5
- $\sigma = S(1 + E)$  VALID ONLY UP TO NECKING EQ 15
- $\epsilon = \ln(1 + E)$  VALID ONLY UP TO NECKING EQ 8
- STRAIN-HARDENING EXPONENT,  $N =$  SLOPE OF LOG  $\sigma$  VERSUS LOG  $\epsilon_p$  PLOT OR  $N \cong \ln(1 + E_{AT\ NECKING})$  (REF 4)
- STRENGTH COEFFICIENT:  $K = \sigma_f / \epsilon_f^n$  EQ 21
- TRUE FRACTURE STRENGTH:  $\sigma_F = P_F/A_F$  EQ 19

Again, note that the formation of a "neck" in a tensile specimen introduces a complex, triaxial stress state in that region. As such, in ductile metals the quantity,  $\sigma_f$  must be corrected using a Bridgeman correction factor as a function of true strain at fracture (see Ref 4, p 252).

- TRUE FRACTURE DUCTILITY:  $\epsilon_F = \ln(A_0/A_F) = 2\ln(D_0/D_F)$  EQ 20
- $\epsilon_F = \ln [1/(1 - RA)]$
- PERCENT REDUCTION IN AREA:  $\%RA = 100 [(A_0 - A_F)/A_0]$
- TOTAL STRAIN = ELASTIC STRAIN + PLASTIC STRAIN:  $\epsilon = \epsilon_E + \epsilon_P = \sigma/E + \epsilon_F(\sigma/\sigma_F)^{1/N} = \sigma/E + (\sigma/K)^{1/N}$  EQ 24

## Cyclic Stress-Strain Behavior of Metals

Table 1 gives typical ranges in many monotonic stress-strain properties of metals, and Table 2 gives specific examples for fairly common steels and aluminum alloys along with their cyclic properties described in this section.

**TABLE 1 RANGES IN MONOTONIC STRESS-STRAIN PROPERTIES OF METALS**

MONOTONIC PROPERTY	TYPICAL RANGE OF ENGINEERING METALS
MODULUS OF ELASTICITY, $E$ , KSI	10 TO $80 \times 10^3$

TENSILE YIELD STRENGTH, $S_{0.2\%Y}$ , KSI	1 TO $3 \times 10^2$
ULTIMATE TENSILE STRENGTH, $S_U$ , KSI	10 TO 400
PERCENT REDUCTION IN AREA, % RA	ZERO TO 90%
TRUE FRACTURE STRENGTH, $\sigma_F$ , KSI	$0.5$ TO $5 \times 10^2$
TRUE FRACTURE DUCTILITY, $\epsilon_F$	ZERO TO 2
STRAIN-HARDENING EXPONENT, $N$	ZERO TO 0.5

Q&T, quenched and tempered.

Source: L.E. Tucker, Deere & Co.

Metals are metastable under application of cyclic loads, and their stress-strain response can be drastically altered when subjected to repeated plastic strains. This is evident by corresponding monotonic and cyclic properties shown in Tables 2 and 3. Depending on the initial state (quenched and tempered, normalized, annealed, cold worked, solution treated and aged, overaged, etc.) and its test condition, a metal may (a) cyclically harden; (b) cyclically soften; (c) be cyclically stable; or (d) have mixed behavior (soften at small strains then harden at greater strains).

Source: R.W. Landgraf, Virginia Polytechnic Institute

In this section, equations similar to those describing the monotonic stress-strain behavior are developed for fatigue analysis. These equations define properties more appropriate to fatigue analyses and are called *fatigue properties*. The reader is also referred to "Recommended Practice for Strain Controlled Fatigue Testing," ASTM E606-92, for the methodology involved in performing such tests.

Determination of constant-amplitude fatigue lives of specimens is customarily performed under conditions of controlled stress (as in the rotating-bending or cantilever-bending type of test) or controlled strain. As a justification for the use of controlled strain while observing the stress response, the ramifications of controlling stress are illustrated in Fig. 6 (Ref 5). As shown, the applied stress amplitude is less than the initial or monotonic yield strength of the steel (as noted by the "linear elastic" strain response during the first 40 cycles). However, because plastic deformation occurs at a microscopic level, the macrolevel response of the steel is the accrual of ever-increasing amounts of plastic strain. As stress cycling proceeds beyond 40 cycles (in this instance), a "runaway" process occurs as the steel undergoes cyclic softening.

FIG. 6 CYCLIC SOFTENING OF A STEEL UNDER CONTROLLED-STRESS CYCLING. SOURCE: REF 5

Compare the above response to a steel of similar hardness (as shown in Fig. 7) under conditions of controlled strain. Although the stress limits decrease with increased cycles, no instability is observed, as happened under controlled stress. As Landgraf (Ref 6) points out, these test conditions represent extremes of completely unconstrained or stress-cycling conditions and completely constrained or strain-cycling conditions.

FIG. 7 CYCLIC SOFTENING OF A STEEL UNDER CONTROLLED-STRAIN CYCLING. SOURCE: REF 6

In actual engineering structures, stress-strain gradients do exist, and there is usually a certain degree of structural constraint of the material at critical locations. Such a condition is most reminiscent of strain control. Therefore, it is more advantageous to characterize material response under strain-controlled conditions than under stress-controlled. Also, when an engineering structure is evaluated in a component test arrangement, strain gages are usually affixed to the structure at locations indicated by the most densely cracked locations in a brittle lacquer coating. When used in an analysis, these strains are converted to stress using the modulus of elasticity.

Why not use the strains directly? Consider the cases illustrated in Fig. 8 and 9, in which total strain is controlled and the stress response is observed. As illustrated in Fig. 8, if the stress required to enforce the strain increases on subsequent *reversals*, the metal undergoes cyclic hardening. (*Reversals* are twice the number of cycles in a completely reversed test,  $R = -1$ . Reversals are preferred to cycles because in pseudo-random spectra, it is impossible to conveniently define a cycle whereas a reversal is simply a change in sign of a given excursion.) The hardness, yield, and ultimate strength increase. Such behavior is characteristic of annealed pure metals (for example, copper), many aluminum alloys, and as-quenched (untempered) steels.

FIG. 8 CYCLIC HARDENING UNDER CONTROLLED-STRAIN-AMPLITUDE CYCLING

FIG. 9 CYCLIC SOFTENING UNDER CONTROLLED-STRAIN-AMPLITUDE CYCLING

As illustrated in Fig. 9, the strain amplitude is controlled, but the stress required to enforce the strain decreases with subsequent reversals. This phenomenon is called cyclic softening. It is characteristic of cold worked pure metals and many steels at small strain amplitudes. During cyclic softening, the flow properties (for example, hardness, yield strength, and ultimate strength) decrease.

By plotting the stress amplitude versus reversals from controlled-strain test results, one can observe cyclic strain hardening and softening, as illustrated in Fig. 10. Thus, through cyclic hardening and softening, some intermediate strength level is attained that represents a steady-state condition (in which case the stress required to enforce the controlled strain does not vary significantly).

FIG. 10 STEADY-STATE STRESS RESPONSE FOR STRAIN-CONTROLLED CYCLING

Some metals are cyclically stable, in which case their monotonic stress-strain behavior adequately describes their cyclic response. The steady-state condition is usually achieved in about 20 to 40% of the total fatigue life in either hardening or softening materials. The cyclic behavior of metals is best described in terms of a stress-strain hysteresis loop, as illustrated in Fig. 11.

FIG. 11 STEADY-STATE STRESS-STRAIN HYSTERESIS LOOP

For completely reversed,  $R = -1$ , strain-controlled conditions with zero mean strain, the total width of the loop is  $\Delta\epsilon$ , or total strain range. (The symbol  $\Delta$  is used throughout this article to signify range.)

$$\Delta\epsilon = 2\epsilon_A \quad (\epsilon_A = \text{STRAIN AMPLITUDE}) \quad \text{(EQ 25)}$$

The total height of the loop is  $\Delta\sigma$ , or the total stress range:

$$\Delta\sigma = 2\sigma_A \quad (\sigma_A = \text{STRESS AMPLITUDE}) \quad \text{(EQ 26)}$$

The difference between the total and elastic strain amplitudes is the plastic-strain amplitude. Since:

$$\frac{\Delta\epsilon}{2} = \frac{\Delta\epsilon_e}{2} + \frac{\Delta\epsilon_p}{2} \quad \text{(EQ 27)}$$

then:

$$\frac{\Delta \epsilon_p}{2} = \frac{\Delta \epsilon}{2} - \frac{\Delta \epsilon_c}{2} = \frac{\Delta \epsilon}{2} - \frac{\Delta \sigma}{2E} \quad (\text{EQ 28})$$

Changes in stress response of a metal occur relatively rapidly during the first several percent of the total reversals to failure. The metal, under controlled strain amplitude, will eventually attain a steady-state stress response.

Now, to construct a cyclic stress-strain curve, one simply connects the locus of the points that represent the tips of the stabilized hysteresis loops from companion specimen tests at several controlled strain amplitudes (see Fig. 12).

**FIG. 12 CONSTRUCTION OF CYCLIC STRESS-STRAIN CURVE BY JOINING TIPS OF STABILIZED HYSTERESIS LOOPS**

In the particular example shown in Fig. 12, it was presumed that three companion specimens were tested to failure, at three different controlled strain amplitudes. Failure of a specimen is defined, typically, as complete separation into two distinct pieces. Generally, the diameter of specimens are approximately 0.25 to 0.375 inches. In actuality, there is a "propagation" period included in this definition of failure. Other definitions of failure appear in ASTM E606-92.

The steady-state stress response, measured at approximately 50% of the life to failure, is thereby obtained. These stress values are then plotted at the appropriate strain levels to obtain the cyclic stress-strain curve. In actuality one would typically test approximately ten or more companion specimens. The cyclic stress-strain curve can be compared directly to the monotonic or tensile stress-strain curve to quantitatively assess cyclically induced changes in mechanical behavior. This is illustrated in Fig. 13. Note that 50% may not always be the life fraction where steady-state response is attained. Often it is left to the discretion of the interpreter as to where the steady-state cyclic stress-strain occurs. In any event, it should be noted on the cyclic stress-strain curve for the material being tested (i.e., cyclic curve at 50% life to failure).

FIG. 13 EXAMPLES OF VARIOUS TYPES OF CYCLIC STRESS-STRAIN CURVES

In Fig. 13(a), when a material cyclically softens, the cyclic yield strength is considerably lower than the monotonic yield strength. Using monotonic properties in a cyclic application can result in predicting fully elastic strains, when in fact considerable plastic strains are present. In T-1 steels or an equivalent HSLA steel, for example, the cyclic yield strength is only about 50% of the monotonic yield strength.

Whereas the steady-state process consumes 20% to 40% of total life in constant-amplitude testing, a single large overload in actual service-type histories can produce an immediate change from the monotonic curve to the cyclic. Assembly or even driving the completed machine "out the door" can cause an instantaneous loss of 50% of the monotonic yield strength in some materials.

Figure 14 illustrates representative behaviors for aluminum alloys and low-strength steels. Such materials may harden or soften or, depending on the strain amplitude, soften and then harden. The latter phenomenon, known as mixed behavior, is illustrated in Fig. 14. Such behavior is common in many HSLA and low-carbon, low-hardness steels (Ref 7, 8).

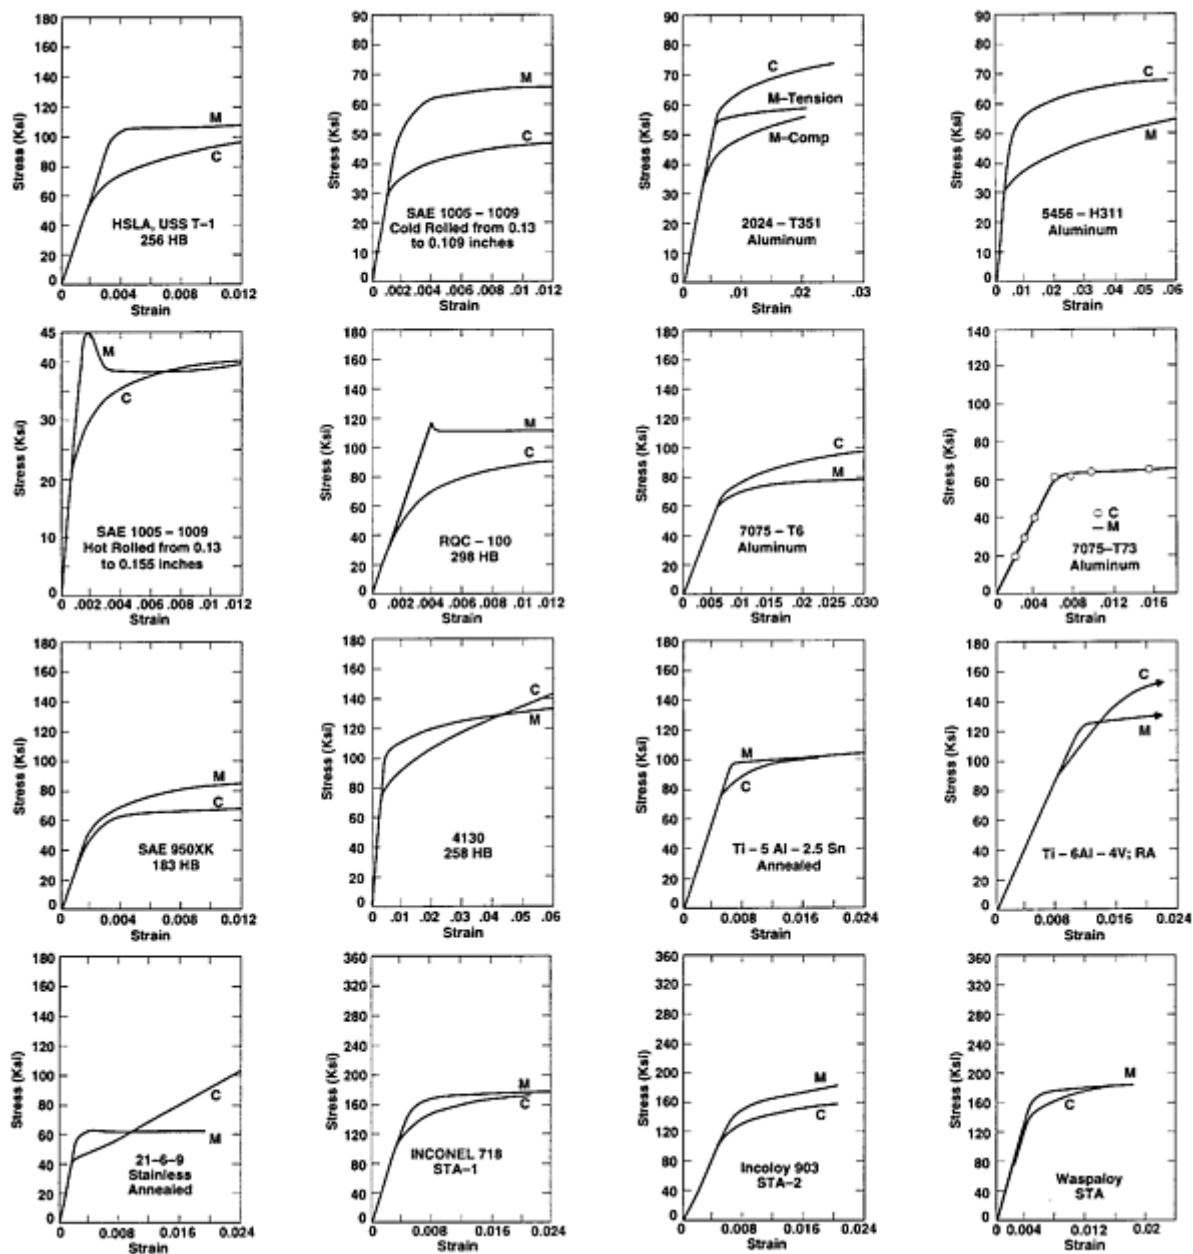

FIG. 14 CYCLIC STRESS-STRAIN RESPONSE COMPARED WITH MONOTONIC BEHAVIOR FOR VARIOUS ALLOYS

If we use the same approach as with the monotonic stress-strain curve, a plot of true stress versus true strain from constant-strain-amplitude test data of companion specimens on log-log paper results in a straight line (see Fig. 15). Again, a power-law function between true stress and plastic strain may be represented as:

$$\sigma_A = K' (\epsilon_p)^N \quad (\text{EQ 29})$$

where  $\sigma_a$  is the steady-state stress amplitude (measured at 50% of life to failure),  $\epsilon_p$  is the plastic-strain amplitude,  $K'$  is the cyclic-strength coefficient, and  $n$  is the cyclic-strain-hardening exponent.

FIG. 15 TRUE STRESS VERSUS PLASTIC STRAIN FOR CYCLIC RESPONSE (LOG-LOG COORDINATES)

Cyclic stress-strain response of a material is characterized by the following relationship:

$$\varepsilon = \frac{\sigma}{E} + \left( \frac{\sigma}{K'} \right)^{1/n'} \quad (\text{EQ 30})$$

The value of  $n'$  varies between 0.10 and 0.20, with an average value very close to 0.15. In general, if  $n$ , the monotonic strain hardening exponent, is initially high it will tend to decrease, or the metal will harden. If  $n$  is initially low it will tend to increase, or the metal will soften.

Another method of determining what a metal will do cyclically was proposed by Smith et al. (Ref 9) and is expressed as:

$$\frac{S_u}{S_{0.2\%y}} > 1.4 \text{ (hardening expected)} \quad (\text{EQ 31A})$$

$$\frac{S_u}{S_{0.2\%y}} < 1.2 \text{ softening expected} \quad (\text{EQ 31B})$$

where  $S_u$  is the monotonic ultimate strength and  $S_{0.2\%y}$  is 0.2% offset yield strength. Between the values 1.2 and 1.4, a metal is generally stable but may harden or soften.

Fatigue-Life Behavior

Ever since Wöhler's work on railroad axles subjected to rotating-bending stresses, fatigue data have been presented in the form of an  $S_a$ - $\log N_f$  curve, where  $S_a$  is the stress amplitude and  $N_f$  is cycles to failure. This is shown in Fig. 16(a).

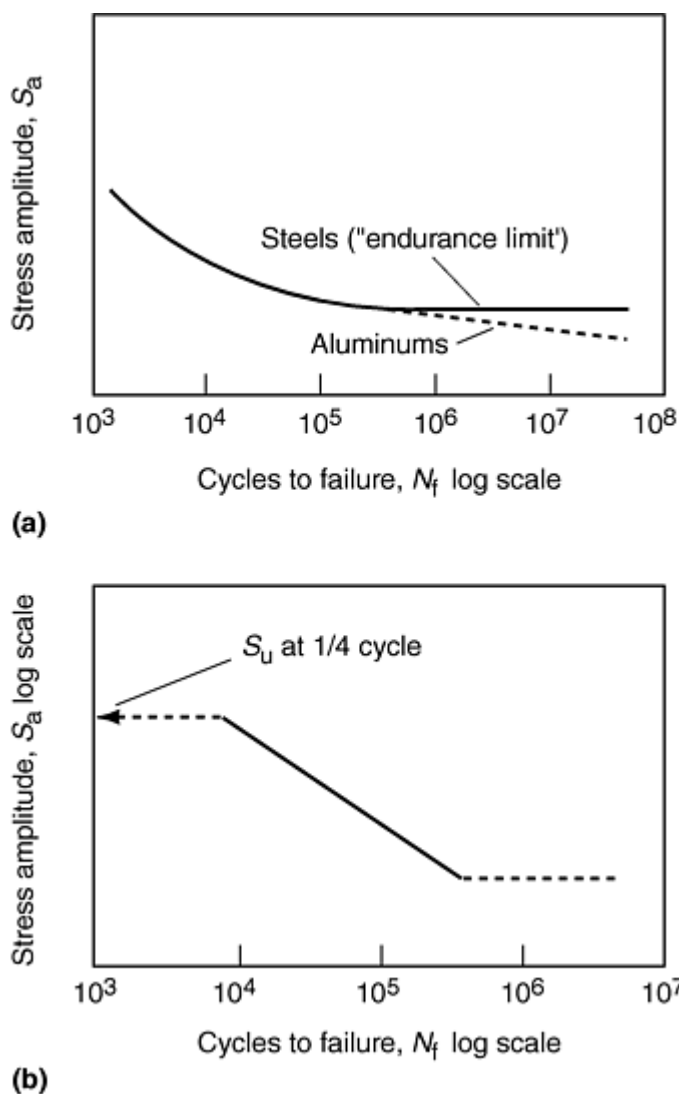

FIG. 16 (A) STRESS VERSUS LOG-CYCLES-TO-FAILURE CURVE. (B) LOG STRESS VERSUS LOG-CYCLES-TO-FAILURE CURVE

Although an "endurance limit" is generally observed for many steels under constant-stress-amplitude testing, such a limit does *not* exist for high-strength steels or such nonferrous metals as aluminum alloys. As a matter of fact, as mentioned previously, a single large overload that is common in many air, sea, ground-vehicle and electronic applications, will unpin dislocations, thereby causing the "endurance limit" to be *eradicated!* This has been shown conclusively by Brose et al. (Ref 10).

Around 1900, Basquin showed that the  $S_a$ -log  $N_f$  plot could be linearized with full log coordinates [see Fig. 16(b)] and thereby established the exponential law of fatigue. In axial tests using engineering stress, the curve "bends over" at short lives and extrapolates to the ultimate tensile strength ( $S_u$ ) at  $\frac{1}{4}$  cycle. Further, in comparing axial test results to rotating-bending test results, we observe that rotating bending gives significantly longer lives, particularly in the low-cycle region (see Fig. 17). The reason for the deviation is the method of calculation of the fiber stress in a bending type of test from Eq 1. This is an elasticity equation, whereas fatigue is caused by plastic deformation (to-and-fro slip). Thus, the assumption of "elastic response" in a cyclic environment can be and is often erroneous. This fact is certainly true in the presence of a notch or other geometric or metallurgical discontinuity. Such possibilities do exist in most common engineering materials.

FIG. 17 STRESS VERSUS LOG-CYCLES-TO-FAILURE CURVES FOR BENDING AND AXIAL-LOADING TESTS OF 4340 STEEL

If true stress amplitudes are used instead of engineering stress, the entire stress-life plot may be linearized, as illustrated in Fig. 18. Thus, stress amplitude can be related to life by another power-law relationship:

$$\sigma_A = \sigma'_F (2N_F)^B \quad (\text{EQ 32})$$

$\Delta\sigma/2 = \sigma_a$  in zero-mean constant amplitude test,  $\sigma_a$  = true stress amplitude.  $2N_f$  = reversals to failure (1 cycle = 2 reversals).  $\sigma'_f$  = fatigue-strength coefficient.  $b$  = fatigue-strength exponent (Basquin's exponent). The parameters  $\sigma'_f$  and  $b$  are fatigue properties of the metal. The fatigue strength coefficient,  $\sigma'_f$ , is approximately equal to  $\sigma_f$  for many metals. The fatigue strength exponent,  $b$ , varies between approximately -0.05 and -0.12.

FIG. 18 LOG TRUE STRESS VERSUS LOG REVERSALS TO FAILURE OF 4340 STEEL. SOURCE: *FATIGUE DESIGN HANDBOOK*, SAE

Around 1955, Coffin and Manson, who were working independently on the thermal-fatigue problem, established that plastic strain-life data could also be linearized with log-log coordinates (see Fig. 19). As with the true stress-life data the plastic strain-life data can be related by the power-law function:

$$\frac{\Delta\epsilon_p}{2} = \epsilon'_f (2N_f)^c \quad (\text{EQ 33})$$

where  $\Delta\epsilon_p/2$  = plastic-strain amplitude;  $\epsilon'_f$  = fatigue-ductility coefficient; and  $c$  = fatigue-ductility exponent. The parameters  $\epsilon'_f$  and  $c$  are also fatigue properties where  $\epsilon'_f$  is approximately equal to  $\epsilon_f$  for many metals, and  $c$  varies between approximately -0.5 and -0.7 for many metals.

FIG. 19 LOG PLASTIC STRAIN VERSUS LOG REVERSALS TO FAILURE OF 4340 STEEL. SOURCE: *FATIGUE DESIGN HANDBOOK*, SAE

It was mentioned previously that total strain has two components: elastic and plastic, or  $\epsilon = \epsilon_e + \epsilon_p$  (Eq 16). Expressed as

the strain amplitudes from a constant-amplitude, zero-mean-strain controlled test:  $\frac{\Delta\epsilon}{2} = \frac{\Delta\epsilon_e}{2} + \frac{\Delta\epsilon_p}{2}$  (Eq 27). Since  $\sigma_a = \sigma'_f (2N_f)^b$  (Eq 32) and:

$$\frac{\Delta\epsilon_e}{2} = \frac{\sigma_a}{E} \quad (\text{EQ 34})$$

one can divide Eq 32 by  $E$ , the modulus of elasticity, to obtain:

$$\frac{\Delta\epsilon_e}{2} = \frac{\sigma'_f}{E} (2N_f)^b \quad (\text{EQ 35})$$

Combining Eq 27, 33, and 35:

$$\frac{\Delta\epsilon}{2} = \underbrace{\frac{\sigma'_f}{E} (2N_f)^b}_{\text{Elastic}} + \underbrace{\epsilon'_f (2N_f)^c}_{\text{Plastic}} \quad (\text{EQ 36})$$

Equation 36 is the foundation for the strain-based approach to fatigue and is called the strain-life relationship. Further, the two straight lines, one for the elastic strain, and one for the plastic strain, can be plotted as has been done in Fig. 20.

FIG. 20 LOG STRAIN VERSUS LOG REVERSALS TO FAILURE

Several conclusions may be drawn from the total-strain-life curve in Fig. 20. At short lives, less than  $2N_t$  (the transition fatigue life where  $\Delta\epsilon_p/2 = \Delta\epsilon_e/2$ ), plastic strain predominates and the metal's ductility will control performance. At longer lives, greater than  $2N_t$ , the elastic strain is more dominant than the plastic, and strength will control performance. An "ideal material" would be one with both high ductility and high strength. Unfortunately, strength and ductility are usually a tradeoff; the optimum compromise must be tailored to the expected load or strain environment being considered in a real history for a fatigue analysis.

By equating the elastic and plastic components of total strain, we can calculate the transition fatigue life as:

$$2N_t = \left( \frac{\epsilon'_f E}{\sigma'_f} \right)^{1/(b-c)} \quad (\text{EQ 37})$$

This is the point on the plot of strain-life where the elastic and plastic strain-life lines intersect and will prove useful in several calculations shown later in this paper.

**Summary of Cyclic Stress-Strain and Strain-Life Relationships.** Four fatigue properties have been introduced:

- $\sigma'_F$ , FATIGUE-STRENGTH COEFFICIENT
- $\epsilon'_F$ , FATIGUE-DUCTILITY COEFFICIENT
- $B$ , FATIGUE-STRENGTH EXPONENT
- $C$ , FATIGUE-DUCTILITY EXPONENT

A functional relationship between strain and life has been introduced. A means of accounting for plastic strain, that causes fatigue, is therefore available (Eq 36):

$$\frac{\Delta\epsilon}{2} = \frac{\sigma'_f}{E} (2N_f)^b + \epsilon'_f (2N_f)^c$$

These relationships apply to *wrought metals only*. When internal defects govern life (as is the case with cast metals, higher-hardness wrought steels, weldments, composite materials and so forth), these principles are not directly applicable, and appropriate modifications to account for "internal micronotches" may be made (Ref 11).

Cyclic stress-strain material properties may be related in the following manner:

$$K' = \frac{\sigma_f'}{(\epsilon_f' n')^b} \quad (\text{EQ 38})$$

Through energy arguments, Morrow (Ref 12) has shown that:

$$B = -N' / (1 + 5N') \quad (\text{EQ 39})$$

and:

$$C = 1 / (1 + 5N') \quad (\text{EQ 40})$$

Thus:

$$N' = B / C \quad (\text{EQ 41})$$

which allows a relationship between fatigue properties and cyclic stress-strain properties. If average values of  $b$  and  $c$  (-0.09 and -0.6, respectively) are inserted into Eq 41,  $n' \cong 0.15$  results. This is in agreement with the observation that, in general, the average value of  $n'$  for most metals is close to 0.15.

As an addendum and caveat to the above, it must be pointed out that the "log-log linear, two straight lines, elastic-plastic approach" doesn't always describe the results of strain-life testing. As early as 1969, Endo and Morrow (Ref 13) showed that several alloys, including SAE 4340, 2024-T4Al, 7075-T6Al, and Ti-8Al-1Mo-1V, did not exhibit a linear relationship for either elastic or plastic strain-life. Sanders and Starke (Ref 14) show that heterogeneous deformation in aluminum alloys also caused deviation from a singular straight line description for elastic and plastic strain-life lines. Also, Radhakrishnan (Ref 15) has demonstrated recently that there is a bi-linear Coffin-Manson low cycle fatigue relationship for aluminum-lithium alloys and dual phase steels. But, what is typically employed in a cumulative damage analysis is the total strain-life relationship and the curve may be "approximated" adequately with two straight, log-log, lines.

**Approximation of Fatigue Properties from Monotonic Properties.** In the absence of adequate data on constant-strain-amplitude, it is often necessary to approximate the strain-life curve from monotonic tensile properties. The Appendix "Parameters for Estimating Fatigue Life" in this Volume describes some of the common approximation methods. The following example is a general approach for estimating fatigue behavior of hardened steels. It is an example intended for illustration only.

## Fundamentals of Modern Fatigue Analysis for Design

M.R. Mitchell, Rockwell Science Center

---

### Example 1: Estimating Fatigue of Hardened Steel

**Fatigue-Strength Limit ( $S_f$ ).** For many steels with hardnesses less than approximately 500 HB, the fatigue limit  $S_f$  at  $2 \times 10^6$  reversals is approximated by:

$$S_f \text{ (ksi)} \cong \frac{S_u}{2} \cong 0.25 \times \text{(HB)} \quad \text{(EQ 42)}$$

where HB is the Brinell hardness number. For example, for a steel of 200 HB:

$$\frac{S_u}{2} \approx \text{HB} / 2 \cong 100 \text{ ksi} \quad \text{(EQ 43A)}$$

$$S_{FL} \cong 50 \text{ KSI} \quad \text{(EQ 43B)}$$

Often the 0.1% offset yield stress from the cyclic stress-strain curve may be used to approximate  $S_f$ . For high-strength steels and nonferrous metals, it is more appropriate to use  $\frac{1}{3} S_u \cong S_f$  at  $10^8$  cycles. In general, however, it is probably more conservative to use  $\frac{1}{2} S_u$  at  $10^6$  cycles for all metals.

**Fatigue-Strength Coefficient ( $\sigma'_f$ ).** A reasonably good approximation for the fatigue-strength coefficient is:

$$\sigma'_f \cong \sigma_F \text{ (CORRECTED FOR NECKING)} \quad \text{(EQ 44)}$$

or for steels to about 500 HB:

$$\sigma_F \text{ (KSI)} \cong (S_u + 50) \quad \text{(EQ 45)}$$

For example, a steel of 200 HB:

$$\sigma'_f \cong \sigma_F \cong 150 \text{ KSI} \quad \text{(EQ 46)}$$

Thus, the intercept at one reversal of the elastic strain-life line is:

$$\frac{\Delta \epsilon_e}{2} \cong \frac{\sigma'_f}{E} \cong \frac{\sigma_f}{30 \times 10^3} = 0.005 \quad \text{(EQ 47)}$$

**Fatigue-Strength Exponent ( $b$ ).** As mentioned previously,  $b$  varies from -0.05 to -0.12 and for most metals has an average of -0.085. In approximating the fatigue strength at  $2 \times 10^6$  reversals with  $\frac{1}{2} S_u$ , it may be shown that:

$$b \cong -1/6 \log \left( \frac{300}{100} \right) = -1/6 (0.477) = -0.0795 \quad (\text{EQ 48})$$

One may now construct the elastic-strain-life line as illustrated in Fig. 21, by either the slope and intercept or the intercept and the fatigue limit at  $2 \times 10^6$  reversals.

FIG. 21 LOG ELASTIC STRAIN VERSUS LOG REVERSALS TO FAILURE

**Fatigue-Ductility Coefficient ( $\epsilon'_f$ ).** It is a common approximation to set the fatigue-ductility coefficient equal to the true fracture ductility ( $\epsilon'_f \approx \epsilon_f$ ).

For the 200-HB steel, that is very ductile, the percent reduction in area is approximately 65% = %RA. Therefore:

$$\epsilon_f \approx \ln \left( \frac{1}{1 - RA} \right) \cong \ln \left( \frac{1}{1 - 0.65} \right) \cong 1 \quad (\text{EQ 49})$$

**Fatigue-Ductility Exponent ( $c$ ).** The fatigue-ductility exponent,  $c$ , is not as well-defined as are the other fatigue properties. According to Coffin (Ref 16),  $c$  is approximately -0.5, whereas according to Manson (Ref 17),  $c$  is approximately -0.6. Morrow (Ref 12) has shown that for many metals  $c$  varies between -0.5 and -0.7, or an average of -0.6.

**Plotting of Strain Life Curve.** Instead of using a slope,  $c$ , to construct the plastic strain-life line, it is advantageous to note the empirical representation of the hardness and transition fatigue life shown in Fig. 22 (Ref 18). For the 200-HB steel in this example, the transition fatigue life is  $2N_t \cong 6 \times 10^4$  reversals. By connecting the intercept of  $\epsilon'_f \cong \epsilon_f = 1$  and the point on the elastic strain-life line at the value of  $2N_t$ , we construct the plastic strain-life line. One may now plot the plastic strain-life line, and algebraically add to it the elastic strain-life line to obtain the total strain-life curve, as illustrated in Fig. 23.

FIG. 22 LOG TRANSITION FAILURE LIFE VERSUS BRINELL HARDNESS FOR STEELS. SOURCE: REF 18

FIG. 23 ESTIMATED CURVE OF LOG STRAIN VERSUS LOG REVERSALS TO FAILURE FOR A STEEL (200 HB)

It should be clear after the examples given that the manner in which metals resist cyclic straining is dependent on both strength and ductility. An idealized situation is depicted in Fig. 24. Consider the steel at 600 HB (a strong metal that resists strain "elastically" on the basis of its high strength) compared to the steel at 300 HB (a ductile metal that resists strain "plastically" on the basis of its superior ductility). The "tough" steel at 400 HB resists strain by a combination of both its strength and ductility. This does not, however, mean that the 400-HB steel is the best material for a specific duty cycle that must be resisted in actual design application. The "best" material must be tailored to the application. This hypothesis will be further expounded in a later section.

FIG. 24 STRAIN-LIFE CURVES FOR A STEEL AT THREE DIFFERENT HARDNESS LEVELS (APPROXIMATION)

The strain-life curves in Fig. 24 all intersect at a strain of 0.01 with life to failure of approximately  $2 \times 10^3$  reversals (1000 cycles). Figure 25 illustrates the real trend for a variety of steels of varying hardnesses and microstructures (Ref 6). Note that the SAE 1010 (a low-carbon, low-hardness steel used in many ground-vehicle components) has a transition fatigue life of approximately  $10^5$  reversals. Therefore, even at  $10^6$  reversals, there will be a certain portion of plastic strain present that would not be accounted for in the stress-based approach to fatigue.

FIG. 25 STRAIN-LIFE CURVES FOR STEELS WITH VARYING MICROSTRUCTURES AND HARDNESSES. SOURCE: REF 6

The advent of modern, closed-loop electrohydraulic testing machines has made the strain-based test procedure and data presentation fairly commonplace. Interested readers are referred to Ref 19, 20, 21 for a compilation of cyclic stress-strain properties and strain-life curves for a variety of materials and conditions.

## Fundamentals of Modern Fatigue Analysis for Design

M.R. Mitchell, Rockwell Science Center

---

### Mean-Stress Effects

To predict the crack-initiation life of actual components, the following need to be considered:

- MEAN STRESS EFFECTS
- SIZE EFFECTS OF GEOMETRIC NOTCHES
- RELATION BETWEEN REMOTELY MEASURED STRESSES AND STRAINS TO STRESSES AND STRAINS AT A NOTCH ROOT WHERE PLASTICITY DOMINATES

The methods used to analyze these factors, when combined with an adequate cycle-counting technique that accrues closed hysteresis loops (for example, rainflow or range pair), fatigue-initiation life of real components or parts can be predicted.

The preceding sections have outlined a contemporary presentation for the strain-based description of the fatigue properties of materials. This section considers the effect of mean stress on fatigue life, that would later be factored into a cumulative fatigue-damage analysis.

As illustrated in Fig. 26, the following nomenclature will be used in accounting for mean stresses:

$$\text{Alternating stress amplitude } (\sigma_a) = \frac{\sigma_{\max} - \sigma_{\min}}{2} \quad (\text{EQ 50})$$

$$\text{Mean stress } (\sigma_o) = \frac{\sigma_{\max} + \sigma_{\min}}{2} \quad (\text{EQ 51})$$

As an illustrative example, let  $\sigma_{\max}$  be 15 ksi and  $\sigma_{\min}$  be -5 ksi. Then:

$$\sigma_a = \frac{15 + 5}{2} = 10 \text{ ksi}, \quad \sigma_o = \frac{15 - 5}{2} = 5 \text{ ksi} \quad (\text{EQ 52})$$

FIG. 26 STRESS VERSUS TIME FOR NONZERO-MEAN-STRESS CYCLING

Mean-stress data are generally presented in terms of constant-life diagrams that are plots of all combinations of alternating and mean stresses resulting in the same finite life to failure. These are illustrated in Fig. 27.

FIG. 27 VARIOUS FORMS OF PRESENTING MEAN-STRESS DATA

The equations for the lines shown in Fig. 27 are the following: Line a (Soderberg):

$$\frac{S_a}{S_{cr}} + \frac{S_o}{S_y} = 1 \text{ or } S_a = S_{cr} \left( 1 - \frac{S_o}{S_y} \right) \quad (\text{EQ 53})$$

Line b (Goodman):

$$\frac{S_a}{S_{cr}} + \frac{S_o}{S_u} = 1 \text{ or } S_a = S_{cr} \left( 1 - \frac{S_o}{S_u} \right) \quad (\text{EQ 54})$$

Line c (Gerber):

$$\frac{S_a}{S_{cr}} + \left( \frac{S_o}{S_u} \right)^2 = 1 \text{ or } S_a = S_{cr} \left[ 1 - \left( \frac{S_o}{S_u} \right)^2 \right] \quad (\text{EQ 55})$$

where  $S_a$  is the alternating-stress amplitude;  $S_{cr}$  is the completely reversed stress amplitude for a given life (i.e.,  $10^6$ ,  $10^5$ , etc.);  $S_u$  is the ultimate tensile strength of the material;  $S_y$  is the yield strength; and  $S_o$  is the mean stress. For the case of tensile mean stresses, as a rule-of-thumb:

1. SODERBERG'S RELATION IS VERY CONSERVATIVE FOR MOST CASES.
2. GOODMAN'S RELATION IS GOOD FOR BRITTLE METALS BUT CONSERVATIVE FOR DUCTILE METALS.
3. GERBER'S RELATION IS GOOD FOR DUCTILE METALS.

The above statements apply only to tensile mean stress. Moreover, there are other ways of accounting for mean stresses, and those cited are used only as typical examples.

As an alternative approach, consider that a mean stress alters the value of the fatigue strength coefficient,  $\sigma'_f$ , in the stress-life relationship. That is, tensile mean stress would reduce the fatigue strength, whereas a compressive mean stress would increase the fatigue strength. Thus, we have:

$$\sigma_A = (\sigma'_F - \sigma_0) (2N_F)^B \quad \text{(EQ 56)}$$

In this equation, tensile mean stresses are positive, and compressive ones are negative. Hence for a tensile mean stress, the new intercept constant ( $\sigma'_f$ ) is decreased relative to  $\sigma'_f$  for zero mean stress, and the intercept is increased for a compressive mean stress::

$$\begin{aligned} (\sigma'_F - \sigma_0) &< \sigma'_F \text{ (TENSILE OR + MEAN)} \\ (\sigma'_F - \sigma_0) &> \sigma'_F \text{ (COMPRESSIVE OR - MEAN)} \end{aligned} \quad \text{(EQ 57)}$$

In terms of the strain-life relationship:

$$\frac{\Delta \epsilon}{2} = \left( \frac{\sigma'_f - \sigma_0}{E} \right) (2N_f)^b + \epsilon'_f (2N_f)^c \quad \text{(EQ 58)}$$

where negative  $\sigma_0$  is for tensile mean stress, positive  $\sigma_0$  is for compressive mean stress. Figure 28 illustrates the effect of a tensile mean stress in modifying the strain-life curve. Consistent with expected behavior, the effect is most significant in the long-term fatigue region.

FIG. 28 MEAN-STRESS MODIFICATION TO STRAIN-LIFE CURVE

As can be seen, there is little or no effect of mean stresses at lives less than approximately the transition fatigue life (the low cycle fatigue region). In this life region, the large amounts of plastic deformation will eradicate any beneficial or detrimental effect of a mean stress, because it will not be sustained. Relaxation of mean stresses (Ref 22) and cyclic-dependent creep (Ref 23) are not covered in detail in this paper, because these phenomena are special instances of material response--particularly when considered in a cumulative-damage analysis (Ref 24, 25).

### Cumulative Fatigue Damage

Analysis of cumulative fatigue damage is a method that addresses the following:

- THE STRAIN-LIFE BEHAVIOR OF METAL FATIGUE RESISTANCE
- THE EFFECT OF MEAN STRESS
- THE EFFECT OF GEOMETRIC NOTCHES
- THE TYPICAL STRAIN-TIME HISTORIES OF COMPONENTS

To ascertain structural life under other constant-amplitude conditions, one must apply cumulative damage criteria to conditions of varying stress or strain amplitudes.

The simple example of a bilevel loading sequence (Fig. 29) can help illustrate the common Palmgren-Miner linear cumulative damage rule, which may be mathematically stated as:

$$d_i = \frac{2N_i}{2N_{f_i}} = \frac{\text{(Reversals applied at } \sigma_{a_i})}{\text{(Reversals failure at } \sigma_{a_i})} \quad \text{(EQ 59)}$$

where  $d$  = damage.

FIG. 29 EXAMPLE OF BILEVEL LOADING SEQUENCE

Accordingly, failure is defined as occurring when:

$$D = \sum_i d_i = \sum_i \frac{2N_i}{2N_{f_i}} = 1 \quad \text{(EQ 60)}$$

In the example shown in Fig. 29, assume that 50 reversals (25 cycles) are applied at  $\sigma_{a1}$ . How many can be applied at  $\sigma_{a2}$  until failure occurs? Using Eq 60, we find that:

$$\sum_i \frac{2N_i}{2N_{f_i}} = \frac{50}{100} + \frac{x}{10,000} = 1 \quad \text{(EQ 61)}$$

Thus,  $x = 5,000$  reversals may be applied at  $\sigma_{a2}$  until failure occurs. However, the problem is not quite this simple. Such things as sequence effects, overstressing and understressing also need to be taken into account.

**Effect of Overstressing and Understressing.** As a simple example of overstressing and understressing phenomena, consider a cyclically softening material subject to the strains corresponding to the steady-state stresses  $\sigma_{a1}$  and  $\sigma_{a2}$  as shown in Fig. 30. Should the lower strain corresponding to the stress,  $\sigma_{a2}$ , be applied first, the materials response will be "linear elastic" and will follow the curve. If "enough" cycles are applied to the metal, the loop will eventually stabilize to the cyclic response and include some plasticity. This phenomenon is called cyclic-dependent yielding, and the hysteresis loop is depicted in Fig. 31. However, if the larger strain is applied after a few of the lower cycles, we will obtain the same

hysteresis loop that we would obtain if the lower strain had not been applied (see Fig. 32). Now imagine that the larger strain had been applied first. The large hysteresis loop would have developed as it did in Fig. 32. As a result, the stress-strain curve would stabilize at the cyclic pattern, and the subsequent application of the lower strain corresponding to the stress  $\sigma_{a2}$  would immediately produce the loop shown in Fig. 31. This is very different from the "fully elastic" loop in that a considerable plastic strain is immediately evident. Thus, the high-low sequence would result in a shorter life than the low-high sequence because of the cyclic-dependent yielding phenomenon.

FIG. 30 MONOTONIC AND CYCLIC STRESS-STRAIN CURVES USED IN BILEVEL LOADING EXAMPLE

FIG. 31 HYSTERESIS LOOP ILLUSTRATING DEVELOPMENT OF PLASTIC STRAIN FROM INITIAL "ELASTIC" RESPONSE

**FIG. 32 HYSTERESIS LOOP ILLUSTRATING DEVELOPMENT OF NONELASTIC RESPONSE**

**Sequence Effects.** Figure 33(a), shows the importance of accounting for sequence effects in a loading history. Presume the larger strain amplitude,  $\epsilon_{a1}$ , is imposed first and after several reversals is transferred to the smaller strain amplitude,  $\epsilon_{a2}$ , from the compressive peak (No. 4). Note from the stress response that a self-imposed tensile mean stress,  $\sigma_o$ , develops, as illustrated in Fig. 33(c). Instead of transferring from the large strain to the small strain from the compression peak, reverse the situation and transfer from the tensile peak; then, as Fig. 34(c) shows, a self-imposed compressive mean stress,  $\sigma_o$ , results because of this particular transfer sequence.

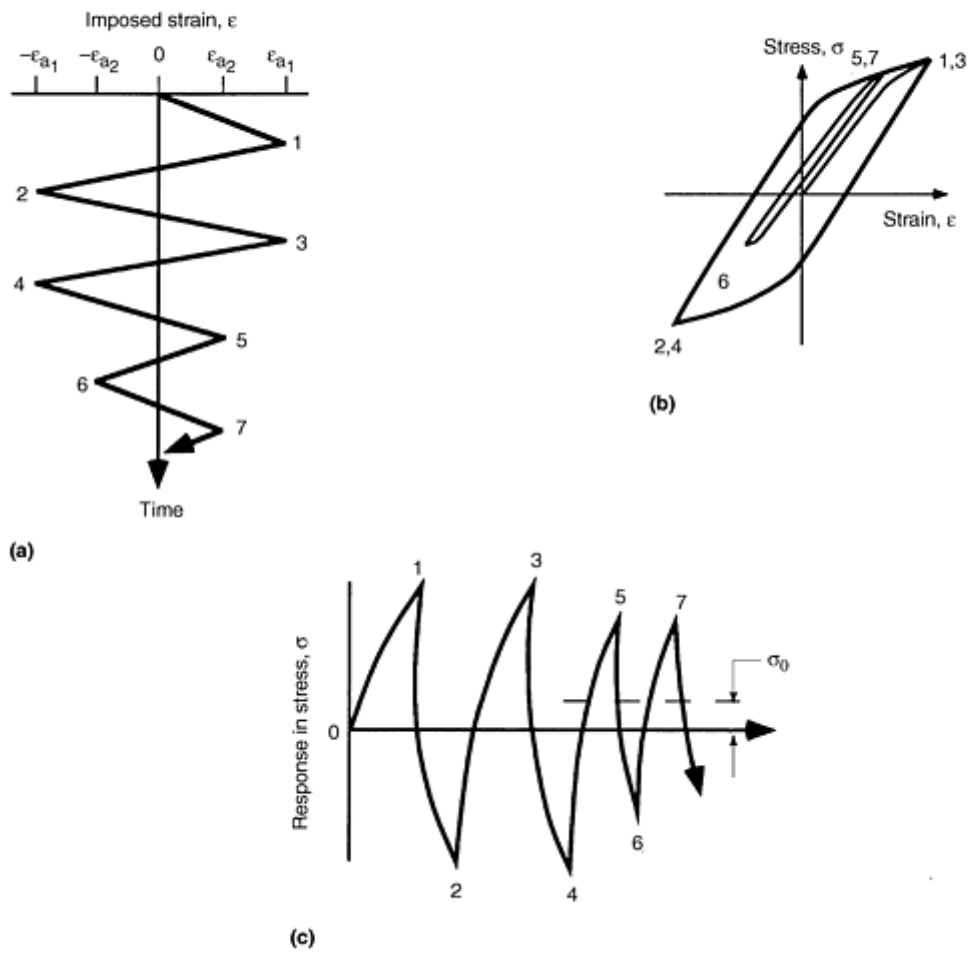

FIG. 33 DEVELOPMENT OF TENSILE MEAN STRESS BECAUSE OF SEQUENCE EFFECT

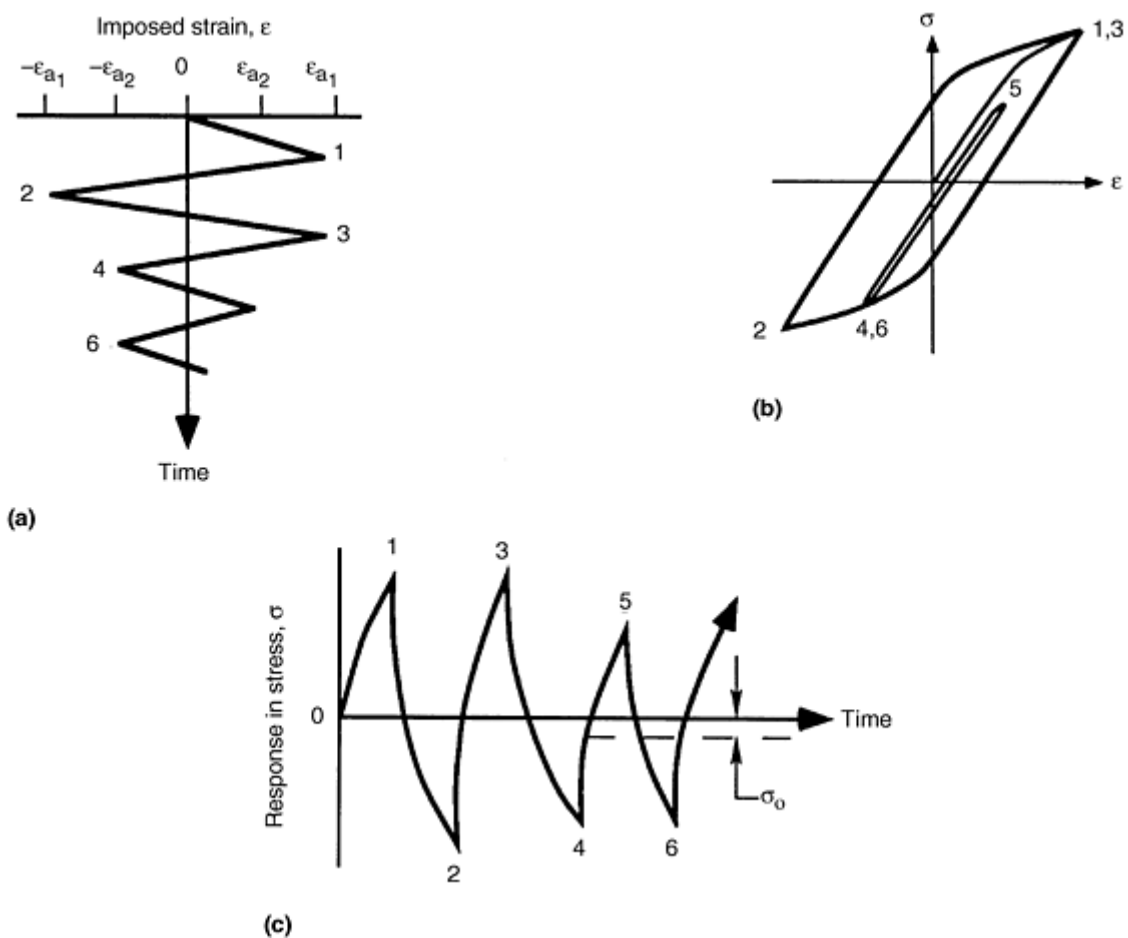

FIG. 34 DEVELOPMENT OF COMPRESSIVE MEAN STRESS BECAUSE OF SEQUENCE EFFECT

Another example of sequence effects is shown in Fig. 35. Load history A (Fig. 35b) and load history B (Fig. 35c) have similar-appearing strain histories with totally different stress-strain response and fatigue life (Fig. 35a) from slightly different initial transients. Load history A has a tensile leading edge as an initial transient, while load history B has a compressive leading edge and a markedly higher fatigue strength (Fig. 35a). This illustrates the difficulty of applying data to new designs without complete and accurate characterization of anticipated and, occasionally, unanticipated load histories.

FIG. 35 FATIGUE DATA (A) SHOWING SEQUENCE EFFECTS FOR NOTCHED-SPECIMEN AND SMOOTH-SPECIMEN SIMULATIONS (2024-T4 ALUMINUM,  $K_F = 2.0$ ). LOAD HISTORIES A AND B HAVE A SIMILAR CYCLIC LOAD PATTERN ( $\Delta S_2$ ) BUT HAVE SLIGHTLY DIFFERENT INITIAL TRANSIENTS ( $\Delta S_1$ ) WITH EITHER (B) A TENSILE LOADING EDGE (FIRST STRESS PEAK AT  $+\Delta S_1/2$ ) OR (C) A COMPRESSIVE LEADING EDGE (FIRST STRESS PEAK AT  $-\Delta S_1/2$ ). THE SEQUENCE EFFECT ON FATIGUE LIFE (A) BECOMES MORE PRONOUNCED AS  $\Delta S_2$  BECOMES SMALLER. SOURCE: D.F. SOCIE, "FATIGUE LIFE ESTIMATION TECHNIQUES," TECHNICAL REPORT 145, ELECTRO GENERAL CORPORATION

**Cyclic-Dependent Stress Relaxation.** An analogous situation to the cyclic-dependent creep under biased stress-cycling conditions mentioned earlier in this paper is the deformation response in biased strain control known as cyclic-dependent stress relaxation. The idealized situation illustrated in Fig. 33 and 34 (in which the compressive and tensile self-imposed mean stresses result from the transfer sequences) is not precisely accurate. As Fig. 36 shows, there is a relaxation of the mean stress under the biased strain conditions. Relaxation rates depend on the material hardness and imposed strain amplitude. As Fig. 37 shows, the harder the metal, the lesser the relaxation rate of the mean stress. Also, the greater the strain amplitude, the greater the relaxation rate. Both responses depend on the amount of sustained cyclic plastic deformation that occurs. A softer steel (for example, SAE 1045 at 280 HB) will display greater amounts of plastic deformation, and thus the relaxation rate of the mean stress will be greater than it will for a harder steel (for example, the SAE 1045 at 560 HB). Similarly, the greater the total strain, the greater the plastic strain in proportion and thus the greater relaxation rate for the mean stress. However, such specialized responses are not generally included in cumulative-fatigue-damage analyses unless the component strain-time history would be heavily biased in either tension or compression.

#### Cycle Counting

The preceding section gave some simple examples of the importance of the sequence of events in a variable-loading history. To assess the fatigue damage for complex histories, one must reduce them to a series of discrete events by employing some type of cycle-counting technique. For purposes of illustration, consider the strain history shown in Fig. 38 (Ref 26).

FIG. 38 IMPOSED-VARIABLE-STRAIN HISTORY AND STRESS RESPONSE. SOURCE: REF 26

The stress-time history is quite different from the corresponding strain-time history, and no clear functional relationship exists between them because of the nonlinear (plasticity) material response. Events C-D and E-D have identical mean strains and strain ranges but quite different mean stresses and stress ranges. (Note that a positive strain is indicated at point E in the strain-time history but that the stress response is compressive.) Following the elastic unloading (B-C), the material exhibits a discontinuous accumulation of plastic strain upon deforming from C to D. When point B is reached, the material "remembers" its prior deformation (A-B), and deforms along path A-D as though event B-C had never occurred.

In this simple sequence, there are four events that resemble constant-amplitude cycling. These events (which are closed hysteresis loops) are: A-D-A, B-C-B, D-E-D and F-G-F. Each event is associated with a strain range and a mean stress. Of the various counting techniques in use (rainflow, range pair, level crossing, and peak counting), rainflow (or its equivalent, range pair) has been shown to produce superior fatigue-life estimates (Ref 27). The apparent reason for the superiority of rainflow counting is that it combines load reversals in a manner that defines cycles by closed hysteresis loops (see Fig. 39).

FIG. 39 SCHEMATIC OF RAIN FLOW COUNTING TECHNIQUE. SOURCE: REF 26

To implement the rainflow counting technique, plot the strain-time history with the time axis vertically downward and imagine the lines connecting strain peaks to be a series of "pagoda roofs." Several rules are imposed on rain "dripping down" from these roofs so that closed hysteresis loops are defined. The following rules govern the manner in which rain flows:

1. PLOT THE HISTORY SO THAT THE LARGEST STRAIN MAGNITUDE OCCURS AS THE FIRST AND LAST PEAKS OR VALLEYS. THIS ELIMINATES HALF-CYCLES WHEN COUNTING.
2. "RAINFLOW" IS INITIATED AT EACH PEAK AND IS ALLOWED TO DRIP DOWN AND CONTINUE--EXCEPT THAT IF IT INITIATES AT A MAXIMUM (POINTS A, B, D, G) IT MUST STOP WHEN IT COMES OPPOSITE A MORE POSITIVE PEAK THAN THE MAXIMUM FROM WHICH IT STARTED. RAINFLOW DRIPPING FROM B MUST STOP OPPOSITE D BECAUSE D IS MORE POSITIVE THAN B. THE CONVERSE RULES ARE ALSO NECESSARY FOR RAINFLOW INITIATED AT A MINIMUM (POINTS A, C, E, F).

3. FINALLY, RAINFLOW MUST STOP IF IT ENCOUNTERS RAIN FROM THE ROOF ABOVE, AS IN THE EVENT FROM C TO D.

Events A-D and D-A are paired to form on full cycle. Event B-C is paired with the partial cycle formed from C-D. Cycles are also formed from E-D and F-G. Obviously, rainflow counting requires a great deal of bookkeeping and is ideally suited to a digital computer. Several algorithms have been published to reduce computation time (Ref 28) and there is now an ASTM standard, E-1049, "Standard Practice for Cycle Counting in Fatigue Analysis," dedicated to this technique.

## Stress Concentrations

Besides material cyclic response and cycle counting in fatigue, changes in geometry act as stress and strain concentrations and therefore affect fatigue. Consideration of notch effects are considered in this section with the following symbols for key variables:

- $E$  = MODULUS OF ELASTICITY
- $S$  = NOMINAL STRESS ON A NOTCHED MEMBER MEASURED REMOTELY FROM THE STRESS CONCENTRATION; FOR EXAMPLE, IN AN AXIAL TEST, THE AXIAL LOAD DIVIDED BY THE NET AREA
- $\epsilon$  = NOMINAL STRAIN (EQUAL TO  $S/E$  ONLY WHEN THE NOMINAL STRAIN IS ELASTIC) MEASURED REMOTELY FROM THE STRESS CONCENTRATION
- $s$  = ACTUAL OR LOCAL STRESS AT THE STRESS CONCENTRATION
- $\epsilon$  = ACTUAL OR LOCAL STRAIN AT THE STRESS CONCENTRATION
- $\Delta S$ ,  $\Delta \epsilon$ ,  $\Delta \sigma$ ,  $\Delta \epsilon$  = PEAK-TO-PEAK CHANGE IN THE ABOVE QUANTITIES DURING ONE REVERSAL OR HALF-CYCLE ( $\Delta$  REPRESENTS RANGE, AS OPPOSED TO AMPLITUDE)
- $K_T$  = THEORETICAL (ELASTIC) STRESS-CONCENTRATION FACTOR =  $\sigma_{MAX}/S$ , WHERE  $\sigma_{MAX}$  IS THE MAXIMUM LOCAL STRESS
- $K_\sigma$  = STRESS CONCENTRATION FACTOR =  $\Delta \sigma / \Delta S$
- $K_\epsilon$  = STRAIN CONCENTRATION FACTOR =  $\Delta \epsilon / \Delta \epsilon$
- $K_F$  = FATIGUE NOTCH FACTOR
- $A$  = MATERIAL CONSTANT WITH DIMENSIONS OF LENGTH

Fatigue failures nearly always initiate at a geometric discontinuity in wrought products, excluding inclusions in high-hardness steels, that are considered microdiscontinuities. (An example is explained in a later section of this paper.) Associated with every notch is a theoretical stress-concentration factor,  $K_t$ , that is dependent only on geometry and

loading mode. In fatigue, notches may be less effective than predicted by  $K_t$ . Therefore, a fatigue-notch factor,  $K_f$ , is frequently employed. It is often determined by the ratio of unnotched fatigue strength to notched fatigue strength at a given life level:

$$K_f = \frac{\sigma_{\text{unnotched}}}{\sigma_{\text{notched}}} \text{ at a finite life} \quad (\text{EQ 62})$$

(for example,  $10^7$  cycles)

Often, a notch-sensitivity index is defined as:

$$q = \frac{K_f - 1}{K_t - 1} \quad (\text{EQ 63})$$

and varies from 0 (no notch effect) to 1 (full theoretical effect).

The value of  $q$  is dependent on the material and the radius of the notch root, as illustrated by a plot of the relationship shown in Fig. 40. It should be apparent that small notches are less effective than large notches, and soft metals are less affected than hard metals by geometric discontinuities that reduce the fatigue resistance.

FIG. 40 NOTCH SENSITIVITY VERSUS NOTCH RADIUS AS A FUNCTION OF HARDNESS FOR STEELS.

Many attempts have been made to determine values of  $K_f$  analytically. One of the more successful is attributed to Peterson (Ref 29) and is expressed as:

$$K_f = 1 + \frac{K_t - 1}{1 + \frac{a}{r}} \quad (\text{EQ 64})$$

where " $a$ " is a material constant dependent on strength and ductility, and is determined from long-life test data for notched and unnotched specimens of known  $K_t$  and tip radius,  $r$ .

Fortunately, " $a$ " can be approximated for ferrous-based wrought metals by the following empirical relationship:

$$a \cong \left( \frac{300}{S_u \text{ (ksi)}} \right)^{1.8} \times 10^{-3} \text{ in.} \quad (\text{EQ 65A})$$

$$a \cong \left( \frac{300}{0.5 \text{ HB}} \right)^{1.8} \times 10^{-3} \cong \left( \frac{600}{\text{HB}} \right)^{1.8} \times 10^{-3} \text{ in.} \quad (\text{EQ 65B})$$

where  $S_u$  (ksi)  $\cong 0.5$  HB (Brinell hardness). As a rule-of-thumb, "a" for normalized or annealed steels  $\cong 0.01$ ; for highly hardened steels  $\cong 0.001$ ; and for quenched-and-tempered steels  $\cong 0.025$  in.

Figure 41 illustrates the effect on  $K_f$  from changing  $r$  for a hard-and-soft metal. When  $r$  is approximately equal to "a," the effect of changing  $r$  and/or  $a$  is most apparent (that is, at the inflection point in the sigmoidal curve). When  $r$  is greater than  $10a$  or less than  $a/10$ , very little change in  $K_f$  will accompany changes in  $r$  and/or "a."

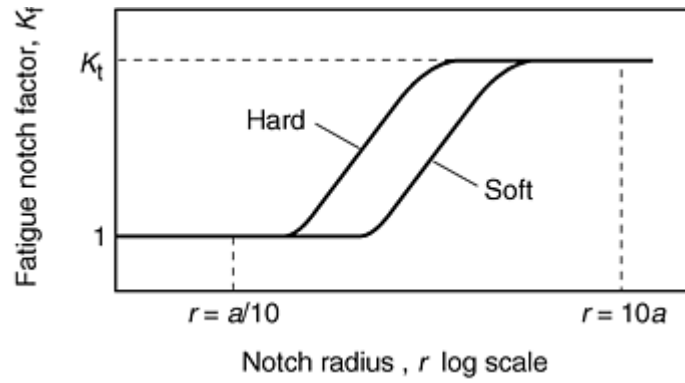

FIG. 41 FATIGUE-NOTCH FACTOR VERSUS NOTCH RADIUS AS A FUNCTION OF RELATIVE HARDNESS.

The previous discussion is an attempt to account for "size effect" of notches in fatigue. Although a functional relationship such as given in Eq 65a and 65b is valid for steels, no clear relationship of this type exists for aluminum alloys. Thus, it is mandatory to conduct notched and unnotched fatigue tests on the aluminum alloy of interest to functionally define "a."

In the low- and intermediate-life region where yielding can occur at a notch, strain concentration as well as a stress concentration must be considered. When yielding occurs,  $K\sigma$  and  $K\varepsilon$  are no longer equal (see Fig. 42). After yielding,  $K\varepsilon$  increases but  $K\sigma$  decreases. To solve this plasticity problem, employ Neuber's rule (Ref 30), in which the theoretical stress-concentration factor,  $K_t$ , is equated to the geometric mean of the stress-concentration factor,  $K\sigma$ , and the strain-concentration factor,  $K\varepsilon$ :

$$K_T = (K_\sigma K_\varepsilon)^{1/2} \quad (\text{EQ 66})$$

For fatigue,  $K_f$  is often substituted for  $K_t$  (Ref 31), so that Eq 66 may be expressed as:

$$K_F = (K_\sigma K_\varepsilon)^{1/2} \quad (\text{EQ 67})$$

Through the definition of the stress-concentration factor,  $K_\sigma = \Delta\sigma/\Delta S$ , and the strain-concentration factor,  $K_\varepsilon = \Delta\varepsilon/\Delta e$ , we may substitute to Eq 67 and obtain

$$K_f = \left( \frac{\Delta\sigma\Delta\varepsilon E}{\Delta S\Delta e E} \right)^{1/2} \quad (\text{EQ 68})$$

where  $E$  has been inserted to present the equation in terms of stress units. Therefore:

$$K_F (\Delta S \Delta \epsilon E)^{\frac{1}{2}} = (\Delta \sigma \Delta \epsilon E)^{\frac{1}{2}} \quad (\text{EQ 69})$$

Illustrated schematically, the quantities of interest are shown in Fig. 43.

FIG. 42 SCHEMATIC OF CHANGE IN STRESS-CONCENTRATION AND STRAIN-CONCENTRATION FACTORS AS YIELDING OCCURS AT NOTCH ROOT

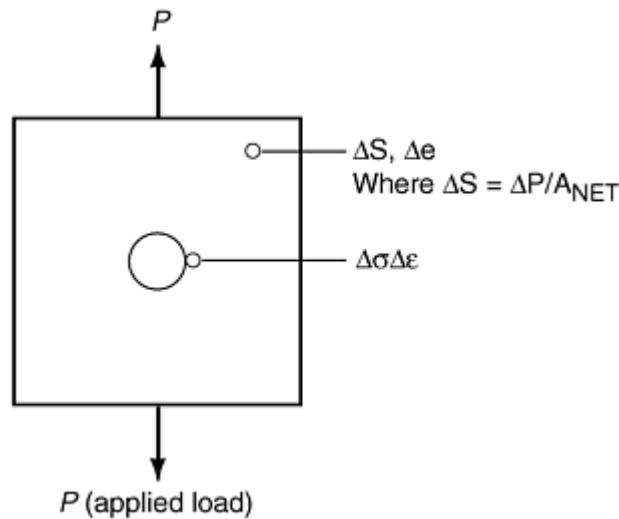

FIG. 43 QUANTITIES OF INTEREST IN A NOTCH ANALYSIS

If the response is nominally elastic, which is often the case in vehicle design,  $\Delta S = E \Delta \epsilon$ , and Eq 69 may be written as:

$$K_F \Delta S = (\Delta \sigma \Delta \epsilon E)^{\frac{1}{2}} \quad (\text{EQ 70})$$

This approach is convenient because:

1. THE RELATIONSHIPS RELATE REMOTELY MEASURED STRESSES AND STRAINS TO LOCAL RESPONSE AT THE CRITICAL LOCATION OF THE NOTCH ROOT.
2. THEY ALLOW THE SIMULATION OF NOTCH FATIGUE BEHAVIOR WITH SMOOTH SPECIMENS.

### 3. THEY ALLOW THE PREDICTION OF NOTCH BEHAVIOR WITH SMOOTH-SPECIMEN DATA.

To illustrate the use of this equation, it is convenient (although not necessary) to use the more simplified case of nominally elastic stressing and to rearrange the terms of Eq 70 to the form:

$$\Delta\sigma\Delta\epsilon = \frac{(K_f\Delta S)^2}{E} \quad (\text{EQ 71})$$

Equation 71 is the relation for a rectangular hyperbola ( $xy = \text{constant}$ ). If a nominal stress, applied to a notched sample starting at zero stress, is increased to some arbitrary "elastic" stress,  $S_1$  (Fig. 44a), it is a relatively simple task to compute the value on the right of Eq 71, if  $K_f$  is known.

FIG. 44 NOMINALLY IMPOSED ELASTIC STRESS AND STRAIN AND LOCAL CHANGES IN STRESS AND STRAIN AT A NOTCH ROOT

There is a family of values of the product of local stress range,  $\Delta\sigma$ , and strain range,  $\Delta\epsilon$ , that is equal to the constant,  $(K_f\Delta S)^2/E$ . However, if the cyclic stress-strain curve for the material of interest is traced on rectangular coordinates (Fig. 44b), there is a unique combination of stress and strain ranges that satisfies the equation. This unique value occurs at the intersection of the cyclic stress-strain curve with the rectangular hyperbola.

If there is a reversal in nominal stress at  $S_1$ , the above procedure is repeated; but the origin of the rectangular coordinate system used for the next step in the sequence is located at point  $P$  in Fig. 44(b). On unloading or for any subsequent events not starting at zero stress and strain, the cyclic stress-strain curve is magnified by a factor of two in order to trace the hysteresis loop.

As a continuation of our example, assume the nominal stress-time sequence to be analyzed is as shown in Fig. 45, with  $S_2 = 0$ . By following the same procedure as above, but with the local stress-strain origin fixed at point  $P$ , a trace of the second event would be as shown in Fig. 46. Of course, such a point-by-point analysis is tedious; in real life, situations must be computerized. This is often accomplished by employing the equation for the cyclic stress-strain curve in the form:

$$\Delta\varepsilon = \frac{\Delta\sigma}{E} + \left(\frac{\Delta\sigma}{K'}\right)^{1/n'} \quad (\text{EQ 72})$$

and taking the product:

$$\Delta\sigma\Delta\varepsilon = \frac{(\Delta\sigma)^2}{E} + \Delta\sigma\left(\frac{\Delta\sigma}{K'}\right)^{1/n'} \quad (\text{EQ 73})$$

By equating Eq 73 to the constant in Eq 71 we have:

$$\frac{(\Delta\sigma)^2}{E} + \Delta\sigma\left(\frac{\Delta\sigma}{K'}\right)^{1/n'} = \frac{(K_f\Delta S)^2}{2} \quad (\text{EQ 74})$$

This equation is solved relatively easily using the Newton-Raphson iteration technique and standard numerical methods.

## Fundamentals of Modern Fatigue Analysis for Design

M.R. Mitchell, Rockwell Science Center

---

### Summary

The strain-life approach to characterizing the fatigue behavior of materials has been presented. An effective means of accounting for plastic strain, that is the cause of fatigue failures, has been given; and a constitutive equation between strain and life was developed. Because materials are metastable under cyclic loads and because a simple tensile stress-strain curve was shown inadequate for fatigue design, a cyclic strain-strain curve was introduced.

To predict the crack-initiation life of actual components:

1. MEAN STRESSES WERE TAKEN INTO ACCOUNT BY A SIMPLE MODIFICATION OF THE STRAIN-LIFE EQUATION.
2. A TECHNIQUE TO ACCOUNT FOR SIZE EFFECT OF GEOMETRIC NOTCHES WAS INTRODUCED.
3. TWO PROCEDURES WERE GIVEN RELATING REMOTELY MEASURED STRESSES AND STRAINS TO STRESSES AND STRAINS AT A NOTCH ROOT WHERE PLASTICITY DOMINATES.

By combining the above "analytical tools" with an adequate cycle-counting technique that accrues closed hysteresis loops (for example, rainflow or range pair), a means was developed to analyze pseudo-random load histories of real components or parts to predict fatigue-initiation life. Some examples of application techniques are described below.

### Example 2: Component-Calibration Techniques

In many practical problems, engineers and designers are required to evaluate the fatigue resistance of prototype components while they are at the "drawing board" stage of development. One method for performing such an analysis is the component-calibration technique, which requires a relationship between applied load and local strains, such as the one shown in Fig. 47 (Ref 32). Such information may be obtained analytically by using finite element models, or experimentally by testing the component. The component would normally be tested by mounting strain gauges at the critical locations, applying one load-unload cycle and measuring the load-strain response. However, this type of test may produce erroneous data because of the cyclic hardening or softening characteristics of the material. For this reason, an incremental-step strain-type test (Ref 33) should be used to obtain load-strain calibration curves from a single component. In this way, the material is cyclically stabilized. Similarly, cyclically stable material properties should be used in subsequent analytical calculations.

FIG. 47 COMPONENT-CALIBRATION CURVE. SOURCE: REF 33

The conversion of applied load to strain is accomplished in the same manner as the conversion of strain into stress. The load-strain response has all the features normally associated with stress-strain response (hysteresis effects, memory, cyclic hardening and softening). Transient material response is normally neglected, so that the load-strain response model accounts only for hysteresis and memory effects. From a computational viewpoint, this technique is the same as those described in the section for stress-strain response. In fact, the load-strain and stress-strain response models can be combined, so that the applied load can be converted to both the local stress and strain with one simple computer algorithm.

Many of the aforementioned methods for analysis of cumulative fatigue damage have been combined with various design philosophies. Several commercially available programs are now readily available to accomplish the necessary calculations for materials selection, design analysis and cumulative fatigue damage. For example, Somat Corporation in Champaign, Illinois has a LifeEst<sup>®</sup> program that is very user-friendly, and is presently being incorporated into the academic curriculum of several major universities as part of their mechanical design courses. But, the reader is cautioned that a thorough understanding of the basic philosophy outlined in this paper and the introductory literature for these programs should be mastered before attempting their implementation.

### Example 3: Variable Histories: Different Steels

Procedures discussed in the preceding sections were used to evaluate the results of an early SAE FD&E Cumulative Fatigue Damage Test Program. Three different load-time histories (see Fig. 48) were applied to the test specimen shown in Fig. 49. Note that the specimen, when loaded, provides both axial and bending components of stress and strain at the notch root. Two steels were used: U.S. Steel's MAN-TEN and Bethlehem's RQC-100. Tests were conducted at several load levels for each spectrum. Fatigue lives ranged from  $10^4$  to  $10^9$  reversals. A complete description of the test program is given in Ref 19.

FIG. 48 THREE DIFFERENT LOAD-TIME HISTORIES. SOURCE: REF 28

FIG. 49 SPECIMEN DESIGN FOR TEST PROGRAM. SOURCE: REF 28

A summary of predicted and actual crack-initiation lives is shown in Fig. 50. These predictions were made using the load-strain curves shown in Fig. 47. For "perfect" correlation, all the data points should lie along the 45° solid line. All but four of the predicted lives are within the factor-of-three scatterband indicated by the dashed lines. This agreement is good, considering that there are two steels, three types of load-time histories, and at least three different load levels.

FIG. 50 PREDICTED VERSUS ACTUAL BLOCKS TO CRACK INITIATION. SOURCE: REF 28

The first example cited was included in this paper as an example of an "early" attempt to predict fatigue lifetime behavior with "state-of-the-art" technology at that time (1978). As has been mentioned repeatedly, the techniques employed today are almost a routine part of components designed to survive fatigue environments (or, at least, they should be).

Of the many examples available in the open literature, the reader is referred to a recent publication, *Case Histories in Fatigue Design*, ASTM STP 1250, R.I. Stephens, Ed., ASTM, 1994. Also, excellent examples appear in *Fatigue Design Handbook*, SAE AE10, Second Edition, 1988, including wheels made of high strength sheet steel, suspension system components, forged connecting rods and axle shafts. Several examples of fatigue lifetime predictions for cast metals are also given that are quite adequate for the purpose intended.

#### Example 4: Cast Metals

The basic techniques for describing the cyclic stress-strain resistance of cast metals is not as straightforward as are those for a wrought metal. Cast ferrous-based products (gray and nodular iron and cast steels) are internally defected structures. As such, the stress-strain resistance of the bulk material, which contains second-phase discontinuities in the form of graphite flakes, nodules, and/or gas porosities, is not an adequate representation of the capacity of the material to resist stresses and strains.

By considering cast metals as a homogeneous steel matrix with "micronotches," we can extend the previously described notch analysis to predict the fatigue-life behavior of these products.

Since fatigue-crack initiation generally occurs in regions where the stress-concentrating effect of the micronotches is greatest, it is justifiable to assume that the fatigue resistance of cast ferrous-based metals is governed by the largest surface discontinuity. For example, in the case of gray iron, the flake type-A (ASTM A247) graphite colonies extend in three-dimensional space to the extent of the eutectic cell walls. Metallographic examination of critical areas in a component can be employed to reveal "the largest" diameter eutectic cell,  $t$ . Approximating the graphite flakes as surface slits, the theoretical stress-concentration factor is given by:

$$K_t = 1 + 2\sqrt{\frac{t}{r}} \quad (\text{EQ 75})$$

where  $r$  is the tip radius of the most notch-effective graphite flake.

The question now is: In a three-dimensional graphite colony, which flake has the most effective tip radius? Mattos and Lawrence (Ref 34) have observed in their treatment of weld flaws that the fatigue-notch factor,  $K_f$ , has a maximum value for the special case of an ellipse with fixed major axis but variable tip radius. Using a similar approach, we may substitute the value of  $K_t$  into Eq 64:

$$K_f = 1 + \frac{2\sqrt{tr}}{r+a} \quad (\text{EQ 76})$$

The maximum value of  $K_f$  occurs when:

$$\frac{dK_f}{dr} = 0 \quad (\text{EQ 77})$$

Thus:

$$K_{f_{\max}} = 1 + \sqrt{\frac{t}{a}} \quad (\text{EQ 78})$$

Peterson's " $a$ " in Eq 78 is defined by Eq 65a and 65b, but the value of hardness (HB) employed must be that of the matrix metal. (HB of the matrix of gray iron, which is approximately an SAE 9200-series steel, is converted from microhardness readings, for example, Vickers or Knoop.) Upon appropriate substitution, it can be shown that

$$K_{f_{\max}} = 1 + 0.1 T^{0.5} \text{HB}^{0.9} \quad (\text{EQ 79})$$

and the "size effect" of graphite in gray iron (viewed as surface slits) is taken into account.

Next in our example, the strain-life behavior of the matrix steel must be determined. This may be accomplished by performing a constant-amplitude, controlled-strain type of test (outlined previously) on a wrought steel matched in hardness, composition and structure to the matrix of the gray iron of interest. Or, in the absence of strain-controlled test data, the approximations for strain-life behavior shown earlier in this paper may be employed--but using the matrix hardness of the iron.

An example of results from such an analysis for a gray iron with fully pearlitic matrix (260 HB) and type A graphite with a 0.08 in. eutectic-cell diameter is shown in Fig. 51, which is presented in a slightly different form than used previously. The vertical axis is the geometric mean of the product of stress and strain that results from a notch analysis. Note also that the  $E_c$  shown in Fig. 51 is the modulus of elasticity of the cast metal that has been employed to account for the limiting case of nominal elastic response.

FIG. 51 NEUBER-TOPPER PARAMETER VERSUS REVERSALS TO FAILURE FOR WROUGHT STEEL (260 HB) AND 0.08-IN. EUTECTIC CELL

Similar analyses have also been performed for nodular irons, cast steels and high-hardness wrought steels in which inclusions govern behavior (Ref 11).

If, in retrospect, one examines closely the concept of "crack initiation" in a gray cast iron, it is obvious that there is only a very brief period of "initiation" in these heavily defected materials where life can be dominated by crack growth. This is also true for other cast metals, such as aluminum-silicon alloys where the free silicon is in the form of lenticles, and for many composite materials, such as metal matrix composites and ceramic matrix composites. A much better means of attacking such life predictions (in the author's opinion) is to use a continuum damage mechanics approach as first employed by Downing (Ref 35) for gray cast iron. Many of the procedures outlined for life prediction using the strain-based approach are similar and the baseline materials data collection procedure is similar. Additional collection is, however, made of the rate of change of, for example, modulus or compliance, peak stresses, crack length, etc., with cycles. The "damage" is then viewed as a rate phenomena (i.e., as that fraction of time spent at a given rate corresponding to a specified strain amplitude to the total time to failure at that strain amplitude).

### Example 5: Effect of Environment

It is a well-established fact that the fatigue life of materials is in many instances drastically altered by the environment in which the materials must perform. Perhaps one of the most significant instances is exhibited by aluminum alloys in saline environments.

As another example of the versatility of the strain-based approach to fatigue-damage analysis, consider the problem of predicting the stress-life behavior of 7075-T73 aluminum alloy containing a geometric notch ( $K_t = 2.52$ ) in a 3.5 wt% NaCl environment. Obviously, this is a somewhat pedagogical example; nonetheless, it will illustrate the basic concept of how to proceed to a more complex damage analysis under component service histories.

Monotonic and cyclic stress-strain curves for 7075-T73 aluminum alloy tested in laboratory air (20 to 50% relative humidity) are shown in Fig. 52. Note that the material is cyclically stable. Data points for the cyclic stress-strain curve

were obtained from companion-specimen results controlled-strain-amplitude tests performed at a constant total strain rate of  $\dot{\epsilon} = 2.4 \times 10^{-3} \text{ sec}^{-1}$  ( $\dot{\epsilon} = f \times \epsilon =$  frequency  $\times$  strain amplitude). A saline environment (or, for that matter, even relative humidity) has a more pronounced effect on the long-life fatigue behavior of aluminum than on short lives. Thus, the saline environment can be considered to degrade basic material properties (to alter the slope,  $b$ , of the elastic strain-life line). Figure 53 shows the strain-life results of smooth specimens tested in a 3.5 wt% NaCl environment compared with the strain-life curve for the specimens tested in laboratory air. The values of the slope,  $b$ , of the respective elastic strain-life lines are -0.15 (3.5 NaCl) and -0.11 (air). (The value of the slope has been modified for periodic overstraining by decreasing the life an order of magnitude of a nonoverstrained value corresponding to  $10^7$  reversals.) Other material properties of interest for subsequent life predictions are given in Table 4.

**TABLE 4 MATERIAL PROPERTIES FOR 7075-T73 ALUMINUM ALLOY**

PROPERTY	LABORATORY AIR	3.5 WT% NaCl ENVIRONMENTS
MODULUS OF ELASTICITY, $E$ , KSI	$10 \times 10^3$	$10 \times 10^3$
FATIGUE-STRENGTH COEFF., $\sigma'_F$ , KSI	89.0	<b>89.0</b>
FATIGUE-DUCTILITY, COEFF., $\epsilon'_F$	0.387	<b>0.387</b>
FATIGUE-STRENGTH EXPONENT, $B$	-0.11	<b>-0.15</b>
FATIGUE-DUCTILITY EXPONENT, $C$	-0.8	<b>-0.8</b>

**FIG. 52 MONOTONIC AND CYCLIC STRESS-STRAIN CURVES FOR 7075-T73 ALUMINUM ALLOY**

**FIG. 53 STRAIN VERSUS LIFE CURVES FOR 7075-T73 ALUMINUM ALLOY TESTED IN LABORATORY AIR AND 3.5 WT% NA CL. SOURCE: REF 36**

Having defined the material properties for 7075-T73 alloy in the 3.5 wt% NaCl environment, the next step in the analysis is the determination of the fatigue-notch factor,  $K_f$ , for the geometric notch with  $K_t = 2.52$ . As mentioned previously, there is no clear functional relationship between  $K_f$  and  $K_t$  through Peterson's equation because each aluminum alloy, depending on thermomechanical processing, has a different value of the length parameter, "a." It was therefore necessary to conduct long-life fatigue tests ( $10^7$  reversals) of notched specimens of 7075-T73. By the quotient of the fatigue strength at  $10^7$  reversals of unnotched specimens to the fatigue strength of notched specimens  $K_f = \sigma_{\text{unnotched}}/\sigma_{\text{notched}}$ , a value of the fatigue-notch factor was determined to be 2.2.

Next, a cumulative-fatigue-damage-analysis program was developed, similar to that of Landgraf et al. (Ref 26), in which the cyclic stress-strain curve was "modeled" by a series of straight-line segments. This particular program must be initialized at the absolute maxima or minima of a digitized input history that are nominal stresses, but must be "elastic." To relate nominal stresses,  $\Delta S$ , to notch root stresses and strains,  $\Delta\sigma$  and  $\Delta\varepsilon$ , Neuber's rule was employed in the form of Eq 71. By proper manipulation of the strain-life equation, it can be shown that:

$$\text{Damage/reversal} = \frac{1}{2N_f} = \left[ \frac{\sigma'_f \Delta\varepsilon_p}{\varepsilon'_f E \Delta\varepsilon_e} \right]^{1/(b-c)} \quad \text{(EQ 80)}$$

and mean stresses ( $\sigma_o$ ) accounted for by modification of the above equation to:

$$\text{Damage/reversal} = \left[ \frac{\sigma'_f \Delta\varepsilon_p}{\varepsilon'_f E \Delta\varepsilon_e} \frac{\sigma'_f}{\sigma'_f - \sigma_o} \right]^{1/(b-c)} \quad \text{(EQ 81)}$$

where  $\Delta\varepsilon_p$  is the local plastic-strain range and  $\Delta\varepsilon_e$  is the local elastic-strain range. In this example, a conditional was employed for input of material-property data: "Cyclic stresses and strains were defined by the laboratory air cyclic stress-strain curve and the effect of environment was to modify only the long-life fatigue resistance of the aluminum alloy (i.e.,  $b$  increases in absolute value as the environmental severity increases)."

Figure 54 compares zero to maximum stress fatigue results of notched specimens tested in a 3.5 wt% NaCl environment, using the techniques described, to the predicted behavior. The agreement between the prediction and test results appears favorable (Ref 36).

FIG. 54 TEST RESULTS AND COMPUTER PREDICTIONS FOR 0-MAX STRESSING OF 7075-T73 ALUMINUM ALLOY IN A 3.5 WT% NaCl ENVIRONMENT. SOURCE: REF 36

The approach described above is not the only means of accounting for environmental effects on the fatigue life of materials. Interested readers are guided to Ref 37 for an excellent review of the effects of environment, frequency, strain rate, metallurgical variables, wave shape, and thermal cycling on the fatigue behavior of metals. The author employs what have been called "frequency modified" relationships.

## Estimating Fatigue Life

Norman E. Dowling, Virginia Polytechnic Institute and State University

---

### Introduction

FATIGUE LIFE ESTIMATES are often needed in engineering design, specifically in analyzing trial designs to ensure resistance to cracking. A similar need exists in the troubleshooting of cracking problems that appear in prototypes or service models of machines, vehicles, and structures.

Three major approaches are in current use: (1) the stress-based (*S-N* curve) approach, (2) the strain-based approach, and (3) the fracture mechanics approach. Both the stress- and strain-based approaches are considered in this article from the viewpoint of their use as engineering methods. Analogous treatment of the fracture mechanics or damage tolerant approach, which is based on following crack growth, is not included here, but is given in several other articles in this Volume (see the Section "Fracture Mechanics, Damage Tolerance, and Life Assessment").

Much of what follows is adapted from selected portions of the book *Mechanical Behavior of Materials: Engineering Methods for Deformation, Fracture, and Fatigue* (Ref 1). The previous article in this Handbook, "Fundamentals of Modern Fatigue Analysis for Design," also contains considerable information of relevance to this article and is frequently referenced.

## Estimating Fatigue Life

Norman E. Dowling, Virginia Polytechnic Institute and State University

---

### Stress-Based (*S-N* Curve) Method

Since the well-known work of Wöhler in Germany starting in the 1850s, engineers have employed curves of stress versus cycles to fatigue failure, which are often called *S-N* curves. Although now supplemented and sometimes replaced by more sophisticated approaches, the stress-based approach continues to serve as a useful tool.

**Component *S-N* Curves.** It is sometimes useful to conduct fatigue tests on an engineering component, such as a machine or vehicle part, or a structural joint. Subassemblies, such as a vehicle suspension system, may also be tested as may a portion of a structure or even an entire machine, vehicle, or structure. The Bailey Bridge panel made from structural steel (Fig. 1) is an example. This is one panel of a modular truss for military and temporary civilian bridges used by the British in World War II. Bailey Bridges were still being manufactured long after the end of the war, and some were used in situations and for lengths of time (10 years or more) that were not envisioned by the original designers. Hence, a fatigue testing program was undertaken, as reported in a 1968 paper by Webber (Ref 2), to provide information on permissible length and severity of bridge usage.

FIG. 1 BAILEY BRIDGE PANEL. REPRINTED WITH PERMISSION OF AMERICAN SOCIETY OF TESTING AND MATERIALS. SOURCE: REF 2

A constant amplitude  $S-N$  curve from this work is shown in Fig. 2. This was obtained by applying cyclic loads to an assembly of panels, with these loads oriented in a plane corresponding to vertical loads on a bridge, which is the vertical direction of Fig. 1. Cracks generally started at a weld near the slot for sway brace shown in Fig. 1 and were visibly growing for at least half of the life. The stresses shown in Fig. 2 were calculated by treating the entire panel as a beam, with the bracing averaged as a web, and with the location of the critical slot giving the distance from the neutral axis of this beam. All tests used the same minimum load corresponding to the dead load of a bridge.

FIG. 2 FATIGUE LIFE CURVE FOR BAILEY BRIDGE PANELS. THE VERTICAL AXIS GIVES MAXIMUM STRESS RANGE,  $\Delta S = S_{MAX} - S_{MIN}$ . SOURCE: REF 2

Such a curve is useful in assessing the life expected for Bailey Bridges under various vehicle weights and histories of usage. The curve lacks generality in that it is applicable only to this particular component cycled with the particular minimum stress used. However, it automatically includes the effects of details such as complex geometry, surface finish, residual stresses from fabrication, and the complex metallurgy at welds. Such factors are difficult to evaluate by any means other than a structural test.

**Mean Stress Effects.**  $S-N$  curves are usually plotted as stress amplitude,  $S_a$ , or stress range,  $\Delta S = 2S_a$ , versus life as cycles to failure,  $N_f$ . For a given stress amplitude, the level of mean stress,  $S_m$ , affects the life, with tensile values shortening life compared with tests at  $S_m = 0$ , and compressive values having the opposite effect. Where various mean stresses may occur, component test results can be obtained to generate a family of  $S_a$  versus  $N_f$  curves, one for each of several  $S_m$  values. An alternative means of considering the mean stress effect is to conduct tests at various values of the ratio  $R = S_{min}/S_{max}$  and plot  $S_{max}$  versus  $N_f$  curves for various  $R$ -values.

However, component test results are expensive to obtain, especially if the extra variable of mean stress is included. Hence, it may be desirable to estimate mean stress effects. It then becomes necessary to have only the  $S-N$  curve for one  $S_m$  or  $R$  value. Usually, the case of completely reversed loading, that is,  $S_m = 0$  or  $R = -1$ , is the one chosen for experimental determination. For nonzero  $S_m$ , this curve may be entered with values of an equivalent completely reversed stress amplitude,  $S_{ar}$ , to obtain the life. Various mathematical expressions are used to estimate  $S_{ar}$ ; the most common is based on the modified Goodman diagram equation:

$$S_{ar} = \frac{S_a}{1 - \frac{S_m}{\sigma_u}} \quad (\text{EQ 1})$$

where  $\sigma_u$  is the ultimate tensile strength of the material. For the above equation and the remainder of this article, mean stresses that are tensile are considered to be positive, and compressive mean stresses are considered negative. Alternative expressions and additional discussion are provided in the previous article in this Volume and in Ref 1, 3, 4, and 5.

An alternative approach is to choose as the single  $S-N$  curve one for zero-to-tension loading, that is,  $R = 0$ . For cases other than  $R = 0$ , this curve is entered with values of an equivalent zero-to-tension stress  $S^*$ . The expression provided by Walker (Ref 6) is often used in this context:

$$S^* = S_{\text{MAX}}(1 - R)^\gamma \quad \text{(EQ 2)}$$

where  $\gamma$  is a material parameter obtained from correlating limited test data of nonzero  $R$ . For ductile metals,  $\gamma = 0.5$  is a reasonable estimate in the absence of test data, in which case Eq 2 reduces to  $S^* = \sqrt{S_{\text{max}} \Delta S}$ .

**Definition of Nominal Stress,  $S$ .** When working with  $S-N$  curves for engineering components, or simulated components such as notched members, it is customary to define a nominal or average stress,  $S$ . For example, such a definition was described above for the Bailey Bridge panel. Some care is needed in defining and using  $S$  as illustrated in Fig. 3.

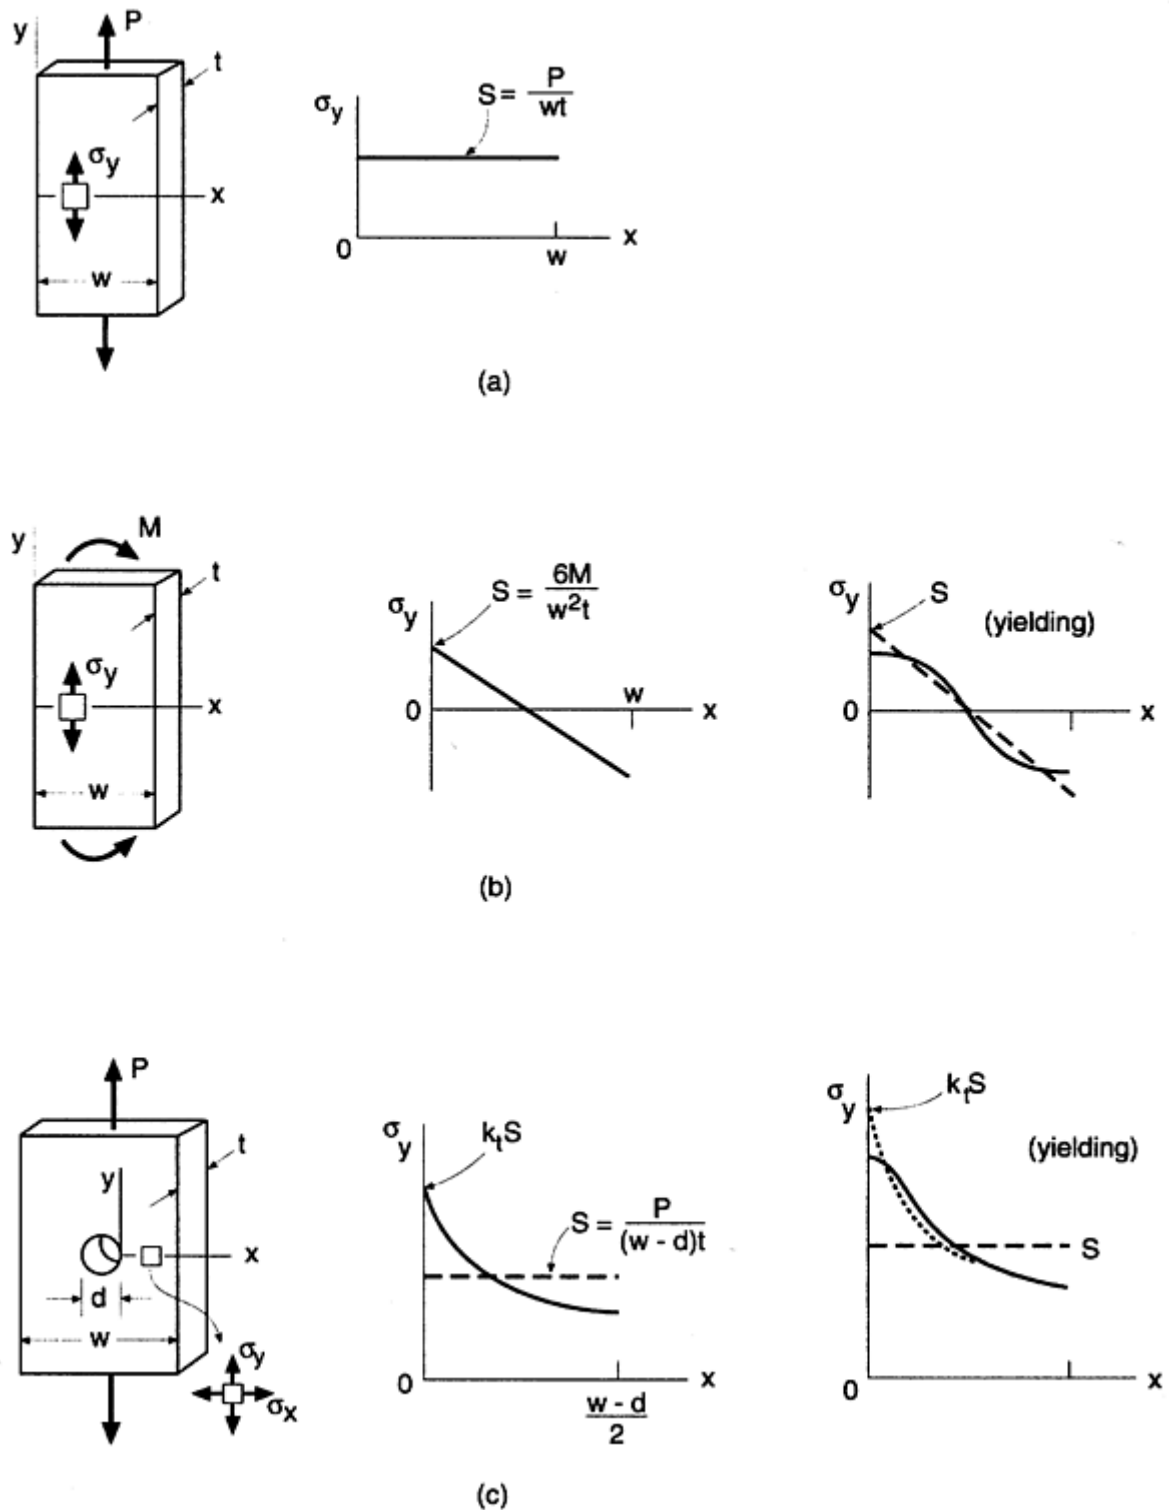

FIG. 3 ACTUAL AND NOMINAL STRESSES FOR SIMPLE TENSION (A), BENDING (B), AND A NOTCHED MEMBER (C). ACTUAL STRESS DISTRIBUTIONS  $\sigma_y$  VERSUS  $x$  ARE SHOWN AS SOLID LINES, AND HYPOTHETICAL DISTRIBUTIONS ASSOCIATED WITH NOMINAL STRESSES  $S$  AS DASHED LINES. IN (C), THE STRESS DISTRIBUTION THAT WOULD OCCUR IF THERE WERE NO YIELDING IS SHOWN AS A DOTTED LINE. SOURCE: REF 1 (P 344)

For simple axial loading of an unnotched member, as in Fig. 3(a), load  $P$  is of course divided by area  $A$  to obtain  $S = P/A$ . This is a reasonable approximation to the actual stress  $\sigma$  in the member, which is at least approximately uniform. For bending, as in (b), the elementary bending stress formula,  $S = Mc/I$ , is used to define  $S$  as the stress at the edge of the member with a cross sectional area moment of inertia,  $I$ . However, this simple analysis does not give the actual stress if

yielding occurs, as a result of the formula being based on the assumption of linear-elastic material behavior. In particular, the actual stress at the edge is lower than  $S$  as shown by a solid line on the diagram to the right in (b). As a result, if  $S-N$  curves for bending and axial loading are compared, they do not agree, as they would if the actual stress  $\sigma$  were plotted. (See Fig. 17 in the previous article in this Volume.)

Consider cases where a stress raiser, such as a notch, groove, hole, or fillet, occurs. (For brevity, any such stress raiser will be generically called a notch.) Nominal stress  $S$  is conventionally defined in such cases as an axial, elastic bending, or elastic torsional stress, or a combination of these. The cross section used for the area  $A$  and the area moment of inertia  $I$  is the net area remaining after removal of material to form the notch. For linear-elastic stress-strain behavior, such an  $S$  is related to the actual stress at the notch by  $\sigma = k_t S$ . The quantity  $k_t$  is an elastic stress concentration factor, defined to be consistent with the (actually arbitrary) definition of  $S$ . Values of  $k_t$  are available from a variety of sources, such as Ref 7.

However, as for the unnotched bending case, the linear-elastic material behavior assumed in obtaining  $k_t$  does not apply beyond yielding. The actual stress  $\sigma$  now becomes less than  $k_t S$  as shown by the solid line on the right in Fig. 3(c). Hence,  $S-N$  curves for notched members plotted as either  $S$  or  $k_t S$  versus life will not agree with curves from simple axial loading. An example is provided by Fig. 4.

**FIG. 4 TEST DATA FOR A DUCTILE METAL ILLUSTRATING VARIATION OF THE FATIGUE NOTCH FACTOR WITH LIFE. THE  $S-N$  DATA IN (A) ARE USED TO OBTAIN  $K'_F = \sigma_A/S_A$  IN (B). THE NOTCHES ARE HALF-CIRCULAR CUTOUTS. SOURCE: REF 1 (P 409)**

Values of  $S$  and  $k_t S$  as conventionally calculated are always proportional to the applied load, such as axial load  $P$ , bending moment  $M$ , or torque  $T$ . For example, for Fig. 3(c),

$$S = \frac{P}{A} \quad (\text{EQ 3})$$

$$k_t S = \frac{k_t P}{A}$$

where  $A$  and  $k_t$  are noted to be constants. On this basis, it is best to view nominal stress  $S$ , and also the elastically calculated notch stress  $k_t S$ , as being merely the applied load scaled in a convenient manner. Neither  $S$  nor  $k_t S$  is in general equal to the actual stress  $\sigma$ . This will be important to remember at several points later in this article.

**Estimated S-N Curves.** Mechanical engineering design books, such as Juvinall (Ref 4) and Shigley (Ref 5), generally give a procedure for estimating component S-N curves (see Fig. 5). First, a life  $N_e$  is specified, such as  $10^6$  cycles for steels, beyond which the S-N curve is assumed to be horizontal. Hence, a fatigue limit, or safe stress below which no fatigue failure is expected, is assumed to exist.

**FIG. 5 ESTIMATING COMPLETELY REVERSED S-N CURVES FOR SMOOTH AND NOTCHED MEMBERS ACCORDING TO PROCEDURES SUGGESTED BY JUVINALL OR SHIGLEY. SOURCE: REF 1 (P 423)**

This fatigue limit stress  $\sigma_{er}$  is first estimated for unnotched material:

$$\sigma_{ER} = M \sigma_U \quad (\text{EQ 4})$$

$$M = M_E M_T M_D M_S M_O$$

where  $m$  is a reduction factor applied to the ultimate tensile strength. The quantity  $m$  is the product of individual reduction factors for several situations that affect S-N curves. In particular,  $m_e$  depends on material,  $m_t$  on type of loading,  $m_d$  on size,  $m_s$  on surface finish, and  $m_o$  on any other effects judged to be relevant. Values for all of these factors are based on empirical data from fatigue tests.

The material-specific factor  $m_e$  gives an estimate of the fatigue limit in bending for small polished test specimens. A factor of  $m_e = 0.5$  is generally applied for steels, and lower values are used for most other metals, such as Juvinall's use of  $m_e = 0.4$  for cast irons and 0.35 for magnesium alloys. A value of  $m_t$  is assigned that depends on the type of loading, such as  $m_t = 1.0$  for bending, and 0.58 for torsion, in both Juvinall and Shigley. The size factor given by  $m_d$  reflects statistical effects that cause lower fatigue strengths to be observed in larger size members. For example, Juvinall recommends  $m_d = 1$  for diameters less than 10 mm,  $m_d = 0.9$  for diameters 10 to 50 mm,  $m_d = 0.8$  for diameters 50 to 100 mm, and so forth.

Surface finishes other than a fine polish are assigned a factor  $m_s < 1$  according to various curves or equations based on empirical data.

For the engineering component itself, a fatigue notch factor,  $k_f$ , is needed for the stress raiser (notch) where fatigue resistance is being evaluated. As described in Eq 62 to 64 in the previous article in this Volume and in Ref 1, 3, 4, 5, and 7), the value of  $k_f$  is obtained by modifying  $k_t$ , the elastic stress concentration factor. The various empirical equations employed for this purpose all depend on the notch tip radius and a material constant that is affected by the ultimate tensile strength. The fatigue limit stress  $S_{er}$  for the notched component is then estimated to be:

$$S_{er} = \frac{m\sigma_u}{k_f} \quad (\text{EQ 5})$$

where the symbol  $S$  denotes a nominal stress defined consistently with the  $k_t$  value used in evaluating  $k_f$ .

The  $S-N$  curve is estimated for lives less than  $N_e$  by establishing a second point, with both Juvinall and Shigley doing so at  $N_f = 10^3$  cycles. The stress at this point for the notched component is:

$$S'_{ar} = \frac{m' \sigma'_u}{k'_f} \quad (\text{EQ 6})$$

where  $m' = 0.9$  for bending or torsion according to both Juvinall and Shigley. For axial loading, Juvinall uses  $m' = 0.75$ , whereas Shigley uses 0.90. The quantity  $\sigma'_u$  is the ultimate strength in tension,  $\sigma_u$ , except that a shear ultimate  $\tau_u$  is used for torsion. Juvinall applies a notch effect at  $N_f = 10^3$  by employing  $k'_f = k_f$ , whereas Shigley differs dramatically by applying  $k'_f = 1$ . Although neither Juvinall nor Shigley provide an estimate for lives shorter than  $10^3$  cycles, it would be reasonable to assume that the curve must pass through the ultimate tensile strength  $\sigma_u$ , or other estimate of component static strength, at  $N_f = 1$ .

Finally, the curve is drawn by connecting the above-described stress values at  $N_f = 1, 10^3$ , and  $N_e$  cycles with straight lines on a log-log plot as shown in Fig. 5. Hence, any straight-line segment has an equation of the form:

$$S_{AR} = AN_f^B \quad (\text{EQ 7})$$

where  $A$  and  $B$  have one set of values for the interval  $1 \cdot N_f \cdot 10^3$ , and another set for  $10^3 \cdot N_f \cdot N_e$ , and where the curve is horizontal at  $S_{er}$  for  $N_f \cdot N_e$ .

**Summary on the  $S-N$  Method.** Estimated  $S-N$  curves are difficult to employ for combined loading cases, such as bending plus torsion on a notched shaft. However, even where the estimate is straightforward, the curve should be regarded as providing nothing more than a very crude estimate that is generally expected to be conservative. Comparison of estimates as recommended by different design books (e.g., Ref 3, 4, 5) reveal major differences, as do comparisons with test data.

Note that actual component fatigue data, as in Fig. 2, automatically include such effects as size, surface finish, geometric detail, and material condition as altered in component manufacture. Because estimates of such effects may be quite inaccurate, it is clear that any actual fatigue data that are available should be used to the maximum extent possible to improve or replace estimated  $S-N$  curves.

## Variable Amplitude Loading

Cyclic loading histories that occur in the actual service of machines, vehicles, and structures often involve irregular variations of load with time. Life estimates for such situations may be made by employing the Palmgren-Miner rule along with a cycle counting procedure. Cycle counting permits an irregular time history to be broken down into individual events that may be evaluated from a constant amplitude  $S-N$  curve.

The time history and the  $S-N$  curve can employ a common variable, which may be actual stress  $\sigma$ , nominal stress  $S$ , load  $P$ , or strain  $\epsilon$ , or else the time history must be transformed to the same variable as the  $S-N$  curve. The cycle counting procedure is the same for time histories of any of these variables, and stress,  $\sigma$ , is used in this section as a generic variable representing any choice. However, the handling of mean stress effects requires special care as discussed near the end of this section.

**Palmgren-Miner Rule.** Consider the relatively simple case where the stress amplitude changes one or more times during cyclic loading (see Fig. 6). Let  $N_1$  cycles be applied at the first stress level  $\sigma_{a1}$ . If the  $S-N$  curve is entered, the number of cycles to failure at this same stress level,  $N_{f1}$ , can be determined. The interpretation can then be made that a life fraction of  $N_1/N_{f1}$  has been exhausted. It is logical to assume that the sum of such life fractions for each stress level will reach unity when fatigue failure occurs:

$$\sum \frac{N_i}{N_{fi}} = 1 \quad (\text{EQ 8})$$

This simple rule was first proposed for use on ball and roller bearings by A. Palmgren of Sweden in the 1920s, but it was not widely applied until after the publication of a paper by M.A. Miner in 1945. Hence, it is called the Palmgren-Miner (P-M) rule, although a 1937 paper by B.F. Langer also employed the same approach. (These early papers are cited in Ref 2.)

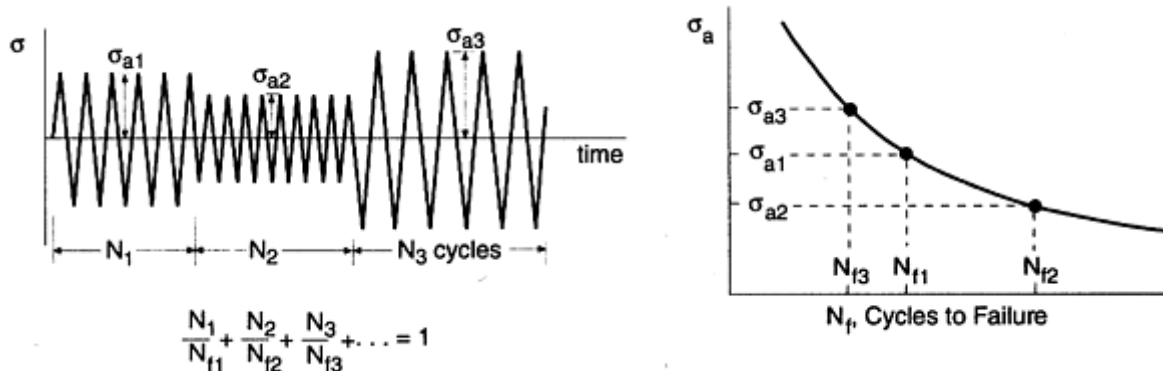

FIG. 6 USE OF THE PALMGREN-MINER RULE FOR LIFE PREDICTION FOR VARIABLE AMPLITUDE LOADING THAT IS COMPLETELY REVERSED. SOURCE: REF 1 (P 383)

If typical variable loading is known for one aircraft flight, one machine operating cycle, or other time interval, Eq 8 can be applied for one repetition of this interval:

$$B_f \left[ \sum \frac{N_j}{N_{fj}} \right]_{\text{one rep}} = 1 \quad \text{(EQ 9)}$$

where  $B_f$  is the number of repetitions to failure. For example, consider the loading of Fig. 7, which is assumed to be repeatedly applied. There are  $N_1$  cycles applied at a particular combination of mean stress and stress amplitude,  $\sigma_{a1}$  and  $\sigma_{m1}$ , and then the mean stress changes, following which  $N_2$  cycles are applied at a different combination,  $\sigma_{a2}$  and  $\sigma_{m2}$ . However, even if these two amplitudes were so small as to be nondamaging, fatigue failure could eventually occur due to the once-per-repetition application of the single large cycle identified as  $\Delta\sigma_3$ , having amplitude  $\sigma_{a3}$  and mean  $\sigma_{m3}$ . For the three levels of cycling, equivalent completely reversed stresses,  $\sigma_{ar1}$ ,  $\sigma_{ar2}$ , and  $\sigma_{ar3}$ , as from Eq 1, must be computed and these values used with the  $S-N$  curve for  $\sigma_m = 0$  to obtain  $N_{f1}$ ,  $N_{f2}$ , and  $N_{f3}$ . Application of Eq 9 then allows the unknown number of repetitions to failure,  $B_f$ , to be calculated. Numerical solutions for two problems of this general type are given in Ref 1 (pp 384-385, 444-445).

FIG. 7 LIFE PREDICTION FOR A REPEATING STRESS HISTORY WITH MEAN LEVEL SHIFTS. SOURCE: REF 1 (P 384)

**Cycle Counting.** If the time variation is irregular, as in Fig. 8, it is not obvious how one should identify the cycles for use of the P-M rule. Before proceeding, note that Fig. 8 gives definitions of some useful terms. The irregular load, stress, or strain history consists of a series of peaks and valleys. A simple range is measured between a peak and the next valley, or between a valley and the next peak. An overall range is measured between a peak and a valley, but the valley occurs later and is more extreme than the one that follows immediately. Similarly, an overall range may be measured between a valley and a later peak.

FIG. 8 DEFINITIONS FOR IRREGULAR LOADING. SOURCE: REF 1 (P 386)

Although a number of different procedures have been employed for identifying cycles, a consensus appears to have been reached that the preferable method is the rainflow method, or the essentially equivalent range pair method (Ref 8). When performing rainflow cycle counting, a cycle is identified or counted if it meets the criterion illustrated in Fig. 9. A peak-valley-peak or valley-peak-valley sequence X-Y-Z is counted as a cycle if the second range (Y-Z) exceeds the first (X-Y). In particular, the cycle has a stress range equal to that of the first range,  $\Delta\sigma_{XY} = \sigma_X - \sigma_Y$ , and a mean stress  $\sigma_m = (\sigma_X + \sigma_Y)/2$ .

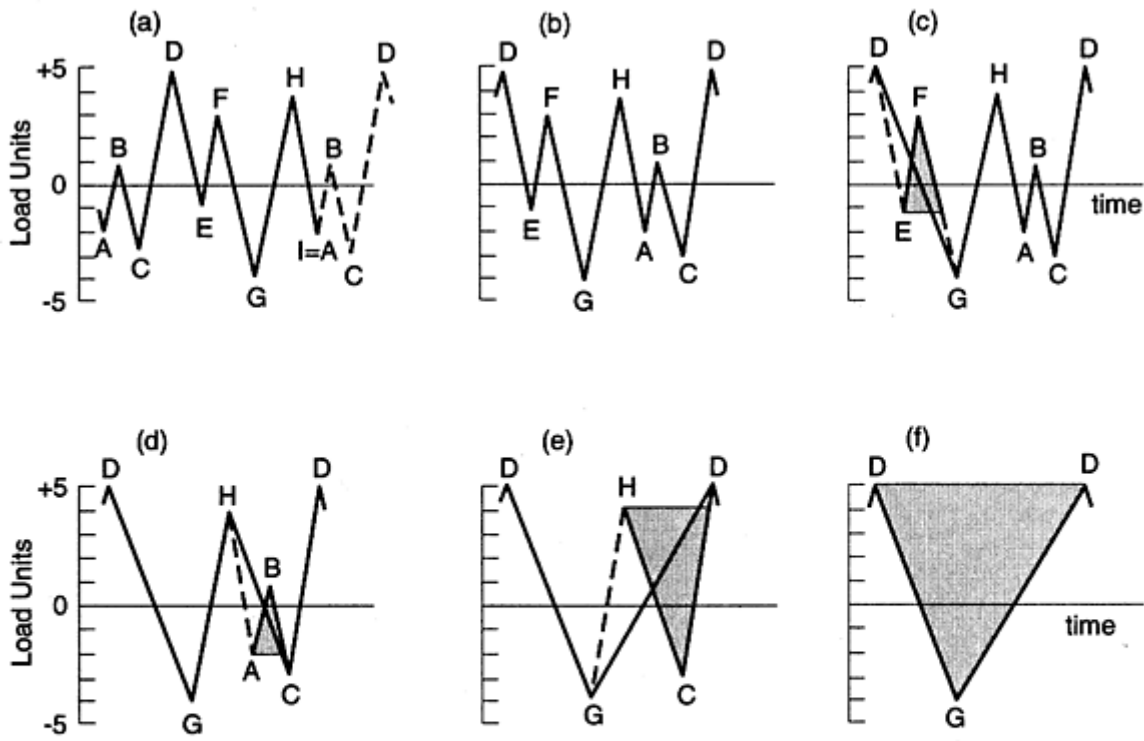

FIG. 9 CONDITION FOR COUNTING A CYCLE USING THE RAINFLOW METHOD. SOURCE: REF 1 (P 386)

Now consider an entire stress history, using the short history of Fig. 10 as an example. First, the history is assumed to be a repeating one that can be assumed to start and stop at any peak or valley. This permits the convenience of assuming that the history begins and ends at the peak or valley having the highest absolute value of stress. Peaks and valleys occurring prior to this extreme event are then moved to the end of the history as shown in Fig. 10(a) and 10(b).

Cycle	Range	Mean
E-F	4.0	1.0
A-B	3.0	-0.5
H-C	7.0	0.5
D-G	9.0	0.5

FIG. 10 EXAMPLE OF RAINFLOW CYCLE COUNTING. SOURCE: ADAPTED FROM REF 8

Then proceed with counting as follows: Start by considering the first three peak or valley events as X-Y-Z of Fig. 9. If a cycle is counted, note its range and mean and remove it from the history to be employed for purposes of further counting. If none is counted, move ahead by one peak or valley and check for a cycle there. Continue counting cycles and moving ahead until the entire history is exhausted. When the process is complete, each peak or valley is noted to have participated in one and only one cycle. Some cycles counted correspond to simple ranges in the original history, but others to overall ranges. The final and largest cycle that is counted always involves the highest peak and lowest valley.

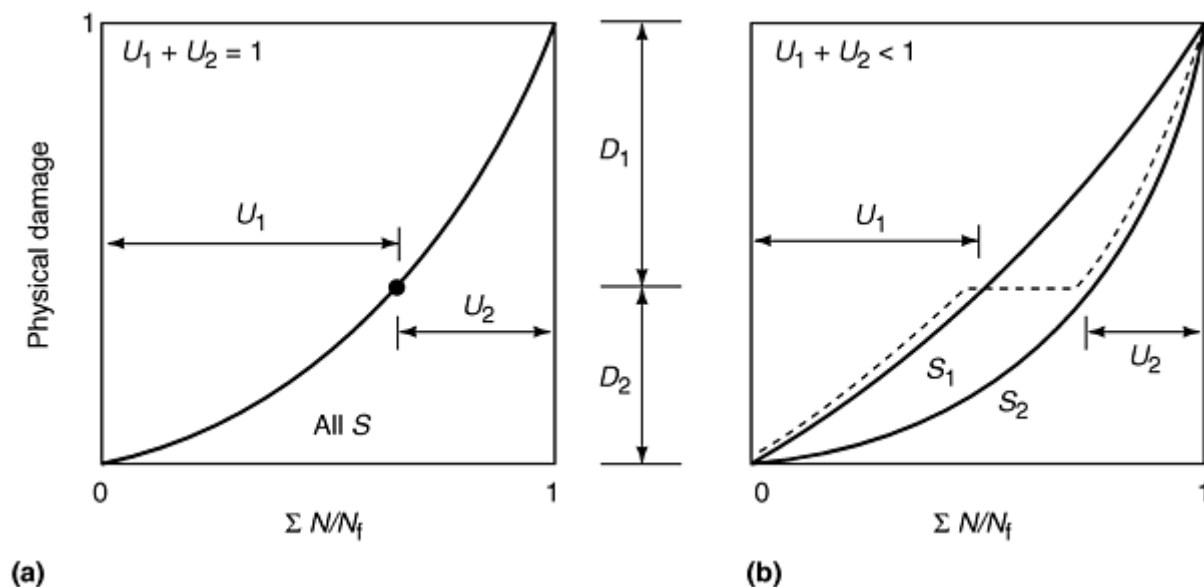

Computer programs for performing the cycle counting are available (Ref 9, 10). For lengthy histories, the range and mean values are often rounded off to discrete values in a range-mean matrix as shown in Fig. 11. A numerical example of a life calculation that involves cycle counting is given in Ref 1 (p 387-389).

FIG. 11 AN IRREGULAR LOAD VERSUS TIME HISTORY FROM A GROUND VEHICLE TRANSMISSION AND A MATRIX GIVING NUMBERS OF RAINFLOW CYCLES AT VARIOUS COMBINATIONS OF RANGE AND MEAN. THE RANGE AND MEAN VALUES ARE PERCENTAGES OF THE PEAK LOAD, AND THESE WERE ROUNDED TO THE DISCRETE VALUES SHOWN IN CONSTRUCTING THE MATRIX. REPRINTED WITH PERMISSION FROM AE-6 FATIGUE UNDER COMPLEX LOADING: ANALYSIS AND EXPERIMENTS, 1977 (REF 11), SOCIETY OF AUTOMOTIVE ENGINEERS, INC.

**Sequence Effects.** For the Palmgren-Miner rule to be valid, the physical damage in the material,  $D$ , which could be crack length, crack density, modulus or compliance change, or other relevant parameter, must be uniquely related to the life fraction,  $U = N/N_f$ . The relationship between  $D$  and  $U$  need not be linear, as long as there is a single monotonically increasing curve for all stress values. This is illustrated in Fig. 12(a).

**FIG. 12 PHYSICAL DAMAGE VERSUS LIFE FRACTION, WHERE THE RELATIONSHIP IS UNIQUE (A) AND NONUNIQUE (B). SOURCE: REF 12**

However, if the  $U$  versus  $D$  curve varies with stress level (see Fig. 12b), a sequence effect can occur, such that the summation of cycle ratios differs from unity. Such effects do indeed occur. For example, assume that a few severe loading cycles that cause plastic deformation are applied at the beginning of a fatigue test. These cycles may advance the damage process sufficiently that subsequent cycles at a low level can proceed to propagate this damage, which would ordinarily take much of the life at the lower level to initiate. Some test data illustrating this effect are given in Fig. 13. A few cycles at high strain lower the strain-life curve in the long-life region. The effect on life increases for lower stress levels and is as large as a factor of 10.

FIG. 13 EFFECT OF INITIAL OVERSTRAIN (10 CYCLES AT  $\epsilon_A = 0.02$ ) ON THE STRAIN-LIFE CURVE OF AN ALUMINUM ALLOY. ADAPTED FROM REF 13 AS BASED ON DATA FROM REF 14

The situation of Fig. 13 corresponds to Fig. 12(b), where damage at the beginning of cycling proceeds more rapidly at a higher stress,  $S_1$ , than it would have at a lower stress,  $S_2$ . Starting at  $S_1$  and changing later to  $S_2$ , a high-low stress sequence, causes  $\sum U < 1$ . Conversely, starting at  $S_2$  and changing to  $S_1$ , a low-high sequence, causes  $\sum U > 1$ .

Periodic overstrains have an effect similar to a high-low sequence. In steels with a distinct fatigue limit, periodic overstrains have the special effect of eliminating this fatigue limit. Data showing this are given in Fig. 14.

FIG. 14 EFFECTS OF BOTH INITIAL AND PERIODIC OVERSTRAIN ON THE STRAIN-LIFE CURVE FOR AN ALLOY

STEEL. THE FATIGUE LIMIT FOR THE NO OVERSTRAIN CASE IS ESTIMATED FROM TEST DATA ON SIMILAR MATERIAL. FROM REF 1 (P 666) AS BASED ON DATA FROM REF 15

A summation of cycle ratios less than unity,  $\sum U < 1$ , is of course a problem as it corresponds to the P-M rule giving a nonconservative life estimate. Component  $S-N$  curves could be adjusted based on overstrain data for the material as in Fig. 13 and 14. For example, component  $S-N$  curves are sometimes extrapolated as straight lines on log-log plots, that is, using Eq 7, thus eliminating any distinct fatigue limit that might be observed in constant amplitude data. Initial or periodic overloads could also be applied during the component  $S-N$  tests. However, this must be done by a special procedure so that residual stresses affecting the life are not introduced by the overloads.

**Local Mean Stress Effects.** In addition to the material-damage-related sequence effects just discussed, an additional cause of sequence effects is related to the local mean stresses at notches affecting life. In particular, local mean stresses are altered by overloads that cause local yielding at the notch. This is illustrated schematically in Fig. 15, where two types of overload cycle are shown, along with the resulting local stress-strain ( $\sigma$ - $\epsilon$ ) behavior at a notch. The tension-compression overload (Fig. 15a) results in a tensile mean stress at the notch during subsequent cycling, and thus a shorter life, than for the compression-tension overload (Fig. 15b), which produces a compressive mean stress. Note that, without these overloads, the local mean stress  $\sigma_m$  would be zero during the low-level cycling at  $S_m = 0$ .

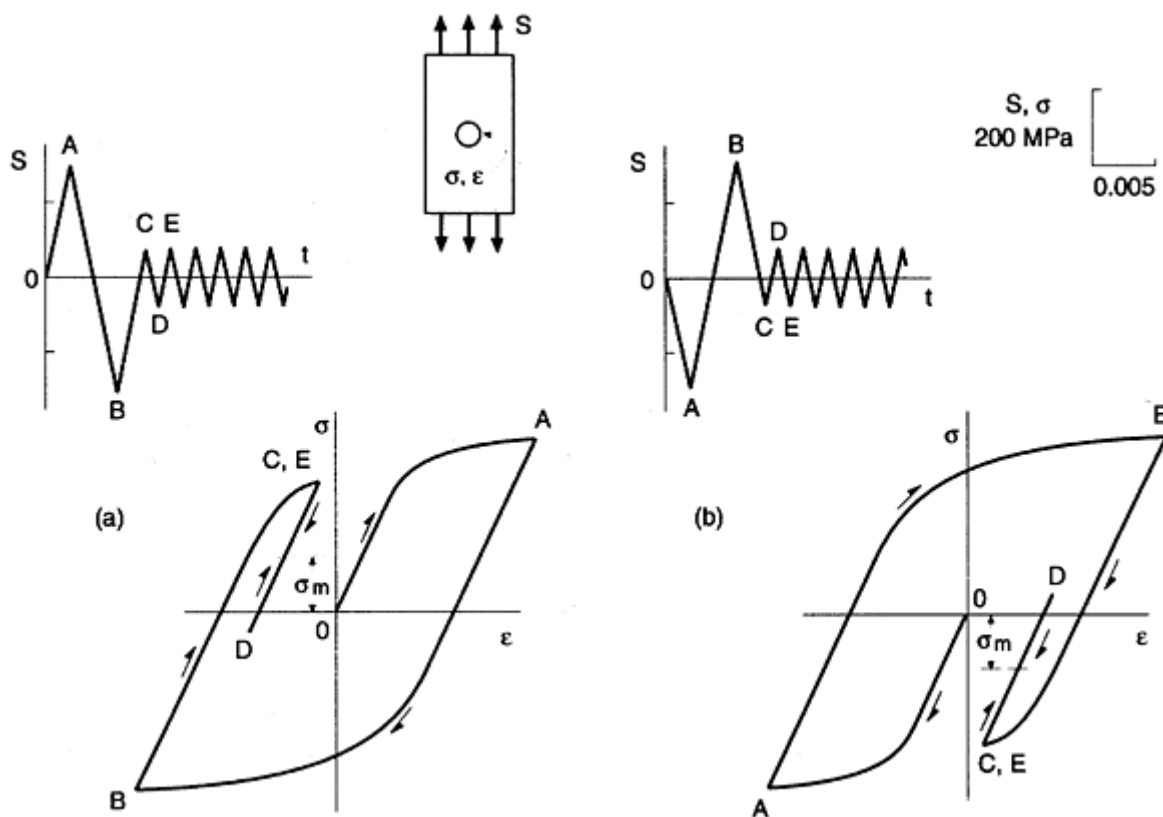

FIG. 15 TWO LOAD HISTORIES APPLIED TO A NOTCHED MEMBER ( $K_T = 2.4$ ) AND THE ESTIMATED NOTCH STRESS-STRAIN RESPONSES FOR 2024-T4 AL. THE HIGH-LOW OVERLOAD IN (A) PRODUCES A TENSILE MEAN STRESS, AND THE LOW-HIGH OVERLOAD IN (B) PRODUCES THE OPPOSITE. ADAPTED FROM REF 16

Sequence effects related to the local mean stress  $\sigma_m$  represent a fundamental difficulty for a stress-based approach employing nominal stresses,  $S$ . The nominal mean stress  $S_m$  is simply not the controlling variable, rather, it is the local mean stress,  $\sigma_m$ . This should not be surprising in view of the discussion above and Fig. 3, where it is noted that nominal stresses  $S$  are in general not actual stresses; they are essentially conveniently scaled applied loads.

For the situation of Fig. 15, note that  $S_m = 0$  for all cycles, so that direct application of Eq 1 would predict no mean stress effect at all, and no difference in life between cases (a) and (b). However, actual test data on notched members show a large effect (see Ref 17 in this article and Fig. 35 in the previous article in this Volume).

Analysis of local mean stresses requires considering the elasto-plastic stress-strain behavior of the material at the notch to obtain values of  $\sigma_m$ , which can then be used in evaluating fatigue life. Analysis of this type is a key feature of the strain-based approach, which is described in the next section of this article.

## Estimating Fatigue Life

Norman E. Dowling, Virginia Polytechnic Institute and State University

---

## Strain-Based Approach

In this approach, local stresses and strains at notches,  $\sigma$  and  $\varepsilon$ , as in Fig. 15, are estimated and used as the basis of life predictions. The  $S$ - $N$  curve used is a strain-life curve, often represented as described in the previous article in this Volume by the following equation:

$$\varepsilon_a = \frac{\sigma'_f}{E} (2N_f)^b + \varepsilon'_f (2N_f)^c, \quad (\text{with } \sigma_m = 0) \quad (\text{EQ 10})$$

where  $\varepsilon_a$  is strain amplitude,  $N_f$  is cycles to failure for completely reversed cycling,  $E$  is the elastic modulus, and  $\sigma'_f$ ,  $b$ ,  $\varepsilon'_f$ , and  $c$  are material fatigue constants. A special cyclic stress-strain curve, as described in the previous article, is also needed:

$$\varepsilon_a = \frac{\sigma_a}{E} + \left( \frac{\sigma_a}{H'} \right)^{1/n'} \quad (\text{EQ 11})$$

where  $\sigma_a$  is stress amplitude, and  $n'$  and  $H'$  are material constants (and where  $H' = K'$  in Eq 29 and 30 of the previous article in this Volume).

**Mean Stress Effects.** A generalized strain-life curve can address mean stress effects in a relationship proposed by Morrow (Ref 18) that is analogous to Eq 1 as follows:

$$\sigma_{ar} = \frac{\sigma_a}{1 - \frac{\sigma_m}{\sigma'_f}} \quad (\text{EQ 12})$$

where  $\sigma_{ar}$  is the equivalent completely reversed local stress amplitude and  $\sigma_a$  and  $\sigma_m$  are also local stresses at the notch. Note that  $\sigma_u$  is replaced by  $\sigma'_f$ , the constant from Eq 10. The quantity  $\sigma'_f$  is approximately equal to the true fracture strength from a tension test, so that it is larger than  $\sigma_u$ , except for low-ductility metals, where it has a value close to  $\sigma_u$ .

Equations 10, 11, and 12 can be combined to generalize the strain-life curve to include mean stress effects:

$$\varepsilon_a = \frac{\sigma'_f}{E} (2N^*)^b + \varepsilon'_f (2N^*)^c$$

$$N_f = \frac{N^*}{\left( 1 - \frac{\sigma_m}{\sigma'_f} \right)^{1/b}} \quad (\text{EQ 13})$$

where  $N^*$  is the life from the strain-life equation for zero mean stress, and  $N_f$  is the actual life as adjusted to include the mean stress effect. A modification of this equation is also used:

$$\varepsilon_a = \frac{\sigma'_f}{E} \left( 1 - \frac{\sigma_m}{\sigma'_f} \right) (2N_f)^b + \varepsilon'_f (2N_f)^c \quad (\text{EQ 14})$$

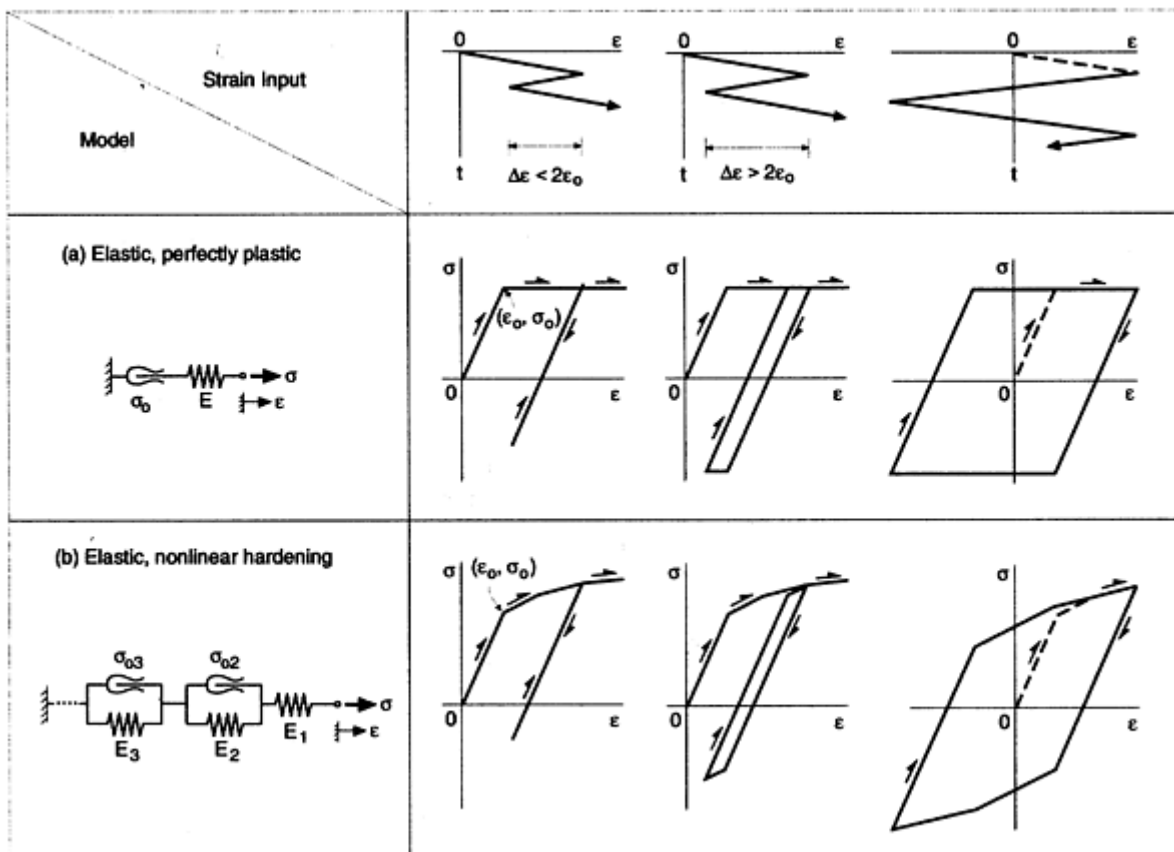

A graphical or iterative numerical solution is required to obtain life  $N_f$  from any of Eq 10, 13, or 14.

An alternative approach to evaluating mean stresses is that of Smith, Watson, and Topper (Ref 19):

$$\sigma_{\max} \varepsilon_a = \frac{(\sigma_f')^2}{E} (2N_f)^{2b} + \sigma_f' \varepsilon_f' (2N_f)^{b+c} \quad (\text{EQ 15})$$

where  $\sigma_{\max} = \sigma_a + \sigma_m$  is the local maximum stress, and the material constants have the same values as in Eq 10. For known values of  $\sigma_{\max}$  and  $\varepsilon_a$ , Eq 15 is solved numerically for  $N_f$ . Alternatively, the quantity  $\sigma_{\max} \varepsilon_a$  can be plotted versus life for particular values of the material constants, and  $N_f$  can then be obtained graphically.

**Elasto-Plastic Stress-Strain Behavior.** To use the strain-based approach, it is necessary to model the elasto-plastic stress-strain behavior that occurs at a notch as in Fig. 15. An analogy with spring and frictional slider rheological models is useful (Ref 20). Consider Fig. 16, model (a). This model corresponds to an elastic, perfectly plastic material. A linear spring of stiffness  $E$  gives an initial elastic response, and the frictional slider moves at a yield stress  $\sigma_0$ . Unloading and reloading may cause only elastic deformation, or the frictional slider may move if the strain excursion is sufficiently large.

**FIG. 16 UNLOADING AND RELOADING BEHAVIOR FOR TWO RHEOLOGICAL MODELS. THE FIRST STRAIN HISTORY CAUSES ONLY ELASTIC DEFORMATION DURING UNLOADING, BUT THE SECOND ONE IS SUFFICIENTLY LARGE TO CAUSE COMPRESSIVE YIELDING. THE THIRD HISTORY IS COMPLETELY REVERSED AND CAUSES A HYSTERESIS LOOP THAT IS SYMMETRICAL ABOUT THE ORIGIN. SOURCE: REF 1 (P 545)**

In model (b), there are one or more spring and slider parallel combinations, which provides a strain-hardening behavior. If the strain excursion on unloading and reloading is sufficiently large, a stress-strain hysteresis loop is formed as for engineering metals. For completely reversed strain cycling, a loop that is symmetrical about the origin is obtained. [Compare (b) to Fig. 7 of the previous article in this Volume.]

The model (b) parameters ( $E_i, \sigma_{oi}$ ) can be adjusted to fit the cyclic stress-strain curve of a particular material, and the model will then provide a reasonable representation of the stable cyclic stress-strain behavior. The transient cyclic hardening or softening stage is not modeled, only the stable behavior after this is complete, nor is the cycle dependent relaxation of mean stress. Such details can be added if desired by making the model parameters act as variables, or by

employing a more general plasticity theory. However, the basic nontransient model is sufficient for most applications and will be employed here.

Consider a spring and slider model that fits the cyclic stress-strain curve as in Fig. 17(a). Let this curve be denoted  $\epsilon = f(\sigma)$ , with Eq 11 being the specific form that is usually employed. If an irregular strain history is imposed on the model, a set of simple rules is seen to describe its behavior. First, after the model reaches the largest absolute value of strain, as at A in Fig. 17(b), stress-strain paths follow a unique curve that is related to the cyclic stress-strain curve,  $\epsilon = f(\sigma)$ , by being expanded with a scale factor of two:

$$\frac{\Delta\epsilon}{2} = f\left(\frac{\Delta\sigma}{2}\right) \quad (\text{EQ 16})$$

The quantities  $\Delta\sigma$  and  $\Delta\epsilon$  are stress and strain changes measured relative to each point where the direction of loading changes, with coordinate axes positive in the direction of loading, as at A, B, C, and D in Fig. 17.

FIG. 17 BEHAVIOR OF A MULTISTAGE SPRING-SLIDER RHEOLOGICAL MODEL FOR AN IRREGULAR STRAIN HISTORY. A MODEL HAVING THE MONOTONIC STRESS-STRAIN CURVE (A) IS SUBJECTED TO STRAIN HISTORY (B), RESULTING IN STRESS-STRAIN RESPONSE (C). ADAPTED FROM REF 21

The second rule is an exception to the first: When the strain next reaches a value where the loading direction was changed, the stress has the same value as before, and the Eq 16 stress-strain path returns to the one that was underway prior to the direction change. This occurs in Fig. 17 at point B', beyond which the behavior is the same as if even B-C-B' had not occurred. This behavior of returning to a previously established stress-strain path is called the memory effect.

At points where the memory effect acts, a closed stress-strain hysteresis loop is completed, such as loop B-C-B' in Fig. 17. Also, for histories reordered to start at the most extreme peak or valley as in Fig. 10, the closed stress-strain loops correspond to the cycles from rainflow counting of the strain history. For Fig. 17, loops B-C-B' and A-D-A' correspond to the rainflow cycles for this short history.

The device of a rheological model is actually unnecessary. It is necessary only to use the factor-of-two (Eq 16) scaling of a smooth continuous cyclic stress-strain curve along with the memory effect to form closed stress-strain hysteresis loops.

**Analysis of Notched Members.** Consider the local strain  $\epsilon$  at a notch and the variation of this with applied load as shown in Fig. 18. An elasto-plastic stress-strain analysis, as by finite elements, could be used to determine the local stresses and strains at the notch. At low loads, only elastic behavior occurs, so that  $\sigma = k_0 S$  and  $\epsilon = \sigma/E$  applies. Once the yield stress is exceeded, yielding occurs in a small region at the notch, and strains are larger and stresses smaller, than would be the case for simple elastic behavior. Yielding spreads with increasing load, and when the entire cross section becomes involved, fully plastic behavior is said to occur.

FIG. 18 LOAD VERSUS LOCAL STRAIN BEHAVIOR OF A NOTCHED MEMBER SHOWING THREE REGIONS OF BEHAVIOR: NO YIELDING (A), LOCAL YIELDING (B), AND FULLY PLASTIC YIELDING (C). SOURCE: REF 1 (P 594)

The approximate procedure called Neuber's rule is often used to estimate local notch stresses and strains (Ref 22). For loading that does not extend into the fully plastic region, Neuber's rule predicts that the following relationship applies:

$$\sigma \epsilon = \frac{(k_t S)^2}{E} \quad (\text{EQ 17})$$

When combined with a stress-strain curve,  $\epsilon = f(\sigma)$ , values for local stress and strain,  $\sigma$  and  $\epsilon$ , can be obtained for any desired value of nominal stress  $S$ . In plots of Eq 17 as a hyperbola on  $\sigma$ - $\epsilon$  axes, the intersection with the stress-strain curve provides the desired  $\sigma$  and  $\epsilon$  values (see Fig. 44 in the previous article, for example).

As an alternative to Neuber's rule, the strain energy density method has been proposed by Glinka (Ref 23). Its application is similar to that of Neuber's rule, and it can be used in place of Neuber's rule in the descriptions that follow in this article.

**Life Estimates for Constant Amplitude Loading.** Figure 19 is an illustrated flow chart for the entire procedure for making a life estimate with constant amplitude loading applied to a notched member. The input information required consists of the applied loading expressed in terms of nominal stress,  $S$ , the geometry, hence the  $k_t$  value, and the cyclic stress-strain and strain-life curves for the material. The latter are denoted as  $\epsilon_a = f(\sigma_a)$  and  $\epsilon_a = h(N_f)$ , respectively, with the forms of Eq 10 and 11 often being employed.

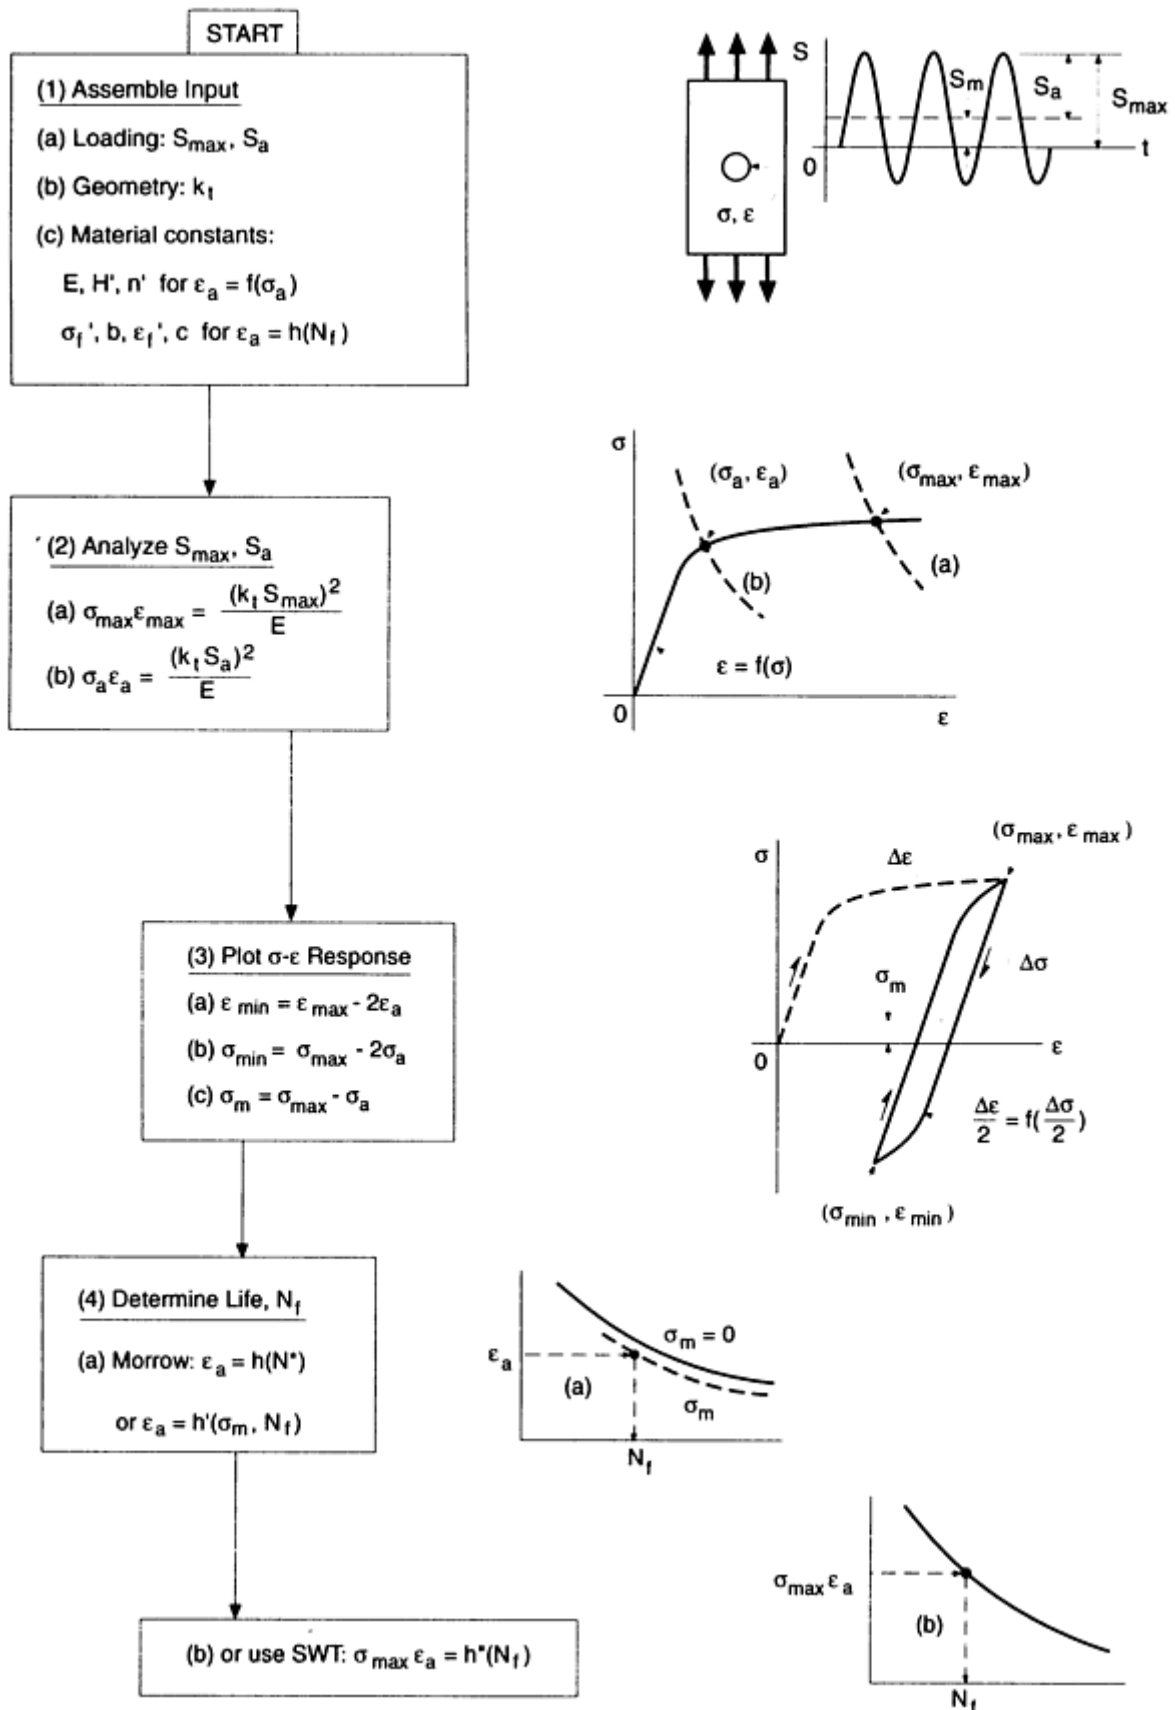

FIG. 19 STEPS REQUIRED IN STRAIN-BASED LIFE PREDICTION FOR A NOTCHED MEMBER UNDER CONSTANT AMPLITUDE LOADING. SOURCE: REF 1 (P 648)

The material is assumed to have stable behavior with its initial monotonic stress-strain curve being the same as the cyclic stress-strain curve, Eq 11. Neuber's rule in the form of Eq 17 is then applied to both the maximum and amplitude values of nominal stress,  $S_{\max}$  and  $S_a$ . Hence, the following equations are solved to obtain the local maximum stress and strain,  $\sigma_{\max}$  and  $\epsilon_{\max}$ :

$$\epsilon_{\max} = \frac{\sigma_{\max}}{E} + \left( \frac{\sigma_{\max}}{H'} \right)^{1/n'} \quad (\text{EQ 18})$$

$$\frac{(k_t S_{\max})^2}{E} = \sigma_{\max} \epsilon_{\max}$$

Similarly, the amplitudes  $\sigma_a$  and  $\epsilon_a$  are obtained from

$$\epsilon_a = \frac{\sigma_a}{E} + \left( \frac{\sigma_a}{H'} \right)^{1/n'} \quad (\text{EQ 19})$$

$$\frac{(k_t S_a)^2}{E} = \sigma_a \epsilon_a$$

Solutions of the above pairs of equations can be thought of graphically as shown in step 2 of Fig. 19, where a hyperbola is intersected with the cyclic stress-strain curve.

Once these stresses and strains are known, the local stress-strain response can be plotted using the factor-of-two expansion of the cyclic stress-strain curve, Eq 16. This is shown as step 3 in Fig. 19. Because relaxation of mean stress is assumed to be small, the mean stress found for the first cycle is assumed to apply throughout the fatigue life.

$$\sigma_M = \sigma_{\max} - \sigma_a \quad (\text{EQ 20})$$

Finally, having evaluated  $\epsilon_a$  and  $\sigma_m$ , the number of cycles to failure  $N_f$  may be calculated from a strain-life curve that includes the mean stress effect, such as Eq 13 or 14. Or the Smith, Watson, and Topper approach can be employed by substituting  $\sigma_{\max}$  and  $\epsilon_a$  into Eq 15 and solving for  $N_f$ . A numerical example is provided by combining Examples 13.3 and 14.3 of Ref 1 (pp 610-611 and 649-650).

**Life Estimates for Variable Amplitude Loading.** The life estimation procedure just described for constant amplitude loading of notched members can be extended to variable amplitude cases by including cycle counting and the memory effect. An illustrated flow chart of the procedure is shown in Fig. 20.

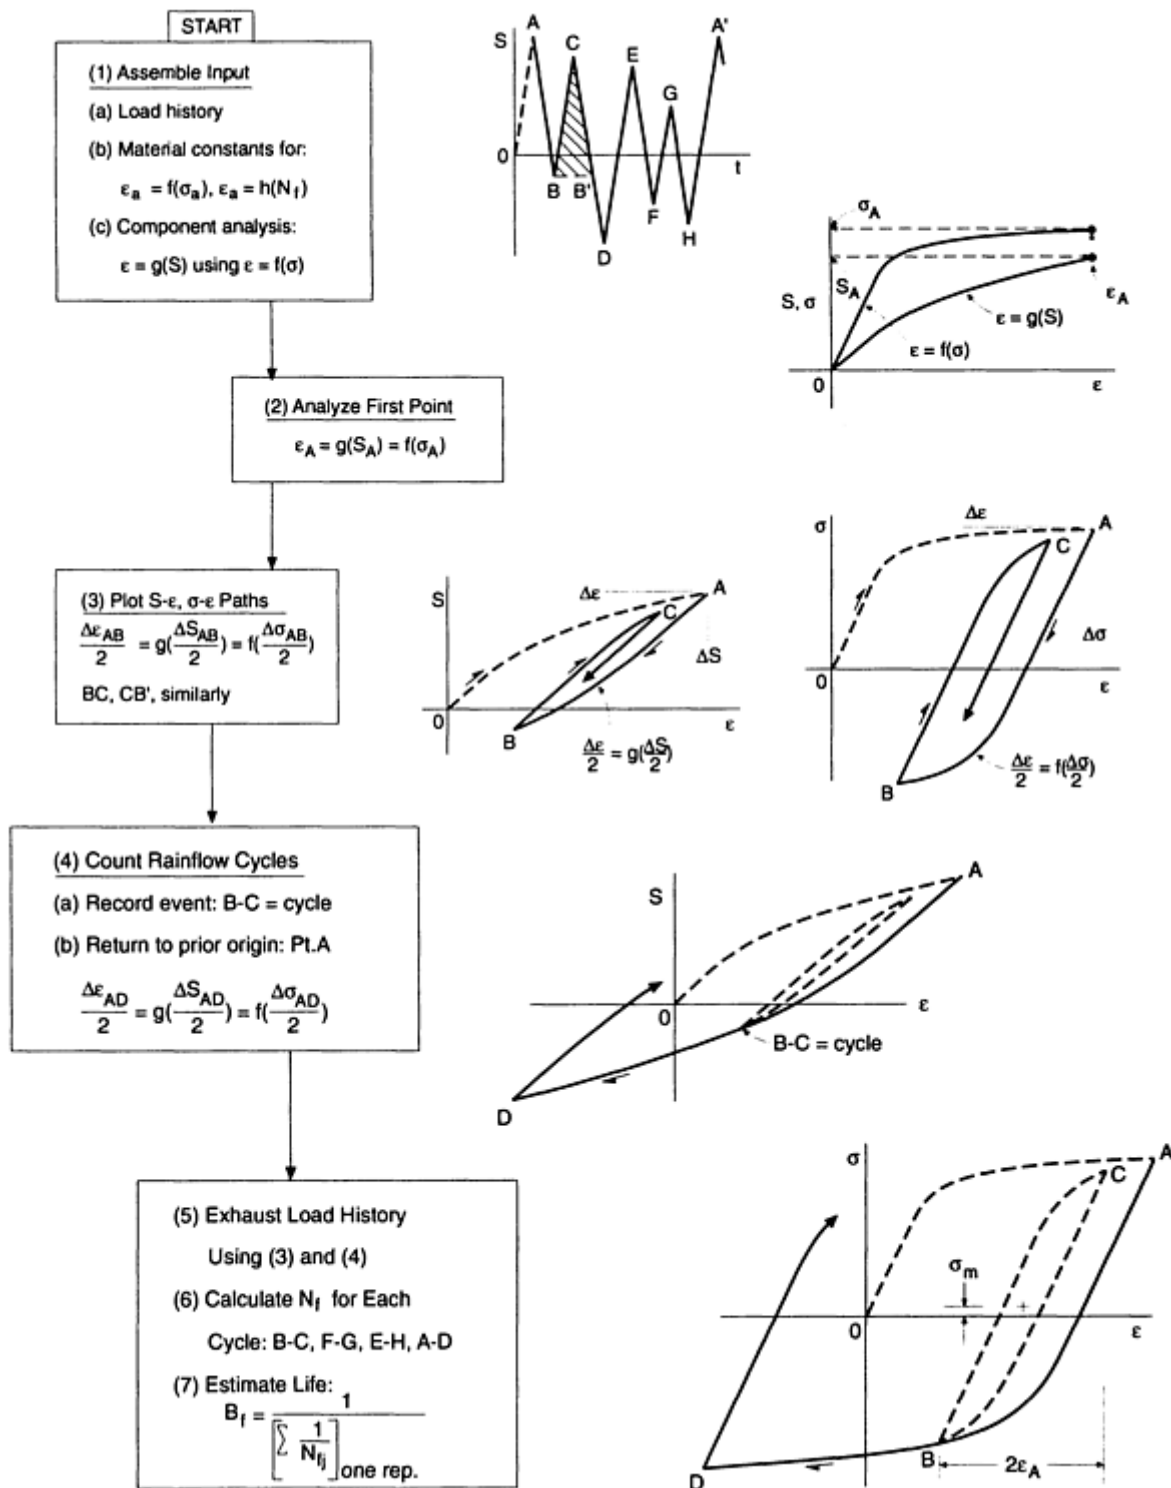

FIG. 20 LIFE PREDICTION FOR AN IRREGULAR LOAD VERSUS TIME HISTORY USING THE STEPWISE PROCEDURE DESCRIBED IN THE TEXT. SOURCE: REF 1 (P 653)

For this analysis, it is useful to solve Neuber's rule with the cyclic stress-strain curve, or perform other analogous mechanics analysis, to obtain a load-strain curve as in Fig. 18. For Neuber's rule and no loading into the fully plastic region, the implicit relationship between  $S_a$  and  $\epsilon_a$  of Eq 19 applies. Let this relationship be denoted  $\epsilon = g(S)$ . Also, reorder the load history so that it starts and ends with the peak or valley having the largest absolute value. (This reordering step can be avoided, but more general cycle counting and stress-strain modeling procedures become necessary.)

The analysis begins by simultaneously following both the load-strain and stress-strain curves,  $\epsilon = g(S)$  and  $\epsilon = f(\sigma)$ , to the first (most extreme) load peak or valley. For example, for point A in Fig. 20, the known  $S_A$  and  $\epsilon = g(S)$  gives  $\epsilon_A$ , and this  $\epsilon_A$  and  $\epsilon = f(\sigma)$  gives  $\sigma_A$ . See step 2 and the corresponding diagram in Fig. 20. Then proceed to each subsequent peak or valley while applying the relationships:

$$\begin{aligned} \frac{\Delta\epsilon}{2} &= g\left(\frac{\Delta S}{2}\right) \\ \frac{\Delta\epsilon}{2} &= f\left(\frac{\Delta\sigma}{2}\right) \end{aligned} \quad (\text{EQ 21})$$

For example, for range  $\Delta S_{AB} = S_A - S_B$ , the first of these gives  $\Delta\epsilon_{AB}$ , and then the second gives  $\Delta\sigma_{AB}$ . Because point A was previously located, these fix point B for both the  $S$ - $\epsilon$  and  $\sigma$ - $\epsilon$  responses. In addition to the end points, Eq 21 can also be used to plot the entire load-strain and stress-strain paths as shown in Fig. 20, step 3.

However, it is also necessary to apply rainflow cycle counting while proceeding through the history. Whenever a rainflow cycle is completed, the memory effect acts, and closed loops are formed in both the  $S$ - $\epsilon$  and  $\sigma$ - $\epsilon$  responses. When a cycle is completed, the initial points of the ranges  $\Delta S$ ,  $\Delta\epsilon$ , and  $\Delta\sigma$  revert back to the peak or valley that applied prior to the beginning of the cycle. For example, when cycle B-C-B' is completed in Fig. 20, the range  $\Delta S_{AD}$  is used with Eq 21 to obtain  $\Delta\epsilon_{AD}$  and  $\Delta\sigma_{AD}$ , so that point D is located for both the  $S$ - $\epsilon$  and  $\sigma$ - $\epsilon$  responses.

The estimated stress-strain response is completely determined as this analysis proceeds. For the example of Fig. 20, the result is shown in Fig. 21. The stress-strain response consists of a set of closed stress-strain hysteresis loops, each of which corresponds to a rainflow cycle. For this example, the loops (cycles) correspond to load excursions B-C-B', F-G-F', E-H-E', and A-D-A'. Because stresses and strains are known for each peak and valley in the load history, the strain amplitude  $\epsilon_a$  and mean stress  $\sigma_m$  are available for each cycle. The corresponding number of cycles to failure  $N_f$  for each cycle is then available from either Eq 13 or 14. Alternatively,  $\epsilon_a$  and  $\sigma_{max}$  with Eq 15 also gives an  $N_f$  value. These  $N_f$  values and the P-M rule then give a life estimate. A numerical example of this type is given in Ref 1 (p 655-658).

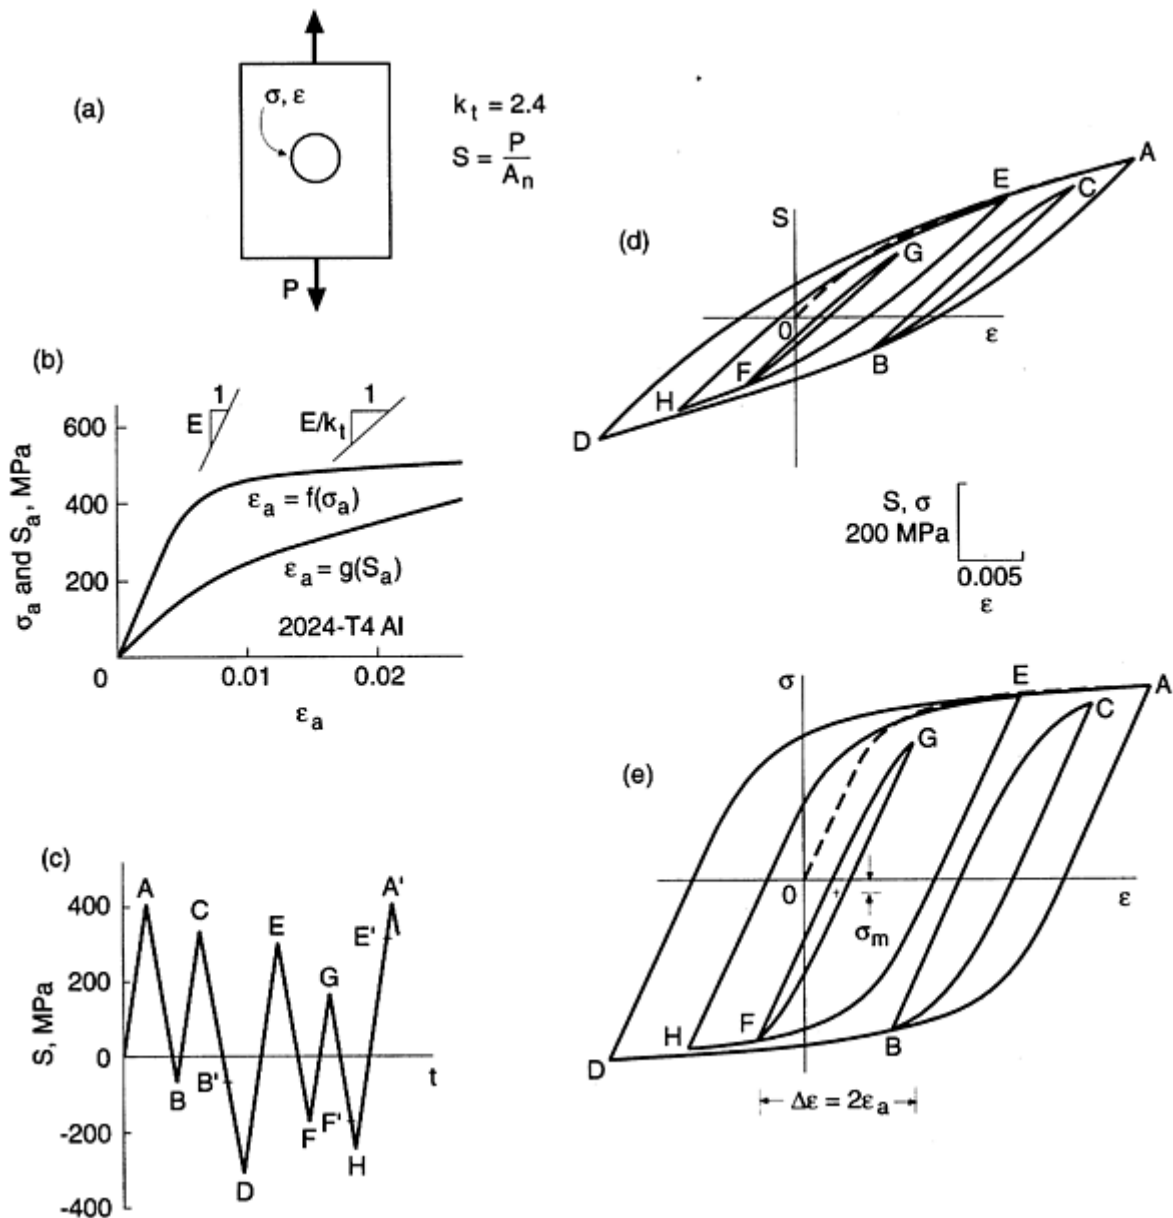

FIG. 21 ANALYSIS OF A NOTCHED MEMBER SUBJECTED TO AN IRREGULAR LOAD VERSUS TIME HISTORY. NOTCHED MEMBER (A), HAVING CYCLIC STRESS-STRAIN AND LOAD-STRAIN CURVES AS IN (B), IS SUBJECTED TO LOAD HISTORY (C). THE RESULTING LOAD VERSUS NOTCH STRAIN RESPONSE IS SHOWN IN (D), AND THE LOCAL STRESS-STRAIN RESPONSE AT THE NOTCH IN (E). ADAPTED FROM REF 13

**Simplified Approach.** The procedure just described assumes that the load history is known as a list of peaks and valleys in order. However, in some cases the only information available is the result of rainflow-cycle counting of the load history in the form of a range-mean matrix, as in Fig. 11. Some of the detailed knowledge of the load history has thus been lost. In such a situation, it is possible to perform a simplified strain-based analysis that determines upper and lower bounds on life for all possible sequences of loading giving a particular rainflow matrix.

This is done by noting that the load-strain and stress-strain loops for all cycles cannot lie outside of the loops for the largest cycle. For example, in Fig. 21,  $S$ - $\epsilon$  and  $\sigma$ - $\epsilon$  loops F-G must lie inside loops A-D. This is shown in Fig. 22. Also, a similar limitation applies to  $S$ - $\sigma$  loops as also shown. This situation and the known values of  $S$  from cycle counting place bounds on the mean stress of each cycle, such as  $\sigma_{mQ}$  and  $\sigma_{mP}$  for loop F-G in Fig. 22. If the worst case (most tensile)

mean stresses for all cycles are employed in a life calculation, a lower bound on life is obtained. Similarly, the best case mean stresses give an upper bound on life.

FIG. 22 SIMPLIFIED PROCEDURE THAT PLACES BOUNDS ON THE MEAN STRESS EFFECT. FOR CYCLE F-G OF FIG. 21, THE MEAN STRESS MUST LIE BETWEEN THE VALUES  $\sigma_{mP}$  AND  $\sigma_{mQ}$ . ADAPTED FROM REF 13

The example load history of Fig. 11 was analyzed in this manner for a particular steel and notched member as shown in Fig. 23. Various scale factors were applied to the load history to generate an entire  $S-N$  curve. The indicated comparison with test data is reasonable. Also, the bounds are quite close at all load levels, which is generally the case for irregular load histories. (The special situation of Fig. 15 would, however, give a wide separation between the upper and lower bounds.) A more detailed description of the procedure for making such a bounded analysis is given in Ref 1, and further details and test data are given in Ref 13.

FIG. 23 MAXIMUM NOMINAL STRESS VERSUS THE NUMBER OF REPETITIONS TO CRACKING, FOR REPEATED APPLICATION OF THE SAE TRANSMISSION HISTORY OF FIG. 11 TO THE NOTCHED MEMBER AND MATERIAL INDICATED. ADAPTED FROM REF 12 WITH DATA FROM REF 11

### Comparison of Methods

The stress-based and strain-based approaches are discussed and compared below, with some comments on their manner of use and limitations.

**Discussion of Stress-Based Approach.** The stress-based approach is most applicable when  $S-N$  curves are available for actual components, or for component-like test members. Component  $S-N$  curves have the major advantage of automatically including effects such as surface finish, residual stresses, weld geometry and metallurgy, and frictional surface contact in joints. The effects of such factors are otherwise generally difficult to include in fatigue life estimates. A major disadvantage is that mean stress effects based on nominal stress may be in error due to sequence effects related to the local notch mean stress actually being the controlling variable (see Fig. 15). Hence, caution is needed for load histories that might cause harmful local notch mean stresses that are not properly analyzed by this approach.

Now consider use of a stress-based approach where no fatigue data are available for the component or for component-like geometries, so that an estimated  $S-N$  curve must be relied upon. The estimate of the fatigue limit and the various related reduction factors, and also  $k_f$ , are based on empirical data. However, the data are fragmentary, and some of the mechanical design books use empirical factors that were developed many years ago. Furthermore, the data used to originally develop these factors are in some areas limited to steels, and where nonferrous metals are included, the data are generally less extensive. An additional concern is that the multiplicative combination of the various reduction factors, as in Eq 4, is basically an assumption that has never been adequately verified. The overall effect of this situation is that estimates of the fatigue limit stress should be considered to be rough estimates only, especially for nonferrous metals. Also, analogous procedures for nonmetals are simply not available.

Consider the estimation of  $S-N$  curves in the intermediate and low-cycle region, as described previously based on Fig. 5. Here, the estimates are extraordinarily crude, as evidenced by large inconsistencies among various mechanical design books. For example, for axial loading, the use at  $10^3$  cycles of  $k'_f = k_f$  and  $m' = 0.75$  by Juvinall (Ref 4) is generally excessively conservative for ductile metals. This differs drastically from the use of  $k'_f = 1$  and  $m' = 0.9$  by Shigley (Ref 5), which may sometimes produce a nonconservative estimate.

Given the tenuous nature of estimated  $S-N$  curves, their use should either be abandoned, or recent and new fatigue data need to be employed to fill in gaps and to refine and extend the estimates.

**Comparison of the Stress- and Strain-Based Approaches.** The strain-based approach has the major advantage compared with any form of stress-based approach of rationally accounting for mean stresses based on local notch stresses. However, in fairness to the Juvinall book (Ref 4), it will be noted that local mean stresses are indeed estimated there based on an elastic, perfectly plastic stress-strain curve using the monotonic yield strength. In Juvinall, this approach is applied only to constant amplitude loading, but it could be logically extended to the variable amplitude case. The altered yield strength caused by cyclic hardening or softening, as reflected in the cyclic stress-strain curve, would still not be included, however.

Comparing the strain-based approach with estimated  $S-N$  curves, it is significant that the crude factors used at intermediate and short life, such as  $k'_f$  and  $m'$  at  $10^3$  cycles, are entirely unnecessary in a strain-based approach. These arise primarily from plasticity and notch effects, and the interaction of these, which is handled in a fairly rigorous manner in the strain-based approach through the use of a load-strain curve,  $\epsilon = g(S)$ . Although approximate methods such as Neuber's rule are often used for notched members to obtain  $\epsilon = g(S)$ , this can be more precisely determined from elasto-plastic finite element analysis or strain measurements. Also, cyclic yielding of unnotched members in bending or torsion can be analyzed, using the cyclic stress-strain curve to obtain  $\epsilon = g(S)$ , so that such cases are also included in the strain-based approach. (See Sections 13.2 and 13.4 in Ref 1.)

**Additional Discussion of the Strain-Based Approach.** In the descriptions earlier in this article, notch strain estimates are described that employ Neuber's rule used with the elastic stress concentration factor,  $k_t$ . However, this is often replaced by  $k_f$ , the fatigue notch factor, as in the previous article in this Volume. Such an additional empirical adjustment may improve accuracy in some cases. As discussed in Ref 1, 24, and 25, the need for a  $k_t$  to  $k_f$  adjustment is thought to be primarily caused by crack growth effects. On this basis, it is the author's opinion that it is preferable to use  $k_t$  in estimating the crack initiation life.

The  $k_t$  to  $k_f$  adjustment will be significant primarily for cases of sharp notches, where cracks are likely to start early, so that crack growth dominates the life. Hence, an alternative to using  $k_f$  is to use  $k_t$  to estimate the crack initiation life, and then fracture mechanics to estimate the crack growth life, so that the total life is obtained. See Ref 25 and also Ref 1 (pp 665-666) for selecting initial crack length for the fracture mechanics part of this analysis.

Recall that estimated  $S-N$  curves use adjustments as in Eq 4 for such factors as surface finish and size effect. It might appear at first that this represents an advantage of stress-based estimated  $S-N$  curves. However, such factors can also be applied to adjust strain-life curves. For example, because surface finish effects act primarily at long life, the exponent  $b$  of Eq 10 can be altered based on a surface effect factor  $m_s$  to lower the strain-life curve in the long life region. (See Section 14.2.4 of Ref 1 for more detail.) A size-effect correction could also be similarly applied, but it is less clear that the adjustment should be confined to only the exponent  $b$ . As already mentioned, recent data need to be analyzed and new data obtained, to improve existing methods of empirically adjusting fatigue life curves.

The strain-based approach as described here is similar to current industrial practice and achieves relative simplicity by making compromises in some areas where greater sophistication is possible. Some of these areas are: 1) limitation to local yielding, 2) neglecting mean stress relaxation, and 3) lack of applicability to multiaxial nonproportional loading cases. These areas and some related work are discussed to an extent in Ref 1 (pp 560-563, 600-601, and 644-645, respectively). Concerning mean stress relaxation, it should be noted that the major effect of local notch yielding in altering the mean stress that would exist if there were no yielding is specifically analyzed by the strain-based approach, as illustrated by Fig. 19. What is neglected is the minor effect of subsequent adjustment of the mean stress after a number of cycles has elapsed.

The area of complex multiaxial loading cases, as in shafts under out-of-phase bending and torsion, is of considerable practical importance and represents the most significant limitation of the strain-based approach as described in this section. Research and trial industrial applications are currently underway toward developing a more general approach that addresses this area; see the next article in this Volume for detailed treatment of multiaxial loading.

**General Discussion on the Palmgren-Miner Rule.** In the preceding description, the simple P-M rule is retained, with specific actions taken as follows to avoid its shortcomings: First, use of rainflow-cycle counting or a similar method is necessary. Otherwise, difficulties in life prediction will be encountered that may appear to be due to the P-M rule. Second, sequence effects can be caused by local yielding at notches altering the local mean stress and thus affecting life. Such effects should be properly analyzed by a strain-based approach. Third, initial or occasional overloads may cause material-damage-related sequence effects. These should be included in life estimates by including them in the stress or strain versus life curve, as in Fig. 13 and 14.

In Ref 26, an approach termed the relative Miner rule is described. This consists essentially of adjusting the P-M rule (Eq 8) so that the sum of cycle ratios is a value other than unity. The adjusted value is obtained from limited data using a load history, stress level, and component geometry as close as possible to the actual application. This provides an empirical adjustment that can account for various uncertainties in life estimates, such as: (1) failure of a stress-based approach to properly handle sequence effects related to local mean stress, (2) material-damage-related sequence effects not otherwise addressed, (3) surface finish, residual stresses, and other fabrication-related details not otherwise accounted for, and (4) inaccuracies in strain-based analysis. The latter category might include the approximate nature of Neuber's rule, stress-relaxation effects, and inaccuracies in mean stress adjustments, as shown by Eq 13, 14, and 15. The relative Miner rule thus has considerable merit. See Ref 26 and other work by the same authors for more details.

**Welded members** comprise a category that merits special comment. Life prediction is complicated by the geometric and metallurgical complexity and variability involved, by the usual presence of complex residual stress fields, and by the frequent presence of initial cracklike flaws. As a result, component  $S-N$  data and a stress-based approach are often used. The strain-based approach is difficult to apply except where welds have well-defined geometry and are of very high quality, that is, relatively free of cracklike flaws. An alternative is to use a fracture mechanics approach based on growth of the weld flaws as cracks. Some success in dealing with the complexities involved through a fracture mechanics approach is demonstrated in Ref 27. Weldment fatigue is also addressed specifically in several articles in this Handbook.

## Multiaxial Fatigue Strength

David L. McDowell, Georgia Institute of Technology

---

### Introduction

MOST ENGINEERING DESIGNS and/or failure analyses involve three-dimensional combinations of stress and strain (multiaxiality) in the vicinity of surfaces and notches, which can be limiting in fatigue applications. This article briefly reviews the state-of-the-art of fatigue correlations for such combined stress states. Basic definitions of multiaxial effective stresses and strains and differences between proportional and nonproportional loading are first introduced to facilitate discussion of various correlating parameters. Some basic correlations for multiaxial fatigue also are presented.

Fatigue crack "initiation" parameters are reviewed, ranging from simple effective stress and strain concepts to more recent critical plane theories. This approach is considered as distinct from fracture mechanics approaches in view of the difficulties in applying the latter to small cracks in rigorous fashion. Typical experimental observations of formation and propagation of small fatigue cracks are considered under various stress states, and the relation to long crack fracture mixed-mode fracture mechanics is explored. Differences between low-cycle fatigue (LCF) and high-cycle fatigue (HCF) behaviors are discussed. Stage I crystallographic and stage II normal stress-dominated growth of microcracks are discussed, along with some observations regarding the influence of combined stress state on the propagation of small cracks.

Finally, several other features of multiaxial fatigue are discussed, including mean stress effects, sequences of stress/strain amplitude or stress state, nonproportional loading and cycle counting, and HCF fatigue limits.

This article also covers the formation and propagation of cracks on the order of several grain sizes in diameter, typically less than 1 mm in length, in initially isotropic, ductile structural alloys. The propagation of mechanically long cracks is not considered.

---

## Multiaxial Fatigue Strength

David L. McDowell, Georgia Institute of Technology

---

### Basic Definitions

The stress tensor,  $\sigma_{ij}$ , can be decomposed into hydrostatic and deviatoric components:

- *HYDROSTATIC STRESS*  $\equiv \sigma_H = \sigma_{KK}/3 = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3 = (\sigma_1 + \sigma_2 + \sigma_3)/3$
- *DEVIATORIC STRESS TENSOR*  $\equiv \sigma'_{IJ} = \sigma_{IJ} - \sigma_H \delta_{IJ}$  WHERE  $\delta_{IJ} = 1$  IF  $I = J$ , 0 IF  $I \neq J$

Here,  $\sigma_1$ ,  $\sigma_2$ , and  $\sigma_3$  are the three principal stresses. The octahedral shear stress is defined as the resolved shear stress on the  $\Pi$ -plane, the plane making equal angles with the three principal stress directions:

$$\tau_{\text{oct}} = \frac{1}{3} \sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_1 - \sigma_3)^2 + (\sigma_2 - \sigma_3)^2} \quad (\text{EQ 1})$$

**Strain Tensor.** Likewise, the strain tensor,  $\epsilon_{ij}$ , is decomposed into a hydrostatic (dilatation) component and a deviatoric part such that:

- **DILATATION**  $\equiv \varepsilon_{KK} = \varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33} = \varepsilon_1 + \varepsilon_2 + \varepsilon_3 = \Delta V/V_0$  FOR SMALL STRAIN, WHERE  $\varepsilon_1$ ,  $\varepsilon_2$ , AND  $\varepsilon_3$  ARE THE THREE PRINCIPAL STRAINS,  $\Delta V$  IS THE VOLUME CHANGE, AND  $V_0$  IS THE INITIAL, REFERENCE VOLUME.
- **DEVIATORIC STRAIN TENSOR**  $\equiv \varepsilon_{IJ}' = \varepsilon_{IJ} - (\varepsilon_{KK}/3)\delta_{IJ}$

The octahedral shear strain may be written as:

$$\gamma_{\text{oct}} = \frac{2}{3} \sqrt{(\varepsilon_1 - \varepsilon_2)^2 + (\varepsilon_1 - \varepsilon_3)^2 + (\varepsilon_2 - \varepsilon_3)^2} \quad (\text{EQ 2})$$

The Scalar Quantities  $\tau_{\text{oct}}$  and  $\gamma_{\text{oct}}$  are considered as equivalent shear quantities for a multiaxial stress/strain state. Alternatively, we may consider the maximum shear stress and strain quantities acting on at most three mutually orthogonal sets of planes that intersect the principal stress/strain axes at 45°:

$$\tau_{\text{max}} = \max_{i,j} \left| \frac{\sigma_i - \sigma_j}{2} \right| \quad (\text{EQ 3})$$

$$\frac{\gamma_{\text{max}}}{2} = \max_{i,j} \left| \frac{\varepsilon_i - \varepsilon_j}{2} \right|, \quad \frac{\gamma_{\text{max}}^p}{2} = \max_{i,j} \left| \frac{\varepsilon_i^p - \varepsilon_j^p}{2} \right| \quad (\text{EQ 4})$$

Both the maximum shear and the octahedral shear quantities are defined for planes with specific orientation with respect to the applied stress/strain state. For proportional loading, all principal stresses change in proportion, so the plane of maximum shear stress remains fixed in orientation. In this case, the expression in Eq 3 holds for the amplitude for maximum shear stress when the amplitudes of principal stresses are substituted. Similarly, for proportional straining, Eq 4 holds when amplitudes are substituted.

In classical theories of yielding of initially isotropic, ductile metals, it is common practice to consider  $\tau_{\text{oct}}$  and  $\gamma_{\text{oct}}$  or  $\tau_{\text{max}}$  and  $\gamma_{\text{max}}$  as conjugate scalar pairs that reflect the intensity of the combined stress/strain state. Yielding is assumed to occur when  $\tau_{\text{max}}$  (Tresca theory) or  $\tau_{\text{oct}}$  (Von Mises or distortion energy theory) reaches some critical value. The Rankine failure criterion  $\sigma_1 = \sigma_{\text{critical}}$  is often applied as a failure criterion for brittle materials.

Uniaxial test data are usually available. In the case of the octahedral shear parameters, the uniaxial equivalent stress and strain quantities are defined as:

$$\bar{\sigma} = \frac{1}{\sqrt{2}} \sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_1 - \sigma_3)^2 + (\sigma_2 - \sigma_3)^2} \quad (\text{EQ 5})$$

Likewise, if  $\sigma_1 \geq \sigma_2 \geq \sigma_3$  and  $\varepsilon_1 \geq \varepsilon_2 \geq \varepsilon_3$ , the uniaxial effective stress and strain quantities based on the maximum shear parameters are defined as:

$$\bar{\varepsilon} = \frac{\sqrt{(\varepsilon_1 - \varepsilon_2)^2 + (\varepsilon_1 - \varepsilon_3)^2 + (\varepsilon_2 - \varepsilon_3)^2}}{\sqrt{2} (1 + \nu)} \quad (\text{EQ 6})$$

$$\begin{aligned} \bar{\varepsilon}^p &= \frac{1}{\sqrt{2}} \gamma_{\text{oct}}^p = \sqrt{\frac{2}{3} [(\varepsilon_1^p)^2 + (\varepsilon_2^p)^2 + (\varepsilon_3^p)^2]} \\ &= \sqrt{\frac{2}{3} \varepsilon_i^p \varepsilon_j^p} \end{aligned} \quad (\text{EQ 7})$$

$$\sigma_{\text{EFF}} = 2\tau_{\text{MAX}} = \sigma_1 - \sigma_3 \quad (\text{EQ 8})$$

$$\epsilon_{\text{eff}} = \frac{\gamma_{\text{max}}}{(1 + \nu)} = \frac{\epsilon_1 - \epsilon_3}{(1 + \nu)} \quad (\text{EQ 9})$$

$$\epsilon_{\text{eff}}^p = \frac{2}{3}\gamma_{\text{max}}^p = \frac{2}{3}(\epsilon_1^p - \epsilon_3^p)$$

The effective Poisson's ratio,  $\nu$ , ranges from approximately 0.3 under fully elastic conditions to 0.5 for the fully plastic case.

**Proportional and Nonproportional Loading.** An important consideration for cyclic deformation and fatigue is whether the axes of principal axes of strain (stress) are fixed with respect to the material. If this is the case, the straining (stressing) is considered as proportional, and the components of the stress or strain tensors increase or decrease in constant proportion. Consequently, the octahedral shear plane and planes of maximum shear remain fixed in orientation as well. In terms of cyclic deformation, proportional loading is often considered as equivalent to uniaxial loading on the basis of effective stress and strain. But there are important differences in the formation and propagation of small fatigue cracks among different stress states, even for proportional loading. In uniaxial straining there are an infinite number of octahedral and maximum shear planes making equal angles with the axis of tension-compression loading. In contrast, pure torsion may be identified with a single set of octahedral or maximum shear planes. Moreover, the normal stress and strain amplitudes to these planes differ between uniaxial and shear cases, and among other states of stress as well.

Estimation of the elastic-plastic deformation under nonproportional loading requires the use of incremental cyclic plasticity theory, in general (Ref 1, 2, 3). The principal axes of stress or strain may remain fixed in direction with the components varying nonproportionally, or more generally the principal axes may rotate.

## Multiaxial Fatigue Strength

David L. McDowell, Georgia Institute of Technology

---

## Correlating Parameters for Multiaxial Fatigue

The subject of multiaxial fatigue has developed over many decades. More complete reviews of the historical development may be found in several recent reviews (Ref 4, 5, 6). Here it is understood that the fatigue crack initiation life,  $N_f$ , corresponds to a crack length on the order of 500 to 1000  $\mu\text{m}$ .

**Static Yield Criteria.** Initial approaches to modeling multiaxial fatigue behavior were based on static yield criteria developed a century ago, as discussed in the previous section. These approaches have been widely used in multiaxial fatigue design, as evidenced by various present-day standards, codes, and design textbooks. Due to their use in plasticity theory,  $\tau_{\text{oct}}$  and  $\gamma_{\text{oct}}$  or  $\tau_{\text{max}}$  and  $\gamma_{\text{max}}$  have been historically employed in fatigue correlations for small cyclic plastic strains of ductile metals. It is assumed that results for different combined stress states should collapse onto one *universal* curve, provided the loading is completely reversed and proportional in nature. Unfortunately, effective stress and strain approaches do not generally correlate fatigue behavior under various stress states such as uniaxial, torsion, and equibiaxial in-plane loading. A typical example appears in Fig. 1, which demonstrates differences between the correlation

of uniaxial fatigue data and torsional fatigue data for smooth specimens based on effective strain range. Torsional loading typically exhibits a much longer life than uniaxial loading for a surface crack length on the order of 1 mm for a given effective strain amplitude. Detailed studies by Socie and colleagues (Ref 6, 7, 8, 9) have clearly demonstrated that significant differences exist in the growth of small cracks among various stress states.

**FIG. 1 CORRELATION OF EFFECTIVE STRAIN AMPLITUDE VERSUS  $N_f$  FOR AXIAL AND TORSIONAL FATIGUE OF HAYNES 188 COBALT-BASE ALLOY AT 760 °C. NOTE THAT THE TORSIONAL DATA ARE SHIFTED TO THE RIGHT. SOURCE: REF 19.**

Haigh (Ref 10) recognized that effective stress was inadequate to correlate multiaxial HCF. Gough et al. (Ref 11, 12) showed that effective stress amplitude was insufficient to correlate HCF under combined bending and torsion, and they introduced the ellipse quadrant and ellipse arc concepts for ductile and brittle materials, respectively. An historically common form that has been used to distinguish fatigue crack initiation behavior among stress states is given by:

$$\bar{\sigma}_A + G(\sigma_H) = C \quad (\text{EQ 10})$$

where  $C$  is a constant for a given fatigue life, subscript "a" denotes amplitude, and  $\sigma_h$  denotes either the amplitude or mean value of hydrostatic stress over a cycle. Sines (Ref 13) proposed a form in which  $g$  is linear in the mean value of  $\sigma_h$  over a cycle. Fuchs (Ref 14) generalized this approach for nonproportional loading. The function  $g(\sigma_h)$  may be interpreted as introducing the effect of mean normal stress on the formation of fatigue cracks. Equation 10 is recognized to be related to a Mohr theory of rupture that augments frictional failure processes with the dependence on normal stress.

**Correlation Based on Triaxiality Factor.** Liberty (Ref 15) introduced the dependence of LCF on  $\sigma_h$  as well. The triaxiality factor ( $TF = \sigma_{kk} / \bar{\sigma}$ ) based on either the amplitude or mean value of these quantities, has been introduced by Davis and Connelly (Ref 16) for ductility reduction due to triaxiality. It was later employed by Manjoine (Ref 17) and others to describe constraint effects in fracture that are not fully correlated by the amplitude of the crack tip singularity. This parameter has been employed by Manson and Halford (Ref 18), Zamrik et al. (Ref 19), and others to reflect the dependence of fatigue crack initiation on combined stress state for a wide range of HCF and LCF conditions. Note that  $TF = 0$  for torsion, 1 for uniaxial loading, and 2 for in-phase, equibiaxial loading. Typical behavior is exhibited by Haynes 188 cobalt-base alloy at 760 °C (Ref 19), as shown in Fig. 1. Use of the triaxiality factor offers somewhat improved correlation of uniaxial and torsional fatigue data (Ref 19) in terms of the following strain-life relation:

$$\begin{aligned}\frac{\Delta \bar{\epsilon}^t}{2} &= \frac{\Delta \bar{\epsilon}^e}{2} + \frac{\Delta \bar{\epsilon}^p}{2} \\ &= Z^{1-TF} \frac{\sigma_f'}{E} (2N_f)^b + \Lambda^{1-TF} \epsilon_f' (2N_f)^c\end{aligned}\quad (\text{EQ 11})$$

where

$$Z = \frac{3}{2(1 + \nu_e)} \frac{\tau_f'}{G} \frac{E}{\sigma_f'} \frac{\epsilon_f'}{\gamma_f'} \quad (\text{EQ 12})$$

and  $\Lambda$  is a ductility parameter ( $\Lambda \approx 2$ ). The elastic Poisson's ratio is given by  $\nu_e$ , while  $E$  and  $G$  are the Young's modulus and shear modulus, respectively, and  $\tau_f'$  and  $\gamma_f'$  are the coefficients in a pure torsion strain-life relation analogous to the right-hand side of the uniaxial equivalent form in Eq 11. Both LCF and HCF (finite life) regimes are addressed.

**Correlation Based on Cyclic Hysteresis Energy.** Another method correlates cyclic hysteresis energy with the number of cycles to crack initiation (Ref 20, 21, 22, 23, 24). For example, Garud (Ref 21) applied this approach in conjunction with incremental plasticity theory to predict the fatigue crack initiation life under complex nonproportional multiaxial loading conditions. As shown in Fig. 2 for 1% Cr-Mo-V steel, the approach does not typically correlate both the uniaxial and torsional fatigue cases, even for completely reversed loading (no mean stress). Garud suggested differential weighting of the contribution of shear components to the hysteresis energy relative to the normal components in order to account for these differences. To effectively collapse uniaxial and torsional data, Ellyin and Kujawski (Ref 24) introduced explicit dependence on mean stress and stress state in the hysteresis energy parameter

$$\frac{\Delta W_d / h(\sigma_m)}{f(\bar{\rho})} = P(2N_f) \quad (\text{EQ 13})$$

where  $\Delta W_d$  is the area under the effective stress/strain hysteresis loop (both elastic and plastic parts),  $\sigma_m$  is the mean value of  $\sigma_{kk}$  over the cycle, and  $\bar{\rho}$  is a constraint factor, defined by  $(1 + \nu) \hat{\epsilon}_{\max} / \hat{\gamma}_{\max}$ , where  $\hat{\epsilon}_{\max}$  is the maximum principal strain in the surface plane and  $\hat{\gamma}_{\max}$  is the maximum shear strain on a plane that intersects the free surface at  $45^\circ$ . Similar to effective stress or strain approaches, hysteresis energy approaches do not infer specific orientations or planes of microcracking.

FIG. 2 CORRELATION OF PLASTIC HYSTERESIS ENERGY VERSUS  $N_f$  FOR 1% CR-MO-V AT 20 °C IN THE LCF RANGE. TORSIONAL DATA ARE SHIFTED TO THE RIGHT. SOURCE: REF 21

**Critical Plane Theories.** Another class of approaches, called "critical plane theories," devote specific attention to the orientation of small cracks in multiaxial fatigue. These theories assert that the most critically damaged plane is one of maximum shear stress or strain amplitude that experiences the maximum normal strain and/or normal stress. These critical plane theories were preceded by some 20 to 30 years by the HCF theories of Stulen and Cummings (Ref 25), Guest (Ref 26) and Findley (Ref 27), which augmented the maximum shear stress amplitude with an additive term involving the normal stress to the plane of maximum shear. Their approaches may be summarized as:

$$\frac{(\sigma_1 - \sigma_3)}{2} + F \left( \frac{(\sigma_1 + \sigma_3)}{2} \right) = G \quad (\text{EQ 14})$$

where  $F$  and  $G$  are constants for a given life and  $\sigma_1$  ( $\sigma_3$ ) is the value of the largest (smallest) peak principal stress. Equation 14 achieved satisfactory correlation of HCF strength under various stress states, predominantly verified under combined bending and torsion.

For proportional loading,  $(\sigma_1 + \sigma_3)/2$  is the amplitude of stress normal to the plane of maximum shear stress amplitude. It is commonly observed that small cracks in ductile polycrystals nucleate and grow early in life on crystallographic planes that are favorably aligned with the maximum shear stress or strain, defined as stage I fatigue crack propagation by Forsyth (Ref 28). Typically, small cracks propagate in this manner until reaching a length on the order of 3 to 10 grain diameters (Ref 29, 30), and then follow a macroscopic mode I path normal to the range of maximum principal stress. Hence, the second term in Eq 14 incorporates the assistance of tensile stress normal to the crack plane in opening the crack during shear-dominated growth early in life. For brittle materials that are more sensitive to normal stress to the maximum shear plane,  $F$  is relatively larger than for ductile materials. Of course, these global strain or stress parameters pertain to the polycrystalline average response and are somewhat loosely related to local driving forces at the crack tip. Nonetheless, they have demonstrated quantitative agreement with experimentally observed behaviors for a wide range of stress states.

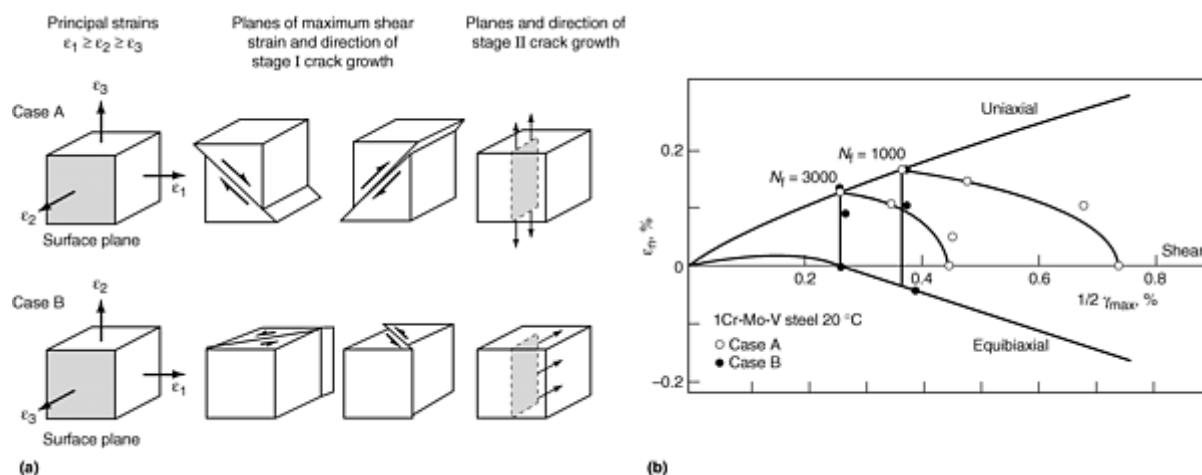

The HCF approach in Eq 14 is a predecessor of similar strain-based relations for stage I microcrack propagation along maximum shear strain amplitude planes under LCF conditions. Brown and Miller (Ref 31) introduced the so-called  $\Gamma$

plane approach, wherein the orientation of the maximum shear strain amplitude planes with respect to the free surface distinguishes two very different types of fatigue crack propagation behaviors, termed cases A and B. They defined a general relationship between the maximum shear strain amplitude,  $\Delta\gamma_{\max}/2$ , and the normal strain amplitude,  $\Delta\varepsilon_n/2$ , to the plane of maximum shear strain amplitude:

$$U_1 \left( \frac{\Delta\gamma_{\max}}{2} \right) = U_2 \left( \frac{\Delta\varepsilon_n}{2} \right) \quad (\text{EQ 15})$$

for a given fatigue crack initiation life, where  $U_1$  and  $U_2$  are nonlinear functions of their arguments. Equation 15 assumes different forms for cases A and B, which are defined by the orientation of maximum shear strain range planes relative to the surface, as shown in Fig. 3(a). The case for which vectors normal to the maximum shear strain amplitude planes lie within the specimen surface is termed case A. Case B is defined by the intersection of the maximum shear strain range planes with the surface. Typical experimental data are plotted in the so-called  $\Gamma$  plane in Fig. 3(b). In some cases, the case B contours are approximately described by  $U_2 = 0$ , although this is not a general relation. In case A, the functions  $U_1$  and  $U_2$  are approximately quadratic in their arguments for ductile metals. This approach has successfully correlated tension-torsion and tension-tension experiments for completely reversed proportional loading. Lohr and Ellison (Ref 32) introduced a slight variation of this approach that considered case B planes to be always more damaging, even if they are not the planes of maximum shear strain range.

**FIG. 3 (A) DISTINCTION BETWEEN CASE A AND B CYCLIC STRAIN STATES. (B) TYPICAL CONTOURS OF COMPLETELY REVERSED FATIGUE CRACK INITIATION DATA FOR 1% CR-MO-V AT 20 °C IN THE  $\Gamma$  PLANE, WHERE  $\gamma_{\max}$  AND  $\varepsilon_n$  REPRESENT AMPLITUDES OF MAXIMUM SHEAR STRAIN AND NORMAL STRAIN TO THIS PLANE FOR EACH CASE. SOURCE: REF 5**

Experiments on thin-walled tubular specimens involving combined axial loading and cyclic internal/external pressure may be used to apply a range of shear strain combined with static mean normal stresses during a cycle. Critical experiments reported by Socie (Ref 6) have shown for several ductile alloys that: (a) augmentation of a maximum shear strain parameter by only hydrostatic stress is insufficient to describe orientations of fatigue cracking that are consistently observed in multiaxial experiments; and (b) even under LCF conditions, the normal stress to the plane of maximum shear strain range plays an important role in delineating the failure plane and correlating mean stress effects. On the basis of observations of the formation and growth of small cracks, Socie (Ref 6, 8) distinguishes between materials that exhibit prolonged stage I propagation behavior along maximum shear planes ("shear dominated") and those that transition at very small crack lengths to stage II ("normal stress-dominated") propagation. Socie has argued that additional effects of the mean normal strain and stress to the plane of maximum shear strain range may be used to augment maximum shear strain amplitude to correlate shear-dominated fatigue behavior.

Fatemi and Socie (Ref 33) and Fatemi and Kurath (Ref 34) have demonstrated robust correlation of fatigue under various stress states for both case A and case B histories with and without mean stress, based on the assumption that peak normal

stress to the plane of maximum range of shear strain directly affects the stage I shear-dominated propagation of small cracks. They proposed the correlative parameter

$$\frac{\Delta\gamma_{\max}}{2} \left[ 1 + K \frac{\sigma_n^{\max}}{\sigma_y} \right] = f_f(N_f) \quad (\text{EQ 16})$$

where  $K$  is a constant,  $\sigma_n^{\max}$  is the maximum normal stress to the plane of maximum shear strain range, and  $\sigma_y$  is the yield stress. Figure 4 presents multiaxial fatigue correlations for both Inconel 718 and 1045 steel with this parameter (Ref 35), typically within a factor of 2 in fatigue life. Furthermore, Socie (Ref 6) has shown that the orientation of microcracking follows the plane(s) of the maximum value of this parameter. Most of the correlations obtained to date pertain to LCF or transition fatigue, rather than HCF. However, the analogy to the HCF relation in Eq 14 suggests more general applicability, at least in the absence of a fatigue limit. Socie (Ref 8) has proposed a Smith-Watson-Topper (Ref 36) generalization for normal-stress dominated materials, which may be associated with an early transition to stage II fatigue crack propagation.

## Small Crack Growth in Multiaxial Fatigue

Crack nucleation processes, as discussed elsewhere in this Volume, are associated with the generation and coalescence of excess vacancies along persistent slip bands (Ref 37, 38, 39) in ductile single crystals or coarse grain polycrystals. In polycrystals, cracks may nucleate via fracture during processing (Ref 37) at intersecting slip bands (or twin) or by blockage of a slip band (or twin) by second-phase particles. A second type of microcracking in polycrystals occurs along grain boundaries due to impurity embrittlement or the presence of voids. Sometimes microcracking in polycrystals occurs at strong grain boundaries due to heterogeneous plastic deformation, governed by the degree of misorientation at the grain boundary, usually associated with a mixed mode of intercrystalline-transcrystalline fracture. These nucleation processes become increasingly dominant at very long lives in materials with minimal processing defects. We focus here on the growth of small cracks in fatigue rather than the nucleation problem. Clearly, propagation of small cracks is an important aspect of the "initiation" of a fatigue crack on the order of 1 mm.

**Characteristics of Small Fatigue Cracks.** Mixed-mode fatigue crack propagation studies have largely focused on the behavior of mechanically long cracks. The problem of the growth of small cracks in fatigue (from lengths on the order of 1 to 500-1000  $\mu\text{m}$ ) has received increased attention. Cracks are considered to be small when all pertinent dimensions are small compared to some characteristic length scale. In the case of microstructurally small cracks, the length scale is on the order of the dimensions of microstructural periodicity (e.g., grain diameter). For physically or mechanically small cracks, it is typically on the order of 5 to 10 times the microstructural scale. Attempting to develop a correlation between  $da/dN$  and  $\Delta K$ , as in the case of mechanically long cracks, the so-called anomalous behavior of microstructurally small cracks has been widely demonstrated. In particular, the cyclic crack growth rate of small cracks may significantly exceed that of long cracks at the same level of  $\Delta K$ , as shown in Fig. 5. Considerable scatter of the fatigue crack growth rate of small cracks at a given  $\Delta K$  level is apparent. At low stress amplitudes (HCF), deceleration of crack growth is often observed, associated with a dip in the  $da/dN$  versus  $\Delta K$  behavior. Subsequently, crack growth may accelerate prior to merging with the long crack data. At sufficiently low amplitudes, small cracks may become arrested. As small cracks propagate, their  $da/dN$  versus  $\Delta K$  responses are typically observed to merge with the long crack response, as shown in Fig. 5.

**FIG. 5 TYPICAL PROPAGATION BEHAVIOR OF SMALL CRACKS. NOTE THAT  $DA/DN$  IS HIGHER FOR A GIVEN  $\Delta K$  THAN FOR LONG CRACKS, AND THE APPARENT SCATTER IN  $DA/DN$  IS SIGNIFICANT. THE BOTTOM DASHED LINE IS A LINEAR EXTENSION OF PARIS REGIME. SOURCE: REF 40**

Experimental observations indicate that the propagation behavior of microstructurally small and physically small cracks depends significantly on both the  $R$ -ratio and stress amplitude, in addition to stress state. Small crack behavior is subject to more scatter due to greater dependence on microstructure.

There are several prevalent explanations for the nonconformity of small/short crack behavior with that of mechanically long cracks:

- DIFFERENCES IN PLASTICITY-INDUCED CLOSURE TRANSIENTS RELATIVE TO LONG CRACKS
- MICROSTRUCTURAL ROUGHNESS-INDUCED CLOSURE/BRIDGING
- INTERACTION WITH MICROSTRUCTURAL FEATURES, THREE-DIMENSIONAL NONPLANAR GROWTH, AND PINNING EFFECTS
- VIOLATION OF VALIDITY LIMITS OF LINEAR ELASTIC FRACTURE MECHANICS (LEFM)

## OR ELASTIC-PLASTIC FRACTURE MECHANICS (EPFM) DUE TO LACK OF SELF-SIMILARITY OF GROWTH AND CYCLIC PLASTIC ZONE/PROCESS ZONE SIZE ON THE ORDER OF CRACK LENGTH

- INTENSIFICATION OF LOCAL DRIVING FORCES RELATIVE TO NOMINAL APPLIED STRESSES AND STRAINS DUE TO HETEROGENEITY AND ANISOTROPY OF CYCLIC SLIP IN THE VICINITY OF THE SMALL CRACK(S), IN ADDITION TO REDUCED CONSTRAINT DUE TO PROXIMITY OF THE FREE SURFACE
- LOCAL MIXED-MODE GROWTH FOR SMALL CRACKS, EVEN FOR REMOTE MODE I LOADING

Some of these factors are more influential at high stress amplitudes and others at low stress amplitudes, for a given  $R$ -ratio. As pointed out by Suresh (Ref 41), low-strain amplitudes (HCF) promote predominantly mode II crystallographic growth and a higher degree of microstructural roughness along the crack faces, leading to enhanced crack-tip shielding effects. Likewise, predominantly remote shear loading may promote quite different roughness-induced crack face interference, and so on. Relatively few of these aspects have been considered in detail for small cracks. For example, the treatment of plasticity-induced closure (e.g., Ref 42) typically assumes validity of LEFM or EPFM concepts, even for microstructurally small cracks, while neglecting microstructural roughness-induced closure/bridging or interaction with microstructural features. Even with this simplification, the application of plasticity-induced closure models requires considerable idealization. On the other hand, models that consider interaction with periodic microstructural barriers (e.g., Ref 43, 44, 45) typically do not consider closure or bridging effects, although they may recognize the lack of applicability of LEFM or EPFM for small cracks. Models for the growth of small cracks have largely been confined to simple uniaxial (mode I) loading conditions; formal treatment of multiaxial loading conditions within the fracture mechanics methodology is challenging in view of the plethora of mechanisms and "local mixity" (a term that represents the combination of different opening and sliding displacements at the crack tip, distinct from the remote loading history). This so-called "local mixity" arises from the nature of crystallographic propagation of stage I cracks. The range of validity of LEFM or EPFM concepts diminishes even further under multiaxial loading conditions.

The data in Fig. 6(a) and 6(b) clearly illustrate some important aspects of multiaxial fatigue crack growth for constant-amplitude loading of two ductile alloys in tension-compression and in torsion. The curved contours represent the locus of normalized cycles,  $N/N_f$ , to growth to a 0.1 mm surface crack, with  $N_f$  corresponding to the number of cycles of growth to a 1 mm surface crack. Regimes of shear-dominated growth (stage I) along maximum shear strain range planes and normal stress-dominated growth (stage II) normal to the range of maximum principal stress are shown. The curve representing the fraction of life to a 0.1 mm crack is termed "crack nucleation" in Fig. 6(a) and 6(b), but it actually reflects microcrack propagation to this length.

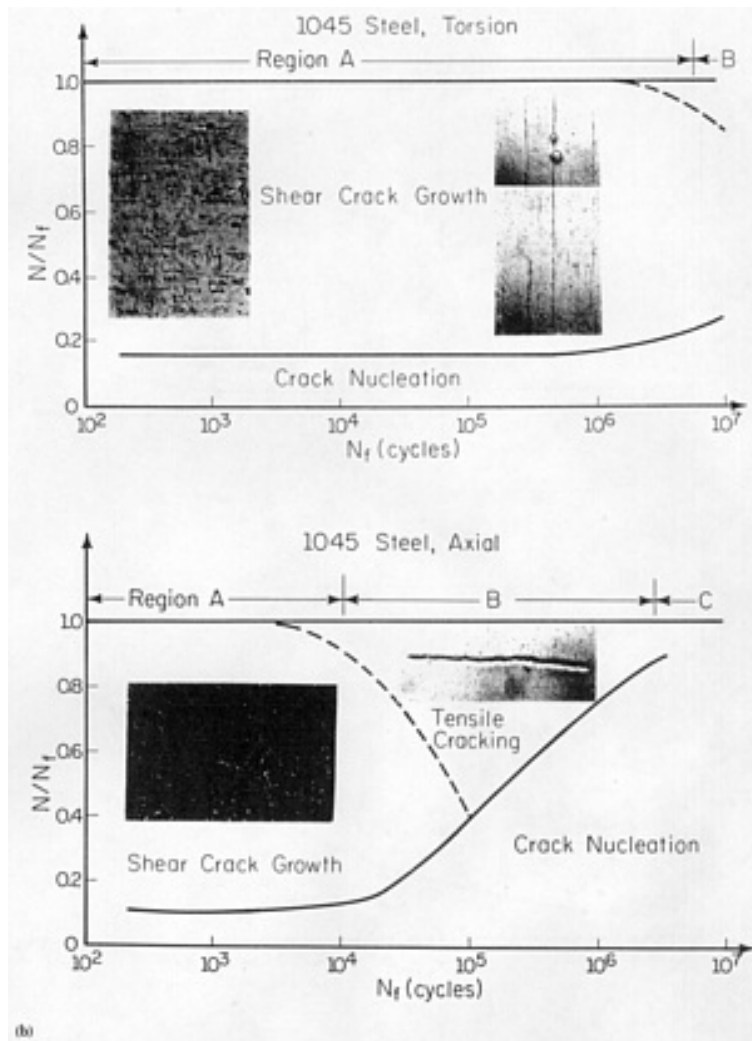

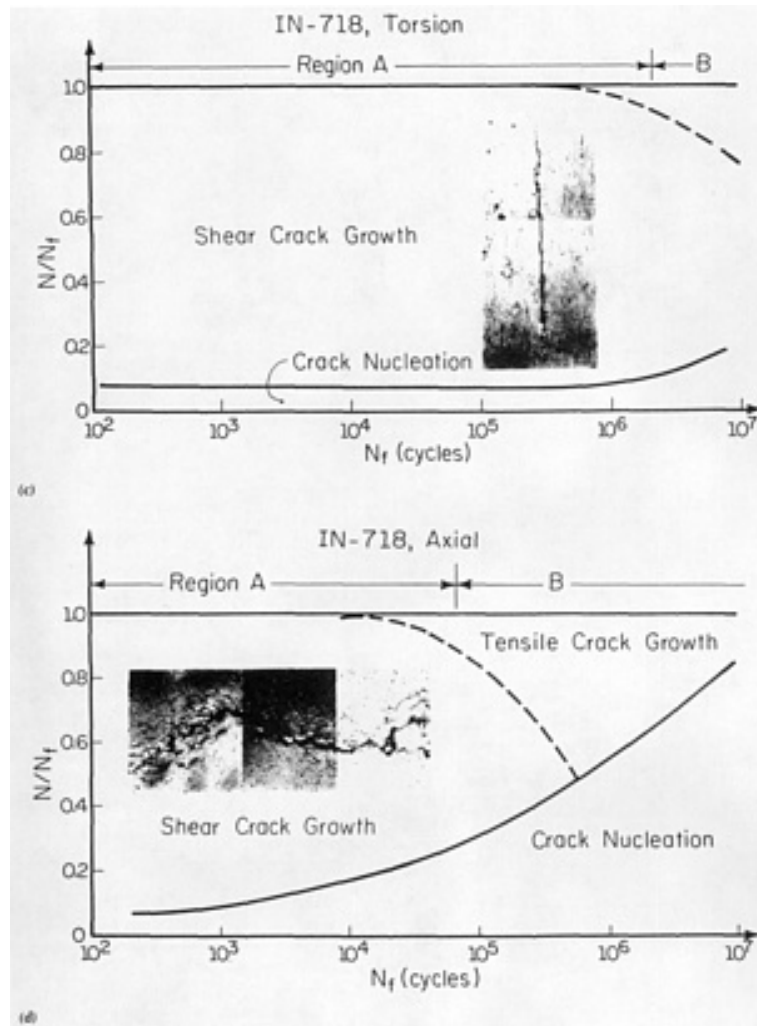

FIG. 6(A) DATA OF SOCIE ON 1045 STEEL FOR LIFE TO 0.1 MM AND 1 MM CRACKS ( $N/N_f = 1$ ) FOR TORSIONAL AND UNIAXIAL LOADING. SOURCE: REF 6

**FIG. 6(B) DATA OF SOCIE ON IN 718 FOR LIFE TO 0.1 MM AND 1 MM CRACKS ( $N/N_f = 1$ ) FOR TORSIONAL AND UNIAXIAL LOADING. SOURCE: REF 6**

The fraction of 1 mm crack life required for growth to a 0.1 mm crack is approximately 10% at high strain amplitudes (e.g., LCF) for both uniaxial and torsional fatigue. Assuming an initial crack size on the order of 10  $\mu\text{m}$ , these data suggest that crack propagation is only weakly dependent on crack length for high strain amplitudes. At increasing lives, the fraction of life spent in growing cracks less than 0.1 mm in length increases, to a much greater extent in uniaxial fatigue than in torsional fatigue. The fact that torsional fatigue exhibits a considerably lower ratio for a given  $N_f$  indicates that the differences reside in the crack propagation behavior. The crack growth behavior is quite nonlinear with respect to crack length for cracks shorter than 0.1mm under HCF conditions, particularly for uniaxial fatigue. This has important consequences in terms of the nonlinear growth behavior of small cracks and in terms of both amplitude and stress state sequence effects. Also, the point of departure from stage I shear-dominated crack growth to stage II normal stress-dominated growth occurs at higher strain amplitudes for uniaxial fatigue. Torsional fatigue appears to promote extended stage I behavior, perhaps associated with low symmetry slip (e.g., single slip) at the local level. Observations under uniaxial straining reveal that small cracks transition from transgranular stage I growth to stage II growth when the ratio of crack length to grain size is in the range of 3 to 10 (Ref 29, 30). The influence of microstructure is also observed to wane at some point during or somewhat after this transition. This transition crack length may also depend on stress state and stress amplitude; these issues are not yet fully resolved. It may be related to the balance of competing mode I and mode II growth mechanisms (Ref 8, 46). Some modeling efforts have been devoted to the role of grain boundary blockage and transmission of slip to adjacent grains (e.g., Ref 45) in defining this transition.

**J-Integral Correlations of Small Fatigue Cracks.** Long crack solutions based on the  $\Delta J$ -integral (Ref 47, 48, 49) have been employed to correlate the propagation of small/short cracks in fatigue. Although some correlations have been obtained under predominantly uniaxial LCF conditions (Ref 50, 51, 52), such treatments ignore the limits of applicability

of long crack solutions that assume homogeneity, isotropy, self-similarity, and a small ratio of cyclic plastic zone to crack length. It is essential to recognize the role of local mode mixity on crack growth. Although all three modes are operative (Ref 53), microstructurally sensitive small crack growth has often been idealized as mixed mode I-II as a reasonable approximation. Mode II is primary in stage I, whereas mode I dominates in stage II (Ref 53). There are presently no well-accepted criteria for mixed-mode stage I growth, and the data in Fig. 6(a) and 6(b) provide some insight into the complexities involved.

Hoshide and Socie (Ref 54) extended the elastic and plastic forms for the standard long crack  $J$ -integral of EPFM (Ref 55) to correlate combined mode I-II axial-torsional fatigue:

$$J = \pi \frac{(\sigma^2 + \tau^2)}{E} a_{eff} + \tilde{J}(n, \lambda_\sigma, \xi_\sigma) \bar{\sigma} \bar{\epsilon}^p a = J_e + J_p \quad (\text{EQ 17})$$

where  $a$  and  $a_{eff}$  are actual and effective crack lengths, and the stress biaxiality ratios are given by  $\lambda_\sigma = \tau/\sigma_{yy}$  and  $\xi_\sigma = \sigma_{xx}/\sigma_{yy}$ , where  $\tau$  and  $\sigma_{yy}$  are the far field shear and normal stresses, respectively, and  $\sigma_{xx}$  is the direct stress parallel to the crack. In general,  $J$  depends on the biaxiality ratios  $\lambda_\sigma$  and  $\xi_\sigma$  and on the strain hardening exponent,  $n$ . Self-similar crack extension is assumed. The growth law for mixed-mode proportional loading was assumed to follow

$$\frac{da}{dN} = \phi_I(\lambda_\sigma, \xi_\sigma) \Delta J^{M_I} + \phi_{II}(\lambda_\sigma, \xi_\sigma) \Delta J^{M_{II}} \quad (\text{EQ 18})$$

where  $\Delta J$  is generalized from Eq 17 by considering the range of stress and strain as in Ref 47, 48, 49. Exponents  $M_I$  and  $M_{II}$  are not equal, in general. Hoshide and Socie used an analogous formulation with  $M_I = M_{II}$  to correlate growth of fatigue cracks of length less than 1 mm in Inconel 718. They correlated the data with a growth law of the form

$$\frac{da}{dN} = C_J (\Delta J)^{M_J} \quad (\text{EQ 19})$$

where  $C_J$  and  $M_J$  depend on the biaxiality ratios. Exponent  $M_J$  varied from 1.31 to 1.45.

**Critical Plane Methods.** Socie et al. (Ref 7) and Berard et al. (Ref 56, 57) have shown that the simple bulk stress and strain range parameters used in critical-plane fatigue crack initiation laws serve to correlate the propagation rate of small cracks in multiaxial LCF. Some studies (Ref 30, 50, 51, 58) have shown that the growth of small cracks does not correlate with a crack length dependence of the  $\Delta J$ -integral of conventional EPFM. For HCF, this dependence differs significantly from that of LEFM (Ref 50). Departure from rigorous applicability of fracture mechanics approaches might be expected, particularly for nonplanar cracks with length on the order of microstructure.

McDowell and Berard (Ref 35) introduced an analogue of the  $\Delta J$ -integral approach to address the growth of small cracks along critical planes in multiaxial fatigue, addressing both case A and case B cracking. For multiaxial LCF, they proposed the law

$$\frac{da}{dN} = D_{am} C_p (1 + \mu\rho)^m (\beta_p(R_n) R_n + 1)^m \left( \frac{\Delta\tau_n}{2} \frac{\Delta\gamma_{max}^p}{2} \right)^m a^m \quad (\text{EQ 20})$$

where the constraint parameter is defined by:

$$\rho = \frac{\Delta\sigma_{kk}/2}{2\Delta\tau_n/2} - R_n \quad (\text{EQ 21})$$

and  $R_n = (\Delta\sigma_n/2)/(\Delta\tau_n/2)$ . Here,  $\sigma_n$  and  $\tau_n$  are the normal and shear stress, respectively, on the plane of maximum range of plastic shear strain. Parameter  $R_n$  varies from zero for completely reversed torsional fatigue to unity for uniaxial or biaxial loading conditions. Parameter  $\beta_p$  introduces dependence of the crack-tip fields and/or crack-tip opening and

sliding displacements on biaxiality. An additional dependence of the microcrack propagation rate on triaxiality is introduced via constraint parameter  $\rho$ , analogous to the  $TF$  factor in Eq 11. Inspection of Eq 20 reveals that this form is similar in nature to that of Eq 16, but the plastic hysteresis energy term  $\Delta\tau_n \Delta\gamma_{\max}^p$  (rather than  $\Delta\gamma_{\max}^p$ ) is weighted by the relative effect of the normal stress amplitude acting on the plane of maximum cyclic shear ( $R_n$ ). Constants  $\mu$  and  $m$  control the influence of constraint and nonlinearity of crack growth, and:

$$C_p = \text{MATH OMITTED} \quad (\text{EQ 22})$$

recovers the independent LCF Coffin-Manson and cyclic stress-plastic strain laws for completely reversed loading in torsional and uniaxial fatigue, respectively, given by:

$$\frac{\Delta\gamma^p}{2} = \gamma_f' (2N_f)^{c_0}, \quad \frac{\Delta\epsilon^p}{2} = \epsilon_f' (2N_f)^c \quad (\text{EQ 23})$$

$$\frac{\Delta\tau}{2} = K_0' \left( \frac{\Delta\gamma^p}{2} \right)^{n_0'}, \quad \frac{\Delta\sigma}{2} = K' \left( \frac{\Delta\epsilon^p}{2} \right)^{n'} \quad (\text{EQ 24})$$

with the additional prescriptions

$$\beta_p(R_n) = \left[ \frac{4 K_0' (\gamma_f')^{(1+n_0')}}{3 K' (\epsilon_f')^{(1+n')}} - 1 \right] (R_n)^{j_p} \quad (\text{EQ 25})$$

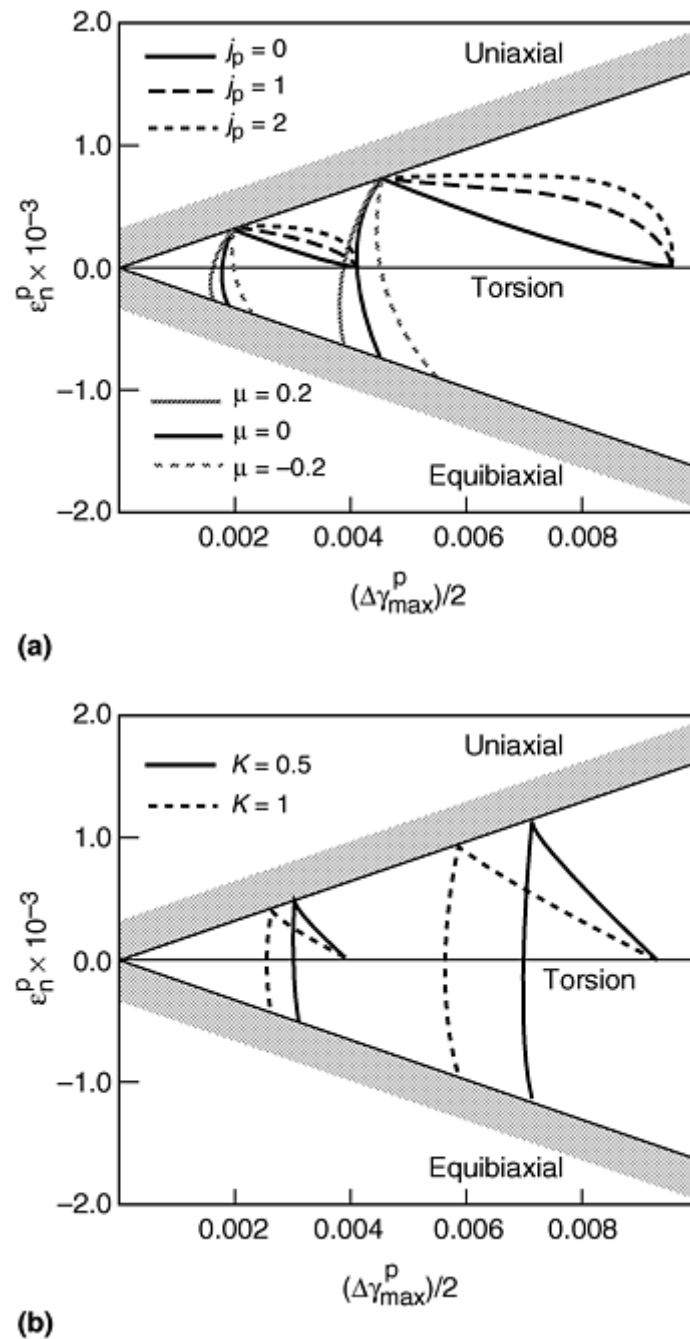

$$m = \frac{-1}{c(R_n) (1 + n'(R_n))} \quad (\text{EQ 26})$$

$$\begin{aligned} C(R_n) &= C_0 + R_n(C - C_0), \\ N'(R_n) &= N'_0 + R_n(N' - N'_0) \end{aligned} \quad (\text{EQ 27})$$

where  $j_p$  is a constant. Coefficient  $D_{am}$  is determined by integrating the expression for constant-amplitude loading conditions between given initial and final crack lengths:

$$D_{am} = 2 \int_{a_i}^{a_f} a^{-m} da \quad (\text{EQ 28})$$

Constant-life plots in the  $\Gamma$  plane for completely reversed LCF (plastic strain range much greater than elastic) loading conditions are shown in Fig. 7(a), based on Eq 20, for 1045 steel (Ref 35). Case A contours for several values of  $j_p$  are presented, along with several case B contours, which depend on the value of  $\mu$ . The overall shape of these case A and B contours is generally in agreement with the form of LCF experimental data (e.g., Fig. 3b). A similar plot for the Fatemi-Socie-Kurath parameter in Eq 16 appears in Fig. 7(b), also in qualitative agreement with data, albeit with less flexible treatment of the shape of the case A and B contours. Such plots form a convenient basis for quickly evaluating the potential of a proposed parameter to correlate both case A and B data, as outlined in Ref 35.

**FIG. 7  $\Gamma_p$  PLANE CONTOUR PLOTS FOR TWO DIFFERENT LOW-CYCLE FATIGUE LIVES PREDICTED BY THE (A) MCDOWELL-BERARD MODEL IN THE  $\Gamma_p$  PLANE FOR  $N = 0.15$  AND AN APPROXIMATE RATIO OF PLASTIC WORK TO FAILURE IN A TORSION TEST TO A TENSION TEST OF TWO, AND (B) THE FATEMI-SOCIE-KURATH MODEL CONTOURS IN THE  $\Gamma_p$  PLANE FOR  $N = 0.2$  AND  $K'/\sigma_Y = 3.5$ . SOURCE: REF 35**

A similar propagation law, consistent with Basquin's Law for uniaxial and torsional loading, was introduced by McDowell and Berard (Ref 35) for predominantly HCF conditions (finite life). The exponent on crack length differed significantly from the LCF case. By superimposing the resulting shear strain-life relations obtained by independent integration of the LCF and HCF relations, a maximum shear strain-life relation was developed to correlate the fatigue life to a crack of length 1 mm. As seen in Fig. 4, the McDowell-Berard method compares well with the Fatemi-Socie-Kurath approach in Eq 16 for completely reversed fatigue of the shear-dominated materials 1045 steel and Inconel 718 under various stress states, ranging from torsion to uniaxial to internal/external pressure. McDowell and Poindexter (Ref 58) extended this approach to address the dependence of the crack propagation rate on stress state and on crack length normalized by transition crack length, which demarcates microstructurally small and physically small crack behavior. Figure 8 shows the key differences between uniaxial and torsional crack propagation as a function of the number of cycles

to a crack of length 1 mm for 1045 steel, as described by the McDowell-Poindexter model, based on fitting the data of Socie in Fig. 6(a).

**FIG. 8 PREDICTED NONLINEAR GROWTH OF MICROCRACKS FOR 1045 STEEL FOR FOUR DIFFERENT CONSTANT-AMPLITUDE FATIGUE LIVES. COMPLETELY REVERSED (A) TORSIONAL FATIGUE AND (B) UNIAXIAL FATIGUE. SOURCE: REF 58**

Some common themes are evident in these critical plane theories. First, the effect of maximum cyclic shear strain is moderated by an additional influence of the normal stress or strain to this plane. This modification is based on the premise that the normal stress assists mode II propagation by opening the crack, thereby reducing crack face asperity or wake plasticity interactions. The notion of constraint may additionally be introduced, as in Eq 20, to reflect the effect of the hydrostatic stress on the local cyclic slip and damage processes ahead of the crack tip, analogous to constraint effects on damage evolution ahead of long cracks. Second, the product of stress and strain ranges in Eq 16 and 20 (and Eq 13, for that matter) is similar to that of EPFM  $\Delta J$ -integral for long cracks, which relates to crack-tip opening displacements.

It is clear from the foregoing discussion that the correlation of small crack growth in multiaxial fatigue for finite life may be framed in terms of a selected parameter for a driving force (Ref 7), provided that key elements are present.

In general, forms such as

$$\frac{da}{dN} = L_I \left( \Delta\gamma_{\max}, \sigma_n^{\max} \text{ or } \epsilon_n^{\max}, \rho, \frac{a}{\beta} \right) \quad (\text{EQ 29})$$

for stage I growth, or

$$\frac{da}{dN} = L_{II} \left( \sigma_n^{\max} \frac{\Delta\epsilon_n}{2}, \rho, \frac{a}{\beta} \right) \quad (\text{EQ 30})$$

for stage II growth appears to adhere to these requirements in the microstructurally sensitive regime, where  $\beta$  represents microstructure barrier length scales. For example, Ogata et al. (Ref 59) employed the relation

$$\frac{da}{dN} = C \left[ (\Delta\gamma_{\max}/2)^2 + B(\Delta\epsilon_n)^2 \right] a \quad (\text{EQ 31})$$

to correlate the propagation behavior of cracks from 100 to 1000  $\mu\text{m}$  in length for in-phase and out-of-phase LCF of austenitic stainless steel at high temperature, where  $C$  and  $B$  are constants. This may be recognized as the incorporation of the Brown and Miller parameter in Eq 15 as the driving force for propagation, with a weak dependence on crack length, consistent with the data in Fig. 6(a) and 6(b) in the LCF regime. Fewer detailed studies of small crack propagation exist for the HCF case. A micromechanical or "first-principles" construction of specific forms of Eq 29 and 30 remains an open issue in multiaxial fatigue.

## Additional Considerations for Multiaxial Fatigue Life Prediction

**Mean Stress Effects.** Particularly under HCF conditions, mean stresses play a key role in fatigue. Even for proportional loading, the correlation of multiaxial mean stress effects is challenging. It is generally observed that torsional mean stresses do not significantly affect fatigue crack "initiation" life, whereas mean normal stresses have a potentially strong effect (Ref 6). Consequently, the mean value of the equivalent stress ( $\bar{\sigma}$ ) is not a very useful quantity for correlation of mean stress effects, even under proportional loading conditions. Likewise, the mean value of hydrostatic stress has been used prominently in HCF parameters (e.g., Eq 10), but it does not isolate the effects of mean stress normal to the plane of stage I or II cracks, as discussed above.

Within the context of the critical plane theory, one can readily interpret common observations regarding mean stress effects under uniaxial and torsional loading conditions. Mean shear stress in torsional fatigue does not result in mean normal stress on the plane(s) of stage I crack propagation (maximum shear). Figure 9 shows the shear plane orientation of stage I microcracks for cases of completely reversed uniaxial and torsional loading. From a macroscopic viewpoint, the stress amplitude normal to the plane of the stage I microcrack in torsional loading is zero, whereas the stress amplitude normal to the shear plane in the uniaxial case is  $\Delta\sigma/4$ . For the same range of shear stress driving the mode II growth of the microcrack, the tensile normal stress in the uniaxial case promotes opening behavior of the stage I crack. This results in a significantly lower life for a given maximum shear stress or effective stress amplitude in completely reversed uniaxial loading as compared to shear, in agreement with experiments such as those in Fig. 1. The effects of tensile mean stress across the crack plane may therefore be understood in terms of an enhanced contribution of mode I opening, as well as an intensification of mode II due to reduction of crack face interference effects induced by local plasticity, crack surface roughness, or a combination of these. It is interesting to note that the fracture mechanics treatment of the fatigue crack propagation of long cracks has long recognized the important role of plasticity-induced closure (Ref 60, 61), as well as that of various other shielding mechanisms that affect the crack-tip driving forces. In contrast, classical crack initiation approaches such as that of Basquin's law for HCF have been modified in somewhat ad hoc fashion to reflect the dependencies on mean stress. In the presence of multiaxial stress states, these ad hoc modifications have adopted many forms, with general recognition of the importance of mean normal stresses in contrast to mean shear stresses.

**FIG. 9 ORIENTATION AND MAGNITUDE OF STRESS NORMAL TO ONE OF THE TWO PLANES OF MAXIMUM SHEAR FOR (A) UNIAXIAL AND (B) TORSIONAL CASES**

To account for mean stress effects, critical plane approaches for stage I microcrack propagation may employ the mean normal stress across the plane of maximum alternating shear strain (Ref 35) or peak normal stress to this plane, as in Eq 16 or Eq 29. This form of mean stress dependence correlates complex mean stress experiments rather well (Ref 6, 35, 62, 63). McDowell and Berard (Ref 35) suggested a form that reduces to conventional mean stress approaches under pure uniaxial and pure torsional loading. It is somewhat more difficult to incorporate mean stress effects in plastic work approaches in a physically meaningful manner (Ref 24, 64). This is also the case for effective stress- or strain-based theories of multiaxial fatigue.

The driving force may be modified to include effects of plasticity-induced closure, in analogy to the concepts of  $\Delta K_{\text{eff}}$  or  $\Delta J_{\text{eff}}$  used for correlation of crack growth rate of long cracks or for short cracks in stage I in the presence of very fine microstructure. However, available models and experimental data (e.g., Ref 61) indicate that small/short cracks are open over nearly the entire stress range under very high cyclic tensile strain (LCF) conditions normal to the microcrack. The HCF torsional mean stress case is not as well understood or characterized for stage I small crack growth, because the interference of crack faces plays an increasingly strong role in mode II and III dominated growth.

**Stress Amplitude Sequence Effects.** Fatigue life prediction under variable loading histories is of great practical importance. The growth of microstructurally and physically small cracks with cycles differs between uniaxial and torsional loading, as discussed in reference to Fig. 6(a) and 6(b). For long fatigue lives, the crack length versus  $N$  relation may be extremely nonlinear, particularly for uniaxial fatigue, whereas it can be nearly linear under LCF conditions.

Figure 8 shows the differences in the nature of propagation as a function of cycles for 1045 steel, as inferred from the data in Fig. 6(a) (Ref 58). This leads to strong amplitude sequence effects, particularly in uniaxial fatigue. In contrast, the crack length versus  $N$  relation in torsional fatigue is more nearly linear, and amplitude sequence effects are less pronounced. These phenomena are likely largely related to differences in crack face interference effects between uniaxial HCF and shear-dominated stage I growth, with little driving force for crack opening (e.g., torsional fatigue). These interference or shielding effects apparently scale quite differently with crack length and effective strain amplitude in uniaxial and torsional fatigue.

**Sequences of Stress State.** Sequences of stress state generate potentially strong history effects. A relevant example is that of combined tension and torsion sequences of thin-walled tubular specimens, as discussed by Miller (Ref 29). A sequence of torsional cycling followed by axial cycling results in a lower lifetime than would be anticipated on the basis of a linear damage rule such as Miner's rule, as shown in Fig. 10. In contrast, uniaxial push-pull followed by torsion results in a significant extension of life relative to the linear rule. Stage I microcracks formed in the torsional cycling effectively propagate as stage II cracks during subsequent uniaxial loading, resulting in a shorter life than continued cycling in torsion. On the other hand, uniaxial loading forms stage I microcracks roughly along  $45^\circ$  planes to the surface, and subsequent torsion is less effective in driving these cracks in stage I or stage II regimes.

(a)

(b)

**FIG. 10 INTERACTION BEHAVIOR. (A) COMPLETELY REVERSED TORSION FOLLOWED BY UNIAXIAL PUSH-PULL AND VICE-VERSA LOADING SEQUENCES. SOURCE: REF 29. (B) COMPLETELY REVERSED TORSION FOLLOWED BY UNIAXIAL PUSH-PULL FOR THREE DIFFERENT CONSTANT-AMPLITUDE FATIGUE LIVES FOR 1045 STEEL, BASED ON THE PROPAGATION CURVES SHOWN IN FIG. 8, WHERE  $N_f$  IS THE SAME FOR THE TORSIONAL AND UNIAXIAL STRESS AMPLITUDES OF EACH SEQUENCE. SOURCE: REF 58**

Two conclusions are as follows. First, the orientation of crack systems formed under a specific loading condition depends on the applied stress state, and it is relevant to the prediction of fatigue life. Second, standard fatigue crack initiation approaches would be unsuitable, in general, for such sequences because they do not specify an orientation for microcrack

propagation. Both of these observations point to the applicability of concepts involving propagation of small cracks along critical planes.

A more general type of nonproportional loading history involves rotation of the principal stresses (strains) or nonproportional variation of components of the stress (strain) *during* each cycle (Ref 33, 65, 66). Under LCF conditions, out-of-phase sinusoidal axial-torsional cycling of tubular specimens may lead to a decreased fatigue crack initiation life relative to in-phase (proportional) loading for ductile metals (Ref 33). For HCF, though, the opposite may be true. In such cases, it is particularly important to employ a suitable incremental cyclic plasticity model (Ref 1, 2, 3) to estimate the ranges of shear strain and normal stress in the material on various planes. As discussed by Chu et al. (Ref 67), the critical plane can then be selected, typically associated with the maximum value of the damage parameter (e.g., Eq 15 or 16) over the cycle.

There are complexities associated with defining and counting cycles under conditions of general nonproportional loading, because the normal stress to the plane of maximum shear strain range may vary independently of the shear strain (Ref 66, 67). Further work is necessary to clarify a life estimation methodology for such cases.

**Fatigue Limit in Multiaxial HCF.** If subgrain-scale small cracks cannot bypass strong barriers at the microstructural scale such as grain boundaries, then a fatigue limit results (Ref 29, 30, 43, 44) at long lives (order of  $10^6$  to  $10^7$  cycles and beyond). Likewise, elastic shakedown or cessation of cyclic microplastic flow may occur due to the heterogeneity of yielding among grains, and this also leads to a fatigue limit (Ref 68). Naturally, this fatigue limit will depend on stress state as well, because the heterogeneity of microslip processes depends on constraint. The dependence of the fatigue limit on combined stress state has been studied extensively (e.g. Ref 11, 12, 13). It has long been known that the fatigue limit (threshold) in bending, for example, cannot be related to that in torsion using deviatoric plasticity arguments. At present, no general theory exists to relate the fatigue limits among different stress states, and empiricism is employed. The same comment applies to threshold stress intensity factors in modes I, II, and III, a related problem. Recent work by Dang-Van (Ref 68) offers some promise in predicting stress state dependence of the HCF fatigue limit by evaluating a local critical slip plane failure criterion of Mohr-type analogous to Eq 10 within grains embedded in a polycrystalline orientation distribution of grains. Such microstructure/stress state couplings are essential to understand the phenomenon. Indeed, it is clear that the fatigue limit is dependent on stress state, including the mix of shear and normal stress, level of triaxiality, and so on.

It is of paramount importance to recognize the role of heterogeneity of microstructure and free surface proximity effects on the propagation of crack-like defects in polycrystals. Fatigue limit(s) for nonpropagating cracks should be consistent with the notion of threshold(s) for small fatigue crack propagation. It is commonly observed that the threshold for microstructurally small cracks is less than that of long cracks. It should be emphasized that such small crack thresholds and fatigue limits may in general be eradicated by overloads that drive the crack past barriers.

## Factors Influencing Weldment Fatigue

F.V. Lawrence, S.D. Dimitrakis, and W.H. Munse, University of Illinois at Urbana-Champaign

---

### Introduction

THERE IS general agreement that the main factors influencing the fatigue life of a weldment are:

- APPLIED STRESS AMPLITUDE
- MEAN AND RESIDUAL STRESSES
- MATERIAL PROPERTIES
- GEOMETRICAL STRESS CONCENTRATION EFFECTS
- SIZE AND LOCATION OF WELDING DISCONTINUITIES

but there is often disagreement as to the relative importance of each.

This article is intended to help engineers understand why the fatigue behavior of weldments can be such a confusing and seemingly contradictory topic, and hopefully to clarify this complex subject. The endless variations in weldment geometry are a major source of difficulty and an alternative classification system will be suggested. For a given weld geometry, it will be concluded that the behavior of structural weldments depends to a rather large extent on the nature of the industrial application, that is, upon the size of the weldment and upon the quality of the welding and the post-welding procedures employed.

**Scope and Sections in this Article.** In what follows, the factors influencing the fatigue behavior of an individual weldment will be reexamined using extensive experimental data and a computer model which simulates the fatigue resistance of weldments. In the next section, the process of fatigue in weldments will be discussed in general terms and the service conditions which favor long crack growth and the conditions which favor crack nucleation will be contrasted. Next, experimental data will be used to show the effect of weldment geometry on fatigue resistance. Several useful geometry classification systems will be compared. In the last section, a computer model will be employed to investigate the behavior of two hypothetical weldments: a discontinuity-containing ("Nominal") weldment and a discontinuity-free ("Ideal") weldment. As will be seen, these two weldments exhibit radically different fatigue behavior and thus are useful paradigms which will help engineers decide how their weldments will behave and how the fatigue resistance of their weldments might be improved.

### Acknowledgements

This article draws on the work of many people and many studies carried out over a period of years. The authors would like to acknowledge the advice and help of our colleagues at the UIUC in the Departments of Theoretical and Applied Mechanics and Mechanical Engineering. The article is based on several studies that were sponsored at various times by the UIUC Fracture Control Program, The Edison Welding Institute, the U.S.Coast Guard, and the Ship Structures Committee. The line drawings of Fig. 4 were drawn by Dr. Gregorz Banas.

### Metallic Fatigue in Weldments

As with any notched metal component, the process of fatigue in weldments can be divided into three periods: crack nucleation, the development and growth of a short crack (stage I), and the growth of a dominant (long) crack to a length at which it either arrests or causes fracture (stage II in Fig. 1).

**FIG. 1 METALLIC FATIGUE. THE STAGES OF FATIGUE INCLUDE CYCLIC SLIP (CRACK NUCLEATION) AND STAGE I AND STAGE II CRACK GROWTH.**

The boundaries between these periods are ill-defined. Nonetheless, it is useful to think of the total fatigue life of a notched metal component or a weldment ( $N_T$ ) as the sum of three life periods: fatigue crack nucleation ( $N_N$ ), short (or stage I) crack growth ( $N_{P1}$ ), and long (or stage II) crack growth ( $N_{P2}$ ):

$$N_T = N_N + N_{P1} + N_{P2} \quad \text{(EQ 1)}$$

The relative contribution of each of these three periods to the fatigue life of weldments is controversial and appears to vary with the geometry of the weld and weldment, the size of the weldment, the nature of the residual stresses present, and the severity of the weld discontinuities existing in the weldment. In this article, it will be useful to imagine that there are two extreme kinds of weldments: "Nominal" weldments, which contain substantial (~0.1 in. depth) weld discontinuities; and "Ideal" weldments, which have blended weld toes and no substantial weld discontinuities (Fig. 2). As will be seen, the fatigue behavior of the "Nominal" and "Ideal" weldments differs greatly.

FIG. 2 CONCEPTUAL DRAWING OF FATIGUE CRACK INITIATION AND GROWTH AT THE TOE OF (LEFT) A "NOMINAL" GROOVE WELDED BUTT JOINT HAVING A SUBSTANTIAL ( $\approx 0.1$  IN. DEPTH) WELD DISCONTINUITY (SLAG ENTRAPMENT) AT THE ROOT OF THE CRITICAL NOTCH (WELD TOE) AND (RIGHT) AN "IDEAL" WELDMENT WITH GOOD WETTING AND NO SUBSTANTIAL DISCONTINUITY AT THE ROOT OF THE CRITICAL NOTCH. ONLY THE RIGHT HALVES OF THESE WELDMENTS ARE ILLUSTRATED. IN THE CASE OF THE "NOMINAL" WELDMENT THE FATIGUE CRACK INITIATES AT THE TIP OF THE PREEXISTING DISCONTINUITY, THAT IS, AT A DEPTH OF  $\approx 0.1$  IN. ALONG THE LINE OF FUSION; WHEREAS IN THE CASE OF THE "IDEAL" WELDMENT, THE FATIGUE CRACK IS PRESUMED TO INITIATE AT THE WELD TOE, POSSIBLY IN WELD METAL.

**Conditions Leading to the Dominance of Long Crack Growth ( $N_{P2}$ ).** For many reasons, stage II crack growth generally dominates the fatigue life of a weldment, while the periods devoted to crack nucleation ( $N_N$ ) and early crack growth ( $N_{P1}$ ) are generally relatively short. Engineers for whom a single failure would be catastrophic and who are forced to use low-quality welding procedures must by necessity adopt a very pessimistic view regarding the fatigue life of weldments and make the rather conservative assumption that:

$$N_T \approx N_{P2} \quad (\text{EQ 2})$$

The basic geometry and/or loading of some weldments leads to a very desirable phenomenon in which a stage II crack slows down rather than accelerates as the crack lengthens. Whenever this occurs, the growth [by the Paris power law  $da/dN = C(\Delta K)^n$ ] of long cracks ( $N_{P2}$ ) can be a major fraction of their fatigue life. Such weldments may never fail but rather may develop long, slow-growing fatigue cracks (Fig. 3). Most weldments have several sites of stress concentration.

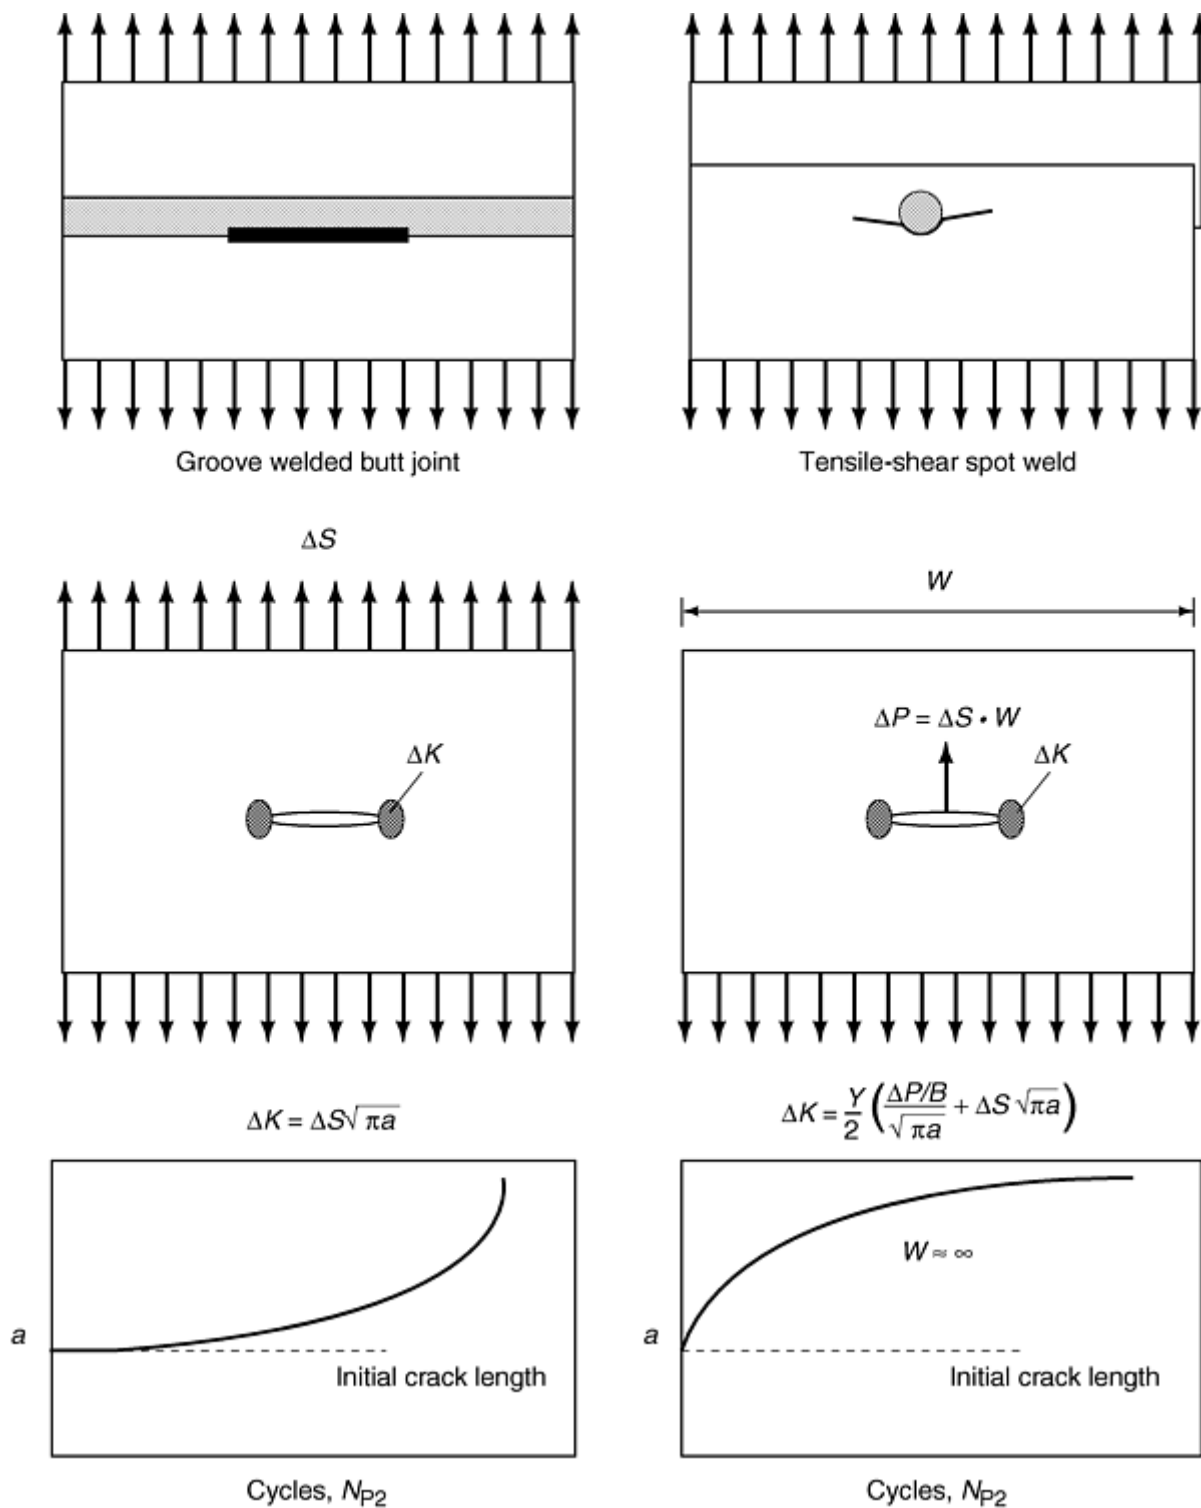

FIG. 3 TWO RADICALLY DISSIMILAR PATTERNS OF STAGE II CRACK GROWTH IN WELDMENTS. THE CRACK GEOMETRY AND LOAD PATH IN THE GROOVE WELDED BUTT JOINT (TOP LEFT) IS SIMILAR TO THE CENTER CRACKED PANEL FOR WHICH THE STRESS INTENSITY FACTOR INCREASES WITH CRACK GROWTH; WHEREAS, THE CRACK GEOMETRY AND LOAD PATH IN THE TENSILE SHEAR SPOT WELD (TOP RIGHT) IS SIMILAR TO THE LOADING PATTERN FOR A BOLT OR RIVET FOR WHICH THE STRESS INTENSITY FACTOR MAY DECREASE WITH CRACK GROWTH. THE DIFFERENCE BETWEEN THE TWO WELDMENTS FAVORS THE ACCELERATION OF FATIGUE CRACK GROWTH WITH INCREASING CRACK LENGTH IN THE CASE OF THE GROOVE WELDED BUTT JOINT AND THE POSSIBLE DEVELOPMENT OF NONPROPAGATING CRACKS IN THE CASE OF THE TENSILE SHEAR SPOT WELD.

Corrosion fatigue is another phenomenon that diminishes the relative importance of crack nucleation ( $N_N$ ) and small crack growth ( $N_{P1}$ ) in weldments. Finally, variable load histories containing many large, damaging events may greatly shorten the fatigue life devoted to  $N_N$  and  $N_{P1}$ .

**Conditions Favoring Crack Nucleation and Early Crack Growth.** While the deleterious effects of weld discontinuities, corrosion fatigue, and some variable load histories can diminish the importance of  $N_N$  and  $N_{P1}$  in weldments, one can also adopt an opposite, more optimistic view of the fatigue life of weldments in which  $N_N$  and  $N_{P1}$  can be a major part of the fatigue life of a weldment and in which the fatigue life of such an "Ideal" weldment can be greater than  $N_{P2}$ . "Fluxless" fusion welding processes such as gas-metal arc welding (GMAW) or gas-tungsten arc welding (GTAW) are capable of producing large weldments in which weld discontinuities at the root of the critical notch are small or even nonexistent. It should be noted that for a weld discontinuity to control the fatigue resistance of a weldment, it must be located at the root of the critical notch so that the worst case can occur, in which the stress concentrations of both the critical notch and the weld discontinuity interact. The fact that fatigue invariably begins at the root of the critical notch reduces the likelihood of randomly distributed weld discontinuities participating in fatigue crack nucleation and early crack growth, which are constrained to the root of the critical notch (i.e., the ripple, the toe, or the root of a weldment). It is also possible that the weld reinforcement may be sufficiently irregular that the worst notch can be located in the weld metal; however, this situation can be avoided by proper welding.

All welding processes can produce either "Ideal" welds free of discontinuities or "Nominal" welds with a 0.1 in. crack-like discontinuity. For example, welding processes such as resistance spot welding produce weldments in which large discontinuities are not found. Thus, high-quality structural welds and welds such as resistance spot welds may not contain large discontinuities, and their behavior may approach that of an "Ideal" weldment. In some applications, however, highly stressed welds in critical locations are less likely (compared to the majority of the population of the welded components) to be considered discontinuity free and like the "Ideal" weldment. Many situations may not involve constant-amplitude or pseudo-constant-amplitude loading, and thus the concern about variable load histories may be a factor. However, welding procedures and postweld treatments can substantially improve the fatigue life of a weldment through increases in any or all of the life periods  $N_N$ ,  $N_{P1}$ , and  $N_{P2}$ , and many applications may allow the assumption of "Ideal" welds and constant-amplitude conditions. In this circumstance, it is reasonable to think of the fatigue life of a weldment as approaching that of the "Ideal" weldment, as depending on  $N_N$  and  $N_{P1}$ , and unlike the "Nominal" weldment susceptible to large improvement.

## Effects of Weldment Geometry

**The Fatigue Behavior of 53 Structural Details.** Some of the common structural details encountered in bridge, ship, and ground-vehicle construction have been catalogued by Munse et al. (Ref 1). The shapes of 53 structural details and variations of these details are shown in Fig. 4. The abbreviations used are given in Table 1, and further information regarding the 53 joints is given in Table 2. This catalogue begins with what would seem to be the simplest shapes and proceeds toward the more complex. Some of the final geometries (e.g., #39) are complex weldments and should really be considered structures. Note that the classification system includes bolted and riveted joints (#8 and #9) and plug and spot welds (#27), which as discussed in the previous section behave in a fundamentally different way. Several details (#28 and #29) are not connections at all, simply notched components. For this reason, this article at first refers to the items in the catalogue as structural details, but later focuses on the welded details.

(A) THE NUMBERING SYSTEM OF MUNSE ET AL. IS RELATED TO THAT OF THE AMERICAN INSTITUTE OF STEEL CONSTRUCTION (AISC, REF 3), BUT THE AISC CLASSIFICATION OF WELDMENTS CONTAINS ONLY 27 SHAPES.

FIG. 4 SELECTED ILLUSTRATION OF 28 DETAILS FROM THE 53 STRUCTURAL WELD DETAILS CATALOGUED BY

**The Influence of Structural Detail Geometry on Fatigue Strength.** The mean strength data in Table 3 suggest that, after the applied stress range, detail geometry is the most important variable affecting a structural detail's fatigue life. The role of geometry can be better assessed if fatigue databank information is edited to suppress the effects of other variables, such as  $R$ -ratio and material strength. (*Note:* It is customary to group together fatigue data for all thicknesses, strengths, and  $R$ -ratios. This practice is inadvisable and leads to an unnecessarily large scatter in fatigue data information. All databanks should be restricted to a standard strength,  $R$ -ratio, and thickness.) In Table 3, the fatigue databank information for many of the structural details listed in Table 2 is reanalyzed and restricted to data for  $R = 0$  tests and data for steels having yield strength less than 50 ksi (345 MPa). In several instances, the AISC classification of the joint was altered by this procedure.

**Scatter of Structural Detail Fatigue Data Resulting from Classification Systems.** The design stresses that an engineer must adopt are as much controlled by the scatter in the fatigue data as by the mean value of strength for a certain design life. Thus, the uncertainty (scatter) in weldment fatigue life is as or more important than the mean value. This scatter has two basic sources: "real" scatter, which results from the random nature of the fatigue variables controlling the fatigue resistance of a detail; and the contribution to the "apparent" scatter, which is an artifact of the classification system imposed. The simplest classification scheme is suggested by Fig. 4 and Table 2. Each detail shape is placed in a class by itself. However, as mentioned in the previous section, grouping together data for tests having different experimental conditions leads to artificially large values in standard deviation of the log of strength(s). Furthermore, as discussed below, the practice producing the greatest amount of apparent scatter is the use of broad classification systems in which details having only roughly similar fatigue resistances are grouped together. Munse and Ang (Ref 2) suggested that the effects of scatter on the desired or required reliability of a particular structural detail could be incorporated into the design procedure by calculating a reliability factor ( $R_F$ ) that shifted the mean curve of a detail's  $S-N$  diagram downward by an amount (Fig. 5) that would guarantee a desired level of safety (or probability of failure):

$$\Delta S_{\text{DESIGN}} = \Delta S_{\text{MEAN}} (R_F) \quad (\text{EQ 3})$$

FIG. 5 THE RELIABILITY FACTOR ( $R_F$ ) IS CALCULATED FOR THE DESIRED LEVEL OF SAFETY GIVEN THE SCATTER IN THE FATIGUE DATA FOR THE DETAIL.

A relation between the reliability factor ( $R_F$ ) shown in Fig. 5 and the coefficient of variation of the mean fatigue strength ( $\Omega_s$ ) is given in Eq 4. As suggested in the last section of this article, a typical value of  $R_F$  for a weldment is 0.7:

$$R_F = \exp\left[-2\sqrt{\ln(1 + \Omega_s^2)}\right] \quad (\text{EQ 4})$$

Table 3 shows that standardizing the databank information frequently alters the mean fatigue strength ( $\Delta S$  at  $10^6$  cycles) and usually reduces the standard deviation in the log of fatigue strength for most structural details. The effects of standardizing the fatigue databank information on the scatter in the fatigue data for a given detail are plotted in the histograms of Fig. 6 and 7. Standardizing databanks greatly reduces the scatter in fatigue data for a given detail and consequently increases the allowable design stresses. (Note: The design stress range ( $\Delta S_{\text{design}}$ ) at a certain life ( $10^6$  cycles) can be estimated from the mean fatigue strength ( $\Delta S_{\text{weld}}$ ) of a weldment at a given life by:  $\log \Delta S_{\text{design}} = \log \Delta S_{\text{weld}} - 2s$ , where  $s$  is the standard deviation of  $\log \Delta S$ ).

FIG. 6 FREQUENCY VS. THE LOG OF THE STANDARD DEVIATION IN FATIGUE STRENGTH IN KSI

FIG. 7 FREQUENCY VS. THE LOG OF THE STANDARD DEVIATION IN FATIGUE STRENGTH IN KSI

The scatter in fatigue information is increased by grouping structural details into a small number of broad categories of decreasing fatigue resistance. The AISC weld category fatigue design method (Ref 3) and other similar approaches group the data for all strengths of steel, all  $R$ -ratios, and all "similar" structural detail geometries together into a single databank for each category. This practice of placing individual structural details into such broad classifications greatly increases the apparent scatter in fatigue data, leads to lower design stresses (Fig. 5), and obscures the effects of many variables that influence the fatigue life of weldments. The data in AISC categories A through F exhibit large scatter and force design stresses 40% or more lower than the mean fatigue strength; that is, this practice results in a reliability factor ( $R_F$ ) of around 0.4 rather than values of 0.9 to 0.6, which reflect the essential nature of weldments (Fig. 8) (Ref 4).

FIG. 8 TYPICAL DATA FOR AISC CATEGORY C WELD DETAILS. DATA TAKEN FROM THE UNIVERSITY OF ILLINOIS AT URBANA-CHAMPAIGN WELDMENT FATIGUE DATABANK. DATA FOR DETAILS 7, 10-14, 19, AND 22-25 ARE IN TABLE 2. TESTS THAT WERE DISCONTINUED BEFORE FAILURE ARE TERMED "RUN OUTS."

**Classifying Weldment Geometry on the Basis of the Site of Fatigue Crack Initiation.** As mentioned above, eliminating the influence of secondary variables such as  $R$ -ratio and strength effects gives a sharper picture of the true effects of structural detail geometry. A simple way of quantifying the severity of the critical notch in a structural detail is to introduce the concept of the fatigue notch factor ( $K_f$ ), a nondimensional, scalar quantity that is defined as:

$$K_f = \frac{\Delta S_{\text{smooth specimen}}}{\Delta S_{\text{weldment}}} \approx 1.43 \left( \frac{\Delta S_{\text{plain plate}}}{\Delta S_{\text{weldment}}} \right) \quad (\text{EQ 5})$$

In the instance of mild steel,  $K_f$  can be determined using plain plate data, assuming that the fatigue notch factor for plain plate is  $K_f = 1.43$ . The experimental definition of the fatigue notch factor ( $K_f$ ) and the use of the mean and standard deviation in design are illustrated in Fig. 9.

**FIG. 9 DEFINITION OF  $K_f$  AND THE ROLE OF THE WELDMENT MEAN STRENGTH ( $\Delta S_{\text{WELDMENT}}$ ) AND THE STANDARD DEVIATION (S) IN LOG OF FATIGUE STRENGTH IN DETERMINING THE DESIGN STRESS RANGE PERMITTED FOR A GIVEN SERVICE LIFE**

The fatigue behavior of only the welded structural details of Tables 2 and 3 are reproduced in Table 4. The site at which the fatigue failure initiates in these weldments is inevitably one of four locations: weld ripple, weld toe, weld root, or a weld termination (Fig. 10). As seen from the comments in Table 4, several weldments are not pure cases of fatigue initiation and growth from either the ripple, toe, root, or termination. These unusual weldments will (for the most part) be eliminated from further consideration and termed "mavericks." For instance, all partial penetration welds must be considered mavericks because their fatigue resistance depends entirely on the size of the incomplete joint penetration (IJP), the magnitude of which is generally unknown. If the "mavericks" are disregarded, it is evident in Table 4 that weldments initiating fatigue cracks at weld ripple and weld toes have the lowest values of  $K_f$  and are the welded details having the higher fatigue strengths. All weldments failing from terminations are among the worst welded details and have the largest values of  $K_f$  and the least fatigue strength. This weldment has been much studied and is often used as the paradigm for the behavior of all weldments.

FIG. 10 FAILURE LOCATIONS IN WELDMENTS: RIPPLE, TOE, ROOT, OR WELD TERMINATION. THE DISTINCTION BETWEEN A WRAPAROUND (CONTINUOUS) TERMINATION AND A SIMPLE TERMINATION (STOP OR START) IS NOT MADE IN THIS DRAWING. THE TERMINATION AND RIPPLE ARE SITES OF FATIGUE CRACK INITIATION ONLY WHEN THE LOAD APPLIED TO THE WELDMENT IS LONGITUDINAL. LIKewise, THE ROOT AND TOE BECOME FATIGUE CRACK INITIATION SITES UNDER TRANSVERSE LOADING.

Each of the welded details of Table 4 categorized as a "pure" case of fatigue crack initiation from either the weld ripple, weld toe, or weld termination was given a designation:

- *RIPPLE (R)*: FAILURE INITIATING FROM THE RIPPLE IN A WELD.
- *TOE (G)*: FAILURE INITIATING FROM THE TOE OF A GROOVE WELD.
- *TOE (F)*: FAILURE INITIATING FROM THE TOE OF EITHER A FULL-PENETRATION, LOAD-CARRYING FILLET WELD OR ANY NON-LOAD-CARRYING FILLET WELD.
- *TOE (F')*: FAILURE INITIATING FROM THE TOE OF A PARTIAL-PENETRATION, LOAD-CARRYING FILLET WELD. THIS CASE IS ACTUALLY A "MAVERICK," BUT IT IS SO IMPORTANT THAT IT IS INCLUDED IN THE COMPARISONS BELOW.
- *TERMINATION (T)*: FAILURE INITIATING FROM THE "START" OR "STOP" OF A FILLET OR GROOVE WELD.

The essential distinctions between the four fundamentally different initiation sites (ripple, toe, root, or weld termination) are summarized in Table 5 from a metallurgy and mechanics perspective. Figures 11, 12, and 13 give schematic diagrams of the weld categories based on sites of fatigue crack initiation and growth.

TABLE 5 ESSENTIAL DIFFERENCES BETWEEN FATIGUE CRACK INITIATION SITES

FATIGUE CRACK	RELEVANT MATERIAL	NOTCH	RESIDUAL STRESSES
---------------	-------------------	-------	-------------------

INITIATION SITE	CONDITION		
RIPPLE	WM	WELD RIPPLE: A PERIODIC ARRAY OF SMALL NOTCHES ON THE SURFACE OF THE WELD BEAD	<b>+S<sub>Y</sub> WM: NO LARGER THAN THE YIELD STRENGTH OF WELD METAL</b>
TOE	HAZ	WELD TOE: A SURFACE NOTCH HAVING NO DEFINED DEPTH AND VARIABLE NOTCH-ROOT RADIUS	<b>+S<sub>Y</sub> BM: NO LARGER THAN THE YIELD STRENGTH OF BASE METAL</b>
ROOT	(TEMPERED) WM	WELD ROOT: A SHARP NOTCH HAVING AN UNKNOWN AND VARIABLE NOTCH-ROOT RADIUS	<b>UNKNOWN: PROBABLY NEAR ZERO IF THE FIT-UP IS NOT TIGHT</b>
TERMINATION	HAZ	<b>WELD TOE: AS ABOVE, EXCEPT IT IS POSSIBLE OR EVEN PROBABLE THAT STARTS WILL INVOLVE A LACK OF FUSION AND THAT STOPS MAY INVOLVE CRATER CRACKS, PIPES, OR HOT CRACKS</b>	<b>+S<sub>Y</sub> WM: POSSIBLY AS HIGH AS THE YIELD STRENGTH OF WELD METAL</b>

WM, weld metal; HAZ, heat-affected zone; BM, base metal

Toe (F'): Load-carrying cruciform joint

FIG. 11 EXAMPLE OF "MAVERICK" JOINT. THE LOAD-CARRYING FILLET WELD IS AN IMPORTANT CASE. FAILURE MAY OCCUR AT EITHER THE WELD TOE OR WELD ROOT. APPLIED AXIAL STRESSES FAVOR ROOT FAILURES. APPLIED BENDING STRESSES FAVOR TOE FAILURES. THE SIZE OF INCOMPLETE JOINT PREPARATION (IJP) CONTROLS THE NOTCH SEVERITY ( $K_F$ ) OF BOTH THE ROOT AND THE TOE, WITH THE RESULT THAT THIS WELD CAN BE AS "GOOD" WELD OR AS BAD AS A TERMINATION, DEPENDING ENTIRELY ON THE SIZE OF THE IJP.

**FIG. 12** EXAMPLES OF "GOOD" WELDS ADDRESSED IN THIS ARTICLE. INITIATION SITES AT A WELD RIPPLE OR A WELD TOE ARE ILLUSTRATED.

**FIG. 13** "BAD" WELD WITH INITIATION SITE AT THE END OF A FILLET WELD

The effect of this system of categorizing weldments is shown in Fig. 14 and 15. In Fig. 14 the standard deviation of the log of strength (ksi units) is plotted versus  $K_f$  for each of the details listed in Table 2. Several interesting observations can be made: First, the scatter in fatigue strength is inversely related to  $K_f$ . The welds having a higher fatigue resistance exhibit more scatter, presumably because fatigue crack initiation plays a larger role. On the other hand, welds having the lowest fatigue resistance have less scatter in their fatigue data, presumably because their behavior is governed entirely by fatigue crack growth. Second, it is obvious that weldments for which fatigue cracks initiate at the ripple or toe have relatively small values of  $K_f$  (1.8 to 2.5); whereas terminations have very high values of  $K_f$  (3.0 to 4.5). The "maverick" load-carrying cruciform (Fig. 11) is seen to range in behavior from as bad as the terminations to as good as a non-load-carrying cruciform weldment.

FIG. 14 VARIATION IN THE LOG OF THE STANDARD DEVIATION IN FATIGUE STRENGTH IN KSI WITH FATIGUE NOTCH FACTOR ( $K_f$ ). THE UNCERTAINTY IN THE FATIGUE STRENGTH OF TERMINATIONS WOULD SEEM TO BE GENERALLY LESS THAN THAT OF THE TOE AND RIPPLE.

FIG. 15 AVERAGE  $S-N$  DIAGRAMS FOR THE WELDED DETAILS IN TABLE 2. THE AVERAGE  $S-N$  CURVES FOR RIPPLE (R), TOE (G), AND TOE (F) ARE SIMILAR. THE FATIGUE BEHAVIOR OF THE "MAVERICK" TOE (F') (PARTIAL PENETRATION LOAD-CARRYING FILLET) RANGES FROM BEING AS BAD AS THE TERMINATIONS TO AS GOOD AS THE TOE (G) AND TOE (F) DATA.

These observations are reinforced by the  $S-N$  diagrams of Fig. 15. It is interesting to note that the slopes of the  $S-N$  diagrams for the terminations are different from the slopes for the ripple and toe categories. The slope of the  $S-N$  diagrams for the terminations portrays a situation in which there is very little, if any, contribution from crack nucleation ( $N_N$ ) and early crack growth ( $N_{P1}$ ) or at least no crack closure. In such a case, the slope of the  $S-N$  diagram is  $-1/n$  or  $-1/3$  for mild

(ferritic-pearlitic) steel. The more nearly horizontal slope for the ripple and toe category welds indicates a substantial crack nucleation ( $N_N$ ) and early crack growth ( $N_{P1}$ ) contribution to their total life. The slopes of  $S-N$  diagrams are an incontrovertible indication of the importance or unimportance of crack nucleation and early crack growth.

**Summary.** Joint geometry has a large influence on the fatigue resistance of weldments. While it is an appealing idea to assemble the fatigue data for weldments into a comprehensive "encyclopedia" organized to reflect their fatigue behavior, such efforts may be hopeless because there are just too many different joint geometries. However, collecting weldment fatigue data into a limited number of broad weld "categories" (which may be an appealingly simple concept for designers) increases the apparent scatter in weldment fatigue data and reduces the allowable design stresses for a required level of safety. The scatter in both the encyclopedia approach and the weld category approach inevitably obscures the effects of the secondary but nonetheless important fatigue variables.

If weldments are classified by the site of fatigue crack initiation, it would seem that "good" weldments (for which fatigue cracks initiate at the weld toe or weld ripple) can be distinguished from "bad" weldments (which are substantially worse than "good" weldments for a variety of reasons) or "mavericks" (for which the fatigue resistance depends largely on the undefined size of a discontinuity or is complicated by ambiguity as to the definition of nominal stress).

## Variables of Weldment Fatigue

In this section, the variables influencing the fatigue resistance of an individual joint geometry (a non-load-carrying cruciform weldment) are investigated with the aid of a computer simulation of weldment fatigue behavior. This weld geometry is used as an example of fatigue behavior of weldments where fatigue failure initiates at a weld toe (i.e., "good" weldments). The behavior of "Nominal" and "Ideal" weldments, that is, non-load-carrying cruciform weldments with and without a 0.1 in. weld discontinuity at the weld toe, is compared and contrasted.

The variables influencing the fatigue life of a weld, such as a non-load-carrying cruciform weldment (Fig. 16), are:

- **APPLIED STRESS AMPLITUDE:** THE REMOTE AXIAL AND BENDING STRESSES ( $\Delta S_A$  AND  $\Delta S_B$ ) AT THE WELD TOE. THE BENDING STRESSES MAY BE APPLIED OR RESIDUAL STRESSES RESULTING FROM WELD FABRICATION DISTORTIONS. WELDING DISTORTIONS MAY NOT INDUCE SECONDARY BENDING STRESSES WHEN THE APPLIED LOAD IS PURE BENDING.
- **MEAN AND RESIDUAL STRESSES:** REMOTE MEAN STRESSES RESULTING FROM THE APPLIED LOAD ( $S_M$ ), WELDING RESIDUAL STRESS AT THE WELD TOE ( $\sigma_R$ ), AND

FABRICATION RESIDUAL STRESSES RESULTING FROM SUBSEQUENT REMOTE WELDING ( $S_{FAB}$ ), WHICH ADD TO THE REMOTE MEAN STRESSES.

- **MATERIAL PROPERTIES:** STRAIN-CONTROLLED FATIGUE PROPERTIES ( $\epsilon'_F$ ,  $\sigma'_F$ ,  $B$ ,  $C$ ) DETERMINE THE RESISTANCE TO CRACK NUCLEATION AND EARLY CRACK GROWTH, WHILE THE CRACK GROWTH PROPERTIES ( $C$ ,  $N$ ) CONTROL THE GROWTH OF FATIGUE CRACKS. THE RESIDUAL STRESSES ARE LIMITED (OFTEN CONTROLLED BY) THE METAL'S YIELD STRENGTH ( $S_Y$ ), SO YIELD STRENGTH OF THE WELDMENT'S CONSTITUENT MATERIALS IS OF GREAT IMPORTANCE IN NON-STRESS-RELIEVED WELDMENTS.
- **GEOMETRICAL STRESS CONCENTRATION EFFECTS:** THE CONCENTRATION OF STRESS AND STRAIN AT A NOTCH SUCH AS A WELD TOE MAGNIFY THE EFFECTS OF THE APPLIED STRESS, THE REMOTE MEAN STRESS, AND THE FABRICATION STRESSES. THUS NOTCHES REDUCE THE FATIGUE LIFE, PARTICULARLY  $N_N$  AND  $N_{P1}$ . THE EFFECTS OF THE NOTCH ARE CAPTURED BY THE FATIGUE NOTCH FACTOR ( $K_F$ ), WHICH INFLUENCES  $N_N$  AND  $N_{P1}$ , AND BY  $M_K$ , WHICH IS THE ELEVATION OF THE RANGE IN STRESS-INTENSITY FACTOR AT THE WELD TOE.
- **SIZE AND LOCATION OF WELDING DISCONTINUITIES:** THE WELD DISCONTINUITIES, BOTH AT THE NOTCH ROOT AND ELSEWHERE, MAGNIFY THE STRESS-CONCENTRATING EFFECTS OF THE CRITICAL NOTCH AND CAN GREATLY REDUCE  $N_N$ ,  $N_{P1}$ , AND  $N_{P2}$ . THE PRESENCE OF A 0.1 IN. PLANAR DISCONTINUITY AT THE WELD TOE OF THE NON-LOAD-CARRYING CRUCIFORM WELDMENT CONSIDERED HERE IS THE CONDITION THAT DISTINGUISHES THE "NOMINAL" FROM THE "IDEAL" WELDMENT.

FIG. 16 SCHEMATIC DIAGRAM OF A NON-LOAD-CARRYING CRUCIFORM WELDMENT SUBJECTED TO AXIAL AND BENDING LOADS AS WELL AS TO GLOBAL RESIDUAL (MEAN) STRESSES GENERATED BY SUBSEQUENT WELDING FABRICATION ( $S_{FAB}$ ). WELDING RESIDUAL STRESSES ( $\sigma_R$ ) ARE CONSIDERED TO EXIST ONLY IN A SMALL VOLUME AT THE WELD TOE.

**The Role of Analytical Models.** The fatigue of weldments is a complicated topic. No two weldments are identical, and weldment fatigue resistance may depend on many variables in a complex, nonlinear way. The effects of the major variables such as stress range and weld geometry are certainly understood, and one can usually predict what will happen if one of these major variables is changed; however, it is difficult to predict what will happen if these and several secondary variables are changed at once. In such a circumstance, the outcome may be counterintuitive.

Computer models can simulate the behavior of complex weldment fatigue. Fracture mechanics crack growth models for  $N_{P2}$  provide the lower-bound estimates of  $N_{P2}$  for the "Nominal" weldment, while the initiation-propagation (I-P) model described below, which combines the linear elastic fracture mechanics (LEFM) estimates of  $N_{P2}$  (the crack propagation life or "P") with estimates of  $N_N$  and  $N_{P1}$  (crack initiation life or "I"), can provide estimates of the upper-bound behavior of the "Ideal" weldment (Ref 5).

$$N_T = [N_N + N_{P1}] + N_{P2} = N_1 + N_{P2} \quad (\text{EQ 6})$$

The I-P model is shown schematically in Fig. 17. Relevant material properties for two steels are listed in Table 6. The I-P model predicts the total fatigue life of a weldment ( $N_T$ ) by making separate estimates of the fatigue crack initiation life ( $N_1$ ) and the fatigue crack propagation life ( $N_{P2}$ ) and summing them.

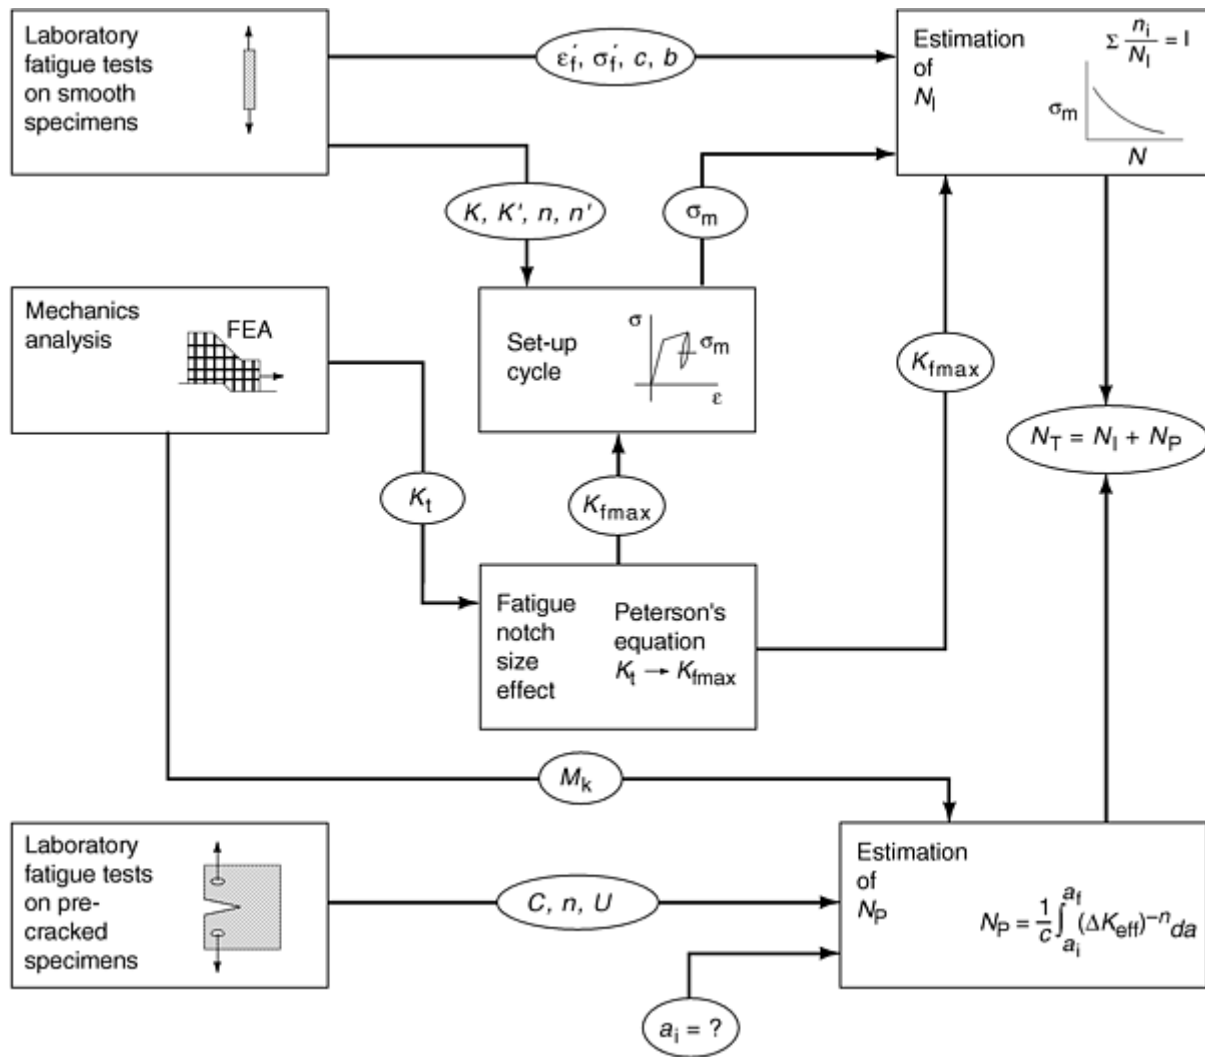

FIG. 17 A SCHEMATIC DIAGRAM SHOWING THE INFORMATION REQUIRED BY AND THE ORGANIZATION OF THE INITIATION-PROPAGATION MODEL

The fatigue crack initiation life ( $N_i$ ) is thought of as the life period spent in crack nucleation and the growth of small cracks through (roughly) the first 50 to 100  $\mu\text{m}$  of the metal, that is,  $N_N$  and  $N_{P1}$ . This life period is captured in the fatigue behavior of smooth specimens, and thus, strain-controlled fatigue life concepts are used to estimate this life period. The severity of the notch presented by the weld toe is quantified using the  $K_{f,max}$  hypothesis, a concept for determining the pessimimum value of fatigue notch factor  $K_f$  using Peterson's equation.

A second noteworthy feature of the  $N_i$  part of the I-P model is the use of the "set-up cycle" analysis to determine the notch-root mean stress remaining after the first few cycles. This analysis approximates the effects of notch-root plasticity during the first few applications of load through the use of Neuber's rule and models the difference in behavior between monotonic (first reversal) and cyclic (subsequent reversals) behavior of the material at the notch root (the grain-coarsened heat-affected zone). This phenomenon is called the Bauschinger effect. The first reversal includes the effects of the initial loading from 0 to  $S_{max}$ , the weld toe (welding) residual stresses ( $\sigma_r$ ), and the residual fabrication stresses ( $S_{fab}$ ). In the "set-up cycle" simulation, the notch-root (welding) residual stresses are treated as an equivalent remote stress by dividing the notch-root residual stresses by  $K_{f,max}$ . The "set-up cycle" analysis provides the initial value of notch-root mean stress for the linear cumulative damage calculation, which considers the exponential decay of the notch-root mean stress during subsequent cycling. Thus,  $N_i$  is calculated considering the notch-root mean stresses established during the first few cycles of load application and their relaxation during the fatigue crack initiation period.

The calculation of  $N_{P2}$  is based on  $\Delta K_{eff}$  and values for the effective stress-intensity ratio ( $U$ ). The  $M_k$  value in Ref 6 was used. The  $R$ -ratio is redefined for the estimation of the  $N_p$ . The notch-root mean stresses are not considered because they exist only in the small volume of material at the notch root; furthermore, in most cases, the I-P model predicts that these

notch-root mean stresses substantially diminish during the crack initiation period. Therefore, only the applied mean stresses and the mean stresses resulting from subsequent fabrication ( $S_{fab}$ ) are assumed to influence crack growth. Crack shape development (Ref 7) is included. For "Ideal" weldments, the initial crack size is arbitrarily taken as  $a_i = 0.01$  in. The final crack size ( $a_f$ ) was determined using LEFM and  $K_{Ic}$ .

For the "Nominal" weldment,  $N_I$  was neglected and  $N_{P2}$  was calculated assuming an initial flaw size  $a_i = 0.1$  in. (2.5 mm).

**Predicted Fatigue Life and Data Comparison.** Figures 18, 19, 20, and 21 show experimental data from the University of Illinois at Urbana-Champaign (UIUC) fatigue databank for a butt joint (#10) and non-load-carrying cruciform weldments (#25) for  $R = 0$  and  $R = -1$  test conditions. In each figure, the predictions of the I-P model for the "Ideal" and "Nominal" weldments are seen to bound the experimental data. When propagation dominates, the slope of the  $S-N$  curve is  $1/n$  or  $1/3$ . When initiation dominates, the slope of the  $S-N$  curve is  $1/b$  or around  $1/8$  to  $1/10$ . Thus, the slope of theoretical and experimental  $S-N$  curves reflect the relative importance of "I" and "P."

FIG. 18 COMPARISON OF THE PREDICTIONS OF THE INITIATION-PROPAGATION MODEL WITH DATA IN THE UNIVERSITY OF ILLINOIS AT URBANA-CHAMPAIGN WELDMENT FATIGUE DATABANK FOR A MILD STEEL, NON-LOAD-CARRYING CRUCIFORM WELDMENT,  $R = 0$

FIG. 19 COMPARISON OF THE PREDICTIONS OF THE INITIATION-PROPAGATION MODEL WITH DATA IN THE UNIVERSITY OF ILLINOIS AT URBANA-CHAMPAIGN WELDMENT FATIGUE DATABANK FOR A MILD STEEL, NON-LOAD-CARRYING CRUCIFORM WELDMENT,  $R = -1$

FIG. 20 COMPARISON OF THE PREDICTIONS OF THE INITIATION-PROPAGATION MODEL WITH DATA IN THE UNIVERSITY OF ILLINOIS AT URBANA-CHAMPAIGN WELDMENT FATIGUE DATABANK FOR A MILD STEEL, DOUBLE-V BUTT WELDMENT,  $R = 0$

FIG. 21 COMPARISON OF THE PREDICTIONS OF THE INITIATION-PROPAGATION MODEL WITH DATA IN THE UNIVERSITY OF ILLINOIS AT URBANA-CHAMPAIGN WELDMENT FATIGUE DATABANK FOR A MILD STEEL, DOUBLE-V BUTT WELDMENT,  $R = -1$

**The Effect of Residual Stresses.** Residual stresses greatly influence the fatigue life of both the "Nominal" and "Ideal" weldments, as shown in Fig. 22. In Fig. 22, the welding residual stresses ( $\sigma_r$ ) and the fabrication stresses ( $S_{fab}$ ) were presumed to be either 0 or their largest possible value, the yield strength of base metal (36 ksi). Both  $N_I$  and  $N_P$  are much affected by fabrication stresses. As can be seen, there is a very large difference between the total lives of both "Nominal" and "Ideal" weldments with and without fabrication stresses. This effect is probably a major source of the reported large difference between fatigue tests using small, simple testpieces and full-scale fatigue tests on complex welded structures in which large fabrication stresses ( $S_{fab}$ ) may exist.

FIG. 22 EFFECT OF RESIDUAL STRESSES ON THE FATIGUE BEHAVIOR OF "NOMINAL" AND "IDEAL" 1.0 IN. PLATE THICKNESS, MILD STEEL, NON-LOAD-CARRYING CRUCIFORM WELDMENTS

The effect of weldment size is a subject of continuing controversy. The predicted effect of size on the fatigue strength at  $10^7$  cycles is shown for both the "Nominal" and "Ideal" weldments in Fig. 23. The predicted behavior of the "Ideal" weldment is similar to the currently anticipated size effect and has a slope of  $\approx -1/3$ . Note that "Ideal" weldments with high fabrication stresses may have a slope greater than  $-1/3$ . The 0.1-in. discontinuity in the "Nominal" weldment leads to essentially no size effect for weldments having  $T > 1.0$  in. (25 mm) and a reversal in the size effect when  $T < 0.7$  in. (18 mm) due to the large size of the initial flaw (0.1-in.) assumed relative to the smaller plate thicknesses considered.

FIG. 23 THE PREDICTED EFFECT OF WELDMENT SIZE FOR BOTH A "NOMINAL" AND "IDEAL" MILD STEEL, NON-LOAD-CARRYING CRUCIFORM WELDMENT

**The Effect of Base Metal Strength.** It is generally believed that the fatigue resistance of non-stress-relieved weldments is independent of its base metal tensile strength. Steels with higher UTS do exhibit a greater fatigue resistance in the absence of (tensile) mean or residual stresses. Unfortunately, higher UTS weldments also have higher yield strengths and thus can sustain much more damaging welding and fabrication residual stresses. So any improvement in intrinsic fatigue resistance resulting from increasing the strength of a base metal is usually more than offset by the damaging effects of tensile residual stresses, which develop during fabrication. If one can induce compressive residual stresses or reduce the size of the as-welded tensile residual stresses, the fatigue strength of higher strength "Ideal" weldments of high-strength materials can be much improved.

The fatigue strength of a mild steel ( $S_y = 36$  ksi) and a quenched-and-tempered steel ( $S_y = 100$  ksi) are compared in Fig. 24, where the higher strength Q&T steels are predicted to perform better when the residual stresses are small or compressive and when crack growth is relatively unimportant, that is, as in the case of small-thickness, "Ideal" weldments.

**FIG. 24 PREDICTED FATIGUE STRENGTH OF A CRUCIFORM WELD MODEL (FIG. 16) FOR MILD STEEL ( $S_y = 36$  KSI, 250 MPA) AND QUENCHED-AND-TEMPERED (QT) STEEL ( $S_y = 100$  KSI, 690 MPA).  $R = 0$ ;  $T$  GIVEN IN INCHES. QUENCHED-AND-TEMPERED STEELS SHOW NO ADVANTAGE FOR ALL NOMINAL TYPES IN ASWELDED (AW), STRESS-RELIEVED (SR), AS-WELDED (AW), STRESS-RELIEVED (SR), AND TENSILE OVERSTRESSED (OS) CONDITIONS.**

**The Effect of Post-Weld-Processing Procedures.** The predicted effect of various post-weld-processing procedures on the fatigue strength of the hypothetical "Ideal" and "Nominal" mild steel nonload carrying cruciform weldments is shown in Fig. 25. The fatigue strength of "Ideal" weldments can be much improved; whereas, that of "Nominal" weldments cannot because most improvement techniques alter the material properties or residual stresses in the near-surface (notch root) material and thus do not much affect crack growth behavior at a depth of 0.1 in. (2.5 mm). Only the fabrication stresses and applied mean stresses are predicted to influence much crack growth behavior at a depth of 0.1 in.

**FIG. 25 THE PREDICTED EFFECT OF VARIOUS FATIGUE STRENGTH IMPROVEMENT TREATMENTS ON THE FATIGUE STRENGTH OF A MILD STEEL, NON-LOAD-CARRYING CRUCIFORM WELDMENT. THE "NOMINAL" JOINT FATIGUE (SHADED AT THE LOWER STRENGTH LEVELS) DID NOT BENEFIT FROM THE INDICATED TREATMENTS AS MUCH AS THE "IDEAL" JOINTS FOR A SIMILAR TREATMENT (UNSHADED BARS). SOME IMPROVEMENT TECHNIQUES CAN CAUSE THE WELDMENT TO EQUAL THE FATIGUE STRENGTH OF PLAIN PLATE (30 KSI). BECAUSE OF ITS ROLLED-IN SURFACE DISCONTINUITIES, PLAIN PLATE HAS A  $K_f \approx 1.43$ . SOURCE: REF 8**

In general, there are essentially two main strategies for improving weldment fatigue strength: alter the residual and mean stresses or improve the stress-concentrating geometry of the critical notch (weld toe) or a combination of both. As noted above, using higher-strength materials is not effective for nonstress-relieved weldments.

**The Combined Effect of Weldment Size and Fabrication Stresses on "Nominal" and "Ideal" Weldments.** Weldments or welding applications can be categorized according to weldment size and weld quality as shown in Fig. 26.

- **LIGHT INDUSTRY APPLICATIONS** IN WHICH THE WELDMENT SIZE IS ABOUT 0.5 IN. OR LESS. FOR SUCH WELDMENTS IT IS PRESUMED THAT THE WELDMENTS ARE "SIMPLE" AND DO NOT THEREFORE ENGENDER HIGH FABRICATION STRESSES, THAT IS,  $S_{FAB} \approx 0$ .
- **HEAVY INDUSTRY APPLICATIONS** IN WHICH THE WELDMENT SIZE IS ABOUT 2.0 IN. IT IS PRESUMED THAT THE WELDMENTS ARE "COMPLEX" AND THEREFORE DO ENGENDER HIGH FABRICATION STRESSES, THAT IS,  $S_{FAB} \approx +S_{YBM}$  (BASE MATERIAL YIELD STRENGTH).
- **HIGH-QUALITY WELDING PROCESSES** SUCH AS GAS-TUNGSTEN ARC WELDING AND GAS-METAL ARC WELDING IN WHICH THE WELD PERFECTION MAY APPROACH THAT OF THE IDEAL WELDMENT.
- **LOW-QUALITY WELDING PROCESSES** IN WHICH THE WELD PERFECTION IS LOW AND A

SUBSTANTIAL INITIAL WELD DISCONTINUITY MUST BE ASSUMED TO BE PRESENT. SUCH WELDMENTS MAY APPROACH THE BEHAVIOR OF THE "NOMINAL" WELDMENT ( $A_1 \approx 0.1$  IN., OR 2.5 MM).

FIG. 26 COMPARISON OF FOUR COMMON INDUSTRIAL SITUATIONS: LIGHT INDUSTRY-HIGH QUALITY WELDING, LIGHT INDUSTRY-LOW QUALITY WELDING, HEAVY INDUSTRY-HIGH QUALITY WELDING, HEAVY INDUSTRY-LOW QUALITY WELDING. MILD STEEL CRUCIFORM WELDMENTS  $R = 0$ . THE SMALL-SIZE, HIGH-WELDING QUALITY WELDMENTS TYPICAL OF THE GROUND VEHICLE INDUSTRY MAY PERFORM SUBSTANTIALLY BETTER THAN LARGER AND MORE COMPLEX, OR LESSER QUALITY WELDMENTS.

**Modeling the Uncertainty in Weldment Fatigue Strength.** In the section "Metallic Fatigue in Weldments" in this article, the scatter or uncertainty in weldment fatigue data overshadowed the effect of most of the fatigue variables discussed in this section. While these variables may have only a moderate effect on the mean fatigue life, they are the source of scatter in the fatigue strength data for a given weldment. This scatter forces low design stresses to avoid frequent failures (as seen in the section "Metallic Fatigue in Weldments" in this article).

A powerful application of the analytical models employed here to estimate the mean fatigue life or strength of a given weldment is to use the model as the basis of a stochastic analysis of weldment fatigue life and to imagine that some or all of the variables considered by the model are stochastic in nature. In this way, the uncertainty in the fatigue resistance of a weldment can be estimated, and the contribution of each fatigue variable to the total uncertainty in fatigue strength of a weldment can be assessed.

The uncertainty in the fatigue life of the "Nominal" weldment has been studied by Engesvik and Moan (Ref 9). For weldments with large welding discontinuities, the major sources of scatter in fatigue data are variation in the size of the weld discontinuity and in the magnitude of the fabrication stresses.

In contrast, the uncertainty in the fatigue life of the "Ideal" weldment depends on a large number of variables. Lawrence and Chang (Ref 8) suggested a simple, approximate expression based on the Basquin-Morrow equation for the fatigue strength of a weldment at long lives, which assumes that at long lives  $N_T \approx N_N + N_{P1}$ , that is  $\approx N_1$ :

$$S_a^T = \frac{(\sigma_f' - \sigma_r) (2N_1)^b}{K_{f,max}^{eff} \left(1 + \frac{1+R}{1-R} (2N_1)^b\right)} \quad (EQ 7)$$

Equation 7 was factored to isolate five important attributes of weldments that determine their fatigue strength: the notch severity of the discontinuity ( $G$ ); the mechanical properties of the material in which fatigue crack initiation and short crack growth takes place ( $P$ ); the applied mean stresses effects ( $MS$ ); the residual stresses resulting from fabrication and subsequent use of the weldments ( $RS$ ); and the self-induced stresses caused by the welding distortions ( $B$ ). Equation 7 was rewritten assuming that the weldments are axially loaded and that the bending stress components are induced by the welding distortions (Ref 4):

$$S_a^A = P \cdot G \cdot RS \cdot MS \cdot (2N_f)^B \quad (\text{EQ 8})$$

where the factors for the effects mentioned above are as follows:

$$P = \sigma'_F \quad (\text{MATERIAL PROPERTIES})$$

$$G = \frac{1}{K_{f,\max}^A} \quad (\text{NOTCH SEVERITY})$$

$$B = \frac{1}{1 + x \left( \frac{K_{f,\max}^B}{K_{f,\max}^A} - 1 \right)} \quad (\text{DISTORTION})$$

$$RS = 1 - \frac{\sigma_r}{\sigma'_f} \quad (\text{RESIDUAL STRESSES})$$

$$MS = \frac{1}{(1 + (2N_f)^b) \frac{(1+R)}{(1-R)}} \quad (\text{MEAN STRESS})$$

If the variables  $P$ ,  $G$ ,  $B$ ,  $RS$ , and  $MS$  can be considered to be normally distributed variates, the coefficient of variation (COV) of the fatigue strength of a weldment ( $\Omega_S$ ) can be approximated (Ref 2) as:

$$\Omega_S^2 \approx \Omega_P^2 + \Omega_G^2 + \Omega_B^2 + \Omega_{RS}^2 + \Omega_{MS}^2 + \Omega_f^2 \quad (\text{EQ 9})$$

where the subscripts P through MS designate the COV of the random variable representing the effects of material properties, notch severity of geometry, welding-distortion-induced stresses, notch-root residual stress, and applied mean stress, respectively.

The estimated sources of uncertainty in weldment fatigue strength data reported by various investigators (Ref 4) are tabulated in Table 7 together with the reliability factor ( $R_F$ , see Eq 4). As can be seen, the sources of the scatter in weldment fatigue data depend on the nature of the joint and how it is loaded. The butt joints (B1 and B2) have very little scatter associated with their reported fatigue data. The load-carrying cruciform weldments (LCC1 and LCC2) have enormous scatter, largely due to welding fabrication distortions that induce secondary stresses during gripping and subsequent axial loading. However, the estimated scatter in the fatigue databank data is much larger than that associated with even the "worst" weldment for the reasons discussed in the section "Metallic Fatigue in Weldments" in this article.

(A) REPORTED BY VARIOUS INVESTIGATORS IN REF 4

These observations are reflected in the plot (Fig. 27) of reliability factor ( $R_F$ ). The values of  $R_F$  were obtained using Eq 4. The value of  $R_F$  for an individual weldment may be as high as 0.9 and as low as 0.7. Average values of  $R_F$  would seem to be around 0.7. The  $R_F$  implied by the use of a fatigue databank entry for a particular weld geometry (e.g., detail 10 in Fig. 4) is estimated at 0.55. The use of weld categories was earlier argued to lead to values of  $R_F$  of around 0.4.

FIG. 27 THE RELIABILITY FACTOR ( $R_F$ ) FOR EACH OF THE DATA SOURCES IN TABLE 7

The form of Eq 9 suggests some interesting but perhaps obvious strategies for reducing the uncertainty in the fatigue strength of an individual weldment:

- *IF THERE IS ONLY ONE LARGE SOURCE OF UNCERTAINTY, THE UNCERTAINTY IN WELDMENT FATIGUE STRENGTH CAN ONLY BE IMPROVED BY ITS REDUCTION, BUT THE UNCERTAINTY IN WELDMENT FATIGUE STRENGTH CAN INCREASE IF ANY OF THE LESSER SOURCES IS PERMITTED TO GROW.*
- *IF THERE IS NO DOMINANT SOURCE OF UNCERTAINTY, THE UNCERTAINTY IN WELDMENT FATIGUE STRENGTH CAN ONLY BE IMPROVED BY REDUCING ALL SOURCES UNIFORMLY, BUT, AS ABOVE, THE UNCERTAINTY IN WELDMENT FATIGUE STRENGTH CAN INCREASE IF ANY ONE OF THE SOURCES IS PERMITTED TO GROW.*

**Summary of Weld Fatigue Variables.** The main variables affecting weld fatigue strength are weldment geometry, weld-distortion-induced bending stresses, and residual stresses. These variables are also the main contributors to the uncertainty in fatigue life. Analytical models can be used to estimate the uncertainty in fatigue strength and to identify the contribution of each source to the overall uncertainty.

## Fatigue of Mechanically Fastened Joints

Harold Reemsnyder, Bethlehem Steel Corporation

---

### Introduction

MECHANICALLY FASTENED structural joints (such as riveted joints and high-strength bolted joints) are used in many fatigue critical applications, and a considerable amount of fatigue testing of mechanically fastened structural joints has been performed to support the development of fatigue provisions in structural design specifications. In general, the important factors affecting the fatigue strength of riveted (hot-driven) and friction bolted joints are clamping force, grip length, type of fastener, fastener pattern, tension-shear ratio, tension-bearing ratio, and type of steel in fastener or main material. These factors are discussed in various publications such as Ref 1 and 2.

Typically the fatigue resistance of high-strength friction bolted joints is superior to that of riveted joints. For example, the fatigue strength of carbon steel joints fastened with A-325 bolts approaches the yield strength of the connected material (Ref 3 and 4) (Fig. 1). On the other hand, the fatigue resistance of carbon steel joints fastened with hot-driven rivets is practically identical to the fatigue resistance of carbon steel plates perforated with circular holes (Ref 5).

**FIG. 1 FATIGUE STRENGTH OF CARBON STEEL STRUCTURAL JOINTS. SOURCE: *STRUCTURAL STEEL DESIGN*, RONALD PRESS, 1974, P 519-551**

Joint design and loading are probably the most critical factors, static strength of the material may not always be a factor. In some codes, fatigue resistance of bolt joints may be considered independent of static strength (Ref 6). For example, in a Swedish design recommendation for bolted connections (Ref 7), the fatigue strength is actually reduced for higher strength bolts, from a stress range of 100-120 MPa (14.5-17.4 ksi) at  $N = 10^7$  cycles for Grade 8.8 bolts, to 80 MPa (11.6 ksi) for Grade 12.9 and higher strength bolts. In the European Convention for Constructional Steelworks' recommendation (Ref 8) a single  $S-N$  curve is given for all steel bolt materials up to Grade 10.9 (max UTS - 1040 MPa), where the stress range at  $N = 0.5 \times 10^6$  cycles is only 26.5 MPa (3.8 ksi). However, static strength may have a significant effect for rolled threads (Fig. 2).

**FIG. 2 AXIAL FATIGUE STRENGTH AT  $10^7$  CYCLES OF BOLT-NUT ASSEMBLIES WITH ROLLED THREADS AND MACHINED THREADS ( $R = -1$ ).**

A summary of many tests on riveted plain carbon and alloy steels (Ref 9) also demonstrates a joint fatigue strength at about 180 MPa (26 ksi) for  $2 \times 10^6$  cycles, despite a range of static tensile strengths of 415 to 690 MPa (60 to 100 ksi). This illustrates the importance of joint design and loading over that of material strength. For example, the tension/shear/bearing ratio is very important in the fatigue life of riveted joints (Fig. 3). In particular, the stress concentrations at the hole surface degrades allowable bearing strength, which thus promotes the use of high-strength bolts instead of rivets. In a bolted joint of proper design it is possible to carry the shear load by friction.

## Fatigue of Mechanically Fastened Joints

Harold Reemsnyder, Bethlehem Steel Corporation

## Threaded Fasteners in Tension

Thread design and clamping forces are two key factors affecting the fatigue resistance of bolted joints. However, fastener strength can be an important variable when threads are rolled (Fig. 2). This is in direct contrast with machined threads, which demonstrate little or no static-strength effect on fatigue endurance (Fig. 2). This demonstrates the importance of surface condition on fatigue crack initiation. Rolled threads demonstrate a superior fatigue resistance due to a combination of compressive residual stresses and smoother surface at the thread root.

The form of the threads, plus any mechanical or metallurgical surface condition is much more important than nominal steel composition in determining the fatigue strength of a particular lot of bolts. Surface composition is, however, a factor. Surface decarburization can cause a significant reduction in the fatigue resistance of steel bolts. Fatigue tests on  $\frac{1}{4}$ -in. diam. steel bolts with a tensile strength of 917 MPa (133 ksi) showed:

DECARBURIZED LAYER, IN.	FATIGUE LIMIT AT $10^7$ CYCLES, KSI
NONE	40
0.001 IN.	27
0.002	25

It is recommended that heat treatment be performed after threading to reduce the deleterious effects of decarburization. Thread-rolling also eliminates effects of decarburization.

The weakest point of an axially load standard bolt and nut combination in fatigue is normally in the bolt threads at about one turn in from the loaded, or bearing, face of the nut where the load transfer from nut to bolt is at maximum value. This area of stress concentration occurs because the bolt elongates as the nut is tightened, thus producing increased loads on the threads nearest the bearing face of the nut, which add to normal service stresses. This condition is alleviated to some extent by using nuts of a softer material that will yield and distribute the load more uniformly over the engaged threads.

Fatigue failures occur with much less frequency under the bolt head or at the thread run-out, and are usually machining errors. For example, failures beneath the bolt head can be caused by poor forging practice, grinding burns, etc. Head failures have also been caused by improper upsetting procedures that result in broken flow lines after machining in the critical head-to-shank fillet region. The stress concentration at the runout of the thread can be reduced by reducing the bolt shank diameter to less than the thread root diameter, or by a stress-relieving groove. The nut should never be run up to the end of the thread unless the shank is undercut below the thread.

Shape and size of the head-to-shank fillet are important, as is a generous radius from the thread runout to the shank. In general, the radius of this fillet should be as large as possible while at the same time permitting adequate head-bearing area. This requires a design trade-off between the head-to-shank radius and the head-bearing area to achieve optimum results. Cold working of the head fillet is another common method of preventing fatigue failure because it induces a residual compressive stress and increases the material strength.

**Effect of Thread Design.** The principal design fracture of a bolt is the threaded section, which establishes a notch pattern in design. Any measures that decrease stress concentration can lead to improved fatigue life. Typical examples of such measures are the use of UNJ increased root radius threads (see MIL-S-8879A) and the use of internal thread designs that distribute the load uniformly over a large number of bolt threads.

The effect of thread form on the fatigue resistance of an axially loaded bolt is shown in Table 1. The Whitworth or British Standard thread (with rounded thread root and crest) is superior in fatigue when compared to the American Standard thread form with flat crest and root (Table 1) (Ref 10). Axial load fatigue tests on "unified" screw threads for use in the USA, Canada, and Britain show a somewhat higher fatigue strength than the British Standard Whitworth (Table 2) (Ref 11). (The unified thread differs from the American Standard thread in that the former has a radius at the thread root while the latter has a flat thread root.)

(A) WHITWORTH THREAD IN PARENTHESES.

As previously noted, the use of softer nuts can reduce the stress concentration at the bearing face of the nut-bolt, where maximum stress concentration occurs. For example, the stress concentration factor at the bearing face of the nut can be reduced from 3.4 to 2.5 by using an aluminum, rather than a steel, nut on a steel bolt (Ref 12). [Note: A galvanic action may occur in corrosive environments with such a combination of two different metals.] Various nut design modifications have also improved fatigue resistance by improving the load distribution (Ref 2).

A general estimate of the notch effect on fatigue strength can be approximated using Peterson's well-known relation for the fatigue notch factor ( $K_f$  = unnotched/notched fatigue strength):

$$K_f = 1 + \frac{K_t - 1}{1 + a/r} \quad (\text{EQ 1})$$

where  $r$  is the notch root radius, and  $a$  is a material constant which is related to the ultimate material strength such that  $a \approx 110/\text{UTS}^2$  ( $a$  in m, UTS in MPa units). The stress concentration factor ( $K_t$ ) depends on geometry. For each groove in a threaded bolt the adjacent threads act as relief notches so that the stress concentration factor is much lower than that of a single groove of the same geometry. Otaki (Ref 13) estimated the stress concentration factor ( $K_t$ ) of a single notch of

thread shape to be 4.3 while for similarly shaped parallel grooves as in a threaded bolt was only 2.52. The effect of bolt diameter on  $K_t$  is shown in Fig. 4 (Ref 14). This method allows an estimate of fastener fatigue limits from fatigue strength of smooth specimens. Rough estimates of a fatigue limit may agree with the fatigue limit given in some codes, while there are large discrepancies with other codes and rules. These differences in fatigue properties are examined in Ref 6 for some European codes.

**FIG. 4 STRESS CONCENTRATION FACTOR ( $K_t$ ) VERSUS BOLT DIAMETER FOR BOLTS WITH STANDARD METRIC THREADS. SOURCE: REF 14**

**Effect of Preload.** Tightening, or preloading, an axially loaded bolt-nut combination increases the fatigue strength significantly. A rule of thumb is "pretension to twice the maximum fatigue load" (Ref 2). Higher clamping forces make more rigid joints and therefore reduce the rate of fatigue crack propagation from flexing. In addition, bolts are most likely to fail by fatigue if the assemblies involve soft gaskets or flanges, or if the bolts are not properly aligned and tightened. In many assemblies, a certain minimum clamping force is required to ensure both proper alignment of the bolt in relation to other components of the assembly and proper preload on the bolt. The former ensures that the bolt will not be subjected to undue eccentric loading, and the latter that the correct mean stress is established for the application.

Preloading, in effect, increases the area carrying the external load from the net area of the bolt to the sum of the clamped faying surfaces plus the bolt net area. The relationship between the bolt load  $P_B$ , the bolt pretension  $Q$ , and the externally applied load  $P$  is expressed by (Ref 2):

$$P_B = Q + \frac{P}{1 + \frac{K_p}{K_b}} \quad (\text{EQ 2})$$

where  $K_b$  and  $K_p$  are, respectively, the stiffnesses of the bolt and clamped parts. The cyclic load in a pretensioned bolt is a function of the external cyclic load and the stiffness ratio  $K_p/K_b$ . The magnitude of the pretension  $Q$  establishes the maximum working load, i.e., the load at which the faying surfaces separate. The load carried by the bolt  $P_B$  may be decreased by decreasing the bolt stiffness  $K_b$ , thus increasing the fatigue resistance of the bolt. For maximum fatigue resistance, soft or flexible inserts between the clamped parts should be avoided. The clamped parts should be flat and tight (i.e.,  $K_p$  should be high relative to  $K_b$ ). Methods for computing  $K_p$  and  $K_b$  are described in Ref 15.

Pretension is gradually reduced during cyclic loading. It appears that loss of pretension is more rapid with machine-cut threads than with rolled threads and also when there are several plies being joined. The interaction of elevated temperature and cyclic loading on bolt preload is also complicated. It appears that fatigue resistance may increase with temperature. However, at long lives, creep, rather than fatigue, may be the controlling failure mode. Bolt preloading is discussed in detail in Ref 1 and 2.

**Tightening of Bolts.** The determination of the actual preload in a given bolt-nut combination is difficult. Tightening with a torque wrench is the simplest but is likely to be inaccurate unless calibrated. Various devices exist that allow the clamping force-torque relation to be established for each bolt-combination. Bolts with built-in indicators of elongation, crushable washers, and bolts with break-off driving elements are also used to control preload.

It is important that this calibration be made for each lot (size, length, thread combination) of bolt-nut pairs used because the force-torque relation is quite sensitive to thread condition, lubrication, and cleanliness. For example, in the case of new, well-lubricated threads, 90% of the torque is used to overcome friction (friction under nut, 50%, thread friction 40%) and only 10% of the torque is available to develop the axial load in the bolt.

For *estimating* purposes, torque may be expressed approximately by (Ref 16):

$$T = K \cdot D \cdot P_B \quad \text{(EQ 3)}$$

where  $T$  = torque,  $K$  = torque coefficient,  $D$  = nominal bolt size, and  $P_B$  = bolt tension.

The unitless torque coefficient,  $K$ , may be taken as 0.2 but is, in reality, a function of thread conditions, geometry, friction between thread contact surfaces, friction between bearing face of turning element (nut or bolt head), etc. A more exact torque-bolt tension relation (Ref 17) for estimating purposes is shown in Fig. 5.

FIG. 5 NOMOGRAPH FOR TORQUE ON BOLTS. SOURCE: REF 17

**Effect of Mean Stress.** Axially loaded mild steel bolts are insensitive to mean stress (Ref 2). A similar insensitivity to mean stress has been shown (Ref 18) for axially loaded high-strength structural bolts. However, in the later case, it was shown that the variability in observed lives increased with decreasing mean stress.

**Studs.** The fatigue resistance of studs is normally greater than that of bolts because the loading at the first turn of thread engagement is less severe. The fatigue resistances of various preloaded stud configurations are compared in Ref 2.

## Fatigue of Mechanically Fastened Joints

Harold Reemsnyder, Bethlehem Steel Corporation

---

### Bolts and Rivets in Bearing and Shear

Many fasteners transfer load through shear by bearing on the sides of holes in the joined plies. Although proportioned in design by assuming all fasteners carry an equal share of the transferred load, the fasteners in the outermost rows carry more load than those in the inner rows.

**Bolted Joints.** In bolted shear joints, fatigue failures are initiated at:

- BOLT HOLES IN THE OUTERMOST ROW WHERE SHEAR TRANSFER IS MAXIMUM,
- A REGION OF FRETTING, OR
- SOME GEOMETRIC STRESS CONCENTRATION OTHER THAN A BOLT HOLE.

Failures at the first two sites are more likely than at some stress concentration other than the bolt hole. Fretting caused by relative movement of the plies is more common at long lives and relatively low stresses. In aircraft design, elaborate joints (e.g., scarfed joints with tapered plies), produce a more uniform shear transfer and, therefore, fretting predominates.

The influence of mean stress, bolt patterns and joint dimensional parameters are similar to those of riveted joints.

**Cold-Driven Rivet Joints in Sheet.** At short lives (less than  $10^5$  cycles), rivets may fail in shear while, at longer lives, sheet failure occurs through the outermost line of rivets with cracks initiated at the rivet holes. Fatigue life is insensitive to mean stress and is, primarily, a function of stress range.

In single-lap joints, the fatigue resistance increases with the ratio of rivet diameter  $d$  to sheet thickness  $t$ , with the ratio of pitch  $p$  to  $d$ , and with the number of rows of rivets. Recommended proportions (Ref 2) of riveted, single-lap joints for high fatigue resistance are listed in Table 3.

**TABLE 3 RIVETED SINGLE-LAP JOINT PROPORTIONS FOR HIGH FATIGUE RESISTANCE**

JOINT	$D/T$	$G/D$	$P/D$	EDGE DISTANCE, INCHES	
				FROM ROW	FROM LINE
SINGLE ROW	3	3	...	2	$1-\frac{1}{2}$ TO 2
DOUBLE ROW:					
IN-LINE	4.5	4	$3-\frac{1}{2}$	3	3
STAGGERED	4.5	4	$2-\frac{7}{8}$ (MIN)		

$d$  = rivet diameter,  $g$  = gage,  $t$  = sheet thickness,  $p$  = pitch. Source: Ref 2

Double-lap joints are superior in fatigue resistance to single-lap joints due to offset loading in the latter. The number of rows of rivets in a double-lap joint appear to have less influence on fatigue resistance than in a single-lap joint, but, again, a high  $d/t$  ratio is desirable. Also, the outer plies should be at least 0.6 times the thickness of the inner ply. Optimum proportions for double-lap joints are similar to those listed in Table 3.

Joints with flush-head rivets generally have poorer fatigue strength than those with protruding heads (Ref 2). Rivet hole fabrication also has a significant influence on fatigue resistance. In order of decreasing fatigue strength, fabrication techniques are: coin-dimpling, spin-dimpling, drilling, and machine-countersinking.

**Hole Sizing and Interference Fits.** The stress concentration factor of a circular hole loaded in bearing with a round pin is significantly higher than an open hole in a remotely loaded tensile strip (see section "Pin Joints" in this article). However, these high local stresses can be reduced by "sizing" or "drifting." The hole is plastically expanded to produce compressive residual stresses by forcing an oversize, smooth ball or pin through the hole.

Tapered bolts and self-sizing or interference bolts (e.g., the Huckbolt) also introduce compressive residual stresses in the hole surface through plastic deformation. Interference bolts can be used in multi-bolt joints but, to be effective, the hole patterns must be accurately matched in all plies. This is accomplished by drilling and reaming the plies held together in a jig assembly.

**Friction Joints.** The most effective means of increasing the fatigue strength of joints is by tensioning the fasteners to clamp the plies together. The load is then transferred from one ply to another by friction of the faying surfaces rather than by shear in the bolts bearing on the plies. The maximum, or slip, load that can be transferred through friction is

$$P_S = K_S \cdot M \cdot N \cdot P_B \quad (\text{EQ 4})$$

where  $K_S$  = coefficient of slip (friction),  $m$  = number of slip planes (number of plies -1),  $n$  = number of bolts, and  $P_B$  = bolt preload or clamping force.

Coefficients of slip for various structural steels are listed below (dry mill scale):

STEEL	$K_S$
A36 (CARBON STEEL)	<b>0.35 (REF 19)</b>
A440 (HIGH-STRENGTH LOW-ALLOY)	<b>0.18 (REF 20)</b>
A514 (QUENCHED AND TEMPERED)	<b>0.20 (REF 21)</b>

An increase in fatigue strength with clamped joints is only achieved if relative slipping is eliminated--otherwise fretting failures are likely. Slipping is best prevented by careful positioning of the bolts over the entire contact area, using smallest possible gage and pitch (allowing for wrench clearance), tightening to a high bolt clamping force, and reducing the contact, or faying, surfaces to a minimum. Unnecessary overhang of plies beyond the first bolt row must be eliminated to prevent fretting.

Clamping causes the plies to behave integrally as if welded together and to more uniformly distribute the total load over the fasteners. The stress concentrations at the holes are reduced by the compressive clamping forces and fatigue failure is generally initiated away from the holes. The fatigue resistance of bolted friction joints is discussed in the next section.

It is essential in assembling bolted friction joints that a consistent, high bolt preload be maintained. This is accomplished through the calibration of torque or pneumatic impact cut-off wrenches. The bolt-tension calibrator is a hydraulic instrument which measures the bolt tension developed by tightening the bolt or nut. The test is made on at least three bolts of each lot (size-grip combination) and the torque or cut-off to develop the required tension is averaged (Ref 22).

An alternate criterion for tightening bolts is the "turn-of-nut" method, Fig. 6, developed in the railroad and automotive industries. Bolts are installed to a specified rotation from the "snug-tight" condition. "Snug-tight" condition is achieved when the bolt tension or preload equals 70% of the specified minimum breaking strength of the bolt (Table 4). Nut rotations when both faces are normal to the bolt axis are (Ref 22):

BOLT LENGTH, 1	NUT ROTATION FROM "SNUG-TIGHT"
1 < 4 DIAMETERS	$\frac{1}{3}$ TURN
4D < 1 < 8D	$\frac{1}{2}$ TURN
8D < 1 < 12D	$\frac{2}{3}$ TURN

**TABLE 4 MINIMUM BOLT BREAKING STRENGTHS**

BOLT DIAMETER, IN.	BREAKING STRENGTH, KSI	
	A325	A490
$\frac{1}{2}$	17.0	<b>21.3</b>
$\frac{3}{4}$	40.1	<b>50.1</b>
1	72.7	<b>90.9</b>
1- $\frac{1}{4}$	102	<b>145</b>
1- $\frac{1}{2}$	<b>147</b>	<b>211</b>

Source: Ref 22

FIG. 6 MEASUREMENT OF BOLT ELONGATION IN A TYPICAL TEST JOINT

The button-head, interference-body bolt, called, variously, interrupted-rib, structural-rib, or Dardelet-rivet bolt, combines the clamping action of a high-strength fastener with that of an interference fastener. The body fit of this fastener is an advantage in the assembly of galvanized materials with low interface friction. The body-bound fit--metal-to-metal contact--also ensures better electrical grounding of structures.

**Hot-Driven Riveted Joints of Structural Plate.** Important factors affecting the fatigue strength of riveted (hot-driven) and friction bolted joints are clamping force, grip length, type of fastener, fastener pattern, tension-shear ratio, tension-bearing ratio, and type of steel in fastener or main material. Failure through the net section occurs in both riveted and bolted joints, but an increase in clamping force of the bolts can cause failure in the gross section (Ref 3). In a riveted joint, fatigue cracks are initiated at the rivet holes while, in friction bolted joints, they are initiated at the edges of the clamped plies. It has been shown that the fatigue resistance of high-strength friction bolted joints is superior to that of riveted joints and that the fatigue strength of carbon steel joints fastened with A-325 bolts approaches the yield strength of the connected material (Fig. 1).

Some research indicates that no steel shows a superiority over carbon steel as plate material in riveted joints subjected to cyclic loading. It has been suggested that the effect of variation in clamping force within a joint or from one joint to another subordinates the relative superiority of one steel over another and produces the great experimental scatter. In addition the fatigue resistance of riveted joints is very sensitive to the tension-shear-bearing ratio (Fig. 2), which masks variations in static strength. As previously noted, high-strength bolted joints transfer the loads through friction and, therefore, avoid the above sensitivity.

**Field Repair and Rehabilitation of Riveted Structures.** The generally accepted method of repair or rehabilitation of elderly riveted structures to extend their service life has been the replacement of entire members that either contain fatigue damage or are suspected to be overstressed in cyclic loading. One program (Ref 23) studied the effectiveness of rehabilitation by replacement of rivets with high-strength structural bolts in critical or fatigue-damaged locations as a more economical alternative to replacement of entire members. Constant amplitude fatigue tests and variable amplitude service simulation tests of full-scale model ore bridge joints and constant amplitude tests of joints removed from an ore bridge showed that rehabilitation of fatigue-damaged members by fastener replacement increases fatigue life 2 to 6 times. The effect on fatigue life extension of increasing bolt tension above the minimum value accepted in present specifications and/or the effect of crack length (up to 1 inch long) at rehabilitation were found to be of secondary importance.

Drilling holes at crack tips is not always effective in arresting fatigue cracks in structural members. Tests on welded crane runway girders have shown that, should the drilled hole miss the crack tip, crack growth could be reinitiated (Ref 24). It is often very difficult to ensure that the hole includes the crack tip. It was concluded, therefore, that this technique is neither sufficiently reliable nor applicable to be recommended as a universal repair for cracks. Instead, a drilled hole with a properly torqued high-strength bolt (70% or more of bolt breaking strength), could be considered as an expedient crack arrestor until a more reliable repair can be implemented. The combination of drilled hole and high-strength bolt has also been used as a temporary crack arrestor on railway cars.

## Fatigue of Mechanically Fastened Joints

Harold Reemsnyder, Bethlehem Steel Corporation

---

### Pin Joints

The most extensive review of the stress concentrations and fatigue resistance of pin joints has been made by Heywood (Ref 2). Stress concentration factors for pin joints have also been presented by Lipson and Juvinal (Ref 25) and Peterson (Ref 26).

The fatigue strength of a single pin joint is extremely low in comparison to that of the base material. The fatigue strength is influenced by the stress concentration factor  $K_t$  which, in turn, is a function of many parameters--geometric and material. The relationship between mean stress and stress range are further complicated by fretting.

**Stress Concentrations in Pin Joints.** The stress concentration factor in the lug of a pin joint is defined as

$$K_t = \frac{\text{maximum stress at hole}}{\text{net-section stress}} \quad (\text{EQ 5})$$

where the net section (on the transverse diameter of the hole) is  $(D-d)/t$ .  $D$ ,  $d$ , and  $t$  are, respectively, lug width, hole diameter, and lug thickness.

As  $d/D$  approaches unity, the lug tends to act as a flexible strap and  $K_t$  goes to unity.  $K_t$  is also a function of the edge distance  $H$  and for  $H/D = 1$  (Ref 2):

$$K_T = 0.6 + 0.95 (D/D) \quad \text{(EQ 6)}$$

and for  $H/D = 0.5$ ,

$$K_T = 0.85 + 0.95 (D/D) \quad \text{(EQ 7)}$$

for values of  $D/d$  from 0.2 to 0.8. Note: Heywood (Ref 2) uses a stress concentration factor  $C_t$  based on the gross area where

$$C_T = K_T / (1 - D/D)$$

In addition to the hole size relative to lug size affecting  $K_t$ , the stress concentration factor is also influenced by:

- LUG HEAD SHAPE
- LUG "WAISTING"
- CLEARANCE AND INTERFERENCE OF PIN
- PIN MATERIAL AND LUBRICATION
- PIN BENDING

A square-shaped lug head has a lower  $K_t$  than a rounded lug head. However, head shape has little effect at large values of  $D/d$ . Reducing the lug width on its loaded side (i.e., "waisting") increases  $K_t$ , as documented in Ref 2. As the clearance between the pin and hole increases,  $K_t$  also increases. Interference fit reduces  $K_t$  but this reduction varies inversely with load (Ref 2).

Heywood (Ref 2) suggests that  $K_t = 3$  is near-optimum for fatigue strength design. The proportions for this  $K_t$  would be  $D/d = 2$ ,  $H/d = 1$ , and  $t/d = 1$ . Heywood also discusses in detail the beneficial effects of interference, compressive residual stresses, and preloaded lugs.

## Bibliography of Stress-Intensity Factors

The description of fatigue crack growth in mechanically fastened joints by stress intensity factor concepts is complicated by:

- THE STATICALLY INDETERMINATE NATURE OF THE STRESS DISTRIBUTION IN THE PLYS ALONG, AND ACROSS, THE HOLE ARRAY
- THE CHANGE IN STRESS DISTRIBUTION DUE TO PLY STIFFNESS CHANGES WITH CRACK GROWTH
- THE INFLUENCE OF HOLE PROXIMITY ON STRESS INTENSITY FACTOR, I.E., NOTCH SHADOW EFFECT

The following sections list some references that address some of these factors for mechanically fastened joints.

**Crack Growth from Holes.** The use of fracture mechanics in aircraft joints with open, cold-worked, and pin-loaded holes, and with interference fit fasteners is described in Ref 27 and 28. Fatigue crack propagation from rivet holes is studied in Ref 29 and 30. Radial cracks at pin-loaded holes and corner cracks are studied in, respectively, Ref 31 and 32.

Dealing with cracks at holes in engineering structures is discussed in Ref 33. Stress-intensity factor solutions for cracks emanating from both open and loaded holes in finite width plates, lugs, and multi-fastener joints are tabulated and plotted in Ref 34. A weight function method is used in Ref 35 to estimate stress-intensity factors for surface and corner-cracked fastener holes.

**Life Extension.** Crack growth in riveted and bolted friction structural joints is discussed in Ref 23. The use of high-strength bolts to retard or arrest crack growth in structures is described in Ref 23 and 24.

**Axially Loaded Round Bars.** The application of fracture mechanics to the fasteners themselves requires stress-intensity-factor solutions for cracks in round bars. Solutions for circumferentially cracked, axially loaded, unnotched, round bars are summarized in Ref 36, 37, 38, while the circumferentially notched case is studied in Ref 39. Solutions are available for axially loaded round bars containing:

- STRAIGHT CRACK FRONTS (REF 40, 41, 42)
- SMALL CURVED CRACK FRONTS (REF 43, 44)
- SEMI-ELLIPTICAL CRACK FRONTS (REF 45, 46)
- SICKLE-SHAPED CRACKS (REF 47)

**Bending in round bars** is treated for:

- STRAIGHT CRACK FRONTS (REF 40, 48, 49, AND 50)
- SEMI-ELLIPTICAL FRONTS (REF 45, 46, 51)
- EDGE-CRACKED BARS UNDER TENSION AND BENDING (REF 52, 53)
- ROUND BARS IN TENSION AND IN BENDING CONTAINING STRAIGHT CRACKS (STRAIGHT AND SEMICIRCULAR CRACKS, RESPECTIVELY, REF 54, 55)

Stress-intensity factors for the surface and the deepest point of cracks varying from nearly straight to semicircular are presented for cylindrical bars in tension and bending in Ref 56. Stress-intensity factor solutions for both straight- and curved-fronted cracks in a bar subjected to either axial load or bending are summarized and compared in Ref 57 and 58.

The stress-intensity factor solutions for cracked, round bars, both with and without threads, subjected to either axial load or bending, are reviewed, compared, and synthesized into a form suitable for the analysis of bolts and studs in Ref 59 (with German and Japanese bibliography).

Compliance solutions are presented for the straight-front edge-cracked solid and hollow round bars in tension (Ref 42) and in bending (Ref 49). The compliance solution of Ref 49 for solid bars in bending has been extended to deeper cracks (Ref 50).

The growth and shape of surface fatigue cracks has been studied and stress-intensity factor solutions have been developed experimentally for tension loaded rods (Ref 60), solid and hollow cylinders (Ref 61), and high-strength bolts (Ref 62). Fracture mechanics predictions of crack shape, size, and life have been compared to observations from tests on shafts in bending and containing semi-elliptical cracks (Ref 51), and surface-cracked shafts in bending with shoulder fillets (Ref 63).

**Fasteners.** The growth of a fatigue crack in a bolt of a bolt-nut combination has been modeled using finite element analysis and fracture mechanics (Ref 64). Stress-intensity factor solutions for axially-loaded, threaded round bars are presented in Ref 53 (bending as well as tension) and 65-68. It should be noted that the analyses of Ref 53, 64, 65 modeled thread-like circumferential projections (two or more) in round bars while Ref 66, 67, 68 modeled thread-like single circumferential grooves in round bars. However, the projections and grooves were not helical. Instead, the planes of the projections and grooves were perpendicular to the axis of the round bar.

More information on the use of fracture mechanics for fasteners is covered in Ref 69, 70, 71, 72, 73, 74, 75, 76, 77, and 78. Stress-intensity factors are also summarized in the Appendix "Summary of Stress-Intensity Factors" of this Volume.

## Statistical Considerations in Fatigue

Paul S. Veers, Sandia National Laboratories

---

## Introduction

STATISTICAL METHODS and probability are useful tools when uncertainty influences important outcomes, which is why many fundamental mathematical aspects of statistical theory began with the casinos of Europe (e.g., Monte Carlo). Knowledge of probability and statistics permits the "house" to put large quantities of capital at risk (on the gaming tables) by creating games with odds only slightly in their favor. Although gamblers win almost half the time, on average the house will win. One of the paradigms of stochastic analysis is known as the "Gambler's ruin problem" (Ref 1), where the time to "ruin" (loss of all capital) is estimated given the slight disadvantage to the player. Notice that it is not a matter of *if* but *when*.

The design of structures subjected to fatigue loadings has produced a substantial interest in statistical aspects, for similar reasons. There is substantial uncertainty as to the outcome, that is, the lifetime of each finished product. In fact, even under the controlled conditions of the laboratory with carefully prepared specimens and loadings, the time to failure in identical tests will vary widely. In addition, in the design of structures, the capital at risk is often high due to the high cost of a single installation, the large numbers of units to be produced, or life-critical applications.

In the early years of fatigue design, attention was mainly focused on the phenomenon of endurance limit in steels. The statistical problem is then reduced to simply comparing a single load level with a single strength number, the endurance limit. Figure 1 schematically illustrates the problem of determining the acceptable distance between the average loading and the average endurance limit. The goal is to produce an acceptably low probability that a combination of higher than average loading and lower than average strength will result in failure. This is exactly analogous to the standard approach to static strength design.

**FIG. 1 SCHEMATIC OF PROBABILISTIC DEFINITION OF LOAD AND RESISTANCE**

The endurance limit approach, as illustrated in Shigley and Mitchell (Ref 2), assumes a carefully prepared test specimen to establish an upper bound on the endurance limit and then applies modifying factors (also called knockdown factors) to reduce the strength to actual conditions. These include factors for surface finish, size effects, reliability, temperature, stress concentration, and, ominously, miscellaneous effects, which include such diverse possibilities as corrosion, electrolytic plating, metal spraying, strain rates, and fretting. Only the factor called "reliability" is related to the sample-to-sample variation in the endurance limit. The importance of the endurance limit is illustrated by the extensive guidance provided for determining the median endurance limit from laboratory data (Ref 3).

Unfortunately, designers these days rarely have the luxury of keeping the maximum stresses below the endurance limit. Such designs are too heavy and costly for the high efficiency demands driven by weight and cost constraints. In reality, loadings can almost never be described by a single stress level, but contain a distribution of stress amplitudes and means. In addition, under variable-amplitude loading the very existence of an endurance limit depends on *all* the stresses staying below it (Ref 4, 5). The simple schematic of Fig. 1 is therefore a poor model for the complexity of a variable-amplitude fatigue analysis, which is discussed in more detail in the articles "Fundamentals of Modern Fatigue Analysis for Design" and "Estimating Fatigue Life" in this Volume.

In general, uncertainty can be divided into random (or aleatory) and statistical (or epistemic) types. Quantities whose uncertainties are random have values that are inherently variable and can be described by distribution functions, exceedance diagrams, or histograms. Random uncertainty cannot be reduced; it is inherent in the quantity. A good example is material strength, which will always vary from sample to sample. The good thing about these uncertainties is that they can be well defined with additional data collection, and acceptable levels of reliability can be selected. However, the variability cannot be reduced. Statistical uncertainties are in some ways harder to deal with because they are usually due to a lack of knowledge of some sort. There may be a single correct value for a parameter, but one doesn't know exactly what the value is. Therefore, this uncertainty can be reduced with additional data collection or analysis, but the distribution of possible values will always be a best guess. Typical examples include a stress concentration that is not known exactly, or uncertain usage and loading, or errors and biases built into the analysis models. Both statistical and random uncertainties need to be considered and accounted for in producing reliable designs (i.e., designs that have an acceptable probability of failure before the target lifetime). Both are typically described by a distribution of possible values for the uncertain parameters using a probability density function (defined below).

There are therefore two parts to dealing with uncertainty in fatigue design: determine the distributions of possible values for all uncertain inputs; and calculate the probability of failure due to all the uncertain inputs. This article reviews each of these parts in turn. First, the sources of uncertainty in a fatigue analysis are discussed. They are divided into four principal areas:

- MATERIAL PROPERTIES
- DISTRIBUTION OF APPLIED STRESS LEVELS WITHIN A GIVEN ENVIRONMENT
- ENVIRONMENTS OR LOADING INTENSITIES

- MODELING OR PREDICTION

Then a probabilistic approach for analyzing the uncertainties and determining a level of reliability (probability of failure) is presented.

This article cannot hope to include all the approaches to dealing with the statistical aspects of fatigue. Several references are included for additional reading. Statistical analysis of fatigue test data can be found in ASTM STP 744 (Ref 6). Wirsching (Ref 7) and Wirsching et al. (Ref 8) give a thorough explanation of the basics of linking probability to fatigue analysis. Thoft-Christiansen (Ref 9) and Madsen (Ref 10) cover the probabilistic analysis. Tangjitham and Landgraf (Ref 11) and Veers et al. (Ref 12) provide a couple of specific application examples. Scatter and variability in fatigue life tests are also covered in the article "Fatigue Data Analysis" in Volume 8 of the *ASM Handbook*.

**Basic Descriptors of Variability and Uncertainty.** One descriptor for variability or uncertainty that is used repeatedly in this article and deserves early definition is the coefficient of variation (COV). It is the ratio of the standard deviation and mean of a random quantity. It can be written in terms of samples  $x_i$  of a random variable  $X$ :

$$\text{COV}_X = \frac{\sigma_X}{m_X}; m_X = \frac{1}{N} \sum_{i=1}^N x_i;$$
$$\sigma_X^2 = \frac{1}{N} \sum_{i=1}^N (x_i - m_X)^2$$

(For  $N < 30$ ,  $N$  is replaced by  $N - 1$  in the estimate of the mean ( $m$ ) and by  $N - 2$  in the estimate of the standard deviation,  $\sigma$ , to produce unbiased estimates.) The COV is nondimensional and can be applied to any quantity that varies. The interpretation of the COV may differ with application, however.

How a quantity varies can be described empirically, and most intuitively, by plotting the relative number of times the quantity falls into various ranges in a histogram. If the histogram cells are integrated, upward or downward, it is possible to determine the relative percentage of time the quantity is below some level, or conversely, will exceed the level. In standard probability theory, these histograms are taken to the limit as cell width goes to zero, become continuous functions, and are known as the probability density function, cumulative density function, and inverse cdf, respectively. A good overview of probabilistic concepts treated in an engineering vein can be found in Ang and Tang (Ref 13).

Quantities with near-zero mean values cannot use the COV as a descriptive parameter; the standard deviation with its dimensional requirement is needed. Fortunately, most of the quantities of interest in fatigue analysis are positive valued and the COV is quite descriptive. If restricted to positive outcomes, only low-COV quantities can be normally distributed (Gaussian distribution), while high-COV quantities are often modeled by Weibull and other one-sided distributions, as discussed below.

## Statistical Considerations in Fatigue

Paul S. Veers, Sandia National Laboratories

---

### Uncertainty in *S-N* Data

As mentioned above, dividing a problem into constituent (albeit sometimes arbitrary) parts can be useful in modeling a large problem. The area that usually comes to mind in fatigue statistics is the scatter in *S-N* data. It is not the only area of statistical importance, as the following sections are intended to show, but it is definitely an area where variability is large. The statistics of the fatigue response of the material cannot be ignored. Schijve (Ref 14) provides a very good discussion of this topic. An ASCE series on fatigue reliability suggests that, in most large structure applications, a COV of 0.6 or higher is appropriate for variation of *S-N* data (Ref 15). Because the uncertainty in an *S-N* curve can (and usually does) represent over half of the total uncertainty in fatigue life estimation, the modelling deserves special attention.

The *S-N* curve is usually established based on the results of numerous constant-amplitude tests to failure at several loading amplitudes and mean stresses. To condense everything to a single *S-N* plot and increase the number of samples in the analysis, the mean and amplitude are usually condensed into an effective stress amplitude using a mean stress correction, such as the Goodman or Gerber models (Ref 16).

The goal of the statistical analysis is generally to find an *S-N* curve at an acceptable probability level, which represents the relationship between effective stress amplitude and lifetime for which less than some small percentage of samples would fail. This curve can then be applied to a deterministic lifetime calculation. If all the other inputs to the calculation are known perfectly (are not random), the outcome is a prediction of a lifetime at which less than the specified percentage of parts will have failed.

It is rare that all the nonmaterial inputs (loads, stress concentrations, etc.) are known perfectly. Additional safety factors need to be applied. It is therefore useful in probabilistic calculations to have a model for the distribution of possible values for the *S-N* curve. Then the uncertainty in *S-N* properties can be combined with the other uncertainties in a unified probabilistic analysis to estimate total probability of failure. Probabilistic analysis is covered below in the section on dealing with uncertainty.

There are numerous and varied approaches to carrying out the statistical analysis of *S-N* data. The ASTM standard for establishing median *S-N* curves at various confidence levels is given in Ref 3. A compilation of papers on statistical

analysis of fatigue data can be found in Ref 6. Some other examples can be found in Ref 10 and 17. There is also an American Society for Testing and Materials standard for statistical analysis of  $S-N$  data (Ref 18).

Two levels of random variable models for  $S-N$  uncertainty are described in this article. The first assumes that all the variation can be captured in a single random variable; the second uses two random variables. These are presented as the simplest approaches that are defensible, statistically speaking, but are not necessarily the absolute best in every situation. The emphasis is on simplicity while producing a random variable model for the distribution of possible fatigue lives at a given stress level.

**Single-Random-Variable Model.** The  $S-N$  curve is often assumed to follow the relationship shown in Fig. 2, given by the equation

$$N = CS^{-B} \quad (\text{EQ 1})$$

This assumes that the curve will be a straight line on a log-log plot.  $C$  is called the  $S-N$  coefficient and  $b$  is the exponent, which is one over the slope of the curve. The median line can be determined by a linear regression on the logarithms of the data:

$$\text{LN}(N) = \text{LN}(C_0) + (-B_0) \text{LN}(S) \quad (\text{EQ 2})$$

solving for the slope,  $-b_0$ , and intercept,  $\text{LN}(C_0)$ . The result is a good estimate of the *median* curve, because a best fit will, on average, result in half of the data on each side of the regression line. The *mean* will not be the same as the median, because the distribution (of the original data) will be skewed. Remember, even though the  $S-N$  curve is traditionally plotted with the stress on the ordinate, stress is actually the independent variable and should be treated as such in the regression analysis. To treat cycles as the independent variable can lead to errors in the regression (Ref 19).

FIG. 2 SCHEMATIC OF  $S-N$  CURVE

With the median value of life determined for all effective stress amplitudes, it is left to determine how much variation about that line is present. If there are sufficient replications, the variation about the median can be established at several stress levels. Without copious replications, the data can again be condensed by estimating the variance of the ratios of the data points divided by the median regression line:

$$X_i = \frac{N_i}{C_0 S_i^{-b_0}} \quad (\text{EQ 3})$$

The overall  $\text{COV}_X$  is calculated from all the ratios,  $X_i$ , using Eq 2.

A distribution of  $X$  can be established by plotting the  $X_i$  on probability paper of various types and searching for the best fit. Many people have their favorite distribution type: some like log-normal, which results from normally distributed logarithms of the data, and some prefer Weibull, which is a natural form for fatigue data because it was originally derived as a model of "weakest link" behavior for fatigue applications. Both are characterized by two parameters (Table 1), which can be derived from the median and COV. With less than about 50 samples it may be difficult to find a significant difference between the fits to the two distribution types. Figure 3 shows the log-normal and Weibull distributions plotted on top of each other for a median of 1 and a COV of 0.6, a typical number for material  $S-N$  data (Ref 15). The largest difference occurs on the lower end of the distributions; the log-normal has a fatter tail on the right and the Weibull has a fatter tail on the left. The two are quite similar in the medium to high range. The difference on the low end can lead to tremendous differences in estimated probability of failure, including a factor of 10 in one example (Ref 20). The Weibull distribution is more conservative, providing more probability of significantly lower fatigue lives. When neither can be clearly established as the best fit, it may be practical to be conservative and assume Weibull, or to use both and compare the results.

**TABLE 1 NORMAL, LOG NORMAL, AND WEIBULL DISTRIBUTIONS**

Statistical distribution	Probability density function (pdf)	Variance	Mean
Normal	$f(x) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right]$	$\sigma^2$	$\mu$
Log normal	$f(x) = \frac{1}{\sqrt{2\pi}\sigma x} \exp\left[-\frac{1}{2}\left(\frac{\ln(x)-\mu}{\sigma}\right)^2\right], x > 0$	$(\exp(\sigma^2) - 1) \exp(2\mu + \sigma^2)$	$\exp\left(\mu + \frac{\sigma^2}{2}\right)$
Weibull	$f(x) = \frac{\beta}{\alpha} \left(\frac{x}{\alpha}\right)^{\beta-1} \exp\left[-\left(\frac{x}{\alpha}\right)^\beta\right], x > 0$	$\alpha^2 \left[ \Gamma\left(1 + \frac{2}{\beta}\right) - \Gamma^2\left(1 + \frac{1}{\beta}\right) \right]$	$\alpha \Gamma\left(1 + \frac{1}{\beta}\right)$

(a)

(b)

**FIG. 3 COMPARISON OF LOG-NORMAL AND WEIBULL FUNCTIONS WITH MEDIAN = 1.0 AND COV = 0.6. (A) PROBABILITY DENSITY FUNCTIONS. (B) EXCEEDANCE DIAGRAMS**

The probabilistic model derived from this data fitting approach is to let the  $S-N$  coefficient,  $C = C_0X$ , be the only random variable. Because  $C = C_0X$ , the distribution shape of  $C$  is the same as for  $X$ . The  $S-N$  exponent is assumed to be a deterministic constant,  $b = b_0$ . All realizations of the  $S-N$  curve then exist as parallel lines of identical slope and variable intercept on a log-log plot, as shown in Fig. 4. (The resulting COV of lifetime is the same at all effective stress levels. Schijve, for example, shows in Ref 14 that this is not necessarily the case. Therefore, this method has a significant limitation of application, but it is simple and often used. See Ref 15 and 21.) The  $S-N$  curve representing a given probability of survival, say the 95% line often used in design, is one of these parallels. The Weibull 95% line for Fig. 3 would lie at 0.25 times the number of cycles at the median line, while the log-normal is 0.41 times the median.

FIG. 4 SINGLE-RANDOM-VARIABLE MODEL OF S-N VARIABILITY

**Two-Random-Variable Model.** Another approach is to create a two-random-variable fit to the data. One can employ standard statistical analysis tools to calculate the linear regression fit to Eq 2 and get estimates of the uncertainty and correlation between the estimated slope and intercept. Most data analysis software packages will do this operation, but it may be difficult to output the actual variance of, and correlation between, the slope and intercept. Some packages output confidence limits only at user-selected levels; more statistically oriented packages provide more detailed information. The results are usually based on the assumption that  $b$  and  $\ln(C)$  are normally distributed. The correct interpretation of the statistical analysis is therefore to assume that  $b$  is normal and that  $C$  is log-normal.

It is important, however, to transform the data before beginning the regression analysis, subtracting the average logarithm of lifetime from all the logarithms,  $Y = \ln(N_i) - m\ln(N)$ , forcing the stress intercept to be at  $Y = 0$ . Without this shift, there will be high correlation between the slope and intercept due to deterministic coupling (i.e., any change in slope would have to be accompanied by a change in intercept to keep the line running through the data). For example, Ronold (Ref 25) fits the two-random-variable model without a shift and finds a correlation of -0.996. When data do not fit a linear curve, the method described by Yu et al. ("Fatigue Data Pooling and Probabilistic Design," ASTM STP 1106, p 197) may be useful. When both  $C$  and  $b$  are modeled as random variables, uneven variation at different stress levels will result. The spread is greater toward the edges of the test data at both high and low stress levels, as illustrated in Fig. 5.

FIG. 5 TWO-RANDOM-VARIABLE MODEL OF S-N VARIABILITY

## Statistical Considerations in Fatigue

Paul S. Veers, Sandia National Laboratories

---

### Applied Stress Levels

There are two levels of statistical description required to define the distribution of applied stresses and the level of certainty for that distribution. Except in the rare case where the cyclic stresses are absolutely fixed in amplitude for all possible situations and over all time, there will be some distribution of loading amplitudes which can and should be described using the tools of probability and statistics. The second kind, or perhaps level, of statistical application is that the exact distribution of cycles to be experienced over the design life is not known.

The fact that stress amplitudes are irregular does not by itself add significantly to the uncertainty in fatigue life estimation. Over most lifetimes, a stable and representative sample of all possible stress amplitudes will occur, one that does not vary significantly in its net damaging effect. The key statistic is the average damage done by the overall distribution of cycles.

The second kind of statistic, one that describes the uncertainty in the actual distribution, does not average out and has a direct impact on the fatigue life uncertainty. The impact can be substantial because the stress amplitudes are raised to the  $b_{th}$  power in the lifetime calculation, where  $b$  is the exponent of the  $S-N$  curve. Because  $b$  can range from 3 to  $>10$ , depending on the application, the amplification of uncertainties in overall level of stress response can be large. For example, a 5% error in stress amplitude results in a 16% error in damage when  $b = 3$ , but produces a 63% error when  $b = 10$ .

**Distributions of Stress Amplitudes.** Stress amplitudes are traditionally described by an exceedance diagram, which is the equivalent of a probability distribution function, with some important differences. Figure 6 shows some exceedance diagrams from Wirsching and Chen (Ref 22). Figure 7 shows equivalent distributions of cycles as probability density functions (pdf's). The pdf is a continuous and normalized form of a histogram where the area under each segment of the curve represents the percentage of all cycle amplitudes within that range. The integral of the pdf is the cumulative distribution function (cdf), which starts at zero and goes to one with increasing amplitude. The complementary cdf, one minus the cdf, is the equivalent of the exceedance diagram.

FIG. 6 EXCEEDANCE DIAGRAMS FOR WEIBULL DISTRIBUTIONS OF VARIOUS SHAPE FACTORS. SOURCE: REF 22

FIG. 7 WEIBULL PROBABILITY DENSITY FUNCTIONS OF VARIOUS SHAPE FACTORS NORMALIZED BY THE MEDIAN

The exceedance diagram is usually normalized by the maximum stress level, which drives most statisticians to distraction. There are few statistics less dependable than the maximum value of the samples of a random process. If measurements are made of an irregular loading, the only thing that can generally be guaranteed is that the maximum value or range will be significantly different each time a sample measurement is taken. More stable statistics include the mean value (first

moment), the variance (second moment), and sometimes higher moments. These are the types of statistics that can be used to describe standard pdf's.

Figures 6 and 7 show Weibull distributions with different shape factors. Because stress amplitudes are always positive, the distributions that describe them are necessarily one sided. The family of Weibull distributions provides a good basis for matching most stress amplitude data found in nature. The Weibull distribution is a two-parameter distribution described by its mean (or median) and shape factor (which is approximately equal to one over the COV). There is a good description of the use of Weibull distributions for simple fatigue calculations in Ref 8. A third parameter can be added by truncating the data on the low end and shifting the distribution. The use of three-parameter Weibulls is described in Ref 23. Winterstein and Lange (Ref 24) illustrate how a quadratic distortion of a Weibull (or other pdf) can improve the fit to wind-driven structural response. With the fourth parameter (the quadratic distortion of the standard, shifted Weibull), the fit to almost any data set can be very good.

The reason for using standard distribution types to describe loading measurements, rather than applying the empirical data directly to the fatigue analysis, is threefold. First, the statistics on which they are based, means and variances, are good descriptors of the process as a whole and can be confidently estimated with smaller data samples. The distributions based on these measures should be less sensitive to sample-to-sample variations in measurements of the loading process. Second, the fatigue life calculations can be simplified greatly by using a known analytical form for the distribution of cycle amplitudes, rather than a set of empirical measurements such as histogram cell frequencies. Third, the uncertainty in the parameters of the fitted distribution can be estimated and used in the probabilistic analysis (Ref 25, 26).

There are reasons to believe that Weibull is a good fit to vibration response data. The Weibull with a shape factor of 2 is known as a Rayleigh distribution and is the natural result of narrow-band random vibration of a linear system (Ref 27). A squaring phenomenon, such as might result from fluid drag forces, will distort the Rayleigh into an exponential distribution (Weibull with shape factor 1.0). Likewise, any nonlinearities in the vibration will distort the distribution of stress amplitudes, but the result is often a Weibull distribution with another shape factor. For systems that are linear, but not perfectly narrow band, estimates of correction factors have been published (Ref 28, 29, 30).

Many loadings are the result not of vibration but of quasistatic response to variable external forces. When the loadings are driven by natural forces, such as winds or waves, the responses are still often modeled well by analytical distributions. When the loadings are driven by human intervention (e.g., maneuvers of vehicles or aircraft), it may be more difficult to fit the responses to simple analytical forms, although it is often still possible (Ref 30). Empirical distributions based on measurement can always be used. However, because the extreme values in the measurements are highly uncertain, and the higher end of the distribution is usually important in fatigue life estimates, it may be better to fit an analytical form over the entire range of measurements. This permits the estimate of high-amplitude cycles to be somewhat influenced by the body of the measurements, not dictated by the extreme values that happen to be captured in a limited experiment.

**Uncertainty in Stress Distribution.** One of the greatest benefits of using an analytical form to model the distribution of stress amplitudes is that the uncertainty in the parameters of the analytical form can be estimated. Of the standard statistical techniques that apply, "bootstrapping" may be the best (Ref 31, 32). Bootstrapping involves resampling the data that has already been collected (with replacement) to create pseudoreplicates of the sample. Distributions are fit to the pseudoreplicates, and statistics can be derived for the parameters of the fitted distributions. The result is an analytical form for the distribution of stress cycles with the parameters of the distribution (e.g., mean, COV, or shape factor) treated as random variables.

## Environments and Loading Intensities

Many environmental factors that affect fatigue durability are not directly connected to loading. Shigley and Mitchell (Ref 2) list several, including temperature, stress concentration, corrosion, electrolytic plating, strain rates, and fretting. There are a host of others, including ultraviolet or ionizing radiation, moisture, and salt spray. These are usually dealt with using knockdown factors on the  $S-N$  curve. Each one will be uncertain and should be described as such. General guidance on these varied sources of uncertainty is not available; each one needs to be dealt with individually.

The description of a particular loading distribution will depend on the intensity of the loading environment. Loading distributions are usually conditional on some environmental parameter. For offshore applications it is "sea state" (Ref 33); for wind loading it is average wind speed (Ref 34); for automobiles, it may be "driver profile" (Ref 35) or road roughness. The total distribution of stresses is the integral over all the environments that the structure (or vehicle) will experience over its lifetime. The distribution of loading intensities can be described similarly to the way that stress amplitude distributions are defined above. The uncertainty in the loading intensities can also be described by making the parameters of the distribution functions random variables, just as was done for stress amplitudes.

Because there is such a wide diversity of applications, it is impossible to make global statements about how to model the variations in environmental intensities. The point to be made is that they should be modeled. It is better not to throw all the stress amplitudes from all the possible loading intensities together into a single pot for fatigue analysis. Rather, stress amplitudes should be defined as a function of loading intensity. Then fatigue analysis can be adjusted to account for applications where the environmental intensities may differ and the fatigue demands may differ as well. Guidance on the

cost of operating in different environments, as well as customized inspections or maintenance schedules (Ref 36), can be established if the analysis depends on the intensity of the environment.

## Modeling or Prediction Errors

Material properties and applied loads must be combined in a fatigue life prediction using some damage accumulation or crack growth model. However, there may be considerable uncertainty in how accurately those models predict lifetime. The model accuracy is heavily obscured by the tremendous scatter in fatigue lives, which is apparent under constant-amplitude loading where there is no need for a model.

The accuracy of the Miner's rule model has been investigated repeatedly. Miner's rule can be stated simply as the assumption that the "damage state,"  $\Delta$ , is estimated by:

$$\Delta = \sum_i \frac{n_i}{N(S_i)} \quad (\text{EQ 4})$$

where  $n_i$  is the number of applied cycles at effective stress amplitude  $S_i$ , and  $N(S_i)$  is the number of cycles to failure at effective stress amplitude  $S_i$ . Failure is assumed to occur when  $\Delta = 1$ . It is a simple model and widely used, especially in high-cycle applications. In experience, the value of  $\Delta$  at failure is often quite different from 1.0.

Wirshing and Wu (Ref 17) gathered data from 12 publications (Ref 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, and 48) aimed at addressing the variability in  $\Delta$  from as far back as 1945 and involving as few as one set of 11 tests to as many as 37 separate sets of variable-amplitude tests. The results are summarized in Table 1. The means range from a low of 0.836 to a high of 1.72, and the COVs range from 0.16 (for a small number of tests) to 0.98 (for a large number of tests). The overall mean is calculated to be about 1.3, and the COV associated with that mean is about 0.8. In two publications, the exact number of tests was not reported, but the mean and COV move up or down by at most 20% when the assumed number of tests in the two incomplete references are doubled and halved.

A COV of 0.8 is a relatively large uncertainty. The Table 2 numbers include the variability inherent in material response, which has been placed at about 0.6 (Ref 15). Even if this is assumed to be 0.6, the remaining COV is about 0.5, also quite high. Inaccuracies in predictions in some of the (perhaps older) references due to misapplication of Miner's rule or other currently discredited damage accumulation models may be a source of additional variability. It had been the practice, in materials with fatigue endurance limits, to assign no damage for cycles with amplitudes less than the endurance limit. We now know that an endurance limit derived from constant-amplitude testing only exists when all the stresses are below it (Ref 4, 5). Cycles below the limit will be damaging in irregular loading where the limit is often exceeded. These variations from report to report due to different modeling approaches would tend to inflate the COV somewhat. It may be that some of the bias and uncertainty in modeling can be reduced by tuning the analysis technique for a specific application. Wirsching (Ref 21), aware of the above results, selected a median value of 1.0 and a COV of 0.3 in offshore applications. It appears that a slightly higher COV might be warranted. As in the case of *S-N* properties, log-normal and Weibull distributions are good candidates, with the Weibull distribution being more conservative.
