**ASIP Master Plan.** Given this information, the contractor can develop the structural integrity plan. This master plan will be, in essence, a PERT or critical path method (CPM) chart for the entire life cycle of the aircraft. This includes the design and analysis phase, the test phase, the manufacturing phase, and the force-management phase. These charts include all requirements, specifications, design criteria, analyses, coupon and component tests, full scale tests--both ground testing (stress and fatigue/fracture) and flight testing, definition of inspection criteria, and individual aircraft tracking techniques. Long-lead-time items are identified, critical paths defined, and possible problem areas identified. Cost and schedule impacts for any of the items contained in the chart should be noted, and alternative paths are identified to minimize these problems.

**Structural Design Criteria.** The second portion of this task is the identification of the structural design criteria. The contracting documents define these criteria. The contractor ensures that his interpretation and the contracting agency's definition agree in all matters. Subservient specifications are identified, and all problems concerning definitions and criteria should be resolved by issuance of this document.

**Damage Tolerance and Durability Control Plan.** In this subtask, a damage tolerance and durability control plan is issued and the various fracture critical components are defined. In addition, the design criteria for each of these fracture critical components need to be identified. These include, but are not limited to, hole preparation, manufacturing inspection criteria and procedures, fail-safe design, inspectable and uninspectable structure. It is from these definitions that inspection intervals and methodology are determined. Also, this subtask involves the determination of the structure that is required to meet the durability requirements of the applicable specifications. This requirement addresses structure that is susceptible to fatigue loading and whose failure may be costly in terms of excessive maintenance or functional problems. The economic life of these components are defined, and must be no less than design service of the aircraft.

The fracture control plan must include the basic experimental data that are used to analytically define the life of the parts, the issuance of a fracture control parts list, traceability of materials, identification on the drawings describing the part as

fracture critical, special processing controls, quality control procedures, vendor certification, and so forth. The durability control plan is similar; however, the controls one must maintain on the various components are less stringent.

**Selection of Materials, Processes, and Joining Methods.** The fourth portion of this task is the selection of the materials, the processing of the materials, and the methods used to join these materials. Trade-off studies are used in preliminary design before final selection of materials are made. The final choice of materials and their processing history is justified. The materials meet the design criteria as required by the contract. Joining the materials becomes increasingly important. Many failures occur where structures are joined together. This includes the use of fasteners, welding, brazing, diffusion bonding, and adhesive bonding. The inspectability, inherent residual stresses caused by the processing itself, environmental degradation, and other factors for these material joints must be discussed to ensure that the optimal choice is made, and that the requirements as set forth in the contract can be met.

**Design Service Life and Usage.** The final part of defining design information in task I of ASIP is the design service life and design usage portion. The data, in the case of ASIP, U.S. Air Force, are the anticipated usages that the contractor needs to know to determine the life of the designed structure. It is also known that initial usage data may not be sufficiently severe, and that measured usage later in the program can establish whether provided data are not severe enough.

**Design Analyses and Development Tests (Task II).** The purpose of this ASIP task is to determine the environment in which the aircraft will operate and then design the various structural components to withstand the loads and stresses for the design life for each of the components. As stated in the various specifications, it is unnecessary for every component to be designed with a life equal to that of the system. It is important that the life of every component be known and that each component be inspectable as its design life require. The types of analysis that are required are described below.

**Design Allowables for Materials and Joints.** For the material and joint allowables, ASIP requires the contractor to use the data available in the various handbooks. These handbooks include *MIL-HDBK-5* (Ref 46), *MIL-HDBK-017* (Ref 47), *MIL-HDBK-23* (Ref 48), and *MCIC-HDBK-01* (Ref 49). Other data can be procured from other sources or generated by the contractor; however, they must be approved by the contracting agency.

**Load Analysis.** An analysis of loading must be conducted by the contractor and must be accomplished in accordance with the appropriate specification. Both the static and dynamic loads that the aircraft and aircraft component will encounter must be described. In this instance, a load analysis implies utilizing the external aircraft parameters such as roll, roll rate, roll acceleration, yaw, yaw rate, yaw acceleration, airspeed, weight and weight distribution, vertical and horizontal acceleration ( $n_z$  and  $n_y$ ), and so forth, and obtaining from these parameters the shear and bending moment on different locations of the airframe. Loads for all flight and landing conditions must be obtained, and these include air loads, ground loads, weapon effect loads, and so forth. In addition, the analysis should include the effects of temperature, frequency, chemical environment, dynamic response of the structure, and so forth.

**Design Load Spectra.** An anticipated service-load spectrum must be defined for design purposes in conjunction with the specification that best defines the anticipated use of the system. This is an anticipated load-time distribution that can be expected over the service life of the aircraft. A difficulty inherent in new systems is that the actual use has not been determined. All that exist are service load spectra for aircraft that have flown in roles similar to that which is presently being designed and built. The load spectrum must take into account maneuver, gust, landing, taxi and take-off loads, and must consist of flight-by-flight type loading. A spectrum with a small and discrete number of loads that is ordered from low to high (or high to low) with a number of cycles in each of these "blocks" is generally not allowed. A random flight by flight spectrum is generally desirable.

The **chemical/thermal environment spectrum** that is assumed for design must also be taken into account. Again the appropriate specification that presents these data for similarly used aircraft must be utilized. Parameters of interest include environment, waveform, and frequency.

**Structural Analysis.** The next eight subtasks in this task discuss the various types of analyses that are required to structurally design a viable aircraft. These analyses are used in conjunction with the load analysis discussed above. These analyses include stress analysis, damage tolerance analysis, durability analysis, sonic fatigue analysis, vibration analysis, flutter analysis, nuclear weapons effect analysis, and non-nuclear weapons effect analysis.

The stress analysis that is to be conducted must be in agreement with the details of the contract requirements, and the non-nuclear weapons effects analysis must follow the guidelines of the design handbook. All the other analyses must be

conducted in concert with the U.S. Air Force specification that describes that particular analysis. Some of these specifications are very detailed in nature, while others are more generic. For example, one may discuss the methodology and procedure for a particular analysis, and another may discuss only the initial conditions that must be addressed and an array of various design concepts that may be used for particular components.

An important part of these subtasks is the interrelationships they have with the testing portions of this effort. For example, there is a requirement for a full-scale fatigue test, durability test, and damage tolerance test. Which ultimate load conditions to be tested, the load distribution desired, and how to obtain this distribution must be determined as the result of the stress analysis. A similar type of analysis needs to be conducted for the durability and damage tolerance test article. In this instance, there is a description of the loading spectrum, where to inspect for flaws during the durability test phase, and where to place the flaws during the damage tolerant test phase.

**Design Development Tests.** The last step in task II of ASIP is the testing of decisions or results from the design and development process. This step may be:

- TESTS REQUIRED TO OBTAIN THE MATERIAL DATA
- COUPON AND COMPONENT TESTS TO ENSURE THAT THE STRESSES AND THE FATIGUE AND FRACTURE CHARACTERISTICS ARE KNOWN
- TESTS TO ALLOW AN INDEPENDENT VERIFICATION FOR BOTH THE STRESSES AND THE FATIGUE AND FRACTURE BEHAVIOR OF THE MATERIAL
- TESTS TO GET MATERIAL ALLOWABLES FOR JOINTS, SPLICES, FITTINGS, AND SO FORTH

The size of the tests ranges from coupons to large full-scale components. A complete set of plans for these tests must be prepared showing the purpose, scope, scheduling, correlation with analyses, impact with design, possible trade-off of designs, and so forth. In addition, these plans must be approved by the U.S. Air Force.

**Full-Scale Testing (Task III).** The purpose of this task is to ensure the "structural adequacy " of the completed airframe. This is accomplished by ground testing and flight testing. It is important to determine the structural adequacy as early as possible in the contract. For this reason, these tests are conducted on the first production article that is released. The tests that are conducted in task III are identical to those that are analyzed in the previous task. These are the ground test articles that include the static test article and a damage tolerant and durability test article. The flight test articles include those from which external load analyses may be obtained, and sonic, vibration, and flutter tests.

**Ground Tests.** The static test again will comply with the specification that has been written to describe this test task. The contractor must submit a plan that will fully describe this test, and this test plan must be approved by the U.S. Air Force. This includes plans, procedures, and schedules. The significant design limit and ultimate design conditions will be tested to allow a thorough evaluation of the airframe. Special environmental factors such as heat and chemical environment must be included as appropriate. The scheduling of this test must be accomplished so as not to impact the schedule for the later flight tests.

The durability and damage tolerance test requires a second airframe (the first airframe being used for the static test). These tests are run consecutively with the durability test being conducted first. Both of these tests will be conducted in accordance with the appropriate specifications. The contractor must prepare a test procedure, plans, and test schedule that must be approved by the U.S. Air Force prior to the start of any testing. It is incumbent that the test spectrum be a random flight-by-flight spectrum and that all durability critical locations be tested. One of the purposes of this test is to determine any additional areas that have not previously been identified as critical. Also, as a result of this test, inspection intervals and modification times for critical structure may be obtained. Therefore, realistic loads and loading geometry are absolutely essential.

As mentioned previously, the article selected for the durability test should be an early airframe, but as representative of actual production design and manufacturing techniques as possible. One lifetime of testing including an inspection of selected components, if necessary, should be completed on this article prior to release of the production contract by the U.S. Air Force. A second lifetime of testing and inspection should be completed prior to delivery of the first production aircraft. If the airframe being tested does not complete two lifetimes without unacceptable cracking, a complete evaluation of the durability design may be required. If this be the case, the original production schedule would be altered.

This decision would be made at the appropriate time. The contractor may, at the discretion of the U.S. Air Force, continue the test for an additional two lifetimes. This would allow for possible life extension of the airframe. The contractor must prepare a cost and schedule that would allow for this possibility.

Subsequent to the durability test, damage tolerance testing would be initiated on the same article. In addition, full-scale test components may be used for additional selected tests. Again, the test plan, procedures, and schedules are required to be approved by the U.S. Air Force prior to testing. Flaws of known characteristics would be physically introduced into the structure prior to testing. The flaw growth behavior would be monitored to ensure that the predictions from earlier analyses and testing are correct.

**Flight Tests.** The primary purpose of the flight and ground operations tests is to ensure that the external load analysis results are in agreement with the measured results. This aircraft will be heavily instrumented and flown in certain mission and flight conditions to compare the results of the analyses with the tests. The ground operations test is primarily a vibration test whose purpose is to verify mass, stiffness, and damping characteristics that would be used in the flutter analysis. The flutter test determines whether the aircraft is free from aeroelastic instabilities (flutter) and has acceptable damping in the area encompassed by the flight envelope.

If any problem is uncovered in these tests, the contractor has to determine the cause, corrective actions, fleet impact, and cost to fix the problem. All problems and fixes along with their schedule and cost impact and fleet consequence have to be submitted to the U.S. Air Force for approval.

**Force Management Data Package (Task IV).** After the aircraft is developed and manufactured, it must be maintained. Again, the maintenance of these aircraft is the responsibility of the U.S. Air Force Matériel Command. To ensure appropriate maintenance actions are conducted, it is important that additional information be developed. It is in task IV that such information is determined. That information consists of five primary items: the final analyses (load analyses, stress analyses, damage tolerance, and durability analyses, etc.), a strength summary of the airframe, a force structural maintenance plan, a load/environment stress survey, and an individual aircraft tracking program. Each of these items is discussed below.

After the various tests are completed, for example, the full scale static test article or the load environment/spectra survey, it may be seen that a discrepancy exists between the stresses determined from the test at certain locations on the aircraft and those obtained from analysis. An investigation is required to determine wherein the inconsistency lies. If the analysis requires a reevaluation, then the equations must be appropriately modified. After the modification occurs, the changes must be approved by the U.S. Air Force. It is this final analysis that would be used by The Air Material Command to determine repairs, modifications, and inspection intervals.

In addition to the final analyses, a strength summary is submitted to the U.S. Air Force. This summary is to be written in a manner that would consolidate the many volumes of data that exist on the particular airframe and allow the user to quickly ascertain the areas that require remedial action if an unforeseen event occurs. It is this type of information that would be made readily available to the user through this document.

The third portion of this task, the force structural maintenance plan, is written to inform the user and the maintenance organization of the inspection and modification requirements for the airframe and its estimated economic life. The information in this plan should be as complete as possible so that the U.S. Air Force can rely on this document for determining long-term costs for the airframe. The initial release of this plan will be based on the design and analysis portions of the program. As more data are obtained from the testing, especially the load and durability portions of the program, the plan would be updated as appropriate. The U.S. Air Force assumes that there would be both an initial and a final plan written into the statement of work for the program, and any additional updates would require a separate negotiation. The contents of this plan, its organization, and structure must be approved by the U.S. Air Force.

The next portion, the load/environment spectra survey, is the largest and most extensive portion of this task. In this subtask, the subcontractor is required to instrument 10 to 20% of the fleet for three years or one design lifetime to determine how the aircraft is actually being flown. This is for later comparison with the assumed spectrum used during design. The parameters that must be recorded include weight, airspeed, altitude, various rates, and accelerations such as pitch, roll, and yaw, "g" levels, and so forth. These data must be collected, synthesized, and analyzed in a manner that allows the maintenance organization to determine the inspection intervals for the various fracture critical parts and to ascertain the economic life vis-à-vis the actual aircraft usage. The contractor has to define the number of aircraft to be instrumented, the instrumentation used, the parameters collected, the algorithms, and so forth. Finally, the actual usage

spectra for the aircraft need to be defined using the collected data as a baseline. From these newly developed spectra, algorithms would be developed that allow the user to utilize these data to determine safety limits and inspection intervals for the aircraft. This entire package of requirements needs to be proposed, using the appropriate U.S. Air Force and government standards, as required, and submitted to the U.S. Air Force for approval.

The last portion of this task is the individual aircraft tracking. This subtask is actually the report aspect of the previous subtask. It is known that various components will need inspections or replacement at different times. In addition, some aircraft will be flown more severely than others. As a result, scheduling of maintenance actions needs to be addressed. It is in this subtask that this will be accomplished.

**Force management (task V)** addresses the required operations that the U.S. Air Force must perform to ensure safety and operational readiness of the individual aircraft and the fleet of aircraft. The U.S. Air Force will rely heavily on the documents and methods previously produced by the contractor to accomplish these operations. There are four parts to this task. Two of these, the load/environment spectra survey and individual airplane tracking data, are identical to those in task IV. The primary difference is that it will be the responsibility of the U.S. Air Force to accomplish them, that is, to obtain the equipment and train personnel both to use the equipment and to obtain valid data from the equipment. The usage of that data and the training of Air Force personnel are paramount.

The final two sections of task V, individual aircraft maintenance times and structural maintenance records, are self-explanatory. They simply say that the U.S. Air Force will determine the inspection intervals and adhere to them, and documentation regarding them is required.

## Engine Structural Integrity Program (ENSIP)

The Engine Structural Integrity Program (ENSIP) (Ref 50) began in the 1970s as a result of a number of structural problems that were occurring on U.S. Air Force turbine engines. These problems not only affected the safety of the aircraft, but also the durability of the engine itself. The cost of maintaining and modifying the engines was escalating at an alarming rate. Both of these sets of problems manifested themselves in fleet readiness. The purpose of ENSIP was to design a procedure that would systematically evaluate the structural integrity of a turbine engine with respect to safety, economic life, and total life-cycle cost. Many papers were written by U.S. Air Force personnel discussing ENSIP. A paper written by Tiffany and Cowie (Ref 51) discusses ENSIP in more detail.

Engine structural integrity is accomplished by ensuring structural safety through the use of damage tolerance design. By using the principles of fracture mechanics, the crack propagation rate can be determined, and periodic inspection ensures safe operation. The components of the engine itself, dependent on the aircraft role and the selected component, have a particular life. The durability requirement of ENSIP dictates that the economic life of each cold component be greater than the design service life. To ensure that the engine can be maintained throughout its service life, ENSIP insists that

new and old parts be interchangeable. In addition, the inspectability and repairability of the various parts must be defined. The environment to which the components are exposed must be defined. This would include thermal (steady-state and transient), pressure, chemical, steady-state and dynamic stresses, and so forth). Because of the unusually harsh environment to which the engine components are exposed, the contractor must prepare a material and process characterization plan that is valid throughout engine development. To ensure that the engine meets its durability criteria, ground tests on a completed engine must be performed. Maintenance actions, when required, must be accomplished. Finally, a policy instituting usage and tracking criteria must be formulated.

As discussed above in ASIP, there are five major tasks associated with ENSIP. Each of these tasks is divided into several subtasks. The major tasks, described in detail in Table 3, are as follows:

- *TASK I: DESIGN INFORMATION*
- *TASK II: DESIGN ANALYSIS, COMPONENT AND MATERIAL CHARACTERIZATION*
- *TASK III: COMPONENT AND CORE ENGINE TESTS*
- *TASK IV: GROUND AND FLIGHT ENGINE TESTS*
- *TASK V: PRODUCTION QUALITY CONTROL AND ENGINE LIFE MANAGEMENT*

### **TABLE 3 ENGINE STRUCTURAL INTEGRITY PROGRAM TASKS**

#### **TASK I: DESIGN INFORMATION**

- **DEVELOPMENT PLANS**
  - ENSIP MASTER PLAN
  - DURABILITY AND DAMAGE TOLERANCE CONTROL PLANS
  - MATERIAL PROCESS CHARACTERIZATION PLAN
  - CORROSION PREVENTION AND CONTROL
  - INSPECTION AND DIAGNOSTICS PLAN
- **OPERATIONAL REQUIREMENTS**
  - DESIGN SERVICE LIFE AND DESIGN USAGE
  - DESIGN CRITERIA

#### **TASK II: DESIGN ANALYSIS MATERIAL CHARACTERIZATION AND DEVELOPMENT TESTS**

- **DESIGN DUTY CYCLE**
- **MATERIAL CHARACTERIZATION**
- **DESIGN DEVELOPMENT TESTS**
- **ANALYSES**
  - SENSITIVITY
  - CRITICAL PARTS LIST
  - THERMAL
  - STRENGTH
  - CONTAINMENT
  - VIBRATION/FLUTTER
  - STRESS/ENVIRONMENT SPECTRA
  - DURABILITY
  - DAMAGE TOLERANCE

- CREEP

- INSTALLED ENGINE INSPECTABILITY
- MANUFACTURING, PROCESS, AND QUALITY CONTROLS

- VSR
- NDI DEMONSTRATION

### TASK III: COMPONENT AND CORE ENGINE TESTS

- COMPONENT TESTS

- STRENGTH
- VIBRATION
- DURABILITY
- DAMAGE TOLERANCE
- CONTAINMENT

- CORE ENGINE TESTS

- THERMAL SURVEY
- VIBRATION STRAIN AND FLUTTER BOUNDARY SURVEY

### TASK IV: GROUND AND FLIGHT ENGINE TESTS

- GROUND ENGINE TESTS

- THERMAL SURVEY
- GROUND VIBRATION STRAIN AND FLUTTER BOUNDARY
- UNBALANCED ROTOR VIBRATION
- STRENGTH
- IMPEDANCE
- CLEARANCE
- CONTAINMENT
- INGESTION
- ACCELERATED MISSION TESTS (AMT)
- DAMAGE TOLERANCE

- FLIGHT ENGINE TEST

- FAN STRAIN SURVEY
- NACELLE TEMPERATURE SURVEY
- INSTALLED VIBRATION
- DETERIORATION

### TASK V: ENGINE LIFE MANAGEMENT

- UPDATED ANALYSES

- ENGINE STRUCTURAL MAINTENANCE PLAN
- OPERATIONAL USAGE SURVEY
- INDIVIDUAL ENGINE TRACKING
- DURABILITY AND DAMAGE TOLERANCE CONTROL ACTIONS (PRODUCTION)

Rather than discuss the intricacies of the specification, it would be beneficial to demonstrate the specific specification requirements for selected areas. The particular functional areas to be discussed are damage tolerance, durability, maintainability, material characterization, environmental definition, ground test methods, and tracking philosophy.

**Damage Tolerance.** According to the specification, damage tolerance criteria must be used on fracture critical parts. A fracture critical part is defined as one "whose failure would result in probable loss of the aircraft as a result of noncontainment or, for single engine aircraft, power loss preventing sustained flight either due to direct part failure or by causing other progressive part failures" (Ref 52).

The specification emphasizes component inspectability. The more inspectable the component, the more often it may be inspected and the shorter the inspection interval will be. The worst case would be a particular component that may be inspected only during engine teardown in the depot. The initial flaw size would be large (the maximum nondetectable flaw size), and the inspection interval would be long (two depot inspection intervals). In those cases where the inspection interval is long, the crack may grow substantially. As a result, adherence to design detail to minimize stress concentrations factors and appropriate material selection is paramount.

**Durability Requirements.** The durability of a particular component is closely tied to its economic life. For cold parts, the primary failure mode is structural cracking. To protect against incipient damage, fracture mechanics methods are used. But to prevent generalized cracking prior to the component attaining its design life, low-cycle fatigue (LCF) methods are generally used. The use of LCF in design and analysis, in conjunction with appropriate material selection and substantiation tests, is the method required to ensure that generalized cracking does not occur during the component design life. The LCF design life is usually equal to the design life of the component based on minimum material properties. For hot parts (those parts in the hot gas stream), the primary failure mode becomes more complicated. The durability of the component is adversely affected by stress rupture and erosion in addition to LCF. The minimum design life for hot parts is one-half the design service life for cold parts.

The durability of the engine and its components is usually obtained by test. Similar to that discussed previously for ASIP, a full-scale test of the production article is desired. A usage history of the engine is determined. The test can be accelerated by omitting many of the times at cruise and stress cycles that would cause no damage. The resultant accelerated mission test (AMT) is equivalent to a lifetime of usage but can be accomplished in a reasonable time. The test article is heavily instrumented and monitored closely, and changes that would either improve mission performance or enhance life are instituted into the design. The economic life of the engine is attained when the cost of repairing the article is unacceptable and continued usage of the unrepaired article impairs its operational capability.

**Design, Analysis, and Test Procedures.** As engine development is an evolutionary process, the manufacturer will continue to use those methods and materials that provide structurally durable and reliable engines. Because the engine will have unique requirements, additional studies will be required to ensure that the fully designed engine has been optimized for its particular role. The basis for this optimization study is definition of the combination of the power setting and times this engine will experience in its particular role. This anticipated usage, the engine duty cycle, is formulated by the contractor and approved by the U.S. Air Force. This duty cycle is ultimately used to provide confidence that the engine design and structure meet the mission requirements and desired economic life requirements of the U.S. Air Force.

The material allowables that are used by the contractor must be verified experimentally. Sufficient data are obtained to allow a statistical substantiation of the material properties. The allowables themselves that are used in design will be  $-3\sigma$  data. The processing of the material must be accomplished from full-size heats that are subsequently machined into test components and specimens. Allowable stress levels, crack growth behavior, inspection capability, and so forth all need to be verified by tests.

A set of tests must be accomplished on the core engine. It is through these tests that thermal and vibration data can be obtained. Other tests will be accomplished in spin pits and on test rigs to gather information that allows the manufacturer to ensure that the desired structural integrity is obtained. Low-cycle fatigue tests and damage tolerance testing may be accomplished on the same components. First these components are tested without flaws, and then flaws are induced and

the components tested to another lifetime. One result of all these tests is a list of critical parts, failure modes, and failure times. Inspection techniques will be enhanced as a result of the knowledge obtained from accomplishment of this test program.

**Ground and Test Flight Verification.** A significant inclusion in the ENSIP requirements is the need to perform ground testing on the production design. The AMT testing gives important information regarding the LCF characteristics of the engine, including the location of previously unknown problems, as well as the damage tolerance behavior of a production engine. Furthermore, as the AMT engine is essentially a "lead-the-force" engine in terms of time, structural and performance behavior can be monitored and information regarding actual engine behavior can be accurately determined.

It is important to schedule the ground testing early enough in the program to allow both the contractor and the U.S. Air Force to determine if the engine meets its performance and structural requirements. As a result, it is necessary for one lifetime of AMT testing to be completed before production approval. AMT testing is also required on a second engine, identical to production, and a third lifetime of testing is necessary using an updated AMT usage history. It is assumed that flight data will then be available for inclusion in the derivation of the test spectrum. Other information that may be obtained from these ground test engines is determination of methods and procedures for inspection that can be used in the field.

Prior to flight test, it is necessary to obtain data that ensure anomalous damage does not occur due to excessive temperature or overspeeding of the engine. Knowing the results of this test plus the results of resonant searches over the entire flight regime then allows the contractor to place the engine in an aircraft for flight test. Instrumentation is placed in the flight engine, the aircraft is flown to several "points in the sky," and data are collected. The data are evaluated and compared with ground test data and analysis. Correlations are made, and techniques are optimized to ensure proper prediction of engine behavior.

With these data and the improved analyses, all locations on the engine that indicated a problem in test or performance will be critically examined. An understanding of all structural problems regarding crack initiation and failure mode will be determined. The result of these studies will culminate in a plan that will reduce the occurrences of these undesirable events. One aspect of this plan can be feedback to production and design to reduce or eliminate the cause of this cracking.

**Engine Life Management.** The purpose of engine life management is to determine where each engine is in its particular life history and to perform the required maintenance work in a timely fashion. To perform the first function, an engine tracking program is required. Engine tracking requires the use of instrumentation on the aircraft to provide knowledge of critical parameters that determine the life of an engine to the maintenance organization. This could include flight hours, rotor speeds, temperatures, take-offs, and so forth. Software programs must be available to take this information from individual engines and process it quickly and succinctly. Additionally, maintenance organizations must be trained in the necessary skills to disassemble, inspect, replace, and repair the various components. After the engine is repaired, testing must be accomplished to ensure proper operation. This portion of the effort is the primary responsibility of the U.S. Air Force. However, the information obtained as a result of ENSIP allows this task to occur.

### Mechanical Subsystems Structural Integrity Program (MECSIP)

The Mechanical Subsystems Structural Integrity Program (MECSIP) (Ref 52) is a program that was initiated by the U.S. Air Force in the late 1980s to expand the integrity process that had been started with ASIP and ENSIP to mechanical subsystems and equipment. The methodology and the approach to MECSIP is similar to the earlier programs. MECSIP was developed to fill a need to have an organized approach with the discipline of the earlier programs to ensure safety, reliability, and durability in mechanical subsystems. The typical subsystems that MECSIP would be used to evaluate include landing gear, crew escape modules, flight control equipment, hydraulic equipment, engine controls and accessories, and so forth. The equipment itself could consist of pumps, valves, actuators, fittings, tubings, and pressure vessels. Because of the breadth of components and systems to which MECSIP is applicable, the specification is broadly written, yet the particular program can be tailored to fit an individual system. The tailoring of the specification to fit the particular system is one of the first tasks in MECSIP.

A significant difference between MECSIP and ASIP/ENSIP is the customer. The contractors who develop the system using ASIP/ENSIP have the U.S. Air Force as their customer. The contractor who utilizes MECSIP generally has as the customer the airframe or engine manufacturer. If the manufacturer is designing and producing a gear pump, the contract is with the engine manufacturer. If the manufacturer is designing and producing landing gear, the customer is the airframe manufacturer. It is these contractors who supply the data needed for design to the mechanical subsystems and equipment manufacturer.

Similar to ASIP and ENSIP, there are six major tasks in MECSIP, each containing several subtasks. These are described in detail in Table 4 and are listed below:

- *TASK I: PRELIMINARY PLANNING AND EVALUATION*
- *TASK II: DESIGN INFORMATION*
- *TASK III: DESIGN ANALYSES AND DEVELOPMENT TESTS*
- *TASK IV: COMPONENT DEVELOPMENT AND SYSTEM FUNCTIONAL TESTS*
- *TASK V: INTEGRITY MANAGEMENT DATA PACKAGE*
- *TASK VI: INTEGRITY MANAGEMENT*

#### TABLE 4 MECHANICAL EQUIPMENT AND SUBSYSTEMS PROGRAM TASKS

##### TASK I: PRELIMINARY PLANNING AND EVALUATION

- PROGRAM STRATEGY
- TRADE STUDIES
- DEVELOPMENT AND REFINEMENT OF REQUIREMENTS
- PRELIMINARY INTEGRITY ANALYSIS

##### TASK II: DESIGN INFORMATION

- MECSIP MASTER PLAN
- DESIGN CRITERIA
- DESIGN SERVICE LIFE/DESIGN USAGE
- CRITICAL PARTS ANALYSES AND CLASS
- M & P SELECTION/CHARACTERIZATION
- PRODUCT INTEGRITY CONTROL PLAN

- CORROSION PREVENTION AND CONTROL

### TASK III: DESIGN ANALYSES AND DEVELOPMENT TESTS

- LOAD ANALYSES
- DESIGN STRESS ENVIRONMENT/SPECTRA DEVELOPMENT
- PERFORMANCE AND FUNCTIONAL SIZING ANALYSIS
- THERMAL/ENVIRONMENT ANALYSIS
- STRESS/STRENGTH ANALYSIS
- DURABILITY ANALYSIS
- DAMAGE TOLERANCE ANALYSIS
- VIBRATION/DYNAMICS/ACOUSTICS ANALYSIS

### TASK IV: COMPONENT DEVELOPMENT AND SYSTEM FUNCTIONAL TESTS

- FUNCTIONAL TESTS
- STRENGTH TESTING
- DURABILITY TESTING
- VIBRATION DYNAMICS/ACOUSTIC TESTING
- DAMAGE TOLERANCE TESTING
- THERMAL AND ENVIRONMENT SURVEY
- MAINTAINABILITY/REPAIRABILITY DEMONSTRATION
- EVALUATION AND INTERPRETATION
- INTEGRATED TEST PLAN

### TASK V: INTEGRITY MANAGEMENT DATA PACKAGE

- FINAL ANALYSES
- MAINTENANCE PLANNING AND TASK DEVELOPMENT
- INDIVIDUAL SYSTEMS TRACKING

### TASK VI: INTEGRITY MANAGEMENT

- OPERATIONAL USAGE SURVEY
- MAINTENANCE RECORDS SERVICE REPORTING
- INDIVIDUAL SUBSYSTEM MAINTENANCE TIMES

**Analyses Required.** One of the first needs of the contractor is to understand his subsystem and equipment and the interrelationship between his mechanical equipment and/or subsystem and the aircraft in which it will be installed. The subsystem manufacturer must be given information regarding the requirements levied on his equipment or subsystem by the system(s) they service. An important aspect of this is to understand the failure modes of his system and the effects the failure of his system would have on the operation and performance of the aircraft itself.

After this information is known, and the requirements for the aircraft become solidified, the equipment and subsystems manufacturer can refine his requirements. Trade studies regarding materials and processes as well as approaches to solving particular needs will have been accomplished. The design of the product may then begin with the contractor performing life and performance goals.

The next step is to gather the necessary design information. This task relates to the manufacturer determining the needs of the system and then tailoring his subsystem to fill those needs. To accomplish this, there are several subtasks that should be completed. One of the most important is the MECSIP Master Plan. This plan formalizes the different steps the

manufacturer must accomplish during this program. This is a living document throughout the program and is updated as frequently as necessary.

The design criteria for the system must be defined. The specific requirements for the subsystem, as determined by the airframe or engine manufacturer, are translated into design requirements. Materials, processes, geometries, operating environment, life requirements, planned maintenance actions, weight, performance, and so forth are determined. The next step would be the classification of parts. Some of the components of the particular subsystem, if they fail, could adversely impact the mission. Other parts may adversely impact the longevity of the system, that is, cause a durability problem. Special considerations must be determined to ensure complete knowledge of the realistic life behavior, and the ramification of failure must be understood. Fracture of gears on a fuel pump can cause immediate system failure, while transistor life as a function of time at temperature is predictable. A failure effects and modes analysis (FEMA) improves the completeness of these plans and increases the utility of the particular analyses.

After the design has been finalized, the various analyses that are required for ASIP and ENSIP are required for MECSIP as well (see Table 4). It should be noted that all aspects of the plans are not applicable to each particular component. For solder connections, material selection may be well defined, whereas for joints vibration analyses may be more significant.

**Testing Required.** The testing that is required demonstrates the accuracy of the analyses and the life and inspection capabilities of the components. Additionally, nondestructive evaluation methodology is demonstrated in this phase of the program. Again the types of tests required are predicated on the components and/or subsystem, their utility, and their failure mode. Because the testing required is extensive, the plans regarding the test design, the test duration, fixtures, and life requirements should be accomplished early in the program to ensure one lifetime of testing prior to production go-ahead. As in the case of ASIP and ENSIP, production articles and/or methods should be used as much as possible. Because these components depend on their location in the engine or airframe, special environmental factors such as temperature, acoustical fatigue, vibration, and chemical environment, can play important roles. These conditions must be properly accommodated during testing.

**Life Management.** The function of life management again falls to the U.S. Air Force. However, the contractor needs to prepare plans regarding inspection locations, inspection intervals, inspection techniques, and so forth. The U.S. Air Force personnel has to know the particular usage spectrum for which these inspections were designed. The software the manufacturer used to develop these inspection intervals should be part of the data package the U.S. Air Force receives. If changes need to be made as a result of in-flight tracking, the U.S. Air Force must have the capability of performing these analyses. In short, life management is a U.S. Air Force action item based on the completeness and accuracy of the tasks performed by the contractor.

## Fracture and Fatigue Properties of Structural Steels

Alexander D. Wilson, Lukens Steel Company

---

### Introduction

THE USE OF FRACTURE MECHANICS in the design of steel structures has been a growing discipline over the past 30 years. Steel structures can cover a diverse number of markets, such as construction of bridges and buildings, pressure vessels, construction and mining equipment, and offshore platforms and ships. Both carbon, high-strength low-alloy (HSLA) and alloy steels are used in these applications. Although some of the end users of these structures have their own steel specifications, the vast majority rely on ASTM specifications, particularly for the basic strength properties and chemical composition. An end user who does have a steel specification often bases it on an ASTM grade with some modification.

Within the ASTM structural and pressure vessel specifications, there are close to 1000 that might be specified. In reality, only a few dozen are actually applied in the industry. A specification is chosen for an application based on the design stresses, which dictate the strength and thickness of the product; the temperature and environment of the application; weldability concerns during fabrication; and of course cost. However, beyond specifying the ASTM grade for an application, often other variables must be considered, particularly when "generic" fracture mechanics properties are applied in the design of the structure. Furthermore, more basic properties such as Charpy V-notch (CVN) impact can often provide some general indication of how these variables affect a key fracture mechanics parameter.

### Fracture Toughness

**Materials and Testing.** Steels used in structural applications can cover a wide variety of chemistries, processing characteristics, and thicknesses. These all can have a significant effect on the fracture mechanics properties. Table 1 lists several popular steel grades for which fracture mechanics data are presented in this article. These grades include low-strength carbon steels and higher-strength alloy steels.

**TABLE 1 POPULAR PLATE STEELS USED IN STRUCTURAL APPLICATIONS**

ASTM STEEL SPECIFICATION	TYPE <sup>(A)</sup>	YIELD STRENGTH, MIN <sup>(B)</sup>		HEAT TREATMENT <sup>(C)</sup>	MICROSTRUCTURE <sup>(D)</sup>
		MPA	KSI		
A516 GRADE 70	CARBON, C-MN	262	38	N+	F-P
A588 GRADE A	HSLA, CU-CR-V	345	50	N+	F-P
A633 GRADE C	HSLA, C-MN-CB	345	50	N	F-P
A808	HSLA, C-MN-CB	345	50	CR	F-P
A514 GRADE F	ALLOY, NI-CR-MO-B	690	100	Q&T	M
A533 GRADE B CLASS 1	ALLOY, MN-MO-NI	345	50	Q&T	B
A710 GRADE A CLASS 3	ALLOY, CU-NI	517	75	Q&T	F-P, B, M

(A) HSLA: HIGH STRENGTH, LOW ALLOY.

(B) SPECIFICATION MINIMUM. LOWER MINIMUMS MAY BE APPLICABLE FOR THICKER PLATES.

(C) N, NORMALIZED; N+, NORMALIZED, BUT MAY BE PRODUCED AS-ROLLED; CR, CONTROL ROLLED; Q&T, QUENCHED AND TEMPERED.

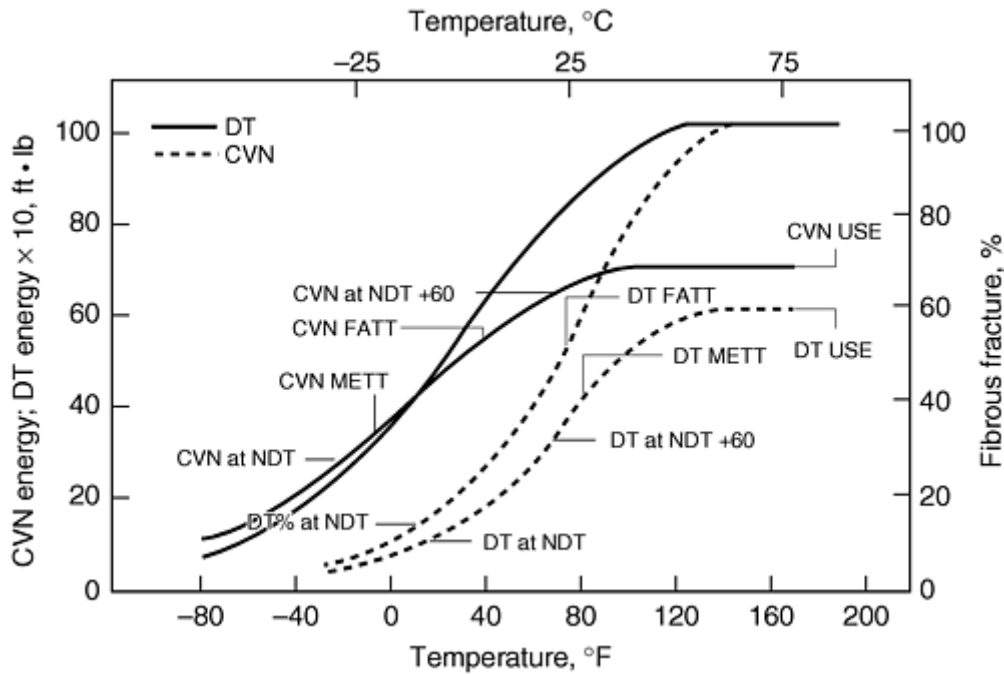

(D) MOST TYPICAL MICROSTRUCTURE: F-P, FERRITE-PEARLITE; M, MARTENSITIC; B, BAINITIC

Test methods for characterizing the fracture mechanics properties of steels have been in development for over 30 years. Prior to the widespread use of fracture mechanics, traditional toughness tests such as the CVN were widely used to characterize steels and establish guidelines for their fitness for service. Many of these approaches are still widely used today. In fact, today the CVN test is the most widely used quality control test for evaluating steel toughness. Therefore, it is important to consider the new fracture test methods in comparison to the traditional ones, such as the CVN. Table 2 lists the popular traditional and newly developed fracture tests in use today. Comparisons between the traditional methods, such as dynamic tear (DT) testing and drop-weight testing (to determine the nil-ductility transition temperature) are useful. This is shown schematically in Fig. 1. Because the DT test specimen is larger and has a sharper notch than the CVN specimen, it tends to shift the transition curve to higher temperatures. In fact, it has been shown that the lower knee of the DT transition curve comes at the nil-ductility transition temperature determined by the drop-weight test.

**TABLE 2 ASTM TESTING SPECIFICATION USED IN FRACTURE TESTING**

ASTM	STANDARD TEST METHODS FOR:	COMMON NAME
E 23	NOTCHED BAR IMPACT TESTING OF METALLIC MATERIALS	CVN
E 604	DYNAMIC TEAR TESTING OF METALLIC MATERIALS	DT
E 208	CONDUCTING DROP-WEIGHT TEST TO DETERMINE NIL-DUCTILITY TRANSITION TEMPERATURE OF FERRITIC STEELS	NDT
E399	PLANE-STRAIN FRACTURE TOUGHNESS OF METALLIC MATERIALS	$K_{IC}$
E813	$J_{IC}$ , A MEASURE OF FRACTURE TOUGHNESS	$J_{IC}$
E 1152	DETERMINING $J$ - $R$ CURVES	...

E 1290	CRACK-TIP OPENING DISPLACEMENT (CTOD) FRACTURE TOUGHNESS MEASUREMENT	CTOD
E 647	MEASUREMENT OF FATIGUE CRACK GROWTH RATES	$DA/DN - \Delta K$

**FIG. 1** COMPARISON OF ABSORBED ENERGY AND FRACTURE APPEARANCE FOR CHARPY V-NOTCH (CVN) AND DYNAMIC TEAR (DT) TESTING OF AN A533B STEEL. METT, MID-ENERGY TRANSITION TEMPERATURE; FATT, 50% FRACTURE APPEARANCE TRANSITION TEMPERATURE; NDT, NIL-DUCTILITY TRANSITION

Steel toughness depends on several metallurgical and fabrication factors, such as whether the steel is rolled, control rolled, normalized, or hardened and tempered. These basic factors are extensively discussed in the literature, along with the important issue of steel cleanliness, particularly as measured by sulfur level (Ref 1). Today structural steel grades can be obtained with sulfur levels limited to as low as 0.001% or as high as 0.040%. Historically, it has been established that "low"-sulfur steels have 0.010% maximum sulfur or better and have inclusion shape control, most popularly obtained by calcium treatment. Low-sulfur steels have fewer nonmetallic inclusions, and calcium treatment further gives inclusion shape control. The influence of sulfur control is very dramatic in its effect on toughness, particularly on the upper shelf, as shown in Fig. 2. Sulfur levels also affect the change in toughness level with different testing orientations, which are commonly designated per ASTM E 389 as LT (longitudinal), TL (transverse), and SL (short transverse, through-thickness).

FIG. 2 THE EFFECT OF PROCESSING OF TWO 102 MM (4 IN.) A633C PLATE STEELS ON THE FULL CHARPY V-NOTCH (CVN) TRANSITION CURVE IN THE THREE MAJOR TESTING ORIENTATIONS. CON, CONVENTIONAL; CAT, CALCIUM TREATMENT

**Fracture Mechanics Toughness.** Most structural steels have a combination of strength and toughness, which makes the use of elastic-plastic toughness testing ( $J_{Ic}$ ; crack-tip opening displacement, or CTOD) more popular than plane-strain fracture toughness ( $K_{Ic}$ ). For example, when comparing the two steel grades A633C and A516-70 in Fig. 3, traditional tests methods (CVN, DT) show the improved behavior of A633C because of its lower carbon levels and the niobium addition. The same benefit is also demonstrated in  $J_{Ic}$  testing in Fig. 4.

FIG. 3 COMPARISON OF THE CHARPY V-NOTCH (CVN) AND DYNAMIC TEAR (DT) TRANSITION TEMPERATURES FOR A NUMBER OF A516-70 PLATES AND A633C PLATES. THE IMPROVED TRANSITION TEMPERATURES FOR A633C ARE DEMONSTRATED. FATT, 50% FRACTURE; METT, MID-ENERGY TRANSITION TEMPERATURE

**FIG. 4 FRACTURE TOUGHNESS ( $K_{Ic}$  ESTABLISHED FROM  $J_{Ic}$ ) COMPARISON FOR A633C AND A516-70 PLATE. BOTH SLOW AND FAST LOADING RATES ARE SHOWN FOR A633C PLATE. CAT, CALCIUM TREATMENT; NDT, NIL-DUCTILITY TRANSITION**

It is also important to quantify the transition to brittle fracture from toughness testing. However,  $J_{Ic}$  and CTOD testing in the transition region can show significant variability in results. Scatter of fracture mechanic toughness in the transition regime is discussed elsewhere in this Volume.

The influence of inclusion control discussed previously can also be characterized by  $J_{Ic}$  and  $J$ - $R$  curve evaluations (Fig. 5 and 6). Improved-cleanliness calcium-treated steels also show both better initiation toughness and propagation toughness. Most structural steels would show a similar benefit, with the benefit increasing as the strength level increases.

FIG. 5  $J$ - $\Delta a$  CURVES FOR TWO A588A STEELS IN NOTED QUALITY LEVELS. CON, CONVENTIONAL; CAT, CALCIUM TREATMENT. THE EFFECTS OF QUALITY AND TESTING ORIENTATION ARE NOTED. SOURCE: REF 2

FIG. 6  $J$ - $T$  CURVES FOR THE TWO A588A STEELS FROM FIG. 5. CON, CONVENTIONAL; CAT, CALCIUM TREATMENT. THE EFFECTS OF QUALITY AND TESTING ORIENTATION ARE NOTED. SOURCE: REF 2

Often it is useful to develop empirical correlations between the various toughness tests. These correlations are easiest to develop for upper-shelf testing where only ductile fracture by microvoid coalescence is the fracture mode. Such empirical

comparisons are commonly made between  $J$  and CVN,  $J$  and CTOD, and CVN and DT. Figure 7 is an example comparing upper-shelf energy (USE) for CVN and DT test values (Ref 3, 4).

FIG. 7 COMPARISON PLOT OF DT AND CVN UPPER-SHELF ENERGY (USE) DATA. SOLID LINE REPRESENTS STATISTICAL CORRELATION OF DT USE = 250 + 6.59 CVN USE WITH  $R^2 = 0.821$ . DASHED LINE REPRESENTS A ROUGH APPROXIMATION OF DT USE = 8.5 CVN USE (CORRELATIONS IN JOULES). SOURCE: REF 3, 4

### Fracture and Fatigue Properties of Structural Steels

Alexander D. Wilson, Lukens Steel Company

---

### Fatigue Crack Growth

The fatigue crack propagation of structural steels is often considered relatively insensitive to changes among grades. However, steel cleanliness has been shown to have a significant influence on fatigue crack growth rate behavior within a steel. For example, significant anisotropy or directionality of behavior between conventional and calcium-treated A588A steels is detailed in Fig. 8. It has been demonstrated that nonmetallic inclusions can accelerate fatigue crack growth, particularly in the through-thickness (SL, ST) and transverse (TL) testing orientations, and particularly at higher  $\Delta K$  levels. Figure 9 (Ref 5) demonstrates this for three other steel grades. These results indicate that cleanliness and loading orientation must be considered when using fatigue crack growth rate data.

FIG. 8 FATIGUE CRACK GROWTH RATE RESULTS FOR TWO A588A STEELS SHOWING COMPARISON OF LS AND SL TESTING ORIENTATIONS. CON, CONVENTIONAL; CAT, CALCIUM TREATMENT. IMPROVED ISOTROPY OF THE CALCIUM-TREATED STEEL IS NOTED.

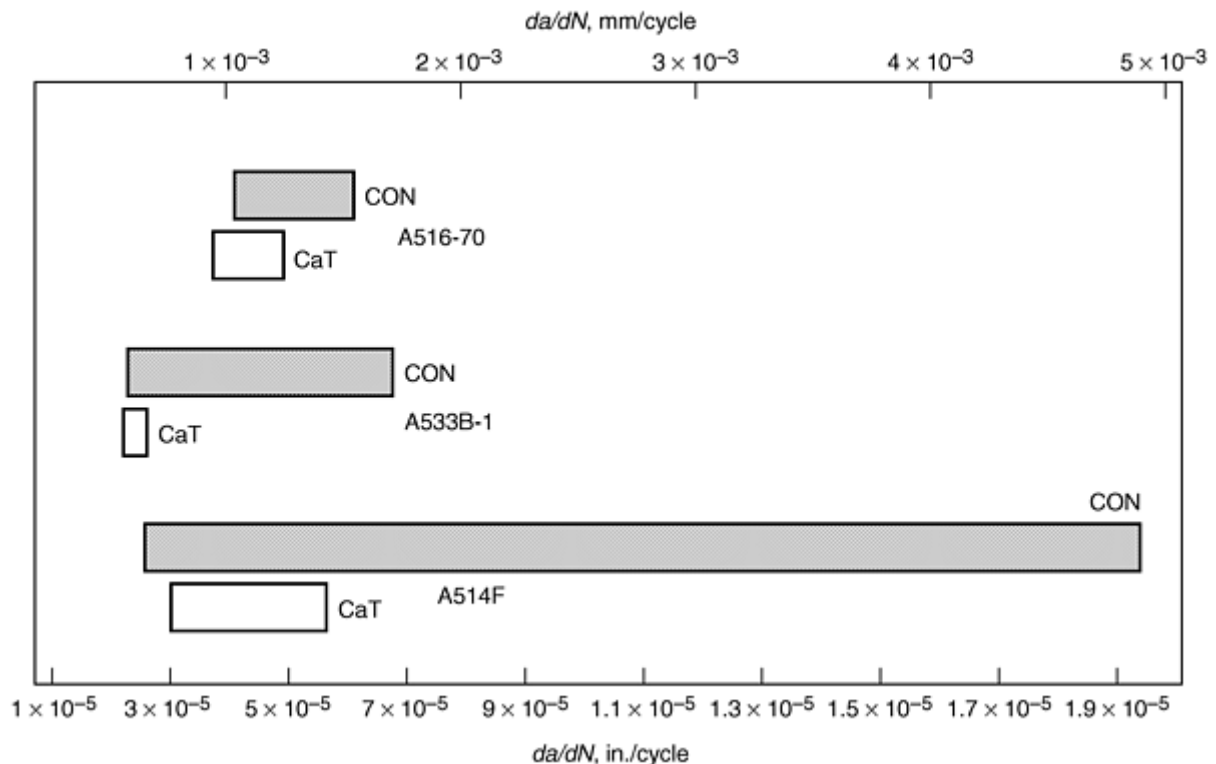

FIG. 9 RANGE OF FATIGUE CRACK GROWTH NOTES AT  $\Delta K = 55 \text{ MPa} \sqrt{\text{m}}$  ( $50 \text{ KSI} \sqrt{\text{in.}}$ ) IN SIX TESTING ORIENTATIONS FOR CONVENTIONAL (CON) AND CALCIUM-TREATED (CAT) QUALITY PLATES OF A516-70, A533B-1, AND A514F. IMPROVED ISOTROPY OF QUALITY LEVELS IS DEMONSTRATED FOR CALCIUM-TREATED PLATE. SOURCE: REF 5

All structural steel data in air can be summarized in a band of data using the Paris equation ( $da/dN = C \Delta K^n$ ), as shown in Fig. 10 and 11. If the environment of the application is other than benign air, there can be a further acceleration of fatigue crack growth (Ref 6). Salt water, for example, can have a strong effect, particularly at slower testing frequencies (Fig. 12). The modeling of this data with the Paris equation still is appropriate, although the data now are all outside the correlation shown earlier (Fig. 13). More detailed coverage of fatigue crack growth behavior and thresholds is provided in the article "Fracture Properties of Carbon and Alloy Steels" in this Volume.

FIG. 10 PLOTS OF  $n$  AND  $C$  FROM THE PARIS FATIGUE CRACK PROPAGATION EQUATION, COMPARING NOTED MICROSTRUCTURES IN A NUMBER OF STEELS WITH VARIOUS QUALITY LEVELS AND TESTING ORIENTATIONS

FIG. 11 COMPARISON OF  $n$  AND  $C$  VALUES FOR THE PARIS FATIGUE CRACK PROPAGATION EQUATION COMPARING THREE GRADES OF STEEL WITH VARIOUS QUALITY LEVELS AND TESTING ORIENTATIONS. NO EFFECT OF STRENGTH LEVEL IS SHOWN.

FIG. 12 BAR GRAPHS COMPARING FATIGUE CRACK GROWTH RATES AT  $\Delta K = 55 \text{ MPa} \sqrt{\text{m}}$  ( $50 \text{ KSI} \sqrt{\text{in.}}$ ) FOR CONVENTIONAL AND CALCIUM-TREATED A633C STEELS. CON, CONVENTIONAL; CAT, CALCIUM TREATMENT. THE EFFECT OF TESTING FREQUENCY IN SALT WATER AND STEEL QUALITY IS DEMONSTRATED.

FIG. 13 PLOTS OF  $N$  AND  $C$  FROM THE PARIS FATIGUE CRACK PROPAGATION EQUATION FOR A633C STEELS IN SALT WATER IN CONVENTIONAL AND CALCIUM-TREATED QUALITY LEVELS AND THREE TESTING ORIENTATIONS (LT, TL, SL). COMPARISON IS MADE TO OVERALL SCATTERBAND OF ALL CARBON AND ALLOY STEELS IN AIR TESTING (37 PLATES FOR 8 STEEL GRADES).

---

### Fatigue Life Behavior

In general, fatigue is classified as either low-cycle or high-cycle. Low-cycle fatigue is more closely associated with the modeling and analysis of localized plastic deformation, which is essentially the cause of fatigue crack initiation. As such, low-cycle fatigue behavior is typically determined from strain-based fatigue testing. This method is useful because it provides a basis to relate component fatigue behavior to localized regions of plastic deformation at notches or other design details. This is briefly discussed in the section "Axial Strain-Life Fatigue" in this article. More detailed information on strain-based fatigue is covered in the article "Fundamentals of Modern Fatigue Analysis for Design" in this Volume.

High-cycle fatigue of steels is often expressed by a fatigue limit, which is the value of stress below which the steel can presumably endure an infinite number of cycles. The fatigue limit should not be confused with fatigue strength, which is the endurance stress under fatigue loading for a specified number of cycles. Fatigue strength is used when materials do not have an apparent fatigue limit.

In general, the stress-life ( $S-N$ ) curve of steels with tensile strengths below about 1100 MPa (160 ksi) has a definite fatigue limit. To a large extent, the fatigue limit depends on the tensile strength (irrespective of whether strengthening is achieved through cold work, transformation hardening, solid-solution alloying, or precipitation hardening). However, the fatigue limit as a ratio of ultimate tensile strength depends on several factors, such as material, loading, and environmental conditions. Moreover, under some conditions (e.g., corrosion fatigue, certain material conditions, or surface stress concentrations), a fatigue limit may not be observed in a steel. If a fatigue limit is observed, it typically occurs above  $10^6$  cycles between the range of  $10^7$  and  $10^8$  cycles.

**Unnotched fatigue limits** of various steels are shown in Fig. 14 as a function of tensile strength from a systematic of fatigue for ferritic, martensitic, and austenitic steels. A broad band encompasses fatigue limits for 11 martensitic (quenched-and-tempered) steels, while the austenitic grade (type 304 stainless) and the ferritic grade (type 430) have a distinct band when correlating fatigue limits to tensile strength. This implies a general basis for estimating fatigue limits. However, typical tensile strengths (such as those reported on mill sheet reports) do not necessarily correlate with actual fatigue limits, because typical mechanical properties may be based on heat treatment and test coupon properties that may not apply to the actual situation.

**FIG. 14 RELATION OF TENSILE STRENGTH AND FATIGUE LIMIT FOR STAINLESS STEELS AND QUENCHED-AND-TEMPERED (Q&T) STRUCTURAL STEELS. (A) TENSILE STRENGTHS VS. REVERSED TENSION-COMPRESSION ( $R = -1$ ) FATIGUE. (B) REPEATED TENSION FATIGUE ( $R = 0$ ) VS. TENSILE STRENGTH. SOURCE: REF 7**

In addition fatigue limits at a given tensile strength are subject to scatter that becomes more pronounced with the presence of inclusions. The relation illustrated in Fig. 14 is based on special tests with steels that contain fewer inclusions than generally expected and thus less scatter. If inclusions or defects are more pronounced, or if testing encompasses steels with widely varying quality, then the scatter of fatigue limits for a given tensile strength should tend to become more asymmetric, because more data would occur in the lower region of the fatigue limit/tensile strength ratio. For the data comparisons in Fig. 14, the relative effects of inclusion size are shown in Fig. 15, where the decrease in relative fatigue strength seems to begin at a defect size of 45  $\mu\text{m}$  and greater (Ref 7).

**FIG. 15 RELATION OF RELATIVE FATIGUE STRENGTH RATIO AND SIZE OF NONMETALLIC INCLUSIONS AT FATIGUE CRACK INITIATION SITE. THE RELATIVE FATIGUE STRENGTH RATIO FOR REVERSED BENDING FATIGUE LIMIT AND THE VICKERS HARDNESS (HV) ARE PLOTTED AGAINST DEFECT SIZE. DEFECT SIZE WAS EVALUATED BY AVERAGING THE LARGEST THREE DIAMETERS OF NONMETALLIC INCLUSIONS FOUND FOR GIVEN HEAT/LOT. THE DATA ARE PLOTTED TENTATIVELY AT THE 20  $\mu\text{m}$  POSITION FOR STEELS REVEALING NO INCLUSION AT CRACK INITIATION SITES. HORIZONTAL LINES INDICATE REGIONS WITH NO INCLUSION AT THE INITIATION SITE, WHILE INCLINED LINES INDICATE REGION WERE DEFECTS GREATER THAN ABOUT 45  $\mu\text{m}$  DECREASE RELATIVE FATIGUE LIMITS. SOURCE: REF 7**

**Notch Effects.** A systematic analysis of notch effects/sensitivity on the fatigue strength of various steels has been performed by The National Research Institute for Metals in Japan (Ref 8) in an ongoing fatigue data sheet project, in which fatigue properties have been examined systematically for engineering materials manufactured in Japan. The effects of temperature and stress concentration factor on high-cycle fatigue properties for nine kinds of engineering steels (Fig. 16) were obtained, and the following conclusions were drawn:

- THE RATIO OF THE FATIGUE STRENGTH OF THE SMOOTH SPECIMENS AT  $10^8$  CYCLES TO THE TENSILE STRENGTH AT THE SAME TEMPERATURE VARIED FROM 0.4 TO 0.6, DEPENDING ON TEMPERATURE AND MATERIAL CONDITIONS. THE MEAN VALUE WAS ABOUT 0.5 (FIG. 17).
- THE FATIGUE STRENGTH OF NOTCHED SPECIMEN TESTING HAD LESS SCATTER THAN TEST RESULTS FOR UNNOTCHED SPECIMENS (FIG. 17), AND THE FATIGUE STRENGTH OF NOTCHED SPECIMENS (EXPRESSED IN TERMS OF "CRACK INITIATION" AT  $10^8$  CYCLES) ALSO CORRESPONDED WELL TO THE TENSILE STRENGTH, INDEPENDENT OF

TEMPERATURE AND MATERIAL CONDITIONS.

FIG. 16 RELATION BETWEEN TENSILE STRENGTH AND FATIGUE STRENGTH OF SMOOTH SPECIMENS AND NOTCHED SPECIMENS

FIG. 17 RELATION BETWEEN TENSILE STRENGTH AND FATIGUE STRENGTH FOR VARIOUS NOTCH FACTORS. SOURCE: REF 8

A notch sensitivity index  $[\eta = (K_f - 1)/(K_t - 1)]$  for the results had a tendency to become small increasing stress concentration factor or with decreasing tensile strength (Fig. 18), where  $K_f$  is the fatigue notch factor, defined as the ratio of unnotched fatigue strength to notched fatigue strength. A slight decrease in  $\eta$  is noted for the lower-strength steel and austenitic grades (Fig. 18).

FIG. 18 RELATION BETWEEN TENSILE STRENGTH AND NOTCH SENSITIVITY INDEX ( $\eta$ ). SOURCE: REF 8

**Axial Strain-Life Fatigue.** The effect of notches on fatigue life can also be considered in terms of strain-life fatigue. Although most engineering components are designed for application in the elastic regime, stress concentrations or notches often cause plastic strains to develop in the vicinity of notches. Fatigue damage is known to be caused by plastic deformation, and analysis of fatigue crack initiation at the root of the notch can be modeled in terms of plastic strain. This use of strain-life fatigue is known as "equivalent fatigue damage," where the plastic deformation of material at the root of the notch is considered equivalent to the plastic strain during cyclic, strain-controlled axial loading of a smooth fatigue specimen. Therefore, strain life data provides useful information in evaluating and understanding the effect of notches on fatigue (see the article "Estimating Fatigue Life" in this Volume). Strain-life data and the typical fatigue life parameters (expressed in terms of fatigue life exponents and coefficients) for both plastic and elastic strain fatigue are also detailed in the appendix "Parameters for Estimating Fatigue Life" in this Volume. In the high-cycle regime, where plastic strain is minor, fatigue life can be characterized by either the stress- or strain-controlled methodology.

In cases where only total strain life ( $\Delta\epsilon = \Delta\epsilon_p + \Delta\epsilon_e$ ) is available, the plastic strain range can often be correlated with the total strain range through an expression of the form:

$$\Delta\epsilon_T = B\Delta\epsilon_P^\gamma \quad (\text{EQ 1})$$

where  $B$  and  $\gamma$  are experimentally determined constants (Ref 9, 10). Equation 1 is only an approximation of the behavior at intermediate strain ranges and breaks down for small values of  $\Delta\epsilon_t$  and large values of  $\Delta\epsilon$  where  $\Delta\epsilon_t \approx \Delta\epsilon_p$ . In addition, some austenitic stainless steels (especially type 301 with the lower nickel content as an austenite stabilizer) may develop martensite in their microstructures during plastic deformation. This metastable aspect of the austenitic grades can have a nonlinear effect on plastic strain fatigue life and is a subject of research.

**Mean stress effects** on fatigue limits of various machinery structural steels are shown in Fig. 19 and 20. Figure 19 gives the relation between fatigue strengths under repeated tension and under reversed tension-compression. A general ratio of 0.78 is found for quenched-and-tempered steels of higher strengths, while it is variable for steels of lower strengths and higher ductilities.

FIG. 19 RELATION OF FATIGUE LIMIT UNDER REPEATED TENSION TO FATIGUE LIMIT UNDER REVERSED TENSION-COMPRESSION. Q&T, QUENCHED AND TEMPERED. SOURCE: REF 7

FIG. 20 FATIGUE LIMIT DIAGRAM RELATING STRESS AMPLITUDE AND MEAN STRESS OF MATERIALS AT DIFFERENT TENSILE STRENGTH LEVELS. SOURCE: REF 7

The same data are expressed as Haigh's diagram (Fig. 20), which gives the relation of amplitude to mean stress of fatigue limit for different strength levels of steels. In this diagram, fatigue limit lines are combined to yield limit lines, indicating

that the material can be used without failure in zones under each curve. The lowest curve, labeled 490 MPa (71 ksi) in tensile strength, represents the trend for low-carbon (S25C) steels in the test program.

### Corrosion Fatigue Strength

Corrosion or electrochemical surface effects are key variables in both fatigue crack initiation and fatigue crack growth. The current emphasis in corrosion fatigue testing is to measure rates of fatigue crack propagation in different environments rather than to specify the total life to failure. Time-to-failure data are typical of *S-N* tests, while crack growth rate testing has stemmed from the change to a "fail safe" criterion from the use of a "safe life" criterion. The fail safe criterion generally assumes that either cracks are present in the material before service or that cracks are initiated very early in the service history. These assumptions suggest that crack growth controls fatigue behavior in most practical applications.

Nonetheless, evaluation of the effect of corrosion on fatigue life is important and useful. In particular, the simultaneous combination of corrosion and fatigue loading can cause large reductions of fatigue strength at long lives and even the elimination of fatigue limits. For example, the fatigue limit of mild steel is eliminated in aqueous environments, depending on the electrochemical potential (Fig. 21). In this case, corrosion fatigue represents the elimination of fatigue crack thresholds ( $\Delta K_{th}$ ) from the presence of an electrolyte.

**FIG. 21 EFFECT OF ENVIRONMENT ON THE FATIGUE LIMITS OF VARIOUS STEELS. (A) ELIMINATION OF FATIGUE LIMIT FOR 1018 STEEL IN SALT SOLUTION. (D) THE DELETERIOUS EFFECT OF AERATED AQUEOUS CHLORIDE ON THE HIGH-CYCLE FATIGUE LIFE OF TEMPERED MARTENSITIC AISI**

Corrosion fatigue strength can also be interpreted as a "notch effect" from the stress concentrations caused by corrosion pits. This effect can be simulated by prior corrosion, where pre-corroded samples are subsequently fatigue tested in air or another passive environment. In this case, fatigue limits are observed, but at a reduced level relative to that for uncorroded (smooth) specimens (Fig. 22). The notch effect from corrosion pitting can also be illustrated when fatigue limits are observed for stainless steels during fatigue testing in aqueous solutions (Fig. 23). Fatigue endurance results for smooth and notched specimens of a 13% Cr ferritic steel in distilled water and salt water are shown in Fig. 23. These environments are seen to cause a large reduction in the endurance limit of the smooth specimens but only a relatively modest effect on the notched specimens. The importance of surface finish and the adverse effect of corrosion, even when it is allowed to occur only before a fatigue test, is of course well known and included in standard texts on fatigue design.

Corrosion fatigue depends on the material, the environment, and how the corrosive environment is applied. For example, specimens submerged in fresh or salt water have better corrosion fatigue resistance than those subjected to a water spray, drip, or wick or those submerged in continuously aerated water. This is due to the great importance of oxygen and the formation of oxide films in the corrosion fatigue process.

The typical fatigue strengths of various structural alloys are summarized in Table 3 for aqueous environments. In general, corrosion fatigue tests on smooth specimens of high-strength steel indicate that very large reductions in fatigue strength or fatigue life can occur in salt water or spray (Fig. 24). For instance, the fatigue strength at  $10^6$  cycles could be reduced to as little as 10% of that in dry air. In these tests, the main role of the environment was corrosive attack of the polished surface, creating local stress raisers that initiated fatigue cracks. Stainless steels also have a lower fatigue strength in seawater than in fresh water, probably because of the presence of chloride ions in seawater. Chlorides are known to attack the protective oxide surface films on stainless steels and therefore expose the underlying material to the environment and affect fatigue strength.

FIG. 24 EFFECT OF SALT SPRAY ON CORROSION FATIGUE OF VARIOUS STRUCTURAL STEELS (UNNOTCHED). SOURCE: REF 19

Corrosion fatigue crack initiation in notched specimens is most effectively characterized by the notch-root plastic strain range calculated by Neuber's method, elastic-plastic finite elements, or fracture mechanics approximation (Ref 13, 14). Figure 25 shows the fracture mechanics method from the results of over 100 experiments with C-Mn and alloy steels in aqueous chloride compared to moist air. The load cycles to produce 1 mm of fatigue crack extension increase with decreasing  $\Delta K/\sqrt{R}$  (where  $R$  is the notch tip radius) and are reduced by chloride (free corrosion) relative to moist air. An endurance limit is observed for moist air, but not for corrosion fatigue. Information on other methods (e.g., Neuber's method) is given in the article "Estimating Fatigue Life" in this Volume.

FIG. 25 THE EFFECT OF CHLORIDE ON THE CORROSION FATIGUE CRACK INITIATION RESISTANCE OF

**Mechanisms of Corrosion Fatigue Crack Initiation.** Although the mechanisms of corrosion fatigue are not well understood, it is known to be an electrochemical process dependent on the environment/material/stressing interaction. Surface features at origins of corrosion fatigue cracks vary with the alloy and with specific environmental conditions. In carbon steels, cracks often originate at hemispherical corrosion pits and often contain significant amounts of corrosion products (Fig. 26). The cracks are often transgranular and may exhibit a slight amount of branching. Surface pitting is not a prerequisite for corrosion fatigue cracking of carbon steels, nor is the transgranular fracture path; corrosion fatigue cracks sometimes occur in the absence of pits and follow grain boundaries or prior-austenite grain boundaries.

**FIG. 26 INITIATION OF FATIGUE CRACKS AT CORROSION PIT FROM A FAILED STEEL TUBING IN A DRILLING APPLICATION (EXAMPLE 1). 50×**

Environmental effects on the nucleation process of fatigue cracks are more extensive for aqueous environments than for gases. The mechanisms of environmentally assisted crack nucleation in aqueous conditions include (Ref 15):

- PITTING, WHERE NUCLEATION OF CRACKS TAKES PLACE AT PITS FORMED THROUGH CORROSIVE ATTACK
- PREFERENTIAL DISSOLUTION, WHERE HIGHLY DEFORMED MATERIAL ACTS AS A LOCAL ANODE WITH THE SURROUNDING UNDEFORMED MATERIAL ACTING AS A LOCAL CATHODE. THE ANODIC REGIONS THEN SERVE AS CRACK NUCLEATION SITES.
- RUPTURE OF PROTECTIVE OXIDE FILMS, WHERE LOCALIZED CORROSION OCCURS IN THE METAL IMMEDIATELY BELOW DEFORMATION-INDUCED RUPTURE OF THE PROTECTIVE OXIDE. FATIGUE THEN STARTS AT THE REGIONS OF LOCALIZED ATTACK.
- SURFACE ENERGY REDUCTION, WHERE ADSORPTION OF ENVIRONMENTAL SPECIES PROMOTES GRIFFITH-TYPE CRACK GROWTH BY REDUCING THE SURFACE ENERGY.

Localized preferential dissolution is unlikely in gaseous environments because development of local electrochemical cells requires the presence of an electrolyte. However, mechanisms have been developed for pitting and for adsorption-induced surface energy reductions in gaseous environments.

**Gas Environments.** Pitting in gases is generally restricted to oxidizing environments. However, even non-oxidizing gases that do not induce pitting may still significantly enhance corrosion fatigue initiation. The pitting model is therefore applicable to specific metal-environment systems. Gas environments can alter the mechanisms of fatigue crack nucleation by (Ref 15):

- OBSTRUCTION OF REVERSIBLE SLIP
- INHIBITION OF CRACK REWELDING IN SLIP BANDS
- REDUCTION OF SURFACE ENERGY AT THE CRACK TIP

- FORMATION OF BULK OXIDE

**Aqueous Corrosion Fatigue.** Important variables in aqueous corrosion fatigue include alloy composition and solution chemistry. In general, corrosion fatigue behavior parallels environment corrosivity, with increasing corrosion rates resulting in decreased fatigue resistance. However, a number of exceptions to this observation have been noted and observed. When improved corrosion fatigue resistance has been observed to be inversely related to corrosion rate, the improvement has generally been ascribed to delays in crack initiation or early propagation caused by dissolution of microcracks or stress concentrators.

Early experiments with mild steel specimens in deaerated 3% sodium chloride solutions showed that a critical corrosion rate was necessary to initiate corrosion fatigue failures (Ref 16). When the same material was exposed to artificial sea water at elevated temperatures, shallow and uniformly distributed pits were found over the surface. These pits served as initiation sites for corrosion fatigue failures. Both of these results thus suggested that corrosion-induced defects could enhance fatigue crack initiation.

However, as previously mentioned, pitting does not always occur in corrosion fatigue. For example, low-carbon steels have been susceptible to corrosion fatigue in acid solutions in spite of a total lack of formation of pits (Ref 17). Similar susceptibility to corrosion fatigue has been observed in steel samples tested in deaerated solutions while under small impressed anodic currents (Ref 18). Thus, the pitting model cannot be a generalized mechanism for corrosion fatigue of metals, and any pitting model is only applicable to a specific metal-environment combination.

**Prevention of Corrosion Fatigue.** Both temporary and permanent solutions for corrosion fatigue involve reducing or eliminating cyclic stress, increasing the corrosion-fatigue strength of the material, and/or reducing or eliminating corrosion. These objectives are accomplished by changes in material, design, or environment.

**Changes in Material or Heat Treatment.** Although heat treatment can be a factor, alloying with chromium is the material change that most effectively reduces the effects of corrosion fatigue on steel. Figure 27 summarizes a comprehensive air and corrosion fatigue program with carbon, low-alloy, and chromium steels, using rotating-bending specimens subjected to fresh water spray (Ref 19). The results in air show the usual behavior, the fatigue limit being approximately proportional to the tensile strength. For the results in water, however, the fatigue strength of the carbon steels and low-alloy steels is almost independent of the tensile strength. All the results on carbon steels, covering a range of carbon content from 0.03 to 1.09%, both annealed and hardened and tempered, showed corrosion fatigue strengths between  $\pm 80$  and  $\pm 150$  MPa ( $\pm 12$  and  $\pm 22$  ksi). For both carbon and low-alloy steels, the corrosion fatigue strength was usually higher in the annealed condition than in the hardened-and-tempered condition. The corrosion-resistant steels, containing  $\geq 5\%$  Cr, showed much greater resistance to corrosion fatigue, approximately proportional to the tensile strength.

FIG. 27 THE INFLUENCE OF STRENGTH AND CHEMICAL COMPOSITION ON THE CORROSION FATIGUE STRENGTH OF STEELS. UNNOTCHED SPECIMENS, ROTATING BENDING FATIGUE STRENGTH,  $20 \times 10^6$  CYCLES,

Although annealing has been beneficial in a few cases, alloying and heat treatment of steels usually have little effect on corrosion fatigue characteristics unless the alloying is undertaken specifically to improve corrosion resistance. In some cases, deleterious heat treatments such as those leading to sensitization in stainless steels have resulted in lower corrosion fatigue resistance.

**Component Design Changes.** Sometimes it is possible to reduce operating stress to increase corrosion fatigue strength. Operating stress may be lowered by reducing either the mean stress or the amplitude of the cyclic stress. This almost always involves a change in component design. Sometimes only a minor change is required, such as increasing a fillet radius to reduce the amount of stress concentration at a critical location. In other instances, more extensive changes are required, such as significantly increasing the cross-sectional area or adding a strengthening rib.

**Corrosion effects** can be lessened by alloying, by providing galvanic protection, or by altering or removing a corrosive environment. Galvanic protection by sacrificial anodes or applied cathodic currents has been successful in reducing the influence of corrosion on fatigue of metals and alloys exposed to aqueous environments, except in such alloys as high-strength steels that are subject to hydrogen-induced delayed cracking. In similar instances, anodic polarization has been used for protection of stainless steels. With passive alloys or alloys that can be polarized to produce passive behavior, crevices must be avoided, because corrosion within crevices may actually proceed more rapidly due to the anode-cathode relationship. For example, in a part made of low-carbon steel, an area under an O-ring can fail by corrosion fatigue in a caustic solution with a pH of 12 at a location where only low cyclic stresses exist. Where pitting corrosion has occurred, corrosion pits may act as stress raisers and thus accelerate fatigue failure.

Inhibitors are sometimes added to the environment or included in organic coatings to eliminate corrosion fatigue. The effect of inhibitors is believed to depend solely on their ability to reduce corrosion rates to acceptable values. However, corrosion fatigue is a complex electrochemical process. For example, experiments performed on boiler steels at 275 °C showed that additions of 0.7 g/L NaOH to distilled water improved the fatigue limit by approximately 20%, but that increasing the NaOH concentration to 200 g/L lowered the fatigue limit by approximately 10% (Ref 16). At the higher alkaline concentrations, intergranular as well as transgranular cracking was observed, indicating that caustic cracking (stress-corrosion cracking) was also occurring during normal fatigue cracking.

There is considerable evidence that dissolved oxygen is important to the mechanism of corrosion fatigue. For example, an improvement in the fatigue life of steel specimens was noted when the specimens were completely immersed at 96 °C, suggesting that this improvement was due to the limited solubility of oxygen at this temperature. Sodium chloride solution dripped through air proved to be extremely damaging to fatigue specimens, whereas a solution dripped through a commercial hydrogen atmosphere resulted in higher fatigue life, with still further improvement as the purity of hydrogen was increased (Ref 16).

Electrochemical polarization may have a marked effect on corrosion fatigue resistance. For example, anodic polarization of carbon steels and of copper alloys has been shown to result in decreases in fatigue lives. For some cases, however, severe anodic polarization actually results in increases in fatigue resistance. Examination of specimens subjected to large amounts of anodic dissolution reveals that surface-initiated cracks are blunted by the corrosive environment, leading to a decrease in stress concentration.

## Fracture and Fatigue Properties of Structural Steels

Alexander D. Wilson, Lukens Steel Company

---

### Fatigue Failure Examples

Simple rules for fatigue-resistance design cannot be stated because of the diversity in function, loads, stresses, materials, and environments. The adverse effect of stress risers and discontinuities within a metal, either at the surface or subsurface, may also arise from primary or secondary working of the material. Some of these factors are illustrated with the following case histories of fatigue failure of various steel components.

**Effect of Thread Design and Low-Frequency Loading on Corrosion Fatigue Failure of a Threaded Low-Carbon Steel Rod:** Submitted by *J.M. Gallardo, Universidad de Sevilla, Spain*. A threaded rod component failed after 10,000 hours of discontinuous service as an anchoring and tensioning element for the traction ropes of a ladle-carrying car on a sea-side harbor crane. One-half of the element was square in section ( $75 \times 75$  mm); the other half was a square-threaded 70 mm diam rod. The fracture occurred in the second thread nearest to the section change. The fastener was made of normalized UNE F1120 steel, which is similar in composition and properties to AISI-SAE 1029.

**Investigation.** The fracture surface was typical of a fatigue fracture. Nearly 90% of the section showed beach marks, the remaining section displayed a final, catastrophic fracture surface. Fracture origin was identified at the second thread root. Cracks were also detected at the first thread root. Chemical analysis (0.27 C, 0.75 Mn, 0.18 Si, 0.011 S, 0.023 P), heat treatment, thread shape, surface roughness, general dimensions, etc. fulfilled initial design.

Unfortunately, the original design was lacking in fatigue-prevention measures. The very first threads, near the section change, were not machined with diminishing flank height to reduce stress concentrations at thread root (Ref 21). A similar reduction can be obtained by using a large thread root radius (Ref 22) such as 0.5 mm (Ref 23) instead of the mean measured value of  $70 \mu\text{m}$ . The aforementioned advisable radius value is referred to a trapezoidal thread of the same dimensions, which has similar load-carrying capabilities and an improved fatigue behavior (Ref 23), compared to the square thread used. Finally, surface roughness, in compliance with design drawings specifications, was  $21.4 \mu\text{m}$  (N11, ISO 1032), but a preferable value is  $0.8/1.6 \mu\text{m}$  (N6/N7) (Ref 24). Three other contiguous rods were tested by magnetic particle; no flaws were found at the threads.

Fastener design and fabrication did not favor fatigue resistance, but three other fasteners working in parallel had shown no flaws. To explain this, a fracture mechanics approach was used to characterize the fatigue process. A scanning electron microscopy survey was performed by measuring the striations spacings ( $da/dN$ ) at several distances ( $a$ ) from fracture origin to determine the crack-growth rate. Stress intensity factor  $K_I$  values were calculated at the crack front center. Load cycle data  $\Delta\sigma$  were obtained from design calculations and the geometric factor for threaded rods (Ref 25).

The resulting Paris-model relationship is presented in Fig. 28. Along with this case-history experimental data, the behavior of a ferritic low-carbon steel (0.15-0.20 C, 0.60-0.90 Mn, 0.04 max P, 0.04 max Si) in air (Ref 26) and API X-65 (0.24 C, 1.35 Mn, >0.02% V and/or 0.005 Nb) in salt water (Ref 26) are compared. Measured crack growth rate is very high in comparison with crack propagation in air. Corrosive media may increase growth rate by a factor of  $10^2$  to  $10^3$ , if the loading cycle frequency is low enough to permit corrosion at the crack tip between two successive jumps (as seen in Fig. 28 for API X-65 in salt water). Nevertheless, corrosion (3% aqueous solution of sodium chloride) is said to produce only slight effects in fatigue behavior of lower-strength steels such as A36 and A588 Grade A, at frequencies higher than 0.2 Hz (Ref 26). However, corrosion fatigue can affect crack growth rates at a lower load-cycle frequency, which in this case was only 0.04 Hz. Furthermore, corrosion products, of high chloride content, were identified inside non-propagated cracks at the first thread.

**FIG. 28 MEASURED RATE OF CRACK GROWTH IN LOW-CARBON STEEL (F1140) IN SEASIDE ENVIRONMENT COMPARED WITH CRACK GROWTH OF LOW-CARBON STEEL IN AIR AND API X-65 STEEL IN SALT WATER**

The very high crack propagation rate measured may explain why only one out of four similar fasteners failed. Integration of Paris equation, between an initial crack size of 100  $\mu\text{m}$  (calculated value of crack depth for the estimated  $\Delta K_{th}$ ) and the measured crack size before final fracture (52.7 mm) gives a steady crack-growth period of  $N = 82300$  cycles. This figure corresponds to 16 months service time, i.e., 13% of the total 10 years that crane was in operation. Minute differences in fatigue initiation process may be responsible for differences in beginning the sustained crack propagation cycle, which, on the other hand, is very fast.

**Conclusions.** The threaded rod failed by corrosion-fatigue. Main factors associated to fracture initiation were thread profile-square, at constant flank height in the first threads and minimum root radius-, very high machining roughness and coastal saline environment. Rapid fatigue crack propagation was attributed to low-frequency cycling in a sea-side corrosive environment. Corrective measures include a recommended 12-month inspection interval and a new fastener design. New fasteners should be designed with higher fillet root radius (0.5 mm), lower surface roughness (ISO N6/N7), gradual transition between square and round sections and diminishing flank height for the first threads.

**Fatigue Failure of Transmission Shaft from Straightening after Heat Treatment:** Submitted by *F. Carrion, Instituto Mexicano del Transporte, Mexico*. The secondary transmission shaft of a heavy weight truck failed after 10,000 Km (or 5% guaranteed life). The piece was AISI 8620 steel with five keyways and a gear (Fig. 29) and a carburized case (0.5 mm deep hard surface of 60-62 HRC) and an interior hardness of 20-25 HRC after heat treatment. The failure always happened at the same point on the second keyway to an estimated 5% of the total manufactured shafts.

FIG. 29 FRACTURE LOCATION AT THE KEYWAY THAT WAS LOADED DURING SHAFT STRAIGHTENING

**Investigation.** From the analysis of the manufacturing process, a wide dispersion of the deformation of the shafts after heat treatment was obtained with an eccentricity ranging from 0.0076 mm to 0.294 mm with an average of 0.122 mm, due to the incorrect positioning of the shafts during the heat treatment. Despite of the degree of deformation, all shafts went through a straightening process in which force was applied at the center of the shaft on the second keyway.

Macroscopic fractography revealed typical beach marks from a tension-compression fatigue failure at low nominal stress. The starting zone was located at the corner of the keyway shaft and the final fracture zone covered about 30% of the fracture surface. Electron microscopic analysis of the crack initiation site revealed two zones: the first corresponding to an impact fracture with the size of the hardened case (0.5 mm), and the second corresponding to the initiation of the typical fatigue fracture. The hardened case was martensite and bainite, and the interior was ferrite and bainite. Grain size in both cases was 7-8 ASTM throughout, and the tensile yield strength of the material was 549 MPa with an ultimate strength of 942 MPa.

A fatigue crack propagation test was done with a modified three-point bending specimen from the ASTM E-648 standard (63 mm long, 6 mm wide, 15 mm high and with a 3 mm groove for the initial crack). Although the specimen size criteria was not met with this width, the tests found that the difference between the length of the crack at the center and the length of the crack at the edge was always less than 10%. This size of specimen was selected due to the interest of investigating the spatial distribution of the fracture mechanics properties of the material across the transversal area of the shaft.

The average of the fracture toughness  $K_Q$  (as an approximate value of  $K_{Ic}$ ) was  $102 \text{ MPa}\sqrt{\text{m}}$ . From a load ratio ( $R$ ) of 0.1 and a constant DP of 1000 kN, the relation between the fatigue crack growth rate ( $da/dN$ ) and the applied stress intensity was obtained using the ASTM E-399 standard formula for the three-point bending specimen. The coefficients for Paris' equation (stage II) were found to be  $n = 2.3$  and  $C = 1.664 \times 10^{-11}$ . With an initial crack of 0.5 mm, a remaining life of 2000 Km was calculated. However, this calculation did not consider the increase of life caused by the variable loads, the change of direction of the crack (initial crack is parallel to the longitudinal axis of the shaft), and the contribution of the initial propagation of the stage I.

**Conclusions.** Crack initiation was due to the impact force during straightening after heat treatment. Once the crack initiated, it grew due to fatigue during operation. The remaining life after cracking of the hardened case is not acceptable. The heat treatment was improved to reduce the dispersion of the deformation of the shafts. The geometry of the keyway also was changed to reduce the stress concentration at that point. An analysis based in fracture mechanics and plasticity theory was done to determine an acceptable limit on the eccentricity of 0.211 mm for the straightening process to avoid cracking.

**Intergranular Fracture with Continuous Carbide Network in a Steel Transmission Gear:** Submitted by *M. Pepi, U.S. Army Proving Ground, Maryland.* A spiral bevel transmission gear from an Army cargo helicopter failed during a training flight leading to an immediate landing. Inspection of the number 2 engine transmission revealed that an 8-tooth segment (out of a 35-tooth gear) had fractured and penetrated the transmission housing. The failed component was fabricated from X-2 steel (a modified H11 tool steel), and carburized to a required case hardness of 59-64 HRC. The broken parts were subject to visual examination, magnetic particle inspection, light optical microscopy, chemical analysis, hardness testing, case depth measurement, X-ray diffraction, scanning electron microscopy (SEM), and energy dispersive spectroscopy (EDS).

**Investigation.** Visual examination and light optical microscopy of the fracture surfaces revealed characteristics consistent with a fatigue failure, including smoothness of fracture and beach marks. The beach marks and radial lines on the fracture surface revealed that the origin was located in the damping ring groove portion of the gear at a darkened half-moon shaped defect. The pre-existing crack was oriented perpendicular to the direction of grinding, suggesting the possibility of a grinding crack/burn. The darkened region had a featureless topography resembling that of a steel surface which has been exposed to a heat treatment atmosphere. Energy dispersive spectroscopy (EDS), in conjunction with a scanning electron microscope (SEM), within the darkened area revealed the presence of sodium. This finding was considered evidence that a pre-existing crack was present during the manufacturing process, since sodium nitrate and sodium dichromate are widely used to black oxide finish steel components. EDS spectra outside this darkened region failed to detect the presence of sodium. Further visual examination and magnetic particle inspection of the remaining component revealed small grinding cracks located in the same area as the fracture origin. A sample was sectioned through the origin to confirm that the pre-existing defect was a grinding crack. The sample was metallographically prepared, and showed evidence of rehardening (white region) and retempering (dark region). In addition, metallography revealed what appeared to be continuous carbide networks (CCN's) in the region of the gear which contained the origin. These networks were not continuous in high stress areas, such as the gear root and flank. Continuous carbide networks are generally caused by an excessive carbon potential during the carburization process, and can act to embrittle the case and reduce the fatigue limit of the component under bending fatigue conditions. Also, these networks render a surface sensitive to grinding, and if cracking occurs, it usually follows the path of the networks.

Metallography combined with microhardness testing of the damping ring groove area (fracture origin location) revealed a greater case depth than specified. The case depth was required to be 0.030-0.050 in., however, the average effective case depth was 0.075 in. It was later learned that the damping ring groove was subject to both the first and second carburization treatments, rather than the required first treatment only (the region was left inadvertently unmasked after the first treatment). The root, fillet, and flank effective case depths all conformed to the governing requirement of 0.030-0.050 in. Chemical analysis was performed to determine the elemental composition of the alloy. The carbon content was determined through combustion-infrared detection, and the sulfur content was found utilizing combustion-automatic titration. The remaining elements (silicon, manganese, phosphorus, tungsten, chromium, vanadium, and molybdenum) were determined using direct current plasma emission spectroscopy. The composition conformed to the governing specification. A 0.013 in. section was sliced from the top of the damping ring groove region, and subject to analysis for carbon content. The weight percent of carbon was 1.31%, suggesting the part was subject to a higher than nominal carbon potential during carburization. Hardness testing was performed on both the case and core of the component. The case hardness met the governing requirements of 59-64 HRC with an average of 61 HRC. The core had an average hardness of 40 HRC which fell within the required range of 36-44 HRC. X-ray diffraction was performed on sections of the fractured gear to determine the stress profile and percent retained austenite. The stress profile was consistent with a properly shot-peened X-2 steel. The percent retained austenite was 8.9%, which met the governing requirement (20% maximum). Fractographic examination of a secondary through fracture revealed intergranular fracture within the case of the damping ring groove area (Fig. 30). The remaining morphology consisted of ductile dimples, indicative of overload fracture. No evidence of fatigue was noted. This finding was evidence that the continuous carbide networks can contribute to an intergranular fracture.

**FIG. 30** SCANNING ELECTRON MICROGRAPH OF A SECONDARY FRACTURE THROUGH THE DAMPING RING GROOVE REGION SHOWING EVIDENCE OF INTERGRANULAR CRACKING AT THE SURFACE. THIS REGION COINCIDED WITH THE ORIGIN AREA ON THE PRIMARY FRACTURE. INTERGRANULAR MORPHOLOGY WAS ATTRIBUTED TO THE CARBIDE NETWORK NOTED WITHIN THE CARBURIZED CASE.

**Conclusions.** The primary fracture origin was located at a pre-existing processing defect, which was a half-moon shaped darkened region. This defect was determined to be a grinding crack/burn, and was considered a contributing factor to the failure of this component. The grinding crack/burn was characterized by an orientation perpendicular to the direction of grinding, a half-moon shape, a darkened, featureless topography, the presence of sodium in the darkened area, and a rehardened and retempered structure adjacent to the fracture origin. Although the morphology of the primary fracture origin (darkened area) was featureless, it was possible that the continuous carbide networks within the carburized case facilitated grinding crack propagation.

**Corrective Measures.** This failure was the second spiral bevel transmission gear to fail in three years. The first failure occurred when a 9-tooth segment of the gear fractured. Although major fire damage made that investigation difficult, it was determined that a fatigue crack had grown before final fracture. The origin of that failure was also determined to be the damping groove region. Steps were taken by the contractor to ensure this type of failure would not recur, including a more thorough magnetic particle inspection in the groove region. In addition, grinding in the damping ring groove has been eliminated and replaced with a turning procedure which should keep heat generation to a minimum and ensure that defects related to grinding will not occur. In addition, a nital etch with 10× magnification step has been added to the inspection process, which should also help to detect future defects. The contractor also agreed to consider material specifications with micrographs of unacceptable case microstructures. This would aid the subcontractor in determining rejectable parts before they are placed into service.

**Failure of an Overhead Crane Drive Shaft Due to Rotating-Bending Fatigue:** Submitted by *J.R. Emmons, Rocketdyne Division, Rockwell International, Canoga Park, CA*. A drive shaft used as part of the drive train for an overhead facilities crane fractured due to low-cycle rotating-bending fatigue, initiating and propagating by combined torsional and reverse bending stresses. The part submitted for examination was a principal drive shaft which fractured in the location of a 90 degree fillet where a wheel hub is machined down to 1.375 in. diameter from a 2.375 in. diameter main shaft. A 0.375 in. wide by 0.125 in. deep keyway was machined into the entire length of the hub, ending approximately 0.062 in. away from the 90 degree fillet (Fig. 31). The hub had fractured, separated from the main shaft, and lodged in the shaft hole of the wheel when the wheel fell away from the shaft. The wheel, together with the fractured hub and the shaft, were submitted for analysis.

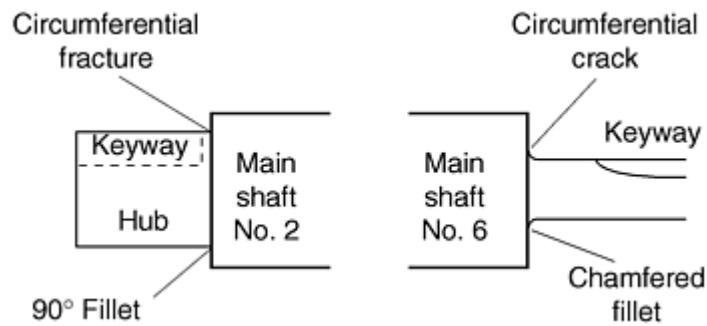

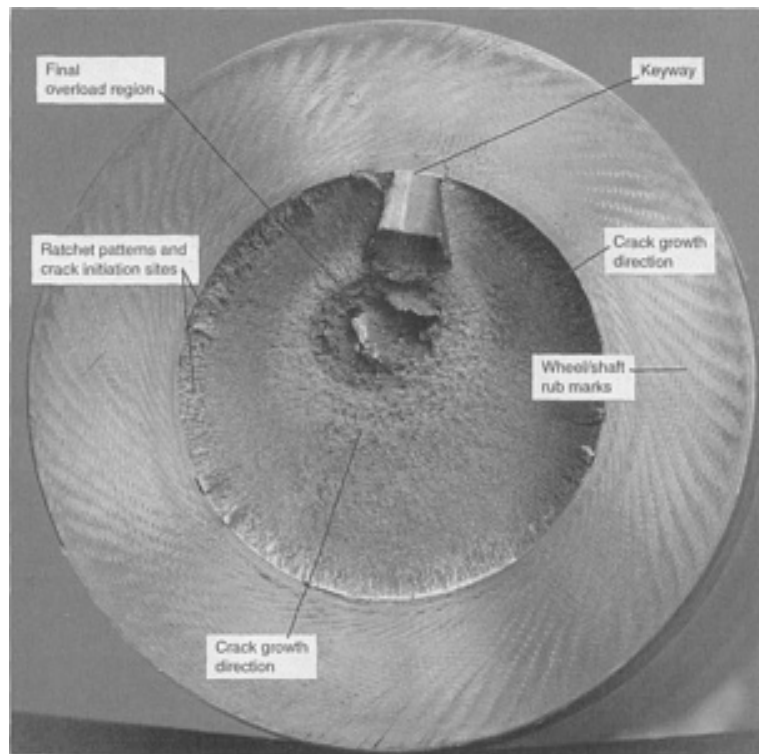

FIG. 31 LOCATIONS OF OBSERVED FRACTURES IN A SHAFT ASSEMBLY

**Investigation.** The pre-service and post-failure radiographic and penetrant inspection records were reviewed for the shaft and were found to be satisfactory. No additional cracks or indications were evidenced. The crack which led to the failure was not present when the shaft was installed. It was estimated that installation had been  $1\frac{1}{2}$  to 2 years prior to the failure. The shaft material was verified as tempered 4150 steel by using wet chemical analysis and metallographic techniques. The hardness and the microstructure were surveyed by preparing metallographic specimens from the fractured hub section. The microstructure was confirmed to be a tempered martensite structure. The surface of the crack was examined at low and high magnifications utilizing optical and scanning electron microscopy.

Two additional shafts had not fractured to failure, but were radiographically and penetrant inspected as part of a verification analysis to determine if the remaining drive shafts were serviceable. One of these shafts was found to have a radial penetrant indication, this time in the chamfered fillet in the one-inch diameter machined motor drive end of the shaft, which is the end opposite to that which fractured in the principal shaft (Fig. 31). This shaft was sectioned diametrically to expose a polished cross section of the indication. One quarter of the radial indication was broken open to expose the crack fracture features for observation in order to determine the mode of fracture. Because of the resultant similarity between this crack and the fracture in the principal shaft, no further forensic work other than basic fractography, was performed on this second shaft.

Figure 32 shows a magnified view of the fractured hub which caused the wheel to break off the principal drive shaft of the overhead crane. The concentric circles revolving around the final overload, along with the ratchet marks around the outer circumference pointing towards the overload, are typical of a crack growth induced by rotating-bending stresses. The ratchet marks are exposing the fatigue initiation sites around the outer perimeter, as verified by high magnification scanning electron microscopy performed later in the investigation. The individual cracks propagated toward a single crack front and then toward the final overload area. Figure 32 shows the darker ductile dimples of the final overload region slightly off-center of the hub. The final overload was probably off-center due to the rotating-bending stresses which initiated the fracture on one side of the hub (most likely the side opposite the final overload) while at the same time driving the crack around the outer circumference producing multiple inward growing crack fronts.

**FIG. 32 FRACTURE SECTION OF STEEL SHAFT**

Heavy corrosion was present traversing the fracture surface, extending for an inward distance of 0.125 in. from the outer edge, as identified in Fig. 32. The corrosion was confirmed to be rust. This corrosion may signify an older portion of the entire crack which may have been growing for quite some time. It was originally suspected that the overall fracture had initiated at the keyway, which is usually the case in shafts where keyways are present, but the forensic analysis provided the contributing evidence that the fatigue cracks actually propagated towards the keyway rather than initiating from it.

**Conclusions.** A drive shaft used to assist in driving an overhead crane for the movement of medium to heavy weight components inside a manufacturing building, fractured at the mating interface with the drive wheel, in the location of a reduced diameter wheel hub machined at a sharp 90 degree fillet from the main bulk shaft. The sharp 90 degree fillet co-existed with a keyway in the vicinity of the fracture, although the keyway did not appear responsible for the failure. A second shaft was cracked in a sharply chamfered region where the main shaft was machined to a reduced diameter to form the motor drive hub opposite the wheel hub end of the shaft. The fracture mode for both shafts was low-cycle rotating-bending fatigue initiating and propagating by combined torsional and reverse bending stresses. All drive shafts were replaced with new designs which eliminated the sharp 90 degree chamfers in favor of a more liberal chamfer which reduced the stress concentration in these areas.

## Fatigue of Coiled Tubing

Terry McCoy and Jerry Foster, Halliburton Energy Services, Duncan, OK

---

Coiled tubing (CT) is used in the oil and energy industries to provide a number of production enhancement and maintenance services. The operational concept of a CT system is to run a continuous string of small-diameter tubing into a well to perform specific well servicing operations without disturbing existing completion tubulars and equipment. When servicing is complete, the small-diameter tubing is retrieved from the well and spooled onto a large reel for transport to and from work locations. Coiled tubing offers many advantages over conventional jointed tubing including time savings, pumping flexibility, fluid placement, reduced formation damage, and safety.

However, the combination of low yield strength, thin wall, small diameter, and plastic strain cycling events limit CT applications. The continuous length of tubing experiences plastic deformation before entering the wellbore during the process of unwinding from the reel and passing through the surface machinery. The plastic strains superposed with high tangential stresses introduces the low-cycle fatigue failure mechanism. Tubing subjected to these operating conditions has a finite life. Many researchers have proposed methods of quantifying the effects of the low-cycle fatigue (Ref 27, 28). The loading conditions inside the wellbore are also complex (but not in the plastic strain regime) and of a dynamic nature. Tubing mechanics algorithms are used to calculate tubing forces, indicate the buckling state, and compute operating stresses.

Tubing integrity (Ref 29) is the limiting factor in establishing the operating envelope (Ref 30). Factors such as yield strength, working depth, working pressure, physical dimensions, and condition of the tubing combine to limit its application. The accepted industry operating boundary of 5000 psi (34.5 MPa) and 15,000 ft (4,572 m) depth evolved from practical experience based on the material properties available in this time period. The operating envelope has been expanded since the introduction of CT as a result of improvements in metallurgy and manufacturing process control. The continuous milling technique improved homogeneity by eliminating the butt welds previously used to join segments of tubing. Continuous milling removed the potential flaws associated with welds. The perfection of the longitudinal seam weld process also contributed to the acceptance of coiled tubing. The manufacturing process includes 100% nondestructive inspection of the product for flaw detection plus full hydrostatic test to 80% of the yield pressure.

The condition of tubing after it has entered service is monitored using visual and analytical tools. The fatigue state is calculated from the records of pressures, forces, plastic-bend events, and the physical parameters of the equipment. Operating techniques are used to mitigate the effects of corrosion by using inhibitors and to minimize stress by proper selection of equipment. Imperfections introduced from the environment such as mechanical damage, corrosion pitting, and cracking may reduce the service life below expectations.

Three basic grades of steel tubing have proven to be acceptable for CT workover operations:

- 70-GRADE WITH MINIMUM YIELD STRENGTH OF 70 KSI (483 MPa)
- 80-GRADE WITH MINIMUM YIELD STRENGTH OF 80 KSI (552 MPa)
- 100-GRADE WITH MINIMUM YIELD STRENGTH OF 100 KSI (690 MPa)

The 70- and 80-grade materials are usually selected for hostile environments because of their inherent resistance to cracking in the presence of wet hydrogen sulfide and other aggressive chemicals.

Coiled tubing is available in outside diameters from 0.75 through 3.50 in. with wall thickness from 0.087 through 0.203 in., and lengths exceeding 25,000 ft (7620 m). The most common OD sizes are 1.25 in. and 1.50 in. The trend is toward greater use of larger tubing sizes, higher strength, and greater wall thickness (*W*).

### Example 1: Failure of Coiled Tubing in a Drilling Application.

Coiled tubing is used in drilling operations because it eliminates the need for a drilling rig and a reduction in equipment requirements and time to completion. Coiled tubing for drilling applications is subjected to multiple plastic-strain cycles while under load in the presence of potentially corrosive fluids, either encountered downhole or pumped from the surface. In one application, coiled tubing (2.000 in. OD × 0.156 in. *W*) with a yield strength of 483 MPa (70 ksi) was used to drill 68 steam injection wells in California for a major oil company. Depth of the wells ranged from 850 to 1000 ft (259 to 305 m). The tubing had used about 50% of its estimated fatigue life when failure occurred.

**Investigation.** The tubing failure was transverse to the tubing axis. Visual examination showed a flat fracture surface (arrow in Fig. 33) that was about  $\frac{1}{2}$  in. (13 mm) in length with the rest of the fracture showing shear lips indicative of tensile overload. The fracture was not associated with the longitudinal weld seam. The field report indicated that a pinhole leak in the tubing was noticed when the tubing was being spooled over the reel and then the tubing "snapped."

**FIG. 33 FRACTURE SURFACE OF COILED STEEL TUBING SHOWING A FLAT FRACTURE (ARROW) INDICATIVE OF FATIGUE**

The flat portion of the fracture surface is typical for fatigue cracking. Fatigue striations were visible when the sample was examined with a scanning electron microscope (SEM). Closer examination showed corrosion pitting on the tubing ID from which the fatigue crack had propagated. The corrosion pits were essentially flat-bottomed and were about 0.010 to 0.012 in. (0.25 to 0.30 mm) deep. Other areas adjacent to the primary fatigue crack also showed small fatigue cracks initiating from corrosion pits (Fig. 26).

The corrosion pitting on the tubing ID was primarily on one side of the tubing. X-ray diffraction analysis of the scale taken from the area in question showed only amorphous iron compounds with a moderate amount of quartz and small amounts of various clays. The exact cause of the corrosion pitting was not determined but may have occurred when the tubing was idle and fluids accumulated at the bottom of the tubing wraps.

Chemical and mechanical property testing performed verified that the CT met specifications. Hardness of the tubing was 92 HRB, which met the specified requirement of 22 HRC maximum. The microstructure of the tubing was typical for this grade of tubing having a fine-grain, ferritic structure. Tubing dimensions showed ovality of 0.082 in. (2.1 mm), indicating that the tubing had been significantly plastically deformed.

**Conclusion.** The CT failed prematurely due to low-cycle fatigue, initiating at ID corrosion pitting. Multiple fatigue cracks initiated at the bottom of ID corrosion pits, one of which predominated and propagated to the tubing OD, causing a pinhole leak. When the tubing was spooled onto the reel, the crack length was sufficient to allow the tubing to "snap" when bent over onto the reel. Although the exact cause of the corrosion was not determined, it is speculated that corrosion occurred during tubing lay-up since the pitting corrosion was isolated to one side of the tubing.

**Corrective Measures.** Corrosive attack on the coiled tubing can be reduced by completely removing fluids or modifying the fluids in the tubing. If water cannot be totally removed from the tubing, then an alkaline solution (to bring pH to 8 or 9) and an oxygen scavenger can be added. The tubing can also be purged by flowing dry nitrogen through the tubing to dry it out, then capping the ends to maintain a noncorrosive atmosphere in the tubing.

### **Example 2: Failure of Coiled Tubing due to Hydrogen Sulfide (H<sub>2</sub>S) Exposure.**

Coiled tubing with 80 ksi (552 MPa) yield strength is manufactured to a maximum hardness of 22 HRC, thereby meeting NACE Standard MR0175 requirement for sour gas service. However, extra precautions must be taken when using this tubing in sour (H<sub>2</sub>S containing) wells because of the plastic cycling the tubing experiences in service. Coiled tubing (1.500 in. OD × 0.095 in. W) with length of 10,000 ft (3,048 m) was being used in Red Deer, Alberta, Canada area for various types of jobs, including sand cleanout, acid wash, and nitrogen lifts. The tubing had been on 38 jobs when the failure occurred. Seventeen of the 38 jobs involved wells containing H<sub>2</sub>S gas. H<sub>2</sub>S concentration varied from 0.1% to 7%. The tubing had seen relatively high usage with 262,630 total running feet (80,050 m). Detailed analysis of the jobs revealed that at the area of failure, the tubing had experienced 70% of its estimated fatigue life.

**Investigation.** The primary failure point was a  $\frac{1}{2}$  in. (13 mm) transverse crack where a leak occurred. Visual examination of the tubing also showed two other transverse cracks that were approximately 0.33 in. (8.4 mm) and 0.18 in. (4.6 mm) in length. Examination under a low-power microscope revealed numerous OD surface fissures, some of which were adjacent to the primary failure area. Most of these fissures or small cracks were associated with longitudinal gouges found on the tubing OD but some were located in areas showing no surface damage.

The fracture surface of the  $\frac{1}{2}$ -in. (13 mm) crack was examined on the scanning electron microscope (SEM). This showed a brittle zone near the OD, identified as a sulfide stress crack (SSC), followed by fatigue cracking (Fig. 34). Sulfide stress cracking is defined as brittle failure by cracking under the combined action of tensile stress and corrosion in the presence of water and hydrogen sulfide (H<sub>2</sub>S). The cracking mode was ascertained through comparison of this failure to known laboratory tested samples. Numerous other small cracks were also noted.

**FIG. 34 FRACTOGRAPH OF TUBING WITH A BRITTLE ZONE NEAR THE OD INDICATIVE OF SULFIDE SCC**

**Conclusion.** Mechanical property testing of the tube sample showed that it met design requirements. Hardness was measured to be 96 to 97 HRB, which is below 22 HRC. Failure occurred initially due to sulfide stress cracking on the tubing OD followed by fatigue crack propagation through to the tubing ID. Although the CT was below the 22 HRC maximum required by NACE Standard MR0175 for use in sour service, the amount of plastic working of the tubing contributed to occurrence of failure before expectations, although the CT did achieve 70% of its expected life.

**Corrective Measures.** In the presence of known corrosive environments, it was recommended that tubing should not be used above 50% of its theoretical fatigue life unless the tubing is closely evaluated. In addition, a lower strength, 70 ksi (483 MPa) yield strength grade may perform better since it should have inherently better resistance to sulfide stress cracking than the higher-strength grades.

## Fatigue Resistance and Microstructure of Ferrous Alloys

Ronald W. Landgraf, Virginia Polytechnic Institute and State University

---

### Introduction

THE BROAD RANGE OF PROPERTY COMBINATIONS available in ferrous alloy systems provides a unique opportunity to control fatigue resistance through microstructural manipulation. Considerable progress has been made in improving the understanding of microstructural effects on fatigue behavior (Ref 1, 2, 3). Such knowledge has provided the basis for a more fundamental approach to designing and processing alloys for increased fatigue performance.

The traditional approach to fatigue design with ferrous alloys, based on endurance limits and infinite life criterion, has been supplanted by approaches based on finite-life behavior that emphasize the cyclic deformation aspects of the fatigue process (Ref 4, 5). Central to these approaches for predicting structural performance in service situations is a set of properties that characterize the cyclic deformation and fracture behavior of an alloy. These properties, which are related to alloy strength, ductility, and strain-hardening characteristics, provide a useful quantitative basis for assessing and interpreting the influence of various microstructural features on material fatigue resistance.

This article will first review general trends in cyclic response for representative commercial alloys to establish the spectrum of cyclic properties attainable through microstructural alteration. Individual alloy classes are then examined in greater detail to assess the current understanding of relationships between microstructure and fatigue resistance. Finally, the role of internal defects and selective surface processing in influencing fatigue performance is discussed.

The following ferrous alloy systems are covered:

- FERRITIC-PEARLITIC STEELS
- MARTENSITIC STEELS
- MARAGING STEELS
- AUSTENITIC STAINLESS STEELS
- CAST IRON AND STEEL

Strengthening mechanisms considered include:

- GRAIN REFINEMENT
- COLD WORKING
- SOLID-SOLUTION STRENGTHENING
- PRECIPITATION STRENGTHENING
- TRANSFORMATION STRENGTHENING
- THERMOMECHANICAL PROCESSING
- SELECTIVE SERVICE PROCESSING

Fatigue resistance is evaluated in terms of:

- CYCLIC STABILITY
- RESISTANCE TO CRACK INITIATION AND PROPAGATION
- NOTCH SENSITIVITY

## Acknowledgement

## Fatigue Resistance and Microstructure of Ferrous Alloys

Ronald W. Landgraf, Virginia Polytechnic Institute and State University

---

## General Trends in Cyclic Behavior

In this section, the spectrum of properties achievable in ferrous systems is surveyed using data for representative commercial alloys. Important characterizing parameters are introduced and key behavioral responses noted.

**Cyclic Deformation Behavior.** Because material flow properties may be altered, often significantly, by reversed deformation, it is necessary to use a *cyclic* stress-strain relation in fatigue studies (Ref 4). Such curves are conveniently characterized in the form of a power-law hardening relation between strain amplitude,  $\epsilon_a$ , and stress amplitude,  $\sigma_a$ , as is often used for monotonic curves:

$$\epsilon_a = \frac{\sigma_a}{E} + \left( \frac{\sigma_a}{K'} \right)^{1/n'} \quad (\text{EQ 1})$$

where  $E$  is the elastic modulus and  $K'$  and  $n'$  are cyclic deformation properties. This formulation allows for direct comparison with monotonic tension curves so that cyclic-hardening or cyclic-softening responses can be quickly assessed. Monotonic and cyclic stress-strain curves for a series of representative steels are compared in Fig. 1. Ferritic-pearlitic steels, such as hot-rolled, low-carbon SAE 1010 and microalloyed SAE 980X, exhibit some cyclic softening at low strains followed by modest cyclic hardening at higher strains. Quenched-and-tempered martensitic steels (SAE 5132, 5160, and 52100) all show significant cyclic softening. Such behavior is typical of a broad range of low- and intermediate-hardness martensitic alloys (Ref 6). Similar softening trends are observed for the precipitation-strengthened 18% Ni maraging steel. Ausformed H-11 tool steel, on the other hand, is seen to cyclic harden above its already high monotonic value. Such high strength levels, obtained by severe hot working of austenite prior to quenching, result in the highest long-life fatigue strengths yet achieved (Ref 7, 8).

FIG. 1 MONOTONIC AND CYCLIC STRESS-STRAIN BEHAVIOR OF REPRESENTATIVE FERROUS ALLOYS

In contrast to these trends is the response of two austenitic stainless steels shown in Fig. 2. In the annealed condition, these steels exhibit pronounced cyclic hardening as a result of a deformation-induced martensitic transformation (Ref 9). Prior cold working also causes transformation hardening as evidenced by substantial increases in monotonic yield strengths. In this condition, cyclic response is reasonably stable.

FIG. 2 STRESS-STRAIN RESPONSES FOR METASTABLE AUSTENITIC STAINLESS STEELS. ANN., ANNEALED; CW, COLD WORKED

A general view of the cyclic responses for a range of ferrous systems is shown in Fig. 3 as a plot of cyclic versus monotonic yield strengths; points above the 45° line indicate cyclic-hardening alloys; those below, cyclic-softening alloys. Ferritic-pearlitic microstructures are seen to be reasonably stable. The pronounced softening of low- and intermediate hardness martensites and maraging alloys is clearly apparent. As-transformed or slightly-tempered martensites exhibit stable to hardening tendencies, as do the metastable austenitic stainless steels.

FIG. 3 CYCLIC VERSUS MONOTONIC YIELD STRENGTHS FOR VARIOUS CLASSES OF FERROUS ALLOYS

The practical significance of these responses depends on the particular application. For example, in notched members, local softening at a notch root could result in redistribution of stress, thus alleviating the stress-concentration effect. In surface-treated members, on the other hand, the effects of favorable residual stresses will be maximized by a high-strength, cyclically stable alloy.

**Fatigue-Life Behavior.** Contemporary fatigue design methods, which are based on local stress-strain concepts, use the following relationship between strain amplitude,  $\epsilon_a$ , and reversals to failure,  $2N_f$ , to quantify the fatigue resistance of a material:

$$\epsilon_a = \frac{\sigma'_f}{E}(2N_f)^b + \epsilon'_f(2N_f)^c \quad (\text{EQ 2})$$

where  $E$  is the elastic modulus, and  $\sigma'_f$ ,  $b$ ,  $\epsilon'_f$ , and  $c$  are cyclic properties related to material strength, ductility, and strain-hardening behavior. The total strain resistance is viewed as the summation of an elastic plus a plastic-strain term. The correspondence between the strain-life curve (Eq 2) and the cyclic stress-strain curve (Eq 1), obtained by plotting each curve on a common strain axis, is shown in Fig. 4. This construction allows direct determination of the steady-state stress amplitude associated with a given strain amplitude. Note that an endurance limit,  $S_f$ , can be estimated from a point on the cyclic curve where the plastic strain becomes vanishingly small--a small plastic-strain offset.

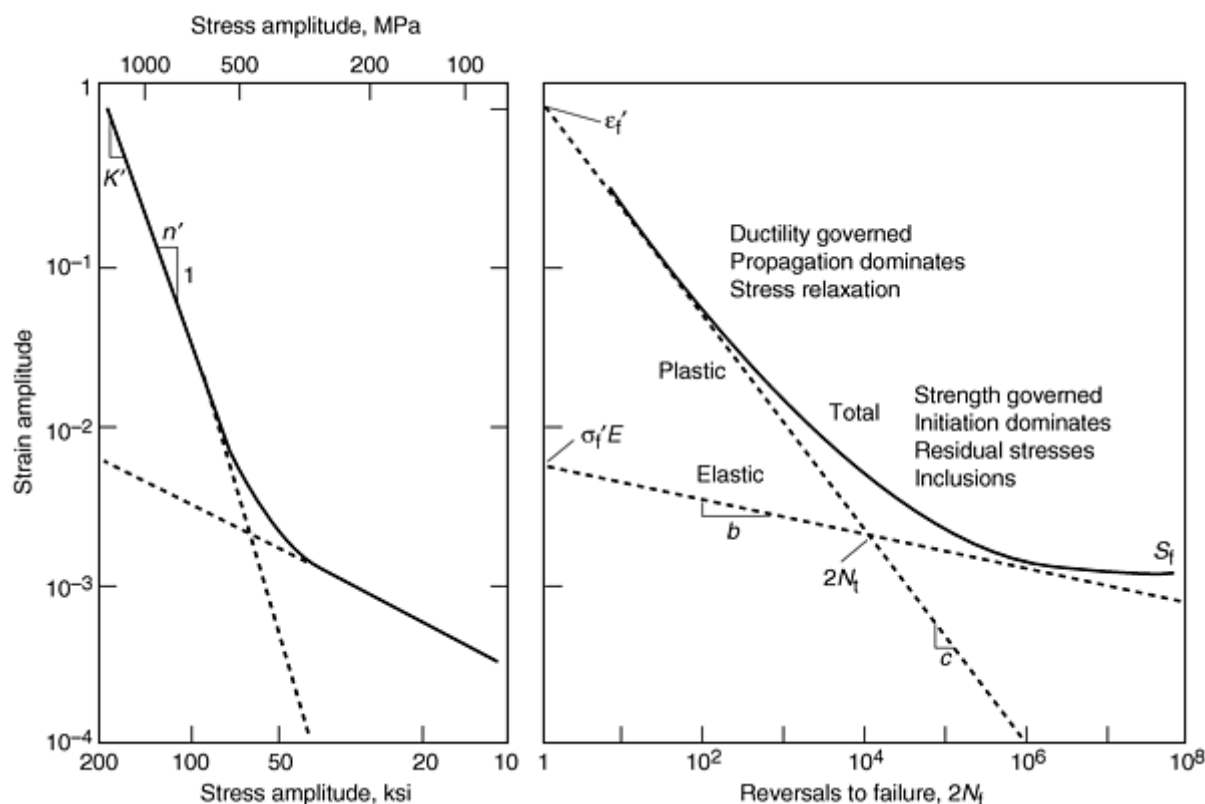

FIG. 4 REPRESENTATION OF STRESS-STRAIN AND STRAIN-LIFE BEHAVIOR

While conveying useful quantitative information, this representation also offers a conceptual scheme for identifying regimes wherein particular mechanisms and behavioral patterns are operative. These regimes are determined primarily by the relative levels of plastic and elastic strain rather than by the absolute fatigue life. At high plastic strains, for example, material ductility is the prime consideration governing fatigue resistance. Cracks are found to initiate relatively early in the life, and crack growth is a dominant failure mode. Conversely, at low plastic strains, strength governs behavior and crack initiation becomes the increasingly dominant event. It is in this regime that material defects, such as inclusions, play a major role. Also, residual-stress effects will be most important here. The transition fatigue life,  $2N_t$  (the life at which the plastic and elastic strain amplitudes are equal), provides a useful zone of demarcation between these two regimes and can be determined from material properties as follows:

$$2N_f = \left( \frac{\epsilon'_f E}{\sigma'_f} \right)^{1/(b-c)} \quad (\text{EQ 3})$$

Strain-life plots for four different steels are compared in Fig. 5; elastic, plastic, and total strain components are shown. The low-carbon SAE 1010 steel is seen to be ductility-governed over most of its life, with a transition fatigue life of about  $10^5$  reversals. The higher-strength martensitic RQC-100 steel shows improved long-life resistance and a shorter transition life. Increasing strength, first by maraging and then by ausforming, further increases long-life resistance and decreases short-life resistance, with an attendant decrease in transition life.

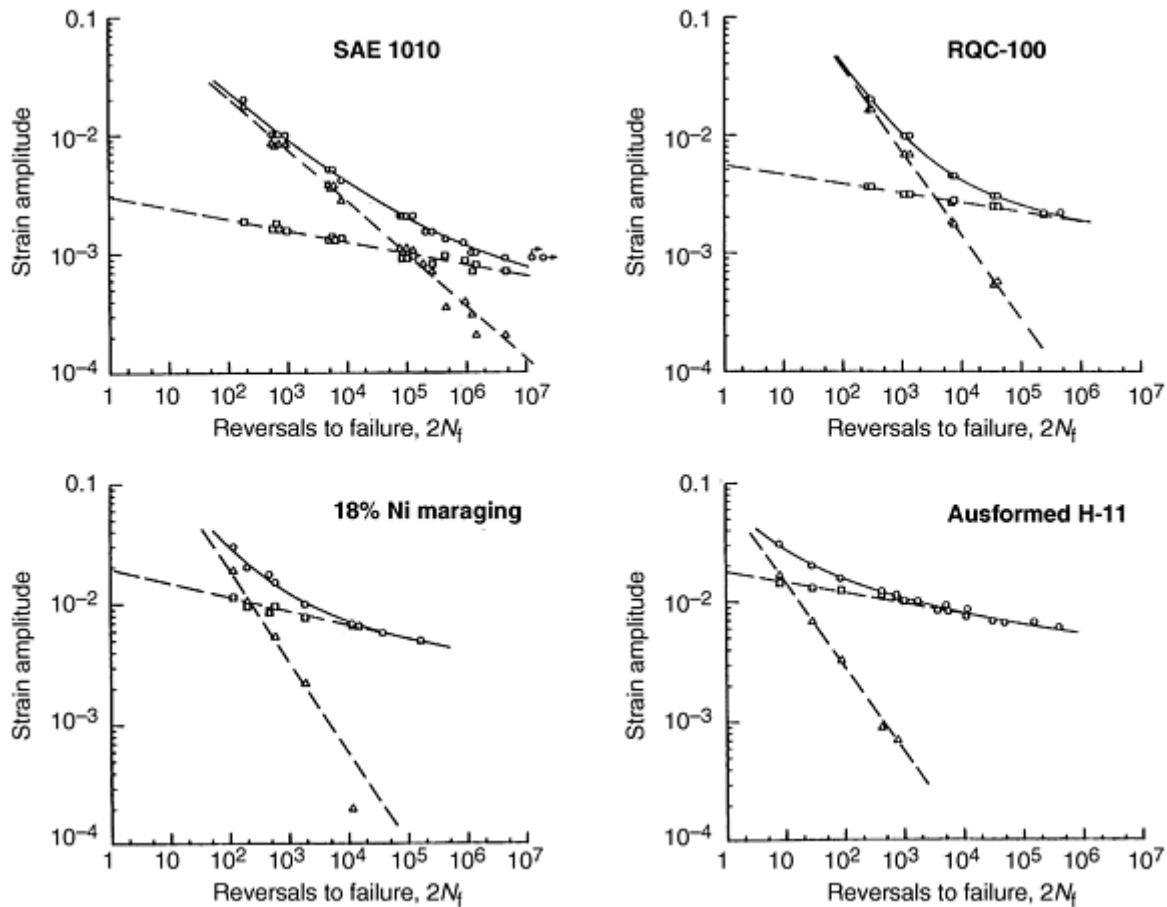

FIG. 5 STRAIN-LIFE CURVES FOR REPRESENTATIVE STEELS

Transition fatigue life as a function of hardness for a variety of ferrous alloys is shown in Fig. 6. A difference of four orders of magnitude in transition life is noted between low-strength alloys and ausformed steel. Decreasing transition life can be associated with the increase of crack-initiation resistance, a factor that accounts for the increased sensitivity of hardened steels to notches and internal defects.

FIG. 6 TRANSITION FATIGUE LIFE AS A FUNCTION OF HARDNESS FOR FERROUS ALLOYS

As further evidence of the influence of strain regime on failure mode, fatigue crack development in an SAE 1045 steel is shown in Fig. 7. Figure 7(a) illustrates behavior near the transition life. Here, slip bands formed early in the life result in multiple crack origins. Inclusions may or may not serve as initiation sites. Crack growth occurs by a linking process through previously slipped material. At a lower strain amplitude (Fig. 7b), slip markings are not observed and isolated cracks form late in life, invariably at inclusions. By way of contrast, the behavior of a low-carbon steel, at an even lower strain level and longer life, is shown in Fig. 8. This photomicrograph, obtained at about 10% of the fatigue life, shows well-developed slip bands and the beginning of microcrack linking. Thus, crack development in low-carbon steel at long lives is similar to crack development observed for hardened steel at short lives. Again, it is the plastic-strain level, rather than life regime, that determines behavior.

FIG. 7 FATIGUE CRACK DEVELOPMENT IN A HEAT-TREATED STEEL (SAE 1045, HARDNESS: 450 HB) AT HIGH (A) AND LOW (B) CYCLIC STRAINS. (A)  $\Delta\epsilon/2 = 0.011$ ,  $2N_f = 2000$ . (B)  $\Delta\epsilon/2 = 0.004$ ,  $2N_f = 53,300$

FIG. 8 FATIGUE CRACK DEVELOPMENT IN A LOW-CARBON STEEL (SAE 1010).  $\Delta\epsilon/2 = 0.002$ ,  $2N_f = 100,000$

These patterns of crack development have important implications for irregular loading histories. Occasional overstrains may initiate cracks in a material that can then propagate at lower strain levels. Dowling (Ref 10) has demonstrated this effect in an SAE 4340 steel, as shown in Fig. 9. Data are compared for tests performed with no overstrains, with initial overstrains, and with periodic overstrains. The first two test conditions result in runouts (no failure) at comparable strain levels. Specimens subjected to periodic over-strains, however, show no runouts at these strain levels; in fact, the data points fall on extrapolations of the finite-life strain curves. This behavior suggests that endurance limits will be lowered, if not eliminated, under spectrum loading conditions.

FIG. 9 INFLUENCE OF OVERSTRAINS ON THE FATIGUE LIFE OF A HEAT TREATED STEEL (SAE 4340, HARDNESS: 350 HB) (REF 10)

**Strength-Ductility Considerations.** The foregoing discussion emphasizes the important interplay between strength and ductility in determining overall fatigue resistance. The true fracture strength and ductility, as determined in a monotonic tension test, are found to be sensitive to many of the metallurgical factors that affect fatigue behavior. Consequently, they provide a useful basis for comparing material characteristics (Ref 11); trends for various alloy classes are shown in Fig. 10. The inverse nature of strength-ductility relations is apparent. The broad scatterbands observed for the conventional ferritic-pearlitic and martensitic alloys suggest that there is considerable latitude available for adjusting these properties. Also, it is seen that improvements are attainable by judicious alloying and processing (for example, maraging and ausforming).

FIG. 10 FRACTURE STRENGTH-DUCTILITY COMBINATIONS ATTAINABLE IN COMMERCIAL STEELS

These trends in strength and ductility are clearly reflected in the strain-life curves shown in Fig. 11. The higher-strength martensitic alloys are found to give superior long-life resistance, whereas the more ductile alloys are superior at short lives. At intermediate lives, because the curves cross one another, less variation is seen in fatigue resistance. The curve for ausformed H-11 steel is included to indicate the upper limit on long-life resistance currently achievable by bulk processing; the fatigue strength of ausformed steel is higher by a factor of seven than the bottom of the ferritic-pearlitic band.

FIG. 11 REPRESENTATIVE STRAIN-LIFE BEHAVIOR FOR FERRITIC-PEARLITIC AND MARTENSITIC STEELS

Representative fatigue crack growth trends are shown in Fig. 12 for ferritic-pearlitic and martensitic alloys (Ref 12) and for an ultrahigh-strength steel (Ref 13). Similarities with Fig. 11 are apparent. In the middle region, there is little variation among materials. The major differences are at the two extremes--that is, in the threshold levels at low growth rates and in fracture toughness levels (indicating unstable growth). The bands shown in Fig. 12 represent the extremes observed in commercial alloys. A point of particular significance here is that microstructures resulting in good long-life fatigue resistance will generally give lower thresholds for crack growth. Thus, it is important to distinguish between resistance to crack initiation and resistance to crack propagation.

FIG. 12 FATIGUE CRACK GROWTH BEHAVIOR FOR REPRESENTATIVE CLASSES OF STEEL (REF 12, 13)

Proceeding with the comparison of materials, Fig. 13 shows that maraging steels, with an uncommonly high combination of strength and ductility, offer high-cycle resistance approaching that of ausformed steel while maintaining excellent low-cycle resistance. The austenitic stainless steels (Fig. 14) offer a wide range of properties, depending on their relative stability to reversed plasticity.

FIG. 13 STRAIN-LIFE BEHAVIOR OF 18% NI MARAGING STEEL

FIG. 14 STRAIN-LIFE BEHAVIOR OF AUSTENITIC STAINLESS STEELS

**General Microstructural Effects.** As a final part of this section, we identify microstructural features that can alter, often significantly, the foregoing trends. These can be classified as effects caused by directionality and inhomogeneity.

**Directionality effects** are particularly apparent in ausformed steel (see Fig. 15). Because of the high level of deformation during processing, an extremely textured structure is obtained. This results in a tendency for cracks to branch and follow weaker longitudinal planes, serving as an effective crack-arrest mechanism in certain applications (Ref 14). If, however, such an alloy were subjected to transverse straining, greatly reduced fatigue performance could be anticipated. In this regard, it is noted that the yield and ultimate strengths of ausformed steel are nearly the same in longitudinal and transverse directions (Ref 15). Fracture strength and ductility, however, are significantly reduced in the transverse direction--further evidence that fracture properties are more reliable indicators of fatigue performance. In general, alloys strengthened by cold working or thermomechanical processing will exhibit direction-dependent properties that may be important in many applications.

FIG. 15 FATIGUE CRACK DEVELOPMENT IN A STRONGLY TEXTURED AUSFORMED H-11 TOOL STEEL

Inhomogeneity effects in a maraging steel are illustrated in Fig. 16. Here, low-hardness, alloy-depleted zones serve as sites for early crack initiation. These zones can appreciably reduce long-life fatigue performance. Such observations are equally relevant to decarburized steels and multiphase alloys, such as dual-phase steels in which the low-carbon ferritic zones serve as preferential crack initiation sites.

FIG. 16 FATIGUE CRACK DEVELOPMENT IN ALLOY-DEPLETED ZONES IN 18% NI MARAGING STEEL

## Fatigue Resistance and Microstructure of Ferrous Alloys

Ronald W. Landgraf, Virginia Polytechnic Institute and State University

---

### Microstructural Considerations

**Ferritic-Pearlitic Alloys.** Details of the fatigue process in iron and iron-carbon alloys are well documented in terms of the structural alterations accompanying cyclic deformation (Ref 16, 17, 18), strain-aging effects (Ref 19), and the influence of microstructure and composition on fatigue properties (Ref 20). Considerable attention has been directed toward increasing the useful strength of low-carbon steels through microalloying and thermomechanical processing (Ref 21). One can see notable progress by comparing, in Fig. 1, the stress-strain curve for SAE 980X with the conventional SAE 1010 steel. Strength has been increased by a factor of three by a combination of grain refinement and precipitation strengthening (Ref 22, 23).

These strengthening effects are examined in more detail in Fig. 17, where monotonic and cyclic yield strengths for a series of model alloys are presented in the form of a Hall-Petch plot. For carbon and carbon-manganese alloys, monotonic yield strengths are found to be much more sensitive to grain refinement than cyclic yield strengths. Large-grain alloys exhibit cyclic hardening, whereas small-grain alloys cyclically soften. This is consistent with observations in iron (Ref 18) showing that a characteristic dislocation-cell structure (that is essentially independent of prior condition) is formed during fatigue. The addition of niobium (columbium) and the resulting precipitation strengthening increase monotonic strength by about 100 MPa (15 ksi); more importantly, cyclic stability is achieved. (The softening observed for the intermediate grain size in Fig. 17 is a result of an underaged condition.)

FIG. 17 EFFECTS OF GRAIN SIZE ON YIELD STRENGTHS OF LOW-CARBON STEELS (REF 24)

Long-life fatigue data on a carbon-manganese steel (Ref 5) are presented in Fig. 18. Not surprisingly, the effect of grain refinement on the endurance limit,  $S_f$ , closely parallels trends in cyclic yield strength. This suggests that a small cyclic offset yield strength would reliably predict long-life fatigue resistance in these alloys. Also shown in Fig. 18 is the influence of grain size on the threshold-intensity range for crack growth. Grain refinement is seen to degrade crack-growth resistance somewhat.

FIG. 18 EFFECT OF GRAIN SIZE ON ENDURANCE LIMIT AND CRACK GROWTH THRESHOLD BEHAVIOR OF LOW-CARBON STEEL (REF 25)

Cyclic stress-strain curves for a series of low-alloy steels are shown in Fig. 19. Using iron as a baseline, this representation clearly shows the effects of alloying and grain refinement on cyclic deformation resistance. Strain-life curves for selected conditions, shown in Fig. 20, confirm the correlation between cyclic stress-strain and strain-life response. Grain refinement and precipitation strengthening are seen to contribute about equally to improvements in long-life fatigue resistance.

FIG. 19 EFFECT OF GRAIN SIZE AND ALLOYING ON CYCLIC STRESS-STRAIN RESPONSE

FIG. 20 STRAIN-LIFE BEHAVIOR AS INFLUENCED BY GRAIN SIZE AND ALLOYING (REF 24)

**Martensitic Alloys.** Quenched-and-tempered martensitic steels, as a class, offer the greatest latitude in tailoring properties for fatigue resistance. Monotonic strength, ductility, and fracture toughness properties for SAE 1045 steel are shown in Fig. 21 as a function of hardness. Of note are the observed optimum in strength properties and the precipitous drop in ductility at about 600 HB. This trend has been attributed to the influence of inclusions and a transition in failure

mode (Ref 26). Fracture toughness exhibits a similar drop at a lower hardness. Interestingly, ausformed steel provides an important exception to these trends.

**FIG. 21 MONOTONIC STRENGTH, DUCTILITY, AND FRACTURE TOUGHNESS AS A FUNCTION OF HARDNESS FOR A MEDIUM-CARBON STEEL (SAE 1045).  $\sigma_f$  IS TRUE FRACTURE STRENGTH,  $S_y$  IS YIELD STRENGTH**

The propensity for tempered martensites to cyclically soften is a point of practical concern. As shown by data for SAE 1045 steel in Fig. 22, maximum softening occurs at intermediate hardnesses, while cyclic stability is approached at both hardness extremes. Stability can be associated with stabilization of the heavily dislocated martensite during quenching. A minimum carbon content of 0.05 to 0.1 wt% is required to achieve stability in as-transformed iron-nickel-carbon martensites (Ref 27). From these observations, it is possible to correlate cyclic responses with carbon content and degree of tempering. The region of cyclic stability or hardening correlates well with the first stage of tempering (that is, up to tempering temperatures of about 200 °C, or 390 °F). In studies of a 4142 steel, Theilen et al. (Ref 28) have attributed such hardening to strain aging. Cyclic softening, observed at higher tempering temperatures, is associated with rearrangement of the dislocation substructure and reduction of the dislocation density. In this respect, behavior is similar to a cold-worked material. Finally, the mixed response at low hardnesses is attributed to removal of yield point at low strains followed by bulk strain hardening at higher strains.

FIG. 22 MONOTONIC AND CYCLIC YIELD STRENGTH AS A FUNCTION OF HARDNESS FOR A MEDIUM-CARBON STEEL (SAE 1045)

Strain-life curves as a function of hardness are presented in Fig. 23 to demonstrate the range of properties available by tempering. This family of intersecting curves provides clear evidence of the crucial interplay of strength and ductility in determining overall fatigue resistance. This information, used in conjunction with life-prediction models, provides a quantitative basis for optimizing material processing for specific applications.

FIG. 23 STRAIN-LIFE BEHAVIOR AS A FUNCTION OF HARDNESS (HB) FOR A MEDIUM-CARBON STEEL (SAE 1045)

**Thermomechanical Processing.** The effectiveness of ausforming in achieving notable improvements in fatigue performance is well established. The success of this process is apparently due to the formation of a well-stabilized substructure (Ref 8, 19). Other techniques involving deformation of martensite have been less effective (Ref 29). The

cyclic behavior of a quenched-and-deformed SAE 4142 steel is compared with a conventionally heat-treated alloy in Fig. 24. Although the monotonic tensile curve is elevated, the compressive curve is lowered, and identical cyclic curves are obtained for the two conditions. It is the directional nature of such strengthening that limits its effectiveness in reversed deformation situations. Deformation processing could improve resistance under unidirectional loading, however.

**FIG. 24 EFFECT OF DEFORMATION PROCESSING ON DEFORMATION RESPONSE OF A MEDIUM-CARBON STEEL (SAE 4142, HARDNESS: 450 HB)**

**Maraging.** Although the resistance of maraging steel to high-cycle fatigue is somewhat lower than might be expected (because of cyclic softening), its overall fatigue characteristics suggest that it would perform well in spectrum-loading situations. Studies of the cyclic responses in maraging steel in both the annealed and aged conditions indicate that cyclic softening of the annealed structure is associated with the formation of a dislocation-cell structure, whereas softening of the aged structure is attributed to the rearrangement of dislocation networks around precipitates (Ref 30).

**Metastable Austenitic Alloys.** Austenitic stainless steels (see Fig. 2) are of interest due to their intriguing capability of transforming to martensite when cyclically strained (Ref 31, 32, 33, 34). Results indicate that such transformations degrade low-cycle resistance; however, improvements in high-cycle and crack growth resistance have been noted. It is possible that this mechanism can be used to improve the performance of notch members through preferential transformation at stress concentrations. In this regard, it is significant that the degree of instability can be controlled through appropriate alloying.

### Fatigue Resistance and Microstructure of Ferrous Alloys

Ronald W. Landgraf, Virginia Polytechnic Institute and State University

---

### Notch Sensitivity and Internal Defects

Microstructure plays a particularly prominent role in determining the sensitivity of ferrous alloys to small geometric stress concentrations and internal defects. Mitchell has studied the behavior of cast irons and steels (Ref 35) and has developed an approach for predicting fatigue performance in internally defective materials based on consideration of matrix properties and the size, shape, and distribution of defects. A schematic of microdiscontinuities treated is shown in Fig. 25; the microdiscontinuities include various graphite morphologies in cast irons, porosity in cast steels, and nonmetallic inclusions in cast and wrought steels. This approach provides guidelines for adjusting matrix properties to best accommodate particular types of defects as well as quantitatively assessing the benefits of improving steel cleanliness.

**FIG. 25** EXAMPLES OF MICRODISCONTINUITIES THAT AFFECT FATIGUE BEHAVIOR OF FERROUS SYSTEMS (REF 35)

The sensitivity of a particular ferrous alloy to internal defects is strongly dependent on their size. When the notch size approaches the size of the microstructural unit (for example, grain size or dislocation-cell size), the material can no longer sustain the stress gradient predicted by continuum theory. Thus, small notches have less influence on behavior than do large notches. Figure 26 shows the effect of notch or defect size on fatigue notch sensitivity for steels at different hardness levels. Notch sensitivity ranges from 0 (no notch effect) to 1 (full theoretical effect). Hardened steel is sensitive to defects two orders of magnitude smaller than is a normalized steel. This explains why inclusions can severely limit the performance of high-strength steel and also why threshold stress intensities are observed to decrease at increasing strength levels. Considerable effort is expended to remove inclusions from high-carbon bearing steels (SAE 52100) for this reason. In addition, the lower-strength, ductile steels are able, through local yielding, to redistribute the high local stresses, thus ameliorating the notch effect.

**FIG. 26 EFFECT OF NOTCH SIZE ON FATIGUE NOTCH SENSITIVITY OF STEELS AS A FUNCTION OF HARDNESS (HB)**

These effects should be considered when selecting materials because the perceived benefits of a high-strength steel may be diminished due to a lower tolerance for notches and internal defects. Also, as mentioned previously, the presence of occasional high cyclic strains will often dictate the choice of a lower-strength, higher-ductility condition. High strength does not necessarily lead to high fatigue resistance. In addition, while inclusions are known to lower fatigue strength, not all inclusions are the same as to their effects. For example, oxides are more deleterious than sulfides. In addition, from a practicing engineers' perspectives, it is possible to specify the acceptable inclusion ratings as well as steel making routes including lowering the sulfur level or treating with rare earth elements to globularize the sulfides.

### Selective Surface Processing

Surface-processing treatments, such as shot peening, induction hardening, carburizing, and nitriding, are commonly used to improve the fatigue resistance of steel components subjected to bending or torsional loading. The influence of these processes on fatigue performance depends, in a complex way, on local material properties, the service loading and, importantly, on the magnitude, distribution, and stability of residual stresses (Ref 36, 37).

**Residual Stress.** The development of compressive residual stress at the surface of components can often result in dramatic improvements in fatigue performance (Ref 38). Residual stress profiles obtained by shot peening a spring steel are shown in Fig. 27. Strain peening--in which a component, such as a spring, is deformed during processing--is seen to impart higher compressive stresses and a deeper pattern of penetration than does conventional peening. For induction hardening, the residual stress pattern, associated with volume changes during transformation, depends on the depth of hardening and, in general, is related to the hardness profile as indicated in Fig. 27(b). Here the favorable surface stresses

are coupled with a higher-strength surface layer which, at long lives, offers further performance improvements. Fatigue failures in peened or induction-hardened components are often found to initiate below the surface.

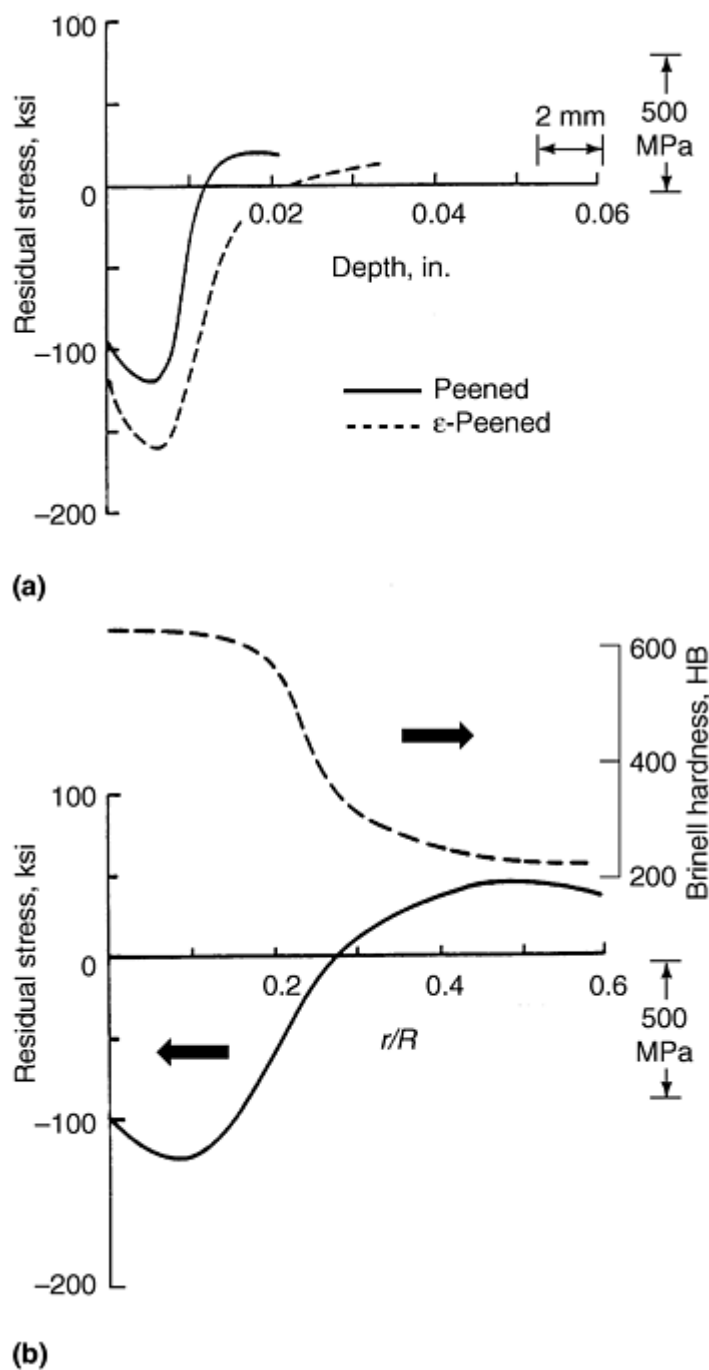

FIG. 27 TYPICAL RESIDUAL STRESS PATTERNS OBTAINED BY SHOT PEENING (A) AND INDUCTION HARDENING (B)

**Cycle-Dependent Stress Relaxation.** It is common to assess residual stress effects on fatigue by treating them as mean stresses (Ref 36). Their effectiveness will depend on their stability under service loading; cyclic-dependent stress relaxation may negate any potential benefits. The resistance of a steel to cyclic stress relaxation can be determined by subjecting axial specimens to biased strain cycling and observing the cyclic change in mean stress. Residual (mean) stress can be expected to relax whenever the applied loading results in reversed plastic straining. Because of the tendency for many steels to exhibit cycle-dependent softening, this may occur at lower stresses than would be anticipated from monotonic yield strengths.

The cyclic stress relaxation behavior of an SAE 1045 steel at three hardnesses is shown in Fig. 28. The ratio of instantaneous mean stress to the first cycle mean stress is plotted against cycles on logarithmic coordinate. The relaxation rate is characterized by the slope of this line,  $r$ , resulting in the following relation:

$$\sigma_{mN} = \sigma_{m1}(N)^R \quad (\text{EQ 4})$$

where  $\sigma_{mN}$  is the mean stress on the  $N$ th cycle, and  $\sigma_{m1}$  is the mean stress on the first cycle. The relaxation exponent,  $r$ , a function of steel hardness and applied strain amplitude, can be estimated using procedures in Ref 36.

FIG. 28 CYCLIC STRESS RELAXATION RATES AS A FUNCTION OF HARDNESS AND STRAIN LEVEL FOR SAE 1045 (REF 36)

**Fatigue Life Prediction.** In order to achieve maximum benefits from surface-processing treatments, it is necessary to consider both surface and subsurface failure modes. Using the previously established analogy between mean and residual stresses, this is conveniently accomplished using the following life relation developed by Morrow (Ref 39):

$$2N_f = \left( \frac{\sigma_a}{\sigma'_f - \sigma_m - \sigma_r} \right)^{1/b} \quad (\text{EQ 5})$$

where fatigue life in reversals,  $2N_f$ , is a function of material properties,  $\sigma'_f$  and  $b$ , stress amplitude,  $\sigma_a$ , mean stress,  $\sigma_m$ , and residual stress,  $\sigma_r$ .

In Fig. 29, the individual stress gradients resulting from processing and applied loading of an induction-hardened shaft are plotted from surface to centerline. These are then combined and plotted as a damage parameter profile as indicated. From Eq 5, the higher the magnitude of this parameter, the shorter the fatigue life. In Fig. 29, the parameter attains a maximum below the surface, thus predicting subsurface crack initiation. This is often observed in surface processes members and, in this instance, is the result of a shallow case depth and the tensile residual stress field subsurface. Life improvements are possible by deepening the case. The optimal processing would result in equal failure likelihood at the surface and subsurface.

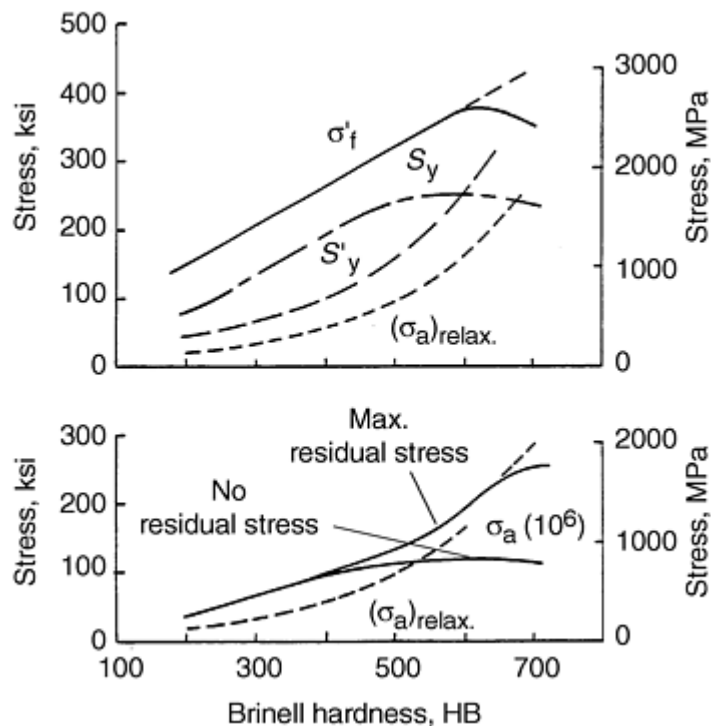

FIG. 29 STRESS AND DAMAGE PARAMETER PROFILES FOR A SURFACE-PROCESSED BENDING MEMBER (REF 36)

**Processing for Fatigue Performance.** To gain additional insight into material characteristics conducive to surface-processing response, it is informative to consider the variation of key properties with hardness. In Fig. 30, trends representative of a range of medium- to high-carbon steels are shown. Fatigue strength, as indicated by  $\sigma'_f$ , increases linearly with hardness, attains a maximum around 600 HB, and decreases slightly thereafter. The decrease is due, in part, to inclusion effects: cleaner steels show less effect. With regard to residual stresses, note that the cyclic yield strength,  $S'_y$ , falls below the monotonic value,  $S_y$ , at hardnesses below 550 HB. Such cycle-dependent softening promotes rapid residual stress relaxation.

### FIG. 30 RESIDUAL STRESS EFFECTS ON LONG-LIFE FATIGUE AS A FUNCTION OF HARDNESS (REF 36)

The stress amplitude threshold for relaxation,  $(\sigma_a)_{\text{relax}}$ , follows the trend of the cyclic yield strength. Furthermore, at hardnesses below 550 HB, stress relaxation can be expected at lives of  $10^6$  reversals or longer. The influence of compressive residual stresses on fatigue resistance at  $10^6$  is largest at the highest hardnesses and diminishes rather rapidly with decreasing hardness. Material characteristics promoting strong residual stress effects include: a monotonic yield strength to achieve a high initial residual and cyclic stability in order to avoid relaxation. These trends suggest that an improvement of approximately a factor of three in long-life fatigue strength is attainable through hardening, with another factor of two possible through residual stress effects.

Nelson et al. (Ref 40) have dramatically demonstrated the powerful effect of residual stress on fatigue. By means of a severe quenching procedure, they were able to obtain a compressive residual stress of 250 ksi (1720 MPa) at the surface of an as-transformed SAE 1045 steel specimen. This resulted in a million-cycle fatigue strength of 230 ksi (1590 MPa).

### Introduction

THE STEELS discussed in this article range from the less expensive mild steels used in bridge construction to the very expensive 18Ni maraging steels used in high-strength pressure vessels and aircraft components. Such steels may differ by more than an order of magnitude in both yield strength and alloy additions as well as in cost per unit weight. It has been clear for some time that selection of ultrahigh-strength steels for critical structures requires application of fracture mechanics principles if high degrees of reliability are to be achieved. In fact, such principles have been applied to selection of steels since the early 1960s in developing rocket motor chambers with improved performance. These concepts have been adopted by the aerospace industry and have since been incorporated into standards for determining fracture toughness of metals and for design of airframes and engine components.

For example, the U.S. Air Force has established damage tolerance requirements (MIL-A-83444) that are applied in the design, fabrication, and inspection of military aircraft. This resulted because of recurring structural failures in military aircraft, such as those caused by problems in material selection, fabrication, and heat treatment of the D6ac steel wing carrythrough structure for the F-111 aircraft. Other government agencies have included damage tolerance requirement specifications, and it is expected that this trend will continue. These concepts have already been extended to medium-strength rotor forging steels in the electric power industry and are gradually being applied to such problem areas as dynamic fracture toughness of roll bars for off-road vehicles and corrosion fatigue of line pipe steel in aggressive hydrogen sulfide environments.

Because these concepts are being applied to a broad spectrum of steels with extreme variations in strength, composition, and microstructure, this article attempts to present typical data for several classes of steels (e.g., ferrite-pearlite steels, Ni-Cr-Mo generator rotor steels, and ultrahigh-strength steels). Within the scope of this article, it is not possible to present sufficient data for the user to apply this as a design manual. Rather, an attempt is made to identify those effects of alloy composition, microstructure, and heat treatment that are most critical to the various types of fracture behavior encountered due to variations in loading, temperature, and environment. More detailed data are covered in other articles in this Volume.

This article is organized into four major sections that address fracture toughness, fatigue crack propagation, sustained-load crack propagation, and fundamental aspects of fracture in steel. Where possible, these major sections are further subdivided to illustrate the effects of variations in alloy chemistry, microstructure, temperature, strain rate (or frequency), and environment on the various fracture toughness or crack growth rate parameters. In the following sections, the metallurgy of steel is given only a summary treatment, being followed by the major mechanical property sections dealing with static fracture toughness,  $K_{Ic}$ ; dynamic fracture toughness,  $K_{ID}$ ; fatigue or sustained-load crack growth rates,  $da/dN$  or  $da/dt$ ; and fatigue or sustained-load thresholds,  $\Delta K_{th}$  or  $K_{th}$ .

Common classes of steels are austenitic (face-centered-cubic) steels, ferrite-pearlite or bainitic (body-centered-cubic) steels, and martensitic (body-centered-tetragonal) steels. The austenitic stainless steels are discussed in a separate article in this Volume. In this article, nearly all of the data deal with ferrite-pearlite steels and steels with tempered-martensite microstructures, although some of the larger components of heat-treated or slowly cooled alloys invariably contain some bainite. Particular emphasis is given to maraging-type steels and high-strength low-alloy (HSLA) steels. The HSLA steels contain niobium (columbium), vanadium, or titanium as microalloying constituents in the form of finely dispersed carbides. The high-nickel maraging steels contain a low-carbon martensite matrix with precipitates of various compositions, after age hardening.

**Typical Compositions and Alloying.** Nominal compositions of some of the steels considered in this article are given in Table 1. Table 1 does not include the compositions for the HSLA and Cr-Mo families of steel, which are large and are covered in separate articles in this Volume. However, this article does provide some comparative data on these major steel types.

With regard to strength, ferrite-pearlite steels generally achieve their strength from carbon in the form of Fe<sub>3</sub>C (pearlite content) or silicon and manganese as solid-solution strengtheners. The exceptions are the HSLA grades, which may be strengthened by niobium, vanadium, or titanium carbides. In both instances, the standard contribution of strength from the inverse square-root grain size relationship is most important. For tempered martensitic steels, carbon is the major strengthener for low tempering temperatures, whereas chromium, tungsten, molybdenum, or vanadium alloy carbides contribute to secondary hardening of alloy steels tempered in the range from 500 to 600 °C (930 to 1110 °F). General comparison of strength is shown in Table 2.

(B) IF COPPER IS SPECIFIED, THE MINIMUM IS 0.20%.

Alloying additions to low-strength ferrite-pearlite steels are minimal. However, for heavy steel sections of higher strength and for ultrahigh-strength steels, alloying additions are of primary consideration for hardenability, strength, and toughness. To expand the austenite stability range, additions of elements such as boron, carbon, chromium, nickel, manganese, molybdenum, and vanadium are most common, whereas copper, tungsten, niobium, and titanium may be added to specialty steels, and silicon and aluminum are added as deoxidants. The latter element may also be added as a grain refiner, because AlN pins grain boundaries and retards ferrite grain growth. Such alloying additions, except boron and carbon, are readily dissolved in ferrite, but some tend to form strong carbides, as originally outlined by Bain and Paxton (Ref 1).

With regard to impact energy and fracture toughness of ferritic steels, manganese or nickel is most commonly added to reduce the ductile-to-brittle transition temperature. In addition, grain refiners such as aluminum may cause net improvements in low-temperature toughness. Rare-earth additions such as cerium often are made for inclusion shape control to improve toughness at higher temperatures in the upper-shelf region. These factors are described in more detail later in this article.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Structural Steels

Before discussing the fracture mechanics properties of ferritic and quenched-and-tempered structural steels, this section briefly reviews some basic types and metallurgical aspects of strengthening mechanisms and fracture toughness for structural steels. Like most materials, toughness generally decreases with increasing yield strength, as shown in Fig. 1 and 2 for HSLA (ferritic-pearlitic) steels and quenched-and-tempered steels, respectively. Improvements in both strength and toughness can be achieved by grain refinement (Fig. 1) with heat treatment or thermomechanical processing methods such as controlled rolling. In general, quenched-and-tempered steels provide a better combination of strength and toughness when compared to as-rolled carbon or HSLA ferritic-pearlitic steels (Table 2, Fig. 3). However, quenching and tempering is a more involved process than the production of as-rolled steels, which is one reason the as-rolled HSLA steels are an attractive alternative. Compared to mild and heat-treated steels (Table 2), the as-rolled HSLA steels also have lower carbon contents, which enhance not only toughness but also weldability for structural fabrication.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Structural Steel Types

Mild (low-carbon) steels are normally considered to have carbon contents up to 0.25% C with about 0.4 to 0.7% Mn, 0.1 to 0.5% Si, and some residuals of sulfur, phosphorus, and other elements. These steels are not deliberately strengthened by alloying elements other than carbon; they contain some manganese for sulfur stabilization and silicon for deoxidation. Mild steels are mostly used in the as-rolled, forged, or annealed condition and are seldom quenched and tempered.

The largest category of mild steels is the low-carbon (<0.08% C, with 0.4% Mn) mild steels used for forming and packaging. Mild steels with higher carbon and manganese contents have also been used for structural products such as plate, sheet, bar, and structural sections. Typical examples include:

STEEL	MINIMUM YIELD STRENGTH	
	MPA	KSI
HOT-ROLLED SAE 1010 STEEL SHEET	207	30
ASTM A 283, GRADE D	228	33
ASTM A 36	250	36

Before the advent of HSLA steels, these mild steels were commonly used for the structural parts of automobiles, bridges, and buildings. In automotive applications, for example, hot-rolled SAE 1010 sheet has long been used as a structural steel. However, as lighter weight automobiles became more desirable during the energy crisis, there was a trend to reduce weight by using higher-strength steels with suitable ductility for forming operations.

The trend for structural steels used in the construction of bridges and buildings has also been away from mild steels and toward HSLA steels. For many years, ASTM A 7 (now ASTM A 283, grade D) was widely used as structural steel. In about 1960, improved steelmaking methods resulted in the introduction of ASTM A 36, with improved weldability and slightly higher yield strength. Now, however, HSLA steels often provide a superior substitute for ASTM A 36, because HSLA steels provide higher yield strengths without adverse effects on weldability. Weathering HSLA steels also provide better atmospheric corrosion resistance than carbon steel.

**Hot-Rolled Carbon-Manganese Structural Steels.** For rolled structural plate and sections, one of the earliest approaches in achieving higher strengths involved the use of higher manganese contents. Manganese is a mild solid-solution strengthener in ferrite and is the principal strengthening element when it is present in amounts over 1% in rolled low-carbon (<0.20% C) steels. Manganese can also improve toughness properties (Fig. 4b).

**FIG. 4 EFFECT OF (A) NORMALIZING AND (B) MANGANESE CONTENT ON THE CHARPY V-NOTCH IMPACT ENERGY OF NORMALIZED CARBON STEELS. (A) IMPACT ENERGY AND TRANSITION TEMPERATURE OF 1040 STEEL PIPE, DEOXIDIZED WITH ALUMINUM AND SILICON. (B) CHARPY V-NOTCH IMPACT ENERGY FOR NORMALIZED 0.30% C STEELS CONTAINING VARIOUS AMOUNTS OF MANGANESE**

Before World War II, strength in hot-rolled structural steels was achieved by the addition of carbon up to 0.4% and manganese up to 1.5%, giving yield strengths of the order of 350 to 400 MPa (50 to 58 ksi). The strengthening of these steels relies primarily on the increase in carbon content, which results in greater amounts of pearlite in the microstructure

and thus higher tensile strengths. However, the high carbon contents of these steels greatly reduce notch toughness and weldability. Moreover, the increase of pearlite contents in hot-rolled carbon and alloy steels has little effect on yield strength, which, rather than tensile strength, has increasingly become the main strength criterion in structural design.

Nevertheless, carbon-manganese steels with suitable carbon contents are used in a variety of applications. If structural plate or shapes with improved toughness are required, small amounts of aluminum are added for grain refinement. Carbon-manganese steels are also used for stampings, forgings, seamless tubes, and boiler plates.

**High-strength structural carbon steels** have yield strengths greater than 275 MPa (40 ksi) and are available in various product forms:

- COLD-ROLLED STRUCTURAL SHEET
- HOT-ROLLED CARBON-MANGANESE STEELS IN THE FORM OF SHEET, PLATE, BAR, AND STRUCTURAL SHAPES
- HEAT-TREATED (NORMALIZED OR QUENCHED-AND-TEMPERED) CARBON STEELS IN THE FORM OF PLATE, BAR, AND, OCCASIONALLY, SHEET AND STRUCTURAL SHAPES

Heat-treated carbon structural steels typically attain yield strengths of 290 to 690 MPa (42 to 100 ksi). The heat treatment of carbon steels consists of either normalizing or quenching and tempering. These heat treatments can be used to improve the mechanical properties of structural plate, bar, and, occasionally, structural shapes. Structural shapes (such as I-beams, channels, wide-flange beams, and special sections) are primarily used in the as-hot-rolled condition because warpage is difficult to prevent during heat treatment. Nevertheless, some normalized or quenched-and-tempered structural sections can be produced in a limited number of section sizes by some manufacturers.

**Normalizing** involves air cooling from austenitizing temperatures and produces essentially the same ferrite-pearlite microstructure as that of hot-rolled carbon steel, except that the heat treatment produces a finer grain size. This grain refinement makes the steel stronger, tougher, and more uniform throughout. Charpy V-notch impact energies at various temperatures are given in Fig. 4(a) for a normalized carbon steel.

**Quenching and tempering**, that is, heating to about 900 °C (1650 °F), water quenching, and tempering at temperatures of 480 to 600 °C (900 to 1100 °F) or higher, can provide a tempered martensitic or bainitic microstructure that results in better combinations of strength and toughness. An increase in the carbon content to about 0.5%, usually accompanied by an increase in manganese, allows the steels to be used in the quenched-and-tempered condition. For quenched-and-tempered carbon-manganese steels with carbon contents up to about 0.25%, low hardenability restricts the section sizes to about 150 mm (6 in.).

**Low-alloy steels** contain alloy elements, including carbon, up to a total alloy content of about 8.0%. Low-alloy steels with suitable alloy compositions have greater hardenability than structural carbon steel and thus can provide high strength and good toughness in thicker sections by heat treatment. Their alloy contents may also provide improved heat and corrosion resistance. However, as the alloy contents increase, alloy steels become more expensive and more difficult to weld. Quenched-and-tempered structural steels are primarily available in the form of plate or bar products.

**Ferritic nickel steels** (5% and 9% Ni steels) are too tough at room temperature for valid  $K_{Ic}$  data to be obtained on specimens of reasonable size, but limited  $K_{Ic}$  data have been obtained on these steels at subzero temperatures by the J-integral method. The 5% Ni steel retains relatively high fracture toughness at -162 °C (-260 °F), and the 9% Ni steel retains relatively high fracture toughness at -196 °C (-320 °F). These temperatures approximate the minimum temperatures at which these steels may be used.

**High-strength low-alloy steels** are a group of low-carbon steels that have small amounts of alloying elements and attain yield strengths greater than 275 MPa (40 ksi) in the as-rolled or normalized condition. These steels have better mechanical properties and sometimes better corrosion resistance than as-rolled carbon steels. Moreover, because the higher strength of HSLA steels can be obtained at lower carbon contents, the weldability of many HSLA steels is comparable to or better than that of mild steel.

High-strength low-alloy steels are primarily hot rolled into the usual wrought product forms (sheet, strip, bar, plate, and structural sections) and are commonly furnished in the as-hot-rolled condition. However, the production of hot-rolled

HSLA products may also involve special hot-mill processing that further improves the mechanical properties of some HSLA steels and product forms. These processing methods include:

- *THE CONTROLLED ROLLING* OF PRECIPITATION-STRENGTHENED HSLA STEELS TO OBTAIN FINE AUSTENITE GRAINS AND/OR HIGHLY DEFORMED (PANCAKED) AUSTENITE GRAINS, WHICH DURING COOLING TRANSFORM INTO FINE FERRITE GRAINS THAT GREATLY ENHANCE TOUGHNESS WHILE IMPROVING YIELD STRENGTH.
- *THE ACCELERATED COOLING* OF, PREFERABLY, CONTROLLED-ROLLED HSLA STEELS TO PRODUCE FINE FERRITE GRAINS DURING THE TRANSFORMATION OF AUSTENITE. THESE COOLING RATES CANNOT BE RAPID ENOUGH TO FORM ACICULAR FERRITE, NOR CAN THEY BE SLOW ENOUGH SO THAT HIGH COILING TEMPERATURES RESULT AND THEREBY CAUSE THE OVERAGING OF PRECIPITATES.
- *THE QUENCHING OR ACCELERATED AIR OR WATER COOLING* OF LOW-CARBON STEELS ( $< 0.08\% \text{ C}$ ) THAT POSSESS ADEQUATE HARDENABILITY TO TRANSFORM INTO LOW-CARBON BAINITE (ACICULAR FERRITE). THIS MICROSTRUCTURE OFFERS AN EXCELLENT COMBINATION OF HIGH YIELD STRENGTHS (275 TO 690 MPA, OR 60 TO 100 KSI), EXCELLENT WELDABILITY AND FORMABILITY, AND HIGH TOUGHNESS (CONTROLLED ROLLING IS NECESSARY FOR LOW DUCTILE-TO-BRITTLE TRANSITION TEMPERATURES).
- *THE NORMALIZING* OF VANADIUM-CONTAINING HSLA STEELS TO REFINE GRAIN SIZE, THEREBY IMPROVING TOUGHNESS AND YIELD STRENGTH.
- *THE INTERCRITICAL ANNEALING* OF HSLA STEELS (AND ALSO CARBON-MANGANESE STEELS WITH LOW CARBON CONTENTS) TO OBTAIN A DUAL-PHASE MICROSTRUCTURE (MARTENSITE ISLANDS DISPERSED IN A FERRITE MATRIX). THE USEFULNESS AND COST EFFECTIVENESS OF THESE PROCESSING METHODS ARE HIGHLY DEPENDENT ON PRODUCT FORM AND ALLOY CONTENT.

High-strength low-alloy steels include many standard and proprietary grades designed to provide specific desirable combinations of properties such as strength, toughness, formability, weldability, and atmospheric-corrosion resistance. These steels are not considered alloy steels, even though their desired properties are achieved by the use of small alloy additions. Instead, HSLA steels are classified as a separate steel category, which is similar to as-rolled mild-carbon steel with enhanced mechanical properties obtained by the judicious (small) addition of alloys and, perhaps, special processing techniques such as controlled rolling. This separate product recognition of HSLA steels is reflected by the fact that HSLA steels are generally priced from the base price for carbon steels, not from the base price for alloy steels. Moreover, HSLA steels are often sold on the basis of minimum mechanical properties, with the specific alloy content left to the discretion of the steel producer.

Although HSLA steels are available in numerous standard and proprietary grades, they can be divided into seven categories:

- *WEATHERING STEELS*, WHICH CONTAIN SMALL AMOUNTS OF ALLOYING ELEMENTS SUCH AS COPPER AND PHOSPHORUS FOR IMPROVED ATMOSPHERIC CORROSION RESISTANCE AND SOLID-SOLUTION STRENGTHENING
- *MICROALLOYED FERRITE-PEARLITE STEELS*, WHICH CONTAIN VERY SMALL (GENERALLY, LESS THAN 0.10%) ADDITIONS OF STRONG CARBIDE OR CARBONITRIDE-FORMING ELEMENTS SUCH AS NIOBIUM, VANADIUM, AND/OR TITANIUM FOR PRECIPITATION STRENGTHENING, GRAIN REFINEMENT, AND POSSIBLY TRANSFORMATION TEMPERATURE CONTROL
- *AS-ROLLED PEARLITIC STEELS*, WHICH MAY INCLUDE CARBON-MANGANESE STEELS BUT WHICH MAY ALSO HAVE SMALL ADDITIONS OF OTHER ALLOYING ELEMENTS TO ENHANCE STRENGTH, TOUGHNESS, FORMABILITY, AND WELDABILITY
- *ACICULAR FERRITE (LOW-CARBON BAINITE) STEELS*, WHICH ARE LOW-CARBON ( $< 0.08\% \text{ C}$ ) STEELS WITH AN EXCELLENT COMBINATION OF HIGH YIELD STRENGTHS, WELDABILITY, FORMABILITY, AND GOOD TOUGHNESS

- *DUAL-PHASE STEELS*, WHICH HAVE A MICROSTRUCTURE OF MARTENSITE DISPERSED IN A FERRITIC MATRIX AND PROVIDE A GOOD COMBINATION OF DUCTILITY AND HIGH TENSILE STRENGTH FOR SHEET FORMING
- *INCLUSION-SHAPE-CONTROLLED STEELS*, WHICH PROVIDE IMPROVED DUCTILITY AND THROUGH-THICKNESS TOUGHNESS BY SMALL ADDITIONS OF CALCIUM, ZIRCONIUM, TITANIUM, OR PERHAPS RARE-EARTH ELEMENTS SO THAT THE SHAPE OF THE SULFIDE INCLUSIONS ARE CHANGED FROM ELONGATED STRINGERS TO SMALL, DISPERSED, ALMOST SPHERICAL GLOBULES
- *HYDROGEN-INDUCED CRACKING-RESISTANT STEELS* WITH LOW CARBON, LOW SULFUR, INCLUSION SHAPE CONTROL, AND LIMITED MANGANESE SEGREGATION, PLUS COPPER CONTENTS GREATER THAN 0.26%

These seven categories are not necessarily distinct groupings, in that an HSLA steel may have characteristics from more than one grouping. For example, all the above types of steels can be inclusion shape controlled. Microalloyed ferrite-pearlite steel may also have additional alloys for corrosion resistance and solid-solution strengthening. A separate category might also be considered for the HSLA 80 (Navy) Ni-Cu-Nb steel (0.04% C, 1.5% Mn, 0.03% Nb, 1.0% Ni, 1.0% Cu, and 0.7% Cr).

**Maraging steels** comprise a special class of high-strength steels that differ from conventional steels in that they are hardened by a metallurgical reaction that does not involve carbon. Instead, these steels are strengthened by the precipitation of intermetallic compounds at temperatures of about 480 °C (900 °F). The term *maraging* is derived from martensite age hardening and denotes the age hardening of a low-carbon, iron-nickel lath martensite matrix.

Commercial maraging steels are designed to provide specific levels of yield strength from 1030 to 2420 MPa (150 to 350 ksi). Some experimental maraging steels have yield strengths as high as 3450 MPa (500 ksi). These steels typically have very high nickel, cobalt, and molybdenum contents and very low carbon contents. Carbon, in fact, is an impurity in these steels and is kept as low as commercially feasible in order to minimize the formation of titanium carbide (TiC), which can adversely affect strength, ductility, and toughness. Other varieties of maraging steel have been developed for special applications.

The absence of carbon and the use of intermetallic precipitation to achieve hardening produce several unique characteristics that set maraging steels apart from conventional steels. Hardenability is of no concern. The low-carbon martensite formed after annealing is relatively soft--about 30 to 35 HRC. During age hardening, there are only very slight dimensional changes. Therefore, fairly intricate shapes can be machined in the soft condition and then hardened with a minimum of distortion. Weldability is excellent. Fracture toughness (Fig. 2) is considerably better than that of conventional high-strength steels. This characteristic in particular has led to the use of maraging steels in many demanding applications.

---

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Fracture Modes

In steels, fractures occur by any of three basic mechanisms--cleavage, intergranular fracture, and dimpled rupture--or by a mixture of these three mechanisms. The first two generally occur below the ductile-to-brittle transition temperature, whereas dimpled rupture occurs above the transition temperature. These mechanisms are briefly described below. Additional information on fracture mechanisms is described in the article "Micromechanisms of Monotonic and Cyclic Crack Growth" in this Volume.

**Cleavage** is a transgranular fracture mode by which fracture occurs along crystallographic planes and after which the fracture surface appears as a series of flat planes. The critical event in cleavage fracture is the nucleation of a cleavage facet as it crosses crystallographic boundaries, causing formation of a new facet. One way to improve the toughness of a steel which fails by cleavage is by reduction of the microstructural unit that controls the facet size. In ferritic steels, the facet size is the ferrite grain size (Ref 2), whereas in the multiphase structures of pearlite and bainite the fracture facet size is controlled by the prior austenite grain size (Ref 3).

**Low-temperature intergranular fracture** can occur by two basic mechanisms: trace-element grain-boundary segregation, or precipitation of films or finely dispersed phases along grain boundaries. Impurity-segregation-induced intergranular fracture is most often called "temper embrittlement"; fracture generally occurs along prior-austenite grain boundaries. Fracture by this mode occurs most frequently in alloy steels containing nickel and chromium that have been tempered in the temperature range from 400 to 560 °C (750 to 1050 °F) or cooled slowly through this range.

Intergranular fracture due to grain-boundary precipitation generally results from improper processing. An example is precipitation of grain-boundary films of titanium carbonitrides in maraging steels on slow cooling through the range from 1000 to 750 °C (1830 to 1380 °F) (Ref 4). Also, in low-alloy steels, high-temperature austenitization above 1300 °C (2370 °F) results in manganese sulfide precipitation along the austenite grain boundaries. These particles then act as void nucleation sites for intergranular dimpled rupture (Ref 5). This phenomenon can also occur in overheated welds.

**Dimpled rupture** is a mode of fracture that occurs above the ductile-to-brittle transition temperature in low-strength steels and over a wide temperature range in high-strength steels. In this type of fracture, voids are nucleated at inclusions, carbides, or other dispersed phases. With increasing plastic strain these voids grow and coalesce, resulting in a fracture surface covered with cuplets of "dimples"--hence the term "dimpled rupture." This fracture mode is also known as "microvoid coalescence" or "plastic fracture."

Dimpled rupture commences by void nucleation at inclusions such as manganese sulfides. Void nucleation events have also been observed at oxides in welds and at titanium carbonitrides in maraging steels. In some materials, such as maraging steel, final fracture occurs by growth and impingement of these voids, resulting in a relatively equiaxed dimple fracture surface. In other materials, the void growth stage is interrupted by the formation of a sheet of voids at small dispersed-phase particles. This mechanism is discussed further in "Effects of Microstructure and Heat Treatment" in this section.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Embrittlement

Several forms of embrittlement in steel can occur during heat treatment or elevated-temperature service. Types of embrittlement include:

- TEMPER EMBRITTLEMENT
- TEMPERED MARTENSITE EMBRITTLEMENT
- BLUE BRITTLENESS
- QUENCH-AGE EMBRITTLEMENT
- GRAPHITIZATION
- STRAIN-AGE EMBRITTLEMENT
- ALUMINUM NITRIDE EMBRITTLEMENT

**Temper Embrittlement and Tempered Martensite Embrittlement.** In many classes of steels, two of the most important metallurgical embrittlement phenomena are temper embrittlement and tempered martensite embrittlement.

Temper embrittlement is quite common in slowly cooled heavy sections of steels tempered in the range from 400 to 560 °C (750 to 1050 °F). Here, segregation of very small amounts of tramp elements such as arsenic, phosphorus, sulfur, antimony, tin, and tellurium may cause weakening of prior-austenite grain boundaries and reductions in notch toughness. For ultrahigh-strength steels, tempered martensite embrittlement arises when tempering is done in the range from 300 to 400 °C (570 to 750 °F), usually because platelike carbides are precipitated along prior-austenite grain boundaries that have already been weakened by impurity segregation during the prior austenitizing treatment (Ref 6). These two types of embrittlement could be observed in the same steel, depending on the thermal cycle. Such a case is indicated for AISI 3340 steel in Fig. 5. Here, thermal heat treatment cycle 1 could produce tempered martensite embrittlement, whereas cycle 2 or cycle 3 could produce temper embrittlement.

**FIG. 5** HEAT TREATMENT CYCLES THAT COULD PRODUCE (1) TEMPERED MARTENSITE EMBRITTLEMENT OR (2) AND (3) TEMPER EMBRITTLEMENT IN A 3340 STEEL. A, AUSTENITE; F, FERRITE; C, CEMENTITE

**Blue Brittleness.** Carbon steels generally exhibit an increase in strength and a reduction of ductility and toughness at temperatures around 300 °C (570 °F). Because such temperatures produce a bluish temper color on the surface of the specimen, this problem has been called blue brittleness. It is generally believed that blue brittleness is an accelerated form of strain-age embrittlement. Deformation in the blue-heat range followed by testing at room temperature produces an increase in strength that is greater than when the deformation is performed at ambient temperature. Blue brittleness can be eliminated if elements that tie up nitrogen are added to the steel (e.g., aluminum or titanium).

**Quench-Age Embrittlement.** If a carbon steel is heated to a temperature slightly below its lower critical temperature and then quenched, it will become harder and stronger but less ductile. This problem has been called quench aging or quench-age embrittlement. The degree of embrittlement is a function of time at the aging temperature. Aging at room temperature requires several weeks to reach maximum embrittlement. Lowering the quenching temperature reduces the degree of embrittlement. Quenching from temperatures below about 560 °C (1040 °F) does not produce quench-age embrittlement. Carbon steels with a carbon content of 0.04 to 0.12% appear to be most susceptible to this problem. Quench aging is caused by the precipitation of carbide and/or nitride from solid solution.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Temper Embrittlement of Steels

Temper embrittlement is a major cause of degradation of toughness of ferritic steels. Numerous components otherwise in sound condition become candidates for retirement if they are severely embrittled. The problem is encountered as a result of exposure of a steel in the temperature range 345 to 540 °C (650 to 1000 °F). Tempering, postweld heat treatments, or service exposure in this range must be avoided. The problem may be avoided by heat treating above this range, followed by rapid cooling. Unfortunately, in the case of massive components such as rotors, no rate of cooling is fast enough and some residual embrittlement may be inevitable. Subsequent to heat treatment, exposure of the component during service in the critical range can also lead to embrittlement.

Many steel components in a plant invariably are exposed to the critical temperature range during service and hence embrittlement cannot be avoided. Some examples are boiler headers, steam pipes, turbine casings, pressure vessels, blades, rotors, and combustion turbine disks. In the case of components that are subject to embrittlement, such as HP/IP rotors and pressure vessels, restrictions are imposed on the startup and shutdown procedures. To avoid the risk of brittle failure during these transients, loading is avoided until a certain temperature has been reached. For instance, rotors are prewarmed up to a certain temperature before loading. Similarly, pressure vessels may sometimes need to be depressurized during shutdown prior to reaching a certain temperature. These requirements result in additional operational and maintenance costs and loss of production. Temper embrittlement phenomena thus adversely affect the longevity, reliability, cycling ability, efficiency, and operating costs of high-temperature equipment. An excellent review of this phenomenon and its characteristics has been published by McMahan (Ref 7).

It is well established at this time that segregation of tramp elements (antimony, phosphorus, tin, and arsenic) to prior-austenite grain boundaries in steel is the principal cause of temper embrittlement. Until the advent of the Auger electron spectroscope in the mid-1960s, no conclusive evidence of such segregation could be obtained. In decreasing order of effect, temper embrittlement is caused by impurity contents of antimony, phosphorus, tin, and arsenic. Antimony is generally not present in large quantities in commercial steels and is therefore neglected from consideration. Arsenic is not a potent embrittler and hence is not very important. Phosphorus and tin are, therefore, the major residual elements of concern.

Among the alloying elements, manganese, silicon, nickel, and chromium are known to exacerbate the effects of impurities. When these elements are present in combination, the effect is further increased. It is well known that nickel and chromium in combination increase embrittlement significantly more than either element alone. For this reason, Ni-Cr-Mo-V steel rotors are considered to be much more susceptible to embrittlement than Cr-Mo-V steel rotors, as shown in Fig. 6 (Ref 8).

FIG. 6 EFFECT OF PHOSPHORUS CONTENT ON THE TEMPER EMBRITTLEMENT ( $\Delta FATT$ ) OF THREE STEP-COOLED FORGING STEELS, SOURCE: REF 8

For a given class of steels, manganese and silicon have the major influence (Fig. 7). The data show considerable synergism among manganese, silicon, phosphorus, and tin. The maximum embrittlement is observed when all these elements are present together. Because sulfur levels formerly could not be minimized, the presence of manganese was always necessary for sulfur control. Silicon was generally added for deoxidation.

FIG. 7 EFFECTS OF MANGANESE, SILICON, PHOSPHORUS, AND TIN ON THE KINETICS OF TEMPER EMBRITTLEMENT AT 480 °C (895 °F) FOR A  $2\frac{1}{4}$  CR-1MO STEEL. SOURCE: REF 9, 10

In modern practice, silicon can be eliminated by replacing it as a deoxidant by alternate deoxidation processes such as vacuum carbon deoxidation. Manganese levels can be reduced commensurate with lower sulfur levels. Control of phosphorus and tin to much lower levels can be achieved by careful selection of scrap iron and better steelmaking practices.

A combination of all these improvements has brought the temper-embrittlement problem under greater control in recent years. Various compositional factors for prediction of temper-embrittlement susceptibilities have evolved over the years (Ref 11, 12, 13). The effects of various alloying elements and their potential roles in temper embrittlement are summarized in Table 3.

**TABLE 3 ROLE OF COMPOSITION IN TEMPER EMBRITTLEMENT OF STEELS**

PHOSPHORUS	CR-MO-BASE STEELS (E.G., $2\frac{1}{4}$ CR-1MO; CR-MO-V)
MAJOR EFFECTS OF ALLOYING ELEMENTS	
NICKEL	RAISES INHERENT RESISTANCE OF STEEL TO BRITTLE FRACTURE; PROMOTES SEGREGATION OF TIN AND SILICON (AND ANTIMONY, IF PRESENT)
CHROMIUM	IMPARTS HARDENABILITY; IMPARTS SOME RESISTANCE TO SOFTENING AT ELEVATED TEMPERATURES; PROMOTES SEGREGATION OF PHOSPHORUS
MANGANESE	IMPARTS HARDENABILITY; SCAVENGES SULFUR; PROMOTES SEGREGATION OF PHOSPHORUS
SILICON	DEOXIDIZES; PROMOTES SEGREGATION OF PHOSPHORUS
MOLYBDENUM	IMPARTS (BAINITIC) HARDENABILITY; IMPARTS RESISTANCE TO SOFTENING; SCAVENGES PHOSPHORUS AND TIN
VANADIUM	IMPARTS RESISTANCE TO SOFTENING; AIDS IN GRAIN REFINEMENT
NIONIUM	IMPARTS RESISTANCE TO SOFTENING; SCAVENGES PHOSPHORUS; AIDS IN GRAIN REFINEMENT

Source: Ref 14

**Effects of Microstructural Factors.** In heavy-section components such as turbine rotors, casings, and steam chests, inhomogeneities in chemical composition as well as thermal gradients during heat treatment often result in nonuniformities in the microstructure. Hence, the risk of temper embrittlement can vary with location in the component. There have been few systematic studies of these effects. Another important variable affecting susceptibility to temper embrittlement is grain size. Unfortunately, it is difficult to isolate grain size effects, because variations in grain size often result in other microstructural changes due to the effect of grain size on hardenability.

**Failure Analysis of Temper-Embrittled Components.** Identification of temper embrittlement as a failure mechanism in a failed component is relatively easy. The presence of large amounts of phosphorus, tin, manganese, and silicon in the steel is an indication that temper embrittlement may be involved. Fractography generally indicates an intergranular fracture with little evidence of ductile dimples on the fracture surface. The extent of the intergranular fracture present is a function of the temperature at which the fracture is produced and the microstructure. It has been observed that a plot of intergranular fracture (%) versus Charpy test temperature for embrittled Cr-Mo-V steels resembles a bell-shape curve with the maximum intergranular fracture being observed at 50% of the fracture-appearance transition temperature (Ref 15). For a given degree of embrittlement, more intergranular fracture is observed in martensitic structures than in bainitic structures (Ref 15).

**Time-Temperature Relationships for Temper Embrittlement.** Temper embrittlement obeys a C-curve behavior in time-temperature plots. At high temperatures, the kinetics of impurity diffusion to grain boundaries are rapid, but the tendency to segregate is low because the matrix solubility for the element increases with temperature. Hence,

embrittlement occurs rapidly but to a small degree. At low temperatures, the tendency to segregate is high, but the diffusion kinetics are not rapid enough to reach maximum embrittlement. The optimum combination of thermodynamic and kinetic factors favoring embrittlement occurs at some intermediate temperature, called the "knee" of the C-curve. For commercial steels of interest, the knee occurs in the temperature range from 455 to 510 °C (850 to 950 °F) but can be shifted up or down depending on the composition, grain size, and microstructure of the steel.

Instability of the microstructure complicates the picture further. With increasing exposure, the carbide structures and compositions evolve into more stable configurations with concomitant changes in the ferrite matrix. It is therefore difficult to represent temper embrittlement kinetics in terms of rate processes with unique activation energies. Attempts to predict long-time behavior based on short-term evaluations have met with little success. For practical purposes, however, it is not uncommon to assume parabolic kinetics, under isothermal conditions.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Fracture Toughness

The concepts of fracture mechanics are concerned with the basic methods for predicting the load-carrying capabilities of structures and components that contain cracks. The fracture mechanics approach is based on a mathematical description of the characteristic stress field that surrounds any crack in a loaded body. When the region of plastic deformation around a crack is small compared to the size of the crack (as is often true for large structures and high-strength materials), the magnitude of the stress field around the crack is commonly expressed as the stress-intensity factor,  $K$ , such that:

$$K = \sigma \sqrt{(a)Y} \quad (\text{EQ 1A})$$

where  $\sigma$  is remotely applied stress,  $a$  is characteristic flaw size dimension, and  $Y$  is a geometry factor determined from linear elastic stress analysis. The stress-intensity factor,  $K$ , thus represents a single parameter that includes both the effect of the stress applied to a sample and the effect of a crack of a given size in a sample. For example, in mode I loading (i.e., tensile loading perpendicular to the plane of the crack), the stress-intensity factor,  $K_I$ , for a crack tip in any body is given by the relationship:

$$K_I = \sigma \sqrt{p a} F(G) \quad (\text{EQ 1B})$$

where  $a$  is crack length and  $f(g)$  is a function that accounts for crack geometry and structural configuration. This general relationship makes it possible to translate laboratory results into practical design information without the need for extensive service experience or correlations. Other relations between the stress-intensity factor and various body configurations; crack sizes, shapes and orientations; and loading conditions are available in the published literature. In this way, linear elastic analysis of small-scale yielding can be used to define a unique factor,  $K$ , that is proportional to the local crack-tip stress field outside the small crack-tip plastic zone.

An underlying principle of fracture mechanics is that unstable fracture occurs when the stress-intensity factor at the crack tip reaches a critical value,  $K_c$ . The fracture toughness,  $K_c$ , varies with the degree of localized constraint to plastic flow along the tip of the fatigue crack. Thus, cracks in very thick members are subjected to higher constraints than cracks in thinner members. The maximum constraint, as defined in ASTM E399, occurs under plane-strain conditions and results in the lowest value of fracture toughness,  $K_{Ic}$  (Fig. 8). Under identical test conditions, the  $K_c$  values for thinner plates are usually higher than those observed under plane-strain conditions (i.e.,  $K_c > K_{Ic}$ ).

FIG. 8 CRITICAL FRACTURE STRESS VS. SECTION SIZE OF 4340 STEEL TEMPERED AT 400 °C (750 °F) TO A YIELD STRENGTH OF 1470 MPA (213 KSI). SOURCE: REF 16

By knowing the critical value of  $K_I$  at failure ( $K_c$ ,  $K_{Ic}$ , or  $K_{Iid}$ ) for a given material of a particular thickness and at a specific temperature and loading rate, the designer can determine flaw sizes that can be tolerated in structural members for a given design stress level. Conversely, the designer can determine the design stress level that can be safely used for an existing crack that may be present in a structure.

In general, fracture-toughness property varies with constraint such that:

- $K_C$  = CRITICAL STRESS-INTENSITY FACTOR FOR STATIC LOADING AND PLANE-STRESS CONDITIONS OF VARIABLE CONSTRAINT (I.E., THIS VALUE DEPENDS ON SPECIMEN THICKNESS AND GEOMETRY, AS WELL AS ON CRACK SIZE)
- $K_{IC}$  = CRITICAL STRESS-INTENSITY FACTOR FOR STATIC LOADING AND PLANE-STRAIN CONDITIONS OF MAXIMUM CONSTRAINT
- $K_{ID}$  = CRITICAL STRESS-INTENSITY FACTOR FOR DYNAMIC (IMPACT) LOADING AND PLANE-STRAIN CONDITIONS OF MAXIMUM CONSTRAINT
- $K_C, K_{IC},$  OR  $K_{ID} = C\sigma\sqrt{a}$

where  $C$  is a constant that is a function of specimen and crack geometry,  $\sigma$  is nominal stress in ksi, and  $a$  is flaw size. Each of these values ( $K_C$ ,  $K_{IC}$ , and  $K_{ID}$ ) is also a function of temperature, particularly for those structural materials exhibiting a transition from brittle to ductile behavior.

The parameter  $K_{IC}$  is a true material property in the same sense as is the yield strength of a material. The value of  $K_{IC}$  determined for a given material is unaffected by specimen dimensions or type of loading, provided that the specimen dimensions are large enough relative to the plastic zone to ensure plane-strain conditions around the crack tip (strain is zero in the through-thickness or  $z$ -direction). Tests on precracked specimens of a wide variety of materials have shown that the critical  $K$  value at the onset of crack extension approaches a constant value as specimen thickness increases, as shown in Fig. 8 for 4340 steel. In general, when the specimen thickness and the inplane dimensions near the crack are large enough relative to the size of the plastic zone, then the  $K$ -value for the onset of crack growth approaches a constant, minimum value,  $K_{IC}$ , of the material. The thickness,  $B$ , required to ensure valid plane-strain behavior is given by:

$$B \geq 2.5 \left( \frac{K_{IC}}{\sigma_{ys}} \right)^2 \quad \text{(EQ 2)}$$

Typical room-temperature toughness of various structural steels is summarized in Table 4.

Traditionally, however, the notch toughness of low- and intermediate-strength steels is described in terms of Charpy V-notch (CVN) test results. The CVN impact specimen is the most widely used specimen for material development, specifications, and quality control. The relationship between  $K_{Ic}$  and CVN impact toughness has been developed empirically by Barsom and Rolfe (Ref 17) for steel with room-temperature yield strengths higher than about 760 MPa (110 ksi). The correlation is shown in Fig. 9 and is given by the equation:

$$\left(\frac{K_{Ic}}{\sigma_{ys}}\right)^2 = \frac{5}{\sigma_{ys}} \left( CVN - \frac{\sigma_{ys}}{20} \right) \quad (\text{EQ 3})$$

where  $K_{Ic}$  is in  $\text{ksi} \cdot \text{in.}^{\frac{1}{2}}$ ;  $\sigma_{ys}$  is in ksi; and CVN is energy absorption, in  $\text{ft} \cdot \text{lb}$ , for a Charpy V-notch impact specimen tested in the upper-shelf (100% shear fracture) region.

### Fracture Mechanics Properties of Carbon and Alloy Steels

#### Effect of Steel Composition and Condition

Among the metallurgical variables that affect toughness, the significant ones are yield strength, microstructure, grain size, content of inclusions, and impurities. Generally, an increase in yield strength results in a decrease in  $K_{IC}$ . Among the various transformation products, tempered martensite exhibits the highest toughness, followed by bainite, followed by ferrite-pearlite structures.

It is important to note that for a given alloy chemistry or microstructural condition, the fracture toughness measured is highly reproducible for tests at different laboratories and for tests with different specimens, as shown for 4340 in Table 4 (Ref 18). The general effects of alloy chemistry and microstructural condition are described below. The next section describes important test variables such as temperature and strain rate.

**Effect of Nickel on Toughness.** As indicated for maraging steels, nickel improves toughness, even though it can be very difficult to separate the effects of chemistry on fracture toughness from the effects of other variables (e.g., hardenability). In one series of experiments in which strength was held constant (Ref 19, 20), an increase in nickel content of about 5% increased fracture toughness by about 50% in the transition temperature range, for a steel with a yield strength of 1175 MPa (170 ksi) at room temperature (Fig. 10). On the other hand, for lower-strength steels with yield strengths ranging from 500 to 700 MPa (73 to 102 ksi) at -100 °C (-150 °F), addition of 3.5% Ni increased fracture toughness by more than 100% (Ref 21), as illustrated in Fig. 11. It should be noted that moderate additions of nickel mainly improve low-temperature fracture toughness through resistance to cleavage, and that little effect may be seen at higher temperatures at which microvoid coalescence is the fracture mode. Such is the case in Fig. 10 at temperatures in the upper-shelf region.

**FIG. 10 EFFECT OF NICKEL CONTENT ON FRACTURE TOUGHNESS OF HIGH-STRENGTH STEELS CONTAINING (IN WT%) 0.35 C, 0.65 MN, 0.35 SI, 0.80 CR, 0.30 MO, 0.10 V, AND VARIOUS AMOUNTS OF NICKEL; ALL STEELS HARDENED TO A YIELD STRENGTH OF 1175 MPA (170 KSI). SOURCE: REF 19, 20**

FIG. 11 EFFECT OF NICKEL CONTENT ON FRACTURE TOUGHNESS OF LOWER-STRENGTH STEELS WITH YIELD STRENGTHS RANGING FROM 500-700 MPA (73-102 KSI) AT -100 °C (-150 °F). SOURCE: REF 21

**Effect of Carbon on Ductile-to-Brittle Transition Temperature.** It is well known that decreasing the carbon content decreases the transition temperature in ferrite-pearlite steels (*ASM Handbook*, Vol 1). This trend is less prevalent in ultrahigh-strength steels if strength is maintained at a constant level by tempering. The effect of carbon content on the fracture toughness transition curves for alloy steels containing 0.28, 0.35, and 0.41% C, with strength maintained at 1175 MPa (170 ksi), is illustrated in Fig. 12. There is little effect in the transition temperature range; however, there is a substantial effect in the upper-shelf region, where microvoid coalescence is the fracture mode.

**FIG. 12 EFFECT OF CARBON CONTENT AND TESTING TEMPERATURE ON FRACTURE TOUGHNESS OF ALLOY STEELS. DATA ARE FOR STEELS CONTAINING (IN WT%) 0.65 MN, 0.35 SI, 0.80 CR, 3.00 NI, 0.30 MO, 0.10 V, AND VARIOUS AMOUNTS OF CARBON; ALL STEELS WERE HARDENED AND TEMPERED TO A YIELD STRENGTH OF APPROXIMATELY 1175 MPA (170 KSI). SOURCE: REF 19, 20**

**Nonmetallic inclusions** (single inclusions or clusters of inclusions) reduce fracture toughness, particularly at high strength levels. The effect of sulfide inclusion content (which is a function of sulfur content) on fracture toughness of 4345 steel is shown in Fig. 13 (Ref 22). Because of this effect, special melting and processing requirements are often specified when alloy steels are selected for certain critical applications, such as aircraft landing gear. Vacuum arc remelting, vacuum induction remelting, and electroslag remelting are three of the special processes that normally produce cleaner steels than more common steelmaking processes.

FIG. 13 EFFECT OF SULFUR CONTENT ON FRACTURE TOUGHNESS OF 4345 STEEL HARDENED AND TEMPERED TO VARIOUS STRENGTH LEVELS. SOURCE: REF 22

Not only does sulfur affect ultrahigh-strength steels, but it may also affect grades of low to medium strengths (Ref 23). This is largely a microvoid nucleation mechanism, and if the sulfide inclusion length is plotted versus crack-tip opening displacement, an inverse relationship is revealed (Fig. 14). The critical crack-tip opening displacement,  $\delta_c$ , is a measure of fracture toughness. Under plain-strain conditions, an approximate relation between  $\delta_c$  and  $K_{Ic}$  is:

$$\delta_c \cong \frac{K_{Ic}^2}{2\sigma_{ys}E} \quad (\text{EQ 4})$$

where  $\sigma_{ys}$  is yield strength and  $E$  is Young's modulus. Thus, one means of improving toughness is to reduce the projected inclusion length by controlling the shape of the inclusions (Ref 23). This can be achieved by adding rare earths, which combine with MnS to form hard-to-deform particles comprised of sulfides, oxides, and/or oxysulfides.

**FIG. 14 RELATIONSHIP BETWEEN PROJECTED INCLUSION LENGTH PER UNIT AREA AND CRACK-TIP OPENING DISPLACEMENT TO FRACTURE IN SULFUR-BEARING STEELS**

**Sulfide inclusion shape control** performs several important roles in HSLA steels. It improves transverse impact energy, and it can minimize lamellar tearing in welded structures by improving through-thickness properties that are critical in constrained weldments. The main objective of inclusion shape control is to produce sulfide inclusions with negligible plasticity at even the highest rolling temperatures. Sulfide inclusions, which are plastic at rolling temperatures and thus elongate and flatten during rolling, adversely affect ductility in the short transverse (through-thickness) direction.

The preferred method for sulfide shape control involves calcium-silicon ladle additions. However, sulfide shape control is also performed with small additions of rare-earth elements, zirconium, or titanium that change the shape of the sulfide inclusions from elongated stringers to small, dispersed, almost spherical globules. This change in the shape of sulfide inclusions substantially increases transverse impact energy and improves formability. Inclusion shape control was introduced with the advent of hot-rolled sheet and light plate having a yield strength of 550 MPa (80 ksi) in the as-rolled condition. This technology has also been extended to include grades with lower yield strengths ranging from 310 to 550 MPa (45 to 80 ksi). The improved formability of these grades is recognized in ASTM A 715.

Inclusion shape control with rare-earth elements is seldom used because rare-earth elements produce relatively dirty steel. Nonetheless, representative improvements in transverse toughness with rare-earth additions are shown in Fig. 15 and 16 (Ref 24, 25). With regard to shape control, Luyckx et al. (Ref 26) demonstrated that when there was a complete change from elongated to globular sulfides, at a cerium-to-sulfur ratio of two, the upper-shelf impact energy became a maximum. This is seen in Fig. 17. As might be expected, there was little effect of rare-earth metal additions on longitudinal properties, because the shape of sulfides is not particularly detrimental to longitudinal fracture toughness in steels of low to medium strength.

FIG. 15 EFFECT OF RARE-EARTH ADDITIONS ON IMPACT PROPERTIES OF AL-SI KILLED X65 PIPELINE STEEL.

**Chemistry Effects on Temper Embrittlement.** As previously mentioned, chemistry also has important influence on temper embrittlement. The use of Auger electron spectroscopy has shown that steels that fail by this mode have severe segregation of trace elements such as antimony, arsenic, tin, and phosphorus along prior-austenite grain boundaries, even though the bulk concentration is in the parts per million range. This segregation exists for only a few atom layers. In Fig. 18, the results of an investigation (Ref 27) on 3340 steel indicate that the transition temperature shift was proportional to the grain boundary concentration of the embrittling trace impurity.

FIG. 18 CHANGE IN DUCTILE-TO-BRITTLE TRANSITION TEMPERATURE AS A FUNCTION OF GRAIN BOUNDARY IMPURITY CONCENTRATION. DATA OBTAINED ON 3340 STEEL DOPED INDIVIDUALLY WITH 0.06% P, 0.06% SN, OR 0.06% SB. A/O, ATOMIC PERCENT. 285 DPH = 890 MPA (129 KSI) ULTIMATE STRENGTH. SOURCE: REF 27

Temper embrittlement is a complex phenomenon, because it is dependent not only on the trace elements present but also on the major alloying additions, such as nickel and chromium. For example, in steels containing the same amounts of trace impurities, Ni-Cr alloys are more susceptible than those having either nickel or chromium separately (Fig. 6 and Ref 28). In either case, the degree of embrittlement can be reduced by lowering the trace element content of the steel. To avoid temper embrittlement, steels with low trace element concentrations and proper ratios of major alloying additions should be used. It is also advisable to avoid service in the embrittling temperature range. A small austenite grain size also inhibits temper embrittlement. It should be noted that this behavior is reversible, that is, it can be eliminated by heating above the temper embrittlement range provided that the material is not subsequently maintained at temperatures in the embrittlement range for extended periods of time.

**Comparison of Modern HSLA Steels with Older Structural Steels.** As previously described, several advances in steelmaking technology have allowed the development of tough, low-carbon HSLA steels for high-strength structural applications. As a general comparison of HSLA steel improvements with older structural steels, Fig. 19 compares impact toughness curves of old and new steels using transverse subsurface specimens. Steel A is a 60 mm ( $2\frac{3}{8}$  in.) carbon-manganese steel that was used in 1975. It has a carbon level of 0.21%. Steel B is a modern 70 mm ( $2\frac{3}{4}$  in.) thick normalized carbon-manganese steel with a carbon level of 0.114% and some microalloying (0.29% Ni, 0.025% Nb, and 0.022% Cu). Steel C is a modern 50 mm (2 in.) thick controlled-rolled and accelerated-cooled thermomechanically controlled processing steel with a carbon level of 0.11% and some microalloying (0.23% Ni, 0.03% Nb, and 0.24% Cu). The yield strengths of steels A, B, and C are 355, 369, and 506 MPa (51, 54, and 73 ksi), respectively. Figure 19 shows the improved fracture toughness of modern steels as indicated by a decrease in the transition temperature and an increase in the upper-shelf energy.

**FIG. 19** CHARPY V-NOTCH IMPACT ENERGY WITH NIL-DUCTILITY TRANSITION TEMPERATURE FOR THREE STEELS: A, 60 MM ( $2\frac{3}{8}$  IN.) THICK OLD CARBON-MANGANESE STEEL (0.21% C) WITH A YIELD STRENGTH OF 355 MPa (51 KSI); B, 70 MM ( $2\frac{3}{4}$  IN.) THICK MODERN CARBON-MANGANESE STEEL (0.114C-0.29NI-0.025NB-0.022CU) WITH A YIELD STRENGTH OF 369 MPa (54 KSI); AND C, 50 MM (2 IN.) THICK THERMOMECHANICALLY CONTROLLED PROCESSING STEEL (0.11C-0.23NI-0.03NB-0.24CU) WITH A YIELD STRENGTH OF 506 MPa (73 KSI)

**Quenched-and-Tempered Steels.** Typical microstructural changes on heat treatment of high-strength steels are accomplished by changing the austenitizing temperature and time at temperature, the quenching rate, and the tempering temperature and time at temperature. Increasing the austenitizing temperature and time has a two-fold effect in that it increases the grain size and/or increases the solutionizing of alloy carbide formers. The former effect may produce mixed results in that austenitizing at 1200 °C (2200 °F) may increase the sharp-crack fracture toughness of an AISI 4340 steel over that obtained using conventional heat treatments; however, the large prior-austenite grains may produce a lower

impact toughness (Ref 29). As discussed in the next section, increased prior-austenite grain size in high-strength steel may also have a detrimental effect on resistance to fatigue cracking. On the other hand, it is well known that reasonable austenitizing temperatures and times are necessary to dissolve the carbide-forming elements prior to quenching.

Variations in quenching rates also influence fracture toughness of alloy steels by causing variations in the as-quenched microstructures. Quenching alloy steels in oil to obtain nearly 100% martensite on quenching will result in higher fracture toughness in the tempered condition than slack quenching and tempering at the same temperature. This condition is discussed by Peterman and Jones (Ref 30) for heat-treated aircraft structures of D6ac steel. Briefly, austenitizing at 900 °C (1650 °F), quenching in salt at 200 °C (400 °F), and tempering at 200 °C resulted in an average fracture toughness of 57 MPa $\sqrt{m}$  (52 ksi $\sqrt{in}$ ), whereas austenitizing at 925 °C (1700 °F), quenching in oil at 60 °C (140 °F), and tempering at 200 °C (400 °F) resulted in an average fracture toughness of 101 MPa $\sqrt{m}$  (92 ksi $\sqrt{in}$ ).

The effects of tempering ultrahigh-strength steels at temperatures in the upper portion of the tempering range are to increase fracture toughness and to reduce yield strength (Fig. 2). In the intermediate tempering temperature regime between 200 and 400 °C (400 and 750 °F), these effects are not always apparent. This is shown in Fig. 20, where fracture toughness at 25 °C (75 °F) is relatively independent of tempering temperature for three different nickel additions (Ref 20). For tests at -73 °C (-100 °F), however, severe tempered martensite embrittlement is partly reduced by addition of 3% Ni and is completely suppressed by addition of 6% Ni (Fig. 21). The effect of carbon level on the degree of tempered martensite embrittlement in a 3% Ni ultrahigh-strength steel is illustrated in Fig. 22. For low-temperature service, it is clear that tempering of such steels in the range from 250 to 350 °C (480 to 660 °F) is to be avoided.

FIG. 20 VARIATION OF ROOM-TEMPERATURE NOTCH-BEND FRACTURE TOUGHNESS WITH TEMPERING TEMPERATURE FOR STEEL CONTAINING (IN WT%) 0.35 C, 0.65 MN, 0.35 SI, 0.80 CR, 0.30 MO, 0.10 V, AND VARIOUS AMOUNTS OF NICKEL. SOURCE: REF 20

**Grain Refinement of Low-Carbon and HSLA Steels.** For lower-strength steels, useful microstructural modifications to improve low-temperature fracture toughness involve decreasing the ferrite or prior austenite grain size. Results from two investigations presented in Fig. 23 show that, for temperatures above  $-150\text{ }^{\circ}\text{C}$  ( $-240\text{ }^{\circ}\text{F}$ ), a substantial improvement in fracture toughness can be achieved through grain refinement (Ref 20, 31, 32). Here, it is indicated that there may be a relationship between  $K_{Ic}$  and grain size,  $d$ . This is shown for both ferrite grain size and prior austenite grain size in Fig. 24 and 25, respectively (Ref 33, 34). Such data have been analyzed by Stonesifer and Armstrong (Ref 34) in terms of a critical plastic zone at the crack tip, with the grain size dependence of  $K_{Ic}$  arising from effects of grain size on yield strength. More simply, it can be said that the plastic constraint in the triaxially stressed zone at the crack tip raises the yield stress to the cleavage fracture stress,  $\sigma_f$ . This has been used by others (Ref 35) and is essentially the Orowan criterion given by:

$$PCF \cdot \sigma_{YS} = \sigma_F \quad (\text{EQ 5})$$

where  $\sigma_{ys}$  is the uniaxial yield stress at the temperature and strain rate of interest and pcf is the plastic constraint factor. The simplest empirical determination of pcf imposed by a plane-strain crack was originally proposed by Hahn and Rosenfield (Ref 36) to be:

$$PCF = 1 + \alpha \{K_{IC} / \sigma_{YS}\} \quad (EQ 6)$$

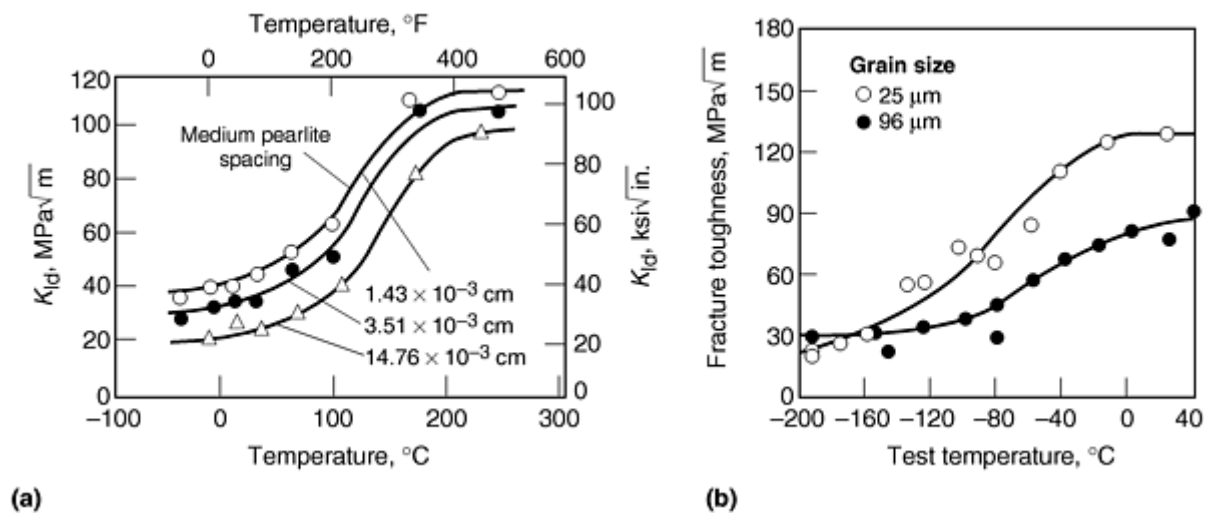

FIG. 23 EFFECT OF GRAIN SIZE ON FRACTURE TOUGHNESS. (A) DYNAMIC FRACTURE TOUGHNESS ( $K_{ID}$ ) CURVES FOR FULLY PEARLITIC STEELS AS A FUNCTION OF TEMPERATURE FOR THREE PRIOR-AUSTENITE GRAIN SIZES. FIG. 25 RELATIONSHIP OF FRACTURE TOUGHNESS TO INVERSE SQUARE ROOT OF GRAIN SIZE. DEPENDENCE OF FRACTURE TOUGHNESS ON PRIOR-AUSTENITE GRAIN SIZE AT FOUR DIFFERENT TEMPERATURES. SOURCE: REF 34

For strain hardening in mild steels, it may be assumed that the value of  $\alpha$  is approximately  $20\sqrt{m}$ , because this would give pcf on the order of 2.5 to 3.0, values that are predicted from elastic-plastic analysis (Ref 37). Relationships for yield and fracture stress dependence on grain size have been independently determined by Curry and Knott (Ref 33) and by Rosenfield et al. (Ref 38) to be, for mild steel:

$$\sigma_{YS}(-120\text{ }^{\circ}\text{C}) = 210\text{ MPA} + (0.73\text{ MPA}\sqrt{m})D^{-\frac{1}{2}} \quad (\text{EQ 7A})$$

and

$$\sigma_F = 343\text{ MPA} + (3.3\text{ MPA}\sqrt{m})D^{-\frac{1}{2}} \quad (\text{EQ 7B})$$

By combining Eq 5, 6, 7a, and 7b, the following equation describing the effect of grain size on  $K_{Ic}$  is obtained:

$$K_{Ic}(\text{AT } -120\text{ }^{\circ}\text{C}) \cong 6.6\text{ MPA}\sqrt{m} + 0.13\text{ MPA} \cdot M(D^{-\frac{1}{2}}) \quad (\text{EQ 8})$$

It can be seen that this equation fits the data in Fig. 24, and gives a good rationalization for the  $1/\sqrt{d}$  dependence of fracture toughness. Such a relationship can also be approximated for A533B steel at room temperature, because Knott (Ref 39) has estimated that  $\sigma_f \cong 2600\text{ MPA}$  for an A533B steel with a  $15\text{ }\mu\text{m}$  grain size. This, along with Stonesifer and Armstrong's determination of the relationship between yield strength and grain size (Ref 34), gives for A533B steel:

$$\sigma_{YS}(\text{AT } 25\text{ }^{\circ}\text{C}) = 572\text{ MPA} + (0.11\text{ MPA}\sqrt{m})D^{-\frac{1}{2}} \quad (\text{EQ 9A})$$

and

$$\sigma_F = 1750\text{ MPA} + (3.3\text{ MPA}\sqrt{m})D^{-\frac{1}{2}} \quad (\text{EQ 9B})$$

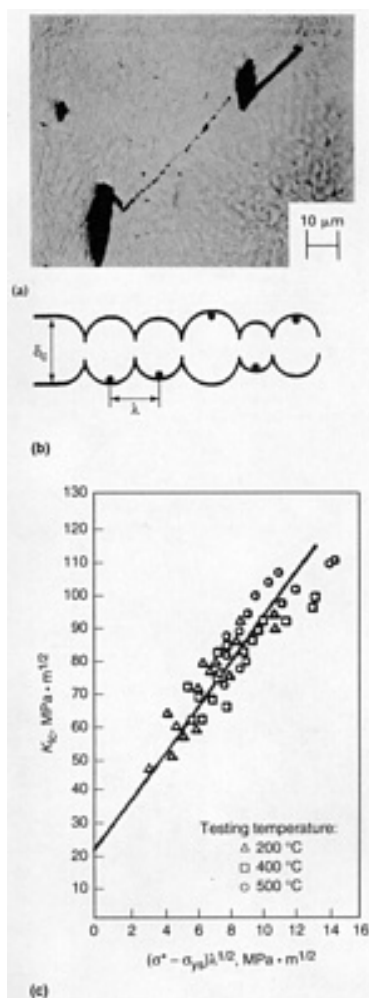

Following the above procedure, this leads to:

$$K_{IC}(AT\ 25\ ^\circ C) \approx 58.8\ \text{MPa}\sqrt{m} + 0.16\ \text{MPa} \cdot M(D^{-\frac{1}{2}}) \quad (\text{EQ } 10)$$

and gives a curve nearly identical to the line drawn through the room-temperature data in Fig. 25 for A533B steel.

It is clear, then, that one goal for improved low-temperature fracture toughness in steels of low to medium strength is a refined grain size such as has been achieved in HSLA steels. The development of fine grain size in these steels through the use of minor alloying additions and lower hot rolling finishing temperatures has resulted in large improvements in fracture toughness (Ref 40).

**Inclusions and Void Nucleation.** Reduced ductility and toughness due to particle nucleation of microvoids is most often observed in high-strength steels. Figure 26(a) shows a metallographic section of a specimen of AISI 4340 steel strained just short of fracture, exhibiting a "void sheet" between large voids that nucleated at lower strains at manganese sulfides. In this case, the smaller voids nucleated at the cementite particles that formed during tempering. Void sheet formation results in duplex dimple size distributions. This process aborts further void growth and tends to reduce fracture toughness. Cox and Low (Ref 41) concluded that void sheet formation is easier in materials with larger-size strengthening precipitates. This is supported by the absence of void sheets in maraging steel having a yield strength of 1380 MPa (200 ksi) and containing precipitates a few hundred angstroms in length and by the presence of void sheets in 4340 steel containing cementite particles 0.17  $\mu\text{m}$  in length. Cox and Low also suggest that this is why maraging steels are tougher than quenched-and-tempered steels of similar strength levels (Fig. 2).

**FIG. 26 EFFECT OF PARTICLES ON FRACTURE TOUGHNESS. (A) VOID SHEETS LINKING THREE INCLUSIONS IN A SECTIONED TENSILE SAMPLE OF 4340 STEEL. (B) SCHEMATIC RELATIONSHIP BETWEEN CRACK TIP**

The key event in dimpled rupture is the void nucleation event, which can be delayed to larger plastic strains by reductions in inclusion size (Ref 41). Toughness can also be improved by increasing the spacing between inclusions so that voids must grow to larger sizes during the fracture process. Reductions in impurities that occur as inclusions reduce the inclusion volume fraction and increase the inclusion spacing, thereby improving  $K_{IC}$ .

The effect of particles has been treated at great length in the literature (Ref 42), but one of the simplest quantitative relationships that has been derived is that of fracture toughness as a function of inclusion spacing. Schwalbe (Ref 42) suggests that the critical crack-tip opening displacement,  $\delta_c$ , should be proportional to the distance between inclusions,  $\lambda$ , as shown schematically in Fig. 25(b). According to Eq 4, this would result in  $K_{IC}$  being proportional to the square root of  $\lambda$ . Such a semiempirical relationship has been found by Priest (Ref 43) for a 0.45C-Ni-Cr-Mo-V steel similar to 4340 steel but with somewhat higher chromium, molybdenum, and vanadium contents. This relationship is given by:

$$K_{IC} = 23 \text{ MPA} \sqrt{m} + 7(\sigma^* - \sigma_{YS})(\lambda)^{\frac{1}{2}} \quad (\text{EQ 11})$$

with  $\sigma^*$  equal to 2000 MPa (290 ksi). In Fig. 26(c), this relationship, shown by the dashed curve, is seen to fit the data for a large variation in  $\lambda$  and for three different test temperatures where dimpled rupture is the microstructural fracture mode. Such observations demonstrate the advantage of providing inclusion-controlled steels for high fracture toughness performance.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Temperature and Strain-Rate Effects

A proper use of fracture-mechanics methodology for fracture control of structures necessitates the determination of fracture toughness for the material at the temperature and loading rate representative of the intended application. The fracture toughness of structural steels can vary significantly with temperature and loading rates, particularly if loading and/or temperature causes a transition from ductile to brittle fracture modes. These general effects on fracture modes and fracture toughness are summarized in Fig. 27 for static and high-strain-rate (impact) loading. This well-known transition from ductile to brittle fracture depends on several parameters. Most structural steels can fail in either a ductile or brittle

manner depending on conditions such as temperature, loading rate, and constraint (e.g., section size). Strength and the composition of the material also affect toughness and the transition rate from ductile to brittle fracture. Thus, the effects of testing temperature and loading rate on fracture toughness vary from one grade of steel to another.

**FIG. 27 FRACTURE-TOUGHNESS TRANSITION BEHAVIOR OF STEEL UNDER STATIC AND IMPACT LOADING. THE STATIC FRACTURE-TOUGHNESS TRANSITION CURVE DEPICTS THE MODE OF CRACK INITIATION AT THE CRACK TIP. THE DYNAMIC FRACTURE-TOUGHNESS TRANSITION CURVE DEPICTS THE MODE OF CRACK PROPAGATION.**

The effects of temperature and load rates can be measured with a variety of specimens, such as CVN impact specimens, the dynamic tear specimen, a plane-strain fracture toughness specimen under static loading ( $K_{Ic}$ ), or a plane-strain specimen under dynamic loading ( $K_{Id}$ ). Traditionally, the fracture toughness and ductile-to-brittle transition behavior of structural steels is based on CVN specimen testing (ASTM test standards A23 and A370). CVN specimens are tested at different temperatures, and the impact notch toughness at each test temperature is determined from the energy absorbed during fracture, the percent shear (fibrous) fracture on the fracture surface, or the change in the width of the specimen (lateral expansion). An example of the ductile-to-brittle transition with temperature for each of these parameters is presented in Fig. 28. The actual values for each parameter and the locations of the curves along the temperature axis are usually different for different steels and even for a given steel composition. Because the change from ductile to brittle behavior occurs over a range of temperatures, it has been customary to define a single temperature within the transition range that reflects the behavior of the steel under consideration. Several equally useful definitions are in use, including the 15 ft · lb temperature, the 15 mil temperature, and the 50% shear temperature.

**FIG. 28** CHARACTERISTICS OF THE TRANSITION-TEMPERATURE RANGE FOR CHARPY V-NOTCH TESTING OF LOW-CARBON STEEL PLATE, AS DETERMINED BY (A) FRACTURE ENERGY, (B) FRACTURE APPEARANCE, AND (C) FRACTURE DUCTILITY. THE DRAWINGS AT LOWER RIGHT IN THE GRAPHS INDICATE: (A) ORIENTATION OF THE SPECIMEN NOTCH WITH PLATE THICKNESS,  $t$ , AND DIRECTION OF ROLLING; (B) LOCATION OF THE TOTAL SHEAR AREA ON THE FRACTURE SURFACE; AND (C) LOCATION OF THE EXPANSION MEASUREMENT IN THIS SERIES OF TESTS--ALL ILLUSTRATED FOR A CHARPY V-NOTCH SPECIMEN. PERCENTAGE OF SHEAR FRACTURE AND LATERAL EXPANSION WERE BASED ON THE ORIGINAL DIMENSIONS OF THE SPECIMEN.

Similar transitions can be observed in plane-strain fracture toughness for structural steel plate (Fig. 29) and several rotor steels (Fig. 30). The rate of increase of  $K_{Ic}$  with temperature does not remain constant, but rather increases markedly above a given test temperature. This transition in plane-strain fracture toughness is related to a change in the microscopic mode of crack initiation at the crack tip from cleavage to increasing amounts of ductile tearing.

FIG. 29 EFFECT OF TEMPERATURE AND STRAIN RATE ON PLANE-STRAIN FRACTURE-TOUGHNESS BEHAVIOR OF ASTM TYPE A36 STEEL. SOURCE: REF 44

FIG. 30 EFFECT OF TEMPERATURE ON FRACTURE TOUGHNESS OF THREE ALLOY STEELS. SOURCE: REF 45

Fractures modes and toughness under various conditions of temperature and load rates can be understood by considering toughness-transition behavior under static and impact loading (Fig. 27). The static fracture toughness transition curve depicts the mode of crack initiation at the crack tip. The dynamic fracture toughness transition curve depicts the mode of crack propagation.

The fracture toughness curve for either static or dynamic loading can be divided into three regions as shown in Fig. 27. In region I<sub>s</sub> for the static curve, the crack initiates in a cleavage mode from the tip of the fatigue crack. In region II<sub>s</sub>, the fracture toughness to initiate unstable crack propagation increases with increasing temperature. This increase in crack initiation toughness corresponds to an increase in the size of the plastic zone and in the zone of ductile tearing (shear) at the tip of the crack prior to unstable crack extension. In this region, the ductile-tearing zone is usually very small and is difficult to delineate by visual examination. In region III<sub>s</sub>, the static fracture toughness is quite large and somewhat difficult to define, but the fracture initiates by ductile tearing (shear).

Once a crack has initiated under a static load, the morphology (cleavage or shear) of the fracture surface for the propagating crack is determined by the dynamic behavior and degree of plane strain at the temperature. Regions I<sub>d</sub>, II<sub>d</sub>, and III<sub>d</sub> in Fig. 27 correspond to cleavage, increasing ductile tearing (shear), and full-shear crack propagation, respectively. Thus, at temperature A, the crack initiates and propagates in cleavage. At temperatures B and C, the crack exhibits ductile initiation but propagates in cleavage. The only difference between the behaviors at temperatures B and C is that the ductile-tearing zone for crack initiation is larger at temperature C than at temperature B. At temperature D, cracks initiate and propagate in full shear. Consequently, full-shear fracture initiation and propagation occur only at temperatures for which the static and dynamic (impact) fracture behaviors are on the upper shelf.

**Strain Rate Effects.** The effect of loading rate is obviously important because of its effect on not only toughness but also the transition temperature (Fig. 27, 29). Strain rate effects are even more important in low- and medium-strength steels such as A36 (Fig. 29), which are strain-rate sensitive. An analysis of plane-strain fracture-toughness data for constructional steels (Ref 44) shows that the fracture toughness transition curve is translated (shifted) to higher temperature values as the rate of loading is increased. Thus, at a given temperature, fracture toughness values measured at high loading rates are generally lower than those measured at lower loading rates. Also, the fracture toughness values for constructional steels decrease with decreasing test temperatures to a minimum  $K_{Ic}$  value of about  $27 \text{ MPa} \sqrt{m}$  ( $25 \text{ ksi} \sqrt{in}$ ). This minimum fracture toughness value is independent of the rate of loading used to obtain the fracture toughness transition curve.

The magnitude of shifts in transition temperatures from strain-rate effects depends on yield strength and has been the subject of several studies (Ref 44, 46, 47, 48). From the work of Barsom (Ref 44), data for steels having yield strengths between 250 and 1725 MPa (36 and 250 ksi), such as those presented in Fig. 31, show that the shift between static and impact plane-strain fracture-toughness curves is given by the relationship:

$$T_{\text{SHIFT}} \text{ (IN } ^\circ\text{F)} = 215 - 1.5\sigma_{\text{YS}} \text{ (IN KSI)} \quad \text{(EQ 12A)}$$

or

$$T_{\text{SHIFT}} \text{ (IN } ^\circ\text{C)} = 119 - 0.12\sigma_{\text{YS}} \text{ (IN MPA)} \quad \text{(EQ 12B)}$$

for steels with yield strengths between 195 and 895 MPa (28 and 130 ksi) where  $\sigma_{\text{ys}}$  is the room-temperature yield strength. There is no transition shift from loading rates for steels with yield strengths greater than about 960 MPa (139 ksi).

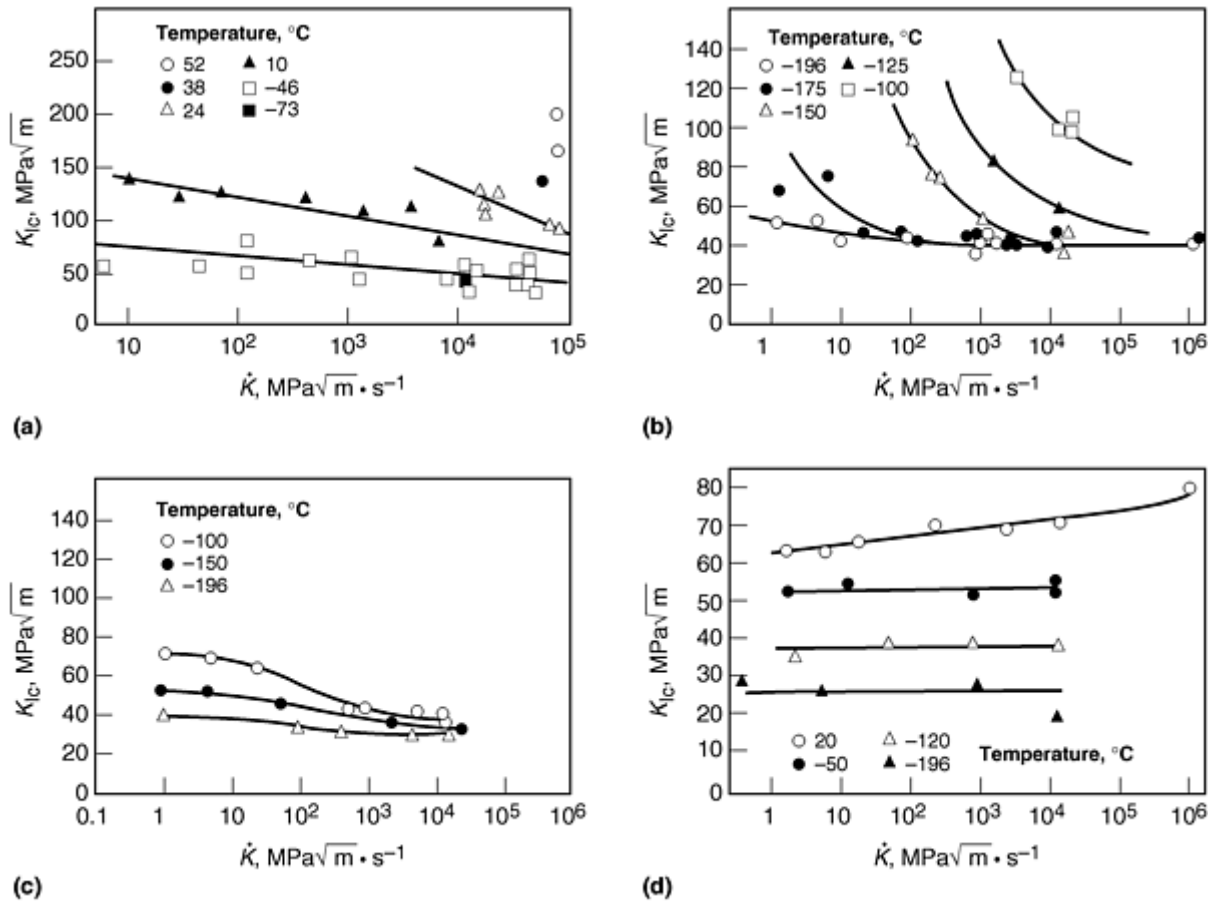

**FIG. 31 EFFECT OF YIELD STRENGTH ON THE SHIFT IN TRANSITION TEMPERATURE BETWEEN IMPACT AND STATIC PLANE-STRAIN FRACTURE-TOUGHNESS CURVES. SOURCE: REF 44**

Similar results have also been verified by Priest (Ref 121) in a large number of tests of low- to medium-strength steels, some of which are illustrated in Fig. 32. Here, up to six test temperatures and six orders of magnitude of loading rate (in  $K$ ,  $\text{MPa} \sqrt{m} \cdot \text{s}^{-1}$ ) were used to determine fracture toughness. It can be seen that there are substantial shifts for low-

strength steels. However, for the steel with a yield strength of 970 MPa (140 ksi) in Fig. 32(d), although there is a change in fracture toughness with test temperature, there is no shift with loading rate.

**FIG. 32 INFLUENCE OF TEMPERATURE AND LOADING RATE ON FRACTURE TOUGHNESS. (A) A533B STEEL;  $\sigma_{ys} \approx 450$  MPa (65 KSI). (B) QT35 STEEL;  $\sigma_{ys} \approx 600$  MPa (87 KSI). (C) NI-CR-MO-V ROTOR FORGING STEEL;  $\sigma_{ys} \approx 670$  MPa (97 KSI). (D) 0.4C-9NI-4CO STEEL;  $\sigma_{ys} \approx 970$  MPa (140 KSI). (YIELD STRENGTHS REPORTED ARE AT ROOM TEMPERATURE.) SOURCE: REF 21**

The combined effect of yield strength and strain rate for steels with yield strengths less than 965 MPa (139 ksi) is given by the following relations for strain rates ( $\dot{\epsilon}$ , in  $s^{-1}$ ) between  $10^{-3} s^{-1}$  and  $10^{-1} s^{-1}$ :

$$T_{SHIFT} \text{ (IN } ^\circ\text{F)} = (150 - \sigma_{YS})\dot{\epsilon}^{0.17} \quad \text{(EQ 13A)}$$

where  $\sigma_{ys}$  is room-temperature yield strength in ksi, or where

$$T_{SHIFT} \text{ (IN } ^\circ\text{C)} = (83 - 0.08\sigma_{YS})\dot{\epsilon}^{0.17} \quad \text{(EQ 13B)}$$

with  $\sigma_{ys}$  in MPa. These relations provide the difference between static and any intermediate or impact plane-strain toughness curves. The strain rate is calculated for a point on the elastic-plastic boundary according to the equation:

$$\dot{\epsilon} = \frac{2\sigma_{ys}}{tE} \quad \text{(EQ 14)}$$

where  $t$  is the loading time for the test and  $E$  is the elastic modulus.

**Dynamic plane-strain fracture toughness ( $K_{I,d}$ )** can be estimated from CVN toughness or the upper-shelf static toughness ( $K_{I,c}$ ). In the upper shelf, the effects of loading rate and notch acuity are not as critical as in the transition region. The effect of loading rate is to elevate the yield strength by about 170 MPa (25 ksi). Thus, Eq 3 may be used to calculate  $K_{I,d}$  values by replacing  $\sigma_{ys}$  with the dynamic yield strength,  $\sigma_{yd}$ , where  $\sigma_{yd} \approx \sigma_{ys} + 25$  ksi. This use of Eq 3 to calculate  $K_{I,d}$  is consistent with the observation that, in the upper-shelf region, the dynamic fracture toughness of steels is higher than the static fracture toughness.

In the transition region, a correlation between CVN toughness and impact fracture toughness ( $K_{I,d}$ ) is given by the equation (Ref 17, 44):

$$\frac{(K_{I,d})^2}{E} = 5(\text{CVN}) \quad (\text{EQ 15})$$

where  $K_{I,d}$  is in  $\text{ksi} \sqrt{\text{in}}$ ,  $E$  is in ksi, and CVN toughness is in  $\text{ft} \cdot \text{lb}$ . The validity of this correlation is apparent from the data presented in Fig. 33 for various grades of steel ranging in yield strength from about 36 to about 140 ksi and in Fig. 34 for eight heats of SA 533B, class 1 steel. Consequently, a given value of CVN impact energy absorption corresponds to a given  $K_{I,d}$  value (Eq 15), which in turn corresponds to a given toughness behavior at lower rates of loading.

**FIG. 33 CORRELATION OF PLANE-STRAIN IMPACT FRACTURE TOUGHNESS AND IMPACT CHARPY V-NOTCH ENERGY ABSORPTION FOR VARIOUS GRADES OF STEEL**

**FIG. 34 CORRELATION OF PLANE-STRAIN IMPACT FRACTURE TOUGHNESS AND IMPACT CHARPY V-NOTCH ENERGY ABSORPTION FOR SA 533B, CLASS 1 STEEL**

The behavior for rates of loading less than impact are established by shifting the  $K_{Ia}$  value to lower temperatures by using Eq 12a and 12b or 13a and 13b. Conversely, for a desired behavior at the minimum operating temperature and maximum in-service rate of loading, the corresponding behavior under impact loading can be established by using Eq 12a and 12b or 13a and 13b, and the equivalent CVN impact value can be established by using Eq 15.

**Scatter of Toughness Data in Ductile-to-Brittle Transition Regime.** Fracture toughness testing of ferrous materials in the ductile-to-brittle transition region is complicated by an extreme amount of scatter in toughness data. Data for pressure vessel steels, for example, typically covers half an order of magnitude (Fig. 35). Some of the scatter is, of course, attributable to experimental errors and specimen-to-specimen differences. Scatter is also caused by the occurrence of different fracture mechanisms (cleavage, tearing, or ductile tearing followed by cleavage) in the transition region. Some experimental work has investigated the use of dynamic fracture to promote cleavage initiation and suppress prior ductile tearing (Ref 49).

FIG. 35 TYPICAL FRACTURE TOUGHNESS SCATTER IN THE DUCTILE-BRITTLE TRANSITION REGION FOR A CARBON STEEL FORGING. PRESSURE VESSEL STEEL (ASTM A508 C12) WITH TEST MATERIAL WAS TAKEN FROM A FORGED HOLLOW CYLINDER NORMALIZED AT 893 °C (1640 °F) FOR 13 H AND AIR COOLED, THEN AUSTENITIZED AT 857 °C (1575 °F) FOR 8.75 H AND WATER QUENCHED. TEMPERING WAS DONE AT 523 °C (973 °F) FOR 9.5 H, FOLLOWED BY A POSTWELD HEAT TREATMENT AT 561 °C (1041 °F) FOR 12 H. THE YIELD STRENGTH AT ROOM TEMPERATURE IS 620 MPa (90 KSI) AND THE ULTIMATE STRENGTH IS 779 MPa (113 KSI). SOURCE: REF 49

**Fracture Mechanics of Steel Fatigue**

Although a considerable amount of life data are available for many steels and other structural materials, the existence of surface irregularities and cracklike imperfections can have a profound effect on the prevention of fatigue failure. As such, fracture mechanics offers a useful method for understanding not only fatigue crack propagation but also the factors that may eliminate or reduce the crack initiation portion of fatigue. Therefore, this section briefly reviews notch effects on crack initiation prior to the more traditional focus of fracture mechanics on fatigue crack propagation.

---

**Fracture Mechanics Properties of Carbon and Alloy Steels****Notch Effects on Crack Initiation**

Initiation of fatigue cracks in structural and equipment components occurs in regions of stress concentrations, such as notches, as a result of stress fluctuation. The material element at the tip of a notch in a cyclically loaded component is subjected to the maximum stress range,  $\Delta\sigma_{\max}$ . Consequently, this material element is most susceptible to fatigue damage and is, in general, the origin of fatigue crack initiation. It can be shown that for sharp notches, the maximum-stress range on this element can be related to the stress-intensity-factor range,  $\Delta K_I$  (Eq 16), as follows (Ref 17):

$$\Delta\sigma_{\max} = \frac{2}{\sqrt{\pi}} \frac{\Delta K_I}{\sqrt{\rho}} = \Delta\sigma(k_t) \quad (\text{EQ 16})$$

where  $\rho$  is the notch-tip radius,  $\Delta\sigma$  is the range of applied nominal stress, and  $k_t$  is the stress-concentration factor.

Fatigue crack initiation behavior of various steels is presented in Fig. 36 for specimens subjected to zero-to-tension bending stress and containing a smooth notch that resulted in a stress-concentration factor of about 2.5. The data show that  $\Delta K_I/\sqrt{\rho}$ , and therefore  $\Delta\sigma_{\max}$ , is the primary parameter that governs fatigue crack initiation behavior in regions of stress concentration for a given steel tested in a benign environment. The data also indicate the existence of a fatigue crack initiation threshold,  $(\Delta K_I/\sqrt{\rho})_{\text{th}}$ , below which fatigue cracks would not initiate at the roots of the tested notches. The value of this threshold is characteristic of the steel and increases with increasing yield or tensile strength of the steel. The data show that the fatigue crack initiation life of a component subjected to a given nominal-stress range increases with increasing strength. However, this difference in fatigue crack initiation life among various steels decreases with increasing stress-concentration factor (Ref 17).

FIG. 36 FATIGUE CRACK INITIATION BEHAVIOR OF VARIOUS STEELS AT A STRESS RATIO OF +0.1. SOURCE REF 17

Finally, fatigue crack initiation data for various steels subjected to stress ratios (ratio of nominal minimum applied stress to nominal maximum applied stress) ranging from -1.0 to +0.5 indicate that fatigue crack initiation life is governed by the total maximum stress (tension plus compression) range at the tip of the notch (Ref 50). The data presented in Fig. 37 indicate that the fatigue crack initiation threshold,  $(\Delta K_I/\sqrt{\rho})_{th}$ , for various steels subjected to stress ratios ranging from -1.0 to +0.5 can be estimated from:

$$\frac{\Delta K_{total}}{\sqrt{\rho}} = 10\sqrt{\sigma_{ys}} \quad (EQ 17)$$

where  $\Delta K_{total}$  is the stress-intensity factor range calculated by using the tension-plus-compression stress range, and  $\sigma_{ys}$  is the yield strength of the material.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Fatigue Crack Propagation

Cyclic loading can cause crack propagation in certain alloy steels at stress intensities as low as one-twentieth of the  $K_{Ic}$  value. Threshold stress intensities may range from 3 to 20 MPa $\sqrt{m}$  (2.7 to 18 ksi $\sqrt{in}$ ). This demonstrates that factors other than continuum plasticity considerations are important.

The general nature of fatigue crack propagation using fracture mechanics techniques is summarized in Fig. 38. A logarithmic plot of the crack growth per cycle,  $da/dN$ , defines the rate of subcritical crack growth from fatigue loading,  $da/dN$ , in terms of the stress-intensity range,  $\Delta K = K_{max} - K_{min}$ . The three regions extend from  $\Delta K$  levels associated with almost zero crack-growth rate to conditions approaching fast fracture.

FIG. 38 SCHEMATIC ILLUSTRATION OF VARIATION OF FATIGUE CRACK GROWTH RATE,  $DA/DN$ , WITH ALTERNATING STRESS INTENSITY,  $\Delta K$ , IN STEELS, SHOWING REGIONS OF PRIMARY CRACK-GROWTH MECHANISM

The fracture mechanics approach for characterizing fatigue crack growth can be used in design applications to estimate maximum flaw sizes that allow a part to reach its design life. This approach is also very useful for conducting failure analyses.

Because predicting service fatigue life often involves integrating crack growth rates over a range of  $\Delta K$  values, the  $da/dN$  versus  $\Delta K$  relationship can be represented by:

$$\left(\frac{da}{dN}\right)^{-1} = \frac{A_1}{(\Delta K)^{n_1}} + A_2 \left[ \frac{1}{(\Delta K)^{n_2}} - \frac{1}{[(1-R)K_c]^{n_2}} \right] \quad (\text{EQ 18})$$

where  $n_1$ ,  $n_2$ ,  $A_1$ ,  $A_2$ , and  $K_c$  are best-fit material constants determined by regression analysis. Equation 18 is general and applies to all three regions of crack growth.

Variables that influence fatigue crack growth behavior are stress ratio, loading frequency (not a factor in benign environments), material chemistry, heat treatment, test temperature, and environment. Nonetheless, results of fatigue crack growth rate tests for nearly all metallic structural materials have shown that the  $da/dN$  versus  $\Delta K$  curves have three

distinct regions (Fig. 38). These three regions are briefly described below, followed by sections covering the testing, environmental, and material factors that affect fatigue crack growth rates.

**Crack Threshold Region.** The behavior in region 1 of Fig. 38 exhibits a fatigue crack growth threshold,  $\Delta K_{th}$ , which corresponds to the stress-intensity factor range below which cracks do not propagate, or in which the crack growth rate becomes diminishingly small. The fatigue crack growth threshold is an important design parameter for such applications as rotating shafts involving low-stress, high-frequency fatigue loading where no crack extension during service can be permitted. In region 1, crack growth is negligible for an almost unlimited number of cycles.

An analysis of experimental results published on nonpropagating fatigue cracks shows that conservative estimates of  $\Delta K_{th}$  for various steels subjected to different stress ratios,  $R$ , can be predicted (Ref 17) from

$$\Delta K_{TH} = 6.4 (1 - 0.85R) \text{ FOR } R \geq +0.1 \quad (\text{EQ 19A})$$

and

$$\Delta K_{TH} = 5.5 \text{ FOR } R < +0.1 \quad (\text{EQ 19B})$$

where  $\Delta K_{th}$  is in  $\text{ksi} \sqrt{m}$ .

Equations 19a and 19b indicate that the fatigue crack propagation threshold for steels is primarily a function of the stress ratio and is essentially independent of chemical or mechanical properties. Other examples of stress ratio effects on crack thresholds are provided in the section "Mean Stress Effects" in this article.

**Linear Fatigue Crack Growth Region.** At intermediate values of  $\Delta K$  (region 2 in Fig. 38), a straight line usually is obtained on a log-log plot of  $\Delta K$  versus  $da/dN$ . This is described by the power-law relationship

$$\frac{da}{dN} = C(\Delta K)^n \quad (\text{EQ 20})$$

where  $C$  and  $n$  are constants for a given material and stress ratio. The Paris crack growth equation is generally valid within the  $\Delta K$  range of 300 to 1800  $\text{MPa} \sqrt{mm}$  (9 to 52  $\text{ksi} \sqrt{in}$ ). Values of  $K$  below about 300  $\text{MPa} \sqrt{mm}$  (9  $\text{ksi} \sqrt{in}$ ) fall in the threshold range where crack propagation does not occur, and values above about 1800  $\text{MPa} \sqrt{mm}$  (52  $\text{ksi} \sqrt{in}$ ) fall in the range where the static mode of fracture occurs as the fracture toughness limit of the material is approached.

Extensive fatigue crack growth rate data for various steels show that the primary parameter affecting growth rate in region 2 is the stress-intensity factor range, and that the mechanical and metallurgical properties of these steels have negligible effects on the fatigue crack growth rate in a room-temperature air environment. The data for martensitic steels fall within a single band, as shown in Fig. 39, and the upper bound of scatter can be obtained (Ref 17) from

$$\frac{da}{dN} (\text{m/cycle}) = 1.35 \times 10^{-10} (\Delta K \text{ MPa} \sqrt{m})^{2.25} \quad (\text{EQ 21A})$$

$$\frac{da}{dN} (\text{in./cycle}) = 6.6 \times 10^{-9} (\Delta K \text{ ksi} \sqrt{in.})^{2.25} \quad (\text{EQ 21B})$$

FIG. 39 SUMMARY OF FATIGUE CRACK GROWTH DATA FOR MARTENSITIC STEELS. SOURCE: REF 17

Likewise, for ferritic-pearlitic steels (Fig. 40), data for region 2 crack growth rates fall within a single band (different from the band for martensitic steels), and the upper bound of scatter can be calculated from

$$\frac{da}{dN} \text{ (m/cycle)} = 6.9 \times 10^{-12} (\Delta K \text{ MPa}\sqrt{\text{m}})^{3.0} \quad \text{(EQ 22A)}$$

$$\frac{da}{dN} \text{ (in./cycle)} = 3.6 \times 10^{-10} (\Delta K \text{ ksi}\sqrt{\text{in.}})^{3.0} \quad \text{(EQ 22B)}$$

Similar results are obtained for a variety of weld metals and heat-affected zone microstructures (Ref 52). The crack growth parameters  $C$  and  $n$  are estimated in Ref 52 at a  $C$  value of  $3 \times 10^{-13}$  and a value of 3, in units of newtons (load) and millimeters (length), for ferritic steels with yield strengths up to 600 MPa (87 ksi). These values are based on the upper limit of air fatigue data shown in Fig. 41.

FIG. 40 SUMMARY OF FATIGUE CRACK GROWTH DATA FOR FERRITE-PEARLITE STEELS. SOURCE: REF 17

FIG. 41 FATIGUE CRACK GROWTH IN THE WELD METAL AND HEAT-AFFECTED ZONES OF CARBON-

Region 2 behavior is relevant to design situations involving a finite number of fatigue cycles. The stress ratio and mean stress have negligible effects on the rate of crack growth in region 2. Also, the frequency of cyclic loading and the wave form (sinusoidal, triangular, square, trapezoidal) do not affect the rate of crack propagation per cycle of load for steels in benign environments (Ref 17).

**Austenitic stainless steels**, described elsewhere in this Volume, have a similar crack growth rate relation in region 2, as follows:

$$\frac{da}{dN} \text{ (m/cycle)} = 5.6 \times 10^{-12} (\Delta K \text{ MPa}\sqrt{m})^{3.25} \quad \text{(EQ 23A)}$$

$$\frac{da}{dN} \text{ (in./cycle)} = 3.0 \times 10^{-10} (\Delta K \text{ ksi}\sqrt{in.})^{3.25} \quad \text{(EQ 23B)}$$

**At high  $\Delta K$  values** (region 3 in Fig. 38), unstable behavior occurs, resulting in a rapid increase in the crack growth rate just prior to complete failure of the specimens. The acceleration of fatigue crack growth rates that determines the transition from region 2 to region 3 appears to be caused by the superposition of a brittle or ductile tearing mechanism onto the mechanism of cyclic subcritical crack extension, which leaves fatigue striations on the fracture surface. These mechanisms occur when the strain at the tip of the crack reaches a critical value (Ref 17). Thus, the fatigue-rate transition from region 2 to region 3 depends on the maximum stress-intensity factor, the stress ratio, and the fracture properties of the material (Ref 17).

Region 3 behavior for rapid crack growth is significant only for applications that may experience very few (of the order of ten or fewer) load and unload cycles (e.g., pressure vessels in which pressure may be discharged only a few times during the service life).

Crack growth behavior and ultimate failure in region 3 can occur in one of two ways (Ref 54, 55, 56). The first possibility is operative for high-strength, low-toughness metals, in which specimen sizes normally used for fatigue crack growth rate testing behave in a linear elastic manner at  $K$  levels equal to  $K_{Ic}$ . In this case, increasing crack length during constant load testing causes the peak stress intensity to reach the fracture toughness,  $K_{Ic}$ , of the material, and the unstable behavior is related to the early stages of brittle fracture.

The second possibility, plastic limit load behavior, is common for ductile metals, particularly if  $K_{Ic}$  is high. In this case, the growing crack reduces the uncracked area of the specimen sufficiently for the peak load to cause fully plastic limit load behavior. When plastic limit load behavior causes unstable crack growth,  $\Delta K$  values have no meaning, because the limitations of linear elastic fracture mechanics have been exceeded. Here, the use of the  $J$ -integral concept, crack opening displacement, or some other elastic-plastic fracture mechanics approach is more appropriate than  $\Delta K$  for correlating the data.

**Fatigue Crack Propagation Modes.** Various microstructural modes in fatigue crack growth are briefly reviewed here prior to detailed discussions on environmental and testing effects. Although it is usual to consider ductile fatigue striations as the prime fatigue fracture mode, it is apparent that other fracture modes often occur, based on reviews (Ref 57, 58) of results from a large number of investigators. As previously mentioned, data indicate that, in general, crack growth in region 2 is relatively insensitive to variations in either microstructure or crack shape. In the threshold region (region 1), the rate of crack growth per cycle drops off rapidly as  $\Delta K$  is decreased. Behavior in this region may exhibit considerable sensitivity to the microstructure of the material. In region 3, the growth rate may become large because the maximum value of the stress-intensity factor at maximum cyclic load approaches the fracture toughness. Here the local stresses are sufficiently large to activate fracture by other microstructural modes, such as intergranular fracture, cleavage fracture, or dimple rupture. In Fig. 42, a series of microstructural fatigue failure modes in steels are shown. Although striations are shown at a  $\Delta K$  of  $30 \text{ MPa}\sqrt{m}$  ( $27 \text{ ksi}\sqrt{in.}$ ), at higher stress intensities it is seen that cleavage fracture, intergranular fracture or microvoid coalescence may occur in addition to striation formation (see Fig. 42b, c, and d). Such modes (Ref 58, 59), particularly intergranular and cleavage fracture, may also appear at lower stress intensities.

**FIG. 42** FRACTOGRAPHY OF FATIGUE CRACK PROPAGATION AT INTERMEDIATE (REGION 2) AND HIGH (REGION 3) GROWTH RATES IN STEELS TESTED IN MOIST AIR AT  $R = 0.1$ . SEE TEXT FOR DETAILS ABOUT REGIONS. (A) DUCTILE STRIATIONS IN 9NI-4CO STEEL AT  $\Delta K = 30 \text{ MPa}\sqrt{m}$ . (B) ADDITIONAL CLEAVAGE FRACTURE IN MILD STEEL AT  $\Delta K = 40 \text{ MPa}\sqrt{m}$ . (C) ADDITIONAL INTERGRANULAR FRACTURE IN 4NI-1.5CR STEEL AT  $\Delta K = 40 \text{ MPa}\sqrt{m}$ . (D) MICROVOID COALESCENCE IN 9NI-4CO STEEL AT  $\Delta K = 70 \text{ MPa}\sqrt{m}$ . SOURCE: REF 57

Because heat treatment, alloy additions, and grain size may affect the tendency toward any microstructural fracture mode, these factors must be considered in addition to yield strength and external loading variables.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Effects of Microstructure and Heat Treatment

In ultrahigh-strength steels, the effect of tempering is relatively small for region 2 growth rates, but the effect may be large near the threshold. An investigation of HP-9-4-30 steel, quenched and tempered to yield strengths of 675, 1235, and 1400 MPa (95, 180, and 200 ksi), showed increases in crack growth rate with increasing yield strength, (Fig. 43). On the other hand, Imhof and Barsom (Ref 60) evaluated AISI 4340 steel at yield strengths ranging from 895 to 1515 MPa (130 to 220 ksi) and found no significant variation in region 2. Whereas the effect on  $da/dN$  may only constitute a factor of two or three (or less) in region 2, there may be order-of-magnitude differences in growth rate near the threshold. This is shown for a 300M steel tempered at 100 to 650 °C (212 to 1200 °F) in Fig. 44. This is a superimposed environmental effect that shows up in laboratory air with as little as 40% relative humidity (Ref 57).

SOURCE: REF 57**

Besides tempering effects, microstructure may also have relatively little effect on region 2 growth (Fig. 45). However, it has been found recently that modified microstructures may produce large variations in region 1 growth and may even extend to region 2 (Ref 62). This is shown in Fig. 46 for a low-carbon steel, where a mixture of about 38% martensite in ferrite produced about the same resistance to crack growth as that indicated in Fig. 45 for ferrite-pearlite microstructures. This is for heat treatment A, as indicated in Fig. 46, where the ferrite phase is continuous. If the thermal cycle is now varied to make the martensitic phase continuous, order-of-magnitude improvements are obtained at low  $\Delta K$  with heat treatment B. Thus, it would appear that substantial improvements in fatigue crack growth resistance near the threshold are possible with microstructural control.

FIG. 46 RATE OF CRACK GROWTH VS.  $\Delta K$  FOR TWO MICROSTRUCTURES IN LOW-CARBON STEEL (0.15-0.20% C, 0.60-0.90% MN, 0.04% MAX P, 0.04% MAX S). SOURCE: REF 62

Another means of microstructural control is the grain size effect on fatigue thresholds,  $\Delta K_{th}$  (Ref 54). One investigation (Ref 63) shows the grain effect on mild steel thresholds (Fig. 47). Although there was no difference in region 2 growth, the threshold values varied from 5.3 to 7.0  $\text{MPa}\sqrt{m}$  (4.8 to 6.4  $\text{ksi}\sqrt{in}$ ) as grain size increased from 7.8 to 55  $\mu\text{m}$ . A collection of data from two reviews (Ref 57, 58) shows this effect very well. Figure 48 shows the beneficial effect of large grain size on thresholds for low-strength steels and the detrimental effect of large grain size for high-strength steels. The former is considered to be related to a cyclic slip or microstructurally sensitive crack path that is controlled by the grain diameter, whereas for the high-strength steel, the effect is considered to be environmentally related (Ref 57). For the low- to medium-strength steels, it is useful to compare the grain size with the reversed plastic zone size,  $R_{P\pm}$ , because many studies (Ref 64, 65, 66) have claimed that this is the controlling microstructural unit. Using twice the plane-strain plastic zone radius and twice the yield stress due to the stress reversal gives:

$$R_{P\pm} \equiv \frac{2\Delta K^2}{6\pi(2\sigma_{ys})^2} = \frac{\Delta K^2}{12\pi(\sigma_{ys})^2} \quad (\text{EQ 24})$$

One way of understanding this is to consider that general cyclic slip will not proceed if the grain size is greater than the reversed plastic zone size. Thus, a description of the fatigue threshold could be obtained by substitution of  $d = RP_{\pm}$

$$K_{TH} = \sigma_{YS}(12\pi D)^{\frac{1}{2}} = 6.14\sigma_{YS}(D)^{\frac{1}{2}} \quad (\text{EQ 25})$$

If threshold values were normalized by grain size and plotted against yield strength, the slope of this curve could then be compared with Eq 25. A collection of data in Fig. 49 plotted in this manner predicts a least-squares slope of 5.0 instead of 6.14. However, if the curve is forced through the origin, the best fit gives a slope of 6.06, which verifies Eq 25 and demonstrates that both ferrite grain size and yield strength have strong effects on low-strength threshold stress intensities.

FIG. 49 EFFECT OF YIELD STRENGTH ON NORMALIZED THRESHOLD STRESS-INTENSITY RANGE

This *does not* necessarily mean that a designer should select large-grained steels for performance. The number of cycles to produce a crack that leads to failure also depends heavily on grain size, with the finest grains giving the best performance. Thus, fine grains appear to be best for resistance to fatigue initiation, and coarse grains appear to be best for resistance to crack propagation for long cracks. In fact, it may be shown that there is a crossover in endurance limit for very short cracks versus long cracks. The short-crack endurance limit is highest for fine-grained steel, and the long-crack endurance limit is highest for coarse-grained steel. A similar crossover has been postulated for high-strength steels, except that the critical parameter is yield strength. This is shown in Fig. 50 for a 300M steel quenched and tempered to wide variations in strength level. Whereas the low-strength material would offer the best performance for long cracks, the high-strength material would be superior for short cracks. This becomes important because the optimization of microstructure depends on whether the structural engineer is designing for crack initiation or crack propagation from a pre-existing flaw.

Crack growth resistance also may be different for cracks that propagate along different directions measured relative to the rolling direction. Figure 51 presents data on crack growth rate for specimens of conventionally melted ASTM A533 type B steel tested for each of six orientations. In this study, the effects of three processing techniques--conventional melting, calcium treatment, and electroslag remelting--were investigated. The electroslag remelted material produced the lowest crack growth rates and the least sensitivity to orientation.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Mean Stress Effects

In both fatigue life and fatigue crack propagation testing, the mean stress intensity is an important variable. Because  $K$  is proportional to stress ( $S$ ), the standard ratio ( $R = K_{\min}/K_{\max} = S_{\min}/S_{\max}$ ) is the variable most often used in fatigue crack growth testing. Unlike stress or strain life ( $S-N$  or  $\epsilon-N$ ) testing (which are usually done in the fully reversed,  $R = -1$ , stress condition), fatigue crack growth data is usually done under cyclic tension,  $R = 0$ . Fatigue crack growth testing at  $R = 0$  or approximately zero is based on the concept that the crack would close during compression loading. In this case, the stress-intensity factor,  $K$ , would vanish. Thus, the compression loads should have little influence on constant-amplitude fatigue crack growth behavior. In general, this is fairly realistic, but under variable-amplitude loading, compression cycles can be important to fatigue crack growth (see the section "Variable-Amplitude Loading" in this article).

The general influence of mean stress effects is shown in Fig. 52. Mean stress effects in region II are small, while larger effects occur in regions I and III. The most commonly used equation to model stress effects in regions II and III is the Forman equation (Ref 67):

$$\frac{da}{dN} = \frac{A(\Delta K)^n}{(1 - R)K_c - \Delta K} \quad (\text{EQ 26})$$

where  $A$  and  $n$  are empirical fatigue material constants and  $K_c$  is the applicable fracture toughness for the material and thickness. The Forman equation is a modification of the Paris equation. Typical mean stress effects in the threshold region are shown in Fig. 53 for manganese-molybdenum-nickel pressure vessel steel (ASTM A533B, class 1, 80 to 100 ksi tensile strength). Figure 54 at  $R = 0.1$  is for comparison.

FIG. 52 GENERAL EFFECT OF MEAN STRESS INFLUENCE ON FATIGUE CRACK GROWTH RATES

**FIG. 53 EFFECT OF STRESS RATIO ON FATIGUE THRESHOLD STRESS-INTENSITY FACTOR RANGE,  $\Delta K_{TH}$ , FOR A533B-1 STEEL. DATA ARE FOR A533B-1 STEEL IN REGION 1, TESTED AT VARIOUS STRESS RATIOS, AT 60 HZ AND 25 °C (75 °F) IN AIR. SOURCE: REF 17**

**FIG. 54 FATIGUE CRACK GROWTH BEHAVIOR OF ASTM A533 B1 STEEL. YIELD STRENGTH OF 470 MPA (70 KSI). TEST CONDITIONS:  $R = 0.10$ ; AMBIENT ROOM AIR, 24 °C (75 °F)**

The effect of negative  $R$ -ratios, which includes compression in the cycle, has not been sufficiently investigated, particularly at the threshold levels. The results of many negative  $R$ -ratio tests on wrought and cast steels, cast irons, and aluminum alloys subjected to constant-amplitude conditions in regions II and III indicate that crack growth rates based on  $\Delta K$  values (which neglect compressive nominal stresses) are similar to  $R = 0$  results, or are increased by not more than a factor of 2 (Ref 68).

**Mean Stress Effects on Fatigue Crack Growth Thresholds.** As shown in Fig. 63(b) and Fig. 64, mean stress effects have a significant influence on fatigue crack growth thresholds. Empirical relations (such as Eq 19a and 19b) have been considered for the effect of stress ratios on thresholds. Two examples are described below.

**Example 1.** In a class of low- to medium-strength steels, the effect of stress ratio on the threshold stress-intensity range,  $\Delta K_{th}$ , apparently is similar for seven different materials, as shown in Fig. 55. For values of  $R$  greater than 0.1,  $\Delta K_{th}$  can be given by:

$$\Delta K_{TH} = C_1(1 - 0.85R) \quad (EQ 27)$$

where  $C_1$  is a constant whose value is  $7.0 \text{ MPa}\sqrt{\text{m}}$  ( $6.4 \text{ ksi}\sqrt{\text{in.}}$ ). Because of the narrow grouping of data in Fig. 55, it must be assumed that these were relatively fine-grained steels without the microstructural influences previously discussed. Where greater influences of strength, grain size, microstructure, or environment are encountered, the constant  $C_1$  would necessarily change and the  $R$ -effect might even be qualitatively different. For example, in vacuum test conditions, the threshold may be independent of  $R$  (Ref 57).

**FIG. 55 EFFECT OF STRESS RATIO ON FATIGUE THRESHOLD STRESS-INTENSITY FACTOR RANGE,  $\Delta K_{TH}$ , FOR SEVERAL STEELS. SOURCE: REF 17**

**Example 2.** Another relationship between  $\Delta K_{th}$  and the applied stress ratio,  $R$ , is provided in BS PD6493:

$$\Delta K_{TH} = 190 - 144 R \text{ MPa}\sqrt{\text{mm}} \quad (EQ 28)$$

This relationship provides the lower bound to all published threshold data for British grade 50D steel in air and seawater (Ref 69). It has been suggested that other data for similar steels and for austenitic steels lie below the PD6493 line (Ref 70). Including these data, the following relationship, based on a 97.7% probability of survival for the data in Fig. 56, has been recommended (Ref 70):

$$\Delta K_{TH} = 170 - 214 R \text{ MPA} \sqrt{\text{mm}} \text{ FOR } 0 \cdot R < 0.5$$

$$= 63 \text{ MPA} \sqrt{\text{mm}} \text{ FOR } R \cdot 0.5$$
(EQ 29)

FIG. 56 FATIGUE CRACK GROWTH THRESHOLD DATA FOR FERRITIC STEELS WITH YIELD STRENGTHS UP TO 600 MPA (87 KSI).  $\Delta K_0$  IS THE THRESHOLD INTENSITY ( $\Delta K_{TH}$ ).

### Fracture Mechanics Properties of Carbon and Alloy Steels

#### Variable-Amplitude Loading

Fatigue testing under constant-amplitude loading is substantially different from variable-amplitude service loads, and many methods have been developed to predict or model variable-amplitude performance from data generated in constant-amplitude testing. Different methods are used for fatigue life ( $S-N$ ) data and crack propagation. More information on various methods is described in the article "Estimating Fatigue Life" in Section 3 and the article "Fatigue Crack Growth under Variable Amplitude Loading" in Section 2 of this Volume.

Prediction of fatigue crack growth rates under variable-amplitude loading can be complicated when retardation or acceleration of crack growth is affected by overloads. It is well known that tensile overstressing during fatigue crack propagation usually causes retardation of crack propagation, its effect being beneficial rather than detrimental (Ref 71). Experimental evidence and theoretical analyses have been accumulated to show that the retardation is due to compressive residual stresses developed within the plastic zone ahead of the fatigue crack by the overstressing (Ref 71).

However, it has also been shown that compressive applied stress relieves the residual stress, resulting in substantial reduction of the retardation effect (Ref 71, 72). In fully reversed tension-compression tests, the retardation was completely suppressed and even some acceleration was observed in the transient period immediately after the overloading (Ref 73, 74). This effect leads to the significant acceleration.

In one case, for example, significant acceleration (more than one hundred times) occurred where a very small number of cycles (e.g., 2 cycles) of overstress were applied intermittently between very large numbers of cycles (of the order of  $10^6$  cycles) of understress below the threshold stress intensity,  $\Delta K_{th}$  (Ref 75). These results indicate that  $\Delta K_{th}$ , which has been thought to be an important design criterion in fracture mechanics, may have less significance as a threshold for fatigue crack propagation under such variable stress conditions. This acceleration can be a vital factor that has to be considered in the design of such components.

When retardation or acceleration of crack growth rates is significant, the prediction of fatigue crack growth rate under variable amplitude loading is complex. Many complex cycle-by-cycle models have been developed and proposed in the literature (Ref 76, 77, 78, 79, 80, 81, 82) to take these factors into account. Some textbooks (Ref 83, 84) also provide introductory descriptions of sequence effects. These models require knowledge of the order of appearance of the peaks and valleys of the loading history, information which is not always available. However, even in simulation loading, for which cycle interaction effects are expected to be important, a simple linear accumulation model can produce good predictions as compared to much more complex models (see, e.g., Ref 76, p 103-114).

**Summation of Crack Increments.** If stress overloads or load history (sequence effects) do not significantly affect fatigue crack growth, then crack growth ( $\Delta a$ ) in each individual cycle of variable-amplitude loading can be estimated from the  $da/dN$  versus  $\Delta K$  curve. Summing the values of  $\Delta a$ , while keeping track of the number of cycles, is a straightforward method of estimating fatigue life under variable-amplitude loading. However, this method does not provide accurate estimates if sequence effects or overstresses cause retardation or acceleration of fatigue crack growth rates.

**Block or Spectrum Loading.** Another approach is to approximate the actual service load with repeated application of different loading sequences of finite length. This procedure is numerically equivalent to the summation of crack increments if the crack length,  $a$ , does not change by a large amount during one repetition of the sample load history.

Block or spectrum loading is often used to predict the life of structural components. To correlate variable-amplitude data with constant-amplitude data, some method of normalizing the varying stress-intensity factor ranges in the spectrum is necessary. One such normalization scheme is to use the root mean square (rms) value of the stress-intensity factor. Here  $\Delta K_{max}$  would replace  $\Delta K$  in the Paris power-law relationship (Eq 20) where  $\Delta K_{rms}$  is given by:

$$\Delta K_{rms} = \sqrt{\frac{\sum_{i=1}^N (\Delta K_i)^2}{N}} \quad \text{(EQ 30)}$$

Barsom (Ref 17) used the loading sequences shown in Fig. 57 to establish a database for evaluation of the  $\Delta K_{rms}$  normalization procedure. The results shown in Fig. 58 show an excellent correlation between the constant-amplitude data ( $\Delta K$ ) and the variable-amplitude data ( $\Delta K_{rms}$ ). It should be emphasized that such an independence of loading sequence may not apply to region 1 crack growth or to situations involving aggressive environments.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Temperature Effects

**High-Temperature Fatigue Crack Growth Rates.** Increasing temperature increases fatigue crack growth rates. A clear trend of crack growth rate increase with increasing temperature can be seen in Fig. 59. In this figure it can be seen that at temperatures up to about 50% of the melting point (550 to 600 °C, or 1020 to 1110 °F), the growth rates are relatively insensitive to temperature, but that the sensitivity increases rapidly at higher temperatures. The crack growth rates for all the materials at temperatures up to 600 °C (1110 °F) relative to the room-temperature rates can be estimated by a maximum correlation factor of 5 (2 for ferritic steels). Additional information on high-temperature steels (such as Cr-Mo steels and austenitic stainless steels) is provided in other articles in this Volume.

FIG. 59 VARIATION OF FATIGUE CRACK GROWTH RATES AS A FUNCTION OF TEMPERATURE AT  $\Delta K = 30 \text{ MPA}\sqrt{m}$  ( $27 \text{ KSI}\sqrt{in}$ )

Temperature can affect crack growth rates in several ways. At high temperatures, ease of dislocation motion, dynamic strain aging, or oxidation can be sufficiently enhanced so that creep-fatigue or environmental-fatigue interactions result. McHenry and Pense (Ref 85) found that the crack growth behavior of HP 9-4-35 steel was not appreciably affected by temperatures as high as 350 °C (650 °F) or changes in frequency from 0.02 to 10 Hz. However, both ASTM A212, grade B (now ASTM A515, grade 70), and A517, grade F steels showed that fatigue crack growth rates increased with increasing testing temperature, as illustrated in Fig. 60. Decreasing the frequency of loading for specimens of A517, grade F steel also increased the rate of crack growth.

**FIG. 60 EFFECT OF ELEVATED TESTING TEMPERATURE ON FATIGUE CRACK GROWTH RATES IN ASTM A212B AND A517F STEELS. SOURCE: REF 85**

**Low-Temperature Fatigue Crack Growth.** The fatigue crack growth behaviors of ferritic steels show dramatic changes at low temperatures, which correlate with their fracture toughness behavior. In general, reduced temperatures have insignificant effects or are slightly beneficial as long as ductile cracking modes are operative. The onset of cleavage, however, ultimately causes a dramatic acceleration of fatigue crack growth at the lowest temperatures. The behavior of 9% Ni steel (Fig. 61) is typical: as the temperature is reduced, there is a slight improvement between 295 and 111 K, followed by a rapid loss of fatigue crack growth resistance between 111 and 4 K (Ref 86). The temperature dependence of fatigue crack growth resistance in this case closely parallels the temperature dependence of fracture toughness.

**FIG. 61 EFFECT OF TEMPERATURE ON THE FATIGUE CRACK GROWTH RATES OF A 9% NI FERRITIC STEEL: REF 86**

At low temperatures, the yield strength may be sufficiently increased so that cleavage is promoted at the fatigue crack tip. In Fig. 62, Stonesifer (Ref 87) shows that very low temperatures produce very high crack growth rates at low  $\Delta K$  levels in A533B steel. It is clear that the slope of the  $-196 \text{ }^\circ\text{C}$  ( $-320 \text{ }^\circ\text{F}$ ) curve is such that  $n$  in the power-law relationship  $da/dN = C(\Delta K)^n$  is an order of magnitude larger for the  $-196 \text{ }^\circ\text{C}$  data than it is for the  $20 \text{ }^\circ\text{C}$  ( $68 \text{ }^\circ\text{F}$ ) data. This effect of testing temperature on the fatigue crack propagation exponent has been reviewed, for a large number of iron-base alloys and steels (Ref 58). The results in Fig. 63 demonstrate the increase in the value of  $n$  with decreasing testing temperature.

FIG. 62 EFFECT OF LOW TESTING TEMPERATURE ON FATIGUE CRACK GROWTH RATES IN A533B STEEL. SOURCE: REF 87

FIG. 63 INFLUENCE OF TESTING TEMPERATURE ON FATIGUE CRACK PROPAGATION EXPONENT FOR IRON-BASED ALLOYS. SOURCE: REF 68

However, from these results, one should not assume that crack growth rates are going to be higher at any temperature below room temperature. In fact, at temperatures only slightly below room temperature, improved resistance to fatigue crack propagation may be observed if severe microcleavage can be avoided. This implies that there is some low temperature where there is a crossover in resistance; this has been discussed elsewhere for iron-base systems (Ref 88).

The important point is that one should avoid extrapolating room-temperature behavior to temperatures below room temperature. To avoid microcleavage phenomena, one solution is to use Fe-Ni steels. The nickel additions decrease the ductile-to-brittle transition and result in low fatigue crack growth exponents, even at  $-196\text{ }^{\circ}\text{C}$  ( $-320\text{ }^{\circ}\text{F}$ ) (Fig. 61, 63).

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Aggressive Environments

Aggressive environments affect fatigue crack growth rates in all regions of growth but most often in regions 1 and 2, where exposure times are much greater. Three patterns of corrosion fatigue behavior that might be observed in steels are indicated in Fig. 64. Figure 65(a) illustrates the corrosion fatigue behavior of AISI 4340 steel quenched and tempered to a yield strength of 1700 MPa (245 ksi) (Ref 89). In distilled water, a 1000-fold increase in the crack growth rate is produced by a 1000-fold decrease in the cyclic frequency. This behavior falls somewhere between types B and C behavior in Fig. 64. Similar behavior is observed for X-65 line pipe steel tested in salt water with a superimposed cathodic potential (Ref 90). However, as shown in Fig. 65(b), the same change in frequency does not produce quite as large a change in fatigue crack growth rate. In addition, the cathodic potential increases the growth rate substantially over the open-circuit case for X-65 steel. Both the effects in Fig. 65 have been associated with hydrogen entry, and in fact most corrosion fatigue of high-and ultrahigh-strength steels is considered to occur by a combined mechanism of hydrogen embrittlement and fatigue.

FIG. 64 SCHEMATIC DIAGRAMS SHOWING THREE TYPES OF CORROSION FATIGUE BEHAVIOR. SOURCE: A. MCEVILY AND R. WEI, *FRACTURE MECHANICS AND CORROSION FATIGUE, PROCEEDING--INTERNATIONAL*

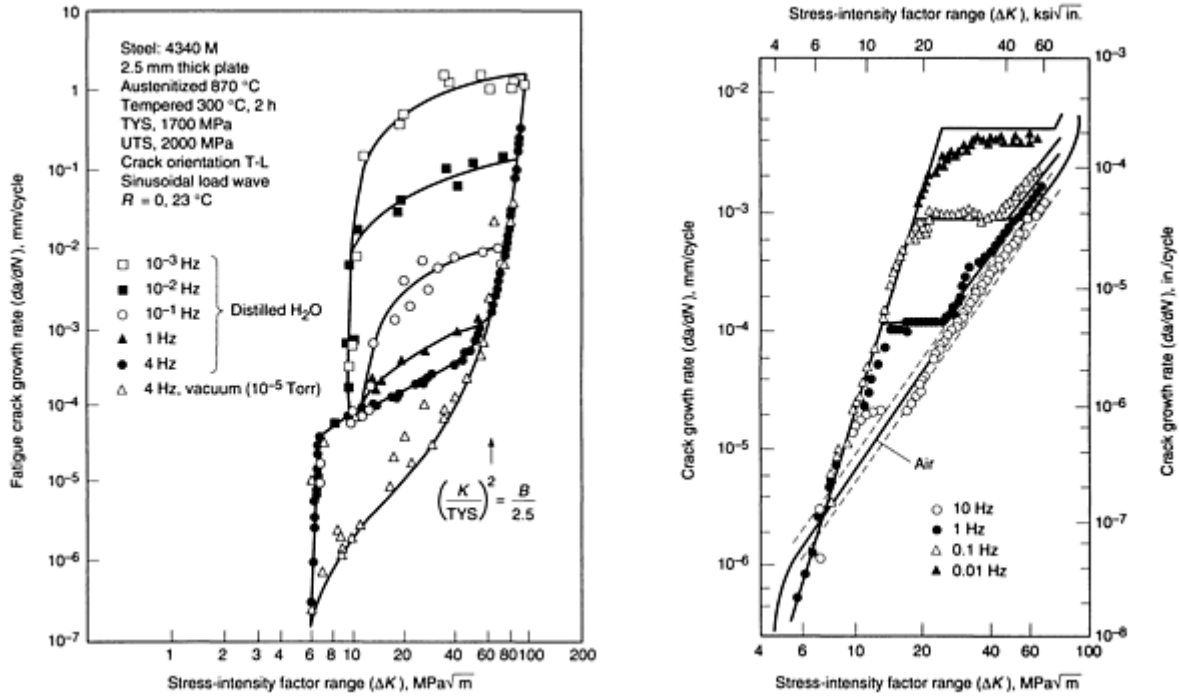

FIG. 65 EFFECT OF CYCLIC FREQUENCY ON CORROSION FATIGUE. (A) HIGH-STRENGTH STEEL 4340 M EXPOSED TO WATER AND VACUUM. SOURCE: REF 89. (B) X-65 LINE PIPE STEEL EXPOSED TO AIR AND SALT WATER WITH A SUPERIMPOSED CATHODIC POTENTIAL. SOURCE: REF 90

Effects of alloying additions are shown in Fig. 66 and 67. First, it can be seen in Fig. 66 that for the identical test frequency, the susceptibility of a 12Ni-5Cr-3Mo maraging steel to corrosion fatigue in a 3% aqueous sodium chloride solution is nearly identical to that of 4340M steel in distilled water. It should be noted that the  $K_{Isc}$  value for this alloy is  $60 \text{ MPa}\sqrt{m}$  ( $55 \text{ ksi}\sqrt{in}$ ), so that nearly all of the environmental effects show up well below the static stress-corrosion threshold,  $K_{Isc}$ . This corresponds most closely to type A behavior in Fig. 64. The same data for 12Ni-5Cr-3Mo at 0.1 Hz are compared with those for two other alloys in Fig. 67. The lowest corrosion-fatigue crack growth rates were achieved in specimens of the 10Ni-Cr-Mo-Co steel.

FIG. 66 EFFECT OF CYCLIC FREQUENCY ON CORROSION FATIGUE FOR 12NI-15CR-3MO MARAGING STEEL. THE STEEL WAS TESTED IN AIR AND IN A 3% AQUEOUS SOLUTION OF SODIUM CHLORIDE WITH SINUSOIDAL LOADING SOURCE: REF 17

**FIG. 67 EFFECT OF COMPOSITION ON CORROSION FATIGUE CRACK GROWTH RATES FOR THREE DIFFERENT HIGH-STRENGTH STEELS. THE STEELS WERE TESTED IN AIR AND IN A 3% AQUEOUS SOLUTION OF SODIUM-CHLORIDE AT 0.1 HZ SOURCE: REF 17**

For lower-strength steels tested in a 3% solution of aqueous sodium chloride, only slight effects were observed in A36, A588 grade A, and A514 grade F steels at frequencies of 0.2 and 1 Hz (Ref 91). However, this was for relatively high growth rates in region 2. It is not clear what effects would occur in region 1 or at lower cyclic frequencies. Results of fatigue crack growth rate tests on specimens of A508-2, A533B, A516, and SA333 in reactor-grade water indicate that the growth rate curves tend to lie in three basic regimes, depending on test conditions (Ref 92).

Corrosion fatigue data for several alloy steels in a variety of environments are given in Table 5. In general, corrosion fatigue depends on cyclic frequency and testing temperature and may occur over a large stress-intensity range and in solutions of any pH value.

**TABLE 5 SELECTED CORROSION FATIGUE CRACK GROWTH DATA FOR STEELS**

STEEL	SOLUTION	FREQUENCY DEPENDENT?	(DA/DN) <sub>SOL</sub> / (DA/DN) <sub>AIR</sub>	STRESS-INTENSITY RANGE, MPa $\sqrt{m}$	REFERENCE

**Inhibiting Corrosion Fatigue.** There is some evidence that inhibitors provide effective passive films or modify the pH at the crack tip (Ref 98). The result in high-strength AISI 4340 steel, shown in Fig. 68, is that growth rates in air at 90% relative humidity are decreased by a factor of about three at a cyclic frequency of 0.167 Hz. These inhibitors were added to the humidified test chamber by means of an organic complex wherein the inorganic inhibitors were incorporated into a quaternary ammonium salt. The result is that the amount of intergranular fracture decreases and the environmental susceptibility to hydrogen embrittlement is reduced.

**FIG. 68 FATIGUE CRACK GROWTH RATE VS. STRESS-INTENSITY FACTOR RANGE,  $\Delta K$ , FOR TYPE 4340 STEEL. CURVE A: 90% RELATIVE HUMIDITY +  $\text{Na}_2\text{Cr}_2\text{O}_7$  +  $\text{NaNO}_2$  +  $\text{Na}_2\text{B}_4\text{O}_7$ . CURVE B: 90% RELATIVE HUMIDITY +  $\text{Na}_2\text{Cr}_2\text{O}_7$ . CURVE C: 90% RELATIVE HUMIDITY ONLY. CURVE D: DRY AIR; RELATIVE HUMIDITY 15%. SOURCE: REF 98**

**Fatigue Crack Growth in Hydrogen Sulfide.** Crude oil with hydrogen sulfide ( $\text{H}_2\text{S}$ ) is a common aggressive environment for application of structural steels. The crack growth rates in sour crude oil with low ( $\sim 1$  ppm) and high (4,700 ppm)  $\text{H}_2\text{S}$  content are presented in Fig. 69. The results show a predominant effect of  $\text{H}_2\text{S}$ . In crude oil with low  $\text{H}_2\text{S}$  content, the growth rates in the low- $\Delta K$  range are lower than in air. This indicates that crude oil alone inhibits the crack growth at low  $\Delta K$  and shifts the threshold to a higher  $\Delta K$  value. Frequency affects growth rate in a similar way to salt water at free corrosion, but to much less a degree. Compared to air, maximum acceleration of growth rate in low- $\text{H}_2\text{S}$  crude oil is only half of that in salt water under free corrosion at the same frequency (0.1 Hz).

**FIG. 69 FATIGUE CRACK GROWTH RATES IN CRUDE OIL WITH TWO LEVELS OF HYDROGEN SULFIDE CONTENT AT THREE FREQUENCIES**

In crude oil saturated with  $\text{H}_2\text{S}$ , contrary to the results in other environments, high acceleration of growth rate persists up to high  $\Delta K$  and is affected by frequency only at high stress intensities. The growth rate curve exhibits a frequency-independent decrease in slope at a growth rate of  $10^{-3}$  mm/cycle. From this value and above, the curve is parallel to the air data, and the crack grows 20 times faster than in air.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Sustained-Load Crack Propagation

Environmentally assisted cracking may occur in any class of steel, given the right combination of environment, tensile stress, temperature, and presence or absence of a superimposed electrical potential. For a given combination, delayed failure may occur within minutes, as in the case of ultrahigh-strength steel fasteners coupled to aluminum in the presence of water, or it may occur years later, as in the case of steam turbine disks exposed to high-purity steam.

Typical results for static loading of precracked specimens of four high-strength steels tested in distilled water are shown in Fig. 70. Each point represents a test of one specimen loaded to a particular level of stress intensity. Failure time periods depend on composition and strength of the steel and on stress intensity, provided that  $K_I$  is above a certain threshold level. The threshold stress intensity here is for tests of relatively thin sheet (plane stress). For considerably thicker plate test conditions (plane strain), the threshold value would be the critical value of  $K_{Isc}$ , which occurs at a significantly lower  $K$ -level than for thin sheet. This thickness transition has been discussed in detail elsewhere (Ref 100), but one should be very careful to evaluate the material in the thickness to be used or have data for a thicker test condition that would provide a conservative estimate. Unfortunately, no simple thickness relationship in terms of  $(K_{Isc}/\sigma_{ys})$  is available that would provide a basic index for  $K_{Isc}$  in the same manner as for  $K_{Ic}$ . Plane-strain versus plane-stress effects also have been described (Ref 105).

FIG. 70 STRESS-CORROSION CRACKING IN FOUR HIGH-STRENGTH STEEL. PRECRACKED SPECIMENS OF FOUR HIGH-STRENGTH STEELS WERE SUBJECTED TO SUSTAINED LOADING IN AN ENVIRONMENT OF DISTILLED WATER. EACH STEEL HAD BEEN HARDENED AND TEMPERED TO A TENSILE STRENGTH OF ABOUT 1650 MPA (240 KSI). SOURCE: REF 99

**Microstructural Fracture Modes**

Examinations of environmentally assisted fractures in specimens of both low- and high-strength steels indicate that cracking may proceed from intergranular fracture to transgranular cleavage to transgranular dimple rupture with increasing applied stress intensity. One or more of these modes may be absent, depending on the microstructure or the strength level of the material as well as on the aggressiveness of the environment.

**Steel Selection**

The most reliable method of preventing stress-corrosion cracking (SCC) of carbon and low-alloy steels is proper materials selection. Strength is perhaps the greatest influence on the SCC resistance of steels under a variety of conditions, with resistance decreasing as strength is increased. Steels with good fracture toughness also resist SCC. For example, a good correspondence between fracture toughness and SCC resistance in aqueous chlorides has been reported for 1034 MPa (150 ksi) steels (Ref 101). A similar correlation between Charpy fracture toughness and SCC in synthetic seawater was observed for steels with yield strengths of 690 to 1380 MPa (100 to 200 ksi) (Ref 102). By contrast, no significant correlation between toughness and SCC resistance in aqueous hydrogen sulfide has been reported for AISI 4xxx series steels (Ref 101).

Because of the predominant influence of strength level on SCC, limitations on steel strengths (or hardnesses) are the main selection criterion. For example, limiting the yield strength of steels used in aqueous chlorides to 690 MPa (100 ksi) is a typical requirement (Ref 103). In contrast, high-yield-strength steels are susceptible to SCC in most aqueous environments (Ref 104, 105). Figure 71 demonstrates that moisture (represented by moist argon) is alone capable of producing cracking in H-11 steel at the 1580 MPa (230 ksi) yield-strength level (Ref 106). Moisture is believed to cause condensation at the crack tip.

**FIG. 71 EFFECT OF RELATIVE HUMIDITY ON CRACK VELOCITY FOR H-11 STEEL WITH A YIELD STRENGTH OF 1580 MPa (230 KSI) IN MOIST ARGON ENVIRONMENTS. SOURCE: APPLIED MATERIALS RESEARCH, VOL 4,**

The most harmful environments are those that contain cathodic poisons (Ref 104, 105). These prevent the association of atomic hydrogen to molecular hydrogen and thus increase the supply of atomic hydrogen. Elements in groups V and VI of the periodic table, such as arsenic, selenium, tellurium, and sulfur, all act as poisons. These elements are listed in order of decreasing potency.

The most common cathodic poison is probably sulfur in the form of  $H_2S$ , as found naturally in "sour" oil wells. For exposure to these environments, hardness in steels is normally limited to 22 HRC (Ref 107). Because high-yield-strength steels usually have hardnesses in excess of 40 HRC, their use is inappropriate.

Of the various forms of SCC of carbon and low-alloy steels, SCC in aqueous chlorides is perhaps the most common. This is due largely to the variety of industries and environments in which aqueous chlorides are encountered. Interestingly,  $K_{Isc}$  for AISI 4340 steel with yield strengths of 1380 and 1720 MPa (200 and 250 ksi) are very similar, regardless of chloride ion content (Ref 105). There is little variation in  $K_{Isc}$  between distilled water and aqueous solutions containing varying amounts of chlorides. Similar behavior is found for the high-alloyed HP 9-4-45 steel (Ref 105). For 18Ni-300 maraging steel,  $K_{Isc}$  is the same in distilled water, 3% NaCl solution, and  $H_2SO_4$  (Ref 105).

Other aqueous solutions that may promote SCC include those containing sulfate, phosphate, or nitrate ions (Ref 105). High-yield-strength steels are also susceptible to organic compounds. This behavior has been attributed to the effect of impurities, similar to the response of titanium alloys to methanol.

The general pattern of behavior appears to be that  $K_{Isc}$  is consistent in aqueous solutions, provided that a poison is not introduced. Relative humidity should be treated as if it were an aqueous solution. The  $K_{Isc}$  for a maraging steel will be consistently higher than that of quenched-and-tempered steels at the same strength level. In general, maraging steels have better SCC resistance than other types of steels with comparable yield strengths (Ref 105, 108). The superiority of maraging steels in terms of  $K_{Isc}$  and crack velocity for chloride-containing and nonchloride aqueous environments is evident from Fig. 72. Steel selection and SCC prevention for some common environments are described below.

FIG. 72 THRESHOLD STRESS INTENSITY ( $K_{ISCC}$ ) VALUES FOR MARAGING STEELS AND OTHER HIGH-STRENGTH STEELS AS A FUNCTION OF YIELD STRENGTH

**Aqueous Chlorides.** Although a clearly defined yield strength threshold for SCC in aqueous chlorides is not apparent, it can be generalized that steels with yield strengths of less than 690 MPa (100 ksi) are resistant (Ref 103). Above this value, SCC in aqueous chlorides can occur, with SCC resistance decreasing with increased yield strength. This strength level corresponds to a threshold stress intensity for SCC of about  $110 \text{ MPa}\sqrt{m}$  ( $100 \text{ ksi}\sqrt{in}$ ).

For steels with yield strengths of less than 1241 MPa (180 ksi), increasing chloride content of SCC-conductive environments apparently increases crack growth rates (Ref 109, 110, 111). This effect is more pronounced at lower chloride levels. However, chloride concentration has been reported to have little influence on the threshold stress level of precracked specimens (Ref 112).

In aqueous chlorides, plastic prestrain to about 5% has little effect on the SCC of low- and medium-strength steels, but as little as 1% prestrain can adversely affect higher-strength steels (Ref 102, 113). Plastic prestrain can, however, result in compressive residual stresses. In such cases, SCC resistance may increase due to inhibiting effects on SCC initiation (Ref 114). Thus, at similar strength levels, cold-drawn wires have been reported to have better SCC resistance than heat-treated wires (Ref 103).

**Hydrogen Sulfide.** As previously noted,  $\text{H}_2\text{S}$  is one of the more aggressive and common SCC agents. The effect of  $\text{H}_2\text{S}$  on the toughness of 4140 steel is shown in Fig. 73. SCC problems in  $\text{H}_2\text{S}$  are more prevalent for steels with higher strength levels and are often associated with hard zones caused by cold working or welding. In  $\text{H}_2\text{S}$  environments, cold working as little as 1% has a strongly detrimental effect on SCC resistance. As shown in Table 6, cold working can impart

SCC susceptibility even to low-strength steels that would not otherwise exhibit SCC. Such effects are believed to be due to increases in both available sites for SCC initiation and hydrogen solubility.

**TABLE 6 EFFECT OF COLD WORK ON STRESS-CORROSION CRACKING (SCC)**

**FIG. 73 STRESS-CORROSION RESISTANCE AND FRACTURE TOUGHNESS OF AISI 4130 AND 4140 STEELS**

Additions of acetic acid to H<sub>2</sub>S-containing solutions promote SCC, probably by both reducing pH and removing protective sulfide films. This latter effect has also been suggested for cyanides. Carbon dioxide has generally been observed to promote SCC both in the laboratory and in service environments. Increasing amounts of chlorides have also been reported to enhance SCC; however, at fixed H<sub>2</sub>S and pH levels, the effects have been minimal (Ref 115).

Perhaps the most comprehensive SCC prevention and control guidelines have been developed for H<sub>2</sub>S service. These guidelines have been summarized in the document commonly referred to as MR-01-75, published by the National Association of Corrosion Engineers (NACE). In general, the NACE guidelines have been supported by service experience, even though SCC can be obtained for some of the recommended materials in laboratory tests.

With respect to carbon and low-alloy steels, NACE MR-01-75 recommendations include limits on hardness levels to avoid hydrogen sulfide SCC. For most steels, hardness is restricted to a maximum of 22 HRC. Certain AISI 4xxx-series steels are allowed at higher hardnesses in the quenched-and-tempered condition, but the user is cautioned that SCC testing

of such materials is advisable. Additionally, MR-01-75 sets limits with respect to nickel content (1% maximum) and degree of cold work, and it specifies required stress-relief heat treatments.

Although not strictly applicable, MR-01-75 is often used for other environments, generally those that, like H<sub>2</sub>S, are believed to cause SCC by hydrogen embrittlement. Examples include gaseous hydrogen service and applications in which steel contact with an acidic aqueous phase could cause hydrogen adsorption.

**Sulfuric Acid.** Stress-corrosion cracking of steel in sulfuric acid solutions is generally associated with high strength levels, although some cases of hydrogen blistering have been reported in mild steels. Stress-corrosion cracking in sulfuric acid solutions has been suggested to be analogous to SCC in aqueous chlorides, producing many similar effects (Ref 116).

**Nitrates.** Reported SCC service failures by nitrates are generally associated with welded steel equipment and/or high-strength steels. To study such failures, laboratory investigations have sometimes used concentrated nitrate solutions. However, SCC can occur at quite low nitrate concentrations in boiling solutions. In these solutions, SCC may be insensitive to concentration increases above a certain level (Ref 117).

For low-carbon steels, cold working reportedly improves SCC resistance in nitrates (Ref 118, 119). At intermediate carbon levels (0.09 to 0.19%), SCC resistance initially decreases and then increases with increasing amounts of cold work (Ref 119). Cold working has also been reported to be more beneficial than heat treatment to a similar strength level for the SCC of steel wires in nitrate solutions (Ref 120). Introduction of residual compressive stresses by shot peening improves the nitrate SCC resistance of steels (Ref 121). Plastic straining appears to be a prerequisite for SCC in hydroxide environments (Ref 122).

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Alloying Effects

Because strength is the dominant factor in steel selection for SCC resistance, the effects of chemistry and alloying can be masked by their effect on strength or hardness. It is also difficult to generalize on the effects of alloying additions on sustained-load cracking because of the vast number of other variables. Nevertheless, a few cases for specific environments have been isolated (Ref 123, 124).

For HSLA steels (Ref 125) in aqueous environments, manganese may lower resistance by producing either untempered martensite or twinned martensite. Nickel may also produce undesirable effects if it causes an increase in retained austenite that leads to formation of untempered martensite after tempering. If no untempered martensite is present, nickel is considered to produce no significant effects on sustained-load cracking. Molybdenum additions on the order of 0.5% enhance resistance. For other elemental additions, either studies have not been made or results have been controversial. Effects of impurity elements are discussed at the end of this section.

For 18-Ni maraging steels, an extensive study (Ref 124) was conducted on 14 alloy heats with varying additions of cobalt, molybdenum, titanium, and aluminum. An alloy parameter, shown as the horizontal axis in Fig. 74, was devised that predicted the  $K_{Isc}$  resistance to an aqueous 3.5% NaCl solution with reasonable accuracy. A linear regression analysis indicated a correlation coefficient of -0.88, which means that this alloy parameter explains about 77% ( $r^2$ ) of the variation in  $K_{Isc}$ . Because the yield strengths range from 1420 to 1960 MPa (206 to 284 ksi) and there were additional possibilities of microstructural influence, it is difficult to account for all variables.

FIG. 74 EFFECT OF ALLOYING ELEMENT PARAMETER ON  $K_{I_{SSC}}$  FOR 18NI MARAGING STEELS IN AN AQUEOUS SOLUTION OF SODIUM CHLORIDE. SOURCE: REF 124

With regard to medium-strength steels, a very extensive study (Ref 126) was conducted on a molybdenum-modified 4130 steel to determine the effect of molybdenum additions on resistance to  $H_2S$  cracking. Here, 12 heats of steel with varying molybdenum contents were tempered to a total of 56 conditions. The resulting  $K_{I_{SSC}}$  values in an aqueous 0.5% acetic acid solution saturated with  $H_2S$  are shown in Fig. 75. In this study the yield strength level was held constant at 760 MPa (110 ksi). It was observed that molybdenum additions of about 0.75% maximized resistance to cracking. Smooth-bar bend tests on the same heats and in the same solution indicated that 0.9% Mo maximized threshold stresses. Many possible suggestions for this improvement were offered, including the control of tramp elements by segregation of phosphorus, arsenic, antimony, and tin to carbide interfaces instead of to prior-austenite grain boundaries.

**FIG. 75 EFFECT OF MOLYBDENUM CONTENT ON  $K_{ISCC}$  FOR ALLOY STEELS. THESE DATA ARE FOR STEEL WITH A YIELD STRENGTH OF 760 MPA (110 KSI) IN AN AQUEOUS 0.5% ACETIC ACID SOLUTION SATURATED WITH HYDROGEN SULFIDE. SOLID CIRCLES DENOTE HEATS WITH VANADIUM ADDITIONS. SOURCE: REF 126**

The conclusion of a previous review (Ref 123) was that alloy chemistry probably has little effect on SCC resistance except for its influence on microstructure and strength. This is possibly true, with the one major exception that tramp elements segregated to prior-austenite grain boundaries seriously decrease threshold stress-intensity factors. Just as it has been shown that phosphorus, sulfur, tin, antimony, arsenic, and tellurium lower fracture toughness, combined effects of temper embrittlement and hydrogen embrittlement during SCC can be very detrimental.

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Effects of Microstructure and Heat Treatment

Fine grain size has been shown to increase the SCC resistance of quenched-and-tempered steels in H<sub>2</sub>S solutions (Ref 127, 128). Similar effects have been observed for carbon steels in nitrates, where increased austenitizing temperature, resulting in grain growth, has adversely affected SCC resistance (Ref 129). Increased cooling rate after austenitizing has also been shown to decrease SCC resistance to nitrate environments (Ref 130). Prolonged aging at temperatures below about 593 °C (1100 °F) reportedly improves SCC resistance in nitrates, but aging at higher temperatures promotes SCC susceptibility (Ref 131, 132, 133).

For quenched-and-tempered steels, the presence of twinned martensite is thought to reduce SCC resistance as it does fracture toughness and hydrogen-embrittlement resistance. The presence of  $\epsilon$  carbides and high dislocation densities also reduces SCC resistance (Ref 134, 135).

In aqueous H<sub>2</sub>S, quenched-and-tempered steels have been shown to have superior SCC resistance compared with normalized-and-tempered steels of similar strength levels (Ref 136). Martensitic microstructures generally give the best SCC resistance at a given strength level, especially if fine spheroidized carbides uniformly dispersed in ferrite (such as is obtained by high-temperature tempering) are present (Ref 137). Bainitic structures have approximately equivalent SCC resistance (Ref 138). The presence of untempered martensite is considered detrimental. Coarse or globular carbides that result from slow cooling and tempering produce an intermediate level of SCC resistance. In nitrate solutions, steels with pearlitic microstructures are superior in SCC resistance compared with steels having fine spheroidized carbides (Ref 139).

Manganese segregation in tempered steels can produce localized regions of increased hardness. This results in a preferential path for SCC in aqueous H<sub>2</sub>S and a corresponding drop in SCC resistance (Ref 140, 141).

Grain-boundary segregants can significantly influence the SCC of steels in environments in which intergranular cracking predominates. These effects have been systematically studied in elevated-temperature nitrate solutions (Ref 142, 143, 144). Following aging treatments to promote segregation, enhanced SCC susceptibility of steels to calcium nitrate was attributed to locally high phosphorus and sulfur levels at grain boundaries (Ref 142). Somewhat mixed results have been reported for silicon and tin in similar environments (Ref 143). In ammonium nitrate solutions, phosphorus, sulfur, arsenic, tin, and antimony (when present with silicon, germanium, selenium, tellurium, and bismuth) strongly promoted intergranular SCC (Ref 144).

Inclusions in steels act as SCC initiation sites and accelerate crack propagation in the major-axis direction of elongated inclusions such as sulfides (Ref 145, 146). Resultant anisotropy of  $H_2S$  SCC has been reported in both plate and tubular products (Ref 147, 148).

The general effect of increased tempering temperatures in many alloy steels is to lower the strength and to increase the  $K_{Isc}$  value from about  $10 \text{ MPa}\sqrt{m}$  ( $9 \text{ ksi}\sqrt{in}$ ) to  $70 \text{ MPa}\sqrt{m}$  ( $64 \text{ ksi}\sqrt{in}$ ) (Fig. 76). In this instance, the behavior parallels fracture toughness. However, it should be emphasized that resistance to SCC does not always parallel fracture toughness. For example, 18-Ni maraging steel typically undergoes a continuous improvement in resistance to SCC with increased aging temperature, while fracture toughness goes through a minimum (Ref 124).

**FIG. 76 CORRELATION BETWEEN TENSILE STRENGTH AND STRESS-INTENSITY FACTOR FOR CRACK PROPAGATION IN ALLOY STEELS IN SEVERAL ENVIRONMENTS. REPORTED VALUES OF STRESS-INTENSITY FACTOR ARE:  $K_{Ic}$  VALUES FOR TESTING IN AIR;  $K_{Isc}$  VALUES FOR TESTING IN AIR;  $K_{Isc}$  VALUES FOR TESTING IN A 3.5% AQUEOUS SODIUM CHLORIDE SOLUTION; AND  $K$  VALUES FOR THRESHOLD CRACKING OF SPECIMENS ELECTROLYTICALLY CHARGED WITH HYDROGEN. SOURCE: *FRACTURE 1977*, VOL 2, UNIVERSITY OF WATERLOO PRESS, 1977, P 255**

For lower-strength conditions, quenched-and-tempered steels, normalized steels, and isothermally transformed steels respond quite differently to sulfide cracking. A series of heat treatments that produced six different types of mixtures of

martensite, ferrite, and untempered martensite demonstrated the superiority of quenched-and-tempered microstructures (Fig. 77). Even though these results were for notched bars loaded in bending, the general ranking with regard to microstructural resistance to SCC should be the same. It was found that microstructures that had fine spheroidizing carbides uniformly distributed throughout the ferrite, which are typically achieved in quenched-and-tempered steels, had superior resistance to sulfide cracking (Ref 149).

## Fracture Mechanics Properties of Carbon and Alloy Steels

### Effects of Temperature and Environment

Temperature and environment may produce unexpected results with regard to predictions of how a material will behave. Even though corrosion attack usually increases as temperature increases, it does not follow that SCC will necessarily be worse. Thus, data obtained for one combination of material, temperature, environment, and loading should not be used for making predictions concerning any other combination. This is aptly illustrated in Fig. 78(a), where it is shown that for AISI 4130 steel tested at one hydrogen pressure, the lower the temperature, the less resistant the material near the threshold. However, there is a crossover effect at high crack velocities, and the material is more resistant at temperatures above and below 53 °C (127 °F). Thus, data obtained as a function of either temperature or stress intensity should not be extrapolated. The effect of hydrogen concentration is more orderly, as shown in Fig. 78(b), where an increase in hydrogen pressure causes an increase in the crack growth rate.

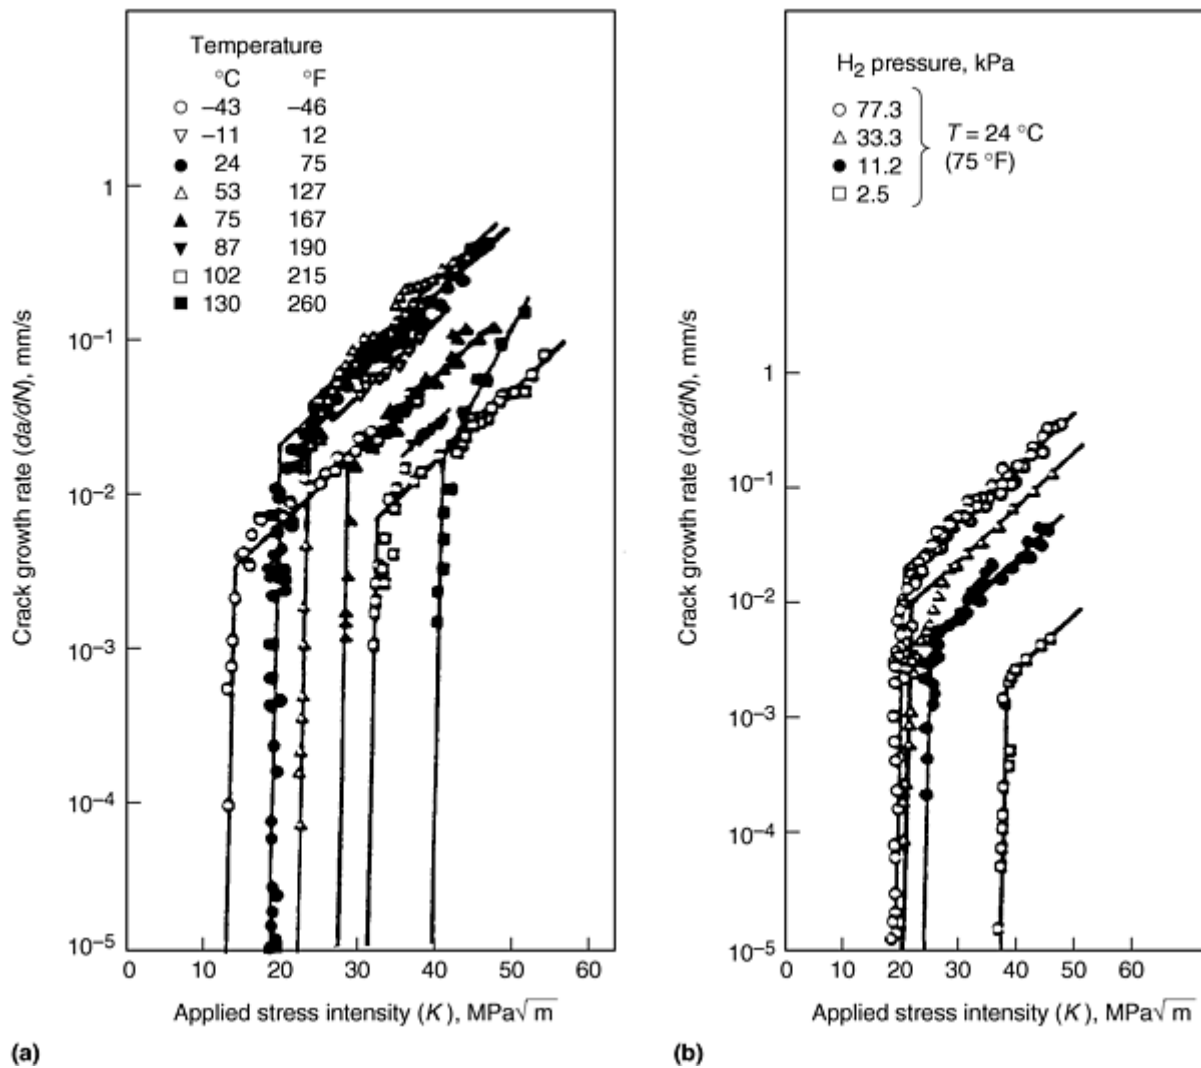

FIG. 78 DEPENDENCE OF CRACK GROWTH RATE,  $DA/DT$  ON APPLIED STRESS INTENSITY,  $K$ , FOR 4130 STEEL WITH A YIELD STRENGTH OF 1330 MPa (193 KSI). (A) AT VARIOUS TEMPERATURES IN HYDROGEN AT A PRESSURE OF 77.3 KPa. (B) AT VARIOUS HYDROGEN PRESSURES AT 24 °C (75 °F). SOURCE: REF 149

In general, any environmental species or electrochemical situation that promotes hydrogen entry will accelerate SCC in medium- and high-strength steels. For low-strength steels, there is a major categorical exception to this in that SCC occurs by anodic dissolution in boiling solutions of nitrates, carbonates, chlorides, and hydroxides as well as anhydrous ammonia. Various combinations of materials and boiling solutions that resulted in SCC, along with the fracture mode observed for each combination, are listed in Table 7 (Ref 150, 151, 152, 153, 154, 155).

TABLE 7 OBSERVATION OF STRESS-CORROSION CRACKING IN LOW-STRENGTH STEELS

BOILING SOLUTION	STEEL	FRACTURE MODE	REFERENCE
20% $NH_4NO_3$	0.19% C	INTERGRANULAR	150
$CA(NO_3)_2NH_4NO_3$	0.02 TO 0.22% C	INTERGRANULAR	150
$KNO_3$ OR $NANO_3$	0.02 TO 0.22% C	INTERGRANULAR	150
4N $NH_4NO_3$	MILD STEEL	INTERGRANULAR	151
4N $NH_4NO_3$	0.32C-0.5MO-3CR	INTERGRANULAR	152
9N NAOH	0.32C-0.5MO-3CR	INTERGRANULAR	152
35% NAOH	MILD STEEL	INTERGRANULAR	151

KOH, NaOH, OR LiOH (300 °C)	MILD STEEL	INTERGRANULAR	153
ANHYDROUS NH <sub>3</sub>	ASTM A-212, A-285	INTERGRANULAR	150
ANHYDROUS NH <sub>3</sub>	0.14C-1.73MN	INTERGRANULAR + CLEAVAGE	151
NA <sub>2</sub> CO <sub>3</sub> -NAHCO <sub>3</sub>	MILD STEEL (VARIABLE TI, C)	INTERGRANULAR	154
NH <sub>4</sub> CO <sub>3</sub> OR NA <sub>2</sub> CO <sub>3</sub> - NAHCO <sub>3</sub>	MILD STEEL (VARIABLE C, SI, NI, CR)	INTERGRANULAR	155
45% MGCL <sub>2</sub>	1 TO 6% NI STEEL	INTERGRANULAR + CLEAVAGE	151

With regard to failure prevention, the effects of SCC can be minimized by choice of steel composition, by cathodic protection against caustic and nitrate embrittlement, or by use of protective coatings or inhibitors. Some successful applications have been: inhibited epoxy coatings on 18-Ni maraging steel exposed to aqueous solutions containing 3% NaCl; 0.2% water additions to vessels containing agricultural ammonia; and film-forming amines added to hydrocrackers containing H<sub>2</sub>S, ammonia, or hydrocyanic acid. Most of these studies were not performed on systems containing cracks, so it is not known how successful such coatings and inhibitors are for dynamic or precracked specimens. As shown in Fig. 79, crack velocities in high-strength 300M steel tested in distilled water can be markedly reduced by adding organic inhibitors, possibly by forming a chemisorbed double layer to prevent hydrogen entry.

### Introduction

CASTINGS offer unique cost advantages over other manufacturing methods for many components, especially those having complex three-dimensional geometry. Unlike built-up assemblies, castings can be designed for function rather than for ease of assembly. However, castings are not specified by designers as often as their advantages would imply, because many designers mistakenly believe that the casting process inherently produces components which contain flaws that deleteriously affect properties and part performance. This situation is changing. The casting process is well understood, and high-integrity castings are being made with the same reliability as forgings. Indeed, castings prove their quality every day in applications as demanding as the rotating hardware in gas turbine engines and primary aircraft structures.

With more demanding structural applications, the fatigue and fracture resistance of castings is of considerable interest to designers of castings. In the past, material selection and product design were based on the results of tension tests, stress-life fatigue tests, and impact tests. This method of design against fatigue and fracture was not always satisfactory. In recent years, design philosophies based on low-cycle fatigue strain versus life behavior, crack propagation, and fracture toughness have emerged as being sound and successful.

This article summarizes the general fatigue and fracture properties of cast steels, with emphasis on general comparisons with wrought steel and usefulness design data based on strain-life and fatigue crack growth testing. Topic coverage includes:

- CYCLIC STRESS-STRAIN BEHAVIOR AND LOW- AND HIGH-CYCLE FATIGUE LIFE BEHAVIOR
- PLANE-STRESS FRACTURE TOUGHNESS
- PLANE-STRAIN FRACTURE TOUGHNESS
- CONSTANT-AMPLITUDE FATIGUE CRACK INITIATION AND GROWTH
- VARIABLE-AMPLITUDE FATIGUE CRACK INITIATION AND GROWTH

The subjects of sustained-load cracking and stress-corrosion cracking, creep crack growth, creep-fatigue behavior, and thermal fatigue are also important to designers; however, these topics are beyond the scope of this article. Reference 1 contains more information on these topics.

Comparisons with wrought steels are emphasized when possible because most available data are for wrought steels at room temperature. However, a significant portion of this article is based on a very comprehensive study of the fatigue and fracture properties of cast steels at room and low climatic temperatures done by R.I. Stephens and his students (Ref 2, 3). The study included fatigue behavior under both constant-amplitude and variable-amplitude loading, for the following grades of cast steel:

- *SAE 0030*: NORMALIZED AND TEMPERED (NT) AT 137 HB (AVERAGE)
- *SAE 0050A*: NORMALIZED AND TEMPERED (NT) AT 192 HB
- *CARBON-MANGANESE STEEL*: NORMALIZED, QUENCHED AND TEMPERED (NQT) AT 174 HB
- *MANGANESE-MOLYBDENUM STEEL*: NORMALIZED, QUENCHED AND TEMPERED (NQT) AT 206 HB
- *AISI 8630*: NORMALIZED, QUENCHED, AND TEMPERED AT 305 HB

The room-temperature ultimate tensile strength and yield strength ranges are 500 to 1150 MPa (72 to 166 ksi) and 300 to 1000 MPa (44 to 143 ksi), respectively. Brinell hardnesses range from 137 to 305 HB and both ferritic-pearlitic and

tempered martensitic microstructures are involved. These cast steels are representative of the carbon and low-alloy cast steels used for structural applications.

## Acknowledgements

The authors are grateful for the work done by Professor Stephens and his students at the University of Iowa, which formed the basis for much of this article. In addition, the authors wish to thank the Steel Founders' Society of America for sponsoring the original work.

## Structure and Property Correlations

Carbon and low-alloy steel castings are produced to a great variety of properties because composition and heat treatment can be selected to achieve specific combinations of properties, including hardness, strength, ductility, fatigue, and toughness. Although selections can be made from a wide range of properties, it is important to recognize the interrelationships among these properties. These general relations are summarized below for toughness, fatigue, and component design factors such as section size and discontinuities.

**Strength and Toughness.** Several test methods are available for evaluating the toughness of steels or the resistance to sudden or brittle fracture. These include the Charpy V-notch impact test, the drop-weight test, the dynamic tear test, and specialized procedures to determine plane-strain fracture toughness. Higher toughness is obtained when a steel is quenched and tempered, rather than normalized and tempered; quenching, followed by tempering, produces superior toughness.

**Charpy impact toughness** is the most common measure of toughness with several types of specimen configurations such as the V-notch or keyhole specimen. The loss in toughness at lower temperatures is more distinct in Charpy V-notch data as compared to keyhole-notch specimen testing, which is why V-notch data are more commonly used to evaluate ductile-brittle transition temperatures.

Typical Charpy V-notch data are shown in Fig. 1 for five common structural cast steels and one cast austenitic stainless steel (CF8). Austenitic steels retain considerable toughness at cryogenic temperatures. Comparative data for other cast stainless steels are summarized in Fig. 2. The lower carbon duplex cast stainless steel grades CF3M, CF8, and CF8M and the austenitic CN7M and CF20 exhibit significantly higher toughness than the stabilized grade of CF8C, and the free-machining grade CF8F (a lower carbon version of C-16). The higher carbon austenitic grades CH-20 and CK-20 show lower impact resistance than the other grades listed.

AND QUENCHED). SOURCE: REF 1

Nil ductility transition temperatures (NDTT) for cast carbon and cast low-alloy steels range from 38 °C (100 °F) to as low as -90 °C (-130 °F) for normalized-and-tempered cast carbon and low-alloy steels in the yield strength range of 207 to 655 MPa (30 to 95 ksi) (Fig. 3). Comparison of the data in Fig. 3 with those of Fig. 4 shows the superior toughness values at equal strength levels that low-alloy steels offer compared to carbon steels. When cast steels are quenched and tempered, the range of strength and of toughness is broadened. Depending on alloy selection, NDTT values of as high as 10 °C (50 °F) to as low as -107 °C (-160 °F) can be obtained in the yield strength range of 345 to 1345 MPa (50 to 195 ksi) (Fig. 4).

FIG. 3 NIL DUCTILITY TRANSITION TEMPERATURES AND YIELD STRENGTHS OF NORMALIZED-AND-TEMPERED COMMERCIAL CAST STEELS

**FIG. 4 NIL DUCTILITY TRANSITION TEMPERATURES AND YIELD STRENGTHS OF QUENCHED-AND-TEMPERED COMMERCIAL CAST STEELS**

An approximate relationship exists between the Charpy V-notch impact energy-temperature behavior and the NDTT value. The NDTT value frequently coincides with the energy transition temperature determined in Charpy V-notch tests.

Plane-strain fracture toughness ( $K_{Ic}$ ) data for a variety of steels reflect the important strength-toughness relationship. Fracture mechanics tests have the advantage over conventional toughness tests of being able to yield material property values that can be used in design equations.

Plane-strain fracture toughness ( $K_{Ic}$ ) data for the various cast steels are in Fig. 5. For quenched-and-tempered nickel-chromium-molybdenum steels, Fig. 5 indicates high  $K_{Ic}$  values of about  $110 \text{ MPa} \sqrt{m}$  ( $100 \text{ ksi} \sqrt{in}$ ) at a 0.2% offset yield strength level of  $1034 \text{ MPa}$  ( $150 \text{ ksi}$ ). At a yield strength level of  $1655 \text{ MPa}$  ( $240 \text{ ksi}$ ),  $K_{Ic}$  values decrease to about  $66 \text{ MPa} \sqrt{m}$  ( $60 \text{ ksi} \sqrt{in}$ ). Data are also plotted in Fig. 5 for wrought plates made of comparable steel of somewhat higher carbon content.

**FIG. 5 PLANE-STRAIN FRACTURE TOUGHNESS  $K_{Ic}$  AND STRENGTH RELATIONSHIPS AT ROOM TEMPERATURE FOR QUENCHED-AND-TEMPERED NICKEL-CHROMIUM-MOLYBDENUM STEELS**

**Tensile Strength and Fatigue Strength Limits.** Cast and wrought steels have similar fatigue (or endurance) limits for notched specimens with comparable tensile strength (e.g., Fig. 6). The endurance ratio (endurance limit divided by the tensile strength) of cast carbon and low-alloy steels as determined by rotating-beam bending fatigue tests (mean stress = 0) is generally taken to be approximately 0.40 to 0.50 for smooth bars. The data given in Table 1 indicate that this endurance ratio is largely independent of strength, although the endurance ratio tends to decrease at higher tensile strengths.

**FIG. 6 FATIGUE ENDURANCE LIMIT VERSUS TENSILE STRENGTH FOR NOTCHED AND UNNOTCHED CAST AND WROUGHT STEELS WITH VARIOUS HEAT TREATMENTS. DATA OBTAINED IN R.R. MOORE ROTATING BEAM FATIGUE TESTS OF NINE STEELS ( $K_T = 2.2$ ). SOURCE: METALS HANDBOOK, VOLUME 1, 8TH ED., 1961**

The fatigue notch sensitivity factor,  $q$ , determined in rotating-beam bending fatigue tests is related to the microstructure of the steel (composition and heat treatment) and the strength. Table 1 shows that  $q$  generally increases with strength--from 0.23 for annealed carbon steel at a tensile strength of 576 MPa (83.5 ksi) to 0.68 for the higher-strength normalized-and-tempered low-alloy steels. The quenched-and-tempered steels with a martensitic structure are less notch sensitive than the normalized-and-tempered steels with a ferrite-pearlite microstructure. Similar results and trends in notch sensitivity have

been reported for tests with sharper notches. Because of the inherent microdiscontinuities in castings, cast steels suffer less degradation of fatigue properties due to notches than equivalent wrought steels.

Endurance limits of cast steels also are less sensitive to the testing direction than wrought steels. For wrought steels, the endurance limit is lower in the transverse direction than in the longitudinal direction of prior working (Fig. 7). This is attributed to the elongation of inclusions in the direction of prior working and the stress concentrating effect of loading normal to the major axis of an essentially elliptical void. Cast steels, however, do not exhibit this directionality since the microdiscontinuities generally have no preferential orientation. It is also common practice to liken the fatigue resistance of cast steels to those of a comparable wrought steel tested in a transverse direction.

**FIG. 7 S-N CURVES ( $R = -1$ ) OF A NORMALIZED AND TEMPERED AISI 4140 WROUGHT STEEL IN THE LONGITUDINAL AND TRANSVERSE DIRECTION AND CAST 4135 STEEL NORMALIZED AND TEMPERED. ### Fatigue of Cast Steel

Besides the effect of strength and external notches (Fig. 6 and 7), the fatigue of cast steels is influenced principally by the following factors:

- SECTION SIZE
- DEFECT SIZE
- STRESS MODES AND WAVEFORM TYPE

These factors are briefly described below with additional information on the strain-life behavior of cast steels. Because fatigue cracks initiate from plastic deformation in regions of stress concentration or inherent discontinuities, strain-life data provide useful information for design analysis. A brief review of inherent notch effects from internal microdiscontinuities is also summarized.

**Section Size Effects.** Increasing section size reduces tensile strength and thus fatigue strength. However, if the fatigue endurance is just a function of tensile strength, then the *endurance ratio* (fatigue limit/tensile strength) would be constant versus section size. This is not strictly true for all castings. In some castings, a slight decrease in the endurance ratio may be observed. In Fig. 8, for example, a slight decrease in endurance ratio is observed for 8635, when compared to 1030 castings.

FIG. 8 FATIGUE ENDURANCE RATIOS OF THREE CAST STEELS VERSUS SECTION SIZE. BANDS SHOW THE RANGE FOR SPECIMENS TAKEN AT DIFFERENT DEPTHS FROM 32 MM, 76 MM, AND 152 MM SQUARES.

**Effect of Defects.** Figure 9 illustrates the typical effect of various defects on fatigue strength of a cast steel. The reduction in fatigue strength depends on defect size (Fig. 10), with the largest defects being the weakest links. The notch effect from defects is described by various relations in terms of the fatigue notch factor ( $K_f$ ). Analysis by de Kazinczy (reported in Ref 4) specifies:

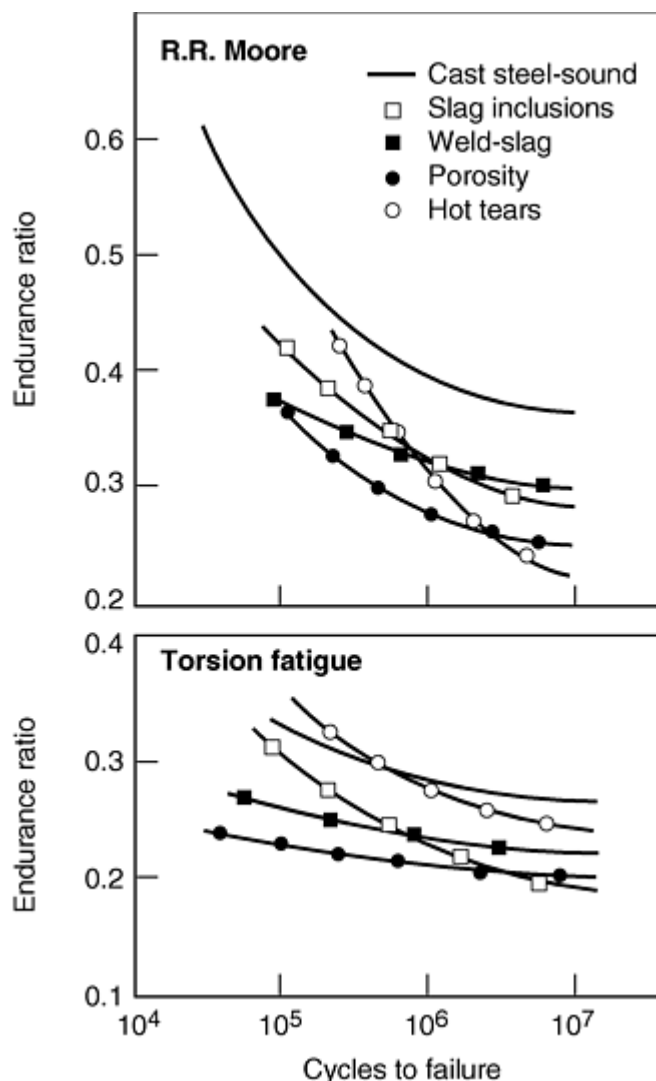

$$K_F = 1 + 0.16 \sqrt{d} \quad (\text{EQ 1})$$

where  $d$  is the defect diameter in mm. However, this relation does not account for the shape of the defect or the matrix strength. Another method (Ref 4) is based on the method of Peterson, which relates  $K_f$  to defect as follows:

$$K_f = 1 + \frac{K_t - 1}{1 + a/r} \quad (\text{EQ 2})$$

where  $K_t$  is the theoretical stress concentration factor,  $r$  is the tip radius of the surface, and  $a$  is a material constant, which for most ferrous alloys is estimated in mm as

$$A = 0.0254 [2070/\text{UTS (IN MPA)}]^{1.8} \text{ MM} \quad (\text{EQ 3})$$

**FIG. 9 EFFECT OF VARIOUS DEFECTS ON ENDURANCE RATIO (FATIGUE STRENGTH/MONOTONIC STRENGTH) OF QUENCHED-AND-TEMPERED 8630 CAST STEEL. (A) R.R. MOORE ROTATING BEAM. (B) TORSION FATIGUE**

FIG. 10 EFFECT OF DEFECT SIZE ON FATIGUE ENDURANCE LIMITS OF CAST STEEL. SOURCE: REF 5

For example, with a hemispherical surface discontinuity ( $K_t \cong 2.5$ ) and an average diameter of 0.40 mm ( $r = 0.20$  mm) for the *largest* microdiscontinuities in a cast steel with a Brinell hardness of 160 HB (and UTS = 3.5 HB = 560 MPa), then:

$$a \cong 0.0254 [3.7]^{1.8} \cong 0.27 \text{ mm}$$

(EQ 4)

$$K_t \cong 1 + \frac{(2.5 - 1)}{(1 + 0.27/0.20)} = 1.6$$

**Applied stress effects** include variations in mean stress, variable amplitude loading, and the differences between torsion and bending. Mean stress effects are commonly addressed with modified Goodman diagrams such as the one shown in Fig. 11 for 8630 steel. Mean stress effects should not differ substantially from notched wrought steels. Variable amplitude fatigue is discussed later with respect to fatigue crack growth.

**FIG. 11 GOODMAN DIAGRAM FOR THE BENDING FATIGUE (R.R. MOORE) OF 8630 CAST STEEL (NORMALIZED AND TEMPERED) FOR DETERMINING THE FATIGUE LIMITS IN TERMS OF CYCLIC STRESS RANGE. THE STRESS RANGE (WHICH IS THE DIFFERENCE BETWEEN MAXIMUM AND MINIMUM STRESS) FOR UNNOTCHED SPECIMENS AT ZERO MEAN STRESS IS ABOUT  $\pm 0.4$  UTS (LINE A), WHILE AT ZERO MINIMUM STRESS ( $R = 0$ ) FOR UNNOTCHED SPECIMENS, THE STRESS RANGE IS REDUCED BY THE AMOUNT SHOWN BY LINE B. THE RANGES FOR CASTINGS WITH DEFECTS AND DISCONTINUITIES ARE SHOWN AS BANDS FOR THE MAXIMUM AND MINIMUM STRESSES, AND THE BANDS INCLUDE DISCONTINUITIES SUCH AS INCOMPLETE PENETRATION OF WELDS, WELD UNDERCUT, WELD-SLAG, SOUND WELDS, SLAG INCLUSION, HOT TEARS, AND CAST SURFACE POROSITY. NOTCHED SPECIMENS WERE MACHINED. NOTCH OF R.R. MOORE SPECIMEN:  $60^\circ$  INCLUDED ANGLE, 0.0015 IN. (0.0381 MM) ROOT RADIUS**

Differences in fatigue behavior for torsional and bending loads are typically described with the assumption of homogeneous and isotropic materials. However, because castings have internal discontinuities, comparison between bending and torsional fatigue is based on a "drilled hole" assumption, where the hole accounts for inherent notch effects from microdiscontinuities (Ref 4). Figure 12 shows a plot of "endurance" ratio in torsion ( $t$ ) to that in bending ( $b$ ) for notched, wrought steels. Dashed lines represent the distortional energy theory and maximum shear stress theory lines for  $t/b = 0.577$  and  $0.5$ , respectively. The data points for the "drilled hole" show best agreement to  $t/b = \frac{3}{4}$  developed in the previous argument. V-notch specimens ( $55^\circ$  circumferential) deviate slightly, due to a difference in stress concentration, but are still in better agreement with  $t/b = \frac{3}{4}$ .

FIG. 12 TORSION AND BENDING ENDURANCE RATIOS (FATIGUE ENDURANCE/MONOTONIC STRENGTH) WITH DRILLED HOLES AND NOTCHED VALUES COMPARED WITH THEORY

Cast metals have  $t/b$  ratios which vary between 0.7 and 1.05 (Ref 5) with an average of 0.85. As such, the concept of a "drilled hole" method seems reasonable. However, an analysis by Vishnevsky (Table 2) concludes that "all the points except one lie above the Maxwell-von Mises criterion indicating that discontinuities present in torsion are not nearly so damaging as they are in bending." Table 2 shows that endurance ratios in torsion are lower than those in bending and that the  $t/b$  ratio average of 0.85 and 0.79 for the QT and HT condition are also in agreement with the drilled-hole argument.

TABLE 2 "ENDURANCE RATIOS" IN BENDING AND TORSION

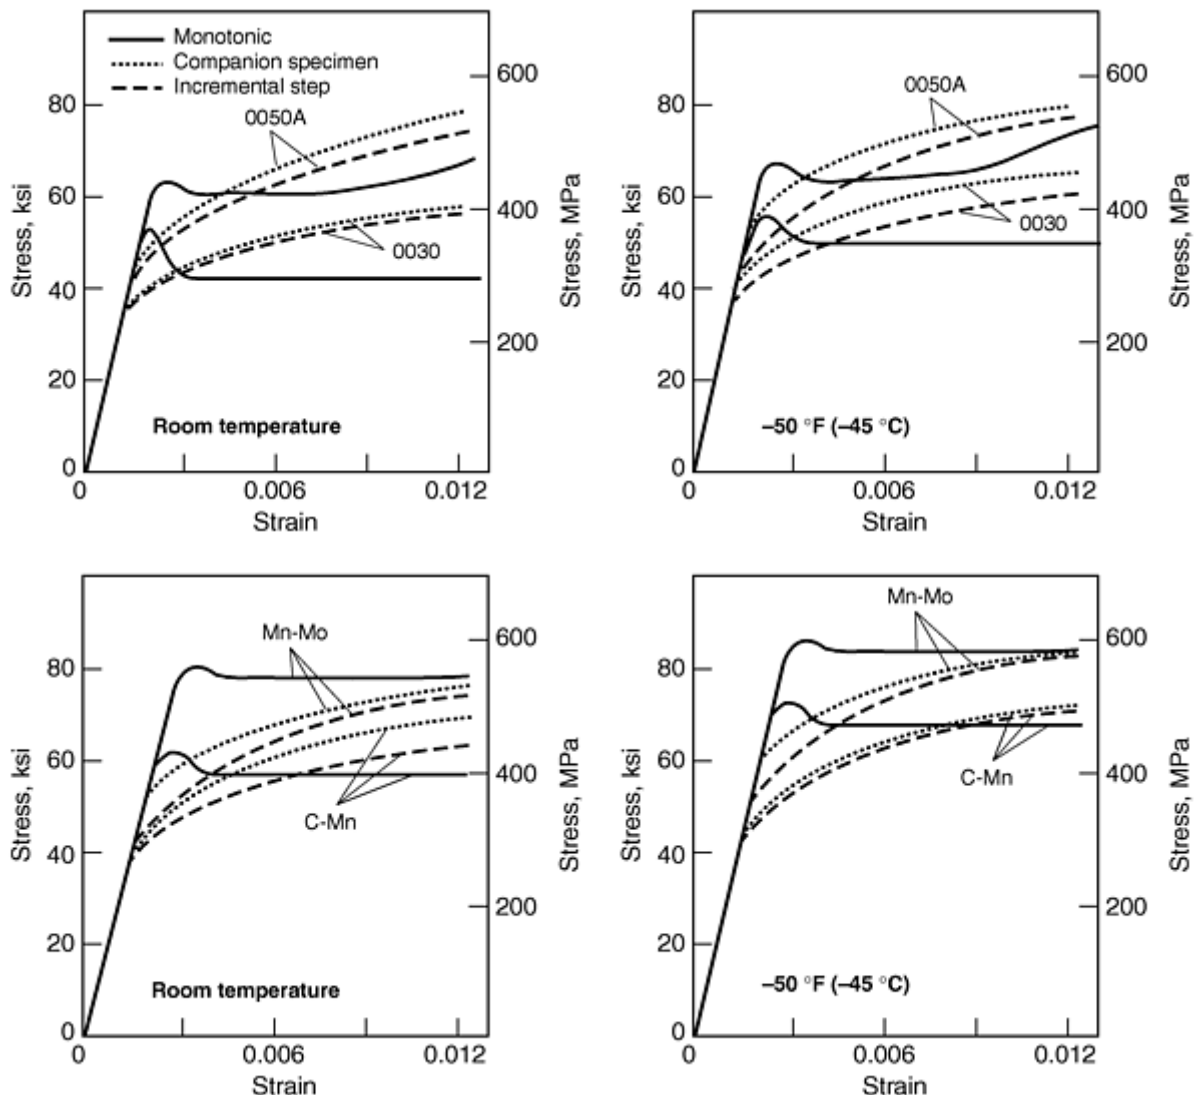

TYPE OF SPECIMEN	ENDURANCE RATIO IN BENDING	ENDURANCE RATIO IN TORSION	(T/B) <sup>(A)</sup>
Q & T

Note: "Endurance ratio" using R.R. Moore specimen. Q&T unnotched 0.390, (0.015 in. *R*) 0.255; Q&T notched (0.001 in. *R*) 0.174;

(A) (T/B) = "ENDURANCE RATIO" IN TORSION/"ENDURANCE RATIO" IN BENDING; AVERAGE FOR Q&T = 0.85.

**Cyclic Stress-Strain Behavior.** Cyclic stress-strain behavior provides a measure of the steady-state cyclic deformation resistance and thus a basis for understanding resistance to crack nucleation. Cyclic stress-strain curves (using the incremental step method and the companion specimen method) are shown in Fig. 13 and 14 for five cast steels at room temperature and low temperature. The cyclic stress-strain curves are initially identical to the monotonic curves and then become nonlinear at stresses or strains of about 20 to 50% below that for monotonic curves.

**FIG. 13 ROOM-TEMPERATURE AND LOW-TEMPERATURE CYCLIC STRESS-STRAIN CURVES FOR TWO FERRITIC-PEARLITIC CAST STEELS (SAE 0050A AND 0030 NORMALIZED-AND-TEMPERED TO AVERAGE HARDNESS OF 192 AND 137 HB, RESPECTIVELY) AND TWO QUENCHED-AND-TEMPERED LOW-ALLOY CAST STEELS (C-MN AND MN-MO STEELS AT 174 AND 206 AVERAGE HB, RESPECTIVELY). STABLE HYSTERSES OF CYCLIC STRESS-STRAIN WERE OBTAINED FROM BOTH COMPANION TEST SPECIMENS AND FROM A SINGLE SPECIMENS SUBJECTED TO INCREMENTAL STRAIN STEPS. FOR THE INCREMENTAL STEP TESTS, EACH STRAIN BLOCK CONTAINED 79 REVERSALS WITH THE MAGNITUDE RANGING FROM 0 TO 0.012. THE STRAIN RATE WAS CONSTANT AND EQUAL TO 0.01/S. SOURCE: REF 2**

**FIG. 14 CYCLIC STRESS-STRAIN OF CAST 8630 STEEL (NQT, 305 HB AVERAGE) AT ROOM TEMPERATURE AND -45 °C (-50 °F). SOURCE: REF 2**

The monotonic upper yield point found in all but the 8630 steel (Fig. 14) was eliminated under the cyclic conditions. At higher strains, the cyclic curves intersect or converge with the monotonic curves for these four steels. These steels cyclic strain soften at the lower strain levels and then cyclic strain harden at the higher strain levels. The cyclic curves for 8630 steel were always equal to or below the monotonic curve and exhibited cyclic strain softening.

A review of available data on wrought steels (Ref 6) indicates that cyclic strain hardening exponent ( $n'$  values) for the cast steels are similar to those for wrought steels. Moreover, the strain hardening and softening behaviors of the cast steels are similar to those for wrought steels. Cyclic strain hardening was found for cast steels when the tensile/yield strength ratio was greater than 1.5. When this ratio was less than 1.3, cyclic strain softening occurred. At intermediate ratios, mixed cyclic strain softening and hardening were observed. These ratios are about 0.1 higher than those for wrought materials (Ref 7). The monotonic yield and tensile strengths, cyclic stress-strain curves, and cyclic yield strengths at the low temperature were about 10% higher than room-temperature results except for 8630 steel.

**Low-Cycle Axial Fatigue Behavior.** Low-cycle axial fatigue tests were conducted on the five steels (Ref 2 and 3) at room and low temperature with  $R = -1$  at constant strain amplitudes from 0.0013 to 0.015, which gave fatigue lives of  $10^2$

to  $10^6$  cycles. Half-life stable hysteresis loops were used to obtain elastic and plastic strain amplitudes. With Young's modulus,  $E$ , obtained from the first-quarter cycle, the elastic strain amplitude was calculated from:

$$\Delta\varepsilon_E/2 = \Delta\sigma/2E \quad (\text{EQ 5})$$

and the plastic strain amplitude was calculated as

$$\Delta\varepsilon_P/2 = \Delta\varepsilon/2 - \Delta\varepsilon_E/2 \quad (\text{EQ 6})$$

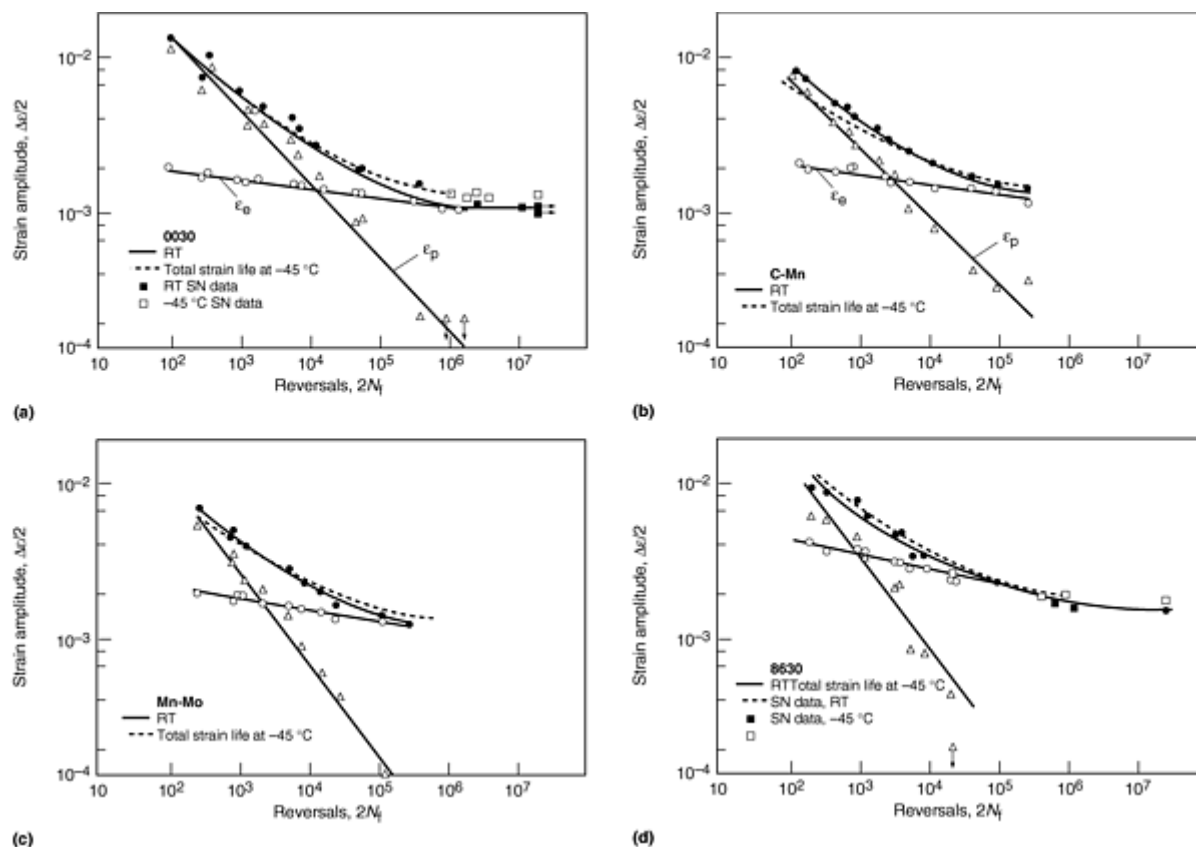

$$= \Delta\varepsilon/2 - \Delta\sigma/2E \quad (\text{EQ 7})$$

where  $\Delta\varepsilon/2$  is the controlled total strain amplitude. These elastic, plastic, and total strain amplitudes are plotted versus number of applied reversals to fracture,  $2N_f$ , on log-log coordinates in Fig. 15 for four of the five cast steels at room temperature (with total life at  $-45^\circ\text{C}$  ( $-50^\circ\text{F}$ ) included for comparison). The elastic and plastic components are represented by the following linear relationships:

$$\Delta\varepsilon/2 = \Delta\varepsilon_E/2 + \Delta\varepsilon_P/2 \quad (\text{EQ 8})$$

$$= \sigma'_F/E \times (2N_F)^b + \varepsilon'_F (2N_F)^c \quad (\text{EQ 9})$$

where  $\sigma'_f$  is the fatigue strength coefficient,  $b$  is the fatigue strength exponent,  $\varepsilon'_f$  is the fatigue ductility coefficient,  $c$  is the fatigue ductility exponent,  $E$  is Young's modulus, and  $2N_f$  is the number of reversals to failure.

(C) MN-MO STEEL (206 HB), AND (D) 8630 CAST STEEL AT 305 HB. TOTAL STRAIN LIFE AT  $-45^\circ\text{C}$  ( $-50^\circ\text{F}$ ) IS INCLUDED. SMOOTH HOURGLASS SPECIMENS WITH A MINIMUM DIAMETER OF 6.4 MM (0.25 IN.) OVER 17.5 MM ( $\frac{11}{16}$  IN.) LENGTH. SOURCE: REF 2**

The low-cycle fatigue material properties are listed in Table 3 along with yield and tensile strengths obtained from the monotonic tension tests. Low-cycle fatigue behavior at the low temperature was equal to or better than at room temperature for lives greater than  $5 \times 10^5$  reversals. Mixed behavior existed at shorter lives. The fatigue strengths at  $10^6$  reversals were from 0 to 30% better at the low temperature. Mixed low-cycle fatigue behavior at low temperatures has also been reported in the literature for wrought steels (Ref 8). In addition, values of low-cycle fatigue material properties for the five cast steels were within the ranges published for wrought steels (Ref 6). The room-temperature fatigue strengths of the five cast steels at  $10^6$  reversals ranged from 208 MPa (30 ksi) for 0030 steel to 370 MPa (53.7 ksi) for 8630 steel. Room-temperature fatigue strengths were within 30 to 40% of the ultimate tensile strength (32 to 46% at the low temperature).

**High-Cycle Axial Fatigue Behavior.** The high-cycle axial fatigue tests were conducted in the same manner as for the low-cycle tests, except that load control was used instead of strain control and the test frequency was 23 to 37 Hz. Failures ranged from  $10^5$  reversals to runouts at  $2 \times 10^7$  reversals. High-cycle ( $10^7$  cycle) fatigue data for 0030 and 8630 cast steels are superimposed with the low-cycle fatigue data in Fig. 15(a) and 15(b), respectively, for the 0030 carbon steel and 8630. The solid circles represent total strain amplitudes for the strain-controlled low-cycle fatigue tests, and the solid squares represent total strain amplitudes from the load-controlled high-cycle fatigue tests. The latter strains were calculated by dividing the applied stress amplitude by Young's modulus because these tests were run in the elastic region. All five cast steels exhibited typical fatigue limits around  $5 \times 10^6$  to  $10^7$  reversals for both test temperatures. Values of the fully reversed fatigue limits,  $S_f$ , obtained from such plots for all five cast steels at both test temperatures, are listed in Table 4 along with the fatigue ratios,  $S_f/S_u$ . The fatigue limits vary from 196 to 293 MPa (28.5 to 42.4 ksi) at room temperature and from 241 to 365 MPa (35 to 53 ksi) at -45 °C (-50 °F). The fatigue ratios vary from 0.26 to 0.42 at room temperature and 0.29 to 0.44 at the low temperature. The fatigue ratios for the 0050A and 8630 steels are lower than those for the other cast steels. Axial fatigue ratios for wrought steels range generally from about 0.37 to 0.43 (75 to 85% of the typical rotating bending fatigue ratio of 0.5).

## Fatigue and Fracture Properties of Cast Steels

S.W. Becker and G.F. Carpenter, NACO Technologies

---

## Fracture Mechanics

The treatment of discontinuities in design has undergone major changes as a result of the wider use of fracture mechanics in the industry. If the plane-strain fracture toughness  $K_{Ic}$  of a material is known at the temperature of interest, designers can determine the critical combination of flaw size and stress required to cause failure in one load application. In addition, designers can calculate the remaining life of a component having a discontinuity, or they can compute the largest acceptable flaw from a knowledge of the crack growth properties ( $da/dN$ ) and fracture mechanics parameters ( $K$ ,  $n$ , and  $C$ ) of a material.

Fracture toughness depends on the volume of plastic deformation near the crack. For thin specimens, the plastic region at the crack tip is constrained and is under plane stress conditions, which produces a relatively high toughness,  $K_c$ . As section thickness increases, fracture behavior approaches plane-strain conditions, and the toughness approaches the inherent lower limit of toughness ( $K_{Ic}$ ) for the material. In the absence of suitable plane-strain fracture mechanics data, approximations can be made on the basis of test results obtained from a variety of tensile, impact, and fatigue tests.

Plane-stress fracture toughness ( $K_c$ ) is usually difficult to obtain because of the complexity of the elastic-plastic behavior at the crack tip. Moreover, the slow stable crack extension prior to fracture makes it difficult to determine the maximum stress-intensity level at crack instability because the crack length is uncertain.

The  $R$ -curve analysis (Ref 9) is applicable for determining  $K_c$  for intermediate-strength materials where the plastic zone size,  $r_y$ , is small relative to the specimen dimensions, where:

$$R_Y = [1/(2\pi)] \times (K/S_Y)^2 \quad \text{(EQ 10)}$$

An  $R$ -curve is a continuous record of toughness development in terms of crack growth resistance,  $K_R$ , plotted against crack extension as the crack is driven under a continuously increasing stress-intensity factor,  $K$ . During slow-stable fracturing, the developing crack growth resistance is equal to the applied stress-intensity factor.

To have a valid plane-stress fracture toughness test, the uncracked ligament should satisfy the following:

$$(W - A) \cdot 8 R_Y$$

$$(EQ 11)$$

where  $w$  is the specimen width and  $a$  is the crack length (or plastic zone corrected length). Values of  $r_y$  near unstable crack extension for five cast steels (Ref 2) ranged from 8 to 18 mm (0.3 to 0.7 in.) and at low temperature ranged from 2.5 to 18 mm (0.1 to 0.7 in.). The validity equation was satisfied only with the 8630 steels at low temperature. The localized plasticity was too large for the other test conditions. However,  $R$ -curves were established with  $K_R$  equal to  $K$  without a plastic zone correction.

**Plane-Strain Fracture Toughness.** The critical value of toughness ( $K_{Ic}$ ) is reached when specimen thickness is large enough to produce plane-strain conditions at the tip of a crack. As the thickness increases, the small plastic zone relative to the thickness produces a stress parallel to the crack tip as the plastic zone attempts to contract in this direction but is prevented from doing so by the large volume of surrounding elastic material. The resulting high degree of triaxial stresses leads to lower toughness and a predominantly flat fracture. This critical  $K$  value, termed plane-strain fracture toughness, or  $K_{Ic}$ , is the minimum toughness and an inherent property of a material.

Typical  $K_{Ic}$  values for various cast steels are summarized in Table 5. Fracture toughness of steels is rarely below 27 MPa  $\sqrt{m}$  (25 ksi  $\sqrt{in}$ ) even at low temperature (Fig. 16). However, this depends on loading rates. If the  $K_{Ic}$  values are known or reliable estimates are available, the flaw tolerance of a given structure can be computed. Except for special cases the  $K_{Ic}$  level should be considered as the onset of rapid fracture.

**J-Integral Method.** When alloys have appreciable ductility and low yield strengths, large specimens are required to obtain valid  $K_{Ic}$  results. In these instances, the path-independent  $J$ -integral is used to estimate fracture toughness by extending fracture mechanics concepts from linear-elastic behavior to elastic-plastic behavior (Ref 10). For linear-elastic behavior, the  $J$ -integral is identical to  $G$ , the strain energy release rate per unit crack extension, which is directly related to the stress intensity factor,  $K$ . Thus, linear-elastic fracture criteria based on  $K_{Ic}$ ,  $G_{Ic}$ , or  $J_{Ic}$  are identical. For mode I linear-elastic plane-strain conditions:

$$J_{Ic} = G_{Ic} = \frac{K_{Ic}^2}{E} \times (1 - \nu^2) \quad (\text{EQ 12})$$

where  $E$  is Young's modulus and  $\nu$  is Poisson's ratio. Because  $J_{Ic}$  characterizes the toughness of materials at or near the onset of crack extension from a preexisting sharp crack, it can be used as a conservative estimate of  $K_{Ic}$  on specimens that contain appreciable ductility but lack sufficient thickness to be tested for  $K_{Ic}$ . Procedures for  $J_{Ic}$  tests are described in Ref 11 and elsewhere in this Volume.

Valid values for  $J_{Ic}$  for six test conditions are listed in Table 6. Also listed are values of  $J_c$ , both lowest and average, for the invalid  $J_{Ic}$  tests. The values of  $K_{Ic}$  and  $K_c$  given in Table 6 were obtained from  $J_{Ic}$  and  $J_c$  values (with an assumed Poisson ratio of  $\nu = \frac{1}{3}$ ). The manganese-molybdenum and 1050A cast steels exhibited the highest and lowest fracture toughness, respectively, at both test temperatures. The three martensitic cast steels (carbon-manganese, manganese-molybdenum, and 8630) had better fracture toughness at room temperature compared with the two ferritic-pearlitic cast steels (0030 and 0050A). However, at the low temperature, the 8630 steel had  $J_c$  less than that of 0030. The 8630 steel had the largest decrease in fracture toughness as the temperature was lowered. The fracture toughness of the carbon-manganese and manganese-molybdenum steels were lowered only 10 to 15% as the temperature was lowered.

- (A) AVERAGE VALUE.  
(B) LOWEST VALUE.

Correlation of  $K_{Ic}$  and Charpy V-notch upper-shelf impact energy was found for the four cast steels with valid  $J_{Ic}$  results at room temperature, as shown in Fig. 17. A similar correlation was not found for the steels tested at the low temperature.

**FIG. 17 CORRELATION BETWEEN ROOM-TEMPERATURE  $K_{Ic}$ , YIELD STRENGTH ( $S_y$ ), AND UPPER-SHELF CHARPY V-NOTCH (CVN) TOUGHNESS FOR FOUR CAST STEELS. IN SI UNITS,  $(K_{Ic}/S_y)^2 = 1170 (CVN/S_y - 0.022)$ . SOURCE: REF 2**

**Fatigue Crack Growth Rates (Constant Amplitude).** Given the similar notched fatigue strength of cast and wrought steels, similar fatigue crack growth rates should also be expected (Fig. 18). Typical Paris-law parameters for intermediate crack growth rates (Region II) are summarized for five cast steels in Table 7 (Ref 2). At low temperature (-45 °C, or -50 °F) a decrease in fatigue crack growth rates was observed by amounts of from 1.2 to 3 for  $R \approx 0$  and from 1 to 2 for  $R = \frac{1}{2}$  at the lower  $\Delta K$  values (Ref 2, 3). At the higher  $\Delta K$  values, the room- and low-temperature data tended to converge or crossover. As  $R$  was increased from 0 to  $\frac{1}{2}$ , the fatigue crack growth rate increased by factors from 1.5 to 3. This increase was slightly higher than that suggested in the literature for wrought steels (Ref 12).

FIG. 18 CONSTANT AMPLITUDE FATIGUE CRACK GROWTH OF CAST AND WROUGHT STEELS AT  $R = 0$  AND  $R = -1$

For  $R \approx 0$  at room temperature, the fatigue crack growth rates for the five cast steels are 2 to 5 times lower than conservative equations proposed by Barsom (Ref 13) for wrought steels. Similar results for similar cast steels were reported by Greenberg et al. (Ref 14) and Kapadia and Imhoff (Ref 15). Thus the fatigue crack growth behavior of cast steels appears to be equal to or better than that of similar wrought steels.

**Threshold Crack Growth Behavior.** Threshold and near-threshold (Region I) fatigue crack growth behavior of the five cast steels at room and low temperature was determined at  $R \approx 0$  and  $R = \frac{1}{2}$  for growth rates between  $10^{-8}$  and  $10^{-10}$  m/cycle ( $4 \times 10^{-7}$  and  $4 \times 10^{-9}$  in./cycle). Compact (Chevron notched) specimens were tested per ASTM E647. The incremental load-shedding method was used to obtain the fatigue crack growth rate data in the near-threshold region. The fatigue crack growth rate of  $10^{-10}$  m/cycle ( $4 \times 10^{-9}$  in./cycle) was used to define the threshold  $\Delta K$ .

A typical plot of the region I and region II data is shown in Fig. 19. It is evident that the threshold  $\Delta K$  value for  $R = \frac{1}{2}$  is about half that for  $R \approx 0$ . All of the steels exhibited similar behavior. The values of  $\Delta K_{th}$  are listed in Table 8. The room-temperature  $R \approx 0$  values were higher than the majority of values reported in the literature for wrought steels (Ref 16).

The  $\Delta K_{th}$  values were higher for the low temperature, except for the 8630 steel at  $R \approx 0$ , for which the values were the same. The  $\Delta K_{th}$  values showed no correlation with other properties such as yield strength, ultimate strength, or fatigue limit.

**Variable Amplitude Fatigue Crack Initiation and Growth.** Constant-amplitude fatigue behavior does not provide information on sequential and interactive effects with variable loading. A more realistic comparison of material or component fatigue behavior can be determined from load or strain histories that closely duplicate or simulate actual service history and environment. SAE International (formerly Society of Automotive Engineers) has developed several service spectra indicative of real-life loading (Ref 2). Variable amplitude tests of five cast steels at room and low temperatures with an as-drilled keyhole notch compact specimen are presented in Ref 2. Eliminating the compression at the four temperatures increased fatigue crack initiation life by factors of 3 to 9, increased short crack growth life by factors of 1 to 4, and increased long crack growth life by factors of 1 to 3. Except for 0050A cast steel, all the average low-temperature fatigue lives for the three different life criteria discussed in Ref 2 were equal to or better than those at room temperature. The increase in crack initiation life was within a factor of 2.5 as was the total fatigue life to fracture. Crack growth life, however, tended to increase as the temperature was lowered and then this trend reversed. The 0050A steel had a continuous decrease in crack growth life for lower temperatures. In general, the three martensitic cast steels (carbon-manganese, manganese-molybdenum, and 8630) had better fatigue resistance with variable amplitude loading at the four temperatures than the ferritic-pearlitic cast steels (0030 and 0050A). The 0030, carbon-manganese, manganese-molybdenum, and 8630 steels are satisfactory for low-temperature conditions, but 0050A is not.

Lee (Ref 3, 17) used constant-amplitude material properties developed for the five steels (Table 6) at room temperature and at  $-45\text{ }^{\circ}\text{C}$  ( $-50\text{ }^{\circ}\text{F}$ ) and several mathematical models to calculate variable amplitude fatigue crack initiation and growth. Comparison of the calculated and experimentally determined fatigue lives showed that total fatigue life calculations were generally within a factor of  $\pm 2$  for all tests. However, greater scatter ( $+7$  to  $-4$ ) was noted for crack initiation life calculations. These results appear to confirm that the models developed for wrought steels can be used for cast steels.

### Introduction

CAST IRONS have several well-known manufacturing and engineering advantages over cast steel, including 30 to 40% lower manufacturing costs relative to cast steel and more desirable performance characteristics, such as better wear resistance and vibration damping. These advantages over cast steel are based on several metallurgical characteristics of cast irons. First, cast iron has melting temperatures (and therefore pouring temperatures) that are 300 to 350 °C (540 to 630 °F) lower than those of cast steel. Second, because of a larger concentration of free carbon and higher silicon, graphitic (gray and ductile) cast iron has the greatest fluidity and the least shrinkage of any ferrous metal. For example, cast steel will generally experience a volume shrinkage of more than 4% during solidification, whereas gray and ductile cast iron shrinkage can be less than 1%, depending on the composition and the processing conditions. This difference in shrinkage allows products to be made to exact dimensions much more easily using gray and ductile cast iron, with very little problem in obtaining pressure tightness as a result of reduced interdendritic shrinkage. In addition, cast irons are more machinable than cast steels, and they are relatively more wear resistant because the graphite acts as a self-lubricating system. Graphite also attenuates sound and mechanical vibration, which makes cast iron ideal for many mechanical applications, such as brakes.

However, the higher carbon concentration responsible for several desirable physical properties and ease of manufacturing with cast iron is, unfortunately, also responsible for the degradation of the ductility and fracture toughness. The carbon, usually present principally as graphite, serves to nucleate fatigue and fracture processes at relatively low strain levels, significantly impairing the fatigue and fracture resistance of cast iron compared with that of cast or wrought steel.

Considerable work has been done to characterize better the fatigue and fracture of cast iron as well as to understand better the micromechanisms that control the fracture process in these systems. The purpose of this article is to summarize the fatigue and fracture behavior of the various types of cast iron as a function of chemical composition, matrix microstructure, and graphite morphology.

The five types of commercial cast iron considered in this article are gray, ductile, malleable, compacted graphite, and white iron. With the exception of white cast iron, all cast irons have in common a microstructure that consists of a graphite phase (usually 8 to 14 vol%) in a matrix that may be ferritic, pearlitic, bainitic, tempered martensitic, or combinations thereof. The four types of graphitic cast irons are roughly classified according to the morphology of the graphite phase. Gray iron has flake-shaped graphite, ductile iron has nodular or spherically shaped graphite, compacted graphite iron (or "vermicular" graphite iron) is intermediate between these two (with graphite in a vermicular or "wormlike" coral shape), and malleable iron has irregularly shaped globular or "popcorn"-shaped graphite that is formed during tempering of white cast iron. These categories of graphite shape have a strong influence on fatigue and fracture properties, although microstructure (tensile strength), component/specimen size, surface condition, chemistry, and temperature also affect the general fatigue and fracture performance of cast irons (Ref 1, 2, 3, 4, and 5).

**Fatigue of Cast Irons**

The fatigue performance of cast irons, in general, is influenced by graphite morphology, matrix microstructure and tensile strength, specimen size, surface condition, surface degradation such as corrosion, and the type of loading stress (e.g., axial, bending, reversed bending, torsion, multiaxial, variable amplitude). The effect of graphite shape on cast iron fatigue has received considerable attention and is a key variable. The free graphite in cast iron acts as an inherent notch that increases stress concentrations for fatigue crack initiation. Therefore, the fatigue performance of cast irons is influenced greatly by the quantity, size, and shape of the graphite phase as well as its interaction with the matrix.

The effect of different graphite morphologies on fatigue is illustrated in Fig. 1, 2, and 3 for three types of cast iron. The flake form of graphite in gray iron increases stress concentrations and thus lowers fatigue strength relative to that of irons that have more spheroidal or compacted graphite forms. In contrast, ductile irons have a nodular graphite, which reduces the concentration of internal stresses and improves the relatively fatigue performance at a given tensile strength. However, gray irons are also less notch sensitive than ductile irons (Table 1).

Most of the available data on cast iron fatigue are based on rotating bending testing where the specimen diameter is generally less than 13 mm (0.5 in.). Results are often reported in terms of fatigue endurance limits (Fig. 1), although testing in the finite life range (below  $10^6$  cycles) is also being emphasized more (Fig. 2, 3). The fatigue endurance limit (or the "knee" in the fatigue curve) usually occurs between  $10^6$  and  $10^7$  cycles. For many tests, if a specimen endures  $10^7$  cycles of a given stress, then it is often assumed that the material would withstand such a stress indefinitely. However, fatigue failures do occur above  $10^7$  cycles in rotating bending fatigue test. Thus, some fatigue limits are based on  $2 \times 10^7$  cycles (Ref 1).

Typical cast iron fatigue data generated in the 1950s and 1960s are summarized in Fig. 4 and Tables 2 and 3. The general relation between tensile strength and fatigue limit (Fig. 4) is determined to a large extent by the strength/microstructure of the matrix, as discussed in more detail later in this article for each particular type of cast iron. Endurance ratios may also be affected by alloying and graphite form, also discussed for particular types of cast iron. More general fatigue characteristics are summarized below.

FIG. 4 RELATION BETWEEN ROTATING-BENDING FATIGUE STRENGTH AND TENSILE STRENGTH OF IRON, BASED ON FATIGUE LIMIT OR FAILURE IN  $10^7$  CYCLES. SOURCE: SEE ANGUS (1960) AND GROVER (1960) IN "SELECTED REFERENCES: PRIOR TO 1980"

**Fatigue Crack Growth.** Fatigue crack initiation is the limiting fatigue mechanism when fatigue life approaches about  $10^6$  cycles or the fatigue-limit regime. Below about  $10^6$  cycles, the majority of fatigue life tends to be consumed by fatigue crack growth for gray, ductile, and compacted graphite irons (Ref 2). For practical purposes, crack initiation in the low-cycle regime ( $10^2$  to about  $10^6$  cycles) can be assumed to occur on the first cycle of loading. Thus, life prediction models for low-cycle fatigue of cast irons should be based on crack growth behavior (Fig. 5 and 6).

FIG. 5 CRACK DEVELOPMENT IN DUCTILE IRON. SOURCE: REF 2

FIG. 6 CRACK DEVELOPMENT IN GRAY IRON. SOURCE: REF 2

The Paris relation,  $da/dN - C(\Delta K)^n$ , is valid for cast iron in the regime of intermediate stress intensities. Fatigue crack growth studies on permanent mold ductile iron castings of a hypereutectic composition (3.6C-3.0Si) indicate that it may be possible to improve the fatigue crack growth resistance by lowering the pearlite content and increasing the nodule count. Crack growth parameters from this study are summarized in Table 4. Results of various investigations on fatigue crack growth rate are shown as a function of the fracture toughness ( $K_{Ic}$ ) in Fig. 7. The crack growth exponent values in permanent mold ductile iron castings are significantly higher than in others. Further, slight reductions in fracture toughness lead to large increases in exponent values.

FIG. 7 VARIATION OF CRACK GROWTH EXPONENT WITH FRACTURE TOUGHNESS IN MAGNESIUM-TREATED CAST IRONS AND STEELS. STEELS DATA IS FROM J. KNOTT, *FUNDAMENTALS OF FRACTURE MECHANICS*, BUTTERWORTH, 1973. SOURCE: REF 7

**Fracture Appearance.** In flake graphite cast irons, it is not generally possible to determine from fracture appearance whether failure has been due to fatigue or to a single overload in tension, because no distinctive fatigue fracture is obtained. This is particularly so with relatively weak flake graphite cast irons. In nodular irons, however, fatigue failures frequently have a distinctive appearance different from that associated with failure by other means.

**Load Variables.** Axial loading or torsional loading cycles are frequently encountered in designing parts of cast iron, and in many instances these are not completely reversed loads. Types of regularly repeated stress variation can usually be expressed as a function of a mean stress and a stress range. Wherever possible, the designer should use actual data from the limited information available. Without precisely applicable test data, an estimate of the reversed bending fatigue limit of machined parts may be made by using about 35% of the minimum specified tensile strength of the particular grade of gray iron being considered. This value is probably more conservative than an average of the few data available on the fatigue limit for gray iron.

An approximation of the effect of range of stress on fatigue limit may be obtained from diagrams such as Fig. 8. Tensile strength is plotted on the horizontal axis to represent fracture strength under static load (which corresponds to a 0 stress range). Reversed bending fatigue limit is plotted on the ordinate for 0 mean stress, and the two points are joined by a straight line. The resulting diagram yields a fatigue limit (maximum value of alternating stress) for any value of mean stress.

**FIG. 8** DIAGRAM SHOWING SAFE AND UNSAFE FATIGUE ZONES FOR CAST IRON SUBJECTED TO RANGES OF ALTERNATING STRESS SUPERIMPOSED ON A MEAN STRESS. EXAMPLE POINT  $P$  SHOWS CONDITIONS OF TENSILE (POSITIVE) MEAN STRESS;  $P'$  SHOWS COMPRESSIVE (NEGATIVE) MEAN STRESS. THE SAFETY FACTOR IS REPRESENTED BY THE RATIO OF  $OF$  TO  $OP$  OR  $OF'$  TO  $OP'$ . FOR CONDITIONS OF CONSTANT TENSILE STRESS,  $DK/DP$  IS THE SAFETY FACTOR.

Few data available are applicable to design problems involving dynamic loading where the stress cycle is predominantly compressive rather than tensile. Other work done on aluminum and steel indicates that for compressive (negative) mean stress, the behavior of these materials could be represented by a horizontal line beginning at the fatigue limit in reversed bending, as indicated in Fig. 8. Gray iron is probably at least as strong as this for loading cycles resulting in negative mean stress, because it is much stronger in static compression than in static tension. It is therefore a natural assumption that the parallel behavior shown in Fig. 8 is conservative.

If, prior to design, the real stress cycle can be predicted with confidence and enough data are available for a reliable  $S-N$  diagram, the casting might be dimensioned to obtain a minimum safety factor of 2 based on fatigue strength. (Some uses may require more conservative or more liberal loading.) The approximate safety factor is best illustrated by point  $P$  in Fig. 8. The safety factor is determined by the distance from the origin to the fatigue limit line along a ray through the cyclic-stress point, divided by the distance from the origin to that point. In Fig. 8 this is  $OF/OP$ .

On this diagram, point  $P'$  represents a stress cycle having a negative mean stress. In other words, the maximum compressive stress is greater than the tensile stress reached during the loading cycle. In this instance, the safety factor is the distance  $OF'/OP'$ . However, this analysis assumes that overloads will increase the mean stress and alternating stress in the same proportion. This may not always be true, particularly in systems with mechanical vibration in which the mean stress may remain constant. For this condition, the vertical line through  $P$  would be used; that is,  $DK/DP$  would be the factor of safety.

Most engineers use diagrams such as Fig. 8 mainly to determine whether a given condition of mean stress and cyclic stress results in a design safe for infinite life. The designer can also determine whether variations in the anticipated mean stress and alternating stress will place the design in the unsafe zone. Usually the data required to analyze a particular set of conditions are obtained experimentally (e.g., Table 5). It is emphasized that the number of cycles of alternating stress implied in Fig. 8 is the number normally used to determine fatigue limits, that is, approximately 10 million. Fewer cycles, as encountered in infrequent overloads, will be safer than indicated by a particular point plotted on a diagram for infinite life. Too few data are available to draw a diagram for less than infinite life.

**TABLE 5 GRAY IRON FATIGUE STRENGTH IN BENDING AND TORSION**

Source: Ref 8

**Fatigue Notch Sensitivity.** Gray irons are less notch sensitive than ductile irons. Because the graphite flakes in gray iron can be thought of as internal notches, gray irons have little or no sensitivity to the presence of additional notches resulting from design features. The strength-reducing effect of the internal notches is included in the fatigue limit values determined by conventional laboratory tests with smooth bars. High-strength irons usually exhibit greater notch sensitivity, but probably not the full theoretical value represented by the stress concentration factor. Normal stress concentration factors (see Ref 9) are probably suitable for high-strength gray irons. Relative notch factors (the ratio of unnotched to notched fatigue strength) for cast irons are in the range of about (Ref 6):

- 1.7 TO 1.8 FOR COMPACTED GRAPHITE IRONS
- LESS THAN 1.5 FOR GRAY IRON
- GREATER THAN 1.85 FOR DUCTILE IRON

**Thermal Fatigue.** When castings are used in an environment where frequent changes in temperature occur, or where temperature differences are imposed on a part, thermal stresses occur in castings and may result in elastic and plastic strains and finally in crack formation. Changes in microstructure, associated with stress-inducing volume changes, as well as surface and internal oxidation, may also be associated with stresses induced by temperature differences.

The interpretation of thermal fatigue tests is complicated by the many different test methods employed by various investigators. The two widely accepted methods are constrained thermal fatigue and finned-disk thermal shock tests (Ref 10, 11).

In general, for good resistance to thermal fatigue, cast irons should have high thermal conductivity, low modulus of elasticity, high strength at room and elevated temperatures, and, for use above 500 to 550 °C (930 to 1020 °F), resistance to oxidation and structural change. The relative ranking of irons varies with test conditions. When high cooling rates are encountered, experimental data and commercial experience show that thermal conductivity and a low modulus of elasticity are most important. Consequently, gray irons of high carbon content (3.6 to 4%) are superior (Ref 10, 11). When intermediate cooling rates exist, ferritic ductile and compacted graphite irons have the highest resistance to cracking but are subject to distortion. When low cooling rates exist, high-strength pearlitic ductile irons or ductile irons alloyed with silicon and molybdenum are best with regard to cracking and distortion (Fig. 9).

FIG. 9 RESULTS OF THERMAL FATIGUE TESTS ON VARIOUS CAST IRONS; SPECIMENS CYCLED BETWEEN 650 AND 20 °C (1200 AND 70 °F). FG, FLAKE GRAPHITE; CG, COMPACTED GRAPHITE; SG, SPHEROIDAL GRAPHITE; UTS, ULTIMATE TENSILE STRENGTH. SOURCE: REF 10

A rather detailed analysis of the behavior of various irons at elevated temperatures is given in Ref 6. Extensive experimental work on cylinder heads is reviewed. A critical analysis of most of the accepted criteria for assessing the quality of irons for castings used at elevated temperatures is also included.

**Constrained Thermal Test.** In the constrained thermal fatigue test (Ref 11), a specimen is mounted between two stationary plates that are held rigid by two columns, heated by high-frequency (450 kHz) induction current, and cooled by conduction of heat to water-cooled grips. The thermal stress that develops in the test specimen is monitored by a load cell installed in one of the grips holding the specimen. As thermal cycling continues, the specimen accumulates fatigue damage in a fashion similar to that in mechanical fatigue testing; ultimately, the specimen fails by fatigue.

Experimental results (Fig. 10) point to higher thermal fatigue for compacted graphite iron than for gray iron and also indicate the beneficial effect of molybdenum. In fact, regression analysis of experimental results indicates that the main factors influencing thermal fatigue are tensile strength (TS) and molybdenum content:

$$\text{LOG } N = 0.934 + 0.026 \cdot \text{TS} + 0.861 \cdot \text{MO}$$

where  $N$  is the number of thermal cycles to failure, tensile strength is in kips (1000 lbs) per square inch (ksi), and molybdenum is in percent.

FIG. 10 RESULTS OF CONSTRAINED THERMAL FATIGUE TESTS CONDUCTED BETWEEN 100 AND 540 °C (212 AND 1000 °F). CG, COMPACTED GRAPHITE; FG, FLAKE GRAPHITE. SOURCE: REF 11

**Finned-Disk Test.** In the finned-disk thermal shock test (Ref 11), the specimen is cycled between a moderate-temperature environment and a high-temperature environment, which causes thermal expansion and contraction. Because thermal conductivity plays a significant role in this type of test, gray iron shows much greater resistance to cracking than compacted graphite iron. Major cracking occurred in less than 200 cycles in all compacted graphite iron specimens, while the unalloyed gray iron developed minor cracking after 500 cycles and major cracking after 775 cycles (Ref 11). Because of its higher elevated-temperature strength, alloyed gray iron was even more resistant to thermal fatigue.

**Corrosion Fatigue of Cast Irons.** A limited amount of information is available in the literature on the corrosion fatigue of cast irons. From a literature review of a few tests in tap and salt water, the fatigue reduction factors due to corrosion were from 1.28 to 1.59 in tap water and 1.55 to 2.47 in sea water for gray irons (Ref 1). Fatigue strengths were reduced by about 7 MPa (1 ksi) when tested in tap water.

Additional corrosion fatigue tests carried out by the British Cast Iron Research Association (Ref 1) were conducted in various environments, as summarized in Tables 6 and 7. The fatigue strength in air, in demineralized water, and in inhibitor-containing water was based on a life of  $50 \times 10^6$  cycles of stress, and the tests in sodium chloride solution were based on  $100 \times 10^6$  cycles of stress. The stress frequency was approximately 3,000 cycles/min. The following conclusions from Ref 1 are noted:

- "CORROSION FATIGUE OF FLAKE GRAPHITE (GRAY) IRONS IN DEMINERALIZED WATER CAN BE PREVENTED BY THE ADDITION TO THE WATER OF KNOWN ALKALINE INHIBITORS EXCEPT BORAX WHICH IS NOT COMPLETELY EFFECTIVE FOR PEARLITIC IRONS. SOLUBLE OILS ARE ALSO EFFECTIVE FOR FLAKE GRAPHITE IRONS."
- "TESTS IN CORROSION-INHIBITED DEMINERALIZED WATER ON BOTH PEARLITIC AND FERRITIC NODULAR (DUCTILE) IRONS REVEALED THAT THE ONLY SATISFACTORY INHIBITOR GIVING MORE OR LESS COMPLETE PROTECTION AGAINST CORROSION

FATIGUE WAS POTASSIUM CHROMATE. SOME PROTECTION WAS OBTAINED WITH SODIUM CARBONATE FOR PEARLITIC IRONS AND THIS, TOGETHER WITH TRI-SODIUM ORTHOPHOSPHATE AND SODIUM NITRITE, WAS EFFECTIVE FOR FERRITIC IRONS. SOLUBLE OILS ARE NOT EFFECTIVE IN PREVENTING CORROSION FATIGUE OF NODULAR GRAPHITE IRONS."

- "ALL INHIBITORS PREVENTED VISIBLE CORROSION OF THE SURFACE, BUT THIS IS NO INDICATION OF THE EFFECTIVENESS OF AN INHIBITOR IN PREVENTING CORROSION FATIGUE."

See Ref 1 for more details.

## Fatigue and Fracture Properties of Cast Irons

S. Lampman, ASM International

---

## Fracture Toughness of Cast Irons

Like the fracture resistance of structural steels and other alloys, the measurement of the fracture resistance of cast irons can be broadly divided into two groups:

- MEASUREMENT OF FRACTURE ENERGY CURVES BASED ON DYNAMIC TEAR TESTS (ASTM E604-83) OR CHARPY IMPACT TESTS
- MEASUREMENT OF RESISTANCE TO CRACK PROPAGATION USING A FRACTURE MECHANICS METHOD, SUCH AS LINEAR ELASTIC FRACTURE MECHANICS (ASTM E 399), ELASTIC-PLASTIC FRACTURE MECHANICS WITH THE  $J$  INTEGRAL (ASTM E 813), CRACK-TIP OPENING DISPLACEMENT (BS 5762) MEASUREMENTS, OR DYNAMIC FRACTURE TOUGHNESS PARAMETERS SUCH AS  $K_{ID}$  OR  $J_{ID}$

Fracture energy curves and dynamic fracture toughness ( $K_{Id}$  or  $J_{Id}$ ) both can be used to evaluate transition temperature behavior, where fracture behavior changes from ductile to brittle. However, comparison of transition temperatures measured in the different dynamic tests (e.g., Charpy impact, dynamic tear energy tests, or  $K_{Id}$  or  $J_{Id}$  tests) is inappropriate. Cast iron yield strengths are rate dependent, and thus transition temperatures are affected when loading rates change from slow bending to impact. Therefore, valid comparison can only be made when loading rate, specimen size, and notch acuity are similar. These different types of fracture toughness tests are discussed elsewhere in this Volume (see the article "Fracture Toughness Testing"). A comparison of the different test methods is also reviewed for cast iron toughness in Ref 5. In general, test bars for the Charpy or Izod impact testing of cast irons are larger than those used for testing steels. Increases in the size of as-cast specimens cause a relative reduction in impact strength and tensile strength.

In metallurgical terms, the general effects of graphite morphology and matrix microstructure are shown in Fig. 11 and 12 for cast irons. Like fatigue fracture, gray iron has the lowest fracture resistance, due to the inherent notch effect from the flake morphology of its graphite. Gray iron is also less notch sensitive, with little or no change in notch toughness at lower temperatures. Ductile-to-brittle transition temperatures are more pronounced for ductile and compacted graphite irons (Fig. 11, 12). The effect of graphite morphology is more pronounced for upper shelf toughness, but below the transition temperature, graphite morphology has little effect on toughness.

**FIG. 11** EFFECT OF GRAPHITE SHAPE ON DYNAMIC FRACTURE TOUGHNESS, ( $K_{Jd}$ ) OF FERRITIC GRADES OF VARIOUS CAST IRONS. THESE RESULTS ARE GENERALLY BASED ON DATA FROM THE LITERATURE, WITH SOME APPROXIMATION WHERE DATA IN LITERATURE IS INCOMPLETE. SOURCE: REF 5

**FIG. 12** EFFECT OF GRAPHITE SHAPE ON FRACTURE TOUGHNESS OF PEARLITIC GRADES OF VARIOUS CAST IRONS. THESE RESULTS ARE GENERALLY BASED ON DATA FROM THE LITERATURE WITH SOME APPROXIMATION IN REGIONS WHERE DATA IS INCOMPLETE. SOURCE: REF 5

Most alloying elements or impurities affect toughness indirectly through their effect on graphite morphology and matrix microstructure. However, silicon and phosphorous are two exceptions. Both of these impurities have a strong influence on toughness (Fig. 13). The effect of microstructure and alloying on toughness is summarized for each specific type of cast iron in the next sections.

FIG. 13 CHARPY V-NOTCH IMPACT ENERGIES OF DUCTILE IRONS. SOURCE: PELLINI, SANDOZ, AND BISHOP, NOTEN DUCTILITY OF NODULAR IRONS, *TRANS. ASM*, VOL 46, 1954, P 418-445

Table 8 is a general summary of room-temperature Charpy toughness for various cast irons. Charpy testing is the most widely used method to evaluate the fracture toughness of cast irons, and additional information can be found in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook* and other reference books on cast irons (Ref 3, 4).

## Gray Cast Iron

**Fatigue Strength.** Notches and surface imperfections have little effect on the fatigue strength of gray cast irons, which is one reason for its use in automobile crankshafts and similar applications. Minimum tensile and fatigue properties of gray cast iron per ISO 185 are summarized in Table 9. The ratio of fatigue endurance limits to ultimate tensile strength has been reported to vary from 0.33 to 0.62 for gray cast irons (Ref 1). Graphite flake size, matrix microstructure (strength), and phosphorous content all influence the endurance ratio. Some general reported values for the endurance ratio have been:

- 0.4 TO 0.7 FOR REPEATED LOADS IN COMPRESSION ONLY (REF 4)
- 0.45 FOR IRONS WITH TENSILE STRENGTHS OF 55 TO 70 MPA (8 TO 10 KSI) (REF 1)
- 0.38 FOR TENSILE STRENGTHS FROM 80 TO 100 MPA (12 TO 15 KSI) WITH ACICULAR-MATRIX MICROSTRUCTURES (REF 1)

Typical values for different loading conditions are summarized in Table 5. The ratio of endurance limits between torsion loading versus bending loads is reported to vary from 0.75 to 1.25 (Ref 4). In general, the fatigue endurance limit ratio with ultimate tensile strength is smaller at higher tensile strengths.

**Impact Strength and Toughness.** of Gray cast irons are not notch sensitive and do not have a pronounced ductile-to-brittle transition temperature (Fig. 11, 12). However, the impact toughness of unnotched gray iron is reported (Ref 4) to decrease about 10 to 20% at -75 °C (-100 °F) and 50% at -185 °C (-300 °F). Gray irons with flake graphite have Charpy V-notch upper-shelf toughness at around 1.4 to 6.8 J (1 to 5 ft · lbf), with higher values obtained with higher-strength-matrix microstructures (Ref 5). This unusual behavior (toughness generally decreases with higher strength) is attributed to the fact that fracture occurs through the graphite flakes rather than through matrix deformation (Ref 5).

Several attempts have been made to measure the fracture toughness of gray iron using fracture mechanics methods (Ref 5). Some results are summarized in Fig. 14. As mentioned above for Charpy toughness, there is a trend of higher toughness at higher strengths. The values of fracture toughness reported in the literature for gray cast iron almost always give either  $K_Q$  or  $K_{max}$ , rather than  $K_{Ic}$ , because of the ambiguity in determining accurately the moment of crack extension. A question then arises as to which of the two is the better measure of the fracture toughness. Bradley observed more than 1.6 mm of crack advance before reaching maximum load in class 35 gray iron (Ref 12). In view of this result and the discussion presented in Ref 5,  $K_Q$  values are considered reasonable and conservative estimates of  $K_{Ic}$ .  $K_{max}$  values would tend to overestimate the fracture toughness of gray cast iron.

FIG. 14 RELATIONSHIP BETWEEN TENSILE STRENGTH AND FRACTURE TOUGHNESS PARAMETERS  $K_Q$  AND  $K_{MAX}$  FOR GRAY CAST IRON. SOURCE: REF 5

### Fatigue and Fracture Properties of Cast Irons

S. Lampman, ASM International

### Ductile Irons

**Fatigue Strength.** Minimum tensile strength and fatigue limits for ductile irons per ISO 1083 are summarized in Table 10. In fatigue applications, ductile irons are generally used in the pearlitic condition (as-cast or normalized). Austempered ductile iron and ferritic ductile iron are also used. Ductile iron is frequency sensitive, and the cycle frequency in testing should not exceed the expected frequency for service.

Fatigue endurance ratios for ductile iron are affected primarily by the matrix microstructure/strength (Fig. 15) and by notch factors (Fig.16) or surface condition. Table 11 summarizes typical reversed bending fatigue results for three standard grades of ductile iron. Results of rotating bending tests carried out by the British Cast Iron Research Association are summarized in Table 12 and are discussed in more detail in Ref 1. Ductile irons follow the expected trend of decreasing fatigue endurance ratios for higher strength of the matrix microstructure. However, heat treatments that result in an increase of tensile strength do not show a proportional increase in the fatigue limit (Table 11). References 1, 2, 3, 4, 5, 6, 7, and 8 and the "Selected References" listed at the end of this article are additional sources of property data on the fatigue of ductile iron.

FIG. 16 EFFECT OF CAST SECTION SIZE ON THE FATIGUE PROPERTIES OF DUCTILE IRONS. SOURCE: METALS HANDBOOK, 9TH ED., VOL 15, P 662

**Charpy Impact Toughness.** Upper-shelf Charpy V-notch energy for ferritic ductile iron is about 14 to 24 J (10 to 18 ft · lbf) as compared to 12 to 19 J (9 to 14 ft · lbf) for malleable iron and 1 to 6 J (0.7 to 4.5 ft · lbf) for gray iron. Data from a comprehensive study show that increasing pearlite content decreases impact toughness (Fig. 13) and that the transition temperature is significantly affected by silicon and phosphorous content.

The effects of various heat treatments on Charpy V-notch impact energy are shown in Fig. 17 for a ductile iron alloyed with about 0.75% Ni. Curve F shows that austempering heat treatment not only improves elongation at high strength but also produces the highest room-temperature impact energy of any of the conventional heat treatments, with the exception of surface-hardened as-cast ductile iron, curve A, with a hardness of 207 HB.

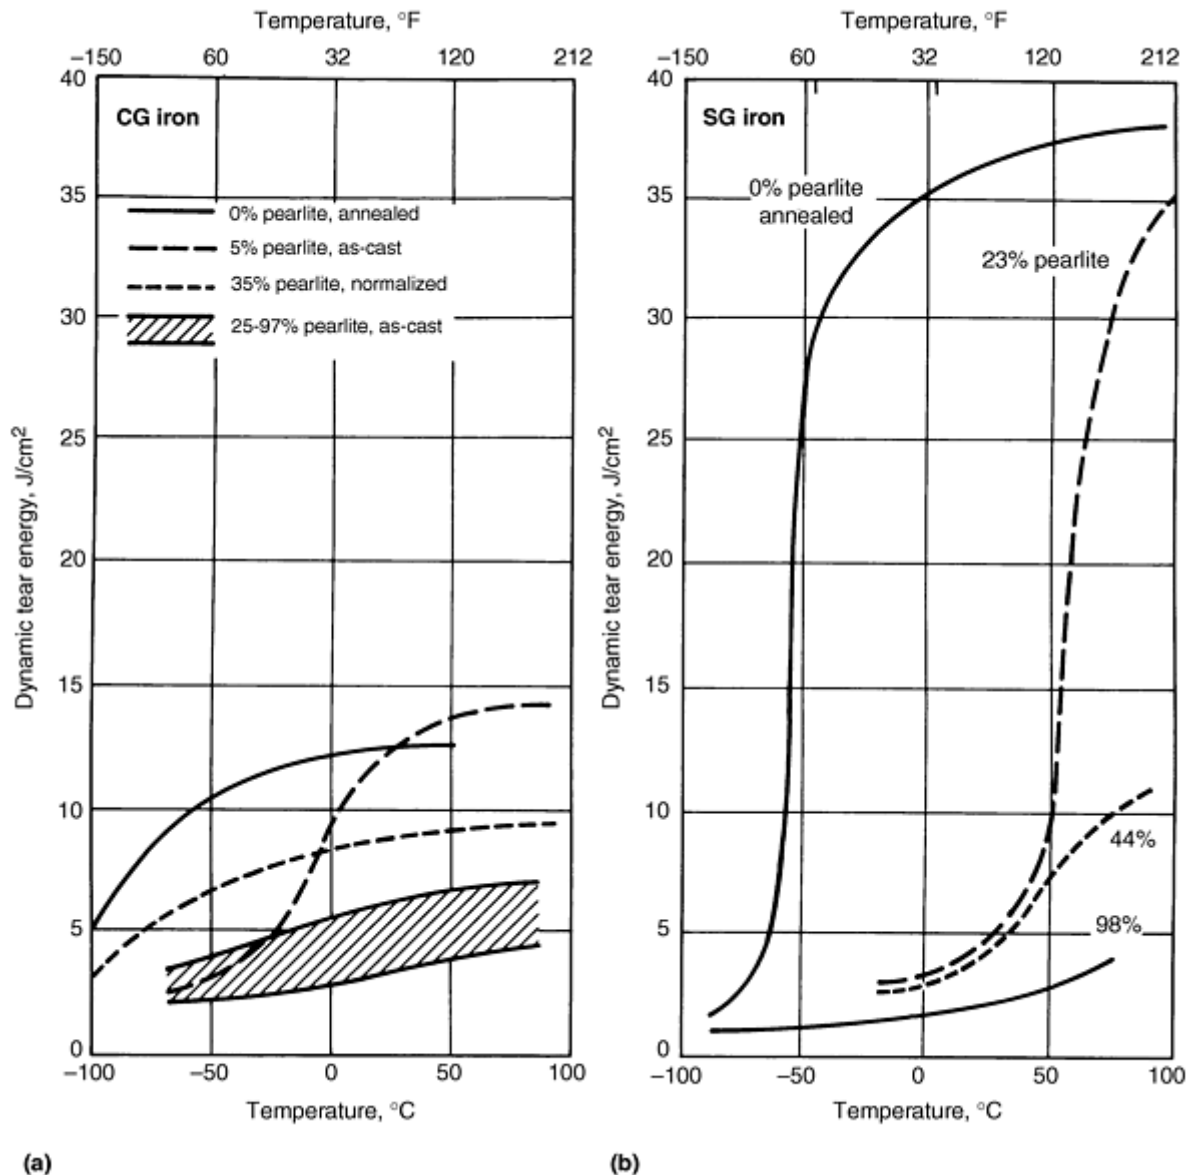

**FIG. 17 EFFECT OF HEAT TREATMENT ON CHARPY V-NOTCH IMPACT PROPERTIES OF DUCTILE IRON. SOURCE: METALS HANDBOOK, 9TH ED., VOL 1, P 42**

The use of Charpy V-notch data is generally inappropriate to determine dynamic fracture toughness of ductile irons (Ref 5). Because graphite debonding dominates the fracture process in ductile iron, Charpy V-notch specimens may be acceptable only when the internodular spacing is less than the standard notch root radius of 0.25 mm. This would require a nodular count of less than 20 mm<sup>-2</sup>, which is below the typical nodular counts in commercial ductile irons.

**Dynamic Tear Energy.** Upper-shelf dynamic tear energy for ferritic ductile iron is about 175 J (129 ft · lbf) for a standard 15.9 mm specimen, as compared to 100 J (73 ft · lbf) for malleable iron (Ref 5). Greater amounts of pearlite in the matrix microstructure reduce the upper-shelf toughness (Fig. 18b). With higher levels of pearlite, the upper-shelf toughness is comparable to that of compacted graphite cast iron (Fig. 18a). Similar comparisons are expected for upper-shelf toughness derived from Charpy testing.

**FIG. 18 EFFECT OF PEARLITE CONTENT ON THE TOUGHNESS OF (A) COMPACTED GRAPHITE (CG) CAST IRON AND (B) SPHEROIDAL GRAPHITE (SG) CAST IRON (I.E., DUCTILE IRON). THIS COMPARISON FOR SEVERAL DIFFERENT MATRIX MICROSTRUCTURES INDICATES THAT THE DELETERIOUS EFFECT OF VERMICULAR GRAPHITE ON FRACTURE TOUGHNESS IN CG IRON IS MUCH MORE PRONOUNCED FOR A FERRITIC MATRIX THAN FOR A PEARLITIC MATRIX. FURTHERMORE, THE COMPACTED GRAPHITE CAST IRON SEEMS TO HAVE A SOMEWHAT LOWER DUCTILE-TO-BRITTLE TRANSITION TEMPERATURE THAN DUCTILE IRON, POSSIBLY BECAUSE THE DUCTILE FRACTURE HAS BEEN MADE EASIER RELATIVE TO CLEAVAGE BY THE FORMATION OF COMPACTED GRAPHITE. SOURCE: REF 13**

**Fracture Toughness.** Early measurements of room-temperature fracture toughness of ferritic ductile irons were almost all incorrect. Systematic increases occurred over time as better test and evaluation methods were developed (Ref 5). Linear elastic fracture mechanics is not suitable for measuring the upper-shelf toughness of ferritic ductile irons unless very large specimens are used. Certain lower-strength grades of ductile iron do not fracture in a brittle manner when tested under nominal plane-strain conditions in a standard fracture toughness test. In the low-strength ductile irons, plane-strain conditions are established only at temperatures low enough to embrittle the ferrite. Otherwise, an increase in the size of the fracture toughness test specimens is necessary to provide the degree of mechanical constraint necessary to obtain a valid measurement of  $K_{Ic}$ .

Plane-strain fracture toughness ( $K_{Ic}$ ) at ambient temperature and upper-shelf regime is estimated at 88 to 90 MPa  $\sqrt{m}$  ( 80 to 81 ksi  $\sqrt{in}$  ) for ferritic ductile irons based on the review of Bradley and Srinivasan (Fig. 19). Upper-shelf  $K_{Ic}$  values of

100 MPa  $\sqrt{m}$  (90 ksi  $\sqrt{in}$ ) or more are also considered possible for ferritic ductile irons, as compared with 75 MPa  $\sqrt{m}$  (68 ksi  $\sqrt{in}$ ) for malleable irons (Ref 5). Typical fracture toughness results are shown in Fig. 19 and 20. These fracture toughness estimates are higher than earlier results (e.g., Table 13); as discussed in Ref 5, the data in Table 13 are not accurate because the specimen was too small for proper toughness results on a ductile material.

**FIG. 19 EFFECT OF MICROSTRUCTURE ON FRACTURE TOUGHNESS OF DUCTILE IRON. THESE RESULTS ARE GENERALLY BASED ON DATA FROM THE LITERATURE, WITH SOME APPROXIMATION IN REGIONS WHERE DATA WERE UNAVAILABLE. SOURCE: REF 5**

FIG. 20 COMPARISON OF FRACTURE TOUGHNESS OF FULLY FERRITIC DUCTILE IRON (GGG-40) WITH FERRITIC DUCTILE IRON WITH 15% PEARLITE IN MATRIX (S-45). SOURCE: REF 5

**Lower-shelf fracture toughness** is more consistent. Typical results for fully ferritic ductile iron and ferritic ductile iron with about 15% pearlite are presented in Fig. 20. The conclusion from review of data available (Ref 5) is that both ferritic and pearlitic ductile irons have similar lower-shelf fracture toughness values of about 23 to 28 MPa  $\sqrt{m}$  (21 to 25 ksi  $\sqrt{in}$ ). At temperatures above -110 °C, the fracture toughness of ferritic ductile iron increases sharply with increasing temperature. The presence of as little as 15% pearlite in ductile iron will cause a significant increase in the ductile-to-brittle transition temperature (Fig. 20). For temperatures around 0 °C, the fracture toughness  $K_{Jc}$  is a very sensitive function of the percentage of pearlite in the matrix, the latter affecting the fracture toughness by lowering the upper-shelf value and, more importantly, by shifting the ductile-to-brittle transition temperature.

**Dynamic Fracture Toughness.** Figures 11 and 12 summarize a review (Ref 5) of dynamic fracture toughness evaluations for ferritic and pearlitic grades of various cast irons. As expected, pearlite reduces upper-shelf toughness and increases transition temperatures.

There are only a few reliable results for  $K_{Id}$  and  $K_{Jd}$  for ferritic ductile iron published in the literature. The upper-shelf dynamic fracture toughness of ferritic ductile iron (with 2.3% silicon and having less than 100 mm<sup>-2</sup> nodule count) as measured by  $K_{Jd}$  is about 90 to 95 MPa  $\sqrt{m}$  (82 to 86 ksi  $\sqrt{in}$ ). This value decreases with increasing nodule count, decreasing nodularity, and increasing pearlite content in the matrix (Ref 5).

## Fatigue and Fracture Properties of Cast Irons

S. Lampman, ASM International

---

### Malleable Cast Irons

There are two basic types of malleable iron: blackheart and whiteheart. Blackheart malleable iron is the only type produced in North America and is the most widely used throughout the world. Whiteheart malleable iron is the older type and is essentially decarburized throughout in an extended heat treatment of white iron. Unless otherwise specified, this article considers only the blackheart type.

Malleable iron, like medium-carbon steel, can be heat treated to produce a wide variety of mechanical properties. The different grades and mechanical properties are essentially the result of the matrix microstructure, which may be a matrix of ferrite, pearlite, tempered pearlite, bainite, tempered martensite, or a combination of these (all containing nodules of temper carbon). This matrix microstructure is the dominant factor influencing the mechanical properties.

Minimum tensile properties and fatigue limits for whiteheart and blackheart malleable irons are summarized in Tables 14 and 15. Fatigue curves for a ferritic malleable iron are shown in Fig. 21 with fatigue curves for various compacted graphite irons. Fatigue curves for the ferritic grades of these two iron types are comparable. Notch radius generally has less effect on fatigue strength than notch depth for ferritic malleable irons (Fig. 22).

FIG. 22 EFFECTS OF NOTCH RADIUS AND NOTCH DEPTH ON THE FATIGUE STRENGTH OF FERRITIC MALLEABLE IRON. SOURCE: METALS HANDBOOK, 8TH ED., 1961, P 370

**Charpy Impact Toughness.** Like compacted graphite cast irons, malleable cast irons have a lower ductile-to-brittle transition than ductile irons with a comparable matrix microstructure. Malleable cast irons are generally regarded as having the best low-temperature toughness of the cast irons due to the lower silicon content (about 1% less silicon than ductile irons), which thus lowers the yield strength and the ductile-to-brittle transition temperature. Ferritic malleable cast iron has an upper-shelf Charpy energy of 13 J (9.5 ft · lbf), compared with 9 J (6.5 ft · lbf) for pearlitic malleable cast iron (Fig. 23). Other investigators have reported a lower transition temperature and a somewhat higher upper shelf Charpy energy of 19 to 20 J for ferritic malleable cast iron and 12 J for pearlitic malleable cast iron (Ref 15, 16). Dramatic reduction in upper-shelf toughness and increase in the ductile-to-brittle transition temperature result from phosphorus concentrations of 0.15% or greater in both ferritic and pearlitic malleable cast iron (Ref 17, 18). The phosphorus not only forms a very low-melting-point phosphide but also degenerates the graphite particle shape.

FIG. 23 CHARPY V-NOTCH TRANSITION CURVES FOR FERRITIC AND PEARLITIC MALLEABLE IRONS. SOURCE: REF 3

**Dynamic Tear Energy.** Figure 24 compares the tear energy of malleable iron with that of various ductile irons. As shown previously for compacted graphite irons (Fig. 18), ferritic malleable iron has a lower ductile-to-brittle transition than ductile iron. These data also show that annealing above the critical temperature reduces upper-shelf toughness compared to subcritical annealing.

FIG. 24 DYNAMIC TEAR ENERGY VERSUS TEMPERATURE FOR FOUR FERRITIC CAST IRONS. SPECIMEN SIZE: 190 MM ( $7 \frac{1}{2}$  IN.) LONG, 130 MM ( $5 \frac{1}{8}$  IN.) WIDE, AND 41 MM ( $1 \frac{5}{8}$  IN.) THICK; 13 MM ( $\frac{1}{2}$  IN.) NOTCH DEPTH. SOURCE: REF 28

**Fracture Toughness.** Some published data (such as those reported in Table 16 and Ref 19, 20, 21, and 22) have attempted to establish linear elastic ( $K_{Ic}$ ) fracture toughness limits for malleable irons. However, as discussed in Ref 5, the fracture toughness of malleable irons needs to be evaluated by an elastic-plastic criterion such as  $K_{Jc}$ . Upper-shelf  $K_{Jc}$  values range from 53 to 73 MPa  $\sqrt{m}$  (48 to 66 ksi  $\sqrt{in}$ ), as summarized in Table 17.

**TABLE 16 FRACTURE TOUGHNESS OF MALLEABLE IRONS FROM EARLY RESULTS**

Source: Ref 5

(A)  $K_{JMAX}$  VALUES WERE RECALCULATED FROM EARLIER WORK AND ARE ASSUMED TO EQUAL  $K_{Jc}$ .

Linear elastic fracture toughness values reported in the literature ( $K_{Ic}$  in Table 16 and  $K_{max}$  or  $K_Q$  in Ref 19, 20, 21, 22, and 23) are invalid in their indication of increases in upper-shelf toughness with increasing strength and/or lowering of temperature (Ref 5). While this may be a reasonable correlation for gray cast iron, it is not so for malleable cast iron. The reason is that a  $J$ -integral approach is needed to calculate the critical  $J$  value at or just before maximum load where crack extension begins (Ref 5). It is inadvisable to use  $K_Q$  or  $K_{max}$  for toughness ranking of malleable irons (Ref 5).

## Fatigue and Fracture Properties of Cast Irons

S. Lampman, ASM International

---

### White Cast Iron

A number of studies have been conducted to determine the fracture toughness of white cast iron (Fig. 25). White cast iron is generally used in applications where abrasion resistance is desirable. Gahr and Scholz (Ref 24) have found that the dynamic fracture toughness ( $K_{Id}$ ) values, measured on  $10 \times 10 \times 55$  mm specimens with a 0.2 mm wide slot, were in the range of 14 to 24  $MPa\sqrt{m}$  (13 to 22  $ksi\sqrt{in}$ ), while the quasistatic fracture toughness values, measured on fatigue precracked compact tension specimens, were in the range of 25 to 33  $MPa\sqrt{m}$  (23 to 30  $ksi\sqrt{in}$ ). Under dynamic loading, austenitic grades of white cast iron had better impact strength than did martensitic grades, though no such clear pattern was noted for  $K_{Id}$  values.

FIG. 25 RELATIONSHIP BETWEEN FRACTURE TOUGHNESS AND HARDNESS FOR WHITE CAST IRONS OF DIFFERENT MICROSTRUCTURES. SOURCE: REF 5

Eriksson (Ref 25) measured a fracture toughness value of  $22 \text{ MPa}\sqrt{m}$  ( $20 \text{ ksi}\sqrt{in}$ ) on a white cast iron sample with martensitic matrix corresponding to a Vicker's hardness value of 633. A comparison of his results (Fig. 25) with those of Gahr and Scholz indicates both lower hardness and lower toughness. This may be due to the presence of some flake graphite in samples tested by Eriksson.

## Bending Fatigue of Carburized Steels

George Krauss, Colorado School of Mines

---

### Introduction

BENDING FATIGUE of carburized steel components is a result of cyclic mechanical loading. The bending produces stresses, which are tensile at the surface, decrease with increasing distance into the component, and at some point become compressive. Such loading is a characteristic of rotating shafts and the roots of gear teeth. Carburizing produces a high-carbon, high-strength surface layer, or high-strength case, on a low-carbon, low-strength interior or core and is therefore an ideal approach to offset the high surface tensile stresses associated with bending. Thus when the design of a component maintains operating stress gradients below the fatigue strength of the case and core microstructures, excellent bending fatigue resistance is established.

There are, however, many alloying and processing factors that produce various microstructures, and therefore variable strength and fracture resistance, of the case regions of carburized steels. When applied surface stresses exceed the surface strength, surface fatigue crack initiation and eventual failure will develop (Ref 1). When the surface strength is adequate, depending on the steepness of the applied stress gradients in relationship to the case/core strength gradient, subsurface fatigue cracking may develop. The purpose of this article is to review the alloying and processing factors that influence the microstructures and bending fatigue performance of carburized steels.

## Bending Fatigue of Carburized Steels

George Krauss, Colorado School of Mines

---

### The Carburizing Process and Microstructure

Bending fatigue performance of carburized steels can vary significantly. One study reported values of experimentally measured endurance limits ranging from 200 to 1930 MPa (29 to 280 ksi), with most values between 700 and 1050 MPa (100 and 152 ksi) (Ref 2). This wide variation in fatigue performance is a result of variations in specimen design and testing, alloying, and processing interactions that produce large variations in carburized microstructures and the response of the microstructures to cyclic loading. A number of books and reviews have addressed the general relationships of processing to the microstructure and properties of carburized steels (Ref 3, 4, 5, 6, 7, 8, 9).

Gas carburizing is the most widely used heat-treating process for parts that must be produced in high volumes, but carburizing is also performed in liquid salt baths (Ref 3, 10), in solid carbonaceous material (Ref 3), by vacuum (Ref 11), and by plasma carburizing (Ref 12). Gas-carburized steels are exposed to atmospheres that contain partial pressures of oxygen-containing components, such as CO, CO<sub>2</sub>, and H<sub>2</sub>O, and therefore generally are subject to some degree of surface oxidation. The resulting surface oxides constitute another microstructural feature that may influence fatigue performance. Vacuum- or plasma-carburized parts that are carburized with partial pressures of only carbon-containing components, such as propane or methane, are not subject to surface oxidation.

The object of all carburizing processes is to expose the surface of a low-carbon steel to a carbon-containing atmosphere where austenite, with its high solubility for carbon, is stable, typically at temperatures between 850 and 950 °C (1560 and 1740 °F). The carbon diffuses into the steel, to a depth determined by steel composition, temperature, and time (Ref 13, 14). The carburized part is then quenched and the austenite transforms to martensite. The quenched parts are most often

subjected to a low-temperature tempering treatment at temperatures between 150 and 200 °C (300 and 400 °F), and very fine transition carbides precipitate in the martensite (Ref 9, 15, 16). The high-carbon, low-temperature-tempered (LTT) martensite that forms at the surface of a carburized part has the very high strength required for excellent bending and rolling contact fatigue (Ref 16). In addition, the sequence of phase transformations during quenching of a carburized part produces surface residual compressive stresses that greatly enhance resistance to bending fatigue (Ref 17, 18). However, microstructural features other than the LTT martensite, as discussed below, frequently affect fatigue performance.

Two major types of microstructures may form in the near-surface case regions of carburized steels (Ref 15, 19). Within both types, there are additional microstructural features (e.g., retained austenite, prior austenite grain size, carbide particles, nonmetallic inclusions, and surface oxides) that, depending on their densities and magnitudes, can influence fatigue performance. The first major microstructure type, illustrated in Fig. 1, consists of relatively coarse plates of LTT high-carbon martensite within a matrix of retained austenite. Typically it is formed by direct quenching of the austenite after lowering the temperature of the part from the carburizing temperature to about 850 °C in order to minimize distortion.

**FIG. 1 TYPICAL NEAR-SURFACE CASE MICROSTRUCTURE OF DIRECT-QUENCHED CARBURIZED STEEL. MARTENSITE PLATES ETCH DARK AND RETAINED AUSTENITE APPEARS WHITE. GAS-CARBURIZED AISI 8719 STEEL (1.06% MN, 0.52% CR, 0.5% NI, 0.17% MO). LIGHT MICROGRAPH, NITAL ETCH**

The second major type of microstructure, illustrated in Fig. 2, consists of lower-carbon martensite, retained austenite, and dispersed carbide particles. This type of microstructure is produced by reheating carburized parts to a temperature between the  $A_1$  and  $A_{cm}$  temperatures of the high-carbon case. At this temperature, carbides form, lowering the carbon content of the austenite. Upon cooling, the martensite that forms in the lower-carbon austenite is fine, with the morphology shifting from plate to lath martensite. The amount of retained austenite between the martensite crystals is reduced by virtue of the higher  $M_s$  temperatures of the lower-carbon parent austenite. The case LTT martensite-retained austenite microstructure of an intercritically reheated carburized part, in fact, is so fine that it cannot be clearly resolved in the light microscope.

**FIG. 2** TYPICAL NEAR-SURFACE CASE MICROSTRUCTURE OF CARBURIZED STEEL (SAE 8620: 0.81% MN, 0.19% MO, 0.48% NI) REHEATED BETWEEN  $A_1$  AND  $A_{CM}$ . ## Bending Fatigue of Carburized Steels

George Krauss, Colorado School of Mines

---

### Bending Fatigue Testing

Most bending fatigue data for carburized steels are presented as plots of maximum stress,  $S$ , versus the number of cycles,  $N$ , to fracture for a specified stress ratio ( $R$ ), which is the ratio of minimum (or compressive) stress to maximum tensile stress ( $R = \min-S/\max-S$ ). Figure 3 shows an example of typical  $S-N$  plots for a series of carburized alloy steels (Ref 6). The  $S-N$  curve consists of two parts: a straight section with negative slope at low cycles and a horizontal section at high cycles (Ref 20). The horizontal line defines the fatigue limit or endurance limit, which is taken to be the maximum applied stress below which a material is assumed to be able to withstand an infinite number of stress cycles without failure. Pragmatically, the endurance limit is taken as the stress at which no failure occurs after a set number of cycles, typically on the order of 10 million cycles. The low-cycle portion of the  $S-N$  plot defines various fatigue strengths or the stresses to which the material can be subjected for a given number of cycles. The more cycles at a given strength, the better the low-cycle fatigue resistance of a material.

FIG. 3 TYPICAL MAXIMUM STRESS ( $S$ ) VS. NUMBER OF CYCLES ( $N$ ) BENDING FATIGUE PLOTS FOR 6 CARBURIZED STEELS.  $R = -1$ . SOURCE: REF 6

Analysis of bending fatigue behavior of carburized steels based on  $S-N$  curves represents a stress-based approach to fatigue and assumes that the carburized specimens deform nominally only in an elastic manner (Ref 20). This assumption

is most valid at stresses up to the endurance limit and is useful when machine components are designed for high-cycle fatigue. However, as maximum applied stresses increase above the endurance limit, plastic strain becomes increasingly important during cyclic loading, and fatigue is more appropriately analyzed by a strain-based approach. In this approach, described in detail in the article "Fundamentals of Modern Fatigue Analysis for Design" in this Volume (and in many other books such as Ref 20 and 21), the total strain range is the sum of the applied elastic and plastic strains, and the strain amplitude is plotted as a function of the strain reversals required for failure at the various levels of strain.

According to the strain-based approach, low-cycle fatigue behavior is determined by plastic strains, while high-cycle fatigue behavior is determined by elastic strains. In particular, ductile materials with microstructures capable of sustaining large amounts of plastic deformation have better low-cycle fatigue resistance, while high-strength materials with high elastic limits and high yield strengths have better high-cycle fatigue resistance. Figure 4 shows the results of strain-based bending fatigue testing of uncarburized and carburized 4027 steel (Ref 22). The more ductile, low-strength uncarburized specimens show better fatigue resistance at low cycles than do the carburized specimens. The performance is reversed at high cycles, where the carburized specimens with their high-strength surfaces show better fatigue resistance, especially those specimens with the deeper cases.

FIG. 4 STRAIN AMPLITUDE VS. REVERSALS TO FAILURE FOR UNCARBURIZED (SOLID SYMBOLS) AND CARBURIZED (OPEN SYMBOLS) 4027 STEEL (0.80% MN, 0.28% SI, 0.27% MO). SOURCE: REF 22

### Specimen Design

Many types of specimens have been used to evaluate bending fatigue in carburized steels. Rotating beam (Ref 23), unnotched four-point bend (Ref 24), notched four-point bend (Ref 25, 26), and cantilever beam (Ref 27, 28, 29) specimens have all been used, and they have in common a maximum applied surface tensile stress and decreasing tensile stress with increasing distance into the specimen. Axial fatigue testing of carburized specimens, which applies the maximum tensile stresses uniformly over the cross section of a specimen, invariably results in subsurface initiation and propagation of fatigue cracks in the core of carburized specimens (Ref 22, 30), and therefore it does not permit evaluation of the resistance of case microstructures to fatigue.

Brugger was the first to use cantilever bend specimens to evaluate the fracture and fatigue of carburized steels (Ref 27). Figure 5 shows a cantilever bend specimen that has evolved from the Brugger specimen. The radius between the change in section simulates the geometry at the root of gear teeth and results in maximum applied surface stresses just where the cross section begins to increase, as shown in Fig. 6 (Ref 29). An important feature of this specimen is the rounding of the corners of the beam section. If the corners are square, the carbon introduced into the corner surfaces cannot readily diffuse into the interior of the specimen. As a result, the corner microstructures may have significantly elevated levels of retained austenite and coarse carbide structures, both microstructural features that influence bending fatigue resistance (Ref 29, 31).

FIG. 5 EXAMPLE OF A CANTILEVER SPECIMEN USED TO EVALUATE BENDING FATIGUE OF CARBURIZED STEELS. SPECIMEN EDGES ARE ROUNDED AND MAXIMUM STRESS IS APPLIED AT THE LOCATION SHOWN IN FIG. 6. DIMENSIONS IN MILLIMETERS. COURTESY OF R.S. HYDE

**FIG. 6 LOCATION OF MAXIMUM STRESS ON THE CANTILEVER BEND SPECIMEN SHOWN IN FIG. 5 AS DETERMINED BY FINITE ELEMENT MODELING. COURTESY OF K.A. ERVEN**

The maximum applied surface tensile stress is the testing parameter plotted in  $S-N$  curves that characterize bending fatigue. However, the applied stress ranges between maximum and minimum values during a fatigue cycle, and two other parameters, mean stress and stress ratio, are important for the characterization of fatigue. The mean stress is the algebraic average of the maximum and minimum stresses in a cycle, and as discussed above, the stress ratio,  $R$ , is the ratio of the minimum stress to the maximum stress in a cycle. Thus  $R$  values may range from  $-1$ , for fully reversed loading that ranges between equal maximum tensile and compressive stresses, to positive values where the stress is cycled between two tensile values (Ref 20). Much of the bend testing of cantilever specimens described below is performed with  $R$  values of  $0.1$  in order to preserve details of the fracture surface.

Figure 7 shows a typical allowable-stress diagram that plots fatigue strength versus mean stress for a given material (Ref 32). The diagram shows that the most severe condition for fatigue is for fully reversed testing with  $R = -1.0$ . As the mean stress increases, the fatigue strength in terms of maximum applied stress increases, but the allowable stress range decreases. Zurn and Razim (Ref 33) have examined the effect of notch severity and retained austenite on allowable-stress/mean-stress diagrams of carburized steels, and they conclude that carburizing, relative to the use of through-hardened steels, is especially effective for parts with sharp notches. In the absence of notches, carburizing is most suitable for parts subjected to fatigue loading at low values of mean stress.

FIG. 7 TYPICAL ALLOWABLE-STRESS-RANGE DIAGRAM. SOURCE: REF 32

The testing of actual machine components is another important approach to the fatigue evaluation of carburized steels. An example of component testing is the bending fatigue testing of single teeth in gears (Ref 34). Gears are fabricated, carburized, and mounted in a fixture so that one tooth at a time is subjected to cyclic loading. Recently, identically carburized specimens of the same steel were subjected to cantilever bend and single tooth bending fatigue testing (Ref 35). The mechanisms of fatigue failure, based on fracture surface examination, were found to be the same, but the single tooth testing showed higher levels of fatigue resistance than did the cantilever testing, a result attributed to the higher surface compressive stresses that were measured in the gear tooth specimens.

### Bending Fatigue of Carburized Steels

George Krauss, Colorado School of Mines

---

### Stages of Fatigue and Fracture

Bending fatigue fractures of carburized steels consist of well-defined stages of crack initiation, stable crack propagation, and unstable crack propagation. The fracture sequence is strongly influenced by the gradients in strength, microstructure, and residual stress that develop in carburized steels. Figure 8 shows a series of scanning electron microscope (SEM) fractographs that characterize the typical fracture sequence of a direct-quenched carburized steel with a near-surface case microstructure similar to that shown in Fig. 1. The cantilever bend specimen from which the fractographs of Fig. 8 were taken was a 4320 steel carburized to a 1 mm case depth at 927 °C (1700 °F), quenched from 850 °C (1560 °F) into oil at 65 °C (150 °F), and tempered at 150 °C (300 °F) for 1 h. The specimen was tested in bending fatigue with an  $R$  value of 0.1 (Ref 36). Figures 8(a) and 8(b) show a low-magnification overview of the initiation, stable propagation, and unstable fracture surfaces, and Fig. 8(c) shows the intergranular initiation and transgranular stable crack propagation zones of the fracture at a higher magnification.

**FIG. 8 FATIGUE FRACTURE IN GAS-CARBURIZED AND MODIFIED 4320 STEEL. (A) OVERVIEW OF INITIATION, STABLE CRACK PROPAGATION, AND UNSTABLE CRACK PROPAGATION. SEM MICROGRAPHS. SOURCE: REF 36**

Intergranular cracking at prior-austenite grain boundaries is an almost universal fracture mode in the high-carbon case of direct-quenched carburized steels (Ref 19, 23, 24, 36, 37). Not only do the fatigue cracks initiate by intergranular cracking, but also the unstable crack propagates largely by intergranular fracture until it reaches the lower-carbon portion of the case, where ductile fracture becomes the dominant fracture mode. In fact, sensitivity of the case microstructures to intergranular fracture makes possible the quantitative characterization of the size and shape of the stable fatigue crack, as shown in Fig. 8(b). The transition from the transgranular fracture of the stable crack to the largely intergranular fracture of the unstable fracture is identified by the dashed line.

A replica study of carburized specimens subjected to incrementally increasing stresses showed that surface intergranular cracks initiated when the applied stresses exceeded the endurance limits (Ref 36). Thus, it appears that in direct-quenched carburized specimens, intergranular cracks are initiated as soon as the applied surface bending stress reaches a level sufficient to exceed the surface compressive residual stress and the cohesive strength of the prior-austenite grain boundary structures. The surface intergranular cracks are shallow, typically on the order of two to four austenite grains, and are arrested, perhaps because of a plastic zone smaller than the grain size at the tip of the sharp intergranular cracks, and the fact that strain-induced transformation of retained austenite in the plastic zone ahead of the crack introduces compressive stresses (Ref 38, 39). The fatigue crack then propagates in a transgranular mode, and when the stable crack reaches critical size, as defined by the fracture toughness, unstable fracture occurs.

The initiation and stable crack zones of carburized steels are quite small and are often difficult to identify. Figure 9, based on the measurement of critical crack sizes in a number of direct-quenched carburized 4320 steels, shows that the size of the unstable cracks ranges from 0.170 to 0.230 mm, and that the cracks therefore become unstable well within the high-carbon portion of the carburized specimens. The small critical crack sizes are consistent with the low fracture toughness of high-carbon steel LTT microstructures susceptible to intergranular fracture (Ref 40). When the critical crack sizes and the stresses at which the cracks become unstable are used to calculate the fracture toughness of the case microstructures of carburized steels (Ref 36), the results show good agreement with the range of fracture toughness, 15 to 25 MPa $\sqrt{m}$ , that has been measured from through-hardened specimens with high-carbon LTT martensitic microstructures (Ref 40). Table 1 shows the data used to calculate the various case fracture toughness values in gas-carburized 4320 steel and the fracture toughness values calculated according to three different fracture toughness equations (Ref 36) as follows:

$$K_{IC} = \frac{1.2\sigma_a\sqrt{a\pi}}{Q} \quad (\text{EQ 1})$$

$$K_{IC} = \frac{\left[1.2\sigma_a + 0.683 \left(\frac{\partial\sigma}{\partial x}\right)a\right]\sqrt{a\pi}}{Q} \quad (\text{EQ 2})$$

and

$$K_{IC} = \frac{M\sigma_a\sqrt{a\pi}}{Q} \quad (\text{EQ 3})$$

where

$$Q = \phi^2 - 0.212 \left(\frac{\sigma_a}{\sigma_{ys}}\right)^2$$

with  $\phi$  the aspect ratio of crack depth ( $a$ ) and crack length ( $c$ ) such that:

$$\phi^2 = 1 + 1.464 \left(\frac{a}{c}\right)^{1.65}$$

SOURCE: REF 36**

The unstable crack that proceeds through the high- and medium-carbon martensitic portions of the case may be arrested when the sensitivity to intergranular fracture decreases at a case carbon content between 0.5 and 0.6% (Ref 41). The continued application of cyclic loading at this point then may cause a secondary stage of stable fatigue crack propagation, characterized by transgranular fracture, resolvable fatigue striations, and secondary cracking (Ref 23, 35, 37). This stage of low-cycle, high-strain fatigue is short and gives way to ductile overload fracture of the core.

## Intergranular Fracture of Carburized Steels

As noted above, intergranular fracture at the prior-austenite grain boundaries of high-carbon case microstructures dominates bending fatigue crack initiation and unstable crack propagation of direct-quenched carburized steels. The intergranular cracking may be associated with other microstructural features, such as the surface oxides generated by gas carburizing, but it generally extends much deeper into a carburized case than the oxide layer. Several studies have documented bending fatigue crack initiation by intergranular fracture even in the absence of surface oxidation, where for example the oxidized surface has been removed by chemical or electropolishing (Ref 24, 25) or no oxidation is present because the specimens were vacuum or plasma carburized (Ref 28).

Figure 10 shows an example of intergranular fatigue crack initiation in a direct-quenched specimen of gas-carburized type 8719 steel (Ref 42). There is a shallow zone of surface oxidation, about 10  $\mu\text{m}$  in depth, but the intergranular cracking extends much deeper into the specimen. Figure 11 shows extensive intergranular cracking in the unstable crack propagation zone in the case of a direct-quenched, gas-carburized 4320 steel. Auger electron spectroscopy shows that such intergranular fracture surfaces have higher concentrations of phosphorus and carbon, in the form of cementite, than do transgranular fracture surfaces removed from prior-austenite grain boundaries (Ref 19, 43, 44). Thus, the brittle intergranular fracture that occurs in stressed high-carbon case microstructures of carburized steels is associated with the combined presence of segregated phosphorus and cementite at prior-austenite grain boundaries. These grain boundary structures are present in as-quenched specimens and do not require tempering for cementite formation, as is typical in the intergranular mode of tempered martensite embrittlement in medium-carbon steels (Ref 15). This embrittlement, termed "quench embrittlement," is found in quenched steels with carbon contents as low as 0.6% (Ref 16). There is evidence that phosphorus segregation stimulates the formation of the grain boundary cementite (Ref 43, 44).

**FIG. 10 INTERGRANULAR BENDING FATIGUE CRACK INITIATION AT THE SURFACE OF A GAS-CARBURIZED AND DIRECT-COOLED SAE 8219 STEEL SPECIMEN. SOURCE: REF 42**

**FIG. 11 INTERGRANULAR FRACTURE IN CASE UNSTABLE CRACK PROPAGATION ZONE IN GAS-CARBURIZED AND DIRECT-COOLED SAE 4320 STEEL. COURTESY OF A. REGULY**

The higher the phosphorus content of a carburized steel, the lower its bending fatigue resistance and case fracture toughness. Figure 12 shows *S-N* curves for a series of gas-carburized and direct-quenched modified 4320 steels with systematic variations in phosphorus content from 0.031 to 0.005% (Ref 43). Endurance limits and low-cycle fatigue resistance increase with decreasing phosphorus content, but little difference is noted between the performance of the 0.005 and 0.017% phosphorus specimens. All of the specimens, even those with the lowest phosphorus content, failed by intergranular initiation of fatigue cracks.

**FIG. 12 EFFECT OF PHOSPHORUS CONTENT ON THE BENDING FATIGUE OF DIRECT-QUENCHED, GAS-CARBURIZED MODIFIED 4320 STEEL WITH 0.005, 0.017, AND 0.031 WT% PHOSPHORUS, AS MARKED. SOURCE: REF 43**

The bending endurance limits of gas-carburized specimens in which fatigue is initiated by intergranular fracture typically range between 1050 and 1260 MPa (Ref 45, 46). This range is based on studies of cantilever bend specimens with good surface finish, rounded specimen corners, nominal amounts of surface oxidation, and loading at  $R = 0.1$ . Variations within this range may be due to variations in austenitic grain size, inclusion contents, retained austenite content, or residual stresses, as discussed below. Nevertheless, the common mechanism of bending fatigue crack initiation of direct-quenched specimens is intergranular fracture at embrittled grain boundaries in a microstructure of LTT martensite and retained austenite, as described in Fig. 1.

Carburized steels with high nickel content do not appear to be as susceptible to intergranular cracking as steels with low nickel content (Ref 14, 47, 48). Also, major changes in the case microstructures of carburized steel, such as those produced by reheating and described relative to Fig. 2, result in bending fatigue crack initiation sites other than embrittled prior-austenite grain boundaries. Microstructural conditions that produce fracture initiation other than by intergranular cracking are also described below.

### Bending Fatigue of Carburized Steels

George Krauss, Colorado School of Mines

### Austenitic Grain Size and Fatigue

Prior-austenite grain size of carburized steels correlates strongly with bending fatigue resistance. Generally, the finer the prior-austenite grain size, the better the fatigue performance. For example, Fig. 13 shows a direct relationship of bending fatigue endurance limit on prior-austenitic grain size, plotted as the inverse square root of the grain size, for several sets of carburized 4320 steels (Ref 49).

FIG. 13 ENDURANCE LIMITS AS A FUNCTION OF PRIOR-AUSTENITE GRAIN SIZE FROM VARIOUS STUDIES OF

The refinement of austenite grain size has several effects on the case microstructure of carburized steels. A finer prior-austenite grain size produces a finer martensitic microstructure on quenching and therefore raises the strength of the carburized case. Increases in strength are beneficial to high-cycle fatigue resistance, as discussed above in the section on bending fatigue testing.

Another very important consequence of fine austenitic grain size is the dilution of the grain boundary segregation of phosphorus. In fact, very fine austenitic grain sizes can eliminate the sensitivity of high-carbon case microstructures to intergranular fracture. As a result, other mechanisms of fatigue crack initiation replace intergranular cracking, generally to the benefit of fatigue performance. The high values of endurance limits shown for the very fine grain specimens in Fig. 13 were associated with fatigue crack nucleation at surface oxidation, not at embrittled prior-austenite grain boundaries. Although, as discussed below, surface oxides form on austenite grain boundaries and fatigue cracks may nucleate on the oxide-covered austenite boundaries, fine-grain specimens show no intergranular fracture below the oxidized surface layers.

The most effective way to produce very fine grains in carburized steels is by slow cooling and reheating of carburized parts at temperatures below the  $A_{cm}$  where austenite and cementite are stable. The cementite particles effectively retard austenite grain growth and reduce the carbon content of the austenite, causing the type of microstructure shown in Fig. 2 to form on quenching. Specimens reheated to above the  $A_{cm}$  may show grain refinement, depending on the temperature of heating, but because all carbides are dissolved, grain size refinement is not as effective as in specimens heated below the  $A_{cm}$ , and the type of microstructure shown in Fig. 1 develops upon quenching (Ref 24). Figure 14 shows austenitic grain size as a function of distance from the carburized surface of gas-carburized 4320 steel specimens in the direct-quenched condition and after one and three reheating treatments (Ref 49). The reheat treatments very effectively reduce the near-surface case grain size where carbon content is the highest and therefore the greatest density of carbide particles is retained during intercritical reheating.

FIG. 14 PRIOR-AUSTENITE GRAIN SIZE AS A FUNCTION OF DEPTH FROM THE SURFACE OF GAS-CARBURIZED 4320 SPECIMENS IN THE AS-CARBURIZED, DIRECT-QUENCHED CONDITION AND REHEATED CONDITIONS.

Intercritical-temperature reheat treatments of carburized steels produce very fine austenitic grain sizes and high endurance limits. Typically the endurance limits are above 1400 MPa (Ref 24, 28, 49). However, the beneficial effects of the reheating on bending fatigue resistance are not due to grain size refinement alone. The reduced carbon content of the austenite when carbides are retained raises  $M_s$  temperatures and reduces the amount of retained austenite in the as-quenched case microstructures. Reduced levels of retained austenite raise the strength of case microstructures and therefore also may contribute significantly to the improved high-cycle fatigue performance of fine-grain, intercritically reheated carburized steels.

### Surface Oxidation and Fatigue

Elements such as chromium, silicon, and manganese, commonly found in low-alloy carburizing steels, readily oxidize during gas carburizing as a result of  $H_2O/H_2$  and  $CO/CO_2$  equilibria in the carburizing gas atmospheres (Ref 4, 50). Other elements, such as molybdenum, nickel, and iron, do not oxidize. Figures 15 and 16 show the characteristics of the surface oxidation in gas-carburized specimens of 20MnCr5 steel containing 1.29% Mn, 0.44% Si, 1.25% Cr, and 0.25% Ni (Ref 51). The oxides grow into the steel and form two zones. In the deeper zone, silicon- and manganese-containing oxides grow on austenite grain boundaries. Figure 16, an SEM fractograph, shows that the grain boundary oxides grow with a lamellar morphology. In the shallower zone, chromium-rich oxides nucleate and grow as dispersed particles within austenite grains. The depths of the oxidized zones depend on the composition of the carburizing gas, the time and temperature of carburizing, and the chemistry of the steel (Ref 52, 53). Because the oxides penetrate into the steel, especially along austenite grain boundaries, surface oxidation is also referred to as internal oxidation or intergranular oxidation (IGO).

FIG. 15 OXIDES (DARK FEATURES) AT SURFACE OF A GAS-CARBURIZED 20 MNCR 5 STEEL CONTAINING

FIG. 16 SURFACE OXIDES ON A FRACTURE SURFACE FROM A SPECIMEN OF THE STEEL IDENTIFIED IN FIG. 15. SOURCE: REF 51

The surface oxidation produced during gas carburizing may or may not significantly reduce bending fatigue resistance. The most severe effects of such oxidation are associated with a reduction in near-surface case hardenability, which results from the removal of chromium, manganese, and silicon from solution in the austenite by the oxide formation (Ref 54, 55, 56). The reduced case hardenability can cause nonmartensitic microstructures, such as ferrite, bainite, and pearlite, to form at the surface of the carburized steel. Not only is the surface hardness reduced, but the residual surface stresses may become less compressive or even tensile.

Figures 17 and 18 show the effects of surface oxidation with reduced hardenability on the bending fatigue and residual stresses of 8620 and 4615 gas-carburized specimens (Ref 57). The 4615 steel has higher hardenability by virtue of higher nickel and molybdenum contents and a lower sensitivity to surface oxidation by virtue of reduced manganese and chromium contents (Ref 57). As a result of the different chemistries, the 8620 steel formed pearlite in the near-surface regions of the case while the microstructure of the 4615 steel, despite some oxidation, consisted only of plate martensite and retained austenite at the surface (Ref 57). These differences in microstructures due to surface oxidation and reduced case hardenability are consistent with the differences in bending fatigue performance and residual stresses shown between the two steels in Fig. 17 and 18. This study illustrates the importance of steel chemistry on controlling surface oxidation and the associated formation of nonmartensitic microstructures in gas-carburized steels. Another approach used to reduce surface oxide formation in steels with low hardenability is to use more severe quenching with higher cooling rates.

**FIG. 17 S-N CURVES FOR DIRECT-QUENCHED GAS-CARBURIZED 4615 AND 8620 STEELS, NOTCHED 4-POINT BEND SPECIMENS. NON-MARTENSITIC TRANSFORMATION PRODUCTS WERE PRESENT ON THE SURFACES OF THE 8620 STEEL SPECIMENS AND ABSENT ON THE 4615 STEEL SPECIMENS. SOURCE: REF 57**

**FIG. 18 RESIDUAL STRESS AS A FUNCTION OF DEPTH BELOW THE SURFACE OF THE DIRECT-QUENCHED GAS-CARBURIZED 4615 AND 8620 STEEL SPECIMENS DESCRIBED IN FIG. 17. SOURCE: REF 57**

If the hardenability of a steel is sufficient to prevent the formation of nonmartensitic microstructures for a given gas carburizing and quenching schedule, surface oxidation has a much reduced effect on bending fatigue performance. In direct-quenched specimens, as discussed above and demonstrated in Fig. 10, intergranular fracture to depths much deeper than the oxidized layers dominates fatigue crack initiation. However, when the conditions for intergranular crack initiation are minimized, as for example by reheating (Ref 24, 49) or shot peening (Ref 58), the surface oxide layers become a major location for bending fatigue crack initiation. Figure 19 shows crack initiation in the oxidized zone of a gas-carburized and reheated specimen of 4320 steel. The initiation is confined to the oxidized zone, and stable transgranular fatigue propagation proceeds directly below the oxidized zone with no evidence of intergranular fracture.

FIG. 19 BENDING FATIGUE CRACK INITIATION IN GAS-CARBURIZED AND REHEATED 4320 STEEL. THE DASHED LINE CORRESPONDS TO MAXIMUM DEPTH OF SURFACE OXIDATION, AND ALL FRACTURE BELOW DASHED LINE IS TRANSGRANULAR. SOURCE: REF 49

## Bending Fatigue of Carburized Steels

George Krauss, Colorado School of Mines

---

### Retained Austenite and Fatigue

Next to LTT martensite, retained austenite is the most important microstructural component in the case of carburized steels. The amounts of retained austenite vary widely, depending on carbon and alloy content, heat-treating conditions, and special processing steps such as shot peening and subzero cooling (Ref 9, 15). Generally, the higher the carbon and alloy content, the lower the  $M_s$  temperature and the higher the retained austenite content in the microstructure. The low-temperature tempering applied to carburized steels, generally performed at temperatures below 200 °C (400 °F), is not high enough to cause the retained austenite to transform, and therefore retained austenite remains an important component of the microstructure. At higher tempering temperatures, retained austenite transforms to cementite and ferrite with attendant decreases in hardness and strength as the martensitic microstructure coarsens (Ref 15).

The role that retained austenite plays in the bending fatigue performance of carburized steels has been difficult to identify because of the variable loading conditions that may be applied to carburized machine components and the complicating effects of other factors, such as residual stresses, grain boundary embrittling structures, and surface oxidation. With respect to loading conditions, it appears that higher amounts of retained austenite are detrimental to high-cycle fatigue and reduce endurance limits (Ref 28, 33, 38), while higher amounts of retained austenite are beneficial for low-cycle, high-strain fatigue (Ref 38, 59, 60).

Reduced retained austenite contents of LTT martensite/austenite composite microstructures increase elastic limits and yield strengths (Ref 61) and therefore benefit stress-controlled, high-cycle fatigue. One of the approaches to reducing the retained austenite content in the case microstructures of carburized steels, as noted above, is to reheat carburized specimens to temperatures below the  $A_{cm}$  and quench to produce the type of microstructure shown in Fig. 2. Invariably such reheating and quenching significantly increases bending fatigue endurance limits compared to direct-quenched specimens of identically carburized specimens (Ref 24, 49). The reheating not only reduces retained austenite but also refines the austenitic grain size, refines the martensitic structure, and reduces susceptibility to intergranular fracture, all features that are known to improve fatigue resistance. Therefore, improved high-cycle fatigue resistance of reheated and quenched specimens is related to a combination of microstructural changes, including low retained austenite contents.

The benefit of retained austenite to strain-controlled, low-cycle bending fatigue is related to the improved ductility and reduced strength and hardness that retained austenite contributes to a composite LTT martensite/austenite case microstructure. In addition, retained austenite, at sufficiently high applied strains and stresses, undergoes deformation-induced transformation to martensite (Ref 62). The volume expansion associated with the strain-induced formation of martensite creates compressive stresses (Ref 39) that lead to reduced rates of fatigue crack growth, accounting for the enhanced low-cycle fatigue performance that is observed in carburized steels with high amounts of retained austenite in the case (Ref 60).

## Subzero Cooling and Fatigue

Cooling carburized steel below room temperature is a processing approach sometimes used to reduce the retained austenite content in the case regions of carburized steels. The transformation of austenite to martensite is driven by temperature changes, and the low  $M_s$  temperatures of high-carbon case regions of carburized alloy steels limit the temperature range between  $M_s$  and room temperature over which martensite forms (Ref 15). Therefore, the temperature range for martensite formation and the reduction of retained austenite is extended by cooling below room temperature. The cooling treatments are variously referred to as subzero cooling, refrigeration treatments, or deep cooling.

In addition to the effects of retained austenite on bending fatigue, as discussed above, any deformation-induced transformation of retained austenite during cyclic loading in service, because of the volume expansion that accompanies the transformation of austenite to martensite, may change the dimensions of a carburized component. Therefore, subzero cooling is one approach to reduce retained austenite in parts that require high precision and stable dimensions throughout their service life. However, several studies show that subzero cooling lowers the bending fatigue resistance of carburized steels. Nevertheless, high-quality, high-performance aircraft and helicopter gears are routinely subjected to subzero cooling without apparent detrimental effects (Ref 63). For example, a commonly used carburizing steel for aircraft gears is 9310, which contains about 3 wt% nickel. The high nickel content lowers the  $M_s$  temperature and increases the amount of austenite at room temperature. The austenite content can be reduced by subzero cooling, probably with adverse effects on localized residual stress, as discussed below. However, the latter adverse effect of subzero cooling may be offset by fine austenite grain size, and high nickel content may improve the fracture toughness and fatigue resistance of carburized steels (Ref 14, 47, 48, 64) to a level where fatigue resistance is not adversely affected by subzero cooling.

In the low-alloy steels commonly used for carburizing, subzero cooling used to reduce retained austenite may reduce the bending fatigue resistance of carburized components. According to Parrish and Harper (Ref 5), refrigeration treatments should be "considered as a last resort," and if they are applied, parts should be tempered both before and after. Figure 20

shows an example of the detrimental effects of subzero cooling on the bending fatigue resistance of carburized specimens. The data were produced in an experimental study of vacuum-carburized specimens of 8620 and EX 24 steel that were deep cooled to  $-196\text{ }^{\circ}\text{C}$  in liquid nitrogen (Ref 31). The overall fatigue performance in this study was complicated by high retained austenite contents and coarse carbide particles at square specimen corners, but the detrimental effect of subzero cooling on bending fatigue performance is clearly demonstrated in Fig. 20.

**FIG. 20 S-N CURVES OF VACUUM-CARBURIZED 8620 AND EX 24 (0.89% MN, 0.24% MO, 0.55% CR) STEELS. THE LOWER CURVES WERE OBTAINED FROM SPECIMENS SUBZERO COOLED TO  $-196\text{ }^{\circ}\text{C}$  AND THE UPPER CURVES WERE OBTAINED FROM SPECIMENS NOT SUBJECTED TO SUBZERO COOLING. SOURCE: REF 31**

The detrimental effect of subzero cooling on the bending fatigue of carburized specimens has been related to changes in residual stress by several investigations (Ref 23, 65, 66). The overall surface residual stresses become increasingly compressive, as measured from the martensite in the case and as expected from the constraint of the expansion that accompanies the transformation of austenite to martensite as temperature is decreased. However, the residual stresses in the austenite phase are measured to be tensile, especially at the surface of the carburized specimens. These tensile stresses would then be expected to lower the surface tensile stresses applied in bending to initiate fatigue cracks. Microcrack formation within martensite plates and at plate/austenite interfaces (Ref 67) may be enhanced by the localized residual stresses induced by subzero cooling (Ref 66), but they could be minimized by maintaining a fine prior-austenite grain size and applying reheating treatments (Ref 68, 69).

### Residual Stresses and Shot Peening

Compressive residual stresses are formed in the case microstructures of carburized steels as a result of transformation and temperature gradients induced by quenching (Ref 17, 18). The magnitude and distribution of the residual stresses therefore are complex functions of the temperature gradients induced by quenching (Ref 70), which in turn are dependent on specimen size and geometry, the hardenability of the steel, the carbon gradient, and the case depth. The residual stresses as a function of case depth are routinely measured by x-ray diffraction (Ref 71), and considerable effort has been applied to modeling residual stress profiles in carburized steels as a function of cooling and hardenability (Ref 72, 73, 74).

Figure 21 shows the range and pattern of compressive residual stresses typically formed in the case regions of direct-cooled carburized steels (Ref 5). The compressive residual stresses offset the adverse effects of factors such as quench embrittlement and intergranular fracture to which high-carbon microstructures are susceptible (Ref 16), and they increase the fracture and fatigue resistance of direct-quenched parts to levels that provide good engineering performance. As discussed above, case residual stresses in carburized steels are adversely modified by subzero cooling, and they are positively modified (made locally more compressive) by the strain-induced transformation of austenite to martensite. Tempering lowers residual compressive stresses because of dimensional changes that accompany the recovery and coarsening of the martensitic microstructure during tempering (Ref 75).

FIG. 21 RANGES AND PATTERNS OF RESIDUAL STRESSES AS A FUNCTION OF DEPTH FOR 70 CARBURIZED STEELS. SOURCE: REF 5

Shot peening is an effective way to increase the case compressive residual stresses in carburized steels (Ref 52, 76, 77, 78) and as a result improve the bending fatigue performance. Shot peening causes deformation-induced transformation of case retained austenite, and the constraint of the associated volume expansion causes the development of additional compressive stresses. Figures 22, 23, and 24 show, relative to unpeened specimens, the decrease in retained austenite, the increase in the case compressive stresses, and the increased bending fatigue performance, respectively, that are associated with shot peening of direct-quenched carburized 4320 specimens (Ref 58).

## Contact Fatigue of Hardened Steels

R. Scott Hyde, The Timken Company

---

### Introduction

CONTACT FATIGUE is the cracking of a surface subjected to alternating Hertzian stresses (Ref 1) produced under combined rolling and sliding loading conditions. In addition to cracking, contact fatigue can result in microstructural alterations, including changes in retained austenite, residual stress, and martensite morphology. When traction forces (frictional) are negligible, this phenomenon is known as rolling contact fatigue. However, frictional forces are always present and thus contact fatigue will be the term used in this article to describe this phenomenon. Contact fatigue is encountered most often in rolling-element bearings and gears, where the surface stresses are high due to concentrated loads that are repeated many times during normal operation. The mechanism of contact fatigue can be understood in terms of several sources of stress concentration, or stress raisers, within the macroscopic Hertzian stress field.

The location of contact fatigue initiation is dependent on the applied normal load, the magnitude of surface tractive forces, and type and location of stress raisers, resulting in surface or subsurface fatigue initiation. Surface initiation is usually controlled by asperities, oxides, defects, and geometry, whereas subsurface initiation is due to inclusions, carbides, defects, and grain boundaries. Other factors that influence fatigue initiation and propagation are microstructure/hardness and residual stress profile.

It is useful to classify contact fatigue damage according to a system that is related to origin, propagation mode, and macroscopic appearance of advanced stages of damage. Material and environmental factors coupled with load, contact geometry, surface microtopography, and conditions of lubrication are the primary variables that combine to determine the predominant mode(s) of contact fatigue damage.

Component damage due to contact fatigue can be reduced through enhancements in lubrication, steel cleanliness, alloy selection, surface finish, geometry and design, and manufacturing techniques. These enhancements focus on providing greater resistance to contact fatigue, thus translating into a more power-dense component or system by improving life or increasing load-carrying capabilities (Ref 2). Improved contact fatigue resistance of bearings and gears depends on the mechanisms of contact fatigue, the controlling metallurgical and tribological factors, and the use of improved, cleaner materials that have been properly heat treated to the optimal hardness and correct microstructure.

## Contact Fatigue of Hardened Steels

R. Scott Hyde, The Timken Company

---

### Cyclic Contact Stresses

Contact stresses are caused by the pressure of one solid in contact with another solid over limited areas of contact (Ref 3). Most machine components are designed on the basis of stress in the main body of the member, that is, in portions of the body not affected by the localized stresses. In other words, damage to most mechanical components is associated with stresses and strains in portions of the component far removed from the points of application of the loads. However, in certain situations the contact stresses between the surfaces of two externally loaded bodies (e.g., meshing gear teeth or contact between the roller or ball and its race in a bearing) can be the significant stresses; that is, the stresses on or

somewhat below the surface of the contact are the major causes of damage to one or both of the bodies. Therefore, analysis of cyclic (Hertzian) stresses provides important information about surface and subsurface stresses for static loading of concentrated contacts, particularly the location of the maximum shear stress below the surface. The following review on dynamic loads and stress variation under rolling/sliding conditions is thus important to the understanding of cyclic stresses that cause contact fatigue.

**Hertzian Shear Stresses at and below the Contact Surfaces.** Damage caused by contact fatigue is the result of cyclic shear stresses developed at or near contact surfaces during operation. The effects on the shear stress field below the surface of a bearing raceway as a cylindrical roller travels across the surface is shown schematically in Fig. 1 (Ref 4). The initial location of the roller is shown at position 1 (Fig. 1a). The material directly below the roller experiences no shear stresses parallel to the coordinate axes,  $\tau_{zy}$  and  $\tau_{yz}$ , but the maximum shear stress,  $\tau_{max}$ , is depicted on planes at  $45^\circ$  to the coordinate axes. The  $\tau_{zy}$  and  $\tau_{yz}$  stresses are referred to as orthogonal shear stress ( $\tau_o = \tau_{zy} = \tau_{yz}$ ) and the  $\tau_{max}$  is referred to as the octahedral shear stress. However, the adjacent material is subjected to shear stresses parallel to the coordinate axes,  $\tau_{zy}$  and  $\tau_{yz}$ , and the material more distant from the roller experiences no applied shear stresses. As the roller moves to position 2 in Fig. 1(b), the shear stresses below the roller become a maximum in the planes oriented  $45^\circ$  to the surface and  $\tau_{zy}$  and  $\tau_{yz}$  tend toward zero. Similar to Fig. 1(a), the adjacent material exhibits shear stresses  $\tau_{zy}$  and  $\tau_{yz}$  equal to a finite value. With the roller in position 3 (Fig. 1c), the shear stresses below the roller again reach a maximum  $\tau_{max}$  on  $45^\circ$  planes and  $\tau_{zy}$  and  $\tau_{yz}$  approach zero. Meanwhile, the adjacent material reverts back to only  $\tau_{zy}$  and  $\tau_{yz}$  having finite values, and the material away from the roller experiences no applied stresses. It should be noted that the shear stress field in position 2 changes direction from Fig. 1(a) to (c). Although  $\tau_o$  is always smaller than  $\tau_{max}$ , for a given point in a contacting body,  $\tau_o$  changes sign as the rolling element approaches and leaves the region above the point. Therefore, the range of the maximum orthogonal shearing stress is  $2\tau_o$ , and for most applications this range is greater than the range of the octahedral shearing stress. These alternating shear stresses cause fatigue and are believed to be the primary contributor to bearing damage. Rolling bearing fatigue is based on the Lundberg-Palmgren theory (Ref 5). The Lundberg-Palmgren theory postulates that the stress responsible for fatigue damage is the orthogonal shear stress, which can be derived from the Hertzian pressure distribution in the contact surface and the subsurface. The orthogonal shear stress amplitude reaches a maximum simultaneously in two planes, one parallel and one perpendicular to the contact surface. Damage resulting from contact stresses starts as a localized, inelastic cyclic deformation (localized yielding or distortion) followed by the initiation and propagation of a crack. Inelastic deformation theories are based on material deformation occurring when either the maximum shearing stress (Tresca's criterion) or the maximum octahedral shearing stress (von Mises criterion) at any point in a component reaches a critical value that causes slip of the crystal along specific crystallographic planes (Ref 3). The maximum shearing stress is given by:

$$\tau_{max} = \frac{1}{2} (\sigma_1 - \sigma_3)$$

where  $\sigma_1$  and  $\sigma_3$  are the maximum and minimum values of the principal stresses at a point. The maximum octahedral shearing stress is given by the equation:

$$\tau_{oct (max)} = \frac{1}{3} \sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2}$$

where  $\sigma_1$  and  $\sigma_3$  are defined as before and  $\sigma_2$  is the third principal stress.

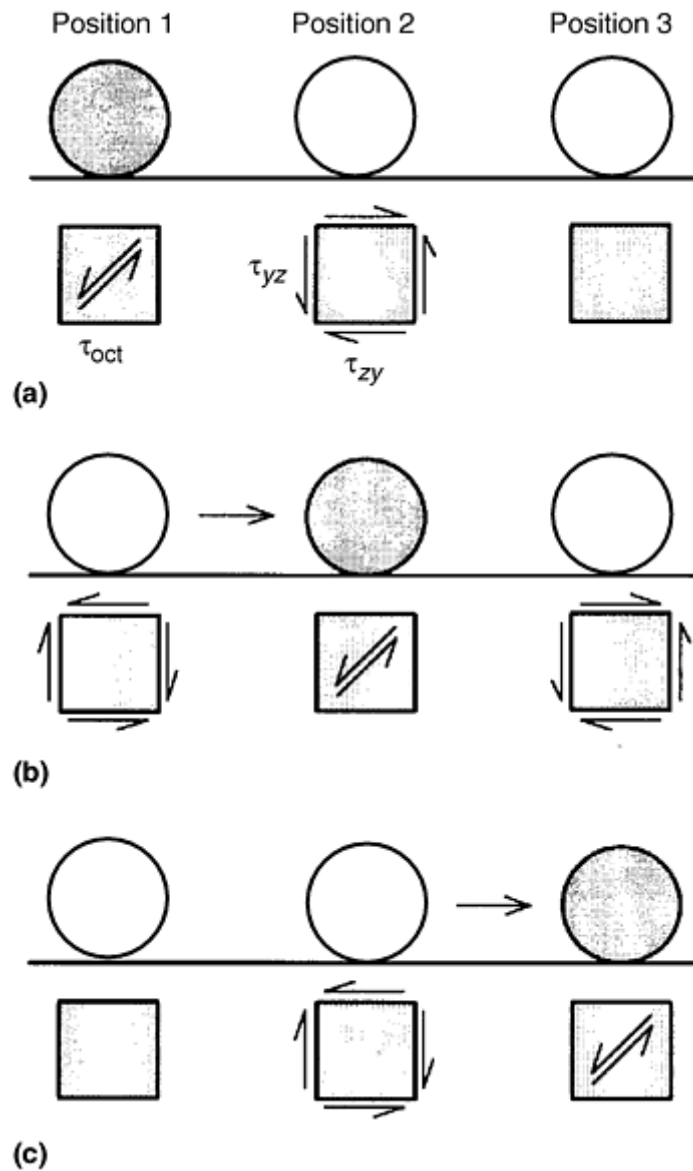

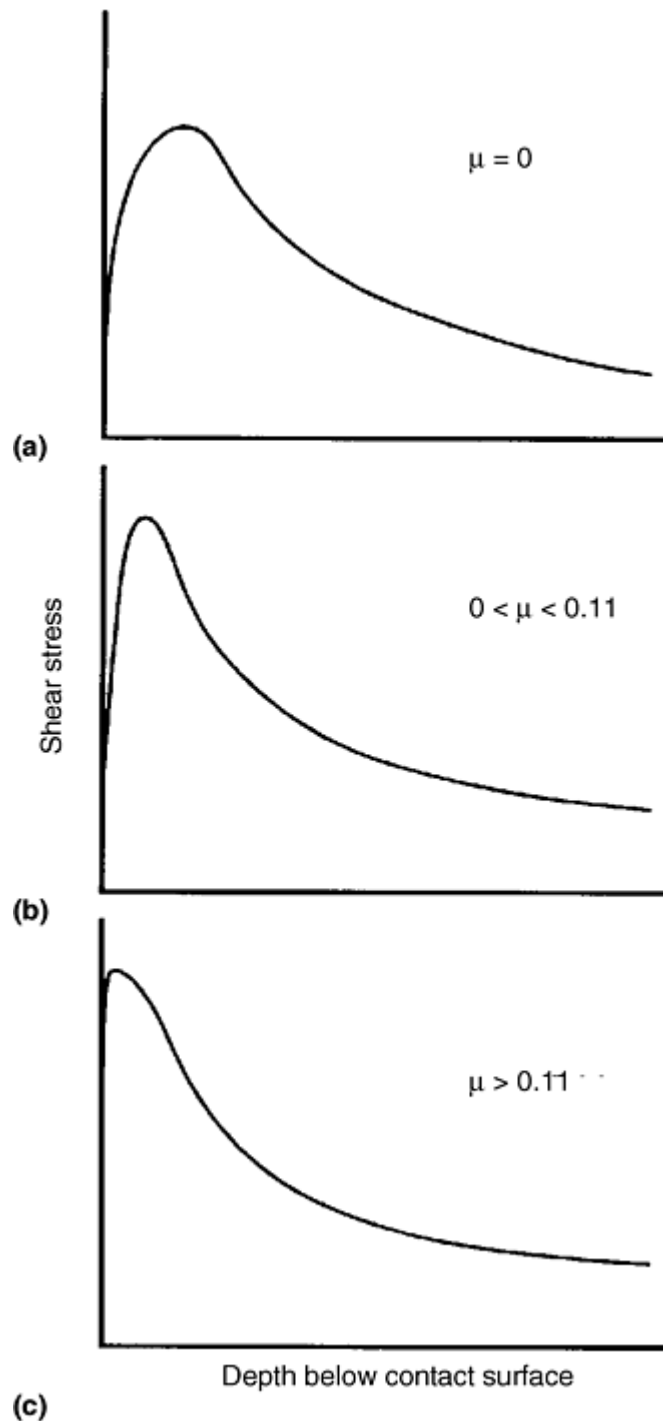

FIG. 1 SCHEMATIC OF THE VARIATION OF SUBSURFACE SHEAR STRESSES AT ONE DEPTH FOR THREE LOCATIONS IMMEDIATELY BELOW, AHEAD, AND BEHIND THE ROLLING ELEMENT; THIS IS A TWO-DIMENSIONAL VIEW FOR "LINE CONTACT" AND ALSO APPLIES TO A PLANE CONTAINING THE ROLLING DIRECTION, THROUGH THE CENTER OF A POINT CONTACT. AT DIFFERENT DEPTHS BELOW THE CONTACT SURFACE, THE VARIATION OF SHEAR STRESSES WILL BE SIMILAR, BUT OF DIFFERENT MAGNITUDE FOR PURE ROLLING. WHEN SLIDING IS SUPERIMPOSED WITH THE ROLLING, THE TANGENTIAL FRICTION FORCES AT THE SURFACE MODIFY THE RANGE OF SHEAR STRESSES FROM THE PURE ROLLING SITUATION AT ANY GIVEN LOCATION AT AND BELOW THE SURFACE.

If normal forces act alone, that is the friction coefficient is zero, the stresses would be (Ref 6):

$$\begin{aligned} \sigma_{1MAX} &= -P_0, \sigma_{2MAX} = P_0, \text{ AND } \sigma_{3MAX} = -0.5P_0 \\ \tau_{MAX} &= 0.30 P_0 \\ \tau_{OCT(MAX)} &= 0.27 P_0 \end{aligned}$$

and these values of  $\tau_{max}$  and  $\tau_{oct(max)}$  occur on the  $z$ -axis at a certain distance below the contact surface. This distance is a function of only contact geometry. Figure 2(a) shows a schematic of stress variations with respect to depth in a solid subjected to static contact stresses only.

**FIG. 2 VARIATIONS IN MAXIMUM SHEAR STRESS AS A FUNCTION OF DEPTH FOR THREE DIFFERENT FRICTION COEFFICIENTS; (A)  $\mu \approx 0$ , (B)  $0 < \mu < 0.11$ , AND (C)  $\mu > 0.11$ . THIS FIGURE IS FOR STATIC LOADING, BUT THE RANGE OF SHEAR STRESS VERSUS DEPTH IS ALSO AT OR VERY NEAR THE SURFACE FOR TANGENTIAL FORCES FROM ROLLING/SLIDING CONTACT.**

However, if tangential forces (frictional) act in addition to the normal forces, both principal and shear stresses increase. It has been found that tangential forces caused by a coefficient of friction equal to 0.33 increases the maximum principal stress by 39%, the maximum shearing stress by 43%, and the maximum octahedral shearing stress by 37% (Ref 6). Furthermore, the location of these maximum shearing stresses changes with variations in friction coefficient, such that, as the friction coefficient increases from zero, depth of the shear stress maxima decreases. Investigation shows that when the coefficient of friction is greater than 0.11 shearing stress maxima are located on the contact surface, but below 0.11 these stress maxima are found a distance beneath the surface (Ref 6). This distance is now a function of both contact geometry

and the degree of tangential forces. Figures 2(b) and 2(c) show schematics of stress variations with respect to depth in a solid subjected to contact stresses and tangential forces.

In order to better understand the mechanism of contact fatigue, an understanding of the design characteristics of the application (rolling-element bearings and gears), the basic applied stresses, and the generation of operating stresses is required. Therefore, bearings and gear characteristics are briefly summarized below. In addition, variations of normal and shear stresses also need to be considered in three dimensions. Three-dimensional variations of normal and shear stresses for point contact and for the ends of line contact in bearings and gears are important under conditions of inadequate crowning or end geometry modifications.

**Rolling-element bearings**, ball and roller, use rolling elements interposed between two raceways and relative motion is permitted by the rotation of these elements. Bearing raceways that conform closely to the shape of the rolling elements are normally used to house the rolling elements. The rolling elements are usually positioned within the bearing by a retainer, cage, or separator. However, in some ball, cylindrical roller, and needle bearings, the elements occupy the available space and locate themselves by contact with each other. Fatigue damage of rolling-element bearings is usually termed rolling contact fatigue due to the negligible tractive forces present in most bearings of this type. Roller bearings develop line-contact loading due to their cylindrical shape, and ball bearings tend to develop point contact loading. This difference, in conjunction with the double-axis rotation inherent in ball bearings, results in variations in contact fatigue fracture appearance (Ref 7).

**Ball bearings** can be divided into three categories depending upon the direction of applied load: radial contact, angular contact, and thrust. Radial contact ball bearings are designed for applications in which loading is primarily radial with only low thrust (axial) loads. Angular contact bearings are used in applications that involve combinations of radial and high axial loads and require precise positioning of shafts. Thrust bearings are used primarily in applications involving axial loads. Roller bearings have higher load-carrying capacities than ball bearings for a given envelope size (outer dimensions) and are usually used in moderate speed, heavy-duty applications. However, improvements in materials, design, and manufacturing have now made the use of these bearings in high-speed applications practical (Ref 4). Principal types of roller bearings are cylindrical, needle, tapered, and spherical.

**Gears** transmit motion and force from one machine component to another. This transmission of motion and force may be in either the same plane and direction or in a different plane and/or direction. Similar to rolling-element bearings, there are many types of gears: spur, worm, helical, and bevel (straight, spiral, and hypoid) (Ref 8). Spur and helical gears transmit motion in the same plane, whereas bevel gears change the plane of motion. The design and function of gears are associated, since the design is based on a specific function. The basic design of gears results in line or point contact of properly aligned teeth, which results in the development of contact stresses. However, because of the occurrence of elastic deformation (deflection) on the surface of loaded teeth and misalignment in service, contact occurs along narrow bands or in small areas instead of along the expected line contact. The radius of curvature of the tooth profile has an effect on the amount of deformation, the width of the resulting contact bands, and the overall contact stress field.

As a contacting gear tooth moves up the profile of the loaded tooth, a sliding-rolling action takes place at the profile interface. At the pitch line, tractive forces are negligible and loading conditions resemble those developed in roller bearings (Ref 9). Above the pitch line, a rolling-sliding action takes over, but the sliding is in the opposite direction. The action on the profile of the contacting tooth is exactly the same as on the loaded tooth, except in reverse order.

In addition to the sliding and contact stresses, gear teeth experience tensile and compressive stresses that are greatest within the root area (Ref 10). However these stresses develop along the tooth profile up to the point of contact and therefore play a role in contact fatigue damage. The main differences between gear types are the degree and direction of sliding action that takes place as a tooth cycles in and out of mesh. The degree of sliding, and thus of tractive forces, are more significant in gears than in rolling-element bearings, resulting in the maximum shear stresses that are much closer to or on the contact surfaces.

## Gear and Bearing Materials

Although this article focuses primarily on the rolling contact fatigue of hardened bearing steels, this section provides a brief overview of the key types of gear and bearing steels. In addition, a brief discussion of nonferrous gear and bearing materials is also included as general background.

For both gear and bearing steels, it is important to recognize the differences between carburized steels and through-hardened steels in terms of material selection, fatigue performance, and failure analysis or fracture appearance. In terms of fatigue behavior, for example, it is understood that through-hardened and case-hardened parts are very different in initiation and propagation periods. Spalls (or more generally macropitting) may propagate slower and sometimes seem to stop for periods in carburized material, possibly because of the usually higher residual stresses near the surface than in through-hardened steel. Through-hardened steels probably have better dimensional stability and accept higher contact stresses because of lower retained austenite. However, carburized steels may be less sensitive to surface-initiated failure and run-in or changes of the surface roughness may be different, occurring in different, perhaps shorter, time periods.

Differences between these two different types of steels may also be a factor in selection of a specific steel dictated by the primary performance characteristics required for specific applications. In other words, specific factors listed in the section "Factors Influencing Contact Fatigue Life" in this article may be more important than others, depending on the specific failure mode(s) expected based on the operating and environmental conditions of a Hertzian contact.

**Gear Materials.** A variety of cast irons, powder-metallurgy materials, nonferrous alloys, and nonmetallic materials are used in gears, but steels, because of their high strength-to-weight ratio and relatively low cost, are the most widely used gear materials. Most gears are made of carbon and low-alloy steels, including carburizing steels and the limited number of low-alloy steels that respond favorably to nitriding.

Among the through-hardening steels in wide use are 1040, 1552, 1060, 4140, and 4340. These steels can also be effectively case hardened by induction heating. Among the carburizing steels used in gears are 1018, 1524, 4026, 4118, 4320, 4620, 4820, 8620, and 9310 (AMS 6260). Many high-performance gears are carburized. Some special-purpose steel gears are case hardened by either carbonitriding or nitriding. Other special-purpose gears, such as those used in chemical or food-processing equipment, are made of stainless steels or nickel-base alloys because of their corrosion resistance, their ability to satisfy sanitary standards, or both. Gears intended for operation at elevated temperatures may be made of tool steels or high modifications of either through-hardened or carburized carbon steel grades.

Because resistance to fatigue failure is partly dependent on the cleanness of the steel and on the nature of allowable inclusions, melting practice may also be a factor in steel selection and may warrant selection of a steel produced by vacuum melting or electroslag refining. The mill form from which a steel gear is machined is another factor that may affect its performance. Many heavy-duty steel gears are machined from forged blanks that have been processed to provide favorable grain flow consistent with load pattern rather than being machined from blanks cut from mill-rolled bar.

**Rolling-element bearing materials** include through-hardened steel, such as 52100, for ball bearings and carburized materials, such as 8620, for roller bearings. A commonly accepted minimum surface hardness for most bearing components is 58 HRC. The carburizing grades have a core hardness range of 25 to 45 HRC.

At surface-hardness values below the minimum 58 HRC, resistance to pitting fatigue is reduced, and the possibility of brinelling (denting) of bearing raceways is increased. Because hardness decreases with increasing operating temperature, the conventional materials for ball and roller bearings can be used only to temperatures of approximately 150 °C (300 °F). Although ball bearings made of high-temperature materials, such as M50 (Fe-0.80C-4Cr-1V-4.25Mo), or roller bearings made of CBS1000M (Fe-0.13C-0.5Mn-0.5Si-1.05Cr-3Ni-4.5Mo-0.4V) are usable to approximately 315 °C (600 °F), the practical limit is actually determined by the breakdown temperature of the lubricant, which is 205 to 230 °C (400 to 450 °F) for the synthetic lubricants that are widely used at elevated temperatures.

Molybdenum high-speed tool steels, such as M1, M2, and M10, are suitable for use to about 425 °C (800 °F) in oxidizing environments. Grades M1 and M2 maintain satisfactory hardnesses to about 480 °C (900 °F), but the oxidation resistance of these steels becomes marginal after a long exposure at this temperature. An important weakness of these highly alloyed materials is their fracture toughness. Also, regardless of operating temperature, bearings require adequate lubrication for satisfactory operation.

For bearings that operate in moderately corrosive environments, AISI type 440C stainless steel should be considered. Its maximum obtainable hardness is about 62 HRC, and it is recommended for use at temperatures below 175 °C (350 °F). However, the dynamic-load capacity of bearings made from type 440C stainless steel is not expected to be comparable to that of bearings made from 52100 steel. The carbide structure of 440C is coarser, the hardness generally lower, and the fracture toughness about one-half that of 52100 steel.

**Materials for Sliding Bearings.** Almost all materials, such as carbon, ceramics, white cast iron, and metal alloys of all kinds, can be used as bearings. These materials may be chosen primarily for corrosion resistance, for prevention of sparking, for resistance to high volumes of abrasives, or simply because they are available. High-performance sliding bearing materials include tin-base or lead-base babbitts, copper-lead alloys, and aluminum alloys containing tin and lead.

Polymers, gray cast irons (with large amounts of graphite), and bronzes are selected as bearing materials because of their ability to survive even though they may be made to poor tolerances or may be operated with occasional lubricant starvation or without maintenance. Poor treatment of these bearings will often appear as adhesive grooving and galling. Where these materials are run against a harder countersurface, there may be metal transfer to that surface.

The lowest cost bearings are bushings of molded polymers (plastics) in which steel shafts rotate. The lowest cost polymers are the nylons and acetals. At low sliding speeds, they usually wear by abrasion due to dirt or the roughness of the surface of the shaft.

For low friction, the more expensive polytetrafluoroethylene (PTFE) is available. Polytetrafluoroethylene is sometimes added to acetals to reduce friction. Graphite and molybdenum disulfide (MoS<sub>2</sub>) are also added; although they decrease friction, these solid lubricants usually do not prevent wear.

## Microstructural Changes from Contact Fatigue

Cyclic contact stresses cause microstructural changes, which are important because they are related to stress levels and the number of cycles. The microstructural changes usually observed in martensitic microstructures from contact fatigue

are known as dark etching areas, butterflies, and white bands. The development of these structural changes depends on the local magnitude of the applied shear stresses and the number of cycles such that, below a certain stress limit or number of cycles, these structural changes are not observed. For example, of these three microstructural changes, the so-called white bands occur from many cycles (approximately 100 million total) after dark etching and butterfly formation. These microstructural changes from cyclic contact stress therefore can be useful because the influence of stress level and number of cycles allows one to infer what loads and stresses have been present in the examination of a damaged or failed bearing or component.

Microstructural alterations from contact fatigue have been reported in the literature since the work published by Jones (*Steel*, Vol 119, p 68-100) in 1946. Different investigators have used different terms for identifying and describing the various structural changes, but most are likely describing only a few different microstructural changes. In addition, most researchers have restricted their methods to light optical microscopy, and the principal problems are reproducibility and standardization of etching and microscopy techniques. The earliest work on the transmission electron microscopic evidence of dislocation cell formation in fatigue-damaged microstructures was provided by O'Brien et al. (Ref 11).

The distinction between through-hardened and carburized steels is also important here. Microstructural alterations are different for 52100 type steels than for carburized steels. The undissolved carbides in 52100 and the higher level of retained austenite in the carburized steels contribute to these differences. Additional differences such as hardness/strength and residual stress gradients found in carburized steels may influence the type and location of the microstructural alterations with respect to load levels and stress cycles. The above-mentioned alterations have been observed in both types of materials and thus, material selection should be based upon manufacturing considerations and operating environments.

**Dark etching areas (DEA)** appear in the region of maximum Hertzian shear stress after a high number of cycles, depending on load (Ref 12). In through-hardened 52100 steel DEA has been initially observed in as few as  $10^6$  cycles at contact pressures exceeding 3500 MPa and at cycles as long as  $10^9$  with contact pressures of 2700 MPa (Ref 19). Many researchers have studied this dark etching phase and have suggested many terms to describe the microstructure, such as "troostite," tempered martensite, low-temperature bainite, and ferrite (Ref 13).

Dark etching areas are produced when a material volume is subjected to contact stresses in which the subsurface flow stress is locally exceeded and the material plastically deforms (Ref 14, 15). Plastic deformation caused by contact stresses occurs by dislocation slip along certain crystallographic planes (Ref 16). For this mechanism, it is typical that slip lines are located orthogonal to each other and form at an angle of about  $45^\circ$  with respect to the contact surface corresponding to the maximum shear stress. Areas appear dark after polishing and etching where slip has occurred in the tempered martensite crystals. The darker these areas appear, the more plastic deformation has occurred in the tempered martensite. From the position and darkness of the DEA, conclusions can be drawn about the heaviest stresses of the material under the contact surface (Ref 17). These areas are present in very localized regions beneath the contact surface, approximately corresponding in depth to the maximum shear stress, which suggests a stress dependence of these microstructural alterations.

The DEAs have somewhat the same microstructure as that of martensite tempered to relatively high temperatures, and some investigators have even theorized such a structural change during contact fatigue is caused by heat generated by cyclic loading (Ref 13). However, distribution of the dark areas is not uniform, but discontinuous, and if heat were the main cause of the structural alteration, distribution of the constituents would be more uniform. Sugino et al. (Ref 18) surmised the possibility that very fine carbides present in the original tempered martensite would dissolve into the matrix by cyclic stressing. This phenomenon is associated with the diffusion of carbon atoms toward heavily dislocated regions, which are caused by inhomogeneous microplastic deformation during the fatigue process (Ref 12). Also, moving dislocations would break the coherence of the carbides with the martensite, or even cut the carbides. This supersaturation of the martensitic matrix due to carbide dissolution is not stable and the reprecipitation of incoherent carbides would occur at such favorable sites as grain boundaries. Furthermore, Sugino et al. postulated that the dissolution of carbides is a function of the degree of slip on discrete crystallographic planes, thus causing the dependence of structural alteration on the orientation of martensite crystals. This dependency is consistent with features of the dark etching areas (Ref 18).

Butterflies, also known as white etching areas, is the term given to frequently observed structural changes that occur due to contact stresses. Figure 3 shows an example of a butterfly in which white areas extend outward from a dark center region. One characteristic feature of butterflies is that they take a definite inclination to the contact surface due to the static shear stresses that develop (Ref 18). The center region of the butterfly, which etches dark, is usually a nonmetallic inclusion. According to Sugino et al. (Ref 18), butterflies originate at almost all kinds of nonmetallic inclusions. However, the statistical result of many observations shows a trend that these structural changes originate most

preferentially at alumina type inclusions (Ref 18). Alumina inclusions form a hard, brittle phase relative to the steel that exhibits an incoherent interface with the matrix microstructure, whereas sulfide inclusions are soft, ductile particles that have a semicoherent interface with the surrounding steel matrix. Table 1 shows inclusion type and appearance correlated with associated frequency to butterfly formation (Ref 18). Sulfides combined with alumina are occasionally found, but sulfides alone are usually not associated with the butterfly structure.

**TABLE 1 LIST OF INCLUSION TYPE AND OCCURENCE ASSOCIATED WITH BUTTERFLY FORMATION**

TYPE OF NONMETALLIC INCLUSION	APPEARANCE OF NONMETALLIC INCLUSION	FREQUENCY OF BUTTERFLIES
MNS	ELONGATED (<3 μM)	RARE
	ELONGATED (>3 μM)	FEW
	VERY THIN AND LONG	NONE
AL <sub>2</sub> O <sub>3</sub>	FINELY DISPERSED STRINGERS	MANY

From the orientation of the white etching areas, it can be assumed that butterflies are generated due to the maximum shear stress, and the depth at which most butterflies are found coincides with the zone of maximum contact stress. Many theories for butterfly formation have been postulated. One theory by Schlicht et al. (Ref 19) explains the formation of butterflies as caused by tensile and shear stresses that develop due to contact stresses in the vicinity of nonmetallic inclusions. Local stresses develop in the vicinity of these inclusions as a result of the elastic modulus differences between the inclusion and the martensite-retained-austenite matrix and/or the weak interfacial energy between the inclusion and the matrix. If the material is overstressed, the elastic energy concentrated in the area of an inclusion is transformed into deformation energy and energy needed to initiate cracks that propagate in the direction of maximum shear stress. The cracked surfaces are pressed together during propagation due to hydrostatic pressure and are plastically deformed. The plastic deformation is associated with adiabatic heating, and consequently the microstructure is reaustenitized. During the reaustenitization, carbides dissolve, and upon subsequent quenching a highly deformed martensite is formed. Other investigations postulate that carbide dissolution is caused by severe deformation of the carbides, resulting in diffusion of carbon from the carbide to a microcrack or interface (Ref 19). This hypothesis does not require the formation of high temperatures and localized reaustenitization of the steel microstructure. However, both theories require that a microcrack be a prerequisite for the formation of the butterflies. The mechanism of butterfly formation is similar to the generation of adiabatic shear bands observed with high impact loading (Ref 19). Also, the martensitic microstructure formed by this method of rehardening resembles a microstructure that is formed during a marquenching process. In both of the above examples, the microstructure that forms exhibits highly deformed martensite, similar to what is observed with butterflies.

The distribution of the butterfly constituent is dependent on various factors, such as the number of cycles and other structural alterations (Ref 20). While the number of butterflies and the size of the zone in which they generate increase with repeated cycles, their density becomes reduced at certain depths. In addition, as the size of butterflies increases with cycles, their growth is suppressed in these same areas. It has been shown that the formation of the DEAs influences the generation and growth of the butterflies such that the region in which butterfly generation is suppressed corresponds to the location of the DEA and the number of cycles at which this suppression occurs also corresponds to the number of cycles needed to generate the DEAs. These dependencies can be explained by considering that plastic deformation, the cause of DEAs, reduces the stress-raising effect around a nonmetallic inclusion and consequently the formation of a microcrack, which is required for the formation of the butterfly. In fact, butterflies have been found at the depth of maximum shear stress prior to the formation of the DEAs. Therefore, the interaction of the two structural changes is not contradictory to the idea that shear stress is essential for their formation.

White bands occur within DEAs after a high number of cycles following DEA and butterfly formation. In through-hardened 52100 steel white bands have been initially observed in as few as  $10^8$  cycles at contact pressures approaching 4000 MPa and at cycles as long as  $10^{11}$  with contact pressures of 2500 MPa (Ref 19). White bands have had different descriptives, such as gray lines, nonetching bands,  $30^\circ$  bands, and deformation bands (Ref 13).

White etching bands are observed at angles between  $20^\circ$  and  $30^\circ$  (shallow bands) with respect to the contact surface (Ref 17). Their inclination is not constant; slight changes are observed with variations in contact conditions, lubrication, and tractional forces (Ref 21). With increased cycles, additional white bands are observed. This second set of white bands form at angles of  $70^\circ$  to  $80^\circ$  (steep bands) with respect to the contact surface and develop within the zone of previous white band formation (Ref 17). These steep bands form after a greater number of cycles and are located closer to the contact surface. With a reverse of motion with respect to the contact surfaces, these bands will develop in a corresponding new orientation, which suggests a stress-related mechanism for their formation (Ref 12).

The white band microstructure was shown by Österlund and Vingsbo (Ref 13) to consist of carbide disks sandwiched between an extremely fine-grain, ferritelike phase, free of resolvable carbides. The mechanism of white band formation can be thought of as a form of mechanical tempering in which dislocation motion adds to the energy needed for carbon diffusion, as opposed to a traditional tempering process in which elevated temperatures and times are required. Due to extensive plastic deformation resulting from contact stresses, a dislocation structure of fine cells develops within the ferritelike phase, thus resembling heavily cold-rolled ferrite (Ref 13). The dislocation density is similar to that of martensite, whereas the dislocation structure is similar to that of heavily strained ferrite. Because the decay of the original tempered martensite is oriented (i.e., specific white band orientation), it can be concluded that white band formation caused by shearing stresses developed during contact loading.

## Contact Fatigue of Hardened Steels

R. Scott Hyde, The Timken Company

---

### Fracture Appearance

The fatigue of hardened steel under cyclic contact stress has been the subject of extensive research using analytical and experimental methods. A rapidly growing number of publications have revealed a large variation in the contact fatigue strength of similar materials when tested under different conditions of contact geometry, speed, lubrication, temperature, and sliding in combination with rolling. These variations result from a poor understanding of the basic mechanism of contact fatigue.

The existence of several distinctly different modes of contact fatigue damage has been recognized, but the factors that control the nucleation and propagation of each type are only partially understood. In addition to a lack of understanding of the basic mechanism, the bearing and gear industries have, in the past, used completely different nomenclature to describe identical fatigue damage modes. The basic mechanism of contact fatigue initiation and propagation is the same, regardless of the application such that bearings, gears, and other contact-stressed components fail in the same manner.

Although bearing and gear industries have used completely different nomenclature to describe contact fatigue in the past, current nomenclature used by both industries is very similar. American National Standard ANSI/AGMA 1010-E96 published in 1996 represents several years' work that emphasized standardized nomenclature for failure modes that is compatible with both gear and bearing industries. Reference 9 (C.A. Moyer, Comparing Surface Failure Modes in Bearings and Gears) uses nomenclature for bearings that is similar to that used in ANSI/AGMA 1010-E96 for gears. In order to improve communication, it is imperative to maintain compatible nomenclature per ANSI/AGMA 1010-E96 such that:

- THE TERM MACROPITTING SHOULD BE USED INSTEAD OF "SPALLING." SPALLING HAS BEEN USED IN THE PAST TO DESCRIBE SEVERAL DIFFERENT FAILURE MODES AND THEREFORE IS CONFUSING. IT SHOULD BE AVOIDED WHERE POSSIBLE.
- THE TERM MICROPITTING SHOULD BE USED INSTEAD OF "PEELING." PEELING IS NOT A GOOD NAME FOR MICROPITTING BECAUSE IT DOES NOT DESCRIBE EITHER THE APPEARANCE OR THE MECHANISM OF THE FAILURE MODE. MICROPITTING IS A MUCH BETTER NAME BECAUSE IT DESCRIBES BOTH APPEARANCE AND MECHANISM AND LINKS THE FAILURE MODE TO MACROPITTING, WHICH IS SIMILAR EXCEPT FOR SCALE.

Fracture origin and appearance of a component damaged by contact fatigue is a function of the applied stresses and material selection, with variations in those applied stresses resulting from environmental factors. Table 2 lists terminology used by the bearing and gearing industries to describe the fracture appearance of contact fatigue-failed components.

### Macropitting

As previously noted, macropitting is a preferred general term that includes spalling (Ref 22) and other forms of macroscale damage (Table 2) caused by Hertzian contact fatigue. Spalling (or macropitting) of bearing raceways or gear teeth is generally due to contact fatigue, which occurs from localized plastic deformation, crack initiation, and finally macropitting from crack propagation in and near the contact surface.

Macropitting or spalling results from the *subsurface* growth of fatigue cracks, which may have a surface or subsurface origin. Figure 4 shows macropit formation by subsurface growth of surface-origin pitting on a gear tooth. The bottom of inclusion-origin macropits form first, and so forth. When circumstances cause surface-origin pitting, crack growth often occurs within and beyond the range of maximum shear stresses in the contact stress field (so-called hydraulic-pressure propagation crack paths that may be due to chemical reactions at the crack tip as well as to lubricant viscosity effects).

**FIG. 4 FRACTOGRAPH SHOWING THE ADVANCED STAGES OF MACROPITTING FATIGUE FOR A HELICAL PINION TOOTH. COURTESY OF GEARTECH**

When fully developed, the craters exist at a depth comparable to that of the maximum alternating Hertzian shear stress. A macropit does not result from the gradual enlargement of a small cavity, but rather results from the subsurface growth of a fatigue crack, which eventually separates from the main body of material (Ref 23). In the example of a gear damaged by crater formation due to surface-origin macropitting (Fig. 4), the craters are generally steep walled and essentially flat bottomed, as the walls and bottom are formed by fracture surfaces. The bottoms of macropits usually form first, and then the crack extends through the contact surface, creating the walls of the crater. However, there are circumstances in which macropits are initiated at or near the contact surface and the crack propagates through the Hertzian shear stress field, forming the walls and then the bottom of the crater (Ref 22).

Macropitting fatigue life is inherently statistical because defect severity and location are randomly distributed among macroscopically identical contact components. Two major classes of macropitting damage are distinguished according to the location of the initiating defect: subsurface-and surface-origin macropitting.

**Subsurface-origin macropitting** results from defects in the bulk material subjected to the Hertzian cyclic stress field. Subsurface-origin macropits (or spalls) are characterized by a smooth area parallel to the contact surface with a steep wall exit (inclined by more than  $45^\circ$  with respect to the contact surface). Sometimes the subsurface defect that caused the damage remains visible after the macropit forms. The defects that cause subsurface-origin macropits are inclusions and/or material microstructure alterations. The defects that most likely produce this type of macropit are located above the depth of maximum alternating Hertzian shear stress. Variables governing the life of a component with respect to this type of macropit are Hertzian shear stress level, material matrix fatigue resistance, defect severity, and defect location.

Inclusion origin fatigue is normally initiated at nonmetallic inclusions below the contact surface and is the primary mode of contact fatigue damage in antifriction bearings (Ref 24, 25, 26). The initiation and propagation of fatigue cracks are the result of cyclic stresses that are locally intensified by the shape, size, and distribution of nonmetallic inclusions in steels. Oxide inclusions from deoxidation, reoxidation, or refractory sources are the most frequently observed origins of inclusion-origin fatigue damage (Ref 26). Sulfide inclusions alone are rarely associated with contact fatigue cracks (Ref 18). The ductility of sulfide inclusions at hot-working temperatures and a relatively low interfacial energy make them less effective stress concentrators than the harder, incoherent oxide inclusions. In addition, oxide inclusions are often present as "stringers" or elongated aggregates of particles, which provide a much greater statistical probability for a point of stress concentration to be in an area of high contact stress.

When a nonmetallic inclusion as described above results in significant stress concentration, two situations are possible: (1) localized plastic flow occurs, and/or (2) a fatigue crack begins to propagate with no plastic flow as observed microscopically. If localized plastic deformation occurs, microstructural alterations begin to develop and the effective stress concentration of the inclusion is reduced. The probability of fatigue crack initiation/propagation is less than before the plastic flow occurred so a macropit may not form. However, if a fatigue crack forms due to the inclusion, prior to any plastic deformation, the stress concentration is increased and crack propagation results in macropitting or spalling fatigue. This hypothesis includes the possibility of a fatigue crack originating from an inclusion that is associated with some sort of microstructural alteration, but also proposes that microstructural alterations are not a necessary step in the initiation/propagation of inclusion origin fatigue.

Early macroscopic propagation of inclusion-origin fatigue takes on a characteristic pattern. Many branching subsurface cracks are formed around the inclusion with propagation often being most rapid perpendicular to the rolling direction, with a resulting elliptical shape for the incipient macropit (or spall). In some instances, the cracked material around the inclusion spalls out early and further propagation is relatively slow, leaving a small macropit with very few subsurface cracks to cause further damage. However, when material has spalled from the contact surface, the result may be debris bruising and denting of other contact areas with subsequent surface origin macropitting.

**Surface-origin macropitting** (or spalling) is caused by defects in the immediate subsurface material subject to asperity scale cyclic stress fields and aggravated by surface tractive forces. These defects are either preexisting defects, such as nicks, dents, grinding furrows, surface discontinuities, and so forth, or microscale pits, which are described later. The distinguishing features of a surface-origin macropit are in the entrance zone of the macropit. The entrance zone may exhibit a shallow-angle entry wall (inclined less than  $30^\circ$  to the contact surface), an arrowhead configuration, the presence of a visible surface defect, or an association with a stress concentration due to design geometry. Surface-origin macropits have been classified by the nature of the defect: geometric stress concentration (GSC) and point surface origin (PSO).

Geometric stress concentration macropits are distributed on the contact surface at the ends of line contact. When the contact geometry, deflection under applied loads, and alignment cause the contact stress to be higher at the end of line contact, fatigue occurs within a narrow band in which the contact stresses are more severe than those associated with inclusions. Figure 5 shows an example of several tapered roller bearing cones that were damaged by GSC macropitting. The GSC macropits can propagate more rapidly in either direction--parallel or transverse to the rolling direction. This mode of contact fatigue is more frequently observed in life tests accelerated due to overload conditions, because contact geometry is designed to produce uniform loading under expected service loads.

**FIG. 5 FRACTOGRAPH SHOWING VARIOUS ADVANCED STAGES OF GEOMETRIC STRESS CONCENTRATION WITH MACROPITTING (SPALLING) FATIGUE OF BEARING RACEWAYS. RELATIVE LIFE NUMBERS ARE INDICATED TO SHOW THAT PROPAGATION IS NOT RELATED TO LIFE.**

Crowning of bearing rollers and gear teeth in line contact situations have been shown to be an effective method of prolonging life or preventing the GSC mode of macropitting. The fact that GSC macropits can occur simultaneously at both ends of a line contact indicates that this mode of contact fatigue is truly the result of end stress concentrations and not simply misalignment. However, misalignment can aggravate the situation by increasing end contact stresses.

Early stages of GSC macropitting exhibit cracks extending to the surface, but it is not clear whether the first cracks always originate at the surface or slightly subsurface. However, the origins are rarely associated with a nonmetallic inclusion, but occasionally an inclusion at the end of line contact will serve as the nucleus for a GSC fatigue macropit.

Point surface origin (PSO) macropits occur randomly distributed on the contact surface, similar to inclusion-type macropits. However, PSO macropits are different in two important aspects: First, there is no consistent association with nonmetallic inclusions, and second, the origin is located at or near the contact surface, whereas with inclusion-origin macropits, the initiation site is located subsurface. These characteristics result in a distinct arrowhead appearance, in which the tip of the arrowhead is the origin and the advanced stages of the macropit develop in a fanned-out appearance

with respect to the tip in the rolling direction. Figure 6 shows an example of a tapered roller bearing cone that was damaged due to PSO macropitting.

**FIG. 6 FRACTOGRAPH SHOWING THE ADVANCED STAGES OF POINT-SURFACE-ORIGIN MACROPITTING FATIGUE OF A BEARING RACEWAY IN WHICH THE ORIGIN IS STILL VISIBLE**

In the advanced stages of propagation, PSO macropits exhibit a brittle appearance and propagation is rapid in both area and depth. However, the depth of cracking is not related to the subsurface contact stress profile. Although PSO macropits do not show a tendency to be associated with inclusions, when conditions are favorable for PSO fatigue, inclusion-type damage sometimes propagates rapidly, and after some macropitting are similar in appearance to PSO fatigue. Point-surface macropitting is often seen propagating from nicks, dents, and debris bruises. A PSO classification indicates the discrete origin of fatigue cracking at or very near the contact surface. A GSC classification indicates a geometric stress concentration due to contact surface profile normal to the rolling/sliding direction, or end-of-contact geometry, in combination with elastic deflections or misalignment in the bearing system.

However, the aforementioned surface anomalies for a PSO classification are common in many contact-loaded applications where PSO macropitting is not encountered and therefore that are not always associated with PSO. Thus, PSO macropitting is better described as a combination of a point-surface origin or initiation followed by hydraulic-pressure propagation (HPP). The occurrence of HPP can be linked to lubricant viscosity and chemical effects--for example, dissolved water and/or aggressive additives (some extreme pressure or EP additives)--that influence fatigue fracture behavior at the crack tip. This type of propagation is due to lubrication trapped within a fatigue crack and has been shown to nearly always promote PSO macropitting or spalling.

Point-surface-origin macropitting below the pitch line on gear teeth has been observed and duplicated in a test rig by combined rolling and sliding forces imposed by phasing gears between the test specimen and a crowned test roller. Without the phasing gears, such that loading conditions were nearly pure rolling, the fatigue was reported to be subsurface inclusion origin. Thus, tangential forces caused by friction in combination with rolling are believed to be the most likely cause of PSO macropitting fatigue. Higher frictional forces are encountered under low lubricant viscosity and/or thin-film conditions and thus results in the presence of PSO macropits.

## **Micropitting**

As previously noted, micropitting is the preferred term for peeling fatigue which is defined as microscale spalling fatigue. It is damage of rolling/sliding contact metal surfaces by the formation of a glazed (burnished) surface, asperity scale microcracks, and asperity scale micropit craters. Micropitting damage is a gradual type of surface fatigue damage that is a complex function of surface topography and its interaction with the lubricant (even under high contact loads, a thin film of lubricant between the contacting surfaces from elastohydrodynamic (EHD) lubrication is present).

Cumulative plastic deformation occurs early in cycling and leads to flattening of asperity tips as the surface-finishing topography is gradually leveled and only smooth, low frequency waviness and scratches at the bottom of deeper furrows remain. The resultant surface has a mirrorlike reflection with finishing lines nearly obliterated and is known as a glazed surface. The surface and immediate subsurface material of a glazed surface are heavily deformed and with continued cyclic stressing, the ductility of the material decreases and microcracks form (Ref 27). The cracks tend to propagate parallel to the contact surface at depths comparable to that of asperity scale shear stresses. A microcracked surface is not usually distinguishable from a glazed surface by the unaided eye, but with microscopy, microcracks opening to the surface may be visible in glazed areas (Ref 22). As the microcracks multiply and propagate, the surface becomes undermined (in asperity dimensions) and multiple microscopic pits form. A micropitted surface appears frosted to the unaided eye with black spots representing the micropits.

Two controlling variables for the occurrence of micropitting are EHD film thickness to roughness ratio and surface microgeometry (Ref 28). In the presence of a sufficiently high EHD film thickness to surface roughness height ratio, micropitting does not occur because the film prevents high-contact microstress in asperity interactions. However, film thickness may be sufficient to prevent generalized micropitting, but not local micropitting in the vicinity of surface defects such as nicks and dents that locally depressurize and thereby thin the EHD film (Ref 22, 26). Tribology features that affect micropitting are both the height and sharpness (RMS height and slope) of the asperities. There is also some evidence that the normal wear in boundary-lubricated gear contacts removes incipient surface-origin pitting, which is one reason why gears may be less prone to spalling (macropitting) from surface-origin spalling under some circumstances.

Micro-Hertzian contact stress fields exist in the vicinity of each asperity ridge in unlubricated or insufficiently lubricated systems (Ref 27). The absolute maximum shear stress along the axis of symmetry of the micro-Hertzian asperity contact is shown to occur at a depth approximately equal to twice the peak-to-valley height of the asperity. The value of this shear stress is many times greater than the macro-Hertzian octahedral shear stress and the range of orthogonal shear stress.

Micropitting (or peeling) is characterized by the limited depth of cracking and propagation over areas rather than propagation in depth. Micropitting fatigue cracks usually propagate parallel to the surface at depths from 2.5 to 13  $\mu\text{m}$  (0.1 to 0.5 mil) and rarely as deep as 25  $\mu\text{m}$  (1 mil) (Ref 26). The high stress gradient that exists in the vicinity of asperities explains why such cracks do not propagate to greater surface depths of the macro-Hertzian contact stress field. In essence, micropitting removes the asperity ridges and relieves the high stress gradient. An additional visual characteristic is that the micropitting occurs more or less in the rolling direction, following finishing lines.

Shear stresses generated due to asperity contact do not affect the location at which the maximum octahedral and orthogonal shear stresses occur (Ref 27). The micro-Hertzian asperity contact field merely increases these stresses above the classical Hertzian theory. Thus, the depth at which subsurface fatigue originates remains unaffected by surface finish (Ref 27). However, traction forces are not considered in classical Hertzian theory and will decrease the depth at which the maximum contact shear stresses occur.

If micro-Hertzian contact stresses exist in the vicinity of asperity ridges, then similar, but larger contact stresses exist around surface defects such as grinding furrows, nicks, dents, and scratches. Because these surface defects raise the absolute micro-Hertzian shear stress, one would expect damage to occur at greater depths than those associated with asperity ridges. Results show that surface origin fatigue commonly occurs at a depth of approximately 25 to 50  $\mu\text{m}$  (1 to 2 mils) below the contact surface (Ref 29). These types of fatigue mechanisms were discussed earlier and referred to as PSO and GSC type fatigue.

Macropitting (or spalling) fatigue is the most hazardous consequence of micropitting (or peeling) (Ref 29). In the absence of preexisting surface defects, surface-origin pitting initiates from micropits through the process of asperity-scale fatigue. More often, the presence of micropits can lead to premature macropitting (or spalling) (Ref 7). The principal operating factor influencing the rate of macropitting from micropits is tractive interfacial stress. When friction is high, macropits form rapidly from the micropits on the surface. If early macropitting does not terminate the operation of a component that has suffered micropitting, then surface material delamination may occur (Ref 27). The original surface is thereby lost over wide areas, and the component becomes inoperative through loss of dimensional accuracy, noise, or secondary damage.

In many cases, micropitting (or peeling) is not destructive to the bearing raceway or gear tooth surface. It sometimes occurs only in patches and may stop after the tribological conditions have been improved by run-in. Run-in is defined as an initial transition process occurring in newly established wearing contacts, often accompanied by transients in coefficient of friction, wear rate, or both, that are uncharacteristic of the long-term behavior of the given tribological system (Ref 30). Gears appear less sensitive to the consequences of surface distress than rolling-element bearings (Ref 7). This may be due to the greater ductility of lower-hardness materials. However, micropitting has been observed in gears as well as bearings.

## Subcase Fatigue

Subcase fatigue can also be defined as a macro-Hertzian contact fatigue mechanism. Subcase fatigue is fracture of case-hardened components by the formation of cracks below the contact surface within the Hertzian stress field (Ref 7). However, the depth at which the cracks form is much greater than those that cause macropitting fatigue, and it is a function of material strength in conjunction with the alternating Hertzian shear stresses. Subcase fatigue is also sometimes referred to as case crushing, but since it results from a fatigue crack that initiates below the effective case depth or in the lower-carbon portion of the case, the former nomenclature will be used throughout this article.

In case-hardened components--produced by carburizing, nitriding, or induction hardening--a gradient of decreasing hardness (shear strength) exists from the case to the core. If the material shear strength gradient is steeper than the gradient in Hertzian shear stress, then the applied-stress-to-strength ratio is least favorable at some depth below the normal maximum Hertzian shear stress region. This depth is usually located at (or near) the case/core interface due to shear strength and stress gradients, in addition to unfavorable tensile residual stresses. The reversal in the sign of the residual stress from compression in the case to tension in the core occurs at or very near the case/core interface, and therefore the Hertzian shear stresses are increased due to the tensile residual stresses.

Once formed, such cracks usually propagate parallel to the case-hardened region until branching-cracks form and propagate toward the surface, resulting in macropit formation (Ref 31). Figure 7 shows micrographs of a gear tooth and a roller specimen in which subcase fatigue cracks had formed and propagated during testing. Note that the main crack formed in a direction parallel to the case-hardened layer with cracks branching towards the surface. Subcase fatigue is usually caused by too thin a case, such as on a nitrided gear tooth, by insufficient core hardness on carburized or induction-hardened parts, or in heavily loaded case-hardened rolling-element bearings (Ref 32).

**FIG. 7 MICROGRAPHS SHOWING ETCHED CROSS-SECTIONS OF (A) A CARBURIZED CYLINDRICAL TEST SPECIMEN (1.9 $\times$ ) AND (B) A CARBURIZED GEAR TOOTH IN WHICH SUBCASE FATIGUE CRACKS INITIATED AND PROPAGATED DURING TESTING. SUBCASE FATIGUE, CALLED CASE CRUSHING BY PEDERSON AND RICE, SHOWS THE EARLY STAGES OF FATIGUE CRACKING IN THE LOWER CARBON PORTION OF THE CARBURIZED CASE. (C) THE DIAGRAM INDICATES HOW THE STRESS AND STRENGTH GRADIENTS COMBINE TO CAUSE THE WEAKEST CONDITION AT THE SUBCASE LOCATION WHERE FATIGUE CRACKING BEGINS. SOURCE: REF 26, 31, AND 33**

Factors that tend to promote the various types of contact fatigue are listed in Table 3. It should be noted that three of the five modes of fatigue damage are influenced by lubrication, including all surface-origin damage modes. Figures 8(a) to (d) show Hertzian shear stresses and material shear strengths as a function of depth below the contact surface. These are an adaptation of the subcase fatigue analysis by Pederson and Rice (Ref 31). As noted earlier, fatigue occurs when the applied shear stress is greater than the shear strength of the material. Thus, the different modes of contact fatigue can be described by determining where these stress profiles cross each other and are shown schematically in Fig. 8.

**TABLE 3 LIST OF CONTACT FATIGUE MODES AND THEIR CONTROLLING FACTORS**

## Contact Fatigue of Hardened Steels

R. Scott Hyde, The Timken Company

---

## Factors Influencing Contact Fatigue Life

Factors influencing contact fatigue life of hardened steel bearings and gears can be roughly classified into four categories: material, lubrication and surface finish, dimensional precision, and environmental conditions. The latter two factors are concerned more with machine element design and will not be discussed in any great detail in this article.

Most factors discussed in this section are dependent upon and different for the type of material in question, through-hardened or carburized. Therefore, material usage should be a function of manufacturing capabilities, operating environments, and more often than not, cost. The influence of several factors, such as retained austenite and hardness, are difficult to resolve. Typically, as retained austenite increases, hardness decreases. This is important in debris denting, in which high surface hardness is desirable to prevent debris denting, but higher levels of retained austenite are desirable to prevent fatigue cracking from debris dents. Therefore, material selection is primarily based upon the desired performance issues, such as wear, fatigue, dimensional stability, debris contamination, and past experience with a given steel.

**Hardness.** As demonstrated earlier in this article, several distinctly different modes of contact fatigue can cause cracks to initiate and propagate independently at various rates; thus the phenomenon appears to be influenced more by highly localized conditions than by the general properties of the bulk material. Early research on contact fatigue utilized mechanical engineering and elastic stress analysis with little emphasis on materials, until an understanding of how material hardness influences contact fatigue life (Ref 33). Contact fatigue measurements on hardened steels indicate an increasing life with increasing component hardness, although there is an optimal hardness range that is application-dependent to ensure maximum contact fatigue life (Ref 34, 35). In addition to hardness, some important metallurgical factors other than a predominantly martensitic microstructure that influence contact fatigue life are inclusions, carbides or other hard second-phase precipitates, retained austenite content, nonmartensitic transformation products (NMTP), grain size, residual stress, heat-treat methods, and steel type (Ref 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49).

**Inclusions.** Numerous research investigations have been reported concerning the metallurgical variables that affect the contact fatigue life of bearings and gears. However, nonmetallic inclusions have been shown to be the single most influential factor on the contact life of hardened steel (Ref 29, 33). Of the nonmetallic inclusions present in steel, the most detrimental of these is alumina, followed by silicates (Ref 18). Types and sizes of inclusions present in steel are governed mainly by the steelmaking practice, and their frequency or severity is referred to as cleanliness. The effect of steel cleanliness (based on electric-arc furnace manufacturing practice) on the contact fatigue life of tapered-roller bearings is shown in Fig. 9. The introduction of ladle refining, inert gas stirring, and inert gas shrouding has improved the life of roller bearings two orders of magnitude and improved steel cleanliness to levels approaching that of vacuum-arc remelted steel (Ref 41).

**FIG. 9 PLOT OF RELATIVE CONTACT FATIGUE LIFE FOR TAPERED ROLLER BEARINGS VERSUS STEEL CLEANNESS FOR SEVERAL STEEL HEATS PRODUCED BY VARIOUS ELECTRIC-ARC FURNACE STEELMAKING PRACTICES**

Another type of oxide that has proved to be detrimental to contact fatigue resistance is known as intergranular oxidation (Ref 50). These oxides form along the surface of a steel during gas carburizing due to the oxygen potential present in the carburizing atmosphere in combination with the presence of elements that have a high affinity for oxygen such as silicon,

chromium, and manganese. These oxides are important in applications such as gears for which the final contact surface remains in the as-carburized condition.

Although total oxygen content is generally accepted as an indication of steel cleanliness, it is not necessarily exclusive with regard to contact fatigue life. In some instances, a steel with low oxygen content and only a few large inclusions will not give the expected increase in fatigue life. Based on observations of inclusions in 52100 and M1 steels, it was concluded that although inclusion location and type are of primary importance to contact fatigue life, size and orientation are also important and oxides and larger carbides/nitrides are more harmful than softer sulfide inclusions (Ref 51).

**Carbides.** Although there have been many studies performed to investigate the effect of inclusions, there has been little research showing the effects of carbides on contact fatigue. Carbides of interest are primarily those found in tool steels. The transition from using 52100 to tool steels in contact-loaded machine elements has taken place because of dimensional stability, retention of hot hardness, wear resistance, and oxidation resistance at elevated temperatures. The larger, primary carbides found in high-alloy steels act as stress raisers to initiate the micropitting mode of contact fatigue under thin lubrication films and contribute to subsurface microstructural alterations (Ref 52). Research has shown that contact fatigue life increases as the size of carbides decrease (Ref 53). A double-quench procedure following a carburizing cycle is used to keep both residual carbides and retained austenite at reasonable levels (Ref 54). A double-quench process involves carburizing followed by an initial quench and subsequent re-austenitization and quenching. This procedure is done to control matrix carbon concentration to avoid excessive retained austenite and massive carbides. In addition, double quenching produces a refined microstructure that also increases material toughness and fatigue resistance.

**Retained Austenite.** The influence of retained austenite has most commonly been referred to as beneficial in contact fatigue, most notably under debris-contaminated lubrication conditions and/or low lubrication film thickness (Ref 55, 56). However, the issue of retained austenite is application dependent because increased retained austenite content results in a lower material hardness for a given heat treatment and carbon content. Nevertheless, a certain amount of properly distributed retained austenite is usually desirable for contact fatigue resistance (Ref 57).

The optimal level of retained austenite depends on expected fatigue modes. For example, the plastic deformation of retained austenite can relax stress concentrations around oxide inclusions. However, with recent improvements in steelmaking practices, oxide concentrations have decreased such that variations in retained austenite offer fewer beneficial effects from inclusion-origin damage. Fatigue damage modes associated with contaminated lubrication are micropitting caused by debris and/or surface-initiated macropitting caused by debris dents, such that fatigue life can be increased by optimizing surface hardness and retained austenite (Ref 58). Increased retained austenite content appears to decrease crack sensitivity (increased fracture toughness) and therefore reduces the damaging effects of debris denting (Ref 59). Furthermore, it is postulated that the plastic deformation or transformation of the retained austenite results in favorable compressive residual stresses that diminish the actual applied cyclic stress.

Although retained austenite has been shown to benefit contact fatigue life, there are situations in which austenite can be a detriment, as related to dimensional stability and surface hardness. During operation, metastable retained austenite will transform under stress and strain to untempered martensite, which results in an associated volume expansion. This volume expansion can create distortion and may result in decreased life, through misalignment and noise. Also, excessive amounts of retained austenite will lower material hardness and result in a decreased resistance to fatigue initiation. To attain a given stability with a higher hardness, a subzero treatment between quenching and tempering is sometimes applied in order to control retained austenite content. However, with a subzero treatment, the mechanical properties of the steel, especially toughness and fatigue resistance, may be significantly reduced (Ref 60). Therefore, the optimal level of retained austenite is application dependent and should be varied based on expected damage mechanism.

Retained austenite content can be controlled by heat treatment, multiple quenching, tempering, cryogenics, and/or alloying. Alloying elements such as carbon, manganese, nickel, molybdenum, and chromium lower the martensite start ( $M_s$ ) temperature of iron and thus produce greater levels of retained austenite. Variations on the concentrations of these elements is reflective of steel grade, and variation of carbon content produces steel types suitable for carburizing (e.g., 8620, 4320, 9310), induction-hardening (e.g., 4140, 1552, 5160), and through-hardening (e.g., 52100, M1, A2) heat treatments. Basically, a steel must have sufficient quantities of the correct alloying elements to produce a component with proper surface and core hardness, in addition to avoiding unwanted nonmartensitic transformation products (NMTP), such as quenching pearlite. Carbon content controls surface hardness, and the other elements aid in controlling core hardness and the amount of NMTP. The NMTP microconstituents--ferrite, pearlite, and bainite--are softer than the martensite matrix, reducing the contact fatigue resistance of steel and thus should be avoided.

Compared with through-hardened steels, carburized and induction-hardened steels produce residual compressive stresses and relatively large amounts of retained austenite in the subsurface region of a component. In general, resistance to contact fatigue is greatest in carburized steels, followed by through-hardened steels, and the induction-hardened steels. In the case of small components, the life of a carburizing steel is slightly longer than that of a through-hardening steel and considerably longer than that of an induction-hardened steel (Ref 56, 57). The fatigue lives of both induction-hardened and through-hardened steels for large components are nearly the same, but carburizing steels last approximately three times longer (Ref 57). The main differences among these steel types exist in hardness, retained austenite, and residual stress distributions resulting from variations in carbon concentration and heat treatment.

**Residual Stresses.** Favorable compressive residual stress profiles, like those found in carburized components, increase the contact fatigue life of bearings and gears (Ref 61). Residual stresses can be formed during heat treatment, subsequent peening processes, and/or cyclic loading. Residual stress can either increase or decrease the maximum Hertzian shear stress according to the following equation (Ref 34):

$$\tau_{oct}^r = -\tau_{oct} - \frac{1}{2} (\pm S_r)$$

where  $\tau_{oct}$  is the maximum shearing stress,  $\tau_{oct}^r$  is the maximum shearing stress modified by the residual stress, and  $S_r$  is the residual stress. The positive/negative sign ( $\pm$ ) indicates that the residual stress may be tensile or compressive, respectively. For the case of compressive residual stresses, fatigue crack initiation and propagation rates are decreased due to a decrease in the effective applied stress and results in longer life.

**Lubrication and tribology** also play important roles in contact fatigue life. As shown in Table 3, it is apparent that lubrication and surface finish can be influential in three out of the five modes of contact fatigue, including all surface-initiated modes. Therefore, it is important to have a basic understanding of lubrication and surface texture variables (roughness, waviness, directionality, and microtopography) to better comprehend the phenomenon of contact fatigue.

These variables include lubricant properties such as absolute viscosity, viscosity index, pressure viscosity coefficient, additives, film thickness, surface roughness, surface tension, and operating temperatures (Ref 62). The absolute viscosity,  $\mu_o$ , is resistance to fluid flow, and the viscosity index and the pressure viscosity coefficient,  $\varphi$ , are measures of fluid viscosity change with temperature and pressure, respectively. Additives are materials incorporated in lubricants to impart new or enhance existing properties, such as anticorrosive, antifoam, detergent, antiscuff, and so forth (Ref 63). The film thickness refers to the distance between two contacting surfaces under lubricated conditions and can be approximated by the empirical Grubin equation (Ref 64):

$$H_o = 0.5 (\mu_o \varphi v_r)^{8/11} (P/\ )^{-1/11} (\Sigma 1/R)^{-4/11}$$

where  $h_o$  is the nominal film thickness,  $v_r$  is the relative velocity of the contacting surfaces,  $P$  is the normal load,  $l$  is the length of contact, and  $R$  is the radius of curvature for the contacting surfaces. The shape of the contact zone and the resultant stresses depend on the magnitude of the load and the characteristics of the EHD film (Ref 65). From the above equation, one can conclude that the most important factors influencing lubricant film thickness are absolute viscosity, pressure viscosity coefficient, and contact surface velocity. Although it is advantageous to know the nominal film thickness, variations will exist from the oil inlet side to the oil exit side and in the vicinity of surface defects that result in local variations in stress distribution and adds to the inherent statistical nature of fatigue damage.

In a surface free of flaws, the surface texture becomes critical as the EHD film thickness approaches the dimensions of the surface roughness. Thus, the calculated film thickness might be less than the combined surface roughness of the contacting surfaces, resulting in asperity contact and the initiation of micropitting fatigue. In addition to surface roughness, it has been suggested that the radius of curvature or slopes of the asperities play an important role in film thickness and effects on micropitting. A surface roughness criterion for determining the extent of asperity contact is based on the ratio of the EHD film thickness to a composite surface roughness. The film parameter is given as  $\Lambda$  (Ref 62):

$$\Lambda = \frac{h_{min}}{(\sigma_1^2 + \sigma_2^2)^{1/2}}$$

where  $h_{\min}$  is the minimum film thickness and  $\sigma_1$  and  $\sigma_2$  are the root-mean-square (RMS) roughness of the two surfaces in contact. At  $\Lambda$  less than 1, operation is in the boundary lubrication regime where macropitting life is relatively short. In fact, macropitting may not occur if it is preempted by micropitting, adhesion, or scuffing. For  $\Lambda$  between 1 and 3, macropitting life is increased, and micropitting, adhesion, and scuffing usually do not occur. For  $\Lambda$  greater than 3, macropitting may still occur, but the contact fatigue life is relatively long (Fig. 10).

**FIG. 10 RELATIONS BETWEEN CONTACT FATIGUE LIFE, MACROPITTING, AND THE FILM PARAMETER ( $\Lambda$ ) FOR EHD LUBRICATION**

Contact fatigue life has been shown to increase with increases in viscosity, pressure viscosity coefficient, and/or velocity. With mineral oils, investigations have shown that macropitting life increases with increasing viscosity (Ref 35). These factors again imply that contact fatigue life increases with increasing EHD film thickness, as shown in Fig. 11. However, many environmental factors influence lubricant film thickness by altering base lubricant properties or modifying the chemical activity of the additive packages. One such factor is temperature, both bulk and local. Changes in bulk temperature may significantly alter lubricant viscosity and thus affect EHD film thickness and overall fatigue performance of surfaces in contact. In addition to bulk temperature, variations in temperature within contact areas may locally impose stress gradients due to thermal expansion (Ref 66). These stress gradients can also alter lubricant viscosity and EHD film thickness. Such stresses are insignificant except under conditions of appreciable sliding, where they become more damaging as  $\Lambda$  decreases (Ref 67). Temperature also affects the rate of all relevant chemical reactions between lubricant and contact surface, affecting both crack initiation and propagation. Temperatures that aid in preventing crack initiation may at the same time promote mechanisms that increase crack propagation rates. High temperatures may degrade lubricants by oxidation in air, thus forming acids that have been shown to decrease contact fatigue strength. In addition to oxidation of lubricants, the physical adsorption of oxygen and water by the lubricant can result in chemical reaction (changes in surface tension) with the contact surfaces and may aid in crack propagation. In addition, the adverse effects of dissolved or entrained contamination on surface tension may also occur from physical adsorption and chemical reaction with the fresh fracture surface at the crack tip, affecting fatigue fracture toughness, including possible hydrogen embrittlement effects.

**FIG. 11 PLOT OF RELATIVE CONTACT FATIGUE LIFE FOR TAPERED ROLLER BEARINGS VERSUS  $\Lambda$  (THE RATIO BETWEEN THE MINIMUM ELASTOHYDRODYNAMIC FILM THICKNESS AND THE ROOT-MEAN-SQUARE ROUGHNESS OF THE CONTACTING SURFACES)**

The propagation of cracks extending to the contact surface (surface or subsurface initiated) can be accelerated by hydrodynamic effects created by lubrication. This phenomenon is referred to as hydraulic pressure propagation (HPP) and was first suggested as a damage mode in 1935 (Ref 23). It has been shown that, during each contact cycle, oil under pressure can open and enter surface cracks of great length and accelerate crack propagation (Ref 68). The HPP mode of fatigue occurs when lubricant viscosity and operating speeds are low and when the contact surface has a relatively high fracture toughness (Ref 33). However, two distinctly different mechanisms for HPP have been proposed: crack propagation due to the development of stresses resulting from hydraulic oil pressure and crack propagation due to chemical interactions between the oil and crack tip.

The characteristics of surface-origin macropits (or spalls) formed due to combined rolling/sliding action, macropits formed due to nominally pure rolling action with low  $\Lambda$  ratios, and macropits formed by propagation of subsurface inclusion origin damage due to HPP are remarkably similar (Ref 33). However, upon metallographic sectioning, HPP macropits show a crack path that is unrelated to the known distribution of shear stresses or any other calculable stresses except for those generated by the lubricant trapped in the crack. Cracks that propagate by HPP are those inclined downward in the rolling direction at a small angle with respect to the contact surface. These observed crack propagations support the mechanism of HPP due to the development of stresses resulting from hydraulic pressure. Alternative mechanisms are possible and may operate in conjunction with the previous mechanism. These mechanisms involve a chemical reaction between the lubricant, additives, and/or impurities in the microstructure of the bearing or gear. One such mechanism is called the Rehbinder Effect after the author of publications on the subject. The Rehbinder Effect is the effect of surface-active materials on the mechanical behavior of crystalline materials. This mechanism reduces crack-extension forces (stresses) by the interaction of polar molecules with the motion of dislocations or reductions in interfacial energy, although it is not considered a corrosion-type mechanism. Increased concentrations of EP-additive packages have been shown to result in reduction of contact fatigue life and have revealed some surface attack. Penetration of more active additives into fine surface cracks led to rapid crack propagation and premature component damage (Ref 68). However, in the case of contaminated lubricants, corrosion of the crack tip may occur and result in crack growth or hydrogen generation. Hydrogen embrittlement is widely prevalent in steels with carbon contents and hardness levels typical of contact-loaded machine elements and may also explain the mechanism of HPP (Ref 69).

### Introduction

The Cr-Mo steels are preferred in the construction of high-temperature components because they possess excellent strength, toughness, and corrosion resistance relative to carbon steels and most low-alloy steels. Components fabricated from Cr-Mo steels serve in the petroleum, petrochemical, fossil power, and pulp and paper industries. The steels are most often used at temperatures of 316 °C (600 °F) and higher, when creep effects, graphitization, or hydrogen attack may be significant in carbon steels.

Like most steels, the Cr-Mo steels respond to heat treatment, and a single composition may be produced in several strength classes. The low-chromium Cr-Mo steels have moderate hardenability. Slow cooling and isothermal annealing during cooling produce ferrite-pearlite microstructures that have long-time stability but relatively low tensile strength and toughness. Rapid air cooling and enhanced cooling produce bainitic steels, which tend to be stronger and tougher. Medium-chromium Cr-Mo steels have moderate hardenability, and air cooling is generally sufficient to produce bainite through-thicknesses of 150 mm (6 in.) and more. The bainitic steels are usually tempered. The high-chromium Cr-Mo steels have excellent hardening ability, and air cooling is sufficient to produce martensite through most thicknesses. Accelerated cooling of the steels is permitted, but care must be taken to avoid cracking. The martensitic steels are always tempered.

**Compositions and Metallurgy.** Nominal compositions for the heat-resistant, Cr-Mo steels are provided in Table 1. The steels range from  $\frac{1}{2}$  to 12% Cr and  $\frac{1}{2}$  to 1% Mo. Product forms include tubes, pipes, forgings, fittings, plates, and castings. Welded tubing and pipes are included. Depending on the product, the maximum use temperature for pressure-boundary applications ranges from 480 to 650 °C (900 to 1200 °F) (Ref 1).

**TABLE 1 SUMMARY OF CR-MO STEELS USED IN HIGH-TEMPERATURE SERVICE**

Nominal Composition	SPECIFICATION	PRODUCT FORM	MINIMUM OR RANGE OF ULTIMATE STRENGTH		MINIMUM YIELD STRENGTH		MAXIMUM USE TEMPERATURE		TYPICAL PRODUCT FORMS	TYPICAL UNS NUMBERS

The  $\frac{1}{2}\text{Cr}-\frac{1}{2}\text{Mo}$  steel is produced to three strength levels and is approved in the ASME Boiler and Pressure Vessel Code (BPVC) for service to 540 °C (1000 °F). The  $1\text{Cr}-\frac{1}{2}\text{Mo}$  and  $1\frac{1}{4}\text{Cr}-\frac{1}{2}\text{Mo}$  steels are produced in three strength levels and are approved for service to 650 °C (1200 °F). The  $1\frac{1}{4}\text{Cr}-\frac{1}{2}\text{Mo}$  steel is the most widely used of the Cr-Mo steels, but the greatest body of information is available for  $2\frac{1}{4}\text{Cr}-1\text{Mo}$  steel. Wrought  $2\frac{1}{4}\text{Cr}-1\text{Mo}$  steel is produced to several strength levels. The annealed steel (class 1) has a largely ferrite-pearlite microstructure, although bainite is often present. The class 1 steel is used in the power industry as superheater/reheater tubing, headers, and main steam line piping for service temperatures to 650 °C (1200 °F). The normalized-and-tempered steel (class 2) is used for heavy-wall pressure vessels in the petroleum and petrochemical industries for temperatures to 480 °C (900 °F). In Europe and Asia, the class 2 material is often used for tubing and piping in the power industry for service to 650 °C (1200 °F). Quenched-and-tempered versions of  $2\frac{1}{4}\text{Cr}-1\text{Mo}$  steels exist. These steels are intended for heavy-wall pressure vessels but are limited to service at temperatures below the creep range because of their susceptibility to hydrogen attack (Ref 2). The 3Cr-1Mo steel is available in two strength levels and has strength properties comparable to those of  $2\frac{1}{4}\text{Cr}-1\text{Mo}$  steel, but improved resistance to hydrogen attack.

Recently,  $2\frac{1}{4}\text{Cr}-1\text{Mo}$  and 3Cr-1Mo steels with vanadium additions have been commercially developed for high-temperature pressure vessels and piping (Ref 3, 4, 5, 6, 7, 8). The vanadium-bearing steels have better strength and are more resistant to hydrogen attack than steels without vanadium additions. The use for vanadium-modified  $2\frac{1}{4}\text{Cr}-1\text{Mo}$  steel and 3Cr-1Mo steel has been for heavy-wall pressure vessels (Ref 4, 5). Further modifications of the  $3\text{Cr}-1\text{Mo}-\frac{1}{4}\text{V}$  steels have been produced by adding titanium, niobium, calcium, and the like (Ref 5, 6). The strength and toughness of the steels are comparable to that of the steels listed in Table 1.

The straight 9Cr-1Mo steel is approved for service in the BPVC to 650 °C (1200 °F), but usage has not been widespread. However, the 9Cr-1Mo-V steel developed in the late 1980s (Ref 8) has been installed as tubing, piping, forgings, and castings in a variety of applications for the power, petroleum, and petrochemical industries and has accumulated up to 15 years of exposure at temperatures in the creep regime. Even more recently, tungsten has been used as a replacement for some of the molybdenum to improve the weldability and toughness of Cr-Mo steels. Three steels included in the grouping include a  $2\frac{1}{4}\text{Cr}-1.6\text{W}$  steel (Ref 9), a 9Cr-2W steel (Ref 10), and a 12Cr-2W steel (Ref 11). The tungsten-bearing steels contain  $\frac{1}{2}\%$  Mo and  $\frac{1}{4}\%$  V, and they are intended for superheater/reheater tubing and piping for steam lines. Steels that contain high carbon or manganese and nickel for improved hardenability are not considered here. These steels are usually restricted to lower-temperature service. Neither are the high-strength Cr-Mo-V steels developed for bolting, turbine casings, rotors, and disks covered here. However, these steels are very susceptible to creep, fatigue, and creep-fatigue damage, so many of the fracture and high-temperature fatigue issues discussed below apply to them.

### Charpy V-Notch (CVN) Toughness

Clean steelmaking practices have significantly improved the toughness of Cr-Mo steels over the last 15 years by reducing the content of residual elements responsible for some types of embrittlement. Refinement of grain size and shape control of inclusions have produced additional improvements in toughness. Typically, the procurement specifications for the Cr-Mo steels require that the room-temperature elongations meet or exceed values in the range of 18 to 22%, depending on the strength and other factors related to the specific grade. A maximum ultimate strength or hardness is sometimes specified to ensure adequate toughness in the delivered product. For thick-section products, such as plates, a supplementary requirement for toughness is available when needed. Toughness criteria derived from the CVN or other types of toughness tests are often invoked for nuclear applications. For most Cr-Mo steels, toughness data are available that include CVN energy, fracture appearance, and lateral expansion over a range of test temperatures that include the brittle-to-ductile transition. The as-normalized or as-tempered toughness of Cr-Mo steels varies with composition,

strength, and microstructure, so it is difficult to produce curves that can be considered typical of a grade or class of steel. Curves for various grades and classes overlap substantially. However, there is a tendency for toughness concerns to increase with increased alloy content and strength level. As the alloy content is increased for better high-temperature strength, the susceptibility to reheat cracking and temper embrittlement increases. Such concerns promote more testing and evaluation.

The preponderance of toughness data reported in the literature for pressure-bearing, high-temperature Cr-Mo steels addresses  $2\frac{1}{4}$ Cr-1Mo steel. Typical CVN toughness data for four heats of annealed  $2\frac{1}{4}$ Cr-1Mo steel plate (SA-387, grade 22, class 1) are plotted in Fig. 1. One heat was air melted, two were vacuum-arc remelted (VAR), and one was electroslag remelted (ESR) (Ref 12). All heats were annealed and furnace cooled, then subjected to a simulated postweld heat treatment (PWHT) of 20 h at 730 °C (1350 °F). In Fig. 1(a), the CVN energies are plotted against temperature. Relative to the air-melted material, the ESR heat exhibited very low transition temperatures and high upper-shelf energies. The VAR heats exhibited good toughness in the longitudinal orientation but possessed higher transition temperatures and upper-shelf energies of only 120 J. The fracture appearance data plotted in Fig. 1(b) followed the same trends. The superior toughness in the ESR steel was attributed to the reduced inclusion content.

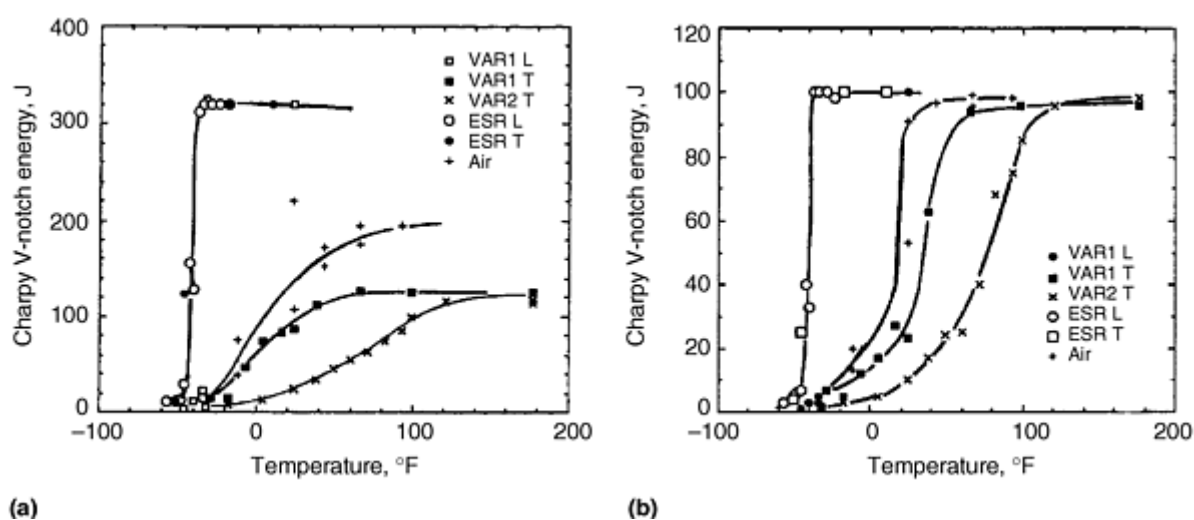

FIG. 1 COMPARISON OF THE CHARPY V-NOTCH ENERGY AND FRACTURE APPEARANCE OF  $2\frac{1}{4}$ CR-1MO STEEL PRODUCED BY AIR, VACUUM-ARC REMELTING (VAR), AND ELECTROSLAG REMELTING (ESR) PRACTICES. SOURCE: REF 12

Charpy V-notch energies for the normalized-and-tempered plates (SA-387, grade 22, class 2) are shown in Fig. 2. Ranges are plotted for steels produced by conventional melting and calcium treatment melting practices (Ref 13). Trends for three sample orientations are included. Substantial improvements were made in both the transition temperature and the upper-shelf energy values by means of the calcium treatment, which reduces sulfur content and refines the grain size.

FIG. 2 COMPARISON OF THE RANGE OF CHARPY V-NOTCH ENERGY FOR  $2\frac{1}{4}$  CR-1MO STEEL (CLASS 2) PRODUCED BY CONVENTIONAL (CON) MELTING AND CALCIUM TREATMENT (CAT) MELTING. SOURCE: REF 13

The toughness of  $2\frac{1}{4}$  Cr-1Mo steel is also affected by the normalizing temperature (through its influence on the grain size and hardenability), the cooling rate from the normalization temperature (through its effect on microstructure), and the tempering parameter (which determines the strength level and microstructure). Tempering and PWHT are important to convert the  $Fe_3C$  to more thermodynamically stable carbides and to soften the hardened heat-affected zone (HAZ) of welds. In the bainitic steels, toughness improves rapidly with tempering. Some examples are shown in Fig. 3, which plots CVN energies against testing temperature for an air-melted heat (Fig. 3a) and a VAR heat (Fig. 3b).

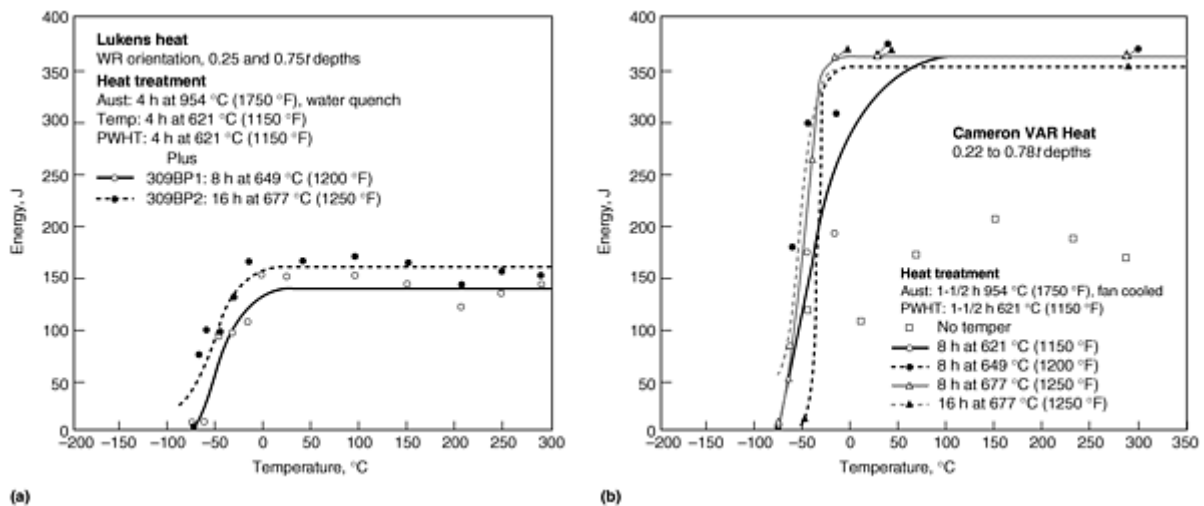

FIG. 3 COMPARISON OF THE EFFECTS OF TEMPERING ON THE CHARPY V-NOTCH (CVN) ENERGY OF  $2\frac{1}{4}$  CR-1MO STEEL (CLASS 2), CONVENTIONAL AND VACUUM-ARC REMELTED (VAR). (A) 152 MM THICK PLATE. (B) 51 MM THICK VAR, FORGED, AND HOT-ROLLED PLATE AFTER A POSTWELD HEAT TREATMENT OF 1.5 H AT 621 °C. SOURCE: REF 14

Wilson et al. (Ref 13) have observed that excessive PWHT may reduce toughness substantially, and they have shown examples for both  $2\frac{1}{4}$ Cr-1Mo and  $1\frac{1}{4}$ Cr-1Mo steels. Figure 4 provides a correlation between the 54 J (40 ft · lb) transition temperature and the tempering parameter for normalized-and-tempered and quenched-and-tempered grade 11 steels. Here, the tempering parameter, TP, is equivalent to the Larson-Miller parameter and is given by:

$$TP = T(20 + \text{LOG } T)/1000$$

where  $T$  is temperature in Kelvins and  $t$  is time in hours.

**FIG. 4 EFFECT OF POSTWELD HEAT TREATMENT ON THE CHARPY V-NOTCH 54 J TRANSITION TEMPERATURE FOR  $2\frac{1}{4}$ CR-1MO STEEL (A387, GRADE 11). N&T, NORMALIZED-AND-TEMPERED; Q&T, QUENCHED-AND-TEMPERED; SR, STRESS RELIEVED. SOURCE: REF 13**

The compositions and heat treatments for the new vanadium-modified Cr-Mo steels have been optimized to ensure good toughness and strength. Some typical CVN energy curves are provided in Fig. 5 for the  $2\frac{1}{4}$ Cr-1Mo-V-Ti-B steel (Ref 4) and in Fig. 6 for 3Cr-1Mo-V-Ti-B steel (Ref 6). The two vanadium-modified steels have similar tempering behavior, but Fig. 5 was chosen to show how the ductile-to-brittle transition temperature is decreased by increased tempering time or temperature, and Fig. 6 was chosen to show how it is increased by increased normalizing temperature, which increases grain size.

FIG. 5 EFFECT OF TEMPERING CONDITIONS ON THE CHARPY V-NOTCH ENERGY CURVE FOR  $2\frac{1}{4}$ CR-1MO-V-TI-B STEEL. SOURCE: REF 4

FIG. 6 EFFECT OF NORMALIZING TEMPERATURE ON THE CHARPY V-NOTCH ENERGY CURVE FOR 3CR-1MO-V-TI-B STEEL. SOURCE: REF 6

Data for the CVN toughness of martensitic 9Cr-1Mo-V steel are included in Fig. 7. Air-melted, high-silicon heats exhibit low upper-shelf energies and high transition temperatures (Ref 15). With reductions in silicon and utilization of clean steelmaking practice, very low transition temperatures and high upper-shelf energies can be achieved for 9Cr-1Mo-V steel.

**FIG. 7 EFFECT OF SILICON AND MELTING PRACTICE ON THE CHARPY V-NOTCH ENERGY CURVE FOR 9Cr-1Mo-V STEEL. SOURCE: REF 15**

The Cr-W-Mo steels are intended for tube and pipes, so extensive characterization of toughness properties has not been undertaken. Nevertheless, they appear to have good properties. The CVN energy for the  $2\frac{1}{4}$ Cr-1.6W steel (SA-213, grade 23) is shown as a function of temperature in Fig. 8. Toughness is excellent in both the as-normalized and PWHT conditions (Ref 9). Similarly, in the normalized-and-tempered condition the toughness of the 9Cr-2W steel (SA-213, grade 92) is excellent, as indicated in Fig. 9 for a tube heat. Reported energies at 0 °C range from 206 to 279 J/cm<sup>2</sup> for tubes and 116 to 162 J/cm<sup>2</sup> for pipes. At 0 °C, the 12Cr-2W steel has CVN energy values in the range of 65 to 330 J/cm<sup>2</sup> for tubes and 66 to 98 J/cm<sup>2</sup> for pipes.

#### Fracture Mechanics

Several degradation mechanisms embrittle Cr-Mo and Cr-W-Mo steels and their weldments: temper embrittlement during long-time exposure, aging embrittlement due to precipitation of brittle phases, creep damage, hydrogen attack, and hydrogen embrittlement. Traditionally, CVN data for exposed material have been used to assess the severity of some degradation mechanisms in regard to structural integrity. A more recent approach has been to perform *J-R* testing on "degraded" material and derive fracture mechanics properties. As part of the development of a fitness-for-service assessment methodology, for example, the Materials Properties Council has collected fracture toughness data for carbon and Cr-Mo steels. These data have been compared to lower-bound curves more or less comparable to the ASME Section III, Appendix G curve for nuclear pressure vessel steels. Data for several grades of Cr-Mo steels are shown in Fig. 10 (Ref 16).

FIG. 10 FRACTURE TOUGHNESS DATA FOR CARBON AND CR-MO STEELS COMPARED WITH LOWER-BOUND CURVES DEVELOPED FOR ASME SECTION III, APPENDIX G

An approach taken by Iwadata et al. (Ref 17) to address temper embrittlement is to correlate the CVN fracture-appearance transition temperature (FATT) against an embrittlement factor. For  $2\frac{1}{4}$ Cr-1Mo and 3Cr-1Mo steels they chose the  $J$  factor, defined by:

$$J = (\%SI + \%MN) (\%P + \%SN) \times 10^4$$

For  $1\frac{1}{4}$ Cr- $\frac{1}{2}$ Mo steel, they used the  $X$  factor, defined by:

$$X = (10P + 5SB + 4SN + AS)/100$$

where the element content is in parts per million. With such a correlation and knowledge of the upper-shelf energy and yield strength, master curves were constructed that could be used to predict  $K_{Ic}$ . Curves for the correspondence of the FATT with the  $J$  factor are shown in Fig. 11 for the Cr-Mo steels exposed up to 75,000 h. Curves for  $K_{Ic}$  versus temperature are shown in Fig. 12 for Cr-Mo steels. Here the term  $K_{Ic-US}$  is derived from the Rolfe-Barsom correlation:

$$(K_{Ic-US}/\sigma_{0.2})^2 = 0.6478 [(CVN_{US}/\sigma_{0.2}) - 0.0098]$$

where  $CVN_{US}$  and  $\sigma_{0.2}$  are the impact energy (in joules) and the 0.2% offset yield strength (in megapascals) at the upper-shelf temperature. The correlation holds for base metal and weld metal.

### Low-Cycle Fatigue

The Cr-Mo steels have a long history of satisfactory performance in high-temperature components. Because the steels exhibit low thermal expansion and high thermal conductivity, relative to austenitic stainless steels, they are less susceptible to fatigue failures induced by thermal-mechanical loading. With continued operation of equipment, increased cyclic operation, and higher service temperatures, however, the risk of fatigue-related failures in Cr-Mo steels increases. At temperatures up to 370 °C (700 °F) and in the low-cycle fatigue (LCF) region, the lower-strength Cr-Mo alloys with better tensile ductility exhibit better LCF resistance. Generally, this is true when the cyclic strain range exceeds 1%. At low strain ranges corresponding to the high-cycle fatigue (HCF) regime, the steels with higher ultimate strengths exhibit better fatigue resistance. Above 370 °C (700 °F), the LCF resistance of Cr-Mo steels is affected by temperature, strain rate, load histogram, and environment. The temperature effect is relatively weak. For some combinations of strain range and strain rate, an improvement in life with increasing temperature is observed, and the improvement appears to result from dynamic strain aging. Above 370 °C (700 °F), the LCF damage mechanism in the Cr-Mo steels involves the formation of cracks in the surface oxide that lead to the penetration of transgranular cracks. These cracks appear as oxide-filled wedges.

The strain-controlled (LCF) of  $2\frac{1}{4}$ Cr-1Mo steel and its weldments has been studied extensively. Annealed (class 1), normalized-and-tempered (class 2), and quenched-and-tempered (A-542) steels have been examined. One collection of LCF data for the annealed steel is provided in Fig. 13 (Ref 18). These data represent three heats for annealed steel (pipe and plate) and isothermally annealed steel (tubing). Testing temperatures ranged from 427 °C (800 °F) to 593 °C (1100 °F). Both load-controlled and strain-controlled data are included, and lives extend over four decades. Additional data for three heats of plate products are plotted in Fig. 14 for temperatures of 371, 427, and 538 °C (700, 800, and 1000 °F) (Ref 19). One low-carbon heat is included. These trends are applicable to continuous cycling at high strain rates (0.001/s and greater) and have formed the basis for the design fatigue curves found in ASME Section III, Division 1, Subsection NH. Although the LCF curves exhibit minimal temperature effects, the cyclic strength varies with temperature, strain rate, and processing history, so the elastic and plastic components of the strain range for a given life may vary substantially. A comparison of the monotonic and cyclic hardening curves for annealed material is shown in Fig. 15 (Ref 20). The cyclic data were obtained from the rising half of the tenth-cycle hysteresis loop and correspond to ranges rather than amplitudes. Strain rates are low (0.005/min.) compared to the rate used for fatigue testing, but the trends suggest that the annealed material is a strain-hardening material rather than a strain-softening material.

FIG. 13 STRAIN-FATIGUE CURVES FOR  $2\frac{1}{4}$ CR-1MO STEEL (CLASS 1) AT 425 °C (800 °F) WITH COMPARISON OF STRAIN LIFE AT 595 °C (1100 °F). OPEN POINTS, ANNEALED; SOLID POINTS, ISOTHERMALLY ANNEALED.  $R = -1$ . SOURCE: REF 18

The LCF for class 2 steels has been well characterized to 600 °C (1110 °F) for tubing by the National Research Institute for Metals (Ref 21). The LCF data for several temperatures and strain rates are shown in Fig. 16. These data indicate a slight decrease in fatigue life with increasing temperature and decreasing strain rate. These steels exhibit cyclic softening. Comparisons of the monotonic and cyclic stress versus strain curves are shown in Fig. 17 (Ref 22).

FIG. 17 CYCLIC STRESS VS. STRAIN CURVES FOR  $2\frac{1}{4}$  CR-1MO STEEL (CLASS 2), DERIVED FROM THE STRESS AMPLITUDE AT HALF LIFE, AT 450 AND 500 °C. STRAIN RATE 0.1% PER SECOND.  $R = -1$ . SOURCE: REF 22

Unpublished data for the  $2\frac{1}{4}$ Cr-1Mo-V and 3Cr-1Mo-V steels indicate LCF behavior similar to that of  $2\frac{1}{4}$ Cr-1Mo (class 2) steel at temperatures in the range of 370 to 540 °C (700 to 1000 °F).

The fatigue behavior of 9Cr-1Mo-V steel has been well characterized from research in the U.S., Asia, and Europe. The LCF curves for three heats and four temperatures are shown in Fig. 18 (Ref 23). Data are tightly grouped at all temperatures.

FIG. 18 STRAIN-FATIGUE CURVES FOR 9CR-1MO-V STEEL AT ROOM TEMPERATURE AND 540 °C (1000 °F). STRAIN RATE,  $4 \times 10^{-3}$  PER SECOND.  $R = -1$ . SOURCE: REF 23

For conditions that involve creep-fatigue interaction, the load histogram is important. Hold time at the compressive or tensile strain limit usually produces shorter fatigue lives. Often, researchers have reported that compressive hold times are more damaging than tensile hold times and produce shorter lives. Explanations for the hold time effects have been offered that relate to mean stress effects and to the oxide cracking mechanism, but no consensus exists in regard to the best method to evaluate creep-fatigue damage in Cr-Mo steels. Linear damage calculations based on cycle fractions and time fractions require continuous cycling data and stress rupture data, and fatigue damage calculations require the type of fatigue data presented above. Most other approaches, such as strain-range partitioning, ductility exhaustion, and frequency separation, require supplementary data that are not provided in this article.

### Fatigue Crack Growth

Often, LCF curves are used to estimate the cycles to fatigue crack initiation in relatively thick sections. Thereafter, subcritical fatigue crack growth procedures are used to estimate remaining life. Typical fatigue crack growth data for annealed  $2\frac{1}{4}$ Cr-1Mo steel are plotted in Fig. 19, 20, and 21 (Ref 24). The effect of temperature is illustrated in Fig. 19, the effect of frequency is illustrated in Fig. 20, and the effect of stress ratio is shown in Fig. 21. Fatigue crack growth curves for 9Cr-1Mo-V steel are provided in Fig. 22 (Ref 25).

## Weldments

Although the fatigue behavior of weldments is covered elsewhere in this Volume, it should be mentioned that the strength, toughness, fatigue, and creep-fatigue behavior of Cr-Mo steel weld metal and weldments is of major concern in the selection of materials and the manufacture of pressure-bearing components. For new construction, the testing requirements for weld metal and weldments are specified in the BVPC Section IX. Filler metals are available that exhibit strength properties comparable or superior to those of base metal, but the hardenability of most Cr-Mo steels is sufficient to produce hard, low-toughness regions in the HAZ of thick-section weldments. A proper PWHT restores toughness

properties. Often, the HAZ contains microstructures developed from heating the base metal to the intercritical zone. Very fine-grain material in this zone tends to have poor high-temperature strength. Under fatigue and creep-fatigue loading, failures often occur in the HAZ of weldments. Because composition, metallurgical structure, loading history, and section geometry strongly influence the life under cyclic loading, high-temperature test data on the fatigue, creep-fatigue, and fatigue-crack-growth of Cr-Mo weldments are not well enough defined to be included here.

**Fatigue and Fracture Properties of Stainless Steels**

S. Lampman, ASM International

**Introduction**

STAINLESS STEELS are used in a wide variety of structural applications. Most of the structural applications occur in the chemical and power engineering industries, which account for more than a third of the market for long and flat stainless steel products (circa 1993, Ref 1). These applications include an extremely diversified range of use, including nuclear reactor vessels, heat exchangers, oil industry tubulars, components for the chemical processing and pulp and paper industries, furnace parts, and boilers used in fossil fuel electric power plants.

Stainless steels of all types contain chromium in amounts ranging from 10 to 30%. The stainlessness and oxidation resistance of stainless steels is primarily dependent on chromium content. Other alloying elements, including silicon, nickel, molybdenum, copper and aluminum, contribute to the general corrosion resistance, but their influence is limited compared to that of chromium. Standard compositions of stainless steels (Table 1) are generally divided by microstructure into the following groups: austenitic types, ferritic types, duplex types, martensitic types, and precipitation hardening types. The following sections briefly summarize the key mechanical characteristics of these stainless steel types with particular emphasis on fracture properties and corrosion fatigue. Typical room-temperature mechanical properties and fatigue endurance limits are summarized in Table 2. Additional information on corrosion and environmentally assisted fracture of stainless steels is contained in Ref 2 and elsewhere in this Volume.

## Stainless Steel Types

Ferritic stainless steels are so named because their body-centered-cubic (bcc) crystal structure is the same as that of iron at room temperature. These alloys are magnetic and cannot be hardened by heat treatment. Ferritic stainless steels contain between 11 and 30% Cr, with only small amounts of austenite-forming elements, such as carbon, nitrogen, and nickel. Their general use depends on their chromium content for corrosion resistance.

In general, ferritic stainless steels do not have particularly high strength (Fig. 1). Their annealed yield strengths range from 275 to 350 MPa (40 to 50 ksi), and their poor toughness and susceptibility to sensitization limit their fabricability and the usable section size. Their chief advantages are their resistance to chloride stress-corrosion cracking, atmospheric corrosion, and oxidation at a relatively low cost.

FIG. 1 GENERAL COMPARISON OF THE HOT-STRENGTH CHARACTERISTICS OF AUSTENITIC, MARTENSITIC, AND FERRITIC STAINLESS STEELS WITH THOSE OF LOW-CARBON UNALLOYED STEEL AND SEMIAUSTENITIC

## PRECIPITATION AND TRANSFORMATION-HARDENING STEELS.

Ferritic stainless steels can be a viable alternative to austenitic steels for some high-temperature structural applications. In view of their lower alloy content and lower cost, ferritic steels have an economic advantage over austenitic steels, stress conditions permitting. Ferritic stainless steels can also be desirable in applications with thermal cycling because ferritic steels have higher thermal conductivities and lower thermal expansion coefficients than austenitic steels. Ferritic steels may therefore allow reductions in thermal stresses and improved thermal-fatigue resistance.

In addition various grades of high-chromium heat-resistant ferritic steels are important alloys for high-temperature structural applications. High-chromium heat-resistant ferritic steels were first developed for use in gas and steam turbine applications. In the early 1940s, a need for improved high-strength, corrosion-resistant materials for gas turbine disks and steam turbine blades, operating at temperatures near 540 °C (1000 °F), led metallurgists in England to increase development work on 12% Cr heat-resistant steels. This research produced two steels (H-46 and FV448) and other alloy steels in the 1950s with improved creep-rupture strengths. During the same time period, other 12% Cr alloys such as AISI 422 (UNS S42200) and Lapelloy were introduced in the United States; they have been used for steam turbine blades and bolting materials for turbine cylinders. Although many of the high-chromium heat-resistant ferritics are not strictly considered stainless steels, the chromium contents are high enough to exhibit corrosion resistance comparable to that of typical stainless steels. These alloys are considered in the article "Fatigue and Fracture Resistance of Heat-Resistant (Cr-Mo) Ferritic Steels" in this Volume.

**Austenitic stainless steels** constitute the largest stainless family in terms of number of alloys and usage. Like the ferritic alloys, they cannot be hardened by heat treatment. Austenitic alloys are nonmagnetic, and their structure is face-centered-cubic (fcc). They possess excellent ductility, formability, and toughness, even at cryogenic temperatures. In addition, they can be substantially hardened by cold work.

Austenitic stainless steels can be subdivided into two categories: chromium-nickel alloys, such as S30400 and S31600, and chromium-manganese-nitrogen alloys, such as S20100 and S24100. The latter group generally contains less nickel and maintains the austenitic structure with high levels of nitrogen. Manganese (5 to 20%) is necessary in these low-nickel alloys to increase nitrogen solubility in austenite and to prevent martensite transformation. The addition of nitrogen also increases the strength of austenitic alloys. Typical chromium-nickel alloys have tensile yield strengths from 200 to 275 MPa (30 to 40 ksi) in the annealed condition, whereas the high-nitrogen alloys have yield strengths up to 500 MPa (70 ksi).

The most common austenitic stainless steel is Type 304, which has been used for critical elevated-temperature applications such as high pressure piping in power generating stations and for very low temperature applications such as liquid helium transfer piping and storage vessels. The alloy is generally used in the annealed condition (heated at 1060 °C, or 1950 °F, to dissolve carbides, and quenched in water or cooled in air at a rate high enough to prevent carbide reprecipitation). Type 304 has high ductility and toughness in this condition over a wide range of service temperatures. Because of its high toughness and relatively low yield strength, plane-strain conditions cannot be obtained on monotonic loading up to the point of unstable crack propagation in precracked fracture toughness specimens of reasonable size. The same limitation applies to all austenitic stainless steels in the annealed condition. Therefore, available fracture mechanics data for these alloys generally are limited to fatigue crack growth rate data ( $da/dN$ ). However, valid monotonic fracture mechanic properties of austenitic stainless steels are an area of active engineering interest (see the article "Fracture Toughness of Austenitic Stainless Steels and Their Welds" in this Volume).

All of the austenitic stainless steels in Table 1 are modifications of Type 304. Increasing the nickel content increases the austenite stability and reduces the work hardening effect. Increasing the chromium content increases the resistance to deformation at elevated temperatures, and also increases the oxidation and corrosion resistance. Addition of molybdenum increases corrosion resistance. Titanium, niobium and tantalum are added to stabilize carbide formation and minimize grain boundary sensitization following welding. Up to 0.30% nitrogen and small amounts of other elements may be added to heats of stainless steel by melting under a nitrogen atmosphere and by additions of master alloys. These additions, as in Kromarc 58, increase the strength of the alloy. Compositions of other austenitic stainless steels have not been included in Table 2 because little or no fracture mechanics data have been available for them.

Of the austenitic grades, most fatigue crack growth rate data have been obtained on Types 304 and 316 because these two stainless steels have been shown to have good fatigue crack growth rate resistance in nuclear reactor environments.

**Martensitic stainless steels** are quenched and tempered for increased strength and good ductility and toughness. These alloys are magnetic, and they have a tensile yield strength of about 275 MPa (40 ksi) in the annealed condition. The strength obtained by heat treatment depends on the carbon content of the alloy. Increasing carbon content increases strength but decreases ductility and toughness. The most commonly used alloy in this family is S41000, which contains about 12% Cr and 0.1% C. This alloy is tempered to a variety of hardness levels, from 20 to 40 HRC. Both chromium and carbon contents are increased in alloys S42000, S44002, S44003, and S44004. The first of these contains 14% Cr and 0.3% C and has a hardness capability of 50 HRC. The other three alloys contain 16% Cr and from 0.6 to 1.1% C. These alloys are capable of 60 HRC and a tensile yield strength of 1900 MPa (280 ksi).

Fatigue strength of martensitic steels (such as in Fig. 2 for Type 410) is similar to that of carbon and low-alloy steels at the same hardness/strength level. As expected, the surface condition is a key variable in crack initiation or high-cycle (SH) fatigue. The sensitivity to surface condition usually increases with higher hardness. Martensitic stainless steels are selected for certain applications in which good corrosion resistance is required along with strength and/or hardness greater than may be obtained in austenitic or ferritic grades.

**Precipitation hardening (PH) stainless steels** have been developed to meet a need for constructional components with good corrosion resistance, with high strength, and with better toughness than that of the martensitic stainless steels discussed above. Many different types of precipitation hardening stainless steels have been developed, and many of them have been used in certain special applications. Common compositions presented in Table 1 have fracture mechanics data available.

The precipitation hardening grades may be divided into three classes. Of those shown in Table 1, 15-5PH, 17-4PH, PH13-8Mo and Custom 455 are martensitic; 17-7PH, PH15-7Mo and AM355 are semiaustenitic; and A-286 is austenitic. The class depends on the microstructure of the steel when it is cooled from the annealing temperature to room temperature, and this in turn depends on the relative amounts of ferrite-promoting and austenite-promoting elements in the chemical composition. Applications of the martensitic and semi-austenitic classes are usually limited to room-temperature and elevated-temperature service. Applications for the austenitic class (face centered cubic) include both cryogenic and elevated-temperature service.

Many variations of multiple-cycle heat treatments may be used in developing a range of strength and toughness properties in the precipitation hardening steels. The steels in the martensitic class (15-5PH, 17-4PH, PH13-8Mo and Custom 455) are usually supplied by the mill in condition A--i.e., in the solution treated condition. Solution treating temperatures range from 815 to 1040 °C (1500 to 1900 °F) depending on composition, and aging temperatures range from 480 to 620 °C (900 to 1150 °F). The microstructures of these steels are martensitic after solution treating (similar to annealed 18Ni maraging steels). Aging produces precipitates of intermetallic compounds, resulting in precipitation hardening. Within the age hardening temperature range, the highest strengths are obtained after aging at 480 °C (900 °F). Aging at 540 or 565 °C (1000 or 1050 °F) results in lower strength but better ductility and fracture toughness.

Heat treatments for the semiaustenitic grades (17-7PH, PH15-7Mo and AM355) require solution annealing at 1040 to 1065 °C (1900 to 1950 °F) and an additional thermal conditioning step prior to aging to develop the desired properties. Heat treatment of A-286 stainless steel is not as effective in increasing its strength as for the martensitic and semiaustenitic grades because of the relatively low strength of the austenitic matrix. Mill forms of A-286 are usually obtained in the annealed condition, annealed at 980 °C (1800 °F). For some applications, annealed A-286 may be re-solution treated at 900 °C (1650 °F) and quenched in oil prior to further processing. After fabrication, components of A-286 stainless steel are aged in the range from 700 to 760 °C (1300 to 1400 °F). On aging, precipitates of intermetallic compounds are formed in the matrix austenite. Aging increases the yield strength from 248 MPa (36 ksi) in the annealed condition to 690 MPa (100 ksi) in the aged condition.

**Duplex stainless steels** are chromium-nickel-molybdenum alloys that are balanced to contain a mixture of austenite and ferrite and are magnetic, as well. Their duplex structure results in improved stress-corrosion cracking resistance, compared with the austenitic stainless steels, and improved toughness and ductility, compared with the ferritic stainless steels. They are capable of tensile yield strengths ranging from 550 to 690 MPa (80 to 100 ksi) in the annealed condition, which is approximately twice the strength level of either phase alone. These alloys are discussed in the article "Fatigue and Fracture Properties of Duplex Stainless Steels" in this Volume.

### Embrittlement

Stainless steels are susceptible to embrittlement during thermal treatment or elevated-temperature service. These thermally-induced forms of embrittlement of stainless steels include sensitization, 475 °C (885 °F) embrittlement, and  $\sigma$ -phase embrittlement as briefly described below. Stainless steels are also susceptible to various forms of environmentally-assisted crack growth by hydrogen embrittlement. This is discussed separately by alloy type.

**Sensitization.** Stainless steels become susceptible to localized intergranular corrosion when chromium carbides form at the grain boundaries during high-temperature exposure. This depletion of chromium at the grain boundaries is termed "sensitization" because the alloys become more sensitive to localized attack in corrosive environments. Sensitization and intergranular corrosion can occur in austenitic, duplex, and ferritic stainless steels, depending on the alloy content and time-temperature exposures required for carbide precipitation.

**Austenitic stainless steels** become susceptible to intergranular corrosion when subjected to temperatures in the range of 480 to 815 °C (900 to 1500 °F). Several approaches have been taken to minimize or prevent the sensitization of austenitic stainless steels. If sensitization results from welding heat and the component is small enough, solution annealing will dissolve the precipitates and restore immunity. However, in many cases this cannot be done because of distortion problems or the size of the component. In these cases, a low-carbon version of the grade or a stabilized composition should be used. Complete immunity requires a carbon content below about 0.015 to 0.02%. Additions of niobium or titanium to tie up the carbon are also effective in preventing sensitization as long as the ratio of these elements to the carbon content is high enough. Stabilizing heat treatments are not very effective.

**Ferritic stainless steels** can be susceptible to sensitization, but ferritic grades with less than 15% Cr can be immune from sensitization. Reducing the carbon and nitrogen interstitial levels improves the intergranular corrosion resistance of ferritic stainless steels.

Sensitization can occur in titanium-stabilized ferritic stainless steels. The thermal treatment that causes sensitization, however, is altered by the addition of titanium.

**Duplex stainless steels** are resistant to intergranular corrosion when aged in the region of 480 to 700 °C (895 to 1290 °F). It has been recognized for some time that duplex grades with 20 to 40 vol% ferrite exhibit excellent resistance to intergranular corrosion.

**475 °C Embrittlement.** Iron-chromium alloys containing 13 to 90% Cr are susceptible to embrittlement when held within or cooled slowly through the temperature range of 550 to 400 °C (1020 to 750 °F). This phenomenon, called 475 °C (885 °F) embrittlement, increases tensile strength and hardness and decreases tensile ductility, impact strength, electrical resistivity, and corrosion resistance.

475 °C embrittlement occurs with iron-chromium ferritic and duplex ferritic-austenitic stainless steels, but not with austenitic grades. Aging at 475 °C (885 °F) can cause a rapid rate of hardening with aging between about 20 and 120 h because of homogeneous precipitation. The rate of hardening is much slower with continued aging from 120 to 1000 h. During this aging period, precipitation increases. Aging beyond 1000 h produces little increase in hardness because of the stability of the precipitates.

Even for a severely embrittled alloy, 475 °C embrittlement is reversible. Properties can be restored within minutes by reheating the alloy to 675 °C (1250 °F) or above. The degree of embrittlement increases with chromium content; however, embrittlement is negligible below 13% Cr. Carbide-forming alloying additions, such as molybdenum, vanadium, titanium, and niobium, appear to increase embrittlement, particularly with higher chromium levels. Increased levels of carbon and nitrogen also enhance embrittlement and, of course, are detrimental to nonembrittled properties as well. Cold work prior to 475 °C (885 °F) exposure accelerates embrittlement, particularly for higher-chromium alloys.

**Sigma-Phase Embrittlement.** The existence of  $\sigma$ -phase in iron-chromium alloys has been identified in over fifty binary systems and in other commercial alloys. Sigma phase has a tetragonal crystal structure and a hardness equivalent to approximately 68 HRC (940 HV). Because of its brittleness,  $\sigma$  often fractures during indentation.

In general,  $\sigma$  forms with long-time exposure in the range of 565 to 980 °C (1050 to 1800 °F), although this range varies somewhat with composition and processing. Sigma formation exhibits C-curve behavior with the shortest time for formation (nose of the curve) generally occurring between about 700 and 810 °C (1290 and 1490 °F); the temperature that produces the greatest amount of  $\sigma$  with time is usually somewhat lower.

In commercial austenitic and ferritic stainless steels, even small amounts of silicon markedly accelerate the formation of  $\sigma$ . In general, all of the elements that stabilize ferrite promote  $\sigma$  formation. Molybdenum has an effect similar to that of silicon; aluminum has a lesser influence. Increasing the chromium content also favors  $\sigma$  formation. Small amounts of nickel and manganese increase the rate of  $\sigma$  formation, but large amounts, which stabilize austenite, retard  $\sigma$  formation. Carbon additions decrease  $\sigma$  formation by forming chromium carbides, thereby reducing the amount of chromium in solid solution. Additions of tungsten, vanadium, titanium, and niobium also promote  $\sigma$  formation.

As might be expected,  $\sigma$  forms more readily in ferritic than in austenitic stainless steels. Coarse grain sizes from high solution-annealing temperatures retard  $\sigma$  formation, and prior cold working enhances it. The influence of cold work on  $\sigma$  formation depends on the amount of cold work and its effect on recrystallization. If the amount of cold work is sufficient to produce recrystallization at the service temperature,  $\sigma$  formation is enhanced. If recrystallization does not occur, the

rate of  $\sigma$  formation may not be affected. Small amounts of cold work that do not promote recrystallization may actually retard  $\sigma$  formation.

The most sensitive room-temperature property for assessing the influence of  $\sigma$  is the impact strength. High-temperature exposure can produce a variety of phases, and embrittlement is not always due solely to  $\sigma$  formation. Therefore, each situation must be carefully evaluated to determine the true cause of the degradation of properties.

## Fatigue and Fracture Properties of Stainless Steels

S. Lampman, ASM International

---

### Ferritic Stainless Steels

**Fracture Toughness.** Ferritic stainless steels have comparatively low ductility (Table 2) and toughness (Fig. 2). Available toughness data for ferritic stainless steels are limited primarily to impact toughness energy. Very little fracture mechanics data are available for ferritic stainless steels.

Ferritic stainless steels are notch sensitive similar to low-carbon and low-alloy steels. Impact toughness of ferritic grade 430 is compared with two other common stainless steels (Fig. 2). The toughness and transition temperatures are influenced by carbon contents, chromium levels, and hardness. When carbon contents exceed about 0.018 wt%, a large increase in transition temperature occurs. Typical effects of composition and test temperature are shown in Fig. 3 and 4.

**FIG. 3** CHARPY V-NOTCH TRANSITION TEMPERATURE RANGE FOR A-COMMERCIALY PRODUCED, ELECTRON-BEAM-MELTED FERRITIC 26CR-1MO. B-QUARTER-SIZE V-NOTCH IMPACT SPECIMENS OF AN AIR-MELTED 26CR-1MO STEEL

**FIG. 4 EFFECT OF VARIATION IN CHROMIUM AND CARBON CONTENT ON THE NOTCH IMPACT TOUGHNESS OF COMMERCIAL FERRITIC STAINLESS STEELS. SOURCE: REF 3**

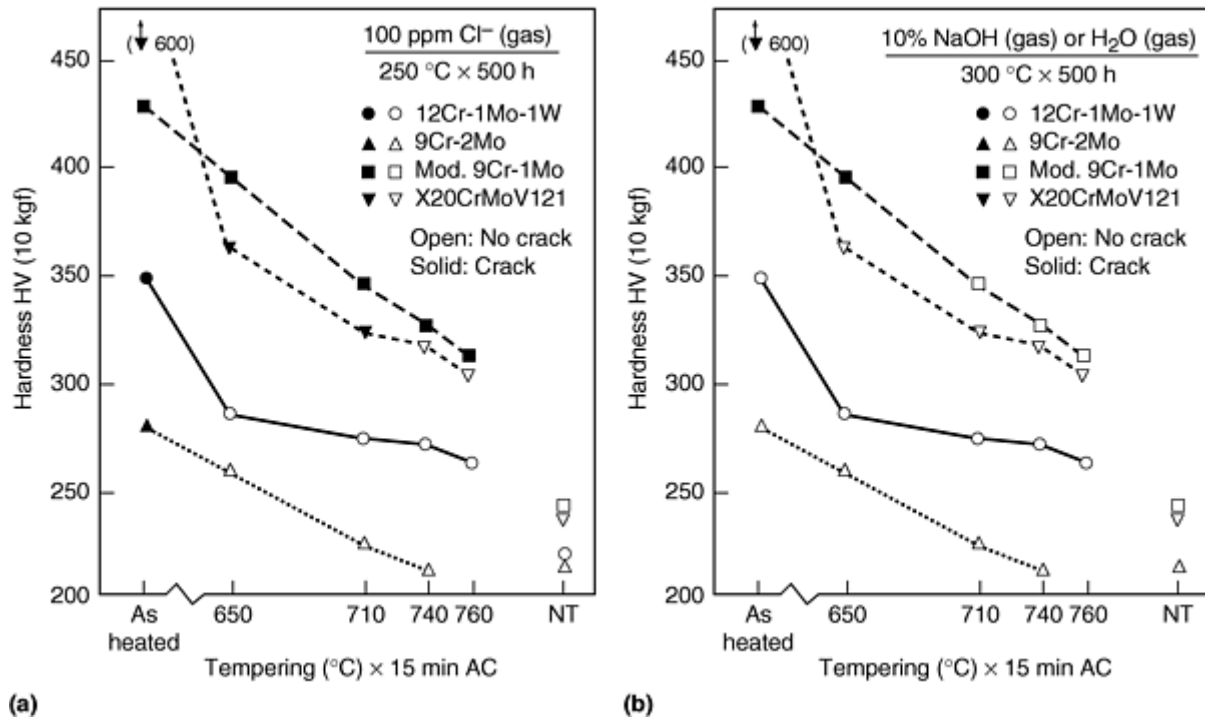

**Stress-Corrosion Cracking (SCC).** Ferritic stainless steels such as Type 405 and 430 have high SCC resistance in chloride solutions (Ref 1, 2, 3), and ferritic grades UNS S44400 (Remanit 4522) and S44800 (Remanit 4575) can be fully resistant to chloride SCC at stress-intensity levels of  $60 \text{ MPa}\sqrt{m}$  ( $55 \text{ ksi}\sqrt{in}$ ) in 22% NaCl solutions at  $105^\circ\text{C}$  ( $220^\circ\text{F}$ ).

Test data from U-bend also confirm good SCC resistance in chloride environments (Ref 1, 2), although SCC of the ferritics has been reported in applications such as:

- TYPE 434, TYPE 430, AND FE-18CR-2MO IN LITHIUM CHLORIDE SOLUTIONS
- SENSITIZED TYPE 446 IN BOILING MAGNESIUM CHLORIDE AND SODIUM CHLORIDE SOLUTIONS
- TYPE 430 F IN THE MARINE ATMOSPHERE
- NICKEL-CONTAINING SUPERFERRITICS AL 29-4-2 (UNS S44800), MONIT (UNS S44635), AND SEA-CURE (UNS S44660) IN BOILING MAGNESIUM CHLORIDE

Chloride SCC resistance of ferritic stainless steels can be reduced by the presence of certain alloying elements, sensitization (induced by heat treatment or welding), cold work, high-temperature embrittlement. For example, the producers of AL 29-4C (UNS S44735), which is shown to be SCC-resistant in U-bend tests, caution that the addition of 1% Ni to the alloy composition will introduce susceptibility to chloride SCC in boiling magnesium chloride environments.

Hardness and microstructure also influence SCC resistance as shown in Fig. 5 from an evaluation of weldment SCC. In the case of 10 vol% NaOH solution and pure water, SCC occurs at hardnesses above 380 HV. In the case of the more severe condition in 100 ppm Cl<sup>-</sup> solution, SCC occurs in all steels after 1250 °C as-heated condition. However, no cracking is observed for two-phase steels (ferrite and δ-ferrite) after post-weld heat treatment (PWHT) (at least above 650 °C for 15 min). The fully martensitic steels had SCC depending on hardness after PWHT. Critical hardness to prevent SCC in 100 ppm Cl<sup>-</sup> solution is about 310 HV. In all test conditions, no SCC is observed for the normalized-and-tempered base metals. Thus, depending on hardness, microstructure, and environment, SCC occurs even in the ferritic steels. The SCC resistance of 12Cr-1Mo-1W-V-Nb steel is superior to conventional 9-12Cr steels, because δ-ferrite decreases the hardness of HAZ and prevents crack propagation.

**FIG. 5 RELATIONSHIP BETWEEN SCC PROPERTIES AND HARDNESS OF SIMULATED HAZ BEFORE AND AFTER TEMPERING OF FOUR HIGH-CHROMIUM FERRITIC STEELS. MAXIMUM HARDNESS OF 600 HV IS OBSERVED IN X20CRMV121 STEEL HEATED AT 1250 °C BECAUSE OF A HIGHER CARBON CONTENT OF 0.2 WT%. HARDNESS DISTRIBUTIONS FOR FULLY MARTENSITIC X20CRMV121 AND MODIFIED 9CR-1MO STEELS ARE HIGHER THAN THOSE OF TWO-PHASE STEELS. 9CR-2MO STEEL IS SOFTER THAN 12CR-1MO-1W-V-NB STEEL DUE TO LOWER CARBON CONTENT WITH 0.06 WT% AND ABSENCE OF STRENGTHENING ELEMENTS SUCH AS V AND NB. SOURCE: REF 4**

**Corrosion Fatigue.** Ferritic stainless steels have similar fatigue behavior as ferritic low-carbon and low-alloy steels in nonaggressive environments. In corrosive environments such as seawater, however, chromium steels have better high-cycle fatigue strength than low-carbon steels (see the article "Fatigue and Fracture Properties of Structural Steels" in this Volume). For example, tests on higher-chromium, low-interstitial 26-1 ferritic stainless steel containing molybdenum (Fe-26.21Cr-1.03Mo-0.001C-0.007N) show a relatively high fatigue strength of 350 MPa (50 ksi) at  $3 \times 10^7$  cycles in an aerated 3% NaCl solution (Ref 2). Fatigue crack growth rates for this alloy is compared in Fig. 6 (Ref 5).

## Fatigue and Fracture Properties of Stainless Steels

S. Lampman, ASM International

## Martensitic Stainless Steels

Types 403 and 410 stainless steels represent the basic compositions of the martensitic stainless steels. These alloys are used in various fracture-critical structural applications. For example, Type 403 martensitic stainless steel is used extensively for steam turbine rotor blades and rotors that operate at temperatures up to 480 °C (900 °F). For this type of application, the components are tempered at 590 °C (1100 °F) or higher, after which embrittlement at service temperatures is negligible.

The fatigue and fracture resistance of martensitic stainless steels is similar to low-alloy martensitic steels with comparable strength and hardness. Typical fatigue strength of various martensitic stainless steels are shown in Fig. 7. Mean stress effects for Type 422 (AISI 616) are given in Fig. 8 (Ref 6).

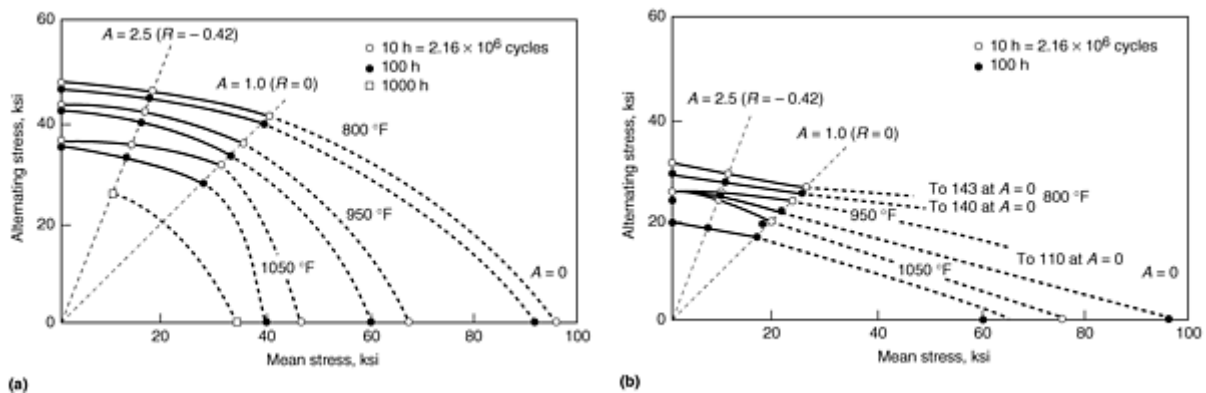

FIG. 8 STRESS RANGE DIAGRAMS FOR AISI 616 (TYPE 422) MARTENSITIC STAINLESS STEEL. (A) UNNOTCHED; (B) NOTCHED.  $A = \text{STRESS AMPLITUDE}/\text{MEAN STRESS}$ , OR  $R = (1 - A)/(1 + A)$ . SOURCE: REF 6

**Fracture Toughness and SCC Thresholds.** Fracture toughness data on martensitic grades are available from various tests on specimens of Types 403, 403 modified, 420, 422, and 431. Table 3 summarizes some valid  $K_{IC}$  test results for Type 420 in air and 3.5% NaCl solution. The specimens tempered at 450 °C (840 °F) had the lowest fracture toughness and the lowest  $K_{ISCC}$  values because of the 450 °C embrittlement. Such embrittlement is caused by formation of fine carbide precipitates and  $Fe_3C$  plates, whereas the low corrosion resistance is caused by chromium depletion through precipitation of  $Cr_7C_3$ . For the specimens tempered at 250 °C (480 °F) and 650 °C (1200 °F), those that were quenched in oil had the highest fracture toughness and the highest  $K_{ISCC}$  values. The highest  $K_{ISCC}$  value was obtained after quenching in oil and tempering at 650 °C (1200 °F). During tempering at 650 °C,  $M_{23}C_6$  precipitates are formed which reduce the hardness but do not cause chromium depletion.

(A)  $K_{ISCC}$  IN 3.5% NaCl SOLUTION.

(B) DID NOT MEET ALL REQUIREMENTS OF ASTM METHOD E399

Valid  $K_{Ic}$  data at room temperature for relatively tough materials like martensitic steels require unusually thick specimens. For example, fracture toughness test data have been obtained by Logsdon (Ref 7) on three heats of Type 403 modified stainless steel using compact specimens from 50 to 200 mm (2 to 8 in.) thick for tests in the temperature range from -196 to +80 °C (-320 to +175 °F). The thicker specimens were used to obtain valid  $K_{Ic}$  data at higher temperatures. In a later study, (Ref 8), 25-mm (1-in.)-thick compact specimens were tested at temperatures from -18 to +150 °C (0 to 300 °F) using the J-integral method. From -18 to +24 °C (0 to 75 °F), the  $K_{Ic}(J)$  data points were close to the fracture toughness curve defined by the  $K_{Ic}$  data points for the larger specimens from the same heat. At higher temperatures, the  $K_{Ic}(J)$  data points apparently define a plateau in toughness values (Fig. 9). Yield strength and fracture toughness are also compared in Fig. 9.

**FIG. 9 FRACTURE TOUGHNESS DATA OBTAINED OVER RANGES OF TEMPERATURE AND SPECIMEN THICKNESS FOR TYPE 403 MODIFIED STAINLESS STEEL.  $K_{Ic}(J)$  SPECIMEN WERE 1 IN. THICK. SOURCE: REF 9**

**Type 431 Fracture Toughness.** Different combinations of yield strength and fracture toughness were obtained by heat treating Type 431 specimens cut from rolled bar (Ref 9). One set of specimens was tempered at 635 °C (1175 °F) for two hours (HT125) and the other was tempered at 290 °C (550 °F) for two hours, cooled in air, and retempered at 290 °C for two hours (HT200). Yield strength and fracture toughness ( $K_{Ic}$  for 2 in. specimens from T-L orientation) were as follows:

- 717 MPA (104 KSI) YIELD STRENGTH AND 93 MPA  $\sqrt{m}$  (85 KSI  $\sqrt{in}$ ) FRACTURE TOUGHNESS FOR HT125 SPECIMENS
- 1137 MPA (165 KSI) YIELD STRENGTH AND 75 MPA  $\sqrt{m}$  (68 KSI  $\sqrt{in}$ ) FRACTURE TOUGHNESS FOR HT200 SPECIMENS

The Type 431 specimens were also tested for SCC thresholds. Results of  $K_{Isc}$  tests in 20% sodium chloride, for compact specimens (T-L) bolt loaded to 95% of the  $K_{Ic}$  value, were  $47 \text{ MPa}\sqrt{m}$  ( $43 \text{ ksi}\sqrt{in}$ ) for the HT125 condition and  $13 \text{ MPa}\sqrt{m}$  ( $12 \text{ ksi}\sqrt{in}$ ) for the HT200 condition.

Corrosion fatigue resistance is dependent on the chromium content. Types 403, 410, and 422 have lower chromium content, which thus lowers pitting and fatigue crack initiation resistance in chloride solutions. Corrosion effects on high-cycle fatigue resistance of Type 410 are shown in Fig. 10 and 11.

FIG. 10 FATIGUE BEHAVIOR OF TYPE 410 MARTENSITIC STAINLESS STEEL IN AIR AND IN A 0.03% NaCl SOLUTION. SOURCE: REF 2

FIG. 11 EFFECT OF NaCl CONCENTRATION ON THE CYCLES TO FAILURE AT AN ALTERNATING STRESS OF 340 MPa FOR A TYPE 410 MARTENSITIC STAINLESS STEEL. SOURCE: REF 2

Fatigue crack growth rates of martensitic stainless steels are less sensitive to environmental effects at room temperature. For example, Clark (Ref 10) reported nearly identical crack growth rates of modified 403 in air, distilled water, seawater, and sulfurous acid (pH 7.3) at room temperature. In these tests, compact specimens from two heats of Type 403 modified were tested in air, distilled water, seawater and sulfurous acid at 24 and 93 °C (75 and 200 °F) and in high-oxygen (40 ppm) and low-oxygen (1 ppm) steam at 100 °C (212 °F). The specimens had been austenitized at 960 °C (1760 °F), quenched in oil, and tempered at 663 °C (1225 °F) for four hours. For these tests,  $R$  ratios were from 0 to 0.1 at a testing

frequency of 30 Hz--except at low  $\Delta K$  levels, when a testing frequency of 160 Hz was used. At room temperature, environmental effects on crack growth were insignificant.

The fatigue crack growth rate properties in air at room temperature and at 93 °C (200 °F) were also the same. At 93 °C, however, distilled water, seawater and sulfurous acid environments increased the rate of fatigue crack growth by factors of approximately 2.5, 3, and 5, respectively, over that for the air environment. The oxygen content of the steam did not influence the rate of fatigue crack growth. In distilled water at 270 °C (520 °F), a slight increase in crack growth rates was also observed for modified Type 403 (Ref 7).

Somewhat different results were obtained from crack growth testing of Type 403 in water at room temperature (Ref 11). Exposure to water at 25 °C resulted in intermediate crack growth rates between those in air and those in water at 100 °C (Fig. 12). However, fatigue crack growth rates in 0.01 M sodium chloride at pH 10 and 100 °C were the same as those in water at 100 °C. At lower cyclic frequencies, the fatigue crack growth rates were higher than at 40 Hz at  $\Delta K$  values above 20 MPa $\sqrt{m}$  (18 ksi $\sqrt{in}$ ). For tests in the 1.0 M sodium chloride solution at 100 °C (212 °F), fatigue crack growth rates were the same as for water at the same temperature (Fig. 13). At 100 °C (212 °F), fatigue crack growth rates in 1.0 M sodium phosphate solution at pH 10 and at 10 and 40 Hz and in 1.0 M sodium silicate at pH 10 and at 10 Hz were practically the same as those in air (Fig. 13).

**FIG. 12 FATIGUE CRACK GROWTH RATES IN TYPE 403 STAINLESS STEEL IN AIR, WATER, AND A 1 M NaCl SOLUTION AT 10 HZ AND AN R RATIO OF 0.5. COMPACT SPECIMENS (0.5 IN. THICK) OBTAINED FROM L-T ORIENTATION OF PLATE THAT HAD BEEN AUSTENITIZED AT 950 °C (1750 °F), COOLED IN AIR, AND TEMPERED AT 650 °C (1200 °F) FOR ONE HOUR TO OBTAIN A YIELD STRENGTH OF 682 MPa (100 KSI). ALL FATIGUE CRACK GROWTH RATE TESTS WERE CONDUCTED AT ROOM TEMPERATURE OR AT 100 °C (212 °F), AT AN R RATIO OF 0.5 AND AT FREQUENCIES OF 0.1 TO 40 HZ. THE SPECIMENS WERE COMPLETELY SUBMERGED IN THE SOLUTIONS DURING TESTING. SOURCE: REF 11**

## Fatigue and Fracture Properties of Stainless Steels

S. Lampman, ASM International

## Martensitic PH Stainless Steels

Martensitic (maraging) precipitation hardening stainless steels are usually purchased in the solution annealed condition with a microstructure of low-carbon martensite. After fabrication, the components are age hardened (maraged) in the temperature range from 480 to 590 °C (900 to 1100 °F) and cooled in air. Aging develops the precipitation hardened

properties in these steels. Heat treatments and corresponding tensile properties are practically the same for Types 15-5PH and 17-4PH. On aging, precipitates of submicroscopic copper compounds form in the martensitic matrix, causing substantial increases in strength and hardness. The composition of 15-5PH is such that no delta ferrite occurs in this alloy, and thus it has good short transverse centerline ductility in wrought products. A small percentage of delta ferrite may be observed in microstructures of 17-4PH stainless steel. An aluminum-containing intermetallic compound precipitates in the martensitic matrix during aging of PH13-8Mo, while intermetallic compounds of copper and titanium are precipitated on aging of Custom 455.

Plane strain fracture toughness ( $K_{Ic}$ ) data for 15-5PH, 17-4PH, PH13-8Mo and Custom 455 martensitic precipitation hardening stainless steels are presented in Tables 4 and 5. For each of these steels, the fracture toughness increases as the aging temperature is increased. Of these four steels, Custom 455 has the highest strength in the H900 and H950 conditions. For forged and rolled bars in the H1000 condition, however, the strength and toughness of Custom 455 are comparable to those of PH13-8Mo. For many applications, either the H1000 or the RH1000 condition represents the best combination of strength and toughness.

**TABLE 4 FRACTURE TOUGHNESS ( $K_{Ic}$ ) DATA FOR MARTENSITIC PH STAINLESS STEELS**

TYPE <sup>(A)</sup>	CONDITION <sup>(B)</sup>	TESTING TEMPERATURE		YIELD STRENGTH		TENSILE STRENGTH		FRACTURE TOUGHNESS

Results of threshold stress corrosion ( $K_{ISCC}$ ) tests on martensitic precipitation hardening stainless steels are presented in Table 6. Sump tank residue water and aqueous sodium chloride solutions may influence the threshold stress-intensity factors of specimens obtained in the L-T orientation in these steels depending on the steel condition and the environment, but the effect is more noticeable for specimens of the T-L orientation and probably still more damaging for specimens of the short transverse orientation. However, no  $K_{ISCC}$  data were located for specimens of the short transverse orientation.

(A) L-T ORIENTATION EXCEPT AS NOTED.

Fatigue crack growth rates for specimens of 15-5PH and 17-4PH (H1050 and H1100) are shown in Fig. 14 for various conditions and environments at room temperature. For specimens in the H1050 condition, increasing the  $R$  ratio from 0.05 to 0.67 and incorporating a one-minute holding period at maximum load in each cycle substantially increased the crack growth rates at  $\Delta K$  values over 40 MPa  $\sqrt{m}$  (36 ksi  $\sqrt{in}$ ). For specimens in the H1100 condition, exposure to a salt solution environment during tests with a one-minute holding period at maximum load increased the fatigue crack growth rates over those of specimens tested in air with one-minute holding time or with continuous cycling (Ref 12).

**FIG. 14 FATIGUE CRACK GROWTH RATES IN WOL SPECIMENS OF 15-5 PH AND 17-4 PH STAINLESS STEEL IN THE H1050 AND H1100 CONDITIONS IN ROOM-TEMPERATURE AIR AND IN A 3.5% NaCl SOLUTION. ADAPTED FROM REF 9**

Fatigue crack growth rate data collected by Crooker, Hasson, and Yoder on specimens of 17-4PH (H1050 and H1150) also show the marked increases in fatigue crack growth rates that accompany increases in load ratio over the range from 0.04 to 0.80 (Ref 13). In comparing fatigue crack growth rates for specimens of 17-4PH stainless steel in a dry argon environment and in a 100% humid argon environment, Rack and Kalish (Ref 14) have shown that high humidity increases fatigue crack growth rates in the absence of oxygen. The specimens were in the H900, H1000, and H1100 conditions, the frequency was 10 Hz, and the  $R$  ratio was 0.1.

Effects of increasing the load ratio,  $R$ , on fatigue crack growth rates of PH13-Mo (H1000) in low humidity air (LHA) and in sump tank residue water (STW) are shown in Fig. 15 (Ref 15). The highest fatigue crack growth rates in this series were obtained on specimens tested at an  $R$  ratio of 0.3 in STW. Increasing the load ratio from 0.08 to 0.3 had a marked effect on the growth rates at all  $\Delta K$  values in the range covered by these tests. Specimen orientation also influenced the results. Fatigue crack growth rates for PH13-8Mo (H1100) specimens tested in air at 0.17 Hz and a stress ratio of zero (Ref 16) are lower at given  $\Delta K$  values than the rates for corresponding specimens in the H1000 condition (Fig. 15).

FIG. 15 FATIGUE CRACK GROWTH RATES IN COMPACT SPECIMENS OF PH 13-8 MO STAINLESS STEEL IN THE H1000 CONDITION FOR ROOM-TEMPERATURE TESTS AT 1 HZ,  $R$  RATIOS OF 0.08 AND 0.3, L-T AND T-L ORIENTATIONS, IN LOW-HUMIDITY AIR (LHA) OR SUMP TANK WATER (STW). CRACK GROWTH RATES FOR H1100 CONDITION AT  $R = 0$  INCLUDED FOR COMPARISON. SOURCE: REF 15 AND 16

Fatigue life of two maraging steels with comparable tensile strength is given in Fig. 16. Reference 17 provides SN curves for several other PH steels at various tensile strengths and stress ratios.

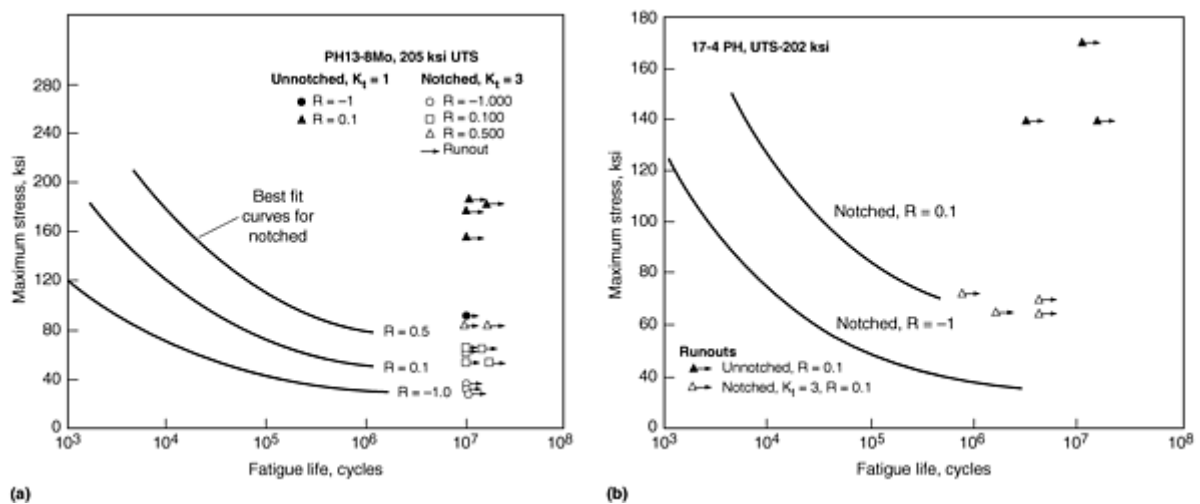

FIG. 16 ROOM-TEMPERATURE AXIAL FATIGUE CURVES OF TWO MARAGING (MARTENSITIC) GRADES OF PRECIPITATION HARDENING STAINLESS STEELS WITH COMPARABLE TENSILE STRENGTH. SOLID SYMBOLS INDICATE RUNOUT FOR UNNOTCHED ( $K_T = 1$ ) SPECIMENS. BEST-FIT SN CURVES ARE SHOWN FOR NOTCHED SPECIMENS ( $K_T = 3$ ) WITH RUNOUTS. ## Fatigue and Fracture Properties of Stainless Steels

S. Lammman, ASM International

## Semi-Austenitic and Austenitic PH Steels

**Semi-Austenitic PH Steels.** Only limited fracture toughness data have been published on the semiaustenitic precipitation hardening stainless steels. Typical  $K_{Ic}$  data are presented in Table 7. The highest toughness was obtained for specimens of AM355 (SCT1000) at a yield strength of 1170 MPa (170 ksi). Increasing the aging temperature from 455 °C (850 °F) to 540 °C (1000 °F) reduced the yield strength only slightly but increased the fracture toughness substantially.

(B) IN 3.5% NA CL SOLUTION.

(C) IN 20% NA CL SOLUTION.

Threshold stress-corrosion cracking ( $K_{Isc}$ ) data also are presented in Table 7 for these steels. Apparently these steels have relatively low resistance to crack growth in aqueous sodium chloride solutions. The highest value for  $K_{Isc}$  in this series was obtained for the AM355 (SCT1000) specimens.

**Austenitic precipitation hardening stainless steel A-286** is the main representative in this category. It contains titanium and small amounts of vanadium and aluminum, which precipitate as intermetallic compounds such as  $Ni_3(Al, Ti)$  and  $Ni_4Mo(Fe, Cr) Ti$  on aging. Various mill forms of the alloy are usually supplied in the annealed condition--Condition A (980 °C, or 1800 °F, for one hour followed by quenching in oil or water). Precipitation hardening occurs on aging in the range from 700 to 760 °C (1300 to 1400 °F) for 16 hours. Other combinations of heat treatments may be used depending on the application. One variation is to re-solution treat at 900 °C (1650 °F) for two hours, quench in oil or water, and age at 700 °C (1300 °F) for 16 hours. This variation results in improved room-temperature properties but less desirable stress-rupture properties.

Because of the high toughness of A-286 stainless steel, even at -269 °C (-452 °F), available fracture toughness data have been obtained only by the J-integral method. Results from several sources are presented in Table 8. Results shown for the series of tests performed by Reed, Tobler, and Mikesell (Ref 18) are lower than the others at room temperature. For this series, the heat treatment and the specimen orientation were not the same as for the others. Results of the  $J_{Ic}$  tests done by Wells et al. (Ref 19) show that toughness increases as the testing temperature is decreased to -269 °C (-452 °F).

Fatigue crack growth rate data have been reported by James (Ref 20) for compact specimens from A-286 stainless steel flat bar 12.7 mm (0.5 in.) thick and round bar 38 mm (1.5 in.) in diameter which had been annealed at 980 °C (1800 °F), quenched in water, and aged at 720 °C (1325 °F) for 16 hours. These specimens were obtained in the L-T, T-L, R-L, and R-C orientations and were tested at room temperature and at 316, 427, and 538 °C (600, 800, and 1000 °F) at an  $R$  ratio of 0.05 in air. Testing frequencies were 3 Hz at room temperature and 0.67 Hz at the elevated temperatures. The summary curves in Fig. 17 show that fatigue crack growth rates tend to increase as the exposure temperature is increased. Variations in the orientation of the specimens from the two product forms had no effect on the fatigue crack growth rates. For these specimens of A-286 alloy, the trend of the fatigue crack growth rates at each temperature was similar to that for 20% cold worked Type 316 stainless steel tested under similar conditions.

**FIG. 17 FATIGUE CRACK GROWTH RATES FOR SPECIMENS OF A-286 STAINLESS STEEL AT ROOM TEMPERATURE AND ELEVATED TEMPERATURES FOR TESTS IN AIR AT 3 HZ (RT) AND 0.67 HZ (ELEVATED TEMPERATURES), AN  $R$  RATIO OF 0.05, AND AT L-T, T-L, R-L, AND R-C ORIENTATIONS. SOURCE: REF 9**

Results of fatigue crack growth rate tests on compact and single-edge-notch specimens of A-286 stainless steel also have been reported by Gamble and Paris (Ref 21). Tests were made at room temperature and at 482 °C (900 °F) in air at  $R$  ratios of 0 and -1. At room temperature, variations in load ratio had no effect on fatigue crack growth rates. At 482 °C (900 °F), however, growth rates at  $R = -1$  were approximately three times greater than for the corresponding  $R = 0$  data. Specimen geometry did not influence the results. Results of the fatigue crack growth rate tests were used in predicting the allowable number of service cycles for gas turbine disks subjected to cyclic thermal stresses.

Fatigue crack growth rates reported by Tobler and Reed (Ref 22) for solution treated and aged A-286 stainless steel specimens tested at -196 and -269 °C (-320 and -452 °F) were lower, at each  $\Delta K$  value, than rates obtained at room temperature. In this respect, A-286 is similar to the other stable stainless steels. Fatigue crack growth rate data reported by Wells et al. (Ref 19) also showed that crack growth rates at -269 °C (-452 °F) were lower than those at room temperature for A-286 in the solution treated and aged condition.

## Fatigue and Fracture Properties of Stainless Steels

S. Lampman, ASM International

---

### Austenitic Stainless Steels

**Fatigue crack growth** (FCG) rates of austenitic stainless steels have been extensively studied, given their widespread use in high-temperature structural parts with cyclic stressing over a wide range of frequencies and load ratios. As previously noted, static fracture mechanics is discussed elsewhere in this Volume.

The general effect of cold work and annealing on the FCG rates of Types 301 and 304 are summarized in Fig. 18 and 19. For annealed Type 301 specimens tested in argon, fatigue crack growth rates at a given  $\Delta K$  value increased as the temperature increased over the testing temperature range (Fig. 18). Fatigue crack growth rates in laboratory air at 20 °C (68 °F) were higher than for corresponding conditions in argon, indicating that the humidity and/or oxygen in the air influenced the growth rates. The warm worked specimens were reduced 65% at 450 to 500 °C (840 to 930 °F), resulting in a substantial increase in strength. Fatigue crack growth rates for the warm worked specimens (see Fig. 18) indicate that the fatigue crack propagation properties of the warm worked alloy are different than those of the annealed alloy. This effect of warm working has been observed for other austenitic stainless steels. These differences are attributed to the extent of the strain-induced transformation at the crack tip. This transformation effect would be most noticeable in Type 301, because it is less stable than the other alloys in the UNS S3xxx series.

**FIG. 18** FATIGUE CRACK GROWTH RATES FOR TYPE 301 STAINLESS STEEL IN THE ANNEALED AND WARM WORKED CONDITIONS, IN AIR AND ARGON ENVIRONMENTS, AND AT TEMPERATURES FROM -30 TO +95 °C (-22 TO +203 °F). THESE RESULTS WERE OBTAINED ON COMPACT SPECIMENS 7 MM (0.28 IN.) THICK AT A CYCLIC FREQUENCY OF 20 HZ WITH A SINUSOIDAL WAVE FORM AT A LOAD RATIO ( $R$ ) OF 0.01. ALL SPECIMENS WERE TESTED IN DRY ARGON EXCEPT ONE SERIES THAT WAS TESTED IN LABORATORY AIR. SOURCE: REF 9

**FIG. 19 FATIGUE CRACK GROWTH RATES FOR ANNEALED AND COLD WORKED TYPE 304 STAINLESS STEEL AT 25 AND 427 °C (77 AND 800 °F), 0.17 HZ, AND AN R RATIO OF 0. SOURCE: REF 16**

Type 304 stainless steel is also used in the cold worked condition for improved strength. A comparison of fatigue crack growth rate data (Fig. 19) shows that the high- $\Delta K$  crack growth rates were lower for the cold worked specimens than for the annealed specimens. Cold working of Type 316 also reduces crack growth rates at comparable  $\Delta K$  values (Fig. 20).

(b)

FIG. 20 EFFECT OF TESTING TEMPERATURE ON FATIGUE CRACK GROWTH OF TYPE 316. (A) ANNEALED TYPE

**316 STAINLESS STEEL TESTED IN AIR AT 0.17 HZ AND AN  $R$  RATIO OF 0. (B) FATIGUE CRACK GROWTH RATES OF 20% COLD WORKED TYPE 316 STAINLESS STEEL FOR L-T AND T-L SPECIMENS AT EACH TEMPERATURE IN AIR; 3 HZ AT 24 °C, 0.67 HZ AT ELEVATED TEMPERATURES:  $R = 0.05$ .**

Because the expected service lives of most components of austenitic stainless steels are many years, an evaluation of the effect of long-time aging at service temperatures is important. Results of fatigue crack growth rate tests on specimens that were tested in the unaged and aged conditions (5000 hours at 593 °C, or 1100 °F) are shown in Fig. 21 (Ref 23). After aging for 5000 hours at this temperature, precipitation of  $M_{23}C_6$  carbides is essentially complete. These results indicate that at 593 °C (1100 °F) there are no deleterious effects of aging on the crack growth rates of specimens that are continuously cycled. When a holding time of 0.1 or 1.0 minute is included in each loading cycle, there tends to be a slight increase in the fatigue crack growth rate at a given  $\Delta K$  level.

(a)

(b)

**FIG. 21 EFFECT OF AGING AND HOLD TIMES ON FCG RATES. (A) EFFECT OF AGING AT 593 °C (1100 °F) FOR 5000 H, AND HOLD TIMES OF 0.1 AND 1.0 MIN FOR EACH CYCLE, ON FATIGUE CRACK GROWTH RATES OF L-T ORIENTED SPECIMENS OF TYPE 304 STAINLESS STEEL TESTED IN AIR AT 0.17 HZ AND AN R RATIO OF 0. (B) EFFECT OF EXPOSURE AT 593 °C (1100 °F) FOR 5000 H, AND HOLD TIMES DURING CYCLING, ON FATIGUE CRACK GROWTH RATE OF 20% COLD WORKED TYPE 316 STAINLESS STEEL AT 593 °C IN AIR. SOURCE: REF 23**

Aging of cold worked specimens of Type 304 at 593 °C (1100 °F) for 5000 hours tends to increase slightly the fatigue crack growth rates of specimens that are continuously cycled at 593 °C (1100 °F) (Ref 23). With holding times of 0.1 and

1.0 minute, the fatigue crack growth rates also increased (Ref 23). However, an opposite effect is observed in aged 316 with hold times (see the section "Aging and Hold Time Effects").

**Effect of Stress Ratio on Fatigue Crack Growth Rates.** Tests on austenitic stainless steels have shown that FCG rates tend to increase as the  $R$  ratio increases, when compared at a given  $\Delta K$  range. For example, Fig. 22 shows fatigue crack growth rates of Type 304 at several stress ratios. In austenitic stainless steels such as 304 and especially Type 301, martensitic transformation can take place as the fatigue crack propagates. This complicates the effect of  $R$  on  $da/dN$  because the crack opening stress intensity factor relative to the maximum stress intensity factor ( $K_{op}/K_{max}$ ) increases and, consequently,  $da/dN$  decelerates with  $K_{max}$  particularly under the condition that  $\sigma_{max}/\sigma_y$  is small. These results are very different from those of other materials, and these fatigue crack growth behaviors correspond to the state of the formation of martensite at the vicinity of fatigue crack surfaces.

(a)

(b)

(c)

**FIG. 22 FATIGUE CRACK GROWTH RATES OF 304 UNDER VARIOUS CONDITIONS. (A) EFFECT OF TESTING TEMPERATURE ON FATIGUE CRACK GROWTH RATES FOR ANNEALED TYPE 304 STAINLESS STEEL TESTED IN AIR AT 0.066 HZ AND AN  $R$  RATION OF 0 TO 0.05. (B) FATIGUE CRACK GROWTH RATES FOR ANNEALED TYPE 304 AND 304L STAINLESS STEELS AT ROOM AND CRYOGENIC TEMPERATURES, 20 TO 28 HZ, AND AN  $R$  RATIO OF 0.1. (C) EFFECT OF STRESS RATIO ON TYPE 304. SOURCE: REF 9 AND 24**

The effect of stress ratio variations can be based on the "effective stress intensity factor,"  $K_{\text{eff}}$ , rather than on  $\Delta K$ , to account for the effect of the range of stress ratios.  $K_{\text{eff}}$  is defined as follows:

$$K_{\text{EFF}} = K_{\text{MAX}} (1 - R)^M \quad (\text{EQ 1})$$

where  $m$  is determined empirically and  $R$  is the load ratio (minimum load/maximum load) on cyclic loading. The crack growth rate law then becomes:

$$DA/DN = C[K_{\text{MAX}}(1 - R)^M]^N \quad (\text{EQ 2})$$

Results of fatigue crack growth rates tests on Type 301 ( $\frac{1}{2}$  hard) at different  $R$  ratios are summarized in Fig. 23 based on  $K_{\text{eff}}$ . This empirical method only applies in the Paris regime (Stage II crack growth rate).

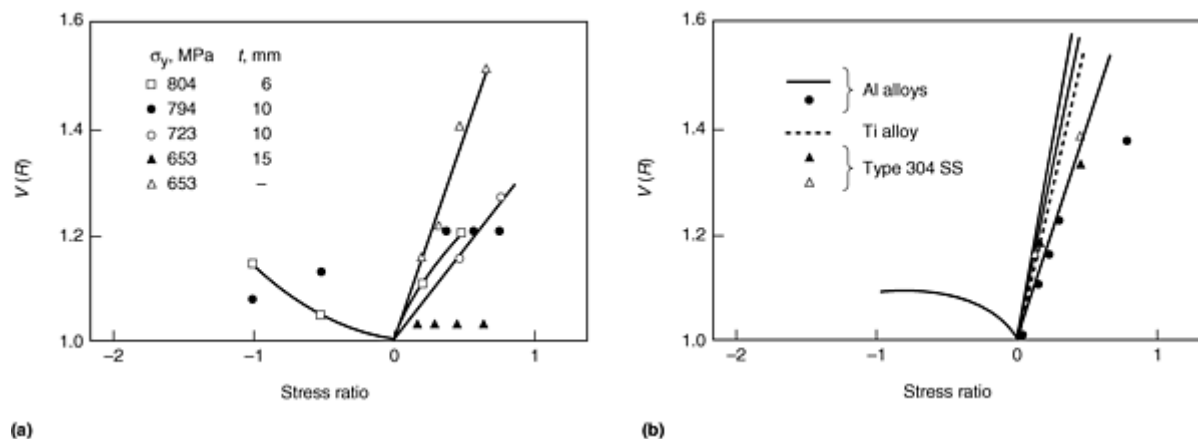

**FIG. 23 SCATTER BAND OF FATIGUE CRACK GROWTH RATES FOR  $\frac{1}{2}$ -HARD TYPE 301 STAINLESS STEEL, TESTED AT 24 °C (75 °F), 10 HZ, AND  $R$  RATIOS OF 0.063 TO 0.807 BASED ON EFFECTIVE STRESS-INTENSITY FACTOR,  $K_{\text{EFF}}$ . SOURCE: REF 9**

Another empirical method for stress ratio effects is based on the relation (Ref 25):

$$\Delta K_R = \Delta K_{R=0}/V(R) \quad (\text{EQ 3})$$

where  $V(R)$  is a correlation function that is derived from empirical data. Figure 24 shows derived values of  $V(R)$  for various materials including Type 304.

**FIG. 24 STRESS RATIO EFFECTS FROM CORRELATION FUNCTION  $V(R)$  FROM PUBLISHED FATIGUE CRACK GROWTH RATE CURVES FOR (A) QUENCHED AND TEMPERED STEELS AT GROWTH RATES BETWEEN  $10^{-8}$  AND  $10^{-7}$  M/CYCLES AND (B) FOR ALUMINUM ALLOYS, TYPE 304 STAINLESS STEEL, AND A TITANIUM ALLOY. SOURCE: REF 25**

Results of fatigue crack growth rate tests also have been reported by James over a range of stress ratios from -0.150 to +0.750 for compact specimens of Type 304 stainless steel at 538 °C (1000 °F) and at a frequency of 6.67 Hz. For these tests, the parameter  $K_{\max}(1 - R)^m$ , or  $K_{\text{eff}}$ , where  $m = 0.5$  (Eq 1), again provided a much better correlation of results than the parameter  $\Delta K$  (Ref 26).

Environmental Effects

Effect of Temperature and Moisture on FCG Rates. Higher temperatures increase crack growth rates as shown in Fig. 24 for various austenitic grades. The curves in Fig. 25 show that, at room temperature, the fatigue crack growth rates for Types 304, 316, 321, and 348 all fall in a narrow band. For tests at 593 °C (1100 °F), however, specimens of Type 316 had the least fatigue crack propagation resistance, whereas specimens of Type 348 had the highest fatigue crack propagation resistance, over the  $\Delta K$  range studied. Results of tests on specimens of Type 304 and 321 were nearly the same at 593 °C (1100 °F) in air.

FIG. 25 FATIGUE CRACK GROWTH RATES FOR ANNEALED TYPES 304, 316, 321, AND 348 STAINLESS STEELS IN AIR AT ROOM TEMPERATURE AND 593 °C (1100 °F), L-T ORIENTATION, 0.17 HZ, AND AN R RATIO OF 0. TESTS WERE MADE ON SINGLE-EDGE-NOTCH CANTILEVER SPECIMENS OF TYPES 321 AND 348 STAINLESS STEELS FROM THE L-T ORIENTATION AT 0.17 HZ WITH AN R RATIO OF ZERO AT ROOM TEMPERATURE AND AT

ELEVATED TEMPERATURES TO 593 °C (1100 °F).

The presence of moisture and oxygen cause an increase in crack growth rates as shown in Fig. 25 for various grades. Fatigue crack growth rate data at 25 °C (77 °F) show that crack growth rates increased slightly with increased humidity when oxygen was present but that high humidity in an inert gas had no significant effect. Fatigue crack growth rates in room air at room temperature were the same for Types 316 and 321 stainless steels. Furthermore, in tests at 649 °C (1200 °F) in dry nitrogen, fatigue crack growth rates for Types 316 and 321 also were the same. In air, however, fatigue crack growth rates in Type 316 specimens increased by a factor of about 22 over rates in an inert environment at the same temperature. The corresponding increase in fatigue crack growth rates for specimens of Type 321 was about 5 times that for the inert environment at 649 °C (1200 °F). If components of these stainless steels are exposed to inert environments instead of to air or oxygen-containing environments, fatigue crack growth rates will be substantially lower than those expected on the basis of tests in air.

The effects of humid air environments on the room-temperature fatigue crack growth rates of specimens of annealed Type 304 stainless steel also are shown in Fig. 26 for specimens cycled at 0.17 Hz with an *R* ratio of zero. At the lower end of the  $\Delta K$  range, fatigue crack growth rates in humid air are substantially greater than crack growth rates in dry air. However, fatigue crack growth rates of specimens of Type 304 stainless steel tested in a pressurized water reactor environment at 260 to 315 °C (500 to 600 °F) with *R* ratios of 0.2 and 0.7 were no greater than the fatigue crack growth rates in air at the same temperature with an *R* ratio less than 0.1 (Ref 27). However, variations in *R* ratios influenced the fatigue crack growth rates in the pressurized water reactor environment.

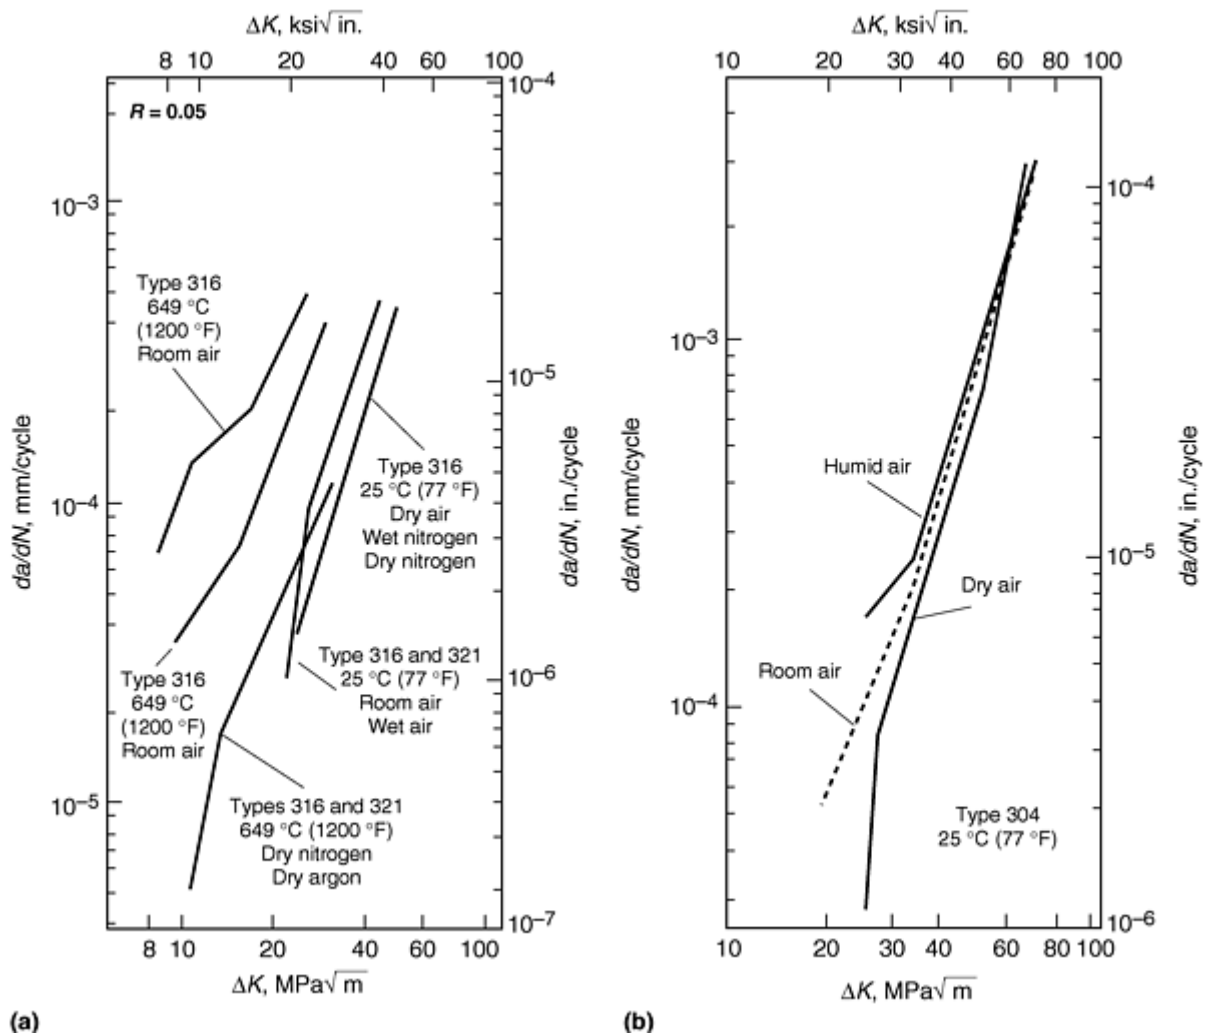

FIG. 26 EFFECT OF ENVIRONMENTS ON FATIGUE CRACK GROWTH RATES. (A) TYPES 316 AND 321 STAINLESS STEELS AT 25 AND 649 °C (77 AND 1200 °F). COMPACT SPECIMENS WERE TESTED IN FATIGUE LOADING ACCORDING TO A SINE WAVE LOADING PATTERNS AT 5 HZ WITH AN *R* RATIO OF 0.05 IN ROOM AIR, DRY AIR,

**HUMID AIR, DRY NITROGEN, WET NITROGEN, AND DRY ARGON. (B) EFFECT OF HUMIDITY ON FATIGUE CRACK GROWTH RATES FOR TYPE 304 STAINLESS STEEL TESTED AT ROOM TEMPERATURE, 0.17 HZ, AND AN R RATIO OF 0. SOURCE: REF 9**

**Heat-to-heat variations** in high-temperature FCG rates do not appear significant for 304 and 316 stainless steels. From FCG tests at 538 °C in air ( $R = 0.05$ , 0.00138 Hz) on specimen from various heats (73-85 HRB and 0.024-0.064 wt% C variations), results indicate that, for the conditions employed, there is no effect of heat-to-heat variations on fatigue crack growth rates for commercially produced Types 304 and 304L stainless steels (Ref 28). Furthermore, there is no apparent effect of grain size and crack orientation (L-T vs. T-L) on fatigue crack growth rates at 538 °C (1000 °F) for the commercial product in the annealed condition. A similar conclusion was reached for Type 316 (Ref 28).

**Aging and Hold Time Effects.** The effect of long-time aging at service temperatures is an important factor for austenitic stainless. As previously noted, aging of Type 304 has little or no effect on FCG rates with continuous (zero hold time) loading (Fig. 21a) or causes a slight increase in FCG rates of cold worked Type 304.

Hold times tend to increase FCG rates of aged Type 304 (Fig. 21a), while hold times have a different effect on aged 316 stainless steel. Fatigue crack growth rates for specimens of Type 316 stainless steel aged at 649 °C (1200 °F) for 6000 hours and tested at 538 °C (1000 °F) were either lower than, or within the scatterband for, specimens tested at 538 °C without aging (Ref 29). Other results are summarized below.

**Cold Worked Type 316.** Effects of holding times on cyclic loading of unaged and aged specimens of 20% cold worked Type 316 are shown in Fig. 21(b) for tests at 593 °C (1100 °F). The frequency for specimens cycled with zero holding time was 0.17 Hz, and the  $R$  ratio was zero. Aging was done for 5000 hours at 593 °C (1100 °F), and testing was done in air. For the unaged specimens, increasing the holding time significantly increased the fatigue crack growth rates as shown. For the aged specimens, holding at maximum load for 0.1 or 1.0 minute for each loading cycle reduced the fatigue crack growth rates over those obtained with no holding time. These data indicate that cold working and aging at 593 °C (1100 °F) before or during service exposure can lead to improved fatigue crack growth resistance and that short hold times at maximum load reduce FCG rates.

**Annealed Type 316.** Similar results are obtained for annealed Type 316 after aging (Fig. 27). Long-time exposure (5000 hours of aging) at 593 °C (1100 °F) in air on the fatigue crack growth rates of specimens of annealed Type 316 substantially reduced the fatigue crack growth rates at  $\Delta K$  levels from 18 to 55  $\text{MPa}\sqrt{m}$  (16 to 50  $\text{ksi}\sqrt{in}$ ) for the continuous cycling tests and over the whole testing range for specimens cycled with 0.1- and 1.0-minute holding times for each cycle. Fatigue crack growth rates for specimens tested without prior exposure and with holding times of 0.1 and 1.0 minute for each cycle were higher than those for specimens cycled continuously under the same conditions. However, the effect of hold time was less significant for specimens that had been aged at 593 °C (1100 °F) before testing at the same temperature. In other work (Ref 30), holding times of up to 8 minutes did not cause significant increases in fatigue crack growth rates at 593 °C (1100 °F) in aged specimens. However, holding for 16 minutes caused marked increases in fatigue crack growth rates.

FIG. 27 EFFECT OF EXPOSURE IN AIR AT 593 °C (1100 °F) FOR 5000 H, AND HOLD TIMES, ON FATIGUE CRACK GROWTH RATES FOR ANNEALED TYPE 316 STAINLESS STEEL AT 593 °C IN AIR

Annealed Type 321 stainless steel aged at 593 °C (1100 °F) for 5000 hours and then tested at 593 °C has shown that long-time exposure at the service temperature does not reduce the fatigue crack propagation resistance in air (Ref 31). Aged specimens tested with zero holding time had lower crack growth rates than corresponding specimens that were not aged.

**Fatigue Crack Growth in Aqueous Environments.** Aggressive environments accelerate crack growth rates of most materials including austenitic stainless steels in aqueous solutions (Ref 32, 33, 34, 35, 36, 37, 38). Figures 28 and 29 are examples of environmentally sensitive crack growth in oxygenated water and chloride solutions at different stress ratios. Figure 28 (Ref 39) illustrates the effect of oxygenated and chloride solutions on crack growth in the near threshold regime, while Fig. 29 (Ref 40) compares FCG rates of 304 and 304L with A508 pressure vessel steels in normal boiling water reactor (BWR) water. Crack growth rates of 304 are accelerated in BWR environments, but they are not significantly different from A508 vessel steel. In contrast, PWR environments have little or no effect on 304 and similar austenitic steel FCG. For example, effects of an environment of pressurized reactor water on the fatigue crack growth rates of a Type 316N stainless steel forging, of cast 316 stainless steel, and of Type 316 welds at 288 °C (550 °F) were evaluated by Bamford (Ref 41). Effects of variations in load ratio, frequency, specimen orientation, and heat-to-heat properties for wrought, cast and weld metal in air and in the reactor water were determined. Results of the study showed that fatigue crack growth rates in the reactor water were not significantly different from FCG rates in air. This suggests the importance of dissolved oxygen in promoting crack growth, as BWR environments have more dissolved oxygen than PWR environments. From early studies on aqueous corrosion fatigue crack growth behavior of pressure vessel steels (SA533-B plate or SA508 forgings), the three most important variables are the cyclic frequency, the applied  $R$  ratio, and

the temperature. The influence of a BWR or PWR coolant on fatigue crack growth only becomes evident at cyclic frequencies below 1.0 Hz, is a maximum at a temperature of 200 °C, and increases with increasing positive  $R$  ratio.

**Mechanisms of Corrosion Fatigue.** Corrosion fatigue involves complex interactions between loading, environmental, and metallurgical variables. The influences of potential and solution pH, and the contributions of individual micromechanisms to crack growth of austenitic stainless steels are discussed in Ref 42, 43, 44, 45. The mechanisms (i.e., anodic dissolution vs. hydrogen embrittlement) for corrosion fatigue of steels in aqueous environments is briefly summarized in Ref 43 with some modeling of chemical/electrochemical reaction control of corrosion fatigue crack growth from the perspective of hydrogen embrittlement for steels HT70, HY130, 304 stainless, and NiCrMoV. Variables that control crack growth are considered in relation to improved design and fracture control procedures.

To assist in the understanding of micromechanisms for corrosion, fatigue crack growth in metastable austenitic steels, the relationships between the crack paths and the underlying microstructure were investigated for annealed and cold-rolled (CR) 304 stainless steels that had been tested in a deaerated 3.5% NaCl solution, air, and vacuum (Ref 44). Corrosion fatigue in the deleterious environments (3.5% NaCl and air) was brittle. In contrast, fatigue cracking in vacuum was ductile, fully transgranular, and noncrystallographic. These results, taken in conjunction with the crack growth and electrochemical reaction data, support hydrogen embrittlement as the mechanism for corrosion fatigue crack growth in 304 stainless steels in 3.5% NaCl solution. Martensitic transformation appears not to be the only responsible factor for embrittlement. Other microstructural components, such as twin and grain boundaries, slip bands, and cold work-induced lattice defects, may play more important roles in enhancing crack growth rates.

**Load History Effects.** Environmentally assisted fatigue crack growth is a complex time-dependent process, which is influenced by not only electrochemical factors but also by load history factors such as rise-time, hold-time, unload-time, and cyclic frequency. Load history factors are important because they affect the allowable time for exposure of growing surface cracks. Therefore, lower frequency loading or increased hold times tend to increase FCG rates.

For example, fatigue crack growth behavior of weld heat-affected zone of Type 304 stainless steel in high-temperature water was examined in Ref 46 to clarify the effects of welding residual stress, cyclic frequency, and thermal aging on crack growth rate. A lower crack growth rate of the HAZ than of the base metal was observed in both the high-temperature water and the ambient air caused by the compressive residual stress. With the effect of the welding residual stress evaluated separately from the environmental effect of the high-temperature water, the crack growth rate increased at a cyclic frequency of 0.0167 Hz but did not increase at 3 and 5 Hz. The crack growth behavior of the thermally aged HAZ at 400 °C for 1800 h was almost the same as that of the unaged material tested at 0.0167 and 5 Hz in the high-temperature water.

In another analysis (Ref 47) fracture-mechanics crack growth tests were conducted on 25.4 mm thick compact tension specimen of Types 304L and 316L stainless steel and Incoloy 825 at 93 °C and 1 atm of pressure in a simulated well-water environment. Crack growth rates were measured under various load conditions: load ratios of  $R = 0.2$  to 1.0 and frequencies from  $2 \times 10^{-4}$  to 1 Hz with rise times of 1-5000 s and peak stress intensities of 25-40  $\text{MPa}\sqrt{\text{m}}$ . The measured crack growth rates are bounded by the predicted rates from the current ASME Section XI correlation for fatigue crack growth rates of austenitic stainless steel in air. Environmentally accelerated crack growth was not evident in any of the three materials when exposed to the room-temperature simulation of water. This is in contrast with the region of accelerated crack growth of these materials (Fig. 30).

**FIG. 30 TIME-BASED CRACK GROWTH RATE VS. FREQUENCY OF STAINLESS STEELS IN 93 °C SIMULATED WELL WATER. SOURCE: REF 47**

**Time-dependent crack growth** encompasses several load history factors that affect crack growth rates in either corrosive or high-temperature conditions. In general, environmental factors become more significant as the cyclic loading frequency decreases. For example, Fig. 31 compares FCG rates at different frequencies for annealed 304 and 316 stainless steels at 538 °C (1000 °F). The pattern is different between 304 and 316, but FCG rates for both steels increase with decreasing frequency. The effect of hold time is more complicated, as previously discussed.

**Creep-Fatigue Crack Growth.** Time-dependent effects become more pronounced when high-temperature creep occurs. In recent years, a large number of models describing fatigue crack growth at high temperatures has been developed. In general, the process of crack growth is usually divided into two parts, that of fatigue and creep. Creep crack growth at hold times may be divided into global and local sections. In the global part, only the continuum damage process is considered; no reference is made to the crack tip stress field. The local part of creep growth includes the nucleation as well as subsequent crack propagation; this is analogous to the process of pure fatigue. These models are discussed in more detail in the article "Elevated-Temperature Crack Growth" in this Volume. References 48 and 49 describe creep-fatigue behavior and fractography of austenitic stainless steels in air and vacuum.

**Corrosion Fatigue.** Crack growth rate under cyclic loads in a corrosive environment ( $da/dt$ ) may be expressed as a sum of contributions by:

- STRESS-CORROSION CRACKING,  $(DA/DT)_{SCC}$
- CORROSION FATIGUE,  $(DA/DT)_{CF}$ , REPRESENTING THE ADDITIONAL CRACK GROWTH UNDER CYCLIC LOADING DUE TO THE ENVIRONMENT; AND
- MECHANICAL FATIGUE,  $(DA/DT)_{AIR}$ , REPRESENTING THE FATIGUE GROWTH IN AIR

The net result is

$$(DA/DT) = (DA/DT)_{SCC} + (DA/DT)_{CF} + (DA/DT)_{AIR} \quad \text{(EQ 4)}$$

The first two terms on the right side of the equation are environment sensitive and depend on loading history variables. In oxygenated-water environments, the environment-sensitive terms can contribute significantly to crack growth rates of austenitic stainless steels (Ref 36, 37 38, 39 40, 41 42, 43 44, 45 46, 47). Under low- $R$  and high-frequency loading, mechanical fatigue dominates. Environmental contributions become more significant as the frequency decreases as previously noted in Fig. 29, 30, and 31. Modeling of time-dependent effects on aqueous high-temperature FCG rates is still an active area of research.

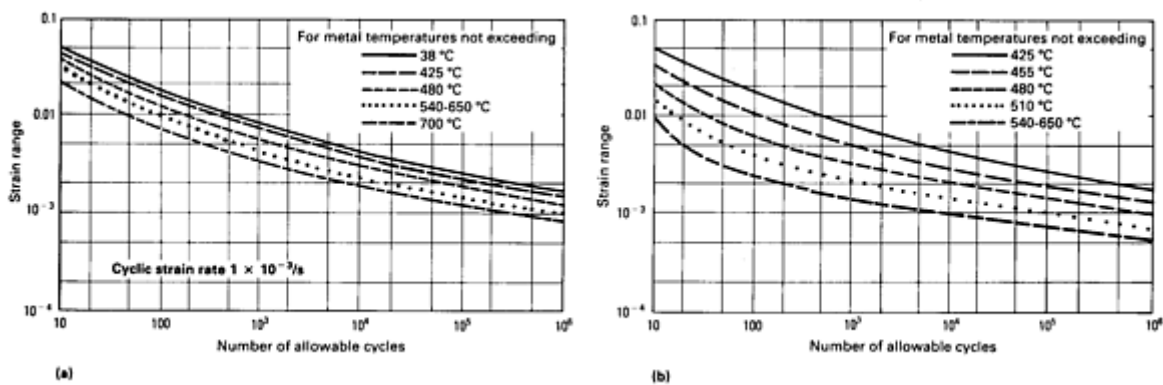

**Fatigue Crack Growth Rates at Cryogenic Temperatures.** Fatigue crack growth rate data were obtained by Tobler and Reed (Ref 22) on specimens of Type 304, 316, and 304L stainless steels (annealed) at temperatures in the range from room temperature to liquid helium temperature ( $-269\text{ }^{\circ}\text{C}$ , or  $-452\text{ }^{\circ}\text{F}$ ). The data for Type 304 were scattered over a range while for Type 304L the data at room temperature described one curve and the data at the cryogenic temperatures were more distinct. These results indicate that cryogenic fatigue crack growth rates for Type 304 do not deviate significantly from room-temperature fatigue crack growth rates over the  $\Delta K$  range studied. Furthermore, if design calculations for Type 304L are based on room-temperature fatigue crack growth rates, the calculations will be conservative for cryogenic exposure.

**Fatigue strength** of austenitic stainless steels is well documented in the literature. Austenitic stainless steels have a distinct fatigue limit and similar endurance ratio as other unnotched steel specimens of similar tensile strength. However, austenitic steels (which are more ductile and resistant to crack growth) appear to be less notch sensitive than other steels (see the article "Fracture and Fatigue Properties of Structural Steels" in this Volume). A similar result of less notch sensitivity for lower-strength austenitic grades is also observed in early work reported by Sisco (Fig. 32).

**FIG. 32 RELATION BETWEEN ENDURANCE LIMIT AND TENSILE STRENGTH FOR POLISHED AND NOTCHED STEEL SPECIMENS. SOURCE: F. SISCO, ALLOYS OF IRON AND CARBON, VOL II, PROPERTIES, MCGRAW-HILL, 1937**

Fatigue properties at elevated temperatures are dependent on several variables including strain range, temperature, cyclic frequency, hold times, and the environment. The fatigue design curves in Fig. 33(a) show the simple case of pure fatigue (that is, continuous cycles without hold times) for 304 and 316 stainless steel. These design curves (from Code Case N-47 in the ASME Boiler Code) have a built-in factor of safety and are established by applying a safety factor of 2 with respect to strain range or a factor of 20 with respect to the number of cycles, whichever gives the lower value. The creep-life fraction is determined by the time-life fraction per cycle using assumed stresses 1.1 times the applied stress and the minimum stress-rupture curves incorporated in the code.

**FIG. 33 DESIGN FATIGUE-STRAIN RANGE CURVES FOR 304 AND 316 STAINLESS STEEL. (A) DESIGN CURVES WITH CONTINUOUS CYCLING (PURE FATIGUE). (B) DESIGN CURVES WITH HOLD TIMES (CREEP-FATIGUE INTERACTION)**

The design curves in Fig. 33(a) are based on a strain rate of  $1 \times 10^{-3}$ /s. If the strain rate decreases, fatigue life also decreases. In Fig. 34, for example, the fatigue lives of several stainless steels are shown for continuous cycling at two

different strain rates. Fatigue life is reduced with a lower strain rate, while grain size has little effect on fatigue life when life is determined from pure fatigue (or continuous cycling).

**FIG. 34 EFFECT OF STRAIN RATE AND GRAIN SIZE ON THE FATIGUE LIFE OF VARIOUS STAINLESS STEELS AT ELEVATED TEMPERATURES. GRAIN SIZE HAS THE GREATEST INFLUENCE ON FATIGUE LIFE WHEN HOLD TIMES ARE INCREASED. TEST CONDITIONS: TOTAL STRAIN RANGE = 1.0%; TEST TEMPERATURE, 593 TO 600 °C (1100 TO 1110 °F). SOURCE: REF 50**

When hold times are introduced, a different set of design curves is used (Fig. 33b) to determine the allowable fatigue-life fraction (creep-life fraction is determined the same way as for continuous cycling). These allowable fatigue-life curves are a more conservative set of curves than those of Fig. 33(a). They incorporate the effect of creep damage by applying a fatigue life reduction factor, which includes hold time effects in addition to the factor of safety (2 in strength and 20 in cycles, whichever gives the lower value). Figure 35 (Ref 50) compares the 540 to 650 °C (1000 to 1200 °F) design curve in Fig. 33(b) with actual fatigue life results from testing 316 stainless at 593 °C (1100 °F) and various hold times. When hold times are introduced, the influence of grain size may also be more pronounced (Fig. 34). More detailed information on creep-fatigue behavior is in *ASM Handbook*, Vol 8, 1985, p 346-359.

FIG. 35 INFLUENCE OF TENSILE HOLD TIMES AT PEAK STRAIN ON FAILURE LIFE OF A SINGLE HEAT OF TYPE 316 STAINLESS STEEL TESTED AT 593 °C (1100 °F). SOURCE: REF 50

## Fracture Toughness of Austenitic Stainless Steels and Their Welds

W.J. Mills, Member of ASM International, Upper St. Clair, PA

---

### Introduction

Austenitic stainless steel alloys are used extensively in heat-resistant structural components in power-generating and chemical industries as a result of their metallurgical stability, excellent corrosion resistance, and good creep and ductility properties at elevated temperatures. In addition, AISI type 300-series stainless steels are the most widely used structural alloys for cryogenic applications, because they exhibit high strength, ductility, and fracture toughness properties as well as low thermal expansion and low magnetic permeability.

Extensive fracture toughness testing of this class of alloys has been conducted to predict the failure conditions for flawed components. This article summarizes the fracture toughness behavior of wrought base metals and welds. Minimum expected toughness values, based on statistical analyses of literature data, are provided for use in fracture mechanics evaluations.

Elastic-plastic fracture mechanics methods are required to characterize fracture properties for austenitic stainless steels due to their ductile response even after high levels of cold work and neutron irradiation. The  $J$ -integral resistance ( $J$ - $R$ ) curve approach is generally used to characterize the fracture behavior of ductile materials; however, the standard ASTM test methods for determining  $J_{Ic}$  and  $J$ - $R$  curves are not generally applicable to this class of high-ductility, high-toughness materials. Modified testing and analysis methods, which are detailed in the next section, have been developed and successfully applied to these materials.

## Fracture Toughness of Austenitic Stainless Steels and Their Welds

W.J. Mills, Member of ASM International, Upper St. Clair, PA

---

### Fracture Toughness Determination

The fracture toughness of stainless steels is determined by both single- and multiple-specimen  $J$ - $R$  curve techniques, but the analysis procedures differ slightly from those described in ASTM E 813 for  $J_{Ic}$  determination and E 1152 for  $J$ - $R$  curve determination. ASTM procedures and size requirements are generally not applicable to these alloys due to their exceptionally high toughness, ductility, and strain hardening capacity. The primary difference involves the crack-tip blunting relationship. The ASTM blunting line is given by:

$$J = 2\sigma_F(\Delta a) \quad (\text{EQ 1})$$

where  $\sigma_f$  is the flow strength, which is equal to the average of the 0.2% offset yield strength and ultimate tensile strength [ $\sigma_f = \frac{1}{2} (\sigma_{YS} + \sigma_{UTS})$ ], and  $\Delta a$  is the crack extension.

For austenitic stainless steels, Eq 1 significantly overpredicts the apparent crack extension associated with the blunting process, which results in nonconservative  $J_{Ic}$  values. The appropriate blunting line for this class of alloys is (Ref 1):

$$J = 4\sigma_F(\Delta a) \quad (\text{EQ 2})$$

The factor of 2 difference in Eq 1 and 2 is related to differences in the constraint factor,  $m$ , relating  $J$  to crack-tip opening displacement, CTOD (Ref 2):

$$J = M\sigma_{YS}(CTOD) \quad (\text{EQ 3})$$

The  $m$  value for intermediate- to high-strength, low strain hardening materials (i.e., Ramberg-Osgood strain hardening exponents,  $N$ , greater than 5) is close to unity (Ref 2), whereas low-strength, high-strain-hardening materials exhibit values of  $m$  on the order of 2 (Ref 1, 3, 4). Because the apparent crack extension associated with blunting is approximately one-third the CTOD (Ref 1, 4) and the yield strength is approximately two-thirds the flow strength (i.e.,  $\sigma_{YS} \approx \frac{2}{3}\sigma_f$ ) for this class of materials (Ref 1), the crack-tip blunting relationship is given by:

$$J = m\sigma_{YS}(CTOD) \approx 2\left(\frac{2\sigma_f}{3}\right)(3\Delta a) = 4\sigma_f(\Delta a) \quad (\text{EQ 4})$$

This equation has been shown to adequately represent the crack-tip blunting behavior for type 304 (Ref 1, 4, 5, 6, 7, 8, 9, and 10), 316 (Ref 10, 11, 12, and 13), 321 (Ref 14), and 347 (Ref 13) stainless steels and their welds (Ref 15, 16, 17).

The  $J$ - $R$  curve is constructed by plotting  $J$ -integral values against the corresponding crack extension values and fitting the  $J$ - $\Delta a$  data with either a linear or power-law regression line (see Fig. 1). The  $J_c$  fracture toughness is then determined at the intersection of the linear regression line with the blunting line, per ASTM E 813-81, or the intersection of the power-law curve with the 0.2 mm offset blunting line, per ASTM E 813-87. (Initiation toughness values are termed  $J_c$ , rather than  $J_{Ic}$ , because they do not strictly meet the analysis methods and size requirements of ASTM E 813.) For modest amounts of crack extension ( $\Delta a < 4$  mm), the two regression analyses provide reasonable fits of the data and yield very similar  $J_c$  values for both welds (Ref 18) and base metals (Ref 19).

FIG. 1 MULTIPLE-SPECIMEN  $J$ - $R$  CURVES FOR 2.5T, 1T, AND 0.577T COMPACT TENSION SPECIMENS. THE  $J_c$

FACTOR DENOTES THE PLANAR DIMENSION PROPORTIONALLY, RELATIVE TO THE STANDARD SPECIMEN IN ASTM E 399. BOTH THE LINEAR AND POWER-LAW  $J$ - $R$  CURVES ADEQUATELY REPRESENT THE DATA AND PRODUCE COMPARABLE  $J_c$  VALUES. SOURCE: REF 21

Austenitic stainless steels typically exhibit tremendous tearing resistance after cracking initiates, as reflected by a steep  $J$ - $R$  curve slope,  $dJ/da$ . Average  $dJ/da$  values reported herein are determined based on the slope of either the linear  $J$ - $R$  curve or the power-law  $J$ - $R$  curve at approximately 2 to 3 mm of crack extension. Values of the tearing modulus ( $T$ ), which represents a dimensionless form of the  $J$ - $R$  curve slope, are computed from the following equation (Ref 20):

$$T = \frac{dJ}{da} \frac{E}{\sigma_f^2} \quad (\text{EQ 5})$$

where  $E$  is elastic modulus.

For modest amounts of crack extension ( $\Delta a < 4$  mm), conventional  $J$ - $R$  curves are relatively independent of specimen size (Ref 21, 22, 23). For example, Fig. 1 (Ref 21) shows that the overall fracture behavior is not radically different for the different size compact tension, C(T), specimens of type 304, so data for all specimen sizes are combined in the linear and power-law regressions to establish  $J_c$ . The two regression analyses provide good fits to the data and result in comparable  $J_c$  and  $dJ/da$  values. Figure 1 also shows that Eq 2 accurately predicts the blunting behavior for type 304, regardless of specimen size.

## Fracture Toughness of Austenitic Stainless Steels and Their Welds

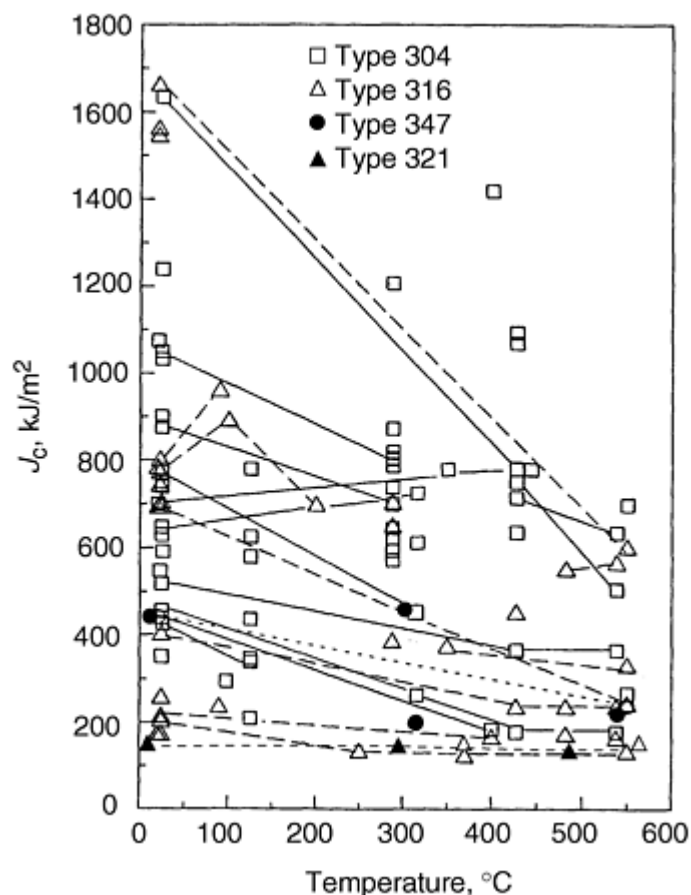

W.J. Mills, Member of ASM International, Upper St. Clair, PA

---

## Fracture Toughness of Base Metal

## Fracture Properties at Ambient and Elevated Temperatures

Extensive fracture toughness testing of type 304 and 316 stainless steels shows that they are extremely resistant to fracture. Both types exhibit a ductile fracture response under a wide variety of conditions, but  $J_c$  values are highly variable, as shown in Fig. 2. It is seen that  $J_c$  values range from 169 to 1660 kJ/m<sup>2</sup> at room temperature and from 130 to 1420 kJ/m<sup>2</sup> at approximately 400 °C. Some of this scatter is due to the lack of a standard  $J_c$  test method, but this effect is small in comparison to heat-to-heat variability and orientation effects. For example, common testing and analysis methods produced a factor of 4 difference in  $J_c$  values for five heats of type 304 (Ref 25) and three heats of type 316 (Ref 52). These findings demonstrate that significant heat-to-heat variability is inherent to austenitic stainless steels.

**FIG. 2 EFFECT OF TEST TEMPERATURE ON  $J_c$  FRACTURE TOUGHNESS.  $J_c$  VALUES FOR THE SAME HEAT ARE CONNECTED BY A LINE. SOURCE: REF 5, 6, 7, 8, 9, 10, 22, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, AND 46 (TYPE 304); REF 4, 10, 11, 12, 13, 25, 29, 33, 34, 38, 43, 47, 48, 49, 50, 51, 52, 53, 54, AND 55 (TYPE 316); REF 13, 56 (TYPE 347); REF 14 (TYPE 321)**

Figure 2 also shows that increasing the test temperature tends to decrease fracture toughness, with the highest toughness heats showing the greatest effect. Low toughness heats show only a very small toughness decrease between 24 and 550 °C. The apparent increase in toughness exhibited by two type 316 heats between room temperature and about 100 °C is believed to be associated with data scatter, rather than an inherent temperature effect. In addition, the type 304 heat showing a slight increase in  $J_c$  between 24 and 443 °C exhibits a factor of 2 reduction in  $dJ/da$ , such that the overall fracture resistance decreases with increasing temperature, consistent with the trends exhibited by the other heats. The decrease in fracture toughness reflects a decrease in both flow strength from 430 to 300 MPa and total elongation from 70 to 40% as temperature increases from 24 to 538 °C.

To account for heat-to-heat variability at ambient and elevated temperatures, a statistical analysis of post-1981 literature toughness data for types 304 and 316 was performed (Ref 19); results are summarized in Table 1. Both  $J_c$  and  $dJ/da$  were found to be distributed lognormally (i.e., logarithms of  $J_c$  and  $dJ/da$  were normally distributed) and were independent of material type. Although median  $J_c$  and  $dJ/da$  values are very high at room temperature (672 kJ/m<sup>2</sup> and 292 MPa,

respectively), the large degree of scatter indicates the likelihood that a significant fraction of heats have values that are considerably lower. Lower bounds for 90%/95% tolerance limits bracketing 90% of the total population at a 95% confidence level are summarized in Table 1. The lower-bound  $J_c$  value of 215 kJ/m<sup>2</sup> and  $dJ/da$  value of 59 MPa, corresponding to a tearing modulus of 75, are relatively high, demonstrating that even the lower toughness heats are resistant to fracture.

**TABLE 1 SUMMARY OF  $J_c$  AND  $dJ/da$  VALUES FOR STAINLESS STEEL BASE METALS AND WELDS**

ALLOY	CONDITION	TEMPERATURE, °C	MEAN $J_c$ , KJ/M <sup>2</sup>	90%/95% L.B. $J_c$ , KJ/M <sup>2</sup>	MEAN $dJ/da$ , MPA	90%/95% L.B. $dJ/da$ , MPA

Source: Ref 19

While the median  $J_c$  value of 421 kJ/m<sup>2</sup> at 400 to 550 °C is about 35% lower than the room-temperature value, the median  $dJ/da$  value of 263 MPa is essentially the same as its room-temperature counterpart. This indicates that the tearing resistance is not degraded at elevated temperatures. The 90%/95% lower-bound  $J_c$  and  $dJ/da$  values at elevated temperatures are 96 kJ/m<sup>2</sup> and 79 MPa, respectively. The lower-bound  $J$ - $R$  curve slope, which corresponds to a tearing modulus of 120, indicates that types 304 and 316 retain excellent fracture resistance at temperatures up to 550 °C.

Figure 2 also provides the  $J_c$  response for types 347 and 321 at ambient and elevated temperatures. Toughness values range from 150 to 450 kJ/m<sup>2</sup> and fall in the lower portion of the toughness interval for types 304 and 316. Nevertheless, these toughness values indicate that type 347 has good fracture resistance between 24 and 550 °C.

Limited fracture toughness testing of other stainless steels has been performed at room temperature, and the results are summarized in Fig. 3. The materials represented in this figure are type 310, PCA, and various nitrogen-strengthened high-manganese alloys. Type 310 exhibits a relatively low  $J_c$  value of 158 kJ/m<sup>2</sup> (Ref 51). The high-manganese alloys, including Nitronic 33 (Fe-18Cr-3Ni-13Mn), Nitronic 40 (Fe-21Cr-6Ni-9Mn), Nitronic 50 (Fe-21Cr-12Ni-5Mn), and X5CrMnN18 18, exhibit intermediate to high toughness values, ranging from 230 to 1400 kJ/m<sup>2</sup> (Ref 57, 58). PCA, a titanium-modified stainless steel (Fe-14Cr-16Ni-2Mo-0.25Ti) that is the most promising candidate austenitic material for the first wall component of fusion devices, has a  $J_c$  of 670 kJ/m<sup>2</sup> (Ref 52).

FIG. 3  $J_c$  VALUES FOR VARIOUS STAINLESS STEELS AT ROOM TEMPERATURE. SOURCE: REF 51 (TYPE 310); REF 52 (PCA); REF 57, 58 (NITROGEN-STRENGTHENED HIGH-MANGANESE STAINLESS STEELS)

The reported  $J_c$  and  $dJ/da$  values demonstrate that stainless steels have exceptionally high fracture resistance at ambient and elevated temperatures; failure requires extensive plastic strains and long critical crack lengths. Therefore, fracture control via a fracture mechanics approach is generally not an important design requirement. Conventional stress and strain design limits, such as those provided in the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code, are sufficient to guard against fracture because they preclude excessive plastic deformation. For applications where margins against ductile fracture must be quantified or where components are subjected to large plastic strains, elastic-plastic  $J$ -integral methods can be used to predict fracture conditions. These methods include the  $J$ -estimation schemes developed by General Electric/Electric Power Research Institute (Ref 59, 60, 61) and Novetech/Electric Power Research Institute (Ref 62), or the Nuclear Regulatory Commission leak-before-break prediction method (Ref 63, 64). Calculation of applied  $J$  values for cracked components requires knowledge of the strain hardening capacity of the material in terms of the Ramberg-Osgood strain hardening relationship:

$$\frac{\epsilon}{\epsilon_{YS}} = \frac{\sigma}{\sigma_{YS}} + C \left( \frac{\sigma}{\sigma_{YS}} \right)^N \quad (\text{EQ 6})$$

where  $\sigma$  is the true stress,  $\epsilon$  is the true strain,  $\epsilon_{YS}$  is the yield strain at the 0.2% offset yield strength value, and  $C$  and  $N$  are the strain hardening coefficient and exponent, respectively. Values of  $C$  and  $N$  for type 304 and 316 stainless steels and their welds are provided in the literature (Ref 17, 25).

### Fracture Mechanisms in Base Metals

The operative cracking mechanism in stainless steel is typically microvoid coalescence, regardless of test temperature. Heat-to-heat variability is associated with differences in both the matrix strength and the density and morphology of

inclusions that serve as microvoid nucleation sites. Large inclusions fail during the early stages of plastic straining, so a high inclusion density drastically reduces the plastic energy required for microvoid coalescence. Typical inclusions include MC-type carbides, calcium aluminates, and manganese sulfides. The strength of the matrix generally depends on the effectiveness of solution annealing in removing plastic deformation introduced during thermomechanical processing. Retention of 1 to 2% cold work is sufficient to restrict plastic deformation during the fracture process.

Figures 4 and 5 compare the inclusion and dimple morphologies for low- and high-toughness heats of type 304 (Ref 25). In the low-toughness heat with a  $J_c$  of  $178 \text{ kJ/m}^2$  (Fig. 4), primary dimples are shallow and confined to the immediate vicinity of the crack plane. Inclusion clusters aligned in the primary working direction fail early in the plastic straining process, creating a preferred crack path. In addition, the relatively high strength exhibited by this heat ( $\sigma_{YS} = 206 \text{ MPa}$ ) reduces the plastic energy required for microvoid coalescence. This combination of a relatively high-strength matrix and aligned inclusion clusters accounts for both the shallow dimples confined to the primary fracture plane and the low fracture toughness.

**FIG. 4 MICROSTRUCTURE AND FRACTURE SURFACE MORPHOLOGY FOR A LOW-TOUGHNESS TYPE 304 HEAT ( $J_c = 178 \text{ kJ/M}^2$ ). (A) TYPICAL MICROSTRUCTURE WITH MC INCLUSION CLUSTERS. (B) FRACTURE PROFILE SHOWING THAT MC-NUCLEATED MICROVOIDS ARE LOCALIZED ALONG THE FRACTURE PLANE. (C) SEM FRACTOGRAPH SHOWING SHALLOW DIMPLES NUCLEATED BY MC INCLUSION CLUSTERS. SOURCE: REF 25**

**FIG. 5 MICROSTRUCTURE AND FRACTURE SURFACE MORPHOLOGY FOR A HIGH-TOUGHNESS TYPE 304 HEAT ( $J_c = 751 \text{ kJ/m}^2$ ). (A) UNIFORM DISTRIBUTION OF RELATIVELY SMALL MC INCLUSIONS AND FINE  $M_{23}C_6$  CARBIDES. (B) FRACTURE PROFILE SHOWING EVIDENCE OF GROSS PLASTICITY AND MC-NUCLEATED MICROVOIDS AWAY FROM THE FRACTURE PLANE. (C) SEM FRACTOGRAPH SHOWING DUPLEX POPULATION OF WELL-DEFINED DIMPLES NUCLEATED BY MC AND  $M_{23}C_6$  CARBIDES. SOURCE: REF 25**

In the high-toughness heat with a  $J_c$  of  $751 \text{ kJ/m}^2$  (Fig. 5), the deep primary dimples and large microvoids away from the crack plane demonstrate that the fracture process involves gross plasticity. The smaller MC-type inclusions in this heat are more resistant to fracture, and the lower-strength matrix ( $\sigma_{YS} = 148 \text{ MPa}$ ) promotes increased plastic deformation. Because there is no preferred crack path, microvoids are nucleated away from the primary fracture plane. Gross plastic deformation is then required for microvoid coalescence, which accounts for the superior fracture toughness.

## Fracture Toughness of Austenitic Stainless Steels and Their Welds

W.J. Mills, Member of ASM International, Upper St. Clair, PA

---

### Fracture Toughness of Welds

Although stainless steel welds are predominantly austenitic, they typically contain a  $\delta$ -ferrite phase that has a body-centered cubic (bcc) structure. This phase is needed to control the weld solidification behavior and inhibit the formation of low-melting-point compounds, such as sulfides and phosphides, that promote microfissuring. Because the ferrite phase is brittle at low temperatures, stainless steel welds exhibit a ductile-brittle transition temperature phenomenon, as shown in Fig. 6 for type 308 welds (Ref 65, 66, 67, 68, and 69). At ambient and elevated temperatures, the ferrite phase behaves in a ductile manner, so the welds are resistant to fracture.

FIG. 6 CHARPY IMPACT ENERGY VS. TEST TEMPERATURE FOR TYPE 308 WELDS SHOWING THE DUCTILE-BRITTLE TRANSITION TEMPERATURE PHENOMENA. SMA, SHIELDED-METAL ARC; SA, SUBMERGED ARC; GTA, GAS-TUNGSTEN ARC. HALF-SIZE CHARPY SPECIMENS (5 × 5 × 25.4 MM WITH A 0.76 MM NOTCH) WERE USED

## Ambient Temperature Fracture Toughness

Figure 7 summarizes the  $J_c$  fracture toughness of types 304/308, 316/16-8-2, and 330 welds at 20 to 125 °C. Five welding processes are represented, including gas-tungsten arc (GTA), shielded-metal arc (SMA), submerged arc (SA), gas-metal arc (GMA), and flux-cored arc (FCA) processes. The fracture toughness is seen to be dependent on weld process, but not composition. This is consistent with findings that type 308 and 16-8-2 welds fabricated using the same welding process and welding parameters yield identical  $J_c$  and  $dJ/da$  values, demonstrating that toughness is independent of filler material (Ref 17).

FIG. 7 SUMMARY OF  $J_c$  FRACTURE TOUGHNESS AT 20-125 °C FOR WELDS. THE MEAN  $J_c$  VALUE FOR TYPES 304 AND 316 BASE METAL IS SHOWN FOR COMPARISON. GTA, GAS-TUNGSTEN ARC; GMA, GAS-METAL ARC; SMA, SHIELDED-METAL ARC; SA, SUBMERGED ARC; FCA, FLUX-CORED ARC. SOURCE: REF 15, 22, 25, 34, 52, 69, 70, 71, AND 72 (GTA); REF 35, 36 (GMA); REF 34, 73 (SMA); REF 17, 34, 68, 74, 75, AND 76 (SA); REF 77 (FCA)

Figure 7 shows that GTA welds consistently exhibit the highest  $J_c$  values, while SA welds yield the lowest. The mean  $J_c$  value for GTA welds is about 25% lower than that for types 304 and 316, represented by the broken line on Fig. 7. The mean  $J_c$  and  $dJ/da$  values for SA welds are about three times lower than their GTA counterpart. Table 1 shows that the 90%/95% lower-bound  $J_c$  and  $dJ/da$  values for the GTA and SA welds are 192 versus 67 kJ/m<sup>2</sup> and 139 versus 72 MPa, respectively.

The SMA and FCA welds tested at room temperature have low to intermediate toughness values. Cryogenic (Ref 78) and high-temperature (Ref 17) data show that the SMA weld process results in tremendous variability, covering the full range of toughness values exhibited by SA and GTA welds. The excessive scatter is attributed to the variability associated with a manual welding process. For design purposes, it is reasonable to assume that the lower-bound toughness for SMA welds

is comparable to that for SA welds. Cryogenic results (Ref 78, 79, 80) reveal that FCA welds can exhibit lower toughness values than SA welds.

The two GMA welds tested at room temperature have high  $J_c$  values. This is consistent with cryogenic data (Ref 78, 79, 81, 82, and 83) that show that  $J_c$  values for GMA welds are comparable to those for GTA welds.

### Elevated-Temperature Fracture Toughness

The same ordering of fracture toughness levels for the various weld processes is observed at elevated temperatures, as shown in Fig. 8. At 427 to 538 °C, GTA welds consistently possess the highest  $J_c$  values (266 to 373 kJ/m<sup>2</sup>), SMA welds have intermediate toughness values (89 to 190 kJ/m<sup>2</sup>), and both SA welds tested in this regime have a  $J_c$  of 76 kJ/m<sup>2</sup>. Table 1 provides mean and lower-bound values of  $J_c$  and  $dJ/da$  for GTA welds at elevated temperatures. The sparse elevated-temperature data base precludes meaningful statistical analysis for SA and SMA welds, so a simple lower-bound approach must be used to establish minimum expected toughness values. The lowest observed  $J_c$  and  $dJ/da$  values at high temperatures are 55 kJ/m<sup>2</sup> and 62 MPa, which are about 15% less than the lower-bound values for SA welds at room temperature.

**FIG. 8 EFFECT OF TEST TEMPERATURE ON  $J_c$  FOR TYPES 304/308 AND 316/16-8-2 WELDS.  $J_c$  VALUES FOR THE SAME WELD ARE CONNECTED BY A LINE. GTA, GAS-TUNGSTEN ARC; SMA, SHIELDED-METAL ARC; SA, SUBMERGED ARC. A DASH OR ASTERISK REPRESENTS EITHER ANOTHER WELDING PROCESS OR A WELD WHERE THE PROCESS WAS NOT IDENTIFIED. SOURCE: REF 10, 16, 17, 18, 22, 24, 29, 34, 35, 36, 38, 40, 43, 46, 54, 68, 69, 70, 74, 75, 76, 84, 85, 86, 87, AND 88 (TYPES 304/308); REF 15, 17, 18, 29, 34, 47, 50, 52, 55, 71, 72, AND 86 (TYPES 316/16-8-2)**

The fracture resistance of electron-beam (EB) welds is high. While no specific fracture toughness values are available, Josefsson (Ref 71) reported that  $J_c$  values for EB welds are about twice those for GTA welds (550 kJ/m<sup>2</sup> at 250 °C and 330 kJ/m<sup>2</sup> at 450 °C).

The exceptionally high toughness for GTA and EB welds precludes rapid fracture concerns in most engineering structures. Although  $J_c$  values for SMA and SA welds can be low, their relatively high tearing resistance indicates that unstable fracture is unlikely except after significant plastic deformation. Consequently, standard stress and strain design limits generally provide adequate protection against failure, and sophisticated elastic-plastic fracture mechanics assessments are not routinely needed.

## Fracture Mechanisms in Welds

Stainless steel welds fail exclusively by a dimple rupture mechanism, where the microvoids nucleate at inclusions and  $\delta$ -ferrite particles. Thus, the overall fracture resistance is controlled by the density and morphology of second-phase inclusions. Type 304/308 and 316/16-8-2 welds have a duplex austenite-ferrite structure with about 4 to 12%  $\delta$ -ferrite. Because  $\delta$ -ferrite is ductile at ambient and elevated temperatures, its volume fraction and morphology do not control the fracture response. Fracture properties are controlled by the density of inclusions rich in manganese and silicon and believed to be manganese silicides and silicates. SA welds have a high density of coarse inclusions (Ref 17, 18, 89) as shown in Fig. 9. SMA welds contain a modest amount of coarse inclusions (Ref 17, 18, 55, and 82), while GMA and GTA welds have a much lower inclusion density (Ref 17, 82, 90). O'Donnell et al (Ref 55) found that the volume fraction of inclusions for an SMA weld is an order of magnitude higher than that in a GTA weld. High silicon contents are generic to the SA weld processes due to silicon pickup from the flux. In SA and SMA welds, the deoxidation process produces oxides rich in manganese and silicon that are sometimes trapped in the molten pool during solidification, thereby accounting for the high density of inclusions. The low density of coarse inclusions in GTA and GMA welds arises from the inert shielding gas protecting the molten pool from oxygen and the lack of a flux. GTA welds tend to have a few small particles, but they resist fracture and do not adversely affect properties (Ref 17).

**FIG. 9** DUPLEX AUSTENITE-FERRITE MICROSTRUCTURE FOR TYPE 308 SUBMERGED ARC WELD SHOWING VERY HIGH DENSITY OF INCLUSIONS RICH IN SILICON AND MANGANESE. SOURCE: REF 17

The fracture surface morphology for GTA welds involves a microvoid coalescence mechanism. Microvoids are nucleated by localized failure or decohesion of the ferrite phase and small precipitates, but only after extensive deformation of both the ferrite and austenite matrix. The ability of the ferrite phase to accommodate plastic deformation and resist fracture accounts for the exceptional fracture toughness displayed by GTA welds. Although ferrite content and morphology have little effect on fracture properties at ambient and high temperatures, significant ductility loss can occur at cryogenic temperatures or after long-term thermal aging. Under these conditions, the ferrite can degrade the fracture resistance of the weld, as discussed later.

The coarse inclusions in SA and SMA welds cannot accommodate plastic deformation, so high secondary stresses develop at the particle-matrix interface. The high stresses cause inclusions to decohere from the matrix at low plastic strains, and the resulting microvoids serve as effective dimple nucleation sites. Figure 10 shows that most of the dimples in SA welds are nucleated by the spherical inclusions. Relatively little plastic deformation is required to initiate microvoids in SA welds, which accounts for their inferior fracture toughness. The modest inclusion density in SMA welds produces intermediate toughness values.

**FIG. 10 SEM FRACTOGRAPH OF TYPE 16-8-2 SUBMERGED ARC WELD WHERE THE MAJORITY OF DIMPLES WERE NUCLEATED BY SPHERICAL INCLUSIONS RICH IN SILICON AND MANGANESE. SOURCE: REF 17**

The superior toughness displayed by EB welds is associated with the absence of coarse inclusions and a refined microstructure produced by rapid cooling rates.

### Fracture Toughness of Austenitic Stainless Steels and Their Welds

W.J. Mills, Member of ASM International, Upper St. Clair, PA

---

### Fracture Toughness of Welding-Induced Heat-Affected Zones

Welding of types 304 and 316 produces heat-affected zones where the grain boundaries are often decorated with ferrite or chromium-rich  $M_{23}C_6$  carbides. Immediately adjacent to the fusion zone, a thin ferrite layer sometimes forms along austenite grain boundaries and extends one to two grain diameters into the heat-affected zone. The ferrite is beneficial because it restricts grain growth and prevents liquation cracking by limiting impurity element diffusion and inhibiting wetting of liquid films (Ref 91, 92). Because the intergranular ferrite is ductile at ambient and elevated temperatures, it does not have an adverse effect on fracture resistance. Welding-induced precipitation of  $M_{23}C_6$  carbides occurs up to 3 mm from the fusion boundary, depending on the carbon content of the base metal, weld travel speed, and heat input (Ref 93). While chromium depletion adjacent to the carbides creates a sensitized structure that is susceptible to corrosion and stress-corrosion cracking, the overall fracture resistance remains high because the intergranular precipitates have little effect on fracture properties (Ref 94). In Fig. 11, fracture toughness values for type 304 and 316 heat-affected zones (Ref 22, 34, 36) are compared with their weld and base metal counterparts. The heat-affected zone toughness is superior to the weld toughness and generally commensurate with that of the base metal. This behavior is observed for welds made with very different heat inputs, including GTA, SMA, and SA welds. In cases where  $J_c$  for the heat-affected zone is reduced relative to the base metal, values of  $dJ/da$  remain exceptionally high, ranging from 135 to 427 MPa. Thus, the limiting toughness for welded joints is typically controlled by the weld fusion zone, not the heat-affected zone.

FIG. 11 COMPARISON OF  $J_c$  VALUES FOR HEAT-AFFECTED ZONE (HAZ), WELD FUSION ZONE (W), AND BASE METAL (BM). VALUES OF  $DJ/DA$ , IN MPA, ARE PROVIDED BEYOND EACH BAR. CRACKS ARE ORIENTED PARALLEL TO THE WELDING DIRECTION. SA, SUBMERGED ARC; GTA, GAS-TUNGSTEN ARC; SMA, SHIELDED-METAL ARC; GMA, GAS-METAL ARC. SOURCE: REF 22, 34, 36

## Fracture Toughness of Austenitic Stainless Steels and Their Welds

W.J. Mills, Member of ASM International, Upper St. Clair, PA

### Effect of Crack Orientation on Base Metal and Weld Toughness

Thermomechanical processing of stainless steels can produce anisotropic microstructures with inclusion stringers aligned in the primary working direction. Because these inclusions fail and nucleate microvoids early in the plastic straining process, they degrade fracture toughness when aligned in the crack propagation direction. In some heats,  $\delta$ -ferrite stringers are aligned in the primary working direction, but this phase is ductile, so it has no adverse effect on toughness. This is supported by the exceptional fracture resistance observed in heats with  $\delta$ -ferrite stringers, even when the crack is parallel to the stringers (Ref 39, 42, 52).

The effect of crack orientation on  $J_c$  for types 304 and 316 and their welds is shown in Fig. 12. Crack orientation is defined in accordance with the ASTM E 616 two-letter code (L = longitudinal [i.e., primary working direction], T = transverse, S = short transverse, R = radial, and C = circumferential). The first letter designates the direction normal to the crack plane and the second is the expected crack propagation direction.

FIG. 12 EFFECT OF CRACK ORIENTATION ON THE FRACTURE TOUGHNESS OF BASE METAL AND WELDS. GMA, GAS-METAL ARC WELDED; L, LONGITUDINAL (PRIMARY WORKING DIRECTION); T, TRANSVERSE; C, CIRCUMFERENTIAL; S, SHORT TRANSVERSE. FOR THE GMA WELDS, THE WELDING DIRECTION IS PARALLEL TO T-L ORIENTED CRACKS AND PERPENDICULAR TO L-T ORIENTED CRACKS. SOURCE: REF 8, 10, 11, 24, 27,

Figure 12 shows that the toughness of the type 304 plate in the T-L orientation is 40% lower than the L-T toughness, while the two type 316L plates show little or no difference in toughness in the L-T and T-L orientations. The small difference in  $J_c$  for the L-T and T-L orientations in some plates arises because plates are often cross-rolled to minimize inclusion alignment in any one particular direction. Nevertheless, inclusions in cross-rolled plates are smeared out normal to the short-transverse direction, which accounts for the significant reduction in toughness for the S-L orientation. The low toughness in this orientation is generally not a concern, because most components are not subjected to significant stresses in the through-thickness direction.

Garwood (Ref 95) characterized the 370 °C fracture toughness of a type 316 plate in six different orientations; the results are summarized in Fig. 13. The toughness is characterized in terms of the  $J$  value at maximum load ( $J_{max}$ ). For stainless steels,  $J_{max}$  is well above  $J_c$ , so it reflects the tearing resistance as well as the initiation toughness. Nevertheless, the trends shown in Fig. 13 provide an overview of crack orientation effects. Although the L-S and L-T orientations have a common crack plane, the different cracking directions yield a 40% difference in toughness. Cracks with an L-S orientation represent a crack-arrester geometry where failed inclusion stringers blunt the crack as it propagates in the through-thickness direction. Hence, the tremendous plastic energy required to extend the crack accounts for the exceptionally high  $J_{max}$  of 1900 kJ/m<sup>2</sup>. The L-T orientation represents a crack-divider geometry where the dimples nucleated by inclusions also blunt the crack, but not as effectively as the L-S orientation. The T-S and T-L orientations have a common crack plane that contains the primary axis of the stringers. Hence, the elongated dimples nucleated by the stringers provide a preferred crack path that accounts for the intermediate toughness for both of these orientations. Through-thickness loading for the S-T and S-L orientations produces by far the worst fracture properties. Because inclusion clusters are parallel to the crack plane, they provide low-energy crack paths, resulting in inferior fracture resistance.

FIG. 13 EFFECT OF CRACK ORIENTATION ON  $J_{MAX}$ , WHICH CORRESPONDS TO THE VALUE OF  $J$  AT MAXIMUM LOAD. L, LONGITUDINAL (PRIMARY WORKING DIRECTION); T, TRANSVERSE; S, SHORT TRANSVERSE. SOURCE: REF 95

Crack orientation effects for piping are summarized in Fig. 12. While the forged pipe has comparable toughness values in the C-L and L-C orientations (Ref 27), the other pipes show significant orientation effects with  $J_c$  in the C-L orientation, being 30 to 70% lower than its L-C counterpart. This orientation effect is attributed to the large stringers aligned in the longitudinal direction (Ref 10), as shown in Fig. 14. When these stringers are perpendicular to the cracking direction (L-C orientation), they nucleate deep, equiaxed microvoids that blunt the crack tip and enable the adjacent material to undergo gross plastic deformation prior to separation (Fig. 14b). In the C-L orientation, stringers aligned in the crack growth direction initiate elongated microvoids ahead of the crack (Fig. 14c). Coalescence of these microvoids causes premature crack advance without significant plastic deformation and results in a 70% lower  $J_c$  and 60% lower tearing modulus (Ref 10).

**FIG. 14 MICROSTRUCTURE OF COMPACT TENSION SPECIMENS FROM TYPE 316 PIPING. (A) STRINGERS ALIGNED IN AXIAL DIRECTION. (B) LONGITUDINAL-CIRCUMFERENTIAL (L-C) ORIENTATION. EXTENSIVE PLASTIC DEFORMATION AND DEEP MICROVOIDS NUCLEATED BY STRINGERS. (C) CIRCUMFERENTIAL-LONGITUDINAL (C-L) ORIENTATION. SHALLOW MICROVOIDS AND LIMITED PLASTIC DEFORMATION. SOURCE: REF 10**

Figure 12 also shows that the fracture toughness of welds is independent of crack orientation: cracks parallel and normal to the welding direction yield equivalent  $J_c$  values. Second-phase particles in the weld fusion zone are not preferentially aligned, which accounts for the lack of an orientation effect.

### Fracture Toughness of Cold-Worked Stainless Steels

While cold work is used to increase the strength of stainless steels, it significantly reduces ductility and fracture toughness. Annealed type 316 has yield strengths between 200 and 300 MPa, but after 5 to 30% cold work, yield strength levels are typically 400 to 600 MPa. The strength is increased at the expense of ductility; total elongation values are reduced from 60-75% in the annealed condition to 20-30% after 20% cold work. The reduced ductility is responsible for the decrease in toughness. Figure 15 summarizes the effect of cold-work-induced strengthening on fracture toughness. Chipperfield (Ref 49) found that the toughness of type 316 is reduced from 254 kJ/m<sup>2</sup> in the annealed condition to 121 kJ/m<sup>2</sup> after 5% cold work and to 70 kJ/m<sup>2</sup> after 30% cold work. Pawel (Ref 52) also found that cold work significantly reduces the toughness of two type 316 heats and a PCA heat. For the low-toughness type 316 heat (represented by open triangles), cold work severely degrades  $J_c$  from 233 to 39 kJ/m<sup>2</sup>. By contrast, the high-toughness heat (represented by circles) shows a much smaller effect, and cold-worked PCA shows an intermediate loss in toughness. Strength levels for these cold-worked materials are similar ( $\sigma_{YS} = 675$  to 715 MPa,  $\sigma_{UTS} = 725$  to 770 MPa), so strength level does not correlate with toughness. The different  $J_c$  responses are associated with variability in inclusion density and morphology. Low-toughness heats generally contain a high density of inclusions, and cold work exaggerates their alignment in the primary working direction. When the inclusion stringers are aligned in the cracking direction, they nucleate elongated microvoids ahead of the crack front, thereby providing a low-energy crack path that significantly degrades fracture resistance.

### Effect of Strain Rate on Base Metal and Weld Toughness

Figure 16 shows that semidynamic and dynamic strain rates do not adversely affect fracture resistance and that in some cases, higher loading rates have a beneficial effect. Semidynamic strain rates ( $\sim 600$  mm/min corresponding to crack initiation times of less than 0.5 s) have a small beneficial effect on both  $J_c$  and  $dJ/da$  (Ref 46, 94). In addition, load-displacement curves obtained under dynamic conditions (15 m/min) are identical to the semidynamic curves, indicating

that the beneficial effects are maintained at very high strain rates (Ref 94). One of the two type 304 heats studied by Marschall (Ref 96) shows a similar response, with  $J_c$  increasing by 15% under semidynamic conditions. The second heat shows a much larger effect, with  $J_c$  increasing by 65%. Chipperfield (Ref 49) characterized the static and dynamic toughness of annealed and cold-worked type 316 and found that in both conditions the toughness response was essentially unaffected by loading rate: dynamic  $J_c$  values were within 7% of their static counterparts.

FIG. 16 EFFECT OF STRAIN RATE ON  $J_c$  AND ON  $dJ/da$  (PROVIDED NEXT TO EACH BAR IN MPA). L, LONGITUDINAL (PRIMARY WORKING DIRECTION); C, CIRCUMFERENTIAL; CW, COLD WORK; SMA, SHIELDED-METAL ARC WELDED. SOURCE: REF 46, 49, 94, 96, AND 97

The toughness of an aged type 308 SMA weld at semidynamic strain rates is also superior to that under static strain rates (Ref 94). While  $J_c$  values for the two strain rates are similar, the 80% increase in  $dJ/da$  under semidynamic conditions results in a substantial improvement in overall fracture resistance. Moreover, dynamic testing of this weld produces load-displacement curves that are identical to the semidynamic curves, here again demonstrating that both the semidynamic and dynamic toughness responses are superior to the static response. Marschall (Ref 96) found even more dramatic strain rate effects for a type 308 SA weld: semidynamic strain rates cause a 130% increase in  $J_c$  and a 40% increase in  $dJ/da$ .

## Effect of Thermal Aging on Base Metal and Weld Toughness

### Aging-Induced Microstructural Changes

Austenitic stainless steels are commonly used in high-temperature applications where aging-induced microstructural changes degrade fracture resistance. High-temperature aging of base materials results in the formation of carbides and intermetallics, including sigma FeCr, FeMo, Fe(CrMo), chi ( $\text{Fe}_{18}\text{Cr}_6\text{Mo}_5$ ) and Laves ( $\text{Fe}_2\text{Mo}$ ) phases (Ref 98, 99). Between 500 and 650 °C, chromium-rich  $\text{M}_{23}\text{C}_6$  precipitation is dominant occurring successively at grain boundaries, twin boundaries, and finally intragranularly. At higher temperatures,  $\text{M}_{23}\text{C}_6$  carbides and  $\sigma$ -phase form in both types 304 and 316, while molybdenum additions in the latter also result in Laves and  $\chi$  precipitation.

The  $\delta$ -ferrite phase in duplex austenitic-ferritic welds is unstable at elevated temperatures. Long-term aging above 500 °C causes the ferrite to transform into austenite,  $\sigma$ -phase, and  $\text{M}_{23}\text{C}_6$  carbides that precipitate along the ferrite-austenite interface (Ref 100, 101). At lower temperatures, 885 °F (474 °C) embrittlement, which is common to ferritic steels with high chromium (Ref 102), is operative in the  $\delta$ -ferrite because its composition is similar to that of a ferritic steel. This mechanism, also known as  $\alpha'$  embrittlement, results from the spinodal decomposition of  $\delta$ -ferrite into low-chromium ( $\alpha$ ) and high-chromium ( $\alpha'$ ) regions (Ref 103, 104). In addition, low-temperature aging produces a nickel- and titanium-rich silicide (G phase:  $\text{Ti}_6\text{Ni}_{16}\text{Si}_7$ ) in the ferrite (Ref 101), some carbide precipitation along the ferrite-austenite interface (Ref 101), and limited  $\text{M}_6\text{C}$  in the matrix.

### Fracture Toughness of Aged Base Metal

The effect of long-term thermal exposure on the fracture toughness of stainless steels is summarized in Fig. 17. Aging at 450 °C for 50,000 h has no effect on fracture toughness (Ref 55). Aging at 550 and 566 °C causes only a modest degradation of fracture resistance, with  $J_c$  being reduced by about 20% after 10,000 h (Ref 10, 94) and by 35% after 50,000 h (Ref 55). The reduction in toughness results from aging-induced  $\text{M}_{23}\text{C}_6$  carbides along grain boundaries that initiate a localized intergranular cracking mechanism. Intergranular cracking is confined to a few isolated regions, while the dominant fracture mechanism is transgranular dimple rupture nucleated by primary MC carbides (Fig. 18). The dominance of the dimple rupture mechanism in both the unaged and aged conditions accounts for the relatively small effect of thermal aging on  $J_c$ .

FIG. 17 EFFECT OF AGING ON THE FRACTURE TOUGHNESS OF BASE METALS. VALUES OF  $DJ/DA$  (IN MPA) ARE PROVIDED IN PARENTHESIS. SOURCE: REF 8, 10, 94

FIG. 18 SEM FRACTOGRAPH FOR TYPE 304 AGED AT 566 °C. TRANSGRANULAR DIMPLE RUPTURE IS DOMINANT, BUT LIMITED INTERGRANULAR CRACKING (DENOTED BY ARROWS) IS ALSO OBSERVED. SOURCE: REF 94

Figure 17 also indicates that aging under stress accelerates toughness loss. Specifically, aging of WN 1.4948 (similar in composition to type 304) for 2000 h at 600 °C while stressed to 65% of the yield strength causes a 40% reduction in  $J_c$  (Ref 8). The loss of toughness is associated with intergranular and intragranular carbide precipitation and development of a stress-induced dislocation substructure characteristic of secondary creep.

Table 2 summarizes the effect of in-service exposure to 450-550 °C for 51,000 h on the fracture toughness of type 321 pipe (Ref 14). The service-exposed pipe displayed a modest reduction in toughness, with the degree of degradation being dependent on test temperature. At room temperature, aging reduced  $J_c$  by 35% but had no effect on  $dJ/da$ . At 300 and 500 °C, aging produced a 5-15% reduction in  $J_c$  and 25-30% reduction in  $dJ/da$ .

### Fracture Toughness of Aged Welds

Figure 19 shows considerable variability in the degree of degradation produced by long-term thermal aging of welds. The greatest toughness loss occurs in the higher-toughness welds. For example, exposing the low-toughness type 316 SMA weld to 550 °C for 50,000 h is seen to have only a modest effect on toughness, as  $J_c$  is reduced from 90 to 70 kJ/m<sup>2</sup> (Ref 55). Aging at 566 °C for 10,000 h causes a 14% reduction in  $J_c$  for the type 308 SMA weld with intermediate toughness (as-welded toughness  $J_c$  of 144 kJ/m<sup>2</sup>) and 21% reduction in  $J_c$  for the type 16-8-2 GTA weld with high toughness (as-welded  $J_c$  of 311 kJ/m<sup>2</sup>) (Ref 10). The fracture-resistant type 308 GTA weld (as-welded  $J_c$  of 770 kJ/m<sup>2</sup>) shows a 60% decrease in toughness after aging at 550 °C for 5000 h (Ref 70). It is noteworthy that most of the toughness loss occurs within the first 1000 h of aging at 550 °C.

**FIG. 19 EFFECT OF AGING ON THE FRACTURE TOUGHNESS OF WELDS.** SMA, SHIELDED-METAL ARC; GTA, GAS-TUNGSTEN ARC. RANGE OF AGING TEMPERATURES: (A) 550 (REF 55, 70) TO 566 °C (REF 10, 94). (B) 475 (REF 69, 70) TO 482 °C (REF 10). (C) 400 (REF 15, 70, 86) TO 450 °C (REF 10, 55)

While fracture surfaces for both the unaged and aged welds are dominated by dimples produced by microvoid coalescence, the dimple size is slightly smaller for the welds aged at 550 and 566 °C. The smaller dimples arise from an increase in the number of microvoid nucleation sites due to aging-induced  $M_{23}C_6$  carbides and  $\sigma$ -phase, as shown in the metallographic-fractographic profiles in Fig. 20 (Ref 94). These profiles are obtained by electropolishing selected areas of the fracture surface so that its topography and underlying microstructure can be characterized simultaneously. It is seen that microvoids in the unaged weld are nucleated by inclusions and  $\delta$ -ferrite particles (Fig. 20a), whereas microvoids in the aged weld are nucleated by inclusions,  $\sigma$ -phase, and  $M_{23}C_6$  carbides (Fig. 20b).

**FIG. 20 SEM METALLOGRAPHIC/FRACTOGRAPHIC INTERFACE FOR TYPE 308 SHIELDED-METAL ARC WELDS. (A) IN THE UNAGED CONDITION, MICROVOIDS ARE NUCLEATED BY  $\delta$ -FERRITE AND SILICON-RICH INCLUSIONS. (B) AFTER AGING  $\delta$ -FERRITE TRANSFORMATION PRODUCTS,  $\sigma$ -PHASE (WHITE PHASE) AND  $M_{23}C_6$  CARBIDES (ON PRIOR AUSTENITE-FERRITE BOUNDARIES) PROVIDE ADDITIONAL MICROVOID NUCLEATION SITES. SOURCE: REF 94**

The different aging responses exhibited by the various welds are attributed to the relative effectiveness of microvoid nucleation sites. While carbides and  $\sigma$ -phase provide additional nucleation sites in SMA welds, their effectiveness in nucleating microvoids is less than that associated with the inclusions already present in the as-welded condition. This accounts for the modest aging effects for SMA welds. In high-toughness GTA welds, the small inclusions and unaged  $\delta$ -ferrite resist failure, so they nucleate microvoids only after extensive plastic deformation. In this case, aging-induced carbides and  $\sigma$ -phase have a pronounced effect on toughness because they are more effective microvoid nucleation sites. It is noteworthy that even though aging of the GTA welds reduces fracture toughness by up to 60%,  $J_c$  values after aging (236 and 300 kJ/m<sup>2</sup>) are still substantially higher than the  $J_c$  value of 144 kJ/m<sup>2</sup> for the unaged SMA weld. This comparison clearly shows that aging-induced carbides and  $\sigma$ -phase are less effective microvoid nucleation sites than the inclusions in SMA welds.

Aging of type 308 (Ref 69) and 16-8-2 (Ref 94) GTA welds at 475 to 482 °C (Fig. 19b) causes about the same degree of toughness loss as 550 to 566 °C aging, although the embrittlement mechanisms are different. During long-term exposure at temperatures below 500 °C, spinodal decomposition of the  $\delta$ -ferrite coupled with G-phase and carbide precipitation are responsible for the aging effects. Electron micrographs of the 475 °C aged weld (Fig. 21) reveal G-phase within the ferrite,  $M_{23}C_6$  carbides along the ferrite-austenite interface, and a mottled ferrite appearance indicative of spinodal decomposition into  $\alpha'$  (Ref 69, 70). Atom probe field ion microscopy of the aged ferrite confirms the spinodal decomposition into iron-rich  $\alpha$  regions and chromium-rich  $\alpha'$  regions with a periodicity of 6.5 nm (Ref 66). The  $\alpha'$  embrittlement hardens the ferrite, making it an effective microvoid nucleation site that reduces upper-shelf fracture energy. The dominant role of the  $\alpha'$  embrittlement mechanism was demonstrated using reversion heat treatment experiments where the aged weld was heat treated at 550 °C for 1 h (Ref 105). Because 550 °C is above the  $\alpha + \alpha'$  miscibility gap and well below the G-phase and  $M_{23}C_6$  solvus temperatures, the ferrite is homogenized while the precipitates are essentially unaffected. This treatment results in a substantial but not full recovery of the notch toughness, demonstrating that the spinodal reaction is responsible for most of the embrittlement while the second-phase precipitates play a minor role.

**FIG. 21 ELECTRON MICROGRAPHS OF AGED TYPE 308 WELD. (A) AGED AT 475 ° C FOR 1000 H, SHOWING MOTTLED STRUCTURE INDICATIVE OF SPINODAL DECOMPOSITION OF THE  $\delta$ -FERRITE AND EXTENSIVE G-PHASE PRECIPITATION. (B) AGED AT 475 ° C FOR 4950 H, SHOWING  $M_{23}C_6$  CARBIDES AT AUSTENITIC-FERRITE INTERFACE IN ADDITION TO G-PHASE PRECIPITATES WITHIN THE  $\delta$ -FERRITE. SOURCE: REF 101**

Embrittlement rates at 400 to 450 °C are relatively slow due to the sluggish kinetics of spinodal decomposition and G-phase precipitation. In this temperature regime (Fig. 19c), some welds show little or no aging effects after 5000 to 50,000 h, while others show a modest toughness loss. Type 308 GTA and SMA welds aged for 10,000 h at 427 °C and type 316 SMA weld aged for 50,000 h at 400 to 450 °C (Ref 55) show essentially no reduction in  $J_c$  or tearing modulus. Aging the type 308 GTA weld at 400 °C for times up to 5000 h causes only a 10% drop in  $J_c$  (from 770 to 700 kJ/m<sup>2</sup>), whereas aging at 475 °C for the same time produces a 60% decrease in toughness (Ref 70). Ould et al. (Ref 86) found that 400 °C exposure for 10,000 to 34,000 h has essentially no effect on the low-toughness weld but causes a 50% decrease in  $J_c$  for an intermediate-toughness weld. Faure et al. (Ref 15) also reported a modest effect of 10,000 h aging at 400 °C for a type 316 GTA weld:  $J_c$  was reduced by 35%.

Although long-term thermal exposure degrades the toughness of welds, the high post-aging  $J_c$  values indicate that sufficient toughness is retained to preclude nonductile fracture. Ductile tearing of aged materials occurs only after substantial plastic deformation, so fracture control of aged stainless steels is typically not a critical engineering issue.

### Fracture Toughness/Charpy Energy Correlations for Aged Stainless Steels

A wealth of data (Ref 65, 69, 70, 105, 106, 107, 108, 109, 110, 111, and 112) shows that thermal aging causes up to a 90% degradation in Charpy V-notch energy for both base metals and welds. For duplex welds, aging not only degrades the upper-shelf energy but also increases the ductile-brittle transition temperature. The Charpy energy response for a type 308 GTA weld aged at 475 and 550 °C is shown in Fig. 22 (Ref 70). At both temperatures, 1000 to 5000 h agings decrease the upper-shelf energy by about 50% and increase the transition temperature by almost 100 °C.

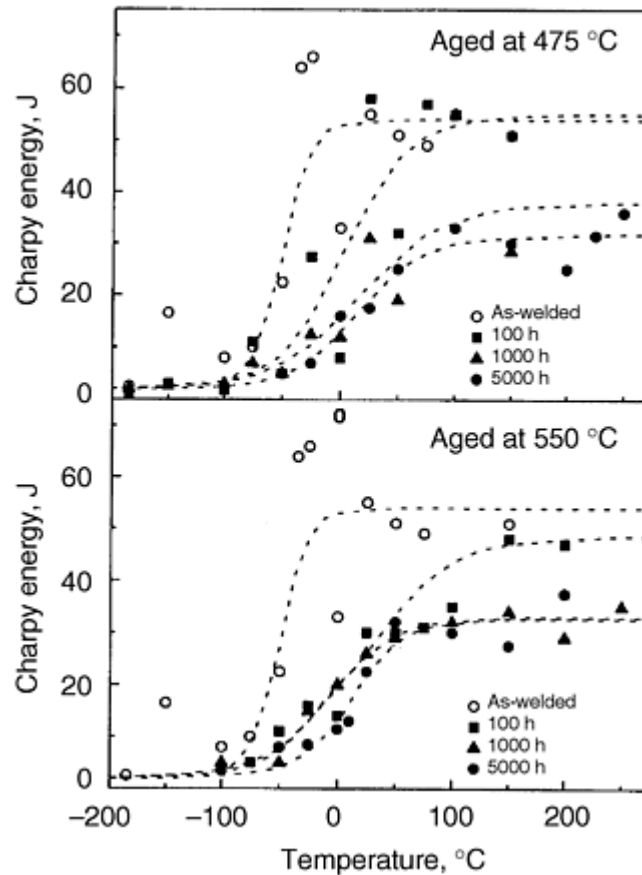

FIG. 22 CHARPY V-NOTCH ENERGY AS A FUNCTION OF TEST TEMPERATURE FOR A TYPE 308 GAS-TUNGSTEN ARC WELD, AGED AT 475 AND 550 °C. SOURCE: REF 70

Sikka (Ref 106) developed the Larson-Miller type relationship in Fig. 23 that predicts the reduction in Charpy energy for type 316 in terms of exposure time ( $t$  in hours) and temperature ( $T$  in K) using:

$$P = T(5.81 + \text{LOG } T) \times 10^{-3} \quad (\text{EQ 7})$$

where  $P$  is the Larson-Miller parameter. Although this correlation cannot account for the effects of composition, orientation, and  $\delta$ -ferrite content in all heats and welds (Ref 94, 112), it provides satisfactory predictions of the degree of embrittlement for many materials. Sikka's observation that equivalent time-temperature combinations per Eq 7 produce similar intergranular carbide microstructures suggests that carbide precipitation is responsible for the aging-induced toughness degradation in type 316. This is consistent with the fractographic observations in Fig. 18(b), where aging-induced  $M_{23}C_6$  precipitates along grain boundaries reduce toughness by nucleating localized intergranular cracks.

FIG. 23 CHARPY V-NOTCH IMPACT ENERGY RATIO FOR AGED VS. UNAGED MATERIALS AS A FUNCTION OF THE LARSON-MILLER TYPE PARAMETER DEVELOPED BY SIKKA (SEE TEXT AND REF 106). SOURCE: REF 106, 107 (TYPE 316); REF 94 (TYPES 304 AND 308)

In contrast to the large degradation in Charpy energy, some fracture mechanics studies (Ref 10, 94, 113) reveal that thermal aging produces only a modest reduction in  $J_c$  and tearing resistance. This behavior is illustrated in Fig. 24 for type 304 and type 308 SMA weld aged at 566 °C for 10,000 h (Ref 94). The 60% reduction in blunt-notch Charpy impact energy for both materials, represented by the solid symbols in Fig. 23, agrees with the Larson-Miller type correlation developed by Sikka. In direct contrast to this response, however, precracked Charpy and fracture mechanics specimens show a much smaller aging effect. Aging reduces  $J_c$  values by about 20% and  $dJ/da$  values by 30%. This is consistent with the 25 to 35% reduction in precracked Charpy impact energy but is much less than the 60% reduction in Charpy V-notch impact energy.

**FIG. 24 EFFECT OF THERMAL AGING ON THE NORMALIZED CHARPY V-NOTCH IMPACT ENERGY, PRECRACKED CHARPY IMPACT ENERGY, AND  $J_c$ . CHARPY TESTS WERE PERFORMED AT 24 °C;  $J_c$  TESTS WERE PERFORMED AT 538 °C. THE UNAGED TYPE 304 CHARPY V-NOTCH SPECIMEN DID NOT FRACTURE AT A NORMALIZED IMPACT ENERGY OF  $\sim 4000$  KJ/M<sup>2</sup>. SOURCE: REF 94**

Fractographic examinations reveal that the large degradation in Charpy V-notch energy after aging is due to differences in the energy required to initiate a crack from a blunt notch (Ref 94). The key fracture surface feature on unaged Charpy V-notch specimens is a series of tear-arrest markings, where cracks initiate but are quickly arrested by the fracture-resistant matrix. The tremendous amount of energy required for crack reinitiation accounts for the high blunt-notch Charpy impact energy in the unaged condition. After aging, there is little or no evidence of arrest markings. In the aged base metal, intergranular  $M_{23}C_6$  carbides render the grain boundaries susceptible to cracking. During the early stages of plastic straining, formation of an intergranular crack ahead of the notch serves as a starter crack that drastically reduces fracture energy. In the aged weld specimens, the  $M_{23}C_6$  carbides and  $\sigma$ -phase provide additional microvoid nucleation sites that enhance cracking and thereby preclude formation of tear-arrest markings. These findings demonstrate that the large reduction in blunt-notch Charpy energy is due to aging-induced microstructural changes that markedly decrease the energy required to initiate a sharp crack. Because conventional Charpy data reflect the energy associated with nucleating a crack, rather than extending a pre-existing crack, they do not necessarily correlate with fracture mechanics properties. In many cases, blunt-notch Charpy data are an overly pessimistic indicator of thermal aging effects for stainless steel components containing cracks or crack-like defects.

In contrast to this behavior, Alexander (Ref 70) found a good correlation between Charpy V-notch energy and fracture toughness for an aged type 308 GTA weld. For this weld, aging-induced microstructural changes appeared to have the same effect on the crack propagation energy and energy required to initiate a crack from a blunt notch. Although Charpy and fracture mechanics data correlate well for some welds, caution must be exercised when using conventional Charpy tests to infer the fracture toughness for this class of materials, because results are dominated by the energy required to initiate a sharp crack from a blunt notch, rather than the energy required to propagate a pre-existing crack.

## Effect of Neutron Irradiation on Base Metal and Weld Toughness

### Irradiation-Induced Microstructure

Neutron irradiation displaces atoms from normal lattice positions, thereby creating point defects. Although most point defects recombine, survivors diffuse and cluster to form an irradiated microstructure consisting of cavities, precipitates, and dislocations. Microstructural evolution is dependent on irradiation temperature, neutron fluence, flux, and energy spectrum (Ref 114, 115, 116, 117, 118, and 119).

At temperatures below 350 °C, irradiation produces a very fine defect substructure consisting of small Frank interstitial loops and "black spot" damage, corresponding to nanometer-diameter vacancy or interstitial clusters. Between 350 and

600 °C, the defect structure coarsens. Black spots are replaced by Frank loops, and eventually network dislocations and cavities evolve at high neutron exposures. Cavities are three-dimensional clusters of vacancies (voids), gas atoms (bubbles), or a combination of the two. Above 400 °C, irradiation induces precipitation of various phases, including G-phase, Ni<sub>3</sub>Si, nickel- and silicon-rich M<sub>6</sub>C, M<sub>2</sub>P, M<sub>3</sub>P, and Laves phase (Ref 114, 115, 116, 120, and 121).

The lattice defect structure and precipitates serve as obstacles to dislocation motion that strengthen the matrix. In addition, irradiation damage causes a large ductility loss and greatly diminished strain hardening capacity as the yield strength approaches the ultimate strength. The irradiation-produced microstructure also promotes a planar slip mechanism, termed dislocation channeling. Specifically, dislocation glide on a narrow band of slip planes sweeps irradiation-produced dislocation loops from the band, creating a defect-free channel with highly deformed voids (Ref 122). Because the channels offer much less resistance to dislocation motion than the unswept regions, subsequent dislocation activity is confined to the dislocation channels. This produces a very heterogeneous deformation mode. The irradiation-induced strengthening and enhanced planar slip cause a pronounced degradation in fracture resistance.

Irradiation at temperatures above 600 °C does not cause significant displacement damage due to removal of lattice defects by annealing. Some degree of strengthening arises from second-phase precipitation, while significant reductions in ductility and toughness result from helium embrittlement. Helium, which is highly insoluble in metals, results from (*n, α*) transmutation of <sup>10</sup>B per the <sup>10</sup>B(*n, α*)<sup>7</sup>Li reaction, and the two-step reaction with natural nickel: <sup>58</sup>Ni(*n, α*)<sup>59</sup>Ni followed by <sup>59</sup>Ni(*n, α*)<sup>56</sup>Fe. It causes high-temperature embrittlement, regardless of whether the material is irradiated at high or low temperatures. During high-temperature exposure, helium diffuses to grain boundaries, rendering them susceptible to intergranular cracking, because helium atoms reduce the grain boundary cohesive strength and helium bubbles serve as local crack nuclei (Ref 118, 123). At temperatures above 600 °C, the helium embrittlement mechanism dramatically degrades the ductility and fracture toughness, but whenever the temperature falls below 600 °C this mechanism is not operative.

The two parameters used to represent irradiation damage are neutron fluence in neutrons per square centimeter and the average number of displacements experienced by each atom, in displacements per atom (dpa). Displacements per atom, calculated as the product of total fluence and spectrum-averaged displacement cross section (Ref 124), is preferred because it accounts for the effectiveness of neutrons at various energies in damaging the lattice.

## Intermediate Temperature Irradiation of Base Metal

The effect of intermediate temperature irradiation on the fracture toughness of types 304 and 316 is shown in Fig. 25. It is seen that irradiation damage can be separated into three regions: a threshold neutron exposure below which there is no loss in toughness, intermediate exposures where toughness decreases rapidly with neutron dose, and a saturation exposure above which increasing irradiation damage produces little or no additional reduction in toughness. The threshold neutron exposure for toughness degradation appears to be about 1 dpa, which is consistent with the threshold exposure of 1 dpa for tensile ductility degradation (Ref 126). Therefore, the tensile and fracture toughness responses for stainless steel components subjected to neutron exposures less than 1 dpa are not significantly affected.

FIG. 25  $J_c$  AS A FUNCTION OF NEUTRON EXPOSURE FOR BASE METALS IRRADIATED AT INTERMEDIATE TEMPERATURES. VALUES OF  $DJ/DA$  (IN MPa) ARE PROVIDED IN PARENTHESES. SOURCE: REF 29, 42, 43, 47, 85, AND 125

Irradiation exposures between 1 and 10 dpa cause a substantial decrease in fracture resistance, with the largest effects occurring in high-toughness heats. At approximately 10 dpa, the degradation in fracture properties saturates at a  $J_c$  value of about 30 kJ/m<sup>2</sup> and at  $dJ/da$  values less than 20 MPa, corresponding to tearing moduli less than 10 (Ref 43). The low tearing modulus indicates that highly irradiated stainless steels have little resistance to tearing at  $J$ -values above  $J_c$ . As a result of the dramatic decrease in toughness and increase in yield strength, postirradiation failures occur in or near the linear-elastic regime. The equivalent critical stress-intensity factor ( $K_{Jc}$ ) computed from the saturation  $J_c$  value is approximately  $70 \text{ MPa} \sqrt{m}$ , based on the following equation (Ref 127):

$$K_{Jc} = (EJ_c)^{\frac{1}{2}} \quad \text{(EQ 8)}$$

With this toughness level and postirradiation yield strengths of 600 to 700 MPa, 2 to 3 cm thick components provide sufficient constraint to satisfy plane-strain conditions. Under these conditions, acceptable load-crack length relationships can be computed using linear-elastic fracture mechanics concepts, based on critical  $K_{Jc}$  levels calculated from Eq 8.

Limited postirradiation testing of other stainless steels reveals that they are also susceptible to irradiation embrittlement. Irradiation of type 348 to a fluence of  $3 \times 10^{22}$  neutrons/cm<sup>2</sup> ( $E > 1 \text{ MeV}$ ) results in  $J_c$  values ranging from 20 to 24 kJ/m<sup>2</sup> (Ref 128), which is slightly lower than the saturation toughness of 30 kJ/m<sup>2</sup> for types 304 and 316. Instrumented impact testing of precracked type 321 specimens irradiated at 230 and 400 °C to doses from 20 to 54 dpa reveals that  $J_{max}$  values are reduced to as low as 50 kJ/m<sup>2</sup> (Ref 129, 130). For highly irradiated materials, initiation of cracking occurs shortly before maximum load, so  $J_{max}$  values slightly overestimate  $J_c$ .

The degradation in toughness results from irradiation-induced strengthening and ductility loss, coupled with increased heterogeneous slip. At high neutron exposures, a fracture mechanism transition from dimple rupture to channel fracture is responsible for the dramatic reduction in toughness. The channel fracture mechanism (Ref 131) involves localized separation along intense dislocation channels, which produces the crystallographic faceted appearance shown in Fig. 26(a) (Ref 43). The stepped facets are steeply inclined to the overall crack plane, demonstrating that their formation involves a shear process rather than cleavage. When channel fracture becomes the dominant mechanism at about 10 dpa, the toughness degradation saturates at about  $30 \text{ kJ/m}^2$  (Ref 43). The reduced data scatter in the saturation regime reflects a tendency of the irradiated alloys to evolve toward a saturation microstructure, where the density of irradiation-produced defects saturates with continued exposure. Because the saturation microstructure is independent of the starting condition, the variability in postirradiation toughness is greatly diminished.

**FIG. 26 SEM FRACTOGRAPHS SHOWING THE STEPPED FACETS INDICATIVE OF CHANNEL FRACTURE. (A) TYPE 316 IRRADIATED TO 17 DPA. (B) A TYPE 308 SHIELDED-METAL ARC WELD IRRADIATED TO 14 DPA. NOTE THE PRESENCE OF MICROVOIDS SUPERIMPOSED ON CRYSTALLOGRAPHIC FACETS IN THE WELD. SOURCE: REF 43**

### Intermediate Temperature Irradiation of Welds

The effect of intermediate temperature irradiation on the toughness of welds is demonstrated in Fig. 27. As with the base metal, irradiation effects can be categorized into the threshold, transition, and saturation regimes. Exposures up to 1 dpa have no significant effect on fracture resistance. In the transition region beyond 1 dpa, fracture resistance diminishes more rapidly than in the base metal because the embrittled  $\delta$ -ferrite serves as an effective microvoid nucleation site. At exposures above 10 dpa, saturation  $J_c$  values range from 10 to  $30 \text{ kJ/m}^2$  and  $dJ/da$  values are less than 20 MPa (Ref 43, 55, 85). Equivalent  $K_{Ic}$  values range from 40 to  $70 \text{ MPa} \sqrt{m}$ . At these toughness levels, 1 to 2 cm thick welded components possess sufficient constraint to induce plane-strain fracture conditions.

FIG. 27  $J_c$  AS A FUNCTION OF NEUTRON EXPOSURE FOR WELDS IRRADIATED AT INTERMEDIATE TEMPERATURES. VALUES OF  $dJ/da$  (IN MPa) ARE PROVIDED IN PARENTHESES. SOURCE: REF 29, 43, 47, 55, 85, AND 125

Fracture surfaces for highly irradiated welds, shown in Fig. 26(b), exhibit channel fracture with small microvoids superimposed on the crystallographic facets (Ref 43). The microvoids are nucleated by failure of embrittled  $\delta$ -ferrite particles, but they cannot develop into dimples due to restricted plastic deformation capabilities after irradiation. These small holes act as stress concentrators and prematurely nucleate channel fracture, which causes saturation  $J_c$  levels for welds to fall below base metal values.

### Low-Temperature Irradiations

The fracture toughness responses for base metals, heat-affected zones, and welds irradiated at low temperatures are summarized in Fig. 28 and 29. Irradiation of types 304, 316, and PCA to 2 or 3 dpa causes a 25 to 60% reduction in  $J_c$  and less than a 40% reduction in  $dJ/da$ . The diminished fracture resistance is due to formation of black spot damage and faulted Frank loops that increase the yield strength from 230 to 650 MPa (Ref 52). The overall fracture resistance remains high after irradiation, except for the type 316 heat with a postirradiation  $J_c$  of 155 kJ/m<sup>2</sup> and  $dJ/da$  of 30 MPa (Ref 52). This air-melted heat contains an unusually high volume of nonmetallic inclusions that promote microvoid coalescence. Hence, the inferior postirradiation toughness reflects the poor tearing resistance of this air-melted heat, coupled with a 90% increase in flow strength after irradiation. The other heats possess good tearing resistance, with postirradiation  $dJ/da$  values ranging from 90 to 290 MPa.

FIG. 28  $J_c$  AS A FUNCTION OF NEUTRON EXPOSURE FOR BASE METALS IRRADIATED AT LOW TEMPERATURES. VALUES OF  $DJ/DA$  (IN MPa) ARE PROVIDED INSIDE PARENTHESES. SOURCE: REF 35, 52

FIG. 29  $J_c$  FRACTURE TOUGHNESS AS A FUNCTION OF NEUTRON EXPOSURE FOR WELDS AND HEAT-AFFECTED ZONE IRRADIATED AT LOW TEMPERATURES. VALUES OF  $dJ/da$  (IN MPa) ARE PROVIDED IN PARENTHESES. SOURCE: REF 35, 52, 71

Figure 29 reveals that the heat-affected zone and welds are more sensitive to low-temperature irradiation than the base metal, which is consistent with the intermediate-temperature response. Irradiation to 2 or 3 dpa causes a 50 to 60% decrease in  $J_c$  and a 40 to 60% decrease in  $dJ/da$  for type 308 GMA and 316 GTA welds and the type 304 heat-affected zone. While the PCA gas-tungsten arc weld shows the greatest irradiation sensitivity, its toughness after irradiation to 3 dpa remains very high, with a postirradiation  $J_c$  of 317 kJ/m<sup>2</sup> and  $dJ/da$  of 130 MPa. The high postirradiation  $dJ/da$  values, ranging from 150 to 260 MPa, indicate that the GTA and GMA welds retain good fracture resistance at intermediate neutron exposures. Moreover, the postirradiation fracture toughness of the PCA electron beam weld is exceptionally high, with a  $J_c$  of 882 kJ/m<sup>2</sup> and  $dJ/da$  of 290 MPa.

Irradiation of the type 304 heat-affected zone to 2 dpa reduces  $J_c$  from 150 to 75 kJ/m<sup>2</sup> and  $dJ/da$  from 102 to 33 MPa. The inferior fracture properties for the irradiated heat-affected zone result from a combination of rather low toughness in the nonirradiated condition and a 50% increase in flow strength after irradiation.

### Postirradiation Fracture Toughness of Cold-Worked Material

Figure 30 shows that intermediate-temperature irradiation of 20% cold-worked type 316 to fluences greater than  $10 \times 10^{22}$  neutrons/cm<sup>2</sup> ( $E > 0.1$  MeV), corresponding to neutron exposures greater than 57 dpa (Ref 132), causes a 50% decrease in  $J_c$  and an order of magnitude reduction in  $dJ/da$  (Ref 133, 134, 135). Postirradiation  $J_c$  values are relatively independent of test temperature between 24 and 538 °C, ranging from 25 to 45 kJ/m<sup>2</sup>, but drop to 6 kJ/m<sup>2</sup> at 649 °C. Tearing resistance is also dependent on test temperature:  $dJ/da$  approaches zero at 24 °C and ranges from 10 to 70 MPa at 200 to 538 °C.

FIG. 30 TEMPERATURE DEPENDENCE OF  $J_c$  FOR NONIRRADIATED AND IRRADIATED 20% COLD-WORKED TYPE 316. VALUES OF  $dJ/da$  (IN MPa) ARE PROVIDED IN PARENTHESES. SOURCE: REF 133, 134, 135

While the nonirradiated material exhibits ductile dimple rupture at all test temperatures, operative fracture mechanisms in the irradiated condition are dependent on test temperature (Ref 134, 135). Interphase fracture between the austenite ( $\gamma$ ) matrix and deformation-induced  $\epsilon$ (hexagonal close-packed) martensite platelets results in the exceptionally low tearing resistance at 24 °C (Ref 135). Channel fracture is the dominant cracking mechanism between 205 and 538 °C, and intergranular fracture due to a helium embrittlement mechanism is responsible for the severe toughness loss at 649 °C (Ref 134).

At intermediate neutron exposures, between 3 and 8 dpa, cold-worked type 316 shows less irradiation sensitivity than its solution-annealed counterpart. Michel and Gray (Ref 85, 136) report that intermediate temperature irradiation of 20% cold-worked type 316 to 8 dpa results in only a 10% reduction in  $J_c$  and has no effect on  $dJ/da$ , as shown in Fig. 31. Well-defined microvoid coalescence is observed in both the nonirradiated and irradiated materials, which is consistent with the irradiation-insensitive response. Although fracture properties are unaffected by irradiation, the flow strength is increased from 585 to 760 MPa.

FIG. 31 EFFECT OF IRRADIATION TO 3 AND 8 DPA ON THE FRACTURE TOUGHNESS OF COLD-WORKED TYPE 316. SPECIMENS WERE IRRADIATED AND TESTED AT THE SAME TEMPERATURE. VALUES OF  $DJ/DA$  (IN MPa) ARE PROVIDED IN PARENTHESES. SOURCE: REF 52, 85, 136

The effect of 90 °C irradiation to 3 dpa on the fracture toughness of two heats of cold-worked type 316 and one heat of cold-worked PCA is also shown in Fig. 31 (Ref 52). The cold-worked PCA and high-toughness heat of cold-worked type 316 show a modest irradiation effect. A more pronounced effect is displayed by the low-toughness heat of cold-worked type 316:  $J_c$  is reduced from 39 to 21 kJ/m<sup>2</sup> and the tearing modulus is zero in both the nonirradiated and irradiated conditions. The inferior fracture resistance for this air-melted heat is due to an exceptionally high density of inclusions. The abundance of large inclusions aligned in the cracking direction, coupled with the cold-worked matrix, promote microvoid nucleation and growth, which causes a low  $J_c$  and zero tearing resistance in the nonirradiated condition. Irradiation strengthening further restricts plastic deformation capabilities and degrades  $J_c$  to 21 kJ/m<sup>2</sup>, even though the neutron exposure is only 3 dpa.

The lower-bound postirradiation  $J_c$  values of 20 to 25 kJ/m<sup>2</sup> for cold-worked type 316 tested at temperatures up to 538 °C correspond to  $K_{Jc}$  values of 55 to 65 MPa  $\sqrt{m}$ . These low toughness levels, coupled with yield strengths on the order of 800 MPa, indicate that fracture of cold-worked stainless steels in the highly irradiated condition is an important design issue and linear-elastic fracture mechanics can be used to predict failure conditions. At 649 °C, helium embrittlement degrades  $J_c$  to 6 kJ/m<sup>2</sup>, corresponding to a  $K_{Jc}$  of only 30 MPa  $\sqrt{m}$ . This low toughness indicates that brittle fracture of highly irradiated stainless steels is an issue at temperatures above 600 °C, where the helium embrittlement mechanism is operative.

### Fracture Toughness of Austenitic Stainless Steels and Their Welds

W.J. Mills, Member of ASM International, Upper St. Clair, PA

---

## Cryogenic Fracture Toughness

### Base Metals

Austenitic stainless steels, which are used extensively at cryogenic temperatures, can be separated into two categories: 1) metastable alloys (e.g., types 304 and 316 and their welds) that undergo a deformation-induced partial transformation of the austenite (face-centered cubic) to  $\alpha'$  (bcc) martensite and  $\beta$ -martensite, and 2) fully stable alloys (e.g., types 310, 330, and the Nitronic series of alloys) that resist phase transformations at cryogenic temperatures as low as  $-269\text{ }^{\circ}\text{C}$ . (The deformation-induced  $\alpha'$  martensite transformation occurring at  $-269\text{ }^{\circ}\text{C}$  is different than the  $\alpha'$  embrittlement due to spinodal decomposition at approximately  $475\text{ }^{\circ}\text{C}$ . Unfortunately, the literature uses the term  $\alpha'$  for both phases.) Evidence of martensitic phases has been detected in the crack-tip plastic zones of type 304 and 316 specimens tested at  $-269\text{ }^{\circ}\text{C}$  (Ref 51, 137, 138, 139, 140, and 141) but not at  $24\text{ }^{\circ}\text{C}$  except after high irradiation exposure.

Nitrogen-strengthened stainless steels, including AISI types 304N, 304LN, 316N, 316LN, and Nitronic alloys, are attractive because nitrogen stabilizes the austenite with respect to the martensite transformation and is an effective strengthener, particularly at  $-269\text{ }^{\circ}\text{C}$ . The effect of interstitial carbon plus nitrogen on the yield strength of type 304 at temperatures between  $22$  and  $-269\text{ }^{\circ}\text{C}$  is shown in Fig. 32 (Ref 142). Increasing the carbon plus nitrogen content from  $0.1$  to  $0.3\text{ wt}\%$  increases strength by  $70\%$  at room temperature and by  $200\%$  at  $-269\text{ }^{\circ}\text{C}$ . At room temperature the effects of carbon and nitrogen are similar, whereas nitrogen is a more potent strengthener with decreasing temperature. Hence, the strength of these alloys can be tailored for demanding cryogenic applications by adjusting the nitrogen concentration.

FIG. 32 EFFECT OF CARBON PLUS NITROGEN CONTENT ON THE YIELD STRENGTH OF TYPE 304. SOURCE: REF 142

The vast majority of austenitic stainless steel base metals do not exhibit a ductile-brittle transition temperature phenomenon, but their fracture toughness may tend to decrease at cryogenic temperatures due to increased strength and reduced ductility. This effect is most pronounced in nitrogen-strengthened alloys where the hardened matrix restricts

plastic deformation. In extreme cases, such as in Nitronic alloys with low nickel and high nitrogen tested near absolute zero, a ductile-brittle transition associated with slip band cracking (see below) can occur. But most austenitic stainless steels are inherently ductile alloys and microvoid coalescence is the dominant cracking mechanism at all temperatures from -269 to 550 °C.

Extensive fracture toughness testing of 300-series stainless steels and their welds has revealed that these materials retain good fracture resistance at cryogenic temperatures. Figure 33 shows the effect of decreasing temperature on  $J_c$  for type 304N, 316, 310, and Fe-Cr-Ni-Mn-N stainless steels. The alloys with deliberate nitrogen additions show reduced toughness with decreasing temperature due to significant strengthening and ductility loss. Decreasing the temperature from 24 to -269 °C causes a two- to three-fold increase in yield strength and at least a factor of 2 decrease in elongation. The most dramatic temperature effect occurs between -196 and -269 °C, where yield strength increases by about 30 to 40% and elongation decreases by 10 percentage points. For types 316 and 310 without nitrogen additions,  $J_c$  increases slightly as temperature is decreased. Their yield strengths at -269 °C (545 and 765 MPa) are less than those for type 304N (794-986 MPa) and Fe-Cr-Ni-Mn-N alloys (986-1540 MPa). Thus, the smaller degree of strengthening experienced by types 316 and 310 accounts for their improved cryogenic fracture resistance.

FIG. 33 EFFECT OF CRYOGENIC TEMPERATURE ON  $J_c$  FOR STAINLESS STEELS. SOURCE: REF 51 (TYPE 316); REF 140, 141 (TYPE 304N); REF 51 (TYPE 310); REF 51, 57, 143 (FE-CR-NI-MN-N)

The -269 °C fracture toughness values for types 316 and 310 are plotted in Fig. 34 as a function of yield strength. The higher yield strengths are achieved by increasing the nitrogen content. While  $J_c$  tends to decrease with increasing strength, there is considerable variability at any particular strength level. To account for data scatter, 90%/95% global tolerance limits bracketing 90% of the population at a 95% confidence level were developed (Ref 19) assuming that  $J_c$  values are log-normally distributed. The best-fit regression line and tolerance limits are represented by the solid and dashed lines. The order-of-magnitude scatter in  $J_c$ , which is consistent with the degree of scatter observed at room temperature (Fig. 2), is attributed to differences in inclusion density and morphology, chemistry, and crack orientation. At strength levels below 700 MPa, the mean  $J_c$  values of 400 to 600 kJ/m<sup>2</sup> at -269 °C are somewhat lower than the mean  $J_c$  of 672 kJ/m<sup>2</sup> at room temperature. This indicates that cryogenic temperatures cause a modest toughness degradation in low-strength, low-

nitrogen stainless steels. As nitrogen content and strength increase, mean  $J_c$  values are significantly lower because these materials show a greater temperature dependence.

FIG. 34 SUMMARY OF  $-269\text{ }^\circ\text{C}$  TOUGHNESS AS A FUNCTION OF YIELD STRENGTH. THE SOLID LINE REPRESENTS A LEAST-SQUARES EXPONENTIAL REGRESSION OF THE DATA, AND THE DASHED LINES CORRESPOND TO LINEARIZED 90/95% TOLERANCE LIMITS. SOURCE: REF 51, 144 (TYPE 316); REF 145 (TYPE 316L); REF 146 (TYPE 316N); REF 139, 143, 144, 147, 148, 149, 150, 151, 152, 153, 154, AND 155 (TYPE 316LN); REF 51, 143 (TYPE 310); REF 138, 156, 157 (TYPE 310S)

Cryogenic fracture toughness values for type 310 and for 310S, a low-carbon version of type 310, are also represented in Fig. 34.  $J_c$  values for these high-nickel stainless steels are consistent with the mean toughness of nitrogen-strengthened type 316, with a yield strength of approximately 800 MPa.

The cryogenic fracture toughness for type 304, summarized in Fig. 35, shows the same trends as that for type 316. Both alloys exhibit an order-of-magnitude scatter in  $J_c$  and comparable reductions in  $J_c$  with increasing strength. It is seen that mean and lower-bound  $J_c$  values for type 304 are about 40% lower than those for type 316.

FIG. 35 SUMMARY OF  $-269 \text{ }^\circ\text{C}$  TOUGHNESS AS A FUNCTION OF YIELD STRENGTH. THE SOLID LINE REPRESENTS A LEAST-SQUARES EXPONENTIAL REGRESSION OF THE DATA, AND THE DASHED LINES CORRESPOND TO LINEARIZED 90/95% TOLERANCE LIMITS. SOURCE: REF 137, 158, 159 (TYPE 304); REF 138, 145 (TYPE 304L); REF 140, 146, 159 (TYPE 304N); REF 57, 159 (TYPE 304LN)

Minimum-expected  $J_c$  levels exceed  $100 \text{ kJ/m}^2$  for type 304 at strength levels less than 600 MPa and for types 316 and 310 at strength levels less than 800 MPa; hence, fracture is not a primary design issue. As strength levels increase, however, the decrease in  $J_c$  causes increased fracture concerns. In the high-strength regime, conventional stress and strain design limits should be supplemented with fracture mechanics analyses to provide adequate protection against fracture for critical engineering applications. Minimum expected toughness values at yield strengths of approximately 1000 MPa are 40 to  $60 \text{ kJ/m}^2$ , corresponding to  $K_{Jc}$  values of 90 to  $110 \text{ MPa } \sqrt{\text{m}}$ . At these toughness levels, 2 to 3 cm thick components provide sufficient constraint to induce plane-strain fracture conditions. As a result, a linear-elastic fracture mechanics methodology can be used to compute critical flaw sizes for large cryogenic components with yield strengths in excess of 1000 MPa.

The difference in fracture toughness behavior between types 304 and 316 is attributed to differences in nickel content. Nickel is beneficial to fracture toughness because it stabilizes the austenite and promotes dislocation cross-slip by increasing the stacking fault energy. Purtscher and Reed (Ref 160) systematically varied the nickel content in 19Cr-4Mn stainless steel and found that increasing it from 9 to 14 wt% more than doubled  $J_c$  without sacrificing strength, as shown in Fig. 36. Types 304 and 304N contain between 8 and 10.5 wt% Ni, while types 316 and 316N contain 10 to 14 wt% Ni. Hence, the lower nominal nickel content in type 304 is responsible for its 40% lower  $J_c$  values relative to type 316. In addition, nickel content partly accounts for the observed heat-to-heat variability. The type 304 heat falling below the lower tolerance limit in Fig. 36 contains 8.0 wt% Ni (Ref 137), the minimum allowable level, and the two points just above the tolerance limit represent only 8.3 and 8.7 wt% Ni (Ref 138, 159).

FIG. 36 EFFECT OF NICKEL CONTENT ON  $J_c$  FOR 19CR-4MN STAINLESS STEEL AT -269 °C. THE YIELD STRENGTH FOR EACH HEAT IS PROVIDED IN PARENTHESIS. SOURCE: REF 160

Manganese and molybdenum additions also improve the overall strength-to-toughness response (Ref 141, 153, 160). The beneficial effect of manganese has been clearly demonstrated by systematically varying the manganese and nitrogen contents in manganese-modified type 304LN (Ref 141, 160). Figure 37 shows that increasing manganese from 1 to 6 wt% doubles  $J_c$  while increasing yield strength by 20%. The role of molybdenum is less clear. Purtscher et al. (Ref 153, 160) found that molybdenum additions up to 3 wt% significantly increased strength while causing a slight decrease in  $J_c$ . The overall strength-to-toughness response, however, tends to improve. The beneficial influence of manganese and molybdenum, like that of nickel, is believed to be associated with enhanced stability of the austenite and increased stacking fault energy (Ref 160).

FIG. 37 EFFECT OF MANGANESE AND NITROGEN CONTENTS ON  $J_c$  FOR MODIFIED TYPE 304LN AT  $-269\text{ }^\circ\text{C}$ . THE YIELD STRENGTH FOR EACH HEAT IS PROVIDED IN PARENTHESES. SOURCE: REF 160

Figure 37 also shows that increasing the nitrogen from 0.1 to 0.2 wt% increases the yield strength of type 304LN at  $-269\text{ }^\circ\text{C}$  by 250 to 300 MPa. But unlike nickel and manganese, nitrogen increases strength at the expense of ductility. Consequently, nitrogen additions significantly degrade fracture resistance.

Nitrogen-strengthened stainless steels with high nickel, manganese, and molybdenum have been developed to take advantage of the improved fracture resistance and yield strengths up to 1800 MPa. High-manganese and high-nickel stainless steels include Nitronic 33, Nitronic 40, Nitronic 50, JN1 (Fe-25Cr-15Ni-4Mn), and others with 13-25 wt% Mn. The strength-to-toughness behavior for these alloys is compared with that for types 304 and 316 in Fig. 38. For yield strengths up to 1200 MPa, the toughness range for the manganese-modified alloys and type 304N are similar. In addition, the rate at which toughness decreases with increasing strength is essentially the same for all materials represented in Fig. 38, but the manganese additions allow yield strength levels up to 1800 MPa to be achieved.

**FIG. 38  $J_c$  AS A FUNCTION OF YIELD STRENGTH FOR FE-CR-NI-MN-N STAINLESS STEELS TESTED AT  $-269\text{ }^\circ\text{C}$ . THE SCATTER BANDS REPRESENT THE RANGE OF TOUGHNESS-STRENGTH VALUES FOR TYPES 316 AND 304. SOURCE: REF 57, 143 (NITRONIC 33); REF 51, 57 (NITRONIC 40); REF 57 (NITRONIC 50); REF 143, 161 (JN1); REF 162, 163, 164, 165, 166, 167, 168, AND 169 (OTHER FE-CR-NI-MN-N ALLOYS)**

Figure 39 shows the strength-to-toughness relationship for stainless steels with high nickel, manganese, and molybdenum, including Kromarc® 58 (23Ni-16Cr-9Mn-2Mo), JK1 (13Ni-2Mo-1.3Mn), JJ1 (12Ni-10Mn-5Mo), and other Fe-Cr-Ni-Mn-Mo-N stainless steels with 13 wt% Ni, 3 to 7.5 wt% Mo, and 1 to 22 wt% Mn. Where strength levels overlap, toughness values for these high-alloy materials correspond to the upper portion of the range for type 316. The lower 90%/95% tolerance limit for Fe-Cr-Ni-Mn-Mo-N alloys is higher than those for the other alloys, indicating that Fe-Cr-Ni-Mo-N alloys possess superior fracture resistance.

**FIG. 39**  $J_c$  AS A FUNCTION OF YIELD STRENGTH FOR FE-CR-NI-MN-MO-N STAINLESS STEELS TESTED AT  $-269$  °C. THE SCATTER BANDS REPRESENT THE RANGE OF TOUGHNESS-STRENGTH VALUES FOR TYPES 316 AND 304. SOURCE: REF 156 (KROMARC 58); REF 145 (JK1); REF 161 (JJ1); REF 170, 171 (OTHER FE-CR-NI-MN-MO-N STAINLESS STEELS)

Microvoid coalescence is the dominant cracking mechanism in most austenitic steels at cryogenic temperatures, but nitrogen-strengthened alloys also exhibit slip-band cracking (Ref 137, 162, 163, 168, and 169) where separation along planar slip bands results in the crystallographic faceted appearance shown in Fig. 40 (Ref 168). Accumulation of dislocation-induced defects along slip bands leads to localized cracking under the influence of resolved tensile stresses. Increasing amounts of slip-band cracking are observed in low-toughness, high-strength alloys, at extreme temperatures. In certain alloys of the Nitronic steels, slip band cracking is the predominant failure mechanism at  $-269$  °C, so that a ductile-brittle transition occurs in the extreme cryogenic regime (Ref 168).

**FIG. 40** CRYSTALLOGRAPHIC FACETS INDICATIVE OF SLIP-BAND CRACKING IN FE-18CR-3NI-13MN-0.37N

Stable and metastable stainless steels exhibit serrated load-displacement curves during tensile and fracture toughness testing at -269 °C, but not at temperatures above -230 °C. A typical example of a serrated load-displacement curve for type 310S is shown in Fig. 41 (Ref 157). The first serrations occur shortly after specimens experience appreciable plasticity, but prior to the onset of measurable crack extension. Their magnitude and periodicity are very reproducible. These features are not associated with phase transformations because they occur in both stable and metastable alloys. Neither are they associated with a fracture mechanism transition, because microvoid coalescence is the dominant fracture mechanism. Basinski (Ref 172) and Tobler (Ref 157) proposed that serrations result from an avalanche of dislocation motion associated with an adiabatic temperature increase. Adiabatic heating has a much greater impact at -269 °C because the specific heats are about 200 to 300 times lower than at room temperature. Typical specific heat values (Ref 173, 174, 175, and 176) for types 304 and 316 are 450 to 500 J kg<sup>-1</sup> K<sup>-1</sup> at room temperature, 140 to 280 J kg<sup>-1</sup> K<sup>-1</sup> at -196 °C, and 2 to 4 J kg<sup>-1</sup> K<sup>-1</sup> at -269 °C. Therefore, small amounts of thermal energy at -269 °C create a substantial adiabatic temperature rise that causes thermal softening due to the lower strength at higher temperatures. Because thermal conductivities are also low at this temperature, the region experiencing higher temperatures is very localized. During the load drop, plastic strain rates associated with an avalanche of dislocation motion in the thermally softened region exceed applied strain rates. Eventually the plastic strain instability arrests when the deformation process becomes stable due to local strain hardening and an increase in specific heat that precludes continued temperature increase. The flow process is then stable until the entire specimen cools to -269 °C and additional plastic straining reinitiates this process, thereby accounting for the reproducibility of the serrations.

FIG. 41 SERRATED LOAD-DISPLACEMENT CURVE FOR TYPE 310S AT -269 °C. SOURCE: REF 157

## Welds

At cryogenic temperatures, welds typically exhibit higher strength and lower toughness than their base metal counterparts. The inferior toughness is associated with the presence of nonmetallic inclusions and  $\delta$ -ferrite, which undergoes a ductile-brittle transition. Under cryogenic conditions, cleavage fracture of the  $\delta$ -ferrite creates a network of microcracks ahead of a crack front. Subsequent cracking of the austenite matrix then causes an overall crack advance. Because cracks preferentially seek out the brittle  $\delta$ -ferrite, the relative amount of cleavage fracture observed on the fracture surface tends to be much greater than the percentage of  $\delta$ -ferrite present in the weld. In addition, as the volume fraction of  $\delta$ -ferrite increases, its interconnected nature provides a low-energy crack path that reduces the overall cracking resistance. For optimum toughness, weld compositions are adjusted to produce the minimum amount of  $\delta$ -ferrite that precludes

microfissuring. Accordingly, cryogenic grades of filler metal are often specially formulated to produce low ferrite levels (i.e., ferrite numbers less than 2) and low-impurity concentrations to minimize the potential for microfissuring.

Figure 42 summarizes the toughness response of welds at  $-269\text{ }^{\circ}\text{C}$ . The GTA, EB, laser, GMA, SMA, SA and FCA welding processes are represented. The wide variation in toughness is associated with differences in welding process, nonmetallic inclusion density,  $\delta$ -ferrite content, and strength. Although toughness responses for the various filler metals overlap, the limited data base indicates that  $J_c$  values for type 308 welds tend to be slightly lower than the nominal values for type 316 welds. This difference is probably related to variations in nickel content: type 308 welds contain 9 to 11 wt% Ni, whereas type 316 welds contain 11 to 14 wt% Ni. There is no systematic difference in  $J_c$  among type 316, 310S, and 330 welds, whereas experimental nitrogen-strengthened welds with high nickel, manganese, and molybdenum typically exhibit higher  $J_c$  values.

**FIG. 42 FRACTURE TOUGHNESS OF WELDS FABRICATED USING DIFFERENT PROCESSES.** GTA, GAS-TUNGSTEN ARC; EB ELECTRON BEAM; L, LASER; GMA, GAS-METAL ARC; SMA, SHIELDED-METAL ARC; SA, SUBMERGED ARC; FCA, FLUX-CORED ARC. SOURCE: REF 81, 177 (TYPE 316); REF 78, 79, 80, 81, 83, 89, AND 177 (TYPE 316L); REF 82, 154 (TYPE 316LN); REF 81 (TYPE 308); REF 73, 79, 81 (TYPE 308L); REF 169 (TYPE 310S); REF 73 (TYPE 330); REF 90, 166, 170, 178, AND 179 (FE-CR-NI-MN-N); REF 90, 170, 178, 180, AND 181, (FE-CR-NI-MN-MO-N)

The trends associated with welding process are consistent with ambient- and elevated-temperature findings. GTA and GMA welds consistently show the highest fracture resistance, while SA and FCA welds possess the lowest. Two FCA welds were found to be very brittle, with valid  $K_{Ic}$  levels of  $66$  and  $79\text{ MPa } \sqrt{m}$ , corresponding to  $J_c$  values of  $20$  and  $25\text{ kJ/m}^2$  (Ref 79). SMA welds display low to intermediate toughness values, with the lowest values (about  $40\text{ kJ/m}^2$ ) being similar to the limiting toughness for SA welds.

Laser and EB welds generally exhibit high fracture toughness values, comparable to those for GTA and GMA welds. Although the type 316 EB and laser welds show only intermediate toughness values of 120 and 100 kJ/m<sup>2</sup>, these values are matched reasonably well to the base metal toughness of 160 kJ/m<sup>2</sup> (Ref 154). Because the EB and laser welding processes remelt the base metal, use of high-toughness base metal heats is expected to increase the weld toughness.

The inferior toughness of SA welds and some SMA welds is associated with a high density of nonmetallic inclusions. These processes tend to produce significant amounts of silicon and oxygen-rich inclusions that serve as effective microvoid nucleation sites, comparable to the behavior at ambient and elevated temperatures. GTA, GMA, EB and laser welding processes produce cleaner welds with superior fracture resistance. Although GMA welds are significantly cleaner than SMA and FCA welds, oxygen pickup from argon-oxygen shield gas increases the amount of oxide inclusions (Ref 82, 83). Thus, when high-oxygen shield gases are used to fabricate GMA welds, the fracture toughness is degraded due to an increase in inclusion density. The low toughness of the FCA welds is attributed to high nitrogen contents (Ref 79). Because this process is self-shielded without an inert shielding gas, it tends to pick up nitrogen from the atmosphere, which increases strength but reduces toughness. Based on these observations, optimum cryogenic fracture resistance can be achieved by selecting: 1) weld processes that minimize inclusion contents, 2) inert shielding gases that minimize oxygen and nitrogen uptake, and 3) filler metal compositions that minimize  $\delta$ -ferrite while guarding against microfissuring.

In Fig. 43, comparison of the -269 °C toughness-to-strength behavior for type 308 and 316 welds (solid symbols) with the base metal response reveals that the weld toughness is often undermatched. At comparable strength levels,  $J_c$  values for SA welds are consistently below the lower-bound toughness for the base metal, while  $J_c$  values for SMA welds straddle the lower-bound toughness limit for the base metal. Toughness values for GMA and GTA welds are within the base metal scatter band.

FIG. 43  $J_c$  VS. YIELD STRENGTH AT -269 °C FOR WELDS. THE SCATTER BAND REPRESENTS THE RANGE OF TOUGHNESS AND STRENGTH VALUES FOR BASE METALS. SOLID SYMBOLS REPRESENT TYPES 308 AND 316; OPEN SYMBOLS AND ASTERISKS REPRESENT FE-CR-NI-MN-N AND FE-CR-NI-MN-MO-N. GTA, GAS-TUNGSTEN ARC; EB, ELECTRON BEAM; GMA, GAS-METAL ARC; SMA, SHIELDED-METAL ARC; SA, SUBMERGED ARC; FCA,

FLUX-CORED ARC. SOURCE: REF 73, 79, 81 (TYPE 308); REF 78, 79, 80, 81, 82, 83, 89, 154, 177, AND 179 (TYPE 316); REF 90, 166, 170, 178, AND 179 (FE-CR-NI-MN-N); REF 90, 170, 178, 180, AND 181 (FE-CR-NI-MN-MO-N)

The toughness of GTA, GMA, EB, and laser welds, with  $J_c$  values typically above 100 kJ/m<sup>2</sup> at -269 °C, is sufficiently high to avoid fracture concerns for most cryogenic applications. Significant plastic deformation is required to cause rapid crack extension, so conventional stress and strain design limits adequately guard against failure. The lower toughness of SA and SMA welds, with lower-bound  $J_c$  values on the order of 40 kJ/m<sup>2</sup>, demonstrates that they are more susceptible to cracking. Hence, for critical cryogenic applications involving SA and SMA welds, fracture is a design concern and fracture mechanics evaluations should be used to demonstrate adequate performance. The 308L FCA welds exhibit a brittle fracture response with valid  $K_{Ic}$  values as low as 66 MPa  $\sqrt{m}$ . Because this type of weld is susceptible to brittle fracture, linear-elastic fracture mechanics analysis should be an integral part of the design to provide protection against unstable fracture.

Microfissure-free and  $\delta$ -ferrite-free welds with high alloy contents are currently being developed to improve both strength and toughness. This includes Fe-Cr-Ni-Mn-N welds with 5 to 20 wt% Ni and 5 to 22 wt% Mn, Fe-Cr-Ni-Mo-N welds with 12 to 25 wt% Ni and 2 to 5 wt% Mo, and Fe-Cr-Ni-Mn-Mo welds with 5 to 20 wt% Ni, 4 to 14 wt% Mn, and 1 to 3 wt% Mo. Strength levels for these welds are typically controlled by nitrogen additions. The high nickel, manganese, and molybdenum contents are designed to improve strength and toughness by enhancing austenite stability, increasing stacking fault energy, and eliminating  $\delta$ -ferrite from the weld fusion zone. As shown in Fig. 43, tensile and fracture toughness data for these welds (open symbols and asterisks) show increased strength and significantly improved fracture resistance for each welding process. The increase in SA weld toughness is particularly noteworthy. It is seen that fracture properties for these developmental welds are closely matched with the base metal toughness.

### Charpy Impact Energy/Fracture Toughness Correlations at -269 °C

A significant amount of work has been performed to explore the possibility of establishing a correlation between Charpy impact energy and  $J_c$  at cryogenic temperatures, so that fracture toughness can be estimated from a simple and inexpensive Charpy test. While limited success has been made at -196 °C (Ref 73, 80, 143, and 177), there is no general correlation between  $J_c$  and Charpy impact energy at -269 °C due to adiabatic heating of the specimen during impact loading (Ref 143, 182, 183, and 184). As a result of the exceptionally low specific heats at -269 °C, adiabatic heating is unavoidable and can cause a large rise in the local temperature. In fact, the actual fracture temperature for Charpy specimens with an initial temperature of -269 °C can be above -200 °C. Thus, Charpy impact energy results for base metal and welds should not be used to estimate  $J_c$  or even infer fracture trends at -269 °C, because such data may they significantly overestimate fracture energy and incorrectly rank materials with different temperature sensitivities.

## Fatigue and Fracture Properties of Duplex Stainless Steels

R. Johansson, Avesta Sheffield AB

### Introduction

WROUGHT DUPLEX STAINLESS STEELS have been used for more than 60 years (Ref 1). Over the years much effort has been devoted to production and welding metallurgy, as well as corrosion research of the duplex stainless steels. Therefore, duplex stainless steels are today established in a wide product range. In most cases duplex stainless steels are selected because they combine high strength and excellent corrosion resistance.

Typical chemical compositions of wrought duplex stainless steels are given in Table 1 (Ref 2), where a general description of the properties of duplex stainless steels is also given. The welding metallurgy of the duplex stainless steels is reviewed in Ref 3. During production and use, many different phases can be present in the duplex stainless steels due to high levels of chromium, molybdenum, and nitrogen. An overview of the metallurgy of the duplex stainless steels has been made in Ref 4.

**TABLE 1 TYPICAL CHEMICAL COMPOSITION OF SOME WROUGHT DUPLEX STAINLESS STEELS**

UNS NUMBER W. NUMBER AFNOR NUMBER SIS NUMBER	TRADEMARKS	TYPICAL CHEMICAL COMPOSITION					PREN <sup>(A)</sup>
		Cr	Ni	Mo	N	OTHER	
<b>MO-FREE GRADES<sup>(B)</sup></b>

Source: Ref 2

- (A) PITTING RESISTANCE EQUIVALENT NUMBER,  $CR + 3.3MO + 16N$ . THE SUPERDUPLEX GRADES ARE CHARACTERIZED BY A VALUE OF  $PREN > 40$ .
- (B) THE 23CR-4NI-0.10N, MOLYBDENUM-FREE GRADE CAN BE USED TO REPLACE THE AUSTENITIC GRADES AISI 304 AND/OR 316.
- (C) THE COMPOSITION 22CR-5NI-3MO-0.17N CAN BE CONSIDERED THE STANDARD DUPLEX STAINLESS STEEL. ITS NITROGEN CONTENT HAS RECENTLY BEEN INCREASED TO FURTHER IMPROVE ITS CORROSION RESISTANCE IN OXIDIZING CHLORIDE-RICH ACID MEDIA (ESSENTIALLY AN INCREASE IN PITTING RESISTANCE). ITS CORROSION RESISTANCE LIES BETWEEN THOSE OF THE AUSTENITIC GRADE AISI 316 AND THE 4-5% MO SUPER AUSTENITIC ALLOYS (904L). THE CHEMICAL ANALYSIS OF THE GRADE CAN BE OPTIMIZED IN ORDER TO OBTAIN A PREN VALUE BETWEEN 33 AND 36.
- (D) THE SUPERDUPLEX GRADE WITH A PITTING INDEX  $PREN > 40$  (WITH OR WITHOUT COPPER AND/OR TUNGSTEN ADDITIONS) IS ESPECIALLY DESIGNED FOR MARINE, CHEMICAL, AND OIL ENGINEERING APPLICATIONS REQUIRING BOTH HIGH MECHANICAL STRENGTH AND RESISTANCE TO CORROSION IN EXTREMELY AGGRESSIVE ENVIRONMENTS (CHLORIDE-CONTAINING ACIDS, ETC.). THE CORROSION RESISTANCE IS EQUIVALENT TO THAT OF THE SUPER AUSTENITIC STEELS CONTAINING 5-6% MO.

## Fatigue and Fracture Properties of Duplex Stainless Steels

R. Johansson, Avesta Sheffield AB

---

### Fatigue Crack Initiation

Fatigue is usually initiated at inclusions, at surface scratches, or at persistent slip bands emerging at the surface. In a corrosive environment the fatigue crack initiation is also influenced by slip bands breaking the thin passive layer at the surface and by corrosion pits acting as notches on the surface.

**Crack Initiation from Local Strains.** The influence of local strains on the initiation of fatigue cracks in duplex stainless steels has been demonstrated by low-cycle fatigue tests (Ref 5, 6, 7). At low strains, below  $10^{-3}$ , the deformation in the austenitic phase controls the fatigue properties of the duplex alloy 22Cr-7Ni-2.5Mo-1.7Mn-0.07N, whereas at higher strains the deformation in the ferritic phase controls the fatigue properties. Cracks nucleate only in the austenitic phase at low strains. Because of the large reversibility of slip in the planar slip mode in the austenitic phase, good fatigue resistance of the duplex alloy is observed. Crack nucleation is delayed and takes place in the austenitic phase. At higher strains, twinning and pencil glide promote early crack initiation in the ferritic phase and thus reduce the fatigue life of the duplex alloy.

The fatigue crack initiation in duplex stainless steels can thus occur first in either the ferritic phase or the austenitic phase. In Ref 8 it is shown on polished specimens of 2205 with 0.11% nitrogen that the crack initiation starts at persistent slip bands in the ferrite. The persistent slip bands were generally more numerous in the ferritic grains. Slip markings in the austenitic grains were less intensive, and only a few cracks were initiated in the austenite.

Higher nitrogen content in duplex stainless steels improves fatigue resistance, as highlighted in Ref 9 and 10 for duplex 2205 with 0.11 and 0.18% nitrogen. Nitrogen is dissolved mostly in the austenite, thus hardening the austenite and leading to an increase in the monotonic and cyclic stress-strain response of the steel. As a consequence the fatigue strength will be increased with increased nitrogen content. In Fig. 1 there is a comparison with the results from a duplex 2205 with a nitrogen content of 0.07%, denoted AF7 (Ref 9). The steel with the lowest nitrogen content has the shortest strain life at low strains.

FIG. 1 FATIGUE STRENGTH CURVES FOR DUPLEX STAINLESS STEELS AF11 AND AF18, AND MANSON-COFFIN CURVE FOR STEEL AF07. SOURCE: REF 9

Depending on strain levels and nitrogen content, crack initiation takes place in both the ferritic and austenitic phases, or only mainly in the ferritic phase. In both tested steels (nitrogen contents of 0.11 and 0.18%) the ferritic phase is the softest, while the hardness of the austenitic phase increases with the nitrogen content. The lower strength of the ferritic phase can result in a concentration of the deformation to the ferrite. This effect can reduce the positive effect of nitrogen at low plastic strains, and the fatigue life might be reduced.

In Ref 9 it is shown that at a plastic strain  $\epsilon_t = 0.8 \times 10^{-2}$ , the slip lines and the crack initiation at the surface appear mostly in the ferritic phase. At  $\epsilon_t = 1.4 \times 10^{-2}$ , slip lines appear in the 0.11% nitrogen steel mainly in the ferritic phase, but in the 0.18% nitrogen steel only in the ferritic phase. At  $\epsilon_t = 2 \times 10^{-2}$ , the slip lines in the low-nitrogen steel are observed in both ferrite and austenite, while in the higher-nitrogen steel only a few slip lines are observed in the austenite. This behavior has been explained by the relative hardness of the two phases (Fig. 2). In both steels the ferritic phase is the softest. Depending on stress levels and nitrogen content, ferrite and austenite will to a certain extent take part in the deformation.

FIG. 2 SCHEMATIC INTERPRETATION OF THE EFFECT OF NITROGEN ON THE LOW-CYCLE FATIGUE BEHAVIOR

## OF DUPLEX STAINLESS STEEL

**Crack Initiation with Corrosion Fatigue.** Corrosion fatigue can on an electrochemical basis be categorized into four types (Ref 11):

- *CORROSION FATIGUE IN THE ACTIVE STATE:* THIS TYPE IS CHARACTERIZED BY CORROSION THROUGHOUT THE ENTIRE FATIGUE LIFE OF THE METAL. MANY CRACKS ARE FORMED, WHICH FREQUENTLY START FROM THE BOTTOM OF CORROSION PITS. THE FRACTURE SURFACE IS ROUGH AND FULL OF FISSURES, AND THE CRACKS ARE FILLED WITH CORROSION PRODUCTS.
- *CORROSION FATIGUE IN THE PASSIVE STATE:* THERE ARE NO PITS AND JUST A FEW CRACKS, WHICH MAKES THIS TYPE DIFFICULT TO DISTINGUISH FROM CONVENTIONAL FATIGUE.
- *CORROSION FATIGUE UNDER UNSTABLE PASSIVITY:* THIS TYPE OF CORROSION FATIGUE OCCURS WHEN THE METAL IS PASSIVE IN THE BEGINNING AND BECOMES ACTIVATED AFTER A CERTAIN NUMBER OF CYCLES BY PROTRUDING GLIDE STEPS OR EXTRUSIONS.
- *CORROSION FATIGUE UNDER DISTURBED PASSIVITY:* TYPICAL EXAMPLES OF THIS TYPE INCLUDE THE SUPERPOSITION OF CORROSION FATIGUE AND STRESS-CORROSION CRACKING, PITTING, OR INTERGRANULAR CORROSION.

A stainless steel, resistant to corrosion fatigue cracking, should therefore have good resistance to different forms of localized corrosion such as stress-corrosion cracking, pitting, and intergranular corrosion. Many duplex stainless steels have a high resistance to local corrosion and therefore also a high resistance to corrosion fatigue.

An investigation of the corrosion fatigue mechanisms of a 22Cr-5Ni-3Mo-0.19N duplex stainless steel (Ref 12, 13) showed that at high stress levels the crack initiation occurred mainly at persistent slip bands in the austenite or near the phase boundaries. At lower stress levels, the cracks initiated mainly at nonmetallic inclusions in the surface region. The fatigue limit in air was 240 MPa (34 ksi). When tested in concentrated chloride solutions at 80 °C (175 °F), the fatigue limit was decreased only to 200 MPa (29 ksi). Under these stable, passive corrosion conditions the duplex steel had a pronounced fatigue limit. When the temperature was raised to 150 °C the corrosion fatigue strength was reduced significantly due to superposition of pitting corrosion.

The corrosion fatigue properties of the duplex alloy in a 3.5% NaCl solution also depends on whether the strain is localized to the austenitic phase or to the ferritic phase (Ref 7). At low stresses the austenitic phase is cathodically protected by the undeformed ferritic phase, and the risk of corrosion fatigue damage is reduced. At higher strains under a free corrosion potential, the anodic dissolution is localized at twins and at ferrite grain boundaries, causing a premature fatigue failure. If a cathodic potential is imposed on the specimen, the heterogeneous deformation in the ferritic phase will promote hydrogen entry, causing hydrogen embrittlement and consequently reducing the fatigue life even more. The presence of strain concentrations encountered as an effect of reversed strains is one reason why corrosion fatigue behavior sometimes differs from the stress-corrosion cracking behavior.

The corrosion fatigue crack initiation and propagation of a duplex stainless steel under different potentials was compared to that of an austenitic steel and a ferritic steel (Ref 14). The crack initiation was tested with a smooth specimen under rotating bending stresses, and the crack propagation tests were performed on standard precracked compact tension specimens. Tests in air were compared to tests in an aerated 3% solution of NaCl at pH = 6. In air, the fatigue limit for the duplex 21Cr-7Ni-2.5Mo steel was higher than that for the austenitic type 316 steel and the ferritic 26Cr-1Mo steel tested. When tested in sodium chloride, the fatigue limit for the ferritic steel was higher than that of the other two steels because of the higher chromium content of the ferritic steel, giving either a tough passive film or at least a passive film that would recover its passivity very rapidly if damaged.

During the corrosion fatigue test, the variation in either specimen potential was measured (Ref 14). The free potential for the duplex steel depended on the stress state. In one test it started at -100 mV, then rose to +100 mV before failure, a mixed potential as a result of the anodic and cathodic processes taking place during the test. The potential decreased more

rapidly at higher stresses due to either the increase of the rate of anodic dissolution or the increase of anodic areas. The current potential curve for the duplex steel shows that the metal is passive below +100 mV and that pits are not repassivated above +100 mV. Corrosion fatigue tests under rotating bending stress and different imposed potentials in sodium chloride (Fig. 3) showed that the fatigue limit was drastically reduced when the imposed potential was +200 mV (Ref 14). Another result from the test is also shown in Fig. 3, where the fatigue limit at a potential of 0 mV is higher than at a free potential.

FIG. 3 ROTATING BENDING FATIGUE STRENGTH OF DUPLEX STAINLESS STEEL IN SALT SOLUTION

In a corrosion fatigue study for three different stainless steels (Ref 15), the time to initiation of the fatigue crack was longer for the duplex steel (22Cr-5Ni-3Mo-0.14N) than for a ferritic or an austenitic stainless steel. The test was performed in an aqueous sulfuric acid (0.05M or 2M) at 30 °C (86 °F) in the passive range under potentiostatically controlled potential. The main reasons for the longer time to crack initiation in the duplex steel were the thicker passive layer and the higher Cr-Fe relation in the passive layer as compared to the other steels tested.

**Suggested Models of Corrosion Fatigue.** A survey of suggested mechanisms for corrosion fatigue initiation and propagation for steels in general is made by Austen in Ref 16. These suggested mechanisms have in some cases led to the formulation of models for corrosion fatigue and computer programs for life prediction. However, the complete modeling of corrosion fatigue, all the way from initiation through notches and short cracks to the crack propagation of long cracks, still remains to be done.

One model for crack initiation (Ref 17, 18) is based on the film rupture mechanism (e.g., Ref 19, 20). The model assumes slip step dissolution and repassivation, and it incorporates mechanical and electrochemical factors. The model does not include general active dissolution, except at slip steps that break through the passive film. Pitting is also neglected. Included in the model are the current decay curve, the bare metal corrosion rate, and the critical slip step height. One example is shown where the calculated fatigue curves are in good agreement with experimental *S-N* data for an austenitic stainless steel. Duplex stainless steels have so far not been included in the experiments.

An attempt has been made, however (Ref 18) to express the critical penetration depth at the surface in terms of fracture mechanics, which could be used when looking at fatigue mechanisms for duplex steels. The fatigue crack growth

threshold of small cracks is described by using the  $K$  concept. A relation is obtained between the critical penetration depth, the critical crack depth, the applied stress, and the fatigue limit of the steel.

## Fatigue and Fracture Properties of Duplex Stainless Steels

R. Johansson, Avesta Sheffield AB

---

## Fatigue Crack Growth

Fatigue crack growth is in most investigations measured on compact tension specimens or three-point bend specimens according to a standard such as the ASTM standard. One early investigation in Ref 21 showed that at high stress-intensity factors (and at  $R = 0.1$ ), the crack propagation rate in a 3% NaCl solution is higher than in air. When the testing frequency was decreased from 20 to 0.5 Hz, the fatigue crack propagation rate increased further (Fig. 4). A similar result was found for a ferritic steel, while an austenitic steel was not influenced. The ferritic and the duplex steels have an extremely passive film. When this film is destroyed by a fatigue crack, an acceleration of the metal dissolution rate is observed, which leads to an increase in the rate of fatigue crack propagation. The austenitic steel, however, has a lower passivity, which facilitates the initiation of a corrosion fatigue crack, particularly at corrosion pits. Once a crack has initiated, the repassivation of the metal or a low dissolution rate leads to propagation rates close to the rates obtained in air.

**FIG. 4 CRACK GROWTH RATES OF AFNOR Z3 CNDU 21-7. SOURCE: REF 21**

The corrosion fatigue crack growth rate was measured in Ref 22 on 25Cr-6Ni-2.4Mo duplex stainless steel at a frequency of 0.17 Hz ( $R = 0.1$ ), with the specimens protected by a cathodic potential in synthetic sea water. The propagation rates in the test with the cathodic polarization were much higher than those in the test with natural corrosion potential, because hydrogen embrittlement accelerates the propagation.

In a test program with several participating organizations (Ref 23), duplex stainless steels were tested in air and in ASTM synthetic sea water. The crack propagation rate for cast and forged materials from a 25Cr-6Ni-3Mo alloy in synthetic sea water ( $R = 0.6$ , frequency 10 Hz) were almost identical at  $10^{-5}$  mm/cycle with  $K = 10 MPa\sqrt{m}$ . However, the fatigue limit under rotating bending stresses in 25 °C synthetic sea water at 30 Hz and  $10^7$  cycles was 350 MPa (50 ksi) for the forged specimens and roughly 200 MPa (29 ksi) for the cast specimens.

The fatigue crack growth of a duplex stainless steel is affected by the deformation status and the presence of brittle and hard phases. In Ref 24 it is shown that the fatigue crack growth threshold,  $\Delta K_{th}$ , increases after 50% cold rolling and even more after 50% cold rolling followed by an annealing at 475 °C (885 °F) for 120 h. The fatigue crack growth,  $da/dN$ , as a function of the stress-intensity amplitude  $\Delta K$  is shown in Fig. 5. The annealing produces a hardening through spinodal decomposition of the ferrite, thus increasing the threshold value.

FIG. 5  $DA/DN$  VS.  $\Delta K$  FOR THE DIFFERENT CONDITIONS TESTED. (A) HOT-ROLLED, AS-RECEIVED. (B) COLD-ROLLED (50%). (C) COLD-ROLLED (50%) AND ANNEALED (120 H, 475 °C). SOURCE: REF 24

One further way of demonstrating the crack propagation rate in duplex stainless steels is to compare the behavior of the duplex alloy with its tie-line single-phase ferritic and austenitic alloys, as has been done in Ref 25. The materials tested were laboratory melts of the duplex alloy 2205 and its tie-line single-phase alloys. The material was tested in its hot-rolled/quenched-and-annealed condition and after a tensile deformation of 8%. Fatigue crack growth data are shown in Fig. 6 and in Table 2. During fatigue crack growth testing the crack is closed during a part of the loading cycle, causing the effective  $\Delta K$  to be less than the nominal  $\Delta K$ . The crack closure,  $K_{cl}$ , can be induced by the crack surface roughness, oxides, or plasticity. In Table 2,  $\Delta K_{th} = \Delta K_{th,eff} + K_{cl}$ .  $\bar{H}$  is a surface roughness parameter measured using quantitative fractography (Ref 26). From Fig. 6 and Table 2, it is evident that the threshold values are decreased after the tensile prestraining. The crack closure values are decreased for the single-phase alloys but not for the duplex alloy. The fracture surface roughness of the ferritic and duplex alloys is not affected by the prestraining. However, there is a smoother fatigue crack surface in the austenitic alloy after prestraining. This means that there is no simple relation between the surface roughness and the crack closure level for any of the alloys in this investigation.

TABLE 2 FATIGUE CRACK GROWTH DATA ( $R = 0$ )

GRADE AND COMPOSITION	$\epsilon$	$\Delta K_{TH}$ , MPA $\sqrt{m}$	$\Delta K_{TH,EFF}$ , MPA $\sqrt{m}$	$K_{CL}$ , MPA $\sqrt{m}$	$\bar{H}$ , M
DUPLEX (0.018C, 2.21CR, 5.8NI, 3.0MO, 0.17N)	0	4.6	3.3	1.3	2.6

FIG. 6  $DA/DN$  VS.  $\Delta K$  FOR DUPLEX, FERRITIC, AND AUSTENITIC STEELS IN UNDEFORMED AND PRESTRAINED CONDITIONS. AVERAGE CURVES FOR EACH STATE. SOURCE: REF 25

The crack growth rate of duplex alloy 2205 at room temperature in air and in a 3% NaCl solution is shown in Fig. 7 from Ref 27. In 3% NaCl the crack growth rate was about a factor of 2 greater than the crack growth in air. When the testing temperature for the NaCl test was increased to 80 °C (175 °F), no influence on the crack propagation rate was experienced (Ref 28). The same was true for the superduplex steel SAF 2507 (Ref 28). It was shown that the threshold value for SAF 2507 was higher than for the 2205 duplex steel and several austenitic and super austenitic steels. However, when air-cooled material of SAF 2507 was compared to quenched material, the threshold value for the air-cooled material was as low as for the other steels tested (Fig. 8). This behavior was claimed to depend on differences in residual stresses.

FIG. 7 CRACK GROWTH RATE FOR 2205 IN AIR, 3% NaCl, AND 3% NaCl WITH 1 PPM CHLORINE. FREQUENCY 0.8 HZ IN AIR AND 0.2 HZ IN THE AQUEOUS ENVIRONMENTS,  $R = 0.5$ . RESULTS WITH CHLORINE ADDITIONS ARE FROM SINGLE TESTS ONLY. SOURCE: REF 27

**FIG. 8 FATIGUE CRACK PROPAGATION RESULTS AT 0.8 HZ IN AIR WITH  $R = 0.5$ , FOR SAF 2507 IN QUENCHED AND AIR-COOLED CONDITIONS. SOURCE: REF 28**

Another superduplex stainless steel, Zeron 100, was embrittled in fatigue by gaseous hydrogen and water (Ref 29). The ferrite matrix failed by cyclic cleavage, while the austenite phase remained unaffected. The embrittled zone size was controlled by the rate of entry of hydrogen to the crack tip. The fatigue crack propagation rate was increased by a factor of 8 in hydrogen as compared to that in air (Fig. 9). All duplex steels were embrittled after annealing in the temperature range of 400 to 500 °C (750 to 930 °F), as was the superduplex steel investigated in Ref 30. After aging for 1000 h at 400 °C (750 °F), the superduplex steel underwent a fatigue crack propagation test at temperatures between 30 and 305 °C (86 and 580 °F). Figure 10 shows that there is an influence of temperature and specimen orientation on the fatigue crack growth: the higher the testing temperature, the higher the crack propagation rate. Fatigue crack propagation in the aged superduplex steel was increased by initiation of cleavage cracks in the ferrite matrix. Further tests on thermally aged Zeron 100 (Ref 31) show that the embrittlement is caused by cleavage in the age-hardened ferrite. A model put forward suggests a strong influence of the ferrite volume fraction and predicts that heat-affected zones with large grain sizes are sensitive to enhanced fatigue crack propagation rates.

**FIG. 9 FATIGUE CRACK GROWTH RATES OF A SUPERDUPLEX STAINLESS STEEL (ZERON 100) IN AIR, ARGON, AND HYDROGEN**

**FIG. 10 EFFECT OF TEMPERATURE AND AGING ON FATIGUE CRACK GROWTH OF A SUPERDUPLEX STAINLESS STEEL (ZERON 100). ORIENTATION B IS CRACK GROWTH IN THE TRANSVERSE DIRECTION, AND ORIENTATION C IS CRACKING IN THE ROLLING DIRECTION. SOURCE: REF 30**

Fatigue crack propagation rates for different aging times and testing temperatures at different  $R$ -values are shown in Fig. 11. The fatigue crack growth rate in Zeron 100 in air varied with crack orientation in wrought structures, as expected (Ref 32). The fracture surface roughness showed little variation and was only somewhat affected by the specimen orientation. The only parameter that varied with crack orientation and crack growth was the number of austenite-ferrite grain boundaries crossed during crack propagation.

## Fatigue and Fracture Properties of Duplex Stainless Steels

R. Johansson, Avesta Sheffield AB

---

### Fatigue Strength

Fatigue strength data useful for designing in duplex stainless steels are available in the literature to some extent. The data shown in the literature are mainly from tests performed in air at room temperature and in NaCl solutions, but some data are related to tests in other specific environments. The literature shows that the fatigue limit in air for the duplex stainless steels is very high and almost equal to the yield strength. In corrosive environments, the fatigue strength for the duplex steels is reduced but remains high. Fatigue tests also show that welded components of duplex stainless steels can withstand high levels of fatigue stresses. The data given in the literature are described as the fatigue limit or the fatigue strength at a specified number of cycles to failure. Nothing is said about confidence levels, but as a first approximation the data could be interpreted as the mean fatigue strength or the mean fatigue limit with a 50% probability of fracture at a low confidence level.

**Fatigue Data for Rotating Bending Stresses.** Duplex stainless steels usually have higher yield stress and tensile strength than the standard austenitic stainless steels. In Ref 33 and 34, duplex stainless steel of grade 2205 (22Cr-5Ni-3Mo-N) with tensile strength of 720 to 740 MPa and plate thickness 15 mm was tested in a rotating bending fatigue machine at 11, 100, and 200 Hz and was compared with austenitic stainless steels. The testing temperature was 40 °C (105 °F).

The testing frequency had no influence on the fatigue level, but the influence of the environment was significant, as shown in Table 3. The fatigue strength for 2205 was higher than the fatigue strength for the austenitic stainless steels. At pH = 1, the austenitic steel without molybdenum (304LN) had the lowest fatigue strength, 40 MPa. This steel is in its active state in this environment, whereas the duplex steel is in its passive state. There were no signs of pitting corrosion on any steel after the different fatigue tests performed. The testing stresses were in all tests lower than the stresses giving stress-corrosion cracking in the same environment. Tests performed on welded specimens showed that the fatigue strength for the duplex steel was higher than in the austenitic steels investigated, one example being a fatigue strength of 150 to 210 MPa for the duplex steel in 3% NaCl with pH = 1.

(A) GERMAN INDUSTRIAL STANDARD

An extensive study of over 40 types of stainless steels was performed in a rotating bend testing machine (Ref 35). One duplex type 329 steel and one duplex type 2205 steel with a yield stress of about 500 MPa reached a fatigue limit at  $10^8$  cycles (70 Hz) of 490 to 500 MPa in air and 400 MPa in 3% NaCl at room temperature. The main conclusion of the investigation was that materials that have both high yield strength and a good corrosion resistance also have the highest fatigue strength.

**Wrought and Cast Comparison (Ref 36).** In a test program with several participating organizations, duplex stainless steels were tested in air and in ASTM synthetic sea water (Ref 36). The fatigue limit under rotating bending stresses in 25 °C synthetic sea water at 30 Hz and  $10^7$  cycles was 350 MPa for the forged specimens and roughly 200 MPa for the cast specimens.

**Transverse and Longitudinal Specimens in Sulfuric Acid (Ref 37).** Rotating bending fatigue of 2205 was investigated under various conditions. At a testing frequency of 50 Hz, the fatigue limit at  $10^7$  cycles was ±350 MPa for longitudinal specimens and ±325 MPa for transverse specimens when tested in air. Specimens with a stress concentration factor of  $\alpha_k = 4.9$  showed a reduced fatigue limit of 170 MPa (24.5 ksi) for longitudinal specimens and 145 MPa (21 ksi) for transverse specimens. Testing in 2M sulfuric acid lowered the fatigue strength to 100 MPa (14.5 ksi) or lower at  $10^7$  cycles. The lower values were found for transverse specimens and for the lower testing frequency of 6.5 Hz, as compared to 50 Hz in the main testing program. Stress concentrations can further reduce the fatigue strength to 50 MPa (7.25 ksi).

**Fatigue Strength in Water (Ref 38).** Fatigue testing was performed in different corrosive environments. The tested material (transverse specimens) were cut out of hot-rolled plates, 15 to 85 mm thick. A four-point rotating bending machine was used at a testing frequency of 25 Hz. The environments examined were distilled water, synthetic sea water (DIN 50905:4), and synthetic white water (pH = 3.5, Cl<sup>-</sup> = 400 ppm,  $\text{SO}_4^{2-}$  = 250 ppm). The fatigue strength for 3RE60 at  $10^7$  cycles decreased with increased severity of the environment, from 320 to 265 MPa.

**Reversed Bending Fatigue.** Fatigue strength under reversed bending stresses in air or in 3% NaCl is summarized in Table 4 from three sources. In a low-frequency test (0.5 Hz) in a 3% NaCl solution the fatigue behavior of DP 3 (25Cr-6Ni-3Mo-0.3W) was investigated (Ref 39). The fatigue limit in reversed bending at  $10^7$  cycles was not decreased in the solution as compared to the result in air. This fatigue limit was ±340 MPa (±49 ksi) for specimens with a yield stress of 610 MPa (88.5 ksi). In the low-cycle range, however, the duplex steel showed a shorter fatigue life in salt water than in air. This behavior could be related to the finding that the crack propagation rate in salt water is larger than that in air. In the tested environment the fatigue limit for stainless steels is increased with increased tensile strength, in contrast to the behavior of carbon and low-alloy steels.

**TABLE 4 FATIGUE STRENGTH UNDER REVERSED BENDING STRESSES**

GRADE	ENVIRONMENT	YIELD STRENGTH, MPA	ULTIMATE TENSILE STRENGTH, MPA	FATIGUE STRENGTH, MPA	REF
-------	-------------	---------------------	--------------------------------	-----------------------	-----

DP3	3% NaCl	610	815	±340	39
2304	AIR	460	695	±445	40
2304	3% NaCl	460	695	±360	40
<b>18-4-3-3</b>	<b>AIR</b>	<b>548</b>	<b>821</b>	<b>±410</b>	<b>41</b>

The duplex stainless steel SAF 2304 (23Cr-4Ni-N) was fatigue tested under reversed bending stresses (Ref 40). In air the fatigue strength at  $2 \times 10^6$  cycles and 20 Hz was  $\pm 445$  MPa (64.5 ksi) for specimens with a yield strength of 460 MPa (66.7 ksi). The fatigue strength was decreased to  $\pm 360$  MPa (52 ksi) when the test was performed in 3% NaCl.

A new high-strength duplex stainless steel intended for railway cars (Ref 41) is 18Cr-4Ni-3Si-3Mn-1Cu with a yield strength above 500 MPa (72.5 ksi) and a fatigue limit in bending fatigue of  $\pm 410$  MPa (59 ksi) at  $10^7$  cycles in air. The fatigue limit for gas metal arc weldments is reduced to  $\pm 375$  MPa (54 ksi).

Fatigue strength under pulsating tensile stresses in air or in 3% NaCl solution is summarized in Table 5 (Ref 42, 43, 44, 45, 46, 47, 48, and 49). An investigation of the corrosion fatigue mechanisms of a 22Cr-5Ni-3Mo duplex stainless steel showed that at high stress levels the crack initiation occurred mainly at persistent slip bands in the austenite or near the phase boundaries (Ref 42, 43). At lower stress levels, the cracks initiated mainly at nonmetallic inclusions in the surface region. The fatigue limit in air was 240 MPa (mean stress 250 MPa,  $2 \times 10^7$  cycles, 50 Hz) (Table 5). When testing was done in concentrated chloride solutions at 80 °C (175 °F), the fatigue limit was decreased only to 200 MPa (29 ksi). Under these stable passive corrosion conditions the duplex steel had a pronounced fatigue limit (Fig. 12). When the temperature was raised to 150 °C (300 °F), the corrosion fatigue strength was reduced significantly (to 70 MPa, or 10 ksi) due to superposition of pitting corrosion.

**TABLE 5 FATIGUE STRENGTH UNDER PULSATING TENSILE STRESSES**

FIG. 12 AIR AND CORROSION FATIGUE BEHAVIOR OF DUPLEX STAINLESS STEEL 22CR-5NI-3MO. 250 MPA MEAN STRESS AT 50 HZ. SOURCE: REF 43

Duplex stainless steel 26Cr-3.5Ni-5.6Mn-2.2Mo-0.3N was tested in air in a neutral chloride solution (pH = 7) and in an acid solution (pH = 2) (Ref 44). The fatigue strength at 80 °C (60 Hz,  $10^8$  cycles,  $R = 0$ ) in the neutral chloride solution is 250 MPa (36 ksi), which is not much lower than in air. However, there is a significant decrease when the pH is lowered to 2 (see Table 5 and Fig. 13). Experiments on stress corrosion in the same media did not show any tendency to stress-corrosion cracking. In a pitting test, however, there was an increase in corrosion current of one order of magnitude when the pH decreased from values between 9 and 4 down to a value of 2. The decrease in fatigue strength with increased acidity was attributed to a decreased stability of the passive film and not to an increased tendency to pitting.

FIG. 13 NUMBER OF CYCLES TO CRACK INITIATION FOR X4 CRMNIMON2664 IN NAACL SOLUTION, PH 7 AND PH 2. SOURCE: REF 44

**Alloys 2205, SAF 2507, and 3RE60.** The fatigue strength of other duplex stainless steels (Ref 45) was tested in air and in a 3% NaCl solution at 45, 80, and 90 °C (110, 175, and 195 °F). The pulsating tensile fatigue strength at  $2 \times 10^6$  cycles for grade 2205 was 487 MPa (70 ksi) (max at  $R = 0.1$ ) in air at 20 °C, 444 MPa (64.4 ksi) in the NaCl solution at 45 °C, and 422 MPa (61 ksi) in the NaCl solution at 80 °C. The test frequency in air was 20 Hz and in the NaCl solution 5 Hz. The decrease in fatigue strength with increasing temperature could be explained by the same decrease in the yield strength. The initiation of fatigue cracks occurred mainly at surface scratches. Only in a few specimens fractured at 80 °C did the initiation of fatigue cracks start at corrosion pits, despite the fact that the fatigue test was performed at a temperature well above the critical pitting temperature.

In the same project some tests were also performed on SAF 2507 (25Cr-7Ni-4Mo-N) in air at 20 °C (68 °F) and in a 3% NaCl solution at 80 and 90 °C (175 and 195 °F). The pulsating fatigue strength in air was 535 MPa (77.5 ksi) and 490 MPa (71 ksi) in the NaCl solution at 80 °C. This decrease could also be referred to the decrease in yield strength with increasing temperature, and there was no evidence of corrosion pits in the specimens after the fatigue test.

Table 5 also lists data from fatigue testing in air at 20 Hz for 3RE60, 2205, and 2507 (Ref 38, 46). Fatigue strength at  $2 \times 10^6$  cycles was 518 MPa (75 ksi) for 3RE60, 470-500 MPa (68-72.5 ksi) for 2205, and 551 MPa (80 ksi) for 2507.

The fatigue limit in air for alloy 2205 under cyclic tensile load at 25 Hz and  $10^7$  cycles was 490 MPa, and it was 380 MPa in 3% NaCl. Different stress concentration factors lowered these figures, for example from 490 to 285 MPa (71 to 41 ksi) in air for a stress concentration factor of 3.9, and from 380 to 240 MPa (55 to 35 ksi) for the same stress concentration factor in 3% NaCl. Values of the fatigue strength under tension-compression loads were also given,  $\pm 175$  MPa (25 ksi) in air at  $10^7$  cycles for smooth specimens (Ref 47, 48).

**The duplex stainless steel DP 9 (23Cr-11Ni-3.3Si)** was tested in air and in boiling 3N HNO<sub>3</sub> (Ref 49). The axial fatigue strength was 180 MPa (26 ksi) in air (max amplitude) and 80 MPa (11.6 ksi) in the boiling acid (104 °C) at  $10^6$  cycles. The crack propagation rate was somewhat higher in the boiling acid than in air.

**Influence of Cold Work.** The effect of cold working on the fatigue properties of the duplex steel A905 (26Cr-6Mn-4Ni-2.5Mo-0.15N) has been investigated (Ref 50). In a pulsating tensile test at 10 Hz in air, the fatigue limit at  $5 \times 10^7$  cycles increased from 520 to 750 MPa (75 to 109 ksi) after 8% cold work (specimens from cold-drawn rods), whereas in 4N NaCl at 80 °C and pH = 5, the corrosion fatigue strength increased from 500 to 700 MPa (72.5 to 101.5 ksi) after 8% cold work. The tensile strength increased from 890 to 1000 MPa (129 to 145 ksi) due to the 8% cold work.

**Environmental Effects and Influence of Testing Frequency.** Tests performed in air and in NaCl in the laboratory are today more or less standard, while tests performed in real process environments are more rare. Rotating bending fatigue tests were performed at 50 Hz in geothermal steam from different geothermal fields (Ref 51). For notched specimens of alloy 2205 the fatigue limit in air was  $\pm 250$  MPa (36 ksi) at  $5 \times 10^6$  cycles. The fatigue strength was reduced to 200 MPa (29 ksi) in one geothermal environment and to 120 MPa (17 ksi) in another environment. The differences in fatigue strength were related to different contents of hydrogen and chlorides. Alloy 2205 was more influenced by the geothermal environments than the austenitic 316 steel.

In the literature cited above on fatigue data, some authors have claimed that there is no influence of the testing frequency on the fatigue limit. This can of course be true for tests performed in rather mild environments and tests that last for shorter time periods. Depending on the type of environment, and whether the steel is in its passive or active corrosion state, there will be an influence of the testing frequency. One example (Ref 38, 52) is duplex steels tested under rotating bending stresses in synthetic white water at test frequencies of 25 and 5 Hz. The reduction in testing frequency decreases the fatigue strength at  $10^7$  cycles from  $\pm 250$  to  $\pm 210$  MPa ( $\pm 36$  to  $\pm 30$  ksi) due to the longer exposure times in the corrosion solution (Fig. 14).

**FIG. 14 FATIGUE TESTING OF 2205 SRG PLUS IN SYNTHETIC WHITE WATER AT 5 AND 25 HZ, 50% PROBABILITY OF FRACTURE**

**Welds and Weldment Geometries.** Usually, when welds are tested, the test specimens are cut out transversal to a weld, and the specimens are then machined and polished before the testing. If the welding has been performed according to the state of the art, there should not be any decrease in fatigue strength for the weld as compared to that of the base material. For example, in Ref 52 the base material of 2205 has roughly the same fatigue strength at  $10^7$  cycles as the submerged arc weld and the electroslag weld.

Fatigue tests carried out in air on joints of a duplex steel (23Cr-4Ni) in the as-welded condition examined joint geometries of butt welds and plates with longitudinal fillet-welded gussets on both sides (Ref 53). Fatigue test results were compared with International Institute of Welding design recommendations and results from the literature. The fatigue strengths of the joint geometries analyzed were as good as those of identical joints in structural steel. The very limited data for duplex stainless steel welded joints indicate fatigue performance comparable to that of C-Mn steel joints (Ref 54). Therefore, the current design *S-N* curves for C-Mn steels may be used for duplex joints.

## Fatigue and Fracture Properties of Duplex Stainless Steels

R. Johansson, Avesta Sheffield AB

---

### Fracture Toughness

The fracture toughness of duplex stainless steels has been evaluated through impact testing and fracture mechanic testing methods such as crack-tip opening displacement (CTOD),  $K_{Ic}$ , and  $J_{Ic}$ . The fracture toughness as measured by the standard testing methods for  $K_{Ic}$  and  $J_{Ic}$  often give very high values, but the requirement for plane strain is not fulfilled. Nevertheless, it is often claimed that the figures given could be interpreted as representative for the plate thickness that has been tested.

**Fracture Modes.** In the solution-annealed condition, fracture surfaces of duplex stainless steels have a ductile appearance with dimples (Ref 55). After aging alloy 2205 at 800 °C (1470 °F), the fracture surface contains numerous delaminations and microvoids, where the latter are much smaller than in the solution-annealed specimens (Ref 55). Aging alloy 2205 at 475 °C for 100 h will lead to unstable crack propagation and a fracture surface of quasicleavage type (Ref 56). Depending on the specimen orientation in a fracture toughness test, crack growth behavior can be evaluated along the rolling direction or perpendicular to it. Parallel to the rolling direction, voids nucleate preferentially in the ferrite phase or at ferrite-austenite phase boundaries (Ref 57). The crack growth perpendicular to the rolling direction takes place across ferrite and austenite grains with some cracking branching at the crack tip (Ref 57).

**Base Material in the Solution-Annealed Condition.** For solution-annealed materials,  $J_{Ic}$  values range from 200 to 800 kJ/m<sup>2</sup> (Ref 55, 56, 57, 58, 59, and 60). In Ref 55, for example,  $J_{Ic}$  values of 0.4 to 0.5 MJ/m<sup>2</sup> for single-edge notched bending (SENB) specimens and 0.7 MJ/m<sup>2</sup> for single-edged notched tension (SENT) specimens have been obtained. The duplex steel (solution-annealed 10 mm plate, 18Cr-5Ni-2.7Mo) was tested according to ASTM E 813. The initial value was low in comparison with the resistance to subsequent crack propagation. Other tests on solution-annealed 2205 (Ref 59) show  $J_{Ic} = 300$  kJ/m<sup>2</sup>.

In the solution-annealed condition, the standard duplex steels have a very high toughness as tested at room temperature. The duplex steels are rather insensitive to variations in solution annealing temperature. In one study, solution annealing at 1050, 1175, or 1300 °C for 1 h respectively and subsequent water quenching did not affect the crack resistance properties of the steel when it was tested at room temperature (Ref 55). The minor change in the relative amounts of ferrite and austenite phases did not in this case have any greater impact on the fracture toughness. However, when the relation

between the two phases is varied over a wider range (0 to 100% of ferrite), there is a marked influence on the elongation values and on the impact toughness. In Ref 61, the alloy with the highest ferrite content had the lowest values. The microstructure in the duplex stainless steels is usually elongated in the rolling direction. This of course has an influence on the fracture toughness, which is higher for test specimens with a crack extension transverse to the rolling direction (Ref 60).

**Influence of Brittle Phases and Precipitations.** The toughness behavior of duplex stainless steels can be summarized in time-temperature embrittlement diagrams of the type shown in Fig. 15 (Ref 62). There is a marked decrease in ductility for many of the duplex steels in the interval between 600 and 900 °C (1110 and 1650 °F) and also at 475 °C (885 °F) or in the range of 450 to 500 °C (840 to 930 °F). Cold-rolled duplex steels will get an even lower impact toughness after aging at 475 °C (Ref 63). When using the duplex steels in applications exposed to elevated temperatures during longer periods, the behavior at temperatures as low as 300 °C (570 °F) must be examined.

**FIG. 15 TIME-TEMPERATURE EMBRITTLEMENT CURVES FOR SOME DUPLEX STAINLESS STEELS. THE CURVES REPRESENT THE 27 J TRANSITION AT ROOM TEMPERATURE FOR STANDARD CHARPY V-NOTCH SPECIMENS. SOURCE: REF 62**

An example of aging treatment and resulting impact toughness is shown in Fig. 16 (Ref 62) for the standard duplex steel 2205. At longer times at 325 °C (615 °F), the impact toughness will decrease, thus limiting the application temperature to 300 °C. The maximum temperature for long-term use of superduplex grades is limited to 280 °C (535 °F) while molybdenum-free duplex grades may be considered for applications up to 325 °C (615 °F) (Ref 64). A summary of all the embrittling phases and precipitations found in duplex and superduplex steels are given in Ref 65 and 66.

**FIG. 16 CHARPY V-NOTCH IMPACT CURVES FOR QUENCH-ANNEALED SAF 2205 AGED AT 325 °C. SOURCE: REF 62**

Fracture toughness data for duplex steels decrease after different heat treatments in the temperature range between 475 and 1200 °C (885 and 2190 °F), the decrease being most pronounced after heating in the interval 475 to 900 °C (885 to 1650 °F) (Ref 67). The decrease at 675 to 900 °C follows 2 h of heat treatment, while at 475 °C the decrease in toughness is slower and reaches the lower values after 24 h of heat treatment. The  $J_{Ic}$  value is decreased from 500 to below 100 kJ/m<sup>2</sup> after only 1 h of heat treatment at 800 °C (Ref 55). Aging of the duplex steel 2205 at 475 °C for 100 h decreased the  $J$ -value from 800 to 200 kJ/m<sup>2</sup> (Ref 56).

Samples of 2205 were sensitized for 2 and 24 h at 675 and 825 °C (Ref 68). Regeneration treatment for 0.5 to 6 h at 1050 °C almost recovered the toughness properties as measured by CTOD, while the stress-corrosion properties were fully recovered only for specimens which were sensitized for the shorter period (2 h).

The fracture toughness is also influenced to some extent by the volume fraction of inclusions and precipitations and the distances between them (Ref 56, 69).

**Welds.** The precipitation of brittle phases influences the ductility of welds. Short-time aging to simulate heat-affected zones has been carried out on grade 2205 (Ref 58, 59). Aging times of 15 min at 875 °C are long enough to have an embrittlement effect, given as a  $J_{Ic}$  value. However, the embrittlement effect after 1 h at 475 °C seems to be rather limited.

The influence of 60 to 85% ferrite on welds in duplex steel 2205 was measured (Ref 70). An increase in ferrite content decreased the fracture toughness values, measured as CTOD.

Weld metals for grade 2205 typically contain 9% Ni. Embrittlement occurs more rapidly in the weld metal than in the base metal. The impact toughness will decrease below the acceptance value of 27 J after 3 to 4 min at 850 to 950 °C (Ref 71).

The heat-affected zone in the superduplex steel UNS 32760 has been simulated (Ref 72, 73). Charpy V-notch values remained at a high level except in tests with very long cooling times. The superduplex steel UNS 32750 was submerged arc welded with different heat inputs and then impact tested (Ref 74). The impact toughness values were acceptable if the heat input was maximized to 2.5 kJ/mm and if the interpass temperature was maximized to 150 °C (300 °F).

## Fatigue and Fracture Properties of Duplex Stainless Steels

R. Johansson, Avesta Sheffield AB

---

## Stress-Corrosion Cracking

Duplex stainless steels are used in environments that may produce anodic or cathodic stress-corrosion cracking (SCC). The behavior of duplex stainless steels under SCC conditions is summarized in Ref 75. As in the case of austenitic stainless steels, the duplex stainless steels have a high protection potential in concentrated chloride solutions.  $\gamma$ -phase formation lowers the resistance against anodic SCC. Welding may also impair the SCC resistance when the cooling rate between 1200 and 800 °C (2190 and 1470 °F) is too high. Builtup weld seams or repair welds may be susceptible to SCC because of the high cooling rate involved that suppresses the reformation of austenite from high-temperature  $\delta$ -ferrite.

The SCC mechanism is closely coupled to mechanical and electrochemical phenomena. In the ferrite, depassivation is essentially determined by mechanical twinning, whereas slip on the ferrite surfaces is insufficient to cause localized depassivation. At lower stress levels, the SCC of the duplex steels seems to be determined by local depassivation of the austenite, while at higher stresses the twinning in the ferrite is responsible for the cracking. At lower stresses the ferrite may in some duplex steels be less deformed than the austenite and may cathodically protect the plastically deformed austenite. At higher stresses, when twinning occurs in the ferrite, the ferrite will depassivate and localized corrosion and cracking will take place.

Stress-corrosion cracking of duplex stainless steels occurs in concentrated chloride solutions such as boiling magnesium chloride, as well as in sour gas environments that contain chloride and hydrogen sulfide (Ref 76). Threshold stresses for SCC of duplex stainless steels in chlorides are generally higher than those of austenitic stainless steels (Fig. 17), although this does depend in part on the test methods used in evaluation (see the next section, "Evaluating SCC Test Data." ). There are also significant variations in chloride SCC resistance among the different commercial grades (Fig. 18) (Ref 77). The data of Fig. 18 suggest that increasing the total chromium, nickel, molybdenum, and nitrogen contents results in increased chloride SCC resistance. These data do not differentiate between effects due to individual alloying elements. In fracture mechanics tests (Ref 78) using precracked fatigue specimens in a 22% NaCl solution at 105 °C (220 °F), two variants of type 329 duplex stainless steel were found to be resistant to chloride SCC at stress-intensity levels of 60 MPa $\sqrt{m}$  ( 55 ksi  $\sqrt{in}$  ).

FIG. 18 RESULTS OF AUTOCLAVE TESTS IN AERATED NEUTRAL CHLORIDE ION SOLUTIONS FOR VARIOUS STAINLESS STEELS. SOURCE: REF 77, 83

**Evaluating SCC Test Data.** Relative SCC rankings of steels depend on both the testing environment and the test method used. For example, data for chloride-induced SCC (Ref 79) were determined for three commercial alloys (type 2304, 2205, and 2507) and some tie-line alloys with 2 to 100% ferrite (Table 6). The results from the stress-corrosion testing are shown in Table 7. The relative ranking of the steel types depends on both the testing environment and the test method used. In the U-bend test, 2205 has a higher susceptibility to cracking than the leaner alloy 2304 in both magnesium chloride and in calcium chloride, while in lithium chloride 2304 is more prone to cracking than 2205.

- (A) FOR U-BEND TESTING THE TIME TO FAILURE IS TAKEN AS THE TIME AT WHICH THE FIRST CRACKS WERE OBSERVED AND IS THE AVERAGE OF FOUR SPECIMENS.
- (B) FOR SLOW STRAIN RATE TESTING TWO EVALUATION PARAMETERS ARE GIVEN: THE NORMALIZED PLASTIC ELONGATION TO FAILURE AND, IN PARENTHESES, THE NORMALIZED AREA REDUCTION.
- (C) RESULTS ARE AVERAGES OF AT LEAST TWO TESTS.

Stress-strain curves (Fig. 19) were recorded as a way to normalize the parameters for the stress-corrosion testing. In Table 7, the slow strain rate test has been evaluated in two ways: by judging the normalized plastic elongation to failure and by judging the normalized area reduction. In the lithium chloride test at 150 °C (300 °F), there was a clear strain rate dependence, but it was difficult to separate the different alloys when elongation to failure was used as a failure criterion. However, when the area reductions were measured, alloy 2304 had a much lower resistance to SCC in all three environments as compared to alloy 2205. In the slow strain rate test at 100 °C (212 °F), the more highly alloyed steel 2507 had better crack resistance in the calcium chloride environment than the two leaner alloyed steels. However, in lithium chloride, 2507 had lower crack resistance.

**FIG. 19 STRESS-STRAIN CURVES FOR AUSTENITIC (A) AND FERRITIC (F) ALLOYS AND ALLOY 2205 IN OIL (O) AND IN 50% LI<sub>2</sub>CL AT 100 °C, ILLUSTRATING THE NECESSITY OF PARAMETER NORMALIZATION FOR STRESS-CORROSION CRACKING EVALUATION**

The stress-corrosion resistance of the tie-line alloys is also dependent on the test type and the testing environment. In the U-bend test in calcium chloride, the ferritic alloy has a much higher resistance to cracking than the austenitic alloy and the duplex alloys have by far the lowest resistance (Ref 79). In slow strain rate testing in lithium chloride, there is a poor differentiation between the alloys, but there is a tendency for the two-phase alloys to have a somewhat higher crack resistance than the others.

The different rankings of the three duplex alloys cannot be explained by fracture path or electrochemical relations. Fracture surfaces from the testing of the tie-line alloys in lithium chloride have been compared at 100 °C. The cracking was transgranular in the ferritic alloy and intergranular in the austenitic alloy. In the two-phase alloys, the surfaces contained parts with transgranular cracking in the ferrite. The crack in some areas followed the ferrite-austenite phase boundaries, revealing entire grains of austenite. In all three duplex alloys, tested in different environments, the fracture

appearance was transgranular in the ferrite and interphase or intergranular in the austenite. In addition, the corrosion potential of the ferritic alloy was in all cases cathodic to that of the austenite, which resulted in cathodic protection of the austenite in almost all studied cases. Thus, neither the electrochemical relation between the ferrite and the austenite nor the behavior of the crack path could explain the different rankings of the three duplex alloys in the tested environments.

Another attempt to understand why different test methods give different rankings of duplex and austenitic alloys has been reported in Ref 80. The conventional monotonic slow strain rate test was compared to a test where a straining was followed by a relaxation period at constant deflection for 23 h. In the first cycle, the steels were strained to 90% of their yield stress, and corresponding deflection was held constant during relaxation. In the coming next cycles the stress was increased by 15 MPa per cycle. The testing was performed in lithium chloride at 100 °C. The stress-corrosion resistance of the 2304 and 2205 duplex steels was superior to that of the standard 316 austenitic stainless steel but inferior to that of the super austenitic stainless steel 254 SMO. Both testing methods yielded the same ranking. It was difficult, however, to see any clear differences between the two duplex steels. The main difference between the austenitic and duplex steels was found in the measurement of the corrosion potential. In the cyclic strain relaxation test, the measured potential for the austenitic alloys had a drop for every loading cycle, while the duplex steel had a pronounced drop in potential only just before final failure. This finding may to some extent explain the different rankings of stainless steels in different stress-corrosion tests. The fracture surface of the duplex steels was transgranular in the ferrite and intergranular around the austenitic phase, while the austenitic steels had both transgranular and intergranular cracking regions.

The influence of creep behavior on SCC was reported in Ref 81. The temperature creep dependence of the duplex stainless steel 2205 was much lower than that of the austenitic 316 steel in the temperature range tested. This behavior, together with the above-mentioned strain relaxation tests, may explain the different ranking of steels in constant-loading tests and in slow strain rate tests.

**SCC in Caustic Solutions.** A range of duplex and austenitic stainless steels were tested in caustic solutions at 200 °C (Ref 82). The solution used in the U-bend test and in the slow strain rate test contained 200 g/L sodium hydroxide and 10 g/L NaCl. The best behavior was shown by the molybdenum-free 23Cr-4Ni steel, which outperformed both the 22Cr-5Ni-3Mo and the 25Cr-7Ni-4Mo-N duplex steels and some austenitic stainless steels.

**SCC Comparison of Austenitic and Duplex Stainless Steels.** With the development of a database, experimental data have been compared for duplex and austenitic stainless steels tested with three different testing methods: the calcium chloride test, the autoclave test, and the drop evaporation test (Ref 83). In the calcium chloride test (Table 8), the duplex steels were ranked as high as highly alloyed austenitic stainless steels. In the autoclave test (Table 8 and Fig. 18), the lower-alloy duplex steels had a better stress-corrosion resistance than standard austenitic steels, but the superduplex steel and the highly alloyed austenitic stainless steels were more resistant. In the drop evaporation test (Fig. 20), the duplex steels are performing better than standard austenitic stainless steels but were outperformed by the austenitic stainless steels S32654 and S31254. It appears, by this author, that tests in autoclaves agree well with actual service conditions and that the drop evaporation test is useful in simulating applications where evaporation may occur and cyclic stresses are involved. An additional summary of stress-corrosion data for duplex stainless steels can be found in Ref 84.

FIG. 20 DEPENDENCE OF THRESHOLD STRESS IN PERCENTAGE OF 0.2% YIELD STRENGTH ON MOLYBDENUM EQUIVALENT FOR AUSTENITIC AND DUPLEX STAINLESS STEELS

**Fractography.** The fracture behavior of the duplex stainless steels during SCC has been investigated for duplex 25Cr-6Ni-3.6Mo steel with slow strain rate testing in boiling 8 M lithium chloride plus 0.025 M thiourea (Ref 85). Fracture surface specimens revealed two different fracture modes (complex and cleavage-like) in adjacent grains. Like most polycrystalline materials, different fracture paths result from different grain orientations, making different cleavage planes active in the different grains. Engineering alloys with polycrystalline structure commonly change from cleavage to complex type of fracture, which is governed by a combination of grain orientation, local microstructure, and stressing conditions. By using the transmission electron microscope, a porous sponge-like film with a thickness of 1000 Å was found between the parent metal and the outer corrosion product. This film was enriched with chromium, nickel, molybdenum, and copper. The study suggests that the dealloying of the ferritic phase and the formation of a sponge-like region is associated with the SCC of the ferritic phase.

## Fatigue and Fracture Properties of Duplex Stainless Steels

R. Johansson, Avesta Sheffield AB

---

## Elevated-Temperature Properties

Duplex stainless steels are generally used in applications up to 300 °C (570 °F). The steels will embrittle if used in the temperature range of 350 to 550 °C (660 to 1020 °F). If long exposure times can be avoided in this region, there are some applications at temperatures above 550 °C (1020 °F) where duplex alloys are a better choice than austenitic alloys.

The thermal cycling properties of a duplex stainless steel, 23Cr-5Ni-1.5Mo, was compared with those of a standard austenitic steel of type 316 (Ref 86). Different thermal cycling tests up to 1125 °C (2060 °F) showed remarkable acceleration of failures in the duplex steel as compared with the austenitic steel. This is related to the large differences in internal stresses between the two phases in the duplex steel and to an extensive grain growth during thermal cycling.

Thermal cycling of a 24Cr-4Ni-1.3Si duplex steel between room temperature and 900 °C (1650 °F) raised microstresses varying from grain to grain (Ref 87). The plastification caused an accumulating change of the shape of the specimen, which gave high residual stresses and internal cracks and damage.

The creep-fatigue behavior of the duplex steel 2205 was studied in a sulfur-containing environment of Ar + 3% SO<sub>2</sub> at 700 °C (Ref 88). Severe sulfidation attack occurred at the external surface of both 2205 duplex and 316 austenitic stainless steel under a combination of creep-fatigue loading and atmosphere. However, the attack on the duplex steel was less severe than the attack on the austenitic stainless steel.

### Selecting Aluminum Alloys to Resist Failure by Fracture Mechanisms

R.J. Bucci, ALCOA Technical Center, G. Nordmark (retired); E.A. Starke, Jr., University of Virginia, Department of Materials Science and Engineering

---

## Introduction

Though virtually all design and standard specifications require the definition of tensile properties for a material, these data are only partly indicative of mechanical resistance to failure in service. Except for those situations where gross yielding or highly ductile fracture represents limiting failure conditions, tensile strength and yield strength are usually insufficient requirements for design of fracture-resistant structures. Strength by itself may not be sufficient if toughness, resistance to corrosion, stress corrosion, or fatigue are reduced too much in achieving high strength.

The achievement of durable, long-lived structural components from high-strength materials requires consideration of severe stress raisers for which possible failure mechanisms are likely to be fatigue, brittle fracture, or fracture from some combination of cyclic and static loading in corrosive environments. Good design, attention to structural details, and reliable inspection are of primary importance in controlling corrosion-fatigue and fracture. Accordingly, designers have traditionally considered the minimization of stress raisers as more important than alloy choice.

However, proper alloy selection does represent an important means of minimizing premature fracture in engineering structures. Obviously, high tensile strength is potentially detrimental in parts containing severe stress raisers for which possible failure mechanisms are likely to be fatigue, brittle fracture, or fracture in combination with corrosion, static loads, and/or cyclic loading. Likewise, selecting ductile alloys of low enough strength to ensure freedom from unstable fracture is limited by economic or technical pressures to increase structural efficiencies. Therefore, optimum alloy selection for fracture control requires careful assessment and balance of trade-offs among the mechanical properties and corrosion behavior required for a given application.

In the aluminum industry, significant progress has been achieved in providing "improved" alloys with good combinations of strength, fracture toughness, and resistance to stress-corrosion cracking. Optimum selection and use of fatigue-resistant aluminum alloys also has become more of a factor for designers and materials engineers for extending fatigue life and/or structural efficiency. This emphasis on alloy development and selection is due, in part, to the greatly enhanced understanding of fatigue processes from the disciplines of strain control fatigue and fracture mechanics. The strain control approach is aimed primarily at fatigue crack initiation and early fatigue crack growth, while fracture mechanics concepts address the propagation of an existing crack to failure. This combination of knowledge from cyclic strain testing and fracture mechanics provides a basis for understanding of fatigue processes beyond the historical emphasis on crack nucleation studies from stress-controlled (stress to number of cycles, or *S-N*) fatigue testing. In this context, this article provides a brief overview on fatigue and fracture resistance of aluminum alloys.

## Characteristics of Aluminum Alloy Classes

A wide variety of commercial aluminum alloys and tempers provide specific combinations of strength, toughness, corrosion resistance, weld-ability, and fabricability. The relatively high strength-to-weight ratios and availability in a variety of forms make aluminum alloys the best choice for many engineering applications. Like other face-centered cubic materials, aluminum alloys do not exhibit sudden ductile-to-brittle transition in fracture behavior with lowering of temperature (Ref 1, 2). Tensile test results indicate that almost all aluminum alloys are insensitive to strain rates between  $10^{-5}$  mm/mm/sec and 1 mm/mm/sec ( $\sim 10^5$  MPa/sec) at room and low temperatures (Ref 2). Therefore, aluminum is an ideal material for structural applications in a wide range of operating temperatures and loading rates.

Aluminum alloys are classified in several ways, the most general according to their strengthening mechanisms. Some alloys are strengthened primarily by strain hardening (-H) while others are strengthened by solution heat treatment and precipitation aging (-T). A second commonly used system of classification is that of the Aluminum Association where the principal alloying element is indicated by the first digit of the alloy designation. Grouping of wrought aluminum alloys by strengthening method, major alloying element, and relative strength are given in Table 1. Another classification system established by the International Standards Organization (ISO) utilizes the alloying element abbreviations and the maximum indicated percent of element present (Table 2). This article utilizes the Aluminum Association system, which is described in more detail in *The Aluminum Association Standards and Data Handbook* (Ref 3) and in Volume 2 of the *ASM Handbook*.

Note: The proposed ISO chemical composition standard for aluminum and its alloys references Aluminum Association equivalents as well as its own identification system. The ISO system is based on the systems that have been used by certain European countries. The main addition element is distinguished by specifying the required content (middle of range) rounded off to the nearest 0.5. If required, the secondary addition elements are distinguished by specifying the required content rounded off to the nearest 0.1, for two elements

(A) THE CHEMICAL SYMBOLS FOR ADDITION ELEMENTS SHOULD BE LIMITED TO FOUR. IF AN ALLOY CANNOT OTHERWISE BE DISTINGUISHED, A SUFFIX IN BRACKETS IS USED: 6063 = AL MG0.7SI; 6463 = AL MG0.7SI(B); AND INTERNATIONAL ALLOY REGISTRATION, 6063A = AL MG0.7SI(A). NOTE THAT SUFFIXES (A), (B), AND SO ON SHOULD NOT BE CONFUSED WITH SUFFIXES OF THE ALUMINUM ASSOCIATION.

Commercial aluminum products used in the majority of structural applications are selected from 2XXX, 5XXX, 6XXX, and 7XXX alloy groups, which offer medium-to-high strengths. Of these, 5XXX and 6XXX alloys offer medium-to-relatively high strength, good corrosion resistance, and are generally so tough that fracture toughness is rarely a design consideration. The 5XXX alloys provide good resistance to stress corrosion in marine atmospheres and good welding characteristics. Notably, this class of alloys has been widely used in low-temperature applications that satisfy the most severe requirements of liquefied fuel storage and transportation at cryogenic temperatures (Ref 2, 4, 5). Alloys of the 6XXX class, with good formability and weldability at medium strengths, see wide use in conventional structural applications. The 2XXX and 7XXX alloys generally are used in applications involving highly stressed parts. Certain alloys and tempers within these classes are promoted for their high toughness at high strength. Stress-corrosion cracking resistance of 2XXX and 7XXX alloys is generally not as great as in other aluminum alloy groups; however, service failures are avoided by good engineering practices and proper selection of alloy and temper or a suitable protective system. The 2XXX and 7XXX alloys see widespread use in aerospace applications. Certain 2XXX and 7XXX alloys provide good welding characteristics at high strength.

Alloys of the 1XXX class are used primarily in applications where electrical conductivity, formability, ductility, and resistance to stress corrosion are more important than strength. The 3XXX alloys, widely used in piping applications, are characterized by relatively low strengths and very good toughness, ductility, formability, brazing, and welding characteristics. The 4XXX alloys are used mainly for welding wire and brazing applications where it is desired to have a lower melting point than in the wire without producing brittleness in the weldment.

**Alloy Selection Concepts.** In any design plan, priority must be given to alloy properties. Optimum alloy choice involves evaluation and decision based on rating characteristics of a material that quantitatively measure resistance to failure by foreseeable failure mechanisms. In some instances, trade-off will be necessary among these material characteristics and among other factors, such as cost, fabricability, availability, expected service life, and maintainability.

Relatively few generalizations can be made that will be valid for all material selection problems; individual problems must be treated separately or on the basis of closely related experience.

An important consideration to the relative ranking of importance of properties to prevent failure is the particular application and basic design strategy to which the selected alloy will be applied. It is pertinent to review basic design philosophies by which aluminum alloys are selected to resist failure by fracture mechanisms. Later discussion will treat alloy selection concepts related to the specific areas of fracture toughness, corrosion, stress-corrosion cracking (SCC), and fatigue.

**Design Philosophies.** In general, design philosophies for the prevention of fracture-type failures are of two basic types: safe life and damage-tolerant (or fail-safe). Neither approach is meant to be used as an extreme, nor is either approach meant to replace need for full-scale design verification tests. Many applications require a "fracture-control plan" to arrive at rational and cost-effective criteria for design, fabrication, and maintenance of reliable structures.

**Safe Life Design Approach.** Traditionally, component life has been expressed as the time (or number of fatigue cycles) required for a crack to be initiated and grow large enough to produce catastrophic failure. Prior to development of reliable crack detection techniques and fracture mechanics technology, little attempt was made to separate component failure into initiation and propagation stages. It was assumed that total life of a part consisted primarily of initiation of a crack, generally by fatigue or stress corrosion. Time for a minute crack to grow and produce failure was considered a minor portion of the service life. In the safe life approach, which is an outgrowth of this assumption, the designer seeks long, safe life by preventing cracks of significant size from occurring during the service life of the structure. In this approach it is the incubation period leading to development of a significant crack that is of major concern.

Small coupon-type specimens, though useful for rating materials and establishing sensitivity of various load and fabrication parameters, are not suitable for establishing the life of the part. A safe-life evaluation of a structure requires a reasonably accurate experimental simulation of the particular item of hardware. Under this procedure, accurately described loads are applied to the structure, life is determined, and a scatter factor is applied to establish the safe life of the structure. Structural "hot spots" are retrofitted as necessary. Generally, such elaborate tests prohibit evaluation of a large number of candidate materials and structural arrangements, since testing of each option may not be feasible because of economic and time constraints. Therefore, design and, consequently, material selection by this approach rely heavily on experience to eliminate need for excessive structural maintenance and retrofit.

**Damage-Tolerant (Fail-Safe) Design Approach.** Damage tolerance describes features of design that prohibit catastrophic loss of structural integrity. Damage tolerance evaluation of structure is intended to ensure that, should serious cracking or damage occur, the remaining structure can withstand reasonable loads without excessive structural deformation until the damage is detected. Consideration must be given to the probable existence of flaws (cracks) in the structure. These flaws could be initiated in service or be present as undetected initial material or fabrication defects. Given a crack-like flaw corresponding to the maximum size escaping reliable detection, life of the part is assumed to be spent propagating this flaw to the critical size that results in unstable fracture. The general design strategy is to select stress levels, configurations, and materials to provide a controlled slow rate of crack propagation with high residual strength. The designer thereby seeks to limit the rate of flaw growth so the largest flaw missed at one inspection will not cause catastrophic failure before one or more later inspections. Analysis procedures depend heavily on the use of crack growth rates and fracture toughness combined with fracture mechanics principles for prediction of crack growth life and fracture strength. Moreover, inspection is an integral part of the fracture control plan. Recognition of these principles and their implications for the safety, reliability, and durability of engineering structures has resulted in engineering standards and codes that impose requirements of fracture mechanics analyses and control of crack behavior. Perhaps the most notable of these is the Air Force structural integrity requirement (Ref 6). With this plan, use of fracture toughness and stress corrosion testing in material procurement is required to ensure that materials with properties lower than those used in design do not appear in the final structure.

## Fracture Mechanics and Toughness

Fracture mechanics is concerned with catastrophic failure associated with crack-like flaws, regardless of how the flaw originated. Important parameters are crack size, local stress in the absence of the crack, yield strength, and materials fracture toughness. Use of these parameters allows prediction of the terminal flaw size in a part. The fracture mechanics approach is based on analysis of crack tip stress-strain fields. When stresses are below the yield stress, the critical stress concentration for fracture lies in the domain of linear elastic fracture mechanics and is an inherent material property  $K_{Ic}$  (plane-strain fracture toughness).

The concepts of fracture mechanics are concerned with the basic methods for predicting the load-carrying capabilities of structures and components containing cracks. The fracture mechanics approach is based on a mathematical description of the characteristic stress field that surrounds any crack in a loaded body. When the region of plastic deformation around a crack is small compared to the size of the crack (as is often true for large structures and high-strength materials), the magnitude of the stress field around the crack is commonly expressed as the stress intensity factor,  $K$ , where:

$$K = \sigma \sqrt{(a)Y} \quad (\text{EQ 1})$$

where  $\sigma$  = remotely applied stress,  $a$  = characteristic flaw size dimension, and  $Y$  = geometry factor, determined from linear elastic stress analysis. The stress-intensity factor,  $K$ , thus represents a single parameter that includes both the effect of the stress applied to a sample and the effect of a crack of a given size in a sample. The stress-intensity factor can have a simple relation to applied stress and crack length, or the relation can involve complex geometry factors for complex loading, various configurations of real structural components, or variations in crack shapes. In this way, linear elastic analysis of small-scale yielding can be used to define a unique factor,  $K$ , that is proportional to the local crack tip stress field outside the small crack tip plastic zone.

These concepts provide a basis for defining a critical stress-intensity factor ( $K_c$ ) for the onset of crack growth, as a material property independent of specimen size and geometry for many conditions of loading and environment. For example, if a combination of  $\sigma$  and  $a$  were to exceed a critical value  $K_c$ , then the crack would be expected to propagate.

Tests on precracked specimens of a wide variety of materials have shown that the critical  $K$  value at the onset of crack extension approaches a constant value as specimen thickness increases. Figure 1 shows this effect in tests with 7075 aluminum alloy specimens over a range of thickness. In general, when the specimen thickness and the inplane dimensions near the crack are large enough relative to the size of the plastic zone, then the value of  $K$  at which growth begins is a constant and generally minimum value called the plane-strain fracture toughness factor,  $K_{Ic}$ , of the material. The parameter  $K_{Ic}$  is a true material property in the same sense as is the yield strength of a material. The value of  $K_{Ic}$  determined for a given material is unaffected by specimen dimensions or type of loading, provided that the specimen dimensions are large enough relative to the plastic zone to ensure plane-strain conditions around the crack tip (strain is zero in the through-thickness or z-direction).

**FIG. 1 FRACTURE TOUGHNESS OF 7075-T6, T651 SHEET AND PLATE FROM TESTS OF FATIGUE-CRACKED CENTER-NOTCHED SPECIMENS (TRANSVERSE). SOURCE: J.G. KAUFMANN IN REVIEW OF DEVELOPMENTS IN PLANE STRAIN FRACTURE TOUGHNESS TESTING, ASTM STP 463, 1970, P 7**

Plane-strain fracture toughness,  $K_{Ic}$ , is also directly related to the energy required for the onset of crack propagation by the formula

$$K_{Ic} = \sqrt{\frac{EG_{Ic}}{1-\nu^2}} \quad (\text{EQ 2})$$

where  $E$  is the elastic modulus (in MPa or psi),  $\nu$  is Poisson's ratio (dimensionless), and  $G_{Ic}$  is the critical plane-strain energy release rate for crack extension (in  $\text{kJ/m}^2$  or  $\text{in.-lb/in.}^2$ ). In simplified concept,  $G_{Ic}$  is the critical amount of strain energy that is released from the elastic stress field of the specimen per unit area of new cracked surface for the first small increment of crack extension. The concepts of  $K_{Ic}$  and  $G_{Ic}$  are essentially interchangeable;  $K_{Ic}$  is generally preferred because it is more easily associated with the stress or load applied to a specimen. The value of  $K_{Ic}$  is measured directly using test methods described in ASTM E-399.

In the plane-strain state, a material is at its lowest point of resistance to unstable fracture. The onset of fracture is abrupt and is most clearly observed in thick sections of low-ductility (high-strength) alloys, when the elastic stress state in a flawed component is highly constrained to that of plane strain. However, when stresses approach or exceed yield values, the elastic stress field surrounding the crack departs from that of plane strain (from the development of an enlarged crack tip plastic zone which generally enhances fracture toughness). With increasing load, slow stable crack extension (tearing) may accompany the increasing plastic zone size. Onset of rapid fracture occurs when increase in crack tip stress field, measured by  $K$  (increase in  $K$  due to increased nominal stress and crack length), equals or exceeds resistance to crack extension (due to an increase in plastic zone size, crack tip blunting, and change from flat to slant fracture). This behavior is most clearly seen in fracture of relatively tough thin plate and sheet alloys. Unstable fracture under these conditions cannot be described as a material property since events leading to rapid fracture are specimen configuration and size dependent. One standardized method for describing elastic-plastic fracture involves the resistance-curve or R-curve concept described in ASTM E561. Briefly, the resistance-curve concept involves measurement of the  $K$  values at which various amounts of crack growth occur in a thin-plate laboratory specimen. Then a plotted curve of  $K$  versus crack growth from the laboratory specimen can be used to predict crack-growth behavior in a structural component of the same

material. Limitations of the method are that the component must have the same thickness as the laboratory specimen and that  $K$  relations must be known for both component and specimen. However, once a resistance curve is obtained for a given material and thickness, it can be used to predict the crack-growth and crack-instability behavior of other components of the same material.

**$J$ -Integral Method.** Another concept for use in the analysis of elastic-plastic fracture is the  $J$ -integral concept, where  $J$  is a nonlinear generalization of  $G$  (the elastic strain energy release rate).  $J$  can be thought of as the amount of elastic-plastic strain energy per unit area of crack growth which is applied toward extending the crack in a specimen under load. A critical value of  $J$ , called  $J_{Ic}$ , is the value required for the start of crack extension from a pre-existing crack. For material having a sufficiently high yield strength or for specimens of sufficient size, elastic stresses control the crack extension, and  $J_{Ic}$  is equal to  $G_{Ic}$ .

An important advantage of the  $J_{Ic}$  test method is that it can accommodate a significant amount of crack-tip blunting and general plastic deformation in the specimen. If the amount of plastic deformation is small enough,  $J_{Ic}$  will be identical to  $G_{Ic}$ , and thus  $J_{Ic}$  can be converted to an approximately equivalent measure of  $K_{Ic}$  (see Eq 2). For large amounts of plastic deformation, a size requirement limits the size of the specimen and, indirectly, the amount of plastic deformation which can be allowed. The specimen size requirement allows a significantly smaller specimen, often ten times smaller, to be tested with the  $J_{Ic}$  procedure than with the  $K_{Ic}$  procedure. So, although the  $J_{Ic}$  test is relatively time consuming due to multiple tests, it can be used over a wider range of material properties and specimen sizes than the  $K_{Ic}$  test. In addition, single-specimen  $J_{Ic}$  test procedures, such as incremental unloading methods, can reduce both testing time and the number of specimens required to obtain  $J_{Ic}$  test data. Another advantage of the  $J_{Ic}$  approach is that it makes possible the prediction of the failure load of cracked high-toughness, medium-strength alloys (with more tendency toward plastic deformation) for fracture-critical applications.

## Alloy Selection for Fracture Toughness

Plane-strain fracture toughness,  $K_{Ic}$ , is particularly pertinent in materials selection because, unlike other measures of toughness, it is independent of specimen configuration. For comparison, the notch toughness of a material, which is most commonly measured by Charpy testing, does depend on the configuration of the specimen. Changes in the size of the specimen or in the root radius of the notch will affect the amount of energy absorbed in a Charpy test. The main reason for this is that the total energy required for initiation of the crack from the notch, for propagation of the crack across the specimen, and for complete fracture of the specimen is measured in a Charpy test. In contrast, a  $K_{Ic}$  test measures only the critical load required for a small extension of a pre-existing crack. Even though  $K_{Ic}$  is more difficult to measure than notch toughness, because of the requirements of a pre-existing crack and a specimen large enough for plane-strain conditions, it is a constant material property and can be more generally applied to materials selection.

In selection of structural materials, the single most important characteristic of  $K_{Ic}$  for nearly all materials is that it varies *inversely* with yield strength for a given alloy. Table 3 is a summary of plane-strain fracture toughness values for a wide variety of aluminum alloys--including 2024 and 7075, which have been used for components which do not require a high level of fracture toughness. Typical data for a lot of one high-toughness aluminum alloy (7475-T7351) are shown in Table 4.

Tough aluminum alloys such as those from the 1XXX, 3XXX, 4XXX, 5XXX, and most 6XXX series do not normally exhibit elastic unstable fracture, either in test panels or in real structures. These alloys are so tough that fracture toughness is rarely a design criterion. Because of this consideration and the relative difficulty of measuring toughness in a design-oriented manner by current methods, fracture toughness information for these alloys is rather limited. Much of the data available for these alloys (Fig. 2) has been developed by extrapolation of correlations from simpler tests such as the simple tear specimen of the design shown in Fig. 3, where the resistance of a material to crack growth in a nonuniform

stress field is evaluated by measurement of appropriate areas under autographic load deformation records. A relative ranking of thin-section fracture toughness by tear tests is shown in Fig. 2 for a number of aluminum sheet alloys and tempers. Particularly, the unit propagation energy (UPE) has been found to be correlated with resistance to stable crack growth in thin sections, measured as  $K_{Ic}$  from wide-panel tests (Ref 1). These alloys are excluded from further consideration in this section.

FIG. 3 TEAR-TEST SPECIMEN AND REPRESENTATIVE TEAR TEST CURVES

Alloys for which fracture toughness is a meaningful design-related parameter fall into two categories:

- CONTROLLED-TOUGHNESS, HIGH-STRENGTH ALLOYS (I.E., THOSE ALLOYS DEVELOPED PRIMARILY FOR THEIR HIGH FRACTURE TOUGHNESS AT HIGH STRENGTH)
- CONVENTIONAL HIGH-STRENGTH ALLOYS, TEMPERS, AND PRODUCTS FOR WHICH FRACTURE TOUGHNESS IS A MEANINGFUL DESIGN PARAMETER, BUT WHICH ARE NOT PROMOTED OR USED FOR FRACTURE-CRITICAL COMPONENTS

The above categories are composed primarily of 2XXX and 7XXX alloys. Controlled-toughness, high-strength commercial products include 2124-T3 and T8-type sheet and plate; 2419-T6 and T8-type sheet, plate, extrusion, and forgings; 7050-T7-type plate, forgings, and extrusions; 7149-T7-type forgings; 7175-T6 and T7-type extrusions and forgings; and 7475-T6 and T7-type sheet and plate.

Recognized conventional high-strength alloys that are not produced to minimum toughness include 2014, 2024, 2219, 7075, 7079, and 7178. Typical strength and fracture toughness properties of several high-strength aluminum products are presented in Table 5. Evaluations have shown (Ref 7) that the fracture toughness of high-strength, precipitation-hardened 2XXX and 7XXX alloys is not adversely affected by high strain rate or moderate temperature reduction.

(A) PARALLEL TO GRAIN FLOW.

(B) NONPARALLEL TO GRAIN FLOW

In general, fracture toughness decreases with increasing yield strength, as indicated by scatter bands of notched yield strength ratio (NYR) and UPE established for a wide variety of commercial 2XXX and 7XXX products. To develop high toughness, the microstructure must accommodate significant plastic deformation, and yet a microstructure that resists plastic deformation is needed for high strength. As indicated by Fig. 4(a) and 4(b), 7XXX alloys have the highest combination of strength and toughness of any family of aluminum alloys. In 7XXX alloys, highest strength is associated with the T6 peak aged temper. Decreasing strength to acceptable levels by overaging provides a way to increase toughness (Fig. 5) as well as resistance to exfoliation, SCC, and fatigue crack growth in some 7XXX alloys. Alloys of the 2XXX class are used in both the naturally aged and artificially aged conditions. Commercial naturally aged 2XXX alloys (viz. T3- and T4-type tempers) provide good combinations of toughness and strength. Artificial aging to precipitation-hardened T8 tempers produces higher strength with some reduction in toughness, but in addition offers greater stability of mechanical properties at high temperatures and higher resistance to exfoliation and SCC.

FIG. 4 COMPARISON OF 2XXX AND 7XXX COMMERCIAL ALUMINUM ALLOYS (A) NOTCH TOUGHNESS VS. YIELD

## STRENGTH. (B) UNIT PROPAGATION ENERGY VS. YIELD STRENGTH

FIG. 5 RELATIONSHIPS OF PLANE-STRAIN FRACTURE TOUGHNESS TO YIELD STRENGTH FOR THE 2XXX AND 7XXX SERIES OF ALUMINUM ALLOYS. SOURCE: R. DEVELAY, *METALS AND MATERIALS*, VOL 6, 1972, P 404

The strength-fracture toughness interaction has been postulated to be the consequence of void link-up created by slip-induced breakdown of submicron strengthening particles, which occurs more readily at high strength levels (Ref 8). If the strengthening (matrix) precipitates are shearable they may promote strain localization which leads to premature crack nucleation and low fracture toughness. Whether or not the strengthening precipitates are sheared or looped and bypassed by dislocations depends on alloy composition and aging treatment. During aging, heterogeneous precipitation usually occurs at grain and subgrain boundaries resulting in soft, solute-denuded PFZ's in the matrix adjacent to the boundaries. The combination of these soft zones, that can localize strain, and grain boundary precipitates, that can aid in microvoid nucleation, also has an adverse effect on fracture toughness. Though this hypothesis remains unproven, it has been clearly demonstrated that the amounts, distribution, and morphology of alloy phases and second-phase particles in alloy microstructure have a large influence on toughness (Ref 9, 10, 11). Developed understanding of the interrelationships of alloy microstructure and fracture mechanisms has led to design of new commercial aluminum alloys offering optimum high strength and high toughness. Primarily, the alloy improvements have evolved through microstructural control obtained by increased purity, modified compositions, and better homogenization, fabrication, and heat treatment practices (Ref 10, 11, 12, 13, 14, 15).

The balance between strength and toughness is greatly affected by a variety of processing parameters, including solution heat treatment, quenching efficiency, deformation prior to aging (for 2XXX alloys) and aging treatment. The solution heat treatment determines the amount of solute in solid solution and the vacancy content, which affects subsequent aging kinetics. Quenching affects both the microstructure and properties by determining the amount of solute that precipitates during cooling and that which is available for subsequent age hardening. It also affects the level of residual stresses which can influence manufacturing costs, fatigue and corrosion behavior. After quenching, methods to obtain a balance of properties include cold working before aging, when practical (T8 temper), and selecting aging times and temperatures to minimize grain boundary precipitates and precipitate-free zones (PFZ). The deformation prior to aging aids in the nucleation and growth of the matrix precipitates which decreases the time to reach peak strength. This, along with low-temperature aging, minimizes the amount of grain boundary precipitates and PFZ's (which adversely affect fracture toughness) at the desired strength level.

Alloy 2124 was the first 2XXX alloy developed to have high fracture toughness. The principal contribution to high toughness was increased purity (low iron and silicon), which minimizes formation of relatively large insoluble constituents ( $>1 \mu\text{m}$ ). The detrimental effect of large constituent phases on the fracture toughness of aluminum alloys has been documented by many investigators. Constituent particles participate in the fracture process through void formation at particle/matrix interfaces or by fracturing during primary processing. Their volume fraction can be minimized by reducing impurity elements, e.g., iron and silicon, and excess solute. The detrimental effect of dispersoids also depends on

their size and the details of their interface with the matrix. For example, the strength-toughness relationships in Fig. 6(b) were determined for 7075 variants containing different dispersoid-forming elements. Because Zr particles are small and coherent with the matrix (strong interface), they are usually not involved in the fracture process.

Resultant improvement for production materials is shown in Fig. 7 (Ref 14). Minimization of insoluble constituents by process control was used to develop 2419 and 2214 as higher-toughness versions of 2219 and 2014, respectively. Biggest gains in fracture toughness of 2XXX alloys by process control have been to the precipitation-hardened T8 tempers which are widely used in applications requiring good resistance to exfoliation corrosion and SCC. The effect of impurity on toughness of other alloys is shown in Table 6.

**FIG. 7 ALUMINUM ALLOYS 2124 AND 7475 ARE TOUGHER VERSIONS OF ALLOYS 2024 AND 7075. HIGH-PURITY METAL (LOW IRON AND SILICON) AND SPECIAL PROCESSING TECHNIQUES ARE NEEDED TO OPTIMIZE TOUGHNESS IN THESE MATERIALS. SOURCE: REF 14**

Grain size and degree of recrystallization can have a significant effect on fracture toughness. The desired degree of recrystallization depends on product thickness, i.e., whether the part is under plane stress or plane strain. In thin products under plane stress, fracture is controlled by plasticity and a small recrystallized grain size is preferable. If the grain size is small enough, plasticity will be enhanced without detrimental, low energy, intergranular fracture. However, for thick products under plane strain, fracture is usually controlled by coarse particles and an unrecrystallized grain structure is preferable.

Alloy 7475 represents one of the most successful applications of alloy design techniques. Its composition and properties are modified from those of alloy 7075 by

- REDUCING IRON AND SILICON CONTENTS

- OPTIMIZING DISPERSOIDS
- ALTERING PRECIPITATES
- CONTROLLING QUENCHING RATE
- CONTROLLING GRAIN SIZE

These modifications result in the toughest aluminum alloy available commercially at high strength levels. For designers this influence is shown most clearly by information on crack lengths for unstable crack growth at specific design stresses, such as that shown in Fig. 8. The crack tolerance of the 7475-T761 alloy sheet is almost three times greater than that of conventional 7075-T6. Similar effects have been noted for plate.

FIG. 8 GROSS SECTION STRESS AT INITIATION OF UNSTABLE CRACK PROPAGATION VS. CRACK LENGTH FOR WIDE SHEET PANELS OF FOUR ALUMINUM ALLOY/TEMPER COMBINATIONS. SOURCE: REF 13

Alloy 7475 represents the highest strength-toughness combinations available in a commercial aluminum alloy. However, patented process controls (in addition to controlling the purity of iron and silicon) are necessary to achieve highest toughness levels in 7475. In comparison to conventional high-strength alloys, the effectiveness of alloy 7475 in developing high toughness at high strength is shown by plane-strain fracture toughness ( $K_{Ic}$ ) data (Fig. 9), plane-stress fracture toughness ( $K_c$ ) data from wide center crack panel tests (Fig. 10), and crack resistance curves (Fig. 11). This advantage is demonstrated by the critical stress-flaw size relationships in Fig. 8. The effect of heat treatment on crack propagation energy is shown in Fig. 6. Controls on production processes for high-toughness alloys 2124 and 7475 should also improve fatigue crack growth resistance.

FIG. 11 CRACK RESISTANCE CURVES FOR ALUMINUM ALLOY 7475 SHEET

**7150-T77 Plate.** In response to a need for improved corrosion resistance, another temper was developed for 7150. Alloy 7150-T77 plate develops the same mechanical properties as does 7150-T6 with significantly improved resistances to both exfoliation corrosion and SCC. The first application was on the C17 cargo transport. This saved a considerable amount of weight because corrosion performance of 7150-T6 and T61 was deemed to be inadequate by the Air Force for this application, and strength of 7050-T76 is considerably lower. The combination of strength and corrosion characteristics of 7150-T77 is attributed to proprietary processing. This processing promotes the development of a precipitate structure which effectively resists the passage of dislocations equivalent to that provided by the T6 temper and simultaneously minimizes the electrochemical differences between the matrix and grain boundaries. Extruded products in T77 do not develop the 70 MPa strength advantage.

**7055-T77 Plate.** The implementation of the T77 temper for 7150 was followed by development of a proprietary material for compressively loaded structures. Alloy 7055-T77 plate offers a strength increase of about 10% relative to that of 7150-T6 (almost 30% higher than that of 7075-T76). It also provides a high resistance to exfoliation corrosion similar to that of 7075-T76 with fracture toughness and resistance to the growth of fatigue cracks similar to that of 7150-T6. In contrast to the usual loss in toughness of 7XXX products at low temperatures, fracture toughness of 7055-T77 at -65 °F (220 K) is similar to that at room temperature. Resistance to SCC is intermediate to those of 7075-T6 and 7150-T77. The attractive combination of properties of 7055-T77 is attributed to its high ratios of Zn/Mg and Cu/Mg. When aged by the proprietary T77 process this composition provides a microstructure at and near grain boundaries that is resistant to intergranular fracture and to intergranular corrosion. The matrix microstructure resists strain localization while maintaining a high resistance to the passage of dislocations. The extruded products in T77 do not develop the 70 MPa strength advantage.

**Low-Temperature Toughness.** Aluminum alloys represent a very important class of structural metals for subzero-temperature applications. Aluminum and aluminum alloys have face-centered-cubic (fcc) crystal structures. Most fcc metals retain good ductility at subzero temperatures. Aluminum can be strengthened by alloying and heat treatment while still retaining good ductility along with adequate toughness at subzero temperatures. Nominal compositions of aluminum alloys that are most often considered for subzero service are presented in Table 7.

Data on fracture toughness of several aluminum alloys at room and subzero temperatures are summarized in Table 8. The room-temperature yield strengths for the alloys in this table range from 142 to 536 MPa (20.6 to 77.7 ksi), and room-temperature plane-strain fracture toughness values for both bend and compact tension specimens range from 22.3 to 39.9 MPa $\sqrt{m}$  (20.3 to 36.3  $\sqrt{in}$ ). This range in numerical values is not as impressive as actual service performances.

Source: *Metals Handbook*, 9th ed., Vol 3, American Society for Metals, 1980, p 746, compiled from several references

(A) 2124 IS SIMILAR TO 2024, BUT WITH HIGHER-PURITY BASE AND SPECIAL PROCESSING TO IMPROVE FRACTURE TOUGHNESS.

(B)  $K_{Ic}(J)$ .

Of the alloys listed in Table 8, 5083-O has substantially greater toughness than the others. Because this alloy is too tough to obtain valid  $K_{Ic}$  data, the values shown for 5083-O were converted from  $J_{Ic}$  data. The fracture toughness of this alloy increases as exposure temperature decreases. Of the other alloys, which were evaluated in various heat-treated conditions, 2219-T87 has the best combination of strength and fracture toughness, both at room temperature and at -196 °C (-320 °F); this alloy can be readily welded.

Alloy 6061-T651 is another weldable alloy. It has good fracture toughness at room temperature and at -196 °C (-320 °F), but its yield strength is lower than that of alloy 2219-T87. Alloy 7039 also is weldable and has a good combination of strength and fracture toughness at room temperature and at -196 °C (-320 °F). Alloy 2124 is similar to 2024 but with a higher-purity base and special processing for improved fracture toughness. Tensile properties of 2124-T851 at subzero temperatures can be expected to be similar to those for 2024-T851.

Several other aluminum alloys, including 2214, 2419, 7050, and 7475, have been developed in order to obtain room-temperature fracture toughness superior to that of other 2000 and 7000 series alloys. Information on subzero properties of these alloys is limited, but it is expected that these alloys would have improved fracture toughness at subzero temperatures as well as at room temperature.

### Selecting Aluminum Alloys to Resist Failure by Fracture Mechanisms

R.J. Bucci, ALCOA Technical Center, G. Nordmark (retired); E.A. Starke, Jr., University of Virginia, Department of Materials Science and Engineering

---

### Stress-Corrosion Cracking of Aluminum Alloys

Stress-corrosion cracking (SCC) is a complex synergistic interaction of corrosive environment and sustained tensile stress at an exposed surface of metal resulting in cracking and premature failure at stresses below yield. In high-strength aluminum alloys, SCC is known to occur in ordinary atmospheres and aqueous environments. Both initiation and crack propagation may be accelerated by chlorides, temperature, and certain other chemical species. Susceptibility to SCC places a limitation on use of high-strength materials in certain applications. However, proper alloy/temper selection, good design and assembly practices, and environmental protection, combined with regular inspections, have proved to be highly successful techniques for the prevention of SCC failure in high-strength parts (Ref 15, 16).

The exact mechanisms responsible for SCC of a susceptible aluminum alloy in a particular environment remains controversial. However, most proposed mechanisms are variations of two basic theories: crack advance by anodic dissolution or hydrogen embrittlement. The controlling factors in these two SCC models are as follows:

*Anodic dissolution* is characterized by:

- GRAIN BOUNDARY PRECIPITATE SIZE, SPACING, AND/OR VOLUME FRACTION
- GRAIN BOUNDARY PFZ WIDTH, SOLUTE PROFILE OR DEFORMATION MODE
- MATRIX PRECIPITATE SIZE/DISTRIBUTION AND DEFORMATION MODE
- OXIDE RUPTURE AND REPASSIVATION KINETICS,

while *hydrogen embrittlement* is characterized by:

- HYDROGEN ABSORPTION LEADING TO GRAIN BOUNDARY OR TRANSGRANULAR DECOHESION
- INTERNAL VOID FORMATION VIA GAS PRESSURIZATION
- ENHANCED PLASTICITY (ADSORPTION AND ABSORPTION ARGUMENTS EXIST)

An important fact to remember is that pure aluminum does not stress corrode, and for any given system, susceptibility usually increases with solute content. This fact, coupled with data and the controlling factors of the two models, suggests that microstructural alterations may influence SCC behavior for a given composition.

It is possible that hydrogen may contribute in the SCC of certain alloys and tempers of aluminum, although a detailed mechanistic understanding of SCC in aluminum alloys still requires more research (Ref 17). Recent literature surveys indicate considerable dispute as to how much, if at all, high-strength Al alloys are embrittled by hydrogen (Ref 18, 19,

20). There has not been enough evidence of hydrogen embrittlement to restrict commercialization of high-strength Al alloys (Ref 21).

## SCC Resistance Ratings

An important step in controlling SCC by proper alloy selection is the SCC ranking of candidate materials. To establish performance that can be expected in service, it is necessary to compare candidate materials with other materials for which either long-term service experience or appropriate laboratory test data are available. Such comparisons, however, can be influenced significantly by test procedures (Ref 22, 23, 24). Laboratory stress-corrosion tests are generally of two types: constant deflection tests of smooth tensile bars or C-ring specimens loaded in aggressive environments, or crack propagation tests of precracked fracture mechanics specimens in aggressive environments. Commonly used criteria for SCC resistance from these tests include:

- STRESS THRESHOLD ( $\sigma_{TH}$ ) BELOW WHICH LABORATORY SPECIMENS DO NOT FAIL IN AGGRESSIVE ENVIRONMENTS
- STRESS INTENSITY THRESHOLD ( $K_{TH}$ ) BELOW WHICH CRACK PROPAGATION DOES NOT OCCUR IN PRECRACKED SPECIMENS
- CRACK VELOCITY MEASUREMENTS ( $DA/DT$ ) VERSUS STRESS INTENSITY IN AGGRESSIVE ENVIRONMENTS

There presently are no foolproof stress-corrosion test methods that are free of special limitations on test conditions and free of problems on interpretation of test results. However, a system of ratings of resistance to SCC for high-strength

aluminum alloy products based on  $\sigma_{th}$  of smooth test specimens has been developed by a joint task group of ASTM and the Aluminum Association to assist alloy and temper selection, and it has been incorporated into ASTM G64 (Ref 25). Definitions of these ratings, which range from A (highest resistance) to D (lowest resistance), are as follows (adapted from G64-91):

- **A: VERY HIGH.** NO RECORD OF SERVICE PROBLEMS; SCC IS NOT ANTICIPATED IN GENERAL APPLICATIONS.
- **B: HIGH.** NO RECORD OF SERVICE PROBLEMS; SCC IS NOT ANTICIPATED AT STRESSES OF THE MAGNITUDE CAUSED BY SOLUTION HEAT TREATMENT. PRECAUTIONS MUST BE TAKEN TO AVOID HIGH SUSTAINED TENSILE STRESSES (EXCEEDING 50% OF THE MINIMUM SPECIFIED YIELD STRENGTH) PRODUCED BY ANY COMBINATION OF SOURCES INCLUDING HEAT TREATMENT, STRAIGHTENING, FORMING, FIT-UP, AND SUSTAINED SERVICE LOADING.
- **C: INTERMEDIATE.** STRESS-CORROSION CRACKING IS NOT ANTICIPATED IF TOTAL SUSTAINED TENSILE STRESS IS MAINTAINED BELOW 25% OF MINIMUM SPECIFIED YIELD STRENGTH. THIS RATING IS DESIGNATED FOR THE SHORT-TRANSVERSE DIRECTION IN PRODUCTS USED PRIMARILY FOR HIGH RESISTANCE TO EXFOLIATION CORROSION IN RELATIVELY THIN STRUCTURES, WHERE APPRECIABLE STRESSES IN THE SHORT-TRANSVERSE DIRECTION ARE UNLIKELY.
- **D: LOW.** FAILURE DUE TO SCC IS ANTICIPATED IN ANY APPLICATION INVOLVING SUSTAINED TENSILE STRESS IN THE DESIGNATED TEST DIRECTION. THIS RATING IS CURRENTLY DESIGNATED ONLY FOR THE SHORT-TRANSVERSE DIRECTION IN CERTAIN PRODUCTS.

Ratings are based on service experience, if available, or on standard SCC tests (ASTM G47, Ref 26) as required by many materials specifications. This exposure represents a severe control environment commonly used in alloy development and quality control. To rate a new material and test direction, according to G47, tests are performed on at least ten random lots and the test results must have 90% compliance at a 95% level of confidence for one of the following stress levels:

- **A: UP TO AND INCLUDING 75% OF THE SPECIFIED MINIMUM YIELD STRENGTH**
- **B: UP TO AND INCLUDING 50% OF THE SPECIFIED MINIMUM YIELD STRENGTH**
- **C: UP TO AND INCLUDING 25% OF THE SPECIFIED MINIMUM YIELD STRENGTH**
- **D: FAILS TO MEET THE CRITERION FOR RATING C**

It is cautioned, however, that these generalized SCC ratings may involve an oversimplification in regard to the performance in unusual chemical environments. In this rating system, a quantitative (numerical) ranking was avoided because current SCC test methods do not justify finite values. Table 9 contains a tabulation of alloys and tempers, product forms, and stressing directions, with the classification of each into one of four categories from ASTM G64-91.

**TABLE 9 RELATIVE STRESS-CORROSION CRACKING RATINGS FOR HIGH-STRENGTH WROUGHT ALUMINUM PRODUCTS**

The associated stress levels for ranking A, B, C, D (see text) are not to be interpreted as threshold stresses and are not recommended for design. Documents such as MIL-HANDBOOK-5, MIL-STD-1568, NASC SD-24, and MSFC-SPEC-552A should be consulted for design recommendations. Resistance ratings are as follows: A, very high; B, high; C, intermediate; D, low (see text)

- (A) RATINGS APPLY TO STANDARD MILL PRODUCTS IN THE TYPES OF TEMPER INDICATED AND ALSO IN TX5X AND TX5XX (STRESS-RELIEVED) TEMPER. THEY MAY BE INVALIDATED IN SOME CASES BY USE OF NONSTANDARD THERMAL TREATMENTS, OR MECHANICAL DEFORMATION AT ROOM TEMPERATURE, BY THE USER.
- (B) TEST DIRECTION REFERS TO ORIENTATION OF DIRECTION IN WHICH STRESS IS APPLIED RELATIVE TO THE DIRECTIONAL GRAIN STRUCTURE TYPICAL OF WROUGHT ALLOYS, WHICH FOR EXTRUSIONS AND FORGINGS MAY NOT BE PREDICTABLE ON THE BASIS OF THE CROSS-SECTIONAL SHAPE OF THE PRODUCT: L, LONGITUDINAL; LT, LONG TRANSVERSE; ST, SHORT TRANSVERSE.
- (C) SECTIONS WITH WIDTH-TO-THICKNESS RATIOS EQUAL TO OR LESS THAN TWO, FOR WHICH THERE IS NO DISTINCTION BETWEEN LT AND ST PROPERTIES.
- (D) RATING NOT ESTABLISHED BECAUSE PRODUCT NOT OFFERED COMMERCIALY.
- (E) RATING IS ONE CLASS LOWER FOR THICKER SECTIONS; EXTRUSIONS, 25 MM (1 IN.) AND THICKER; PLATE AND FORGINGS, 38 MM (1.5 IN.) AND THICKER

**Precracked specimens** and linear elastic fracture mechanics (LEFM) methods of analysis have also been widely used for SCC testing in recent years. It was anticipated that this new technique would provide a more quantitative measure of the resistance to the propagation of SCC of an alloy in the presence of a flaw. The test results are generally presented in a graph of the crack velocity versus the crack driving force in terms of a stress-intensity factor,  $K$ . Although the full diagram is required to describe the performance of an alloy, numbers derived from the diagram such as the "plateau velocity" and the "threshold stress intensity" ( $K_{th}$  or  $K_{Isc}$ ) can be used to compare materials. Effective use of the precracked specimen testing procedures, however, have proven very difficult to standardize, and there currently is no commonly accepted rating system for rating the resistance to SCC based on these descriptors. It is noteworthy that ranking of alloys by these criteria corresponds well with the ratings obtained with smooth specimens in ASTM G64.

## Alloy Selection for SCC Resistance

In general, high-purity aluminum and low-strength aluminum alloys are not susceptible to SCC. Occurrence of SCC is chiefly confined to higher-strength alloy classes, such as 2XXX and 7XXX alloys and 5XXX Al-Mg alloys containing 3% or more Mg, particularly when loaded in the short-transverse orientation. Historically, in higher-strength alloys (e.g., aircraft structures) most service failures involving SCC of aluminum alloys have resulted from assembly or residual stresses acting in a short-transverse direction relative to the grain flow of the product (Ref 15, 18, 21). This is generally more troublesome for parts machined from relatively thick sections of rolled plate, extrusions, or forgings of complex shape where short-transverse grain orientation may be exposed. The specific alloy/temper combinations 7079-T6 (now obsolete), 7075-T6, and 2024-T3 have contributed to 90% of all service SCC failures of aluminum alloy products.

Within the high-strength alloy classes (2XXX, 7XXX, 5XXX), broad generalizations that relate susceptibility to SCC and strength or fracture toughness do not appear possible (Fig. 12). However, for certain alloys useful correlations of these properties with SCC resistance may be made over restricted ranges of the alloy's strength capability. For example, progressively overaging 7075 products from the T6 peak strength temper to T76 and T73 lowers strength but increases SCC resistance. However, "underaging" 7075 plate to T76 and T73 strength levels does not improve resistance to SCC.

**FIG. 12 RELATIONSHIP BETWEEN ESTIMATED STRESS-CORROSION CRACKING "THRESHOLD STRESSES" AND THE TENSILE YIELD STRENGTH (A) AND FRACTURE TOUGHNESS (B) OF A WIDE VARIETY OF ALUMINUM ALLOYS AND TEMPER. DATA SHOW THAT THERE IS NO GENERAL CORRELATION. SOURCE: REF 16**

Controls on alloy processing and heat treatment are key to assurance of high resistance to SCC without appreciable loss in mechanical properties and great accomplishments have been made. General developments are discussed below in several alloy classes.

**2XXX Alloys (Ref 28).** Thick-section products of 2XXX alloys in the naturally aged T3 and T4 tempers have low ratings of resistance to SCC in the short-transverse direction. Ratings of such products in other directions are higher, as are ratings of thin-section products in all directions. These differences are related to the effects of quenching rate (largely determined by section thickness) on the amount of precipitation that occurs during quenching. If 2XXX alloys in T3 and T4 tempers are heated for short periods in the temperature range used for artificial aging, selective precipitation along grain or subgrain boundaries may further impair their resistance.

Artificial aging of 2XXX alloys to precipitation-hardened T8 tempers provides relatively high resistance to exfoliation, SCC, and superior elevated-temperature characteristics with modest strength increase over their naturally aged counterparts (Ref 27). Longer heating, as specified for T6 and T8 tempers, produces more general precipitation and significant improvements in resistance to SCC. Precipitates are formed within grains at a greater number of nucleation sites during treatment to T8 tempers. These tempers require stretching, or cold working by other means, after quenching from the solution heat treatment temperature and before artificial aging. These tempers provide the highest resistance for SCC and the highest strength in 2XXX alloys. This significant progress in improving fracture toughness of 2XXX alloys in T8 tempers is demonstrated by alloy 2124-T851 (also known as Alcoa 417 Process 2024-T851), which has had over 30 years of experience in military aircraft with no record of SCC problems. Typical data on 2XXX alloys are shown in Fig. 13.

**Aluminum-Lithium Alloys.** Some studies on aluminum-copper-lithium alloys indicate that these alloys have their highest resistance to SCC at or near peak-aged tempers. Underaging of these alloys (e.g., 2090) is detrimental; overaging decreases resistance only slightly. The susceptibility of the underaged microstructure has been attributed to the precipitation of an intermetallic constituent,  $Al_2CuLi$ , on grain boundaries during the early stages of artificial aging. This constituent is believed to be anodic to the copper-rich matrix of an underaged alloy, causing preferential dissolution and SCC. As aging time increases, copper-bearing precipitates form in the interior of the grains, thus increasing the anode-cathode area ratio in the microstructure to a more favorable value that avoids selective grain-boundary attack. Similar studies of stress-corrosion behavior are being conducted on aluminum-lithium-copper-magnesium alloys (e.g., 8090).

Newer Al-Li alloys have been developed that have lower lithium concentrations than 8090, 2090, and 2091. These alloys do not appear to suffer from the same technical problems. The first of the newer generation was Weldalite 049 which can attain a yield strength as high as 700 MPa and an associated elongation of 10%. A refinement of the original alloy, 2195, is being considered for cryogenic tanks for the U.S. Space Shuttle. Alloy 2195 offers many advantages over 2219 for cryogenic tanks. Its higher strength coupled with higher modulus and lower density can lead to significant weight savings. Alloy 2195 also has good corrosion resistance, excellent fatigue properties, has a higher strength and fracture toughness at cryogenic temperatures than at room temperature, can be near-net shaped formed, and can be welded with proper precautions. However, further development work is required to identify optimum processing conditions that will ensure that the required combination of strength and fracture properties is obtained in the final product.

Other alloys containing less than 2% Li are being considered. Preliminary work indicates that new Al-Li alloy plate can be developed to provide a superior combination of properties for the bulkheads of high-performance aircraft, and analyses indicate that new Al-Li alloy flat-rolled products and extrusions would be competitive with polymer matrix composites for the horizontal stabilizer of commercial jetliners.

**5XXX Alloys (Ref 28).** These strain-hardening alloys do not develop their strength through solution heat treatment; rather, they are processed to H3 tempers, which require a final thermal stabilizing treatment to eliminate age softening, or to H2 tempers, which require a final partial annealing. The H116 or H117 tempers are also used for high-magnesium 5XXX alloys and involve special temperature control during fabrication to achieve a microstructural pattern of precipitate that increases the resistance of the alloy to intergranular corrosion and SCC. The alloys of the 5XXX series span a wide

range of magnesium contents, and the tempers that are standard for each alloy are primarily established by the magnesium content and the desirability of microstructures highly resistant to SCC and other forms of corrosion.

Although 5XXX alloys are not heat treatable, they develop good strength through solution hardening by the magnesium retained in solid solution, dispersion hardening by precipitates, and strain-hardening effects. Because the solid solutions in the higher-magnesium alloys are more highly supersaturated, the excess magnesium tends to precipitate out as  $Mg_2Al_3$ , which is anodic to the matrix. Precipitation of the phase with high selectivity along grain boundaries, accompanied by little or no precipitation within grains, may result in susceptibility to SCC.

The probability that a susceptible microstructure will develop in a 5XXX alloy depends on magnesium content, grain structure, amount of strain hardening, and subsequent time/temperature history. Alloys with relatively low magnesium contents, such as 5052 and 5454 (2.5 and 2.7% Mg, respectively), are only mildly supersaturated; consequently, their resistance to SCC is not affected by exposure to elevated temperatures. In contrast, alloys with magnesium contents exceeding about 3%, when in strain-hardened tempers, may develop susceptible structures as a result of heating or even after very long times at room temperature. For example, the microstructure of alloy 5083-O (4.5% Mg) plate stretched 1% is relatively free of precipitate (no continuous second-phase paths), and the material is not susceptible to SCC. Prolonged heating below the solvus, however, produces continuous precipitate, which results in susceptibility.

**6XXX Alloys (Ref 28).** The service record of 6XXX alloys shows no reported cases of SCC. In laboratory tests, however, at high stresses and in aggressive solutions, cracking has been demonstrated in 6XXX alloys of particularly high alloy content, containing silicon in excess of the  $Mg_2Si$  ratio and/or high percentages of copper.

**7XXX Alloys Containing Copper (Ref 28).** The 7XXX series alloy that has been used most extensively and for the longest period of time is 7075, an aluminum-zinc-magnesium-copper-chromium alloy. Introduced in 1943, this aircraft construction alloy was initially used for products with thin sections, principally sheet and extrusions. In these products, quenching rate is normally very high, and tensile stresses are not encountered in the short-transverse direction; thus, SCC is not a problem for material in the highest-strength (T6) tempers. When 7075 was used in products of greater size and thickness, however, it became apparent that such products heat treated to T6 tempers were often unsatisfactory. Parts that were extensively machined from large forgings, extrusions, or plate were frequently subjected to continuous stresses, arising from interference misfit during assembly or from service loading, that were tensile at exposed surfaces and aligned in unfavorable orientations. Under such conditions, SCC was encountered in service with significant frequency (Ref 29).

The problem resulted in the introduction (in about 1960) of the T73 tempers for thick-section 7075 products. The precipitation treatment used to develop these tempers requires two-stage artificial aging, the second stage of which is done at a higher temperature than that used to produce T6 tempers. During the preliminary stage, a fine, high-density precipitation dispersion is nucleated, producing high strength. The second stage is then used to develop resistance to SCC and exfoliation. The additional aging treatment required to produce 7075 in T73 tempers, reduces strength to levels below those of 7075 in T6 tempers. Excellent test results for 7075-T73 have been confirmed by extensive service experience in various applications. Environmental testing has demonstrated that 7075-T73 resists SCC even when stresses are oriented in the least favorable direction, at stress levels up to 300 MPa (44 ksi). Under similar conditions, the maximum stress at which 7075-T6 resists cracking is about 50 MPa (7 ksi).

Utilizing T7-type overaged tempers is a primary way to ensure improved resistance to exfoliation and SCC in 7XXX alloys. The T73 temper for alloy 7075 was the first aluminum alloy temper specifically developed to provide high resistance to stress-corrosion cracking with acceptable strength reduction from the T6 temper. Favorable evidence of this alloy's high resistance covers over 35 years of testing experience and extensive use in critical applications with no reported instances of failure in service by stress-corrosion cracking. This experience surpasses that of all other high-strength aluminum alloys and has become a standard of comparison for rating newer alloys and tempers (Ref 30).

Several commercial 7XXX alloys (7049-T73 and T76, 7175-T74 and 7050-T73, T74, and T76) offer combinations of strength, fracture toughness, and resistance to SCC superior to those combinations provided by conventional high-strength alloys, such as 7075-T6 and 7079-T6 (Ref 27). Alloys 7x49 and 7x50 were developed specifically for optimum combinations of the above properties in thick sections. Increased copper content provided good balance of strength and SCC resistance, while restriction of the impurity elements iron and silicon provided high toughness. Of particular note are 7149-T7451 and 7150-T7451 plate alloys, which offers optimum combinations of toughness, SCC resistance, and strength. Certain high-strength 7XXX alloys with lower copper content, such as 7079 and weldable 7005, exhibit excessive strength reduction when overaged to a T73-type temper, and a commercial stress-corrosion-resistant temper does not exist for these alloys. When using these alloys in existing commercial tempers, appreciable short-transverse

tensile stresses, about 10 ksi (69 MPa) or above, should be avoided where exposure to an aggressive environment is of concern.

Alloy 7175, a variant of 7075, was developed for forgings. In the T74 temper, 7175 alloy forgings have strength nearly comparable to that of 7075-T6 and has better resistance to SCC (Fig. 14). Newer alloys--such as 7049 and 7475, which are used in the T73 temper, and 7050, which is used in the T74 temper--couple high strength with very high SCC resistance and improved fracture toughness. The superior performance is evident for alloys in the T7 tempers (Fig. 15) (Ref 31, 32).

**FIG. 14 CRACK PROPAGATION RATES IN STRESS CORROSION TESTS USING 7XXX SERIES ALUMINUM ALLOYS, 25 MM THICK, DOUBLE CANTILEVER BEAM, SHORT-TRANSVERSE ORIENTATION OF DIE TRANSVERSE ORIENTATION OF DIE FORGINGS AND PLATE, ALTERNATE IMMERSION TESTS, 23 °C. SOURCE: M.O. SPEIDEL, MET. TRANS., VOL 6A, 1975, P 631**

FIG. 15 SCC PROPAGATION RATES FOR VARIOUS ALUMINUM ALLOY 7050 PRODUCTS. DOUBLE-BEAM SPECIMENS (S-L) BOLT-LOADED TO POP-IN AND WETTED THREE TIMES DAILY WITH 3.5% NaCl. DATA FOR ALLOYS 7075-T651 AND 7079-T651 ARE FROM REF 31; SOURCE: REF 32

The T76 tempers, which also require two-stage artificial aging and which are intermediate to the T6 and T73 tempers in both strength and resistance to SCC, are developed in copper-containing 7XXX alloys for certain products. Comparative ratings of resistance for various products of all these alloys, as well as for products of 7178, are given in Table 9.

The microstructural differences among the T6, T73, and T76 tempers of these alloys are differences in size and type of precipitate, which changes from predominantly Guinier-Preston (GP) zones in T6 tempers to  $\eta'$ , the metastable transition form of  $\eta(\text{MgZn}_2)$ , in T73 and T76 tempers. None of these differences can be detected by optical metallography. In fact, even the resolutions possible in transmission electron microscopy are insufficient for determining whether the precipitation reaction has been adequate to ensure the expected level of resistance to SCC. For quality assurance, copper-containing 7XXX alloys in T73 and T76 tempers are required to have specified minimum values of electrical conductivity and, in some cases, tensile yield strengths that fall within specified ranges. The validity of these properties as measures of resistance to SCC is based on many correlation studies involving these measurements, laboratory and field stress-corrosion tests, and service experience.

**T77 Tempers.** Until recently, overaging to T76, T74, and T73 tempers increased exfoliation resistance with a compromise in strength; strength was sacrificed from 5 to 20% to provide adequate resistance. The T77 temper, however, provides resistance to exfoliation with no sacrifice in strength, and resistance to SCC superior to that of 7075-T6 and 7150-T6. The highest strength aluminum alloy products, 7055 plate and extrusions, are supplied primarily in the T77 temper. Alloy 2024 products are also resistant to intergranular corrosion in the T8 temper, but fracture toughness and resistance to the growth of fatigue cracks suffer relative to 2024-T3.

New processing for 7150, resulting in 7150-T77, offers a higher strength with the durability and damage tolerance characteristics matching or exceeding those of 7050-T76. Extrusions of 7150-T77 have been selected by Boeing as fuselage stringers for the upper and lower lobes of the new 777 jetliner because of the superior combination of strength, corrosion and SCC characteristics, and fracture toughness. Alloy 7150-T77 plate and extrusions are being used on the new C17 cargo transport. Use of this material saved considerable weight because corrosion performance of 7150-T6 was deemed to be inadequate.

The implementation of the T77 temper for 7150 was followed by development of new 7XXX products for compressively loaded structures. Alloy 7055-T77 plate and extrusions offer a strength increase of about 10% relative to that of 7150-T6 (almost 30% higher than that of 7075-T76). They also provide a high resistance to exfoliation corrosion similar to that of 7075-T76 with fracture toughness and resistance to the growth of fatigue cracks similar to that of 7150-T6. In contrast to the usual loss in toughness of 7XXX products at low temperatures, fracture toughness of 7055-T77 at  $-65^\circ\text{F}$  (220 K) is similar to that at room temperature. Resistance to SCC is intermediate to those of 7075-T6 and 7150-T77 products. The attractive combination of properties of 7055-T77 is attributed to its high ratios of Zn/Mg and Cu/Mg. When aged to T77 this composition provides a microstructure at and near grain boundaries that is resistant to intergranular fracture and to intergranular corrosion.

**Copper-free 7XXX Alloys (Ref 28).** Wrought alloys of the 7XXX series that do not contain copper are of considerable interest because of their good resistance to general corrosion, moderate-to-high strength, and good fracture toughness and formability. Alloys 7004 and 7005 have been used in extruded form and, to a lesser extent, in sheet form for structural applications. More recently introduced compositions, including 7016, 7021, 7029, and 7146, have been used in automobile bumpers formed from extrusions or sheet.

As a group, copper-free 7XXX alloys are less resistant to SCC than other types of aluminum alloys when tensile stresses are developed in the short-transverse direction at exposed surfaces. Resistance in other directions may be good, particularly if the product has an unrecrystallized microstructure and has been properly heat treated. Products with recrystallized grain structures are generally more susceptible to SCC as a result of residual stress induced by forming or mechanical damage after heat treatment. When cold forming is required, subsequent solution heat treatment or precipitation heat treatment is recommended. Applications of these alloys must be carefully engineered, and consultation among designers, application engineers and product producers, or suppliers is advised in all cases.

Overaging (T7x tempers) improves the SCC resistance of copper-containing alloys such as 7075, whereas for the low-copper alloys, like 7079, a considerable amount of overaging is required with severe strength penalty to improve the stress-corrosion resistance. In general, increasing the copper content decreases the crack velocity (Fig. 16) (Ref 33). The effect can be mainly attributed to the change in the electrochemical activity of the precipitates as a function of their copper content. In the 7XXX series alloys the  $\eta$  phase is very active and anodic with respect to the film-covered matrix. If the alloy contains copper, copper both dissolves in the matrix and enters the  $\eta$  phase, making both more noble. As a result, the mixed potential at the crack tip shifts to a more noble value. The decrease in the crack velocity can then be attributed to the reduced rate of dissolution of the more noble precipitates, or reduced rate of hydrogen ion reduction and hydrogen adsorption at the crack tip at the more noble potential.

**FIG. 16 EFFECT OF OVERAGING AND COPPER CONTENT ON SCC RESISTANCE OF AN AL-ZN-MG ALLOY IN 3.5% NaCl SOLUTION. SOURCE: REF 33**

**Casting Alloys (Ref 28).** The resistance of most aluminum casting alloys to SCC is sufficiently high that cracking rarely occurs in service. The microstructures of these alloys are usually nearly isotropic; consequently, resistance to SCC is unaffected by orientation of tensile stresses.

Accelerated laboratory tests, natural-environment testing, and service experience indicate that alloys of the aluminum-silicon 4XX.X series, 3XX.X alloys containing only silicon and magnesium as alloying additions, and 5XX.X alloys with magnesium contents of 8% or lower have virtually no susceptibility to SCC. Alloys of the 3XX.X group that contain copper are rated as less resistant, although the numbers of castings of these alloys that have failed by SCC have not been significant.

Significant SCC of aluminum alloy castings in service has occurred only in the highest-strength aluminum-zinc-magnesium 7XX.X alloys and in the aluminum-magnesium alloy 520.0 in the T4 temper. For such alloys, factors that require careful consideration include casting design, assembly and service stresses, and anticipated environmental exposure.

### Fatigue Life of Aluminum Alloys

Although high-strength aluminum alloys with high toughness have drastically lowered the probability of catastrophic failures in high-performance structures, corrosion fatigue requirements will continue to bear the burden for low-maintenance, durable, long-life structures. Good design, attention to structural details, and reliable inspection are of primary importance to controlling fatigue, and designers have traditionally considered these factors more important than alloy choice. However, a primary challenge facing designers and the materials engineer alike is extension of fatigue life and/or increased structural efficiency through optimum selection and use of fatigue-resistant alloys.

Differences in the fatigue performance of engineering materials can be translated into longer life, reduced weight, and reduced maintenance costs of present engineering structures. Fatigue improvements in aluminum, titanium, and steel alloys have been demonstrated through modifications to alloy composition, fabricating practice, and processing controls. Better understanding of fatigue mechanics has led to new hypotheses having the potential to lead to commercialization of improved alloys for fatigue.

Early work at Alcoa on large numbers of smooth and notched specimens demonstrated that wide variations in commercial aluminum alloys caused little or no detectable difference in fatigue strengths (Ref 34, 35). When early fatigue crack growth experiments categorized fatigue crack growth rates of aluminum alloys into one band, for example Fig. 17, it was generalized that fatigue resistance of all aluminum alloys were alike (Ref 36, 37). As a consequence of these early beliefs, further efforts to develop fatigue-resistant aluminum alloys were minimized, and though several conceptual improvements have been advanced in laboratory experiments (Ref 13), none to date have reached commercial levels. For alloys developed to provide improved combinations of properties such as strength, corrosion resistance, and fracture

toughness, fatigue resistance was determined as a last step before products were offered for sale, only to ensure that fatigue resistance was not degraded.

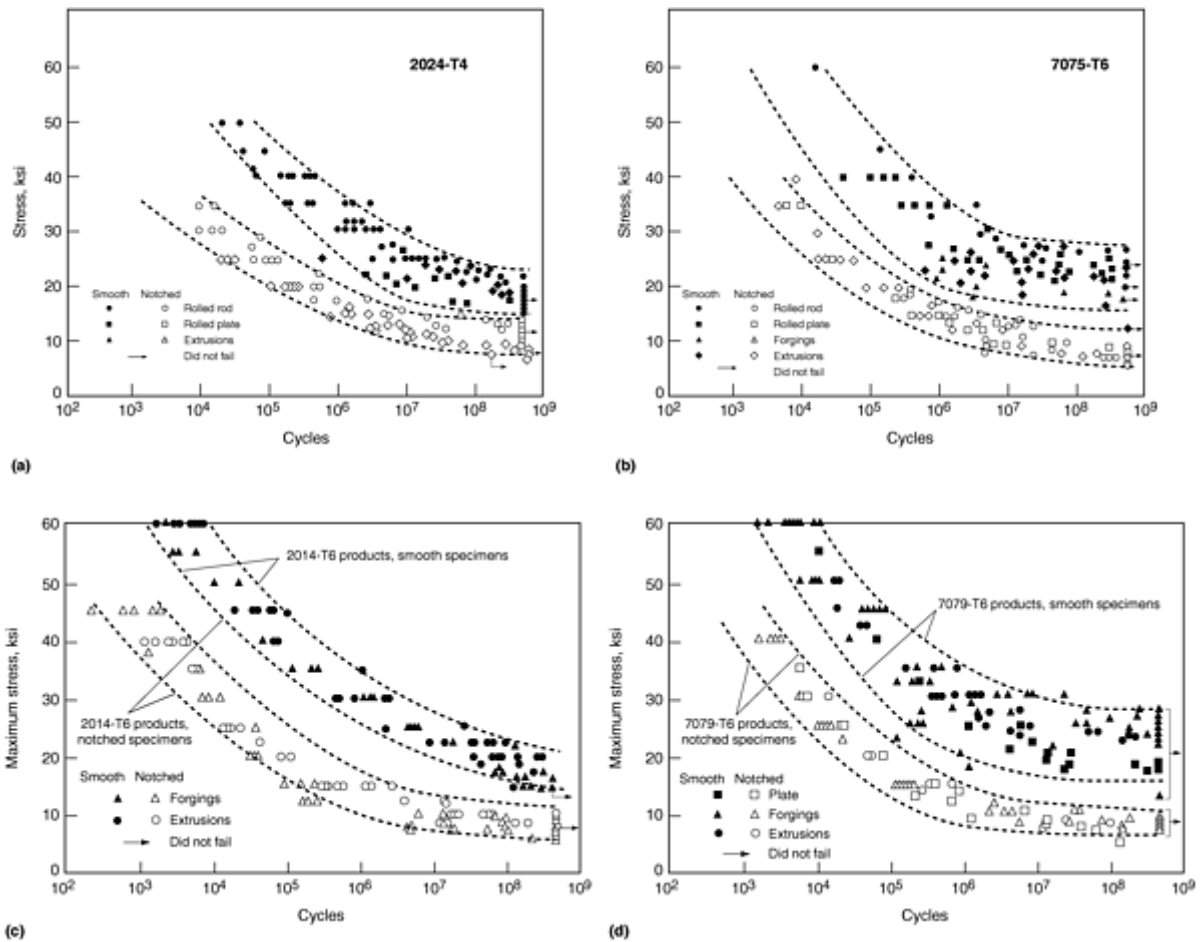

FIG. 17 SCATTER BAND LIMITS FOR FATIGUE CRACK GROWTH RATE BEHAVIOR FOR A RANGE OF ALUMINUM ALLOYS. SOURCE: REF 26

Despite early conclusions from laboratory data, users discovered that certain aluminum alloys performed decidedly better than others in service when fluctuating loads were encountered, and therefore any generalization that all aluminum alloys are alike in fatigue is not wholly appropriate for design use. For example, alloy 2024-T3 has long been recognized as a better fatigue performer in service than alloy 7075-T6. In part, this may be explained by designers using higher design stresses on the basis of higher static strength of 7075-T6. However, results of Fig. 18(b) show alloy 7075-T6 to have broader scatter for smooth specimens and a lower bound of performance for severely notched specimens that is below that for alloy 2024-T4 (Fig. 18a). Broader scatter is also evident for 7079 compared to 2014 (Fig. 18c and d).

**FIG. 18 VARIATION IN ROTATING-BEAM FATIGUE FOR (A) 2024-T4, (B) 7075-T6, (C) 2014-T6, AND (D) 7079-T6 ALLOYS. NOTCHES (60°) WERE VERY SHARP ( $K_T > 12$ ) WITH A RADIUS OF ABOUT 0.0002 IN. RESULTS ARE FROM OVER A THOUSAND ROTATING-BEAM TESTS PERFORMED IN THE 1940S. SOURCES: R. TEMPLIN, F. HOWELL, AND E. HARTMANN, "EFFECT OF GRAIN-DIRECTION ON FATIGUE PROPERTIES OF ALUMINUM ALLOYS" ALCOA, 1950 AND *ASTM PROCEEDINGS*, VOL 64, P 581-593**

Most fatigue data were obtained from the basic stress-controlled cycling of notched and unnotched coupons in rotating-beam, axial, and flexure-type sheet tests. Test results from coupon specimens are useful for rating fatigue resistance of materials. However, material selection by the traditional  $S-N$  approach requires large numbers of material characterization tests for each material to simulate a myriad of possible service conditions.  $S-N$  data are also strongly influenced by many factors, such as specimen configuration, test environment, surface condition, load type, and stress ratio. Therefore, caution is required when translating coupon test results to a particular application. Evaluation of more than one material in component testing is needed to assist in final accurate material selection.

Nonetheless, extensive efforts have led to major improvements in the ability to characterize cyclic behavior and fatigue resistance of materials. Recognition of the importance of controlling basic elements of test procedure have led to development of recommended practices for establishing basic  $S-N$  fatigue data (Ref 38). The emerging disciplines of strain control fatigue and fracture mechanics have greatly enhanced understanding of fatigue processes. The strain control approach is aimed primarily at low-cycle fatigue crack initiation and early fatigue crack growth, while fracture mechanics concepts address the propagation of an existing crack to final failure. Each of these approaches is reviewed in the following sections.

### S-N Fatigue

High-cycle fatigue characteristics commonly are examined on the basis of cyclic *S-N* plots of rotating-beam, axial, or flexure-type sheet tests. Many thousands of tests have been performed, and a collection of aluminum alloy *S-N* data is contained in the publication *Fatigue Data Book: Light Structural Alloys* (ASM, 1995). Early work on rotating-beam tests is summarized in Fig. 19. There seems to be greater spread in fatigue strengths for unnotched specimens than for notched specimens. This appears to be evidence that the presence of a notch minimizes differences, thus suggesting similar crack propagation after crack initiation with a sharp notch. In this context, the spread in smooth fatigue life is partly associated with variations in crack initiation sources (at surface imperfections or strain localizations). In general, however, the *S-N* approach does not provide clear distinctions in characterizing the crack initiation and crack propagation stages of fatigue.

FIG. 19 COMPARISON OF FATIGUE STRENGTH BANDS FOR 2014-T6, 2024-T4, AND 7075-T6 ALUMINUM ALLOYS FOR ROTATING-BEAM TESTS. SOURCE: R. TEMPLIN, F. HOWELL, AND E. HARTMANN, "EFFECT OF GRAIN-DIRECTION ON FATIGUE PROPERTIES OF ALUMINUM ALLOYS," ALCOA, 1950

The *S-N* response curves for rotating-beam fatigue strength of unnotched aluminum alloys tend to level out as the number of applied cycles approaches 500 million. This allows some rating of fatigue endurance, and estimated fatigue limits from rotating-beam tests have been tabulated for many commercial aluminum alloys (Table 10). Fatigue limits should not be expected in aggressive environments, as *S-N* response curves don't tend to level out when corrosion fatigue occurs. Rotating-beam strengths determined in the transverse direction are not significantly different from test results in the longitudinal direction. The scatter band limits in Fig. 20 show relatively small effects attributable to working direction, particularly for the notched fatigue data.

Rotating-beam data have also been analyzed to determine whether fatigue strength can be correlated with static strength. From a plot of average endurance limits (at  $5 \times 10^8$  cycles) plotted against various tensile properties (Fig. 21), there does not appear to be any well-defined quantitative relation between fatigue limit and static strength. This is consistent with results for most nonferrous alloys. It should be noted that proportionate increases in fatigue strength from tensile strengths do appear lower for age-hardened aluminum alloys than for strain-hardened alloys (Fig. 22). A similar trend appears evident for fatigue strength at  $5 \times 10^7$  cycles (Fig. 23).

Effect of Environment. A key source of variability in  $S-N$  data is environment (Ref 39, 40, 41). Even atmospheric moisture is recognized to have a little corrosive effect on fatigue performance of aluminum alloys. Much high-cycle  $S-N$  testing has been carried out in uncontrolled ambient lab air environments, thereby contributing to scatter in existing data. This factor should be recognized when comparing results of different investigations.

Most aluminum alloys experience some reduction of fatigue strength in corrosive environments such as seawater, especially in low-stress, long-life tests (e.g., Fig. 24). Unlike sustained-load SCC, fatigue degradation by environment may occur even when the direction of principal loading with respect to grain flow is other than short-transverse. Fatigue response to environment varies with alloy, so final alloy selection for design should address this important interaction. When accumulating data for this purpose, it is recommended that any testing be conducted in a controlled environment, and preferably the environment of the intended application. However, an environment known to be more severe than that encountered in service is often used to conservatively establish baseline data and design guidelines. Because environmental interaction with fatigue is a rate-controlled process, interaction of time-dependent fatigue parameters such as frequency, waveform, and load history should be factored into the fatigue analysis (Ref 39, 40, 41).

**FIG. 24 AXIAL STRESS FATIGUE STRENGTH OF 0.8 MM 2024, 7075, AND CLAD SHEET IN AIR AND SEAWATER,  $R = 0$ . SOURCE: REF 33**

Typically, the fatigue strengths of the more corrosion-resistant 5XXX and 6XXX aluminum alloys and tempers are less affected by corrosive environments than are higher-strength 2XXX and 7XXX alloys, as indicated by Fig. 25. Corrosion fatigue performance of 7XXX alloys may, in general, be upgraded by overaging to the more corrosion-resistant T7 tempers (Ref 42, 43, 44, 45, 46, 47), as indicated by results shown in Fig. 26 and 27. With 2XXX alloys, the more corrosion-resistant, precipitation-hardened T8-type tempers provide a better combination of strength and fatigue resistance at high endurance than naturally aged T3 and T4 tempers. However, artificial aging of 2XXX alloys is accompanied by loss in toughness with resultant decrease in fatigue crack growth resistance at intermediate and high stress intensities (Ref 45, 46).

FIG. 27 CYCLIC STRESS INTENSITY RANGE,  $\Delta K$ , VS. CYCLIC FATIGUE CRACK GROWTH RATE,  $\Delta a/\Delta N$ , OF LABORATORY-FABRICATED HIGH-STRENGTH 7XXX ALUMINUM ALLOYS

Interaction of a clad protective system with fatigue strength of alloys 2024-T3 and 7075-T6 in air and seawater environments is shown in Fig. 24. In air, the cladding appreciably lowers fatigue resistance. In seawater, benefits of the cladding are readily apparent.

**Reduced Porosity Materials.** \*The size of microporosity in commercial products is affected by the forming processes used in their production. A recent program was undertaken to determine whether the fatigue strength could be improved by the control of microporosity. Five variants of 7050 plate were produced to provide a range of microstructures to quantify the effects of intrinsic microstructural features on fatigue durability (Table 11). The first material, designated "old-quality" material, was produced using production practices typical of those used in 1984. The material is characterized by extensive amounts of centerline microporosity. Despite the centerline microporosity, this material still meets all existing mechanical property specifications for thick 7050 plate. Current quality production material, designated "new-quality" material, was also used, characterized by reduced levels of centerline microporosity compared to the old-quality material. The new-quality material represents the current benchmark for commercially available material. The processing methods used in the production of the new-quality material are a result of a statistical quality control effort to improve 7050 alloy thick plate (Ref 48). Material taken from two plant-scale production lots of each quality level provided the material for this program. Both materials are 5.7 in. thick 7050-T7451 plate. Static mechanical property characterization of the two 7050 plate pedigrees showed no significant differences in properties other than an increase in short transverse elongation for the new-quality material (Ref 49), and both materials meet the AMS material specification minimums. The fact that both materials meet the property requirements of the AMS specification underscores the limitation of existing specifications in that they do not differentiate intrinsic metal quality.

TABLE 11 SUMMARY OF THE 7050 PLATE MATERIALS USED IN THE STUDY OF THE EFFECT OF MICROPOROSITY ON FATIGUE

MATERIAL	PRODUCT THICKNESS, IN.	KEY MICROSTRUCTURAL FEATURES
----------	------------------------	------------------------------

OLD-QUALITY PLATE	5.7	LARGE POROSITY
NEW-QUALITY PLATE	5.7	POROSITY
LOW-POROSITY PLATE	6.0	SMALL POROSITY, CONSTITUENT PARTICLES
LOW-PARTICLE PLATE	6.0 (T/4)	SMALL CONSTITUENTS, THICK PLATE GRAIN STRUCTURE
THIN PLATE	1.0	REFINED GRAIN SIZE AND CONSTITUENT PARTICLES

**Effect of Microporosity on Fatigue.** Smooth axial stress fatigue tests were performed for both the old-quality and the new-quality plate materials. The tests were done on round bars with a gage diameter of 12.7 mm (0.5 in.). Gage sections were sanded longitudinally to remove circumferential machining marks. Testing was done at a maximum stress of 240 MPa (35 ksi), a stress ratio  $R = 0.1$ , and cyclic frequency of 10 Hz in laboratory air. The specimen orientation was long-transverse (L-T) relative to the parent plate. The specimens were removed from the midthickness (T/2) plane of the plate where microporosity concentration is the greatest (Ref 49). The lifetimes of the specimens are plotted in Fig. 28 on a cumulative failure plot, where the data are sorted in order of ascending lifetime and ordinate is the percentile ranking of the specimens relative to the total number of tests. Thus, the lifetime corresponding to the 50% point on the ordinate represents the median lifetime, where half of the specimens failed prior to that lifetime and half failed at longer lifetimes. The data show that the cumulative distribution of fatigue lifetimes for the new-quality material is substantially longer than for the old-quality material.

**FIG. 28 CUMULATIVE SMOOTH FATIGUE LIFETIME DISTRIBUTORS FOR OLD-QUALITY AND NEW-QUALITY PLATE (SEE TEXT FOR DEFINITIONS). TESTS CONDUCTED AT 240 MPa (35 KSI) MAX STRESS,  $R = 0.1$**

Fatigue tests were also performed for the old-and new-quality materials using flat specimens containing open holes. Tests were performed at four stress levels for each material pedigree at a stress ratio of  $R = 0.1$  and cyclic frequency of 25 Hz in laboratory air. As with the round specimens, L-T specimens were removed from the T/2 plane of the plate. The holes were deburred by polishing with diamond compound only on the corners and not in the bore of the hole; this resulted in

slight rounding of the corners. The fatigue lifetime data are plotted in Fig. 29 as an  $S-N$  plot. Also plotted for both materials are the 95% confidence limits for the  $S-N$  curves. The confidence limits were obtained from a Box-Cox analysis of the data, which enables statistical determination of the mean  $S-N$  response and the 95% confidence limits (Ref 39). The data clearly show that, at equivalent stresses, the new-quality material exhibited longer lifetimes than the old-quality material.

FIG. 29 OPEN-HOLE FATIGUE LIFETIMES FOR NEW-QUALITY AND OLD-QUALITY PLATE (SEE TEXT FOR DEFINITIONS). TESTS CONDUCTED AT  $R = 0.1$

### Strain Control Fatigue

Considerable evidence suggests that failure data are more usefully presented in the form of strain-life curves, and that strain-based cumulative-damage life predictions are generally more reliable than conventional stress-based approaches (Ref 51, 52, 53). Strain-based prediction methods are capable of addressing interaction effects of variable load history and are better suited to handle "what if" situations than traditional stress approaches. In addition, they require a significantly reduced number of material characterization and component verification tests to make a material selection and/or design decision. Strain control fatigue is also essential in the understanding of crack initiation because, without localized plastic strain at areas of stress concentration in a structure, failure cannot occur. At high plastic strains, fatigue experiments on aluminum alloys (Ref 54) have shown that homogeneous slip (i.e., distribute plastic strain and avoid strain concentration sites) prolongs fatigue life to crack initiation. Recognized factors that promote homogeneous slip and/or increase low-cycle fatigue life are decreased coherency of strengthening particles, increased magnesium content, and minimization and more uniform distribution of second-phase particles, which serve as initiation sites. Effects of alloy microstructure on fatigue initiation life depend on the level of strain.

In general, strain-life fatigue is based on the division of cyclic stress-strain response into plastic and elastic components (Fig. 30a), where the relation between stress and strain depends on the strength-ductility properties of the material (Fig. 30b) and also the cyclic hardening or softening of the material. For most metals, stress-strain hysteresis behavior (Fig. 30) is not constant, as cyclic softening or hardening can occur by reversed loading and cyclic straining. Generally (Ref 55, 56, 57), materials that are initially soft exhibit cyclic hardening, and materials that are initially hard undergo cyclic softening.

(a)

(b)

**FIG. 30 STRESS-STRAIN HYSTERESIS LOOP UNDER CYCLIC LOADING. (A) ELASTIC AND PLASTIC STRAIN RANGE. (B) HYSTERESIS LOOPS SHOWING IDEALIZED STRESS-STRAIN BEHAVIOR FOR DIFFERENT TYPES OF MATERIALS.**

With strain-life fatigue, the elastic and plastic components may be separated and plotted on a strain life curve (Fig. 31). A plot on logarithmic coordinates of the plastic portion of the strain amplitude (half the plastic strain range) versus the fatigue life often yields a straight line, described by the equation

$$\frac{\Delta \epsilon_p}{2} = \epsilon'_f (2N_f)^c \quad (\text{EQ 3})$$

where  $\epsilon'_f$  is the fatigue ductility coefficient,  $c$  is the fatigue ductility exponent, and  $N_f$  is the number of cycles to failure ( $2N_f$  is the number of load reversals). In contrast, elastic strains influence fatigue behavior under long-life conditions, where a stress-based analysis of fatigue is charted by plotting stress amplitude (half the stress range) versus fatigue life on logarithmic coordinates. The result is a straight line having the equation

$$\frac{\Delta \sigma}{2} = \sigma'_f (2N_f)^b \quad (\text{EQ 4})$$

where  $\sigma'_f$  is the fatigue strength coefficient and  $b$  is the fatigue strength exponent.

Where:  $\sigma'_f$  = Fatigue strength ductility coefficient  
 $\epsilon'_f$  = Fatigue ductility coefficient  
 $b$  = Fatigue strength exponent  
 $c$  = Fatigue ductility exponent

FIG. 31 STRAIN CONTROL FATIGUE LIFE AS A FUNCTION OF ELASTIC-, PLASTIC-, TOTAL-STRAIN AMPLITUDE

The elastic strain range is obtained by dividing Eq 4 by Young's modulus  $E$ :

$$\frac{\Delta \epsilon_e}{2} = \frac{\sigma'_f}{E} (2N_f)^b \quad (\text{EQ 5})$$

The total strain range is the sum of the elastic and plastic components, obtained by adding Eq 3 and 5 (see Fig. 31):

$$\frac{\Delta \epsilon}{2} = \epsilon'_f (2N_f)^c - \frac{\sigma'_f}{E} (2N_f)^b \quad (\text{EQ 6})$$

For low-cycle fatigue conditions (frequently fewer than about 1000 cycles to failure), the first term of Eq 6 is much larger than the second; thus, analysis and design under such conditions must use the strain-based approach. For long-life fatigue conditions (frequently more than about 10,000 cycles to failure), the second term dominates, and the fatigue behavior is adequately described by Eq 4. Thus, it becomes possible to use Eq 4 in stress-based analysis and design.

This approach offers the advantage that both high-cycle and low-cycle fatigue can be characterized in one plot. From this relationship it is seen that long-life fatigue resistance is governed by the elastic line, while short-life fatigue resistance is governed by the plastic line (Ref 58). Within a bounded range of alloy types and microstructures, controlled strain fatigue lives greater than  $10^4$  cycles typically increase with increasing strength. On the other hand, low-cycle controlled strain fatigue lives for the same alloys generally increase with increasing ductility where ductility can be defined as  $\ln(1/1-RA)$ ,  $RA$  being reduction of area determined from the standard tension test. The reciprocal strength-ductility relationship implies that materials selected on the basis of long-life resistance may not perform as well in low-cycle applications, and vice-versa. This is illustrated in Fig. 32 by the crossover in the strain-life relationships of X7046, a high-strength alloy, and 5083, a moderate-strength/high-ductility alloy. Results of strain control fatigue experiments on high-strength 7XXX laboratory-fabricated microstructures (Fig. 33) show similar crossover trends that can be correlated with strength and ductility. The observed crossovers imply that alloy selection, dependent on estimation of fatigue initiation life, requires identification of the most damaging cycles in the component fatigue spectrum for proper interpretation of mechanical property tradeoffs. This is accomplished using knowledge of the component strain spectrum, from strain gaged parts and/or stress analysis, and cumulative damage assessment of strain-life data. A compilation of fatigue strain-life parameters for various aluminum alloys is given in Table 12 and the appendix "Parameters for Estimating Fatigue Life" in this Volume. Corresponding monotonic properties are given in Table 13. Additional details on state-of-the-art fatigue analysis methods are given in Ref 59, 60, 61, 62, and Section 3 "Fatigue Strength Prediction and Analysis" in this Volume.

### Microstructure and Strain Life

\*\*

Plastic strain has been recognized as a controlling parameter in fatigue, and microstructures that homogeneously distribute the strain are desirable. Any microstructural feature that concentrates plastic strain or that results in an inhomogeneous distribution of plastic strain leads to undesirable local stress concentrations and large slip offsets at surfaces. Mechanisms representing these effects are illustrated schematically in Fig. 34, which shows two microstructural features that can result in strain localization: shearable precipitates, Fig. 34(a) and precipitate free zones (PFZs), Fig. 34(b). These can lead to early crack nucleation and enhanced metal/environment interactions.

**FIG. 34 SCHEMATIC REPRESENTATION OF TWO MICROSTRUCTURAL FEATURES THAT RESULT IN STRAIN LOCALIZATION.  $\tau^*$  REPRESENTS STRESS CONCENTRATION AT INDICATED AREAS OF GRAIN BOUNDARIES. (A) SHEARABLE PRECIPITATES. (B) PRECIPITATE-FREE ZONES**

The following discussions briefly review the effect of shearable precipitates and PFZs on the strain life of aluminum alloys. These two microstructural features are considered because of their importance in commercial alloys. Inhomogeneous deformation similar to that in Fig. 34(a) can also occur in irradiated materials in which glide dislocations remove radiation defects, forming cleared channels of defect-free material. Low-stacking-fault-energy materials may also exhibit planar slip, but inhomogeneous deformation is not prevalent because softening in the slip plane does not occur. Inhomogeneous deformation similar to that in Fig. 34(b) may occur in two-phase materials having a soft and a hard phase. To some extent, localized deformation occurs in *all* materials at low stress and strain amplitudes.

The effect of shearable precipitates and PFZs on plastic-strain localization can be reduced by microstructural modification to improve fatigue life (see Table 14). The degree of plastic strain localization is primarily determined by the slip length and degree of age hardening. Because extensive age hardening and corresponding high yield strength are desirable, focus is placed on ways of improving the fatigue life by reducing the slip length. A reduction in grain size seems to be the most effective method for alloys that can contain both shearable precipitates and PFZs.

UNRECRYSTALLIZED STRUCTURES	IMPROVES	IMPROVES
REDUCTION OF GRAIN SIZE	IMPROVES	IMPROVES

STEPS IN GRAIN BOUNDARIES	NO EFFECT	IMPROVES
ALIGNMENT OF GRAIN BOUNDARIES	NO EFFECT	IMPROVES

To definitively determine the influence of microstructure on fatigue life, it may be necessary to test in the low-cycle fatigue (LCF) regime under stress as well as strain control. Some microstructural features, through their effect on cyclic deformation behavior and resulting softening and/or hardening, may improve or reduce the observed fatigue life, depending on the control mode. In addition, high-cycle fatigue (HCF) tests are important because in this region the influence of the yield stress usually dominates. It should also be emphasized that the microstructural parameters that accelerate or delay fatigue crack nucleation may have the opposite effect on fatigue crack propagation.

## Precipitate Shearing

Overaging homogenizes slip and increases fatigue resistance in the low-cycle region where "ductility-controlled" fatigue dominates. This behavior, as it relates to the formation of nonshearable precipitates, alters fatigue properties, as shown in the Coffin-Manson life plots of Fig. 35. The two curves are for an underaged (with shearable precipitates) and an overaged (with nonshearable precipitates) 7050 alloy having identical yield strengths and strain to fracture (Ref 63). The fatigue life of the overaged alloy is consistently longer than that of the underaged alloy. The curves converge at low and high plastic strain amplitudes in these strain-controlled tests for the following reasons: For large strain amplitudes, all slip is homogeneous, regardless of the deformation mechanism, primarily due to multiple-slip activation. For small strain amplitudes, the sample with nonshearable precipitates hardens more extensively (due to the generation of geometrically necessary dislocations) than the sample with shearable precipitates (which normally softens). Consequently, for a strain-controlled test, failure occurs earlier than anticipated for the samples with nonshearable precipitates. Larger differences between the two heat treatments would occur under stress-controlled conditions, because the samples that harden would resist plastic deformation and those that soften would not.

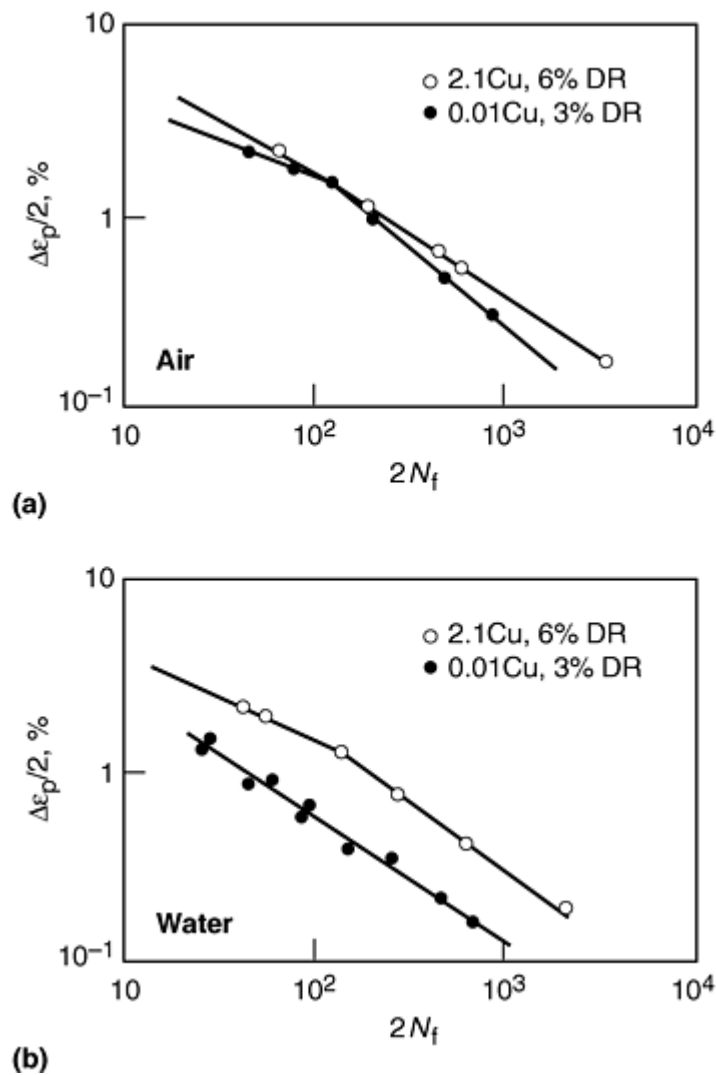

FIG. 35 STRAIN-LIFE CURVES FOR SAMPLES OF 7050 ALLOY WITH SHEARABLE PRECIPITATES (4 H AT 120 °C, OR 250 °F) AND NONSHEARABLE PRECIPITATES (96 H AT 150 °C, OR 300 °F)

Aggressive environments enhance the differences in fatigue life when one compares alloys having shearable precipitates (inhomogeneous deformation) with alloys having nonshearable precipitates (homogeneous deformation). This is illustrated by the Coffin-Manson life plots of LCF samples cycled in dry air and distilled water (Fig. 36). The aggressive H<sub>2</sub>O environment decreases the fatigue life of the alloy with shearable precipitates by almost an order of magnitude when compared with the inert environment for the same plastic strain amplitude. The aggressive environment has little or no effect on the alloy with nonshearable precipitates. The degree of coherency in these Al-Zn-Mg-Cu alloys (Ref 64) was modified by changing the copper concentration. Increasing the copper content in the strengthening precipitates of 7XXX alloys results in earlier loss of coherency (Ref 63) and increases the probability of dislocation looping when compared with alloys containing lesser amounts of copper with the same aging treatment. Cyclic deformation of the lower-copper-content alloys with shearable precipitates produced localized slip bands (Ref 64), which intensified metal/environment interactions. The nonshearable precipitates of the high-copper-content alloy prevented the occurrence of such inhomogeneous deformation.

**FIG. 36 STRAIN-LIFE CURVES FOR SAMPLES OF AL-ZN-MG-X CU ALLOYS WITH SHEARABLE PRECIPITATES (0.01% CU) AND NONSHEARABLE PRECIPITATES (2.1% CU). DR, DEGREE OF RECRYSTALLIZATION. (A) CYCLED IN DRY AIR. (B) CYCLED IN DISTILLED WATER. SOURCE: REF 64**

**Addition of Nonshearable Precipitates.** Although overaging homogenizes slip and increases the resistance of an alloy to fatigue crack nucleation, it normally results in a reduction in static strength. Consequently, it is sometimes beneficial to have a dispersion of nonshearable precipitates intermixed with shearable precipitates. Some commercial alloys have alloying additions (for example, manganese and chromium in 2XXX and 7XXX aluminum alloys, respectively) that form small (0.1 to 0.2  $\mu\text{m}$ ), incoherent dispersoids during high-temperature homogenization treatments. The primary purpose of these small intermetallic compounds is to control grain size and shape. However, they also disperse slip and inhibit the formation of intense slip bands. Therefore, plastic deformation is more homogeneous, and early crack nucleation due to intense slip bands is avoided.

Figure 37 shows the results of a stress-controlled test of two 2XXX alloys--one (X2024) contains only shearable precipitates and the other (2024) both shearable and nonshearable precipitates. At all stress levels, alloy 2024 has a much longer fatigue life than X2024. It is important to note that the alloys have comparable tensile strengths--a necessity for a valid comparison in a stress-controlled test. The X2024 alloy having only shearable precipitates developed sharp, intense slip bands and a higher density of crack nuclei earlier in the fatigue life than did the alloy containing nonshearable dispersoids.

FIG. 37 S-N CURVES FOR COMMERCIAL AND EXPERIMENTAL 2024 ALLOYS WITH COMPARABLE TENSILE STRENGTHS. BOTH ALLOYS CONTAINED A DISTRIBUTION OF 5  $\mu\text{M}$  DIAM IRON- AND SILICON-RICH INCLUSIONS; THE COMMERCIAL ALLOY ALSO CONTAINED 0.1 TO 0.2  $\mu\text{M}$  DIAM MANGANESE-RICH INCLUSIONS. EXPERIMENTAL ALLOY X2024 WAS FREE OF THE MANGANESE INCLUSIONS AND EXHIBITED LOWER FATIGUE STRENGTH DUE TO HIGH CRACK DENSITY FROM SHARP SLIP BANDS. SOURCE: PELLOUX AND STOLTZ REF 65

**Unrecrystallized Structures.** Figure 36 demonstrates that an alloy containing shearable precipitates has lower fatigue strength than a similar alloy containing nonshearable precipitates. Those results were obtained on material having a low (3 to 6%) degree of recrystallization. A larger difference in fatigue lives would have been observed if the alloys were fully recrystallized. Unrecrystallized structures also promote homogeneous deformation and reduce the influence of the type (shearable or nonshearable) of precipitates.

Figure 38 shows Coffin-Manson life plots of an Al-Zn-Mg-Cu alloy with shearable precipitates (Ref 64). Two different degrees of recrystallization were tested in three different environments. The specimens having the largest volume fraction of unrecrystallized structure showed the greatest fatigue resistance in each environment. However, as expected, an aggressive environment enhanced the difference observed between specimens having a mostly unrecrystallized structure (homogeneous deformation) and those with a more recrystallized structure (inhomogeneous deformation). The dislocation substructure in the unrecrystallized regions and the nonshearable precipitates along subgrain boundaries reduce slip lengths and thus homogenize deformation. On the other hand, localized planar slip occurred in the recrystallized grains, resulting in an enhanced environmental effect and early crack nucleation.

FIG. 38 INFLUENCE OF DEGREE OF RECRYSTALLIZATION (DR) AND ENVIRONMENT ON THE STRAIN-LIFE

## BEHAVIOR OF AN AL-ZN-MG-1.6 CU ALLOY WITH SHEARABLE PRECIPITATES

For alloys with nonshearable precipitates, the degree of recrystallization has no effect on fatigue life, regardless of environment (Fig. 39). Further, the effect of the environment was small. Slip distances, which are controlled by the spacings of the nonshearable precipitates, are much smaller than the mean intercept length between subgrain boundaries.

FIG. 39 INFLUENCE OF DEGREE OF RECRYSTALLIZATION (DR) AND ENVIRONMENT ON THE STRAIN-LIFE BEHAVIOR OF AN AL-ZN-MG-2.1 CU ALLOY WITH NONSHEARABLE PRECIPITATES

**Grain Size.** A reduction in grain size results in beneficial effects that delay crack nucleation in alloys containing shearable precipitates. Reduced grain size reduces the slip length, and thus the stress concentration, by reducing the number of dislocations in a pileup. A reduction in slip length also reduces the number of dislocations that can egress at a free surface (and thus the slip-step height and extrusion/intrusion size). Another beneficial effect of grain-size reduction involves the volume of material needed to satisfy the von Mises criterion (Ref 66). In essence, this criterion requires multiple slip to occur in polycrystalline materials in order to preserve the external form of the specimen and maintain cohesion at the grain boundaries. However, as Calnan and Clews (Ref 67) have suggested, multiple-slip systems need only operate in the immediate vicinity of the grain boundary, whereas slip may occur on either duplex or single systems in the body of the grains. Consequently, the smaller the grain size, the larger the volume fraction of material deformed by multiple slip and the more homogeneous the overall deformation.

Figure 40 illustrates the beneficial effect of reducing grain size for an alloy containing shearable precipitates (Ref 68). The ternary alloy had an equiaxed grain structure with a mean intercept length of 0.5 mm. Coarse planar slip and intense slip bands, which were later sites for crack nuclei, occurred early in the life of the large-grained material. The Al-Zn-Mg-Zr alloy had smaller elongated grains with mean grain dimensions of approximately 0.03 by 0.05 by 0.10 mm. Slip in the fine-grained material was less intense, and crack initiation was delayed. This is further illustrated in Fig. 40 by the fact that cycles to initiation for the fine-grained material exceeded cycles to failure for the coarse-grained material under the same plastic strain amplitude.

**FIG. 40 EFFECT OF GRAIN SIZE ON THE STRAIN-LIFE BEHAVIOR OF AN ALLOY WITH SHEARABLE PRECIPITATES. THE AL-ZN-MG ALLOY HAD LARGE GRAIN SIZE; THE AL-ZN-MG-ZR ALLOY, SMALL GRAIN SIZE. SOURCE: REF 68**

Again it is noted that the two curves converge at low plastic amplitudes (long life) for this strain-controlled test. As mentioned previously, this is due to differences in cyclic-hardening behavior. The strain-hardening exponent,  $n'$ , of the Al-Zn-Mg-Zr alloy is approximately twice that of the ternary alloy, a fact attributed to a larger degree of multiple slip and more frequent dislocation-dislocation interactions in the Al-Zn-Mg-Zr alloy than in the Al-Zn-Mg alloy. The convergence would not have been observed in a stress-controlled test.

Figure 41 shows the grain-size effect in a stress-controlled test for a high-purity 7075 alloy (X7075) aged to contain shearable precipitates (Ref 69). Since the flow stress is determined by the interaction of dislocations with the coherent precipitates, the yield stress is approximately the same for both alloys. Optical examinations of the specimen surfaces show that cracks nucleate much earlier in specimens having the large grain size. Cracks nucleated at intense slip bands for both grain sizes. However, the slip bands were much more pronounced in specimens with a large grain size of  $200 \mu\text{m}$ . For specimens with small grain size ( $30 \mu\text{m}$ ), cracks at slip bands could be detected only in grains that were statistically larger than average.

**FIG. 41 EFFECT OF GRAIN SIZE ON THE STRESS-LIFE BEHAVIOR OF AN X7075 ALLOY WITH SHEARABLE PRECIPITATES. SOURCE: REF 69**

## Precipitate-Free Zones

A solute-depleted PFZ is weaker than the matrix and can be the site of preferential deformation. This preferential plastic deformation leads to high stress concentrations at grain-boundary triple points (Fig. 34) and to early crack nucleation. The magnitude of the stress concentrations will be a function of the grain-boundary length and the difference in shear strength of the age-hardened matrix and the soft PFZ.

Because the strain localization occurs in a region free of solute, overaging the matrix precipitates or adding dispersoids does not homogenize the deformation. This is clearly illustrated by comparing results for underaged and overaged specimens of large-grained Al-Zn-Mg alloy (Fig. 42). The tensile yield strength and strain to fracture are approximately the same for both specimens. As mentioned previously, the underaged alloy has shearable precipitates, which results in strain localization, the formation of intense slip bands, and early crack nucleation under cyclic loading. Overaging was one method described for homogenizing deformation; however, this method is not effective for large-grained material. Preferential deformation in the PFZ also leads to strain localization and results, for this particular case, in the same fatigue life. For the same reason dispersoids distributed throughout the matrix would not inhibit strain localization in the PFZ.

**FIG. 42 STRAIN-LIFE CURVES OF LARGE-GRAINED AL-ZN-MG ALLOY WITH SHEARABLE PRECIPITATES WHEN UNDERAGED (4 H AT 120 °C, OR 250 °F) AND NONSHEARABLE PRECIPITATES PLUS PFZS WHEN OVERAGED (96 H AT 150 °C, OR 300 °F). SOURCE: REF 64**

**Reduction of grain size** is a very effective method of reducing early crack nucleation due to preferential deformation in the PFZ. This reduces the slip distance and lowers the stress concentrations at grain-boundary triple points. The fracture mode can likewise change from a low-energy intergranular to a higher-energy transgranular mode.

The effectiveness of reducing the grain size is illustrated in Fig. 43, which shows Coffin-Manson life plots of two overaged Al-Zn-Mg alloys, described previously (Ref 68). The small-grained Al-Zn-Mg-Zr alloy has a much longer life than does the large-grained Al-Zn-Mg alloy. The improvement in life is attributed to increasing the cycles to crack initiation. For the lower plastic strain amplitudes, a convergence is noted for long lives ( $10^4$  cycles) for this strain-controlled test. Since the fine-grained material hardens more at low strains, the stress to enforce the applied strain is greater at long lives, and this affects the life improvement due to the fine grains.

FIG. 43 EFFECT OF GRAIN SIZE ON THE STRAIN-LIFE BEHAVIOR OF AN ALLOY WITH NONSHEARABLE PRECIPITATES PLUS PFZS. THE AL-ZN-MG ALLOY HAD LARGE GRAIN SIZE; THE AL-ZN-MG-ZR, SMALL GRAIN SIZE. SOURCE: REF 68

No such convergence is observed for a stress-controlled test (Fig. 44) for a similar alloy (X7075) and heat treatment (Ref 69). Optical examination revealed that cracks were nucleated at grain boundaries parallel and perpendicular to the stress axis for the large-grained material, but only at grain boundaries perpendicular to the stress axis for the fine-grained material. This is a direct result of reducing the slip length and thus the local stress concentration. Cracks appearing parallel to the stress axis are a result of the tension-compression employed and the high stress concentrations at triple points in the large-grained material (Ref 69).

FIG. 44 EFFECT OF GRAIN SIZE ON THE STRESS-LIFE BEHAVIOR OF AN X7075 ALLOY WITH NONSHEARABLE PRECIPITATES PLUS PFZS. SOURCE: REF 69

**Steps in Grain Boundaries.** The previous section described the use of grain-size reduction as a means of decreasing the slip length in the PFZ and thus the local stress concentration. This resulted in improved resistance to fatigue crack nucleation and increased fatigue life. Thermomechanical processing is another method that can be used to reduce the slip length in the PFZ. If enough cold deformation is employed to introduce steps (or "ledges") into the grain boundaries, the effective slip length within the PFZ is drastically reduced (similar to a small grain size), with corresponding improvement in resistance to fatigue crack nucleation. Figure 45 shows the results of a stress-controlled test for two high-purity 7075 alloys, one cold worked 50% to produce grain-boundary steps. The cold work drastically reduced the incidence of grain-boundary cracking and improved the fatigue life at high stress amplitudes. At low stress amplitudes and long fatigue lives, crack nucleation occurred at inclusions for both alloys. This effect is most likely due to lower stress concentration at inclusions.

**FIG. 45 EFFECT OF GRAIN-BOUNDARY LEDGES ON THE STRESS-LIFE BEHAVIOR OF AN X7075 ALLOY CONTAINING NONSHEARABLE PRECIPITATES AND PFZS**

This raises another important point about microstructure. Many alloys have large inclusions, which may concentrate strain during cyclic deformation and lead to early crack nucleation. This detrimental effect can be reduced substantially by lowering the impurity levels. This is illustrated in Fig. 46, which shows that a significant improvement in the HCF life of 7075 alloy is obtained by lowering the iron and silicon content (7475 alloy).

**FIG. 46 EFFECT OF INCLUSION DENSITY ON THE STRESS-LIFE BEHAVIOR OF TWO 7XXX ALLOYS: HIGH INCLUSION DENSITY, ALLOY 7075; LOW INCLUSION DENSITY, ALLOY 7475**

**Alignment of Grain Boundaries.** Like many other commercial alloys, high-strength aluminum alloys have dispersoids that inhibit grain growth during high-temperature processing and subsequent heat treatment. For these alloys, the resulting grain shape is characteristic of the processing treatment; for rolled plate it has a pancake shape. If these alloys are aged to contain nonshearable precipitates and have a solute-depleted PFZ, detrimental strain localization could occur only in the PFZ parallel to the long grain dimension and only if the PFZ is inclined to the stress axis. If the stress axis is parallel or perpendicular to the long grain dimension, there will be no shear stress parallel to the grain boundary, and preferential deformation within the PFZ will be restricted. Grain-boundary alignment is then as effective in restricting deformation in the PFZ as are steps produced by thermomechanical treatment (TMT), as shown by the stress-life curves in Fig. 47.

**FIG. 47 EFFECT OF ALIGNMENT OF GRAIN BOUNDARIES--AND ALIGNMENT PLUS STEPS IN GRAIN BOUNDARIES--ON THE STRESS-LIFE BEHAVIOR OF A 7475 ALLOY CONTAINING NONSHEARABLE PRECIPITATES AND PFZS**

**Thermomechanical Processing.** Fatigue strength of age-hardened aluminum alloys can be improved in some cases by TMT involving cold work before or during aging. McEvily et al. (Ref 70, 71) found that the fatigue life of Al-Mg and Al-Zn-Mg alloys is increased marginally by cold working prior to aging, perhaps because of partial elimination of grain-boundary PFZs. Ostermann (Ref 72) showed that the long-life fatigue strength and fatigue ratio of smooth 7075 aluminum specimens were increased about 25% by cold working in the partially aged condition (Fig. 48). On the other hand, Reimann and Brisbane (Ref 62) found that the fatigue-life curves for notched 7075 ( $K_t = 3$ ) were essentially unchanged by TMT, and suggested that TMT may affect crack initiation rather than crack growth.

**FIG. 48 S-N CURVES OF 7075 ALUMINUM ALLOYS WITH AND WITHOUT TMTS. AXIAL LOADING WITH  $R = 1$ . THREADED 13 MM (0.5 IN.) ROUND, 75 MM (3 IN.) LONG HOURGLASS SPECIMENS (50 MM, OR 2 IN., RADIUS) WITH 5 MM (0.2 IN.) NET SECTION DIAMETER WERE MACHINED AND LONGITUDINALLY POLISHED. A TMT WAS GIVEN TO BOTH COMMERCIAL AND HIGH-PURITY BARS BY SOLUTION ANNEALING AT 460 °C (860 °F) FOR 1 H, WATER QUENCHING, AGING AT 100 °C (212 °F) FOR 1 H, SWAGING AT ROOM TEMPERATURE, AND AGING AT 120 °C (250 °F) FOR 16 H. THE COMMERCIAL ALLOY, C7075-TMT, WAS REDUCED 30% IN CROSS SECTION, WHEREAS THE HIGH-PURITY ALLOY, X7075-TMT, WAS SWAGED ONLY 10% BECAUSE OF SPECIMEN SIZE LIMITATIONS. SOURCE: REF: 72**

The benefit of TMT is, however, not necessarily limited to crack initiation retardation. Crack growth retardation also has been observed as a result of cold working 2024 aluminum samples prior to aging (Ref 74). DiRusso and coworkers (Ref 75) compared the behavior of T6 and TMT 7075 aluminum and concluded that smooth TMT specimens have lower strength than T6, whereas notched samples may have higher strength. Other results (Ref 76) also demonstrate a significant improvement in fatigue strength in the long-life regime for both smooth and notched ( $K_t = 8$ ) specimens of 7075 as a result of TMT (Fig. 49). The underlying cause of improvement is probably refinement and homogenization of microstructure as a result of TMT, and the consequent deformation by dispersed slip during cyclic loading (Ref 72). Other work (Ref 77) suggests that fatigue crack propagation rates in both 2024 and 2124 aluminum alloys depend on precipitate type and dislocation density. The substantial improvement in fatigue strength of notched samples tested at  $R = 0$  strongly suggests that microstructural changes due to TMT can promote increased resistance to crack propagation as well as crack initiation during fatigue cycling of 7075.

### Fatigue Crack Growth of Aluminum Alloys

A material's resistance to stable crack extension under cyclic loading is generally expressed either in terms of crack length,  $a$ , versus number of cycles,  $N$ , or as fatigue crack growth rate,  $da/dN$ , versus crack tip cyclic stress intensity factor range,  $\Delta K$ , using fracture mechanics concepts. The latter approach is particularly useful in damage-tolerant design for estimating the influence of fatigue crack growth on the life of structural components. Baseline data for flaw growth predictions is usually established from constant load-amplitude cyclic loading of precracked specimens. Crack length is measured as a function of elapsed cycles, and these data are subjected to numerical analysis to establish rates of crack growth. Crack growth rates are expressed as function of the applied cyclic range in stress intensity factor,  $\Delta K$ , calculated from expressions based on linear elastic stress analysis. Fracture mechanics assumes that fatigue crack growth in an engineering structure occurs at the same  $da/dN$  of the precracked specimen when the range and mean stress intensity factors for both configurations are the same. Component crack propagation life may therefore be estimated by numerical integration of crack growth rates established from the laboratory coupon specimen.

The typical relationship between fatigue crack growth rate and  $\Delta K$  observed for most alloys when tested in a non-hostile environment is often classified by the three regions (Ref 78) as shown in Fig. 50. Within region A, crack growth rates become vanishingly small (approximately less than  $10^{-5}$  mm/cycle) with decreasing  $\Delta K$ , and there exists, within this region, a fatigue stress intensity threshold below which pre-existing cracks do not appear to grow. For many long and infinite life applications, growth of fatigue cracks at very slow rates comprise a major portion of component life, yet low fatigue crack growth rate data on aluminum alloys (and other structural alloys) are rather limited due to the relative high cost and time required to establish this information. Designers using fracture mechanics concepts are interested in low  $\Delta K$  fatigue crack growth rate information since these rates correspond to early stages of crack formation and propagation where remedial measures can be instituted. In region B, behavior is often characterized by a linear relationship between  $\log da/dN$  and  $\log \Delta K$ . Region B rates are of great practical interest, since they are generally associated with damage sizes for in-service inspection of high-performance parts. Final stages of fatigue crack propagation are characterized by region C as  $\Delta K$  (or more specifically  $K_{max}$ ) approaches the critical stress intensity,  $K_{Ic}$  or  $K_c$ . Region C growth rates are highly dependent on stress ratio, alloy toughness, and specimen thickness (if not plane strain). Tougher alloys exhibit better

constant amplitude fatigue crack growth resistance in regions B and C (Ref 79, 80, 81, 82) as indicated by 7075-T6 and high-toughness alloy 7475-T6 data of Fig. 51 (Ref 83).

FIG. 51 BENEFIT OF HIGH-TOUGHNESS ALLOY 7475 AT INTERMEDIATE AND HIGH STRESS INTENSITY. SOURCE: REF 83

In examining fatigue crack growth rate curves for many materials exhibiting very large differences in microstructure, the striking feature is the similarities between these curves, not the differences. This point is illustrated by Fig. 52, a compilation of data for 2XXX and 7XXX series aluminum alloys. The differences in crack growth rate between these alloys are important from the viewpoint of integrating along any one of them to obtain the lifetime of a structure, but from a mechanistic point of view, these differences are small. A larger range of metals can be represented by a single curve if the driving force ( $\Delta K$ ) is normalized by modulus. These data exclude the effect of environment (mainly water vapor) which is a major factor affecting fatigue crack growth rates.

**FIG. 52 MINOR INFLUENCES OF DIFFERING MICROSTRUCTURES ON FATIGUE CRACK GROWTH RATE CURVES: DATA FROM TWELVE 2XXX AND 7XXX ALUMINUM ALLOYS WITH DIFFERENT HEAT TREATMENTS. SOURCE: REF 73**

The considerable use of the fracture mechanics approach in the evaluation of fatigue crack growth rates in aluminum alloys is evident from a four-part Compendium of Sources of Fracture Toughness and Fatigue-Crack Growth for Metallic Alloys published in the *International Journal of Fracture* (Ref 85, 86, 87, 88). Another key reference is the *Damage Tolerant Design Handbook* (Ref 89).

### Effect of Composition, Microstructure, and Thermal Treatments

In general, fatigue crack growth rates in non-hostile environments fall within a relatively narrow scatter band, with only small systematic effects of composition, fabricating practice or strength, as illustrated by Fig. 52, 53, and 54. There are many sources of fatigue crack growth rate data which show the effects of various physical and microstructural variables on fatigue life of aluminum alloys (Ref 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105), but there is little agreement on the key variables and there are few significant approaches for improving the fatigue crack growth resistance of these alloys. However, some generalizations can be made.

FIG. 53 CRACK GROWTH COMPARISON. MANY COMMERCIAL ALUMINUM ALLOYS SHOW SIMILAR FATIGUE CRACK PROPAGATION RATES IN AIR, AS INDICATED ABOVE. SOURCE: REF 90

FIG. 54 SUMMARY OF FATIGUE CRACK GROWTH RATE DATA FOR ALUMINUM ALLOYS 7075-T6 AND 2034-T3. SOURCE: REF 91

As discussed in the section "Microstructure and Strain Life" in this article, metallurgical microstructures that distribute plastic strain and avoid strain concentration help reduce crack initiation. Those metallurgical factors which contribute to increased fracture toughness also generally contribute to increased resistance to fatigue crack propagation at relatively high  $\Delta K$  levels. For example, as illustrated in Fig. 51, at low stress intensities the fatigue crack growth rates for 7475 are about the same as those for 7075. However, the factors that contribute to the higher fracture toughness of 7475 also contribute to the retardation of fatigue crack growth, resulting in two or more times slower growth for 7475 than for 7075 at  $\Delta K$  levels equal to or greater than about  $16 \text{ MPa} \cdot \sqrt{\text{m}}$  ( $15 \text{ ksi} \cdot \sqrt{\text{in}}$ ). A similar trend has been observed for 2124-T851, which exhibits slower growth than 2024-T851. Smooth specimens of alloys 2024 and 2124 exhibit quite similar fatigue behavior. Because fatigue in smooth specimens is dominated by initiation, this suggests that the large insoluble particles may not be significant contributors to fatigue crack initiation. However, once the crack is initiated, crack propagation is slower in material with relatively few large particles (2124) than in material with a greater number of large particles (2024).

Staley (Ref 90) summarized the role of particle size in influencing fatigue crack growth in aluminum alloys, as shown in Fig. 55 (Ref 106). The influence of alloy composition on dispersoid effect is shown in Fig. 56. The general trend in Fig. 56 is that for more finely dispersed particles, the fatigue crack propagation life is increased. Whereas dispersoid type appears to have a relatively small effect on mean calculated life, the smaller precipitates provided by aging produce a much larger effect.

### Selecting Aluminum Alloys to Resist Failure by Fracture Mechanisms

R.J. Bucci, ALCOA Technical Center, G. Nordmark (retired); E.A. Starke, Jr., University of Virginia, Department of Materials Science and Engineering

---

### Effect of Processing and Microstructure

The extensive use of age-hardenable aluminum alloys at high strength levels, i.e., greater than 520 MPa (75 ksi), has been hampered by poor secondary properties of toughness, stress-corrosion resistance, and fatigue resistance, particularly in the short transverse direction. Some secondary property improvements have been obtained by employing slight changes in alloy chemistry (Ref 107, 108), different grain refining elements (Ref 92), or removal of the impurity elements Fe and Si (Ref 109, 110, 111). Such research has led to the development of alloys with improved fracture toughness and stress-corrosion resistance compared to the extensively used 7075. However, significant improvements in fatigue resistance have not been realized with these methods.

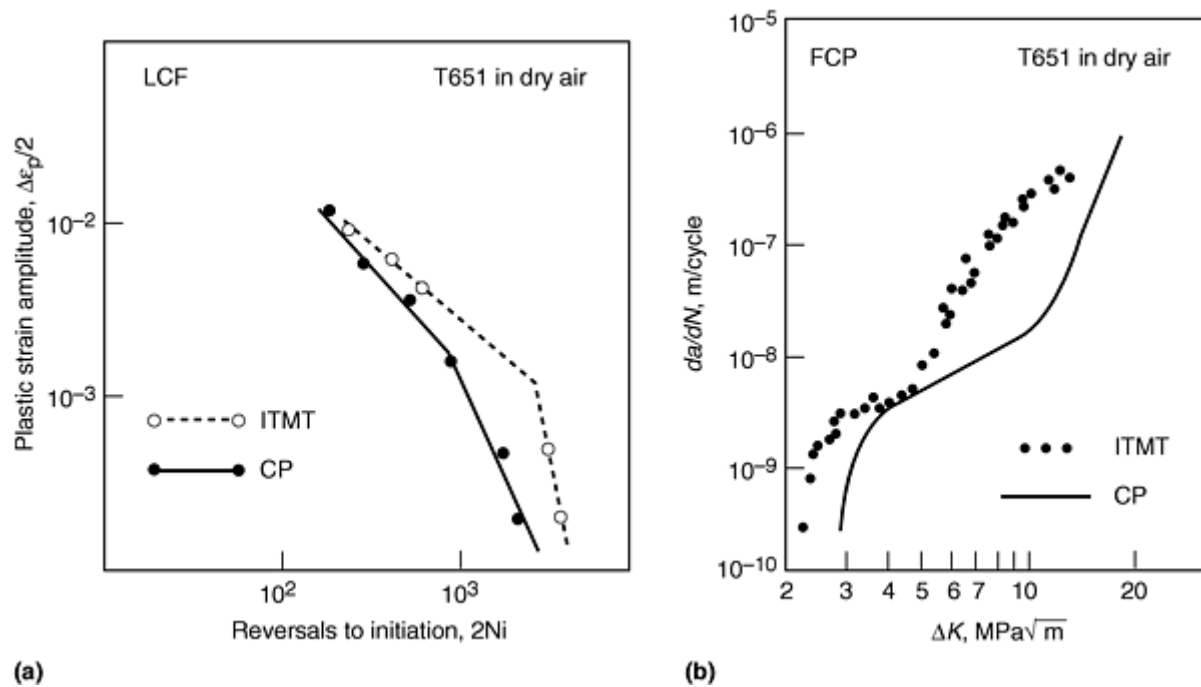

Microstructure control through modification of conventional primary processing methods has been examined as a way of upgrading the fatigue properties of these alloys. These methods, called thermomechanical treatments (TMT), include thermomechanical aging treatments (TMA) and intermediate thermomechanical treatments (ITMT), which are specialized ingot processing techniques applied before the final working operation. In general, for high-strength aluminum alloys, a

fine grain structure produced by ITMT improves fatigue-crack-initiation resistance but reduces fatigue-crack-propagation resistance when compared with a typical pancake-shape, partially recrystallized, hot worked structure (Fig. 57) (Ref 112). This effect is more pronounced when the strengthening precipitates are shearable and the grain size determines the slip length. Figure 58(a) compares the LCF curves of ITMT and commercially pure (CP) 7XXX alloys. The ITMT material shows a significant increase in reversals to initiation for all strain amplitudes. The ITMT fine grain structure homogenizes the deformation, and the decrease in strain localization improves the resistance to fatigue-crack initiation. The convergence of the curves at high strain amplitudes results from homogenization of deformation by high strains.

**FIG. 57** CRACK GROWTH DATA FOR COMPACT TENSION SPECIMENS FROM COMMERCIALY PROCESSED (CP) PLATE AND EXPERIMENTAL INTERMEDIATE THERMOMECHANICAL TREATMENT (ITMT) MATERIAL IN THE AS-RECRYSTALLIZED (AR) CONDITION AND THE AS-RECRYSTALLIZED PLUS HOT-ROLLED (AR + HR) CONDITION. THE CP 7050 MATERIAL WAS PARTIALLY RECRYSTALLIZED (<50%) AND SPECIMENS WERE FROM THE CENTER (CP-C) AND THE BOTTOM OR TOP EDGE (CP-E) OF THE PLATE. SCATTER BANDS INCLUDE DATA FOR SPECIMENS OF BOTH L-T AND T-L ORIENTATIONS. TESTS CONDUCTED AT 10 CPS AND 20 CPS IN DRY AIR WITH  $R = 0.1$ . SOURCE: REF 112

**FIG. 58 EFFECTS OF INTERMEDIATE THERMOMECHANICAL TREATMENTS (ITMT) ON (A) FATIGUE CRACK INITIATION AND (B) FATIGUE CRACK PROPAGATION OF 7XXX ALUMINUM ALLOYS. SOURCE: REF 113**

Unfortunately, homogeneous deformation increases the rate of crack propagation because it allows single straight-running cracks during subcritical crack growth. The planar slip and inhomogeneous deformation of CP material enhance crack branching, increase the total crack path, and lower the effective stress intensity at the tip of the crack, all of which lower crack-growth rates (Ref 114). Figure 58(b) compares the fatigue crack propagation curves of the same material and shows the detrimental effect that a fine grain structure has on the fatigue crack propagation rate.

Combined effects of grain size, deformation mode, and environment on propagation behavior are shown in Fig. 59 (Ref 115) for ITMT-7475. Both aging treatment and grain size significantly affect the fatigue crack growth rates (FCGRs) measured in vacuum (Fig. 59a). Decreasing the grain size by ITMT and averaging, both of which homogenize deformation and decrease the reversibility of slip, increase FCGRs. Although the same trends are observed in air (Fig. 59b), the magnitude of the effect is considerably reduced due to environment-enhanced growth.

**FIG. 59 EFFECTS OF GRAIN SIZE AND AGING TREATMENT ON THE FCGR OF INTERMEDIATE THERMOMECHANICAL TREATMENT (ITMT) ALLOY 7045: (A) TESTS IN VACUUM, AND (B) TESTS IN LABORATORY AIR. DIFFERENCES IN A VACUUM COULD NOT BE ACCOUNTED FOR BY CLOSURE EFFECTS. SOURCE: REF 115**

The results in Fig. 59 are consistent with other studies that show that slip character and grain size can have a pronounced effect on the fatigue crack growth behavior of age-hardenable aluminum alloys. When the strengthening precipitates are coherent with the matrix (underaged condition) they are sheared by dislocations promoting coarse planar slip and inhomogeneous deformation. This favors fracture along slip planes and the occurrence of zigzag crack growth and crack branching. When the strengthening precipitates are incoherent with the matrix (overaged condition), they are looped and bypassed by dislocations promoting more homogeneous deformation and reducing crack tortuosity. A reduction in grain size (by enhancing multiple slip at low  $\Delta K$  values) and an aggressive environment (by decreasing the plasticity needed for fracture) can also reduce crack tortuosity although the oxides formed in air can have an opposite effect on crack growth rates by increasing crack closure. The slower crack growth rates associated with planar slip and large grains have been attributed to:

- SLIP BEING MORE REVERSIBLE
- THE TORTUOSITY OF THE CRACK PATH
- THE  $\Delta K$  OF ZIGZAG AND BRANCHED CRACKS BEING SMALLER THAN THE  $\Delta K$  CALCULATED ASSUMING A SINGLE CRACK NORMAL TO THE STRESS AXIS
- ENHANCED CLOSURE ASSOCIATED WITH INCREASED SURFACE ROUGHNESS

A reduction in grain size and averaging reduce the reversibility of slip and crack tortuosity. Consequently, it is not surprising that the 18  $\mu\text{m}$  grain size in Fig. 59(b), overaged material had the fastest crack growth of all the conditions studied. The different fatigue crack growth rates for the various materials may be related to the difference in the extent of crack closure that they exhibited in the air environment, as discussed in Ref 115. However, in a vacuum, differences in growth rates for the various materials could not be accounted for by closure effects. The influence of environment and in particular the improvement in fatigue crack growth resistance in vacuum is well known. The extent of the improvement depends on aging condition and grain size, with the most significant improvements derived for coarse-grained material in

an underaged condition. One factor which may account for this is the marked extent of slip reversibility in the underaged material compared with the multiple slip situation in the overaged material.

**Effects of Product Form and Orientation.** The rate of fatigue crack propagation in aluminum alloys is relatively insensitive to product form and orientation. This is illustrated in Fig. 60 for thick 5083-O plate that was evaluated for use in tankage for liquefied natural gas; growth rates in specimens from four orientations were well within the range for replicate tests in any one orientation (Ref 116). It would be expected that in the high  $\Delta K$  range, differences in growth rate would reflect differences in toughness, and therefore would indicate somewhat higher growth rates for stressing normal to the plane of the product--that is, in the S-L and S-T orientations. Product thickness also seems to have a small effect, as illustrated by the data for 5083-O in Fig. 61 and Ref 116.

**FIG. 60 EFFECT OF ORIENTATION ON FATIGUE CRACK GROWTH RATES IN 180 AND 196 MM (7.0 AND 7.7 IN.) 5083-O PLATE. SOURCE: REF 116**

**FIG. 61 FATIGUE CRACK GROWTH RATES FOR 5083-O PLATE IN THICKNESSES OF 25, 70, AND 178 MM (1, 1.8, AND 7 IN.). SOURCE: REF 116**

**Effects of Exposure Temperature.** Although no significant amount of fatigue testing has been done at temperatures above room temperature, there has been a great amount of testing at subzero temperature, particularly at  $-196\text{ }^{\circ}\text{C}$  ( $-320\text{ }^{\circ}\text{F}$ ). In general, fatigue crack growth rates below room temperature are about the same as, or lower than those, at room temperature (Fig. 62).

**FIG. 62 EFFECT OF TEMPERATURE AND HUMIDITY ON FATIGUE CRACK GROWTH IN 180 MM (7.0 IN.) 5083-O PLATE. SOURCE: REF 116**

**Effect of Humidity.** The role of humidity and environment is a well-known factor affecting crack growth. As shown in Fig. 62, growth rates for alloy 5083-O are appreciably higher in moist air than in dry air (Ref 116). Growth rates in water solutions of sodium chloride are similar to those in moist air.

Data for Alclad 7075-T6 in Fig. 63 (Ref 117) illustrate that even relatively low levels of moisture can accelerate crack growth rates. Unless relative humidity is below 3 to 5%, it seems best to consider that accelerated fatigue crack growth rates are likely in service.

FIG. 63 EFFECTS OF MOISTURE ON FATIGUE CRACK GROWTH RATES IN ALUMINUM ALLOYS. SOURCE: REF 101

**Effect of Load-Time History.** Selection of the appropriate type of load cycle to be used in evaluating fatigue crack propagation rates of aluminum alloys has been found to be particularly critical. Staley (Ref 106) and Bucci et al. (Ref 118) noted that the variable amplitude crack propagation testing offers the following advantages: (a) increased sensitivity to microstructural effects; (b) relevancy to design through consideration of important effects of load history, especially overload/plastic zone interactions; (c) practical interpretation when results are expressed in terms of crack size versus fatigue life; and (d) suitability for automated testing and analysis. Bucci further indicated that there are important interactions between microstructure and crack growth under variable amplitude cyclic loading that are not accounted for in constant amplitude testing. Ratings of alloys based on constant amplitude testing are not very likely to provide realistic indications of fatigue performance under the usual service-type variable amplitude loading. The primary cause of this difference is that variable amplitude loading includes the effects of crack growth retardation on fatigue crack propagation-effects that cannot be demonstrated in constant amplitude testing. Crack growth retardation is caused by tension overloading and consequent plastic deformation. The variable amplitude test is believed to be more sensitive to alloy difference, and it clearly provides more useful information for alloy development investigations.

For example, as illustrated by the data for alloys 7075 and 7050 in Fig. 64 (Ref 119), quite different results are obtained in constant amplitude tests than in tests with single overloads every 4000 or 8000 cycles. Thus, information on the variation in load level during fatigue cycling is required for correct characterization of the fatigue behavior of aluminum alloys. More detailed information is provided in the article "Fatigue Crack Growth under Variable Amplitude Loading" in this Volume.

FIG. 64 RELATIVE RANKING OF FATIGUE LIFE OF 7075 AND 7050 ALUMINUM ALLOYS UNDER CONSTANT AMPLITUDE AND PERIODIC SINGLE OVERLOAD CONDITIONS. SOURCE: REF 119

**Effect of Load Ratio,  $R$ .** The effect of stress or load ratio on fatigue crack growth rate (load ratio,  $R$ , is the ratio of minimum to maximum load in the fatigue cycle) is well known. This effect is shown for alloy 7075-T6 sheet about 2.5 mm (0.1 in.) in Fig. 65 (Ref 120). In general, and in all the data presented here, an increase in  $R$  at the same  $\Delta K$  level causes an increase in growth rate. A modification of the Paris equation [ $da/dN = C(\Delta K)^n$ ] that accounts for the effects of load ratio is the Forman equation, which is as follows:

$$\frac{da}{dN} = \frac{C(\Delta K)^n}{(1-R)K_c - \Delta K} \quad (\text{EQ 7})$$

For the data in Fig. 65, the Forman equation gives a good representation of the variation of  $da/dN$  with  $R$  for a wide range of crack growth rates.

### Crack Growth in Alloy Selection and Design

Generally, fatigue crack growth resistance has only modest variations among present high-strength aluminum alloy mill products. Environmental factors, particularly moisture and chlorides, are more significant than material differences in affecting crack growth rates (Fig. 66). Separation of material differences in fatigue behavior is further confounded by the generally accepted practice of plotting results on log coordinates where relatively small shifts in a data trend could have a significant impact on the life of a part. For example, the width of the  $da/dN$  band in Fig. 17 represents a factor of ten, affording considerable room for improvement if alloys can be selected or developed that confine their behavior to the crack growth rate lower bound. Moreover, many designers of high-performance structures will concede that a 50% life improvement or 10% weight reduction afforded by design to higher stress without reduction in fatigue strength is significant.

**FIG. 66 INFLUENCE OF ENVIRONMENT AND CYCLE FREQUENCY ON FATIGUE CRACK GROWTH ( $R = 0$ ) OF ALUMINUM ALLOY 7075-T6. SOURCE: REF 121**

Although material differences generally have only a modest effect on fatigue crack growth rates, research work has established statistically significant effects of alloy microstructure and composition on fatigue crack growth resistance of high-strength aluminum alloys (Ref 43, 44, 45, 46). These programs, which consisted of a set of highly controlled experiments on laboratory-fabricated 2XXX (Al-Cu-Mg-Mn) and 7XXX (Al-Zn-Mg-Cu) microstructures, permitted the following conclusions on fatigue crack growth resistance under constant amplitude loading:

- HIGH-PURITY AND LOWER-COPPER VERSIONS OF ALLOY 2024 (I.E., 2124 AND 2048) PROVIDE IMPROVED RESISTANCE TO REGIONS 2 AND 3 FATIGUE CRACK GROWTH OVER THEIR 2024 COUNTERPART BECAUSE OF IMPROVED FRACTURE TOUGHNESS.
- IMPROVED TOUGHNESS THROUGH INCREASED PURITY RESULTED IN GREATEST IMPROVEMENTS IN 2XXX ALLOY FATIGUE CRACK PROPAGATION LIFE IN ARTIFICIALLY AGED T8-TYPE TEMPERS.
- TOUGHNESS AND RESISTANCE TO FATIGUE CRACK PROPAGATION INCREASE AS STRENGTH DECREASES IN UNDERAGED AND PEAK-AGED TEMPERS OF AL-CU-MG-MN ALLOYS CONTAINING LOW LEVELS OF COLD WORK. OVERAGED 2XXX TEMPERS PROVIDE INFERIOR COMBINATIONS OF STRENGTH, TOUGHNESS, AND RESISTANCE TO FATIGUE CRACK GROWTH.
- COMPARED TO CONVENTIONAL 7XXX ALLOYS, SUCH AS 7075, "IMPROVED" 7475 AND 7050 ALLOYS PROVIDE GREATER FATIGUE CRACK GROWTH RESISTANCE, IN ADDITION TO BETTER COMBINATIONS OF STRENGTH, TOUGHNESS, AND SCC RESISTANCE.
- OVERAGING 7XXX ALLOYS TO T7-TYPE TEMPERS AND INCREASING THE COPPER CONTENT TO LEVELS OF ALLOY 7050 APPEARS TO INCREASE RESISTANCE TO FATIGUE

**CRACK GROWTH BY INCREASING RESISTANCE TO CORROSIVE ATTACK BY WATER VAPOR. (NOTE: THE NOMINAL COPPER CONTENTS ARE 1.6 AND 2.3% FOR ALUMINUM ALLOYS 7075 AND 7050, RESPECTIVELY.)**

Fatigue resistance of 2XXX and 7XXX microstructures have been rated by constant-amplitude crack growth life in 76 mm (3 in.) wide center crack tension specimens (Ref 45). Life was then correlated with toughness (Fig. 67) and yield strength (Fig. 68). Good fatigue crack growth resistance of 2XXX alloys shows high correlation with increasing toughness and/or decreasing strength. Fatigue crack growth resistance of 7XXX alloys shows less correlation to toughness and/or strength. Instead, 7XXX alloy rating is better characterized by microstructure and resistance to environment.

**FIG. 67 RELATIONSHIP BETWEEN FATIGUE CRACK PROPAGATION PERFORMANCE AND FRACTURE TOUGHNESS FOR LABORATORY-FABRICATED 2XXX AND 7XXX ALUMINUM ALLOY SHEET. MEAN CRACK GROWTH LIFE IS THAT LIFE AVERAGED OVER FOUR EXPERIMENTAL CONDITIONS FOR EACH ALLOY. THE FOUR CONDITIONS WERE TWO FREQUENCIES, 2 AND 20 HZ, AND TWO ENVIRONMENTS, LOW (<5%) AND HIGH (>90%) RELATIVE HUMIDITY AIR. LIFE WAS DETERMINED FROM TESTS OF 75 MM (3 IN.) WIDE CENTER CRACK TENSION PANELS WHERE  $\Delta K$  VARIED FROM 6.6 TO 16.5  $\text{MPa}\sqrt{\text{m}}$  (6 TO 15  $\text{KSI}\sqrt{\text{in.}}$ ) UNDER A CONSTANT-**

STRESS AMPLITUDE OF  $\Delta\sigma = 36.5 \text{ MPA (5.3 KSI)}$  AND  $R = 0.33$

WIDE CENTER CRACK TENSION PANELS WHERE  $\Delta K$  VARIED FROM 6.6 TO 16.5 MPA  $\sqrt{m}$  (6 TO 15 KSI  $\sqrt{in.}$ ) UNDER A CONSTANT-STRESS AMPLITUDE OF  $\Delta\sigma = 36.5 \text{ MPA (5.3 KSI)}$  AND  $R = 0.33$ .**

**Effects of Load History on Fatigue Resistance of Aluminum Alloys.** Constant-amplitude fatigue data provide a basic reference and are a prerequisite for making and improving cumulative damage computations. However, an important factor to be considered in addressing fatigue performance of aluminum alloys is the interaction of in-service load history (generally variable amplitude rather than constant amplitude) with material and environmental parameters (Ref 40, 43, 44, 122, 123). It has been amply demonstrated under variable load history that high tensile overloads (at levels of stress intensity that do not promote significant tearing as  $K$  approaches  $K_c$ ) produce significant delays in crack growth during subsequent fatigue cycles at lower amplitudes (see, for example, Fig. 69). The crack growth retardation is generally attributed to a reduction in crack tip stress intensity caused by residual plastic deformation or crack branching resulting from the overload. Compressive loads, hold times, or environmental effects are known to remove some of the benefits produced by the high overloads. However, fatigue crack propagation lives of components subjected to load

histories with high tensile overloads are generally greater than linear damage life predictions assuming no load interaction effect (e.g., Fig. 70). Overload-delay phenomena have been well documented in the literature (Ref 124, 125).

FIG. 69 CRACK GROWTH RETARDATION PRODUCED BY PERIODIC SINGLE SPIKE OVERLOAD IN ALUMINUM ALLOY 7075-T6. SOURCE: REF 43

FIG. 70 CRACK PROPAGATION TESTS UNDER FLIGHT-BY-FLIGHT AND CONSTANT-AMPLITUDE LOADING FOR DIFFERENT ALUMINUM ALLOYS. SOURCE: REF 126

Crack growth under variable amplitude loading sometimes shows alloy differences that are not readily apparent from constant-amplitude tests, the method most commonly used to rate alloy fatigue performance (Ref 123). Factors such as cyclic hardening, crack growth retardation characteristics, alloy strength-toughness combination (as varied by temper),

and alloy-microstructure interaction with load history and environment all may have appreciable influence on spectrum fatigue life of a particular alloy. For example, Fig. 70 shows that ratings of fatigue crack growth resistance for several aluminum alloys tested under constant amplitude and flight simulation loading differ (Ref 126). Figure 71 shows that an approximate 12% strength reduction from T76 to T73 temper variation in alloy 7475 resulted in a life improvement which, in effect, made the difference between meeting and not meeting a two lifetime damage tolerant design requirement on a fracture-critical aircraft part (Ref 127). However, the magnitude of the improvement was not predictable from constant amplitude data.

**FIG. 71 EFFECT OF OVERAGING ON PART THROUGH CRACK GROWTH OF ALUMINUM ALLOY 7475 SUBJECT TO 500 H BLOCK FLIGHT-BY-FLIGHT FIGHTER SPECTRUM LOADING IN SUMP TANK WATER. SOURCE: REF 127**

Figure 72 is replotted data from Ref 128 that shows fatigue crack growth lives of aluminum alloy 7050 established from flight simulation testing of precracked center crack tension panels. Strength level was varied by heat treatment. Results show that up to a yield strength of about 500 MPa, monotonic decrease in life is associated with monotonic increase in strength. However, increases in 7050 strength beyond 500 MPa results in increased life until a strength level of about 580 MPa, where resistance to fatigue crack propagation diminishes again. The transition behavior indicated by results of Fig. 72 can be related to competing mechanisms that control the fatigue crack growth process. Related work (Ref 43, 44) showed that the dominant mechanism depends on the interaction of loading conditions, specimen configuration, and alloy microstructure.

**FIG. 72 EFFECT OF YIELD STRENGTH ON FATIGUE CRACK PROPAGATION LIFE OF ALLOY 7050 FORGING UNDER FLIGHT SIMULATION LOADING**

The point to be emphasized by these illustrations is that complex competing alloy load-interaction mechanisms may be present in variable amplitude fatigue situations. Those mechanisms that dominate are, in part, application-dependent. Therefore, constant-amplitude loading may not always be sufficient or, for that matter, appropriate for rating alloys for optimum selection and/or design of fatigue-critical parts, and spectrum testing may be necessary. Though appreciable effort has been directed at establishing understanding and predictability of crack growth under variable load history, relatively little has been done to qualitatively rate crack growth retardation characteristics from one alloy to another. This work is confounded by the fact that alloy rating is somewhat spectrum- and environment-dependent. Use of appropriate standardized spectra for certain classes of applications (e.g., fighter, bomber, transport aircraft, automotive spectra) and standard test environments provides a database for basic alloy comparisons and improved understanding.

As illustrated by the preceding discussion, caution should be exercised in design use of  $K_{Ic}$ , for anything other than calculating critical flaw size, since  $K_{Ic}$  may not necessarily be correlated with  $da/dN$ , retardation characteristics, or alloy-crack growth interactions with environment.

## Fatigue and Fracture Properties of Aluminum Alloy Castings

Theodore L. Reinhart, Boeing Commercial Airplane Group

---

### Introduction

CASTING QUALITY has steadily improved over the years such that castings have become a viable alternative in structural applications for military and commercial aircraft. The steady improvement in casting quality is driven by several factors. In some cases, casting is the only viable alternative manufacturing method. In addition, the flexibility of the casting can be used to great advantage in reducing overall manufacturing costs, particularly for complex, three-dimensional structures. Competition and cost pressure also have intensified efforts by aircraft manufacturers to reduce costs through the use of near-net shape manufacturing methods such as casting. However, even with an economic advantage, a casting must meet the same performance criteria as competing design using wrought members and various joining technologies. Such cases are an area of great interest for aircraft structural designers.

With improvements in casting quality and the potential economic advantage of casting technology, cast aluminum alloys are being considered for weight and cost reductions of primary aircraft structures. Despite their acknowledged importance, aluminum castings have until recently been relegated to secondary applications in commercial aircraft structure. Castings have been used extensively in engines and systems, for example, in flight controls, wheels, and so forth, but not in many "primary" structural (carrying significant flight loads) applications. More recently, however, the use of castings in nontraditional applications has been facilitated by improvements in both casting alloys and processes. Casting producers have invested considerable money in applied research and, where possible, borrowed from the lessons learned by the aluminum producers. This has translated into cleaner castings with reduced levels of internal discontinuities, intermetallics and oxides, and better control of microstructures for improved strength, and fatigue and fracture resistance.

In this context, this article reviews the fatigue and fracture properties of aluminum alloy castings from the perspective of both design and manufacturing considerations. Fatigue and fracture resistance is often a limiting factor in the design of primary structures, and thus this article provides an overview of the roles played by microstructure, manufacturing processes, and test conditions in determining the fatigue and fracture properties of aluminum casting alloys. Because it is not possible to cover all the work done on all aluminum casting alloys, the following two alloy systems commonly used in aviation and aerospace are emphasized:

- ALLOYS A356 AND A357/D357 (ALL-T6), MEMBERS OF THE DUAL-PHASE AL-SI-MG SYSTEM, THE MOST COMMONLY SPECIFIED
- ALLOY A201-T7 FROM THE SINGLE-PHASE AL-CU SYSTEM, WITH HIGHER MECHANICAL PROPERTIES BUT MORE LIMITED PRODUCIBILITY

The role of casting design is also briefly discussed with respect to fatigue and fracture performance.

### Casting Design and Manufacture

The ability of an engineered component to perform a particular function is governed as much by design as by material properties. Trade studies involving engineered materials (in this case aluminum alloys) sometimes go no further than the properties tables of a reference book. However, attempts to compare diverse design concepts can be misleading. For most design properties, wrought alloys can be found that show advantage over the cast alloy. However, a thorough trade study must take into account the capabilities of the manufacturing processes. For example, the casting process affords the designer a number of unique advantages (Ref 1). In terms of structural shapes with a high degree of complexity, casting allows greater flexibility in design. Improved fatigue design is also possible by virtue of:

- CONTINUOUS LOAD PATHS (INTERSECTING MEMBERS ARE CONTINUOUS; IN A BUILT-UP DESIGN, THE ENGINEER IS OFTEN FACED WITH BREAKING ONE MEMBER OR ANOTHER INTO TWO AND THEN ADDING SPLICE DETAILS TO RECONNECT THEM DURING ASSEMBLY)
- "SOFT" SECTION TRANSITIONS
- FILLET AND CORNER RADII CAN BE TAILORED TO REDUCE STRESS CONCENTRATIONS
- FEWER RIVET/FASTENER HOLES (POTENTIAL CRACK STARTERS)
- FEWER LAP JOINTS (POTENTIAL CORROSION SITES)

The engineer is often able to produce a cast design that weighs no more than the traditional design (e.g., Ref 2). In fact, a modest weight reduction is sometimes achieved (Ref 1, 3, 4). Cost reduction is achieved by virtue of reduced part count, assembly labor, and related costs. Typical cost reductions are 35% or more when replacing a complex, three-dimensional built-up assembly.

With respect to casting processes, the great majority of development and production programs have used the so-called "sand-chill composite" mold process (hereafter referred to simply as "sand" process for brevity). Recent work by investment casting suppliers has, however, enabled a few companies to produce aluminum alloy castings (for example, D357) with tensile properties on a par with sand castings. Some European aircraft manufacturers apparently prefer castings made by the investment process. They are, in fact, somewhat ahead of their American counterparts in terms of applications. For example, the first structural casting went into service on an Airbus aircraft circa 1985 (Ref 1).

**Weld Rework on Castings and its Effect on Fatigue and Fracture.** Foundries often perform modest amounts of welding on castings (always prior to heat treatment) to correct surface defects. This action returns the casting to the "drawing specified" condition and is thus called "rework" (as opposed to "repair," which is discussed in the next section). The static properties of weld-reworked castings have been reasonably well studied, but few references on fatigue and fracture are available. With respect to alloys, only the Al-Si-Mg system has been studied in depth. The Al-Cu system, being inherently hot short, is welded less frequently and is not as well characterized.

The majority of work seems to show that fatigue life is not degraded when welding is properly performed. Apodaca et al. (Ref 5) studied the properties of weld-reworked F-5 pylon castings. In these smooth-bar, axial tests no significant differences were noted between results for welded and unwelded (parent) material. Ozelton et al. (Ref 6) found similar results. Mitchell et al. (Ref 2) reported slightly longer life for weld-reworked A357-T6 specimens tested with  $R = +0.02$  and 260 MPa (38 ksi) maximum stress: 48,388 cycles average for welded and 41,880 for parent metal. However, Oswalt et al. (Ref 7) found different results: slightly longer life for A357-T6 parent metal for stresses below about 100 MPa (15 ksi). However, comparisons with other works are difficult at best, due to differences in casting properties, quality, welding procedures, and fatigue testing procedures.

For fracture properties, the only readily available work (Ozelton et al., Ref 6) found that weld rework had no apparent effect on crack growth rates in D357-T6. Fracture toughness, on the other hand, was actually somewhat higher for the welded material.

In general, welding produces a very fine microstructure in the fusion zone of Al-Si-Mg castings. It also tends to produce a distribution of very fine gas pores, sometimes in excess of that found in the adjacent parent metal. The interactions of these features in determining fatigue life has not been studied in depth.

**Weld repair** differs from rework in that postweld heat treatment is not done; it is sometimes employed by aircraft maintenance crews to render damaged castings usable. Of course, weldment tensile properties are greatly reduced as a result. For example, in alloy A357-T6, yield strength may be reduced by 50% or more. Consequently, weld repairs are performed only in cases where service stresses are low.

A review of the literature turned up two cases in which weld repair was performed on fatigue test articles:

- HANSON ET AL. (REF 8) PERFORMED FATIGUE TESTS ON TWO ALLOY A201-T7 SPOILERS WITH WELD REPAIRS. THEY CONCLUDED THAT WELD REPAIR PROCEDURES WERE ADEQUATE FOR FIELD REPAIR FUNCTIONS.
- OZELTON ET AL. (REF 6) PERFORMED WELD REPAIR ON A PRECRACKED OPEN-HOLE FATIGUE SPECIMEN TO OBSERVE CRACK GROWTH BEHAVIOR IN THE WELD. PRIOR TO WELDING, THE SPECIMEN WAS SUBJECTED TO TWO LIFETIMES OF A MODIFIED F-18 LOWER WING ROOT SPECTRUM. THE RESULTING 0.09 IN. CRACK WAS WELDED, THE HOLE WAS REAMED, AND THE TEST WAS CONTINUED TO FAILURE.

**Effect of Hot Isostatic Pressing (HIP).** It is well known that the elimination of internal voids by HIPing has a generally favorable effect on the smooth-bar fatigue life of castings. Both Al-Si-Mg and Al-Cu cast alloys show similar results. However, there is some discord in the literature. For example, Kennerknecht et al. (Ref 9) found that HIPing did not have a significant effect on fatigue life in notched specimens ( $K_t = 1.5$ ) and open-hole specimens ( $K_t = 3.0$ ) in alloy D357-T6. They did, however, report slightly lower crack growth rates in HIPed material.

In addition, Rading et al. (Ref 10) compared the fatigue crack growth rates of alloy A206-T7 (Al-4.75% Cu) with varying degrees of porosity. They concluded that HIPing did little to improve  $da/dn$ , even though it reduced porosity from 4 to 0.4%. An explanation was offered to the effect that HIPing closes pores but cannot "heal" them due to the presence of oxides on the pore surfaces. However, no metallographic evidence was offered in support of this explanation. If this did in fact occur, then one would expect a reduction in fatigue life due to early crack initiation at the hypothetical collapsed, unhealed pores; however, the available fatigue data indicate the opposite (e.g., Ref 9).

**Effect of Casting Discontinuities on Fatigue and Fracture.** Casting properties depend greatly on the effect of various discontinuities, but it can be difficult to quantify the effect of a single type of discontinuity. This is so because the processing steps taken to produce castings with fine microstructure also tend to minimize the presence of unwanted actors--dross (oxide inclusions), gas porosity, microshrinkage, and the like. This being the case, some investigators have resorted to using nonstandard practices in an attempt to introduce various quantities of a certain discontinuity type into the test castings. Data produced from such programs are, unfortunately, of questionable relevance from an engineering perspective. However, few other data on this subject are to be found and so are presented here only for the purposes of illustration. The effects of two often-discussed discontinuities, gas porosity and dross, are briefly reviewed.

**Gas Porosity.** A number of investigators have studied the effects of gas porosity, possibly because it is relatively easy to quantify by metallographic or radiographic inspection (although standards for the latter method are semiquantitative at best). Briefly, the effects of gas porosity on the properties of Al-Si-Mg alloys are as follows:

- FATIGUE LIFE IS REDUCED AS POROSITY LEVEL IS INCREASED, BASED ON A NUMBER OF INVESTIGATIONS (SUCH AS REF 6) AND DISCUSSED LATER IN THE SECTION "EFFECTS ON FATIGUE CRACK INITIATION" IN THIS ARTICLE.
- FATIGUE CRACK GROWTH RATES ARE NOT GREATLY AFFECTED (REF 6), ALTHOUGH INVESTIGATORS (REF 9) REPORTED THAT ALLOY D357-T6, WHEN SUBJECTED TO POROSITY-ELIMINATING HIPING, SHOWED REDUCED RATES.
- FRACTURE TOUGHNESS IS NOT GREATLY AFFECTED (REF 6, 11).

**Dross.** The role of dross has been studied to a lesser extent than that of gas porosity, possibly because dross is much more difficult to detect and quantify. Also, the presence of dross and gas porosity are related. Aluminum oxide inclusions have been reported to serve as nucleation sites for gas pores (Ref 12).

Therefore, at any given level of dissolved hydrogen in a melt, castings poured with "dirty" metal will contain more gas porosity than those poured with "clean" metal. As a result, it is somewhat difficult to characterize the effects of the two independent of one another. Despite these difficulties, it is clear that dross can adversely affect alloy strength (Ref 13). Ozelton et al. (Ref 6) attempted to introduce dross ("less dense foreign material") into alloy D357-T6 test plates by pouring molten metal down the mold risers rather than the downsprue. Castings with foreign material corresponding with ASTM E155 grades A/B, B, and C were more susceptible to crack initiation based on results of stress-life tests, as would be expected. By way of contrast, the investigators found that crack growth rates and fracture toughness levels were not significantly affected (Ref 6).

## Al-Si-Mg Cast Alloys

Cast aluminum alloys A356 and A357/D357 (Tables 1 and 2) are part of the Al-Si-Mg alloy family and are the most commonly specified cast aluminum alloys for aircraft applications. This alloy system is a favorite of foundrymen and their customers, as the fluidity provided by silicon additions allows casting of complex, thin-walled components.

High-strength (ultimate tensile strength of 345 MPa, or 50 ksi) alloy A357-T6 castings were in production in the United States by the late 1960s. The alloy was used in the F-5 Northrop fighter wing pylon, which is still remarkable in size, complexity, uniformity of mechanical properties and production quantity (more than 15,000 in a twenty-year span) (Ref 2). The principles of controlled solidification were used to obtain a fine microstructure and a high degree of soundness in an alloy of tightly controlled composition.

The capability to produce high-strength castings with thin walls (less than 2.5 mm, or 0.1 in.) was developed over several decades with some initial work in the mid-1960s. Work by Goehler et al. (Ref 14) led to several new applications, for example, the alloy A357 Krueger flap for the Boeing model 737 aircraft. Several significant programs from the 1970s demonstrated both the technical viability and economic benefits of thin-wall castings in aircraft components:

- VOUGHT/USAF A-7 CAST ALUMINUM SPOILER (1976, REF 8)
- BOEING/USAF YC-14 BULKHEAD ("CAST") PROGRAM (1976-1979, REF 3)

In both programs, full-scale cast test articles were subjected to static, fatigue, and damage tolerance tests. Both test articles met aircraft performance specifications. The CAST program in particular is viewed by some investigators (Ref 4) as the technical foundation for aircraft structural castings. The U.S. Air Force/Boeing Air-Launched Cruise Missile AGM-86B took advantage of the results of the CAST program to produce the entire missile body. The cast design enabled the Air Force to realize tremendous savings in both cost and schedule.

Investigations at Boeing (Ref 15) and Northrop (Ref 6) led to the further refinement of alloy A357 and the associated production controls. The product, registered as alloy D357 (AMS 4241), found application in the F-16 air inlet duct. A cast replacement duct design enabled the contractor to widen the throat of the duct while maintaining the existing external profile (made necessary by a switch to a more powerful engine). Destructive test data generated during production of the inlet and other castings were used to formulate statistically based design allowables for the alloy (Ref 16)--a unique feature of alloy D357. The allowables were the product of tighter restrictions on alloy composition, nondestructive inspection criteria, and production practices. Since 1986, the alloy has been specified for other critical castings in both military and civil aircraft.

### Microstructure and Properties

The Al-Si-Mg alloys are two-phase systems, where magnesium provides age-hardening, and silicon is present in the microstructure of the age-hardened alloy as both interdendritic eutectic and in the  $Mg_2Si$  strengthening precipitate. In general, the microstructural features that most strongly affect mechanical properties are:

- DENDRITE-ARM SPACING
- SIZE AND DISTRIBUTION OF SECOND-PHASE PARTICLES AND INCLUSIONS

Both the primary aluminum dendrite size and the size and morphology of the silicon eutectic depend heavily on processing parameters such as solidification rate, the presence of chemical modifiers, and solution heat treatment. The size and distribution of  $Mg_2Si$  precipitate particles depend on quench rate, magnesium content, and aging treatment.

Ideally, these features would be the only considerations in the design of casting processes. However, because of the physical and chemical properties of molten aluminum alloys, the founders and users must also take into account such phenomena as shrinkage, gas porosity, and nonmetallic inclusions usually from dross (i.e., thin aluminum oxide films formed during melting and pouring). In addition, if undesirable trace elements (especially iron) are present, large acicular intermetallic compounds may also be present. Figures 1(a) and 1(b) illustrate two extremes of microstructure.

**FIG. 1** TYPICAL MICROSTRUCTURE OF AL-SI-MG CASTING. (A) PHOTOMICROGRAPH SHOWING COARSE DENDRITIC STRUCTURE AND ACICULAR SILICON EUTECTIC (INVESTMENT CAST 354-F ALLOY AT 250 $\times$ ). (B) PHOTOMICROGRAPH SHOWING FINE DENDRITIC AND HEAVILY MODIFIED SILICON EUTECTIC (200 $\times$ )

All these features influence the static, fatigue, and fracture properties of the alloys, and a tremendous amount of work by producers and users has been done to characterize and improve the product; a few examples are given in Ref 3, 6, and 15. It is beyond the scope of this paper to summarize them here. However, the key role of microstructural fineness is summarized here due to its well-known beneficial influence on strength, toughness, and overall fatigue and fracture resistance.

**Premium (high-strength, high-toughness) castings** combine a number of conventional casting procedures in a selective manner to provide premium strength, soundness, dimensional tolerances, surface finish, or a combination of these characteristics. As a result, premium engineered castings typically have somewhat higher fatigue resistance than conventional castings. Table 3 gives typical fatigue limits on various premium castings.

(D) FATIGUE STRENGTH FOR  $10^6$  CYCLES

The production of premium-quality castings is an example of understanding and using the solidification process to good advantage. Depending on the casting process, various methods are used to engineer the rates and directions of molten metal solidification within the mold. For example, in the sand-chill composite process, metallic chills placed at selected locations within the mold provide greatly enhanced solidification rates. In the shell investment casting process, since the ceramic shell molds are routinely preheated prior to pour, metallic chills are of limited value. Alternative heat extraction methods such as the use of cryogenic or other fluids are therefore used to promote more rapid solidification.

### Fatigue and Fracture Properties of Aluminum Alloy Castings

Theodore L. Reinhart, Boeing Commercial Airplane Group

---

### Effects of Microstructural Fineness

**Measurement of Microstructural Fineness.** Microstructural fineness is related to the size of the primary aluminum dendrites and the interdendritic silicon eutectic phase. Fineness is measured by quantitative systems such as the dendrite arm spacing (DAS) (Ref 17) or the cell count method (Ref 15). Silicon particles are usually characterized by an aspect ratio (Ref 15). When considering effects on properties, it is somewhat difficult to consider the two separately because the steps taken to achieve fine dendrite size (enhanced solidification) also modify the silicon, that is, particle size and aspect ratio are reduced. The two will therefore be treated together.

**Effect on Fatigue Life.** The beneficial effect of refined microstructures for improved fatigue life has been known for decades, and one of the best demonstrations of this is an early work (Ref 18) that shows with good clarity the systematic variations of microstructure, tensile, and fatigue properties with respect to distance from a chill in alloy 356 plus beryllium test casting. The investigator showed that both fatigue strength and ultimate tensile strength decreased with increasing distance from the chill. Figure 2 shows the stress-life relationships for specimens taken at various distances from the chill; the microstructural explanation (or part of it in terms of dendrite cell size) is shown in Fig. 3--at any given maximum stress level, fatigue life is related to microstructural fineness in terms of the mean dendrite cell size.

**FIG. 2 STRESS-LIFE CURVES FOR SPECIMENS TAKEN AT VARIOUS DISTANCES FROM A CAST IRON CHILL EMBEDDED IN THE MOLD. ALLOY 356 WITH BERYLLIUM ADDITION. FROM REF 18**

**FIG. 3 FATIGUE LIFE AS A FUNCTION OF STRESS LEVEL AND MEAN DENDRITE CELL SIZE FOR ALLOY 356 PLUS BERYLLIUM. 1, 35 ± 2.5 KSI; 2, 30 ± 2.5 KSI; 3, 25 ± 2.5 KSI; 4, 20 ± 2.5 KSI; 5, 15 ± 2.5 KSI. FROM REF 18**

Other works show similar trends. For example, Fig. 4 (Ref 19) shows fatigue life as a function of DAS for alloy A357-T6. Ozelton et al. (Ref 6) studied the effects of "nonoptimum" processing on the fatigue life of alloy D357-T6. Smooth specimens with coarser microstructure had shorter fatigue lives, but the effect was less pronounced for notched fatigue specimens (Fig. 5).

FIG. 4 FATIGUE LIFE AT 165 MPa (24 KSI) MAXIMUM STRESS FOR ALLOY A357-T6 AS A FUNCTION OF DENDRITE ARM SPACING. FROM REF 19

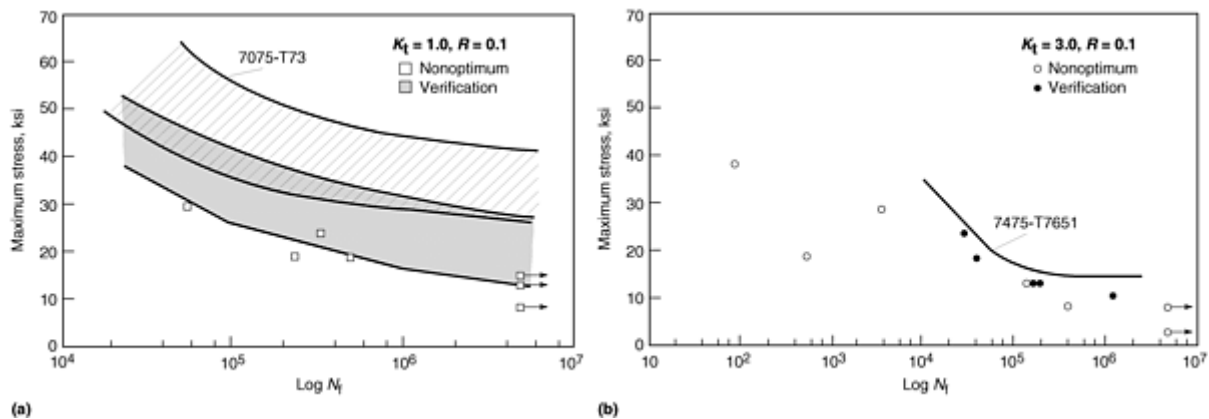

FIG. 5 STRESS-LIFE FATIGUE DATA FOR D357-T6 WITH NONOPTIMUM (RELATIVELY COARSE) MICROSTRUCTURE. (A) SMOOTH ( $K_T = 1.0$ ) SPECIMENS. (B) NOTCHED ( $K_T = 3.0$ ) SPECIMENS. FROM REF 6

**Effects on Fatigue Crack Initiation.** Many investigators (e.g., Ref 6, 19, 20, 21, 22, 23) cite the role of various discontinuities--usually gas porosity, microshrinkage, or dross--in fatigue crack initiation. The effect of microstructural refinement on fatigue life may be explained in part by the fact that rapid solidification produces not only fine dendrites and highly modified silicon, but also tends to distribute any available dissolved hydrogen as numerous, minute, rounded pores. Slower solidification, on the other hand, provides time needed for the formation of larger gas pores. A similar trend applies to microshrinkage. Larger pore/cavity size is generally accepted as providing sites for early crack initiation and, hence, shorter fatigue life. One investigator (Ref 19) concluded that casting discontinuities of size similar to the silicon eutectic particles in alloy A357-T6 will not have a detrimental effect on fatigue strength.

When specimens with stress concentration factor ( $K_T$ ) greater than 1.0 are considered, initiation is often found to occur at geometric features (holes/notches) as opposed to process-related discontinuities. Comparisons of smooth and open-hole specimens machined from cast alloy D357-T6 test plates ( $K_T = 1.0$  and 3.0, respectively) by the author (Ref 24) showed

that cracks initiated at small dross (aluminum oxide) inclusions at the polished surfaces of  $K_t = 1.0$  specimens. In the latter type, initiation occurred at the hole shoulder or at "rifle" marks in the bore.

**Effects on Crack Growth Rates.** Results are divided, to some extent, with respect to the effect of microstructural refinement on crack growth in Al-Si-Mg alloys. At least one work (Ref 21) concluded that coarser microstructure gave favorable results; however, others such as Ozelton et al. (Ref 6) report little or no apparent effect. Figure 6 shows  $da/dn$  versus  $\Delta K$  curves for alloy D357-T6 with typical microstructures shown in Fig. 7(a) and 7(b). Note the relatively large dendrites and the rodlike silicon in the material labeled "nonoptimum." The investigators concluded that this had no effect on  $da/dn$ ; however, Fig. 6 seems to suggest higher rates for the "nonoptimum" material at higher  $\Delta K$  levels (above 10  $\text{ksi}\sqrt{\text{in}}$ ).

FIG. 6 FATIGUE CRACK GROWTH RATE OF ALLOY D357-T6 WITH NONOPTIMUM (RELATIVELY COARSE) MICROSTRUCTURE. FROM REF 6

FIG. 7 TYPICAL MICROSTRUCTURES FOR ALLOY D357-T6. (A) RELATIVELY FINE. AS-POLISHED. 50 $\times$ . (B)

Lee et al. (Ref 25) found that the fatigue crack growth characteristics of cast alloy A356-T6 were a function of a variety of factors; prominent among them was the effect of silicon particle size and morphology (degree of modification). They found different mechanisms at work in cast alloy with unmodified versus strongly modified silicon:

- CRACK GROWTH IN UNMODIFIED MATERIAL OCCURRED BY CLEAVAGE/CRACKING OF SILICON PARTICLES. THE TENDENCY FOR PARTICLE CRACKING INCREASES WITH PARTICLE SIZE (ASPECT RATIO).
- IN ALLOY WITH MODIFIED SILICON, DECOHESION OF THE SILICON PARTICLES AND THE MATRIX OCCURS. IT IS BELIEVED THAT THIS METHOD OF CREATING A NEW INTERFACE REQUIRES MORE ENERGY THAN DOES PARTICLE CRACKING (WHICH MAY EXPLAIN THE SLOWER CRACK GROWTH RATES IN THE MODIFIED MATERIAL).

**Effect on Fracture Toughness.** Several examples illustrate the role between refined microstructure and improved fracture toughness. For example, Ozelton et al. (Ref 6) found that alloy D357-T6 with coarse microstructure had significantly lower plane strain fracture toughness ( $K_{Ic}$  in the 17 to 18 ksi $\sqrt{in}$  range) than material with fine structure ( $K_Q$  about 24 ksi $\sqrt{in}$ ). Other examples are demonstrated for dynamic fracture toughness (Ref 11) and Charpy impact energy of alloy A356-T6 subjected to different solidification rates, chemical modification, and various solution treatment times (Ref 12). As expected, processing conditions that yielded fine dendrites and silicon particles also imparted relatively high impact energy levels.

The significance of fine microstructure is a key factor for improved fatigue life, slower crack growth, and higher fracture toughness. However, other metallurgical factors have important effects as well. Yield strength, for example, is determined primarily by magnesium content and heat treatment (Ref 3, 15, 26). Oswalt and Maloit (Ref 26) characterized the yield strength-toughness relationship for alloy D357-T6. Figure 8 shows the effects of aging at 160 °C (325 °F) up to 12 h; data from Ref 11 are shown superimposed. The investigators also found a correlation between the notch yield ratio (NYR = notch tensile strength divided by tensile yield strength) and fracture toughness; a similar relationship for alloy A357 is reported in Ref 13.

FIG. 8 YIELD STRENGTH-TOUGHNESS RELATIONSHIP FOR ALLOY D357-T6 AGED AT 160 °C (325 °F) (0 TO 12 H). NYR, NOTCH TENSILE STRENGTH DIVIDED BY TENSILE YIELD STRENGTH. FROM REF 26

---

## Composition Effects

**Residual Iron.** Several investigators have studied the effects of residual elements, especially iron, on the properties of Al-Si-Mg casting alloys. Iron forms an intermetallic beta phase with an acicular platelet morphology in many aluminum alloys (both cast and wrought). These platelets act as stress raisers in the alloys and are known to have adverse effects on mechanical properties and fabrication characteristics. And, as it turns out, both fatigue life and fracture toughness can be affected as well. Wickberg et al. (Ref 27) found that an increase in the nominal iron content of alloy A356-T6 from 0.2 to 0.4% resulted in a noticeable reduction in fatigue life--refer to Fig. 9.

FIG. 9 INFLUENCE OF ALLOY A356-T6 IRON CONTENT ON FATIGUE LIFE. FROM REF 27

Beryllium was originally included in alloy A357-T6 in the composition to mitigate the effects of iron. It does so by modifying the intermetallic morphology from that of a platelet to an indistinct, more rounded shape. Tan et al. (Ref 28) studied the effects of beryllium additions on the fracture toughness of permanent-mold cast alloy A357 with relatively high and low iron levels. They found the following:

- THE FRACTURE TOUGHNESS OF BERYLLIUM-FREE ALLOYS WAS REDUCED SLIGHTLY ( $K_{IC}$  FROM ABOUT 25 TO 21  $\text{MPa}\sqrt{m}$  BY AN INCREASE FROM 0.01 TO 0.15% FE.
- BERYLLIUM IS EFFECTIVE IN MITIGATING THE EFFECTS OF IRON IN ALLOYS WITH 0.15% FE.
- BERYLLIUM HAS NO APPARENT BENEFICIAL EFFECT ON LOW-IRON (0.01%) ALLOY.

### Al-Cu Cast Alloys

The Al-Cu (and, in some cases, Ag) alloy system offers higher strength than the Al-Si-Mg alloys--at the expense of producibility. Because of the tendency of the Al-Cu system toward hot shortness, only relatively simple casting designs can usually be produced. Nonetheless, alloys such as A201 are used in various applications such as jet engine front frames. Alloy composition and mechanical property minimum values are given in Tables 1 and 2, respectively.

**Microstructure and Mechanical Properties.** Because Al-Cu alloys lack a pronounced second phase, the effects of microstructure on tensile properties are more subtle. Ozelton et al. (Ref 6) characterized the effects of grain size on the properties of HIPed alloy A201-T7. HIPing reduces internal porosity and microshrinkage to very low levels; when this was done, it was found that grain size, and hence solidification rate, had little effect on tensile properties. On the other hand, in the absence of HIPing, solidification rate determines the concentration of internal voids in alloy A201 (Ref 29). In this case, tensile elongation is higher under conditions of rapid solidification.

Fatigue life is similarly affected by solidification rates and its consequences on microstructural fineness and the presence of voids. In general, fatigue life drops with distance from the chill, as noted for all conditions of alloy KO-1 (later designated A201) in Ref 29. The decrease is attributed to the increase in microporosity with distance from the chill. Ozelton et al. (Ref 6) found that grain size had no apparent effect on the fatigue life of HIPed alloy B201-T7 (B201 is a modified version of alloy A201).

Likewise, Ozelton et al. (Ref 6) found that grain size had no apparent effect on the crack growth rate (Fig. 10) or fracture toughness in HIPed alloy B201. Chien et al. (Ref 29), on the other hand, found that crack growth rates in alloy KO-1 were slower for coarse-grained alloy (see Fig. 11). Despite the slower  $da/dN$  fatigue life in coarse-grained KO-1 was relatively short (Ref 29), indicating that initiation occurred earlier (probably the result of higher microshrinkage content). Thus, it appears that grain size has only an indirect effect on crack growth in single-phase alloys such as A201.

**FIG. 10 CRACK GROWTH RATE CURVES FOR COARSE- AND FINE-GRAINED HIPED ALLOY B201-T7. FROM REF 6**

FIG. 11 CRACK GROWTH RATE CURVES FOR ALLOY KO-1 (NOW A201) AS A FUNCTION OF DISTANCE FROM MOLD CHILL. FROM REF 29

**Effect of Discontinuities.** The presence of internal discontinuities is a significant factor in determining fatigue and fracture properties. Several studies on the effects of HIPing on alloy A201-T7 (Ref 30 and 31) provide relevant information. For example, both investigations reported improved fatigue life in HIPed alloy, such as shown in Fig. 12. However, Mocarski et al. (Ref 30) reported no effect on crack growth rates (see Fig. 13). They did find a modest increase (about 6%) in plane strain fracture toughness as a result of HIPing.

FIG. 12 STRESS-LIFE FATIGUE DATA FOR ALLOY A201-T7 CASTINGS WITH AND WITHOUT HIPING. FROM REF 30

FIG. 13 FATIGUE CRACK GROWTH RATES FOR ALLOY A201-T7 CASTINGS WITH AND WITHOUT HIPING. FROM REF 30

**Environmental Effects.** Fatigue and fracture properties tests are expensive, and tests involving special conditions (such as high/low temperature, the presence of corrosives, etc.) add to the costs. This may explain, in part, the limited data on this subject as noted below.

**Temperature Effects.** The author is aware of two substantive studies in this area. Tirpak (Ref 32) documented fatigue and fracture properties for alloys A357-T6 and A201-T7 from ambient temperature to 200 °C (392 °F); fatigue relationships are shown in Fig. 14 and 15. Misra et al (Ref 33) showed that fracture toughness and crack growth rates for alloy A357-T6 are not affected by temperature over the range from ambient to -196 °C (-320 °F).

FIG. 14 STRESS-LIFE FATIGUE DATA AT THREE TEST TEMPERATURES FOR ALLOY A201-T7. FROM REF 32

FIG. 15 STRESS-LIFE FATIGUE DATA AT THREE TEST TEMPERATURES FOR ALLOY A357-T6. FROM REF 32

**Humidity Effects on Fatigue Crack Growth.** Doyle et al. (Ref 34) reported that high (but unspecified) humidity level increased the crack growth rate in specimens machined from alloy A357-T6 F-16 vertical stabilizer frames. However, when the data are compared with that from the CAST program (Ref 3), it is seen to be within the scatter band of tests conducted in normal laboratory air (see Fig. 16).

FIG. 16 FATIGUE CRACK GROWTH RATES FOR ALLOY A357-T6 TESTED IN NORMAL LABORATORY AIR AND IN "HIGH HUMIDITY" AIR. FROM REF 33

**Corrosives (Salt) Effects.** Only two references were found regarding corrosion effects in salt environments. Czyryca (Ref 35) studied the corrosion-fatigue behavior in the low-stress, long-life regime for alloy A356-T6. Rotating beam tests ( $R = -1$ ) conducted in air and seawater produced failure stress levels of 10 and 5 ksi, respectively, at 100 million cycles. Metallographic examinations showed fatigue cracks originating at pits caused by selective phase attack (corrosion of the silicon eutectic). Corrosion-fatigue cracks followed a path through the interdendritic region.

Mocarski et al. (Ref 30) performed crack growth tests on alloy A201-T7 specimens in laboratory air in 3.5% saltwater. They found no significant difference between the two sets of results.

**Effects of Loading Conditions.** Materials screening tests are usually performed using constant-amplitude loading conditions. When evaluating the suitability of metallic materials for military aircraft applications, several investigators have used custom-tailored loading conditions ("spectrum fatigue"). Tirpak and Ruschau (Ref 36) studied the responses of alloys 7050-T76, A201-T7, and A357-T6 to a tension-compression load history chosen to represent that of a lower wing location on a fighter aircraft. They found that A357-T6 had the lowest crack growth rates over the range of stress intensities tested. Figure 17 summarizes the data. Under spectrum fatigue loading, the results differ from those under constant amplitude, tension-only loading. For purposes of comparison, refer back to Fig. 6; note that the curve for the wrought reference material (7075-T7351) crosses over the D357 curve in this case. This crossover was not found by Tirpak et al. for spectrum loading conditions.

### Component Tests

A number of programs involving static, fatigue, and damage tolerance testing of full-scale cast test articles are documented in the literature. A brief review of several prominent programs is offered below.

- *VOUGHT A-7 CAST SPOILER (REF 8)*: TEN ALLOY A201-T7 CAST COMPONENTS WERE SUBJECTED TO STATIC AND/OR FATIGUE TESTS. A BASELINE BUILT-UP SPOILER WAS ALSO TESTED. THE CAST COMPONENTS MET ALL PERFORMANCE CRITERIA--STATIC, FATIGUE, AND RESIDUAL STRENGTH.
- *"CAST" PROGRAM YC-14 FORWARD BULKHEAD (REF 3)*: STATIC, FATIGUE, AND DAMAGE TOLERANCE TESTS WERE PERFORMED ON A FULL-SCALE BULKHEAD. THE ALLOY A357-T6 TEST ARTICLE MET ALL PROGRAM REQUIREMENTS.
- *USAF/GENERAL DYNAMICS F-16 VERTICAL STABILIZER SUBSTRUCTURE (REF 34)*: THE SUBSTRUCTURE WAS ASSEMBLED INTO AN F-16 VERTICAL STABILIZER, COMPLETE WITH GRAPHITE-POLYIMIDE COMPOSITE SKINS, AND SUBJECTED TO STATIC, FATIGUE, AND DAMAGE TOLERANCE TESTS. THE ASSEMBLED STABILIZER MET ALL PROGRAM REQUIREMENTS.
- *AEROSPATIALE A320 ACCESS DOOR SUBSTRUCTURE*: A CONVENTIONAL BUILT-UP ACCESS DOOR AND A DOOR WITH CAST SUBSTRUCTURE WERE SUBJECTED TO CYCLIC PRESSURE TESTS. CRACK INITIATION IN THE CONVENTIONAL DOOR OCCURRED AT  $10^5$  CYCLES; INITIATION OCCURRED AT  $3 \times 10^5$  CYCLES IN THE DOOR WITH CAST SUBSTRUCTURE.

These results were achieved using cast alloys with relatively modest properties. Thus, the influence of design on component performance is evident.

## Considerations for Future Work

This article attempts to briefly summarize the general relationships between microstructure, processing, coupon properties, and component performance. In so doing, some points for possible future consideration may include the following:

- *WELD REWORK OF AL-SI-MG CASTINGS*: KNOWLEDGE OF THE INTERACTION BETWEEN THE VERY FINE WELD METAL MICROSTRUCTURE AND GAS POROSITY, AND HOW IT AFFECTS WELD FATIGUE LIFE, WOULD BE USEFUL. IN ADDITION, THE DEVELOPMENT OF OPTIMIZED WELDING PROCEDURES FOR ALLOYS SUCH AS D357-T6 WOULD BE OF GREAT VALUE TO BOTH CASTING SUPPLIERS AND USERS.
- *FATIGUE LIFE MODELING*: A STUDY OF FATIGUE LIFE OF ALLOY D357-T6 AS A FUNCTION OF DISTANCE FROM A SAND MOLD CHILL, AS WAS DONE BY BAILEY (REF 18) FOR A356, WOULD BE USEFUL TO THOSE ENGAGED IN CASTING DESIGN AND/OR THE DEVELOPMENT OF COMPUTER MODELING TOOLS.
- *PERFORMANCE ANALYSIS OF CAST COMPONENTS*: PROJECTS TO GAIN A BETTER UNDERSTANDING OF CASTING COMPONENT PERFORMANCE ARE NEEDED. FOR EXAMPLE, THE WAY THAT LOADS ARE REDISTRIBUTED WHEN A CRACK FORMS IN A CAST COMPONENT IS NOT WELL UNDERSTOOD.
- *ALLOY DEVELOPMENT*: THE EXISTING ALLOYS HOLD A GREAT DEAL OF POTENTIAL FOR INCREASED UTILIZATION. A NEW CASTING ALLOY WOULD HAVE TO PROVIDE SIGNIFICANT IMPROVEMENTS IN PROPERTIES WHILE STILL PROVIDING EXCELLENT CASTABILITY AND WELDABILITY--AT A COMPETITIVE PRICE, OF COURSE.

### Introduction

THE USE OF ALUMINUM for structural applications has increased significantly in recent years, and more applications are likely to emerge as designers and engineers are required to decrease the weight of structural components. Many of these structures and structural components are used in environments that subject them to dynamic loading. Despite the difficulties in designing against fatigue failure, aluminum is used successfully in many fatigue critical applications in structures such as aircraft, ships, trucks, cars, and bridges. The continued safe operation of these structures requires reliable information on the performance of the parent aluminum alloys, the welded aluminum joints necessary to form a component, and the larger-scale structural details.

In general, the response of a joint is determined by both global and local parameters. Global influences include the level of load that the structure is designed to support, the level of redundancy that is built into the structure, the structural load path, and so forth. Often of more significance in determining fatigue performance is the influence of local effects, such as local stress fields, defect conditions, residual stress state, and material properties. This article briefly reviews the factors that affect the fatigue strength of aluminum alloy weldments.

The progressive failure mechanisms that operate in welded joints are no different from those in the metals which they join. However, welds are usually located at a structural (global) stress concentration, typically introduce a severe notch (i.e., local stress concentration), often contain microstructures that represent an unfavorable alteration of the parent metal microstructure, frequently contain planar or volumetric discontinuities, and typically contain high tensile residual stresses. Most of the data presented for welded details have been obtained from test programs conducted on relatively small specimens (Ref 1). Due to the significance of residual stresses on the fatigue performance of welded construction (Ref 2, 3), direct applicability of these data to welded aluminum components is limited (Ref 4, 5, 6, 7, 8). These programs have generally shown that the data obtained from large specimens indicate a lower fatigue performance than smaller-specimen data. As a result, recent revisions of both North American and European specifications (Ref 9, 10) reflect the results of tests on full-scale structures.

## Fatigue Strength of Aluminum Alloy Welds

Jeffrey S. Crompton, Edison Welding Institute

---

## Fatigue Performance of Aluminum Welds

A number of factors, both global and local, influence the fatigue performance of welded aluminum joints. Among the most significant are:

- MAGNITUDE, NATURE, AND RANGE OF THE APPLIED STRESSES
- PROPERTIES OF THE BASE ALLOY
- STRESS CONCENTRATIONS ASSOCIATED WITH THE WELDMENT, WHICH ARE STRONGLY INFLUENCED BY A NUMBER OF OTHER PARAMETERS, SUCH AS JOINT TYPE, INTERNAL AND EXTERNAL GEOMETRY, AND JOINT SIZE
- LEVEL OF RESIDUAL STRESS, WHICH CAN BE INFLUENCED BY POSTWELD HEAT TREATMENT, WELD PROCEDURE, AND POSTWELD MECHANICAL STRESS RELIEF

Of these, by far the most significant in determining the fatigue life of aluminum alloy weldments are the stress concentrations associated with the weldment and the residual stresses present in the weld. Base alloy properties lead to secondary influences.

The magnitude, nature, and range of applied stresses influence the fatigue failure of aluminum weldments in much the same manner as for other materials and weldments. As the mean level of stress or the range of applied stress increases, the fatigue life of the specimen, joint, or structure decreases. Similarly, the nature of the loading influences the observed fatigue life through its effect on local stresses. Loading in either tension, bending, or torsion will give rise to differing stress states in the specimen, and since localized stress is the cause of fatigue failure, significant changes in fatigue performance may result.

---

## Parent Alloy Effects

Some aspects of fatigue behavior can be affected by parent alloy selection, although this is generally a secondary factor in terms of the fatigue performance of welded aluminum joints. Typical endurance limit values for smooth-sided specimens of general structural alloys without welds are given in Table 1. It has been observed (Ref 11) that the endurance limit is approximately half of the tensile strength when considering general structural alloys with a tensile strength between 240 and 480 MPa. Alloys whose strength exceeds this upper value tend not to show this behavior, since their increased notch sensitivity limits fatigue life.

## TABLE 1 TYPICAL ENDURANCE LIMIT VALUES OF WROUGHT ALUMINUM ALLOYS

ALLOY AND TEMPER	FATIGUE ENDURANCE LIMIT, MPA <sup>(A)</sup>
2014-T6	124.11

In welded aluminum joints, the effect of the mechanical properties of the parent alloy on fatigue strength is not as significant as that reported for welded steel joints. The results of investigations of butt-welded aluminum joints (Ref 12) show that for ultimate tensile strengths up to approximately 345 MPa, there is no significant increase in fatigue strength for either 5xxx- or 7xxx-series alloys. However, 2xxx alloys with ultimate tensile strengths greater than 345 MPa exhibit higher average fatigue strengths. A comparison (Ref 13) of the fatigue performance of as-welded smooth butt joints in a range of structural aluminum alloys is shown in Fig. 1. It is evident that any significant differences in fatigue behavior occur away from the fatigue endurance limit.

FIG. 1 RESULTS OF AXIAL FATIGUE TESTS OF ALUMINUM ALLOYS AS-WELDED BUTT JOINTS IN  $\frac{3}{8}$ IN. PLATE. SOURCE: REF 1

At short lives, fatigue life is more closely related to the different strengths of the materials used. At long lives, alloy type exerts little influence, and a common curve is often used for design approaches. At these long lives the predominant mechanism of failure is by crack growth under fatigue loading. Figure 2 shows that there is little influence of alloy type on fatigue crack growth behavior (Ref 7). Consequently, little difference in fatigue life defined by crack growth approaches would be expected. Similarly, although the heat treatment and temper of an alloy may significantly affect the mechanical properties of the parent alloy, it has been reported (Ref 12) that alloy temper has little effect on the fatigue performance of as-welded smooth butt joints (Fig. 3).

### Fatigue Strength of Aluminum Alloy Welds

Jeffrey S. Crompton, Edison Welding Institute

### Joint Configuration

The fatigue life of a welded joint or structure is almost always limited by the fatigue life of the weld details. In general, the fatigue life of a component can be broken down into two phases: initiation and propagation. For smooth components, the crack initiation period represents the largest proportion of the total fatigue life. This is particularly noticeable at high fatigue lives, where the fatigue crack initiation period may exceed 95% of the fatigue life. In welded structures, the positioning of welds at structural discontinuities and the localized stress concentrations obtained in a weld detail change this response. The stress concentrations increase the local stresses and act to reduce the initiation period. Alternatively, the discontinuities associated with the weld toe region behave as preexisting cracks, and the fatigue life is then determined by the fatigue crack propagation behavior.

The high stress concentration inherent in the geometry of a fillet weld causes low fatigue strength in such joints. The joint designs with poorest fatigue resistance are the nonsymmetrical types, such as strap, tee, and lap joints in which large secondary stresses are developed. Poor fatigue resistance is also observed in non-load-carrying attachments or reinforcements to a plate (Tables 2, 3, and 4).

<b>5456-H321</b>	<b>351.65</b>	...	<b>137.9</b>	<b>110.32</b>	<b>16</b>

These effects are widely documented and are the basis for classification of structural joints for which statistical minima of fatigue strength have been developed (Ref 14). These classifications are appropriate for alloys in the endurance limit regime since there is little significant difference between alloy performance.

The effect of localized stress concentration on the fatigue performance of welded aluminum butt joints is illustrated in Fig. 4, 5, and 6. As-welded specimens possessed a weld bead, which itself provides a source of localized stress concentration. In specimens where the weld bead was removed, the stress concentration was removed, resulting in longer fatigue lives.

Many stress concentration sites exist in more commonly used joint configurations. These may be simple geometrical discontinuities from weld joint design or discontinuities that arise from the welding procedure. Of these, factors that produce a defective weld (e.g., excessive porosity, lack of fusion, etc.) act to produce severe internal stress concentrations, which may or may not override the effects produced by external factors such as structural discontinuities.

In general, the choice of filler metal and method of edge preparation exert little influence on welded joint fatigue behavior (Fig. 7 and 8). Single-V welds are usually superior (Table 5); lack of fusion and poor root pass problems often occur in double-V or square joints.

The fatigue strength of welded joints is relatively unaffected by the tensile strength of the material. This is because the majority of the fatigue life of a welded joint is spent in the propagation of fatigue cracks to critical sizes. Although tensile strength may be affected by changes in alloys, heat treatment, or temper, crack propagation rates are relatively insensitive to such changes.

## Fatigue Strength of Aluminum Alloy Welds

Jeffrey S. Crompton, Edison Welding Institute

---

### Residual Stress Effects

Residual stresses in weldments are produced by the local thermal expansion, plastic deformation, and subsequent shrinkage associated with the thermal cycling that occurs during welding. The precise distribution of residual stresses in a welded joint is complex and depends on a number of factors. Fatigue performance is significantly affected by the level of residual stress present in the weldment. If tensile residual stresses are present, the crack initiation phase is shortened, resulting in a reduction in fatigue life.

Extensive measurements and experimental data on residual stress distribution and its effect on fatigue life have been generated (Ref 16, 17, 18, 19, 20). Typical residual stress values may be as low as 20% of the parent alloy yield value or up to 45% of the heat-affected zone (HAZ) yield value. The influence of residual stresses on fatigue performance has been noted by a number of workers (Ref 21, 22) (Fig. 9). The effect of the residual stress depends on the maximum value and on the stress ratio of the applied stress. For a stress ratio of 0.5, there is little difference in fatigue strength between as-welded and stress-relieved specimens. For a stress ratio of -0.5, fatigue life improves for the stress-relieved specimens. At a stress ratio of zero, the fatigue strength at  $1 \times 10^7$  cycles is approximately 40% higher for the stress-relieved material.

**FIG. 9 EFFECT OF STRESS RELIEF ON FATIGUE STRENGTH OF 5456-H3221 LONGITUDINAL BUTT WELDS. SOURCE: REF 23**

The residual stress distribution is also influenced by the welding sequence and welding process (Ref 24), which may explain some of the differences in fatigue response that have been attributed to the influence of weld processing parameters (Ref 12, 25, 26). The buildup of restraint across the weld is a primary influence on the residual stress distribution across the weld. The restraint can be affected by factors such as preheat, weld bead, positioning, and end restraint, and thus determination of the effect of weld processing not attributable to the change in residual stress distribution is difficult.

### Improvement of Fatigue Performance

As has been shown, the fatigue life of aluminum weldments is primarily determined by two factors: the stress concentrations associated with the weld detail and the residual stresses associated with the weld. Consequently, there are two primary categories of techniques that can result in improved fatigue life:

## Techniques that modify the weld toe geometry

- MACHINING
- GRINDING
- WATER JET EROSION
- REMELTING TECHNIQUES (E.G., TUNGSTEN-INERT GAS, OR TIG, DRESSING)

These techniques improve fatigue strength because they remove the slag intrusions that form at the weld toes. They also modify the weld toe geometry, thereby reducing the stress concentration effect.

## Techniques that impose a compressive residual stress field

- HAMMER PEENING
- SHOT PEENING
- NEEDLE PEENING
- SPOT HEATING
- LOCAL COMPRESSION

The introduction of compressive residual stresses in the surface material effectively reduces the tensile component of any applied stress, and thus reduces the crack propagation rate during the early stages of crack growth.

Fatigue performance can also be enhanced by using improved welding procedures. Recent developments in solid-state welding technology (Ref 27) have enabled the production of welds in aluminum that do not possess some of the geometrical and material inhomogeneities commonly found with conventional welding technology. Friction stir welding (FSW) has been found to produce fatigue properties superior to those obtained from specimens produced by metal-inert gas (MIG) and plasma keyhole welding (Ref 27). These data are shown in Fig. 10 and 11 for alloys 6005 and 6082 for a range of temper conditions.

### Fatigue Strength of Aluminum Alloy Welds

Jeffrey S. Crompton, Edison Welding Institute

---

### Size Effects on Fatigue Performance

Considering the significant influence of weld geometry and residual stress distribution on the fatigue performance of welded aluminum joints, it is not surprising that the fatigue results obtained from small-scale specimens demonstrate distinctly higher fatigue limits than those obtained in full-scale sections. In a study of the effect of changing attachment plate size from 3 to 24 mm while maintaining a constant local weld toe geometry, Maddox (Ref 28) has shown significant differences in S-N data. This has led to the proposal that scale correction factors can be used that allow estimation of the fatigue strength of components of differing thicknesses. This scale correction factor has been proposed to be:

$$\text{Scale factor} = \left( \frac{12}{T_{\text{eff}}} \right)^{0.25} \text{ for plate thicknesses } T \geq 12 \text{ mm}$$

and

$$\text{Scale factor} = \left( \frac{2T}{L} \right)^{0.25} \left( \frac{12}{T} \right)^{0.13} \text{ for plate thicknesses } T < 12 \text{ mm}$$

Here  $T_{\text{eff}}$  is the effective thickness, which is  $0.5 L$  if  $L/T < 2$ , where  $L$  is the toe separation of the welds, and  $T$  is  $L/T > 2$ .

In a similar manner, many results (Ref 5, 7, 15, 29, 30) have indicated that larger-scale beam structures have lower fatigue lives than those predicted from small-scale specimens. Obviously, one explanation for this behavior is the potential difference in the residual stress distribution of the welded joints brought about by the different degrees of restraint imposed on the weld by the structural fabrication techniques. In addition, the complex stress distributions associated with the gradients affect both the localized stress, thereby potentially influencing crack initiation, and the driving force for crack growth. By considering the combined effects of residual stress, complex local stress distributions, and steep stress gradients, Jaccard (Ref 7) has been able to evaluate accurately the fatigue life of complex structural welded aluminum components.

## Fatigue and Fracture Properties of Titanium Alloys

---

### Introduction

TITANIUM is used for two primary reasons: structural efficiency, which derives from its combination of high strength and low density; and resistance to corrosion by chlorides and oxidizing media, which derives from its strong passivation tendencies. Titanium, like most structural materials, is supplied in all mill product forms, and several titanium alloys are available to meet specific needs.

In general, titanium and titanium alloys have a well-earned reputation for reliability in service. In no small measure, this is a result of the double and triple vacuum arc melting procedures employed throughout the industry in producing the alloys. That reputation is protected also by the excellent corrosion resistance exhibited by titanium. Titanium does not corrode in salt water. Crack initiation in titanium is almost always mechanically induced; only under very special circumstances will cracks initiate due to a combination of an environment and static stress.

This article summarizes the key variables that affect the fracture toughness, fatigue life, and subcritical crack growth of titanium alloys. Several metallurgical and environmental variables influence the fracture behavior of titanium alloys. Because of the many possible effects of chemistry, microstructure, texture, environment, and loading, it is not possible to quantify the crack growth behavior of titanium alloys unless these factors are closely controlled. Alloys within a given class, such as alpha-beta alloys, show parallel trends in their fracture toughness and crack propagation behaviors. To the extent that they have been studied, the trends for interstitial effects are similar for all alloys, the higher levels of interstitials leading to faster fatigue crack propagation and lower  $K_{Ic}$ . A similar trend is observed for variations in microstructure. Those microstructures (Widmanstätten or recrystallization annealed) that give the highest  $K_{Ic}$  values generally yield the lowest crack growth rates, whether under fatigue or sustained loads. However, increases in  $K_{Ic}$  from microstructural changes do not always lead to lower fatigue crack growth rates. For example, if small surface cracks are considered, a higher toughness can lead to higher fatigue crack growth rates.

---

## Fatigue and Fracture Properties of Titanium Alloys

### Strength and Toughening

---

Table 1 summarizes some of the common grades of commercially pure titanium and alloy types. These grades have varying amounts of impurities (e.g., carbon, hydrogen, iron, nitrogen, and oxygen). Some "modified" grades also contain small palladium additions (Ti-0.2Pd) and nickel-molybdenum additions (Ti-0.3Mo-0.8Ni). Because small amounts of interstitial impurities greatly affect the mechanical properties of pure titanium, it is not convenient to distinguish between the various grades of unalloyed titanium on the basis of chemical analysis. Titanium mill products are more readily distinguished by mechanical properties, as noted in Table 1 for various specification grades.

Titanium alloys are grouped into classes (Table 2), depending on the room-temperature composition of the alpha crystal (hexagonal close-packed) and/or the beta crystal (body-centered cubic) phase structure. Stable transformation and phase compositions from the high-temperature beta phase are altered by alloying additions, which are typically classified as alpha stabilizers or beta stabilizers. Vanadium, iron, and hydrogen are beta stabilizers, while aluminum, oxygen, and nitrogen are examples of alpha stabilizers. The following sections briefly review the general strengthening and toughening principles for the three groups of titanium alloys. The common Ti-6Al-4V alloy is described separately.

## Fatigue and Fracture Properties of Titanium Alloys

### Alpha-Beta Alloys

**Ti-6Al-4V.** The most important titanium alloy is Ti-6Al-4V, which has found application for a wide variety of aerospace components and fracture-critical parts. With a strength-to-density ratio of  $25 \times 10^6$  mm ( $1 \times 10^6$  in.), Ti-6Al-4V is an effective lightweight structural material and has strength-toughness combinations between those of steel and aluminum alloys.

The Ti-6Al-4V alloy is most commonly used in the annealed condition. However, the alloy contains a small amount of beta phase (about 10 vol% at room temperature), which imparts some hardenability by heat treatment in sections less than 25 mm (1 in.) thick. The key to hardening is to quench from high in the alpha-beta field and then age at a lower temperature. A typical strengthening heat treatment consists of heating for 1 h at 955 °C (1750 °F) and water quenching, followed by heating for 4 h at 540 °C (1000 °F) and air cooling. When alloy Ti-6Al-4V is processed improperly after heating into the beta field, alpha phase can form preferentially along the prior beta grains. Extensive hot work is required to break up such structures. Because cracks tend to propagate in or near interfaces, this type of structure can provide loci for crack initiation and propagation and thereby lead to premature failure.

In the annealed condition, the Ti-6Al-4V alloy derives its annealed strength from several sources, the principal source being substitutional and interstitial alloying of elements in solid solution in both alpha and beta phases. Oxygen, nitrogen, hydrogen, and carbon are the interstitial elements, which generally increase strength and decrease ductility. Aluminum is the most important substitutional solid solution strengthener. Its effect on strength is linear. Other, less important sources of strengthening are interstitial solid solution strengthening, grain size effects, second-phase (beta) effects, ordering in alpha, age hardening, and effects of crystallographic texture.

At room temperature, Ti-6Al-4V is about 90 vol% alpha, and thus the alpha phase dominates the physical and mechanical properties of the alloy. However, the overall effects of processing history and heat treatment on microstructure are complex. The microstructure depends on both processing history and heat treatment, and the microstructure that combines highest strength and ductility is not necessarily the microstructure that provides optimum fracture toughness or resistance to crack growth. Improvements in  $K_{Ic}$  can be obtained by providing either a microstructure of transformed beta or an equiaxed structure composed mainly of regrowth alpha that has both low dislocation densities and low concentrations of aluminum and oxygen (the so-called "recrystallization annealed" structure).

Transformed structures enhance toughness, primarily because fractures in such structures must proceed along tortuous, many-faceted crack paths. Transformed, Widmanstätten-like microstructure occurs from  $\beta \rightarrow \alpha + \beta$  transformation during cooling from the beta-phase field. The effect on toughness is summarized in Tables 3 and 4.

**TABLE 3 TYPICAL FRACTURE TOUGHNESS OF HIGH-STRENGTH TITANIUM ALLOYS**

(A) HEATED FOR 1 H AT INDICATED TEMPERATURE AND THEN AIR COOLED.

(B) VALUES IN PARENTHESES CALCULATED FROM LINEAR LEAST-SQUARES EXPRESSION RELATING % TRANSFORMATION TO  $K_{IC}$

Another microstructure of special interest in obtaining maximum fracture toughness is one produced by so-called recrystallization annealing. In this process, the alloy is heated to a temperature about 70 °C (125 °F) below the transformation temperature, held for a time, and then very slowly cooled. Most of this structure is continuous primary alpha phase and regrowth alpha (that is, alpha that has formed on the preexisting primary alpha phase). The primary alpha existed at the upper temperature and nucleated the regrowth alpha during cooling. This procedure is well established for the Ti-6Al-4V extra-low interstitial (ELI) alloy, and typical data for the recrystallization annealed alloy are shown in Fig. 1. The slow cooling should be terminated at about 700 °C (1300 °F) to avoid ordering the  $Ti_3Al$  formation. This is less important for the ELI grade than for the standard grade. A real virtue of the recrystallization annealed microstructure is that substantial toughness is achieved while maintaining ductility and high strength (Fig. 1). Such a microstructure also tends to reduce scatter in the data, thus permitting higher design criteria.

FIG. 1 FRACTURE TOUGHNESS AND YIELD STRENGTH OF TI-6AL-4V GRADES. SOURCE: METALS PROGRESS, MARCH 1977

Within the permissible range of chemistry for a specific titanium alloy and grade, oxygen is the most important impurity insofar as its effect on toughness and strength. As might be expected, hydrogen also has an effect on toughness (Table 5). Very low hydrogen contents (less than about 40 ppm) enhance toughness. This effect is particularly dramatic with hydrogen contents below 10 ppm.

TABLE 5 EFFECT OF HYDROGEN CONTENT ON ROOM-TEMPERATURE  $K_{IC}$  IN ALLOY TI-6AL-4V AFTER FURNACE COOLING FROM 927 °C (1700 °F)

(A) SPECIMENS WERE TESTED IN ACCORD WITH ASTM E 399 BUT WERE LOADED RAPIDLY (TOTAL TESTING TIME = 10 S).

**Hydrogen Embrittlement and Stress-Corrosion Cracking.** Hydrogen damage of titanium and titanium alloys is manifested as a loss of ductility (embrittlement) and/or a reduction in the stress-intensity threshold for crack propagation. The damage is caused by hydrides, which form as hydrogen diffuses into the material during exposure with either gaseous or cathodic hydrogen. Because the phenomenon depends on both hydrogen diffusion and hydride formation, there may be a peak in hydrogen embrittlement as a function of temperature. The exact level of hydrogen at which a separate hydride phase is formed depends on the composition of the alloy and the previous metallurgical history.

Stress-corrosion cracking (SCC) is related to hydrogen embrittlement as it falls into two general categories: anodic-assisted cracking and cathodic-assisted cracking. Anodic SCC (active path corrosion) involves the dissolution of metal during the initiation and propagation of cracks. Cathodic SCC (embrittlement by corrosion product hydrogen) involves the deposition of hydrogen at cathodic sites on the metal surface or on the walls of a fissure or crack and its subsequent absorption into the metal lattice. The close interaction of these two mechanisms accounts for the diversity of SCC phenomena. Typical SCC thresholds of Ti-6Al-4V are summarized in various conditions in Fig. 2 and Table 6.

STAEHLE, ED., PLENUM PRESS, 1980, P 111

In aerospace applications, there is a natural concern that chemical environmental factors such as water, salt water, or jet fuel will alter toughness in critical components. Data obtained on annealed standard grade Ti-6Al-4V indicate the following environmental effects on the apparent value of fracture toughness:

- LABORATORY AIR,  $56 \text{ MPa}\sqrt{m}$  ( $51 \text{ KSI}\sqrt{in}$ )
- JP4 FUEL,  $47 \text{ MPa}\sqrt{m}$  ( $43 \text{ KSI}\sqrt{in}$ )
- 3.5% SALT SOLUTION,  $34 \text{ MPa}\sqrt{m}$  ( $31 \text{ KSI}\sqrt{in}$ )

**Deformation Modes.** Crucial to the toughness question is the size of the plastic zone that can form ahead of a propagating crack. That size, simplistically, depends on the yield strength. Having a high yield strength and a relatively low elastic modulus, Ti-6Al-4V can store more energy elastically than most metals before plastic deformation begins. The elastic modulus depends on the direction in which it is measured in a single crystal of titanium.

The plastic zone ahead of an advancing crack is not uniform in cross section because of the anisotropic alpha phase. It varies in a macroscopic sense in response to the microstructure phase and morphology. It also varies from grain to grain in accordance with crystal type, whether alpha or beta, and with crystal orientation. To complicate matters further, Poisson's ratio and its plastic counterparts necessarily depend on direction on both the macro and micro scales. Events occurring in and around a crack tip and its associated plastic zone in Ti-6Al-4V are, for these reasons, complex indeed. Toughness in the Ti-6Al-4V alloy is not yet quantifiable from first principles. Nevertheless, there is a great deal of empirical information available for Ti-6Al-4V from which some general rules can be developed.

**High-strength alpha-beta alloys** include Ti-6Al-6V-2Sn and Ti-6Al-2Sn-4Zr-6Mo. Alpha is the dominant phase in these alloys, but to a lesser extent than in Ti-6Al-4V. These alloys are stronger and more readily heat treated than Ti-6Al-4V. These features arise from the increased solid solution strengthening afforded by tin and zirconium, which have relatively small effects on the transformation temperature, and from the increased amounts of beta phase that result from the larger vanadium and molybdenum additions.

The microstructure of these alloys follows some trends similar to those for Ti-6Al-4V, although the combination of strength and toughness tends to be higher than in Ti-6Al-4V (Fig. 3). These alloys generally follow the trends of Ti-6Al-4V relating microstructure and mechanical properties. As a general rule, the yield stress of alpha-beta alloys is highest

when the microstructure consists of a mixture of primary alpha and a fine alpha-beta mixture. In Ti-6Al-4V, high strength is achieved by a martensitic product ( $\alpha'$ ), which is produced by a solution treatment followed by water quenching and an aging treatment, or often called "solution treat and age" (STA). In more heavily beta-stabilized alpha-beta alloys such as Ti-6Al-2Sn-4Zr-6Mo, solution treatment is followed by air cooling, which retains much of the beta phase in a metastable state. Both of these treatments (STA in Table 7) are followed by an aging reaction, although subsequent aging of the as-quenched  $\alpha'$  or the metastable beta phase leads to different metallurgical reactions. Other common heat treatments for alpha-beta alloys are summarized in Table 7.

TABLE 7 SUMMARY OF HEAT TREATMENTS FOR ALPHA-BETA TITANIUM ALLOYS

HEAT TREATMENT DESIGNATION	HEAT TREATMENT CYCLE	MICROSTRUCTURE
DUPLEX ANNEAL	SOLUTION TREAT AT 50-75 °C BELOW $T_{\beta}^{(A)}$ , AIR COOL AND AGE FOR 2-8 H AT 540-675 °C	PRIMARY $\alpha$ , PLUS WIDMANSTÄTTEN $\alpha + \beta$ REGIONS
SOLUTION TREAT AND AGE	SOLUTION TREAT AT $\sim 40$ °C BELOW $T_{\beta}$ , WATER QUENCH <sup>(B)</sup> AND AGE FOR 2-8 H AT 535-675 °C	PRIMARY $\alpha$ , PLUS TEMPERED $\alpha'$ OR A $\beta + \alpha$ MIXTURE
BETA ANNEAL	SOLUTION TREAT AT $\sim 15$ °C ABOVE $T_{\beta}$ , AIR COOL AND STABILIZE AT 650-760 °C FOR 2 H	WIDMANSTÄTTEN $\alpha + \beta$ COLONY MICROSTRUCTURE
BETA QUENCH	SOLUTION TREAT AT $\sim 15$ °C ABOVE $T_{\beta}$ , WATER QUENCH AND TEMPER AT 650-760 °C FOR 2 H	TEMPERED $\alpha'$
RECRYSTALLIZATION ANNEAL	925 °C FOR 4 H, COOL AT 50 °C/H TO 760 °C, AIR COOL	EQUIAXED $\alpha$ WITH $\beta$ AT GRAIN-BOUNDARY TRIPLE POINTS
MILL ANNEAL	$\alpha + \beta$ HOT WORK, ANNEAL AT 705 °C FOR 30 MIN TO SEVERAL HOURS, AIR COOL	INCOMPLETELY RECRYSTALLIZED $\alpha$ WITH A SMALL VOLUME FRACTION OF SMALL $\beta$ PARTICLES

(A)  $T_{\beta}$  IS THE  $\beta$ -TRANSUS TEMPERATURE FOR THE PARTICULAR ALLOY IN QUESTION.

(B) IN MORE HEAVILY  $\beta$ -STABILIZED ALLOYS, SUCH AS TI-6AL-2SN-4ZR-6MO OR TI-6AL-6V-2SN, SOLUTION TREATMENT IS FOLLOWED BY AIR COOLING. SUBSEQUENT AGING CAUSES PRECIPITATION OF  $\alpha'$  PHASE TO FORM AN  $\alpha + \beta$  MIXTURE.

In general, higher fracture toughness at comparable strength is obtained in alpha-beta alloys with an acicular (i.e., transformed) structure from beta treatments or STA than from alloys with equiaxed structures. This is characteristic of all alpha-beta alloys but is especially pronounced in higher-strength alloys such as Ti-6Al-2Sn-4Zr-6Mo. The data in Table 8 show that beta-processed forgings of Ti-6Al-2Sn-4Zr-6Mo have decidedly superior strength-toughness combinations. Moreover, in the alpha-beta processed condition this alloy can exhibit very low toughness values. For example, at a yield-strength level of 1150 MPa, a toughness of  $26 \text{ MPa}\sqrt{m}$  corresponds to a critical flaw size of  $\sim 0.5 \text{ mm}$ . The high toughness of the beta-forged material correlated well with the change in fracture topography from a flat transgranular fracture in alpha-beta forged material to an irregular intergranular fracture in beta-forged material, as discussed above. This alloy is currently used almost exclusively as a forging alloy, and, as a result, no data are available for commercially produced plate.

The data in Table 8 for Ti-6Al-2Sn-4Zr-2Mo also show that this alloy is generally quite tough. Thus, the improvement in toughness that can be achieved by beta forging is less significant than that attainable in Ti-6Al-2Sn-4Zr-6Mo. The effect of forging on the toughness and yield strength of Ti-6Al-6V-2Sn is shown in Fig. 4.

FIG. 4 INFLUENCE OF YIELD STRENGTH ON FRACTURE TOUGHNESS OF TI-6AL-6V-2SN. ELI, EXTRA-LOW INTERSTITIAL; STA, SOLUTION TREATED AND AGED.  $F_{Ty}$ , TENSILE YIELD STRENGTH

The effect of texture on toughness has been studied to a limited degree for Ti-6Al-4V and Ti-6Al-2Sn-4Zr-6Mo. In general, the alloys with relatively intense transverse basal textures have greater fracture resistance when the crack propagation direction is perpendicular to the majority of the basal planes (i.e., the transverse direction). The one exception to this appears to be Ti-6Al-4V ELI, for which the opposite appears to be true. Fracture-resistance data obtained from  $R$  curves of materials with strong basal transverse textures are shown in Table 9. Note that the  $R$  curves for the ELI material differ from the others inasmuch as the incremental crack growth,  $\Delta a$ , that preceded unstable fracture was smaller by a factor of 5 in the LT specimens compared with the TL specimens. This may account for the apparent reversal in the effect of texture on  $K_R$  in this material. One possible explanation for this apparent reversal is based on the relative amounts of twinning that occur in the crack-tip plastic zone. Both oxygen content and texture affect the extent of twinning. Because twinning occurs in response to  $c$ -axis loading, the extent of twinning in material of basal transverse texture should be considerably greater in TL specimens than in LT specimens. Extensive twinning would make the material more compliant, which is consistent with the  $R$  curves for low-oxygen material. Increasing oxygen dramatically reduces the incidence of twinning. Thus, in the low-oxygen material, crack-tip plasticity may be enhanced by twinning, with an attendant increase in toughness.

## Fatigue and Fracture Properties of Titanium Alloys

### Alpha Alloys

Alpha alloys such as Ti-6Al-2Sn-4Zr-2Mo and Ti-8Al-1Mo-1V (Table 2) are used primarily in jet engine applications and are useful at temperatures above the normal range for Ti-6Al-4V. These alloys have better creep resistance than Ti-6Al-4V, and creep resistance is enhanced with a fine acicular (Widmanstätten) structure.

Generally speaking, alpha alloys contain less beta phase than Ti-6Al-4V. Age hardening treatments are thus not very effective and are, moreover, deleterious to creep resistance. These alloys therefore are usually employed in the solution annealed and stabilized condition. Solution annealing may be done at a temperature some 35 °C (63 °F) below the transformation temperature, and stabilization is commonly produced by heating for 8 h at about 590 °C (1100 °F). These alloys are more susceptible to the formation of ordered  $Ti_3Al$  ( $\alpha_2$ ) structures, which promotes SCC as described below for three common alloys in this class. However, alloy Ti-3Al-2.5V is also sometimes considered an alpha alloy, as it often contains less beta than Ti-6Al-4V. The alloy Ti-3Al-2.5V is essentially immune to SCC in boiling sea water and simulated sour-gas well brines at room temperature. Like CP titanium, Ti-3Al-2.5V is also immune to hot-salt cracking.

## Fatigue and Fracture Properties of Titanium Alloys

### Ti-5Al-2.5Sn

Ti-5Al-2.5Sn (UNS R54520) is a medium-strength, all-alpha titanium alloy with very high fracture toughness. The ELI grade of Ti-5Al-2.5Sn (UNS R54521) is especially well suited for service at cryogenic temperatures and exhibits an excellent combination of strength and toughness at -250 °C (-420 °F). The standard grade is used in applications demanding good weld fabricability, oxidation resistance, and intermediate strength at service temperatures up to 480 °C (900 °F). Typical combinations of strength and toughness of the two grades are summarized in Table 10.

Ti-5Al-2.5Sn ELI is employed for liquid hydrogen tankage and high-pressure vessels at temperatures below -195 °C (-320 °F), structural members, and turbine parts. However, the ELI grade is quite difficult to hot work into some product forms, particularly when converting from ingot to billet, because of shear cracking, often referred to as strain-induced porosity.

Because tin and aluminum promote the formation of ordered Ti<sub>3</sub>Al ( $\alpha_2$ ) structures, Ti-5Al-2.5Sn is one of the titanium alloys most susceptible to SCC. Like step-cooled Ti-8Al-1Mo-1V, the Ti-5Al-2.5Sn alloy is susceptible to corrosion cracking in distilled water (Fig. 5). The elevated-temperature stress-corrosion resistance of this alloy in the presence of solid salt also is lower than that of other commonly used titanium alloys.

## Fatigue and Fracture Properties of Titanium Alloys

### Ti-6242S

Ti-6Al-2Sn-4Zr-2Mo-0.08Si (Ti-6242S or Ti-6242Si) is one of the most creep-resistant titanium alloys and has an outstanding combination of tensile strength, creep strength, toughness, and high-temperature stability for long-term applications at temperatures up to 425 °C (800 °F). Ti-6242S is sometimes described as a near-alpha or superalpha alloy, but in its normal heat-treated condition this alloy has a structure better described as alpha-beta, as noted in Table 7 and 8. An example of thermomechanical processing (TMP) effects on the strength-toughness combination is given in Table 11.

**Stress-Corrosion Cracking.** Under stress, Ti-6Al-2Sn-4Zr-2Mo has been shown to be subject to SCC at room temperature in the presence of aqueous chloride solution and a preexisting crack (the so-called accelerated crack-growth type of salt-stress corrosion) and at elevated temperatures in the presence of a halogen salt (e.g., NaCl). The SCC susceptibility of Ti-6242 in hot salt appears to be less than that of Ti-8Al-1Mo-1V and Ti-6Al-4V. In ambient salt solution, the SCC threshold of Ti-6242 in the STA condition is comparable to mill-annealed Ti-8Al-1Mo-1V (Table 12).

(A) STA, SOLUTION TREAT AND AGE; MA, MILL ANNEAL; DA, DUPLEX ANNEAL; WQ, WATER QUENCH; ST, SOLUTION TREAT.

A substantial amount of laboratory testing on the hot-salt SCC behavior of Ti-6242 has been performed, but like other susceptible alloys (such as Ti-8Al-1Mo-1V), no failure in service has been attributed to hot-salt cracking. The likely reason for this is the critical relationship between stress and environment, which needs to peak simultaneously for extended periods of time for cracking to occur. Actual engine environmental conditions are unique and are considered less conducive to stress corrosion than laboratory exposure conditions. Possible ameliorating engine conditions are high air velocities, high pressures, salt-air conditions, oil contamination, and/or unique operating cycles.

**Hot-salt SCC behavior of Ti-6242** in laboratory tests is influenced by several factors. Oxygen is necessary for hot-salt cracking to occur. At least one study has shown that cracking will not occur in more susceptible Ti-5Al-2.5Sn when the environmental pressure is reduced below 10  $\mu$ m. Although the role of water (moisture) has not been clearly established, it appears that water is also a necessary environmental component in the cracking process.

**Effect of Processing.** There appears to be little difference between mill annealing and duplex annealing of Ti-6242 bar. Heavy forging can reduce the embrittlement and cracking thresholds. The cracking thresholds reported for sheet at 100 h exposure are generally lower than those reported for bar. Triplex annealing may improve cracking slightly more than a duplex anneal.

## Fatigue and Fracture Properties of Titanium Alloys

### Ti-8Al-1Mo-1V

Ti-8Al-1Mo-1V (Ti-811) can be characterized as a near-alpha alloy with several alpha alloy characteristics, such as good creep strength and weldability. However, the alloy does have alpha-beta characteristics, such as a mild degree of hardenability. Ti-811 is generally used in the annealed condition, where lamellar alpha morphology from transformed beta is produced by duplex annealing for toughness (Table 13). An acicular alpha from beta fabrication or heat treatment improves fracture toughness in air but has less effect on fracture toughness in salt water (Table 13). Triplex annealing produces enhanced creep resistance.

**TABLE 13 TYPICAL TOUGHNESS OF TI-8AL-1MO-1V AT ROOM TEMPERATURE**

Ti-811 is used for airframe and turbine engine applications demanding short-term strength, long-term creep resistance, thermal stability, and stiffness. Ti-811 is predominantly an engine alloy and is available in three grades, including a "premium grade" (triple melted) and a "rotating grade," for use in rotating engine components.

Like the alpha-beta alloys, Ti-811 is susceptible to hydrogen embrittlement in hydrogenating solutions at room temperature, in air or reducing atmospheres at elevated temperatures, and even in pressurized hydrogen at cryogenic temperatures. Ti-811 is susceptible to SCC in hot salts (especially chlorides) and to accelerated crack propagation in aqueous solutions at ambient temperatures. The environment in which this alloy is to be used should be selected carefully to prevent material degradation.

**Stress-Corrosion Cracking.** Ti-8Al-1Mo-1V is one of the most susceptible titanium alloys to SCC which stems from the increased tendency to form the highly ordered  $Ti_3Al$  ( $\alpha_2$ ) phase when aluminum content exceeds 5 wt%. This low-ductility ordered phase forms in the 400 to 700 °C (750 to 1290 °F) temperature range and increases crack velocity and decreases  $K_{Isc}$  as volume fraction increases. Oxygen levels above 0.20 to 0.25 wt% also promote SCC, again due to a transition from wavy to planar slip. The SCC fracture mode in Ti-811 and other susceptible alpha alloys is transgranular, with the fracture path highly oriented in unidirectionally processed (textured) material and more random in martensitic structures.

Ti-811 generally remains susceptible to SCC whether the structure is equiaxed alpha or martensitic (quenched from the beta phase field). In general, SCC susceptibility of equiaxed alpha alloys diminishes with decreasing grain size, whereas step-cooled Ti-811 has the greatest susceptibility in that smooth specimens will produce cracking in ambient neutral salt solutions. In contrast, mill-annealed Ti-811 has susceptibility in the presence of stress risers, such as a fatigue crack or machined notch. Step-cooled Ti-811 also exhibits SCC in distilled water.

**Effect of Halide Solutions.** Addition of halide ions such as  $Cl^-$ ,  $Br^-$ , and  $I^-$  increases the SCC susceptibility of Ti-811 and can induce susceptibility in other conditions that are immune to SCC in distilled water. Other ionic species in solution can have a neutral or even an inhibitive effect on Ti-811 SCC if the alloy is not highly susceptible. These species include  $NO_3^-$ ,  $SO_4^{2-}$ ,  $F^-$ ,  $OH^-$ ,  $CrO_4^{2-}$ , and  $PO_4^{3-}$ . The inhibitive influence diminishes as halide levels increase. Little influence of nonoxidizing cations such as  $Na^+$ ,  $K^+$ , or  $Li^+$  is noted. However, oxidizing cations such as  $Cu^{+2}$  may raise  $K_{Isc}$  values, depending on alloy heat treatment.

**$K_{Isc}$  Behavior.** Because titanium alloys exhibit no stage I type crack growth in neutral solutions (i.e., the slowest crack velocities measured are approximately  $10^{-3}$  cm/s), it may be concluded that true  $K_{Isc}$  thresholds exist below which cracks will not propagate. This is not the case in highly acidic solutions, where both stage I and II cracking behavior is observed. Increasing acidity generally reduces  $K_{Isc}$  and increases stage II cracking velocity. Increasing alkalinity appears to have no obvious or significant effect on SCC behavior relative to neutral conditions. As hydroxide concentrations exceed 1M, increasing inhibition may be expected.

**Effect of Potential.** In most SCC-susceptible titanium alloys, anodic or cathodic polarization tends to inhibit SCC and increase  $K_{Isc}$  values. However, the anodic and cathodic polarization inhibition phenomenon is not as apparent in highly susceptible alloys, such as step-cooled Ti-811. In highly acidic solutions, however, stage II crack velocity is independent of applied potential. As a result, inhibition via cathodic polarization is not achievable in highly acidic solutions.

**Cracking.** Ti-811 is one of the least resistant titanium alloys to hot-salt cracking. Chloride, bromide, and iodide salts have all been shown to produce cracking; fluoride and hydroxide salts have not. The cation associated with the salt has also been reported to affect cracking susceptibility. The severity of attack has been shown to increase as follows:

Cracking is normally intergranular in nature, but it depends largely on alloy type. Alpha alloys exhibit both transgranular and intergranular fracture, depending on whether the material was annealed above or below the beta transus, respectively. Alpha-beta alloys exhibit predominantly intergranular fracture.

From a practical standpoint, hot-salt cracking appears to be restricted to the laboratory. No in-service failure has been attributed to hot-salt cracking.

---

## Fatigue and Fracture Properties of Titanium Alloys

### Beta Alloys

An alloy is considered to be a beta alloy if it contains sufficient beta stabilizer alloying element to retain the beta phase without transformation to martensite on quenching to room temperature. A number of titanium alloys (Table 2) contain more than this minimum amount of beta stabilizer alloy addition. In a strict sense there is no truly stable beta alloy because, even the most highly alloyed beta will, on holding at elevated temperatures, begin to precipitate omega, alpha,  $Ti_3Al$ , or silicides, depending on temperature, time, and alloy composition. All beta alloys contain a small amount of aluminum, an alpha stabilizer, in order to strengthen alpha that may be present after heat treating. The composition of the precipitating alpha is not constant and will depend on the temperature of heat treatment. The higher the temperature in the alpha-beta phase field, the higher the aluminum content of alpha will be.

The beta- and beta-rich alpha-beta alloys offer the opportunity to tailor the strength-toughness properties combinations to a specific application. That is, moderate strength with high toughness or high strength with moderate toughness can be achieved. This is generally not possible for other types of titanium alloys because they cannot be heat treated over a very wide range. At moderate strength levels, say 965 MPa (140 ksi) and above, the fracture toughness of the beta alloys can be processed to achieve higher values than for the other types (alpha and alpha-beta alloys).

To accomplish these higher toughnesses, however, the processing window is tighter than that normally used for the other alloy types. For the less highly beta-stabilized alloys, such as Ti-10V-2Fe-3Al for example, the thermomechanical process is critical to the properties combinations achieved as this has a strong influence on the final microstructure and the resultant tensile strength and fracture toughnesses that may be achieved.

This is somewhat less important in the more highly beta-stabilized alloys, such as Ti-3Al-8V-6Cr-4Mo-4Zr (Beta C) and Ti-15V-3Cr-3Al-3Sn. In these the final microstructure, precipitated alpha, is so fine that microstructural manipulation through thermomechanical processing is not as effective. In these cases the aging heat treatments, sequence and temperature, are more critical. The key is to obtain a uniform precipitation. This may be obtained by a low-high aging sequence or, with residual cold or warm work, possibly a high-low aging sequence. When highly alloyed beta alloys, such as Beta C, are cold worked prior to aging, high strength can be obtained with good ductility because cold work induces finer and more uniform precipitation.

The thermomechanical processing must, however, be controlled to provide a uniform microstructure throughout the cross section of the material and, in conjunction with the heat treatment, avoid the occurrence of extensive grain boundary alpha or a precipitate-free zone near the grain boundaries.

---

## Fatigue and Fracture Properties of Titanium Alloys

### Solute-Lean Beta Alloys

Solute-lean beta alloys are sometimes classified as beta-rich alpha-beta alloys, and this class includes Ti-10V-2Fe-3Al and proprietary alloys such as Ti-17 (Ti-5Al-2Sn-2Zr-4Mo-4Cr) and Beta CEZ (Ti-5Al-2Sn-4Zr-4Mo-2Cr). As noted above, toughness depends on TMP. For example, TMP of Ti-10V-2Fe-3Al achieves the desired final microstructure through manipulation of alpha phase morphology. Microstructural objectives range from fully transformed, aged beta structures to controlled amounts of elongated primary alpha in an aged beta matrix, characterized by extremely fine secondary (aged) alpha. The latter microstructure is preferred for most aerospace applications (specifications) and forms the basis for most commercial use of the alloy in forgings. There would also appear to be an optimum amount of primary alpha to achieve maximum toughness (a 10% volume fraction of elongated primary alpha has significantly higher fracture toughness than 30 vol%).

Ti-10V-2Fe-3Al is a deep-hardening, metastable, near-beta alloy that may be thermomechanically processed to a range of strength levels combined with excellent fracture toughness (Table 14). The preferred forging process to meet the above mechanical-property criteria is controlled beta forging followed by controlled alpha-beta forging. This, in combination with final thermal treatment, provides the optimum combination of strength, ductility, toughness, fatigue, and fracture-related properties. Ti-10V-2Fe-3Al may be conventionally alpha-beta forged and thermally treated. With such

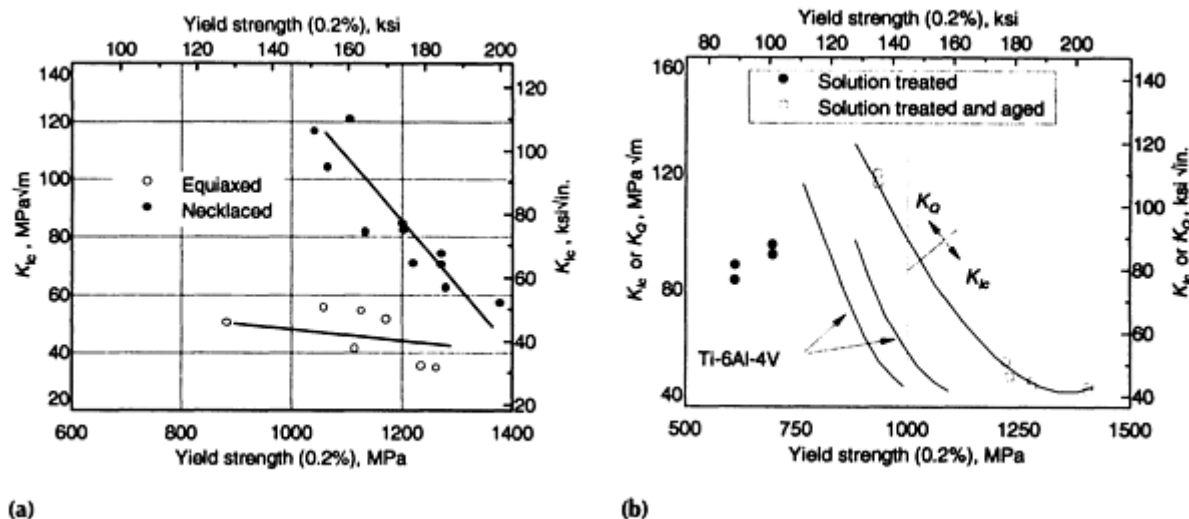

conventional processes, the alloy achieves high strength and fatigue properties and superior ductility, but poor toughness and fracture-related properties. The stress-corrosion threshold has been reported to be at least 80% of  $K_{Ic}$  except when it is stressed in the short transverse direction, where it is 70% of  $K_{Ic}$ .

Ti-5Al-2Sn-4Zr-4Mo-2Cr (Beta CEZ) is another beta-rich alpha-beta alloy with toughness enhanced by TMP. Equiaxed microstructures are characterized by toughness ranging from 45 to 55 MPa  $\sqrt{in}$  (40 to 50 ksi  $\sqrt{in}$ ). Toughness of the lamellar structure ranges from 60 to 90 MPa  $\sqrt{in}$  (54 to 82 ksi  $\sqrt{in}$ ), whereas the necklaced microstructure has a toughness ranging from 65 to 95 MPa  $\sqrt{in}$  (59 to 86 ksi  $\sqrt{in}$ ) (see Fig. 6). Low-temperature toughness usually ranges from 30 to 45 MPa  $\sqrt{in}$  (27 to 41 ksi  $\sqrt{in}$ ) at -253 °C (-423 °F).

### Solute-Rich Beta Alloys

Highly beta-stabilized alloys, such as Ti-3Al-8V-6Cr-4Mo-4Zr (Beta C) and Ti-15V-3Cr-3Al, obtain a good combination of strength and toughness in the aged condition (Tables 15 and 16). Trend lines for some other near-beta alloys are compared in Fig. 3 with other types of titanium alloys.

**Hydrogen Effects.** Beta alloys can absorb large quantities of hydrogen, on the order of 4000-5000 ppm, but hydrides do not form in beta despite the high degree of supersaturation. However, when alpha is present, hydrides can form at alpha-beta interfaces at relatively low hydrogen contents at room temperature. Hydrogen tolerance depends on the particular alloy and condition, and considerable work remains to be done to understand the behavior of hydrogen in both alpha-beta and beta alloys.

## Fatigue and Fracture Properties of Titanium Alloys

---

### Fatigue Life Behavior

L. Wagner, Technical University of Brandenburg at Cottbus, Germany

---

The fatigue life ( $N_F$ ) of structural parts is the sum of crack nucleation life ( $N_I$ ) and crack propagation life to final fracture ( $N_P$ ):  $N_F = N_I + N_P$ . Fatigue tests on titanium alloys have shown that at high stress or strain amplitudes, the ratio  $N_I/N_F$  can be as small as 0.01 (Ref 1, 2). Therefore, the resistance to crack propagation determines fatigue life in the low-cycle fatigue (LCF) regime. With regard to crack propagation in structural parts, it is useful to distinguish between small surface cracks (microcracks) and long through-cracks (macrocracks), because the dependence of crack growth on microstructural parameters such as grain size or phase dimensions can be contradictory (Ref 3). As a rule of thumb, the fatigue life for small, highly stressed components (small critical flaw size) is mainly controlled by microcrack growth, while for large components operating at low stress levels (large critical flaw size), macrocrack growth behavior is more important. The purpose of this section is to outline the current understanding of the effects of the main variables (i.e., microstructure and texture) on the fatigue life of titanium and its alloys. As opposed to steels or aluminum alloys, titanium alloys are generally free of defects such as inclusions or pores. However, fatigue behavior in titanium alloys is very sensitive to surface preparation. Thus, this section also deals with the effect of mechanical surface treatments on fatigue life. Macrocrack growth behavior in titanium alloys is treated in the next section, "Fatigue Crack Growth," while this section is limited to fatigue crack nucleation and microcrack propagation.

## Fatigue and Fracture Properties of Titanium Alloys

### Effect of Microstructure

**Unalloyed Titanium.** Fatigue life in unalloyed titanium depends on grain size, interstitial contents, and degree of cold work, as illustrated in Fig. 7. Decreasing the grain size from 110 to 6  $\mu\text{m}$  improves the fatigue limit ( $10^7$  cycles) in commercially pure titanium from 180 to 240 MPa (26 to 35 ksi) (Fig. 7a) (Ref 4). The effect of oxygen content on the  $S-N$  curves of high-purity titanium, shown in Fig. 7(b), correlates to the increase in yield stress. Cold work also increases yield stress and thus improves the fatigue performance as shown in Fig. 7(c). Fatigue limits of unalloyed titanium depend on interstitial contents, but the ratio of fatigue limits and yield strength appears relatively constant at room temperature (Ref 5). The ratio of fatigue limit and yield stress does show a temperature dependence (Ref 4). Temperature effects on a low-iron grade of ASTM grade 2 are shown in Fig. 8.

**Full Alpha Experimental Alloy.** Fatigue life of an alpha alloy is mainly affected by grain size, degree of age hardening, and oxygen content of the alloy. Fatigue cracks in an experimental Ti-8.5Al binary alloy usually nucleate along planar slip bands within the alpha grains (Ref 6). For a given  $\Delta K$ , microcracks in the coarse-grained material grow faster than in its fine-grained counterpart. This is related to the higher density of grain boundaries in the fine-grained material, because grain boundaries act as strong obstacles to crack growth in this material. The superior performance of the fine-grained material with respect to microcrack growth is in contrast to macrocrack results (Ref 7) showing better ranking of the coarse-grained material. The latter is mainly caused by crack front geometry effects (Ref 8) and crack closure (Ref 7, 9), which are not significant for microcracks but can be pronounced for macrocracks, particularly in coarse-grained material. Both crack front geometry effects and crack closure slow the growth rate of macrocracks. Age-hardening results in faster microcrack growth in Ti-8.5Al, presumably due to the marked loss in tensile ductility.

**Near-Alpha and Alpha-Beta Alloys.** In addition to alpha grain size, degree of age hardening, and oxygen content, the fatigue properties of the two-phase near-alpha and alpha-beta alloys are strongly affected by the morphology and arrangement of both alpha and beta phases. Basically, fully lamellar, fully equiaxed, and duplex (primary, alpha phase in a lamellar matrix) microstructures can be developed in near-alpha and alpha-beta alloys. Important microstructural parameters are the prior beta grain size or colony size of the alpha and beta lamellae and the width of the alpha lamellae in fully lamellar microstructures. Additional parameters for duplex structures are grain size and volume fraction of the primary alpha ( $\alpha_p$ ) phase. Tensile properties of fully lamellar, fully equiaxed, and duplex microstructures of Ti-6Al-4V are compared in Table 17.

TABLE 17 TENSILE PROPERTIES IN TI-6AL-4V (AGED 24 H AT 500 °C)

The fatigue life of these microstructures is shown in Fig. 9. A decrease in the width of the alpha lamellae from 10 to 0.5  $\mu\text{m}$  in fully lamellar microstructures improves the fatigue strength from 480 to 650 MPa (Fig. 9a) (Ref 10). Similarly, a decrease in the alpha grain size from 12 to 2  $\mu\text{m}$  in fully equiaxed structures increases the fatigue strength from 550 to 720 MPa (Fig. 9b) (Ref 10). A decrease in the width of the alpha lamellae from 0.5 to 1  $\mu\text{m}$  in duplex microstructures increases the fatigue strength from 480 to 575 MPa (Fig. 9c) (Ref 12).

Typical crack nucleation sites are shown in Fig. 10 (Ref 13). Fatigue cracks in fully lamellar microstructures nucleate at slip bands within the alpha lamellae (Fig. 10) or at alpha zones along prior beta grain boundaries (Ref 14). Because both resistance to dislocation motion and resistance to fatigue crack nucleation depend on the width of the alpha lamellae, there is a direct correlation between fatigue strength and yield stress (Table 17). Fatigue cracks in the fully equiaxed

microstructure nucleate at slip bands within the alpha grains (Fig. 10b). Thus, the fatigue strength correlates to the alpha grain size dependence of the yield stress (Table 17). Fatigue cracks in duplex microstructures can nucleate in the lamellar matrix, at the interface between lamellar matrix and the  $\alpha_p$  phase, or within the  $\alpha_p$  phase. The exact nucleation site depends on cooling rate (Ref 14), volume fraction, and size of the  $\alpha_p$  phase (Ref 15, 16). An example of crack nucleation within lamellar regions is shown in Fig. 10(c).

Owing to the high silicon content (0.45 wt%) in the near-alpha alloy TIMETAL 1100 and the resulting high silicide solvus temperature,  $T_{SS}$ , fine prior beta grain sizes and correspondingly small colony sizes can be realized in TIMETAL 1100 by beta annealing the material below  $T_{SS}$  (Ref 17, 18, 19). Tensile properties of fine- and coarse-grained fully lamellar microstructures and those of duplex structures with two different  $\alpha_p$  volume fractions are compared in Table 18.

Decreasing the prior beta grain size in fully lamellar structures (Table 18) significantly increases tensile ductility. No marked differences in ductility were observed in duplex structures by varying  $\alpha_p$  volume fractions between 20 and 60%. Note that lamellar and duplex structures have similar yield stresses due to the same cooling rate used from the solution anneal. *S-N* curves of TIMETAL 1100 are given in Fig. 11. Reducing the prior beta grain size in fully lamellar microstructure (Fig. 11a) as well as decreasing the  $\alpha_p$  volume fraction in duplex structures (Fig. 11b) improves fatigue life in both the low-cycle fatigue (LCF) and high-cycle fatigue (HCF) (Ref 20, 21).

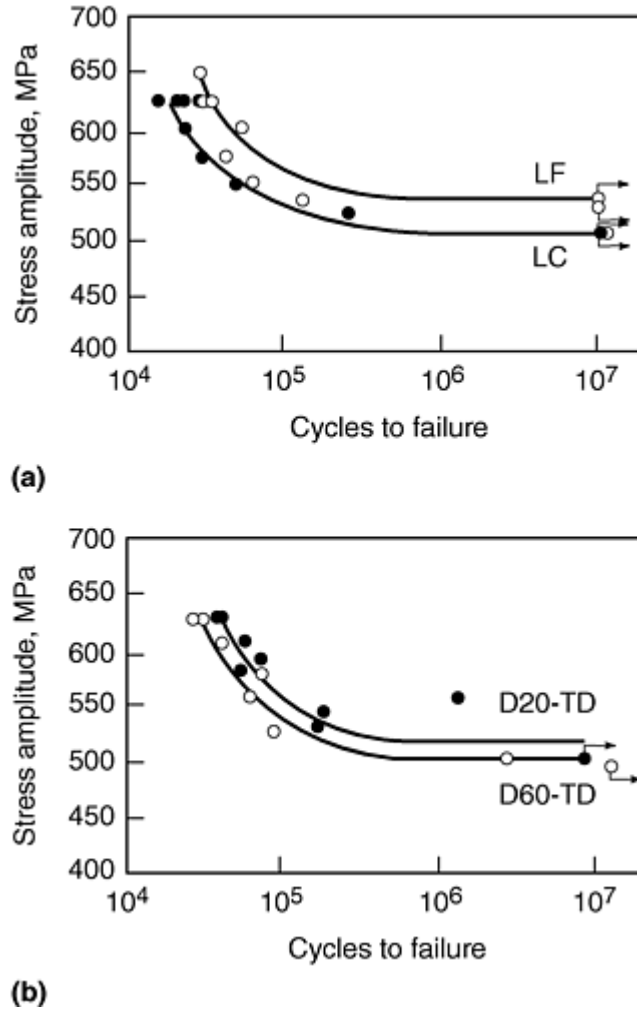

FIG. 11 *S-N* CURVES ( $R = -1$ ) IN TIMETAL 1100. (A) FULLY LAMELLAR MICROSTRUCTURES. EFFECT OF PRIOR  $\beta$  GRAIN SIZE. (B) DUPLEX MICROSTRUCTURES. EFFECT OF  $\alpha_p$  CONTENT. SOURCE: REF 20, 21

Typical growth behavior of microcracks in two extreme microstructures of Ti-6Al-4V, a coarse lamellar and an equiaxed structure is shown in Fig. 12 (Ref 8). Plotting  $da/dN$  versus  $\Delta K$  (Fig. 13), the crack growth resistance in the coarse lamellar microstructure is clearly seen to be inferior to the equiaxed. Similar results are reported on the beta eutectoid alloy Ti-2.5Cu (Ref 22). This is mainly related to the comparably low density of phase boundaries in the coarse lamellar microstructure that is also reflected in the low tensile ductility (Table 17). Crack growth studies on fine lamellar and duplex structures in Ti-6Al-4V have shown that their  $da/dN$ - $\Delta K$  curves lie in between coarse lamellar and equiaxed structures (Ref 8).

FIG. 13  $DA/DN-\Delta K$  CURVES OF MICROCRACKS IN TI-6AL-4V. CL, COARSE LAMELLAR; EQ, EQUIAXED.

SOURCE: REF 8

Reducing the prior beta grain size in lamellar microstructures of TIMETAL 1100 (Fig. 14a) and decreasing the  $\alpha_p$  volume fraction of duplex structures (Fig. 14b) improves crack growth resistance and thus fatigue life in the LCF regime (Ref 20, 21). The latter seems to be related to the absence or less frequent occurrence of  $\alpha_p$  clusters at low  $\alpha_p$  volume fractions. These  $\alpha_p$  clusters in duplex structures with high  $\alpha_p$  volume fractions can act as large single grains through which microcracks can easily propagate.

FIG. 14  $DA/DN-\Delta K$  CURVES OF MICROCRACKS IN TIMETAL 1100. (A) FULLY LAMELLAR MICROSTRUCTURE. EFFECT OF PRIOR  $\beta$  GRAIN SIZE. (B) DUPLEX MICROSTRUCTURE. EFFECT OF  $\alpha_p$  CONTENT. SOURCE: REF 20, 21

**Beta Alloys.** Depending on the alloy class (solute-rich or solute-lean) the following microstructural parameters are important in determining fatigue life: beta grain size, degree of age hardening, and precipitate-free regions in the solute-rich alloys such as Beta C. In addition, grain boundary  $\alpha$ ,  $\alpha_{GB}$ ,  $\alpha_p$  size and volume fraction are important in solute-lean alloys such as Ti-10-2-3 (Ref 23).

Typical microstructures in Beta C are shown in Fig. 15 comparing a conventionally aged (Fig. 12a) and a two-step aged (Fig. 12b) condition (Ref 24). Compared to conventional aging, two-step aging results in a more homogeneous precipitation of alpha particles in the beta grain interiors. Tensile properties of these structures are listed in Table 19. The two-step aging of 4 h at 440 °C plus 16 h at 560 °C was chosen to enable a comparison of fatigue behavior with the conventional aging cycle (16 h at 540 °C) on the basis of identical yield stresses.

TABLE 19 TENSILE PROPERTIES IN BETA-C

FIG. 15 MICROSTRUCTURES IN TI-3AL-8V-6CR-4MO-4ZR. (A) CONVENTIONALLY AGED. (B) TWO-STEP AGED. SOURCE: REF 24

The *S-N* curves of the various conditions of Beta C are shown in Fig. 16. While aging clearly improves HCF strength due to the increase in yield stress, two-step aging is superior to conventional aging by about 50 MPa. The inferior performance of conventional aging is caused by the presence of precipitate-free regions within the beta grains (Fig. 15a), which were identified as fatigue crack nucleation sites (Fig. 17). Microhardness measurements have shown that these regions have strengths comparable to the solution-heat-treated reference (Ref 24).

FIG. 17 FATIGUE CRACK NUCLEATION IN CONVENTIONALLY AGED TI-3AL-8V-6CR-4MO-4ZR. SOURCE: REF 24

Microcrack growth in the various conditions of Beta C is shown in Fig. 18 in terms of  $da/dN-\Delta K$  curves (Ref 25). No significant differences were observed among the various conditions. This result is in agreement with studies on long through-cracks in C(T)-type specimens (Ref 26). Obviously, the wide variation in fatigue crack growth resistance as observed in the class of alpha-beta alloys is not possible in solute-rich beta alloys.

The alloy Ti-10-2-3 represents the class of solute-lean beta alloys in which the microstructure can be varied to a larger extent through the possible presence of  $\alpha_p$  in volume fractions similar to those in alpha-beta alloys (Ref 27, 28, 29, 30). Typical microstructures in Ti-10-2-3 with 15 and 30 vol%  $\alpha_p$  are shown in Fig. 19 and 20, respectively (Ref 31). In addition, a beta-annealed structure (0%  $\alpha_p$ ) and a structure with 5 vol%  $\alpha_p$  are compared with the tensile properties of these typical conditions in Table 20.

**FIG. 19 MICROSTRUCTURE OF TI-10V-2FE-3AL WITH 15%  $\alpha_p$  CONTENT, WHICH IS CONSIDERED ABOUT OPTIMAL FOR STRENGTH AND TOUGHNESS. SOURCE: REF 31**

**FIG. 20 TI-10V-2FE-3AL WITH 30%  $\alpha_p$  SOURCE: REF 31**

The  $S-N$  curves of the various microstructures are shown in Fig. 21. Typical fatigue crack nucleation sites can be seen in Fig. 22. Fatigue cracks nucleated at beta grain boundaries in the beta-annealed structure (Fig. 22a), within the beta grains (Fig. 22b), and at thick alpha zones along beta grain boundaries (Fig. 22c) for material with 15 and 30%  $\alpha_p$ , respectively. The superior performance of microstructures with low  $\alpha_p$  contents of 5 and 15% seems to be related to both the absence of a continuous  $\alpha_{GB}$  layer and their comparatively high strengths (Table 20). This is also reflected in the high ratio  $\alpha_a(10^7)/\alpha_{0.2}$  amounting to 0.58 and 0.55 for the microstructures with  $\alpha_p$  volume fractions of 15 and 5%, respectively. This ratio is only 0.45 for the beta-annealed microstructure, indicating the presence of a soft  $\alpha_{GB}$  film that not only dramatically affects ductility (Table 20) but also reduces the resistance to fatigue crack nucleation without affecting the macroscopic yield stress. Increasing the  $\alpha_p$  content to 30% increases the ratio  $\alpha_a(10^7)/\alpha_{0.2}$  to 0.52. This corresponds to a decrease in strength differential between  $\alpha_{GB}$  and the grain interior, because the loss in macroscopic yield stress now reflects the contribution of the high volume fraction of the soft  $\alpha_p$  phase in the beta matrix and the concomitant low contribution of precipitation hardening by  $\alpha_s$  (Ref 31).

**Effect of Texture on Fatigue Life.** While beta alloys are considered fairly isotropic due to their body-centered cubic structure, the mechanical properties of alpha and alpha-beta alloys can be quite anisotropic. Due to the anisotropy of the hexagonal alpha lattice structure and the resulting directionality of mechanical properties in single crystals, polycrystals in textured material with high volume fractions of the alpha phase can be quite anisotropic with respect to fatigue performance. Because the texture in alpha-beta alloys can be varied to a larger extent than in alpha alloys, the effect of crystallographic texture on fatigue behavior has been mainly studied in Ti-6Al-4V (Ref 32, 33, 34, 35). In contrast to beta-annealed (fully lamellar) microstructures, which normally have a nearly random texture, various types of textures can be developed in the alpha phase of the fully equiaxed and duplex microstructures.

The four basic types of textures are basal (B), transverse (T), mixed basal/transverse (B/T), and weakly textured (WT). These textures are achieved by appropriate TMP, and the *S-N* curves of fully equiaxed microstructures of Ti-6Al-4V with various types of sharp textures are shown in Fig. 23 and 24 (Ref 10). The highest HCF strength, about 725 MPa, was obtained by testing the B/T type of texture parallel to the rolling direction (RD). The lowest HCF strength, 580 MPa, was measured for a T-type of texture tested perpendicular to RD in the rolling plane (TD). Comparing these results from fatigue testing in air (Fig. 23) with those in vacuum (Fig. 24), it is seen that laboratory air acts as a corrosive environment for Ti-6Al-4V and that the loss in fatigue strength due to the air environment strongly depends on crystallographic texture and loading condition. For example, the drop in fatigue strength is most pronounced for B/T- and T-textures in loading directions where higher yield stresses are observed due to the stress axis perpendicular to the basal planes (B/T-TD, T-TD). This behavior is thought to be due to the stress-corrosion susceptibility of alpha-beta titanium alloys for loading directions perpendicular to the basal planes (Ref 36). Compared to fully equiaxed and fully lamellar microstructures, the HCF strength of duplex structures is less affected by environment, presumably due to the absence of alpha/alpha phase boundaries (isolated  $\alpha_p$  grains) (Ref 10). The effect of degree of texture can be seen in Fig. 25. A decrease in deformation degree for unidirectional rolling at 800 °C from 75 to 60% results in a slight loss of the HCF strength, from 650 to 590 MPa (Ref 37).

## Fatigue and Fracture Properties of Titanium Alloys

### High-Cycle Fatigue Strength

Fatigue limits (or endurance limits) represent the value of stress below which a material can presumably endure an infinite number of cycles. For many conditions, fatigue limits may be observed at  $10^7$  cycles or more. In other cases, however, fatigue limits are not observed. These cases are generally attributed to periodic overstrains or the absence of hardening, as with very low oxygen levels (Fig. 26). Also, the absence of a fatigue limit in Ti-6Al-4V alloy can be associated with subsurface initiations, especially at cryogenic temperatures (Ref 39).

FIG. 26 EFFECT OF LOW OXYGEN AND YIELD STRENGTH ON TI-6AL-4V FATIGUE LIMITS. SOURCE: REF 38

About 80 to 90% of HCF life involves the nucleation of surface cracks, which can be greatly influenced by stress concentrations (such as corrosion pits or notches) or surface residual stress. These factors are briefly reviewed and discussed below, and the next section describes various surface treatments for improved HCF.

**Notch Effects.** The HCF strength of wrought Ti-6Al-4V at  $10^7$  cycles is typically between about 135 to 275 MPa (20 to 40 ksi) ranges for notched ( $K_t = 3$ ) specimens (Fig. 27). The static tensile strength has even less influence on fatigue strength for notched specimens than for unnotched specimens (Fig. 28). It should also be noted that fatigue limits of unnotched Ti-6Al-4V and other titanium alloys reveal more scatter than quenched-and-tempered low-alloy steels. For example, extensive tensile and smooth-bar fatigue testing on Ti-6Al-4V and regression analysis has been performed to see if a correlation exists between  $10^7$  cycle fatigue strength and yield or tensile strength (Ref 42). In both cases the coefficient of correlation was smaller than 0.1, indicating that essentially no correlation exists. This tends to point out an important difference between titanium alloys and steels, that the effects of microstructures on fatigue is a more complex variable, especially for the different variations of microstructures associated with dual-phase materials such as alpha-beta alloys or the solute-lean beta alloys such as Ti-10V-2Fe-3Al.

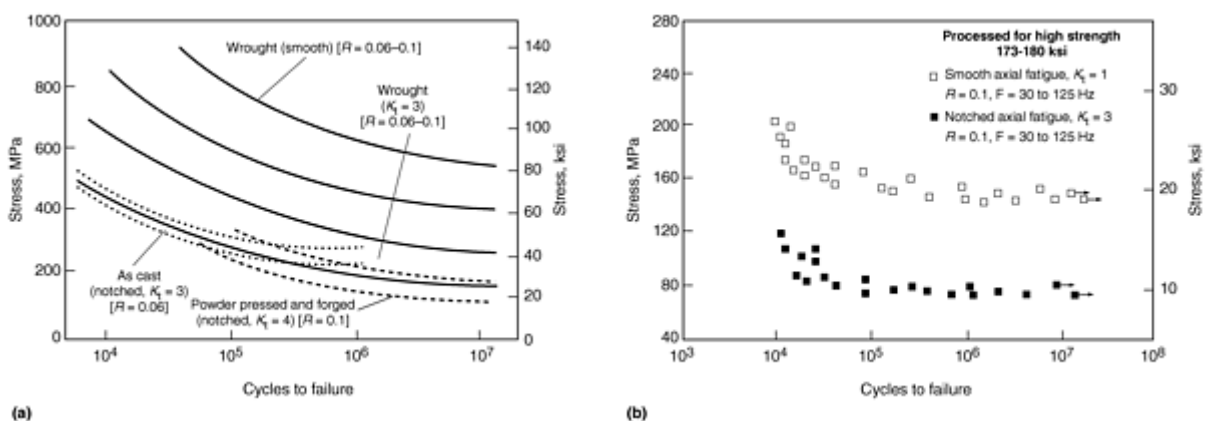

FIG. 27 NOTCH EFFECTS ON (A) TI-6AL-4V AND (B) TI-10V-2FE-3AL. SOURCE: MIL HDBK-697A, 1974, AND REF 40

FIG. 28 NOTCHED AND UNNOTCHED FATIGUE LIMIT OF TI-6AL-4V. 6.35 MM (0.25 IN.) FATIGUE LIMITS AT  $10^7$  CYCLES DETERMINED BY HIGHEST STRESS AMPLITUDE AT WHICH SPECIMENS RAN  $10^7$  CYCLES WITHOUT FAILURE. REF 41

**Effect of Residual Stress.** Surface residual stress can be a predominant factor influencing fatigue, and the residual stress effect is most pronounced in the infinite-life stress range of the endurance-limit regime (Fig. 29). Surface residual stress is important, but the effect is not simple because of the combined influences of residual stress, cold-worked structure, and surface roughness on HCF strength. However, when surface roughness is within a reasonable range of 2.5 to 5  $\mu\text{m}$  (100 to 200  $\mu\text{in.}$ , arithmetic average), residual surface stress can be a more potent indicator of fatigue resistance than surface roughness (Ref 43). For many machining and finishing operations, residual stress and surface roughness are closely related, which accounts for the traditional correlation between fatigue strength and surface roughness.

FIG. 29 ENDURANCE LIMIT OF TI-6AL-4V VS. RESIDUAL STRESS FROM VARIOUS FINISHING METHODS. AA, ARITHMETIC AVERAGE. SOURCE: REF 43

**Effect of Mean Stress on Fatigue Life.** It has long been recognized that near-alpha and alpha-beta alloys can be highly mean stress sensitive with regard to HCF strength (Ref 44, 45). This so-called anomalous mean stress effect is best seen in a Smith diagram where the maximum allowable stress is plotted versus the mean stress (Fig. 30) (Ref 46). At low tensile mean stresses, the fatigue performance of duplex structures is markedly inferior to fully lamellar structures in TIMETAL 1100. These results confirm earlier work on Ti-6Al-4V (Ref 47). While the exact mechanism for this anomalous mean stress sensitivity is still not fully understood, from Ref 46 and 47 the following conclusions can be drawn:

- THE ANOMALOUS MEAN STRESS EFFECT IS CRACK NUCLEATION CONTROLLED.
- THE ANOMALOUS MEAN STRESS EFFECT IS ALSO PRESENT IN INERT ENVIRONMENTS.
- BETA-ANNEALED (FULLY LAMELLAR) MICROSTRUCTURES USUALLY DO NOT SHOW THIS EFFECT.
- IN ALPHA-BETA ANNEALED (FULLY EQUIAXED OR DUPLEX) MICROSTRUCTURES, THE DEGREE OF THE ANOMALOUS MEAN STRESS SENSITIVITY DEPENDS ON CRYSTALLOGRAPHIC TEXTURE AND LOADING DIRECTION.

New results on TIMETAL 1100 (Ref 48) indicate that the anomalous mean stress sensitivity is absent at elevated temperatures (Fig. 30).

## Fatigue and Fracture Properties of Titanium Alloys

### Effects of Surface Treatments

Mechanical surface treatments such as shot peening, polishing, or surface rolling can be used to improve the fatigue life in titanium alloys (Ref 49, 50). In most cases, three surface properties are altered:

- SURFACE ROUGHNESS
- DEGREE OF COLD WORK OR DISLOCATION DENSITY
- RESIDUAL STRESSES

Because fatigue failure represents the sum of both crack nucleation and crack propagation life, the changes induced by such treatments can have contradictory influences on the fatigue strength. The surface roughness determines whether fatigue strength is primarily crack nucleation controlled (smooth) or crack propagation controlled (rough) (Ref 50). For smooth surfaces, a work-hardened surface layer can delay crack nucleation owing to the increase in strength. In rough surfaces, the crack nucleation phase can be absent, and a work-hardened surface layer is detrimental to crack propagation owing to the reduced ductility (Ref 51). Near-surface residual compressive stresses are clearly beneficial, as they can significantly retard microcrack growth once cracks are present (Table 21, Ref 49).

**TABLE 21 EFFECTS OF SURFACE PROPERTIES ON FATIGUE LIFE OF TITANIUM**

<b>SURFACE PROPERTY</b>	<b>CRACK NUCLEATION EFFECT</b>	<b>MICROCRACK PROPAGATION EFFECT</b>
SURFACE ROUGHNESS	ACCELERATES	<b>NO EFFECT</b>
DEGREE OF COLD WORK OR DISLOCATION DENSITY	RETARDS	<b>ACCELERATES</b>
<b>RESIDUAL COMPRESSIVE STRESSES</b>	<b>MINOR OR NO EFFECT</b>	<b>RETARDS</b>

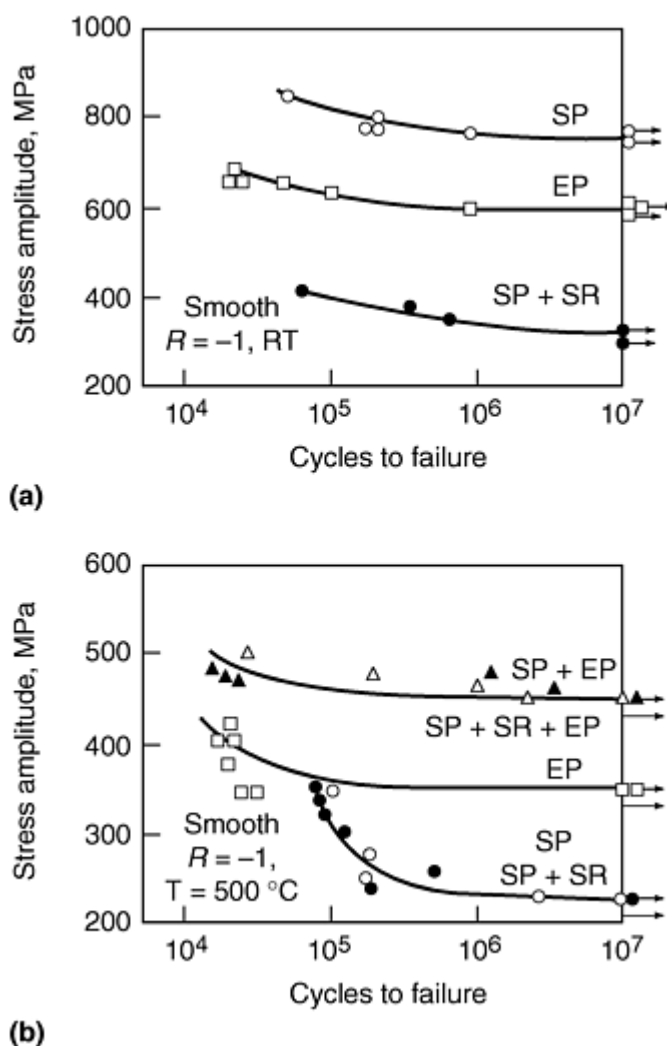

Source: Ref 49

It must be kept in mind that the changes induced by mechanical surface treatment are not necessarily stable. In particular:

- RESIDUAL STRESSES CAN BE REDUCED OR ELIMINATED BY A STRESS-RELIEF TREATMENT
- DEGREE OF COLD WORK (DISLOCATION DENSITY) CAN BE REMOVED BY RECRYSTALLIZING
- SURFACE ROUGHNESS CAN BE REDUCED BY AN ADDITIONAL SURFACE TREATMENT (E.G., POLISHING)

Furthermore, the beneficial residual compressive stresses can be reduced by cyclic plastic deformation (i.e., during fatigue loading in service).

These factors can be taken into account to design surface treatments for titanium alloys that are appropriate to the application. For example, Fig. 31 shows a series of *S-N* curves for Ti-6Al-4V at room temperature and at elevated temperature (Ref 52). As a reference condition, an electropolished surface is considered that is free of residual stresses and cold work and has a mirror finish. Compared with EP, shot peening (SP) significantly improves the HCF strength at room temperature. At elevated temperature, however, SP lowers HCF strength to values below that of the reference condition. This can be explained by considering the individual contributions of the surface properties to fatigue life. For example, stress relieving (SR) 1 h at 600 °C after SP (SP + SR) decreases the endurance limit of the SP condition at room temperature but does not alter the HCF strength at 500 °C. In effect, SR is redundant when cyclic loading occurs at high temperature. If the compressive residual stresses were the only mechanism operating, one could conclude that SP cannot be used to improve fatigue performance at elevated temperatures. However, an additional surface treatment that reduces the surface roughness, in the present case electropolishing (SP + EP), demonstrates that work hardening the surface layer can also be exploited to improve HCF strength, irrespective of whether a stress relief treatment is applied (SP + SR + EP) or not. The degree of near-surface cold work (dislocation density) is not significantly altered by SR and thus raises the HCF strength.

**FIG. 31** *S-N* CURVES ( $R = 1$ ) FOR TI-6AL-4V WITH A FINE LAMELLAR MICROSTRUCTURE. SP, SHOT PEENED; EP, ELECTROPOLISHED; SR, STRESS RELIEVED. (A) ROOM TEMPERATURE. (B) 500 °C. SOURCE: REF 52

Microcrack growth rates in the conditions SP and SP + SR are compared to the reference EP in Fig. 32. At room temperature (Fig. 32a), crack growth is drastically retarded in SP, but it is accelerated in SP + SR as compared to EP. The difference in growth rate between curves SP and SP + SR is caused by the residual compressive stresses in SP, while the

difference between curves SP + SR and EP is related to the high dislocation density in the SP + SR condition. At elevated temperature (Fig. 32b), no difference in microcrack growth was measured between curves SP and SP + SR owing to residual stress relaxation at that temperature. The inferior performance of SP and SP + SR compared to the reference is due to the negative effect of high dislocation densities (low residual ductility) on crack growth resistance (see Table 21).

(a)

(b)

FIG. 32 MICROCRACK GROWTH IN TI-6AL-4V. SP, SHOT PEENED; EP, ELECTROPOLISHED; SR, STRESS RELIEVED. (A) ROOM TEMPERATURE. (B) 500 °C. SOURCE: REF 52

**Thermomechanical Surface Treatments.** Surface microstructure of titanium can be tailored or varied to enhance fatigue crack initiation resistance at the surface, while still maintaining a bulk interior to meet differing requirements (e.g., as in the carburizing of steels). As demonstrated in the following examples, cold working induced by mechanical surface treatments can be used to develop a surface microstructure that is different from that in the bulk, thus combining the optimum features of both, even in cases where conventional TMP may not be practical, as in thick sections. A distinct advantage to be gained by altering the surface microstructure in this way is that such alterations are more stable than those induced by mechanical surface treatments alone.

**Surface Treatment of Alpha-Alloys.** A mechanical surface treatment in combination with a subsequent recrystallization makes it possible to combine the high strengths and endurance limits associated with fine grains with the superior long through-crack fatigue crack growth behavior and fracture toughness of the coarse grains. To maximize the total fatigue life in thicker sections, fine grains are needed on the surface, where good resistance to crack initiation and microcrack growth is critical, and coarse grains are needed in the interior, where they can reduce the driving force to long crack growth. In one study, shot peening followed by a heat treatment of 1 h at 820 °C was performed on coarse-grained Ti-8.5Al to cold work and recrystallize the surface. The improvement in fatigue limit owing to the fine (20 μm) surface grains as opposed to the coarse grains in the bulk (100 μm) was significant, roughly 50 MPa at 350 °C (Fig. 33) (Ref 52).

**FIG. 33 S-N CURVES FOR COARSE-GRAINED TI-8.5AL AT 350 °C WITH AND WITHOUT THERMOMECHANICAL SURFACE TREATMENT FOR LOCAL GRAIN REFINEMENT. SOURCE: REF 49**

**Near-alpha and alpha-beta alloys** are often intended for elevated-temperature service (e.g., in gas turbines), so creep resistance is an important consideration. On this basis, lamellar microstructures would be preferable. However, these microstructures have poor fatigue resistance, particularly in the LCF regime, where surface crack growth determines fatigue life. In such cases, a variation in phase morphology between the surface and the core can be obtained by mechanically working the surface by shot peening and then heat treating. The improvement in S-N behavior (at high temperature) gained by this thermomechanical surface treatment is shown in Fig. 34 for Ti-6242 with a creep-resistant lamellar core and a fatigue-resistant fine equiaxed surface layer (Ref 52).

FIG. 34 S-N CURVES FOR TI-6242 AT 550 °C WITH A FINE LAMELLAR MICROSTRUCTURE AND WITHOUT A THERMOMECHANICAL SURFACE TREATMENT. SOURCE: REF 49

**Beta Alloys.** Both shot peening and surface rolling in combination with specially developed aging treatments have been applied to Ti-3Al-8V-6Cr-4Mo-4Zr (Ref 53, 54) to selectively age harden only the surface. This new thermomechanical surface treatment shows promise for improving properties of high-strength springs and fasteners. Figure 35 shows the near-surface region for shot-peened material both without and with a selective surface aging (SSA) treatment. The high strength of the surface increases the fatigue limit to values above those of a conventional bulk aging treatment, while the high ductility of the solution-heat-treated (SHT) condition in the interior provides good notched ductility and toughness (Ref 49). Fully reversed notched fatigue behavior for this alloy after surface rolling with and without SSA is shown in Fig. 35. Rolling alone increases the notched fatigue limit of the SHT condition (expressed as nominal stress times a concentration factor) from the low value of 400 MPa to 1100 MPa. Depending on the subsequent aging treatment, the S-N behavior can deteriorate slightly (SSA1) or be even further improved (SSA2). These results suggest that the residual compressive stresses present in the as-rolled condition are significantly relieved by the SSA1 treatment but not the SSA2 treatment (Ref 49).

FIG. 35 S-N CURVES FOR TI-3AL-8V-6CR-4MO-4ZR. SSA, SELECTIVE SURFACE AGING; SHT, SOLUTION HEAT TREATED. SOURCE: REF 49

Mechanical surface treatments such as shot peening and surface rolling can be applied alone or in combination with heat treatments to obtain optimum properties in mechanically loaded titanium parts. The particular treatment applied should reflect the type of alloy (alpha, alpha-beta, or beta) to make use of its characteristic response to heat treatment and/or TMP.

# Fatigue and Fracture Properties of Titanium Alloys

---

## Fatigue Crack Growth of Titanium Alloys

J.K. Gregory, Martin-Luther University Halle-Wittenberg

---

Just as  $K_{Ic}$  is important for calculating allowable loads in the presence of a flaw, it is also important to estimate remaining life when fatigue is one of the primary failure mechanisms. If inspections are regularly performed to detect cracks, as is the case in aircraft, fracture mechanics methods can be used to predict residual life and specify inspection intervals, providing that fatigue crack growth data are available that correspond to the material and loading conditions appropriate to the application. When plotted as  $da/dN$  versus  $\Delta K$ , fatigue crack growth (FCG) rates of titanium alloys generally lie between those of steels and aluminum alloys. This results from the use of  $\Delta K$  to characterize the stress field at the crack tip, because  $K$ , as a linear elastic fracture mechanics parameter, by nature depends itself on the elastic modulus. It should be kept in mind that  $\Delta K$  is not strictly valid for titanium alloys with a significant volume fraction of alpha grains, because the alpha phase is anisotropic, and the derivation of  $K$  assumes isotropic elastic behavior. Nonetheless,  $K$  is widely used to describe crack growth behavior in titanium alloys. Typical FCG behavior for titanium as compared to steel and aluminum at a low load ratio is shown in Fig. 36. More so than in steel and aluminum, microstructural variations can significantly influence FCG rates and thresholds, but they are more or less pronounced according to specific loading and environmental conditions.

**FIG. 36** RANGE OF FATIGUE CRACK GROWTH RATES IN TITANIUM ALLOYS, WHICH LIE BETWEEN THOSE OF STEELS AND ALUMINUM ALLOYS. SOURCE: REF 55, 56

The sections below first outline the interaction between microstructure, crack geometry, and load ratio in determining FCG and threshold, giving examples for commercial-purity (CP) Ti, near-alpha, alpha-beta, near-beta, and metastable beta alloys. FCG is commonly held to be slower in coarse microstructures than in fine microstructures. However, this is only true when cracks are long and the stress ratio is low (i.e., less than roughly 0.3).

The importance of environment is discussed briefly. In general, FCG is more strongly affected by the environment in the alpha phase than in the beta phase. The influence of temperature is presented for alloys that are recommended for use at high temperatures (near-alpha, alpha-beta, and in some cases metastable beta) and cryogenic temperatures (ELI grades with enhanced toughness). Finally, the available data for FCG in weldments are presented and analyzed in terms of microstructure and residual stresses.

## Fatigue and Fracture Properties of Titanium Alloys

### Metallurgical Effects on FCG

The possible influences of microstructure are specific to the alloy type. For example, in CP Ti or alpha alloys, grain size, interstitial (oxygen) content, and cold work can be varied. Figure 37 shows the influence of grain size on FCG at  $R = 0.07$  for different grades of CP Ti. In general, the higher the oxygen content, the greater the influence of grain size, and vice versa (Ref 57). FCG rates in fine-grained material, (i.e., 20-35  $\mu\text{m}$  or ASTM 7-8) are relatively insensitive to oxygen

content. When grain size is increased to roughly  $220 \mu\text{m}$ , or ASTM 1.5, FCG rates not only are significantly lower than in fine-grained material, but a higher oxygen content can further lower FCG rates (Ref 57). Cold work would presumably cause slightly increased FCG rates by reducing residual ductility.

**FIG. 37 INFLUENCE OF GRAIN SIZE ON FATIGUE CRACK GROWTH AT  $R = 0.07$  FOR CP TI WITH VARYING OXYGEN CONTENTS. UNDER THESE LOADING CONDITIONS, FATIGUE CRACK GROWTH IS LOWERED BY COARSE GRAINS AND INCREASED OXYGEN CONTENT. SOURCE: REF 57**

In near-alpha and alpha-beta alloys, the phase morphology (lamellar vs. equiaxed) is the most important microstructural feature (Ref 58, 59). Figure 38 (Ref 59, 60, 61) shows FCG rates at  $R = 0.1$  for Ti-6Al-4V in both mill-annealed and coarse lamellar (beta-annealed) conditions. The fine, mill-annealed microstructure exhibits much higher FCG rates than the lamellar microstructure, particularly at lower  $\Delta K$  values. Although this is commonly observed for long-crack data measured on standard fracture mechanics specimens, it must be kept in mind that when cracks are small or when specimen dimensions are small compared to the length of the crack front, coarse lamellar microstructures exhibit much higher FCG rates than fine microstructures (Ref 58). This is discussed below in the section "Small/Short Cracks."

**FIG. 38** TYPICALLY FATIGUE CRACK GROWTH RATES FOR TI-6AL-4V IN A LAMELLAR AND FINE EQUIAXED CONDITION AND FOR TI-10V-2FE-3AL AND TI-3AL-8V-6CR-4MO-4ZR. FATIGUE CRACK GROWTH RATES TEND TO BE LOWER IN LAMELLAR MICROSTRUCTURES THAN IN FINE EQUIAXED MICROSTRUCTURES IN TI-6AL-4V. FATIGUE CRACK GROWTH IN NEAR- $\beta$  AND METASTABLE  $\beta$  ALLOYS IS USUALLY SLIGHTLY HIGHER THAN THAT OF FINE EQUIAXED ( $\alpha + \beta$ ) ALLOYS. SOURCE: REF 59, 60, 61

When both alpha grains and lamellar regions are present, as in duplex microstructures, FCG rates are intermediate between those of fine-grained and fully lamellar microstructures (Ref 62). Oxygen content also influences FCG rates in two-phase alloys in the same manner as in CP Ti; however, the effect is so minor as to be easily masked by other microstructural changes, presumably because the grain sizes in these alloys are always less than 20  $\mu\text{m}$ .

As was shown for CP Ti, FCG in fine-grained material is not very sensitive to interstitial content. The difference between FCG rates in mill-annealed Ti-6Al-4V in both the standard and ELI grades is roughly a factor of 2 (Ref 63).

In near-beta and metastable beta alloys, grain size, the degree of age-hardening, and amount of cold work are possible microstructural parameters to be considered. The few data available suggest that FCG in these alloys is insensitive to grain size and degree of cold work (or residual deformation from hot working). Age hardening has only a minor influence on FCG (Ref 60, 61). Figure 38 shows typical FCG rates for the near-beta and metastable beta alloys Ti-10V-2Fe-3Al and Ti-3Al-8V-6Cr-4Mo-4Zr, respectively. FCG rates are slightly higher than those of fine-grained near-alpha and alpha-beta alloys. This is partially because of the slightly lower elastic modulus of the beta matrix, which tends to shift FCG curves to lower  $\Delta K$  values. Although significantly lower FCG rates have been reported for Ti-10V-2Fe-3Al which was solution heat treated with no subsequent aging cycle (Ref 60), this condition exhibits virtually nil ductility and very poor fracture toughness.

In CP-Ti and in near-alpha and alpha-beta alloys, a preferred crystallographic orientation, or texture in the alpha phase, can affect FCG. A preferred orientation in the alpha phase can be indirectly assessed by measuring the elastic modulus. In commercial alloys, values of roughly 100 GPa indicate that few basal planes are loaded in tension, while values as high as 130 GPa can be found when many basal planes are loaded in tension. Normally, a higher elastic modulus is expected to lower FCG rates at a given  $\Delta K$ . However, a high proportion of basal planes in the crack plane leads to more rapid crack growth in CP Ti (Ref 64) and alpha-beta alloys (Ref 65, 66), because cleavage is the preferred mode of crack advance on these planes. Figure 39 shows FCG rates in air for Ti-6Al-4V in a fine equiaxed condition (alpha grain size of 1-2  $\mu\text{m}$ ) loaded parallel and perpendicular to the basal planes. It was noted in Ref 66 that this texture effect is absent in vacuum, and in Ref 65 that an influence of texture becomes more pronounced in a salt water environment, suggesting that the acceleration mechanism is related to environment. For near-beta and metastable beta alloys, little data are available regarding the effect of texture on FCG. Where different sample orientations in rolled plate have been investigated, virtually no difference in FCG behavior has been found, suggesting that the influence of texture is negligible (Ref 67).

FIG. 39 INFLUENCE OF TEXTURE ON FATIGUE CRACK GROWTH IN TI-6AL-4V. FATIGUE CRACK GROWTH RATES ARE HIGHER WHEN BASAL PLANES ARE LOADED IN TENSION. THE ELASTIC MODULUS IN TENSION FOR THE BASAL TEXTURE (B) IS 109 GPa; FOR THE TRANSVERSE TEXTURE (T), 126 GPa. THE YIELD STRESS IS ROUGHLY 1150 MPA FOR BOTH. TD, TRANSVERSE TEXTURE TESTED PERPENDICULAR TO THE ROLLING DIRECTION. SOURCE: REF 66

## Fatigue and Fracture Properties of Titanium Alloys

### Fatigue Fracture Modes

A wide variety of characteristic features on fracture surfaces have been observed, and they depend on both the underlying microstructure and loading and environmental conditions. Crack advance can proceed through the alpha phase by a structure-insensitive striation-forming mechanism (i.e., one that involves plastic deformation, or structure-sensitive faceted fracture, which produces cleavage-like facets, Ref 64, or cyclic cleavage, Ref 68). In the latter case, the facets are identical to those produced by cleavage during fast fracture. However, while conventional cleavage during FCG in titanium is associated with high FCG rates and salt water environments, two conditions must generally be met in order to observe cyclic cleavage: the principal tensile stress must be within 50° of the normal to the basal plane, and the FCG rates must be sufficiently low (Ref 64). For this purpose, FCG rates are considered low if the calculated cyclic plastic zone size is comparable to the alpha grain size (Ref 69, 70). When the tensile axis lies almost in the basal plane, cleavage and/or cyclic cleavage does not occur, and striations whose spacing correlates reasonably well with measured FCG rates can be found in alpha grains.

Titanium alloys that contain both alpha and beta phases can consist of alpha grains with the beta phase at grain boundary triple points ("equiaxed" or "mill annealed"), consist of alpha grains separated by lamellar regions ("duplex"), or be fully lamellar ("transformed beta"). The alpha grains can give rise to fracture surface features, as previously described. Depending on the orientation of the lamellar packets, lamellar regions can either exhibit parallel markings that can potentially be mistaken for striations (Ref 71) or cause "blocky" fracture (Ref 70). The latter results from the tendency for cracks to propagate alternately along the basal planes of the alpha lamellae or between the lamellae. This blocky fracture has an asperity height that is comparable to the lamellar packet size and therefore corresponds to a high degree of out-of-plane cracking. Because duplex microstructures contain both alpha grains and lamellar regions, which themselves can have various orientations relative to the loading axis, they also exhibit complex fatigue fracture surfaces (Ref 70). By comparison, the near-beta and metastable beta alloys have simple fracture modes. If material is in the solution-heat-treated condition, planar slip in the beta phase can cause a high roughness that is comparable to the grain size, as well as slip traces on the fracture surface. If material has been age hardened, fatigue fracture is transgranular with a very low degree of roughness, presumably because no microstructural features are present that can cause the crack to deviate from the macroscopic plane (Ref 72).

## Fatigue and Fracture Properties of Titanium Alloys

### Metallurgical Effects on Threshold

The threshold stress-intensity factor,  $\Delta K_{th}$ , measured at low  $R$ -ratios is strongly dependent on microstructure in titanium alloys that consist primarily of the alpha phase. An increase in grain size combined with an increased oxygen content can cause higher thresholds in CP Ti and alpha alloys. The highest thresholds are observed in lamellar microstructures for near-alpha and alpha-beta alloys, as well as the beta-eutectoid alloy Ti-2.5Cu (which consists of alpha plus a mixture of alpha and Ti<sub>2</sub>Cu rather than alpha plus beta). Low threshold values of roughly 3 MPa  $\sqrt{m}$  are found in age-hardened metastable beta alloys. Thresholds are slightly higher for material in the solution-heat-treated condition. Table 22 shows values for threshold  $\Delta K$  for several alloys in various microstructural conditions, tested in air at different  $R$ -ratios. Because most of the older available data were gathered prior to any general agreement regarding the measurement of  $\Delta K_{th}$ , values of  $\Delta K$  measured at FCG rates of  $10^{-9}$  m/cycle are given.

## Fatigue and Fracture Properties of Titanium Alloys

### Influence of Stress Ratio

When comparing FCG data, in particular thresholds, care should be taken to ensure that the stress ratios are identical. The high-threshold  $\Delta K$  values measured at low  $R$ -ratios are not intrinsic material constants, but rather extrinsic parameters (i.e., they depend on the geometry of the crack relative to the sample size). In titanium, the extrinsic contribution to  $\Delta K_{th}$  is primarily caused by roughness-induced crack closure (Ref 79). As the  $R$ -ratio increases, threshold  $\Delta K$  values for all alloys and microstructures converge to a value of about  $2 \text{ MPa}\sqrt{m}$ , independent of composition and/or metallurgical factors. Figure 40 shows the scatterband from Ref 56, showing the influence of  $R$ -ratio on measured threshold for various

alloys and microstructural conditions. Also shown on this diagram are the  $\Delta K$  values corresponding to FCG rates of  $10^{-9}$  m/cycle from Table 22.

FIG. 40 THRESHOLD  $\Delta K$  VALUES FROM REF 56 TOGETHER WITH  $\Delta K$  AT  $10^{-9}$  M/CYCLE FROM REF 57, 59, 72, 73, 74, 75, 76, 77, AND 78 AS A FUNCTION OF  $R$ -RATIO. WIDELY DIFFERING VALUES AT LOW  $R$ -RATIO CONVERGE TO ROUGHLY  $2 \text{ MPa}\sqrt{m}$  AS  $R$ -RATIO INCREASES.

If the extrinsic contribution of  $\Delta K$  that is related to closure is subtracted from the applied  $\Delta K$ , the effective stress intensity that drives FCG,  $\Delta K_{\text{eff}}$ , is obtained. For numerical modeling of FCG rates, this  $\Delta K_{\text{eff}}$  is considerably more useful than the applied  $\Delta K$ . For example, the FCG rates at  $R$ -ratios ranging from 0.7 to -5.0 in a duplex microstructure of Ti-6Al-4V were found in Ref 68 to be brought into coincidence very well when plotted as  $da/dN$  versus  $\Delta K_{\text{eff}}$ , where  $\Delta K_{\text{eff}}$  was empirically calculated as:  $\Delta K_{\text{eff}} = 1.63/(1.73 - R) \Delta K$ .

## Fatigue and Fracture Properties of Titanium Alloys

### Small/Short Cracks

The behavior of small cracks under cyclic loading is particularly important for parts that experience high-frequency fatigue, such as turbine blades and vanes. Of special significance for service is the fact that the high-threshold  $\Delta K$  values obtained on standard fracture mechanics specimens are not necessarily applicable to small or short cracks. In fact, any metallurgical changes that decrease FCG rates in standard specimens tend to increase them in small crack specimens. For example, in Ti-6Al-4V, the most rapid FCG rates for small cracks are observed in coarse lamellar microstructures, and the lowest FCG rates are observed in fine-grained or duplex microstructures. Fine lamellar microstructures exhibit intermediate FCG rates (Ref 77). Figure 41 shows an example of this effect, comparing the near-alpha alloy IMI 685, which has an aligned lamellar microstructure, with the fine-grained alpha-beta alloy IMI 318. This discrepancy between FCG in long versus short cracks arises because in short cracks, the contribution to the extrinsic threshold owing to closure is small, leaving only the intrinsic threshold, which is determined primarily by the density of microstructural barriers to crack propagation, namely grain or lamellar packet boundaries (Ref 77). This is depicted schematically for various specimen geometries as relationships between grain size and crack front in Fig. 42. As short cracks grow, asperities in the crack wake combine with shear ahead of the crack tip to develop closure effects that prevent the crack from experiencing the complete range of the applied  $\Delta K$ . In situ measurements using laser interferometry on a model alloy, Ti-8Al, have demonstrated that a minimum of roughly 2 mm in length measured as the surface trace is required for a crack to have developed closure behavior comparable to that of a crack in a standard specimen (Ref 81). These data are shown in Fig. 43 as closure level as a function of crack length. Empirical correlations in IMI 685 having a coarse aligned lamellar microstructure showed that lengths of 3.5 mm are necessary in order for short corner cracks to behave as long cracks (Ref 82). Hence, surface cracks can be expected to exhibit higher FCG rates than long cracks at low  $R$ -ratios if the depth is less than several millimeters. It has been suggested that FCG testing on standard specimens can be performed in lieu of the more difficult small crack experiments if data are obtained on long crack specimens at a sufficiently high  $R$ -ratio (Ref 83). However,  $R$ -ratios greater than 0.7 are required in order to reasonably reproduce small crack data for lamellar (Ref 75) and duplex two-phase (Ref 73) microstructures. Furthermore, if the crack size is comparable to the microstructural unit size, the validity of  $\Delta K$  can be doubtful, because the material cannot be considered a continuum.

FIG. 41 FATIGUE CRACK GROWTH RATES FOR THE NEAR- $\alpha$  ALLOY IMI 685 HAVING AN ALIGNED LAMELLAR MICROSTRUCTURE AND THE FINE-GRAINED  $\alpha$ - $\beta$  ALLOY IMI 318. LAMELLAR MICROSTRUCTURES EXHIBIT LOWER FATIGUE CRACK GROWTH RATES THAN FINE MICROSTRUCTURES IF LONG THROUGH-CRACKS ARE CONSIDERED, BUT HIGHER FATIGUE CRACK GROWTH RATES WHEN SMALL/SHORT CRACKS ARE CONSIDERED. ## Fatigue and Fracture Properties of Titanium Alloys

### Environmental Effects

For titanium alloys, air must be considered an aggressive environment. Compared to FCG rates in vacuum or inert gas, FCG is much faster for CP Ti (Ref 57), near-alpha (Ref 84, 85) and alpha-beta alloys (Ref 65, 66, 86, 87) when tested in air. Both oxygen and hydrogen are elements with which titanium can readily react under ambient conditions. The accelerating effect of air on FCG has been attributed to residual moisture (Ref 66, 88), which is thought to oxidize the fresh titanium surface and release hydrogen, resulting in local embrittlement (Ref 84, 88). At a given frequency, FCG rates increase as the environment becomes more aggressive. In particular, liquids that contain halide ions, which can destroy the protective oxide layer of titanium, have been identified as being extremely detrimental to FCG resistance. A variety of aggressive environments were investigated in Ref 86 and demonstrate that FCG rates in solutions that contain  $\text{Cl}^-$  or  $\text{I}^-$  ions are up to 10 times faster than in distilled water (Fig. 44).

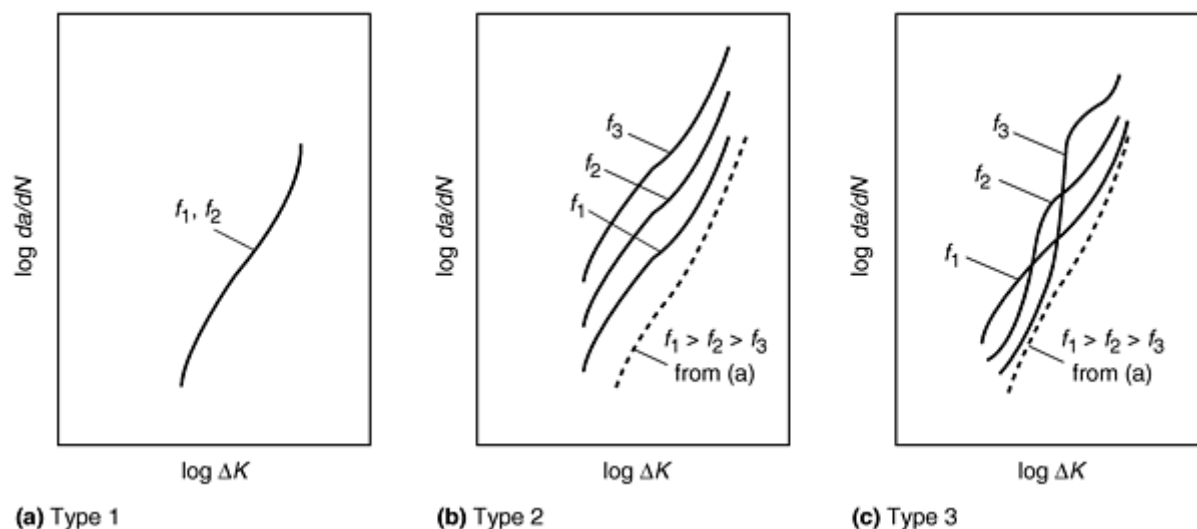

FIG. 44 FATIGUE CRACK GROWTH RATES FOR TI-6AL-4V IN VARIOUS LIQUID ENVIRONMENTS. WATER IS AGGRESSIVE COMPARED TO AIR, AND A HIGH CONCENTRATION OF HALIDE IONS CAUSES RAPID FATIGUE CRACK GROWTH RATES. SOURCE: REF 86

Although air is an aggressive environment for titanium alloys with a large fraction of the alpha phase, the loading frequency does not have a pronounced effect on FCG rates under ambient conditions. In more aggressive environments, the effect of loading frequency becomes significant. In Ref 89, environments were classified into three groups according to the possible influence of loading frequency. These are shown schematically in Fig. 45. In nominally inert environments

such as vacuum, helium, argon, or air, FCG rates in titanium exhibit little or no effect of frequency (Fig. 45a). In liquids such as methanol, a "normal" frequency effect is found, in that higher FCG rates are found at lower frequencies (Fig. 45b). In halide-containing solutions such as salt water, "cyclic SCC" with a characteristic discontinuity in the  $da/dN$ - $\Delta K$  curve is found (Fig. 45c). The lower the loading frequency, the lower the  $\Delta K$  value at which the discontinuity is observed, where the limiting value is such that  $K_{\max} = K_{\text{Isc}}$ . This observation is valid for near-alpha and alpha-beta alloys for which  $K_{\text{Isc}}$  is significantly lower than  $K_{\text{Ic}}$ . For near-beta and metastable beta alloys, no significant acceleration in FCG was found in aqueous 3.5% salt solutions as compared to air (Ref 72), and, equivalently, no effect of loading frequency in salt water has been observed (Ref 72, 90).

## Fatigue and Fracture Properties of Titanium Alloys

### Temperature Effects

As temperature is increased, the mechanical properties of titanium alloys change in that yield stress and elastic modulus decrease. The tendency to react with the environment, most importantly the degree of oxidation, becomes much more pronounced. Titanium hydrides, which can form in the alpha phase and cause rapid FCG, are less stable at elevated temperature (Ref 91). Thus, at high temperatures, FCG rates depend on both environment and frequency.

Near-alpha alloys intended for use up to 550 °C (1020 °F) have been the most frequent subjects of investigation. One unusual effect found is that at slightly elevated temperatures (i.e., at 150 °C, or 300 °F), FCG rates are lower than at room temperature (Ref 92). This is presumably related to the fact that needle-like hydrides that can form ahead of the crack tip are less stable at the higher temperature, so that FCG behavior actually improves. At still higher temperatures, FCG rates increase again so that at 260 to 300 °C (500 to 570 °F), behavior similar to that at room temperature is found for both long (Ref 93) and short (Ref 94) cracks. At still higher temperatures, between 400 to 650 °C (750 to 1200 °F), FCG rates are significantly higher than those measured under ambient conditions for  $\Delta K$  values of up to approximately  $25 \text{ MPa}\sqrt{m}$  (Ref 94, 95). An example of the magnitude of this influence is shown in Fig. 46(a). The temperature influence in near-alpha alloys cannot be rationalized using only simple mechanics considerations. Attempts to correlate FCG data obtained at different temperatures, using an elastic-plastic parameter similar to a crack-tip opening displacement (CTOD) calculated as  $(\Delta K)^2/E\sigma_y$ , have not been successful, as demonstrated in Fig. 46(b). This is likely to result from the facts that elastic modulus does not have the effect on FCG in the alpha phase that would normally be expected and that the anisotropy of slip and fracture (cleavage vs. striations) can change with temperature. In general, microstructures that exhibit lower FCG rates at room temperature also exhibit lower FCG rates at elevated temperature (Ref 74). This is shown in Fig. 47 for long cracks in Ti-1100 having both a basket weave and a duplex microstructure. These data also show the substantial decrease in threshold  $\Delta K$  caused by the high temperature.

FIG. 46 FATIGUE CRACK GROWTH IN BETA-PROCESSED TI-1100 AT 23, 593, AND 650 °C. (A)  $DA/DN-\Delta K$ . (B) THE SAME DATA PLOTTED AS  $DA/DN$  VS.  $(\Delta K)^2/E\sigma_y$ . THE CORRELATION WITH A CTOD-LIKE PARAMETER DOES NOT HOLD WELL FOR THE HIGHLY ANISOTROPIC  $\alpha$ -PHASE, BECAUSE THE DEPENDANCE OF FATIGUE CRACK GROWTH ON ELASTIC MODULUS IS COMPLEX. SOURCE: REF 95

FIG. 47 FATIGUE CRACK GROWTH RATES AT ROOM TEMPERATURE AND AT 600 °C FOR TI-1100 IN TWO MICROSTRUCTURAL CONDITIONS. MICROSTRUCTURAL DEPENDENCIES FOUND AT ROOM TEMPERATURE GENERALLY HOLD AT ELEVATED TEMPERATURE. SOURCE: REF 74

Although the metastable beta alloys are not intended for elevated-temperature service as monolithic materials (the upper limit for the service temperature is approximately 350 °C), FCG in laminates of  $\beta$ 21S has been investigated owing to interest in this alloy as a potential matrix material for composites with boron-type filaments at up to 760 °C (Ref 96). While FCG rates at room temperature and 482 °C are similar, temperatures greater than 650 °C (1200 °F) cause both substantial increases in FCG rate and decreases in threshold (Fig. 48a). At these temperatures, the ductility is so high that linear elastic fracture mechanics is not applicable, and elastic-plastic fracture mechanics parameters must be used. In contrast to the near-alpha alloys, data obtained at various temperatures could be correlated reasonably well using  $(\Delta K)^2/E\sigma_y$  (Ref 92), as shown in Fig. 48.

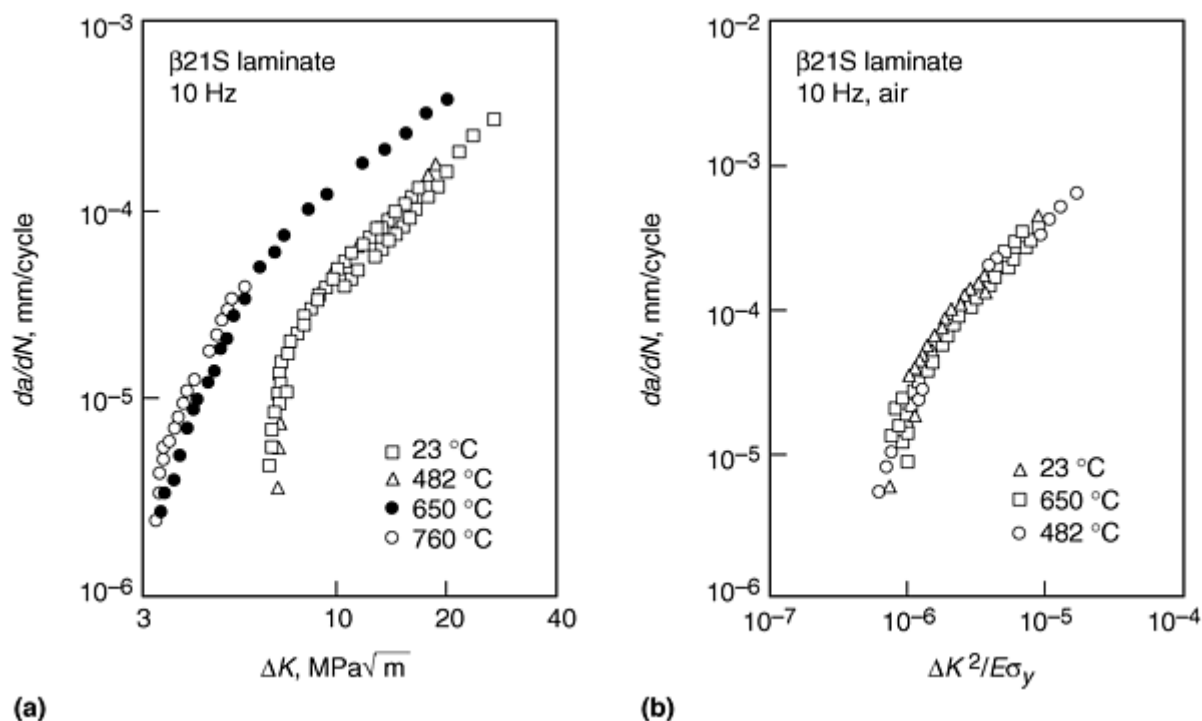

FIG. 48 FATIGUE CRACK GROWTH IN LAMINATES OF  $\beta$ -21S AT VARIOUS TEMPERATURES BETWEEN 23-760 °C. (A)  $DA/DN$ - $\Delta K$  CURVES. (B) DATA AT 23-482 °C PLOTTED AS  $DA/DN$  VS.  $(\Delta K)^2/E\sigma_y$ . THE CORRELATION USING THE CTOD-LIKE PARAMETER IS GOOD FOR THE BCC  $\beta$  PHASE. SOURCE: REF 96

At low temperatures, many materials become brittle as plastic deformation becomes more difficult. Titanium hydrides are thermodynamically more stable at low temperatures; however, diffusion becomes less rapid (Ref 91). Hence, FCG rates at low temperatures depend on environment as well as on internal hydrogen content. Although titanium alloys that consist primarily of the alpha phase do not exhibit the pronounced ductile-to-brittle transitions common to steels, low-temperature applications usually specify the ELI grades of titanium, because they have higher toughness than their conventional counterparts. This is particularly true for applications at cryogenic temperatures. Hence, FCG data at very low temperatures tend to be available only for these alloys. Both Ti-5Al-2.5Sn (ELI) (Ref 97) and the compositionally similar alloy VT5-1ct (Ref 98) exhibit FCG rates at cryogenic temperatures (20 and 11 K, respectively), very similar to those at room temperatures at  $\Delta K$  values of up to  $40 \text{ MPa}\sqrt{m}$ . At higher  $\Delta K$  values, the significantly reduced fracture toughness at the low temperature causes the transition from the linear regime to the fast fracture regime to shift to lower values of  $\Delta K$  in the  $da/dN$ - $\Delta K$  curve. This can be seen in Fig. 49 as scatterbands for Ti-5Al-2.5Sn (ELI). A similar result was obtained at  $R = 0.5$  (Ref 97). While Ref 97 tested at room temperature in air and at low temperature in liquid hydrogen, Ref 98 determined the influence of temperature and environment by measuring FCG in both air and vacuum. Taking FCG under ambient conditions as a baseline,  $da/dN$  was significantly reduced and the threshold  $\Delta K$  increased from roughly 7 to  $15 \text{ MPa}\sqrt{m}$  when tested in vacuum, irrespective of whether the temperature was 93 or 293 K. Environment can thus be said to be far more important than low temperature, at least for these alloys.

**FIG. 49** COMPARISON BETWEEN FATIGUE CRACK GROWTH AT ROOM TEMPERATURE IN AIR AND AT 20 K IN LIQUID HYDROGEN FOR TI-5AL-2.5SN TESTED AT  $R = 0.05$ , SHOWN AS SCATTERBANDS. THE REDUCED FRACTURE TOUGHNESS AT 20 K CAUSES THE TRANSITION TO THE FAST FRACTURE RANGE TO SHIFT TO LOWER  $\Delta K$  VALUES. SOURCE: REF 97

In metastable beta alloys, distinct ductile-to-brittle transitions have been observed and have been found to shift to higher temperatures as internal hydrogen content is increased (Ref 99). This is to be expected from the body-centered cubic beta phase and should be kept in mind when these alloys are considered for service at low temperatures. The influence of decreasing temperature on FCG rates in the binary alloy Ti-30Mo depend in a complex manner on internal hydrogen content (Ref 100). For a low (22 wt ppm) hydrogen content, comparable to that of commercial metastable beta alloys, FCG at 123 K was slightly lower than at 340 K (Fig. 50). At 190 and 233 K, FCG rates were lower than those at 123 K by roughly a factor of 2. At a high (1200 wt ppm) internal hydrogen content, FCG rates were more rapid at 123 K than at 340 K by about a factor of 3. The effects of temperature and/or hydrogen content were more pronounced at FCG rates lower than  $10^{-9}$  m/cycle. The contribution of closure to  $\Delta K$  in the near-threshold regime was found to be favored by ductility; hence, high hydrogen contents and low temperatures reduce the extrinsic contribution to threshold.

FIG. 50 COMPARISON BETWEEN FATIGUE CRACK GROWTH AT 340 AND 123 K FOR TI-30MO WITH BOTH A LOW (22 WT PPM) AND A HIGH (1200 WT PPM) HYDROGEN CONTENT (AFTER REF 100). THE TEMPERATURE DEPENDENCE OF FATIGUE CRACK GROWTH IN THE  $\beta$  PHASE DEPENDS ON THE INTERNAL HYDROGEN CONTENT. SOURCE: REF 100

## Fatigue and Fracture Properties of Titanium Alloys

### Weldments

In all types of titanium alloys, microstructures in the fusion zone and in the heat-affected zone can be completely different from that in the base metal. Grain coarsening can occur in CP Ti, near-alpha, alpha-beta, near-beta, and metastable beta alloys. In near-alpha and alpha-beta alloys, the temperature excursion above the beta transus results in lamellar microstructures. In metastable beta alloys, alpha precipitates can form, coarsen, or be dissolved, depending on the local time-temperature cycle. Owing to the reactivity of titanium with oxygen, great care must be taken to prevent oxygen take-up during welding, which can influence FCG rates as well as other mechanical properties. Finally, the rapid cooling rates from elevated temperatures cause residual stresses, which when superposed on applied stresses can have a great influence on FCG rates.

In grade 2 CP Ti, closure levels are significantly higher in weld metal than in the base metal (Ref 101), which is attributed to an increase in grain size. Experimental determination of FCG rates in various weldments of near-alpha and alpha-beta alloys (Ref 102, 103, 104, 105) using C(T) specimens have shown that FCG in the fusion or heat-affected zone is always much lower than in the untreated base metal, whether welding was done by gas-tungsten arc (Ref 102, 105), electron beam (Ref 104), or laser beam (Ref 103). An example is shown in Fig. 51 for crack orientations parallel and perpendicular to the welding direction. While a change in microstructure from mill-annealed (Ref 102) or duplex (Ref 104) to fine lamellar could qualitatively rationalize the improved FCG resistance when FCG is parallel to the weld, FCG in weldments is in fact more strongly dependent on residual stresses than on microstructure. On the one hand, the threshold  $\Delta K$  values obtained at the low  $R$ -ratios of 0 or 0.1 lie between 15 and 20 MPa $\sqrt{m}$ , which is significantly higher than the values of 8 to 12 MPa $\sqrt{m}$  commonly observed in these alloys. On the other hand, the measurement (Ref 105) or elimination of residual stresses by a postweld heat treatment (Ref 103, 104), as well as the testing of FCG in weldments for cracks normal to the weld (Fig. 51b), unambiguously demonstrate the importance of residual stresses. Independent of orientation, a stress relief treatment of 4.5 h at 625 °C (1160 °F) caused FCG rates in weldments to increase almost to those of the base metal (Fig. 51). Furthermore, the retardation in FCG rates found for cracks normal to the weld (Fig. 51b) cannot be explained solely by microstructure.

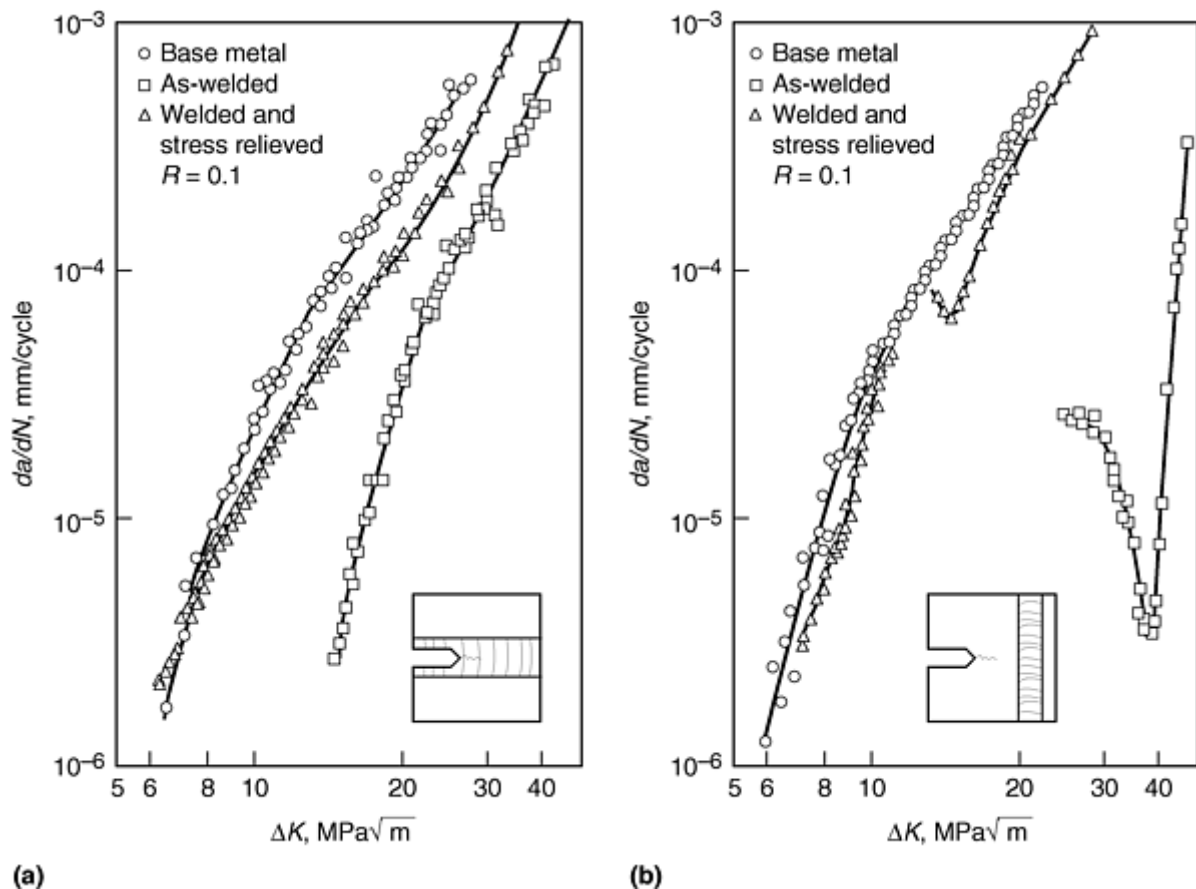

FIG. 51 FATIGUE CRACK GROWTH IN LASER BEAM WELDMENTS OF TI-6AL-4V BOTH WITHOUT AND WITH A POSTWELD STRESS RELIEF TREATMENT OF 4.5 H AT 625 °C (1160 °F). (A) FATIGUE CRACK GROWTH PARALLEL TO WELD. (B) FATIGUE CRACK GROWTH PERPENDICULAR TO WELD. THESE DATA SUGGEST THAT RESIDUAL STRESSES IN THE WELDMENT CONTRIBUTE TO LOW FATIGUE CRACK GROWTH RATES AND/OR HIGH THRESHOLDS. SOURCE: REF 103

FCG data for the metastable beta alloy Ti-15V-3Cr-3Al-3Sn can be interpreted similarly, in part because FCG in these alloys is so insensitive to microstructure. Aging treatments of either 8 h at 480 °C or 8 h at 510 °C were performed after gas-tungsten arc welding, resulting in a factor-of-2 increase in FCG rate at  $\Delta K$  values greater than 20  $\text{MPa}\sqrt{m}$  over the as-welded condition (Ref 106). The FCG behavior of the postweld heat-treated material is almost identical to that of conventionally aged material, suggesting that the lower FCG rates in the as-welded condition could also conceivably be caused by residual stresses.

## Fatigue and Fracture of Nickel-Base Superalloys

Bruce F. Antolovich, Metallurgical Research Consultants, Inc.

---

### Introduction

NICKEL-BASE SUPERALLOYS have been in continuous use since the late 1930s, when the Nimonic alloys were introduced in the first jet aircraft engines (Ref 1). Some authors consider superalloys to have been developed by Wilhelm Rohn in Germany in the 1920s and 1930s (Ref 2). These nickel-iron-chromium alloys were developed primarily for heat and corrosion resistance and were an early application of vacuum induction melting (Ref 3). Nonetheless, the vast majority of use by tonnage of nickel-base superalloys is found in turbines both for aerospace applications and for land-based power generation. These applications require a material with high strength, good creep and fatigue resistance, good corrosion resistance, and the ability to be operated continuously at elevated temperatures.

Nickel-base superalloys are used primarily in turbine blades (called "buckets" in land-based power turbines), turbine disks, burner cans, and vanes. The operating temperatures of these components range from the relatively mild temperature of 150 °C (300 °F) up to almost 1500 °C (2730 °F). Additionally, several components experience large temperature gradients; for example, turbine disks range from 150 °C (300 °F) at the center to 550 °C (1020 °F) at the rim where the blades are attached. In addition to the high temperatures they must endure, the blades are also subject to an extremely corrosive environment--namely, the products of combustion. The primary loading, which results mainly from centripetal acceleration of the rotating blades and disk, in conjunction with the high temperature, leads to creep deformation. Finally, fatigue cycles result from each engine startup and shutdown as the load changes from zero to maximum and back to zero. For some military engines, thrust settings are varied so greatly that they can also be considered as a fatigue cycle.

Turbine components thus experience thermomechanical loading and fatigue as well as creep-fatigue interactions. The good combination of strength and toughness, as well as an unusual yield behavior (in which the yield strength increases with increased temperature up to about 700 °C, or 1290 °F), continues to make nickel-base superalloys the material of choice for high-performance, high-temperature applications.

Other uses, both actual and proposed, for nickel-base superalloys include:

- CRYOGENIC APPLICATIONS, SUCH AS THE COMPRESSOR SECTION OF LIQUID ROCKET ENGINES

- AIRFRAME SKINS FOR HIGH-SPEED AIRCRAFT AND REENTRY VEHICLES
- SUPERCONDUCTING APPLICATIONS

Polycrystalline superalloys, although still being developed, are nevertheless quite well understood and will be covered only briefly. The interested reader should consult several other comprehensive reviews (Ref 4, 5, 6, 7). This article will cover fracture, fatigue, and creep of nickel-base superalloys, with additional emphasis on directionally solidified and single-crystal applications.

## Fatigue and Fracture of Nickel-Base Superalloys

Bruce F. Antolovich, Metallurgical Research Consultants, Inc.

---

## Physical Metallurgy

The microstructure of nickel-base superalloys has a profound effect on their performance. Fortunately, their microstructure is quite simple--consisting of a solid-solution-strengthened austenitic face-centered cubic (fcc) matrix, coherent intermetallic precipitates with an  $L1_2$  crystal structure, along with carbides and other phases occurring either in the matrix or at grain boundaries (Ref 8). This microstructure can be significantly influenced by appropriate thermomechanical treatments and composition modifications to create specific microstructures that are resistant to creep, oxidation/corrosion, fatigue crack propagation, and so forth. Compositional modifications are made to affect the microstructure, improve castability of single-crystal and directionally solidified components, enhance various mechanical properties, and decrease susceptibility to environmental attack. These compositional modifications can be quite complex: The dichotomy between an elegant, simple microstructure and a rather complex composition is quite striking.

Although nickel-base superalloys are strengthened by both precipitates and solute atoms, an extensive treatment of these strengthening mechanisms is beyond the scope of this article. Instead, they will be discussed only as they pertain to fracture, fatigue, and creep. Precipitation hardening of nickel-base superalloys has been exhaustively studied and has an elegant fundamental basis. For more detailed information on strengthening mechanisms in nickel-base superalloys, consult Ref 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, and 19.

## Phases

The microstructure of nickel-base superalloys consists primarily of the following phases:

- AUSTENITIC MATRIX, USUALLY CALLED  $\gamma$
- COHERENT INTERMETALLIC PRECIPITATES, USUALLY CALLED  $\gamma'$
- CARBIDES
- BORIDES
- TOPOLOGICALLY CLOSE-PACKED (TCP) PHASES

Early superalloys had volume fractions of 30 to 40%  $\gamma'$ ; more modern superalloys have volume fractions of up to 75%.

**Austenitic Matrix.** The  $\gamma$  matrix, as stated before, has an fcc crystal structure that can contain solute elements, thereby giving rise to solid-solution strengthening. Typical of solid-solution strengthening, the degree of strengthening corresponds to the difference in atomic size between the base material and the substitutional atoms. Chromium, molybdenum, and tungsten have all been observed to be strong solid-solution strengtheners, whereas others, including cobalt, iron, titanium, and aluminum, have only minor strengthening effects (Ref 20, 21). Both groups of solid-solution elements have been noted to have atomic sizes that vary from nickel by 1 to 13% (Ref 21). Finally, some of these alloying elements serve to increase the flow stress of the alloy as a whole by decreasing the stacking fault energy of the matrix, thereby reducing cross-slip of dislocations (Ref 21). Quantitative estimates of the increase in flow stress are given in Ref 22 and 23.

The  $\gamma'$  precipitates possess a nominal  $\text{Ni}_3\text{Al}$  composition and have an  $L1_2$  crystal structure, often referred to as a derivative fcc structure. The aluminum atoms assume corner positions and the nickel atoms assume the face positions, as shown in Fig. 1. As with the matrix, element substitutions do occur. In fact,  $\gamma'$  is often referred to as  $(\text{Ni},\text{Co})_3(\text{Al},\text{Ti})$  instead of  $\text{Ni}_3\text{Al}$ . The precipitates play a crucial role in strengthening nickel-base superalloys. Additionally, their unusual yield behavior imparts an unusual yield behavior to the entire alloy. (Recall that  $\text{Ni}_3\text{Al}$  has a yield strength that increases with temperature up to about 700 °C, or 1290 °F, and then decreases with increasing temperature.)

**FIG. 1 UNIT CELL FOR  $\text{Ni}_3\text{Al}$ . VARIOUS ELEMENTS SUCH AS TITANIUM MAY SUBSTITUTE EXTENSIVELY FOR THE ALUMINUM AND SIGNIFICANTLY AFFECT THE MECHANICAL PROPERTIES OF THE PRECIPITATES.**

Gamma-prime precipitates are spherical or cuboidal, depending on their size and misfit parameter,  $\delta$ . Mismatch is defined as:

$$\delta = \frac{a_p - a_m}{a} \quad (\text{EQ 1})$$

where  $a_p$  is the lattice parameter of the precipitate,  $a_m$  is the lattice parameter of the matrix, and  $\bar{a}$  is the average lattice parameter.

The shape of the precipitate is that which will reduce the free energy of the system. The two competing components of free energy are surface energy and strain energy, both of which vary with size and shape. In a general way, the surface energy varies with the square of the characteristic precipitate dimension, whereas the strain energy varies with the cube of this dimension. Thus, at small sizes, where the surface energy dominates, the surface area assumes the smallest possible value by forcing the precipitate to have a spherical geometry. As the size increases, the strain energy dominates and the precipitate assumes a shape to minimize it, even at the expense of the surface energy.

Keeping in mind that fcc structures have cubic elastic symmetry and the [001] directions are "soft," it can be seen that as the size increases, a shape in which strains occur primarily in the [001] directions will dominate since strain along these directions involves a lower energy. A cube with parallel {001} <100> systems in both the precipitates and the matrix meets these requirements. Increasing  $\gamma/\gamma'$  mismatch reduces the required precipitate size to transition to a cuboidal shape, since increasing the mismatch increases the amount of strain that must be accommodated. Of course, the precipitates can change geometry under the effect of mechanical loading provided that there is a nonzero mismatch. This effect has been manifested in the formation of  $\gamma'$  "rafts," which form perpendicular to the loading direction under creep conditions and may lead to improved creep properties (Ref 24, 25, 26, 27). It has been reported that the formation of rafts is usually, though not always, associated with negative mismatch (Ref 27, 28, 29).

**Carbides** occur both in the matrix and at the grain boundaries. Typical carbide compositions include  $M_{23}C_6$ ,  $M_6C$ , and MC. Although carbides were initially thought to be deleterious to the creep behavior of nickel-base superalloys, subsequent experience has shown them to increase the creep resistance of polycrystalline alloys by making grain-boundary sliding more difficult.

The effects that these carbides have on the mechanical behavior of the superalloys depends on their morphology and location. MC carbides have an fcc structure, usually have a coarse cubic morphology, and are distributed randomly throughout the alloy (Ref 21). When they occur in grain interiors, they are often found interdendritically (Ref 21). Common compositions include TiC, TaC, HfC, and CbC (Ref 21). Their effects on mechanical behavior are minimal; rather, their importance is related to their effects on the formation of certain microstructures.  $M_{23}C_6$  carbides, on the other hand, play a very large role in the mechanical behavior of superalloys. They have been observed to form primarily on grain boundaries in alloys with a high chromium content (Ref 21). As stated before, they are generally beneficial and increase creep resistance by preventing grain-boundary sliding. However, they can cause early rupture failures by forming cellular structures at the grain boundary. Finally,  $M_6C$  carbides serve to control grain size due to their high-temperature stability in comparison with the other carbides (Ref 21). In essence, they act as zener pinning points for grain boundaries.

Carbides serve other purposes as well, primarily for control and development of microstructure. The interested reader is directed to Ref 21 and 30, 31, 32.

Borides tend to segregate to the grain boundaries. They generally are of the type  $M_3B_6$  and are quite hard. Their hardness reduces grain-boundary tearing and thus increases the creep resistance of the alloy. Furthermore, boron tends to occupy vacancies on the grain boundaries, thereby reducing the diffusion rates and increasing the creep resistance of the alloy.

**Deleterious Phases.** In addition to the matrix,  $\gamma'$  precipitates, carbides, and borides, several additional phases occur that tend to be deleterious to the mechanical properties of the alloy. These include  $\delta$ ,  $\sigma$ ,  $\mu$ , and Laves phases. The  $\delta$  phase has a hexagonal close-packed (hcp) structure and  $Ni_3X$  composition and tends to occur at the grain boundaries. Unlike the borides, this is not a desirable phase, for it forms cellular structures at the grain boundary and thus decreases the notch stress-rupture strength. It has also been observed to precipitate intergranularly in a Widmanstätten morphology, reducing strength but not ductility (Ref 4). The  $\sigma$ ,  $\mu$ , and Laves phases all occur in platelike TCP form and generally occur at the grain boundaries (Ref 21). These phases are deleterious at both low and high temperatures. At low temperatures, their hardness and geometry lead to intergranular cracking. At higher temperatures, they reduce the solid-solution strengthening of the  $\gamma$  matrix by depleting alloying elements and also lead to intergranular fracture for the same reasons as listed for low temperatures (Ref 21, 33, 34).

## Effects of Grain Boundary and Grain Size

As expected, many of the mechanical properties of superalloys depend on grain size. Furthermore, since it is widely recognized that many failure processes initiate at grain boundaries, the importance of understanding these two parameters is quite evident.

Grain-size effects are in essence a trade-off between good creep resistance and premature failure due to grain sliding and reduced tensile strength (Ref 4). Fine grains are known to reduce creep resistance through increased grain-boundary sliding. On the other hand, excessively large grains can cause the formation of large microcracks. The relative size of the grain to the component has also been found to be important. It has been shown that rupture life and creep resistance increased with increasing component size to grain size ratio (Ref 35). Furthermore, for equivalent component size to grain size ratios, thinner sections exhibited lower rupture strengths. These effects are related to constraint; in thin sections there is little material to impede grain-boundary sliding and creep cracks open up prematurely. Grain size is typically controlled through carbides,  $\gamma'$  precipitates, and other particles that provide pinning points through a zener mechanism.

As one would expect, grain-boundary chemistry plays an important role. Small additions of zirconium and boron, which segregate to the grain boundaries presumably because of their odd size compared to the other alloying elements, have been found to dramatically increase creep properties (Ref 36, 37, 38, 39). Although the reasons for the increased life are not completely clear, it has been postulated that the zirconium and boron atoms segregate to the grain boundaries and fill vacancies, thus reducing the coefficient of diffusion and hence creep (Ref 40). Finally, the grain-boundary chemistry has been modified to allow casting of more intricate shapes through the addition of hafnium. Hafnium additions serve to form stable, randomly arranged, fine MC carbides on the grain boundaries (Ref 34). These stable carbides serve to inhibit the amount of  $M_{23}C_6/M_6C$  carbides formed on the grain boundaries. If there were no inhibition, there would be an excess of these carbides, which could interconnect and provide an easy path for cracking. Furthermore, the addition of hafnium raises the oxidation resistance of the superalloy as a whole.

## Single-Crystal and Directionally Solidified Alloys

Single-crystal (SX) and directionally solidified (DX) components were recognized quite early as a possible technique to increase the temperature creep resistance of nickel-base superalloys--primarily through the elimination of boundary-initiated cracking mechanisms. Although SX and DX alloys are designed to overcome many of the same problems, DX alloys are also affected by the presence of grain boundaries parallel to the primary loading direction. Complex part geometries and high thermal gradients produce enough loading perpendicular to the grain boundaries that grain-boundary strengthening must be addressed. Even with these complications, the dramatically lower production costs associated with DX blades has proved to be a continuing driving force behind their development. In fact, the second generation of DX alloys now outperforms their first-generation SX counterparts (Ref 41). However, the second generation of SX alloys outperforms their DX counterparts.

In general, most of the comments for polycrystalline alloys apply to SX and DX alloys. Obvious exceptions include grain-boundary effects for single crystals--although even this is not quite straightforward in engineering practice, for it is quite rare that SX components are true monocrystals. Manufacturing techniques have necessarily included compositional modifications to improve the castability of these alloys. It is important to remember that even though the microstructures of polycrystalline, DX, and SX alloys appear similar in the grain interiors, the grain-boundary effects play an important role in determining the mechanical behavior of these alloys. Attention will be focused on the SX alloys.

Single crystals, similar to individual grains within polycrystalline alloys, typically develop dendrites along  $\langle 100 \rangle$  directions. The concentration of carbides such as  $M_{23}C_6$  is much lower than their polycrystalline counterparts. This is because there is no requirement for grain-boundary hardening, and carbide formers can be kept at a low level. Therefore, the carbon content is generally kept below 50 ppm.

**Casting Defects and Compositional Modifications.** The principal defects found in SX and DX alloys include spurious grain boundaries, equiaxed grains, "freckles," low-angle boundaries, subgrains, splaying, recrystallized grains, and porosity (Ref 42). Compositional additions are used to control these defects and, with one important exception, are very similar for SX and DX alloys.

**Freckles** consist of small chains of equiaxed grains oriented parallel to the  $\langle 001 \rangle$  solidification direction (Ref 43). They have been attributed to convective instabilities associated with compositional segregation during the solidification process. A good correlation has been established between increased tendency to freckle and high levels of rhenium and tungsten and low levels of tantalum. As rhenium is a desirable compositional addition due to its strengthening effect, many of the SX alloys have elevated tantalum compositions (Ref 44) in an effort to counterbalance the effect of high

levels of rhenium. Other elements do not significantly affect freckling (Ref 43). Freckle formation has also been shown to be a function of dendrite arm spacing, which in turn is a function of the cooling rate. Increasing the cooling rate to a critical level has also been shown to suppress freckle formation (Ref 16).

**Spurious grain growth** affects both SX and DX superalloys. Simply put, spurious grain growth occurs when a grain grows in a completely arbitrary direction as a result of constitutional super-cooling and/or nucleating agents in the melt ahead of the liquid/solid interface. Usually, these grains are not equiaxed but rather are long and slender, having aspect ratios of up to 3:1 (Ref 43). As with the case of freckles, compositional modifications (e.g., increased tantalum levels) and appropriate heat treatments (e.g., increased cooling rates) can reduce or eliminate these defects.

**Composition Modifications for Improved Performance.** Not all compositional modifications are made in order to address castability issues. Several elements have been shown to be very effective in increasing the high-temperature performance of SX and DX nickel-base superalloys. One compositional modification that has been associated with the transition from first- to second-generation SX alloys has been the addition of rhenium. This element acts as a solid-solution strengthener by partitioning to the  $\gamma$  matrix and increasing the  $\gamma/\gamma'$  misfit (Ref 45). Furthermore, small rhenium clusters form and act as additional barriers to dislocation movement (Ref 46).

Tables 1 and 2 show the compositions of first- and second-generation SX alloys, respectively. Comparable alloys from Canon-Muskegon and Pratt & Whitney show this rhenium addition quite clearly, as evidenced by the CMSX-2 to CMSX-4 and PWA 1480 to PWA 1484 developments. A third generation of SX alloys is continuing this trend; for example, CMSX-10 has 6 wt% Re (Ref 47). In fact, rhenium has been such a success as a solid-solution strengthener that its use is spreading to polycrystalline nickel-base superalloys. Unfortunately, rhenium tends to promote freckling and usually requires increased levels of tantalum to counteract this tendency.

## Fatigue and Fracture of Nickel-Base Superalloys

Bruce F. Antolovich, Metallurgical Research Consultants, Inc.

---

## Fatigue Crack Propagation

Fatigue crack propagation (FCP) in nickel-base superalloys is very important. Rates of FCP depend on a variety of intrinsic and extrinsic parameters. Intrinsic parameters include the physical metallurgy, mechanical metallurgy, and microstructure of the alloy (as well as others), and extrinsic parameters include factors such as temperature, environment, and loading histories. Considering the number of variables, development of an all-inclusive model to predict rates of FCP has proved to be impossible; instead, empirical or phenomenological approaches are typically used for quantitative rate predictions. Such predictive models usually are based on fracture mechanics. In addition to quantitative FCP rate modeling, the qualitative effects of intrinsic and extrinsic parameters have been the subject of much research. Finally,

with the introduction over the last two decades of SX and DX components, the existing FCP rate models have become less useful. The fracture behavior of SX and DX components does not correspond to the traditional fracture mechanics basis of many of these models.

## Effects of Microstructure

The effects of microstructure on FCP of nickel-base superalloys have been studied and reported on extensively. Usually, papers with experimental data present the results of a study on the behavior of a single nickel-base superalloy for which the effects of microstructural variables such as  $\gamma'$  size and morphology and grain size are examined. The experiments are conducted under certain external conditions, such as temperature, environment, waveform loading type, and so on. These conditions are rarely constant from paper to paper; as such, it is somewhat difficult to establish trends that can be applied to all alloys. Instead, the predictions should be viewed as a starting point.

The effects of grain size and  $\gamma'$  were studied for four different alloys: Inconel 718, Waspaloy, Astroloy, and René (Ref 48, 49, 50, 51). The results of these studies universally showed a high dependence of FCP rate on grain size and a possible dependence on  $\gamma'$  size. Increasing the grain size and decreasing the  $\gamma'$  size were observed to decrease the FCP rate. This dependence on grain size has been reported in several other studies (Ref 48, 49, 50, 52, 53). Additionally, it has been reported that FCP rates increase with increasing strength (Ref 53).

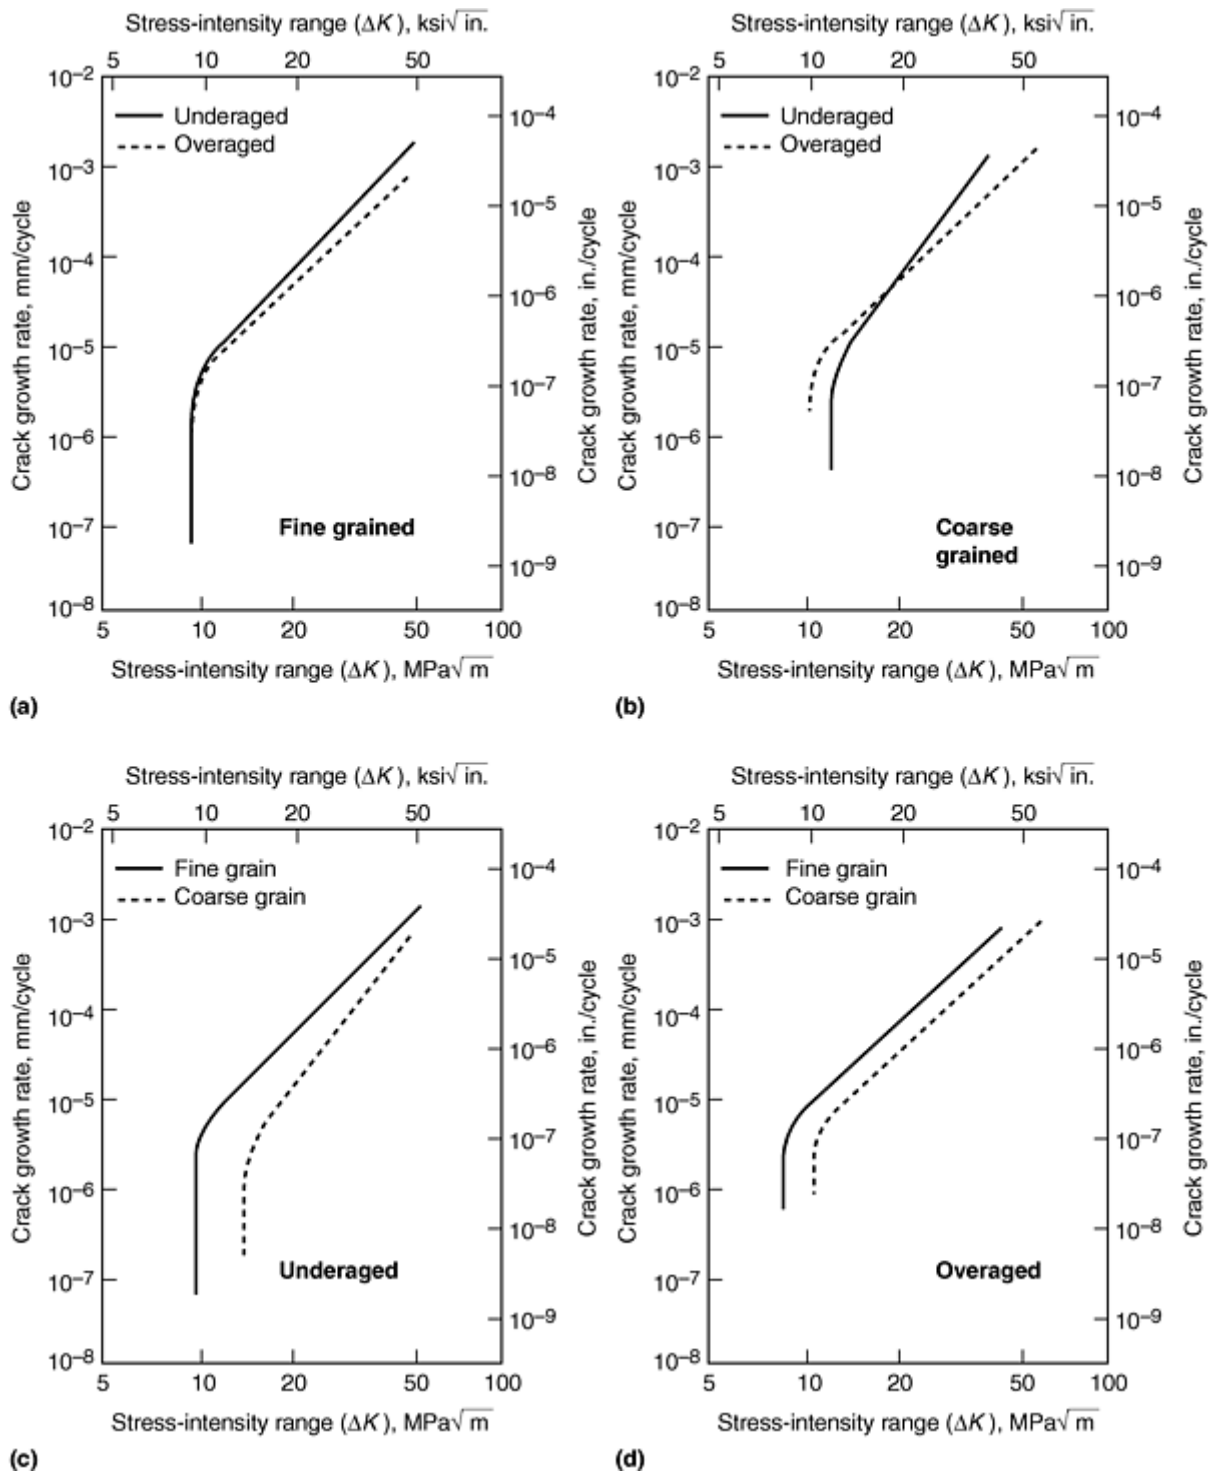

Results from a study on Waspaloy (Ref 50) examined the effects of grain size and  $\gamma'$  size. Heat treatments were used to provide specimens with grain sizes of either ASTM 3 or 9 with  $\gamma'$  sizes of either 8 or 90 nm. Regardless of  $\gamma'$  size, coarse-grain specimens always had lower propagation rates than fine-grain specimens. Specimens with equivalent grain sizes showed lower FCP rates for small  $\gamma'$  rather than large  $\gamma'$ . These results are shown in Fig. 2. Studies taken from both low-cycle fatigue (LCF) and FCP studies were used to examine the deformation mechanisms. The large-grain/small-precipitate specimens were found to exhibit particle shearing by the dislocations, whereas the small-grain/large-precipitate specimens deformed by looping. The intermediate rates were found to depend slightly on the degree of deformation inhomogeneity; lower rates of FCP corresponded to greater degrees of inhomogeneity.

**FIG. 2 DEPENDENCE OF FCP RATE ON  $\gamma'$  SIZE AND GRAIN SIZE IN WASPALOY TESTED AT ROOM TEMPERATURE. SOURCE: REF 50**

In a study of Inconel 718, the effects of  $\gamma''$  size and grain size were likewise examined (Ref 51). Grain sizes of 250 and 25  $\mu\text{m}$  were examined, with precipitate sizes of 150 and 20 nm diam disks. Rates of FCP were found to exhibit the same dependence on grain size as in the previously cited study. The FCP dependence on  $\gamma''$  precipitate size, however, was not the same. For the fine-grain specimens, larger precipitates were observed to have lower FCP rates than small precipitates. Coarse-grain specimens exhibited two regimes: one in which specimens with small precipitates exhibited lower FCP rates and another in which they exhibited higher FCP rates (Fig. 3). These results, when viewed only in terms of precipitate size effect, seem to contradict the results of the previous study. Investigation of the deformation mechanisms suggested that shearing was operative regardless of precipitate size. Furthermore, deformation in the specimens with large precipitates was found to exhibit faulting, with correspondingly more inhomogeneous slip than specimens with small precipitates. When viewed in terms of deformation inhomogeneity, the Inconel 718 results appear to be in accordance with the previously cited Waspaloy results.

**FIG. 3 EFFECT OF PRECIPITATE AND GRAIN SIZE ON FCP RATES IN INCONEL 718 TESTED IN AIR AT 425 °C (800 °F),  $R = 0.05$ , 0.33 HZ. (A) FINE GRAIN; UNDERAGED VERSUS OVERAGED. (B) COARSE GRAIN; UNDERAGED VERSUS OVERAGED. (C) UNDERAGED; FINE GRAIN VERSUS COARSE GRAIN. (D) OVERAGED; FINE GRAIN VERSUS COARSE GRAIN. SOURCE: REF 51**

Another study examined the effects of microstructural variables such as antiphase boundary (APB) energy, volume fraction of  $\gamma'$  precipitates, and  $\gamma/\gamma'$  mismatch using model alloys of varying composition and heat treatments (Ref 54). The results, when viewed solely in terms of slip planarity and reversibility, show that increases in both factors have the effect of reducing the rate of FCP (Ref 55). Other published works are in agreement with these conclusions (Ref 56).

A possible explanation for the correlation between increased slip planarity and lowered FCP rates may be based on surface roughness effects (Ref 57). Although the effects and mechanisms of roughness have been extensively

investigated, essentially surface roughness lowers the effective value of  $\Delta K$  by contact of the opposing fracture surfaces prior to the complete release of load. If an alloy exhibits high slip planarity, the fracture surfaces usually will take on a faceted appearance, where the facets occur on the octahedral planes of individual grains. Although each facet will present a smooth face, the unoriented polycrystalline nature of the material ensures that these facets will have different orientations, thus creating surface roughness.

Figure 4 shows the surface roughness of René 95 specimens with differing grain sizes. The surface area of this crack can be considerably larger than a projected surface area that would correspond to a "smoother" crack surface, as shown in Fig. 5. Thus, crack growth rates, which are usually measured macroscopically and correspond to projected crack lengths, may in fact be higher than indicated. It has also been proposed that the local stress-intensity factor is lower due to the "slant" nature of the local crack, resulting in lower propagation rates. Such an effect would be expected to be secondary in nature, for numerical results show that small cracks that deviate from the expected path normal to the load by up to  $30^\circ$  have a stress-intensity factor virtually identical to cracks normal to the loading direction (Ref 58). Nonetheless, the effects of surface roughness on lowering FCP rates are well documented.

FIG. 4 FRACTURE SURFACES OF RENÉ 95 TESTED AT  $540^\circ\text{C}$  ( $1000^\circ\text{F}$ ) AND  $0.34\text{ Hz}$ . (A) MATERIAL HAD COARSE GRAIN SIZE, FINE  $\gamma'$  PRECIPITATES ( $\sim 0.1\ \mu\text{m}$ ), AND A CRYSTALLINE APPEARANCE. (B) MATERIAL HAD FINE GRAIN SIZE AND CONTAINED LARGE  $\gamma'$  PRECIPITATES ( $\sim 0.3\ \mu\text{m}$ ), AND THE FRACTURE SURFACE WAS FLATTER THAN THAT IN (A). BOTH MICROGRAPHS CORRESPOND TO  $\Delta K$  OF  $65\ \text{MPa}\sqrt{\text{m}}$  ( $60\ \text{KSI}\sqrt{\text{in}}$ ). SOURCE: REF 111

FIG. 5 VARIOUS MEASURES OF CRACK LENGTH ILLUSTRATING THE DIFFERENCE BETWEEN PROJECTED AND

**SURFACE MEASUREMENTS.** NOTE THAT THE PROJECTED LENGTHS ARE ALWAYS LESS THAN THE TOTAL LENGTH AS MEASURED BY THE "PERIMETER." ASSUMING CONCURRENCY OF LOADING DIRECTION AND DIRECTION 1, PROJECTED CRACK LENGTH 1 WOULD CORRESPOND TO THAT MEASURED USING A TRADITIONAL MEASURING TECHNIQUE, SUCH AS TRAVELING MICROSCOPE OR ELECTROPOTENTIAL DROP. IT ALSO CORRESPONDS TO CRACK LENGTHS OF "SMOOTH" CRACKS.

Although the effects of intrinsic parameters on FCP rates can be easily seen, the complexity of the interrelationships between various intrinsic parameters prevents a single conclusion based on independent parameters such as  $\gamma'$  size and morphology or grain size. Rather, the microstructure and physical metallurgy must be controlled to produce a desired effect--namely, the promotion of planar slip through methods such as lowered APB and/or  $\gamma/\gamma'$  mismatch or large grains and small  $\gamma'$  precipitates.

## Effects of Extrinsic Parameters

Some common parameters that are considered to be extrinsic in nature include temperature, frequency, environment, specimen geometry,  $K_{max}$ ,  $K_{min}$ ,  $\Delta K$ ,  $R$  ratio, and overload ratio (Ref 59). The effects of extrinsic parameters are very difficult to address individually; they all, to one extent or another, affect one another. In addition to the normal extrinsic parameters relating to loading, the environmental parameters are particularly important for nickel-base superalloys, which are almost invariably used in an extremely high-temperature, corrosive environment.

**Temperature/Environment Interactions.** The importance of environmental effects has been discussed and researched extensively (Ref 60). A study of René 95 compared the LCF rates of specimens with subsurface cracks with those of specimens containing surface cracks. Presumably the specimens with subsurface cracks would be "shielded" from the effects of environment. As expected, the lives of the specimens with surface cracks were much shorter than those with subsurface cracks.

These findings were extended by a study of environmental effects on FCP (Ref 61). For a given value of  $\Delta K$ ,  $da/dN$  was found to be heavily dependent, although not monotonically, on temperature (Fig. 6). However, in the region most applicable to turbine engines (i.e., at temperatures above 500 °C, or 930 °F), increasing temperature was observed to increase the rate of crack propagation. For an assumed thermally activated singular environmental interaction, an Arrhenius-type equation is expected to describe the effects of temperature on FCP rate:

$$\frac{da}{dN} = A \exp \left\{ \frac{-Q(\Delta K)}{RT} \right\} \quad (\text{EQ 2})$$

where  $A$  is a constant and  $Q(\Delta K)$  is the apparent activation energy. As implied, the apparent activation energy is a function of  $\Delta K$ . Possible explanations include a dilatation of the lattice due to the imposed strains ahead of the crack tip (Ref 62). This dilatation would be expected to be linear with the strains and hence with  $(\Delta K)^2$ . The apparent activation energy would then be expected to decrease linearly with  $(\Delta K)^2$ . Such behavior has been noted in other materials, such as steel (Ref 63) and titanium (Ref 64). It should be strongly emphasized that this Arrhenius-type equation only describes thermally activated mechanisms. For example, temperature-dependent crack-tip oxide cracking would not be modeled well by the Arrhenius equation over all temperature ranges.

FIG. 6 EFFECTS OF TEMPERATURE ON FCP RATES OF RENÉ 95 FOR CONSTANT  $\Delta K$ . SOURCE: REF 61

Not all temperature-dependent increases in FCP rates can be modeled with Arrhenius-type equations. Rather, environmental effects can change the cracking mechanisms. For example, fracture surfaces may undergo a transition from intergranular to transgranular cracking with changes in environment, as was shown for Inconel 718 (Ref 65). Tests conducted at 650 °C (1200 °F) at a frequency of 0.1 Hz with sinusoidal loading and  $R = 0$  showed transition from transgranular to intergranular with a change from helium to oxygen and sulfur-bearing environments. Such results suggest a weakening of grain boundaries and consequent formation of preferential crack paths along the boundaries. Fatigue crack propagation rates increased dramatically under the presence of the hostile oxygen and sulfur-bearing environments. Interestingly, unstressed prior exposure to the hostile environments did produce significant surface attack, thus precluding exposure tests as an indicator of potential environmental effects.

Environmental effects do not always lead to higher FCP rates (Ref 4). One frequently observed environmental effect is oxide formation on the crack surface and at the crack tip accompanied by lower FCP rates. Reduction of FCP rate for the case of oxidation products forming at the crack tip has been reported to be caused by the prevention of crack resharping during unloading (Ref 66). Alternatively, it has been proposed that microcreep at the crack tip is responsible for crack-tip blunting with consequent reduction in stress intensification (Ref 4). Such an explanation would obviously introduce a hold time and/or frequency effect as well.

Without crack-tip resharping, the stress intensification is reduced along with FCP rates. Such an explanation would predict decreasing FCP rates with increasing temperatures and/or tensile hold times/lower frequencies. Experimental studies of René 95 revealed these trends (Ref 67). However, there is a clear changeover point on a  $da/dN$  versus  $\Delta K$  curve. Above a certain  $\Delta K$  level, the FCP rates show a discontinuous increase--possibly associated with the onset of crack-tip oxide cracking. As previously mentioned, oxides have also been observed to form as asperities on the fracture surface. These oxides then may contribute to surface-roughness-induced closure, thus reducing the effective  $\Delta K$  levels and consequent crack growth rates.

The previous examples show several modes of affecting FCP rates. One type of mode is purely extrinsic, such as directly controlling  $\Delta K$ . In another, extrinsic parameters such as environment indirectly affect other extrinsic parameters such as oxide-induced closure (as opposed to the purely intrinsic parameter of grain-size effects on surface roughness and consequent closure). Finally, some extrinsic parameters affect intrinsic parameters such as cracking mechanisms. Often there are competing effects. For example, a study on the effect of temperature and environment on FCP rates in model nickel-base superalloys showed that although the intrinsic fatigue resistance as measured by FCP rates was up to 30 times greater in high vacuum than in air, the rates in vacuum were not 30 times lower due to an absence of oxide-induced closure effects (Ref 70). (As an aside, this study pointed out that as FCP rates increase, the behavior becomes more and more like that of specimens tested in vacuum, due to a lack of time for diffusion penetration at the crack tip.)

Although the effects of loading waveform and frequency have been discussed briefly, a few additional remarks are in order. First, a large effect on fatigue life is shown not only by time per cycle (Ref 71) but also by waveform (Ref 4). For example, the loading rate of a triangle waveform will be lower than that of a square waveform with the same frequency. The change in loading rate can affect the deformation mechanisms and hence the FCP rates.

Second, the retardance or acceleration of FCP rates depends strongly on temperature and frequency. Changing deformation and cracking mechanisms and formation of oxides all are temperature dependent and can accelerate or retard crack growth. Extremely high time-based crack growth rates due to high  $\Delta K$  levels or high loading frequencies tend to "shield" a material from environmental effects.

Third, the loading waveform has a significant effect on FCP lives. Introduction of a dwell time through a trapezoid or square waveform can have differing effects, depending on material properties, length of dwell, and load ratio. The effects of compressive dwell, as shown in Fig. 7, seem to be largest for fine-grain superalloys (Ref 69). It also should be noted that dwell effects cannot be explained entirely in terms of creep or microcreep. Compressive dwell (negative  $R$  ratio) has been found to be particularly damaging (Ref 69, 70, 71, 72).

**FIG. 7 EFFECT OF DWELL TIME ON FATIGUE LIFE OF POWDER METALLURGY INCONEL 100 TESTED AT 650 °C (1200 °F). TESTS WITH NO DWELL WERE CONDUCTED AT 0.33 HZ. SOURCE: REF 69**

Unfortunately, the complexity of environmental interactions makes it difficult to predict quantitatively their effects on FCP rates. In fact, the large number of competing mechanisms even makes it difficult to predict qualitatively the effects on FCP rates. Experimental results can help the engineer understand which competing mechanisms are operating and eventually which will dominate. However, even with this understanding, it is quite difficult, even under laboratory conditions, to quantitatively predict FCP rates for untested environment/temperature combinations. For the present, in order to accurately predict FCP rates, tests generally must be run under conditions that are as close as possible to those met in service by the part. Regardless of the difficulty of quantitative prediction, understanding the mechanisms of crack advance are very useful in making incremental design changes for new alloys.

## Modeling FCP Rates

Most, though not all, of the modeling of FCP rates in nickel-base superalloys used for life prediction has been empirical in nature and frequently based on fracture mechanics arguments and parameters. As such, results are usually valid only for a single temperature/environment/loading combination. For example, one empirical model is given by (Ref 73):

$$\log \left( \frac{da}{dN} \right) = C_1 \sinh (C_2 \log \Delta K + C_3) + C_4 \quad (\text{EQ 3})$$

where  $C_1$ ,  $C_2$ ,  $C_3$ , and  $C_4$  are empirical constants that are condition specific; and  $\Delta K$  is the stress-intensity range ( $K_{\max} - K_{\min}$ ). Aside from the obvious dependence on the temperature/environment combination, the empirical constants  $C_1$  to  $C_4$  are also heavily dependent on  $R$ , loading frequency, and loading waveform. While it is easy to determine the values of  $C_1$  to  $C_4$  through experimentation and regression analysis, a significant amount of testing must be done to cover appropriate temperature/environment/loading combinations. (This form of equation also suggests symmetry about an inflection point-behavior which has not been observed experimentally or justified physically.) An alternative that also allows the direct introduction of  $R$ -ratio effects is given by (Ref 74):

$$\frac{1}{\left( \frac{da}{dN} \right)} = \frac{A_1}{(\Delta K)^{n_1}} + \frac{A_2}{(\Delta K)^{n_2}} + \frac{A_2}{[K_c (1 - R)]^{n_2}} \quad (\text{EQ 4})$$

where  $A_1$  and  $A_2$  are functions of the load ratio,  $R$ . Again, a fair amount of experimental work must be carried out in order to develop the constants. Another possible model incorporates not only the load ratio but also the fracture toughness of the material (Ref 75):

$$\frac{da}{dN} = \frac{C \Delta K^n}{[(2 - R) K_{Ic} - \Delta K]} \quad (\text{EQ 5})$$

where  $K_{Ic}$  is the fracture toughness of the material. Finally, one of the most widely used and recognized models is the classic Paris law equation (Ref 76):

$$\frac{da}{dN} = C (\Delta K)^n \quad (\text{EQ 6})$$

For superalloys at room temperature in intermediate crack growth, a correlation exists between the FCP rate and Young's modulus of the alloy and can be incorporated into the Paris law (Ref 77):

$$\frac{da}{dN} = 1.7 \times 10^6 \left( \frac{\Delta K}{E} \right)^{35} \text{ m/cycle} \quad (\text{EQ 7})$$

As can be seen, there are many available empirical models, ranging from the simple and effective Paris law to more complicated models. It must be noted that these equations are useful solely for life predictions but do not give insight into the mechanisms of crack propagation or techniques to improve life under FCP. A compilation of models of this class can be found in Ref 78.

A great deal of work has attempted to integrate intrinsic parameters into life prediction models. Some are based on dislocation arguments (Ref 79, 80) and are summarized in Ref 59. Other models, originating with McClintock (Ref 81), try to incorporate LCF models with FCP models based on the assumption that the cracking directly at the crack tip is essentially an LCF-type behavior in which damage occurs in a process zone (Ref 82, 83, 84, 85). A common element of these two types of models is extraordinarily complicated equation forms. For example, the dislocation-based model presented by Yokobori et al. (Ref 80) can take the form (Ref 59):

$$\frac{da}{dN} \propto \left( \frac{\Delta K}{\sigma_{cy} \sqrt{s}} \right)^{[2n' (p+1)^2 / (1+n')(p+2)] + [1/(1+n')]} \quad (\text{EQ 8})$$

where  $\sigma_{cy}$  is the initial cyclic yield stress,  $n'$  is the cyclic strain-hardening exponent,  $p$  is the exponent on the stress in the equation for dislocation velocity, and  $s$  is the characteristic distance near the crack tip over which applied shear stress is averaged.

The integrated LCF/FCP model of Antolovich et al. (Ref 82) takes on the form:

$$\frac{da}{dN} = \frac{C}{(\sigma'_{yc} \epsilon'_1 E)^{1/\beta}} \cdot \frac{1}{L^{1/(\beta-1)}} \Delta K^{2\beta} \quad (\text{EQ 9})$$

where  $\sigma'_{yc}$  is cyclic yield,  $E$  is Young's modulus,  $C$  is a constant, and  $L$  is the assumed LCF process zone size. As can be seen, there is direct integration of intrinsic material properties into each of these models, but each retains a  $\Delta K$  dependence.

## Single-Crystal Alloys

Fatigue modeling of SX nickel-base superalloys has been the subject of much research (Ref 70, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, and 102). Although numerous alloy systems and testing variables have been examined, many observations have been made that appear to be generally applicable to SX nickel-base superalloys with large volume fractions of  $\gamma'$  precipitates. These generally applicable observations apply both to macroscopic fracture surface morphologies and to the effect of changing testing variables (e.g., environment, temperature, and load ratio). However, on the microstructural level, generalization of observations does not appear to be as applicable.

**Fracture Surface Morphologies and Crack Advance Mechanism.** Fracture surfaces on most SX nickel-base superalloy specimens, regardless of temperature, environment, crystallographic orientation, or even applied state of stress, appear to have three common aspects (Ref 86, 87, 88, 90, 92, 94, 96, 97, 99, 101, 102):

- REGIONS IN WHICH THE CRACK APPEARS TO PROPAGATE ON {111} PLANES AND SHOWS NO EVIDENCE OF BEING DEFLECTED BY  $\gamma'$  PRECIPITATES. FIGURES 8 AND 9 SHOW AN EXAMPLE OF THIS CRACKING MORPHOLOGY (REF 103).
- REGIONS IN WHICH THE CRACK PROPAGATES MACROSCOPICALLY ON A PLANE NORMAL TO THE LOADING DIRECTION, WITH  $\gamma'$  PRECIPITATES AND THE RESIDUAL DENDRITIC STRUCTURE CLEARLY VISIBLE ON THE SURFACE. FIGURE 10 SHOWS AN EXAMPLE OF THIS PRECIPITATE AVOIDANCE MORPHOLOGY (REF 103).
- REGIONS IN WHICH THE CRACK GROWS MACROSCOPICALLY NORMAL TO THE LOADING DIRECTION, WITH NO CLEAR CRYSTALLOGRAPHIC PLANE OR  $\gamma'$  PRECIPITATES VISIBLE

The relative extent of these regions and their locations all change with changing variables and materials. However, all three regions appear on all specimens, with few exceptions. Figure 11 shows fracture surfaces from specimens with two different orientations that exhibit all three morphological aspects (Ref 105).

EACH SPECIMEN CLEARLY SHOWS EVIDENCE OF DENDRITIC MACROSTRUCTURE IN THE NON-CRYSTALLOGRAPHIC PORTIONS OF THE FRACTURE SURFACE. CRYSTALLOGRAPHIC FACES CORRESPOND TO {111} PLANES. VACUUM ENVIRONMENT. SOURCE: REF 103

**Crystallographic crack propagation** has been observed in both single-crystal and polycrystal nickel-base superalloys (Ref 87, 88, 90, 92, 94, 96, 97, 99, 101, 102). These regions have been referred to as "faceted" in polycrystals, as well as in single crystals where the length of cracking on a particular  $\{111\}$  plane is small. In single crystals, the crystallographic crack growth appears always to occur on  $\{111\}$  planes (i.e., no crystallographic cracking on cube planes). For those specimens tested under nominal single-mode conditions such as those created by compact-tension (CT)-type specimens, the crack transitions between intersecting  $\{111\}$  planes in such a fashion as to attempt to maintain a macroscopic crack plane normal to the loading direction (Ref 90, 101). However, depending on the loading direction relative to the crystallographic orientation, the crack may grow macroscopically on a plane that is not normal to the loading direction (Ref 94). Even so, as the crack grows farther and farther from the plane normal to the loading direction, it will transition to an intersecting  $\{111\}$  plane that returns it closer to the normal plane (Ref 94, 96, 102).

**Noncrystallographic Crack Propagation.** Two types of noncrystallographic crack propagation are typically observed: one in which the  $\gamma'$  precipitates are clearly visible on the fracture surface and another in which they are not (Ref 90, 96). Gamma-prime precipitates do not appear on the fracture surface near catastrophic failure where a finite amount of crack growth appears with each cycle. Since this region is of limited interest, it will not be discussed further. When the fracture surface does contain  $\gamma'$  precipitates, the relative amount of this noncrystallographic crack growth appears to be affected by crystallographic orientation, temperature, environment, and applied  $\Delta K$ . The effect of these parameters on the promotion of noncrystallographic crack growth is inverse to that for crystallographic crack growth. This is to be expected, because the fracture surface is composed only of noncrystallographic regions and crystallographic regions.

**Influence of External Variables on Crack Growth Morphologies.** The extent of crystallographic crack growth appears to be influenced by temperature, environment, crystallographic orientation, and applied  $\Delta K_I$ . The effects of changing crystallographic direction do not lend themselves to generalization. Increasing the temperature generally decreases the amount of crystallographic crack growth, regardless of environment. There is not widespread agreement on the mechanisms responsible for this behavior.

The effects of environment can be shown most clearly by comparing the results of tests in laboratory air and in vacuum, where other testing conditions are held constant. At lower temperatures, the effect of changing the environment appears to be inconsequential to the amount of crystallographic crack growth. At elevated temperatures, specimens tested in vacuum have more crystallographic crack growth than those tested in air. Those tested in air sometimes exhibit no observable crystallographic crack growth. It has been proposed that the reduction of crystallographic crack growth is tied to diffusion of oxygen (Ref 99). Although single crystals have no grain boundaries for oxygen diffusion, the residual dendritic structure has been proposed as a diffusion path for oxygen (Ref 97). According to this proposal, the diffusion paths are weakened by the oxidation, resulting in a preferred path for crack propagation. The diffusion arguments are particularly compelling--explaining both the environmental effects and the temperature effects. A transition from noncrystallographic to crystallographic and back to noncrystallographic crack growth has been reported when going from low to high  $\Delta K$  values. The physical basis for this correlation has not been established. Furthermore, the applicability of  $\Delta K$  for this class of material is uncertain. Nonetheless, it has been widely reported that crystallographic cracking occurs only at intermediate values of  $\Delta K_I$ .

The fact that crystallographic cracking occurs on  $\{111\}$  planes suggests that cracking is intimately tied to glissile dislocation movement on slip planes. This has led to predictive models for planes of crack propagation based on stress fields affecting dislocation movement. One proposed model suggests that dislocation movement on  $\{111\}$  planes damages these planes, thereby weakening them (Ref 90). A normal stress to these planes can then break them apart, advancing the crack. A parameter based on the product of the shear stress resolved in the direction of the Burgers vector and the normal stress to the plane containing the Burgers vector has been proposed as a crack driving force (Ref 90). The slip system that maximizes this parameter will dictate the plane on which crack propagation will occur. This proposed model provides a rational mechanism for the observed non-self-similar crack growth.

**Fatigue Crack Growth Rate Modeling.** Although many researchers have investigated fatigue behavior in single crystals or in materials with a very large grain size, only a few have proposed new models or modified existing models (Ref 90, 92, 94, 96, 97, 102). These models are based on either micromechanics or macroscale observations. The former approach is usually dislocation based, whereas the latter is usually based on global quantities such as energy release rate. Two factors that further complicate modeling efforts include the elastic anisotropy of the material and the non-self-similar crack growth. An example of the elastic anisotropy of PWA 1480 is shown in Fig. 12.

FIG. 12 ELASTIC MODULUS OF PWA 1480 AT ROOM TEMPERATURE. SOURCE: REF 42

A significant body of experimental evidence suggests that fatigue crack growth in both SX and polycrystalline materials is intimately tied to dislocation emission from the crack tip (Ref 104, 105, 106). Three models have been proposed in which this association with crack advance is the basis for proposed correlating factors for crack growth rates (Ref 90, 96, 102). A common element of all three approaches is the utilization of the resolved shear stress in the direction of the Burgers vector,  $\tau_{rss}$ . The resolved shear stress depends on all elements of the stress tensor, which in turn depends on all three modes of stress-intensity factor (Ref 107):

$$\sigma_{ij} = \frac{K_i}{\sqrt{2\pi r}} f_{ij}(\theta, \mu) \quad (\text{EQ 10})$$

$i = \text{Ia, IIa, or IIIa (anisotropic modes)}$

Note that the anisotropic forms of the field equations are necessary due to the anisotropy of single crystals that exhibit cubic symmetry. The values of  $\mu$  are developed from the characteristic equation:

$$C_{11}\mu^4 - 2C_{16}\mu^3 + (2C_{12} + C_{66})\mu^2 - 2C_{16}\mu + C_{22} = \quad (\text{EQ 11})$$

where  $C_{ij}$  are the elements of the elastic stiffness matrix.

One correlating factor for crack growth rates based on the shear stress resolved in the direction of the Burgers vector is the resolved shear stress-intensity coefficient (RSSIC) (Ref 102), which is defined as:

$$\tau_{rss} = \frac{\text{RSSIC}}{\sqrt{2\pi r}} \quad (\text{EQ 12})$$

Equation 12 implies a number of different values of RSSIC--one for each slip system. This implies that specific values of  $\theta$  must be used when calculating the stress tensor. This equation can be combined with the full set of anisotropic field equations for a more direct definition of RSSIC:

$$\text{RSSIC} = [\mathbf{B}_i] [\mathbf{C}_{ij}] \quad (\text{EQ 13})$$

$$[K'_{IA}, K'_{IIA}, K'_{IIIA}F(\theta_S)] [C_{I'J'}]^T [N_{J'}]$$

where double primes indicate material principal axes, single primes indicate specimen principal axes,  $C_{i'j'}$  is the matrix of direction cosines,  $\mathbf{b}_i$  is the Burgers vector, and  $\mathbf{n}_j$  is the unit vector normal to the slip plane.

It must be reiterated that this definition of RSSIC is valid only for a particular slip system, leading up to 12 independent values of RSSIC for materials with fcc crystal structures. The choice of which RSSIC value to use as a correlating variable adds subjectivity and limits the usefulness of this approach. Furthermore, the fracture mechanics basis of this approach is two dimensional. As will be shown later, this is a rather significant limitation.

Other researchers have extended the RSSIC-based models (Ref 98). A slightly more rigorous definition of the resolved shear stress-intensity parameter is given by:

$$K_{rss} = \lim_{r \rightarrow \infty} \tau_{rss} \sqrt{2\pi r} \quad (\text{EQ 14})$$

In a direct comparison of crack growth rates for a single specimen using  $\Delta K_{rss}$  and  $\Delta K_I$  as correlating functions, no apparent benefit is seen. The curves for each correlating parameter follow each other except for a fixed offset on the  $\Delta K$  axis. Additionally,  $\Delta K_I$  was naturally shown to depend on whether a state of plane stress or plane strain was assumed. Holding all other conditions constant, the value of  $\Delta K_I$  was shown to be approximately twice as high under conditions of plane stress than under plane strain. Although  $\Delta K_I$  was not evaluated critically as to its applicability for use with single crystals, the investigators did show that it was an effective aid in qualitatively understanding crack growth mechanisms, as will be discussed later.

Several researchers have used crack growth models that are based on energy arguments (Ref 92, 94, 98). Although the maximum energy dissipation rate criterion has been used for predicting which crack planes will be subject to cracking, this function has not been used extensively as a correlating parameter for predicting rates of crack growth (Ref 98). Nonetheless, this type of criterion does show some promise.

A different approach that has been used more extensively is a modification of the  $\Delta K_{eff}$  concept (Ref 92, 94). The term  $\Delta K_{eff}$  is defined following the definitions of total energy release rate (Ref 107):

$$\Delta K_{eff} = \left( \frac{G}{C_I} \right)^{1/2} = \left[ \Delta K_I^2 + \frac{C_2}{C_1} \Delta K_{II}^2 + \frac{C_3}{C_1} \Delta K_{III}^2 \right] \quad (\text{EQ 15})$$

Using this definition of  $\Delta K_{eff}$  as a correlating function, crack growth rates for various orientations from various types of specimens appear to initially correlate well. Testing under multiaxial conditions shows that changing the loading path in stress space results in poor correlation between  $da/dN$  and  $\Delta K_{eff}$ . Critical examination of the theoretical basis and the practical implementation of this model reveals the sources of some of these deficiencies. The theoretical basis of this model is the linear addition of energy release rates associated with each loading mode. This total energy release rate is then normalized by one of the constants in the characteristic equation (Eq 11). Although the addition of the scalar quantity of energy release rate is clearly on sound mathematical ground, its use as a correlating function makes several material behavior assumptions that are subject to debate. The essential assumption is that each mode of loading is equally damaging to the material (i.e., that equivalent energy release rates, regardless of which mode generates them, would result in equivalent crack growth rates). The physical basis of this assumption is not obvious. Furthermore, the difficulty in accommodating different loading paths in stress space suggests that it is probably incorrect.

Examination of the experimental technique for finding the stress-intensity factors for each mode also reveals possible shortcomings. Mode I and II stress-intensity factors have been calculated using the well-characterized boundary integral equation (BIE) technique (Ref 58, 108, 109, 110). This technique has been shown to show close agreement with ASTM results for the CT-type specimen. Stress-intensity factors for mode III are estimated based on an assumed crack geometry. The assumed crack is self-similar and is inclined relative to the thickness of the specimen.  $K_{III}$  was calculated based on the through-thickness shear stresses. These stresses were in turn estimated by taking the state of stress calculated from the two-dimensional approach and applying boundary corrections. The assumption of self-similarity is open to discussion, as

pointed out in Ref 94. Furthermore, the non-self-similarity of the crack raises questions as to the applicability of the applied boundary corrections.

## Fatigue and Fracture of Nickel-Base Superalloys

Bruce F. Antolovich, Metallurgical Research Consultants, Inc.

---

### Creep

As previously stated, the relatively constant rotational velocities of turbines, in conjunction with their high operating temperatures, produce creep loading. Fortunately, nickel-base superalloys possess quite good creep resistance and creep rupture strengths. Creep crack growth (CCG) must be considered since it can lead to a catastrophic failure while creep elongation is also quite important from a design point of view due to the tight dimensional tolerances typically found in turbine engines. A full treatment of both subjects is beyond the scope of this article, instead, attention will be focused upon creep crack growth.

### Modeling Creep and Creep-Fatigue Crack Growth Rates

Because there are superimposed fatigue cycles and creep cycles, crack growth is usually addressed as a CCG problem. Experimental work usually consists of square wave loading (with low or very low frequencies) or triangle wave loading. In order to facilitate the analysis of overall crack growth rates, much effort has been expended to partition the total crack growth rates into fatigue and creep components. Because of the extensive database of FCP rates in which  $\Delta K$  is treated as an independent variable for correlation of FCP rates in terms of crack extension per cycle ( $da/dN$ ), there has been an effort to cast similarly cast CCG rates in terms of  $\Delta K$ . A study of CCG rates for typical superalloys has resulted in an expression correlating  $K$  with 100 h of life prior to failure. One of the assumptions is that there exists a critical strain ahead of the crack tip that can serve as a criterion for CCG (Ref 111). The value of  $K$  required to produce failure within 100 h is given by:

$$K = (3\delta_0 \sigma_{ys}E + 0.3\sigma_{ys}E D *)^{\frac{1}{2}} \quad (\text{EQ 16})$$

where  $\delta_0$  is the initial crack-tip displacement,  $\sigma_{ys}$  is the yield strength,  $E$  is Young's modulus,  $*$  is the critical strain, and  $D$  is the grain diameter. Equation 16 captures the association between resistance to CCG and large grain size, which has been validated experimentally elsewhere (Ref 110). However, this model does not address the problem of crack growth rate ( $da/dt$ ).

Several parameters based on modifications to the  $J$ -integral exist to predict crack growth rates, including  $C^*$ ,  $C(t)$ , and  $C_t$  (see the article "Elevated-Temperature Crack Growth" in this Volume). For example,  $C^*$  is a relatively straightforward modification of the  $J$ -integral in which strain components are replaced by strain-rate components:

$$C^* = \int_{\Gamma} W_s^* dy - T_1 \left( \frac{\partial \dot{u}_1}{\partial x} \right) ds \quad (\text{EQ 17})$$

where

$$W_s^* = \int_0^{\dot{\epsilon}_{min}} \sigma_{ij} d\dot{\epsilon}_{ij}$$

and  $\Gamma$  is the path contour from the lower crack surface to the upper crack surface,  $ds$  is the incremental arc length along  $\Gamma$ ,  $\mathbf{T}_i$  is the traction vector along path  $\Gamma$ ,  $x$  and  $y$  are Cartesian coordinates with their origin at the crack tip,  $\mathbf{u}_i$  is the displacement vector,  $\sigma_{ij}$  is the stress tensor, and  $\epsilon_{ij}$  is the strain-rate tensor.

It should be noted that Eq 17 is valid only for secondary creep in which the creep strains dominate any existing elastic or plastic strains. Typical constitutive equations describing this type of creep take on a power-law expression:

$$\dot{\epsilon} = A \sigma^N \quad (\text{EQ 18})$$

where  $A$  and  $n$  are the creep coefficient and exponent, respectively.

For the case of transient creep, Saxena (Ref 112) has defined the  $C_t$  parameter:

$$C_t = -\frac{1}{B} \frac{\partial U_t^*}{\partial a} \quad (\text{EQ 19})$$

where  $B$  is specimen thickness and  $U_t^*$  is instantaneous stress power. This expression represents the instantaneous stress power dissipation rate, whereas  $C^*$  represented the steady-state rate. The expressions for  $C_t$  take on a variety of forms, depending on the material and creep regime. A good summary is provided in Ref 113.

As mentioned before, creep and fatigue combine to create creep-fatigue loading. Modeling of crack growth rates under creep-fatigue loading usually is based on a partitioning of crack growth between fatigue and creep components:

$$\frac{da}{dN} = \left( \frac{da}{dN} \right)_{\text{cycle}} + \left( \frac{da}{dN} \right)_{\text{time}} \quad (\text{EQ 20})$$

Establishment of expressions for  $(da/dN)_{\text{time}}$  based on  $C_t$  and the modified parameter,  $(C_t)_{\text{avg}}$ , have been investigated (Ref 114, 115). For small-scale creep:

$$\left( \frac{da}{dt} \right)_{\text{avg}} = \frac{1}{t_h} \left( \frac{da}{dN} \right)_{\text{hold}} \quad (\text{EQ 21A})$$

$$(C_t)_{\text{avg}} = \frac{1}{t_h} \int_0^{t_h} C_t dt \quad (\text{EQ 21B})$$

The following two expressions can then be used:

$$\frac{da}{dt} = b_2 [(C_t)_{\text{avg}}]^{p_2} \quad (\text{EQ 22A})$$

$$\left( \frac{da}{dN} \right)_{\text{time}} = b'_2 \left( K^4 t_h^{-(n-3)(n-1)} \frac{F^v}{F} \right)^{p_2} \quad (\text{EQ 22B})$$

These equations can then be used in conjunction with expressions for  $(da/dN)_{\text{cycle}}$  to model total crack growth rates (Ref 113).

## Influence of Microstructure and Physical Metallurgy

As mentioned earlier, larger grains tend to lower CCG rates as well as FCP rates. Furthermore, serrated grain boundaries, produced by slow cooling of a warm-worked alloy and associated zener pinning as  $\gamma'$  nucleates at the grain boundaries, have also been shown to lower CCG rates. Lowered creep rates due to serrated boundaries have been reported in Ref 116 and 117. Raj and Ashby (Ref 116) proposed the following model correlating boundary sliding to parameters that quantify the serrated grain boundaries:

$$\dot{U} = \frac{8 \tau_a \Omega \lambda}{\pi kT h^2} D_v \left( 1 + \frac{\pi \delta D_B}{\lambda D_v} \right) \quad (\text{EQ 23})$$

where  $\dot{U}$  is the grain-boundary sliding rate,  $\tau_a$  is applied shear stress,  $\lambda$  is the periodicity of the boundary perturbation,  $h$  is the double amplitude of boundary perturbation,  $D_B$  is the grain-boundary diffusion coefficient,  $D_v$  is the volume diffusion coefficient,  $\Omega$  is atomic volume, and  $\delta$  is the thickness of grain-boundary diffusion zone. Clearly, increased serration height decreases the rate of grain-boundary sliding and consequent creep. These general observations are corroborated by Ref 117, as shown in Fig. 13.

FIG. 13 EFFECTS OF SERRATED GRAIN BOUNDARIES UPON TIME TO FAILURE FOR IN-792 AT 704 °C (1300 °F). SOURCE: REF 117

## Single Crystal Considerations

As was the case with FCP, creep for single crystals merits closer examination of the unique effects that monocrystalline form imposes on creep behavior. In general, SX and DX components exhibit vastly superior creep properties than their polycrystalline counterparts. This is shown in Fig. 14, which compares the creep behavior of polycrystalline equiaxed Inconel 100, directionally solidified DS 200 HF, and single-crystal CMSX-2 (Ref 118). For SX alloys, crystallographic orientation also plays a major role in creep-rupture lives and creep elongation. However, these effects are highly temperature dependent, as shown in Fig. 15 and 16.

FIG. 14 STRESS-RUPTURE LIVES OF SINGLE-CRYSTAL CMSX-2, DIRECTIONALLY SOLIDIFIED DS 200 HF, AND EQUIAXED INCONEL 100 VS LARSON-MILLER PARAMETER. SOURCE: REF 25

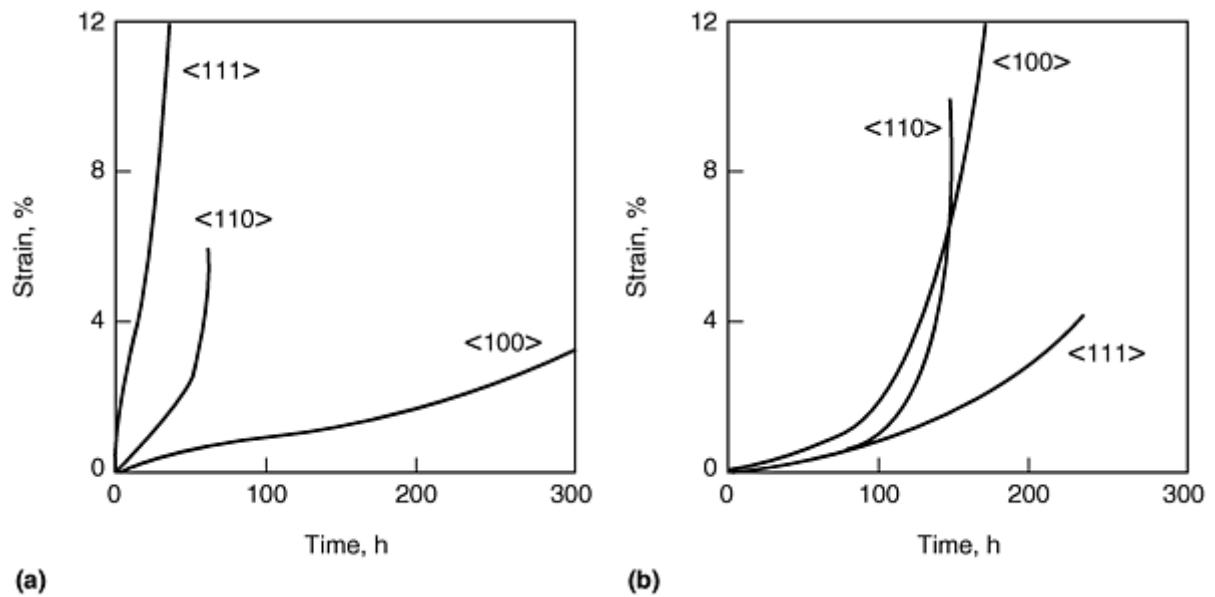

FIG. 15 STRESS-RUPTURE LIVES AS A FUNCTION OF ORIENTATION. (A) SPECIMENS TESTED AT 760 °C (1400 °F). SOURCE: REF 25. (B) SPECIMENS TESTED AT 960 °C (1760 °F). SOURCE: REF 119

**FIG. 16 CREEP ELONGATION OF PWA 1480 AS A FUNCTION OF TEMPERATURE AND ORIENTATION. (A) 760 °C (1400 °F). (B) 980 °C (1800 °F). SOURCE: REF 42**

The microstructure of SX nickel-base superalloys has been found to play a significant role in creep resistance. Gamma-prime precipitate size and geometry are particularly important. Analysis of these effects is somewhat complicated by the microstructural changes that affect the precipitates. The influence of  $\gamma'$  size is well illustrated for the case of CMSX-2, where it is varied between approximately 0.25 and 0.65  $\mu\text{m}$  through appropriate heat treatments (Ref 119). Figure 17 shows the effect of  $\gamma'$  size on creep-rupture times as well as time to reach a strain of 1% for two different temperatures. In each case,  $\gamma'$  precipitates of about 0.5  $\mu\text{m}$  seem to produce the best creep resistance.

(a)

(b)

FIG. 17 CREEP-RUPTURE TIMES AS A FUNCTION OF  $\gamma'$  SIZE FOR CMSX-2. (A) 760 °C (1400 °F); 750 MPA (110 KSI). (B) 950 °C (1740 °F); 240 MPA (35 KSI). SOURCE: REF 24

Precipitate morphology is another important factor. Two different heat treatments were used to produce irregularly shaped precipitates (combinations of spheres and cubes) or regularly shaped cuboidal precipitates. Examination of the deformation mechanisms for the two microstructures showed relatively inhomogeneous and homogeneous deformation for the irregular and regularly shaped precipitates, respectively (Fig. 18). Correspondingly, the creep-rupture behavior for the specimens with a microstructure consisting of regularly shaped  $\gamma'$  precipitates was more favorable than that of the irregularly shaped  $\gamma'$  precipitate microstructure (Fig. 19). As mentioned before, under certain conditions the  $\gamma'$  precipitates coalesce and form "rafts" (Fig. 20). These rafts form perpendicular to the loading direction and can dramatically improve the creep resistance of the alloy.

## Conclusions

The FCP and creep behavior of nickel-base superalloys are heavily interdependent upon extrinsic and intrinsic factors. Furthermore, intrinsic microstructural features such as  $\gamma'$  size and morphology, which directly affect FCP and creep performance, are subject to change under the combined effects of loading and temperature. Directionally solidified and single crystals must also include orientation dependence for FCP and creep behavior. Changes in extrinsic parameters such as temperature may be quite beneficial for one environment but detrimental for another. Considerable care must be exercised in order to take into account all extrinsic and intrinsic factors when making quantitative or qualitative FCP or CCG rate predictions. Nonetheless, with appropriate care, an engineer can make meaningful predictions of FCP or CCG behavior.

While polycrystalline superalloys remain quite useful due to lower production costs than DX and SX alloys, their performance is generally lower. The lower production costs for DX components in comparison with SX counterparts ensures their future use and development. Unfortunately, many of the life prediction models developed for polycrystalline alloys are not directly applicable to their SX and DX counterparts. Nonetheless, their superior performance for military and commercial applications ensures that their use will continue to increase. Considerable efforts are being made in the development of appropriate life prediction models and seem likely to continue.

## Fatigue Properties of Copper Alloys

Jack Crane, Consultant, John O. Ratka, Brush Wellman, and John F. Breedis, Olin Brass

---

## Introduction

COMPARED to most structural materials, relatively few applications of copper alloys involve cycling stressing. The most common use of copper alloys under dynamic loading is in rotating electrical machinery used for power generation. This application involves copper and very dilute copper alloys, which are not covered in this article. The reader is referred to Ref 1 for information on fatigue of copper.

One application of copper alloys requiring resistance to fracture after two or three highly stressed reverse bend cycles relates to the use of leadframe in insertion mounted microelectronic devices. The "leadbend fatigue" test involves repeated 90 degree bending and straightening of the leadframe leads. The test was designed to ensure that materials used for leadframes would not be susceptible to fracture if leads were straightened after inadvertent deformation during handling. This subject is covered in Ref 2 and 3, which describe the test method, list many of the alloys used for leadframes, and provide comparative leadbend fatigue data. With the increasing use of surface-mounted devices, the leadbend fatigue test and this property have become less important.

Copper alloys whose fatigue characteristics are covered in this article are used in applications involving repeated flexing: springs used for contacts and connectors, bellows, and Bourdon tubes. Alloys used for these applications include the

brasses, bronzes (tin-, silicon-, aluminum-, and combinations thereof), and beryllium coppers. Copper-nickel-tin spinodally hardened alloys are also used in connectors and contacts. Flexural fatigue properties of all these classes of alloys in strip form are presented in this article. Heavier copper alloy sections subjected to cyclic loading are largely confined to the beryllium coppers for applications such as aircraft landing gear bushings, races and rollers for rolling-element bearings, and oil and gas downhole hardware such as antigalling thread-saver subs and instrument housings. Rotating-beam fatigue results are reported for beryllium copper alloy C17200.

The alloy designations and compositions of alloys covered in this article are given in Table 1. Copper alloys are classified by the International Unified Numbering System (UNS) designations, which identify alloy groups by major alloying element.

**TABLE 1 ALLOY DESIGNATIONS AND COMPOSITIONS**

<b>UNS DESIGNATION</b>	<b>NOMINAL COMPOSITION, %</b>
C17200	<b>1.9 BE, 0.25 CO</b>
C17410	<b>0.3 BE, 0.4 CO</b>
C17510	<b>0.4 BE, 1.8 NI</b>
C26000	<b>30 ZN</b>

C65400	<b>3.1 SI, 1.6 SN, 0.05 CR</b>
C68800	<b>23 ZN, 3.4 AL, 0.4 CO</b>
C72050	<b>3.2 NI, 0.75 SI, 0.2 MG</b>
C72900	<b>15 NI, 8 SN</b>
<b>C76200</b>	<b>29 ZN, 12 NI, 0.5 MN</b>

The brasses, nickel silvers, and bronzes covered in this article are strengthened by cold work, the exception being C70250, the copper-nickel-silicon-magnesium alloy, which is strengthened by combinations of cold work and precipitation hardening. The beryllium coppers are strengthened by cold work and/or precipitation hardening. The spinodally strengthened copper-nickel-tin alloy is cold worked and aged. The temper designations used for the materials tested are listed in Table 2. These designations are used throughout the text and figures. Because of their ability to be precipitation hardened, C70250 and beryllium copper alloys can be tailored across a wide range of strength and conductivity combinations.

### Alloy Metallurgy and General Mechanical Properties

**Brasses.** Both the standard cartridge brass (C26000, 70Cu-30Zn) and the higher-strength aluminum brass (C68800) offer excellent combinations of strength and formability and are widely used as spring materials. The microstructure of C26000 is an all- $\alpha$  solid solution. In addition to a copper-zinc-aluminum solid solution, C68800 contains a second-phase cobalt aluminide that acts as a grain refiner.

**Nickel-Silvers.** The copper-nickel-zinc alloy C76200 is a nickel-modified brass. The nickel modification offers improved strength over conventional brasses. This family of alloys is used in springs of all types.

**Bronzes.** Tin bronze (C51000) is one of the most widely used alloys for springs that require strength higher than standard brass. It is also used for bellows and Bourdon tubes. It is essentially a single-phase alloy.

The silicon-aluminum-bronze alloy (C63800) and the silicon-tin-bronze alloy (C65400) both are used in a broad range of electronic and electrical springs. The microstructure is a single-phase solid solution, with a coarse second-phase particulate (cobalt silicide in the case of C63800).

The nickel-silicon alloy C70250 has wide application in electrical and electronic springs. It combines moderately high conductivity and formability with high strength. The alloy microstructure consists of an  $\alpha$  solid solution and a second-phase nickel silicide that provides precipitation hardening.

**Beryllium Coppers.** Commercial wrought beryllium copper alloys contain from 0.2 to 2.0 wt% Be and 0.2 to 2.7 wt% Co (or up to 2.2 wt% Ni), with the balance primarily copper. Within this compositional band, two distinct classes of commercial materials have been developed: high-strength alloys and moderate-conductivity alloys.

Wrought high-strength alloys (C17000 and C17200) contain 1.6 to 2.0 wt% Be and nominal 0.25 wt% Co. Wrought moderate-conductivity alloys (C17500 and C17510) contain 0.2 to 0.7 wt% Be and nominal 2.5% Co (or 2 wt% Ni). The leanest alloy is C17410, which contains less than 0.4 wt% Be and 0.6 wt% Co.

Additional detailed information on the composition, physical metallurgy, mechanical properties, and thermal treatments of beryllium copper alloys, including casting alloys and special tempers and alloys, can be found in Ref 4.

**Spinodal Alloys.** The family of copper-nickel-tin alloys spinodally strengthened during aging is represented here by the highest-strength version, the 15Ni-8Sn alloy C72900 used for connectors. Optimum strength and formability are obtained by a combination of cold working followed by aging.

## Fatigue Testing

**Strip.** Bend fatigue testing of strip was performed in conformance with the ASTM B 593 standard method for copper alloy spring materials. This method employs a fixed-cantilever, constant-deflection machine. The tapered test sample is held as a cantilever beam in a clamp at one end and deflected near the opposite end of the apex of the tapered section. Testing was done in a Krouse machine, with the force applied to the sample by a cam and rod linkage. A wide range of bending load ratios can be applied with this method. Typically, load ratios are chosen between  $R = -1$  and 0 to simulate reverse bending and unidirectional bending, respectively. The test frequency is approximately 20 Hz.

Test samples were made from commercial materials. Gages covered 0.20 to 0.38 mm (0.008 to 0.015 in.) for the beryllium coppers and spinodal alloys and 0.25 to 1.5 mm (0.010 to 0.060 in.) for the remaining alloys. Samples of the as-rolled strip were milled to the required test specimen geometry. The rolled surface was left intact and the milled edges deburred.

The required deflection is determined by using either the cantilever simple beam equation or measured with strain-gaged samples under dynamic conditions. The maximum outer fiber bending stress is calculated by:

$$S = \frac{6PL}{bd^2}$$

where  $S$  is the desired bending stress,  $P$  is the applied load at the connecting pin (apex of the sample triangle),  $L$  is the distance between the connecting pin and the point of stress,  $b$  is the specimen width at length  $L$  from the point of load application, and  $d$  is the specimen thickness.

A load cell at the fixed end of the sample is used to detect change in the sample loading resulting from a macroscopic crack initiation. The load cell information is relayed to a monitoring circuit that determines the test completion based on the failure criteria required.

**Rotating Beam.** Fatigue tests of materials representing heavy section products made from rod, bar, and plate were conducted by the rotating-beam method following ASTM E 647 guidelines.

### Fatigue Data

#### Strip

**Nonaging Alloys.** All flexural fatigue data are reported as  $S-N$  curves, where  $S$  is the maximum stress in flexure and  $N$  is the number of cycles to failure. Failure is defined as complete specimen fracture. Fatigue strength is defined here as the maximum stress without failure after 100 million cycles of reversed bending. Figures 1, 2, 3, 4, 5, and 6 present  $S-N$  curves for the solid-solution (nonaging) strengthened alloys (with or without a second-phase grain refiner). In general, fatigue strength follows tensile strength monotonically, but there are exceptions where fatigue strength is relatively insensitive to temper and a few cases, most notably C51000 but also C65400, where crossovers occur. This behavior has been observed before in tin-bronze alloys (Ref 5, 6).

FIG. 1 S-N CURVES FOR C26000. LONGITUDINAL LOADING,  $R = -1$

FIG. 2 S-N CURVES FOR C68800. LONGITUDINAL LOADING,  $R = -1$

FIG. 3 S-N CURVES FOR C76200. LONGITUDINAL LOADING,  $R = -1$

FIG. 4 S-N CURVES FOR C51000. LONGITUDINAL LOADING,  $R = -1$

FIG. 5 S-N CURVES FOR C63800. LONGITUDINAL LOADING,  $R = -1$

FIG. 6 S-N CURVES FOR C65400. LONGITUDINAL AND TRANSVERSE LOADING,  $R = -1$

For many copper alloy systems, transverse tensile and yield strengths are substantially higher than longitudinal strengths, and this characteristic is reflected normally by higher transverse fatigue strengths, as shown in Fig. 6. Although transverse data are not shown for the other alloys, similar behavior is observed. In general, low-stacking-fault-energy (SFE) alloys such as C68800 and C63800, as well as C65400, exhibit greater directionality, more so than the beryllium coppers or C70250.

FIG. 7 S-N CURVES FOR C70250. LONGITUDINAL LOADING,  $R = -1$

The C70250 alloys are shown in Fig. 7 for three tempers. At higher cycles, the temper effect is minimal; at lower cycles, there is some temper dependence.

All of the curves shown in Fig. 1, 2, 3, 4, 5, 6, and 7 represent fatigue stresses at which 50% of the samples would be expected to fail. The data should therefore be treated as representative and not be used for design purposes. Table 3 lists tensile properties and fatigue strengths for the alloys shown in Fig. 1, 2, 3, 4, 5, 6, and 7.

**Beryllium Coppers: Heat-Treatable and Heat-Treated Alloys.** Fatigue data shown here for beryllium copper alloys are represented by a band, the lower bound determined by the lowest stress to cause failure and the upper bound determined by regression analysis of failure data from four or more commercial lots of materials. These upper bound curves are equivalent to the 50% failure curves shown in Fig. 1, 2, 3, 4, 5, 6, and 7.

Beryllium copper in the solution-annealed or cold-rolled condition prior to age hardening is referred to as being in the heat-treatable temper. Examples of the bending fatigue behavior of C17200 strip heat-treatable tempers are shown in Fig. 8. The effect of cold reduction, up to 37% for the TD04 temper, has only a small effect on the fatigue response.

**FIG. 8 BENDING FATIGUE CURVES FOR BERYLLIUM COPPER C17200 STRIP IN THE HEAT-TREATABLE CONDITION. LONGITUDINAL LOADING,  $R = -1$**

Figure 9 demonstrates the effect of age hardening to peak strength after cold work on fatigue behavior--about a 70 MPa (10 ksi) increase in fatigue strength. The differences due to prior cold work become pronounced at  $R = 0$  (unidirectional) stressing (Fig. 10). The benefit available for unidirectional stressing is useful for switch designs that operate in unidirectional bending.

**FIG. 9 BENDING FATIGUE CURVES FOR HEAT-TREATED (PEAKAGED) C17200 STRIP. LONGITUDINAL LOADING,  $R = -1$**

FIG. 10 BENDING FATIGUE CURVES FOR HEAT-TREATED (PEAKAGED) C17200 STRIP. LONGITUDINAL LOADING,  $R = 0$

The fatigue response for age hardened C17510 (TH04), the higher-conductivity alloy with lower strength (Fig. 11), demonstrates that fatigue strengths achievable at this higher conductivity level are comparable to the higher-strength beryllium copper C17200 in the solution-treated and cold-worked, unaged condition (see Fig. 8).

FIG. 11 BENDING FATIGUE CURVES FOR C17510 TH04 STRIP. LONGITUDINAL AND TRANSVERSE LOADING,  $R = -1$

**Beryllium Coppers: Mill-Hardened Strip.** Mill hardening consists of age hardening to a specific strength level as part of the manufacturing process. This process can reduce or eliminate the need for age hardening after component forming that is required for the age-hardenable tempers. The data in Fig. 12 represent two mill-hardened tempers of C17200 strip. The TM04 temper is a medium-strength product (760 to 930 MPa, or 110 to 135 ksi, yield strength); the TM08 temper offers the greatest strength available (1035 to 1240 MPa, or 150 to 180 ksi, yield strength). The TM08 temper shows greater stress to failure at high cycles than the TM04 temper. Both tempers show very little directionality at either load ratio, as illustrated by comparing Fig. 12 and 13. Compared to the heat-treated tempers in Fig. 9, the TM08 temper displays the greater fatigue strength in reverse bending; however, in contrast, the TH04 temper displays the greatest fatigue strength in unidirectional bending (Fig. 10).

FIG. 12 BENDING FATIGUE CURVES FOR C17200 TM04 AND TM08 STRIP TEMPERS. LONGITUDINAL LOADING,  $R = 0$  AND  $-1$

FIG. 13 BENDING FATIGUE CURVES FOR C17200 TM04 AND TM08 STRIP TEMPERS. TRANSVERSE LOADING,  $R = 0$  AND  $-1$

C17410 is manufactured in two mill-hardened strip tempers, designated by their manufacturer as TH02 and TH04. Typical mill-hardened tempers are designated TMx. These alloys do not require additional aging by the customer. Figures 14 and 15 show the fatigue curves for these alloys. The lower-strength (TH02) temper generally shows greater fatigue strength in reverse bending than the higher-strength temper. This is in contrast to the tensile strength/fatigue trend seen in C17200 alloys. The difference between the two tempers is diminished in unidirectional bending. Fatigue strengths around 550 MPa (80 ksi) are achieved for unidirectional bending. In general, the reverse bending fatigue response of this alloy compares to the fatigue strength of the C17200 mill-hardened strip, but shows slightly reduced response unidirectionally.

FIG. 14 BENDING FATIGUE CURVES FOR C17410 TH02 STRIP. LONGITUDINAL AND TRANSVERSE LOADING,  $R = -1$

FIG. 15 BENDING FATIGUE CURVES FOR C17410 TH04 STRIP. LONGITUDINAL AND TRANSVERSE LOADING,  $R = -1$

Edge condition can severely affect the fatigue response of strip products, particularly high-strength alloys. Electrical and electronic spring contacts are usually manufactured by stamping, slitting, electrodischarge machining, or chemically etching. Each of these operations can impart some degree of damage to the affected edge. The effect of slit edges, simulating stamped conditions, on fatigue response were addressed in Ref 7, which studied stamped versus milled edge samples. The results confirmed that high-cycle fatigue is surface dependent in strip and that careful application of fatigue data to a design is critical.

Table 4 lists tensile and fatigue strengths of the beryllium copper alloys shown in Fig. 8, 9, 10, 11, 12, 13, 14, and 15.

TABLE 4 TENSILE AND FATIGUE STRENGTHS OF SELECTED TEMPER OF THE BERYLLIUM COPPER ALLOYS IN FIG. 8, 9, 10, 11, 12, 13, 14, 15

**Spinodal Alloy.** *S-N* data for alloy C72900 are shown in Fig. 16 for TM02, 04, and 06 tempers. Fatigue strengths at 100 million cycles in reversed bending are in the range of 220 to 275 MPa (32 to 40 ksi) for all three tempers. These curves represent averaged data comparable to *S-N* curves in Fig. 1, 2, 3, 4, 5, 6, and 7.

FIG. 16 *S-N* CURVE FOR C72900 IN TM02, TM04, AND TM06 TEMPERS. LONGITUDINAL LOADING,  $R = -1$

### Heavy-Section Beryllium Copper

Rotating-beam *S-N* curves are shown in Fig. 17 for C17200 in age-hardened tempers TF00 and TH04. Generally speaking, the smaller the diameter or size, the greater the fatigue strength. This behavior is linked directly to the microstructure, which will be discussed in the following section.

FIG. 17 ROTATING-BEAM FATIGUE CURVES FOR C17200 TF00 AND TH04 ROD AS A FUNCTION OF DIAMETER

## Discussion

As noted earlier, fatigue strength for copper alloys is usually defined as the stress sustainable without failure for 100 million cycles. [For the average (50% failure) curves, this actually means 50% will fail at this stress level.] For this high-cycle condition, most of the life is spent in crack nucleation, assuming the component in question does not have mechanical defects or other notches in the high-stress area.

High SFE alloys exhibit fatigue crack nucleation within persistent slip bands--markings produced by cyclic microplastic deformation. This is not an apparent mode of crack nucleation for low-SFE alloys. In general, cold work has a more beneficial effect on fatigue strength of low-SFE alloys versus copper and high-SFE copper alloys. Reducing grain size generally increases fatigue strength. This effect diminishes with increasing cold work.

Resistance to microplastic deformation and enhancement of fatigue life can be produced by precipitation hardening if the precipitate phase is stable under cyclic loading. This is the case for beryllium copper and copper-nickel-tin precipitates.

**Beryllium Coppers.** Microstructure plays an important role in the fatigue performance of beryllium copper alloys. Age-hardened structures contain a mixture of metastable precipitates within a copper alloy matrix. The metastable precipitates dominate the deformation behavior of these alloys because of the small size, high volume fraction, homogeneous

distribution, and high elastic strain contribution within the copper matrix. Aging, therefore, significantly affects fatigue behavior.

The high-strength C17200 alloys and C17410 contain a stable cobalt beryllide intermetallic, and C17510 contains a nickel beryllide. These beryllides are considerably larger than the precipitates and spaced sufficiently apart (i.e., long mean free path) so they do not contribute significantly to the fatigue performance.

An overaged structure will generally result in improved bending or rotating fatigue performance. Even though overaging results in somewhat lower strength, the net result is an improvement in fatigue life, because overaging prolongs the crack nucleation stage. Overaging causes the precipitate/matrix orientation relationship to progress to form incoherent  $\gamma$  phase from the metastable coherent Guinier-Preston zones (GPZ).

Conversely, the fatigue crack propagation behavior worsens as the alloys are overaged (Fig. 18). Deformation becomes highly localized at the grain boundaries as a result of the heterogeneous cellular reaction forming the equilibrium  $\gamma$  phase while creating adjacent regions within the grain boundaries of solute-depleted copper. Dislocation pileups at the grain boundaries are not adequately blunted and propagate easily into the boundaries, resulting in a crack path "short circuit." Nonetheless, the increase in crack propagation rate for overaged versus peak-aged material does not alter the overall improved life associated with the overaged condition.

### Introduction

Magnesium possesses the lowest density of all structural metals, having about 25% the density of iron and approximately 33% that of aluminum. Because of this low density, both cast and wrought magnesium alloys (Tables 1 and 2) have been developed for a wide variety of structural applications in which low weight is important, if not a requirement. In this context, this article briefly summarizes the fatigue and fracture resistance of magnesium alloys.

### Fatigue

Most of the fatigue data for magnesium alloys are  $S-N$  curves dating from the 1930s to 1960s. Strain-life ( $\epsilon-N$ ) curves for magnesium alloys are very rare, and most fatigue crack growth behavior data have originated from work conducted in the former Soviet Union. Data from these sources are compiled in Ref 1.

Like other alloys, fatigue strength of magnesium alloys depends on tensile strength (Fig. 1). However, the ratio of fatigue strength to tensile strength is not as well defined for magnesium alloys as for steels. This is due, in part, to the effect of strengthening mechanisms on fatigue strength. For example, solid-solution strengthening increases the fatigue strength of magnesium alloys, whereas cold working and precipitation strengthening produce little improvement in fatigue strength at longer lives (Ref 3).

FIG. 1 ROTATING BENDING FATIGUE STRENGTH VS. ULTIMATE TENSILE STRENGTH OF MAGNESIUM ALLOYS (SMALL SMOOTH SPECIMENS). SOURCE: REF 2

Axial fatigue  $S-N$  curves for AZ91E and WE43 are shown in Fig. 2, along with comparative data for A357 aluminum. The flat curve typical of magnesium alloys contrasts with that of aluminum where there is a marked change in slope between low- and high-cycle regimes. These different shapes of curve indicate that, although A357 performs well at low cycles, the situation changes so that WE43 has the better properties at high cycles. AZ91E has significantly lower properties in the low-cycle regime as a result of lower strength and porosity, but at high cycles the difference is not so marked.

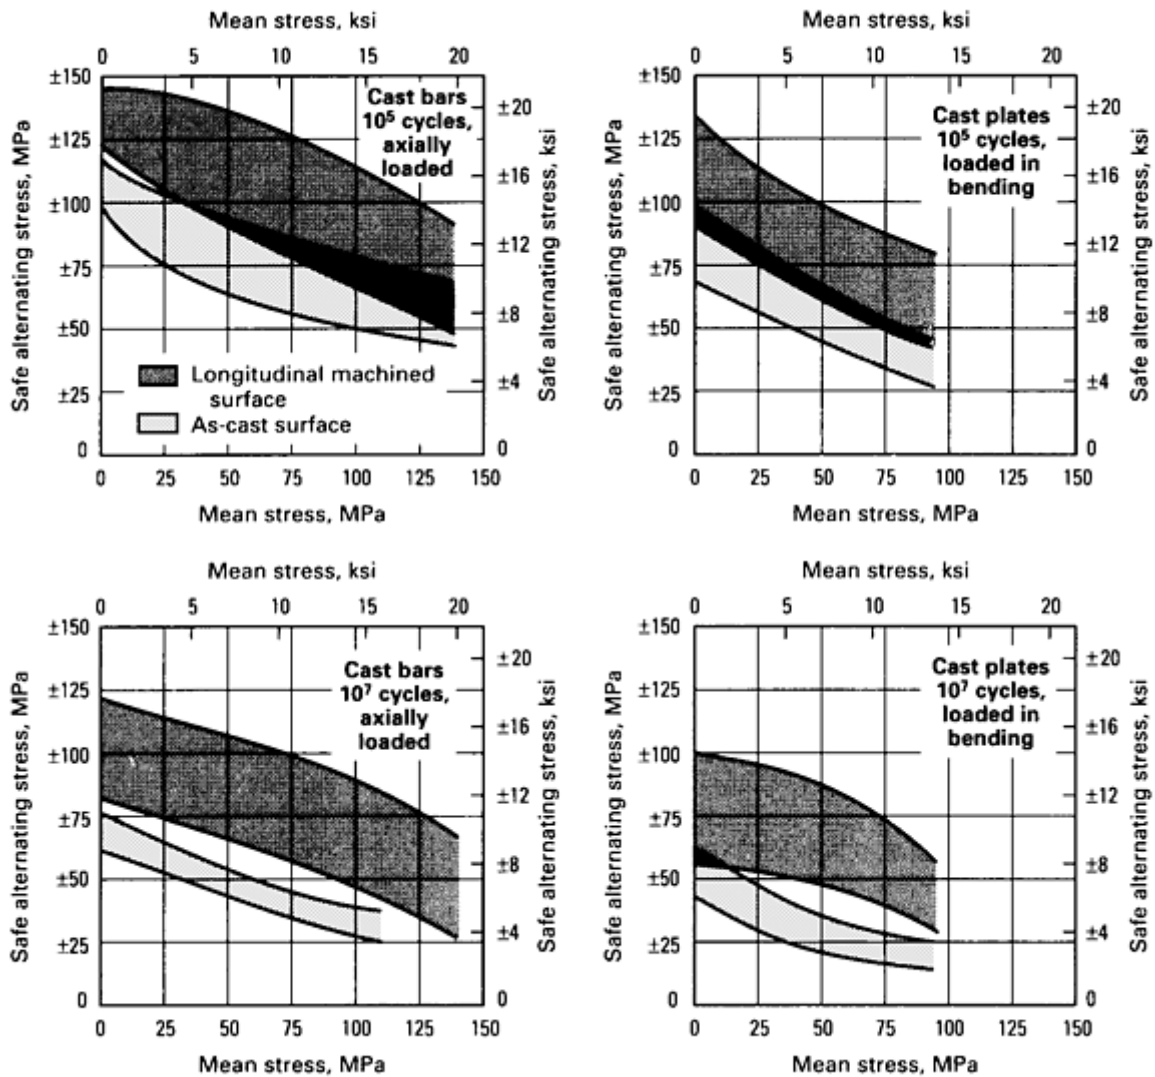

FIG. 2 FATIGUE PROPERTIES OF A357, AZ91E, AND WE43.  $R = 0.1$ . SOURCE: REF 4

**Fatigue Mechanisms.** The initiation of fatigue cracks in magnesium alloys is related to slip in preferably oriented grains and is often related to the existence of micropores. For pure magnesium, crack orientation is more strongly influenced by grain boundaries than the slip (Ref 3).

The initial stage of fatigue crack growth usually occurs from quasicleavage, which is common in hexagonal close-packed structures such as magnesium. Further crack growth micromechanisms can be brittle or ductile and trans- or intergranular, depending on metallurgical structure and environmental influence. Some magnesium alloys can have either a hexagonal or body-centered cubic structure, depending on their chemical composition.

**Effect of Surface Condition.** High-cycle fatigue strength is influenced primarily by surface condition. Sharp notches, small radii, fretting, and corrosion are more likely to reduce fatigue life than variations in chemical compositions or heat treatment. For example, removing the relatively rough as-cast surfaces of castings by machining improves fatigue properties of the castings (see Fig. 3).

**FIG. 3 EFFECT OF SURFACE TYPE ON THE FATIGUE PROPERTIES OF CAST MAGNESIUM-ALUMINUM-ZINC ALLOYS. SOURCE: METALS HANDBOOK, 9TH ED., VOL 2, ASM INTERNATIONAL, 1979, P 461**

When fatigue is the controlling factor in design, every effort should be made to decrease the severity of stress raisers. Use of generous fillets in re-entrant corners and gradual changes of section greatly increase fatigue life. Conditions in which the effects of one stress raiser overlap those of another should be eliminated. Further improvement in fatigue strength can be obtained by inducing stress patterns conducive to long life. Cold working the surfaces of critical regions by rolling or peening to achieve appreciable plastic deformation produces residual compressive surface stress and increases fatigue life.

Surface rolling of radii is especially beneficial to fatigue resistance because radii generally are the locations of higher-than-normal stresses. In surface rolling, the size and shape of the roller, as well as the feed and pressure, are controlled to obtain definite plastic deformation of the surface layers for an appreciable depth (0.25 to 0.38 mm, or 0.010 to 0.015 in.). In all surface working processes, caution must be exercised to avoid surface cracking, which decreases fatigue life. For example, if shot peening is used, the shot must be smooth and round. The use of broken shot or grit can result in surface cracks.

**Test Effects.** As with other alloys, several test variables affect the fatigue strength of magnesium alloys. As expected, notched specimens and increasing  $R$  ratios decrease fatigue strength (Fig. 4a and 4b). The size of parts also reduces bending fatigue strength.

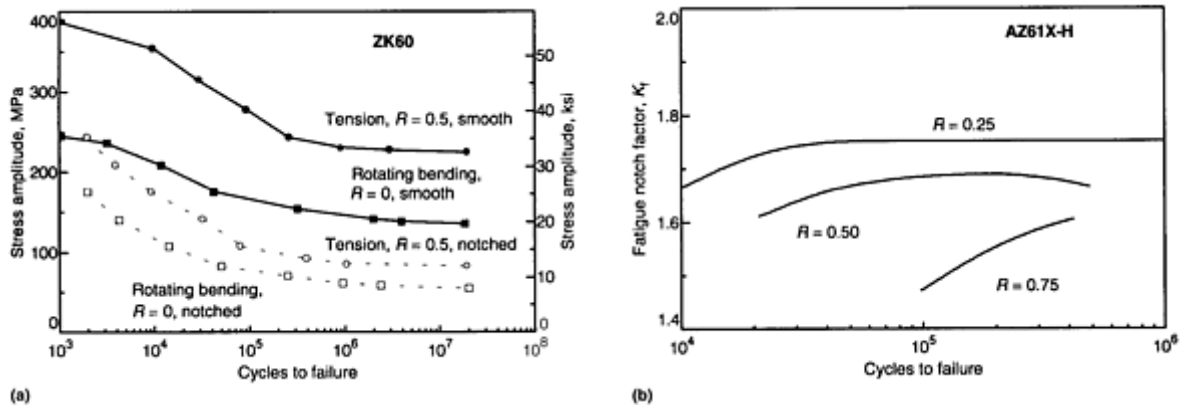

FIG. 4 EFFECT OF STRESS RATIO AND NOTCHES ON FATIGUE OF TWO MAGNESIUM ALLOYS. (A) ROTATING BENDING AND TENSION-COMPRESSION S-N CURVES OF ZK60. (B) FATIGUE LIFE OF AZ61X-H WITH DIFFERENT NOTCH FACTORS. SOURCE: REF 5

Generally, thicker portions of castings have greater microporosity and thus reduced fatigue strength, and thick extended bars (>75 mm diameter) and large forgings can experience reduced fatigue strength and increased notch sensitivity. Fatigue strength is also affected by specimen size (Fig. 5), because larger specimens provide greater surface area for crack initiation.

FIG. 5 EFFECT OF SPECIMEN SIZE ON FATIGUE STRENGTH OF MAGNESIUM ALLOYS (SMOOTH, ROTATING BENDING SPECIMENS). SOURCE: REF 6

## Fatigue and Fracture Resistance of Magnesium Alloys

### Fatigue Crack Growth

As previously mentioned, availability of fatigue crack growth data on magnesium alloys is rather limited because most fatigue crack growth data were generated in the former Soviet Union. However, in examining fatigue crack growth rate curves for many materials, the striking feature is the similarity of curves normalized by modulus. Although from an engineering viewpoint, the differences in crack growth rate between alloys can be important when integrating along  $da/dN$  curves to obtain the lifetime of a structure, a large range of metals can be represented by a single curve if the driving force is normalized by modulus, as illustrated in Fig. 6 (Ref 7). The effect of environment is important, particularly water vapor (see Fig. 7 for magnesium alloy ZK60A).

### Fatigue and Fracture Resistance of Magnesium Alloys

#### Fracture Toughness

Typical values of magnesium alloy toughness are summarized in Table 3 (Ref 9). The critical stress intensity factor,  $K_{Ic}$ , a material constant, is the largest stress intensity the material will support, under conditions of plane strain, without failing catastrophically. If  $K_{Ic}$  is known for the material, and the geometry and stress are known for the part, the largest crack that can be tolerated can be calculated. The larger the critical stress intensity factor, the larger the flaw size that can be tolerated.

(E) SPECIMEN DIMENSIONS: TOTAL WIDTH, 1 IN.; NOTCHED WIDTH, 0.700 IN.; THICKNESS, 0.60 IN.; 60° V-NOTCH WITH 0.0003 IN. RADIUS.

One of the most difficult problems in fracture mechanics is the prediction of failure when section stresses approach or exceed yield values. Under these conditions, the critical stress intensity ( $K_{IC}$ ) lies outside the domain of linear elastic fracture mechanics and is not a material constant. In such cases, the *apparent*  $K_{IC}$  depends on specimen geometry and flaw size. An example of variations in apparent  $K_{IC}$  values outside the domain of linear conditions is shown in Fig. 8 for magnesium alloy HM21A-T8 (Ref 10).

FIG. 8 VARIATION OF APPARENT FRACTURE TOUGHNESS ( $K_{IC}$ ) WITH CRACK SIZE. SOURCE: REF 10

The  $J$ -integral method has been used as a fracture criterion for nonlinear fracture mechanics. From tests on various alloys including magnesium alloy AZ31B, the  $J$ -integral is a valid fracture criterion for monotonic loading of thin section metals by Mode I stress systems. The results indicate that for a wide range of material behavior and specimen size  $J_c$  is not a function of crack length or specimen geometry. Additional details of the results are given in Tables 4 and 5. Statistical data for CT (compact tension) specimens are presented in Table 4 and compared with the mean values for data from CC and DEC (double edge cracked) specimens in Table 5. Standard deviations for  $J_c$  from CT specimens are seen to be on the order of  $\pm 11\%$  of the mean for most of the alloys. These data can be put in the perspective of linear elastic fracture mechanics by the conversion:

$$K_C = \sqrt{(E J_c)}$$

### Fatigue and Fracture Resistance of Magnesium Alloys

#### Stress-Corrosion Cracking

Wrought and cast magnesium alloys (particularly those containing aluminum) are susceptible to stress-corrosion cracking (SCC) when statically loaded below their yield strengths in some environments. Early studies found susceptibility for wrought forms but little or no susceptibility for cast forms. However, the presence of aluminum as an alloying element is the main factor affecting SCC susceptibility, rather than cast or wrought form. For aluminum-containing magnesium alloys, SCC susceptibility is comparable to that of wrought and cast forms of similar composition (Fig. 9, Ref 11).

FIG. 9 DATA COMPARING SIMILAR CAST AND WROUGHT MAGNESIUM ALLOYS DURING LONG-TERM STRESS-

**CORROSION CRACKING (SCC). LONG-TERM RURAL-ATMOSPHERE SCC DATA COMPARE SIMILAR-COMPOSITION AZ61 SHEET, EXTRUDED AZ61, AND SAND-CAST AZ63. ALTHOUGH THERE IS A GREAT DEAL OF SCATTER IN THESE DATA, ALL THREE MATERIALS EXHIBITED SIMILAR BEHAVIOR AT THE HIGHER STRESS LEVELS. AT LOWER STRESS LEVELS, THE CAST ALLOYS BECAME MORE RESISTANT TO SCC. SOURCE: REF 11**

While all magnesium alloys will stress corrode to some extent, the most susceptible are those containing aluminum as an alloying element. Magnesium alloys containing aluminum should not be designed for prolonged exposure to stresses near the yield point. Residual stresses from operations such as welding or machining must also be relieved by heat treatment (Ref 9). Service failures normally result from excessive residual stress produced during fabrication (Ref 12, 13, 14, 15, 16, 17, 18). Speidel (Ref 19), in a comprehensive review of more than 3000 unclassified failure reports from aerospace companies, government agencies, and research laboratories in the United States and five Western European countries, estimated that approximately 10 to 60 magnesium aerospace component SCC service failures occurred each year from 1960 to 1970. Of this total, more than 70% involved either cast alloy AZ91-T6 or wrought alloy AZ80-F, both of which contain aluminum. In contrast, magnesium alloys without aluminum do not, in practice, have a stress-corrosion problem (Ref 9). The broad class of alloys containing zirconium are also sufficiently insensitive that SCC is not a problem in practice.

Stress-corrosion cracking of magnesium alloys can occur in many environments. In general, the only solutions that do not induce SCC are either those that are nonactive to magnesium, such as dilute alkalis, concentrated hydrofluoric acid, and chromic acid, or those that are highly active, in which general corrosion predominates. More information on the effect of air, water, and aqueous solutions is contained in Ref 20.

**Effects of Alloy Composition.** Pure magnesium is not susceptible to SCC when loaded up to its yield strength in atmospheric and most aqueous environments (Ref 13, 21, 22, 23, 24). The only reports of SCC of pure magnesium have emanated from laboratory tests in which specimens were immersed in very severe SCC solutions (Ref 25, 26, 27).

As previously mentioned, aluminum-containing magnesium alloys have the highest SCC susceptibility, with the sensitivity increasing with increasing aluminum content, as illustrated in Fig. 10 (Ref 28). An aluminum content above a threshold level of 0.15 to 2.5% is reportedly required to induce SCC behavior (Ref 14, 29, 30), with the effect peaking at approximately 6% Al (Ref 31). The aluminum- and zinc-bearing AZ alloys, which are the most commonly used magnesium alloys, have the greatest susceptibility to SCC. Alloys with higher aluminum content, such as AZ61, AZ80, and AZ91, can be very susceptible to SCC in atmospheric (Fig. 11) and more severe environments (Fig. 12), while lower-aluminum AZ31 is generally more resistant. However, it too can suffer SCC under certain conditions.

FIG. 10 STRESS VS. TIME-TO-FAILURE ( $T_F$ ) FOR MAGNESIUM-ALUMINUM ALLOYS IN AQUEOUS 40 G/L NaCl + 40 G/L  $Na_2CrO_4$ . SOURCE: REF 28

FIG. 11 STRESS CORROSION OF SAND-CAST AZ91C (T4 AND T6) IN RURAL ATMOSPHERE. SOURCE: REF 9

FIG. 12 STRESS VS. TIME-TO-FAILURE ( $T_F$ ) FOR THE TWO-PHASE ALLOYS AZ80 (MG-8.5AL-0.5ZN) AND AZ61 (MG-6AL-1ZN) IN AQUEOUS 40 G/L NaCl + 40 G/L  $Na_2CrO_4$

Magnesium-zinc alloys that are alloyed with either zirconium or RE elements, but not with aluminum, such as ZK60 and ZE10, have intermediate SCC resistance (Fig. 13), and in some cases SCC has not been a serious problem. However, SCC can still occur in atmospheric environments at stresses as low as 50% of the yield strength, although life is significantly longer than for Mg-Al-Zn alloys.

FIG. 13 STRESS CORROSION OF ZK60A-T5 EXTRUSION IN RURAL ATMOSPHERE. SOURCE: REF 9

Magnesium alloys that contain neither aluminum nor zinc are the most SCC resistant. Magnesium-manganese alloys, such as M1, are among the alloys with the highest resistance to SCC, and they are generally considered to be immune when loaded up to the yield strength in normal environments. In fact, SCC of Mg-Mn alloys has been reported only in tests involving stresses higher than the yield strength (Ref 11, 32) and/or exposure to very severe laboratory environments (Ref 33). Alloys QE22, HK31, and HM21 are also resistant to SCC, exhibiting SCC thresholds at approximately 70 to 80% of the yield strength in rural-atmosphere tests (Ref 11).

Magnesium-lithium alloys are of commercial interest because of their higher stiffness and lower density compared with other magnesium alloys. Tests in humid air have resulted in SCC failures of Mg-Li-Al alloys, but SCC did not occur during testing of Mg-Li alloys strengthened with zinc, silicon, and/or silver instead of aluminum (Ref 34).

The earliest investigations of SCC of magnesium and magnesium alloys focused on the influence of alloy chemistry and microstructure, which were just gaining recognition as controlling factors in magnesium corrosion behavior (Ref 35, 36). The overwhelming majority of these studies used a chromate-chloride electrolyte (typically  $40 \text{ g}^{-1}$  each) because of its relevance to service conditions, in which chloride ions present in the environment attempt to penetrate a chromate-inhibited magnesium surface. These solutions cause especially severe cracking, but magnesium is also affected similarly by neutral solutions containing only chlorides or even distilled water (Ref 37).

A recent study (Ref 38) sought to compare the stress-corrosion behavior of rapidly solidified alloys to that of cast Mg-Al alloys, paying special attention to the role played by hydrogen and repassivation kinetics. This investigation, which was the first for rapidly solidified Mg-Al alloys, showed that all the alloys, as well as pure magnesium, failed by transgranular SCC in a chromate-chloride electrolyte at displacement rates between  $5 \times 10^{-5}$  and  $9 \times 10^{-3} \text{ mm s}^{-1}$ . This failure mode was manifested in quasi-cleavage on the fracture surfaces and in lower maxima in stress intensity and displacement, and it was concluded that transgranular SCC probably occurs in these materials as a result of hydrogen embrittlement. Results from constant displacement rate testing were explained by a hydride formation model using realistic estimates for the diffusivity of hydrogen in magnesium. Based on repassivation results, dissolution appears incapable of achieving the

observed crack growth rates. Potential pulse and scratching electrode experiments demonstrated superior repassivation behavior for rapidly solidified Mg-Al alloys compared with their as-cast counterparts, indicating that homogeneity retards pit nucleation and thereby retards the development of local environments that impair repassivation. Increasing the aluminum content from 1 to 9% improved the repassivation rate of rapidly solidified alloys. This study also showed that repassivation participates in this SCC mechanism, probably by localizing the corrosion reactions and controlling the amount of hydrogen that enters the unprotected alloy surface when film rupture occurs.

## Fatigue and Fracture Resistance of Magnesium Alloys

### Corrosion Fatigue

Substantial reductions in fatigue strength are shown in laboratory tests using NaCl spray or drops. Such tests are useful for comparing alloys, heat treatments (Fig. 14), and protective coatings. Effective coatings, by excluding the corrosive environment, provide the primary defense against corrosion fatigue.

FIG. 14 FATIGUE OF COMMERCIAL PURE 9980A MAGNESIUM (UNS M19980) IN AIR AND IN VACUUM. CONDITIONS: CANTILEVER BENDING,  $R = -1$ , 30 HZ, ROOM TEMPERATURE. SOURCE: *J. SPACECRAFT ROCKETS*, VOL 5, 1968, P 700-704

A fundamental study of the corrosion fatigue of magnesium alloys is that of Speidel et al. on high-strength magnesium alloy ZK60A (Ref 8, 39) (Fig. 7). All magnesium alloys behave similarly with respect to environmentally enhanced subcritical crack growth, according to Speidel et al. They found that both stress-corrosion and corrosion-fatigue cracks propagate in a mixed transgranular-intergranular mode. They measured the corrosion-fatigue crack growth for all of the aqueous environments shown in Fig. 7 and compared the corrosion fatigue with stress-corrosion-behavior. They found that:

- CORROSION-FATIGUE CRACK GROWTH RATE IS ACCELERATED BY THE SAME ENVIRONMENTS AS THOSE THAT ACCELERATE STRESS-CORROSION CRACK GROWTH (I.E., SULPHATE AND HALIDE IONS).
- THE BOUNDARY BETWEEN REGIONS II AND III IN NABR SOLUTIONS OF THE  $DA/DN$  VERSUS  $\Delta K$  CURVE IS HIGHER THAN THE STRESS-CORROSION THRESHOLD ( $K_{ISCC}$ ), WHICH OCCURS AT A MUCH LOWER STRESS INTENSITY.
- THERE IS A DISTINCT BOUNDARY BETWEEN REGIONS II AND III FOR ALL THE MEDIA GIVEN IN FIG. 7 (EXCEPT DRY ARGON). THIS BOUNDARY OCCURS AT ABOUT THE SAME STRESS INTENSITY ( $\sim 14 \text{ MPa } \sqrt{m}$ ) AS  $K_{ISCC}$  IN DISTILLED WATER.

**Surface Protection.** It is common practice to protect the surface of magnesium and its alloys, and such protection is essential where contact occurs with other structural metals because this may lead to severe galvanic corrosion. Methods available for magnesium are summarized below. Additional information is contained in *Surface Engineering*, Volume 5 of the *ASM Handbook*.

- Fluoride anodizing involves alternating current anodizing at up to 120 v in a bath of 25% ammonium bifluoride, which removes surface impurities and produces a thin, pearly white film of  $\text{MgF}_2$ . This film is normally stripped in boiling chromic acid before further treatment because it gives poor adhesion to organic treatments.
- Chemical treatments involve pickling and conversion of the oxide coating. Components are dipped in

chromate solutions, which clean and passivate the surface to some extent through formation of a film of  $\text{mg}(\text{oh})_2$  and a chromium compound. Such films have only slight protective value, but they form a good base for subsequent organic coatings.

- Electrolytic anodizing includes proprietary treatments that deposit a hard ceramic-like coating, which offers some abrasion resistance in addition to corrosion protection (e.g., dow 17, hea, and mgz treatments). Such films are very porous and provide little protection in the unsealed state, but they may be sealed by immersion in a solution of hot dilute sodium dichromate and ammonium bifluoride, followed by draining and drying. A better method is to impregnate with a high-temperature curing epoxy resin (see below). Resin-sealed anodic films offer very high resistance to both corrosion and abrasion, and in some instances they can even be honed to provide a bearing surface. Impregnation is also used to achieve pressure tightness in casting that are susceptible to microporosity.
- Sealing with epoxy resins: the component is heated to 200 to 220 °c to remove moisture, cooled to approximately 60 °c, and dipped in the resin solution. After removal from this solution, draining, and air drying to evaporate solvents, the component is baked at 200 to 220 °c to polymerize the resin. Heat treatment may be repeated once or twice to build up the desired coating thickness, which is commonly 0.025 mm.
- Standard paint finishes: the surface of the component should be prepared as in the methods described above, after which it is preferable to apply a chromate-inhibited primer followed by a good-quality top coat.
- Vitreous enameling can be applied to alloys that do not possess too low a solidus temperature. Surface preparation involves dipping the work in a chromate solution before applying the frit.
- Electroplating: several stages of surface cleaning and the application of pretreatments, such as a zinc conversion coating, are required before depositing chromium, nickel, or some other metal.

Magnesium alloy components for aerospace applications require maximum protection. Schemes involving chemical cleaning by fluoride anodizing, pretreatment by chromating or anodizing, and sealing with epoxy resin, a chromate primer, and a top coat are sometimes mandatory.

## Introduction

AN UNDERSTANDING of the mechanical and fatigue properties of solders used in electronic packaging is a requirement for better design of solder joints and the development of accelerated tests and improved solders. Fatigue failures of a solder joint in an electronic device result from the imposition of strain caused by the joining of materials with different thermal expansivity under conditions of thermal cycling. This process of thermal fatigue in a given device is controlled by the total strain. The strain levels are determined by thermal expansion mismatch of materials used in a package, thermal gradients in a package, temperature excursions during service, the geometry of the solder joint, and compliance of the joint system.

However, even though failure of solder joints is due to thermal fatigue, most of the data available are for isothermal fatigue of solders. Isothermal tests are easier to control, conduct, and interpret, and they are less costly than thermomechanical fatigue tests. Methods to relate isothermal fatigue data to thermal fatigue data are being developed. The long-range objective of solder fatigue research is to use isothermal properties along with short-time thermomechanical behavior to predict solder joint lifetime. It will be shown (based on the experimental data, metallurgical observations, and the micromechanically based theory of the solder behavior) that the thermomechanical fatigue tests that are used to verify the quality of solder joints can be replaced with isothermal tests. In fact, an isothermal fatigue test called the mechanical deflection system (MDS) test was developed and implemented for reliability assessment of solder joints (Ref 1).

**Variables Affecting Isothermal Fatigue of Solders.** The most important variables during isothermal fatigue of solders are mode of loading, strain range, ramp time, hold times, temperature, and environment (as discussed later in this article). Factors such as solder composition, microstructure, aging conditions, specimen design, and fatigue life definition should be critically reviewed.

Because of processing needs and operational requirements, solders of different compositions are used in electronic packaging. While there are some similarities in fatigue behavior of different solders, all are different materials with specific microstructural, mechanical, and fatigue properties. It is important to stress that because of the very high sensitivity of solder microstructure to impurities and aging conditions, solders of the same composition may have different mechanical properties if aged differently. Therefore, application of solder fatigue and mechanical property data available in the literature to a specific solder and application must consider all of the conditions under which the data were obtained to avoid erroneous assessment of the reliability of a solder joint.

**Isothermal fatigue data for solders** have been developed for specimens of different design, ranging from a solder joint in a real device (Ref 2, 3, 4), two plates joined by solder (Ref 5, 6, 7, 8, 9) to a bulk specimen (Ref 10, 11, 12, 13, 14) tested under different loading conditions: tension (Ref 11, 12, 13), shear (Ref 3, 4, 5, 6, 7, 8, and 9), bending (Ref 15), and torsion (Ref 2, 10). Different fatigue life criteria have been used at different laboratories: visible cracking proportioned from total fracture (Ref 15), a predetermined drop in load (Ref 2, 3, 4, 5, 6, 10, 14, 16, 17), start of the drop of the maximum tensile stress (Ref 11, 12, 13, 14) or of the tensile stress-compressive stress ratio (Ref 14), and predetermined increase in resistance (Ref 3, 15). A different definition of failure leads to a different fatigue life. For example, when end of fatigue life in near-eutectic solder was defined as the number of cycles to reduce the initial tensile stress to 75, 50, or 10% of its initial value, the different definitions of fatigue life led to different slopes of Coffin-Manson plots (Ref 18). Thus, it is very often difficult, if not impossible, to compare data developed at different laboratories and correlate these data to the fatigue life of the solder joint in the device.

**Microstructural Properties of Solders and Other Ductile Polycrystalline Materials.** The behavior of solders operating in a high-temperature environment is very complex and far from understood. Temperature, strain rate, and strain range alter the mechanical properties of the materials, shift the source of material nonlinearity within different levels of the internal structure, and frequently define the fracture regime. Intergranular failure occurs when the inelastic behavior is localized near grain boundaries; hence dislocation creep and grain-boundary slip dominate, both of which are associated with the cavitation process (Ref 19, 20). Dislocation glide is typical at the upper stress extreme and leads to transgranular failure mechanism, while diffusional creep is characteristic at lower stresses.

In general, the total deformation is composed of elastic, recoverable inelastic, and plastic portions. The irreversible (plastic) deformation is responsible for damage processes, while the microstructural recovery allows for relaxation of the residual stresses stored in the internal structure and brings the microstructure into its equilibrium configuration. The damage and recovery processes minimize free energy: The first leads to the energy dissipation; the second minimizes the internal energy inside grains. Recovery dominates within the range of conditions that favor creep mechanisms, and the amount of the recovered inelastic strain is proportional to the magnitude of stress applied during the creep process (Ref 21).

The recovery phenomenon can be driven by several mechanisms, among them: partial recovery of grain shape, relaxation of grain-boundary dislocation pileups leading to reversible grain-boundary slip, or void sintering. In all these cases, grain boundaries are explicitly involved in the recovery process. Frequently, these mechanisms operate together. Extensive studies of these phenomena for tin-lead solders were conducted by Schneibel (Ref 22), Betrabet and Raman (Ref 19), and Tien and Attarwala (Ref 23). All the experimental data suggest that the continuously evolving internal structure has a critical influence on the behavior of solders, especially when fatigue load conditions are applied.

A fatigue model of solders, if predictive, should incorporate the overall creep behavior and the microstructural recovery processes. Such a model was derived by Zubelewicz (Ref 24) and presented at the Lead Free Solders Workshop (Ref 25). It was shown that the solder fatigue life is explicitly dependent on the recoverable and irreversible evolution of the solder microstructure. Particularly, this theory explains the effect of high versus low frequency of cycling, and the differences in fatigue life caused by the isothermal versus thermomechanical test conditions. The experimental results and the understanding of the behavior of solders lead to the conclusion that an isothermal test should and does provide meaningful reliability data for solder joints used in electronic industry.

### Isothermal Fatigue of Solder Materials

**Effect of Strain Range on Fatigue Life.** Increasing the strain range during cycling of materials leads to a decrease in the number of cycles to failure. Low-temperature ( $<0.3$  absolute melting point,  $T_m$ ), low-cycle fatigue data for many metals may be fit to the empirical Coffin-Manson relationship (Ref 26, 27):

$$N_f^\beta \epsilon_p = C \quad (\text{EQ 1})$$

where  $N_f$  is the number of cycles to failure,  $\epsilon_p$  is the plastic strain range, and  $\beta$  and  $C$  are constants. For most metals the constant  $\beta$  is equal to approximately 0.5. Despite the fact that this relationship was developed for fatigue of metals at low homologous temperature, this relationship and its modifications are used widely for prediction of fatigue lives of solders.

Isothermal fatigue data for high-lead, 95Pb-5Sn solder (Ref 15), developed under bending conditions, was reported to obey the Coffin-Manson relationship in the temperature range of 25 to 85 °C. In this temperature range, the exponent  $\beta$  was found to be equal to 0.43 to 0.46 in the strain range of 0.1 to 5.0% and a frequency of 1800 cycles per day. The Coffin-Manson relationship failed to describe the experimental data for this solder at temperatures equal to or higher than 120 °C. At strain ranges higher than 1%, the exponent  $\beta$  became approximately 1 (Ref 15).

95Pb-5Sn solder was found to obey approximately the Coffin-Manson relationship when tested in torsion from 0.05 to 2.0% at frequency of 1 Hz (Fig. 1) (Ref 10). At 1.0% total strain at room temperature, transgranular cracking was observed. At 150 °C, the solder failed at the grain boundaries.

FIG. 1 FATIGUE OF 95PB-5SN SOLDER IN TORSION AT 25 °C. SOURCE: REF 10

Indalloy 151 (92.5Pb-5Sn-2.5Ag) tested in shear in the 0.5 to 3% plastic shear range at 35 °C was found to obey approximately the Coffin-Manson relationship (Fig. 2) (Ref 8). However, the exponent  $\beta$  was found to be higher than 0.5; the actual value for  $\beta$  varied from 0.68 to 0.95, depending on fatigue life definition. The fractured surfaces were relatively featureless examples of ductile failure. Very shallow holes as well as occasional perpendicular cracks were observed.

FIG. 2 FATIGUE OF IN151 (92.5PB-5SN-2.5AG) SOLDER IN SHEAR AT 35 °C. SOURCE: REF 18

Solders have low melting points, and room temperature is close to or above  $0.5 T_m$ . The Coffin-Manson relationship is not expected to describe the fatigue data for solders even at room temperature because deviation from the Coffin-Manson relationship at low strain ranges (below 1%) is found for many steels fatigued at high temperatures (Ref 28). Indeed, it is evident that the data for 96.5Pb-3.5Sn solder (Fig. 3) (Ref 11) tested at low strain ranges in tension-tension cannot be well fit to a single log-log straight line. The data are much better represented by two straight lines with a breakpoint at approximately 0.3% plastic strain. The break in the lines in the Coffin-Manson plot has been attributed to the change in the fracture mode from intergranular at low strains to mixed transgranular-intergranular at high strains (Ref 11). In part, the deviation from the Coffin-Manson plot for this solder at low strain ranges can be attributed to environmental reactions, namely oxidation (Ref 29, 30).

FIG. 3 FATIGUE OF 96.5PB-3.5SN SOLDER IN TENSION AT 25 °C. RAMP TIME ( $T_R$ ) IS 0.1 TO 2.5 S. SOURCE: REF 11

The Coffin-Manson relationship was found to be valid for 60Sn-40Pb solder (Ref 5, 6, 18) tested in shear in the high 1 to 10% plastic strain range at 35 and 150 °C at a frequency of 0.3 Hz. The slope  $\beta$  was approximately 0.5 at temperatures below 150 °C and decreased to 0.37 at 150 °C. An intergranular mode of failure was observed. Practically no deviation from the Coffin-Manson relationship was detected for 60Sn-40Pb solder tested in 0.5 to 10% shear strain range (Ref 31). However, the choice of failure criterion significantly influenced the slope of the Coffin-Manson plot. No deviation from Coffin-Manson relation was found for 60Sn-40Pb in tests of lap joints without hold time under strain as well as under load control (Fig. 4) (Ref 32).

FIG. 4 FATIGUE OF 60SN-40PB SOLDER IN SHEAR AT 25 °C. SOURCE: REF 32

The importance of the testing procedure (compliance of the testing system, in particular) on the solder fatigue results was demonstrated during fatigue studies of 63Sn-37Pb solder (Ref 33) (Fig. 5). The solder was tested under strain and stroke controls. For the same total strain range, the fatigue life was an order of magnitude longer in stroke-controlled tests (a more compliant system) than in strain-controlled tests (stiffer system).

**FIG. 5 FATIGUE OF 63SN-37PB SOLDER IN SHEAR AT 25 °C. STRESS RATIO (R) IS -1; FREQUENCY IS 0.1 HZ. SOURCE: REF 33**

62Sn-36Pb-2Ag solder that was tested in tension-tension isothermal fatigue over 0.3 to 3.0% total strain range did not obey the Coffin-Manson relationship at low strain ranges (Ref 34). The data for this solder (bulk specimens) are plotted in Fig. 6 together with the results of tests for 60Sn-40Pb solder (small solder joints) performed under plastic shear strain control (Ref 5). To compare the fatigue data obtained in tensile fatigue test to data obtained in shear fatigue tests, the equivalent von Mises strain ( $\epsilon_{VM}$ ) is used. The same definition of failure must be used. Tensile strain ( $\epsilon_{tens}$ ) is equivalent to von Mises strain. Shear strain ( $\gamma$ ) relates to von Mises strain as follows:

$$\gamma = \sqrt{3}\epsilon_{VM} \quad (\text{EQ 2})$$

or:

$$\epsilon_{TENS} = \sqrt{1/3}\gamma = 0.577\gamma \quad (\text{EQ 3})$$

This figure is very important because it shows that bulk and solder joint specimens of very different geometry and tested in different loading modes can give comparable results.

**FIG. 6** FATIGUE ON 62SN-36PB-2AG, 97SN-3AG, 91SN-9ZN (BULK, TENSION, TOTAL STRAIN CONTROL), AND 60SN-40PB (SMALL SPECIMEN, SHEAR, PLASTIC STRAIN CONTROL) SOLDERS. SOURCE: REF 17

As already discussed, for low-cycle, high-stress conditions, inelastic deformation is dominant, and a plastic-strain criterion (the Coffin-Manson relationship) is used. However, use of only plastic strain as a failure criterion may not be sufficient for a reliable assessment of solders. A more accurate failure criterion is needed to combine the effects of both stress and strain. A hysteresis-energy criterion of fatigue failure appears to be a very good choice in solder-fatigue research. The hysteresis energy is a scalar quantity and has a cumulative effect.

The fundamental hypothesis in deriving the energy-based failure criterion is that, under cycling of stress and strain, fatigue damage is proportional to the change in the internal strain energy. A change in the internal strain energy is assumed to be reflected in the hysteresis stress-strain curve.

A damage function that includes stress as well as inelastic strain range was proposed as the basic measure of low-cycle fatigue damage at elevated temperature (Ref 35). It is assumed that low-cycle fatigue is essentially a crack propagation process; therefore, only the tensile part of the cycle is considered. In general, a damage function of the form  $\sigma_{\max} \epsilon_p$  or  $\tau_{\max} \gamma_p$  is considered to be a sufficiently accurate approximation of the proposed measure of fatigue damage. This damage function replaced the plastic strain in the Coffin-Manson and frequency-modified Coffin-Manson relationships. A good correlation between the number of cycles to failure and the damage function was found for steels and nickel-base superalloys tested at elevated temperatures (Ref 35).

Plastic hysteresis energy per cycle is assumed to be proportional to the damage function of the form:

$$D = \sigma_{\text{MAX}} \epsilon_p \text{ OR } D = \tau_{\text{MAX}} \gamma_p \quad (\text{EQ 4})$$

where  $\sigma_{\max}$  and  $\tau_{\max}$  are the maximum tensile and shear stresses, respectively, and  $\epsilon_p$  and  $\gamma_p$  are plastic tensile and shear strains, respectively.

The relationship between the fatigue life and the damage per cycle (damage function) for 60Sn-40Pb and 62Sn-36Pb-2Ag solders is depicted in Fig. 7 (Ref 36, 37). It is obvious that the data points for these solders are much closer than in the case where the von Mises plastic-strain criterion is used (Fig. 4). Similarly, the energy-based criteria were shown to describe the fatigue properties of solder joints better than the Coffin-Manson relationship (Ref 38).

**FIG. 7 FATIGUE OF 62SN-36PB-2AG, 97SN-3AG, 91SN-9ZN (BULK, TENSION, TOTAL STRAIN CONTROL), AND 60SN-40PB SMALL SPECIMEN, SHEAR, PLASTIC STRAIN CONTROL) SOLDERS AT 25 °C. SOURCE: REF 17**

Separation of the lead-rich and tin-rich phases and cracking through the tin-rich matrix were found to be the main modes of fracture in near-eutectic solders (Ref 8, 9, 14, 39). Failure of near-eutectic fine-grain solders under high-strain-range conditions was found to proceed through a coarsening mechanism. The solder coarsened first, and then cracks formed and propagated in the coarsened region (Ref 7, 8, 9). Practically no coarsening of solder is observed at low strain ranges (Ref 14, 39), and in coarse-grain solder at higher strains (Ref 5, 6).

The fatigue data for 97Sn-3Ag and 91Sn-9Zn bulk solders (tension, total strain control) (Ref 16, 17) are compared with the data for bulk 62Sn-36Pb-2Ag (tension, total strain control) and 60Sn-40Pb simulated solder joint specimens (shear, plastic strain control) (Ref 5, 6). Figure 6 uses the equivalent von Mises strain ( $\epsilon_{VM}$ ). It is evident that fatigue life of tin-silver and tin-zinc solders is longer than that of near-eutectic solders at the same plastic strain range. In Fig. 7, fatigue data are plotted versus the damage function. It is obvious that the data points for all solders are practically on the same line; that is, damage criterion brings the data points closer than the plastic-strain-range criterion. The reason for this is the fact that the damage function considers not only strain, but also stress. This figure shows that bulk and solder-joint specimens of different compositions, sizes, geometries, and fatigued in different loading modes can give very close results.

**Effect of Frequency on the Fatigue Life (No Hold in the Cycle).** At temperatures well below one-half of the absolute melting point, frequency has little effect on the fatigue life of most metals. When the temperature is increased over half of the absolute melting point, a reduction in frequency decreases the number of cycles to failure in isothermal fatigue for many metals including solders (Ref 5, 6, 11, 12, 13, 14, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58). This behavior arises because at high temperatures, processes such as creep, void formation, and environmental attack, which are time dependent, play important roles in damage accumulation.

J.F. Eckel (Ref 40) found during studies of the fatigue behavior of lead in a rotating bend test that at the strain ranges of 0.27 to 0.65% there was a marked influence of frequency on fatigue life. The time to failure,  $t_f$ , and the number of cycles to failure were related to frequency,  $f$ , by the following empirical relations:

$$T_F = BF^{-M} \quad (\text{EQ 5})$$

$$N_F = BF^{1-M} \quad (\text{EQ 6})$$

where  $b$  and  $m$  are constants. The frequency exponent  $m$  for lead in these tests was found to be equal to 0.7 at 43 °C at all strains tested (Ref 40).

A combination of the Coffin-Manson relationship (Eq 1) and Eckel's Eq 6 led to the frequency-modified Coffin-Manson relation of the form:

$$N_f^b \epsilon_P F^{1-M} = C \quad (\text{EQ 7})$$

Equations 5 and 6 were found to be valid for chemical grade lead and lead with 1% Sb (Ref 49) tested at room temperature in reverse bending (zero mean strain) in the strain range from 0.1 to 1.0%. However, the value of  $m$  was found to depend on the strain range and to vary from 0.4 to 0.8. The effect of frequency on fatigue life was found to be stronger at high strains. It was also observed that the stiffer the lead alloy the less its fatigue life was affected by the variation in frequency.

The number of cycles to failure for 60Sn-40Pb solder systematically tested in shear at 35 and 150 °C was reduced substantially when the frequency of cycling was decreased below approximately  $3 \times 10^{-4}$  Hz at 35 °C and  $3 \times 10^{-3}$  at 150 °C (Ref 5, 6). The frequency constant was 0.42 for frequencies below  $3 \times 10^{-4}$  Hz in tests with plastic shear strain of 10% at 35 °C (Fig. 8). At frequencies above the  $3 \times 10^{-4}$  Hz, the decrease in the number of cycles to failure with increasing time per cycle was less significant (the frequency exponent was 0.84).

**FIG. 8 EFFECT OF CYCLE FREQUENCY ON FATIGUE LIFE OF 60SN-40PB SOLDER AT 35 °C. PLASTIC SHEAR STRAIN ( $\Delta\gamma_p$ ) ~10%. SOURCE: REF 6**

The effect of frequency on fatigue life of 95Pb-5Sn solder was evaluated in bending tests ranging from 0.033 to 192 s/cycle and in strain ranges from 0.5 to 4.0% (Ref 15). Eckel's relations (Eq 6 and 7) were found to be valid with a frequency exponent  $m$  equal to 0.75 at all strains tested.

For 96.5Pb-3.5Sn solder, practically no change in the number of cycles to failure was observed on varying frequency in the comparatively high frequency region (Ref 11, 12). A reduction in the number of cycles to failure with decreasing frequency below  $10^{-2}$  Hz was found at 25, 50, and 80 °C (Fig. 9) for all strain ranges tested. The behavior of this solder obeys the general trends found by Eckel.

FIG. 9 EFFECT OF CYCLE FREQUENCY ON FATIGUE LIFE OF 96.5PB-3.SN SOLDER. TOTAL STRAIN RANGE ( $\Delta\epsilon_T$ ) IS 0.60%. SOURCE: REF 11

Lowering the cycle frequency below 0.1 Hz at 35 °C and below 0.01 Hz at 150 °C reduced the number of cycles to failure of 92.5Pb-5Sn-2.5Ag solder (Ref 18). The frequency exponents were approximately 0.75 at 150 °C and 0.61 at 35 °C.

The effect of frequency on fatigue life of tin-zinc and tin-silver appears to be less significant than for tin-lead near-eutectic solders (Fig. 10) (Ref 16, 17).

FIG. 10 EFFECT OF CYCLE FREQUENCY ON FATIGUE LIFE OF 62SN-36PB-2AG, 97SN-3AG AND 91SN-9ZN SOLDERS AT 25 °C, NO HOLD. TOTAL STRAIN RANGE ( $\Delta\epsilon_T$ ) IS 1%. SOURCE: REF 17

**Effect of Hold Time on Fatigue Life.** Hold (dwell) times introduced in the cycle at maximum and/or minimum strains, stresses, or temperatures affect the fatigue life of materials depending on the kind of material and testing conditions.

Tensile hold time is very damaging during high-temperature fatigue of many materials such as steels (Ref 43, 51, 52, 53, 54, 55), other metal alloys (Ref 47, 53, 56, 57), and solders (Ref 11, 12, 13, 14, 16, 17, 39, 58, 59, 60). The number of cycles to failure decreases when tensile hold time is increased. A saturation in the number of cycles to failure with increasing hold time is detected for a number of metals.

Often the reduction in fatigue life of metals due to tensile hold is accompanied by a transition from the transgranular to the intergranular mode of fracture. Cavitation on grain boundaries is observed. Therefore, the effect of tensile hold time on fatigue life is attributed mainly to creep (cavitation) (Ref 46, 47, 48, 61, 62).

Hold time at maximum strain has a similar dramatic effect on the number of cycles to failure of low-tin tin lead, tin-lead near-eutectic, and tin-zinc and tin-silver eutectic solders (Ref 11, 12, 13, 14, 16, 17, 39) (Fig. 11, 12): A few minutes of hold time reduce the number of cycles to failure by almost an order of magnitude, and further increases in hold time eventually lead to saturation in number of cycles to failure.

FIG. 11 EFFECT OF TENSILE HOLD TIME ON FATIGUE LIFE OF 96.5PB-3.5SN SOLDER AT 25 °C. RAMP TIME ( $T_R$ ) IS 2.5 S. STRAIN RANGE ( $\Delta\epsilon$ ) IS 0.75%. SOURCE: REF 11

**FIG. 12 EFFECT OF TENSILE HOLD TIME ON FATIGUE LIFE OF 62SN-36PB-2AG, 97SN-3AG AND 91SN-9ZN SOLDERS. RAMP TIME ( $T_R$ ) IS 1 S. TOTAL STRAIN IS 1%. SOURCE: REF 17**

The saturation in the number of cycles to failure with increasing tensile hold time per cycle may be explained either by exhaustion of creep processes or saturation of environmental attack during holds.

Tests performed for low-tin lead-base solder in air and vacuum (Ref 29, 30) at 0.80% total strain range indicate that only some of the fatigue life reduction with increasing tensile hold time can be attributed to environmental attack. The number of cycles to failure saturated in vacuum as it did in air. However, the fatigue life in vacuum was found to be only slightly greater than in air (Fig. 13). Therefore, most of the damage during fatigue with hold time at this strain range has to be attributed to creep and probably to the formation and growth of voids on grain boundaries. Voids were found on grain boundaries during fatigue of 98Pb-2Sn (Ref 63) and 97.5Pb-3.5Sn (Ref 29) solders.

**FIG. 13 EFFECT OF TENSILE HOLD TIME ON FATIGUE LIFE OF 96.5PB-3.5SN SOLDER IN AIR AND VACUUM AT ROOM TEMPERATURE. SOURCE: REF 29**

When the effects of ramp time with no holds in the cycle and effect of tensile hold time on fatigue life of solders are compared, it becomes obvious that the effect of tensile hold time on fatigue life of solders is much more dramatic than the effect of ramp time (Fig. 14, 15) (Ref 34). The difference in the effects of ramp time and hold time on solder fatigue life was attributed to differences in strain rates operating in solder during ramp and hold time. Strain rates during very short hold times are much less (by an order [s] of magnitude) than strain rates during even very long ramp times (Ref 64). Because the fatigue failure micromechanisms for solders are very sensitive to strain rates, the effects of hold time and ramp times on fatigue of solders are dramatically different.

FIG. 14 EFFECT OF RAMP TIME ON FATIGUE LIFE OF 62SN-36PB-2AG SOLDER IN TESTS WITH AND WITHOUT TENSILE HOLD TIME ( $T_{HT}$ ) (AT 25 °C; NO COMPRESSIVE HOLD TIME). SOURCE: REF 34

FIG. 15 EFFECT OF TENSILE HOLD TIME ON FATIGUE LIFE OF 62SN-36PB-2AG SOLDER IN TESTS WITH DIFFERENT RAMP TIMES ( $T_r$ ) AT 25 °C; NO COMPRESSIVE HOLD TIME). TOTAL STRAIN RANGE IS 1%. SOURCE: REF 34

Isothermal fatigue life of 60Sn-40Pb solder in tests with equal tensile and compressive hold times in the cycle was found to be unaffected by such combinations of hold times (Fig. 8) (Ref 6, 65). For 62Sn-36Pb-2Ag solder, addition of compressive hold time to a cycle with tensile hold time increased the number of cycles to failure (Fig. 16) (Ref 34).

**FIG. 16** EFFECT OF COMPRESSIVE HOLD TIME ON FATIGUE LIFE OF 62SN-36PB-2AG SOLDER IN TESTS WITH AND WITHOUT TENSILE HOLD TIME ( $T_{HT}$ ) AT 25 °C. TOTAL STRAIN RANGE IS 1%. RAMP TIME ( $T_R$ ) IS 1S. SOURCE: REF 34

Combination of both tensile and compressive hold times during testing of 96.5Sn-3.5Pb solder in air was found to be more damaging than tensile or compressive hold times separately (Fig. 17) (Ref 11).

**FIG. 17** EFFECT OF TENSILE HOLD TIME ( $T_{HT}$ ) AND COMPRESSIVE HOLD TIMES ( $T_{HC}$ ) ON FATIGUE LIFE OF 96.5PB-3.5SN SOLDER AT 25 °C. RAMP TIME ( $T_R$ ) IS 2.5 S. TOTAL STRAIN RANGE ( $\Delta\varepsilon_T$ ) IS 0.75%. SOURCE: REF 11

It is obvious that the effect of hold time is very profound during fatigue of solders. Effects of different hold times on the fatigue life of solders depend on the type of solders and on testing procedures; thus, this should be considered carefully during estimations of fatigue lives of solders.

**Effect of Temperature on Isothermal Fatigue of Solders.** As a rule, the isothermal fatigue life of metals decreases as temperature increases. However, the degree of fatigue life change depends on the material and testing conditions. For near-eutectic tin-lead solders, such as 63Sn-37Pb in the 25 to 80 °C range (Ref 14, 39, 66) and 60Sn-40Pb in 35 to 150 °C range (Ref 5, 6) and the -60 to 150 °C (Ref 10) temperature ranges, the effect of temperature was insignificant for all strain ranges and modes of loading investigated.

The effect of temperature on fatigue of low-tin tin-lead solders is much more pronounced than for near-eutectic tin-lead solders. The fatigue life of 95Pb-5Sn solder at strains lower than 1.0% was found to be much shorter at 150 °C than at room temperature or -60 °C (Ref 9).

The fatigue life of 95Pb-5Sn solder was shown to decrease when temperature was increased from room temperature to 120 °C and to be practically the same at 120 and 150 °C (Ref 15).

Fatigue life of 96.5Pb-3.5Sn solder at 80 °C was found to be almost the same as at 100 °C (Ref 11, 12, 66). The fatigue life of this solder was found to be the shortest at these temperatures. The solder fatigue life dependence on temperature appears to follow an Arrhenius-type equation only between 25 and 80 °C.

The effect of temperature on fatigue life of this low-tin tin-lead solder is a function of frequency: the change in the number of cycles to failure with temperature at a frequency less than 0.01 Hz is less than that at higher frequency. This converts to an apparent activation energy of 24 to 26 kJ/mole at low frequency and 40.6 kJ/mole at high-frequency testing conditions.

The temperature effect on fatigue life of low-tin lead-base solder also is different in tests with hold time and without hold time. The effective activation energies are 24 kJ/mole and 40 kJ/mole, respectively (Ref 11, 66). Thus, fatigue of low-tin tin-lead solder under low-strain-rate conditions (long ramp time and/or hold time in the cycle) is characterized by low activation energy. Different effective activation energies result from different failure mechanisms under different testing conditions.

**Aging Effects in Solders.** Solders are multiphase low-temperature melting materials, where the solubility in each phase decreases with a decrease in temperature. Precipitation of the second phase out of solid solution and phase coarsening occur at room temperature after the solder joint is solidified. Such precipitation affects the mechanical and fatigue properties of solders. The effect of aging on solder behavior was found to be a function of composition and initial microstructure of the solder.

Room-temperature aging increases the tensile strength of comparatively coarse low-tin tin-lead solder (Fig. 18) (Ref 11) and affects the fatigue life of coarse 63Sn-37Pb solder (Fig. 19, Ref 39), but the effect saturates after approximately one week of aging.

**FIG. 18** EFFECT OF AGING ON TENSILE PROPERTIES OF 96.5PB-3.5SN SOLDER AT 25 °C. STRAIN RATE IS  $1.7 \times 10^{-3} \text{ S}^{-1}$ . SOURCE: REF 11

**FIG. 19 EFFECT OF AGING (AFTER 2 H AT 150 °C) ON FATIGUE LIFE OF 63SN-37PB SOLDER AT 25 °C. TOTAL STRAIN IS 0.65%. RAMP TIME IS 1 S. SOURCE: REF 39**

The cooling (fast or slow) during solder solidification affects the initial microstructure of 60Sn-40Pb solder. The fine microstructure of rapidly cooled solders leads to higher initial strength (Fig. 20, Ref 67, 68). However, room-temperature aging leads to coarsened microstructures in both fine and coarse solders, and after 100 days the slow-cooled solder was the less coarsened of the two. The shear strength of both solders was reduced to almost the same level. Fatigue resistance of this solder was found to gradually decrease with time. The main conclusion from this work (Ref 68) was that aging may neutralize the effects of initial microstructure on mechanical properties of solders.

**FIG. 20 EFFECT OF COOLING RATE AND AGING ON SHEAR STRENGTH OF 60SN-40PB SOLDER. SOURCE: REF 67**

In order to carry out a systematic study of fatigue properties of solders, the microstructure must be standardized or varied in a controlled manner. Researchers frequently do not give the treatment schedules followed, and this leads to ambiguity when comparing results between studies.

**Environmental Effects in Solder Fatigue.** The environment affects the fatigue lives of many materials including lead (Ref 51) and solders (Ref 29, 30). A critical partial pressure for oxygen ( $10^{-2}$  torr) was found below which the fatigue life of lead was greatly increased (Ref 69). At the same time, the failure mode was changed from intergranular at higher partial pressure to transgranular at lower partial pressure of oxygen.

Fatigue life of metals in vacuum is usually higher than in air. However, the difference between the fatigue lives in air and in vacuum for a given material is a function of strain range and strain rate; the higher the strain range and the higher the strain rate, the smaller the effect of an aggressive environment (Ref 29, 30, 70). For both high-lead (Fig. 21) and tin-lead eutectics, fatigue lives in air and vacuum are practically the same at strain ranges greater than 1%.

**FIG. 21 FATIGUE LIFE OF 90PB-10SN SOLDER IN AIR AND VACUUM. STRESS RATIO ( $R$ ) IS -1; FREQUENCY ( $N$ ) IS 0.1 HZ. ( $\gamma$ ) IS 300 K. SOURCE: REF 70**

At lower strains, fatigue life of high-lead tin-lead solder is different in air and in vacuum (Fig. 22) (Ref 29, 30): The behavior of this solder does not follow the Coffin-Manson relationship in vacuum or in air (Ref 11, 12, 13). However, the deviation from the Coffin-Manson relationship is less in vacuum; thus, only part of the deviation in air is due to environmental attack. The increase in fatigue life of solder in vacuum over that in air and the less frequent intergranular failure observed in 96.5Pb-3.5Sn solder in vacuum indicate that the intergranular mode of failure is accelerated by air, presumably due to oxidation at grain boundaries.

## Solder Joint Reliability

Solder joints are known as one of the weakest elements of electronic assemblies. Throughout the years, a significant effort has been made to develop specifications and procedures to control solder joint quality. The principal assumption is that the standard reliability test should mimic the electronic device on/off cycles in an accelerated manner. Among the most common stress tests is an accelerated thermal cycling (ATC) test. Test vehicles or functional parts are placed in a thermal chamber and tested long enough to generate meaningful statistical results that can be used for reliability assessment of assemblies. Although the ATC test is referred to as accelerated, it takes several weeks before solder joints start failing, and much more time to make some statistical sense of the data. Therefore, some engineers tend to shorten the evaluation process and even further accelerate it without a complete understanding of the test limitations. This can lead to confusing reliability data, faulty quality assessments, and erroneous business decisions. It is not surprising that the electronic industry is looking for alternative test techniques that both accurately predict product quality and shorten the verification process. Unfortunately, thermomechanical cycling can not be accelerated above the limits that are imposed by thermal mass of the tested product. Therefore, the most encouraging option is to develop an isothermal mechanical test that would replicate the ATC joint failures in a much faster manner.

**Solder Joint Reliability Assessment Using Isothermal Fatigue Testing.** From experimental data, metallurgical observations, and elements of a micromechanically based theory of the behavior of solder materials developed by the authors, the traditional ATC test used may possibly be replaced with the much faster and more controllable isothermal mechanical deflection system (MDS) test in the future. The MDS test does have some limitations. It is valid only if the MDS fracture mechanisms match the expected field failure mechanisms. The experimental data and the theoretical investigations reviewed in this article show that the ATC and MDS mechanisms can closely approximate each other for testing component durability.

The mechanical deflection system (MDS) test is an isothermal test where cyclic out-of-plane deformation is imposed on an assembled printed wiring board at isothermal conditions with the temperature usually set above the ambient condition (Ref 1). A portion of the applied deformation is transferred to the solder joints and causes the joints to fail. Proper

selection of the deformation, test temperature, and cyclic frequency promotes the creep/fatigue failure mechanisms that are typical at field or the ATC test environment. Extensive research has demonstrated that MDS failure mechanisms match quite well the ATC mechanisms while reducing test time up to two orders of magnitude.

The most powerful applications of the MDS test are in the area of an assembly process optimization. It can also be used for design verification and reliability projection or as a near-real-time assembly line monitor.

The MDS test was verified for several technologies, among them J-leaded and gull-wing interconnects, ball and column grid array, and other surface mount interconnects. Usually, the MDS test is capable of failing nearly all the monitored solder joints during the test with a test time of hours instead of weeks or months. The test sensitivity in detecting defective joints is greater than under the ATC test conditions. Mechanical deflection system testing, when compared with thermal cycling, imposes a greater magnitude of axial deformation to the solder joints, and therefore the fully developed cracks in solder joints produce an electrical open condition in the monitored circuit. Assemblies subjected to thermal stress conditions require very accurate resistance measurements (usually four-point measurements) to detect failed solder joints. Furthermore, the MDS test conditions are precisely controlled. This includes both the out-of-plane deformation and the constant-temperature test environment.

**Examples of MDS Testing.** Mechanical deflection system testing has proved itself as an excellent technique for optimization of assembly processes. The test sensitivity in detecting defects as well as a very short test time make MDS the best, or perhaps, the only candidate for this application. Four test cases will be presented here to illustrate the MDS test capabilities. First, the ceramic ball grid array (CBGA) technology developed by IBM was tested to correlate MDS and ATC fatigue data. Second, thirty-two-leaded thin small outline package (TSOP) technology was tested to optimize the rework process of removing and reassembling new packages. Next, ceramic quad flat package (CQFP) and IBM-developed fine-pitch technology were tested to optimize assembly process windows. In the last example, MDS testing was used to optimize assembly process parameters to ensure good quality of plastic and ceramic ball grid array packages.

**MDS versus ATC Comparison for CBGA Packages.** The goal of the evaluation was to verify the MDS-induced joint failures when compared with the ATC failures and to correlate the MDS and ATC failure distributions for CBGA packages. For a true comparison, MDS and ATC tests were conducted concurrently using identical test vehicles and assembly processes. The CBGA solder joints were composed of a high-lead ball (90Pb-10Sn) attached by eutectic tin-lead solder to the substrate and the card pads. In all the MDS and ATC test cases, the fatal cracks propagated near the copper-tin intermetallic layer or along the interface of the high-lead ball and eutectic solders. First, thermal cycling was conducted at near-field low-stress conditions, where the temperature cycling was set between 20 and 55 °C at a frequency of 0.001 Hz. This test was very time consuming, taking more than six months to generate first failure. The number of modules on test was insufficient to draw statistically valid conclusions. Therefore, the next cell of CBGA modules was ATC tested at a higher stress level to accelerate the damage process of the joints while preserving the same failure mechanism. This time, the temperature cycling was set between 20 and 80 °C with a frequency of 0.0005 Hz.

On the other hand, the MDS test was conducted at ambient temperature, two opposite edges of the board were twisted against each other with the magnitude of 0.6 degrees/in. of the board length, and the frequency of cycling was 0.1 Hz. When comparing the MDS and ATC failure mechanisms, both the mechanisms are very similar. Mean fatigue lives are not the same, but can be brought to the same values when needed (Fig. 23).

FIG. 23 LOG NORMAL PROBABILITY PLOTS OF SOLDER BALL FAILURES IN MDS AND ATC TESTS. SOURCE: REF 1

The MDS and ATC tests generated very similar results, but were accomplished in different time frames. The MDS test needed only 16 h for all the modules to fail, while the ATC test took nine weeks to bring 50% of the modules to failure.

**MDS Rework Process Assessment for TSOPs.** Forty TSOP modules were tested to evaluate rework process. The rework process consisted of removing previously assembled components and replacing them with new ones. Also, the evaluation was designed to compare two types of TSOPs, standard TSOPs with short leads and TSOPs with longer and more compliant leads. The MDS- and ATC-induced failure mechanisms were found to be similar, with a more significant grain coarsening in the ATC cell. In both cases, cracks initiated in the joint hill and propagated near the lead/solder interface. Mechanical deflection system testing was conducted at ambient temperature. Out-of-plane deformation was cyclically applied to the test vehicle with the angle of twist equal to 0.9 degrees/in. of the card length at frequency of 0.1 Hz. The statistical distributions of failures are presented in Fig. 24.

FIG. 24 LOG NORMAL PROBABILITY PLOTS FOR TSOP JOINT FAILURES. TEST CASES: REWORKED STANDARD

The rework process was not optimized at the time the test was conducted. There was a significant population of early failures, but also the very same process produced very good joints (note the upper tail of the distribution). Based on the data, it was quite easy to optimize the process against the best-performing population of joints. Note that the standard ATC test, being very lengthy in time, would expose only the defective joints, and therefore the rework process would be improved but not truly optimized by eliminating the population of the worst-performing joints.

Also, the TSOPs that have the longer (more compliant) leads increased fatigue life by approximately two times when compared with the standard TSOPs.

**Assembly Process Optimization for CQFPs.** Fine-pitch technologies can exhibit excellent reliability, but require an optimized and tightly controlled assembly process. The CQFPs have very compliant leads that reduce the stress in solder joints. In some cases, the leads may even fail sooner than the joints, depending on the lead material, shape, and also on the test conditions. However, solder joints are still considered the prime reliability concern for these technologies. Because the isothermal MDS cycling is executed through a considerably compliant means (lead), this induces a creep-fatigue failure mechanism assisted with microstructural recovery processes that were discussed earlier. This phenomenon needs special consideration at higher frequency cycling (about 0.1 Hz) and becomes less important when allowing solder to creep by applying a few minutes dwell at the cycle reversals and/or elevating the test temperature. When taking all of the above under consideration, the MDS test conditions were set as follows: angle of twist was set at 0.75 degrees/in. of the board length; temperature was equal to 115 °C; cyclic frequency was set at 0.1 Hz. In this case, the temperature was set notably higher than in all the other test cases. The objective of the test was to optimize the assembly process for the best combination of the pad sizes and solder volumes. Six test cells were selected as shown in Table 1. The test results are presented using three quantities. In each test case, the first upper number represents the first failure in the test, the second number is the mean fatigue life, and the third is scattering of the fatigue data (sigma of log normal statistical plot). The mean life and sigma were determined from log normal probability plots (Fig. 25).

**TABLE 1 SUMMARY OF FATIGUE LIFE RESULTS FOR MDS TESTS**

PAD NO.	FATIGUE LIFE AND SCATTER <sup>(A)</sup> , CYCLES × 10 <sup>3</sup> , FOR SOLDER VOLUME			
	1	2	3	4
I	11.6 (FIRST FAILURE) 20.3 (MEAN) σ= 0.21	14.4 21.4 (MEAN) σ = 0.18		
II		14.0 22.0 (MEAN) σ = 0.19	9.0 15.2 (MEAN) σ = 0.19,	
III			<b>10.0</b> <b>19.9 (MEAN)</b> <b>σ = 0.24</b>	<b>1.8</b> <b>14.8 (MEAN)</b> <b>σ = 0.59</b>

(A) TOP VALUE FOR EACH PAD IS THE NUMBER OF CYCLES (× 10<sup>3</sup>) TO THE FIRST FAILURE. THE SECOND NUMBER IS THE MEAN FATIGUE LIFE WITH A LOGNORMAL FIT WITH STANDARD DEVIATION, σ.

**FIG. 25 MULTIPLE-SAMPLE LOG NORMAL PROBABILITY PLOTS OF SOLDER JOINTS IN MDS TEST OF CERAMIC QUAD FLAT PACKAGE. (A) PAD I; SOLDER VOLUMES 1 AND 2. (B) PAD II; SOLDER VOLUMES 2 AND 3. (C) PAD III, SOLDER VOLUMES 3 AND 4. SOURCE: REF 1**

First, the highest and medium solder volumes (1 and 2) were analyzed for the largest pad (I) (Fig. 25a). The two probability plots look almost identical. This indicates that there is no reliability exposure in either of the two cases. However, the highest volume (No. 1) caused some bridging of the solder between pads; therefore, the combination of the highest solder volume and largest pad is not acceptable (yield problem).

Next, test results for solder volumes 2 and 3 and medium pad (II) were analyzed and presented in Fig. 25(b). Both the plots have similar scattering of failures, but the joints assembled with the lower volume of solder (No. 3) exhibit lower mean fatigue life. The smallest pad (III) in combination with the two lowest volumes of solder (3 and 4) caused significant reliability problems (Fig. 25c). Much earlier failures were observed in these cells. The fatigue data show a bimodal statistical distribution of the failures. The main population of the failures seems to follow the previous results; however, the tail of the distributions indicates that the defective joints in the cell may cause field exposure.

**Assembly Process Optimization for Plastic and Ceramic Ball Grid Array Packages.** New technology deployment into volume manufacturing is often a serious concern. The cost of new technology development including the development of the infrastructure for timely introduction of a product is an extremely costly process. The costs are even higher when the expenses related to the lengthy assessments of the product reliability are added. However, the risk of not testing for reliability is even greater.

In the case of new technology deployment, it is imperative that one understand and recognize the product exposures. Assessment of pad geometry, pad metallurgy or finish, package selection, and solder metallurgy and therefore reflow process are all factors that play very important roles. When there is a choice, any user would like to know the reliability impact of the selection.

Mechanical deformation system testing was deemed the best approach for evaluating some of these factors in the selection of ball grid array (BGA) packaging technology. A study was conducted by a member team with interest in developing the infrastructure for the success of the BGA technology. The team consisted of an electronic systems manufacturer, a possible user of the technology, a supplier of BGA packaging technology, and a printed circuit board fabricator. Boards were fabricated to exercise the following parameters:

- PAD GEOMETRY
- PAD METALLURGY
- BALL GRID ARRAY PACKAGE TYPES

Specifically, the test conducted used pads that were "dog bone" or "flag," with either hot-air solder-leveling or bare copper with an organic coating over the copper pad. The two package types investigated included plastic as well as ceramic BGAs. The results of the study conducted by Ninohira, Yee, and Rao (Ref 71) for the team are summarized in Table 2.

**TABLE 2 FATIGUE TEST RESULTS OF DOG-BONE AND FLAG PADS OF PLASTIC AND CERAMIC BGA PACKAGES**

<b>SURFACE METALLURGY</b>	<b>PACKAGE TYPE</b>	<b>DOG-BONE MEAN CYCLES</b>	<b>DEVIATION (<math>\sigma</math>)</b>	<b>FLAG MEAN CYCLES</b>	<b>DEVIATION (<math>\sigma</math>)</b>
HASL	PBGA	16,806	0.35195	14,338	<b>0.38099</b>
HASL	CBGA	11,949	0.46592	15,491	<b>0.3056</b>
OCC	PBGA	17,904	0.26247	14,057	<b>0.43629</b>
<b>OCC</b>	<b>CBGA</b>	<b>9,318</b>	<b>0.48876</b>	<b>13,898</b>	<b>0.33654</b>

HASL, Hot air solder leveled; OCC, organic coating on copper

## Fracture and Fatigue of DRA Composites

John J. Lewandowski and Preet M. Singh, Case Western Reserve University

---

## Introduction

DISCONTINUOUSLY REINFORCED ALUMINUM (DRA) composites with SiC particulate (SiC<sub>p</sub>) or alumina particulate (Al<sub>2</sub>O<sub>3p</sub>) reinforcements are increasingly being considered for structural applications in the aerospace and automotive industries. The reinforcements have higher strength, higher elastic modulus, and lower Poisson ratio than the matrix alloy (Table 1). The use of metal-matrix composites in structural applications is attractive because of their exceptionally good stiffness-to-weight and strength-to-weight ratios, while processing may be conducted using casting, powder metallurgy, or in situ techniques. Secondary processing can significantly improve the strength and ductility of DRA materials (Ref 3, 4, 5), as shown in Fig. 1, which illustrates the effects of hot deformation processing (e.g., swaging) on the subsequent uniaxial tension properties of squeeze-cast A-356 DRA (Ref 5). Despite such improvements via hot deformation processing, the composites still possess lower ductility and toughness than unreinforced alloys. It is often these fracture-related properties that limit the further use of metal-matrix composites in fracture-critical applications.

**TABLE 1 ELASTIC PROPERTIES OF COMMONLY USED REINFORCEMENTS IN DRA MATERIALS**

MATERIAL	ELASTIC MODULUS, GPA	POISSON RATIO
SIC	400	0.14-0.17

FIG. 1 EFFECTS OF THE AMOUNT OF HOT WORK ON TENSILE PROPERTIES OF SQUEEZE-CAST COMPOSITES. SOURCE: REF 5

This article reviews the tensile properties and toughness characteristics of DRA composites in terms of particle spacing, particle size, volume fraction, matrix alloy, and matrix microstructure. Both fracture toughness data and impact toughness data are summarized. Where available, information on  $J_{Ic}$  and tearing modulus data for  $Al_2O_3$  and SiC-reinforced aluminum alloys are presented. Included in the discussion on tensile deformation are the effects of confining pressure on the ductility of such materials, as this data are relevant to the behavior of these materials under more complex stress states and also correlates with the formability of such materials. A brief summary of DRA fatigue resistance is also included.

## Uniaxial Tension Properties

Various authors have studied microstructure/mechanical property relationships for DRA composites (Ref 6, 7, 8, 9, 10, 11, 12, 13) and other composite materials (Ref 14, 15, 16). A simplistic rule of mixtures is often used to explain the trends in the elastic properties of the composites (Ref 14), whereas other, more precise models account for the size, shape, and distribution of particulates on the elastic properties (Ref 15, 16, 17, 18, 19, 20, 21, 22, 23, 24). Elastic modulus values in excess of 100 GPa are possible with reinforcement levels in excess of 20 vol% SiC<sub>p</sub>. It has been demonstrated that the use of finer-sized particulates increases the 0.2% offset yield strength (Ref 9, 12, 25, 26) and the work hardening rate, while reducing the level of damage via reinforcement fracture events during tensile straining, as discussed below.

**Particle-Associated Damage Accumulation during Tensile Straining.** Various investigators (Ref 6, 9, 10, 12, 13) have shown that reinforcement-related damage evolves during straining of DRA materials, and that the extent and type of damage depends on SiC<sub>p</sub> size, matrix heat treatment, strength, microstructure, and alloy type. Figures 2 and 3 show the effects of global plastic strain on the percentage and number of cracked SiC<sub>p</sub> on the gage surface of duplicate and triplicate MB78 (i.e., Al-7Zn-2Mg-2Cu powder metallurgy alloy) composite specimens in the underaged (UA), overaged (OA), and solution-annealed (SA) conditions, respectively. The percentage of cracked SiC<sub>p</sub> shown in Fig. 2 and 3 is the average of results from every selected area on each specimen, which comprises over 10,000 particles for each specimen at each strain. Included in all figures are the *absolute number* of cracked SiC<sub>p</sub> at each strain. The results, consistent with previous work (Ref 6, 9, 10, 12, 13, 27, 28, 29), clearly show that the number of cracked SiC<sub>p</sub> for each condition increases with an increase in applied global plastic strain,  $e_{gp}$ . Comparison of Fig. 2 and 3 shows that the total average numbers of SiC<sub>p</sub> cracked at the fracture strain for the 13  $\mu$ m OA and the 13  $\mu$ m SA specimens were far less than that obtained in the 13  $\mu$ m UA specimens. At very low strains (i.e., <1%) all specimens provided similar average values for cracked SiC<sub>p</sub>, while higher plastic strains produced greater differences between the SA specimens and either the UA or OA specimens. The 13  $\mu$ m UA specimens exhibited a slightly greater average amount of SiC<sub>p</sub> fracture at each strain in comparison to the 13  $\mu$ m OA specimens, in addition to a greater fracture strain.

FIG. 2 PERCENTAGE AND ABSOLUTE NUMBER OF CRACKED SiC<sub>p</sub> ON GRIDDED SPECIMEN SURFACE AS A FUNCTION OF THE APPLIED GLOBAL PLASTIC STRAIN FOR 13 MM UNDERAGED (UA) SPECIMENS. TRIPPLICATE SPECIMENS TESTED ON IDENTICAL MATERIALS. SOURCE: REF 12

**FIG. 3 PERCENTAGE AND NUMBER OF CRACKED SiC<sub>p</sub> ON GRIDDED SPECIMEN SURFACE AS A FUNCTION OF THE APPLIED GLOBAL PLASTIC STRAIN FOR 13 MM OVERAGED (OA) AND 13 MM SOLUTION-ANNEALED (SA) SPECIMENS. DUPLICATE SPECIMENS TESTED FOR OA AND SA MATERIAL. SOURCE: REF 12**

Figures 4, 5, and 6 show the distribution of cracked SiC<sub>p</sub> along the gage length at each strain for each heat treatment for MB78 material containing 13 μm SiC<sub>p</sub>. Both the percentage of cracked SiC<sub>p</sub> and the number of cracked SiC<sub>p</sub> at each location are plotted as a function of position along the specimen for each global strain. Integration of the number of cracked SiC<sub>p</sub> at each location and strain provided in Fig. 4, 5, and 6 will produce the total number of cracked SiC<sub>p</sub> on the specimen gage surface summarized in Fig. 2 and 3. Figures 4, 5, and 6 clearly show that both the percentage and absolute number of the cracked SiC<sub>p</sub> at each strain were not constant along the gage length, and that a low background level of cracked SiC<sub>p</sub> exists at 0% strain. However, for any given local area, the number of cracked particles increased with an increase in the global plastic strain,  $e_{gpl}$ , although the absolute numbers remained different for different areas of the specimens throughout the test.

FIG. 4 DISTRIBUTION OF THE LOCAL PERCENTAGE OF CRACKED  $SiC_p$  ALONG THE GAGE LENGTH OF AN MB78 + 15%  $SiC_p$  13 MM UNDERAGED TENSILE SPECIMEN. SOURCE: REF 12

FIG. 5 DISTRIBUTION OF THE LOCAL PERCENTAGE OF CRACKED  $SiC_p$  ALONG THE GAGE LENGTH OF AN MB78 + 15%  $SiC_p$  13 MM OVERAGED SPECIMEN. SOURCE: REF 12

**FIG. 6 DISTRIBUTION OF THE LOCAL PERCENTAGE OF CRACKED  $\text{SiC}_p$  ALONG THE GAGE LENGTH OF AN MB78 + 15%  $\text{SiC}_p$  13 MM SOLUTION-ANNEALED SPECIMEN. SOURCE: REF 12**

Metallographic examination showed that  $\text{SiC}_p$  with higher aspect ratios was preferentially aligned along the extrusion direction. Particles larger than the mean particle size and those with larger aspect ratios preferentially cracked in all heat treatments, consistent with previous reports (Ref 6, 8, 12, 29, 30, 31, 32). Figure 7 shows that large and elongated  $\text{SiC}_p$  are cracked in the 13  $\mu\text{m}$  UA specimen unloaded at 6.3%  $e_{\text{gpl}}$  and that there is no evidence of matrix failure.

**FIG. 7 MICROGRAPH SHOWING CRACKED  $\text{SiC}_p$  ON THE SURFACE OF A 13 MM UNDERAGED SPECIMEN AFTER ABOUT 6.3% GLOBAL PLASTIC STRAIN,  $E_{\text{GPL}}$ . SOURCE: REF 12**

In addition to  $\text{SiC}_p$  fracture, the 13  $\mu\text{m}$  OA material exhibited matrix cracks which were readily apparent at around 2.0%  $e_{\text{gpl}}$ . In contrast, only cracks in the  $\text{SiC}_p$  were apparent at 2.0%  $e_{\text{gpl}}$  in the 13  $\mu\text{m}$  UA material. Figure 8 shows some examples of the matrix cracks and cracks near the  $\text{SiC}_p$ /matrix interfaces that were present on the surface of the 13  $\mu\text{m}$  OA material strained to 3.5%  $e_{\text{gpl}}$ . In some cases, the matrix cracks appeared to be associated with grain boundary regions, as shown in Fig. 8. The 13  $\mu\text{m}$  SA specimen exhibited the minimum number of  $\text{SiC}_p$  cracked of all of the tested conditions, while Fig. 9 also shows examples of surface matrix cracks exhibited in a 13  $\mu\text{m}$  SA specimen after 9.9%  $e_{\text{gpl}}$ , which is near the fracture strain of the material. In contrast to the OA material, the matrix cracks in the SA material did not appear to be associated with grain boundary regions. The total fracture strain was similarly affected by heat treatment: the 13  $\mu\text{m}$  SA specimen fractured at 10%  $e_{\text{gpl}}$ , as compared to 4%  $e_{\text{gpl}}$  for the 13  $\mu\text{m}$  OA specimen and about 6%  $e_{\text{gpl}}$  for the 13  $\mu\text{m}$  UA specimen.

FIG. 9 MICROGRAPH SHOWING CRACKS IN SiC<sub>p</sub> AND IN THE MATRIX ON THE SURFACE OF A 13 MM SOLUTION-ANNEALED SPECIMEN AFTER ABOUT 9.9% GLOBAL PLASTIC STRAIN,  $E_{GPL}$ . SOURCE: REF 12

The unloading modulus and reloading modulus were measured on the interrupted tensile tests on the MB78 monolithic materials in the UA, OA, and SA conditions. There was no significant change in the modulus during unloading of the MB78 monolithic materials in any condition, strained to  $e_{gpl} = 10\%$ . In contrast, increases in  $e_{gpl}$  produced large decreases in the subsequent unloading and reloading elastic modulus of the MB78 DRA composites. This change in the elastic modulus was exhibited for each of the heat treatments, although to different extents. Figure 10 plots the ratio of the "measured" modulus at each strain,  $E$ , to the starting modulus,  $E_0$ , for each condition tested. A value of 1.0 for  $E/E_0$  indicates no change in modulus. The number of cracked SiC<sub>p</sub> increased with increasing strain in the MB78 DRA materials containing 13  $\mu\text{m}$  average size SiC<sub>p</sub>, as exhibited by Fig. 2, 3, 4, 5, and 6. In particular, the area near the location of catastrophic fracture showed a large increase in the number of cracked particles.

The unloading modulus and reloading modulus were measured on the interrupted tensile tests on the MB78 monolithic materials in the UA, OA, and SA conditions. There was no significant change in the modulus during unloading of the MB78 monolithic

FIG. 10 EFFECT OF GLOBAL PLASTIC STRAIN ON  $E/E_0$  FOR DIFFERENTLY HEAT-TREATED MB78 + 15% 13 MM SiC<sub>p</sub> DRA MATERIALS. SA, SOLUTION ANNEALED; UA, UNDERAGED; OA, OVERAGED. SOURCE: REF 12

Figures 11, 12, and 13 summarize results from the various studies (Ref 10, 12, 13) that have measured the evolution of particle-related damage on different DRA materials. Figure 11 shows the percentage of cracked SiC<sub>p</sub> as a function of the fracture strain in the respective specimens. Details of the matrix material, volume fraction and size of reinforcement, and heat treatment are available elsewhere (Ref 13). These results indicate that there is no correlation between fracture strain and the percentage of cracked SiC<sub>p</sub>. However, the data collected in Fig. 11, 12, 13, and combine various matrices and types of reinforcement. Figures 12 and 13 provide separate data on DRA materials with Al<sub>2</sub>O<sub>3</sub> and SiC reinforcements,

respectively. Again there is no direct correlation between the fracture strain and the percentage of cracked particles. These results agree with the results shown in Fig. 2 and 3, which reveal that the SA-MB78 DRA specimens had the highest strain to fracture but did not have the highest percentage of cracked particles at fracture. The results also indicate that the local stress/strain experienced by the reinforcement depends on the microstructural details of the DRA constituents (e.g., matrix composition and microstructure, reinforcement type, size, orientation, and matrix/reinforcement interface characteristics).

Figures 14, 15, and 16 show results taken from the same studies (Ref 10, 12, 13) where the percentage of cracked particulates is plotted versus the true stress at failure. In most cases, this stress was simply the ultimate tensile strength, because the failure strains were typically less than 5%. Figures 14 and 15 fail to reveal any correlation of applied true stress to the percentage of cracked particles, even for DRA materials of the same matrix and particle size. Thus, Fig. 11, 12, 13, 14, and 15 clearly show that both global strain-based models and global stress-based models are unable to explain particle damage or total damage without taking microstructural effects into account. Although global stress and strain are important parameters in damage evolution, as the amount of particle-related damage always increases with an increase in global stress or strain, the mechanism and extent of damage evolution is controlled by the microstructure and conditions that control local stress conditions.

It is clear from a review of Fig. 7, 8, and 9 and previous work (Ref 12) that other modes of damage apart from particle damage contribute to the changes in the elastic modulus or Poisson ratio (Ref 33) with increasing strain. Very little work (Ref 7, 33) has been carried out to monitor Poisson ratios with applied stress/strain, but some researchers have monitored changes in the elastic modulus with applied strain. Figure 17 summarizes data for elastic modulus changes from the work of various authors (Ref 10, 12, 13, 30, 34) and shows that the extent and path of overall damage are different for different DRA materials. The results indicate that different heat treatments can change the fracture mechanisms and extent of overall damage for nominally the same DRA material.

**Effects of Confining Pressure on Ductility and Damage Evolution in DRA Materials.** The deformation and fracture behavior under complex stress states is often accomplished via testing with superposed hydrostatic pressure. Initial work conducted on the effects of superposed pressure indicated that significant enhancements in ductility can be obtained in both particulate-reinforced (Ref 35, 36, 37, 38, 39) and whisker-reinforced (Ref 36) systems, although the magnitude of the pressure-induced ductility increase in both the monolithic and composite systems appears to be dependent on the nature of operative damage mechanisms (Ref 12, 35, 36, 37, 38). These early works also demonstrated that the flow stress of such materials can be pressure sensitive (Ref 25, 26). Initial work proposed that such pressure sensitivity is a result of the pressure-induced suppression of the damage (Ref 35, 36), while subsequent work showed that pressure-induced dislocation generation near the reinforcement/matrix interfaces is also partly responsible for local hardening around the particles (Ref 25).

Figures 18 and 19 are cumulative plots summarizing the effects of superposed pressure on the ductility (i.e., reduction in area) for a variety of metallic alloys and composites, respectively. Embury et al. (Ref 39) assessed the damage in the deformed and undeformed A356/SiC<sub>p</sub> system in the T6 condition with detailed metallographic studies and subsequent image analysis. Their examination of polished longitudinal sections revealed that the large plastic deformation accompanying the high ductility promoted by superposed pressure produces a change in SiC<sub>p</sub> distribution. Embury and coworkers (Ref 39) found a subsequent enhancement in ductility in both the unreinforced A356 and the A356 composite material under the influence of hydrostatic pressure, as indicated in Fig. 18 and 19. Work by Lewandowski et al. (Ref 12, 25, 35, 37) has similarly investigated the effects of superposed pressure on ductility and damage evolution in 2xxx, 7xxx, and 6061 aluminum alloys and composites in the UA and OA conditions. A significant pressure dependence on ductility was found for all of the composite systems and microstructures, as shown in Fig. 19. The unreinforced alloys also showed a dependence of ductility on pressure, with the exception of the 2xxx (Ref 35, 37) and 7xxx (Ref 41) materials tested in the UA condition. The unreinforced 2xxx and 7xxx materials deformed and failed in shear by the initiation and propagation of localized shear, which is not significantly affected by the levels of pressure used. These results are a clear indication that microstructural changes have a significant impact on the type of damage (i.e., shear, void nucleation, and growth) and that ductility depends on superposed hydrostatic pressure. The differences in the magnitude of ductility response to pressure of the remaining monolithic materials shown in Fig. 18 are also partly due to the different ratios of superposed pressure to

the flow stress of the matrix employed. Damage evolution in the monolithic materials was quantified in terms of the area fraction of voids (Ref 27) and was shown to decrease with increasing levels of superposed hydrostatic pressure, consistent with previous work (Ref 42, 43).

Considerable work on DRA materials has shown that damage may evolve via reinforcement fracture, failure of reinforcement/matrix interfaces, failure in the matrix, or a combination of the above (Ref 6, 12, 36). The superposition of hydrostatic pressure did not change the brittle nature of the reinforcement in such studies, although damage evolution was suppressed with increasing levels of confining pressure (Ref 12, 35, 36, 37, 38, 39). Singh and Lewandowski (Ref 12) conducted extensive metallographic and image analyses on longitudinal sections of samples fractured in tension with superposed pressure, 7xxx composites in the UA and OA conditions. Figures 20 and 21 show the percentage of cracked SiC versus the distance from the fracture surface in longitudinal sections taken in multiple specimens, tested at either 0.1 MPa or with superposed pressure. Despite the large increase in strain to failure with superposed pressure, a reduction in the amount of particle cracking was measured. Studies at 0.1 MPa additionally showed that the composite in the OA condition failed with a smaller amount of particle cracking than did the UA specimens, although considerable matrix damage and particle/matrix cavitation was obtained in the former. The effect of pressure was to inhibit all types of damage (i.e., matrix, particle/matrix interface, SiC<sub>p</sub> cracking). Recent work on AZ91 magnesium and AZ91 magnesium composites have revealed some similar features, as shown in Fig. 20 and 21, although the details are under investigation. Accompanying this suppression of damage was an elevation in the flow stress of the composites upon superposition of pressure (Ref 25, 36). Transmission electron microscopy of composites simply pressurized revealed that such elevation of initial flow stress was also partly caused by the pressure-induced generation of dislocations in the matrix adjacent to the reinforcement (Ref 25). Recent work on the mechanical behavior of 1100 Al/Al<sub>2</sub>O<sub>3</sub> composites containing either 10 or 15 vol% reinforcement also reveals an increase in the yield strength of this system upon testing under pressure.

## Fracture and Fatigue of DRA Composites

John J. Lewandowski and Preet M. Singh, Case Western Reserve University

---

### Toughness

**Toughness of DRA Systems.** To the extent possible, this section summarizes published data about the effects of systematic changes in reinforcement volume fraction, reinforcement size, and similar parameters on the resulting toughness of DRA. Figures 22 and 23 summarize the effects of reinforcement volume fraction on the fracture toughness of various DRA systems. The  $J_{Ic}$  data presented were collected from works where  $J_{Ic}$  testing was conducted as well as by converting some of the  $K_{Ic}$ ,  $K_Q$ , and  $K_{EE}$  data to  $J_{Ic}$  data via the relationship  $J = K^2(1 - \nu^2)/E$ . The data demonstrate the general loss in toughness with increasing volume fraction of reinforcement, up to a reinforcement level of 40 vol%, as well as the significant effects of matrix selection and matrix temper. Figures 22 and 23 include data for DRA based on various aluminum alloys, including 1100, 2xxx, 6xxx, 7xxx, 8xxx, and model Al-Si alloys containing brittle Si particles.

FIG. 22 COMPILATION OF FRACTURE TOUGHNESS DATA VS. VOLUME FRACTION OF REINFORCEMENT. REFERENCE 44 CONTAINS DATA SOURCES.

FIG. 23 COMPILATION OF  $J_{IC}$  DATA VS. VOLUME FRACTION OF REINFORCEMENT. SOME DATA WERE CONVERTED FROM  $K_{IC}$ ,  $K_Q$ , AND  $K_{EE}$  DATA. REFERENCE 44 CONTAINS DATA SOURCES.

The effects of matrix strength and heat treatment on the fracture toughness of both monolithic and DRA materials are more fully shown in Fig. 24, 25, and 26, which plot the fracture toughness versus yield strength and tensile strength. For a given alloy system, the changes in strength were obtained via heat treatment. In the unreinforced alloys, it has generally been observed that the toughness decreases with an increase in strength up to peak strength, and then the toughness recovers upon additional aging (Ref 31, 45, 46), as shown in Fig. 24. This has been demonstrated on a variety of 7xxx monolithic materials (Ref 31, 45, 46), as well as 6xxx and 2xxx (Ref 47) systems. In contrast, none of the composite systems appear to recover the toughness upon overaging, as shown in Fig. 25 and 26 for DRA materials based on 2xxx (Ref 48, 49), 6xxx (Ref 48, 50), or 7xxx (Ref 6, 8, 31) systems.

This lack of toughness recovery upon overaging has been attributed to a change in the mechanisms of fracture nucleation and growth in such systems (Ref 6, 8, 12, 48). In the 7xxx DRA system, analysis of sequentially strained tensile specimens has indicated that the mechanisms of damage accumulation are significantly affected by aging treatment (Ref 12). Underaged specimens exhibited a predominance of reinforcement fracture at all ranges of strain, while the overaged specimens exhibited matrix failure and failure near the reinforcement/matrix interfaces. The rate of damage accumulation, as monitored by the decay in elastic modulus, was also shown to occur at a faster rate in the overaged material (Ref 12). Analysis of fracture surface features of underaged and overaged DRA specimens has similarly revealed differences in the fracture morphologies between underaged and overaged specimens, also indicative of the effects of microstructure on the

operative damage mechanisms occurring ahead of a crack tip in such materials (Ref 6, 31, 48). In situ straining/observation of fracture evolution ahead of crack tips has similarly revealed an effect of matrix microstructure on the nature of crack propagation (Ref 6, 8).

Reinforcement size and aspect ratio have been considered. One of the more dramatic differences in behavior exists between whisker- and particle-reinforced materials. Whisker materials show substantially different strength and toughness behavior and exhibit greater strengthening, greater anisotropy, and lower toughness (Ref 51, 52). On a more limited scale, reinforcement particle size effects have been examined in powder metallurgy DRA materials. Recent experiments on x2080/SiC extrusions, which examined reinforcement particles of  $\sim 4 \mu\text{m}$  average size (Federation of European Producers and Abrasives [FEPA] grade F-1000),  $\sim 10 \mu\text{m}$  average size (FEPA grade F-600), and  $\sim 36 \mu\text{m}$  average size (FEPA grade F-280) at particle loadings of 10, 20, and 30 vol%, have proven that the toughness/yield strength relationship is not greatly affected by particle size (Fig. 27), while the toughness/tensile strength relationship (Fig. 28) favors the finer-particle materials (Ref 53). Such behavior is consistent with the higher work hardening and lower damage development rate (e.g., via particle cracking) (Ref 25) in the finer-particle materials. Recent work (Ref 12) has shown higher work hardening and less particle fracture in the finer-particle material.

FIG. 28 TOUGHNESS/TENSILE STRENGTH RELATIONSHIPS FOR X2080/SiC/XXP DRA MATERIALS

The Charpy impact toughness of aluminum alloys is similarly reduced via the introduction of discontinuous reinforcement. Figures 29 and 30 summarize recent data obtained on 2xxx, 6xxx, and 7xxx materials in the unnotched and notched conditions, respectively. Although the data are somewhat limited in comparison to the fracture toughness data presented in Fig. 22, 23, 24, 25, and 26, it again appears that there are both matrix alloy and matrix temper effects on the impact energy of the monolithic materials, while the impact toughness of the composites is generally low regardless of heat treatment.

**Crack Growth Resistance.** It is clear that the flaw tolerance of both monolithic materials and DRA materials is of critical importance in design. While a number of investigators have used the approach of Rice and Johnson (Ref 44, 54) to characterize the toughness of DRA materials, it has also been observed in fracture toughness tests on such materials that fracture often propagates catastrophically. Thus, the issue of crack growth resistance of such materials may also be relevant. While the above data reviewed for fracture toughness generally characterize the crack initiation resistance of such materials, it is also important to characterize the crack growth resistance of such materials. Of the various methods proposed to evaluate crack growth toughness of materials, the tearing modulus concept introduced by Paris et al. (Ref 55) has found widest acceptance. The tearing modulus parameter is a measure of the resistance of the material to tearing and an indication of the stability of crack growth. The tearing modulus, proportional as it is to  $dJ/da$ , is a measure of the strain energy that must be provided to the crack tip to enable it to advance by a unit crack length. Few investigations have measured both the crack initiation and crack growth resistance of both monolithic and DRA materials.

Figure 31 summarizes the available data on 6xxx and 7xxx systems as well as a model Al-Si alloy containing Si particles. The data again suggest a large effect of matrix alloy composition and heat treatment on the tearing modulus for the materials systems summarized. It is shown that reinforcement additions significantly reduce the crack growth resistance, while matrix aging to an overaged condition in the 7xxx material further reduces the crack growth resistance. In addition, the effects of matrix strength and ductility on the crack growth resistance are shown in the model Al-SiC materials, where aging to the T6 condition eliminates any tearing resistance compared to the T4 condition.

FIG. 31 TEARING MODULUS DATA FOR VARIOUS DRA SYSTEMS INCLUDING 6061/AL<sub>2</sub>O<sub>3</sub>, MB78/SiC, AND AL-SI-MG/SI. REFERENCE 44 CONTAINS DATA SOURCES.

**The Next Generation of DRA Composites for Improved Toughness.** Additional improvements to the strength/toughness combinations of DRA materials may be possible via improvements in both primary and secondary processing routes as well as judicious selection of matrices, reinforcement, and heat treatments (Ref 53, 56). Recent works (Ref 6, 44, 53, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72) have shown that extrinsic toughening approaches such as lamination, microstructural toughening, and ductile-phase toughening may increase toughness without sacrificing the strength/toughness combination or the enhanced stiffness. Recent reviews (Ref 44, 53, 56) have summarized some of the potential benefits and processing routes for such approaches.

## Fatigue Behavior

Discontinuously reinforced aluminum composites have complex fatigue behavior (Ref 73), which can be improved or degraded by the incorporation of reinforcement, depending on the loading mode and the type of fatigue test ( $S-N$ ,  $\epsilon-N$ , or crack growth). The general fatigue process is also complex. In composite materials, as in many unreinforced metals, factors that improve resistance to the initiation of a crack lead to a decrease in the resistance to the growth of a crack. An example of this is the influence of reinforcement on the fatigue behavior of aluminum alloys. In underaged aluminum alloys, reinforcement leads to an improvement in stress-controlled fatigue behavior but produces an increase in fatigue crack propagation rates. In contrast, in overaged aluminum alloys, reinforcement improves not only the stress-controlled fatigue behavior but also the resistance to fatigue crack propagation. Under stress-controlled high-cycle fatigue conditions, a high volume fraction of fine reinforcement particles is preferred for fatigue crack initiation resistance. For fatigue crack growth resistance, a high volume fraction of coarser particles is preferred.

**Stress-Life Behavior.** The high-cycle  $S-N$  fatigue life of discontinuously reinforced metals is generally higher than that of comparable unreinforced alloys (Fig. 32). This behavior can be understood by the influence of reinforcement on modulus and work hardening. In general, the incorporation of reinforcement leads to an increase in work hardening rate and a decrease in ductility under both monotonic and cyclic loading. Thus, the high-cycle fatigue strength (at lower or intermediate stresses) is generally improved by reinforcement, although there are exceptions (Fig. 33). Notch effects are shown in Fig. 34.

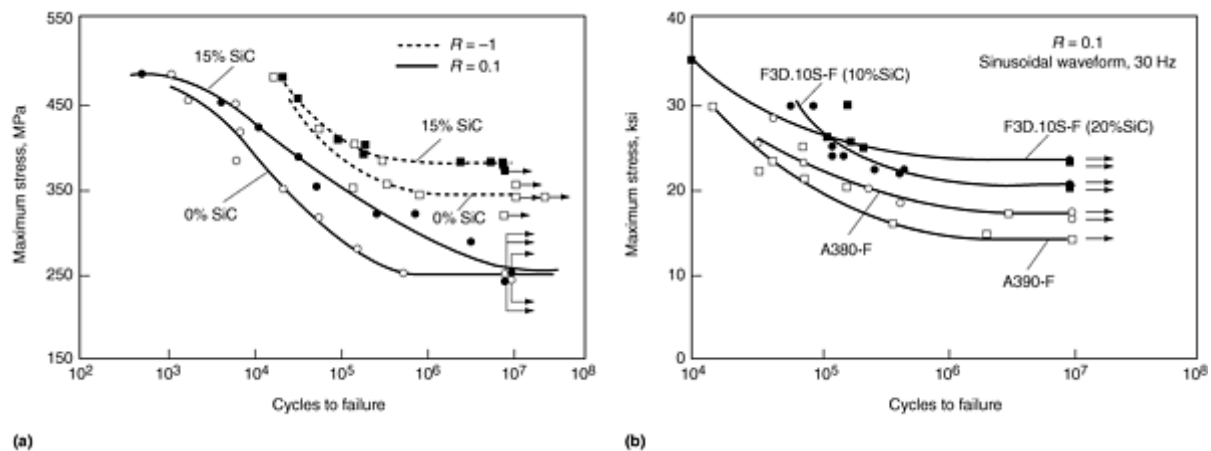

FIG. 32 EFFECT OF REINFORCEMENT ON STRESS LIFE. (A) X2080-T4 ALUMINUM ALLOY AT  $R = -1$  AND  $R = 0.1$ . (B) DURALCAN GRADE F3D.XXS-F AXIAL FATIGUE. SOURCE: REF 74, 75

FIG. 33 AXIAL FATIGUE OF DRA COMPOSITE F3A.XXT61. SOURCE: REF 75

FIG. 34 NOTCHED FATIGUE STRENGTH OF DRA COMPOSITE (DURALCAN W2A.15-T6). SOURCE: REF 75

In low-cycle (high-stress) testing, the fatigue strength converges with that of unreinforced counterparts. In this regime, fatigue is ductility controlled, and therefore the lower tensile and cyclic ductilities of reinforced metals become a more dominant factor.

**Strain-Life Behavior.** In contrast to stress-life, the total strain-life behavior of a discontinuously reinforced matrix is almost without exception lower than that of an unreinforced matrix (Fig. 35) (Ref 73). This behavior is again understood in terms of the higher modulus of reinforced metal. Under strain control, the elastic strains are lower in the composite

than in an unreinforced matrix, and the increased portion of plastic strain accelerates the formation of fatigue damage (Ref 73).

FIG. 35 STRAIN-LIFE FATIGUE CURVE OF X2080-T4 COMPOSITE WITH AND WITHOUT REINFORCEMENT. STRESS CONTROLLED,  $R = -1$ , AT ROOM TEMPERATURE. SOURCE: REF 73

**Fatigue Crack Propagation.** At low  $R$  values (under about 0.3), the introduction of a reinforcement phase results in higher thresholds (Fig. 36a), a steeper Paris region (Fig. 36b), and a transition to unstable fracture at lower  $\Delta K$  levels. The latter behavior is characteristic of all discontinuously reinforced metal-matrix composites and is a direct consequence of the lower fracture toughness in composites compared to unreinforced alloys (Ref 73). However, the influence of reinforcement on the near-threshold and midrange growth behavior can be more complicated than this. In some cases, threshold levels, as well as near-threshold and midrange growth rates in composites, may be higher than, lower than, or roughly equivalent to the values observed in unreinforced alloys (Fig. 37). Although only limited data are available on the effects of volume fraction, it appears that the effect on crack growth is consistent with roughness-induced closure (Ref 73).

## Fatigue of Composite Laminates

### Introduction

KNOWLEDGE of fatigue behavior at the laminate level is essential for understanding the fatigue life of a laminated composite structure. In fact, most published fatigue data have addressed laminates with or without a notch. Relatively little fatigue data exist on composite structures. Investigations have demonstrated that sufficient fatigue life for a composite structure is achieved if it is designed to satisfy static strength requirements (Ref 1, 2). Fatigue failure mechanisms, *S-N* relations and characterization, and statistical life prediction models of composite laminates are described in this article. Data on aramid-aluminum (ARALL) and titanium matrix composites are also included. More detailed coverage on polymer composites is contained in Ref 3.

## Fatigue of Composite Laminates

### Fatigue Failure

Composite materials exhibit very complex failure mechanisms under static and fatigue loading because of the anisotropic characteristics of their strength and stiffness. Fatigue failure is usually accompanied by extensive damage that multiplies throughout specimen volume, in contrast to the localized formation of a predominant, single crack, as is common in isotropic, brittle materials. The four basic failure mechanisms in composites are layer cracking, delamination, fiber breakage, and fiber-matrix interfacial debonding. Any combination of these can cause fatigue damage that will result in reduced strength and stiffness. Both the type and degree of damage vary widely, depending on material properties,

laminations (including stacking sequence), and type of fatigue loading. It has been observed that, in general, damage development under fatigue loading is similar to that under static loading, except that fatigue at a given stress level causes additional damage as fatigue cycles increase.

**Layer Cracking.** In multidirectional laminates under in-plane loading, failure from layer cracking usually occurs in succession from the weakest layer to the strongest. For example, successive transverse cracks in the off-axis layers of a  $(0^\circ/90^\circ/\pm 45^\circ)_s$  graphite-epoxy laminate subjected to uniaxial tension are expected to occur as the load increases. The first crack occurs in the  $90^\circ$  layers; with increasing load, more cracks develop, but they are still confined to the  $90^\circ$  layers. As the load increases further, cracks occur in the adjacent  $45^\circ$  layers, appearing at the tips of the  $90^\circ$  cracks in most cases, and extending to the interface of the  $+45^\circ/-45^\circ$  layers (see Fig. 1). Subsequently, the number of cracks increases with the load (Fig. 2) until final laminate failure takes place. However, some laminates reach a crack density limit, after which no new cracks occur before final failure, despite additional loading. The crack density limit for a given layer depends on its thickness and appears to be independent of laminate type (Ref 4, 5, 6, 7).

**FIG. 1 PHOTOMICROGRAPHS SHOWING CRACK PATTERNS UNDER STATIC LOADING:  $[0^\circ/90^\circ/\pm 45^\circ]_s$ . (A) 440 MPA OR 65 KSI. (B) 483 MPA OR 70 KSI**

FIG. 2 INCREASE OF NUMBER OF CRACKS FOR  $[0^\circ/90^\circ/\pm 45^\circ]_s$  LAMINATE SUBJECTED TO STATIC LOADING

During fatigue loading, more cracks occur in each layer, and reach a crack density limit, than during static loading. For instance, many cracks in the  $-45^\circ$  layers of the  $(0^\circ/90^\circ/\pm 45^\circ)_s$  laminate occur during fatigue loading, whereas few or none occur during static loading. In addition, many axial cracks initiate at the tips of the transverse cracks and extend along the axial direction as fatigue cycles increase. The multiplication process of transverse cracks in the course of the fatigue cycle is shown in Fig. 3. The damage ratio is defined here as the ratio of the crack density at  $n$  cycles to the crack density at final failure. Cracks in all off-axis plies are grouped together. Most of the crack multiplication occurs during the first 20% of the fatigue life. A significant amount of fatigue life remains after reaching the crack density limit. Cracks in the  $90^\circ$  layers of the  $(0^\circ/90^\circ/\pm 45^\circ)_s$  laminate are found at fewer than one million cycles at a fatigue stress level of 170 MPa (25 ksi), which is less than the 280 MPa (40 ksi) stress level at which the first layer fails under static loading.

FIG. 3 INCREASE OF NUMBER OF CRACKS FOR  $[0^\circ/90^\circ/\pm 45^\circ]_s$  LAMINATE SUBJECTED TO FATIGUE LOADING

The  $0^\circ$  layers are also susceptible to cracking in the fiber direction because of the transverse stress resulting from a mismatch in Poisson's ratio between different layers. Because this transverse stress is usually small, axial cracking in  $0^\circ$  layers may not occur under static loading. However, under fatigue loading, axial cracking can occur, for example, in cross-ply laminates such as  $(0^\circ/90^\circ)_s$ .

**Delamination.** In composite laminates, free-edge delamination under in-plane axial loading is caused by interlaminar stresses that are highly localized around the free edge (Ref 8). The nature of interlaminar stresses with regard to their magnitude and sign can be accurately calculated using an analytical model (Ref 9). The magnitude and distribution of interlaminar stress components vary widely depending on the type of laminate, stacking sequence, properties of the constituent materials, and type of loading. For a given laminate, the stacking sequence significantly influences free-edge delamination. As an example, consider a quasi-isotropic laminate with two stacking sequences,  $(0^\circ/90^\circ/\pm 45^\circ)_s$  and  $(0^\circ/\pm 45^\circ/90^\circ)_s$ . The  $(0^\circ/90^\circ/\pm 45^\circ)_s$  laminate does not show any delamination under static tension, whereas the latter laminate shows extensive delamination under static tension. Figure 4 shows a photomicrograph of a free edge and an x-ray radiograph of the specimen width showing delamination in the  $(0^\circ/\pm 45^\circ/90^\circ)_s$  laminate under static tension. At about 350 MPa (50 ksi) of the applied tension, delamination occurred and extended almost instantly over the entire length of the specimen, taking irregular paths at the interfaces of the  $90^\circ/90^\circ$ ,  $90^\circ/45^\circ$ , and  $45^\circ/45^\circ$  plies. The change in the delamination path happened for the most part at the transverse crack tips. The delamination also grew continuously toward the middle of the specimen from both free edges as the load increased (Fig. 4). In fatigue, the onset of delamination occurred very early (and at fatigue stress levels that were smaller than static stress levels) and propagated

rapidly toward the middle of the specimen width as the cycles increased. The lower bound of the delamination-free stress level for a predetermined life cycle is expected to vary, depending upon the type of laminate. In addition to interlaminar tensile stress, other factors, such as transverse cracking and interlaminar shear stress, appear to affect the onset and growth of delamination (Ref 10). The  $(0^\circ/90^\circ/\pm 45^\circ)_s$  laminate, which has a compressive interlaminar normal stress, does not show any delamination under static tension, but under tensile fatigue, considerable delamination occurs at the interface between the  $\pm 45^\circ$  and  $-45^\circ$  plies. The interlaminar shear stress at the  $+45^\circ/-45^\circ$  interface is not large enough to reach the interlaminar shear strength under static loading, but under fatigue loading, the shear stress becomes significant because of the high fatigue sensitivity of the epoxy matrix. Figure 5 shows delamination growth as a function of fatigue cycle for a  $(0^\circ/90^\circ/\pm 45^\circ)_s$  graphite-epoxy T300/5208 laminate. However, the growth of delamination in this case is much slower than is the case with interlaminar tension.

= 620 CYCLES

**Fiber break and interface debonding** differ widely, depending on the properties of the constituent materials and fiber defects. In most advanced composites, such as boron and graphite fiber with polymer matrix, the strain-to-failure is greater in the matrix than in the fibers. Therefore, fibers can break, because of defects or weakness, before the matrix fails. The crack created by a fiber break grows into the matrix, as load increases, along a path varying with matrix and interface properties. If bonding is strong, the crack grows into the matrix, resulting in a fairly smooth fracture surface across the section. With a weak bond, the crack is more likely to lead to interfacial debonding and extensive fiber pull-out. An intermediate bond shows irregular failure surfaces with some fiber pull-out. These failure mechanisms occur under static and fatigue loading, although fatigue failure depends on the sensitivity of the matrix, interface, and fiber. Because in most advanced composites the matrix remains elastic until the composite fails, fatigue damage in the interface is negligible, except at the site of fiber breaks. Consequently, the modulus and strength of a unidirectional laminate subjected to fatigue loading along the fiber direction do not decrease until fracture is imminent.

## Fatigue of Composite Laminates

### S-N Relation

The fatigue behavior of a material is basically expressed in the form of a relation between applied maximum fatigue stress ( $S$ ) and fatigue life (number of cycles to failure,  $N$ ). In composite laminates, the  $S$ - $N$  relation primarily depends on the constituent material properties (Ref 11, 12). Most advanced fibers are very insensitive to fatigue, and the resulting composites show good fatigue resistance. Figure 6(a) shows the  $S$ - $N$  curves for a variety of laminates of AS 4/3502 graphite-epoxy. The ordinate represents the fatigue strength ratio, which is the ratio of fatigue stress to static strength. The laminates with matrix-dominant failure modes exhibit a smaller fatigue resistance than the laminates with fiber-dominant failure modes. The slope of the  $S$ - $N$  curve for the  $[0^\circ]_{8T}$  laminate is relatively flat because of the fatigue insensitivity of the graphite fiber. Consequently, the slope of the  $S$ - $N$  curve tends to increase as the content of the  $0^\circ$  ply decreases, as shown in Fig. 7 (Ref 13). The fatigue strength of a  $(\pm 45^\circ)_s$  laminate is frequently used to determine the longitudinal shear fatigue strength. The fatigue strength in compression-compression fatigue is slightly greater than that in tension-tension fatigue (Fig. 8) for a  $(0^\circ/45^\circ/90^\circ/-45^\circ)_{2s}$  graphite-epoxy laminate. The static tensile and compressive strengths for this laminate are practically identical. The extensive damage incurred during tension-tension fatigue is mainly responsible for the reduction in tensile fatigue strength. The fatigue strength of multidirectional laminates is closely related to the  $0^\circ$  fatigue strength, as shown in Fig. 9, unless the laminate undergoes extensive damage during fatigue.

FIG. 8 TENSION-TENSION AND COMPRESSION-COMPRESSION FATIGUE TESTS OF  $[0^\circ/45^\circ/90^\circ/-45^\circ]_{2s}$  CARBON-FIBER-REINFORCED PLASTIC T300-5208

FIG. 9 FATIGUE AND STATIC STRENGTHS NORMALIZED WITH RESPECT TO UNIDIRECTIONAL TENSILE STRENGTHS

**Mean Stress.** A constant-amplitude fatigue loading may be regarded as a fully reversed cyclic loading superimposed on a constant load. Consequently, the fatigue strength at a chosen cycle may be expressed in terms of alternating the stress,  $S_r$ , and mean stress,  $S_m$ . The values of  $S_m$  and  $S_r$  are given by the following equations:

$$S_M = (S_{MAX} + S_{MIN})/2$$

$$S_R = (S_{MAX} - S_{MIN})/2$$

where  $S_{max}$  and  $S_{min}$  are the maximum and minimum fatigue stresses, respectively.

Figure 10 shows the effect of mean stress on fatigue life in the form of a constant-life diagram (Ref 14). This diagram is practically symmetrical with respect to the alternating stress axis,  $S_r$  ( $R = -1$ ), although the peaks of constant-life curves tend to lie slightly in the tension-dominant fatigue region. This indicates that the  $S-N$  behavior of the composite is independent of the type of fatigue loading (that is, tension-tension, tension-compression, or compression-compression) as long as the tensile and compressive strengths are equal. In tension-compression fatigue, the fatigue failure in the tension-dominant region ( $T > C$ ) in Fig. 10 was accompanied by severe matrix damage. This effect on the  $S-N$  relation appears to be balanced out by the fact that the compressive stress is much more detrimental to the residual strength of damaged specimens than is the tensile stress. The peak of the constant-life curve for a  $(0^\circ/\pm 30^\circ)_s$  graphite-epoxy lies in the positive mean stress region because of the lower static compressive strength (Ref 15).

FIG. 10 EFFECT OF MEAN STRESS ON FATIGUE LIFE OF  $[0^\circ/45^\circ/90^\circ/-45^\circ]_{2s}$  CARBON-FIBER-REINFORCED PLASTIC T300-5208

**Notch.** With metals, the problem of stress concentration resulting from various notches (circular holes and cracks) is complicated by the many factors that influence behavior under cyclic stresses. In notched specimens, combined stresses are produced and vary widely in the region around the notch. Furthermore, any damage that occurs during fatigue will change the stress distribution around the notch. The foregoing factors have made it difficult to predict the fatigue strengths of notched specimens from the fatigue strengths of the unnotched specimens. In contrast to metals, the reduction in fatigue strength resulting from the presence of a notch is found to be insignificant in most composite laminates (Ref 14, 16, 17). The value of fatigue notch factor (the ratio of the fatigue strength of an unnotched specimen to the fatigue strength of a notched specimen at  $N$  cycles) is much smaller than the static stress-concentration factor, and is close to unity in many cases. The good fatigue resistance of notched specimens is mainly due to the fact that damage relaxes the stress concentration around the notch.

**Bolted Joint Fatigue.** Fatigue behavior of a bolted joint is similar to the fatigue behavior of notched composites. The residual strength generally increases with the fatigue cycle toward the unnotched net section strength (Ref 18). This strength increase is mainly due to damage that occurs around fasteners, reducing the stress concentration. The residual strength of a bolted joint depends on the degree of fitness of the bolt. When a loose bolt in a hole is stressed back and forth, the hole elongates at an increasing rate, and failure is rapid. This is why it is important that all bolts in composites be fit tightly. A tight fit also promotes uniform sharing of load between multiple fasteners.

Bolt torque pressure has a significant effect on both static strength and fatigue strength (Ref 18, 19). Each strength is improved considerably, compared to the pin-bearing case, which has no torque pressure, as shown in Fig. 11 (Ref 18). High torque virtually eliminates hole elongation that is due to fatigue and also results in a smaller temperature increase. With loose-fit bolts, a large increase in bolt temperature due to friction at high frequency is one of the major problems. This is associated with a decrease in mechanical properties because of temperature elevation.

FIG. 11 EFFECT OF TORQUE-UP ON BOLTED JOINT FATIGUE LIFE

Fatigue strength of a bolted joint is also influenced by many other factors, such as type of joint (single or double), geometry of fastener head, interference fit, and so forth. Figure 12 shows the typical  $S-N$  relation of a bolted joint of graphite-epoxy laminate of  $[0^\circ_s/\pm 45^\circ_2/90^\circ]_s$  orientation with two different fatigue loadings. The fatigue life is indicated in terms of fatigue cycles required to produce a 0.50 mm (0.02 in.) elongation of the fastener hole. Tension-compression fatigue ( $R = -1$ ) reduces fatigue strength of the bolted joint for most laminate types. The stacking sequence also influences fatigue strength.

FIG. 12 EFFECT OF R RATIO OF AN FATIGUE LIFE

**Helicopter Rotor Blade Fatigue.** The helicopter rotor blade is the first large-volume use of a composite material as a primary airframe structure. During its service life, the helicopter experiences a severe high-cycle fatigue environment, typically on the order of  $10^7$  to  $10^8$  cycles. The blades show excellent performance with unlimited fatigue life when the composite materials are properly used in rotor blade design (Ref 20, 21, 22). The results of tests performed on the tail and

main rotor blades of the Westland Sea King helicopter are reported in Ref 20. Blade construction is typically of a hollow D-spar composed largely of unidirectional glass-reinforced epoxy tape with internal and external woven wraps. A bolted joint is used at the root end with local reinforcement of the spar. The fatigue testing involved both structural part and complete (full-sized) structure tests. The structural part fatigue tests were performed for the four critical areas of the blade chosen for the test under a programmed series of loading blocks designed to correspond closely to actual flight conditions. The early design of tail rotor blade root end specimens indicated a weakness in the blade spar. Design and manufacturing changes were made at the root end to provide a new standard blade. After the fatigue testing at a fully factored, programmed load of two root end specimens, no failure occurred and unlimited fatigue life was shown.

## Fatigue of Composite Laminates

### Fatigue Data Analysis and Life Prediction

**Weibull Distribution and Parameters Estimation.** A random variable,  $X$ , has a Weibull distribution with shape parameter  $\alpha$  and scale parameter  $\beta$  if its cumulative distribution function,  $F_X(x)$ , is:

$$F_X(x) = P_r \{X \leq x\} = 1 - \exp \left[ -\left(\frac{x}{\beta}\right)^\alpha \right] \quad (\text{EQ 1})$$

where  $X > 0$  and  $F_X(x)$  represents the probability of the random number  $X$  being less than or equal to  $x$ -experimental. On the other hand, the distribution for the  $n$ -ordered data ( $x_1 \leq x_2, \dots, \leq X_n$ ) is given by the medium rank:

$$F_X(x_i) = 1 - \frac{i - 0.3}{n + 0.4} \quad (\text{EQ 2})$$

The following relation exists:

$$\begin{aligned} \mu = \text{expected value of } X &= \beta \cdot \Gamma\left(1 + \frac{1}{\alpha}\right) \\ \alpha^2 = \text{variance of } X &= \beta^2 \left\{ \Gamma\left(1 + \frac{2}{\alpha}\right) - \Gamma^2\left(1 + \frac{1}{\alpha}\right) \right\} \end{aligned} \quad (\text{EQ 3})$$

where  $\Gamma$  is the gamma function.

A maximum-likelihood method is widely used for estimating Weibull parameters  $\alpha$  and  $\beta$ :

$$\frac{\sum_{i=1}^n x_i^{\hat{\alpha}} \ln X_i}{\sum_{i=1}^n x_i^{\hat{\alpha}}} - \frac{1}{\hat{\alpha}} - \frac{\sum_{i=1}^n \ln x_i}{n} = 0 \quad (\text{EQ 4})$$

and

$$\hat{\beta} = \left[ \frac{1}{n} \sum_{i=1}^n x_i^{\hat{\alpha}} \right]^{1/\hat{\alpha}} \quad (\text{EQ 5})$$

where  $\hat{\alpha}$  is the Weibull shape parameter estimated from fatigue data.

An efficient iterative technique for obtaining the solution of  $f(\hat{\alpha}) = 0$  is to use the Newton-Raphson method, in which the  $(j + 1)$ st successive approximation,  $\hat{\alpha}_{j+1}$  to  $\hat{\alpha}_j$ , is given by:

$$\hat{\alpha}_{j+1} = \hat{\alpha}_j - F(\hat{\alpha}_j)/F'(\hat{\alpha}_j) \quad (\text{EQ 6})$$

The maximum-likelihood method has the advantage in that the confidence intervals for  $\alpha$  and  $\beta$  can be computed and it can be applied to a life-test model in which censoring is progressive, that is, a model in which a portion of the survivors is withdrawn from life test several times during the test.

The 95% confidence interval (one-sided) for  $\beta_i$  can be obtained from Table 1 (Ref 23) as follows:

$$P_R\{\hat{\alpha} \text{LN}(\hat{\beta}_i/\beta_i) \leq l_{0.95}^*\} = 0.95 \quad (\text{EQ 7})$$

Let us denote the lower bound of 95% confidence interval for  $\beta_i$  by  $\underline{\beta}_i$ . Then:

$$\underline{\beta} = \hat{\beta}_i \text{EXP} [-(I_{0.95}^*/\hat{\alpha})] \quad (\text{EQ 8})$$

TABLE 1 PERCENTAGE POINTS  $I_{\gamma}^*$  SUCH THAT  $P_R \{ \hat{\alpha} \text{ IN } (\hat{\beta}_i/\beta) < I_{\gamma}^* \} = \gamma$

<b>50</b>	<b>0.195</b>	<b>0.253</b>	<b>0.328</b>

Source: Ref 18

An A-allowable (or B-allowable) material fatigue design value is defined by the probabilistic statement that we can be 95% confident of the assertion that the probability of surviving the A-allowable value is at least 0.99 (or 0.90 for B-allowable). Therefore, A-allowable  $X_{Ai}$  under the stress level  $S_i$ , where  $i = 1, 2, \dots, m$ , can be obtained by solving the following:

$$R(x_{Ai}) = \exp \left[ - \left( \frac{x_{Ai}}{\underline{\beta}_i} \right)^{\hat{\alpha}} \right] = 0.99 \quad (\text{EQ 9})$$

where  $\underline{\beta}_i$  is the 95% confidence lower limit for  $\beta_i$ , that is:

$$X_{Ai} = \underline{\beta}_i [-\text{LN}(0.99)]^{1/\hat{\alpha}} \quad (\text{EQ 10})$$

**Pooling Technique.** To obtain the  $S-N$  relationship,  $m$  levels of stress are employed with  $n$  specimens tested at each level of stress. The shape parameter and scale parameter (characteristic fatigue life) can be obtained from the pooled fatigue data  $x_{i1}, x_{i2}, \dots, x_{in}$  (under its level of stress), where  $i = 1, 2, \dots, m$ . By assuming that the shape parameter  $\alpha$  for each stress level is equal to that for every other level, the pooled estimation of  $\alpha$  can be obtained by normalizing the data, that is, by letting  $Y_{ij} = X_{ij}/\beta_i$ , for  $i = 1, 2, \dots, m$ . The maximum-likelihood equations for the normalized data are:

$$\frac{\sum_{i=1}^m \sum_{j=1}^n y_{ij}^{\hat{\alpha}} \ln Y_{ij}}{\sum_{i=1}^m \sum_{j=1}^n y_{ij}^{\hat{\alpha}}} - \frac{1}{\hat{\alpha}} - \frac{\sum_{i=1}^m \sum_{j=1}^n \ln Y_{ij}}{n \cdot m} = 0 \quad (\text{EQ 11})$$

and

$$\hat{\beta}_i = \left[ \frac{1}{n} \sum_{j=1}^n X_{ij}^{\hat{\alpha}} \right]^{1/\hat{\alpha}} \quad \text{where } i = 1, 2, \dots, m \quad (\text{EQ 12})$$

This pooled estimate is more efficient than the one introduced in Eq 4 and 5. As before, the solutions of Eq 11 and 12 can be obtained by the iterative technique of the Newton-Raphson method. Table 2 (Ref 24) is useful in computing the confidence interval of  $\beta$ .

**S-N Curve Characterization.** Traditionally, the fatigue behavior of materials is expressed by the relationship between fatigue stress and fatigue life, that is, cycle to failure. Although no universally accepted rules are available for S-N characterization, the following discussion may be used as a general guide. Constant-amplitude fatigue tests are normally conducted under three to five different stress levels. The values of the extreme stress levels are approximately chosen so that the fatigue cycles under the extreme stress levels range between  $10^3$  and  $10^6$  cycles. The values of other intermediate stress levels are arbitrarily chosen. The number of specimens to be tested at each stress level depends on the size of scatter in the data and the availability of specimens and test time, but approximately four to ten specimens are typical for composite laminates. Large variation in fatigue life data is common in composites, and hence an S-N curve obtained from mean lifetimes only may be in error. In view of the foregoing variability in test results, a procedure developed for a more accurate evaluation of fatigue strength is discussed below.

Let us assume that the fatigue data follows a classical power law and a two-parameter Weibull distribution. The S-N curve takes the form:

$$KS^B N = 1 \quad (\text{EQ 13})$$

where K and b are parameters. The K and b can be estimated using the least squares linear regression, because Eq 13 becomes a straight line after logarithmic transformation. The fatigue life,  $N_i$ , for each stress level,  $S_i$ , can be replaced by Weibull fatigue characteristic life,  $\beta_i$ . Taking natural logarithms, we obtain:

$$\text{LN } \hat{\beta}_i = -B \text{ LN } S_i - \text{LN } K \quad (\text{EQ 14})$$

The values of b and K can be easily determined by applying the least squares linear regression analysis.

**Fatigue Life Prediction.** Because composite laminates exhibit very complex failure processes, no one analytical model has been able to account for all possible processes. Consequently, statistical life prediction methodologies have frequently been adopted. A strength degradation model that is capable of predicting the statistical distribution of both fatigue life and residual strength is discussed in Ref 25 and 26.

## Fatigue of Composite Laminates

---

### ARALL and GLARE Fiber-Metal Laminates

Glenn Nordmark, Alcoa Technical Center (retired)

---

Fiber-metal laminates are a relatively new material developed for the aerospace industry. They offer a combination of improved strength and fatigue properties together with reduced density, giving airframe manufacturers the opportunity to achieve 20 to 30% weight savings. This section describes how fiber-metal laminates are produced, discusses their various product forms, reviews the effects of stretching on their fatigue properties, and summarizes their residual strength and durability.

Fiber-metal laminates are a hybrid material composed of alternating layers of high-strength aluminum alloy sheet and fiber-reinforced epoxy adhesive (Fig. 13). The principal benefit of fiber-metal laminates is their ability to impede and self-arrest fatigue crack growth. In a monolithic aluminum sheet, a fatigue crack can grow until the panel fails. In fiber-metal laminates, a fatigue crack develops only in the aluminum layer or layers. The fibers remain intact in the wake of the crack due to their high strength and toughness. As the crack grows, the fibers bridging the crack carry an increasing portion of the load, decreasing the stress intensity at the crack tip and consequently arresting its growth. In addition to the superior fatigue crack growth properties, fiber metal laminates are stronger, lighter, and more damage tolerant than aluminum alloy 2024-T3 sheet.

### Fatigue of Composite Laminates

#### Fiber-Metal Laminate Types

The properties of fiber-metal laminates can be modified by varying fiber-resin systems, aluminum alloy and sheet gage, stacking sequence, fiber orientation, surface preparation techniques, and the degree of post stretching. A variety of lay-up configurations are available for aramid fiber-metal laminates, ARALL, and glass fiber-metal laminates, GLARE.\* The lay-up configurations are represented by two numbers: the first number represents the layers of aluminum; the second represents the interspaced adhesive layers. Typical laminate configurations vary from 2/1 (two layers of aluminum alloy sheet with one adhesive layer sandwiched in between), to 5/4 (five layers of aluminum sheet with four adhesive layers interspaced), though laminates with more layers may be produced as required.

Before lay-up and cure, the aluminum unclad surfaces are anodized and primed to provide good bond integrity and to inhibit aluminum bondline corrosion in the event of moisture intrusion. Either chromic acid or phosphoric acid anodizing surface treatment for the aluminum layers may be used. For added corrosion protection, or polished sheet applications, cladding can be applied to one or both of the laminate outer surfaces.

During curing, due to the difference in thermal expansion coefficients between the aluminum layers and the fiber-adhesive layers, a small tensile residual stress will occur in the aluminum sheets and a corresponding compressive strength in the fiber layers. This is called the "as-cured" condition. However, the sign of the residual stresses can be reversed favorably by plastically stretching the laminate after curing. This is called "post stretching."

**ARALL laminates** are aramid fiber-metal laminates, that are unidirectionally reinforced with a 50% fiber volume adhesive prepreg of high-modulus aramid fibers. These laminates were developed for tension-dominated fatigue applications where the stress field is primarily unidirectional. The standard ARALL laminate product types are:

- ARALL-1 LAMINATE

- ALLOY 7475-T6
  - 120 °C (250 °F) CURE PREPREG
  - 0.4% PERMANENT STRETCH
- ARALL-2 LAMINATE
    - ALLOY 2024-T3
    - 120 °C (250 °F) CURE PREPREG
    - WITH OR WITHOUT 0.4% STRETCH
- ARALL-3 LAMINATE
    - ALLOY 7475-T76
    - 120 °C (250 °F) CURE PREPREG
    - 0.4% PERMANENT STRETCH
- ARALL-4 LAMINATE
    - ALLOY 2024-T8
    - 175 °C (350 °F) CURE PREPREG
    - WITH OR WITHOUT 0.4% STRETCH

The influence of post stretching on the fatigue properties is shown in Fig. 14.

FIG. 14 THE INFLUENCE OF POST STRETCHING ON THE FATIGUE PROPERTIES OF 3/2 ARALL-2 LAMINATES

**GLARE laminates** are glass fiber-metal laminates and are a more recent development that complement ARALL laminates. GLARE laminates are unidirectional or biaxially reinforced with a 60% fiber volume adhesive prepreg of high-strength glass fibers. The high-strength glass fiber with improved tensile strength, compression properties, and adhesive properties relative to aramid fiber make it attractive as biaxial reinforcement for fiber-metal laminates. The higher tensile strength of the glass fiber allows for the laminate to be layed-up in cross-ply configurations and still offer improved tensile strengths in both the L and LT directions relative to ARALL. The improved compression properties of the glass fiber allow GLARE laminates to be used in the as-cured condition for tension-tension, tension-compression, and  $R = 0$  fatigue loading conditions. The standard types of GLARE laminates are:

- GLARE-1
  - 7475-T6 ALUMINUM ALLOY
  - UNIDIRECTIONAL GLASS PREPREG
  - 0.5% POST-STRETCHED
  
- GLARE-2
  - 2024-T3 ALUMINUM ALLOY
  - UNIDIRECTIONAL GLASS PREPREG
  
- GLARE-3
  - 2024-T3 ALUMINUM ALLOY
  - CROSS-PLY GLASS PREPREG
  - 50% OF FIBERS IN L DIRECTION
  - 50% OF FIBERS IN LT DIRECTION
  
- GLARE-4
  - 2024-T3 ALUMINUM ALLOY
  - CROSS-PLY GLASS PREPREG
  - 30% OF FIBERS IN L DIRECTION
  - 70% OF FIBERS IN LT DIRECTION

Figure 15 shows the fatigue properties of both unidirectional and biaxially reinforced GLARE laminates. Typical mechanical properties of ARALL and GLARE are given in Table 3.

#### Fatigue of Composite Laminates

#### Fatigue Properties

The fibers in ARALL and GLARE laminates provide extraordinary resistance to the development of fatigue cracks. In fact, conventional *S/N* fatigue data are rarely reported for unnotched ARALL and GLARE specimens. First, the stress required to develop any sort of fatigue failure is a high percentage of the strength of the aluminum sheet. Second, although microcracks will initiate at stresses of 275 MPa (40 ksi) and higher, the presence of the fibers restrains the crack opening so that the propagation slows and stops at short lengths. As the loading is continued, more and more microcracks develop and the specimen elongates until a saturation point is reached at which the fibers are carrying all of the load. Tests are generally terminated on the basis of decreased stiffness or increased elongation rather than a failure of the test section.

For structural use, the performance in the presence of stress concentrations or cracks is generally critical; accordingly, test programs have concentrated on obtaining data relevant to these structural concerns. Tests at Delft University and Alcoa Technical Center have evaluated fiber-metal laminates under various structural conditions and the influence of temperature, humidity, thermal cycling, outdoor exposure station monitoring, the effect of static and dynamic loading on corrosion behavior, and the influence of pitting corrosion on fatigue crack initiation (Ref 27, 28, 29). The durability of ARALL and GLARE laminates appears to be very good. An advantage for ARALL in no-load transfer joints has also been demonstrated for practical structures.

Tests at several laboratories showed that mildly notched ARALL-1 specimens had higher fatigue strengths than monolithic aluminum specimens (Fig. 16). The only two results that plot below the average curve for 7075-T6 sheet are specimens whose fibers were transverse to the direction of loading. Naturally, the fibers do not resist transverse loadings and only serve to lessen the thickness of aluminum resisting the loads in that direction. Beyond  $10^6$  cycles, the advantage for the longitudinal specimens was even greater than the plot indicates, because cracks had not developed in the test sections when their tests were terminated.

**FIG. 16 NOTCH FATIGUE BEHAVIOR OF 3/2 ARALL-1 LAMINATE, NOMINALLY 0.053 IN. (1.3 MM) THICK. SOURCE: REF 27**

As demonstrated in Fig. 17, the fatigue crack growth rates obtained for center-cracked ARALL and GLARE specimens are 10 to 100 times slower than those determined for aluminum alloy sheet. The advantage comes primarily from the crack bridging of the fibers in the wake of the crack. The fibers are fully effective only if they are aligned within a few degrees of the loading direction. The drop-off as the angle between the fiber orientation and the direction of loading increases is illustrated in Fig. 18. The cross-ply fibers of the GLARE-3 and GLARE-4 laminates therefore make them a preferred choice for biaxial loadings.

FIG. 17 CRACK GROWTH BEHAVIOR OF GLARE FIBER-METAL LAMINATE AND 2024-T3 ALUMINUM ALLOY.  $S_{MAX} = 120$  MPA (17.4 KSI).  $R = 0.05$ . FREQUENCY = 10 HZ.

## Fatigue of Composite Laminates

### Damage Tolerance

Fiber-metal laminates exhibit excellent damage tolerance properties. The residual strength of the material after fatigue, corrosion, or impact damage is superior to that of monolithic aluminum. In all cases, damage will be visible and the detectability and inspectability will be comparable, but less critical, than similar damage in aluminum structures. The fracture toughness of GLARE (Fig. 19) is comparable to that of high-toughness aluminum alloys (e.g., 2024-T3) and outperforms any composite material.

FIG. 19 FRACTURE TOUGHNESS OF GLARE FIBER-METAL LAMINATE

ARALL panels with sawcut flaws have a lower residual strength than monolithic 2024-T3 with sawcut flaws. However, ARALL panels with fatigue precracks have a higher residual strength than fatigue precracks 2024-T3 panels, for two reasons: the fibers in the wake of the crack remain unbroken, and the delamination zone around the crack effectively enlarges the fibers' "strain-length." Using glass fibers instead of aramid fibers further improves the residual strength of fiber-metal laminate panels (Fig. 20).

FIG. 20 A COMPARISON OF RESIDUAL STRENGTH AS A FUNCTION OF  $K_T$  FOR 2024-T3 ALUMINUM AND VARIOUS FIBER-METAL LAMINATE TYPES

**Impact Toughness.** Impact causes the most critical types of damage in composite materials, decreasing the static strength of an unnotched specimen by 25 to 40%. In ARALL laminates, the fibers are the weakest link. The fibers in the outer aramid layer opposite the impact site fail first. This is immediately followed by failure of the aluminum layers, and a crack appears perpendicular to the fiber direction. In GLARE, the aluminum layer opposite the point of impact fails, creating a crack in the fiber direction, while the fibers remain intact. (Only 2/1 and 3/2 lay-ups of GLARE have been tested.) The use of glass fibers improves damage resistance significantly (Table 4). A danger for pure composite materials is that they often show no visible signs of damage. After impact, this is not the case for fiber-metal laminates because the dent in the outer aluminum layer makes impact damage easily detectable (Ref 30).

TABLE 4 QUASISTATIC INDENTATION TEST

MATERIAL	MAX FORCE, N	MAX DISPLACEMENT, MM	ABSORBED ENERGY, J
2024-T3	6.2	6.6	<b>17.3</b>
ARALL-2	3.2	5.6	<b>8.5</b>
GLARE-3	6.4	7.4	<b>18.3</b>
CARBON/PEI	2.5	4.7	<b>4.3</b>
ARAMID/PEI	<b>2.8</b>	<b>6.4</b>	<b>6.3</b>

Note: Clamped plate, diameter 80 mm (3.15 in.). Impactor  $R = 7.5$  mm (0.3 in.). Sheet thickness  $t = 1.4$  mm (0.055 in.).

Strength reduction in fatigue of post-impact specimens is small, about 10%. In practice, crack extension is on the order of 5 mm combined with a decreasing crack growth rate and, in most cases, crack arrest.

**Repairability.** The damage-tolerant repair of fiber-metal laminates can be accomplished using the same procedures used for monolithic aluminum structures (conventional riveted or bonded patch techniques). Patch materials can be of the same material and thickness as the original structure or of substantially thicker aluminum sheets.

A potential application for GLARE 3 and GLARE 4 is the damage-tolerant repair of cracked aluminum skins. Its high blunt notch strength, moderate stiffness, and excellent fatigue resistance make GLARE an ideal material for repairing aluminum structures.

The primary reason for this fatigue-life improvement is the favorable bearing load distribution that occurs in the repair joint. The lower modulus of GLARE 3, combined with the thinner GLARE patch needed (both as compared to 2024-T3) effectively reduces the critical first rivet row bearing loads. The result is a 25% lighter repair that is two to three times more fatigue resistant than a standard repair, while avoiding the costly and time consuming steps of producing a tapered aluminum patch.

## Fatigue of Fiber-Reinforced Metal-Matrix Composites

W.S. Johnson, Georgia Institute of Technology

---

CONTINUOUS-FIBER-REINFORCED metal-matrix composites (MMCs) offer several attractive properties, such as high strength- and stiffness-to-weight ratios. In general they are more resistant to environments than polymer-matrix composites and can be used at higher temperatures. The major drawback to the use of MMCs is their cost. Therefore, many of their potential applications are limited to where there exists no viable lower-cost alternative.

Titanium MMCs are currently being considered as structural materials for high-temperature applications where weight savings is a premium. Some potential applications of these materials are hypersonic flight vehicles, advanced aircraft engines, missiles, advanced supersonic transports, and advanced fighter aircraft. All of these applications expose the material to repeated mechanical loadings and thermal cycles. In addition, stresses are induced in the composite constituents due to temperature change because of the coefficient of thermal expansion mismatch between the fiber and matrix materials. This, coupled with the different strengths and failure modes of the fiber, matrix, and fiber/matrix interface, contributes to a complex problem in predicting and tracking damage initiation and progression in laminated composites.

The damage initiation and progression process for a number of MMCs has been summarized elsewhere, with the emphasis on aluminum-matrix composites (Ref 31, 32). This section briefly describes examples of fatigue damage and some of the controlling parameters of the fatigue behavior of several titanium-matrix laminates (notched and unnotched) at room temperature and the influence of the fiber/matrix interface strength and the thermal residual stresses on the fatigue damage propagation mode. Coverage is limited to a compilation of previous research on titanium MMCs done primarily by the author and his colleagues at the NASA Langley Research Center using the SCS-6/Ti-15-3 composite system, which is based on titanium alloy Ti-15V-3Cr-3Al-3Sn (Ti-15-3). This metastable beta strip alloy is considered a potential matrix material for high-temperature MMCs because it can be economically cold formed into relatively thin sheets while retaining good mechanical properties (Ref 33). The composite laminates are made by hot pressing Ti-15-3 foils between unidirectional tapes of silicon-carbide fibers. The fibers (designated SCS-6 by Textron Specialty Materials) are 0.142 mm in diameter and are assumed to have isotropic properties with a modulus of 400 GPa. Textron Specialty Materials fabricated panels of each of the following lay-ups:  $[0]_8$ ,  $[0_2/\pm 45]_s$ ,  $[0/90]_{2s}$ ,  $[0/90/0]$ , and  $[0/\pm 45/90]_s$ . The fiber volume fractions ranged from 32.5 to 39%, depending on the particular panel. A panel of "fiberless" composite was made identically to the composite but without placing the fiber mats between the foils during fabrication.

Other possible matrix materials include beta alloy TiMetal\*\* 21S and several titanium aluminides, which also have been studied with SCS-6 fibers. The fabrication processes for these materials are very similar to that described for Ti-15-3. The failure mechanisms are also similar, although the resistance to environmental attack at high temperature varies with the matrix material, as does the fiber/matrix interfacial strength. These differences do result in differences in damage

initiation sites and crack propagation behavior. The tests were conducted at NASA Langley Research Center as described in Ref 34. Failure mechanisms are covered in Ref 35.

This research has established a good fundamental understanding of fatigue damage initiation and propagation in continuous-fiber-reinforced titanium matrix composites at both room and elevated temperatures. The causes of initial damage on both the global and local levels are becoming well defined. Seemingly insignificant factors, such as thermal residual stresses and interfacial strengths, play profound roles in almost every aspect of the fatigue life, from initiation to fracture, and thus they must not be overlooked. Further understanding is required of environmental effects at very high temperatures and time-at-temperature effects. A more complete collection of papers on this subject, including life prediction approaches for titanium MMCs, can be found in the volume cited in Ref 35.

## Fatigue of Composite Laminates

### Fatigue of Unnotched Specimens

In the unnotched laminates, damage starts as fiber/matrix interface failures in the off-axis plies. This results in a stiffness loss early in the fatigue life. These failed interfaces in the off-axis plies result in a bilinear stress-strain response for the laminate. This could present potential design problems.

The fatigue life of the unnotched laminates tested under the same temperatures, cyclic frequencies, and time-at-temperature conditions was shown to be a function of the stress range in the 0° fibers for isothermal, nonisothermal, and thermomechanical fatigue conditions. However, the relationship between the 0° fiber stress range/cycles to failure did vary for different temperatures and time-at-temperature conditions, indicating a fiber/matrix reaction effect, matrix oxidation effect, and/or an accumulative strain effect at elevated temperatures.

Unnotched fatigue tests were conducted at 650 °C on the SCS-6/Ti-15-3 laminates described above (Ref 36). The cyclic stress range in the 0° fibers versus number of cycles to failure is plotted with the room-temperature data in Fig. 21. The elevated-temperature data are more scattered than the room-temperature data. At this elevated temperature the matrix could creep during cycling, and creep ratcheting (an accumulation of strain) would result. As the strain accumulates, the maximum stress in the fiber increases. The laminates with off-axis plies would be expected to creep more than the [0]<sub>8</sub> laminate, and thus the cyclic *R*-ratio of the fiber stress will be higher for the [0/±45/90]<sub>8</sub> and [0/90]<sub>2s</sub> laminates. This may,

in part, explain why the  $[0/\pm 45/90]_s$  and  $[0/90]_{2s}$  laminate results fall below the  $[0]_8$  laminate results in Fig. 21 when based only on the measured  $0^\circ$  fiber stress range.

FIG. 21  $0^\circ$  FIBER STRESS RANGE VERSUS NUMBER OF CYCLES TO FAILURE AT 650°C AND ROOM TEMPERATURE. SOURCE: REF 36

Figure 22 compares the maximum strain versus cycles to failure of a unidirectional composite to the maximum strain versus cycles to failure of the matrix loaded in strain control (Ref 36). The fatigue test of the unidirectional specimen was considered to be an in situ fatigue test of the fibers. For high maximum strains (short lives), the initial damage developed in the fibers and the composite had a shorter life than the matrix alone. For low maximum strains (long lives), the initial damage developed in the matrix and the matrix had a shorter life than the composite. Where the two curves intersect, both the matrix and the fibers were equally likely to develop fatigue damage. During high stress (short life) testing, there are many fiber breaks but no significant matrix cracking. Medium-life testing results in both fiber breaks and some short matrix cracks in the specimens.

FIG. 22 THE LIFE OF THE UNIDIRECTIONAL COMPOSITE AND THE MATRIX AS A FUNCTION OF MAXIMUM

Similar results were found by Sanders and Mall (Ref 37) under strain-controlled testing at 427 °C. The low-stress, long-life specimen exhibits no fiber breaks but several long matrix cracks. Therefore, it is reasonable to use the fatigue response of the matrix materials and the in situ 0° fiber to predict at which strain levels the fiber will fail before matrix cracking and at which strain levels matrix cracking will precede fiber failure. Majumdar and Newaz (Ref 38) showed that the fatigue life was more a function of strain range than of applied stress range. They also showed a number of fatigue damage mechanisms in the Ti-15-3/SCS-6 system with 15 and 41% fiber volume fraction.

Nicholas and Russ (Ref 39) presented data on SCS-6/Ti-24Al-11Nb that show the effect of stress ratio, frequency, and hold time on isothermal elevated-temperature fatigue. Elevated-temperature testing in a vacuum results in fatigue lives as much as 10× longer than identical tests in air. This has been shown for Ti-15-3 matrix (Ref 40) and for Ti-22Al-23Nb (Ref 41).

**Thermomechanical Fatigue.** Both thermal and mechanical stresses are developed in the constituents of a laminate during thermomechanical fatigue (TMF). Constituent stresses are not necessarily related to the measurable laminate strains, so an analysis is needed to calculate the constituent and laminate behavior of arbitrary lay-ups subjected to arbitrary combinations of mechanical and thermal loading. The VISCOPLY code is a micromechanics analysis (Ref 42) based on constituent properties developed by NASA Langley. The program uses the vanishing fiber diameter (VFD) constitutive model to calculate the orthotropic properties of the plies. These ply properties are then used in a laminated plate analysis to predict overall laminate response. Both the fiber and the matrix can be modeled as a thermo-viscoplastic material. Combinations of thermal and mechanical loads can be modeled. Sequential jobs can be run for various load and temperature profiles. Fiber and matrix average stresses and strains in each ply and the overall composite response under thermomechanical loading conditions are calculated. The VISCOPLY program, due to the nature of the VFD model, does not account for local stress concentrations around the fiber or for lateral constraint in a ply due to the presence of the fiber. However, based upon the author's experience using the VFD model for over 12 years on numerous MMCs, the model predicts general laminate response very well, usually within 10% of measured response for laminates containing at least some 0° fibers.

The VISCOPLY program was used to predict the laminate response of unidirectional SCS-6/Ti-15-3 composites (Ref 43) and to determine thermo-viscoplastic material constants (Ref 44). The prediction captures the essence of the loading-unloading behavior of the composite. The fatigue behavior as a function of maximum applied stress for in-phase and out-of-phase TMF is shown in Fig. 23. The in-phase loadings resulted in earlier failures, but the specimens lost very little stiffness prior to failure. On the other hand, the out-of-phase loadings resulted in significant stiffness loss due to matrix cracking prior to failure. The VISCOPLY program was used to predict the fiber and matrix stresses during an in-phase and an out-of-phase TMF cycle between 93 and 538 °C and between 45 and 896 MPa. The fiber stresses were highest for the in-phase test, explaining the earlier laminate fatigue failures. However, the matrix stresses were higher for the out-of-phase loadings, explaining the earlier matrix cracking and the resulting stiffness loss measured during the out-of-phase loadings (Ref 43, 44). When each test shown in Fig. 23 was analyzed and the 0° fiber stress range was plotted versus the number of cycles to failure, the in-phase and out-of-phase data collapsed into a narrow band, as shown in Fig. 24.

FIG. 23 THE MAXIMUM APPLIED STRESS AS A FUNCTION OF CYCLES TO FAILURE UNDER THERMOMECHANICAL FATIGUE (TMF). SOURCE: REF 45

FIG. 24 THE STRESS RANGE IN THE 0° FIBERS AS A FUNCTION OF CYCLES TO FAILURE. DATA FROM BOTH THE IN-PHASE AND OUT-OF-PHASE TESTS FORM ONE BAND. SOURCE: REF 45

Other TMF and isothermal data were analyzed and are plotted in Ref 43. Within a given test condition (temperature, loading frequency, time at temperature, etc.), the 0° fiber stress range seems to correlate with the number of cycles to failure. Gao and Zhao (Ref 45) also have determined that failure is controlled by the 0° fibers. However, as the test conditions change the fatigue behavior of the fibers appears to change. Because the plot is of stress range in the fiber, the increased loading of the fiber due to matrix stress relaxation is not accounted for. Higher temperatures and slower cycling would both contribute to the shifting of more load to the fiber from the matrix. Additional time at temperature could also cause additional fiber/matrix interface reactions that could affect the mechanical behavior (Ref 46, 47).

**Effect of Interface Strength and Residual Stresses on Fatigue.** Naik et al. (Ref 47) investigated the effect of a high-temperature cycle (1010 °C) used to simulate a superplastic forming/diffusion bonding (SPF/DB) fabrication cycle on the mechanical properties of a [0/90/0] lay-up of SCS-6/Ti-15-3. The high-temperature SPF/DB cycle increased the strength and stiffness of the matrix material, had little or no effect on the fiber properties, but significantly reduced the static and fatigue strength of the laminate, as shown in Fig. 25. The fracture surfaces showed a change in the failure mode due to the SPF/DB cycle. In the as-fabricated (ASF) specimen, the fiber/matrix interface was weaker and the thermal

residual stresses were less compressive than in the SPF/DB specimen; thus, the damage tended to grow around the fibers, debonding the fiber/matrix interface. This produced a tortuous crack path in the matrix and extensive fiber pull-out. In the SPF/DB specimen the residual stresses were high enough and the fiber/matrix interface strong enough to cause the matrix cracks to grow through the fiber, resulting in a planar failure surface with little or no fiber pull-out. A shear-lag analysis indicated that the latter failure mode produced a greater stress concentration in the first fiber ahead of the crack, thus explaining the reduction in strength of the SPF/DB specimen.

**FIG. 25 S-N CURVE FOR THE AS-FABRICATED AND THE SUPER-PLASTIC FORMING/DIFFUSION BONDING (SPF/DB) SPECIMENS. THE STATIC STRENGTH ( $N = 0$ ) IS 25% HIGHER FOR THE AS-FABRICATED SPECIMEN.**

These results (Ref 47) indicate that for a high-strength matrix material, such as a titanium alloy, one can make the fiber/matrix interface too strong, thus sacrificing laminate strength by changing the mode of failure. Conversely, if the interface is too weak, the required load transfer between fiber and matrix necessary for optimum moduli and shear properties will not occur.

## Fatigue of Composite Laminates

### Fatigue of Notched Specimens

Fatigue behavior near local stress concentrations can be complex. The initiation process at a notch may be different from the subsequent damage growth process. Depending on the design philosophy adopted, one process may be more important than the other; however, both damage initiation and growth need to be understood.

**Fatigue Crack Initiation.** Fatigue damage initiation at notches can be predicted using unnotched matrix data and an effective strain parameter that accounts for orthotropic stress concentration and residual thermal stresses in the matrix. Good correlation between the predicted and experimental results has been obtained for several different lay-ups for both center-hole and edge-notched specimens. Matrix fatigue cracks have been found to grow long distances in the laminate without breaking the 0° fibers in the crack path. Fiber/matrix interface debonding early in the fatigue life results in a significant reduction in the stress concentration in 0° fibers at a notch tip. The calculated stress concentrations for virgin notched specimens can be used to calculate damage initiation in a virgin specimen, but they do not apply to damage propagation or fracture in the specimen after damage has initiated.

From fatigue crack initiation tests for several different lay-ups and notch geometries, cracks initiated in the matrix material and grew without breaking fibers (Ref 48). To explain the matrix crack initiation process, Hillberry and Johnson (Ref 49) developed strain-controlled matrix fatigue data by replotting stress data in terms of the Smith-Watson-Topper effective strain parameter,  $\Delta\epsilon_{\text{eff}}$  (Ref 50), as shown in Fig. 26. Hillberry and Johnson (Ref 49) modified the Smith-Watson-Topper effective strain parameter to predict cycles to fatigue damage initiation in the matrix material next to a notch. The modification includes the calculated thermal residual stresses in the matrix ( $\sigma^T$ ) and the orthotropic stress concentration factor,  $K_T$ , as follows:

$$\Delta\epsilon_{\text{EFF}} = [(K_T\epsilon_{\text{MAX}} + \sigma^R/E_M) K_T(\Delta\epsilon/2)]^{\frac{1}{2}}$$

where  $E_m$  is the matrix modulus,  $\epsilon_{\text{max}}$  is the maximum applied strain to the specimen, and  $\Delta\epsilon$  is the applied strain range.

FIG. 26 STRAIN-CONTROLLED MATRIX FATIGUE DATA PLOTTED IN TERMS OF THE EFFECTIVE STRAIN CRITERION. SOURCE: REF 49

For each experimental test, the effective strain parameter was calculated using the above equation and plotted versus the number of cycles to observed crack initiation. The results are shown in Fig. 27. Very good agreement was found between the experiments and predictions based on the matrix fatigue data alone.

FIG. 27 THE SOLID LINE IS THE EFFECTIVE STRAIN VERSUS NUMBER OF CYCLES TO FAILURE FOR THE MATRIX MATERIAL. THE SYMBOLS ARE THE CALCULATED EFFECTIVE STRAINS IN THE MATRIX AT THE NOTCH TIP VERSUS NUMBER OF CYCLES TO OBSERVED CRACK INITIATION. SOURCE: REF 49. ADDITIONAL DATA CAN BE SEEN IN REF 63.

The residual stress in the matrix is an important contributor to the total effective strain. At lower values of  $\Delta\epsilon_{eff}$  in Fig. 27 (e.g., 0.0035),  $\sigma^r/E$  is 35% of the  $(K_t\epsilon_{max} + \sigma^r/E)$  term. Without the residual stress term, the effective strain parameter would be reduced by 59%. At higher values of  $\Delta\epsilon_{eff}$  in Fig. 27 (e.g., 0.0065), the effective strain parameter would be reduced by 46% because the  $\sigma^r/E$  is 21% of the  $(K_t\epsilon_{max} + \sigma^r/E)$  term. Obviously, if the composite data points were shifted down by these percentages, the effective strain parameter would not correlate the data. This illustrates the importance of including the residual stress term in the modified effective strain parameter.

**Fatigue Crack Growth from Notches.** Fatigue cracks were observed in notched  $[0]_8$ ,  $[0/90]_{2s}$ , and  $[0/90/0]$  laminates at cyclic stress levels above those required for crack initiation but well below the laminate net section static strength (Ref 49). The specimens were periodically radiographed during the tests to monitor fiber breaks. After the tests (but prior to specimen failure), the specimen surfaces were either polished or acid etched to reveal the matrix cracks and fibers in the surface ply. Multiple matrix cracks had initiated at and grown from the notches. Harmon and Saff (Ref 51) reported similar results for unidirectional SCS-6/Ti-15-3 center-hole specimens. Figure 28 shows a typical matrix crack growing from the edge of a hole in a  $[0/90]_{2s}$  specimen. The polished surface clearly shows that the matrix crack grew around and past the fibers. Also, a long debond between the fiber next to the hole and the matrix on the side toward the hole was seen. This type of debonding can significantly reduce the stress concentration at the edge of the notch. One can nominally predict the stress level at which the fibers next to the notch should fail, based on the applied loading and calculated stress concentration for the undamaged state. However, because of damage such as that shown in Fig. 28, the stress concentration may be reduced so that only the matrix would fail and not the fibers.

**FIG. 28 MATRIX CRACK GROWING PAST FIBERS. LOCALIZED DEBONDING OF THE MATRIX FROM THE FIBER CAN BE SEEN. SOURCE: REF 48**

Bigelow and Naik (Ref 52) developed a macro-micromechanics finite element approach to calculate the local stresses around a continuous fiber at a global stress discontinuity, such as a notch tip. This approach was used by Bigelow and Johnson (Ref 53) to predict the notch-tip interface stresses in the matrix material due to a remote stress of 1 MPa on a double-edge-notched  $[0/90]_{2s}$  SCS-6/Ti-15-3 specimen with the same geometry as the specimen described above. This type of analysis can give good insight into the cause of fiber/matrix interface failure such as that shown in Fig. 28. The axial stress is high due to the local stress concentration. Once the notch-tip  $0^\circ$  fiber/matrix interface debonds, the stress concentration will decrease by approximately one-third (Ref 53).

**Prediction of Growth Rates in Bridged Cracks.** Bakuckas and Johnson (Ref 54) conducted an analytical and experimental investigation of the effect of fiber bridging on fatigue crack growth in  $[0]_8$  SCS-6/Ti-15-3. The specimens tested contained center slits with initial notch-length-to-width ratios of 0.30 and 0.35. Under constant-amplitude loading the crack growth rate decreased as the crack length increased. The fiber bridging reduced the crack driving force as the crack grew. Because the crack in the composite grows only in the matrix material, the crack growth rate in the composite should correlate with the crack growth rate in the matrix material alone if the correct crack driving force in the matrix,  $\Delta K_{mat}$ , is defined. Figure 29 shows crack growth rate versus  $\Delta K$  data for the Ti-15-3 material. The figure also shows the composite data plotted with  $\Delta K_{app}$ , the crack driving force calculated without accounting for the fiber bridging. The  $\Delta K_{app}$  does not collapse the composite crack growth data to the Ti-15-3 data. The effect of the fibers bridging the matrix crack must be incorporated into the definition of  $\Delta K_{mat}$ .

**FIG. 29** CRACK GROWTH RATE DATA FROM THE TI-15-3 MATERIAL COMPARED WITH THE CRACK GROWTH DATA FROM THE COMPOSITE. THE SOLID SYMBOLS ARE THE COMPOSITE CRACK GROWTH DATA ASSUMING NO FIBER BRIDGING. THE OPEN SYMBOL DATA ARE CORRECTED FOR BRIDGING, ASSUMING THE INDICATED SHEAR STRESSES. SOURCE: REF 54

Several fiber bridging models that combine a continuum fracture mechanics analysis and a micromechanics analysis have been investigated (Ref 55, 56, 57). In all of these models, the intact fibers in the wake of the matrix crack are modeled using a continuous closure pressure. Fiber/matrix debonding occurs as the crack progresses past each fiber. An unknown constant shear stress  $\tau$  is assumed to act on the debonded fiber/matrix interface. The model proposed by McMeeking (Ref 57) provided the most accurate predictions of the measured fiber/matrix debond length and crack opening displacements for test data, as well as collapsing the  $da/dN$  data, as shown in Fig. 29. The values of  $\tau$  used to fit the data are also shown in Fig. 29. Bakuckas and Johnson (Ref 58) modified the fiber bridging models to include thermal residual stresses. This resulted in a more predictive model, because one value of  $\tau$  was able to correlate all the data for a given fiber and matrix combination.

Larsen et al. (Ref 59) have documented crack growth and the associated mechanisms in SCS-6/Timetal 21S using several lay-ups,  $R$ -ratios, and stress levels. They have also developed an effective stress-intensity approach to correlate the crack growth data. Zheng and Ghonem (Ref 60) have conducted similar work on the SM1240/Timetal 21S unidirectional composites. Bowen (Ref 61) has studied the crack growth behavior of unidirectional lay-ups of SCS-6/Ti-15-3, SCS-6/Ti-6Al-4V, SCS-6/Timetal 21S, and SM1240/Ti-6Al-4V. These tests were conducted by cyclic load on a notched bend specimen. Davidson (Ref 62) has performed microstructural observations pertaining to the fiber bridging phenomenon in SCS-6/Ti-15-3. Emphasis was placed on determining the slip that occurs between the matrix and the fiber as a result of debonding during the fiber bridging process.

**Effect of Matrix Cracking on Residual Strength.** Matrix cracks initiate and grow from notches at cyclic stress levels of less than one-third of the ultimate strength of notched virgin specimen. In cases where only matrix cracks occur with no accompanying fiber failures, one needs to be able to assess the effect of this damage on residual strength. Bakuckas et al. (Ref 63) conducted an experimental and analytical study of  $[0/90]_{2s}$  laminate containing a center-hole specimen with a ratio of hole diameter to specimen width of 0.33. The residual strengths were experimentally determined for a virgin specimen and for a specimen that was saturated with matrix cracks after being subjected to cyclic loading between 25 and

250 MPa for 200,000 cycles. The residual strengths were 525 MPa and 325 MPa, respectively. The matrix cracks resulted in a strength reduction of 38%. Thus, the effect of the matrix cracks was significant.

The three-dimensional finite element program PAFAC (Ref 64) was used to determine the effects of the matrix cracks on the stress concentration in the  $0^\circ$  fibers and to predict the residual strengths of both the virgin and post-fatigued specimens. For the virgin condition the composite was initially modeled with the undamaged properties of the matrix and fiber and assuming a perfect fiber/matrix interface. As the virgin specimen was analytically loaded, the fiber/matrix interfaces were assumed to fail in the  $90^\circ$  plies, as previously discussed. For the post-fatigued test the modulus of the matrix was reduced by 69% to account for the saturated state of the matrix cracks. The modulus reduction was determined by calculating the required matrix modulus to account for the stiffness loss in the unnotched crack-saturated portion of the specimen. The fiber strength was determined from unnotched coupons by recording the strain to failure and multiplying it by the fiber modulus. The predicted and measured residual strengths are shown in Fig. 30. The point at which the predicted notch-tip  $0^\circ$  fiber stress crosses the fiber strength line represents the predicted laminate failure. The  $[0/90]_{2s}$  laminate failure was observed to be catastrophic (i.e., when the first fiber failed, the specimen failed). Using this micromechanics-based strength prediction methodology for the notched laminate resulted in excellent predictions.

FIG. 30 AXIAL STRESS IN THE  $0^\circ$  FIBER NEXT TO THE HOLE AS A FUNCTION OF APPLIED STRESS FOR THE VIRGIN AND POST-FATIGUED CONDITION IN  $[0/90]_{2s}$  SCS-6/TI-15-3 LAMINATES,  $V_f = 0.355$ . THE APPLIED STRESS AT WHICH THE  $0^\circ$  FIBER STRESS REACHES THE FIBER STRENGTH CORRESPONDS TO THE NOTCHED STRENGTH FOR BOTH CONDITIONS. SOURCE: REF 63

## Residual Strength of Composite Aircraft Structures with Damage

C.C. Poe, Jr., NASA Langley Research Center

---

## Introduction

OVER THE PAST DECADE or so, secondary and primary structures of numerous commercial and military airplanes have been made of composites. Secondary structures are much more numerous than primary structures. Some of the primary structures being made of carbon-epoxy are vertical tails of the Airbus A300-340 series and the Boeing 777 transports and the wings and fuselages of the B-2 bomber. NASA and its contractors have completed two of three phases of the Advanced Composite Technology (ACT) program to develop composite wings and fuselages for commercial transport airplanes with costs that are competitive with those of current metal airplanes. Structural design criteria for these airplanes include damage tolerance requirements that specify the ability of a structure to operate safely with initial defects or in-service damage. Defects such as porosity, delamination, lack of bond between co-cured parts, and wrinkles in fibers can develop when composite materials are processed. Composite parts can also be scratched and gouged during manufacturing, shipping, and assembly. Low-velocity impacts can cause serious damage to carbon-epoxy even when the damage is not readily visible. Sources of low-velocity impacts are falling tools and equipment, runway debris, hail, birds, and even collisions with other airplanes and ground vehicles. Both metal and composite airplanes can be damaged by high-velocity impacts from parts of rotating machinery that fail in turbofan engines and penetrate the skin and supporting structure (discrete source damage). All of the aforementioned defects and damage are relevant to commercial and military airplanes. In addition, military airplanes can suffer ballistic damage, which is analogous to discrete source damage in civilian airplanes.

For U.S. commercial airplanes, certification criteria regarding defects and damage in composite materials are given in the Federal Airworthiness Regulations (FAR) Part 25 and FAA Advisory Circular (AC) 20-107A. They can be summarized as follows:

- **NONDETECTABLE DEFECTS AND DAMAGE:** STRUCTURE MUST WITHSTAND ULTIMATE LOAD 1.5 TIMES LIMIT LOAD
- **DETECTABLE DAMAGE:** STRUCTURE MUST WITHSTAND LIMIT LOAD (MAXIMUM EXPECTED LOAD)
- **DISCRETE SOURCE DAMAGE:** STRUCTURE MUST CARRY 70% OF LIMIT MANEUVER LOADS AND 40% OF LIMIT GUST LOADS COMBINED WITH MAXIMUM APPROPRIATE CABIN PRESSURE. (DISCRETE SOURCE DAMAGE IS SELF-EVIDENT, ALLOWING THE CREW TO FLY WITH MINIMUM LOADS.)

For military airplanes, similar requirements are contained in the Aircraft Structures, General Specifications for AFGS 87-221.

With regard to detectable damage, AC 20-107A specifies that "The extent of initially detectable damage should be established and be consistent with the inspection techniques employed during manufacture and in service." Simple, inexpensive visual methods are preferred for in-service inspections. The AFGS 87-221 specifies the lower limit for visible damage to be a 2.5 mm deep dent or damage from a 25.4 mm diam impactor with 135 J, whichever is least. However, more recently, arguments are being made for a 1.3 mm-dent threshold for commercial transports.

For metal skins of commercial transport structures, discrete source damage is usually represented by a cut. The length of cut has traditionally been two bays of skin including one severed stiffener or frame (see Fig. 1). Similar configurations are cited in MIL-A-83444 for "fail safe crack arrest structure." For composite laminates, cuts are more likely to give a lower bound to tension strengths. See the results in Fig. 2 for cuts, impact damage, and holes (Ref 1, 2, 3). As will be shown subsequently, the strengths for cuts in Fig. 2 would probably have been lower had the laminates been as thick as those with holes. In the NASA ACT program, the two-bay crack has also been used to represent the upper limit for detectable damage. Thus, a strength analysis of the two-bay crack is important for damage tolerance certification of composite structures.

FIG. 1 SKETCHES OF DISCRETE SOURCE DAMAGE FOR FUSELAGE

FIG. 2 TENSION STRENGTHS FOR IMPACT DAMAGE, OPEN HOLES, AND CUTS

This paper was organized around the damage tolerance criteria listed above. It includes sections on defects, low-velocity impacts, and strength analysis for a two-bay crack. The section on defects is relatively short because impact and discrete source damage tend to be more critical. The section on impact includes subsections on resin toughness, laminate thickness, specimen size and impactor mass, and post-impact fatigue. An understanding of how specimen size and thickness and impactor mass affect impact response is essential to relating coupon and structural test results. The section on strength analysis for a two-bay crack presents both the linear elastic fracture mechanics (LEFM) and the R-curve methods for predicting strength.

### Defects

The reduction in compressive strength with increasing size of porosity and delamination (Ref 4) is shown in Fig. 3 for an AS4/3501-6 wing skin laminate. The strengths were normalized by strength without defects or damage. Porosity and delaminations less than 2% and 4 cm in diameter, respectively, caused less than 20% reduction in compressive strength. Defects of this size can be detected initially in the factory using conventional ultrasonic methods. Tensile strengths are largely unaffected by these types of matrix defects. Thus, for both tension and compression, porosity and delaminations tend not to be critical.

FIG. 3 COMPRESSIVE STRENGTH VERSUS DEFECT SIZE FOR AS4/3501-6 WING SKIN LAMINATE

The effect of wrinkles is shown in Fig. 4 for  $[90_2/0_2/90_2/0_2/90_2/\bar{0}_{2W}]_s$  T300/P1700 polysulfone laminates (Ref 5). Compressive strength with wrinkles normalized by compressive strength without wrinkles is plotted against crimp angle of the wrinkles. Each ply was 0.20 mm thick. The wrinkles were made in the middle two plies as indicated by the subscript W (see Fig. 4). The curve was fit to the data. The wrinkles reduced compressive strengths as much as 25 to 35% on the average for the largest crimp angle. These wrinkles will also reflect acoustic waves, but to a lesser degree than delaminations, and perhaps can also be detected using conventional ultrasonic methods (or by x-ray if tracer fibers are used). Sometimes wrinkles are visible on the surface and can be detected by visual inspection. The author had an experience where wrinkles in 16-ply quasi-isotropic T300/5208 laminates caused a significant reduction in tensile strength. As will be shown subsequently, the defects in Fig. 3 and 4 are generally less severe than low-velocity impact damage.

#### Low-Velocity Impacts

**Resin Toughness.** Low-velocity impacts from hail, runway debris, dropped tools, and so forth, present a special problem for carbon composites. Impacts, especially those made by a blunt object, may cause considerable internal damage without producing visible indications on the surface. For relatively thin laminates, damage to the resin can be widespread without damage to the fibers. A schematic of matrix damage for a  $[-45/0/45/90]_{3s}$  T300/934 laminate (Ref 6) is shown in Fig. 5. (The loading direction and  $0^\circ$  fiber direction are synonymous throughout this paper.) In the left-hand figure, the delaminations within each interface resemble a pair of wedges that begin at a ply crack (transverse shear crack) in the lower ply and terminate at a ply crack in the upper ply. In the right-hand figure, an assembly of delaminations is shown for four consecutive interfaces (one repeating group of plies). The wedge-shaped delaminations resemble a spiral staircase. Although not shown in Fig. 5, the diameter of the wedges varies through the thickness much as a parabolic transverse shear stress distribution.

FIG. 5 SCHEMATIC SHOWING PLAN VIEW OF IMPACT DAMAGE THROUGH FIVE CONSECUTIVE INTERIOR PLYS OF A  $[-45/0/45/90]_{3s}$  T300/934 LAMINATE

For the more common carbon/epoxy composites, numerous investigators have demonstrated that static indentation tests produce essentially the same damage as low-velocity impact tests for a given impact force. Figure 6 contains a graph of damage diameter  $d_o$  versus contact force  $F$  for static indentation and falling-weight impact tests (Ref 7). Open and solid symbols indicate data from static indentation and impact tests, respectively. The 7.0 mm thick  $[45/0/-45/90]_{6s}$  AS4/3501-6 and IM7/8551-7 plates were made from prepreg tape. The 3501-6 resin is a "brittle" epoxy, and the 8551-7 resin is a "toughened" epoxy. The plates were clamped over a 12.7 cm diam circular opening for the static indentation tests and a 12.7 cm square opening for the impact tests. A 12.7 mm diam hemisphere was used for the indenter and tup. The mass of the impactor was 4.63 kg. The damage diameters were calculated for a circle with area equal to the damage area in C-scan images. Both composite materials were penetrated in the static indentation tests as indicated by the vertical lines on the right. For both materials, the data for static indentation and impact tests are in agreement. The contact force to initiate damage  $F_1$  (initiate in the sense that damage was visible in a C-scan image) is indicated by the vertical lines on the left. After initiation, damage diameter increased in proportion to contact force, which corresponds to a constant value of transverse shear strength per unit length  $Q^*$ .

$$Q^* = \frac{F}{\pi d_o} \quad (\text{EQ 1})$$

Both  $Q^*$  and  $F_1$  are measures of damage resistance. The values of  $Q^*$  and  $F_1$  for the toughened IM7/8551-7 material were 216% and 150%, respectively, of those for the AS4/3501-6 material.

FIG. 6 DAMAGE DIAMETER FOR [45/0/-45/90]<sub>6s</sub> IM7/8551-7 AND AS4/3501-6 LAMINATES WITH 12.7 MM DIAM INDENTER

Impact force can be calculated from the following equations (Ref 7) using energy balance considerations and assuming that the transverse displacements are given by the quasistatic solution.

$$\frac{1}{2} m_i v_i^2 = \frac{1}{2} \frac{F_{\max}^2}{k} + \frac{2}{5} \frac{F_{\max}^{5/3}}{n_0^{2/3} R_i^{1/3}} \quad (\text{EQ 2})$$

where

$$n_0 \approx \frac{4}{3} E_2 \text{ for } E_i \gg E_2 \quad (\text{EQ 3})$$

and where  $F_{\max}$  is the impact force,  $m_i$  is the mass of the impactor,  $v_i$  is the velocity of the impactor,  $R_i$  is the radius of the spherical impactor,  $E_i$  is the modulus of the impactor,  $k$  is the flexural stiffness of the plate for a quasistatically applied impact force, and  $E_2$  is the modulus of the plate in the thickness direction. The first term on the right-hand side of Eq 2 accounts for flexural displacements, and the second term accounts for Hertzian indentation. For thin plates, the Hertzian term is negligible, and impact force increases in proportion to the square root of the product of kinetic energy and flexural stiffness.

Impact forces for the falling-weight tests in Fig. 6 are plotted against kinetic energy of the impactor in Fig. 7. The solid symbols indicate when the impacts caused damage large enough to be visible in a C-scan. Impact forces calculated using Eq 2 are also plotted for comparison. A value of  $n_0 = 4.52$  GPa determined by experiment was used instead of Eq 3. The differences between elastic constants for the two materials were too small to warrant plotting two curves for the energy balance equation. As will be shown subsequently, the relatively large impactor mass should result in a quasistatic

response as assumed in Eq 2. Indeed, the measured and calculated impact forces agree for the one test for which damage was not visible in the C-scan. However, for all the impact tests with damage visible in C-scans, the test values of impact force were less than the predicted values. The discrepancies, which increased with increasing damage size, were caused by the reduction in flexural stiffness due to the delamination-type damage. Equation 2 does not account for impact damage. The measured impact forces were probably greater for IM7/8551-7 than for AS4/3501-6 because the damage was smaller (see Fig. 6).

**FIG. 7 IMPACT FORCE VERSUS IMPACTER KINETIC ENERGY FOR  $[45/0/-45/90]_{6s}$  IM7/8551-7 AND AS4/3501-6 LAMINATES AND A 12.7 MM DIAM TUP**

Postimpact compressive strengths for the 7.0 mm thick  $[45/0/-45/90]_{6s}$  AS4/3501-6 and IM7/8551-7 plates in Fig. 6 and 7 are plotted in Fig. 8. The static indentation specimens were 12.7 cm square, and the impact specimens were 12.7 cm wide and 25.4 cm long. All edges were simply supported during the strength tests. Undamaged strengths are plotted at  $d_o = 0$ . The strengths were normalized by modulus to represent far-field failing strains, and the lines were fit to the data. Because the delamination-type damage prevents adjacent plies from fully stabilizing one another in compression, failure initiates prematurely in the damaged region by sublaminar buckling and strengths are significantly below the undamaged strengths. The average undamaged strength ratio for the AS4/3501-6 material was 20% greater than that for the IM7/8551-7 material. However, when  $d_o$  exceeded 20 mm, the postimpact strengths for the two materials were about the same for a given  $d_o$ . For values of  $d_o$  greater than 40 mm (about 30% of the specimen width), the free edges probably exaggerated the strength reductions. That is, very wide specimens would have been stronger for the same  $d_o$ .

FIG. 8 POSTIMPACT COMPRESSIVE STRENGTHS FOR  $[45/0/-45/90]_{6s}$  IM7/8551-7 AND AS4/3501-6 LAMINATES WITH 12.7 MM DIAM INDENTER

**Laminate Thickness.** Figure 9 contains a graph of damage diameter,  $d_o$ , versus contact force  $F$  for 16-, 24-, 32-, and 48-ply laminates from static indentation tests (Ref 8) and falling-weight impact tests (Ref 9). The  $[45/0/-45/90]_{ns}$  AS4/3501-6 uniweave laminates were made using a resin-film-infusion (RFI) process. The average thickness per ply was 0.14 mm. The falling-weight impact tests were conducted with a 5.31 kg weight and a 12.7 mm diam hemispherical tup. The plates were clamped over a 7.62 cm square opening for the static indentation tests and over a 7.62 by 12.7 cm rectangular opening for the impact tests. The damage diameters were calculated for a circle with area equal to the damage area in C-scan images. The results for static indentation and impact tests are in reasonably good agreement. After damage initiated, damage diameter increased in proportion to contact force (in a manner similar to that shown in Fig. 6). Also, the values of  $Q^*$  for the 48-ply RFI laminate and the AS4/3501-6 tape laminate in Fig. 6 are in good agreement. However, the value of  $F_1$  for the 48-ply RFI laminate is more than 30% greater than that for the AS4/3501-6 tape laminate in Fig. 6. Values of  $F_1$  increased with increasing thickness to approximately the  $3/2$  power, and the values of  $Q^*$  increased with increasing thickness to approximately the 0.3 power. Thus, damage resistance increased with increasing thickness, more so for  $F_1$  than  $Q^*$ .

FIG. 9 DAMAGE DIAMETER FOR  $[45/0/-45/90]_{NS}$  AS4/3501-6 UNIWEAVE (RFI) WITH A 12.7 MM DIAM INDENTER

Only the 16-ply composite in Fig. 9 was actually penetrated in the static indentation tests, and no laminates were penetrated in the impact tests. However, for the largest impact forces, the impactor appears to be on the verge of penetrating the 16-, 24-, and 32-ply laminates. The largest impact forces correspond to 2.54 mm dents. Although the forces were essentially equal for penetrating the 16-ply laminate and for making a 2.54 mm deep dent,  $d_o$  was considerably greater for the dent than the penetration. The difference between the sizes of damage in the impact and static indentation tests could be associated with viscoelastic effects.

Values of average impact force for the impact tests in Fig. 9 are plotted against dent depth in Fig. 10. Values of  $F_1$  in Fig. 9 are plotted at zero dent depth. The impact force to cause a dent of a given depth increased with increasing thickness much as  $F_1$ . In general, impact force exhibits asymptotic behavior with increasing dent depth; the impact force to make a 2.54 mm deep dent was not significantly greater than that to make a 0.127 mm deep dent. For the two thickest laminates, the departure from monotonically increasing impact force is probably not statistically significant.

FIG. 10 IMPACT FORCE TO PRODUCE DENTS OF VARIOUS DEPTHS FOR  $[45/0/-45/90]_{NS}$  AS4/3501-6 UNIWEAVE (RFI) WITH A 12.7 MM DIAM INDENTER

Impact forces for the 16-, 24-, 32-, and 48-ply  $[45/0/-45/90]_{NS}$  AS4/3501-6 uniweave RFI plates are plotted against kinetic energy of the impactor in Fig. 11. All of the specimens were dented, and damage was visible in C-scans. Impact forces predicted using Eq 2 with  $n_o = 4.52$  GPa are also plotted for comparison. The predicted impact forces increase approximately with thickness to the  $3/2$  power. The test values of impact force also increased with increasing thickness, but not as much as predicted. The discrepancy increased with increasing thickness. The delamination-type damage reduced the impact force (in a manner similar to that shown in Fig. 7). The reduction in flexural stiffness is proportionately less for a thin laminate than a thick laminate. Thus, the test and predicted values of impact force for the 16- and 24-ply laminates with the least damage were in reasonably good agreement.

FIG. 11 IMPACT FORCE VERSUS IMPACTOR KINETIC ENERGY FOR  $[45/0/-45/90]_{NS}$  AS4/3501-6 UNIWEAVE

## (RFI) AND A 12.7 MM DIAM TUP

As shown previously, both impact force and damage resistance increase with increasing thickness. Thus, the net effect of increasing thickness is not obvious. For this reason, damage diameters in Fig. 9 for the falling-weight tests are plotted against kinetic energy of the impactor in Fig. 12. For the most part, damage size is independent of thickness, and the data are well represented by the average solid curve. The reader should be aware that the results in Fig. 12 should be quite different for a sandwich with face sheets of the same thickness because a sandwich is much stiffer than the face sheets alone and the impact forces would tend to be much larger.

FIG. 12 DAMAGE DIAMETER VERSUS IMPACTER KINETIC ENERGY FOR  $[45/0/-45/90]_{NS}$  AS4/3501-6 UNIWEAVE (RFI) AND A 12.7 MM DIAM TUP

Average postimpact compressive and tensile strengths are plotted against damage diameter in Fig. 13 for the falling-weight tests in Fig. 9, 10, 11, and 12. The compression and tension specimens were 10.2 cm wide by 15.2 cm long and 10.2 cm wide by 25.4 cm long, respectively. For the compression specimens, sides and ends were simply supported. For the tension specimens, sides were unsupported and 10.2 cm of each end were placed in a set of hydraulic grips. The strengths were normalized by modulus to represent far-field failing strains. Undamaged strengths for a similar 48-ply RFI laminate (Ref 10) are plotted as horizontal lines for reference. The strengths were higher for tension than compression, especially for the smallest damage sizes, and generally decreased with increasing damage size. The damage extended from 20 to 80% across the specimen width. Thus, the strength reductions were probably exaggerated by edge effects, much as in Fig. 8. The best-fit curve for compressive strength in Fig. 8 for the 48-ply AS4/3501-6 tape material is in good agreement with the 48-ply AS4/3501-6 RFI material.

FIG. 13 POSTIMPACT TENSILE AND COMPRESSIVE STRENGTHS FOR  $[45/0/-45/90]_{NS}$  AS4/3501-6 UNIWEAVE (RFI) AND A 12.7 MM DIAM TUP

The 16- and 24-ply compression specimens in Fig. 13 gave evidence of premature Euler buckling, probably contributing to the relatively low compressive strengths for the two smallest values of  $d_0$ . Thus, without buckling, the compressive strengths probably would have varied little with thickness, and C-scan damage size would be a convenient matrix for assessing postimpact compressive strength. On the other hand, tensile strengths increased significantly with increasing thickness. As noted previously, delamination-type damage reduces compressive strength but not tensile strength. Because fiber damage is confined to the contact region, fiber damage is much smaller in size than matrix damage. Thus, C-scan damage size is matrix damage size and not a convenient metric for assessing postimpact tensile strength. Because damage sizes in Fig. 12 were largely independent of thickness for a given impactor kinetic energy, a graph of strength versus impactor kinetic energy would have an appearance similar to that of Fig. 13 with regard to thickness variations.

Dent depth is an important metric for assessing postimpact strength. Thus, the postimpact tensile and compressive strengths in Fig. 13 are plotted against dent depth in Fig. 14. The strengths exhibit asymptotic behavior with dent depth. For the 0.1 mm deep dents, the tensile strengths were 80 to 97% of undamaged strength, but the compressive strengths were only 37 to 49%. For the 1 mm deep dents, the tensile strengths were 43 to 49% of undamaged strength, and the compressive strengths were 22 to 36%. For the 2.5 mm deep dents, tensile strengths were 34 to 39% of undamaged strength, and the compressive strengths were 22 to 36%. Thus, when dent depth increased from 1 to 2.5 mm, the tensile strengths decreased only 10 to 24% and the compressive strengths were unchanged.

FIG. 14 POSTIMPACT TENSILE AND COMPRESSIVE STRENGTHS VERSUS DENT DEPTH FOR  $[45/0/-45/90]_{NS}$  AS4/3501-6 UNIWEAVE (RFI) AND A 12.7 MM DIAM

In contrast to tensile strengths plotted against C-scan damage sizes in Fig. 13, the tensile strengths plotted against dent depths in Fig. 14 are largely independent of thickness, indicating that fiber damage is also largely independent of thickness. On the other hand, compressive strengths decrease significantly with increasing thickness when plotted against dent depths. Therefore, dent depth is a more convenient metric than C-scan damage size for assessing postimpact tensile strength, but C-scan damage size is a more convenient metric than dent depth for assessing postimpact compressive strength.

In very thick laminates, low-velocity impacts cause mostly fiber damage and very little delamination-type damage (Ref 11). Fiber breaks in the seventh layer of a 36 mm thick filament-wound motor case made of AS4/HBRF-55A are shown in Fig. 15. (Fibers were damaged only in layers 1 through 7 of the 76-layer laminate.) An enlargement of the fiber breaks is shown on the right-hand side of Fig. 15. The layers were separated following pyrolysis of the specimen. The layup was  $\{(\pm 56.5)_2/0/[\pm 56.5]_2/0\}_3/(\pm 56.5)_2/0\}_7/(\pm 56.5/0)_2/(\pm 56.5)_2/(0/90)_c$  where  $90^\circ$  is the axial direction of the cylinder. The underlined layers were about 1.6 times as thick as the other layers, and the innermost  $(0/90)_c$  layer is a layer of plane weave cloth. The damage was made by static indentation using a 25.4 mm diam hemispherical indenter with a contact force of 54.3 kN. The locus of fiber breaks has the appearance of a "crack." More than one "crack" was present in damaged layers nearer the surface, and the direction of the cracks in each layer was generally perpendicular to the fiber direction in that layer. Delaminations outside of the contact region were not observed in radiographs.

FIG. 15 FIBER DAMAGE IN SEVENTH LAYER OF 36 MM THICK AS4/HBRF-55A FILAMENT-WOUND CASE

The maximum depth of fiber damage  $\delta$  normalized by contact radius,  $r_c$  (Ref 11) is plotted against average contact pressure  $p_c$  in Fig. 16. The damage was made by static indentation with spherical indenters of three diameters. The contact radius was calculated assuming Hertzian contact. Damage depths were calculated using Love's solution for hemispherical pressure applied to a semi-infinite, isotropic body, and a maximum shear stress criterion with a shear stress of 262 MPa. Damage is predicted to initiate at a critical value of contact pressure below the surface at a depth of  $\delta/r_c = 0.482$ . The damage does not extend much beyond the contact region for pressures up to 1000 MPa as shown in the figure. The isotropic solution models the maximum damage depth quite well. However, in contradiction to the shear stress criterion, damage was always observed in contiguous layers from the surface down. One should expect the isotropic solution to be in greatest error near the surface where highly anisotropic layers dominate. Also, friction, which was not taken into account, may alter the stresses significantly near the surface.

**FIG. 16 DEPTH OF FIBER DAMAGE NORMALIZED BY CONTACT RADIUS IN 36 MM THICK AS4/HBRF-55A FILAMENT-WOUND CASE**

Several effects of indenter radius are not obvious in Fig. 16. For Hertzian contact (Ref 11), the contact force can be written

$$F = (\pi p_c)^3 \left( \frac{R_i}{n_o} \right)^2 \quad (\text{EQ 4})$$

Thus, the contact force to initiate damage for the 50.8 mm diam indenter is 16 times that for the 12.7 mm diam indenter. Similarly, the contact radius can be written

$$R_C = \pi P_C R_I / N_O \quad (\text{EQ 5})$$

Thus, damage size for the 50.8 mm diam indenter is 4 times that for the 12.7 mm diam indenter for a given average contact pressure. Therefore, the sharpness of the indenter has a significant effect on the force to initiate damage and on damage size. The former is intuitive, but not the latter.

Postimpact tensile strengths (Ref 12) are plotted against impact force in Fig. 17 for the 36 mm thick filament-wound motor case. The strengths were normalized by the average of 19 undamaged tensile strengths. The range associated with  $\pm 1$  standard deviation of undamaged strengths is shown on the ordinate. The damage was made by falling weights with 12.7 and 25.4 mm diam spherical indenters. The straight lines were fit to the data. The solid symbols indicate that the impacts caused barely visible dents, probably less than 0.5 mm deep. These dents correspond to average contact pressures  $p_c$  less than 703 MPa. The vertical lines, which indicate impact forces to initiate damage for the two indenter diameters, correspond to an average contact pressure of 563 MPa (see also Fig. 16). As noted previously, calculations assuming Hertzian contact give a factor of four between impact forces for the two indenters to initiate damage. A similar factor exists between the impact forces to cause barely visible dents. The strengths for the nonvisible dents were lower for the 25.4 mm diam indenter than those for the 12.7 mm diam indenter. Thus, the more blunt indenter resulted in a lower allowable for nonvisible impact damage.

FIG. 17 POSTIMPACT TENSILE STRENGTH FOR A 36 MM THICK AS4/HBRF-55A FILAMENT-WOUND CASE

The origin for the strength axis is not shown in Fig. 17 because the strength reductions are less than 20%. Notice that the minimum strength is 88% of the undamaged strengths for the 12.7 mm diam tup. For thin laminates, the tension strengths in Fig. 13 were also high for a 12.7 mm diam tup and the shallowest dent, about 80 to 97% of the undamaged strengths.

**Specimen Size and Impacter Mass.** Previously, test specimens were small and impacters were relatively massive, resulting in quasistatic response. Scaling small coupon results to large structures that do not respond quasistatically can be difficult. In Ref 7, dynamic finite element analyses were made of 7.0 mm thick AS4/3501-6 [45/0/-45/90]<sub>6s</sub> plates impacted with various masses having a 12.7 mm diam tup. In Fig. 18, the maximum calculated values of impact force are plotted against the frequency ratio  $\omega^2/(k/m_i)$  for a constant value of impacter kinetic energy equal to 13.5 J. In the

frequency ratio,  $\omega$  is the natural frequency of the plate and  $\sqrt{k/m_i}$  is a pseudonatural frequency of the impacter mass  $m_i$  attached to a spring that has a stiffness  $k$  equal to the flexural stiffness of the plate for a quasistatically applied impact force. For homogeneous uniformly thick plates,  $\omega_2/(k/m_i) = (m_i/m_p)/\alpha^2$ , where  $\alpha = 0.471$  and  $0.371$  for simply supported and clamped boundaries, respectively. Results are plotted for three square plates with various sizes and boundary conditions: one was 12.7 cm with clamped boundaries, one was 12.7 cm with simply supported boundaries, and one was 25.4 cm with simply supported boundaries. Although the curves contain cusps and impact force does not vary monotonically with impacter mass, the general trend is for impact force to decrease with increasing impacter mass, particularly for the largest plate. Also, impact force is generally smaller for the larger plate and is less for simply supported than clamped boundary conditions.

**FIG. 18** CALCULATED IMPACT FORCE VERSUS NATURAL FREQUENCY RATIO SQUARED FOR AS4/3501-6 [45/0/-45/90]<sub>6S</sub> AND AN IMPACTER KINETIC ENERGY = 13.5J

The time of contact from the dynamic finite element analyses decreased with decreasing impacter mass. Thus, the number of reflections from the boundaries before the impact force reached a peak decreased with decreasing impacter mass. When impacter mass was to the left of the vertical dashed lines in Fig. 18, no reflections returned before the impact force reached a peak. To the right of the vertical lines, one or more reflections returned before the impact force reached a peak. A cusp occurs in the curves whenever the number of reflections changes. Thus, to the left of the vertical lines, impact force is not affected by plate size or boundary conditions. (Had impact force been plotted against the absolute value of impacter mass, the three curves would have coincided to the first cusp.) The horizontal dashed lines in Fig. 18 represent calculations with Eq 2 and  $n_o = 4.52$  GPa, which was derived assuming quasistatic response. For large values of impacter mass, the dynamic analysis curves asymptotically approach Eq 2 as the number of reflections become large.

Experimental values of impact force (Ref 13) are plotted against impacter kinetic energy in Fig. 19 for plates of three sizes (masses): 10.2 cm diam circular plates (0.073 kg), a 24.1 cm square plate (0.50 kg), and a 53.3 cm square plate (2.5 kg). (The plate sizes were actually the sizes of the openings over which the plates were clamped.) Each of the two largest plates was tested multiple times. The plates were made from AS4/3501-6 tape with a layup of [45/0/-45/90]<sub>6S</sub> and a nominal thickness of 6.7 mm. The impacter was a falling weight with a 5.31 kg mass and a 12.7 mm diam hemispherical tip. Predictions were made using Eq 2 with  $n_o = 4.52$  GPa and plotted for comparison. The corresponding values of  $(m_i/m_p)/\alpha^2$  were 15, 77, and 530 in the order of decreasing plate size. Based on the analytical results in Fig. 18, only the impact response for the smallest plates should have been quasistatic. Thus, without impact damage, one would expect the predicted values to be greater than the measured values for the two largest plates, especially for the 53.3 cm square plate that is twice the size of the largest plate in Fig. 18. As noted previously, damage made the measured impact forces fall below the predictions for the smallest plate. However, the test and predicted values for the midsize plate are in agreement, suggesting that the damage offset the transient nature of the response. And for the largest plate, the test values are indeed larger than the predicted values, even with damage. For two of the three impacts to the 53.3 cm square plate, the impacts did not cause visible damage in C-scans as indicated by the open symbols. The results with and without damage follow

the same trend line indicating that damage had negligible effect on flexural stiffness for the largest plate, much as in the case of the thinnest plates in Fig. 11. Therefore, it is less important to account for damage when predicting impact force for plates with low flexural stiffness.

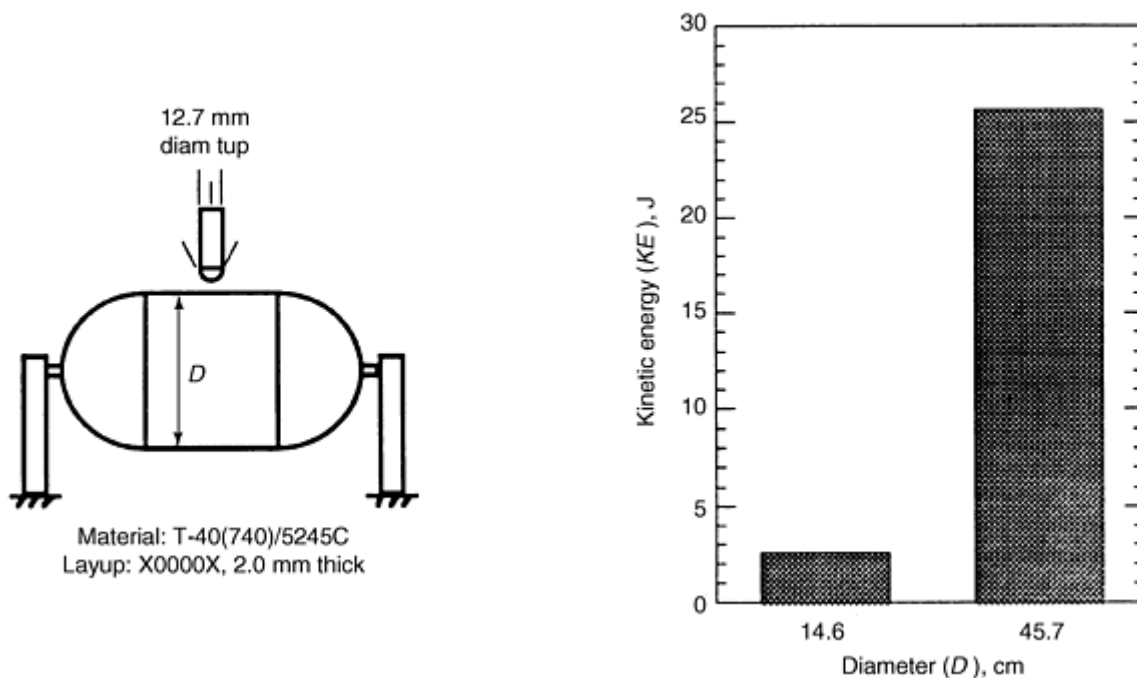

FIG. 19 IMPACT FORCE VERSUS IMPACTER KINETIC ENERGY FOR  $[45/0/-45/90]_{6s}$  AS4/3501-6 LAMINATES OF VARIOUS SIZES

Minimum impacter kinetic energy to reduce burst pressure (Ref 14) is plotted in Fig. 20 for filament-wound pressure vessels of two sizes. The cylindrical sections of the 14.6 and 45.7 cm diam vessels were wet-wound with the same numbers of hoop and helical layers so that only size was different. The minimum kinetic energy for the large cylinder is about ten times that for the small cylinder. This size effect is consistent with that in Fig. 19 where the kinetic energy to initiate damage for the largest plate is more than four times that for the smallest plate.

**FIG. 20 MINIMUM IMPACTOR KINETIC ENERGY TO REDUCE BURST PRESSURE OF SMALL AND LARGE PRESSURE VESSELS.**

Postimpact compression failing strains (Ref 4) are plotted against impactor kinetic energy in Fig. 21 for coupons and three-spar stiffened panels. The "hard" skins were nominally 6.3 mm thick and were made with [38/50/12] and [42/50/8] layups for coupons and panels, respectively. (The notation [38/50/12] indicates the percentage of 0° plies, ±45° plies, and 90° plies, respectively.) The 17.8 by 30.5 cm coupons were clamped over a 12.7 cm square opening and impacted using a 4.5 kg impactor with a 12.7 mm diam tup. The coupons were then trimmed to a 12.7 by 25.4 cm compression after impact specimen. (More details for this test method are given in Ref 15.) The stiffened panels were 61 by 46 cm. The spacing of the bolted titanium spars (stiffeners) was 14 cm, and the distance between inside edges of the C-section spars was 12 cm. A 25.4 mm diam tup and 11 kg impactor was used for the panel tests. The two panels impacted with 54 and 81 J energies were impacted two times in the transverse centerline (over skin only), once midbay of the center spar and left-hand spar and once midbay of the center spar and right-hand spar. The 27 J impact was at only one midbay location. The 135 J impacts were at three locations on each panel: once midbay, once over the skin only but near the edge of a spar, and once over a spar. A curve was fit to the coupon results. Except for panels with multiple 135 J impacts, failures were catastrophic, and failing strains were essentially equal for coupons and for panels. Failures of the panels with multiple 135 J impacts were not catastrophic. After fracture arrest by the spars, the loads were increased 36 and 61% to cause complete failure. The initial failing strains for the panels with multiple 135 J impacts agreed with an extrapolation of the coupon data.

**FIG. 21 POSTIMPACT COMPRESSIVE STRENGTH VERSUS IMPACTER KINETIC ENERGY FOR 6.3 MM THICK AS4/3501-6 COUPONS AND PANELS WITH THREE BOLTED SPARS**

The agreement between failing strains of the coupons and three-spar panels in Fig. 21 indicates that the damage in the panels at the midbay impact site was critical and was equal in size to the damage in the coupons. Equal damage implies equal impact forces. In order for the impact forces to have been equal, the flexural stiffnesses of the panels and coupons would have to be equal. The flexural stiffness of a spar was estimated to be more than 60 times that of the midbay skin. Assuming that most of the out-of-plane deformation during a midbay impact takes place between spars, the stiffened panels can be treated as semi-infinite clamped plates with a width of 12 cm (distance between spars). Using equations in Ref 16 for a transverse force applied over a small radius to an isotropic clamped plate, the difference between flexural stiffnesses of a 12.7 cm square plate and a 12 cm semi-infinite plate is only 14%. Thus, for midbay impacts, the spars reduced the effective size of the stiffened panel during impact to that of the coupons.

Falling-weight tests are used to simulate tool drops, whereas gas-gun tests are used to simulate hail or runway stones and debris. Stones and hail have very small masses relative to tools. Damage size (Ref 13) is plotted against impacter kinetic energy in Fig. 22 for falling-weight and gas-gun tests conducted on plates of three sizes. Impact forces for the falling-weight data were plotted in Fig. 19. The mass of the falling-weight impacter was 5.31 kg, and a 12.7 mm diam hemispherical tup was attached to the end. The diameter and mass of the gas-gun projectile was 10.2 mm and 0.036 kg, respectively. Thus, the velocities of the gas-gun projectile were 12 times those of the falling weight. For the small and midsize plates, the damage sizes were essentially equal for the falling-weight and gas-gun tests. However, the falling weight did not even damage the largest plate for energies less than 40J; whereas, the gas gun damaged the large plate as much as the midsize plate.

**FIG. 22 DAMAGE DIAMETER VERSUS IMPACTER KINETIC ENERGY FOR FALLING-WEIGHT IMPACT TESTS AND GAS-GUN TESTS CONDUCTED ON [45/0/-45/90]<sub>6S</sub> AS4/3501-6 LAMINATES**

As noted previously, the mass ratios for the falling-weight tests were  $(m_i/m_p)/\alpha^2 = 15, 77$ , and  $530$  in the order of decreasing plate size. The corresponding mass ratios for the gas-gun tests were  $0.10$ ,  $0.53$ , and  $3.6$ . The small ratios indicate that the response was transient for all the gas-gun tests (see also Fig. 18). Thus, without damage, the impact forces for the gas-gun tests should have been larger than those for the falling-weight tests. Indeed, for the largest plate, the damage sizes for the gas gun tests were larger than those for the falling-weight tests. However, for the small and midsize plates, damage for the gas-gun tests was not larger than that for the falling-weight tests. As noted previously, damage reduces impact force, and probably ameliorated the differences between impact forces and resulting damage sizes for the gas-gun and falling-weight tests. The mass ratios for the two largest plates are so small that the reflections probably did not return before the peak impact forces were attained. Thus, the damage caused by the gas gun was essentially equal in size for the midsize and largest plates.

Impact forces (Ref 12) are plotted against impacter mass in Fig. 23 for 36 mm thick filament-wound rings. (Strengths for specimens cut from these rings were plotted in Fig. 17.) The impacter kinetic energy was approximately 73 J, and the impacter masses ranged from 2.8 to 18.6 kg. A 25.4 mm tup was attached to the end of the impacters. The 30 cm long rings were cut from a 76 cm diam case. One ring was empty, and one was filled with inert rocket propellant. The masses of the empty and filled rings were 40 and 288 kg, respectively. As in the gas gun tests, impacter masses were less than ring masses. Damage was not visible for any of these tests. Impact force decreased with increasing impacter mass, as also shown by the graph of finite element results in Fig. 18, indicating transient response. Impact forces were larger for the filled ring than the empty ring, indicating that the mass of the inert propellant caused the impacts to be even more transient, more to the left in Fig. 18.

FIG. 23 IMPACT FORCE VERSUS IMPACTOR MASS FOR 73 J IMPACTS WITH A 25.4 MM DIAM TUP TO FILLED AND EMPTY 36 MM THICK AS4/HBRF-55A FILAMENT-WOUND CASES

Calculations of impact force are plotted in Fig. 23 that bound the test results. The lower bounds were made with the energy balance model (Eq 2 with  $n_o = 4.52$  GPa). The values of flexural stiffness for the empty and filled rings, which were determined experimentally, were 5.08 and 6.34 MN/m, respectively. The upper bounds were calculated with the following "two mass Hertzian spring model" (Ref 12).

$$\frac{1}{2} m_i v_i^2 = \frac{2 (1 + m_i/m_p) F_{\max}^{5/3}}{5 n_o^{2/3} R_i^{1/3}} \quad (\text{EQ } 6)$$

Equation 6 considers Hertzian contact of two hemispherical bodies, one is soft (plate) and the other is hard (impactor). The masses of both bodies are present because peak contact force is assumed to occur when the relative velocity of the two bodies is zero. The values of impact force calculated with Eq 2 were less than one-half of those calculated with Eq 6 for the range of masses shown. The test values for the smallest impactor mass were in reasonable agreement with Eq 6. However, the test values diverge from Eq 6 and approach Eq 2 with increasing mass. From Fig. 16, impactor mass would have to exceed 10 times the mass of a flat plate before the test values and Eq 2 would be in agreement.

**Postimpact Fatigue.** For in-plane loading, carbon/epoxy composites have "superb fatigue properties" compared to metals (Ref 17). However, growth of impact damage during fatigue loading and the resulting reduction in compressive strength between inspections may be critical (Ref 4). The ratio of maximum compressive fatigue stress to static strength for two carbon/epoxy composites with impact damage (Ref 18) is plotted against fatigue cycles to failure in Fig. 24. The average static strengths are represented as 1 cycle. The "smoothed" solid and dashed curves were fit through the test data. The fatigue loading was constant amplitude with a minimum compressive stress of one-tenth the maximum compressive stress. An impactor with a 12.7 mm diam hemispherical tup was used to make 2.54 mm dents on the average. The specimens were 12.7 by 25.4 cm. One composite was made of toughened IM7/8551-7 prepreg tape, and the other was made by laying down layers of dry uniweave fabric, stitching the stack, and introducing resin by the RFI process. The layouts for the two composites were [45/0/-45/90]<sub>6s</sub>, and the typical thicknesses were 7.45 and 9.22 mm for the tape and

stitched material, respectively. Cycles to failure for the two materials nearly coincide. The fatigue stress ratios asymptotically approached 0.67.

FIG. 24 CONSTANT AMPLITUDE COMPRESSION FATIGUE FOR  $[45/0/-45/90]_{6s}$  LAMINATES WITH IMPACT DAMAGE RESULTING IN 2.54 MM DENT

Recall from the introduction that the FAA criteria require that structure carry ultimate load with barely visible impact damage (BVID) and limit load with visible impact damage (VID). Thus, the compressive fatigue stress ratios of 1 and  $\frac{2}{3}$  in Fig. 24 correspond to ultimate and limit-load conditions, respectively, with BVID. Taking a 2.54 mm dent as the threshold for VID and assuming that values of normalized compressive fatigue stress would not decrease with increasing dent depth and tup diameter, the stress ratios in Fig. 24 represent an allowable compression stress with BVID. Because the compression fatigue stress ratios are greater than  $\frac{2}{3}$  (the maximum expected load) up to  $10^6$  cycles, compressive fatigue is not critical for these two materials with BVID. It is also not expected that compressive fatigue would be critical for conventional epoxy tape laminates with BVID.

Although structure must carry ultimate load with BVID, structure need only carry limit load with VID. Now the compressive fatigue stress ratio of 1 in Fig. 24 corresponds to limit-load condition. Because the stress ratios are below limit-load condition, factors of safety may be required for growth of VID between inspections. Airlines typically inspect all exposed, exterior surfaces for obvious damage approximately every 2000 flight hours and exterior and interior structure that involve disassembly approximately every 14,000 flight hours. These inspections are sometimes called "C" and "D" checks, respectively. In addition to visual inspection methods, nondestructive inspection methods (ultrasonics, radiography, eddy current, etc.) are used for "D" checks. Assuming 1-h flights and one load cycle per flight, the "C" and "D" checks are shown as vertical lines in Fig. 24 for a factor of safety of four. (Factors of safety greater than four would move the vertical lines even farther to the right.) The vertical lines for "C" and "D" checks intersect the lower curve at 0.74 and 0.69, respectively. These ratios correspond to factors of safety of 1.35 ( $1/0.74$ ) and 1.45 ( $1/0.69$ ). Note that a

factor of safety of 1.5 would be equivalent to treating VID as BVID. Assuming one load cycle per flight of limit load is probably conservative. Spectrum tests would be necessary to establish accurate factors of safety.

## Tension Strength Analysis for Two-Bay Crack

Numerous models and methods have been developed to predict strength of composites with cracklike cuts and tension loads. The following is a partial list given in the order of increasing requirements for computational resources and fracture parameters.

1. LINEAR ELASTIC FRACTURE MECHANICS (LEFM) (REF 3, 19, 20)
2. POINT STRESS (REF 20)
3. AVERAGE STRESS (REF 20)
4. MAR-LIN MODEL (REF 20)
5. DAMAGE ZONE CRITERION (REF 21)
6. R-CURVE METHOD (REF 19)
7. DAMAGE ZONE MODEL (REF 22)
8. STRAIN SOFTENING METHOD (REF 23)

All of the above models and methods represent a composite material as an anisotropic continuum amenable to classical lamination theory. Methods 1 to 6 generally require only linear analyses. Method 1 requires no tests to determine fracture parameters, but is generally accurate only when matrix damage at the notch tips is small compared with notch length. Methods 2 to 6 require several fracture parameters per laminate and method 7 requires a fracture curve for each laminate. Methods 7 and 8 require nonlinear finite element analyses as well as fracture parameters for each laminate. Only methods 5 to 8 explicitly account for damage growth at the notch tips (stable tearing). The LEFM and R-curve methods, which require only linear analyses, will be used below to illustrate the bounds for linear and nonlinear behavior.

**Linear Elastic Fracture Mechanics (LEFM) Method.** Values of fracture toughness (Ref 24) are plotted against thickness (number of plies) in Fig. 25 for middle-cracked, compact, and three-point-bend specimens made from a quasi-isotropic laminate. Compact and three-point-bend specimens with thickness less than 64 plies could not be tested because of large bearing stresses. Fracture toughness values were calculated using stress-intensity factor equations with initial cut length and failure load. Anisotropy generally has little effect on stress-intensity factor solutions for plane problems. Thus, stress-intensity factor solutions for isotropic, homogeneous plates were used throughout this section. For the middle-cracked specimens, fracture toughness decreased with increasing thickness and asymptotically approached a constant value. For laminates 64 plies and thicker, values of fracture toughness were approximately a constant (between 0.97 and 1.18 GPa  $\sqrt{mm}$ ) for all three types of specimens. For thin laminates, broken fibers in 0° plies and matrix cracks and delaminations were revealed at the ends of the cuts when the laminates were depled following an application of load to near failure (Ref 25). For the thick laminates, broken fibers in 0° plies at the ends of the cuts were found throughout, but the matrix cracks and delaminations were confined to the outermost four plies; the interior plies were well bonded. Thus, the strengths for thin laminates were dominated by matrix cracks and delaminations at the ends of the cut but not those for the thick laminates.

FIG. 25 FRACTURE TOUGHNESS FOR CENTER-CRACK, COMPACT, AND THREE-POINT SPECIMENS FOR  $[0/\pm 45/90]_{NS}$  T300-5208 LAMINATES

The fracture toughness of laminates (Ref 26) was expressed in terms of the elastic constants using a point-strain-type failure criterion as follows:

$$K_Q = Q_C E_X \xi^{-1} \quad (\text{EQ 7})$$

where

$$\xi = (1 - \sqrt{\nu_{xy}\nu_{yx}}) (\cos^2 \alpha + \sqrt{E_x E_y^{-1}} \sin^2 \alpha) \quad (\text{EQ 8})$$

$$Q_C = \varepsilon_{TUF} \sqrt{2\pi \bar{d}_o} \quad (\text{EQ 9})$$

$E$  is Young's modulus,  $\nu$  is Poisson's ratio,  $x$  and  $y$  are Cartesian coordinates,  $\alpha$  is the angle that the principal load-carrying fibers make with a line perpendicular to the cut,  $\varepsilon_{tuf}$  is the tensile failing strain of the fibers, and  $\bar{d}_o$  is the "characteristic distance." (The angle  $\alpha=0$  for laminates in which  $0^\circ$  plies carry the majority of the load.) A median value of  $\sqrt{2\pi \bar{d}_o} = 1.5 \text{ mm}^{\frac{1}{2}}$  was determined by analyzing fracture data for numerous layups and materials.

Values of  $Q_C/\varepsilon_{tuf} = \sqrt{2\pi \bar{d}_o}$  (Ref 27) are plotted against number of ply groups in Fig. 26 for three T300/5208 laminates including the laminate in Fig. 25. For laminates thicker than 16 ply groups, the values of  $Q_C/\varepsilon_{tuf}$  are between 1.23 and 1.65  $\text{mm}^{\frac{1}{2}}$ , and the standard deviations are small. For thinner laminates, the mean values range between 1 and 4  $\text{mm}^{\frac{1}{2}}$ , and the standard deviations are large. As noted previously, the discrepancy between values of fracture toughness for thin and thick laminates is largely associated with matrix cracks and delaminations at the ends of the cut. For thin laminates, the mean fracture toughness of the three layups decreases with decreasing number of  $90^\circ$  plies. Accordingly, the fracture toughness of the thin  $[0/\pm 45]_{NS}$  laminates increased with increasing thickness and that of the  $[0/90]_{NS}$  and  $[0/\pm 45/90]_{NS}$

laminates decreased with increasing thickness. Therefore, LEFM is not generally valid for thin laminates, and the application of LEFM to thin laminates may be conservative or unconservative, depending on layup and resin toughness.

FIG. 26 FRACTURE TOUGHNESS VERSUS NUMBER OF PLY GROUPS FOR SEVERAL  $[0/\pm 45/90]_{ns}$  T300/5208 LAMINATES

**R-Curve Method.** The R-curve method can be used for materials that exhibit significant stable damage growth at the ends of cuts. In ASTM E 561 (Ref 28), crack-growth-resistance curves (R-curves) and crack-driving-force curves (F-curves) are expressed in terms of stress-intensity factor. However, for composites, it is convenient to use  $Q_c/\epsilon_{tuf}$  instead of stress-intensity factor to normalize for layup and material. (Of course,  $d_o$  could be used as well.) The R- and F-curves can be calculated by:

$$\frac{Q_c}{\epsilon_{tuf}} = \frac{\xi K}{\epsilon_{tuf} E_x} \quad (\text{EQ 10})$$

where  $K$  is the stress-intensity factor. For a uniaxially loaded sheet of width  $W$  containing a central crack of length  $2a$ ,

$$K = \epsilon_o \sqrt{\pi a \sec(\pi a/W)} \quad (\text{EQ 11})$$

where  $\epsilon_o$  is the far-field strain,  $a = a_o + \Delta a$ ,  $a_o$  is cut half-length, and  $\Delta a$  is the damage growth at each end. Failure is assumed to occur when the increase in crack driving force exceeds the increase in crack growth resistance, which can be expressed by the following partial derivative:

$$\left. \frac{\partial}{\partial \Delta a} \left( \frac{Q_c}{\epsilon_{tuf}} \right) \right|_F \Big|_{\epsilon_o = \epsilon_{oc}} \geq \left. \frac{\partial}{\partial \Delta a} \left( \frac{Q_c}{\epsilon_{tuf}} \right) \right|_R \quad (\text{EQ 12})$$

where  $\epsilon_{oc}$  is the far-field failing strain and the F and R indicate F- and R-curves, respectively. The R-curve method is illustrated in Fig. 27, where an R-curve and several F-curves for a uniaxially loaded 91 cm wide sheet with a 23 cm long

central crack are plotted. The F-curve labeled  $\epsilon_0 = \epsilon_{oc}$  is tangent to the R-curve satisfying Eq 12. The F-curves labeled  $\epsilon_{oc} + \Delta\epsilon_0$  and  $\epsilon_{oc} - \Delta\epsilon_0$  are in the neighborhood of the solution to Eq 12. For all the R-curve predictions in this paper, Eq 12 was solved graphically for far-field failing strain by calculating F-curves for increments of  $\epsilon_0$  until the F-curve was tangent to the R-curve.

**FIG. 27 GRAPHICAL SOLUTION FOR R-CURVE METHOD USING F-CURVES FOR UNIAXIALLY LOADED SHEET WITH CENTRAL CRACK**

An R-curve is shown in Fig. 28 for a 13-ply fuselage crown laminate made of 190 gm/m<sup>2</sup> prepreg tape using a tow-placement process. Values of  $Q_c/\epsilon_{tuf}$  (Ref 19) are plotted against damage growth. Values of  $Q_c/\epsilon_{tuf}$  are calculated using Eq 10 and 11. The values of  $\Delta a$ , which were measured in radiographs like those in Fig. 29 and from measurements of crack-opening displacements (COD), agree well. The COD was measured by a compliance gage located midway between the ends of the cut. The intense dark regions in the radiographs at the ends of the cuts in Fig. 29 indicate broken 0° fibers. The growth of 0° fiber breaks occurred incrementally; each growth resulted in a jump of the COD and an audible sound. The COD is given by

$$COD = 4A\epsilon_0\beta^{-1} \quad \text{(EQ 13)}$$

and the growth was calculated using

$$\Delta A = COD \beta (4\epsilon_0)^{-1} - A_0 \quad \text{(EQ 14)}$$

where  $\beta$  is a factor that corrects for anisotropy. The value of  $\beta$ , which is unity for an isotropic material, was determined experimentally.

FIG. 28 R-CURVE FOR  $[\overline{+45/0/90/\overline{+30/0}}]_s$  AS4/938 FUSELAGE CROWN LAMINATE ( $2A_0 = 23$  CM AND  $W = 91$  CM)

FIG. 29 RADIOGRAPHS OF DAMAGE GROWTH AT ENDS OF CUT IMMEDIATELY BEFORE FAILURE FOR  $[\overline{+45/0/90/\overline{+30/0}}]_s$  AS4/938 FUSELAGE CROWN LAMINATE

The maximum value of  $Q_c/\epsilon_{tuf}$  in Fig. 28 is about 63% greater than the LEFM value, and the maximum growth was 34% of the cut length. Of the 63% increase, approximately 48% was due to the increase in strength and only 15% to the increase in cut length. Thus, strength predictions using LEFM would result in a margin of approximately 48%.

Tensile failing strain predictions using the R-curve and LEFM (Ref 19) are plotted against cut length in Fig. 30. The F-curves were calculated using Eq 10 and 11 with  $\epsilon_{tuf} = 0.0148$ . Failing strains were multiplied by the finite width correction factor  $\sqrt{\sec(\pi a/W)}$  to account for variations in specimen width. The tests and LEFM predictions agree only for cuts

$\leq 2.5$  cm, and the tests and R-curve predictions agree only for cuts  $\geq 7.6$  cm. Thus, both fracture toughness and R-curve depend on cut length for this laminate.

FIG. 30 PREDICTED FAILING STRAINS USING R-CURVE AND LEFM FOR  $[\overline{+45/0/90/\overline{+30/0}}]_s$  AS4/938 FUSELAGE CROWN LAMINATES.  $W \cdot 8A_0$

R-curves for short cuts along with that for the 23 cm long cut in Fig. 28 are plotted in Fig. 31 for the  $[\overline{+45/0/90/\overline{+30/0}}]_s$  fuselage crown laminate (Ref 19). All of the R-curves were calculated using COD measurements. Indeed, the crown laminate does not exhibit a unique R-curve. For a given  $Q_c/\epsilon_{tuf}$ , the amount of damage growth increases with increasing cut length. The envelope of F-curves were calculated using test values of  $\epsilon_{oc}$  for the various cut lengths in Fig. 30. Failing strains calculated using the "envelope" R-curve will by definition be in agreement with the test results for all cut lengths. R-curves used in the following section were determined using the envelope of the F-curves for tests of specimens with various cut lengths.

FIG. 31 R-CURVES FOR  $[\overline{+45/0/90/\overline{+30/0}}]_s$  AS4/938 FUSELAGE CROWN LAMINATES WITH VARIOUS CUT LENGTHS.  $W \cdot 8A_0$

**Applications to Stiffened Panels.** Tensile failing strains for large flat fuselage panels with straps and hat-section stiffeners (Ref 19) are plotted against cut length in Fig. 32 and 33, respectively. The panel with straps in Fig. 32 contained a 25 cm long cut and that with hat-section stiffeners in Fig. 33 contained a 35 cm long cut. The central stiffener in both panels was also cut, and the skins were  $[\overline{+45/0/90/\overline{+30/0}}]_s$  AS4/938 tow-placed fuselage crown laminates. The stiffness ratio  $E_x t$  of the straps was 56% of that of the skin and that of the hat-section stiffeners was 100% of that of the skin, where  $E_x$  is the modulus in the loading direction and  $t$  is the thickness. The panel with straps in Fig. 32 failed catastrophically at an applied strain of 0.00275 with about 25 mm of damage growth at each end of the cut. The damage at the cut ends in the panel with hat-section stiffeners in Fig. 33 grew into the stiffeners (about 18 cm at each end of the cut) before catastrophic failure at an applied strain of 0.00274.

FIG. 32 TEST AND PREDICTED FAILING STRAINS FOR THREE-STRINGER  $[\overline{+45/0/90/\overline{+30/0}}]_s$  AS4/938 FUSELAGE CROWN PANEL (76 BY 213 CM)

FIG. 33 TEST AND PREDICTED FAILING STRAINS FOR FIVE-STRINGER  $[\overline{+45/0/90/\overline{+30/0}}]_s$  AS4/938 FUSELAGE CROWN PANEL (160 BY 348 CM)

Tension failing strains calculated using LEFM and an R-curve are also plotted against cut length in Fig. 32 and 33. The envelope of F-curves in Fig. 31 was used for the R-curve. Approximate, closed-form equations for the stress-intensity

factor in Ref 19 were used with Eq 10 to calculate F-curves for the various cut lengths. The elevation of the stress-intensity factor by the cut stiffener was taken into account. The stiffener was assumed to disbond after the crack tip passed the edge of the intact stiffener, and the failing strain was assumed to be constant thereafter. The jumps in failing strains occur when the end of the cut (LEFM) or the end of the cut plus damage growth (R-curve) coincides with the edge of the intact stiffener. The shaded regions indicate cut lengths for fracture arrest and subsequent increase in failing strain to catastrophic failure. For cut lengths to the left of a shaded region, failure is catastrophic. The failure of the panel in Fig. 32 was catastrophic, but the damage in Fig. 33 grew into the stiffener before failure as predicted. The tests and R-curve calculations were in best agreement, 14% below and 16% above the test values for the straps and hat-section stiffeners, respectively. Failing strains calculated using LEFM were only 66 and 36% of those calculated using the R-curve for the straps and hat-section stiffeners, respectively.

It should be noted that flat panel results cannot be applied directly to shells with longitudinal cracks and internal pressure because stress-intensity factors for pressurized shells can be much greater than those for flat plates. In Fig. 34, stress-intensity correction factors from Ref 29 are plotted against  $a/\sqrt{Rt}$  for isotropic pressurized cylinders and spheres. For a wide body fuselage with a cut equal to two times the frame spacing,  $a/\sqrt{Rt}$  can be as large as five. In that case, the stress-intensity factor for an unstiffened cylinder would be more than five times that for a flat unstiffened plate. Analytical results for specially orthotropic cylinders are given in Ref 30 and 31. These results were experimentally verified for 30 cm diam pressurized composite cylinders with longitudinal cuts in Ref 32. Frames and tear straps are able not only to reduce the stress-intensity factor (Ref 33), they can also turn a fracture and limit a failure (Ref 34).

FIG. 34 STRESS-INTENSITY CORRECTION FACTORS FOR PRESSURIZED SHELLS WITH CUTS

The tensile failing strain for a large flat wing panel with blade stiffeners (Ref 19 and 35) is plotted against cut length in Fig. 35. The five-stringer panel was made using a stitched multi-axial knit fabric and a Resin Film Infusion (RFI) process. The skin was made from 6 layers of multi-axial warp-knit fabric that were stitched together using 6 stitches per square cm of 1600 denier Kevlar 29 thread (3 mm pitch with 5 mm spacing). The skin was 8.4-mm thick, and each layer of fabric was equivalent to a tape layup of  $[45_{153}/-45_{153}/0_{320}/90_{173}/0_{320}/-45_{153}/45_{153}]$ , where the subscripts give the areal weight of the layer in grams per square meter. The T-section stiffeners were made by stitching together 8 layers of the multi-axial warp-knit fabric to form the blades and folding out 4 layers each to form the two flanges. The flanges were stitched to the skin using 6 stitches per square cm. The stitched, stiffened skin preform was infiltrated with 3501-6 resin.

FIG. 35 TEST AND PREDICTED FAILING STRAINS FOR FIVE-STRINGER, STITCHED  $[0/45/0/-45/0/45/0]_{3S}$  AS4/3501-6 WING PANEL (102 BY 203 CM)

The panel contained a 7-in. long cut that also severed the central stiffener. The fracture initiated at the ends of the cut at a strain of 0.0023, propagated to the edge of the stiffener, and was arrested. With increasing load, the fracture turned and grew parallel to the stiffener. At a strain of 0.0034, failure occurred at the grips. Thus, the stitched stiffeners resulted in a 48% increase in failing strain.

Failing strains calculated using LEFM are also plotted against cut length in Fig. 35. Fracture data were not available to determine an R-curve. The LEFM calculations, which were made similar to those in Fig. 32 and 33, greatly underestimated the failing strain. The F-curve equations (driving force) from Ref 19 were based on failure of the adhesive bond between skin and stiffeners as the fracture in the skin advanced beneath the stiffener. The bond failure ameliorated the effectiveness of the stiffener in reducing the crack driving force. However, the stitches bridged the adhesive bond much as mechanical fasteners do and greatly increased the effectiveness of the stitched stiffeners over that of the bonded stiffeners.

More accurate F-curves can be calculated using numerical techniques such as finite elements. For example, an F-curve was calculated for a curved panel with stiffeners, pressure loading, and a two-bay crack in Ref 36. Large out-of-plane displacements were taken into account. Using an R-curve, the residual strength was predicted successively.

### Summary

#### Defects

- Porosity and delaminations that can reduce compression strengths significantly are likely to be detected during manufacture using conventional ultrasonic methods. Tension strengths are largely unaffected by matrix defects.
- Ply wrinkles can reduce tension and compression strength more than porosity and delaminations and are more difficult to detect using ultrasonics.

#### Low-Velocity Impacts

##### Resin toughness

- Damage resistance was greater for thin laminates made from toughened epoxy resins than those made from conventional epoxy resins. On the other hand, compression after impact strengths were essentially equal for the toughened and conventional epoxy resins when damage size in c-scans was equal.

##### Laminate thickness

- Impact damage in thin laminates (2 to 7 mm) initiates as matrix cracking and delaminations. With increasing impact force, fibers also break.
- Damage resistance of thin laminates increased markedly with increasing thickness for a given impact force but tended to be independent of thickness for a given impact energy.
- Tension and compression strengths of thin laminates were reduced 50% or more from impacts that caused dents deeper than 1 mm.
- Impact damage in thick (36 mm) laminates consists of matrix cracks and broken fibers in the outermost laminae directly below the contact region.
- For thick laminates, impact force to initiate damage is proportional to the impactor radius squared, and the depth of damage is proportional to the impactor radius.
- For nondetectable impact damage, tension strengths of thick laminates decreased with increasing impactor radius.

##### Specimen size and impactor mass

- Impacts are approximately quasistatic when the impactor mass is greater than 100 times the plate mass.
- For thin laminates, impact damage reduced impact force markedly for small plates, but not for large plates.
- Impact energy to reduce burst pressure of large, thin pressure vessels was an order of magnitude times that of small pressure vessels with the same membrane laminate.
- Failing strains of thin coupon type specimens and three-stringer panels with bolted stiffeners were equal for a given impact energy. When energy levels were greater than 135 j, the initial failures were arrested by the stiffeners and final failure strains were 136 to 161% of the initial failure strains.
- For large plates and a given impact energy, impacts by small masses (runway debris, etc.) Caused much more damage to thin laminates than impacts by large masses (tools, etc.). For small plates, the damage was of similar size in c-scans.

## Post-impact fatigue

- Constant amplitude compression fatigue tests indicate that fatigue lives for nondetectable impact damage are probably adequate but those for detectable damage may need to be verified by spectrum tests.

## Tension Strength Analysis for Two-Bay Crack

- Linear elastic fracture mechanics (lefm) can be used to predict the strength of thick laminates, but the use of a nonlinear theory such as the r-curve may be necessary to avoid undue conservatism for thin laminates.
- Special techniques may be required to determine an r-curve that is independent of crack length.
- Approximate equations for stress-intensity factors for the two-bay crack and bonded stiffeners gave reasonably accurate strength predictions.

## Fatigue of Brittle Materials

### Introduction

THE DEVELOPMENT of toughened ceramics (based on the technologies and understanding of toughening mechanisms such as *in situ* phase transformation, fiber bridging, ductile-particle toughening, and other toughening methods) is the basis for closer consideration of ceramic materials for possible structural applications. As a result, more attention is being given to the fatigue of ceramics and other brittle materials, because of the importance of cyclic loading in many of the potential applications of ceramics, such as high-temperature engine components and biomedical materials. However, because ceramic and other highly brittle materials have been considered free of cyclic fatigue effects, only limited property data on ceramic fatigue are available.

This article summarizes some of the current understanding of the mechanisms and mechanical effects of fatigue processes in highly brittle materials, with particular emphasis on ceramics. Topics include room-temperature fatigue crack growth in monolithic (single-phase) ceramics, transformation-toughened ceramics, and ceramic composites under cyclic compression; cyclic damage zones ahead of tensile fatigue cracks; crack propagation under cyclic tension or tension-compression loads; and elevated-temperature fatigue crack growth in monotonic and composite ceramics.

It is perhaps appropriate at this juncture to clarify the terminology used in the description of cyclic failure. In the metallurgy, polymer science, and mechanical engineering communities, the word *fatigue* is a well-accepted term for describing the deformation and failure of materials under cyclic loading conditions. However, in the ceramics literature, the expression *static fatigue* refers to stable crack propagation under sustained loads in the presence of an embrittling environment (which is commonly known as stress-corrosion crack growth in the metallurgy and engineering literature). The expression *cyclic fatigue* is used in the ceramics community to describe cyclic load deformation and fracture. In keeping with the well-established universal conventions, and in an attempt to avoid confusion, the term *fatigue* is used in this article to denote deterioration and fracture of both metals and nonmetals due only to cyclic loads.

## Fatigue of Brittle Materials

### Crack Growth Behavior

Brittle solids are known to be susceptible to subcritical crack growth in monotonic tension under the influence of an environment. This stress corrosion or static fatigue process has been studied extensively in a wide variety of glasses, oxide ceramics, transformation-toughened ceramics, and other brittle materials. For most inorganic glasses, moisture is responsible for enhanced subcritical flaw growth and for deterioration in strength and other mechanical properties. Even small amounts of water vapor can markedly reduce the lifetime of the component under static loading conditions. Most oxide ceramics also contain glassy silicate phases at grain boundaries and interfaces; these amorphous regions are prone to environmental degradation comparable to that found in glass ceramics. Even if the amount of glass phase present in a ceramic is negligible, the embrittlement from water vapor or impurities can lead to strength deterioration.

The study of sustained load cracking has been more predominant than the study of cyclic fatigue effects, due in part to the very limited crack-tip plasticity of ceramics and other highly brittle materials (Ref 1). Highly brittle materials (such as rocks, concrete, silicate glasses, zincblende structures, diamond structures, aluminum oxides, mica, boron carbides, nitrides, and other ceramics at room temperature) have strong covalent or ionic bonding, which essentially limits any pronounced mobility of point defects and dislocations. In contrast, dislocation motion (slip) has traditionally been considered a necessary condition for fatigue, given the close relationship between cyclic stresses and the motion of dislocations in ductile metals. Therefore, highly brittle solids have long been considered free of true cyclic fatigue effects, based on a typical understanding of cyclic slip as the basis of metal fatigue.

Experimentally, unequivocal demonstrations of a true cyclic-fatigue phenomenon in ceramics are also rare, due in part to the difficulty of performing subcritical crack growth tests on such brittle materials. Another reason for not considering fatigue of brittle solids is the considerable scatter in stress-life data for brittle materials. The scatter in stress-life data for both monotonic and cyclic loading of brittle materials makes it difficult to decipher intrinsic fatigue effects from the data. Most explanations of fatigue in ceramics and other brittle materials are based on so-called "static fatigue," which is considered to be a noncyclic-load effect based on sustained-load processes or environmentally assisted (stress-corrosion) cracking processes under monotonic loads.

However, persuasive evidence now exists on true cyclic fatigue effects in ceramics and other highly brittle materials. The first unequivocal demonstrations of fatigue effects in brittle solids are based on both tensile fatigue (Fig. 1) (Ref 2, 3) and compressive fatigue effects on crack initiation and fatigue crack growth in a wide variety of notched ceramics and ceramic composites (Ref 4, 5, 6, 7), attributable solely to cyclic variations in imposed loads. This section briefly reviews the key mechanisms and mechanical features of cyclic fatigue in ceramics. Fractographic features of ceramic fatigue can resemble fractographs of monotonic overload failures, because fatigue fracture in ceramics rarely shows evidence of fatigue striations. However, cyclic loads do have distinguishable mechanistic and mechanical effects on ceramics.

**FIG. 1 VARIATION OF FATIGUE CRACK PROPAGATION RATE,  $DA/DN$ , WITH APPLIED STRESS INTENSITY RANGE,  $\Delta K$ , FOR MGO-PSZ CERAMIC, TESTED IN ROOM-TEMPERATURE AIR (45% RELATIVE HUMIDITY) AT A LOAD RATIO  $R$  OF 0.10 AND A CYCLIC FREQUENCY OF 50 HZ. DATA FOR VARYING LOAD RATIO (0.10 TO 0.46) AND CYCLIC FREQUENCY (1 TO 50 HZ) ARE INCLUDED FOR COMPARISON. SOURCE: REF 2**

**Fatigue Mechanisms in Ceramics.** Despite the absence of dislocation plasticity, many ceramics exhibit cyclic fatigue degradation at room and elevated temperatures. This is based on a broader understanding of fatigue damage as a consequence of kinematic irreversibility in microscopic deformation (i.e., the irreversibility of the to-and-fro motion of dislocations). The processes that impart kinematic irreversibility to microscopic deformation during the fatigue of brittle solids and ductile metals are summarized in Table 1.

Source: Ref 8

Kinematic irreversibility of cyclic slip in a ductile metal or alloy can be promoted by a variety of mechanistic processes (see Table 1 and Fig. 2). The roughened surface profile created at the surface by the persistent slip bands (PSBs) and the strain incompatibility between the PSBs and the adjoining matrix render the PSB-matrix interface a prime site for the nucleation of fatigue cracks.

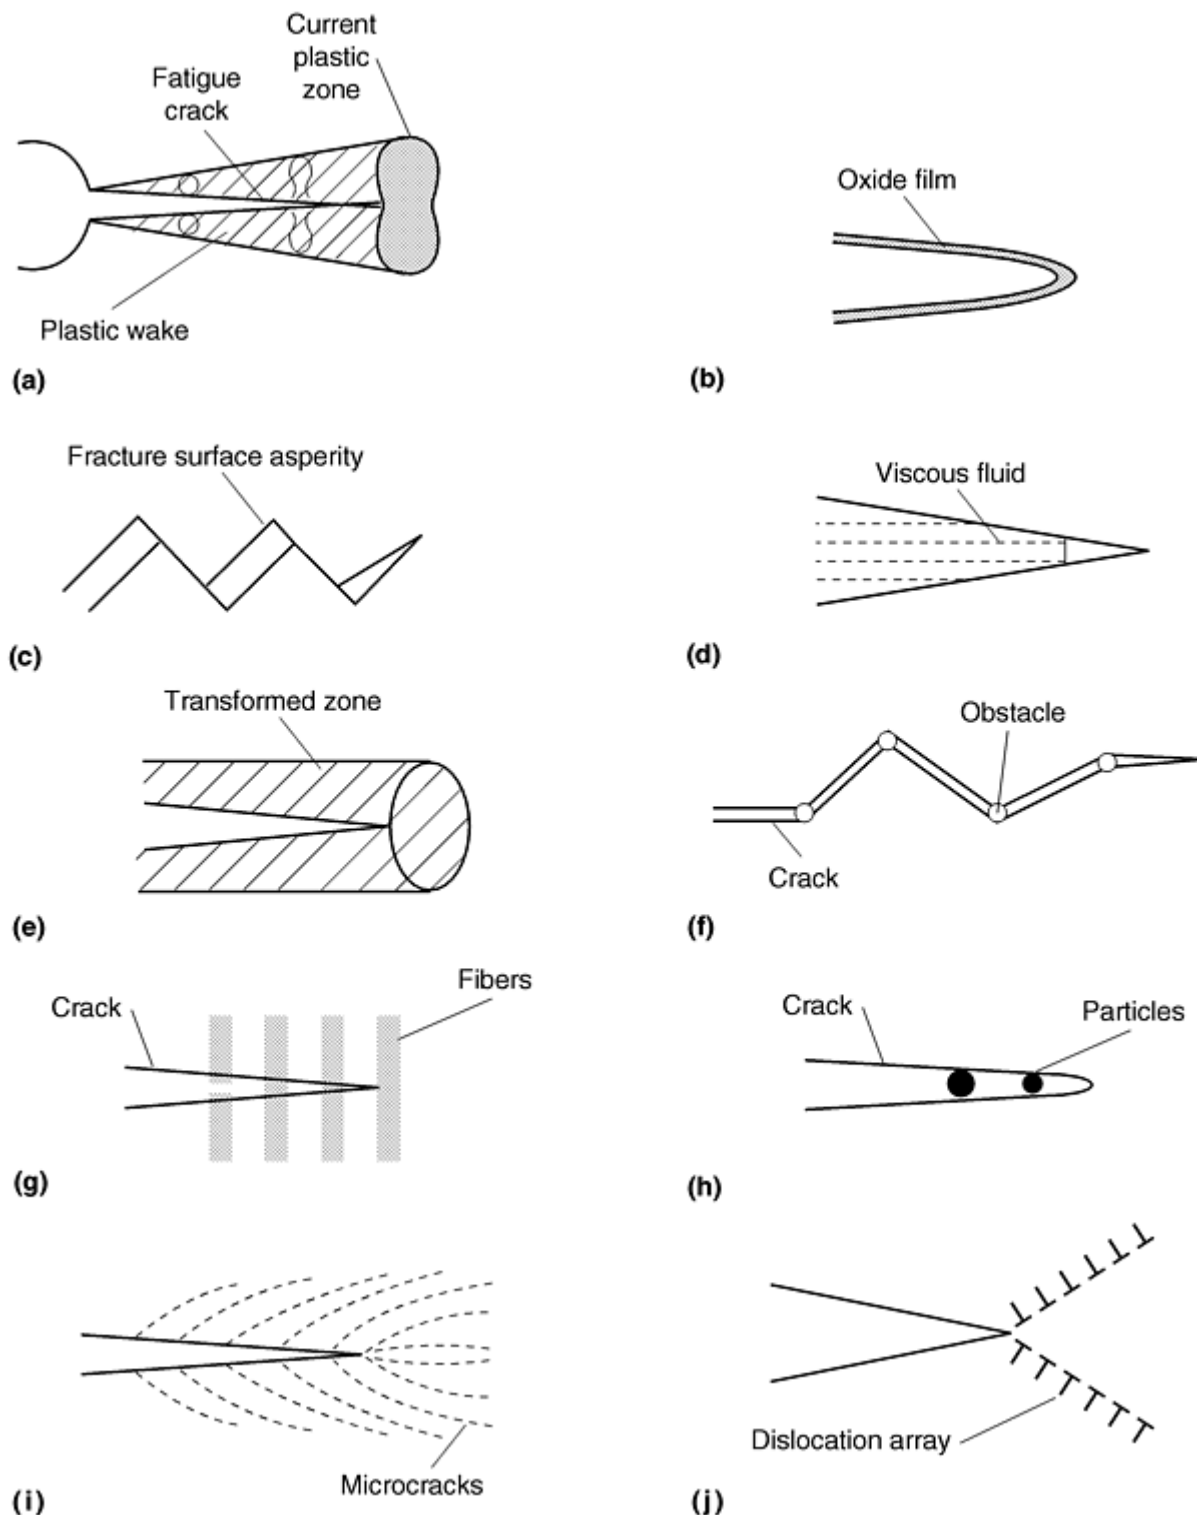

FIG. 2 A SCHEMATIC ILLUSTRATION OF THE VARIOUS MECHANISMS THAT MODIFY THE EFFECTIVE DRIVING FORCE CRACK ADVANCE IN BOTH DUCTILE AND BRITTLE SOLIDS. (A)-(E) CRACK CLOSURE DUE TO PLASTICITY, OXIDES, FRACTURE SURFACE ROUGHNESS, VISCOUS FLUIDS, AND PHASE TRANSFORMATIONS, RESPECTIVELY. (F) CRACK DEFLECTION. (G)-(H) CRACK BRIDGING BY FIBERS AND PARTICLES, RESPECTIVELY. (I)-(J) SHIELDING OF THE CRACK TIP BY MICROCRACKS AND DISLOCATIONS, RESPECTIVELY. SOURCE: REF 8

The principal mechanism for fatigue crack initiation in both ductile metals and brittle solids is the generation of permanent strains in the vicinity of the notch tip by kinematically irreversible deformation. The mechanisms of this permanent deformation can be as diverse as dislocation plasticity, microcracking, martensitic transformations, creep, interfacial sliding, crazing, or shear flow.

Although the basic mechanisms of cyclic crack growth in ceramics are still preliminary and not clearly defined, two basic classes of mechanisms (Ref 9, 10) are possible where failure is associated with a dominant crack (in many materials, both types may operate in concert):

- *INTRINSIC MECHANISMS*, WHERE, AS IN METALS, CRACK ADVANCE RESULTS FROM DAMAGE PROCESSES IN THE CRACK-TIP REGION THAT ARE UNIQUE TO CYCLIC LOADING (JUST AS STRIATION GROWTH UNDER CYCLIC LOADING IS DISTINCT FROM MICROVOID COALESCENCE OR CLEAVAGE UNDER MONOTONIC LOADING IN METALS).
- *EXTRINSIC MECHANISMS*, WHERE THE CRACK-ADVANCE MECHANISM IS IDENTICAL TO THAT FOR MONOTONIC LOADING, BUT THE UNLOADING CYCLE PROMOTES ACCELERATED CRACK GROWTH BY REDUCING THE EFFECT OF CRACK-TIP SHIELDING.

Schematics of both mechanisms are shown in Fig. 3. A few examples have been tentatively identified in real-world ceramics. For instance, the enhanced microcracking zones ahead of fatigue cracks in  $\text{SiC}_w\text{-Al}_2\text{O}_3$  composites at high temperatures (where  $\text{SiC}_w$  represents SiC whiskers) may represent an intrinsic mechanism, and the wearing away of interlocking grain bridges in fatigue cracks in coarse-grained  $\text{Al}_2\text{O}_3$  at ambient temperatures may be an extrinsic mechanism (Ref 10). Much more research is required to elucidate these mechanisms and to model them quantitatively before realistic guidelines can be established for designing ceramic microstructures that have improved fatigue resistance.

### Intrinsic mechanisms

1. Accumulated localized microplasticity/microcracking (damage)

2. Mode II and III crack propagation on unloading

3. Crack tip blunting/resharpening

a. Continuum

b. Alternating shear

4. Relaxation of residual stresses

### Extrinsic mechanisms

1. Degradation of transformation toughening

- Degree of reversibility of transformation
- Cyclic accommodation of transformation strain
- Cyclic modification of zone morphology

2. Damage to bridging zone

a. Friction and wear degradation of...

Unbroken ligaments

Whisker/fiber reinforcements

b. Crushing of asperities and interlocking zones

3. Fatigue of ductile reinforcing phase

**FIG. 3 SCHEMATICS OF SOME POSSIBLE CRACK-ADVANCE MICROMECHANISMS THAT MAY OCCUR DURING CYCLIC FATIGUE CRACK GROWTH IN CERAMICS AND CERAMIC-MATRIX COMPOSITES. SOURCE: *ADVANCED MATERIALS & PROCESSES*, AUG 1993**

**Tensile Fatigue Crack Growth.** One of the first demonstrations of ceramic fatigue crack growth is based on tension-tension cycling in a magnesia/partially stabilized zirconia (MgO-PSZ) ceramic (Fig. 1). Tests were conducted based on the premise that other inelastic deformation mechanisms may prevail in these materials, including microcracking, transforming, or transformation "plasticity" (Ref 2, 3). Data indicate that crack growth rates are a power-law function of the stress-intensity range  $\Delta K$ , that they are sensitive to frequency and load ratio, and that they show evidence of crack closure analogous to behavior in metals (Ref 11). Cyclic deformation of MgO-PSZ ceramics has also been demonstrated (Ref 12).

**Compressive Load Fatigue.** As previously mentioned, stable crack growth, attributable solely to cyclic stresses (even in the absence of embrittling environments), was first demonstrated for notched ceramics and ceramic composites under compressive loads (Ref 4, 5). During cyclic compressive loading, cracks display mode I behavior by advancing along the plane of the notch in a direction macroscopically perpendicular to the compression axis. This mode I fatigue crack growth in compression occurs in metals, hard materials (such as cemented carbides), ceramics, polymers, cement mortar, and a variety of organic and inorganic composites (Ref 4, 7, 13, 14, 15). Both crystalline and amorphous solids also have mode I fatigue crack growth behavior under cyclic compression, despite differences in their fatigue constitutive response and failure mechanisms.

This fatigue crack growth phenomenon is regarded as a true mechanical fatigue effect on account of the following experimental observations:

- Mode I fatigue crack growth occurs *perpendicular* to the compression axis in brittle solids subjected only to cyclic loads. Monotonic compressive stresses promote a splitting mode of failure *parallel* to the stress axis.
- There is a gradual increase in crack length with an increase in the number of compression cycles.
- Although an embrittling environment can modify the rate of crack growth, mode I fatigue fracture in cyclic compression is not a consequence of environmental effects in that it can take place even in a vacuum.
- The rate of crack growth is strongly influenced by such mechanical fatigue variables as mean stress, stress range, and stress state.
- Crack closure plays an important role in determining the rate of crack growth.

Under compressive loading, if the deformation response of the material at the notch tip is characterized by the unloading path "B" in Fig. 4--where no permanent strains are retained upon unloading--no residual stresses are generated. However, if it is characterized by the unloading path "C" or "D" in Fig. 4--where permanent deformation occurs--large residual tensile stresses are generated locally at the notch tip.

**FIG. 4 IDEALIZED SCHEMATIC OF THE CONSTITUTIVE BEHAVIOR OF A BRITTLE SOLID IN CYCLIC COMPRESSION. PATH A: NON-LINEAR DEFORMATION DURING COMPRESSION LOADING. PATH B: THE IDEALIZED SITUATION WHERE MICROSCOPIC DEFORMATION IS FULLY REVERSIBLE. PATHS C AND D: UNLOADING BEHAVIOR WHERE PERMANENT STRAINS ARE RETAINED WITHIN THE DEFORMATION ZONE--PATH C FOR ELASTIC UNLOADING AND PATH D FOR LINEAR UNLOADING THAT IS BETWEEN PATHS B AND C.**

Constitutive models for metallic and ceramic materials have shown that the local tensile stresses are of sufficiently high magnitude to induce crack initiation perpendicular to the compression axis (i.e., along the plane of the notch). Because residual stresses are self-equilibrating, a tensile residual stress in the immediate vicinity of the notch tip is accompanied

by a compressive residual stress field in regions away from the notch tip. The tensile residual field is fully embedded within a zone of material that is compressively stressed.

As the fatigue crack advances from the notch tip, there is a progressive reduction in the extent of the residual tensile field and an increased level of crack closure due to the contacting fracture surfaces. These two factors lead to a gradual deceleration of the compression fatigue crack, with the crack arresting completely after propagating a certain distance "a" (Fig. 5).

FIG. 5 SCHEMATIC REPRESENTATION OF FATIGUE CRACK LENGTH,  $a$ , AS A FUNCTION OF THE NUMBER OF COMPRESSION CYCLES,  $N$

The saturation crack growth distance can be as much as tens of millimeters in thin sheets of metals subjected to cyclic compression, whereas in ceramic materials it is typically a millimeter or less. The rate and total distance of compressive fatigue crack growth depends on variables such as grain size, reinforcement content, specimen geometry, notch geometry, environment, and the number of debris particles formed within the crack due to repeated contact between the crack faces in cyclic compression. Figure 6 shows the effect of debris removal after every 5000 compression cycles.

FIG. 6 VARIATION OF FATIGUE CRACK LENGTH  $a$ , MEASURED FROM THE NOTCH TIP, AS A FUNCTION OF THE NUMBER OF COMPRESSION CYCLES IN  $\alpha$ -ALUMINA OF GRAIN SIZE =  $18 \mu\text{m}$  (CURVE A). CURVE B SHOWS THE INCREASE IN CRACK GROWTH RATES AS A CONSEQUENCE OF REDUCING CRACK CLOSURE BY THE REMOVAL OF DEBRIS PARTICLES FROM THE CRACK AFTER EVERY 5000 COMPRESSION CYCLES USING

Experiments based on crack initiation in cyclic compression in ceramic composites have been useful in studying the effects of fatigue loads on the service life of structural ceramics (see, e.g., Ref 16). Consider, for example, the case of hot-pressed  $\text{Si}_3\text{N}_4$  that is reinforced with SiC whiskers. It is known that the addition of 20 to 30 vol% SiC to the  $\text{Si}_3\text{N}_4$  matrix can lead to an increase in fracture toughness by more than a factor of two over that of the unreinforced matrix material. However, when the composite contains stress concentrations, the application of cyclic compressive loads causes fatigue cracks to initiate more easily in the composite than in monolithic  $\text{Si}_3\text{N}_4$ . This effect can be rationalized by noting that the stress-strain curve for the composite is more nonlinear than that for the matrix material. Unloading from a far-field compressive stress can promote a higher degree of permanent deformation which, in turn, may lead to larger residual tensile stresses ahead of the stress concentration.

Mode I flaw growth ahead of stress concentrations also offers a capability to introduce controlled fatigue precracks in brittle materials prior to the determination of fracture toughness, creep crack growth, or fatigue crack growth in tension. An advantage of this technique is that fatigue cracks can be introduced in brittle solids such as ceramics and ceramic composites and in ductile metals, using similar cyclic compression test conditions and specimen geometries. Furthermore, the cyclic compression precracking method is the only known technique for introducing fatigue precracks in circumferentially notched cylindrical rods of brittle solids (which are used for quasistatic and dynamic mode I and mode III fracture tests). A drawback of this method, however, is that the depth of the fatigue crack is typically less than a millimeter in brittle solids.

**Cyclic Damage Zone.** The phenomenon of crack growth under cyclic compression is a consequence of the development of a cyclic damage zone ahead of the stress concentration. Cyclic damage zones evolve when permanent strains are retained within the deformation zone ahead of a flaw or a notch. The evolution of permanent strains in the damage zone is evident from the existence of open microcracks in the fully unloaded state.

Fatigue damage zones develop ahead of cracks subjected to tensile or compressive loads. Cyclic damage in tensile fatigue of ceramics is qualitatively similar to that in metals. However, the cyclic damage zone from microcracking in ceramics is significantly smaller than the reverse plastic zone for a metal or elastic-plastic solid.

## Fatigue of Brittle Materials

### Ceramic Fatigue Data

Fatigue data for ceramics are extremely limited. While stress or strain versus life ( $S/N$ ) data have been developed for many monolithic ceramics (Ref 17, 18), there have been only a few studies of the cyclic constitutive behavior. Similar information for ceramic-matrix composites is also hard to find, although the situation is improving. A few laboratories are generating fatigue crack propagation data for many monolithic and composite ceramic systems. Traditional metal-fatigue variables, such as mean stress (Ref 19), variable-amplitude loading (Ref 17), and environment (Ref 20), are also beginning to be studied. Other current research is documented in the articles listed in "Selected References" at the end of this article.

Test results show that the fatigue effect can be significant in many ceramics. For example, fatigue thresholds are generally as low as 50% of the material's fracture toughness,  $K_{Ic}$ , and the velocities of cyclic-fatigue cracks in ceramics can exceed those produced under sustained (static fatigue) loading at the same stress intensity by many orders of magnitude.

Although the fatigue database is rapidly expanding, little work has been done on crack-initiation phenomena. Some limited studies have addressed ceramic fatigue at high temperatures (Ref 21, 22), but little work has addressed the effects of environment on ceramic fatigue at high temperatures. The preliminary work that has been done suggests that creep under sustained loading might predominate over cyclic fatigue for some ceramic materials at very high temperatures.

**Fatigue Crack Growth Testing.** The general method of fatigue crack growth testing of ceramics can be identical to that given in ASTM Standard E 647-86A for measuring fatigue crack growth rates in metallic alloys. Crack growth rates are determined between approximately  $10^{-11}$  m/cycle (close to the fatigue threshold  $\Delta K_{TH}$ ) and  $10^{-5}$  m/cycle (approaching instability). They are measured under either manual or computer-controlled  $K$ -decreasing and  $K$ -increasing conditions, with a normalized  $K$ -gradient set typically at about  $0.08 \text{ mm}^{-1}$ .

The creation of the precrack is perhaps the most critical aspect of the test, because it is extremely difficult to directly initiate a precrack in a machined notch of a ceramic without breaking the sample. Precracking is successfully done using cyclic compression loads, but the practice is not always reliable for all tests. Another technique is to machine a wedge-shaped starter notch into the specimen and apply a low-frequency cyclic load (e.g., a 50 Hz sine wave) at a load ratio of about 0.1 until crack growth of any degree is electronically detected. Loading is then immediately reduced. This precracking process may take as long as several days and is where most inadvertent failures occur. However, once a through-thickness crack of several millimeters in length has been obtained, further crack growth testing is comparatively routine.

**Typical fatigue crack growth data** are shown in Fig. 7 for MgO-PSZ ceramics with varying levels of toughness by heat treatment (Ref 3). The data indicate a conventional Paris-law relation,  $da/dN \sim \Delta K^m$ , with a log-log slope ( $m$ ) of 21 to 42, compared to an  $m$  value of 2 to 4 for most metals. Table 2 is a summary of tensile fatigue crack growth characteristics of a variety of ceramic materials. A comparison with metal alloys is shown in Fig. 8.

## TABLE 2 A SURVEY OF SOME EXPERIMENTAL RESULTS ON TENSION OR FULLY REVERSED FATIGUE OF CERAMIC MATERIALS

Fractographic features of ceramic fatigue failures resemble monotonic overload failures, because fatigue fracture in ceramics is predominantly transgranular with no evidence of fatigue striations. This is one reason that it was previously held that there are no cyclic fatigue effects in ceramics. However, cyclic loads do have a real effect on the fracture resistance of ceramics. A comparison of the rates of fatigue crack growth measured under cyclic loads with rates of stress-corrosion cracking measured under sustained loads at comparable stress intensities indicated that cyclic crack growth rates in ceramics can be many orders of magnitude faster, and can occur at stress intensities far lower than that required for sustained-load cracking (Ref 2, 3). This is illustrated in Fig. 9 for mid-toughness MgO-PSZ tested in moist air. Here, cyclic crack velocities plotted as a function of time ( $da/dt$ ) are compared with corresponding stress-corrosion crack velocities measured under sustained loads. At equivalent  $K$ -levels, cyclic crack growth rates can be seen to be up to seven orders of magnitude faster under cyclic loads.

FIG. 9 SUBCRITICAL CRACK GROWTH BEHAVIOR IN MGO-PSZ SHOWING A COMPARISON OF CYCLIC CRACK VELOCITIES,  $DA/DT$ , FROM THE PRESENT STUDY WITH SUSTAINED-LOAD CRACKING DATA OF BECHER FOR 55% RELATIVE HUMIDITY AIR AND DISTILLED WATER. NOTE HOW FATIGUE-INDUCED CRACK GROWTH IS MUCH FASTER THAN ENVIRONMENTALLY ASSISTED CRACK GROWTH UNDER MONOTONIC LOADING CONDITIONS. SOURCE: REF 2

## Fatigue of Brittle Materials

### High-Temperature Fatigue

High-performance ceramics are being developed as candidate materials for structural components capable of operating at elevated temperatures. However, very little experimental information exists on the resistance of these materials to cyclic loads at elevated temperatures. This lack of data is partly a reflection of the difficulties in conducting crack growth experiments at temperatures typically in excess of 1000 °C. A limited amount of experimental work conducted in the 1970s (Ref 23, 24) indicated that the rates of cyclic crack growth in some ceramic materials at elevated temperatures can be derived on the basis of the time-integration of static crack growth data (with the time to failure in fatigue expressed by an integral number of cycles plus a fraction of a cycle). However, more comprehensive experimental studies on both monolithic ceramics and ceramic composites have shown that, in general, cyclic crack growth rates cannot be predicted on the basis of static crack growth results (Ref 16, 21, 25). In addition, transmission electron microscopy of the crack-tip damage zones indicate differences in microscopic failure mechanisms between static and cyclic crack growth.

Typical fatigue crack growth characteristics (in the Paris regime) of a 90% pure alumina (grain size range = 2-10  $\mu m$ ) in 1050 °C air environment are listed in Table 2. Also presented in this table are similar results for an  $Al_2O_3/33$  vol%  $SiC_w$  composite fatigue tested in 1400 °C. Both these materials exhibit subcritical crack growth with Paris exponents that are significantly lower than those listed in Table 2 for the other ceramic materials at room temperature.

Figure 10 illustrates the effect of load ratio  $R$  and cyclic frequency on the elevated-temperature fatigue crack growth behavior of fiber-reinforced alumina (Ref 21). The influence of  $R$  on crack growth in this material is similar to that seen in ductile metals in the near-threshold regime of fatigue. Figure 11 shows the crack velocity  $da/dt$  for the composite as a function of the stress intensity factor  $K_I$  under monotonic loads in air at high temperature. In Fig. 11, the crack velocities under cyclic loads are *lower* than those under static loads. Furthermore, the cyclic crack growth response is affected by the frequency of the stress cycle. A similar behavior is also found for the 90% pure alumina ceramic (Fig. 12). The differences between static and cyclic crack growth response seen in Fig. 11 and 12 cannot be explained on the basis of the time-dependent crack growth models presented by Evans and Fuller (Ref 23), or by a time-integration model, all of which assume that the static and cyclic crack growth mechanisms are identical. The trend of slower fatigue crack growth under cyclic tensile loads than in monotonic tension (flexure) is also counter to that seen for room-temperature tests where tension-compression fatigue loads accelerate crack growth rates compared to the static load.

FIG. 11 CRACK GROWTH VELOCITY  $DA/DT$  PLOTTED AS A FUNCTION OF THE STRESS INTENSITY FACTOR ( $K_I$  OR  $K_{MASS}$ ) FOR STATIC AND CYCLIC LOAD FRACTURE IN  $Al_2O_3$ -33 VOL% SiC COMPOSITE IN AIR AT 1400 °C.

FIG. 12 EXPERIMENTALLY DETERMINED SUSTAINED-LOAD CRACK VELOCITY AS A FUNCTION OF  $K_I$  FOR 90% PURE ALUMINA IN 1050 °C AIR. SOURCE: REF 8

In commercially synthesized alumina, such as the 90% pure alumina for which results are shown in Table 2, the grain-boundary regions consist of an amorphous phase that is introduced during fabrication. Upon exposure to elevated temperature, the amorphous phase becomes viscous. The flow of the glass phase (under the influence of an applied stress) along grain boundaries imparts a nonlinear (creep) deformation at the crack tip. The resultant crack-tip damage causes crack growth to occur under both static and cyclic loading conditions. The overall mechanisms of monotonic and cyclic fracture are thus very similar. However, the pumping of the molten glass film within the crack by the cyclic loads (which squeeze the film out of the crack) and the fretting contact between the crack faces due to crack closure are processes specific to fatigue. Furthermore, the strain-rate sensitivity of the viscous flow of the amorphous film, in conjunction with the time dependence of environmental interactions with  $\text{SiC}_w$ , renders the crack growth process frequency-sensitive under cyclic loads. Recent work (Ref 25) has shown that in fine-grained alumina ceramics of very high purity (i.e., with little pre-existing amorphous phases at grain boundaries), the propensity for stable crack growth is essentially suppressed under both static and cyclic loading conditions. The pre-existing amorphous films along grain boundaries thus appear to play a major role in governing the quasistatic and cyclic crack growth characteristics of monolithic alumina and in determining the differences in apparent crack growth rates between monotonic and fatigue fracture.

In certain materials, such as  $\text{Al}_2\text{O}_3\text{-SiC}_w$  composite, the oxidation of  $\text{SiC}_w$  at temperatures typically above 1250 °C can lead to the formation of an amorphous glass phase, even if the material retains essentially no amorphous phases after processing. The molten flow of this glass phase causes cavities to nucleate and grow along the whisker-matrix interface and matrix grain boundaries. The resulting development of microscopic flaws in the composite is manifested as a diffuse microcrack zone ahead of a tensile fatigue crack. The presence of open microcracks in the fully unloaded state is indicative of the development of permanent strains within the crack-tip damage zone. Cyclic loads affect the viscous flow of the glass phase and the resulting interfacial cavitation in different ways than monotonic loads. Furthermore, bridging of the faces of the microcracks by the whiskers (and the associated crack closure effect) or frictional sliding along the

debonded matrix-whisker interface in the damage zone ahead of the crack tip may modify the near-tip stress intensity factor under cyclic loads differently than under monotonic loads.

**Summary.** In summary, a limited amount of experimental work conducted in the 1970s on ceramic materials in the elevated-temperature environment indicated that any apparent cyclic fatigue effect might merely be a manifestation of creep crack growth, and that cyclic crack growth rates could be predicted on the basis of static fracture data because of the overall similarity in the mechanisms of failure under static and cyclic loads. However, in recent years, more controlled experiments covering a wider range of test variables, microstructures, and temperatures have shown that, in general, cyclic crack growth data are distinct from sustained load fracture results (Ref 17, 18, 19). The following general trends are observed with elevated-temperature crack growth (Ref 8):

- **STATIC-LOAD CRACKS PROPAGATE MUCH FASTER THAN CYCLIC FATIGUE CRACKS IN CERTAIN CERAMICS UNDER SPECIFIC CONDITIONS OF TEMPERATURE, FREQUENCY, ETC., WHEREAS THE REVERSE MAY BE SEEN UNDER DIFFERENT CONDITIONS.**
- **CRACK GROWTH UNDER BOTH STATIC AND CYCLIC TENSILE LOADS OCCURS BY A PREDOMINANTLY INTERGRANULAR FAILURE MODE.**
- **CYCLIC CRACK GROWTH RATES ARE SENSITIVE TO BOTH THE LOADING RATE (I.E., TEST FREQUENCY) AND WAVEFORM. AN INCREASE IN TEST FREQUENCY RESULTS IN A DECREASE IN CRACK VELOCITIES, BECAUSE THE CRACK IS SUBJECTED TO A SMALLER AMOUNT OF TIME AT THE PEAK TENSILE STRESS. AS THE FREQUENCY IS REDUCED OR THE MAXIMUM STRESS INTENSITY FACTOR IS RAISED, THE CYCLIC FRACTURE DATA BEGIN TO APPROACH THE STATIC FRACTURE DATA. CYCLIC LOAD WAVEFORMS WITH INCREASING HOLD-TIMES AT THE PEAK TENSILE STRESS BRING THE FATIGUE LIFE CLOSER TO THE STATIC LIFETIME AT COMPARABLE VALUES OF MAXIMUM APPLIED STRESS (REF 21, 22).**
- **THE PRESENCE OF A GLASS PHASE ALONG THE GRAIN BOUNDARIES HAS A STRONG EFFECT ON THE MECHANISMS OF CRACK GROWTH. WHILE STABLE CRACK GROWTH OCCURS IN THE 90% PURE ALUMINA OVER A RANGE OF STRESS INTENSITY FACTOR SPANNING 1.5 TO 5 MPa  $\sqrt{m}$  , SUCH SUBCRITICAL FRACTURE IS ESSENTIALLY SUPPRESSED IN A FINE-GRAINED, 99.9% PURE ALUMINA, APPARENTLY DUE TO THE ABSENCE OF A CRITICAL AMOUNT OF GLASS PHASE.**
- **IT IS NOT POSSIBLE TO PREDICT ACCURATELY THE CYCLIC CRACK GROWTH RATES ON THE BASIS OF STATIC DATA.**

Fracture patterns from both static and cyclic crack growth are characterized by microscopically undulating fracture paths along grain boundaries, periodic branching or jumping of the crack front, bridging of the crack faces by ligaments of the viscous amorphous film, and bridging of the crack faces by grain facets. However, under cyclic loading conditions, further changes in the effective driving force seem to take place as a consequence of:

- **THE FORMATION OF DEBRIS PARTICLES OF THE ALUMINA CERAMIC DUE TO REPEATED CONTACT BETWEEN THE CRACK FACES**
- **FRETTING AND INCREASED (ROUGHNESS-INDUCED) CRACK CLOSURE ARISING FROM MISMATCH BETWEEN FRACTURE SURFACE ASPERITIES**
- **"SQUEEZING OUT" OF THE AMORPHOUS GLASS FILM AND DEBRIS PARTICLES FROM WITHIN THE CRACK BY THE PUMPING ACTION OF THE CRACK WALLS**
- **THE DEPENDENCE OF VISCOUS DEFORMATION WITHIN THE GLASS PHASE ON THE LOADING RATE AND CYCLIC FREQUENCY**

## Fatigue of Brittle Materials

### Life Prediction

Life prediction is a major problem for ceramics or ceramic-matrix composites. Because the measured slopes (exponents) of fatigue crack growth rate data (Fig. 8) and the reciprocal slopes of  $S/N$  curves are so large, the sensitivity of projected life to applied stress can be unacceptably high. Life prediction is further complicated by "small" fatigue cracks that can grow at rates far higher than those for equivalent long cracks and at applied stress intensities far below the long-crack threshold (Fig. 13, 14). "Small" in this context is defined relative to the size of the equilibrium or steady-state shielding zone (i.e., comparable in size to the extent of the crack bridging zone in the wake of the crack tip). The explanation for this seemingly anomalous behavior is that small cracks, by virtue of their limited wake, are unable to develop the same extent of crack-tip shielding. (The effect is identical to the small-crack effect widely reported for metals, where fatigue crack closure provides the dominant shielding mechanism.)

FIG. 13 SMALL-CRACK GROWTH RATES AS A FUNCTION OF APPLIED STRESS INTENSITY ( $K_{MAX}$  OF THE LOADING CYCLE) FOR A  $SiC_w-Al_2O_3$  COMPOSITE. THE SMALL CRACKS PROPAGATE AT APPLIED STRESS INTENSITY LEVELS WELL BELOW THE LONG-CRACK THRESHOLD,  $\Delta K_{TH}$ , AND SHOW AN APPARENT NEGATIVE DEPENDENCY ON  $K_{MAX}$ . SOURCE: REF 17, 18

FIG. 14 SMALL-CRACK GROWTH OF MGO-PSZ CERAMIC WITH A MID-TOUGHNESS ( $K_c \sim 10 \text{ MPa} \sqrt{m}$ ) MICROSTRUCTURE. SOURCE: REF 17, 18

With detailed knowledge and quantitative modeling of the shielding mechanism, it is often possible to normalize long- and small-crack data by characterizing them in terms of the near-tip or net stress intensity (i.e., after subtracting the stress intensity due to shielding) (Ref 48). However, it is questionable whether this technique is practical for routine engineering use with ceramics in actual service.

**Fracture Mechanic Lifetime Prediction Compared with That for Metals.** In safety-critical applications of metals, damage-tolerant design and life-prediction procedures generally rely on the integration of crack velocity/stress intensity ( $da/dN$  vs.  $\Delta K$ ) curves to estimate the time or number of cycles for a presumed initial defect of size  $a_0$  to grow to critical size,  $a_c$  (Eq 1). The cracked structure is subjected to an alternating stress,  $\Delta\sigma$ , and the applied (far-field) stress-intensity factor  $K$  can be defined in terms of the applied stress,  $\sigma$ , and a geometry factor,  $Q$ , so that:

$$DA/DN = C\Delta K^M = C[Q\Delta\sigma\sqrt{(\pi a)}]^M \quad (\text{EQ 1})$$

$$\text{WHERE } K = Q\sigma\sqrt{(\pi a)} \quad (\text{EQ 2})$$

The projected number of cycles,  $N_f$ , to grow a crack to critical size is then given by:

$$N_f = \frac{2}{(m-2) C Q^m \pi^{m/2} \Delta\sigma^m} \left[ \frac{1}{a_0^2} - \frac{1}{a_c^2} \right] \quad (\text{EQ 3})$$

assuming a crack growth relationship of the form of Eq 1, where  $m \neq 2$ .

Although crack growth data are now available for many advanced materials, the approach may prove difficult to apply in practice because of the large power-law dependence of growth rate on stress intensity, which implies that the projected life will be proportional to the reciprocal of the applied stress raised to a large power. So, for example, for metallic structures ( $m \sim 2$  to 4), a factor of two increase in applied stress,  $\sigma$ , reduces the projected life,  $N_f$ , by roughly an order of magnitude. For intermetallic structures ( $m \sim 10$ ), the reduction may be three orders of magnitude. And, for ceramic structures, where  $m$  generally exceeds 20 (and can be as high as 50 to 100), a factor of two increase in applied stress reduces the projected life by 6 to 30 orders of magnitude.

Thus, conventional damage-tolerant criteria for ceramics imply that marginal differences in assumptions of in-service stresses will lead to significant variations in component life projections. Furthermore, any fluctuation of applied stress or the imposition of overloads (which are frequently encountered in service) may also result in highly nonconservative design lives. Use of this approach also is complicated by two other facts:

- ACCEPTABLE PROJECTED LIFE FOR THE CERAMIC MAY BE GUARANTEED ONLY BY RESTRICTING THE INITIAL DEFECT TO AN EXTREMELY SMALL SIZE.
- IT IS DIFFICULT TO INCLUDE SMALL-CRACK EFFECTS.

**Fatigue Threshold.** An alternative to the fracture mechanics approach is to redefine the critical crack size,  $a_c$ , in terms of the fatigue threshold,  $\Delta K_{TH}$ , below which crack growth is presumed to be dormant. This is essentially a crack-initiation criterion, where  $\Delta K_{TH}$  is taken as the effective toughness, rather than the fracture toughness  $K_c$ . However, this procedure does not address small-crack effects, which may arise at loads considerably below those required for the growth of long cracks.

Also, as for many high-strength metallic materials, crack-initiation effects in ceramics and intermetallics may involve a very significant portion of lifetime under alternating loads. Therefore, despite its potential limitations, the fracture mechanics approach provides results that are typically highly conservative in the sense that they assume crack growth from the first loading cycle. Although the degree of this conservatism is difficult to quantify, due in part to the paucity of data from crack-initiation studies, the disadvantages of the approach may in fact be considerably outweighed by neglecting the cycles required for initiation. As a result, selection of a damage-tolerant methodology is currently on a case-by-case basis, with the choice often affected by the requirements of specific regulatory agencies.

**S/N Data.** The importance of fatigue crack initiation does, however, suggest an additional design criterion for ceramic components. This more traditional approach is based on S/N data. In addition to simple consideration of the fatigue limit, a more sophisticated methodology might include a damage mechanics assessment that uses detailed finite-element stress analyses for components of complex shape, and a statistical evaluation of the pre-existing defect population. While currently limited to large structures where numerous defects may be present, this approach also could be appropriate for small ceramic parts.

**Fatigue and Bioceramics.** The susceptibility of ceramics to fatigue degradation under cyclic loading has important consequences for bioceramics. While some life predictions involving static (environmentally enhanced) fatigue of ceramics for artificial joint applications have been conducted, very little cyclic fatigue data and few life prediction

procedures exist for ceramics operating under physiological loads and environments. Such analyses are crucial for reliable use of bioceramics. For example, artificial prostheses such as pyrolytic-carbon heart-valve devices must be designed for fatigue lives longer than patient life; because the human heart typically beats 38 million times each year, fatigue life must exceed 1 billion cycles. Indeed, several recent structural failures of mechanical heart valves manufactured from pyrolytic carbon have been attributed to progressive fracture by fatigue (Ref 48). Note, however, that the morphology of fracture surfaces formed under cyclic loading conditions in ceramics is almost identical to that produced by fracture itself. This resemblance, which indicates that fracture and fatigue crack-advance mechanisms are similar, greatly complicates failure analysis. References 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, and 48 provide information on fatigue and fracture of bioceramic materials.

## Toughening and Strengthening Models for Nominally Brittle Materials

A.G. Evans, Harvard University

---

### Introduction

IN MATERIALS that do not develop macroscopic inelastic strain prior to failure, stress concentrations arise at strain intensification sites. The design procedure for such materials requires that the ultimate tensile strength (UTS) be compared with these concentrated stresses. This design strategy has deficiencies caused by the weakest link scaling of the UTS and the extreme value nature of the stochastics. It can be alleviated by using higher-toughness materials. A more robust design strategy can be implemented if the material has a capacity to exhibit inelastic strain. Such strain diminishes stress concentrations, leading to a decreased sensitivity to manufacturing flaws, notches, and impacts. The effects are analogous to plasticity in metals. This article addresses these issues and the opportunities for enhancing the "design friendliness" by optimizing toughness and by inducing inelastic strain.

The design of structural components with nominally brittle materials is largely determined by their elastic moduli, density, and tensile strength. The fracture toughness does not enter in an explicit manner. It is understood that a minimum toughness is needed to ensure reliability, but the required toughness is not well defined; it is experience based. Inelastic strain (ductility) is more tangible than toughness because of the associated ability to redistribute stress. Some of the factors involved in design and reliability are addressed in this article, through considerations of the toughness and "ductility" of nominally brittle materials. This article also describes toughening by various bridging mechanisms, as well as process zone effects and their interaction with the bridging rupture zone. Finally, phenomena that give rise to exceptional toughness and notch-insensitive mechanical behavior are described.

---

### Toughness Models

The propagation of cracks in brittle solids is resisted by microstructure (Ref 1, 2, 3, 4, 5). The associated toughening phenomena all involve inelastic deformations that occur in reinforcing phases through transformations (Ref 6, 7, 8, 9), microcracking (Ref 10, 11), and twinning, as well as plasticity (Ref 13, 14), and internal friction (Ref 4, 5). Toughening is manifest as a fracture resistance,  $\Gamma_R$ , that increases with crack extension,  $\Delta a$  (Fig. 1) (Ref 2, 5, 6, 7). Concepts of initiation toughness,  $\Gamma_0$ , steady-state toughness,  $\Delta \Gamma_S$ , and tearing index,  $\lambda$ , are needed to characterize this behavior.

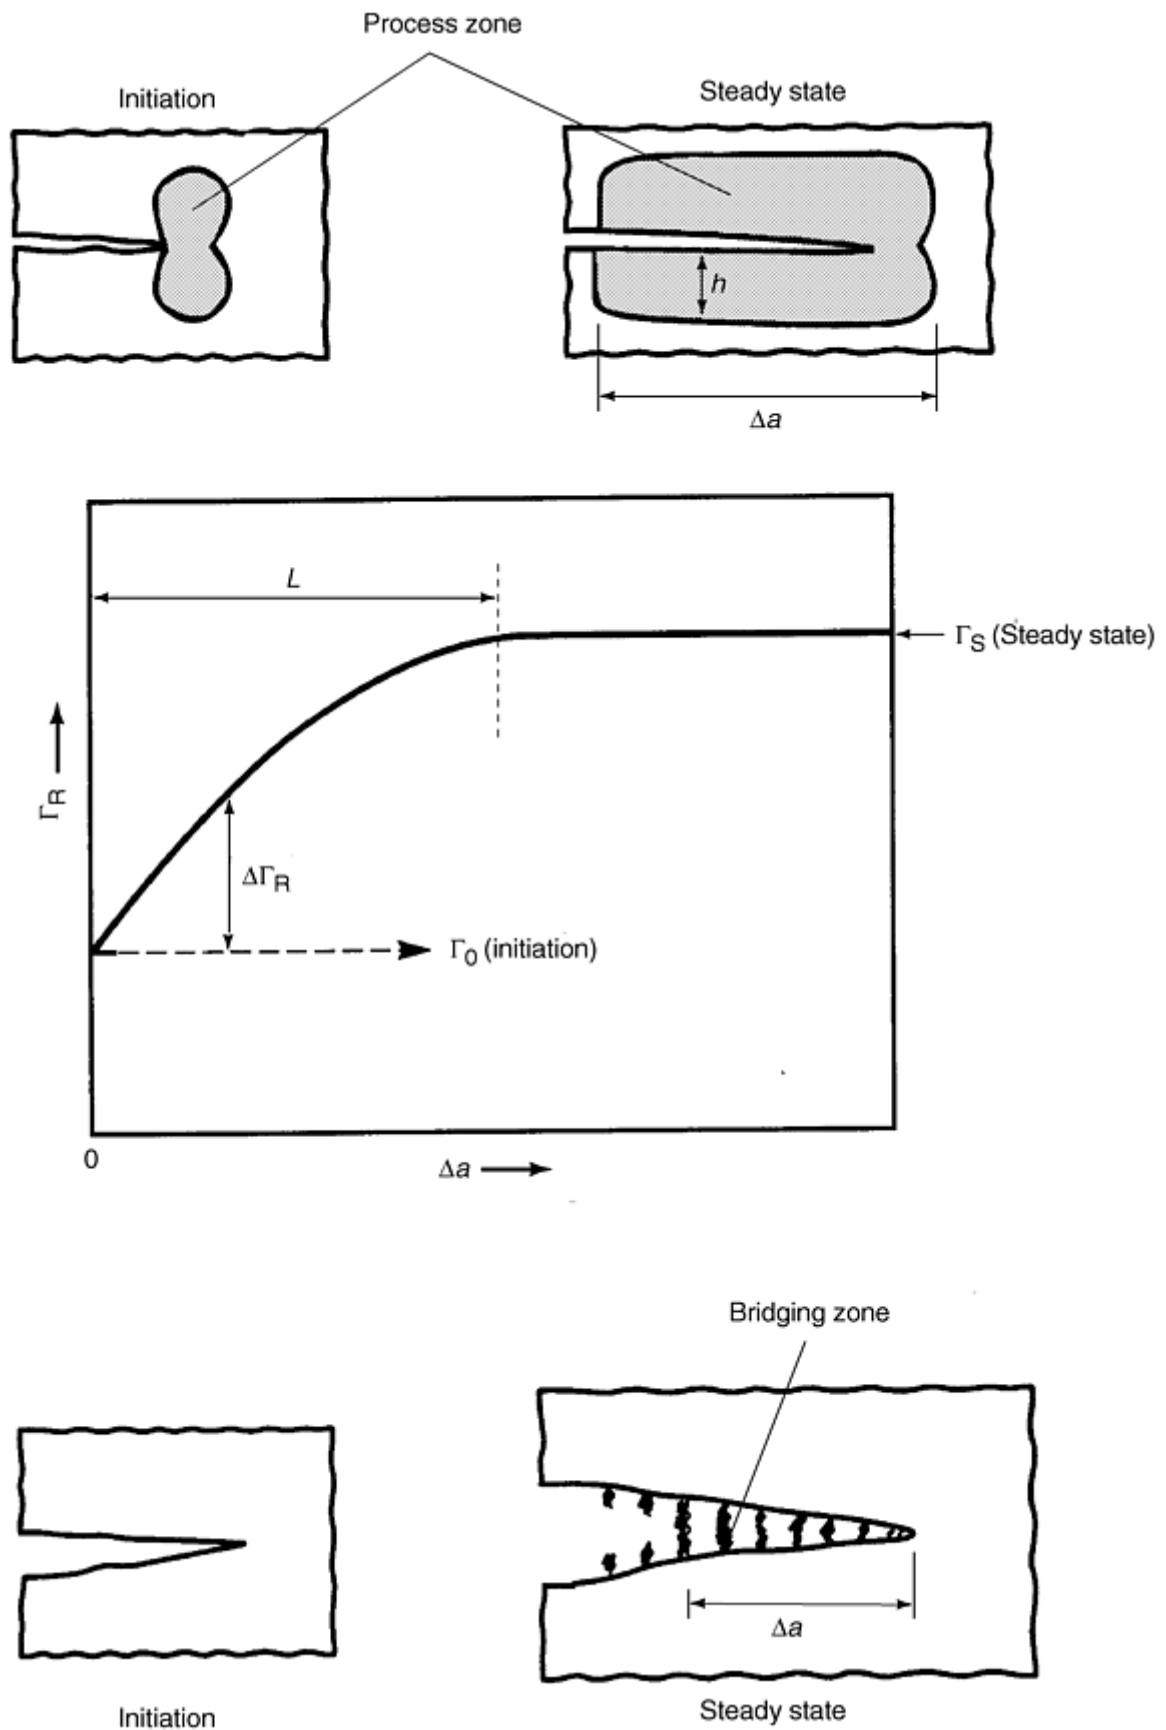

FIG. 1 A SCHEMATIC OF A RESISTANCE CURVE SHOWING THE EVOLUTION OF THE INELASTIC ZONES AND THE PARAMETERS THAT CHARACTERIZE THE BEHAVIOR

A simplification of the actual resistance behavior provides perspectives on the role of these quantities in the performance of toughened materials. A simplified relation for transient toughening ( $\Delta a \cdot L$ ) having a sound theoretical basis (Ref 15) is given by:

$$D \Gamma_R = \Gamma_R - \Gamma_0 \approx D \Gamma_S \sqrt{(\Delta a / L)} \quad (\text{EQ 1A})$$

and for steady-state ( $\Delta a \cdot L$ ):

$$D \Gamma_R = \Delta \Gamma_S \quad (\text{EQ 1B})$$

where  $L$  is a reference length related to the inelastic zone size. The tearing index is a measure of the slope of the resistance curve and is defined as:

$$\lambda = (\Delta \Gamma_S / \Gamma_0)^2 / L \quad (\text{EQ 2})$$

It has units of length. The UTS of a material,  $S$ , relates to the fracture resistance through the size of the flaws,  $a_0$ , and the tearing index in accordance with (Ref 16):

$$S / S^* = [(\Lambda / 2)(\sqrt{1 + \Lambda} - 1)]^{\frac{1}{2}} \quad (\text{EQ 3})$$

where  $\Lambda$  is a non-dimensional strengthening index, related to the tearing index by:

$$\Lambda = \lambda A_0 \quad (\text{EQ 4})$$

and  $S^*$  is the UTS of the untoughened material. The larger  $\Lambda$ , the more beneficial the effect of the toughening on the strength and reliability. The implication is that the attainment of "beneficial" toughening requires an optimization based on  $L$ , as well as  $\Delta \Gamma_S$ , through  $\lambda$  and  $\Lambda$ . That is, the toughening models must address both quantities.

The toughening involves inelastic deformation mechanisms. These mechanisms enable dissipation and energy storage as cracks extend (Ref 2, 6, 17). They can be modeled in terms of stress/displacement constitutive laws for representative volume elements (Fig. 2). This is achieved by homogenizing the properties of the material around the crack. This approach rigorously describes high-toughness materials in which the inelastic region around the crack is appreciably larger than the spacing between the relevant microstructural entities.

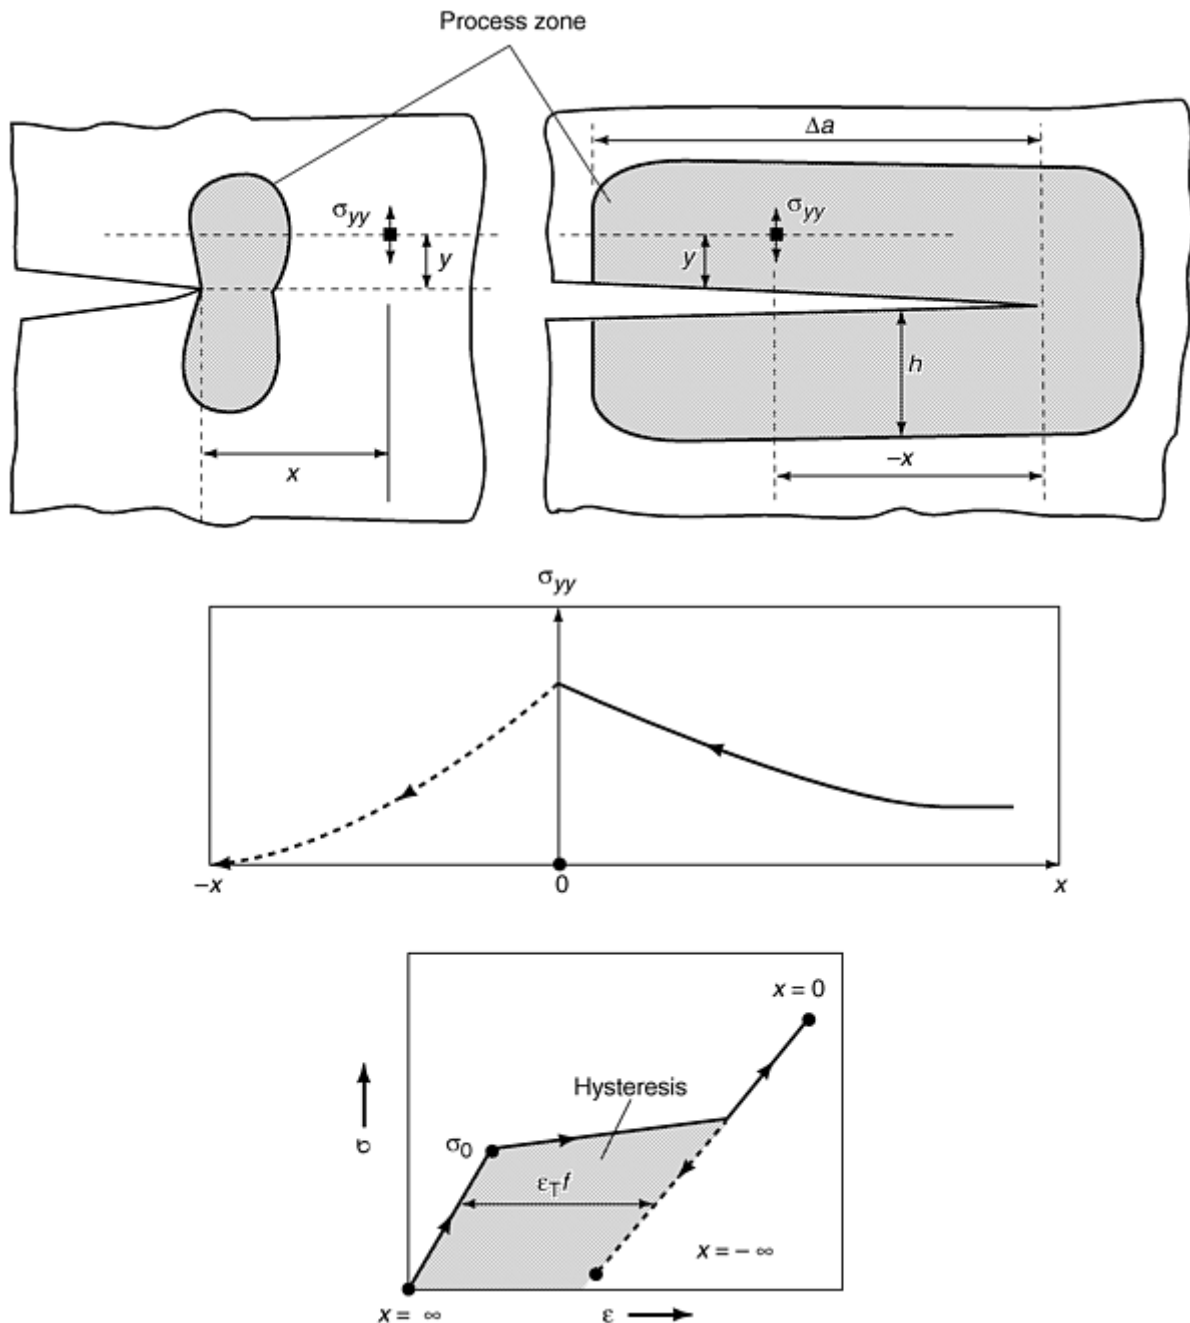

FIG. 2 A SCHEMATIC OF CRACK EXTENSION IN THE PRESENCE OF A PROCESS ZONE AND THE STRAIN/STRESS HISTORY EXPERIENCED BY AN ELEMENT OF MATERIAL WITHIN THE ZONE

The known mechanisms involve inelastic zones having two distinct configurations: zones that concentrate in a thin region around the crack plane and rupture as the crack extends, referred to as bridging or Dugdale zones (Fig. 2); and regions that extend normal to the crack plane and remain in a deformed but intact state after the crack has propagated through the material, designated process zones. Process and bridging zone mechanisms may operate simultaneously and synergistically (Ref 18). Toughening by bridging is caused by tractions along the crack surface induced by intact inelastic material ligaments. Usually, the tractions soften as the crack extends. Then, in steady state the toughening  $\Delta\Gamma_s$  is (Ref 14, 15):

$$\Delta\Gamma_s = B [T_0 U_C] \quad (\text{EQ 5})$$

where  $u_c$  is the crack opening at the edge of the bridging zone,  $t_0$  is the peak traction, and  $b \approx \frac{1}{2}$ . The inelastic zone length is (Ref 15):

$$L \approx C [EU_c/T_0] \quad (\text{EQ 6})$$

where  $c \approx 0.12\pi$ . The tearing index is thus:

$$\lambda = (B^2C)^{-1} [t_0^3 U_c / E\Gamma_0^2] \quad (\text{EQ 7})$$

Note the particularly strong influence of the traction  $t_0$  on the strengthening. Ductile reinforcements, as well as brittle fibers and anisotropic grains, toughen by means of bridging tractions.

Process zone toughening may be characterized by the product of the critical stress for activating the inelastic strain mechanism,  $\sigma_0$ , the associated stress-free strain,  $\varepsilon_T$ , and the zone height,  $h$ , in accordance with the stress-strain hysteresis of material elements within the process zone (Fig. 2) (Ref 6):

$$\Delta\Gamma_S = 2H\sigma_0\varepsilon_T \quad (\text{EQ 8})$$

The reference length is governed by the zone height (Ref 6, 7):

$$L = CH \quad (\text{EQ 9})$$

where  $c \approx 3$ . Moreover, the process zone height is related to the critical stress by (Ref 6, 7):

$$H = D [E\Gamma_0\sigma_0^2] \quad (\text{EQ 10})$$

where  $d$  is a mechanism dependent coefficient of order, 0.1. The tearing index is thus:

$$\lambda = (4D/C) [\varepsilon_T^2 E/\Gamma_0] \quad (\text{EQ 11})$$

Note that at this level of simplification, the only inelastic material property affecting the strengthening is the transformation strain,  $\varepsilon_T$ . The critical stress and the zone height are of secondary importance, in contrast to their primary influence on the steady-state toughening. Because of this, the strengthening flexibility for process zone toughening is appreciably less than that for the bridging mechanisms. Transformation, microcrack, and twin toughening are process zone mechanisms. Plastic deformation also provides process zone toughening, but it is characterized in a different manner.

These strengthening and toughening predictions are often optimistic, because there are important short crack effects (Ref 19). For  $a < 5L$ , interactions between the inelastic zones at the opposite crack tips reduce the toughening. Modeling of these effects requires numerical procedures with a full constitutive description of the inelastic deformations. This topic is not addressed in this article, though it is crucially important. Some appreciation for the magnitude of the effect is provided by results obtained for transformation toughening (Fig. 3).

FIG. 3 THE EFFECT OF CRACK LENGTH ON THE STRENGTHS ENABLED BY TRANSFORMATION TOUGHENING

Conversely, in some materials, the inelastic zone can become larger than all of the relevant dimensions, such as the crack length and the ligament size, leading to large scale bridging (LSB) or large scale yielding (LSY) (Ref 5, 20). LSB or LSY result in exceptional toughness. In such materials, the strengthening given by Eq 3 is not the most useful engineering quantity. Instead, the notch sensitivity or notch strength,  $S_n$ , relative to the strength of the unnotched material,  $S_0$ , has greater practical significance (Ref 21). In the limit, LSB causes steady-state multiple cracking (Ref 4, 5), wherein the stress needed to extend cracks becomes independent of the crack length. Then, the toughness is so large that other properties become more critical, particularly embrittlement and creep.

## Toughening and Strengthening Models for Nominally Brittle Materials

A.G. Evans, Harvard University

---

### Bridging Mechanisms

Reinforcing elements can be either ductile or brittle. The former comprise dual-phase alloys, polymer blends, and metal-toughened ceramics. Such reinforcement schemes rely on plasticity to create ligaments and dissipate energy (Fig. 4). When the elements are brittle, bridging requires either microstructural residual stresses or weak interfaces. Large local residual stresses caused by thermal expansion mismatch are capable of suppressing local crack propagation and, thereby, may allow intact ligaments to exist behind the crack front (Ref 22). When these ligaments eventually fail in the crack wake, energy is dissipated through acoustic waves and causes toughening. Low-fracture-energy interfaces are more effective. They cause the crack to deflect and debond the interfaces. The debonds acquire mode II (shear) characteristics, leading to friction, stability, and intact ligaments (Ref 23). As the crack extends, further debonding occurs, subject to friction. Eventually, the bridging material fails, either by debonding around the ends or by fracture. Following reinforcement failure, additional friction may occur along the debonded surfaces. The energy dissipation upon crack propagation thus includes terms from the energy of the debonded interfaces, the acoustic energy dissipated upon reinforcement failure, and frictional dissipation (Fig. 4) (Ref 2, 23). The latter is typically dominant. Moreover, the internal friction can become exceptionally large, resulting in toughness approaching those for ductile metals (Ref 23, 24).

FIG. 4 A SCHEMATIC INDICATING THE DISSIPATION THAT OCCURS WITH A BRIDGING ZONE. (A) DUCTILE LIGAMENTS. (B) BRITTLE REINFORCEMENTS

### Ductile Phases

The material systems that exhibit plasticity-induced toughening have three distinct microstructures: isolated ductile reinforcements in an elastic matrix, interpenetrating ductile/elastic networks, and a ductile matrix with a dispersed elastic phase. The first two represent most metal-toughened ceramics and intermetallics. The latter includes most metal-matrix composites and rubber-toughened polymers. An important difference between the first two microstructures and the third concerns the potential for macroscopic plastic strain. Plastic strain in the former is limited by the elastic network, such that the only ductile material experiencing extensive strain is that stretching between the crack surfaces in the bridging zone. The latter materials develop an additional plastic zone that enables further, often substantial, inelastic dissipation. This behavior and its coupling to the rupture zone are elaborated in the following section.

Ductile ligament toughening in an otherwise elastic material is contingent on the ligament failure mechanism, through the stress/stretch relation. Without debonding, the stress attains high levels because of the elastic constraint of the matrix (Ref 13, 25), but then decreases as the crack opens because of necking. Debonding reduces the constraint but increases the plastic stretch to failure (Ref 13, 26). The latter contribution to the dissipation dominates, causing the dissipation to increase as the debond length increases. The toughness attributed to ductile bridging can be reexpressed by noting that the stress scales with the uniaxial yield strength,  $Y$ , of the ligaments and that the plastic stretch is proportional to the radius of the cross section of the reinforcements,  $R$ . Consequently, the asymptotic toughening is (Ref 26):

$$\Delta\Gamma_s = \chi FRY \quad (\text{EQ 12A})$$

and the zone length is:

$$L = \beta RE/Y \quad (\text{EQ 12B})$$

where  $f$  is the volume fraction of the reinforcement.  $\chi$  and  $\beta$  are "ductility" parameters that also depend on the extent of the interface debonding,  $d$ . (Note that  $Y$  can increase as  $R$  decreases because of strain gradient effects, Ref 27). Values of  $\chi$  and  $\beta$  have been obtained both by calculation and by experiment (Ref 13, 14, 26, 28, 29). For well-bonded interfaces with ductile phases that fail by necking to a point,  $\chi \approx 0.5$  and  $\beta \approx 0.1$ , both increasing as the strain hardening increases. Less ductile ligaments that rupture prematurely have correspondingly smaller  $\chi$  and  $\beta$ . In systems subject to debonding,  $\chi$  and  $\beta$  depend on the reinforcement morphology. For interpenetrating or continuous reinforcing phases,  $\chi$  and  $\beta$  are increased by debonding, because the dissipation is spread laterally away from the crack plane:  $\chi$  approaches 8 for large  $d/R$ . For discontinuous phases, debonding around the ends of the reinforcement diminishes  $\chi$  and  $\beta$ .

The tearing index for such materials is obtained from Eq 2, 12a, and 12b as:

$$\Lambda = [(\chi F)^2/\beta] [RY^3/E\Gamma_0^2] \quad (\text{EQ 13})$$

The important implication is that the scaling that controls strength and reliability is most strongly affected by the yield strength of the reinforcing material,  $Y$ , and its ductility, through  $\chi$ . Other factors are relatively unimportant.

## Brittle Reinforcements

The highest toughnesses are achievable in systems containing "weak" interfaces, which enable debonding and allow dissipation by internal friction. There are major effects on the toughness of the morphology of the debond planes (roughness), the residual stresses, the failure stochastics of the reinforcements, and the stiffnesses of the constituent phases (Ref 30). A prerequisite to such toughening is that the debond criterion be satisfied (Ref 31). Initial interface debonding at the crack front requires that the relative toughness of the interface ( $\Gamma_i$ ) and the reinforcement ( $\Gamma_p$ ) be small enough to lie within the debond zone depicted in Fig. 5 (typically  $\Gamma_i/\Gamma_p \cdot \frac{1}{4}$ ). The extent of initial debonding is small, but further debonding is induced in the crack wake as the crack extends. The extent of further debonding is governed largely by the residual field, the debond surface roughness, and the friction coefficient (Ref 32). Reinforcement failure involves stochastics, subject to a friction stress  $\tau$  (Ref 33, 34, 35, 36). Large  $\tau$  causes the stress to vary rapidly and induces reinforcement failure close to the crack, leading to a small pullout length,  $p$ , and vice versa. The consequent tractions are relatively complex (Ref 37). Insight is gained from solutions for aligned, brittle fibers. At the simplest level, the behavior of short, strong, aligned reinforcements, subject to friction, can be explored. For this case (Ref 16, 37):

$$\Delta\Gamma_S = F\tau(P/R)^2 R \quad (\text{EQ 14A})$$

$$L = (C/2)ER/F\tau \quad (\text{EQ 14B})$$

where  $R$  is the reinforcement radius and  $p$  their length, such that  $p/R$  is the aspect ratio. The corresponding tearing index is:

$$\lambda = (2/C) [(F\tau)^3 R (P/R)^4 / E\Gamma_0^2] \quad (\text{EQ 14C})$$

Note the major influences of the aspect ratio and the friction stress. However, this toughening and strengthening situation occurs only if the reinforcement strength,  $S$ , satisfies (Ref 37):

$$S > \tau(P/R) \quad (\text{EQ 15})$$

When the reinforcements are long and aligned, but susceptible to fracturing as the crack extends, the tractions are more complex (Ref 37):

$$T/FS_L = \sqrt{W} \text{EXP} [-\alpha_M W^{(M+1)/2}] \quad (\text{EQ 16})$$

where  $m$  is the Weibull shape parameter associated with the reinforcements,  $S_L$  is their average strength at length  $L_r$ , and:

$$\begin{aligned} W &= 8\lambda^2 (U/L_R) \\ \alpha_M &= [\Gamma(1 + 1/M)]^M / [M + 1] \\ \lambda &= [E/2E_M (1 - F)] \sqrt{(E_r/S_L)} \\ L_R &= S_L R / \tau \end{aligned}$$

where the subscripts  $m$  and  $r$  refer to the matrix and reinforcements, respectively, and  $\Gamma$  is the gamma function. Even in this simplified case, the friction stress and the reinforcement strength have interactive effects on toughening and strengthening that are not evident without detailed analysis. Consequently, for practical implementation, the integrated effect of these variables on the behavior in the presence of strain concentrators, such as notches, is more useful, as manifest in the notch sensitivity (Ref 21, 23). These effects are elaborated in the following section.

FIG. 5 A DEBOND DIAGRAM FOR BRITTLE REINFORCEMENT

Tough materials having the above characteristics are made by creating the appropriate interphase between the reinforcement and matrix. The most common approach comprises a dual coating: the inner coating satisfies the debonding, friction, and compliance requirements, while the outer coating provides protection against the matrix during processing (Ref 30, 38, 39).

### Anisotropic Grains

Low-fracture-energy planes or grain boundaries can allow debonding, as in reinforced materials with weak interfaces, such that toughening involves the same considerations. Certain anisotropic ceramics with elongated grains (particularly alumina and silicon nitride) exhibit such toughening (Ref 40). In these materials, the dominant effect is the friction that operates along the rough, nonaligned, debonded grain boundaries (Ref 16, 41). The trends are thus broadly consistent with the above results for short, strong reinforcements. That is, the toughening and the strengthening increase as the grain radius,  $R$ , and their aspect ratio,  $p/R$ , increase, provided that the flaws are unchanged (that is,  $a_0$  is fixed).

Intermetallics such as Ti-Al also toughen in this manner because of extreme anisotropy in the cleavage energies (Ref 42, 43). But in this case, the energy of the additional surface created by debonding and ligament formation appears to be more important than the friction. The relevant toughening and strengthening parameters are then (Ref 43):

$$\begin{aligned}
 \Delta\Gamma_s/\Gamma_L &= \omega \\
 L &= CR\omega/\chi^2 \\
 \lambda &= (\Gamma_L/\Gamma_0)^2 \omega\chi^2/R
 \end{aligned}
 \tag{EQ 17}$$

where  $\Gamma_L$  is the cleavage energy on the "tough," transverse planes, and  $\omega$  and  $\chi$  are non-dimensional quantities that depend only on the aspect ratio and orientation of the ligaments formed by debonding (Fig. 6).

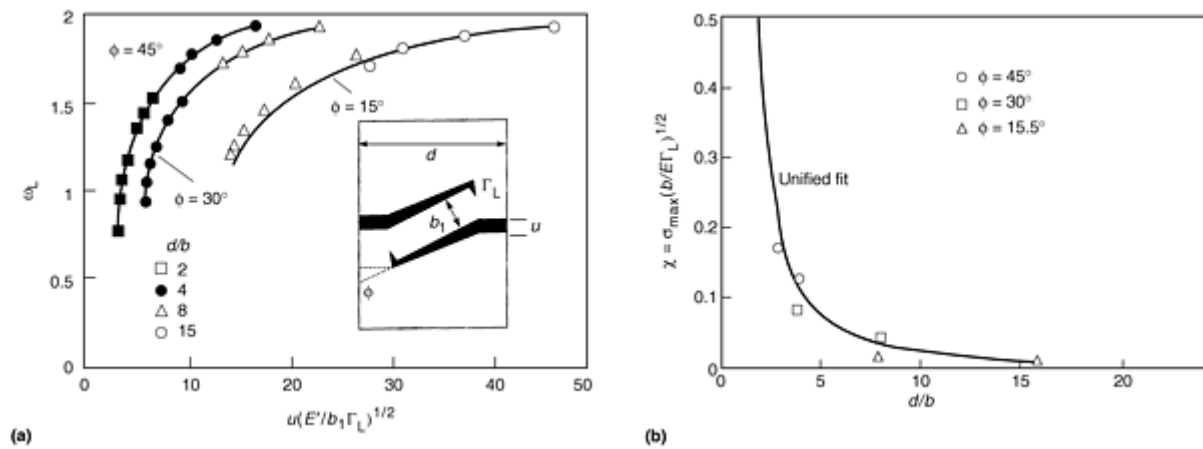

FIG. 6 NON-DIMENSIONAL PARAMETERS THAT AFFECT LIGAMENT TOUGHENING

The salient point is that, when such a mechanism prevails, there can be no effect of the ligament width,  $R$ , on the toughening. The only quantities affecting this behavior are the aspect ratio and the orientations of the ligaments that form, as well as the cleavage energies. Conversely, the strengthening is influenced by the ligament size, with the opposite trend to that associated with frictional toughening. That is, the strengthening increases as the microstructure is refined and  $R$  is diminished.

## Toughening and Strengthening Models for Nominally Brittle Materials

A.G. Evans, Harvard University

### Process Zone Mechanisms

Many materials remain nonlinear once inelastic deformation has commenced (beyond  $\sigma_0$ ). In such materials, the tip energy release rate  $G_{tip}$  is zero (Ref 44). It is possible to model the process zone dissipation only upon coupling with a failure zone along the crack plane (Ref 45, 46). This situation is elaborated below for plastic zone dissipation. This complexity does not exist when the nonlinear deformation process saturates, such that the stress-strain curve becomes linear at large strains. In this case,  $G_{tip}$  is finite, because there is no dissipation in the elastic saturation zone (Ref 6, 7, 8, 9). The crack growth criterion then requires that  $G_{tip}$  attain the local toughness of the material immediately ahead of the crack, which may have been modified from that in the pristine material. This saturation approach has been applied to transformation and microcrack toughening.

**Saturation Toughening.** Transformation toughening is dominated by a dilatational stress-free strain. Then a frontal process zone has no effect on  $G_{tip}$ , and initial crack growth must occur without toughening (Fig. 2). Upon crack extension, process-zone elements unload in the wake, hysteresis occurs, and toughening develops. Steady-state toughening is attained at  $L/h \approx 3$ . The material within the zone behind the crack tip experiences unloading as the crack extends, so the J-integral becomes path dependent and must be superseded by a conservation integral  $I$ . At the tip, the familiar result is (Ref 6):

$$I = J = G_{TIP} \quad (\text{EQ 18A})$$

But, remote from the tip (Ref 6):

$$I = G_{\infty} - 2 \int_0^h U(Y)DY \quad (\text{EQ 18B})$$

where  $U(y)$  is the residual energy density in the wake. Equating  $I$  for the near-tip and remote paths gives:

$$\Delta\Gamma_R = 2 \int_0^h U(Y)DY \quad (\text{EQ 18C})$$

Material elements in the process zone undergo a complete loading/unloading cycle as they translate from the front to the rear of the crack tip during crack advance. Hence, each element is subject to the residual stress work contained by the hysteresis loop (Fig. 2). The residual energy density is (Ref 6):

$$U(Y) = \sigma_0 \varepsilon_T F + B^* (F \varepsilon_T)^2 / 2 [1 - B^*/B] + E(\varepsilon_T F)^2 / 9(1 - \nu) \quad (\text{EQ 19})$$

where  $B$  is the bulk modulus and  $B^*$  is the slope of the stress-strain curve of the transforming material. Note that  $B$  and  $f$  are invariant when the transformation is supercritical, that is, when all of the transformable material undergoes transformation within the process zone ( $y < h$ ). In this case (Ref 6):

$$B^* = 2E/3(1 + \nu) \quad (\text{EQ 20})$$

and the latter two terms in Eq 19 cancel. The toughening is then given exactly by Eq 8 and the tearing index by Eq 11. Typically, the transformation is subcritical, leading to a gradient in the fraction of transformed material within the process zone. That is,  $B$  and  $f$  depend on  $y$ . The resultant toughening is lower than Eq 8. It must be determined from Eq 19 by imposing the function  $f(y)$ , obtained by either measurement or calculation (Ref 9, 47).

Similar phenomena occur in materials susceptible to microcracking (Ref 2, 10). Stress-activated microcracks occur within regions of local residual tension, caused for example by thermal expansion mismatch between phases. There is an associated dilatation, governed by the residual opening of the microcracks. The microcracks also reduce the elastic modulus within the process zone. The dilatational contribution to the toughening has precisely the same form as that associated with transformations, but with  $f\varepsilon_T$  replaced by  $\theta_T$ . For penny-shaped microcracks (Ref 10):

$$\theta_T = (32/27)(1 + \nu)N\varepsilon_0 \quad (\text{EQ 21})$$

where  $n$  is the microcrack density and  $\varepsilon_0$  is the misfit strain between the phases. However, other phenomena are also involved in determining the toughening and strengthening. The modulus change reduces the stress ahead of the crack, but it has only a small (and subtle) effect on the energy release rate. The toughening is thus modest and may be zero. This effect depends on the microcrack density but not on the zone height. In general, toughening due to the dilatational and modulus effects are not additive; interaction terms are involved. Moreover, the microcracks have a degrading influence on the toughening that partially counteracts these effects. That is, they reduce the tip toughness through the area fraction of the crack plane they occupy.

**Plastic Zone Toughening.** The dissipation occurring within a plastic zone can be simulated only by invoking a finite rupture region along the crack plane (Ref 45, 46). This zone couples the stresses and displacements into the plastic zone. All realistic rupture laws have the form depicted in Fig. 7, characterized by a peak stress,  $\sigma^*$ , and a dissipation,  $\Gamma^*$ . For inelastic bridging in an elastic material, described above,  $\sigma^*$  equates with  $t_0$  (Ref 9). When plasticity occurs outside the rupture zone, there is an extra contribution to the toughening. Small scale yielding (SSY) simulations of the resistance for a material subject to power law hardening (uniaxial yield strength,  $\sigma_0$ , and hardening rate,  $N$ ) are summarized in Fig. 7. When the stresses that operate in the rupture zone are relatively small ( $\sigma^*/\sigma_0$  less than approximately 2), a plastic zone is unable to develop before rupture occurs. Then, the toughness is strictly that associated with bridging and rupture (Ref 12). For relatively stronger rupture zones, a plastic zone is induced. The resulting dissipation increases rapidly as  $\sigma^*/\sigma_0$  and  $N$  increase. When  $\sigma^*/\sigma_0$  reaches  $\sim 5$ , the plastic zone extends indefinitely and the crack cannot propagate: that is, the SSY toughness is unbounded. In this case, LSY simulations would be needed to address crack growth. The SSY toughening parameters are:

$$\Delta\Gamma_s/\Gamma_0 = G(\sigma^*/\sigma_0, N) + 1 \quad (\text{EQ 22A})$$

$$L = R_0 \xi(\sigma^*/\sigma_0, N) \quad (\text{EQ 22B})$$

where  $R_0$  is the plastic zone size:

$$R_0 = \phi(E\Gamma_0/\sigma_0^2) \quad (\text{EQ 22C})$$

and where  $g$ ,  $\xi$ , and  $\phi$  are non-dimensional functions having the approximate form:

$$G \approx [\sigma^*/\sigma_0 - 2]^{1/\alpha N}$$

$$\xi \approx G^{2\alpha N}$$

where  $\alpha \approx 2$  and  $\phi \approx 0.1$ .

## Toughening and Strengthening Models for Nominally Brittle Materials

---

A.G. Evans, Harvard University

---

### Notch Sensitivity and Inelastic Strain

**Notch Strength.** For engineering application, the notch sensitivity is most useful (Ref 21). Simulation of the stress  $\sigma$  needed to extend a dominant crack, length  $a$ , from an initial unbridged region (or notch), length  $a_0$ , is achieved by using the bridging tractions (such as Eq 16). As this occurs, a maximum stress is reached coincident with simultaneous failure of the intact reinforcements. This stress is the notch strength,  $S_n$ . The ratio of this strength to that for the unnotched material,  $S_0$ , is the relevant design parameter. Such behavior is illustrated for a material with strong, short, aligned reinforcements in Fig. 8. This behavior has the envelope (Ref 37):

$$\begin{aligned} \sigma/S_0 &= (2/\pi) \cos^{-1} (A/A_0) \\ S_0 &= F\tau P/2R \end{aligned} \quad \text{(EQ 23)}$$

where this envelope occurs for small  $Q$ , representative of small values of the friction stress where

$$Q = (2F E_R/EA) (A_0\tau/RE_R) \quad \text{(EQ 24)}$$

and where  $A$  is an anisotropy parameter of order unity. As  $Q$  increases, crack growth is truncated by material failure, at diminishing strength levels. The resulting notch strength is given by:

$$S_N/S_0 = \sqrt{(1 + 3\pi Q/2)} \quad \text{(EQ 25)}$$

FIG. 8 CRACK EXTENSION STRESS FOR MATERIALS REINFORCED WITH SHORT, STRONG, BRITTLE REINFORCEMENTS

The corresponding notch behavior when the reinforcements are longer and susceptible to failure as the crack grows is summarized in Fig. 9 (Ref 37). Note the minimal notch sensitivity when the Weibull shape parameter,  $m$ , is small. When the toughening enabled by internal friction becomes large, a steady-state cracking condition is reached (Ref 5). At this condition, a matrix crack may extend across the component without failing the reinforcements. In this case, multiple matrix cracking is induced. This occurs prior to attainment of the UTS (Ref 23, 24). The consequence is macroscopic inelastic strain, with "ductilities" on the order of 1%. These inelastic strains redistribute stress in an efficient manner, such that the material may become notch insensitive (Fig. 10) (Ref 48, 49). The toughness then has no practical significance. The approach used to characterize these materials, as with metals, involves characterizing the inelastic strains (Ref 50).

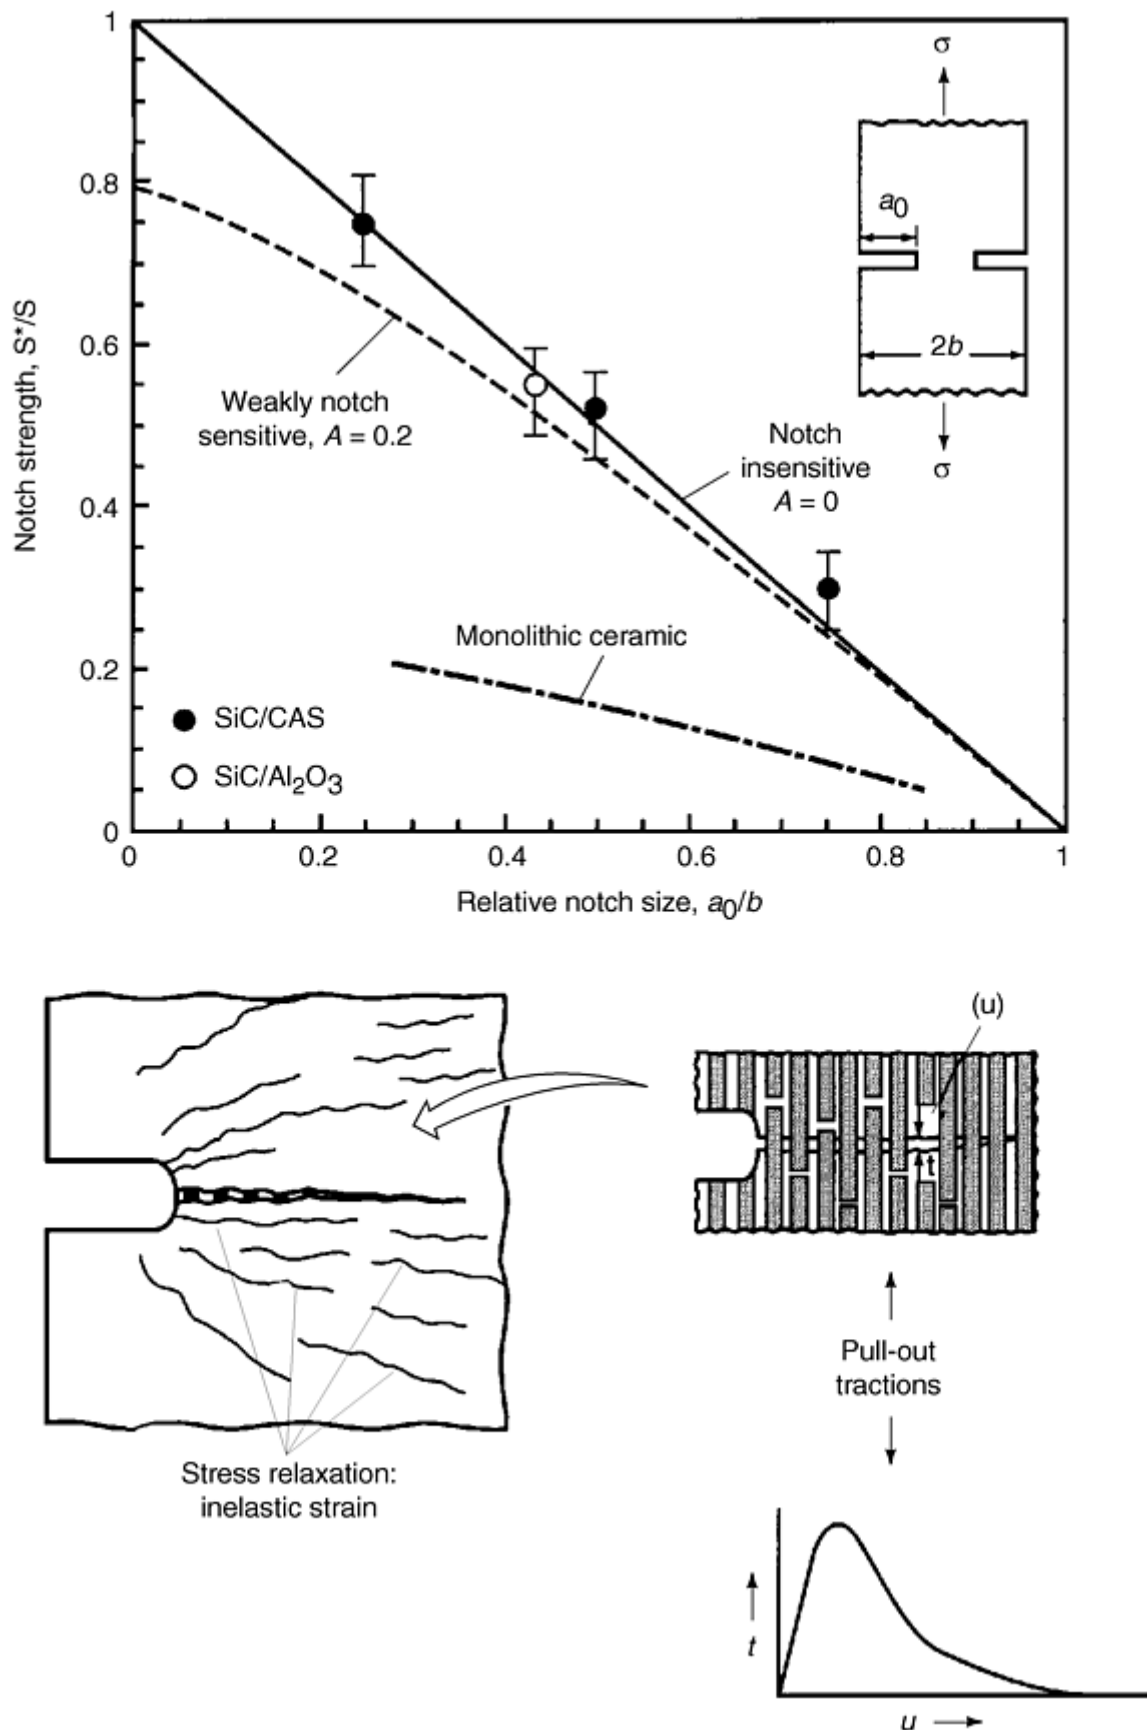

FIG. 9 THE CALCULATED NOTCH SENSITIVITY FOR A MATERIAL WITH LONG, BRITTLE REINFORCEMENTS THAT MAY FRACTURE AS THE CRACK EXTENDS

**FIG. 10 THE NOTCH INSENSITIVITY FOUND EXPERIMENTALLY FOR CERAMIC-MATRIX COMPOSITES CAUSED BY STRESS REDISTRIBUTION**

**Inelastic Strains.** A mechanism-based strategy for characterizing and implementing inelastic strains and for calculating stress redistribution is illustrated using results for ceramic-matrix composites (Ref 23). These composites exhibit inelastic deformations when matrix microcracks are stabilized. This is achieved by using either fiber coatings or porous matrices to deviate cracks toward the loading axis (Fig. 5). The resultant composite microstructure and the ensuing mechanical responses resemble those found in various naturally occurring materials, such as wood. The inelastic strain is governed primarily by the number density of cracking sites and the friction stress that operates along the debonded crack surfaces. A cell model represents most of the features (Fig. 11). Two stresses characterize the inelastic strain: a friction stress  $\tau$  and a debond stress  $\sigma_i$  (Fig. 11). The latter is related to the debond toughness for the coating and the residual stress (Ref 51). The consequent inelastic tensile strain  $\varepsilon$  has linear and parabolic terms, given by (Ref 52):

$$\varepsilon = (1 + \Sigma^T)\sigma/E^* + 2L\sigma^2(1 - \Sigma_i)(1 + \Sigma_i + 2\Sigma^2) - \sigma^T/E \quad (\text{EQ 26})$$

where  $E^*$  is the diminished elastic modulus caused by matrix cracking,  $\sigma^T$  is the misfit stress (related to the residual stress),  $\Sigma_i$  is the non-dimensional debond stress,  $\Sigma_i = \sigma_i/\sigma$ ,  $\Sigma^T = \sigma^T/\sigma$ , and  $L$  is an interface friction index, given by (Ref 52):

$$L = \frac{b(1 - af)^2R}{4f^2\tau dE_m} \quad (\text{EQ 27})$$

where  $d$  is the crack spacing. The coefficients  $a$  and  $b$  are of order unity. The parameters  $E^*$ ,  $L$ , and  $\Sigma_i$  (evaluated from hysteresis loops) (Ref 52) provide understanding about the separate influences of debonding, friction, and matrix cracking on the inelastic strain. They also provided the insight needed to develop a constitutive law  $\sigma(\varepsilon)$  compatible with finite element codes.

FIG. 11 BASIC CELL MODEL (HYSTERESIS LOOPS) USED TO CHARACTERIZE THE INELASTIC STRAINS THAT OCCUR IN CERAMIC-MATRIX COMPOSITES AND THEIR DEPENDENCE ON THE INTERFACE FRICTION.  $\bar{\epsilon} = U/D$ ,  $F = R/B$ .

A law derived on this basis that characterizes all plane stress states in the (1,2) directions is (Ref 50):

$$\begin{aligned}\sigma_1 &= \frac{E_0}{1 - \nu_0^2} (\epsilon_1 + \nu_0 \epsilon_2) + \Delta\sigma_I \cos^2 \theta + \Delta\sigma_{II} \sin^2 \theta \\ \sigma_2 &= \frac{E_0}{1 - \nu_0^2} (\epsilon_2 + \nu_0 \epsilon_1) + \Delta\sigma_I \sin^2 \theta \\ &\quad + \Delta\sigma_{II} \cos^2 \theta \\ \tau &= \frac{E_{45}}{2(1 - \nu_{45})} \gamma_{12} - (\Delta\sigma_I - \Delta\sigma_{II}) \sin \theta \cos \theta\end{aligned}\tag{EQ 28}$$

where  $\tau$  is now the macroscopic shear stress;  $\epsilon_{1,2}$  are the normal strains;  $\gamma_{12}$  is the shear strain;  $\Delta\sigma_{I,II}$  are the stress drops upon matrix cracking at fixed strain, parallel and normal to the fiber directions;  $\theta$  is the angle between (1) and the fiber direction;  $E_{0,45}$  are the Young's modulus in the fiber direction and at  $45^\circ$ , respectively; and  $\nu_{0,45}$  are the corresponding values of the Poisson ratio. Some calculations of stress redistribution in a pin-loaded configuration are summarized in Fig. 12. A comparison with experiment is also shown. These results establish that appreciable stress reduction is enabled by the inelastic strain, resulting in a response insensitive to the strain concentration caused by the hole (Ref 50, 53):

**FIG. 12 STRESS REDISTRIBUTION AROUND A HOLE IN A PIN-LOADED CERAMIC-MATRIX COMPOSITE: EXPERIMENTS AND FINITE-ELEMENT MODELING (FEM) CALCULATIONS**

### Toughening and Strengthening Models for Nominally Brittle Materials

A.G. Evans, Harvard University

---

### Future Work

Some important phenomena have yet to be adequately explored, particularly short crack effects induced by overlap of the strain fields from the two crack fronts and the free surfaces. These effects diminish the tearing index and adversely affect the strengthening that can be gained by activating the toughening mechanisms. Establishing these characteristics is an important priority for future modeling.

Ductilizing has a much greater influence on reliability than increasing the toughness. A future endeavor would address new methods for improving ductility.

## Fatigue and Fracture Behavior of Glasses

James R. Varner, New York State College of Ceramics at Alfred University

---

## Introduction

SILICATE GLASSES, which comprise nearly all glasses of commercial interest, are linearly elastic, brittle materials. The cyclic fatigue exhibited by metals thus is not a problem in glasses. However, glasses do experience static fatigue, which is time-dependent failure of glass placed under constant load in an environment containing water or water vapor. The mechanism is stress corrosion, crack growth caused by stress-assisted reaction with liquid water or water vapor at the crack tip. Stress corrosion occurs under constant or changing loads. Therefore, glasses subjected to cyclic loading will experience incremental crack growth each time the stress at the crack tip exceeds a critical value, and failure may occur, but the mechanism is stress corrosion, not cyclic fatigue. The development of glass fiber-optic cables for voice and data transmission was accompanied by renewed interest in fatigue of glasses. Glass fibers in fiber-optic systems must be able to withstand sustained loads for many years in environments that may contain significant amounts of water. Engineers must be able to make lifetime predictions of fiber-optic systems based on reliable data and tested theories. Static fatigue and stress-corrosion cracking of glasses have been intensely researched, but these phenomena are far from well understood. Important nuances are still being debated in the literature.

This article discusses only silicate glasses--more specifically, soda-lime-silicate glass (the most widely used glass, used in products such as windows, containers, drinking glasses, etc.), borosilicate glass (used in cookware and laboratory glassware, for example), and vitreous silica (the basis for fiber-optic systems). Fracture behavior will be described first, in order to discuss the brittle nature of glass and provide the background needed for understanding fatigue in glasses. The phenomenon of static fatigue will be documented using examples from the literature, and explanations for it given. Lifetime prediction will be addressed by discussing methods of testing--dynamic fatigue and slow-crack-growth studies--and methods of calculation. Finally, the role of surface damage in strength and fatigue behavior will be discussed.

---

## Fatigue and Fracture Behavior of Glasses

James R. Varner, New York State College of Ceramics at Alfred University

## Fracture Behavior

At ambient temperatures, glass fractures in a completely brittle way. There is no evidence of plastic or viscous flow, either macroscopically (i.e., no necking or other permanent change in dimensions) or microscopically (i.e., no slip bands or flow lines). Permanent deformation of glass at ambient temperatures does occur in complex, concentrated loading situations, such as during indentation with a sharp indenter or during abrasion or machining. Shear bands are observed under indentations in soda-lime-silica glasses, for example. However, brittle fracture in the form of very complex crack formation accompanies this permanent deformation when the applied load exceeds a critical value. All modes of loading of practical importance include a tensile component, and it is this tension that causes cracks to form and glass parts to fail. Fracture of brittle materials is discussed in the previous article in this Volume. For the present discussion of fatigue, it is useful to emphasize some key features about brittle fracture of glasses.

Applied stresses are concentrated at crack tips. In fact, stresses at crack tips are often orders of magnitude larger than the applied stress. The stresses become this high because of (1) the geometry of the crack and (2) the lack of stress-relieving plastic deformation. Both factors are important, since stresses are also concentrated at crack tips in metals, but local plastic deformation may keep these stresses from reaching the value needed for catastrophic failure. Fracture occurs when the stresses at the crack tip exceed the bond strengths in the glass network. The well-known Griffith equation (Ref 1) provides one way to relate crack geometry to fracture strength:

$$\sigma_F = \left( \frac{2E\gamma}{\pi c} \right)^{1/2} \quad (\text{EQ 1})$$

where  $\sigma_F$  is fracture strength,  $E$  is modulus of elasticity,  $\gamma$  is surface energy, and  $c$  is crack length (if it is a surface crack). For a given glass, therefore, the crack size determines the strength. While it is true that Eq 1 is based on geometrical assumptions that are not exactly valid for all surface cracks, the inverse relationship between strength and crack size that is expressed still holds. Using fracture mechanics, a similar equation can be developed, which also shows that the strength is inversely proportional to the size (length) of the crack:

$$\sigma_F = \frac{YK_{Ic}}{c^{1/2}} \quad (\text{EQ 2})$$

where  $Y$  is a geometrical factor related to crack and specimen geometry, and  $K_{Ic}$  is the critical stress-intensity factor (fracture toughness) of the glass. Equation 2 is valid for any crack, as long as an appropriate value for  $Y$  is known.

With rare exceptions, surface cracks are the sources of failure, the fracture origins, in glasses. There are four reasons for this:

1. GLASSES USUALLY HAVE FEW INTERNAL FLAWS, ESPECIALLY FLAWS THAT ARE EFFECTIVE IN CONCENTRATING STRESSES.
2. RELATIVELY LARGE CRACKS ARE PRODUCED ON GLASS SURFACES DUE TO CONTACTS BETWEEN THE GLASS AND HARD OBJECTS. THIS WILL BE DISCUSSED LATER IN MORE DETAIL.
3. FOR MANY LOADING SITUATIONS, THE MAXIMUM TENSILE STRESS IS ON THE SURFACE.
4. SURFACE CRACKS ARE EXPOSED TO THE ENVIRONMENT.

As will be discussed, the last three of these reasons also relate to static fatigue of glass.

### Static Fatigue

If a glass rod at room temperature in normal air is subjected to a constant load in three- or four-point bending, failure often occurs after some time has passed, rather than at the instant the load was applied. The rod was able to support the load at first; therefore, the maximum tensile stress must have been below the fracture stress,  $\sigma_F$ . Over time, something happened to cause strength degradation. In terms of Eq 2, there must have been either a change in  $Y$  (i.e., a change in the geometry, or shape, of the crack) or a change (i.e., an increase) in  $c$ , the crack length, since  $K_{Ic}$  is a material constant. This rod experiment is one example of the phenomenon of static fatigue, and it is also the classic way of measuring static fatigue--namely, by measuring the time to failure at a given applied load. Static fatigue of fibers may be measured by two-point bending or by applying uniaxial tension. If this experiment is performed using different loads, the time to failure will be seen to increase as the applied load decreases. Figure 1 shows an example of this type of experiment (Ref 2).

FIG. 1 LOG-LOG STATIC FATIGUE PLOT OF AVERAGE TIME TO FAILURE,  $T$ , VERSUS APPLIED STRESS. DATA ARE FOR VITREOUS SILICA AND ARE TAKEN FROM REF 3. SOURCE: REF 2

The role of water in static fatigue of glass was recognized early on (Ref 4), even though the mechanism was not understood. Consequently, researchers examined different glass compositions and confirmed that those that are known to be more resistant to attack by water exhibit longer times to failure at a given load (Ref 5). Another approach was to try the time-to-failure experiments in air containing different amounts of water vapor, as well as in water itself (Ref 6). As shown in section (a) of Table 1, static fatigue is more pronounced--that is, times to failure are shorter at a given load--when there is more water vapor present, and shorter still in liquid water.

TABLE 1 TIME TO FAILURE AT  $\sigma_F/\sigma_N = 0.5$  (DESIGNATED  $T_{0.5}$ ) FOR SODA-LIME-SILICA SPECIMENS TESTED IN FLEXURE

RH, relative humidity. Data taken from Ref 6

It was discovered that one effective way to eliminate the influence of water was to conduct the experiments in liquid nitrogen (Ref 4), and the results thus obtained were accepted as being free from static fatigue. The practice developed of normalizing strength at failure with respect to the liquid nitrogen strength,  $\sigma_N$ . Static fatigue data can then be presented on a graph of  $\sigma/\sigma_N$  versus time to failure,  $t$ . Mould and Southwick (Ref 6), however, showed that using normalized time-to-failure values produced what they termed a "universal fatigue curve." One example of this is shown in Fig. 2, in which  $\sigma/\sigma_N$  is plotted versus  $\log(t/t_{0.5})$ , where  $t$  is the time to failure and  $t_{0.5}$  is the time to failure at  $\sigma/\sigma_N = 0.5$  (Ref 6). The data presented in section (b) of Table 1 fall on the curve shown in Fig. 2. Plotting  $\sigma/\sigma_N$  versus time to failure (not normalized) results in six separate curves for the six conditions of surface abrasion used in the experiments. Normalizing the time to failure produces the universal fatigue curve. Mould and Southwick (Ref 6) showed that the surface condition of the glass influences the results, as shown by the data presented in section (b) of Table 1. The time to failure at  $\sigma/\sigma_N = 0.5$  of abraded rods tested in water is shorter when the abrasion is more severe.

**FIG. 2 UNIVERSAL FATIGUE PLOT OF NORMALIZED STRESS (STRESS ON SPECIMEN DIVIDED BY FRACTURE STRESS AT  $-196\text{ }^\circ\text{C}$ ),  $\sigma/\sigma_N$  VERSUS  $\log(t/t_{0.5})$  (LOAD DURATION DIVIDED BY THE LOAD DURATION AT  $\sigma/\sigma_N = 0.5$ ). DATA ARE FOR ABRADED SODA-LIME-SILICA SPECIMENS AND ARE TAKEN FROM REF 6.**

Still other experiments showed that average strengths increase when the specimens are stored in water (for 24 h, for example) prior to testing (Ref 5, 7). This last observation seems to conflict with those that show more rapid fatigue (i.e., strength degradation) in static fatigue tests in water. The difference is that the specimens stored in water are not under load. Once the mechanism of static fatigue has been explained, the reason for the different effects in these two cases will be clear.

To summarize, water plays an important role in static fatigue of glasses. The susceptibility of a given glass to static fatigue increases when more water is present and when the glass exhibits more severe surface damage. Glasses that are inherently more resistant to water attack, such as vitreous silica, are less susceptible to static fatigue. Aging abraded rods in water with no load on the specimens increases the average fracture strength. On the other hand, aging pristine vitreous silica fibers in water with no load on specimens can decrease strength (Ref 26). Several theories that attempt to explain all these observations will now be examined.

Charles and Hillig (Ref 8) provided concepts of stress corrosion that are still held to be essentially correct, albeit with some modifications. Tensile stress at a crack tip increases the rate of reaction of water with the glass. As a consequence, in the theory proposed by Charles and Hillig, the crack tip becomes sharper, and the crack grows longer; they considered the sharpening to be the more important of the two phenomena. [Today, the prevalent view is that "large" cracks are sharp, and that it is crack growth which is the mechanism responsible for fatigue. More on the issue of blunt and sharp cracks can be found in Ref 28.] As this slow crack growth occurs, the stress concentration at the crack tip increases, since a sharper, longer crack is a more effective concentrator of stress. Eventually, the stress reaches the bond strength of the network-forming structural units in the glass, and the piece breaks. This qualitative description of the Charles-Hillig theory of stress corrosion can be used to explain some of the observations documented earlier.

First of all, static fatigue itself occurs because of slow crack growth due to stress corrosion. Under a constant load, surface cracks exposed to water in the environment grow until they become long enough to cause failure at that load, that is, until they bring the stress concentration at the crack tip to the required level. When larger cracks are present initially, less time is required at a given load before the required amount of slow crack growth takes place--hence the dependence of static fatigue on surface condition. Slow crack growth is faster at higher applied loads, because the stresses at the crack tips are higher; therefore, the time needed for the required amount of slow crack growth is shorter, and times to failure are shorter. Static fatigue is not seen at liquid nitrogen temperature, because the rate of chemical reaction of the water with the glass is extremely low. Slow crack growth is slower in glasses that are more resistant to water attack; therefore, these glasses exhibit lower susceptibility to static fatigue. The positive effects on strength produced by aging abraded glass in water are due to rounding or blunting of crack tips when no applied stress, or very low applied stress, is present. A resharping must occur when a high enough load is applied before slow crack growth can proceed. Higher strengths are measured. The lower strengths measured after aging pristine vitreous silica fibers in water (Ref 26) may be explained by surface roughening, as shown by the work by Inniss et al (Ref 27). Charles and Hillig (Ref 8) developed a quantitative approach for predicting the velocity of slow crack growth and, therefore, the time needed before failure occurs. As discussed next, more recent models have been developed that are better at lifetime prediction.

Michalske and Freiman (Ref 9) and Michalske and Bunker (Ref 10) proposed a chemical mechanism for reactions at crack tips that predicts slow crack growth (static fatigue) in water and similar liquids. Their model for the reaction between water and vitreous silica involves a three-step process, as shown in Fig. 3. Si-O-Si bonds at crack tips are strained as a result of the stresses concentrated there. In step 1, an H<sub>2</sub>O molecule comes close to the oxygen in a strained Si-O-Si bond and orients itself such that one set of the lone electron-pair orbitals on the oxygen of the water molecule aligns toward one Si. At the same time, a hydrogen bond develops between one H and the O. Step 2 really involves two simultaneous transfers at these two sites: (1) electron transfer from the O in the water molecule to the adjacent Si and (2) proton transfer to the O of the Si-O-Si bond. This forms two new bonds. The strain on the Si-O-Si bond enhances the tendency for this to happen. This leaves a hydrogen bond between the O of the water molecule and the transferred H. Step 3 is the breaking of this hydrogen bond, leaving two Si-OH "surfaces." Other liquids or gases may behave similarly if they have structure and bonding similar to water--that is, lone-pair orbitals at one location on the molecule and proton donor sites at another. In fact, ammonia (NH<sub>3</sub>), hydrazine (N<sub>2</sub>H<sub>4</sub>), and formamide (CH<sub>3</sub>NO) have been shown to cause slow crack growth in vitreous silica (Ref 11).

FIG. 3 SCHEMATIC OF PROPOSED MODEL FOR THE REACTION SEQUENCE BETWEEN  $H_2O$  AND A STRAINED SI-O-SI BOND AT A CRACK TIP. SOURCE: REF 11

At this point, the picture seems clear: The reaction of water with glass is enhanced at crack tips owing to high strains in the network-forming bonds in those regions. Cracks lengthen (and sharpen?), which eventually causes fracture of the piece under load. However, models of water attack are just that--models. The specific attack mechanisms are still not known with certainty. Also, when equations for predicting lifetimes are developed from these theories, and when fatigue susceptibility is tested in other types of experiments, the picture loses its clarity. There is no question that water is involved in fatigue, or that stress-assisted crack growth in some form is involved, but there are questions about what happens in detail. In order to proceed further, these other types of experiments need to be explained and illustrated with some results.

## Fatigue and Fracture Behavior of Glasses

James R. Varner, New York State College of Ceramics at Alfred University

---

### Dynamic Fatigue

The obvious disadvantages of time-to-failure studies are the extremely long times needed for failure at low loads and the need for testing large numbers of specimens owing to the statistical nature of glass strength. One way to address the issue of long times is to use the technique called dynamic fatigue. Instead of applying a constant load (stress) to the specimen, a constant *rate* of loading (stress/second) is applied. Sets of specimens tested at lower rates of loading break at lower average strengths than sets tested at higher rates. The principle involved is that there is more time for crack growth to occur when the load is being increased slowly; therefore, the lowering of the strength due to slow crack growth is more pronounced. At very high loading rates, there is virtually no time for significant crack growth to occur before the stress at the crack tip reaches the critical value for fracture. Dynamic fatigue experiments are often done with the specimens immersed in water in order to investigate the maximum fatigue effect.

Average values of stress at failure are plotted versus stressing rate on a log-log graph. The slope of the best-fit straight line through the data points is  $1/(N + 1)$ , where  $N$  is the fatigue resistance parameter. An example is shown in Fig. 4 (Ref 29). The equation upon which this is based is from Charles (Ref 13):

$$\sigma_{AF} = C\beta^{1/N+1} \quad (\text{EQ 3})$$

where  $\sigma_{af}$  is the applied stress at which failure occurs,  $C$  is a constant, and  $\beta$  is the rate of stress application.

**FIG. 4** EXAMPLE OF A LOG-LOG DYNAMIC FATIGUE PLOT OF BREAKING STRESS VERSUS STRESSING RATE. DATA ARE FOR WETTED SODA-LIME-SILICA RODS AND ARE TAKEN FROM REF 29. THE SLOPE OF THE LINE  $[1/(N + 1)]$  IS 14.

The parameter  $N$  provides a simple way to characterize the fatigue resistance of glasses. A high value of  $N$  is associated with a high fatigue resistance. According to Ritter et al. (Ref 12),  $N$  for soda-lime-silica glass is about 13 to 17; for borosilicate glass, 27 to 40; and for vitreous silica, 32 to 38. These are for measurements done in water.

### Crack Velocity Measurements

Yet another method for studying fatigue susceptibility of glasses is to examine slow crack growth directly. This is done using crack velocity measurements, so-called  $V$ - $K$  experiments, in which controlled growth of well-defined macroscopic

cracks in fracture mechanics specimens is monitored. Regardless of the particular test geometry, the goal is to obtain the  $V$ - $K$  curve, which gives the relationship between crack velocity,  $V$ , and the stress-intensity factor,  $K$ , for the glass. A schematic of such a curve is shown in Fig. 5 (Ref 11). This is a semilog plot:  $\log(\text{velocity})$  versus  $K_I$ . Although the curve is divided into several regions, region I is of primary interest in characterizing fatigue behavior, since crack growth in this region is controlled by the rate of reaction of water (or water vapor) with the glass. Region II is a transition region in which part of the crack tip is exposed to water and part is running dry (Ref 14). In region III, the crack is moving so fast that water cannot reach the crack tip fast enough to have any effect on crack growth. Cracks in laboratory tests of static or dynamic fatigue and cracks in glass articles in service grow for the greatest length of time in region I. The velocity of crack propagation is exponentially dependent on the stress-intensity factor in region I, so the  $V$ - $K$  data in region I should lie on a straight line when plotted on semilog paper. The slope of this line is the fatigue resistance parameter,  $N$ .

**FIG. 5 SCHEMATIC  $V$ - $K$  CURVE FOR A GLASS SHOWING ALL POSSIBLE REGIONS (EXPLAINED IN TEXT); THE SLOPE OF REGION I REPRESENTS THE FATIGUE RESISTANCE PARAMETER. SOURCE: REF 11**

Wiederhorn (Ref 15), among others, showed that the velocity of crack propagation at a given  $K_I$  depends on the relative humidity, with higher velocities for higher humidities or liquid water. However, the slope of region I of the  $V$ - $K$  curve does not depend on the relative humidity. It does depend on glass composition and on pH, as shown in Fig. 6 (Ref 16).

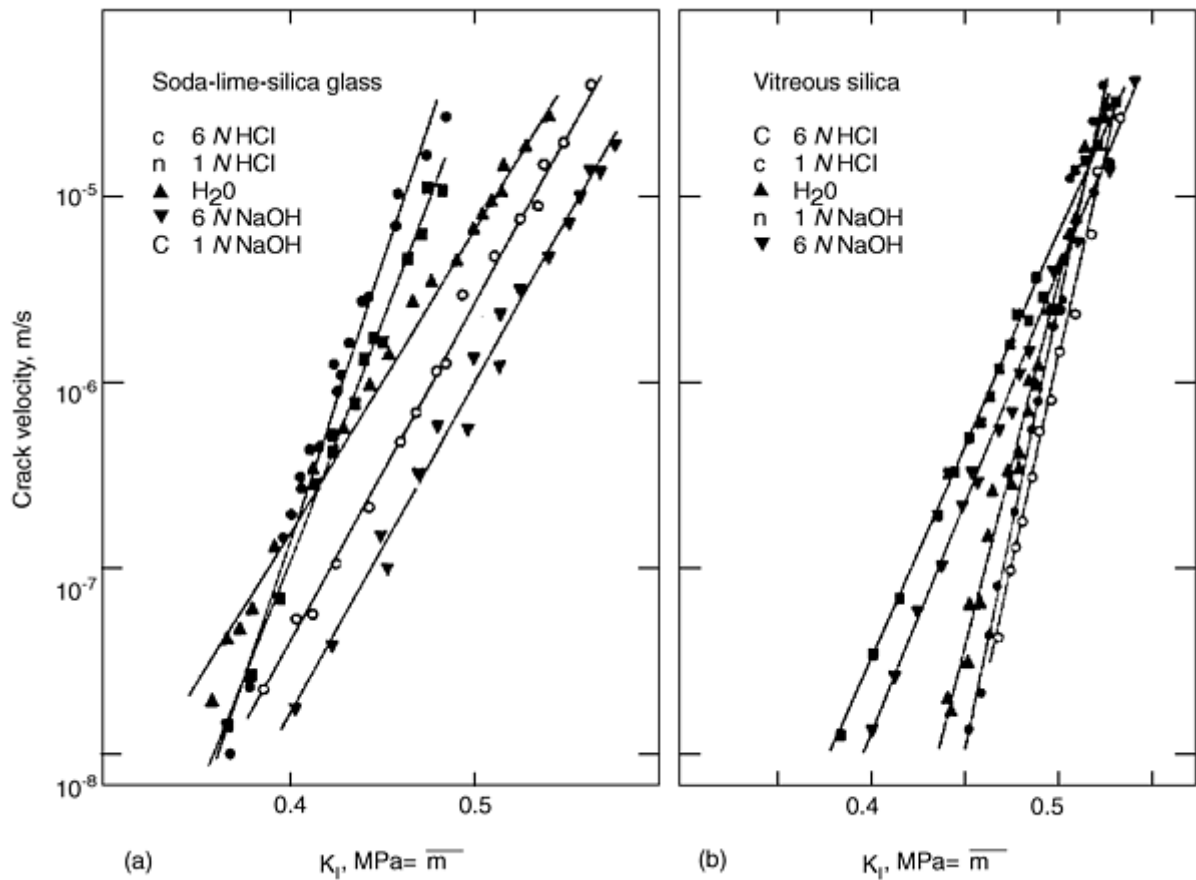

FIG. 6 V-K CURVES SHOWING THE EFFECT OF PH OF CRACK GROWTH IN SODA-LIME-SILICA GLASS (A) AND VITREOUS SILICA (B). DATA TAKEN FROM REF 16. SOURCE: REF 11

### Fatigue and Fracture Behavior of Glasses

James R. Varner, New York State College of Ceramics at Alfred University

### Comparison of Results

Static fatigue, dynamic fatigue, and crack velocity measurements are three different ways of determining the fatigue resistance parameter. Ideally, results obtained using the three techniques should be the same for tests done on the same glass composition under the same environmental conditions. However, this is not necessarily the case. For example, Ritter (Ref 17) showed that  $N$  values obtained using universal fatigue curves and  $V$ - $K$  curves for three glass compositions

differed. These results are summarized in Table 2. There is no agreement among the  $N$  values obtained from the universal fatigue curves and from the  $V$ - $K$  curves for these three glasses. In fact, the  $N$  values from the universal fatigue curves show no dependence on composition, whereas the  $N$  values from  $V$ - $K$  data seem to be obviously different for the three glasses. Notice too that the  $N$  values for the abraded specimens are consistently much lower than those for the specimens that were polished in hydrofluoric acid or tested as pristine fibers (i.e., freshly drawn fibers tested without being touched along the length put under maximum stress).

**TABLE 2 VALUES OF  $N$  FOR THREE GLASS COMPOSITIONS OBTAINED FROM THE SLOPE OF THE UNIVERSAL FATIGUE CURVE (UFC) OR FROM THE SLOPE OF THE  $V$ - $K$  CURVE**

GLASS	CURVE (SURFACE TREATMENT)	TEST CONDITION	FATIGUE RESISTANCE PARAMETER, $N$
SODA-LIME-SILICA	UFC (ABRADED)	WET	29
	UFC (HF POLISHED)	50 AND 100% RH	74
	$V$ - $K$	WATER	35
BOROSILICATE	UFC (ABRADED)	100% RH	31
	UFC (HF POLISHED)	100% RH	58
	$V$ - $K$	WATER	62
VITREOUS SILICA	UFC (ABRADED)	50% RH	31
	UFC (PRISTINE FIBER)	100% RH	68
	$V$ - $K$	WATER	72

Source: Ref 17

Explanations for these discrepancies can be found by exploring differences in the specimens and methods of testing in more detail. The abraded specimens had many small surface cracks, surface cracks in the HF-polished specimens had been transformed into shallow etch pits, and macroscopic "through" cracks (i.e., cracks extending through the entire thickness of the specimen) were used in the  $V$ - $K$  tests. The reason for the very different  $N$  values obtained for abraded and for pristine or HF-polished specimens of the same glass is that the flaws were very different in these two cases. Sharp surface cracks were present in the abraded specimens, so crack growth could begin as soon as sufficient stress was applied. Any flaws present on the pristine surfaces were so small that a crack nucleation step probably was involved before crack growth could occur. The time needed to nucleate a crack might be longer than the time needed for that crack to grow to the point where fracture occurs. Unfortunately, there are discrepancies about this in the literature, with reports of lower  $N$  values for specimens with smaller flaws (Ref 18). The smaller flaws were produced using diamond indenters, which could produce yet another surface condition. As for the lack of a composition influence in the data presented by Ritter (Ref 17) for the abraded specimens, residual stresses associated with the surface flaws could be a contributing factor, as pointed out by Lawn et al. (Ref 18, 19).

These conflicting results can cause confusion on the part of someone trying to understand the fundamentals of fatigue of glasses. It is important to realize the implications of different surface conditions, especially when surface cracks or other discontinuities are produced in different ways. A pristine or acid-polished surface has very different flaws than does a surface that has been abraded, or one that has been abraded and annealed, or one that has been indented at low loads, or one that has been indented at high loads. These are just some of the surface treatments that have been used to investigate static and dynamic fatigue of glasses. Crack velocity studies are different again, in that they involve macroscopic cracks that extend through the entire thickness of the glass.

What is one to do when faced with a decision about conducting fatigue tests? Crack velocity tests should provide the best information about the susceptibility of the glass to reaction with water. The slope of the  $V$ - $K$  curve in region I (see Fig. 5) is related directly to the rate of reaction of water with the glass, as discussed earlier. Therefore, these tests should be used to provide this kind of fundamental information. On the other hand, real cracks encountered in service conditions are seldom through cracks. Surface cracks or other surface flaws represent the vast majority of cases involving fatigue.

It is most useful to select a surface condition and a test geometry that most nearly duplicate what is expected in service. For example, glass optical fibers are coated immediately after being drawn, and thus have pristine surfaces. The fibers are

subjected to uniaxial tension and bending when they are placed in service. Testing of abraded fibers would involve examining a surface condition that is very unlikely to be encountered in service. On the other hand, testing of the coated fibers, or of freshly drawn uncoated fibers, or even of fibers with carefully made low-load indentations would duplicate service conditions. The fibers should be loaded using uniaxial tension or using extreme bending. Simulation of service conditions is a desirable goal in realistic fatigue testing.

### Lifetime Prediction

The primary goal of investigating fatigue of glasses is to predict the lifetime of a glass article in service. Given that crack growth occurs when glass is under load in the presence of water, how long will it be before the glass breaks? Alternatively, how significant is the strength degradation when a piece of glass has been loaded under certain conditions? Will glass optical fibers, for example, remain intact for 25 years under the expected service conditions? The key to predicting lifetimes is knowing how cracks grow. Using fracture mechanics, the issue is knowing how crack velocity,  $V$ , is related to the stress-intensity factor,  $K$ .

Earlier, it was stated that  $V$  depends exponentially on  $K$  in region I of the  $V$ - $K$  curve. In fact, that is one commonly used  $V(K)$  function; another is a power law:

$$V = V_c \left( \frac{K}{K_c} \right)^N \quad (\text{EQ 4})$$

where  $V_c$  is a constant,  $K_c$  is the critical stress-intensity factor (fracture toughness), and  $N$  is the fatigue parameter. Both equations work equally well in the velocity range where data are taken (Ref 20). However, neither equation accounts for stage IA of Fig. 5, and extrapolations to low velocities differ markedly, as illustrated in Fig. 7 (Ref 21). The velocities predicted by the two approaches differ by orders of magnitude at a stress intensity of  $0.2 \text{ MPa}\sqrt{\text{m}}$ . In this case, the exponential law seems to agree well with the data down to the lowest measured velocity, about  $10^{-10} \text{ m/s}$ . Gupta et al. (Ref 2) recently proposed a way to generate the  $V$ - $K$  relationship from static fatigue data. Their method involves no assumptions about the form of the  $V$ - $K$  function, and they are able to calculate  $V$ - $K$  curves from static fatigue data. Figure 8 shows values of  $V$  versus  $K$  obtained using their proposed method (the filled circles labeled Ref 3) and values from other published reports for vitreous silica at room temperature in air. The relative humidities in the other results ranged from 20 to 100%. Note how the calculated  $V(K)$  data (the Ref 3 results) seem to merge with the other high- $K$  results. In their opinion, this confirms the dominance of crack growth in fatigue. Assuming this is the case, all the data in Fig. 8, including the calculated values, can best be represented by a power law:

$$\text{LOG } V = 1.05 + 10.7 \text{ LOG } K \quad (\text{EQ 5})$$

Note that velocities down to  $10^{-16}$  m/s were analyzed using this method, far lower than can be measured in crack velocity experiments, which usually go no lower than about  $10^{-10}$  m/s.

### Surface Damage

This final section deals with the surface cracks that are, for the most part, responsible for static fatigue failure of glass articles in service. Few glass products are free from surface cracks. Glass fibers used in optical waveguides may be one such product, since the pristine surfaces are coated immediately after forming, thus preventing direct contact with the glass surface. Static fatigue still occurs, but most probably involves a crack nucleation phase that may be more important than the crack growth phase, as noted earlier. The surfaces of most glass products are exposed to contact with hard objects, however, and this often results in cracks. The literature on contact damage on glass surfaces is extensive; only the essential elements will be presented here. The reader is referred to the list of "Selected References" at the end of this article for sources of additional information.

Contact damage can be produced by objects that are blunt (spheres, shoulders of bottles) or sharp (grains of an abrasive). Objects can be large (bottles, hammers, stones) or small (sand particles). Contact can be slow (indentation) or fast (impact). The type of damage that results from contact depends primarily on whether the object is blunt or sharp and on whether the glass tends to densify under pressure. The rate of contact generally has little influence on the type of damage produced. (Rate is important at temperatures high enough for the glass to be in the regime where it behaves viscoelastically, such as during some stages of the forming process.) In general, contact with a blunt object will produce shallow, circular cracks on the surface, which may flare out into cone-shaped cracks that extend into the glass. A sharp object tends to produce some cracks that are normal to the glass surface and which extend radially away from the location of contact and some cracks that are nearly parallel to the surface and which may intersect the surface, resulting in the loss of chips of glass next to the contact site. In the case of both blunt and sharp objects, the cracks that extend into the glass are primarily responsible for strength degradation and, therefore, are more directly involved in fatigue. Residual stresses are present, even after crack formation occurs, and these can cause crack growth even in the absence of externally applied stresses.

Contact damage can occur anytime during the lifetime of a glass article. Some damage may occur in production, for example, when bottles bump against one another on conveyor belts. Most contact damage occurs once the object is placed in service. Think of the opportunities for contact damage to be produced on an automobile windshield, for example. There is abrasion from wiper blades and from the cloths or towels used in cleaning; there are impacts from particles or even stones kicked up by other vehicles. The nearly daily production of additional contact damage in a case like this provides yet another complication in lifetime prediction, since long-term growth of small flaws could be overshadowed by short-term growth of even one large flaw produced much later. The complex morphologies and residual stresses of contact damage sites must be considered when attempting to simulate these conditions in laboratory experiments, especially when the goal is obtaining data for lifetime prediction.

## Parameters for Estimating Fatigue Life

---

## Introduction

IT HAS LONG BEEN RECOGNIZED that fatigue data, when resolved into elastic and plastic terms, can be represented as linear functions of life on a logarithmic scale. Figure 1 schematically shows this representation of elastic and plastic components, which together define the total fatigue life curve of a material. The general fatigue-life relation, expressed in terms of the strain range ( $\Delta\epsilon$ , where  $\Delta\epsilon$  is the strain change from cyclic loading), is as follows:

$$\Delta\epsilon = \Delta\epsilon_E + \Delta\epsilon_P \quad (\text{EQ 1})$$

where  $\Delta\varepsilon_e$  is the elastic strain range,  $\Delta\varepsilon_p$  is the plastic strain range, and where:

$$\frac{\Delta\varepsilon_e}{2} = \frac{\sigma'_f}{E} (2N_f)^b \quad (\text{EQ 2})$$

$$\frac{\Delta\varepsilon_p}{2} = \varepsilon'_f (2N_f)^c \quad (\text{EQ 3})$$

Therefore, the total strain amplitude (or half the total strain range,  $\Delta\varepsilon/2$ ) can be expressed as the sum of Eq 2 and 3 such that:

$$\frac{\Delta\varepsilon}{2} = \varepsilon'_f (2N_f)^c + \frac{\sigma'_f}{E} (2N_f)^b \quad (\text{EQ 4})$$

where  $\varepsilon'_f$  is the fatigue ductility coefficient,  $\sigma'_f$  is the fatigue strength coefficient,  $b$  is the fatigue strength exponent,  $c$  is the fatigue ductility exponent, and  $N_f$  is the number of cycles to failure.

**FIG. 1** SCHEMATIC OF FATIGUE LIFE CURVE WITH THE MANSON FOUR-POINT CRITERIA FOR THE ELASTIC AND PLASTIC STRAIN LINES.  $D$  IS THE TENSILE DUCTILITY,  $\sigma_f$  IS THE FRACTURE STRESS (LOAD AT FRACTURE DIVIDED BY CROSS-SECTIONAL AREA AFTER FRACTURE), AND UTS IS CONVENTIONAL ULTIMATE TENSILE STRENGTH. SOURCE: REF 1, 2

These four empirical constants ( $b$ ,  $c$ ,  $\sigma'_f$ ,  $\varepsilon'_f$ ) form the basis of modeling strain-life behavior for many alloys, although it must be noted that some materials (such as some high-strength aluminum alloys and titanium alloys) cannot be represented by Eq 4.

For many steels and other structural alloys, substantial data have been collected for the four parameters in Eq 4. In many cases, the four fatigue constants have been defined by curve fitting of existing fatigue life data (e.g., Ref 3). A collection of this data is tabulated at the end of this article.

The four fatigue constants can also be estimated from monotonic tensile properties. With the availability of extensive data, however, these techniques are not widely used (Ref 4). Nonetheless, this article briefly summarizes the "four-point method" as a method to estimate fatigue life behavior from tensile properties. This method can be compared with the fatigue and tensile properties tabulated at the end of this article.

In addition, it should also be mentioned that the four fatigue constants are also related to the following parameters:

$$K' = \frac{\sigma_f'}{(\epsilon_f')^{n'}} \quad (\text{EQ 5})$$

$$n' = \frac{b}{c} \quad (\text{EQ 6})$$

where  $K'$  is the cyclic strength coefficient and  $n'$  is the cyclic strain hardening exponent in the power-law relation for a log-log plot of the completely reversed stabilized cyclic true stress ( $\sigma$ ) versus true plastic strain ( $\epsilon_p$ ) such that  $\sigma = K' (\epsilon_p)^{n'}$ . The use of power-law relationship is not based on physical principles, although the relationships in Eq 5 and 6 may be convenient for mathematical purposes. The parameters  $K'$  and  $n'$  are usually obtained from a curve fit of cyclic stress-strain data (Ref 4).

## Parameters for Estimating Fatigue Life

---

### Four-Point Method

Numerous studies have been devoted to the development of techniques for estimating strain-controlled fatigue characteristics (per Eq 4). For the most part, these studies dealt with data generated under completely reversed strain cycling (i.e.,  $R = -1$ , or  $A = \infty$ ) and usually attempted to relate fatigue properties with tensile properties. Extensions of these studies have carried the estimating procedures a step further, addressing the correlation of fatigue data obtained at various strain ratios ( $R$ ).

Two common methods for approximating the shape of a fatigue curve are the "method of universal slopes" and the "four-point correlation" method. These two methods have been known for many years and are described in various references (for example, Ref 2 and 5). The method of universal slopes, first proposed by Manson (Ref 2), is based on the relation:

$$\Delta\epsilon = 3.5 \frac{\text{UTS}}{E} (N_f)^{-0.12} + \epsilon_f^{0.6} (N_f)^{-0.6} \quad (\text{EQ 7})$$

where UTS is ultimate strength,  $E$  is modulus of elasticity, and  $\epsilon_f$  is true fracture ductility, or  $\ln [1/(1 - RA)]$ .

This approximation thus requires only tensile strength, modulus, and reduction in area (RA). However, note that it is based on strain range ( $\Delta\epsilon$ ) rather than strain amplitude ( $\Delta\epsilon/2$ ).

The four-point method also allows construction of fatigue life curves from more readily available handbook data (i.e., monotonic tensile data). This method can be compared with the traditional strain-based approach (Fig. 1) or a stress-based approach. In both cases, the four-point method is based on the premise that total fatigue life per Eq 4 can be estimated as the sum of elastic strain (Eq 2) and plastic strain (Eq 3) components. The step-by-step process for locating points on the plastic- and elastic-strain-life lines is described below for both strain-based and stress-based data.

**Strain-Based Four-Point Method.** The four-point method initially was developed in terms of strain range by Manson (Fig. 1). The four points in Fig. 1 are determined as follows:

1. *POINT  $P_1$  ON THE ELASTIC STRAIN LINE* IS POSITIONED AT  $N_F = 0.25$  CYCLES (WHERE A MONOTONIC TEST IS  $\frac{1}{4}$  OF ONE FATIGUE CYCLE) AND AT AN ELASTIC STRAIN RANGE OF  $2.5 \sigma_F/E$  (WHERE  $\sigma_F$  IS THE FRACTURE STRESS IN A TENSILE TEST AND  $E$  IS THE ELASTIC MODULUS).
2. *POINT  $P_2$  ON THE ELASTIC STRAIN LINE* IS POSITIONED AT  $N_F = 10^5$  CYCLES AND AT AN ELASTIC STRAIN RANGE OF  $0.9 \text{ UTS}/E$ , WHERE UTS IS THE CONVENTIONAL ULTIMATE TENSILE STRENGTH.
3. *POINT  $P_3$  ON THE PLASTIC STRAIN LINE* IS POSITIONED AT  $N_F = 10$  CYCLES, WHERE THE PLASTIC STRAIN RANGE IS  $0.25D^{\frac{3}{4}}$  AND  $D$  IS THE CONVENTIONAL LOGARITHMIC DUCTILITY (ALSO KNOWN AS  $\epsilon_F$ ).
4. *POINT  $P_4$  ON THE PLASTIC STRAIN LINE* IS POSITIONED AT  $N_F = 10^4$  CYCLES, WHERE THE PLASTIC STRAIN RANGE IS GIVEN BY  $\Delta\epsilon_P$  (AT  $10^4$  CYCLES) =  $0.0069 - 0.525 \Delta\epsilon_E$  (AT  $10^4$  CYCLES), WHERE THE ELASTIC STRAIN-RANGE LINE AT  $N_F = 10^4$  CYCLES; ( $\Delta\epsilon_E$  AT  $10^4$ ) IS SHOWN AS  $\Delta\epsilon^*_E$  IN FIG. 1.

**Fracture Stress.** Point  $P_1$  depends on fracture stress, which is not readily available in literature. However, fracture stress (which is the load at fracture divided by the area as measured after fracture) can be estimated (Ref 2) by means of the following approximate relationship among fracture stress, ultimate tensile stress, and fracture ductility; thus,

$$\sigma_F = \text{UTS} (1 + D) \quad (\text{EQ 8})$$

This relation follows from Fig. 2, where each point is fixed by the data for one material. This calculation and that relating to the four-point method for defining the elastic and plastic strain-range lines were developed by Manson based on the materials listed in Table 1.

**Graphical Solution by Manson.** On the basis of the approximate equality in Eq 8, Manson noted that when  $E$  is known, only two tensile properties--ultimate tensile strength (UTS), and the reduction in area (to give  $D$ )--are needed to position the lines in Fig. 1 and thus obtain a prediction of fatigue behavior. Figure 3 shows a convenient graphical solution by Manson for locating the four points in Fig. 1. For example, if  $UTS/E$  is 0.01 and the reduction in area is 50% ( $D = 0.694$ ), the value of  $P_2$  from the right-hand scale is 0.009 and that of  $P_3$  from the top scale is 0.18. Locating the point with the coordinates  $UTS/E = 0.01$  and reduction in area equal to 50% gives values for  $P_1$  and  $P_4$  of 0.042 and 0.0009,

respectively. These points will locate the two strain-range lines, and the total strain-range curve can then be positioned to relate  $\Delta\epsilon$  and  $N_f$  for the material in question.

FIG. 3 GRAPHICAL SOLUTION TO OBTAIN THE FOUR POINTS ( $P_1$ ,  $P_2$ ,  $P_3$ , AND  $P_4$  IN FIG. 1) TO POSITION THE ELASTIC AND PLASTIC STRAIN-RANGE LINES. BASED ON ANALYSIS OF FATIGUE DATA FOR MATERIALS IN TABLE 1. SOURCE: REF 2

**Stress-Based Four-Point Method.** The four-point also applies to the construction of a stress-based  $S-N$  fatigue curve, as shown in Fig. 4. The four points A, B, C, and D in Fig. 4 can be defined in terms of either stress or strain. In terms of strain, the points are identical to points  $P_1$ ,  $P_2$ ,  $P_3$ , and  $P_4$  in Fig. 1. For construction of an  $S-N$  fatigue curve, the points are determined as described below.

**FIG. 4 SCHEMATIC SUMMARY OF FOUR-POINT METHOD FOR ESTIMATING FATIGUE STRENGTH OR STRAIN LIFE. SOURCE: REF 6**

**Point A** (in terms of stress) is simply the ultimate tensile strength of the metal, plotted on the vertical axis of the graph at  $N = \frac{1}{4}$ . As in the strain-based approach, this assumes that the simple tensile test represents one-fourth of a single, completely reversed fatigue cycle--the peak positive value of the applied stress.

**Point B**, the right-hand locator of the elastic curve, is defined as the fatigue-endurance limit, if the metal has one; otherwise, point B is the endurance strength. Some ferrous alloys have an endurance limit, that is, a stress level below which fatigue failure will never occur, regardless of number of cycles. This is generally around  $10^7$  or  $10^6$  cycles, at which point the fatigue curve approaches zero-slope, or a horizontal line.

Many metals, particularly those that do not work harden, have no detectable endurance limit. Their long-life fatigue curves never become truly horizontal. For these metals, a pseudo-endurance limit, called endurance strength, is reported. Usually, this value is defined as the failure stress at some large number of cycles, for example,  $10^7$  to  $10^{10}$ .

Point B can also be obtained from tensile-test data--a virtue of this technique, as handbook values for fatigue-endurance strengths or limits are often not available. Use Fig. 5 (Ref 6) to find the fatigue-endurance value from yield strength and true ultimate tensile strength for the material. Simply calculate the "ductility parameter" from handbook tensile data using the equation on the horizontal axis of the graph. Then find the "endurance-to-yield" strength ratio for the appropriate material. Multiply this ratio by "yield strength" to find the endurance value, which is point B.

**FIG. 5 PLOT FOR ESTIMATING FATIGUE-ENDURANCE LIMITS (POINT B IN FIG. 4) FOR COMMON STRUCTURAL ALLOY GROUPS. SOURCE: REF 6**

Beyond point B, the ratio of ultimate tensile strength to yield strength can be used to approximate the slopes of the long-life portion of the fatigue curve. According to many researchers, a ratio greater than 1.2 suggests that the material strain hardens sufficiently to produce a pronounced endurance limit value, and the curve assumes a zero slope. For ratios less than 1.2, however, the curve will continue to drop beyond point B. The lower the ratio below 1.2, the further the fatigue curve deviates from a horizontal, zero-slope line beyond point B.

Because both endurance strength and endurance limit are reported in terms of stress, this value must be divided by Young's modulus for the metal if the fatigue curve is being constructed in terms of strain.

**Point C** is a value known as "fracture ductility." If natural, or true, strain at fracture for a simple tension test is known (which would be the distance between gage points at fracture divided by initial gage length), fracture ductility is the natural log of this value.

In most cases, however, reduction of area for a simple tensile test is given in handbooks. As before in the discussion on the universal slopes method, fracture ductility,  $\epsilon_f$ , is estimated.

$$\epsilon_f = \ln \frac{100}{100 - RA} \quad \text{(EQ 9)}$$

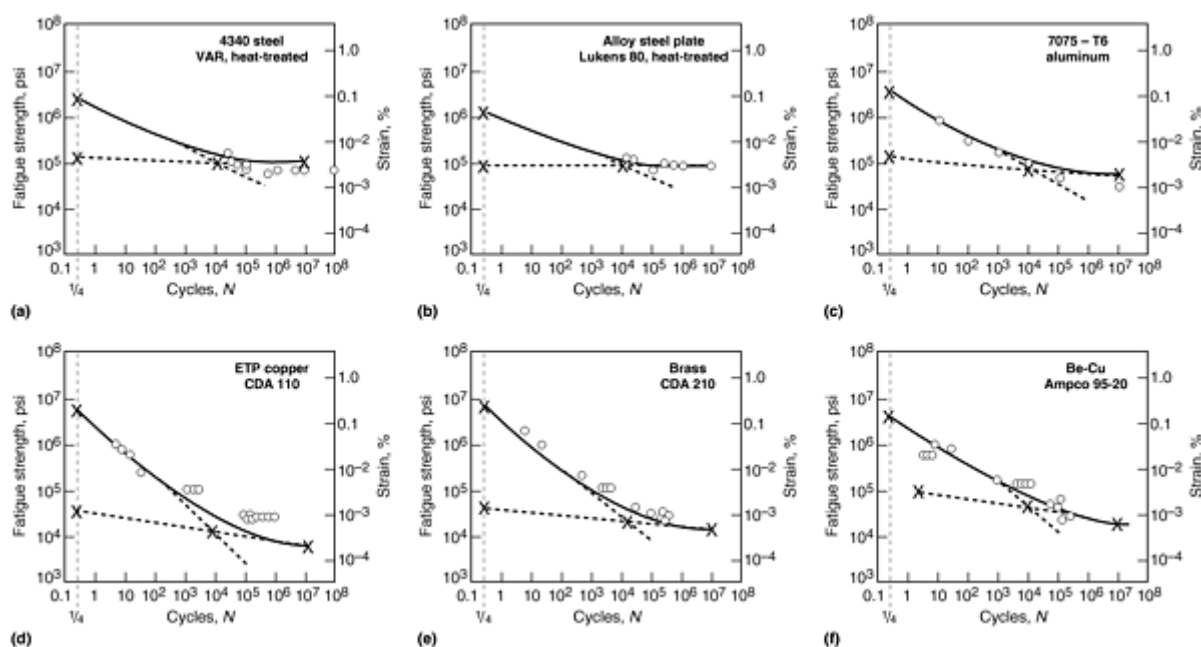

where RA is reduction of area in %.

Because fracture ductility is in units of strain, this value must be multiplied by Young's modulus to obtain point C in terms of stress. In all cases, point C is also plotted at  $N = \frac{1}{4}$ .

**Point D** is defined as the intersection of the plastic and elastic curves at  $10^4$  cycles. (According to the theory of "universal slopes," elastic and plastic strain curves intersect at  $N = 10^4$ ). Thus, locate point D on the elastic curve and draw the plastic curve between points C and D. Now the fatigue curve can be drawn as the arithmetic summation of the elastic and plastic lines.

**Comparison with Data for Steel, Aluminum, and Copper Alloys.** To demonstrate the validity of the method described here, actual fatigue test results for various steel, aluminum, and copper alloys were compared with curves approximated from handbook data (Ref 6). In addition, a more recent analysis by J.H. Ong (*Int. J. Fatigue*, Vol 15, 1993, p 13-19) on 49 steels demonstrates that the predicted values by the four-point correlation method and the universal slopes method give satisfactory agreement with experimental data. The analysis by Ong shows that the four-point methods gives the best estimates for predicting fatigue properties from uniaxial tension tests.

Of the six comparisons shown (Fig. 6a- 6f), fatigue data for steels and aluminum were taken from published sources. The measurements for copper fatigue are original, taken from tests on simulated squirrel-cage rotor, bar-to-end ring joints for induction motors.

**FIG. 6** COMPARISON OF ACTUAL FATIGUE TEST RESULTS (OPEN CIRCLES) WITH FATIGUE CURVES CONSTRUCTED BY THE FOUR-POINT METHOD FROM TENSILE DATA. TOTAL FATIGUE LIFE IS A SOLID LINE AND ELASTIC AND PLASTIC COMPONENTS ARE DASHED LINES CONSTRUCTED FROM TENSILE DATA POINT (SHOWN BY X'S). (A) 4340 STEEL. (B) ALLOY STEEL PLATE (LUKENS 80). (C) 7075-T6 ALUMINUM. (D) ELECTROLYTIC-TOUGH-PITCH (ETP) COPPER. (E) BRASS. (F) BE-CU ALLOY. SOURCE: REF 6

Because these parts had been brazed prior to testing, the copper fatigue test data were assumed to represent essentially annealed material. Trace-ability of the data is not "ideal" in these cases, as handbook tensile data for the approximated curves were selected for truly annealed materials. Nevertheless, correlation between fatigue test data and the curves drawn from annealed tensile data is quite good, indicating that this technique appears to be perfectly acceptable for copper alloys as well.

Figures 6(a) to (f) were prepared from actual fatigue-test data (open circles) and from handbook tensile data (X's). Fatigue curves constructed according to the techniques outlined in this article are shown in solid curves. Elastic and plastic strain curves used in the construction of the fatigue curves are dashed. While this is no substitute for thorough, conventional fatigue testing, reasonable correlation between the actual fatigue data and the simulated curves indicates that this technique can be a quick shortcut for approximating fatigue-life information.

## Parameters for Estimating Fatigue Life

## Transition Fatigue Life

The four-point method and the method of universal slopes are based, in part, on an assumed fatigue transition life at  $N_t = 10^4$  cycles. The fatigue transition life (which is considered the point of division between fatigue life dominated by elastic strains or life dominated by plastic strains) does occur approximately at approximately  $10^4$  cycles for quenched-and-tempered carbon and low-alloy steels. In general, however, the fatigue transition life is expected to increase as the ductility of a material increases and strength decreases. Figure 7 (Ref 7, 8, 9), for example, shows this effect for various steels as a function of hardness. Higher-strength steels resist plastic deformation over a larger range, while softer steels may undergo plastic strain at a higher fatigue life. Transition fatigue life and tensile properties for some nonferrous alloys also are given in Table 2.

**FIG. 7 TRANSITION FATIGUE LIFE (EXPRESSED IN TERMS OF LOAD REVERSAL) AS A FUNCTION OF**

**Effect of Mean Stress or Strain ( $R$  ratio) on Transition Life.** The fatigue transition life in one study (Ref 10) was determined to be independent of the strain ratio ( $R\epsilon$ ) as shown schematically in Fig. 8. Furthermore, in plastic strain region (regime II in Fig. 8), the effects of strain ratio are considered negligible. In regime II, where there are large amounts of plastic strain present, there are no effects of strain ratio, and the fatigue life behavior is essentially as if all testing is done in a completely reversed mode. In this regime, the elastic and plastic slopes for all strain ratios are equivalent to those slopes for the completely reversed data of regime I, and a universal strain-normalized life equation describes the fatigue behavior of the material. These characteristics allow development of a fairly simple basis for defining the effects on strain ratios on fatigue life, as described in more detail in Ref 10.

**FIG. 8** SCHEMATIC OF THE STRAIN RANGE-LIFE RELATIONSHIP AS A FUNCTION OF STRAIN RATIO,  $R\epsilon$ . THE LIFE IS AFFECTED BY  $R\epsilon$  IN REGIME I ONLY. IN REGIME II, THE MEAN STRESS IS ALWAYS NEARLY ZERO, AND  $R\epsilon$  HAS LITTLE OR NO EFFECT ON LIFE. SOURCE: REF 10

### Summary of Strain-Life Constants

The four fatigue-life parameters in Eq 1 can be determined either by curve fitting actual fatigue life test data or by approximating the constants from tensile properties. Each method has its limitations. Nevertheless, the four constants in Eq 1 do provide a model for fatigue life for many alloys (for example, those in Fig. 9 and Table 3 from the early work by Manson and others in Ref 11).

**Curve Fitting from Fatigue Test Data.** Tables 4(a), 4(b), 5, 6, and 7 at the end of this article summarize fatigue-life constants determined from curve fitting of fatigue test data for several alloys. As previously mentioned, some materials (such as some high-strength aluminum alloys and titanium alloys) cannot be adequately represented by the four fatigue constants in Eq 1. The strain range for the actual data is also an important factor. Errors can occur when extrapolating fatigue life estimates outside the range of the original data. Nevertheless, the basis for the four constants in Eq 1 do provide a model for many structural alloys.

Source: Adapted from Ref 12

(A) SIM. HAZ = SIMULATED HEAT-AFFECTED ZONE, STA = SOLUTION TREATED AND AGED, QT = QUENCHED AND TEMPERED.

**Fatigue Constant Approximations.** Although the four fatigue constants are often adequately defined from available data, the following approximations can be useful in estimating their values.

**Fatigue strength coefficient,  $\sigma'_f$ .** A fairly good approximation is  $\sigma'_f \approx \sigma_f$  (where  $\sigma_f$  is fracture stress with necking corrections). For steels with hardnesses below 500 HB:  $\sigma_f \approx \text{UTS} + 50$  ksi. Other values in estimating  $\sigma'_f$  include (Ref 7):

$$\begin{aligned} \sigma'_F &= \sigma_F \\ \sigma'_F &= 1.09 \sigma_F \\ \sigma'_F &= 0.92 \sigma_F (B = -0.12) \\ \sigma'_F &= 1.15 \sigma_F (B = -0.12) \end{aligned}$$

**Fatigue strength exponent, b.** The exponent  $b$  varies from -0.05 to -0.12 for most metals with an average of -0.085.

**Fatigue ductility coefficient,  $\epsilon'_f$ .** As described earlier for the universal slopes method, a fairly good approximation for this coefficient is  $\epsilon'_f \approx \epsilon_f$  (monotonic fracture ductility) with  $\epsilon_f = 1 \ln [1/(1 - \text{RA})]$  and where RA is the reduction in area. Other values in estimating  $\epsilon'_f$  include (Ref 7):

$$\begin{aligned}\epsilon'_F &= 0.35 \epsilon_F \\ \epsilon'_F &= 0.5 \epsilon_F \quad (C = -0.6) \\ \epsilon'_F &= 0.75 (\epsilon_F)^{0.75} \quad (C = -0.6) \\ \epsilon'_F &= 0.76 (\epsilon_F)^{0.6} \quad (C = -0.6) \\ \epsilon'_F &= 0.50 \epsilon_F \\ \epsilon'_F &= 0.71 \epsilon_F\end{aligned}$$

**Fatigue ductility exponent,  $c$ .** The exponent  $c$  is not as well defined as the other parameters. A rule-of-thumb approach must be followed rather than an empirical equation (Ref 4). Estimated values include:

- COFFIN FOUND  $C$  TO BE ABOUT -0.5.
- MANSON FOUND  $C$  TO BE ABOUT -0.6.
- MORROW FOUND THAT  $C$  VARIED BETWEEN -0.5 AND -0.7.

Fairly ductile metals (where  $\epsilon_f \approx 1$ ) have average value of  $c = -0.6$ . For strong metals (where  $\epsilon_f \approx 0.5$ ) a value of  $c = -0.5$  is probably more reasonable (Ref 4).

## Summary of Stress-Intensity Factors

Alan Liu, Rockwell International (retired)

---

## Introduction

LINEAR ELASTIC FRACTURE MECHANICS (LEFM), which constitutes the majority of practical fracture mechanics applications, can be based on either energy calculations or stress-intensity calculations (Ref 1). The methods are related and provide identical results in predicting fracture loads of structures containing sharp flaws of known size and location. However, the stress-intensity approach is more generally used because it deals directly with crack-tip stresses and strains, which are more commonly used in engineering.

The stress-intensity concept is based on the parameter  $K$ , which quantifies the stresses at a crack tip. Using the conventional theory of elasticity, it is possible to calculate the stress field at the tip of a crack in an arbitrary body with an arbitrary crack under arbitrary loading. Using the coordinate system shown in Fig. 1, the crack-tip stresses for Mode I loading are:

$$\sigma_{ij} = \frac{K_I}{\sqrt{\pi 2r}} f_{ij}(\theta) + C_1 r^0 + C_2 r^{1/2} + \dots \quad (\text{EQ 1})$$

FIG. 1 ARBITRARY BODY AND COORDINATE SYSTEMS UNDER MODE I LOADING

If  $r$  is very small, the first term of the solution is very large (infinite for  $r = 0$ ); therefore, the other terms can be neglected. Because all cracking and fracturing take place at or very near the crack tip (where  $r \rightarrow 0$ ), it is justifiable to use only the first term of the solution to describe the stress field in the area of interest. For the stress in the  $y$ -direction along the plane  $\theta = 0$ , the function  $f_{yy}(\theta) = 1$ , so that:

$$\sigma_{yy} = \frac{K_I}{\sqrt{2\pi r}} \text{ for } \theta = 0 \quad (\text{EQ 2})$$

where the subscript I denotes Mode I loading.

Equation 2 shows that the crack-tip stress in the  $\sigma_{yy}$  direction depends on the distance  $r$  from the crack tip. A similar relation applies to other directions, or if the entire stress field is taken into account. As a general solution, Eq 2 applies to any geometry under Mode I loading. A specific solution is shown in Fig. 2 for a through-thickness crack in a plate section.

FIG. 2 DISTRIBUTION OF STRESSES NEAR THE TIP OF A THROUGH-THICKNESS CRACK IN A PLATE. SOURCE: REF 1

The stress near the crack tip (Eq 2) is also directly proportional to the applied stress ( $\sigma$ ), as long as stresses are in the elastic regime. Therefore, under elastic conditions:

$$\sigma(\text{APPLIED}) \propto \sigma_{YY} = K_I / \sqrt{2\pi r} \quad (\text{EQ 3})$$

which means that a stress intensity,  $K_I$ , can be defined in terms of the applied stress and a distance  $r$  near the crack tip. The precise relation between the applied stress and  $K_I$  depends on geometry, as described in this article for various part configurations and crack geometries. This forms the basis for defining stress-intensity factors ( $K_I$ ) for fracture mechanics.

The discussions remain valid even if there is some plastic deformation in the region near the crack tip. In reality, a material exhibits some plastic deformation near the crack tip when stresses exceed the yield strength ( $\sigma_{YS}$ ) for small values of  $r$  (as  $r$  approaches zero in Eq 2). However, it can be shown that the size of the so-called plastic zone at the crack tip (Fig. 3) is determined by the value of  $K$  (Ref 2). Consequently, for equal values of  $K$ , the plastic zones are equal, and the stresses and strains acting on the boundary of the plastic zone are equal. This being the case, equal behavior will take place inside the plastic zones (similitude for equal  $K$ ). Thus, if the material exhibits a fracture for a certain value of  $K$ , it will always exhibit fracture at that value of  $K$ .

FIG. 3 CRACK-TIP STRESS DISTRIBUTION UNDER (A) ELASTIC CONDITIONS AND (B) ELASTIC-PLASTIC CONDITIONS

However, those arguments require that one condition be satisfied: The plastic zone must be so small that its size is determined fully by  $K$  and by  $K$  only. This will be the case if the plastic zone does not extend beyond a value of  $r$ , at which the first term in Eq 1 is still much larger than all other terms; otherwise, the constants  $C_1$ ,  $C_2$ , and so on in Eq 1 will become significant. In general, this will not occur until the value of  $K_I/\sigma_{YS}$  exceeds about 2 (this also depends on geometry). If it does occur, LEFM is no longer valid, and elastic plastic fracture mechanics (EPFM) must be used, although the use of LEFM can be stretched further with simple approximations (Ref 2).

## Summary of Stress-Intensity Factors

Alan Liu, Rockwell International (retired)

---

### LEFM Geometry Factors

This article summarizes and describes some Mode I stress-intensity factors ( $K$ ) for various crack geometries commonly found in structural components. A great majority of all practical fracture cases are Mode I problems.

Combined-mode loading is more difficult to deal with, but if the modes are in phase (and remain proportional), the crack in a very early stage of development will turn into a direction in which it experiences only Mode I, unless it is prevented from doing so due to geometrical confinement. (When the modes are independent and/or out of phase, combined-mode loading presents a problem for which no accepted solution is available.) In view of this, fracture mechanics is generally confined to Mode I.

Equation 2 is a general solution for Mode I crack problems, such that the parameter  $K_I$  accounts for all effects of loading and geometry and thus defines the crack-tip stress field in its entirety. However,  $K_I$  in Eq 2 is an undefined quantity in terms of a general arbitrary case; it does not define the crack-tip stress field parameter ( $K$ ) in terms of the applied load and the particular geometry of the crack and part configuration. Therefore, the practical definition of  $K$  depends on the relation between the crack-tip stress ( $\sigma_{yy}$ ) in terms of the applied stress (Eq 3). This relation between applied stress ( $\sigma$ ) and crack-tip stress ( $\sigma_{yy}$ ) is governed by the particular geometry of a crack in a part.

For a given structural configuration and applied stress, the definition of  $K$  can be determined by a number of analytical methods. For purposes of illustration and a simple introduction, however, first consider a plate of width  $W$  containing a through-thickness crack of length  $2a$  (Fig. 4a). As long as the stresses are elastic, the stress at any point is proportional to the applied stress ( $\sigma_{yy} \propto \sigma$ ). It must be expected that the crack-tip stress will also depend on the crack size. Because  $\sigma_{yy}$  depends on  $1/\sqrt{r}$  according to Eq 2, it is inevitable that it depends on  $\sqrt{a}$ ; otherwise, the dimensions would be wrong. Hence, a simple argument shows that:

$$\sigma_{yy} \propto \frac{\sqrt{a}}{\sqrt{2\pi r}} \quad (\text{EQ 4})$$

This proportional relation can be used to define an explicit relation between the applied stress ( $\sigma$ ) and the crack-tip stress ( $\sigma_{yy}$ ) such that:

$$\sigma_{yy} = \frac{\beta\sigma\sqrt{\pi a}}{\sqrt{2\pi r}} \quad (\text{EQ 5})$$

where  $\beta$  is a dimensionless constant. The crack-tip stresses will be higher when  $W$  is smaller. Thus,  $\beta$  must depend on  $W$ . It is known that  $\beta$  must be dimensionless, yet  $\beta$  cannot be dimensionless and depend on  $W$  at the same time, unless  $\beta$  depends on  $W/a$  or  $a/W$ , that is,  $\beta = f(a/W)$ . Comparison of Eq 2 and 5, then, shows that:

$$K_I = \beta \left( \frac{a}{W} \right) \sigma \sqrt{\pi a} \quad (\text{EQ 6})$$

where the first term  $\beta$  is expressed as a function of  $a/W$ . If the crack-tip stress is affected by other geometric parameters--for example, if a crack emanates from a hole, the crack-tip stress will depend on the size of the hole--the only effect on the stress-intensity factor (and the crack-tip stresses) will be in  $\beta$ . Consequently,  $\beta$  will be a function of all geometric

factors affecting the crack-tip stress:  $\beta = \beta(a/W, a/L, a/D)$ . Crack-tip stresses are always given by Eq 2; the value of  $K$  in Eq 2 is always given by Eq 6. All effects of geometry are reflected in one geometric parameter,  $\beta$ .

**FIG. 4** CRACK-TIP STRESS-INTENSITY ( $K_I$ ) IN TERMS OF APPLIED STRESS ( $\sigma$ ) FOR (A) A CENTER-CRACKED PLATE AND (B) AN EDGE-CRACKED PLATE UNDER UNIFORM TENSION. THE CRACK SHOWN IN (A) IS DEFINED AS  $2a$  AND THE CRACK SHOWN IN (B) IS DEFINED AS  $a$ , BECAUSE OF THE CONVENTION THAT ANY CRACK WITH TWO TIPS IS DEFINED AS  $2a$  AND ANY CRACK WITH ONE TIP IS DEFINED AS  $a$ . THERE IS NO OBJECTION TO DEFINING THE CRACK IN (A) AS  $a$ , BUT ALL QUANTITATIVE EXPRESSIONS WILL THEN DIFFER BY A FACTOR OF  $\sqrt{2}$ .

The geometric factor or function (termed  $\beta$  elsewhere in this Volume, as in Eq 6) has been calculated and compiled for many generic geometries in various handbooks (Ref 3, 4, 5, 6) and other references listed at the end of this article. The general expression for stress intensity (Eq 6) is re-expressed in some cases as  $K = \sigma Y \sqrt{\pi a}$ , where  $Y$  is the function  $\beta(a/W)$  in Eq 6. In this article, the symbol  $\beta$  is used as a term for specific geometric factors as defined in specific cases in this article. In such cases, the term  $Y$  represents the complete geometric function of  $\beta(a/W)$  in Eq 6. In general, the expression for stress intensity is defined by the geometric factor [ $Y$ , or  $\beta(a/W)$ ] that depends on a given structural configuration and crack geometry. The value of  $K$  can be determined by a number of analytical methods (e.g., finite element, boundary integral equation, weight function, boundary collocation, etc.). This article will not get into the technicality of these methods. Only the results (mainly extracted from open literature) are presented here. However, it is significant to point out that each  $K$  value can be determined for a specific crack size in an explicit structural (or test specimen) configuration. In this case, the dimensionless factor ( $\beta$  or  $Y$ ) would be defined when  $K$  is normalized by  $\sigma$  and

$\sqrt{(\pi a)}$ . After a series of  $K$  values for various crack sizes across the entire crack plane are determined, a close-form equation can then be obtained by fitting a curve through all the geometric factors.

This article is only intended to be a summary of some Mode I stress-intensity factors for crack geometries commonly found in structural parts. The following sections consider

- A CRACK IN A SHEET (OR PLATE)
- A CRACK ORIGINATED AT A CIRCULAR HOLE IN A SHEET (OR PLATE)
- A PIN-LOADED LUG
- A ROUND BAR (WHICH CAN BE A PIN OR A BOLT)
- A HOLLOW CYLINDER (I.E., A TUBE)

The crack may be a through-the-thickness crack or a part-through crack (commonly known as a surface crack, or corner crack). The part may be subjected to uniaxial tension, or bending, or it may be loaded by a pair of concentrated forces or the combination of the pin and the reaction loads (e.g., an attachment lug). Many of these stress-intensity solutions have become available only recently and have not been incorporated into any existing handbooks. Although very important in the design and analysis of air transport structures, stress-intensity solutions for a metal sheet (or plate) attached with metal stringers (or manufactured with integral stiffeners) are not included here. Readers are referred to the "Selected References" section at the end of this article. A bibliography of stress intensity factors for mechanical fasteners is also contained in the article "Fatigue of Mechanically Fastened Joints" in this Volume.

**Compounding of Geometric Factors.** When  $\beta$  is a function of more than one variable, it is desirable to separate the  $\beta$  function into a series of dimensionless parametric functions, where each segment represents an explicit boundary condition. Therefore Eq 6 can be rewritten as:

$$K = [\sigma \sqrt{(\pi a)}] \Pi \alpha \quad (\text{EQ 7A})$$

where  $\Pi \alpha$  is the product of a series of dimensionless parametric functions, or factors, accounting for the influence of the part and the crack geometries and loading condition. In the absence of any geometric influence, for example a through-the-thickness crack in an infinitely wide sheet under uniform farfield tension,  $\Pi \alpha$  approaches unity ( $\beta = 1$ ) and Eq 7a reduces to the basic stress-intensity expression:

$$K = \sigma \sqrt{(\pi a)} \quad (\text{EQ 7B})$$

where  $\sigma$  is the applied stress and  $a$  is the half-length of the through-the-thickness crack (Fig. 4). As before,  $K$  is a physical quantity (not a factor) with dimensional units of  $\text{ksi}\sqrt{\text{in.}}$  or  $\text{MPa}\sqrt{\text{m}}$ . In this article the term *stress intensity factor* is loosely defined; it might mean  $K$ , or a geometric factor (such as  $\alpha$  in Eq 7a or  $\beta$  or  $Y$ , as discussed earlier).

The advantage of separating geometric factors into several individual segments is obvious. The fracture mechanics analysis can build around a compounded equation to suit the crack model under consideration by combining several known solutions. The method of compounding is quite simple, but complete coverage is beyond the scope of this article. Several articles that describe the compounding technique are listed in the "Selected References" section at the end of this article.

## Through-the-Thickness Crack in a Plate

Through-the-thickness cracks may be located in the middle of a plate (in which case they are called center cracks, Fig. 4a); at the edge of a plate (edge cracks, Fig. 4b); or at the edge of a hole inside a plate.

## Uniform Farfield Loading

There are many stress-intensity factor solutions for the center crack subjected to farfield uniform tension stress. Among them, the Isida solution (Ref 7, 8) is regarded as being the most accurate by the fracture mechanics community. It accounts for the boundary effect (the free edges that define the width and length of the panel). As derived from Eq 7b, which is for a crack in an infinite sheet, the stress-intensity expression can be written as:

$$K = [\sigma \sqrt{(\pi a)}] \varphi \quad (\text{EQ 8})$$

where  $\sigma$  is gross cross-sectional area stress (i.e., ignoring the crack). The geometric factor  $\varphi$  is a dimensionless function of the ratio of crack length to panel width and the ratio of panel length to panel width, as given in Fig. 5. For a panel having its length greater than two times the width, the effect of panel length on  $K$  vanishes. According to Feddersen (Ref 9), the finite-width correction factors (i.e., the curve labeled as  $L \geq 2W$  in Fig. 5) can be represented by a secant function (sec). That is:

$$\varphi_W = \sqrt{\sec(\pi a/W)} \quad (\text{EQ 9A})$$

Here the secant function, in radians, is commonly known as the width correction factor for the center crack panel configuration. If the crack is located off the centerline of the plate, Eq 9a is replaced by the eccentricity correction factors given in Fig. 6. According to Newman (Ref 10), this set of curves can be approximated by the following equations:

$$\varphi_A = \sqrt{\sec[(\pi a/2b_1) \cdot (1 - 0.22(e/b)^3)]} \quad (\text{EQ 9B})$$

$$\varphi_B = \sqrt{\sec[(\pi a/2b_1) \cdot (1 - 0.37(e/b)^{0.5} + 0.1(a/b_1)^{1.5})]} \quad (\text{EQ 9C})$$

where the subscripts "A" and "B" refer to the two crack tips indicated in the figure,  $e$  is the distance from the center of the crack to the centerline of the specimen,  $b = W/2$ , and  $b_1 = b - e$  (the distance from the center of the crack to the nearest edge of the specimen). When  $e = 0$ , either Eq 9b or 9c is reduced to Eq 9a.

FIG. 5 STRESS-INTENSITY FACTORS FOR A THROUGH-THE-THICKNESS CRACK LOADED IN TENSION, WHERE  $K = \sigma\phi\sqrt{\pi a}$

FIG. 6 STRESS-INTENSITY FACTORS FOR AN ECCENTRICALLY CRACKED PLATE LOADED IN TENSION

**Edge Crack.** For a limiting case in which the crack is right at the edge of the plate (edge crack), the  $\varphi$  factor is given by (Ref 11) as:

$$\varphi_E = \text{SEC } \beta [(\text{TAN } \beta) / \beta]^{\frac{1}{2}} \cdot [0.752 + 2.02 (A/W) + 0.37 (1 - \text{SIN } \beta)^3] \quad (\text{EQ 9D})$$

where  $a$  is the total crack length measured from the edge of the plate across the width  $W$ , and  $\beta$  is a specific geometric factor for this case such that  $\beta = \pi a / (2W)$ . The subscript "e" stands for the edge crack,  $\varphi_e = 1.122$  at  $a/W = 0$ .

**Crack Emanating from a Hole.** In the case where a crack is originated at the edge of a circular hole inside an infinitely wide sheet,

$$K = [\sigma \sqrt{(\pi c)}] \varphi_N \quad (\text{EQ 10})$$

where  $\sigma$  is the gross cross-sectional area stress (i.e., again ignoring the hole and the crack),  $c$  is the crack length measured from the edge of the hole (not from the center of the hole), and  $\varphi_n$  is the Bowie solution for cracks coming out from a

circular hole (Ref 11 and 12). According to Ref 13, the Bowie solution (see Fig. 7) can be fitted by the following equations:

$$\varphi_1 = 0.707 - 0.18 \cdot \lambda + 6.55 \cdot \lambda^2 - 10.54 \cdot \lambda^3 + 6.85 \cdot \lambda^4 \quad (\text{EQ 11A})$$

and

$$\varphi_2 = 1 - 0.15 \cdot \lambda + 3.46 \cdot \lambda^2 - 4.47 \cdot \lambda^3 + 3.52 \cdot \lambda^4 \quad (\text{EQ 11B})$$

where  $\lambda = (1 + c/r)^{-1}$  and  $r$  is the radius of the hole. The subscripts 1 and 2 stand for a single crack, and two symmetric cracks, respectively. Alternatively, the Bowie solution can be approximated by the following equation (Ref 14):

$$\varphi_N = F_1 \cdot (F_2 + C/R)^{-1} + F_3 \quad (\text{EQ 11C})$$

where  $F_1 = 0.8733$ ,  $F_2 = 0.3245$ , and  $F_3 = 0.6762$  for a single crack and  $F_1 = 0.6865$ ,  $F_2 = 0.2772$ , and  $F_3 = 0.9439$  for double symmetrical cracks.

FIG. 7 STRESS-INTENSITY FACTORS FOR CRACK(S) COMING OUT FROM A CIRCULAR HOLE

To include the finite width effect:

$$K = [\sigma \sqrt{(\pi c)}] \cdot \varphi_N \cdot F_N \quad (\text{EQ 11D})$$

where

$$f_1 = \frac{\sqrt{\sec[(\pi/2) \cdot (2r + a)/(W - a)]}}{\sqrt{\sec[(\pi/2) \cdot (2r/W)]}} \quad (\text{EQ 11E})$$

and

$$f_2 = \frac{\sqrt{\sec[(\pi/2) \cdot (r + a)/(W/2)]}}{\sqrt{\sec[(\pi/2) \cdot (2r/W)]}} \quad (\text{EQ 11F})$$

where  $n = 1$  for a single crack,  $n = 2$  for two symmetric cracks, and the hole is located in the center of the plate.

### Point Loading of a Center Crack

A crack of length  $2a$ , subjected to forces per unit thickness  $P$ , acting at the center of the crack surfaces, is located centrally in a rectangular plate of height  $2H$  and width  $2b$  (Fig. 8). The expression for the stress-intensity factor in this case is  $K = PY/\sqrt{\pi a}$ , where  $Y$  is the geometric factor, as shown in Fig. 8 (Ref 15).

FIG. 8 STRESS-INTENSITY FACTORS FOR A CENTRAL CRACK IN A RECTANGULAR PLATE WITH OPPOSING FORCES AT THE CENTER OF THE CRACK, FROM THE COLLOCATION SOLUTION BY NEWMAN (REF 15), WHERE  $K = PY/\sqrt{\pi a}$ , WHERE  $P$  IS THE FORCE (LOAD) PER UNIT THICKNESS

### Summary of Stress-Intensity Factors

Alan Liu, Rockwell International (retired)

---

### Point Loading of Edge Crack

In case the forces are applied at a point on the surface of an edge crack (Fig. 9), the stress-intensity factor is defined as  $K = 2P \cdot Y/\sqrt{\pi a}$ , where the geometric factor  $Y$  is defined by the Tada solution (Ref 3) as:

$$Y = \alpha_1 - \alpha_2 + \alpha_3 \cdot \alpha_4 \quad \text{(EQ 12A)}$$

where

$$\alpha_1 = 3.52 (1 - \lambda)/(1 - \beta)^{3/2} \quad \text{(EQ 12B)}$$

$$\alpha_2 = (4.35 - 5.28\lambda)/(1 - \beta)^{\frac{1}{2}} \quad (\text{EQ 12C})$$

$$\alpha_3 = [(1.3 - 0.3\lambda^{3/2})/(1 - \lambda^2)^{\frac{1}{2}}] + 0.83 - 1.76\lambda \quad (\text{EQ 12D})$$

$$\alpha_4 = 1 - (1 - \lambda)\beta \quad (\text{EQ 12E})$$

where  $\lambda = c/a$  and  $\beta = a/b$ . When the load is applied right at the edge of the plate (i.e.,  $\lambda = 0$ ), Eq 12a reduces to:

$$Y = 3.52/(1 - \beta)^{3/2} - 4.35/(1 - \beta)^{\frac{1}{2}} + 2.13(1 - \beta) \quad (\text{EQ 12F})$$

### The Compact Specimen

Although it is not a common configuration to be considered for structural analysis, the compact specimen (Fig. 10) is specified in ASTM E 399 and E 647 as the standard specimen geometry for generating material  $K_{Ic}$  and fatigue crack growth rate data. Therefore, the ASTM-recommended stress-intensity equation for the compact specimen is included here. The equation given in the *1995 Annual Book of ASTM Standards*, Volume 03.01, is:

$$K = (P/(T \sqrt{W})) \cdot F(\alpha_1) \cdot F(\alpha_2) \quad (\text{EQ 13})$$

where

$$F(\alpha_1) = 0.886 + 4.64 \alpha - 13.32 \alpha^2 + 14.72 \alpha^3 - 5.6 \alpha^4 \quad (\text{EQ 13A})$$

and

$$F(\alpha_2) = (2 + \alpha)/(1 - \alpha)^{3/2} \quad (\text{EQ 13B})$$

where  $\alpha = a/W$  and where again  $P$  is the force per unit thickness. Equation 13 is accurate within 0.5% over the range of  $a/W$  from 0.2 to 1. As shown in Fig. 10, the height of the specimen ( $H$ ), the length of the chevron notch, and the loading pin location ( $h$ ), are functions of the specimen width ( $W$ ). The ASTM-recommended dimension for the thickness  $B$  is as follows:

- FOR  $K_{IC}$  TESTS, THE PREFERRED THICKNESS IS  $W/2$ . ALTERNATIVELY,  $2 \cdot W/B \cdot 4$  (WITH NO CHANGE IN OTHER PROPORTIONS) IS ALLOWED.
- FOR FATIGUE CRACK GROWTH RATE TESTS,  $B$  CAN BE IN THE RANGE OF  $W/20$  TO  $W/4$ .

FIG. 10 THE COMPACT SPECIMEN CONFIGURATION. PIN HOLE DIAMETER IS 0.25  $W$ .

For test data reported in the earlier literature, an older version of the  $K$ -equation (e.g., one from the 1972 edition of the ASTM standard) might have been used. That is:

$$F(\alpha_1) = 29.6 \alpha^{\frac{1}{2}} - 185.5 \alpha^{3/2} + 655.7 \alpha^{5/2} - 1017.0 \alpha^{7/2} + 754.6 \alpha^{9/2} \quad (\text{EQ 13C})$$

for specimens where  $H/W = 0.6$ , or

$$F(\alpha_1) = 30.96 \alpha^{\frac{1}{2}} - 195.8 \alpha^{3/2} + 730.6 \alpha^{5/2} - 1186.3 \alpha^{7/2} + 638.9 \alpha^{9/2} \quad (\text{EQ 13D})$$

for specimens where  $H/W = 0.486$ . The second part of the geometric correction factor,  $F(\alpha_2)$  did not exist in earlier versions of the equation.

### Part-Through Crack in a Plate

---

A part-through crack originated on the surface of a plate is usually modeled as one-half of an ellipse. As shown in Fig. 11, either the major or the minor axis of the ellipse may be placed on the front surface of the plate, depending on the configuration. The length and depth dimensions of the crack are designated as  $2c$ , and  $a$ , respectively. The crack shape is described by an aspect ratio  $a/2c$  (or  $a/c$ ).

**FIG. 11 CONFIGURATION OF A SEMI-ELLIPTICAL SURFACE CRACK. THIS FIGURE SHOWS THE C-TIP IS AT EITHER END OF THE MAJOR AXIS (ALONG THE SURFACE). THE A-TIP IS AT THE MAXIMUM DEPTH OF THE MINOR AXIS. IN THIS ARTICLE C-TIP(S) ARE ALWAYS ON THE SURFACE, A-TIP IS ALWAYS AT THE MAXIMUM DEPTH WHETHER C IS GREATER THAN A, OR VICE VERSA. THIS DEFINITION ALSO IS APPLICABLE TO THE CORNER CRACK(S) AT A CIRCULAR HOLE CONFIGURATION.**

---

### Farfield Tensile Loading

For a plate subjected to uniform farfield tension, the expression for  $K$ , for some point on the periphery of a semielliptical crack in a semi-infinite solid, is adopted from Ref 16 as:

$$K = [\sigma \sqrt{(\pi a/Q)}] \cdot F\varphi \cdot \alpha_F \quad (\text{EQ 14})$$

where the applied stress  $\sigma$  is equated to the applied load (force) over the full cross section of the plate (ignoring the crack). Both  $Q$  and  $f\varphi$  are parameters accounting for the shape of the ellipse. Initially,  $Q$  was presented in the literature as a

function of  $\Phi$  and the  $\sigma/F_{ty}$  ratio, where  $\Phi$  is a crack shape parameter (the complete elliptical integral of the second kind presented in Fig. 12) and  $F_{ty}$  is the material tensile yield strength. As explained in Ref 2 and 3, the term  $\sigma/F_{ty}$  is used for converting the physical crack length to the effective crack length (to include the effect of crack tip plasticity, Fig. 3). Having this term deleted from  $Q$ , the elastic  $K$  is solely related to  $\Phi$ . In the remainder of this article  $\Phi$  and  $\sqrt{Q}$  are regarded as the same (without plasticity correction).

FIG. 12 ELLIPTICAL INTEGRAL  $\Phi$

The angular function  $f^\varphi$  has the following form:

$$F^\varphi = [(A/C)^2 \cdot \cos^2 \varphi + \sin^2 \varphi]^{1/4} \quad (\text{EQ 15A})$$

for  $a/c \leq 1$ , and

$$F^\varphi = [(C/A)^2 \cdot \sin^2 \varphi + \cos^2 \varphi]^{1/4} \quad (\text{EQ 15B})$$

for  $a/c > 1$ .

In Eq 15a and 15b,  $\varphi$  is a parametric angle measured from the plate surface toward the center of the crack (i.e.,  $\varphi = 0^\circ$  is on the plate surface and  $\varphi = 90^\circ$  is at the maximum depth of the crack). This terminology is used in all open literature for defining the position of a point on the ellipse. However, it is not an angle that actually connects the center of the ellipse to a specific point on the physical crack periphery. To translate  $\varphi$  to  $\beta$  (the angle between the plate surface and a specific point on the periphery of the ellipse, Fig. 13), the following relationship between  $\varphi$  and the geometric angle  $\beta$  can be used:

$$\beta = \text{TAN}^{-1} [(A/C) \cdot \text{TAN } \varphi] \quad (\text{EQ 16})$$

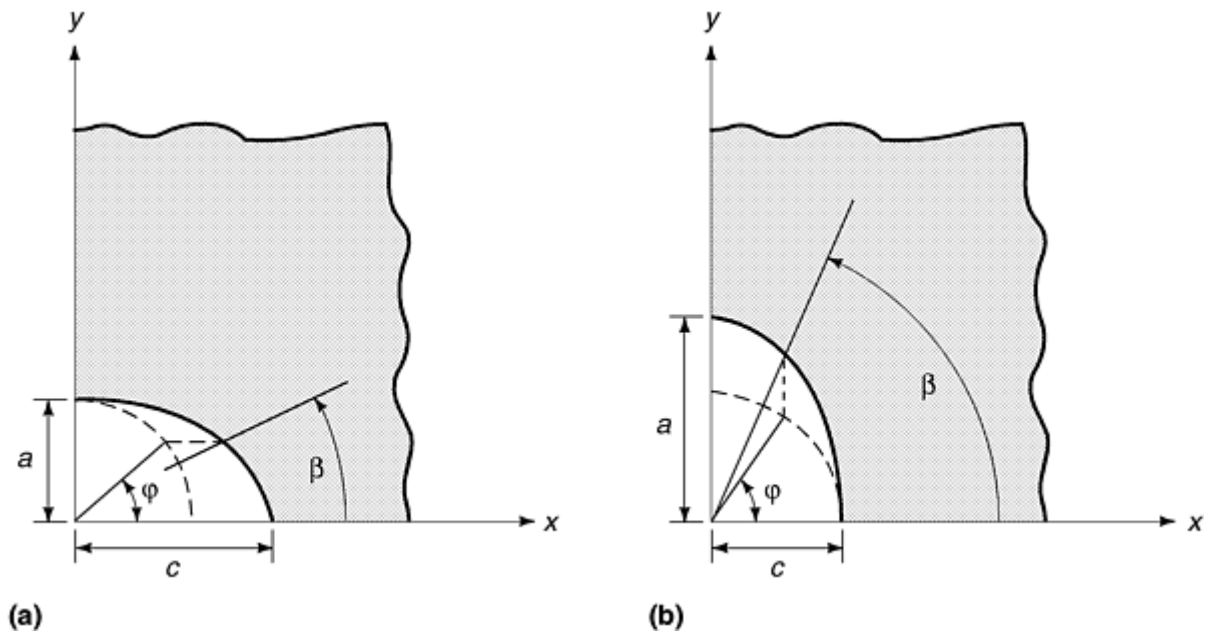

FIG. 13 DEFINITION OF  $\varphi$  AND  $\beta$  FOR AN ELLIPTICAL CRACK. (A)  $A/C < 1$ . (B)  $A/C > 1$ .

Finally, the parameter  $\alpha_f$  in Eq 15a and 15b is called the front face influence factor. It is a function of  $a/c$  and  $\varphi$ . For a given  $a/c$  ratio,  $f_\varphi$  is a function of  $\varphi$ . Therefore, the combination of  $\alpha_f$ ,  $f_\varphi$ , and  $1/\sqrt{Q}$  is the source of the variance in  $K$  values along the crack periphery. Each point along the crack front grows a different amount in different directions. As a result, the crack shape continuously changes as the crack extends. In making structural life prediction, a minimum of two  $K$  values (i.e., at the maximum depth, and on the surface) are required for each crack size and its corresponding aspect ratio. A demonstration of the fundamentals of  $K$  variation (as a function of  $a/c$  and  $\varphi$ ) is given in Fig. 14. Further discussion of Fig. 14, along with discussions of finite element solutions, is presented in the following section of this article.

FIG. 14 VARIATION OF STRESS-INTENSITY FACTORS FOR A SHALLOW CRACK IN A SEMI-INFINITE SOLID, WHERE  $\sigma F = K/\sqrt{\pi a}$  AND  $F = F_s/\sqrt{Q}$ , ACCORDING TO EQ 17A

### Summary of Stress-Intensity Factors

Alan Liu, Rockwell International (retired)

### Part-Through Crack in a Finite Plate

For a crack in a rectangular plate of finite thickness and width, the solution for  $K$ , (with a given crack size and shape) should account for the influence of the width and the front and back faces of the plate. Finite element solutions (for cracks subjected to tension or bending) have been developed by Newman and Raju (Ref 17, 18) and updated by Raju et al. (Ref 19). The new data (the values of  $K/(\sigma\sqrt{\pi a/Q})$ ) are presented in Tables 1 and 2. These data have been built into the crack library in the NASA/FLAGRO computer program (Ref 20), with which interpolations are accomplished by using a nonlinear table lookup routine to obtain stress-intensity factors that are not available in the tables. Comparisons of the new and old data are shown in Fig. 15, 16, 17, 18, 19, 20, 21, and 22. In some cases the differences are significant.

The old data were curve fitted, and a general expression for  $K$ , which included a group of correction factors for the width and the front and back faces of the plate, was developed by Newman and Raju (Ref 17, 18). These stress-intensity correction factors are included here because the equations are in close form, covering a full range of geometric combinations, and have been used for some time by fracture mechanics analysts in the aircraft/aerospace industry:

$$K = \sigma \cdot F_S \cdot \sqrt{(\pi a/Q)} \quad (\text{EQ 17A})$$

where  $\sqrt{Q}$  is  $\Phi$  (Fig. 12), as previously discussed, and  $F_S$  is a function of  $a/c$ ,  $a/t$ ,  $c/W$ , and  $\varphi$  such that:

$$F_S = [M_1 + M_2(A/T)^2 + M_3(A/T)^4] \cdot G_1 \cdot F_\varphi \cdot F_w \quad (\text{EQ 17B})$$

For  $a/c \leq 1$ :

$$M_1 = 1.13 - 0.09 (A/C) \quad (\text{EQ 18A})$$

$$M_2 = -0.54 + 0.89/[0.2 + (A/C)] \quad (\text{EQ 18B})$$

$$M_3 = 0.5 - 1/[0.65 + (A/C)] + 14.0(1 - A/C)^{24} \quad (\text{EQ 18C})$$

$$G_1 = 1 + [0.1 + 0.35(A/T)^2] \cdot (1 - \sin \varphi)^2 \quad (\text{EQ 18D})$$

$$f_w = \sqrt{\sec[(\pi c/W) \cdot \sqrt{(a/t)}]} \quad (\text{EQ 18E})$$

and  $f_{\varphi}$  is given by Eq 15a.

By inputting large values of  $W$  and  $t$  in Eq 17b, the configuration of a shallow crack ( $a/c \cdot 1$ ) in a semi-infinite solid (i.e., without the presence of other boundaries such as width and back face) is obtained. The stress-intensity factor  $F = K/\sigma \sqrt{\pi a}$  which is equal to  $F_s/\sqrt{Q}$  (Eq 17a) has been computed for several points on the crack periphery (for several  $a/c$  ratios) and is plotted in Fig. 14. Conceptually, the location of the highest  $K$  value is at the maximum depth (for  $a < c$ ). However, the highest  $K$  value is on the surface of the plate when  $a \cdot c$ . As shown in Fig. 14, the switching actually takes place at  $a/c \cong 0.8$ . For this flaw shape (i.e.,  $a/c \cong 0.8$ ), all the  $F$  values along the crack boundary are approximately the same. Thus, crack growth rates at each point along the crack boundary are approximately the same. Therefore, whether the crack starts as a scratch (having  $a \ll c$ ) or a deep cavity (having  $c \ll a$ ), given time its flaw shape will eventually stabilize at  $a/c \cong 0.8$ .

**For  $a/c > 1$ :**

$$M_1 = [1.0 + 0.04(C/A)] \cdot (C/A)^{\frac{1}{2}} \quad (\text{EQ 19A})$$

$$M_2 = 0.2(C/A)^4 \quad (\text{EQ 19B})$$

$$M_3 = -0.11(C/A)^4 \quad (\text{EQ 19C})$$

$$G_1 = 1 + [0.1 + 0.35(C/A)(A/T)^2] \cdot (1 - \text{SIN } \varphi)^2 \quad (\text{EQ 19D})$$

and  $f_w$  is given by Eq 18e and  $f_{\varphi}$  is given by Eq 15b.

In case the plate is subjected to bending load, Eq 17a becomes

$$K = \sigma \cdot F_s \cdot H \cdot \sqrt{(\pi a/Q)} \quad (\text{EQ 20})$$

where  $\sqrt{Q}$  is  $\Phi$  (Fig. 12) and  $F_s$  is given in Eq 17b for uniform tension. The applied stress ( $\sigma$ ) is equal to  $Mc/I$  (where  $M$  is the bending moment and  $I$  is the moment of inertia). For  $a/c \leq 1$ , the function  $H$  has the form

$$H = H_1 + (H_2 - H_1) \cdot \text{SIN}^{\rho} \varphi \quad (\text{EQ 21A})$$

where

$$\rho = 0.2 + A/C + 0.6 (A/T) \quad (\text{EQ 21B})$$

$$H_1 = 1 - 0.34(A/T) - 0.11 (A/C) \cdot (A/T) \quad (\text{EQ 21C})$$

$$H_2 = 1 + F_1(A/T) + F_2(A/T)^2 \quad (\text{EQ 21D})$$

In Eq 21d, the factors  $F_1$  and  $F_2$  are as follows:

$$F_1 = -1.22 - 0.12(A/C) \quad (\text{EQ 21E})$$

$$F_2 = 0.55 - 1.05(A/C)^{0.75} + 0.47(A/C)^{1.5} \quad (\text{EQ 21F})$$

A final note on part-through crack growth behavior is directed at the estimate of stress-intensity factors while the crack front is approaching the back face of the plate. Usually, there is a discontinuity where the calculation of  $K$  is suddenly switched from the part-through crack solution to the through crack solution. This is commonly known as the *transition phenomenon*. Literature containing discussion of the techniques in handling this problem is listed in the "Selected References" at the end of this article.

## Corner Crack(s) at a Circular Hole

The problem of corner crack(s) at a circular hole configuration (Fig. 23) has received considerable attention from the fracture mechanics community because of its effect on the life of aircraft structures. The first set of test data (on fatigue and fracture strength of specimens containing a circular hole) was presented at the Air Force Conference in 1969 (Ref 21). Since then, considerable efforts have been directed at the development of analytical and semiempirical solutions. The latest study was published in 1995 (Ref 22). Prior to the development of a complete set of finite element solutions by Newman and Raju in 1983 (Ref 18), Liu's one-dimensional semiempirical equation (Ref 23) was widely adopted by fracture mechanics analysts in the aircraft/aerospace industry.

FIG. 23 CORNER CRACKS AT AN OPEN HOLE UNDER UNIFORM TENSION

The two-dimensional, curve-fitted equations of Newman and Raju (Ref 18) are presented in the following paragraphs. This group of equations covers a full range of geometric variables and has been accepted by the fracture mechanics community for more than a decade.

---

### Double Crack Configuration

For the double symmetric crack configuration:

$$K = \sigma \cdot F_{CH} \cdot \sqrt{(\pi a/Q)} \quad (\text{EQ 22})$$

where  $\sigma$  again is the applied stress (load over cross section ignoring the hole and the crack) and  $\sqrt{Q}$  is  $\Phi$  (Fig. 12). If the panel length ( $2h$ ) is sufficiently long,  $F_{ch}$  is a function of  $a/c$ ,  $a/t$ ,  $r/t$ ,  $r/W$ ,  $c/W$ , and  $\varphi$ . That is:

$$F_{CH} = [M_1 + M_2(A/T)^2 + M_3(A/T)^4 \cdot G_1 \cdot G_2 \cdot G_3 \cdot F\varphi \cdot F_W] \quad (\text{EQ 23A})$$

**For  $a/c < 1$ :**

$$G_2 = (1 + 0.358\lambda + 1.425\lambda^2 - 1.578\lambda^3 + 2.156\lambda^4)/(1 + 0.13\lambda^2) \quad (\text{EQ 23B})$$

where

$$\lambda = \{1 + (C/R)\} \cdot \text{COS}(0.85\varphi)\}^{-1} \quad (\text{EQ 23C})$$

The functions  $G_3$  and  $F_W$  are as follows:

$$G_3 = [0.1 + 0.04(A/C) \cdot [1 + 0.1(1 - \text{COS } \varphi)^2] \cdot [0.85 + 0.15 (A/T)^{\frac{1}{4}}] \quad (\text{EQ 23D})$$

$$F_W = \sqrt{\sec[(\pi r/W) \cdot \sec(\pi(2r + nc)/2(W - 2c + nc))] \cdot \sqrt{(a/t)}} \quad (\text{EQ 23E})$$

where  $n = 1$  for a single crack and  $n = 2$  for double cracks. The other functions (i.e.,  $M_1$ ,  $M_2$ ,  $M_3$ ,  $G_1$ , and  $f\varphi$ ) are the same as those previously given for the surface flaw.

**For  $a/c > 1$ :**

$$G_3 = [1.13 + 0.09(C/A)] \cdot [1 + 0.1(1 - \text{COS } \varphi)^2] \cdot [0.85 + 0.15 (A/T)^{\frac{1}{4}}] \quad (\text{EQ 23F})$$

The functions  $G_2$  and  $F_W$  are given by Eq 23b and 23e, respectively. The other functions (i.e.,  $M_1$ ,  $M_2$ ,  $M_3$ ,  $G_1$ , and  $f\varphi$ ) are the same as those previously given for the surface flaw.

---

## Summary of Stress-Intensity Factors

Alan Liu, Rockwell International (retired)

### Single Corner Crack

The stress-intensity factors for a single corner crack at a hole can be estimated by using Eq 22 with a conversion factor given by (Ref 24):

$$K_{\text{one crack}} = K_{\text{two cracks}} \cdot \sqrt{(4/\pi + ac/2tr)/(4/\pi + ac/tr)} \quad (\text{EQ 23G})$$

Implementation of these equations may be cumbersome because of their complexity. To simplify the lengthy calculations in Eq 22 let  $F = F_{\text{ch}}/F_{\text{W}}/\sqrt{Q}$  so that Eq 22 can be rewritten as:

$$K = \sigma \cdot F \cdot F_{\text{W}} \sqrt{(\pi a)} \quad (\text{EQ 24})$$

Parametric curves (for  $F$  versus  $a/t$ ) for three commonly used hole diameters ( $2r = 6.35, 12.7,$  and  $19.05$  mm, or  $0.25, 0.5,$  and  $0.75$  in.) have been developed and are graphically presented in Fig. 24, 25, 26, 27, 28, and 29. Again, the techniques to handle the transition from part-through crack to through crack are documented in the open literature. Some of the publications are listed in the "Selected References" section at the end of this article.

### Crack at Pin Hole in a Lug

Two types of attachment lugs are considered in this article, the straight lug and the tapered lug (Fig. 30). The stress-intensity factors for cracks at the bore of the pin hole are summarized below.

(a)

(b)

FIG. 30 ATTACHMENT LUG CONFIGURATIONS. (A) STRAIGHT. (B) TAPERED

---

## Summary of Stress-Intensity Factors

Alan Liu, Rockwell International (retired)

---

### The Straight Lug

Figure 31 presents the finite element solutions of stress-intensity factors for an axially loaded straight attachment lug. The pin load is applied at the direction normal to the base of the lug ( $\theta = 0^\circ$ ). Either the bearing stress,  $\sigma_{br}$ , or the gross area stress,  $\sigma_o$ , can be used to compute stress intensity. That is, for a single through-the-thickness crack on one side of the pin hole (perpendicular to the direction of loading,  $P$ ) according to Ref 25:

$$K = \sigma_{BR} \cdot F_{RB} \cdot \sqrt{(\pi c)} \quad \text{(EQ 25A)}$$

Because  $\sigma_{br} = P/2R_i t$  and  $\sigma_o = P/2R_o t$ , Eq 25a can be rewritten as:

$$K = \sigma_O \cdot F_{RB} \cdot R_O/R_I \cdot \sqrt{(\pi c)} \quad (\text{EQ 25B})$$

The values of  $F_{RB}$  for five  $R_O/R_I$  ratios are given in Fig. 31.

**FIG. 31** NORMALIZED STRESS-INTENSITY FACTORS FOR SINGLE THROUGH-THE-THICKNESS CRACKS EMANATING FROM A STRAIGHT LUG SUBJECTED TO A PIN LOADING APPLIED IN THE 0° LOADING DIRECTION. SOURCE: REF 25

Equations 25a and 25b can be modified to analyze a corner crack. Two methods have been proposed (Ref 25). The method that involves analysis at two crack tips (i.e., Points A and C of the corner crack) is rather complicated and incomplete and will not be discussed here. In the one-parameter method, the crack shape (i.e.,  $a/c$  ratio) is assumed to be constant and equal to 1.33. The stress-intensity factor at the lug surface point (i.e., Point C) is computed using a corner crack correction factor:

$$\Phi_{71} = 1 - 0.2886/[1 + 2(A/C)^2 + (C/T)^2] \quad (\text{EQ 25C})$$

and Eq 25a or 25b becomes:

$$K^C = K \cdot \Phi_{71} \quad (\text{EQ 25D})$$

where the superscript C stands for corner crack and  $K$  is the stress-intensity factor for the through-the-thickness crack, given by Eq 25a or 25b.

### The Tapered Lug

All the equations listed above for the straight lug are also applicable to the tapered lug (with a new set of  $F_{RB}$  factors). The  $F_{RB}$  factors for  $0^\circ$  loading are presented in Fig. 32. Limited finite element data are available for tapered lugs loaded in other directions. The through crack solutions for  $\theta = 180^\circ$ ,  $-45^\circ$ , and  $-90^\circ$  are presented in Fig. 33, 34, and 35, respectively.

#### Crack in a Solid Cylinder

This type of crack usually has an almond shape, as shown schematically in Fig. 36. In the remainder of this section we will refer it as a crack on the shank of a bolt, or at the thread of a bolt. However, one should keep in mind that this kind of

crack can be found in any circumferential plane of a solid round bar. The stress-intensity solutions presented herein are applicable to both.

FIG. 36 DEFINITION OF CRACK DIMENSIONS FOR AN ALMOND-SHAPED CRACK IN A SOLID CYLINDER

The nomenclature for this crack type is defined in Fig. 36, where  $a$  is the crack depth, the point (Point A) that travels through the diameter of the cylinder;  $b$  is the crack length (i.e., one-half of the crack tip-to-tip circumferential arc);  $d$  is the minor diameter at the thread of a bolt (or a notched round bar); and  $D$  is the diameter of a rod or the diameter at the unthreaded portion of a bolt, depending on the application.

Due to the geometric difference between a cylinder and a plate, this crack cannot be treated as an edge crack or as a thumbnail crack in a rectangular cross section. It is in a class by itself. Many fracture mechanics analysts believe (Ref 26, 27) that this type of crack has the shape of a circular arc, rather than one-half of an ellipse. The center of the circle floats in between the free surface of the cylinder and a point infinitely far away from the cylindrical surface. As the crack front passes through the center of the rod, the crack front curvature will become flattened, approaching a straight crack front despite the fact that a circular shape (by geometric definition) had been maintained at all times. Experimental observations on crack growth in unthreaded and threaded rods (Ref 28, 29, 30, 31, 32) seem to support this claim.

### Partly-Circular Crack in a Bolt

For an almond-shaped crack in a bolt, a large portion of the crack growth activity will take place in only one-half of the cylindrical crack plane, that is, where  $a \cdot D/2$  (or  $a \cdot d/2$ ), before it becomes critical. Experimental data has also shown that the crack maintains a circular shape and a constant  $a/b$  ratio in this region. Referring back to the semielliptical flaw problem, a constant flaw shape during crack growth implies that the  $K$  values along the crack periphery are nearly constant. However, this is not the case here because the crack tip on the surface, which travels along the circumference of the cylindrical cross section, has to travel a longer distance than the crack middle point (which propagates in the depth direction), in order to keep up with the crack shape aspect ratios. That is,  $db/dN > da/dN$  in each increment of crack extension. This means that the  $K$  value at Point B would be higher than that at Point A. Therefore, a two-dimensional crack growth scheme is more suitable for this type of crack geometry. However, if the relationship between  $a/D$  and  $a/b$  is clearly established, and the  $K$  values (or the geometric factor of  $\beta$  or  $Y$ ) at locations on the crack propagation path are specifically determined for the expected crack geometries, crack growth can be predicted by monitoring only one point on the crack periphery (i.e., by treating the crack configuration as if it were a one-dimensional crack). In this section the geometry factor  $Y$  will be expressed as a function of  $a/D$  (or  $a/d$ ) for stress-intensity factors at Point A. Justifications for using this approach were made by showing good correlations between the stress-intensity equations (presented below) and available test data (Ref 27). A bibliography of stress-intensity factors for mechanical joints is also given in the article "Fatigue of Mechanically Fastened Joints" in this Volume.

### Crack on Bolt Shank or Thread

For a crack originated on the circumferential surface of an unthreaded (or threaded) cylinder, the one-dimensional crack-tip stress intensity,  $K$ , can be defined as:

$$K = S \cdot Y \cdot \sqrt{(\pi a)} \quad \text{(EQ 26A)}$$

where  $S$  is the applied stress [equal to  $4P/(\pi D^2)$ ,  $4P/(\pi d^2)$ ,  $32M/(\pi D^3)$ , or  $32M/(\pi d^3)$ , depending on the application]. The equation below is suitable for cracks on the shank of a bolt, or at the root of a screw thread, subjected to either tension or bending:

$$Y = \lambda \cdot \text{EXP}[\beta X] + A + BX + CX^2 + DX^3 + EX^4 + FX^5 + GX^6 \quad (\text{EQ 26B})$$

Here,  $x$  equals  $a/D$  or  $a/d$ , whichever is appropriate. In the case of an unthreaded cylinder the first two terms in Eq 26b do not exist, because these terms cover the local stress concentration caused by the screw thread. The magnitude of the exponential term decreases rapidly as crack length increases. The values of the coefficients are given in Table 3. A graphical presentation of Eq 26b is shown in Fig. 37.

**FIG. 37 STRESS-INTENSITY FACTORS FOR THREADED AND UNTHREADED CYLINDERS**

It should be noted that  $\lambda$  and  $\beta$  are associated with the stress concentration factor and the local stress distribution near the notch root (or screw thread). It is expected that their values may vary, depending on the depth, the root radius, and the

pitch angle of the thread. Therefore, it would be conceptually impossible to have a single curve for  $Y$  cover a wide range of geometric details. The values listed in Table 3 for  $\lambda$  and  $\beta$  represent a mixture of geometries that were used in the development of analytical and experimental data. The finite element models had a  $45^\circ$  pitch angle with root radii in a range of 0 to 0.125 mm. The test data were generated from notched specimens that either contained machined grooves that simulated the 12-UNF-3A screw thread (having a root radius of 0.38 mm) or had an unknown geometry. Although these values (for  $\lambda$  and  $\beta$ ) certainly will not be universally suitable for all the local geometries encountered in practice, it is conceivable that they are applicable to most thread geometries as long as the crack size is not too small. In any event, Table 3 is a guide to making crack growth life estimates.

## Crack on the Circumferential Plane of a Hollow Cylinder

In this category of cracks we consider the through-the-thickness crack and the thumbnail crack originated on the inner or outer wall of a hollow cylinder (a tube; a pipe; or a pressure vessel) that is subjected to axial loads (i.e., uniform tension, bending, or both).

---

## Summary of Stress-Intensity Factors

Alan Liu, Rockwell International (retired)

---

## Through-the-Thickness Crack

The nomenclature for this crack type is defined in Fig. 38, where  $M$  is the bending moment;  $P$  is the tensile load;  $\alpha$  is the angle that represents one-half of the crack tip-to-tip circumferential arc;  $t$  is the thickness of the cylinder wall;  $R$  is the average radius of the inner and outer cylinder wall;  $c$  is half the crack length ( $R\alpha$ );  $S_t$  is the tension stress ( $P/(2\pi Rt)$ ); and  $S_b$  is the bending stress ( $M/(\pi t R^2)$ ). The stress-intensity equation is:

$$K = S \cdot F \cdot \sqrt{(\pi c)} \quad \text{(EQ 27A)}$$

where  $S$  can be designated as  $S_t$  or  $S_b$ , depending on the loading condition. Likewise,  $F$  can be designated as  $F_t$  or  $F_b$ . The dimensionless factors ( $F_t$  and  $F_b$ ) are given in Eq 27a as a group of close-form solutions. However, application of these equations may be cumbersome because of their complexity. To help readers cut through the lengthy calculations, these

factors have been computed for several specific  $R/t$  ratios (with an assumed Poisson ratio of 0.3). The results are presented in Fig. 39 and 40. Each of these curves was fitted by a polynomial equation:

$$F = A + B\alpha + C\alpha^2 + D\alpha^3 + E\alpha^4 + F\alpha^5 + G\alpha^6 \quad (\text{EQ 27B})$$

The coefficients are listed in Tables 4 and 5. For  $R/t$  ratios not included in these tables, interpolated values for  $F_t$  or  $F_b$  can be used.

FIG. 38 A CIRCUMFERENTIAL THROUGH-THE-THICKNESS CRACK IN A HOLLOW CYLINDER

FIG. 39 STRESS-INTENSITY FACTORS FOR CIRCUMFERENTIAL THROUGH CRACKS IN HOLLOW CYLINDERS

FIG. 40 STRESS-INTENSITY FACTORS FOR CIRCUMFERENTIAL THROUGH CRACKS IN HOLLOW CYLINDERS SUBJECTED TO BENDING (EQ 27A AND 27B)

It should be noted that the solution of Eq 27a was developed on the basis of the thin-wall theory (for  $R/t \geq 30$ ). Figures 39 and 40 and Tables 4 and 5 can be used for tubes having thicker walls or smaller curvatures (i.e.,  $R/t < 30$ ). Although  $R/t = 7$  is included in these figures and tables, it is recommended that  $R/t = 15$  be considered the limit of applicability.

### Part-Through Crack

For a thumbnail crack on the inner or outer wall of a hollow cylinder (Fig. 41), the expression for  $K$  is given by Ref 33 as:

$$K = S \cdot F \cdot \sqrt{(\pi a)} \quad \text{(EQ 28)}$$

where  $S$  can be  $S_t$  or  $S_b$ , depending on the loading condition. In either case,  $F$  is a function of  $a/c$ ,  $R/t$ , and  $a/t$ . The values of  $F$  for internal and external cracks subjected to tension or bending are given in Tables 6 and 7.

### Summary of Stress-Intensity Factors

Alan Liu, Rockwell International (retired)

---

## Pressurized Cylinder and Sphere

### Axial Cracks in Cylinder

In this section we consider a long cylinder subjected to internal pressure. A through-the-wall-thickness crack or a part-through crack is placed along the length of the cylinder (Fig. 42). The length of the cylinder is sufficiently long (as compared to the length of the crack), and the end effect on crack-tip stress intensity is not considered.

FIG. 42 AXIAL CRACKS IN A HOLLOW CYLINDER

**Through-the-Thickness Crack.** In a pressurized thin-wall cylinder (Fig. 42), the elastic stress-intensity factor of Folias/Erdogan is given by Ref 34 as:

$$K = S \cdot Y \cdot \sqrt{(\pi c)} \quad (\text{EQ 29A})$$

where

$$Y = (1 + 0.52\lambda + 1.29\lambda^2 - 0.074\lambda^3)^{\frac{1}{2}} \quad (\text{EQ 29B})$$

where  $\lambda = c/\sqrt{(Rt)}$ ,  $S$  is the  $pR/t$  stress, and  $R$  is the inner radius of the cylinder. Equation 29a accounts for the effects of shell curvature on stress intensity. Poisson's ratio is assumed to be  $\frac{1}{3}$ . The applicable range is  $0 < \lambda < 10$ .

**Part-Through Crack.** Now consider a pair of thumbnail cracks symmetrically located on the inner or outer wall of a hollow cylinder (Fig. 42). The expression for  $K$  can be written as:

$$K = S \cdot \alpha \cdot \sqrt{(\pi a/Q)} \quad (\text{EQ 30A})$$

where  $S = pR/t$ , and  $\alpha$  is a function of  $R/t$ ,  $a/c$ ,  $a/t$ ,  $\varphi$ , and the nonuniform tangential stresses acting on the crack plane. Having the nonuniform stress distribution normalized to the  $pR/t$  stress, the  $\alpha$  function can be written as (Ref 35):

$$\alpha_1 = (T/R) \cdot R^2/(R^2 - R^2) \cdot [2H_0 - 2H_1(A/R) + 3H_2(A/R)^2 - 4H_3(A/R)^3] \quad (\text{EQ 30B})$$

for an internal crack, or

$$\alpha_0 = (T/R) \cdot R^2/(R^2 - R^2) \cdot [2G_0 + 2G_1(A/R) + 3G_2(A/R)^2 + 4G_3(A/R)^3] \quad (\text{EQ 30C})$$

for an external crack.

Here  $r$  and  $R$  are the outer and inner radius of the cylinder, respectively. The  $H$  and  $G$  values are functions of  $R/t$ ,  $a/c$ ,  $a/t$ , and  $\varphi$ . Each  $H$  or  $G$  value corresponds to a particular loading distribution. The subscript 0 corresponds to uniform tension; subscript 1 to linear distribution; subscript 2 to quadratic; and subscript 3 to cubic. Using the  $H$  and  $G$  values given in Ref 33,  $\alpha_i$  and  $\alpha_o$  values for the pressurized cylinder were computed for 11  $R/t$  ratios (1, 1.5, 2, 3, 4, 6, 8, 10, 20, 30, and  $\geq 50$ ).

Let  $F = \alpha/\sqrt{Q}$  so that Eq 30a is reduced to:

$$K = S \cdot F \cdot \sqrt{(\pi a)} \quad \text{(EQ 30D)}$$

The computed  $F$  values are presented in Tables 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, and 18. In Ref 33, the stress-intensity factor tables listed  $H$  and  $G$  values for only five  $R/t$  ratios (1, 2, 4, 10, and  $\geq 50$ ), in combination with three  $a/c$  ratios (0.2, 0.4, and 1.0) and five  $a/t$  ratios (0, 0.2, 0.5, 0.8, and 1.0). For other  $R/t$  ratios listed in Tables 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, and 18, the  $F$  values have been obtained by linear interpolation. Likewise, interpolated  $F$  values can be used for other parametric combinations not included in these tables.

Although the  $\alpha$  factors were originally derived for the double crack configuration, they are also applicable to the single crack configuration. When Eq 30a or 30d is used for the single crack configuration, the maximum error is 4% (higher than the actual value), depending on the  $a/c$  ratio.

### Summary of Stress-Intensity Factors

## Crack in Pressurized Sphere

Currently, the Erdogan solution for a through-the-thickness crack (Ref 20) is the only solution available for the pressurized spherical shell (Fig. 43):

$$K = S \cdot Y \cdot \sqrt{(\pi c)} \quad (\text{EQ 31})$$

where  $Y = (1 + 3\lambda^{1.9})^{0.4}$ ,  $\lambda = c/\sqrt{(R/t)}$ ,  $S$  is the  $pR/2t$  stress; and  $R$  is the average of the inner and outer radii. This equation accounts for the effects of shell curvature on stress intensity. The Poisson ratio is assumed to be  $\frac{1}{3}$ . The applicable range is  $0 < \lambda < 3$ .

### **Abbreviations and Symbols**

- ABBREVIATIONS AND SYMBOLS
- $\delta$
- crack tip opening displacement, CTOD
- $\delta_M$
- CTOD at maximum load in measurement of fracture toughness
- $\epsilon$
- actual or local strain at stress concentration
- $\epsilon_E$
- elastic strain
- $\epsilon_{EL}$
- elastic strain
- $\epsilon_{IN}$
- inelastic strain
- $\epsilon_M$
- mean strain
- $\epsilon_M, \epsilon_{MECH}$
- mechanical strain rate
- $\epsilon_{MAX}$
- maximum strain
- $\epsilon_{MIN}$
- minimum strain
- $\epsilon_P$
- plastic strain
- $\epsilon_{PL}$
- plastic strain
- $\dot{\epsilon}_{PL}$
- plastic strain rate
- $\epsilon_{PL,CUM}$
- cumulative plastic strain
- $\epsilon_{PL,MAX}$
- maximum plastic strain
- $\epsilon_{PL,MIN}$
- minimum plastic strain
- $\epsilon_{PL,S}$
- plastic strain amplitude of saturation
- $\epsilon_{TH}$
- thermal strain rate
- $\Delta\epsilon$
- strain range
- $\Delta\epsilon, \Delta\epsilon_{NET}$
- net strain range
- $\Delta\epsilon/2$
- strain amplitude
- $\Delta\epsilon_E/2$
- elastic strain amplitude
- $\Delta\epsilon_M, \Delta\epsilon_{MECH}$
- mechanical strain range
- $\Delta\epsilon_P/2$
- plastic strain amplitude
- $\Delta\epsilon_P, \Delta\epsilon_{PL}$
- plastic strain range
- $\Delta\epsilon_{TH}$
- thermal strain range
- $\eta_{PL}$
- coefficient in  $J_{pl}$  calculation
- $\mu$
- shear modulus

- $\gamma$
- shear strain or stacking fault energy
- $\gamma_{AP}$
- amplitude of plastic shear strain
- $\gamma_{AP,M}$
- shear strain amplitude in matrix
- $\gamma_{AP,PSB}$
- shear strain amplitude in PSB
- $\gamma_{SF}$
- stacking fault energy
- $\rho$
- dislocation density, mass density or accumulated plastic strain
- $\sigma$
- actual or local stress at a stress concentration
- $\sigma_0$
- mean stress in strain life method
- $\sigma_A$
- stress amplitude,  $\sigma_a = (\sigma_{max} - \sigma_{min})/2$
- $\sigma_{CE}$
- critical stress in emergency condition
- $\sigma_{CU}$
- critical stress in upset condition
- $\sigma_F$
- friction stress amplitude
- $\sigma_H$
- hydrostatic energy
- $\sigma_M$
- mean stress,  $\sigma_m = (\sigma_{max} + \sigma_{min})/2$
- $\sigma_{MAX}$
- maximum local stress
- $\sigma_{MIN}$
- minimum local stress
- $\sigma_P$
- minimum permissible residual strength
- $\sigma_S$
- saturation stress amplitude
- $\sigma_Y$
- yield stress
- $\sigma_{UTS}$
- ultimate tensile strength
- $\sigma_{YS}$
- yield strength
- $\sigma_Y$
- effective yield strength
- $\sigma_{YD}$
- dynamic yield strength
- $\Delta\sigma$
- stress range, or alternating component of  $\sigma$
- $\Delta\sigma$
- stress range
- $\Delta\sigma/2$
- stress amplitude
- $\tau_A$
- amplitude of resolved shear stress
- $\tau_S$
- shear stress amplitude in saturation
- $\tau_F$

- flow shear stress
- $\tau_G$
- athermal flow stress component
- $\tau^*$
- thermal flow stress component
- $\nu$
- Poisson's ratio or displacement
- $\nu_{PL}$
- plastic component of displacement
- $\phi$
- phase
- $A$
- crack length, size, or size effect in fatigue notch factor equation
- $A_0$
- initial or starting crack length
- $A_C$
- critical crack size
- $A_D$
- detected crack size
- $A_E$
- effective crack length
- $A_F$
- final crack length
- $A_P$
- maximum permissible crack size
- $\Delta A$
- crack extension
- $\Delta A_E$
- effective crack extension
- $A$
- the ratio of alternating to mean load values,  $A = \sigma_a / \sigma_m$
- $A(B)$
- arc bend specimen
- AMT
- accelerated mission test
- $A(T)$
- arc tension specimen
- $A(T)$
- arc-shaped specimen (in tension)
- ATC
- accelerated thermal cycling
- $A/W$
- crack length to depth ratio
- $B$
- uncracked ligament length
- $B_N$
- Burgers vector
- $B$
- specimen thickness
- BCC
- body-centered cubic
- BFS
- back face strain
- CA
- constant amplitude
- CC
- center cracked

- CG
- center of gravity
- CT
- compact type
- CCT
- center-cracked tensile (specimen)
- C(T)
- compact tension specimen
- CTE
- coefficient of thermal expansion
- CTOD
- crack tip opening displacement
- C(W)
- crack-line-wedge-loaded
- $D$
- distance between corresponding partial dislocations
- $DA/DN$
- fatigue crack growth per cycle
- $D_c$
- dislocation cell diameter of saturation
- DC(T)
- disk-shaped compact tension specimen
- DCCW
- diamond counterclockwise
- DCW
- diamond clockwise
- $E$
- nominal strain measured remotely from stress concentration
- $E$
- elastic (Young's) modulus
- EHL
- elastohydrodynamic lubrication
- EMF
- electromagnetic field
- ENSIP
- Engine Structural Integrity Program
- EPFM
- elastic-plastic fracture mechanics
- $F$
- frequency
- $F_{PSB}$
- volume fraction of persistent slip bands
- $F_{TU}$
- ultimate tensile strength
- $F_{TY}$
- yield strength
- FCC
- face-centered cubic
- FCGR
- fatigue crack growth rate
- FEM
- finite-element method
- FEMA
- failure effects and modes analysis
- $G$
- shear modulus
- $H$

- total time of safe operation, or time available for fracture control
- $\Delta H$
- activation energy
- HCP
- hexagonal close-packed
- HR
- Hui-Riedel (stress field)
- HRR
- Hutchinson-Rice-Rosengren (stress field)
- $I$
- moment of inertia
- IF
- isothermal fatigue
- IP
- in-phase
- IST
- incremental step test
- $J$
- $J$  integral fracture parameter
- $J_2$
- Second Invariant of Deviatoric Stress
- $J_C$
- $J$  measurement of fracture toughness for unstable fracture
- $J_{EL}$
- elastic component of  $J$
- $J_I$
- $J$  based fracture initiation fracture toughness
- $J_{PL}$
- plastic component of  $J$
- $J_Q$
- provisional value of  $J_{Ic}$
- $J_U$
- $J$  measurement of fracture toughness for unstable fracture
- $\Delta J$
- cyclic  $J$ -Integral
- $K$
- yield stress in shear
- $K$
- crack-tip stress intensity factor
- $K_C$
- critical stress intensity for static failure, or plane-stress fracture toughness
- $K_F$  OR  $K_{Ic}$
- fatigue notch factor,  $k_f = \text{unnotched fatigue strength}/\text{notched fatigue strength}$
- $K_I$
- stress intensity in Mode I (tension-compression)
- $K_{IC}$
- plane strain fracture toughness
- $K_{ID}$
- dynamic fracture toughness
- $K_{JC}$
- critical stress intensity based on  $J$  integral
- $K_{MAX}$
- maximum value of  $K$  in a  $K$ - $R$  curve test
- $K_Q$
- provisional value of  $K_{Ic}$  test
- $K_T$  OR  $K_{Tc}$
- theoretical (elastic) stress concentration factor

- $\Delta K$
- stress intensity range
- $\Delta K_{\text{EFF}}$
- effective stress intensity range,  $\Delta K_{\text{eff}} = \Delta K - \Delta K_{\text{closure}}$
- $\Delta K_{\text{I}}$
- mode I stress intensity factor range
- $\Delta K_{\text{I,TH}}$
- mode I fatigue crack growth threshold
- $\Delta K_{\text{TH}}$
- threshold stress intensity range
- LCF
- low cycle fatigue
- LEFM
- linear elastic fracture mechanics
- $M$
- bending moment
- $M(\text{T})$
- center-cracked tension specimen
- $M(\text{T})$
- middle tension specimen geometry
- $M_{\text{D}}$
- maximum temperature below which deformation-induced martensite formation occurs
- MDS
- mechanical deflection system
- $M_{\text{S}}$
- martensite start temperature
- MSD
- multiple-site damage
- $N$
- number of cycles
- $N_{\text{F}}$
- number of cycles to failure
- $2N_{\text{F}}$
- number of reversals to failure
- $2N_{\text{T}}$
- transition fatigue life
- NDT
- nil ductility transition temperature
- NDT
- nil ductility
- OL
- overload
- OP
- out-of-phase
- $P$
- applied load
- $P_{\text{A}}$
- load amplitude or  $S_{\text{a}}$
- $P_{\text{F}}$
- load for fatigue precracking
- $P_{\text{M}}$
- mean load (also  $S_{\text{m}}$ )
- $P_{\text{MAX}}$
- maximum load in fracture toughness test
- $P_{\text{MIN}}$
- minimum load
- $P_{\text{P}}$

- minimum permissible residual strength load
- $P_Q$
- provisional load
- $P_S$
- service load
- $P_U$
- design load
- $\Delta P$
- range of applied load in fatigue
- PLB
- persistent Lüders band
- POD
- probability of detection
- PSB
- persistent slip bands
- PSE
- principal structural elements
- $Q$
- notch sensitivity index,  $q = (K_f - 1)/(K_t - 1)$
- $R$
- ratio of minimum load to maximum load,  $R = \sigma_{\min}/\sigma_{\max}$ , or  $R = (1-A)/(1+A)$
- $R_{CP}$
- cyclic plastic zone radius
- $R_P$
- rotation factor in CTOD test, plastic zone radius
- $R_P$
- plastic zone radius
- $S$
- nominal stress or stress measured remotely from stress concentration
- $S_0$
- mean stress
- $S_A$
- stress amplitude,  $S_a = \Delta S/2$
- $S_{A,MAX}$
- maximum stress amplitude of a stress spectrum
- $S_{AR}$
- completely reversed stress amplitude
- $S_{ER}$
- fatigue limit stress for a notched component (with completely reversed stress,  $S_{ar}$ )
- $S_{IJ}$
- deviatoric stress
- $S_{ij}^c$
- deviatoric back stress
- $S_M$
- mean stress (see also  $S_0$ )
- $S_{MF}$
- mean stress in flight
- $\Delta S$
- stress range
- SE(B)
- single edge-notched bend
- SE(B)
- single-edge notched bending specimen
- SE(T)
- single-edge notched specimen in tension
- SEN
- single-edge notched (specimen)

- $SIC_p$
- particulate silicon carbide reinforcement
- $SIC_w$
- whisker silicon carbide reinforcement
- SRP
- strain range partitioning
- SSC
- small-scale secondary creep
- SSY
- small scale yielding
- $T$
- thickness or time
- $T_C$
- cycle time (seconds, minutes)
- $T_F$
- time to failure
- $T_0$
- transition temperature
- $T_M$
- melting temperature
- $T_{MAX}$
- maximum temperature in a cycle
- $T_{MIN}$
- minimum temperature in a cycle
- TEM
- transmission electron microscope/microscopy
- TF
- thermal fatigue, or triaxiality factor
- TMF
- thermo-mechanical fatigue
- TMF DCCW
- thermo-mechanical fatigue diamond counter-clockwise
- TMF DCW
- thermo-mechanical fatigue diamond clockwise
- TMF OP
- thermo-mechanical fatigue out-of-phase
- TMP IP
- thermo-mechanical fatigue in-phase
- $U$
- plastic work per unit area to advance crack
- VA
- variable-amplitude
- $W$
- specimen width
- WFD
- widespread fatigue damage
- $Y$
- yield strength or generalized geometry factor
