## Statistical Considerations in Fatigue

Paul S. Veers, Sandia National Laboratories

---

## Dealing with Uncertainty

The emphasis of this article to this point has been on modeling the sources of uncertainty and inherent randomness as random variables. This section attempts to point out how these descriptions can be combined to produce a probability of failure result. Attention is centered on the inputs and outputs of the analytical approaches, which are now available as commercial software packages that are easy to use. The intent here is to make the probabilistic modeling capability known and lead the interested reader to a more thorough treatment in the references.

**Applying Probability.** Let me begin this section with a story. I had just finished a presentation on applying structural reliability methods to dealing with uncertainty in the fatigue analysis of a particular class of problems. The approach (discussed below) requires that distributions (pdf's) be assigned to all uncertain inputs. The probability of failure before a specified lifetime is then calculated. The first audience response was from a distinguished and senior researcher from a highly esteemed university, a man whose knowledge and opinion I hold in high regard. He gave a brief lecture on the danger involved in attempting to design in the absence of a complete set of material test data. To guess at the correct

range of possible values without sufficient laboratory-generated data is to invite disaster, he said. The second comment came from the director of engineering for a major corporation. He agreed with the researcher up to a point, but said that, unfortunately, he and his staff are rarely given the luxury of getting all the answers before a decision needs to be made. The constraints of the market-place (and sometimes the corporation) do not allow sufficient time and money to completely define the critical material or structural response properties. Designers are forced to do the best job they can with the data available and use good "engineering judgment."

The idea that a probabilistic tool will tempt designers away from thorough testing before making design choices is off target; decisions are routinely made without complete data! The feeling that a probabilistic analysis is an attempt to get away without doing your homework in the test laboratory may be widespread, but probabilistic methods should never be used that way. While it is true that any tool may be abused, it is a perversion of probabilistic methods to assume more certainty than you have. The primary issue is establishing exactly what is or is not known. Creating distribution models that describe the relative likelihood of different values of important inputs is a good exercise. If the value of an important input is completely unknown, the distribution of possible values should reflect that reality by being very wide. In the best case, probabilistic analysis forces designers to be completely honest about their level of knowledge. It makes them document the distribution of possible values that are assumed for all the inputs, instead of trying to account for all the uncertainties with one or a few safety factors applied at the end. In fact, one very useful application of probabilistic analysis is in establishing safety factors and design criteria that will produce an agreed-on level of reliability, that is, a predetermined probability of failure or, in the fatigue case, of premature failure (Ref 10, 22, 25, 26, and 33).

Every designer of fatigue-sensitive structures would like to know the lifetime of the design with perfect accuracy. The design could then be fine tuned to eliminate needless costs while maintaining acceptable durability. Unfortunately, designers are often disappointed with fatigue life predictions. Not only are the techniques difficult to apply, requiring a daunting level of detail of the machine and its environment, but the results are highly sensitive to changes in the inputs (Ref 34). Ranges of plausible answers from two months to ten years erode the value of the results and make the process frustrating. The knowledge that this sensitivity is inherent to the fatigue problem is of little comfort. This sensitivity suggests that an appropriate range of uncertainty be reported, reflecting both natural variability and professional ignorance of precise structural behavior, mechanical fatigue laws, and so forth. A good designer will therefore put appropriate safety factors on all the uncertain quantities that affect fatigue life. It would be beneficial, however, to provide a more quantitative measure of the design conservatism. This in turn suggests that the proper question may be not "What is the actual fatigue life of this component?" but rather, "With what probability will the component meet its target design life?" Such questions are naturally addressed by the theory of structural reliability.

**Analytical Methods.** The ability to calculate the probability of failure for truly complex (i.e., realistic) problems has developed rapidly and fairly recently. The first probabilistic analysis capability successfully applied to structural reliability was the awkwardly named mean-value first-order second-moment method (Ref 49). To oversimplify greatly, it assumes that everything in the world is Gaussian, uses the nice property that the sum of Gaussian distributed variables is Gaussian, and provides probabilities of failure for the standard normal (or Gaussian) distribution of the difference between loading and resistance. This approach worked fairly well for static loading problems where there are often additive loadings. It suffers from the fact that the world is not Gaussian and not all uncertain factors are additive. Hassofer and Lind (Ref 50) created a generalized safety index that solved many of the problems of the simpler index but was still highly limited in application.

Fatigue life prediction is often composed of many multiplicative, rather than additive, factors. The next logical step was to assume that the logarithm of the world is Gaussian. Then the sum of the logarithms (product of physical variables) is also Gaussian and many of its nice features can again be exploited. This was done by Wirsching (Ref 21) for fatigue of offshore structures. This approach also has limited application because of the restriction of distribution type and problem formulation.

Rackwitz and Fiessler (Ref 51) greatly expanded the applicability of probabilistic analysis when they created a numerical procedure that transforms all the random variables into uncorrelated Gaussians and then numerically estimates the probability of failure in the transformed space. They first approximated the failure region linearly and called the analysis FORM (first order reliability method). An extension to approximate the failure region with a second-order fit is called SORM (second order reliability method). Both are well described in Ref 9 and 10. With FORM/SORM there is no longer any restriction on the assumed pdf of the random variables. Also, a virtually unlimited number of random variables can be included in the analysis. Other approaches in the same vein, but using novel numerical techniques, have been developed by Wu, including the Wu/FPI algorithm (Ref 52) and the advanced mean value method (Ref 53).

The analyst using these approaches does not need to do the probabilistic analysis; that is accomplished by the computer algorithm, just as rainflow counting is no longer done by drawing drips off pagoda roofs, but is left to software subroutines. The required inputs are the distribution functions and correlations between all the random variables describing the uncertainties. The form of the problem does not matter as long as one can calculate (numerically) the state of the response (failed or not) given values for all the random variables. The numerical analysis searches the space of possible values for the region that contains combinations most likely to occur and that result in premature failure. It then solves for the probability that those combinations will occur. Some codes that perform this probabilistic analysis are marketed under the names RELAX and FPI (USA), STRUREL (Germany), and PROBAN (Norway).

Analyses programmed in the failure evaluation subroutines have been enormously varied, from simple closed-form functions to large finite-element analyses. Good examples can be found for an automotive application (Ref 11, 35, 54), for offshore structures (Ref 10, 36), and for wind turbines (Ref 12, 55, 56).

These probabilistic tools can be applied to fatigue-life and crack-growth problems in the following ways. For fatigue-life problems, one starts with a deterministic analysis capability for the time to failure. An objective function is created by defining a time to failure less than a specified target lifetime as "unsafe." The probabilistic analysis package, given the deterministic capability and the objective function, will select a set of values for all the random inputs (usually starting with the mean values) and calculate the time to failure. The directional gradient of the difference between the calculated time and the target is also determined in the space of the random variables. Various optimization methods are then used to search for the set of values of the random variables that results in a time to failure equal to the target value. The space occupied by all possible values resulting in "unsafe" time to failure is integrated to determine the total probability of the unsafe condition.

In crack-growth applications the "unsafe" condition can be defined to reflect the possibility of growing to a critical crack length between inspections (or within the component lifetime). In this case the deterministic analysis calculates the crack growth from some initial size (the distribution of which may be determined by the probability of detection characteristics of the inspection technique) until the next scheduled inspection. Probabilistic analysis is done as in the fatigue-life case. The probability that the crack has reached a critical size before the next inspection is estimated. A probability sufficiently large to cause concern means that the inspection must be scheduled earlier. Conversely, if the probability is sufficiently small, the inspection interval can be increased.

FORM/SORM and advanced mean value techniques provide more information than just the probability of failure. Importance factors are also calculated as a natural part of the analysis. Importance factors indicate the relative magnitude of the effect of each random variable on the probability of failure. Variables that could change in value throughout the assigned input distribution without significantly altering the overall probability of failure show low importance. The controlling random variables (uncertainties) are thus flagged for special attention. It is also a fairly simple task to conduct sensitivity studies, because the calculations are usually very fast. The advanced mean value method is particularly good at mapping out the probability of failure versus some parameter, such as probability of failure versus time, although any of the above-mentioned analytical approaches can be used to achieve this result.

**Simulation.** Another way to calculate the probability of premature failure is to calculate the fatigue lifetime repeatedly, using different values for the uncertain quantities in each calculation. If the values are selected at random from the distribution of possible values, the approach is called "Monte Carlo analysis" (Ref 57, 58). The probability of failure is equal to the fraction of outcomes that have shorter than desired lifetimes. Monte Carlo methods have become quite popular due to the ready availability and ease of repeated numerical analyses. However, if the probability of failure is low, which is usually the desired situation, the number of simulations required to accurately estimate the probability is very high. Depending on the desired accuracy, between 100 and 1000 failure outcomes are necessary. For low fractions of failure outcomes this translates into millions of repeated calculations. Some standard statistical software packages do offer capabilities for Monte Carlo analysis, so the investment in time can be relatively short, and with the ready availability of fast computing, simulation may be the fastest way to answer for the probability of failure. Simulation will not provide importance factors, however, unlike structural reliability methods such as FORM/SORM or the advanced mean value method. Sensitivity studies using simulation may also be so time consuming as to be prohibitive. More advanced simulation techniques have also been developed for probabilistic analysis; a good overview can be found in Bjerager (Ref 59).

## Planning and Evaluation of Fatigue Tests

Wolfgang-Werner Maennig, Department of Mechanical Engineering, Division of Material Sciences, Technische Fachhochschule Berlin (retired), Germany

---

## Introduction

PLANNING AND EVALUATION describes the scientific approach to obtaining valid measures of fatigue performance from *S/N*-type fatigue data. The need for this approach arises from fatigue scatter. If a whole *S/N* curve is based on only ten specimens, it appears well-defined and may display an obvious fatigue limit. However, as more specimens are tested, failures are discovered below the first-appearing fatigue limit. So what should the real (safe) limit be? When components are tested, fatigue performance and scatter can be even more problematic. For example, the so-called "fatigue limit" of screws is only 5 to 15% of the ultimate tensile strength with a scatter in fatigue strength at a comparable or even a bigger size. Thus errors of 100% and more are possible. For cast metals and welded structures the situation is usually worse. Small changes in the composition of materials and the heat treatment, construction, and processing of parts also can have considerable influence on fatigue strength and scatter.

This extraordinary scatter is explained by the repetition of relatively small loads, which enables weak properties of the materials to become dominant. Such properties include the local fluctuations of the composition; the different sizes and orientations of grains; the distribution and sizes of slag inclusions and of segregations; the distribution and local concentrations of solute atoms and pre-existing dislocations; tiny scratches and corrosion points at the surface; cavities, blisters, and blow holes; and microstructural defects in general. The superposition of so many weakening factors leads to the evolution of microcracks as well as macrocracks. As a result the cycles to fracture for several parts or specimens will be very different. To overcome this problem, one has either to test an unacceptably large number of specimens or to apply

a scientific approach to the planning and evaluation of the tests. This article describes the latter approach based on a determination of the probabilities for detected fracture positions within the observed range of scatter. This method leads to the evaluation of special ranges for stresses (or strains) and the cycles to fracture with well-defined probabilities of fracture suitable for design or engineering use.

## Planning and Evaluation of Fatigue Tests

Wolfgang-Werner Maennig, Department of Mechanical Engineering, Division of Material Sciences, Technische Fachhochschule Berlin (retired), Germany

### The Fatigue Diagrams

Figure 1(a) is a schematic of constant-amplitude ( $\pm S_a$ ) stress cycling about a possible mean value ( $S_m$ ) that leads to fracture of a single part or specimen after  $N$  cycles. This result is condensed to Fig. 1(b), where the tiny vertical dash on the line for the level  $S_a$  represents the life result of the one fractured specimen. Testing of  $n = 10$  specimens leads to the schematic of Fig. 1(c), which provides some idea of typical scatter. In the case of the so-called "service-load" (in which the stress amplitude is not constant), a frequently used approach is to attribute the fracture position to the highest existing amplitude  $S_a^*$  instead of to the magnitude of that amplitude from the test life or fracture point of the specimen (Fig. 2a and b). The test life of the fractured specimen might be expected at a much higher number of cycles for fracture than in the case of constant amplitude. This is a result of the many cycles with amplitudes that are smaller than  $S_a^*$ . As shown in Fig. 2(c), the scatter of  $n = 10$  specimens also will become much bigger, because the variation of the random application of the amplitudes gives an additional strong influence on life behavior. Service load programs are extremely different. Therefore it is necessary to give additional information, for example by a name that describes the program. Altering of  $S_a^*$  will be done with the other amplitudes in the same relation. The principles of planning and evaluation of fatigue tests are the same for constant amplitudes and service (variable-amplitude) load, although special load history methods are used to quantify variable-amplitude fatigue life (see the article "Estimating Fatigue Life" in this Volume).

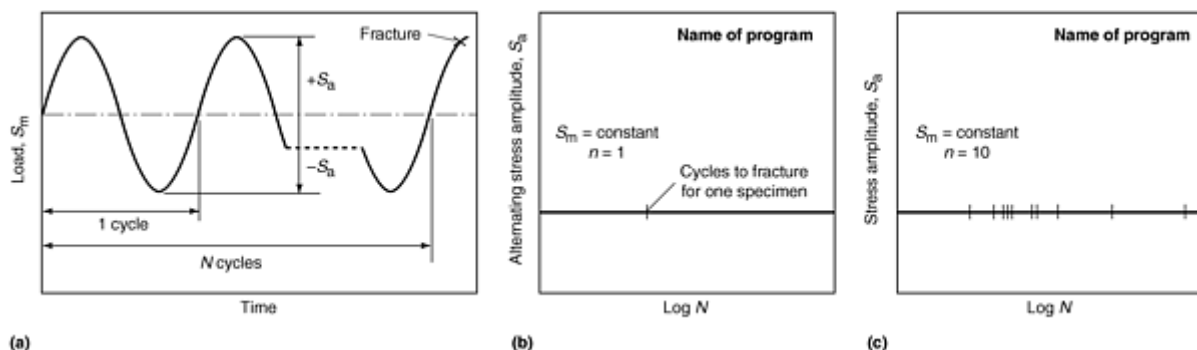

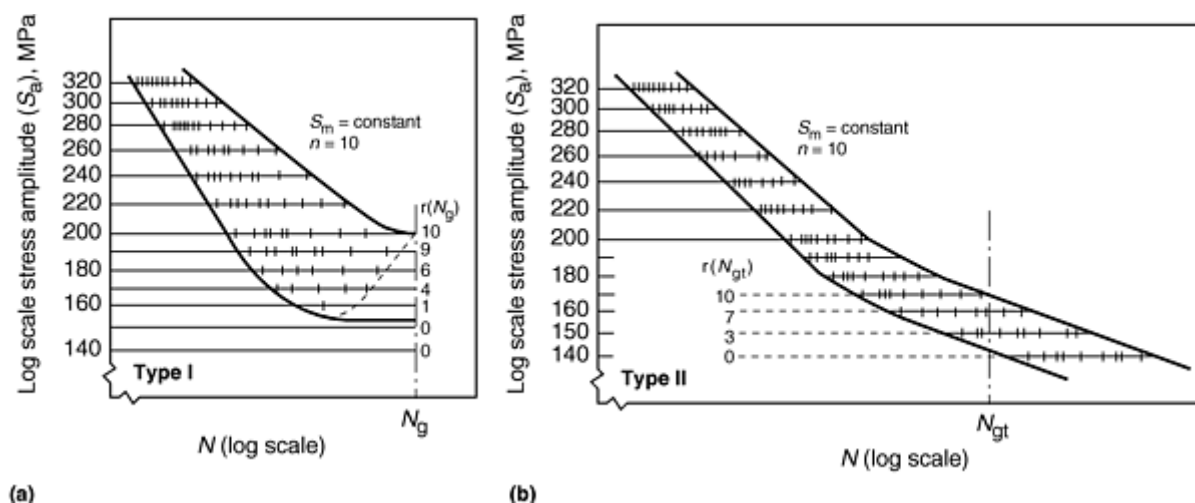

FIG. 1 SCHEMATIC OF CONSTANT-AMPLITUDE ( $S_a$ ) STRESS CYCLING ABOUT A MEAN LOAD  $S_m$ . (A) THE ALTERNATING LOAD PLOTTED VS. TIME. (B) FRACTURE FOR ONE SPECIMEN PLOTTED VS. THE NUMBER OF CYCLES,  $N$ . (C) FRACTURES FOR TEN SPECIMENS AT ONE CONSTANT LEVEL OF ALTERNATING LOAD  $S_a$  PLOTTED VS.  $N$

**FIG. 2 VARIABLE-AMPLITUDE LOADING AND SCHEMATIC OF DATA PRESENTATION. (A) ALTERNATING LOAD VARYING WITH TIME. (B) FRACTURE OF ONE SPECIMEN PLOTTED BY MAXIMUM ALTERNATING LOAD ( $S^*_A$ ) VS. NUMBER OF CYCLES,  $N$ . (C) FRACTURE OF TEN SPECIMENS PLOTTED VS.  $S^*_A$  AND CYCLES TO FAILURE**

Constant amplitudes and service load might be applied also in the form of controlled deformations instead of controlled loads, for example in the form of elongation, torsion, and bending. In strain-controlled fatigue testing, the loads are not controlled and very often will decrease. Under constant strain, the stress intensity remains constant as the crack grows; under constant load, it increases as the crack grows and therefore the rate of growth increases also. This explains the difference in life and the higher numbers of cycles for fracture in strain-controlled tests as compared to stress-controlled tests. The scatter of results, however, is the same in principle, although perhaps scatter is larger in strain-controlled fatigue tests. The principles of planning and evaluation are also the same for stress- or strain-controlled cycling.

Testing of specimens in 13 different levels of load typically leads to two types of diagrams (Fig. 3a, b) (Ref 1, 2). In the type I diagram there is no fracture below the level with the alternating load  $S_a = 160$  MPa (23 ksi), and the number of broken specimens will decrease below  $S_a = 200$  MPa (29 ksi) (Fig. 3a). The fractures appear in the range bordered by the dotted line, well separated from the greatest number of cycles ( $N_g$ ). No fractures are expected outside this dotted range; the nonfractured specimens are real survivors.  $N_g$  is a significant value for this type of diagram. In case of constant load-amplitude it is  $10^7$ , and with acceptable small errors it is  $2 \times 10^6$  for probabilities of fracture  $\cdot 10\%$  (Ref 1, 2, 3).

**FIG. 3 FATIGUE EXPERIMENTS FOR TYPES I AND II OF THE FATIGUE DIAGRAM. THE DOTTED LINE IN (A) DEMONSTRATES THE SEPARATION OF THE FRACTURES FROM THE ORDINATE IN  $N_g$ . SEE TEXT FOR DETAILS. SOURCE: REF 1, 2**

In the case of the type II diagram, all specimens will fracture below 200 MPa (29 ksi) if we cycle long enough (Fig. 3b). In this case, the performance requirements and the needed number of cycles for a technical design form a basis to choose a "technological greatest number of cycles ( $N_{gt}$ )" as a "cut off," where all fracture positions above  $N_{gt}$  are declared (by definition only) to be survivors. With this definition, there is no gap between  $N_{gt}$  and the detected fracture positions below 200 MPa. By this principal difference it is often possible to distinguish between Fig. 3(a) and 3(b) and thus the diagrams of type I and II. This distinction might become less noticeable if the lower part of the range of fractures in Fig. 3(b) has a very small slope.

A more generalized form of type I is in Fig. 4(a). The ordinate in  $N_g$  and its intersection with the shell lines of the fracture positions allows a tripartition. In the range of finite endurance all specimens will fail before  $N_g$ , in the range of infinite endurance none will fail, and in the range of transition about 50% will fail. The horizontal border between the transition region and the infinite-endurance region is the famous fatigue endurance limit (noted here as  $S_{FL}$ ). Below and to the left of the lower shell line, there are no fractures; above and to the right of the upper shell line, all specimens are fractured. The passage from no fractures to all fractures happens between the shell lines, and thus probabilities of fracture ( $P_F$ ) of 0% (1%) and 100% (99%) can be assigned to these shell lines,\* which is the object of this article. *Note:* The probability of

survival ( $P_S$ ) could also be used, but it is not advisable for two reasons. First, it demands inverse thinking in case of comparison of results. Further,  $P_S + P_F = 1$  will not hold. There remains a difference, its size depending from the number  $n$  of specimens (Ref 4).

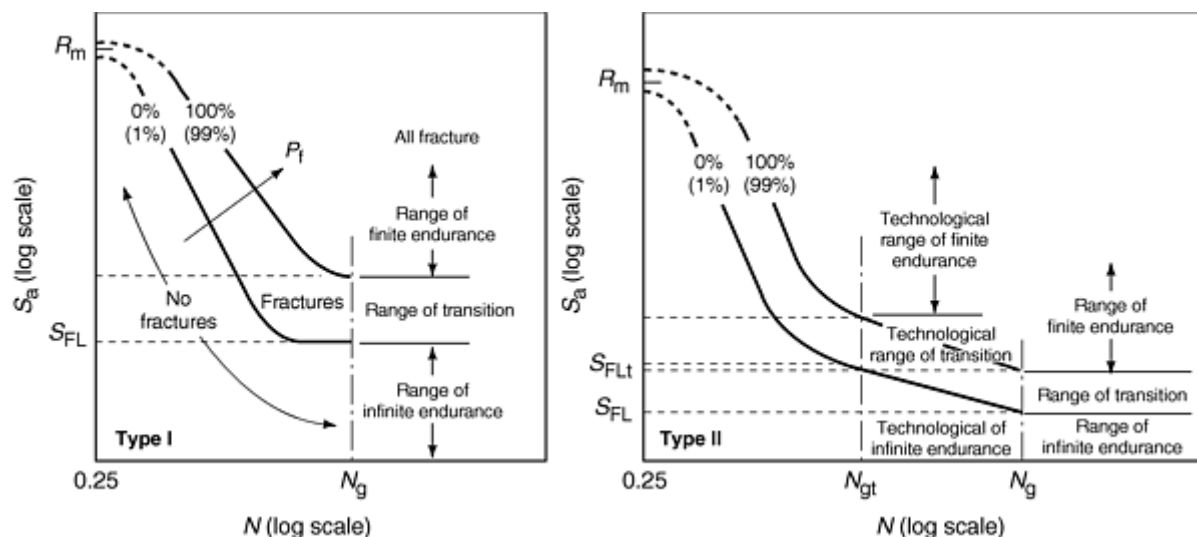

FIG. 4 RESULTS OF FATIGUE DIAGRAMS IN CONDENSED FORM AND THE TRIPARTITION OF THE TWO TYPES. SHELL LINES AT 0 AND 100% HAVE PARENTHEICAL VALUES NOTED AT (1%) AND (99%), WHICH ARE PREFERRED BECAUSE USUALLY THE NUMBER OF TEST SPECIMENS IS SMALL AND THEREFORE IT IS DIFFICULT TO HAVE MEANING 0 AND 100% VALUES. (A) TYPE I DIAGRAM. (B) TYPE II DIAGRAM

The type II fatigue diagram also has the ranges as type I (Fig. 4b), but  $N_g$  may approach  $10^{12}$  to  $10^{13}$  cycles, and a meaningful fatigue limit may be small (e.g., unnotched  $S_{FL}$  at 20 MPa for aluminum and its alloys and at 40 MPa for copper and its alloys). Such fatigue limit values have poor experimental basis because  $N_g$  is too high. Practically, tests are stopped always before  $N_g$  and thus a fatigue limit will not be found for the metals with type II diagrams although it may exist (Fig. 4b).

In the type II diagram (Fig. 4b), there is a "small-slope" part (before  $N_g$ ) that does not exist in the diagram of type I. It begins at about  $2 \times 10^6$  or  $5 \times 10^6$  cycles, ending at  $N_g$ . This is quite an interesting range for many purposes, for example cars and aircraft. According to the technical needs of the component, an  $N_{gt}$  value will be set. This again allows the tripartition of the diagram, but now into "technological (or engineering-based) ranges" of the finite endurance, infinite-endurance, and transition. Thus it becomes possible to evaluate a *technological fatigue limit* ( $S_{FLt}$ ), which is strongly dependent on the chosen  $N_{gt}$ . Therefore it is necessary to write, for example,  $S_{FLt}(10^8) = 120$  MPa (17.4 ksi) if  $N_{gt} = 10^8$ .

The general methods for estimating fracture probabilities are principally the same for both types of the fatigue diagram. From what is known today, the type I diagram belongs with the body-centered cubic metals, such as unalloyed and low-alloy steels, if not hardened; molybdenum and its alloys; probably (though not conclusively) high-alloy ferritic steels; and perhaps Al-Mg and Cu-Sn alloys in the solution-treated (not age-hardened) condition, though they belong to the face-centered cubic metals (Ref 1, 5). The type II diagram generally occurs for all face-centered cubic metals, such as aluminum and copper and its alloys (exceptions noted above); probably austenitic steels and martensitic steels; and perhaps also the hexagonal close-packed metals such as titanium alloys. The uncertainty of some of the above statements is due to poor planning and evaluation of fatigue tests in the past.

### Evaluating the Ranges of Fatigue Diagrams

There are two principal methods for evaluating fatigue curves. First, the (technological) ranges of infinite-endurance and of transition are determined separately. If a whole fatigue diagram is needed, both ranges can be joined afterward, and this is preferable on a scientific basis. More often and nearly always in engineering practice, only one range or even only one value out of one region will be needed and evaluated. The methods to do this are described in the numbered sections below.

Secondly, both ranges can be determined and evaluated all at once by using a homogenous mathematical method called the Wolfsburger Model, developed by R. Müller for Volkswagen (Ref 6). It is a very difficult mathematical procedure, and it needs, for the same level of reliability, no fewer specimens. Perhaps this is one reason why no independent data evaluation and comparison has become known. Yet it is the only model and mathematical treatment of fatigue data that allows one to calculate not only fatigue values but also first confidence intervals in a satisfactory way. Furthermore it has been used down to probabilities of fracture of only  $10^{-6}$  ( $10^{-4}\%$ ). No one other than R. Müller dared to extrapolate so far. One has to consider also that R. Müller had 500 specimens and thus gave experimental proof of the suitability of his method only down to about 0.2% probability of fracture.

### Evaluating the Range of Transition

**The Classical Way.** The classical method of evaluating the (technological) range of transition (i.e., just above the infinite-endurance range in Fig. 4) can be illustrated with the data in Fig. 3(a), where  $n = 10$  specimens were tested in seven levels of alternating load in the range of transition and below. In level  $S_a = 200$  MPa (29 ksi)  $r = 10$  specimens are broken, thus  $r = n = 10$ . This means that the level is just at the border and belongs also to the range of finite endurance. In the two lower levels  $r = 0$  had been found; we use only level  $S_a = 150$  MPa (21 ksi) and its result. The levels  $S_a = 150$  MPa and  $S_a = 200$  MPa are the most important because their evaluations indicate the smallest errors (Ref 7). In Fig. 3(a) and 3(b) obviously the probability of fracture ( $P_F$ ) rises with higher stress levels. There has been some discussion about how to calculate  $P_F$ . Theoretical studies and some comparative investigations (Ref 4) lead to:

$$\begin{aligned}
 P_F &= 100 (3R - 1)/(3N + 1) \\
 P_F(R = 0) &= 0.5P_F(R = 1) = 100/(3N + 1)
 \end{aligned}
 \tag{EQ 1}$$

where  $P_F$  is given as a percentage.

The values of  $P_F = P_F(r)$  according to Eq 1 are evaluated for each level and plotted in Fig. 5(a) arithmetically on the ordinate over the logarithmic alternating loads  $S_a$  of the levels. (This is done here only for demonstration of the logic.) The result is a curve in S-form which is usually symmetrical to the point of deflection. By use of a transformation function ( $T$ ), the S-curve is transformed into a straight line, which is convenient for extrapolation (Fig. 5b). Substantial research has been done to select the right transformation function (e.g., Ref 1, 2, 6, 8). Only two functions have been left over by these works: the Gaussian cumulative probability, which is available in the forms of Probit tables and of "probability paper" (normality paper), and the  $\sqrt[3]{\ln(P)}$  transformation. Both transformations give similar results with some minor differences. The Gaussian function has been tested often. Probability paper is easily available much more in special shops for technical drawings and papers, yet its applications by computer is more difficult. One has to either store large Probit tables or do more difficult programming. The  $\sqrt[3]{\ln(P)}$  function is not only simple for the computer but can also be easily applied on hardcopy tables and graphs.

**FIG. 5 THE WAY OF EVALUATING THE (TECHNOLOGICAL) RANGE OF THE TRANSITION REGION. (A) ARITHMETIC PROBABILITIES VS. ALTERNATING LOAD FOR THE TYPE I DIAGRAM IN FIG. 3(A). (B) TRANSFORMATION OF THE DATA IN (A) BY THE TRANSFORMATION  $T$  CONVERTS THE CURVED LINE IN (A) INTO A STRAIGHT LINE ON A GAUSSIAN PROBABILITY SCALE FOR THE TYPES I AND II DIAGRAMS IN FIG. 3(A) AND 3(B).**

A sample calculation using the classical method in the case of a Type I diagram is shown in Table 1, where results are implemented into Fig. 5(a) and 5(b). A straight line allows the evaluation of alternating loads with defined probabilities. In the example of Fig. 5(b),  $S_{FL1} = 147.2$  MPa and  $S_{FL99} = 211.3$  MPa for probabilities of fracture at 1 and 99%.  $S_{FL10} = 159.1$  MPa and  $S_{FL90} = 195.3$  MPa for probabilities of fracture at 10 and 90%. An additional point is evaluated at  $S_{FL0.1} = 138.5$  MPa.

**TABLE 1 CALCULATION OF THE PROBABILITIES OF FRACTURE IN THE RANGE OF TRANSITION FOR THE TYPE I FATIGUE DIAGRAM ACCORDING TO FIG. 3(A) AND EQ 1**

ALTERNATING LOAD, MPA	$R$	$(3R-1)/(3N+1)$	$P, \%$
200	10	29/31	<b>93.55</b>
190	9	26/31	<b>83.9</b>
180	6	17/31	<b>54.8</b>
170	4	11/31	<b>35.5</b>
160	1	2/31	<b>6.45</b>
<b>150</b>	<b>0</b>	<b>1/31<sup>(A)</sup></b>	<b>3.23</b>

(A)  $P(R = 0) = 0.5P(R = 1)$

Which of these values should be used for engineering? The size of scatter in the range of transition can be described as a line or by two or more points. Thus a value such as  $S_{FLx}$  alone is not useful. Two materials might have the same value for  $S_{FLx}$  and might behave very differently (see "Presentation and Comparison of Results" in this article). Theoretically each combination of two points of the straight line is sufficient. It is only convention to pair  $S_{FL10}$  with  $S_{FL90}$  and  $S_{FL1}$  with  $S_{FL99}$ .

The  $S_{FL10}$  value is sometimes requested in industrial standards, and the ratio  $S_{FL90}/S_{FL10}$  is in this case a good description for the scatter of the distribution. The  $S_{FL1}$  value usually is preferred as the lower limit for the range of transition and thus for a good approximation of  $S_{FL}$  itself. The ratio  $S_{FL99}/S_{FL1}$  is also a good description of not only the scatter of the distribution but also the size (or scatter range) of the transition region. This can be seen easily from the experimental results of Fig. 3(a).

The probability paper (of Fig. 5(b)) also allows determinations of values much closer to 0 and 100% probability of fracture (e.g.,  $S_{FL0.1}$  and  $S_{FL99.9}$  or even  $S_{FL0.0001}$  and  $S_{FL99.9999}$ ) because the paper is not limited in both directions. The Gaussian normal distribution and (in this case) the Gaussian cumulative normal distribution obviously is only a very good technical approximation to the practical distribution in the range of transition. Theoretically it cannot be valid because this would mean  $S_{FL0} = 0$  and  $S_{FL100} = \infty$ . Both results are unacceptable on the ground of experience. In fact, the Gaussian distribution is almost never valid strictly in theory but is often good practically. The function  $\sqrt{\ln(P)}$  is limited at  $P = 100\%$  and unlimited for  $P \rightarrow 0$ .

It is also necessary to discuss whether  $S_{FL0.1}$  is perhaps a better approximation of  $S_{FL} = S_{FL0}$  than  $S_{FL1}$ . No scientific investigation of this point is known. Indeed, it is not known how the results of Fig. 3(a) and 5(b) would be altered if hundreds of specimens were tested in each level instead of only ten. It is only customary to use  $S_{FL1}$ . In Fig. 5(b), it gives a satisfying value also if one compares with Fig. 3(a). The remaining 1% probability of fracture gives a basis for protection against the risks from employing too small a number of specimens and the resulting uncertainty. Such values are used in the calculation of ball bearing life, for example.

The evaluation of the range of transition in a type II diagram (Fig. 3b) is shown in Table 2 and in Fig. 5(b) for the chosen  $N_{gt}$  according to Fig. 3(b).

**TABLE 2 CALCULATION OF THE PROBABILITIES OF FRACTURE IN THE TECHNOLOGICAL RANGE OF TRANSITION FOR TYPE II DIAGRAM ACCORDING TO FIG. 3(B) AND EQ 1**

ALTERNATING LOAD, MPA	$R$	$(3R-1)/(3N+1)$	$P, \%$
170	10	29/31	<b>93.55</b>
160	7	20/31	<b>64.5</b>
150	3	8/31	<b>25.8</b>
<b>140</b>	<b>0</b>	<b>1/31<sup>(A)</sup></b>	<b>3.23</b>

(A)  $P(R = 0) = 0.5P(R = 1)$

In the classical way of evaluating the (technological) range of transition, a minimum of ten specimens should be tested in each level of alternating load. Basic statistical laws and a bit of experience (Ref 1, 2, 9) suggest that the minimum number of specimens should be increased if the range of the transition region or the ratio  $S_{FL99}/S_{FL1}$  becomes bigger. The  $m$  values in Table 3 give a first-order estimate of the needed numbers. The number of levels should be about 4. This allows some correction of the statistical influence of the small number of specimens, as has been done in Fig. 5(b) for type I. Preferably there should be an upper level with  $r$  near to  $n$  and a lower level with  $r$  near to zero. This gives the best results because the possible errors become smallest (Ref 4, 7).

**TABLE 3 VALUES  $D$  AND  $M$  FOR USE WITH THE BOUNDARY TECHNIQUE**

FACTOR	NOTCHED SPECIMEN	SMOOTH SPECIMEN	SIMPLE PARTS	PARTS LIKE BOLTS	COMPLICATED PARTS, THE FORM:	
					WELL DEFINED	POORLY DEFINED
$D$	0.05-0.15	0.1-0.3	0.2-0.4	0.4-1.2	0.4-1-?	<b>0.6-?</b>
$M$	<b>1-1.2</b>	<b>1-1.7</b>	<b>1.4-2</b>	<b>2-3.2-?</b>	<b>2.2-3.2-?</b>	<b>2.2-?</b>

Note:  $d$  gives an estimation of the size of the (technological) range of the transition region;  $m$  is a multiplying factor to apply on 10 and gives  $n$ , the number of specimens needed in one level ( $m = 2, n = 20$ ).

**Quick Solutions.** There are problems in arriving at a firm evaluation using the classical method. First and mainly, the above-described recommendations for the number of levels and specimens in the levels are high, too high in many practical cases. Too much testing time would be needed. Second, the classical way does not give a method for positioning the needed levels. For example, the tested level 140 MPa in Fig. 3(a) could not be evaluated and thus would become a waste of time and money. Three methods try to give some help on this problem.

**The two-point strategy (Ref 10)** tries to establish two levels close to 50% probability of fracture and to reach a better estimation of  $S_{FL50}$ . The first and main objection is that one single point in the range of transition cannot give its description. Second, levels close to 50% probability will have the biggest possible errors out of statistical laws. This can be appreciated in every table of binomial or hypergeometrical distributions (e.g., Ref 7). Thus advantage from establishing two levels near 50% probability is even more doubtful. Third, nobody needs values with 50% probability of fracture really. Finally, this strategy contains no rule to find the two levels.

**The staircase method (Ref 11, 12, 13)** won a lot of attention when it was introduced because it includes a way to find the wanted levels. However, it concentrates itself around the 50% level of probability of fracture. In addition, in the description based on Ref 11, 12, 13, only half of the tested specimens are used for evaluation, an unbearable waste. In Ref 14 the staircase method was studied comparatively. It was proved that the results depend very strongly on the number of specimens and the properly chosen step-width. Without pretests, 20 specimens were found to be necessary for the evaluation of a fracture probability of 50%, 40 specimens for the probabilities 10 and 90%, and 50 specimens for the probabilities 1 and 99%. This means that the staircase method is less suitable than other known methods. An attempted improvement (Ref 15) brought little or no advantage. Finally, it is difficult to choose the correct step-width.

The Boundary Method (Ref 4, 7, 9, 16, 17, 18) uses only two levels and tries to place them near the lower and upper borders of the (technological) range of the transition. According to Fig. 5(b) two such levels are sufficient theoretically. Practical comparative studies (Ref 4) and theoretical studies (Ref 7) have proved the suitability of the method. It leads to conservative values. For example, the values  $S_{FL1}$  and  $S_{FL10}$  will be preferably too low if there are deviations. If the values happen to be too big, the deviations will be relatively smaller for theoretical reasons. Likewise, values such as  $S_{FL90}$  and  $S_{FL99}$  will become more preferably too high and therefore safer. Smaller deviations are combined with values too low.

The boundary technique has been tested with success in several laboratories (e.g., Ref 9, 18). Today it is in use worldwide. Even the classical evaluation of the (technological) scatter range of the transition region is often begun with this method. Additional levels of alternating load testing can be well placed afterward. In Ref 9 the Boundary Technique proved best regarding the needed number of specimens, although by an error the most worthy levels of alternating load had not been used for that method.

The boundary technique starts by testing one randomly chosen specimen at any level of alternating load (see Fig. 6). In the case of a type I fatigue diagram it is a private recommendation to use a load near to  $R_{P0.001}$ , the unidirectional tensile stress that yields a plastic deformation of 0.001%. Tests will then be done until  $N = N_g$  or  $N_{gt}$ . If no fracture happens before this limit, the next specimens will be tested at higher levels raised stepwise until the opposite event happens, that is, fracture before  $N_g$  or  $N_{gt}$ . The stress level with the first opposite event becomes the first fully tested level. This means that nine additional specimens have to be tested. If the first tested specimen fractures before  $N_g$  or  $N_{gt}$ , the next specimens will be tested stepwise on lower levels of alternating load, until the opposite event happens: no fracture!

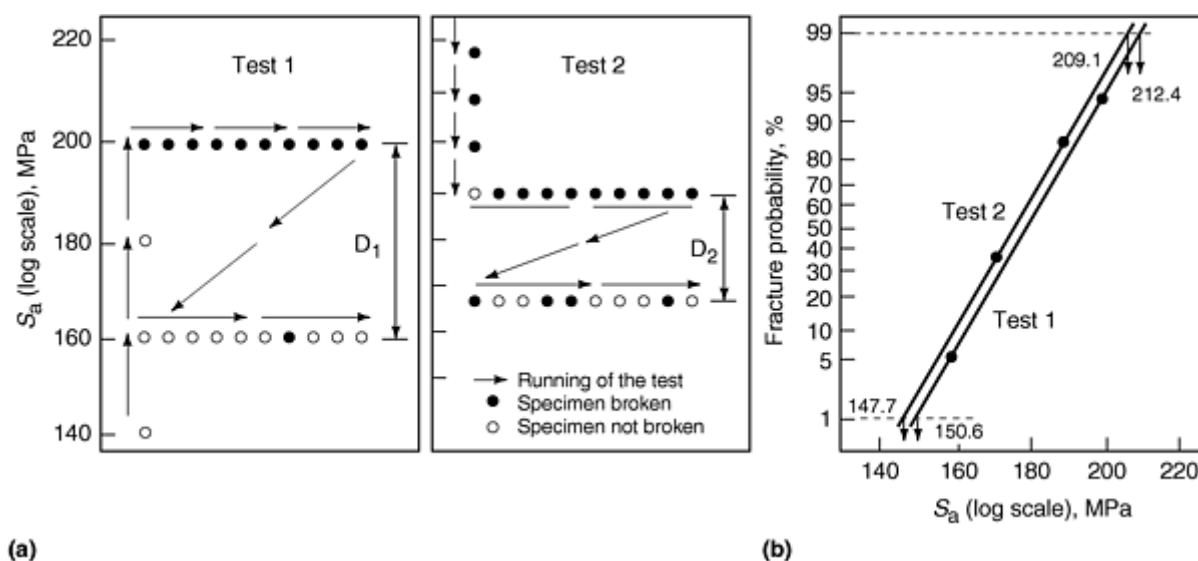

FIG. 6 THE WAY OF (A) RUNNING AND (B) EVALUATING TWO TESTS USING THE BOUNDARY TECHNIQUE

For the second level of alternating load, the distance  $D$  (see Fig. 6) has to be estimated. It is given by:

$$\begin{aligned} D &= (1 - R/N) \cdot D \cdot S_A \text{ IF } R < 0.5N \\ D &= (- R/N) \cdot D \cdot S_A \text{ IF } R > 0.5N \end{aligned} \quad (\text{EQ 2})$$

where  $S_a$  is the alternating load of the first tested level and  $d$  is the estimated size of the (technological) range of the transition region according to Table 3.

In Fig. 6, two tests are presented that refer to Fig. 3(a) and its results. Test 1 was started too low. Raising in big steps led to the first opposite event: fracture in  $S_a = 200$  MPa. A total of  $n = 10$  specimens were tested there, and all fractured. Obviously the full range of transition had been passed during the tracing. Equation 2 with  $d = 0.2$  out of Table 3 led to the second level,  $S_a = 160$  MPa, with one fractured specimen out of ten. Is it possible that a level of 200 MPa is already too high, deep in the region of finite endurance? No, it is not. According to Fig. 3(a), the highest fracture position is close to

$N_g = 10^7$ . Further the next lower level had in the minimum the one tested specimen with "no fracture," and the level at 160 MPa had one fracture in ten specimens. As mentioned above, the distribution in the range of transition is symmetric. One has to conclude that the level 200 MPa is just the counterpart of the level 160 MPa, each of them close to the borders of the range, providing a good comprehension of the range of the transition region. Evaluation of test 1 in Fig. 6 under the use of Eq 1 gives values for  $S_{FL1}$  and  $S_{FL99}$  that are close to those in Fig. 5(b).

Test 2 was started too high, and the alternating load had to be lowered in the next levels. The first opposite event, no fracture, happened at  $S_a = 190$  MPa, which thus became the first tested level. Yet no other specimen survived,  $r = 9$ . This time  $d = 0.1$  was taken and according to Eq 2 the second and lower level became  $S_a = 170$  MPa with  $r = 4$ .

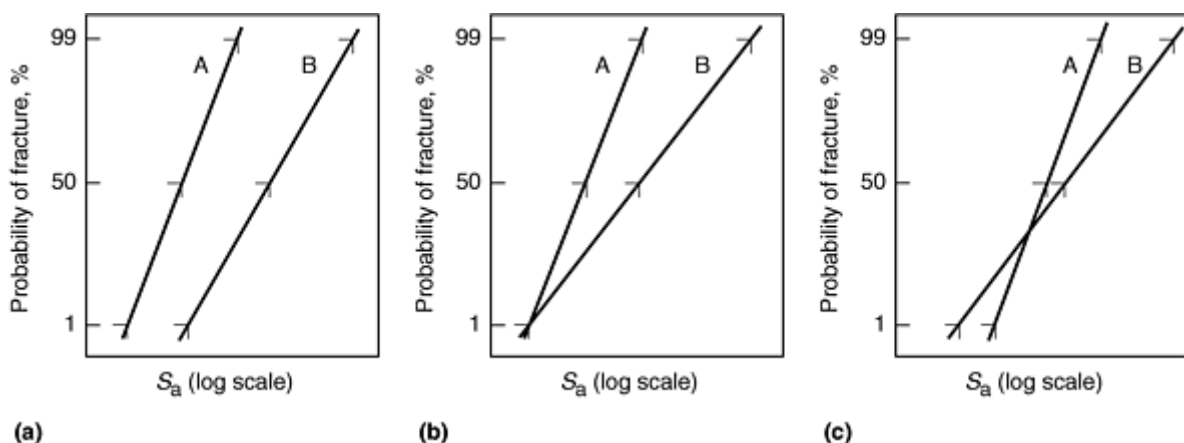

Figure 6 shows excellent results compared with Fig. 5(b). Yet normally Fig. 5(b) is not known, because it is the intention of the Boundary Technique to avoid such expensive investigations. Therefore, it is not advisable to trust the results of test 2 because  $r = 4$  or  $P_F = 35.5\%$  in the lower level, and the possible errors out of principal statistical laws are too big (Ref 7). A third level at  $S_a = 150$  MPa should be tested if specimens are still available. Generally, levels with 26 to 74% probability of fracture should be mistrusted. The possible adverse effect of testing such levels is bigger as the adjacent level becomes more distant from the wanted value  $S_{FLx}$  (Ref 4, 7).

If in tests 1 and 2 the value  $d = 0.3$  had been taken for estimation of  $D$ , the second and lower level would have been 140 MPa with  $r = 0$ , according to Fig. 3(a). Use of that and evaluation would have given a fatigue limit or  $S_{FL1}$  too low and therefore too safe. This explains why practitioners tend to take bigger values for  $d$  instead of values that are too small if the second level is the lower one. The situation is different if the second level is the upper one. A big value of  $d$  might result in placing the upper level too high, outside the (technological) range of transition, already clearly in the (technological) range of finite endurance. This would influence the evaluation of the  $S_{FLx}$  values, although not strongly. In Ref 19 different fatigue diagrams were studied for this problem. It was proven that significant deviations will be obtained only if the biggest number of cycles in that upper level is smaller than  $10^6$ .

Tests 1 and 2 needed two and three tracing specimens, which could not be included in the evaluation. This is a good average; in practice one to five will be necessary. Thus a minimum of 25 specimens should be provided for use with the boundary technique. Ten further specimens are advisable for a case that demands a third level, such as test 2.

If the (technological) range of transition is very large, more specimens have to be prepared for each level of alternating load, as suggested by general statistical laws and some experience (e.g., Ref 9). A first approximation is given with the values  $m$  in Table 3 from Ref 1. Whether a test is started too high or too low has no influence on the results of the evaluation. Yet starting too high usually results in time savings, because all tracing specimens will fracture before  $N_g$  or  $N_{gt}$ . That might mean a difference of one or more days.

**Presentation and Comparison of Results.** In the rare scientific cases, the evaluation results for the (technological) range of transition can be transferred into graphs such as Fig. 4(a) and 4(b) with numeric scales. This gives the best information to those who have no special training in fatigue. Discussion and comparison of results by using only one value, for example  $S_{FL1}$ , should be avoided. For  $S_{FL50}$  it should be forbidden. Experienced engineers use diagrams that give full information, such as Fig. 7.

**FIG. 7 PRINCIPAL POSSIBILITIES FOR THE COMPARISON OF TWO CONDITIONS, A AND B, IN THE (TECHNOLOGICAL) RANGE OF THE TRANSITION. (A) CONDITION B IS BETTER THAN CONDITION A. (B AND C) CONDITION A IS BETTER THAN CONDITION B. SEE TEXT FOR DETAILS.**

In the case of Fig. 7(a), obviously condition B is better because all its values are to the right of those of condition A. The slightly bigger size of the range of transition will not alter this result. In the case of Fig. 7(b), the values  $S_{FL99}$  and  $S_{FL50}$  of condition B are bigger than those of condition A. The values  $S_{FL1}$  are the same. Nevertheless, an experienced engineer will prefer condition A. First, there is no intention to sell parts, engines, or aircraft if they have probabilities of fracture bigger than 1%. Therefore the bigger values  $S_{FL50}$  and  $S_{FL99}$  of condition B are not preferable; all values below  $S_{FL1}$  or below 1% of condition B are worse than those of condition A. Second, and even more important, the reliability of the lines has to be considered. If both had been evaluated with the same number of specimens and even with similarly well-placed levels of alternating load, condition B is less reliable because in this condition the size of the range of transition is just twice as big as in condition A (which might be expressed by calculating for both conditions the ratios  $S_{FL99}/S_{FL1}$ ). In order to obtain the same reliability one has to increase the number of tested specimens in condition B with a multiplying factor:  $(\text{size range B}/\text{size range A})^{0.5} = 2^{0.5} = 1.4$  from general statistical laws. If the number of specimens was  $n = 10$  in the levels of condition A, those for condition B have to be raised to  $n = 14$  afterward. Having done that, a new comparison might be started.

In the case of Fig. 7(c), the lines for A and B have an intersection at about 35% probability of fracture. This means that condition B will lead to fractures at lower alternating loads than condition A below 35%. This is unbearable; thus, condition B is worse. Additionally, in condition B the range of transition is again twofold bigger.

Neglecting these simple rules has already brought serious consequences. Often comparisons have been done by using only the values  $S_{FL50}$ , or perhaps only poor approximations to that, because no adequate planning had been done. On the basis of  $S_{FL50}$  values, condition B always would be better in Fig. 7. One famous example for such a consequence is the so-called *geometrical size effect*. It means that bigger (longer and/or larger-diameter) parts have smaller fatigue values than smaller parts, even if the same material has been used. Figure 7(b) gives an exact description of the situation that will occur if we take condition A for bigger parts and condition B for the smaller ones. Of course, if one concentrates the material of several small parts into a big part, one also concentrates its faults (e.g., inclusions). Thus, it becomes very unlikely that bigger parts will have so small and few faults that fractures will happen at big alternating loads. The line for condition A becomes steeper and the size of the range of transition becomes smaller. Yet there is still the largest defect, which has the largest consequence of fatigue life and has to be in one of the many smaller parts as well as in one of the few bigger parts. Thus, the lower border of the range of transition has to be the same for both conditions A and B. According to Ref 20 the two conditions meet at about 1%.\*\* Or, there is no geometrical size effect if one does qualified investigations and evaluations.

## Evaluation of Finite-Endurance Range

Evaluation of the range (Fig. 4a) or the technological range (Fig. 4b) of finite endurance is similar to that for the transition region. However, each level of alternating load is evaluated separately for the finite-endurance region. There are also some additional problems. Usually the distribution is not symmetrical about the point of inflection, and therefore it is problematical to apply symmetrical  $T$  functions for transformation. This means that the experimental values usually fit less well on a straight line for regression. Further, it is not good practice to use functions for estimating the probabilities that are associated with the transformation functions theoretically. The possible influence of the probability functions should be used to correct the suitability of the transformation functions.

Many investigations have been made of this point (e.g., Ref 1, 2, 4, 8, 16, 17). For example, 56 different data groups in Ref 8 were used to test three transformation functions and 10 probability functions in all possible combinations.

According to Ref 8, the  $\sqrt[3]{\ln(P)}$  transformation function and the Gaussian cumulative normality distributions (Probit function, probability paper) are suitable. For the estimation of the probabilities, the functions  $P_F = (i - 0.3)/(n + 1)$  and  $P_F = (i - 0.417)/(n + 0.166)$  were best. In this case,  $i$  is the order number of the fractured specimens. The functions  $(i - 0.535)/(n - 0.07)$ ;  $(i - 0.375)/(n + 0.25)$ ;  $(2i - 1)/2n = (i - 0.5)/n$ ; and  $(3i - 1)/(3n + 1)$  were nearly as good, the first of them being the best in that group.

**General Rules.** The needed number of specimens in one level is given by (Ref 1):

$$\begin{aligned}
N &= 10 \text{ IF } N_{\text{MAX}}/N_{\text{MIN}} \cdot 10:1 \\
N &= 15 \text{ IF } 10:1 \cdot N_{\text{MAX}}/N_{\text{MIN}} \cdot 30:1 \\
N &= 20 \text{ IF } N_{\text{MAX}}/N_{\text{MIN}} \cdot 30:1
\end{aligned}
\tag{EQ 3}$$

The number of needed levels of alternating load is determined by the rule that the median  $P_{50}$  with 50% probability of fracture should not shift from one level to the other more than:

$$\begin{aligned}
\varphi &= \sqrt[2]{10} = 3.16 \text{ FOR ENGINEERING DECISIONS,} \\
\text{OR } \varphi &= \sqrt[3]{10} = 2.16 \text{ FOR HIGH RELIABILITY OR SMALL CONFIDENCE INTERVALS}
\end{aligned}
\tag{EQ 4}$$

Yet increasing the number of specimens in the levels increases the reliability more than lowering the shift (Ref 2). The positioning of a second level after having evaluated a first one is made easy by using the sufficiently exact equations:

$$\begin{aligned}
N_{50} &= C \cdot S_A^{-K} \\
(N_{50/2}/N_{50/1}) &= (S_{A1}/S_{A2})^K
\end{aligned}$$

and with Eq 4:

$$S_{A2}/S_{A1} = [\sqrt[2]{\varphi}]^{-1}
\tag{EQ 5}$$

where  $K$  is a value for the slope of the range of finite endurance (see Fig. 11). With some experience with  $K$  and Table 4 it is possible to choose  $S_{A2}/S_{A1}$  at once. If there is no experience at all, one might start with  $6 \leq K \leq 9$ , preferably with the higher values. The latter will lead to smaller distances of levels. After having the results of two levels one is able to calculate a more correct value using:

$$K = (\text{LOG } N_{50/1} - \text{LOG } N_{50/2}) / (\text{LOG } S_{A2} - \text{LOG } S_{A1})
\tag{EQ 6}$$

**TABLE 4 VALUES OF  $S_{A2}/S_{A1}$  VARYING WITH  $K$  AND  $\varphi$**

DECADE	$\varphi$	$K$								
		4	5	6	7	8	9	10	11	12
1/2	3.16	0.750	0.796	0.825	0.848	0.866	0.880	0.892	0.902	<b>0.908</b>
1/3	<b>2.16</b>	<b>0.826</b>	<b>0.858</b>	<b>0.880</b>	<b>0.896</b>	<b>0.909</b>	<b>0.918</b>	<b>0.926</b>	<b>0.933</b>	<b>0.938</b>

Note:  $S_{A2}$  is the lower level.

In practical work, three different tasks have to be done. First, the (technological) range of finite endurance has to be determined for a given field. Second, the alternating load has to be determined for a given number of cycles and to a given probability. Finally, at a given level of alternating load, the range of fractures has to be determined with caution in terms of statistical safety.

**Evaluation of the Range of Finite Endurance, Comparison of Results, and Conjunction with the Range of the Transition Region.** With only three additional levels of alternating load, the range of finite endurance will be evaluated with a shift of 1/2 decade for  $N_{50}$ . It is described above that the level 200 MPa was determined for the onset of the range of the transition region. All specimens had fractured before  $N_g = 10^7$ . The observed numbers of cycles were (in  $10^3$ ): 723, 1403, 200, 7002, 560, 1963, 408, 4211, 1570, 880. The biggest and smallest numbers are  $7002 \times 10^3$  and  $200 \times 10^3$  cycles; therefore  $N_{\text{max}}/N_{\text{min}}$  are about 35:1 · 30:1. This means that ten additional specimens had to be tested in the same level according to Eq 3. This is very risky, because one or two specimens might not fracture if we regard Fig. 5(b) as having established  $S_{FL99} = 211.3$  MPa. Thus, additional specimens in the level 200 MPa might become a waste in our task to determine the range of finite endurance. Yet we will use the existing results to estimate the position of the next level. We arrange the results according to the number of cycles, assigned order numbers  $i$ , and calculate:

$$P_F = 100(I - 0.417)/(N + 0.166)$$

where  $P_F$  is given as a percentage. For  $S_a = 200$  MPa:

<b><i>I</i></b>	<b><i>N</i></b>	<b><i>P</i>, %</b>
1	$200 \times 10^3$	<b>5.73</b>
2	$408 \times 10^3$	<b>15.6</b>
3	$560 \times 10^3$	<b>25.4</b>
4	$723 \times 10^3$	<b>35.2</b>
5	$880 \times 10^3$	<b>45.1</b>
6	$1403 \times 10^3$	<b>54.9</b>
7	$1570 \times 10^3$	<b>64.8</b>
8	$1963 \times 10^3$	<b>74.6</b>
9	$4211 \times 10^3$	<b>84.4</b>
<b>10</b>	<b><math>7002 \times 10^3</math></b>	<b>94.3</b>

The results are plotted in Fig. 8. By a regression line the cycles  $N_1$ ,  $N_{10}$ ,  $N_{50}$ ,  $N_{90}$ , and  $N_{99}$  with the probabilities of fracture 1, 10, 50, 90, and 99% are evaluated as follows:  $N_1 = 108 \times 10^3$ ,  $N_{10} = 302 \times 10^3$ ,  $N_{50} = 1157 \times 10^3$ ,  $N_{90} = 4381 \times 10^3$ , and  $N_{99} = 13,570 \times 10^3$  (over  $10^7$ !). We want a shift of a half decade and estimate  $K = 11$ . According to Table 4, the upper level is thus  $S_{a1} = S_{a2}/0.902 = 200/0.902 = 221.7$  MPa and 220 MPa will be used. The tests in this level with ten specimens yielded the following results for  $S_a = 220$  MPa ( $N$  in  $10^3$ ):  $N = 4257$  (specimen 1),  $N = 879, 799, 1388, 271, 308, 2073, 227, 347$ , and  $N = 669$  (specimen 10). For this case,  $N_{\max}/N_{\min} = 4257/227 = 19/1$ , and we have to test five other specimens according to Eq 3. Results for the additional five specimen tests for  $S_a = 220$  MPa ( $N$  in  $10^3$ ) are:

<b>SPECIMEN</b>	<b><i>N</i></b>
11	<b><math>1154 \times 10^3</math></b>
12	<b><math>393 \times 10^3</math></b>
13	<b><math>250 \times 10^3</math></b>
14	<b><math>196 \times 10^3</math></b>
<b>15</b>	<b><math>548 \times 10^3</math></b>

Indeed, the range became a bit bigger because  $N_{\min} = 196$  now. For the experimental ranking order, the probabilities  $P$  turn out as follows (with  $S_a = 220$  MPa):

<b><i>I</i></b>	<b><i>N</i></b>	<b><i>P</i>, %</b>
1	$196 \times 10^3$	<b>3.8</b>
2	$227 \times 10^3$	<b>10.4</b>
3	$250 \times 10^3$	<b>17</b>
4	$271 \times 10^3$	<b>23.6</b>
5	$308 \times 10^3$	<b>30.2</b>
6	$347 \times 10^3$	<b>36.8</b>
7	$393 \times 10^3$	<b>43.4</b>
8	$548 \times 10^3$	<b>50</b>

9	$669 \times 10^3$	<b>56.6</b>
10	$799 \times 10^3$	<b>63.2</b>
11	$879 \times 10^3$	<b>69.8</b>
12	$1154 \times 10^3$	<b>76.4</b>
13	$1388 \times 10^3$	<b>83</b>
14	$2073 \times 10^3$	<b>89.6</b>
<b>15</b>	<b><math>4257 \times 10^3</math></b>	<b>96.2</b>

Drawing of the regression line gives  $N_1 = 76 \times 10^3$ ,  $N_{10} = 187 \times 10^3$ ,  $N_{50} = 560 \times 10^3$ ,  $N_{90} = 1819 \times 10^3$  and  $N_{99} = 4519 \times 10^3$  cycles (Fig. 8). With Eq 6 we control  $K$ :

$$K = (\text{LOG } 1157 - \text{LOG } 560)/(\text{LOG } 220 - \text{LOG } 200) = 0.3151/0.0414 = 7.6$$

Thus, the first estimation is seen to be wrong; therefore, we take  $K = 8$ . By means of Table 4 and Eq 5 this leads to the next level of alternating load, namely 254 MPa; 250 MPa is taken with results as follows ( $S_a = 250$  MPa):

<b><i>I</i></b>	<b><i>N</i></b>	<b><i>P, %</i></b>
1	$115 \times 10^3$	<b>5.7</b>
2	$129 \times 10^3$	<b>15.6</b>
3	$169 \times 10^3$	<b>25.4</b>
4	$178 \times 10^3$	<b>35.2</b>
5	$230 \times 10^3$	<b>45.1</b>
6	$271 \times 10^3$	<b>54.9</b>
7	$280 \times 10^3$	<b>64.8</b>
8	$305 \times 10^3$	<b>74.6</b>
9	$326 \times 10^3$	<b>84.4</b>
<b>10</b>	<b><math>568 \times 10^3</math></b>	<b>94.3</b>

In this case,  $N_{\max}/N_{\min} < 10/1$  and we need no further specimens. Evaluation by a regression line gives  $N_1 = 65 \times 10^3$ ,  $N_{10} = 114 \times 10^3$ ,  $N_{50} = 230 \times 10^3$ ,  $N_{90} = 464 \times 10^3$ , and  $N_{99} = 831 \times 10^3$ , and the values are plotted in Fig. 8. They call for renewed control of  $K$ :

$$K = (\text{LOG } 560 - \text{LOG } 230)/(\text{LOG } 250 - \text{LOG } 220) = 0.3865/0.0555 = 7.0$$

The next higher level, according to Eq 5 and Table 4, is  $250/0.848 = 295$  MPa. At this level of alternating load the results were:

<b><i>I</i></b>	<b><i>N</i></b>	<b><i>P, %</i></b>
1	$59 \times 10^3$	<b>5.7</b>
2	$80 \times 10^3$	<b>15.6</b>
3	$90 \times 10^3$	<b>25.4</b>
4	$98 \times 10^3$	<b>35.2</b>
5	$100 \times 10^3$	<b>45.1</b>

6	$107 \times 10^3$	54.9
7	$117 \times 10^3$	64.8
8	$128 \times 10^3$	74.6
9	$158 \times 10^3$	84.4
10	$177 \times 10^3$	94.3

The evaluation by a regression line gives the values  $N_1 = 46 \times 10^3$ ,  $N_{10} = 67 \times 10^3$ ,  $N_{50} = 105 \times 10^3$ ,  $N_{90} = 165 \times 10^3$ , and  $N_{99} = 243 \times 10^3$  cycles. Altogether with 35 specimens the range for the finite endurance has been determined between  $46 \times 10^3$  and  $4519 \times 10^3$  cycles.

**FIG. 8** EVALUATION OF THE LEVELS OF ALTERNATING LOAD 220, 250, AND 295 MPa IN THE RANGE OF THE FINITE ENDURANCE. THE LEVEL 200 MPa BELONGS AS WELL TO THE RANGE OF THE FINITE ENDURANCE AS TO THE RANGE OF THE TRANSITION. IT WAS EVALUATED PREFERABLY FOR DETERMINATION OF  $N_{50}$  AND ESTIMATION OF THE POSITION OF THE NEXT LEVEL 220 MPa, ALTHOUGH NOT ENOUGH SPECIMENS WERE TESTED.

The four regression lines in Fig. 8 have different slopes. That happens often and explains why the estimation of the expected shift in Eq 5 is related to the median value,  $N_{50}$ .

The presentation of the ranges of finite endurance is done by drawings such as Fig. 3(a) and 3(b) and usually in conjunction with the range of transition also, if it has been determined. This is done in Fig. 9. Obviously the 1, 10, 90, and 99% points in the range of finite endurance are not very good on regression lines. This is quite typical of that range and results from the small number of specimens at each level, which is not big enough to compensate for the strong statistical influence. The regression lines for 1, 10, 90, and 99% give some correction toward the population. No scientific study has yet allowed correction for whole ranges of finite endurance. It exists only for single levels (see below). Out of personal experience the following recommendations are offered: The number of specimens according to Eq 3 is already a minimum, good enough for clean metals such as aluminum- or copper-base alloys or clean steels, but it may be scanty for lower-quality carbon steel (as in this case), and quite probably it is not sufficient for cast metals, welded structures, and service-load conditions.

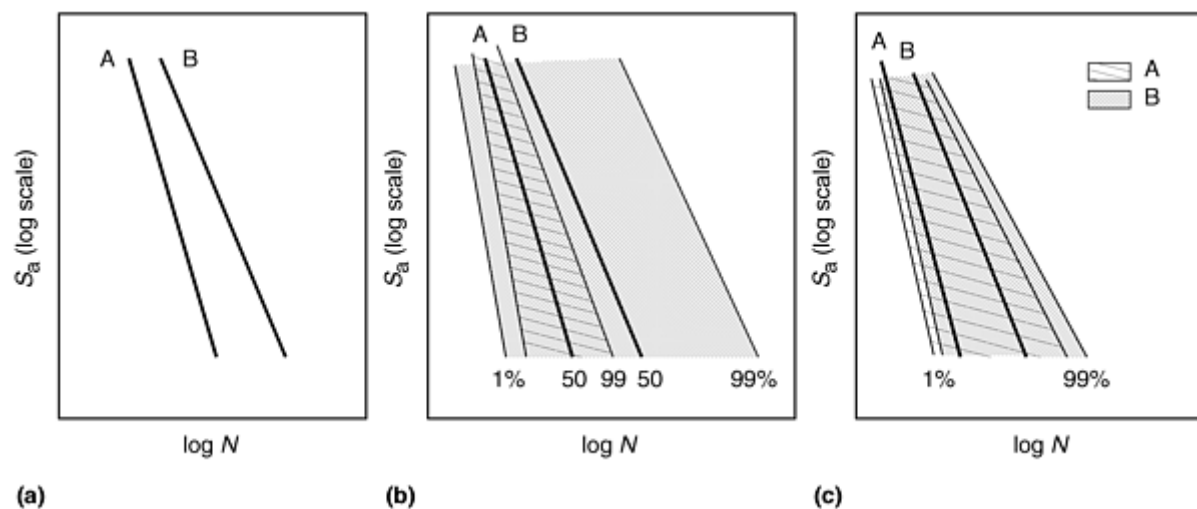

FIG. 9 EVALUATION OF THE RANGE OF FINITE ENDURANCE IN FIG. 8 AND CONJUNCTION WITH THE RANGE OF TRANSITION IN FIG. 5(B) TO THE TYPE I FATIGUE DIAGRAM

The joining of the ranges of the finite-endurance and the transition regions are not problematic in the case of Fig. 9. Only the point  $N_{99}$  of the level 200 MPa is not in harmony. This will not be a problem, because that level did not have enough specimens tested in the range of finite endurance. Its evaluation there was done only for the estimation of  $K$ , using  $N_{50}$ . Yet sometimes the conjunction becomes difficult because both ranges have been determined independently in different ways and with too few specimens. Perhaps corrections are necessary. For example,  $S_{FL99}$  might be shifted on the ordinate up or down. In this case, some other  $S_{FLx}$  may have to be shifted. According to Fig. 5 they have to be corrected by a new straight line through the shifted  $S_{FL99}$ .

It is mentioned above that  $N_g$  might be lowered to  $2 \times 10^6$  if only probabilities below 10% are important. This is visible in a typical way in Fig. 9. By that reduction  $S_{FL1}$  would be influenced not at all,  $S_{FL10}$  a little bit, and  $S_{FL90}$  and  $S_{FL99}$  heavily. As a fact,  $2 \times 10^6$  is already partially in the range of the finite-endurance region. If one reduces  $N_g$  in order to save time, one has to consider the consequences. For example, the conjunction of the ranges of finite endurance and of transition will become difficult. In that case,  $S_{FL1}$  will be fully acceptable and  $S_{FL10}$  will be nearly acceptable, but all values above will be too big to a remarkable degree.

The comparison of the ranges of finite endurance has to be done by regarding the *whole* ranges over the full width of probabilities of fracture. In Fig. 10(a), conditions A and B are represented by two lines only. Both conditions were determined with the same number of specimens. Condition B clearly seems to be better than condition A. However, in Fig. 10(b), the thick lines for conditions A and B represent 50%, and the ranges are given fully. The range of condition B is much wider, and its 1% line is left of that of the range of condition A. Thus, condition A is better. First, the values for

1% probability of fracture are at higher cycles; second, the values of condition A are much more reliable, because a much smaller range had been determined with the same number of specimens. For example, a slight change of slag inclusions or composition of high-strength screws might produce the change from condition A to condition B.

**FIG. 10** COMPARISON OF RESULTS IN THE RANGE OF THE FINITE ENDURANCE. THE POSITION OF THE THICK LINES IS CONSTANT IN THE THREE SUBFIGURES. (A) CONDITION B IS BETTER THAN CONDITION A. (B) THE THICK LINES REPRESENT 50% OF PROBABILITY. CONDITION A BECOMES BETTER BECAUSE THE RANGE OF CONDITION B IS MUCH BIGGER AND ITS 1% LINE IS LEFT OF THAT OF CONDITION A. (C) THE THICK LINES HAD NO DEFINED PROBABILITIES OF FRACTURE BECAUSE NO QUALIFIED EVALUATION HAD BEEN DONE; BOTH ARE SITUATED A BIT EXTREMELY IN THEIR EVALUATED RANGES, WHICH HAVE ABOUT THE SAME WIDTH. CONDITION A IS BETTER BECAUSE ITS 1% LINE IS RIGHT OF THAT CONDITION B.

In Fig. 10(c), the two lines for conditions A and B were positioned without any planning or evaluation. Thus, the lines do not represent a defined probability of fracture. Full determination of the ranges might show up that the thick line of condition A was just at the left side of its range and that the one for condition B was more at the right side. Again, condition A is better, although both ranges have the same width about. The 1% line of condition A has the higher values and lies to the right of condition B.

**Evaluation of the Alternating Load Belonging to a Given Number of Cycles and a Given Probability of Fracture.** Some standards demand the evaluation of the alternating load  $S_{ax}(N_d)$  with a given probability of fracture,  $x$ , which belongs to a predetermined number of cycles for fracture,  $N_d$ . A typical demand is  $S_{a10}(10^5)$ . This value is determined from previous examples (Fig. 9). A value for the probability 1% might be determined as well.

From Fig. 9 it is easy to see that the  $S_{a10}$  value is expected to become 262 MPa. The way (Ref 21) to determine it in an accurate manner and with a minimum of specimens is demonstrated in Fig. 11. In Fig. 11(a) only the ordinate in  $N_d$  is known. This value is used instead of  $N_g$  or  $N_{gt}$  and the Boundary Technique is applied. Figure 11(b) shows results in which the start level happened to be too high. Specimens 1 to 3 all fractured before  $N_d$  as  $S_a$  was readied at stepwise lowered levels. The first opposite event (i.e., fracture beyond  $N_d$ ) happened with specimen 4, marked by a thick dash. At this stress level, nine additional specimens will be tested in the beginning. Equation 3 has to be considered, and the number of specimens may have to be raised after a first evaluation. In the case of Fig. 11(b), ten specimens are considered sufficient. Points I and II, with 10 and 90% probability of fracture, respectively, are determined in level 1 by evaluation as in Fig. 8. Point I is not far from the wanted point, WP, which might relate to level 1 as shown in Fig. 11(c). This might lead to the only theoretically correct conclusion: a level 2 would be fine for determination of points III and IV and, in consequence, determination of WP. However, there are severe objections:

- THE STATISTICAL INFLUENCE ON THE SCATTER OF THE POSITIONS OF FRACTURE MIGHT BE SO STRONG THAT POINT F WILL BE FOUND INSTEAD OF POINT III, AND POINT Z IN THE ZENITH WILL BE EVALUATED INSTEAD OF THE THEORETICALLY CORRECT VALUE WP. IN PRACTICAL WORK, EVALUATION OF BOTH POINTS I AND III MIGHT BE

SLIGHTLY INACCURATE, SUCH THAT POINT I IS TOO HIGH AND POINT III IS TOO LOW. THE EFFECT MIGHT BE THE SAME. THIS EXAMPLE OF A HEAVY FAULT IS NOT VERY EXTREME, THUS A SITUATION AS GIVEN BY LEVELS 1 AND 2 IS NOT RELIABLE ENOUGH AND SHOULD BE AVOIDED.

- LEVEL 2 MIGHT NEED MORE SPECIMENS THAN LEVEL 3. NEVERTHELESS, THE RESULTS OF LEVEL 2 MIGHT BE LESS RELIABLE STATISTICALLY.
- THE POSITION OF LEVEL 2 MIGHT ALREADY BE IN THE RANGE OF TRANSITION, AND IF SO SOME SPECIMENS WILL NOT FRACTURE. THUS, LEVEL 2 WOULD NOT BELONG TO THE RANGE OF THE FINITE-ENDURANCE REGION. THIS CASE SHOULD BE AVOIDED. (NOTE: NEVERTHELESS IT WILL BE GIVEN SOMETIMES AND NO FURTHER SPECIMENS MIGHT BE AVAILABLE. AN EVALUATION IS POSSIBLE IF THE NUMBER OF UNFRACTURED SPECIMENS IS SMALL RELATIVELY TO THE NUMBER OF TESTED SPECIMENS (<20%). FOR THIS PURPOSE THE UNFRACTURED SPECIMENS WILL GET THEIR ORDER NUMBERS TOO, THE HIGHEST ONES OF COURSE. THAT MAKES IT POSSIBLE TO GIVE THE OTHER SPECIMENS THE CORRECT ORDER NUMBERS AND PROBABILITIES OF FRACTURE. DURING EVALUATION (AS IN FIG. 8) IN SUCH A LEVEL THE UNFRACTURED SPECIMENS WILL ALL GET THE SAME POSITION  $N_G$  OR  $N_{GT}$ , YET DIFFERENT PROBABILITIES. THE EVALUATION BY DRAWING A STRAIGHT LINE WILL USE THE POSITIONS OF THE FRACTURED SPECIMENS PREFERABLY. THE RELIABILITY OF THE RESULTS IS LOWER.)
- LEVEL 2 NOT ONLY MIGHT NEED MORE SPECIMENS, BUT WITHOUT ANY DOUBT IT WILL NEED MUCH MORE TESTING TIME THAN LEVEL 3. THUS TESTING AT LEVEL 2 WILL BE MORE EXPENSIVE.

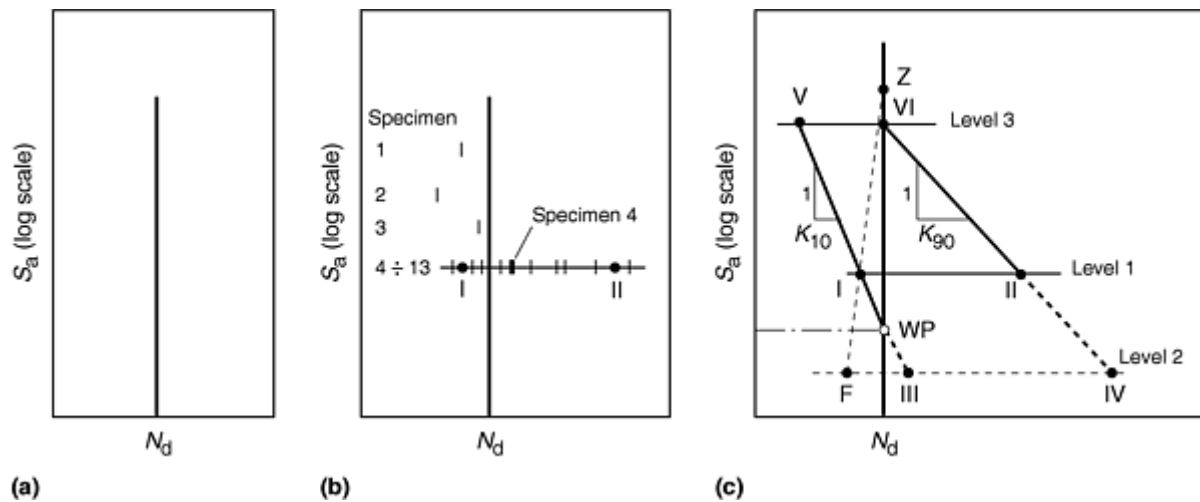

FIG. 11 EVALUATION OF THE ALTERNATING LOAD  $S_{Ax}$  ( $N_D$ ), WHICH BELONGS TO A PREDETERMINED VALUE OF PROBABILITY  $X$  AND CYCLES TO FRACTURE  $N_D$ , WHERE  $X = 10\%$ . (A) ONLY  $N_D$  IS KNOWN. (B) BY MEANS OF THE BOUNDARY TECHNIQUE AND THREE TRACING SPECIMENS, A LEVEL IS FOUND WHERE THE FIRST OPPOSITE EVENT (FRACTURE RIGHT OF  $N_D$ ) WILL BE FOUND. ALTOGETHER TEN SPECIMENS ARE TESTED THERE AND THE POINTS I AND II WITH 10 AND 90% PROBABILITY OF FRACTURE ARE EVALUATED. (D) THE WANTED POINT, WP, IS DETERMINED AFTER FINDING AND EVALUATING LEVEL 3. SEE TEXT FOR DETAILS. SOURCE: REF 21

In order to find the upper level 3, a line has to be drawn from point II in the lower level to point VI, the intersection with the ordinate in  $N_d$ , giving the position and alternating load of the upper level. Mathematically this can be done by:

$$\text{LOG } S_{\text{UPPER}} = \text{LOG } S_{\text{LOWER}} + (\text{LOG } N_{90\text{LOWER}} - \text{LOG } N_D)/K \quad (\text{EQ 7})$$

where  $\log N_{90\text{lower}}$  means point II.

The Boundary Technique might make the first level the upper one. In this case a line has to be drawn from point V in the upper level to point I. Mathematically this will be done by:

$$\text{LOG } S_{\text{LOWER}} = \text{LOG } S_{\text{UPPER}} + (\text{LOG } N_{10\text{UPPER}} - \text{LOG } N_{\text{D}})/K \quad (\text{EQ 8})$$

where  $\log N_{10\text{upper}}$  refers to point V. The problem is the estimation of the right value for  $k$ . It becomes more difficult if a value of  $x = 1\%$  for  $S_{\text{ax}}(N_{\text{d}})$  is wanted. No scientific study is known for  $k$ , and there have been only a few experiences. The one reported here belongs to 50% values or lines, and those for 1, 10, 90, and 99% are different, as might be seen in Fig. 9 and 11(c), where the values  $K_{10}$  and  $K_{90}$  are defined. Every laboratory has to develop its own experience. Using  $k_{50}$  instead for the beginning will give a higher position of the upper level, because the line from point II to point VI becomes steeper. This is not bad. Yet the use of  $k_{50}$  for finding the lower level will result in too low a lower level, and this might become a problem, as explained above.

Alternatively, the first level might be in the midst. This will be seen by the fact that  $N_{\text{d}}$  is in the center of the range of fractures in that level, close to the median  $N_{50}$ . In such a case it might be dared to use the first choice for the upper level and to go downward afterward. This is given if we take 295 MPa in Fig. 9 as a first and upper level and evaluate by use of Eq 8 to 220 MPa for the lower level. Connection of the crossed 10% points in those two levels by a straight line would lead to practically the same result,  $S_{\text{a}10}(10^5) = 262$  MPa. Using the other tested levels would give about the same result. Thus all appears to be very fine, but the approach is not practical. In the example of Fig. 9, the same results were always used, and there the points lay on well-defined straight lines. This is not guaranteed in practice. In all likelihood, repetition with the next batch of specimens out of the same population (tested at the same levels) would give different results. No known scientific study has faced that problem and determined safety factors for correction. Safety factors that might be used are explained below, based on the evaluation of one level only. The evaluated  $S_{\text{ax}}(N_{\text{d}})$  should be divided by those factors and thus be lowered in the interest of safety.

The method illustrated in Fig. 11 might also be used for searching a restricted area in the range of the finite-endurance region with a minimum of specimens, as a preliminary measure before more intensive experiments are started. In Ref 21 a more sophisticated method is used to evaluate point WP in Fig. 11(c) directly. Unpublished comparative studies indicate that this method is not safe enough. The fault previously described for point F happened too often.

**Safe Evaluation of Fatigue Data in a Predetermined Level of Alternating Load.** Consider that an unlimited number of specimens in one level could represent a population. From general statistical laws, we know that for each population there are two borderlines within which the possible results of samples will be found (Fig. 12). This means that we have to expect that some results out of a limited number of samples will differ from that one of the unlimited population. For example, the very steep sample 1 will give much too high a value for the 1% probability of fracture, and sample 4 will give too low a value for  $N_1$ . Nevertheless, samples 1 and 4 have the same median as the general population. For the samples 2 and 3 the medians are different, yet the errors for a 1% value are smaller. An enlargement of the sample size will cause the distribution to approach the theoretical borderlines and enlarge their radius. Thus the possible errors will be reduced. To a limited degree, the possible errors are dependent on the steepness of the sample lines, in other words on their ranges or, as a very practical tool, on the relations  $R_1 = N_{99}/N_1$  or  $R_{10} = N_{90}/N_{10}$ .

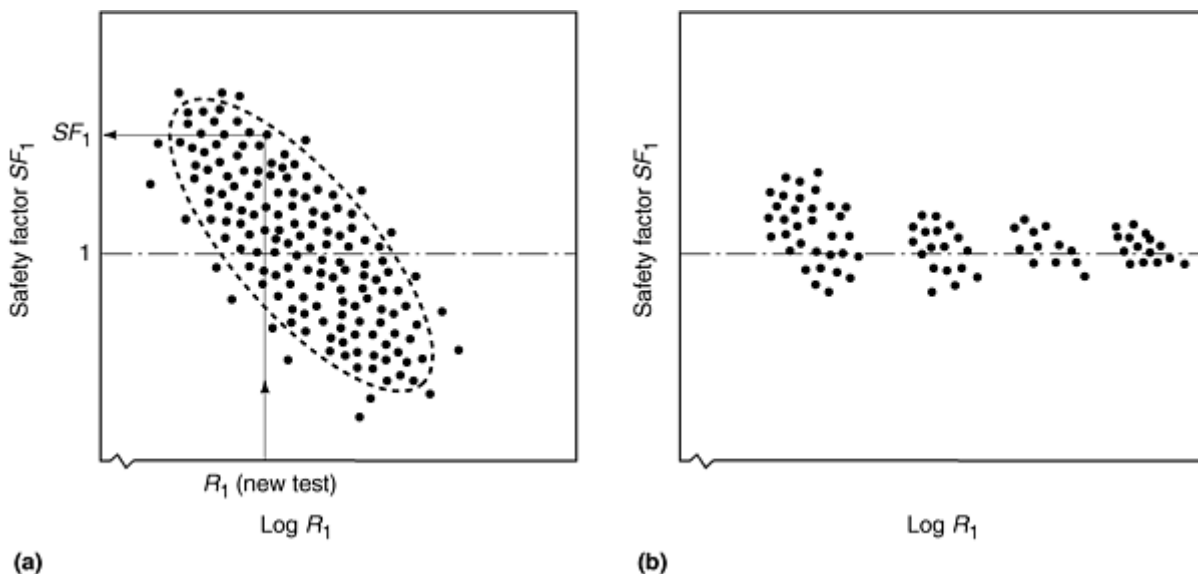

FIG. 12 THE REGRESSION LINES OF THE POPULATION OF SPECIMENS AND OF FOUR OF MANY POSSIBLE SAMPLES FROM THE POPULATION WITHIN ITS DOTTED BORDERLINE FOR A GIVEN SAMPLE SIZE

In Ref 8 this problem was studied on 56 data groups that were taken for approximations to populations and were evaluated for  $N_1$  and  $N_{10}$ . Afterward, samples were drawn out of the populations, and their values  $N_1$ ,  $N_{10}$ ,  $R_1$ , and  $R_{10}$  were evaluated. Equation 3 was considered. The comparison with the  $N_1$  and  $N_{10}$  values of the populations gave safety factors  $SF_1$  and  $SF_{10}$ , which mean the correction of the samples toward the population. The plotting of the safety factors over the values  $R_1$  and  $R_{10}$  was done in diagrams such as Fig. 13(a) and 13(b). In the case of homogeneous populations, all possible values for the safety factors grouped themselves in a restricted area (Fig. 13a). The dotted line of this restricted area might represent a confidence of 95 or 99%. This means that 5 to 1% of all safety factors might be outside of the dotted lines. The restricted area is symmetrical about the value  $SF = 1$ . Its position and width is typical for the investigated materials (for the scatter of results conforming to Fig. 12). Half of the points are below and above the horizontal line through  $SF = 1$ . Theoretically this would allow correction of every point by application of the appropriate safety factor. Points below  $SF = 1$  mean that the values  $N_1$  or  $N_{10}$  of the samples are too safe (too low in regard to those of the population). Yet there is no indication whether the sample is on the safe or unsafe side of the population. For the sake of safety, one has to use only the values of  $SF > 1$  and to calculate  $N_1$  and  $N_{10}$ :

$$N_{XCORRECTED} = N_{XSAMPLE} / SF_X \quad (\text{EQ 9})$$

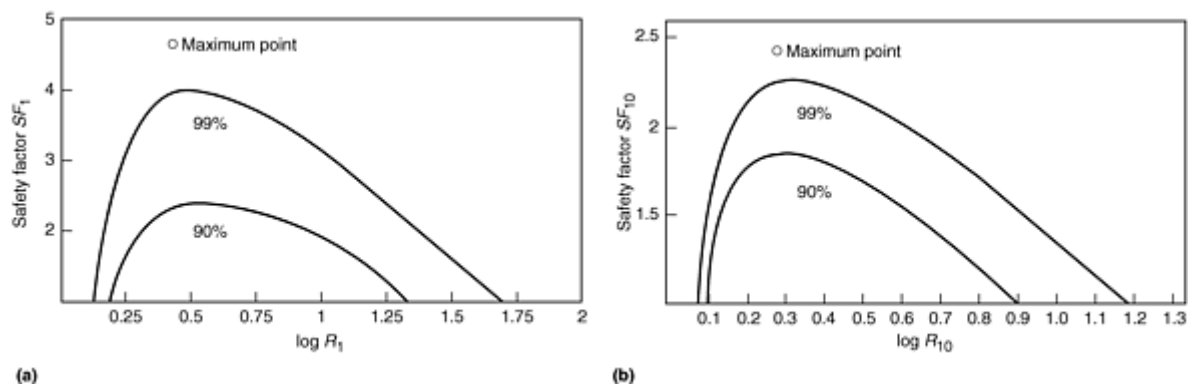

**FIG. 13 (A) SCHEME OF THE RELATION BETWEEN RANGE  $R_1$  AND SAFETY FACTOR  $SF_1$  IN THE CASE OF HOMOGENOUS POPULATIONS. (B) ONE POSSIBLE SCHEME FOR AN INHOMOGENEOUS POPULATION**

In the case of inhomogeneous populations, distributions as in Fig. 13(b) were found.

In practical work, one has only a sample. After evaluation as in Fig. 8, values such as  $N_1$ ,  $N_{10}$ ,  $R_1$ , and  $R_{10}$  are available. For example, one goes with  $R_1$  into Fig. 13(a), finds  $SF_1$ , and corrects  $N_1$  by use of Eq 9. Of course, the problem is the source of Fig. 13(a). Interested laboratories have to excavate their stored data and determine the diagrams for safety factors themselves for their special needs.

For the situation of a laboratory with no appropriate population, one option is to cautiously consider whether or not their sample can be represented by the 55 data groups in Ref 8 (excepting the data group for cast iron, for which Eq 3 was not sufficient). The 55 data groups contain alloys such as AlMg, AlCuMg, cheap steels, steels low alloyed with Cr and Mo or with Cr and Ni, one steel with 0.02% C, 18% Ni, 8% Co, and 5% Mo. The alternating loads were deflection with triangular form of momentum; rotating bending with trapezoid form of momentum; prismatic specimens with one-sided notch at the surface; with a thin specimen as used in fracture mechanics in mode I. Possibly, Fig. 14 (Ref 8) might be used as a crutch. The price will be to find bigger risk factors, as in diagrams for one special population. In any case, Fig. 14 should not be used for samples out of cast alloys or welded structures, or to investigate the effects of service load, combined alternating loads, corrosion, or humidity.

**FIG. 14 SAFETY FACTOR  $SF_1$  VARYING WITH RANGE  $R_1$  FOR 55 DATA GROUPS COMBINED IN ONE DIAGRAM FOR 1% PROBABILITY OF FRACTURE. EIGHT RANDOM STARTS; PROBABILITY FUNCTION  $P = (I - 0.417)/(N + 0.166)$ ; TRANSFORMATION FUNCTION  $^3 \sqrt{\ln(P)}$  OR GAUSSIAN CUMULATIVE NORMALITY (PROBIT); CONFIDENCE LINES FOR 90 AND 99% WHICH REPRESENT ONLY 90 AND 99% OF ALL DETERMINED VALUES, NOT OF THE POPULATION. (B) AS IN (A), EXCEPT  $SF_{10}$  FOR 10% PROBABILITY OF FRACTURE AND RANGE  $R_{10}$ . SOURCE: REF 8**

## Extrapolation from the Range of Finite Endurance into the Range of Transition

It is a common desire to extrapolate from evaluations in the range of the finite endurance into the range of the transition. The needed number of specimens and the testing time, even with the Boundary Technique, is believed to be too high to be feasible in some cases. In Ref 2 it is proven that such an extrapolation is not possible by the use of simple lines (as in Fig. 10a).

Another way is to find a diagram by a basic study, as in Fig. 9, and to test new incoming batches of parts with theoretically the same features at only one level of alternating load, for example 220 MPa. A rejection of the incoming charge of parts will be planned for a defined change in the considered level. For example, an important change might be seen if the range of fracture positions becomes much broader or has a shift to the left in such a way that  $N_1$  will be at  $2 \times 10^4$  cycles in level 220 MPa. In this case one might conclude that  $S_{FL1}$  is much lower than 147 MPa.

This way is full of risks. First, although the upper border of the range of transition approaches the range of the finite-endurance region, there is no reason to believe that the lower border of the range of transition ( $S_{FL1}$ ) has any logical connection with the range of the finite-endurance region. No scientific proof or indication is known for that. On the contrary, it is trivial that different phenomena of physical metallurgy play the main role in both ranges. Thus it is conceivable that any change in the properties of the material might enlarge the range of transition without influencing much the range of the finite endurance. In regard to Fig. 9 this might mean that the results in level 220 MPa remain untouched, even though the 1% line goes much lower and  $S_{FL1}$  will therefore become smaller.

Second, consider a professional who believes in a logical connection between a level in the range of the finite endurance and the lower border ( $S_{FL1}$ ) of the range of transition. If the incoming batch of parts has a much broader range  $N_{99}/N_1$  in the level 220 MPa, it will need more specimens for reliable evaluation. Usually those will not be prepared, and the consequence might be that randomly the chosen sample will give values for acceptance nevertheless. This risk becomes much stronger if the planned number of specimens is chosen too small from the very beginning, in this example 10 instead of 15. Another batch of incoming parts might have a range  $N_{99}/N_1$  which is only a bit smaller than usual, say  $N_{90}/N_{10}$  as in Fig. 9. Perhaps the charge will not be rejected, although it might belong to a fatigue diagram that has a lower range of finite endurance and thus also a lower range of transition and  $S_{FL1}$ . In still another case, the range  $N_{99}/N_1$  of the new charge of parts might be excellent and no rejection will be possible. Also, this time the range of finite-endurance might be much lower and the  $S_{FL1}$  value lower as a consequence.

A much more reliable solution would be to choose level 140 MPa in the case of Fig. 9 and to settle the demand for no fractures in ten specimens up to  $2 \times 10^6$  cycles. This would mean  $2 \times 10^7$  cycles altogether. A resonance fatigue testing engine might be trimmed to 150 cycles per second, or 540,000 cycles per hour. (Resonance testing machines are relatively cheap and do not need much energy. They are sufficient for the range of transition and for the lower part of the finite-endurance region in case of constant amplitudes, as in Fig. 1.) Thus the ten specimens could be tested within 37 h running time, or easily in 48 h, including machine setup by trained operators. If that is still too much time, one has to use several testing machines, gage them against one another, and run the sample out of the incoming batch of parts on all machines at the same time. (The gaging should be done statically as well as by running fatigue tests with big samples of equal specimens that are from the same population without any doubt. A careful planning of the tests is also necessary.) There are practically no risks involved in choosing the level if it is well established. The risks of using several machines will depend on the quality of the gaging. In any event, the risks should be smaller than those of testing a level in the range of the finite endurance in order to estimate the lower border of another range.

In our example, at the level  $S_a = 140$  MPa one has to expect a result of "no fracture" within the 10 specimens. If there happens to be 1 fracture, it is possible and perhaps even likely that this sample has a lower  $S_{FL1}$  value. And if there is more than 1 fracture it should be taken as being proven that the  $S_{FL1}$  value is lower than in the population. In other words, the new delivery does not belong to the population and has to be refused. An agreement might be made to take and test a second sample from the new delivery if there is 1 fracture in the first sample tested. The delivery might be accepted if there is no fracture in the second sample.

## Effect of Surface Conditions and Processing on Fatigue Performance

Brian Leis, Battelle-Columbus

---

### Introduction

SURFACE CONDITION and manufacturing-related surface alterations strongly influence fatigue resistance. Data that characterize their effects provide the means to extend life prediction methods (which are based on the behavior of idealized test specimens) to applications more typically found in industrial design applications. The effect of a surface treatment or modification is case specific. That is, the effect depends on how a process alters local composition, alters or orients local microstructure, introduces long- or short-range self-stresses (residual stresses) due to constraint, and/or alters the surface finish, which depends on the specific process parameters and the material that the process is applied to. The extent to which these surface changes improve fatigue life are measured by comparison to reference data developed using typical smooth laboratory test specimens.

Surface treatments or modifications are effective because many materials are subject to service conditions that degrade material performance by contact of the surface with some external factor, such as an aggressive environment. Surface modifications are particularly effective in applications where the serviceability is limited by fatigue (or a fatigue-related mechanism such as corrosion fatigue) because the fatigue process, which involves reversed slip in homogeneous materials, occurs most readily at a surface. (Slip at a surface is enhanced in the absence of grain-to-grain compatibility and the freedom for slip along slip planes with a component normal to the surface.) Finally, surface modifications are popular because the modification is localized at the surface and so the modification can be made cost-effectively.

Surface modifications have been used to improve fatigue performance for decades. Early applications include improved resistance to environmental effects, as for example the use of clad aluminum, introduced in the 1950s to improve corrosion-fatigue resistance. Early applications also used case heat treatment to harden a thin shell of material to achieve a higher steel hardness, with the anticipated increase in fatigue endurance or wear resistance as in hardened steel shafts and gears. Surface processing has historically also made use of treatments that created local compression residual stresses. This was done either by external working, as with shot peening, or by mechanical loading prior to service, which created compression residual stresses at the surface through local yielding in components with strain gradients. In principle, the

same concepts employed in some cases since the 1950s are still being used today. However, the recent schemes involve more sophisticated technologies, such as localized laser processing, ion-beam bombardment, and so on.

This article presents an approach to characterizing the effects of surface treatments to enhance fatigue properties, with particular concern for wear, corrosion, and thermal effects. The effect of processing on performance in this context could be illustrated by experimental data sets representing specific materials, typical test geometries, and a range of different processing methods used to enhance resistance as compared to results for laboratory tests. Such a presentation format would catalog available data, but it would not, nor could it, cover all current applications. More importantly, it could not provide insight useful in assessing the possible effects of new processes or new materials, nor could one identify the best way(s) to improve fatigue resistance in a given application.

For these reasons, the approach taken here is to present and illustrate trends in available data with respect to influences on microstructure, orientation, residual stress effects, and surface effects. In this way the available data provide guidance for both current and future applications. Following this generic discussion, data specific to the more common processes are presented to document the extent of the effect on fatigue resistance and deformation behavior.

The general outline of this article follows some possible procedural steps in evaluating processing effects on fatigue performance (Fig. 1). The article begins with general information on the role of residual stress and the baseline established by typical polished smooth specimen testing for comparison of the effects of surface treatments and modifications. With this backdrop, considerations in selecting fabrication or subsequent surface processing procedures to improve fatigue resistance are discussed in terms of their respective effects on fatigue performance. This article then considers the development of test data to quantify the effect of a procedure on a given application. Thereafter, the less satisfactory alternative is addressed, adapting previously generated data to estimate trends in the improvement from a given processing effect. In this case the extent of the improvement is estimated by adjusting baseline properties to account for the expected improvement, based on patterns established from the literature for a similar material and process.

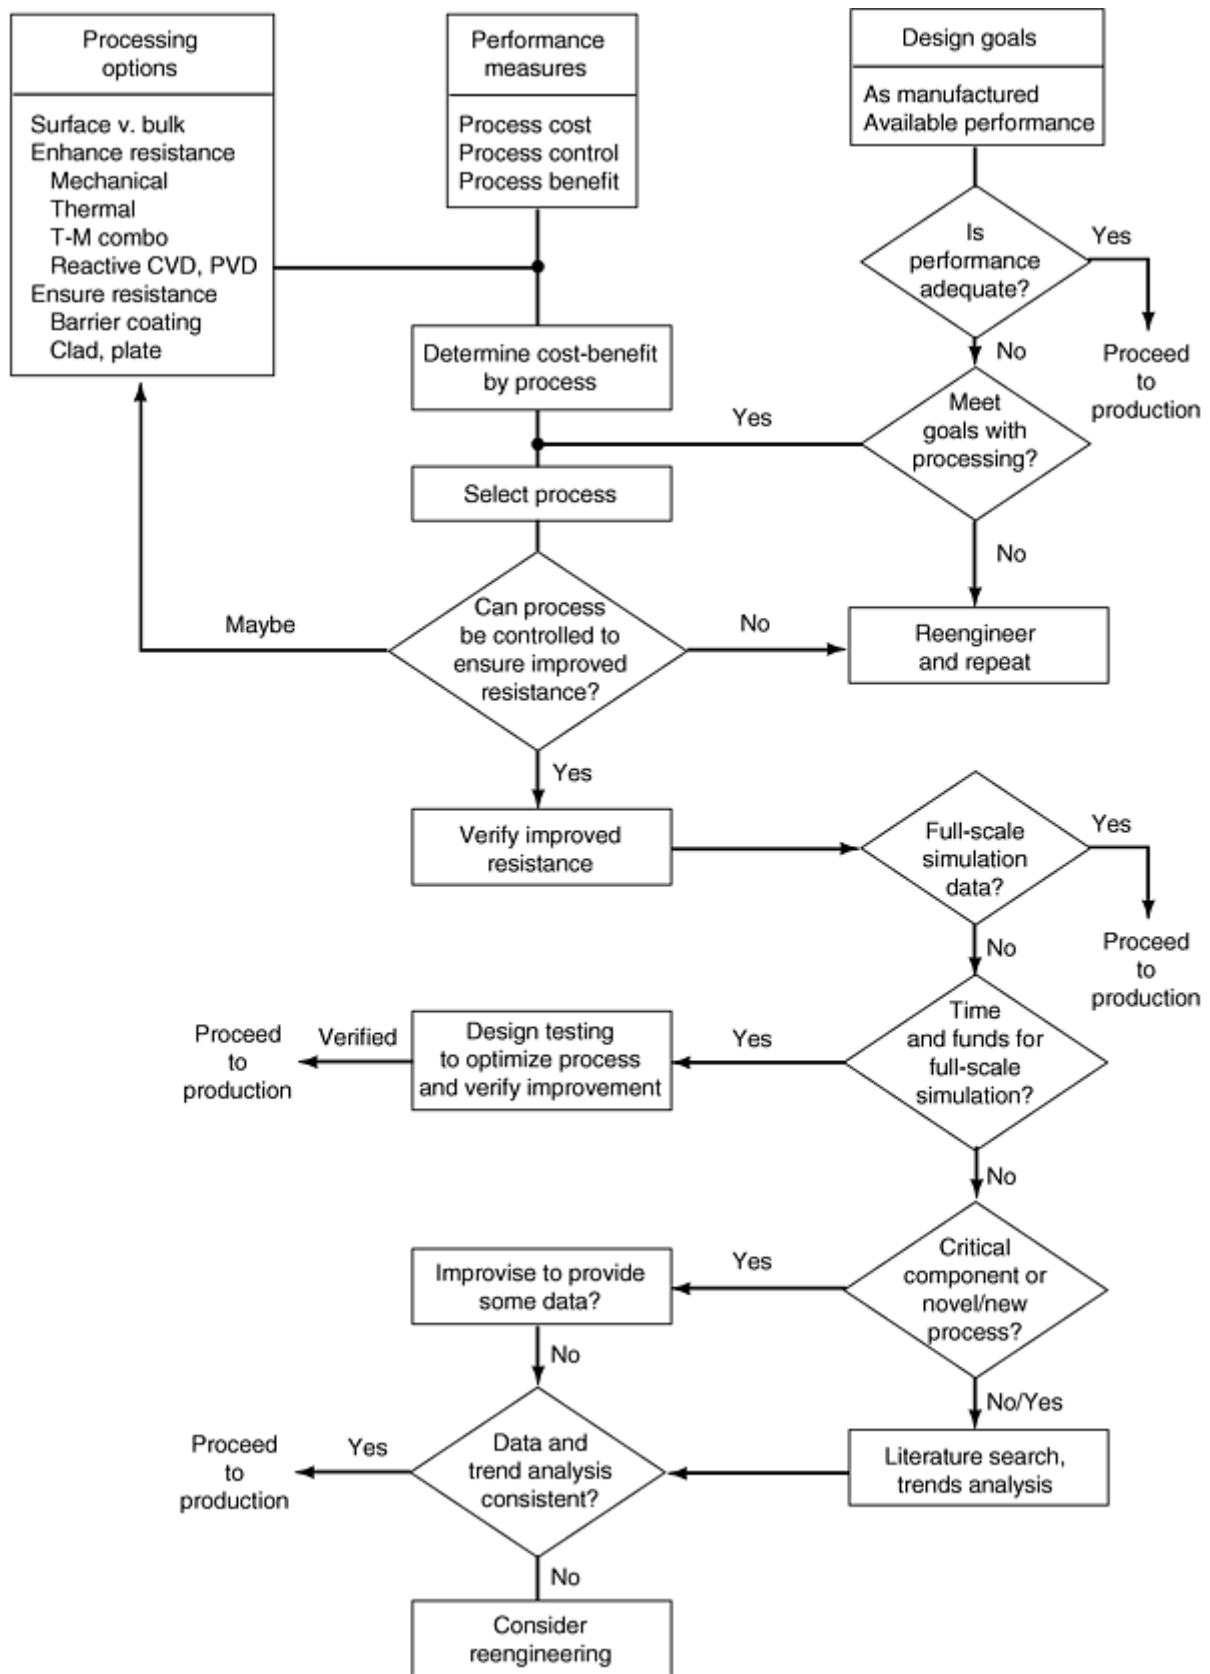

FIG. 1 CONCEPTUAL PROCEDURE FOR EVALUATING PROCESSING EFFECTS ON FATIGUE PERFORMANCE

This article is neither material nor application specific. It reflects the behavior of materials such as steels, cast irons, and aluminum alloys and considers to some extent both crack initiation and propagation to the degree that each is affected by surface treatment and modifications. Fabrication and subsequent processing procedures relying on thermal, thermal-

mechanical, and mechanical processes applied to the base material are addressed, and other methods that add to or modify the surface are discussed in terms of surface effects, residual stress effects, and chemistry and microstructure effects. Two examples and details about specific processing and fabrication effects on crack initiation for a range of materials also are included to serve as a guide for applications encountered in design.

## Effect of Surface Conditions and Processing on Fatigue Performance

Brian Leis, Battelle-Columbus

---

### Residual Stresses and Processing

It has long been recognized that residual stress and surface condition influence fatigue. Smooth test specimens are typically polished and enhance fatigue, whereas precracked specimen geometries may by virtue of their preparation contain longer-range residual stresses. Actual component fabrication may also involve processes that modify the surface or relieve the residual stresses, altering the fatigue resistance from that anticipated. The stress gradient in a component almost certainly will be different from that of a test specimen. The correlation, or lack of it, between simple specimen fatigue data and fatigue lives obtained with real components is a well-known concern that is influenced by several possible sources of material differences between the specimen and an application component.

In particular, several generations of mechanical and metallurgical engineers have dealt in some way with the interrelation between the surface condition of a material and the resulting fatigue strength. From the early days of analyzing the failures of rotating and reciprocating machinery, the detriment of sharp corners, steps in shaft diameters, and tooling marks has been well recognized. In addition, the surface roughness measurement is very significant in relation to exhibited fatigue life; there is a direct quantitative correlation between surface roughness and fatigue.

However, the apparent relation between surface roughness and fatigue is in reality much more complex. Typical plots of fatigue strength versus surface roughness in a given material are often produced experimentally by different surface finishing methods, such as grinding, turning with different tool radii, rough polishing, finish polishing, and lapping. To a large extent, the surface residual stresses resulting from these different finishing methods are key. For example, rough grinding typically produces high tensile residual stresses; "fine" grinding, lower tensile stresses; polishing and sanding, moderate compression; lapping and polishing, high (but shallow) compressive stresses, and so on. It is now realized that variations in residual stress produced in the surface by the finishing methods often are the main influence on fatigue life, not the surface roughness itself (Ref 1).

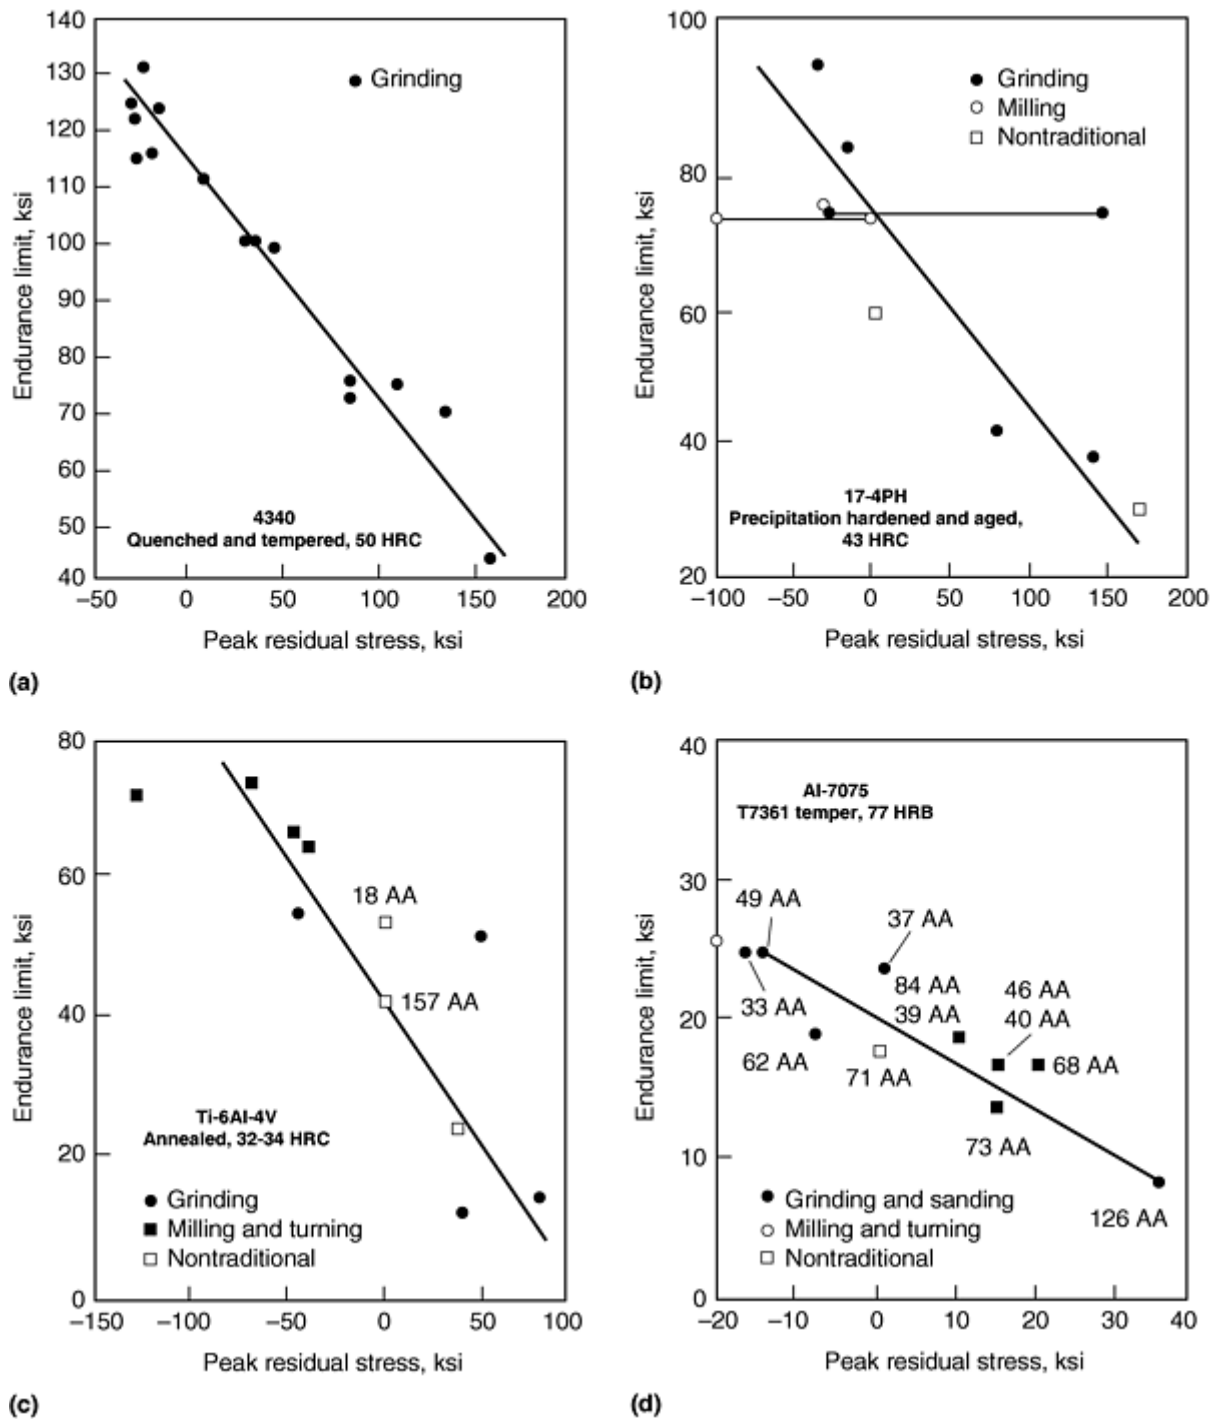

From a systematic study described in Ref 1, general surface integrity and fatigue strength are consistently related by the surface residual stress with some general observations:

- IN MANY CASES, SURFACE RESIDUAL STRESS IS THE SINGLE MOST IMPORTANT FACTOR INFLUENCING FATIGUE BEHAVIOR AFTER THE INHERENT STRENGTH OF THE MATERIAL ITSELF IS CONSIDERED.
- THE RESIDUAL STRESS EFFECT IS MOST PRONOUNCED IN THE ENDURANCE LIMIT REGIME ( $10^7$  CYCLES), ALTHOUGH SIGNIFICANT EFFECTS OF RESIDUAL STRESS CAN BE SEEN IN THE HIGHER STRESS RANGES (LOW-CYCLE FATIGUE REGION), WHICH YIELD LIVES OF  $10^3$  TO  $10^5$  CYCLES.
- THE EFFECT OF RESIDUAL SURFACE STRESS ON FATIGUE TENDS TO DIMINISH AS TEST TEMPERATURES ARE INCREASED SIGNIFICANTLY, PRESUMABLY RELATED TO THE RELAXATION OF RESIDUAL STRESS DUE TO THE THERMAL EXPOSURE.
- THE EFFECT OF SURFACE FINISH OR ROUGHNESS WITHIN REASONABLE RANGES (UP TO 100 TO 200  $\mu$ IN., ARITHMETIC AVERAGE) ON FATIGUE STRENGTH IS MUCH LESS THAN HAS BEEN TRADITIONALLY ACCEPTED BY THE ENGINEERING COMMUNITY. RESIDUAL STRESS CAN BE A MUCH MORE POTENT FACTOR. GROSS SURFACE DISCONTINUITIES ARE, HOWEVER, CLEARLY DETRIMENTAL.
- SURFACE RESIDUAL STRESS ALSO AFFECTS THE STRESS CORROSION RESISTANCE OF THOSE MATERIALS/CONDITIONS SENSITIVE TO THIS PHENOMENON. TENSILE

RESIDUAL STRESSES IN THE SAME DIRECTION AS APPLIED EXTERNAL STRESS CAN SIGNIFICANTLY REDUCE THE THRESHOLD OF CRACK INITIATION IN SENSITIVE MATERIALS/ENVIRONMENTAL CONDITIONS.

- COMPLEX SURFACE CONDITIONS, SUCH AS THOSE PRODUCED BY CARBURIZING AND SUBSEQUENT CASE HARDENING, EXHIBIT THE SAME TREND, ALTHOUGH THE INCREASE IN FATIGUE STRENGTH OBSERVED (IN THIS CASE) IS PROBABLY ATTRIBUTABLE TO BOTH COMPRESSIVE RESIDUAL STRESSES RELATED TO THE CARBURIZING/HARDENING PLUS CONCOMITANT PHASE CHANGES, AS WELL AS TO THE INCREASE IN THE INHERENT STRENGTH OF THE HIGHER CARBON, HIGHER HARDNESS OF THE SURFACE.
- SHOT PEENING IS PARTICULARLY COMPLEX IN ITS ANALYSIS AND CAN BE DISCUSSED IN OVERVIEW ONLY IN GENERAL TERMS. PEENING GENERALLY PRODUCES RESIDUAL SURFACE COMPRESSION; IT ALSO TYPICALLY CAUSES WORK HARDENING. BOTH TEND TO INCREASE FATIGUE LIFE. PEENING, HOWEVER, ALSO CAN CAUSE MICROCRACKING, MICROTearing, THE FORMATION OF SMALL LAPS AND SEAMS, AND SIGNIFICANT SURFACE ROUGHENING IN THE "OVERPEENED" CONDITION. THE NET RESULT IS COMMONLY AN INCREASE IN FATIGUE STRENGTH WITH MODERATE PEENING BUT A DEGRADATION OF PROPERTIES IF MULTIPLE OR REDUNDANT PEENING CYCLES ARE APPLIED. UNDOUBTEDLY, THE ENHANCEMENT DUE TO THE DEVELOPMENT OF COMPRESSIVE RESIDUAL STRESSES IS A FACTOR IN THE BEHAVIOR OF PEENED SURFACES, BUT IS ONLY ONE OF THE FACTORS THAT ARE ACTIVE.

The observed relationship between residual stress in the surface zone and fatigue strength as measured by the  $10^7$  cycle endurance limit is shown in Fig. 2 for 4340 steel; 17-4PH, a typical austenitic steel; Ti-6Al-4V; and aluminum alloy 7075, typical of high-strength aluminum alloys. While Fig. 2(a) involves only grinding, Fig. 2(b) to (d) show data from surface finishing methods including grinding, sanding, milling, and turning, and nontraditional methods such as electrical discharge machining, electrochemical machining, electropolishing, and chem-milling. In Fig. 2(b), two of the 17-4PH specimens exhibited distinct double peaks in the residual stress profile, as indicated in this figure. In the case of the titanium alloy (Fig. 2c), two different chemical milling procedures (nontraditional) were used that resulted in widely varying surface finishes; both exhibited virtually no residual stress. The aluminum alloy tended to exhibit smaller differences in fatigue strength levels, due in part to the lower strength level in comparison to that of the other materials.

**Standard Specimen Fatigue Data as a Benchmark.** Fatigue properties are normally determined using standard specimens, which often do not reflect the conditions that exist in real components or reflect the type of surface treatment or modifications that might be used to improve fatigue resistance to meet design objectives. For example, the standard smooth specimen is lathe turned and often has a ground or polished surface.

In contrast, in practical situations fatigue cracks often initiate on a mill-scale, sheared, or plated surface, or at a surface that is roughened due to plastic flow associated with significant stretching due to forming. In turn, these surfaces may be subjected to some subsequent reworking and processing to offset the reduction in fatigue resistance as compared to the

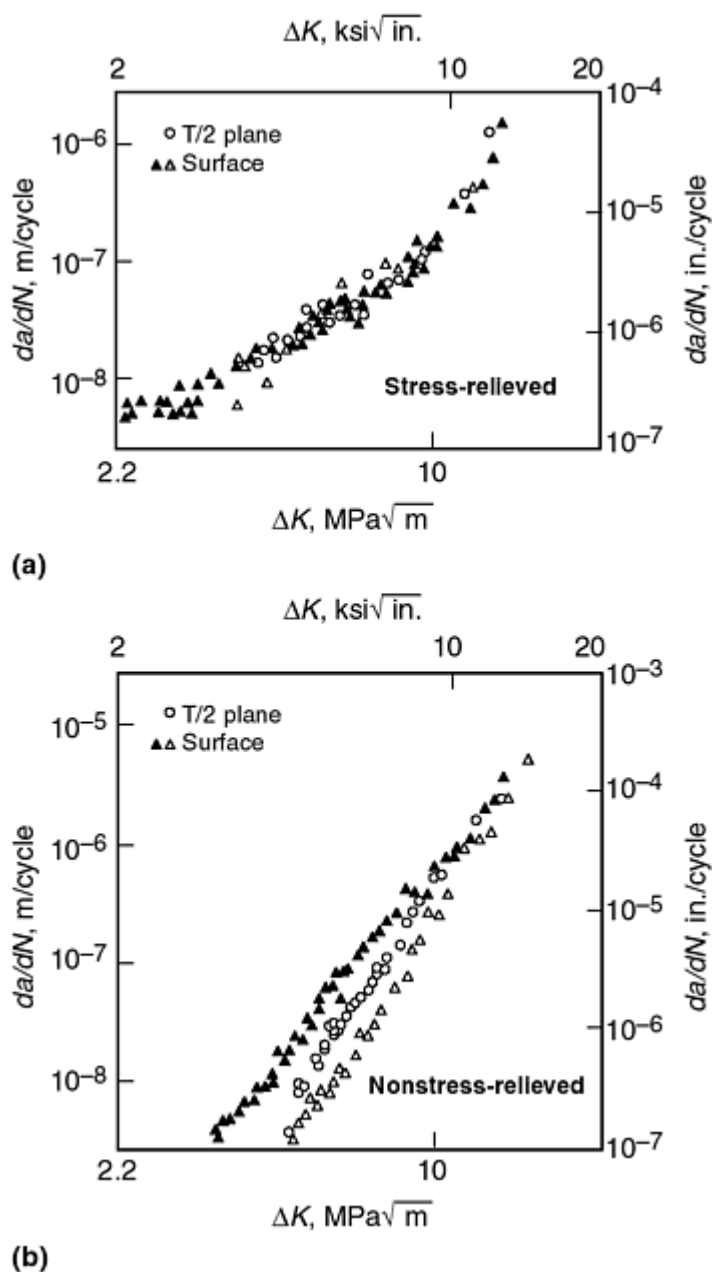

polished smooth specimen. Because fatigue crack initiation in homogeneous materials occurs at the surface, surface conditions that diminish stress raisers (finish) enhance fatigue properties or protect against degradation (wear, corrosion, etc., via functionally gradient materials). A rougher surface thus shortens the life in the high-cycle fatigue regime, although surface treatments can improve fatigue life (Fig. 3). In these cases, it is also important to consider the inherent residual stresses, as noted above.

**FIG. 3 INFLUENCE OF SURFACE ROUGHNESS AND FINISH ON FATIGUE RESISTANCE OF SMOOTH SPECIMENS. ROUGHNESS AND FINISH EFFECTS INCLUDE SOME RESIDUAL STRESS EFFECTS, AS NOTED IN TEXT. SOME SURFACE TREATMENTS, SUCH AS HARD CHROME PLATING, CAN PRODUCE SURFACE CRACKS, WHICH RESULT IN A LOWER LIFE. SOURCE: REF 2**

In most cases, standard specimens are designed to minimize residual stresses. ASTM E 606 (Ref 3) discusses smooth specimen preparation with a view to minimizing initial stresses in the specimens. Likewise, ASTM E 647 (Ref 4) warns of the effect of residual stresses and provides guidance to assess their potential influence on crack propagation data. In contrast, actual hardware may contain residual stresses and related gradients due to processing such as surface hardening methods or shot peening. Mean stresses influence fatigue life, and the effect of residual stress can also be accounted for as a mean stress effect. This influence of residual stress is illustrated in Fig. 4 for precracked (fatigue crack growth) specimen test results (Ref 5).

**FIG. 4 INFLUENCE OF RESIDUAL STRESSES ON PRECRACKED SPECIMENS. COMPACT TENSION SPECIMEN,  $R = 1/3$ , FREQUENCY 20 HZ, DRY AIR (RELATIVE HUMIDITY  $< 10\%$ ). (A) STRESS RELIEVED. (B) PARENT SLAB. SOURCE: REF 5**

In addition, it may be difficult to represent the microstructural and composition gradients that exist at critical areas and along crack paths using standard specimen sizes and geometries. It also should be emphasized that the "best" material under standard conditions may not be the best under practical conditions. This confusing circumstance develops in situations where the benefit of one material (say higher endurance stresses at long fatigue lives, which arise because of increased hardness in polished smooth specimens) is offset by the rough surface in the application, which reduces the life through notch sensitivity (that has been increased by the increased hardness). Increased notch sensitivity, formation of quench cracks, and a range of other negative factors may develop when uncontrolled changes are introduced in order to enhance fatigue performance.

The final point of emphasis relates to components for which there is a significant fraction of the total life involved in both crack initiation and propagation. Attempts to improve long-life fatigue resistance by using more refined microstructures may lead to decreases in crack growth thresholds (Fig. 5). Refined grain sizes tend to increase the long-life fatigue strength for smooth specimens, but they also tend to decrease the threshold for cracking in precracked specimens, at least for some materials. In such cases, the choice of the "best" material is not straightforward. To complicate matters further,

processing may produce a variation in microstructure throughout a component. Figure 5 might suggest that a refined surface structure, coupled with a coarser structure in the midthickness, would represent an optimum processing procedure for some lower-strength steels (in some applications). However, for high-strength steels an optimum processing procedure could involve maintenance of a refined surface structure throughout the thickness.

FIG. 5 INFLUENCE OF GRAIN SIZE ON NORMALIZED FATIGUE THRESHOLDS IN THREE MATERIALS. SOURCE: REF 6

It follows from the above discussions that standard specimens represent factors that affect fatigue in ways that may differ significantly from the conditions in real components. This does not mean that the standard specimens and related test standards are ill-conceived. Standard specimen designs and test conditions are typically defined so that a common basis for comparison of properties exists between materials. It is this common or standard basis for comparison that permits the engineer to assess which is the "best" material for the application. It remains the responsibility of the engineer to account for differences between standard conditions and service applications. Likewise, it remains the responsibility of the engineer to ensure that the apparent benefits of surface treatments and modifications made to improve fatigue resistance will have the intended effect in practice. Selected full-scale component testing may be necessary to accomplish this. In general, standard specimens and test conditions tend to maximize fatigue resistance or minimize fatigue damage, as compared to practical conditions.

**Effect of Processing and Fabrication**

Figures 2, 3, 4, and 5 suggest that the design analysis cycle can move forward only if data on the effects of fabrication and surface processing are available for the range of viable materials, covering the scope of fabrication and processing methods that are both practical and economically attractive. Unfortunately this is seldom the case. Necessary data simply are not available to cover this spectrum of materials and processes. Designers are often obliged to move forward in the presence of very limited data. In some cases they can develop data using standard tests to quantify the improvement that can be expected from a given surface process for a given set of processing parameters. However, seldom are designers afforded the luxury of data that cover all fabrication and processing situations. Accordingly, this section discusses fabrication and processing effects from the standpoint of why/how the effect develops and how one can assess its significance using either standard specimen data and/or application-specific experiments. Trends in surface processing and related fabrication effects are presented for a range of processing procedures and materials at the end of this article. Throughout it is assumed that the reader is familiar with the various fabrication and processing methods and is acquainted with the key parameters for controlling these methods. Further background on fabrication and processing methods may be found in companion volumes of the *ASM Handbook* series.

The effects of various processing or fabrication procedures are outlined briefly in Tables 1, 2, 3, and 4. The effects are analyzed first as physical effects, and they are described in terms of their tendency to alter the material, the stress field, and/or the surface, as compared to that of the standard smooth or precracked specimens.

(A) M, MATERIAL/MICROSTRUCTURE CHANGE; SS, SURFACE RESIDUAL STRESS EFFECT; S, SURFACE ALTERATION

**Material effects** include cold work (increased hardness), microstructure (type, orientation, and size), composition (chemistry), hot work, and electrochemical alteration. When cold work (plastic flow) is confined or occurs locally in a gradient (notch root, bent beam), the cold work also influences the stress field by creating compressive (or tensile) residual stresses that are concentrated at the surface. Surface residual stresses are reacted by lower, nominal stresses in the bulk elastic field. Material and cold-work-induced hardness and residual stresses are both key factors in fabrication, as

can be seen from Table 1. Increased hardness and residual stresses due to cold work are also key factors in mechanical processing, as is evident in Table 3.

**Residual stresses** concentrated at the surface may also be created by thermal gradients during the quench cycle of thermal processing, mechanical gradients due to phase transformation on the quench cycle, or plastic deformation of surface grains by shot peening or rolling. Both processing techniques may cause the surface to yield in tension. When the processing transients are completed, the surface yielding may lead to a steep gradient of compressive residual stress at the surface that is reacted by much lower elastic tensile stresses in the core. Because of this gradient, fatigue cracks may initiate subsurface. A complete fatigue life analysis for such a case probably should consider the behavior at the surface as well as at several sites below the surface. Quenching from high temperatures also produces a change in the material, usually most evident as a refined structure with increased hardness (see Table 2).

It is noteworthy that residual (self or internal) stresses are always balanced within a part. Compressive stresses are normally sought at critical areas to reduce tensile mean stress effects. In contrast, preloading into compression at critical areas may reduce the range of the local stress cycle that will enhance fatigue performance. In both cases, equilibrium requires that the compressive stresses be balanced by tensile stresses. Wise design of a component and its processing/fabrication procedure will ensure that the tensile stresses are located in noncritical areas.

**Surface alteration** is important for both fabrication and surface processing. The surface that develops in practice is much rougher than that of the polished specimen, so that surface invariably shows up as a negative factor in Tables 1, 2, 3, and 4. In contrast, the tables show that increased hardness (strength), local compressive residual stresses (thermal or mechanical), and changes in material structure (that increase strength or tend to refine/clean up the microstructure) are beneficial.

As noted above, surface roughness may be difficult to separate from the more dominant effect of residual stress in a specific procedure. However, surface condition can be critical, because crack-like features or blunt notches on the surface can quickly sharpen into cracks. Care must be taken to ensure that quality control procedures are implemented to preclude surface defects or roughness. Otherwise, the fatigue life can be orders of magnitude less than standard smooth specimen data. In cases where process variations lead to roughened surfaces, controls on the process should be implemented to preclude such detrimental effects in practice.

---

## Effect of Surface Conditions and Processing on Fatigue Performance

Brian Leis, Battelle-Columbus

---

### Effects on Fatigue Performance

Tables 1, 2, 3, and 4 are useful in selecting fatigue performance data to characterize fabrication and processing effects. For example, consider a part that is most economically produced by forging. The factors in Table 1 suggest some guidelines for designing forging dies and processing procedures. For wrought forms such as forgings, it is well known that fatigue resistance is direction-dependent when working creates a strongly oriented structure. An order-of-magnitude decrease in fatigue life can occur when cracks are allowed to initiate and grow along a strongly oriented structure. Obviously, cutting across this elongated structure to expose end grains would cause a major life penalty. It follows that forging dies and subsequent machining should be chosen to avoid either exposing end grains or creating macroscopic grain patterns that could be exposed accidentally in service or through subsequent reworking. Shot peening could be considered as one approach to offset the reduced resistance caused by end grain. As such, Table 1 indicates that care should be taken to account for orientation, laps, and end grains, with secondary concern for hot working.

The factors listed in Table 1 are also useful in assessing how to design specimens to be cut from actual hardware to characterize fatigue performance and in assessing the merits of various surface processing. First, critical locations and probable cracking planes should be identified. Care should be taken in this step to account for stress redistribution and changes in load transfer that may activate other critical locations or redirect the cracking path. The next step makes use of Tables 1, 2, 3, and 4 to identify which areas of the component should be sampled to characterize properties. For the forging example, key areas to be characterized would include crack paths parallel to strongly oriented microstructure, for precracked samples, and areas of exposed (intersected) end grain, for smooth specimens. The next step is to design test specimens that place the cracking direction perpendicular to the test load and provide for adequate gripping. Plausible

methods to improve fatigue resistance at these locations can then be identified and samples prepared for comparative fatigue testing. It will often be impossible to obtain standard specimens, so some creativity may be necessary. The final step is to develop data, but care should be taken to avoid aspects of the standard test methods that alter the surface from service conditions, such as polishing.

When the opportunity does not exist to develop application-specific material/fabrication and processing fatigue data, the designer can make use of the factors in Tables 1, 2, 3, and 4 and literature data to estimate fatigue performance data and benefits from surface processing. Estimating performance data parallels the steps taken in developing actual test results. As outlined in the preceding paragraph, locations that represent critical areas and crack paths have to be identified and the related fatigue data must be estimated. If the factors in Tables 1, 2, 3, and 4 have been used in selecting the fabrication and processing methods and procedures, and if these factors have then been implemented successfully, there is a reasonable chance that the related change in fatigue life as compared to the smooth specimen data will be realized. The analyst should still estimate the effect of fabrication and processing for use in design, erring on the conservative side unless full-scale testing is done to support the estimation procedure.

The key question in estimating the effect of a fabrication or processing method for a given application is: How does one judge the significance of the effect relative to standard specimen data? Related questions are: How well can fabrication or processing be controlled? How sensitive will the fatigue life be to variations in fabrication or processing? How well do data for similar materials (or perhaps distinctly different materials chosen as a reference in estimating fatigue behavior) represent the material at hand for the procedure being considered?

General answers to these key questions are not possible, but by categorizing fabrication and processing methods according to their physical effects, similarities between methods are apparent. Within a given generic material there are classes of material with comparable structures and strengths, so microstructural and cold work effects may be comparable. Finally, given that surface effects range from the influence of a notch to that of a crack, fracture mechanics for blunt cracks (Ref 7) could be used to estimate the role of the surface effects based on the related toughness. In all cases the estimate should be benchmarked with results from some comparable circumstances to ensure that the estimate is reasonable and conservative. In the absence of benchmark tests, an adequate factor of safety should be used. Here "adequate" is judged by the criticality of the component to continued safe operation. Care should also be taken to ensure that the factor of safety reflects the degree of uncertainty in the estimation process. When the factor of safety becomes too large because of large uncertainty or high criticality, consideration should be given to developing application-specific data supported by benchmark component tests.

**Assessing Fabrication and Surface Processing Effects on Fatigue Resistance.** Estimates of fatigue performance dealing with initiation performance embrace all factors indicated in Tables 1, 2, and 3. However, because surface is not a factor in crack propagation, the propagation performance literature focuses more on material effects and to a much lesser extent on residual stress effects. It should be noted that when compressive residual stresses are higher than the imposed tensile stress, the crack tip remains closed with minimal crack growth.

The focus here is on fatigue performance, but it should be remembered that stress-strain response, which is used in some crack initiation life analyses, may also depend on fabrication and processing. In particular, stress-strain response is sensitive to microstructural changes and accumulated strain. For steels the effect of microstructural changes on stress-strain response is reasonably estimated by data for other steels with a similar microstructure at a comparable hardness level. The effect of accumulated strain on stress-strain behavior for ferrous metals varies. Increased hardness generally leads to elastic response at higher strain levels, but cyclic softening might negate this effect. Thus, cyclic strains approaching or exceeding the initial mechanical strain that caused the hardening often generate a stress-strain response similar to the stable curve of the "virgin" material. The behavior of aluminum alloys is less patterned. Testing should be done if there is a significant change from virgin material due to fabrication and processing.

Fatigue performance is tabulated and graphed for a wide variety of steels and aluminum alloys in a range of handbooks. The purpose here is to illustrate how to use such performance data and to cite the most relevant data sources (e.g., Ref 8, 9, 10, and 11). These data can also be used to estimate the influence of a given procedure for a given material. The following two examples illustrate how to estimate the effect of processing as compared to standard specimens.

### **Example 1: Effect of Finishing and Surface Modification.**

The problem is to estimate the effect of fabrication on the fatigue crack initiation performance of a 1045 steel component (235 HB average) subject to fully reversed axial loading.

**Solution:** Fatigue performance in this case is assessed in terms of allowable stress to survive for a given number of cycles. Specific data representing the fatigue strength at  $10^7$  cycles for this situation can be found in Ref 9 in the form of a modified Goodman diagram. Taking the polished specimen as the reference ( $S/2 = 49$  ksi at  $10^7$  cycles), the results are as follows:

AS FORGED	<b><math>\sim 0.38 \times</math> FATIGUE STRENGTH OF POLISHED SPECIMEN</b>
HOT ROLLED	<b><math>\sim 0.51</math></b>
TURNUED	<b><math>\sim 0.71</math></b>
GROUND	<b><math>\sim 0.88</math></b>
ION NITRIDING	<b><math>\sim 1.5</math> ON A POLISHED SURFACE</b>

This table shows that a very strong penalty on allowable stress is paid if the component incurs stresses near the fatigue limit and the surface is left in an as-forged or an as-hot-rolled condition, as compared to some final machining operation applied in critical areas. The beneficial effects of surface treatment, such as ion nitriding, could also have a role. The same steel after ion nitriding of a polished surface has a hardness at the surface on the order of about 350 HB, with a corresponding increase in long-life fatigue strength of about 1.5. Initiation in this context is subsurface, so that the detrimental effects of finish noted above are not a factor, except that the benefit of the surface modification will be diminished on a lower-quality surface. In this context, the benefits of surface modification follow only after the surface is prepared for modification, and the detrimental effects of surface roughness do not intervene to shorten the time for crack initiation.

Finite-life fatigue behavior can be estimated if the fatigue strength data are used in conjunction with data for polished specimens for this material condition as shown for each of the fabrication methods in Fig. 6. It is common practice (for many steels) to assume that a fatigue limit exists beyond about  $2 \times 10^6$  cycles ( $4 \times 10^6$  reversals), as indicated in the figure.

**FIG. 6 EXAMPLE OF ESTIMATED FATIGUE LIFE CURVES USING DERATING FACTORS (SEE TEXT) FROM A 49 KSI ENDURANCE LIMIT FOR A 1045 STEEL STANDARD (SMOOTH) SPECIMEN**

Differences between the fatigue strength produced by these fabrication procedures and the smooth specimen response are due primarily to surface condition, because microstructural and hardness differences are normalized by comparing results at a given hardness. Because surface does not significantly influence a "strength" coefficient, it is reasonable to assume that the fatigue strength coefficient for polished specimens represents that for the other fabrication conditions. Therefore, finite-life elastic-strain-life behavior can be conservatively estimated by connecting the fatigue strength coefficient for the standard specimen with the corresponding point at  $2 \times 10^6$  cycles for the fabrication process of interest. The stress-life behavior can be estimated from the elastic-strain-life behavior through the modulus. Finally, inelastic cycle strain quickly creates surface slip steps that cause significant surface roughness. The influence of fabrication-induced surface roughness

on the plastic strain life curve can therefore be assumed to be negligible. Thus, the total strain life response can be estimated by adding the plastic response for the standard smooth specimen to the appropriate elastic response, as shown in Fig. 6.

### Example 2: Effect of Fabrication on Fatigue Crack Growth.

The problem is to estimate the effect of fabrication on fatigue crack propagation performance on an aluminum alloy (7075-T6) component subject to axial fatigue cycling at  $R = -0.33$ .

**Solution:** Fatigue performance in this case is assessed in terms of differences in growth rate at the same effective stress-intensity factor range. For simplicity it is assumed that  $\Delta K = \Delta K_{\text{eff}}$ . Data useful in assessing the influence of fabrication address the dependence of growth rate on microstructural orientation. Such data are tabulated in handbooks (e.g., Ref 10) for a variety of materials and conditions. The longitudinal (L) orientation is typical of most standard specimen orientations, whereas the transverse (T) orientation is typical of cracking parallel to highly oriented microstructures such as those that may develop in forging, extrusion, drawing, forming, casting, and some weldments. The effect of fabrication as compared to typical bar and plate products is evident in the difference in rates between L and T orientations, with the extent depending on the difference in orientation.

## Fretting Fatigue

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

### Introduction

FRETTING is a special wear process that occurs at the contact area between two materials under load and subject to slight relative movement by vibration or some other force. Damage begins with local adhesion between mating surfaces and progresses when adhered particles are removed from a surface. When adhered particles are removed from the surface, they may react with air or other corrosive environments. Affected surfaces show pits or grooves with surrounding corrosion products. On ferrous metals, corrosion product is usually a very fine, reddish iron oxide; on aluminum, it is usually black. The debris from fretting of noble metals does not oxidize.

Under fretting conditions, fatigue strength or endurance limits can be reduced by as much as 50 to 70% during fatigue testing (e.g., see Fig. 1a). During fretting fatigue, cracks can initiate at very low stresses, well below the fatigue limit of nonfretted specimens. In fatigue without fretting, the initiation of small cracks can represent 90% of the total component life. The wear mode known as fretting can cause surface microcrack initiation within the first several thousand cycles, significantly reducing the component life. Additionally, cracks due to fretting are usually hidden by the contacting components and are not easily detected. If conditions are favorable for continued propagation of cracks initiated by fretting, catastrophic failure can occur (Fig. 1b). As such, prevention of fretting fatigue is essential in the design process by eliminating or reducing slip between mated surfaces.

**FIG. 1 (A) COMPARISON OF FATIGUE LIFE FOR 4130 STEEL UNDER FRETTING AND NONFRETTING CONDITIONS. SPECIMENS WERE WATER QUENCHED FROM 900 °C (1650 °F), TEMPERED 1 H AT 450 °C (840 °F), AND TESTED IN TENSION-TENSION FATIGUE. NORMAL STRESS WAS 48.3 MPa (7 KSI); SLIP AMPLITUDE WAS 30 TO 40 μm. (B) EXAMPLE OF CATASTROPHIC FAILURE DUE TO FRETTING OF A FLANGED JOINT**

The initiation of fatigue cracks in fretted regions depends mainly on the state of stress in the surface, particularly stresses caused by high friction. The direction of growth of the fatigue cracks is associated with the direction of contact stresses and takes place in a direction perpendicular to the maximum principal stress in the fretting area. After formation due to fretting, cracks propagate initially under shear (mode II) conditions under the influence of the near-surface shear stress field due to friction of fretting. Beyond that, tensile (mode I) crack propagation under bulk cyclic stresses controls further propagation.

Because mode I bulk crack propagation is covered in detail throughout this Volume, this article focuses on what, if any, measures the design engineer has at his or her command to avoid or minimize crack initiation and fretting fatigue. The topics covered in this article are:

- MECHANISMS OF FRETTING AND FRETTING FATIGUE
- TYPICAL OCCURRENCES OF FRETTING FATIGUE
- FRETTING FATIGUE TESTING
- PREVENTION METHODS

Many investigators have contributed to the theoretical and practical research in the field of fretting and fretting fatigue, and the information in this section is derived from their work. Several general texts are available (Ref 1, 2, 3, and 4). Reference 5 is another key source for information and illustrations of fretting fatigue failures. In addition, more current discussions and background are also provided in the book *Fretting Fatigue* (R.B. Waterhouse and T.C. Lindley, Ed.), ESIS, Mechanical Engineering Publications, 1994. The article "On Fretting Maps" by O. Vingsbo and S. Söderberg (*Wear*, Vol 126, 1988, p 131-147) is another useful general reference on fretting.

As yet, general techniques or models permitting prediction of crack initiation due to fretting are limited. However, an understanding of the factors contributing to fretting fatigue can help minimize the risk and extent of damage. The examples presented in this article from case studies, theoretical work, and laboratory investigations are intended to assist the reader in recognizing the potential for fretting fatigue in design and materials selection. General principles and practical methods for the abatement or elimination of fretting fatigue are summarized in Table 1.

## Fretting Fatigue

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

---

## Fretting and Fretting Fatigue Mechanisms

In general, fretting occurs between two tight-fitting surfaces that are subjected to a cyclic, relative motion of extremely small amplitude. Although certain aspects of the mechanism of fretting are still not thoroughly understood, the fretting process is generally divided into the following three parts: initial conditions of surface adhesion, oscillation accompanied by the generation of debris, and fatigue and wear in the region of contact.

Fretting wear occurs from repeated shear stresses that are generated by friction during small amplitude oscillatory motion or sliding between two surfaces pressed together in intimate contact. Surface cracks initiate in the fretting wear region. The relative slip amplitude is typically less than 50  $\mu\text{m}$  (0.002 in.), and displacements as small as  $10^{-4}$   $\mu\text{m}$  have produced fretting. Generation of fine wear debris that usually oxidizes is an indication of fretting wear (Fig. 2). The following factors are known to influence the severity of fretting:

- **CONTACT LOAD.** AS LONG AS FRETTING AMPLITUDE IS NOT REDUCED, FRETTING WEAR WILL INCREASE LINEARLY WITH INCREASING LOAD.
- **AMPLITUDE.** THERE APPEARS TO BE NO MEASURABLE AMPLITUDE BELOW WHICH FRETTING DOES NOT OCCUR. HOWEVER IF THE CONTACT CONDITIONS ARE SUCH THAT DEFLECTION IS ONLY ELASTIC, IT IS NOT LIKELY THAT FRETTING DAMAGE WILL OCCUR. FRETTING WEAR LOSS INCREASES WITH AMPLITUDE. THE EFFECT OF AMPLITUDE CAN BE LINEAR, OR THERE CAN BE A THRESHOLD AMPLITUDE ABOVE WHICH A RAPID INCREASE IN WEAR OCCURS (REF 4). THE TRANSITION IS NOT WELL ESTABLISHED AND PROBABLY DEPENDS ON THE GEOMETRY OF THE CONTACT.
- **FREQUENCY.** WHEN FRETTING IS MEASURED IN VOLUME OF MATERIAL REMOVED PER UNIT SLIDING DISTANCE, THERE DOES NOT APPEAR TO BE A FREQUENCY EFFECT.
- **NUMBER OF CYCLES.** AN INCUBATION PERIOD OCCURS DURING WHICH FRETTING WEAR IS NEGLIGIBLE. AFTER THE INCUBATION PERIOD, A STEADY-STATE WEAR RATE IS OBSERVED, AND A MORE GENERAL SURFACE ROUGHENING OCCURS AS FRETTING CONTINUES.
- **RELATIVE HUMIDITY.** FOR MATERIALS THAT RUST IN AIR, FRETTING WEAR IS HIGHER

IN DRY AIR THAN IN SATURATED AIR.

- **TEMPERATURE.** THE EFFECT OF ELEVATED TEMPERATURE ON FRETTING DEPENDS ON THE OXIDATION CHARACTERISTICS OF THE MATERIAL.

**FIG. 2 FRETTING WEAR SCARS. (A) ON STEEL (ARROWS INDICATE FATIGUE CRACK). COURTESY OF R.B. WATERHOUSE, UNIVERSITY OF NOTTINGHAM. (B) ON HIGH-PURITY NICKEL. COURTESY OF R.C. BILL, NASA LEWIS RESEARCH CENTER**

In terms of fatigue, the following three primary variables contribute to shear stresses at the surface and hence are important for crack initiation and initial propagation of fretting fatigue cracks:

- NORMAL LOAD (E.G., CONTACT PRESSURE)
- RELATIVE DISPLACEMENT (SLIP AMPLITUDE)
- COEFFICIENT OF FRICTION

The other primary variable is the bulk tensile stresses that control crack propagation beyond the limit of the surface-induced stress field. Secondary factors, including surface roughness, surface contaminants, contact size, debris accumulation, and environment affect fretting fatigue through their influence on the primary variables. Effective lubrication will reduce friction stresses and wear particle accumulation.

**Fretting Modes and Contact Conditions.** The oscillatory motion responsible for fretting can be induced by system vibrations or by cyclic loading of one of the components. The relative displacement can be either amplitude controlled or load controlled, or a combination of both. Methods to control fretting fatigue depend on which of these two modes dominates the contact conditions.

**Stress Conditions.** The nominal macroscopic normal stress between the two surfaces is defined by the normal force divided by the nominal area of contact. Subsurface stress distributions can be computed using Hertzian calculations and the macroscopic contact geometry. The normal stress is also influenced by geometric stress concentrations. The real area of contact is limited to the contacting tips of the microscopic asperities on each of the surfaces, and the local (microscopic) normal stress is dictated by the yield strength of the softer of the two materials. Superimposed on the local normal stresses are shear stresses resulting from the friction of relative displacement of the two contacting members. The magnitude of the shear stresses induced by asperity contact depends on the coefficient of friction (due to adhesive forces between, and interpenetration of, asperities), the local load, asperity geometry, the elastic moduli of the two surfaces, and the amplitude of relative displacement.

**Strain Conditions.** If the amplitude of oscillation is small, the shear strains are elastic, and the contact condition is one of sticking or *no-slip*. Even under microelastic displacements fatigue cracks can form due to reverse bending at the bases of the contacting asperities. If the amplitude of oscillation is large, depending on the strength and ductility of the asperities in contact, and on the adhesive forces acting between them, the asperities will be forced to pass over one another and *slip* occurs\* With slip, the possibility of wear exists from either adhesion, abrasion, or delamination. All of

these material removal mechanisms lead to a roughening of the surface, the creation of sites for crack initiation, and the generation of wear debris. Cracks can also be initiated by pitting that occurs during fretting.

**Conditions for Slip.** The local contact conditions may be predominantly displacement controlled or load controlled. In displacement-controlled fretting contacts undergoing full slip, the amplitude of motion is controlled by the external displacements, an example being the relative displacement imposed on adjoining strands of a wire rope passing over a pulley. For force-controlled fretting contacts, the displacement will depend on the macroscopic shear force, the normal force, and the coefficient of friction; for example, the mating forces of a bolted flange or a hub/shaft press fit interface. No slip occurs until the shear stress exceeds the product of the normal force and local coefficient of friction. The condition for slip is met when

$$\tau > \mu \sigma_N \quad (\text{EQ 1})$$

where  $\tau$  is the local shear stress,  $\mu$  is the coefficient of friction between contacting surfaces, and  $\sigma_n$  is the local normal stress.

Regions of both slip and no-slip can occur at an interface of contacting solids. This is most easily seen for convex contacts using the elastic stress analysis of a sphere pressed into a plate by Mindlin (Ref 6) (Fig. 3). The normal (Hertzian) stress field is an elliptical distribution with the maximum stress occurring under the center of the contact. The shear stresses, which promote relative slip, are a maximum at the edges of the contact (limited by yielding) and a minimum in the center. The forces resisting sliding due to the shear stress are given by  $\mu N$ . The condition pictured is known as *partial slip*. As  $\mu N$  is increased, the region of sticking expands, and vice versa. When the shear forces of fretting are superimposed on this stress field, the result is a smaller "stick" area. This analysis can also apply to a cylindrical contact or can be adapted to microscopic asperity contacts.

FIG. 3 STRESS DISTRIBUTION FOR HEMISPHERICAL CONTACT PRESSED INTO FLAT PLATE. SOURCE REF 6

For contact between nominally flat surfaces, the stress state is different, though the slip condition is still defined by Eq 1. The macroscopic stress concentrations for well-defined geometries can be computed using finite-element modeling (FEM) analysis, although wear will change the assumed contact geometry. A general treatment of the subject can be found in Ref 3.

**Fatigue Crack Nucleation from Fretting.** Crack nucleation due to fretting must involve a stress concentration or discontinuity. At the microscopic level, examples include: microcracks formed at the base of asperities due to reverse bending fatigue of the asperities, stress concentrations in the pits left by sheared adhering "cold-welded" asperity junctions, corrosion pits that form due to removal of protective oxides by fretting, grooves due to abrasion, or delamination of a thin surface region whose work-hardening capacity has been exhausted. At the macroscopic level, cracks are proposed to form solely as a result of geometric stress concentrations, usually at the edges of the fretting

contact region, where shear stresses are predicted to be highest, at some microscopic inhomogeneity. The two views are not significantly different. The second view is more amenable to modeling and FEM analysis.

The location of crack nucleation depends on the contact conditions. Under *full slip*, in the absence of stress concentrations at the edge of the contact, cracks can nucleate anywhere in the contact region. The number of asperity interactions per cycle depends on the asperity distribution (surface roughness) and the amplitude of relative motion. Several cracks may be formed. Their stress fields can interact and lead to a decrease in the stress field associated with a single crack. This may explain why multiple nonpropagating cracks are often found in association with fretting. Under *partial-slip conditions*, the cracks always form at the border between the slip and the no-slip regions. In this case, multiple cracks are proposed to result from the movement of the slip/no-slip boundary due to the generation of debris (Ref 7). Though less likely, cracks can also form in the region of *no slip* (full sticking) due to reciprocating subsurface shear stresses associated with reversing elastic deformation of the contacting asperities and stress concentrations at their bases leading to local microplastic deformation and fatigue.

**Fatigue Crack Propagation during Fretting Fatigue.** Crack propagation is initially driven by the stress state dominated by the surface shearing. As such, when viewed in cross section, the crack direction initially appears at an angle to the surface of between 35 and 55°. Mode II crack propagation dominates this region. The mode II propagation may be dependent on material parameters such as grain size, texture, and phase morphology. Because the surface shear stresses fall off rapidly with depth, the crack will either arrest, or, if static or alternating tensile stresses exist in the bulk material, will change direction and run perpendicular to the surface as the driving forces come under the control of the bulk tensile forces (Fig. 4). The depth at which this occurs depends on the magnitude of the surface shear stresses, which depend on the coefficient of friction and normal contact stress. For Hertzian stresses of convex contacts, this depth is on the order of the half-width of the contact area. Beyond this depth, mode I crack propagation analysis can be used to predict the growth rate under the bulk stress state.

**FIG. 4 EXAMPLE OF FRETTING FATIGUE CRACK VIEWED IN CROSS SECTION. COURTESY OF R.B. WATERHOUSE, UNIVERSITY OF NOTTINGHAM**

A phenomenon peculiar to fretting is that some of the fatigue cracks do not propagate because the effect of contact stress extends only to a very shallow depth below the fretted surface. At this point, favorable compressive residual stresses retard or completely halt crack propagation. Under full-slip conditions, the wear rate caused by fretting occasionally outpaces the growth rate of surface-initiated fatigue cracks. In this situation, fretting wear preempts fretting fatigue.

### Note cited in this section

\* IN FRETTING, THE TERM "SLIP" IS USED TO DENOTE SMALL AMPLITUDE SURFACE DISPLACEMENTS, IN CONTRAST TO "SLIDING," WHICH DENOTES MACROSCOPIC DISPLACEMENTS. ADDITIONALLY, IN THIS ARTICLE SLIP DOES NOT REFER TO THE MECHANISM OF FATIGUE RESULTING AS A CONSEQUENCE OF DISLOCATION MOTION.

---

### Fretting Fatigue

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

---

### Typical Systems and Specific Remedies

Fretting generally occurs at contacting surfaces that are intended to be fixed in relation to each other, but that actually undergo minute alternating relative motion that is usually produced by vibration. Fretting generally does not occur on contacting surfaces in continuous motion, such as ball or sleeve bearings. There are exceptions, however, such as contact between balls and raceways in bearings and between mating surfaces in oscillating bearings and flexible couplings. Common sites for fretting are in joints that are bolted, keyed, pinned, press fitted, or riveted; in oscillating bearings, splines, couplings, clutches, spindles, and seals; in press fits on shafts; and in universal joints, baseplates, shackles, and orthopedic implants.

Three general geometries and loading conditions for fretting fatigue are considered in this section:

- PARALLEL SURFACES CLAMPED TOGETHER WITH SOME TYPE OF FASTENER, SUCH AS A BOLTED FLANGE OR RIVETED LAP JOINT
- PARALLEL SURFACES LOADED BY MEANS OF A PRESS OR INTERFERENCE FIT, SUCH AS A GEAR OR WHEEL ON A SHAFT
- CONVEX CONTACTS, AS FOUND BENEATH A CONVEX WASHER, BETWEEN CROSSED CYLINDERS SUCH AS WIRE ROPE STRANDS, OR A SPHERE OR A CYLINDER IN A BEARING RACE

Specific remedies to reduce fretting are given for these common examples. When fretting occurs, it often cannot be eliminated but can be reduced in severity.

**Parallel Contact with External Loading (Fastened Joints).** Bolted flanges in pipe systems are common locations for fretting fatigue. Cracks can occur in the plate either under a bolt head or washer (load controlled), on the inside diameter of the bolt through-hole (displacement controlled), or on the surface of one plate at the point of contact with the end of the other plate (load controlled) (Fig. 5a). Lap joints are found in both heavy plates and thin sheets such as aircraft skins. Fretting can occur in the joint or under the head of a countersunk screw, bolt, or rivet (Fig. 5b).

FIG. 5 TYPICAL LOCATION OF FRETTING FATIGUE CRACKS IN (A) A BOLTED FLANGE, AND (B) A LAP JOINT

For both these geometries, the reduction or abatement of fretting severity depends on whether the motion is load controlled or displacement controlled. If it is displacement controlled, then reducing the contact stress and minimizing coefficient of friction at the interface is recommended. For lap joints however, a reduction in coefficient of friction may result in insufficient load transmitted by the interface, transferring the load to the fasteners and leading to their failure. For load-controlled motions, it may be possible to increase either the clamping force and coefficient of friction to completely eliminate relative motion between the two contacting members. While adhesives can be used to eliminate the relative motion, their use complicates future disassembly. If motion cannot be completely eliminated, then minimizing the coefficient of friction may help, although this will likely lead to an increased slip amplitude. Alternatively, a thin compliant layer, such as rubber or other polymer, may be able to absorb the deflection and prevent contact between the two members.

For pin joints, fretting can occur on diagonally opposite sides of the pin at the points of contact with the hole due to vibrations or reversing loads. In these cases, White (Ref 8) showed that an increase in fatigue strength can be achieved by machining flats on the sides of the pins to prevent contact at the position of maximum stress, thus removing the region where fretting occurs (Fig. 6).

FIG. 6 (A) FRETTING LOCATIONS IN PIN JOINT. (B) MATERIAL REMOVAL TO ELIMINATE REGION OF HIGHEST STRESS

**Parallel Surfaces without External Loading.** Hubs, flywheels, gears, and other types of press-fit wheels, pulleys, or disks on shafts are subject to fretting fatigue caused by reverse bending strains compounded by the stress concentration where the shaft meets the disk (Fig. 7a). The introduction of lubricant in the interface can make matters worse by increasing the relative slip. In this case, it is best to attempt a strong interference fit. This can be achieved through cooling

the shaft and heating the bore of the hole during assembly in order to produce sufficiently high normal stresses to completely eliminate slip within the interface. After assembly, both surfaces will also be in a state of compressive stress, providing further resistance to fatigue crack propagation. Finally, if possible, a stress-relieving groove or large radius on the shaft (Fig. 7b) should be incorporated into the design.

FIG. 7 (A) LOCATION OF FRETTING FATIGUE CRACKS IN WHEEL ON SHAFT. (B) STRESS REDUCTION GROOVES

Gas turbine rotor blade roots and other dovetail joints are potential locations of fretting fatigue failures (Fig. 8a). In this case, the loading conditions are variable and depend on the rotational speed. For these situations, stress-relieving grooves can be incorporated into the design (Fig. 8b). Coatings to reduce the coefficient of friction (and hence the surface shear forces) can also help. Experiments by Ruiz and Chen on simulated blade/disk dovetail joints at 600 °C indicated that shot peening followed by electroplating with a 10  $\mu\text{m}$  thick Co/C surface layer was effective (Ref 9). Another example is provided in the article by Johnson in Ref 5 (paper 5).

FIG. 8 (A) LOCATION OF FRETTING FATIGUE CRACKS IN DOVETAIL JOINT. (B) STRESS REDUCTION GROOVES

**Convex Surfaces.** Fretting fatigue in control cables or wire ropes is caused by small relative displacements between the individual strands as the cable flexes in passing over pulleys, or by varying stresses from wind or water currents (Fig. 9). Stainless steel control cables are particularly susceptible because of the high friction and galling propensity between the strands. Fatigue fractures of the inner strands of the cables make detection by visual inspection virtually impossible until the ends of the fractured strands pop out through the outer strands. Wire rope fretting fatigue in control cables is an example of displacement-controlled contact. As such, large pulley diameters as a function of cable cross section can be specified in the design in order to decrease the displacement and minimize fretting fatigue. Incorporation of lubricant in the cable will reduce strand-to-strand shear forces, but only as long as the lubricant is contained within the rope interior by the outer strands. Takeuchi and Waterhouse report that electrodeposited zinc coatings helped prevent fretting fatigue of wire rope in sea water (Ref 10). The zinc provides both a reduction in the effects of corrosion and a low shear strength surface film that reduces friction.

**FIG. 9** EXAMPLES OF FRETTING ON INNER STRANDS OF DRAG LINE WIRE ROPE

In rolling-element bearings, high Hertzian normal stresses occur beneath the contact of bearing balls in their races. Control system or oscillatory pivot bearings are often subjected to a low amplitude, but high frequency, dithering motion leading to fretting or false brinelling between the balls and the race. (The difference between false brinelling and fretting is discussed in the article "Fretting Wear" in Volume 18 of the *ASM Handbook*.) Continuous rotation of one of the races can help prevent fretting under these circumstances (Ref 11).

For convex washers and other convex contacts, a coating, nonmetallic shim, or lubricating film can help reduce the surface shear forces.

## Fretting Fatigue

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

### Testing, Modeling, and Analysis

When fretting fatigue is encountered or anticipated, laboratory tests are usually required to find a solution. Test results can also be used to develop an empirical model and are required for validation if a model is to be used for design changes. This section presents types of fretting fatigue tests, the forms of results found in the literature, and the effect of variables on fretting fatigue from different research test programs.

**Types of Fretting Fatigue Tests.** Fretting fatigue tests are designed to accomplish one of three goals. The first is a test to predict or duplicate field failures and evaluate the effect of design changes or treatments based on replication or simulation of service components and conditions. This is most useful if all the service conditions are known and can be replicated or appropriately scaled, but the results will have limited applicability. A second type of test uses a simple geometry and setup. The contact conditions may not be well defined or directly applicable to a specific application, but they are assumed to be the same for every specimen set and many tests can be conducted at a reasonable cost for screening new material combinations. In the third type of fretting fatigue test, well-defined geometries and controlled and/or monitored loads and displacements are used. These more fundamental tests are intended to evaluate the effect of specific variables such as amplitude, clamping loads, reciprocating stresses, environments, or palliative methods, and to develop and validate fretting fatigue models. In order to apply published test results to a specific component, the test parameters must be well defined and understood for each engineering application. At present, work is under way to standardize test methods in order to assist with this endeavor (Ref 2).

For most fretting fatigue testing, fretting pads are positioned on opposite faces of the sample and can be either single or double footprints of flat or convex contact geometry. The relative displacement between the pads and the sample can be driven independently or can be controlled by the loads and motion of the system (Fig. 10). Of the four methods for cyclic loading of fretting fatigue specimens, general trends indicate that torsional specimens had the smallest drop in fatigue strength, while the largest drop was for tests carried out under rotating-bending or plane-reverse-bending conditions, with plane push-pull testing falling in between (Ref 7).

FIG. 10 EXAMPLES OF FRETTING FATIGUE TEST CONFIGURATIONS. (A) CANTILEVER BEAM REVERSE BENDING WITH SINGLE PADS. (B) ROTATING FULLY REVERSING BENDING WITH DOUBLE FOOT-PAD BRIDGES AND PROVING RING

The influence of fretting on fatigue strength can be determined by two basic methods. In one method, a sample is subjected to a certain number of cycles of fretting, followed by standard fatigue testing to failure without fretting. Plots of fretting cycles versus total cycles are recorded. This method has been used to determine the number of cycles for fatigue crack detection under the given geometry, material, normal stress, applied reversing stress and relative slip amplitude (Ref 12).

**Influence of Fretting on S-N Plot.** In the second method, the sample is subjected to fretting for the entire test. The fretting fatigue life or strength is determined by plotting the number of cycles to failure on an S-log N curve where S is the alternating stress. The strength-reduction factor (SRF) is defined by the ratio of the plain fatigue strength to the fretting fatigue strength as shown in Fig. 11 and is attributed to a decrease in crack nucleation time. A shift in cycles to failure at a given strength level is attributed to an increase in crack propagation rate and is often observed under corrosive environments.

**FIG. 11 EFFECT OF FRETTING ON FATIGUE STRENGTH REDUCTION (SRF) THROUGH CRACK INITIATION. SRF IS EQUAL TO DIFFERENCE BETWEEN SOLID AND DASHED LINES.**

The number of cycles to failure can be defined either as full specimen rupture or by initiation of a propagating (into the bulk stress region) crack. Crack length can be determined either from cross-sectional metallography or by specimen compliance methods.

**Stress Analysis, Modeling, and Prediction of Fretting Fatigue.** Testing, stress analysis, and modeling are complementary techniques required for understanding and predicting fretting fatigue behavior. For well-defined conditions, test results provide input to models. These models aim to predict crack initiation location, time, propagation rate, and the effect of changes in variables on these factors. At present, prediction of fretting fatigue is less developed than for plain (unnotched) fatigue. The main limitation is that continuum mechanics approaches do not consider microstructural inhomogeneities, and crack nucleation is controlled by such factors as well as "short" fatigue crack propagation.

Most of the early work in stress field modeling for fretting fatigue uses, as a starting point, analysis similar to that by Mindlin (Ref 6) of a sphere pressed into a half plane and expand this to consider other geometries and imposed shear loads. If stress fields are computed using FEM analysis, an assumed contact geometry and coefficient of friction are used and loads are imposed at various mesh locations in order to compute stresses and subsequent strains. Alternatively, displacements can be imposed and strains and stresses computed. To facilitate modeling, the stress singularity associated with an abrupt contact geometry change, such as at the edge of a bolted flange or a hub/shaft interface, is accommodated by plastic deformation and a limiting stress is assumed. Current models are limited in that changes in contact geometry due to wear and variations in coefficient of friction due to lubrication or debris accumulation are difficult to take into account.

Experiments have been undertaken and models have been proposed for both the full- and partial-slip regimes and are based on empirical observations. Full-slip and partial-slip conditions can be achieved by varying the test configurations.

In addition, while most fretting contacts are some combination of load and displacement controlled, laboratory experiments can be designed either to drive the fretting pads independently (displacement controlled), or to allow them to move as a consequence of the clamping force and displacement of the "beam" sample (load controlled).

For fretting under conditions of full slip, two early models predict the SRF due to fretting. Nishioka and Hirakawa (Ref 13) derived the following equation to describe the fretting fatigue strength limit determined using their displacement-controlled experiment setup with full-slip conditions under the fretting pads (Fig. 10).

$$\sigma_{FWL} = \sigma_{WL} - \mu P_o \{ 1 - E^{(-S/K)} \} \quad (\text{EQ 2})$$

where  $\sigma_{fwl}$  is the fretting fatigue strength,  $\sigma_{wl}$  is the plain fatigue strength,  $\mu$  is the coefficient of friction at the fretting interface,  $p_o$  is the clamping pressure,  $S$  is the slip amplitude (in mm), and  $K$  is a constant dependent on the material and surface condition (on the order of  $3.4 \times 10^{-3}$  mm in Ref 13).

In later work of Wharton et al. (Ref 14), a similar form was developed in which notch sensitivity of the base material was taken into account. The reduction in fatigue strength due to fretting was then proposed to also be proportional to the shear stress resulting from the contact pressure of the cylindrical fretting pads, inversely proportional to the contact width, and given by the equation:

$$\sigma_{WF} = \sigma_{WO} - Q(8\mu P/\pi B) \quad (\text{EQ 3})$$

where  $\sigma_{wf}$  is the fatigue strength with fretting,  $\sigma_{wo}$  is the fatigue strength without fretting,  $q$  is the notch sensitivity factor,  $\mu$  is the coefficient of friction at the fretting interface,  $P$  is the load per unit length, and  $b$  is the contact width under the fretting pads (mm). Note that both these predictions show that SRF is worse as  $\mu P$  or  $\mu P_o$  is increased.

For probable location of fretting fatigue crack nucleation in the partial slip regime, the approach of Ruiz and Chen (Ref 9) can be used. In their analysis of a dovetail interface, a fretting parameter representing the energy available for causing fretting damage, and given by the product of the slip amplitude ( $\delta$ ) and shear stress ( $\tau$ ) at points under the interface, was computed. Next, the product  $\sigma\tau\delta$ , called the fretting fatigue parameter, is computed, where  $\sigma$  is the maximum surface tensile stress (resulting from the bulk cyclic loading). A fretting fatigue crack is predicted to occur where the local value of  $\sigma\tau\delta$  in the interface exceeds an empirically determined critical value, or, fretting occurs when:

$$\sigma\tau\delta \geq \sigma\tau\delta_{\text{CRIT}} \quad (\text{EQ 4})$$

If  $\sigma\tau\delta$  and  $\sigma\tau\delta_{\text{crit}}$  can be experimentally determined, then the designer can use this value as a design guide. Note that both the slip amplitude and the shear stress depend on the coefficient of friction (with opposite responses) and the imposed loading. Analysis by Nowells and Hill (Ref 15) of this work provided a theoretical justification and a possible method for predicting "initiation" (or nucleation) time based on the total accumulated incremental strain. With further effort, it appears that the composite parameter approach can be applied to fretting fatigue in the full-slip regime and can be expanded to include plasticity.

Other models may be used to determine whether the conditions at the interface will be of full or partial slip and to predict the location of the partial slip. These are generally FEM studies and make use of assumed macroscopic contact conditions and bulk material properties. The text by Hills and Nowell covers this area; yet it is claimed that no current models exist that can predict crack initiation times strictly from the knowledge of the states of stress, strain, and displacement on a macroscopic scale (Ref 16). Though experiments are required to determine  $\sigma\tau\delta_{\text{crit}}$ , the most probable location of cracking may be predicted using FEM analysis and the criteria of Ruiz and Chen (Ref 9). If conditions are sufficiently well defined, the slip characteristics of the interfaces may also be predicted. Whether the interface is in full slip or the extent of partial slip will help guide the choice of palliative. This article presents some palliatives that have been applied successfully in the past for fretting abatement. However, the designer is advised to apply discretion in applying techniques listed, because results depend on the particular condition. In their review, Gordelier and Chivers (Ref 17) attribute contradictory effects of similar treatments on fretting fatigue to the differing effects on the base materials and to the different contact conditions.

## Fretting Fatigue

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

---

## Variables Investigated during Fretting Fatigue Tests

Of the dozens of variables that can potentially affect fretting (Ref 18), the three primary variables that control fatigue crack initiation are surface contact stress, slip amplitude, and coefficient of friction. All other variables are secondary and affect fretting and fretting fatigue through their influence on the primary variables. Unfortunately, much contradictory data appear in the literature (Ref 17). The contradictions concern whether the fretting conditions were displacement controlled or load controlled and the interactions of the secondary variables between each other and the primary variables. This section presents the results of various investigations into the effect of variables on fretting fatigue.

**Contact Stress and Alternating Stress.** Contact stresses include both normal and shear stresses imposed at the sample surface. The cyclic shear stresses at the surface are the cause of crack nucleation (where the propensity to cracking from the stress state is also affected by pits, corrosion, and other forms of surface degradation). The magnitude of shear stresses depend on the imposed forces and displacements, the coefficient of friction, macroscopic stress concentrations, and local asperity geometries and distribution. Nishioka and Hirakawa (Ref 19) reported that fretting fatigue strength based on fatigue crack "initiation" (or nucleation) was found to decrease linearly with increasing normal force. For fretting fatigue strength based on fracture, they found a critical contact pressure, above which no further degradation occurred. Although their experiments did not reach this level, a sufficiently high normal force can sometimes result in the closure of cracks initiated by fretting through the superposition of a compressive stress.

Alternating stress is the stress imposed on the bulk sample, characterized by an amplitude and a mean stress. For fully reversing bending (which occurs on a rotating shaft), the mean stress is zero. Nishioka and Hirakawa performed experiments in reverse bending on annealed and induction-hardened medium-carbon steel under displacement-controlled conditions (full slip). They found that the mean stress did not affect the range of alternating stress amplitude for fatigue crack initiation due to fretting, but that it did affect crack propagation (Ref 19).

Wharton et al. also found that the percentage of fatigue life reduction due to fretting, defined by crack propagation to failure, was independent of applied alternating stress level for 70/30 brass and for a 0.7% carbon steel (Ref 20). These experiments were performed in rotating bending using flat fretting pad contacts (Ref 21, 22). Ruiz and Chen found that peak contact stress was important at 600 °C, but at room temperature the fretting parameter ( $\tau\delta$ ) dominated (Ref 9). This was attributed to the nature of the oxide and the influence of the wear debris.

**Displacement (Slip Amplitude) and Direction.** For conditions of full slip, there is general agreement in the literature that the effect is most severe for slip amplitudes of 20 to 25  $\mu\text{m}$ . In work on 4130 steel Gaul and Duquette (Ref 23) found that, for clamping pressures of 20 to 41 MPa (3 to 6 ksi), a minimum in the fatigue life at a given alternating stress occurred at a slip amplitude of 20  $\mu\text{m}$ . At amplitudes higher than this, the wear rate due to fretting exceeded the rate of crack growth rate just after initiation and the fretting fatigue strength increased. A similar critical amplitude of relative slip, on the order of 15 to 20  $\mu\text{m}$ , was found by Nishioka and Hirakawa (Ref 13) for both induction-hardened and quenched-and-tempered medium-carbon steel samples. Clamping pressures of 120 MPa (17 ksi) were used in their work. They also concluded that the fatigue SRF due to fretting can be minimized if the fretting amplitude (relative slip) can be kept below 5  $\mu\text{m}$ .

An effect related to slip amplitude is that of contact width. Experiments showed that larger-diameter cylinders had a greater detrimental effect on fretting fatigue life for the same line contact stress than small-diameter cylinders (Ref 24). This may be caused by increased partial slip or more asperity contacts per stress cycle.

Nowell and Hills (Ref 15) looked at the effect of slip amplitude through elastic modeling of fretting fatigue in the partial-slip regime. In low-amplitude fretting experiments using cylindrical radii fretting pads pressed against an in-plane tension/compression loaded Al/4Cu alloy sample, they found a critical contact width for fretting fatigue damage. They also found that a transition between long and short fatigue lives occurred for microslip amplitudes of 0.9 to 1.2  $\mu\text{m}$  in the slip zones. This is considerably smaller than the maximum damage displacement of 20 to 30  $\mu\text{m}$  found by Nishioka and Hirakawa and others in their full-slip experiments on steel samples.

The results of work by Collins and Tovey (Ref 25) indicated that fretting motion in the same direction as the cyclic stress had a greater effect than fretting in the perpendicular direction. They used this result to conclude that cracks are nucleated by adhesive wear rather than by abrasive plowing via the expected orientation from each mode.

**Coefficient of Friction.** The coefficient of friction probably has the greatest influence on fretting fatigue. It influences both slip amplitude and shear stress, though in opposite ways. The influence of different material combinations on fretting fatigue life has been reported to be due to the coefficient of friction (Ref 14). For load-controlled fretting, an increase in coefficient of friction can prevent slip over the whole contact region and reduce or eliminate fretting fatigue. For amplitude-controlled fretting, the opposite effect can be expected and a reduction in the coefficient of friction is desired since the surface shear stresses are reduced. Reduction in coefficient of friction for clamped (bolted or riveted) joints has been shown to be detrimental in some cases because the lower coefficient of friction between the overlapping plates increased the load-carrying requirements of the bolts or rivets leading to failures initiating at the hole edges (Ref 26).

**High Temperature.** Fretting fatigue strength decreases with increasing temperature for titanium alloys (Ref 27), but was found to increase for the nickel-base alloy Inconel 718 (Ref 28) due to the formation of a protective oxide glaze. Such glazes typically lower the coefficient of friction. For iron-base alloys, both hard and soft flame-sprayed coatings based on molybdenum have shown success in improving the fretting fatigue strength at 300 °C. Overs et al. (Ref 29) attribute the improvement to MoO<sub>2</sub> glaze formation.

**Environment and Corrosive Media.** The effect of environment on fretting fatigue depends on the material and its corrodibility. Fretting action readily destroys passivating films on materials that are normally corrosion resistant. Poon and Hoepfner found that when fretting and corrosion occur simultaneously, the effect of corrosion on fatigue is dominant (Ref 30). As such, many palliatives or remedies for fretting fatigue can be viewed in terms of their effectiveness on corrosion fatigue.

In mildly corrosive aqueous environments, such as weak sodium chloride solutions representative of human body fluids, the fretting fatigue strength of materials not resistant to corrosion is reduced compared with fretting fatigue in air. Corrosion-resistant materials such as austenitic stainless steel and titanium have reduced fretting fatigue strengths in both environments due to the disruption by fretting of the otherwise protective oxide (Ref 31).

Endo found that ductile carbon steels are not affected by water vapor in fretting fatigue (Ref 32). Nishioka and Hirakawa found corrosion to be a secondary factor in fretting fatigue in their work on medium-carbon steels by comparing test data from argon and air experiments (Ref 33). Somewhat in contrast, Endo found that the fretting fatigue strength of carbon steel was higher in argon than in air, explaining that while the crack initiation rate is almost the same, the crack propagation rate is lower in argon (Ref 32).

Aluminum alloys are known to be very sensitive to water corrosion under dynamic conditions. Endo found that both crack initiation and propagation are accelerated by traces of water vapor due to corrosive attack, but not by oxygen. In the case of argon versus air experiments, the removal of oxygen was found to decrease the tangential stress due to soft aluminum wear debris accumulating between the mating surfaces (Ref 32). The alumina formed on aluminum would, if broken, be expected to be more abrasive and give rise to higher shear stresses than soft metallic wear debris.

Compared with tests in air, Ti-6Al-4V alloy was found to be adversely affected by corrosive atmospheres of humid argon and 1% NaCl at alternating stress levels above 120 MPa (17 ksi), but improved fatigue life was observed below 90 MPa (13 ksi) (Ref 34). The nature of the corrosion product was proposed to play a major role, in some cases forming a compacted layer that shielded the metal against crack initiation. Hoepfner reports that steel does not exhibit such a strong dependence on corrosion product (Ref 35).

Corrosion or oxidation are not required in the fretting process. Metallic fretting debris will form with gold or platinum contacts, or other nonoxidizable materials (Ref 36).

**Microstructure and Material.** If the design requirements will permit their use, annealed materials were found to be less susceptible to fretting fatigue than in the work-hardened state (Ref 20). Similarly, cast structures were less susceptible than forged structures (Ref 37). These results infer that if fatigue crack nucleation is through a wear mode involving exhaustion of work hardening, then prior-worked materials have a significantly shorter nucleation period.

Reeves and Hoepfner (Ref 38) found that carbon steel in the martensitic condition was more resistant to fretting fatigue than in the normalized (ferrite-plus-pearlite) steel due to the higher hardness and wear resistance of the martensitic steel. Nishioka and Hirakawa also found the fatigue limit to be higher on induction-hardened versus annealed steel (Ref 19). These results infer that more wear-resistant materials have better fretting fatigue properties.

**Copper-Base Alloys.** Wharton et al. (Ref 20) found that 70/30 brass did not show a strength limit in either plain fatigue or fretting fatigue. However, they found that the fretting fatigue strength at a given number of cycles was reduced by a fixed proportion over the plain fatigue strength for two microstructural conditions, independent of applied stress. The reduction was 61 and 74%, for annealed and work-hardened brass, respectively.

**Ferritic Alloys.** Endo and Goto (Ref 39) found that fatigue cracks generally initiated in ferrite grains, and propagated perpendicular to the sliding direction through a pearlitic region, irrespective of the orientation of the pearlite plates. Their experiments were performed under reverse bending. They also reported that, for two-stage tests on a medium-carbon steel (ferrite-plus-pearlite microstructure), no further reduction in fatigue life occurred if the fretting was continued for the entire test or was stopped after one-quarter of the total life. They concluded that the saturation point in the fretting cycles versus total fatigue cycles curve correspond to the point at which cracks that were initiated during fretting had grown to a depth where they propagated solely due to the macroscopic repeated stress (Ref 39).

**Titanium Alloys.** For three alpha + beta titanium microstructures, a fine or acicular microstructure was found to be more resistant to damage, defined by the number of propagating cracks found after a given number of cycles at a fixed stress, than a coarser-annealed structure (Ref 40). The finer alloy structure also had a lower SRF.

## Fretting Fatigue

S.J. Shaffer and W.A. Glaeser, Battelle Memorial Institute

---

## Prevention or Improvement

Fretting can be minimized or eliminated in many cases by one or more of the methods outlined in Table 1. Additional techniques in the design stages to diminish the effect of fretting on fatigue are discussed in more detail below in terms of:

- *MODIFICATION OF THE SURFACE STRESS STATE BY INTRODUCTION OF COMPRESSIVE STRESSES, REDUCTION OF SURFACE SHEAR STRESSES, OR ELIMINATION OR REDUCTION OF RELATIVE MOTION*
- *APPLICATION OF PRINCIPLES FOR WEAR AND FRACTURE TOUGHNESS IN SELECTION OF MATERIALS, COATINGS, AND LUBRICANTS*

## Surface Stress Modification

**Design for Introduction of Residual Compressive Stress.** The only treatment or remedy that has been shown to be universally effective in improving fretting fatigue is the introduction of residual compressive stresses. The compressive stress will reduce the driving force for both crack initiation and propagation. Residual compressive stresses can be imparted through high and uniform clamping forces or interference fits, plastic deformation of the surfaces, phase changes, and precipitation or diffusion/thermal treatments. If sufficiently deep, superposition of the compressive stress can also decrease the tensile stress field on the propagating crack in the base material.

**Plastic deformation by means of shot peening, surface rolling, or ballizing** the inside diameter of through-holes has the secondary effect of work hardening of the surface. In some cases, this work hardening leads to higher resistance to fretting wear. Waterhouse and Saunders (Ref 41) have attributed the increase in fretting fatigue strength of austenitic stainless steels by shot peening to an increase in surface hardness to 400 HV, compared to 150 HV for the bulk material, resulting in an increase in the fretting fatigue strength to that of the plain fatigue strength without fretting. In contrast, Leadbeater et al. (Ref 42) found that the improved fretting fatigue life in an aluminum 2014A alloy by shot peening was most likely due only to residual compressive stresses. They determined that while increasing surface roughness had a small beneficial effect, work hardening did not influence fretting fatigue properties.

Cold-working methods are not effective in applications where temperatures during service, or those generated locally due to fretting, would lead to annealing of the previously work-hardened surface.

**Nitriding** is a very effective palliative for steels. It introduces residual compressive stresses in the surface, and local hardening through solid solution strengthening can decrease the areas of real contact of self-mated ferrous material couples. Both chemical and ion implantation nitriding methods can be used. The effectiveness of carburizing will vary. Although the strength and hardness of the surface will be increased, the heat treatment required to create the martensitic

transformation, carburizing can produce either compressive or tensile residual stresses depending on the section size and shape. Tensile stresses of course would be detrimental.

**Avoidance of Stress Raisers.** Reducing geometric stress raisers in the vicinity of the contact will help prevent fretting fatigue crack nucleation. Examples were presented in the section "Parallel Surfaces without External Loading" and in Fig. 7 and 8. Local stress raisers due to pitting by wear or pits caused by corrosion can be prevented by corrosion-resistant coatings such as zinc or by cathodic protection.

**Spacers or Shims.** If the amplitude of relative displacement is small, it may be possible to absorb all of the transmitted shear stresses through the elasticity of a thin, flexible layer such as rubber. The effectiveness of this method depends on the modulus of the layer, its thickness, the severity of the normal load, and whether the relative motion is displacement controlled. For aluminum alloys used for aircraft skins at temperatures up to 150 °C, Taylor reports in work by Harris (Ref 43) that several investigations have shown the success against fretting fatigue of a joint bonded with isocyanate epoxy resin loaded with MoS<sub>2</sub>. It is likely that the solid lubricant lowered the transmitted shear stresses while the resin prevented metal-to-metal contact. It has also been reported that both pure aluminum and copper are effective shim materials to be used against steel for reducing the transmitted shear stresses (Ref 24).

**Lubricants.** By using lubricants to lower the coefficient of friction, shear stresses resulting from the normal load will be decreased. Again, the amplitude of displacement may be increased. Oils and greases tend to be forced from the interface. Rough surfaces, such as those left by a shot-peening operation, can help retain liquid lubricants. Surface finishes that deliver oil to the fretting site are beneficial. Liquid lubricants can be effective on wire rope, where there is some containment of the lubricant due to the outer strands. Solid lubricants tend to be worn away over time and therefore have limited effectiveness.

**Relative Motion.** If the relative motion of the two members can be eliminated, the fatigue life can then be computed using standard methods found elsewhere in this Volume. The design concern then shifts to minimizing the stress concentration at the edges of the contact. Methods for eliminating motion include increasing the normal load and/or increasing the coefficient of friction of the interface to expand the region of no-slip to the entire contact.

**Surface Roughness.** Surprisingly, a deliberately rough surface finish may be the best for minimizing fretting fatigue damage. Waterhouse suggests machining grooves in the surface of one of the two contacting members, preferably the one that is not subjected to the major cyclic stresses (Ref 44). It was suggested that the benefit found in this work on aluminum was due to a minimization of the extent of any one contact area. An alternative explanation is that the debris generated during fretting may be more readily trapped in the grooves, thus promoting both a lubricating effect and a reduction in the local stresses due to support by the compacted debris.

## Wear and Cracking Resistance

**Material Selection for Fretting Fatigue Resistance.** Two guides for materials selection choices should be used. The first is materials and treatments selected for avoidance of fretting damage, hence minimizing crack nucleation (see Table 2). Materials with low propensity for adhesion are described by Rabinowicz (Ref 45) in terms of the inverse of metallurgical compatibility. Typically, dissimilar couples are preferred. Self-lubricating components, such as porous metal washers impregnated with lubricant, can be used. Materials with high work-hardening capacity or dynamic recrystallization characteristics can also minimize fatigue crack initiation.

**TABLE 2 RELATIVE FRETTING RESISTANCE OF VARIOUS MATERIAL COMBINATIONS**

COMBINATION	FRETTING RESISTANCE
ALUMINUM ON CAST IRON	<b>POOR</b>
ALUMINUM ON STAINLESS STEEL	<b>POOR</b>
BAKELITE ON CAST IRON	<b>POOR</b>
CAST IRON ON CAST IRON, WITH SHELLAC COATING	<b>POOR</b>
CAST IRON ON CHROMIUM PLATING	<b>POOR</b>
CAST IRON ON TIN PLATING	<b>POOR</b>

CHROMIUM PLATING ON CHROMIUM PLATING	<b>POOR</b>
HARD TOOL STEEL ON STAINLESS STEEL	<b>POOR</b>
LAMINATED PLASTIC ON CAST IRON	<b>POOR</b>
MAGNESIUM ON CAST IRON	<b>POOR</b>
BRASS ON CAST IRON	<b>AVERAGE</b>
CAST IRON ON AMALGAMATED COPPER PLATE	<b>AVERAGE</b>
CAST IRON ON CAST IRON	<b>AVERAGE</b>
CAST IRON ON CAST IRON, ROUGH SURFACE	<b>AVERAGE</b>
CAST IRON ON COPPER PLATING	<b>AVERAGE</b>
CAST IRON ON SILVER PLATING	<b>AVERAGE</b>
COPPER ON CAST IRON	<b>AVERAGE</b>
MAGNESIUM ON COPPER PLATING	<b>AVERAGE</b>
ZINC ON CAST IRON	<b>AVERAGE</b>
ZIRCONIUM ON ZIRCONIUM	<b>AVERAGE</b>
CAST IRON ON CAST IRON WITH COATING OF RUBBER CEMENT	<b>GOOD</b>
CAST IRON ON CAST IRON WITH MOLYKOTE LUBRICANT	<b>GOOD</b>
CAST IRON ON CAST IRON WITH PHOSPHATE CONVERSION COATING	<b>GOOD</b>
CAST IRON ON CAST IRON WITH RUBBER GASKET	<b>GOOD</b>
CAST IRON ON CAST IRON WITH TUNGSTEN SULFIDE COATING	<b>GOOD</b>
CAST IRON ON STAINLESS STEEL WITH MOLYKOTE LUBRICANT	<b>GOOD</b>
COLD-ROLLED STEEL ON COLD-ROLLED STEEL	<b>GOOD</b>
HARD TOOL STEEL ON TOOL STEEL	<b>GOOD</b>
LAMINATED PLASTIC ON GOLD PLATING	<b>GOOD</b>

Source: J.R. McDowell, in *Symposium on Fretting Corrosion*, STP 144, ASTM, 1952

The second materials selection guide is the use of alloy compositions and thermomechanical treatments for existing alloys that improve their fatigue crack propagation resistance, as described elsewhere in this Volume and in a variety of mechanical properties handbooks (Ref 46, 47, 48).

**Soft coatings** provide a "sacrificial," low shear strength layer that reduces the magnitude of the oscillatory shear stresses transmitted into the substrate. Both a lower coefficient of friction and a lower shear strength contribute. A coating that dynamically recrystallizes under service conditions would be expected to be effective. Situations where creep of the soft coating results must be avoided, as the introduction of excessive clearance or a decrease in preload on bolts or washers can occur. In addition, low friction of soft coatings can lead to larger relative displacements for load-controlled fretting.

**Diffusion treatments** such as sulfidized coatings on steel were shown to be effective in delaying the initiation of a propagating fatigue crack in carbon steels in the laboratory when impregnated with a suitable oil-in-water emulsion (Ref 49), and subsequently applied successfully to compressor blade roots (Ref 44).

**Hard coatings** minimize the areas of real contact and penetration by opposing asperities and are less prone to adhesive wear. However, hard coatings have high friction coefficients. As such, high shear stresses are transmitted into the coating, which can limit their effectiveness. Care must be taken in design of coating thickness to avoid high shear stresses at the depth of the coating/substrate interface, which is typically a plane of weakness.

Additionally, hard coatings such as chromium platings are often filled with cracks, and sprayed molybdenum coatings usually contain pores. These defects in the coatings can serve as initial sites for fatigue cracks to develop and propagate into the substrate. Post-coating shot peening is recommended. Improvement in both electro-deposited chromium and nickel coatings was achieved by thermal diffusion processing followed by shot peening (Ref 44).

While hard coatings can reduce the overall fatigue strength compared with that of samples tested without prior fretting, under fretting fatigue conditions they typically show an improvement over uncoated materials. A pretreatment, such as shot peening or vapor blasting, may be required to compensate for the reduction in normal fatigue strength due to the hard coating. In the case of carbon steel, sprayed molybdenum coatings were found to increase the fretting fatigue strength from 33 to 72% of the normal fatigue strength compared with uncoated samples (Ref 50).

**Nonmetallic coatings** offer improvement in fretting fatigue resistance through the lowering of the coefficient of friction and the prevention of metal-to-metal welding at asperity contacts. The same types of substances that are considered solid "boundary" lubricants for wear control can be used. Conversion coatings produced by phosphating and anodizing, polymer sheets of nylon or polytetrafluoroethylene, and polymerized epoxy resins can all be used. In the case of porous coatings, impregnation with oils or greases can provide effective means of reducing or eliminating the occurrence of fretting fatigue when operating in the full-slip regime, over the supply life of the lubricant.

## Contact Fatigue

W.A. Glaeser and S.J. Shaffer, Battelle Laboratories

---

### Introduction

CONTACT FATIGUE is a surface-pitting-type failure commonly found in ball or roller bearings. This type of failure can also be found in gears, cams, valves, rails, and gear couplings. Contact fatigue has been identified in metal alloys (both ferrous and nonferrous) and in ceramics and cermets.

Contact fatigue differs from classic structural fatigue (bending or torsional) in that it results from a contact or Hertzian stress state. This localized stress state results when curved surfaces are in contact under a normal load. Generally, one surface moves over the other in a rolling motion as in a ball rolling over a race in a ball bearing. The contact geometry and the motion of the rolling elements produces an alternating subsurface shear stress. Subsurface plastic strain builds up with increasing cycles until a crack is generated. The crack then propagates until a pit is formed. Once surface pitting has initiated, the bearing becomes noisy and rough running. If allowed to continue, fracture of the rolling element and catastrophic failure occurs. Fractured races can result from fatigue spalling and high hoop stresses.

Rolling contact components have a fatigue life (number of cycles to develop a noticeable fatigue spall). However, unlike structural fatigue, contact fatigue has no endurance limit. If one compares the fatigue lives of cyclic torsion with rolling contact, the latter are seven orders of magnitude greater (Ref 1). Rolling contact life involves ten to hundreds of millions of cycles.

### Examples of Contact Fatigue

Contact fatigue produces a surface damage that is unique and well recognized. Familiar examples are found in fatigue of ball and roller bearings. A typical failure in a roller bearing is shown in Fig. 1. Although this spall is small, it would grow in size until roller fracture would occur, as bearing operation continues.

**FIG. 1** SCANNING ELECTRON MICROGRAPH OF A FATIGUE SPALL ON A ROLLER FROM A ROLLER BEARING AFTER 630,000 CYCLES. ROLLER IS AISI 1060 STEEL, HARDENED TO 600 HV. SPALL IS 400  $\mu\text{M}$  WIDE BY 700  $\mu\text{M}$  LONG.

One classic shape of a fatigue spall in a ball bearing is a delta shape, as shown in Fig. 2 with a diagram of the pit (Ref 2). The apex of the pit is the initiation point, usually the location of a surface defect like a dent. The pit grows in a fan shape, becoming wider and deeper as it grows in the direction of ball travel. Not all spalls in ball-bearing races are of the shape shown in Fig. 2.

**FIG. 2 ANATOMY OF A RACE SPALL IN A BALL BEARING. (A) TYPICAL DELTA SHAPE WITH THE APEX AT THE ORIGIN. (B) PROFILES OF THE SPALL. SOURCE: REF 2**

Figure 3 shows a fatigue spall near the race shoulder of a deep-groove ball bearing. The spall appears to have been formed by the joining of several pits. The fact that the spall occurred close to the race shoulder may have distorted the contact state of stress, causing a multiple origin.

**FIG. 3 MULTIPLE SPALL NEAR A RACE SHOULDER**

Fatigue in roller bearings may differ from ball-bearing contact fatigue. Quite often the pitting occurs in the inner race at the contact zone of the roller ends. In some cases, contact stress peaks at the roller ends and pitting originates in these locations. Roller-end pitting can be a sign of misalignment.

**Cams and Gears.** Valve lifter cams and rollers are subject to contact fatigue. An example is shown in Fig. 4 (Ref 3). The character of the damage is very similar to that found in rolling contact bearings. The example shown in Fig. 4 was found in both cam nose and lifters during automobile engine tests (Ref 3). Lifters were nodular iron, and cams were flake graphite cast iron. Fatigue cracks were associated with cracked carbides, graphite flakes, and hard inclusions.

**FIG. 4 CONTACT FATIGUE SPALLING OF CAM LIFTER SURFACE. SOURCE: REF 3**

Contact fatigue occurs in gears along the pitch line. The geometry of tooth mesh is such that rolling occurs at the pitch line while sliding occurs at the addendum as the gears come out of mesh. An example of pitch line contact fatigue is shown in Fig. 5 (Ref 4). The pits seen on the teeth will grow in size and depth, ultimately resulting in tooth fracture.

**FIG. 5 PITCH LINE SPALLING OF MEDIUM-HARDENED GEARS. SOURCE: REF 4**

Another form of contact fatigue, known as micropitting, occurs in bearings. An example is shown in Fig. 6. This feature can show up over the entire raceway surface. It is often the result of too thin a lubricant film or excessive surface roughness and sometimes heavy loading.

**FIG. 6 MICROPITTING OF ROLLER BEARING OUTER RACE. SCANNING ELECTRON MICROGRAPH, (A) 57× AND (B) AT HIGHER MAGNIFICATION**

In gears, micropitting is termed frosting and in the present ANSI/AGMA standard it is considered a form of contact fatigue. For bearings, gears, and any contact, micropitting can be reduced by improved surface finish, reduced temperature or loads, and providing sufficient elastohydrodynamic film.

**Rails.** Spalling and "shelly" -type failures occur on track rails from wheel-track rolling contacts. An example of shelly failure is shown in Fig. 7 from Kilburn (Ref 5). The name comes from the morphology of the fracture surface in the bottom of the spall. Shelly failures are serious because they lead to rail fracture and derailments. Rail spalling has been reduced in recent years by the use of higher carbon steels for rails.

### Mechanisms of Contact Fatigue

The state of stress produced by rolling contact is concentrated in a small volume of material and produces intense plastic strain. The strain accumulates as the same volume is stressed with each rolling cycle until a crack is initiated and forms a spall. In the real world of contact fatigue, the mechanisms involved can be quite complex. Most models assume a condition of ideal geometric surfaces and little input by heat generation, environmental conditions, and inhomogeneities of materials. Hertz stress analysis assumes a circular, elliptical, or line contact surface area between curved surfaces (depending on the geometry of the contacts) and a parabolic pressure distribution with the maximum pressure at the center of the contact.

The subsurface state of stress involves a hydrostatic component that inhibits tensile fracture. Analysis of the subsurface stress state indicates that a maximum shear stress exists at a given depth below the surface. The stress distribution is shown in Fig. 8. The maximum shear stress is shown increasing with depth below the surface as discussed by Kloos and Schmidt (Ref 6).

3D contact pressure distribution for curved contacts

## FIG. 8 STRESS DISTRIBUTIONS AT A CONTACT SUBSURFACE

The curves shown are based on two different mathematical approaches to the estimation of contact state of stress. Both approaches produce a shear stress distribution quite close to each other. The  $z$  axis scale is  $Z/B$ , where  $B$  is the minor axis length of the contact ellipse and the usual direction of rolling motion. Note in Fig. 8 that the maximum shear stress depth is about the same as the dimension of  $B$ . However, with increased traction or tangential force, the maximum shear stress moves closer to the surface. In hardened martensitic steels used in ball and roller bearings, the subsurface shear stresses produce plastic deformation in the martensitic structure. The residual strain increases with increase in rolling cycles. This has been shown by x-ray measurements during rolling contact experiments (Ref 7).

Many researchers have studied the microstructural changes that occur as a result of the buildup of subsurface strain (Ref 8, 9, 10). In AISI 52100 steel, a common rolling-contact-bearing material, the accumulation of strain initially is associated with the formation of a dark etching zone below the surface. Further strain causes the formation of light etching bands caused by the formation of a new ferrite phase. Then carbides in the high stress region begin to show decay and break up. Other microstructural features include "butterflies" or white etching wings radiating out from large hard inclusions. Some features depend on the level of contact stress. For example, butterflies are often associated with high contact stress (2000 to 4000 MPa), as discussed in more detail in the article "Contact Fatigue of Hardened Steel" in this Volume.

In a detailed study of butterfly formations in AISI 52100 steel ball bearings by Becker (Ref 11), both through-hardened AISI 52100 steel and carburized SAE 8620 steel bearing races were used. Contact stress was 3280 MPa (480 ksi). Butterflies were found in sectioned posttest races. They were always oriented at about  $40^\circ$  to the surface and oriented in the rolling direction. The "wings" of the butterflies were found to be composed of a mix of heavily strained, ultrafine-grained ferrite and fine carbide particles. Hardness was measured as close to 1000 HV--harder than the martensitic matrix surrounding the butterflies. Fine cracks were also found on the edges of the butterfly wings. The same structures were found in the carburized case in the 8620 steel. Becker says in Ref 11: "The breakdown of the matrix microstructure to ferrite and carbide is caused by very high stress concentration either at hard inclusions or at pre-existing cracks."

Contact fatigue is also surface generated. In fact, surface-originating spalls are more prevalent than subsurface-generated cracks. Proving subsurface fracture origin is difficult because a metallographic section only shows a profile of the crack which, in three dimensions, may have a surface origin. The higher the tangential force or traction, the more likely will be surface-generated contact fatigue. With shear stresses higher and closer to the surface, surface defects (dents, scratches, etc.) all contribute to higher incidence of surface-originating fatigue. Figure 2 shows a race spall that started at a dent in the race. This produced a delta-shaped spall as the cracking progressed from the origin. Sections through the spall show it to be shallow at the origin and deeper at the other end. Photomicrographs of a developing spall (Fig. 9, Ref 4) caused by a dent shows a ridge between the dent and the crack. This is typical and causes disruption in the oil film. The arrow shows the direction of movement of the balls over the race. The section through the developing spall shows the subsurface crack propagating down into the race at an angle to the surface.

FIG. 9 DEVELOPING SPALL. (A) TOP VIEW OF DEVELOPING SPALL AT RACE SURFACE DENT. (B) SECTION

As the developing spall matures, a surface layer loosens and eventually breaks out, leaving a pit. While the pit develops, the loose layer batters the fracture surface, obliterating the surface features. Fractographic analysis is not a likely option for investigating contact fatigue.

### Rolling Contact Bearing Life

Ball and roller bearings have been subject to the most extensive life testing of all contact fatigue components. Bearing catalog lives are based on fatigue failure considerations. It is assumed that no ball or roller bearing gives unlimited service. Owing to the special stress state experienced by rolling contact bearings, bending or push-pull tensile fatigue results cannot be applied to their life calculations. There is significant scatter in life tests for rolling contact bearings. The Weibull distribution is used in statistical analysis of bearing-life tests. A typical bearing-life Weibull plot is shown in Fig. 10 (Ref 12).

FIG. 10 WEIBULL PLOT OF BALL-BEARING LIVES DISTRIBUTION. SOURCE: REF 12

Two life values in the distribution are shown. The  $L_{10}$  life, or the life at which 10% of all the bearings have failed is used for bearing selection. Lundberg and Palmgren (Ref 13) developed a relationship that can be used to predict bearing life for any load, using the life for standard load in the relation:

$$L = (C/P)^P$$

where  $L$  is the fatigue life in revolutions  $\times 10^6$ ;  $C$  is the standard load ( $C$  is defined as the load that gives an  $L_{10}$  life of one million revolutions);  $P$  is the selected load; and  $p$  is 3 for ball bearings and 10/3 for roller bearings.

The predicted life from the above relationship is, of course, based on bearing tests, analyzed statistically. It does not take into account other factors that impact on bearing life. Lubrication is a powerful factor in bearing life. Since the discovery of thin-film lubrication, elastohydrodynamic (EHD) lubrication of rolling contact bearings, the effect of film thickness on bearing life, has received considerable attention. Tests have shown that the lubricant film thickness is influenced by bearing speed and lubricant viscosity and less by load. A bearing performance map was developed by Harris (Ref 2). The performance map is shown in Fig. 11. It has been in general use for a number of years. The lubricant film coefficient,  $\Lambda$ , determined by dividing EHD film thickness by a surface roughness factor, relates to the present film or percentage time the surfaces are totally separated by a lubricant film. If  $\Lambda$  is less than 1, the bearing is likely to not attain the  $L_{10}$  life predicted by the Weibull distribution. If  $\Lambda$  exceeds 4, then one might expect longer life than predicted.

FIG. 11 BALL-BEARING PERFORMANCE MAP. SOURCE: REF 2

Steel microstructure also has a significant effect on bearing life. Of greatest importance is the cleanliness of the steel. Because hard inclusions have been found to enhance the fatigue crack process, steelmaking methods have been modified to eliminate or substantially reduce the production of hard inclusions. Consumable electrode vacuum melting has produced bearing-grade steels that have dramatically improved bearing reliability. In many cases, bearing failure is now related to wear rather than to contact fatigue. Good surface finish is necessary for long bearing life. As was noted, contact fatigue is initiated by surface defects like dents and deep scratches. Surface defects not only cause asperity contact in thin-film lubrication, but dents have been shown to disturb the EHD film and cause local film breakdown.

The possibility of a fatigue limit for rolling contact (deviation from the inverse load power law) has been investigated. Tallian (Ref 14) has analyzed test data from bearing tests run at high  $\Lambda$  values under conditions free of contaminants and debris and found deviations from the theoretical life suggesting a fatigue limit. This is shown in the plot in Fig. 12. Further information on bearing life is described in the article "Fatigue and Life Prediction of Bearings" in this Volume.

### Minimizing Contact Fatigue

The study of rolling contact behavior has indicated new approaches that might further improve the contact fatigue resistance of these systems. One important problem in the application of rolling contact systems is the wide scatter in failure lives. Zaretsky (Ref 15) indicates that in a group of 30 ball bearings the ratio of the longest to the shortest life may be as much as 20 times. Bearing-catalog ratings are based on  $L_{10}$  lives or the time in which 10% of the bearings have failed. The same scatter can be expected in other rolling contact components such as gears and cams. Bearing-fatigue life is sensitive to bearing load. Generally, it is assumed that life is inversely proportional to maximum Hertz stress to the 9th power. The exponent can be as high as 12 for roller bearings. Lubricant composition, microstructure, and geometry of rolling contacts can influence these exponents of life. Zaretsky, Poplawski, and Peters (Ref 15) give a good summary of life exponents from various tests for a number of bearing configurations. This also includes case-carburized consumable electrode vacuum arc remelted AISI 9310 spur gears. The  $L_{10}$  lives varied inversely with the stress to the 8.4 power for the spur gears.

Reducing the scatter in bearing lives so that the distribution would be compressed toward the longer lives would intrinsically improve bearing lives. Improving rolling-element precision, surface finish, and homogeneity of

microstructure should reduce scatter somewhat. Lubrication also is effective. Ensuring that a rolling contact component is operating within satisfactory EHD conditions relative to surface finish is essential. Cleanliness of the operating environment and reasonable protection from corrosion are also important.

Because of the sensitivity of contact fatigue life to contact stress, reduction of contact stress can significantly improve bearing life. Of course, accurate estimation of the actual operating contact stress is important. Contact stress can be reduced by spreading out the area contact with a soft solid thin film applied to the surfaces (bearing races, for instance). Conversely, hard coatings have been used to improve fatigue life of bearing steels (Ref 16).

High-speed ball bearings have an increased ball contact stress owing to centrifugal forces. Such increased stress levels are sufficient to cause significant reduction in fatigue life even in very clean precision ball bearings. Reduction in the ball mass can reduce this effect and increase life to reasonable levels. Significant advances have been made by the use of silicon-nitride balls for high-speed bearings. Because of the lower density of silicon nitride, centrifugal forces in the bearing are reduced. Hybrid ball bearings with silicon-nitride balls have surpassed bearing grade steel in rolling contact performance (Ref 17, 18, 19). These bearings are finding use in gas turbines and high-speed machine tools.

Race fracture in high-speed ball bearings can be avoided by using a carburizing grade steel with increased fracture toughness (M50 NiL) (Ref 20) instead of through-hardening steels like AISI 52100. Carburizing to a depth below the estimated maximum shear depth will provide the required resistance to contact fatigue. Cleanliness of the steel will still be an important factor in bearing life.

The residual stress state in the near surface of rolling contact elements resulting from heat treatment and machining have an influence on contact fatigue life. By imposing compressive residual stresses, gear life can be improved. This can be accomplished by shot peening and burnishing. Nitriding gear steel will produce the desired compressive residual stresses to inhibit crack propagation.

As power systems become lighter and more compact, bearings, gears, and other rolling elements will have to operate at higher speeds. Although even at this time not all is understood about the mechanisms of contact fatigue, advances in improved reliability and component life are being made. Research and testing continue to try to narrow the life scatter and increase the predicted life of rolling contact parts.

## Fatigue and Fracture Control for Powder Metallurgy Components

Randall M. German and Richard A. Queeney, The Pennsylvania State University

---

### Introduction

POWDER METALLURGY (P/M) is one of the most diverse approaches to metalworking. The main attraction of P/M technology is the ability to fabricate high-quality, complex parts to close tolerances in an economical manner. In essence, P/M converts a metal powder from a semifluid state into a strong, precise, high-performance shape. Key steps include the shaping or compaction of the powder and the subsequent thermal bonding of the particles by sintering. These two steps can be combined into a single operation, for example in hot powder forging or hot isostatic pressing. All P/M processes are fairly automated with relatively low energy consumption, high material utilization, and low capital costs. These characteristics align P/M with current concerns over manufacturing productivity. Consequently, the field is experiencing growth and progressively replacing traditional metalforming operations over a wide range of applications and materials. As illustrations, P/M is used in the fabrication of lamp filaments (tungsten), dental restorations (precious metals), self-lubricating bearings (bronze), automotive transmission gears (steels), armor piercing projectiles (tungsten alloys), welding electrodes (copper), nuclear power fuel elements (uranium dioxide), orthopedic implants (cobalt and titanium alloys), high-temperature filters (stainless steels), aircraft brake pads (iron-copper-tin-carbon), rechargeable batteries (nickel), and jet engine components (superalloys).

There are three basic approaches to powder metallurgy processing (Ref 1). The most common method, termed pressing and sintering, is to fill a die cavity with loose powder and apply a uniaxial compaction pressure to the powder. This pressure deforms and densifies the powder to approximately 85 to 90% of theoretical density. Subsequently, the pressed powder is heated to a temperature where atomic diffusion gives rise to interparticle bonding, but with little densification. Accordingly, the final product is porous. Such a technique is in widespread use for forming moderately complex shapes for mechanical systems using ferrous powders. The open continuous pore structures that exist in these P/M products dominate fracture and fatigue behavior. Additionally, many filters, electrodes, capacitors, batteries, and other porous structures are formed in a similar manner using low compaction pressures. Such high-porosity structures should not be employed in a fatigue-sensitive environment.

Alternatively, small particles are shaped into useful components at low pressures with the assistance of an organic binder, such as wax, by injection molding, tape casting, or extrusion. The particle-packing density is relatively low, typically only 60% of theoretical. After shaping, the binder is removed by either heat or solvent extraction, and the powder is densified by sintering at a high temperature. These approaches give a final density that is usually between 94 and 100% of theoretical. They are slower and more costly than die compaction, but they deliver greater shape complexity and improved mechanical response measures. Thus, techniques such as powder injection molding are in widespread use for computer, biomedical, and firearm applications, especially using stainless steels. Because the pores are small, closed, and spherical, they have less detrimental effect on fracture and fatigue properties.

Finally, a powder can be subjected to a combination of heat and stress simultaneously. This allows full densification and is widely employed in the fabrication of structural metals, composites, and high-temperature alloys. Variations include forging, hot pressing, hot isostatic pressing, extrusion, and roll forming. Alloys fabricated this way are usually based on aluminum, titanium, steel, nickel, or refractory metal systems, but include composites and intermetallics. Because there is no residual porosity, fracture and fatigue properties are totally dependent on the microstructure, especially any inhomogeneities or contaminants. When properly performed, these processes result in full-density P/M products that have mechanical responses superior to those of their wrought equivalents, largely because of the microstructure homogeneity.

**P/M Materials**

Many metals are available via P/M techniques. Aluminum and its alloys are highly compressible as powders; green densities of 90% of theoretical are common. They can be sintered or hot consolidated using extrusion, forging, hot pressing, and hot isostatic pressing. As summarized in Table 1, typical strengths for the press and sinter approach are in the 200 MPa (29 ksi) range with 2% elongation to fracture. Higher strengths are available by dispersion strengthening and deformation processing, including hot isostatic pressing and extrusion. In the best cases, fatigue endurance limits (or fatigue strength at about  $10^7$  cycles) approach about 200 MPa (29 ksi). Some of the high-performance rapidly solidified P/M products provide excellent strength retention to high temperatures.

(A) BALANCE AL.

(B) MA, MECHANICALLY ALLOYED; HIP, HOT ISOSTATICALLY PRESSED; P+S, PRESSED AND SINTERED

Copper, brass, and bronze are sintered from particles, where the typical applications are not fatigue sensitive. Cemented carbides, such as WC-Co and TiC-Ni, are sintered using a liquid phase to deliver a full-density structure, often by the application of a high pressure at the end of the sintering cycle. The elimination of residual pores has considerable impact on fracture resistance, giving a fracture strength in the 1700 to 3000 MPa (245 to 435 ksi) range. Unfortunately, the basic materials are brittle, so fracture toughness is usually in the range of 10 to 20 MPa  $\sqrt{m}$ , depending on cobalt (or other matrix phase) content and carbide grain size.

Stainless steel P/M products are usually selected for their corrosion resistance. However, they are capable of highly variable final response measures, depending on the composition, density, and microstructure. For precipitation-hardenable alloys such as 17-4 PH, yield strengths of 1100 MPa (160 ksi) with 12% elongation are possible with fatigue endurance limits in the 500 MPa range (72 ksi). Alternatively, for austenitic stainless steels such as 316L, a sintered yield strength of 250 MPa (36 ksi) and considerable ductility (30% or more) are common.

By far the largest segment of the P/M applications rely on iron-base alloys. Generally, a powder is pressed in uniaxial tooling to near-final dimensions, but not to full density. Dimensional control during sintering is very important, and usually size can be held to within  $\pm 0.025$  mm of specification, with concentricity to 0.1 mm, squareness to 0.05 mm, and density to  $0.1 \text{ g/cm}^3$ . Strength typically exhibits a small scatter of  $\pm 35$  MPa ( $\pm 5$  ksi) and elongation exhibits a scatter of  $\pm 2\%$ . In most sintered structural steel components, over 90% of the composition is iron. Table 2 gives examples of common P/M alloy compositions. In all cases, the mechanical properties increase with the final density.

**TABLE 2 COMMON FERROUS P/M CLASSES**

DESIGNATION	COMPOSITION
PURE IRON (STEEL)	MAX 1% C
COPPER STEEL	1-22% CU, MAX 1% C
IRON-NICKEL	1-3% NI, MAX 2.5% CU, MAX 0.3% C
NICKEL STEEL	1-8% NI, MAX 2.5% CU, MAX 1% C
LOW-ALLOY STEEL	0.3-2% NI, 0.5-1% MO, 0.4-0.8% C
INFILTRATED STEEL	8-25% CU, MAX 1% C
PHOSPHORUS STEEL	0.4-0.8% P, LOW C
SINTER-HARDENED STEEL	1-3% CR, 1-2% MN, 2% NI, 0.4-0.8% C

Iron-copper-carbon compositions are the most common in production, because copper forms a liquid phase during sintering that greatly aids particle bonding. This system illustrates the properties possible with P/M. Copper and graphite (carbon) are mixed with iron, and during sintering the copper forms a liquid phase. Wrought materials of equivalent compositions are not possible due to extensive segregation in the molten state. The mechanical properties are degraded by whatever pores remain after sintering. Tables 3 and 4 provide examples of the property degradation by listing the hardness, strength, ductility, and impact energy versus density for two Fe-Cu-C alloys. Table 3 shows a density effect for an Fe-2Cu-0.8C alloy, while Table 4 includes both density and heat treatment effects for an Fe-10Cu-0.3C alloy. In these tables the fatigue life was measured at  $10^7$  fully reversed cycles ( $R = -1$ ). Note that, for example, hardness and strength actually change less with increases in density than does the fatigue endurance strength. This reflects the greater sensitivity of the dynamic properties to pore structure as compared with the quasistatic tensile properties.

Nickel is another common addition to ferrous P/M alloys for improved strength. In low concentrations, phosphorus is used due to its potent hardening of iron and formation of a liquid phase at temperatures above 1050 °C (1920 °F). The liquid aids sintering, pore spheroidization, and alloy hardening, but usually these additives are selected for magnetic properties, not mechanical properties, with a popular composition containing 0.45% P. Most of these alloys are formed by mixing powders that are alloyed as part of the sintering cycle, because of the higher compressibility of the elemental powders as compared with that of prealloyed powders.

There are several other widely employed P/M materials. Tool steels are usually fabricated to full density by liquid-phase sintering or hot isostatic pressing. Cobalt-base alloys, titanium alloys, and superalloys are fabricated to full density by hot isostatic pressing. Table 5 compares the mechanical properties of Ti-6Al-4V alloys fabricated by three processing routes. A very useful group of P/M alloys are the tungsten heavy alloys. These are based on W-Ni-Fe mixtures that are densified by liquid-phase sintering. Table 6 gives the typical mechanical properties of sintered tungsten heavy alloys. These are full-density products, but despite the high sintered density they lack good fatigue properties due to the two-phase microstructure. Like tungsten, most of the other refractory metals (molybdenum, tantalum, titanium, chromium, niobium, and rhenium) are fabricated from powders.

Low-cost composites are fabricated using P/M techniques. Particle reinforcement requires mixing of the constituents and consolidation to full density. A popular combination is Al-SiC. Sample mechanical properties of this composite as fabricated by vacuum hot pressing are given in Table 7, where the SiC content ranges from 0 to 40 vol%. Again, the fatigue properties of these composites are not very attractive because of the differential elastic modulus between the reinforcement and matrix.

### **Porosity Effects**

An inherent physical characteristic of P/M materials is the presence of pores. The role of porosity in determining fatigue endurance in powdered metals is akin to that of porosity that is induced through metal solidification in casting or welding. However, the porosity that is characteristic of sintered powdered metals, and of those materials subsequently deformation processed, may differ in character and influence from solidification porosity. In all cases, porosity catches the attention of the design engineer because it immediately conjures up images of classical stress concentrators. In addition, porosity featuring sharp re-entrant corners, a possibility for marginally equilibrium-sintered powder particle boundaries, may be more accurately viewed as crack precursors. Pore geometry can be altered by modifications to the sintering cycle, such as a longer hold time or higher temperature, wherein the smoother pores improve strength, fatigue life, and fracture resistance.

Ductility is sensitive to the pore structure, but impact, fracture, and fatigue behavior have the greatest sensitivities. In general, dynamic strength responses are the most sensitive. Even in those materials possessing full density, inferior properties can occur due to microstructural defects. Recent applications have pushed P/M into very demanding applications, a good example being the automotive connecting rod. Such rods are formed by hot forging a porous P/M preform using an alloy of Fe-2Cu-0.8C. They weigh nearly 650 g. The ultimate tensile strength is 825 MPa (120 ksi), with a yield strength of 550 MPa (80 ksi) and fatigue endurance limit of 255 MPa (37 ksi). With expansion of P/M fabrication technology into dynamically loaded components, there arise performance limitations associated with fracture and fatigue. For static tensile properties, there is a good basis for predicting the effect of residual porosity on strength (Ref 2, 3, 4, and 5). Recent research has had an emphasis on fatigue and fracture behavior to fill the database void.

Porosity is especially important to the high-cycle fatigue life (Ref 6, 7, 8, and 9). Pores play a role in both crack initiation and propagation, typically increasing the threshold stress intensity for crack initiation but lowering the resistance to crack propagation (Ref 10). For an alloy of Fe-2Ni-0.8C the fatigue endurance limit at  $10^7$  reverse cycles is between 200 and 250 MPa at a density of  $7.1 \text{ g/cm}^3$  (approximately 10% porosity). That is approximately 35% of the tensile strength, and many porous injection-molded materials exhibit similar ratios of fatigue strength to tensile strength. Closed pores are less detrimental than those that are interconnected and open to the external surface. Surface pores act as the preferred site of fatigue crack initiation by acting as stress concentrators (Ref 11). The simplest view of a pore would be that of a spherical hole embedded in a continuous matrix whose response parameters are identical with that of a fully dense form of exactly the same metallurgical state. Since the maximum, most positive, principal stress is the controlling load parameter for high-cycle fatigue endurance, the embedded pore in a tensile field is a reasonably approximate model for a stressed porous metal without interacting stress fields (one of less than 10% porosity). One can expect the local pore-dominated

stress field to control local events such as crack initiation and threshold stress intensity values ( $\Delta K_{th}$ ). For an embedded pore, the local stress fields are related to the far-field (applied) design stresses (Ref 12):

$$\sigma_{local} = \sigma_{design} \left[ \frac{27 - 15\nu}{2(7 - 5\nu)} \right] \quad (\text{EQ 1})$$

Note that, for the average steel,  $\nu = 0.30$ , and the local stresses are magnified by a factor of about 2. The concentrated stress field does not persist far beyond the embedded pore, being reduced to 105% of the design value at a distance of  $2a$  (where  $a$  is the pore radius) from the pore center, thus possibly exerting little influence on far field parameters.

If the pore features sharp re-entrant corners, the elastic concentrated stresses are more accurately predicted from an elliptical hole example. However, these same pores are unlikely to exhibit smooth ellipsoidal morphologies, and their concentration effects can be more usefully predicted by the proportionality (Ref 13):

$$\sigma_{local} \approx 2\sigma_{design} \sqrt{\frac{a}{\rho}} \quad (\text{EQ 2})$$

Here,  $a$  is the major pore length normal to the maximum principal stress direction, and  $\rho$  is the radius of curvature at the sharp corner. Suffice to say that the calculated stress concentration value can be large for a nonspheroidized pore.

Due to the stress-raising properties of pores, and the fact that most fatigue failures originate at free surfaces, treatments aimed at surface densification and serendipitous surface strengthening (e.g., coining, shot peening, ausrolling) raise the fatigue endurance limit (Ref 14, 15, 16). As a consequence, the current models for fatigue response in porous sintered materials have a major dependence on the pore microstructure: the models address the total porosity, alloying homogeneity in near-pore regions, pore size, pore shape, and interpore separation distance (Ref 6, 17, 18, 19, 20, 21, 22, 23, and 24). Round pores provide improved resistance to crack propagation. Pores act as linkage sites through which cracks can propagate. Microstructure-based fatigue models for ferrous alloys have had to address seemingly contradictory porosity effects: round pores retard stable fatigue crack propagation but increase crack extension growth rates by contributing linkage sites. While extant theories successfully explain some porosity effects on crack propagation, no total predictive model has been created that embraces microstructure effects (Ref 18, 20, 22). The presence of pores in the reversed plastic zone that is the site of propagating crack damage does not lend itself to facile analysis.

Pore structure changes are obtainable through processing and material variations: powder variables (particle size distribution, particle shape); compaction variables (type of lubricant, amount of lubricant, tool motions, maximum pressure); sintering variables (hold time, maximum temperature, atmosphere); and postsintering treatments. Figure 1 compares the pore structure in two sintered stainless steels to emphasize this point. Smaller particles result in faster sintering and higher strengths and toughness. Associated with the smaller particle sizes are smaller final pores. At lower densities (around  $6.6 \text{ g/cm}^3$  or 18% porosity in steels), a high relative content of small particles is beneficial to fatigue resistance, while at higher densities (over  $7.1 \text{ g/cm}^3$  or less than 10% porosity), larger particles prove beneficial. The difference relates to the ligament size between pores, which is the determinant of fatigue. There are three pore microstructure parameters relevant to the fatigue resistance of porous P/M materials: pore size, pore curvature, and pore spacing. These largely reflect the role of stress concentration with respect to the advancing fatigue crack, as noted above (Ref 6). Thus, lower porosity contents, smoother (rounder) pores, and wider interpore separations increase the fatigue endurance strength.

Fatigue cracks have been successfully analyzed with regard to their propagation response, and the cyclic growth of a crack can be predicted by the modified Paris growth law:

$$\frac{da}{dN} = A (\Delta K_{eff})^n \quad (\text{EQ 3})$$

where the material parameters  $A$  and  $n$  must be experimentally determined for any given material microstate, including different distributions of porosity. The stress analytical variable  $\Delta K_{eff}$ , the effective stress intensity range, factors out that portion of the total stress range that relieves the stresses holding the crack flanks closed, the opening stress range  $\Delta\sigma_{op}$ , leaving only the stress range component that displaces the crack faces relative to each other. In the presence of appreciable levels of mean stress, the relation between load design parameters and fatigue crack propagation rates is given by:

$$\frac{da}{dN} = \frac{C \Delta K^n}{(1 - R)K_c - \Delta K} \quad (\text{EQ 4})$$

Here, the total stress-intensity factor range  $\Delta K$  is the load variable, but the fatigue ratio  $R = \sigma_{min}/\sigma_{max}$  and the fracture toughness  $K_c$ , or  $K_{Ic}$  for a low-ductility sintered member, enter into the fatigue crack propagation response, as do the material constants  $C$  and  $n$ .

Regardless of which of the three fatigue crack propagation relations are relevant in a particular service context, their collective utility lies in predicting member lifetimes, or precise segments of that lifetime. Thus, in the case of the Paris law:

$$N = \int_0^{N_t} dN = \int_{a_0}^{a_c} \frac{da}{A(\Delta K)^n} \quad (\text{EQ 5})$$

The calculated endurance cycles to failure,  $N$ , can be from an initial flaw size  $a_0$  that may be the minimum detectable to final fracture at  $a = a_c$ , where:

$$K_{IC} = \sigma_{MAX} \sqrt{\pi a_c} \quad (\text{EQ 6})$$

Again, the fracture toughness of the material plays a role in determining structural endurance. The fracture resistance  $K_{Ic}$ , or  $K_R$  in the case of more ductile sintered materials (Ref 25), is known to be porosity sensitive (Ref 26). As a first estimate, the sensitivity is about a 100 MPa  $\sqrt{m}$  gain in toughness per percentage point of porosity reduction in quenched and tempered steels. Copper-infiltrated steels have toughnesses that run from 40 to 50% those of wrought steels (Ref 27, 28). However, their static strengths are equivalent, reflecting the inability of the steel skeleton to absorb the same level of strain energy release as a fully dense body of the same material.

The material parameters in the modified Paris equation (Eq 3) are sensitive to the porosity state, a not unexpected result since the coefficient and exponent are related to the plastic zone size  $r_p$  ahead of the advancing crack, the only region of irreversible deformation. The coefficient  $A$  in Eq 3 increases with increasing porosity fraction (Ref 29), resulting in faster growth rates for comparable  $\Delta K_{eff}$  values. With higher coefficient measures but constant exponent  $n$  values, the threshold stress intensity range  $\Delta K_{th}$ , below which no crack growth is thought to occur, also decreases with porosity increase. However,  $\Delta K_{th}$  values for fully dense materials are sufficiently low that it is not at all clear in what way they could be successfully employed in design practice if service stresses are to be set at appreciable fractions of the yield or tensile strength. The reversed plastic zone size is given by (Ref 30):

$$r_p = \frac{K_I^2}{6\pi\sigma_y^2} \quad (\text{EQ 7})$$

When the plastic zone size is of the same size as the average pore diameter, it is effectively enlarged by the high strain field in the vicinity of the pore. The net result of the enlarged effective plastic zone is reflected in higher values of the exponent  $n$  (Ref 11), and the enlarged zone is even more pronounced in the response of short cracks driven by the locally raised stress/strain fields associated with design stress concentrators (Ref 15). Copper-infiltrated steels (Ref 27, 28) are as fatigue and fracture resistant as fully dense wrought medium-strength steels. Although the performance standards are not up to those of fully dense martensitic steels, copper infiltration represents a considerable cost saving over forging to full density, while maintaining the cost advantage inherent in press and sinter P/M.

Typical fatigue endurance limits (or fatigue strengths at about  $10^7$  cycles) are collected in Table 8 for several P/M materials. This compilation includes several ferrous alloys, reflecting the high interest in P/M fatigue for automotive applications. There are variations in density, alloying, and sintering cycles to show the relative effects on sintered properties. Systematic testing of various alloys has shown that slight changes in the particle size distribution or alloying homogeneity can affect these properties. For example, in the Fe-2Ni-0.8C alloy system, shifts in just the iron powder source lead to  $\pm 33$  MPa ( $\pm 4.8$  ksi) variations in the fatigue endurance strength. Accordingly, the values in Table 8 are for relative ranking purposes only and cannot be used as an accurate basis for design of fatigue-sensitive components.

Fracture studies of P/M alloys are usually restricted to impact testing, and often this is performed in the unnotched condition because of the low toughness of porous materials. Fracture toughness measurements on P/M materials are relatively rare. Tables 9 and 10 summarize some prior findings. Table 9 demonstrates the density effect on tensile properties and  $K_{Ic}$ , for an Fe-Ni-Mo-C steel. Note that as the porosity decreases, the strength essentially doubles, ductility increases substantially (a nearly tenfold gain), the impact energy goes up by a factor of 4, and fracture toughness increases threefold. Table 10 collects several examples of the mechanical properties of ferrous alloys and one titanium alloy as representative values obtainable via P/M. Clearly, porosity negatively affects the fracture toughness in most materials. The fracture toughness of P/M steels is essentially a linear function of density (Ref 18), with sensitivities of about 100 MPa $\sqrt{m}$  gain in toughness per percentage point of porosity reduction. In low-density P/M materials, the fracture crack propagation is rapid because the pore structure amplifies the stress and provides an easy path. At low porosity levels, an advancing fracture crack can be blunted by the pores, effectively forming microcracks that improve toughness (Ref 31).

### Other Factors Determining Fatigue and Fracture Resistance

It is well established that porosity is the major detriment to fatigue life for P/M materials. Beyond porosity, the sintered microstructure is a factor. Even in full-density materials fabricated by hot isostatic pressing, microstructure has a role. Weak links in the microstructure become evident during fracture. For porous structures, these weak links prove to be

microstructural inhomogeneities, typically resulting from incomplete diffusional homogenization. Often powders (such as iron, nickel, and graphite) are mixed in the compaction stage. During heating the intent is for the mixed powders to homogenize to form a uniform microstructure, but this often is inhibited by too short a hold time at the peak temperature. Consequently, the alloying elements are poorly distributed and give point-to-point composition and microstructure changes, which are especially evident in postsintering heat treatment response. Accordingly, during fatigue or fracture, the weak links become the preferred failure paths. Most notable are the negative effects from inadequate homogenization of carbon to ensure uniform strength (Ref 18).

Little is known about the sensitivity of fatigue and fracture to loading conditions for P/M material. Table 11 compares the  $2 \times 10^6$  fatigue endurance strengths for Fe-1.5Cu-0.6C at  $7.1 \text{ g/cm}^3$  density using bending and axial fatigue tests. The table also includes a comparison with two loading stress ratios (half-cycle and fully reversed,  $R = -1$ ) and two notch conditions (unnotched and notched) (Ref 18). In these cases the unnotched loading shows little sensitivity to axial versus bending fatigue, but a large sensitivity is evident in the presence of notches. The notch sensitivity factor is reported to range between 0.32 and 0.43 for many of the common pressed and sintered P/M alloys (Ref 32).

**TABLE 11 FATIGUE PROPERTIES OF FE-1.5CU-0.6C**

NOTCH FACTOR, $K$	STRESS RATIO, $R$	ENDURANCE STRENGTH, MPA AT $2 \times 10^6$ CYCLES
<b>AXIAL</b>

Full-density materials also suffer from residual microstructure artifacts that degrade the microstructure. In hot isostatically compacted powders, the achievement of 100% density is still insufficient to guarantee competitive fracture toughness, fatigue life, or even impact toughness. Thermally induced porosity is a subtle problem in many full-density P/M products. After consolidation the material is pore free, but it may contain small quantities of adsorbed gas. Once the product is put into high-temperature heat treatment or service, this residual gas precipitates to form pores if there is no compressive stress. In hot isostatically pressed titanium alloys, gas precipitation reportedly gives a 10 to 20% decrement in fatigue endurance strength (Ref 33).

Another difficulty rests in slight contaminants located on the interfaces that were previously particle surfaces, a feature termed prior particle boundary decorations. Figure 2 shows such decorations in a fully densified P/M steel. Improper powder handling or cleaning prior to consolidation are the primary detriments. These contaminants remain on the powder interfaces, even though the structure is fully densified. Consequently, a small contamination film runs throughout the structure, providing an easy fracture path that is often traced to a trivial impurity level. The fracture path is along the prior particle boundaries and has a characteristic morphology, as shown in Fig. 3. In hot isostatically pressed Ti-6Al-4V there is substantial fatigue life improvement due to removal of the contaminant, with a change from 450 MPa endurance strength to 600 MPa due to powder cleaning prior to consolidation (Ref 34).

**FIG. 2** PRIOR PARTICLE BOUNDARY PRECIPITATES FORMED ON A HOT ISOSTATICALLY PRESSED STEEL AS THE RESULT OF CONTAMINATION DURING POWDER FABRICATION. 500×

**FIG. 3** A FRACTURE SURFACE SHOWING PREFERENTIAL FAILURE ALONG PRIOR ARTICLE BOUNDARIES. 150×

One option for limiting the detrimental effects from prior particle boundary decorations is to forge the structure after hot isostatic pressing, a process often used in producing aerospace structures to ensure ultimate reliability. The forging operation upsets the microstructure and breaks apart the continuous films of contamination. The alternative is to resort to clean handling and processing, where the powder is produced by rapid solidification and kept under inert conditions during handling. These steps, which minimize segregation and contamination, are employed in the production of aerospace components, microelectronic structures, and high-performance filters.

### Steps to Improve Fatigue and Fracture Resistance

Surface pores are particularly detrimental to sintered materials with respect to fatigue life (Ref 35). Accordingly, carbonitriding and other surface strengthening and sealing treatments are most useful. Common treatments include shot peening, case hardening, repressing and resintering, coining, sizing, surface ausrolling, and postsintering heat treatments. For example, in pressed and sintered ferrous alloys, the endurance limit can be increased on small cross sections (6 by 6 mm) by at least 20% through shot peening. Carbonitriding is even more effective and can double the fatigue endurance limit. A typical carbonitride cycle involves heating to 940 °C in a mixture of ammonia and carbon dioxide for 4 h to form a 0.5 mm deep carbon-rich layer. Surface grinding is another approach to improved fatigue strength. The larger the cross section of the material, the less benefit possible from surface treatments, because bulk material states will dominate mechanical response.

The double press and double sinter approach was largely the only viable option for improving density and strength in traditional press and sinter P/M. This is more costly and involves extra tooling. A newly employed technique for improved fatigue life and fracture toughness in pressed and sintered ferrous alloys is to sinter at higher temperatures. The typical sintering temperature for steels is about 1120 °C, largely because of conveyor belt limitations in the furnaces. New materials of construction (ceramic belts) and new conveyor mechanisms (pusher plate and walking beam designs) allow higher-temperature processing regimes. Additionally, vacuum sintering usually is not limited in temperature, so it is viable for high-performance components. There is more sintering densification at the higher temperatures, so the density gain alone improves properties. Induced changes in the pore shape and size also improve fracture and fatigue properties. Several examples of the property gains are evident in Table 8. In a comparison of density gains versus sintering temperature effects, it is usually concluded that a change from 1120 to 1280 °C is equivalent to a density gain from 7.1 to 7.4 g/cm<sup>3</sup> in terms of both fracture toughness and fatigue endurance strength.

For small components the surface treatments are most useful, because the compressive forces extend through a major portion of the microstructure. However, for the porous materials with large cross sections, the need is to sinter at higher temperatures to improve fatigue and fracture. Further, designs that minimize density gradients will assist in minimizing fatigue failure. The high-density regions have a higher fatigue strength, and the difference in strength with density often results in failure at the interface between high- and low-density regions. For fatigue-sensitive components, the tolerable range of densities is less than 0.05 g/cm<sup>3</sup> within the structure. As with all fatigue-sensitive components, consideration must be given to surface finishing and processing optimization. The keys to improved performance are reduction in the total porosity, elimination of segregation and contamination, and manipulation of the pore microstructure.

There are some unique design opportunities where the microstructure of P/M materials offers a fatigue advantage in spite of the porosity. Because many alloys are formed from mixed powders, there is often an enrichment of the alloying addition near pores. The resulting higher strength aids local strength and fatigue life. Surprisingly, when properly exploited this effect gives higher fatigue and fracture strength to porous structures formed from mixed elemental powders, compared to those formed from prealloyed powders (Ref 36). Unfortunately, pores reduce the elastic modulus, strength, ductility, hardness, and other mechanical properties, so a high-density structure usually proves most successful in fatigue-sensitive applications. Indeed, the high sensitivity to porosity mandates that porosity be tightly controlled (density held within 0.05 g/cm<sup>3</sup>) in regions of high stress concentrations. At a given strength level the P/M steels exhibit less notch sensitivity than wrought steels, because pores inherently act to blunt cracks and redistribute the load, especially under complex loading. Open pores, which dominate the sintered microstructure for densities below 92% of theoretical, retard

fatigue crack propagation. Surface densification of P/M steels from shot peening, sizing, coining, surface rolling, or carbonitriding all prove beneficial in improving fatigue strength because of pore closure and surface compressive stresses.

### Safety Factors for P/M Materials

Several factors contribute to scatter in the fracture and fatigue properties of P/M materials. There is the obvious error in testing, where the range of highest fatigue strength to lowest fatigue strength for a single test condition may be 4%. Further, there is typically a notch sensitivity and test error. Consequently, a safety factor of 1.4 is often cited as appropriate for sintered P/M alloys (Ref 18). This means that a peak cyclic stress of about 70% of the fatigue endurance strength is the maximum recommended in service.

## Fatigue and Life Prediction of Gears

Darle W. Dudley

---

### Introduction

GEARS can fail in many different ways, and except for an increase in noise level and vibration, there is often no indication of difficulty until total failure occurs. In general, each type of failure leaves characteristic clues on gear teeth, and detailed examination often yields enough information to establish the cause of failure. The general types of failure modes (in decreasing order of frequency) include fatigue, impact fracture, wear, and stress rupture (Table 1). The leading causes of failure appear to be tooth-bending fatigue, tooth-bending impact, and abrasive tooth wear.

**TABLE 1 FAILURE MODES OF GEARS**

FAILURE MODE	TYPE OF FAILURE
FATIGUE	TOOTH BENDING, SURFACE CONTACT (PITTING OR SPALLING), ROLLING CONTACT, THERMAL FATIGUE
IMPACT	TOOTH BENDING, TOOTH SHEAR, TOOTH CHIPPING, CASE CRUSHING, TORSIONAL SHEAR
WEAR	ABRASIVE, ADHESIVE

In an analysis of more than 1500 studies, the three most common failure modes, which together account for more than half the failures studied, are tooth-bending fatigue, tooth-bending impact, and abrasive tooth wear.

Source: *Metals Handbook*, 9th ed., Vol 11, *Failure Analysis and Prevention*, ASM International, 1986

This article summarizes the various kinds of gear wear and failure and how gear life in service is estimated. Hopefully, gears are properly designed, made of good material, and accurately machined so that the life of the gear is adequate for the service intended. The manner in which gears wear in service and the various kinds of failure that may occur determine how gear life in service is estimated. In addition, the kinds of flaws in material that may lead to premature gear failure are discussed. Gear life is influenced primarily by geometric accuracy, gear-tooth contact conditions, and material condition or flaws. Metallurgical quality is just as important as gear-tooth geometric accuracy, and both must be under good control by those designing, making, or inspecting gears.

### **Gear Tooth Contact**

The way in which tooth surfaces of properly aligned gears make contact with each other is responsible for the heavy loads that gears are able to carry. In theory, gear teeth make contact along lines or at points; in service, however, because of elastic deformation of the surfaces of loaded gear teeth, contact occurs along narrow bands or in small areas. The radius of curvature of the tooth profile has an effect on the amount of deformation and on the width of the resulting contact bands. Depending on gear size and loading, the width of the contact bands varies from about 0.38 mm (0.015 in.) for small, lightly loaded gears to about 5 mm (0.2 in.) for large, heavily loaded gears.

Gear tooth surfaces are not continuously active. Each part of the tooth surface is in action for only short periods of time. This continual shifting of the load to new areas of cool metal and cool oil makes it possible to load gear surfaces to stresses approaching the critical limit of the gear metal without failure of the lubricating film.

The maximum load that can be carried by gear teeth also depends on the velocity of sliding between the surfaces, because the heat generated varies with rate of sliding as well as with pressure. If both pressure and sliding speeds are excessive, the frictional heat developed can cause destruction of tooth surfaces. This pressure-velocity factor, therefore, has a critical influence on the probability of galling and scoring of gear teeth. The permissible value of this critical factor is influenced by gear metal, gear design, character of lubricant, and method of lubricant application.

Lubrication is accomplished on gear teeth by the formation of two types of oil films. The reaction film, also known as the boundary lubricant, is produced by physical adsorption and/or chemical reaction to form a desired film that is soft and easily sheared but difficult to penetrate or remove from the surface. The elastohydrodynamic film forms dynamically on the gear tooth surface as a function of the surface speed. This secondary film is very thin, has a very high shear strength, and is only slightly affected by compressive loads as long as constant temperature is maintained.

Certain rules about a lubricant should be remembered in designing gearing and analyzing failures of gears:

- **LOAD IS TRANSFERRED FROM A GEAR TOOTH TO ITS MATING TOOTH THROUGH A PRESSURIZED OIL FILM. IF NOT, METAL-TO-METAL CONTACT MAY BE DETRIMENTAL.**
- **INCREASING OIL VISCOSITY RESULTS IN A THICKER OIL FILM (KEEPING LOAD, SPEED, AND TEMPERATURE CONSTANT).**
- **HEAT GENERATION CANNOT BE CONTROLLED ABOVE A CERTAIN MAXIMUM VISCOSITY (FOR A GIVEN OIL).**
- **BREAKDOWN OF THE OIL FILM WILL OCCUR WHEN THE GEAR TOOTH SURFACE-**

EQUILIBRIUM TEMPERATURE HAS REACHED A SPECIFIC VALUE. THE SCUFFING LOAD LIMIT OF MATING TOOTH SURFACES IS SPEED DEPENDENT. WITH INCREASING SPEED, THE LOAD REQUIRED TO BE SUPPORTED BY THE REACTION FILM DECREASES, WHILE THE LOAD THAT CAN BE SUPPORTED BY THE INCREASING ELASTOHYDRODYNAMIC FILM INCREASES. THE RESULT IS A DECREASING SCUFFING LOAD LIMIT TO A CERTAIN SPEED AS THE REACTION FILM DECREASES; THEN, AS THE SPEED PICKS UP TO WHERE THE ELASTOHYDRODYNAMIC FILM INCREASES, THE SCUFFING LOAD LIMIT INCREASES. THIS ALLOWS AN INCREASE IN OVERALL LOAD-CARRYING CAPACITY (ASSUMING NO CHANGE IN TEMPERATURE THAT WOULD CHANGE VISCOSITY).

- AT CONSTANT SPEED, SURFACE-EQUILIBRIUM TEMPERATURE INCREASES AS LOAD INCREASES, WHICH LOWERS THE SCUFFING LOAD LIMIT OF THE REACTION FILM (SURFACE-EQUILIBRIUM TEMPERATURE IS ATTAINED WHEN THE HEAT DISSIPATED FROM THE OIL IS EQUAL TO THE HEAT EXTRACTED BY THE OIL).

Damage to and failures of gears can and do occur as a direct or indirect result of lubrication problems.

**Spur and Bevel Gears.** Spur gear teeth are cut straight across the face of the gear blank, and the mating teeth theoretically meet at a line of contact (Fig. 1a) parallel to the shaft. Straight teeth of bevel gears also make contact along a line (Fig. 1b) that, if extended, would pass through the point of intersection of the two shaft axes. As teeth on either spur or bevel gears pass through mesh, the line of contact sweeps across the face of each tooth. On the driving tooth, it starts at the bottom and finishes at the tip. On the driven tooth, the line of contact starts at the tip and finishes at the bottom.

**FIG. 1** TOOTH CONTACT LINES ON A SPUR GEAR (A), A BEVEL GEAR (B), AND A LOW-ANGLE HELICAL GEAR (C). LINES ON TOOTH FACES OF TYPICAL TEETH ARE LINES OF CONTACT.

**Helical, Spiral Bevel, and Hypoid Gears.** Gear tooth contact on helical, spiral bevel, and hypoid gears is similar to that developed on a stepped spur gear (Fig. 2). Each section, or lamination, of the spur gear makes contact with its mating gear along a straight line; each line, because of the offset between sections, is slightly in advance of its adjacent

predecessor. When innumerable laminations are combined into a smoothly twisted tooth, the short individual lines of contact blend into a smoothly slanted line (Fig. 1c) that extends from one side of the tooth face to the other and sweeps either upward or downward as the tooth passes through mesh. This slanted-line contact occurs between the teeth of helical gears on parallel shafts, spiral bevel gears, and hypoid gears.

**FIG. 2 LINES OF CONTACT ON A STEPPED SPUR GEAR. THE HEAVY LINE ON A TOOTH FACE OF EACH GEAR SECTION REPRESENTS THE INSTANTANEOUS LINE OF CONTACT FOR THAT SECTION. THIS OFFSET-CONTACT PATTERN IS TYPICAL FOR HELICAL, SPIRAL BEVEL, AND HYPOID GEARS. LINES ON TOOTH FACES ARE LINES OF CONTACT.**

The load pattern is a line contact extending at a bias across the tooth profile, moving from one end of the contact area to the other end. Under load, this line assumes an elliptical shape and thus distributes the stress over a larger area. Also, the purpose of spiral bevel gearing is to relieve stress concentrations by having more than one tooth enmeshed at all times.

The greater the angle of the helix or spiral, the greater the number of teeth that mesh simultaneously and share the load. With increased angularity, the length of the slanted contact line on each tooth is shortened, and shorter but more steeply slanted lines of contact sweep across the faces of several teeth simultaneously. The total length of these lines of contact is greater than the length of the single line of contact between straight spur-gear teeth of the same width. Consequently, the load on these gears is distributed not only over more than one tooth but also over a greater total length of line of contact. On the other hand, the increased angularity of the teeth increases the axial thrust load and thus increases the loading on each tooth. These two factors counterbalance each other; therefore, if the power transmitted is the same, the average unit loading remains about the same.

Helical gears on crossed shafts make tooth contact only at a point. As the teeth pass through mesh, this point of contact advances from below the pitchline of the driving tooth diagonally across the face of the tooth to its top, and from the top of the driven tooth diagonally across its face to a point below the pitchline. Even with several teeth in mesh simultaneously, this point contact does not provide sufficient area to carry an appreciable load. For this reason, helical gears at angles are usually used to transmit motion where very little power is involved.

**Worm Gears.** In a single-enveloping worm gear set, in which the worm is cylindrical in shape, several teeth may be in mesh at the same time, but only one tooth at a time is fully engaged. The point (or points) of contact in this type of gear set constitutes too small an area to carry an appreciable load without destruction of the metal surface. As a result, single-enveloping worm gear sets are used in applications similar to those for helical gears on crossed shafts: to transmit motion where little power is involved.

Considerable power must be transmitted by commercial worm gear sets; therefore, the gears of these sets are throated to provide a greatly increased area of contact surface. The gear tooth theoretically makes contact with the worm thread along a line curved diagonally across the gear tooth. The exact curve and slant depend on tooth design and on the number of

threads on the worm relative to the number of teeth on the gear. Usually, two or more threads of the worm are in mesh at the same time, and there is a separate line of contact on each meshing tooth. As meshing proceeds, these lines of contact move inward on the gear teeth and outward on the worm threads. To secure smooth operation from a gear of this type, the teeth of the gear and sometimes the threads of the worm are usually altered from theoretically correct standard tooth forms. These alterations result in slightly wider bands of contact, thus increasing the load-carrying capacity of the unit. Load-carrying capacity also depends on the number of teeth in simultaneous contact. Exact tooth design varies from one manufacturer to another, and for this reason, the patterns of contact also vary.

In a double-enveloping worm gear set, the worm is constructed so that it resembles an hourglass in profile. Such a worm partly envelopes the gear, and its threads engage the teeth of the gear throughout the entire length of the worm. The teeth of both the worm and the gear have straight-sided profiles like those of rack teeth, and in the central plane of the gear, they mesh fully along the entire length of the worm.

The exact pattern of contact in double-enveloping (or double-throated) worm gear sets is somewhat controversial and seems to vary with gear design and with method of gear manufacture. It is generally agreed, however, that contact is entirely by sliding with no rolling and that radial contact occurs simultaneously over the full depth of all the worm teeth.

**Operating Loads.** Gears and gear drives cover the range of power transmission from fractional-horsepower applications, such as hand tools and kitchen utensils, to applications involving thousands of horsepower, such as heavy machinery and marine drives. However, neither the horsepower rating nor the size of a gear is necessarily indicative of the severity of the loading it can withstand. For example, the severity of tooth loading in the gear train of a 186 W ( $\frac{1}{4}$  hp) hand drill may exceed that of the loading in a 15 MW (20,000 hp) marine drive. Factors other than horsepower rating and severity of loading can affect gear strength and durability, particularly duration of loading, operating speed, transient loading, and environmental factors such as temperature and lubrication.

### Gear Tooth Surface Durability and Breakage

Metal gears are normally lubricated with an oil or a grease. Some small, nonmetallic gears have limited capability to run without lubrication, due to the self-lubricating properties of the material.

When metal gears are adequately lubricated with a clean lubricant, there is very little abrasive wear of the contacting tooth surfaces. However, the tooth surface may be quickly damaged by scuffing if (in combination with poor surface finish and low-viscosity lubricant) the load intensity, temperature, and rubbing speed are too high. Scuffing consists of small radial tears in the tooth surface. It is most apt to happen where the tip of one tooth is contacting the lower flank of a mating tooth (Fig. 3).

FIG. 3 AN EXAMPLE OF GEAR TOOTH SCUFFING. NOTE RADIAL SCRATCH LINES

Pitting may occur after some millions or billions of tooth contacts. In general, pitting almost never occurs before 10,000 contacts. Pitting is a fatigue failure where small cracks form in the tooth surface and then grow to the point where small, round bits of metal break out of the tooth surface (Fig. 4).

**FIG. 4 PITTED GEAR TEETH. NOTE MICROFITTING AT THE PITCH LINE, SCATTERED MACROPITS, AND ONE AREA OF GROSS PITTING NEAR THE LEFT END.**

Tooth breakage (such as in Fig. 5) is normally the situation where a crack starts in the root fillet, below the contacting surface, and then the crack grows such that a whole tooth breaks off in a cantilever-beam-type of failure. In wide-face gears, one end of the tooth may break off, leaving the tooth intact for the rest of the face width.

**FIG. 5 MISALIGNED GEAR HAS TOOTH BREAKAGE AT ENDS OF TEETH.**

Traditionally, the gear designer first determines a pitch diameter and a face width for the pinion that are large enough for the pinion to last for the required service life with a probability of failure of no more than 1 in 100. This determination is based on a possible pitting fatigue failure. It is assumed in the beginning that the surface finish, the tooth accuracy, the lubrication, and the needed profile and helix modifications will all be carried out well enough to avoid any serious risk of scuffing.

Normally, the pinion is more apt to fail in pitting than the gear, so the sizing of the pinion tends to determine the needed size of the gear. (The gear pitch diameter equals the pinion pitch diameter multiplied by the ratio. If the gear has four times as many teeth as the mating pinion, then the pitch diameter of the gear is four times greater than the pinion pitch diameter.)

After the pitch diameter of the pinion has been determined, the size of the teeth are determined by calculations regarding a possible failure in tooth breakage. A broken tooth tends to be catastrophic to a gear unit, so the designer usually makes the teeth large enough so that they are definitely less apt to fail in breakage mode than in a pitting mode. This makes the

design life of a gear unit primarily dependent on its surface fatigue capacity (pitting resistance) rather than on its cantilever beam capacity (capacity to resist tooth breakage).

### Life Determined by Contact Stress

The surface contact stress,  $S_c$ , between gear teeth (discussed further in Ref 1 with in-depth presentations of gear rating calculations and concepts) may be calculated by a simplified formula:

$$S_c \text{ (IN PSI)} = C_K (KC_D)^{0.5} \quad \text{(EQ 1)}$$

where  $C_k$  is the geometry factor for durability (see Table 2),  $K$  is the index of tooth loading severity for pitting (see Eq 2), and  $C_d$  is the overall derating factor for durability (see Table 3). The index of tooth loading for pitting is called the "K-factor." For spur or helical gears, the  $K$ -factor is:

$$K = \frac{W_t}{Fd} \left( \frac{m_G + 1}{m_G} \right) \quad \text{(EQ 2)}$$

where  $W_t$  is the tangential driving force (in pounds),  $F$  is the net face width in contact (in inches),  $d$  is the pinion pitch diameter (in inches), and  $m_G$  is the ratio of gear teeth to pinion teeth.

Note: These derating factors should be considered illustrative only. For a prime mover that is rough running and a driven device that is rough running, the derating needs to be more than shown above. Likewise, for a very smooth-running prime mover and a low-inertia, smooth-running driven device, lower derating factors may be justified. Field experience in vehicles, aircraft, and ships tends to be the best guide for choosing the right derating factor.

The tangential driving force is obtained from the horsepower being transmitted by the combination of pinion and gear, the speed of the pinion in revolutions per minute, and the pitch diameter of the pinion in inches. Thus:

$$W_t = \frac{P \times 126,050}{n_p \times d} \text{ lb} \quad (\text{EQ 3})$$

where  $P$  is the horsepower transmitted and  $n_p$  is the speed of the pinion (in rpm).

### Example 1: Surface Durability of Gear.

To show how the above equations work, consider a practical problem of an electric motor (running at a design speed of 1800 rpm) that drives a fan at 450 rpm and transmits power at a constant 30 hp. If the pinion driven by the motor has 22 teeth at a 15° helix angle and the normal diametral pitch of the teeth is 10, what are the calculated  $K$ -factor and contact stress when the mating gear has a face width 1.0 times the pinion pitch diameter? The normal pressure angle is 20°. The tooth design is 25% extra addendum of the pinion and 25% shorter addendum for the gear.

The first step is to obtain the pinion pitch diameter:

$$d = \frac{N_p}{p_n \cos \psi} \text{ in.} \quad (\text{EQ 4})$$

where  $N_p$  is the number of pinion teeth,  $\psi$  is the helix angle, and  $P_n$  is the normal diametral pitch. For the problem described above, then:

$$d = \frac{22}{10 \cos (15^\circ)} = 2.2776 \text{ in.}$$

$$F = 1.0 \times 2.2776 = 2.28 \text{ in.}$$

$$W_t = \frac{30 \times 126,050}{1800 \times 2.2776} = 922.4 \text{ lb}$$

$$K = \frac{922.4}{2.2776 \times 2.28} \frac{(4.0 + 1)}{(4.0)} = 222.0$$

$$S_c = 4558 (222.0 \times 2.5)^{0.5}$$

$$= 107,380 \text{ psi}$$

Table 2 does not have 22/88 tooth numbers, so in calculating  $S_c$ ,  $C_k$  was determined from Ref 2.

After the contact stress has been calculated, a rating curve sheet needs to be used to determine what life can be expected. Figure 6 shows typical contact stress values plotted against numbers of tooth contacts. This curve sheet is drawn for gearing having these qualifications:

- MATERIAL QUALITY: NORMAL INDUSTRY QUALITY (GRADE 1 PER REF 2)
- PROBABILITY OF FAILURE: NOT OVER 1 IN 100
- LUBRICATION: FULL OIL FILM, WHICH IS REGIME III
- HARDNESS: BOTH PINION AND MATING GEAR AT LEAST AS HARD AS VALUE SHOWN ON SURFACE DURABILITY FIGURE

FIG. 6 SURFACE DURABILITY CURVE FOR GEAR LIFE RATING (CONTACT STRESS VS. CYCLES) FOR NORMAL INDUSTRY QUALITY MATERIAL (GRADE 1 PER REF 2)

**Determination of Gear Life.** To explain how gear life is determined, the discussion can be based on the same sample problem. The calculated contact stress was 107,380 psi. From Fig. 6 the following life values are obtained for steel gears (through hardened):

- 210 HB:  $1.1 \times 10^6$  CYCLES
- 300 HB:  $2.0 \times 10^8$  CYCLES
- 60 HRC: OVER  $1.0 \times 10^{10}$  CYCLES

The next step is to calculate the number of pinion cycles for some different lengths of time at full rated load, where:

$$\begin{aligned} \text{CYCLES} &= (\text{RPM}) \times (60 \text{ MIN/H}) \times (\text{NO. OF HOURS}) \\ &= 1800 \times 60 \times \text{NO. OF HOURS} \end{aligned}$$

Taking some different numbers of hours, the following results are obtained:

TIME AT RATED POWER, H	NO. OF PINION CYCLES
500	$54 \times 10^6$
2000	$216 \times 10^6$
20,000	$2.16 \times 10^9$

Determination of adequate gear life requires some reasoning. Inexpensive equipment that is used infrequently and is seldom used at full rated power might be satisfactory if it had only a 500-hour capability at full rating. The design under consideration would be quite inadequate for 500 hours if the teeth were at low hardness, such as 210 HB. However, if the pinion and gear were at 300 HB hardness, they would have enough capacity for 500 hours and almost enough for 2000 hours.

At full hardness of 60 HRC, the situation changes considerably. The calculated life capacity is well over 10 billion cycles (on the pinion). Only a little over 2 billion cycles are needed for a life of 20,000 hours. The gear has only one-quarter of the pinion cycles, which is just a little over 0.5 billion cycles. If the gear hardness is the same as that of the pinion, the gear certainly has adequate capacity.

**Derating Factors.** In the above calculation, the derating factor ( $C_d$ ) of 2.50 may seem high but can be explained. The values given in Table 3 are based on an assumption of *average* conditions and a failure from pitting conditions of situation 1, 2, or 3 (see Table 4 and later discussions). A derating factor lower than 2.0 may even be acceptable for a 2 in. (50 mm) pinion if the driving and driven units are very light (low mass) and run *very* smoothly. When a low derating factor such as 1.5 is used, there is usually fairly extensive pitting. If the concept of a "failure" is situation 4 or 5 (Table 4), field experience may show that the gears can survive even though the derating is too low for situations such as situations 1, 2, and 3 in Table 4.

**TABLE 4 SITUATIONS AND CONCEPTS OF PITTING FAILURES IN GEARS**

DESCRIPTION	RECOMMENDED ACTION
<b>SITUATION 1</b>	
SOME MICROPITTING AND A FEW MACROPITS ON THE PINION. NO GEAR PITTING.	<b>SCRAP THE PINION, EVEN THOUGH IT IS STILL QUITE RUNNABLE. IT MAY NOT LAST UNTIL THE NEXT SCHEDULED OVERHAUL.</b>
<b>SITUATION 2</b>	
MICROPITTING AND APPRECIABLE MACROPITTING (E.G., 3-10% OF THE TOOTH SURFACE OF THE PINION). ALMOST NO PITTING ON GEAR.	<b>SCRAP THE PINION, BECAUSE METAL DEBRIS IN THE OIL SYSTEM IS A SERIOUS HAZARD TO THE BEARINGS. PREMATURE BEARING FAILURE MAY OCCUR AT ANY TIME.</b>
<b>SITUATION 3</b>	
MICROPITTING AND CONSIDERABLE MACROPITTING (E.G., 15-40% OF THE SURFACE). ONE OR MORE GROSS PITS. DAMAGE TO BOTH PINION AND GEAR.	<b>SCRAP THE GEARS. DAMAGE TO THE TOOTH SURFACE MAY LEAD TO TOOTH BREAKAGE, STARTING IN A BADLY PITTED LOCATION.</b>
<b>SITUATION 4</b>	
MACROPITTING OVER 50-100% OF THE PINION TOOTH SURFACE. GROSS PITTING PRESENT. REMOVAL OF METAL THINS THE TEETH AND DISRUPTS LOAD SHARING BETWEEN TEETH. GEAR UNIT HAS GREATLY INCREASED NOISE AND VIBRATION.	<b>SCRAP THE GEARS. COMPLETE FAILURE IS IMMINENT. FOUNDATION BOLTS MAY BREAK. BEARINGS ARE PROBABLY IN THE PROCESS OF FAILURE.</b>
<b>SITUATION 5</b>	
MACROPITTING ALL OVER THE TEETH. ALSO CONSIDERABLE GROSS PITTING. TEETH ARE THINNED SO MUCH BY WEAR THAT THE TIPS ARE BECOMING SHARP LIKE A KNIFE.	<b>SCRAP THE GEARS. A THINNED TOOTH MAY ROLL OVER AND JAM THE DRIVE--IF IT DOESN'T BREAK OFF FIRST.</b>

If a derating factor of 1.50 had been used, the calculated stress at 10 billion cycles would be reduced by the square root of the change in the derating factor. This works out to  $(1.50/2.50)^{0.50} = 0.775$ . This makes the calculated contact stress drop

to 83,220 psi. At this value, a through-hardened steel at 300 HB has a life of over 10 billion cycles. This is enough for a life of 20,000 hours.

Now consider the variables for the 2.50 derating factor. The first of three major factors is a derating factor of 1.4 for typical experience with industrial fan drives. These run somewhat rough, and gear people evaluate this as a 1.4 application factor.

With a face width equal to the pitch diameter, there will normally be some misfit across the wide face. In addition, the accuracy of tooth spacing will not be close to perfect. For an industrial application, the tooth spacing accuracy is probably AGMA quality level 9. This requires a derating factor of about 1.4 for small gearing such as a 2 in. (50 mm) pinion.

It is also necessary to consider dynamic overload due to the masses in the drive system and the tooth spacing accuracy. In this sample problem, the 2.125 pitch diameter pinion running at 1800 rpm has a pitch line velocity of 1073 ft/min (327 m/min). This kind of drive at this speed could be expected to have a dynamic overload factor of  $1.00/0.80 = 1.25$ .

The overall derating factor is obtained by multiplying these three factors such that  $1.4 \times 1.4 \times 1.25 = 2.45$  (this is rounded off to 2.50).

For the values shown in Fig. 6, the geometry factor ( $C_k$ ) may look quite conservative when compared to values used in bearing design. Part of this is due to the relatively high component of sliding in gear tooth contacts. For spur and helical gearing, pure rolling occurs only at the pitch line. Above and below the pitch line there is appreciable sliding. Also, the geometric shape of bearings is simpler than that of toothed gears. This helps in both quality of fit and quality control of material.

Another factor in comparing rolling element bearings to gears is probability of failure. Bearings are considered somewhat expendable and are generally designed with a probability of failure of 10 in 100 rather than the 1 in 100 that is normal for gearing. In some cases of expendable gearing, a factor of 10 failures in 100 is used for the rating curve. If Fig. 6 was redrawn for the 10 to 100 probability, all curves shown would allow about 17% more stress. The approximate life for a stress of 107,380 psi (740 MPa) works out as follows:

HARDNESS, HB	APPROXIMATE LIFE AT PROBABILITY OF FAILURE OF:	
	1 OUT OF 100	10 OUT OF 100
210	1.1 MILLION CYCLES	<b>20 MILLION CYCLES</b>
<b>300</b>	<b>180 MILLION CYCLES</b>	<b>3.5 BILLION CYCLES</b>

**Pitting Failure.** The degree of risk to be assumed in a gear design is a most important consideration. The above results show more than a 15 times longer life by going from a very low risk of failure to a still somewhat low risk of failure. If a 10 out of 100 degree of risk was tolerable, then the gear set being considered would have adequate pitting life for 20,000 hours at 300 HB.

The concept and definition for contact stress of pitting failures is another very significant consideration. Pitting failure is not easy to define, and a gear designer needs to use judgment based on experience. In general, a *pitted* gear tooth will still run, whereas broken-off gear teeth will so damage a gear that it is either impossible or impractical to continue to operate the gear unit.

Table 4 shows five different levels of tooth damage due to pitting that govern whether or not a pinion and a mating gear have failed by pitting. In aircraft or space vehicle gearing, situation 1 is cause for failure. In long-life turbine gearing, situation 2 is quite apt to be considered a failure. According to the calculated life given earlier in this article, the gear failed when it reached situation 3.

In some factory and farm applications, gears that have reached situation 4 are still kept in service. The cost of replacement and a forgiving environment where noise and vibration can be tolerated may prompt the gear user to keep running the gears. Situation 5 is the ultimate. If the pinion won't turn under power or the pinion does turn and the gear does not turn, there is just no question about the gears having failed!

From what has been discussed so far, the method used in the gear trade to calculate gear life should be quite clear. It should be evident, though, that much experience and judgment are needed to properly decide when a pitted and worn gear should be taken out of service and scrapped.

Although there are good guidelines for evaluating the things that derate gears, it still takes much data and experience to set numerical values that are just right for a particular product application. For instance, long-life turbine gearing is very expensive, and downtime in rebuilding a broken main gear drive may be much more expensive than replacing a gear unit. This means that the designer of turbine gearing is very concerned about having an adequate overall derating factor and close control over gear material quality. Grade 2 material is often specified rather than grade 1 material. Grade 2 steel is rated to carry about 25% more contact stress than grade 1 when carburized but only about 10% more stress when through hardened.

In the vehicle field (trucks, tractors, and automobiles), gearing is not highly expensive and a replacement gear unit can often be installed within a few hours. The designer of the gears may use a relatively low overall derating. The designer learns by thousands of similar units in service how to set the derating factor and how to control geometric quality and material quality so that adequate gear life is obtained.

The standards of the American Gear Manufacturers Association (AGMA) give recommendations for how to rate many kinds of gears and how to specify geometric and material quality. AGMA standards define established gearing practices for the gear trade. In the industrial field, contracts for geared machinery generally specify that the gearing supplied must be in accordance with applicable AGMA standards.

The allowable contact stress for gears made of grade 1 material (per Ref 2) is drawn for the lubrication condition of regime III (full oil film). Many gears that are small and run at relatively slow pitch line speeds are in regime II (partial oil film) or regime I (wet with oil but with almost no elastohydrodynamic (EHD) oil film thickness).

As of December 1995, there is no national standard for how to rate gears for allowable contact stress when they are in regimes II or I. There is much field experience, though, with gears running with an inadequate EHD oil film thickness. Work is underway to add material to AGMA standards to cover the problem of an inadequate oil film thickness.

Figure 7 shows how the allowable contact stress may change for grade 1 carburized steel gears at 60 HRC. Note the dashed curves for regimes II and I.

**FIG. 7 REGIMES OF LUBRICATION FOR CARBURIZED GEARS OF NORMAL INDUSTRY QUALITY MATERIAL (GRADE 1 MATERIAL, PER REF 2)**

**Life Determined by Bending Stress**

The bending stress of a pinion or a mating gear tooth (Ref 1, 2) may be estimated by a simplified formula:

$$S_T = K_T U_L K_D \quad \text{(EQ 5)}$$

where  $K_t$  is a geometry factor (see Table 5),  $U_1$  is the index of tooth loading severity for breakage (see Eq 6 below), and  $K_d$  is the overall derating factor for bending stress (see footnote in Table 3). The bending stress derating factor ( $K_d$ ) is approximately the same as the overall derating factor ( $C_d$ ) unless there is a wide face width. When the aspect ratio is around 0.25, the  $C_d$  for contact stress and the  $K_d$  for bending stress are about equal. At an aspect ratio of 1.0,  $K_d$  may be about 80% of  $C_d$ .

The index of tooth loading for breakage is often called "unit load." Its value for spur or helical teeth is:

$$U_1 = \frac{W_t P_n}{F} \quad (\text{EQ 6})$$

where  $W_t$  is the tangential driving force (same value as in Eq 3),  $F$  is the net face width in contact, and  $P_n$  is the normal diametral pitch (1/in.).

$P_n$  is the inverse of the tooth size in a plane normal to a helical tooth. The diametral pitch ( $P_d$ ) is the inverse of the tooth size in a plane normal to the axis of gear. The relation between the two is:

$$P_D = P_N \cos(\text{HELIX ANGLE, } \psi) \quad (\text{EQ 7})$$

The tangential load for tooth strength is the same quantity as the tangential load used for contact stress calculations (Eq 3).

The derating factor for strength is sometimes taken as the same value as is used for surface durability. In some cases of gears with favorable contact ratios, there may be justification to use a somewhat lower derating factor for strength. The points of high beam stress are some distance away from the points of maximum contact stress. This tends to allow the beam stress to spread out more than the contact stress. (In this brief article, it is not practical to show how to reduce the derating factor for the tooth strength calculations.) For the sample problem below it is reasonable to use  $K_d = 2.0$ . (The pitting derating,  $C_d$ , was 2.5.)

### Example 2: Rating Gear Life with Bending Stress.

In Example 1 of this article, the numerical values are  $W_t = 922.4$  lb,  $P_n = 10$ , and  $F = 2.28$ . For the data just given, the unit load index is:

$$U_1 = \frac{922.4 \times 10}{2.28} = 4045.4 \text{ psi (27.9 MPa)}$$

The geometry factor is taken as 1.75 (see Table 5). The calculated bending stress becomes:

$$S_T = 1.75 \times 4045.4 \times 2.0 = 14,159 \text{ PSI (97.6 MPa)}$$

The tooth bending stress can now be used to determine allowable cycles from a rating curve, such as Fig. 8. Figure 8 shows typical bending stresses plotted against tooth contacts. This curve sheet is drawn for gearing having these qualifications:

- MATERIAL QUALITY: GRADE 1
- PROBABILITY OF FAILURE: NOT OVER 1 IN 100
- LUBRICATION: FULL OIL FILM, WHICH IS REGIME III
- HARDNESS: BOTH PINION AND MATING GEAR AT LEAST AS HARD AS VALUE SHOWN ON BENDING STRENGTH FIGURE (FIG. 8)

FIG. 8 BENDING STRENGTH CURVE FOR GEAR LIFE RATING OF NORMAL INDUSTRY QUALITY MATERIAL (GRADE 1 PER REF 2)

The expected life of both the pinion and the gear, from a tooth breakage standpoint, can now be determined for the calculated stress of 14,159 psi (97.6 MPa) for the pinion and a calculated stress of 14,321 psi (98.7 MPa) for the gear. (The gear has the same unit load as the pinion and the same derating factor. However, the geometry factor for the gear from Ref 1 is 1.77, compared to 1.75 for the pinion.)

Based on Fig. 8, the pinion stress of 14,159 psi (97.6 MPa) is well below all the curves. If a pinion life of 20,000 hours was desired, the bending stress allowable could be about 23,000 psi (158.5 MPa) even for the through-hardened, 210 HB steel. This means that with 22 pinion teeth, the "life" of the pinion is determined by pitting and not by tooth breakage.

Suppose the pinion had the same diameter but had 40 teeth instead of 22 teeth. The bending stress would increase, because the normal diametral pitch would be about 18. The derating would not change for an increased number of teeth, and the geometry factor would tend to decrease a small amount. This means that a 40-tooth pinion meshing with a 160-tooth gear would have a calculated bending stress of about 22,300 psi (153.8 MPa).

If the normal diametral pitch was changed to 18.18182, the pitch diameters of the pinion and gear would not change with 40 pinion teeth and a 15° helix. The *K*-factor for pitting would not change, and the change in the geometry factor for

durability would be a small decrease. This means that it is possible to change numbers of teeth to adjust bending stress and not have much change in the contact stress.

In this sample problem, "life" determined by contact stress is very short at 210 HB, but it is almost enough for 2000 hours at 300 HB. The pinion could have 40 teeth at 300 HB because the allowable bending stress is up to 32,000 psi (220 MPa) at 2000 hours ( $216 \times 10^6$  million cycles). With the bending stress at 24,274 psi (167.4 MPa) there is a modest amount of extra margin in bending strength, but not nearly as much as at 22 teeth.

From a practical standpoint, it is quite desirable to control the life of a gear set and have an appreciable extra margin of bending strength. Having lots of small teeth instead of fewer and larger teeth is not desirable from two other standpoints: in general, parts with fewer teeth cost less to make; and larger teeth can stand somewhat more wear.

In summary, this example shows that 22 teeth on a pinion is a reasonable design. There is no good reason to use 40 teeth, even though the bending stress would be allowable.

### Gear Tooth Failure by Breakage after Pitting

The preceding section covered tooth breakage by the tensile stress in the root fillet. Another kind of common tooth breakage in gearing starts somewhat high on the tooth profile rather than in the root fillet. When a gear is damaged by pitting, a crack can start at a pit, spread lengthwise, and go all the way through the tooth. On wider-face-width gears, a triangular piece of tooth often breaks out. This piece may be as wide as one-third or one-half of the face width. The break may progress as deep as the root fillet at one end and run out at the outside diameter at the other end. The "eye" where the crack started may be at the pitch line, or it may be in the lower flank of the tooth.

If a pinion or gear continues in service after an appreciable part of the tooth is gone, the now-overloaded remainder of the tooth is likely to break off. Sometimes, even though several teeth have portions broken off, the gears continue in service because the increased noise and vibration are not enough to attract attention. Then one or more teeth are completely removed by successive chunks breaking off (see Fig. 9).

**FIG. 9 END OF TOOTH BROKEN BECAUSE OF GROSS PITTING. NOTE CRACKS IN REMAINING PART OF TOOTH.**

In narrow-face-width gears, such as those where the face width is about equal to the tooth height, a break starting at a pit tends to remove the tooth across the whole face width.

The normal calculation of bending stresses is not useful in designing gears to avoid tooth breakage starting at pits. The logic of this kind of trouble must be considered *an incident of tooth breakage caused by pitting*.

Gears that are case hardened by carburizing are the most susceptible to this trouble. Gears with a nitrided case are not quite as susceptible because the nitrided case depths tend to be thinner. A pit in a thin case is not quite as great a stress riser as a pit in a deep case. To prevent pitting altogether, though, deep carburized case depths may be needed.

Through-hardened gears in the 300 to 400 HB range are also quite critical. In general, gears are not used that are around 500 HB. At 450 HB and higher, a through-hardened gear is usually so brittle that it will fracture with even a small amount of surface distress.

The concepts of pitting failure given in Table 4 are quite useful in regard to the risk of tooth breakage stemming from pitting. In situation 1, the pitting is relatively minor, so there is very little danger of tooth breakage starting at a pit.

In situation 2, there is a moderate risk of some area on the tooth surface having enough macropits to start a tooth breakage crack when the pinion or gear has a carburized case. Through-hardened parts at 300 HB are not so notch sensitive and will probably not develop cracks from pits. Through-hardened parts at 210 HB are not notch sensitive. There is not much risk of cracks from pits at this level of hardness.

In situation 3, the much heavier pitting is quite risky for carburized gear teeth and moderately risky for through-hardened gears at 300 HB. However, through-hardened gears at 210 HB do not have much risk.

In some special cases where the pinion is quite hard (e.g., 360 HB) and the gear is much lower in hardness (e.g., 300 HB), there may be such serious *ledge wear* on the gear due to micro- and macropitting that a whole layer of metal is worn away from the gear tooth. This can result in the addendum of the gear being forced to carry all the load. This tends to double the stress in the gear root fillet, and gear teeth then break off due to the greatly increased stress.

Ledge wear that occurs in helical gears over a long period of time is not too dangerous if both the pinion and gear have about the same amount of wear. The big danger of tooth breakage comes when one pitted gear has little or no ledge wear and the mating gear has serious ledge wear. Figure 10 shows an example of a gear tooth with ledge wear and in danger of breaking. (The pinion that mated with this gear had some pitting but essentially no ledge wear.)

**FIG. 10 HELICAL GEAR WITH SERIOUS LEDGE WEAR DUE TO MICRO- AND MACROPITTING**

In situations 4 and 5, hard gears cannot survive without tooth breakage. Low-hardness gears that run at relatively slow pitch line speeds often survive for years without tooth breakage, even though the pitting and wear are severe.

In summary, tooth breakage due to pitting is a high risk with hard gears and may not be much of a risk if the gears are of low hardness and not running fast.

### Flaws and Gear Life

Metallurgical flaws may seriously reduce the life of gears. The calculations for the life of gear teeth assume that the material in the gear is not flawed by a mistake in processing the part. If the material is grade 1 (Ref 2), the quality is not as good as for grades 2 or 3, but it is assumed that the quality is normal for the grade specified. For instance, the microstructure for grade 1 is not specified to a limit as close as that for grade 2. Also, the cleanliness of the steel in grade 1 does not have to be as good as the cleanliness for grades 2 or 3.

Some of the more common flaws that affect the life of gear teeth are:

- CASE DEPTH FOR CARBURIZED, NITRIDED, OR INDUCTION-HARDENED TEETH TOO THIN OR TOO THICK
- GRINDING BURNS ON CASE-HARDENED GEARS
- NONHOMOGENOUS STRUCTURE, VOIDS, HARD SPOTS, SOFT SPOTS, ETC.
- ALLOY SEGREGATION
- CORE HARDNESS TOO LOW NEAR THE ROOT DIAMETER OR AT THE MIDDLE OF THE FACE WIDTH
- FORGING FLOW LINES PRONOUNCED AND IN THE WRONG DIRECTION
- QUENCHING CRACKS
- COMPOSITION OF STEEL NOT WITHIN SPECIFICATION LIMITS

When gears fail prematurely, the normal first step of an investigator is to make some calculations of gear life to see if the gear unit size was large enough for the rated life. If these calculations show that a gear unit rated for something like 10 years of life was indeed large enough and had the right materials specified, then it becomes a matter of concern to investigate factors such as lubrication system, behavior of driving and driven equipment, operating environment, and material quality (perhaps some serious metallurgical flaw (or flaws) exist).

Quite often the case depth is not right. The gear drawing should specify the right case depth for the midpoint of the tooth flank. Besides the middle of the tooth, the case depth needs to be right at the lower flank of the tooth. The case depth at the tip of the tooth is also critical.

The case depth may be right at midheight but too thin at the lower flank and root fillet. This is often caused by inadequate carbon gas penetration between teeth. In large gears, heat soak back after quenching may reduce the hardness considerably. Too much case depth at the tooth tip may cause the tooth tips to be so brittle that they break off in service. (This has happened off and on in gears used in mining.)

If large, through-hardened gears are quenched too drastically, there may be hidden cracks in the gear body. On the other hand, an inadequate quench may cause the hardness of the gear teeth to be below specifications in the middle of the face width or near the root diameter of the teeth.

Case-hardened gears can be ground by several different methods. There is always a risk of grinding too fast or having inadequate cooling at the grinding location. Grinding burns and grinding cracks must be avoided to get the potential life out of the gears.

When scrap material is melted to make steel, there is a hazard that something in the melt will produce a local hard spot or a local soft spot. There may also be stringers of inclusions. There is a well-developed art of producing steel ingots that can be made into steel billets of uniform good material for a toothed gear. Good gears require good steel.

When gear parts are forged, the flow lines in the forging should not be in the wrong direction at critical stress points, such as the root fillet of a gear tooth or where a thin web meets a thin gear rim. Rolled bar stock that is not forged may have flow lines in the wrong direction for a critical gear part. Normal gear rating practice is based on the assumption that the forging or rolling of the stock to make the gear blank is done right for the configuration of the gear part.

Another flaw to be concerned about is the chemical composition of the steel in the gear. Sometimes mistakes are made and the steel for a gear is taken out of the wrong bin. Through-hardening steels have different compositions than case-hardening steels.

Sometimes an improper substitution is made. For example, it quite often happens in worldwide operations that a readily available local steel is substituted for the specified steel that was just right for the rating and method of manufacturing used in another country. It is then quite a shock to have gears failing in a year or two that should have lasted for 10 or more years.

In summary, quite a number of metallurgical flaws can seriously reduce gear life. Metallurgical quality in gears is just as important as geometric accuracy in gears. For further data in regard to metallurgy and heat treating, see ANSI/AGMA 2004-B89, *Gear Materials and Heat Treatment Manual*. Appropriate references are made to a substantial number of ASTM, SAE, and military standards. Detailed specifications that define metallurgical requirements for grade 1, 2, and 3 gear materials are given in ANSI/AGMA 2001-C95, *Fundamental Rating Factors and Calculation Methods for Involute Spur and Helical Gear Teeth* (Ref 2). Grade 1 is considered normal industrial quality, grade 2 is extra high quality, and grade 3 is super quality. Grade 2 is used mostly for high speed, long life gearing. Grade 3 is often used for critical aerospace gearing.

## Bores and Shafts

Besides proper gear design, geometric accuracy, and good gear material, associated components in a gear train can also be important. This section briefly reviews some components in the design and structure of each gear and/or gear train that must be considered in conjunction with the teeth.

A **round bore**, closely toleranced and ground, may rotate freely around a ground shaft diameter, rotate tightly against a ground diameter by having a press fit, or be the outer race of a needle bearing that gives freedom of rotation. Each application has unique problems. A ground bore is always subject to tempering, burning, and checking during the grinding operation. A freely rotating bore requires a good lubrication film, or seizing and galling may result. The bore used as a bearing outer race must be as hard as any standard bearing surface and is subject to all conditions of rolling contact, such as fatigue, pitting, spalling, and galling. The bore that is press fit onto a shaft is subject to a definite amount of initial tensile stress. Also, any tendency for the bore to slip under the applied rotational forces will set up a unique type of wear between the two surfaces that leads to a recognizable condition of fretting damage.

A spur or a helical round bore gear acting as an idler, or reversal, gear between the input member and the output member of a gear train has an extremely complicated pattern of stresses. The most common application is the planet pinion group in wheel-reduction assemblies or in planetary-type speed reducers. Typical stress patterns are as follows:

- THE TENSILE AND COMPRESSIVE STRESSES IN THE BORE ARE DUE TO BENDING STRESSES OF THE GEAR BEING LOADED AS A RING.

- THE MAXIMUM TENSILE AND COMPRESSIVE STRESSES IN THE BORE INCREASE AS THE LOAD ON THE TEETH INCREASES.
- THE MAXIMUM TENSILE AND COMPRESSIVE STRESSES IN THE BORE INCREASE AS THE CLEARANCE BETWEEN THE BORE AND THE SHAFT IS INCREASED.
- THE MAXIMUM TENSILE AND COMPRESSIVE STRESSES IN THE BORE INCREASE AS THE RATIO OF THE SIZE OF THE BORE TO THE ROOT DIAMETER OF THE TEETH IS INCREASED.
- DURING ONE REVOLUTION OF THE GEAR UNDER LOAD, THE TEETH GO THROUGH ONE CYCLE OF COMPLETE REVERSAL OF STRESSES, WHEREAS EACH ELEMENT OF THE BORE EXPERIENCES TWO CYCLES OF REVERSALS.

Three modifications of the round bore alter stress patterns considerably:

- *OIL HOLES* THAT EXTEND INTO THE BORE ARE INTENDED TO LUBRICATE THE ROTATING SURFACES. EACH HOLE MAY BE A STRESS RAISER THAT COULD BE THE SOURCE OF A FATIGUE CRACK.
- *TAPERED BORES* ARE USUALLY EXPECTED TO BE SHRINK FITTED ONTO A SHAFT. THIS SETS UP A VERY HIGH CONCENTRATION OF STRESSES, NOT ONLY ALONG THE ENDS OF THE BORE BUT ALSO AT THE JUNCTURE ON THE SHAFT.
- A *KEYWAY* IN THE BORE ALSO CREATES A STRESS-CONCENTRATION AREA. A KEYWAY IS ALSO REQUIRED TO WITHSTAND A VERY HIGH LOAD THAT IS CONTINUOUS. IN FACT, THE APPLIED LOAD TO THE SIDE OF THE KEYWAY IS DIRECTLY PROPORTIONAL TO THE RATIO OF TOOTH PITCHLINE RADIUS TO THE RADIUS OF THE KEYWAY POSITION. FATIGUE FAILURE AT THIS POINT IS COMMON.

**Splined Bores.** The loads applied to the splined-bore area are also directly proportional to the ratio of pitchline radius of the teeth to the pitchline radius of the splines. However, the load is distributed equally onto each spline; therefore, the stress per spline is usually not excessive. It is possible for an out-of-round condition to exist that would concentrate the load on slightly more than two splines. Also, a tapered condition would place all loadings at one end of the splines, which would be detrimental both to the gear splines and to the shaft.

Heat treating of the splined area must be monitored closely for quench cracks. Grinding of the face against the end of the splines can also cause grinding checks to radiate from the corners of the root fillets.

**Shafts.** The shafts within a gear train, as well as the shank of a pinion that constitutes a shaft in function, are very important to load-carrying capacity and load distribution. They are continually exposed to torsional loads, both unidirectional and reversing. The less obvious stressed condition that is equally important is bending. Bending stresses can be identified as unidirectional, bidirectional, or rotational. When the type of stress is identified, one can explore the causes for such a stress.

There can be a number of stresses applied to a shaft that are imposed by parts riding on it. For example, helical gears will transmit a bending stress, as will straight and spiral bevel gears; round bores may be tight enough to cause scoring and galling; a splined bore may cause high stress concentration at the end face; runout in gears may cause repeated deflections in bending of the shaft; and loose bearings may cause excessive end play and more bending.

## Fatigue and Life Prediction of Bearings

Charles Moyer, The Timken Company (retired)

---

### Introduction

ROLLING ELEMENT FATIGUE has been recognized since the turn of the century, with fatigue life testing beginning in the early 1900s by rolling bearing manufacturers. Because of the high stresses imposed on bearings, steel with a hard matrix was required. However, the hard matrix, along with other factors to be discussed, meant that the matrix was very sensitive to loading and other external conditions that could lead to incipient material cracking and thus to contact fatigue. In the early tests, large scatter in fatigue life was experienced. This persists and indicates that close correlation of the incipient cracks and running time should not be expected (Ref 1).

Internal stress raisers, such as nonmetallic inclusions or carbides, are the beginning sites for incipient cracking. Because of the varying severity, the magnitude of the stress raisers is difficult to calculate, so that rolling fatigue, basically a problem of stress concentrations, displays the scatter mentioned or shows a clear statistical nature.

The high stresses involved come about from the geometry of bearings, which produces a concentration of load in the contacts in a small volume of the material within a bearing (Ref 2). Stresses were first computed based on the basic bearing internal geometries, and the stress distribution within and beneath the contact area was determined using the basic equations proposed by Hertz (Ref 3) in 1881. From such fundamental work, along with considerable fatigue test results that established various fatigue and material "constants," the first bearing ratings and fundamental life theories were proposed.

Following the work of Grubin in 1949 (Ref 4), Dowson and Higginson in 1966 (Ref 5), and Dowson and Toyoda in 1978 (Ref 6), to name just a few, the important role of lubricant in the contacts of bearings was next understood. It was recognized that the type of lubricant and the thickness of the lubricant film impacted bearing fatigue life and even influenced modes of failure. Considerable work has been done to relate failure modes, including fatigue, to bearing life.

As knowledge in all these areas grew, it was possible to understand the requirements for a bearing to develop longer life and produce acceptable life in a variety of adverse environments, such as low speed, high speed, elevated temperatures, misalignment, and contamination. This work, drawing heavily on much experimental data, is the basis for the present level of bearing life prediction.

### Bearing Materials

As stated, it was determined early in the 1900s that special material was required to give sufficiently long fatigue life for bearings. One percent carbon-chromium through-hardening steels were used for ball and cylindrical roller bearings and other types, perhaps influenced in Europe by familiarity with chromium-type tool steels (Ref 2, 7). U.S. manufacturers included low-carbon (0.20%) case-carburizing steels in bearing manufacture, primarily in the tapered roller bearing industry. Both steel types are still used, and examples of each are listed in Tables 1 and 2. Bearing steel types, microstructure, heat treatment, and specialty bearing steels are discussed in the article "Bearing Steels" in Volume 1 of the *ASM Handbook* (Ref 7).

High-quality steel, free from nonmetallic inclusions or other stress raisers, is a primary requirement to produce bearings that achieve extended fatigue life. Over the years, steel manufacturers have strived to produce cleaner bearing steel. The continual increases in bearing ratings, especially over the last 20 years, can be attributed to these improvements. After World War II, the requirements for significantly improved steels for bearings used in gas turbine engines demonstrated the performance improvements that vastly cleaner steels could provide (Ref 8). Besides clean steel, aerospace bearing applications needed high-speed capabilities (up to and then exceeding 2.4 million DN, where DN is bearing bore in millimeters times bearing speed in rpm) and materials capable of up to and above 200 °C (400 °F) (Ref 9).

The experience gained in developing and testing such materials provided the bearing industry valuable insight into refinements that could be achieved with industrial-grade bearings by better control of tolerances, better manufacturing methods, and better finishing techniques. Thus, over the past 20 years as cleaner steels improved bearing life, it was recognized that rather than materials limiting fatigue, processing and surface-related shortcomings (e.g., rough surface finish, surface defects, deep grinding grooves, handling nicks or defects from the ingress of hard debris) were now limiting life (Ref 10, 11, 12). The most recent efforts have been to try to lower surface roughness and make material processing changes that will better resist the incipient damage of contaminants, including debris and other life-limiting factors.

The role of residual stresses in bearings after manufacture has also been recognized (Ref 13). Heat treatments that minimize or avoid tensile stresses are recommended, especially for inner raceway rings that develop hoop tensile stresses from tight, interference fits on shafts. Very often, carburizing steels (as given in Table 2) are used for inner races and for bearings that require greater surface ductility, greater resistance to debris particles, and a higher level of core toughness, along with the compressive residual surface stresses that help reduce fatigue crack propagation through the bearing cross section (Ref 7).

Through-hardening steels can carry the somewhat higher contact stresses that are prevalent in ball bearings. Through-hardening steels may also give better dimensional stability over temperature extremes, because of lower retained austenite, and these advantages may dictate their use in some inner ring applications. Care should be taken, however, to minimize tensile residual stresses in through-hardened steel races. It is known that control of surface grinding for bearing steels (avoiding abusive grinding forces and high-temperature gradients) can minimize tensile residual stresses (Ref 14). With soft wheels, low wheel speeds, shallow cuts, and proper grinding fluid, El-Helieby and Rowe produced compressive residual stresses on EN31 steel (chemistry related to AISI 52100 through-hardening steel) following these practices. Although such practices may be too time-consuming for industrial use, eliminating surface damage can lead to improved fatigue life with any type of bearing steel.

## Fatigue and Life Prediction of Bearings

Charles Moyer, The Timken Company (retired)

### Bearing Fundamentals

**Surface Contact and Stresses.** Bearings are described by their rolling elements as ball or roller bearings or by their contact footprints as point or line (Fig. 1a, b). A point contact forms an ellipse, where the area is defined by the semi-axes  $a$  and  $b$  (Fig. 1a). For line contact, a rectangle is formed, where the area is defined by  $L$  times  $2b$  (Fig. 1b). These small, concentrated areas explain the high stresses developed on and below the immediate bearing contact surfaces.

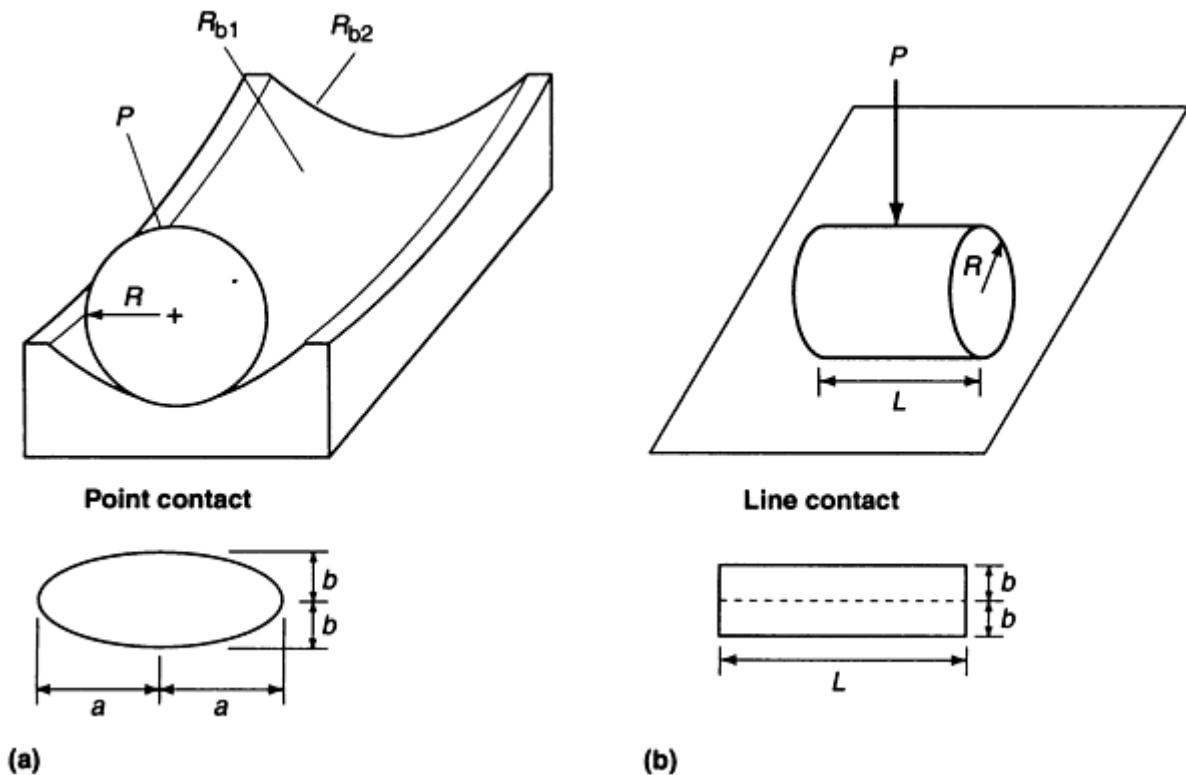

FIG. 1 GEOMETRY FOR (A) POINT CONTACT AND (B) LINE CONTACT, SHOWING THE GENERAL CONTACT SHAPES PRODUCED FOR EACH GEOMETRY

Maximum compressive stress ( $q_0$ ) and half-width contact ( $b$ ) for point contact (Fig. 1a) are calculated from the following equations:

$$q_0 = \frac{3P}{2\pi \cdot ab} = 23600 \cdot \frac{P^{1/3}}{\mu\nu} (S_c 1/R)^{2/3} \quad (\text{EQ 1})$$

$$B = 0.004498 \nu (P/S_c 1/R)^{1/3} \quad (\text{EQ 2})$$

where the constants in the above equations assume bearing steel with elastic modulus of 207 MPa ( $30 \times 10^6$  psi) and Poisson's ratio of 0.3. Constants for other materials can be found in Ref 8. Approximate values of  $\mu$  and  $\nu$  can be taken from Fig. 2.  $S_c$  is the summation of curvatures in Fig. 1(a) as follows:  $S_c 1/R = 1/R_{b1} + 1/R_{b2} + 1/R + 1/R$ .

FIG. 2 PLOT OF GEOMETRY FACTOR VS. TRANSCENDENTAL FUNCTIONS  $\mu$  AND  $\nu$  IN EQ 1 AND 2 AND RELATED TO THE SEMIMAJOR/SEMIMINOR AXES  $A/B$ .  $\delta^*$  IS THE DIMENSIONLESS CONTACT DEFORMATION OR APPROACH FACTOR FOR THE TWO BODIES IN CONTACT.

Maximum compressive stress ( $q_0$ ) and half-width contact ( $b$ ) for line contact (Fig. 1b) is as follows:

$$Q_0 = 2290 (P/L)^{1/2} \cdot (1/R_1 + 1/R_2)^{1/2} \quad (\text{EQ 3})$$

$$B = 0.0002779 (P)^{1/2} [L(1/R_1 + 1/R_2)]^{1/2} \quad (\text{EQ 4})$$

where again the constants in these equations assume bearing steel with elastic modulus of 207 MPa ( $30 \times 10^6$  psi) and Poisson's ratio of 0.3. Constants for other materials can be found in Ref 8.

**Fatigue Life of Bearings.** Considerable fatigue testing over the years developed the relationships between stress and life and then to bearing load, as evidenced by the work of Clinedinst (Ref 15) and Lundberg and Palmgren (Ref 16). While

Clinedinst based his early load ratings on the maximum contact pressure,  $q_0$ , Lundberg and Palmgren recognized that fatigue cracks usually start below the contact surface near the depth of a maximum shear stress, such as  $T_0$  (the range of orthogonal shear). They perceived a change in the material near inclusions below the surface, microcrack development, and then propagation of the cracking to the surface with formation of a pit or spall. This mode of subsurface spall development has become the classical mode of fatigue failure for bearings running under good operating conditions. An adequate lubricant film, reasonable temperatures, and reasonable environmental conditions are the conditions for which bearing rating life or higher should be achieved.

The Lundberg-Palmgren power equation (Eq 5), based on a measure of the statistical life scatter of a group of identical bearings (Ref 17), relates the strength dependency (life) with the magnitude (volume) of the stressed material within the bearings (Ref 18). Life dispersion is represented by the Weibull dispersion parameter (slope) "e." The volume of material stressed ( $V$ ) is related to a bearing by considering the product of:

- $A$ , AS THE HALF MAJOR AXIS OF THE PRESSURE ELLIPSE
- $L$ , AS THE CIRCUMFERENCE OF THE CRITICAL RACEWAY
- $Z_0$ , AS THE DEPTH FROM CONTACT SURFACE TO THE LOCATION OF  $T_0$ , THE MAXIMUM SHEAR STRESS AMPLITUDE

The power equation is:

$$\ln(1/S) \sim \frac{T_0^c \cdot N^e \cdot V}{Z_0^h} \quad (\text{EQ 5})$$

where  $S$  is the probability of survival and  $z_0$  is the depth to where the amplitude of the shear stress  $T_0$  is greatest. The depth  $z_0$  is also used to determine volume ( $V$ ). In Ref 16, it is considered that the depth below the surface where microscopic material changes become the origin site of fatigue also influences fatigue propagation, so  $z_0$  is included twice in Eq 5. Life ( $N$ ) is expressed in millions of stress cycles. The three exponents "e," "c," and "h" are considered life dispersion factors or material constants, and they are not independent. Equation 5 then becomes:

$$\ln(1/S) \sim \frac{T_0^c \cdot N^e \cdot a \cdot l}{Z_0^{(h-1)}} \quad (\text{EQ 6})$$

By considering actual bearing contact geometry, the contact stresses (Eq 1 and 3), the number of rolling elements, their diameter relative to the inner and outer race diameters, and the appropriate material constants, it is possible to develop a relationship of bearing load to life in millions of revolutions. The load at a specific life is defined as the basic dynamic load capacity, "C." Lundberg and Palmgren did this in their original works (Ref 16, 19), but although much of their basic approach still is used, considerable change has taken place. Current load capacity equations are given in the ISO Standard and the two American National Standards (Ref 20, 21, 22). There are 12 rating equations, covering radial and thrust ball and roller bearings. Two are cited here, simply to illustrate the source of the present exponents as given in the radial equations, because the exponent values affect bearing life prediction. The ball bearing radial rating equation is:

$$C_R = F_{CM} (I \cdot \cos \alpha)^{0.7} \cdot Z^{\frac{2}{3}} \cdot D_w^{1.8} \quad (\text{EQ 7})$$

where  $F_{cm}$  is the factor based on bearing component geometry, accuracy, manufacturing quality, and normal bearing steel;  $D_w$  is the ball diameter in millimeters or inches;  $i$  is the number of rows of rolling elements in a bearing;  $Z$  is the number of rolling elements per row; and  $\alpha$  is the nominal contact angle of the bearing in degrees. When  $D_w$  is above 25.4 mm (1 in.), the exponent becomes 1.4 and the rating equation changes (see Ref 21).

The roller bearing radial rating equation is:

$$C_R = F_{CM} (I \cdot L_{WE} \cdot \cos \alpha)^{7/9} \cdot Z^{\frac{3}{4}} \cdot D_{WE}^{29/27} \quad (\text{EQ 8})$$

where  $D_{we}$  is the roller diameter applicable in the calculation of load ratings, in millimeters or inches; and  $L_{we}$  is the roller length used in the calculation of roller bearing load ratings, in millimeters or inches.

Values of  $F_{cm}$  are given in standards. Based on bearing geometries that can be measured, it is possible to calculate generic ratings for any rolling element bearing. Because these ratings are developed by consensus within standards working committees, they represent neither minimum nor maximum values. Machine designers should review the most current handbooks of bearing manufacturers for specific ratings and more accurate life estimates.

Besides the significant experimentally determined material and manufacturing constant within  $F_{cm}$ , an experimental relationship between load and fatigue life is in all the standards. The relation of rating capacity  $C$  and actual bearing load  $P$  to  $L-10$  life is:

$$L-10 = (C/P)^p \times (\text{ONE MILLION REVOLUTIONS}) \quad (\text{EQ 9})$$

where  $L-10$  is the basic rating life in millions of revolutions with 90% probability of survival, and  $p = 3$  for ball bearings, or  $10/3$  for roller bearings.

When  $P = C$ , the  $L-10$  life is exactly one million revolutions. At 500 rpm,  $L-10$  is only  $33\frac{1}{3}$  hours. Depending on the bearing design, this  $L-10$  is generally above the elastic limit for a bearing. Bearing ratings ( $C$  load) are in reality reference loads, used only to calculate  $L-10$  life for bearings with Eq 9. Actually, it is advisable to stay below about 50% of  $C$  for most applications. Figure 3 shows how the load-fatigue life changes with five values of  $p$ . The three inside exponents, 3,  $10/3$ , and 4, are used in the standards.

FIG. 3 EFFECT OF LOAD-LIFE EXPONENT WITH ONE MILLION REVOLUTIONS REFERENCE POINT

**Sources of Rating/Life Exponents.** Past experimental determination of the load-life exponent  $p$  for ball bearings (Ref 16, 23) are the basis of the exponent 3 in the standards. The actual values of the exponent in Ref 23 were  $2.87 \pm 0.35$  at  $L-10$  and  $2.80 \pm 0.31$  at  $L-50$  (median life), so that considering the confidence bands, an exponent of 3.0 was acceptable based on a database of almost 5000 deep-groove ball bearings.

For roller bearings, an exponent of 4.0 (assumed at  $L-50$  life) was determined in Ref 19 from 6 test series of 30 spherical roller bearings each, with loads ranging from about 0.15 to 0.4  $P/C$ . Exponent values of 4.22 at  $L-10$  life and 4.08 at  $L-50$  (median) life were obtained in Ref 24 based on rig testing at 1840 to 2910 MPa (267 to 422 ksi) from four test series with a cylindrical roller bearing inner raceway against a loading ring. The test specimens in Ref 19 and 24 were not modified

to avoid edge loading or end-of-contact stress concentrations. However, with rollers and/or raceways crowned for elliptical contact or profiled for "optimized" contact, a load-life exponent of 10/3 was considered acceptable (Ref 19) and confirmed with recent tests (Ref 25). The exponent 10/3 has been used in Eq 9 for roller bearings in the bearing standards for many years. The ANSI/AFBMA Standard 11-90 (Ref 22) recognizes that depending on the load, whether with crowned or profiled contact in a roller bearing, truncation and edge stresses can occur. Roller bearing contact lengths and internal or end-of-contact modifications are not standardized, so how specific bearings are influenced by truncation must be obtained from the manufacturer.

Besides the material constant in  $F_{cm}$  and the load-life exponent ( $p$ ), the life dispersion parameter ( $e$ , or the Weibull slope) is experimentally determined. Figure 4 shows a large group of tested roller bearings with failures plotted in order of increasing life. The plot is on Weibull probability paper, and the data plot is close to the line for the Weibull slope ( $e$ ), which equals 1.6 for this sample. In Ref 16 and 19, similar plots were made and it was concluded that a slope of 1.11 (= 10/9) could be used for ball bearings and 1.125 (= 9/8) could be used for roller bearings. Lundberg and Palmgren (Ref 16) also ran tests on bearings with a range of roll diameters ( $D_a$  sizes) of 1.5 to 25 mm. The resultant exponent on the roll diameter relative to capacity was 1.8. Considering all these experimental factors, it was possible to solve for the other "material constants"  $c$  and  $h$  (see Eq 5 and 6). Using the following from Ref 16 (p 15, Eq 51):

$$D_A = 1.8 = (2C + H - 5)/(C - H + 2) \quad \text{(EQ 10)}$$

From Ref 16 (p 15, using the transformed Eq 54 for point contact):

$$C - H = 3(P)(E) - 2 = 3(3)(10/9) - 2 = 8 \quad \text{(EQ 11)}$$

From Ref 16 (p 16, using the transformed Eq 55 for line contact):

$$C - H = 2(P)(E) - 1 = 2(4)(9/8) - 1 = 8 \quad \text{(EQ 12)}$$

**FIG. 4** EXAMPLE OF A GROUP OF TESTED BEARINGS, RANGING FROM 12 TO 85 MM BORE, ALL RUN WITH SAE 20 OIL AND 38 °C INLET OIL TEMPERATURE RATIONALIZED SO EACH SAMPLE  $L_{10}$  WAS EQUAL TO 1.0. THE FATIGUED BEARINGS, ORDERED BY INCREASING LIFE, PLOT CLOSE TO THE WEIBULL LINE (SLOPE) OF 1.6.

Combining Eq 10 and 11 or Eq 10 and 12, the values of  $c = 3\frac{1}{3}$  and  $h = 7/3$  are determined. From these, the experimental basis of the exponents in the present rating equations (Eq 7, 8) can be seen.

*Rating/life exponents for ball bearings are:*

$$\text{EXPONENT FOR } D_w(D_A) = 1.8$$

$$\text{EXPONENT FOR } Z = 1 - 1/(P) = 1 - 1/(3) = \frac{2}{3}$$

$$\text{EXPONENT FOR } (I \cos \alpha) = 1 - 1/(P)(E) = 1 - 1/(3)(10/9) = 7/10$$

*Rating/life exponents for roller bearings are:*

$$\text{EXPONENT FOR } D_{WE} = (C + H - 3)/(C - H + 1) = (3\frac{1}{3} + 7/3 - 3)/(3\frac{1}{3} - 7/3 + 1) = 29/27$$

$$\text{EXPONENT FOR } Z = 1 - 1/P = 1 - 1/(4) = \frac{3}{4}$$

$$\text{EXPONENT FOR } (I \cos \alpha) = 1 - 1/PE = 1 - 1/(4)(9/8) = 7/9$$

This background information about the source of the exponents in the rating equations for ball and roller bearings and in Eq 9 illustrates the experimental input in the system of calculating rolling bearing life prediction as contained in the present bearing standards.

The generic forms of the basic dynamic load rating equations in the standards (Ref 20, 21, 22) are good reference ratings based on reasonable consensus through the Engineering Committees of the American Bearing Manufacturers Association (ABMA), but as the background discussion illustrates, many of the experimental factors still in the standards may need to be updated. References 26, 27, 28, 29, 30, 31 attempt to cover some of the changes proposed for better predicting bearing fatigue life. Lorösch (Ref 26) gives the first indication that rolling bearings, run in a clean environment under lower load that causes no microstructural alterations in the stressed contact region, can have significantly extended life. Ioannides and Harris (Ref 27) essentially generalize the Lundberg-Palmgren model (Eq 6) and include a limiting stress below which fatigue failure may not occur. In essence this means that the load-life exponent  $p$  may increase at lower loads.

If rolling contact fatigue then follows an  $S-N$  curve, one might expect life scatter to increase at lower stress as with other fatigue (Ref 32). There are limited data to suggest that life scatter does increase (i.e., Weibull slope decreases) for both bearings and gears under lower stress (Ref 33), so that at low loads, near an endurance limit, extended life scatter would make it more difficult to estimate failures. Lubrecht et al. (Ref 28) review the new life theory (Ref 27) and consider a possible range of values for the fatigue limit stress and how surface irregularities can be handled.

Dominik (Ref 29) gives specific factors (constants  $c$ ,  $h$ ,  $p$  and  $e$ ), experimentally determined for tapered roller bearings, then proposes a specific rating equation for these bearings. Zhou and Nixon (Ref 30) present another specific bearing rating model that includes the equation from Ref 29, but also includes the film thickness and surface roughness ratio in a micro-macro contact model aimed at predicting bearing life for different surface textures. Tallian (Ref 31) reviews some dozen existing engineering and research models and proposes a new model based on all major life-influencing factors. It is clear that considerable activity leading to improved bearing life prediction is ongoing. The ideal operating conditions that give extended  $L-10$  rating life are fairly limited in real applications, so most recent bearing manufacturer catalogs/handbooks have updated means to calculate  $L_{na}$ , which is an  $L-10$  life rating adjusted by several life adjustment factors first introduced in 1972.

## Fatigue and Life Prediction of Bearings

Charles Moyer, The Timken Company (retired)

---

### Bearing Life Prediction

The bearing standards in 1972 (Ref 34, 35) first included the concept of life adjustment factors. The three factors considered were reliability, material, and application. In equation form this became:

$$L_{NA} = A_1 A_2 A_3 (C/P)^P \times (\text{ONE MILLION REVOLUTIONS}) \quad (\text{EQ 13})$$

or

$$L_{NA} = A_1 A_2 A_3 (L-10) \quad (\text{EQ 14})$$

where  $L_{na}$  is calculated from the  $L-10$  life rating adjusted by the following combination of factors:  $a_1$ , the reliability factor for other than 90%;  $a_2$ , the material factor (1972), now called the special bearing properties factor (1990); and  $a_3$ , the application or environmental conditions factor, which primarily recognizes the lubricant condition in a bearing but which also recognizes alignment and internal load distribution and contamination, liquid or solid.

**Reliability Factor,  $a_1$ .** For a single bearing, the probability that it will reach the specified life is its reliability. For a group of identical bearings run under identical conditions, the reliability is the percent that reach the specified life. For  $L-10$  rating life there is 90% probability that a bearing will achieve this life. The reliability factor,  $a_1$ , given in the standards and many bearing handbooks, is based on a Weibull slope "e" equal to 1.5. The factor  $a_1$  values from 90 to 99% reliability are:

RELIABILITY, %	LIFE FACTOR, $A_1$
90	1.00
95	0.62
96	0.53
97	0.44
98	0.33
99	0.21

These life factors indicate that the standards and others (Ref 25, 36) consider that bearings deviate to higher lives for failure probabilities less than 10% (i.e., higher reliabilities). If data are at hand that show that other Weibull slope values could be used to determine the life factor, then the following equation can be used to calculate  $a_1$ :

$$A_1 = [9.4912 \ln(100/R)]^{1/E} \quad (\text{EQ 15})$$

where  $a_1$  is the reliability life factor ratio,  $R$  is the reliability expressed as percent survival, and  $e$  is the Weibull slope or life dispersion parameter.

**Special Bearing Properties Factor,  $a_2$ .** The bearing standards have never supplied values for  $a_2$ , simply saying in 1972 that  $a_2$  could be used for bearings that incorporated improved materials and processing. By 1990, the  $a_2$  factor was for special bearing properties described as follows: "A bearing may acquire special properties, as regards life, by the use of a special type and quality of material and/or special manufacturing processes and/or special design" ( Ref 20, 21).

Significantly cleaner steels are now available. Examples are steels produced by vacuum-arc remelting (VAR) and electroslag melting or remelting (ESR). Other melting practices, such as vacuum induction melting vacuum-arc remelting (VIMVAR), were developed for use in critical applications such as the aerospace industry. Many applications include high-temperature steels for bearing operations at temperatures of 150 to 475 °C (300 to 890 °F), M-50, M-50NL, CBS-600\* or CBS-1000M\*\*. Air melt steels for conventional applications have shown significant improvements since 1972 and this is recognized by revised ratings in recent bearing catalogs.

Bearing users need to contact the bearing manufacturer to determine specific ratings and obtain new  $a_2$  factors for current special steels. Values of  $a_2$  range from 0.6 to over 6 for different chemistries, melting practices, cleanliness levels, and metal working, heat treatment, and surface modification practices. Information on  $a_2$  is included in Chapter 3 of Ref 37.

Special manufacturing and special design changes have also been significant, leading to improved internal profiles and reduced contact finishes so that under a wider range of operating conditions the contact surfaces are completely separated. By inputting specifics of these designs into a computer program, along with application information and lubricant conditions, it is possible to quantify specific  $a_2$  values for bearing users (Ref 28, 30). However, because determining  $a_2$  this way requires fairly extensive computer programs, the details are proprietary and not generally available.

**Operating Conditions Factor,  $a_3$ .** Beyond load, which is important but already accounted for, adequacy of lubrication is central to  $a_3$ . Basic rating life assumes that normal lubrication provides a lubricant film that is equal or slightly greater than the composite roughness of the contact surfaces. The film thickness (EHL) divided by composite roughness is termed  $\lambda$ . References 6 and 38 are examples of elastohydrodynamic lubrication (EHL) film calculations for line contact and point contact conditions. Lubricant properties (absolute viscosity and pressure coefficient of viscosity at operating temperature), radii of the contacting surfaces, mean surface velocity of the surfaces, load, and the elastic moduli of the contacting bodies are needed for the lubricant film calculation.

The composite roughness is usually measured in terms of root mean square (RMS) roughness in the rolling direction with a cutoff length of 0.8 mm. There is some indication that the contact width in the rolling direction acts as a functional filter and that measurement cutoff length closer to the contact width might be more meaningful for  $\lambda$  (Ref 39). However, the important point is that the cutoff be known for the actual measurements and for comparisons of several  $\lambda$  values, so that consistent film and composite roughness determinations can be made. The calculation of composite roughness  $\sigma_q$  is:

$$\sigma_Q = (R_{q1}^2 + R_{q2}^2)^{\frac{1}{2}} \quad \text{(EQ 16)}$$

where  $R_{q1}$  and  $R_{q2}$  are the RMS roughness measurements of the two surfaces.

A considerable amount of published data has shown strong correlation of  $\lambda$  versus bearing fatigue life. The correlation is especially close for tests over a range of  $\lambda$  done with one specific type of bearing (Ref 40, 41). Tallian (Ref 42) collected such data from seven sources, including Ref 40 and 41. The plot of relative fatigue life [ $N-\lambda$  divided by  $N$ -catalog versus  $\lambda$ ] that he generated is shown in Fig. 5. Some 83 bearing test groups are included and indicate life scatter but also a definite trend of  $\lambda$  versus fatigue life. Considering the asperity slope along with possible traction coefficients for mixed to boundary lubrication, Tallian was able to explain some of the scatter. Bearing type and material differences and all the different testing machines and test lubricants were other contributing factors to the scatter.

FIG. 5 PLOT OF RELATIVE LIVES VS.  $\lambda$  FOR THREE ASPERITY SLOPE CURVES. SOURCE FOR DASHED CURVE: REF 37. SOURCE FOR OTHER CURVES: REF 42

The three solid curves in Fig. 5 are based on the model described in Ref 42 for three levels of asperity slope. Curve 1 is for a 0.0341 radian (Rad) (1 degree, 57.2 minutes) RMS composite asperity slope, curve 2 is for 0.141 rad (48.5 minutes), and curve 3 is for 0.0601 rad (3 degrees, 26.6 minutes). The dashed curve, taken from Ref 37 (p 200), shows a similar trend for  $\lambda$  values under 2.0. More recent data indicate that this ASME-STLE curve is probably conservative for the higher  $\lambda$  values. It can be seen that fatigue life is extended at high values and that surface roughness and asperity slope have little influence, because the contact surfaces are almost completely separated by the lubricant film. As  $\lambda$  is reduced, it is clear that fatigue life decreases, and for  $\lambda$  below 1.0, fatigue occurs below catalog or rating expected life.

**Bearing Damage Modes.** Bearing fatigue mode is also influenced by  $\lambda$ . For high  $\lambda$ , fatigue is primarily material related, at subsurface or near-surface fatigue initiation sites as outlined in Table 3. Figure 6(a) shows a subsurface inclusion spall, and Fig. 6(b) is a transverse section that shows the crack development below the surface. As a bearing operating condition

can be described by lower  $\lambda$ , even going below 1.0, surface-related fatigue is more common. General roughness and higher asperity slopes can lead to surface distress or microspalling. Perhaps because of a thinner film and higher surface traction, the maximum shearing stress approaches the surface, and microhertzian stress at asperities can exceed the macrohertzian stresses that define the classical stressed volume. Very often microspalling is more apparent on the smoother surface in contact, but the rougher surface may have micropits forming at asperity peaks. Surface fatigue can also begin at localized stress raisers such as grinding grooves, surface inclusions, edge conditions, nicks and dents from handling, or hard debris ingested into the bearing contact.

**TABLE 3 RELATING CONTACT FATIGUE DAMAGE MODE TO  $\lambda$**

$\lambda$	CONTACT FATIGUE MODE (INITIATION)	MATERIAL INFLUENCE	SURFACE ROUGHNESS INFLUENCE	GEOMETRY INFLUENCE
RATIO >3.0	SUBSURFACE FATIGUE, INCLUSION <sup>(A)</sup>	IMPORTANT	MINOR	<b>IMPORTANT</b>
RATIO 3-1.0	SUBSURFACE/NEAR SURFACE, MOSTLY INCLUSION	IMPORTANT	"SHARP"/HIGH ASPERITIES IMPORTANT	<b>IMPORTANT</b>
RATIO 1-0.3	SOME INCLUSION, SOME SURFACE RELATED	SOMEWHAT IMPORTANT	IMPORTANT FOR SURFACE AND NEAR SURFACE FATIGUE	<b>SOMEWHAT IMPORTANT</b>
RATIO <0.3	SURFACE RELATED <sup>(B)</sup>	MINOR	IMPORTANT	<b>LESS IMPORTANT</b>
ANY RATIO	LOCALIZED STRESS RISERS	MIXED	MIXED	<b>MIXED</b>
	PSO--DENTS, GROOVES, AND SURFACE INCLUSIONS	MINOR	SOMEWHAT IMPORTANT	<b>MINOR</b>
	<b>GSC--EDGE FATIGUE</b>	<b>SOMEWHAT IMPORTANT</b>	<b>MINOR</b>	<b>IMPORTANT</b>

PSO, point surface origin, fan-shaped spall propagation starting on the surface. GSC, geometric stress concentration starting at end of line contact.

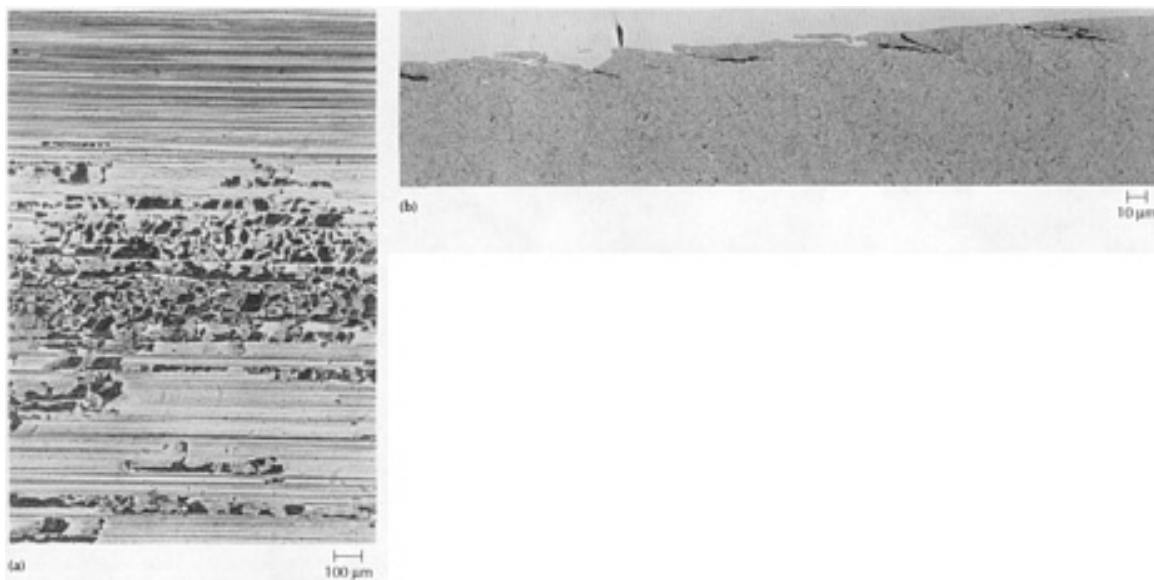

(A) FATIGUE ORIGINATES AT NONMETALLIC INCLUSION IN THE MAXIMUM SHEAR ZONE BELOW THE SURFACE.

(B) CALLED PEELING OR MICROPITTING FOR BEARINGS

**FIG. 6 NEAR-SURFACE FATIGUE INITIATION SITE FROM INCLUSION ORIGIN FATIGUE. (A) INCIPIENT CRACKING FROM SUBSURFACE INCLUSION SPALL. (B) CRACK DEVELOPMENT BELOW THE RACEWAY SURFACE**

The surface appearance of microspalling (Fig. 7a, b) shows how shallow the cracks formed are. Localized, point surface origin (PSO) fatigue starting at a debris bruise is shown in Fig. 8. Point-surface origin fatigue can propagate at larger  $\lambda$  values, based on the severity of the stress raiser. Under thicker films the propagation may not be as rapid and the arrowhead shape may not be very pronounced. An example of edge loading from geometric stress concentration (GSC) failure is given in Fig. 9. This usually happens in line contact bearings, but it can occur with any type of exaggerated misalignment.

**FIG. 7 APPEARANCE OF MICROSPALLING (PEELING OR FROSTING APPEARANCE) FROM THIN LUBRICANT FILM. (A) MAGNIFIED SHALLOW PITTING ALONG ASPERITY RIDGES. (B) TRANSVERSE SECTION SHOWS SHALLOW CRACKING FROM MICROSPALLING.**

**FIG. 8 POINT SURFACE ORIGIN FATIGUE. (A) SPALL INITIATED AT DEBRIS BRUISE ON ROLLER (4.55×). (B) ENLARGED VIEW OF DENT (100×)**

**FIG. 9 GEOMETRIC STRESS CONCENTRATION, EDGE LOADING ON A BEARING OUTER RACEWAY, MISALIGNED SO THAT ONLY HALF THE RACE PATH CARRIED THE LOAD**

**Other Fatigue Failure Considerations.** Fatigue below the expected rating life can also occur if a bearing is starved for lubrication, either from lack of supply or by blockage such as entrapped debris before the contact region. Seeing that a full film of lubricant reaches the bearing is a basic requirement.

Improper, excessive fitting practices can lead to fatigue cracks that produce inner raceway section fracture. Sometimes excessive fretting contributes to this fracture or initiates cracks on a raceway outside diameter. Because of severe fretting, nonround outer raceway seats, or hard particles left on the shaft or seat, bending fatigue (perhaps aggravated by corrosion) can lead to bearing ring fracture. The separator or cage for the rolling elements of a bearing may be mishandled

so that wear takes place or eccentric motion occurs, leading to bridge or ring segment fatigue fracture. Care in mounting bearings includes avoiding any cage damage.

Bearing life is also shortened by operating conditions that, beyond promoting contact fatigue, promote wear. It may be adhesive wear that is mild (limited to run-in), or the wear may lead to irreversible scuffing, smearing, or even final seizure. Abrasive wear can also occur, very often from particles causing grooving or denting with ridges that cause serious surface stress raisers, often leading to surface-related fatigue. Corrosive wear from water, acidic contaminants, or aggressive additive breakdown in the lubricant can also shorten bearing life. Fretting is a microscale version of adhesive, abrasive wear, often with corrosion that can again limit bearing performance.

There can also be plastic flow (Ref 43) caused by loading over the material yield point, yielding aggravated by high temperature, or brinelling that usually occurs under impact or high load, nonrotating conditions. Bearings can suffer electrical damage by grounding of electrical current through the bearing contacts. Under stationary conditions or slow rotation, the current causes localized melting and vaporization of individual asperities, while the surrounding material is rehardened and tempered. Under continuous current passage and bearing rotation, the electrical damage has a washboard appearance, called fluting, that is severe and leads to noise and fatigue of the damaged surfaces.

Finally, one of the most common failures for bearings is burnup, caused by inadequate lubricant supply, plugged lubrication lines, inadequate seals, improper/infrequent maintenance, or excessive preload or speed. The result is heat generation at a rate that exceeds heat transfer from the bearing so that material flows plastically and bearing geometry is destroyed. All these failure modes can be avoided if bearings have effective lubrication, so that adequate lubricant films are prevalent within the bearing, temperatures are within limits, and loads and speeds do not extend beyond the operating design parameters established for any specific system.

## Fatigue of Springs

Mark Hayes, Spring Research and Manufacturers' Association

---

## Introduction

Over half of all metallic springs that fail in testing or service do so by a fatigue mechanism. Sometimes the fatigue crack is initiated by preexisting defects or cracks, corrosion, wear, or mechanical damage, but in the majority of cases there is no significant "fault" identified that has initiated failure. Once initiated in consequence of repeatedly applied stress, a fatigue crack will grow some distance through the spring section until the effective spring section is reduced and can no longer support the maximum applied stress, at which time overload failure will occur. Fatigue is a likely failure mechanism for all types of springs (compression, extension, torsion, leaf, presswork, spiral, constant force, disc, etc.) as well as for all spring sizes (fatigue occurs in springs made from materials 0.1 mm thick to 80 mm diameter). Springs are invariably manufactured from high-strength materials, the most important of which are carbon steels, low-alloy steel, stainless steels, and nickel, cobalt, copper, and titanium alloys, and all are susceptible to fatigue failure. For more information about spring material composition and properties see the article "Steel Springs" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook* (formerly 10th Edition *Metals Handbook*).

## Fatigue Mechanisms and Performance Factors

**Short Crack Incubation.** More than 95% of all spring fatigue failures initiate at the surface, and high-integrity surfaces are better for resisting fatigue crack initiation. The importance of crack initiation is clear when the following observations are considered regarding fatigue testing of springs:

- SPRINGS MOSTLY FAIL AT ONE POSITION, EVEN IF A LONG LENGTH OF MATERIAL IS EXPOSED TO THE MAXIMUM STRESS IN CYCLIC LOADING.
- IT IS VERY UNUSUAL TO FIND ANY EVIDENCE OF FATIGUE CRACKING AWAY FROM THE FRACTURE ITSELF WHEN FAILED SPRINGS ARE EXAMINED METALLOGRAPHICALLY.
- WHEN A LARGE NUMBER OF SPRINGS ARE TESTED OVER A GIVEN STRESS RANGE, THE SCATTER IN CYCLES TO FAILURE IS VERY LARGE (FIG. 1).

Generally the initiation crack is too small to see during metallographic examination, but once propagation starts, it occurs relatively quickly and usually before other cracks in the process of initiating have started to propagate. The variability and importance of initiation for the first small crack results in scatter, which is why spring fatigue data are treated in a statistical manner. In addition, failure of a metallic spring by a fatigue mechanism is almost always sudden and catastrophic: there is no warning of impending failure. The spring is working completely satisfactorily one minute and is in two pieces the next. There also are no nondestructive or other methods available for predicting imminent failure.

**FIG. 1 SCATTER IN THE FATIGUE LIFE FOR SHOT-PEENED CARBON STEEL SPRING WIRE (ASTM A 227, CLASS II STEEL). IT IS NOT UNCOMMON FOR SOME SPRINGS TO SURVIVE 10 MILLION CYCLES WHEN OTHER SPRINGS FROM THE SAME BATCH, TESTED AT THE SAME TIME, HAVE FAILED AT 400,000 CYCLES. THE S-N CURVE SHOWN HERE GIVES THE RESULTS OF 55 FATIGUE TESTS CARRIED OUT ON SHOT-PEENED SPRINGS.**

The mechanism of crack initiation is typically investigated by examination of the resultant fracture surfaces, and this article provides several examples. However, for most springs with high-integrity surface quality and a clearly defined position of maximum stress, failure is generally initiated at the position of maximum stress (e.g., on the inside surface of an active coil in a parallel sided compression spring, or at the outside surface of a torsion spring at the position where an external tangential leg meets the coiled body of the spring).

**Stresses and Fracture Appearances.** Most springs are generally subjected to torsion or bending stresses. Helical compression, extension, and volute springs and torsion bars are the most common spring forms that are stressed in torsion. Consequently, the fatigue fracture surface of these springs is frequently at 45° to the wire, strip, or bar axis, and the final overload failure takes up a characteristic helicoidal shape. Torsion springs (so named after their load output, torque); leaf springs; clock, spiral, and constant-force springs; most spring pressings; disc springs or belleville washers; and the hooks of extension springs are all stressed in bending. The fatigue fracture surface of these springs is initially at 90° to the bending stress.

Having established that there are only two main stress regimes for typical spring loading, it is necessary to emphasize that the calculation of stress values in springs is not always straightforward, because there tend to be small bending stresses additional to the main torsional stresses in compression springs, and likewise a small element of torsion in springs for which the principal stress mode is bending. Furthermore, there are many possibilities for stress raisers to be present in springs (surface defects, effectively notches, in springs made from wire, bar, or strip material, burrs on the edge of strip materials, holes stamped in flat springs, etc.). In addition, it is not usually possible to obtain an accurate measure of stress by strain gaging, because springs are too small or too sharply curved. Finite element analyses can be helpful for establishing stress levels in some circumstances, but at high deflections and stresses, close to the elastic limit, finite element methods are not so accurate. Hence, whenever stress is referred to in this chapter, it has been calculated by classical mechanics, generally using the formulas given by Wahl (Ref 1), and no allowance has been made for stress raisers or residual stresses.

**Residual Stress and Surface Roughness.** For a given spring material with a certain strength and surface quality, residual stress is a key variable that influences fatigue resistance. Residual stresses are certain to be generated during spring manufacture, and so the stress threshold for fatigue crack propagation will be reached at much lower applied stresses when residual tensile stresses are present. When compressive residual stresses are present, the applied stress necessary to reach the stress threshold for fatigue crack growth will have to be high to negate the residual compressive stress. In addition, fatigue resistance is affected by surface roughness (which is why shot peening rather than shot blasting is widely employed in spring manufacturing).

Residual stress and surface roughness are interrelated phenomena that are correlated, to some degree, by the surface and the process. For example, rough grinding typically produces high tensile residual stresses; "fine" grinding, lower tensile stresses; polishing and sanding, moderate compression; lapping and polishing, high (but shallow) compressive stresses, and so on. In reality, residual stress produced in the surface by the finishing methods is the key effect on fatigue life, not the surface roughness itself.

When the independent effects of residual stress and surface roughness are considered, the effect of residual stress on fatigue resistance appears to be a more potent factor than surface roughness. The effect of surface roughness (within reasonable ranges, say up to 2.5 or 5.0  $\mu\text{m}$ , arithmetic average) is much less than traditionally considered by the engineering community, according to a broad study of various finishing processes (e.g., polishing and peening) on the fatigue life of several alloys (see W.P. Koster, *Effect of Residual Stress on Fatigue of Structural Alloys, Practical Applications of Residual Stress Technology*, ASM International, 1991, p 1-10). Thus, surface residual stress is a predominant factor affecting fatigue life, provided that gross surface discontinuities are avoided.

If the surface residual compressive stress is increased by controlled surface engineering, it is possible that the maximum applied stress occurs below the surface. When these circumstances arise (as they should in a well shot-peened spring), fatigue fracture initiation may not be at the surface of the spring, but rather may occur at between 150 and 400  $\mu\text{m}$  below the wire, bar, or strip surface. However, in order to initiate a fatigue crack from below the surface, it is necessary that a significant stress raiser exist at this position, and almost invariably this stress raiser is a nonmetallic inclusion. In addition, this inclusion has to be greater than 15  $\mu\text{m}$ , based on observations of many investigators (Ref 2, 3, 4) and the observations of investigators at the Spring Research and Manufacturers' Association (Ref 5), who have examined hundreds of spring fatigue failures by scanning electron microscopy. Inclusions influence fatigue fracture appearance only when the springs have been shot peened or surface engineered to produce a residual compressive stress, and when the inclusion is larger than 15  $\mu\text{m}$ .

However, it is not only observations of fractures that lead to the conclusion that the inclusion must be 15  $\mu\text{m}$ . A short-crack theory of fatigue mechanisms in high-strength materials (Ref 6) also predicts that short cracks need to "incubate" to 10 to 15  $\mu\text{m}$  before fatigue cracks propagate. Although cracks of 15  $\mu\text{m}$  could be observed metallographically, it is not surprising that such small cracks at the surface, or subsurface, would be missed when metallographic examinations are undertaken of springs that have failed by fatigue. This is consistent with the common observation of fatigue failure only at one position, with no additional cracking observed when springs are examined metallographically.

**Critical Factors Affecting Spring Fatigue Performance.** The above discussions have briefly summarized the factors of surface integrity, applied stress, residual stress, and subsurface crack initiation. However, it is also worth listing practical factors that have a direct bearing on spring performance, and the circumstances in which fatigue could occur.

Fatigue failure can occur after as few as 4000 cycles when a spring is subject to very high bending stresses close to the elastic limit of the material, but usually 10,000 to 50,000 cycles are required to cause fatigue failure. The probability of

fatigue failure is related to fundamental material factors (such as residual stress), but also to each of the following application factors:

- SPRING MATERIAL TYPE AND STRENGTH
- STRESS CONDITIONS SUCH AS MAXIMUM APPLIED STRESS, APPLIED STRESS RANGE, STRESS REGIME (BENDING, TORSION, OR A COMBINATION), AND NUMBER OF CYCLES AT MAXIMUM STRESS RANGE
- SURFACE QUALITY
- SPRING MANUFACTURING PROCESSES, RESIDUAL STRESS, AND SURFACE ROUGHNESS
- ENVIRONMENT, CORROSION, AND TEMPERATURE
- RATE OF APPLICATION OF LOAD
- WEAR AND FRETTING
- EMBRITTLEMENT AND CRACKING

There are two notable absentees from this list. First, fatigue crack growth rate is of relatively little concern, because the key to preventing fatigue failure in springs is the avoidance of crack initiation. Second, impact failure seldom occurs in springs (even at very low temperatures at which spring materials are very brittle), because springs deflect elastically as a consequence of impact loading. (However, under high load rates, impact conditions may become important if the spring could become subject to sufficiently high deflections that the coils could impact with one another, the end coil, or adjacent components.)

In addition, even though springs generally fail at only one position under laboratory conditions, in actual service multiple cracking is more frequently observed. The reasons for this difference are believed to include the following:

- IN SERVICE, COMPRESSION SPRINGS OFTEN FAIL IN SUCH A WAY THAT THE COILS INTERLOCK AND THE SPRING CAN AND DOES CONTINUE TO OPERATE AFTER FIRST FAILURE. HOWEVER, STRESS LEVELS INCREASE AFTER THE FIRST FATIGUE FAILURE, SO A SECOND FATIGUE CRACK GROWS RAPIDLY, CAUSING A SECOND BREAK.
- IN SERVICE, ENVIRONMENTAL INFLUENCES (HOWEVER SLIGHT) ARE LIKELY TO PLAY A ROLE, AND A CHARACTERISTIC OF SPRINGS THAT FAIL BY CORROSION FATIGUE, OR FATIGUE INITIATED BY SMALL CORROSION PITS, IS THAT THEY FAIL INTO THREE OR MORE PIECES.
- IN SPRINGS THAT FAIL IN SERVICE, APPARENTLY BY A FATIGUE MECHANISM, FATIGUE CRACK INITIATION MAY BE DUE TO THE PRESENCE OF MATERIAL DEFECTS, CRACKS, BURRS, OR OTHER PREEXISTING FAULTS.

**Material Type and Strength.** Typically, springs are only manufactured from high-strength (or high-hardness) materials. The maximum strength utilized is often determined by considerations of formability (in small springs) or from concern over the risk of brittle failure.

**Stress conditions,** such as maximum stress and mean stress, are obvious fatigue factors. The fatigue performance of springs is usually illustrated by modified Goodman diagrams, like Fig. 2, which covers actual fatigue data for carbon steel compression springs made from both the lower-strength (class I) and the higher-strength (class II) ASTM A 227 wire. The Goodman diagram does not apply if the spring is subject to periodic or occasional overloads. Cumulative damage due to such overloading is a more difficult question that is addressed elsewhere in this Volume. Moreover, Fig. 1 and 2 only illustrate the case for compression springs loaded between two applied torsional stresses. These diagrams would not be applicable if the stress regime were in bending, or if a combination of torsional and bending stresses were present. Figures 1 and 2 also are limited to springs loaded from only one side of their unloaded position. Some springs can operate from either side of their unloaded position, in which circumstances the benefits to be gained from prestressing are not applicable.

FIG. 2 GOODMAN DIAGRAM FOR 10 MILLION CYCLE FATIGUE LIFE AND 95% PROBABILITY OF SURVIVAL FOR COLD-DRAWN CARBON STEEL WIRE SPRING (ASTM A 227, 1.5-4.0 MM WIRE SIZES)

**Surface Quality.** After a spring material is selected based on strength requirements and environments, the next most important factor is surface quality. Typical surface defects found in spring materials are seams, laps, and decarburization. The maximum depth of such defects can be controlled by raw material producers, and it is limited in the better international spring material specifications (e.g., no defects permitted that exceed a depth of 1% of the wire diameter or 40  $\mu\text{m}$ , whichever is smaller). Forty  $\mu\text{m}$  is the smallest surface defect that can reliably be detected by eddy-current methods.

**Spring Manufacturing Processes.** The most common spring manufacturing processes may each have some influence on residual stress or surface roughness and will thereby affect spring fatigue performance. The most important principles involved are that:

- FORMING A SPRING WILL GENERALLY INVOLVE BENDING WIRE OR STRIP TO THE REQUIRED SHAPE. IN THIS PROCESS THE SPRING MATERIAL WILL BE OVERBENT AND WILL THEN SPRING BACK. THE RESIDUAL STRESSES ARE THOSE CONSEQUENT UPON THE SPRINGBACK.
- STRESS RELIEVING, OR LOW-TEMPERATURE HEAT TREATMENT, AFTER SPRING FORMING WILL STABILIZE THE SPRING SHAPE AND RELIEVE SOME, BUT NOT ALL, OF THE RESIDUAL STRESSES INTRODUCED DURING FORMING. IF SPRINGS ARE HARDENED AND TEMPERED OR AUSTEMPERED AFTER FORMING, THE RESIDUAL STRESSES WILL BE VERY CLOSE TO ZERO.
- PRESTRESSING IS A PROCESS WIDELY USED IN THE SPRING INDUSTRY IN WHICH THE SPRING IS DEFLECTED BEYOND ITS NORMAL WORKING POSITION, DELIBERATELY CAUSING PLASTIC DEFORMATION OF THE MATERIAL IN THE LOADING DIRECTION AND THEREBY INDUCING A HIGHER ELASTIC LIMIT AND BENEFICIAL RESIDUAL STRESSES.
- SHOT PEENING IS THE SINGLE MOST IMPORTANT PROCESS FOR FATIGUE RESISTANCE IN MOST DYNAMICALLY LOADED SPRINGS.
- OTHER SURFACE ENGINEERING PROCESSES THAT ARE CAPABLE OF ENHANCING RESIDUAL COMPRESSIVE STRESSES AND/OR SURFACE ROUGHNESS OF SPRINGS INCLUDE ION IMPLANTATION, NITROCARBURIZING, LASER SHOCK PROCESSING, CAREFULLY CONTROLLED PHYSICAL VAPOR DEPOSITION, AND ELECTROPOLISHING,

BUT AS YET THESE PROCESSES ARE OF LIMITED COMMERCIAL IMPORTANCE.

- CORROSION PROTECTION PROCESSES DO NOT GENERALLY HAVE A LARGE INFLUENCE ON FATIGUE RESISTANCE, BUT THEY MAY IMPART A SMALL RESIDUAL TENSILE STRESS IN A SPRING SURFACE, AND THEY ARE CONSEQUENTLY DETRIMENTAL. EXAMPLES OF SUCH PROCESSES ARE THE USE OF PREGALVANIZED WIRE AND ELECTROPLATING SPRINGS WITH ZINC OR OTHER METALS.

**Rate of Application of Load.** If a load is applied (or removed) quickly from a spring, the spring may not react as fast as the load is applied. A spring has a natural frequency that determines its maximum speed of operation. Also, under conditions of dynamic loading a spring, or spring mass system, may be prone to resonance. In either of these circumstances, the actual stress range for the spring may be significantly higher than that calculated, and consequently the fatigue performance may be much worse than expected.

**Wear and fretting** sometimes occur when a spring is in contact with nearby components or itself. The wear resistance of spring materials is quite good, but the wear region is obviously more susceptible to fatigue failure. Fretting fatigue occurs when mated parts undergo small oscillatory displacement relative to each other, as in the case of leaf springs, for example (Ref 7).

**Embrittlement or Cracking.** Hydrogen or liquid metal embrittlement may cause springs to fail if these embrittlement conditions arise when the spring is under load, without the need for any fatigue mechanism. However, if the embrittlement or cracking occurred as a consequence of residual tensile stresses, then the precracked spring can fail very early as a consequence of dynamic loading. Examples of such fatigue failures have occurred in springs with small quench cracks, stress-corrosion cracks, coiling cracks (through failure to stress relieve silicon chromium steel immediately after coiling), and liquid metal embrittlement by solder or other lead, tin, zinc, or cadmium alloys.

## Fatigue of Spring Steels

As previously noted, the selection of spring material is usually based on factors besides strength, such as formability, surface condition, cost, or the risk of embrittlement. Steels for springs include carbon steels in the mid- to high-carbon range (AISI 1050-1095) for cold-formed or wound springs, and low-alloy steels such as AISI 4160, 6150H, and 8660H

for hot-wound forms. For small springs, music wire (ASTM A 228) is the highest-quality carbon steel (with a surface quality almost comparable to that of valve spring wire). Hard-drawn wire (ASTM 227) is the least expensive and has the lowest surface quality. Valve spring wires (such as ASTM A 230, A 232, and A 401) are more expensive, and have higher surface quality and are suitable for slightly higher temperature use. For corrosion and heat resistance, cold-drawn stainless steel 302 wire (ASTM A 313) has moderate surface quality and is available in several tempers. It is more expensive than carbon steel for designs requiring diameters over about 0.3 mm (0.012 in.) but less costly than music wire under 0.3 mm (0.012 in.) because of the lack of need for plating. Stainless steel type 316 is good for spring wire because it has better corrosion resistance than 302, particularly in salt water.

The conventional  $S-N$  diagrams (such as in Fig. 3) are a useful start for general comparisons of fatigue strength. However,  $S-N$  curves are not available for the wide variety of loading conditions that may occur in spring design. Scatter in fatigue life (Fig. 4) is another key variable that requires statistical analysis of some type.

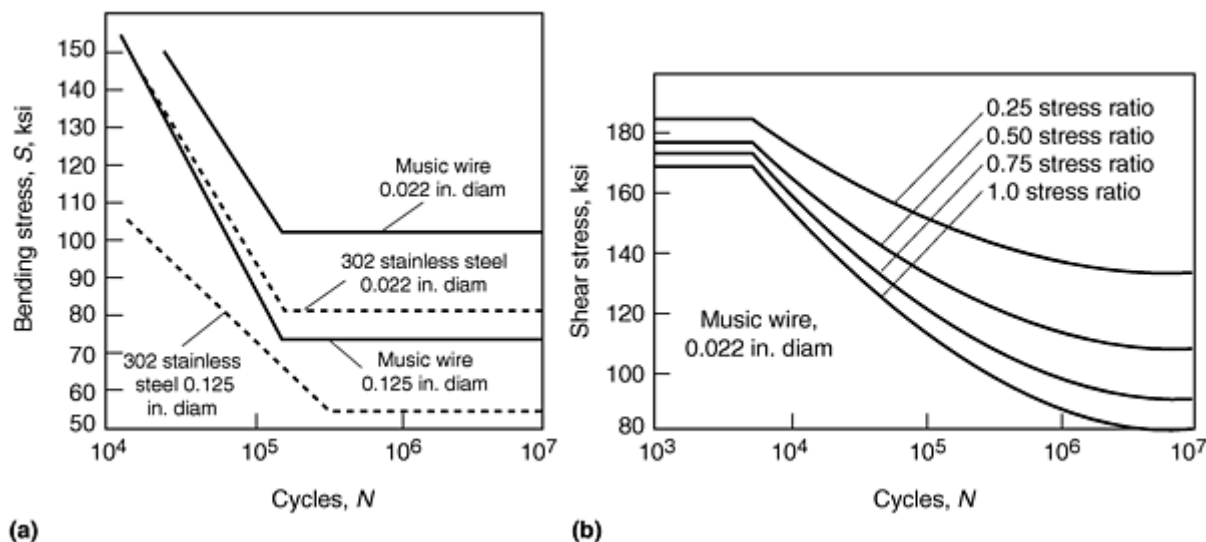

FIG. 3 BENDING AND SHEAR FATIGUE STRENGTH. (A) BENDING FATIGUE OF VARIOUS SPRING WIRE. (B) SHEAR FATIGUE CURVES FOR MUSIC WIRE (0.022 IN. DIAM) AT VARIOUS STRESS RATIOS. SOURCE: REF 8

FIG. 4 TYPICAL SCATTER BAND IN FATIGUE TESTS OF MUSIC WIRE HELICAL SPRINGS, STRESS RANGE ZERO TO MAXIMUM. WIRE SIZE 0.022-0.048 IN. SOURCE: REF 9

In addition, shot peening is a key factor for fatigue resistance in most dynamically loaded springs. For leaf springs this process is sometimes carried out in conjunction with prestressing, the so-called strain peening process, in order to gain exceptionally high levels of residual compressive stress. Optimizing the shot peening process has been the subject of

much research, but it is almost always beneficial (Ref 10), even when carried out under non-optimum conditions. An early example of shot peening effects on fatigue is shown in Fig. 5.

**FIG. 5 EFFECT OF PRESTRESSING AND SHOT PEENING ON FATIGUE CURVES FOR TYPICAL COMPRESSION SPRINGS MADE OF CHROME-VANADIUM WIRE (ASTM A231, 1.5-4.0 MM WIRE SIZES)**

**Scatter and Statistical Analysis of *S-N* Data.** The considerable scatter in fatigue strength data is attributable to a variety of factors, including defect frequency and variations in strength with changes in diameter. Two methods of statistical analysis are briefly summarized below.

**Confidence Limits.** Figure 1 is a typical *S-N* curve for shot-peened compression springs made from hard-drawn carbon steel. In this instance the wire size was 2.5 mm diameter, at which size the tensile strength of this grade of wire was about 1800 MPa. Superimposed upon the actual data points given in Fig. 1, a line has been drawn that represents the 90% probability of survival. For each maximum applied stress value, it is a fairly simple mathematical exercise, using Weibull statistics (Ref 11) or other methods, to estimate the number of cycles at which 90% of the springs would have been expected to break. Having calculated the 90% probability of survival at each stress value, then it is relatively easy to fit the 90% curve to the data, using the characteristic shape of line given in Fig. 1.

**Probit Method.** No one designs for even a 10% chance of failure, and hence a more sophisticated statistical treatment of spring fatigue data is necessary for spring designers to know the stress value at which no springs will be susceptible to fatigue failure in service.

Table 1 shows a pattern to the number of fatigue tests at each maximum stress value in Fig. 1. The testing was deliberately arranged so that  $x$  springs were tested at the stress at which 25 to 75% would fail,  $1.5x$  springs for the stress at which 80 to 90% would fail or survive, and  $2x$  springs for the stress at which 95% would fail or survive. This pattern of testing is the type required for the simplest analysis according to the probit method (Ref 12, 13). From probit analysis, it is possible to predict confidence limits for stress values at which no more than one in ten, one in a thousand, or one in a million springs would be expected to fail. The probit method of statistical analysis is the most widely used method in Europe and Japan for analyzing spring fatigue data so that safe design stresses can be calculated that will lead to very low risks of failure by fatigue in service (Ref 14). In practice, confidence limits vary rather widely unless a very large number of fatigue tests have been undertaken.

**TABLE 1 SPRING FATIGUE DATA FROM FIG. 1**

<b>MAXIMUM STRESS, MPA</b>	<b>NUMBER TESTED</b>	<b>NUMBER BROKEN</b>	<b>IDEAL PERCENTAGE OF FAILURE FOR PROFIT</b>	<b>ACTUAL PERCENTAGE</b>
1080	7	7		
1000	12	12	95	<b>100</b>
960	9	8	80-90	<b>89</b>
920	6	3	25-75	<b>50</b>
880	9	2	10-20	<b>22</b>
<b>840</b>	<b>12</b>	<b>0</b>	<b>5</b>	<b>0</b>

A probit analysis is useful only if it has been carried out for precisely the same wire type and size as the spring designer wishes to use, and if the fatigue testing was carried out under appropriate stress conditions (including residual stresses from surface engineering). Hence, probit data is of limited applicability, but it can be more useful if probit analyses are carried out at two or, preferably, three initial stress values for a given spring material type (and surface condition), because this will enable the construction of a Goodman diagram (Fig. 2). In order to draw Fig. 2 it was necessary to carry out at least two probit analyses on shot-peened springs and two probit analyses on springs that had not been shot peened. Experience has shown that the effect of wire size on the shape and size of Goodman diagrams is relatively small, so Fig. 2 is valid for all wire sizes between 1.5 and 4.0 mm, despite the differences in the tensile strength of these wires. Similarly, the diagram is applicable to class I and class II (higher tensile strength) wires, the only modification to the diagram being the higher maximum stress allowable in the class II wire.

The Goodman diagram in Fig. 2 is for springs that are required to operate for 10 million cycles. The diagram would have a larger area, and hence allow larger stress ranges, if it were drawn up for springs that will never operate for more than one million cycles. For ASTM A 227 material, the diagram would not need to be smaller in area if the springs were required to operate for more than 10 million cycles. It is generally accepted that in this grade, a spring that survives 10 million cycles will survive forever. This is not true for springs made from shot-peened oil-tempered silicon chromium wire (e.g., ASTM A 401) for which failures between ten and fifty million cycles have frequently been recorded, but nonetheless silicon chromium is generally regarded as the best material available today for dynamic performance springs.

**Goodman diagrams** are the most useful source of fatigue data for designers of springs, but using published Goodman diagrams requires understanding of the applicable design circumstances. If in doubt, fatigue testing of samples is advised. Testing is advised whenever a spring design is close to the design limit given on a Goodman diagram (some of which are drawn up on the basis of only 95% probability of survival), or if the actual spring differs from the published data in terms of surface quality, prestressing, surface engineering, operating environment, larger wire size than that for which the Goodman diagram is applicable, or other factors. With these important qualifications in mind, typical Goodman diagrams are shown in Fig. 2, 6, and 7. Design curves and allowable stresses for dynamic loading of springs should also be considered from various design publications, such as those listed in "Selected References: Spring Design," at the end of this article.

## Fatigue of Springs

Mark Hayes, Spring Research and Manufacturers' Association

---

### Examination of Failed Springs

Springs may fail as a result of corrosion, various types of embrittlement, relaxation, overload, or fatigue (see, e.g., "Failures of Springs" in *Failure Analysis and Prevention*, Volume 11 of *ASM Handbook*, formerly 9th edition *Metals Handbook*). Sometimes these causes act in combination, but the most common is fatigue, which may occur after as little as a few thousand operations. The characteristics of fatigue failure in springs are readily identified by experienced investigators, but these characteristics are briefly summarized below.

When examining spring fatigue failures, it is almost always prudent to check the structure and hardness adjacent to the fracture surface. This is most readily accomplished by taking metallographic transverse and longitudinal sections from behind the fracture initially. These sections should be mounted in plastic, polished to a 1  $\mu\text{m}$  finish and then hardness tested. If the material hardness is approximately correct, the sections should be examined metallographically for surface defects or gross internal faults to check that the material is to specification, particularly with respect to surface quality. Etching will reveal the structure of the material, which should always be uniform throughout, and any surface decarburization present in carbon or low-alloy steels should be within the prescribed limits of the specification. It is self-evident that surface defects or decarburization represent sites of weakness from which fatigue cracks are likely to initiate.

Springs may suffer fatigue failures because of some fault in the raw material, non-optimum spring manufacture, or an environmental influence in service. However, springs may also fail because the stress range and number of cycles exceed the Goodman diagram limits for that spring. Hence, the applied stress should be calculated whenever possible, so that an estimation of the likely fatigue performance may be made by comparing the calculated stresses with the best available published data. In estimating stresses it is necessary to consider dynamic aspects as well as the magnitude of stresses at the working positions, because the actual stresses could be considerably higher than is immediately apparent, perhaps due to resonance or impact loading effects. The possibility of stress raisers, wear due to contact with adjacent components, or residual tensile stresses from manufacture also needs to be considered. Stress calculations are best accomplished by use of commercial computer-assisted design programs, or from first principles of mechanics using texts such as Wahl (Ref 1). Finite element methods in association with load testing may also be used, but experience has shown that these methods may be insufficiently accurate at the large deflections at which springs are usually used.

**Beach marks or striations**, which are the identifying feature of fatigue in many components, are not always present in spring fatigue fracture surfaces. The absence of beach marks has led some investigators to misdiagnose the reason for spring failure. Beach marks are more likely to be present if the spring material is comparatively soft (40 to 45 HRC), but they are seldom present when higher-strength spring materials fail by fatigue.

**General Fracture Appearance.** Some fracture features are always present in spring fatigue. For example, the fracture surface from spring fatigue invariably has a region that is flat in topography, often with clear "river markings" showing the position or positions at which the fatigue crack started. This flat region never extends over the whole fracture surface, because the fatigue crack, which caused the flat region, will reduce the effective section from which the spring is manufactured. When the fatigue crack has grown far enough, the remaining material will no longer be able to support the load on the spring and so will fail by an overload mechanism.

The direction of propagation of the fatigue crack will generally be at  $90^\circ$  to the principal axis of the spring section if the spring is stressed in bending, or at  $45^\circ$  if the spring is stressed in torsion. However, if the spring is stressed in torsion, the stage I fatigue crack may initiate in the resolved shear stress direction before switching to the stage II tensile direction.

The final overload failure is often referred to as stage III of a fatigue failure. When fatigue cracks initiate below the surface in compression springs (because of surface compressive stresses from shot peening), the cracks propagate in the 45° direction. A typical example is Fig. 8.

**FIG. 8 SEM PHOTOMICROGRAPH SHOWING THE FRACTURE SURFACE OF A SHOT-PEENED 302 STAINLESS STEEL SPRING THAT HAD FATIGUE INITIATION AT AN INCLUSION THAT WAS 300  $\mu\text{M}$  BELOW THE WIRE SURFACE. 21 $\times$**

These characteristics can usually be identified by the simple expediency of examining the fracture surface on a binocular microscope. A scanning electron microscope (SEM) is generally not needed to recognize a fatigue failure, but it is necessary to use an SEM to confirm fatigue as the failure mechanism when springs are manufactured from wire or strip that is less than about 1 mm in diameter or thickness. In addition, the SEM is often necessary to reveal details of the position at which a fatigue crack initiated. For instance, a small corrosion pit or some mechanical damage may be present at the fatigue origin, which could easily be irresolvable or overlooked on examination with a binocular microscope alone.

**Springs stressed in bending** have their fatigue fracture origin at the tensile surface of the bend. Typically, this position will be at the inside of a hook on an extension spring, or where the moving tangential leg meets the body of a torsion spring, in which case the position of maximum stress will be at the outside surface if the torsion spring is loaded in the wind-up direction, as is invariably recommended. In strip springs the position of maximum stress is often at the outside surface of a bend, particularly if the spring "hinges" about this bend. In clock, constant-force, or spiral-type springs there is a very long length of the outside surface of the strip where the stress is maximum and is equal across the width of the strip. In these springs there are often numerous fatigue cracks formed before complete failure occurs.

### **Example 1: Corrosion Fatigue Failure of 302 Stainless Steel Spring.**

After only two months of use in a printing operation, type 302 stainless steel springs were breaking into several pieces. The springs were operating over a very small deflection and were regulating the flow of ink, in which they were constantly immersed.

Visual examination revealed clear evidence of fatigue fractures on every piece of the spring, and each of the fractures was oriented at 45° to the wire axis. Figure 9 shows crack arrest marks and fatigue striations (beach marks), which are not always expected in the fracture surface of spring fatigue failures, as noted above. Clear evidence of pitting corrosion at the fatigue fracture origin can also be seen. However, the portions of spring showed no evidence of red rust and had a bright (greenish from the ink) surface, indicating that the corrosion pitting was local in nature.

**FIG. 9 OPTICAL PHOTOGRAPH OF THE FATIGUE REGION OF A STAINLESS STEEL COMPRESSION SPRING THAT FAILED DUE TO CORROSION FATIGUE. NOTE BEACH MARKS ON THIS FRACTURE. AS NOTED IN TEXT, BEACH MARKS ARE OFTEN NOT PRESENT IN FRACTURE SURFACE OF SPRING FATIGUE FAILURES, WHICH MAKES THIS CASE SOMEWHAT UNUSUAL. 40×**

Analysis of the ink in which the spring was operating revealed that free chloride ions were present. The extent of the pitting damage was surprising, but once initiated the corrosion was rapid because the surface of the stainless steel could not repair itself, because there was no oxygen present in the alcohol-based ink. The solution was to use an alternative ink that contained no free chloride ions, and three years later the springs are working satisfactorily. All the companies involved in this problem were surprised that corrosion fatigue was the problem, because no rust could be seen and the operating stresses were insufficient to initiate fatigue.

### **Example 2: Aqueous Corrosion Fatigue of Type 302 and 304 Stainless Steel Springs.**

After six months of operating a new chicken house, a farmer noticed that the majority of the water feeders had stopped working. The water feeders operated on the principle that when the chickens pecked a plastic bowl, a compressed spring released a squirt of water. If the spring broke, no water came out.

The small compression springs were made from 0.8 mm diameter type 302 stainless steel, and the operating stresses were safely within the design limits given by the Goodman diagram. These springs were so small that it was necessary to use a SEM to identify why they had failed. Some were in three or four pieces, but most had only one fracture and did not show any evidence of mechanical or corrosion damage. On the SEM it was observed that the springs contained numerous cracks only on their inside surface, and these cracks were all at 45° to the wire axis. The cross patterns made by these cracks were recognized as the classic indication of corrosion fatigue.

The solution was to select a grade of spring steel that would be more corrosion resistant than 302 stainless. Glass bead peening would probably have been beneficial too, but the springs were too small for this process. Type 304 stainless steel springs were tried, but these also failed, albeit after two or three times longer service than 302. Inconel 600 was eventually used, and no complaints about thirsty chickens have been received since.

### **Example 3: Effect of Spring Unwinding on Fatigue.**

This example involves an agricultural tine, which is a relatively large double torsion spring with outer legs that are used to sweep through hay or other crops and turn them over. The tine machinery manufacturer submitted several examples of failed tines made from hard-drawn carbon steel, wanting to learn whether the life could be significantly improved.

Visual examination revealed that the wear pattern on the outside of the long legs of the tines was consistent with them having been used in the wind-up direction, as recommended. The mechanical damage on the broken tines was not thought to be excessive, and the leg angle was close to that specified on the drawing, indicating that it had not been significantly abused in service. Abuse (such as use in very stony ground) would have caused plastic deformation. Inevitably there was some rust on the failed tines, but no evidence of pitting could be seen.

Visual examination of the fracture surface showed that bending fatigue was almost certainly the cause of failure, but despite the clear evidence that the tine had been used in the wind-up direction, the fatigue fracture origin was on the inside surface of the legs, at the point where they joined the coiled body of the spring. No evidence of corrosion pits at the origin of the fatigue crack could be seen.

Inquiries were made concerning the process route used to manufacture the tines. The springmaker reported that the hard-drawn carbon steel had been coiled, stress relieved at 200 °C, and painted, explaining that the stress relieving temperature had been kept as low as possible in order to maximize the retention of beneficial residual stresses from coiling. This is a good practice for dynamically loaded torsion springs.

In this instance, however, it appeared that the tines were being wound up by loading them with hay. When the load was released, the tines were springing back through the neutral unloaded position and into the unwind direction. This movement into the unwind direction was happening often enough to initiate fatigue. The solution was to increase the stress relieving temperature to reduce the residual stresses from coiling and hence improve fatigue performance. This may give rise to earlier fatigue failure in the wind-up direction, of course, but the net effect is to prolong the tine life significantly.

## Introduction

THE CONCEPTS of fracture mechanics are basic ideas for developing methods of predicting the load-carrying capabilities of structures and components containing cracks. Though virtually all design and standard specifications require the definition of tensile properties for a material, these data are only partly indicative of inherent mechanical resistance to failure in service. Except for those situations where gross yielding or highly ductile fracture represents limiting failure conditions, tensile strength and yield strength are often insufficient requirements for design of failure-resistant structures. Brittle fracture can also occur if toughness, resistance to corrosion, stress corrosion, or fatigue resistance are reduced too much in achieving high strength.

The concepts of fracture mechanics are concerned with the basic methods for predicting the load-carrying capabilities of structures and components containing cracks. The fracture mechanic approach is based on a mathematical description of the characteristic stress field that surrounds any crack in a loaded body. When the region of plastic deformation around a crack is small compared to the size of the crack (as is often true for large structures and high-strength materials), the magnitude of the stress field around the crack is related to the stress-intensity factor,  $K$ , with:

$$K = \sigma(\sqrt{a})Y(A/W)$$

where  $\sigma$  = remotely applied stress,  $a$  = characteristic flaw size dimension,  $Y$  = geometry factor that depends on the ratio of the crack length,  $a$ , to the width,  $W$ , determined from linear elastic stress analysis. The stress-intensity factor,  $K$ , thus represents a single parameter that includes both the effect of the stress applied to a sample and the effect of a crack of a

given size in a sample. The stress-intensity factor can have a simple relation to applied stress and crack length, or the relation can involve complex geometry factors for complex loading, various configurations of real structural components, or variations in crack shapes. In this way, linear elastic analysis of small-scale yielding can be used to define a unique factor,  $K$ , that is proportional to the local crack tip stress field outside the small crack tip plastic zone.

These concepts provide a basis for defining a critical stress-intensity factor ( $K_{Ic}$ ) for the onset of crack growth, as a material property independent of specimen size and geometry for many conditions of loading and environment. In general, when the specimen thickness and the in-plane dimensions near the crack are large enough relative to the size of the plastic zone, then the value of  $K$  at which growth begins is a constant and generally minimum value called the plane-strain fracture toughness factor,  $K_{Ic}$ , of the material. The parameter  $K_{Ic}$  is a true material property in the same sense as is the yield strength of a material. The value of  $K_{Ic}$  determined for a given material is unaffected by specimen dimensions or type of loading, provided that the specimen dimensions are large enough relative to the plastic zone to ensure plane-strain conditions around the crack tip (strain is zero in the through-thickness or  $z$ -direction). Therefore, plane-strain fracture toughness,  $K_{Ic}$ , is particularly pertinent in materials selection because, unlike other measures of toughness, it is independent of specimen configuration.

In the plane-strain state, a material is at its lowest point of resistance to unstable fracture. The onset of fracture is abrupt and is most clearly observed in thick sections of low-ductility (high-strength) alloys, as discussed in more detail in this article. Originally, the technology of fracture mechanics was limited to relatively high-strength materials that could be tested in sizes that met certain requirements for linear-elastic displacement during slow testing of specimens of certain configurations. More recent advancements in the state of the art, such as  $R$ -curve and  $J$ -integral tests, have extended the use of fracture mechanics to elastic-plastic conditions which are associated with lower-strength materials and smaller section sizes. However, when stresses approach or exceed yield values, the elastic stress field surrounding the crack departs from that of plane strain (from the development of an enlarged crack tip plastic zone which generally enhances fracture toughness). With increasing load, slow stable crack extension (tearing) may accompany the increasing plastic zone size. Onset of rapid fracture occurs when increase in crack tip stress field, measured by  $K$  (increase in  $K$  due to increased nominal stress and crack length), equals or exceeds resistance to crack extension (due to an increase in plastic zone size, crack tip blunting, and change from flat to slant fracture). This behavior is most clearly seen in fracture of relatively tough thin plate and sheet alloys. Unstable fracture under these conditions cannot be described as a material property since events leading to rapid fracture are specimen configuration and size dependent.

Finally, the technology of fracture mechanics has been applied to fatigue crack growth rate assessment under various conditions, environmental and stress-corrosion problems, dynamic fracturing, and determinations of the effects of elevated and cryogenic testing temperatures. These developments, which have occurred in the past 35 years, have led to broad use of fracture mechanics and to greater confidence in the design of fracture-critical structures.

## General Fracture Control Concepts

**Examples and Sequence of Events Leading to Brittle Fracture.** Brittle fracture is defined as fracture that takes place at stresses below the net section yield with very little observable plastic deformation and minimal absorption of energy. Such fracture occurs very abruptly with little or no warning and can take place in all classes of materials. It is a major goal of structural engineering practice to develop methodologies (analytical and experimental) to avoid such fractures as they are associated with massive economic impacts and frequently involve loss of life. One notable example of brittle fracture occurred with the World War II Liberty ships which experienced numerous failures of this type. The most spectacular example of this problem was the U.S.S. Schnectady whose hull completely fractured while it was docked in San Diego. The fractured ship is shown in Fig. 1. This fracture was in part related to the welding methods that

were used to construct the ships. When riveting was introduced to replace some of the welded structures, the incidence of fracture was markedly reduced.

**FIG. 1 FRACTURE OF THE USS SCHENECTADY AT PIER IN SAN DIEGO**

Brittle fracture has also plagued the aviation industry. In the 1950's several Comets, the first commercial jet aircraft, produced in Britain, mysteriously exploded while in level flight. The cause was eventually traced to a design defect in which high stresses around the windows (caused by sharp corners) caused small cracks to initiate from which the fractures initiated. In the late 1960's and early 1970's the U.S. fighter aircraft, the F-111, experienced catastrophic failure of the wing through box (the structure at which the wings join to the fuselage). Failures of the F-111 were related to choice of a very brittle material (D6AC--a high-strength tool steel) and a heat-treating procedure that produced non-uniform microstructures. In 1988, the upper fuselage of a Boeing 737 operated by Aloha Air fractured without warning during level flight over the Pacific ocean! The reasons for this were related to corrosion of the Al alloy that is used as a skin material.

In addition to the above examples can be added numerous bridges, train wheels, heavy equipment, etc. In virtually every case, the reasons for brittle fracture can be found in inappropriate choice of materials, manufacturing defects, faulty design, and a lack of understanding of the effects of loading and environmental conditions. In all of the cases cited, there was severe economic loss and/or loss of life. For these reasons, it is an important engineering and ethical undertaking to reduce such accidents caused by brittle fracture to an absolute minimum.

In the above examples there are some common factors. Brittle fracture generally occurs in high-strength alloys (D6AC steel for the F-111 wing box, high-strength Al alloys for the Comets and 737), welded structures (Liberty ships, bridges) or cast structures (train wheels). It is significant that all failures started at small flaws which had escaped detection during prior inspection (in some cases, e.g., F-111, many previous inspections). Subsequent analysis showed that in most instances, small flaws slowly grew as a result of repeated loads or a corrosive environment (or both) until they reached a critical size. After reaching critical size, rapid, catastrophic failure took place. The following sequence of events is usually associated with brittle fracture:

1. A SMALL FLAW FORMS EITHER DURING FABRICATION (E.G., WELDING, RIVETING) OR DURING OPERATION (FATIGUE, CORROSION).
2. THE FLAW THEN PROPAGATES IN A STABLE MODE DUE TO REPEATED LOADS, CORROSIVE ENVIRONMENTS OR BOTH. THE INITIAL GROWTH RATE IS SLOW AND UNDETECTABLE BY ALL BUT THE MOST SOPHISTICATED TECHNIQUES. THE CRACK GROWTH RATE ACCELERATES WITH TIME BUT THE CRACK REMAINS "STABLE."
3. SUDDEN FRACTURE OCCURS WHEN THE CRACK REACHES A CRITICAL SIZE FOR THE PREVAILING LOAD CONDITIONS. FINAL FRACTURE PROCEEDS AT ALMOST THE

## VELOCITY OF SOUND!

**Some Experimental Approaches to Fracture Control.** Initial approaches to understanding fracture involved recognition that the quantity of toughness was associated with a material's ability to absorb energy. The area under the stress-strain diagram,  $U$ , is a measure of the energy required to rupture one unit volume of the material in question. This quantity is one measure of the toughness of the material.

$$U = \int_0^{\epsilon_f} \sigma(\epsilon) D\epsilon \quad (\text{EQ 1})$$

Thus those materials which have a good combination of strength and ductility should, in this view, exhibit good toughness. Thus it is clear that diamond (which is very strong but which has virtually no ductility) will be brittle while steel (which has a good combination of strength and ductility) will be tough.

For materials which do not contain flaws and which are loaded in uniaxial tension, this approach is sufficient. However, in many engineering applications a notch is present and impact loads are applied. The notch has the effect of introducing a three-dimensional state of stress. Such stress states reduce the level of the maximum shear stress. For example, in the extreme case of hydrostatic tension (or compression) the shear stress in the body is zero. However, in metallic materials of interest, plastic deformation occurs as a result of shear stresses. Thus the triaxial stress state reduces the ability of the material to deform plastically and the toughness is correspondingly reduced. Similarly, impact loading reduces the amount of thermal energy available for plastic deformation and the toughness is further reduced.

**The Charpy test** accounts for both of these effects and is widely used to compare the relative behavior of materials under impact loads in the presence of a notch as a function of temperature. This test is very simple, inexpensive and widely used (as discussed in detail elsewhere in the *ASM Handbook* series). Some typical fractured Charpy specimens at various levels of ductility are shown in Fig. 2. The brittle fractures are flat in appearance with no shear lips (ridges at the sides of the tested specimens, Fig. 2). With increased ductility, the area of the specimen covered by shear lips increases progressively. The macroscopic appearance of the fracture surface (i.e., flat vs. shear lips) is related to the state-of-stress under which fracture took place and will be an important consideration when discussing fracture mechanics below.

**FIG. 2 PHOTOGRAPHS OF FRACTURED CHARPY SPECIMENS WITH DUCTILE (D) AND BRITTLE (B) FRACTURES**

**Fatigue SN Curves.** Traditionally, fatigue behavior has been characterized by the rotating beam test in which the number of cycles to failure of an unnotched specimen is plotted as a function of the applied cyclic stress. This results in the so-called  $S/N$  curve. When a corrosive medium is present, stressed immersion tests are used to evaluate the stress-corrosion cracking characteristics. The results of these tests (as well as tensile and Charpy tests) are of value for comparative purposes. However they do not account for the fact that cracks may already be present nor do they provide

guidance for making valid, quantitative predictions. In the following sections, approaches to fracture that allow quantitative predictions to be made are developed.

**Griffith Theory: An Analytic Approach to Brittle Fracture.** All of the preceding approaches to studying fracture suffer from the common limitation that they cannot be used to predict fracture loads of components.

In 1924, the British physicist A.A. Griffith (Ref 1) developed an approach to put fracture prediction on an analytic basis. He started by noting that the strength of a brittle material that exhibited linear elastic behavior is given by:

$$\sigma_{th} = \left( \frac{2E\gamma_s}{a_0} \right)^{1/2} \quad (\text{EQ 2})$$

where  $E$  is Young's modulus,  $\gamma_s$  is specific surface energy,  $a_0$  is lattice parameter, and  $\sigma_{th}$  is theoretical cohesive strength.

Equation 2 gives the theoretical strength of a defect-free, brittle material. If reasonable numbers are substituted into Eq 2, strengths are predicted that are orders of magnitude higher than those that are observed. This discrepancy was attributed to small *pre-existing* flaws which could greatly reduce the fracture strength. Using this concept, Griffith developed an analytic approach to predict the conditions under which the flaws would propagate unstably.

He considered a panel of thickness  $t$  containing a crack of length  $2a$  subjected to a remote stress  $\sigma$  (Fig. 3). By carrying out a sophisticated mathematical analysis, he was able to determine the conditions under which the energy of the system would be reduced should the crack extend. Such conditions favor continued crack extension since systems tend naturally to minimize their energy. The results are expressed in the following equation:

$$\sigma_G = \left[ \frac{2E\gamma_s}{\pi a} \right]^{1/2} \quad (\text{EQ 3})$$

where  $\sigma_G$  is stress to fracture,  $2a$  is crack size, and  $\gamma_s$  is specific surface energy.

**FIG. 3 CLASSICAL GRIFFITH CRACK. THE GRIFFITH EQUATION (I.E., EQ 3) REPRESENTS A MINIMUM CONDITION THAT MUST BE MET FOR FRACTURE TO TAKE PLACE. THE DOTTED CIRCLE REPRESENTS A CYLINDER OF MATERIAL WHICH CARRIES LITTLE OR NO LOAD.**

Equation 3 is known as the Griffith equation. Since it was developed on the basis of minimizing the energy of the system, it can be thought of as an energetically necessary condition for fracture. However, it may not always be sufficient for fracture as explained below.

Equation 3 applies only to brittle materials which do not deform plastically. Examples of such materials are glasses and most ceramic materials such as  $Al_2O_3$  and  $SiO_2$ . However most structural components are fabricated from metals which do undergo plastic deformation. The effects of plastic deformation were accounted for by Orowan (Ref 2) by simply noting that the effective surface energy (which includes the work of plastic deformation around the fracture surface) can be substituted for the true surface energy in the Griffith equation. In practice, this effective surface energy was simply an adjustable parameter used to force agreement with observed fracture loads and crack lengths. Conceptually, it is given by:

$$\gamma_E = \gamma_S + \gamma_P \quad \text{(EQ 4)}$$

where  $\gamma_p$  is work of plastic deformation,  $\gamma_s$  is true surface energy, and  $\gamma_e$  is effective surface energy.

For metals and polymers,  $\gamma_p$  is much greater than  $\gamma_s$  and to a good approximation:

$$\gamma_P \approx \gamma_E$$

(EQ 5)

It should be noted that the Griffith equation and the corresponding Orowan modification apply only to the limited geometry shown in Fig. 3. To be useful in an engineering sense, a methodology must be developed which is applicable for a broad range of geometries. In the next section, the basis of fracture mechanics is reviewed.

## Linear Elastic Fracture Mechanics

The methods considered thus far are geometry-limited approaches to understanding fracture. Ideally, a material constant is sought as an index of the material's toughness, which is independent of geometry and which along with a good stress analysis can be used to predict fracture loads and critical crack sizes. In other words, this toughness value could be determined using a simple laboratory test and also be used to predict the flaw size at which fracture will occur in flawed components of arbitrary geometry. Conversely, given the flaw size it should be possible to predict the maximum safe operating stress. This is precisely what "fracture mechanics" is all about: specification of appropriate measures of toughness, determination of such measures by experimental techniques and incorporation of numbers into design to predict the conditions under which fracture will occur.

**Crack Tip Stresses: The Field Equations.** Consider a structural component containing a sharp crack. Assume that it is loaded so that the opposite faces of the crack are displaced vertically without horizontal offset. This is called Mode I or opening mode and is shown schematically in Fig. 4. For materials which are homogeneous, isotropic, and linearly elastic (i.e., obey Hooke's law) any stress component in the vicinity of the crack tip is given by the following equation:

$$\sigma_{ij} = \frac{K}{\sqrt{2\pi r}} f_{ij}(\theta) \quad (\text{EQ 6})$$

where  $\sigma_{ij}$  is the stress component of interest,  $r$ ,  $\theta$  is polar coordinates with the origin at the crack tip, and  $f_{ij}(\theta)$  is function of  $\theta$  that depends on the stress component being considered.

**FIG. 4 MODE I CRACK SHOWING THE COORDINATE SYSTEM AND STRESS COMPONENTS. A MODE I CRACK OPENS SUCH THAT ALL POINTS ON THE CRACK SURFACES ARE DISPLACED PARALLEL TO THE Y-AXIS.**

In this notation, the "i" subscript refers to the plane on which the stress component acts and the "j" component refers to the direction. For example if  $i, j = x$ , then the stress component is  $\sigma_{xx}$  which is the tensile stress acting in the x direction on the plane normal to the x axis. When  $i \neq j$ , shear stresses are defined.

The set of equations represented by Eq 6 is called the field equations. Regardless of the method of loading, they always have the same form in  $r$  and  $\theta$  for Mode I. The parameter  $K$  is a measure of the magnitude of the stress field in the crack tip region and is called the stress-intensity parameter. It is given in SI units of  $\text{MPa} \sqrt{m}$  or in English of  $\text{ksi} \sqrt{in}$ . From the field equations, we see that independent of geometry, when the values of  $K$  are the same, the crack tip stress fields are identical.

Specific formulas for  $K$  depend on the load/crack geometry and numerous solutions for  $K$  can be found in references such as Ref 3 and 4. Some simple load-crack geometries and their corresponding stress intensities are shown in Fig. 5. In Fig. 5 (a-c), the dimensions of the body are assumed to be very large compared to the dimension of the crack. When the crack size is not negligible compared to the dimensions of the component, the stress-intensity parameter increases compared to what it would be for a crack of the same size and loading conditions in a larger body.

FIG. 5 SOME TYPICAL LOAD/CRACK GEOMETRIES AND THEIR CORRESPONDING STRESS-INTENSITY PARAMETERS. (A) TUNNEL CRACK, (B) PENNY CRACK, (C) WEDGE OPENED CRACK, (D) ECCENTRICALLY LOADED CRACK

Part of this increase may be understood intuitively by noting that there is less area ahead of the crack through which to transmit force. This means that the stresses in the crack tip region must be higher than for an equivalent crack in a larger body. In this case, the stress-intensity parameter is obtained by applying a multiplier to the corresponding expression for  $K$  in a semi-infinite body. This factor depends on the relative dimensions of the crack (as measured by  $a$ ) and the

specimen width (as measured by  $W$ ) as well as on the load/crack geometry. For example, the multiplier for a center cracked specimen (Fig. 5) is (Ref 4):

$$\alpha = \left[ \frac{W}{\pi a} \tan \frac{\pi a}{W} \right]^{1/2} \quad (\text{EQ 7})$$

**A Fracture Mechanics Based Fracture Criterion.** Equation 6 predicts that  $\sigma \rightarrow \infty$  as  $r \rightarrow 0$ . However, this situation is unrealistic; no material is capable of withstanding infinite stress. Instead, the material will tend to deform plastically near the crack tip and absorb energy in the process. The preceding analysis must be modified to include a small zone of plasticity at the crack tip. The modified stress distribution is shown schematically in Fig. 6. The small plastic enclave is called a plastic zone and its extent directly ahead of the crack is denoted by  $R_p$ . This plastic enclave is very important in metals and polymers since it is the region in which energy is absorbed and is responsible for the relatively high fracture toughness of metals compared to all other materials.

FIG. 6 STRESS DISTRIBUTION AHEAD OF CRACK IN WHICH SMALL-SCALE PLASTICITY IS INCLUDED

The plastic zone size depends on both  $K$  and  $\sigma_{ys}$  and is given by:

$$R_p = C \left( \frac{K}{\sigma_{ys}} \right)^2 \quad (\text{EQ 8})$$

The constant,  $C$ , depends on various factors including thickness and deformation characteristics of the material. It usually has a value between  $1/\pi$  and  $1/3\pi$ . Since Eqs 6, 7, and 8 are valid for linear elastic bodies, they only apply when  $R_p$  is much smaller (i.e.,  $R_p < 10\%$  of the crack size) than the crack size and other physical dimensions of the body. As  $K$  increases (e.g., by increasing the load)  $R_p$  also increases and the material in the plastic enclave becomes more severely strained. As a result of this direct relationship between  $K$  and the strains at the crack tip, it can be hypothesized that:

$$\text{AT FRACTURE, } K \rightarrow K(\text{CRITICAL}) \quad (\text{EQ 9})$$

In other words, there is a critical value of the stress-intensity parameter at which fracture will take place. This is the fundamental assumption of fracture mechanics and is the basis of computing fracture stresses and critical crack lengths.

**Fracture Mechanics and State-of-Stress under Plane Strain (Thick Sections and High-Strength Materials).** The value of  $K(\text{critical})$  depends not only on the material being considered but also on the thickness of the material in

which the crack is found. This can be understood by considering the impediments to plastic deformation that exist in the vicinity of the crack tip and how these impediments vary with thickness. As previously noted, toughness is manifested primarily through plastic deformation at the crack tip; anything that impedes crack tip plastic deformation will reduce the toughness. The high stresses in the crack tip region are such that the material ahead of the crack tip tends to plastically deform normal to the crack plane. Simultaneously, the material tends to contract parallel to the crack plane. If the section size is sufficiently thick, the contraction is opposed by the bulk of lowly stressed material and an additional stress component develops parallel to the crack plane.

This state-of-stress is called plane strain\* and develops when plastic deformation at the crack tip is severely limited. When plasticity is limited, the fracture toughness is also limited since plastic deformation is the most important source of toughness for most structural materials. The value of the stress-intensity parameter at which fracture occurs in thick sections is called the plane-strain fracture toughness and is denoted by the symbol  $K_{Ic}$ .  $K_{Ic}$  represents the toughness of the material above some critical thickness and is a material constant. It is a realistically conservative measure of the material's toughness and is widely used for engineering calculations, as described in subsequent sections. Plastic restraint at the crack tip is also promoted by high strength and limited ductility. Examples of high-strength materials of limited ductility are tool steels, ceramics, and glass. Mild steels, stainless steels, and many polymers are examples of low-strength, high-toughness materials.

**Plane Stress (Thin Sections and Low-Strength Materials).** In contrast to the preceding section, low-strength, ductile materials or very thin sections of high-strength materials develop much less constraint to plastic deformation parallel to the crack surface. In the limit, there is no stress opposing through-the-thickness deformation and the only stresses that are present are in the plane of the specimen. Such conditions are termed plane stress\*\* and the value of the stress-intensity parameter at which fracture occurs for under plane stress is called the plane-stress fracture toughness,  $K_c$ . The toughness under plane-stress conditions is higher than under plane-strain conditions for a given material under most practical conditions. The effect of thickness on toughness is illustrated in Fig. 7. Numerous experimental results of fracture toughness measurements have shown that for most engineering alloys, plane strain develops when the thickness reaches the following value:

$$B = 2.5 \left( \frac{K_{Ic}}{\sigma_{ys}} \right)^2 \quad (\text{EQ 10})$$

FIG. 7 EFFECT OF THICKNESS ON STATE-OF STRESS AND FRACTURE TOUGHNESS AT THE CRACK TIP

Thus for a high-strength aluminum alloy such as 7050 for which  $K_{Ic}$  is about 28 MPa  $\sqrt{m}$  (25 ksi  $\sqrt{in}$ ) and the yield strength is about 520 MPa (75 ksi), the thickness at which plane strain occurs is about 0.72 cm (0.28 in.). For 300 grade maraging steel, the critical thickness is 0.25 cm (0.1 in.).

Fracture mechanics is most useful when designing with high-strength materials of limited ductility. For such materials, the plane-strain fracture toughness  $K_{Ic}$  is the most important practical measure of toughness. The reason for this is that plane-strain conditions can develop even for relatively thin section sizes as shown above. The plane-strain fracture toughness,  $K_{Ic}$ , represents a practical minimum and is the most widely used measure of fracture toughness. For these reasons, we will limit our discussion to plane-strain conditions. This is consistent with current engineering practice.

**The Morphology of Fracture Surfaces.** The macroscopic appearance of the fracture surface depends on the amount of plastic deformation which accompanies fracture. This is equivalent to saying that the appearance depends on the state-of-stress. The fracture surface can then be used to gain insight into the conditions prevailing at the time of fracture. For fracture under plane-stress conditions, the fracture surface will be inclined at  $45^\circ$  to the sides of the specimen. For plane strain the fracture surface will be very flat. Schematic crack surface morphologies are shown in Fig. 8.

**FIG. 8 SCHEMATIC CRACK SURFACE MORPHOLOGIES FOR (A) PLANE STRESS AND (B) PLANE STRAIN. THE CRACK DIRECTION IS NORMAL TO THE PLANE OF THE PAPER.**

The fracture surface also can reveal the point of initiation. It frequently occurs that there are "chevron" marks on the fracture surface and these point back towards the origin of fracture as seen in Fig. 9. Fracture surfaces contain other information on a much finer scale about the nature of the fracture process and these are discussed later in this article.

**FIG. 9 MACROSCOPIC CHEVRON MARKINGS ON THE FRACTURE SURFACE POINTING BACK TO THE FRACTURE ORIGIN. ASTM A517H PLATE. SOURCE: METALS HANDBOOK, 9TH ED., VOL 12, FRACTOGRAPHY, 1987, P 347**

**Example: Maximum Stress to Fracture.** Suppose that the fracture toughness of an aluminum alloy has been determined to be  $30 \text{ MPa } \sqrt{m}$  ( $27 \text{ ksi } \sqrt{in}$ ) and a penny shaped crack of diameter 1.6 cm (0.63 in.) has been located in a thick plate that is to be used in uniaxial tension. Calculate the maximum allowable stress that can be imposed with fracture. Assume plane-strain conditions prevail. The yield stress of the material is 500 MPa (72.5 ksi).

**Solution.** The stress-intensity parameter formula for a penny-shaped crack is given by:

$$K = 2\sigma \left( \frac{a}{\pi} \right)^{1/2} \quad (\text{EQ 11})$$

where  $a$  is crack radius and  $\sigma$  is applied stress.

At fracture, the applied stress intensity is equal to the plane-strain fracture toughness. In equation form,  $K = K_{Ic}$ . Rearranging Eq 11 and substituting appropriate values gives:

$$\sigma = K/2[\pi/A]^{1/2} = 30/2[\pi/0.008]^{1/2}$$

$$\sigma_F = 297 \text{ MPa}$$

Thus fracture will occur well below the material's yield stress. This calculation shows that there is no guarantee that fracture will not occur simply because the nominal applied stresses are below the yield stress.

**Example: Calculation of the Maximum Safe Flaw Size.** Maraging steel (350 grade) has a yield of approximately 2450 MPa (355 ksi) and a toughness of  $55 \text{ MPa } \sqrt{m}$  ( $50 \text{ ksi } \sqrt{in}$ ). A landing gear is to be fabricated from this material and the design stresses are 70 per cent of yield. Assuming that flaws must be 0.25 cm (0.1 in.) to be detectable, is this a reasonable stress at which to operate? Assume that small edge cracks are present. The stress-intensity parameter for this geometry is:

$$K = 1.12 \sigma \sqrt{\pi a} \quad (\text{EQ 12})$$

**Solution.** The flaw size at which fracture occurs is calculated by noting that at fracture  $K = K_{Ic}$ .

$$a_f = 0.797/\pi (K_{Ic}/\sigma_d)^2 = \frac{0.797}{\pi} \left[ \frac{55}{1715} \right]^2$$

$$= 2.6 \times 10^{-4} \text{ m} \quad (\text{EQ 13})$$

Thus, critical flaws may escape detection even though the design stresses for the part are below the yield stress. Consequently, the stress is too high to ensure safe operation of the landing gear. It must be reduced to the point at which the critical flaw size is greater than the minimum detectable crack size (0.25 cm).

**Relation of Fracture Toughness to Tensile Properties.** As a practical matter, most microstructural modifications that increase the strength of materials cause corresponding decreases in the fracture toughness. It has been shown that the fracture toughness is related to other mechanical properties through the following expression (Ref 5):

$$K_{IC} \propto n (E \sigma_{YS} \epsilon_F)^{1/2} \quad \text{(EQ 14)}$$

where  $n$  is strain-hardening exponent,  $E$  is Young's modulus,  $\sigma_{ys}$  is yield strength, and  $\epsilon_f$  is the fracture strain. Considerable care must be exercised when using this equation. Strictly speaking, the critical stresses and strains should be determined under multi-axial conditions to replicate the crack-tip conditions. Generally, the fracture toughness decreases with increasing strength since both  $n$  and  $\epsilon_f$  decrease with increasing strength. However, this trend is not always followed and noteworthy exceptions have been studied in high-strength steel systems (Ref 6, 7, 8).

Equation 14 should be viewed as being indicative of a trend more than a precise formula for computing the plane-strain fracture toughness. The direct calculation of fracture toughness from other mechanical properties is complicated by the fact that toughness is a property that manifests itself under the triaxial stress conditions that prevail at the crack tip. This means that the various quantities contained in Eq 14 would have to be measured under conditions of plane strain; such information is not usually available.

Another factor to consider is microstructural anisotropy that may develop as a result of processing. Table 1 shows that fracture toughness depends on orientation. When the crack plane is parallel to the rolling direction, segregated impurities and intermetallics that lie in these planes represent easy fracture paths and the toughness is low. When the crack plane is perpendicular to these weak planes, decohesion occurs and crack tip blunting or stress reduction takes place, thus effectively toughening the material. On the other hand, when the crack plane is parallel to the plane of these defects, the crack can propagate very easily and the toughness is reduced.

**Application of Fracture Mechanics to Various Classes of Materials.** Fracture mechanics was initially developed so that high-strength materials of limited ductility could be used safely in engineering situations. This formulation is referred to as linear elastic fracture mechanics (LEFM). In order to apply the LEFM methodology correctly, fracture must occur under essentially elastic conditions. Practically, this means that there can only be limited plastic deformation at the crack tip at the time of fracture. Additionally, plane-strain conditions should prevail and there should only be a single well-defined crack. The materials for which the LEFM approach works well are:

- HIGH-STRENGTH METALLIC ALLOYS SUCH AS HEAT-TREATED MARTENSITIC STEELS, PRECIPITATION-HARDENED ALUMINUM ALLOYS USED IN THE AEROSPACE INDUSTRY, TITANIUM ALLOYS, AND NI-BASE ALLOYS
- CERAMIC MATERIALS WHICH ARE ESSENTIALLY BRITTLE
- POLYMERS OF LIMITED INELASTIC DEFORMATION

One important class of materials for which fracture mechanics is frequently not applicable is composites. In composites, cracks tend to be spatially distributed throughout the material. In this situation the usual fracture mechanics requirement of a single, well-defined crack is not met. Also, the requirements of homogeneous and isotropic materials are not met for most composite systems. Of course, fracture mechanics is very applicable to ceramics even at high temperatures because the ductility of these materials is limited.

**Experimental Determination of Fracture Toughness.** The plane-strain fracture toughness is a materials parameter of considerable engineering significance. The American Society for Testing and Materials (ASTM) has developed detailed procedures for determination of  $K_{Ic}$  (Ref 9).

Specimens are designed so as to minimize material and loading requirements. Frequently a compact type (CT) specimen, shown in Fig. 5(d), is used to experimentally determine the fracture toughness as well as other fracture properties which are discussed later in the chapter. The first step in carrying out a fracture toughness test is to grow a fatigue starter crack at a low rate at the base of the machined notch. Such cracks are used to ensure reproducibility and to simulate service conditions. The specimen is then loaded to failure at a specified rate. The load vs. displacement curve is recorded. For the test to be valid, the load/displacement curve must be virtually linear and the crack front must be essentially straight. If these requirements are met, the toughness is calculated using expressions provided by the ASTM standard E-399. For the CT specimen, the expression for calculating the fracture toughness from experimentally measured quantities is:

$$K_{Ic} = \frac{P}{B\sqrt{W}} \cdot f(a/W) \quad (\text{EQ 15})$$

where  $K_{Ic}$  is plane-strain fracture toughness,  $P$  is appropriately chosen fracture load,  $B$  is specimen thickness,  $W$  is specimen width, and  $f(a/W)$  is calibration function. Values of the calibration function are provided in Table 2. It should be noted that  $K_{Ic}$  calculated in this manner must be subjected to various validation checks before it may be considered to be the plane-strain fracture toughness.

Source: Ref 9

A considerable amount of data on fracture toughness has been analyzed for reliability and compiled by the Metals and Ceramics Information Center. These data are very useful for engineering calculations and are available in a handbook and additional supplements (Ref 10). Note that for metallic materials, as discussed previously, the fracture toughness often depends on the orientation of the specimen relative to processing directions. It is thus important to be sure that values of fracture toughness that are used are appropriate for the structure of the component being considered.

### Notes cited in this section

- \* PLANE STRAIN MAY BE THOUGHT OF AS A STRESS STATE IN WHICH THERE IS NO THROUGH-THE-THICKNESS DEFORMATION. MATHEMATICALLY IT IS EQUIVALENT TO SAYING THAT  $\epsilon_{ZZ}, \gamma_{ZY}, \gamma_{ZX} = 0; \epsilon_{XX}, \epsilon_{YY}, \gamma_{XY} \neq 0$ .
- \*\* PLANE STRESS IS DEFINED MATHEMATICALLY AS THAT STRESS STATE FOR WHICH  $\sigma_{ZZ}, \tau_{ZW}, \tau_{ZY} = 0; \sigma_{XX}, \sigma_{YY}, \tau_{XY} \neq 0$ .

### Fatigue Fracture

In a very schematic way, we may view fatigue as involving the following steps:

1. CYCLIC DEFORMATION WHICH CAUSES INTERNAL DAMAGE IN THE FORM OF DISLOCATION DEBRIS.
2. THE FORMATION OF A CRACK AFTER SUFFICIENT DAMAGE HAS BEEN CAUSED BY THE CYCLIC LOADING.
3. PROPAGATION OF THE CRACK TO A SIZE WHERE IT BECOMES UNSTABLE FOR THE LOADS BEING APPLIED.

While the "smooth bar" ( $S/N$ ) approach to fatigue alluded to previously is undoubtedly useful, certain drawbacks arise in certain engineering situations:

- MOST PARTS DO NOT HAVE SMOOTH, HIGHLY POLISHED SURFACES.
- IN GENERAL, THE FATIGUE LIFE IS MADE UP OF AN INITIATION PHASE AND A PROPAGATION PHASE. HOWEVER, IN THE SMOOTH BAR OR  $S/N$  METHODOLOGY, RESULTS ARE USUALLY GIVEN IN TERMS OF THE TOTAL LIFE TO FAILURE WITH NO INDICATION OF THE FRACTION OF LIFE SPENT IN THE INITIATION AND PROPAGATION PHASES.
- MOST STRUCTURES USUALLY CONTAIN SMALL PRE-EXISTING CRACKS. THESE CRACKS ARE FREQUENTLY UNAVOIDABLE, AND ARISE FROM FABRICATION PROCEDURES AND MATERIAL DEFECTS. THEY WILL PROPAGATE UNDER REPEATED LOADS UNTIL THEY BECOME CRITICAL AT WHICH POINT FRACTURE OCCURS. IN SUCH CASES, THE ENTIRE LIFE IS SPENT IN THE PROPAGATION PHASE.

For these reasons, a knowledge of the crack growth rate behavior is imperative if the overall fatigue life is to be computed.

In the fracture mechanics approach, the crack growth rate (i.e., the amount of crack extension per loading cycle) is correlated with the cyclic variation of the stress-intensity parameter  $K$ . This approach allows estimating useful safe life and inspection intervals, and it has been experimentally demonstrated that for many conditions, the rate of fatigue crack growth can be represented by the Paris equation, which has the form (Ref 11):

$$\frac{da}{dN} = C (\Delta K)^m \quad (\text{EQ 16})$$

where  $a$  is crack length,  $N$  is cycle,  $C$ ,  $m$  is material parameters, and  $\Delta K = K_{\max} - K_{\min}$ . The stress-intensity range is  $\Delta K$ . This simple formula does not take into account the effect of the load (or stress) ratio  $R$  (i.e.,  $P_{\max}/P_{\min}$ ). As  $R$  increases the crack growth rate generally increases and this increase depends on the material being considered. For example, steels are relatively insensitive to load ratio effects while some aluminum alloys show a marked  $R$  ratio dependence.

More generally, the crack growth rate is represented by:

$$\frac{da}{dN} = f(\Delta K, R) \quad (\text{EQ 17})$$

Various formulations of the above equation have been proposed and one of these is discussed later.

The stress-intensity parameter range characterizes the cyclic stresses and strains ahead of the crack tip and uniquely characterizes the crack growth rate through a relationship such as Eq 16. Since the zone ahead of the crack which experiences cyclic plasticity (i.e., the fatigue plastic zone) is very small, plane-strain conditions can develop even for small thicknesses. This is an important conclusion since it means that data can be obtained from thin specimens and applied quite generally.

**Example Problem: Calculation of Fatigue Lives.** The crack growth rate of ferritic/pearlitic steels is given by the equation:

$$\frac{da}{dN} = 3.6 \times 10^{-10} (\Delta K)^{3.0} \quad \text{(EQ 18)}$$

where  $\Delta K$  is given in units of ksi  $\sqrt{\text{in}}$  and  $da/dN$  is in units of in./cycle. Assume that a part contains an edge crack that is 0.05 in. long. The stresses vary from 0 to 50 ksi and the fracture toughness is 100 ksi  $\sqrt{\text{in}}$ . Compute the life of the part.

**Solution.** For this geometry, the stress-intensity parameter is given by:

$$\Delta K = 1.12 \Delta \sigma \sqrt{\pi a}$$

Rigorously, the expression should be  $\Delta K = \Delta \sigma \cdot \sqrt{\pi a} + \sigma \sqrt{\pi} \cdot (1/2) \cdot a^{-1/2} \cdot \Delta a$ . However, since  $\Delta \sigma \pi a$  in a given cycle is much larger than  $\Delta a$ , to a very good approximation we may write  $\Delta K = \Delta \sigma \sqrt{\pi a}$ .

Using the information given in the problem statement and the above expression the crack growth rate is given by:

$$\frac{da}{dN} = 3.52 \times 10^{-4} \cdot a^{3/2}$$

This equation can be integrated from the initial condition of  $N = 0$  and  $a = a_0 = 0.05$  in. to the final condition of  $N = N_f$  and  $a = a_f$ . The final crack length  $a_f$  occurs when  $K_{\max} = K_{Ic}$ . Integrating yields:

$$N_f = 2.84 \times 10^3 \int_{a_0}^{a_f} \frac{da}{a^{3/2}}$$

Integration of the right-hand side of the equation gives:

$$N_f = 5.68 \times 10^3 \left[ \frac{1}{\sqrt{a_0}} - \frac{1}{\sqrt{a_f}} \right]$$

As mentioned above  $a_f$  depends on the fracture toughness and maximum stress. For the geometry being considered this is given by:

$$a_f = \frac{1}{\pi} \left( \frac{K_{Ic}}{\sigma} \right)^2 = \left[ \frac{100}{1.12 \times 50} \right]^2 = 1.02 \text{ in.}$$

Substituting into the expression for life gives:

$$N_F = 5.68 \times 10^3 [1/\sqrt{0.05} - 1/\sqrt{1.02}] = 1.98 \times 10^4$$

The part is thus expected to last almost 20,000 cycles.

**Other  $da/dN$  and  $\Delta K$  Relationships.** The representation of the crack growth rate (in Eq 16) is essentially correct for a reasonably wide domain of stress-intensity ranges. However, additional factors must be considered at both low and high stress-intensity ranges. When the stress-intensity range is low, a point will be reached where the average crack growth rate approaches the interatomic spacing. Physically, a crack cannot propagate a fraction of an interatomic spacing; however, we must remember that the measured crack growth rate in a typical experiment represents an *average* across an entire crack front. In some regions the crack may be stopped while in others it may be moving. For practical purposes, the threshold stress-intensity range ( $\Delta K_{th}$ ) occurs when the average crack growth rate is less than  $10^{-12}$  m/cycle. For values of  $\Delta K$  less than  $\Delta K_{th}$  the crack growth rate is effectively zero. Equation 16 cannot be used to describe the crack growth behavior in the threshold regime. Also, when the stress-intensity parameter becomes so large that it approaches the fracture toughness,  $K_{Ic}$ , the rate of crack growth becomes much more rapid than that predicted by Eq 16 since, in addition to the fatigue process, a considerable amount of local tensile failure occurs during each cycle. Again, Eq 16 no longer provides a correct representation of the crack growth behavior. Over the broad range of stress-intensity parameters, fatigue crack growth rates may be represented by an equation of the form (Ref 12):

$$\log \frac{da}{dN} = C_1 \sinh \{C_2 \log (\Delta K) + C_3\} + C_4 \quad (\text{EQ 19})$$

where  $C_1$  is material constant and  $C_2, C_3, C_4$  are functions of load ratio, frequency, and temperature.

The above equation is represented schematically in Fig. 10. Numerous other empirical expressions have also been proposed to describe crack growth behavior from  $\Delta K_{th}$  to values of  $\Delta K$  when  $K_{max}$  approaches  $K_{Ic}$ . Regardless of the representation, the life may always be computed by integrating the crack growth curve as was done in the preceding example problem. It is worth noting that use of Eq 16 is usually conservative for the threshold to intermediate crack growth rate regime. While Eq 16 underestimates the growth rate for large  $\Delta K$  values near the upper limit, the underestimate is small. This is because as the stress intensity approaches the fracture toughness of the material, the crack is growing so rapidly that very few cycles are accumulated in this regime. Use of threshold data must be done very judiciously due to the fact that a small error in threshold can lead to significant overestimates of the fatigue life.

**FIG. 10 SCHEMATIC REPRESENTATION OF FATIGUE CRACK PROPAGATION BEHAVIOR. IN REGIME I THE CRACK GROWTH RATE IS LOW SINCE THE THRESHOLD FOR CRACK PROPAGATION IS APPROACHED. IN REGIME II THE SO-CALLED PARIS LAW IS OBEYED WHILE IN REGIME III THE CRACK GROWTH RATE INCREASES ABOVE THAT PREDICTED BY THE PARIS EQUATION SINCE THE FRACTURE TOUGHNESS OF THE MATERIAL IS APPROACHED AND THERE IS LOCAL TENSILE OVERLOAD FRACTURE.**

**Summary of Fatigue Crack Propagation.** The life of components containing pre-existing flaws can be computed in principle using fracture mechanics concepts. For complex load/crack geometries and stress patterns, the equations for  $\Delta K$  are complex. In addition, the  $da/dN$  vs.  $\Delta K$  relationships may be quite complicated (or perhaps not even available in functional form). Such conditions do not lead to easily evaluated integrals for the fatigue life as was the case in the example problem.

However, the life of a component can always be computed through step-wise numerical integration techniques similar in principle to the technique that was used in the example problem. In this scheme an increment of crack growth  $\Delta a$  is selected. The number of cycles associated with a growth increment  $\Delta a$  is obtained from  $\Delta N = \Delta a / (da/dN)$ . All of the  $\Delta N$ 's are added up from the initial crack length to the final crack length. In such cases, it is most efficient to use computers to do the actual computations.

### Environmental Effects

The presence of aggressive environment reduces the ability of a given material to bear load. In general, there are usually a number of environments for any given material which will lead to environmentally induced fracture. A particular environment does not attack all materials. Environmentally induced failures always occur as over a period of time as the deleterious environment reacts with the material to degrade material properties. In other words, if a specimen of a material is subjected to stress (frequently below the yield strength) in an environment in which it is susceptible to attack, for the most part failure does not occur instantaneously upon application of the load. Depending on the applied load level, the time to failure may vary considerably. This is shown in Fig. 11 for a high-strength steel in a simulated sea water environment consisting of 3.5% salt (NaCl). This phenomenon is also called delayed failure. This example is particularly appropriate for selecting steels for marine applications such as ship hulls and offshore platforms. For both applications, it is attractive to consider the use of high-strength steels to save weight. However, the allowable stress levels in structural members of this high-strength steel in sea water environment are not dictated by the yield strength but rather by the level of stress above which environment-induced fracture occurs. Therefore the strength and environmental resistance of these steels have to be carefully balanced in order to optimize weight. In most large structures, it is necessary to consider the case of pre-existing cracks and to characterize the materials with such cracks present. These cracks usually result from processing and fabrication, although in some instances they may also occur during use. In this section we briefly review the fracture mechanics approach to environmentally-induced fracture.

FIG. 11 APPLIED STRESS VERSUS LIFE OF TENSILE TYPE SPECIMENS IN SIMULATED SEA WATER FOR STAINLESS STEELS

**Fracture Mechanics Approach.** As for fatigue, stress-corrosion cracking can also be described within a fracture mechanics framework. In this approach, it is assumed that a crack already exists and it is the extension of the crack that governs the life of the component. Under such conditions it would be expected that the rate of crack growth would correlate with the magnitude of the applied stress-intensity parameter. In fact, it has been demonstrated that SCC rates of cracked specimens correlate *uniquely* with the stress-intensity parameter and that any attempt to correlate the crack growth rate with stress alone leads to logical inconsistencies (Ref 13).

In general there is a threshold for stress-corrosion cracking, denoted  $K_{Isc}$ , below which crack growth is not observed. Above this level, increases in stress intensity produce increases in the real time crack growth rate  $da/dt$ . Depending on the material and the mechanism of crack extension, further increases in the stress intensity do not produce significant

increases in the crack growth rate. This can be understood in terms of a transport-controlled step in which the *maximum* potential for acceleration of the crack growth rate by the crack tip stress field has been reached. At this point, the rate is governed by how rapidly the corrosive media can be transported to the crack tip or the limiting value of diffusion of a damaging species into the bulk material. The crack growth rates are more sensitive to parameters such as temperature, pressure, pH levels, etc. As  $K$  approaches  $K_{Ic}$ , tensile fracture mechanisms begin to appear, the process becomes mechanically dominated, and the crack growth rates again increase with  $K$  (Region III in Fig. 12a). Final failure occurs at  $K_{Ic}$  at which point the crack is moving at a substantial fraction of the velocity of sound and is essentially free of the environment. An idealized SCC curve is shown in Fig. 12(a) while actual experimental data are shown in Fig. 12(b).

IN REGIME II THE MECHANICAL ENHANCEMENT HAS ATTAINED A MAXIMUM AND CRACKING IS TRANSPORT CONTROLLED. IN REGIME III THE PROCESS IS MECHANICALLY DOMINATED. FINAL FRACTURE OCCURS VERY RAPIDLY NEAR  $K_{Ic}$ . (B) EXPERIMENTAL CRACK GROWTH RATE AS A FUNCTION OF STRESS INTENSITY FOR A HIGH STRENGTH**

## STEEL IN HUMID AIR FROM REF 14

The life of a cracked component in an aggressive environment may be calculated by an integration technique, similar in principle to that used to calculate fatigue lives. In order to compute the life, the crack growth rate as a function of  $K$  must be known as well as other factors such as operating stresses, initial crack length, fracture toughness of the material and the geometry of the part in which the crack is embedded. These concepts are illustrated in the following problem.

**Example: Estimation of Life in Corrosive Environment.** The crack growth rate of a high-strength steel in  $H_2O$  at  $80^\circ C$  ( $175^\circ F$ ) is given by:

$$\frac{da}{dt} = 9.32 \times 10^{-5} K - 2.08 \times 10^{-3}$$

Here  $K$  is in  $MPa \sqrt{m}$ ,  $a$  is in meters and  $t$  is in days. Calculate the life of the part assuming that edge cracks of length  $2.02 \times 10^{-3}$  m are initially present. Assume that  $K_{Ic}$  is  $55 MPa \sqrt{m}$  and that the part is subjected to a constant stress of  $345 MPa$ .

**Solution.** The initial stress intensity is given by (from Fig. 5):

$$K_I = 1.12 \times 345 \times (\pi \times 2.02 \times 10^{-3})^{1/2} = 30.8 MPa \sqrt{m}$$

The threshold stress intensity may be calculated assuming:

$$\frac{da}{dt} = 0 \text{ at } K = K_{Isc}$$

This gives a value of about  $22.3 MPa \sqrt{m}$  for  $K_{Isc}$ . Since  $K_i > K_{Isc}$  the crack will grow by a SCC process.

The rate of growth is given by:

$$\begin{aligned} \frac{da}{dt} &= 9.32 \times 10^{-5} \times 1.12 \times 345 \sqrt{\pi a} - 2.08 \times 10^{-3} \\ &= 0.0640 a^{1/2} - 2.08 \times 10^{-3} \end{aligned}$$

The above equation can be integrated:

$$t_f = \int_{t=0}^{t=t_f} dt = \int_{a=a_0}^{a_f} \frac{da}{0.0640 a^{1/2} - 2.08 \times 10^{-3}}$$

The crack length at fracture may be computed by noting that at this point  $K = K_{Ic}$ :

$$a_f = \frac{1}{\pi} \left[ \frac{K_{Ic}}{1.12 \sigma} \right]^2 = \frac{1}{\pi} \left[ \frac{55}{386.40} \right]^2 \approx 6.45 \times 10^{-3}$$

Using tables of integrals,  $t_f \sim 2.5$  days.

## Summary

This article has introduced a powerful methodology for computing the onset of fracture (i.e., the fracture stress given a crack of a certain size, or a critical crack size given an applied stress). In practical terms a material containing a crack will fracture when the value of the stress-intensity parameter reaches a critical value. This value is denoted by the symbol  $K_{Ic}$  and is called the plane-strain fracture toughness. The value of  $K_{Ic}$  is independent of the load/crack geometry. It can be measured experimentally and formulas for the stress-intensity parameter as a function of crack size, crack shape, applied stress (or load), and geometry of load application are readily available.

The rate of crack growth can be characterized by the stress-intensity parameter range for fatigue loading. The fatigue crack growth rate curves may be integrated to yield the fatigue life of an propagating crack.

Cracking in a corrosive environment may also be considered in a fracture mechanics framework. In this case the stress intensity is related to the temporal crack growth rate. The crack growth rate equation can be integrated to obtain the life of a cracked component in an aggressive medium.

In the following articles, fracture mechanics is used to characterize behavior in several important alloy systems and mechanisms of toughening, fatigue crack growth, and crack growth in corrosive media.

## Fracture Resistance of Structural Alloys

K.S. Ravichandran, The University of Utah, and A.K. Vasudevan, Office of Naval Research

---

### Introduction

FRACTURE MECHANICS is a multidisciplinary engineering topic that has foundations in both mechanics and materials science. From the perspective of a metallurgist, fracture mechanics often emphasizes mathematical mechanics, where the primary focus is on analytical methods. However, the microstructural aspects of fracture mechanics (quantified in terms of various measures of fracture toughness such as  $K_{Ic}$ ,  $K_{Ic}$ , or  $K_{IId}$ ) is important for several reasons. First, in many applications, fracture toughness is useful for design and/or as a quality control parameter. Secondly, fracture mechanics provides a more meaningful measure of fracture resistance in the presence of cracks or defects than other material properties such as ductility. Therefore, fracture mechanics plays a major role in both the application and the development and production of structural materials for petroleum, chemical, mining, aerospace, and naval applications.

The objective of this article is to summarize the microstructural aspect of fracture resistance in structural materials. The intent is to selectively compile and compare information on microstructure and fracture resistance of structural materials from literature and some of the author's work. The article begins with brief coverage on basic fracture principles, followed by material examples. Included in this text are examples of steels, aluminum alloys, titanium alloys, cermets, and composites. More detailed coverage is provided in other sections in this Volume.

---

### Basic Fracture Principles

The mechanics of the fracture process (in either elastic or elastic-plastic conditions) is understood by considering a body with a crack length  $a$  subjected to an applied tensile stress  $\sigma$ . For purely brittle fracture originating from this crack, Griffith postulated that the critical rate of strain energy released during unstable crack extension,  $G_c$ , is related to the surface energy of the material,  $\gamma$ , as:

$$G_c = 2\gamma \quad (\text{EQ 1})$$

$$G_c = \frac{\pi \sigma_c^2 a}{E} \quad (\text{EQ 2})$$

where  $\sigma_c$  is the critical stress at the onset of fracture and  $E$  is the elastic modulus. From the linear elastic stress field ahead of a sharp crack, Irwin found that at regions very close to the crack tip, the stress normal to the fracture plane,  $\sigma_{yy}$ , is related to the stress-intensity factor,  $K$ , as:

$$\sigma_{yy} \approx \frac{K}{\sqrt{2\pi r}} \quad (\text{EQ 3})$$

where  $K = \sigma\sqrt{\pi a}$ ,  $\sigma$  is applied stress, and  $r$  is the distance from the crack tip on the crack plane.  $K$  is a measure of buildup or concentration of stress at the tip of a sharp crack. If fracture occurs from the crack, then the local critical value of  $\sigma_{yy}$  at which fracture occurs (e.g., by cleavage) is reflected as the critical value of  $K$ . Irwin further showed that  $K$  and the strain energy release rate,  $G$ , are related as:

$$G = \frac{K^2}{E} \quad (\text{EQ 4})$$

It then follows that fracture will occur from the crack when the critical stress intensity at the crack tip,  $K = K_c$ , is reached, corresponding to  $G = G_c$ . Due to this simplicity,  $K_c$  has been accepted as a useful parameter representing fracture resistance of materials in engineering applications.

If the crack size is much smaller than the body dimensions, the relationship between fracture toughness,  $K_c$ , and fracture stress,  $\sigma_c$ , can be simply written as:

$$K_c = \sigma_c\sqrt{\pi a} \quad (\text{EQ 5})$$

However, when the size of the crack from which fracture occurs is significant in relation to body dimensions:

$$K_c = \sigma_c\sqrt{\pi a} F\left(\frac{a}{W}\right) \quad (\text{EQ 6})$$

where  $F(a/w)$  is a function that accounts for the effects due to the finiteness of the body and is dependent on the shape of the body. The values of these factors can be found in handbooks on fracture mechanics as well as in the ASTM standard for fracture toughness testing, E 399. The appendix of this Volume also contains updated information on geometry factors,  $F(a/W)$ .

The above fracture relationships are strictly applicable to brittle materials in which the energy dissipation due to plastic deformation is almost negligible. Many structural materials, particularly those in the high-strength category, show evidence of plastic deformation and have fracture toughness levels higher than those that can be estimated from surface energy (Eq 1) alone. Hence, the modified form of Eq 1 to account for this additional contribution to fracture resistance due to plastic deformation can be written as:

$$G_c = \underbrace{2\gamma}_{\text{(elastic)}} + \underbrace{\Gamma \sigma_y \delta_c}_{\text{(plastic)}} \quad (\text{EQ 7A})$$

or in terms of fracture toughness:

$$K_c = \sqrt{2E\gamma + \Gamma E\sigma_y \delta_c} \quad (\text{EQ 7B})$$

where  $\Gamma$  is constant,  $\sigma_y$  is the material yield stress, and  $\delta_c$  is the critical opening displacement at the crack tip at the onset of fracture. The first term is the energy consumed in the creation of two fracture surfaces during fracture and is considered to be independent of microstructure. The second term,  $\sigma_y \delta_c$ , represents approximately the energy consumed in plastic deformation accompanying fracture, a strong function of microstructure. Because the latter is several times higher than the former, the surface energy term is often ignored in the case of metallic structural materials.

From Table 1 it is evident that crack-tip plasticity accounts for much of the fracture resistance of structural metals. This fact makes it possible to alter microstructure for optimizing fracture resistance, through variables that influence strength and ductility, such as strain hardening, dislocation-particle interactions, and slip behavior. The mechanism of crack propagation depends on microstructural features as classified by Schwalbe (Fig. 1). This forms the basis of the discussion on individual alloys later. Further, due to an increase in elastic modulus, the ranges of fracture toughness values

obtainable by microstructure manipulation increases in the order of aluminum alloys, titanium alloys, and iron alloys (Fig. 2).

**FIG. 2 FRACTURE TOUGHNESS AS A FUNCTION OF STRENGTH FOR HIGH-STRENGTH STRUCTURAL ALLOYS**

Fracture toughness values for materials are obtained by testing precracked compact tension or three-point bend specimens, following the ASTM E 399 test procedure. A measure of fracture resistance can also be obtained from Charpy specimens used in impact toughness testing. However, for comparison with linear elastic fracture mechanics specimens, precracked specimens are often used. Figure 3 illustrates the correlation between the critical strain energy release rates for fracture ( $K_{Ic}^2/E$ ) and total energy absorbed per unit fracture area of precracked Charpy specimens, tested in slow bending, for different materials. This confirms that the critical strain energy release rate represents the energy required to cause fracture, even in the presence of plastic deformation. An approximate measure of this can also be obtained from simple Charpy specimens, as an alternative to the ASTM standard for fracture toughness test procedure.

FIG. 3 THE CORRELATION BETWEEN ENERGY RELEASE RATE AND FRACTURE ENERGY OF CHARPY SPECIMENS FOR VARIOUS MATERIALS

### Fracture Resistance of Structural Alloys

K.S. Ravichandran, The University of Utah, and A.K. Vasudevan, Office of Naval Research

### Fracture Resistance of High-Strength Steels

Although engineering applications use many types of steels (such as mild steels, high-carbon steels, and alloy steels), only high-strength alloy steels are described in this article because of the general inverse relationship between strength and fracture toughness (Fig. 4). Examples of such steels include high-strength low-alloy steels, tool steels, dual-phase steels, maraging steels, and precipitation-hardenable stainless steels. The development of strength and toughness in these steels is linked to such factors as the size and distribution of carbides and nitrides, relative proportions of martensite and austenite phases, and grain size. In general, as shown in Fig. 4, high-fracture-toughness steels have ductile (low-carbon) martensite and retained metastable austenite as dominant phases in the microstructure. Steels that contain predominantly ferritic and pearlitic structures have relatively low fracture toughness. Table 2 summarizes the effects of microstructure on toughness.

TABLE 2 EFFECTS OF MICROSTRUCTURAL VARIABLES ON FRACTURE TOUGHNESS OF STEELS

MICROSTRUCTURAL PARAMETER	EFFECT ON TOUGHNESS
GRAIN SIZE	INCREASE IN GRAIN SIZE INCREASES $K_{IC}$ IN AUSTENITIC AND FERRITIC STEELS
UNALLOYED RETAINED AUSTENITE	MARGINAL INCREASE IN $K_{IC}$ BY CRACK BLUNTING
ALLOYED RETAINED AUSTENITE	SIGNIFICANT INCREASE IN $K_{IC}$ BY TRANSFORMATION-INDUCED TOUGHENING
INTERLATH AND INTRALATH	DECREASE $K_{IC}$ BY INCREASING THE TENDENCY TO

CARBIDES	CLEAVE
IMPURITIES (P, S, AS, SN)	DECREASE $K_{IC}$ BY TEMPER EMBRITTLEMENT
SULFIDE INCLUSIONS AND COARSE CARBIDES	DECREASE $K_{IC}$ BY PROMOTING CRACK OR VOID NUCLEATION
HIGH CARBON CONTENT (>0.25%)	DECREASE $K_{IC}$ BY EASILY NUCLEATING CLEAVAGE
TWINNED MARTENSITE	DECREASE $K_{IC}$ DUE TO BRITTLINESS
MARTENSITE CONTENT IN QUENCHED STEELS	INCREASE $K_{IC}$
FERRITE AND PEARLITE IN QUENCHED STEELS	DECREASE $K_{IC}$ OF MARTENSITIC STEELS

FIG. 4 FRACTURE TOUGHNESS AS A FUNCTION OF YIELD STRENGTH FOR STRUCTURAL STEELS. TRIP, TRANSFORMATION-INDUCED PLASTICITY

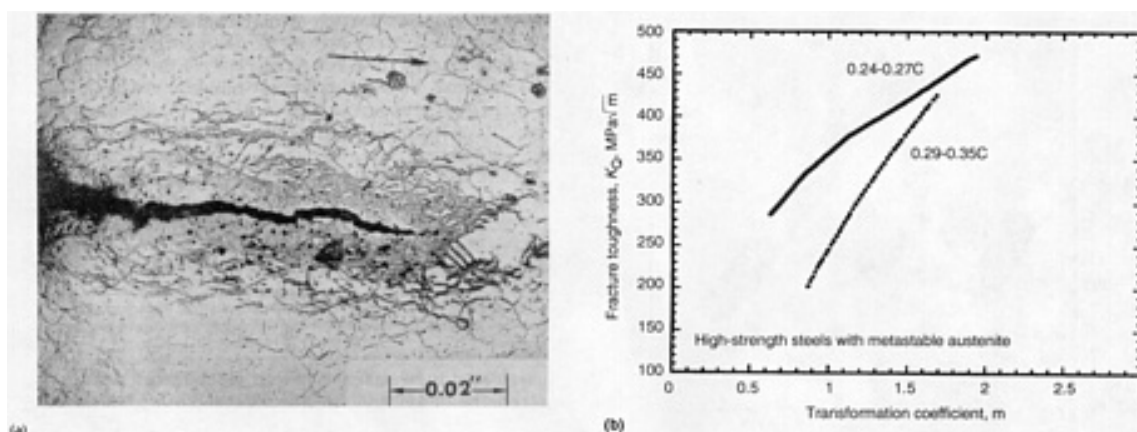

Maraging (martensite-aging) steels, based on the Fe-Ni-Ti system, have very high strength and high fracture toughness and are designed with very low levels of carbon (<0.05%) and high levels of alloying elements (typically 18% Ni, 3% Ti, and 1 to 2% Co). The benefit of low carbon is twofold: crack-initiating carbides are absent and the martensite matrix is more ductile. In addition, maraging steels contain retained austenite (due to the high nickel content), which causes extensive plastic deformation and strain-induced martensitic transformation at the crack tip during fracture, thus increasing the fracture resistance. The strengthening lost by the elimination carbides is replaced by precipitation of fine  $(Fe,Ni)_3Ti$  phases from martensite, obtained by aging. However, under certain conditions, precipitation of phases at grain boundaries leads to deterioration in toughness. Hence, chemistry, processing, and heat treatment conditions should be designed to avoid the grain boundary precipitation. Typical heat treatment of a maraging steel involves austenitization and oil quenching or air cooling, followed by aging at high temperature in the  $\alpha + \gamma$  field.

**Metastable Austenite-Based Steels.** Transformation-induced plasticity (TRIP) steels with high contents of nickel and manganese retain high-temperature face-centered cubic austenite ( $\gamma$ ) at room temperature, upon quenching. By a judicious choice of composition, this austenite is designed to be metastable after quenching and transformable during deformation. The deformation and the volume change accompanying the austenite-to-martensite transformation increase the energy required for extension of a moving crack, resulting in high fracture toughness. The fracture toughness of such steels

depends on the stability of austenite, measured in terms of the transformation coefficient,  $m$ , in the following relationship between the volume fraction of martensite formed ( $V_{\alpha}$ ) and tensile strain ( $\epsilon$ ):

$$V_{\alpha} = M \sqrt{\epsilon} \quad (\text{EQ 8})$$

The higher the tensile strain or crack opening displacement at the tip, the larger the volume fraction of transformed martensite and the higher the TRIP effect on toughness, as illustrated in Fig. 5. These steels possess the highest fracture toughness levels attainable in steels and hence are used in mining, drilling, and other applications requiring wear and erosion resistance.

**FIG. 5 TRIP STEEL CRACK AND TOUGHNESS. (A) FORMATION OF MARTENSITE AROUND A CRACK IN A TRIP STEEL. (B) THE EFFECT OF AUSTENITE TRANSFORMATION ON THE FRACTURE TOUGHNESS OF METASTABLE AUSTENITIC STEELS**

**Quenched-and-Tempered Steels.** Fracture resistance in quenched-and-tempered steels is achieved by eliminating coarse alloy carbides, increasing hardenability to minimize ferrite formation, and alloying to retain austenite at room temperature.

An increase in the austenitization temperature, besides coarsening the grain size, dissolves carbides and nitrides present in steels. This eliminates the crack nucleation from carbides, thereby increasing the fracture toughness, as shown in Fig. 6 for two steels. The required austenitization time is also critical, and both time and temperature are chosen according to the amount of carbon and alloying elements in the steel. The effect of tempering temperature on fracture toughness depends on the type of prior austenitization treatment (Fig. 7). For example, the heat treatment involving austenitization at 1200 °C (2190 °F), followed by an ice brine quench and refrigeration in liquid nitrogen, results in high fracture toughness levels at all tempering temperatures, compared to austenitizing at 870 °C (1600 °F) and quenching in oil. The higher fracture toughness levels of the former is attributed to the formation of 100% refined martensite upon quenching. Heat treatment at 870 °C (1600 °F) results in a mixture of blocky ferrite and upper bainite having continuous films of carbides at lath boundaries. This leads to low fracture toughness due to easy crack propagation along the lath boundaries at low tempering temperatures. However, at higher tempering temperatures, elimination of continuous carbide film by spheroidization increases the fracture toughness. In addition, in some alloy steels, retained austenite contributes to further increases in fracture toughness, by either crack-tip blunting or strain-induced transformation.

FIG. 6 THE EFFECT OF AUSTENITIZATION TEMPERATURE ON THE FRACTURE TOUGHNESS OF TWO QUENCHED-AND-TEMPERED STEELS

FIG. 7 THE EFFECT OF TEMPERING TEMPERATURE ON FRACTURE TOUGHNESS

Fracture toughness in steels also depends on the nature of martensite (low-carbon ductile martensite or high-carbon twinned martensite). Supersaturated carbon in martensite increases the twinning to accommodate the strains in iron lattice

due to carbon. The low fracture toughness levels of some martensitic steels at low tempering temperatures are due to the presence of brittle twinned martensite. An increase in the twin density of martensite results in low fracture toughness, as shown in Fig. 8.

FIG. 8 FRACTURE TOUGHNESS AND MARTENSITE TWIN DENSITY AS A FUNCTION OF MARTENSITE START TEMPERATURE FOR AN FE-CR-C STEEL

Inclusions decrease fracture toughness (Fig. 9) by promoting crack nucleation by inclusion fracture, void nucleation at the particle-matrix interface, and early coalescence. This reduces the extent of void growth before fracture, limiting the plastic energy absorption in the process zone at the crack tip. A decrease in sulfur level in steel increases the spacing between the inclusions, thereby increasing the size of the plastically deformed process zone. This contribution to increased fracture toughness can be rationalized in terms of Kraft's model:

$$K_{IC} \approx \sqrt{2 \pi E n d_T} \quad (\text{EQ 9})$$

where  $n$  is the monotonic strain hardening exponent and  $d_T$  is the size of the process zone at the crack tip, proportional to the spacing between crack/void nucleating inclusions.

FIG. 9 THE EFFECT OF SULFUR ON THE FRACTURE TOUGHNESS VS. STRENGTH RELATIONSHIP

### Fracture Resistance of Structural Alloys

K.S. Ravichandran, The University of Utah, and A.K. Vasudevan, Office of Naval Research

### Fracture Resistance of Aluminum Alloys

Aluminum alloys based on Al-Cu (2xxx series), Al-Mg-Si (6xxx series), Al-Zn-Mg (7xxx series), and, recently, Al-Li (8xxx and 209x series) are the predominant age-hardenable alloys, used extensively in aerospace and other medium- to high-strength structural applications. Typical examples are alloys 2024, 2124, 6061, 7075, 7150, 7475, 8090, and 2091. Due to complex chemistry, precipitation, and intermetallic compound formation in aluminum alloys, control of the size and distribution of age-hardening coherent precipitates and incoherent intermetallic phases is critical in achieving a balance of strength and resistance to fracture and stress-corrosion cracking. Table 3 lists some important precipitate phases and intermetallic compounds that form in aluminum alloys. While the precipitates control strength, intermetallic compounds that form during solidification primarily control ductility and fracture toughness.

TABLE 3 A LIST OF PRECIPITATES AND INTERMETALLIC COMPOUNDS IN ALUMINUM ALLOYS

PRECIPITATE PHASES (BENEFICIAL)	INTERMETALLIC COMPOUNDS (DETRIMENTAL)
AL <sub>2</sub> CU	AL <sub>7</sub> CU <sub>2</sub> FE
AL <sub>2</sub> CUMG	MG <sub>2</sub> SI
MGZN <sub>2</sub> , MG <sub>2</sub> SI	AL <sub>12</sub> MN <sub>2</sub> CR
AL <sub>2</sub> ZN <sub>3</sub> MG <sub>3</sub>	AL <sub>20</sub> CU <sub>2</sub> MN
AL <sub>3</sub> ZR, AL <sub>3</sub> LI	(FE, MN)AL <sub>6</sub>

Typical heat treatment of an aluminum alloy involves solution treatment, quenching in water, and aging at a suitable temperature for a specified period of time. Additionally, warm or cold working, such as stretching after solution treatment, is performed to control the size and distribution of precipitates. Such thermomechanical processing routes for high-strength aluminum alloys have been well developed to impart desirable combinations of strength, ductility, fracture toughness, and stress-corrosion cracking resistance.

Fracture resistance in aluminum alloys is strongly sensitive to purity, aging, the presence of intermetallic compounds, thermomechanical treatment, grain size, and orientation or texture. Typical fracture toughness values of selected aluminum alloys are given in Table 4. Table 5 gives a list of variables and the nature of their effect on the fracture toughness of aluminum alloys.

**TABLE 4 STRENGTH AND FRACTURE TOUGHNESS LEVELS FOR SELECTED ALUMINUM ALLOYS**

ALLOY	0.2% YIELD STRENGTH, MPA	$K_{IC}$ , MPA $\sqrt{m}$
2014-T6	436	20
2024-T851	443	21
2124-T851	435	26
7075-T7351	391	31
<b>7079-T651</b>	<b>502</b>	<b>27</b>

**TABLE 5 EFFECTS OF PROCESSING/MICROSTRUCTURAL VARIABLES ON THE FRACTURE TOUGHNESS OF ALUMINUM ALLOYS**

VARIABLE	EFFECT ON FRACTURE TOUGHNESS
QUENCH RATE	DECREASE IN $K_{IC}$ AT LOW QUENCH RATES
IMPURITIES (FE, SI, MN, CR)	DECREASE IN $K_{IC}$ WITH HIGH LEVELS OF THESE ELEMENTS
GRAIN SIZE	DECREASE IN $K_{IC}$ AT LARGE GRAIN SIZES DUE TO COARSE GRAIN BOUNDARY PRECIPITATION
GRAIN BOUNDARY PRECIPITATES	INCREASE IN SIZE AND AREA FRACTION DECREASE $K_{IC}$
UNDERAGING	INCREASES TOUGHNESS
PEAK AGING	INCREASES FRACTURE TOUGHNESS
OVERAGING	DECREASES FRACTURE TOUGHNESS
GRAIN BOUNDARY SEGREGATES (NA, K, S, H)	LOWER FRACTURE TOUGHNESS IN AL-LI ALLOYS

Figure 10 illustrates the effects of intermetallic-forming elements (Cr, Zr, Fe, Si, and Mn) on fracture in terms of the relationship between fracture resistance (measured in terms of the unit propagation energy in fracturing a notched bar) and tensile yield strength for two different orientations of crack propagation. Zirconium addition is beneficial due to the grain-refining effect of  $Al_3Zr$  phase. Chromium and manganese primarily lead to intermetallic compound formation and hence must be reduced to achieve a combination of high fracture toughness and high strength. Most of the intermetallic compounds form at grain boundaries in wrought alloys and at interdendritic regions in cast alloys. This is the primary reason for lower levels of fracture toughness, especially when a crack propagates in the short transverse plane (plane of rolling), in which the grain boundary area intersected by the crack plane is high compared to other orientations.

FIG. 10 THE EFFECT ON TOUGHNESS OF ELEMENTS THAT FORM INTERMETALLIC COMPOUNDS

The detrimental effect of intermetallic particles on fracture toughness can be understood from a simple relationship. The critical fracture strain,  $\epsilon_c$ , of a ligament between the crack tip and a crack/void nucleating particle is related to the particle volume fraction,  $V_f$ , as:

$$\epsilon_c = f\left(\frac{1}{V_f}\right) \quad (\text{EQ 10})$$

The fracture toughness of aluminum alloys is related to the critical fracture strain as:

$$K_{Ic} \approx \sqrt{\frac{2 C E \epsilon_c \sigma_y n}{(1 - \nu^2)}} \quad (\text{EQ 11})$$

where  $C$  is a constant and  $\nu$  is the Poisson's ratio. As the volume fraction of brittle intermetallic particles is reduced, fracture toughness increases. For a given volume fraction of particles, fracture toughness also increases with increase in yield strength and the strain-hardening exponent of the matrix. From Eq 11, fracture toughness levels of several aluminum alloys can be predicted (Fig. 11) with good accuracy.

FIG. 11 THE EFFECT OF PARAMETER  $n\sqrt{\sigma_y}$  ON THE FRACTURE TOUGHNESS OF ALUMINUM ALLOYS

Figure 12 shows the effect of grain size on the fracture toughness of a 7xxx alloy tested with crack propagation in the long transverse direction. The decrease in fracture toughness is attributed to the increase in grain boundary fracture at large grain sizes. The increased intergranular fracture also coincides with the thickening of precipitates (e.g., the size of  $MgZn_2$  precipitates in Fig. 13) at grain boundaries under prolonged aging. This behavior is also reflected in the change in fracture mode from transgranular to intergranular. This suggests that reduced grain boundary area accompanied by coarse grain boundary precipitation is detrimental to the fracture toughness of aluminum alloys.

FIG. 12 THE EFFECT OF GRAIN SIZE ON THE FRACTURE TOUGHNESS OF A 7XXX ALLOY

FIG. 13 7075 AL ALLOY. (A) THE EFFECT OF GRAIN BOUNDARY PRECIPITATE SIZE ON FRACTURE TOUGHNESS AND FRACTURE MORPHOLOGY. (B) EQUILIBRIUM GRAIN BOUNDARY  $\eta$ -MgZn<sub>2</sub> PRECIPITATES AT GRAIN BOUNDARIES

Figure 14 shows the broad range of data of fracture toughness and yield strength for both 2xxx and 7xxx alloys as affected by the degree of aging. Overaging generally results in low fracture toughness levels for a given yield strength and alloy type, compared with underaging. This is attributed to the increased occurrence of intergranular failure, consistent with the observations illustrated in Fig. 12 and 13.

**FIG. 14 THE EFFECTS OF ALLOY TYPE AND AGED CONDITION ON THE STRENGTH/FRACTURE TOUGHNESS RELATIONSHIP FOR ALUMINUM ALLOYS**

The variables influencing fracture toughness of Al-Li alloys are similar to those that affect other age-hardenable aluminum alloys. These include degree of aging, area fraction of grain boundary precipitates, impurities, and orientation. However, Al-Li alloys are more anisotropic due to strong texture formation, relative to aluminum alloys, and hence they show a much stronger sensitivity of fracture toughness to orientation.

---

### Fracture Resistance of Titanium Alloys

Titanium alloys are primarily used in aerospace applications owing to their good combination of specific strength, ductility, and fracture toughness. As in steels and aluminum alloys, this combination is achieved by careful control of two-phase microstructures. Among the two phases ( $\alpha$  and  $\beta$ ),  $\beta$  is more ductile and is preferable in increasing the fracture toughness of titanium alloys. The three broad classes of titanium alloys are near- $\alpha$ ,  $\alpha + \beta$ , and  $\beta$  alloys, grouped according to the levels of  $\alpha$  or  $\beta$  stabilizing elements. Typically,  $\beta$  content by volume is: near- $\alpha$ , <10%;  $\alpha + \beta$ , 10-25%; and  $\beta$ , >25%. Figure 15 shows the fracture toughness/strength relationship maps for different titanium alloys. Metastable  $\beta$  alloys possess the highest combination of strength and toughness. This arises from a large volume fraction of  $\beta$  phase and fine aged- $\alpha$  precipitates.

FIG. 15 THE RELATIONSHIP BETWEEN FRACTURE TOUGHNESS AND STRENGTH FOR DIFFERENT CLASSES OF TITANIUM ALLOYS AND MICROSTRUCTURES

Unlike steels and aluminum alloys, titanium alloys are generally free from inclusions and intermetallics that form during solidification. Neither is there precipitation and coarsening of brittle phases, so the control of microstructure for fracture toughness is less difficult. Microstructure plays a major role in controlling the fracture toughness of titanium alloys. Microstructure control is primarily achieved by mechanical processes, such as hot/cold working and heat treatment involving solution treatment followed by quenching and aging or slow cooling. Table 6 lists the fracture toughness values of a typical titanium alloy under different microstructural conditions. In general, for a given  $\beta$  phase content, fracture toughness increases with an increase in the amount of lamellar  $\alpha$  as well as an increase in the aspect ratio of  $\alpha$  phase.

TABLE 6 FRACTURE TOUGHNESS LEVELS OF TI-6AL-4V ALLOY IN DIFFERENT MICROSTRUCTURAL CONDITIONS

MICROSTRUCTURE	0.2% YIELD STRENGTH, MPA	ELONGATION, %	$K_{IC}$ , MPA $\sqrt{m}$
$\beta$ -PROCESSED (ALIGNED LAMELLAR $\alpha$ )	903	12	78
$\alpha+\beta$ PROCESSED (EQUIAXED $\alpha$ IN AGED $\beta$ MATRIX)	917	16	53
RECRYSTALLIZED (FULLY EQUIAXED $\alpha$ )	925	19	47

The dominant variables that influence fracture toughness in titanium alloys are the interstitial elements, grain size, microstructural morphology, and relative proportions of  $\alpha$  and  $\beta$  phases. Table 7 lists these variables and the nature of their effect on fracture toughness.

TABLE 7 EFFECT OF MICROSTRUCTURAL VARIABLES ON THE FRACTURE TOUGHNESS OF

## TITANIUM ALLOYS

VARIABLE	EFFECT ON FRACTURE TOUGHNESS
INTERSTITIALS (O, H, C, N)	DECREASE IN $K_{IC}$
GRAIN SIZE	INCREASE IN GRAIN SIZE DECREASES $K_{IC}$
LAMELLAR COLONY SIZE	INCREASE IN COLONY SIZE INCREASES $K_{IC}$
$\beta$ PHASE	INCREASES IN $\beta$ VOLUME FRACTION, CONTINUITY INCREASE $K_{IC}$
GRAIN BOUNDARY $\alpha$ PHASE	INCREASES IN THICKNESS AND CONTINUITY INCREASE $K_{IC}$
SHAPE OF $\alpha$ PHASE	INCREASE IN ASPECT RATIO OF $\alpha$ PHASE INCREASES $K_{IC}$
ORIENTATION	CRACK ORIENTED FOR EASY CLEAVAGE ALONG BASAL PLANES GIVES LOW $K_{IC}$

Figures 16 and 17 illustrate that increases in oxygen and hydrogen levels in Ti-6Al-4V alloy decrease fracture toughness. This is caused by an increase in the planarity slip, promoted by the ordering of  $Ti_3Al$  phase, which causes easy crack nucleation at grain and phase boundaries. This tendency to ordering is also increased at high aluminum contents, and hence compositions of commercial alloys rarely exceed 6% Al. Hydrogen causes cleavage and interface cracking due to the formation of hydrides ( $TiH_2$ ). Alloys with high levels of  $\beta$  phase can dissolve more hydrogen, thereby preventing the decrease in fracture toughness due to hydrogen. The other interstitial elements, carbon and nitrogen, have low solid solubility in titanium and form fine  $TiC$  and  $TiN$  dispersions when the solubility level is exceeded. These particles drastically decrease the ductility as well as the fracture toughness of titanium alloys and hence must be eliminated.

FIG. 16 THE EFFECT OF OXYGEN LEVEL ON THE FRACTURE TOUGHNESS OF TI-6AL-4V ALLOY

FIG. 17 THE EFFECT OF HYDROGEN LEVEL ON THE FRACTURE TOUGHNESS OF TI-6AL-4V ALLOY

The effect of  $\beta$  grain size on fracture toughness is illustrated in Fig. 18 for Ti-5.2Al-5.5V-1Fe-0.5Cu alloy. There is an inverse relationship of fracture toughness to  $\beta$  grain size. As the grain size increases, the tendency to intergranular fracture increases, due to the weakening effect of fine 0.2  $\mu\text{m}$  thick particles at the  $\beta$ - $\beta$  grain boundary. This is primarily due to the increased density of grain boundary precipitates as a result of the reduction in available grain boundary area.

FIG. 18 THE EFFECT OF GRAIN SIZE ON THE FRACTURE TOUGHNESS OF A TITANIUM ALLOY

The same alloy was heat treated differently to produce thick continuous  $\alpha$  phase at the grain boundary, which increased fracture toughness (Fig. 19). However, for this to occur, the grain interior (aged  $\beta$  matrix) should be stronger than  $\alpha$ .

**FIG. 19 THE EFFECT OF THE THICKNESS OF GRAIN BOUNDARY  $\alpha$  PHASE ON THE FRACTURE TOUGHNESS OF A TITANIUM ALLOY**

The orientation of crack plane in a fracture toughness test with respect to the rolling direction of the titanium alloy plate has a significant effect, due to the preferred orientation of hexagonal close-packed crystal grains having limited slip systems, relative to body-centered cubic and face-centered cubic crystals. The effect of orientation on the fracture toughness/strength relationship is illustrated in Fig. 20. While a strong inverse relationship between fracture toughness and yield strength is seen for the longitudinal orientation, it is less strong in the transverse orientation. The effect of orientation on fracture toughness arises due to the relative orientation of slip systems such as  $\{0001\} \langle 1120 \rangle$ ,  $\{1010\} \langle 1120 \rangle$  with respect to the crack plane. This is also evident from the variation of elastic modulus with orientation, presented in Table 8.

**TABLE 8 EFFECT OF TEXTURE ON THE FRACTURE TOUGHNESS OF TI-6AL-2SN-4ZR-6MO ALLOY**

<b>ORIENTATION</b>	<b>0.2% YIELD STRENGTH, MPA</b>	<b><math>E</math>, MPA</b>	<b><math>K_{IC}</math>, MPA <math>\sqrt{m}</math></b>
LONGITUDINAL	953	107,000	<b>75</b>

<b>SHORT TRANSVERSE</b>	<b>926</b>	<b>104,000</b>	<b>49</b>

FIG. 20 THE EFFECT OF CRACK PLANE ORIENTATION ON THE FRACTURE TOUGHNESS OF TI-6AL-4V ALLOY

It is clear that the key to improving the combination of strength and toughness in titanium alloys is to increase  $\beta$  phase content, increase the lamellar  $\alpha$  volume fraction and the aspect ratio of  $\alpha$  phase, and reduce planarity of slip and interface embrittlement by reducing the levels of oxygen, hydrogen, carbon, and nitrogen.

### Fracture Resistance of Composites

**Brittle Matrix-Ductile Phase Composites.** Ductile phases have been used to improve the fracture resistance of many structural materials, including ceramics, intermetallics, glasses, and other low-toughness materials, such as steels having a hard martensitic structure. Table 9 lists some brittle materials and the possible ductile phase reinforcements that can be used to improve the fracture toughness levels. Such an alloy design concept generally increases fracture toughness with little sacrifice in strength. The ductile phases absorb energy by plastic deformation during crack propagation. Bridging of the crack and the constrained deformation of ductile phase contribute to the increase in toughness. In general, the fracture toughness increases with an increase in the volume fraction of ductile phase (Fig. 21). For such composites, the critical strain energy release rate,  $G_c$ , for unstable fracture can be expressed as the sum of fractional energy absorbed in fracturing the brittle and ductile phases:

$$G_C = (1 - V_F) G_M + V_F \sigma_0 A_0 \chi \quad \text{(EQ 12)}$$

(MATRIX)                      (DUCTILE PHASE)

where  $\sigma_0$  is the flow stress,  $a_0$  is the radius of ductile phase,  $G_m$  is the energy release rate of the brittle matrix, and  $\chi$  is a measure of microstructural constraint. A modified form for the above equation for the plane strain fracture toughness,  $K_{Ic}$ , can be written as:

$$K_{Ic} = \sqrt{\frac{E_c (1 - \nu_m^2) (1 - V_f) K_m^2}{(1 - \nu_c^2) E_m} + \frac{V_f E_c \sigma_0 a_0 \chi}{(1 - \nu_c^2)}} \quad (\text{EQ 13})$$

where  $E_c$  and  $\nu_c$  are respectively the elastic modulus and the Poisson's ratio of the composite, and  $K_m$ ,  $E_m$ , and  $\nu_m$  are respectively the fracture toughness, elastic modulus, and Poisson's ratio of the matrix material. For the case of plane stress,  $E_c/(1 - \nu_c^2)$  and  $E_m/(1 - \nu_m^2)$  are to be replaced by  $E_c$  and  $E_m$ , respectively. The parameter  $\chi$  (usually in the range of 2 to 6) is a measure of the constraint experienced by the ductile phase in the elastic matrix during deformation. If  $\chi$  is known, in addition to matrix and particle properties, fracture toughness of the composite can be estimated with reasonable accuracy.

**TABLE 9 BRITTLE MATERIALS AND THE POSSIBLE DUCTILE PHASES**

MATERIAL	DUCTILE PHASE
CERAMICS: $Al_2O_3$ , GLASS, $ZrO_2$ , SiC, $Si_3N_4$	Ti, Ni, Pb, Al, Fe
INTERMETALLICS: TiAl, NiAl, CoAl, $Nb_5Si_3$ , $Cr_3Si$	Ti, Nb, Co, Mo, Cr
MARTENSITE	AUSTENITE, FERRITE

**FIG. 21 FRACTURE TOUGHNESS TREND FOR GLASS HAVING EMBEDDED DUCTILE ALUMINUM PARTICLES**

Figure 22 shows the correlation between the measured fracture toughness and the calculated toughness, following Eq 13. The good agreement suggests that Eq 13 adequately represents the functional dependence of fracture toughness on important microstructural parameters of the composite. Increases in the size, volume fraction, and yield strength of the ductile phase, together with an increase in composite modulus, should significantly increase the fracture toughness. The effect of Young's modulus of matrix on the composite fracture toughness is not significant. A major contribution to fracture toughness is the constraint factor, which is a measure of increase in resistance to the in situ plastic deformation of ductile phase, as imposed by the surrounding elastic matrix.

FIG. 22 THE CORRELATION BETWEEN MEASURED AND CALCULATED FRACTURE TOUGHNESS LEVELS OF SEVERAL BRITTLE MATERIALS HAVING DUCTILE PHASES AS REINFORCEMENTS.

**WC-Co Cermets.** The case of WC-Co cermets is similar to that of the above-described ductile phase composites, except that the ductile cobalt phase surrounds the brittle WC almost completely. Figure 23 illustrates the fracture path through the cermet microstructure. The volume fraction of cobalt in these cermets is usually between 0.1 and 0.3. The cermets are made by presintering WC to obtain a skeleton with continuous porosity and then infiltrating the skeleton with molten cobalt. In general, a decrease in WC particle size and an increase in cobalt volume fraction increases the fracture toughness of cermets (Fig. 24). Because of the thin layer of cobalt present between WC grains, its in situ deformation behavior during fracture is similar to the deformation of a thin ductile copper strip sandwiched between hard tool steel platens. In order to estimate the fracture toughness of cermets, this deformation analogy can be incorporated in Eq 13 for the constraint factor  $\chi$ , through the relationship

$$\chi = \frac{\sigma_{\text{eff}}}{\sigma_0} = \left[ 1 + \frac{2k}{3} \left( \frac{d}{2h} \right) \right] \quad (\text{EQ 14})$$

where  $\sigma_0$  is the bulk flow stress of the binder in the absence of any constraint and  $\sigma_{\text{eff}}$  is the flow stress of the binder in situ in the microstructure. The constant  $k$  is defined as the maximum shear factor, which is taken as 0.577, and  $d$  and  $h$  are respectively the width of the rigid platen and the thickness of the ductile layer. In the case of cermets, as a first approximation,  $d$  and  $h$  can be considered to represent the mean WC particle diameter and the thickness of the cobalt binder, respectively. An increase in cobalt binder thickness and a decrease in WC particle size would therefore increase the constraint for deformation and hence the fracture toughness. Figure 25 compares experimental data with the theoretically calculated fracture toughness levels using Eq 13 and 14. The good correlation suggests that Eq 13 and 14 capture the effects of important microstructural parameters on the fracture toughness of cermets and can be used in the design of cermet composition and microstructure.

**FIG. 25 THE CORRELATION BETWEEN THE MEASURED AND CALCULATED FRACTURE TOUGHNESS LEVELS OF WC-CO CERMETS HAVING VARYING SIZES AND VOLUME FRACTIONS OF WC AND COBALT**

**Metal-Matrix Composites.** Light metals such as aluminum and magnesium are reinforced with particulates and whiskers based on SiC, Al<sub>2</sub>O<sub>3</sub>, TiC, and so on to increase the stiffness and high-temperature strength. These composites are made by dispersing reinforcements in liquid metal and casting or by mixing with metal powder and hot pressing. In general, the size and spacing of particles, the strength of the interface between the particles, and the aspect ratio of the whiskers influence the strength and fracture toughness of composites. Figure 26 illustrates the fracture toughness levels of aluminum alloys reinforced with second-phase particles, showing a decrease in fracture toughness at large particle volume fractions.

FIG. 26 THE EFFECT OF DISPERSOIDS ON THE FRACTURE TOUGHNESS OF ALUMINUM-BASE METAL-MATRIX COMPOSITES

The fracture toughness of metal-matrix composites can be estimated approximately from:

$$K_{1c} \propto \sqrt{E \sigma_y \varepsilon_f l^*} \quad (\text{EQ 15})$$

where  $\varepsilon_f$  is the fracture strain of the ligament between the crack tip and the closest particle and  $l^*$  is the size of the process zone at the crack tip, usually taken as interparticle spacing. From this equation, it is clear that decreasing the interparticle spacing by increasing the volume fraction of dispersions reduces the fracture toughness of composites.

Figure 26 shows two composites, 6061 Al-Mg-Si alloy reinforced with various amounts of SiC particles and a rapidly solidified Al-Fe-V-Si alloy containing intermetallic particles. The trend is similar for both materials. There are two mechanisms by which reinforcements can affect fracture toughness. First, plastic flow localization at the interface and interface decohesion can significantly reduce the extent of void growth before ultimate failure, thus reducing fracture toughness. This is the case for the particulate composites. Alternatively, crack-tip blunting and crack path deviation around whiskers can increase fracture toughness by increasing the energy required for crack extension. However, for this to occur, the matrix-whisker interface must be strong. In reality, the interface is weaker due to reaction between the matrix and the whiskers during processing and the presence of oxides on the surfaces of whiskers. This effect is illustrated in Fig. 27, which shows that both orientations (whiskers oriented normal or parallel to crack plane) lead to a decrease in fracture toughness due to interface fracture. Figure 28 shows the crack path and whiskers are oriented differently with respect to the crack propagation direction in fracture toughness tests. The decrease in fracture toughness in the latter orientation is higher, due to increased weak interface area.

### Introduction

FRACTURE TOUGHNESS is defined as a "generic term for measures of resistance to extension of a crack" (Ref 1). The term fracture toughness is usually associated with the fracture mechanics methods that deal with the effect of defects on the load-bearing capacity of structural components. Fracture toughness is an empirical material property that is determined by one or more of a number of standard fracture toughness test methods. In the United States, the standard test methods for fracture toughness testing are developed by the American Society for Testing and Materials (ASTM). These standards are developed by volunteer committees and are subjected to consensus balloting. This means that all objecting points of view to any part of the standard must be accounted for. Other industrial countries have equivalent standards writing organizations that develop fracture toughness test standards. In addition, international bodies such as the International Organisation for Standardisation (ISO) develop fracture toughness test standards that have an influence on products intended for the international market. In this review of fracture toughness testing, the ASTM approach will be emphasized to give the article a consistent point of view.

The standard fracture toughness test methods have been written mostly with metals in mind. Toughness testing of nonmetals is also an important consideration. For many nonmetals, the equivalent standard for metals is adapted with some possible modification. Fracture toughness test methods that are written specifically for a particular nonmetal are mostly in preparation. Therefore, this review emphasizes those standards written for metals without intending to make them apply exclusively to metals.

**General Fracture Toughness Behavior.** As a general background before discussing the details of fracture toughness testing and analysis, fracture toughness behavior and the parameters used to describe it are discussed. Fracture toughness is defined as resistance to the propagation of a crack. This propagation is often thought to be unstable, resulting in a complete separation of the component into two or more pieces. Actually, the fracture event can be stable or unstable. With unstable crack extension, often associated with a brittle fracture event, the fracture occurs at a well-defined point and the fracture characterization can be given by a single value of the fracture parameter. With stable fracture, often associated with a ductile fracture process, the fracture is an ongoing process that cannot be readily described by a point (Ref 2). This fracture process is characterized by a crack growth resistance curve or *R* curve. This is a plot of a fracture parameter versus the ductile crack extension,  $\Delta a$ . An example *K*-based *R* curve is shown in Fig. 1. Sometimes a single point is chosen on the *R* curve to describe the entire process; this is mostly done for convenience and does not give a complete quantitative description of the fracture process.

FIG. 1 SCHEMATIC OF  $K$ -BASED CRACK RESISTANCE ( $R$ ) CURVE WITH DEFINITION  $K_{Ic}$

Whether the fracture is ductile or brittle does not directly influence the deformation process that a component or specimen might undergo during the measurement of toughness (Ref 2). The deformation process is generally described as being linear-elastic or nonlinear. This determines which parameter is used in the fracture toughness test characterization. All loading begins as linear-elastic. For this, the primary fracture parameter is the well-known crack tip intensity factor,  $K$ , originally defined by Irwin (Ref 3) and described elsewhere in this Volume. If the toughness is relatively high, the loading may progress from linear-elastic to nonlinear during the toughness measurement and a nonlinear parameter is needed. The nonlinear parameters that are most often used in toughness testing are the  $J$ -integral (Ref 4), labeled  $J$ , and the crack tip opening displacement (CTOD), labeled  $\delta$  (Ref 5). Because all loading starts as linear-elastic, the nonlinear parameters are all written as a sum of a linear component incorporating  $K$  and a nonlinear component. This is illustrated with the individual descriptions of the various methods in this article.

**Test Methods Covered.** The test methods covered include linear-elastic and nonlinear loading, slow and rapid loading, crack initiation, and crack arrest. The development of the test methods followed a chronological pattern; that is, a standard was written for a particular technology soon after that technology was developed. Standards written in this matter tend to become exclusive to a particular procedure or parameter. Because most fracture toughness tests use the same specimens and procedures, this exclusive nature of each new standard did not allow much flexibility in the determination of a toughness value. The newer approach is to write standards to encompass all parameters and measures of toughness into a single test procedure. This approach is labeled the common method approach and is being developed by ASTM as well as by many standards organizations in other countries. The standards for fracture toughness testing are periodically revised, and several new ones are often in development. New methods under development are briefly discussed at the end of this article, and Volume 3.01 of the *ASTM Annual Book of Standards* should be consulted for the current version of the tests mentioned in this article.

The fracture toughness test is generally conducted on a test specimen containing a preexisting defect; usually the defect is a sharp crack introduced by fatigue loading and called the precrack. The test is conducted on a machine that loads the specimen at a prescribed rate. Measurements of load and a displacement value are taken during the test. The data resulting from this are subjected to an analysis procedure to evaluate the desired toughness parameters. These toughness results are then subjected to qualification procedures (or validity criteria) to see if they meet the conditions for which the toughness parameters are accepted. Values meeting these qualification conditions are labeled as acceptable standard measures of

fracture toughness. The standard fracture toughness test then has these ingredients: test specimens, types, and preparation; loading and instrumentation requirements; measurements taken; data analysis; and qualification of results. The following sections then discuss the various standard fracture toughness test methods following this format. The fracture toughness test methods written as ASTM standards follow a prescribed format. It is not always easy to determine the step-by-step procedure required to conduct the test from the standard. The sections below, which describe the various methods, follow a format of a step-by-step procedure rather than the format of the actual standards. The application of the fracture toughness result to the evaluation of structural components containing defects is not explicitly covered in the ASTM standard test methods. Nor is it covered in this article. The description of the fracture toughness test methods follow a somewhat chronological outline, beginning with the methods that use the linear-elastic parameter  $K$ . After this, the methods that use the nonlinear parameters  $J$  and  $\delta$  are discussed. Finally, the methods in development that should be completed and in the standards books before the end of the century are also discussed.

## Fracture Toughness Testing

John D. Landes, University of Tennessee, Knoxville

---

## Linear-Elastic Fracture Toughness Testing

Fracture mechanics and fracture toughness testing began with a strictly linear-elastic methodology using the crack-tip stress-intensity factor,  $K$ . Later, nonlinear parameters were developed. However, the first test methods developed used the linear-elastic parameters and were based on  $K$ . These methods are described first in this article.

**Plane-Strain Fracture Toughness ( $K_{Ic}$ ) Test (ASTM E 399).** The first fracture toughness test that was written as a standard was the  $K_{Ic}$  test method, ASTM E 399. This test measures fracture toughness that develops under predominantly linear-elastic loading with the crack-tip region subjected to near-plane-strain constraint conditions through the thickness. The test was developed for essentially ductile fracture conditions, but can also be used for brittle fracture. As a ductile fracture test, a single point to define the fracture toughness is desired. To accomplish this, a point where the ductile crack extension equals 2% of the original crack length is identified. This criterion is illustrated schematically with a  $K$ - $R$  curve in Fig. 1. This criterion gives a somewhat size-dependent measurement, and so validity criteria are chosen to minimize the size effects as well as restrict the loading to essentially linear-elastic regime. The various elements of the  $K_{Ic}$  test are discussed in a little more detail than are some of the other tests for fracture toughness measurement. In this way, it can serve as a model for the other discussions. The details of this test can be found in Ref 6.

**Test Specimen Selection.** The first element of the test is the selection of a test specimen. Five different specimen geometries are allowed. These are the single edge-notched bend specimen, SE(B), compact specimen, C(T), arc-shape tension specimen, A(T), disk-shape compact specimen, DC(T), and the arc-shape bend specimen, A(B). Many of these specimen geometries are used in the other standards as well. They are shown schematically here in Fig. 2(a) through (e). The acronyms are standard ASTM nomenclature given in Ref 1. The bend and compact specimens (Fig. 2a and b, respectively) are traditional fracture toughness specimens used in nearly every fracture toughness test method. The other

three are special geometries that represent special component structural forms. Therefore, most fracture toughness tests are conducted with either the edge-notched bend or compact specimens. The choice between the bend and compact specimen is based on:

- THE AMOUNT OF MATERIAL AVAILABLE (THE BEND TAKES MORE)
- MACHINING CAPABILITIES (THE COMPACT HAS MORE DETAIL AND COSTS MORE TO MACHINE)
- THE LOADING EQUIPMENT AVAILABLE FOR TESTING (DISCUSSED NEXT)

All of the specimens for the  $K_{Ic}$  test must be precracked in fatigue before testing. Refer to the standard, E 399 (Ref 6), for details on precracking.

**FIG. 2 SPECIMENS TYPES USED IN THE  $K_{Ic}$  TEST (ASTM E 399). (A) SINGLE EDGE-NOTCHED BEND, SE(B). (B) COMPACT SPECIMEN, C(T). (C) ARC-SHAPE TENSION SPECIMEN, A(T). (D) DISK-SHAPE COMPACT SPECIMEN, DC(T). (E) ARC-SHAPED BEND SPECIMEN, A(B)**

The choice of the specimen also requires a choice of the size. Because the validity criteria depend on the size of the specimen, it is important to select a sufficient specimen size before conducting the test. However, the validity criteria cannot be evaluated until the test is completed; therefore, choosing the correct size is a guess that may turn out to be wrong. There are guidelines (Ref 6) for choosing a correct size, but no guarantee that the chosen size will pass the validity requirement. The test specimens must also be chosen so that the proper material is sampled. This means that the location in the material source and the orientation of the sample must be correct and accounted for. The ASTM standards have a

letter system to specify orientation (Ref 1). As the specimens are being prepared, requirements for tolerances on such things as locations of surfaces, size and location of the notch and pin holes, and surface finishes must be followed.

**Loading Machines and Instrumentation.** The next step in the test procedure is the choice of a loading machine and the preparation of loading fixtures and instrumentation for recording the test data. Most tests are conducted on either closed-loop servo-hydraulic machines or a constant-rate crosshead drive machine. The first allows load, displacement, or other transducer control, but is more expensive. It is preferred for precracking, which is usually done at a constant load range so load control is desired. The second type of loading machine is less expensive and may give more stability, but allows only crosshead control. Because this is required in most of the fracture toughness tests, this type of machine is quite satisfactory for the actual fracture toughness testing but is not so good for precracking.

Loading fixtures must be designed for the test. Two types can be used; choice of loading fixture depends on the test specimen chosen. The bend specimens SE(B) and A(B) use a bend fixture. The tension specimens C(T), DC(T), and A(T) require a pin-and-clevis loading. These two types of fixtures are illustrated in Fig. 3(a) and 3(b). Note in Fig. 3(a) that the bend loading is three point; this is the case for all bend-loaded specimens. Also note in Fig. 3(b) that the clevis has a loading flat at the bottom of the pin hole. This allows free rotation of the specimen arms during the test and is essential for getting good results.

FIG. 3 TEST FIXTURES FOR THE  $K_{Ic}$  TEST SPECIMENS. (A) FIXTURES FOR THE BEND TEST. (B) CLEVISES FOR

## THE COMPACT SPECIMEN

For the  $K_{Ic}$  test, a continuous measurement of load and displacement is required during the test. The load is measured by a load cell, which should be on all loading machines. The measurement of displacement is usually done with a strain-gaged clip gage that is positioned over the mouth of the crack in the specimen. An example of a clip gage is shown in Fig. 4. Figure 3(a) shows the bend specimen with a clip gage in place. The standards give guidelines for the working requirements of the load and displacement gages used in the tests.

FIG. 4 AN EXAMPLE CLIP GAGE FOR DISPLACEMENT MEASUREMENT (ALL DIMENSIONS IN MM)

The loading of the specimen is done at a prescribed rate. It must be done fast enough so that any environmental or temperature interactions are not a problem. On the other hand, it must be done slowly enough so that it is not considered a dynamically loaded test. For the  $K_{Ic}$  test, the load must be applied at a rate so that the increase in  $K$  is given by the range

0.55 to 2.75 MPa  $\sqrt{m}/s$ . The loading is done in displacement control, which usually means test machine crosshead control. During the loading, the load and displacement are measured continuously. This can be done autographically or digitally.

**Test Data and Analysis.** The load-and-displacement record provides the basic data of the test. The data are then analyzed to determine a provisional  $K_{Ic}$  value labeled  $K_Q$ . This provisional value is determined from a provisional load,  $P_Q$ , and the crack length. The  $P_Q$  value is determined with a secant slope on the load-and-displacement record (Fig. 5). The  $P_Q$  value is determined by drawing the original loading slope of the load-versus-displacement record. A slope of 5% less than the original slope is then drawn from the origin. For a monotonically increasing load, the  $P_Q$  is taken where the 5% secant intersects the load-versus-displacement curve; this is illustrated as type I in Fig. 5. For other records in which an instability or other maximum load is reached before the 5% secant, the maximum load reached up to and including the possible intersection of the 5% secant is the  $P_Q$ . Type II illustrated in Fig. 5 is an example of one of the other types of load-versus-displacement records. The 5% secant corresponds to about 2% ductile crack extension; this may be physical crack extension or effective crack extension related to plastic zone development. Unstable failure before reaching the 5% offset also marks a measurement point for  $P_Q$  at the maximum load reached at the point of instability.

FIG. 5 TYPICAL LOAD-VERSUS-DISPLACEMENT RECORD FOR THE  $K_{Ic}$  TEST, TWO TYPES

The  $P_Q$  value is used to determine the corresponding  $K_Q$  value. This is calculated from the equation:

$$K = P F(a/W)/B\sqrt{W} \quad (\text{EQ 1})$$

where  $P$  is load,  $B$  and  $W$  are specimen thickness and width, and  $f(a/W)$  is a calibration function that depends on the ratio of crack length to specimen width,  $a/W$ , and is given in the standard. For the calculation of  $K$ , a crack length value,  $a$ , is required. This comes from a physical measurement on the fracture surface of a broken specimen half. The specimen must be fractured into halves if it is not already that way from the test. The crack length is measured to the tip of the precrack using an averaging formula in the test standard. This value of crack length normalized with width,  $W$ , is used in the calibration function  $f(a/W)$  to determine the  $K_Q$  value.

The  $K_Q$  is provisional  $K$  value that may be the  $K_{Ic}$  if it passes the validity requirements. The two major validity requirements are to ensure that crack resistance does not increase significantly with crack growth and that linear-elastic loading and plane-strain thickness are achieved. The first of these two requirements is quantified as:

$$\frac{P_{\max}}{P_Q} \leq 1.10 \quad (\text{EQ 2})$$

which limits the  $R$ -curve behavior to an essentially flat trend and ensures some physical crack extension. The second requirement is:

$$a, B \geq 2.5 \left( \frac{K_Q}{\sigma_{ys}} \right) \quad (\text{EQ 3})$$

which guarantees linear-elastic loading and plane-strain thickness.  $P_{\max}$  is the maximum value of load reached during the test. An example of  $P_{\max}$  is shown in Fig. 5;  $\sigma_{ys}$  is the 0.2% offset yield strength. Values of  $K_Q$  that pass these validity requirements are labeled as valid  $K_{Ic}$  and are reported as such in a standard prescribed reporting of test results.

**Fatigue precracking** should be done in accordance with ASTM E 399. The  $K$  level used for precracking each specimen should not exceed about two-thirds of the intended starting  $K$ -value for a given environmental exposure. This prevents fatigue damage or residual compressive stress at the crack tip, which may alter the fracture toughness behavior, particularly when testing at a  $K$ -level near the  $K_Q$  value for the specimen.

Chevron notches are sometimes used to facilitate starting such mechanical precracks (see the Appendix at the end of this article). These modifications also may be necessary to control fatigue precracking of some materials.

**Rapid-Load  $K_{Ic}(t)$ .** A value of fracture toughness labeled  $K_{Ic}(t)$  can be determined for a rapid-load test. Details of this method are given in a special annex to the method E 399 (Ref 6). For the static loading rate  $K_{Ic}$  value, the maximum loading rate is defined as  $2.75 \text{ MPa } \sqrt{m}/s$ . Anything faster than that is labeled as a rapid-load fracture toughness. The specimen apparatus and procedure are much the same as for the regular  $K_{Ic}$  test. Special instructions are given to ensure that the instrumentation can handle the rapidly changing signals. The interpretation of results must be based on a dynamic value of the yield stress,  $\sigma_{YD}$ . An equation for  $\sigma_{YD}$  is given in the Annex to E 399. Results are reported as  $K_{Ic}(t)$ , where the loading time of the test is written in parentheses after the measured toughness value.

**$K$ - $R$  Curve (ASTM E 561).** Ductile fracture toughness behavior is measured by a crack growth resistance curve or " $R$ -curve," which is defined as "a plot of crack-extension resistance as a function of slow-stable crack extension" (Ref 1). Although many ductile fracture processes can be measured as a single point, such as with  $K_{Ic}$ , the  $R$ -curve is a more complete description of the fracture toughness. When the  $R$ -curve increases significantly, a single-point measurement is even less descriptive of the actual fracture toughness. Steeply rising  $R$ -curves occur in many metallic materials but especially in thin plate or sheet materials. The steeply rising  $R$ -curve makes the single-point definition more size- and geometry-dependent and does not lend to structural evaluation.

The  $K$ - $R$  curve is a good method for fracture toughness characterization in cases where the  $R$  curve is steeply rising but the fracture behavior occurs under predominantly linear-elastic loading conditions. The  $K$ - $R$  curve procedure is given by ASTM E 561 (Ref 7). The objective of the method is to develop a plot of  $K$ , the resistance parameter, versus effective crack extension,  $\Delta a_e$ . The method allows three different test specimens, the compact, C(T), the center-cracked tension panel, M(T), and the crack-line-wedge-loaded specimen, C(W). The compact specimen is shown in Fig. 2(b). The center-cracked tension panel and the crack-line-wedge-loaded specimens are shown in Fig. 6(a) and 6(b), respectively. The first two specimens use a conventional loading machine with fixtures that are specified in the test method. The C(W) specimen is wedge loaded to provide a stiff, displacement-controlled loading system (Fig. 6b). This can prevent rapid, unstable failure of the specimen under conditions where the  $R$  curve toughness is low so that the  $R$  curve can be measured to larger values of  $\Delta a_e$ . All specimens must be precracked in fatigue.

(a)

(b)

FIG. 6 (A) CENTER-CRACKED TENSION SPECIMEN, M(T). (B) CRACK-LINE-WEDGE-LOADED COMPACT SPECIMEN, C(W), IN LOADING FIXTURE.

The instrumentation required on the specimens is similar to that for the  $K_{Ic}$  test, except for the case of the C(W) specimen. The basic test result is a plot of load versus a displacement measured across the specimen mouth. From this, an effective crack length is determined from secant offset slopes to the load-versus-displacement record (Fig. 7). An effective crack extension is the difference between the original and effective crack lengths. Effective crack length is determined from the slope of the secant offset using the appropriate compliance function, which relates this slope to crack length. The  $K$  is determined as a function of the load and corresponding effective crack length. This is given by:

$$K = P F(A_E/W)/B\sqrt{W} \quad (\text{EQ 4})$$

The resulting plot of  $K$  versus effective crack length is the desired  $K$ - $R$  curve fracture toughness. The result is subjected to a validity requirement that limits the amount of plasticity. For the C(T) and C(W) specimens

$$B = (W - A) \cdot (4/\pi) (K_{MAX}/\sigma_{YS})^2 \quad (\text{EQ 5})$$

where  $b$  is the uncracked ligament length,  $\sigma_{ys}$  is the 0.2% offset yield strength, and  $K_{max}$  is the maximum level of  $K$  reached in the test. For the M(T) specimen the net section stress based on the physical crack size must be less than the yield strength.

FIG. 7 SECANT OFFSET MEASUREMENT OF EFFECTIVE CRACK LENGTH.

For the C(W) specimen, a load is not measured. The data collected are a series of displacement values taken at two different points along the crack line, one near the crack mouth and one nearer the crack tip. From the two different displacement values, an effective crack length can be determined from the ratio of the two displacement values and from calibration values given in a table in E 561. From the crack length and displacement a  $K$  value can be determined and the  $K$ - $R$  curve constructed. The toughness result is then a curve of  $K$  versus  $\Delta a_e$ , somewhat similar to the one in Fig. 1.

**Crack Arrest,  $K_{Ia}$  (ASTM 1221).** This procedure allows a toughness value to be determined based on the arrest of a rapidly growing crack, which may be lower than the initiation value. The specimen and procedure are somewhat different from the previously discussed toughness test methods that determine initiation toughness values only. The specimen for crack arrest testing is called the compact-crack-arrest compact specimen (Fig. 8). It is similar to the crack-line-wedge-loaded specimen, C(W), of the  $K$ - $R$  curve method and requires wedge loading in order to provide a very stiff loading system to arrest the crack. The notch preparation is different from the other standards in that the specimen has a notch with no precrack. Generally, a brittle weld bead is placed at the notch tip to start the running crack, although other methods are allowed. The running crack advances rapidly into the test material and must be arrested by the test material to produce a  $K_{Ia}$  result. The only instrumentation on the specimen is a displacement gage. A load cell is placed on the loading wedge, but it does measure the load on the specimen. The displacements at the beginning of the unstable crack extension and at the crack arrest position are measured and converted to  $K$  values. To eliminate effects of nonlinear deformation, which cannot be directly measured with only a displacement gage, a series of loads and unloads are conducted on the specimen until the unstable cracking occurs. When the specimen is unloaded, the crack tip can be marked by a procedure called "heat tinting." Heat tinting consists of marking the physical crack extension by heating the

specimen until oxidation occurs on the crack. The specimen is then broken open, and the crack extension measured on the fracture surface.

FIG. 8 CRACK-LINE-WEDGE-LOADED COMPACT-CRACK-ARREST SPECIMEN

The value of  $K_{Ia}$  is determined from a displacement value and the crack length at the arrest point. Validity is determined from the size criterion:

$$W - A \cdot 1.25 (K/\sigma_{YD})^2 \quad (\text{EQ 6})$$

where  $\sigma_{YD}$  is a dynamic yield strength. To complete a successful  $K_{Ia}$  test, careful attention must be paid to the instruction in E 1221 (Ref 8).

## Nonlinear Fracture Toughness Testing

Linear-elastic parameters are used to measure fracture toughness for relatively low toughness materials that fracture under or near the linear loading portion of the test. For many materials used in structures it is desirable to have high toughness, a value at least high enough so that the structure would not reach fracture toughness before significant yielding occurs. For these materials, it is necessary to use the nonlinear fracture parameters to measure fracture toughness properties. The two leading nonlinear fracture parameters are  $J$  and  $\delta$ . For high toughness materials, fracture is often by a ductile mechanism, but this is not necessarily the case for all materials.

**$J_{Ic}$  Testing (ASTM E 813).** One of the first tests developed using the  $J$  parameter is the  $J_{Ic}$  test per ASTM E 813 (Ref 9). In this test, an  $R$  curve is developed using  $J$  versus  $\Delta a$  pairs and a point near the beginning of the  $R$  curve is defined as  $J_{Ic}$  "a value of  $J$  near the onset of stable crack extension" (Ref 9). The specimens for the  $J_{Ic}$  test are the bend SE(B) and compact C(T). These specimens are similar to the ones used for  $K_{Ic}$  testing in Fig. 2(a) and 2(b); however, the compact specimen for  $J$  testing has a cutout on the front face so that a displacement gage can be mounted directly on the load line; that is, in the line of the applied loads (Fig. 9). The loading fixtures required are the bend fixture for the bend (Fig. 3a) and the pin-and-clevis for the compact (Fig. 3b). Again, a clevis with a loading flat at the bottom of the pin hole in the clevis is essential to get free rotation of the specimen. The instrumentation required is the load cell and a displacement measuring clip gage. If the electrical potential system is used additional instrumentation is required. The clip gage for the  $J_{Ic}$  test requires more resolution than that for the  $K_{Ic}$  test if a single specimen test method is used. For the bend specimen, a loadline clip gage is needed to measure  $J$ . Additionally, a second clip gage can be used over the crack mouth if a single specimen method is used.

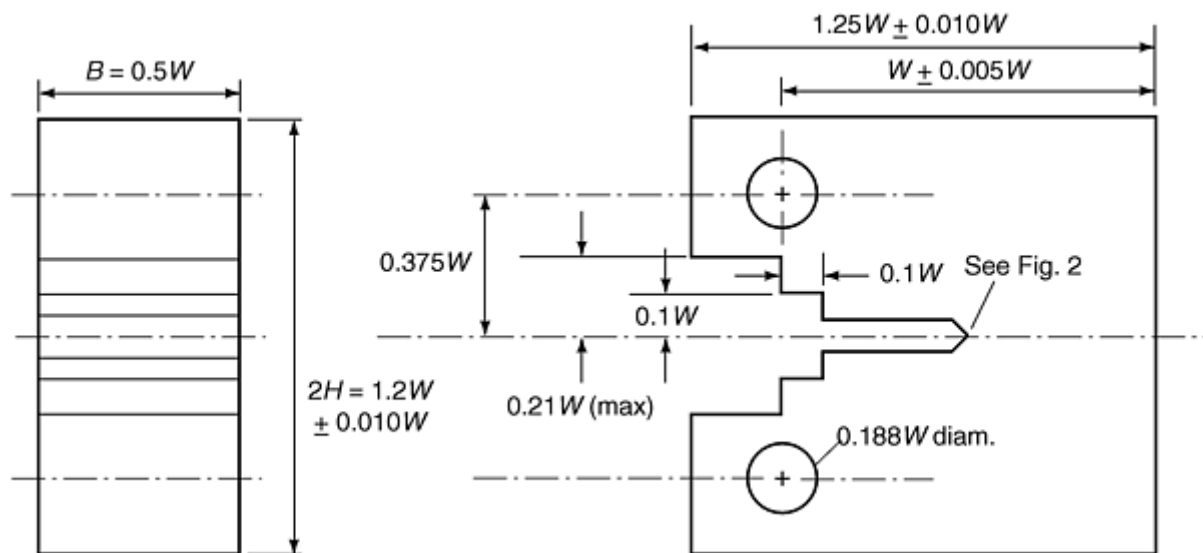

FIG. 9  $J_{Ic}$  COMPACT SPECIMEN WITH LOADING CUTOUT

**$J_{Ic}$  Test Procedures.** The basic output of the test is a plot of  $J$  versus physical crack extension ( $\Delta a$ ). (Unlike the  $K$ - $R$  curve method, which uses effective crack extension, the  $J_{Ic}$  test uses physical crack extension.) To obtain the required  $J$  versus  $\Delta a$  data measurements of load, displacement and physical crack length are required during the test. There are two techniques used to develop these data. The first is the multiple-specimen test method, in which each specimen develops a single value of  $J$  and  $\Delta a$  but no special crack monitoring equipment is needed during the test. Crack extension is measured on the fracture surface at the conclusion of the test. However, for this technique a number of specimens are required to develop the plot of  $J$  versus  $\Delta a$  values needed for the result. The other method is the single specimen test from which all the  $J$  versus  $\Delta a$  values are developed from one test. To accomplish this, a method of crack length monitoring is needed

during the test. The primary method for crack length monitoring during the test is called the elastic unloading compliance method, in which crack length is measured from an elastic slope. The measurement of the elastic slope requires only a clip gage that measures displacement. The compact specimen uses the gage mounted on the load line. The bend specimen could use two gages: one on the loadline to measure  $J$  and one over the crack mouth to measure slope. The second single-specimen method is the electrical potential crack monitoring system, in which the electrical resistivity of the specimen is measured and correlated with crack length during the test. This is a secondary method to measure crack length and is not described in detail in the E 813. It requires some additional expertise on the part of the tester to use.

The test procedure depends on the method of crack length monitoring. For the multiple-specimen test, five or more specimens are loaded to prescribed displacement values that are thought to give some physical crack extension but not complete separation of the specimen. This results in a number of individual load-versus-displacement records, as shown in Fig. 10. When the prescribed displacement is reached, the specimen is unloaded and the crack tip is marked by heat tinting.

FIG. 10 LOAD VERSUS DISPLACEMENT FOR MULTIPLE-SPECIMEN TESTS

The single-specimen method using elastic compliance is initially loaded in the same way; however, during the test partial unloadings are taken to develop elastic slopes from which crack length can be evaluated using compliance relationships (Fig. 11). The compliance relationships are given in E 813 (Ref 9). For the electrical potential method, the load, displacement, and potential change are measured simultaneously. Potential changes are related to crack length through either an analytical or empirical correlation.

FIG. 11 LOAD VERSUS DISPLACEMENT WITH UNLOADING SLOPES

**Data Evaluation.** From these test results,  $J$  is evaluated from the load-versus-loadline displacement record. The  $J$  is calculated from a linear combination of an elastic term and a plastic term given as:

$$J = J_{el} + J_{pl} = \frac{K^2 (1 - \nu^2)}{E} + \frac{\eta_{pl}}{Bb} \int_0^{v_{pl}} P dv_{pl} \quad (\text{EQ 7})$$

where  $K$  is the stress-intensity factor,  $E$  is elastic modulus,  $\nu$  is Poisson's ratio,  $P$  is load,  $v_{pl}$  is plastic displacement,  $B$  is specimen thickness,  $b$  is specimen uncracked ligament ( $W - a$ , where  $W$  is specimen width) and  $\eta_{pl}$  is a coefficient that has values of  $\eta_{pl} = 2$  for the SE(B) specimen of Fig. 2(a) and  $\eta_{pl} = 2 + 0.522b/W$  for the compact specimen of Fig. 9. Equation 7 is the basic  $J$  formula for the case of a nongrowing crack. It is based on a  $K$  equivalence for the elastic component of  $J$  and an area term for the plastic component of  $J$ . Alternate  $J$  formulas are given in E 813 (Ref 9) for the growing crack.

The crack length is used to determine  $\Delta a = a - a_0$ , where  $a_0$  is the original crack length at the beginning of the test. For the multiple specimen method, all  $\Delta a$  values are determined from measurements taken from the broken surface of the test specimen. For some metals, heat tinting does not oxidize the crack surfaces and another method of marking the crack extension, for example post-test fatiguing, can be used. The specimen is broken in two after the heat-tint procedure, usually at a low temperature to induce brittle fracture for easy reading of the ductile crack extension and to otherwise minimize plastic deformation during this procedure. Crack lengths  $a_0$  and  $a_f$ , original and final, are measured on the fracture surface. A nine-point measurement and averaging method is used because the crack front is usually not straight and regular. This procedure is described in E 813 (Ref 9). For the single-specimen methods for which crack length monitoring systems are used, the crack length is evaluated at prescribed points during the test. For example, in the elastic unloading compliance method, a crack length can be determined at each unload. Typically, about 15 of 30 data pairs,  $P$ ,  $\nu$ , and  $a$  are evaluated for each test. For single-specimen tests, a physical measurement of the final crack length is made at the end of the test using the same procedure that is followed for the multiple-specimen test, so that this value can be used to compare with the final crack length evaluated by the crack monitoring system.

The  $J$  versus  $\Delta a$  results form a part of the  $J$ - $R$  curve and are the basic data of the  $J_{Ic}$  method. The objective is to get  $J$  versus  $\Delta a$  values in a certain restricted range. These data are then subjected to a prescribed evaluation scheme to choose a point on the  $J$ - $R$  curve that is near the initiation of stable cracking. The method for developing the  $J_{Ic}$  is somewhat complicated, and the details are given in E 813 (Ref 9). Basically, the  $J$  versus  $\Delta a$  pairs are evaluated to see which fall in a prescribed range. The pairs falling in the correct range are fitted with a power-law equation:

$$J = C_1 (\Delta a)^{C_2} \quad (\text{EQ 8})$$

where  $C_1$  and  $C_2$  are constants. A construction line is drawn, and the intersection of this with the fitted line, Eq 8, is the evaluation point for a candidate  $J_{Ic}$  value. This candidate value is labeled  $J_Q$ . A schematic of the process of  $J_{Ic}$  evaluation is shown in Fig. 12.

FIG. 12  $J_{Ic}$  EVALUATION SCHEME

The candidate  $J_Q$  value is subjected to qualification criteria to see if it comprises an acceptable value. The basic one is to guarantee a sufficient specimen size:

$$B, B \cdot 25(J_Q/\sigma_Y) \quad (\text{EQ 9})$$

where  $\sigma_Y$  is an effective yield strength and

$$\sigma_Y = (\sigma_{YS} + \sigma_{UTS})/2 \quad (\text{EQ 10})$$

where  $\sigma_{ys}$  and  $\sigma_{uts}$  are the yield strength and ultimate tensile strength, respectively.

If the qualification requirements are met, the  $J_Q$  is  $J_{Ic}$  and the results are reported following the prescribed format in E 813 (Ref 9).

***J-R Curve Evaluation (ASTM E 1152).*** A more complete evaluation of fracture toughness for ductile fracture based on  $J$  is the  $J-R$  curve procedure in ASTM E 1152 (Ref 10). This standard uses the same specimens, instrumentation, and test procedures as the  $J_{Ic}$  test. The  $J-R$  curve test cannot be conducted with the multiple-specimen test procedure; it must use a single-specimen procedure. The purpose of the  $J-R$  curve is to develop points of  $J$  versus  $\Delta a$ ; these comprise the fracture toughness value, a single value of  $J$  is not required. The single-specimen methods are again the elastic unloading compliance method and the electrical potential method. Qualification criteria are given in the E 1152 (Ref 10). The  $J_{Ic}$  and  $J-R$  curve methods are very similar, hence a combined  $J$  standard is being prepared.

**Crack Tip Opening Displacement (CTOD) (ASTM E 1290).** The crack tip opening displacement method of fracture toughness measurement was the first one that used a nonlinear fracture parameter to evaluate toughness (Ref 5). The first

CTOD standard was written by the British Standards Institution (Ref 11). Subsequently, ASTM E 1290 was written as the U.S. version of this test method (Ref 12). The basic idea of the test method is to evaluate a fracture toughness point for brittle fracture or to evaluate a safe point for the case of ductile fracture. The primary measurements of toughness are at unstable fracture before significant ductile crack extension, labeled  $\delta_c$ , unstable fracture after significant crack extension,  $\delta_u$ , or the point of maximum load in the test,  $\delta_m$ . The method originally had a point near the beginning of stable crack extension,  $\delta_i$ , that was measured as a point on an  $R$  curve in a similar manner to  $J_{Ic}$ . This point was subsequently removed from the test method.

The CTOD standard uses the same bend and compact specimens that are used in the  $J_{Ic}$  test; thus the same loading fixtures are used. The method requires measurement of load and displacement during the test. The formulas for  $\delta$  calculation use a combination of an elastic and a plastic component for  $\delta$ :

$$\delta = K^2 (1 - \nu^2) / 2 \sigma_{ys} E + R_p (W - A_0) V_p / [R_p (W - A) + A_0 + Z] \quad (\text{EQ 11})$$

In this equation, the elastic component of  $\delta$  is based on an equivalent  $K$  and the plastic component is based on a rigid plastic rotation of the specimen about a neutral stress point at  $r_p (W - a_0)$  from the crack tip. In Eq 11,  $\nu$  is Poisson's ratio,  $\sigma_{ys}$  is the yield strength,  $r_p$  is a rotation factor,  $v_p$  is a plastic component of displacement,  $W - a_0$  is the uncracked ligament length, and  $z$  is the position of the clip gage from the crack measurement position.

For many years the CTOD test was the only one that measured toughness for a brittle, unstable fracture event using a nonlinear fracture parameter. In addition, the method allows the measurement of toughness after a "popin," which is described as a discontinuity in the load-versus-displacement record usually caused by a sudden, unstable advance of the crack that is subsequently arrested.

## Test Methods in Preparation

The development of standard fracture toughness test methods is not completed. By the end of 1995, four new test methods were being prepared for fracture toughness testing. They are:

- THE COMBINED  $J$  STANDARD
- THE COMMON TEST METHOD
- THE TRANSITION FRACTURE TOUGHNESS STANDARD

- THE STANDARD FOR TESTING OF WELDMENTS

Because these methods will likely become test standards in the next few years, it is important to describe them briefly here as a likely reference in the future.

**Combined  $J$  Standard (E1737-96).** Because the  $J_{Ic}$  and  $J$ - $R$  curve test standards are very similar in many respects, they are in the process of being combined into a single test standard for the ASTM standard books as ASTM E1737-96. The combined  $J$  standard will allow the measurement of both the  $J$ - $R$  curve and the  $J_{Ic}$  point. Whereas the traditional  $J$ -based standards only allowed measurements of fracture toughness for ductile fracture (where stable cracking occurs with no unstable cracking and an  $R$  curve is used to measure toughness), the combined standard will have a single-point evaluation of unstable, brittle fracture based on  $J$ . The specimens and procedures for brittle fracture are the same as for the  $J_{Ic}$  and  $J$ - $R$  curve tests; however, the test would end with sudden unstable crack advance. The parameter  $J$  is evaluated at the point of unstable cracking and labeled  $J_c$  if the unstable fracture is before significant stable cracking occurred and labeled  $J_u$  if it is after significant stable cracking.

The combined  $J$  test will use the same techniques as E 813 and E 1152. The single-specimen elastic unloading compliance method is the standard procedure. Electrical potential measurement of crack advance is allowed, and a detailed description of the technique is given in the standard. In addition, the multiple-specimen method is allowed, but only for measurement of a  $J_{Ic}$  point.

An additional feature of the new combined  $J$  standard is an initialization procedure to ensure that the initial portion of the  $J$ - $R$  curve is aligned properly with the initial measured crack length. The E 813 method of  $J_{Ic}$  measurement did not specifically align the initial portion of the curve and could give artificially raised or lowered values of  $J_{Ic}$  reflecting the offset in the initial  $J$ - $R$  curve alignment.

**Common Fracture Toughness Test Method (E1820-96).** The most universal of the test methods for fracture toughness will be the common test method approach. This allows a measurement of fracture toughness using the linear-elastic parameter,  $K$ , or the nonlinear parameters  $J$  or  $\delta$ , whichever is appropriate to the result of the test. The idea of the method is that most of the fracture toughness tests use the same specimens, instrumentation, and test procedures. The exclusive nature of each test method described above was derived from the historical development of the fracture mechanics methodology. However, the way individual methods are written gives a good chance that a test can give an invalid or unqualified result with no way to use the analysis procedure of another test method to try to obtain an acceptable result. The common method approach is designed so that nearly every test can deliver some acceptable measurement of fracture toughness.

The common method will use the same specimens and loading fixtures as  $K_{Ic}$ , but will allow measurement of toughness for both brittle and ductile fracture mechanisms. The method allows the option of a single-specimen or a multiple-specimen procedure when crack extension must be measured for the development of an  $R$  curve. The common test method concept of combining all measurements of fracture toughness into a single standard rather than having many specialized standards has become popular around the world, and most of the standards writing organizations have either recently developed a version of the common test standard or are in the process of developing one. The ASTM common method for fracture toughness testing is in preparation as ASTM E1820-96.

**Transition Fracture Toughness Testing (1997-1998).** The transition fracture toughness has long been a problem area for fracture toughness testing. The transition fracture behavior is usually brittle, sometimes after an initial period of ductile crack extension. The toughness values show extensive scatter and size dependency that cause difficulty in the characterization of toughness for the evaluation of structures. The scatter and size dependency has been attributed to statistical influences and constraint differences (Ref 13). The characterization of toughness relies mainly on the statistical handling of the data. The test method in preparation concentrates mainly on these aspects. The specimens, fixtures, instrumentation, test procedures, and calculation of toughness parameters will follow existing standards. The evaluation of the statistical aspects are handled with a Weibull statistical distribution (Ref 13). From this, a median value of toughness is identified from the scatter; that median value of toughness is aligned on a master curve. From the master curve, the toughness distribution at other temperatures can be identified. Also from the statistical distribution, a percentage lower bound confidence level of toughness can be identified. For example, a 95% lower bound confidence level can be determined from the statistical distribution as a function of temperature in the transition. The transition fracture toughness standard is in development and should be available in 1997 or 1998. There are presently no documents to reference for this method, but it would be in the same Volume as all of the other fracture toughness test standards.

**Fracture Testing of Weldments (year of issue uncertain).** The final test method in preparation is the fracture of weldments test method. Weldments do not require a different set of parameters, specimens, or equipment for toughness testing; however, there are special problems for the testing of weldments that are not contained in the other standards. Weldments have a composite of materials starting in the base metal, going through the heat-affected zone and into the weld metal. Such things as the placement of the notch for the sampling of the correct material, the precracking procedure to get the crack to grow in an acceptable manner, and handling of such things as distortion and residual stresses will be covered in the standard. The parts that are common with the other standards will not be covered in this method, but the tester will be referred to the other standards to complete the testing and analysis after the special problems inherent to the testing of weldments have been taken care of. This standard presently needs additional verification before it is proposed for standards balloting.

## Appendix 1: Chevron Notched Specimens

Chevron-notched specimens can be used to determine the fracture toughness of materials that are difficult to precrack, materials unavailable in large section sizes, and materials that are economically prohibitive to test using other specimen configurations. A natural crack initiates at the notch tip and extends in a stable manner as the load increases during testing. This eliminates fatigue precracking and simplifies interpretation of results.

As previously mentioned in this article, ASTM E 399 centers attention on the start of crack extension from a fatigue precrack. In contrast the chevron-notched specimen method makes use of a steady-state propagating crack or a crack at the initiation of a crack jump. Although both methods are based on the principles of linear elastic fracture mechanics, this distinction, coupled with differences in test procedures, causes fracture toughness values measured by the chevron-notched specimen method to be somewhat higher than those obtained using ASTM E 399.

Chevron-notched specimens were originally used for determining the fracture toughness of brittle materials that were difficult to fatigue precrack. These materials exhibited nearly ideal linear-elastic behavior and required only maximum load to failure for calculating fracture toughness. Use of chevron-notched specimens was extended to ductile materials that required impractically large specimens for determination of fracture toughness by other methods. The thin chevron slots provide good plane-strain constraint at the crack ends, resulting in smaller specimen sizes for valid fracture toughness values from a given material. Thus, chevron-notched specimens have gained acceptance due to some economic advantages over other specimen configurations for determining fracture toughness of metallic engineering alloys and other engineered materials, such as ceramics and glass.

## Specimen Description

Chevron-notched specimen geometries (Fig. 13) can be divided into two broad categories: specimens with rectangular cross sections (short bar) and those with round cross sections (short rod). Both straight and curved chevron slots are used with either specimen cross section, depending on the side-slot machining equipment available. A curved slot is made by plunge cutting with a circular blade, whereas a straight slot is cut by using an electrical discharge wire or by feeding a circular cutter through the specimen.

FIG. 13 CHEVRON NOTCH TEST CONFIGURATION FOR BOTH BAR AND ROD

The very thin chevron slot significantly reduces the size of the nonplane-strain zone at the flank ends of the crack. This increased triaxial constraint allows valid fracture toughness determinations for a given metallic alloy to be made using much smaller specimens than required by ASTM E 399. For example, a 12-mm by 12-mm by 19-mm (0.5-in. by 0.5-in. by 0.75-in.) chevron-notched specimen of SAE 15B35 steel, quenched and tempered to 50 HRC with a yield strength of 1120 MPa (162 ksi) and  $K \approx 80 \text{ MPa} \sqrt{m}$  (72.8 ksi  $\sqrt{\text{in}}$ ), would weigh about 0.02 kg (0.05 lb). An ASTM E 399 compact tension specimen of the same material would be 25 mm by 64 mm by 61 mm (1.0 in. by 2.5 in. by 2.4 in.) and weigh 0.73 kg (1.62 lb).

Besides smaller specimen sizes, the chevron slot serves three additional critical functions. First, the slot defines the crack plane and propagation direction, providing a simple method for orienting the fracture with respect to the bulk material. Second, the slot forces crack initiation at the point of the "V" when the load is applied. Finally, the chevron slot configuration produces stable crack initiation and growth, because the crack front widens as it advances. This is advantageous when testing brittle alloys that are difficult to fatigue precrack.

Common specimen geometries are shown in Fig. 14 and 15. Slot thickness and slot configurations (Table 1) have been extensively tested and analyzed for various specimen geometries and accurate determination of fracture toughness (Ref 14, 15, 16, 17, 18, 19, 20, 21, 22, 23). Figure 15 shows a curved chevron notch pattern for fracture toughness testing under development for aluminum alloys. Tests on aluminum alloys have shown that these parameters correlate closely with  $K_{Ic}$  (Ref 24) and that useful plane-strain fracture toughnesses can be measured with a specimen that is smaller than that used in the ASTM E 399 test. More recent references on the use of chevron-notched specimens are listed in the "Selected References" at the end of this article.

**FIG. 15** SHORT BAR TOUGHNESS ALUMINUM-ALLOY SPECIMENS WITH CURVED CHEVRON NOTCHES

The Society of Automotive Engineers has adopted aerospace recommended procedure ARP 1704 for determination of fracture toughness using chevron-notched specimens, and the ASTM chevron-notched test method is specified in ASTM E 1304. Although the SAE recommended test practice exists for these specimen geometries, the SAE test has not been included in any aircraft company specifications to date. Further information in alternate geometries for chevron-notched specimens is described in *Mechanical Testing*, Vol 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

## **Brittle Materials**

Chevron-notched specimens made from very hard, brittle materials, such as glass, ceramics, and carbides, exhibit nearly ideal linear elastic behavior. Crack initiation occurs at  $I$ , where the loading first deviates from linearity (Fig. 16a). The crack then extends in a stable manner throughout the test. The load required to advance the crack increases to a smooth maximum at the critical crack length. This maximum load is used to calculate fracture toughness. The critical crack length is dependent only on specimen geometry and is independent of material. Therefore, there is no need to measure crack length when determining fracture toughness.

(a)

(b)

FIG. 16 SCHEMATIC OF (A) ELASTIC SPECIMEN BEHAVIOR, AND (B) ELASTIC-PLASTIC SPECIMEN BEHAVIOR. FOR THE ELASTIC-PLASTIC BEHAVIOR SHOWN IN (B)  $\bar{F}$  IS THE AVERAGE LOAD BETWEEN POINTS  $R$  AND  $S$  ON THE CURVE AND LOCATES BOTH  $A'$  AND  $B'$  ON THE UNLOADING LINES.

The rationale for using linear elastic fracture mechanics principles for calculating fracture toughness of an ideal elastic material is illustrated in Fig. 16(a). Unloading from either  $R$  or  $S$  is linear to 0. Therefore, the shaded area represents the irrecoverable work to form the fracture surface (i.e., the fracture toughness of the material). The following equation is used to calculate the fracture toughness of the specimens shown in Fig. 14 (Ref 18, 19, 20, 21, 22, 23):

$$K = \frac{(AF)}{(B)^{3/2}}$$

where  $K$  is the fracture toughness obtained from chevron-notched specimens,  $F$  is maximum load,  $B$  is specimen diameter for short rods or thickness for short bars, and  $A$  is a dimensionless calibration constant dependent only on specimen geometry.

The currently recommended calibration constant for the specimens shown in Fig. 14 and 3 is 22.0. The equations and calibration constants for the specimens shown in Fig. 4 are given in Ref 14, 15, 16, 17 and Ref 19.

## Metal Alloys

Most chevron-notched specimens made from practical engineering alloys exhibit elastic-plastic behavior when tested. A plot of load versus mouth opening displacement for ideal elastic-plastic behavior is shown in Fig. 16(b). Unloading from  $R$  and  $S$  is offset from 0 to  $C$  and  $D$ , respectively. This offset is the result of yielding in two plastic zones in the specimen: the plane-stress plastic zone and the plane-strain plastic zone.

The plane-stress plastic zone occurs at the crack tip where the crack intersects the bottom of the chevron notch. The size of this zone is dependent on chevron-notch acuity. Sufficient constraint usually is generated to adequately minimize the plane-stress plastic zone size when one of the following criteria is met:

- THE CHEVRON SLOT THICKNESS IS LESS THAN 1.5% OF THE SHORT ROD DIAMETER OR SHORT BAR THICKNESS.
- THE CHEVRON SLOT BOTTOMS ARE SHARP POINTED, AS WITH A 60° INCLUDED ANGLE AT THE BOTTOM OF THE SLOTS.
- THE PLASTIC ZONE SIZE IS LESS THAN 0.2% OF THE SPECIMEN DIAMETER OR THICKNESS.

However, the plane-strain plastic zone is located at the crack tip within the bulk of the specimen. Yielding in the plane-strain plastic zone partially relieves the stress at the crack tip. Therefore, the crack is apparently longer than is the actual case and thus the measured fracture toughness values are too low.

A plasticity factor,  $P$ , is used to adjust the fracture toughness to the proper value. The plasticity factor is measured experimentally from the load versus mouth opening displacement plot in Fig. 13 as follows:

$$P = \frac{(B' - A')}{(D - C)}$$

Note that the plasticity determination requires a plot of load versus displacement and two specimen unloadings and reloadings. Useful fracture toughness values are obtained when  $-0.05 < P < 0.1$ . When too large,  $P$  is reduced for a given material with sharper chevron slot acuity and/or larger specimen size.

There is no assurance that the peak load will occur at the critical crack length in elastic-plastic tests. However, for both linear elastic and elastic-plastic tests, the critical crack length occurs at a critical unloading slope ratio,  $r_c$ , which is a constant for any particular specimen configuration. The unloading slope ratio is defined as the unloading slope divided by the slope of the initial elastic loading path. Therefore, the correct load,  $F_c$ , to use for calculating fracture toughness is located where an unloading line having the critical unloading slope intersects the load displacement curve. This line is found from vertical interpolation between two actual unloading lines. This interpolation is done either graphically on the load versus displacement plot or automatically with a computer.

Fracture toughness for elastic-plastic behavior for the specimens shown in Fig. 14 is then calculated using the following equation:

$$K = \left[ \frac{(AF_c)}{B^{3/2}} \right] \left[ \frac{(1+P)}{(1-P)} \right]$$

where  $A$  is a dimensionless calibration constant dependent only on specimen geometry (the currently recommended calibration constant for the specimens shown in Fig. 14 is 22.0),  $F_c$  is the load at the critical unloading slope ratio,  $B$  is specimen diameter for a short rod or thickness for a short bar, and  $P$  is the plasticity factor.

### Appendix 2: Dynamic Fracture Toughness Testing

A rapid loading rate can influence the value of the measured fracture toughness. Usually the effect is to make toughness lower and the transition occur at a higher temperature when the fracture mode is brittle and to do just the opposite, that is, raise the toughness when the fracture mode is ductile. Many structural components can experience a high loading rate in service; therefore, it is often important to measure the toughness under high loading rates, a condition generally labeled dynamic. In the past, many requirements for fracture toughness data specified dynamic loading conditions. Before the quantitative approach to fracture toughness testing with the nonlinear parameters  $J$  and  $\delta$  were developed, and fracture toughness measurement was limited to that characterized with the linear-elastic  $K$ , qualitative dynamic fracture testing had to be used whenever the linear-elastic  $K$ , qualitative dynamic fracture testing had to be used whenever the linear-elastic requirements could not be met. The Charpy V-notch impact test was one of the first of these types of tests and proved to give extremely valuable, though qualitative information about the toughness of a material. With the further development of the fracture mechanics methods, these qualitative tests could be replaced by more quantitative types of tests. However, new quantitative fracture toughness tests are slow to develop.

Appendix A7 of method E399 allows a measurement of  $K_{Ic}(t)$  which is a  $K_{Ic}$  test at a higher loading rate than the traditional quasi-static  $K_{Ic}$  test. Dynamic testing using the nonlinear  $J$  and  $\delta$  parameters are under consideration but are not near to completion at this point. Therefore, the more qualitative dynamic tests are still being used for dynamic loading conditions. Two of these test methods are presented here in Appendix 2 to supply additional information about dynamic loading fracture testing. They are the dynamic tear test with its related application to fracture control analysis called the ratio-analysis diagram and the instrumented impact test. These tests do not provide direct fracture toughness results in terms of a fracture parameter that can be used to analyze structural safety and reliability. Rather they give information that can be used in a qualitative way. For example, to make material comparisons or to establish safe ranges of temperature for operation of a component. In most cases the information gathered with these tests can be used with empirical correlations to estimate actual fracture toughness values. For the dynamic tear test the ratio-analysis diagram can be used to make the application to fracture control directly from these correlative graphs without a need to use the fracture mechanics calculations. The correlative approach has an appeal to the nonexpert in that fracture control information can be directly inferred without need for a special fracture mechanics education. For the more expert person the direct fracture mechanics approach may be more desirable because analysis is done following well known procedures. Therefore, assumptions, limitations, and conservatism involved in the fracture prediction are all well known to the analysts.

To serve the needs of all fracture control analyses both the direct fracture mechanics approach to measuring fracture toughness and applying it with fracture parameters and the correlative approach of using qualitative fracture data and empirical correlation graphs plays an important role in designing for safety and reliability.

### Dynamic Tear Tests

Many metals and alloys, especially at lower strength levels are too tough and too ductile to fracture under plane-strain conditions in the sizes normally used in structures. In an effort to obtain reliable values of fracture toughness of ductile metals and alloys, the Naval Research Laboratory introduced the dynamic tear (DT) test. This test is intended to evaluate metals and alloys over a wider range of fracture toughness than can other fracture-toughness tests. Correlation of DT toughness and  $K_{Ic}$  toughness has been published (Ref 25).

The standard DT-test specimen is similar to the Charpy specimen, but has greater depth and has a proportionately deeper notch, which is sharpened by a pressed knife edge. The DT-test specimen is broken by impact opposite the notch in a manner similar to the Charpy specimen, and the energy not absorbed is measured by the swing of the pendulum, if this type of machine is used, or by deformation of lead or aluminum plates if a drop-weight machine is used. Details on DT testing of metallic materials can be found in ASTM E 604 (Ref 26) and in Ref 27.

The DT test is a 1964 modification of the NRL drop-weight tear test (DWTT), which originally had a deep, sharp crack introduced by an electron-beam weld, rather than a notch. A different modification of the DWTT was introduced in 1963 by Battelle Memorial Institute. The Battelle DWTT, described in ASTM E 436 (Ref 28), uses a shallow notch pressed by

a sharp chisel edge, rather than a deep crack or notch. In the Battelle DWTT, only the fracture appearance is recorded, while in the DT test, the energy to fracture the specimen is recorded.

**Ratio-Analysis Diagram (RAD).** From consideration of fracture mechanics and plastic-flow properties, and from numerous measurements, a RAD can be constructed to represent many of the conditions relating to material selection for fracture control. The conception and development of this tool has been discussed (Ref 29). Simplified versions of RADs for steels, aluminum alloys, and titanium alloys originally presented in Ref 29 are given here in Fig. 17, 18, and 19. On the ordinate scales are values of DT energy and values of  $K_{Ic}$  that correspond to the DT values. The  $K_{Ic}$  scale is extended to the point corresponding to a 1-to-1 ratio of  $K_{Ic}$  to  $\sigma_{YS}$  (yield strength) for the best alloy of those to be considered. Sloping lines representing various ratios of  $K_{Ic}$  to  $\sigma_{YS}$  are drawn. By the equations of fracture mechanics, these ratios can be related to the critical flaw (crack) depth expected to initiate fracture in a plate of a particular thickness. Each sloping line is applicable to a certain critical thickness. Such a line can be constructed by plotting values of toughness versus yield strength for each alloy being considered for a design. If the thickness in the design is less than the critical thickness denoted by the sloping line, crack tips in the part will not be stressed under plane-strain conditions and either elastic-plastic or gross-yielding behavior can be expected. If design thickness is greater than critical thickness, the part can sustain even greater crack-tip stress intensity before crack extension will begin.

Because the modulus of elasticity is implicit in the relations between  $K_{Ic}$  and crack size, different diagrams are required for steel, aluminum alloys, and titanium alloys. Furthermore, at a given yield strength, different alloys have different fracture-toughness levels. Consequently, the diagrams may be divided into quality corridors based on test results for alloys with high, intermediate, and low toughness. With a RAD, it is then possible to guide the selection of alloys and working yield strengths so as to place the metal in either the ductile regime or the fracture mechanics regime, as may be appropriate for the cost or risk involved. Results obtained in DT tests extend fracture analysis beyond the linear-elastic fracture mechanics range.

### Charpy and Dynamic Toughness

**Correlations of Charpy Toughness with Fracture Toughness.** Several empirical attempts have tried to correlate the Charpy impact energy with  $K_{Ic}$  to allow a quantitative assessment of critical flaw size and permissible stress levels. Most

of these correlations are dimensionally incompatible, ignore differences between the two measures of toughness (in particular, loading rate and notch acuity), and are valid only for limited types of materials and ranges of data. Additionally, these correlations can be widely scattered. However, some correlations can provide a useful guide to estimating fracture toughness; for example, some design criteria for nuclear pressure vessel and bridge steels are partially based on such correlative procedures (Ref 30, 31).

Some of the more common correlations are listed in Table 2 with appropriate units. Note that some of the correlations attempt to eliminate the effects of loading rate; the dynamic fracture toughness,  $K_{Id}$ , is correlated with Charpy energy.

1.0 ksi = 6.8948 MPa; 1.0 ksi  $\sqrt{\text{in}} = 1.099 \text{ MPa} \sqrt{\text{m}}$  ; 1.0 ft · lbf = 1.356 J. Note: CVN is the designation for Charpy impact energy;

$\sigma_y$  is the yield stress; and  $E$  is the Young's modulus.

Other attempts have been made to improve and explain some of the correlations (see, for example, Ref 39). A study has also been conducted using a portion of the Charpy energy to separate initiation and propagation components in the Charpy test (Ref 40). The results from this study for an upper shelf  $J_{Ic}$  correlation for pressure vessel steels were not significantly better than the Rolfe-Novak correlation listed in Table 2. A statistically based correlation for lower bound toughness has been developed for pressure vessel steels (Ref 41, 42), which may eventually replace the ASME  $K_{IR}$  curve described previously. Thus, simple and empirical correlations can be used as general guidelines for estimating  $K_{Ic}$  or  $K_{Id}$  within the limits of the specific correlation. Correlations using sharp-notch Charpy specimens have also been made and are discussed in *ASM Handbook*, Volume 8, *Mechanical Testing* (1985).

## Instrumented Impact Testing

An instrumented-impact test is a modification of the Charpy test (and other impact tests) that allows recording of load and energy versus time, which correlates with deflection. From the record of load versus deflection, it is possible to determine the elastic portion of the stress-strain curve, the onset of crack extension, the energy for crack initiation, and the energy for crack propagation. With use of the instrumented impact test on precracked specimens, values of  $K_{Id}$  may be obtained under the same restrictions and in a similar manner as valid  $K_{Ic}$  values.

**Instrumented Charpy Impact Test.** The use of additional instrumentation with a standard Charpy impact machine allows augmented monitoring of the analog load/time response of Charpy V-notch specimen deformation and fracturing. The primary advantage of instrumenting the Charpy test is the additional information obtained while maintaining low cost, small specimens, and simple operation. The most commonly used approach is application of strain gages to the striker to sense the load-time behavior of the test specimen.

One of the primary reasons for the development of the instrumented Charpy test was to apply existing notch bend theories (slow bend) to the dynamic three-point bend Charpy impact test. Obtaining load information during the standard Charpy V-notch impact test establishes a relationship between metallurgical fracture parameters and the transition temperature approach for assessing fracture behavior (Ref 43).

Interest in instrumented impact testing has expanded to include testing of different types of specimens (precracked, large bend), variations in test techniques (low blow, full-size components), and testing of many different materials (plastics, composites, aerospace materials, ceramics, etc.). The rapid growth in the application of instrumented impact testing has produced a correspondingly large demand for standardized test methods. However, no standard currently exists for instrumented Charpy testing. Typical dynamic fracture toughness of a structural steel is shown in Fig. 20.

**FIG. 20** COMPARISON OF STATIC ( $K_{Ic}$ ), DYNAMIC ( $K_{Id}$ ), AND DYNAMIC-INSTRUMENTED ( $K_{Idi}$ ) IMPACT FRACTURE TOUGHNESS OF PRECRACKED SPECIMENS OF ASTM A533, GRADE B, STEEL, AS A FUNCTION OF TEST TEMPERATURE. THE STRESS-INTENSITY RATE WAS ABOUT  $1.098 \times 10^4 \text{ MPA } \sqrt{\text{m}} \cdot \text{S}^{-1}$  ( $10^4 \text{ KSI } \sqrt{\text{in.}} \cdot \text{S}^{-1}$ ) FOR THE DYNAMIC TESTS AND ABOUT  $1.098 \times 10^6 \text{ MPA } \sqrt{\text{m}} \cdot \text{S}^{-1}$  ( $10^6 \text{ KSI } \sqrt{\text{in.}} \cdot \text{S}^{-1}$ ) FOR THE DYNAMIC-INSTRUMENTED TESTS. SOURCE: *FRACTURE CONTROL AND PREVENTION, USE OF PRECRACKED CHARPY*

**General Test Requirements.** The International Institute of Welding first attempted to standardize the instrumented Charpy test, but concluded that the test was not sufficiently documented, and the effort was discontinued (Ref 44). A few years later, two significant events prompted serious consideration of standardization. The development of the  $K_{IR}$  curve by the Pressure Vessel Research Committee and its inclusion in the ASME Code, Section III, created the need for dynamic initiation toughness,  $K_{Id}$ , data. The formation of an ASTM Task Group (E24.03.03) to standardize precracked Charpy testing also encouraged standardization.

Simultaneously, two other related groups began formulating procedures and conducting interlaboratory round robins. A Pressure Vessel Research Committee/Metals Property Council Task Group on Fracture Toughness Properties for Nuclear Components developed procedures for measuring  $K_{Id}$  values from precracked Charpy specimens (Ref 45). Also, the Electric Power Research Institute (EPRI) funded work to develop the "EPRI Procedures" (Ref 46). Currently, only subtle differences exist between the two sets of procedures (Ref 47).

**Precracked Charpy Test.** By inducing a fatigue precrack in the Charpy specimen, the notch acuity and depth restrictions are eliminated. Early work concentrated on correlations with fracture toughness using only the total absorbed energy (i.e., uninstrumented testing). These energy values usually are normalized per unit area below the fatigue crack; the normalized energy values are designated as  $W/A$ .

Most of the correlations of  $W/A$  with fracture toughness have been conducted using slow-bend specimens. The basic problem in reaching an impact correlation is the difference in loading rates between the Charpy impact and the static  $K_{Ic}$  tests, particularly for loading rate sensitive materials (Ref 48). A general trend exists for a correlation between  $K_{Ic}^2/E$  and  $W/A$ , but the limited data and scatter make this difficult to utilize (Ref 38). A better correlation with  $K_{Id}$  may be possible. The reason for using  $K_{Ic}^2/E$  as the basis is the approximate proportionality between  $K_{Ic}^2/E$  and  $W/A$ , based on a presumed fracture mechanics relationship (Ref 48).

The precracked Charpy  $W/A$  values can also be used to estimate the nil-ductility transition temperature. The typical technique defines an inflection point between lower shelf and transition region behavior as the estimated nil-ductility transition temperature (Ref 49). Some exceptions have been noted to this approach (Ref 50).

The types of data and test techniques used for instrumented precracked Charpy testing are the same as those for instrumented Charpy impact testing. The greatest advantage of precracking is the transformation of the Charpy V-notch specimen into a dynamic fracture mechanics test piece. The direct calculation of fracture toughness (within certain limitations) is now possible using the instrumented load-time information. See, for example, the calculation of fracture toughness of ferritic steels from precracked Charpy specimens (Ref 51).

## Time-to-Fracture Tests

Interpretation of load-time records obtained in instrumented impact tests with precracked Charpy specimens can be difficult, particularly when the early time range is considered. This difficulty and the use of a quasi-static evaluation procedure for determining the dynamic impact fracture toughness  $K_{Id}$  restricts the range of applicability of the test. To achieve sufficiently small times-to-fracture, the impact velocity must be limited. The maximum allowable velocity depends on the toughness of the material to be tested. These difficulties and restrictions are overcome by applying the concept of impact response curves for measurement of the impact fracture toughness  $K_{Id}$  (Ref 52, 53, 54).

The technique of measuring impact fracture toughness,  $K_{Id}$  with impact response curves and time-to-fracture measurements has several advantages over the conventional quasi-static technique described previously in this article in the section on precracked Charpy testing. The impact response curve technique represents a fully dynamic evaluation. Kinetic effects are correctly accounted for during the entire impact event. The method can thus be applied to all experimental test conditions, particularly in the short time-to-fracture range, i.e., when high impact velocities are used or brittle materials are tested.

This method does not require a calibrated instrumentation of the hammer, which is usually a prerequisite in impact experiments designed to determine the load at crack initiation. The data-measuring procedure consists of two separate

tasks: determination of the impact response curve and the measurement of the time-to-fracture. The more complicated determination of the impact response curve need only be carried out once.

The time-to-fracture of a precracked Charpy specimen subjected to impact loading can be obtained from signals of two uncalibrated strain gages, one of which is located on the top of the striking hammer and the other on the specimen to the side of the crack tip. The leading edge of the signal from the hammer strain gage marks the beginning of the impact event. The onset of crack propagation, on the other hand, is indicated by the rapid drop in load registered by the crack tip strain gage. The time-to-fracture,  $t_f$ , is the interval between the two signals. Typical oscillograms of time-to-fracture measurements are shown in Fig. 21. Typical data results are shown in Fig. 22.

## Concepts of Fracture Control and Damage Tolerance Analysis

David Broek, FractuREsearch

---

### Introduction

FRACTURE CONTROL is the concerted effort to ensure safe operations without catastrophic failure by fracture. Very seldom does a fracture occur due to an unforeseen overload on the undamaged structure. Fractures are usually the end result of crack growth from a small defect or flaw. Due to repeated or sustained "normal" service loads, a crack may develop (starting from a flaw or stress concentration) and slowly grow in size. Cracks and defects impair the strength of the component. Thus, during the continuing development of the crack, the structural strength decreases until it becomes so low that the service loads cannot be carried any more, and fracture ensues.

If fracture is to be prevented, the strength should not drop below a certain safe value. This means that cracks must be prevented from growing to a size at which the strength would drop below an acceptable limit. In order to determine which size of crack is admissible, one must be able to calculate how the structural strength is affected by cracks (as a function of their size), and in order to determine the safe operational life, one must be able to calculate the time in which a crack grows to the permissible size. Damage tolerance analysis is used to obtain this information.

Damage tolerance is the property of a structure to sustain defects or cracks safely, until such time that action is (or can be) taken to eliminate the cracks by repair or by replacing the cracked structure or component. In the design stage, one still has the options to select a more crack-resistant material or improve the structural design to ensure that cracks will not become dangerous during the projected economic service life. Alternatively, periodic inspections may be scheduled, so that cracks can be repaired or components replaced when cracks are detected. Either the time to retirement (replacement) or the inspection interval and type of inspection must follow from the crack growth time calculated in the damage tolerance analysis.

Inspections can be performed by means of any nondestructive inspection technique, but destructive techniques such as proof testing are essentially inspections. If a burst occurs during hydrostatic testing of a pipe line, for example, then there was apparently a crack of sufficient size to cause the burst. The proof test detects defects above a certain size under controlled circumstances (e.g., with water pressure) to prevent catastrophic failure during operation when the line is filled with oil or gas.

Fracture control is a systematic process to prevent fracture during operation. The extent of the fracture control measures depends on the criticality of the component, the economic consequences of the structure's being out of service, and the damage that would be caused by a fracture failure. Fracture control of a hammer may be as simple as selecting a material with sufficient fracture resistance. Fracture control of an airplane includes damage tolerance analysis, tests, and subsequent inspection and repair/replacement plans. Inspections, repairs, and replacements must be scheduled rationally using the information from the damage tolerance analysis.

The mathematical tool employed in damage tolerance analysis is fracture mechanics; it provides the concepts and equations used to determine how cracks grow and affect the strength of a structure. Acclaimed inaccuracies are due to inaccurate inputs much more often than to inadequacy of the concepts. Although further improvements of fracture mechanics concepts may well be desirable from a fundamental point of view, it is unlikely that damage tolerance analysis can be much improved, as its accuracy is determined mostly by assumptions and (predicted) loads and stresses. Therefore, the accuracy of all assumptions and input data must be clearly understood and identified, and the results of damage tolerance analysis must be used judiciously by engineers. In this context, damage tolerance analysis can give useful answers to questions that hitherto could not be answered at all. The answers may only be preliminary, but a reasonable answer is better than none. This and the following article describe the key principles and practical guidelines to obtain useful and reasonable answers from damage tolerance analysis.

## Concepts of Fracture Control and Damage Tolerance Analysis

David Broek, FractuREsearch

---

### Principles of Fracture Control

Establishment of a fracture control plan requires knowledge of the structural strength as it is affected by cracks, and knowledge of the time involved for cracks to grow to the permissible size. Thus, damage tolerance analysis has two objectives, namely, to determine:

- THE EFFECT OF CRACKS ON STRENGTH (MARGIN AGAINST FRACTURE)
- THE CRACK GROWTH AS A FUNCTION OF TIME

Figure 1 shows the effect of crack size on strength, where the strength is expressed in terms of the load,  $P$ , the structure can carry before fracture occurs (fracture load). Supposing that a new structure has no significant defects ( $a = 0$ ), then the strength of the structure is the design strength ( $P_0$ ).

**FIG. 1 RESIDUAL STRENGTH DIAGRAM IN TERMS OF LOAD (OR FORCE).  $J$ , DESIGN SAFETY FACTOR;  $G$ , SAFETY FACTOR BASED ON RESIDUAL STRENGTH**

In every design a safety factor is used. This factor may be applied in different ways. Usually the safety factor is applied to load. For example, if the maximum anticipated service load is  $P_s$ , the structure is actually designed to sustain  $j \cdot P_s = P_u$ , where  $j$  is the safety factor. The designer sizes the structure in such a manner that the stress is equal to, or slightly less than, the tensile strength when the load is  $P_u$ . Alternatively, the safety factor can be applied to the allowable stress: if the actual material strength (tensile strength) is  $F_{tu}$ , the structure is sized in such a way that the stress at the highest service load,  $P_s$ , is less than or equal to  $F_{tu}/j$ . Because load and stress are usually proportional, the structural part is actually capable of carrying  $j \cdot P_s = P_u$ . The value of  $j$  is between 3 (many civil engineering structures) and 1.5 (aircraft).

It is emphasized that  $P_s$  is the highest service load. If the service load varies, the load may well be much less than  $P_s$  most of the time. For example, the loads on cranes, bridges, off-shore structures, ships, and airplanes are usually much less than  $P_s$ . Only in exceptional circumstances does the load reach  $P_s$ . At other times the load is only a fraction of  $P_s$ , so that the margin against failure is much larger than  $j$ , except in extreme situations.

The new structure has a strength  $P_u$ . If the load should reach  $P_u$  the structure fails. The probability of this occurring is not zero, but experience has shown that it is acceptably low if the prescribed safety factor is adhered to. If cracks are present, the strength is less than  $P_u$ . This remaining strength under the presence of cracks is generally referred to as the *residual strength* ( $P_{res}$ ). Therefore, the diagram in Fig. 1 is called the residual strength diagram. With a residual strength  $P_{res} < P_u$  the safety factor has decreased to  $j = P_{res}/P_s$ , which is less than  $j = P_u/P_s$ . In concert, the probability of fracture failure has become higher.

With a crack of size  $a$ , the residual strength is  $P_{res}$ . Should a load  $P = P_{res}$  occur, then fracture takes place. If a load  $P_{res}$  does not occur and service loading continues at lower loads, the crack may continue to grow by fatigue. If continued crack growth occurs, then the residual strength decreases further. If nothing is done, fracture will eventually occur under normal service loads. This is what must be prevented.

The above discussion implies that the limit should be set somewhat above  $P_s$ . For example, one may require that the residual strength never be less than  $P_p = g \cdot P_s$ , where  $g$  is the remaining safety factor and  $P_p$  is the minimum permissible residual strength. The design engineer (or user) does not usually decide what should be the initial safety factor  $j$ . The factor is prescribed by rules and regulations issued by engineering societies (e.g., ASME) or government authorities (e.g., FAA, DoD). These rules or requirements should also prescribe  $g$ . This has not been done for all types of structures yet, and the ASME code, for example, approaches the problem somewhat differently (see the section "Damage Tolerance Requirements" in this article).

Provided that the shape of the residual strength diagram is known and  $P_p$  has been prescribed, the maximum permissible crack size follows from the diagram. In order for damage tolerance analysis to determine the largest permissible crack, the first objective must be the calculation of the residual strength diagram of Fig. 1. If  $a_p$  can be calculated directly from  $P_p$  it may not be necessary to calculate the entire residual strength diagram, but only the point  $(a_p, P_p)$ . However, this is seldom possible and rarely time saving. In general, calculation of the entire diagram is preferable. The residual strength diagram will be different for different components of a structure and for different crack locations; permissible crack sizes will be different as well.

Knowing that the crack may not exceed  $a_p$  is of little help, unless it is known when the crack may reach  $a_p$ . The second objective of the damage tolerance analysis is then the calculation of the crack growth curve, shown diagrammatically in Fig. 2. Under the action of normal service loading the cracks grow by fatigue at an ever faster rate, leading to the convex curve shown in Fig. 2.

**FIG. 2 GENERAL CRACK GROWTH CURVE SHOWING TIME INTERVAL,  $H$ , TO REACH MAXIMUM PERMISSIBLE CRACK SIZE,  $A_p$**

Starting at some crack size  $a_0$  the crack grows to  $a_p$ . Provided that one can calculate the curve in Fig. 2, one obtains the time  $H$  of safe operation (until  $a_p$  is reached). If  $a_0$  is for example an (assumed or real) initial defect, then the component or structure must be repaired or replaced after a time  $H$ . Alternatively,  $a_0$  may be the limit of crack detection by inspection. This crack  $a_0$  will grow to  $a_p$  within a time of  $H$ . Because crack growth is not allowed beyond  $a_p$ , the crack must be detected and repaired or otherwise eliminated before the time  $H$  has expired. Therefore, the time between inspections must be less than  $H$ ; it is often taken as  $H/2$ . In any case, the time of safe operation by whatever means of fracture control follows from  $H$ .

---

## Concepts of Fracture Control and Damage Tolerance Analysis

David Broek, FractuREsearch

---

## Concepts of Damage Tolerance Analysis

Before any fracture control can be exercised, the residual strength diagram of Fig. 1 and the crack growth curve of Fig. 2 must be calculated. Although crack growth may occur by other mechanisms than fatigue (e.g., stress corrosion, creep, etc.), the discussion in this section will be limited to fatigue crack growth.

The first step in damage tolerance analysis is the calculation of  $a_p$ , or rather, of the residual strength diagram. Usually, the residual strength diagram is expressed in terms of stress rather than load, as in Fig. 3(a). Different fracture criteria may apply ( $K$ ,  $J$ , or others), depending on the material used for the structure, so the calculations of the residual strength diagram are dealt with in detail in a separate article, "Residual Strength of Metal Structures." For the purpose of this discussion, an analysis based on  $K$  is sufficient.

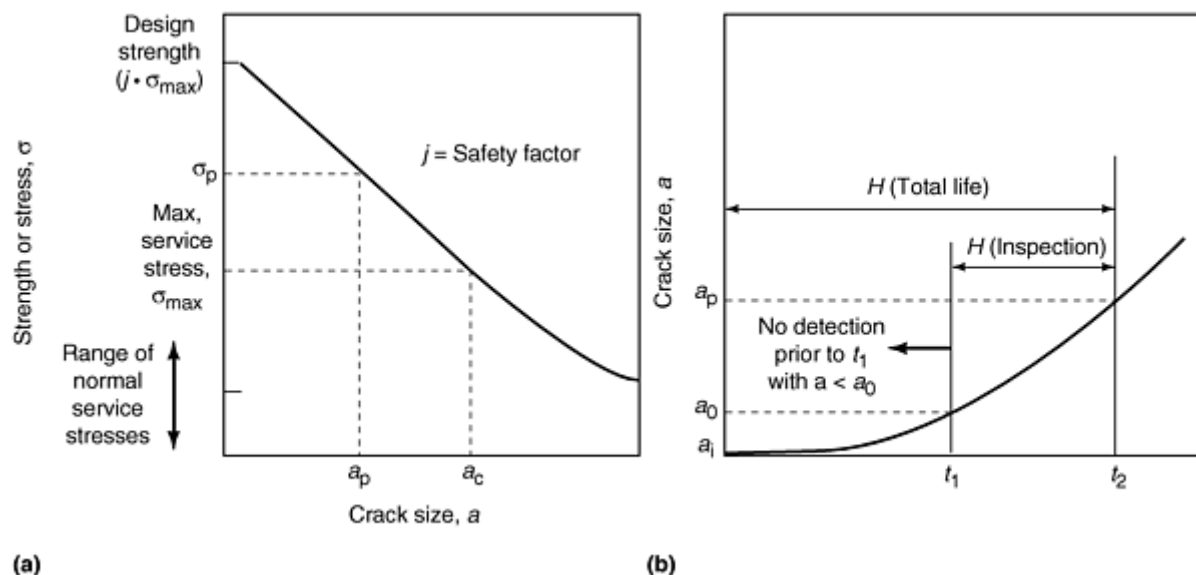

FIG. 3 KEY PARAMETERS FOR FRACTURE CONTROL. (A) RESIDUAL STRENGTH IN TERMS OF STRESS. (B) CRACK GROWTH AND TIME PERIOD WHEN INSPECTION CAN BE PERFORMED

Using  $K$ , the residual strength,  $\sigma_c$ , follows from:

$$\sigma_c = K_c \beta \sqrt{\pi a} \quad (\text{EQ 1})$$

where  $K_c$  is the toughness of the material,  $\beta$  is the geometry factor defined by the details of the structure, and  $a$  is the crack size. Given the toughness,  $K_c$ , a residual strength diagram can be calculated easily by taking different values of  $a$  and calculating  $\sigma_c$ . This calculation is adequate if  $\sigma_c$  is sufficiently below yield stresses. For high stresses (as  $a$  approaches zero), the criterion of plastic collapse must be introduced (see "Residual Strength of Metal Structures"). Once the diagram is established, the permissible crack size  $a_p$  can be read from the resulting diagram (plot) for the required  $\sigma_p$  (Fig. 3a).

The second step is to calculate the crack growth curve (discussed in detail in the article "The Practice of Damage Tolerance Analysis" in this Volume). The rate of crack growth is a function ( $f$ ) of  $\Delta K$  and  $R$  (the stress ratio) such that:

$$DA/DN = F(\Delta K, R) \quad (\text{EQ 2})$$

The precise nature of  $f$  (such as the Paris law or the Forman equation) is discussed elsewhere in this Volume. The problem is to obtain the crack growth curve ( $a$  vs.  $N$ ) by integration of Eq 2, *fatigue crack growth rates* as follows:

$$N = \int_{a_0}^{a_p} DA/F(\Delta K, R) \quad (\text{EQ 3})$$

where  $\Delta K = \beta \Delta \sigma \sqrt{\pi a}$ , and where  $\beta$  reflects the geometry of the particular structural detail. In the general case, solution of Eq 3 can be accomplished only by numerical integration performed by a computer. (Details are provided in the article

"The Practice of Damage Tolerance Analysis" in this Volume.) For the purpose of the present discussion we shall assume that the resulting crack growth curve (Fig. 3b) can be so obtained.

Once the two curves are known, decisions on how to exercise fracture control can be made in accordance with the foregoing. The residual strength analysis provides the permissible crack size,  $a_p$ , and the crack growth analysis provides the value of  $H$ , the time available to exercise fracture control.

---

## Concepts of Fracture Control and Damage Tolerance Analysis

David Broek, FractuREsearch

---

### Fracture Control Measures

When the residual strength diagram has been calculated (Fig. 3a), the maximum permissible crack size  $a_p$  follows from the minimum permissible residual strength. The other information from analysis is the crack propagation curve. It shows how a crack develops by fatigue as a function of time. The maximum permissible crack  $a_p$ , following from the residual strength analysis of Fig. 3(a), can be plotted on the calculated crack growth curve as in Fig. 3(b).

There are several ways in which this information can be used to exercise fracture control. In all cases, the time period  $H$  is the essential information needed. The following options are available for the implementation of fracture control:

- PERIODIC INSPECTION
- FAIL-SAFE FEATURES
- DURABILITY DESIGN OR MANDATED RETIREMENT (SAFE-LIFE APPROACH)
- PERIODIC (DESTRUCTIVE) INSPECTION BY PROOF TESTING; REPAIR AFTER FAILURE IN PROOF TEST (IF FEASIBLE)

Damage tolerance requirements sometimes prescribe the fracture control procedure. For example, commercial aircraft requirements prescribe nondestructive periodic inspection.

**Periodic Inspection.** Safety is ensured when cracks are eliminated before reaching  $a_p$ . Therefore, cracks must be discovered before that point by means of periodic inspection. Whatever the inspection method, there is a certain size of crack,  $a_0$ , that is not likely to be detected. This implies that discovery and repair must occur in between  $a_0$  and  $a_p$  as shown in Fig. 3(b). For any inspection done before or at time  $t_1$ , the crack will be missed; should the next inspection be at  $t_2$ , the crack would already be too long (having reached  $a_p$ ). Hence, the inspection interval,  $I$ , must be shorter than  $H$  (inspection)  $= t_2 - t_1$ . It is often taken as  $I = H/2$ , but a more rational procedure to determine inspection intervals can be employed. Naturally, a crack once discovered must be repaired at the operator's earliest convenience. Because  $a_p$  is a permissible and not a critical crack, and because detection commonly occurs at sizes less than  $a_p$ , immediate repair may not be necessary, but any complacency will defy all analysis and inspection efforts.

Regardless of how long or short the inspection interval, safety is maintained with some reservation. Whether inspections must be performed every day (i.e.,  $I = 1$  and  $H = 2$  days) or every year (i.e.,  $I = 1$  and  $H = 2$  years), there would always be two inspections between  $a_0$  and  $a_p$ . Although a daily inspection may be cumbersome, the achieved safety is not really different in the cases of daily or yearly inspections. If a crack is missed in daily inspections, a potential fracture will occur sooner, but if a crack is missed in yearly inspections, fracture will occur nonetheless before the year is over. If short inspection intervals are undesirable, one has the option of selecting a more refined inspection procedure with a smaller  $a_0$ . Then  $H$ , and hence the inspection intervals, will be longer.

It does not matter either at which time the crack initiates (Fig. 4). Inspections scheduled at an  $H/2$  interval will always give two opportunities for detection, regardless of when crack growth begins, provided that inspections are scheduled at  $H/2$  intervals starting from hour zero (even if initially the chance of a crack is small). Similarly, if the interval is chosen as  $H/3$ , there will always be three inspections between  $a_0$  and  $a_p$ .

FIG. 4 TWO POSSIBILITIES FOR CRACK DETECTION WITH  $H/2$ , REGARDLESS OF WHEN CRACK STARTS

**Fail safety** (in the context of fracture control and damage tolerance) is essentially a variation of fracture control by periodic inspection: cracks or failed members must be detected and repaired. The only difference is that the structure is designed to tolerate more damage than that which is observed. Fail safety can be achieved by means of crack arresters or multiple load paths.

For example, crack arresters are designed specifically to prevent an advancing crack from reaching critical crack size. Alternatively, a pipeline or pressure vessel can be designed so that cracks will cause leaks rather than breaks (see "Leak-Before Break" in the article "Operating Stress Maps for Failure Control"). Because a leak is presumably obvious, no special inspections are necessary other than frequent checks for leaks. The same can be accomplished by providing multiple load paths (e.g., parallel redundant members). When properly designed, the structure can still sustain  $\sigma_p$  when one member fails. Inspection for cracks would not be required, but regular checks for failed members would be. Of course, member failure must be obvious, because a second member will soon develop cracks when it must carry additional load.

**Durability (or Safe-Life) Fracture Control.** A safe-life approach to fracture control is applied to structures with hard-to-detect cracks (e.g., inaccessible locations) or when "initial" crack size limits are below inspectability thresholds. If no inspections can or will be done, a small initial crack ( $a_i$ ) could be assumed to exist initially in the new structure. The time,  $H$ , for the crack to grow from  $a_i$  to  $a_p$  is then the available safe life. In that case the structure or component must be retired or replaced after, for example,  $H/2$  hours. This is called the durability approach.

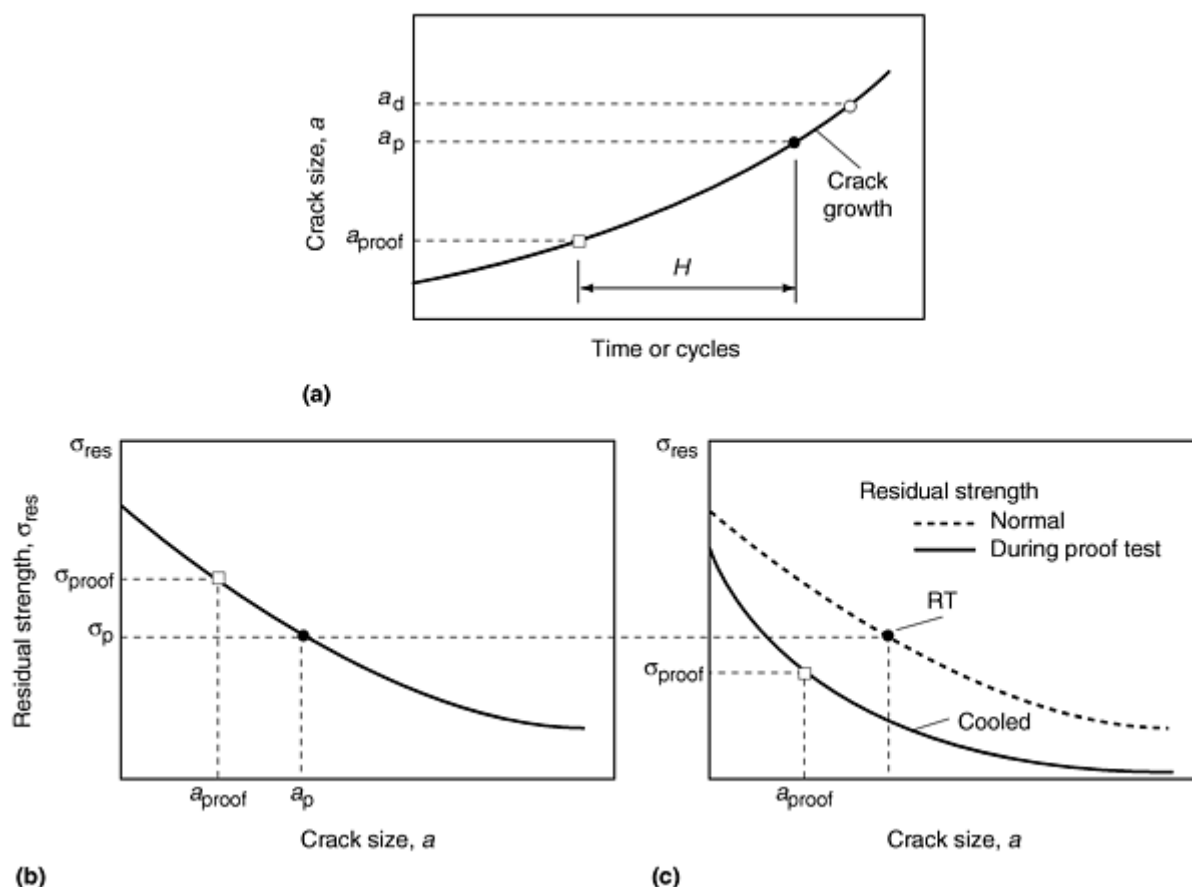

A durability analysis (based on  $S-N$  data) and/or tests are used to establish a "design life." To account for scatter or uncertainties in the operating conditions, retirement or replacement are then mandated at fraction (e.g.,  $\frac{1}{5}$  to  $\frac{1}{3}$ ) of that design life. Crack growth and inspection intervals are not involved. The drawbacks of this approach are:

- THE CRITICAL DEPENDENCE ON THE DURABILITY ANALYSIS AND SAFETY FACTOR (WHICH MAY BE INADEQUATE)
- THE HIGH COSTS OF RETIRING COMPONENTS WITHOUT AN OBVIOUS "CAUSE"

Nonetheless, some components (such as landing gear) are designed to safe-life criteria, because cracks are noninspectable (the materials have low toughness) and proof tests are not practical.

Another problem with the durability approach is how the size of  $a_i$  is assumed. The assumption of an initial crack size may be difficult or unclear for high-quality components (that may be essentially defect free). In welded structures the assumption of an initial flaw is more realistic. Welds often contain defects such as porosity or lack of fusion. In particular, the latter is a sharp defect equivalent to a crack of about equal size.

**Destructive Inspection by Proof Testing.** If the toughness is very low, the maximum permissible flaw,  $a_p$ , may be smaller than the detectable crack,  $a_d$  (Fig. 5). This can also be the case when the structure is so large that inspections for cracks are impractical (e.g., a 1000 mile pipeline), so that the "detectable" crack size is effectively infinite. In such situations, proof testing may be another fracture control option.

**FIG. 5 DESTRUCTIVE INSPECTION WITH PROOF TEST. (A) CRACK GROWTH. (B) DETECTION OF CRACKS EQUAL TO OR GREATER THAN PROOF SIZE. (C) LOWER PROOF LOAD WITH COOLING**

As an example, consider a component that is subjected to a proof stress,  $\sigma_{proof}$ . Fracture will occur if a crack  $a_{proof}$  is present, as shown in Fig. 5(b). Conversely, if no fracture occurs, the maximum possible crack is  $a_{proof}$ , so that a safe operational period  $H$  (for growth from  $a_{proof}$  to  $a_p$ ) is ensured. If the proof test is repeated every  $H$  hours, a period of at least  $H$  hours of safe operation is available after each successful proof test. Should failure occur during the proof test (i.e., a crack of size  $a_{proof}$  is detected), then a repair or replacement is made. The life can be extended forever, provided that proof tests are always conducted at the proper interval,  $H$ .

**Pipelines and pressure vessels** are eminently suitable for the proof test approach. A line or vessel normally filled with gas or dangerous chemicals can be proof tested (hydrotested) with water. A failure during the proof test would happen under controlled circumstances, causing a water leak only. In many cases, hydrotests are already performed anyway. Selecting the proof stress level and interval on the basis of fracture mechanics analysis, to calculate  $H$ , would give these a rational foundation.

**Proof tests on structures other than pressurized containers** are often hard to perform. However, if the component can be easily loaded (or easily removed), the option is available and has been exercised (on wing hinges of F-111 aircraft). Cooling the structure or component during the proof test causes a drop in toughness, which permits the use of

lower proof stress to "detect" the same  $a_{proof}$  (as shown in Fig. 5c). After the test and warmup, the original toughness and residual strength are restored.

**The Probability of Missing the Crack.** All information needed to determine  $H$  and the inspection interval can be calculated, except for the detectable crack size. The latter must be obtained from inspection experience, which may be difficult to quantify. The length of the inspection interval (or the time period available for inspection,  $H$ ) also is very sensitive to the (choice of) detectable crack size, because the slope of the crack growth curve is small for small cracks (Fig. 3b). Consequently, an *assumption with regard to the detectable crack size* may have more weight in determining the inspection interval than the painstaking and costly damage tolerance analysis. This is unsatisfactory. A more rational procedure for establishing inspection intervals is desirable.

Detection of cracks larger than the "detectable size" is not a certainty. It is affected by many factors: the skill of the inspector; the specificity of the assignment (e.g., one specific location, as opposed to a whole wing or bridge); the accessibility and viewing angles; exposure (e.g., part of a crack may be hidden behind other structural elements), possible corrosion products inside the crack; and so on. In general, discrimination of flaws depends on detection response levels (or crack size) and the level of the application noise (Fig. 6). Analysis of signal and signal plus noise are common in electronic devices, optics, and other discrimination processes. However, it is important to recognize that the dominant noise source in a nondestructive evaluation (NDE) process is not electronic noise that may be reduced by filtering, multiple sampling, and averaging techniques, but is instead the noise due to nonrelevant signals generated in applying the NDE procedure to a specific hardware element.

FIG. 6 SIGNAL/NOISE DENSITY DISTRIBUTION FOR (A) LARGE, (B) MEDIUM, AND (C) SMALL FLAW SIZE

The outcome from an NDE measurement/decision process needs to be understood as a problem in conditional probability. When an NDE assessment is performed for the purpose of crack detection, the outcome is not a simple accept/reject (binary) process, as is frequently envisioned. It is actually the product of conditional acceptance due to the interdependence of the measurement and decision responses. In general, the four possible outcomes from an inspection process are:

- **TRUE POSITIVE:** A CRACK EXISTS AND IS DETECTED.
- **FALSE POSITIVE:** NO CRACK EXISTS BUT ONE IS IDENTIFIED.
- **FALSE NEGATIVE:** A CRACK EXISTS BUT IS NOT DETECTED.
- **TRUE NEGATIVE:** NO CRACK EXISTS AND NONE IS DETECTED.

Typically, the probability of crack detection depends on crack size in the manner shown in Fig. 7. There is a certain crack size,  $a_0$ , below which detection is physically impossible. For example, for visual inspection this would be determined by the resolution of the eye, or for ultrasonic inspection by the wavelength. In reality,  $a_0$  is larger than these physical limits. The probability of detection is never equal to 1, even for large cracks; any crack may be missed. It follows that the probability curve must have the general form shown in Fig. 7.

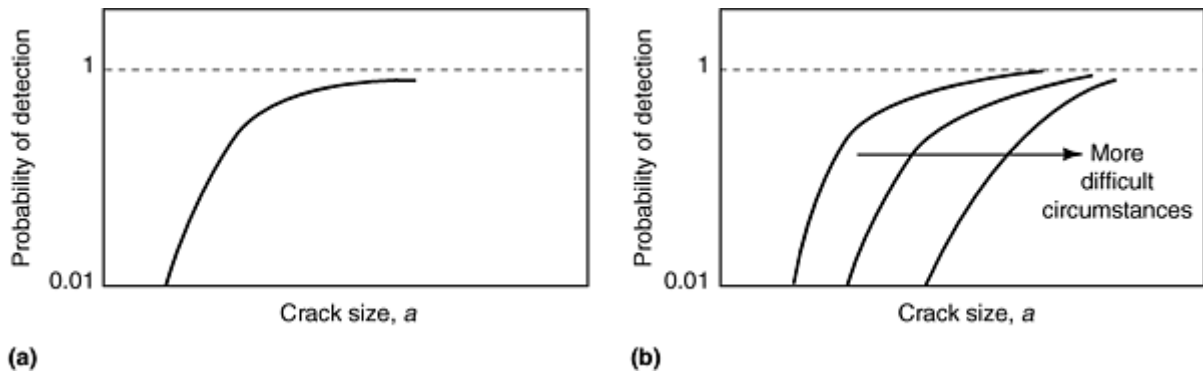

FIG. 7 PROBABILITY OF CRACK DETECTION IN ONE INSPECTION. (A) BASIC CURVE. (B) EFFECT OF ACCESSIBILITY, AND SPECIFICITY, OR OTHER DIFFICULTY FACTOR

A crack is subject to inspection several times before it reaches the permissible size. At successive inspections, the crack will be longer, and the probability of detection higher, but there is still a chance that it will go undetected. Consider 100 cracks growing at equal rate (same population), all in the same stage of growth (same size). Let the probability of detection at a certain inspection be  $p = 0.2$ . The probability that a crack will be missed is then  $q = 1 - p = 0.8$ . That means that 80 cracks will go undetected. At the next inspection the cracks are longer; let the probability of detection then be  $p = 0.6$ , so that  $q = 0.4$ . Thus of the remaining 80 cracks,  $0.4 \times 80 = 32$  cracks will go undetected. Apparently the cumulative probability that a crack will be missed in successive inspection is  $Q = q_1 * q_2 * \dots * q_n$ . In the above example,  $Q = 0.8 \times 0.4 = 0.32$ . Of the 100 cracks, 32 cracks remain undetected after two inspections. The cumulative probability of detection is  $P = 1 - Q$ . In the above example,  $P = 0.68$ . Of the 100 cracks, 68 were detected after two inspections, but 32 were missed.

Figure 8 shows what happens if inspection intervals are determined as  $I = H/2$ , where  $H$  is the time required for crack growth from  $a_d$  to  $a_p$ . The detectable crack size,  $a_d$ , might be selected as a crack with a certain probability of detection. For example, the detectable crack size could be defined as  $a_{50}$ , a crack with 50% probability of detection. Such a criterion certainly has appeal, because it seems consistent, yet it still leads to inconsistencies.

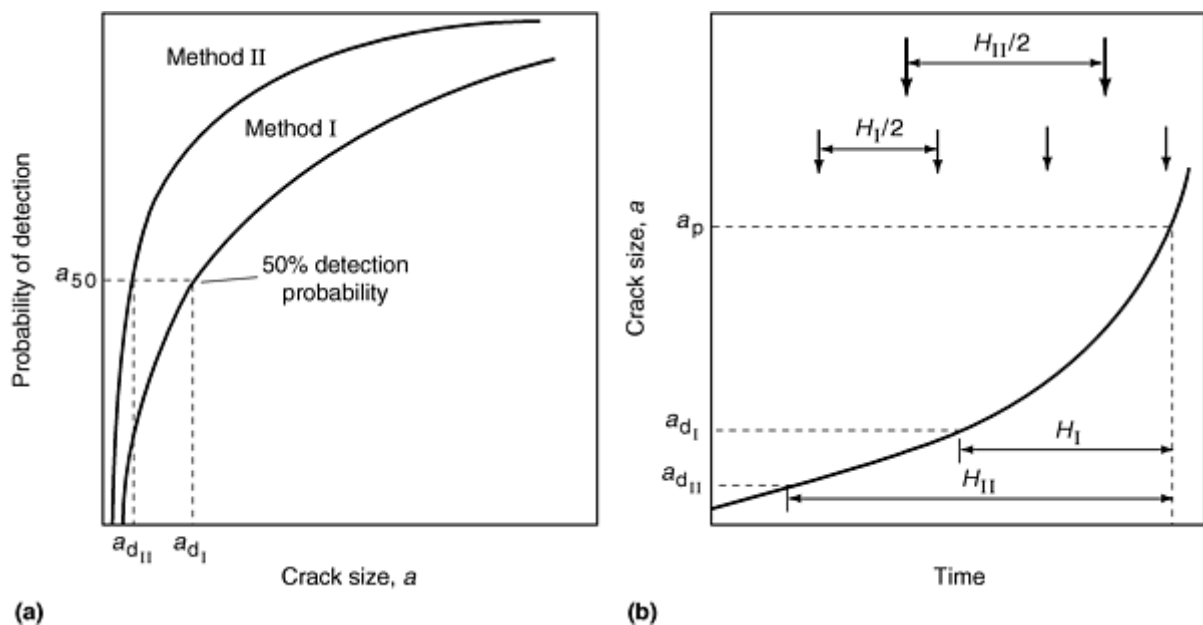

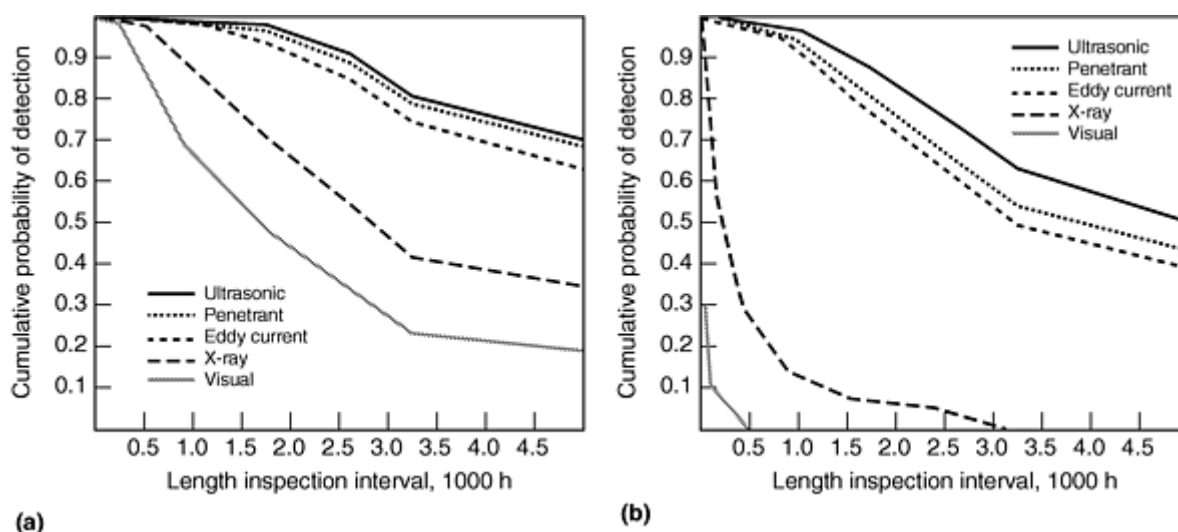

FIG. 8 INSPECTION INTERVALS BASED ON  $H/2$ . (A) PROBABILITY OF DETECTION FOR TWO INSPECTION METHODS. (B) INSPECTION TIMES ON CRACK GROWTH CURVE

For the case of Fig. 8 either method I or method II could be prescribed. The detectable crack sizes,  $a_{50}$ , lead to different inspection intervals,  $H_I/2$  and  $H_{II}/2$ . Inspections would take place as indicated by arrows in Fig. 8(b). The two methods would be equivalent but certainly do not provide equal probability of detection, which is unsatisfactory. The probability-of-detection curves are different for the two procedures in Fig. 8. The cracks would be inspected for the first time when they still have a size smaller than  $a_{50}$ . At this first inspection, the probability of detection is not zero (unless  $a < a_0$ ). There is a distinct probability,  $p_1$ , that the crack is already detected during that first inspection; the probability that it is missed is  $q_1 = 1 - p_1$ . At the next inspection the crack is larger, and the probability of detection is  $q_2$ , and so forth. By the time the crack reaches  $a_p$ , it has been inspected  $n$  times. The cumulative probability of the crack having been detected at any one of these inspections can be calculated as in the example above.

The length of the inspection interval can be established so as to provide a consistent safety level (cumulative probability of detection), independent of the shape of the crack growth curve, the accessibility, and the specificity of the inspection. The target cumulative probability of detection could be set, for example, at 95 or 98% and be specified in damage tolerance requirements. Given the calculated crack growth curve, the permissible crack size, and the probability of detection for the relevant specificity and accessibility, the cumulative probability of detection can be calculated for different lengths of the inspection interval. When the results are plotted, the interval for the desirable probability of detection can be obtained from the curve (Fig. 9). The interval will be different for different inspection methods, crack growth curves, accessibility, and specificity, but the cumulative probability of detection is always the same (equal safety). The problems with  $H/2$  are then eliminated automatically (Ref 1, 2, 3, 4).

**FIG. 9 CUMULATIVE PROBABILITY OF CRACK DETECTION AS A FUNCTION OF THE LENGTH OF THE INSPECTION INTERVAL. (A) CASE 1 OF FIG. 10. (B) CASE 2 OF FIG. 10**

A computer can perform the calculation for different interval lengths (Ref 5), provided that the crack growth curve calculated in the damage tolerance analysis and the applicable inspection parameters to the probability of detection curve are provided as input. Typical computer results are shown in Fig. 9(a) and 9(b) for the two crack propagation curves in Fig. 10. The criterion  $I = H/2$  would assign the same inspection interval to both cracks. This would lead to different cumulative probabilities of detection for case 1 and case 2. In order to ensure the same probability in both cases, the intervals must be shorter in case 2. Although refinements can be made, the above provides a rational procedure to establish inspection intervals for which the probability of detection is independent of the inspection technique, the crack growth curve, and the assignment. The procedure is finding acceptance in the aircraft industry.

FIG. 10 TWO HYPOTHETICAL CRACK GROWTH CURVES USED IN FIG. 9

### Fracture Control Plans

The optimum fracture control plan depends on the consequences of a fracture. If the number of fractures experienced is considered to be an acceptable level with a certain fracture control plan at acceptable costs, the plan is close to optimum. Before implementation of a fracture control program, the objectives must be identified. If a structure can sustain assumed damage under an assumed loading condition, it is not necessarily safe, despite all analysis. Before defining the permissible residual strength or permissible crack size, the desired level of safety should be established, even if only qualitatively. It will appear that every component and structure calls for different fracture control requirements.

Fracture control measures must be in accordance with the acceptable risk. On the basis of rules and regulations issued by governments or engineering societies, the designer or manufacturer prescribes the details of the fracture control plan and the operator implements this plan through maintenance, inspection, repair, or replacement. The plan must be suitable for a particular structure and for the potential operators. Professional operators of pressure vessels, airplanes, and the like can implement more complex fracture control measures than the general public operating automobiles. Here the concern is with those cases where materials selection alone does not provide adequate safeguards against fractures. Table 1 provides conceptual control plans for a variety of circumstances.

**TABLE 1 FRACTURE CONTROL PLANS**

PLAN	CONDITION	FRACTURE CONTROL METHODS
<b>PLANS FOR ANTICIPATED CRACKS DETECTABLE BY INSPECTION</b>		
PLAN I	FOR INITIAL DEFECT NOT EXPECTED TO GROW BY FATIGUE	<ul style="list-style-type: none"> <li>• CALCULATE PERMISSIBLE SIZE OF DEFECT.</li> <li>• IF STRESS CORROSION CAN OCCUR, CALCULATE WHICH SIZE OF DEFECT CAN BE SUSTAINED INDEFINITELY GIVEN THE <math>K_{ISCC}</math> OF THE MATERIAL.</li> <li>• INSPECT ONCE USING A TECHNIQUE THAT CAN RELIABLY DETECT DEFECTS OF THE CALCULATED SIZES.</li> <li>• ELIMINATE ALL DETECTED DEFECTS LARGER THAN THOSE OF THE CALCULATED SIZES.</li> </ul>
PLAN II	FOR ALL DEFECTS (INITIAL OR INITIATING LATER) THAT WILL GROW DURING SERVICE--THESE WILL REACH CRITICAL SIZE	<ul style="list-style-type: none"> <li>• IF POSSIBLE, SHOW BY ANALYSIS (OR TESTS) THAT THE STRUCTURE CAN SUSTAIN WITHOUT FAILURE SUCH LARGE DEFECTS THAT THE DAMAGE WILL BE OBVIOUS (E.G., READILY APPARENT LEAK OR FAILED COMPONENT; FAIL SAFETY). REPAIR WHEN DAMAGE IS DISCOVERED.</li> <li>• IF THE ABOVE CANNOT BE SHOWN, CALCULATE PERMISSIBLE CRACK SIZE.</li> <li>• ESTABLISH CRACK SIZE THAT CAN BE DETECTED RELIABLY.</li> <li>• CALCULATE TIME FOR CRACK GROWTH.</li> <li>• IMPLEMENT PERIODIC INSPECTION BASED ON CRACK GROWTH CALCULATION.</li> <li>• START INSPECTION IMMEDIATELY BECAUSE TIME OF CRACK INITIATION IS NOT KNOWN.</li> <li>• REPAIR OR REPLACE WHEN CRACK IS DETECTED.</li> </ul>
<b>PLAN FOR ANTICIPATED CRACKS NOT DETECTABLE BY INSPECTION</b>		
PLAN III	FOR PARTS WHERE A IS SO SMALL THAT IT DEFIES INSPECTION	<ul style="list-style-type: none"> <li>• MAKE BEST ESTIMATE OF POSSIBLE INITIAL DEFECTS.</li> <li>• CALCULATE PERMISSIBLE CRACK SIZE <math>A_p</math>.</li> <li>• CALCULATE CRACK GROWTH LIFE FROM INITIAL DEFECT SIZE TO <math>A_p</math>.</li> <li>• REPLACE/RETIRE AFTER CALCULATED LIFE EXPIRES (USING ADEQUATE FACTOR).</li> </ul>
<b>PLAN FOR STRUCTURES FOR WHICH INSPECTION IS NOT FEASIBLE, BUT PROOF TESTING IS POSSIBLE</b>		
PLAN IV	FOR COMPONENTS OR STRUCTURES THAT CAN BE PROOF TESTED AND WHERE FAILURE DURING PROOF	<ul style="list-style-type: none"> <li>• DETERMINE FEASIBLE PROOF TEST PRESSURE OR LOAD.</li> <li>• CALCULATE MAXIMUM CRACK SIZE <math>A_{PROOF}</math> THAT COULD BE PRESENT AFTER PROOF</li> </ul>

	TESTING IS NOT A CATASTROPHE (E.G., LEAK BEFORE BREAK)	<p>TEST.</p> <ul style="list-style-type: none"> <li>• CALCULATE MAXIMUM PERMISSIBLE CRACK <math>A_p</math>.</li> <li>• CALCULATE CRACK GROWTH TIME, <math>H</math>, FROM <math>A_{PROOF}</math> TO <math>A_p</math>.</li> <li>• REPEAT PROOF TEST BEFORE <math>H</math> HAS EXPIRED (USING ADEQUATE FACTOR).</li> </ul>
<b>PLANS FOR CRACKS DISCOVERED IN SERVICE</b>		
PLAN V	FOR DETECTED CRACKS FOR WHICH NO ANALYSIS IS DONE	<ul style="list-style-type: none"> <li>• REPAIR OR REPLACE UNCONDITIONALLY.</li> </ul>
PLAN VI	FOR DETECTED CRACKS FOR WHICH ANALYSIS IS DONE (IF IMMEDIATE REPLACEMENT IS IMPRACTICAL)	<ul style="list-style-type: none"> <li>• SHOW BY ANALYSIS THAT A LARGER DEFECT CAN BE SUSTAINED.</li> <li>• CHECK GROWTH DAILY; DRILL STOP HOLE IF PERMISSIBLE (AS AN INTERIM MEASURE).</li> <li>• PREPARE FOR REPAIR OR REPLACEMENT AT EARLIEST CONVENIENCE.</li> <li>• DETERMINE EXACT SIZE AND SHAPE OF CRACK.</li> <li>• FIND MATERIALS DATA; IF POSSIBLE, CUT TEST SPECIMENS FROM STRUCTURE.</li> <li>• OBTAIN RELIABLE LOAD AND STRESS INFORMATION.</li> <li>• CALCULATE <math>A_p</math>.</li> <li>• CALCULATE TIME, <math>H</math>, FOR GROWTH TO <math>A_p</math>.</li> <li>• PREPARE FOR REPAIR OR REPLACEMENT BEFORE <math>H</math> (WITH ADEQUATE FACTOR) EXPIRES.</li> <li>• IF CRACK GROWS FASTER THAN CALCULATED, UPDATE PROGNOSIS AND SPEED UP REPLACEMENT OR REPAIR ACTIONS. IF POSSIBLE, REDUCE OPERATIONAL LOADS. REPAIR OR REPLACE AS SOON AS POSSIBLE.</li> </ul>
PLAN VII	FOR STRUCTURES IDENTICAL TO THOSE IN WHICH A CRACK WAS PREVIOUSLY DETECTED	<ul style="list-style-type: none"> <li>• USE PARTS OF CRACKED OR FAILED STRUCTURE TO OBTAIN MATERIAL PROPERTIES.</li> <li>• IMPLEMENT PLAN II, III, OR VI.</li> </ul>

**Detectable Cracks.** Table 1 shows the ingredients of fracture control plans for structures in which cracks are detectable by inspection. If initial defects will not grow during service, plan I is applicable. If defects, whether initial or developing later, may grow under service loading, a crack eventually will become critical, unless it is readily discovered and repaired. Inspections should be scheduled in accordance with plan II.

**Cracks Not Detectable by Inspection.** Cracks may not be detectable, either because their permissible size is so small that it defies inspection, the location is not accessible, or the structure is so large that inspections are not feasible. Plan III is applicable in such cases. Plan IV involves destructive inspection by proof testing to show that no cracks larger than  $a_{proof}$  are present. If larger cracks are present, a failure will occur during the proof test, but this failure must not be catastrophic in its consequences.

**After Crack Detection.** Although fracture control calls for immediate repair or replacement when a crack is discovered, this is not always convenient. Large savings may be realized if remedial action can be scheduled for the next major overhaul or shutdown, or if operations can continue until a new part or component has been manufactured and received. Whether this is possible depends upon the fracture control plan in force. A well-conceived plan II already contains information on crack growth and residual strength. Using this information as an initial safeguard, operation can be continued, but the analysis should be updated and plan VI should be put into action. A crack may be discovered accidentally in a structure not subject to a fracture control plan. When no analysis is to be done, plan V is the only possible course, but it is recommended that analysis be done and that plan VI be followed. Recurrence of the incident can be prevented using plan VII.

## Concepts of Fracture Control and Damage Tolerance Analysis

David Broek, FractuREsearch

---

### Damage Tolerance Requirements

**Requirements for Commercial Airplanes.** The U.S. Federal Aviation Requirements [FAR.25b], enforced in a similar way in other countries, stipulate that the residual strength with damage present must not fall below the so-called limit load  $P_L$ , so that  $P_p = P_L$ . The limit load is, generally speaking, the load anticipated to occur once in the aircraft life. Given  $P_p$ , the residual strength diagram provides the maximum permissible crack size  $a_p$ .

In essence, the above is the complete requirement; little more is necessary. To satisfy the requirement, the manufacturer is obliged to design in such a manner that cracks can be detected before they reach  $a_p$  and to prescribe to the operator where and how often to inspect. Similarly, the operator is obliged to follow the manufacturer inspection instructions. Fracture control by these rules must be exercised by inspection. The excuse that some cracks are noninspectable is not justifiable (except, of course, if components are designed by safe-life criteria as in the case of landing gear). Every crack will become detectable if large enough. Thus, the requirement forces structural designs that are tolerant of damage large enough for detection, which promotes fail-safe design with multiple load path and crack arrest features.

Although there is a problem in the definition of detectable cracks, an (arbitrary) specification of detectable size would not improve the requirement, because detectability depends on the type of structure, its location, and its accessibility. The best way to determine inspection intervals is based on the cumulative probability of detection, as discussed. A useful improvement of the requirements would specify the desirable cumulative probability of inspection.

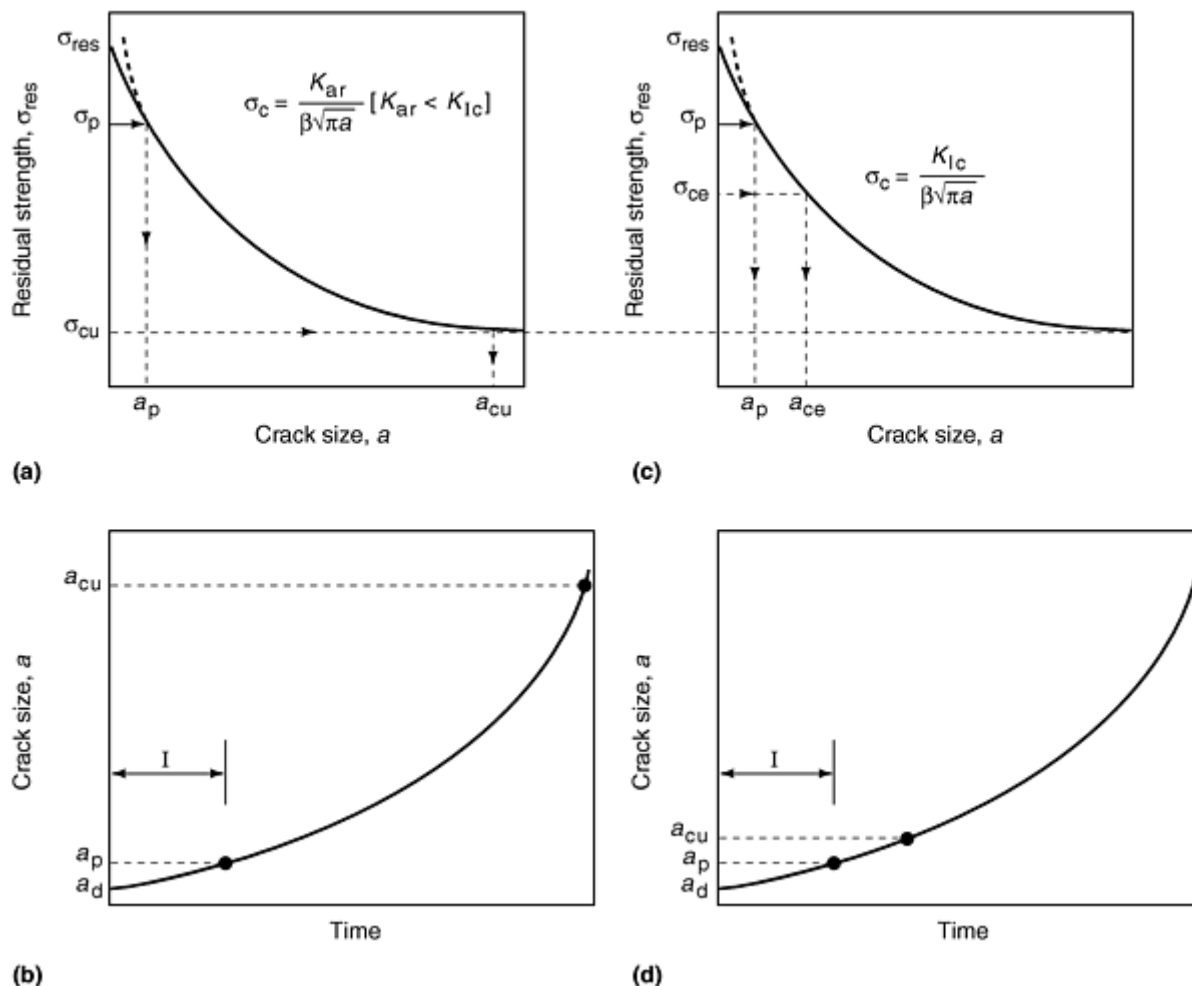

The U.S. Air Force requirements (adopted by some other forces as well but usually in a modified form) make a distinction between non-fail-safe and fail-safe structures (crack arrest or multiple load path). More stringent requirements apply to non-fail-safe structures. The military requirements (MIL-A-87221, MIL-A-83444, and MIL-STD-1530) go into great detail with regard to the assumptions to be made in the analysis for initial crack size and crack development. Otherwise they are very similar to those for commercial aircraft.

**ASME and Other Requirements.** Other damage tolerance requirements exist for ships and offshore structures and for nuclear pressure vessels. Requirements for ships and offshore structures are issued by shipping bureaus, such as Lloyds of London, Veritas (Norway), and American Bureau of Shipping. Similar requirements exist for military ships. Those for ships are essentially preventive requirements; no analysis is necessary. Ships of a certain size and over must be equipped with so-called arrest strakes, which are located at the gunwale, at the bilge, and sometimes at mid-decks. They are longitudinal strakes of a higher-toughness material than the normal hull plating.

The damage tolerance requirements for nuclear pressure vessels are contained in the ASME boiler and pressure vessel code, section XI and its appendix A. The requirements essentially provide acceptance limits for cracks detected in service. A variety of possible crack configurations and locations are identified. The requirements then provide the crack sizes for each case that may be left unattended. Should a detected crack exceed the prescribed limits, one has two options: repair weld or perform analysis.

If the option to perform analysis is selected, the following damage tolerance requirements apply:  $K < \text{Arrest toughness}/\sqrt{10}$  for upset conditions, and  $K < \text{Toughness}/\sqrt{2}$  for emergency and faulty conditions, where  $K$  is the stress intensity at these conditions. Strangely enough, these requirements are expressed in terms of the stress intensity and

toughness. However, with the fracture condition of  $K = \text{Toughness}$  (in the upset condition, at the stress  $\sigma_{cu}$ ) fracture would occur if  $\beta_p \sigma_p \sqrt{\pi a_p} = \text{Toughness}$ . If the actual stress intensity must be smaller by a factor  $\sqrt{10}$ , it follows that  $\sigma_{cu}/\sigma_p \approx \sqrt{10} = 3.16$ , assuming  $\beta_p \approx \beta_{cu}$ . This means that a safety factor of 3.16 must remain with regard to upset conditions. Thus, the requirement can be stated in terms of the minimum permissible residual strength  $\sigma_p$ . It follows that  $\sigma_p = \sigma_{cu}/3.16$ , in accordance with the previous discussions. This case is displayed in Fig. 11(a) using the same nomenclature as before.

**FIG. 11 ASME REQUIREMENTS FOR: (A) PERMISSIBLE CRACK SIZE ( $A_p$ ) FOR UPSET CONDITION (WHERE  $K_{AR}$  IS ARREST TOUGHNESS). (B) CRACK GROWTH FOR UPSET CONDITION. (C) PERMISSIBLE CRACK SIZE FOR EMERGENCY CONDITION ( $L = \text{INSPECTION INTERVAL}$ ). (D) CRACK GROWTH FOR EMERGENCY CONDITION. (NOTE: PERMISSIBLE CRACK SIZE,  $A_p$ , IS ACTUALLY DENOTED AS  $A_f$  IN THE ASME CODE.)**

At the same time, the stress intensity must be less than the toughness divided by  $\sqrt{2}$  for the emergency conditions (stress  $\sigma_{ce}$ ). Using the same arguments as above, the minimum permissible residual strength,  $\sigma_p$ , must provide a safety factor of  $\sqrt{2} = 1.41$  with regard to upset conditions. This is shown in Fig. 11(c).

Different toughnesses are used in the two cases, the arrest toughness and the regular toughness. Because the former is less than the latter, there are effectively two residual strength curves in play, as shown in Fig. 11. This does not change the principle of the analysis. In either case the permissible crack size  $a_p$  follows from the residual strength diagram as shown. Obviously, it is impossible to satisfy both requirements exactly. One is always more severe than the other. If it can be foreseen which of the two generally is the severest, the requirement can be simplified.

The requirement presents an alternative. Instead of the above, one may satisfy the following requirements:

- $A_P \leq A_{CU}/10$  UPSET AND OPERATING CONDITIONS
- $A_P \leq A_{CE}/2$  EMERGENCY CONDITIONS

where  $a_{cu}$  is the critical crack (causing fracture at upset conditions and  $a_{ce}$  is the critical crack in emergency conditions. (In the ASME code,  $a_p$  is denoted  $a_f$ .) Thus:

$$A_{CU} = 10A_P \quad (\text{EQ 4})$$

$$K = \beta_{CU} \sigma_{CU} \sqrt{\pi \times 10 a_P} = \beta_P \sigma_P \sqrt{\pi a_P} \quad (\text{EQ 5})$$

so that

$$\beta_P \sigma_P / \beta_{CU} \sigma_{CU} = \sqrt{10} = 3.16 \quad (\text{EQ 6})$$

This requirement will be identical to the one stated previously if  $\beta_P = \beta_{CU}$ . Because  $a_{cu}$  is a longer crack than  $a_p$ , in general  $\beta_{cu} > \beta_p$ , so that the requirement leads to a safety factor somewhat smaller than 3.16. The same arguments hold for  $a_p$  and  $a_{ce}$ . Both sets of requirements apparently attempt to set the same conditions, and only one is necessary.

Once a crack is detected and analysis is preferred instead of immediate repair, crack growth must be analyzed as well. Fatigue crack growth must be calculated starting at  $a_d$ , which is the crack actually present and discovered, and continuing over the period until the next inspection (shutdown). Over this period the crack may not grow beyond  $a_p$  as determined by the criteria discussed above. This condition is shown in Fig. 11(b) and 11(d). The requirements fully prescribe the analysis procedure as well as the toughness and rate data. (Use of other analysis and data is subject to approval by authorities.) The analysis procedure is mostly in agreement with general practice (Ref 6).

The requirement is specifically for a case where a crack is detected in service. One may then prove by analysis that this crack is not dangerous during further operation until the next shutdown. In the ASME requirements, the damage tolerance analysis is used to decide whether a structure with a *known crack* can be left in service without repair. Besides, analysis is not used to determine the inspection interval. The approach for aircraft has an important difference, in that cracks must be repaired and the analysis is used to ensure detection and repair a *potential crack*, not to determine whether it is safe to fly with a *known crack*. This statement is not meant as criticism, but rather as a clarification of the difference in approach.

## Fracture Mechanics and Fatigue Design

Fracture mechanics does not provide revolutionary new insights for fatigue design. It merely confirms what has been known for many years. Probably the most important rule in designing for high-fatigue performance is that stress concentrations should be kept at a minimum. Fracture mechanics merely emphasizes the significance of this. Without a stress concentration, the stress intensity for a small crack ( $\beta \approx 1$ ) is  $K = \sigma \sqrt{\pi a}$ . For a small crack emanating from a

notch or fillet, the geometry factor approximately equals the stress concentration factor:  $\beta \approx k_t$ , putting the stress intensity at  $K = k_t \sigma \sqrt{\pi a}$ .

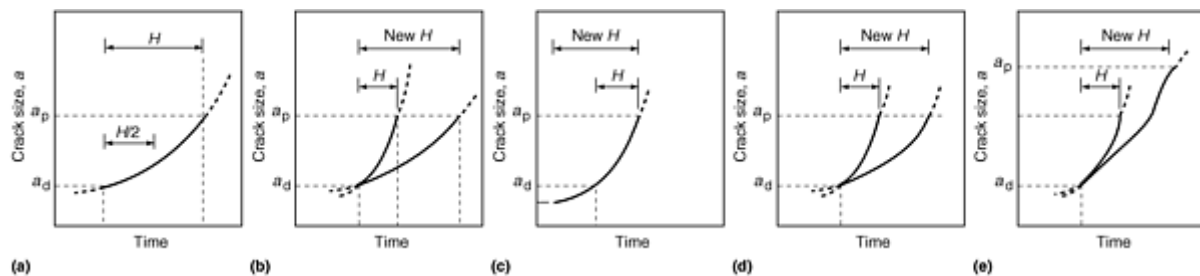

Because fatigue crack growth depends roughly on the third power of  $K$ , small cracks at stress concentrations grow faster by about  $k_t^3$ . Thus, a crack emanating from a simple hole grows about nine times faster than one of equal size starting at a smooth surface. Most service cracks start at stress concentrations, and the implications are self-evident.

The sole objective of damage tolerance analysis is to establish fracture control measures so that cracks can be eliminated before they become dangerous, by either repair or replacement of the component. There is no excuse for a fracture that results from known cracks, regardless of what analysis predicts.

If crack discovery demands repair, a new problem arises. Not only must the repair be adequate to restore strength, it must also be analyzed for damage tolerance again.

A repair cannot be treated too casually. A simple cover plate usually does not suffice; such a repair may rather aggravate the situation and cause new cracks in due time. Repairs must be designed to cause gradual transfer of loads to reduce the stress concentration. Fracture control measures must be reinstated for the repair.

The time available for fracture control is the time of safe operation, ( $H$ ), which is governed by the residual strength and the crack growth curve. If  $H$  is short, frequent inspections must be scheduled, or the component must be replaced soon. As long as all fracture control decisions are indeed based on  $H$ , safety will be maintained. But long inspection intervals or replacement times are desirable from an economic point of view. The question then is which measures can be taken to improve the situation when  $H$  is too small to be economically acceptable. Possible options (Fig. 12) are summarized below.

**FIG. 12 WAYS TO INCREASE INSPECTION INTERVAL. (A) BASE CASE. (B) USE OF BETTER MATERIAL. (C) USE OF MORE SENSITIVE INSPECTION METHOD. (D) (DETAIL) DESIGN WITH LOWER STRESS. (E) REDUNDANCY (FAIL-SAFE) OR CRACK ARRESTERS**

**Option (a): Use of a Material with Better Properties (Fig. 12b).** A higher toughness will provide a somewhat larger  $a_p$ , but generally speaking it is not of great influence on  $H$ ; most of the life is in the early phase of crack growth. Increasing toughness ( $a_p$ ) affects only the steeper part of the curve, which in general has only a small effect.

**Option (b): Selection of a Better Inspection Procedure (Fig. 12c).** Improving the inspection technique, (e.g., by selecting a more sophisticated inspection procedure) reduces detectable crack sizes. This usually has a significant effect on  $H$  because of the small slope of the initial part of the crack growth curve. The penalty will be a more difficult inspection, but the inspection interval will be longer, so fewer inspections will be needed.

**Option (c): Redesign or Lower Stress (Fig. 12d).** The crack growth curve is governed by the stress intensity. Reducing the stress by 15%, for example, will reduce  $K$  by 15%. Because crack growth rates are roughly proportional to  $K^3$ , a 15% reduction in stress will increase  $H$  by a factor  $1.15^3 = 1.5$ . Such a stress reduction seldom requires a general "beef up" of the structure; cracks occur where the local stresses are high, and the stress reductions are needed only locally. Reduction of stress concentrations, larger fillet radii, and less eccentricity will add hardly any material, cost, or weight.

Redesign may also affect  $K$ ; a reduction in  $\beta$  is just as effective as a reduction in  $\sigma$ . In the above example of the reduced stress concentration, the effect is actually in  $\beta(k_i)$  instead of in  $\sigma$  (the nominal stress does not change). The redesign may be in the production procedure, so that cracks occur in the cross-grain direction instead of along exposed grain boundaries.

**Option (d): Providing Redundance and Arresters (Fig. 12e).** Building the structure out of more than one element provides multiple load paths. In a well-designed multiple load path structure, only inspections for a failed member may be necessary, provided that the fasteners or welds can transfer the load of the failed member by shear.

All of these options can be exercised during design. It is crucial, therefore, that damage tolerance analysis commence in the early design phase when modifications are still possible. Once the design is finalized, the options for improvement are drastically reduced. For finalized designs and existing structures, Option (b) (Fig. 12c) is often the only recourse, although doublers or arresters sometimes can be added later.

### The Practice of Damage Tolerance Analysis

David Broek, FractuREsearch

---

### Introduction

DAMAGE TOLERANCE ANALYSIS consists of three parts:

- CALCULATION OF THE RESIDUAL STRENGTH DIAGRAM TO OBTAIN THE PERMISSIBLE CRACK SIZE
- CALCULATION OF THE CRACK GROWTH CURVE
- CALCULATION OF THE INSPECTION INTERVAL

The last item is discussed in the article "Concepts of Fracture Control and Damage Tolerance Analysis" in this Volume.

In most cases the residual strength analysis is performed with linear elastic fracture mechanics and is based on the stress-intensity factor,  $K$ , and the toughness (the plane strain fracture toughness,  $K_{Ic}$ , or the plane stress fracture toughness,  $K_{Ic}$ ). Linear elastic conditions are assumed for this article. Residual strength analysis on the basis of elastic-plastic fracture mechanics and plastic fracture mechanics is discussed in the article "Residual Strength of Metal Structures" in this Volume.

In this article it is assumed that crack growth is predominantly by fatigue rather than by corrosion, creep, or other mechanisms. This does not exclude the combination of (mechanical) fatigue and stress corrosion (i.e., corrosion-assisted fatigue). After all, fatigue crack growth is almost always corrosion assisted, because at least one corrodent, humid air, is usually present. It is the occurrence of cyclic loading, rather than the presence of a corrodent, that puts crack growth in the category of fatigue. The response of the material, in terms of the crack growth rate,  $da/dN$ , includes the effect of corrosion.

### Input to the Analysis

Damage tolerance analysis, whether of crack growth or residual strength (with the limitations expressed) is based on the stress-intensity factor,  $K$ :

$$K = \beta \sigma \sqrt{\pi a} \quad (\text{EQ 1})$$

where  $\sigma$  is the applied stress,  $a$  is the crack size, and  $\beta$  is the nondimensional geometry factor that incorporates all the geometrical complications of the structure at hand.

For residual strength analysis, the fracture criterion is usually:

$$K = K_{IC} \text{ (OR } K_C) \quad (\text{EQ 2})$$

in which  $K_{IC}$  is the plane strain fracture toughness and  $K_C$  is the plane stress fracture toughness. To obtain the residual strength diagram, the following equation must be solved for a number of  $a$  values:

$$\sigma_C = K_{IC} \text{ (OR } K_C) / \beta \sqrt{\pi a} \quad (\text{EQ 3})$$

However, in general the establishment of the residual strength diagram is more complicated than this, as explained in the article "Residual Strength of Metal Structures" in this Volume.

In fatigue, the crack growth data are expressed as a function of the stress-intensity range,  $\Delta K$ , and the stress ratio,  $R$ , as:

$$DA/DN = F(\Delta K, R) \quad (\text{EQ 4})$$

Calculation of the crack growth curve requires integration of Eq 4 with  $K$  expressed per Eq 1. The expression for  $\Delta K$  includes  $\Delta\sigma$  as per Eq 1, where  $\Delta\sigma$  is the stress range in the cycle (or any particular cycle). Few structural parts are subjected to constant-amplitude loading. In general, the loading is random or semirandom, so that  $\Delta\sigma$  is different from cycle to cycle. Thus, the following input is required for the analysis:

- MATERIAL DATA IN TERMS OF  $K_{IC}$  (OR  $K_C$ ), RATES IN TERMS OF RATE DIAGRAM,  $DA/DN = F(\Delta K, R)$ , AND THE YIELD STRENGTH,  $F_{TY}$
- THE GEOMETRY FACTOR,  $\beta$ , AS A FUNCTION OF CRACK SIZE FOR THE STRUCTURE AT HAND
- THE STRESS HISTORY (I.E., THE SEQUENCE OF STRESS VALUES,  $\Delta\sigma$ , TO WHICH THE DETAIL IN QUESTION WILL BE SUBJECTED)

The following discussions briefly consider the crucial aspects of obtaining material data and geometry factors, then turn to the problem of crack growth analysis through the integration of Eq 4. This integration can seldom, if ever, be performed in closed form; therefore, numerical integration by computer is indicated. Most crack growth analysis computer programs contain extensive libraries of material data and geometry factors, which tend to give the user a false sense of security. *The selections made by the user* from these libraries are what make or break the analysis. The damage tolerance analyst must be thoroughly familiar with what follows in this article and would do well to become versant with other aspects of the problem (Ref 1).

## Material Data

Damage tolerance analysis is based on material property data such as fracture toughness,  $K_{Ic}$  or  $K_c$ , and yield strength,  $F_{ly}$ . Fracture toughness is relevant for the calculation of residual strength, but otherwise it has no effect on the calculated crack growth curve (unless crack growth is described from curve-fitting models such as the Forman equation or the Collipriest equation).

Innocuous as it may seem, the yield strength has an overriding effect if the crack growth analysis must account for crack retardation after overloads or in low-cycle fatigue. This issue is so complicated that the reader is well advised to consult the literature (e.g., Ref 1, 2) before attempting to deal with it. Retardation may well change the result of the crack growth analysis by a factor of 2 or more, depending on the yield strength value used. However, most analysts prefer to ignore crack retardation because doing so is more conservative. That being the case, the only input of relevance is the rate diagram for the material, of which a typical example is shown in Fig. 1.

(a)

(b)

FIG. 1 FINDING THE BEST REPRESENTATION OF RATE DATA (ASTM A 533B STEEL AT 26 °C, OR 500 °F). (A) RE-PREDICTION OF CRACK GROWTH. (B) RATE DATA

**Curve Fitting  $da/dN$  Data.** Data sets such as that shown in Fig. 1 (b) must be interpreted before they can be used in analysis. Clearly, the "scattered" data points cannot be used directly. In some cases a growth rate equation may be desirable; in particular, if the data appear to fall on straight lines, the Paris or Walker equation may be convenient (Ref 1, 2). Most computer programs have options for the use of a number of equations but also permit the use of tabular data. The latter eliminates the need for force-fitted (sometimes poorly fitted) equations.

All equations derive from "curve" fitting and have no physical basis. None of them is fundamentally better than any other, and none is more universally useful than any other. The most appropriate equation is the one that gives the best fit for the case at hand. Fits are often obtained by using a least squares fit of the  $da/dN - \Delta K$  data. This is all that can be done if the original raw test data ( $a$  versus  $N$ ) are not available (the original crack growth data usually are not reported in handbooks or other literature). The best fit through the  $da/dN - \Delta K$  data must then be used, although the "best" fit may not give the best predictions if the analysis is required to cover a wide range of  $\Delta K$  values.

A measured crack growth curve is shown in Fig. 1(a) and the  $da/dN$  data are shown in Fig. 1(b). In this case a straight line is appropriate (Paris equation,  $da/dN = C_P (\Delta K)^{m_P}$ ). A least squares fit of these data provides  $C_P = 6.496 \times 10^{-11}$  and

$m_p = 3.43$ . When these parameters are used in a crack growth analysis to re-predict the original crack growth curve, the result is as shown in Fig. 1(a), which is certainly not the best fit to the actual crack growth curve. In this case the curvature of the predicted curve seems appropriate (the value of  $m_p$  is correct), but there is a more or less proportional error, which can be corrected by adjusting  $C_p$ . The predicted life is too long as compared to the test life by a factor of  $1,937,483/1,871,080 = 1.035$ . Multiplication of  $C_p$  by this factor ( $C_p = 1.035 \times 6.496 \times 10^{-11} = 6.72 \times 10^{-11}$ ) will result in a better prediction, as shown in Fig. 1(a).

The regression fit of the  $da/dN$  data is not necessarily the best fit for analysis. In curve-fitting procedures, every data point gets equal weight, yet the points for high  $da/dN$  affect only a small portion of the life. The points for low  $da/dN$  are the relevant data during most of the life and should weigh more in the curve fitting. In the above example, the curvature of the predicted curves was appropriate, and only  $C_p$  needed adjustment. If the curvature is found to be incorrect,  $m_p$  must be adjusted first by trial and error. This usually causes wild gyrations in the predicted curve, but these can be ignored. The objective is to arrive at a line with the proper curvature, which will have the proper  $m_p$ . Once this  $m_p$  value is found, the curve can be adjusted by adjusting  $C_p$  in the manner discussed.

Clearly, fitting an equation is not trivial; it requires judgment and re-prediction of the original data using a predictive computer code. But if the original crack growth curve is not available, there is no other option than to fit the  $da/dN$  data as well as possible. This can be done by regression, but regression analysis may be a refinement and not necessarily an improvement over a hand-drawn best fit line.

**Dealing with Scatter in Fatigue Crack Growth Data.** Statistical procedures used to account for scatter are seldom in accord with physical reality. Most statistical procedures address data analysis without direct consideration of the physics and mechanics of the problem. For example, the 90% confidence curves are commonly determined by using the individual  $da/dN$  data points as the statistical population sample, yet applying the correct mathematics does not lend credence to the physical result.

The three main sources of scatter are:

- CONSISTENT DIFFERENCES BETWEEN HEATS A AND B OF THE SAME ALLOY
- LOCAL DIFFERENCES DUE TO INHOMOGENEITIES AND "WEAK SPOTS"
- MEASUREMENT ERRORS

Essentially, only the first source of scatter is relevant; the other two have little bearing on the problem.

**Consistent differences between various heats or batches of materials**, and to a certain degree differences from location to location in one batch or plate, will be reflected in a more or less consistent difference in crack growth curves. As a consequence, the rate also will be consistently different, as shown in Fig. 2. This is true material scatter and must be accounted for in an analysis, because the exact properties of the batch used in the structure are not known.

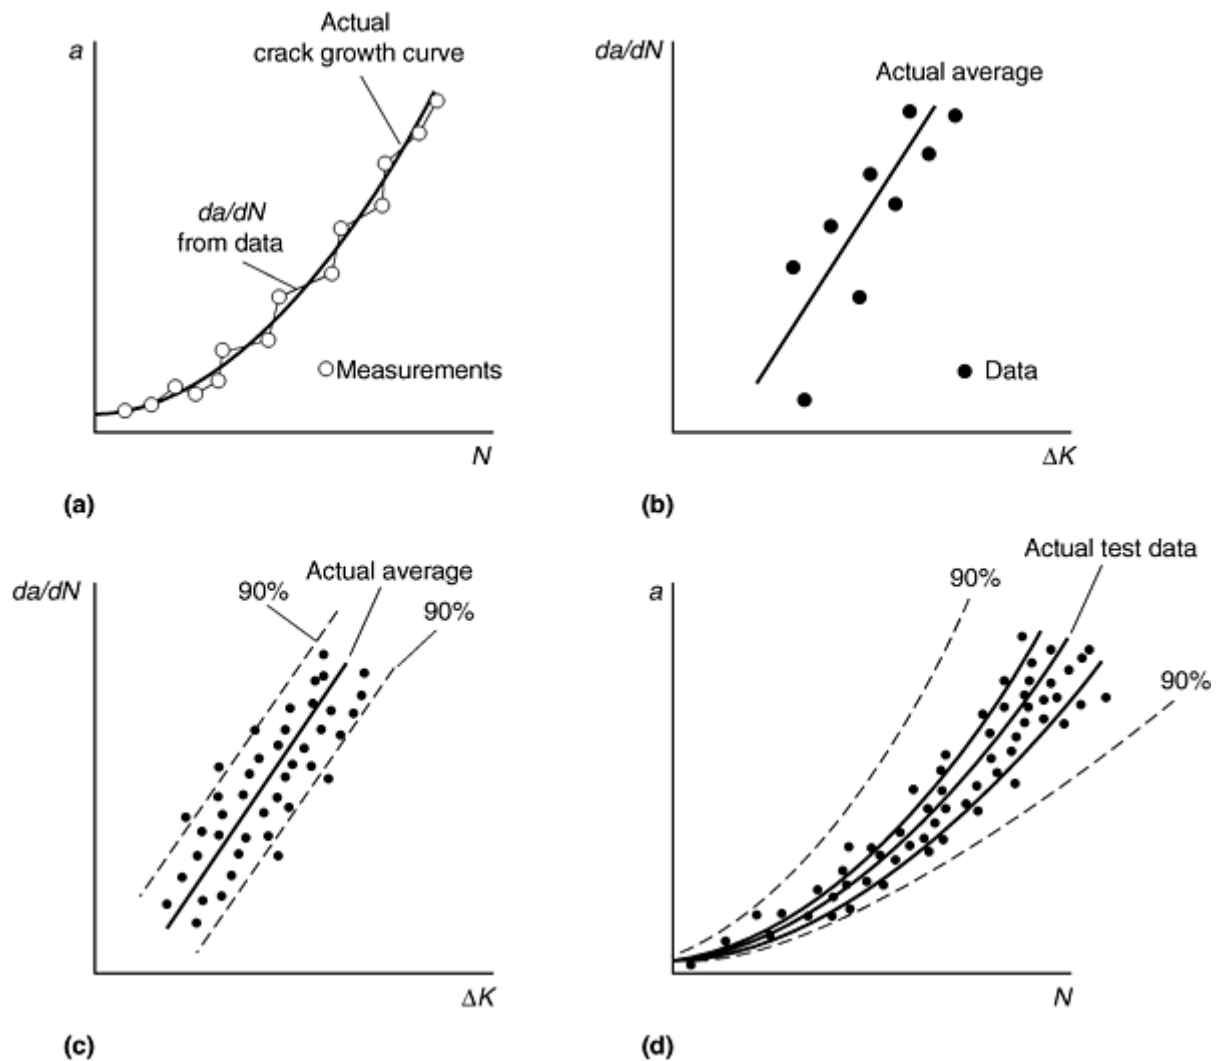

FIG. 2 TYPICAL TRUE SCATTER IN FATIGUE CRACK GROWTH. (A) CRACK GROWTH CURVES. (B) RATES

Scatter due to inhomogeneities and "weak spots" may occur throughout the material, but only locally. At some locations the crack will accelerate, but soon afterward it will resume normal behavior. Another crack (in a different specimen) will encounter such "weak" spots at other locations and will speed up locally (at different stages in life than the first one), then resume normal growth. Similarly, it will sometimes slow down locally. On the whole, the two crack growth curves will be identical, as shown in Fig. 3(a). Also, the rate data will be identical, except that each test will provide a few outlying data points due to local higher or lower rates, as indicated in Fig. 3(b). The outlying data points occur at different locations in the two tests. If, instead of two tests, many tests are performed on specimens from the same plate, more and more outlying data points will appear and the scatter will seem to become well established (Fig. 3c).

**FIG. 3 SCATTER DUE TO INHOMOGENEITIES AND MEASUREMENT OF FATIGUE CRACK GROWTH. (A) DATA. (B) RATES OF CRACK GROWTH. (C) SCATTERBAND. (D) RE-PREDICTION OF CRACK GROWTH CURVES VERSUS CYCLES ( $N$ )**

Figure 3(d) results from taking the upper and lower (or 90% confidence) bounds of this scatter (Fig. 3c), then reconstructing crack growth curves on this basis. Clearly, the upper and lower bound data lead to unrealistic results, because all measured crack growth curves are essentially identical. This is caused by the implicit assumption that in some cases, all crack growth could be through a continuous string of weak spots (note that this scatter is caused by local weak spots). This is an untenable assumption. Weak spots are local; in each case only a few will be encountered. The entire bulk will not be one great weak spot. Hence, the average curve is the relevant one; the "scatter" is only apparent, not real.

**Measurement errors** do occur, but in general, the crack size will not be consistently overmeasured or undermeasured. Even if the measurement were always over or under, it would result only in a shift of the crack growth curve. The error in the rates would be small:

$$\begin{aligned} [A_2 + \delta - (A_1 + \delta)] / \Delta N &= (A_2 - A_1) / \Delta N \\ &= \Delta A / \Delta N \end{aligned} \quad \text{(EQ 5)}$$

The main reason for the problem is that the differentiation (the procedure for obtaining  $\Delta a$ ) tends to exaggerate measurement inaccuracies. For example, consider a measurement that is accurate within 0.005 in., about as high an accuracy as can be attained. If  $a = 0.5$  in. nominally, its value is between 0.495 and 0.505 in.; the possible error is only 1%. Let the next measurement be 0.52 in., indicating a crack size between 0.515 and 0.525, again with an accuracy of 1%. The value of  $\Delta a$  is then between  $0.525 - 0.495 = 0.030$  and  $0.515 - 0.505 = 0.010$ , with an expected value of  $0.52 - 0.50 =$

0.020. Hence, the error in rate will be as large as 50% ( $0.020 \pm 0.010$ ). This problem is not unique for crack growth; it always occurs where (numerical) differentiation is performed.

To counteract this problem, ASTM E647 recommends taking a moving average for the rate determination. Yet the differentiation will still exaggerate measurement inaccuracies, which will appear as exaggerated "scatter" in the rate diagram. If a sufficient number of such values are accumulated, the scatterband may become impressive, even if the other sources of scatter are completely absent. The resulting problem is the same as was discussed on the basis of Fig. 3. Upper and lower bounds would give crack growth curves bearing no relation to the tests, because all tests essentially showed the same crack growth curves. Determining a 90% confidence band with a statistical treatment that does not account for this reality is inappropriate.

**Implications.** Most of the scatter observed in data plots can be ignored, because it is apparent scatter only. The line representing the average of the data is the only realistic one (Fig. 3). However, it is prudent to account for the batch-to-batch, heat-to-heat, and manufacturer-to-manufacturer variations, because it is not known a priori which batch of material will be used in the structure. As a rule of thumb, these effects can cause a difference of about a factor of 2 between worst and best crack growth rates.

**Corrosion-Assisted Fatigue Crack Growth.** Should the environmental effect result in data of the form given in Fig. 4, none of the common equations is applicable and a tabular representation of the data is indicated. In the case of variable-amplitude loading,  $\Delta K$  varies considerably from one cycle to the next. In one cycle, the  $\Delta K$  may call for rates at the "plateau" level of Fig. 4, whereas in the next cycle  $\Delta K$  may be low and call for rates close to the threshold. The baseline data were obtained for gradually increasing  $\Delta K$ . The environmental effect is time dependent and is measured at "chemical equilibrium" at the crack tip, but it is questionable whether the effect is the same in variable-amplitude loading. The equilibrium condition for a totally different  $\Delta K$  cannot be reached immediately in one cycle. Computer codes do not consider this problem.

**FIG. 4 CRACK GROWTH IN X-65 LINE PIPE STEEL IN 3.5% SALT WATER AT -1.04 V (SATURATED CALOMEL ELECTRODE) AND AT FOUR FREQUENCIES. SOURCE: REF 3**

Should the environment change during crack growth, another problem arises. In winter the environment is cold, dry air; in summer it is warm, wet air. There may be 100% relative humidity in winter, but cold air contains much less moisture than warm air, even if saturated. For example, air with 100% relative humidity at room temperature contains approximately 30,000 ppm of water, but air with 100% relative humidity at  $-55\text{ }^{\circ}\text{C}$  ( $-70\text{ }^{\circ}\text{F}$ ) contains only about 200 ppm of water. (Relative humidity is the fraction of the possible moisture content.)

This problem occurs for transport vehicles, bridges, airplanes, and many other structures exposed to weather. While the following example is for an airplane, it applies to other structures. A wing full of fuel may warm up considerably when the airplane is serviced, standing in the sun. During ascent, when many of the gust loadings are encountered, the material is warm, the air is warm, and the moisture content is high. During flying in the stratosphere, the structure and fuel cool to  $-55\text{ }^{\circ}\text{C}$  ( $-70\text{ }^{\circ}\text{F}$ ). Cyclic loading still occurs, but crack growth rates in this environment may be less than those in wet air by a factor of 3. Upon descent, the structure is cold but the air is warm with much more water, and the air may contain pollutants, which cause much higher growth rates.

Clearly, such a changing environment defies any theory and any modeling. Only pragmatic engineering is of use. Pragmatism can be exercised in many ways, depending on goals, outlook, and the level of conservatism desirable. Assumptions must be made, and they can have far-reaching consequences. No categorical recipes can be given, only an example. Consider a case where the data set can be represented by a Paris or Walker equation, all with the same exponent(s), so that environment changes will affect only the coefficient  $C$ . By estimating the relative times spent in each environment, one can calculate a weighted average of  $C$ . Naturally, this assumption is disputable, but so are all other assumptions. Clearly, the time spent in the different environments can only be estimated, so more "refined" assumptions are as good as the above estimates.

## Geometry Factors

In order to analyze any fracture or crack growth problem, the analyst must know the geometry factors for  $K$  or  $J$  (the crack growth energy release rate), or both, for the structural crack of interest. Geometry factors for many generic configurations have been compiled in handbooks (Ref 4, 5, 6). These can be used for generic loading and geometries, but actual structural details are unique, and ready-made handbook solutions cannot be expected to be available.

In such a case a solution can be obtained in principle by means of finite element analysis. However, this type of analysis may be too costly because of the complexity of the structural details, or for many other reasons. Fortunately, simple procedures can provide geometry factors quickly and with good accuracy (Ref 1):

- USE HANDBOOK SOLUTIONS COMBINED WITH SUPERPOSITION AND COMPOUNDING.

- USE GREEN'S FUNCTIONS OR WEIGHT FUNCTIONS, IN COMBINATION WITH FINITE ELEMENT STRESS ANALYSIS OF THE UNCRACKED STRUCTURE IF NECESSARY.

These procedures are included in some general-purpose fracture mechanics computer programs, but they can be done easily by hand in a short time using a handbook (Ref 4, 5, 6). The stress-intensity factor is defined as  $K = \beta \sigma \sqrt{\pi a}$ , in which  $\sigma$  is the nominal stress away from the crack. The geometry factor  $\beta$  accounts for the fact that average stresses in the cracked section are higher, as well as for all free boundaries affecting the crack-tip stress as expressed by  $K$ . Thus  $\beta = \beta(a/W, a/D, a/S, \dots)$ , where  $W$ ,  $D$ , and  $S$  are relevant structural dimensions or in general  $\beta = \beta(a/L)$ , where  $L$  has a generalized length. Determining geometry factors requires deriving the function  $\beta(a/L)$  for the specific loading and geometry details relevant to the crack to be analyzed. The way in which the function is to be used in crack growth and fracture analysis depends on the definition of stress as well. Additional information on geometry factors and new information not contained in handbooks is in the appendix "Summary of Stress Intensity Factors" in this Volume.

**The Reference Stress.** In the case of uniform applied stress, there is no problem in the definition of  $\sigma$  in the stress-intensity factor as described above. But if the stress distribution is nonuniform it may not be immediately obvious which stress should be used.

Before turning to the case of nonuniform stress distributions, it may be worthwhile to consider an example. For a central crack of size  $2a$  in a plate of width  $W$  under uniform tension, it has been shown that  $\beta = \sqrt{\sec(\pi a/W)}$  and that  $K = \beta \sigma \sqrt{\pi a} = [\sec(\pi a/W)]^{1/2} \sigma \sqrt{\pi a}$ . Should one insist on using a reference stress different from  $\sigma$  in this expression, one can legitimately do so. For example, one could use the average stress in the cracked section,  $\sigma_{\text{net}}$ , which is given by  $\sigma_{\text{net}} = \sigma W/(W - 2a)$ . Then  $K$  would become:

$$K = (1 - 2a/W) \sqrt{\sec \pi a/W} \sigma_{\text{NET}} \sqrt{\pi a} = \beta \sigma_{\text{NET}} \sqrt{\pi a} \quad (\text{EQ 6})$$

where  $\beta = (1 - 2a/W) \sqrt{\sec \pi a/W}$ .

Obviously, the values of  $K$  so obtained are identical to those based on  $\sigma$ . Consistent use of Eq 6 in a residual strength analysis would provide as output the fracture stress in terms of  $\sigma_{\text{net}}$  (from which  $\sigma$  could be obtained). Similarly, cyclic stress input in a crack growth analysis should be in terms of  $\sigma_{\text{net}}$ , and the input for  $\beta$  should be in accordance with Eq 6. In this case a reference stress other than  $\sigma$  offers no advantage, but the example illustrates the principle. Any reference stress can be used, provided that  $\beta$  is adjusted such that the product  $\beta \sigma$  remains unaffected. The  $\beta$ -input must be for the proper reference stress, and the input of stress ranges, exceedance diagrams, stress histories, and/or stress occurrences must be in terms of the reference stress. The output will be in terms of the reference stress as well and may require interpretation.

**Compounding.** In the general expression for the stress-intensity factor  $K = \beta \sigma \sqrt{\pi a}$ , the geometry factor  $\beta$  accounts for the effect of all boundaries. That is,  $\beta = f(a/W, a/D, \dots)$ , where  $W$ ,  $D$ , and so on are relevant dimensions of the structure. In many cases the individual effects of these boundaries can be found in handbooks. Their composite effect is obtained by compounding, which is multiplication of all individual effects.

Possibly the most prominent example of compounding is demonstrated by the classical solution for the elliptical surface flaw (Fig. 5). (Other solutions have since been obtained; see Ref 7 and 8.) The various boundary effects are due to the back free surface (BFS), front free surface (FFS), width ( $W$ ), and crack front curvature (CFC):

$$K = \beta_{\text{BFS}} \beta_{\text{FFS}} \beta_{\text{W}} \beta_{\text{CFC}} \sigma \sqrt{\pi a} \quad (\text{EQ 7})$$

or simply  $K = \beta \sigma \sqrt{\pi a}$ . If  $W$  is large,  $\beta_{\text{W}} = 1$  and  $\beta_{\text{BFS}} = 1.12$ . Then the classical solution provides:

$$\beta_A = 1.12 \beta_{FFS}/Q \quad (\text{EQ 8})$$

where  $\beta_{FFS}$  and  $Q$  can be found in handbooks (Fig. 5).

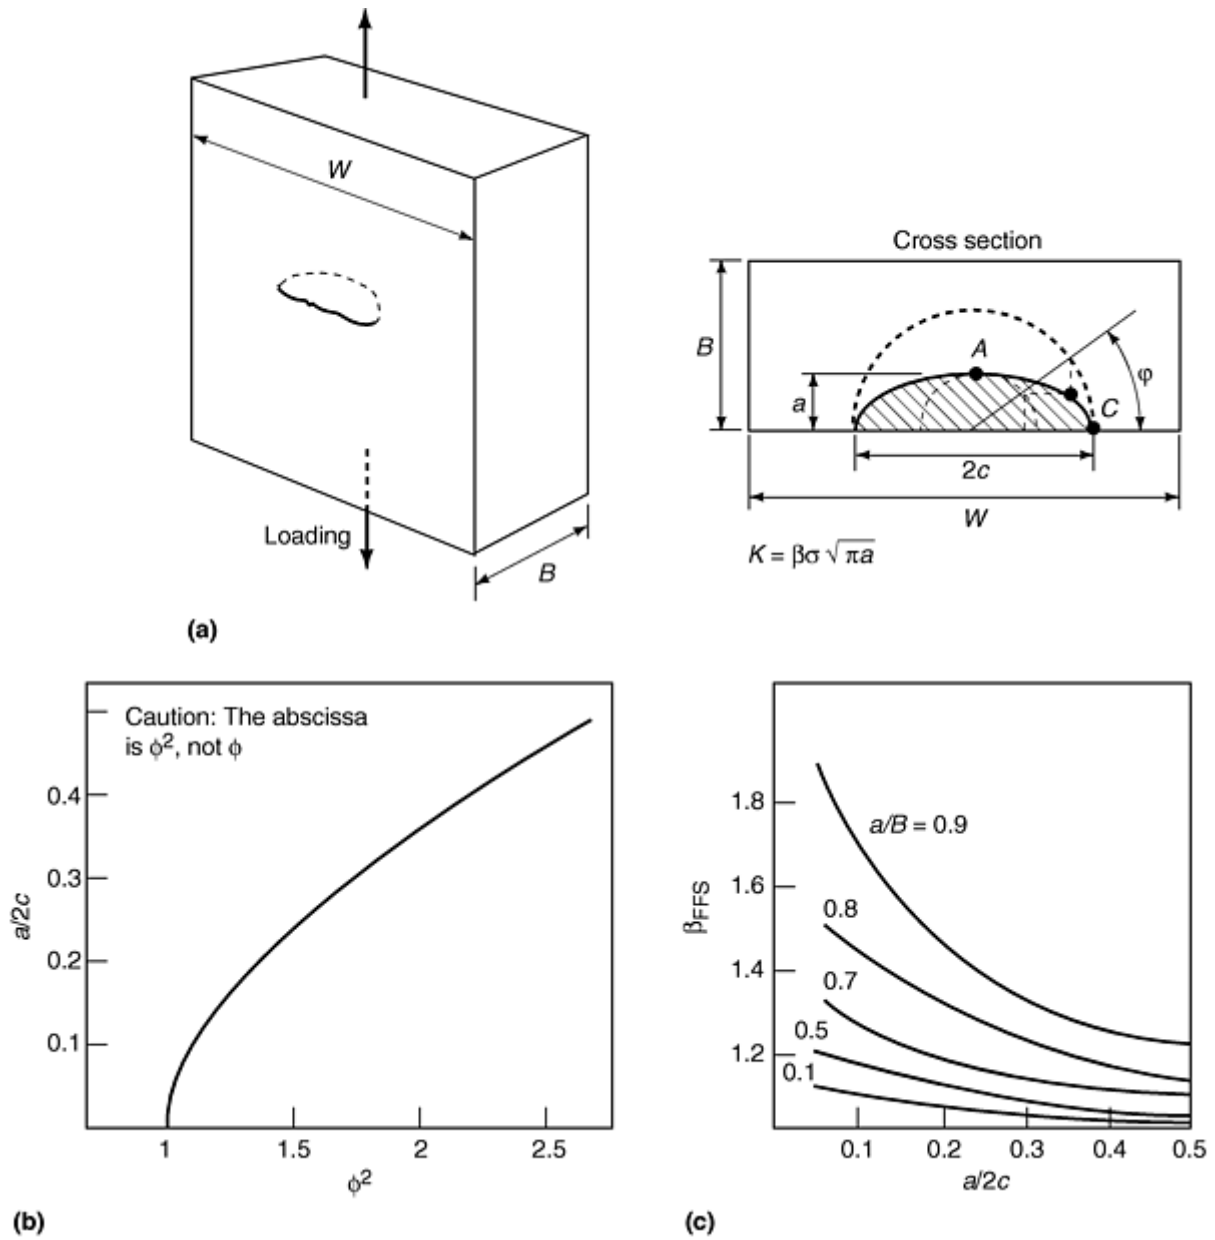

FIG. 5 GEOMETRY FACTORS FOR SURFACE FLAW. (A) CONFIGURATION. (B) GEOMETRY FACTORS FOR SHAPE. (C) GEOMETRY FACTOR FOR FRONT FREE SURFACE

In obtaining  $\beta$  for a structural crack in a complex geometry, the effect of the individual boundaries can be found in handbooks. By compounding these effects the "total"  $\beta$  is obtained. Rigorous compounding adheres to slightly different rules (Ref 9), but the procedure shown here is generally used and accepted.

**Superposition** is addition of stress-intensity factors due to various mode I loadings. For example, in a combination of bending (ben) and tension (ten), the total crack-tip stress is:

$$\sigma_{ij} = \frac{K_{\text{ben}}}{\sqrt{2\pi r}} f_{ij}(\theta) + \frac{K_{\text{ten}}}{\sqrt{2\pi r}} f_{ij}(\theta) = \frac{K_{\text{total}}}{\sqrt{2\pi r}} f_{ij}(\theta) \quad (\text{EQ 9})$$

Because the solution of the crack-tip stress field is universal, the functions  $f_{ij}(\theta)$  in both terms are identical, and the total stress intensity is:

$$K_{TOTAL} = K_{TEN} + K_{BEN} \quad (\text{EQ 10})$$

First the separate  $\beta$  values must be obtained by compounding. Then, after the superposition is complete, the final  $\beta$  value must be obtained for a suitable reference stress, because damage tolerance analysis is based on  $K = \beta \sigma \sqrt{\pi a}$ .

$$K_{TOTAL} = \beta_{BEN} \sigma_{BEN} \sqrt{\pi a} + \beta_{TEN} \sigma_{TEN} \sqrt{\pi a} \quad (\text{EQ 11})$$

In order to obtain  $\beta$  for the combination, a reference stress must be selected. This can be  $\sigma_{ten}$ ,  $\sigma_{ben}$ ,  $\sigma_{total} = \sigma_{ben} + \sigma_{ten}$ , OR any other suitable stress. Selection of  $\sigma_{total}$  provides:

$$\begin{aligned} K &= (\beta_{BEN} \sigma_{BEN} / \sigma_{TOTAL} + \beta_{TEN} \sigma_{TEN} / \sigma_{TOTAL}) \sigma_{TOTAL} \sqrt{\pi a} \\ &= \beta \sigma_{TOTAL} \sqrt{\pi a} \end{aligned} \quad (\text{EQ 12})$$

Thus,  $\beta$  becomes the weighted average (with regard to the stresses) of those for the two loading conditions. In this manner geometry factors can be obtained easily, even for complicated geometries and loading conditions (Ref 1).

## The Practice of Damage Tolerance Analysis

David Broek, FractuREsearch

## Integration of Crack Growth Rates

**Constant-Amplitude Loading.** The crack growth curve for a structural crack is obtained from integration of the rates:

$$DA/DN = F(\Delta K, R) \text{ OR } DN = DA/F(\Delta K, R) \quad (\text{EQ 13})$$

Integration provides:

$$N = \int_{a_0}^{a_p} DA/F(\Delta K, R) \quad (\text{EQ 14})$$

Generally, the integration is done numerically. It can seldom be performed in closed form, because of the complexities of the function  $f$ ,  $\beta$  in  $\Delta K$ , and the stress history.

The  $\beta$  for a structural crack is usually a lengthy polynomial in  $a/W$  or is known only in tabular form. Numerical integration is indicated even if the function  $f$  is simple and  $\Delta\sigma$  is constant (independent of  $a$ ). If  $\Delta\sigma$  is constant (constant amplitude), it can be taken out of the integration. The remaining parameters in  $\Delta K$  all depend on the crack size  $a$ , so what must be integrated is  $N = A \int F'(a) da = F(a)$ . As in any integration, this is the area under the curve  $F'(a)$ , shown in Fig. 6. The very definition of integration is that this area is obtained as the sum of the area of many rectangles of height  $F'(a)$  and width  $da$ , the area of each of which is height times width. In closed-form integration, the size of  $da$  vanishes to zero, which gives the true result.

FIG. 6 INTEGRATION OF FATIGUE CRACK GROWTH

In a numerical integration, the step size  $da$  is not infinitesimally small but finite. However, it is quite obvious from Fig. 6 that the result is accurate anyway, because the overshoot triangles at the top left of the rectangles very quickly compensate for the undershoot triangles at the top right of the rectangles. Indeed, numerical integration is a very "forgiving" procedure. Before the computer age, when numerical integrations had to be done by hand, one wanted to make large steps to get done quickly. The (small) inaccuracies thus introduced were compensated for by integration rules such as the Simpson rule. With the computer, the step size can be made so small that the error becomes negligible.

Based on Fig. 6, the integration procedure is then:

$$\begin{aligned} A_J &= A_0; N = 0 \\ A_I &= A_J \\ \beta_I &= F(A_I/W) \\ \Delta K_I &= \beta_I \Delta\sigma \sqrt{\pi a_i} \\ DA/DN &= F(\Delta K_I, R) \\ \Delta A_I &= \delta A_I \text{ (E.G. } \delta = 0.01) \end{aligned} \quad (\text{EQ 15})$$

$$\Delta N_I = \Delta A_I / (DA/DN)_I$$

$$N_J = N_I + \Delta N_I$$

$$A_I = A_J + \Delta A_I$$

IF  $A_J < A_p$  THEN RETURN TO BEGINNING

The process also involves checks to stop it when the crack reaches the edge of the component, when  $\Delta K = K_c$ , or when  $\beta$  changes (e.g., a surface crack becomes a through-thickness crack).

**Cycle-by-Cycle Counting with Variable-Amplitude Loading.** When the loading is of variable amplitude, the stress in every cycle is different from the previous stress. The integration as shown above is then not possible, because  $\Delta K$  may be very different from that in the previous cycle. We must then resort to cycle-by-cycle integration (i.e., the step size in the integration is one cycle only). For this cycle,  $\Delta K$  is obtained for cycle  $i$  using the proper  $\beta$  value and the  $\Delta\sigma$  value appropriate for that cycle. The crack growth,  $da$ , follows from Eq 13. It is added to the existing  $a$  value and the process is repeated for the next cycle.

If there is retardation, *the crack growth rate in any one cycle depends on that in previous cycles.* In that case the history must be remembered in order for the growth in the next cycle to be calculable at all. However, justified or not, most users prefer to ignore retardation because doing so is conservative. In that case, crack growth in any one cycle is independent of that in the previous cycle.

Hence, without retardation the integration often can be done as a quasiconstant-amplitude computation. This reduces the computation time from hours or minutes to a few seconds, depending on the complexity of the stress history. The computer applies all cycles in the history at each quasiconstant-amplitude step. It adds the crack growth of all these cycles and then determines an effective equivalent cycle that would provide the same crack growth, and it evaluates how many of those cycles are needed to extend the crack over an increment of, say, 1% of the current crack size. In essence, therefore, a weighted average of crack growth is determined for all cycles in the stress history, recognizing that any one cycle in the history may occur at any one time.

### Sources of Error

Sources of error in damage tolerance analysis can be classified as:

- UNCERTAINTY AND ASSUMPTIONS IN DATA INPUT
- UNCERTAINTY DUE TO ASSUMPTIONS ABOUT FLAWS
- INTERPRETATIONS OF, AND ASSUMPTIONS IN, STRESS HISTORY
- INACCURACIES IN STRESS INTENSITY
- COMPUTER MODELING ERRORS

In each of these categories, a number of factors contribute to inaccuracies in the analysis. Table 1 provides rough estimates of particular errors, given as a factor on life (not as a percentage error). The numbers are from analysis experience.

**TABLE 1 ERROR SOURCES IN DAMAGE TOLERANCE ANALYSIS**

CATEGORY	CAUSE OF ERROR	COMMENT	POSSIBLE FACTOR ON
----------	----------------	---------	--------------------

			CALCULATED LIFE
INTRINSIC SHORTCOMINGS OF FRACTURE MECHANICS	LINEAR ELASTIC FRACTURE MECHANICS	SMALL ERROR IN $A_p$ FOR SMALL CRACKS OR SMALL PARTS	1.1-2
DATA INPUT	$K_{IC}$ , OR $K_C$ , $J_R$	ERROR IN $A_p$	1.1-1.2
	$DA/DN$ DATA	NORMAL SCATTER	1.1-1.5
	ASSUMPTION 90% BAND	APPARENT SCATTER	1-2
	ASSUMPTION VARIABLE ENVIRONMENT	E.G., WEIGHTED AVERAGES	1-2
	EQUATIONS FOR $DA/DN$	UNNECESSARY FORCE FITS	1.5
ASSUMPTIONS	DIRECTION (E.G., LT VS. SL)	WRONG DATA APPLIED	1-2
	INITIAL FLAW SIZE	VERY INFLUENTIAL	1-3
	SHAPE	SURFACE FLAWS	1-2
	DEVELOPMENT	E.G., MULTIPLE CRACKS, LOAD TRANSFER, ETC.; CONTINUING DAMAGE	1.1-2
INTERPRETATION OF STRESS HISTORY	SEQUENCE	SEMIRANDOM VS. RANDOM	1.5
	TRUNCATION	IMPROPER TRUNCATION	1.1-1.3
	CLIPPING	ASSUMPTIONS	1.5-2
STRESS INTENSITY	LOADS/STRESSES	MEASUREMENT	1-1.5
		ANALYSIS 15%	1-1.5
RETARDATION	MODEL	SMALL IF CALIBRATED	1.1-1.3
	STATE OF STRESS	IF NOT ACCOUNTED FOR	1.1-1.5
	YIELD STRENGTH	IF, SAY, 10% TOO LOW	1.5-2.0

Note: If all errors were to work in the same direction, the total life could be miscalculated by a factor of 1-24,000.

**Data Input.** Retardation models are not ideal, but calibrated models provide results in which the error in life is generally only around 10% (given as a factor of 1.1 in Table 1), and in only a few exceptions does it run as high as 30% (given as a factor of 1.3). This is under conditions where  $\beta$ ,  $da/dN$ , stress history, and calibration factors are known. Misinterpretation of scatter and force fitting of unsuitable equations may well introduce a factor of 2, and even careful assumptions may cause a factor of 1.5. The situation is worse for mixed environments where the data used are a weighted average for separate environments.

**Flaws.** By assuming a "conservative" circular flaw instead of an elliptical flaw, one may unwittingly introduce another factor of 2 (Ref 1). Moreover, many flaws are not elliptical, so the assumption of ellipticity can also cause errors. Assumptions about initial flaw size may introduce errors that are equally large. Assumptions about flaw development, continued cracking when cracks run into holes, and so on are also influential.

**Load history** is always an approximation. Loads and number of occurrences must be approximated, and decisions have to be made about clipping and truncation. The simple clipping of a few loads can have dramatic effects (Ref 1), so the decision on clipping should be made by damage tolerance experts, not load experts. Improper sequencing is another error driver. Randomizing a load history that in reality was semirandom (mild weather and storms) can cause great differences (Ref 1).

**Stress-intensity** errors are drivers of intermediate importance. Crack growth is roughly proportional to the third power of  $K$ . Because  $K = \beta\sigma\sqrt{\pi a}$ , all errors in life are proportional to the errors in  $\beta$  and  $\sigma$  to approximately the third power. A 10% error in stress causes a factor on life of  $1.1^3$ , or 1.33. Errors in stress stem from errors in loads and stress analysis.

The stresses may be obtained within 10% for the given load, but the load also contains an error. Hence, the final stress may have an error larger than 10%, possibly 15%. This causes a factor on life between  $0.85^3$  and  $1.15^3$ , or 0.61 and 1.5, the expected life being 1. The error in  $\beta$  is also included in the stress intensity. If this error can be reduced (e.g., from 5 to 3%), the gain is only from a factor of  $1.05^3$  to a factor of  $1.03^3$ , or from 1.15 to 1.09, a small improvement indeed in comparison with other factors.

**Computer modeling errors** may be due to the integration scheme and/or rounding. A crack growth calculation is a simple numerical integration that does not give rise to large errors, but rounding can sometimes cause significant errors, especially in cycle-to-cycle integration where  $da$  (one cycle) is very small. This is an intrinsic problem of numerical computers. Personal computers provide eight significant figures in single precision and 16 in double precision. Double precision may be necessary in adding small numbers to large numbers, as when the small crack growth in one cycle is added to a large crack ( $a + da$ ).

For example, assume that in a particular cycle  $da$  is evaluated as:

$$7.45 \times 10^{-8} = 0.000,000,074,500,000 \quad (\text{EQ 16})$$

This occurs properly in eight significant figures; leading zeros do not count. If the crack size is 12, the results will be:

$$\begin{aligned} A + DA &= 12.000,000 + 0.000,000,0745 \\ &= 12.000,000 \end{aligned} \quad (\text{EQ 17})$$

Because 12.000,000 has eight significant figures,  $da$  will be rounded off and not be counted. It will appear as if there is no growth. This might occur in a similar way in 10 million successive cycles. The total growth would then have been:

$$10,000,000 \times (7.45 \times 10^{-8}) = 0.745 \quad (\text{EQ 18})$$

so that  $a + da = 12.745$ . However, in each cycle the growth was rounded off, and after the 10 million cycles  $a$  is still 12. Double precision will mend this problem, but only to a degree:

$$\begin{aligned} A + DA &= 12.000,000,000,000,00 \\ &+ 0.000,000,0745 = 12.000,000,074,500,00 \end{aligned} \quad (\text{EQ 19})$$

Indeed, after 10 million cycles the size will be 12.745. However, if  $da$  appears to be  $7.45 \times 10^{-16}$ , this crack growth will still be ignored. Fortunately, the above problem seldom arises, but the use of double precision is recommendable at one place in the software, namely where  $a + da$  is evaluated.

In the case that all errors discussed are active (which depends on the complexity of the problem), the total life (Table 1) could be miscalculated by a factor of 24,000. Naturally, errors generally will not all operate in the same direction, and some will compensate for others. However, the reliability of the result is affected much more by assumptions than by the shortcomings of fracture mechanics or computer software. It is not worthwhile to improve the strong links in a chain; the weak link must be improved. The weak links are the assumptions about rate data, clipping, flaw size, flaw shape, and so on, not the geometry factors, fracture mechanics concepts, and calibrated retardation models.

**Implications.** The magnitude of the inaccuracies due to assumptions should be assessed by repeating the analysis using different assumptions. It should be second nature to a damage tolerance analyst to perform calculations a number of times to evaluate the effects of assumptions with regard to stresses, loads, stress history, clipping levels, and so on. The common practice of making "conservative" assumptions everywhere assumes that all errors work in the same direction. Realism and sound judgment are necessary. Even with the best estimates the answer will be in error, but it will be closer to the truth. In the end, a safety factor should be applied as in a conventional design.

## Residual Strength of Metal Structures

David Broek, FractuREsearch

---

### Introduction

COMPLETE DAMAGE TOLERANCE ANALYSIS requires calculation of both the fatigue crack growth curve and the residual strength diagram. Calculation of the complete residual strength diagram is needed for determining the maximum permissible crack size ( $a_p$ ), which may be smaller than the critical crack size ( $a_c$ ). Calculation of the fatigue crack growth curve is needed for determining when the crack may reach  $a_p$ .

Problems can occur if either step is ignored. For example, often only the crack growth curve is calculated, because many computer programs have an automatic cutoff when the stress intensity,  $K$ , reaches the plane strain fracture toughness,  $K_{Ic}$ , or the plane stress fracture toughness,  $K_c$  (Ref 1, 2). This criterion allows crack growth to  $a_c$  instead of to the more conservative  $a_p$ . In addition, this criterion more often than not gives false information about  $a_c$ , even if linear elastic fracture mechanics (LEFM) applies to the material in question. This is discussed in more detail below.

It is also of little use (although it is often done) to calculate only the residual strength diagram and  $a_p$ . Knowing that a crack is smaller than permissible is of little comfort if further growth causes a fracture tomorrow. Hence, the crack growth curve must also be calculated. (See the article "The Practice of Damage Tolerance Analysis" in this Volume.)

The procedure to be followed for LEFM cases is reviewed in this article, along with elastic-plastic fracture mechanics (EPFM) and plastic fracture mechanics (PFM) procedures. The problem will be approached generally to show that LEFM and PFM are special cases of EPFM. Because the so-called "collapse condition" is crucial to the limitations of both LEFM and EPFM, collapse is briefly discussed first.

### Collapse and Net Section Yield

Consider two parallel bars of the same size and of the same material, as in Fig. 1(a). Each carries half of the total load; the strain in the bars is equal, causing an elongation,  $\Delta L$ . If the left bar is cut in two, the right bar will have to carry all the load. Assuming no bending, the stress, the strain, and the elongation will be twice as high as before. The left bar carries no stress at all, and the gap between the two halves of the left bar is  $2\Delta L$ .

**FIG. 1 EFFECT OF CUTS (CRACKS) ON STRESS AND STRAIN DISTRIBUTION. (A) TWO PARALLEL BARS. (B) TWO WELDED BARS OR ONE PIECE**

Next, consider the case where the left and right bar are attached (e.g., welded), as in Fig. 1(b). If the bars are intact, the situation is identical to the previous case. However, if the left bar is cut, a different situation develops. When the top half of the right bar is strained, the top half of the left bar must necessarily undergo approximately the same strain. Both bars being of the same material (same modulus of elasticity,  $E$ ), equal strain in the bars dictates equal stress. Thus, each bar still carries the same stress and each bar carries half the load. However, because the left bar is cut, the right bar alone must carry all the load across the cut. Below the cut, the two bars are again attached and must strain equally. Consequently, the bottom halves of the bar again share the load equally.

The attachment sets the condition for approximately equal strain and equal stress in both bars, almost all the way to the cut. Close to the cut, the load of the left bar must be transferred to the right bar, which will then carry the total load over a short distance. The load from the left bar must be transferred to the right and back over such a small distance that the additional load cannot be distributed evenly. Instead, most of the extra load will be carried by a small portion of the right

half, so that higher stresses occur close to the cut (Fig. 1b): there is a stress concentration at the cut. It does not matter whether the bars are welded or are one piece. Transfer of the load from the cut half to the right half takes place by shear.

It is helpful to consider load path (load flow) lines, imaginary lines that indicate, for example, how one unit of load is transferred from one loading point to the other (Fig. 2). For uniform load, the flow lines are straight and evenly spaced, indicating that the load is evenly distributed (uniform stress). If the load path is interrupted by a cut, the flow lines must go around this cut within a short distance, as shown. At the tip of the cut the flow lines are closely spaced, indicating that more load is flowing through a smaller area, which means higher stress.

FIG. 2 "LOAD-FLOW" LINES. (A) NO CRACK. (B) WITH CRACK. (C) AT CRACK. (D) STRESS DISTRIBUTION FOR INCREASING LOAD AND PLASTICITY

Assuming that the material does not exhibit strain hardening (horizontal stress-strain curve beyond yield), the stress cannot increase further after yielding occurs. Hence, by the time the entire section is yielding (fracture may occur before this can happen), the stress distribution in the section is as shown in Fig. 2(d). Note that even stress distributions may not be reached if fracture occurs before the entire ligament yields. Obviously, with the given stress-strain curve without work hardening, the cross section with the notch cannot carry any more load once the entire cross section is yielding, because the yielding will continue uninhibited until fracture results. This is called plastic collapse. Thus, the maximum load-carrying capability is:

$$P_{MAX} = B (W - A) F_{TY} \quad \text{(EQ 1)}$$

where  $a$  is the crack depth,  $W$  is the total width, and  $B$  is the thickness. This failure load is called the collapse load or limit load. The nominal stress in the full-width part is  $\sigma = P/BW$ . Hence, the part fails when the nominal stress is:

$$\sigma_{FC} = P/W = F_{TY} (W - A)/W \quad \text{(EQ 2)}$$

This is the equation of a straight line (as a function of the notch depth  $a$ ). If fracture occurs as a consequence of collapse, the strength,  $\sigma_{fc}$ , is the residual strength.

If the material work hardens, the notched cross section can carry a higher load. In general, however, the entire cross section cannot carry a stress equal to the tensile strength. Apparently, collapse will occur at an average ligament stress somewhat higher than the material yield strength,  $F_{ty}$ , but less than the ultimate tensile strength,  $F_{tu}$ . The average ligament stress at which collapse occurs is called the collapse strength,  $F_{col}$ .

For a non-work-hardening material,  $F_{col} = F_{ty}$ , and at best  $F_{col} = F_{tu}$ . It is not easy to determine  $F_{ty}$  and  $F_{tu}$  other than by a tensile test, and similarly, it is not easy to determine  $F_{col}$  other than by a test on a cracked sample.

For a work-hardening material, Eq 2 changes into:

$$\sigma_{FC} = F_{COL} (W - A)/W \quad (\text{EQ 3})$$

which is also the equation of a straight line as a function of notch depth.

This discussion applies only to the case of uniform applied loading. If there is bending (or other stress gradients in the applied stresses), the conditions for collapse are slightly more complicated (Ref 1).

## The Energy Criterion for Fracture

The principle of energy conservation applies during every physical process. Whether a certain event can or will occur can often be determined by equating the energy available for the event and the energy required to make it happen.

Fracture requires energy. Experiments show that the energy is not constant but rather increases while fracture is in progress. It is possible to account for this rise; the problem becomes somewhat more complicated, but it can still be solved rationally (Ref 1, 2). However, in many practical cases, the rise can be ignored because the process cannot be stopped.

We will denote the fracture energy as  $W$ . Thus, we are considering the amount of energy  $\Delta W$  to propagate a crack of size  $a$  over a small distance  $\Delta a$ . Mathematically, this is  $dW/da$ .

**The available energy**, also called the driving energy or released energy, is the energy available to make fracture happen. Two sources can deliver the energy required: the work done by the applied loads and the strain energy stored in the material. If a crack of size  $a$  advances to size  $a + da$ , the applied loads may do some work, and the strain energy contained in the body will change. The net sum of these two types of energy is the available energy. It can be shown (Ref 1, 2) that the net result always equals the absolute change in strain energy,  $U$ , namely  $dU/da$  per unit thickness:

$$DU/DA = (DU_{TOTAL}/DA)/T \quad (\text{EQ 4})$$

where the subscript "total" stands for the full thickness and  $t$  is the thickness.

The strain energy per unit volume equals the area under the stress-strain curve. If the stress-strain curve is a straight line (linear elastic), this area equals  $\frac{1}{2}\sigma\varepsilon$ , where  $\sigma$  is the stress and  $\varepsilon$  is the strain. For a nonlinear stress-strain curve, the area is  $C\sigma\varepsilon$ , where the constant  $C$  depends on the curvature. The total strain energy in a body of length  $L$ , width  $w$ , and thickness  $t$  is  $U_{total} = \alpha\sigma\varepsilon Lwt$ , in which  $\alpha$  may be a complicated function of the geometry and curvature of the stress-strain curve. Per unit thickness,  $U = \alpha\sigma\varepsilon Lw$ . Because  $\alpha$  and  $\varepsilon$  are dimensionless, while  $\sigma$  has the dimension of force/length-squared and  $L$  and  $w$  have the dimension of length, the dimension of  $U$  is that of force. Differentiation to crack size effectively means division by a length, so the units of  $dU/da$  are force/length.

This means that  $dU/da$  and  $dW/da$  have the dimension of N/m or lb/in., which is equivalent to  $\text{N} \cdot \text{m}/\text{m}^2$  or  $\text{in.} \cdot \text{lb}/\text{in.}^2$ . Because the unit of energy (work) is length times force, the unit of fracture energy is work per unit area. Thus,  $dU/da$  is

the energy available for fracture per unit thickness and per unit crack extension. Similarly,  $dW/da$  is the energy needed for fracture, again per unit thickness and per unit crack extension.

**The Stress-Strain Curve and the Available Energy.** It is necessary to find a quantitative expression for the available energy,  $dU/da$ . For uniaxial tension, this is possible with an equation (preferably a simple equation) for the stress-strain curve. The Ramberg-Osgood equation is useful:

$$\varepsilon = \sigma/E + \sigma^N/F \quad (\text{EQ 5})$$

where  $N$  is the so-called strain-hardening exponent. For lack of a better name,  $F$  is called the nonlinear modulus. The total strain consists of a linear and a nonlinear part:

$$\varepsilon = \varepsilon_{\text{ELASTIC}} + \varepsilon_{\text{PLASTIC}} \quad (\text{EQ 6})$$

Other common forms of the Ramberg-Osgood equations may be used instead. Equation 6 is used here to improve insight into the equations that follow.

The total strain energy in a body (per unit thickness) equals the area under the load-displacement curve (Fig. 3). The sample with the larger crack ( $a + da$ ) has a lower overall stiffness, so its load displacement curve is lower (Fig. 3c, 3d). Suppose a sample with a crack of size  $a$  is loaded to  $P_1$ . The strain energy in that sample is equal to the area OAD in Fig. 3(b). Further suppose that fracture would occur at load  $P_1$ , at constant displacement  $\delta_1$ . After fracture to  $a + da$ , the total strain energy would equal the area OBD. The released strain energy equals the hatched area between the two curves (Fig. 3d), this being the available energy if fracture indeed occurs. Also, the fracture energy equals that area. While Fig. 3(d) considers the case of fracture at constant displacement, it can be shown (Ref 1, 2) that fracture under constant load would deliver energy equal to the absolute change in strain energy ( $dU/da$  per unit thickness).

FIG. 3 LOAD DISPLACEMENT AND ENERGY RELEASE. (A) PLATE WITH CRACK. (B) LOAD DISPLACEMENT WITHOUT CRACK. (C) LOAD DISPLACEMENT FOR TWO CRACK SIZES. (D) ENERGY RELEASE AT CONSTANT DISPLACEMENT. (E) WORK DONE BY THE LOAD AT CONSTANT LOAD

Were the stress-strain curves to consist of a linear part only, the available energy would equal that shown in Fig. 3(d). In the case of nonlinear stress-strain curves, the difference with Fig. 3(d) is often quite small, so that LEFM applies.

**Quantification of Fracture Energy.** Fracture occurs when the available energy equals the energy required for fracture. Therefore, the criterion for fracture is:

$$DU/DA = DW/DA \quad (\text{EQ 7})$$

By implication, fracture will not occur when Eq 7 cannot be satisfied. There is no fracture when the area in Fig. 3(d) is smaller than the (required) fracture energy, and if there is no fracture, no energy will be released either. If we increase the load, more energy can be delivered, and if this higher deliverable energy equals the required fracture energy, fracture will occur.

The energy criterion can be quantified easily for a linear stress-strain curve. The earliest attempt to incorporate the nonlinearity of the stress-strain curve was by Rice in 1968 (Ref 3). He expressed  $dU/da$  in terms of a complicated integral. (For this reason,  $J = dU/da$  is often called the  $J$ -integral.) As shown below, an expression for  $J$  can be obtained without that integral. With hindsight and dimensional analysis, the problem can be solved in a simple way.

Equation 7 expresses the failure criterion.  $U$  contains the product  $\alpha\sigma\varepsilon$ , the strain energy per unit volume, where  $\alpha$  is a dimensionless constant that depends on the shape of the stress-strain curve and the shape of the body. One is at liberty to define  $\sigma$  as the stress at any location. It can be the local stress at any place or the applied stress, as long as one recognizes that the dimensionless  $\alpha$  depends on the choice. It is advantageous, but not necessary, to choose  $\sigma$  as the applied stress, away from the crack.

Because  $\sigma$  has units of force/area, and  $\alpha$  and  $\varepsilon$  are dimensionless, while  $dU/da$  must have units of energy/unit area (or force · length/area), the proper dimension for  $dU/da$  can be obtained only if the quantity  $\alpha\sigma\varepsilon$  is multiplied by one that has the unit of length. Clearly and unavoidably,  $dU/da$  must depend on the size of the crack,  $a$ , which has dimensions of length. Therefore, the expression for  $dU/da$  has to be:

$$DU/DA = \alpha\sigma\varepsilon A \quad (\text{EQ 8})$$

which has unit dimensions of energy/unit area (e.g.,  $\text{N} \cdot \text{m}/\text{m}^2$  or  $\text{in.} \cdot \text{lb}/\text{in.}^2$ ). While this expression for  $dU/da$  is obvious from dimensional analysis, it follows from other considerations as well (Ref 1). Consequently, the criterion for fracture of Eq 7 becomes:

$$\alpha\sigma\varepsilon A = DW/DA \quad (\text{EQ 9})$$

where  $\alpha$  depends on the shape of the stress-strain curve and the geometry of the body. In its simplest form,  $\alpha = f(a/w, N)$ . With the Ramberg-Osgood equation, we can separate the linear and nonlinear parts of  $dU/da$  and arrive at:

$$\alpha_{\text{LINEAR}}\sigma\varepsilon A + H_{\text{NONLINEAR}}\sigma\varepsilon A = DW/DA \quad (\text{EQ 10})$$

Further, when we substitute  $\varepsilon = \sigma/E$  and  $\varepsilon = \sigma^N/F$  for the elastic and plastic parts (ignoring anisotropy), the final expression becomes:

$$\pi\beta^2 (A/W) \sigma^2 A/E + H(A/W, N) \sigma^{N+1} A/F = DW/DA \quad (\text{EQ 11})$$

where the fracture energy  $dW/da$  is a measure of toughness. The coefficients have been replaced by  $\alpha = \pi\beta^2$  for the linear part and by  $H$  for the nonlinear part. The first term for the linear part is identical to the second term with  $N = 1$  and  $F = E$ .

We have now arrived at a quantifiable expression for the fracture energy. The equation contains two unknown geometry factors,  $\beta$  and  $H$ . ( $E$ ,  $F$ , and  $N$  can be obtained from the measured stress-strain curve.) Both  $\beta$  and  $H$  can be calculated (see the appendix to this article, "Computation of Geometry Factors.")  $\beta$  can be easily established (Ref 1) for almost any geometry. For example, for a center crack in a rectangular body of width  $W$ , the expression for  $\beta$  is:

$$\beta = \sqrt{\sec(\pi a/W)} \quad (\text{EQ 12})$$

Determining  $H$  is more difficult, but it has been calculated for some cases (Ref 4). Table 1 shows values of  $H$  for center cracks.

**TABLE 1 VALUES FOR  $H$  FOR CENTER-CRACKED PANELS IN PLANE STRESS**

### Toughness and Geometry Factors

**Measurement of Toughness.** Provided that  $\beta$  and  $H$  are known, the toughness of any material can be measured by means of two tests. A normal tensile test yields elongation as a function of load, from which the stress-strain curve can be obtained. The stress-strain curve is curve fitted to Eq 5 to obtain  $E$ ,  $F$ , and  $N$ . The second test is performed on a coupon with a crack of any geometry for which  $\beta$  and  $H$  are known, although ASTM has standardized certain specimen types. The length of this crack,  $a$ , is known, and the load to failure of the specimen is measured. Given width and thickness, the applied stress at fracture can be obtained from the load. Together the two tests provide all the information needed to calculate the toughness:  $E$ ,  $F$ , and  $N$  from the tensile test;  $\beta$ ,  $H$ , and  $a$  from the size of the crack, and  $\sigma$ , the fracture stress measured in the second test. According to convention,  $dU/da$  and  $dW/da$  are evaluated per crack tip. The convention implies that a central crack is defined as  $2a$ . If one wishes to use established values for  $\beta$  and  $H$ , the convention must be followed.

The definition of toughness is provided in Eq 11. Over time, the three terms in Eq 11 have been given a variety of shorthand names. For the two terms on the left side of the equation, the most common shorthand names have been  $G$  and  $J$ , respectively. Sometimes  $J$  is used for the sum of the two. Many researchers use  $J_{\text{elastic}}$  and  $J_{\text{plastic}}$ . The shorthand

expressions for the term on the right side have been  $R$ ,  $J_R$ ,  $J_C$ , and others. Hence, the following equalities all express the same thing as Eq 11:

$$\begin{aligned} G + J &= J_C \\ G + J &= J_R \\ J_{ELASTIC} + J_{PLASTIC} &= J_C \text{ (OR } J_{IC}) \end{aligned} \quad \text{(EQ 13)}$$

The most important assumption underlying Eq 11 is that the material is nonlinear elastic (Ref 2). It is assumed that the same nonlinear curve is followed during unloading as during loading. Loading presents no problems, because the nonlinear curve is certainly followed during loading. However, during unloading much of the deformation of the nonlinear part is not retrievable. This means that the associated nonlinear part of the strain energy is not retrievable either and is not available to deliver the required fracture energy. The validity of  $J$  breaks down after a small amount of unloading, even if this is due to crack extension. The point at which this happens is not fixed and can be determined only by finite element analysis (Ref 5). For this reason, variations of  $J$  have been proposed.

**LEFM and EPFM.** Table 2 shows typical results for center-cracked panels where  $H$  is known. In many cases the second term in Eq 11 is very small compared to the first. Under this condition (LEFM), it is justifiable to neglect the second (plastic) term:

$$\beta^2 \sigma^2 \pi A / E = DW / DA \quad \text{(EQ 14)}$$

This can be reduced to:

$$\begin{aligned} \beta \sigma \sqrt{\pi a} &= K_{IC} \\ K &= K_{IC} \end{aligned} \quad \text{(EQ 15)}$$

where  $K$  is the stress-intensity factor and  $K_{IC}$  is the LEFM fracture toughness, defined as  $K_{IC} = \sqrt{EdW/da}$ . Hence, in LEFM the residual strength can be calculated from:

$$\sigma_{RES} = K_{IC} / \beta \sqrt{\pi A} \quad \text{(EQ 16)}$$

In Eq 16,  $K_C$  can be substituted for  $K_{IC}$ .

<b>FAILURE CONDITION</b>	<b>LEFM</b>	<b>EPFM</b>	<b>COLLAPSE</b>

(A) NEGLIGIBLE COMPARED TO 94.2

In another case in Table 2, the situation is reversed: the first term is negligible with regard to the second. Under this condition (PFM), only the plastic term needs to be carried:

$$H\sigma^{H+1} A/F = DW/DA \quad (\text{EQ 17})$$

Then the residual strength ( $\sigma_{res}$ ) can be obtained as:

$$\sigma_{RES} = (FJ_C/HA)^{1/N+1} \quad (\text{EQ 18})$$

where  $J_c = dW/da$ .

In the remaining case (EPFM), neither term is negligible and both must be carried. The residual strength is obtained by solving the following equation for  $\sigma$ :

$$\pi\beta^2\sigma^2 A/E + H\sigma^{N+1} A/F = J_C \quad (\text{EQ 19})$$

For the LEFM and PFM cases (Eq 16 and 18), the equations can be solved directly for  $\sigma$  to obtain the residual strength. However, no solutions exist for algebraic equations with powers higher than four, so for the EPFM case (Eq 19), the residual strength can be obtained only by iteration. Fortunately, fast converging iteration schemes can be employed that obtain the solution quickly, especially if a computer is used.

It is now clear that LEFM and PFM are but limiting cases of the general equation, Eq 19, for EPFM. The use of these limiting cases is perfectly legitimate, provided that one term is negligibly small (Table 2). It is also clear that, for the purpose of tests and residual strength analysis, there is no need to express  $J$  as an integral. Undeniably, the integral has been historically useful in the development of EPFM, but it has little significance for practical toughness testing and damage tolerance analysis. Its remaining use is in the computation of the geometry factor  $H$ , as a convenience and not as a fundamental necessity. (See the appendix to this article, "Computation of Geometry Factors.")

**The Geometry Factors  $\beta$  and  $H$ .** Only one geometry factor,  $\beta$ , is needed for LEFM, and only one geometry factor,  $H$ , is needed for PFM, but both are required for EPFM. Values of  $\beta$  have been obtained in abundance (mostly by numerical analysis) and have been compiled in handbooks (Ref 6, 7, 8). Using the principles of superposition and compounding (Ref 1), these solutions can be used to obtain  $\beta$  for almost any conceivable case (see also the article "The Practice of Damage Tolerance Analysis" in this Volume).

So far, however, values for  $H$  have been obtained for only a few geometries, again by numerical analysis, and handbooks for  $H$  are small. The reason is that computation of  $H$  is expensive; not only must the analysis be nonlinear, but the dependence of  $H$  on  $N$  requires that  $H$  be computed for a range of  $N$  values. However, in time, handbooks for  $H$  may be expected to become as comprehensive as those for  $\beta$ .

Before this happens it is to be hoped that analysts start using Eq 14, because an unnecessary complication was introduced when presently available  $H$  values were computed (Ref 9). The developers of the first " $H$ -handbook" (Ref 11, 12) chose to use a different expression for the Ramberg-Osgood equations than the one used in Eq 2, namely:

$$\varepsilon_{TOTAL}/\varepsilon_0 = \sigma/\sigma_0 + \alpha(\sigma/\sigma_0)^N \quad (\text{EQ 20})$$

There is no fundamental objection to this expression, but there is an important practical objection. Equation 5 contains three parameters ( $E, F, N$ ), while Eq 20 contains four ( $\varepsilon_0, \sigma_0, \alpha, N$ ). If only three are needed, the use of four implies that one parameter is merely a function of the other three and is expendable. It also means that one of the parameters may be chosen freely (e.g.,  $\varepsilon_0$ ). The developers insist that  $\varepsilon_0$  must be chosen because  $\varepsilon_0 = \sigma_0/E$ , where  $\sigma_0$  is the yield strength of

the material, but that is merely their choice (see pages 102-108 of Ref 1). Any value of  $\sigma_0$  is permissible as long as  $\epsilon_0 = \sigma_0/E$ . It would have been preferable if the superfluous parameter  $\alpha$  had been eliminated for Eq 16 to read:

$$\epsilon_{\text{TOTAL}}/\epsilon_F = \sigma/\sigma_F + (\sigma/\sigma_F)^N \quad (\text{EQ 21})$$

where  $\sigma_f = F^{1/N}$  as in Eq 2 and  $\epsilon_f = \sigma_f/E$  (where  $\sigma_f$  is the stress for which the plastic strain equals unity). This would only mean replacing  $F$  by  $\sigma_f^N$  in all the above equations, merely for mathematical convenience. Be that as it may, we are left with a superfluous parameter,  $\alpha$ , which obviously depends on the other three (because of the assumptions made), by:

$$\begin{aligned} \epsilon_0 &= \sigma_0/E \\ \alpha &= \alpha_0^N \epsilon_0 F \end{aligned} \quad (\text{EQ 22})$$

With the use of Eq 16 the equations for  $J_{\text{plastic}}$  (Eq 17, 19) can be written as:

$$J_{\text{PLASTIC}} = \alpha \sigma_0 \epsilon_0 C H_1 (P/P_0)^{N+1} \quad (\text{EQ 23})$$

In this equation  $P$  is the load and  $P_0$  is the load at collapse, supposing that  $\sigma_0$  were the collapse strength. Instead of the crack size,  $a$ , the unbroken ligament,  $c$ , is used. Finally,  $h_1$  is the geometry factor provided in the handbook (Ref 4). Clearly, the load  $P$  is related to the stress,  $P_0$  is related to  $\sigma_0$ , and the ligament  $c$  is related to the crack size,  $a$ :

$$\begin{aligned} P &= G\sigma \\ P_0 &= K\sigma_0 \\ C &= (W/2A - 1) \\ A &= LA \end{aligned} \quad (\text{EQ 24})$$

where  $g$ ,  $k$ , and  $l$  are just functions of the geometry. With this knowledge, the complicated Eq 23 turns into:

$$J_{\text{PLASTIC}} = (\sigma_0^N / \epsilon_0 F) \sigma_0 \epsilon_0 L A H_1 (G/K)^{N+1} (\sigma/\sigma_0)^{N+1} \quad (\text{EQ 25})$$

which reduces to:

$$J_{\text{PLASTIC}} = H \sigma^{N+1} A/F \quad (\text{EQ 26})$$

where  $H = lh(g/k)^{N+1}$ . Equation 26 is the basic form of the equation already presented as Eq 11. Equation 23 is just a complicated version of the same. Obviously,  $\alpha$ ,  $\sigma_0$ , and  $\epsilon_0$  can be divided out; they are superfluous. This should be expected; a collapse load cannot enter into  $J$  because the stress-strain equation used has no limit. The elastic energy release,  $G$ , could be expressed in the same manner by using  $P = g\sigma$ ,  $P_0 = k\sigma_0$ , and  $\sigma_0 = \epsilon_0 E$ :

$$G = \pi \beta^2 \sigma_0 \epsilon_0 (K/G)^2 (P/P_0)^2 \quad (\text{EQ 27})$$

Introducing the collapse load does not make  $G$  dependent on same; it merely amounts to multiplying the numerator and denominator by the same number, which does not change the basic equation. Collapse does not enter LEFM or EPFM equations, and an artificial introduction does not change this fact. Collapse is a competing condition that must be assessed separately.

Two other objections can be raised against Eq 23. Instead of just one geometry parameter,  $H$ , one must use the four geometry parameters given in Eq 23 and 24:  $h$ ,  $g$ ,  $k$ , and  $l$ . Every time a calculation is performed, double work is necessary: parameters must be derived and are subsequently divided out. Naturally, one could, once and for all, calculate  $H$  from  $H = lh(g/k)^{N+1}$  and from then on use Eq 17 and 19. This was done to obtain the  $H$  values in Table 1. The second objection is that  $J$  is expressed in the load  $P$ , while in engineering one works with stress. Therefore Eq 19 is more useful;

all other fracture mechanics equations are expressed in stress for this very reason. For complicated structures the conversion from load to stress is done in the design stage, not at the time of fracture analysis. Once more, it is necessary to urge that future computations and compilations of  $H$  be based on Eq 19. Practical fracture mechanics has no need for unnecessary and irrelevant complications.

## Residual Strength of Metal Structures

David Broek, FractuREsearch

---

## Calculation of the Residual Strength Diagram

Depending on the case (LEFM, EPFM, or PFM), the complete residual strength diagram is obtained by solving one of the equations (Eq 16, 18, or 19) for a range of  $a$  values. (Twelve to 16 values for  $a$  are usually sufficient to establish the curve for plotting.) If  $\beta$  and  $H$  are simple functions or available in tabular form, the computations for LEFM and PFM can be accomplished quickly with a hand calculator or a spreadsheet computer program. The iterative solution of Eq 19 must be programmed, so the use of a dedicated software program for residual strength analysis is advisable. Some damage tolerance software is equipped with these capabilities.

First, consider the use of LEFM and Eq 16. Obviously, solutions can be obtained for any geometry (any  $\beta$ ), but for the purpose of this discussion assume that  $\beta$  is given by Eq 12 for a center-cracked plate. Then if  $a = W/2$  (the whole plate is already cracked),  $\beta$  becomes infinite, so that Eq 19 provides  $\sigma_{\text{res}} = 0$ , as it should (Fig. 4a). Imagine for a moment that  $\beta$  is universally equal to 1. Then Eq 16 represents the equation for an orthogonal hyperbola with the two axes as asymptotes. For  $\beta = 1$  the resulting curve is therefore the modified hyperbola shown in Fig. 4(a).

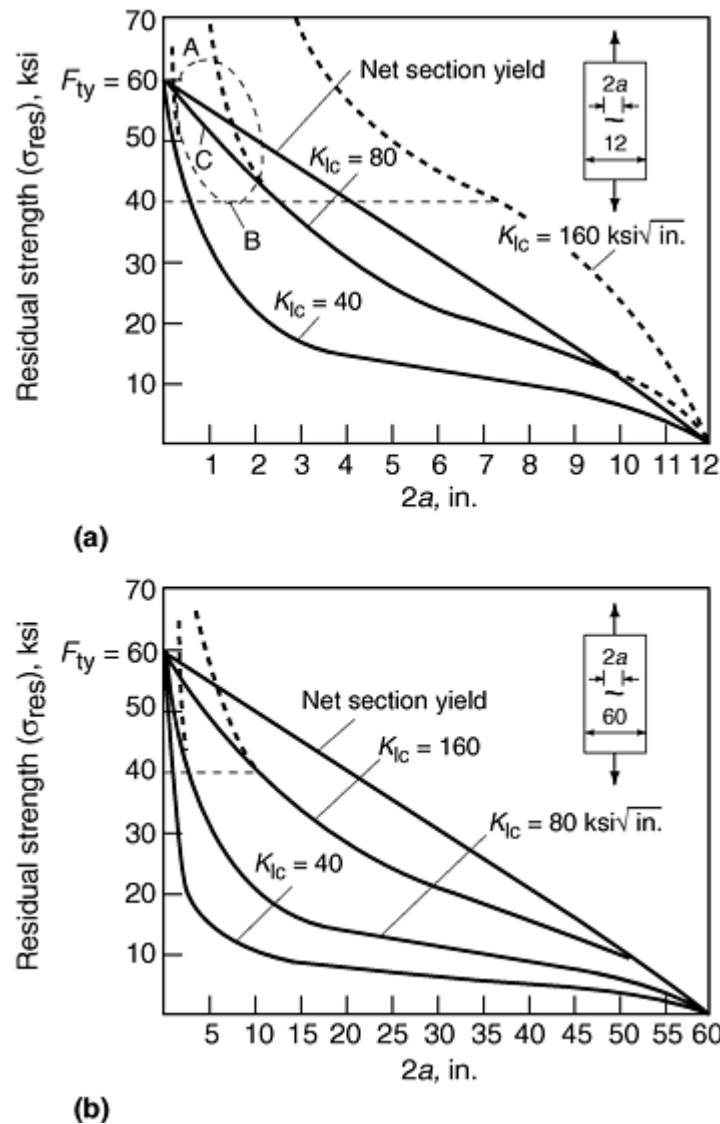

FIG. 4 EFFECT OF PANEL SIZE ON RESIDUAL STRENGTH WITH MATERIAL YIELD STRENGTH ( $F_{TY}$ ) OF 415 MPa (6 KSI). (A) PANELS 300 MM (12 IN.) WIDE. (B) PANELS 1525 MM (60 IN.) WIDE

For very small  $a$  the value of  $\beta_i$  is indeed equal to unity, so that the left-hand part of the curve tends to infinity (vertical dashed lines in Fig. 4b). Substitution of  $a = 0$  in Eq 14 gives  $\sigma = \infty$ . Naturally, an infinite strength is impossible, because the (residual) strength of an uncracked plate or structure is equal to  $F_{tu}$ .

As discussed above, if the predicted fracture stress is higher than the stress causing failure by collapse, then collapse will prevail. This is the case when the result of Eq 3 is less than the result of Eq 16. The lower of the two is the actual residual strength discussed. It appears that there are three situations in which a collapse failure could prevail:

- THE TOUGHNESS IS VERY HIGH.
- THE CRACK IS VERY SMALL.
- THE WIDTH  $W$  IS VERY SMALL.

These situations are illustrated in Fig. 4 and 5. For the material with  $K_{Ic} = 175 \text{ MPa}\sqrt{\text{m}}$  ( $160 \text{ ksi}\sqrt{\text{in.}}$ ), a panel that is 300 mm (12 in.) wide always fails by collapse, but a panel of the same material that is 1500 mm (60 in.) wide fails by Eq 16. Apparently, for a particular structural configuration, failure may occur by collapse (unconditionally leading to fracture) in certain instances and by fracture in other instances. Collapse always prevails if the cracks are small. At any

toughness, Eq 16 puts the fracture stress at infinity when the crack size approaches zero. Thus, the residual strength curve will always rise asymptotically to infinity for small  $a$ . This means that there will always be a point at a certain small  $a$  where collapse failures will prevail, regardless of how low the toughness is.

FIG. 5 EFFECT OF PLATE SIZE ON FAILURE AND COLLAPSE. RESIDUAL STRENGTH (SOLID LINES) IS THE LOWEST VALUE OF THE SUPERIMPOSED CURVES FOR  $\sigma_{FR}$ ,  $\sigma_{TI}$ , AND  $\sigma_{FC}$ .

Thus, the left part of the curve will always be in error, whether the toughness is high or low. For  $a = 0$ , the strength is  $F_{tu}$  (or less), while for large  $a$ , Eq 16 applies (the curve in Fig. 4). Obviously, the behavior between  $a = 0$ ,  $\sigma \cong F_{ty}$ , and the curve for large  $a$  cannot be as A or B in Fig. 4(a). Hence, if one assumes curve C (tangent to the curve), the assumption cannot be far from the truth; it certainly will be adequate for engineering analysis.

It is important to understand that two plates of different sizes, but of the same material, can fail differently: one by collapse, the other by fracture. This is depicted in Fig. 4 and 5. If, as in the case of Fig. 5, a plate of the smaller size  $W_3$  is used in a test, the failure occurs by collapse. Hence, the value of the stress intensity at the time of failure would still be lower than the toughness, because  $K$  has not yet reached the toughness.

In the case of EPFM and PFM, the residual strength diagram is calculated in the same manner, through the use of Eq 18 and 19 instead of Eq 16. Some general damage tolerance software provides all options, includes libraries for  $\beta$  and  $H$ , and performs the necessary compounding and superposition. (See the article "The Practice of Damage Tolerance Analysis" in this Volume.)

Contrary to common belief, the same problem is encountered in PFM and EPFM, because Eq 18 and 19 also predict an infinite strength for  $a \rightarrow 0$ . Of course, artificialities, such as those leading to Eq 23 and 27, do not cure this ill. Thus, whether one uses LEFM, EPFM, or PFM, the competing condition for collapse must always be evaluated. The actual residual strength is the lower of the two. This is one of the reasons that the permissible crack size does not follow simply from a cutoff in crack growth analysis.

**The Failure Analysis Diagram.** The conditions discussed above are illustrated in a so-called failure analysis diagram (Ref 10) that was developed in Great Britain. The failure analysis diagram can be used to represent the whole gamut of fractures, from brittle to fully plastic, as shown in Fig. 6. Stress intensity is plotted along the ordinate; stress, along the abscissa. The stress is limited by collapse and the stress intensity is limited by the toughness.

FIG. 6 FAILURE ANALYSIS DIAGRAM. (A) REGIMES OF FRACTURE MECHANICS. (B) ELASTIC-PLASTIC REGION. (C) NORMALIZED DIAGRAM

The limits of  $K_c$  at one end and collapse at the other end require that there be a limiting line from  $K_c$  to  $\sigma_{fc}$ . The end portions of this contour must be straight, so that there is only a relatively small curved part. The top horizontal part is governed by LEFM and the vertical portion is governed by collapse. The curved part is the regime of EPFM. For many applications it may be permissible to approximate the diagram by two straight lines (Fig. 6b). The failure analysis diagram is usually presented in normalized form by plotting  $K/K_c$  and  $\sigma/\sigma_{fc}$  so that the intercepts with the axes are at 1 (Fig. 6c). This normalization makes the diagram universal.

The use of the failure analysis diagram can best be demonstrated by an example. Consider a material with  $K_{Ic} = 55 \text{ MPa}\sqrt{\text{m}}$  ( $50 \text{ ksi}\sqrt{\text{in.}}$ ) and  $F_{col} = 415 \text{ MPa}$  ( $60 \text{ ksi}$ ). Assume that the "structure" is a center-cracked panel, 12 in. wide, with a crack  $2a = 2 \text{ in.}$  subjected to a stress of 10 ksi. The nominal stress at collapse according to Eq 2 would be  $\sigma_{fc} = 60(12 - 2) = 50 \text{ ksi}$ . Thus,  $\sigma/\sigma_{fc} = 10/50 = 0.20$ . The stress intensity is  $K = \beta\sigma\sqrt{\pi a}$ , so that with  $\beta \approx 1$  its value is  $K = 10\sqrt{\pi \times 1} = 17.7 \text{ ksi}\sqrt{\text{in.}}$ . Thus,  $K/K_c = 0.35$ . Now the point  $\sigma/\sigma_{fc} = 0.20$  with  $K/K_c = 0.35$  can be plotted in the diagram as point A in Fig. 7. If the stress is raised to 20 ksi, the stress intensity becomes  $K = 20\sqrt{\pi \times 1} = 35.5 \text{ ksi}\sqrt{\text{in.}}$ , and  $K/K_c = 35.5/50 = 0.71$ . Further,  $\sigma/\sigma_{fc} = 20/50 = 0.40$ . This produces point B in the diagram.

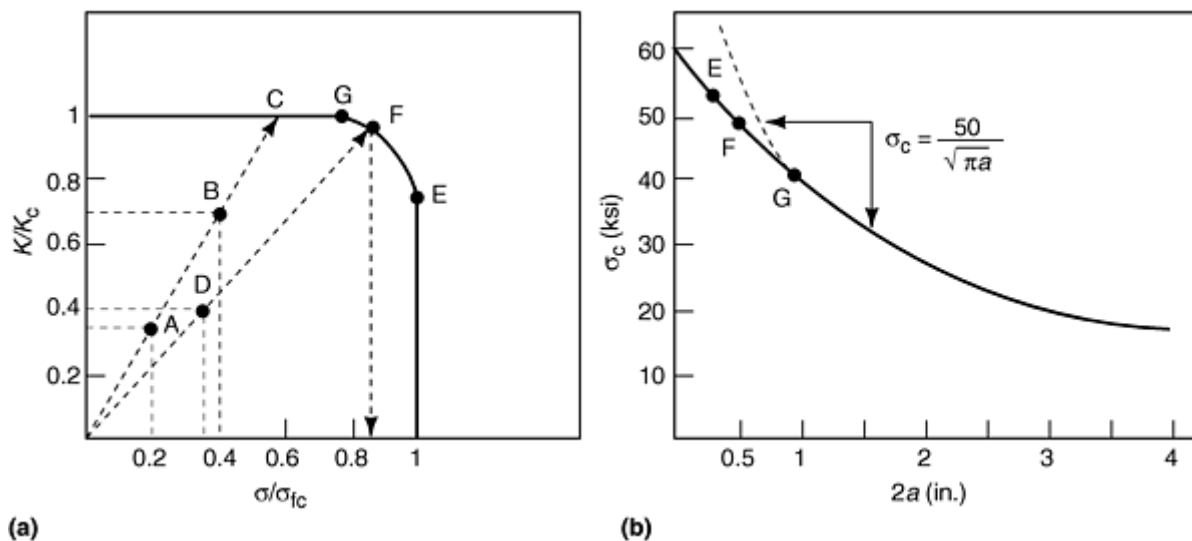

FIG. 7 FAILURE ANALYSIS DIAGRAM. (A) CONSTRUCTION (SEE TEXT FOR DETAILS). (B) COMPARABLE POINTS IN RESIDUAL STRENGTH DIAGRAM (COMPARE FIG. 4)

Clearly,  $K/K_c$  and  $\sigma/\sigma_{fc}$  increase proportionally. Therefore, a straight line through the origin provides all combinations of  $K$  and  $\sigma$ . Fracture occurs where this line intersects the fracture locus. Judgment of the proximity of fracture can be made from the distance between a point and the contour. Extension of the line will also show whether fracture occurs by LEFM, EPFM, or collapse. In the present example, LEFM applies (point C).

In its normalized form, the failure analysis diagram is the same for all materials and structures, regardless of  $K_c$  and  $F_{col}$ . Given the scatter in material behavior, an approximation of the curved part will suffice for many purposes. A more precise diagram (curved part) can be drawn based on EPFM.

The use of the diagram for a particular application requires calculation of the stress at collapse and the stress intensity at a given stress and crack length. This permits calculation of  $K/K_c$  at that stress, which can be plotted. The diagram presents a means for assessing the proximity of fracture, and it shows what kind of fracture to expect, putting the three areas of fracture analysis (LEFM, EPFM, and collapse) in perspective. It is useful in conjunction with, not instead of, the residual strength diagram, as it can be derived from the latter. Its significance is that it illustrates, from a technical point of view, that the EPFM fracture criterion is not very sensitive, and also that in EPFM, collapse must be treated separately, as a competing condition.

## Appendix: Computation of Geometry Factors

### Geometry Factors

Because the geometry factor,  $\beta$ , that appears in both  $J$  and  $K$  is for the elastic case, it is independent of the stress-strain properties. For a given configuration and crack size, it can be obtained by several kinds of numerical analysis, finite element analysis presently being the most prominent. Given a geometry and crack size,  $a$ , two analyses are performed with an arbitrary load of, say, 1000 N. In one case, the crack size is  $a$  and in the second case it is  $a + \Delta a$ . In both cases, the strain energy,  $U$ , per unit thickness is calculated. From this,  $dU/da$  is obtained as  $(U_1 - U_2)/\Delta a$ . Then  $\beta$  can be obtained from  $\beta\sigma\sqrt{\pi a} = \sqrt{E \times dU/da}$ , where  $a$ ,  $\sigma$ , and  $E$  are known. Alternatively, because  $J = dU/da$ , the  $J$ -integral can be calculated from the finite element analysis result, from which  $\beta$  can be obtained in the same manner as above.

The above computation needs to be done only once for a range of crack sizes. Many of the resulting geometry factors are presented in handbooks (Ref 6). Because the procedure is relatively easy, geometry factors have been obtained for many generic configurations. By using these handbook solutions, the geometry factors for many more configurations and loading conditions can be obtained by means of compounding and superposition (Ref 1).

The geometry factor,  $H$ , for  $J$  can be obtained in the same manner. Indeed, by obtaining two solutions for  $a$  and  $a + \Delta a$ , one arrives at  $J = dU/da$  without the use of the  $J$ -integral. But it is more convenient to evaluate the  $J$ -integral from the results of the finite element analysis, in the same manner as can be done for  $K$  and  $\beta$ . For  $H$ , however, the computation is more expensive because the finite element analysis must be nonlinear, which increases computation time greatly. Besides, the computations must be repeated for a range of  $N$  values, because  $H$  depends on  $N$ . For each case,  $H$  is obtained from  $H\sigma^N a/F = J (= dU/da)$ , where  $\sigma$ ,  $a$ ,  $N$ , and  $F$  are known and  $J$  is calculated in the analysis.

The computation of  $H$  for one geometry (and the necessary range of  $N$  values) requires on the order of 100 times the effort needed to calculate  $\beta$  for the same case, so the " $H$ -handbook" (Ref 4) is small. Besides,  $H$  values for other

configurations cannot be obtained so easily by superposition and compounding, unless one uses estimation schemes (Ref 1).

Unfortunately, although the above procedure was used in compiling the *H*-handbook (Ref 4), it is based on a needlessly complicated definition of *J* (containing three unnecessary parameters, as given in Eq 23). The *H* values shown in Table 1 were derived from  $h_1$  (the geometry factors presented in the handbook) by sanitizing the expression for *J* to that of Eq 17. The *J*-integral is useful for the computation of geometry factors, but for fracture mechanics applications, *J* can be derived without the integral.

### Introduction

FAILURES in engineering structures are still common today, despite the fact that modern tools for designing structures are very sophisticated and readily available. Computer-aided design, finite-element stress analysis, computerized material property databases, and an array of process simulation tools are among the many design aids accessible to the engineer. In addition, over the past 20 to 30 years national and international codes and standards have been developed for many industries, and these provide explicit guidelines on such issues as material selection, design methods, standardized load histories, and safety factors (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16).

In general, most of today's fabricated components and structures are welded, and invariably the weld joint is the most critical area from the performance perspective. An examination of structural and component failures documented in open literature over the past 50 years or so clearly indicates that failures predominantly start at connections, and in particular at weld joints. Placement of a weld onto a metallic material imparts many detrimental features, which include changes in microstructure and mechanical properties, introduction of welding residual stresses, local elevation of the applied stress, and introduction of weld imperfections. Depending on the operating environment and loading conditions, one or more of these features could lead to failure by a number of different mechanisms. Even though today's engineers are armed with good tools, and they comply with specific industry/regulatory codes or standards for design and manufacturing, failures are still inevitable. There are many reasons why in-service failures can occur, including:

- LACK OF KNOWLEDGE OF SERVICE LOADS AND CYCLES
- LACK OF KNOWLEDGE OF THE OPERATING ENVIRONMENT
- IMPROPER SPECIFICATION OF THE DESIGN LIFE
- IMPROPER USE OF THE DESIGN METHOD AND LACK OF CONSIDERATION OF KEY FAILURE MODES
- USE OF INCORRECT MATERIAL PROPERTIES FOR DESIGN
- IMPROPER SELECTION OF MATERIALS AND WELDING PROCEDURES
- LACK OF INSPECTION DURING FABRICATION AND VARIABILITY IN FABRICATION PRACTICE
- OPERATION OF EQUIPMENT/COMPONENT BEYOND DESIGN SPECIFICATION

In welded structures, fatigue cracking is by far the most common failure mechanism, and unstable fracture (although rare) is perhaps the most dramatic, occurring without warning and often leading to serious consequences. This article discusses the various options for controlling fatigue and fracture in welded steel structures, the factors that influence them the most, and some of the leading codes and standards for designing against these failure mechanisms. It excludes high-temperature fracture, environmental cracking, and nonferrous materials.

## Fatigue and Fracture Control of Weldments

Tarsem Jutla, Caterpillar Inc.

---

## Fracture Control Plans for Welded Steel Structures

**Weld Imperfections.** All welded structures contain imperfections to some level of examination, and the joint itself is a discontinuity in the structure. Welding imperfections (Fig. 1) fall into three broad categories: planar imperfections, volumetric imperfections, and geometrical imperfections.

FIG. 1 DEFECTS AND DISCONTINUITIES IN WELDED JOINTS

**Planar imperfections** are sharp crack-like features that can substantially reduce the fatigue strength of a welded joint or cause initiation of brittle fractures. Examples include hydrogen cracks, lamellar tears, lack of fusion, reheat cracks, solidification cracks, and weld toe intrusions. The last group are nonmetallic intrusions at the weld toe region that act as crack starters for fatigue. They are present on a microscopic level, and on average they are typically 0.1 mm (0.004 in.) in depth and can be as much as 0.4 mm (0.016 in.) deep (Ref 17). These features are the primary reason why fatigue in welds is dominated by crack propagation.

**Volumetric imperfections** include porosity and slag inclusions. Because these types of imperfections tend to be nearly spherical in form, their notch effect is minor and they usually have little or no influence on the fatigue behavior. However, they do reduce the load-bearing area of the weld and hence reduce the static strength of the joint.

**Geometrical imperfections** include misalignment, overfill, stop/starts, undercut, and weld ripples. Geometric imperfections have the effect of locally elevating the stress over and above the general stress concentration due to the joint geometry. Methods for calculating the stress concentration factor due to misalignment are readily available (Ref 18). However, unintentional misalignment that occurs during fabrication cannot be allowed for during design, and this can only lead to early failures. Guidance is also available on acceptable levels for undercut, overfill, and location of stop/starts (Ref 19). Weld ripples become stress concentrators for fatigue only when the weld is loaded axially.

**Failure Modes.** Depending on the operating environment and the nature of the applied load, a steel structure or component operating under ambient conditions can fail in many different modes. The potential failure modes for welded fabrications are:

- UNSTABLE FRACTURE (BRITTLE OR DUCTILE)
- DUCTILE FRACTURE
- PLASTIC COLLAPSE
- BUCKLING
- FATIGUE
- CORROSION FATIGUE
- CORROSION
- STRESS-CORROSION CRACKING
- HYDROGEN-INDUCED CRACKING

The first four modes of failure occur under static load. While brittle fracture can occur at nominal stresses substantially below the yield point and with negligible overall deformation, ductile fracture, plastic collapse, and buckling are often preceded by significant plasticity. The remaining five failure modes can be broken down into fatigue and environmental cracking.

Figure 2 summarizes the different loading paths that can result in failure of a statically or cyclically loaded structure (assuming environmental effects are not significant). The loading paths range from initiation of fatigue cracks to crack propagation under cyclic loading, which could then potentially lead to brittle fracture under nominally elastic conditions (applied stresses well below yield) or to plastic collapse (overload of the remaining structure).

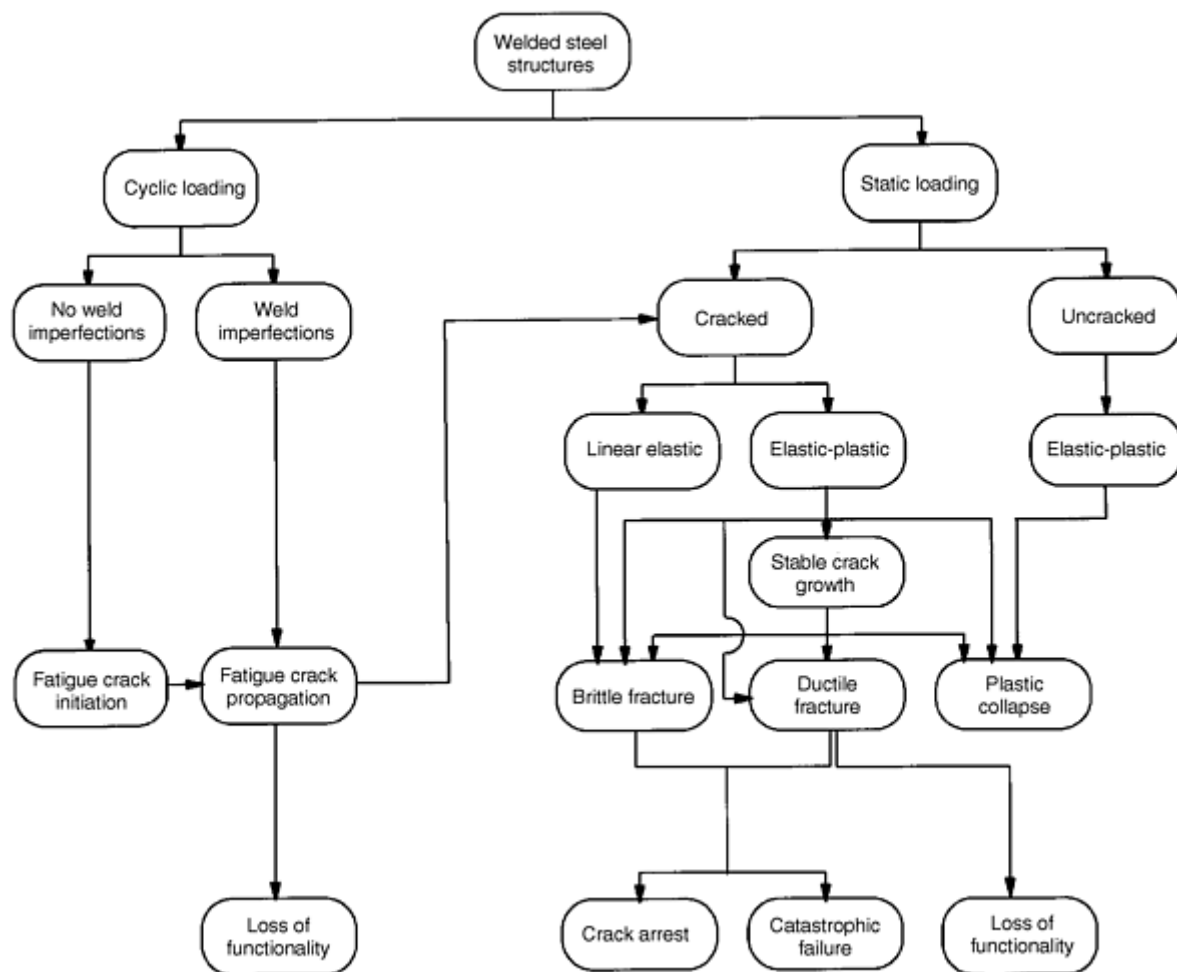

FIG. 2 FRACTURE PATHS FOR WELDED STEEL STRUCTURES

**Fracture Control Methods.** Figure 3 shows a schematic of a weld joint in a structure subjected to cyclic loading. As stated earlier, there are preexisting metallurgical discontinuities in welded joints to some degree. In Fig. 3 these are referred to as start-of-life defect size,  $a_0$ . If the applied loading conditions are favorable, fatigue cracks start from the initial starter cracks represented by  $a_0$  and propagate into the material. The instantaneous fatigue crack size at any stage during its life is referred to as  $a_i$ , and the rate of crack growth is controlled by the material properties and by the applied loading conditions. During this stage the crack will continue to grow in a stable manner until critical conditions are reached for failure. These critical conditions could be loss in the functionality of the structure/component due to increase in compliance of the load-bearing member, or failure of the remaining ligament material ahead of the growing fatigue crack by unstable fracture or plastic collapse. The critical flaw dimension,  $a_c$ , at the onset of this condition is controlled by the applied loading conditions and by material properties such as fracture toughness and flow strength.

**FIG. 3 SCHEMATIC REPRESENTATION OF A CRACK GROWING IN SERVICE UNDER FATIGUE LOADING. FAILURE OCCURS IF  $A_f \geq A_c$ .  $A_0$ , START-OF-LIFE DEFECT SIZE;  $A_f$ , DEFECT SIZE DUE TO FATIGUE CRACK GROWTH;  $A_c$ , CRITICAL DEFECT SIZE DUE TO UNSTABLE FRACTURE OR PLASTIC COLLAPSE**

Extension of preexisting cracks or crack-like features in a stable manner (through fatigue cracking or ductile tearing) or in an unstable manner (through brittle fracture) depends on three critical parameters: the applied loading conditions, the resistance of the material to crack extension, and the size of the crack. This combination represents the classical basis for fracture mechanics. For a given crack, the applied loading conditions (primary stresses from application loads) and secondary stresses (e.g., welding residual stresses and stress concentration effects) provide the crack driving force, which is resisted by the material ahead of the crack to extension, whether this is under stable or unstable conditions. In fracture mechanics terms,  $\Delta K_{th}$  is frequently used as the resistance of the material to crack extension for fatigue. For unstable fracture, toughness parameters such as  $K$ ,  $J$ , and crack-tip opening displacement (CTOD) are used. The general principles described here are schematically shown in Fig. 4. The concept of arresting a propagating crack is also introduced. In certain industries, designing-in the ability to arrest a running crack can prevent serious consequences or reduce the amount of damage.

**FIG. 4 SCHEMATIC REPRESENTATION OF THE CONDITIONS FOR STABLE AND UNSTABLE FRACTURE AND CRACK ARREST**

The above discussion provides a basis for defining the various fatigue and fracture control plans that are used in industry. These are schematically shown in Fig. 2, and they can be broken down as: approaches to fatigue control, approaches to fracture control, or approaches to crack arrest.

**Approaches to fatigue control** include: 1) avoid fatigue crack initiation, 2) avoid fatigue crack growth, and 3) assume that fatigue crack growth will occur and design to prevent unstable fracture. In welded joints, initiating a fatigue crack is rare. Most of the time is spent in propagating preexisting features in the weld area. Only in certain circumstances, such as machined joints or specially treated welds, can designing for crack initiation become an option.

**Approaches to fracture control** include: 1) avoid unstable fracture initiation, and 2) assume that unstable fracture may occur and design for crack arrest. For most welded fabrications, the second option is not acceptable. Catastrophic failures are avoided by specifying adequate "initiation" toughness for both the weld area and the base material at the minimum design temperature. However, for applications such as storage vessels and ship structures (particularly oil tankers), it should be comforting to know that when a brittle fracture is initiated, the crack will not extend far before coming to rest. In this case, the second option is a secondary means to minimize the damage by arresting the brittle fracture close to the initiation site.

**Approaches to crack arrest** include: 1) crack arrestors built into the structures (e.g., "rat holes,") 2) change in section, or addition of stiffeners and 3) materials selection (use of materials with high crack arrest toughness).

In the next two sections, the above approaches are discussed in the context of fatigue and fracture separately. The important factors associated with each of these failure modes are identified.

## Fatigue and Fracture Control of Weldments

Tarsem Jutla, Caterpillar Inc.

---

## Fatigue in Welded Joints

It is now commonly accepted that attaching a weld to a cyclically loaded structural member can change the service performance of that member significantly. This is often illustrated by comparing the fatigue lives of welded and plain components. As shown in Fig. 5, with all things being equal, attaching a weld to a load-carrying member can not only reduce the fatigue strength substantially, but also lower the fatigue limit. In this example, the fatigue limit of the welded component is one-tenth of that of the plain component. As a consequence of this phenomenon, it is frequently found that in cyclically loaded welded components the design stresses are limited by the fatigue strength of the welded joints.

**FIG. 5 COMPARISON OF FATIGUE BEHAVIOR OF A WELDED JOINT AND PARENT METAL**

There are several reasons why a weld reduces the fatigue strength of a component. These reasons fall into the following categories:

- STRESS CONCENTRATION DUE TO WELD SHAPE AND JOINT GEOMETRY
- STRESS CONCENTRATION DUE TO WELD IMPERFECTIONS
- WELDING RESIDUAL STRESSES

In order to be able to design against fatigue in welded structures, it is important to understand the influence of these factors on the performance of welded joints.

**Stress Concentration due to Weld Shape and Joint Geometry.** Making a welded joint either increases or decreases the local cross-sectional dimensions where the parent metal meets the weld. Generally, any change in cross-sectional dimensions in a loaded member will lead to concentration of stress. Thus, it is inevitable that the introduction of a weld will produce increase in the local stress. The precise location and the magnitude of stress concentration in welded joints depends on the design of the joint and on the direction of the load. Some examples of stress concentrations in butt welds and fillet welds are given in Fig. 6. In Fig. 6(b) the weld does not carry any load, but it nevertheless causes concentration of stress at the toes of the welds. Indeed, the weld toe is often the primary location for fatigue cracking in joints that have good root penetration. In situations where the root penetration is poor or the root gap is excessive, or in load-carrying fillet welds where the weld throat is insufficient, the root area can become the region of highest stress concentration. Fatigue cracks in these situations start from the root of the weld and generally propagate through the weld (Fig. 7).

**FIG. 6 EXAMPLES OF STRESS CONCENTRATIONS IN WELDED JOINTS**

FIG. 7 FATIGUE CRACKING FROM THE WELD ROOT

The geometry/shape parameters that influence fatigue of welded joints by affecting the local stress concentration include plate thickness ( $T$ ), attachment toe-to-toe length ( $L$ ), attachment thickness ( $t$ ), weld toe radius ( $r$ ), weld angle ( $\theta$ ), and the profile of the weld surface (convex vs. concave). See Fig. 8. It is generally found that the fatigue strength of a welded joint decreases with increasing attachment length (Fig. 9a), increasing plate thickness (Fig. 9b), increasing weld angle (Fig. 9c, d), decreasing toe radius (Fig. 9e), and misalignment (Fig. 9f). The results given in Fig. 9 are experimental but have been confirmed by finite-element stress analysis of the local weld area. Thurlbeck and Burdekin (Ref 20) show that decreasing the ratio of attachment length to thickness ( $L/T$ ) from 2.0 to 0.375 will increase the relative fatigue strength by a factor of about 1.2. Similar results are obtained for changing the weld angle from  $90^\circ$  to  $22.5^\circ$ . By far the largest influencing parameter is the weld toe radius, which, for example, can increase the fatigue strength over the range  $r = 1.0$  to 8.0 mm (0.04 to 0.3 in.) by a factor of 1.3, effectively doubling the life. The weld toe stress concentration factor,  $K_t$ , is a function of all these geometry variables, and a number of formulas are available for butt welds and cruciform joints subjected to bending or tensile load (Ref 21, 22). The following formula is for a T-joint subjected to bending load:

$$K_t = 1 + \left[ \frac{1 - \exp \left[ -0.90 \sqrt{\frac{T}{2l} + 1} \right]}{1 - \exp \left( -0.45\pi \sqrt{\frac{T}{2l} + 1} \right)} \right] \left[ \frac{0.13 + 0.65 \left( 1 - \frac{r}{T} \right)^4}{\left( \frac{r}{T} \right)^{1/3}} \right] \tanh \left[ \frac{\left( \frac{2l}{T} \right)^{1/4}}{1 - \frac{r}{T}} \right] \quad (\text{EQ 1})$$

with the validity boundaries  $r/T = 0.02$  to  $0.2$ ,  $l/T = 0.5$  to  $1.2$ , and  $\theta = 30$  to  $80^\circ$ .

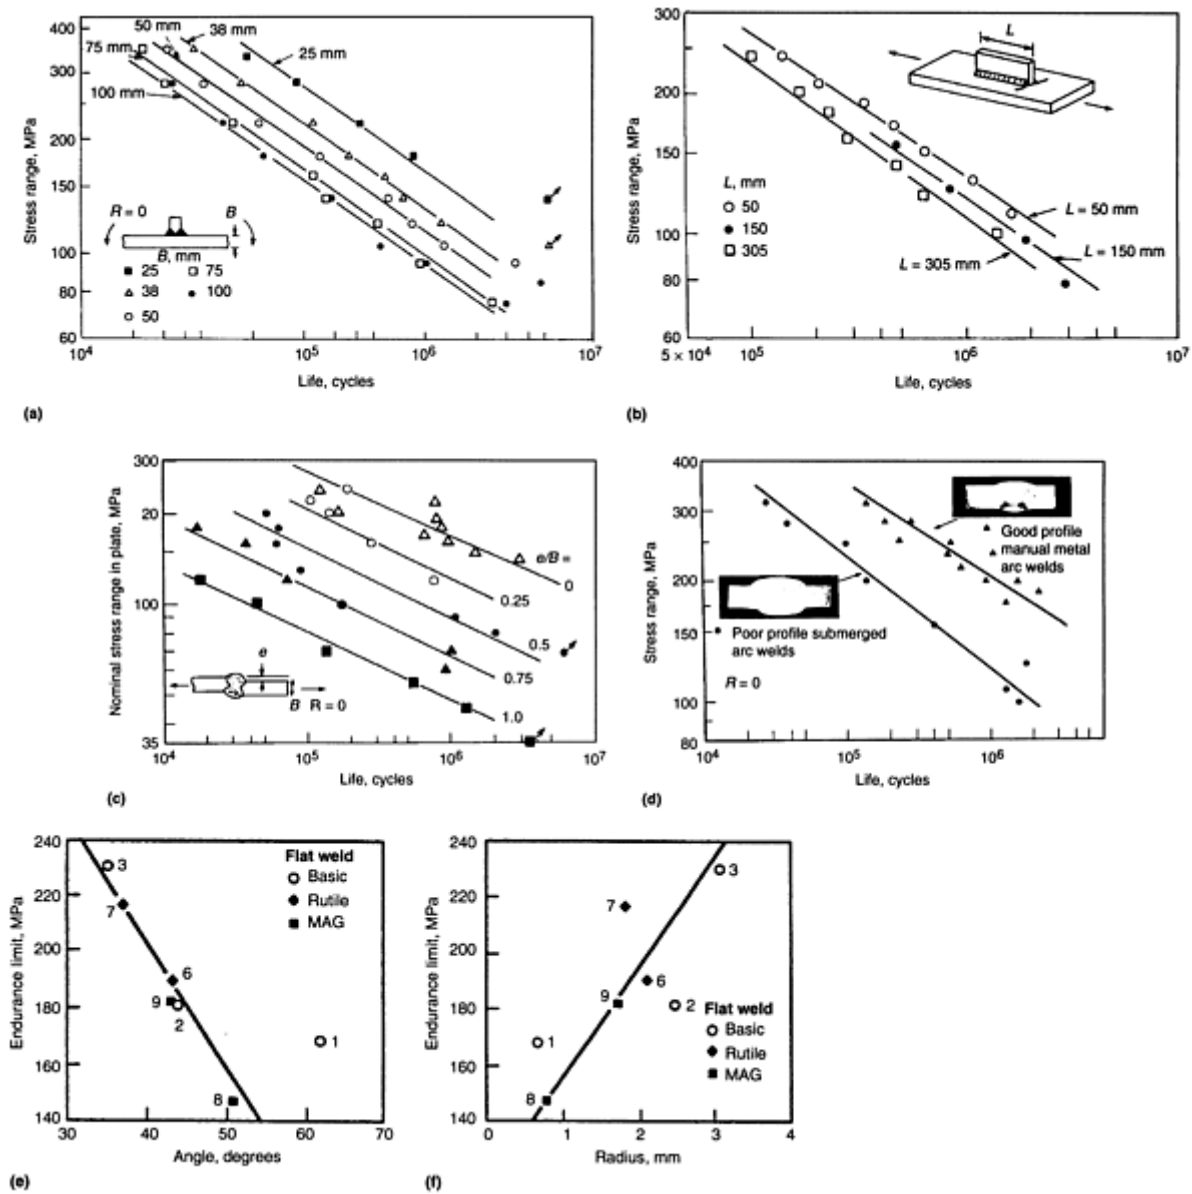

FIG. 8 GEOMETRY PARAMETERS THAT AFFECT WELD TOE STRESS CONCENTRATION.  $R$ , WELD TOE ROOT RADIUS;  $\theta$ , WELD ANGLE;  $L$ , TOE-TO-TOE WELD LENGTH

**FIG. 9 GEOMETRY FACTORS AFFECTING FATIGUE IN WELDED JOINTS. (A) EFFECT OF PLATE THICKNESS. (B) EFFECT OF ATTACHMENT LENGTH. (C) EFFECT OF MISALIGNMENT. (D) EFFECT OF WELD PROFILE. (E) EFFECT OF WELD TOE ANGLE (REF 49). (F) EFFECT OF WELD TOE RADIUS (REF 49)**

Misalignment is another geometry-related parameter that can influence the fatigue performance of a welded joint. Misalignment can manifest itself in several ways, angular and axial misalignments being the most common. Generally fatigue strength decreases with increasing misalignment, as shown in Fig. 9(f). Formulas to calculate the local weld stress concentration factor due to misalignment are now well established (Ref 18).

The degree of influence of the geometry parameters cited above can vary significantly with the loading condition (e.g., tension vs. bending) and the joint type.

**Stress Concentration due to Weld Discontinuities.** It is found from stress analysis of an idealized model of a fillet weld loaded in the transverse direction that the stress concentration factor ( $K_t$ ) at the weld toe is about 3. This is comparable to  $K_t$  for a hole in a plate. In view of this, it would be reasonable to expect that the fatigue behavior of a fillet weld is similar to that of a plate with a hole. However, as shown in Fig. 5, the fatigue performance of the welded joint is substantially lower, implying that other factors come into play for welded joints.

As stated above, weld imperfections are to some extent controllable and can be avoided during fabrication, or their effects can be included in the design. The difference observed in Fig. 5 has been attributed by some researchers to the presence of microscopic features at the weld toe. These features are small, sharp nonmetallic intrusions and are present in most, if not all, welds. The extent and distribution of these features vary with the welding process, and also possibly with the quality of the steel plate and its surface condition. The exact source of these intrusions is not precisely known, but it is believed that slag, surface scale, and nonmetallic stringers from a dirty steel are the primary causes. An example of a weld toe intrusion is given in Fig. 10. The combined effect of these sharp crack-like features and concentration of stress due to the weld geometry is that fatigue cracks initiate very early on, and most of the life is spent in crack propagation.

FIG. 10 EXAMPLE OF WELD TOE INTRUSIONS

Planar weld imperfections (e.g., hydrogen cracks, lack-of-side wall fusion) are clearly to be avoided because they will substantially reduce the fatigue life. Volumetric imperfections such as slag inclusions and porosity can be tolerated to some extent (Ref 19), because the notch effect of these imperfections is generally lower than that of the weld toe (Fig. 11).

FIG. 11 EFFECT OF VOLUMETRIC DEFECTS ON FATIGUE. (A) SLAG INCLUSION IN BUTT WELD. CRACKING FROM WELD TOE. (B) POROSITY IN BUTT WELD. CRACKING FROM WELD TOE. (C) TRANSVERSE GROOVE WELDS CONTAINING POROSITY

**Welding Residual Stresses.** In welded structures, it is normally found that residual stresses are present in the weldment area, and these can be high and can approach the yield strength of the material. These stresses occur as a result of the thermal expansion and contraction during welding, as a result of the constraint provided by the fabrication or by the fixtures, and as a result of distortion in the structure during fabrication (often referred to as reaction stresses). These

stresses are localized to the weld zone and are self-balancing (i.e., both tensile and compressive stresses are present). Transverse to the weld toe the residual stress is typically tensile and can approach yield point. When a load cycle is applied to the structure, it is superimposed onto the residual stress field, and the effective stresses acting at the weld joint can fluctuate down from yield level (Fig. 12). The range of each cycle remains unchanged, but the effective mean stress can be significantly different from the applied mean stress. Because of the dominance of crack propagation in welded joints and the presence of high tensile residual stresses, the mean stress effect is negligible, and fatigue life is controlled by the stress range (Fig. 13).

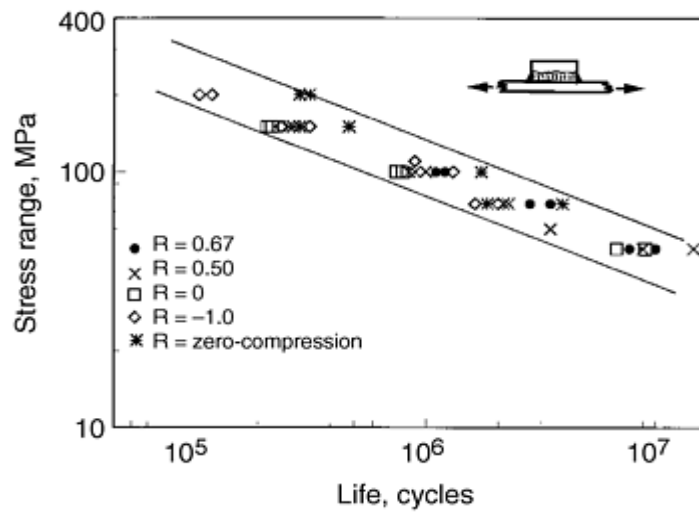

FIG. 12 SUPERPOSITION EFFECT OF APPLIED AND LOCAL WELDING RESIDUAL STRESSES

(a)

(b)

(c)

FIG. 13 INFLUENCE OF WELDING RESIDUAL STRESS ON FATIGUE. (A) EFFECT OF APPLIED STRESS RATIO ON AS-WELDED JOINTS. (B) EFFECT OF STRESS RELIEF AS A FUNCTION OF TENSILE LOAD CYCLE. ALL SPECIMENS STRESS RELIEVED. (C) EFFECT OF STRESS RELIEF AS A FUNCTION OF TENSION-COMPRESSION LOAD CYCLE. ALL SPECIMENS STRESS RELIEVED

Reducing residual stresses using postweld heat treatment can improve fatigue life, but only if the applied load cycles are partially or fully compressive. For fully tensile applied loads, postweld heat treatment does not improve the fatigue life (Fig. 13b). Thus, it is important to know the exact nature of applied loads before a decision is made on the need to heat treat a welded structure. Indeed, it should be noted that stress relief of welded joints is never fully effective. Residual stresses up to yield point have been measured in stress-relieved pressure vessels and in up to 75% of yield in stress-relieved nodes in offshore structures. Due consideration has to be given to the complexity of the overall structure when stress relieving and to the time and temperature of the process.

**Effect of Material Properties.** Because crack propagation dominates the fatigue life of welded joints, material properties have no effect on fatigue strength. This is illustrated in Fig. 14, where it can be seen that data points for steels with different strengths fall within the same scatter band. Thus, using a high-strength steel to improve fatigue life will not be beneficial for welded structures.

FIG. 14 FATIGUE TEST RESULTS FROM FILLET WELDS IN VARIOUS STRENGTHS OF STEEL

**Microstructure.** A fatigue crack starting at the weld toe will immediately grow into the heat-affected zone (HAZ) and then into the base metal. During this period it will propagate through a variety of microstructures, and as can be seen from Fig. 15, its growth rate will not be influenced in any way. Thus, the variety of HAZ microstructures (and hardness levels) in the weldment area have little or no effect on the rate at which the crack grows.

FIG. 15 CRACK GROWTH RATE DATA SHOWING NO INFLUENCE OF WELD METAL, HAZ, OR BASE METAL

**Fracture Toughness.** As with tensile strength, the fracture toughness of the weld metal, the HAZ, or the base metal does not influence the crack growth rate. This can be deduced from Fig. 15, which represents a variety of materials with different strength levels and toughness values. The only influence of fracture toughness is the limiting size the fatigue crack could reach before the material fails in an unstable manner. Tougher materials are able to tolerate bigger fatigue cracks.

**Methods for Improving the Fatigue Life of Welded Joints.** Postweld fatigue life improvement techniques are becoming popular for increasing the fatigue life of weld joints. From the preceding sections it can be seen that three factors influence fatigue of welded joints: stress concentration due to joint and weld geometry, stress concentration due to localized defects, and welding residual stresses. Improvement in fatigue life can be obtained by reducing the effects of one or more of these parameters. This is particularly true for cracks starting from the weld toe, which is by far the most common failure site. In load-carrying fillet welds, however, cracks can start at the weld root and propagate through the weld throat until failure occurs. In this case, additional weld metal to increase the weld throat dimension will result in reduction in shear stress and, hence, a corresponding increase in fatigue strength.

Because the most common failure site is the weld toe, many postweld treatments for this region have been developed to improve the fatigue life. These techniques largely rely on removing the detrimental intrusions at the weld toe, reducing the joint stress concentration, or modifying the residual stress distribution. There are primarily two broad categories of postweld techniques: modification of the weld geometry and modification of the residual stress distribution (Ref 23, 24). A complete list is given in Fig. 16. Methods that reduce the severity of the stress concentration or removal of weld toe intrusions include grinding, machining, or remelting. These techniques essentially focus on altering the local weld geometry by removing the intrusions and at the same time on achieving a smooth transition between the weld and the plate. Typical profiles of burr ground and tungsten inert gas (TIG) dressed welds are given in Fig. 17. Because weld toe intrusions can be up to 0.4 mm (0.016 in.) in depth, the general guideline is that the grinding or machining operation must penetrate at least 0.5 mm (0.02 in.) into the parent plate. In these procedures the depth, the diameter of the groove, and the direction of the grinding marks become important issues. In TIG and plasma dressing, the weld toe is remelted in order to

improve the local profile and also to "burn" away or move the intrusions. With these techniques, the position of the arc with respect to the weld toe and the depth of the remelt zone are two critical variables. Controlling the shape of the overall weld profile has also been recognized as a method of improving the fatigue life. The American Welding Society (AWS) weld profile procedure using the "dime" test reduces the weld geometry  $K_t$  and hence increases the fatigue life (Ref 25, 26).

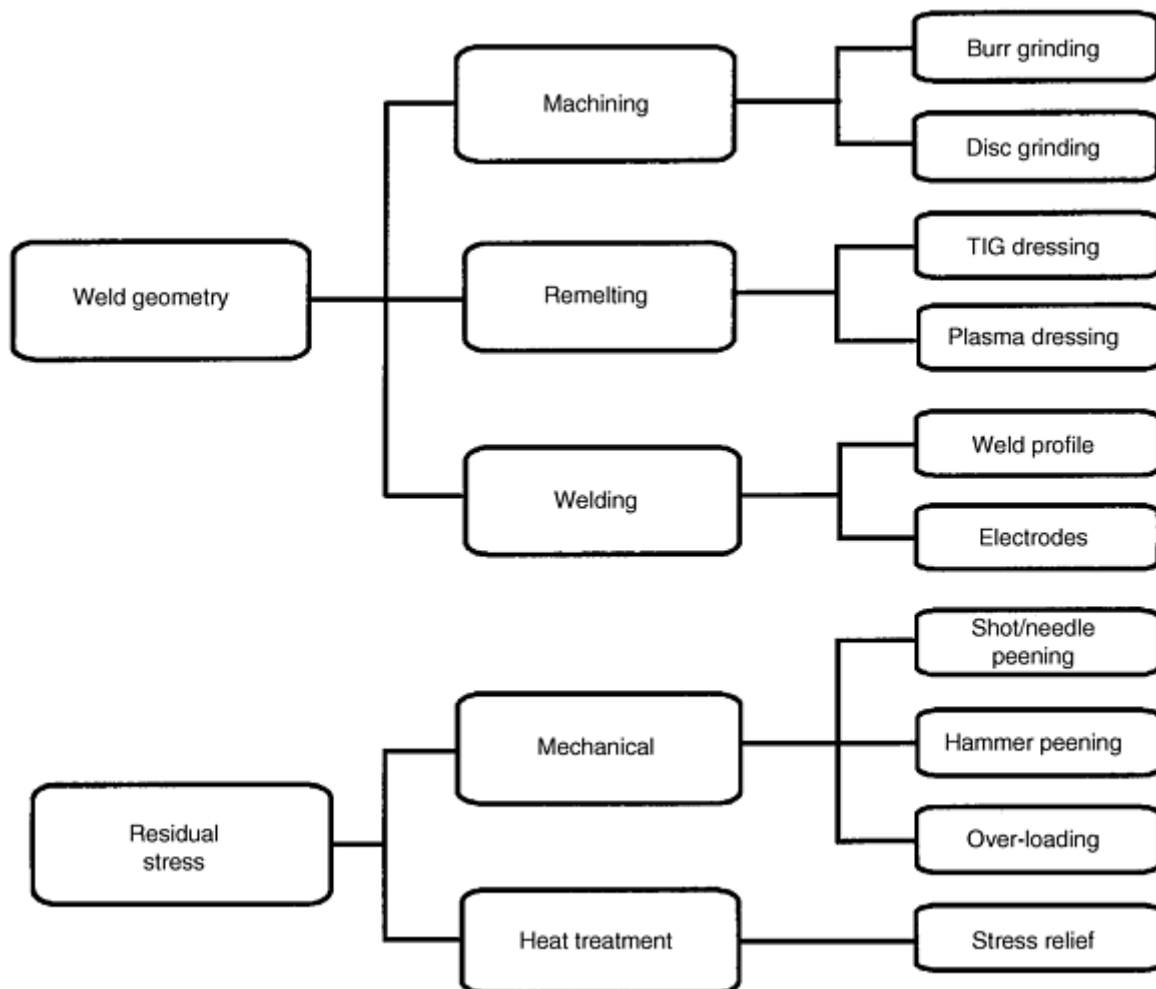

FIG. 16 RANGE OF POSTWELD FATIGUE LIFE IMPROVEMENT TECHNIQUES

**FIG. 17 TYPICAL PROFILES FOR (A) BURR GRINDING AND (B) TUNGSTEN INERT GAS DRESSING OF WELD TOE**

Methods that modify the residual stress field include heat treatment, hammer and shot peening, and overloading. Postweld heat treatment is known to reduce tensile residual stresses but does not eliminate them completely. The benefits of postweld heat treatment can be realized only if the applied loads are either partially or fully compressive. Overloading techniques rely on reducing the tensile residual stress field and/or introducing compressive stresses at the weld toe. Exact loading conditions for a complex structure are difficult to establish, so this technique is rarely used. To obtain significant improvement in fatigue strength, it is necessary to introduce compressive stresses in the local area in a consistent and repeatable manner. The three peening techniques (shot, needle, and hammer peening) aim to achieve this by cold working the surface of the weld toe. As with the grinding methods, it is necessary to penetrate the parent plate and deform to a depth of at least 0.5 mm (0.02 in.). Hammer peening is perhaps the best technique to do this, and it has the advantage of removing the weld toe intrusions by cold working them out. Peening techniques require special equipment and can present safety challenges for noise control. They are very difficult to automate and control in production.

A comparison of the improvement in fatigue strength obtained by some of these techniques is given in Fig. 18. It can be seen that hammer peening is perhaps the best technique, perhaps because it reduces or eliminates intrusions as well as introducing compressive stresses. Burr grinding, which is easier to implement, also produces significant improvement in fatigue life. Disc grinding and burr grinding are probably the most frequently used methods for improving the fatigue life of welded joints.

### Fracture Control in Welded Structures

The brittle fracture of ships during World War II stimulated intensive research into avoiding catastrophic failures in fabricated structures. The nature of this type of failure provides no warning, and the aftermath is often spectacular (Fig. 19). These early failures led to many studies to identify the parameters that need to be controlled in order to avoid brittle fractures. Toughness of the material was one parameter that emerged from these studies. Much of the early work focused on measuring the toughness of steels used in ship structures, using notched-bar impact specimens. The most widely used impact specimen is the Charpy V-notch impact test, and today the test has become one of the necessary means of ensuring that the weld metal, the base metal, and the HAZ have sufficient toughness to avoid unstable fractures.

FIG. 19 EXAMPLE OF BRITTLE FRACTURE IN SHIP STRUCTURES

The Charpy test evaluates both the *initiation* of brittle fracture as well as its subsequent *propagation*. The significance attached to controlling fracture initiation or propagation has influenced much of the fracture research work since the early period, and it has resulted in two philosophies for fracture control.

U.S. researchers concluded that because of the highly heterogeneous nature of welds, it would be impractical and risky to try to control brittle fracture initiation in welded structures. It was argued that "pop-in" of fractures from brittle regions was likely and that the steel toughness should be sufficient to prevent a pop-in from propagating into a full-scale fracture. Pellini et al. (Ref 27) used this concept to propose the first practical design tool linking the required fracture toughness to temperature and design stress. The approach was presented in the form of a fracture analysis diagram (Fig. 20) that has a constant shape, where the position of the curve along the temperature axis is indexed to the "nil-ductility temperature" (NDT), which is obtained from the drop weight test. This approach has been widely used for fracture control of many types of structures, and as far as is known, there have been no brittle fractures in steels that meet the NDT criteria.

FIG. 20 PELLINI'S FRACTURE ANALYSIS DIAGRAM

The competing approach is to try to control initiation of the fracture. This has been advocated mostly by the Europeans, and now more recently by the North Americans. The initiation approach is intimately linked to fracture mechanics concepts, and in many codes and standards it has been used to specify toughness requirements for weld and base metals and has been valuable in establishing flaw acceptance criteria for inspection. For welded joints it was recognized that initiation of fracture took place under the influence of high tensile residual stresses and stress concentration effects, which led to the use and advancement of postyield fracture criteria, primarily through the development of fracture mechanics approaches for CTOD. The onset of brittle fracture requires the presence of a flaw of critical dimensions, low toughness, and stress (primary and secondary) of critical magnitude. Here the discussion focuses only on toughness and on the specification of toughness levels for welded regions and parent materials to avoid fracture initiation. The factors that influence the initiation of unstable fracture are identified.

**Factors Affecting Fracture Toughness.** The toughness of a material can be measured using a standard Charpy V-notch specimen, as stated above, or by using a fracture mechanics test specimen. The commonly referenced results from Charpy impact tests include the impact energy required to fracture the specimen, the lateral expansion, and the percent shear fracture appearance at the specified temperature. The latter two are intended as measures of ductility. In contrast to the Charpy test, fracture mechanics toughness tests fall into two groups: linear elastic fracture mechanics tests ( $K_{Ic}$ ) and elastic-plastic fracture mechanics tests (CTOD,  $J$ -curves, and  $R$ -curves). The major advantage of using fracture mechanics specimens is that the data from these tests can be used directly in fracture mechanics fitness-for-service procedures to assess the tolerance of the structure to the presence of defects and cracks. The parameters that affect the toughness of a material include:

- MATERIAL GRADE AND CHEMISTRY
- STRENGTH AND HARDNESS
- MICROSTRUCTURE AND LEVEL OF IMPURITIES
- GRAIN ORIENTATION
- SIZE OF STRUCTURE OR SPECIMEN (CONSTRAINT)
- NOTCH/CRACK ACUITY

- LOADING RATE
- TEMPERATURE

Some of these are discussed below in the context of welded regions.

In conventional structural steels that have a ferritic microstructure, both Charpy and fracture mechanics toughness tests show a transition from ductile to brittle behavior with decreasing temperature. Figure 21 shows Charpy energy transition curves for a variety of steels and for a number of other materials. At higher temperatures, in the upper-shelf regime, a ferritic material behaves in a fully ductile manner and is capable of absorbing considerable amounts of energy when deformed. At these temperatures, ferritic materials are generally considered tough. As the temperature is reduced, a transition to lower-shelf behavior occurs. In this regime ferritic materials are brittle, and fracture occurs in a cleavage mode. The decrease in toughness (energy absorbed) from upper-shelf behavior can be substantial, and for some materials the transition temperature range is very small.

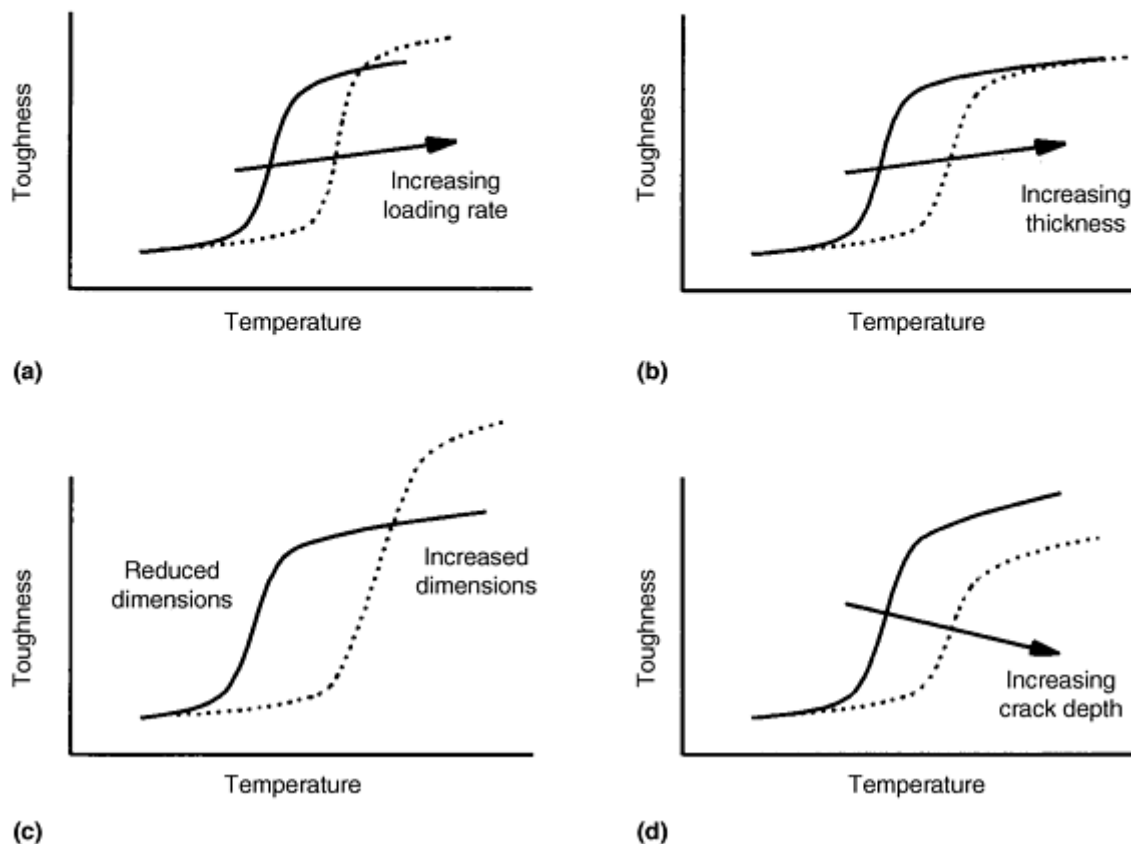

FIG. 21 DUCTILE-TO-BRITTLE TRANSITION CURVES FOR A VARIETY OF MATERIALS

From Fig. 21 it is clearly evident that toughness is a function of the material type and the yield strength. Furthermore, the transition behavior is affected by the size and type of the specimen, the loading rate, and the notch acuity. Generally, the toughness is reduced with increasing loading rate, increasing specimen size, increasing notch acuity, increasing thickness, and increasing crack depth (Fig. 22). Thus, neither the fracture strength nor the toughness is a sole predictor or criterion for fracture control. This can present challenges to a design engineer who would like to be able to predict conditions for the onset of brittle fracture from some simple specifiable material properties. Also, this indicates that it is important to match the test specimen size and test conditions closely with the local region in the actual structure.

**FIG. 22 EFFECTS OF LOADING RATE, THICKNESS, SPECIMEN DIMENSIONS, AND CRACK DEPTH ON THE DUCTILE-TO-BRITTLE TRANSITION BEHAVIOR**

For welded joints, the challenge of generating toughness information is increased further by the nonhomogeneous nature of the region. Variations in notch location and orientation can result in significantly different toughness values. The weld HAZ presents particular difficulties in toughness measurements owing to its narrow width. For example, in structural steels welded using typical arc energies, the transformed HAZ is usually no more than 3 to 4 mm (0.12 to 0.16 in.) wide. Within this distance there are wide ranges of microstructures and properties (Fig. 23), and the critical region of interest may be 1 mm (0.04 in.) or less. Despite their small size, brittle regions within the HAZ can have a significant influence on the integrity of a structure with respect to failure by brittle fracture. A number of catastrophic brittle fractures of engineering structures, including pressure vessels, storage tanks and bridges, in which the fracture started in the HAZ testify to this (Ref 28).

**FIG. 23 SCHEMATIC DIAGRAM OF THE VARIETY OF MICROSTRUCTURES THAT CAN BE OBTAINED IN THE HAZS OF MULTIPASS WELDS. GR, GRAIN REFINED; IC, INTERCRITICAL; SC, SUBCRITICAL; ICGC, INTERCRITICAL GRAIN COARSENEED; SCGC, SUBCRITICAL GRAIN COARSENEED**

Figure 24 shows some examples of notch locations and orientations in the weld metal and the HAZ for measurement of fracture toughness. While placement of the notch in the weld metal is simple and straightforward, HAZ notch location can be difficult. Some industries have developed specific procedures that simplify Charpy testing of HAZ and ask for through-the-thickness notches located at the fusion boundary (FB), FB + 2 mm (0.08 in.), and FB + 5 mm (0.2 in.). Although a certain amount of information on the variation in HAZ toughness can be obtained from these tests, their primary aim is to ensure that a certain level of quality in workmanship is maintained. Results obtained from Charpy testing of the HAZ have to be treated with caution, because it has been shown that the blunt notch of this type of test specimen can miss sampling local regions of low toughness (Ref 29). This caution also applies to Charpy testing of multipass welds, because it is well known that in the transition regime, depending on the orientation of the Charpy notch, bimodal fracture behavior can be obtained at the same test temperature. This is because the notch of one test specimen may sample microstructure exhibiting upper-shelf behavior, and a specimen from the adjacent location may sample low-toughness microstructure (Ref 30). Thus, weldment toughness data can exhibit significant scatter, particularly in the transition regime, and care has to be taken in interpreting the results.

**FIG. 24** EXAMPLES OF NOTCH LOCATIONS FOR TOUGHNESS TESTING OF WELD METALS (A AND B) AND HAZ (C THROUGH G)

Although both Charpy and fracture mechanics toughness test standards are now well established for parent material (Ref 31, 32, 33), the complex nature of the weld joint has hindered the development of standardized procedures for measuring the toughness. At the time of this writing, both ASTM and BSI were developing draft standards for weldment toughness testing, but restricted to weld metal. An essential requirement for tests on welded joints is that the test welds should be fully representative of the service structure of interest. This requirement is based on the knowledge that the fracture toughness of weld metals and weld HAZs may be critically dependent on such factors as:

- WELDING PROCESS AND CONSUMABLES
- BASE METAL COMPOSITION
- JOINT THICKNESS
- PREHEAT AND INTERPASS TEMPERATURE
- HEAT INPUT
- WELDING POSITION
- JOINT CONFIGURATION
- RESTRAINT
- POSTWELD HEAT TREATMENT
- TIME BETWEEN WELDING AND TESTING

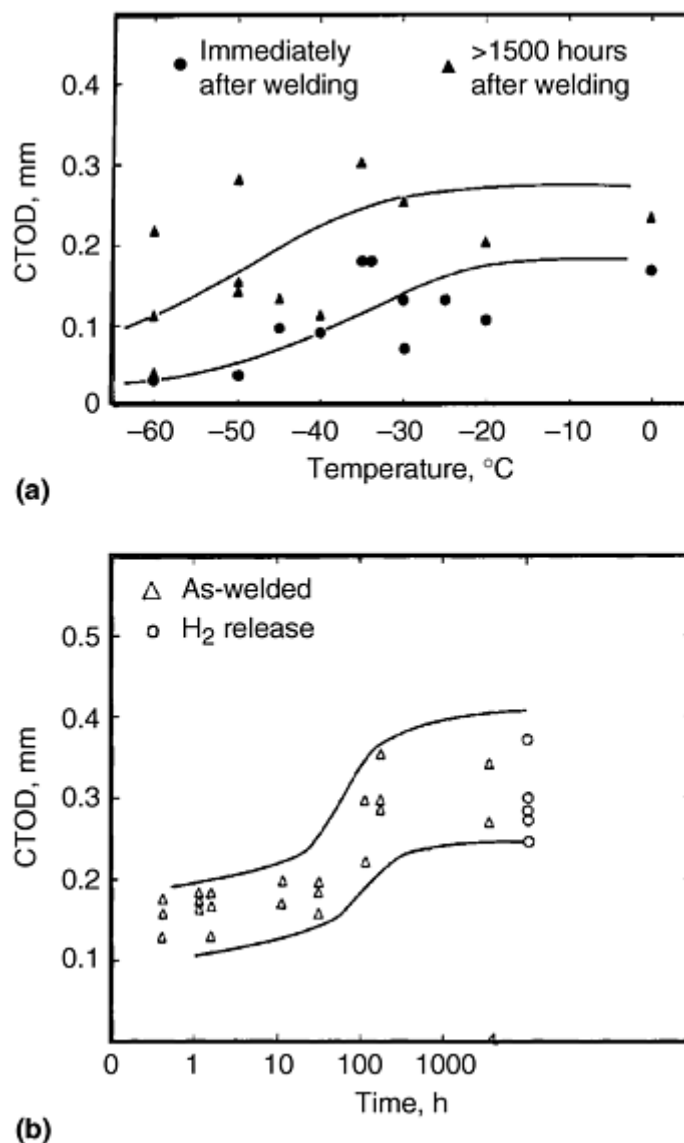

Information on the effects of these welding factors can be obtained from Ref 34.

**Embrittlement Mechanisms.** Localized embrittlement in welded regions can occur by a number of mechanisms, and these can increase the risk of brittle fracture initiation. The three most common mechanisms are hydrogen embrittlement, strain aging, and temper embrittlement. Each of these mechanisms can reduce the toughness of the material, either soon after welding or during service. There are many catastrophic failures associated with these embrittlement mechanisms (Ref 35), and an effective fracture control plan has to include their potential effect.

**Hydrogen Embrittlement.** Hydrogen in steels and welded joints can be introduced in several ways. In welding, hydrogen from the arc atmosphere can dissolve into the liquid weld pool, and if the weld cools rapidly, a significant quantity may be retained in the weldment at low temperatures. Alternatively, in the petrochemical industry, hydrogen can be absorbed by the containment vessel during service when the medium in the vessel contains diffusible hydrogen. Sufficient hydrogen levels will cause cracking in the weld metal and the HAZ, but lower levels of hydrogen can cause other problems, including the formation of "fish eyes" and embrittlement of the material. Hydrogen embrittlement in weld metal often manifests as a loss of ductility and fracture toughness. The susceptibility of a material to hydrogen

embrittlement is dependent on the chemistry and microstructure, and therefore the different regions of the weldment will embrittle differently due to the presence of hydrogen.

The data given in Fig. 25(a) for a weld in a C-Mn steel shows that the fracture toughness transition curve shifts to the right in the presence of hydrogen, and the upper shelf is lowered. Hydrogen embrittlement therefore affects the complete transition curve, regardless of the failure mode. However, it should be noted that the effects of hydrogen embrittlement are sensitive to the strain rate. The trends observed in Fig. 25(a) may not be apparent with a Charpy test that is conducted at high strain rates, compared to a CTOD fracture toughness test. Thus, caution should be observed when attempting to measure the hydrogen embrittlement effects using a Charpy V-notch toughness test.

**FIG. 25 IMPORTANCE OF TIME AND HYDROGEN RELEASE TREATMENT ON FRACTURE TOUGHNESS. (A) EFFECT OF HYDROGEN ON FRACTURE TOUGHNESS IMMEDIATELY AFTER WELDING. (B) EFFECT OF TIME ON AS-WELDED SPECIMENS**

Earlier it was stated that the toughness of the weld metal or the HAZ is dependent on the time between welding and testing. This is largely due to the presence of hydrogen and its diffusion over time. For structures that will not be subjected to subsequent hydrogen environment during service, it would be misleading to test the weldment soon after fabrication. The presence of the diffuseable hydrogen could lower toughness, as shown in Fig. 25(b). This figure shows that a true value of toughness is obtained more than 100 h after welding, but this time is dependent on the size of the weld and the amount of hydrogen present. An alternate way to ensure that the hydrogen effects are dispelled is to soak the welded sample for a few hours at 150 °C (300 °F) before testing. This is referred to as hydrogen release heat treatment.

**Strain Aging.** The thermal and strain cycles that accompany welding can give rise to "dynamic" strain aging embrittlement. This is caused by the diffusion of carbides and free nitrogen into dislocations in the steel matrix. These dislocations, generated through the straining mechanism, become pinned (their movement is inhibited), thus increasing the yield strength (effectively the stress required to move the dislocations). Strain aging may also result in an increase in tensile strength, and it is usually accompanied by reduction in toughness. Strain aging in welds is often thought to occur in the root regions, which are highly restrained and receive complex thermal cycling. Strain age embrittlement has caused many failures in service, one example being the Ashland storage tank failure in January 1988 (Ref 36). An oil tank owned by Ashland Petrochemical Company ruptured as it was being filled for the first time after reconstruction, and as a consequence, approximately 4 million gallons ( $15 \times 10^6$  liters) of diesel fuel were released. The failure was attributed to a small defect left behind from an oxyfuel cutting process close to the circumferential seam. The material ahead of the defect had been strain aged by the welding process, thus lowering the local toughness. The material toughness away from the defect was found to be high. As a consequence of the presence of the defect, the low toughness at the crack tip (on a cold day), and high local weld residual stresses, the oxyfuel cutting defect triggered a brittle fracture that caused the complete collapse of the storage tank.

**Temper embrittlement** is the loss in toughness of alloy steels on exposure to temperatures in the range 325 to 575 °C (620 to 1065 °F). It occurs in coarse austenite grain microstructure (e.g., HAZs and weld metal) in which no ferrite is formed on the prior-austenite grain boundaries. It is caused by migration of elements such as Mn, Si, Sb, As, Sn, and P to high-angle austenite grain boundaries, which become embrittled. The risk of temper embrittlement can be reduced by promoting fine-grained austenite microstructure in weld and HAZ regions. The degree of embrittlement is often specified as the temperature shift in the Charpy transition curve (Fig. 26).

**FIG. 26 SCHEMATIC DIAGRAM SHOWING THE EFFECT OF TEMPER EMBRITTLEMENT ON TOUGHNESS**

**Toughness Requirements for Avoidance of Brittle Fracture.** This section does not review the toughness requirements in different industries for avoidance of brittle fracture. Reference 37 provides excellent coverage of this topic.

Analysis of early Charpy V-notch data of ship steels indicated that initiation of brittle fracture occurred only in those steels showing less than 13.5 J (10 ft · lbf) Charpy energy, and cracks propagated only in those steels showing less than 27 J (20 ft · lbf). This gave rise to the 20 J (15 ft · lbf) criterion, which, although not universally applicable, has nevertheless been widely used. Today, most codes specify fracture toughness requirements that consider the influences of parameters such as tensile properties, heat treatment condition, constraint, and material grade. All these factors influence the material ductility and the ductile-to-brittle transition temperature. Explicit specification of toughness requirements for weld metal and HAZ is rare, although some industry codes and standards assume that the toughness specification for base metal also applies to weld metal and HAZ. Material toughness requirements are generally part of comprehensive fracture control plans that include quality control, material selection and fabrication, and inspection. Account is taken of the in-service environment, degradation of properties during service (e.g., aging), applied loading condition, temperature cycles, and the consequences of catastrophic failure.

Toughness requirements differ widely in the broad spectrum of industries, but they generally reflect the degree of conservatism needed for the specific structure and the consequences of failure. An example of a code that embodies all the factors and provides a comprehensive fracture control plan, including crack arrest, is the Canadian Offshore Structures

Standard (Ref 7). In this standard, the problem of fracture control is approached by considering both the susceptibility of a structural element to fracture initiation and the consequences of its failure. This leads to the definition of a  $3 \times 3$  matrix that corresponds to three levels of failure consequences, based on risk to life and environment. There is a requirement of increasing crack arrest capability in the base metal as failure becomes less tolerable, this capability being measured by the Pellini drop weight test. Fracture initiation is primarily seen as a weld metal and HAZ problem, and CTOD fracture toughness requirements for cases of high initiation susceptibility reflect this. In the Canadian standard the following Charpy requirements for fracture initiation are based on correlations with CTOD:

<b>SPECIFIED MINIMUM YIELD STRENGTH (SMYS) OF BASE METAL, MPA</b>	<b>CHARPY ENERGY, J</b>
$\leq 270$	<b>27</b>
$270 < \text{SMYS} \leq 410$	<b>SMYS/10</b>
<b>&gt;410</b>	<b>41</b>

Table 1 shows the risk matrix reproduced from the standard. For each of the boxes in Table 1, the corresponding toughness requirements and test temperatures are given, as shown in Table 2, where  $T$  is the toughness design temperature of the structural element. For crack arrest, no break performance in the drop weight test is required at the specified temperature. Note that the standard includes the effects of stress relief.

Source: Ref 7

For more rigorous fracture toughness specifications, some codes allow the requirements to be specified on the basis of fracture mechanics analysis, where the effects of a known or a hypothesized flaw, the applied loading conditions, and the heat treatment condition are considered for the specific structure. The toughness specifications are usually based on parameters such as  $K$ ,  $J$ , or CTOD, and they are generally required for the full plate or joint thickness (Ref 34).

## Fatigue and Fracture Control of Weldments

Tarsem Jutla, Caterpillar Inc.

---

## Codes and Standards

**Fitness-for-Service Codes and Standards for Fatigue and Fracture Control.** Since the mid-1970s, a number of fracture mechanics assessment procedures have been developed that enable the significance of weld discontinuities to be assessed on a fitness-for-service basis. Using this concept, a structure is considered fit for the intended service if it can operate safely throughout its design life. The adoption of fitness-for-service concepts in several industry standards has resulted in the development of rigorous fatigue and fracture control plans. In addition to allowing the integrity of a structure to be assessed, a fitness-for-service code enables the remaining life to be computed.

The use of fitness-for-service technology in design and inspection can result in a number of significant advantages. The major benefit undoubtedly is that this technology allows individual flaws to be assessed and allows the operator to decide whether or not to repair. Although adoption of a fitness-for-service approach may allow weld discontinuities to remain in

a structure, it should also lead to a safer structure, because parameters that could potentially cause the crack to become unsafe are taken into consideration.

Given that a flaw or a discontinuity is found in a weld, fracture mechanics analysis can be performed by computing the crack driving force (which is a function of the applied stresses, the flaw size, and the geometry) and comparing this with the resistance of the material to crack extension (which is the fracture toughness of the material in which the crack resides). In the sections that follow, procedures to calculate the crack driving force for fatigue and fracture are briefly discussed.

### Fracture Mechanics

**Fitness-for-Service Codes.** A number of different fitness-for-service assessment methodologies for calculating allowable or critical flaw sizes are currently in use throughout the world. A comprehensive review can be found in Ref 38.

Common methodologies in use today include:

- BSI 7608:1993 (REF 6)
- BSI PD 6493:1991 (REF 16)
- CEGB R6 (REF 39)
- EPRI/GE J AND CTOD ESTIMATION SCHEME (REF 10)
- DEFORMATION PLASTICITY FAILURE ASSESSMENT DIAGRAM (REF 40)
- THE LOCAL APPROACH (REF 41)
- WES 2805 (REF 42)
- IIW APPROACH (REF 8)
- API 579 APPROACH (REF 43)
- ASMI IX APPROACH (REF 44)

A survey conducted by Burdekin (Ref 45) under the auspices of Commission X of the International Institute of Welding (IIW) found that PD 6493:1980 (Ref 15) was the most widely used assessment method. This document has been revised, and the latest version (entitled "Guidance on Methods for Assessing the Acceptability of Flaws in Fusion Welded Structures") was released in August 1991. At the time of this writing, the third revision to PD 6493 was in progress. While some of the approaches listed above differ, their fundamental basis is the same, and in this article the intention is to point the reader to established and validated fracture mechanics procedures. In this context, some of the procedures outlined in PD 6493:1991 are briefly described.

**Fracture Mechanics Methods for Fracture Control.** BSI PD 6493:1991 includes three different fracture assessment routes, to enable structures to be assessed at a level of complexity appropriate to the problem under consideration. The Level 1 approach is based on the CTOD design curve method, which forms the basis of the elastic-plastic fracture assessment procedure included in BSI PD 6493:1980. This approach has a deliberate safety factor built into the calculations, and it results in computation of "tolerable" crack sizes.

In PD 6493:1991 the Level 1 approach is presented as a method for performing preliminary assessments. The Level 2 approach is based on a plane-stress plastic collapse modified strip yield model, and there is no inherent safety factor. This method is the preferred assessment level for the majority of applications. The Level 3 method is the most sophisticated assessment level in the proposed revisions and would normally be used only for the assessment of high-work-hardening materials when the Level 2 approach has proved too restrictive or when a tearing instability analysis is required. The fracture assessment model adopted in the Level 3 approach is based on the reference stress model proposed by Ainsworth (Ref 46). This assessment level requires extensive material characterization data, including details of the stress-strain behavior of the material in which the defect is located. This presents a challenge for the HAZ. All three levels can be

undertaken in terms of the stress-intensity factor,  $K$  (or  $K$  derived from fracture resistance  $J$ ) or the CTOD fracture mechanics parameters. Level 2 approach is based on procedures similar to CEGB R6 Rev. 2, and the Level 3 approach is based on CEGB R6 Rev. 3. These codes have been extensively used in the electric utilities industry in the U.K.

In all three levels of fracture assessment, the resistance of a structure to failure is determined using a failure assessment diagram (FAD). The  $y$ -axis of the FAD indicates the resistance of the structure to brittle fracture, while the  $x$ -axis assesses its resistance to plastic collapse. The failure assessment curve interpolates between these two limiting failure modes.

The Level 2 assessment procedure, which is recommended as the primary method, has a FAD that is defined by:

$$K_r \sqrt{\delta_r} = S_r \left[ \frac{8}{\pi^2} \ln \sec \left( \frac{\pi}{2} S_r \right) \right]^{-\frac{1}{2}} \quad (\text{EQ 2})$$

where  $K_r$  is the ratio of the applied stress-intensity factor to the fracture toughness  $K$ ,  $\sqrt{\delta_r}$  is the ratio of the applied CTOD to the material CTOD, and  $S_r$  is the stress ratio that is taken as the ratio between the net-section stress and the flow strength of the material.

For a given flaw, both  $K_r$  or  $\sqrt{\delta_r}$  and  $S_r$  are determined using appropriate solutions, and these are plotted as a coordinate of a point onto the FAD (Fig. 27). If the point falls within the envelope of the failure locus, the flaw is considered safe. If the point falls outside the locus, the flaw is unacceptable.

**FIG. 27 FAILURE ASSESSMENT DIAGRAM CONCEPT FOR ASSESSING CRACKED COMPONENTS FOR BRITTLE FRACTURE AND PLASTIC COLLAPSE**

The FAD to assess the integrity of a structure assumes that the size of the flaw is known. In order to compute limiting flaw size, say for inspection purposes, a point that lies on the failure assessment line and corresponds to the applied loading conditions has to be determined. This is achieved using iterative techniques by plotting a series of assessment points as a function of flaw size. The point that intersects the failure line gives the limiting size of a flaw. By performing these calculations for a series of crack aspect ratios, tolerable flaw size plots of the type given in Fig. 28 can be generated. This type of plot can be used either to set inspection levels or to allow known flaws to be assessed. In the same way, an iterative process has to be used to generate the critical fracture toughness for some hypothetical (or assumed) flaw size and assumed loading conditions. This computed value can then be directly used for material selection.

FIG. 28 EXAMPLE OF A "TOLERABLE" FLAW SIZE PLOT DERIVED USING FRACTURE MECHANICS PRINCIPLES

Another approach that is sometimes used to ensure that catastrophic failure does not occur is leak-before-break. This design philosophy has been developed primarily for applications where the crack extends in a stable manner by such mechanisms as stable tearing or fatigue crack growth. This approach can be invoked only if the crack shape at breakthrough can be precisely predicted. In most cases it is generally assumed that the defect length at breakthrough is 2 to 3 times the plate thickness. However, there have been instances where defects up to 10 times the plate thickness have been found during inspection of petrochemical plants. Leak-before-break becomes less likely as the defect length increases, so it should be invoked with great caution.

## Fatigue and Fracture Control of Weldments

Tarsem Jutla, Caterpillar Inc.

---

### Method for Fatigue Control

The two most widely used approaches for fatigue control in welded joints are the *S-N* curve approach and fracture mechanics assessment methods. Both approaches are used extensively for design and in-service assessment of welded fabrications, and they are included in many industry and regulatory codes as standardized procedures.

The ***S-N* curve approach** for fatigue control in "nominally sound" welded joints is the simplest and most widely used in a variety of industries. The approach is based on the results of extensive welded joint fatigue tests during the early 1970s. It was found that welded joints could be classified into groups, with each group having a specific *S-N* curve. There are a number of design classification approaches in existence, for example AWS D1.1 (Ref 26), AASHTO-Bridge Code (Ref 6), and BS 7608 (Ref 11), but the fundamental basis for them is the same. In Fig. 29, a typical set of fatigue design curves, where BS 7608 is taken as a reference, each joint detail is placed into one of nine classes: A, B, C, D, E, F, F2, G, or W. Class A is the parent material *S-N* curve obtained from uniform, machined, and polished specimens; class W is the welded joint *S-N* curve based on nominal shear stress on the minimum weld throat area; and classes B through G are the welded joint *S-N* curves for joints of decreasing fatigue performance (or increasing joint stress concentration factor and notch severity). This approach is based on actual weld joint test data, so the joint classification takes into consideration the influence of the local stress concentration created by the weld geometry, effects of local discontinuities (e.g., weld toe intrusions), and residual stresses. The design stress, therefore, is the nominal stress adjacent to the weld detail under consideration. However, where joints are situated in regions of stress concentration resulting from the gross shape of the structure (e.g., adjacent to a hole), then it is necessary to consider the additional concentration of stress when the nominal stress range is calculated. *S-N* curves are used in design either to determine the maximum allowable cyclic stress for a given fatigue design life or to estimate the design life for a given set of operating conditions.

FIG. 29 MEAN MINUS TWO STANDARD DEVIATION S-N CURVES FOR WELDED JOINTS. SEE TEXT FOR DEFINITIONS OF LETTER SYMBOLS.

**Fracture Mechanics Approach.** The second most widely used design approach for welded structures uses fracture mechanics as its fundamental basis. As stated earlier, the majority of the fatigue life of a welded joint is spent in propagating existing crack-like features. Consequently, the analysis of fatigue cracking in welded joints is well suited to fracture mechanics, which can be used to predict the fatigue strength of nominally sound welds by considering the propagation of a fatigue crack from the inherent discontinuities that exist at the weld toe and the weld root. Fracture mechanics also can be used to predict the life of a joint with a weld discontinuity.

In documents such as PD 6493:1991, it is recommended that where possible, the fatigue crack growth relationship based on the Paris law should be used:

$$DA/DN = C(\Delta K)^M \quad (\text{EQ 3})$$

where  $\Delta K$  is the applied stress-intensity factor range,  $a$  is the crack size,  $N$  is the number of cycles, and  $C$  and  $m$  are constants that depend on the material and environment. This crack growth law is bounded by the threshold value for  $\Delta K$ ,  $\Delta K_{th}$ , and the critical value of  $K_{max}$  for fracture toughness,  $K_c$ , as a maximum. Experience with this crack growth law shows that it can be used to make reasonable estimates of the fatigue lives of welded joints, particularly when the initial crack size is relatively large. However, the actual sigmoidal shape may need to be represented in case of random loading assessments, and assessments for which  $K_{max}$  is close to  $K_c$  in the idealized relationship of Eq 3 can be nonconservative.

In general, the stress-intensity factor range,  $\Delta K$ , can be expressed as:

$$\Delta K = Y M_K (\Delta \sigma) \sqrt{\pi a} \quad (\text{EQ 4})$$

where  $\Delta\sigma$  is the stress range,  $Y$  is a function of geometry and loading, and  $M_k$  is a factor incorporating the stress concentration effect of the weld. The relationship between  $\Delta\sigma$  and the fatigue life  $N$  for an initial crack size  $a_0$  and maximum crack size  $a_c$  is obtained by substituting Eq 4 into Eq 3, then integrating and rearranging to give:

$$\int_{a_0}^{a_c} \frac{da}{(YM_k \sqrt{\pi a})^m} = C(\Delta\sigma)^m N \quad (\text{EQ 5})$$

$M_k$  factors are normally obtained by finite-element analysis of the type of joint and loading under consideration, and they are expressed in a nondimensional form.  $M_k$  factors are a function of the weld geometry parameters shown in Fig. 8:

$$M_k = F(R/T, L/T, \theta) \quad (\text{EQ 6})$$

General expressions for  $M_k$  factors have been produced by Thurlbeck and Burdekin (Ref 20), and these can be used with standard stress-intensity factor solutions to predict fatigue life.

Maddox (Ref 47) has carried out a series of fatigue crack propagation tests on various parent steels, weld metals, and HAZ microstructures (Fig. 15). He found no significant variation in crack propagation rates among any of the materials tested when the growth occurred by the striation mechanism. Based on such information, in BSI PD 6493:1991 firm recommendations are given for crack growth rate data. The option is available to use specific crack growth rate data for the material of interest, but otherwise the following upper-bound crack growth rate constants for ferritic steels (up to 600 MPa, or 87 ksi) operating in nonaggressive environments are recommended:

$$DA/DN = 3 \times 10^{-13} (\Delta K)^3 \text{ (N, MM UNITS)} \quad (\text{EQ 7})$$

The use of this crack growth relationship represents approximately 97.7% probability of survival. Higher crack growth rates may occur in weld metals and HAZs when the normal crack growth (by striation mechanism) is accompanied by cleavage or microvoid coalescence. Under such circumstances the value for constant C can be increased to  $6 \times 10^{-13}$ . For structural ferritic steels operating in marine environments up to 20 °C (68 °F), the following crack growth constants are recommended:

$$DA/DN = 2.3 \times 10^{-12} (\Delta K)^3 \text{ (N, MM UNITS)} \quad (\text{EQ 8})$$

For design purposes, it is sometimes necessary to estimate the limiting flaw size that will not extend by fatigue during service. The limiting crack size below which fatigue crack growth will not occur can be calculated using threshold concepts based on  $\Delta K_{th}$ . Near threshold  $da/dN$  becomes very sensitive to a number of variables including the applied stress ratio  $R$  (minimum stress/maximum stress). The following threshold stress-intensity factor ranges, representing the mean minus two standard deviations, are recommended for ferritic steels operating in air or seawater environments and also for austenitic stainless steels:

$$\Delta K_{TH} = 170 - 214R \text{ (N, MM UNITS) FOR } 0 \leq R \leq 0.5 \quad (\text{EQ 9})$$

$$\Delta K_{TH} = 63 \text{ (N, MM UNITS) FOR } R > 0.5 \quad (\text{EQ 10})$$

Welding residual stresses must be taken into account when calculating the stress ratio. Using the above expressions, it is possible to calculate the limiting flaw size that will not extend by fatigue during service.

Using the fracture mechanics fatigue crack growth procedures described above, the user can determine the number of cycles (or time) needed for a crack to extend from an initial size to a final size. This information can be used in a powerful way to define inspection criteria, and in particular inspection intervals. Alternatively, it can be used to compute the remaining life of a welded component, before failure by unstable fracture or plastic collapse becomes a reality. Another important use of this technology is the establishment of flaw acceptance criteria for nondestructive examination (NDE) of welded joints. Here the process is reversed by first defining the total design life of the structure and the final flaw size for fracture, then computing the initial crack size for that life cycle. This computed value of the flaw size can be used directly for specifying NDE flaw acceptance levels. Adoption of this approach should enhance the safety of the structure, because

all failure modes are considered and the flaw acceptance levels are specifically calculated rather than being based on workmanship criteria.

### Introduction

FRACTURE MECHANICS has developed into a useful tool in the design of crack-tolerant structures and in fracture control; it also has a place in failure analysis. Fracture mechanics can provide helpful quantitative information on the circumstances that led to the failure, and it can be used to prescribe preventive measures to avoid the recurrence of failures in similar components.

This article illustrates the role that fracture mechanics can play in failure analysis. It will be seen that the investigator has to draw on several disciplines (materials engineering plus analytical and experimental mechanics) and requires more expertise than has been traditionally needed for a failure analysis. This article describes the important failure criteria as relations between design (e.g., section geometry) and materials factors (e.g., fracture toughness), which are used to correlate fracture mechanics analysis to the observations of a failure analysis. Descriptions include an indication of how the factors are typically evaluated. Finally, a group of failure analysis examples illustrate how fracture mechanics parameters can be determined and how they may be fitted into an overall failure investigation.

It should be emphasized at the outset that a full fracture mechanics analysis is usually not required to understand failures that have occurred and to prevent similar failures, particularly in cases where the costs are relatively low, people have not been injured, and even when litigation is involved (Ref 1). Many failures can be corrected by appropriate specification of standard properties, good metallurgical practice, and proper design (see, e.g., three cases of brittle fracture described in Ref 2).

However, there are occasional failures involving large costs, extensive damage, and injuries, where it is not clear whether the best fracture control technology was used. Some questions that can be addressed by fracture mechanics are:

- Was the structure or operating component properly inspected periodically to detect potentially critical cracks?
- If cracks were found, was a proper analysis performed to determine whether continued safe operation was possible, and, if so, for how long?
- What modifications need to be made to similar structures to promote safe operation?

Approaches to such questions can be aided by the study of the fracture mechanics evaluations of real failures that have been investigated in the past.

**Benefits and Limitations.** While fracture mechanics is a well-developed approach to the study of failures, there is a gap between theory and practice, because it is often difficult to obtain exact values for many of the inputs into the analysis when structural failure occurs. If the failure conditions are well understood, the material is uniform, and the geometry is relatively simple, fracture mechanics can work well. But, in many situations, conditions are far less than ideal and fracture mechanics can only provide a reality check.

When fracture mechanics analysis indicates that failure should not have occurred based on the measurement of flaw size, material properties, and operating conditions, other factors that may have altered any of these conditions at the failure region must be investigated more thoroughly.

The benefits of uncovering the sources of significant differences between calculated and measured stresses are improvements in fracture control, such as use of tougher materials, reduced stress concentrations, and selection of better inspection procedures.

## Fracture Mechanics in Failure Analysis

Alan R. Rosenfield

---

### Using Fracture Mechanics in Failure Analysis

The investigator should first carry out a traditional failure analysis and determine the failure mechanism(s), the nature and location of the fracture origin, and the operating conditions.

The more detailed fracture mechanics evaluation requires numerical evaluation of a relation between mechanical properties, loads, and crack geometry. The first objective of this evaluation is to use the input data to determine whether the failure could have been predicted. If the occurrence of failure is not consistent with a fracture mechanics analysis, certain factors have not been considered and the investigator must search them out.

Such an analysis should include fractography to reveal whether the failed part contained serious defects and whether final failure was preceded by fatigue crack growth or stress-corrosion cracking. The information thus gained may be sufficient to explain the failure and to prevent future occurrences.

### Analysis of Final Fracture Conditions

To perform the analysis of conditions leading to final fracture, all of the quantitative information must be collected that is necessary for the investigator to evaluate the failure condition:

$$K_I \geq K_{IC} \quad (\text{EQ 1})$$

where  $K_I$  is the applied stress intensity (the demand placed on the cracked part by loading) and  $K_{IC}$  is the fracture toughness (the resistance of the metal to fracture). If Eq 1 is satisfied, it can be deduced that a sound analysis has been performed. On the other hand, if poor agreement is obtained, some factors have not been properly accounted for (e.g., residual stress). There is no well-accepted criterion for reasonable agreement; probably a discrepancy of less than 25% between both sides of Eq 1 is acceptable, while a 50% discrepancy would certainly indicate further evaluation of the failure. The in-between region is uncertain.

Because the inputs into Eq 1 are never certain, the best that can be hoped for is approximate agreement between calculated and measured stresses. *Furthermore, because of these uncertainties, it is not possible to use a structural failure to back-calculate an unknown property or stress with any degree of reliability.* An additional potential complication is the occurrence of extensive local plasticity, which requires the use of elastic-plastic fracture mechanics, characterized by the J-integral, but this refinement is rarely necessary for analyzing real failures.

**Evaluation of stress intensity** can be done either experimentally (Ref 3, 4), such as by use of photoelasticity, or analytically using finite element methods (Ref 5). These techniques are particularly useful for complicated geometries and provide the quantity:

$$K_I/\sigma = G \quad (\text{EQ 2})$$

where  $\sigma$  is the stress on the component, and  $g$  is defined as the ratio of stress intensity to stress. Equation 1 then becomes:

$$\sigma \geq K_{IC}/G \quad (\text{EQ 3})$$

and the analysis now becomes a comparison between the stress calculated from Eq 3 and the stress believed to be acting on the body.

Stress intensity factors are discussed in more detail elsewhere in this Volume for simple geometries. As an example, the following equation for stress intensity can be used for pressurized pipes:

$$K_I = F\sigma \sqrt{pa} \quad (\text{EQ 4})$$

so that Eq 1 becomes:

$$\sigma \geq K_{IC}/F \sqrt{pa} \quad (\text{EQ 5})$$

where  $a$  is the crack length and the  $f$  factor depends on crack size, crack shape, component size, and loading pattern (tension, bending, pressure, etc.). For through-wall cracks,  $a$  is conventionally taken to be half the crack length. This is equivalent to calling  $a$  the total crack length and setting  $f = 0.707$ .

**Evaluation of stress** can be done using standard strength-of-materials equations if the configuration is simple (Ref 6) or by finite element analysis if the configuration is complex. However, errors can arise because the stress to be used in Eq 3 or 5 is not necessarily limited to the operating stress. Residual stresses and extraneous loads (such as impact) may also play an important role in fracture and must be taken into account.

Fatigue loadings complicate the picture. The stress used in Eq 3 or 5 must be the peak stress,  $\sigma_{\max}$ , where the fluctuating stress  $\Delta\sigma = \sigma_{\max} - \sigma_{\min}$ .

**Evaluation of fracture toughness** requires measurements (by appropriate test methods as described in the article "Fracture Toughness Testing" in this Volume) using material from the failed part. Unfortunately, this recommended practice is not always followed; handbook values of fracture toughness are often used instead of toughness measurements on material in the vicinity of the failure.

The investigator must also compare fracture mechanisms of the part and any test samples. Note that the failure mechanism (such as brittle cleavage or ductile rupture) does not enter explicitly into evaluation of Eq 3 and 5. The investigator must verify that the fracture mechanics test specimen fails by the same mechanism as that of the actual failure. If the specimen fails by dimpled rupture and the component by cleavage, a serious overestimate of the  $K_{IC}$  value will result.

Because fracture toughness varies with material orientation, the  $K_{IC}$  specimen must be machined to ensure that the crack growth plane and direction are the same as those of the failure. The investigator must also recognize that the ASTM procedure requires precise control of fatigue precracking and environment. The subcritical crack growth of the failed component is unlikely to lie within the ASTM envelope, so the effective  $K_{IC}$  value of the failure can be different from the ASTM value. Finally, large errors can arise if the failure was in an atypical region (such as a weld, heat-affected zone, or a hot spot) and the toughness is measured on base metal.

An additional toughness error can arise in certain situations where the actual toughness is higher than  $K_{IC}$ . This elevation is found in thin sections of low-strength alloys and is due to the ability of the metal to deform plastically and partially relieve the stresses at the crack tip. Reference 7 gives some examples of such situations.

**Statistical Evaluation.** Uncertainty in fracture toughness (Ref 8) can be very significant, particularly for cleavage fracture where the standard deviation of  $K_{IC}$  values is typically 25% of the mean.

Ideally, a complete statistical evaluation of the properties of the material is desirable, but it is not generally available. The nearest approach to general agreement is for structural steels and weld metals in the ductile-brittle transition region, where a three-parameter Weibull distribution is used (Ref 9):

$$F = 1 - \text{EXP} \{ -[(K_{IC} - K_1)/K_0]^4 \} \quad (\text{EQ 6})$$

where  $F$  is the cumulative failure probability and  $K_1$  and  $K_0$  are fitting parameters. Representative coefficients of variation (standard deviation/mean, expressed as a percentage) for a variety of plates and weldments are summarized in Table 1. Individual data sets for the MIL-HDBK-5E entries in Table 1 are unique combinations of alloy designation, heat treatment, product form, and orientation, while the other high-strength alloy entries are less restrictive. It would appear that the typical coefficient of variation for handbook values of  $K_{IC}$  of these materials is on the order of 10 to 20%, depending on how well characterized the materials are.

**TABLE 1 VARIABILITY IN FRACTURE TOUGHNESS**

MATERIAL	COEFFICIENT OF VARIATION, %

Source: Ref 8

- (A) MULTIPLE LOTS OF MATERIAL. OTHERWISE SINGLE PLATES OR WELDMENTS ARE REPORTED.
- (B) DATA SETS WITH MORE THAN 100 ENTRIES.
- (C) VALUES AT 100-150 °C.
- (D) BASED ON THREE-PARAMETER WEIBULL DISTRIBUTION, WITH EXPONENT = 4; VARIABILITY ARISES FROM VARIATION IN THE  $K_1:K_0$  RATIO.
- (E) ESTIMATE BASED ON THE TENTH PERCENTILE OF 485 TESTS.

An analogous situation holds for upper-shelf toughness values for structural steels. Note that this section of the table includes J-integral variability ( $J_{IC}$ ), which appears to be about twice that for  $K_{IC}$ , as would be anticipated from the relation  $K_{IC} \propto \sqrt{J_{IC}}$ . For multiple base-plate data sets, the coefficient of variation of  $K_{IC}$  is somewhat larger than 13%, compared

to about 8% for single plates. Based on all of the upper-shelf data, a working hypothesis is that the coefficient from handbook values is also 10 to 20% for both plates and weld metals.

The first entry for the lower-shelf and transition regions of steel was calculated using Eq 6, which represents a very large database (Ref 10, 11). If the coefficient of variation of crack-tip opening displacement, in terms of which much of the weld data are reported, is also twice that of  $K_{Ic}$ , a typical coefficient for  $K_{Ic}$  data below the upper shelf would be on the order of 20% for both base plate and weld metal. The heat-affected zone data exhibit an even larger coefficient of variation, and this is a serious concern.

**Estimating Toughness.** Several estimation methods for fracture toughness values have been developed. These include measurement of the crack-tip profile in the scanning electron microscope (Ref 12), correlations based on Charpy and tensile tests and on microstructure (Ref 13), and handbook values of toughness of an alloy nominally the same as that of the failed part. Estimates deduced using any of these methods should be treated with great caution, because the magnitude of the error is usually unknown and can be large.

**Evaluation of crack size and shape** may be done visually, because actual failures often involve catastrophic growth of cracks that are several centimeters in size. However, the fracture surface at the origin is often lost or badly damaged and crack geometry has to be reliably estimated. In the event that the crack is very small, microscopic measurements may be required to reveal crack geometry. Conventionally, the size of a through-thickness crack is taken to be its average length, while the size of a surface crack is taken as its maximum depth.

**Evaluation of crack geometry and loading pattern (the  $f$  factor)** can be made using handbook values (Ref 14, 15, 16), provided that both the loading pattern and the crack size and shape are known. Finite element calculations are required for complicated geometries but are expensive and are not often essential, because  $f$  can usually be estimated roughly to sufficient accuracy.

**Stress Estimates from Fatigue Striation Spacings.** If subcritical crack growth occurred by fatigue, striation spacings can be used to estimate the alternating component of stress intensity (Ref 17), designated  $\Delta K = \Delta K_{max} - \Delta K_{min}$ . Because  $\Delta K$  is proportional to (striation spacing)<sup>1/4</sup>, a large error in spacing measurement leads to a small error in  $\Delta K$ . However, large errors in striation spacings and hence in  $\Delta K$  are possible in materials such as high-strength steels, where striations may not be as distinct as they are for aluminum alloys, for example. Also, surface damage, such as by rubbing, can obliterate striations.

If striation measurements are used, the alternating stress can be calculated as follows:

$$\Delta\sigma = \Delta K/G \quad (\text{EQ 7A})$$

$$\Delta\sigma = \Delta K/F \sqrt{pa} \quad (\text{EQ 7B})$$

In Eq 7b, the subcritical crack length  $a$  is evaluated at the striation location, and is not the final crack size.

## Fracture Mechanics in Failure Analysis

Alan R. Rosenfield

### Subcritical Fracture Mechanics (SCFM)

The growth of the crack that eventually leads to fracture occurs by mechanisms entirely different from the fracture itself. During most of the cracking process, the crack is much smaller than the one that would cause fracture at the prevailing stress. Therefore, the crack-tip stress field is less severe, and the size of the plastic zone smaller than at the time of fracture. Due to this small plastic zone, SCFM can often be approached using elastic concepts. If the crack size is close to critical (fracture), this may no longer be true, but because by far the longest time is spent in the growth of much smaller cracks, it is justifiable to use LEFM to obtain the time for crack growth with good accuracy. A notable exception is creep crack growth.

**Fatigue.** In the case of cyclic loading, crack growth occurs by fatigue. The amount of growth in one cycle depends on the crack tip stress field, which is described by  $K$ . During a load cycle,  $K$  varies from a minimum  $K_{\min} = \sigma_{\min} \beta \sqrt{pa}$  to a maximum  $K_{\max} = \sigma_{\max} \beta \sqrt{pa}$ , over a range  $\Delta K = \Delta\sigma \beta \sqrt{pa}$ , where  $\sigma_{\min}$  is the minimum stress in the cycle,  $\sigma_{\max}$  is the maximum stress in the cycle, and  $\Delta\sigma$  is the stress range  $\Delta\sigma = \sigma_{\max} - \sigma_{\min}$ .

It must be expected that the amount of growth per cycle depends on  $\Delta K$  and  $K_{\max}$ . If one defines a stress ratio  $R$  as  $R = K_{\min}/K_{\max}$ , the above statement is equivalent to the assertion that the amount of growth per cycle depends on  $\Delta K$  and  $R$ . Use of  $\Delta K$  and  $R$  is often more convenient because  $R = K_{\min}/K_{\max} = \sigma_{\min} \beta \sqrt{pa} / \sigma_{\max} \beta \sqrt{pa} = \sigma_{\min}/\sigma_{\max}$ . Hence, in the case of constant-amplitude loading where  $\sigma_{\min}$  and  $\sigma_{\max}$  do not change from cycle to cycle,  $K$  remains constant, while  $K_{\max}$  would depend on crack size.

The amount of growth per cycle is the rate of growth. This means that the above statement is equivalent to:

$$\frac{da}{dN} = \text{dependent on } \Delta K \text{ and } R \quad (\text{EQ 8})$$

where  $N$  is the number of cycles, and  $da/dN$  is the rate of growth.

It cannot be known *a priori* how  $da/dN$  depends on  $\Delta K$  and  $R$ ; this information must be provided by a test of the material. By measuring the rate of growth in a test and plotting the growth rates as a function of  $\Delta K$  (calculated from  $\Delta K = \beta \Delta \sigma \sqrt{\pi a}$ ), the dependence on  $\Delta K$  is obtained, and in a similar fashion, tests at different  $R$  stress ratios provide the dependence on  $R$ . Crack size as a function of time (number of cycles) is obtained by integration:

$$N = \int_{a_1}^{a_2} \frac{da}{da/dN} \quad (\text{EQ 9})$$

The integration is typically performed numerically using a computer. If data for a fixed value of  $R$  fall nearly on a straight line on a log-log scale, the rate data can be represented by the Paris equation. Unfortunately, the Paris equation covers only one  $R$  value. If the lines for different  $R$  values are parallel, one could use the modified equation:

$$\frac{da}{dN} = \frac{C_0}{(1-R)^n} \Delta K^m \quad (\text{EQ 10})$$

where  $n$  and  $C_0$  are also empirical constants. By noting that  $R = K_{\min}/K_{\max} = (K_{\max} - \Delta K)/K_{\max}$  so that  $K_{\max} = \Delta K/(1-R)$ , Eq 10 becomes:

$$\frac{da}{dN} = C_0 \frac{\Delta K^m}{(1-R)^n} \Delta K^{m-n} \quad (\text{EQ 11})$$

substituting for  $R$  and letting  $p = (m - n)$ :

$$\frac{da}{dN} = C_0 K_{\max}^n \Delta K^p \quad (\text{EQ 12})$$

Equation 12 is known as the Walker equation. Its advantage over the Paris equation is that it covers all values of  $R$ .

Many other equations are used. It should be pointed out, however, that no equation has any physical meaning: all are curve-fitting equations. There is no objection to their use if they fit the data. However, if the numerical integration must be done by a computer, use of the original data in tabular form is as convenient as use of a sometimes poor fitting equation.

**Stress-Corrosion Cracking.** In the case of stress-corrosion cracking, the rate of growth will depend on  $K$ , by the same arguments used for fatigue. In this case, the rate of growth depends directly on time so that the growth rate  $da/dt$  is:

$$\frac{da}{dt} = f(k)$$

Again, the rates must be obtained from a test. Integration of the rate data for the loading and  $\beta$  of a structure will provide the crack size as a function of time.

For combined stress-corrosion and fatigue cracking, one obtains  $da/dN$  from a cyclic-loading test in the appropriate environment. Again, a numerical integration will provide the crack-growth curve for the structure regardless of the shape of the  $da/dN$ - $\Delta K$  data. Complications due to load interaction and load-environment interaction must be considered.

In the case of stress corrosion at sustained load, the stress intensity must exceed a certain minimum value for crack growth to occur. This minimum value is known as the stress-corrosion threshold, denoted by  $K_{\text{ISCC}}$ . The threshold value is best determined by performing tests on cracked specimens and by measuring the time to fracture. A plot of the stress intensity applied as a function of time to failure will show an asymptote, which is  $K_{\text{ISCC}}$ . If growth does occur, it will continue to occur because  $K$  increases, and a failure will result. Conversely, if no failure occurs, no crack growth occurs; therefore, the stress intensity at the asymptote is indeed the threshold.

**Fatigue-Crack Growth.** Fatigue-striation counts (if possible) generally provide a reasonable account of the crack-growth rates and crack-growth curve. If the crack-growth-rate behavior of the material and the stresses are known, the stress intensity can be calculated, and a comparison can be made between actual and anticipated properties for a conclusion about the adequacy of the material. Conversely, if the stresses are not known, the measured rates and the rate properties can be used to estimate what the acting stresses were. This procedure will at least provide the magnitude of the stresses.

From the amount of crack growth (crack size at fracture), known stresses, and growth-rate properties, a reasonable insight can always be obtained regarding the question of misuse, for example, continuous overloading. The time to failure and final crack size are determined using fracture mechanics, as discussed above. When the results are not in accordance with the observations, the analysis can be repeated to determine how much higher (or lower) the stresses would have had to have been to produce the cracking time and extent of cracking as observed.

Any change of loading or change in environment during the cracking process is likely to leave its mark. Such changes produce a change in crack-growth rate, which is usually associated with a change in microfracture topography (surface roughness). Because the roughness affects the reflection of light, a change in roughness will appear as a line (beach mark). Any beach mark is an indication of a change in circumstances during cracking. The beach marks on fatigue-crack surfaces are well known. Similar marks may occur on stress-corrosion-crack surfaces due to changes in loading or environment.

A beach mark is clearly the delineation of the crack front at some point during the cracking process. Thus, the crack size at the time of the change is known. If any information on the nature of possible changes is known, the crack size at which they occurred can be used to obtain information on rate properties or stresses in the manner discussed above. If there is no information about the nature of the changes, such information (when it is a change in loading in particular) can be obtained from known growth-rate properties: the time for growth between beach marks can be calculated, and the stress required to produce the observed crack sizes estimated.

**Ductile striations** are the most commonly observed fatigue features that occur in the microstructurally insensitive intermediate  $\Delta K$  regime. The undulating or ripple-like fatigue striations appear to be correlated to a normalized stress-intensity range,  $\Delta K$ . Although there are exceptions, such regular striations have been found to correlate to  $\Delta K/E$  (stress-intensity range over Young's modulus), as shown in Fig. 1. A good correlation is:

$$\text{Striation spacing} \approx 6 \left( \frac{\Delta K}{E} \right)^2$$

## FIG. 1 CORRELATION OF FATIGUE STRIATION SPACING WITH $\Delta K$ NORMALIZED BY YOUNG'S MODULUS ( $E$ )

Figure 1 illustrates the application of this equation to many material types. More quantitative relationships have interpreted this growth mechanism to be proportional to the crack tip displacement. Such displacements may be changed by microstructural variations of either the flow stress or crack path. Thus, within the scatter band of Fig. 1, and in some cases outside it, microstructure may play a role.

### Case Studies of Failure Analyses Using Fracture Mechanics

Reports of a number of fracture-mechanics-based failure analyses have been published. Four examples (from Ref 18) are summarized in this section in order to illustrate the state of the art of the approach. Some simplifications and slight alterations have been made to the published reports in order to increase clarity. They were chosen to illustrate both typical procedures and the departures from ideal textbook procedures that can be encountered in practice. One striking point about these case studies is the very frequent need to estimate factors that are unknown or uncertain.

The "Selected References" at the end of this article also lists collections of case studies, which include examples involving fracture mechanics concepts. These collections provide insight into how to perform fracture mechanics analysis and also should give the reader insight as to how to decide whether such an analysis would be helpful.

Some of the collections of case studies discuss common characteristics of failures. For example, Fig. 2 shows that fatigue was the dominant mechanism for numerous industrial failures that the author investigated, while Fig. 3 points out that he found that errors in production (such as in design, material selection, and fabrication) were much more common than errors in operation (Ref 19). Section changes leading to stress concentrations are known to be a particular problem. There are three caveats regarding Fig. 2 and 3:

- BECAUSE SERVICE FAILURES ARE VERY RARE, IT SHOULD NOT BE CONCLUDED THAT USE OF DEFECTIVE PARTS IS WIDESPREAD.
- THE POSSIBILITY OF SERVICE FAILURES DUE TO PRODUCTION DEFICIENCIES IS LIMITED BY THE USE OF SAFETY FACTORS AND THE PRACTICE OF PROOF TESTING BY OVERSTRESSING.
- THE DISTRIBUTIONS IN FIG. 2 AND 3 ARE NOT VALID FOR EVERY APPLICATION. FOR EXAMPLE, GAS-TRANSMISSION PIPELINE FAILURES ARE MOST COMMONLY CAUSED BY ACCIDENTAL DAMAGE DUE TO THIRD-PARTY IMPACT.

FIG. 2 DISTRIBUTION OF FAILURES ACCORDING TO MECHANISM. SOURCE: REF 19

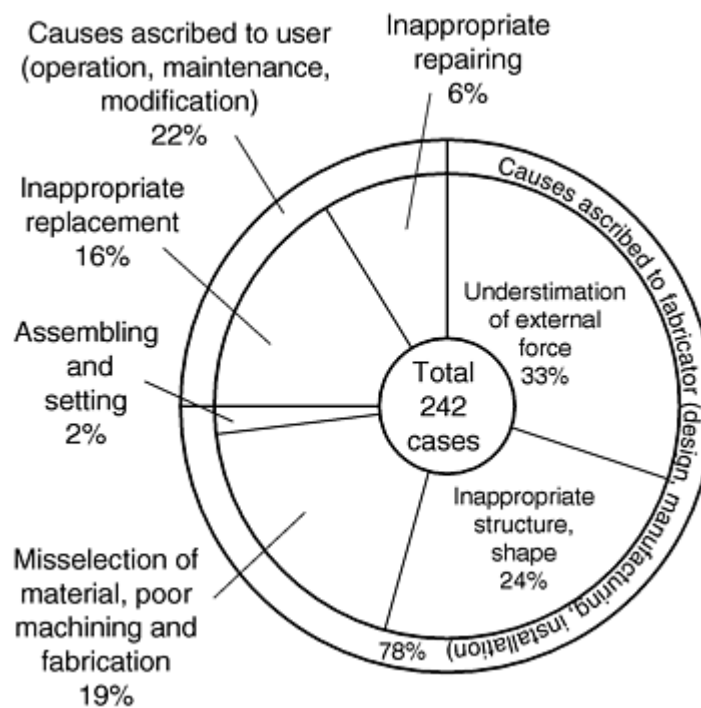

FIG. 3 DISTRIBUTION OF FAILURES ACCORDING TO CAUSE. SOURCE: REF 19

Some insight has been obtained into the relative importance of fracture mechanics parameters when failure occurs from pre-existing cracks. The two criteria deduced from Ref 8 are that failure is most likely to occur when crack size is greater than 25 mm (1 in.) and the ratio of fracture toughness ( $K_{Ic}$ ) to yield strength is less than  $0.16\sqrt{m}$  ( $1\sqrt{in}$ ). Because of the relatively small number of failures discussed in Ref 8, it cannot be argued that these failures provide general rules as to which cracked structures are safe and which are likely to fail. However, they do point out the danger of allowing components made from low-toughness materials and containing large cracks to remain in service.

### Failure of a Cryogenic Pressure Vessel

**Background (Ref 18, p 43).** This example is a rather straightforward application of fracture mechanics analysis with a satisfactory result, despite some uncertainties in the data. A cryogenic pressure vessel used in petrochemical manufacture exploded. The vessel operated at  $-130\text{ }^{\circ}\text{C}$  ( $-202\text{ }^{\circ}\text{F}$ ) and was made from a special fine-grained low-carbon steel. The failure initiated and first propagated in the neck or dome region of the vessel.

A traditional failure investigation using fractographic examination revealed evidence of fatigue crack growth, possibly corrosion assisted, at the origin. Several years after the explosion a more detailed investigation was undertaken to evaluate where safe operation could be ensured for similar vessels still in service. A "leak-before-break" philosophy was adopted; it assumed that operating vessels are safe if the critical crack length is greater than the wall thickness, under which conditions the subcritical crack would penetrate the wall and cause leakage before rupture would occur. Unfortunately, only a small piece of the failed vessel was available for examination.

**Fracture Mechanics Analysis.** Because of the complex geometry, a finite element calculation of *stress* was performed. The calculation revealed that the highest hoop stress was in the neck region, where the service failure did originate, and amounted to 80 MPa (11.6 ksi) at the outer wall and 60 MPa (8.7 ksi) at the inner wall. *Fracture toughness* is highly variable at the failure temperature; measurements on the same grade of steel from a similar vessel indicated a range from 39 to 67 MPa $\sqrt{m}$  (36 to 61 ksi $\sqrt{in}$ ). In the earlier investigation, critical *crack length* had been estimated to be in the range of 40 to 130 mm (1.6 to 5.1 in.). The crack was assumed to be a through-wall crack so that the *f factor* was 0.707 (see "Evaluation of Stress Intensity" in this article).

A range of hoop stress was calculated from Eq 5 by combining the largest estimated crack length with the smallest measured fracture toughness and vice versa. Because the result ranged from 87 to 267 MPa (12.6 to 38.8 ksi), the actual hoop stress of 80 MPa (11.6 ksi) could lead to failure if the crack was as large as the largest estimate and the fracture toughness had its lowest probable value. Moreover, the investigation confirmed that the critical crack size was greater than the wall thickness so that leak-before-break could be anticipated.

**Evaluation.** The investigators concluded that the failed vessel must have leaked prior to the rupture but that the leakage had not been detected. They urged more careful and extensive inspection of similar vessels still in service.

## Fracture Mechanics in Failure Analysis

Alan R. Rosenfield

## Failure of a Liquid Propane Gas Cylinder

**Background (Ref 18, p 75).** This is another example of straightforward analysis, but one in which the fracture mechanics evaluation did not markedly contribute to resolving the problem.

Five liquid propane gas (LPG) cylinders ruptured after about one year of service. The breaks were all longitudinal and about 400 to 500 mm (16 to 20 in.) long (Fig. 4). Visual observation of one of the failed cylinders revealed that the inner surface was scored with deep-drawing flaws of approximately the same length as the through crack. Examination of the fracture surface showed that a crack had initiated at one of these flaws and had propagated by cleavage almost to the outer surface. Final fracture involved formation of a small shear lip at the outer surface of the cylinder.

FIG. 4 RUPTURED LIQUID PROPANE GAS CYLINDER

calculated failure stress, indicating that accidental overpressure could be eliminated as a primary failure cause.

The cylinders were of welded construction and were made from a deep-drawn 0.13% C plain carbon steel with a yield strength of 326 MPa (47 ksi). Following postweld heat treatment, the cylinders were proof tested by pressurization at 3.1 MPa (450 psi). Operating pressure was 1.38 MPa (200 psi).

**Fracture Mechanics Analysis.** *Stress* was calculated using the simple equation for hoop stress of a pressurized cylinder; the result was 78 MPa (11.3 ksi). *Fracture toughness* was measured using a center-cracked panel machined from steel close to the location of the actual fracture. Of three specimens tested, only one failed by cleavage and its  $K_{Ic}$  value was 50 MPa $\sqrt{m}$  (45 ksi $\sqrt{in}$ ). The other specimens failed by dimpled rupture and could not be used to evaluate the toughness of the fractured cylinder. Because the crack propagated in the through-thickness direction, the critical *crack length* was taken to be the depth of the deep-drawing flaw, about 1.3 mm (0.05 in.). The *f factor* was calculated using a handbook of stress intensity values by treating the flaw as a straight-edge crack. This estimation is acceptable for a crack that is much wider than it is deep and led to a value of  $f = 2.1$ .

Using Eq 5, the predicted failure stress was found to be 372 MPa (54 ksi), which is about five times as high as the value of 78 MPa (11 ksi), calculated from the operating pressure. A test of the undamaged pressure relief valve demonstrated that it would be activated at 2.2 MPa (320 psi), corresponding to a hoop stress of 124 MPa (18 ksi), which is still well below the

FIG. 5 FRACTURE SURFACE OF SHROUD PLATE. APPROXIMATELY FULL SCALE

**Evaluation.** Because the crack geometry was well established, the large error in predicted stress could not be attributed to errors in either crack length or the *f factor*. A hardness traverse was made around the circumference and it was found

that there was a strong gradient, with a value of 170 HV in the region of the rupture and 90 HV at a location 180° from the rupture.

The investigators concluded that the cylinder had not been properly heat treated after welding. This error led to two contributions to the failure:

- THE RESIDUAL STRESSES WERE NOT RELIEVED. RESIDUAL STRESSES ADDED TO THE PRESSURE STRESS COULD ACCOUNT FOR THE DIFFERENCE IN CALCULATED AND OPERATING STRESS.
- LOCAL EMBRITTLEMENT HAD OCCURRED DUE TO HEATING DURING WELDING. THIS SUGGESTS THAT THE REPORTED FRACTURE TOUGHNESS VALUE WAS NOT REPRESENTATIVE, BECAUSE THE TIP OF THE CRACK IN THE FRACTURE TOUGHNESS SPECIMEN WAS NOT CLOSE ENOUGH TO THE EMBRITTLED REGION.

While the published report of this investigation does not contain explicit recommendations, it is clear that the ruptures of the cylinders were caused by manufacturing deficiencies that could be corrected.

## Fatigue Failure of a Large Fan

**Background (Ref 18, p 37).** This example illustrates analysis of a fatigue failure. A large fan, which provided draft for a coal-fired power plant, shattered. The fan had been in service for only ten days following periodic scheduled maintenance. The failure originated in a shroud plate, which showed evidence of extensive fatigue crack growth. The steel was described as low carbon, medium strength, with no details on manufacture being given.

The failure origin was close to a weld, but some details were not available because the mating surface to the origin was never found. Figure 5 shows the fracture surface with the initiating defect on the bottom side, a surface flaw 1.8 mm (0.07 in.) deep and 15 mm (0.6 in.) long. Most of the fracture surface exhibited fatigue markings indicating that the critical crack size at failure was much larger than the surface flaw.

**Fracture Mechanics Analysis.** Both static and alternating components of *stress* were evaluated using a finite element analysis. The static stress was 110 to 120 MPa (16 to 17.5 ksi), and the alternating stress was 10 to 15 MPa (1.5 to 2 ksi). *Fracture toughness* was measured using standard ASTM techniques and was found to be  $65 \pm 9 \text{ MPa}\sqrt{m}$  ( $59 \pm 8 \text{ ksi}\sqrt{\text{in}}$ ). *Critical crack size* and *crack shape* were measured, but not reported, by the investigators. Figure 4 suggests that a good approximation for the onset of final failure would be a through crack about 110 mm (4.3 in.) long. The *f factor* for a through crack is 0.707 (see "Evaluating Stress Intensity" in this article).

Using the above inputs, the failure stress was calculated to be in the range of 135 to 178 MPa (19.6 to 25.8 ksi), averaging somewhat greater than the combined steady-state and alternating stresses (120 to 135 MPa, or 17.5 to 19.6 ksi).

**Evaluation.** Although there was sufficient information at this point to provide remedies to prevent similar failures, the investigators decided to verify their stress evaluation by measuring fatigue striations on the small piece that was left from the failure. Using this technique they found that the cyclic stresses were greater than  $\pm 50 \text{ MPa}$  ( $\pm 7.25 \text{ ksi}$ ), which would add sufficiently to the steady-state stress to put the total stress firmly within the calculated failure range. However, strain gaging of a similar fan never revealed the presence of such unexpectedly high fluctuating stresses.

In stating their recommendations, the investigators pointed out that the steel was operating on its lower shelf and was probably too brittle for the application. In addition, they were troubled by the uncertainty in the magnitude of the fluctuating stress. They therefore suggested that similar fans were likely to fail. A number of improvements adopted as a result of this failure included use of a tougher steel, design changes, improved welding procedures, and more stringent inspections.

## Failure of a Gas Transmission Pipeline

**Background (Ref 18, p 173).** This example illustrates the problem of performing a fracture mechanics analysis in failures where there is massive damage to the structure.

A gas-transmission pipeline ruptured, the gas was ignited, and the resulting fire burned for over one hour before it could be extinguished. The pipeline was made from a 0.3 wt% C plain carbon steel and was 760 mm (30 in.) in diameter with 9.5 mm (0.375 in.) wall thickness. It was buried to a depth of 1 m (40 in.) and had been cathodically protected, with the protection adjusted some months before the failure.

The failure was about 5.5 m (18 ft) long and was confined to a single section of pipe, arresting at a girth weld at one end and by tearing off (spiraling) at the other (see Fig. 6). When the fragments had been collected it was found that one face of the fracture at the origin in piece 5-1 was covered with dirt. This region had a microstructure of either quenched-and-tempered martensite or bainite, which would not be anticipated in this steel in the as-rolled condition. The uncovered opposite face (piece 4-1) showed metallographic evidence of re-austenization, indicating that the fire had been severe enough to generate very high temperatures. More important, the heat treatment caused by the fire had altered the steel in the region of the fracture origin so that its properties at the time of the explosion could not be determined experimentally. The maximum measured hardness near the origin of piece 5-1 was 300 HK, but the investigator concluded that this piece had been tempered and that the hardness was originally higher at the origin.

**FIG. 6 FAILURE PATTERN IN PIPE. DOTTED LINES INDICATE SUBSEQUENT TORCH CUTS. SHADED REGION WAS PARTIALLY PROTECTED FROM HEAT OF FIRE BY A DIRT COVER.**

Fractographic examination revealed a semielliptical surface flaw at the origin that was 4.4 mm (0.175 in.) deep by 4.2 mm (0.165 in.) wide. While some intergranular fracture was observed, most of the fracture was by cleavage.

**Fracture Mechanics Analysis.** Using the standard equation for hoop stress in a cylinder pressurized to 3.9 MPa (560 psi), the operating *stress* was found to be 152 MPa (22 ksi). No direct estimate of *fracture toughness* at the origin could be made because of the heat treatment caused by the fire. The proper choice of critical *crack length* for this geometry is its depth of 4.4 mm (0.175 in.), while the *f factor* is 1.8.

Because fracture toughness was unknown, it had to be calculated from Eq 5, with the result being  $32 \text{ MPa} \sqrt{m}$  ( $29 \text{ ksi} \sqrt{in}$ ). The investigator concluded that the only way that such a low toughness could be achieved in this pipeline steel was if the origin was at a local hard spot, whose hardness might have been as high as 600 HK (55 HRC).

**Evaluation.** The data available to the investigator suggested the possibility that either stress-corrosion cracking or hydrogen stress cracking was the cause of the failure. Both of these mechanisms require high stress, high strength, and hydrogen absorption.

Existence of a local hard spot could satisfy the strength requirement and contribute to the stress requirement. The presence of the hard spot would lead to a local residual stress and a flat region because of its greater resistance to deformation during fabrication. The local stress could then be higher than the calculated value because of residual stresses associated with nonuniform deformation (out-of-roundness of the pipe) and also because of the geometric irregularity.

The hardness and the metallographic observation of tempered martensite or bainite indicated that the strength of the hard spot was higher than the nominal strength of the steel. It is plausible that the hard spot region was susceptible to the embrittlement processes at the time of fracture.

Hydrogen access was found to be likely, in that deterioration of the protective coating was observed in the undamaged section of the pipeline away from the fracture.

In summary, the rupture was probably caused by access of hydrogen to a susceptible site on the pipeline, even though this scenario could not be definitely proved.

### Operating Stress Maps for Failure Control

P.F. Timmins, President, Risk Based Inspection Inc.

---

### Introduction

FRACTURE MECHANICS CONCEPTS give engineers and inspectors the means to assess service situations for potential failure. An operating stress map (Fig. 1) is one way to assess potential fracture for an alloy of given toughness and operating stress. Operating stress maps are based on the same principle as a residual strength diagram, in that both diagrams are based on a plot of the following equation ( Eq 16 in the article "Residual Strength of Metal Structures" in this Volume) for elastic fracture mechanics:

$$\sigma_c = K_{IC}/\beta \sqrt{p a_c} \quad (\text{EQ 1})$$

plotting of this equation illustrates the regions where different combinations of stress and crack size are of concern, or where fracture mechanics or net section yield applies for a given ratio of operating stress and yield stress.

FIG. 1 OPERATING STRESS MAP OF A THROUGH-THICKNESS CRACK IN FORGED PLATE OF TI-6AL-4V WITH YIELD STRENGTH ( $\sigma_y$ ) OF 790 MPa (115 KSI) AND  $K_{Ic}$  OF 83 MPa $\sqrt{m}$  (75 KSI $\sqrt{in}$ )

This article describes the basis of "operating stress maps" based on Eq 1, as an alternative to the British CEGB (Central Electricity Generating Board) R6 method (Ref 1), which is based on failure assessment diagrams (FADs). The CEGB R6 method has received much attention (Ref 2), and it is useful in conjunction with (but not instead of) diagrams based on the critical stress relation (Eq 1). The use of operating stress maps was developed by the author (Ref 3) as a tool for assessing potential fracture in new or existing structures. If operating equipment contains a crack of initial length  $a_1$ , and, during inspection intervals, it grows by some mechanism to length  $a_2$  (less than the critical length), the growth rate may be low enough to allow operation until the next shutdown before the critical crack length is achieved, thus allowing time for repairs to be made during the shutdown. Alternatively, the operating stress may be reduced, giving a larger critical crack length according to Eq 1. This relation in Eq 1 between operating stress and crack length (or depth, depending on geometry) is the basis for deriving an operating stress map.

However, it must be emphasized that an analysis of damage tolerance cannot be based on Eq 1 alone. As discussed in the article "Residual Strength of Metal Structures" in this Volume, any analysis of damage tolerance requires information on both subcritical crack growth rates and the residual strength for a maximum permissible crack size ( $a_p$ ). A crack smaller than  $a_p$  may in fact be unacceptable if subcritical crack growth rates are large enough to reach critical crack ( $a_c$ ) and fracture before the next outage or scheduled maintenance. Therefore, calculation of  $a_p$  from a residual strength diagram must be supplemented by information on when a crack may reach  $a_p$  or  $a_c$ . Damage tolerance analysis must also account for net section yield (where fracture is governed by plastic deformation regardless of flaw size).

## Operating Stress Maps for Failure Control

P.F. Timmins, President, Risk Based Inspection Inc.

### Constructing an Operating Stress Map

The process of constructing an operating stress map is based on the same principles used in constructing so-called "residual strength diagrams." Operating stress maps can be added to, depending on the particular service conditions or geometry. For example, a subcritical growth mechanism rate law can be incorporated to determine the time available between crack detection and growth to critical (i.e., unstable) size.

The method presented here provides maps for through-thickness and surface crack geometries. A number of maps are presented; however, the intention is that engineers will be able to construct their own maps to meet specific needs. In addition, operating stress maps are compared to the use of FADs in the British CEBG R6 method.

Construction of an operating stress map is based on calculations of net section yield and fracture mechanics. For purposes of simplicity, this section describes the construction of a through-thickness crack (Fig. 2) in the linear elastic regime. For a through-thickness crack of length  $2a$  in a plate (or a panel, a vessel wall, or line-pipe), the geometry factor  $\beta$  is one. For an edge crack in the same plate,  $\beta = 1.12$ . It is also important to note the convention used for crack length. If a crack has two tips (as in a through-thickness crack), then the total crack length is twice the crack length on one side ( $2a$ ). The depth of an edge or surface crack,  $a$ , corresponds to the crack size. Other more complicated geometries are discussed in the section "Fracture Control Applications" in this article.

FIG. 2 DEFINITION OF QUANTITIES IN CONSTRUCTING AN OPERATING STRESS MAP FOR A THROUGH-THICKNESS CRACK ( $\beta = 1$ ) IN A PLATE OF WIDTH  $W$ . WHEN APPLIED STRESS IS AT THE CRITICAL LEVEL ( $\sigma$

c), THE CRACK OF LENGTH  $2a$  PROPAGATES ACROSS THE PLATE OF WIDTH  $W$ .

Plane strain fracture toughness ( $K_{Ic}$ ) is the inherent minimum toughness limit and thus provides a conservative toughness value for plotting an operating stress map with Eq 1. Plane strain conditions represent maximum constraint and occur when section thickness ( $B$ ) is:

$$B \geq \left( \frac{K_{Ic}}{\sigma_y} \right)^2 \cdot 2.5 \quad (\text{EQ 2})$$

$$B \leq \left( \frac{K_{Ic}}{\sigma_y} \right)^2 \cdot 0.3 \quad (\text{EQ 3})$$

The plastic zone at the crack tip is larger in plane stress than in plane strain, and less constraint and higher toughness occur in plane stress. Thus  $K_{Ic}$  is a conservative measure for constructing an operating stress map. Although Eq 2 and 3 define basic regimes of plane strain and plane stress toughness, there is no clearcut transition point between the two conditions. Cracks behave under conditions of either predominantly plane strain or predominantly plane stress.

**Net Section Yield.** When crack size becomes very small, Eq 1 is not adequate in calculating a safe limit for operating stress (or residual strength). As  $a_c$  approaches zero,  $\sigma_c$  approaches infinity, which is clearly erroneous. If the stress is much higher than the yield strength, then the entire plate is yielding and the plastic zone is as large as the plate. In this situation, the plastic zone would have become too large for  $K$  to be applicable much before the yield stress is reached.

In this situation of small crack sizes, the residual strength or safe operating stress is determined by calculation of net section yield (Fig. 3). If  $P$  is the applied load, and  $W$  and  $B$  are the width and thickness of the plate, the nominal remote stress is  $\sigma = P/BW$ , while the average stress over the net section is  $\sigma_{net} = P/B(W - 2a)$ , so that:

$$\sigma = \sigma_{net} \frac{W - 2a}{W} \quad (\text{EQ 4})$$

The whole net section yields when  $\sigma_{net} = \sigma_y$ , which occurs when:

$$\sigma = \sigma_y \frac{W - 2a}{W} \quad (\text{EQ 5})$$

This equation represents a straight line between the points ( $\sigma = \sigma_y$ ;  $2a = 0$ ) on the ordinate and ( $\sigma = 0$ ;  $2a = W$ ) on the abscissa (Fig. 3b). If the residual strength curve,  $\sigma_c = K_{Ic}/\beta\sqrt{pa}$ , is shown in the same diagram, it turns out that (usually) there are two regions in which the predicted residual strength is larger than the stress for net section yield at very large crack sizes and at small crack sizes (Fig. 4).

FIG. 3 NET SECTION YIELD FOR SMALL CRACKS. (A) AVERAGE NET SECTION STRESS. (B) NET SECTION YIELD LINE

FIG. 4 TANGENT APPROXIMATION FOR SHORT CRACKS WITH  $\beta \approx 1$

For small crack sizes, the general procedure recommended by Feddersen (Ref 4) is to draw a tangent from the yield strength value to the critical stress curve,  $\sigma_c = K_{Ic} / \beta \sqrt{\pi a}$  (Fig. 4). For a through-thickness crack (where  $\beta = 1$ ), the point of tangency is always at  $2/3 \sigma_{ys}$  and  $W/3$  (Fig. 4). As plate width becomes smaller, the net section yield line (Eq 5) moves left until it is tangent to the  $\sigma_c$  curve at  $2/3 \sigma_y$  (Fig. 5). All operating stresses on the net section yield line represent a condition for failure, regardless of crack size.

FIG. 5 OPERATING STRESS MAP OF TI-6AL-4V PLATE WITH A THROUGH-THICKNESS CRACK AND NET SECTION YIELD LINES FOR TWO PLATE WIDTHS ( $W$ ). SAME MATERIAL AS IN FIG. 1,  $\sigma_Y = 790$  MPA (115 KSI) AND  $K_{Ic} = 83$  MPA  $\sqrt{m}$  (75 KSI  $\sqrt{in}$ )

Because the point of tangency for  $\beta=1$  is at  $2/3 \sigma_y$  and  $2a = W/3$ , then the operating stress at this point can be calculated from Eq 1. From the fact that the operating stress is  $2/3$  the tensile yield stress and  $a = W/6$ , it follows that:

$$\frac{2}{3} \sigma_y = \frac{K_{Ic}}{\sqrt{\pi W/6}} \quad (\text{EQ 6})$$

or

$$W = \frac{27}{2\pi} \left( \frac{K_{Ic}}{\sigma_y} \right)^2 \quad (\text{EQ 7})$$

These relationships (Ref 5) give the minimum plate width for which  $K_{Ic}$  applies. This value of plate width is also the maximum that will fail at net section yield, as will all smaller plates, irrespective of the crack length.

A complete diagram is important when analyzing a structure for fracture criticality. Once the residual strength curve ( $\sigma_c$  in Eq 1) is drawn, the line for net section yield can be constructed, and it can be seen immediately whether or not the residual strength should be found from the curve ( $K_{Ic}$ ) or from the tangent to the curve. The whole  $\sigma_c$  curve has to be determined before the tangent can be constructed. In any analysis, understanding of crack growth behavior is also required (see the section "Subcritical Crack Growth" in this article).

**Empiricism and  $K_{Ic}$ .** The main reason for using the stress intensity approach in failure control is that the equations relate crack size to the operating stress, so the units are of stress and dimension. The less meaningful but cheap tests that have been used for years to describe toughness behavior are notched-bar impact tests.

There are empirical relationships in the literature that relate impact data to the more meaningful, but more expensive, fracture toughness data. Unfortunately, there are about 36 different relationships available, and they must be used for specific conditions. However, two relationships are used quite commonly (Ref 6). For conditions approaching upper shelf toughness values:

$$\left(\frac{K_{Ic}}{\sigma_y}\right)^2 = 4\left(\frac{CVN}{\sigma_y} - 0.1\right)\left(\text{in.}, \frac{\text{ft lb}}{\text{ksi}}\right) \quad (\text{EQ 8A})$$

OR

$$\left(\frac{K_{Ic}}{\sigma_y}\right)^2 = 0.52\left(\frac{CVN}{\sigma_y} - 0.02\right)\left(\text{m}, \frac{\text{J}}{\text{MPa}}\right) \quad (\text{EQ 8B})$$

and for conditions toward the lower shelf (Ref 7):  $K_{Ic} = 12\sqrt{CVN}$  (all units), where CVN = Charpy toughness.

## Subcritical Crack Growth

As previously noted, an analysis of damage tolerance in terms of the residual strength also requires information on crack growth prior to reaching the critical stress,  $\sigma_c = K_{Ic}/\beta\sqrt{pa_c}$ . Understanding of the crack growth behavior is necessary to estimate the time before critical crack length,  $a_c$ , is reached. For example, if subcritical crack growth behavior is known, crack length can be plotted versus time (Fig. 6). From a detected crack length,  $a_d$ , then the time to reach  $a_c$  can be estimated. This section briefly describes fatigue crack growth behavior. More detailed discussions of crack growth behavior of particular materials and service conditions (e.g., corrosion fatigue and stress corrosion cracking) are covered in other articles in this Volume.

$$da/dN = \frac{A(\Delta K)^n}{(1 - R) K_{Ic} - \Delta K} \quad (\text{EQ 9})$$

where  $A$  and  $n$  are empirical constants. This Forman equation (Ref 8) is general because  $R$  is accounted for. It has a vertical asymptote as  $\Delta K = (1 - R)K_{Ic}$  and an asymptote at the fatigue crack growth threshold,  $\Delta K_{th}$ . However, neither this nor the Paris equation, nor any other of the 32 rate equations, are derived from first principles. The relations are, to a large extent, empirical curves from data.

FIG. 6 EXAMPLE OF SUBCRITICAL CRACK GROWTH PLOT FOR FATIGUE CRACK GROWTH OF A SURFACE CRACK IN QUENCHED-AND-TEMPERED STEEL

More sophisticated relationships that consider crack growth retardation and a variety of geometries for a wide range of materials are currently available. Such a system is the NASA/FLAGRO computer program developed by Royce Forman at NASA, which provides a comprehensive package (Ref 9).

**Fatigue Crack Growth Integration Example: SAE 1020 Steel.** A wide plate of cold-rolled SAE 1020 steel has the following properties:

- YIELD STRENGTH,  $\sigma_Y = 630$  MPA
- YOUNG'S MODULUS,  $E = 207$  GPA
- ULTIMATE TENSILE STRENGTH, UTS = 670 MPA
- PLANE STRAIN FRACTURE TOUGHNESS,  $K_{IC} = 104$  MPA  $\sqrt{m}$

The plate is subjected to constant-amplitude uniaxial cyclic loads from 200 MPa ( $\sigma_{max}$ ) to -50 MPa ( $\sigma_{min}$ ). To find the fatigue life that would be attained if an initial through-thickness edge crack were no greater than 0.5 mm in length:

$$K_{MAX} = (1.12) (200) \sqrt{\pi(0.0005)} = 9 \text{ MPA} \sqrt{m}$$

The final crack length,  $a_c$ , can be determined by setting  $K_{max}$  at fracture equal to  $K_{IC}$ :

$$\Delta K = \Delta \sigma \beta \sqrt{\pi a}$$

$$\frac{da}{dN} = c(\Delta K)^m = c(\Delta \sigma \beta \sqrt{\pi a})^m = c(\Delta \sigma)^m (\pi a)^{m/2} \beta^m$$

which can define a critical crack size:

$$a_c = \frac{1}{\pi} \left( \frac{K_{Ic}}{\sigma_{max} \beta} \right)^2$$

Integrating the rate equation:

$$\begin{aligned} N_f &= \int_0^{N_f} dN = \int_{a_i}^{a_c} \frac{da}{c(\Delta\sigma)^m (\pi a)^{m/2} \beta^m} \\ &= \frac{1}{c(\Delta\sigma)^m (\pi)^{m/2} \beta^m} \int_{a_i}^{a_c} \frac{da}{a^{m/2}} \end{aligned}$$

If  $m \neq 2$ , then:

$$\begin{aligned} \int_{a_i}^{a_c} \frac{da}{a^{m/2}} &= \frac{a^{-(m/2)+1}}{-m/2+1} \Big|_{a_i}^{a_c} \\ &= \frac{a_c^{(-m/2)+1} - a_i^{(-m/2)+1}}{-m/2+1} \therefore N_f \\ &= \frac{a_c^{(-m/2)+1} - a_i^{(-m/2)+1}}{(-m/2+1)c(\Delta\sigma)^m (\pi)^{m/2} \beta^m} \end{aligned}$$

which is the general integration of the Paris equation when  $\beta$  is independent of crack length,  $a$ , and when  $m$  is not equal to 2. This equation is not correct if  $\beta$  is a function of  $a$ , which is the usual case.

Because specific crack growth data were not given for the SAE 1020 steel, a reasonable first approximation could use the conservative empirical equation for ferritic-pearlitic steels (see the article "Fracture Mechanic Properties of Carbon and Alloy Steels" in this Volume):

$$\frac{da}{dN} = c(\Delta K)^m = 6.9 \times 10^{-12} (\Delta K)^{3.0}$$

Although this equation was developed for  $R = 0$ , the small compressive stress, 50 MPa, will not have much effect on crack growth and can be neglected. Thus,

$$\Delta\sigma = 200 - 0 = 200 \text{ MPA}$$

Also,

$$a_c = \frac{1}{\pi} \left( \frac{K_{Ic}}{\sigma_{max} \beta} \right)^2 = \frac{1}{\pi} \left( \frac{105}{200 \times 1.12} \right)^2$$

Substituting,

$$\begin{aligned} N_f &= \frac{(0.068)^{-3/2+1} - (0.0005)^{-3/2+1}}{(-3/2+1)(6.9 \times 10^{-12})(200)^3 (\pi)^{3/2} (1.12)^3} \\ &= \frac{(0.068)^{-0.5} - (0.0005)^{-0.5}}{-2.16 \times 10^{-4}} = 189,000 \text{ cycles} \end{aligned}$$

**Stress-corrosion cracking rates** can depend on many factors, including temperature, chemistry of the environment, microstructure, and the stress intensity at the crack tip. Stress corrosion growth laws are similar to those described by fatigue crack extension (Fig. 7), but there is no single unified theory to explain SCC.

**FIG. 7 SCHEMATIC PLOT OF STRESS CORROSION CRACKING VELOCITY AGAINST STRESS INTENSITY FACTOR**

Stress-corrosion cracking degrades  $K_{Ic}$  to a level  $K_{ISCC}$ , below which crack growth does not occur. In between  $K_{ISCC}$  and  $K_{Ic}$ , a growth law will operate, but it will be peculiar to a given alloy and environment.

If circumstances arise for detection of SCC, it becomes prudent to generate operating stress maps for  $K_{ISCC}$  and  $K_{Ic}$ . Such maps are presented in Fig. 8 and 9 and for 4340 steel, from the data of Yokobori et al. (Ref 10). These maps are for surface crack geometries of various aspect ratios.

**FIG. 8** STRESS-CORROSION CRACKING (SCC) OPERATING STRESS MAP FOR 4340 STEEL WITH SURFACE CRACK ( $A/C = 0.6$ ). MATERIAL CONDITION: QUENCHED AND TEMPERED;  $K_{IC} = 127 \text{ MPa}\sqrt{m}$ ;  $\sigma_Y = 1168 \text{ MPa}$ ;  $K_{ISCC} = 40 \text{ MPa}\sqrt{m}$

**FIG. 9 STRESS-CORROSION CRACKING (SCC) OPERATING STRESS MAP FOR 4340 STEEL WITH SURFACE CRACK ( $A/C = 0$ ). SAME STEEL CONDITION AS IN FIG. 8:  $K_{Ic} = 127 \text{ MPa}\sqrt{m}$ ;  $\sigma_y = 1168 \text{ MPa}$ ;  $K_{ISCC} = 40 \text{ MPa}\sqrt{m}$**

The operating stress map in Fig. 8 indicates that 4340 with a  $K_{ISCC}$  of  $40 \text{ MPa}\sqrt{m}$  can be operated safely at 25% of the yield strength, with surface cracks of aspect ratio  $a/c = 0.6$  present up to maximum depth of 10 mm. The environment used must be one that gives rise to the  $K_{ISCC}$  value used.

Deeper cracks can be tolerated, but because the crack growth rate law is not known, the time-to-failure of such cracks cannot be predicted from the data available. A complete set of operating stress maps may be generated for surface cracks of various aspect ratios, through-thickness cracks, and edge cracks.

**Corrosion Fatigue.** There is not yet a generally accepted growth law for corrosion fatigue. The  $da/dN$  versus  $\Delta K$  curves have a shape similar to those of fatigue and SCC curves. Testing in a similar environment under loading conditions similar to those expected in the application is needed to characterize corrosion fatigue crack growth rates.

## Operating Stress Maps for Failure Control

P.F. Timmins, President, Risk Based Inspection Inc.

## Comparison with Failure Assessment Diagrams

As discussed in the article "Residual Strength of Metal Structures" in this Volume, the failure assessment diagram (fad) is used to assess potential fracture in the whole range of conditions from brittle to fully plastic behavior. The FAD used in the CEGB R6 method is useful in conjunction with (but not instead of) the residual strength or operating stress diagram, because a FAD can be derived from the latter. The example below also illustrates the simplicity of using an operating stress map in comparison to the FAD method. An operating stress map (or a residual strength diagram) relates operating stress directly to crack size, while the FAD method gives a proximity of fracture number as a "safety margin against failure" and requires several equations. Nonetheless, the FAD has significance because it illustrates from a technical view the competing conditions of plastic collapse and linear (elastic) fracture mechanics.

The CEGB R6 method (Ref 1) uses a failure assessment diagram (Fig. 10), which plots the ratio  $K_r = K/K_c$  versus the ratio  $S_r = \sigma/\sigma_{fc}$  (where  $\sigma_{fc}$  is the stress for plastic collapse). This normalization makes a universal diagram, where  $K_r$  represents the limit for elastic fracture and  $S_r$  represents the limit for plastic collapse. The diagram provides a graphical illustration of competing conditions and a basis for estimating the regime of elastic-plastic fracture between the two limits. Failure would occur in the region outside the envelope bounded by the axes and the assessment curve. This graphical approach is instructive, because it illustrates that elastic-plastic fracture mechanics (EPFM) does not require sensitive fracture criterion. This method of failure assessment is used in the example below.

**FIG. 10 FAILURE ASSESSMENT DIAGRAM BASED ON THE STRESS INTENSITY RATIO ( $K_R = K/K_C$ ) AND STRESS RATIO ( $S_R = \sigma/\sigma_{FC}$ ) WHERE  $\sigma_{FC}$  IS THE PLASTIC COLLAPSE STRESS. GENERAL REGIONS ARE SHOWN FOR LINEAR ELASTIC FRACTURE MECHANICS (LEFM) AND ELASTIC PLASTIC FRACTURE MECHANICS (EPFM).**

### Example 1: CEGB R6 Method in Failure Assessment.

The FAD method can be illustrated with an example similar to that originally set by Spiekhout (Ref 2) in the R6 format. Consider a cast steel plate with a surface flaw and the following conditions:

- DEPTH OF SURFACE FLAW,  $A = 7$  MM
- LENGTH OF SURFACE FLAW,  $L = 35$  MM (1.38 IN.)
- YIELD STRENGTH,  $\sigma_Y = 430$  MPA (62 KSI)
- ULTIMATE TENSILE STRENGTH, UTS = 589 MPA (85 KSI)
- PLANE STRAIN FRACTURE TOUGHNESS,  $K_{IC} = 32$  MPA  $\sqrt{m}$  (29 KSI  $\sqrt{in}$ )

The operating stress ( $\sigma$ ) is 170 MPa (25 ksi), and the stress for plastic collapse ( $\sigma_{fc}$ , or  $\sigma_{MC}$ ) is estimated as follows:

$$\sigma_{FC} \approx (\sigma_Y + UTS)/2 = 510 \text{ MPA}$$

This value for plastic collapse and the operating stress are used to define the value  $S_r$  as follows:

$$S_R = \sigma/\sigma_{FC} = 170/510 = 0.33$$

The ratio  $K_r = K_I/K_{IC}$  is then derived from British standard PD6493 (Fig. 11) (Ref 11) as follows:

$$\frac{\text{Crack depth}}{\text{Platethickness}} = \frac{t}{e} = \frac{7}{108} = 0.065$$

and

$$\frac{\text{Crack depth}}{\text{Cracklength}} = \frac{t}{l} = \frac{7}{35} = 0.2 \text{ aspect ratio}$$

Therefore:

$$\frac{a}{e} = 0.06$$

and the surface crack geometry is thus converted to a through-thickness geometry such that  $a = 6.5$  mm. With  $K_I = \beta\sigma_c \sqrt{\pi a}$  and with  $\beta = 1$  for a through-thickness crack:

$$K_I = 170 \sqrt{\pi \bullet 6.5} = 24.3 \text{ MPA} \sqrt{m}$$

Therefore the ratio  $K_r$  is defined as follows:

$$K_r = \frac{24.3}{32} = 0.76$$

From the FAD (Fig. 10), the point falls within the curve, so failure will not occur. The safety factor against failure is:

$$\frac{OX}{OY} = 1.3$$

In revision 3 of R6,  $S_r$  is changed to  $L_r$  and the limits imposed on  $L_r$  are reduced. In revision 2,  $S_r$  never exceeded 1.

FIG. 11 RELATIONSHIP BETWEEN ACTUAL FLAW DIMENSIONS AND THE PARAMETER A FOR SURFACE FLAWS

### Example 2: Operating Stress Map in Failure Assessment.

Consider the same example of a cast steel plate with a surface flaw using an operating stress map. The operating stress map is shown in Fig. 12 for the data based on the following equation for an elliptical crack (see "Complex Geometry Factors" in the next section):

$$K_{lc} = \frac{1.12 \sigma_c \sqrt{\pi a}}{\Phi}$$

With an aspect ratio of  $7/35 = 0.2$ ,  $\Phi = 1.016$  (since  $a/2c = 0.2$ ). Solving for  $a_c$ , then:

$$a_c = \frac{32^2 \cdot 1.016^2}{1.12^2 \cdot 170^2 \cdot \pi} = \frac{1057.03}{113,904.29} = 0.00928 \text{ m}$$

$$a_c = 9.3 \text{ mm, or}$$

$$a \cdot \sigma_c^2 = \frac{1057.03}{3.941} = 268$$

$a$  and  $\sigma_c$  are varied to produce the operating stress map.

FIG. 12 OPERATING STRESS MAP WITH A PLOT OF CRITICAL STRESS ( $\sigma_c$ , EQ 1) FOR CAST STEEL PLATE WITH A SURFACE CRACK ( $A/C = 0.2$ ). MATERIAL CONDITION: QUENCHED-AND-TEMPERED STEEL,  $\sigma_Y = 430 \text{ MPa}$  (62 KSI), ULTIMATE TENSILE STRENGTH = 590 MPa (85 KSI),  $K_{Ic} = 32 \text{ MPa}\sqrt{\text{m}}$  (29 KSI $\sqrt{\text{in}}$ ), AND PLATE THICKNESS = 108 MM (4.25 IN.). HIGHER TOUGHNESSES ARE INSERTED FOR COMPARISON.

Changes in  $K_{Ic}$ . Increasing the value of  $K_{Ic}$  to  $101.25 \text{ MPa}\sqrt{\text{m}}$  would change  $K_r$  for the FAD as follows:

$$K_r = \frac{24.3}{101.25} = 0.24$$

Thus, with  $S_r = 0.33$  and  $K_r = 0.24$ , the point on the FAD (Fig. 10) is such that failure will not occur and the safety factor against failure is:

$$\frac{OB}{OA} = 2.64$$

With an operating stress map (Fig. 12):

$$a_c = \frac{101.25^2 \cdot 1.016^2}{1.12^2 \cdot 170^2 \cdot \pi} = 92.9 \text{ mm, or}$$

$$a \cdot \sigma_c^2 = \frac{10,582.24}{3.941} = 2685.15$$

**Operating Stress Maps for Failure Control**

P.F. Timmins, President, Risk Based Inspection Inc.

**Summary of Linear Elastic Fracture Mechanics Concepts**

A brief summary of linear elastic fracture mechanics (LEFM) concepts is provided below as background for explanation of the application of LEFM in damage tolerance analysis. Additional information is also contained in the articles "XX" and "XXX" in this Volume.

The stress-intensity factor,  $K$ , is a scaling factor that relates applied mechanical stresses to the intensification of stresses at the tip of a crack. For a general body under tensile (mode I) loading (Fig. 13), the stress-intensity factor near the crack tip ( $K_I$ ) (at  $\theta=0$  in Fig. 13) is:

$$\sigma_{YY} = K_I / \sqrt{2\pi r} \quad (\theta = 0) \quad \text{(EQ 10)}$$

where  $r$  is the distance from the crack tip. All the effects of loading, geometry, and crack size are incorporated into one parameter,  $K_I$ . For different geometries, crack sizes, and loading,  $K_I$  will have a different value, but apart from the value of  $K$ , the stress field will be the same. Equation 10 is the general solution for all crack problems. The parameter  $K$  governs the field, and  $K$  is the only significant parameter for all crack problems. Once  $K$  is known, the near-crack-tip stress field is known in its entirety.

FIG. 13 GENERAL COORDINATE SYSTEM FOR EXPRESSION OF CRACK-TIP STRESSES WHERE  $\sigma_{ij} = (K_I / \sqrt{\pi 2r}) F_{ij}(\theta) + C_1 R^0 + C_2 R^{\frac{1}{2}} + \dots$

As a general solution, Eq 10 can be expressed in terms of a geometric factor and crack size according to Eq 1,  $K = \beta \sigma \sqrt{pa}$ . All effects of geometry are reflected in one geometric parameter  $\beta$ . This geometric parameter has been calculated

for many generic geometries, and the results have been compiled in various handbooks. (See also the appendix "Stress Intensity Factors" in this Volume.)

The stress intensity  $K_I$  represents the mechanical side of the equation; the toughness,  $K_c$ , is the material side. Fracture occurs when  $K_I = K_c$ . This is analogous to the statement that yielding will occur when the stress,  $\sigma$ , equals the yield stress,  $\sigma_y$  where  $\sigma$  is the mechanical side of the equation. Thus, if the material exhibits a fracture for a certain value of  $K$ , it will always exhibit fracture at that value of  $K$  (similitude for equal  $K$ ).

These arguments remain valid even if some plastic deformation occurs. However, one condition must be satisfied: the plastic zone must be so small that its size is determined fully by  $K$  and by  $K$  only. This will be the case if the plastic zone does not extend beyond a value of  $r$ , at which the first term in the expansion series (Fig. 13) is still much larger than all other terms. Otherwise, the constants  $C_1$ ,  $C_2$ , and so on (see caption equation in Fig. 13) will become significant. In general, this will not occur until the value of  $K_I/\sigma_y$  exceeds about 2 (this also depends on geometry). If it does occur, LEFM is no longer valid, and elastic plastic fracture mechanics (EPFM) must be used, although the use of LEFM can be stretched further with simple approximations (see the article "Residual Strength of Metal Structures" in this Volume). Some typical factors affecting  $K$  in the application of LEFM are briefly summarized below.

**Geometry Factor  $\beta$  for Crack-Tip Stress Intensities ( $K_I$ ).** As long as stresses are elastic, then the stress in the region near the crack tip ( $\sigma_{yy}$  in Eq 10) is proportional to the applied stress ( $\sigma$ ). Consider the case of a plate (Fig. 14a) with a large width ( $W$ ) and a through-thickness center crack. It is expected that the crack-tip stress depends on the crack size. Because  $\sigma_{yy}$  depends on  $1/\sqrt{r}$  according to Eq 10, it is inevitable that it depends on  $\sqrt{a}$ ; otherwise, the dimensions would be wrong. Hence, a general relation for  $\sigma_{yy}$  is:

$$\sigma_{yy} = \frac{\beta\sigma\sqrt{\pi a}}{\sqrt{2\pi r}} \quad (\text{EQ 11})$$

where  $\beta$  is a dimensionless constant. The crack-tip stresses will be higher when  $W$  is smaller. Thus,  $\beta$  must depend on  $W$ . It is known that  $\beta$  must be dimensionless, yet  $\beta$  cannot be dimensionless and depend on  $W$  at the same time, unless  $\beta$  depends on  $W/a$  or  $a/W$ , that is,  $\beta = f(a/W)$ . Comparison of Eq 10 and 11, then, shows that:

$$K_I = \beta \left( \frac{a}{W} \right) \sigma \sqrt{\pi a} \quad (\text{EQ 12})$$

FIG. 14 CRACK-TIP STRESS INTENSITY ( $K_I$ ) IN TERMS OF APPLIED STRESS ( $\sigma$ ) FOR (A) A CENTER-CRACKED PLATE AND (B) AN EDGE-CRACKED PLATE UNDER UNIFORM TENSION

If the crack-tip stress is affected by other geometric parameters--for example, if a crack emanates from a hole, the crack-tip stress will depend on the size of the hole--the only effect on the stress-intensity factor (and the crack-tip stresses) will be in  $\beta$ . Consequently,  $\beta$  will be a function of all geometric factors affecting the crack-tip stress:  $\beta = \beta(a/W, a/L, a/D)$ . Crack-tip stresses are always given by Eq 10; the value of  $K$  in Eq 10 is always given by Eq 12.

For a through-thickness crack in a plate (Fig. 14a),  $\beta = 1$  and the length is  $2a$  when the crack has two tips. For a small edge crack, the length is  $a$  and  $\beta = 1.12$  (Ref 12).

**Complex geometry factors** are summarized below and in Fig. 15. These approximations agree well with more complex expressions.

FIG. 15 ELLIPTICAL AND CIRCULAR CRACKS. (A) TENSILE LOADING AND CRACK PLANE. (B) EMBEDDED CIRCULAR CRACK. (C) EMBEDDED ELLIPTICAL CRACK. (D) SURFACE HALF-ELLIPTICAL CRACK. (E) QUARTER-ELLIPTICAL CORNER CRACK. (F) QUARTER-ELLIPTICAL CORNER CRACK EMANATING FROM A HOLE. (G) ELLIPTICAL CRACK PARAMETERS. (H) VALUES OF  $\Phi$

For the crack at a hole shown in Fig. 15(g), no rigorous solution currently exists and controversy exists over the variation of  $K_{Ic}$  along the crack front (Fig. 16), such that consensus dictates the  $K_{Ic}$  value chosen (Ref 13).

FIG. 16 TEST DATA FOR CORNER CRACKS AT HOLES

$\beta$  values may be "compounded" (Ref 14) to give a total geometry factor. For example, a surface crack close to a weldment may have  $\beta$  compounded or a stress concentration ( $k_t$ ) value built into it. (Compounding  $\beta$  values means multiplying them together. Building in a  $k_t$  value means adding to an extra factor to increase the  $\beta$  value.)

The  $k_t$  for fatigue notch is given by (Ref 15):

$$k_t = 1 + \frac{K - 1}{1 + (a/r)} \quad (\text{EQ 13})$$

where  $K$  = elastic stress concentration factor;  $r$  = root radius; and  $a$  = material parameter, which is a function of ultimate tensile strength. Other  $k_t$  values for different geometries are available in the literature (Ref 15, 16).

$K_{Ic}$  values may be added or subtracted, depending on geometry. For example,  $K_{Ic}$  for a part of a geometry may be known, and  $K_{Ic}$  for the remaining part of the desired geometry may be known. The total value of  $K_{Ic}$  needed is:

$$K_{Ic} (\text{TOTAL}) = K_{Ic} (\text{PART 1}) + K_{Ic} (\text{PART 2})$$

The easy way to remember this is to add the  $K_{Ic}$  and multiply the  $\beta$  factors.

**Embedded Elliptical Crack.** For an embedded elliptical crack in the plane shown in Fig. 15(a), where  $2a$  is the minor diameter and  $2c$  is the major diameter (Fig. 15c), the critical stress intensity factor ( $K_{Ic}$ ) is given by (Ref 17):

$$K_{Ic} = \frac{\sigma_c \sqrt{\pi a}}{\Phi} \left[ \sin^2 \alpha + \left( \frac{a}{c} \right) \cos^2 \alpha \right]^{1/4} \quad (\text{EQ 14})$$

where  $\sigma$  is the angle shown in Fig. 15(g) and  $\Phi$  is the double elliptical integral, which depends on the crack aspect ratio,  $a/c$ . Values of  $\Phi$  are shown in Fig. 15(h), where  $\Phi$  varies from 1.0 to 1.51 for  $a/c$  ranging from zero (slender ellipse) to unity (circle). The stress intensity varies along the elliptical crack tip: the maximum value at the minor axis and the minimum value at the major axis. In fatigue, this crack would grow into a circle with a uniform stress intensity at all points.

**Circular Embedded Crack.** For a circular embedded crack (Fig. 15b),  $K_{Ic}$  is:

$$K_{Ic} = \sigma_c \sqrt{\pi a} \left( \frac{2}{\pi} \right) \quad (\text{EQ 15})$$

Surface elliptical cracks tend to grow to other elliptical shapes due to the free surface effect. A general expression for the semielliptical surface crack (Fig. 15d) is:

$$K_{Ic} = \frac{\sigma_c \sqrt{\pi a}}{\Phi} M_f \cdot M_b \left[ \sin^2 \alpha + \left( \frac{a}{c} \right)^2 \cos^2 \alpha \right]^{1/4} \quad (\text{EQ 16})$$

where  $M_f$  is a front face correction factor and  $M_b$  is a back face correction factor:  $M_f$  and  $M_b$  are functions of  $\alpha$ .

For a semielliptical crack in a thick plate,  $K_{Ic}$  at the deepest point is approximated by:

$$K_{Ic} = \frac{1.12 \sigma_c \sqrt{\pi a}}{\Phi} \quad (\text{EQ 17})$$

where an  $M_f$  factor of 1.12 is analogous to the free edge correction of the single edge crack.

**Quarter-Circular Corner Crack.** For the quarter-circular corner crack ( $a/c = 1$ , Fig. 15e) with two free edges,  $K_{Ic}$  is approximated by:

$$K_{Ic} = \frac{(1.12)^2 \sigma_c \sqrt{\pi a}}{\Phi} \quad (\text{EQ 18})$$

**Crack-Tip Plasticity.** Even when the analysis is based in LEFM, there is always a region of plasticity in the form of a "roll" at the leading edge of the crack tip (Fig. 17). The radius of this roll of plastic deformation or plastic zone depends on the condition of constraint at the crack front. The nature of this "roll" can be understood as a consequence from the theory of elasticity, where the crack-tip stress according to Eq 10 would be infinite for  $r = 0$  regardless of the value of  $K$ . This is, of course, a nonphysical result. In reality, a material will exhibit plastic deformation that limits the stress (Fig. 17 and 18).

**FIG. 17 CONTRACTION AND CONSTRAINT FROM CRACK-TIP PLASTICITY. HIGH STRESS AND STRAIN AT THE CRACK TIP IN THE X- AND Y-DIRECTIONS CAUSE A CONTRACTION IN THE Z-DIRECTION. HOWEVER, BECAUSE THE CRACK ITSELF IS STRESS FREE, NO CONTRACTION OCCURS BEHIND THE CRACK FRONT. FURTHER AWAY FROM THE CRACK, THE STRESSES ARE LOW; THEREFORE, THE CONTRACTION IS SMALL. THUS, THERE IS A THIN CYLINDRICAL-LIKE ZONE OF MATERIAL AT THE CRACK TIP WANTING TO CONTRACT A GREAT DEAL, WHILE THE SURROUNDING MATERIAL DOES NOT NEED TO CONTRACT. IF THIS ZONE IS LONG AND THIN, ITS CONTRACTION WILL BE PREVENTED BECAUSE IT IS ATTACHED TO THE SURROUNDING MATERIAL. THE SURROUNDING MATERIAL WILL CONSTRAIN THE CONTRACTION BY EXERTING A TENSION STRESS UPON THE CYLINDRICAL ZONE IN THE Z-DIRECTION SO AS TO KEEP  $\epsilon = 0$ .**

(a)

(b)

FIG. 18 CRACK-TIP STRESS DISTRIBUTION. (A) ELASTIC. (B) ELASTIC-PLASTIC

The radius of this roll of plastic deformation or plastic zone depends on the condition of constraint at the crack front. The most common situation is that of plane strain, and the plastic zone "size" or radius of the plastic roll is given by (Ref 18):

$$r_p = \frac{1}{6\pi} \left( \frac{K_{Ic}}{\sigma_y} \right)^2 \quad \text{(EQ 19)}$$

where  $1/6\pi$  is determined experimentally. In plane stress:

$$r_p = \frac{1}{2\pi} \left( \frac{K_c}{\sigma_y} \right)^2 \quad (\text{EQ 20})$$

where  $1/2\pi$  is determined experimentally.

**Plane Strain and Plane Stress Constraint Conditions.** The amount of constraint depends on the length-to-diameter ratio of the cylindrical zone of material at the crack tip that needs to undergo large contractions. If the zone is long, there is plane strain; if the zone is short, there is plane stress. For the through-thickness crack shown in Fig. 17, the length of the zone equals the thickness. Therefore, for this situation, the thickness determines whether there is plane strain or plane stress: large thicknesses will give plane strain, and small thicknesses will give plane stress. Therefore, the toughness will depend on thickness. Once there is complete constraint, the situation cannot worsen, so the toughness does not decrease further once it reaches  $K_{Ic}$ .

Because constraint is determined by the length-to-diameter ratio of the cylindrical zone defined above, section thickness determines constraint conditions for plane strain and plane stress toughness (Eq 2 and 3) of a through-thickness crack. However, for part-through cracks (surface flaws and corner cracks), the length of the zone does not depend on the thickness. In the case of part-through cracks the state of stress is always plane strain (unless the flaw is almost completely through). Hence, one should use  $K_{Ic}$ , not  $K_c$ , regardless of thickness.

**Evaluating Manufacturing or Fabrication Discontinuities.** Numerous questions arise in equating fabrication discontinuities to solutions for elliptical cracks. For example, the ASME Section XI Boiler and Pressure Vessel Code formulation is an innately conservative one: that is, to define the effective fracture mechanics discontinuity as an ellipse that surrounds or fully encloses the fabrication discontinuities (Ref 19). Situations arise when this approach becomes impossible. In some cases, a center-cracked plate geometry may be assumed in the failure control of large-diameter, welded vessels (see the next section of this article).

## Operating Stress Maps for Failure Control

P.F. Timmins, President, Risk Based Inspection Inc.

---

## Fracture Control Applications

Operating stress maps provide useful information for fracture control in a variety of applications. Real industrial applications are described in this section for both through-thickness cracks and surface cracks. Examples include determination of a safe level of pressure for a large-diameter vessel, criteria for "leak-before-break" operation, and the use of operating stress maps to evaluate surface cracks in weldments and castings.

### Example 3: Safe Operating Pressure of a Large Pressure Vessel with a Surface Crack.

As mentioned in the previous section of this article, it may not always be possible or necessary to analyze defects or discontinuities in terms of solutions for elliptical cracks. In some cases, fracture control can be based on predicted behavior for a surface crack that grows into a through-thickness crack. When a crack of surface length  $2a$  grows through a vessel wall, two outcomes are possible:

- THE CRACK GROWS NO FARTHER AND IS STABLE.
- THE CRACK GROWS CATASTROPHICALLY AND THE VESSEL BREAKS.

In some cases, fracture control may be verification of the first possibility.

For example, consider a large-diameter vessel with a torispherical head of 304 stainless steel. The outside surface of the vessel has evidence of some intergranular corrosion, and the plant manager wants to know if the vessel can be placed in operation at decreased pressure. The operating pressure,  $P$ , for a torispherical head (from ASME Section VIII, Div. 1) is:

$$P = \frac{SEt}{0.885L + 0.1t}$$

or:

$$SE = \frac{P(0.885L + 0.1t)I_v}{t}$$

where  $P$  = pressure in psig,  $S$  = stress in psig,  $E$  = joint efficiency = 1,  $L$  = inside crown radius in inches,  $t$  = minimum thickness in inches, and  $I_v$  = estimated stress concentration factor.

For a 3500 mm (138 in.) radius of the sphere with a minimum thickness of 9.5 mm (0.375 in.), the stress concentration is  $I_v = 2$  for a 760 mm (30 in.) opening and the stress would be:

$$S = \frac{P(0.885 \times 138 + 0.1 \times 0.375)2}{0.375}$$

such that  $S = 10,266$  psi (70 MPa) if the operating pressure is 15 psig (1 MPa).

The vessel dome is 304 stainless steel with a tensile yield strength of 240 MPa (35 ksi) and an operating stress map for through-thickness cracks as shown in Fig. 19. Inspection of the operating stress map reveals that for a wall stress of  $S = 10$  ksi (70 MPa) for  $P = 15$  psig (1 MPa), the critical crack length is 140 in. (3555 mm). With a head radius of 138 in. (3500 mm), operation below 15 psig (1 MPa) could be considered safe. If the surface flaw grew to a through-thickness crack, it would not be expected to grow catastrophically with an operating pressure below 15 psig.

FIG. 19 MAP OF  $\sigma_c$  FOR COLD-WORKED AND ANNEALED 304 STAINLESS STEEL WITH A THROUGH-THICKNESS CRACK ( $\beta = 1$ )

#### Example 4: Leak-Before-Break Analysis.

Operating stress maps of through-thickness cracks can also provide information on leak-before-break conditions. As in the preceding example, when a surface crack grows through a vessel wall, the crack may grow catastrophically, or the crack may be stable (in which case pressurized vessels would leak). Thus, an analysis of through-crack conditions can identify operating stresses for leak-before-break, as illustrated in the two following examples.

**Case 1: Leak-Before-Break for a Longitudinal Seam Weld.** The situation is a 304 stainless steel vessel cylindrical section, which has a longitudinal seam weld. The vessel contains an innocuous liquid at room temperature. The vessel outer diameter ( $2 R_o$ ) is 96 in. (2440 mm) with a 0.25 in. (6.35 mm) wall thickness. With an operating pressure ( $P$ ) of 50 psig (345 kPa) the wall stress ( $S$ ) is ( $E = 1$ ):

$$\begin{aligned}
 SE &= \frac{PR_o - 0.4Pt}{t} \\
 &= \frac{50 \times 48 - 0.4 \times 50 \times 0.25}{0.25} \\
 &= 9580 \text{ psi}
 \end{aligned}$$

From the operating stress map (Fig. 19), the crack length at 9.580 ksi is about 140 in., giving rise to a wall thickness of 70 in. The actual value of wall thickness is 0.25 in. The situation for unstable, catastrophic crack growth is two orders of magnitude greater than the true vessel thickness. This vessel will always leak before break under the conditions specified.

**Case 2: Leak-Before-Break Conditions of a Weld Discontinuity.** Consider a vessel in which there is a continuous discontinuity in the head in the head-to-shell weld (Fig. 20). The thickness in the weld region is 0.875 in. (22 mm). The discontinuity is 0.25 in. (6.35 mm). The minimum thickness is  $0.625 - 0.25 = 0.4$  in., from the diagram. In this case, the

material is A285C with a  $K_{Ic}$  of  $77 \text{ ksi}\sqrt{\text{in.}}$ , and a yield stress of 30 ksi (205 MPa). The owner would like to operate the vessel safely with  $P = 50 \text{ psig}$ , outer radius  $R_o = 48 \text{ in.}$ ,  $E = 1.7$ , and  $t = 0.4 \text{ in.}$  (minimum from Fig. 20). Thus:

$$t = \frac{PR_o}{2SE + 0.4P}$$

$$0.4 = \frac{50 \times 48}{2SE + 0.4 \times 50}$$

$$S = \frac{2392}{0.56}$$

$$= 4271.4 \text{ psi}$$

FIG. 20 WELD DISCONTINUITY IN LEAK-BEFORE-BREAK ANALYSIS (SEE TEXT, CASE 2 OF EXAMPLE 4)

From the operating stress map for the ASTM A285C steel (Fig. 21), the net section yield line with  $W = 0.875 \text{ in.}$  (plate width for through-thickness crack of 0.25 in.) indicates that elastic fracture mechanics does not apply in this case because, at the plate width and the operating stress of 4.271 ksi, failure will always be by net section yielding. Thus, with a crack length of  $2 \times 0.25 = 0.5 \text{ in.}$ , at the operating stress of 4.271 ksi, the vessel is safe to operate.

FIG. 21 OPERATING STRESS MAP WITH NET SECTION YIELD LINES AND CRITICAL STRESSES FOR ASTM A285C WELDMENT

Consider now the case where one side of the weld is ground off. The wall thickness is now reduced to  $0.45 - 0.25 = 0.2$  in. (5 mm). With:

$$t = \frac{PR_0}{2SE + 0.4P}$$

$$S = \frac{2396}{0.28} = 85,571 \text{ psi}$$

For the edge crack of 0.2 in., the operating stress of 8.557 ksi would be safe also.

This example indicates the need to always consider the net section yielding, where elastic fracture mechanics does not apply.

### Example 5: Fracture Control with a Surface Crack.

A casting made in 1.5Ni-Cr-Mo steel is to be operated at half of its yield stress (740 MPa) and one application of load. It has a surface crack, the major axis of which is ten times the length of the minor axis. The fracture toughness ( $K_{Ic}$ ) of the

steel is measured at  $86 \text{ MPa}\sqrt{\text{m}}$ . There are two ways to analyze the surface crack for fracture control: by calculations and by operating stress mapping. Fatigue problems lend themselves to solutions by numerical integration.

In operating stress mapping, the operating stress is normalized by the yield stress to produce maps for various aspect ratios. For example, Fig. 22 is an operating stress map for cast 1.5%Ni-Cr-Mo steels from the data in Table 1. Calculations based on complex formulas are examined and compared to the result predicted by the operating stress map for the Ni-Cr-Mo cast steel.

FIG. 22 RATIO OF CRITICAL STRESS AND YIELD STRENGTH FOR AS-CAST 1.5%NI-CR-MO STEEL. MATERIAL CONDITION:  $K_{Ic} = 86 \text{ MPA}\sqrt{\text{m}}$  ( $78 \text{ KSI}\sqrt{\text{in.}}$ );  $\sigma_y = 740 \text{ MPA}$  ( $107 \text{ KSI}$ )

Method 1: Formula Calculations. The critical defect size may be calculated as:

$$a_{cr} = K_{Ic}^2 \left[ \frac{\Phi - 0.212 \left( \frac{\sigma_c}{\sigma_y} \right)^2}{1.21 \pi \sigma_c^2} \right] \quad (\text{EQ 21})$$

where  $K_{Ic}$  is plane strain fracture toughness,  $\sigma_c$  is gross working stress normal to the major axis of the crack,  $a_{cr}$  is critical depth of a surface flaw (i.e., half the width of an embedded crack),  $\sigma_y$  is 0.2% proof stress, and  $\Phi$  is double elliptical integral. As a simplification of Eq 21, let

$$Q = \left[ \Phi^2 - 0.212 \left( \frac{\sigma_c}{\sigma_y} \right)^2 \right] \quad (\text{EQ 22})$$

$$\text{so then } \left[ \frac{a}{Q} \right]_{cr} = \frac{K_{Ic}^2}{1.21 \pi \sigma_c^2}$$

For embedded cracks, the coefficient on the denominator is taken as unity.

To define the shape of the crack,  $a/2c$  can be considered to represent the crack size aspect ratio, where  $a$  is the minor and  $2c$  is the major axis of an ellipse (when  $a/c = 1$ , the ellipse becomes a circle). The relationship between  $\Phi$  and  $a/2c$  is given in Fig. 23 for easy reference.

FIG. 23 ELLIPTICAL FUNCTION VS. ASPECT RATIO ( $A/2C$ )

In this example,  $a/2c = 0.1$  and  $\sigma_c = 740/2$ . Using these values in Eq 22:

$$\begin{aligned} \left(\frac{a}{Q}\right)_{cr} &= \frac{K_{Ic}^2}{\sigma_c^2} \times \frac{1}{1.21 \pi} \\ &= \frac{86^2}{370^2} \times \frac{1}{3.80} \\ &= 0.0540 \times 2.263 = 0.0142 \end{aligned} \quad \text{(EQ 23)}$$

that is,  $a_{cr} = Q \times 14.2$  mm.

Now, for  $a/2c = 0.1$  (from Fig. 23),  $\Phi = 1.05$  and

$$\begin{aligned} Q &= \Phi^2 - 0.212 \left(\frac{\sigma_c}{\sigma_y}\right)^2 \\ &= 1.05^2 - 0.212(0.5)^2 \\ &= 0.971 \end{aligned}$$

Inserting this value for  $Q$  in Eq 23, then  $a_{cr} = 0.971 \times 14.2$  mm = 13.78 mm.

**Method 2: Calculation with the Residual Strength Equation.** Consider the same calculation using the residual strength equation (Eq 1) as follows:

$$K_{Ic} = \frac{1.12\sigma_c\sqrt{\pi a}}{\Phi}$$

where  $K_{Ic} = 86 \text{ MPa}\sqrt{\text{m}}$ ,  $\sigma_c = 370 \text{ MPa}$ , and  $\Phi = 1.05$  (from Fig. 23,  $a/2c = 0.1$ ). Therefore:

$$a = \frac{86 \times 1.05}{1.12 \times 370 \times 3.142} = 15 \text{ mm}$$

Compared to the value of 13.78 mm from the preceding calculation, there is a difference of 1.22 mm or 8.1%.

In Fig. 22, the operating stress map yields a value for  $a$  of about 14 mm for  $\sigma_c$  of 370 MPa. Also, if section thickness,  $B$ , is considered and the back surface correction  $M_b$  is used, then for crack depths of up to  $a/B$  of 0.25 with  $a/2c$  still at 0.1 (Fig. 24), the preceding equation holds true.

FIG. 24 EFFECT OF BACK-FACE CORRECTION ON ASPECT RATIO

### Example 6: Simplified Calculations for Fracture Control with Surface Cracks.

As shown in Example 5, the residual strength equation (Eq 1) is a basis for fracture control analysis. Other calculations are described below.

**Estimating Effect of Transformation Stress on Fracture.** During the water quenching of Christmas tree steel valve cast component, 30 mm in section, the transformation stress generated was 120 MPa. The measured  $K_{Ic}$  was  $25 \text{ MPa}\sqrt{\text{m}}$ , and the 0.2% proof stress was 600 MPa.

The maximum size of surface defect specified in production was 0.50 mm. It is necessary to determine the tolerable crack size (with the aspect ratio of the crack,  $a/2c = 1/10$ ) and how transformation stresses affect crack growth.

If the transformation stress is 120 MPa, then from the residual strength equation:

$$K_{Ic} = \frac{1.12\sigma_c\sqrt{\pi a}}{\Phi}$$

and with  $a/2c = 0.1$ ,  $\Phi = 1.05$ , then:

$$a = \frac{1.05^2 \cdot 25^2}{1.12^2 \cdot 120 \cdot \pi}$$

$$= \frac{689}{56,548.6} = 12.2 \text{ mm}$$

The size specified in production is therefore safe, because cracks would have to grow to a depth of 12.2 mm to reach critical levels for catastrophic fracture. However, if the transformation stress approaches the yield stress, then:

$$a = \frac{1.05^2 \cdot 25^2}{1.12^2 \cdot 600^2 \cdot \pi} = 0.48 \text{ mm}$$

This critical depth is too close to the specified size (0.5 mm) to be safe.

**Fracture of a Pump Casing.** The fracture of a pump casing during pressure testing gave rise to the fact that an internal crack had extended 5 mm by 2 mm. The fracture stress was 1000 MPa.

The steel had been subjected to heat treatment that led to a 0.2% proof stress of 1200 MPa and  $K_{Ic} = 50 \text{ MPa}\sqrt{\text{m}}$ . Determine the operating stress necessary to cause fracture using the relationship for an embedded elliptical crack:

$$K_{Ic} = \frac{1.12\sigma_c\sqrt{\pi a}}{\Phi}$$

$$\sigma_c^2 = \frac{50^2 \cdot 1.05^2}{1.12^2 \cdot 0.001 \cdot \pi} = 838 \text{ MPa}$$

This critical stress estimate of 838 MPa is within 16% of the observed 1000 MPa fracture stress.

## Failure Control in Process Operations

P.F. Timmins, Risk Based Inspection Inc.

---

## Introduction

FAILURE CONTROL METHODS for piping and process systems encompass the inspection, monitoring, life assessment, repair, maintenance, and life extension of various engineering components used in power plants, chemical processing plants, and refineries. Major costs are associated with each of these steps, and cost-effective implementation of failure control can be viewed, in general terms, from the standpoint of economic loss and the risk of asset loss. For the various types of equipment in process systems, the significance of failure can be ranked as a function of failure probability and the cost of failure (Fig. 1). The types of process equipment most important in controlling risk of asset loss, listed in decreasing order of importance, appear to be piping, reactors, tanks, and process towers (Fig. 1). This ranking suggests the priority areas for inspection, monitoring, life assessment, repair, and maintenance.

**FIG. 1 ASSET LOSS RISK AS A FUNCTION OF EQUIPMENT TYPE. SOURCE: W.G. GARRISON, LOSS PREVENTION, *HYDROCARBON PROCESSING*, SEPT 1988**

Another key factor is the definition of failure. While complete breakage or rupture may be the ultimate and self-evident criterion of failure, more conservative definitions are invariably employed to retire a component prior to such unforeseen and catastrophic failure. Failure of a component may generally be defined as the inability of the component to perform its intended function reliably, economically, and safely. For example, various definitions of failure for high-temperature process equipment are listed in Table 1.

**TABLE 1 FAILURE CRITERIA AND DEFINITIONS OF HIGH-TEMPERATURE COMPONENT CREEP LIFE**

#### HISTORY-BASED CRITERIA

- 30 TO 40 YEARS HAVE ELAPSED
- STATISTICS OF PRIOR FAILURES INDICATE IMPENDING FAILURE
- FREQUENCY OF REPAIR RENDERS CONTINUED OPERATION UNECONOMICAL
- CALCULATIONS INDICATE LIFE EXHAUSTION

#### PERFORMANCE-BASED CRITERIA

- SEVERE LOSS OF EFFICIENCY INDICATING COMPONENT DEGRADATION
- LARGE CRACK MANIFESTED BY LEAKAGE, SEVERE VIBRATION, OR OTHER MALFUNCTION
- CATASTROPHIC BURST

#### INSPECTION-BASED CRITERIA

- DIMENSIONAL CHANGES HAVE OCCURRED, LEADING TO DISTORTIONS AND CHANGES IN CLEARANCES
- INSPECTION SHOWS MICROSCOPIC DAMAGE
- INSPECTION SHOWS CRACK INITIATION
- INSPECTION SHOWS LARGE CRACK APPROACHING CRITICAL SIZE

## CRITERIA BASED ON DESTRUCTIVE EVALUATION

- METALLOGRAPHIC OR MECHANICAL TESTING INDICATES LIFE EXHAUSTION

Source: R. Viswanathan and R.B. Dooley, *Creep Life Assessment Techniques for Fossil Plant Boiler Pressure Parts*, Proceedings of International Conference on Creep, JSME-IME-ASTM-ASME, Tokyo, Apr 1986, p 349-359

Component-retirement decisions are often based on economic justification rather than on technical need. A logical and technically based decision may, for instance, involve a sequence of steps such as remaining-life calculations based on operating history, inspections, material testing, assessment of remaining life, and final disposition of the component in terms of continued service, repair, or replacement. Unfortunately, there are major cost factors associated with each of these steps. The cost of the component itself is usually a small fraction of the cost of disassembling the unit as necessary and performing all of the above operations. If, after all of this, a wrong decision is made and the component fails in service, the economic penalties are severe. The owner of the plant has to weigh all of these economic factors carefully and not make decisions purely on a technical basis. A conservative but not uncommon approach has therefore been simply to replace critical components in a plant after 30 to 40 years, regardless of the technical merits of such action.

Nonetheless, maintenance can have a dramatic impact on profitability (Fig. 2). Corrective maintenance or unplanned maintenance is the most costly. In Fig. 2, this form of maintenance is reflected as unity on the unit cost basis shown. Preventive maintenance (planned maintenance on a fixed time scale) is about 60% of the cost of corrective maintenance. Predictive maintenance (maintenance on a sliding time scale) is about 40% of the cost of corrective maintenance. Clearly, predictive maintenance or proactive maintenance is desirable. If inspection, maintenance and operations departments are organized to run in the predictive or proactive mode, then their costs will be reduced and the profitability of the process operation will increase.

FIG. 2 RELATIVE COST OF MAINTENANCE APPROACHES. SOURCE: POWER PLANT DIAGNOSTICS GO ON-LINE, MECHANICAL ENGINEERING, DEC 1989

This article focuses on the subject of proactive or predictive maintenance, with particular emphasis on the control and prediction of corrosion damage for life extension and failure prevention. Corrosion is a prime source of failure in process systems, and corrosion-related problems are among the most expensive and hazardous in various process industries. Predictive or proactive maintenance programs are used for life extension. However, if a predictive maintenance program is not in place, then condition assessment is required, because it is fundamental to the continued safe operability and reliability of refinery or process equipment. Condition or life assessment is also discussed in this article.

### Predictive Maintenance

Predictive maintenance differs from traditional preventive maintenance in that key equipment parameters are monitored as preliminary indications of failure. Vibration monitoring and signature analysis of rotating or reciprocating equipment is one industrial example of a predictive maintenance system. Another example is leak detection systems with acoustic emission sensors. The objectives of this maintenance approach are to monitor the performance and reliability of critical components or subcomponents and to reduce age-related failures in the traditional "bath tub" reliability curve (Fig. 3).

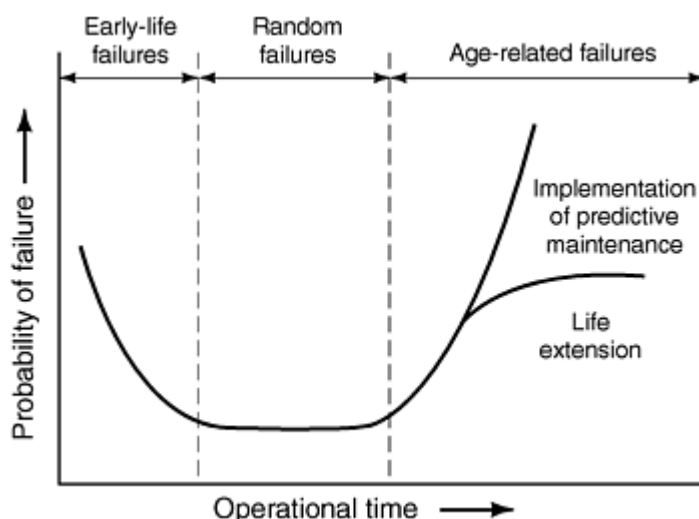

FIG. 3 TYPICAL RELIABILITY CURVE ILLUSTRATING THE CONCEPTUAL OBJECTIVE OF LIFE EXTENSION

Nondestructive testing and inspection techniques are being improved and used more often to improve the reliability and safety of chemical and refinery plants. Early meaningful detection of deterioration can provide the basis for repairs or changes in operating conditions that may extend equipment life. However, some conditions can be difficult to assess by nondestructive inspection. For example, embrittlement from hydrogen, carburization, and strain aging can be difficult to determine. Nonetheless, useful nondestructive methods (Table 2) include not only conventional methods such as ultrasound, radiography, magnetic particles, and dye penetrants, but also eddy current testing, capacitive strain gage testing, replication metallography, and borescope examination of internal piping. More extensive discussion is contained in the article "Detection and Monitoring of Fatigue Cracks" in this Volume.

TABLE 2 INSPECTION AND MEASUREMENT TECHNIQUES FOR CORROSION CONTROL

TECHNIQUE	DESCRIPTION
ACOUSTIC EMISSION	MEASURES THE LOCATION, INITIATION, AND PROPAGATION OF CRACKS AND DEFECTS UNDER STRESS IN METALS
DYE PENETRANT	SIMPLE PROCEDURE FOR LOCATING SURFACE CRACKS. REQUIRES SHUTDOWN FOR INTERNALS
MAGNETIC PARTICLE	SURFACE AND SUBSURFACE CRACK AND DEFECT LOCATION, SEAMS, AND INCLUSIONS

RADIOGRAPHY	X-RAY AND GAMMA-RAY ( $Co^{60}$ , $Ir^{192}$ ) WALL-THICKNESS MEASUREMENT AND CRACK AND DEFECT LOCATION
THERMOGRAPHY	IDENTIFIES LACK OF BOND, HOT SPOTS, LOCAL THINNING, AND TEMPERATURE CHANGES DUE TO POOR/WET LAGGING
ULTRASONICS	INDICATES INTERNAL DEFECTS, POROSITY, LACK OF FUSION, CRACK LOCATION, AND WALL THICKNESS
VISUAL EXAM	IDENTIFIES LOCALIZED CORROSION, EROSION PITTING, DEPOSIT SCALING AND FOULING PROBLEMS, AND STAINING AND CORROSION LEAKAGE DUE TO CRACKING
SENTINEL HOLES	SMALL TELLTALE HOLES DRILLED FROM OUTSIDE OF CARBON STEEL PIPEWORK TO DEPTH OF CORROSION ALLOWANCE. WEEPAGE INDICATES REPLACEMENT IS REQUIRED
WEIGHT LOSS COUPONS	TRADITIONAL METHOD OF LIMITED SENSITIVITY BUT USED IN ALL ENVIRONMENTS. TYPE OF CORROSION OBSERVED IS AN IMPORTANT INDICATOR
ELECTRICAL RESISTANCE	MEASURES CHANGE IN PROBE RESISTANCE. WIDELY USED FOR CARBON STEEL FABRICATIONS IN GAS AND LIQUID PHASES. AUTOMATED READINGS
CORROSION POTENTIAL	IDENTIFIES CORROSION CONDITIONS (I.E., ACTIVE, PASSIVE, PITTING, STRESS-CORROSION CRACKING REGIMES) IN IONICALLY CONDUCTIVE MEDIA
LINEAR POLARIZATION RESISTANCE	AN ELECTROCHEMICAL DC METHOD USED FOR MEASUREMENT OF UNIFORM CORROSION. STANDARD ELECTROCHEMICAL TECHNIQUE. TYPICALLY REQUIRES A CONDUCTIVE ELECTROLYTE, BUT SOME NEW PROBES HAVE A CONDUCTIVE SEPARATOR BETWEEN THE METAL PROBE ELEMENTS
ZERO RESISTANCE AMMETRY	ESTABLISHED METHOD FOR ASSESSING GALVANIC CORROSION BETWEEN DISSIMILAR METALS, BUT CAN BE USED WITH NOMINALLY "IDENTICAL" ELECTRODES IN SOME APPLICATIONS
HYDROGEN PROBES	MEASURES RATE OF DIFFUSION OF HYDROGEN THROUGH STEELS, EITHER BY MEANS OF A PRESSURE GAGE OR BY ELECTROCHEMICAL TECHNIQUES
THIN LAYER ACTIVATION	MEASURES CHANGE OF RADIOACTIVITY AS A LOCAL IRRADIATED AREA CORRODES
ELECTROCHEMICAL IMPEDANCE	AN AC METHOD USED FOR GENERAL CORROSION MEASUREMENTS SIMILAR TO LINEAR POLARIZATION RESISTANCE. MORE VERSATILE AND ACCURATE THAN DC MEASUREMENTS
ELECTROCHEMICAL NOISE	A MORE RECENT TECHNIQUE USED FOR ASSESSING GENERAL CORROSION AND POTENTIAL FLUCTUATIONS ASSOCIATED WITH LOCALIZED CORROSION

Implementation of a predictive maintenance system requires the identification of critical components or weak links that could justify continuous monitoring or detailed time-based examination. For example, an asset risk diagram (Fig. 1) is one way of identifying equipment priorities for failure control. Each major piece of equipment is then critically examined in terms of weak links and their failure mechanisms. Corrosion is a prime source of failure in process systems, and corrosion-related problems are probably the most expensive and hazardous in the process industries today. Nonetheless, many failures involve more than one factor; that is, one process may initiate cracking and other processes may eventually lead to failure. For example, fatigue failures that cause tubes or pipes to leak may start at corrosion pits.

Failure mechanisms for a given component or process must be understood for effective implementation of predictive maintenance. Failure mechanisms typically are classified according to temperature. At high temperature, damage mechanisms include embrittlement, creep, thermal fatigue, hot corrosion, oxidation, and erosion. At lower temperatures, corrosion, erosion, pitting, corrosion fatigue, stress corrosion, and hydrogen embrittlement can play major roles.

Following the work of Stoneburg et al. (Ref 1), evaluation of defects and the type of analysis applied often depend on the failure mechanism or mode of operation that led to the defect. For instance, a manufacturing defect that was found some years later would require a remaining-life analysis based on fracture mechanics. A defect produced by misuse of equipment may require a different kind of analysis. It is very important to determine the root cause of the defect in order to apply the appropriate analysis, so an understanding of the applicable failure categories is necessary.

All plants operating with corrosive elements in the process, or in corrosive environments such as salt air or acids from nearby processes, have an obvious concern with process equipment degradation, originating either internally or externally. However, a noncorrosive process with high-velocity flow or unseen cavitation is also a major concern, because wall-thickness degradation is usually unexpected and visually undetectable from the exterior of the process equipment. Other service-related defects leading to failure include cracking, embrittlement, creep, and mechanical and thermal fatigue. Insulation that becomes wet may cause and hide corrosion. Many of these defects are visually undetectable from the exterior of process equipment until failure has occurred (i.e., through-wall propagation or excessive distortion).

Over the years, experience and advancements in nondestructive examination (NDE) techniques and equipment have led to an improvement in the ability to detect defects in process equipment. This improvement has led to the detection of original manufacturing defects in existing process equipment that may not have been detected at the time of manufacture. This does not necessarily indicate a lack of quality in older process equipment, but it may indicate that many manufacturing defects have no effect on the integrity or service life of the equipment and that a high level of confidence can be placed in the current NDE technology.

Once a piece of equipment is in service, it cannot be assumed that it will not require further evaluation. It is imperative to obtain and maintain all the design documents for process equipment, and to never accept shipment of new equipment or changes without those documents. It is far easier to verify design drawings and engineering changes than to destructively examine equipment in order to resolve an issue. A typical example of this is weld backing rings that are left in place on the inside of a vessel. These backing rings assist the manufacturer in making the closing weld on process equipment. If the backing ring is discovered during an in-service radiographic examination, the analyst must determine whether the material is compatible with the process fluid and whether the ring is integral or protected from coming into contact with the process fluid. All of this may be resolved when thorough documentation is available; otherwise, it may be impossible to determine without destructive examination. Other improper designs may make use of the incorrect material for the service or process that the equipment will support. Poor construction details can lead to in-service failure. For instance, rough edges or joints may collect corrosive material that leads to pitting and accelerated degradation.

During examinations, indications should be characterized and recorded as to their type and size. Each indication should then be evaluated. The first step in classifying indications is to compare them to the acceptance criteria of the applicable consensus code (e.g., ASME Section VIII). All indications that meet the code acceptance criteria (e.g., Ref 2 and 3) are considered adequate, and no further evaluation is required. Indications that exceed the code acceptance criteria are normally considered defects and require additional evaluation. Code acceptance criteria are established based on quality control levels that are arbitrary yet conservative. As such, indications that do not exceed the code acceptance criteria are accepted without further consideration. Indications that exceed the code acceptance criteria are rejectable per that code, but they are not necessarily unacceptable. Further analysis as to their fitness for continued service is required.

### Corrosion Monitoring

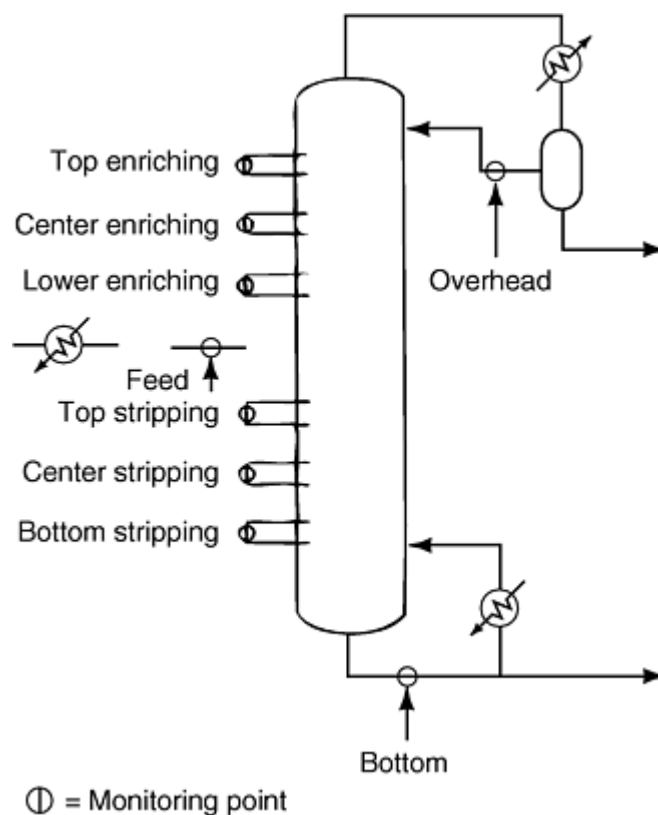

Corrosion monitoring has become an important aspect of the design and operation of modern industrial plants because it alerts plant engineering and management personnel to damage caused by corrosion and the rate of the deterioration. A large variety of techniques are available for corrosion monitoring in plant corrosion tests. The most widely used and simplest method involves the exposure and evaluation of the corrosion in actual test coupons (specimens). The ASTM standard G 4 was designed to provide guidance for this type of testing.

In the selection of a corrosion monitoring method, a variety of factors should be considered. First, the purpose of the test should be understood by everyone concerned with the corrosion monitoring program. The cost and applicability of the methods under consideration should be known, and it is important to consider the reliability of the method selected. In many cases, it will be desirable to include more than one method in order to provide more confidence in the information generated.

**Monitoring Locations.** A principal part of any corrosion monitoring program is deciding where to locate the monitoring devices. Because corrosion will probably not occur uniformly throughout the plant, it is desirable to find sites at which the highest corrosion rates will be experienced.

The problems involved in developing corrosion monitoring programs for a plant are illustrated in the example of a distillation column. The most logical points for corrosion monitoring in a distillation column are the feed point, the overhead product receiver, and the reboiler or bottoms product line. These points are the locations at which the highest and lowest temperatures are encountered, as well as the points at which the most and least volatile products are concentrated. However, these points are usually not the locations of the most severe corrosion.

The species causing the corrosion often concentrate at an intermediate point in the column because of chemical changes within the column. Therefore, if there is a possibility of concentrating a corrosive species within the distillation column, several monitoring points would be required throughout the column (Fig. 4). A monitoring program can be restricted to the most corrosive location within the column once this area has been identified.

**FIG. 4 DISTILLATION COLUMN SHOWING PREFERRED LOCATIONS OF MONITORING PROBES OR OTHER DEVICES**

Another problem with distillation columns is that the liquid on trays tends to be frothy, which creates difficulties for electrochemical methods. One solution is to install bypass loops that remove liquid from the column, pass it over the corrosion monitoring probes, and reinject it at a lower point in the column. This practice avoids the problem of foam and froth and provides a more controlled flow rate over the corrosion monitoring equipment. Use of a bypass loop also allows removal of liquid samples at times of high corrosion rates.

**Redundancy** is also important in designing corrosion monitoring programs. The use of at least two different types of monitoring devices at any location is often desirable. For example, the use of an electrical resistance probe with a polarization resistance probe allows measurement of both instantaneous corrosion rates and an average corrosion rate. The data thus obtained can be correlated, and this is very helpful in identifying spurious or inaccurate readings.

In another approach, the polarization resistance probe is weighed before and after the test in order to correlate mass loss with the average corrosion rate that the probe suffered. There is reason to expect that the electrochemical value is in error if the average corrosion rate and the mass loss of the probe do not agree. Also, to obtain time-averaged corrosion rate values, independent coupons can be installed together with polarization resistance probes.

A variety of corrosion monitoring approaches must be used when designing pilot or demonstration plants. Coupon tests can be very helpful in selecting optimum materials for processes based on pilot plant experience. Polarization resistance monitoring is very useful for determining whether certain processing conditions cause corrosive situations to develop. Because the corrosion mechanisms are often not well understood, and because the result of erroneous information can be serious redesign or exposure to unexpected hazards, redundancy in the design of such monitoring systems is important in pilot plants.

The process stream can be sampled in locations other than distillation columns. A sample tap can be helpful in conjunction with polarization resistance devices. The alarm on polarization resistance monitoring equipment can be used to signal the need to remove samples. This is particularly desirable in the case of pilot plant operation, in which wide variations in processing conditions are encountered. It is also helpful in plants that produce different products in the same equipment.

High-velocity gas streams in pipes may cause problems with conventional monitoring systems. In this case, the presence of an aqueous phase is usually restricted to a thin layer on the surface of the pipe. A probe that protrudes into the pipe may miss the liquid layer that is present only close to the pipe wall. A flush-mounted surface probe can be used in such cases. This probe permits the measurement of polarization resistance in order to estimate the corrosion rate of the pipe wall.

Probe location is also critical in storage tanks containing nonaqueous liquids. The most corrosive location in these tanks may be at the liquid level if the liquid in the tank has a density exceeding that of water. In this case, the corrosion monitoring probe should be mounted on a floating platform so it can detect the presence of a corrosive aqueous phase. However, when the liquid stored in the tank is less dense than the water, the probe should probably be positioned at the bottom of the tank.

**Interpretation and Reporting.** In-service monitoring, more than any other type of corrosion testing, requires the utmost skill in interpretation and reporting. Important economic decisions are often based on the test results. A number of standards provide guidelines for certain procedures, but none is comprehensive. To plan an appropriate test program, the investigator must know or have good advice on both the chemistry and the mechanics of the processes involved; that is, the investigator must understand the entire corrosion system. There must be a strong emphasis on the strategy of the program and a searching analysis of the test results. It is important to prepare detailed records of what was done as part of the experiment, and it is also important to document any unplanned changes that occur in the process stream or the equipment during the investigation. Without a valid interpretation and effective (timely) reporting, the price of the work can be significantly greater than the cost of time and materials. However, the consequences of corrosion failures go beyond additional costs. Also involved are personal safety risks (and liability), hazard potentials, and product quality and pollution problems.

## Corrosion Monitoring Methods

The primary purpose of corrosion monitoring is to estimate the condition of the equipment so that planned turnarounds can be scheduled and replacement of equipment can be anticipated. Frequent measuring also helps minimize the duration of corrosive upset conditions.

**Corrosion Coupons.** If properly located, the coupon is a reasonably accurate tool. In addition to producing corrosion data in measurable terms (mpy or mm/yr), the coupon is helpful in identifying the type of corrosion activity present at the point where the coupon is located in the system. Pitting on the coupon surface indicates activity from a strong acid or acid salt, such as hydrochloric acid or ammonium chloride. General thinning indicates the activity of hydrogen sulfide on the coupon.

Coupons are widely used to monitor inhibitor programs in, for example, water treatment or refinery overhead streams. With retractable coupon holders, the coupons can be extracted from the process without having to shut down in order to determine the corrosion rate. Coupons can be designed to detect such phenomena as crevice corrosion, pitting, and dealloying corrosion. For example, some pulp mill bleach plant washer drums are electrochemically protected to mitigate crevice corrosion. Specifically designed crevice corrosion test coupons are used to monitor the effectiveness of the electrochemical protection program. These coupons are periodically removed from the equipment and examined for evidence of crevice corrosion.

Coupon testing does have important limitations. First, coupon testing cannot be used to detect rapid changes in the corrosivity of a process. Second, localized corrosion cannot be guaranteed to initiate before the coupons are removed, even with extended test durations. Coupons only show corrosion that has already taken place, and a single coupon will not show whether corrosion was uniform or occurred all at once. Generally, a retractable coupon must be left in the system for 20 to 30 days before reliable information can be obtained. The coupon will not record upset conditions rapidly or measure the true corrosion activity in the system if it is improperly placed.

Third, the calculated or measured corrosion rate of the coupon may not translate directly to that of the equipment. Despite every effort to achieve equivalence, differences in mass and coupon area/solution volume ratio are usually sufficient to render direct comparison meaningless. For example, the metal surface temperature of the coupon is governed by the process stream that surrounds it. Where a cooling medium is present on the other side of the metal surface, the skin temperature of the tube is lower than the temperature of the surrounding hydrocarbon. The cool tube skin could cause surface water condensation at temperatures above the anticipated water dewpoint in the process fluid. Coupons would not indicate corrosion activity of this nature. Useful correlations can be established by monitoring the corrosion rate of the equipment with ultrasonic thickness monitoring and by comparing this corrosion rate with the calculated rate for equivalent coupons.

Lastly, certain forms of corrosion cannot be detected with coupons. The principal limitation is the simulation of erosion-corrosion and heat transfer effects. Careful placement of the coupons in the process equipment can slightly offset these weaknesses.

Erosion-corrosion is related to process turbulence, and process turbulence is often a function of equipment design. Because coupons tend to shield one another from the effects of process turbulence, field coupon testing is not reliable as a method of simulating erosion-corrosion.

For heat transfer effects, specially designed coupons are required that simulate effects such as those found in heating elements or condenser tubes. Coupons range in design from thermowell-shaped devices to sample tubes in a test heat exchanger. Thermowell-shaped devices are heated or cooled on the inside and project into the process stream. Heat transfer tests can also be conducted in the laboratory. In this environment, the coupon forms part of the wall of the test vessel and can therefore be heated or cooled from one side. Because of the cost involved, heat transfer coupon tests are usually carried out on only one (or perhaps two) alloys that have been selected from a larger group.

**Preparing, Installing, and Interpreting Coupons.** Corrosion coupons may be flat or cylindrical and may be installed in any accessible location. It must be remembered that coupons measure corrosion only where they are placed. Coupons show corrosion that has already taken place, and a single coupon will not show whether the corrosion was uniform or occurred all at once.

Different types of coupon holders or chucks are used, depending on the system, the pressure, the location, or other factors. Most coupons are run in a 25 or 50 mm (1 or 2 in.) threaded plug. Flat coupon holders hold two coupons, while cylindrical coupon chucks may contain eight or more. The multichuck coupons allow a coupon to be pulled at intervals to see if the corrosion rate is uniform or not.

High-pressure systems require a special coupon check and insertion device. The insertion tool fits into a special attachment on the pipe or vessel that has a high-pressure chamber with a valve on each end. The inner valve is closed, the retrieval tool inserted, and the inner valve opened. The tool is then run in and left. The procedure is reversed to remove the coupon.

The industry guide for preparing, installing, and interpreting coupons is NACE standard RP-07-75. The primary consideration is that all coupons be treated exactly alike. A method of preparation that does not alter the metallurgy of the coupon is required. Grinding and sanding of coupons should be controlled to avoid metallurgical changes and to provide a consistent and reproducible surface finish.

Coupons should be handled carefully and stored in noncorrosive envelopes until they are installed. Rust spots caused by improper handling, fingerprints, and so on may initiate a pit that is not representative of the system being evaluated. Prior to installation, the weight, serial number, date installed, name of system, location of coupon, and orientation of the coupon and holder should be recorded. The coupons are left in the system for a predetermined number of days and then removed.

When the coupons are removed, the serial number, date removed, observations of any erosion or mechanical damage, and appearance should be recorded. A photograph of the coupon may be valuable in some cases. The coupons should then be placed in a moisture-proof envelope impregnated with a vapor phase inhibitor and taken immediately to the laboratory for cleaning and weighing. The coupons can be blotted (not wiped) dry prior to being placed in the envelope.

The laboratory receives the coupon and inspects, cleans, and weighs it. A report is issued showing the thickness loss, any pitting observations, and any other observations of interest.

**Electrical resistance probes** are specially designed corrosion coupons. Their corrosion rate is calculated from measurement of electrical resistance rather than mass loss. These measurements are made by installing a wire or other device fabricated from the material in question in such a way that its electrical resistance can be conveniently measured. Corrosion reduces the cross section of the exposed element; therefore, its electrical resistance will increase with exposure time if corrosion is taking place. A temperature-compensating element should be incorporated in such a probe, because the resistance of the probe is also influenced by the temperature.

Electrical resistance probes measure the remaining average metal thickness. To obtain the corrosion rate, measurements are made over a period of time, and the results are plotted as a function of exposure time. The corrosion rate can be determined from the slope of the resulting plot. There are several advantages to this approach. Because probes are relatively small, they can be installed easily. For determination of the metal remaining, the probe can be wired directly to a control room location or to a portable resistance bridge at the probe location.

There are also some disadvantages to this approach. Vessel and piping walls must be penetrated in order to install the probes; such penetration results in the potential for leaks. It is expensive to direct-wire the probe to a control room location, and such work must be carried out with care to avoid spurious signals and errors. On the other hand, it is time-consuming and sometimes impossible to take measurements at the probe site with a portable bridge. The temperature compensation device reacts slowly, and it can be a source of error if the temperature varies when the measurement is taken. Corrosion rate measurements obtained in short periods of time can be inaccurate because the method measures only the remaining metal, not the rate of attack; this increases the signal-to-noise ratio in short exposures. This method provides no information on localized attack.

**Ultrasonic thickness measurements** can be used to monitor corrosion rates in situ. Ultrasonic thickness measurements involve placement of a transducer against the exterior of the vessel in question. The transducer produces an ultrasonic signal. This signal passes through the vessel wall, bounces off the interior surface, and returns to the transducer. The thickness is calculated by using the time that elapses between emission of the signal and its subsequent reception, along with the velocity of sound in the material. To obtain a corrosion rate, a series of measurements must be made over a time interval, and the metal loss per unit time must be determined.

Measurement errors can occur when vessel walls are at high or low temperatures. Serious problems may exist in equipment that has a metallurgically bonded internal lining, because it is not obvious from which surface the returning signal will originate. Despite these drawbacks, the ultrasonic thickness approach is widely practiced where it is necessary to evaluate vessel life and suitability for further service. It must be kept in mind, however, that depending on the type of transducer used, the ultrasonic thickness method can overestimate metal thicknesses when the remaining thickness is under approximately 1.3 mm (0.05 in.).

**Polarization Resistance Measurement.** Unlike the previously discussed methods, which provide information on remaining thickness, the technique of polarization resistance provides an estimate of the corrosion rate. The theory behind the technique is that the corrosion rate of a probe is inversely proportional to its polarization resistance, that is, the slope of the potential-current response curve near the corrosion potential. It is necessary in a plant situation to use a probe that enters the vessel in the area where the corrosion rate is desired. The electrodes of the probe are fabricated from the material in question. An electronic power supply polarizes the specimen about 10 mV from the corrosion potential. The resulting current is recorded as a measure of the corrosion rate. Polarization resistance yields an instantaneous estimate of corrosion rate.

There are several limitations to this approach. The corroding environment must be an electrolyte with reasonably low resistivity. High-resistivity electrolytes produce erroneously low corrosion rates. The vessel wall must be penetrated, and this involves concerns regarding leaks, personnel safety, and other problems. The ability to use direct wiring from the probe location to a remote control room is desirable, but the installation of these wiring systems is costly. In addition, these systems do not provide information on localized corrosion, such as pitting and stress-corrosion cracking. Also, the corrosion rate values are approximate at best, and the method is best suited for use during periods when substantial corrosion rate changes occur.

**Measurement of Corrosion Potentials.** The use of corrosion potential measurements for in-service corrosion monitoring is not as widespread as the use of polarization resistance. However, this approach can be valuable in some cases, particularly where an alloy could show both active and passive corrosion behavior in a given process stream. For example, stainless steels can provide excellent service as long as they remain passive. However, if an upset occurs that would introduce either chlorides or reducing agents into the process stream, stainless alloys may become active and may

exhibit excessive corrosion rates. Corrosion potential measurements would indicate the development of active corrosion, and they may be coupled with polarization resistance measurements as additional confirmation of high corrosion rates.

The success of corrosion potential measurements depends on the long-term stable performance of a standard reference electrode. Such electrodes have been developed for continuous pH monitoring of process streams, and their application for measuring corrosion potentials is straightforward. However, the conditions of temperature, pressure, electrolyte composition, pH, and other possible variables can limit the applications of these electrodes for corrosion monitoring service.

**Hydrogen Probes.** The concept of the hydrogen probe is based on the fact that one of the cathodic reaction products in nonoxidizing acidic systems is hydrogen. The hydrogen atoms thus generated diffuse through the thickness of the vessel and are liberated at the exterior surface.

Hydrogen probe analysis measures the corrosion rate, unlike ultrasonic thickness measurements and other techniques that measure remaining wall thickness. However, hydrogen probe analysis is limited to systems in which the temperature is close to ambient and the diffusion rate of hydrogen is high. Gas pipeline service is the most common application. In this case, corrosion can occur when hydrogen sulfide, water, and sometimes carbon dioxide are present. This approach has another variation that consists of simply attaching a chamber to the exterior of the pipe and monitoring hydrogen liberation through increasing pressure.

Commercial devices are available for corrosion monitoring by this technique, although it is questionable whether such devices could be positioned and allowed to operate unattended for extended periods of time. In addition, these units have all of the problems associated with any electrochemical measuring device, namely the need for complex electronic equipment and wiring and the need for operators and installers with a sensitivity to the requirements of such equipment. Also, this method is in practice limited to steel, which has a high hydrogen diffusivity and low solubility of hydrogen. Exterior hydrogen monitoring does not supply a quantitative measurement of hydrogen damage.

**Analysis of Process Streams.** Another useful in-service corrosion monitoring technique is analysis of the process streams for the presence of corrosion products. This straightforward approach usually does not require the installation of specialized equipment. For example, process streams from the bottom of the distillation column can be routinely sampled, and atomic absorption analysis techniques can be used to determine such heavy metals as iron, nickel, and chromium at very low levels. The concentration of such impurities is then directly proportional to the corrosion rate multiplied by the area of metal corroding, if the only source of metal ions is corrosion and if the corrosion products are not precipitating. One problem is that the corroding area may not be known with certainty; if not, the results are relative. However, they do help to determine whether conditions have improved.

**Sentry Holes.** Small sentry holes can be drilled into the outside of a vessel or pipe at areas that are considered particularly susceptible to corrosion. The holes are drilled to the pressure design thickness. Thus, when corrosion has almost consumed the corrosion allowance, the appearance of a small leak indicates that action must be taken to prevent a major failure. Sentry holes may be threaded, or they may have nipples attached to facilitate plugging. Nondestructive testing is frequently performed in the area near the leak to determine the extent of the damage before repair or shutdown.

## Predictive Corrosion Control

Corrosion is a key source of failure in process systems, and predictive corrosion control follows the predictive maintenance approach of extending plant reliability by reducing age-related failures (Fig. 3). The general approach involves the collection and systematic analysis of operational corrosion behavior and data on key plant equipment that is critical for safety or reliability. A general example of a predictive control flow chart is shown in Fig. 5.

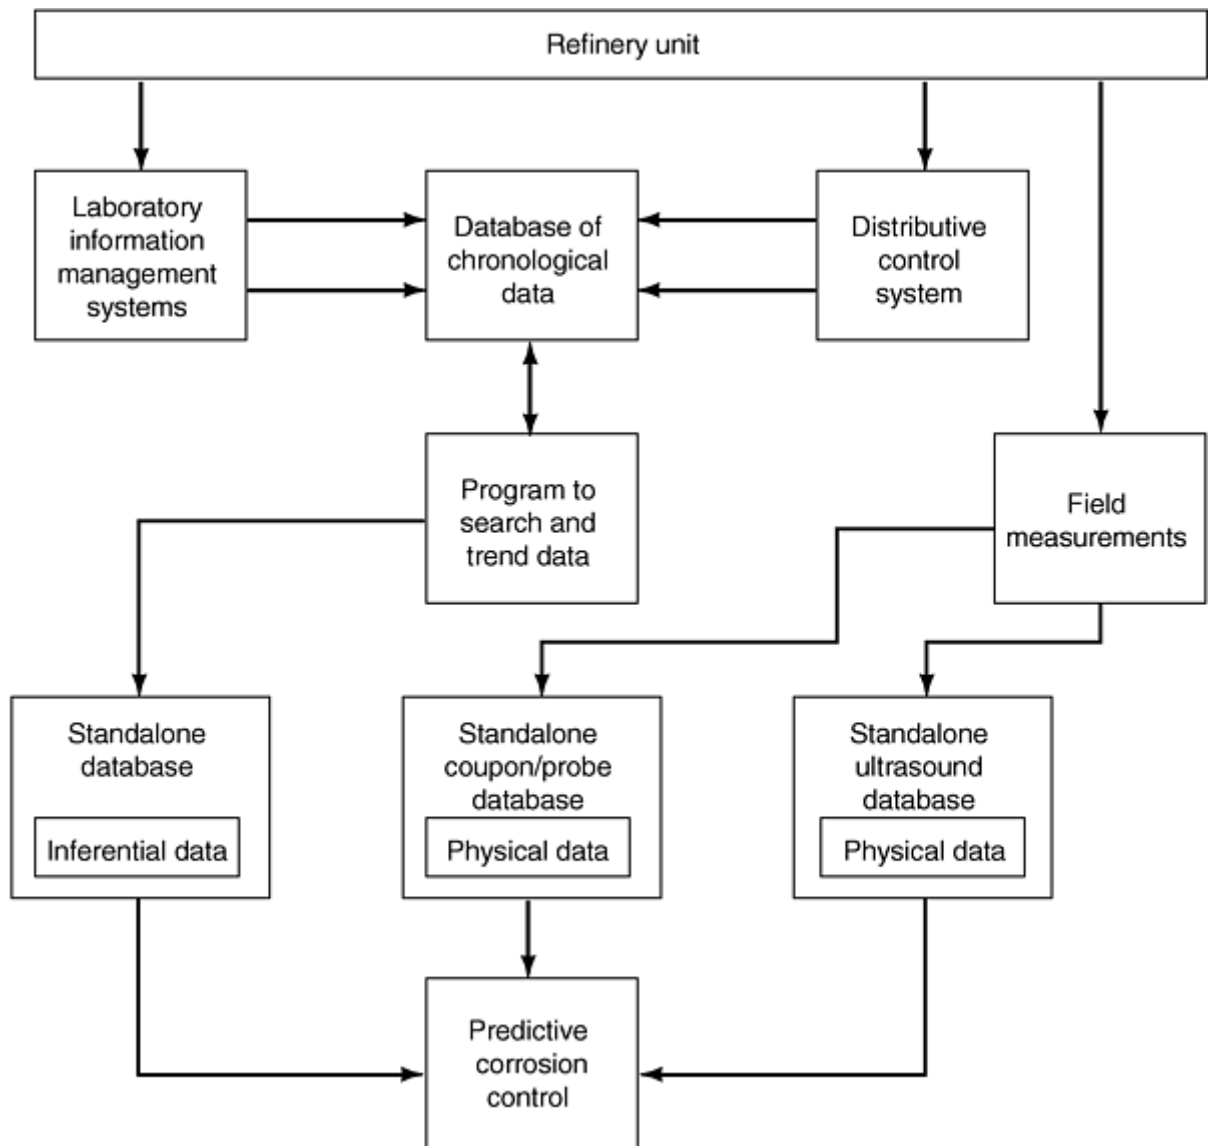

FIG. 5 FLOWCHART OF A TYPICAL PREDICTIVE CORROSION CONTROL SYSTEM

A key step in developing a predictive corrosion control program is to identify critical components in a given process unit, based on a risk assessment such as that in Fig. 1 or some other prioritization criteria. The first step is to first subdivide each process unit into functional sections (e.g., preheat train, heater, reactor, overheads, pumpharounds, etc.). For a given unit, it is helpful to sketch the system under consideration and draw in areas of concern. Figure 6 is an example. Key components can be identified with an asset risk analysis, which in the case of Fig. 1 ranks piping high, followed by reactors. Which piping has the greatest risk in a given unit or section remains to be determined.

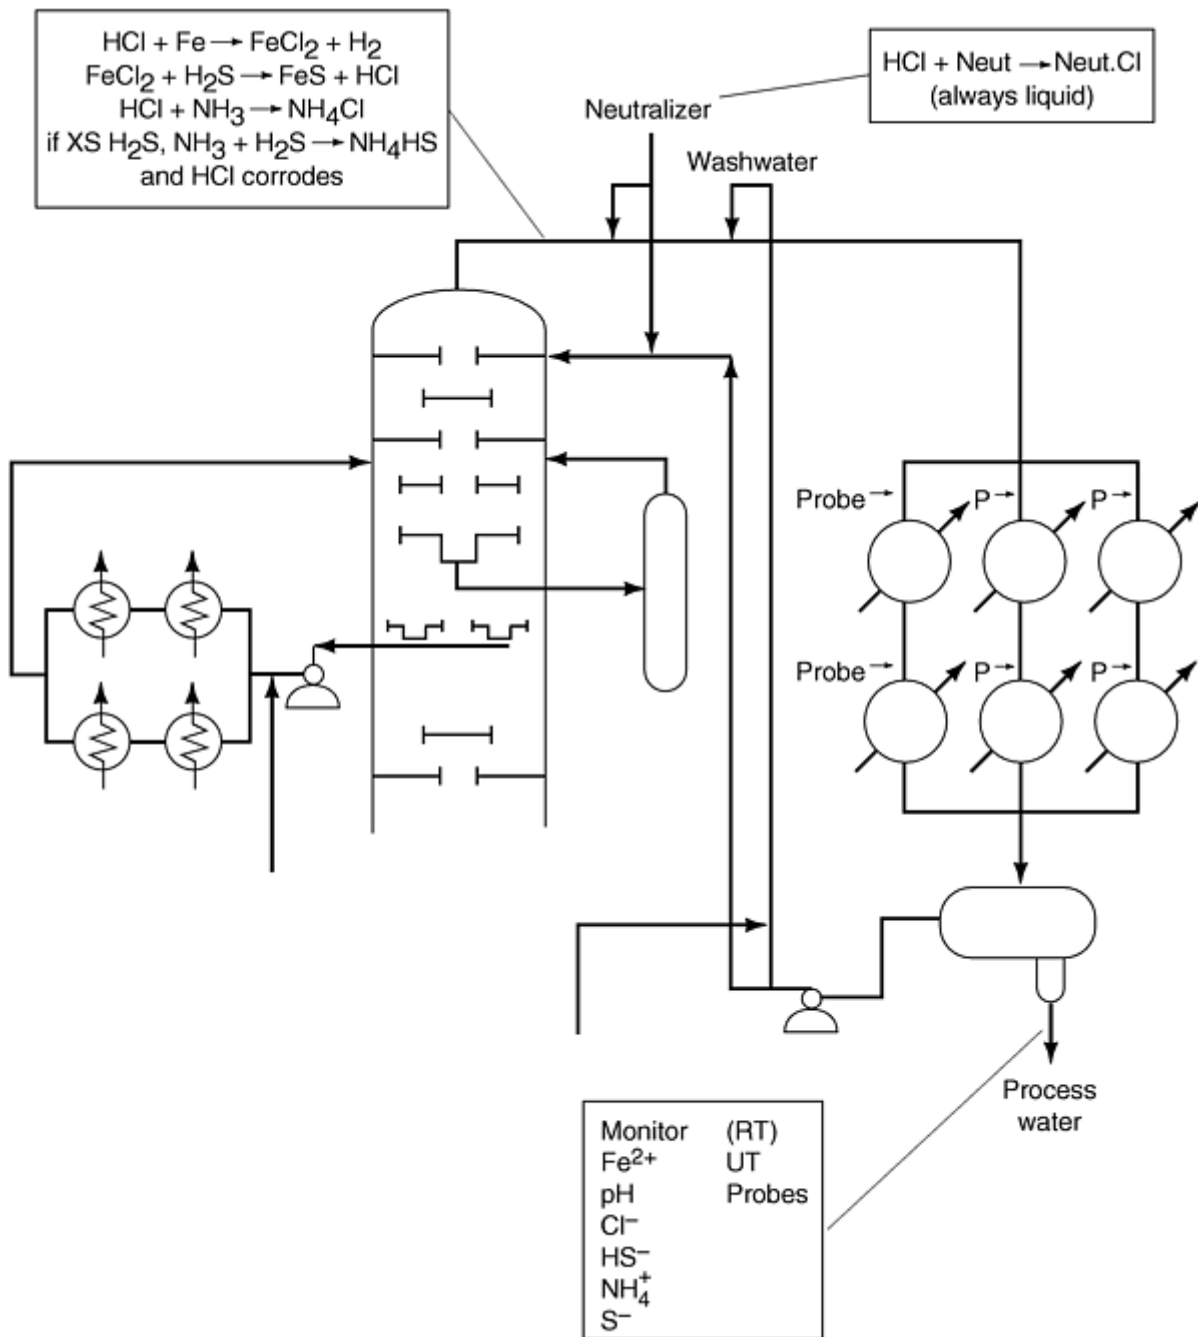

FIG. 6 EXAMPLE OF SYSTEM SCHEMATIC USED TO DEFINE CRITICAL POINTS FOR CORROSION CONTROL

The next step is to analyze the corrosion mechanisms and failures and determine critical areas for monitoring. Sometimes sections are divided according to the mechanisms of aqueous corrosion or high temperature. For example, aqueous corrosion is predominant in overheads and pumparounds, while high-temperature corrosion is the main concern in a preheat train, reactor, or bottoms. High-temperature corrosion is generally controlled by metallurgy, because the mechanisms are typically hot sulfur attack and hot hydrogen attack. Aqueous phase corrosion is generally controlled by process control and chemical inhibition, because the mechanisms are typically wet hydrogen sulfide, ammonium bisulfide, carbonates, hydrogen chloride, and ammonium chloride.

Complete understanding of the corrosion mechanisms and the system is essential for further development of a predictive corrosion control program with a given unit or section. To illustrate the complexity of such a program, corrosion factors for a crude unit overhead are summarized in the following section.

### Corrosion Mechanisms in a Crude Unit Overhead

A typical crude unit overhead system is representative of the aqueous corrosion experienced in many refinery systems. In a crude unit, the most aggressive corrosion is typically from concentrated hydrochloric acid (HCl). A substantial portion of the acid comes from ammonium chloride near the dewpoint of water in a system. Few metallurgies will withstand the combination of corrosives that are found near the dewpoint of water in a sour crude unit overhead system. Consequently, mitigation and corrosion control of carbon steel handling ammonium chloride (NH<sub>4</sub>Cl) is generally by filming inhibitors and sustained wash water rates.

**Oxygen and Oxidizing Agents.** Oxygen and other materials present in the feedstock (e.g., ferric chloride and cupric chloride) act as oxidizing agents and can play a role in the corrosion process that occurs on any unit. In an environment such as the crude unit, free oxygen is generally not a source of corrosion attack, because oxygen readily reacts with hydrogen sulfide (H<sub>2</sub>S) to form elemental sulfur:

The presence of free sulfur in an overhead system confirms that oxygen is getting into the system. Elemental sulfur cannot distill up a crude tower. Sulfur has a boiling point of 444 °C (831 °F) and would be in the bottoms from the fractionator if it were present in the crude.

It is widely recognized that the presence of oxygen or oxidizing agents rapidly accelerates corrosion in a process unit. In one laboratory study, the following relationship between oxygen and H<sub>2</sub>S was observed:

CORRODENT, 6.0 PH	CORROSION RATE OF METAL LOSS, MM/YR (MILS/YR)
H <sub>2</sub> S ONLY	0.76(30)
O <sub>2</sub> , 1 PPM	0.35(14)
O <sub>2</sub> , 1 PPM, PLUS H <sub>2</sub> S	3.0(120)

As can be seen from these data, there is a synergistic influence on corrosion when the corrosives are present together. In this case, the rate of metal loss was increased by four times over the highest corrosion shown by either corrosive. In a second study, corrosion activity increased from 0.7 to 2.4 mm/yr (27 to 95 when oxygen was added to H<sub>2</sub>S). A similar increase in corrosion activity would be present with other oxidizing agents, such as ferric and cupric chloride.

Oxygen contamination sources include water washes. In one instance, corrosion rates more than tripled when accumulator wash water rates were recycled ten times rather than three. Oxygen and other oxidizing agents can be introduced with crude feedstock, slop oils, and desalter wash water. Oxygen levels in water must be controlled to be below 50 parts per billion (wt).

**Hydrochloric acid** is a major cause of corrosion in most crude units. The acid is formed in the crude preheat exchanger and in the crude atmospheric furnace by hydrolyzing magnesium chloride and calcium chloride present in the crude to form hydrogen chloride. The reactions are of the type:

In the overhead, tower top, or top pumparound near the water dewpoint, a low pH condition is produced by the corrosion mechanism:

At lower temperatures, or at an elevated pH in the presence of H<sub>2</sub>S, the corrosion mechanism is:

After hydrogen chloride dissolves in the water near the point of initial condensation, the strong acid attacks the metal surface, producing a pitted appearance. The corrosion products are metal chloride salts. Further, when the pH of the water in this region is below 5.0, HCl also dissolves any metal sulfide corrosion products that are present. These corrosion products tend to be carried away from the site of the corrosion attack. Hydrogen sulfide, a weak acid that is present in most systems, dissolves in the water where it reacts with the metal chloride, that is, ferrous chloride, producing iron sulfide. Iron sulfide (FeS) is insoluble in water and precipitates from the aqueous phase, causing fouling on the surface of the heat transfer equipment. Because FeS tends to precipitate from the water phase, HCl is then free to react a second or third time with the metal surface.

It is important to understand that the system is extremely dynamic, such that there is a tendency for small pockets to form where each corrosion reaction is occurring. All corrosion reactions tend to occur simultaneously in these systems. Mitigation and corrosion control of carbon steels handling HCl is by neutralization and/or inhibition by chemical treatments, in addition to sustained wash water rates.

**Ammonium Chloride.** Reactions involving ammonia and hydrogen chloride result in a vapor phase reaction between ammonia and hydrogen chloride gas:

In the presence of heat and a small amount of water:

This HCl is free to attack the metal surface:

and in the presence of H<sub>2</sub>S:

Ammonium chloride (NH<sub>4</sub>Cl) is formed between a strong acid and a moderately weak base. For this reason, the salt is an acid salt. Ammonium chloride (NH<sub>4</sub>Cl) has the ability to absorb water from steam at temperatures above the dewpoint of water. This can produce a saturated solution of NH<sub>4</sub>Cl when at the boiling point of water, and the salt can easily have a pH as low as 3.3. Also, slightly moistened NH<sub>4</sub>Cl has good adhesive qualities. Because of this, the salt has a tendency to stick to wetted metal surfaces.

When the hygroscopic NH<sub>4</sub>Cl contacts water, it ionizes into ammonium ions and chloride ions. Once the chloride ion enters the water it is very stable and stays in the aqueous phase. The ammonium is not nearly as stable and decomposes to a more stable hydrogen ion and ammonia gas (NH<sub>3</sub>). Ammonia has a very high vapor pressure and tends to escape from the aqueous phase back into the vapor.

As ammonia flashes into the vapor phase, it leaves a concentrated hydrochloric solution behind. Hydrochloric acid attacks the metal surface, producing a metal chloride corrosion product. The strong acid will dissolve any metal sulfide or metal oxides that may be present on the metal surfaces of the equipment. This type of secondary attack on sulfide-oxide metal films is particularly aggressive at a pH below 5.0.

**Other Corrosives.** Some types of crude release small quantities of sulfur trioxide when they are heated. Sulfur trioxide is very hygroscopic and forms sulfuric acid readily. Sulfuric acid is a strong acid and can rapidly accelerate corrosion. In a crude unit, this acid is not usually found in high concentrations in the atmospheric tower, but high concentrations have been found on occasion in the vacuum tower overhead water. This is probably because the vacuum furnace operates at 70 to 100 °C (130 to 185 °F) higher than the atmospheric furnace. Control of corrosion from this acid is handled in a manner which is very similar to control over corrosion from HCl and ammonium chloride.

In some oilfield operations, carbon dioxide is injected into the wells to increase crude oil recovery and production. When carbon dioxide dissolves in water it becomes carbonic acid. This acid is weak and can drive the pH of a system down to only about 4.5 at the temperatures present in the system. However, the addition of H<sub>2</sub>S increases the aggressive nature of the weak acid. Neutralization and inhibition with a filming inhibitor provide acceptable control over the acid.

Ammonia can also be classified as a corrosive in systems that have been alloyed with copper-base metallurgies. This type of corrosion attack accelerates rapidly with increasing pH and is especially aggressive at pH ranges above 8.5.

## Corrosion Control in a Crude Unit Overhead

**Crude Oil Desalting.** The first step to failure control on a crude unit is optimizing the desalter unit. The major corrosive coming from the desalting unit is magnesium chloride, which is hydrolyzed to form HCl in the desalter, preheat exchangers, and furnace. The desalter can also be a source of ammonia and other corrosives that can influence overhead corrosion control.

Chloride-containing salts in crude are found in three forms: sodium chloride (NaCl), calcium chloride (CaCl<sub>2</sub>), and magnesium chloride (MgCl<sub>2</sub>). The chloride distribution may be different for each crude type, but in general the distribution is NaCl, 75%; CaCl<sub>2</sub>, 15%; and MgCl<sub>2</sub>, 10%.

Magnesium chloride starts to hydrolyze at temperatures above 120 °C (250 °F). Calcium chloride starts to hydrolyze to form hydrogen chloride by the mechanism given below:

SALT	SALT HYDROLYSIS TO ACID
MgCl <sub>2</sub>	MgCl <sub>2</sub> + 2H <sub>2</sub> O → Mg(OH) <sub>2</sub> + 2HCl ↑
CaCl <sub>2</sub>	CaCl <sub>2</sub> + 2H <sub>2</sub> O → Ca(OH) <sub>2</sub> + 2HCl ↑
NaCl	NaCl + H <sub>2</sub> O → NaOH + HCl ↑

Suppose the desalted crude from a unit contains sufficient salt to generate a concentration of 115 ppm of chlorides in the condensed water in the overhead. If the system is sour and ammonia is used for pH control, the level of HCl found in the water that initially condenses could be as high as 1150 ppm. This level of hydrochloric acid could easily drive the pH of the water at dewpoint down to 1.5. No metallurgy could withstand this level of acidity at the temperatures present at dewpoint. Thus, HCl concentrations in the overhead water require the optimization of desalting.

Another, less apparent reason to optimize the desalting operation is the cost associated with poor crude dehydration or water separation from the crude. Poor water separation increases the quantity of water that must be condensed in the overhead system, and this costs the refinery extra money to vaporize and then cool the water. In addition, steam can occupy 7 to 10 times more volume than crude in the preheat. An increase in steam could increase pressures in the atmospheric tower, which could reduce the quantity of light ends that are separated from the flashed crude.

From the standpoint of corrosion control, increased quantities of water in the desalted crude increase the quantity of steam in the overhead. This raises the dewpoint temperature of water in the overhead. Suppose that a dewpoint of 107 °C (224

°F) is in the overhead. Water carryover in the desalter could easily raise the dewpoint of the water to 125 °C (260 °F) in the overhead. If the tower top temperature is 116 °C (242 °F), a relatively dry, noncorrosive tower top could become a very wet tower top. This could result in an aggressive level of corrosion attack on the top tray in the tower. Corrosion in the tower top is aggressive dewpoint corrosion.

Ammonia contamination in the desalter stabilizes crude emulsions and can upset overhead corrosion control. Some refiners have injected sulfuric acid into the desalter with the wash water. This procedure consumes ammonia, because ammonium sulfate is formed. Ammonium sulfate is extremely stable and will not sublime or dissociate at the temperatures present in the preheat. The problem with sulfuric acid is that the material can be carried over, causing sulfuric acid corrosion activity in the overhead. This type of attack can be extremely aggressive.

The best pH for good desalting is between 5.0 and 6.5. If bases are introduced, emulsion stability in the desalter is increased.

The primary source of ammonia in the desalter is from the sour water strippers that process sour water from delayed cokers, thermal crackers, and fluid cracking units. These units produce large quantities of ammonia and H<sub>2</sub>S. Phenolic compounds produced in the cracking operation are partially soluble in high-pH waters. Phenols are pollutants that are closely monitored in discharge water from the refinery. Because of the overload that phenols place on water treatment facilities, many plants use the desalter as a waste disposal unit for phenols. If the sour water stripper is operated to minimize both the H<sub>2</sub>S content and the ammonia content in the stripped water, there is no problem with using this water in the desalter. Unfortunately, few refineries operate their strippers to optimize ammonia removal. When this situation is allowed to exist, corrosion control becomes increasingly difficult.

**Caustic Injection.** Good corrosion control in a crude unit overhead system is relatively easy to obtain if overhead water chloride concentrations are maintained in the range of 40 to 50 ppm, measured as NaCl. When chlorides exceed this level, control becomes increasingly difficult. At a chloride level above 100 ppm in the overhead water, corrosion control is very difficult. If the desalting unit has been optimized, and overhead chlorides are above the target of 40 to 50 ppm, the use of caustic soda should be considered to reduce overhead chloride concentrations.

Sodium chloride is a stable salt that does not hydrolyze in appreciable quantities until a temperature of about 525 °C (980 °F) is reached. Sodium hydroxide converts the salts that hydrolyze easily into more stable NaCl:

Note that caustic neutralizes any acid in the crude and, being a strong base, also displaces weaker bases in the salts found in crude. It is almost impossible to stoichiometrically calculate the amount of caustic needed to reduce overhead concentrations to acceptable levels.

**Disadvantages of sodium hydroxide injection** into desalted crude include the following:

- THE REACTION PRODUCTS, HYDROXIDES, ARE INSOLUBLE IN CRUDE AND CONTRIBUTE TO EXCHANGER FOULING AND FURNACE COKING IN ATMOSPHERIC AND VACUUM FURNACES.
- UNREACTED CAUSTIC CAN INCREASE FOULING AND COKING TENDENCIES IN THE PREHEAT SYSTEM.
- ON OCCASION, UNREACTED CAUSTIC HAS CAUSED FURNACE TUBE STRESS CRACKING AND EMBRITTLEMENT.
- CAUSTIC CAN INFLUENCE THE FOAMING AND EMULSIFICATION CHARACTERISTICS OF THE CRUDE.
- THE STRONG BASE AND THE REACTION PRODUCTS CAN CAUSE FOAMING IN THE ATMOSPHERIC AND VACUUM TOWER FLASH ZONES.
- SODIUM CONTENTS IN RESIDUAL FUELS MAY BE INCREASED.
- SODIUM CONTENT IN COKE PRODUCED AT THE DELAYED COKER INCREASES.

- SODIUM IS A POISON ON EQUILIBRIUM CATALYSTS.
- CAUSTIC CAN REDUCE THE ACTIVITY OF MANY ANTIFOULANTS.

An extremely conservative approach should be taken to injecting caustic into any preheat system.

**Filming Inhibitors.** Adequate control over the corrosive process is not possible without adequate neutralization of the acids in the system and proper use of a filming inhibitor. Inhibition and neutralization are particularly important, because without the proper application of both, the corrosion process will continue.

Corrosion is inhibited if the metal is separated from its environment by an inert and impervious barrier. The barrier, or film, must satisfy a number of requirements to function as a suitable inhibitor. For example, it must firmly adhere to metal surfaces; be continuous, dense, and nonporous; and be relatively nonreactive.

Two types of inhibitor are used in process units: oil soluble and water soluble. The filming mechanism is slightly different for each type, although both inhibitors are polar compounds.

The oil-soluble inhibitor uses the hydrocarbon in the process stream to provide the protective barrier. The inhibitor molecule is polar. One end of the molecule is called an oil-soluble tail. Its function is to dissolve in the hydrocarbon that is present in the stream. The chemical composition of this portion of the inhibitor determines in what hydrocarbon streams the inhibitor will be soluble. Many inhibitors are soluble in butane and heavier hydrocarbon. Extremely hydrocarbon-soluble inhibitors generally provide better filming inhibition.

At the opposite end of the filming inhibitor is the polar head, the portion of the inhibitor that is attracted to the metal surface. The exact mechanism of this attractive force is not completely understood; however, what probably occurs is that the polar head forms a coordinate bond with the metal surface. The attraction is called absorption. The bond is pH-dependent, and high-pH conditions break the bond between the metal surface and the polar head. When such a condition exists, the polar head portion of the inhibitor may be preferentially attracted toward water, as opposed to the metal surface.

## Measurement

**Corrosion Coupons.** If properly located, the coupon is a reasonably accurate tool. The primary purpose of measuring the corrosion activity on a unit is to provide an estimate of the condition of the equipment so that planned turnarounds can be scheduled and replacement of equipment anticipated. Frequent measuring also helps minimize the duration of corrosive upset conditions. It is well documented that short upset conditions can cause very serious corrosion activity in an overhead system.

In addition to producing corrosion data in measurable terms (mpy or mm/yr), the coupon is helpful in identifying the type of corrosion activity present at the point where the coupon is located in the system. Pitting on the coupon surface would indicate activity from a strong acid or acid salt, such as hydrochloric acid or ammonium chloride. General thinning indicates the activity of hydrogen sulfide on the coupon.

However, where a cooling medium is present on the other side of the metal surface, the skin temperature of the tube is lower than the temperature of the surrounding hydrocarbon. The cool tube skin could cause surface water condensation at temperatures above the anticipated water dewpoint in the hydrocarbon. Coupons would not indicate corrosion activity of this nature. This is especially important in units which use cold crude as a heat exchange medium for hot overhead vapors.

**Corrosometer Probe.** If properly placed, the corrosion probe is a fast, accurate method for determining relative corrosion activity in a system. The probe produces data in meaningful terms (mpy or mm/yr) for periods as short as one week. Upset conditions can be observed in even shorter periods. The major limitation of the probe lies in the placement. Also, the probe is not sensitive to cool tube skin condensation conditions, and it is not a reliable corrosion measuring tool in systems that are extremely sour because the probe element measures corrosion product laydown as metal thickness. If sulfiding corrosion activity accelerates, the corrosion probe tends to show increasing metal thickness rather than metal loss.

**Sample Analysis.** One of the more useful measuring methods available is sample analysis. Unlike the probe or coupon, the sample indicates corrosion activity through the entire overhead system at one point in time, or continuously, depending on the type of sampling (i.e., remote or online). Sample analysis is used to identify the level of corrosives in the system and the products produced as a result of their presence.

The level of metal corrosion product found in overhead water from a process unit is a function of corrosion activity, filmer inhibitor emulsification tendencies, the pH of the water, and the H<sub>2</sub>S concentration. Inhibitors that emulsify hydrocarbon badly tend to increase the level of metal corrosion products found in hydrocarbon streams. In most units, the principal corrosion product is a metal sulfide. Inhibitors that cause excessive emulsification tend to hold these corrosion products up in the hydrocarbon stream. Also, as the pH rises above 6.0, FeS may preferentially stay with the hydrocarbon phase, or it may concentrate at the interface between the water and hydrocarbon in the accumulator water leg. When this condition exists, sample analyses of overhead water alone are not very significant.

Samples of overhead hydrocarbon product should be run to supplement data generated from analyses of water samples. Typical sample analyses from an overhead system should include:

<b>SAMPLE</b>	<b>ANALYSES</b>
<b>OVERHEAD WATER</b>	<b>PH</b>
	<b>CHLORIDES</b>
	<b>TOTAL IRON</b>
	<b>AMMONIA</b>
	<b>HYDROGEN SULFIDE</b>
<b>OVERHEAD HYDROCARBON</b>	<b>TOTAL IRON</b>
	<b>INHIBITOR RESIDUAL</b>
	<b>WATER CONTENT</b>

Sample analysis data are difficult to interpret and can be misleading, so sample data should be subjected to trend analysis. The major value of the sample is that it provides the ability to identify and correct upset conditions rapidly on the unit. This capability is extremely important. It has ensured the success of many corrosion control programs.

### **Condition and Life Assessment**

Condition and life assessment involve defining a critical crack size for a given component and measuring existing crack sizes by NDE or other inspection techniques. Life assessment requires an understanding of the factors affecting critical crack size and the methods for crack measurement. Under certain circumstances, any defect or flaw observable in a component by visual or other NDE methods constitutes grounds for retirement. Under other circumstances, NDE observations are combined with crack growth analysis to determine remaining life. The conservative approach is to replace components based on crack initiation. However, with increasing awareness of fracture mechanics considerations, it is possible to consider the crack tolerance of components.

Techniques that use crack initiation as a failure criterion include calculations based on history, extrapolations of failure statistics, strain measurements, accelerated mechanical testing, microstructural evaluations, oxide scale growth, hardness measurements, and advanced NDE techniques. For crack-growth-based analysis, the NDE information, results from stress analysis, and crack growth data are integrated and evaluated with reference to a failure criterion.

Remaining-life determination is generally confined to equipment that is degraded by creep, fatigue, hot hydrogen attack, or combinations of these mechanisms. In the absence of a predictive corrosion control program (or, more generally, predictive maintenance for life extension), condition assessment is required, because it is fundamental to the continued safe and reliable operation of refinery or process equipment. For the most part, however, life assessment is based on educated guesses from various approaches, generally nondestructive, deterministic, or phenomenological approaches. A recent review by Scasso (Ref 4) of the Italian Welding Institute focuses on the regulatory approach adopted by Europe and the U.S. The findings are summarized in Tables 3, 4, 5, and 6.

The Finnish standard SFS 3280:E provides a credible deterministic approach (Ref 5). The scope of SFS 3280:E is to provide guidance in the monitoring of creep and the assessment of the degree of creep in tubes, pipe systems, and headers, that have been designed on the basis of creep strength, and in comparable steel constructions. The objectives of assessing the degree of creep are to establish the intervals between inspections and to estimate the residual service life of the constructions.

#### Critical Crack Sizes

The critical crack size ( $a_c$ ) can be defined in a number of ways, based on fracture toughness, ligament size, crack-growth-rate transitions, or other considerations as appropriate. A common definition for many heavy-section components is based

on the fracture toughness of the material. Several alternative criteria can be used to establish a value for the critical crack size: a flow-stress-governed failure criterion, a  $J_{Ic}$ -controlled failure criterion, and a limiting creep-crack growth rate criterion.

The first two criteria are employed in a scenario in which rupture occurs during or immediately following a startup transient, in the absence of creep. The third criterion is used in a scenario where failure occurs by creep-crack growth under operating conditions. The lowest value of critical crack size determined by use of these criteria is then used for remaining-life analysis. The use of combined failure criteria to define the safe operating pressure for a pipe is illustrated in Fig. 7.

**FIG. 7 COMBINED FAILURE CRITERIA FOR A PIPE UNDER INTERNAL PRESSURE. SOURCE: R. VISWANATHAN, DAMAGE MECHANISMS AND LIFE ASSESSMENT OF HIGH-TEMPERATURE COMPONENTS, ASM INTERNATIONAL, 1989, P 247**

Stress level is not the only factor that affects the definition of critical crack size. Often critical crack sizes decrease with time due to embrittlement or aging. For example, severely embrittled bolts, vessels, and rotors may have critical crack lengths below the detection limits of conventional testing techniques.

In other instances,  $a_c$  may be large but the rate of crack growth may be so high that once a crack initiates, it reaches critical size rapidly. Many environmentally induced failures in highly stressed components exhibit this behavior. For instance, in generator retaining rings and in steam turbine blades where crack growth under corrosive conditions is encountered, the presence of a pit or pitlike defect is cause for retirement.

With respect to material behavior, the major problem is the unavailability of data pertaining to crack growth and toughness in the service-degraded condition specific to the component. While considerable data may be available on materials in the virgin condition, the data bank on service-exposed materials is very small. Nondestructive methods are needed to determine those properties with specific reference to a given component.

In welded components, the problem is further compounded by the fact that a weldment contains a complex microstructure of many zones with varying material properties. Failure can occur through any of these zones or at the interfaces between them. In cases where crack growth rates might be rapid, conventional NDE techniques are often inadequate to detect the initial crack.

The uncertainties in interpretation of NDE results can sometimes be overwhelming. Difficulties in distinguishing between innocuous versus harmful flaws and identifying their orientations can lead to uncertainties in life assessment. If there are numerous indications closely spaced, the manner of treating them in terms of a linkup analysis could be very crucial. Geometric discontinuities such as fillets, section transitions, and weld backing rings interfere with NDE signals and mask flaws. Guidance on the assessment of cracks and flaws may be obtained from the article "Operating Stress Maps for Failure Control" in this Volume.

## Creep Life Assessment

Failure due to creep can be classified as resulting either from widespread bulk damage or from localized damage. The structural components that are vulnerable to bulk damage (e.g., boiler tubes) are subjected to uniform loading and uniform temperature distribution during service. If a sample of material from such a component is examined, it will truly represent the state of damage in the material surrounding it. The life of such a component is related to the creep-rupture properties.

On the other hand, components that are subjected to stress (strain) and temperature gradients (typical of thick-section components) may not fail by bulk creep rupture. It is likely that at the end of the predicted creep-rupture life, a crack will develop at the critical location and propagate to cause failure. A similar situation exists where failure originates at a stress concentration or at pre-existing defects in the component. In this case, most of the life of the component is spent in crack propagation, and creep-rupture-based criteria are of little value. Therefore, this section briefly reviews creep life assessment from the perspective of creep-rupture properties and creep crack growth. Practical methods based on replication and parametric approaches are described at the end of this article.

## Creep Rupture Life

Although it is relatively easy to quantify damage in laboratory creep tests conducted at constant temperature and stress (load), components in service hardly ever operate under constant conditions. Start-stop cycles, reduced power operation, thermal gradients, and other factors result in variations in stresses and temperatures. Procedures are needed that will permit estimation of the cumulative damage under changing exposure conditions.

**Damage Rules.** The most common approach to calculation of cumulative creep damage is to compute the amount of life expended by using time or strain fractions as measures of damage. When the fractional damages add up to unity, then failure is postulated to occur. The most prominent rules are as follows:

- *LIFE-FRACTION RULE (LFR) (REF 6):*

$$\sum \frac{t_i}{t_{ri}} = 1$$

- *STRAIN-FRACTION RULE (REF 7):*

$$\sum \frac{\epsilon_i}{\epsilon_{ri}} = 1$$

- *MIXED RULE* (REF 8):

$$\sum \left( \frac{t_i}{t_{ri}} \right)^{1/2} \left( \frac{\epsilon_i}{\epsilon_{ri}} \right)^{1/2} = 1$$

- *MIXED RULE* (REF 9):

$$k \sum \left( \frac{t_i}{t_{ri}} \right) + (1 - k) \sum \left( \frac{\epsilon_i}{\epsilon_{ri}} \right) = 1$$

where  $k$  is a constant;  $t_i$  and  $\epsilon_i$  are the time spent and strain accrued at condition  $i$ ; and  $t_{ri}$  and  $\epsilon_{ri}$  are the rupture life and rupture strain under the same conditions.

### Example: Life-Fraction Rule Calculation.

The purpose of this example is to illustrate the use of the LFR. A piping system, made of  $1 \frac{1}{4}$  Cr- $\frac{1}{2}$  Mo steel designed for a hoop stress of 7 ksi, was operated at 540 °C (1000 °F) for 42,500 h and at 550 °C (1025 °F) for the next 42,500 h. From the minimum curve of Larson-Miller parameter for the steel, it is found that, at  $\sigma = 48$  MPa (7 ksi):

$$T_R \text{ AT } 1000 \text{ }^\circ\text{F} = 220,000 \text{ H}$$

$$T_R \text{ AT } 1025 \text{ }^\circ\text{F} = 82,380 \text{ H}$$

Life fraction expended,  $t/t_r$ , at 1000 °F

$$= \frac{42,500}{220,000} = 0.19$$

Life fraction expended,  $t/t_r$ , at 1025 °F

$$= \frac{42,500}{82,380} = 0.516$$

The total life fraction expended is 0.71.

**Validity of Damage Rules.** Goldhoff and Woodford (Ref 10) studied the Robinson life-fraction rule and determined that for a Cr-Mo-V rotor steel it worked well for small changes in stress and temperature. Goldhoff (Ref 11) assessed strain-hardening, life-fraction, and strain-fraction rules under unsteady conditions for this steel. While all gave similar results, the strain-fraction rule was found to be the most accurate.

From careful and critical examination of the available results, the following overall observations can be stated (Ref 12).

- ALTHOUGH SEVERAL DAMAGE RULES HAVE BEEN PROPOSED, NONE HAS BEEN DEMONSTRATED TO HAVE A CLEARCUT SUPERIORITY OVER ANY OF THE OTHERS. THE LFR IS THEREFORE THE MOST COMMONLY USED.
- THE LFR IS CLEARLY NOT VALID FOR STRESS-CHANGE EXPERIMENTS. UNDER SERVICE CONDITIONS WHERE STRESS MAY BE STEADILY INCREASING DUE TO CORROSION-RELATED WASTAGE (E.G., IN BOILER TUBES), APPLICATION OF THE LFR WILL YIELD NONCONSERVATIVE LIFE ESTIMATES; THAT IS, THE ACTUAL LIFE WILL BE LESS THAN

THE PREDICTED LIFE. ON THE OTHER HAND, RESIDUAL-LIFE PREDICTIONS USING POSTEXPOSURE TESTS AT HIGH STRESSES WILL YIELD UNDULY PESSIMISTIC AND CONSERVATIVE RESULTS.

- THE LFR IS GENERALLY VALID FOR VARIABLE-TEMPERATURE CONDITIONS AS LONG AS CHANGING CREEP MECHANISMS AND ENVIRONMENTAL INTERACTIONS DO NOT INTERFERE WITH TEST RESULTS. HENCE, SERVICE LIFE UNDER FLUCTUATING TEMPERATURES AND RESIDUAL LIFE BASED ON ACCELERATED-TEMPERATURE TESTS CAN BE PREDICTED REASONABLY ACCURATELY BY USE OF THE LFR.
- THE POSSIBLE EFFECTS OF MATERIAL DUCTILITY (IF ANY) ON THE APPLICABILITY OF THE LFR NEED TO BE INVESTIGATED. A MAJOR LIMITATION IN APPLYING THE LFR IS THAT THE PROPERTIES OF THE VIRGIN MATERIAL MUST BE KNOWN OR ASSUMED. POSTEXPOSURE TESTS USING MULTIPLE SPECIMENS OFTEN CAN OBTAIN THE NEED FOR ASSUMING ANY DAMAGE RULE.

## Creep Crack Growth

Gross and uniform creep deformation of components is usually the exception rather than the rule. Localized defects and stress concentrations often play decisive roles in failure. Under these circumstances, the growth of cracks and defects is governed by the creep ductility of the material.

Extensive creep crack growth data pertaining to Cr-Mo piping steels have been collected, analyzed, and consolidated (Ref 13, 14). It has been observed that a crack tip driving force parameter,  $C_t$ , that takes time-dependent creep deformation into account correlates much better with crack growth rates,  $da/dt$ , than the traditionally used elastic stress intensity factor,  $K$ . The relation between  $da/dt$  and  $C_t$  can be expressed as:

$$\frac{da}{dt} = bC_t^m$$

To perform a remaining-life assessment of a component under creep-crack growth conditions, two principal ingredients are needed: an appropriate expression for relating the driving force  $C_t$  to the nominal stress, crack size, material constants, and geometry of the component being analyzed; and a correlation between this driving force and the crack growth rate in the material, which has been established on the basis of prior data or by laboratory testing of samples from the component. Once these two ingredients are available, they can be combined to derive the crack size as a function of time. The general methodology for setting inspection intervals using this approach has been described elsewhere (Ref 12, 15).

A number of variables have been identified as affecting the crack growth rate by modifying  $b$ ,  $C_t$ , or  $m$  (Ref 16):

- IN-SERVICE DEGRADATION INCREASES  $DA/DT$  BY INCREASING  $C_T$  IN THE CASE OF DUCTILE MATERIALS AND BY INCREASING  $M$  AND/OR  $B$  FOR BRITTLE MATERIAL.
- CRACK GROWTH RATES IN WELDS, FUSION LINES, AND HEAT-AFFECTED ZONE (HAZ) MATERIALS ARE AT LEAST A FACTOR OF 5 HIGHER COMPARED TO THOSE IN BASE METAL.
- THE PRESENCE OF LOCALIZED CHAINS OF INCLUSION, ASSISTED BY SEGREGATION OF IMPURITIES TO INTERFACES SUCH AS GRAIN BOUNDARIES AND FUSION LINES, CAUSES SIGNIFICANT INCREASES IN CREEP-CRACK GROWTH RATES.
- THE PRESENCE OF LARGE AMOUNTS OF IMPURITIES IN THE STEEL ACCELERATES CRACK GROWTH BY INCREASING  $M$ .
- ALL MATERIAL AND EXPERIMENTAL VARIABLES THAT REDUCE CREEP DUCTILITY RESULT IN HIGHER CRACK GROWTH RATES.
- TEMPERATURE CAN HAVE MIXED EFFECTS ON CRACK GROWTH. IN CASES WHERE THE EFFECT OF TEMPERATURE IS MERELY TO INCREASE CREEP RATE, THE  $DA/DT$  INCREASES WITH INCREASE IN TEMPERATURE DUE TO INCREASE IN  $C_T$ . ON THE OTHER HAND, IF A TRANSITION FROM A BRITTLE TO DUCTILE CONDITION IS INVOLVED, INCREASE IN TEMPERATURE MAY ACTUALLY DECREASE THE CRACK GROWTH RATES.
- CRACK TIP CONSTRAINT HAS A PRONOUNCED EFFECT ON CRACK GROWTH.

ASSUMPTIONS REGARDING PLANE STRESS OR PLANE STRAIN CONDITIONS CAN HAVE A PRONOUNCED EFFECT ON  $DA/DT$ .

- INCLUSION OF PRIMARY CREEP, IN ADDITION TO THE SECONDARY CREEP, IN CALCULATING  $C_T$  RESULTS IN LARGER VALUE OF  $DA/DT$  AND REDUCED REMAINING LIFE.

Additional information on creep-crack growth is contained in the article "Elevated-Temperature Crack Growth" in this Volume.

### Hydrogen Cracking in Wet H<sub>2</sub>S

Cracking resistance of steels is a major concern in refining and petrochemical industries where aqueous H<sub>2</sub>S is present. The generally accepted theory of the mechanism for hydrogen damage in wet H<sub>2</sub>S environments is that monatomic hydrogen is charged into steel as a result of sulfide corrosion reactions that take place on the material surface. The primary source of atomic hydrogen available at internal surfaces of pipeline and vessel steels is generally the oxygen-accelerated dissociation of the H<sub>2</sub>S gas molecule in the presence of water. The basic reaction is:

The FeS formed on the surface of the steel is readily permeated by atomic hydrogen, which diffuses further into the steel.

This diffusion of atomic hydrogen into steel is associated with three distinct forms of cracking:

- HYDROGEN-INDUCED CRACKING
- STRESS-ORIENTED HYDROGEN-INDUCED CRACKING
- HYDROGEN STRESS CRACKING (ALSO KNOWN AS SULFIDE STRESS CRACKING AND SULFIDE STRESS-CORROSION CRACKING)

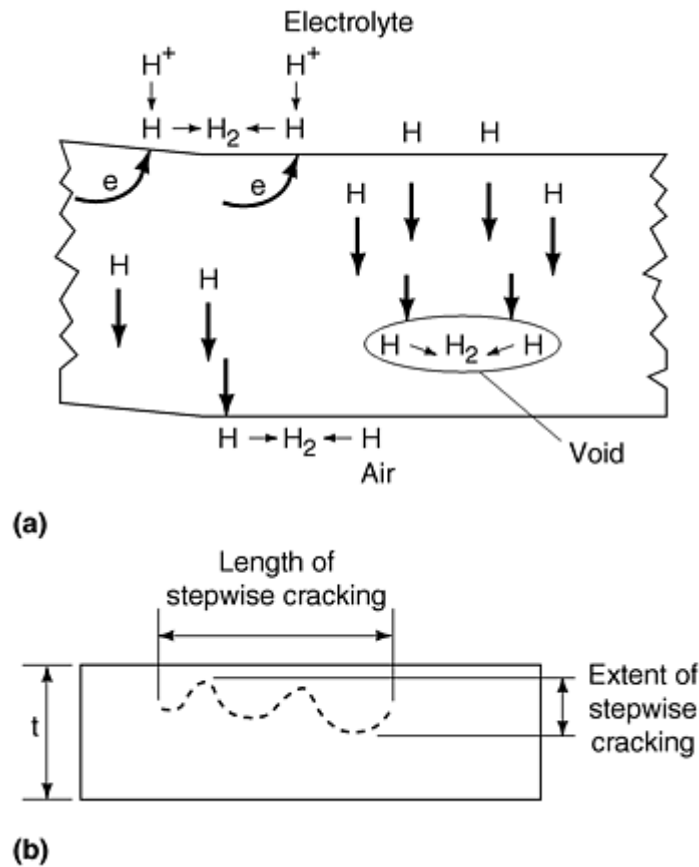

Hydrogen-induced cracking (HIC) and stress oriented hydrogen-induced cracking (SOHIC) are both caused by the formation of hydrogen gas ( $\text{H}_2$ ) blisters in steel. Hydrogen-induced cracking, also called stepwise cracking or blister cracking, is primarily found in lower-strength steels, typically with tensile strengths less than about 550 MPa (80 ksi). It is primarily found in line pipe steels.

In contrast, hydrogen stress cracking does not involve blister formation, but it does involve cracking from the simultaneous presence of high stress and hydrogen embrittlement of the steel. Hydrogen stress cracking occurs in higher-strength steels or at localized hard spots associated with welds or steel treatment. As a general rule of thumb, hydrogen stress cracking can be expected to occur in process streams containing in excess of 50 ppm  $\text{H}_2\text{S}$  (although cracking has been found to occur at lower concentrations).

The basic factors of these cracking modes include temperature, pH, pressure, chemical species and their concentration, steel composition and condition, and welding or the condition of the weld HAZ. This section briefly reviews HIC, SOHIC, and hydrogen stress cracking of line pipe and pressure vessel steels in aqueous  $\text{H}_2\text{S}$  environments with respect to differences between these types of cracking and important variables for failure control.

## Hydrogen-Induced Cracking

Hydrogen-induced cracking, also known as stepwise or blister cracking, manifests itself in low-strength steels in the form of small cracks and/or blisters. This type of cracking is typically oriented parallel to the rolling plane of the steel and is associated with inclusions and segregation bands in the material. These cracks can appear in the absence of an applied stress and propagate by linking up in a stepwise manner (Fig. 8), leading to component failure by reducing the effective thickness of the material. The driving force for crack propagation is the buildup of hydrogen pressure in the cracks.

**FIG. 8 HYDROGEN BLISTERING AND STEPWISE CRACKING IN STEEL. (A) SCHEMATIC OF BLISTER FORMATION PROCESS. (B) SCHEMATIC OF STEPWISE CRACKING. SOURCE: *INTERNATIONAL METALS REVIEW*, VOL 30 (NO. 6), 1985, P 291-301**

The internal hydrogen blisters form quickest at internal discontinuities in the steel, which can be hard spots of low-temperature transformation products or laminations. However, manganese sulfide (MnS) inclusions are the primary sites for this to occur. The formation of  $H_2$  at these sites is facilitated by the gap that exists around MnS due to the favorable variation in expansion coefficients between the steel and MnS. Elongated sulfides are particularly attractive sites for formation of  $H_2$ .

Increasing  $H_2$  pressure at these sites leads to hydrogen damage, such as hydrogen blistering, longitudinal cracking and, through interaction of plastic zones at the ends of these sites, a delayed shear reaction frequently referred to as stepwise cracking. As cracks initiate and propagate, they begin to link up with others, and a series of stepwise cracks can propagate through the material. An applied stress is not required.

**Controlling HIC of Pipe Steel.** There are three methods of controlling HIC in new and replacement plant. One method is to prevent the  $H_2S$  molecule from undergoing the dissociation process by controlling the gathered gas composition. Secondly, the creation of a tenacious, impervious film on the steel surface would inhibit corrosion.

The elimination of favorable sites for  $H_2$  formation in the steel is another preventive measure. Shape control of sulfide inclusions is perhaps the best way to minimize the tendency toward HIC in line pipe steels. Elongated MnS inclusions promote crack initiation and propagation due to the high stresses at the tips of the inclusions. However, the addition of calcium or rare earths to the steel makes the sulfides spherical, and because of their hardness, they remain spherical after processing. Reduction of the sulfur content is also beneficial in reducing the susceptibility of steels to HIC.

**Copper and Cobalt Alloying.** Other alloying additions that reduce hydrogen permeation, such as copper up to about 0.25% (Ref 17) and cobalt (Ref 18), are also beneficial. A Pacific Rim supplier produced an ASTM A 516 GR70 steel with a 1 wt% Co addition, which resulted in greatly reduced absorbed hydrogen at pH levels around 3 (Ref 18). Further, a similar steel from the same supplier, with a 1 wt% Co + 0.3 wt% Cu addition, had a significant benefit in that the

observed hydrogen permeation rate in the NACE solution + H<sub>2</sub>S showed a downward trend after 200 hours. Steel with only the 0.3 wt% Cu addition appeared to follow an increasing rate after this time (Ref 18).

**HIC Control for Existing Plant.** Selecting appropriate steel grades or suppliers is satisfactory for both new and replacement units, but for existing plant components, replacement cost, particularly in terms of production downtime, is extremely high. The problem, then, is inspecting an existing plant that is prone to hydrogen blistering and defining when unsafe conditions prevail such that maintenance is cost-effective. Important in defining these conditions are the inclusion species present and the types of blistering present.

**Inclusions Species.** Existing plant units are generally constructed from C-Mn steels, which meet the required compositional codes but have a high distribution of MnS and alumina (Al<sub>2</sub>O<sub>3</sub>) inclusions. These steels, which are generally fully killed, tend to present a twofold problem in terms of hydrogen behavior as it diffuses through.

MnS inclusions are such that the difference in expansion coefficients between these inclusions and the C-Mn steel matrix creates a gap around these inclusions. Atomic hydrogen readily forms molecular hydrogen in these interfaces.

Al<sub>2</sub>O<sub>3</sub> inclusions are such that the inclusion exerts a stress on the surrounding matrix to the extent that hydrogen in the region of these inclusions produces hydrogen embrittlement of the matrix in the inclusion vicinity. This is due to the stress field, coupled with the formation of H<sub>2</sub> at the interfaces. The embrittled matrix allows easy propagation of wedges created around these inclusions by H<sub>2</sub> such that longitudinal cracking in these Al<sub>2</sub>O<sub>3</sub> stringer regions is an easy process.

Similarly, Al<sub>2</sub>O<sub>3</sub> stringers in close proximity exhibit earlier delayed shear cracks, or stepwise cracks, than MnS inclusions. Determining total residual aluminum and sulfur is a way to identify the predominant inclusion species within a given grade of C-Mn steel. This can serve as a guide to the early nature of hydrogen blistering.

**Types of Blistering.** In aluminum-killed steels of high sulfur content, the predominant inclusion species are Al<sub>2</sub>O<sub>3</sub> stringers and probably duplex MnS-Al<sub>2</sub>O<sub>3</sub> inclusions. Blisters in the form of longitudinal cracks occur in the Al<sub>2</sub>O<sub>3</sub> stringers initially. Subsequent formation of an internal cavity is at these sites and, as is frequently observed, at MnS-Al<sub>2</sub>O<sub>3</sub> inclusions.

Further developments ensue. The linking of cavities occurs by the delayed shear or stepwise cracking process. This type of cracking tends to form between internal blisters and the internal surfaces of pipe or vessels.

Blisters themselves are classified into two categories (Ref 19). In type I, the steel on either side of the blister is intact. In type II, the steel between the blister and the internal surface is degraded by corrosion to the extent that the effective wall thickness of the pipe or vessel is the ligament that exists between the external wall surface and the blister surface.

It may be supposed that modeling of these four hydrogen-diffusion-controlled processes is easy using an elastic-plastic fracture mechanics approach to determine plastic zone sizes and assumed inclusion distributions, based on the Jernkontorets chart, for example. However, such modeling fails because no acceptable value for the diffusion coefficient of hydrogen in C-Mn steel is available.

**Nondestructive Evaluation.** For large problem plant units, which are invariably covered with insulating material and then an aluminum alloy jacket, the practical forms of NDE that can be used to detect blisters and similar change are ultrasonic testing, radiography, and acoustic emission.

For towers and large vessels, a common practice is to cut holes in the insulation material at the areas most likely to be damaged and examine these regions with an ultrasound device, usually a thickness meter or a shear-wave scope. The area is then mapped, and repeat inspections may be carried out to provide a growth rate and pattern for any blisters detected. Various objections based on statistical validity can be raised against this approach. However, there is no other cost-effective method.

Four types of HIC defects result from H<sub>2</sub> formation at internal surfaces in C-Mn steel: longitudinal cracking, stepwise cracking or delayed shear, and type I and type II blistering. Pointers as to the early form that blistering may take can be derived from residual aluminum and sulfur levels in the steels. The more complex type I and type II blistering may be differentiated using, for example, shear wave ultrasonics. In any event, it is probably safer to always assume type II blistering and monitor the remaining wall thickness.

## Stress-Oriented Hydrogen-Induced Cracking

Stress-oriented hydrogen-induced cracking is a form of classical HIC in which the cracking has a specific orientation with respect to an applied and/or residual stress. Similar to the HIC mechanism, SOHIC tends to stack up in the wall thickness direction, typically in the HAZs of welds where residual stresses are high and at areas of high applied stress or areas of stress concentration. SOHIC is characterized by the stacking of HIC in a direction perpendicular to the axis of principal applied stress and by the microscopic interlinking of the "stacked" hydrogen-induced cracks (Ref 20, 21, 22, 23). The interlinking cracks are both perpendicular to the stress and parallel to the axis defined by the nonmetallic inclusions (Fig. 9).

FIG. 9 SCHEMATIC OF STRESS-ORIENTED HYDROGEN-INDUCED CRACKING. SOURCE: REF 23

This type of cracking has often been observed in the base metal adjacent to weld HAZ, which typically are areas of highest residual stress. SOHIC is often important in wet  $H_2S$ , but it also has been observed in anhydrous hydrogen fluoride environments (Ref 24). SOHIC can occur in HIC-susceptible materials stressed to as little as 30% of the specified minimum yield strength (SMYS) in the absence of a weld (Ref 21). The implication of SOHIC is that it causes through-wall hydrogen stress cracking of a material that otherwise would be resistant.

Failure control of SOHIC is best achieved by postweld heat treatment to reduce residual stresses, but this method alone cannot guarantee the elimination of SOHIC, because the operating stress may preclude stress concentration reduction.

## Hydrogen Stress Cracking

Hydrogen stress cracking was first identified in the production of sour crude oils when high-strength steels used for well-head and down-hole equipment cracked readily after contacting produced water that contained  $H_2S$ . Hydrogen stress cracking was not experienced by refineries and petrochemical plants until the introduction of high-pressure processes that required high-strength bolting and other components in gas compressors. With the increased use of submerged arc welding for pressure vessel construction, it was found that weld deposits significantly harder and stronger than the base metal could be produced. This led to transverse cracking in the weld deposit.

Hydrogen stress cracking is typically transgranular and contains sulfide corrosion products. It should not be confused with hydrogen-induced stepwise cracking. The mechanism of hydrogen stress cracking has been the subject of many investigations, most of which attempted to address the cracking seen in high-strength steels instead of the lower-strength steels used in refinery and petrochemical plant equipment. It occurs primarily at ambient temperature.

**Mechanisms.** In general terms, hydrogen stress cracking occurs in the same corrosive environments that lead to hydrogen embrittlement. As in the case of hydrogen embrittlement and hydrogen blistering, hydrogen stress cracking of steels in refinery and petroleum plants often requires the presence of cyanides. Hydrogen sulfide affects corrosion rates and hydrogen absorption and directly affects the maximum allowable hardness of the HAZ or the cracking threshold stress. For example, the allowable maximum hardness value decreases 30 HB, and the allowable threshold stress decreases by 50%, for a tenfold increase in  $H_2S$  concentration (Ref 25).

**Prevention.** The most effective way of preventing hydrogen stress cracking is to ensure proper metallurgical condition of the steel. For example, line pipe failures of this type may be prevented in several ways if the hard spots can be located. Success has been achieved by using internal NDE devices based on the magnetic flux-leakage principle to locate hard spots. Once the hard spots are located, they can be removed, shielded to prevent the cathodic current from reaching them, or tempered to reduce the hardness. Failures tend to occur only in areas with hardnesses exceeding 30 HRC. Hard spots also are now prohibited by API 5L, "Specification for Line Pipe" and must be inspected for during the production of pipe. One of the best inspection techniques is to examine the pipe surface visually for flat spots.

For welds, hardness is limited to 200 HB (Ref 26). Because hard zones can also form in the HAZs of welds and shell plates from hot forming, the same hardness limitation should be applied in these areas. Guidelines for dealing with the hydrogen stress cracking that occurs in refineries and petrochemical plants are given in API 942 (Ref 27) and NACE RP-04-72 (Ref 28).

Postweld heat treatment of fabricated equipment will greatly reduce the occurrence of hydrogen stress cracking. The effect is twofold: First, there is the tempering effect of heating to 620 °C (1150 °F) on any hard microstructure, and second, the residual stresses from welding or forming are reduced. The residual stresses represent a much larger strain on the equipment than internal pressure stresses.

A large number of the ferrous alloys, including the stainless steels, as well as certain nonferrous alloys are susceptible to hydrogen stress cracking. Cracking may be expected to occur with carbon and low-alloy steels when the tensile strength exceeds 620 MPa (90 ksi). Because there is a relationship between hardness and strength in steels, the above strength level approximates the 200 HB hardness limit. For other ferrous and nonferrous alloys used primarily in oil field equipment, limits on hardness and/or heat treatment have been established in NACE MR-01-75 (Ref 29). Although oil field environments can be more severe than those encountered during refining, the recommendations can be used as a general guide for material selection.

With the grades of steels typically used in the oil and gas industry, hydrogen stress cracking is typically observed in the HAZs of welds. Susceptible areas can be identified by high hardness values. However, small localized hard zones can be present in the HAZ and can initiate cracking even though the macrohardness (Rockwell C or Brinell hardness) is low. Therefore, at times microhardness testing may be prudent.

### Practical Life Assessment in Creep Regime

**Replication Methods.** Surface replication is a well-known sample preparation technique that can be used to assess the condition of high-temperature power plant and petrochemical components from creep damage. The usual method of metallographic investigation involves cutting large pieces from components, which thus renders the component unfit for service. In contrast, surface replication allows examination of microstructural damage without cutting sections from the component (see the article "Replication Microscopy Techniques for NDE" in the *ASM Handbook*, Volume 17, *Nondestructive Evaluation and Quality Control*, 1989).

Replication techniques are sufficiently sophisticated to allow classifications of microstructural damage (such as in Table 7, for example) that can be directly correlated to life fractions (Fig. 10). A distinct correlation exists for these data, such that a minimum and maximum remaining life fraction can be specified such as in Table 8, for example (Ref 30, 31). For assessed consumed life fraction,  $X$ , after exposure time,  $T_{exp}$ , the remaining life ( $T_{rem}$ ) is

$$T_{REM} = T_{EXP} (1/X - 1)$$

The qualitative-quantitative relation is advantageous because data from surface replication can be predictive in terms of generating a conservative minimum- and a maximum-life estimate. The maximum life is useful in predictive maintenance environment, as it would dictate the planning of future repairs or replacement.

**TABLE 7 NEUBAUER CLASSIFICATION OF CREEP DAMAGE**

DAMAGE LEVEL (NEUBAUER)	DESCRIPTION	RECOMMENDED ACTION
1	UNDAMAGED	<b>NO CREEP DAMAGE DETECTED</b>
2	ISOLATED	<b>OBSERVE</b>
3	ORIENTED	<b>OBSERVE, FIX INSPECTION INTERVALS</b>
4	MICROCRACKED	<b>LIMITED SERVICE UNTIL REPAIR</b>
5	MACROCRACKED	<b>IMMEDIATE REPAIR</b>

Source: Ref 30

**TABLE 8 CORRELATION OF DAMAGE LEVEL AND LIFE FRACTION CONSUMED**

DAMAGE LEVEL	CONSUMED LIFE FRACTION RANGE X	REMAINING LIFE FACTOR (1/X - 1)	
		MINIMUM	MAXIMUM
1	0.00-0.12	7.33	UNKNOWN
2	0.04-0.46	1.17	24.00
3	0.3-0.5	1.0	2.33
4	0.3-0.84	0.19	2.33
5	0.72-1.00	0 = FAILED	0.39

Source: Ref 31

**FIG. 10 RELATION BETWEEN NEUBAUER DAMAGE RATING (TABLE 7) AND CONSUMED LIFE FRACTION. SOURCE: REF 30, 31**

**Parametric Methods.** Extrapolation to service stress and temperature are performed using the appropriate extrapolation rule of the general form

$$P(\sigma) = C(T, T_{RUP})$$

where the stress ( $\sigma$ ), temperature ( $T$ ), and rupture life ( $T_{rup}$ ) are related by various functional form P and C, such as the frequently used Larson-Miller parametric relation (Ref 32) where

$$P = (T_D + 460) (C + \text{LOG } L_D) \times 10^{-3}$$

where C is a constant and P is the Larson-Miller parameter,  $T_d$  is the design steel temperature, and  $L_d$  is the design life. By adopting the preceding approaches, either singularly or combined (depending on the availability of data), useful practical assessments of the remaining life of refinery equipment in the creep regime can be achieved.

## Practical Life Assessment in Creep Regime

**Replication Methods.** Surface replication is a well-known sample preparation technique that can be used to assess the condition of high-temperature power plant and petrochemical components from creep damage. The usual method of metallographic investigation involves cutting large pieces from components, which thus renders the component unfit for service. In contrast, surface replication allows examination of microstructural damage without cutting sections from the component (see the article "Replication Microscopy Techniques for NDE" in the *ASM Handbook*, Volume 17, *Nondestructive Evaluation and Quality Control*, 1989).

Replication techniques are sufficiently sophisticated to allow classifications of microstructural damage (such as in Table 7, for example) that can be directly correlated to life fractions (Fig. 10). A distinct correlation exists for these data, such that a minimum and maximum remaining life fraction can be specified such as in Table 8, for example (Ref 30, 31). For assessed consumed life fraction,  $X$ , after exposure time,  $T_{exp}$ , the remaining life ( $T_{rem}$ ) is

$$T_{REM} = T_{EXP} (1/X - 1)$$

The qualitative-quantitative relation is advantageous because data from surface replication can be predictive in terms of generating a conservative minimum- and a maximum-life estimate. The maximum life is useful in predictive maintenance environment, as it would dictate the planning of future repairs or replacement.

**TABLE 7 NEUBAUER CLASSIFICATION OF CREEP DAMAGE**

DAMAGE LEVEL (NEUBAUER)	DESCRIPTION	RECOMMENDED ACTION
1	UNDAMAGED	<b>NO CREEP DAMAGE DETECTED</b>
2	ISOLATED	<b>OBSERVE</b>
3	ORIENTED	<b>OBSERVE, FIX INSPECTION INTERVALS</b>
4	MICROCRACKED	<b>LIMITED SERVICE UNTIL REPAIR</b>

FIG. 10 RELATION BETWEEN NEUBAUER DAMAGE RATING (TABLE 7) AND CONSUMED LIFE FRACTION. SOURCE: REF 30, 31

**Parametric Methods.** Extrapolation to service stress and temperature are performed using the appropriate extrapolation rule of the general form

$$P(\sigma) = C(T, T_{RUP})$$

where the stress ( $\sigma$ ), temperature ( $T$ ), and rupture life ( $T_{rup}$ ) are related by various functional form  $P$  and  $C$ , such as the frequently used Larson-Miller parametric relation (Ref 32) where

$$P = (T_D + 460) (C + \text{LOG } L_D) \times 10^{-3}$$

where  $C$  is a constant and  $P$  is the Larson-Miller parameter,  $T_d$  is the design steel temperature, and  $L_d$  is the design life. By adopting the preceding approaches, either singularly or combined (depending on the availability of data), useful practical assessments of the remaining life of refinery equipment in the creep regime can be achieved.

## Stress-Corrosion Cracking and Hydrogen Embrittlement

Gerhardus H. Koch, CC Technologies, Inc.

---

## Introduction

STRESS-CORROSION CRACKING (SCC) is a cracking phenomenon that occurs in susceptible alloys, and is caused by the conjoint action of a tensile stress and the presence of a specific corrosive environment. For SCC to occur on an engineering structure, three conditions must be met simultaneously, namely, a specific crack-promoting environment must be present, the metallurgy of the material must be susceptible to SCC, and the tensile stresses must be above some

threshold value. This cracking phenomenon is of particular interest to users of potentially susceptible structural alloys, because SCC occurs under service conditions, which can result, often without any prior warning, in catastrophic failure. Many different mechanisms for SCC have been proposed, but in general these mechanisms can be divided into two general groups, namely the anodic dissolution mechanisms and cathodic mechanisms. The parameters that control SCC can be divided into materials, environmental, and mechanical parameters. In this article, an overview of the SCC behavior of different engineering materials is presented with emphasis on carbon and low-alloy steels, high-strength steels, stainless steels, nickel-base alloys, aluminum alloys, and titanium alloys. Although these materials do not encompass all materials susceptible to SCC, they comprise the most commonly used materials in a wide range of industries.

### Key Factors of SCC

**Materials Factors.** The alloy composition and microstructure have a great effect on the susceptibility of a material to SCC in a particular environment. The bulk alloy composition may affect the formation and stability of a protective film on the surface. The alloy composition includes the nominal composition, the presence of constituents, and the presence and composition of impurities or trace elements. The metallurgical condition, which affects the susceptibility to SCC, includes the strength level, the presence of phases in the matrix and at the grain boundaries, the composition of the phases, the grain size and orientation, grain-boundary segregation, and residual stresses.

An example of strong influence of alloy composition and microstructure on the susceptibility to SCC is given by austenitic stainless steels, where chromium and molybdenum promote the formation of passive films on the surface. Trace elements such as carbon at concentrations greater than 0.03 wt%, may cause sensitization by forming chromium carbides at the grain boundaries and depleting zones around the carbides of chromium, thereby rendering the steel susceptible to intergranular SCC (IGSCC). Austenitic stainless steels will fail transgranularly in high-temperature chloride solutions.

Similarly, the susceptibility of aluminum alloys to SCC strongly depends on the microstructure, which can be modified by heat treatment. The 7000 series aluminum alloys are precipitation-hardening alloys, and the peak-aged microstructure (T6) is the most susceptible to SCC. Overaging to the T76 or T73 condition usually reduces or eliminates the susceptibility to cracking. Peak aging of this alloy results in a fine distribution of coherent precipitates, which give strength to the alloy. However, the heat treatment also results in the formation of large incoherent precipitates at the grain boundaries and the depletion of solute in the region adjacent to the grain boundaries.

**Environmental Factors.** Stress-corrosion cracking of susceptible alloys is environment specific. The environmental effects can simply be summarized by listing the alloy/environment combinations in which SCC has been observed. Table 1 (Ref 1) shows a partial list of alloy/environment combinations, which has, in recent years, increased in number. For example, transgranular SCC of copper and SCC of stainless steels and nickel-base alloys in high-purity water can be added to the list. Although a list such as shown in Table 1 can be used as a general guideline for materials selection, it should be realized that SCC depends on a great many factors other than the bulk environment. Environments that cause SCC are usually but not necessarily aqueous, and specific environmental parameters must be in specific ranges for cracking to occur. These include, but are not limited to:

- TEMPERATURE
- PH
- ELECTROCHEMICAL POTENTIAL
- SOLUTE SPECIES
- SOLUTE CONCENTRATION
- OXYGEN CONCENTRATION

Source: Ref 1

Changing any of these environmental parameters may significantly affect the crack nucleation process or the rate of crack propagation. Although the parameters listed above are important in controlling the rate of SCC, conditions inside a propagating crack and at the crack tip, which actually control the crack propagation process, are often quite different from the so-called bulk environmental parameters. The pH inside cracks often differs from that in the bulk environment. In low-alloy steels containing about 1 wt% Cr, dissolution and hydrolysis of chromium can result in a lowering of the pH to values near 4 (Ref 2).

In the case of stainless steels, the pH value in cracks can range from 0 to 3, with the lowest pH values associated with concentrated salt solutions containing chromium and ferrous ions. The pH inside cracks of aluminum and aluminum alloys is generally in the range of 3 to 4, while the pH inside propagating cracks in titanium alloys can be as low as 1 (Ref 2).

Stress-corrosion cracking consists of a crack nucleation and propagation phase. Very little is known about the conditions that control the nucleation of a crack, other than that the thermodynamic and kinetic conditions must be right for the crack to nucleate. For example, for anodically assisted SCC, metal dissolution and subsequent formation of a protective oxide film must be thermodynamically possible. The thermodynamic requirement of simultaneous dissolution and film formation has led to the identification of critical potentials at which SCC can occur. The thermodynamic conditions at which dissolution and film forming occurs is described by potential-pH (Pourbaix) diagrams. For example, the Pourbaix diagram in Fig. 1 describes the conditions at which metal dissolution and film formation on carbon steel can occur in different environments such as phosphate, nitrate, and carbonate/bicarbonate solutions. The effects of many of the external parameters listed above, such as pH, temperature, potential, and solute and oxygen concentration can have a great effect on thermodynamic stability and thus on the susceptibility to SCC. The diagram indicates that severe susceptibility to SCC is encountered when a protective film such as carbonate, phosphate, or magnetite is thermodynamically stable.

FIG. 1 RELATIONSHIP BETWEEN PH-POTENTIAL CONDITIONS FOR SCC SUSCEPTIBILITY OF CARBON STEEL IN VARIOUS ENVIRONMENTS AND THE STABILITY REGIONS FOR SOLID AND DISSOLVED SPECIES ON THE ELECTROCHEMICAL EQUILIBRIUM DIAGRAM. REF 1

In addition to the thermodynamic stability requirements for crack nucleation and propagation, kinetic requirements also need to be met. As in the thermodynamic requirements for SCC, environmental parameters such as potential, pH, solute and oxygen concentration, temperature, and crack-tip chemistry have a strong effect on the crack nucleation and crack growth kinetics. Figure 2 shows examples of potentiodynamic polarization curves for alloy 600, alloy 800, and type 304 stainless steel in a 10% NaOH solution at 288 °C (550 °F), indicating the various potential regions for susceptibility to SCC. The figure shows that for all three alloys the active-passive transition region presents the critical potential range for SCC to occur. However, the critical potentials, as well as the mode of cracking, are different for each alloy.

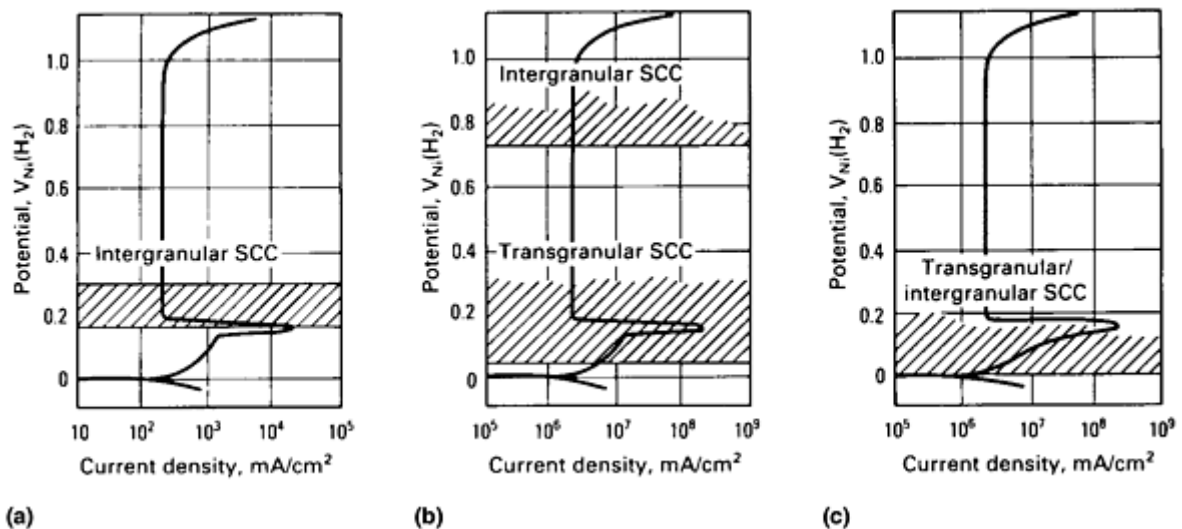

FIG. 2 POTENTIODYNAMIC POLARIZATION CURVES AND POTENTIAL VALUES AT WHICH INTERGRANULAR AND TRANSGRANULAR SCC OCCURS IN A 10% NaOH SOLUTION AT 288 °C (550 °F). (A) ALLOY 600, (B) ALLOY

**Mechanical Factors.** Threshold stresses and stress-intensity factors, the presence of a stress-independent crack-growth regime, and the dependence of cracking to strain rate are important features in determining the susceptibility of alloys to SCC. The threshold stress is typically the stress value obtained from constant-load testing below which SCC does not occur and can serve as a simple measure for susceptibility of a material to SCC in a certain environment.

The stress-intensity factor ( $K$ ) is a parameter that describes the relationship between the applied stress and crack length for specific specimen geometries. Figure 3 shows the stress-intensity factor  $K$  as a function of the crack propagation rate  $da/dt$ . The threshold is defined in this figure by the minimum detectable crack growth rate. The threshold stress intensity is generally associated with the development of a plastic zone at the crack tip. Stage I crack growth shows a rapid increase in crack growth rate, while in Stage II the crack growth rate is independent of the stress intensity.

**FIG. 3 SCHEMATIC DIAGRAM OF STRESS-CORROSION CRACK VELOCITY AS A FUNCTION OF STRESS-INTENSITY FACTOR  $K$**

The stress-corrosion crack propagation is usually studied with linear elastic fracture mechanics (LEFM), which assumes little plasticity at the tip of the propagating crack, such that the stress state is triaxial or plane strain. When the plastic zone size exceeds a certain value, either by increased stress, by propagation in a ductile material, or by crack propagation in a thin member, the stress state becomes biaxial or plane stress, and LEFM is not applicable. Then the more fundamental parameters, the energy release rate or  $J$ -integral, can be applied to describe the propagating stress-corrosion crack (Ref 3).

The slow-strain-rate technique provides an excellent way to determine the susceptibility of an alloy to SCC (Ref 4, 5). However, the strain-rate behavior strongly depends on the alloy/environment combination. For example, for most materials the critical strain rate, at which the maximum susceptibility is obtained, is  $10^{-6}$ /s. This critical strain rate points to a cracking mechanism whereby the rate of anodic dissolution is equal to the rate of protective film formation. If a higher strain rate is applied, the mechanical fracture will be more rapid than the rate of anodic dissolution. On the other hand, when a lower strain rate is applied, anodic dissolution will continue to blunt the crack, and SCC cannot occur. When other SCC mechanisms are predominant, the critical strain rate may be at a higher value, as is often the case with internal hydrogen embrittlement, or there may be no critical value, which occurs when the susceptibility decreases with decreasing strain rate. This has been observed in cases where the mechanism of SCC is thought to be hydrogen embrittlement.

## Stress-Corrosion Cracking Mechanisms

It is unlikely that a single mechanism for SCC exists. The specific mechanism that is operative depends on the type of material, environment, and loading conditions. Although many models have been proposed, they can be divided into two main groups, namely those based on anodic dissolution and those that involve mechanical fracture.

**Anodic Dissolution Models.** The SCC mechanisms, which fall under the anodic dissolution model include the active path intergranular SCC and the film-rupture model. The active-path intergranular SCC results from a difference in alloy composition at the grain boundary, and the crack velocity can be described by Faraday's equation:

$$DA/DT = I_a M / ZF\rho$$

where  $i_a$  is the anodic current density,  $M$  is the atomic weight,  $z$  is the valence,  $F$  is Faraday's constant, and  $\rho$  is the material density. This equation assumes that the crack tip remains bare, and that the crack walls remain relatively inactive. It has been shown (Ref 6) that the Faradaic relationship is applicable to various material/environment combinations (see Fig. 4).

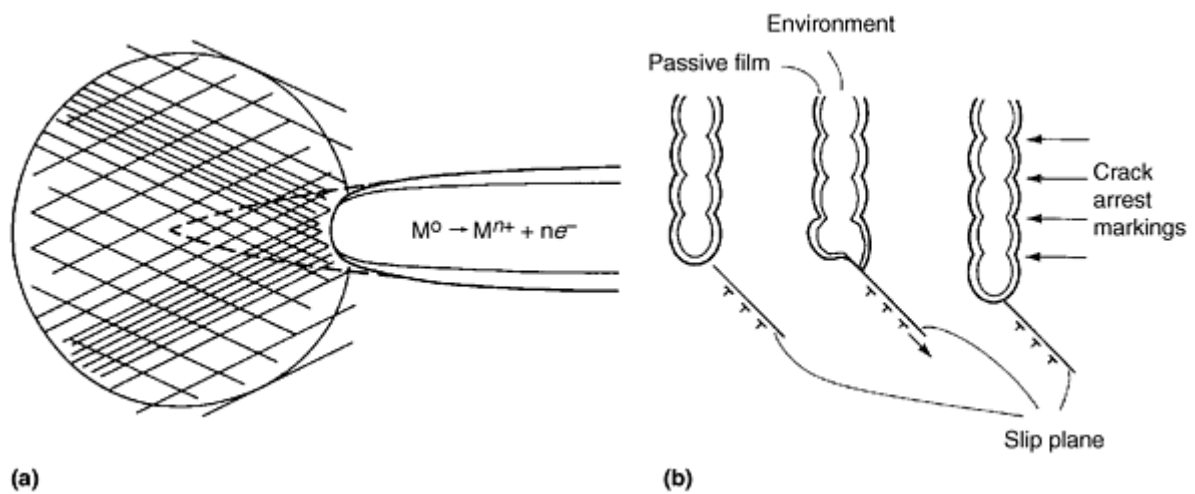

FIG. 4 RELATIONSHIP BETWEEN THE AVERAGE CRACK-PROPAGATION RATE AND THE OXIDATION (I.E., DISSOLUTION AND OXIDE GROWTH) KINETICS ON A STRAINING SURFACE FOR SEVERAL DUCTILE ALLOY/AQUEOUS ENVIRONMENT SYSTEMS (REF 6)

The film-rupture SCC model assumes that the stress at the crack tip acts to open the crack tip and rupture the protective surface film. The bare metal then dissolves rapidly, resulting in crack growth. There are essentially two schools of thought, one assuming that the crack tip remains bare because the rate of dissolution is higher than the rate of repassivation (Ref 7, 8). The second assumes that the crack tip repassivates completely and is periodically fractured by the emergence of slip steps (see Fig. 5) (Ref 9, 10, 11, 12). Although considerable evidence has been found for both mechanisms, crack arrest markings or striations have been found on both intergranular and transgranular fracture surfaces, supporting the notion that crack propagation in both cases is discontinuous. However, because transgranular SCC fracture surfaces have very sharp cleavage markings, which match precisely on opposite fracture surfaces, a film rupture and dissolution model is not a likely mechanism for transgranular SCC (Ref 13).

**FIG. 5 SCHEMATIC REPRESENTATION OF CRACK PROPAGATION BY THE FILM-RUPTURE MODEL. (A) CRACK TIP STAYS BARE AS A RESULT OF CONTINUOUS DEFORMATION (REF 7, 8). (B) CRACK TIP PASSIVATES AND IS RUPTURED REPEATEDLY (REF 9, 10, 11, 12).**

**Mechanical Fracture Models.** There are several proposed SCC models that fall under this category. These include the corrosion tunnel model, the adsorption-enhanced plasticity model, the tarnish rupture model, the film-induced cleavage model, the adsorption-induced brittle fracture model, and the hydrogen embrittlement model.

The **corrosion tunnel model** assumes that tunnels of corrosion form at the crack tip until the remaining ligaments fracture in a ductile manner. The crack would thus propagate by alternating corrosion and ductile rupture, which would result in a grooved fracture surface with evidence of microvoid coalescence on the peaks, as is illustrated in Fig. 6(a). Silcock and Swann (Ref 14) pointed out that this mechanism is not consistent with fractographic features on stainless steels and suggested that the stress at the crack tip changes the morphology of the corrosion damage, such that the tunnels become flat slots (Fig. 6b). It was concluded that transgranular SCC of austenitic stainless steels could be explained in terms of this model and the formation and mechanical separation of corrosion slots (Ref 14).

**FIG. 6 CORROSION TUNNEL MODELS. (A) SCHEMATIC OF TUNNEL MODEL SHOWING THE NUCLEATION OF A CRACK BY THE FORMATION OF CORROSION TUNNELS AT SLIP STEPS AND DUCTILE DEFORMATION AND FRACTURE OF THE REMAINING LIGAMENTS. (B) SCHEMATIC DIAGRAM OF THE TUNNEL MECHANISM OF SCC AND FLAT-SLOT FORMATION AS PROPOSED IN REF 14**

The **adsorption-enhanced plasticity model** for SCC assumes that certain species from the environment adsorb to the crack tip by chemisorption (Ref 15, 16, 17). Fractographic studies were used to demonstrate that transgranular cleavage occurs by slip at the crack tip in conjunction with the formation of microvoids ahead of the crack. Further, the chemisorption supposedly facilitates the nucleation of dislocations at the crack tip, promoting the shear process responsible for the cleavagelike fracture. Although fractography has not offered any direct evidence of the validity of this model, similarities between the different types of failure, SCC, liquid metal embrittlement (LME), and hydrogen embrittlement (HE), may be explained by the adsorption-enhanced plasticity model.

The **tarnish rupture model** explains both transgranular and intergranular SCC by the formation of a brittle surface film that fractures under applied stress (Ref 18, 19). When the film fractures, bare metal is exposed to and reacts rapidly with the environment to form a new surface film. Thus, by this mechanism, the crack propagates by alternating film growth and fracture. This model predicts discontinuous crack propagation, which would result in crack-arrest markings on the fracture surface and also in penetration of the film ahead of the crack tip.

The **film-induced cleavage model** proposes that dealloying and/or vacancy injection could induce brittle fracture (Ref 20). Sieradzki and Newman (Ref 21) developed this concept into a model where a surface film could induce cleavage fracture by assuming that a thin film forms on the surface. According to this model, a brittle crack nucleates in this film and propagates through the film across the film-substrate interface into the ductile metal substrate. Once the crack enters the ductile metal, it will continue to propagate in a brittle manner for some time and will eventually blunt and stop, after which the process of film formation and brittle fracture repeats itself.

The adsorption-induced brittle fracture or stress-sorption model is based on the assumption that adsorption of species from the environment can lower the interatomic bond strength and the stress required for cleavage fracture (Ref 21, 22). Similar mechanisms have been proposed for liquid metal embrittlement and hydrogen embrittlement (Ref 23). According to this model the crack propagates continuously, with the crack propagation rate controlled by the rate at which the embrittling species arrive at the crack tip. The model does not explain how a sharp crack tip can be maintained in an otherwise ductile material.

The hydrogen embrittlement model has been proposed as an operating mechanism for several material/environment systems. Hydrogen can enter an alloy lattice from both gaseous and aqueous phases. In an aqueous phase where corrosion reactions take place, both anodic and corresponding cathodic reactions occur. In many cases, hydrogen ion reduction is the cathodic reaction where hydrogen atoms are formed on the surface. While some of the hydrogen atoms combine to form hydrogen gas, other hydrogen atoms remain adsorbed to the surface. Because of the high partial hydrogen pressure or fugacity (thousands of psi), there exists a driving force for the hydrogen atoms to be absorbed into the lattice.

Hydrogen-induced cracking has been proposed as the SCC mechanism for carbon and high-strength ferritic steels, nickel-base alloys, titanium alloys, and aluminum alloys.

**SCC of Carbon and Low-Alloy Steels**

Stress-corrosion cracking of carbon and low-alloy steels is a significant problem in several industries, including power generation, oil and gas production, gas transmission, oil refining and processing, and pulp and paper processing.

**Materials Factors.** Alloying has a significant effect on the susceptibility of carbon steel to SCC in various environments. Table 2 gives an overview of the effect of alloying elements on the susceptibility to SCC of two low-alloy steels (Ref 24). It should be noted that the elements listed in the table not only affect SCC behavior, but also affect other properties such as strength and welding characteristics. The carbon content generally has a significant effect on the susceptibility to SCC, with the SCC resistance decreasing as the carbon content increases (Ref 25, 26, 27, 28). However, the SCC resistance of alloyed steel appears to be less dependent on the carbon content (Ref 29). Manganese has an adverse effect on the SCC resistance of medium-carbon steels in chloride environments, as well as in hydrogen sulfide and nitrate environments (Ref 25, 30, 31). High sulfur and phosphorus alloy concentrations have reduced the SCC resistance of carbon steel in hydrogen sulfide, as well as in nitrate solutions (Ref 32, 33). Nitrogen levels below 0.01% increase the susceptibility to SCC in nitrate solutions, but higher levels appear to be beneficial (Ref 34). The other alloying elements listed in Table 2 have generally a beneficial effect on SCC resistance.

Low-carbon steels can be divided into ferritic-pearlitic and quenched-and-tempered types. Quenched-and-tempered heat treatments are applied to increase the yield strength above 621 MPa (90 ksi). Fine grain size generally increases the resistance of quenched-and-tempered steels to SCC in a number of environments (Ref 35, 36). Further, the presence of twinned martensite in these steels has an adverse effect on SCC resistance, as do the presence of  $\epsilon$ carbides and high dislocation densities (Ref 37, 38, 39, 40). Martensitic microstructures generally provide the highest SCC resistance, particularly if fine spheroidized carbides are uniformly dispersed in the ferrite. A bainite structure also has a beneficial effect on SCC resistance (Ref 41), while untempered martensite is considered detrimental (Ref 42).

Grain-boundary segregations, which contain elements such as phosphorus and sulfur, have an adverse effect on the intergranular SCC of carbon steel in several environments (Ref 43). Other elements that promote intergranular SCC include arsenic, tin, and antimony (Ref 44). Finally, intermetallic inclusions, such as sulfides, have been shown to act as nucleation sites for cracking and also to accelerate crack propagation (Ref 45, 46).

**Mechanical Factors.** The strength level has a significant effect on the resistance of carbon steels to SCC, with the resistance decreasing as the strength is increased (Ref 47). Steels with yield strengths less than 1241 MPa (180 ksi) are often considered resistant to aqueous chloride SCC (Ref 48). However, because SCC has occasionally been observed in lower-strength steels, the assumption has been made that steels should have yield strengths below 689 MPa (100 ksi) to be resistant to SCC (Ref 49).

**Environmental Factors.** There are several environments that can induce SCC in carbon and low-alloy steels. Some of these environments, which are specific to certain industrial applications, will be discussed in the following paragraphs.

**Aqueous Chlorides.** Stress-corrosion cracking is common to various industries in which aqueous chlorides are encountered, including marine, aerospace, power generation, oil and gas production and refinement, and construction. Although SCC is generally associated with the presence of an aqueous phase, it has been reported in vapor, with crack growth rates increasing with an increase in relative humidity (Ref 50).

Although chloride concentration has little effect on the  $K_{Isc}$  (Ref 51), it does increase crack propagation rates, with the effect more pronounced at the lower chloride concentrations (Ref 52, 53). Lowering the pH and increasing the temperature were found to have significant detrimental effects on the SCC resistance (Ref 54, 55, 56).

**Hydrogen Sulfide.** Stress-corrosion cracking in environments that contain hydrogen sulfide commonly occurs in the production, transmission, and refining of oil and gas, and failures have been reported on gas and oil well tubulars, wellhead equipment, pipelines, process piping, and pressure vessels. It is generally assumed that water must also be present, and that the susceptibility to cracking increases with increasing hydrogen sulfide concentration.

The pH level in solutions that contain hydrogen sulfide has been found to have a significant effect on the susceptibility of steels to SCC. Although SCC can occur at pH levels up to about 9, and up to about 12 for steels with high strengths, reduced pH values will result in a decrease in SCC threshold levels (Ref 57, 58, 59, 60). Increased temperatures have been found to decrease the susceptibility to SCC in hydrogen sulfide, with the maximum susceptibility to SCC near room temperature (Ref 61, 62).

Stress-corrosion cracking in hydrogen sulfide, also termed hydrogen sulfide cracking, has been attributed to a hydrogen embrittlement mechanism.

**Sulfuric Acid.** Stress-corrosion cracking of steel in sulfuric acid is generally associated with high strength levels and is suggested to be analogous to SCC in aqueous chloride solutions (Ref 63).

**Hydrogen Gas.** Cracking of carbon steels has been reported in pressure vessels containing high-pressure hydrogen gas and has been associated with weld and nozzle forgings of medium-strength steels (Ref 64, 65). It was demonstrated that the susceptibility to cracking in hydrogen gas increases with increasing strength of the steel (Ref 66, 67). Although cracking has been observed over a wide range of temperatures, the maximum susceptibility occurs at or near room temperature (Ref 68). The presence of small amounts of oxygen or sulfur dioxide was shown to inhibit cracking in gaseous hydrogen (Ref 69, 70).

**Caustic Solutions.** Stress-corrosion cracking of carbon steel in sodium hydroxide or caustic solution has been well documented and has been most commonly associated with steam boilers. Caustic cracking has also been identified as the cause of cracking of continuous digesters used in the pulp and paper industry (Ref 71). Cracking generally occurs in highly stressed areas where the caustic can concentrate. Plastic deformation is considered to be a prerequisite for caustic cracking (Ref 72, 73). Stress-corrosion cracking occurs over a wide range of hydroxide concentrations, between 5 and 70%, and in a temperature range of 100 to 349 °C (212 to 660 °F) (Ref 72, 74, 75).

Caustic cracking has been shown to occur in a very narrow range of electrochemical potentials near the active-passive transition on polarization diagrams (Ref 76, 77). This potential range is thought to be associated with the presence of a protective magnetite film. Small additions of oxygen and/or chlorides promote SCC, while addition of larger amounts promote passivation by having a strong oxidizing effect and hence inhibit cracking (Ref 78, 79).

**Ammonia.** Carbon steels have been used widely for transportation and storage of ammonia. Recent surveys have shown that a large number of leaks could be attributed to SCC (Ref 80). Stress-corrosion cracking in this environment has been found in cold-formed and welded steel (Ref 80), and the presence of oxygen and carbon dioxide is required for cracking to occur (Ref 81).

**Carbonate/Bicarbonate Solutions.** Stress-corrosion cracking of natural gas transmission pipelines has been attributed to aqueous solutions of carbonate/bicarbonate ( $\text{CO}_3\text{-HCO}_3$ ) and occurs over a very limited potential range from about -670 to -770 mV versus Cu/CuSO<sub>4</sub> at 75 °C (Ref 82, 83). This potential range is associated with the active-passive transition in a potentiodynamic polarization curve. Stress-corrosion cracking also occurs over a limited pH range around 9. The mechanism of this specific form of SCC is anodic dissolution-film rupture. Plastic deformation at the crack tip ruptures the protective passive film and exposes fresh metal which undergoes anodic dissolution. Depending on the dissolution rate and the crack extension rate, the crack tip may repassivate or continue to propagate. Passivation of the crack walls maintains a sharp aspect ratio of the crack, which is necessary to concentrate plasticity at the crack tip.

Recently, transgranular SCC on pipelines was discovered, which was correlated with low-pH (pH <8) dilute CO<sub>2</sub>-containing environments (Ref 84, 85). This form of SCC has been termed low-pH or nonclassical SCC. In contrast with the high-pH SCC, low-pH SCC does not appear to be sensitive to potential, and in fact it was demonstrated that the severity of low-pH SCC does not increase with increasing negative potential. Comparing low-pH with high-pH SCC also has demonstrated that while the high-pH cracking occurs under constant load or constant displacement testing, the low-pH cracking does not occur under these loading conditions. The latter exhibits crack growth only under cyclic loading conditions (Ref 86). The most plausible mechanism for crack propagation in the low-pH environment is a hydrogen-related mechanism, with the most likely source of hydrogen being carbonic acid, which is formed by the dissolution of CO<sub>2</sub> in the ground water.

## Stress-Corrosion Cracking and Hydrogen Embrittlement

Gerhardus H. Koch, CC Technologies, Inc.

---

### SCC of High-Strength Steels

Steels with yield strengths greater than 1240 MPa (180 ksi) fall under the general group of high-strength steels (Ref 54). The steels in this group include quenched-and-tempered low-alloy steels and maraging steels. These steels are all highly susceptible to SCC, even in benign environments, such as water vapor, which would only cause minimal corrosion. The quenched-and-tempered steels have a tempered martensitic microstructure, where carbon is an important alloying element. These high-strength steels come in a low-alloy and a high-alloy variety. Maraging steels obtain their strength from martensite formation, followed by the growth of precipitates, such as Ni<sub>3</sub>Mo and Ni<sub>3</sub>Ti, during aging, and unlike in the case of the quenched-and-tempered steels, carbon is not an alloying element but rather an impurity, which reduces the strength and fracture toughness by forming TiC (Ref 87).

**Material Factors.** Although alloying elements have a significant effect on the resistance of a steel to SCC, these effects are difficult to assess, because they also may influence the yield strength, which in turn affects the susceptibility to SCC. For example, titanium is known to increase the resistance of maraging steel to SCC, but also increases the yield strength contributing to a decrease in resistance to SCC (Ref 88). The effect of carbon is detrimental to the SCC resistance ( $K_{Isc}$ ) of AISI 4340 steel up to a concentration of 0.4% (Ref 89, 90). Likewise, manganese addition in amounts up to 3% lowers the resistance to SCC. Other elements investigated include phosphorus ( 0.05%), sulfur ( 0.03%), chromium ( 2.5%), molybdenum ( 1.2%), cobalt ( 3.5%), and silicon, none of which were found to affect the resistance to SCC. Finally, nickel has been shown to have little effect on SCC when present in concentrations of up to 9%.

The effect of silicon addition on the SCC susceptibility has been researched in detail (Ref 91, 92). Although small amounts of silicon do not affect SCC, concentrations above 1.5% have been found to decrease crack growth and increase the time to failure. On the other hand, the combined effect of silicon and manganese was found to lower the  $K_{Isc}$ , by promoting phosphorus segregation during austenitization (Ref 92).

Maraging and quenched-and-tempered steels exhibit different susceptibilities to SCC, with the former having high resistance and the latter low resistance to SCC (Ref 93). Figure 7 shows the time-to-failure data for bend specimens subjected to alternate immersion in a 3.5% NaCl solution (Ref 94). While the time-to-failure is only hours or days for the

D6-Air-Cooled (D6AC) steel at a yield strength of 100 MPa (220 ksi), the time to failure for the 18Ni-250 maraging steel is of the order of months for a yield strength of 1720 MPa (250 ksi). An explanation for the susceptibility to SCC of the quenched-and-tempered steels can be given in terms of a combination of factors, namely, the presence of  $\epsilon$ -carbide, high dislocation density, and coherency strains between twinned martensitic platelets, which lower the yield strength (Ref 93).

FIG. 7 ALTERNATE-IMMERSION SCC DATA FROM SMOOTH BEND SPECIMENS (REF 94)

Because SCC in high-strength steels is generally intergranular, it is obvious that the compositional variations at the grain boundaries are important. In all types of steel, residual elements tend to precipitate at the prior-austenite grain boundaries and exert their deleterious effect on SCC at these boundaries. Thus, if the prior-austenite grain size is made as fine as possible, a maximum in SCC resistance can be achieved. Austenitizing treatments of 18Ni-300 grade maraging steel were found to have little effect on  $K_{Isc}$ , but the rate of stress-corrosion crack growth was found to decrease with decreasing prior-austenite grain size (Ref 95).

Different annealing and aging treatments in 18Ni-300 maraging steel, reaching the same yield strength, do not affect the value of  $K_{Isc}$  (Ref 96). However, the crack growth rate does increase with decreasing aging temperatures. Although SCC in high-strength steels is generally intergranular, the grain size was found to have no influence on the  $K_{Isc}$  of AISI 4340 steel, but a significant increase in crack velocity with increasing grain size was found.

Figure 8 demonstrates that cold working of 18Ni maraging steels prior to aging decreases the susceptibility to SCC (Ref 94). The figure further shows a ranking of the different types and treatments of steel. Ausforming and light tempering result in a significant increase in  $K_{Isc}$  of H11 steel (Ref 97). Similar improvement in resistance to SCC has been shown in quenched-and-tempered D6AC steel (see Fig. 9).

FIG. 8 RESULT OF BENT-BEAM TESTS IN AERATED DISTILLED WATER. SPECIMENS WERE EXPOSED AT 75% OF THE YIELD STRESS (REF 94).

FIG. 9 EFFECT OF AUSFORMING ON SCC OF D6AC STEEL IN DISTILLED WATER (REF 97)

**Environmental Factors.** High-strength steels are generally susceptible to most aqueous environments, including environments containing water vapor. The most common damaging species is chloride, while those environments that contain cathodic poisons are extremely harmful as well (Ref 93, 98). These include species such as arsenic, antimony, selenium, tellurium, and most importantly, sulfur. The poisons prevent the recombination of atomic hydrogen into molecular form, facilitating hydrogen to absorb into the steel matrix. Sulfur occurs in the form of H<sub>2</sub>S, which is naturally found in sour oil wells.

Other environments that may promote SCC include aqueous solutions containing sulfate, phosphate and nitrate ions, and various organic compounds (Ref 54).

The electrochemical potential and pH of a solution have a significant effect on the SCC of high-strength steels (Ref 47). Although an impressed cathodic potential has little effect on the  $K_{Isc}$  of AISI 4340 steel in seawater or 3.5% NaCl aqueous solutions, it significantly affects the crack growth rate (see Fig. 10) (Ref 54, 88, 99, 100). Generally, the effect of pH on  $K_{Isc}$  in SCC of quenched-and-tempered steel is small, except when it is below 1 or above 9. Highly acidic conditions promote cracking, and highly basic conditions reduce or even prevent cracking, presumably by preventing pitting corrosion. It is generally believed that the pH and potential at a propagating crack tip promote the local hydrogen ion reduction reaction and hence hydrogen absorption into the matrix and hydrogen embrittlement.

FIG. 10 EFFECT OF APPLIED POTENTIAL ON CRACK GROWTH RATES OF VARIOUS STAINLESS STEELS IN AN AQUEOUS CHLORIDE ENVIRONMENT (REF 54)

**Mechanisms of SCC in High-Strength Steels.** Extensive research has confirmed that hydrogen embrittlement is the most likely mechanism of SCC of high-strength low-alloy steel. Local environments, such as potential and pH at the tips of propagating cracks, were found conducive to conditions for hydrogen embrittlement. Similarities between fracture appearance of stress-corrosion cracks and cracks formed in gaseous hydrogen further confirmed a hydrogen-related fracture mechanism for SCC.

The four principal fracture mechanisms that have been proposed are:

- THE PRESSURE THEORY (REF 101)
- THE SURFACE ENERGY THEORY (REF 102)
- THE DECOHESION THEORY (REF 103, 104)
- THE ENHANCED PLASTICITY THEORY (REF 106, 107, 108)

The pressure theory (Ref 101) is based on the concept that molecular hydrogen precipitates in preexisting voids in the metal. When the pressure is built up in the voids, the resulting stress reduces the applied stress force fracture. This theory has not been supported by experimental evidence.

The surface energy theory (Ref 102) postulates that hydrogen, adsorbed at the metal surface, acts to lower the surface free energy, lowering the stress required for cracking. Again no experimental support for this model has been offered.

The decohesion model has been developed from Troiano's original theory that electrons donated from dissolved hydrogen enter the incompletely filled *d*-bond (Ref 103). The cohesive strength of the metal is then reduced by the increased electron density, which causes an increase in interatomic spacing. Experimental work by Fu and Painter (Ref 106) on iron aluminide has suggested that hydrogen embrittlement results from depletion of *d*-bonding charge from iron sites in the ordered aluminide lattice.

The hydrogen-enhanced localized plasticity (HELP) model suggests that hydrogen in the lattice reduces the shear stress required for dislocation motion at the crack tip, easing the local plastic flow associated with crack propagation. This theory of hydrogen-induced SCC has been supported experimentally by Birnbaum's work on thin foils of several metals, including steel, using an environmental cell in a high-voltage transmission electron microscope (Ref 107, 108).

### SCC of Stainless Steels

Stainless steels are a group of iron-base alloys that contain a minimum of 11% Cr to prevent general corrosion in unpolluted atmospheric environments. The susceptibility of stainless steels to SCC strongly depends on the composition, microstructure, and heat treatment of the steels. Figure 11 shows a composite diagram of the alloys in the stainless steel family, starting from the basic Fe-19Cr-10Ni (304) stainless steel (Ref 109). The figure indicates four separate groups, namely, austenitic, ferritic, duplex, and martensitic and precipitation-hardening stainless steels. These different stainless steels can be susceptible to SCC in various environments, including aqueous chlorides, caustic, high-temperature pure water, polythionic acid thionates, sulfides, and radiation fields. The stainless steels of the four basic groups--austenitic, ferritic, duplex, and martensitic and precipitation-hardening stainless steels--will be discussed in some detail in the following sections.

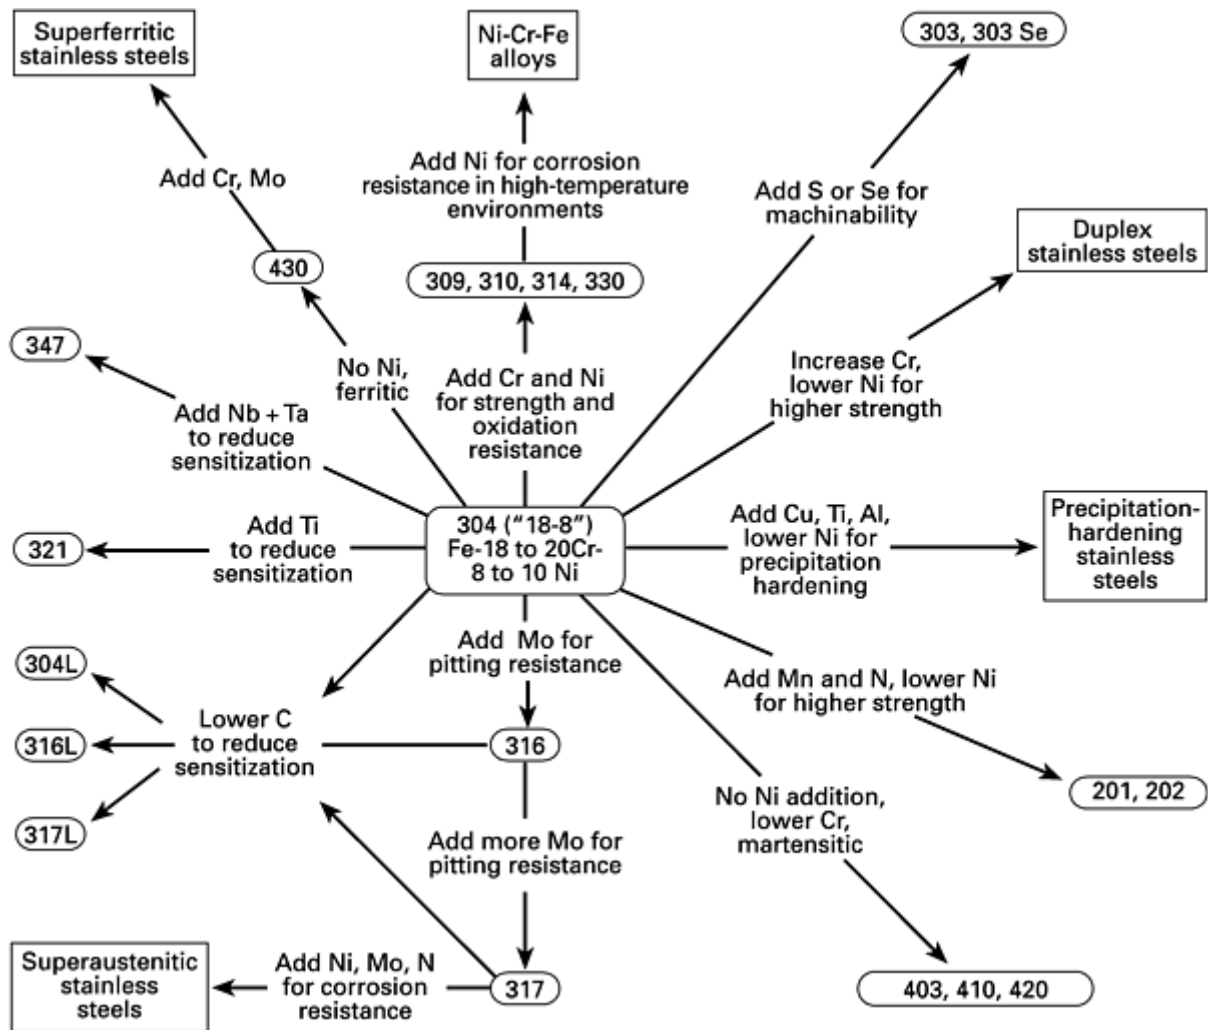

FIG. 11 SCHEMATIC DIAGRAM SHOWING COMPOSITIONAL AND PROPERTY LINKAGES IN THE STAINLESS STEEL FAMILY OF ALLOYS (REF 109)

**Austenitic stainless steels**, based on the Fe-18Cr-10Ni alloy, are particularly susceptible to intergranular SCC in several environments. Sensitization of the microstructure of austenitic stainless steels is a feature that plays an important role in SCC of these steels, and considerable effort has gone into the development of alloys that resist sensitization. Carbon is present in austenitic stainless steels as austenite stabilizer. At concentrations between 0.03 and 0.7% C, the equilibrium structure at room temperature should contain austenite,  $\alpha$ -ferrite, and carbide ( $M_{23}C_6$ ). Carbon concentrations up to 0.03% C should be soluble in austenite up to a temperature of 800 °C (1470 °F). Austenite that contains more than 0.03% C precipitates  $M_{23}C_6$  upon cooling below the solubility line (Ref 110). However, at relatively rapid cooling rates, the precipitation reaction is suppressed, and the austenite is supersaturated with carbon. If this supersaturated austenite is heated into the austenite +  $M_{23}C_6$  field, precipitation of chromium-rich  $M_{23}C_6$  will take place at the austenite grain boundaries. When the chromium does not diffuse back into the austenite adjacent to the grain-boundary carbides, a zone depleted of chromium will be formed around the carbides, which has lower resistance to corrosion. This type of structure, which is known as sensitized structure, can be obtained by slow cooling, heat treatment, elevated-temperature service, or welding (Ref 111).

In order to minimize sensitization, various steps can be taken: (1) reduce the carbon concentration below 0.03% (for example, types 304L, 316L, and 317L stainless steels), (2) heat treat to rediffuse chromium back into the chromium-depleted zone, and (3) add titanium (type 321 stainless steel) or niobium (type 347 stainless steel) to precipitate carbides at higher temperature, so that no carbon is left to precipitate as chromium-rich carbide. The latter treatments result in so-called stabilized grades, which may suffer from another form of corrosion attack, known as knifeline attack (Ref 111). Carbon strengthens the matrix, and when its concentration is lowered, the strength may be reduced. To compensate for this loss in strength, nitrogen has been added as an alloying element (Ref 112).

In addition to carbon, titanium, and niobium, which affect the degree of sensitization of austenitic stainless steels and hence their susceptibility to intergranular SCC, there are other alloying elements that affect the susceptibility to transgranular SCC (Fig. 12) (Ref 111, 113, 114). The elements designated "beneficial" are nickel, cadmium, zinc, silicon, beryllium, and copper. It should be noted that the beneficial effect of nickel only applies to austenitic stainless steels. Figure 12 further shows many elements that have a detrimental effect on SCC.

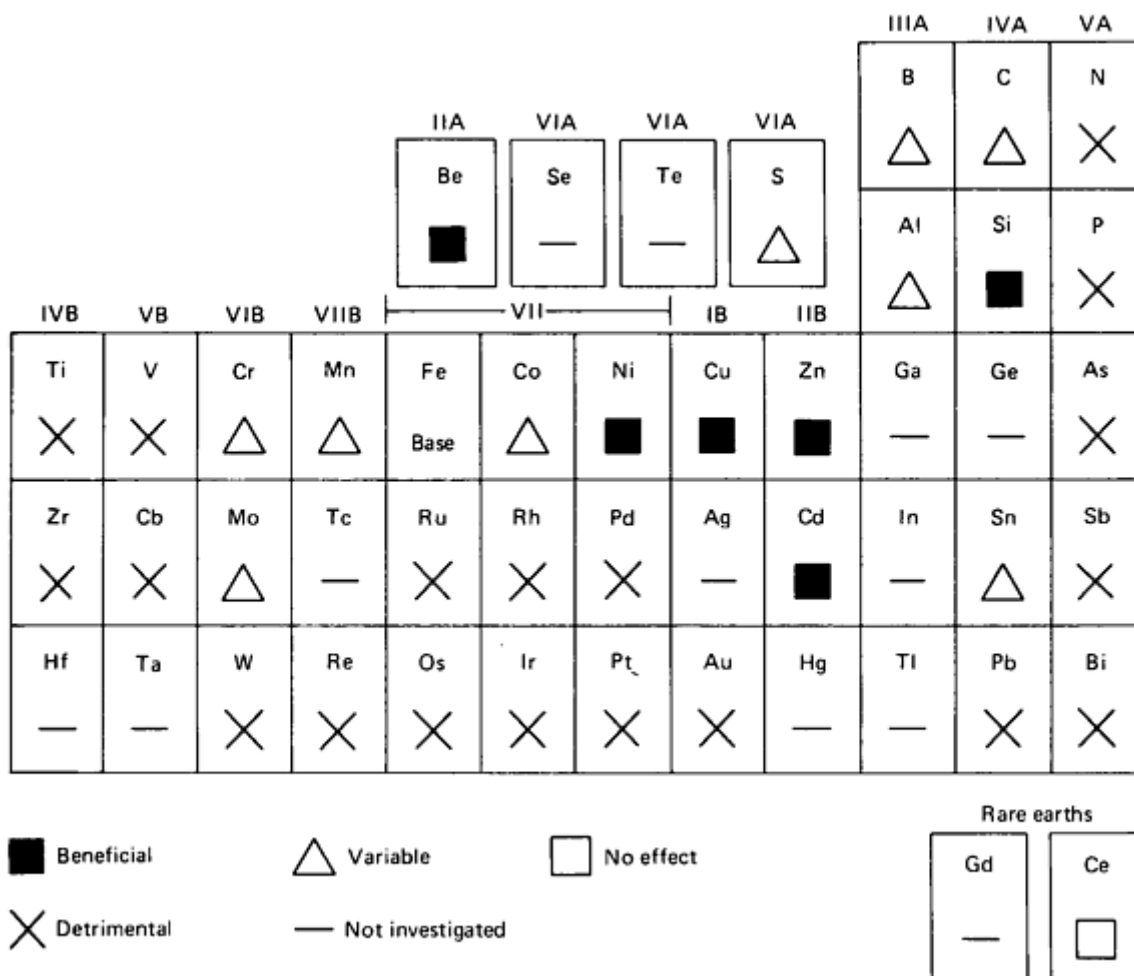

FIG. 12 EFFECT OF VARIOUS ALLOYING ELEMENTS ON THE RESISTANCE OF AUSTENITIC STAINLESS STEELS TO SCC IN CHLORIDE SOLUTIONS (REF 111)

The microstructure of austenitic stainless steels has a significant effect on the susceptibility to chloride SCC. The various phases and microstructural features found in stainless steels are shown schematically in Fig. 13 (Ref 115). The presence of ferrite improves the resistance to SCC by interference with cracks propagating across austenite grains. In order to be effective, a significant amount of ferrite is required, such that the alloy composition of duplex stainless steels is reached. The  $\sigma$  or  $\sigma'$  phases have an effect on sensitization of grain boundaries, similar to that of carbides. However, few attempts have been made to study the effect of these phases on chloride SCC.

FIG. 13 SCHEMATIC DRAWING OF THE MICROSTRUCTURAL FEATURES FOUND IN STAINLESS STEELS (REF 115)

Ferritic stainless steels have been reported to have high resistance to SCC (Ref 116, 117, 118). However, SCC of ferritic stainless steels has been reported for specific alloy/environment combinations (Ref 119, 120, 121). Materials factors that have been identified as detrimental to the chloride SCC cracking of ferritic stainless steels include the presence of certain alloying elements, sensitization, cold work, high-temperature embrittlement, and the precipitation of  $\alpha'$  (at 475 °C, or 887 °F) (Ref 109). Although it is not clear whether these effects are directly related to chloride SCC or represent manifestations of other phenomena such as hydrogen embrittlement or stress-aided intergranular corrosion, the effects can be detected in the standard boiling magnesium chloride test.

The alloying elements that are detrimental to the resistance of ferritic stainless steel to chloride SCC, include copper, nickel, molybdenum (in the presence of nickel), cobalt (in the presence of molybdenum), ruthenium, sulfur, and carbon (Ref 109). Figure 14 shows that the concentrations of nickel and copper needed for cracking are relatively low (Ref 122). Similarly low concentrations for molybdenum and cobalt are needed for chloride SCC of ferritic stainless steels.

**FIG. 14 EFFECT OF COPPER AND NICKEL CONTENTS ON THE SCC RESISTANCE OF U-BEND SPECIMENS OF FERRITIC FE-18CR-2MO-0.35TI-0.015C-0.015N STAINLESS STEELS EXPOSED TO A MAGNESIUM CHLORIDE SOLUTION BOILING AT 140 °C (284 °F) (REF 122)**

Any structural features that reduce the ductility of ferritic stainless steels such as the formation of carbonitrides or  $\alpha'$ , and cold work can reduce the resistance of these steels to SCC (Ref 122, 123).

Hydrogen embrittlement has been identified as the cause of SCC of ferritic stainless steels when they are cathodically polarized in aqueous environments (Ref 124, 125). For example, the super ferritic stainless steels 29-4C and Sea-Cure exhibit hydrogen embrittlement when they are cathodically polarized to potentials in the range of -0.9 to -1.4 V (SCE) (Ref 124). Hydrogen embrittlement of these alloys can also occur when they are exposed to acidic environments, or in the presence of hydrogen-ion recombination poisons. The fracture mode of hydrogen embrittlement in these superferritic stainless steels is transgranular cleavage.

**Duplex stainless steels** with 10 to 28% Cr and 4 to 8% Ni contain both austenite and ferrite. An attractive feature of these alloys is that they have much higher strength than either the austenitic or the ferritic stainless steels. Although duplex stainless steels are susceptible to chloride SCC, the threshold stress for SCC is generally much higher for duplex stainless steels (Fig. 15) (Ref 126). The microstructural parameters that have a significant effect on the susceptibility to chloride SCC are the presence of  $\sigma$  phase and the ferrite content. The presence of  $\sigma$  phase has been shown to be detrimental to SCC resistance in boiling 35% MgCl<sub>2</sub> at 125 °C (257 °F) (Ref 126). Ferrite has been shown to affect the resistance to chloride SCC in boiling 42% MgCl<sub>2</sub>, with the resistance reaching a maximum at 40% and decreasing on either side of this value (Ref 127, 128).

**FIG. 15 EFFECT OF APPLIED STRESS ON THE TIMES TO FAILURE OF VARIOUS STAINLESS STEELS IN A BOILING MAGNESIUM CHLORIDE SOLUTION (REF 126)**

Welding of duplex stainless steels may have a significant effect on the resistance to chloride SCC (Ref 111, 126). Welding can destroy the duplex structure of an annealed material by forming continuous regions of ferrite along the weld

HAZ. In addition, welding can result in the formation of carbonitrides,  $\alpha'$ , and precipitate-free zones, which contribute to the susceptibility to SCC.

**Martensitic and precipitation-hardening stainless steels** are used in heat-treated conditions when high strength is required. These steels are susceptible to SCC in aqueous chloride environments with or without sulfides present. The mechanism of SCC in aqueous chloride environments such as marine environments is generally accepted to be hydrogen embrittlement (Ref 121). Martensitic and precipitation-hardening alloys are susceptible to hydrogen embrittlement in marine environments at yield strengths above 1035 MPa (150 ksi) (Ref 129). In precracked specimens, hydrogen embrittlement may occur at lower yield strengths. Tempering, in the case of martensitic stainless steels, and overaging, in the case of precipitation-hardening steels, can significantly increase the resistance to hydrogen embrittlement, but also lower the yield strength (Ref 130); see Fig. 16 for an Fe-12Cr-1Mo-0.33V-0.25C martensitic stainless steel.

**FIG. 16 EFFECT OF TEMPERING TEMPERATURE ON THE CRACKING RESISTANCE AND YIELD STRENGTH OF AN FE-12CR-1MO-0.33V-0.25C MARTENSITIC STAINLESS STEEL (REF 130)**

**Environmental Factors in SCC of Stainless Steels.** Austenitic stainless steels are susceptible to intergranular and transgranular SCC in aqueous chloride environments. Intergranular cracking occurs in sensitized stainless steels in chloride environments such as NaCl or seawater environments, while transgranular SCC occurs in nonsensitized steels (chloride SCC). Most of the early evaluations of chloride SCC was conducted in boiling magnesium chloride (Ref 131). This test has been standardized as ASTM G 36.

Other environments that induce SCC in austenitic stainless steels are high-temperature water and various sulfur compounds. High-temperature water SCC denotes SCC in the cooling water of nuclear reactors and has been used to describe intergranular SCC of weld heat-affected zones (HAZs) in type 304 stainless steel piping exposed to oxygenated boiling water reactor (BWR) coolants. Figure 17 shows a compilation of data on the stress-corrosion susceptibility of type 304 stainless steels in high-temperature water at various dissolved oxygen and chloride concentrations (Ref 132). The figure indicates that sensitized type 304 stainless steel can undergo SCC at dissolved oxygen concentrations between 0.15 and 0.3 ppm and chloride concentrations between 0.02 and 0.5 ppm. These oxygen and chloride ranges span the BWR operating ranges. A quantitative and predictive model developed by Ford and coworkers (Ref 133, 134, 135) is based on the slip-dissolution/film-rupture model. In this model, a thermodynamically stable oxide film is ruptured by an increase in the strain in the steel matrix. Faraday's law is then used to relate the amount of subsequent crack propagation to the oxidation charge density associated with dissolution and oxide growth. This model predicts stress-corrosion crack

propagation for austenitic stainless steels in 288 °C (550 °F) water within a factor of two and is therefore used in the nuclear power industry as a crack-propagation prediction tool.

**FIG. 17 CONCENTRATION RANGES OF DISSOLVED OXYGEN AND CHLORIDE THAT MAY LEAD TO SCC OF TYPE 304 IN HIGH-PURITY WATER AT TEMPERATURES RANGING FROM 260 TO 300 °C (500 TO 570 °F). THE APPLIED STRESSES ARE GREATER THAN THE YIELD STRENGTH AND TEST TIMES ARE GREATER THAN 1000 H, OR STRAIN RATES ARE GREATER THAN  $10^{-5}$ /S (REF 132).**

Intergranular SCC of austenitic stainless steels occurs in various sulfur-containing environments. For example, SCC occurs in catalytic reformers used in the oil-refinery industry, when the steels are in contact with the condensates of reforming furnaces, containing polythionic acids ( $H_2S_xO_6$ , where  $x = 3, 4, \text{ or } 5$ ) (Ref 136, 137). More recent studies (Ref 138, 139) have shown that of all the polythionic acids, only tetrathionic acid ( $H_2S_4O_6$ ) could induce SCC. A laboratory test for resistance to polythionic cracking has been standardized as ASTM G 35.

Other sulfur-containing compounds that induce intergranular SCC include sulfides, thiosulfates, and sulfate solutions. Stress-corrosion cracking in hydrogen sulfides ( $H_2S$ ) is of interest in downhole environments, while SCC in thiosulfate solutions is of interest to the nuclear industry. Borate solutions are stored in stainless steel tanks for use as spray in case of nuclear accidents. In addition to borate, the solution also contains thiosulfate anions, which react with the iodine fissure products. Stress-corrosion cracking of stainless steels in these borate solutions has been attributed to the presence of the thiosulfate (Ref 140).

Austenitic stainless steels are also susceptible to SCC in caustic solutions (Ref 132). The resistance of stainless steels to caustic cracking is of interest to the power, chemical process, and pulp and paper industries. Data have shown that austenitic stainless steels are particularly susceptible to caustic cracking when the temperature approaches 100 °C (212 °F). The presence of oxygen in caustic solutions has been reported to have a detrimental effect on the susceptibility to SCC. Specifically, it has been shown that caustic cracking of austenitic stainless steel is very severe in aerated solutions of sodium hydroxide and that high levels of both nickel and chromium in the alloy appear to be necessary to resist caustic cracking (Ref 141). Caustic SCC can be mitigated by the addition of phosphates, chlorides, and chromates to the environment (Ref 142, 143, 144, 145).

Ferritic stainless steels generally have a high resistance to chloride SCC. However, SCC of ferritic stainless steels have been reported for type 434, type 430, and Fe-18Cr-2Mo in lithium chloride solutions (Ref 119), for sensitized type 446 in boiling magnesium chloride and sodium chloride solutions (Ref 120), for type 430F in marine atmospheres (Ref 121), and for the nickel-containing superferritics, AL 29-4-2, Monit, and Sea-Cure, in boiling magnesium chloride (Ref 146). As in the case of austenitic stainless steels, cathodic polarization can prevent chloride SCC of ferritic stainless steels.

Ferritic stainless steels have been reported to be resistant to caustic SCC. Rather, these alloys exhibit uniform corrosion or intergranular corrosion in caustic environments. However, SCC of type 446 and E-Brite 26-1 heat treated at 871 °C (1600 °F) was reported after exposure to 50% NaOH at 316 °C (600 °F) (Ref 141).

### SCC of Nickel-Base Alloys

Nickel-base alloys are often used because of their high resistance to corrosion and SCC in various environments. However, SCC can occur under specific combinations of environment, microstructure, and applied stress. The number of environments that have been recognized to cause SCC in nickel-base alloys has increased over the years, as shown in Table 3 (Ref 147). The table shows that depending on their composition, these alloys can be susceptible to SCC in environments ranging from aqueous halide solutions to various acids, high-temperature pure water, steam, to sulfur compounds.

(B) MINIMUM.

**Materials Factors.** The composition of nickel-base alloys can range from binary systems to multicomponent systems with several alloying elements serving different applications. Major alloying systems are Ni-Cu, Ni-Mo, Ni-Cr-Fe, Ni-Cr-Fe-Mo, and Ni-Cr-Mo-W (Ref 148). In addition, impurities such as carbon, nitrogen, sulfur, phosphorus, tin, and silicon may be present in various concentrations. Copper and molybdenum are added to increase the resistance to reducing environments. Chromium is added to provide resistance to oxidizing environments. Molybdenum and tungsten are added to chromium-containing alloys to increase the resistance to pitting and crevice corrosion in halide environments. Niobium and titanium are added to prevent the formation of chromium carbides. In precipitation-hardenable alloys niobium, aluminum, and titanium also combine with nickel to form coherent intermetallic phases.

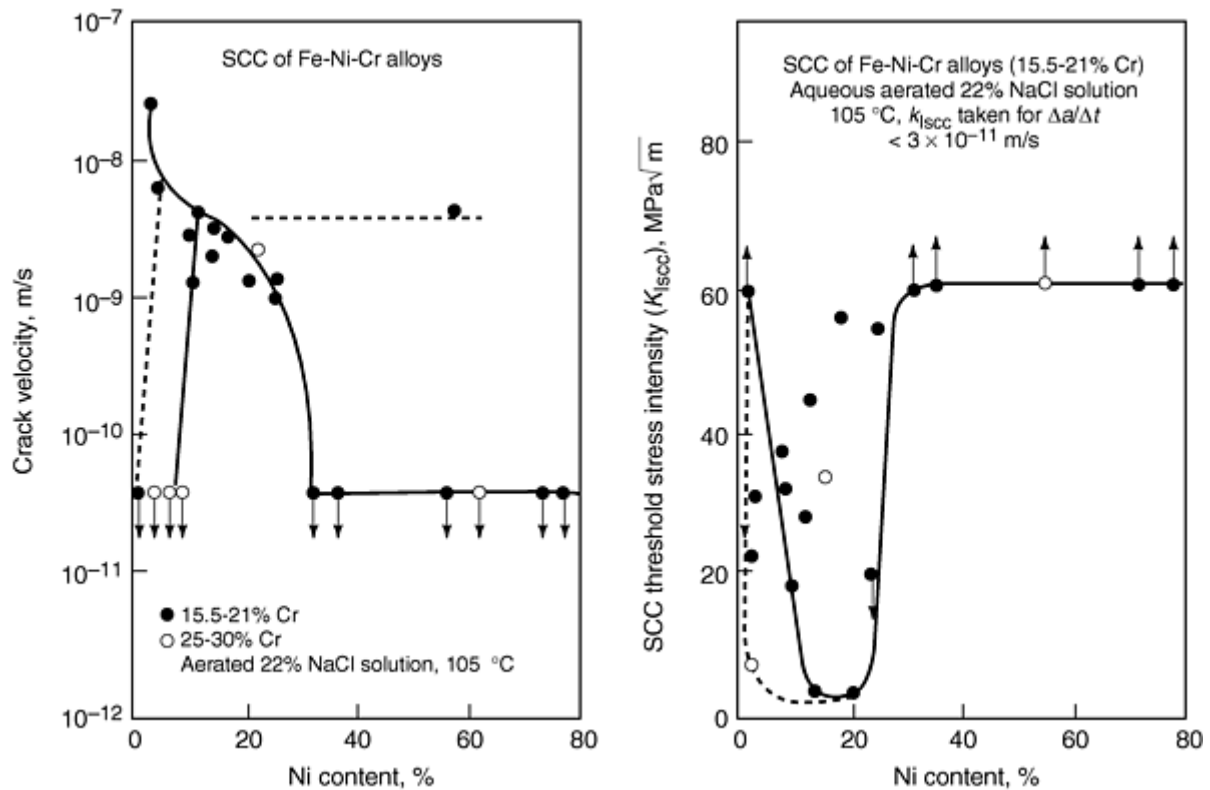

Commercially pure nickel (200) is primarily used in the handling of caustic solutions. The Ni-Cu alloys (alloy 400), and the age-hardenable Ni-Cu alloy (alloy K-500) are primarily used for seawater applications. The Ni-Mo alloys (alloys B and B-2) are used in the chemical processing industry for handling reducing acids. The Ni-Cr-Fe alloys (alloys 600, 800, Nimonic 75, and alloy 690) find wide application in the nuclear power industry as steam generator tubing and turbine wheel components. The Ni-Cr-Fe-Mo alloys (alloys 825, G3) are generally used in industries, where corrosion resistance is required. The precipitation-hardenable Ni-Cr-Fe-Mo alloy 718, first developed for aerospace applications, is now used in the nuclear and oil and gas industries. Finally, the Ni-Cr-Mo-W alloys, such as alloys C276 and C22, are used mainly in the chemical process, oil and gas and pollution control industries because of their high resistance to corrosion in contaminated acids.

As in the case of austenitic stainless steels, the precipitation of carbides plays an important role in the susceptibility of nickel-base alloys to SCC. In nickel-base alloys, carbides can be classified as primary and secondary carbides (Ref 147, 148). The primary carbides form during solidification and include the MC types, where M is niobium, tantalum, or titanium, and the  $M_6C$  types, where M is usually molybdenum or tungsten. These precipitates are difficult to dissolve and have little effect on the susceptibility to SCC. The secondary carbides precipitate as a result of heat treatment and welding, typically along the grain boundaries, and are detrimental to intergranular corrosion and SCC resistance because of their associated chromium-depletion zones. Carbides in nickel-base alloys can be classified as those rich in chromium ( $Cr_7C_3$  or  $Cr_{23}C_6$ ), and those that are rich in refractory elements such as  $Cr_{21}(Mo-W)_2C_6$ .

In addition to carbides, intermetallic phases form that may influence the susceptibility of nickel-base alloys to SCC. The  $\gamma$ ,  $\gamma'$ , and  $\gamma''$  and  $\delta$  are coherent precipitates that are desirable for increased strength (Ref 149, 150, 151). The  $\gamma$  phase is a face-centered cubic (fcc) precipitate, while the  $\gamma''$  is a  $DO_{22}$ -ordered coherent precipitate (metastable  $Ni_3Nb$ ). The  $\gamma'$  is a coherent precipitate ( $L_{12}$ ), which is a metastable version of  $Ni_3(Al,Ti,Si)$  and normally present in age-hardenable alloys. The  $\delta$  phase has, like the  $\gamma''$  phase, an ideal composition of  $Ni_3Nb$ , and has an orthorhombic crystal structure. The detrimental intermetallic phases are generally the  $\sigma$ ,  $\mu$ , and Laves phases. The  $\sigma$  phase has a complex tetragonal layered structure and tends to nucleate from  $M_{23}C_6$  carbides, to which it is structurally related (Ref 152). The molybdenum-rich  $\mu$  phase has a complex rhombohedral structure and occurs in chromium-containing nickel-base alloys with large amounts of molybdenum and tungsten. The Laves phase is an ordered ( $A_3B$ ) structure that forms if the local concentration of niobium is high.

An extensive study was conducted by Streicher on the effects of microstructure on Ni-Cr-Mo alloys (C and C-276) on localized corrosion and SCC (Ref 153). It was demonstrated that these alloys have experienced varying degrees of susceptibility to SCC as a result of carbide and  $\mu$ -phase precipitation. The study by Streicher (Ref 153) indicated that solution-annealed alloys were not susceptible to SCC in boiling 45%  $MgCl_2$ , and that the precipitation of  $M_6C$  was much more detrimental to the SCC resistance than the  $\mu$  phase.

**Environmental Factors in SCC of Nickel-Base Alloys.** Generally, nickel-base alloys are not susceptible to SCC in aqueous halide solutions. Stress-corrosion cracking has been observed in these solutions, however, when the temperature is high enough. At temperatures slightly above the boiling point of chloride solutions, no cracking is observed in alloys with nickel content above 35% (Ref 154). Figure 18 shows the effect of nickel content on the crack growth rate and  $K_{Isc}$  for Fe-Ni-Cr alloys in hot chloride solutions. The figure clearly shows that the alloy is the most susceptible at a nickel concentration of about 20 wt%. At lower and higher concentrations, the resistance to SCC increases dramatically.

**FIG. 18 EFFECT OF NICKEL CONTENT ON THE MAXIMUM CRACK GROWTH RATE AND THRESHOLD STRESS-INTENSITY FACTOR FOR FE-NI-CR ALLOYS IN HOT CHLORIDE SOLUTIONS (REF 154)**

Cracking has been observed in several precipitation-hardening nickel-base alloys (e.g., alloy 718) exposed to hot HCl, whereas no cracking was found in solid-solution-strengthened alloys (Ref 155). It was speculated that the combination of changes in distribution of alloying elements between the  $\alpha$  and  $\beta$  phases, chromium depletion at the grain boundaries, and changes in the deformation mode may have contributed to the increased susceptibility of alloy 718 to SCC.

Generally, nickel-base alloys are resistant to SCC in fluoride, bromide, and iodide environments. However, in a few special cases SCC has been observed. Graf and Wittich (Ref 156) demonstrated that aqueous solutions containing cupric fluoride would cause SCC of Nickel 400. An Ni-Cu alloy with 33% Cu was found to be the most susceptible to cracking. Nickel alloys with less than 30% Cu or more than 40% Cu are resistant. The reason that SCC is limited to the vapor phase rather than liquid was said to result from the enrichment of a thin layer of aqueous hydrogen fluoride with copper fluoride corrosion products. The presence of oxide was found to cause the formation of cupric fluoride, accelerating SCC. Nickel-chromium alloys, such as alloy 600, have been used in components exposed to hydrogen fluoride vapors to minimize SCC (Ref 147).

Stress-corrosion cracking of nickel-base alloys has been observed in concentrated bromide solutions used as packer fluids (Ref 157). The susceptibility to SCC in these environments has been attributed to the presence of H<sub>2</sub>S. Transgranular SCC of nickel-base alloys in iodide environments has been encountered in the manufacturing of acetic acid (CH<sub>3</sub>COOH), where potassium iodide is used as promoter.

Nickel-base alloys have found wide use in sulfur-containing environments, which are encountered in oil and gas production and in refinery operations (Ref 158, 159, 160). These environments include the sulfide (H<sub>2</sub>S) environments that may also include chloride, carbon dioxide, and elemental sulfur, as well as sulfur-oxyanions such as thiosulfate, tetrathionate, and polythionic acid. Early investigations of Ni-Cr-Mo alloys found that under cathodic polarization by galvanic coupling with carbon steel, intergranular cracking could occur in an H<sub>2</sub>S + CO<sub>2</sub> + Cl<sup>-</sup> environment (Ref 161). When increasing the temperature, the susceptibility to SCC increases, but in the absence of galvanic coupling with carbon steel, the cracking is transgranular. Elemental sulfur (S<sub>8</sub>) is often present, and recent studies of nickel-base alloys in sour

environments have indicated that  $S_8$  is extremely detrimental to localized corrosion and SCC of nickel-base alloys in brine solutions (Ref 162). No explanation has been offered in the literature with regard to the mechanism by which  $S_8$  affects cracking in these environments. Acidification by HCl or  $CH_3COOH$  has been shown to increase the susceptibility of nickel-base alloys to both  $H_2S$  and  $H_2S + S_8$  environments (Ref 157, 163, 164, 165), while increasing the pH by adding NaOH has been shown to prevent SCC in these environments (Ref 157, 164).

Metastable oxyanions, such as thiosulfates and polythionates, can also induce intergranular SCC in sensitized Ni-Cr-Fe alloys (Ref 111, 137, 166). Much work has been done on intergranular cracking of alloy 600 because of its extensive use as steam generator tubing in pressurized water reactors (PWRs) (Ref 167). From this research it has become apparent that intergranular SCC of Ni-Cr-Fe alloys in the presence of metastable sulfur oxyanions can be avoided by using prolonged heat treatments (e.g., 15 h at 700 °C, or 1290 °F, for alloy 600), which replenish the chromium-depleted zone.

Stress-corrosion cracking failures have been experienced in other nuclear plant environments, including high-temperature pure-water environments and caustic environments. It is well known that solid-solution strengthened alloys, such as alloy 600, and precipitation-hardened alloys, such as alloys 750 and 718, are susceptible to intergranular SCC in deaerated high-purity water at temperatures of about 300 to 350 °C (570 to 660 °F) (Ref 168, 169, 170, 171). The effect of dissolved oxygen on the intergranular SCC susceptibility of alloy 600 in high-temperature water has been reviewed in detail (Ref 172, 173). The accelerating effect of oxygen is well documented and is even more significant in creviced structures (Ref 174).

Stress-corrosion cracking of the solid-solution-strengthened alloy 600 in hot caustic environments at temperatures of 350 °C (660 °F) has been studied extensively, because of the use of this alloy for steam generator tubing in PWRs (Ref 141, 175, 176, 177, 178, 179). All the austenitic Ni-Cr-Fe alloys are susceptible to SCC, and alloy 690 is the most resistant of the commercial alloys. Only pure nickel seems to be immune to cracking.

### SCC of Aluminum Alloys

Stress-corrosion cracking of aluminum alloys can occur in several different environments, ranging from water condensate to salt water solutions. Only aluminum alloys that are precipitation-hardening alloys and contain soluble alloying elements, such as copper, magnesium, silicon, and zinc, are susceptible to SCC. The susceptibility of these alloys to SCC strongly depends on the heat treatment, which results in specific microstructures. Thus, because the susceptibility depends so strongly on the microstructure resulting from heat treatment, heat treatments have been developed to reduce and even eliminate the susceptibility to SCC. However, as will be discussed in later sections, such heat treatments also can result in a loss of strength.

The susceptibility of aluminum alloys is strongly dependent on alloy composition. There are basically five commercial alloy types, namely Al-Cu-Mg (2000 series) alloys, Al-Cu-Li (2000 and 8000 series) alloys, Al-Mg (5000 series) alloys, Al-Mg-Si (6000 series) alloys, and Al-Zn-Mg (7000 series) alloys. The Al-Cu and Al-Zn-Mg alloys are precipitation-hardening alloys, whereas the Al-Mg alloys are not considered heat treatable and do not develop their strength through heat treatment.

Water or water vapor is the key environmental factor in SCC of aluminum alloys. Halide ions (Cl<sup>-</sup>, I<sup>-</sup>, and Br<sup>-</sup>) have a significant effect in accelerating SCC, with chloride having the greatest effect. In general, the susceptibility to SCC is greater in neutral solutions than in alkaline solutions and greater still in acidic solutions.

**Aluminum-Copper-Magnesium (2000 Series) Alloys.** The Al-Cu-Mg alloys were the first heat-treatable, high-strength aluminum alloys and are still widely used. Al-Cu and Al-Cu-Mg alloys derive their strength from precipitation hardening, which is achieved by solution heat treatment, followed by rapid cooling, and either natural aging at room temperature (T4 temper) or artificial aging at elevated temperatures (T6 temper). Cold working after the quench further increases the strength, resulting in the T3 temper; artificially aging results in the T8 temper.

Thick-section products of the 2000 series alloys, such as 2024, 2014, and 2219 in the T3 and T4 tempers have a low resistance to SCC in the short-transverse direction (Ref 180, 181, 182). If these alloys in the T3 and T4 tempers are heated for short periods in the temperature range used for artificial aging, selective precipitation along the grain boundaries may further decrease the resistance to SCC. Coarse Al-Cu precipitates form along the grain boundaries, depleting the regions adjacent to the grain boundaries of solute (Ref 183). At longer heating times, as specified for the T6 and T8 tempers, the precipitation becomes more homogeneous, and the resistance to SCC increases.

The precipitates are formed within the grains at a greater number of nucleation sites during treatment to the T8 temper. This temper requires cold working after quenching from the solution annealing treatment, and it provides the highest strength and resistance to SCC before artificial aging in the 2000 series alloys.

There is a consensus among the majority of researchers (Ref 184) that the mechanism of both intergranular corrosion and SCC is crack-tip anodic dissolution along the grain boundaries. The anodic or dissolving phase could be the solute-depleted zone along the grain boundary, the grain boundary itself, or the coarse grain boundary precipitates.

**Aluminum-Copper-Lithium (2000 and 8000) Series Alloys.** The Al-Cu-Li alloys, such as 2090, and Al-Li-Cu-Mg alloys, such as 8090, have higher strength than the typical Al-Cu alloys, but are more susceptible to intergranular SCC (Ref 185, 186, 187). The alloys have their highest resistance to SCC at or near the peak-age tempers. While underaging increases the susceptibility significantly, overaging has only a small effect. The susceptibility of the underaged alloys has been attributed to the precipitation of intermetallic constituent particles (Al<sub>2</sub>CuLi) at the grain boundaries. These constituent particles are believed to be anodic to the copper-rich matrix, resulting in crack-tip anodic dissolution along the grain boundaries. With increasing aging time, copper-containing precipitates form inside the grains. It has been speculated that the formation of these precipitates may increase the anode-cathode area ratio in the microstructure such

that preferential grain boundary attack is avoided. Similar behavior has been observed with SCC of Al-Li-Cu-Mg alloys such as 8090 (Ref 188).

**Aluminum-Magnesium (5000) Series Alloys.** Aluminum-magnesium alloys are not considered heat treatable and do not develop their strength by precipitation hardening. However, these alloys can be processed to H3 tempers, which require a final thermal stabilizing treatment to eliminate age softening, or to H2 tempers, which require a final partial annealing (Ref 182). The H116 or H117 tempers are also used for high-magnesium alloys and involve special temperature control during fabrication to achieve a fine distribution of  $Mg_5Al_8$  precipitates that increases the resistance to intergranular corrosion and SCC (Ref 189).

Although 5000 series aluminum alloys are not heat treatable, they can develop good strength through solution hardening by magnesium in solid solution, dispersion hardening by precipitates ( $Mg_2Al_3$ ), and strain-hardening effects.

Cold-rolled and stabilized tempers of Al-Mg alloys with magnesium contents above 5% are usually very susceptible to SCC. Because the solid solutions in these alloys are more highly supersaturated, the excess magnesium tends to precipitate out as  $Mg_2Al_3$ , which is anodic to the alloy matrix (Ref 182). The precipitation of a continuous string of this phase along the grain boundaries, accompanied by little or no precipitation inside the grains, results in a highly susceptible alloy. Alloys with relatively low magnesium content, such as 5052 and 5454 (2.5 and 2.7% Mg, respectively), do not form continuous grain boundary precipitates and are therefore resistant to intergranular SCC. On the other hand, alloys exceeding magnesium concentrations of approximately 3%, such as 5083, when in strain-hardened tempers, may develop susceptible microstructures as a result of heating or even after long times at room temperature.

Although anodic dissolution appears to be the mechanism for SCC in the 5000 series aluminum alloys, some authors (Ref 190, 191) have postulated that SCC is caused by hydrogen embrittlement of strings or seams of  $\beta$ -phase ( $Al_8Mg_5$ ), which form along the grain boundaries. If the  $\beta$ -phase is continuous, the susceptibility to SCC is much greater.

**Aluminum-Magnesium-Silicon (6000) Series Alloys.** Alloys of the 6000 series alloys are used in applications requiring intermediate strength and high resistance to SCC (Ref 192). The most common commercially used alloy is 6061. The 6000 series aluminum alloys are strengthened by precipitation hardening. Although there have been no reported cases of SCC of this group of alloys, certain abnormal thermal treatments, such as a high solution annealing temperature, followed by a slow quench, can make these alloys susceptible to SCC in the naturally aged T4 condition.

**Aluminum-Zinc-Magnesium-Copper (7000) Series Alloys.** The 7000 series aluminum alloys are precipitation-hardening alloys and are used in applications requiring the highest strength. One of the oldest and most commonly used alloys is alloy 7075, which was introduced as a high-strength aircraft alloy in 1943.

The resistance of most 7000 series alloys in the peak-age temper to SCC is very low when loaded in the short-transverse direction. Particularly, the low-copper-content alloys 7079-T69 and 7039-T61 and T64 are highly susceptible to SCC. Because the heat treatment has a significant effect on the susceptibility of the 7000 alloys, the various stages of heat treating have been investigated to obtain more resistant microstructures (Ref 182, 193, 194, 195, 196, 197, 198). The rate of cooling from the solution treatment temperature through a critical temperature range of 398 to 288 °C (750 to 550 °F) has a pronounced effect on the susceptibility of the copper-bearing 7000 series alloys, such as 7075, to intergranular corrosion (Ref 93). Although high quenching rates increase the resistance to intergranular corrosion of copper-bearing alloys, increasing the quenching rate has no effect on the susceptibility of these alloys to SCC in the short-transverse direction. However, in the case of copper-free 7000 series alloys, the resistance to SCC in sodium chloride solutions increases with decreasing cooling rate (Ref 194).

In order to increase the resistance to SCC, a number of overaging treatments have been developed (Ref 195, 196, 197, 198). The T73 overaging treatment, which is generally achieved by a two-stage heat treatment, provides a high degree of SCC resistance. However, this heat treatment also results in a loss of strength of about 14% compared with the T6 temper. An alternative temper is the T76 temper, which was originally developed to improve the resistance to intergranular and exfoliation corrosion. Moreover, some increase in resistance to SCC with no reduction in strength can be achieved with this temper.

Since the early development of the 7075 alloy, several 7000 series alloys have been developed to improved mechanical, fracture, corrosion, and SCC properties. These alloys include 7050, 7175, 7475, 7017, 7018, 7178, and 7079. The latter two alloys were early modifications of 7075 with the intent to improve mechanical and fracture behavior. These alloys demonstrated extreme and untreatable susceptibility to corrosion and SCC.

The SCC mechanism of 7000 alloys is extensively studied, and the majority of researchers considers SCC to be caused by hydrogen-induced cracking (Ref 184). However, there are several explanations as to the mechanism of hydrogen involvement. These include:

- INCREASED LOCALIZED PLASTICITY (REF 199, 200)
- BRITTLE HYDRIDE FORMATION (REF 201, 202, 203)
- FISSURES INTRODUCED IN THE PASSIVE FILM
- REDUCED COHESIVE STRENGTH (REF 190, 203)
- NUCLEATION OF MICROVOIDS (REF 204)
- VOID PRESSURIZATION WITH HYDROGEN BUBBLES (REF 205)
- CRACK BLUNTING WITH HYDROGEN BUBBLES (REF 206)

Other mechanisms that have been considered for SCC of 7000 alloys include the brittle rupture of the passive film, anodic dissolution of either the grain boundary, or the precipitates at the grain boundary.

**Mechanical Factors.** Many wrought aluminum alloy products have highly directional grain structures. These directional structures result in anisotropic behavior with respect to susceptibility to intergranular SCC (Ref 182). The resistance to intergranular SCC is the highest when the stress is applied in the longitudinal direction, the lowest in the short-transverse direction, and intermediate in the other directions. The differences in directional susceptibility are the most noticeable in the more susceptible tempers, such as T3 for 2000 series alloys and T6 for 7000 series alloys, but are usually much lower in temper produced by extended precipitation (overaging) treatments, such as T6 and T8 for the 2000 series alloys and T73, T736, and T76 for the 7000 series alloys.

The component configuration and the anticipated direction and magnitude of the stress often control the selection of alloy and temper. For example, for thin section products, peak hardness tempers may be selected because there are no stresses in the short-transverse direction. On the other hand, more resistant tempers may be required for thick sections or forgings, where significant stresses may be present in the short-transverse direction.

## Stress-Corrosion Cracking and Hydrogen Embrittlement

Gerhardus H. Koch, CC Technologies, Inc.

---

## SCC of Titanium Alloys

Titanium alloys are well known for their excellent resistance to corrosion in many aggressive environments. This resistance results from the ability of titanium to form and maintain a coherent tenacious and self-healing surface oxide film, typically rutile (TiO<sub>2</sub>) (Ref 207, 208). In the early application of titanium alloys catastrophic failures were experienced, which were attributed to SCC. For example, in the mid-1950s titanium alloys were found to be susceptible to SCC in red-fuming nitric acid (Ref 209, 210), and in the early 1960s titanium alloy missile tanks containing anhydrous methanol or N<sub>2</sub>O<sub>4</sub> experienced catastrophic stress-corrosion failures (Ref 209, 210, 211). In more recent years, titanium and its alloys have found broader application, ranging from supersonic aircraft and deep-sea submersibles to downhole application for geothermal brine and deep sour gas well service (Ref 207, 208). These particular environments could promote SCC of certain titanium alloys.

## Material Factors

Titanium exists in two forms. At low temperature the metal has a close-packed hexagonal (HCP) structure--the  $\alpha$  phase--while at temperatures above 880 °C (1650 °F) the metal has a body-centered cubic (bcc) structure--the  $\beta$  phase (Ref 210). The commercial titanium alloys are typically categorized into four basic types, namely:  $\alpha$ , near- $\alpha$ ,  $\alpha + \beta$ , and  $\beta$ . A list of selected commercial alloys is given in Table 4 (Ref 208). The  $\alpha$  alloys include commercially pure or unalloyed titanium, and those alloys that contain  $\alpha$ -stabilizing alloying elements, such as aluminum, tin, and the interstitials, oxygen, nitrogen, and carbon. The strength of the  $\alpha$  alloys is derived from solid-solution hardening. The  $\beta$  phase is stabilized by either molybdenum, vanadium, niobium, tantalum, manganese, or chromium.

**TABLE 4 DESIGNATIONS AND NOMINAL COMPOSITIONS OF SELECTED COMMERCIAL TITANIUM ALLOYS**

Source: Ref 208

The  $\alpha$ , near- $\alpha$ , and ( $\alpha + \beta$ ) alloys are particularly susceptible to SCC in a variety of environments. In these alloys the  $\alpha$  phase is the susceptible phase. The SCC behavior of this phase is particularly sensitive to the aluminum and oxygen content. The susceptibility of  $\alpha$ -phase containing alloys increases at aluminum concentrations of  $\geq 5$  wt%, which results from the increased tendency to form  $Ti_3Al$  ( $\alpha_2$ ), which has an ordered hexagonal structure ( $DO_{19}$ ) (Ref 210, 212). This ordered phase forms in the temperature range of 400 to 700 °C (750 to 1290 °F). The microstructure has little influence on the susceptibility of  $\alpha$  alloys, whether it is equiaxed or martensitic.

In near- $\alpha$  and ( $\alpha + \beta$ ) alloys, the  $\alpha$  phase is also the phase susceptible to SCC. Unlike in the case of  $\alpha$  alloys, the microstructure of the near  $\alpha$  and ( $\alpha + \beta$ ) alloys, which results from the various heat and processing treatments, has a

significant effect on the susceptibility to SCC (Ref 210). The degree of susceptibility is directly related to the grain size, volume fraction, and mean free path of the susceptible  $\alpha$  phase. Because the  $\beta$  phase is ductile and resistant to SCC, it can act as crack arrester (Ref 213, 214). Thus, structures that have an increased volume fraction of  $\beta$  phase, or where the  $\beta$  phase forms a continuous network breaking up the  $\alpha$  phase, are more resistant to SCC. Figure 19 shows the  $K_{Ic}$  and  $K_{Isc}$  values for the ( $\alpha + \beta$ ) alloy Ti-6Al-4V in various metallurgical conditions in a 3.5% NaCl aqueous solution (Ref 210). A fine equiaxed structure in which the  $\beta$  phase is dispersed throughout the  $\alpha$  matrix, and which results from processing in the  $\alpha + \beta$  field, is much more susceptible to SCC than the structure in which the  $\beta$  phase is lamellar, resulting from processing in the  $\beta$  field. A particularly SCC-resistant microstructure is the transformed  $\beta$  microstructure, which results in either a martensitic or so-called Widmanstätten or basketweave structure. Fine  $\alpha$  platelets surrounded by a continuous  $\beta$  phase and smaller prior- $\beta$  grains are more resistant to SCC than long  $\alpha$  platelets in transformed  $\beta$  structures. The martensitic phases  $\alpha'$  and  $\alpha''$ , which are formed upon quenching from the  $\beta$  region, are also resistant to SCC (Ref 213, 214).

FIG. 19 RANGE OF  $K_{Ic}$  AND  $K_{Isc}$  VALUES FOR TI-6AL-4V IN VARIOUS METALLURGICAL CONDITIONS IN A 3.5% AQUEOUS NA CL SOLUTION AT 24 °C (75 °F) (REF 210)

**Beta Alloys.** Although the  $\beta$  titanium alloys are more resistant to SCC, they are somewhat susceptible to either transgranular or intergranular SCC, depending on the alloy composition and microstructure (Ref 215, 216). Intergranular cracking has been observed in a few  $\beta$  alloys where fine  $\alpha$  precipitates have formed at lower aging temperatures. Beta-phase alloys where the  $\beta$  phase is stabilized with molybdenum, vanadium, niobium, or tantalum are resistant to SCC, whereas alloys stabilized by the eutectic element manganese and chromium are susceptible to transgranular SCC. Transgranular SCC of the  $\beta$  phase is known to occur in Ti-8Mn with a  $\beta + \alpha$  structure and in solution-treated Ti-13V-11Cr-3Al (Ref 213).

## Environmental Factors

Although titanium and titanium alloys are resistant to SCC in many common operating environments, there are several environments that promote SCC. The environments that are known to promote SCC of specific titanium alloys are listed in Table 5 (Ref 208). Some of the more common cracking environments include aqueous solutions and organic compounds such as methanol.

**TABLE 5 ENVIRONMENTS KNOWN TO PROMOTE STRESS-CORROSION CRACKING OF COMMERCIAL TITANIUM ALLOYS**

(A) RT, ROOM TEMPERATURE.

**Aqueous Environments.** The  $\alpha$  and  $(\alpha + \beta)$  titanium alloys are susceptible to SCC in aqueous environments, and the degree of susceptibility depends on the species present in the solution, the pH, temperature, and viscosity of the solution. In certain metallurgical conditions, some highly susceptible titanium alloys have exhibited susceptibility to SCC in distilled water (Ref 210). These alloys include Ti-8Al-1V-1Mo, Ti-5Al-2.5Sn, and Ti-11.5Mo-6Zr-4.5Sn. Additions of halides, chloride, bromide, and iodide ions increase the susceptibility and make alloys that are otherwise not susceptible to SCC in distilled water susceptible to cracking. Chloride ions have been found to have the greatest effect on the susceptibility to SCC, and hence much of the data available have been generated in 3.5% NaCl and seawater at ambient temperature (Ref 217, 218, 219). An example of the effect of chloride ion concentration on the cracking velocity of a susceptible alloy is given in Fig. 20 (Ref 219).

FIG. 20 INFLUENCE OF CHLORIDE CONCENTRATION ON THE SCC BEHAVIOR OF TI-8AL-1MO-1V IN AQUEOUS CHLORIDE SOLUTIONS AT 25 °C (77 °F) (REF 219)

The addition of other anions does not increase the susceptibility to SCC and may in some cases inhibit SCC. Examples of such neutral or inhibiting ions are  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{OH}^-$ ,  $\text{CrO}_4^{2-}$ , and **MATH OMITTED** (Ref 217, 218).

Solution pH and temperature and electrochemical potential have a significant effect on the susceptibility of titanium alloys to SCC. Increasing acidity increases the susceptibility to cracking, while increasing alkalinity appears to have no obvious or significant effect. At high hydroxide concentrations, greater than 1M, inhibition may be expected. Little data are available on the effect of temperature. While the critical stress intensity for crack initiation ( $K_{Isc}$ ) in Ti-8Al-1V-1Mo in a neutral 3.5% NaCl solution does not vary with temperature, the crack velocity is strongly temperature dependent (Fig. 21) (Ref 219).

FIG. 21 EFFECT OF TEMPERATURE ON SCC VELOCITY OF TI-8AL-1MO-1V (NOTCH-BEND SPECIMENS) IN A 3.5% AQUEOUS NA CL SOLUTION (REF 219)

The effects of potential must be considered because titanium alloy components are often coupled to other metals when incorporated into a structure. Anodic or cathodic polarization tends to inhibit stress-corrosion crack initiation and increase the  $K_{Isc}$  of several susceptible alloys, as is illustrated in Fig. 22 (Ref 220). This effect has not been observed for the highly susceptible alloys, such as Ti-8Al-1V-1Mo.

**FIG. 22 EFFECT OF POTENTIAL ON CRACK INITIATION STRESS FOR  $\alpha + \beta$  TITANIUM ALLOYS IN VARIOUS HALIDE SOLUTIONS AT 25 °C (77 °F) (REF 220)**

Three basic mechanisms have been proposed for SCC in aqueous environments (Ref 213, 214). The first mechanism is a film rupture model, which claims that crack nucleation results from planar slip and the formation of wide slip steps that rupture the protective surface oxide film. The crack nucleation is highly dependent on (1) the degree of slip planarity and slip-step width, which concentrates the slip, (2) the oxide film repassivation kinetics, and (3) the strain rate.

A second mechanism is based on anodic dissolution at highly localized sites of stress concentration. This model assumes a balance between the rate of dissolution at the crack tip, the crack-tip stress intensity, and the crack-tip environment. Fractographic evidence has demonstrated that SCC in the  $\alpha$  phase is mechanical in nature, and therefore a third mechanism may be more appropriate.

The third mechanism is based on a hydrogen-assisted cracking phenomenon (Ref 221). Hydrogen that results from the corrosion reaction is absorbed into the matrix and can migrate and concentrate near the crack tip. Localized hydrogen embrittlement ahead of the crack tip may then promote crack propagation. Only the  $\alpha$  phase in  $\alpha$  and ( $\alpha + \beta$ ) alloys are subject to hydrogen embrittlement, because local precipitation of brittle titanium hydride forms ahead of the crack tip, promoting crack propagating by cleavage through the hydride. The  $\beta$  phase in ( $\alpha + \beta$ ) alloys is not susceptible to hydrogen embrittlement, but has high hydrogen solubility and can therefore act as means of transport for hydrogen.

**Methanol.** Titanium alloys are highly susceptible to SCC on methanol liquid and vapor (Ref 210). The fracture mode can be intergranular or transgranular, depending on alloy composition and stress intensity (Ref 222). Intergranular failure in methanol is observed in alloys that are not susceptible to SCC in aqueous solutions, such as the grade 1 and 2 alloys, and  $\beta$  alloys such as Ti-13V-11Cr-3Al. Intergranular SCC in methanol generally involves anodic dissolution and requires little or no stress to propagate. The level of impurities in methanolic solutions has a significant effect on this failure mode. In fact, intergranular SCC in methanolic solution requires traces of halides or halogen (Ref 223). Furthermore, water represents a cracking inhibitor when added above a certain level. For example, a safe minimum water content to prevent intergranular SCC of Ti-6Al-4V in methanol is 1.5 wt%.

Transgranular SCC in methanol is generally observed in those alloys that are susceptible to SCC in aqueous solutions. As in the case of intergranular SCC, a trace level of halides or halogens is required for transgranular SCC to occur, and water can act as an inhibitor when added in sufficient quantity. However, SCC of alloys that are susceptible to cracking in distilled water, such as Ti-8Al-1V-1Mo cannot be inhibited by adding water. Numerous other species have been identified that inhibit transgranular SCC in methanolic solutions (Ref 223). These include nitrate and sulfate ions, and metallic ions such as  $Al^{3+}$ ,  $Zr^{4+}$ ,  $Cd^{+}$ , and  $Sn^{2+}$ .

The SCC mechanism is a mixture of oxide film rupture, dissolution, and hydrogen embrittlement (Ref 208). Crack nucleation is associated with rupture of the passive oxide film. Because  $TiO_2$  formation is not possible in a water-free or water-lean environment, titanium continues to dissolve, forming a nonprotective titanium methylete, or methoxide, surface film:

In both reactions atomic hydrogen is a by-product that can be absorbed into the matrix and promote crack propagation by hydrogen embrittlement, such as hydride formation in the  $\alpha$  matrix.

**Other Environments.** In addition to the environments discussed above, titanium alloys have demonstrated various degrees of susceptibility to SCC to several environments. These environments include:

- ORGANIC SOLVENTS, SUCH AS CARBON TETRACHLORIDE ( $CCL_4$ ), METHYLENE CHLORIDE ( $CH_2CL_2$ ), METHYLENE IODIDE ( $CH_2I_2$ ), TRICHLOROETHANE ( $CH_3CCL_3$ ), AND TRICHLOROETHYLENE ( $C_2HCL_3$ ) (REF 210)
- HOT CHLORIDE SALT (REF 210, 224)

- OXIDIZING NITROGEN-OXIDE COMPOUNDS, SUCH AS NITROGEN TETROXIDE ( $N_2O_4$ ), AND RED-FUMING NITRIC ACID (REF 225, 226, 227)
- MOLTEN SALTS (REF 228)
- LIQUID AND SOLID METALS, SUCH AS CADMIUM (REF 210, 229, 230, 231)
- GASEOUS ENVIRONMENTS, INCLUDING HYDROGEN GAS (REF 221) AND MOIST CHLORINE GAS (REF 232)

### **Mechanical Factors in Ti-Alloys**

Most commercial titanium alloys demonstrate resistance to SCC in loaded smooth or notched configurations but become susceptible at very high stress intensities, such as those associated with highly stressed precracked components. In addition to the stress-concentration effects, material thickness, orientation and loading mode, and rate can have a significant effect on the SCC behavior (Ref 233, 234). Figure 23 shows a diagram that indicates that the susceptibility to SCC decreases with decreasing thickness and that there is a critical thickness below which SCC does not occur (Ref 234). This critical thickness is dependent on the alloy composition, heat treatment, orientation, and loading rate. Apparently, the critical thickness relates to the transition from plane strain to plane stress.

(b)

**FIG. 23 EFFECT OF SPECIMEN THICKNESS ON THE SCC SUSCEPTIBILITY OF TITANIUM ALLOYS. (A) FRACTURE TOUGHNESS OF DUPLEX-ANNEALED TI-8AL-1MO-1V AND MILL-ANNEALED TI-6AL-4V, TESTED IN AIR AND IN 3.5% NaCl. (B) VARIATION OF FRACTURE TOUGHNESS WITH SPECIMEN THICKNESS.  $T_{CRIT}$ , SPECIMEN THICKNESS BELOW WHICH SCC DOES NOT OCCUR**

The mode of SCC in  $\alpha$ , near- $\alpha$ , and  $(\alpha + \beta)$  alloys is transgranular cleavage, with the fracture plane along  $\{10\bar{1}7\}$ , which is a  $15^\circ$  angle from the basal plane (0001) (Ref 221, 235). The basal plane is usually aligned parallel to the rolling direction, and therefore, the susceptibility of the  $\alpha$ -titanium alloys is strongly orientation dependent, particularly in processed material. Figure 23 shows that the resistance of these alloys to transgranular SCC is the least in the transverse direction, resistance to SCC: TL < SL < LT (Ref 230).

Because the cleavage plane for the bcc  $\beta$  phase is typically {100}, transgranular SCC of susceptible alloy is less orientation dependent.

## Stress-Corrosion Cracking and Hydrogen Embrittlement

Gerhardus H. Koch, CC Technologies, Inc.

---

### Evaluation of Stress-Corrosion Cracking

In order to determine the susceptibility of alloys to SCC, several types of testing are available. If the objective of testing is to predict the service behavior or to screen alloys for service in a specific environment, it is often necessary to obtain SCC information in a relatively short period of time, which requires acceleration of testing by increasing the severity of the environment or the critical test parameters. The former can be accomplished by increasing the test temperature or the concentration of corrosive species in the test solution and by electrochemical stimulation. Test parameters that can be changed to reduce the testing time include the application of higher stresses, continuous straining, and precracking, which allows by-passing of the crack nucleation phase of the SCC process.

Stress-corrosion specimens can be divided into two main categories, namely smooth, and precracked or notched specimens. Further distinction can be made in the loading mode, such as constant deflection, constant load, and constant extension or strain rate. These different loading modes will be discussed in more detail in the following sections.

During alloy processing operations used in the production of wrought alloys, the metal is forced in a predominant direction, so that the grains are elongated in the direction of flow. Because it is important to relate the application of stress and the grain flow direction, two conventions are used to relate the two parameters. In one system, which is primarily used for smooth specimens, the three stressing directions are designated by indicating the direction of the stress, namely longitudinal (L), long-transverse (LT), transverse (T), and short-transverse (Fig. 24) (Ref 236).

FIG. 24 GRAIN ORIENTATIONS IN STANDARD WROUGHT FORMS OF ALLOYS (REF 236)

A second system, which is particularly useful for precracked specimens, indicates both the cracking plane and the direction of crack propagation. The system uses three letters (L, T, and W) to indicate three perpendicular directions, namely L for the longitudinal direction, T for the thickness direction, and W for the width direction. The crack plane is indicated by the direction normal to the crack, and the crack propagation is indicated by one of the directions L, T, or W. Figure 25 demonstrates the various orientations for a double-cantilever-beam (DCB) specimen (Ref 237).

FIG. 25 FRACTURE PLANE IDENTIFICATION. L, DIRECTION OF GRAIN FLOW; T, TRANSVERSE GRAIN DIRECTION; S, SHORT TRANSVERSE GRAIN DIRECTION; C, CHORD OF CYLINDRICAL CROSS SECTION; R, RADIUS OF CYLINDRICAL CROSS SECTION; FIRST LETTER, NORMAL TO THE FRACTURE PLANE; SECOND LETTER, DIRECTION OF CRACK PROPAGATION IN FRACTURE PLANE (REF 237)

Other parameters that play an important role in SCC testing are surface condition and residual stress. The nucleation of stress-corrosion cracks strongly depend on initial surface reactions, and thus the surface condition of the test specimens, particularly smooth specimens, has a significant effect on the test results. Smooth test specimens are often tested with a mechanically (machined or abraded) or (electro)chemically treated surface. It is very important to avoid or to remove machining marks or scratches perpendicular to the loading direction (Ref 238).

## Smooth Specimen Testing

Smooth SCC specimens allow for the evaluation of the total SCC life, which includes crack nucleation and propagation. Testing can be conducted under constant extension or strain, constant load, and constant extension or strain rate. The selection of a specific test method for SCC strongly depends on the particular service application, and the time allowed for testing.

**Constant Extension Testing.** Constant extension or constant strain tests on smooth specimens are widely used and do not require elaborate testing fixtures. Depending on the specific configuration of the test articles, different types of constant extension tests are being used, the most common being bent-beam, U-bend, C-ring, and tensile type specimens.

**Bent-Beam Specimens.** The different types of bent-beam specimens are illustrated in Fig. 26 (Ref 239). These specimens may be used to test sheet plate and flat extruded material, or wires and extrusions with a circular cross section. The figure shows that the bending can be accomplished in several ways depending on the dimensions of the specimen. Stressing of the specimen is accomplished by bending the specimen in a stressing device, while restraining the ends. During stress-corrosion testing both specimen and stressing device are exposed to the test environment. The most simple loading arrangement is the two-point loaded bent-beam, which can only be used on relatively thin sheet or wire material. The elastic stress at the mid-point of the specimen can be estimated from the following equation:

$$L = (KTE/\sigma) \text{SIN}^{-1} (H/KTE)$$

where  $L$  is the specimen length,  $\sigma$  is the maximum stress,  $E$  is the elastic modulus,  $H$  is the length of holder,  $t$  is the specimen thickness, and  $k$  is the empirical constant (1.280).

FIG. 26 SCHEMATIC SPECIMEN AND HOLDER CONFIGURATIONS FOR BENT-BEAM SPECIMENS. (A) TWO-POINT LOADED SPECIMEN. (B) THREE-POINT LOADED SPECIMEN. (C) FOUR-POINT LOADED SPECIMEN. (D) WELDED DOUBLE-BEAM SPECIMEN.  $L$ , SPECIMEN LENGTH;  $H$ , LENGTH OF THE HOLDER;  $t$ , SPECIMEN THICKNESS;  $y$ , MAXIMUM DEFLECTION;  $A$ , DISTANCE BETWEEN OUTER AND INNER SUPPORTS;  $h$ , LENGTH OF THE SPACER; AND  $s$ , THICKNESS OF THE SPACER. (REF 239)

**Three-Point Bend Specimens.** Three-point bend tests are commonly used because of the ease of load application and the ability to use the same loading rigs for different stresses. The load is applied by turning a bolt in the rig, deflecting the specimen. The elastic stress at the mid-point of the specimen is calculated from the following equation:

$$\sigma = 6ETy/H^2$$

where  $\sigma$  is the maximum tensile stress,  $E$  is the elastic modulus,  $t$  is the specimen thickness,  $y$  is the maximum deflection, and  $H$  is the length of holder.

This test has a number of disadvantages. First, dissimilar metal corrosion and/or crevice corrosion can occur under the bolt. Secondly, once the crack has formed, the stress condition changes such that the outer layer of the specimen is not subject to a tensile stress only, but to a complex combination at tensile and bending stresses. The propagating crack will then deviate from the centerline. Thus, the three-point bend test can only be used as a qualitative test to assess the susceptibility to stress-corrosion cracking. With the four-point bend test, described in the next paragraph, tensile stresses can be maintained during the growth of the crack.

**Four-Point Bend Specimens.** Four-point bend testing provides a uniform tensile stress over a relatively large area of the specimen. The elastic stress in the outer layer of the specimen between the two inner supports can be calculated from the following equation:

$$\sigma = 12ETy/(3H^2 - 4A^2)$$

where  $\sigma$  is the maximum tensile stress,  $E$  is the elastic modulus,  $t$  is the specimen thickness,  $y$  is the maximum deflection,  $H$  is the distance between outer supports, and  $A$  is the distance between outer and inner supports.

**U-bend specimens** are prepared by bending a strip 180° around a mandrel with a predetermined radius (Fig. 27). The figure shows that bends less than 180° are also used. Standardized test methods are described in ASTM G 30 (Ref 240). Because of the ease of fabrication, a large amount of specimens can be fabricated, and this test is therefore widely used to qualitatively evaluate the susceptibility of alloy and heat treatment to stress-corrosion cracking.

FIG. 27 SCHEMATIC TWO-STAGE STRESSING OF A U-BEND SPECIMEN (REF 240)

A good approximation of the strain at the apex of the U-bend is:

$$\epsilon = T/2R, \text{ WHEN } T < R$$

where  $t$  is the specimen thickness and  $R$  is the radius of the bend.

Then, an appropriate value for the maximum stress can be obtained from the stress-strain curve of the test material.

**C-ring specimens** are commonly used to determine the susceptibility to stress-corrosion cracking of alloys in different product forms (Ref 241). This test is particularly useful for testing of tubing, rod, and bar in the short-transverse direction, as is illustrated in Fig. 28. The specimens are typically bolt loaded to a constant strain or constant load per ASTM G 338 (Ref 241) and if the stresses in the outer layers of the apex of the C-rings are in the elastic region, the stresses can be accurately calculated using the following equations:

$$D_F = D - \frac{\sigma D^2}{4ETZ}$$

where  $D$  is the outer diameter of the C-ring before stressing,  $D_F$  is the outer diameter of stressed C-ring,  $\sigma$  is the elastic stress,  $\Delta D$  is the change of  $D$  at the desired stress,  $d$  is the mean diameter ( $D - t$ ),  $t$  is the wall thickness,  $E$  is the elastic modulus, and  $Z$  is the correction factor for curved beam.

FIG. 28 SAMPLING PROCEDURE FOR TESTING VARIOUS PRODUCTS WITH C-RINGS. (A) TUBE. (B) ROD AND BAR. (C) PLATE (REF 241)

The stress on C-ring specimens can be more accurately determined by attaching circumferential and transverse strain gages to the stressed surface. The circumferential ( $\sigma_C$ ), and transverse ( $\sigma_T$ ) elastic stresses can be calculated with (Ref 242, 243):

$$\sigma_C = E/(1 - \mu^2) \times (\epsilon_C + \mu\epsilon_T)$$

$$\sigma_T = E/(1 - \mu^2) \times (\epsilon_T + \mu\epsilon_C)$$

where  $E$  is the elastic modulus,  $\mu$  is the Poisson's ratio,  $\epsilon_C$  is the circumferential strain, and  $\epsilon_T$  is the transverse strain.

**Tensile Specimens.** For specific purposes, such as alloy development, a large number of stress-corrosion specimens need to be evaluated. Tensile specimens have been used for this purpose where specimens used to determine tensile properties in air are adapted to SCC, as discussed in ASTM G 49. When uniaxially loaded in tension, the stress pattern is simple and uniform, and the magnitude of the applied stress can be accurately determined. Specimens can be quantitatively stressed by using equipment for application of either a constant load, a constant strain, or an increasing load or strain.

This type of test is one of the most versatile methods of SCC testing because of the flexibility permitted in the type and size of the test specimen, the stressing procedures, and the range of stress level. It allows the simultaneous exposure of

unstressed specimens (no applied load) with stressed specimens and subsequent tension testing to distinguish between the effects of true SCC and mechanical overload.

A wide range of test specimen sizes can be used, depending primarily on the dimensions of the product to be tested. Stress-corrosion test results can be significantly influenced by the cross section of the test specimen. Although large specimens may be more representative of most structures, they often cannot be prepared from the available product forms being evaluated. They also present more difficulties in stressing and handling in laboratory testing.

Smaller cross-sectional specimens are widely used. They have a greater sensitivity to SCC initiation, usually yield test results rapidly, and permit greater convenience in testing. However, the smaller specimens are more difficult to machine, and test results are more likely to be influenced by extraneous stress concentrations resulting from nonaxial loading, corrosion pits, and so on. Therefore, use of specimens less than about 10 mm (0.4 in.) in gage length and 3 mm (0.12 in.) in diameter is not recommended, except when testing wire specimens.

Tension specimens containing machined notches can be used to study SCC and hydrogen embrittlement. The presence of a notch induces a triaxial stress state at the root of the notch, in which the actual stress will be greater by a concentration factor that is dependent on the notch geometry. The advantages of such specimens include the localization of cracking to the notch region and acceleration of failure. However, unless directly related to practical service conditions, the results may not be relevant.

Tension specimens can be subjected to a wide range of stress levels associated with either elastic or plastic strain. Because the stress system is intended to be essentially uniaxial (except in the case of notched specimens), great care must be exercised in the construction of stressing frames to prevent or minimize bending or torsional stresses.

The simplest method of providing a constant load consists of a dead weight hung on one end of the specimen. This method is particularly useful for wire specimens. For specimens of larger cross section, however, lever systems such as those used in creep-testing machines are more practical. The primary advantage of any dead-weight loading device is the constancy of the applied load.

Constant-strain SCC tests are performed in low-compliance tension-testing machines. The specimen is loaded to the required stress level, and the moving beam is then locked in position. Other laboratory stressing frames have been used, generally for testing specimens of smaller cross section.

**Constant Load Testing.** Although the constant extension tests are widely used for evaluating the susceptibility of alloys to stress-corrosion cracking because of the ease of specimen preparation and the ability to test a large number of specimens at one time, there is one major drawback. Once stress-corrosion cracks have formed, the gross cross-section stress decreases, which will eventually cause the crack to stop. Application of a constant or a static load provides an alternative test method that represents some actual field conditions that can provide threshold values. It should be cautioned, however, that such threshold values are strongly dependent on the method of loading (i.e., dead weight or spring) and the specimen size and cannot be considered a materials property. Moreover, Fig. 29 (Ref 244) shows that as a crack develops, the stress at the crack tip increases, possibly decreasing the time-to-failure.

(b)

FIG. 29 SCHEMATIC COMPARISON OF DETERMINATION OF THRESHOLD STRESS INTEGRITY FACTOR ( $K_{ISCC}$  OR  $K_{TH}$ ). (A) CONSTANT-LOAD ( $K$ -INCREASING) TEST. (B) CONSTANT CRACK OPENING DISPLACEMENT ( $K$ -DECREASING) TEST (REF 244)

**Constant Strain Rate Testing.** Constant or slow strain rate testing is a very useful technique to evaluate the susceptibility of materials to SCC in a relatively short period of time (Ref 244, 245). Typical strain rates range between  $10^{-5}/s$  and  $10^{-7}/s$ , but for most materials the typical strain rate is at  $10^{-6}/s$ . The strain sensitivity to SCC can change for different alloys, even of the same metal. Figure 30 (Ref 245) shows that for the 2000 series aluminum alloys, the critical strain rate for the highest susceptibility to cracking is  $10^{-6}/s$ , whereas no such critical strain rate exists for the 7000 series aluminum alloys. This difference in slow strain rate behavior of the two alloys may indicate different mechanisms for

stress-corrosion cracking. The slow strain rate behavior indicates that the principal mechanism for cracking of the 2000 series alloys is film rupture--anodic dissolution model, while the predominant mechanism for cracking of the 7000 series alloys is hydrogen embrittlement.

FIG. 30 STRAIN RATE REGIMES FOR SCC OF 2000, 5000, AND 7000 SERIES ALUMINUM ALLOYS IN A 3% AQUEOUS NaCl SOLUTION PLUS 0.3% H<sub>2</sub>O<sub>2</sub> (REF 245)

The parameters that are typically measured in slow strain rate testing to determine the susceptibility to SCC are:

- TIME TO FAILURE
- PERCENT ELONGATION
- PERCENT REDUCTION IN CROSS-SECTIONAL AREA AT THE FRACTURE SURFACE
- REDUCTION IN ULTIMATE (UTS) AND YIELD (YTS) TENSILE STRESS
- PRESENCE OF SECONDARY CRACKING ON THE SPECIMEN GAGE SECTION
- APPEARANCE OF THE FRACTURE SURFACE

In order to assess the susceptibility of a material to SCC, the results of the slow strain rate test in a particular environment must be compared with those in an inert environment, such as dry nitrogen gas.

### Precracked Specimen Testing

The use of precracked specimens in the evaluation of SCC is based on the engineering concept that all structures contain cracklike flaws (Ref 246, 247). Moreover, precracking can contribute to the susceptibility to SCC of alloys such as titanium alloys, and this susceptibility may not always be evident from smooth specimens.

Precracking eliminates the uncertainties that are associated with crack nucleation and can provide a flaw geometry for which a stress analysis is available through fracture mechanics. Expressing stress-corrosion characteristics in terms of fracture mechanics provides a relationship between applied stress, crack length, and crack growth in a corrosive environment. When the plasticity can be ignored, or in other words, when the plastic zone ahead of the propagating crack is below a certain value and a triaxial or plane strain stress state exists at the crack tip, linear elastic fracture mechanics (LEFM) can be applied to describe the relationship between crack length ( $a$ ) and the applied stress ( $\sigma$ ) by the stress intensity factor  $K$ :

$$K = \sigma \sqrt{a} \cdot F$$

where  $F$  is a polynomial factor that accounts for the specimen geometry. Linear elastic fracture mechanics, and thus the  $K$  factor, cannot be used to describe the relationship between applied stress and the crack length when there is significant plasticity or when the stress state at the crack tip is biaxial or plane stress. Then, a more fundamental parameter, the  $J$  integral, is used.

Almost all standard plane strain fracture mechanics test specimens can be adapted to SCC testing. Several examples are illustrated schematically in Fig. 31 (Ref 248). ASTM Standard E 399 describes the allowable specimen dimensions and test procedures for precracked specimens.

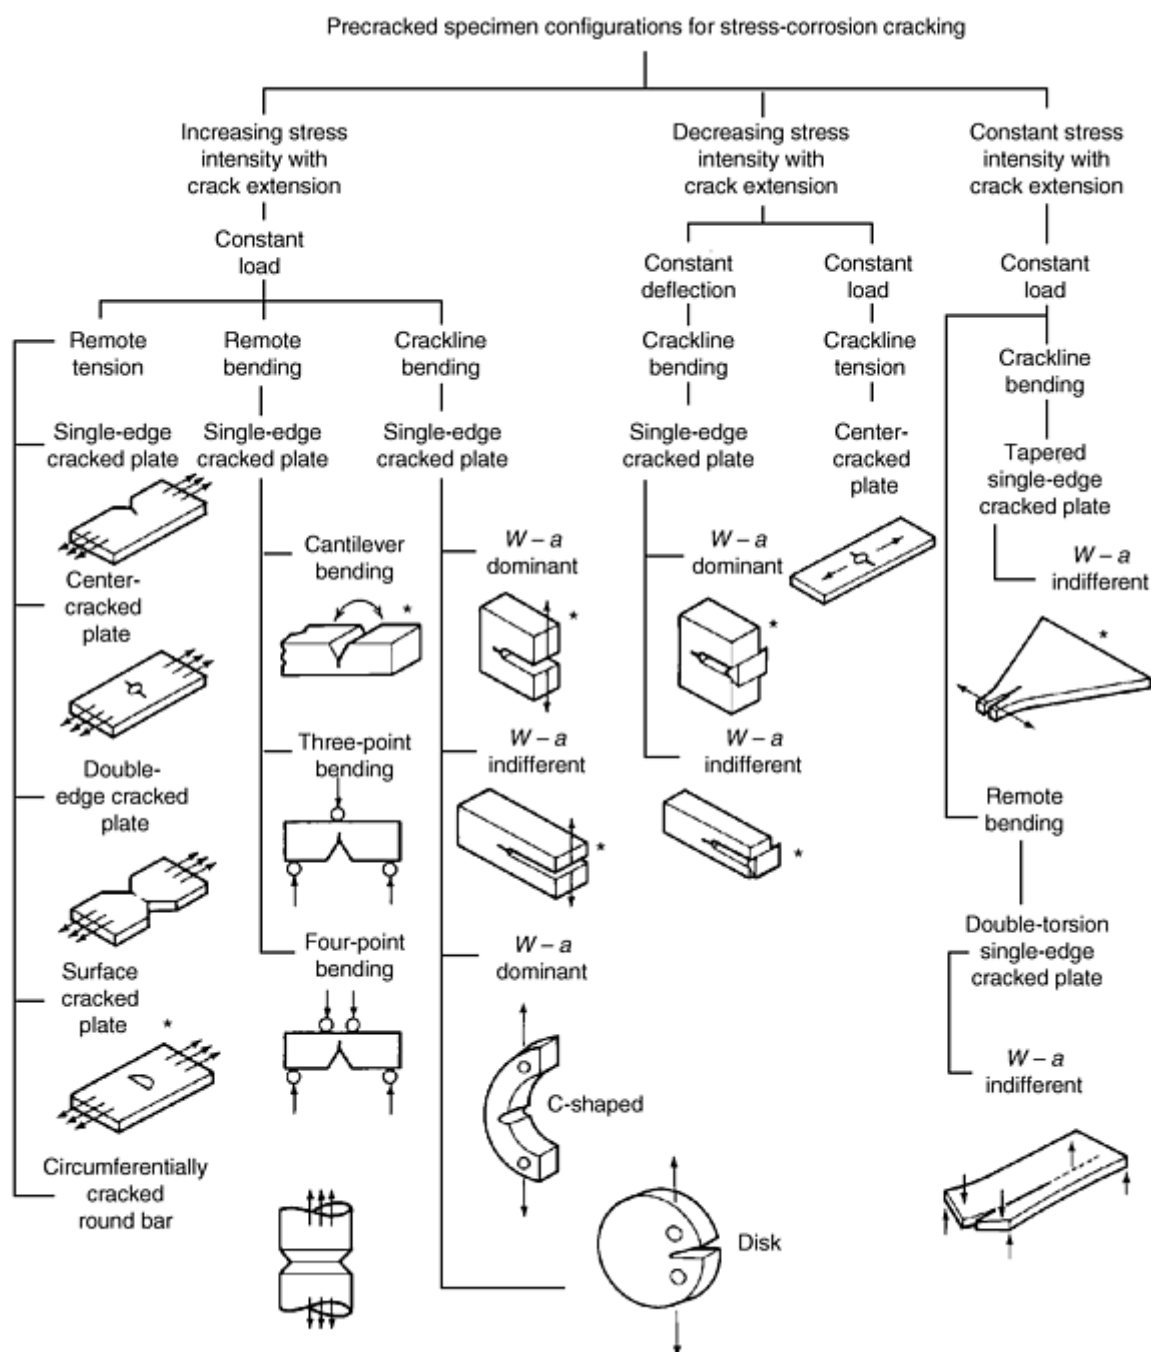

FIG. 31 CLASSIFICATION OF PRECRACKED SPECIMENS FOR SCC TESTING (REF 248)

**Specimen Preparation.** When using precracked fracture mechanics specimens, specific dimensional requirements need to be considered, as well as crack configuration and orientation. The basic dimensional requirement for application of

linear elastic fracture mechanics is that dimensions are such that plane strain condition can be maintained. In general, for a valid  $K$  measurement, neither that crack length nor the specimen thickness should be less than  $2.5 (K_{Ic}/\sigma_Y)^2$ .

Several designs of initial crack configuration are available. ASTM E 399 recommends that the notch root radius is not greater than 0.127 mm (0.005 in.), unless a chevron notch is used, in which case it may be 0.25 mm (0.01 in.). In order to start out with a crack as sharp as possible, ASTM E 399 describes procedures for precracking. The  $K$  level used for precracking should not exceed about two-thirds of the intended initial  $K$  value. This procedure prevents the forming of compressive stresses at the crack tip, which may alter the SCC behavior of the alloys.

Aluminum alloys can also be precracked by the pop-in method, where the wedge-opening method is used to the point of tensile overload. This method cannot be used for steels and titanium alloys, because of the strength of these alloys.

**Loading Procedures.** Stress-corrosion crack growth in precracked specimens can be studied in  $K$ -increasing and  $K$ -decreasing tests (Ref 244). In constant load or  $K$ -increasing tests, crack growth results in increased crack opening, which keeps the environment at the crack tip and corrosion products from interfering with crack growth. One of the problems with this mode of loading is that with increasing  $K$ , the plastic zone ahead of the crack tip may increase and at some point interfere with crack propagation. Moreover, for this type of testing bulky and relatively expensive equipment is required.

Constant displacement ( $K$ -decreasing) tests do not have the problems of the  $K$ -increasing tests indicated above. The plastic zone ahead of the crack tip does not increase with increasing crack size, so that the stress condition always remains in the plane strain mode. Also, the constant displacement tests can be self-loaded, and thus external testing equipment is not needed. Because in these tests the stress-intensity factor decreases with increasing crack growth, the stress-corrosion threshold stress intensity factor ( $K_{Isc}$ ) can be easily determined by exposing a number of specimens loaded to different initial  $K_I$  values. This can even be accomplished by crack arrest in one specimen.

A major problem with this test method occurs when corrosion products form in the crack, blocking the crack mouth and interfering with the environment at this crack tip. Moreover, the oxide can wedge open the crack and change the originally applied displacement and load.

**Measurement of Crack Growth.** In order to quantify the crack growth behavior in precracked stress-corrosion specimens, the crack length needs to be monitored, so that the crack velocity ( $da/dt$ ) can be calculated, and the relationship between the increasing  $K$  and the crack velocity can be determined. There are basically three methods to monitor the growth of stress corrosion cracks: (1) visual/optical measurements, (2) measurement of the crack-opening displacement using clip gages, and (3) the potential drop measurement, which monitors the increase in resistance across two on either side of the propagating crack (Ref 249).

### Introduction

HIGH-TEMPERATURE operating requirements for parts and equipment have drastically increased over the past 20 to 30 years, and businesses such as the utility, aircraft, and chemical industries are greatly dependent on the safe and efficient operation of such equipment. In the power-generation industry, for example, components operate for extended periods of time at temperatures between 0.3 to 0.5 of their absolute melting temperature and have design lives that are limited by creep. Defense and aerospace applications rely heavily on materials that maintain their integrity in the presence of combinations of high temperature and stress (Ref 1). Also, in other cases, as the original design lives are expiring, assessment of the remaining life of components currently in operation with the objective of extending the component service life has become an economic and safety consideration (Ref 2). Many facilities are now relying on retirement-for-cause philosophy to determine the end of service life for parts (Ref 3, 4, 5).

Despite the sophisticated methods of flaw detection that are available, defects and impurities are commonly present in all large components and can potentially escape detection. In the high-temperature regime, components fail by the accumulation of time-dependent creep strains at these defects, which with time evolve into cracks causing eventual failure. This results in financial losses in repair and downtime costs as well as possible loss of human life (Ref 6). This article focuses on the concepts for characterizing and predicting elevated-temperature crack growth in structural materials. Both creep and creep-fatigue crack growth will be considered, focusing mainly on test methods. For a discussion on the application of the data in life prediction, refer to Ref 1, 5, and 7.

### Creep and Creep-Fatigue

Failures that are attributed to creep result from either widespread or localized creep damage (Ref 8). If the part is subjected to uniform stress and temperatures, the damage is likely to be widespread and failure by creep rupture is apt to result. This is most commonly observed in thin section components such as steam pipes. Components with localized damage, which is a result of nonuniform stress and temperature distribution found most commonly in large structures, are more prone to fail as a result of creep crack propagation rather than stress rupture.

Service conditions experienced by components can also involve cyclic loading and unloading at elevated temperatures. Hence, in these situations, crack growth occurs not only under static loading (creep conditions), but creep-fatigue interactions play a major role in the initiation and growth of cracks. Components operating at high temperatures experience changes in conditions from beginning to end of each operating cycle, resulting in transient temperature gradients. Considering the case of steam turbines as an example, cracks in castings are typically located at the steam inlets of high-pressure and intermediate-pressure turbine sections because the local thermal stresses are higher. The primary cause of crack initiation and propagation in turbine casings is fatigue and creep-fatigue and occasionally brittle fracture due to high transient thermal stresses (Ref 4). Thermal stresses are responsible for fatigue and creep-fatigue crack growth (CFCG) in the lower-temperature regions, while creep contributes to crack growth in regions where temperature exceeds 427 °C (800 °F) (Ref 7).

**Creep-Ductile Materials.** Creep and creep-fatigue crack growth is a common occurrence in most engineering materials operating at high temperatures. Materials classified as creep-ductile have the ability to sustain significant amounts of crack growth prior to failure. Also, crack growth in these materials is accompanied by significant amounts of creep deformation at the crack tip. Therefore, a complete understanding of crack growth mechanics and damage mechanisms is required for accurate predictions of life of high-temperature components made from such materials. A typical flow diagram of this methodology is shown in Fig. 1. Examples of such materials include Cr-Mo steels, stainless steels, and Cr-Mo-V steels.

FIG. 1 METHODOLOGY FOR PREDICTING CRACK PROPAGATION LIFE USING TIME-INDEPENDENT FRACTURE MECHANICS

This damage in creep-ductile materials at high temperatures is usually in the form of grain-boundary cavitation. It has been most commonly observed that this cavitation initiates at second-phase particles or defects on the grain boundaries (Ref 9). Nucleation and growth of these cavities lead to coalescence of these voids, eventual crack formation, and growth (Ref 10), which is the primary mechanism of creep crack growth. Failure due to creep-fatigue interaction can be described from two points of view (Ref 11): influence of cyclic loading on cavitation damage and influence of cavitation on cyclic initiation and propagation. These mechanisms are illustrated in Fig. 2, adapted from Ref 11. Three prominent mechanisms for fatigue crack growth at elevated temperatures, in the presence of hold times, are (1) alternating slip mechanism (crack-tip blunting mechanism), (2) fatigue crack growth caused by grain-boundary cavitation, and (3) influence of corrosive environment.

**FIG. 2 SCHEMATIC REPRESENTATION OF MECHANISTIC ASPECTS OF CREEP-FATIGUE. (A) EFFECT OF CYCLING ON CAVITATION DAMAGE. (B) EFFECT OF CAVITATION ON CYCLIC CRACK GROWTH. SOURCE: REF 11**

**Creep-Brittle Materials.** A second class of high-temperature structural materials is known as creep-brittle materials, which include high-temperature aluminum alloys, titanium alloys, nickel-base superalloys, intermetallics, and ceramic materials. The primary difference between this class of materials and the creep-ductile materials discussed previously is that creep crack growth in these materials is usually accompanied by small-scale creep deformation and by crack growth rates that are comparable to the rate at which creep deformation spreads in the cracked body. As discussed later in this

article, this has a significant influence on the crack tip parameters that characterize crack growth rates. Because of these differences, the time-dependent fracture mechanics (TDFM) concepts described in the subsequent discussion will address these two types of material behavior separately.

## Time-Dependent Fracture Mechanics

**Stationary-Crack-Tip Parameters.** As previously mentioned, crack growth in creep-ductile materials lags considerably behind the spreading of the creep zone. Therefore, a practical assumption of a stationary crack tip is made when searching for crack-tip parameters (although the limitations and validity of this assumption in defining crack-tip parameters are discussed later in the section "Conditions with Growing Cracks." ) In order to describe the mechanics of creep and creep-fatigue crack growth, an understanding of the stress-strain-time response at the crack tip of a body subjected to a load in creep-temperature regime must be developed first. The stages of the evolving deformation zone ahead of a crack tip when a member is subjected to a load in the creep regime is shown in Fig. 3. The initial response of the body is elastic-plastic, and the crack-tip stress field is proportional to the stress-intensity factor,  $K$ , if the scale of plasticity is small compared with the crack size (Ref 12, 13). If the plastic zone is not small, the  $J$ -integral characterizes the instantaneous crack tip stresses and strains (Ref 14). With increasing time, creep deformation causes the relaxation of the stresses in the immediate vicinity of the crack tip, resulting in the formation of the creep zone, which continually increases in size with time. Because the parameters  $K$  and  $J$  are independent of time, they are not able to uniquely characterize the crack-tip stresses and strains within the creep zone. The parameters  $C^*$ ,  $C(t)$ , and  $C_I$  have been developed to describe the evolution of time-dependent creep strains in the crack-tip region (Ref 15, 16, 17, 18) and will be discussed later in this section. Within these creep regions, the crack-tip stress and strain fields resemble the Hutchinson-Rice-Rosengren (HRR) fields noted in elastic-plastic fracture mechanics (Ref 19, 20).

**FIG. 3 FORMATION OF DEFORMATION ZONES AHEAD OF CRACK TIP UPON INITIAL LOADING IN THE CREEP REGIME**

For a body undergoing creep, the uniaxial stress-strain-time response for a material that exhibits elastic, primary, secondary, and tertiary creep is given by:

$$\dot{\epsilon} = \frac{\dot{\sigma}}{E} + A_1 \epsilon^{-p} \sigma^{n_1(1+p)} + A\sigma^n + A_3 \sigma^{n_3} (\epsilon - A\sigma^n t)^{p_3} \quad (\text{EQ 1})$$

where  $\epsilon$  and  $\sigma$  are the strain and stress, respectively, and  $\dot{\epsilon}$  and  $\dot{\sigma}$  denote their time derivatives. The values of  $A$ ,  $A_1$ ,  $A_3$ ,  $p$ ,  $p_3$ ,  $n$ ,  $n_1$ , and  $n_3$  are the creep regression constants derived from creep deformation data. The terms on the right-hand side of the equation represent the elastic, primary, secondary, and tertiary creep strain contributions, respectively. This equation is convenient for analyzing the creep deformation behavior of cracked bodies under creep loading conditions.

The crack-tip stress and strain behavior for a creeping body change with time, as a result of continuous evolution of the creep zone. The changes in the creep deformation zone follow the progression shown in Fig. 4. During the initial stage of small-scale creep, the creep zone is small compared with the crack size and the remaining ligament. Primary creep strains accumulate at a faster rate than the secondary creep strains; therefore, the primary creep strains initially dominate this region. Next, the primary creep zone continues to expand, and the secondary creep zone begins to evolve within the primary creep zone. Then the primary creep zone envelopes the entire remaining ligament, while the secondary creep zone continues to grow in size within the primary creep zone. Eventually, the secondary creep zone engulfs the entire remaining ligament. In heavily cavitating materials, the tertiary creep zone begins as a small zone near the crack tip, but can eventually cover the entire remaining ligament. In chromium-molybdenum steels, cavitation is usually limited to a small region near the crack tip, and the consideration of tertiary creep strains is not relevant in estimating the crack tip parameters.

**FIG. 4 CREEP ZONE EVOLUTION. (A) SMALL SCALE PRIMARY CREEP CONDITIONS. (B) SECONDARY ZONE EVOLVING WITHIN THE PRIMARY ZONE. (C) SECONDARY ZONE BECOMING COMPARABLE IN SIZE WITH THE EXTENSIVE PRIMARY ZONE. (D) EXTENSIVE SECONDARY ZONE ENVELOPING OVER THE ENTIRE LIGAMENT (STEADY-STATE CREEP CONDITIONS)**

**Cracked Body Deforming under Steady-State Creep Conditions.** When steady-state creep conditions dominate, as shown in Fig. 4(d), the relationship between stress and strain rate, Eq 1 simplifies to the so-called Norton relation:

$$\dot{\epsilon} = A \sigma^N \quad (\text{EQ 2})$$

For these conditions, the crack-tip parameter,  $C^*$ , was defined by Landes and Begley (Ref 15) and Nikbin, Webster, and Turner (Ref 21) by analogy to the  $J$ -integral. The  $C^*$ -integral is defined as follows:

$$C^* = \int_{\Gamma} W^* dy - T_i \left( \frac{\partial u_i}{\partial x} \right) ds \quad (\text{EQ 3})$$

where

$$W^* = \int_0^{\dot{\epsilon}_{mn}} \sigma_{IJ} D\dot{\epsilon}_{IJ} \quad (\text{EQ 4})$$

is the strain energy rate density associated with the point stress and strain rate. In Eq 3,  $\Gamma$  is an arbitrary counterclockwise line contour starting at the lower crack surface and ending on the upper crack surface enclosing the crack tip and no other defect,  $T_i$  is the component of the traction vector in the direction of the outward normal, and  $ds$  is the increment in the contour path. Figure 5 illustrates this integral on a reference crack-tip coordinate system. A more detailed account of these notations can be found in Ref 22, 23, 24.

FIG. 5 SCHEMATIC OF THE CONTOUR INTEGRAL IN TERMS OF CRACK-TIP COORDINATE SYSTEM USED TO DEFINE  $C^*$ .  $\mathbf{n}$  IS THE UNIT NORMAL VECTOR.

$C^*$  is a path-independent integral whose value can be obtained by calculation of the integral along an arbitrary path, as mentioned before. The  $C^*$ -integral is also related to the energy rate or power difference between two identically loaded specimens having incrementally different crack lengths; therefore,  $C^*$  can be measured at the loading pins of the specimen and defined in that way by:

$$C^* = -\frac{1}{B} \frac{dU^*}{da} \quad (\text{EQ 5})$$

where  $B$  is the specimen thickness and  $U^*$  is the steady-state energy rate (or stress-power) difference between two specimens in which the crack lengths differ by an incremental amount  $da$ , but are otherwise identical. The  $C^*$ -integral also describes the strength of the crack-tip stress and strain-rate singularities (Ref 25):

$$\sigma_{ij} = \left( \frac{C^*}{I_n A r} \right)^{1/(n+1)} \tilde{\sigma}_{ij}(\Theta) \quad (\text{EQ 6})$$

$$\dot{\epsilon}_{ij} = A \left( \frac{C^*}{I_n A r} \right)^{1/(n+1)} \tilde{\dot{\epsilon}}_{ij}(\Theta) \quad (\text{EQ 7})$$

where  $r$  is the distance from the crack tip,  $\Theta$  is the angle from the plane of the crack, and  $\tilde{\sigma}_{ij}(\Theta)$  and  $\tilde{\dot{\epsilon}}_{ij}(\Theta)$  are angular functions specified in Ref 26.  $A$  is the Norton law coefficient in the relation between stress and steady-state creep rate.  $I_n$  is a constant dependent on the steady-state creep exponent  $n$ , whose values may be found in tables (Ref 26). For most values of  $n$  of practical interest,  $I_n$  can be expressed approximately as 3 for plane-stress conditions and 4 for plane-strain conditions. Thus,  $C^*$  characterizes the strength of the crack-tip-stress singularity commonly known as the Hutchinson-Rosengren-Rice (HRR) singularity.

Using the load-line deflection rate, which can be measured directly from the specimen, the applied load and crack length,  $C^*$  can be determined by (Ref 27):

$$C^* = \frac{P \dot{V}_{SS}}{BW} \eta \left( \frac{a}{W}, n \right) \quad (\text{EQ 8})$$

where  $W$  is the specimen width,  $B$  is the specimen thickness,  $\dot{V}_{SS}$  is the steady-state load-line deflection rate, and  $\eta$  is a geometric function that is also dependent on the crack length to width ratio,  $a/W$ , and the secondary creep exponent,  $n$ .

This method of determining  $C^*$  has been successfully used under laboratory conditions with test specimens, most commonly center crack panels and compact tension specimens. For the compact tension geometry, the value of  $\eta$  can be approximated as follows (Ref 2, 28, 29, 30):

$$\eta = \frac{n}{n+1} \left[ \frac{2 + 0.522 \left( 1 - \frac{a}{W} \right)}{1 - \frac{a}{W}} \right] \quad (\text{EQ 9})$$

where the term  $n/n+1$  on the right-hand side of the equation is strictly valid for secondary creep only and is replaced by  $n_1/n_1+1$  when most of the test time is spent under primary creep conditions (Ref 31). The  $C^*$ -integral can also be determined from expressions analogous to the analytical expressions for estimating the fully plastic portion of the  $J$ -integral. This method is useful when the experimental values of the load-line deflection rates are not available and either plane-strain or plane-stress conditions prevail. When planar conditions are prevalent (assumption for most thick or very thin in-service members),  $C^*$  can be calculated as follows for compact tension specimens (Ref 12, 24, 32):

$$C^* = A (W - a) h_1 \left[ \frac{P}{\beta \zeta B (W - a)} \right]^{n+1} \quad (\text{EQ 10})$$

where  $h_1$  depends on  $a/W$ ,  $n$ , and the state of stress (Ref 33),  $\beta$  equals either 1.455 or 1.071 for plane-strain or plane-stress conditions, respectively, and:

$$\zeta = \left[ \left( \frac{2a}{W-a} \right)^2 + 2 \left( \frac{2a}{W-a} \right) + 2 \right]^{1/2} - \left[ \left( \frac{2a}{W-a} \right) + 1 \right] \quad (\text{EQ 11})$$

**Elastic plus Secondary Creep Conditions.** As previously mentioned, the creep deformation zone changes with time and these zones evolve from small-scale to extensive creep conditions. For a cracked body to reach extensive secondary creep conditions, a characteristic transition time,  $t_T$ , has been proposed for when  $C^*$  becomes valid from the time of initial loading (Ref 32, 34):

$$t_T = \frac{K^2(1-\nu^2)}{(n+1)EC^*} \quad (\text{EQ 12})$$

For times less than the calculated value of  $t_T$ , stress redistribution in the crack-tip region cannot be ignored. Thus Eq 2 must be modified to include the elastic term in addition to the power-law creep term. Under these circumstances,  $C^*$  is path-dependent and it no longer uniquely determines the crack-tip stress fields given by Eqs 6 and 7. The size of the secondary creep zone ( $r_c$ ) can be determined by the relationship (Ref 32):

$$R_c(\sigma, T, N) = \alpha K^2 (EAT)^{2(N-1)} \tilde{\Gamma}(\sigma, N) \quad (\text{EQ 13})$$

where  $n$  is the creep exponent and  $\alpha$  is a function of the state of stress and  $n$ , and is given by:

$$\alpha = \frac{1}{2\pi} \left[ \frac{(n+1)I_n}{2\pi(1-\nu^2)} \right]^{2(n-1)}$$

and  $I_n$  is a dimensionless parameter related to the HRR stress field (Ref 26).

For several applications, the transition times may be large in comparison with the average operating time between start-up and shutdown for components. If operational shutdown is accepted as a part of normal operating mode, it is reasonable to infer that some components may never actually reach steady-state conditions, thereby spending their service life in the small-scale and transition creep regimes. Thus  $C^*$  is not applicable for characterizing creep crack growth in these components. Furthermore, primary creep behavior must be incorporated in the above analysis for it to be generally useful.

Even under small-scale creep, in the immediate vicinity of the crack tip, the creep strain rates exceed the elastic strain rates; therefore, selection of any integration path in the creep-dominated region will yield path-independence for the  $C^*$ -integral. The  $C^*$ -integral taken along a path near the crack tip has been called the  $C(t)$  parameter and has been shown to characterize the amplitude of the crack-tip stress and strain fields (Ref 13, 35). For small-scale secondary creep (SSC) conditions,  $C(t)$  can be approximated by the following equation (Ref 32, 34):

$$[C(t)]_{SSC} \cong \frac{(1 - \nu^2) K^2}{(n + 1) Et} \quad (\text{EQ 14})$$

As the extensive creep conditions become prevalent,  $C(t)$  becomes equal to  $C^*$ , and it also becomes completely path-independent. An interpolation formula for analytically estimating  $C(t)$  during small-scale to extensive creep conditions for elastic-secondary creep conditions is given by (Ref 35):

$$C(t) \cong \frac{(1 - \nu^2) K^2}{(n + 1) Et} + C^* \quad (\text{EQ 15})$$

**Consideration of Primary Creep in Crack-Tip Parameters.** Primary creep can be present in the small-scale as well as extensive creep conditions and can be of considerable importance in many elevated-temperature components such as chromium-molybdenum steels (Ref 24). Under extensive primary creep conditions, the second term in Eq 1 becomes dominant. Integrating this term and solving for  $\epsilon$  results in  $\epsilon = \sigma^{n_1+1} [A_1 t (1 + p)]^{1/(1+p)}$ . Because for a given material,  $A_1$ ,  $p$ , and  $n_1$  are constants, the accumulated strain is a function of stress and time. Furthermore, the strain and strain-rate dependence on stress and time is separable. Because of this property, the  $C^*$ -integral is path-independent for extensive primary creep; however, its value changes with time. Primary creep can also be included in the estimation of  $C(t)$  under small-scale creep conditions. The transition time for the progression of small-scale primary creep conditions to evoke extensive primary creep conditions,  $t_1$ , is defined by (Ref 36):

$$t_1 = \frac{1}{n_1 + 1} \left( \frac{J}{C^*} \right)^{p+1} \quad (\text{EQ 16})$$

where  $J$  is the  $J$ -integral (Ref 14). For  $t > t_1$ , extensive primary creep conditions prevail and as mentioned earlier,  $C^*$  is path-independent at a fixed time and thus defined as  $C^*(t)$ , whose value changes with time. It uniquely characterizes the instantaneous crack-tip stresses.  $C^*(t)$ -integral can be related to another path-independent integral,  $C_h^*$ , which is independent of time, by the following equation (Ref 36, 37):

$$C^*(t) = \frac{C_h^*}{(1 + p)t^{p/(1+p)}} \quad (\text{EQ 17})$$

Thus, the time dependence of  $C^*(t)$  can be separated from the crack-size and load-dependent parameter,  $C_h^*$ , which can be determined analytically much like  $J$  and  $C^*$ . For compact specimens (Ref 16):

$$C_h^* = [A_1 (1 + p)]^{1/(1+p)} (W - a) h_1 \left[ \frac{P}{\beta \zeta B (W - a)} \right]^{n_1 + 1} \quad (\text{EQ 18})$$

where  $A_1$ ,  $p$ , and  $n_1$  are the primary creep constants from Eq 1. With continuing evolution of the secondary creep zone within the primary creep zone, the elapsed time for the secondary zone to overtake the primary-zone boundary and engulf the remaining ligament is derived by (Ref 37):

$$t_2 = \left[ \frac{(n+p+1) C_h^*}{(n+1)(1+p) C^*} \right]^{(1+p)/p} \quad (\text{EQ 19})$$

In a manner similar to the determination of the secondary creep zone size, the extent of the primary creep zone during small-scale creep can also be determined:

$$R_C(\sigma, T, N) = \alpha' K^2 [E(A_1 T)^{1/(1+p)}]^{2/(n_1-1)} \tilde{r}(\sigma, N_1) \quad (\text{EQ 20})$$

where  $\alpha'$  is a function of the state of stress and the primary creep exponent  $n_1$ .

A condition commonly observed is one in which both primary and secondary creep strains occur simultaneously in the ligament. The  $C^*(t)$ -integral in this regime can be approximated by the following relationship (Ref 22):

$$C^*(t) \approx \frac{C_h^*}{(1+p)t^{p/(1+p)}} + C_s^* \quad (\text{EQ 21})$$

where  $C_s^*$  is the steady-state value of the  $C^*$ -integral. The  $C(t)$ -integral also characterizes the amplitude of the HRR fields under these conditions and a wide range expression for  $C(t)$  is approximated by (Ref 16):

$$C(t) \approx [C(t)]_{\text{SSC}} + C^*(t) = [C(t)]_{\text{SSC}} + C^* \left[ \left( \frac{t_2}{t} \right)^{p/(p+1)} + 1 \right] \quad (\text{EQ 22})$$

The parameter  $C(t)$  is useful for characterizing the creep crack growth for the small-scale and steady-state regimes. However, one significant disadvantage of  $C(t)$  is that it cannot be measured in the small-scale (transient) region and can only be calculated analytically. In the extensive creep regime,  $C(t) = C^*$  so it can be measured from the load-line displacement readings directly from a test specimen as given earlier in Eq 8.

**The  $C_t$  Parameter.** Because  $C(t)$  cannot be measured at the load-line under small-scale conditions, another parameter,  $C_t$ , has been proposed and shown to characterize creep-crack growth rates under a wide range of creep conditions (Ref 18, 38). The  $C_t$  parameter is defined as the instantaneous rate at which stress-power is dissipated and can be measured at the loading pins in the entire regime from small-scale to extensive creep. Thus by definition,  $C_t$  is equal to  $C^*(t)$  and  $C(t)$  in the extensive regime (Ref 24) and is given by (Ref 18):

$$C_t = \lim_{\Delta a \rightarrow 0} - \frac{\Delta U_t^*}{B \Delta a} = - \frac{1}{B} \frac{\partial U_t^*}{\partial a} \Big|_{V_c} \quad (\text{EQ 23})$$

where  $B$  is the specimen thickness,  $a$  is crack length, and  $\Delta U_t^*$  is the instantaneous difference in the stress power between two cracked bodies that have incrementally differing crack lengths of  $\Delta a$  but are otherwise identical.

For small-scale creep conditions, the Irwin concept of effective crack length has been modified to define a stationary crack to accommodate the expression for  $C_t$  (Ref 18, 38):

$$A_{\text{EFF}} = A + \chi \dot{r}_C \quad (\text{EQ 24})$$

In this equation,  $\chi$  is the scaling factor, which is approximately equal to  $\frac{1}{3}$  as determined by finite element analysis (Ref 39, 40),  $\dot{r}_c$  is the creep zone size,  $a_{\text{eff}}$  is the effective crack length, and  $a$  is the physical crack length. This leads to an expression for  $C_t$  in the small-scale creep regime (Ref 18, 24) in which the load-line deflection can be directly measured during the test:

$$(C_t)_{\text{SSC}} = \frac{P(\dot{V}_c)_{\text{SSC}}}{BW} \frac{F'}{F} \quad (\text{EQ 25})$$

where

$$F\left(\frac{a}{W}\right) = \frac{KB\sqrt{W}}{P}; \quad F'\left(\frac{a}{W}\right) = \frac{dF}{d\left(\frac{a}{W}\right)}$$

Analytically, the small-scale creep deflection rate can be determined by (Ref 38):

$$(\dot{V}_c)_{\text{SSC}} = \frac{2B(1-\nu^2)}{EP} K^2 \chi \dot{r}_c \quad (\text{EQ 26})$$

Substituting Eq 26 into Eq 25, an equation which directly relates  $(C_t)_{\text{SSC}}$ ,  $K$  and  $\dot{r}_c$  is determined:

$$(C_t)_{\text{SSC}} = 2(1-\nu^2) \chi \left(\frac{F'}{F}\right) \frac{K^2 \dot{r}_c}{EW} \quad (\text{EQ 27})$$

Using Eq 27, an analytical expression for a stationary crack can be derived for  $(C_t)_{\text{SSC}}$  in which knowledge of load-line deflection is not needed, assuming that constants in the appropriate creep constitutive laws are available (Ref 38). For example, for elastic, secondary creep  $(C_t)_{\text{SSC}}$  can be given by:

$$(C_t)_{\text{SSC}} = \frac{4\alpha \chi \tilde{r}_c (1-\nu^2)}{E(n-1)} (EA)^{2(n-1)} \frac{K^4}{W} \frac{F'}{F} \left(\frac{1}{t}\right)^{(n-3)(n-1)} \quad (\text{EQ 28})$$

where  $\alpha$  has been previously defined.

An expression for estimating  $C_t$  for a wide range of creep conditions from small-scale creep to extensive creep and also including primary creep has been derived that is very similar to the way in which  $C(t)$  is derived (Ref 2, 18, 41):

$$C_T = (C_T)_{\text{SSC}} + C^*(T) \quad (\text{EQ 29})$$

where the value of  $(C_t)_{\text{SSC}}$  can be either experimentally determined from Eq 25 or analytically determined from Eq 27. If Eq 25 is used, the expression to measure  $C_t$  experimentally over the entire secondary creep range is given as (Ref 38):

$$C_t = \frac{P(\dot{V}_c - \dot{V}_{\text{SS}})}{BW} \left[ \frac{F'}{F} \right] + C^* \quad (\text{EQ 30})$$

where the load-line deflection rate in extensive creep conditions is subtracted from the total rate of deflection caused by creep.

Furthermore, a wide range expression for determining  $C_1$  in the presence of primary and secondary creep conditions has been determined in a similar manner as Eq 22 (Ref 41, 42):

$$C_1 = \frac{P \left[ \dot{V}_c - \dot{V}^*(t) \right]}{BW} \frac{F'}{F} - C^* \left[ \left( \frac{t_2}{t} \right)^{\rho/(1+\rho)} + 1 \right] \quad (\text{EQ 31})$$

where  $\dot{V}^*_c(t)$  is the load-line deflection rate under extensive primary-secondary creep conditions.

**Conditions with Growing Cracks.** As previously stated, all the crack-tip parameters discussed thus far are based on the assumption of a stationary crack tip. Crack growth can significantly alter the crack-tip stress fields if the rate of crack growth is comparable to the rate at which creep deformation spreads at the crack tip. For a crack progressing with a velocity  $\dot{a}$ , the stress fields are dependent on the crack velocity by (Ref 43):

$$\sigma_{ij} = \alpha \left[ \frac{\dot{a}}{AEr} \right]^{1/(n-1)} \tilde{\sigma}_{ij}(\Theta) \quad (\text{EQ 32})$$

This stress field is alluded to as the Hui-Riedel (HR) field. By solving for  $r$  in Eq 6 and 32 and then setting them equal, it can be shown that for steady-state creep, stress distribution within the HR field is (Ref 44):

$$\sigma_{ij} = \left( \frac{EC^*}{\dot{a}} \right)^{1/2} \beta_1(\Theta) \quad (\text{EQ 33})$$

It is intuitive from this equation that the extent of the HR field must be small in comparison to the extent of the HRR field for  $C^*$  (or  $C_1$ ) to uniquely characterize the creep crack growth rate. By equating Eq 32 and 33, an estimation of the HR field size can be obtained. For materials in which the crack growth behavior is characterized by  $C^*$  (or  $C_1$ ), the size of the HR zone has been estimated to be on the order of  $0.01 \dot{A}$  which is negligible (Ref 43). This implies that  $C^*$  is a viable parameter even in the presence of growing cracks, provided the crack growth is slow in comparison to the rate of spread of creep deformation. This condition can be ensured by applying deflection-rate partitioning as shown below (Ref 27, 29):

$$\begin{aligned} \dot{V} &= \dot{V}_c + \dot{V}_p + \dot{V}_e \\ &= \dot{a} \left[ \left( \frac{\partial V_c}{\partial a} \right)_p + \left( \frac{\partial V_p}{\partial a} \right)_p \right] + \dot{V}_c \end{aligned} \quad (\text{EQ 34})$$

The term on the left side of Eq 34 is the total load-line deflection rate at constant load, while the first two terms on the right side are the deflection rates due to crack growth as a result of elastic and plastic compliance change, and the third term is due to creep deformation. The contribution of deflection due to creep is found by subtracting the deflection rates attributed to the change in elastic and plastic compliances from the total deflection rate:

$$\dot{V}_c = \dot{V} - \dot{a} \frac{B}{P} \left[ \frac{2K^2}{E} + (m+1)J_p \right] \quad (\text{EQ 35})$$

where  $J_p$  is the plastic portion of  $J$  and  $m$  is the plasticity exponent. Stationary crack tip parameters can only be used as long as the second term in the right-hand side contributes negligibly to  $\dot{V}_c$ . This condition is ensured by allowing only those data for which  $\dot{V}_c/\dot{V} \geq 0.8$  (Ref 45).

### Creep-Brittle Materials

In many situations, the crack growth rate is comparable to the rate of expansion of the creep zone, and the crack can no longer be assumed to be effectively stationary within an expanding creep field. These conditions are typical of creep-brittle materials, where the rate of creep strain accumulation at the crack tip is comparable to crack extension rates and where crack growth significantly perturbs the crack-tip stress field. Stated in another way, the HR field is no longer small in comparison to the extent of the HRR fields. Thus, the stationary-crack-tip parameters no longer characterize the crack-tip conditions and can no longer be expected to correlate uniquely with creep crack growth rate.

In creep-brittle materials, the rate of deflection caused by creep deformation represents only a small percentage of the total deflection rate; therefore, in the absence of significant plasticity, the rate of deflection caused by change in elastic compliance is comparable to the total deflection rate. Because the elastic contribution is analytically determined and the total deflection rate is experimentally measured, Eq 35 can sometimes erroneously yield negative creep deflection rates due to experimental error in the total deflection rate measurement. The negative creep deflection rates result in negative  $C_t$  values, which have no clear physical interpretation. Negative  $C_t$  values can also sometimes result if the creep zone size decreases (Ref 46), which is often the case in creep-brittle materials following incubation or toward the end of the test even in creep-ductile materials when stable crack growth sets in and the crack grows very rapidly. This aspect will be discussed in more detail in the next section.

Because Eq 35 is accurate only when the creep deflection rate dominates the total deflection rate, the equation lacks precision for creep contributions less than 80% of the total deflection (Ref 45). Therefore, the use of this equation and also the crack-tip parameters  $C_t$  and  $C^*$  is not suitable in creep-brittle materials.

Under special circumstances, time-independent fracture parameters, such as the  $J$ -integral (Ref 19, 20) or  $K$ , may correlate with the creep crack growth rate in creep-brittle materials. At elevated temperatures, some aluminum alloys have exhibited such creep-brittle behavior. For example, correlations between the creep crack growth rate and  $K$  have been established for aluminum alloys 2219-T851 (Ref 47, 48), 2519-T87 (Ref 49), and to a limited extent for 8009 (Ref 50). Similar correlations have also been demonstrated for other creep-brittle materials such as Ti-6242 (Ref 51) and for carbon-manganese steels at temperatures of 360 °C (680 °F) as discussed later in this article.

The precise conditions under which  $K$  or  $J$  characterize the crack growth behavior of creep-brittle materials are not yet well understood. However, the creep deformation resistance of creep-brittle materials is believed to be a significant factor.

The accumulation of creep strain ahead of the crack tip is impeded in creep-brittle materials by microstructural features such as precipitates or dispersoids, and simultaneously decreasing rupture ductility increases the crack growth rate. As a result, the creep crack growth rate and the rate of creep strain accumulation in the crack-tip region are comparable. The movement of the crack perturbs the crack-tip stress fields, and it is no longer possible to represent the crack-tip fields using the Riedel-Rice formulation (Ref 32). In an idealized situation, one can imagine that the creep zone boundary and the crack tip in the plane of the crack move at equal speeds. Thus, the creep zone size at the crack tip remains constant, and using a coordinate system that moves with the crack tip as reference, the crack-tip stress field is also constant and completely determined by  $K$ . If it is assumed that the creep zone size remains small with respect to the pertinent length dimensions of the specimen and the shape also remains constant, creep crack growth is expected to correlate uniquely with  $K$ . In practice, all these conditions are most likely seldom met. Nevertheless, correlations between creep crack growth rates and  $K$  have been observed. However, the limitations of such correlations are not well understood. This remains an area of active research.

**Incubation Period.** When a cracked specimen is first loaded at elevated temperature, the material ahead of the crack tip is free from prior creep damage and, therefore, time-dependent crack growth does not begin instantly. Creep crack growth studies have shown that crack extension occurs following a specific time period, which has been termed incubation time. Incubation models based on ductility exhaustion and creep cavitation concepts have been developed (Ref 10, 52, 53); however, incubation time currently lacks a precise definition among researchers because it is unknown if the crack actually remains stationary during this period or if the crack grows at an indiscernible rate. Some researchers have defined the incubation period as the time required for the crack to grow through the initial creep zone size (Ref 54), while others have defined it based on a certain increase in the direct current potential drop output when utilizing the potential drop technique to monitor crack extension (Ref 55).

The incubation period is more pronounced in creep-brittle materials than in creep-ductile materials, and it can comprise nearly 90% of the total test time during creep crack growth testing of creep-brittle specimens. Thus, incubation period is vitally important when considering the creep crack growth characteristics of creep-brittle materials. The correlation between the creep crack growth rate and the stress-intensity factor displays a steep slope in creep-brittle materials, indicating that the crack growth rate rapidly increases for very small increases in  $K$ . The  $K$ -range, therefore, over which creep crack extension occurs prior to specimen fracture is small. Thus, once the crack begins to grow, the test material cannot sustain stable crack extension for a significant duration before failure occurs, a characteristic that limits the engineering application of the material. Some studies, however, indicate that the incubation period required prior to crack extension quickly increases for small decreases in the initial  $K$ -level (Ref 49). For some critical  $K$ -levels and below, the incubation time may be so large that the crack effectively remains stationary within the testing time frame. Total time to failure, therefore, must be considered to be a combination of the incubation period prior to crack initiation and the crack growth period following crack initiation. Evaluation of the test material for engineering applications cannot solely rely on the  $da/dt$ - $K$  correlation, but must take into account the time required to initiate creep crack growth.

### Crack-Tip Parameters for Creep-Fatigue Crack Growth

From previous sections,  $C_t$  appears to be the most appropriate crack-tip parameter for correlating creep crack growth over the regime from small-scale creep to extensive creep conditions for creep-ductile materials. The average value of  $C_t$ ,  $(C_t)_{avg}$ , is used for characterizing the average crack growth rate,  $(da/dt)_{avg}$ , in creep-fatigue experiments (Ref 56, 57, 58, 59, 60).

The value of  $(C_t)_{avg}$  is determined by two methods. The first method is suitable for specimens when load-line deflections during hold time are available, while the second is well suited for components when the load-line deflection must be calculated using the deformation laws for the material. Expressions for calculating  $(C_t)_{avg}$  from laboratory experiments and in components have been developed (Ref 56, 61, 62, 63). The discussion here focuses on calculating  $(C_t)_{avg}$  from experimental measurements because the primary emphasis in this article is on test methods for characterizing creep and creep-fatigue crack growth.

For materials whose deformation behavior is characterized by elastic, secondary creep,  $(C_t)_{avg}$  can be determined as follows (Ref 63):

$$(C_t)_{avg} = \frac{\Delta P \Delta V_c}{B W t_h} \frac{F'}{F} - C^* \left( \frac{F'}{F} \frac{1}{\eta} - 1 \right) \quad (\text{EQ 36})$$

where  $\Delta P$  is the applied load range,  $\Delta V_c$  is the load-line deflection change due to creep during hold time  $t_h$ . Because the amount of crack extension during hold times is small, the change in total deflection during hold times is approximately equal to  $\Delta V_c$ . The remaining variables have been previously defined. As previously noted for compact specimens, the ratio  $(F'/F)^{1/\eta} \approx 1$ , thus Eq 36 can be written as (Ref 57):

$$(C_t)_{avg} = \frac{\Delta P \Delta V_c}{B W t_h} \frac{F'}{F} \quad (\text{EQ 37})$$

It is also noted that the  $\Delta V_c$  value in Eq 37 includes both primary and secondary creep contributions to the load-line deflection change. Thus Eq 37 also accounts for primary creep deformation in the estimation of  $(C_T)_{avg}$ . The  $(da/dt)_{avg}$  is calculated as follows:

$$\left(\frac{da}{dt}\right)_{avg} = \frac{1}{t_h} \left[ \left(\frac{da}{dN}\right) - \left(\frac{da}{dN}\right)_{cycle} \right] \quad (\text{EQ 38})$$

where  $(da/dN)_{cycle}$  is the cyclic crack growth rate and has to be obtained from a continuous cycling fatigue crack growth rate test for which the rise and decay times are usually the same as the trapezoidal waveform used in the creep-fatigue crack growth tests. The overall crack growth rate,  $da/dN$ , is calculated from the crack length measurements during the creep-fatigue crack growth test.

## Creep Crack Growth Testing

Creep crack growth tests are performed in accordance with ASTM E 1457, "Measurement of Creep Crack Growth Rates in Metals" (Ref 45) using the compact specimen geometry. The test procedure involves heating precracked specimens to the prescribed test temperature and applying a constant load until significant crack extension or specimen failure occurs. During the test, the crack length and load-line deflection are constantly monitored with time. The reduced test data compare the time rate of crack growth,  $da/dt$ , in terms of an elevated-temperature crack growth parameter described in the earlier section of this article.

## Equipment

**Specimen Configuration.** The most widely used specimen configuration for creep and creep-fatigue crack growth testing is the compact-type (CT) specimen as shown in Fig. 6. Certain special dimensional requirements such as notch configuration and specimen width-to-thickness ratios can be found in ASTM specifications (Ref 45). Other configurations such as the center-cracked tensile (CCT) panel and single-edge notch (SEN) specimens have also been used; however,

due to several reasons of convenience, the CT specimen geometry remains the most suitable geometry for creep and creep-fatigue crack growth testing. First, the transition time for extensive creep conditions to develop in CT specimens is longer than in CCT specimens for the same  $K$  and  $a/W$  for specimens of same width ( $W$ ) (Ref 64). Because of the longer transition times in the CT specimens, the condition that  $t_c/t_1 \ll 1$  during creep-fatigue testing, where  $t_c$  is the cycle time, is more easily satisfied. Another advantage of the CT specimen is that a clip-gage can be conveniently placed at the load-line to measure the deflection change. This is important for reliable and direct measurement of load-line deflection change, which is the measured quantity required to calculate the crack-tip parameters. Perhaps the most important advantage of CT specimens is that the magnitude of the applied load for the same applied value of  $K$  is significantly lower than for CCT specimens. Thus, smaller load capacity machines and smaller fixturing can be used for testing.

FIG. 6 TYPICAL COMPACT TENSION SPECIMEN DIMENSIONS (IN INCHES) FOR A 1.00 IN. THICK (1T) SPECIMEN PER ASTM E 1457. SPECIMEN THICKNESS ( $B$ ) IS RELATED TO WIDTH ( $W$ ) AS  $B = 0.5W \pm 0.005 W$ .

**Test Machine.** Creep crack growth testing should be performed in either deadweight or servomechanical test machines that are capable of maintaining a constant load over an extended period of time. During the duration of the testing, variations in loading must not exceed  $\pm 1.0\%$  of the nominal value at any time. When using cantilever-type deadweight creep machines, it is important that the lever remain as close to horizontal as possible. The cantilever loading conditions are performed such that the loading ratios are 20 to 1 or 10 to 1, depending on the level length. Significant deviation of the cantilever from the level position results in significant variations in the load on the specimen. ASTM E 4 "Practices for Load Verification of Testing Machines" (Ref 65) details the required accuracy for the test equipment.

Creep-fatigue tests can be conducted under either load-controlled or displacement-controlled conditions. Figure 7 (Ref 66) shows various waveforms used for load-controlled testing in which the specimen is cycled between a fixed maximum and minimum load value. The displacement versus time and crack size versus time responses in these tests are shown schematically in Fig. 8(a). Displacement-controlled tests involve cycling between fixed displacements as shown schematically in Fig. 8(b) (Ref 66) along with the corresponding changes in the load-line displacement and the load versus time and crack size versus time responses.

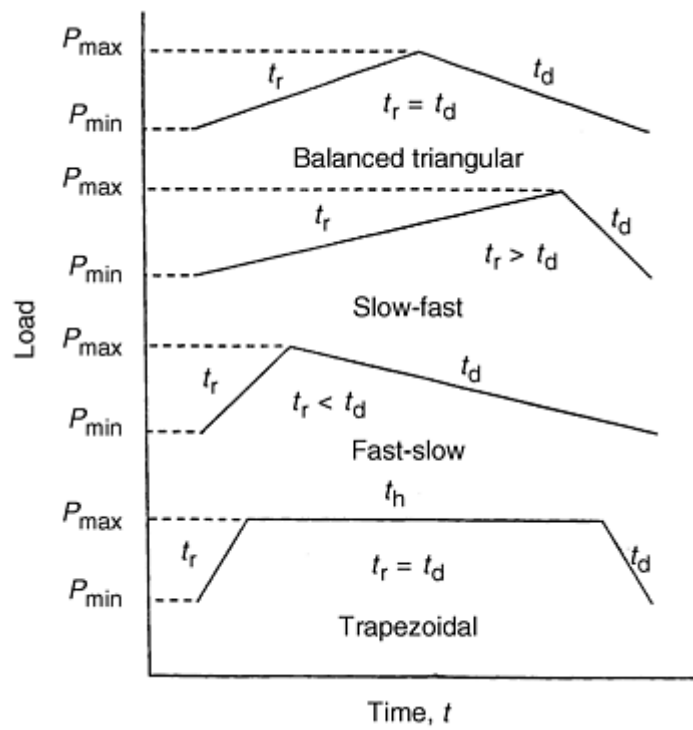

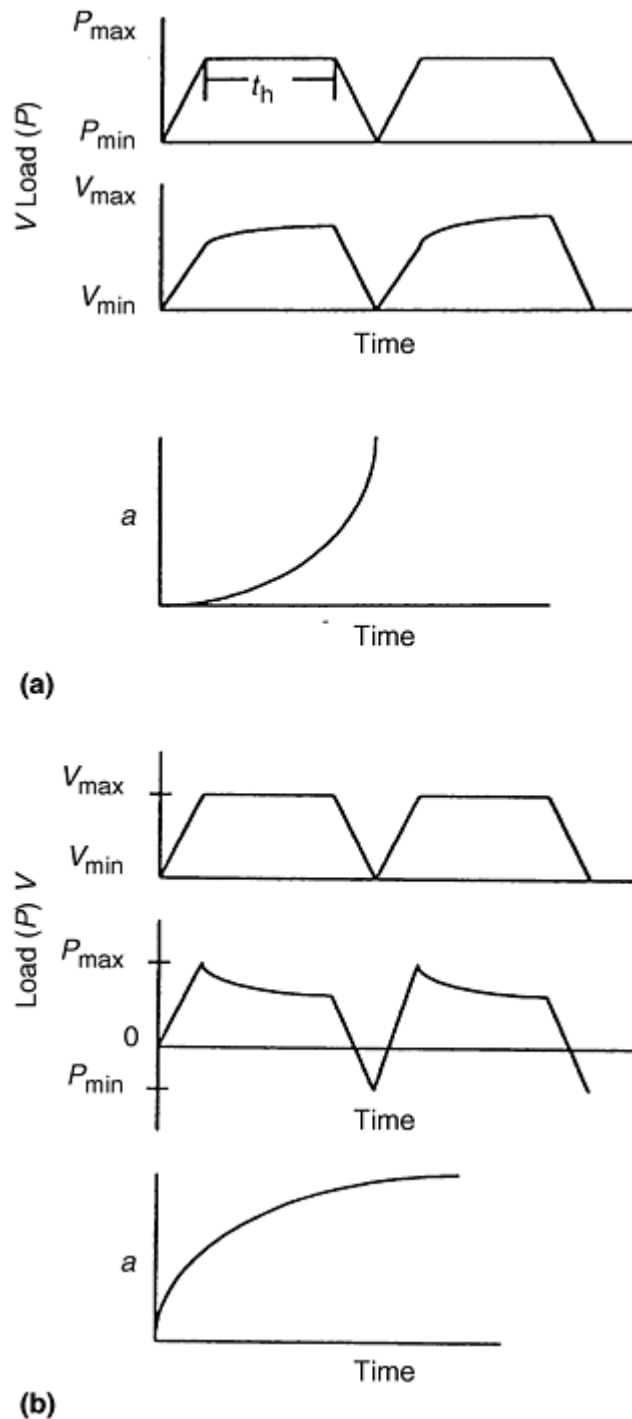

FIG. 7 TYPICAL LOADING WAVEFORMS USED DURING CREEP-FATIGUE CRACK GROWTH TESTING. SOURCE: REF 66

**FIG. 8 SCHEMATIC COMPARISON OF LOAD-CONTROLLED (A) AND DISPLACEMENT-CONTROLLED (B) TESTING UNDER TRAPEZOIDAL LOADING. SOURCE: REF 66**

The majority of the creep-fatigue testing performed to date has been under load-control conditions, largely because it is more convenient. Displacement-controlled testing requires specially designed grips that ensure that the specimen does not buckle or experience any torsional stresses during the compressive portion of the loading. However, this type of testing has some advantages over load-controlled testing, as discussed below.

In load-controlled tests, the net section stress ahead of the crack rises continuously as the crack grows. Thus, the stress-intensity factor continuously increases with crack growth while the size of the remaining ligament decreases. The scale of plasticity or creep in the specimen increases as the test progresses causing ratcheting in the specimen with accumulation of inelastic deflection after each cycle. In displacement-controlled tests, the applied load decreases with crack extension,

as shown in Fig. 8(b), and the specimen deflection is forced to the minimum value at the end of each cycle. Therefore, ratcheting of displacement cannot occur (Ref 67), and data can be collected for greater crack extensions than in load-controlled tests. Load-controlled tests are suitable for low crack growth rates, and displacement amplitude tests are more suitable for higher crack growth rates ( $>4 \times 10^{-6}$  mm/cycle) and longer hold time tests. Gladwin et al. (Ref 68) have noted that added complication due to static modes of fracture (e.g., tearing) may influence the creep-fatigue damage process in positive  $R$  load-controlled tests. Therefore, the apparent accelerations in crack growth rate associated with the hold time (creep damage) may be a result of, for example, stable tearing effects due to large deformations caused by ratcheting effects rather than the result of true creep-fatigue interaction (i.e., accelerated fatigue crack growth because of creep damaged material) (Ref 68). This problem is avoided when testing is performed under displacement range control.

**Specimen heating** is usually performed in electric resistance furnaces or convection laboratory ovens. Temperature control should be within  $\pm 2$  °C ( $\pm 3$  °F) for tests performed at temperatures up to 1000 °C (1800 °F) and  $\pm 3$  °C ( $\pm 5$  °F) for tests above 1000 °C (1800 °F). Specimens are usually tested in air at atmospheric pressure; however, inert atmosphere environments and vacuum conditions have been used and aid in the reduction of the effects of oxidation and other forms of corrosion. Thermocouples are used to monitor the specimen temperature. The thermocouples should be located in the uncracked ligament within a 2 to 5 mm (0.08 to 0.2 in.) region around the crack plane. Thermocouples should be in intimate contact with the specimen. Ceramic insulation is recommended for covering the individual lines to prevent shorting of the temperature circuit.

**Fixturing.** Pin-and-clevis assemblies are used to support test specimens in the load frames. This type of fixturing is used on both top and bottom specimen faces and allows in-plane rotation during specimen loading and during subsequent crack extension. Materials used for these fixtures must be creep resistant and able to withstand the loading and temperatures employed. The fixtures can be fabricated from grades 304 and 316 stainless steel, grade A286 steel, Inconel 718 and Inconel X-750 in the annealed or solution-treated condition. After fabrication, hardenable parts should be heat treated so that they develop resistance to creep deformation.

**Fatigue precracking** is performed on creep test specimens to eliminate any effects of the machined notch and to provide a sharp crack for initial crack growth. The methodology for fatigue precracking is described extensively in ASTM E 399, "Test Method for Plane-Strain Fracture Toughness of Metallic Materials" (Ref 69) and also briefly in the article "Fracture Toughness Testing" in this Volume. The precracking is to be carried out on the material in the same condition in which it is to be tested for creep crack growth behavior. The precracking can be performed between room temperature and the anticipated test temperature. The equipment used to precrack should allow symmetric load distribution in reference to the machined notch, and the maximum stress-intensity factor during the operation,  $K_{max}$ , should be controlled within  $\pm 5\%$ . The procedure may be carried out at any frequency that allows accurate load application, and the specimen should be precracked to at least a length of 2.54 mm (0.100 in.).

The initial precracking is conducted at stress intensities high enough to allow crack initiation and growth out of the machined starter notch and with growth of the precrack, the load is decreased to avoid transient effects and to allow lower stress intensities for the creep test. The load values for precracking,  $P_f$ , are determined so as not to exceed the following value (Ref 45):

$$P_f = \frac{0.4B_N (W - a_0)^2 \sigma_{YS}}{(2W + a_0)} \quad (\text{EQ 39})$$

where  $B_N$  is the corrected specimen thickness,  $W$  is the specimen width, and  $a_0$  is the initial crack length measured from the load-line and  $\sigma_{YS}$  is the yield strength. During the final 0.64 mm (0.025 in.) of fatigue precrack extension, the maximum load should not be larger than  $P_f$  as determined from above or a load such that the ratio of the stress-intensity factor range to the Young's modulus ( $\Delta K/E$ ) is equal to or less than  $0.0025 \text{ mm}^{\frac{1}{2}}$  ( $0.0005 \text{ in.}^{\frac{1}{2}}$ ) (Ref 45), whichever is smaller. In doing so it is ensured that the final precrack loading does not exceed the initial load used during creep crack growth testing.

The crack length during precracking can be measured optically with a traveling microscope if the test is being performed at room temperature, and if the precracking is performed at elevated temperature, the electric potential drop technique can be used. Measurement of the fatigue precrack should be accurate within 0.1 mm (0.004 in.). Measurements should be made on both surfaces, and the value should not vary more than 1.25 mm (0.05 in.). If the surface cracks exceed this range, further extension is necessary until these criteria are met.

## Required Measurements

**Crack Length Measurement (Electric Potential Method).** In monitoring the crack propagation during the elevated-temperature creep test, crack extensions must be resolved to at least 0.1 mm (0.004 in.). Because optical measurement techniques within an enclosed furnace are not feasible and the through-thickness crack fronts sometime differ significantly from observed surface lengths, crack length measurements are most commonly made during an elevated-temperature creep test using the electric potential drop technique. By applying a fixed electric current, any increase in crack length (a corresponding decrease in uncracked ligament) results in an increase in electric resistance, which is noted as an increase in output voltage across the output locations.

The current input and voltage output lead locations for typical CT and CCT specimens are shown in Fig. 9. These leads can either be welded onto the specimen or connected with screws. The choice of application method is dependent on material and test temperature. For softer materials tested at lower temperatures, threaded connections would be acceptable, but for harder materials and especially at higher temperatures, welding of leads is recommended. The leads should be sufficiently long to allow current input devices and output voltage measuring instruments to be well away from the furnace to avoid excessive heating. The leads should also be approximately the same length and contain similar junctions to avoid excessive lead resistance, which contributes to the thermal voltage,  $V_{th}$  as described below. Use of 2 mm (0.08 in.) diameter stainless steel wires have been shown to work well because of superior oxidation resistance at elevated temperature; however, any oxidation-resistant material capable of carrying a current that is stable at the test temperature may be utilized as lead connectors. Nickel and copper wires have been successfully used as lead material for lower temperature tests.

(a)

(b)

**FIG. 9 INPUT CURRENT AND VOLTAGE OUTPUT LEAD LOCATIONS FOR TYPICAL COMPACT (A) AND CENTER-CRACKED TENSION SPECIMENS (B)**

When using the direct current electric potential method, the instantaneous voltage  $V$  and the initial voltage  $V_0$  usually deviate from the indicated readings. This is due to the thermal voltage,  $V_{th}$ , which is caused by several factors, such as differences in the junction properties of the connectors used, differences in the resistance of the output leads, differing output lead lengths, and temperature differences in output leads themselves. Measurements should be taken of the  $V_{th}$  prior to the load application and at various times during the test. These measurements are made by turning off the current source and recording the output voltage. Before analyzing the crack length data, the values of  $V_{th}$  should be subtracted from the respective  $V$  and  $V_0$  in order to determine the actual crack extension.

Knowing the corrected original voltage,  $V_0$ , and the corrected instantaneous change in voltage during crack extension,  $V$ , the crack length in a CT specimen can be computed by using the following closed form equation (Ref 55, 70):

$$a_i = \frac{2W}{\pi} \cos^{-1} \left\{ \frac{\cosh\left(\frac{\pi Y_0}{2W}\right)}{\cosh\left[\frac{V}{V_0} \cosh^{-1}\left(\frac{\cosh\frac{\pi Y_0}{2W}}{\cos\frac{\pi a_0}{2W}}\right)\right]} \right\} \quad (\text{EQ 40})$$

where  $a_i$  is the instantaneous crack length,  $a_0$  is the original crack length after precracking,  $Y_0$  is the half separation distance between the voltage output leads,  $V_0$  is the initial output voltage before load application,  $V$  is the instantaneous output voltage, and  $W$  is the specimen width.

Materials with high electrical conductivities can experience fluctuations in  $V_{th}$ . These fluctuations can be of the same magnitude as the voltage changes that accompany crack extension and could mask this information. Because of the potential variation in thermal voltage, the direct current electric potential method should not be the only nonvisual technique for crack length measurement. The use of more sophisticated electric potential setups, such as the reversing potential method, is recommended.

Crack lengths, both initial and final, are required to differ by no more than 5% across the specimen thickness. Maintaining a straight crack front is sometimes dependent on material and material thickness. Upon post test examination, thicker specimens have been noted to experience crack tunneling, or nonstraight crack extension. Crack tunneling (thumbnail-shaped crack fronts) is common in non-side-grooved (or parallel-sided) specimen configurations (Ref 8). This occurrence is a direct result of the conditions being closer to plane stress near the surfaces of the specimen and plane strain in the center, which results in higher crack growth rates near the specimen center. Side grooving of test specimens on the crack plane has been shown to greatly reduce this problem. Side grooves up to 25% in reduction are acceptable, but reductions of approximately 20% have been found to work well for many materials. The included angle of the grooves is typically less than  $90^\circ$  with a root radius less than or equal to  $0.4 \pm 0.2$  mm ( $0.016 \pm 0.008$  in.). It is prudent to perform the side grooving after fatigue precracking because precracks are hard to see when located in the grooves.

**Load-Line Deflection Measurements.** Continuous displacement measurements are needed in the determination of the crack-tip parameters for the duration of the testing. These displacement readings should be taken directly from the load-line as much as possible. For CT specimens, the measuring device should be attached on the machined knife edges of the specimens. For CCT specimens, the deflection is to be measured on the load line at points that are  $\pm 35$  mm ( $\pm 1.40$  in.) from the crack centerline. The measurement of the displacement can be directly measured by placing an elevated-temperature clip gage (either strain gages for temperatures up to approximately  $150^\circ\text{C}$  ( $300^\circ\text{F}$ ) or capacitance gages for higher temperatures) on the specimen and placing the entire assembly inside the furnace. If this type of device is not available, the displacements may be transferred outside the furnace with a rod-and-tube assembly that is connected to a displacement transducer--either a direct current displacement transducer (DCDT), linear variable displacement transducer (LVDT), or capacitance gage--outside the furnace. In these transfer-type displacement devices the transfer rod and tubes

should be fabricated of material that experiences low thermal expansion and is thermally stable (Ref 45). The resolution of these deflection measurement devices should be a minimum of 0.01 mm (0.0004 in.) or less.

If measurements cannot be taken directly on the specimen load-line, deflection can be measured from the test machine crosshead movement with the use of dial gages and/or the displacement transducers noted above. Under the constant loading conditions, the crosshead/load-train deflection will be primarily due to the test specimen with the exception of the initial deflection, which will contain some elastic contributions.

With smaller-sized specimens, the reduced notch dimensions will not accommodate a clip-on load-line gage. Past research has used a modified rod-and-tube extensometer connected to an external DCDT, the arms of which were attached on the outer surface (top and bottom faces) of the specimens on the load-line just above the pinholes (Ref 71). Clevises with deep throats can be used to accommodate this extensometry.

**Data Acquisition.** The measurements taken during the testing, electric potential voltage, load-line displacement, temperature, and cycles for creep-fatigue tests can be recorded continuously with the use of strip chart recorders, voltmeters, or digital data acquisition systems. The resolution of these acquisition systems should be at least one order of magnitude better than the measuring instrument. However, no matter which technique is used, it is important to remember the thermal voltage in the electric potential readout should be measured at least once every 24 h as described previously.

## Typical Test Procedures

**Test Setup.** Because of the inherent scatter observed in most test situations, more than one test per condition is suggested so that data confidence intervals can be obtained. In creep and creep-fatigue crack growth testing, variables such as microstructural differences, load precision, environmental control, and, to a lesser degree, data processing contribute to scatter (Ref 45).

Prior to installation in the testing machine, the test specimen should be fitted with electric potential leads. The exposed surface of the potential leads that are on the interior of the furnace can be covered with ceramic insulators or other shielding to avoid direct contact with the furnace elements and other components (thermocouples, extensometry, etc.) inside the furnace. After securing of the test specimen in the clevises with clevis pins, a slight load not exceeding 10% of the intended test load may be applied to improve the axial stability of the load train. The extensometer is then placed on the load line of the specimen, and care is taken to ensure that the knife edges are securely in contact. The thermocouples are then placed in contact with the specimen on the crack plane in the uncracked ligament region. Figure 10 displays a close-up of a fully fitted 0.25T-CT test specimen prior to furnace heating. The furnace is then placed into position, sealed, and started. Specimen heating should be performed gradually to avoid overshooting the test temperature because the aforementioned temperature control limits also apply to specimen heating. The current in the electric potential system should also be on during the furnace heating because resistance heating of the specimen occurs by the applied current. Once the test temperature is achieved and stable, the specimen is allowed to "soak" for at least 1 h per 25 mm (1 in.) of specimen thickness at the test temperature prior to applying load. Once sufficient time at temperature has been achieved, a set of measurements are recorded in the no-load condition for the reference conditions. Then the load is carefully applied in order to avoid inertial loading. The choice of load or  $K$  level is dependent on the crack growth rates required during the test. Ideally, crack growth rates should be the same as those encountered by the material during service. The time of specimen loading should be as short as possible, and another set of measurements of electric potential and displacement are recorded immediately upon completion of loading as the initial loading condition (time = 0).

**FIG. 10 TYPICAL INSTALLED SPECIMEN READY FOR CREEP CRACK GROWTH TESTING**

For creep-fatigue crack growth testing, additional consideration is given to specimen loading because cyclic tests are required. The hold time should be selected in conjunction with the  $K$ -level such that crack extensions of approximately 5 mm (0.2 in.) are obtained during the planned duration of the test. The hold time should also be selected such that the deflection that accumulates during the hold time is approximately three to five times the sensitivity of the displacement gage/amplifier system used. The loading waveshape should simulate the service loading conditions. As mentioned above, load-controlled testing can be performed under a variety of waveforms. For power-plant components and gas turbines used in airplanes, a trapezoidal waveform is a good approximation. The rise-decay and hold times should be representative of the relative times of fatigue and creep loading conditions in service.

**Post Test Measurements.** Once the test is completed, either due to specimen failure or by attainment of sufficient crack growth, the load is removed, the furnace is turned off, and the specimen is allowed to naturally cool and is then removed from the loading clevises. The original crack length (after precracking) and the final crack length (resulting from creep crack growth) are measured at nine equally spaced locations along the crack front. All the data are processed using computer programs that utilize either the secant method or seven-point polynomial method to calculate the deflection rates,  $dV/dt$ , crack growth rates,  $da/dt$  and the crack-tip parameters discussed previously. The details of these methods can be found in the ASTM E 1457 (Ref 45).

### Crack Growth Correlations

**Creep Crack Growth.** The experimental creep crack growth rate data for creep-ductile materials have been shown to correlate with the  $C^*$ -integral and the  $C_t$  parameter. As demonstrated in previous discussion,  $C_t$  and  $C^*$  are identical in the extensive creep regime. However,  $C_t$  is also valid in the small-scale and transition regimes where  $C^*$  is no longer path-independent and therefore does not uniquely characterize the crack-tip stress fields. Because  $C_t$  is more general than  $C^*$ , it has been chosen as the primary parameter for correlating creep crack growth in the discussion that follows. Figure 11 shows the creep crack growth rate of 1Cr-1Mo-V steel obtained from specimens that were 254 mm (10 in.) wide and had nominal thicknesses of 63.5 mm (2.5 in.) (Ref 72). These experiments were performed at the National Research Institute for Metals (NRIM) in Japan (Ref 72). In these tests, the initial crack growth rate occurred in the small-scale and the transition creep regions, while in the latter part of the test extensive creep conditions prevailed. The arrows mark the direction in which data were collected. Note that a high  $C_t$  value was obtained in the initial portion of the tests that progressively decreased to a minimum value and then subsequently increased. This was the pattern in both the tests identified by the specimen numbers VAH1 and VAH2. The authors note that the crack growth rates uniquely correlate with  $C_t$  during the increasing and decreasing portions of the tests, lending support to the theory that  $C_t$  can correlate crack growth rates over the wide range of conditions from small-scale to extensive creep.

**FIG. 11 CREEP CRACK GROWTH RATE FROM SPECIMENS OF 63.5 MM (2.5 IN.) THICKNESS IN WHICH CRACK GROWTH OCCURRED IN SMALL-SCALE, TRANSITION, AND EXTENSIVE CREEP REGIMES. SOURCE: REF 51**

Figure 12 shows the creep crack growth rates for several chromium-molybdenum steels correlated with  $C_t$  (Ref 73). These data were consolidated from several experimental studies, essentially proving that consistency in the data can be obtained from one laboratory to another during creep crack growth testing. It is also observed that when  $da/dt$  is correlated with  $C_t$  (or  $C^*$  for that matter, in the case of extensive creep), a first-order normalization of temperature effects are obtained. Because  $C_t$  and  $C^*$  are obtained from the product of the load,  $P$ , and the creep displacement rate,  $\dot{V}_c$ , where one is applied and the other is a response dependent on temperature, it is expected that to some extent the correlation between  $da/dt$  and  $C_t$  is independent of temperature (Ref 73). However, when changing the temperature will result in fundamental changes in creep deformation and damage mechanisms, such normalization of temperature effects is not expected.

FIG. 12 CREEP CRACK GROWTH RATE FOR CHROMIUM-MOLYBDENUM STEELS (TESTED AT 1000 TO 1022 °F) COMPILED FROM VARIOUS LABORATORIES. SOURCE: REF 7

Figure 13 shows the correlation between  $da/dt$  and  $C^*$  for 304 stainless steel where compact as well as center crack tension geometries were used for obtaining the data (Ref 12). This demonstrates the geometry independence of such data. All tests in this study were in the extensive creep conditions, thus no distinction is made between  $C_t$  and  $C^*$ .

FIG. 13 CREEP CRACK GROWTH RATE FOR 304 STAINLESS STEELS AT 594 °C (1100 °F) WITH DIFFERING SPECIMEN GEOMETRIES. SOURCE: REF 27

Figure 14 shows creep crack growth rate data from specimens of different sizes from the 1Cr-1Mo-V steel (Ref 37). It is noted that the data from the specimens 6.25 mm (0.25 in.) thick seem to lie at the lower end of the scatterband while the

data from the specimens 63.5 mm (2.5 in.) thick seem to lie on the upper end of the scatterband. There seems to be a systematic effect of thickness indicating a state-of-stress effect. Therefore, in generating creep crack growth rate data, it is essential to give proper consideration to the thickness of the specimen, depending on the end use of the data.

FIG. 14 CREEP CRACK GROWTH RATE FOR 1CR-1MO-V STEELS WITH DIFFERING SPECIMEN SIZES. SG, SIDE GROOVED. SOURCE: REF 51

Figure 15 shows the creep crack growth rate as a function of  $K$  for a highly cold-worked carbon-manganese steel tested at  $360^\circ\text{C}$  ( $680^\circ\text{F}$ ) (Ref 74). At this temperature, this material exhibits creep-brittle behavior. These correlations are very sensitive to the effects of temperature. Similar correlations have been shown for nickel-base alloys (Ref 75, 76), cold-worked 316 stainless steel (Ref 29), Ti-6242 alloy (Ref 51), and for 2519 Al alloy (Ref 49). Conditions for the unique correlation between  $da/dt$  and  $K$  are not well understood for creep-brittle materials, and this continues to be an area of considerable research.

FIG. 15 CREEP CRACK GROWTH RATE FOR A TYPICAL CREEP-BRITTLE MATERIAL. SOURCE: REF 74

**Creep-Fatigue Crack Growth Correlations.** Figure 16 (Ref 61) shows plots of  $da/dN$  versus  $\Delta K$  for a 2.25Cr-1.0Mo steel at 595 °C (1100 °F). The regression line through the elevated-temperature fatigue test ( $t_h = 0$ ) is used to get the cycle-dependent part in modeling the creep-fatigue data. The lack of correlation between  $da/dN$  and  $\Delta K$  for the creep-fatigue tests is evident from the data scatter in this figure. Such lack of correlation has also been shown in Cr-Mo-V steel (Ref 77). An increase in the  $da/dN$  with increasing hold time for fixed  $\Delta K$  has also been reported by Saxena and Bassani (Ref 78). This is due to the increasing contribution of time-dependent crack growth (Ref 79). Creep damage at the crack tip, influence of the environment, or microstructural changes such as formation of cavities that occur during loading at elevated temperatures could be responsible for this behavior (Ref 58).

FIG. 16  $DA/DN$  VERSUS  $\Delta K$  FOR A 2 CR-1MO STEEL AT 594 °C (1100 °F) TESTED WITH AND WITHOUT

The average time-dependent crack growth rates,  $(da/dt)_{avg}$ , are correlated with  $(C_t)_{avg}$ . Figure 17 (Ref 17) is a plot of  $(da/dt)_{avg}$  versus  $(C_t)_{avg}$  for 2.25Cr-1.0Mo steel, for various hold times at elevated temperatures. All data show a clear trend and fall into a narrow scatterband despite the range of hold times used. Similar trends have also been shown for 1.25Cr-0.5Mo steel as shown in Fig. 18 (Ref 60). This strongly indicates the usefulness of  $(C_t)_{avg}$  in characterizing creep-fatigue rates. Furthermore, the creep crack growth (CCG) data for each of these materials has also been plotted on these graphs. However,  $da/dt$  has been correlated with  $C_t$  for the creep crack growth data. All the creep and creep-fatigue crack growth rate data show the same trend. This has the important implication that life prediction procedures for these materials would be considerably simplified because CCG data could be used to predict the life of components under creep-fatigue conditions and vice versa. In comparing a  $(da/dt)_{avg}$  versus  $(C_t)_{avg}$  relation of creep-fatigue with a  $da/dt$  versus  $C_t$  relation of CCG, it must be kept in mind that although  $C_t$  and  $(C_t)_{avg}$  are equivalent parameters with the same physical interpretation, their exact values may differ slightly in the small-scale creep regime by a constant factor for a given material (Ref 60). The value of this constant ranges from 1 to 1.3 for different materials (Ref 60).

FIG. 17 CORRELATION OF MEASURED CRACK GROWTH RATES WITH THE  $C_T$  CALCULATED FROM EXPERIMENTAL MEASUREMENTS (REF 61) FOR 2.25CR-1.0MO STEEL AT 594 °C (1100 °F). (NOTE  $DA/DT$  VERSUS  $C_T$  PLOTTED FOR THE CREEP CRACK GROWTH DATA AND  $(DA/DT)_{AVG}$  WITH  $(C_T)_{AVG}$  FOR THE CREEP-FATIGUE DATA)

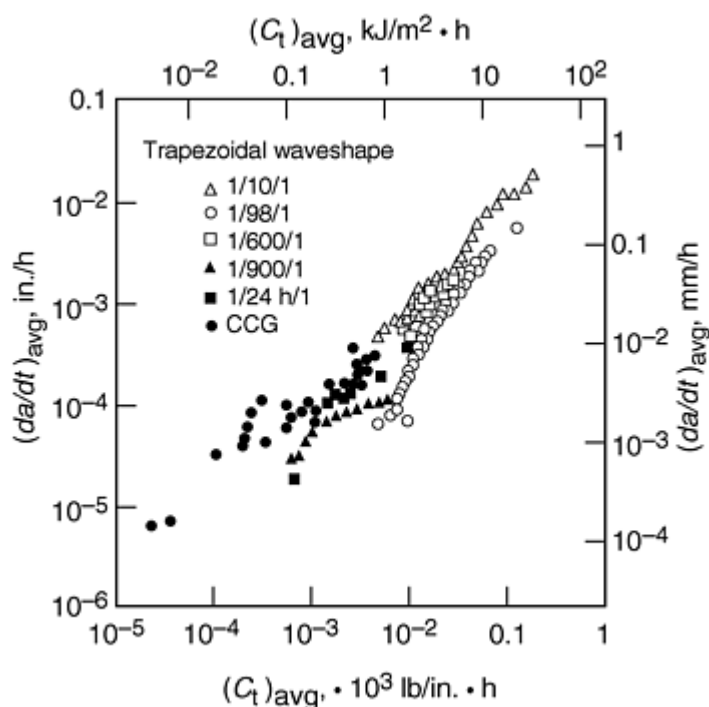

FIG. 18 COMPARISON BETWEEN CREEP AND CREEP-FATIGUE CRACK GROWTH DATA IN TERMS OF THE ESTIMATED  $(C_t)_{avg}$  FOR 1.25CR-0.5MO STEEL AT 538 °C (1000 °F). SOURCE: REF 59, 60

The time dependence of the life-prediction model is obtained by generating a regression line through all the data. The total fatigue crack growth rate per cycle is a linear summation of the cycle and time-dependent crack growth rates. Such an expression obtained for 2.25Cr-1.0Mo steel at 595 °C (1100 °F) under trapezoidal loading waveshapes is given in the following equation (Ref 57) for SI units (mm/h, MPa $\sqrt{m}$ , and  $C_t$  in  $\text{kJ/m}^2 \cdot \text{h}$ ):

$$\frac{da}{dN} = 1.08 \times 10^{-6} \Delta K^{1.94} + 1.46 \times 10^{-2} \left[ (C_t)_{avg} \right]^{0.722} t_h$$

In English units (in./h, ksi $\sqrt{\text{in.}}$ , and  $C_t$  in units  $10^3 \text{ lb/in.} \cdot \text{h}$ ) the relation is:

$$\frac{da}{dN} = 5.11 \times 10^{-8} \Delta K^{1.94} + 2.40 \times 10^{-2} \left[ (C_t)_{avg} \right]^{0.722} t_h$$

The first term in the equations above represents the cycle-dependent crack growth rate and the other term represents the time-dependent crack growth rate. These equations can be effectively used to predict the service life of high-temperature components made of 2.25Cr-1.0Mo steel under both creep and creep-fatigue crack growth conditions at 595 °C (1100 °F). An upper and lower scatterband can also be generated for the data in Fig. 17 and 18 for design purposes. This model has been established under the assumption that the crack growth during hold time is only due to creep deformation. Any other time-dependent effects like oxidation at the crack tip have not been considered (Ref 57). Neither have any synergistic effects due to any complicated interactions of the creep and fatigue mechanisms of crack growth during unloading/reloading been incorporated. However, with the assumption that the unloading/reloading times are much smaller compared with the hold times, their exclusion seems justified (Ref 57). If such effects were to be considered,

depending on the material, an equation of the type presented above would be too simplistic in its description of the creep-fatigue behavior of a material. This remains a subject of future research.

## Introduction

CURRENT FRACTURE MECHANICS theory treats cyclic crack growth as a linear elastic phenomenon. The residual strength of a test coupon, or a structural component, is frequently computed based on linear elastic fracture indexes. Elastic-plastic, or fully plastic analysis such as the  $J$ -integral approach is used when large scale yielding occurs. All the existing crack growth analysis methods for spectrum life prediction basically deal with using material constant amplitude crack growth rate data to compute crack growth history of a structural element. For crack growth at high temperature, the conventional crack growth methodology that was based on material room temperature behavior will no longer be applicable.

The need for an updated fracture mechanics technology that can handle the combined effects of temperature, stress amplitude, cyclic frequency, and dwell time was first recognized by researchers in the nuclear and aircraft engine industries and government agencies. Substantial research efforts have been made since the mid-1970s. Summaries of the accomplishments have been documented in a number of review papers, listed here as Ref 1, 2, 3, 4, 5, 6, 7, 8, and 9. Application of these new technologies to damage tolerance analysis of aircraft structures is discussed in Ref 10, 11, 12, 13.

The key products developed during this period (mid-1970 to 1991) include:

- NEW FRACTURE MECHANICS INDEXES FOR CHARACTERIZING MATERIAL RESIDUAL STRENGTH AND SUSTAINED LOAD CRACK GROWTH AT HIGH TEMPERATURE, NAMELY, THE STEADY-STATE CREEP PARAMETER  $C^*$ , AND THE TRANSIENT CREEP PARAMETER,  $C_T$  (SEE PREVIOUS ARTICLE)
- A LARGE QUANTITY OF TEST DATA REVEALING THE VARIOUS ASPECTS OF HIGH-TEMPERATURE CRACK GROWTH BEHAVIOR
- COMPUTER MODELS FOR CONSTANT AMPLITUDE CRACK GROWTH AT HIGH TEMPERATURE (REF 14, 15)
- AN UPDATED COMPUTER CODE FOR SPECTRUM CRACK GROWTH LIFE PREDICTION (REF 16)

This article discusses the variables affecting the material crack growth rate behavior and those essential elements in making spectrum crack growth life prediction. In addition, life assessment for bulk creep damage is briefly reviewed. More extensive discussions of these methods are presented in Ref 17 on a component-specific basis for boilers, turbines, pressure vessels, and advanced steam plants.

### Assessment of Bulk Creep Damage

The current approaches to creep damage assessment of components can be classified into two broad categories: (1) history-based methods, in which plant operating history in conjunction with standard material property data is employed to calculate the fractional creep life that has been expended, using the life-fraction rule or other damage rules and (2) methods based on postservice evaluation of the actual component.

In history-based methods, plant records and the time-temperature history of the component are reviewed. The creep-life fraction consumed for each time-temperature segment of the history can then be calculated and summed up using the lower-bound ISO data and the life-fraction rule, or other damage rules.

The most common approach to calculation of cumulative creep damage is to compute the amount of life expended by using time or strain fractions as measures of damage. When the fractional damages add up to unity, then failure is postulated to occur. The most prominent rules are as follows:

- *LIFE-FRACTION RULE*,  $\sum T_i/T_{RI} = 1$
- *STRAIN-FRACTION RULE*,  $\sum \epsilon_i/\epsilon_{RI} = 1$
- *MIXED RULE*,  $\sum (T_i/T_{RI})^{1/2} (\epsilon_i/\epsilon_{RI})^{1/2} = 1$
- *MIXED RULE*,  $K \sum (T_i/T_{RI}) + (1 - K) \sum (\epsilon_i/\epsilon_{RI}) = 1$

where  $k$  is a constant,  $t_i$  and  $\epsilon_i$  are the time spent and strain accrued at condition  $i$ , and  $t_{ri}$  and  $\epsilon_{ri}$  are the rupture life and rupture strain under the same conditions.

The life-fraction procedure usually is inaccurate because of errors in assumed history, in material properties, and in the life-fraction rule itself. The temperature-history information may be somewhat refined by supplemental information concerning the current oxide-scale thickness and microstructural details. In spite of such refinements, only gross estimates of creep damage are obtained using the calculation technique.

Direct postservice evaluations represent an improvement over history-based methods, because no assumptions regarding material properties and past history are made. Unfortunately, direct examinations are expensive and time-consuming. The best strategy is to combine the two approaches. A history-based method is used to determine if more detailed evaluations are justified and to identify the critical locations, and this is followed by judicious postservice evaluation. Table 1 summarizes the techniques that are in use for life assessment and some of the issues pertaining to each technique (Ref 17).

Source: Ref 17

Current postservice evaluation procedures include conventional nondestructive evaluation (NDE) methods (e.g., ultrasonics, dye-penetrant inspection, etc.), dimensional (strain) measurements, and creep-life evaluations by means of accelerated creep testing. All of these methods have limitations. Normal NDE methods often fail to detect incipient creep damage and microstructural damage, which can be precursors of rapid, unanticipated failures. Due to unknown variations in the original dimensions, changes in dimensions cannot be determined with confidence. Dimensional measurements fail to provide indications of local creep damage caused by localized strains such as those in heat-affected zones of welds and regions of stress concentrations in the base metal. Cracking can frequently occur without manifest overall strain. Furthermore, the critical strain accumulation preceding fracture can vary widely with a variety of operational material parameters and with stress state.

A common method of estimating the remaining creep life is to conduct accelerated rupture tests at temperatures well above the service temperature. The stress is kept as close as possible to the service stress value, because only isostress-varied temperature tests are believed to be in compliance with the life-fraction rule. The time-to-rupture results are then plotted versus test temperature. By extrapolating the test results to the service temperature, the remaining life under service conditions is estimated.

Implementation of the above procedure requires a reasonably accurate knowledge of the stresses involved. For cyclic stressing conditions, and in situations involving large stress gradients, selection of the appropriate stress for the isostress tests is uncertain. Furthermore, the procedure involves destructive tests requiring removal of large samples from operating components. There are limitations on the number of available samples and the locations from which they can be taken. Periodic assessment of the remaining life is not possible. The costs of cutting out material, machining specimens, and conducting creep tests can add up to a significant expenditure. These costs are further compounded by the plant outage during this extended period of evaluation and decision making. Development of nondestructive techniques, particularly those based on metallographic and miniature-specimen approaches, has therefore been a major focus of the programs aimed at predicting crack initiation (see the article "Failure Control in Process Operations" in this Volume).

## Creep Crack Growth

As described in previous sections of this article, creep crack growth can be characterized in terms of fracture mechanic crack growth by the steady-state (large-scale crack growth regime) parameter  $C^*$  and the transient parameter  $C_t$ . The parameter  $C_t$  is theoretically equivalent to  $K$  (the crack-tip stress-intensity factor) under small-scale creep. It becomes  $C^*$  when the amount of creep deformation approaches steady-state creep condition. Therefore,  $C_t$  can be used for the entire range of creep deformations. Because  $K$  is a more convenient parameter and all the crack growth analysis methodologies

have been developed based on  $K$ , the use of  $K$  (in lieu of  $C_I$ ) is preferable when situation permits. If a material is creep-resistant, its creep zone size will be smaller than those creep zones in the creep ductile materials. Upon reviewing and analyzing creep crack growth data (Table 2), most high-temperature superalloys for aircraft belong to this creep-resistant category of materials. In such cases, the linear elastic index  $K$  may, in some cases, adequately characterize the high-temperature crack growth behavior in these alloys.

(A) NET SECTION FAILURE PER REF 2.

(B) BOTH THE AS-PROCESSED AND THE USED MATERIALS WERE TESTED. SOURCES: AS LISTED.

For heavy-walled process equipment, initiation criteria can be combined with crack-growth data to perform fracture-mechanic analysis of localized damage by creep crack growth. To estimate critical crack sizes for end-of-life under brittle-fracture conditions, nondestructive methods are needed for characterizing the toughness of the in-service components. Several methods, including Auger analysis, chemical analysis, miniature-specimen testing, chemical etching, electron microscopy, and others, have been explored for ferritic steels.

To perform a remaining-life assessment of a component under creep crack growth conditions, two principal ingredients are needed: (1) an appropriate expression for relating the driving force  $K$ ,  $C^*$ , or  $C_t$  to the nominal stress, crack size, material constants, and geometry of the component being analyzed; and (2) a correlation between this driving force and the crack growth rate in the material, which has been established on the basis of prior data or by laboratory testing of samples from the component. Once these two ingredients are available, they can be combined to derive the crack size as a function of time. The general methodology for doing this is illustrated below, assuming  $C_t$  to be the driving crack-tip parameter.

**Estimating  $C_t$ .** The generalized expression for calculating  $C_t$  from measurements of load versus deflection rates on laboratory samples is defined (in Eq 36 of the previous article). Under extensive creep conditions,  $C_t$  can be simply calculated from the  $C^*$  expression ( Eq 8 in previous article).

Another analytical expression for calculating  $C_t$  has been given as (Ref 2):

$$C_t = \frac{4 \alpha \beta (1 - \nu^2) K^4}{E(n-1) W} \times (EA)^{2(n-1)} t^{-(n-3)(n-1)} \frac{F'}{F} + C^* \quad (\text{EQ 1})$$

where  $\beta$  has a value of approximately 1/7.5. In Eq 1, the first term denotes the contribution from small-scale creep and the second term denotes the contribution from steady-state, large-scale creep. The first term is time-variant whereas the

second term is time-invariant. In the limit of  $T \rightarrow 0$ , approaching small-scale creep conditions, the first term dominates, implying that  $K$  is the controlling parameter in crack growth, with time also explicitly entering the relationship. In the limit  $t \rightarrow \infty$ , the first term becomes zero and  $C_t$  becomes identical with  $C^*$ . In Eq 36,  $F$  is a function of  $(a/W)$  and  $F'$  is given by  $dF/d(a/W)$ . In Eq 43,  $\alpha$  is a constant whose value is a function of  $n$ , and  $A$  and  $n$  are the Norton law coefficients.

Equation 1 can be used to estimate  $C_t$  from an applied load (stress) and from a knowledge of the elastic and creep behavior of the material, the  $K$  calibration expression, and the  $C^*$  expression for the geometry of interest. The  $K$  and  $C^*$  expressions can be found in handbooks--at least for selected geometries. The material properties  $A$  and  $n$  can be obtained from creep tests. The  $C^*$  expressions (for example, in Ref 39) are not as abundantly available for different geometries as the  $K$  expressions. At the present time, this is viewed as a limitation of the technology. More detailed descriptions of the derivations of the  $C^*$  and  $C_t$  expressions, and the manner of obtaining some of the constants and calculating their values, are presented in the previous article. Procedures for estimating  $C^*$  based on the reference-stress approach also have been described by Ainsworth et al. (Ref 40).

**Life Assessment under Creep Crack Growth with  $C_t$ .** The general expression for  $C_t$  given in Eq 1 essentially reduces to the form

$$C_T = \sigma \dot{\epsilon} (A, N) A H (\text{GEOMETRY}, N) \quad (\text{EQ 2})$$

where  $\sigma$  is the stress far from the crack tip, obtained by stress analysis,  $\dot{\epsilon}$  is the strain rate far from the crack tip, which is a function of the constants  $A$  and  $n$  in the Norton relation (see Eq 2 in the previous article "Elevated-Temperature Crack Growth"),  $a$  is the crack depth from NDE measurements, and  $H$  is a tabulated function of geometry and the creep exponent  $n$ . The values of  $A$  and  $n$  are either assumed from prior data or generated by creep testing of samples. By assembling all the constants needed, the value of  $C_t$  can be calculated.

Once  $C_t$  is known, it can be correlated to the crack-growth rate through the constants  $b$  and  $m$  in the following relation:

$$\dot{a} = b C_t^m \quad (\text{EQ 3})$$

Values of the constants  $b$  and  $m$  for all the materials analyzed by Saxena et al. are listed in Table 3. It can be shown (from Eq 6 and 7 of the previous article) that  $m$  should have the approximate value  $n/(n+1)$ , where  $n$  is the creep-rate exponent.

Combining Eq 2 and 3 provides a first-order differential equation for crack depth,  $a$ , as a function of time,  $t$ . Theoretically, this equation can be solved by separating variables and integrating. However, the procedure is complicated by the time dependency of  $C_t$  and the  $a$  (crack size) dependency of the term  $H$  in Eq 3. To circumvent this, crack growth calculations are performed with the current values of  $a$  and the corresponding values of  $da/dt$  to determine the time increment required for incrementing the crack size by a small amount  $\Delta a$ ; that is,  $\Delta t = \Delta a / \dot{a}$ . This provides new values of  $a$ ,  $t$ , and  $C_t$ , and the process is then repeated. When the value of  $a$  reaches the critical size  $a_c$  as defined by  $K_{Ic}$ ,  $J_{Ic}$  wall thickness, remaining ligament thickness, or any other appropriate failure parameter, failure is deemed to have occurred.

Although this procedure appears complex at first sight, the calculations are relatively easy once the principles are understood. Computer programs have been developed that perform the entire analysis on personal computers. The only judgment involved is in selecting proper values for the constants  $A$ ,  $n$ ,  $b$ , and  $m$ , because large scatter in creep and crack growth data necessitates subjective choices. If actual creep and/or crack growth tests could be performed, more accurate results could be obtained. Several case histories are available in the literature to acquaint the reader with the procedures involved (Ref 17).

A sample output may be in the form of a table of crack depth versus time or a plot of crack size versus remaining life (Fig. 1). This plot was generated for a thick-wall cylinder under internal pressure containing a longitudinal crack. The outside radius and wall thickness of the cylinder were assumed to be 45.7 and 7.62 cm (18 and 3 in.), respectively, and the hoop stresses were calculated for internal pressures of 8.96 and 13.79 MPa (1.3 and 2 ksi). Material properties in the degraded condition (hot region) as well as in the undergraded condition were considered. The results show that the remaining life is a function of the stresses as well as of prior degradation. Plots of this type could be used to determine remaining life or to set inspection criteria and inspection intervals. Examples of remaining-life analyses are presented in Ref 17 on boilers and rotors.

**FIG. 1** TYPICAL OUTPUT FROM CRACK GROWTH ANALYSIS SHOWING REMAINING LIFE VERSUS INITIAL CRACK SIZE FOR AN INTERNALLY PRESSURIZED CYLINDER OF 1.25CR-0.5MO STEEL AT 538 °C (1000 °F). SOURCE: REF 17

Ainsworth et al. have recently described a unified approach for structures containing defects (Ref 40). This approach incorporates structural failure by rupture, incubation behavior preceding crack growth, and creep crack growth in a single framework. Service life is governed by a combination of time to rupture, time of incubation, and time of crack growth. All of these quantities are calculated using a reference stress that is specifically applicable to the geometry of the

component and is derived analytically or based on scale-model tests. If the desired service life exceeds the calculated rupture time, retirement may be necessary. In the opposite situation, further analysis is carried out to calculate the incubation time during which no crack growth is expected to occur. If the calculation indicates that the incubation time  $t_i$  is less than the desired service life, then a crack growth analysis is performed to calculate the crack growth life  $t_g$ . If the total life,  $t_i + t_g$ , is less than the desired service life, safe operation beyond that point would be considered undesirable. This approach seems very promising and is the subject of further investigation.

## High-Temperature Fatigue Crack Growth

As previously mentioned in the section "Creep Crack Growth," the use of the linear elastic stress intensity factor ( $K$ ) may be adequate for analyzing high-temperature fracture resistance of creep-resistant superalloys. This section briefly summarizes the factors affecting high-temperature fatigue crack growth in the context of traditional  $K$ -factor analysis.

If cyclic crack growth testing at high temperature is done in a traditional way (i.e., with a sinusoidal or symmetrically triangular waveform at a moderately high frequency), the crack growth rates are functions of  $\Delta K$  and  $R$  similar to those at room temperature with the following exceptions: (1) for a given  $R$ , the value of the crack threshold  $\Delta K_{th}$  is higher at higher temperature, and (2) for a given  $R$ , the terminal  $\Delta K$  value is higher at higher temperature because  $K_c$  is usually higher at a higher temperature (due to the fact that the material tensile yield strength is lower at a higher temperature). A schematic representation of these temperature influences, on  $da/dN$  is shown in Fig. 2. It should be noted that crack

growth rates are not always higher at temperatures higher than room temperature as implied in Fig. 2. Depending on frequency and  $\Delta K$  range, some material (particularly those sensitive to environment) may exhibit slower crack growth rates at intermediate temperatures. Moisture, which might have acted similarly to a corrosive medium, was vaporized by heat; therefore, the magnitude of the environmental fatigue component (which inherently associates with crack propagation) would be reduced (Ref 41).

FIG. 2 SCHEMATIC OF TEMPERATURE EFFECT ON FATIGUE CRACK THRESHOLD AND GROWTH RATES

In the power-law (Paris equation) crack growth regime, the effects of temperature, stress ratio ( $R$ ), and hold times have been investigated for many high-temperature alloys. Typical behavior and crack growth results for specific alloys are covered elsewhere in this Volume. However, a general comparison of temperature effects on fatigue crack growth of several different high-temperature alloys is shown in Fig. 3. Because the reported data are obtained at various  $\Delta K$  ranges and temperature ranges, the general comparison is based on a constant  $\Delta K$  (arbitrarily chosen as  $30 \text{ MPa}\sqrt{\text{m}}$ , or  $27 \text{ ksi}\sqrt{\text{in.}}$ ). A clear trend of crack growth rate increase with increasing temperature can be seen as shown in Fig. 3. At temperatures up to about 50% of the melting point ( $550$  to  $600 \text{ }^\circ\text{C}$ , or  $1020$  to  $1110 \text{ }^\circ\text{F}$ ), the growth rates are relatively insensitive to temperature, but the sensitivity increases rapidly at higher temperatures. The crack growth rates for all the materials at temperatures up to  $600 \text{ }^\circ\text{C}$  relative to the room-temperature rates can be estimated by a maximum correlation factor of 5 (2 for ferritic steels).

FIG. 3 VARIATION OF FATIGUE CRACK GROWTH RATES AS A FUNCTION OF TEMPERATURE AT  $\Delta K = 30$   $\text{MPa}\sqrt{\text{m}}$  ( $27 \text{ KSI}\sqrt{\text{in.}}$ ). SOURCE: REF 17

Besides temperature, cyclic frequency, or duration of a stress cycle (e.g., with hold time), is a key variable in high-temperature crack growth. At high frequency--that is, fast loading rate with short hold time (or no hold time)--the crack growth rate is cycle dependent and can be expressed in terms of crack growth per cycle ( $da/dN$ ). At low frequency (or with long hold time), however, the crack growth rate is time dependent; that is,  $da/dN$  is in proportion to the total time span of a given cycle. For tests of different cycle times, all crack growth rate data points are collapsed into a single curve of which  $da/dt$  is the dependent variable. A mixed region exists in between the two extremes. The transition from one type of behavior to another depends on material, temperature, frequency, and  $R$  (Ref 42). For a given material and temperature combination, the transition frequency is a function of  $R$ . The frequency range at which the crack growth rates remain time dependent increases as  $R$  increases (Ref 42). The limiting case is  $R$  approaching unity. It is equivalent to crack growth under sustained load, for which the crack growth rates at any frequency will be totally time dependent.

To further understand the complex interaction mechanisms of stress, temperature, time, and environmental exposure, a vast amount of experimental and analytical data was compiled (from a bibliography of 42 references) and reviewed. Crack growth behavior for 36 types of loading profiles, which were in excess of 60 combinations in material, temperature, frequency, and time variations, were examined. A compilation of the results is presented in Ref 12. The evaluation method was to classify the data into groups representing a variety of isolated loading events. In this way, the phenomenological factors that influence load/environment interaction mechanisms can be determined. It also enables micromechanical modeling to be made to account for the contribution of each variable to the total behavior of crack growth. A composite of these load segments also provides a basis for spectrum loading simulation.

At room temperature, cyclic frequency and the shape of a stress cycle have an insignificant effect on either constant amplitude or spectrum crack growth behavior. The magnitude and sequential occurrences of the stress cycles are the only key variables affecting room-temperature crack growth behavior. Therefore, an accurate representation of the material crack growth rate data as a function of the stress amplitude ratio (i.e., the so-called crack growth law or crack growth rate equation), and a load interaction model for monitoring the load sequence effects on crack growth (the commonly called crack growth retardation/acceleration model), are the only two essential elements in cycle-dependent crack growth life

predictive methodology. However, the time factor in a given stress cycle (whether it is associated with hold time or low frequency), which promotes time-dependent crack growth behavior, might play a significant role in high-temperature crack growth. Therefore, the section below briefly reviews cycle-dependent versus time-dependent crack growth.

**Cycle-Dependent Versus Time-Dependent Crack Growth.** Research conducted on conventional high-temperature superalloys, Inco 718 in particular, has shown that sustained load creep crack growth rate data can be used to predict cyclic crack growth in the time-dependent regime (Ref 43, 44). In those regions in which the cycle-dependent and the time-dependent phenomena are both present, implementation of a semiempirical technique may be required. A summary on formulating a procedure to predict crack growth in the time-dependent regime is given in this section.

Applying the Wei-Landes superposition principle for subcritical crack growth in an aggressive environment (Ref 45), crack growth rate for a given stress cycle can be treated as the sum of three parts:

1. THE UPLOADING PART (I.E., THE LOAD RISING PORTION OF A CYCLE)
2. THE HOLD TIME
3. THE DOWNLOADING (UNLOADING) PORTION OF A CYCLE

Therefore

$$\frac{da}{dN} = \left( \frac{da}{dN} \right)_r + \left( \frac{da}{dN} \right)_H + \left( \frac{da}{dN} \right)_d \quad (\text{EQ 4})$$

It has been shown frequently, by experimental tests, that the amount of  $da$  for the unloading part is negligible unless the stress profile is unsymmetric, and the uploading time to the unloading time ratio is significantly small (that is, the unloading time, compared to the uploading time, is sufficiently long). For simplicity, this discussion is limited to those cases based on two components only, that is, by setting  $(da/dN)_d$  equal to zero. However, the  $(da/dN)_r$  term may be cycle-dependent, or time-dependent, or mixed. This term consists of two parts; one part accounts for the cyclic wave contribution, and another part accounts for the time contribution. Consequently, Eq 4 can be rewritten as:

$$\frac{da}{dN} = \left( \frac{da}{dN} \right)_c + \left( \frac{da}{dN} \right)_t + \left( \frac{da}{dN} \right)_H \quad (\text{EQ 5})$$

The first term on the right-hand side of Eq 5 represents the cycle-dependent part of the cycle. It comes from the conventional crack growth rate data at high frequency; that is, it follows those crack growth laws cited in the literature (such as the Paris and Walker equations). In reality, when a stress cycle is totally cycle dependent, the magnitude of the second term on the right-hand side of Eq 5 will be negligibly small. On the other hand, when a stress cycle is totally time dependent, the contribution of  $(da/dN)_c$  to the total  $da/dN$  is negligible; thereby the validity of Eq 5 in respect to full frequency range is maintained.

When a crack growth rate component exhibits time-dependent behavior, it is equivalent to crack growth under a sustained load of which the crack growth rate description is defined by  $da/dt$  (instead of  $da/dN$ ) as:

$$\frac{da}{dt} = C(K_{\max})^m \quad (\text{EQ 6})$$

This quantity is obtained from a sustained-load test. To express the second term on the right-hand side of Eq 5 in terms of  $da/dt$ , consider a generalized function that can describe  $K$  at any given time in a valley to peak cycle. That is:

$$K(T) = R \cdot K_{\max} + 2K_{\max} \cdot (1 - R) \cdot T_r \cdot f \quad (\text{EQ 7})$$

where  $t_r$  is the time required for ascending the load from valley to peak, and  $f$  is the frequency of the cyclic portion of a given load cycle. For symmetric loading, Eq 7 gives  $K(t) = K_{\min}$  at  $t_r = 0$ , and  $K(t) = K_{\max}$  at  $t_r = 1/2f$ . The amount of crack extension over a period  $t_r$  can be obtained by replacing the  $K_{\max}$  term of Eq 6 by  $K(t)$ , and integrating, that is,

$$\left(\frac{da}{dN}\right) = C \int_0^{t_r} [K(t)]^m dt \quad (\text{EQ 8})$$

For any positive value of  $m$ , Eq 8 yields

$$\left(\frac{da}{dN}\right)_t = C (K_{\max})^m (t_r R_m) \quad (\text{EQ 9})$$

where

$$R_M = (1 - R^{M+1}) / [(M + 1) (1 - R)] \quad (\text{EQ 10})$$

Therefore, for a given  $K_{\max}$ ,  $(da/dN)_t$  increases as  $R$  increases in the time-dependent regime. This trend is opposite to that commonly observed in the high-frequency (cycle-dependent) regime.

The third term on the right-hand side of Eq 5 simply equals  $da/dt$  times the time at load. Recognizing that the first term on the right-hand side of Eq 9 is actually equal to  $da/dt$ , finally, Eq 5 can be expressed as:

$$\frac{da}{dN} = \left(\frac{da}{dN}\right)_c + \frac{da}{dt} (t_r R_m) + \frac{da}{dt} t_H \quad (\text{EQ 11})$$

where  $t_H$  is the hold time.

The applicability of Eq 11 is demonstrated in Fig. 4 and 5. In these figures, the test data were generated from the Inco 718 alloy, at 649 °C, having various combinations of  $\Delta K$ ,  $R$ ,  $t_H$ , and  $f$ . The test data, which were extracted from the open literature (Ref 43, 44), are presented in the figures along with the predictions.

FIG. 4 HIGH-TEMPERATURE FATIGUE CRACK GROWTH RATES OF INCO 718 (ACTUAL AND PREDICTED RATES,

$R = 0.1$ )

**FIG. 5 HIGH-TEMPERATURE FATIGUE CRACK GROWTH RATES OF INCO 718 (ACTUAL AND PREDICTED RESULT,  $R = 0.5$ )**

One of the two data sets in Fig. 4 was generated using trapezoidal stress cycles with a frequency of 1 Hz (i.e., 0.5 s for uploading, and 0.5 for unloading) and varying  $t_H = 1$  to 500 s. The data points for the other data set were obtained by conducting tests at various frequencies without hold time. A constant  $\Delta K$  level (either  $25 \text{ MPa}\sqrt{\text{m}}$  or  $36 \text{ MPa}\sqrt{\text{m}}$  with  $R = 0.1$ ) was applied to all the tests. Crack growth rate per cycle was plotted as a function of total time per cycle. For example, for a total cycle time of 100 s, it would mean that the test was conducted at a frequency of 1 Hz with  $t_H = 99$  s, or  $f = 0.01$  Hz without hold time. The predictions were made by using Eq 6 and 11 with  $C = 2.9678 \times 10^{-11} \text{ m/s}$  and  $m = 2.65$ . The value for the  $(da/dN)_c$  term was set to those experimental data points for  $f = 10$  Hz. It is seen that the correlation between Eq 11 and the trapezoidal load test data is quite good.

It is also shown in Fig. 4 that Eq 11 correlates with those triangular load test data in the time-dependent region ( $f \leq 0.02$  Hz, or total time  $\geq 50$  s) but fails to predict the crack growth rates in the mixed region ( $0.02 < f < 10$  Hz). For this group of data, a better correlation was obtained by using the latest version of the Saxena equation (Ref 46):

$$\frac{da}{dN} = \left( \frac{da}{dN} \right)_c + C_4 \Delta K^\alpha [1/\sqrt{f} - 1/\sqrt{f_0}] \quad (\text{EQ 12})$$

where  $f_0$  is the characteristic frequency, which separates the cycle-dependent and the mixed regions. For those data sets in Fig. 4, the value for  $f_0$  was assumed to be 10 Hz. Using a procedure given by Saxena (Ref 47), it was determined that  $C_4 = 1.075 \times 10^{-10}$ ,  $\alpha = 2.35$ .

The example case shown in Fig. 5 involves all three loading variables,  $t_H$ ,  $t_r$ , and  $R$  (as compared to those data sets shown in Fig. 4, of which the crack growth rates were functions of  $t_H$  and  $R$  or  $f$  and  $R$ ). The test condition for this data set was:  $R = 0.5$ ,  $f = 0.01$  Hz (i.e.,  $t_r = 50$  s),  $t_H = 50$  s,  $K_{\text{max}} = 20$  to  $140 \text{ MPa}\sqrt{\text{m}}$  ( $\Delta K = 10$  to  $70 \text{ MPa}\sqrt{\text{m}}$ ). A very good match was obtained (up to  $\Delta K = 35 \text{ MPa}\sqrt{\text{m}}$ ). It thus appears that Eq 11 is superior to the other crack growth models. A comparison with the SINH model (Ref 14), a model that is widely used by the engine industry, is shown in Fig. 5.

In conclusion, crack growth behavior of a stress cycle having a trapezoidal wave form can be predicted by using the combination of conventional high-frequency  $da/dN$  data, sustained load data ( $da/dt$ ), and Eq 11. For these stress cycles having a triangular wave form, test data for a specific frequency in question may be required. Otherwise, a set of test data

containing several frequencies is needed for developing those empirical constants in the Saxena equation. It should be noted that Eq 12 is basically an empirical function for curve fitting and data interpolation; it is not a scientific rule that dictates the frequency effect on crack growth behavior. Therefore, although not essential, it is desirable to have an all-around method that can describe the  $da/dN$  behavior in the mixed region.

**Summary.** As long as load/environment interactions are absent, the total crack growth rate for a loading block containing both triangular and trapezoidal stress cycles will be

$$\left(\frac{da}{dN}\right)_{\text{total}} = \sum_i \left(\frac{da}{dN}\right)_i$$

where  $i$  denotes the  $i$ th loading step in the entire group of loads under consideration. The amount of  $da$  for each loading step is determined by using Eq 11 or 12.

An attempt to extend the existing load interaction models (for room temperature) to handle high-temperature crack growth under variable amplitude and variable waveform loadings involving all three types of crack-tip deformation modes (i.e., plasticity, creep, and environment-induced damage) is more speculative and beyond the scope of this article. Significant modifications on characterization of material properties and the load interaction and damage accumulation models are required due, in part, to the numbers of variables involved in defining the high-temperature crack growth behavior. The complexity of high-temperature crack growth is summarized in a comparison of all the major elements involved in room-temperature and high-temperature crack growth (Table 4).

**TABLE 4 COMPARISON OF FRACTURE MECHANICS ELEMENTS FOR ROOM-TEMPERATURE AND HIGH-TEMPERATURE CRACK GROWTH**

	<b>ROOM TEMPERATURE</b>	<b>HIGH TEMPERATURE</b>
DEPENDENT VARIABLES	$DA/DN$	$DA/DN, DA/DT, MIXED$
FUNCTIONS OF	$R$ -RATIO	$R$ -RATIO, TEMPERATURE, FREQUENCY, WAVEFORM
CONTROLLING PARAMETER	$K, J$	$K, C_T, C^*$
CRACK-TIP DEFORMATION MODE	PLASTICITY ( $F_{TY}, N$ )	PLASTICITY ( $F_{TY}, N$ )
		STRESS RELAXATION DUE TO CREEP ( $E, A, N, T$ )
		ENVIRONMENTAL DIFFUSION COEFFICIENTS ( $Q, R, T$ )
SPECTRUM LIFE	SINGLE MODE FOR LOAD INTERACTION	MULTIPLE MODES FOR LOAD/TEMPERATURE/TIME INTERACTIONS

## Thermal and Thermomechanical Fatigue of Structural Alloys

Huseyin Sehitoglu, Department of Mechanical and Industrial Engineering, University of Illinois

---

### Introduction

STRUCTURAL ALLOYS are commonly subjected to a variety of thermal and thermomechanical loads. If the stresses in a component develop under thermal cycling without external loading, the term *thermal fatigue* (TF) or *thermal stress fatigue* is used. This process can be caused by steep temperature gradients in a component or across a section and can occur in a perfectly homogeneous isotropic material. For example, when the surface is heated it is constrained by the cooler material beneath the surface, and thus the surface undergoes compressive stresses. Upon cooling, the deformation is in the reverse direction, and tensile stresses could develop. Under heat/cool cycles, the surface will undergo TF damage. Examples of TF are encountered in railroad wheels subjected to brake-shoe action, which generates temperature gradients and, consequently, internal stresses (Ref 1, 2).

On the other hand, TF can develop even under conditions of uniform specimen temperature, instead caused by internal constraints such as different grain orientations at the microlevel or anisotropy of the thermal expansion coefficient of certain crystals (noncubic). Internal strains and stresses can be of sufficiently high magnitude to cause growth, distortion, and surface irregularities in the material (Ref 3). Consequently, thermal cycling results in damage and deterioration of the microstructure. This behavior has been observed in pure metals such as uranium, tin, and cadmium-base alloys and in duplex steels with ferritic/martensitic microstructures.

The term *thermomechanical fatigue* (TMF) describes fatigue under simultaneous changes in temperature and mechanical strain (Ref 4, 5). Mechanical strain is defined by subtracting the thermal strain from net strain, which should be uniform in a specimen. The mechanical strain arises from external constraints or externally applied loading. For example, if a specimen is held between two rigid walls and subjected to thermal cycling (and is not permitted to expand), it undergoes "external" compressive mechanical strain. Examples of TMF can be found in pressure vessels and piping; in the electric power industry, where structures experience pressure loadings and thermal transients with temperature gradients in the thickness direction; and in the aeronautical industry, where turbine blades and turbine disks undergo temperature gradients superimposed on stresses due to rotation. In the railroad application discussed earlier, when external loading due to rail/wheel contact is considered, then the material undergoes the more general case of TMF. The temperature rise on the surfaces of cylinders and pistons in automotive engines combined with applied cylinder pressures also represents TMF. Based on the mechanical strain range, the results of TF and TMF tests should correlate well.

A distinction must be drawn between isothermal high-temperature fatigue as cyclic straining under constant nominal temperature conditions versus TMF. As such, isothermal fatigue (IF) can be considered a special case of TMF. In most the deformation and fatigue damage under TMF cannot be predicted based on IF information. Therefore, TMF experiments have been considered in studies of both stress-strain representation and damage evolution.

Sometimes the term *low-cycle thermal fatigue* or *low-cycle thermomechanical fatigue* is used. Low-cycle fatigue (LCF) can be identified two ways: (1) high-strain cycling where the inelastic strain range in the cycle exceeds the elastic strain range and (2) where the inelastic strains are of sufficient magnitude that they are spread uniformly over the microstructure. Fatigue damage at high temperatures develops as a result of this inelastic deformation where the strains are nonrecoverable. In low-cycle cases, the material suffers from damage in a finite (short) number of cycles. Thermomechanical fatigue is often a low-cycle fatigue issue. For example, in railroad wheels only severe braking applications--occurring infrequently over thousands of miles--contribute to damage, fewer than 10,000 cycles take place during a wheel's lifetime. Similarly, the largest thermal gradients and transients in jet engines develop during startup and shutdown. The total number of takeoffs and landings for an aircraft is fewer than 30,000 cycles over the lifetime of an aircraft. In the laboratory, investigations often are conducted under low-cycle conditions to complete the experiments in a reasonable period of time.

The inability to predict TMF damage from the IF database continues to challenge engineers and researchers. Thermomechanical fatigue encompasses several mechanisms in addition to "pure" fatigue damage, including high-temperature creep and oxidation, which directly contribute to damage. These mechanisms differ, depending on the strain-temperature history. They are different from those predicted by creep tests (with no reversals) and by stress-free (or constant-stress) oxidation tests. Microstructural degradation can occur under TMF in the form of (1) overaging, such as coarsening of precipitates or lamellae; (2) strain aging in the case of solute-hardened systems; (3) precipitation of second-phase particles; and (4) phase transformation within the temperature limits of the cycle. Also, variations in mechanical properties or thermal expansion coefficients between the matrix and strengthening particles (present in many alloys) result in local stresses and cracking. These mechanisms influence the deformation characteristics of the material, which inevitably couple with damage processes.

Because of the importance of TMF in real-world applications, considerable attention has been devoted to the problem via workshops and symposiums. Ever since the early 1950s and 1960s, TMF experiments have been reported by research groups in the United States, Europe, and Japan. A number of books, review articles, and symposia proceedings on the subject have been published (Ref 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, and 20). The advent of computer control and servohydraulic testing equipment has allowed simultaneous, accurate control of temperature and strain. Consequently, research in the field has flourished.

The database of TMF research, however is small compared to the IF database. Experiments involving TMF remain difficult and expensive. The use of IF data to predict the performance of a material under TMF has been demonstrated to have drawbacks. The use of isothermal LCF and mechanical strain-range results at the maximum temperature end (or at a temperature with low IF resistance) may still be nonconservative. Attempts have been made to relate TMF crack growth to IF crack growth using linear elastic fracture mechanics (LEFM) concepts, but further refinements incorporating elastic-plastic fracture mechanics (EPFM) are needed. Many of the existing models do not account for the interaction of the mechanical strain with temperature. This interaction is rather complex and not well understood.

A distinction must be drawn between TMF and thermal shock (Ref 6, 21). Thermal shock involves a very rapid and sudden application of temperature (due to surface heating or internal heat generation), and the resulting stresses are often different from those produced under slow heating and cooling (i.e., quasi-static) conditions. Physical properties, such as specific heat and conductivity (which do not appear in low-strain-rate cases), appear explicitly in the thermal shock case. The rate of strain influences the material response and should be considered in damage due to thermal shock or in selection of materials for better thermal shock resistance.

Finally, if the body is subjected to thermal cycling conditions with superimposed net section loads, the component will undergo thermal ratcheting, which is the gradual accumulation of inelastic strains with cycles (Ref 22, 23). Failure due to thermal ratcheting involves both fatigue and ductile rupture mechanisms. The "two-bar structure" will be used to illustrate thermal ratcheting in a later section. Thermal ratcheting sometimes occurs unintentionally in thermomechanical tests when a region of the specimen is hotter than the surrounding regions, resulting in a bulge in the hot region.

This article provides an overview of the experimental methods in TF and TMF and presents experimental results on structural materials that have been considered in TF and TMF research. Life prediction models and constitutive equations suited for TF and TMF are also covered.

### Mechanical Strain and Thermal Strain

Free (unrestrained) thermal expansion and contraction produce no stresses. When the thermal expansion of a body is restrained upon uniform heating, thermal stresses develop. Consider the case where a bar is held between two rigid walls and subjected to thermal cycling. The length of the bar cannot change during heating and cooling. Let  $T_0$  be the reference temperature at which the bar was placed under *total constraint*. The compatibility equation for this bar is given as:

$$\epsilon_{\text{NET}} = \epsilon_{\text{TH}} + \epsilon_{\text{MECH}} = \alpha(T - T_0) + \epsilon_{\text{MECH}}$$

In this case the net strain is zero, and all of the thermal strain is converted to mechanical strain. The thermal strain is defined as the product of coefficient of thermal expansion and the temperature range  $T - T_0$ , where  $T$  is the current temperature. Then,

$$\epsilon_{\text{MECH}} = -\alpha(T - T_0)$$

Sometimes the total constraint case is identified as  $\dot{\epsilon}_{\text{th}}/\dot{\epsilon}_{\text{mech}} = -1$ . When this ratio is larger than -1, some free expansion and contraction occur, and the term *partial constraint* is used. If the  $\dot{\epsilon}_{\text{th}}/\dot{\epsilon}_{\text{mech}}$  ratio is lower than -1, the condition is known as *overconstraint* (Ref 24). Therefore, the constraint influences the mechanical strain for a given thermal strain. Mechanical strain comprises elastic strain and inelastic strain (once yield stress is reached) and is the key parameter in TMF studies. The stress/mechanical-strain behavior shown in Fig. 1 is highly idealized; the material exhibits no hardening after yielding, the tension and compression strength are the same, and elastic modulus is independent of temperature. Upon heating, the bar is elastic and follows the stress-strain curve along  $OA$ . At  $A$ , the bar yields in compression, and upon further increase in temperature the mechanical strain on the bar increases along  $AB$ . The bar accumulates inelastic strain along  $AB$ . If the bar is cooled from  $B$ , it will deform in the reverse (i.e., tensile) direction. When the initial temperature is reached, the bar will return to zero mechanical strain, but a residual tensile stress will exist in the bar at point  $C$ . If the bar is again heated to the maximum temperature, the material will cycle between the stress point  $B$  and  $C$ . The bar is operating within the "shakedown" regime. It is unlikely that the bar will fail under these conditions because there is no plastic flow after the first reversal.

FIG. 1 IDEALIZED STRESS-STRAIN BEHAVIOR UNDER TOTAL CONSTRAINT

Next, consider the case when the thermal strain in the first heating portion of the cycle exceeded twice the elastic strain and a mechanical strain corresponding to point *D* is reached. Upon cooling back to the initial temperature,  $T_0$ , the bar will yield in tension and inelastic flow will occur until point *E* is reached. Upon reheating, the bar will deform in the reverse direction (dashed line) until it reaches point *D* in compression. A hysteresis loop develops as a result of this thermal cycle. Under alternate heat/cool cycles, forward and reverse yielding will occur every cycle, resulting in failure in a finite number of cycles.

The constrained bar model is conceptually easy to visualize, but in real structures the condition can be different from total constraint. This will be analyzed later in this article.

### Experimental Techniques in TF and TMF

Table 1 summarizes different heating methods for TF and TMF. The advantages and disadvantages of each technique are listed, as are the materials examined. In early work, experimenters subjected specimens alternately to high and low temperatures with no external loading. One way to accomplish this procedure was by immersing the specimens in cold and hot fluidized beds, which can be operated up to 1150 °C (2100 °F) (Ref 49). Over the years, various wedge-shape specimen geometries have been used.

**TABLE 1 SUMMARY OF TMF AND TF TEST METHODS**

<b>TYPE OF TEST</b>	<b>HEATING METHOD</b>	<b>ADVANTAGES</b>	<b>DISADVANTAGES</b>	<b>MATERIALS STUDIED</b>	<b>REFERENCE</b>
TF	IMMERSION IN HOT AND COLD OIL BATH	SIMPLICITY OF THE EXPERIMENT	TRANSIENT STRESS STRAIN COULD BE PRESENT AND SHOULD BE CALCULATED	NONCUBIC CRYSTALS, INCLUDING TIN, ZINC, CADMIUM	3
TMF	DIRECT RESISTANCE	RAPID HEATING; ALLOWS SPACE TO MOUNT THE EXTENSOMETER AND PYROMETER FOR CRACK GROWTH MEASUREMENTS	ELECTRIC ISOLATION OF GRIPS; LOCAL HEATING OF CRACK TIPS	CONDUCTIVE MATERIALS, STAINLESS STEEL	25, 26, 27, 28, 29, 30, AND 31
TMF AND TF	INDUCTION (10-450 KHZ, 5-40 KW CAPACITY)	RAPID HEATING; COMPLEX SPECIMEN GEOMETRIES PERMITTED; INERT ENVIRONMENT TESTING USING BELLOWS	EXPERIENCE WITH COIL DESIGN REQUIRED; ELECTRIC NOISE IN THE STRAIN SIGNAL DUE TO HIGH-FREQUENCY MAGNETIC FIELDS; HIGH COST OF UNIT	ALUMINUM, COPPER, STEELS, NICKEL-BASE SUPERALLOYS	24, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, AND 45
TMF AND TF	QUARTZ LAMP (RADIATION)	INEXPENSIVE; UNIFORM TEMPERATURE OVER DIFFERENT ZONES OF THE SPECIMEN	SHADOW EFFECTS; SLOW COOLING RATES; ENFORCED COOLING NEEDED	NICKEL- AND COBALT-BASE SUPERALLOYS, METALLIC COMPOSITES	46, 47, AND 48
TF	FLUIDIZED BED	GOOD FOR SCREENING TF RESISTANCE OF MATERIALS	STRESS-STRAIN TEMPERATURE TRANSIENTS MUST BE CALCULATED AND SURFACE OXIDATION REMOVED	NICKEL-BASE SUPERALLOYS	49, 50, 51, AND 52
TF	BURNER HEATING; FLAME HEATING	GOOD FOR SCREENING TF RESISTANCE OF MATERIALS; SURFACE HOT CORROSION DAMAGE REPRESENTATIVE OF SERVICE	STRESS-STRAIN TEMPERATURE TRANSIENTS MUST BE CALCULATED	NICKEL-BASE SUPERALLOYS, STEELS	53
TF	THERMAL FATIGUE UNDER BENDING	UNDER REVERSED BENDING ONE SURFACE	STRESS-STRAIN GRADIENTS MUST BE CALCULATED	NIMONIC ALLOYS	54

		UNDERGOES OP, THE OTHER UNDERGOES IP			
<b>TF</b>	<b>DYNAMOMETER (FRICTION HEATING)</b>	<b>VERY HIGH TEMPERATURES ON SURFACE REACHED; REPRESENTATIVE OF SERVICE</b>	<b>OXIDES ARE WEDGED INTO CRACKS; FRICTION CHARACTERISTICS CHANGE WITH TIME</b>	<b>0.5 TO 0.7% C STEELS</b>	<b>1, 2</b>

The crack growth can be observed and the data presented as a function of maximum temperature. If the results are to be compared to IF or TMF tests, the stresses and strains should be calculated (Ref 51, 55) with the finite-element method (FEM) or other numerical methods. The geometry and strain-temperature variation for the wedge specimen are shown in Fig. 2. Note that as the temperature increases, the strain-temperature variation is out of phase (OP). The minimum strain is reached within 10 s. At times beyond 10 s, the strain-temperature variation is in-phase (IP). Upon cooling, the reverse behavior was observed. Relative thermal fatigue resistance of many alloys can be classified with fluidized-bed experiments. This technique has proved to be of considerable value in examining the role of directional solidification, grain size, and  $\gamma'$  size and morphology in superalloys (Ref 51, 52, 56). The  $\epsilon$ - $T$  variation in Fig. 2(b) resembles the TMF diamond counterclockwise (DCCW) history that will be discussed later.

Part	$R_p \pm 0.001$	$2R \pm 0.01$

FIG. 2 (A) WEDGE GEOMETRY FOR TF STUDIES. DIMENSIONS GIVEN IN INCHES. (B) STRAIN-TEMPERATURE

Instead of the fluidized-bed technique, burner heating and quartz lamp heating can be applied to the specimens. More recently, Remy and colleagues (Ref 47) used the quartz heating method to study the thermal fatigue behavior of nickel- and cobalt-base superalloys. Their specimen geometry was slightly different from the wedge used in early studies, but the principles of the method were the same. The use of quartz lamps is considerably more economical than other thermal fatigue heating methods. Simovich (Ref 34) developed a different specimen design: 5 cm diam disk (Fig. 3). This specimen was heated axisymmetrically using an induction heater with no external load, and a temperature gradient was developed in the radial direction. Cooling water was pumped through the large hole; the dark spot at the right marks a typical location for thermocouples. The maximum temperature considered was 650 °C (1200 °F) and the cycle time was approximately 60 s (controlled by induction heating). Using an axisymmetric model, Simovich calculated the circumferential stresses upon cooling and compared these results to experimental measurements. Under these conditions, cracks near 7 mm (0.3 in.) appeared in less than 2000 cycles in 0.7% C class steels.

**FIG. 3 DISK SPECIMEN, SHOWING RADIAL CRACKS LARGER THAN 6.35 MM, USED BY SIMOVICH (REF 34) IN THERMAL FATIGUE STUDIES ON STEELS. THE DARK SPOT AT THE RIGHT IS USED FOR TEMPERATURE SENSING.**

All the experiments discussed thus far involved no external loading. Thermomechanical fatigue experiments with externally imposed strain were pioneered by Coffin (Ref 4, 25), who plotted the results versus plastic strain range. Both hollow and solid specimen designs were used. The hollow design allows more rapid heating and cooling. On the other hand, the solid specimen design lowers the possibility of buckling. Most IF experiments have been conducted on solid specimens; to obtain meaningful comparisons, such specimens should also be used in TMF studies.

Currently used techniques include resistance heating (Ref 4, 25, 26, 27, 28, 29), quartz lamp heating (Ref 46, 47, 48), and induction heating (Ref 24, 32, 33, 34, 35, 36, 37, 38). Induction heating is preferred, and the actual temperature gradient in the specimen should be known. Temperature measurements have been accomplished with spot-welded thermocouples, strapped-on thermocouples, or pyrometers. The temperature must be continuously monitored throughout the test. Infrared pyrometers are preferred in order to avoid potential failure originating from thermocouple beads or oxides formed at the thermocouple/specimen intersection. If thermocouples are chosen, a backup thermocouple is advised in case one should break off. A different temperature profile at different specimen locations could result in specimen barreling or instability effects. Depending on the thermal mass (i.e., grips) at the ends of the specimen and the "chimney" effect with induction or quartz heating, the coils or the lamp power in different zones of the specimen should be adjusted to avoid temperature gradients more than 5 °C (9 °F). Coffin (Ref 57) has observed progressive thickening of the sample cross section at one region and progressive thinning at another region. Manson (Ref 6) has shown that if a local region of the specimen undergoes higher temperatures relative to the major length of the specimen, localized plastic strains and creep will occur in this region due to reduced yield stress. In some cases, when localized deformation as described above occurred, experimenters accounted for it in their analysis; interpretation of the results, however, is rather complex. Optimizing the dynamic rather than the static temperature profiles circumvents this problem and should be completed before a serious TMF research program is undertaken.

Quartz or alumina rod extensometers are used to control and measure the net strain during TMF experiments. Net strain is defined as the deflection divided by the initial gage length. Special attention should be paid in mounting the extensometer

in the presence of an induction coil. The ends of the rods can be conical or chisel edged. At high temperatures, the spring load on the rods should be reduced to avoid penetration and notching of the specimen. In early studies, diametral strain measurements were made on hourglass specimens and converted to axial strain (Ref 4, 25, 28). The conversion requires Poisson's ratio and modulus of elasticity as a function of temperature and could have caused some errors in strain determination.

Thermal strain compensation is achieved by cycling the temperature at zero load before the test and determining the thermal strain as a function of temperature and time. Thermal strain can be defined using the coefficient of thermal expansion (CTE). Mechanical strain that produces stresses is defined by subtracting the thermal strain from the net strain. A good calibration and a good extensometry are required, because in TMF the mechanical strain range could be much lower than the thermal strain range.

Figure 4 shows a schematic of a modern TMF test system (currently used at the University of Illinois at Urbana-Champaign). The test machine is a digital-control servohydraulic test frame. There are two close loops (C/L) in the control system. The control tower receives axial strain, position, and load signals from the test frame and sends them to a Macintosh computer fitted with a general-purpose instrumentation bus (GPIB) board. The computer, using Labview software, generates strain and temperature histories, which are transmitted to the temperature controller and to the control tower. Data collection is performed with the Labview software, and the results are displayed on the monitor during the experiment. A noncontact infrared pyrometer device has been used for temperature measurements. Specimens were heated using a high-frequency induction heater with a 15 kW capacity. The test system can perform TMF IP and OP tests, IF tests, and other complex strain-temperature variations.

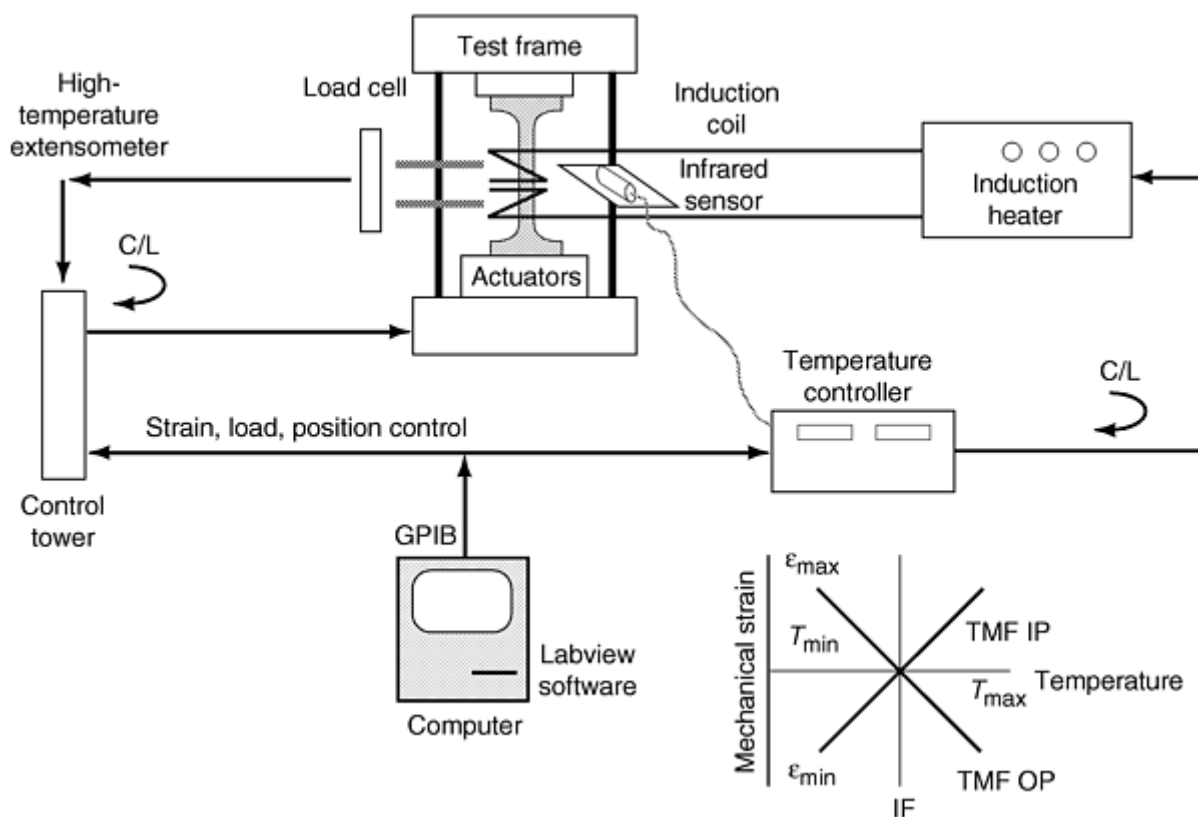

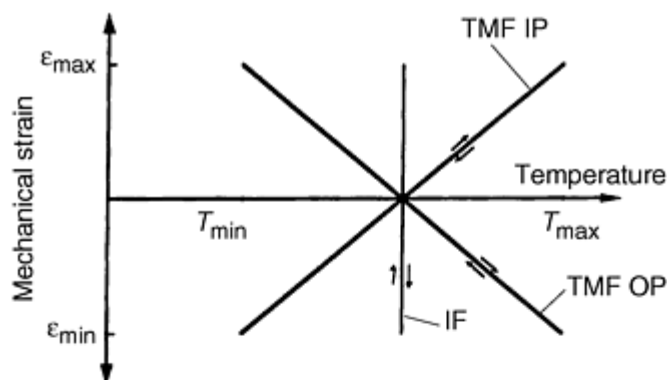

FIG. 4 SCHEMATIC OF A MODERN TMF SYSTEM

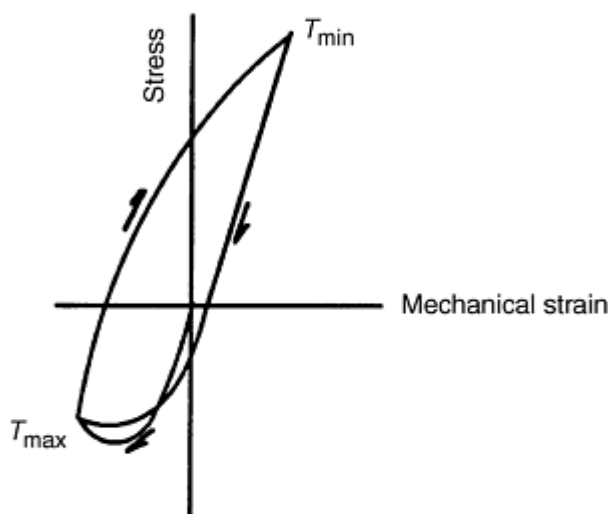

### TMF IP versus TMF OP

Mechanical strain/temperature waveform is classified according to the phase relation between mechanical strain and temperature. In-phase TMF means that peak strain coincides with maximum temperature; out-of-phase TMF means that peak strain coincides with minimum temperature. These two cases are shown in Fig. 5(a), along with the IF case. Generic hysteresis loops corresponding to the TMF OP and TMF IP cases are shown in Fig. 5(b) and 5(c), respectively. For a TMF cycle, the hysteresis loops are "unbalanced" in tension versus compression. In the TMF OP case, considerably more

inelastic strains develop in compression relative to tension. The opposite behavior occurs in the TMF IP case. Some TMF experiments have been conducted under  $R_\epsilon = -1$  (i.e., completely reversed) conditions. Other TMF experiments have been conducted under  $R_\epsilon = -\infty$  (maximum mechanical strain is zero; see Fig. 1 [Ref 24]) and  $R_\epsilon = 0$  conditions (minimum mechanical strain is zero [Ref 4]).

(c)

FIG. 5 (A) MECHANICAL STRAIN/TEMPERATURE VARIATION IN TMF OP, TMF IP, AND IF. (B) TMF OP STRESS-

## STRAIN RESPONSE. (C) TMF IP STRESS-STRAIN RESPONSE

The inelastic strain is defined by subtracting the elastic strain from the mechanical strain:

$$\epsilon_{in} = \epsilon_{mech} - \frac{\sigma}{E\{T(t)\}} \quad (\text{EQ 1})$$

For computational purposes, pairs of stress and temperature data points are needed. The variation in elastic modulus,  $E\{T(t)\}$ , as a function of temperature should be determined from isothermal experiments. A stress/inelastic strain hysteresis loop can be constructed using Eq 1. If there are hold periods during the TMF cycle, the equation will still be valid. The mechanical strain range,  $\Delta\epsilon_{mech}$ , is shown in Fig. 6. The stress range in a TMF cycle is also shown for the OP case. The loop for the IP case is similar, but reversed. Note that at the minimum strain (point *B*) the stress is not necessarily a minimum. Inelastic deformation with softening due to decrease in strength with increasing temperature is observed during *AB*. At *B* the maximum temperature is reached. Upon cooling, the behavior is elastic, followed by plastic deformation at the low-temperature end.

FIG. 6 DEFINITIONS OF STRESS RANGE AND MECHANICAL STRAIN RANGE IN TMF

For engineering purposes, the inelastic strain range of a thermomechanical cycle can be determined to a first approximation by subtracting the elastic strains computed at the maximum and minimum strain levels. This gives:

$$\Delta\epsilon_{in} \approx \Delta\epsilon_{mech} - \left( \frac{|\sigma_B|}{E_B} + \frac{|\sigma_C|}{E_C} \right) \quad (\text{EQ 2})$$

where  $E_C$  is the elastic modulus at the maximum strain and  $E_B$  is the elastic modulus corresponding to the minimum strain. Equation 2 slightly underestimates the inelastic strain range compared to the more exact equation. Note that the inelastic strain range includes the plastic strain, creep strain, and other strain components (e.g., transformation strain). Separation of plastic and creep strains in a TMF cycle is not straightforward. If needed, it can be done experimentally (Ref 58) by stress hold at selected points of the hysteresis loop or via constitutive models including plasticity and creep. Several constitutive models have been proposed for thermomechanical cyclic loadings and will be discussed later.

Just as in IF conditions, the TMF response of engineering materials involves cyclic hardening, cyclic softening, or cyclically stable behavior, depending on the microstructure, the maximum temperature level, and the phasing of strain and temperature. However, the behavior can be somewhat complex because of strain-temperature interaction. A material can harden, soften, or be cyclically stable at  $T_{\max}$  of the cycle; likewise, at  $T_{\min}$  the material can cyclically soften, harden, or be stable. Two possibilities are shown in Fig. 7. In Fig. 7(a), the material softens at  $T_{\max}$  and remains cyclically stable at  $T_{\min}$ . The material can cyclically soften at high temperature due to thermal recovery, causing coarsening of the microstructure, and in this case the hysteresis loops appear to "climb" in the tensile direction. Therefore, the tensile mean stress increases with increasing number of cycles. The microstructural coarsening could subsequently affect the strength at  $T_{\min}$ , with the maximum stress in the cycle dropping with increasing number of cycles. Thereafter, the climbing of the hysteresis loops stops and the range of stress in the cycle decreases. This behavior has been documented in Ref 59. In the second example (Fig. 7b), stable behavior is observed at  $T_{\max}$ , but the strength at  $T_{\min}$  increases because of dynamic or static strain-aging effects. In this case, the hysteresis loops also climb in the tensile direction and, at the same time, overall stress range increases. Examples of this are discussed in Ref 60.

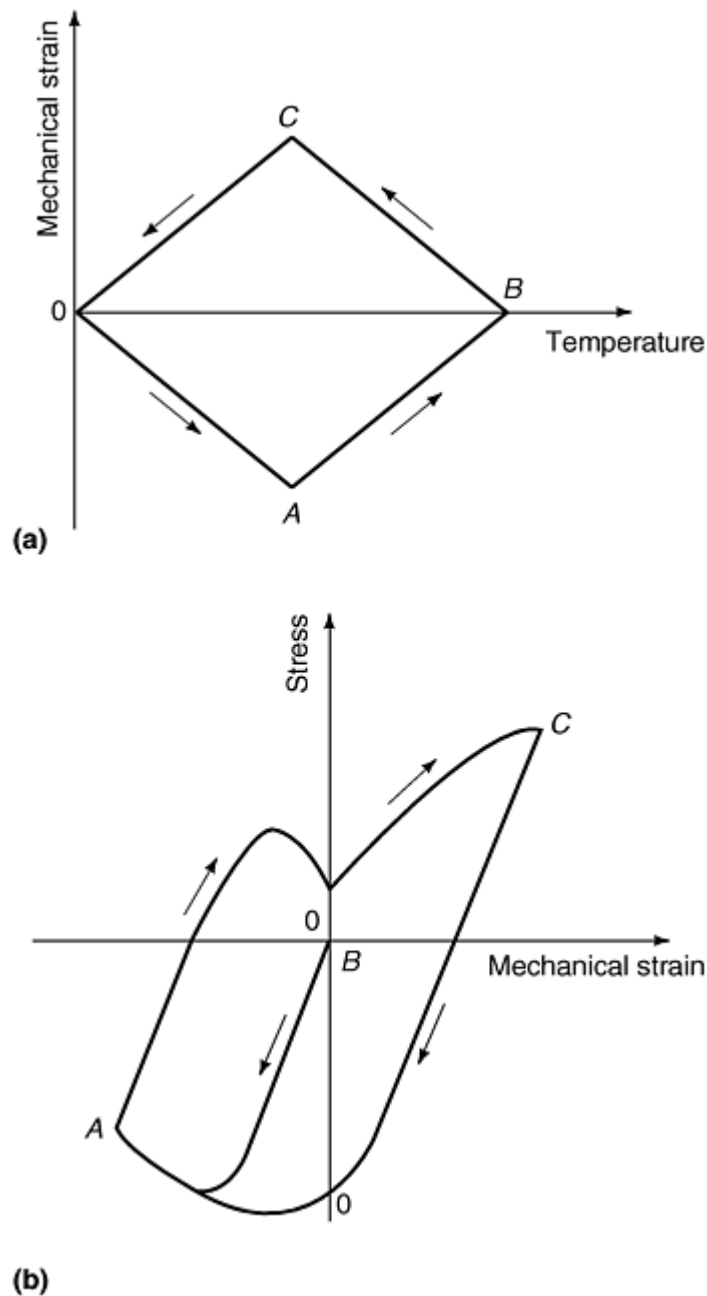

FIG. 7 STRESS-STRAIN RESPONSE UNDER CYCLIC SOFTENING (A) OR CYCLIC HARDENING (B) CONDITIONS

### Other Strain-Temperature Variations in TF and TMF

Diamond (or baseball) TMF strain variation is obtained by changing the mechanical strain and temperature  $90^\circ$  or  $270^\circ$  out of phase. The diamond path should be specified as clockwise (DCW) or counterclockwise (DCCW), which could influence TMF life. The strain-temperature variation and the generic hysteresis loops for the DCCW case are shown in Fig. 8. In many structural alloys studied, the DCW and DCCW were not as damaging as TMF IP or TMF OP, because at the maximum temperature neither the strains nor the stresses were at a maximum. It is important to study the diamond TMF histories; they are encountered in many practical situations, such as turbine blades. Examples of more complex strain-temperature histories observed in service will be discussed in a later section.

**FIG. 8 STRAIN-TEMPERATURE VARIATION (A) AND SCHEMATIC OF STRESS-STRAIN RESPONSE (B) FOR THE DCCW CASE**

A variation of the diamond history was proposed in the early 1970s (Ref 28). The term *bithermal fatigue* was coined in the mid-80s by NASA researchers (Ref 30). In this case, the tensile portion of the loop is applied at one temperature,  $T_1$ , and the compressive portion of the loop is conducted at a different temperature,  $T_2$ . The temperature is changed,  $T_1 \leftrightarrow T_2$ , at zero stress. Advantages of this technique are that the tests can be conducted without the need for TMF computer software and the results more readily related to IF tests. If the thermal strains are large, however, the extensometer must have the range and the resolution to handle strain control at both temperature extremes. Also, some creep recovery due to internal stresses could occur during the zero stress temperature excursions.

## Thermal and Thermomechanical Fatigue of Structural Alloys

Huseyin Sehitoglu, Department of Mechanical and Industrial Engineering, University of Illinois

---

### TF and TMF of Structural Alloys

#### Carbon Steels, Low-Alloy Steels, and Stainless Steels

One of the early laboratory investigations of thermal fatigue in steels was conducted at the University of Illinois to further understand TMF in railroad wheels (Ref 1, 2). During the brake-shoe action on a railroad wheel, the rim is constrained by the surrounding cooler hub and the plate. Upon heating, circumferential compressive stresses develop; upon cooling, yielding in the tensile direction can occur. Under repeated brake applications, TF cracks can develop. This is simulated in the laboratory with a wheel dynamometer and a brake-shoe heating. Thermal cracks can grow to a size sufficient to exceed the fracture toughness of the material, resulting in catastrophic fracture.

Later experiments were conducted by Simovich (Ref 4), who subjected disk specimens to TF with induction heating. In this case, disks approximately 50 mm (2 in.) in diameter were heated and cooled with induction, generating a temperature gradient in the radial direction. The steel developed radial cracks that grew to sizes near 10 mm (0.4 in.). Simovich conducted a thermal analysis and stress analysis of the disk and correlated the fatigue results as a function of mechanical strain and stress range.

Well-controlled TMF experiments using direct resistance heating were conducted by Coffin at General Electric. The effect of prestrain on the fatigue life of type 347 stainless steel under thermal cycling has been established (Ref 4), as has the maximum temperature effect (up to 600 °C, or 1110 °F). The role of strain hold period in reducing TMF lives was established for periods of from 6 to 180 s. The influence of the hold period was explained as an increase in the inelastic strain range of the cycle. Coffin also examined the effect of thermal cycling on the subsequent stress-strain response and noted strain hardening of the material. Papers by Coffin (Ref 4) and Manson (Ref 5) were the first to propose a relationship between plastic strain range and life was proposed; this was later coined as the low-cycle fatigue, or Coffin-Manson, equation.

Coffin's results on type 347 stainless steel are shown in Fig. 9. The specimens were subjected to total constraint ( $\epsilon_{net} = 0$ ). The mean temperature was maintained constant at 350 °C (660 °F), and the maximum temperature considered was as high as 650 °C (1200 °F). The horizontal axis (log scale) is the fatigue life, defined as fracture of the specimen. The vertical axis (linear coordinates) is given in terms of temperature range and mechanical strain. In the experiments of Coffin, these two quantities are not exactly equal because of deformation of supports and temperature distribution along the length of the tube. Therefore, the mechanical strain range is slightly lower than the thermal strain range in these experiments. The specimen is hot in tension and cold in compression and is undergoing TMF OP loading. Whether the specimen is clamped at the minimum temperature or the maximum temperature influences only the mean strain and has very little, if any, influence on fatigue life.

**FIG. 9 RESULTS OF TMF EXPERIMENTS BY COFFIN (REF 4) UNDER TOTAL CONSTRAINT FOR ANNEALED TYPE 347 STAINLESS STEEL**

Coffin used resistance heating and developed a cam-and-lever mechanism to apply independent strains on the sample. This design has been duplicated in a number of subsequent TMF investigations in Japan, the United States, and the former Soviet Union. For example, research on constrained specimens was conducted on railroad wheel material, and hysteresis loops were established for carbon steels (0.4 to 0.7% C) at temperatures reaching 500 °C (930 °F) (Ref 39).

In Great Britain, the thermal fatigue resistance of carbon steels, alloy steels, and cast irons was investigated by Baron and Bloomfield (Ref 38) in the early 1960s. They used induction heating of an edge of a cold specimen. The strains were not measured or calculated for this case, but results have been displayed using  $T_{max}$  versus cycles to form a crack of finite size. The maximum temperature considered was 900 °C (1650 °F), where most steels transform to austenite, and martensite formed upon rapid cooling, resulting in rapid formation of cracks. At high temperatures austenitic stainless steels were found to be superior to other steels, while some of the nodular irons approached the TMF resistance of plain carbon steels.

Thermomechanical fatigue research on steels has attracted considerable attention in Japan. Kawamoto et al. (Ref 29) conducted TMF experiments on 0.7% C steels and 18-8 stainless steels. They confirmed that the hold periods reduced fatigue life and suggested that hold periods allow formation of metal carbides and oxides at grain boundaries. They found no considerable difference between IP and OP cycling when the results were compared based on mechanical strain range. They made the noteworthy observation that under TMF the lives were shorter than under IF, even when the IF test was conducted at the maximum temperature of the thermal cycle.

Taira and colleagues (Ref 35, 36, 37) have authored a number of key TMF papers covering a range of steels, including 1016 steel, chromium-molybdenum steels, and type 304 stainless steel. They used the mechanical strain range and plastic strain range to compare their data obtained under thermal cycling of 1016 steel in the temperature range of 100 to 600 °C (210 to 1110 °F). It is expected that considerable creep and oxidation effects are present in these steels at temperatures exceeding 500 °C (930 °F). Taira et al. (Ref 61, 62) also conducted thermal ratcheting tests under TMF OP conditions with stress control. Thermomechanical fatigue damage was predicted from creep-rupture data for these experiments.

Fujino and Taira (Ref 63) demonstrated that for type 304 stainless steel (at 200 to 750 °C, or 390 to 1380 °F) the TMF IP lives were shorter than the TMF OP case by nearly a factor of four. Their results are shown in Fig. 10 for carbon steel and for type 304 stainless steel. Isothermal fatigue data at 425 and 750 °C (800 and 1380 °F) for type 304 and at 400 and 500 °C (750 and 930 °F) are given. The TMF OP lives were lower than IF lives in carbon steel, whereas for the stainless steel they were similar to the IF lives at maximum temperature of the cycle. The researchers made measurements of grain-boundary sliding and found evidence of it in TMF IP cases, but not in TMF OP or IF loadings. As the maximum temperature was lowered from 750 to 600 °C (1380 to 1110 °F) in TMF experiments (Ref 36), the TMF OP, TMF IP, and IF results at  $T_{max}$  of the cycle converged. It is clear that grain-boundary sliding due to unbalanced displacements at the microlevel becomes more pronounced as the maximum temperature in the cycle is increased.

**FIG. 10 RESULTS OF FUJINO AND TAIRA (REF 53) ON CARBON STEEL AND TYPE 304 STAINLESS STEEL, SHOWING MORE DAMAGE IN TMF IP RELATIVE TO TMF OP**

Other studies in Japan were conducted by Udoguchi and Wada (Ref 31), who considered H46 martensitic stainless steel and type 347 stainless steel under TMF OP conditions with a maximum temperature of 700 °C (1290 °F) and 1040 steel with a maximum temperature of 400 °C (750 °F). Their results also confirmed that the TMF resistance is inferior to IF even when the results are compared at  $T_{max}$ . One of the most systematic investigations of TMF of steels was undertaken by Kuwabara and Nitta in the mid to late 1970s (Ref 40, 41). They conducted TMF OP and TMF IP experiments on type 304 stainless steel under continuous cycling and also in the presence of tensile or compressive hold periods (300 to 600 °C, or 570 to 1110 °F). The TMF IP lives were shorter than TMF OP lives, but comparison with IF lives at 600 °C (1110 °F) showed that IF tests were more damaging. In another set of experiments on type 304, they showed that TMF IP and TMF OP were comparable when the maximum temperature was only 550 °C (1020 °F) (Ref 42); still, more intergranular cracking was observed for the IP case relative to the IF and OP cases. A hold period on these steels drastically reduced the TMF IP lives, but had little effect on the TMF OP behavior. The trends were somewhat reversed when chromium-molybdenum-vanadium steels were investigated; 1Cr-Mo-0.25V (Ref 43) (examined between 300 and 550 °C, or 570 and 1020 °F) and nickel-molybdenum-vanadium forged steel (Ref 44) exhibited shorter lives in TMF OP compared to TMF IP. This behavior is consistent with the propensity of these alloys to suffer from considerably higher oxidation damage relative to stainless steels. For both alloys, higher surface crack density was measured in the TMF OP case. At high strains TMF OP and TMF IP results converged. In early studies, Manson et al. (Ref 64) demonstrated the significant surface cracking due to oxidation effects in low-alloy steels; the TMF results were consistent with the shorter lives observed in PC (plasticity in tension reversed by creep in compression) type cycling relative to CP (creep in tension reversed by plasticity in compression) type cycling for this class of alloys.

Research at NASA (Ref 58) considered type 316 stainless steel subjected to temperature cycling in the range of 230 to 815 °C (445 to 1500 °F). Considerable creep strains were measured, and thermal recovery was present in these TMF experiments. Later, Halford and colleagues (Ref 30) conducted bithermal IP and bithermal OP tests on type 316, which showed good agreement with the earlier TMF OP and TMF IP tests. Their results showed that TMF IP was more damaging than TMF OP, a finding confirmed by Miller and Priest (Ref 19) on the same class of stainless steel. Sheffler (Ref 28) conducted bithermal TMF OP and TMF IP tests on type 304 stainless steel and demonstrated that both OP and IP lives were shorter than the IF data at maximum temperature of the cycle. Similarly, for the A-286 alloy the bithermal IP lives were shortest compared to OP and IF results. Sheffler made the TMF and IF comparisons for tests conducted at the same frequency and in ultrahigh vacuum. An interesting observation was that cavities formed due to unreversed grain-boundary displacements cannot be fully accommodated by intergranular sliding.

In Canada, Westwood (Ref 27, 65) conducted TMF tests on type 304 in the temperature range of 350 to 700 °C (660 to 1290 °F). The results showed good agreement between TMF IP and IF tests conducted at  $T_{max}$  of the thermal cycle, while the lives under TMF OP were longer. Although a larger difference between TMF IP and IF is expected at these temperatures, the lifetimes are generally consistent with previous data reported for similar materials.

Hysteresis response and life was studied by Jaske (Ref 66) on 1010 steel subjected to thermal cycling in the range of 95 to 540 °C (200 to 1000 °F). The cyclic hardening phenomenon was noted when the maximum temperature was below 425 °C (800 °F), possibly due to strain-aging effects. The TMF lives were significantly shorter than IF lives, even when the IF results from the maximum temperature were considered. The results of this study are shown in Fig. 11. The mechanical strain range versus life is plotted for TMF OP, TMF IP, and IF cases. There appears to be crossover in lives between TMF OP and TMF IP slightly below a strain range of 0.02. All the TMF data shown fall below the IF curves. This is consistent with the findings of Fujino and Taira (Ref 63). Similarly, Laub (Ref 67) studied 1010 steel used in heat exchangers and subjected specimens to total constraint TMF OP cycling where the mean temperature of the cycle was maintained constant. The most severe case examined was a mean temperature of 315 °C (600 °F) and a maximum temperature of 760 °C (1400 °F). Considerable oxidation of crack tips has been noted at temperatures exceeding 480 °C (900 °F).

FIG. 11 RESULTS OF JASKE (REF 66) ON TMF OF 1010 CARBON STEEL. NOTE: (6) INDICATES A 6 MIN HOLD TIME AT MAXIMUM TEMPERATURE.

Finally, in the work of Sehitoglu on 1070 steel, the stress-strain response was determined under total/partial and overconstraint TMF OP conditions with a minimum temperature of 150 °C (300 °F) and a maximum temperature of 700 °C (1290 °F). In later studies, Sehitoglu and his students investigated variable amplitude effects in TMF (Ref 59), environment effects in TMF (Ref 68, 69), phasing effects (TMF OP versus TMF IP) (Ref 68), strain-temperature changes conducive to strain aging (Ref 60), and notch effects and crack growth behavior under TMF (Ref 24, 60). A temperature-time history for a two-step TMF OP loading (total constraint) is shown in Fig. 12(a). One block includes one major cycle plus 100 minor (sub) cycles (Ref 33). In this case the major cycle underwent 150 ↔ 600 °C (300 ↔ 1110 °F) cycling under total constraint and the minor cycle experienced 500 ↔ 600 °C (930 ↔ 1110 °F). Because of considerable coarsening of the microstructure due to high-temperature exposure, the strength of the material at 150 °C (300 °F) is considerably lowered and the inelastic strain range of the cycle increases. The fatigue lives for these types of histories, where  $\Delta T_{sub} = 0, 100, 150, \text{ and } 200$  °C (30, 210, 300, and 390 °F), are shown in Fig. 12(b). This diagram indicates the dramatic deterioration of fatigue life in the presence of subcycles. On the same class of steels, Neu and Sehitoglu (Ref 68, 69) observed a typical crossover of the fatigue lives: At high strains IP tests were more damaging than OP, whereas the trend reversed at small strains. In tests conducted in a helium environment, the TMF IP experiments were more damaging than the TMF OP. The results of TMF OP and TMF IP experiments in air and in helium environment are shown in Fig. 13. The use of maximum-temperature IF data obtained for strain rates comparable to the TMF test predicted the trends, but a more sophisticated TMF life model has been proposed. Some of these studies will be discussed.

FIG. 13 COMPARISON OF TMF OP AND TMF IP EXPERIMENTS IN AIR AND IN HELIUM. SOURCE: REF 68, 69

Mughrabi and his group in Germany (Ref 70) recently conducted both TMF IP and TMF OP tests on type 304L stainless steels. They observed a higher stress amplitude in TMF relative to IF when the TMF cycle coincides with temperatures near  $450\text{ }^{\circ}\text{C}$  ( $840\text{ }^{\circ}\text{F}$ ), where maximum dynamic strain aging occurs. Similar to the work of Sehitoglu et al. (Ref 33), they found that as the maximum temperature is increased, the maximum stress in the cycle occurs before the maximum temperature and maximum strain are reached. Thermomechanical fatigue IP tests revealed shorter lives when creep damage became more pronounced, whereas cavitation damage was not observed in the TMF OP case.

It is difficult to compare the results of one investigator to another, especially in TMF loading cases. This is because the TMF strain rates or frequency is dictated by the heating and cooling system, which is unique to the investigator. Even if the same heating method is used, there are no standards for TMF specimen geometry or for test control software, and the tests are often slowed down to ensure proper agreement between temperature and strain. Improved hardware and software would lead to greater reliability and consistency among different laboratories.

**Environmental Effects.** Coffin (Ref 71, 72) was the first to emphasize the significance of oxide damage in steels. At temperature exceeding  $500\text{ }^{\circ}\text{C}$  ( $930\text{ }^{\circ}\text{F}$ ), an oxide layer forms on the surface of iron-base alloys. The iron oxides that form are brittle and facilitate crack advance into the substrate. This layer experiences a mechanical strain, which can result from one or a combination of the following: (1) strain from the applied mechanical loading in the material, (2) mismatch in the thermal expansion coefficients among the different stoichiometries of the oxides and substrate (Ref 33 and 73), (3) load due to the volume difference between the substrate and the various oxides (e.g.,  $\text{Fe}_2\text{O}_3$ ,  $\text{Fe}_3\text{O}_4$ , and  $\text{FeO}$ ) (Ref 74, 75), and (4) other factors discussed in Ref 68. These mechanisms could affect the morphology of the surface oxide as well as the growing oxide-induced crack. Tensile oxide fracture facilitates crack initiation and crack growth, because the repeated oxide fracture can channel crack growth into the substrate. In TMF OP, the oxide forms near maximum temperature and upon cooling undergoes tension and fractures locally. Skelton (Ref 76) has shown that on 0.5Cr-Mo-V steels the crack growth rate in air is nearly an order of magnitude faster than in vacuum, with crack growth rates in steam environment falling between these two extremes.

One way to separate environmental damage from fatigue and creep damage is by performing tests in an inert or nonoxidizing atmosphere. Although a number of studies have been conducted on LCF under nonoxidizing environments (Ref 77, 78, 79), only two studies have been made on TMF of steels under an inert environment (Ref 28, 68). Sehitoglu and Neu devised a unique method of testing the specimen surrounded by bellows in which helium is trapped. The experiments were conducted under both TMF IP and TMF OP conditions. The increase in life relative to air results in the TMF OP case was nearly a factor of five, whereas in the TMF IP case the lives were not significantly influenced. The results are shown in Fig. 13.

Under conditions where creep mechanisms are dominant compared to environmental interaction effects, the fatigue life in air is about the same as in an inert atmosphere (Ref 78). However, when an environmental contribution exists, the fatigue life of smooth specimens is increased by a factor of 2 to 20 in a nonoxidizing atmosphere compared to tests performed in air (Ref 68, 76, 77, 79).

**Strain Rate and Temperature Effects.** Sehitoglu and his students conducted numerous investigations of 0.7% C steels (used in railroad wheels) and established the stress-strain behavior over the temperature range of 150 to 170 °C (300 to 1290 °F) (Ref 80, 81, 82). The effects of maximum temperature, strain aging, and thermal recovery due to spheroidization effects on stress-strain response have been identified. The effects of alloying were also examined. Early experiments have been reported on TMF behavior of carbon steels; unfortunately, the hysteresis loops have not been provided in these cases.

The influence of strain rate and temperature on life has been examined by Majumdar (Ref 83), who conducted experiments with a minimum temperature of 425 °C (800 °F) and a maximum temperature of 595 °C (1100 °F). They showed that at strain rates equal to or higher than  $10^{-4}$ /s, the fractures are predominantly transgranular. For strain rates lower than  $10^{-4}$ /s, however, the fractures become intergranular and the lives are shorter than the isothermal lives at maximum temperature. Majumdar also investigated the effect of hold time and demonstrated that hold periods reduce the cycles to fatigue.

The strain rates used in TMF studies vary in a narrow range. In his original study, Coffin (Ref 4) considered the influence of hold time and demonstrated that the cycles to fatigue decreased by a factor of three when the hold time increased from 6 to 180 s. Several high-strain-rate experiments were conducted by Taira and colleagues (Ref 61, 62) and Udoguchi and Wada (Ref 31) in their work on steels. Strain rates on the order of  $10^{-4}$ /s were considered, which correspond to cycle times of 60 s. On the other extreme cycle, times near 30 min were considered (Ref 58). In most TMF research, the cycle time is on the order of 2 to 4 min, which corresponds to  $5 \times 10^{-5}$ /s. Direct resistance and induction heating methods can readily be used to produce strain rates on the order of  $5 \times 10^{-5}$ /s. Higher strain rates and the accompanying rapid temperature changes could produce temperature gradients in the specimen and make interpretation of the results difficult. Kuwabara and Nitta (Ref 84) examined the relationship between cycle time and TMF life in the range of 2 to 20 min. As the cycle time was increased, the fraction of intergranular cracks increased in the TMF IP case; however, the TMF OP results were not sensitive to strain rate. Commensurate with this finding is that TMF IP lives decreased with increasing cycle time while TMF OP lives remained constant.

Carbon steels undergo metallurgical changes in the form of coarsening of the pearlite lamellae and, ultimately, spheroidization at temperatures exceeding 400 °C (750 °F). Strain plays an important role in the spheroidization of pearlite. Deformation sets up subboundaries within the cementite, which are then rounded by diffusion driven by chemical potential gradients at the interface. This rounding of the interface edges leads to a complete band of ferrite separating the cementite. Many of these divisions occurring throughout the cementite break the lamellae up into segments, which then spheroidize. Strain-accelerated spheroidization can greatly reduce the time necessary to spheroidize a specimen at a given temperature.

In Fig. 14 the maximum stress in the TMF OP cycle is plotted versus the mechanical strain range in the cycle. Because the  $T_{\min}$  was maintained constant in these experiments, higher strain ranges were achieved with higher maximum temperature. As the temperatures exceed the 500 °C (930 °F) value (or when the mechanical strain amplitude exceeds 0.003), the maximum stress decreases gradually with increasing mechanical strain. There are two main implications of this result: (1) the maximum stress cannot be used as a predictor of fatigue damage because for the same maximum stress there are two corresponding strain levels, one in the low-temperature and the other in the high-temperature regime (see discussion in Ref 33), and (2) the softening of the material at 150 °C (300 °F) means that the resistance of the material to deformation has decreased and the inelastic strain in the cycle has increased, producing enhanced damage.

FIG. 14 DECREASE IN MAXIMUM STRESS IN TMF OP CASE DUE TO THERMAL RECOVERY. SOURCE: REF 45

**Microstructural Changes in Steels.** The mechanical properties below the transformation temperature (body-centered cubic, or bcc, phase) and above the transformation temperature (austenite face-centered cubic, or fcc, phase) are considerably different (Ref 85). Two series of creep tests were performed under constant stress and temperature. Creep tests were conducted at temperatures of 400, 450, 500, and 550 °C (750, 840, 930, and 1020 °F) on 1070 steel well below the transformation temperature of 660 °C (1220 °F); the second series was conducted to investigate creep at temperatures above the austenitic transformation at temperatures of 700 and 800 °C (1290 and 1470 °F). It was found that both the transient and steady-state creep strain rates in the fcc phase were higher than the creep rates predicted with bcc phase properties by two orders of magnitude.

The second series of relaxation experiments (Ref 85) differed from the previous set in that, before each experiment, the specimen was heated to above its austenitic transformation temperature, to 925 °C (1700 °F), and was held at this temperature for 1 h. Then the specimen was rapidly cooled in air to the desired temperature of 500 or 550 °C (930 or 1020 °F), and the experiment proceeded as outlined above. Results indicate that the final stresses are similar for experiments with preheating and experiments without preheating to 925 °C (1700 °F), considering that preheat experiments indicate an initial stress about 50% lower than experiments without preheating.

The effect of phase transformations during thermal fatigue has been explored by Nortcott and Baron (Ref 86), who noted that repeated formation of austenite and martensite during the TF cycle generally leads to cracking of the material. Similarly, Sehitoglu (Ref 24) considered TMF experiments beyond 650 °C (1200 °F) on 1070 steels where the hysteresis loops recorded displayed the transformation effect. Thermal expansion characteristics are influenced by the nature of austenitic transformation. The mean value of  $\alpha$  for 1070 steel below the transformation temperature is  $8.34 \times 10^{-6}$  1/°F, whereas the mean value for  $\alpha$  above the transformation temperature is  $1.52 \times 10^{-5}$  1/°F. The coefficient of thermal expansion can be defined two ways: (1) tangent to the thermal strain-temperature curve, or (2) as a secant modulus, the slope of the line connecting the thermal strain point to the origin. It is important to specify whether the CTE is a tangent or a secant value. When phase transformations occur, it is advisable to use a secant modulus; this avoids the problem of rapid changes in the tangent modulus upon phase transformation.

Many steels undergo strain aging, which results in considerable hardening in a TMF test or a test that involves exposure of the material to temperatures below 400 °C (750 °F). Certain temperature-strain histories in solute-hardened materials

produce strain aging, and thus strengthening, of the material. Thermomechanical fatigue studies under strain-aging conditions for steels and nickel-base superalloys have been discussed in Ref 20. Strengthening is caused by interstitial solute atoms, which anchor the dislocation motion. If the pinning of the dislocations occurs during deformation, the term *dynamic strain aging* is used (Ref 87). If the aging occurs under a constant load (after some plastic deformation), it is called *static strain aging* (Ref 87).

Static strain-aging experiments have been conducted on both 1020 and 1070 steels (Ref 80). The material was cycled at 20 °C (70 °F), but was exposed to the aging temperature time at zero stress every reversal. The experimental results are shown in Fig. 15. In these experiments, the deformation is at 20 °C (70 °F) but with intermittent exposure to 300 °C (570 °F) (up to 30 min) at zero load of the cycle. Increase in room-temperature strength as high as 30% has been measured after 40 reversals. The strain range of the hysteresis loops is  $0.005 + \Delta\sigma/2E$ , where  $\Delta\sigma$  is the stress range and  $E$  is the elastic modulus at 20 °C (70 °F). Since this material is cyclically stable at room temperature, the observed strengthening is attributed to strain aging. The specimen is cycled at a strain rate of  $2 \times 10^{-3}/s$ .

FIG. 15 EXPERIMENTAL  $\sigma$ - $\epsilon$  RESPONSE UNDER TMF STRAIN-AGING CONDITIONS. SOURCE: REF 80

Thermal recovery effects have been observed in steels when temperatures exceed 500 °C (930 °F). In the case of pearlitic steels, the lamellae structure coarsens and, ultimately, a spheroidized material results. Examples of the microstructural change are illustrated in Fig. 16. Consequently, these changes alter the stress-strain response of the material. Figure 16(a) shows the mean lamellae thickness to be nearly 145 Å. As the microstructure becomes spheroidized (Fig. 16b), the mean spheroidite diameter is much larger than any of the cementite thicknesses. The coarsening process takes the form of an early breaking-up of the lamellae, followed by spheroidite growth. This difference in size is apparent in Fig. 16. This phenomenon was documented in early studies by Sehitoglu (Ref 25, 34, 82). Table 2 summarizes the microstructural damage mechanisms identified by various experiments on steels.

### TMF of Aluminum Alloys

Only a handful of experiments has been reported on the elevated-temperature behavior of aluminum alloys. At temperatures exceeding 150 °C (300 °F), aluminum alloys undergo creep damage in the form of grain-boundary cavitation (Ref 89) and intergranular crack growth (Ref 90). Under TMF conditions with  $T_{\text{mean}} = 200$  °C (390 °F), creep damage is expected to occur under both OP and IP conditions. Extensive studies on the fatigue of aluminum (Ref 91, 92, 93) at room temperature revealed accelerated fatigue damage in air relative to a vacuum environment. At elevated temperatures the environment (oxidation) effect is expected to be more pronounced (Ref 94, 95, 96). Figure 17 compares TMF OP and TMF IP lives for aluminum alloys 2xxx-T4, a powder metallurgy material with minimal porosity level. In the experiments,  $R_{\epsilon} = -1$ , the minimum temperature was 100 °C (210 °F), and the maximum temperatures were 200 and 300 °C (390 and 570 °F). A crossover in lives occurred for the 100  $\leftrightarrow$  200 °C case, but there was no such crossover for the 100  $\leftrightarrow$  300 °C case (Ref 90). Two other studies on TMF of aluminum alloys have been reported (Ref 97, 98). In Ref 97, a cast Al-Si-10Mg alloy was studied under total constraint TMF OP conditions; the mechanical strain increased proportionally with increasing maximum temperature. The minimum temperature was maintained constant at 50 °C (120 °F). The most severe case studied was under 50  $\leftrightarrow$  350 °C (120  $\leftrightarrow$  660 °F) conditions, and considerable cyclic softening was observed both at the low- and high-temperature ends of the cycle. In Ref 98, the cast alloys Al319 and Al356 were considered. This work studied the role of dendrite arm spacing, porosity level, composition, and heat treatment.

FIG. 17 COMPARISON OF TMF OP AND TMF IP LIVES FOR AL 2XXX-T4. SOURCE: REF 95

Relatively very few studies have been conducted on the TMF aluminum alloys. The major issues are the following:

- OXIDATION HAS AN INFLUENCE ON FATIGUE DAMAGE BOTH AT ROOM TEMPERATURE AND AT ELEVATED TEMPERATURES. A NUMBER OF FUNDAMENTAL STUDIES HAVE BEEN MADE OF IF OF ALUMINUM AT ROOM TEMPERATURE AND A FEW VACUUM TESTS AT ELEVATED TEMPERATURES (REF 99), BUT THERE ARE NO REPORTED EXPERIMENTS UNDER TMF LOADING. BASED ON THE WORK OF BHAT AND LAIRD (REF 99), CONSIDERABLE OXIDATION DAMAGE IS PRESENT IN POLYCRYSTALLINE ALUMINUM ALLOYS.
- IF THE MAXIMUM TEMPERATURE EXCEEDS THE AGING TEMPERATURE, THEN CONSIDERABLE SOFTENING CAN BE OBSERVED IN TMF DUE TO CHANGES IN THE SHAPE AND SIZE OF THE PRECIPITATES. THE AGING TEMPERATURES CAN VARY FROM 150 TO 200 °C (300 TO 390 °F).
- CREEP DAMAGE HAS BEEN OBSERVED AT TEMPERATURES EXCEEDING 200 °C (390 °F) IN TMF EXPERIMENTS. THE CREEP DAMAGE IS IN THE FORM OF DISTRIBUTED CRACKS. WHEN CREEP DAMAGE WITH DIFFUSE CRACKS OCCURS, CONTINUUM DAMAGE MECHANICS CONCEPTS WOULD BE APPROPRIATE. IN THIS CASE, THE  $\sigma$ - $\epsilon$  BEHAVIOR OF A DAMAGED MATERIAL CAN BE DESCRIBED BY USING EFFECTIVE STRESS AND HYDROSTATIC STRESS INTEGRATED OVER THE CYCLE (REF 100).

### TMF of Nickel-Base High-Temperature Alloys

Much has been published on the high-temperature behavior of nickel-base superalloys--the development of which is ongoing, including the use of coating treatments. The major advantage of nickel-base superalloys over other metals is their useful TMF operating range, which extends to  $T_{max}/T_m = 0.8$ , where  $T_{max}$  is the maximum temperature in the cycle and  $T_m$  is the melting temperature in degrees Kelvin. On the other hand, when  $T_{max}/T_m$  values exceed 0.5, the TMF strength of steels is considerably lowered.

Depending on the test temperature, the superalloys may show either cyclic softening or cyclic hardening behavior. The hardening behavior is attributed to dislocation buildup at the precipitate/matrix interface. On the other hand, softening behavior is considered to be due to precipitate shearing, increased dislocation climb facilitated by increased diffusion rates, and reduced dislocation densities caused by recovery processes (for a review, see Ref 101 and 102).

Similar to IF tests, TMF experiments exhibit a temperature and strain range dependence of cyclic stress response. Castelli et al. (Ref 103) observed cyclic hardening of Hastelloy X under OP cycling at  $\Delta\varepsilon_m = 0.006$  over a temperature range of 600 to 800 °C (1110 to 1470 °F). When the temperature range was increased to 800 to 1000 °C (1470 to 1830 °F), cyclic softening was observed. Marchand et al. (Ref 104) tested B-1900+Hf under TMF OP and TMF IP at a temperature range of 400  $\leftrightarrow$  925 °C (750  $\leftrightarrow$  1700 °F). Cyclic stress-strain curves revealed cyclic hardening at low strain ranges and cyclic softening at high strain ranges when compared to cyclic stress-strain response at  $T_{max}$ . Sehitoglu and Boismier (Ref 105), working with polycrystalline Mar-M247 (500  $\leftrightarrow$  870 °C), found gradual cyclic softening for most of the life at small strains, whereas cyclic hardening was observed at high strains. Stress-strain behavior has been found for René 80 (Ref 106), Mar-M247 (Ref 105), and Mar-M246 (Ref 107), CMSX-6 single crystals (Ref 108), and on Inconel 617 by Macherauch and colleagues (Ref 109). They studied Inconel 617 and reported significant hardening at  $T_{max}$  of 750 to 850 °C (1380 to 1560 °F). When the maximum temperature was higher than 950 °C (1740 °F), the response was stable.

A number of Japanese investigators have published results on TMF of superalloys. An extensive study of superalloys has been undertaken by Kuwabara et al. (Ref 42), who considered Inconel 718, Inconel 738LC, Inconel 939, Mar-M247, and René 80. For Inconel 718, the temperatures were 300  $\leftrightarrow$  650 °C (570  $\leftrightarrow$  1200 °F); for the other alloys, 300  $\leftrightarrow$  900 °C (570  $\leftrightarrow$  1650 °F). For Inconel 718, Inconel 939, and Mar-M247, shorter lives were demonstrated for the TMF IP case in the high strain range and a crossover in life at small strain levels. The Inconel 738LC and René 80 exhibited shorter lives for the TMF OP case relative to TMF IP. Taira et al. (Ref 36) considered Hastelloy X in the temperature ranges 300  $\leftrightarrow$  900 °C and 300  $\leftrightarrow$  750 °C (570  $\leftrightarrow$  1650 °F and 570  $\leftrightarrow$  1380 °F) and found that TMF IP lives are considerably shorter than the TMF OP case. These results are shown in Fig. 18.

FIG. 18 COMPARISON OF TMF OP AND TMF IP LIVES FOR HASTELLOY X. SOURCE: REF 36

In Great Britain, extensive thermal fatigue studies have been reported by Glenny and Taylor (Ref 110) on Nimonic and directionally solidified nickel alloys. The duration of the thermal cycle (immersion times) and the maximum temperature effect (up to 920 °C, or 1690 °F) have been examined, and intergranular cracking has been noted. Tilly (Ref 111) used the tapered-disk geometry with the fluidized-bed technique under 20  $\leftrightarrow$  920 °C (70  $\leftrightarrow$  1690 °F) conditions. This author also conducted reverse bend tests with temperature cycling of 350  $\leftrightarrow$  1000 °C (660  $\leftrightarrow$  1830 °F) in air and in vacuum and showed an increase in fatigue life in vacuum relative to air of nearly a factor of two. The lives were lower than those predicted based on IF data at  $T_{max}$ .

Other TF experiments have been conducted by Woodford and Mowbray (Ref 50) on the nickel-base superalloys Inconel 738 and René 77 using the tapered-disk specimen. The hysteresis behavior was calculated at the disk periphery, and the temperature-strain phasing was similar to the DCW type. Crack length was monitored as a function of cycles. The temperature range was 22  $\leftrightarrow$  920 °C (72  $\leftrightarrow$  1690 °F) for both materials. These investigators made the important observation of  $\gamma'$ -depleted zones in the vicinity of crack tips. In these regions, aluminum is depleted and the  $\gamma'$  structures break down. Bizon and Spera (Ref 51) considered 22 nickel-base superalloys using the fluidized-bed technique. They noted the positive role of directional solidification and coatings on TF life.

Most nickel-base superalloys exhibit a crossover of the TMF IP and TMF OP mechanical strain-life curves. In this case, TMF IP fatigue lives are shorter than TMF OP lives at high mechanical strain ranges, but are greater than TMF OP lives at low mechanical strain ranges. The crossover occurs at approximately  $\Delta\epsilon_m = 0.0045$ . Kuwabara et al. (Ref 42) observed the crossover in life curves for Inconel 718 and Mar-M247 under temperature cycling of  $300 \leftrightarrow 650 \text{ }^\circ\text{C}$  and  $300 \leftrightarrow 900 \text{ }^\circ\text{C}$  ( $570 \leftrightarrow 1200 \text{ }^\circ\text{F}$  and  $570 \leftrightarrow 1650 \text{ }^\circ\text{F}$ ), respectively. Bill et al. (Ref 112) investigated Mar-M200 at mechanical strain ranges greater than 0.01 and over a temperature range of  $495 \leftrightarrow 1000 \text{ }^\circ\text{C}$  ( $925 \leftrightarrow 1830 \text{ }^\circ\text{F}$ ). These results are shown in Fig. 19.

**FIG. 19** COMPARISON OF TMF OP AND TMF IP LIVES FOR POLYCRYSTALLINE MAR-M200. SOURCE: REF 112

Nelson et al. (Ref 113) studied B-1900+Hf at a temperature range of  $540 \leftrightarrow 870 \text{ }^\circ\text{C}$  ( $1000 \leftrightarrow 1600 \text{ }^\circ\text{F}$ ) and also observed a crossover corresponding to a mechanical strain range of 0.0045. Ramaswamy and Cook (Ref 114) conducted tests on Inconel 718 at  $\Delta\epsilon_m = 0.015$  and over temperature ranges of  $345 \leftrightarrow 565 \text{ }^\circ\text{C}$  and  $345 \leftrightarrow 650 \text{ }^\circ\text{C}$  ( $650 \leftrightarrow 1050 \text{ }^\circ\text{F}$  and  $650 \leftrightarrow 1200 \text{ }^\circ\text{F}$ ) and found TMF IP to be more damaging than TMF OP. However, they noted that René 80 ( $760 \leftrightarrow 870 \text{ }^\circ\text{C}$ , or  $1400 \leftrightarrow 1600 \text{ }^\circ\text{F}$ ) also showed a crossover in the TMF life curves. The TMF OP lives were shorter than the TMF IP cases (Ref 115); this has been attributed to high mean stresses in the TMF OP case. Gayda et al. (Ref 116) found that for coated PWA 1480 at inelastic strain ranges of less than 0.2%, the TMF OP lives are significantly longer than TMF IP, whereas in the high strain regime the TMF OP and TMF IP lives are comparable.

In the past, TMF life has been approximated by IF life at the maximum temperature of the TMF cycle using the same mechanical strain range. This appears to be applicable for TMF OP conditions. Experiments conducted by Bill et al. (Ref 112) on Mar-M200 revealed that IF life at  $T_{\max}$  was slightly longer than TMF OP life ( $500 \leftrightarrow 1000 \text{ }^\circ\text{C}$ , or  $930 \leftrightarrow 1830 \text{ }^\circ\text{F}$ ). The IF lives may have been greater because the IF tests were conducted at a frequency 100 times greater than that of the TMF tests. Nelson et al. (Ref 113) also found a correlation between IF life at  $T_{\max}$  and OP life ( $540$  to  $870 \text{ }^\circ\text{C}$ , or  $1000$  to  $1600 \text{ }^\circ\text{F}$ ) for B-1900+Hf. Malpertu and Rémy (Ref 117) conducted TMF experiments on Inconel 100 utilizing a cycle similar to a counterclockwise  $135^\circ$  cycle over a temperature range of  $600$  to  $1050 \text{ }^\circ\text{C}$  ( $1110$  to  $1920 \text{ }^\circ\text{F}$ ). Initiation life was the same as the IF initiation life at  $T_{\max}$ . There is a correlation between TMF OP life and IF life at  $T_{\max}$ , but there are discrete differences in the damage mechanisms.

A few TMF studies have included nonproportional phasing of the mechanical strain and temperature. Nonproportional loading cycles are very important because they more closely approximate a service-induced strain-temperature history of an actual component. An example is the diamond-shape history, where the maximum and minimum mechanical strain occur at the median of the temperature range. Embley and Russell (Ref 115) conducted DCW history tests on Inconel 738 and found lives approaching two orders of magnitude longer than TMF OP and TMF IP lives over the same temperature range ( $425$  to  $870 \text{ }^\circ\text{C}$ , or  $800$  to  $1600 \text{ }^\circ\text{F}$ ). Nelson et al. (Ref 113) conducted TMF experiments on B-1900+Hf utilizing a counterclockwise elliptical strain-temperature cycle at  $540$  to  $870 \text{ }^\circ\text{C}$  ( $1000$  to  $1600 \text{ }^\circ\text{F}$ ). They discovered a fivefold increase in life over TMF OP lives.

Guedou and Honnorat (Ref 48) considered three alloys--Inconel 100, AM1, and DS 200--subjected to DCW and DCCW histories with a  $650 \leftrightarrow 1100$  °C ( $1200 \leftrightarrow 2010$  °F) temperature range. The AM1 is a single-crystal alloy, DS-200 is directionally solidified, and Inconel 100 is polycrystalline. Based on mechanical strain range, AM1 exhibited the best properties. Isothermal fatigue data at  $T_{\text{mean}}$  was closest to the TMF mechanical strain life curve. Bernstein et al. (Ref 118) considered Inconel 738LC both in the coated and uncoated state under 425  $\leftrightarrow$  870, 915, and 980 °C (800  $\leftrightarrow$  1600, 1680, and 1800 °F) conditions. They found shorter lives for the coated material relative to the uncoated material. They discussed the turbine blade strain-temperatures extensively (in particular, the role of the startup and shutdown) and showed that the TMF OP cycle best describes the engine conditions.

Recently Halford et al. (Ref 30) have proposed the use of bithermal fatigue cycles as a simple alternative to TMF testing. Bithermal results have been interpreted with strain range partitioning (SRP) as a predominantly PC or CP type of loading. Bithermal experiments conducted on B-1900+Hf were directly related to TMF results by use of an appropriate damage rule. Other research on TMF OP of Hastelloy X has been reported by Kaufman and Halford (Ref 119) in the ranges 505  $\leftrightarrow$  905 °C and 425  $\leftrightarrow$  925 °C.

Recent research on TMF in Europe centers around Remy et al. at École de Mines (Ref 117, 120), Guedou at Snecma (Ref 48), Bressers and various colleagues at Petten (Ref 121), and Mughrabi and his students in Germany (Ref 70, 108). Remy and coworkers (Ref 120) studies the crystallographic orientation effect on the cyclic  $\sigma$ - $\epsilon$  behavior of AM1 superalloy in the temperature range of 600  $\leftrightarrow$  1100 °C. These results are summarized in Fig. 20(a) for the [001] and [111] orientations. The inelastic strain range in the cycle was found to be strongly orientation dependent, with [001] producing smaller inelastic strains than [111] (Fig. 20a). This is evident when the stress/inelastic-strain loops are compared for the case of mechanical strain range of 1.2%. The longest fatigue lives among five crystal orientations were found for the [001]-oriented specimens (Fig. 20b).

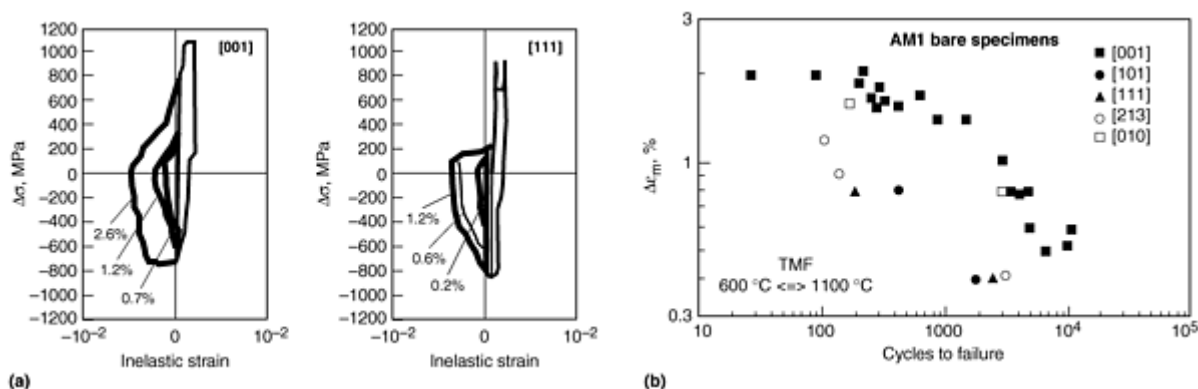

FIG. 20 EFFECT OF CRYSTALLOGRAPHIC ORIENTATION ON TMF BEHAVIOR OF AM1. SOURCE: REF 120

Bressers et al. (Ref 121) used a 135° OP cycle (i.e., diamond counter clockwise, DCCW) and studied the TMF behavior of SRR99 in the coated and uncoated condition. They considered both  $R = 0$  and  $R = -\infty$  cases and monitored the crack length as a function of cycles. The role of oxidation is emphasized in their model. Mughrabi and coworkers (Ref 108) studied CMSX-6 single-crystal superalloys of [001] orientation under 600  $\leftrightarrow$  1100 °C conditions and documented the coarsening of precipitates during TMF. They confirmed that the mean stress in nickel-base superalloys play a considerable role. The life under TMF OP was considerably shorter than under TMF IP (five times), with DCW (diamond clockwise) and DCCW cases between these two extremes. This study also confirms that inelastic strain range is not a good correlator of life when failure occurs in a finite number of cycles with very small  $\Delta\epsilon_{\text{in}}$  components. They noted that when the  $\gamma'$  structure rafts, soft  $\gamma$ -matrix channels permit unconstrained dislocation motion. Also, during the high-temperature phase of the cycle dislocation climb and during the low-temperature end of the cycle, cutting of the particles has been observed.

Other work from Europe includes Marchionni et al. (Ref 122), who have been studying an oxide dispersion ( $Y_2O_3$ ) Inconel alloy. The TMF OP and TMF IP results are similar and lie within the scatter of data. Macherauch and his group at Karlsruhe (Ref 109) have reported TMF OP and TMF IP experiments on Inconel 617, showing TMF IP damage to be

more significant than TMF OP. The maximum temperature was in the range of 850 to 1050 °C, while the minimum temperature was 600 °C.

**Strain Rate and Frequency Effects.** Strain rate can affect cyclic stress-strain response as well as fatigue life. In studies conducted on René 80 (Ref 123), Hastelloy X (Ref 103), Mar-M246 (Ref 49), and Mar-M200 (Ref 124), it has been reported that decreasing the frequency resulted in a decrease in the stress range; no change in the relative hardening and softening behavior has been observed. There is abundance of information on the strain-rate effects under IF conditions, including decreasing frequency, lowering strain rates, or introducing hold times (Ref 118, 124, 125, 126). These effects are attributed to increased environmental and creep damage (Ref 126, 127, 128). Only in rare cases do the strain rate or hold times have no effect (Ref 112, 129) or does decreasing the strain rate or introducing hold periods increase fatigue life (Ref 124, 130, 131). This latter behavior can be explained based on a reduced creep component caused by reduced cyclic stresses when  $\gamma'$  precipitate coarsening occurs.

There have been no systematic attempts to alter the strain rate (analogous to IF experiments), but some TMF experiments have introduced a hold period at maximum temperature. The effect of compressive hold periods on TMF of Inconel 738 has been established by Bernstein et al. (Ref 118), who reported shortened cycles to failure. In nickel-base superalloys, if the hold period in TMF OP results in stress relaxation in compression, high tensile mean stresses develop upon reversed loading--which is detrimental to fatigue life.

**Environmental Effects.** The effects of the environment on nickel-base superalloys at elevated temperatures are very complex. Environmental damage can affect both crack initiation and crack propagation and has a detrimental effect on fatigue life. Crack nucleation often originates from preferentially oxidized grain boundaries (Ref 126, 130, 132, 133). Grain boundaries are preferentially oxidized because they are paths of rapid diffusion and their composition may differ from that of the matrix (Ref 105, 107, 134, 135). An example of oxidation at grain boundaries and intergranular initiation in Mar-M247 subjected to TMF IP conditions is shown in Fig. 21. The experiment was conducted under TMF IP 500  $\leftrightarrow$  870 °C conditions.

**FIG. 21 GRAIN-BOUNDARY OXIDATION AND CRACKING IN MAR-M247. SOURCE: REF 105**

Rémy et al. (Ref 136) oxidized precracked specimens and compared the crack growth with that of virgin specimens. These experiments revealed crack growth rates as much as three orders of magnitude higher than the virgin samples. They proposed a modified fracture mechanics approach to handle the crack growth under repeated oxide fracture; the oxidation constants were determined via integration over the cycle. The different TMF strain/temperature waveforms (600  $\leftrightarrow$  1050 °C) were predicted with their model.

Under elevated-temperature conditions, a protective oxide scale forms on the surface of the specimen, separating the substrate from the environment. However, spalling and cracking of the protective oxide scale occur due to stresses developed in the scale. The principal sources of stress in the oxide scale are the thermal stresses due to the difference between the thermal expansion coefficients of the oxide and the matrix. Although there is zero thermal stress at the oxide

formation temperature, upon cooling by  $\Delta T$ , a stress is generated in the oxide layer. Oxide spikes penetrate from the surface toward the inside of the substrate. The oxide spike morphology could form at the surface or at the coating/substrate interface upon failure of the coating. The problem of stress fields associated with oxide spikes has been studied by Kadioglu and Sehitoglu (Ref 107, 135). In their work, an oxide spike was modeled as a semispherical surface in homogeneity. The stress field in the vicinity of the oxide spike was calculated using a technique based on Eshelby's method. Then the calculated strain at the tip of the oxide spike was used in the life prediction model. Strains at the oxide tips increase considerably as the ratio of oxide elastic modulus to metal elastic modulus decreases. The stresses under different levels of thermal mismatch also were shown. Sample results are presented in Fig. 22. The geometry of the oxide intrusion (spike) is shown in Fig. 22(a). The variation of  $\sigma_{ij}/(E_m \epsilon^{th})$ , which is the stress tensor normalized by the product of matrix modulus and thermal mismatch strain, as a function of distance measured from the surface is shown in Fig. 22(b). The term  $\Gamma = E_{ox}/E_m$  is the oxide to matrix modulus ratio, and  $X_3/c$  represents the normalized distance normal to the free surface. The  $X_3/c > 1$  represents the matrix region ahead of the oxide intrusion, while  $X_3/c < 1$  represents the oxide. The critical parameter extracted from these studies is  $\Delta \epsilon_m^{ox}$ , the mechanical strain range at the tip of the oxide. This result was used in the life prediction model described in Ref 135.

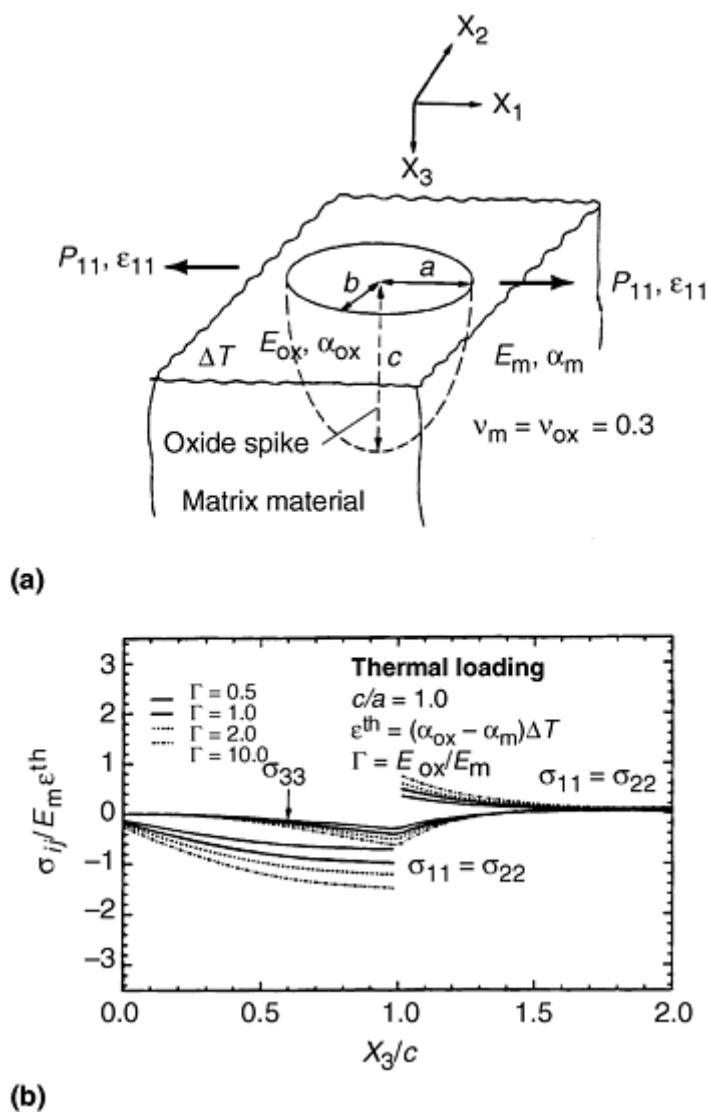

FIG. 22 (A) GEOMETRY OF AN OXIDE SPIKE (INTRUSION). (B) OXIDE STRESSES AS A FUNCTION OF  $\alpha$  AND  $E$  MISMATCH. SOURCE: REF 107

Oxidation characteristics of nickel-base superalloys can vary widely. The oxidation products formed vary with alloy composition, temperature, and time at temperature. A general oxidation characterization for nickel-base superalloys at 870 °C (1600 °F) can be drawn from Ref 137 and 138. Initially, a continuous film of  $Al_2O_3$  forms. Diffusional mass transport of chromium through the  $Al_2O_3$  layer allows the formation of an outer layer of  $Cr_2O_3$ . Eventually, spinels of

$\text{Ni}(\text{Cr},\text{Al})_2\text{O}_4$  are formed. Some  $\text{TiO}_2$  may also be formed. This sequence of events is a specific case. The oxides formed will vary from alloy to alloy and with variations in temperature and time of exposure.

Oxidized surfaces usually are associated with an adjacent zone of alloy depletion. This is characterized by a zone depleted of  $\gamma'$  precipitates. Several studies have reported the existence of  $\gamma'$ -depleted zones (Ref 105, 107, 113, 126, 131, 132, 133). The  $\gamma'$ -depleted zone is caused by the loss of aluminum to the formation of oxides. This zone may also be depleted of solid-solution-strengthening elements such as chromium. The fatigue characteristics of such a layer may be markedly different in the initial cracking stages. Deformation bands develop in precipitate-free areas and lead to premature microcracking and fatigue failure (Ref 139). Due to oxidation of the crack tip, a region depleted of oxide-forming elements will be formed ahead of a fatigue crack. As a result, the crack will propagate into a region having changed mechanical properties. Crack growth in each cycle may be controlled by the size of the environmentally affected zone at the crack tip (Ref 126).

Steady-state formation of the oxide and alloy-depleted layers is governed by parabolic rate kinetics (Ref 128, 130, 138, 140). The rate of oxidation and alloy depletion is considered to be affected by the application of stress. It has been shown that oxidation and alloy depletion increases when stress is applied (Ref 108, 138). The effect of stress on environmental attack may vary with alloy composition and exposure conditions.

**Coating Effects in Superalloys.** Environmental degradation due to oxidation and corrosion may be prevented by using protective coatings. Various types of coatings have been used to reduce the deleterious effect of the environment (Ref 33, 45). Many of the coatings developed fulfill their protection role against oxidation or corrosion of the base material. Three main types of coatings have been used to protect superalloys: (1) diffusion coatings, (2) overlay coatings (MCoCrAlY, where M is nickel or cobalt), and (3) thermal barrier coatings (TBCs).

The predominant oxide formed on the coating is  $\text{Al}_2\text{O}_3$ . The overlay coatings consist of Ni(Co,Fe),Cr, Al, and Y, and are called MCoCrAlY type. Finally, TBCs have been used to limit the heat flow into the base alloy. The materials most commonly considered as TBCs are general oxides such as  $\text{ZrO}_2$  and  $\text{Al}_2\text{O}_3$ . The low thermal expansion coefficient of the ceramic coatings and the relatively high thermal expansion coefficient of the base alloy result in a large mismatch strain, which encourages the propagation of cracks in the coating. The presence of porosity, discontinuities, random microcracking, and a columnar structure with grain boundaries to the surface, known as coating segmentation, has also been observed.

Under TMF conditions, coatings undergo complex stress-strain changes and at the low-temperature end of the cycle could fracture. Various researchers have found coatings to provide benefit, depending on the temperature (Ref 107, 128, 135, 141, 142, 143, 144). In some cases, however, a reduction in the fatigue lives of some directionally solidified alloys (Ref 141) and other nickel-base superalloys (Ref 145, 146) has been noted. Goward (Ref 147) has investigated the TMF behavior of aluminide and CoCrAlY coatings. The tests were conducted under fully reverse condition by cycling the temperature between 425 and 925 °C. In these tests, the low-aluminum CoCrAlY coating exhibited a much higher resistance to crack initiation than the higher-aluminum CoCrAlY.

The effects of protective coatings on TF of superalloys have been studied by alternately immersing a variety of tapered disk and wedge-type specimens into hot and cold fluidized beds (Ref 148, 149). However, the strain/temperature cycle was not precisely known in these experiments. Thermomechanical fatigue tests in which the temperature and strain can be controlled separately have been used to investigate the effects of coatings on superalloys (Ref 150, 151, 152). Among the various forms of strain/temperature phase relations, the most damaging is TMF OP. In fact, it was reported that coated superalloys exhibited shorter lives under TMF OP than under TMF IP (Ref 150, 151).

Under service conditions, additional strains on the coatings may arise due to thermal expansion mismatch, elastic moduli mismatch, diffusion between coating and substrate, phase transformation, or chemical reaction with the environment. These additional strains and stresses alter the crack initiation and propagation resistance of the materials, resulting in spallation of protective oxide scales and/or coating or early crack formation, which allows oxidation attack into the base alloy. To improve the fatigue performance of the coated components, these strains should be minimized by adjusting the mechanical and metallurgical properties of the coatings (provided that oxidation/corrosion resistance capability is maintained). Therefore, a life prediction methodology that will relate coating performance to the mechanical/physical properties of coating/substrate systems and environmental conditions is needed.

Coating cracking lives have been successfully correlated with total strain, which is the summation of the thermal expansion mismatch strain and the mechanical strain (Ref 152, 153). A fatigue crack growth model has also been

proposed by Strangman (Ref 154). In this work, the penetration of a coating crack into the base metal has been analyzed using the fracture mechanics approach. In another approach (Ref 155), the life of a coated system was considered as the summation of the number of cycles to initiate a crack through the coating, the number of cycles for the coating crack to penetrate a small distance into the substrate, and the number of cycles to propagate the substrate to failure. In a recent study (Ref 151), the mechanical damages for the coating and the substrate have been calculated separately and then combined to produce an optimum prediction damage parameter. The predicted lives for coated superalloys were within a factor of two for TMF OP tests. The two-bar model representing the coating and the substrate has been used to determine the constitutive stress-strain loop for the coating under TMF conditions. Then, the number cycles to initiate a crack in the coating has been estimated by the hysteretic energy method (Ref 156). With this approach, the fatigue life of overlay coatings was estimated within a factor of 2.5 in the case of TMF conditions (Ref 155). Although the two-bar model is one dimensional, it captures the first-order effects of the coatings on the behavior of base alloys. To study the effect of biaxiality requires nonlinear FEM due to the highly nonlinear behavior of the coating/substrate system (Ref 157).

Swanson et al. (Ref 156) have conducted isothermal fatigue tests at 760, 925, and 1040 °C and TMF tests by cycling the temperature between 425 and 1040 °C on PWA 286 (NiCoCrAlY+Si+Hf) overlay and PWA 273 (NiAl, outward diffusion) aluminide-coated single-crystal PWA 1480 alloy. Their tests used hollow tubes as test specimens. They found that, in many cases, coating cracks had progressed into the PWA 1480 alloy and directly caused failure. In some specimens, however, the coating cracks did not extend into the substrate, and failure was caused by a crack initiated from the uncoated inner surface. The coating cracks penetrated into the substrate in both OP and IF tests for specimens coated with PWA 273, but only in the OP tests for specimens with overlay coating. In this case, coating-initiated cracking was the dominant failure mode. It was difficult to draw a general conclusion about the effects of coatings on fatigue life from this work due to variation of specimen design and orientations, frequencies used, cycle type, and strain ranges applied.

Wright (Ref 128) has examined the oxidation-fatigue interactions in René N4. Isothermal tests were performed on uncoated, aluminide-coated, and preoxidized alloy at 1095 °C. The test results showed that although there were no differences in the fatigue life of coated and uncoated specimens in low-frequency tests ( $f = 1/2$  cycle/min), fatigue life increased significantly during high-frequency tests ( $f = 20$  cycle/min). Glennly and Taylor (Ref 56), Bizon and Spera (Ref 51), and Woodford and Mowbray (Ref 50) have investigated the thermal fatigue characteristics of uncoated and coated superalloys using a variety of tapered-disk and wedge-type specimens. However, the available data from these studies are difficult to interpret due to the large variety of specimen shapes, thermal cycle shapes, and differences in the definition of failure criteria.

In summary, the following general rules apply for the TMF of nickel-base superalloys:

- FOR SINGLE CRYSTALS, THE BEST TMF RESISTANCE HAS BEEN OBTAINED IN THE [001] DIRECTION. IN THIS DIRECTION, THE ELASTIC MODULUS (AND THUS THE STRESSES) DEVELOPED IS LOWER THAN IN OTHER DIRECTIONS; CONSEQUENTLY, FOR A GIVEN MECHANICAL STRAIN RANGE THE PLASTIC STRAIN RANGE IS LOWEST AMONG ALL POSSIBLE DIRECTIONS. DIRECTIONALLY SOLIDIFIED ALLOYS REMOVE THE GRAIN BOUNDARIES TRANSVERSE TO THE PRINCIPAL STRESS AND ALSO LOWER THE ELASTIC MODULUS IN THAT DIRECTION RELATIVE TO POLYCRYSTALLINE MATERIALS. FOR POLYCRYSTALLINE NICKEL-BASE SUPERALLOYS, GRAIN SIZE AND COATINGS INFLUENCE TMF LIVES.
- BECAUSE OF THE UNBALANCED NATURE OF INELASTIC DEFORMATION IN TMF, MEAN STRESSES ARE SUSTAINED AND DO NOT RELAX. THE MEAN STRESSES PLAY A CONSIDERABLE ROLE AT FINITE LIVES, BECAUSE THE PLASTIC STRAIN RANGE IS SMALLER THAN THE ELASTIC STRAIN RANGE.
- COMPLEX CHEMISTRIES OF OXIDES FORM WITH PROPERTIES DIFFERENT FROM THOSE OF THE SUBSTRATE, RESULTING IN INTERNAL STRESSES AND OXIDE FRACTURE THAT CHANNELS THE CRACK INTO THE MATERIAL. CONSIDERABLE DEPLETION IN THE VICINITY OF OXIDES HAS BEEN MEASURED.
- AT SMALL STRAINS AND LONG LIVES, OXIDATION DAMAGE PERSISTS. DEPENDING ON STRESS AND TEMPERATURE, CREEP DAMAGE APPEARS TO BE MORE SIGNIFICANT AT SHORT LIVES.
- FOR THE MAJORITY OF NICKEL-BASE ALLOYS AT TEMPERATURES ABOVE 700 °C, TMF RESULTS DISPLAY STRAIN-RATE SENSITIVITY. GENERALLY, AS THE STRAIN RATE IS

REDUCED OR HOLD PERIODS ARE INTRODUCED, THE CYCLES TO FAILURE ARE LOWERED.

- FOR MOST NICKEL-BASE SUPERALLOYS, TMF IP DAMAGE IS LARGER THAN TMF OP DAMAGE AT HIGH STRAIN AMPLITUDES, WHEREAS THE TREND IS REVERSED AT LONG LIVES. THE DIAMOND CYCLE OFTEN PRODUCES LIVES THAT FALL BETWEEN THE TMF IP AND TMF OP EXTREMES.

**Microstructural Changes.** Under TMF conditions considerable changes in nickel-base superalloy microstructure have been known to occur, including changes in the size and morphology of  $\gamma'$  precipitates and the formation of dislocation networks around precipitates. For polycrystalline nickel-base superalloys exposed to temperatures above 800 °C, TMF OP loading results in transgranular propagation and TMF IP results in intergranular propagation.

Castelli et al. (Ref 103) and later Castelli and Ellis (Ref 32) observed cyclic hardening of Hastelloy X under TMF OP at  $\Delta\epsilon_m = 0.006$  over a temperature range of 600 to 800 °C. In this alloy dynamic strain aging occurs in the region from 200 to 700 °C, and precipitation of chromium-rich precipitates also produces hardening. When the temperature range was increased to 800 to 1000 °C, cyclic softening was observed. Since this is a solute-hardened superalloy, it undergoes considerable dynamic strain aging when the temperature is at 600 °C. Considerable precipitation of  $M_{23}C_6$  carbides also occurs in the vicinity of dislocations, which coarsens at high temperatures and loses its effectiveness as the additional hardening mechanism. Examples of extensive hardening for Hastelloy X in TMF are shown in Fig. 23. Both TMF IP and TMF OP results are shown for 400  $\leftrightarrow$  600 °C conditions. The results are obtained at strain rates of  $5 \times 10^{-5}$ /s conditions. Strengthening increases by more than a factor of two over several thousand cycles. The IF results at 595 and 425 °C are also shown for comparison.

FIG. 23 CYCLIC HARDENING FOR HASTELLOY X UNDER TMF CONDITIONS. SOURCE: REF 103

Thermal recovery processes in TMF have been documented by Sehitoglu and Boismier (Ref 105) and by Kadioglu and Sehitoglu (Ref 135) in the form of  $\gamma'$  coarsening and eventual rafting of the  $\gamma'$  microstructure.

Research on TF and TMF has described several microstructural changes that influence deformation (stress-strain) behavior as well as fatigue lifetime. Some, but not all, of the findings are listed in Table 3. The most important mechanisms are:

- AGING OF THE MICROSTRUCTURE WHEN EXPOSED TO HIGH TEMPERATURES
- REPEATED OXIDE RUPTURE DUE TO MISMATCH IN MECHANICAL AND PHYSICAL PROPERTIES OF MATRIX AND OXIDE
- STRAIN AGING IN THE CASE OF SOLUTE-HARDENED MATERIALS AT THE ELEVATED-TEMPERATURE END, RESULTING IN CONSIDERABLE HARDENING
- ENHANCED GRAIN-BOUNDARY DAMAGE DUE TO UNEQUAL DEFORMATION DURING THE CYCLE
- CARBIDE PRECIPITATION AT GRAIN BOUNDARIES AT HIGH TEMPERATURE

AM1 SINGLE CRYSTAL		ENVIRONMENT INITIATED DAMAGE IN TMF DIFFERS FROM CASTING DEFECT INITIATED DAMAGE IN IF	48

IN 738 LC (COATED AND UNCOATED)		LOWER LIVES FOR COATED OP CASE BECAUSE OF COATING FRACTURE	118
CMSX-6 (SINGLE CRYSTALS)	SOFT $\gamma'$ MATRIX FORMATION, CUTTING OF PARTICLES AT LOW TEMPERATURES, DISLOCATION CLIMB DURING HIGH-TEMPERATURE PORTION OF THE CYCLE		108

### Other Structural Alloys

Several classes of advanced materials have been investigated under TMF loading conditions. Thermomechanical fatigue of titanium aluminide has been investigated by Wei et al. (Ref 159) under total constraint  $25\text{ }^{\circ}\text{C} \rightleftharpoons 750\text{ }^{\circ}\text{C}$ ,  $25\text{ }^{\circ}\text{C} \rightleftharpoons 900\text{ }^{\circ}\text{C}$  conditions. The role of hydrogen and helium environment was investigated and the lives were  $\times 2$  higher in helium environment relative to air. On a similar material ( $\text{Ti}_3\text{Al}$ ) Mall et al. (Ref 160) studied TMF crack growth under OP and IP cases.

TMF data on cobalt-base superalloys have been published by Reuchet and Rémy (Ref 140) and Kalluri and Halford (Ref 161). Early research by Sheffler and Doble (Ref 162) on TMF of tantalum alloys showed that the TMF IP lives are considerably shorter than the TMF OP case. These materials have been investigated as an alternative to nickel-base superalloys, but their cost and/or performance characteristics have not been superior to nickel-base superalloys. Undoubtedly, they will find some specialty applications.

Thermomechanical fatigue is of considerable interest in the electronics industry. Failure mechanisms are currently being investigated in aluminum thin films in integrated circuits and in lead-tin solders undergoing temperature, current density, and mismatch in thermal expansion conditions. Recent TMF data on 63Sn-37Pb solder alloys (Ref 163) have been published. In these experiments the material is subjected to simultaneous shear loading and temperature cycling. It is important to note that if the specimen is subjected to shear and temperature, a set of material planes will experience TMF OP loading and the other orthogonal planes will undergo TMF IP loadings.

Starting in mid-1980, interest grew in metal-matrix composites (metal reinforced with ceramic particulates whiskers or fibers). These materials, although expensive, have been touted for lower thermal expansion coefficient, higher elastic modulus relative to matrix, and better high-temperature properties. Although some properties have improved with these new classes of 'advanced' materials, the TMF resistance of these materials is not superior to that of the monolithic alloy. This is partly due to difficulties in the processing uniformity and detrimental residual stresses. Karayaka and Sehitoglu (Ref 164, 165), VanArsdell et al. (Ref 166, 167), and Sehitoglu (Ref 168) have authored a number of papers on TMF OP and IP of Al2024 reinforced with SiC particulates with volume fractions of SiC in the range 15% to 30%. Recent work (Ref 169, 170) focused on TMF of Timetal 21s (titanium alloy) reinforced with SiC (SCS-6) composites studied under TMF OP and TMF IP conditions (stress-control). Under TMF IP fiber damage was dominant and under TMF OP environment damage in the matrix or at interfaces was found to be most important. Sample results are shown in Fig. 24 for TMF OP and TMF IP loading conditions under stress control. The experimental techniques developed in Ref 46 were utilized. The results are plotted in an  $S_{\max}\text{-}N_f$  format. Under TMF IP, conditions, the lives are controlled by the fiber failure while for TMF OP case the damage mechanism is a combination of environmental and fatigue processes. We note that at long lives the TMF OP is far more damaging. At high stresses there is crossover and TMF IP damage exceeds the TMF OP damage.

FIG. 24 TMF OP AND TMF IP FOR SiC/TITANIUM ALUMINIDE COMPOSITE. SOURCE: REF 169

### Thermal and Thermomechanical Fatigue of Structural Alloys

Huseyin Sehitoglu, Department of Mechanical and Industrial Engineering, University of Illinois

---

### Multiaxial Effects in TF and TMF

The multiaxial effect is one of the least explored aspects of TF and TMF loadings. When a surface is heated the stresses are generally biaxial and this phenomenon has been discussed by Manson (Ref 6). Manson discusses thermal shock as well as slow heating cases where a two-dimensional stress state develops. Taira and Inoue (Ref 171) considered the biaxial stress fields in their TF analysis. In their experimental work they cooled a solid cylinder at one end, and plotted their TF results using the von Mises equivalent strain range and showed good agreement with uniaxial tests on .16% steel. Recent research considers TMF under multiaxial loadings (Ref 172) where axial-torsional loading is applied simultaneously with temperature.

## Crack Initiation and Crack Propagation

**Crack Initiation in TF and TMF.** Crack initiation within nickel-base superalloys can occur intergranularly at oxidized surface exposed grain boundaries or transgranularly. Transgranular initiation can be caused by heterogeneous planar slip which produces initiation along persistent slip bands at free surfaces (Ref 125, 139, 173). Transgranular initiation can also occur at pores, inclusions, and carbides (Ref 117, 139). Transgranular crack initiation is more prominent at low temperatures and high frequencies. This is because the contributions from the creep and environmental components of damage are minimal. Gell and Leverant (Ref 126) indicated that one of the first observed effects of an increased creep component is a transition from transgranular to intergranular initiation. Runkle and Pelloux (Ref 174) found under IF conditions, as temperature is increased, initiation changes from transgranular to intergranular for Astroloy. A similar transition was observed for a decrease in strain rate by Nazmy (Ref 127) for IN 738 under IF loading at 900 °C (1650 °F).

At high temperatures crack initiation is predominantly intergranular (Ref 124, 130, 131, 174). This is attributed to increased damage contributions from creep and environmental attack. Environmental attack appears to be the more dominant of the two damage mechanisms. Intergranular crack initiation typically occurs at oxidized surface connected grain boundaries which are often accompanied by an adjacent zone of  $\gamma'$  depletion (Ref 50, 102, 118, 130, 131). Preferential grain boundary environmental attack occurs because of the easier path of oxygen diffusion. The decrease in fatigue life with increased temperature and decreased frequency can partially be attributed to the transition from transgranular to intergranular crack initiation. In general, intergranular crack initiation occurs at a faster rate than transgranular initiation (Ref 126). In the work of Kadioglu and Sehitoglu (Ref 107) the Mar-M246 exhibited intergranular crack initiation followed by a switch to transgranular crack growth.

**Crack Propagation in TF and TMF.** It is important to know the mode of crack propagation to develop physically meaningful fracture mechanics or micro-mechanical models to characterize the crack driving force. The interaction of creep damage and environmental attack and their effects on crack propagation under TMF conditions can be very complicated. In general, TMF OP produces transgranular crack propagation while intergranular fracture is observed for TMF IP case, within representative service temperature ranges (300-1000 °C) at moderate strain rates ( $10^{-3}$  to  $10^{-6}$ /s). TMF experiments conducted on B-1900+Hf at temperature ranges of 427-925 °C (Ref 153) and 538-871 °C (Ref 113) revealed predominantly transgranular OP crack propagation and intergranular IP propagation. Kuwabara and Nitta (Ref 42) observed intergranular crack propagation for IN 718 (300-650 °C) and Mar-M247 (300-900 °C) under TMF IP

loading. Milligan and Bill (Ref 124) performed TMF experiments on Mar-M200 (500-1000 °C) and found intergranular crack propagation and internal grain boundary cracking for TMF IP case, while TMF OP produced mixed transgranular and intergranular cracking. Ramaswamy and Cook (Ref 175) also observed transgranular cracking under TMF OP and intergranular cracking under TMF IP tests conducted on IN 718 (343-565 °C and 343-649 °C) and René 80 (760-871 °C). Intergranular crack propagation in TMF IP case is attributed to a tensile creep component that results in ratcheting at the microlevel resulting in weakening of the grain boundaries. In a study conducted on Mar-M247 similar results have been observed (Ref 105).

Rau et al. (Ref 176) performed TMF crack growth tests on Mar-M200 DS (427-927 °C) and B-1900+Hf (316-927 °C) under strain control. The Mar-M200 DS out-of-phase crack growth rates were greater than in-phase. The  $T_{max}$  IF crack growth rates for B-1900+Hf were the same as out-of-phase TMF crack growth rates. Leverant et al. (Ref 153) also tested B-1900+Hf (427-927 °C) under strain control. It was observed that out-of-phase and in-phase TMF crack propagation rates were the same. Heil et al. (Ref 177) conducted TMF crack growth tests on IN 718 under load control at a temperature range of 427-649 °C (800-1200 °F). They discovered that in-phase loading produced greater crack growth rates than out-of-phase loading. The subject of TMF crack growth rates needs to be investigated further. Figure 25 shows their result compared on the basis of the stress intensity range. These experiments were conducted under load control  $R = 0.1$  conditions. The 90° refers to DCW and the 270° refers to DCCW load-temperature history. The 0° refers to TMF IP and 180° refers to TMF OP. They found that TMF IP is more damaging than TMF OP in 718 based on  $\Delta K$ . Heil et al. forwarded a simple model incorporating crack growth from cycle and time dependent damage. Their results are intuitively correct in view of the fact that the crack closure phenomenon will be minimum for the TMF IP case.

FIG. 25 CRACK GROWTH RATES IN TMF OP AND TMF IP CASES FOR INCONEL 718. SOURCE: REF 177

Okazaki and Koizumi (Ref 178, 179) in Japan used the J-Integral to correlate crack growth rates under TMF IP conditions for low-alloy ferritic steel (Co-Mo steel). Sehitoglu (Ref 24) correlated crack growth rates in TMF OP (150 °C ↔ 400 °C to 600 °C) and IF results from room temperature using the range in crack opening displacement. Gemma et al. (Ref 180) considered crack growth in both DS Mar-M200 and B-1900 alloys under TMF OP conditions with 427 °C ↔ 1038 °C and showed that lower crack growth rates were obtained when the loading axis and the grain growth direction coincided

confirming the benefit of DS alloys. In the UK, Skelton (Ref 181) studied crack growth in steels (Alloy 316, Alloy 800, 1/2Cr-Mo-V) and used both the linear elastic and elasto-plastic fracture mechanics parameters. The elasto-plastic crack growth parameter was  $C(\epsilon^{in})^n a^Q$  where  $C$ ,  $n$ , and  $Q$  are constants,  $a$  is crack length, and  $\epsilon^{in}$  is inelastic strain. Skelton used this parameter for small cracks both for TMF and thermal shock conditions.

Recent research from Wright Patterson Air Force Base (Ref 160) has investigated TMF crack growth in titanium aluminide. Similar to IN718 the TMF IP crack growth rates were higher than TMF OP. The LEFM parameter  $\Delta K$  was used. The authors noted a distinct difference between superalloys and aluminides in that the crack tip blunts in aluminide and sustained load cracking do not occur.

Jordan and Meyers (Ref 182) conducted TMF OP, TMF IP experiments as well as a DCCW type cycle. Higher crack growth rates were noted for the TMF OP case relative to IF test at  $T_{max}$  for the case 427 °C  $\leftrightarrow$  871 °C. Several elasto-plastic fracture mechanics parameters have been used including the strain-intensity range, stress-intensity range and the range in J-integral.

### Temperature-Strain Variations in Service

McKnight et al. (Ref 183) conducted finite element analysis of turbine blades with a simplified mission cycle. The purpose was to analyze tip cracking due to thermomechanical fatigue. In their analysis of a hollow, air cooled turbine blade they did focus at a tip cap designated as a 'squealer tip' just below the leading edge. They showed that at this critical location, the blade experiences a TMF OP type of cycle with a small amount of ratcheting in the compressive direction. The analysis indicated that the mechanical strain range (the principal strain component) in the critical location was near 0.31% after several cycles and the maximum temperature was as high as 1100 °C. Both the maximum and the minimum mechanical strains were negative. The strain temperature was predominantly a TMF OP cycle with an initial temperature of 300 °C. Under these conditions the lifetime of René 80 simulated on a laboratory sample was 3000 cycles as established by Kaufman and Halford (Ref 119).

Embley and Russell (Ref 115) studied strain temperature phasings that are rather complex and representative of those experienced by turbine blades. Bernstein and colleagues (Ref 118) also studied 'faithful' histories typical of leading edge of turbine blades. A schematic of this history is given in Fig. 26. The schematics in Embley and Russell (Ref 115) work and Bernstein's paper are similar. We note that during the startup the behavior is of TMF OP type. Higher strains in the compressive direction are achieved for 'fast' acceleration relative to 'normal' acceleration. The temperature does not reach a maximum at the acceleration peak; the temperature reaches a maximum during the steady state operation (the load/unload portion). Upon normal shutdown the strain increases in the tensile direction as temperature is reduced. In the case of an emergency shutdown the tensile mechanical strains reached can be considerably higher.

FIG. 26 STRAIN/TEMPERATURE HISTORY ON A TURBINE BLADE. SOURCE: REF 118

Heating and cooling of the surface of a thick structure under the impingement of steam has been considered by Skelton (Ref 76). When the surface is exposed to the steam at 550 °C (1020 °F) it undergoes compression (OP behavior) because it is surrounded by the cooler material. With time, the temperature front moves into the structure, the temperature gradient reduces, and the surface unloads elastically at temperature. During steady state conditions the strain remains constant and some relaxation of the stress can occur. When the steam is shut off, the surface wants to contract but is again constrained by the warmer surrounding material. The surface then undergoes tension and the maximum stress in the cycle is reached corresponding to the minimum temperature.

The current railroad wheel design has evolved as a result of TF experiments on actual wheels and also from thermomechanical elasto-plastic analysis of stresses under braking conditions. The original wheel design had a straight

plate region which produced higher stresses (due to the constraint) than the curved plate design. The curved plate design is shown in Fig. 27(a). Localized heating due to friction occurs at the tread area. The results of a FEM analysis are given in Fig. 27(b). The circumferential stress-mechanical strain behavior under the brake-shoe (at the tread region of the wheel) is depicted in Fig. 27(b). The times and temperatures are also shown during the different stages of the heating process (Ref 184). The analysis was conducted for a 50HP application to the surface for a period of 1 h followed by 1 h cooling, then 5 min cool down to room temperature. The minimum stress develops 15 minutes into the 50HP application and upon subsequent rise in temperature the material softens. At the end of the heating period (60 min) the peak temperature at the surface has reached 615 °C (1139 °F). We note that the tensile stresses upon cooling are near 200 MPa (29 ksi).

FIG. 27 RAILROAD WHEEL DESIGN AND STRESS/MECHANICAL STRAIN

Often in engineering applications an approximate measure of inelastic strains and stresses are needed without the execution of an elasto-plastic FEM analysis. If the results of an elastic FEM analysis are available, the results of such an analysis can be used to estimate the inelastic strains. As pointed out earlier by Manson (Ref 6), the elastic strains calculated from FEM are assumed as total strains. Then, given the total strains, corresponding stresses and inelastic strains can be determined. This approach is referred to as 'strain invariance principle' and has been successfully demonstrated for TF analysis of the wedge specimen (Ref 13).

### Thermal Ratcheting

To understand thermal ratcheting, a two bar structure shown schematically in Fig. 28 is considered. The two bars are in series and are subjected to a net section load,  $P_n$ , and one of the bars undergoes thermal cycling. In the present model, Bar 2 remains at a steady temperature of  $T_0$  and Bar 1 undergoes thermal cycling such that the maximum temperature is  $T_0$  and the minimum temperature is  $T_0 - \Delta T$ . Several regimes of material behaviors can be identified. These are (i) elastic (high-cycle fatigue), (ii) elastic shakedown (high-cycle fatigue), (iii) reversed plasticity (thermomechanical fatigue, low-cycle fatigue, and (iv) ratcheting regimes (shown as progressive and excessive distortion regions). In the first mode, all strains are elastic. In the second mode, one of the two bars yields during the first half of the cycle followed by elastic response in both bars.

FIG. 28 SCHEMATIC OF A TWO-BAR STRUCTURE AND TEMPERATURE HISTORY ON BARS 1 AND 2. SOURCE: REF 185

In the third mode, called plasticity, one of the bars yields plastically while the second bar remains elastic. TMF occurs in this regime. In the ratcheting case, one bar yields during the cooling half of the cycle while the second bar yields in the same direction during the heating portion of the cycle. This results in accumulation of strains in the tensile direction and ultimately failure due to a combined fatigue and ductility exhaustion mechanism. The equilibrium equation is

$$P_N = \sigma_1 A_1 + \sigma_2 A_2$$

and the compatibility equation ( $\delta l = \delta_2$ ) is

$$\epsilon_1 L_1 = \epsilon_2 L_2$$

where  $\epsilon_1$  is the net strain on Bar 1 given as

$$\begin{aligned} \epsilon_1 &= \epsilon_1^e + \epsilon_1^{in} + \epsilon_1^{th} \\ \epsilon_2 &= \epsilon_2^e + \epsilon_2^{in} \end{aligned}$$

where  $\epsilon_1^e$ ,  $\epsilon_1^{in}$ ,  $\epsilon_1^{th}$  represent elastic, inelastic, and thermal strain components.

A common way of representing the different deformation regimes is to plot the dimensionless parameter  $E\theta\Delta T/\sigma_y$  versus the  $P_n/P_L$  where  $P_L$  is the limit load determined from the yield strength  $\sigma_y$  at  $T_0$  and  $\theta$  is the thermal expansion coefficient. We note that similar results would be obtained by considering a pressure vessel subjected to a temperature gradient across the wall thickness and subjected to an internal pressure. The regime of 'thermal ratcheting' and TMF are

shown in Fig. 29. The experimental results obtained from various tests are also shown in the diagram. The letter "P" denotes plasticity, "R" denotes ratcheting, "S" stands for shakedown, and HCF stands for high-cycle fatigue. The stress-net strain response of a two-bar structure with  $P_n/P_L = 0.5$  and  $\Delta T = 150\text{ }^\circ\text{C}$  ( $270\text{ }^\circ\text{F}$ ) are shown in Fig. 30 for a 304 stainless steel. We note that Bar 1 undergoes tension upon cooling. Therefore, the response depicted in Fig. 30 is termed "OP" (temperature is a minimum when stress is a maximum).

FIG. 29 DIAGRAM SHOWING THE OPERATING REGIMES OF COMPONENT BEHAVIOR. SOURCE: REF 185

FIG. 30 RATCHETING OF THE TWO-BAR STRUCTURE FOR TYPE 304 STAINLESS STEEL. SOURCE 185

These experiments were conducted by using two servohydraulic test systems with command signals from a microcomputer which enforces equilibrium and compatibility of the two-bar structure. Similar experiments have been reported by Swindeman and Robinson (Ref 186) using 2.25Cr-1Mo steel. In addition to thermal cycling they also considered compression hold period effects on ratcheting.

Thermal ratcheting experiments have been conducted under stress control cycling or constant stress with superimposed thermal cycling (Ref 61, 62). Taira (Ref 88) has proposed constitutive models for predicting the transient and steady-state stage of deformation under these conditions and forwarded creep rupture as the mechanism of failure under this type of cycling. Also, Russ et al. at WPAFB (Ref 187) conducted stress control TMF experiments which resulted in thermal ratcheting in titanium aluminides.

## Thermal and Thermomechanical Fatigue of Structural Alloys

Huseyin Sehitoglu, Department of Mechanical and Industrial Engineering, University of Illinois

---

## Thermal Shock

Thermal shock occurs under rapid temperature change conditions and results in thermal stresses that cause fracture of the material. There are three main differences between thermal shock and thermal fatigue: (i) thermal shock is a single application of a temperature change while thermal fatigue means repeated thermal cycling, (ii) physical properties such as specific heat and thermal conductivity influence the stresses developed which is not the case in the case of quasistatic thermal stress because the strain rates are high in the thermal shock case, the sensitivity of the material to strain rate is important, and (iii) the stresses generated in thermal shock are high enough that fracture toughness level is important while it does not enter in thermal fatigue considerations. In this section, we will be only concerned with thermal shock behavior of structural metallic materials and not the more well studied thermal shock in ceramics. Thermal shock in metals can be encountered in hot working manufacturing applications, such as the rapid temperature rise in the bore of a gun barrel, friction heating conditions such as in disk brakes, and rapid startups such as that in space shuttle main engines. The thrust chamber of the space shuttle has an inner liner with axial flow coolant channels constructed from copper or a copper-zirconium-silver alloy. During the firing cycle liquid hydrogen enters the channels to cool the chamber (or the hot gas wall) and a severe temperature rise occurs within a second.

The flame heating has been used to simulate engine environment and involves very rapid heating of the surface (Ref 21). The Association of American Railroads used flame heating on the rim of a rotating wheel of 0.7% C steel which was then subjected to a water quench when the same region rotated through a water pool. In this case, because the surface

temperatures were above the transformation temperature, thermal cracks developed upon quenching to room temperature. Baron (Ref 188) employed a tapered disk specimen similar to Glenny and Taylor (Ref 56) and using induction heating, reached heating of the order of 1 s. Rapid heating of a surface while the bulk remains cool can produce thermal shock conditions. For more details of thermal shock, the reader is referred to the text by Manson (Ref 6). More recently, Skelton (Ref 181) has studied crack growth under 'thermal shock' conditions.

Another variation of thermal shock is called 'thermal striping.' In thermal striping fatigue the surface temperature fluctuations develop due to mixing of fluid streams which impinge on the surface of structures. A temperature gradient develops through the component wall and the frequencies are generally much higher than in classical TF tests.

## Life Prediction under TF and TMF

The question has been raised when correlating IF and TMF results as to what equivalent temperature should be used for meaningful comparisons. The maximum stress in a TMF experiment may not be at the maximum temperature and also the maximum strain may not coincide with the maximum temperature. Even though conventional IF data at the maximum temperature of a TMF cycle have been used to predict TMF lives, many researchers have shown that nonconservative predictions can still result (Ref 18, 40, 41, 42, 43, 44, 59, 60, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83) with this approach. It is essential to compare TMF and isothermal fatigue data at similar strain rates so that time-dependent damage mechanisms in both cases correspond.

Both environmental damage and creep damage on the material contribute to fatigue damage at elevated temperatures. A number of oxidation damage mechanisms have been proposed. These include (a) enhanced crack nucleation and crack growth by brittle surface oxide scale cracking (Ref 130, 189, 190), (b) grain-boundary oxidation which results in intergranular cracking (Ref 130, 134), and (c) preferential oxidation of second-phase particles (Ref 140). Oxidation and fatigue can interact resulting in a life much less than either of them acting alone. TMF OP loading is more damaging whenever the rate of oxide fracture damage exceeds that of creep damage. Oxidation damage accelerates with increasing  $\Delta\epsilon$ ,  $T_{max}$ , or increasing thermal coefficient mismatch of metal and oxide. The low ductility of oxides promotes cracking. If repeated oxidation is very severe for a given alloy, this could result in shorter TMF OP lives compared with TMF IP lives over a wide range of life regime. Low-carbon steels and low-alloy Cr-Mo steels exhibit shorter lives under TMF OP compared with TMF IP. These materials are known to be susceptible to oxidation damage. The TMF OP curve will be also lowered if the mean stress effects become significant. In the TMF OP case, tensile mean stresses develop which are conducive to minimal contact between crack surfaces and rapid crack growth rates.

Many mechanisms have been proposed to explain creep-induced damage and creep-fatigue interactions. These include (a) coalescence of intergranular voids ahead of an advancing crack (Ref 191, 192), (b) a greater crack tip plastic zone resulting from the summation of the plastic zones of voids ahead of a crack (Ref 193), (c) grain-boundary sliding

initiating wedge-type cracks at grain boundaries (Ref 89), and at hard second-phase particles on the grain boundaries (Ref 194), (d) grain boundaries acting as weak paths for flow localization and crack growth (Ref 195), and (e) the modification of the crack tip strain fields in the absence of cavities (Ref 196). It would be expected that a number of these creep mechanisms would operate under both isothermal and TMF conditions depending on the alloy.

The models developed for TMF studies can broadly be divided into two categories: the continuum-based models (using parameters such as strain range, stress range, product of maximum stress and strain range, and plastic work) and physical damage equations (incorporating oxidation damage kinetics, microstructural observations, and creep damage mechanism). The major issue is how these equations perform at log lives where TMF data are scarce. Extrapolation of short-life data to long lives has limitations because the severity of the mechanisms will change. Therefore, models based on physical mechanisms and not empirical fits to data are preferred when predictions in the long-life regime are considered. We finally note that microstructural coarsening and other metallurgical instabilities are encountered in alloys at high temperatures and this could result in a decrease in lives for both the TMF OP and TMF IP cases.

**Oxidation Damage and Oxidation Fatigue Laws.** Specific modeling of oxide failure processes has been attempted by a number of investigators and are given in Ref 197, 198, 199, 200, 201, 202, and 203. The range of mechanisms include separation of an oxide film at a slip step (Ref 197), failure due to mismatch of the coefficient of thermal expansion (Ref 198), failure due to growth stresses (Ref 199, 200, 201, 203), interfacial shear failure (Ref 202), failure due to oxide buckling (Ref 203), and fatigue failure of oxide (Ref 68, 69, 135). These models are listed in Table 4.

TABLE 4 SUMMARY OF OXIDE FAILURE MECHANISMS AND MODELS

Ref	Mechanisms of failure	Equation
197	Separation of an oxide film at a slip step	$\frac{\sigma_f}{E_{ox}} = [\epsilon_f/0.38(1 - K)] (h_c/a)^{1/4} \sin(w), \text{ Tensile failure}$ $\frac{\tau_f}{E_{ox}} = [\epsilon_f/2(1 + n)^{1/2}] (h_c/a)^{1/2} \cos(w), \text{ Shear failure}$ <p> <math>h</math> = oxide thickness, <math>E_{ox}</math> = oxide modulus  <math>\sigma_f</math> = fracture strength, <math>\tau_f</math> = shear strength  <math>a</math> = interfacial layer thickness, <math>K</math> = dimensionless parameter, <math>w</math> = geometry constant                 </p>
198	Tensile failure due to $\alpha$ mismatch	$\sigma_f = \frac{E_{ox} \Delta T (\alpha_{ox} - \alpha_m)}{1 + \frac{E_{ox}}{E_m} \left( \frac{h_c}{h_m} \right)}$ <p> <math>E</math> = elastic modulus  <math>h_c</math> = critical rupture thickness of oxide  <math>h_m</math> = thickness of metal  <math>\Delta T</math> = uniform temperature change                 </p>
199	Failure due to compressive hoop strain during growth	$h_c = \frac{d \epsilon \rho_m (56 + 16x)}{112 \rho_{ox}}$ <p> <math>FeO_x</math>  <math>\rho_m</math> = density of metal  <math>\rho_{ox}</math> = density of oxide  <math>h_c</math> = critical rupture thickness                 </p>
200	Scale displacement ( $M$ ) causing compressive stress on convex surfaces	$\text{metal loss} = H = \frac{12\gamma}{E_{ox}} \left[ \frac{R^2}{M^2 \phi} \right]^{1/3}$ <p> <math>R</math> = radius of metal surface  <math>m = \phi(1 - \alpha) - (1 - V)</math>  <math>\phi</math> = oxide/metal ratio                 </p>
200	Loss of scale integrity when oldest part of oxide sustains strains average stored energy	$S = \frac{1}{2} h \frac{E \epsilon^2}{2\gamma}$ <p> <math>h</math> = metal thickness lost  <math>\epsilon</math> = strain on oxide failure                 </p>
201	Growth stresses	$\sigma_f = \frac{E_m (h_m)^2}{6 r h_c}$ <p> <math>r</math> = radius of curvature  <math>h_c</math> = critical rupture thickness  <math>E_m</math> = elastic modulus of metal  <math>h_m</math> = thickness of base metal                 </p>
202	Interfacial shear failure	$\tau_f = \frac{h_c E_{ox} \Delta T (\alpha_m - \alpha_{ox})}{L + \left( 1 + \frac{E_m h_c}{E_{ox} h_m} \right)} (1 - \nu)$
203	Buckling of oxide	$\alpha \Delta T = \left[ \frac{(h_c)^4}{a^4} + \frac{w}{E_{ox} h_c} \right]^{1/2}$ <p> <math>\alpha \Delta T</math> = thermal strain in oxide  <math>h_c</math> = critical oxide rupture thickness  <math>a</math> = crack length                 </p>
68, 69	Fatigue failure of oxide	$h = \frac{B K_{peff} \rho^\beta}{\bar{h}_f}$ <p> <math>h</math> = oxide intrusion depth  <math>\bar{h}_f = \frac{\delta_0}{(\Delta \epsilon_m)^2 \phi \dot{\epsilon}^a}</math> </p> <p> <math>B, \beta, \delta_0, a</math> = constants; <math>K_{peff}</math> = parabolic oxidation constant  <math>h_f</math> = critical rupture thickness; <math>\Delta \epsilon_m</math> = applied mechanical strain range  <math>\phi</math> = phasing factor for thermomechanical loading                 </p>
135		$\bar{h}_f = \frac{\delta_0}{(\Delta \epsilon_m^{ox})^2 \phi \dot{\epsilon}^a}$ <p> <math>\Delta \epsilon_m^{ox}</math> = Local (oxide tip) mechanical strain range                 </p>

The majority of the models proposed characterize failure due to scale growth stresses or temperature change conditions. The effect of mechanical strains on oxidation is not well understood. Many of the models consider uniform oxide thickness. Experimental observations, however, indicate nonuniform thickness in the form of oxide intrusions (Ref 135).

A summary of oxidation-fatigue laws is given in Table 5 (Ref 1, 2, 3, 4, 25, 26, 27, 28, 29, 34, 46, 47, 48). The models depicted in Table 5 specifically address fatigue plus oxidation damage. Despite the lack of quantitative understanding of oxidation-fatigue, the models provide a qualitative description of the oxidation-fatigue process. The earliest oxidation-fatigue model is that proposed by Coffin (Ref 72, 126) and is referred to as the frequency modified life approach. Antolovich and coworkers (Ref 130) recognized the formation of oxide spikes at preferential grain boundaries in Ni alloys and proposed a strain-life relation incorporating oxidation kinetics. Liu and Oshida (Ref 134) modified fracture mechanics parameters and accounted for accelerated crack growth upon oxide film rupture at crack tips. Rémy and Reuchet's (Ref 140) model incorporates crack growth according to a Dugdale type of model modified to account for oxidation of metal and carbides. The model proposed by Sehitoglu and coworkers (Ref 68, 69, 105, 107, 135) incorporates an oxidation phasing factor and accelerated oxidation under mechanical straining conditions. This is based on measurement of oxide thicknesses and observations of oxide failure at the surface and at crack tips. The details of this model will be illustrated later.

**TABLE 5 SUMMARY OF OXIDATION-FATIGUE LAWS**

Several observations should be made on these models. Since the experimental data that form their foundations have been obtained primarily under IF conditions, the use of these relations for thermomechanical loading is not recommended. The Neu-Sehitoglu model incorporates a varying oxidation severity depending on the strain-temperature history and can handle TMF cases.

Depending on the material, OP or IP loading condition, and whether or not tensile or compressive hold periods are encountered, oxidation damage could be significantly greater than creep damage. By performing experiments in controlled atmospheres, the mechanisms of oxide failure can be isolated and more easily interpreted.

**Creep Damage and Creep Fatigue Models.** A summary of creep laws is given in Table 6. The strain range partitioning method (Ref 50, 62) separates the inelastic strain range into four generic components (pp = plastic-plastic, pc = plastic-creep, cp = creep-plastic, cc = creep-creep). Plastic-plastic stands for plasticity in tension reversed by plasticity

in compression; plastic-creep stands for plasticity in tension reversed by creep in compression; etc. Recently, the method has been modified to handle time effects on the strain components, and a total strain range version has also been proposed. The application of the model to TMF has been outlined where stress hold experiments conducted at various points around the stress-strain hysteresis loop are needed (Ref 50).

**TABLE 6 SUMMARY OF CREEP-FATIGUE LAWS**

Ref	Experiments/mechanism	Equation
58, 64	Isothermal: creep damage in tension versus compression	$\frac{1}{N_{pred}} = \frac{F_{pp}}{N_{pp}} + \frac{F_{pc}}{N_{pc}} + \frac{F_{cp}}{N_{cp}} + \frac{F_{cc}}{N_{cc}}$ $N_{pred} = \text{predicted life}$
204	Isothermal: time-cycle fraction rule, Miner-Robinson Rule	$D = \sum \frac{N}{N_f} + \sum \frac{t}{t_f}$ $N_f = \text{cycles to failure}, t_f = \text{time to failure}$
205	Isothermal: nonlinear damage	$D_f = 1 - (1 - N/N_f)^{p+1}$ $D_c = 1 - (1 - N/N_c)^{q+1}$
206	Isothermal	$D = \sum \frac{N}{N_f} + \sum \frac{\dot{\epsilon}}{\epsilon_f}$ $\dot{\epsilon} = \text{creep strain rate}, \epsilon_f = \text{creep ductility}$ $p, q = \text{constants}, N_f = \text{cycles to failure}$
207	Isothermal: void growth at crack tips	$\frac{da}{dt} = \alpha \left( \frac{K^2}{t} \right)^{\beta n + 1}$ $\beta = \text{void growth exponent}, n = \text{stress exponent}$ $K = \text{stress intensity}, t = \text{time}, da/dt = \text{crack growth rate}$
83, 191	Isothermal: void growth in tension, void healing in compression	$\frac{dD_c}{dt} = \left( \frac{\dot{\epsilon}^m}{\dot{\epsilon}_c} \right)  \dot{\epsilon}^{in} $ $\frac{dD_f}{dt} = (1 + \alpha D_c) (\dot{\epsilon}_{f0})^{-(m+1)} \epsilon^m  \dot{\epsilon}^{in} $ $\dot{\epsilon}^{in} = \text{creep strain rate}, \dot{\epsilon}_{f0} = \text{creep ductility}$ $\alpha, m, m_c, \dot{\epsilon}_{f0}, \dot{\epsilon}_c = \text{constants}, D_c = \text{creep damage}, D_f = \text{fatigue damage}$
208	Isothermal: decrease in crack closure load	$da/dN = C(U\Delta K)^m$ $U = U_0 + (1 - 0.5/F(S_{max}/\sigma_0)) \{ 1 - \exp(-6 \times 10^3 (S_{max}/\sigma_0)^m \frac{t_h \dot{\epsilon}_0}{(\sigma_c/\sigma_0)^m}) \}^2$ $U_0 = \text{time independent effective stress ratio}, \sigma_0 = \text{yield strength}, \sigma_c = \text{creep strength}, m = \text{creep exponent}$ $S_{max} = \text{maximum stress}, t_h = \text{hold period in tension}$
68, 69	Thermomechanical: intergranular, cracking	$D^{creep} = \phi^{creep} \int_0^{t_c} A e^{(-\Delta H/RT)} \left( \frac{\alpha_1 \bar{\sigma} + \alpha_2 \sigma_H}{K} \right)^m dt$ <p>(Terms defined in the text)</p>
118	TMF life model	$N_f = C_0(\Delta \epsilon)^{C_1} (t_h)^{C_2} \exp\left(\frac{C_3}{A}\right)$
209	Microcrack propagation in TMF	$\frac{da}{dN} = C_f(\Delta J)^{m_f} + C_c \dot{\epsilon}^m + C_o(\Delta J)^{m_o}(\Delta t)^\Psi$ <p>(Summation of crack growth from fatigue, creep, and oxidation contributions)</p>

Source: Ref 58, 64, 204, 205, 206, 207, 83, 191, 208, 68, 69, 118, 209

The time-cycle fraction rule (adopted as an ASME Code, Ref 204) involves linear summation of fatigue and creep damage, where the fatigue damage is expressed as cycle ratio and the creep damage is written as a time ratio. Creep damage is determined from stress-rupture diagrams, and fatigue damage is obtained from the strain-life equation. Since experimental results indicate that predictions based on the time-cycle fraction rule can be nonconservative, a modified time-cycle fraction rule has been proposed by Lemaitre and Plumtree (Ref 205) with applications involving cumulative damage. Recognizing that creep ductility is a function of strain rate, a ductility exhaustion approach has also been proposed which defines creep damage as strain rate to ductility ratio (Ref 206).

Several researchers considered creep-fatigue to be a crack propagation-controlled problem where the creep mechanism is assumed to influence the fatigue crack growth or vice versa. Majumdar and Maiya (Ref 83) considered the influence of creep cavity growth ahead of a crack growing by fatigue in their damage-rate equations. In their model, sintering of

cavities occurs in compression, effectively reversing the creep damage occurring in tension. The model is suitable for materials that exhibit copious cavitation. These damage-rate equations have recently been applied to thermomechanical fatigue loadings (Ref 191).

The model of Saxena and Bassani (Ref 207) accounts for cavity formation ahead of a crack tip and modified the crack tip stress fields; therefore, modified fracture mechanics parameters have been used to handle fatigue-creep crack growth. In the absence of cavities, the crack tip stress-strain fields are still modified; this is the basis for a modified crack closure model proposed by Sehitoglu and Sun (Ref 208). The model by Neu and Sehitoglu (Ref 68, 69) incorporates effective stress and hydrostatic stress components and a creep phasing factor which depends on the thermomechanical history.

By performing tests in a helium environment, oxidation damage is eliminated leaving only the fatigue-creep damage. This allows the constants in the fatigue-creep damage term to be formulated directly.

In the Neu-Sehitoglu model (Ref 68, 69), to characterize the oxidation rate at different partial pressures of oxygen, the  $(PO_2)^{1/q}$  term should be placed on the right-hand side of the growth law where  $q$  is a constant and  $PO_2$  is the partial pressure of oxygen in the testing environment. In general,  $K_p$  will not be constant for a cycle which undergoes a varying temperature history. Therefore, an effective oxidation constant,  $K_p^{eff}$  is defined. The growth of voids and intergranular cracks occur predominantly under tensile loading. Consequently, to take into account the load asymmetry, the creep damage term is a function of effective and hydrostatic stress components (see Ref 68, 69, and 105 for details). The constitutive model proposed by Slavik and Sehitoglu (Ref 80), which utilizes two state variables, was used in the simulations, but other constitutive models can also be used. In Table 6 we did not show some of the commonly used life prediction models including the  $\sigma_{max} \Delta \epsilon^{in}/2$ , a quantity related to tensile hysteresis energy, and the  $\Delta W_p$ , plastic work or the total hysteresis energy parameters. As pointed out by Halford (Ref 18) the use of these parameters in TMF places rather unrealistic restrictions on the flow ( $\sigma$ - $\epsilon$ ) and failure behavior of existing structural materials.

Prediction of TMF OP lives for 1070 steel are shown in Fig. 31. The minimum temperature is maintained at 150 °C (300 °F) in these experiments and the mechanical strain increases proportionally with maximum temperature with  $\dot{\epsilon}_{th}/\dot{\epsilon}_{mech} = -1/2$  in the first case and  $\dot{\epsilon}_{th}/\dot{\epsilon}_{mech} = -2$  in the second case. The predictions with the model are shown as solid lines. The  $\dot{\epsilon}_{th}/\dot{\epsilon}_{mech} = -2$  is termed *partial constraint* and the case  $\dot{\epsilon}_{th}/\dot{\epsilon}_{mech} = -1/2$  is termed *overconstraint* (Ref 24, 68, 69).

FIG. 31 THERMOMECHANICAL FATIGUE OP LIFE PREDICTION FOR STEELS UNDER  $\dot{\epsilon}_{TH}/\dot{\epsilon}_{MECH} = -\frac{1}{2}$  AND  $\dot{\epsilon}_{TH}/\dot{\epsilon}_{MECH} = -2$  CONDITIONS. SOURCE: REF 68, 69

## Thermal and Thermomechanical Fatigue of Structural Alloys

Huseyin Sehitoglu, Department of Mechanical and Industrial Engineering, University of Illinois

---

### Constitutive Equations Suitable for TMF

Recent research on high-temperature deformation has produced a considerable number of constitutive models. Two classes of constitutive models suitable for thermomechanical loading have been reviewed by Slavik and Sehitoglu (Ref 81).

**Nonunified Creep Plasticity Models and Their Use in Thermal Loading.** In the first class of models a time-dependent creep strain is added to the plastic strain resulting in the so-called nonunified models. The plastic strain can be described by the classical von Mises yield criteria and Prager or Ziegler rules. In the paper by Slavik and Sehitoglu (Ref 81), the Drucker-Palgen model (Ref 210) was used. The different strain rate components and other important parameters are given in Table 7.

**TABLE 7 NONUNIFIED PLASTICITY MODEL**

Elastic strain rate	$\dot{\epsilon}_{ij}^e = ((1 - \nu) \dot{\sigma}_{ij} - \nu \dot{\sigma}_{kk} \delta_{ij})/E - ((1 - \nu)\sigma_{ij} - \nu \sigma_{kk} \delta_{ij}) \frac{\partial E}{\partial T} \cdot \frac{\dot{T}}{E^2}$
Thermal strain rate	$\dot{\epsilon}_{ij}^{th} = \theta \dot{T} \delta_{ij}$
Yield criteria	$f = \frac{1}{2} (S_{ij} - S_{ij}^c) (S_{ij} - S_{ij}^c) - k^2 = 0$
Plastic strain rate	$\dot{\epsilon}_{ij}^p = H \left[ \frac{\partial f}{\partial S_{ij}} \frac{\partial f}{\partial S_{kl}} \dot{S}_{kl} + \frac{\partial f}{\partial T} \dot{T} \right]$
Creep strain rate	$\dot{\epsilon}_{ij}^c = B(\bar{\sigma})^{s-1} S_{ij} \exp(-\Delta H/RT)$
Plastic modulus	$H = A' J_2^{N/2} / (1 \pm \beta(\exp - p/\rho_0))$
Accumulated plastic strain	$p = \int_0^t \left( \frac{2}{3} \dot{\epsilon}_{ij}^p \dot{\epsilon}_{ij}^p \right)^{1/2} dt$

Source: Ref 81

Source: Ref 81

In Table 7 the first row gives the elastic strain rate of an isotropic material where the elastic modulus is a function of temperature. The second row is the thermal strain rate for an isotropic material. The yield criteria is the von Mises type where  $k$  is the yield stress in shear and the center of the yield surface is permitted to move in stress space. The equations for this translation are given in Ref 81. The plastic strain rate is normal to the yield surface and also changes with temperature as shown in Table 7. The creep strain rate is expressed as a function of equivalent stress and the creep rate is in the same direction as the deviatoric stress rate. The plastic modulus, the slope of the stress-plastic strain rate, varies with plastic strain history such that it exponentially approaches a steady state value. The plastic strain history is described by the accumulated plastic strain which is a scalar positive quantity.

The advantages of this model are the following: (1) it can use the existing database of plastic and creep properties, (2) it conforms to existing FEM codes, and (3) it does not require special integration schemes. Experimental results and predictions of TMF OP behavior of 1070 steel with the above equations are given in Fig. 32(a) and 32(b) (Ref 81), respectively. In this case, 150 °C  $\leftrightarrow$  450 °C cycling under 'overconstraint' ( $\dot{\epsilon}_{mech} = -2, \dot{\epsilon}_{th}$ ) is shown. "Overconstraint" means that the mechanical strain is larger than the thermal strain because during heating the material is also subjected to a

negative net strain as shown in Fig. 32(a). The prediction of the stress-strain response with the nonunified model is satisfactory (Fig. 32b).

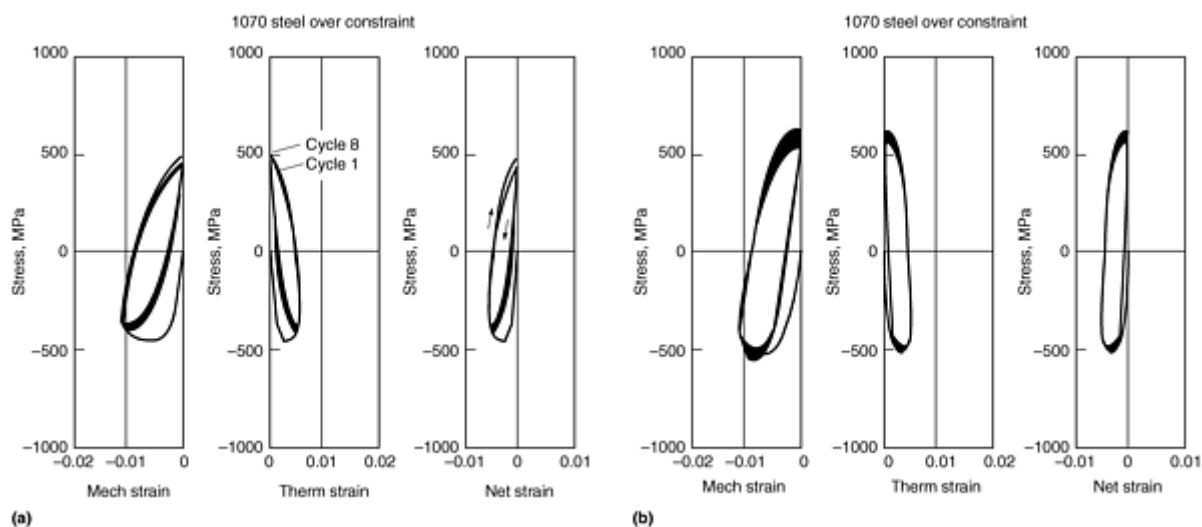

FIG. 32 THERMOMECHANICAL FATIGUE (OUT-OF-PHASE) STRESS STRAIN OF 1070 STEEL. (A) EXPERIMENTAL. (B) PREDICTION USING NONUNIFIED EQUATIONS. SOURCE: REF 81

**Unified Creep Plasticity Models and Their Use in Thermal Loading.** These models, termed *unified models*, have the potential to predict creep-plasticity interactions and strain rate effects more accurately than the nonunified models. A unified model that has been widely used was proposed by Bodner and Partom (Ref 211) and later modified for cyclic loading (Ref 212). The simulations of TMF OP with this model are given in Fig. 33 (Ref 81). Comparison of experimental results shown in Fig. 33(a) and predictions shown in Fig. 33(b) prove that the model is satisfactory. In Fig. 33(a) the stress-net strain response is shown under  $150\text{ }^{\circ}\text{C} \rightleftharpoons 600\text{ }^{\circ}\text{C}$  and total constraint ( $\dot{\epsilon}_{\text{mech}} = -\dot{\epsilon}_{\text{th}}$ ) conditions. In this case, the net strain is zero and the mechanical strain is equal but opposite of thermal strain.

(b)

FIG. 33 THERMOMECHANICAL FATIGUE (OUT-OF-PHASE) STRESS STRAIN OF 1070 STEEL. (A) EXPERIMENTAL. (B) PREDICTION USING BODNER'S MODEL. SOURCE: REF 81

In the unified models, there is no yield surface assumption. Inelastic strain rates are permitted at small levels of effective stress which is usually the deviatoric stress-deviatoric backstress. The unified models are often composed of two state variables, the deviatoric back stress,  $S_{ij}^c$  and the drag stress,  $K$ . The back stress can be used to predict the Bauschinger effect in room-temperature loading and also the transient and steady state creep response at high temperatures. The drag stress,  $K$ , accounts for cyclic hardening or softening, and the influence of plasticity on creep or vice versa. The strain rate sensitivity is determined by the flow rule. The general form of these unified relations is given in Table 8. We note that Bodner's original form did not include a back stress.

**TABLE 8 TWO UNIFIED MODELS USED FOR TMF  $\sigma$ - $\epsilon$  PREDICTION**

Source: Ref 80, 211, 212

Ref	Flow rule	Back stress	Drag stress
80	$\dot{\epsilon}_{ij}^{in} = \frac{3}{2} f(\bar{\sigma}/K) \frac{S_{ij} - S_{ij}^c}{\bar{\sigma}}$ $f\left(\frac{\bar{\sigma}}{K}\right) = \begin{cases} A \left(\frac{\bar{\sigma}}{K}\right)^n & \frac{\bar{\sigma}}{K} \leq 1 \\ A \exp\left[\left(\frac{\bar{\sigma}}{K}\right)^m - 1\right] & \frac{\bar{\sigma}}{K} > 1 \end{cases}$	$\dot{S}_{ij}^c = \frac{2}{3} h_{\alpha} \dot{\epsilon}_{ij}^{in} - r_{\alpha} S_{ij}^c$ $h_k = B(k_{sat} - K) \dot{\epsilon}^{in}$ $r_k = C(K - K_{rec})$	$\dot{K} = h_k - r_k + \Theta \dot{T}$
211, 212	$\dot{\epsilon}_{ij}^{in} = f\left(\frac{K^2}{J_2}\right) S_{ij}$ $f\left(\frac{K^2}{J_2}\right) = \left(\frac{D_0^2}{J_2} \exp\left[-\left(\frac{n+1}{n}\right)\left(\frac{K^2}{3J_2}\right)^n\right]\right)^{0.5}$		$\dot{K} = m(K_1 - K) \cdot \dot{W}^{in} - A \left(\frac{K - K_i}{K_1^*}\right)^r \exp\left(\frac{-\Delta H}{RT}\right)$

The first equation in Table 8 is the flow rule where  $\dot{\epsilon}_{ij}^{in}$  is the inelastic strain rate (which is the combination of plastic and creep strains),  $\bar{\sigma}$  is the effective stress,  $S_{ij}$  is the deviatoric stress,  $S_{ij}^c$  is the deviatoric back stress, and  $K$  is the drag stress. The second equation describes the evolution of back (internal) stress where  $h_{\alpha}$  is the hardening function for the back stress and  $r_{\alpha}$  is the recovery function for the back stress. The third equation depicts the evolution of drag stress where  $h_k$  is the hardening function for the drag stress,  $r_k$  is the recovery function for the drag stress, and  $\Theta$  is the thermally activated drag stress change term (defined as  $\partial K_i / \partial T$ ). The term that distinguishes different models is the choice of the flow rule,  $f(\bar{\sigma}/K)$  and the manner in which the hardening and recovery functions are determined. Different deformation mechanisms (plasticity, power law creep, diffusional creep) have been identified in deformation mechanism maps (Ref 47) but have not been explicitly considered. Sehitoglu and Slavik confirmed that at high strain rates the strain rate effective stress relation has the form of the exponential function (i.e., rate insensitive behavior) while at lower strain rates the relation between inelastic strain rate and effective stress is consistent with the power law creep relation. An experimentally based unified constitutive model has been proposed earlier by Sehitoglu and Slavik (Ref 80, 81). A list of functions and corresponding experiments to determine these constants follow:

FUNCTION	EXPERIMENTAL DETERMINATION
FLOW RULE, $F$	HIGH AND LOW STRAIN RATES, YIELD STRENGTH MEASUREMENTS IN TENSILE OR COMPRESSIVE MONOTONIC TESTS
HARDENING OF BACK STRESS	HIGH STRAIN RATE (ROOM AND HIGH TEMPERATURE)
RECOVERY OF BACK STRESS	LOW STRAIN RATE OR CREEP (HIGH TEMPERATURE)
HARDENING OF	HIGH STRAIN RATE CYCLING (ROOM AND HIGH TEMPERATURE)

DRAG STRESS	
RECOVERY OF DRAG STRESS	<b>REST PERIODS (HIGH TEMPERATURE) CHANGE OF <math>K_0</math> WITH TEMPERATURE</b>
$\Theta$	<b>CHANGE OF <math>K_0</math> WITH TEMPERATURE</b>

The material constants for the Slavik-Sehitoglu model for different class of materials are listed in Tables 9, 10, and 11. These are 1070 steel (Ref 80), Mar-M247 (Ref 105), René 80 (Ref 213), Al<sub>2xxx</sub>-T4 (Ref 96, 164) and Ti- $\beta$ 21S (Ref 214). These tables are also summarized in Ref 215 and explained in Ref 80.

Predictions of material response utilizing this relation are given in Fig. 34 (Ref 80). The experimental results were shown earlier in Fig. 14. In these experiments (total constraint TMF OP), the minimum temperature was constant at 150 °C (300 °F). Because of thermal recovery effects, the drag stress decreases upon exposure to high temperatures and this results in loss of strength at the minimum temperature. Note that the model (solid rectangular points) predicts the decrease in maximum stress with increasing mechanical strain very accurately. Because of the thermal recovery effects, the maximum stress in the cycle decreases with increasing mechanical strain range. The agreement between experiment and prediction is excellent. It is possible to incorporate additional terms to predict such phenomena such as strain aging and dynamic recovery into the constitutive models. Other TMF and IF simulations with this unified model can be found in Ref 80, 96, 105, 164, and 213. Simulations for the case of strain aging for the 1070 steel have been demonstrated in Ref 80 and are further discussed below.

FIG. 34 PREDICTION OF MAXIMUM STRESS IN THE TMF OP CASE IN 1070 STEEL. SOURCE: REF 80

Certain temperature-strain histories in solute-hardened materials produce strain aging, hence strengthening of the material. Thermomechanical fatigue studies (under strain aging conditions for steels and nickel-base superalloys) have been discussed in Ref 60 and 215. Strengthening is caused by interstitial solute atoms which anchor the dislocation motion. If the pinning of the dislocations occurs during deformation, the term "dynamic strain aging" is used (Ref 87). If the aging occurs under a constant load (after some plastic deformation), it is called "static strain aging" (Ref 87).

Static strain aging experiments were conducted on 1070 steel. The material is cycled at 20 °C but is exposed to the aging temperature time at zero stress every reversal. A schematic of the strain-temperature history and the results for 1070 steel was shown earlier in Fig. 15. The predictions using the unified formulation are given in Fig. 35. The prediction of the strengthening under these conditions is very favorable. The details can be found in Ref 80 and 215.

FIG. 35 PREDICTION OF 1070 STEEL RESPONSE UNDER STRAIN AGING CONDITIONS. SOURCE: REF 80

Finally, we note that other unified models have been tested under TMF loadings but not as extensively as the Slavik and Sehitoglu model. For example, Miller (Ref 216) proposed a unified model which he checked against experimental TMF IP data on PWA 663. His predictions were satisfactory. Walker (Ref 217) proposed a model for high-temperature/time-dependent loadings that was also applied to predict TMF behavior.

### Introduction

THE LIFE of a structural component is limited by its ability to resist the effects of its usage history, which may consist of cyclic loads, fluctuations in temperature, or a corrosive environment. Even with anticipated usage, the material properties of a component degrade over time, and that degradation can eventually result in failure. One of the mechanisms by which this process occurs, fatigue, is the initiation and growth of cracks. Fatigue is a primary cause of failure in aircraft structures. For this reason, a reliable prediction of component fatigue life is critical to aircraft safety.

Life extension using the damage tolerance design method has become more prominent in the aviation industry. As the average age of the world's transport fleet continues to rise, this analysis technique becomes more widespread. With the increasing cost of new aircraft, operators find it more economical to refurbish and maintain their existing aircraft than to purchase new ones. The resulting increase in the number of aircraft that are being operated beyond their expected service life raises important safety questions regarding the structural integrity of these aircraft. To answer these questions, several approaches have been developed that attempt to provide some measure of the useful life of aircraft structural components. These approaches are either based upon fatigue methods, which can employ statistical data and testing to arrive at an estimate of component life, or damage tolerance methods which arrive at a reasonable inspection interval to ensure component safety. This latter method is based upon the growth rate of cracks assumed to exist in the component as a result of fatigue, accidental damage, or material and manufacturing defects.

The effect of corrosion, and the degradation it imposes upon materials is complex and not readily deterministic as a function of time. Aircraft manufacturers select materials and processes to impede the effect of corrosion, and users of the aircraft attempt to preclude the destructive nature of corrosion as a regular part of their inspection program. This article provides a general overview of these approaches to corrosion identification and prevention, and discusses their application to the process of extending the life of aircraft structural components.

### Analysis Methods

The analysis methods that are used to determine the life of aircraft are those using fatigue methods and those using the methods of fracture mechanics. The similarities in these methods are the input information, i.e., discrete localized stresses and the stress time history (stress spectrum) of the component being analyzed. The differences in these methods are the initial condition and the inspection interval. The initial condition in fatigue is a pristine (unflawed) condition in the component, while fracture mechanics assumes an initial flaw of a given size and geometry. The fatigue test is complete at specimen failure. Two pieces of information are known in a fatigue test; the number of cycles to failure, and the loading that the specimen (component) experienced. In a fracture mechanics test, these two are known as well as the number of cycles (flight) for the crack to grow a given distance. This additional information allows the analyst to determine recurring inspection intervals as the growth behavior of the flaw is identified.

**Fatigue life methods** are empirical in nature, using statistical techniques to establish safe estimates of fatigue life from  $S-N$  or  $\epsilon-N$  test data. A safe estimate is one in which the probability of component failure within a specified time frame is very remote. Component life estimates using these methods are typically based upon material and load data gathered from axial loading tests, material component tests, and full-scale testing. In axial loading tests, test samples of the material are subjected to tension-compression or tension-tension cycles until failure. The data are then presented in the form of an  $S/N$  curve, which may depict maximum stress, minimum stress, or stress amplitude versus the number of cycles to failure. The fatigue life obtained from an  $S/N$  curve represents the time for a flaw to initiate and propagate to failure. Because the loading is cyclical, the stress ratios are defined to be a function of the minimum and maximum stresses for a given test.

The two most commonly used ratios are the  $R$  factor (the ratio of minimum stress to maximum stress) and the  $A$  factor (the ratio of alternating stress to mean stress) such that:

$$R \text{ ratio} = \frac{\sigma_{\min}}{\sigma_{\max}}$$

$$A \text{ ratio} = \frac{\sigma_a}{\sigma_m}$$

where the stress amplitude ( $\sigma_a$ ) =  $(\sigma_{\max} - \sigma_{\min})/2$  and the mean stress ( $\sigma_m$ ) =  $(\sigma_{\max} + \sigma_{\min})/2$ . The stress factors are related directly:

$$R = (1 - A)/(1 + A)$$

$$A = (1 - R)/(1 + R)$$

and thus  $R = -1$  and  $A = \infty$  under fully reversed loading (zero mean stress). The  $R$  factor is normally used in airframe design, while the  $A$  factor is used in engine design.

$S/N$  curves are created by averaging the data points from tests conducted on an appropriate sample size of the material. In most cases, a test is run to failure at three or four different stress levels to determine the shape of the  $S/N$  curve. Remaining samples are then tested to failure at the same selected stress levels and the results are averaged to produce a curve that reflects a 50% probability of failure. If a large enough number of data points are collected for various stress levels, a probability-stress-life plot can be constructed as shown in Fig. 1. For a given stress level, a fatigue life can be chosen corresponding to an acceptable probability of failure. Statistical models commonly used in these plots are the Weibull and log normal distributions (Ref 1).

FIG. 1 TYPICAL PROBABILITY-STRESS-LIFE-PLOT

**Constant-Amplitude Fatigue Limit.** Testing a material under constant amplitude (often at  $R = -1$ ,  $A = \infty$ ) can be used to define a fatigue limit. For low-strength steels, the data points on an  $S/N$  curve tend to approach an asymptote as the number of cycles becomes large. The stress value corresponding to this region is referred to as the fatigue limit of the material. For those materials which do not exhibit this region, such as high-strength steels and aluminum alloys, the fatigue limit often is defined as the stress value corresponding to  $10^7$  cycles (Ref 2). A fatigue limit is useful in designing components for 'infinite' life, but in practice the mean stress is not always zero. Constant-life diagrams, such as the Soderberg line shown in Fig. 2, serve as a guide in fatigue design by relating non-zero mean stress cases to the fatigue

limit and other properties of a material (Ref 3). Combinations of mean and alternating stress which fall on or beneath the line correspond to an indefinite fatigue life for a component. The Soderberg line provides conservative estimates for ductile materials. Other relationships, such as the Goodman line (Ref 4) or Gerber parabola (Ref 5), provide comparable results.

FIG. 2 PLOT OF THE SODERBERG RELATIONSHIP

**Variable Amplitude Loading.** In reality, aircraft components are likely to be subjected to variable amplitude loading rather than the simplified constant amplitude loading assumed so far. Determining the fatigue life of a component under these conditions requires a method that can relate the variations in mean and alternating stress to fatigue data obtained from constant amplitude loading tests. One such method is the Palmgren-Miner Rule (Ref 6, 7), which has the mathematical form:

$$\sum_{i=1}^m \frac{n_i}{N_i} = 1$$

where  $n_i$  represents the number of cycles of damage and  $N_i$  represents the life of a component at a number of levels of mean and alternating stress. For each combination of stresses in the spectrum, the fraction of damage done by each is added together to obtain a total damage fraction. The reciprocal of this fraction provides a measure of the number of loading spectra that a component can sustain before failure. This estimate is based upon the assumptions that the relationship between  $n$  and  $N$  is linear and that the fatigue life is independent of the order in which the stresses are applied. In most cases, these assumptions are only marginally valid, and fatigue life estimates obtained using the Palmgren-Miner Rule are adjusted through testing or by dividing by a suitable safety factor (Ref 8).

**Fracture mechanics methods** are concerned with the initiation and propagation of cracks. Fracture mechanics is based upon the fundamental assumption that all structures, whether new or in service for many years, contain minute flaws which, under the proper conditions, can cause fracture. These flaws can be in the form of material irregularities, such as an inclusion or void, or they can be created during the manufacturing process. A scratch on the inside surface of a fastener hole caused by a dull drill bit is an example of a manufacturing defect. In-service structures can sustain flaws from their environment and maintenance practices. Manufacturing and maintenance procedures are closely regulated in the aviation industry to prevent the creation of flaws, especially in the vicinity of stress concentrations. However, it is an accepted fact that flaws will always exist.

**Residual Strength and Griffith Criterion.** Once a crack initiates, it will continue to grow longer under the action of repeated loads or due to the service environment, until failure occurs. As the crack lengthens, the rate at which it grows

will increase. Failure occurs when the magnitude of the stress concentration produced by the crack and at the crack tip exceeds the residual strength of the structure. The residual strength is a measure of the highest stress a structure can carry for a given crack size before failing.

In order to determine the residual strength of a structure, the relationship between the crack tip stress field and crack length must be established. In 1920, Griffith proposed that a crack can propagate in a solid only if the energy available for crack growth equals or exceeds the energy required (Ref 9). The energy required for crack growth, referred to as the crack resistance, represents the energy necessary to break atomic bonds in the formation of new crack surfaces. Griffith arrived at his theory by experimenting with glass rods, where the crack resistance consisted solely of surface energy as a result of the brittle nature of glass. For ductile materials, such as metals, the crack resistance consists primarily of plastic energy, as the material at the crack tip must yield before crack growth can occur.

Griffith's theory is essentially a statement of conservation of energy. The potential energy contained within a solid before an increment of crack growth must equal the potential energy remaining in the solid after crack growth plus any energy increases or decreases resulting from external work done on the solid or energy lost to the surroundings. By analyzing a uniformly stressed plate with a preexisting crack in its center and applying the principle of minimum potential energy, Griffith arrived at an equation relating applied stress to crack length. The general form of Griffith's equation is:

$$G = \frac{\pi\sigma^2 a}{E}$$

where  $G$  is the elastic energy release rate,  $\sigma$  is the stress applied to the plate,  $a$  is half the crack length, and  $E$  is Young's modulus. The elastic energy release rate represents the energy available for crack growth. When  $G$  equals or exceeds a certain critical value, crack growth will occur.

**Stress Intensity Factor.** Irwin expanded upon Griffith's theory by determining the crack tip stress field for an edge crack in a thin plate (Ref 10). When the crack is small compared to the dimensions of the plate, Irwin found the following relationship:

$$K_I = \sigma\sqrt{\pi a}$$

where  $K_I$  is defined as the stress intensity factor,  $\sigma$  is the stress applied at the edges of the plate, and  $a$  is the crack length. The subscript, I, denotes mode I crack loading. Three modes of loading are possible for a crack in a solid: mode I, referred to as a tensile or 'opening mode,' mode II, referred to as shear or a 'sliding mode,' and mode III, referred to as torsion or a 'tearing mode.' For a crack in a plate, mode I loading is created by normal stresses on the edges of the plate which tend to separate the opposing surfaces of the crack. Mode II loading is created by shear stresses in the plane of the plate and mode III by shear stresses perpendicular to the plane of the plate. Stress intensity factors can be defined for all three loading conditions, but mode I tends to be the most critical condition for component life and failure.

The stress intensity factor is a useful parameter that integrates material properties, loading conditions, and geometry into the relationship between structural strength and crack size. It is not a stress concentration factor. For finite geometries, the equation for the stress intensity factor takes the form:

$$K_I = \sigma\sqrt{\pi a}\beta$$

The dimensionless factor,  $\beta$ , is a function of geometry and crack size. For a plate with a central crack subject to uniform tension,  $\beta$  is a function of the ratio of crack size to plate width. For a plate subject to uniform tension with a hole in its center and a crack emanating from one side of the hole,  $\beta$  is a function of the ratio of crack size to hole radius. Stress intensity factor solutions exist for many combinations of loading conditions and geometry. Since these solutions are based upon linear elastic stress analysis, the principle of superposition can be used to solve more complex cases.

The stress intensity factor is related to the elastic energy release rate by the equation:

$$G = \frac{K_I^2}{E} \text{ for plane stress (i.e., thin plates)}$$

$$G = \frac{(1 - \nu^2) K_I^2}{E} \text{ for plane strain (i.e., thick plates)}$$

where  $\nu$  is Poisson's ratio. From these relationships, it becomes clear that if a critical value of  $G$  exists, above which fracture will occur, a critical stress intensity factor,  $K_{Ic}$ , must also exist. This critical value is referred to as the fracture toughness.

Fracture toughness is a material property that is determined through load-displacement tests. Typically, the crack opening displacement is plotted as a function of applied load, and the fracture toughness is calculated from the load corresponding to a certain percentage of crack extension. The results of these tests are dependent upon many factors, such as temperature, material temper, crack geometry, and specimen geometry, and must be applied carefully. The American Society for Testing and Materials (ASTM) has written a specification defining this test and its parameters (Ref 11). Plane strain fracture toughness tests have well-defined criteria for specimen and crack geometry. Compact tension and bend specimens are generally used with their dimensions carefully selected to ensure plane strain conditions. Plane stress fracture toughness tests are not as clearly defined and usually require much larger specimens (Ref 12). Knowledge of fracture toughness for a given set of material conditions, coupled with the equation for stress intensity factor, allows the critical crack length, the largest crack size a structure can withstand before failure, to be calculated for any applied load. This value is important in the design of damage tolerant structures.

**Crack Growth Relationships.** Once the critical crack length is known, the next question that arises is how long will it take an existing crack to propagate from a certain initial crack size to the critical crack length? This question can be answered by developing an equation that describes the behavior of a crack under conditions of stable growth. The term stable growth refers to crack growth that occurs when the elastic energy release rate is just equal to the crack resistance ( $G = R$ ). When the elastic energy release rate exceeds the crack resistance, relatively rapid, unstable crack growth, referred to as fracture instability, will result. Fracture instability occurs at the critical crack length. One of many relationships that are assumed to describe stable crack growth is the Paris equation:

$$\frac{da}{dN} = C(\Delta K)^n$$

where  $C$  and  $n$  are material constants, and  $\Delta K$  is the alternating stress intensity factor (Ref 13). This equation states that the change in crack length per cycle is a function of the difference between the maximum and minimum stress intensity factors. Since stress intensity is a function of stress as well as crack length,  $\Delta K$  relates the stress spectrum directly to the crack growth rate. Tests have shown that below a certain value of  $\Delta K$ , referred to as the threshold stress intensity factor ( $\Delta K_{th}$ ), the crack growth rate is very small. Therefore, crack growth is assumed to occur only when  $\Delta K$  exceeds the threshold.

Figure 3 shows a double logarithmic plot of  $da/dN$  data for 2024-T3 aluminum at  $R = 0$ . The Paris equation predicts that the data points should lie on a straight line of slope  $n$ . As can be seen, the plot clearly consists of several slopes, pointing out the limitations of the Paris equation.

**FIG. 3 CRACK GROWTH DATA FOR 2024-T3 ALUMINUM.** 2024-T3 AL, 0.090 IN. SHEET, L-T DIRECTION, 70 °F, LAB AIR; FREQUENCY, 0.3 TO 20 HZ; CC SPECIMENS, 0.090 IN. THICK, 12.0 IN. WIDE. SOURCE: *DAMAGE TOLERANT HANDBOOK*, MCIC HANDBOOK, HB-01

Other equations have been developed that attempt to account for the variations in slope and  $R$  factor (Ref 14, 15, 16). While these equations are applicable over certain ranges and  $R$  factors, none of them is applicable over the full range of  $\Delta K$  values for all cases. Nonetheless, these equations are useful for estimating the time required for an existing crack in a structure to grow from its initial size to the critical crack length, providing some measure of the life of the structure. In most instances, a crack growth equation can be found that conforms to the test data over a limited range of  $\Delta K$  values. For this reason, many computer programs contain several crack growth models, allowing the user to select the applicable crack growth equation. Additionally, these crack growth programs have as an option, an algorithm that allows the user to input raw test data. The crack growth program then interpolates the crack growth rate as a function of  $\Delta K$  from the input data.

## Life Assessment Procedures

**Safe-Life Approach.** The relevance of fatigue in aircraft design was not always readily understood. During the 1950s, the loss of several Comet aircraft within a short period of time prompted an investigation into the structural integrity of the Comet's fuselage. A pressurization test on a sample aircraft revealed that the combination of fatigue and stress concentration at the corner of a window was the probable cause of the failures (Ref 17). These accidents as well as others prompted the development of fatigue methods for aircraft design. Using these methods, the safe-life approach predicts a replacement time for aircraft components, usually specified as a number of allowable landings or flight hours. The replacement time is based upon the time required for failure, which is obtained from component fatigue tests. In most cases, a component is designed so that the replacement time for that component exceeds the expected service life of the aircraft. However, critically loaded components, such as engine rotors or landing gear, can have much shorter replacement times. Once a component reaches its replacement time, its safe-life is considered to be used up and it is retired, whether or not any fatigue cracks are present. Ideally, a component designed according to safe-life principles will be replaced before it develops a fatigue crack. There were, however, two significant problems inherent in this method:

- THE SAFETY OF AN AIRCRAFT WAS NOT PROTECTED IF IT CONTAINED A MANUFACTURING OR MAINTENANCE INDUCED DEFECT.
- RETIREMENT TIMES WERE NOT BASED UPON STATISTICALLY BASED SAFETY FACTORS. TO PROTECT SAFETY, THE SELECTED SAFETY FACTOR WAS CONSERVATIVE. AS A RESULT, MANY COMPONENTS WERE PREMATURELY RETIRED.

**Fail-Safe Approach.** The fail-safe approach to aircraft fatigue design was developed during the 1960s and implemented in a number of commercial aircraft (Ref 18). The goal of the fail-safe philosophy is to design multiple load path structures, such that if an individual element should fail, the remaining elements would have sufficient structural integrity to carry the additional loads from the failed element until the damage is detected through scheduled maintenance inspections. In addition to multiple load path structures, crack stoppers are also commonly used in fail-safe designs. Crack stoppers, which typically consist of materials with a high fracture toughness, are used to supplement the residual strength of the surrounding structure and prevent cracks from propagating to failure. An example of a crack stopper is a stringer in a pressurized fuselage. The stringer reduces the amount of energy available for crack growth, slowing or stopping the advance of a crack that crosses it. Ideally, an aircraft designed according to fail-safe principles can sustain damage and remain airworthy until the damage is detected and repaired. This necessitates periodic inspection to examine the structure to determine if the primary load carrying member contains cracks. The frequency of these inspections is typically assigned by the manufacturer based upon service experience. This method does not consider the initiation and growth (linking up) of small cracks at fastener holes. As a result, the loss of several 'fail-safe' aircraft in the mid 1970s emphasized the need to locate cracks and repair damage before failure occurred (Ref 19).

**Damage Tolerance Approach.** In the early 1970s, the U.S. Air Force initiated a number of standards and specifications that led to a new method of fatigue design-damage tolerance (Ref 20, 21). Based upon fracture mechanics techniques, the damage tolerance approach redefined the basis for analyzing fatigue cracks in aircraft structures. With economic and safety advantages over the previous methods, the damage tolerance philosophy was eventually adopted by the commercial aircraft industry as well (Ref 22, 23). The objective of the damage tolerance approach is to detect cracks in principal structural elements before they propagate to failure. A principal structural element (PSE) is defined as any aircraft structure carrying flight, ground, or pressurization loads, whose failure could result in the loss of the aircraft. By establishing inspection intervals for these elements based upon the time it takes a crack to grow from an initial detectable size to the critical crack length, the objective of the damage tolerance approach can be achieved.

Before inspection intervals can be established for an aircraft, its usage profile must be defined. This profile describes the various flight conditions, such as taxi, climb, cruise, descent, and landing impact, and the amount of time spent at each gross weight, speed, and altitude. The usage profile is then used to create a load factor spectrum at the center of gravity of the aircraft, based on the frequency of occurrence of each increment of load factor, and to identify the principal structural elements of the aircraft. An inspection interval must be established for each principal structural element. This task is accomplished by converting the load factor spectrum into a stress spectrum for each location and incorporating the effects of the service environment. Using crack growth equations, such as the Forman equation, the stress spectrum is combined with material properties data and stress intensity factor solutions applicable to each principal structural element to determine the number of cycles or flight hours to failure. This number is usually divided by a factor of two to arrive at the inspection interval. Dividing by a factor of two ensures that, should a principal structural element develop a crack, it will be inspected at least once before the crack propagates to failure.

Unlike the safe-life approach where components are retired whether or not they are damaged, damage tolerant components are only replaced if a crack is found during an inspection. It is important to note that, although the detectable crack size dictates the time between inspections to a certain degree, any size crack found during an inspection mandates replacement of the damaged component. In addition to its economic advantages, the damage tolerance approach also allows for a reduction of safety factors in design. Since fracture mechanics provides a more precise characterization of crack behavior, the large scatter factors typical of fatigue methods are not required.

Damage tolerant components are designed on the basis of residual strength as shown in Fig. 4. The residual strength of a cracked component decreases as the crack grows longer. After a certain amount of time, the residual strength of the component will fall below the maximum expected service stress, at which time failure of the component becomes probable. The inspection interval must be made short enough to locate the damage before a crack reaches a length likely to result in failure. The task of the designer is to produce components that have sufficient residual strength to withstand the maximum stresses expected, while at the same time, maximizing the critical crack length. Some of the ways in which

this task can be achieved are by selecting a material with good fracture toughness, eliminating stress concentrations, or integrating crack stoppers into the design.

FIG. 4 SCHEMATIC OF A RESIDUAL STRENGTH DIAGRAM

The above discussion has focused on the deterministic aspects of damage tolerance. Stochastic methods, such as risk analysis, also play a role. Combining the data generated from deterministic analysis with stochastic factors such as manufacturing quality, risk analysis attempts to assess the probability of fracture of principal structural elements. An initial flaw in a principal structural element is represented by an Equivalent Initial Flaw Size Distribution (EIFSD), which is obtained from tests that determine the distribution of times it takes a crack of some initial size to reach a specified reference size (Ref 24). This distribution of times is referred to as the Time to Crack Initiation (TTCI) distribution. This approach differs from a deterministic analysis which assumes a single value for the initial flaw size. Once the TTCI distribution is known, the EIFSD may be obtained for any service time. Inspection intervals are then established based upon the amount of time it takes the crack sizes at the lower end of the distribution to reach the critical crack length. These inspection intervals may later be modified to account for the quality of maintenance and inspection capability (the probability of detecting cracks).

### Life Limiting Factors

To extend the life of an aircraft, one first must understand those factors which limit its life. It is the purpose of the following discussion to briefly discuss some of those aspects that control the durability of the aircraft. The life of an aircraft is dependent upon a number of variables, such as flight profiles, usage rate, external environment, material selection, and design philosophy. The first two of these (flight profile and usage rate) affect the design life of the aircraft, i.e., the number of expected safe flight hours. The external environment affects corrosion, and therefore component life, while material selection (composite versus metal structure) and design philosophy affect individual components. In a study conducted by the NTSB, they found that in the fifteen years between 1970 and 1985, corrosion or fatigue was involved in 77 out of 579 aircraft incidents (Ref 25). These many incidents may be greatly reduced through improved design methods and inspection procedures.

It is interesting to note that while the aircraft is operational, the dynamic factors (fatigue, flutter, vibration) are the responsible parameters for determining the life aspects of selected components, but while the aircraft is sitting on the ground, corrosion behavior is normally the dominant driver. It should be noted that this is not the case in the galley, lavatories, and bilge areas. There are factors, however, that exacerbate both these conditions. These are manufacturing and maintenance actions which allow for both the premature initiation and propagation of cracks and also enhance the onset and continuing damage of corrosion. These may be dings, scratches, grinding marks, improper cleaning, non-removal of drilled or reamed material, etc.

**Manufacturing defects** may be subdivided into two broad categories. These are material defects and mechanical defects. Both these type of defects generally exist in the aircraft at the time the product leaves the manufacturer. The material defect may manifest itself as a result of a metallurgical anomaly. This anomaly or metallurgical defect may occur as a result of faulty furnace control during heat treating, improper plating which may result in unwanted hydrogen in high-strength steel, processing problems (forging laps, shuts, undesirable grain structure, etc.), welding defects, etc. A second type of material defect may occur in composite materials. Defects that occur in composite materials include debonding, poor ply adhesion, improper cleaning, and non-removal of ply separation material.

For example, a material defect caused failure of an F-111 aircraft which used D6AC steel in the wing box. Material allowables were obtained through a testing program. Unfortunately, the test specimens to determine the toughness of the steel had a section thickness different from the material placed upon the aircraft. The material located on the aircraft had a toughness substantially lower, approximately half, than the toughness of the material used in the test program due to the difference in thermal behavior during heat treatment. Additionally, a forging lap was present in the material used for the joint. The crack was not observed during inspection, and the material was placed onto the aircraft with the forging lap present. The aircraft was flown for 107 flights safely, at which time catastrophic failure occurred causing the destruction of the aircraft and the death of the pilot (Ref 26).

Subsequent inspection noted the presence of the flaw, and a rigorous test program indicated a significant difference in material toughness between the coupons used in the original test program, and the forging used on the aircraft. As a result of this failure, means to periodically inspect the components were required. After much deliberation, the method utilized was a proof test. Chambers were built that housed the F-111, and a system was designed and fabricated that would lower the temperature of the chamber below nil ductility transition (NDT) for the steel. The aircraft was placed into the chamber, the temperature stabilized, and fixtures would load the wing box as required. If a crack equal to or greater than critical existed in the structure, failure would occur. If no failure occurred, the aircraft would be able to safely fly another flight interval. This inspection technique was repeated for each aircraft as appropriate.

There are a number of examples where failures of structural components initiated from manufacturing defects. For military aircraft, these include T-38 and F-5 (improper use of a router caused these aircraft to lose wings as a result of fatigue cracking) (Ref 27), civilian aircraft include United Flight 232 which failed near Sioux City, Iowa in July, 1989 (Ref 28), and failures of titanium discs on an RB211 engine (Ref 29). The Sioux City mishap was due to a manufacturing problem in a titanium fan disc, while the RB211 failures were due to tensile residual stresses due to processing of the titanium. These residual stresses when added to the normal operating stresses caused an effective operating stress that had sufficient magnitude to lower the fatigue life of the structure. It can be seen that these manufacturing defects occur as a result of both manufacturing assembly and material processing.

**Corrosion** is a source of time-dependent metal damage that requires protection of structure according to FAA regulations (Ref 30). In addition, the FAA has issued an Advisory Circular (AC) on corrosion (Ref 31). This document discusses the types of corrosion, those areas on the aircraft susceptible to corrosion, inspection techniques, the agents which cause corrosion, and methods of corrosion removal and component rework. The AC is not meant to be all-inclusive, but is a useful primer for those interested in corrosion. In the *ASM Handbook* Volume 13, an article "Corrosion in the Aircraft Industry" discusses the many types of corrosion found in aircraft along with many illustrative examples (Ref 32).

In most cases, corrosion itself does not lead to structural failure, but it is the most expensive aspect of maintaining structural integrity. One operator of a fleet of aircraft indicated that 95% of the parts that were removed on his aircraft were removed as a result of corrosion (Ref 25). The damage that is caused to the aircraft can manifest itself as corrosion and paint degradation. Both of these are exacerbated by the presence of salt water, acid rain, and sunshine. As a result, the down time of the aircraft, whether it is kept in a hanger or on the flight line, and its primary geographical location all become important variables in the determination of the inspection intervals and types of inspections that are required.

The effect of corrosion needs to be addressed by denoting the types of corrosion and where they can occur, inspection techniques to find the corrosion in situ, and repair or replacement methods to remove the offending material. Each of these areas is an extensive technical topic, which is beyond the scope of this article. In abbreviated form, corrosion may be broken into two broad categories: enhanced fatigue crack growth due to corrosion and general corrosion. General corrosion includes the degradation of coatings due to atmospheric conditions. Several types of corrosion (Table 1) occur in aircraft, and these different types of corrosion must be defined and located. As an example, Boeing developed a Corrosion Task Force to accumulate and review all corrosion problems existing on their aircraft (Ref 33). Boeing developed a program that identified, to a specific usage baseline, the location, type, and inspection intervals for their aircraft. If a particular aircraft were based in an area that has a more severe environment, these intervals would be decreased. As a result of this task force, Boeing now has corrosion prevention and control programs on their aircraft, and has developed a Corrosion Design Handbook. The feedback between the users of the aircraft and its manufacturers has led to designs which decrease corrosion.

UNIFORM CORROSION

**Environmentally Enhanced Fatigue Crack Growth.** Crack growth analysis is normally performed using material properties obtained in laboratory air. It is well known that the introduction of active environments (sump water, salt water, and fuel) increase crack growth rate (Ref 34, 35, 36, 37). Along with the environment, other important factors include the cyclic frequency and shape. It has been shown that the greater the time the material is exposed to a high stress in an aggressive environment, the greater the crack growth rate (Ref 38, 39). Analysts have developed many techniques to account for the enhanced crack growth rate in hostile environments, but no universal method has yet been determined. Generally, the analyst uses the increased crack growth rate of the particular environment (cyclic, chemical, and temperature), and it has been found that the inspection intervals decrease. However, the alternating stresses that cause the crack to grow occur in flight, where the effect of salt water (a ground environment condition) is absent. Additionally, at high altitudes, the temperatures are decreased thereby slowing the chemical reactions. In wet wings, the effect of the chemical environment is always present, however the temperature decreases as altitude increases. The complexity of accurately determining the advance of the crack is a substantive problem. An approach that is used by the Air Force to aid in solving this problem is through the use of a *Corrosivity Factor* (Ref 40). This method documents the air bases at which the particular aircraft was assigned, and then each base was assigned a particular Corrosivity Factor. This empirical approach allows determination of crack growth rate, and thus inspection intervals as a function of the particular location of the aircraft and its corrosive behavior as a function of that location.

**Improper Maintenance.** The manufacturer of the aircraft system presents many documents with that system as part of its delivery. These include pilots handbooks, structural repair manuals, corrosion manuals, etc. It is imperative that these manuals be adhered to in a rigid fashion. It is easy to devise methods that may be shorter and easier than those discussed in the manual, but the manufacturer selected that particular procedure for sound reasons. It is a danger to deviate from these methods for the deviation itself may place undue stress or cause latent damage to components apart from those being examined. This high stress or latent damage can lead to premature failure of these other components, and that may result in undesirable consequences. Additionally, the personnel performing the particular functions must take special care to ensure that the maintenance action itself does not result in damage to the aircraft. American Airlines Flight 191 crashed in Chicago in May, 1979 as a result of improper maintenance actions (Ref 41).

The previously mentioned crash of a U.S. Air Force T-38 trainer occurred as a result of a router mark on the lower skin of the wing. The mark was quite small, but as the stresses were significant, a crack initiated and grew until failure occurred. The fatigue crack, at failure, was only 0.097 in. deep. A similar mark also caused the crash of an F-5 aircraft. From these examples, it may be seen that extreme care during maintenance and the inspection following maintenance must be addressed to ensure that proper procedures and techniques are rigorously followed.

**Multiple Site Damage.** The effect of fatigue crack growth on the life of aircraft has been much studied in recent years. Since the accident involving Aloha Airlines Flight 243 in April, 1988, the interest regarding multiple site damage has increased significantly (Ref 42). The Air Force, through their specifications, account for multiple site damage by assuming that each fastener has a crack of a particular size, and the most critical location has a crack with a significantly larger size. As the aircraft is utilized, both these types of cracks grow, albeit at different rates. There are methods that are commonly used to retard multiple site damage. These include fastener selection, metal working, and component geometry. Additionally, much analytical and test work has been accomplished to study the effect of many small cracks and their linking together. Methods and procedures that are used are discussed in this section.

The onset of multiple site damage (MSD) especially in fuselage structure in the first row of rivets in joints is a serious concern. It is well known that in a riveted, load carrying structure, the load is transferred from one panel to another through the rivets. If there are a number of rows of these rivets (assuming a lap joint shown in Fig. 5), the highest load is in the first row of rivets, the second highest load in the second row of rivets, etc. The loads in the holes adjacent to these rivets are twofold. One needs to consider both the far field stress (the pressure loads), and the local loading of the rivets on the skin (the bearing load). It is the superposition of these separate loads that must be considered in this type of structure. Much work has been accomplished in determining these loads, and a paper by Swift discusses a solution that is based upon an experimental study (Ref 43).

FIG. 5 LAP SPLICE JOINT

The localized or bearing loads are quite high, but the length over which they are dominant is quite small. However, the initiation of a crack by these loads has much significance. Because a crack may be initiated in a short time period, the crack growth life of the structure must be carefully analyzed. If an existing crack is located on an airframe, or if the user wishes to make a change or addition which necessitates additional cutouts in the fuselage structure, a doubler must be added. The design of the doubler, and the method of attachment of the doubler to the existing structure must be ascertained. Because the loads from the skin are placed into the doubler through the fastener, and Newton's Laws dictate displacement compatibility of the fastener/doubler/skin system, the thickness of the doubler greatly affects the load on the fastener. As the doubler thickness increases, the load induced on the fastener increases, with a resulting decrease in crack initiation time. This decrease in crack initiation time greatly affects the life of the overall structure. Other aspects of the fastener design also play a large role in structural life. This includes fastener spacing and type, and hole preparation.

## Life Extension and Damage Tolerance of Aircraft

Mitchell P. Kaplan and Timothy A. Wolff, Willis & Kaplan, Inc.

---

### Life Extension Techniques

Methods of extending aircraft life are dependent upon a multiplicity of factors. The damage tolerance portion of life extension depends primarily upon three independent variables. These are the material properties, usage history, and the damage intrinsic to the material component itself. Knowledge of these variables and their interaction, if any, allows determination of component life. In other instances, fatigue initiation or crack growth may determine the life of a particular part or component. In these latter instances, knowledge of the geometry and location of the flaw, and the loading and usage of the aircraft become increasingly important. To extend the life of the structure it is necessary to quantify (either deterministically or statistically) the information obtained from field experience on either these or like aircraft, and then have analysis techniques that allow the user to determine inspection procedures and techniques, and their appropriate timing to extend the life of the selected components. In those instances where corrosion and its growth may be the driving factor behind the life of the particular structural member, the determination of component life is much less straightforward. There is no known method for determining either corrosion initiation or propagation times. As a result, periodic inspections to seek out the existence of corrosion is the only viable method. This is accomplished by preventative means. What becomes important is the geographical location of the airport where the aircraft is parked, material selection, surface preparation, surface protection, material removal and cleaning methods. It is these factors that dictate component replacement, and thus may be the relevant factor in aircraft life.

The FAA has issued Advisory Circular 91-56, "Supplemental Inspection Program for Large Transport Category Airplanes," dated May 6, 1981, with its purpose being the issuance of a supplemental inspection document (SID) (Ref 44), and Advisory Circular 91-60, "The Continued Airworthiness of Older Airplanes," dated June 13, 1983 with its purpose to expand the scope of the previous advisory circular to other airplanes (Ref 45). The SID informs the user of the changes required in the maintenance actions as the aircraft accumulates an increasingly larger number of service hours. The inspection program defined by the SID requires the user to continually re-evaluate the inspection procedures and intervals based upon usage, service experience of the particular fleet of aircraft, and advances in technology (analyses, testing, inspection procedures, etc.). The SID emphasized obtaining this information on principal structural elements. The interested reader should examine these documents, and additionally Ref 46 and the article "Damage Tolerance Certification of Commercial Aircraft" in this Volume.

**Corrosion Protection.** The inspection of components to ensure that corrosion has not initiated and grown to a condition where part clean-up or replacement is necessary must be accomplished. But prior to this, it is important to design the

particular components in a fashion that impedes this insidious growth. There are several different approaches to counteract the onset and growth of corrosion. Many of these methods are applicable to only one type of component, but there are methods that lend themselves to several portions of the aircraft. The methods that the manufacturer may use to attain a longer corrosion initiation time can fall into several categories. These include appropriate selection of materials, judicious choices for materials that are used in contact with one another, the design of the metallurgy of the material for the intended loading, and the coating or surface treatment of the material itself.

Aluminum, as an alloy, has been used on aircraft for many years. However, the alloy itself and its heat treatment have changed substantially. Manufacturers have used duralumin (2024) in the 1940s, 7178, 7079, and 7075 in the 1960s. The first two of these alloys, 7178 and 7079, were both of higher strength than the 2000 series alloys, but the stress-corrosion cracking susceptibility was substantially greater. As a result of the increased degradation in active environments, these alloys were no longer used in aircraft design. The alloy 7075 was first used in its high-strength temper, T6. It was found that the alloy in this temper was susceptible to stress-corrosion cracking. Experiments determined that if this alloy was overaged, and used in the T76 or T73 condition, its resistance to stress-corrosion cracking was enhanced. There was, of course, a trade-off. By going to the overaged condition, the strength of the alloy was lessened.

Aluminum alloys were also susceptible to surface corrosion, pitting corrosion, and exfoliation. It was found that by cladding the alloy with pure aluminum, the resistance to these types of corrosion was enhanced. For many aircraft usages, these alloys are now being used in the clad condition. It should be noted that the clad is removed at fastener holes due to the machining process. The fasteners are usually countersunk, and as a result, the clad material is removed in their vicinity. Rivets for aircraft are generally manufactured from 2117 aluminum, therefore, no galvanic reaction occurs at the skin/rivet interface. When steel bolts are used, they are usually cadmium plated to minimize galvanic corrosion. Other surface treatments of aluminum, in addition to priming and painting the surface, include Alodine and anodizing.

Another material commonly used in the manufacture of aircraft is titanium. This alloy is stiffer and stronger than aluminum, yet not as dense as steel. Its corrosion resistance is quite good, although it is susceptible to chloride. As a result, both sea water and methyl chloride can cause corrosion in titanium.

The remaining metal that is used widely on aircraft is steel. As low-alloy steels are commonly used on aircraft, the effect of corrosion must be continually addressed. A primary location of steel is in the landing gear. In this usage, steel is the preferred material because of its high strength and stiffness. To minimize the amount of material used, the selected alloy is generally used in its high-strength condition. As the strength levels are increased, the material becomes chemically more active. For this reason, many of the steel alloys (4340, 4140, 300M, etc.) are coated or plated, usually with cadmium, to prevent exposure with the atmosphere.

**Mechanical Techniques of Controlling Multiple Site Damage.** A typical lap splice joint, shown in Fig. 5, can attach a stringer to the outer skin of the aircraft, and have a crack arrest strip integral to the design. Since these rivets are highly loaded due to both pressurization and fuselage bending loads, and additionally having superimposed localized bearing loads, small cracks can initiate and propagate. And, as the Aloha accident has shown, a sudden failure in a panel can cause several additional panels to fail almost instantly. The MSD is the existence and linking of these small cracks into a large panel crack that can lead to catastrophic consequences.

The design of the doubler helps determine both the stress concentration at the doubler/skin interface, and the inspectability of the structure itself. These two considerations are both important in evaluating MSD. The location of the skin/stringer or the skin/longeron interface attachment has a known load. The known load at the first rivet away from the attachment is substantially similar, but the thickness at that location is substantially smaller. The smaller cross sectional thickness results in higher stresses. Because the length over which the stress increase occurs is limited, a stress concentration results. To avoid these stress concentrations, designs that alleviate the stress increase may be considered. These designs may include a tapered skin, a tapered doubler, or the tying in of the first rivet at different rows. To aid in inspecting the structure, the designer may include a doubler designed with tabs that allow inspection of the skin material in a straightforward manner. Figure 6 illustrates these designs.

FIG. 6 DOUBLER DESIGNS THAT REDUCE FIRST FASTENER LOAD

The bearing stress on a rivet is dependent upon its pitch (the distance between adjacent rivets). For an aircraft skin that is 0.040 in. thick and subject to a stress of 15 ksi, the shear flow would be 600 lb/in. For a basic five row doubler joint (0.040 in. skin and 0.050 in. doubler) with a rivet spacing of 1.00 in. and a rivet diameter of 0.125 in., a displacement compatibility analysis would indicate a maximum shear load of 176 lb/rivet on the outer row of rivets. The bearing stress from these rivets would be 35 ksi. As the allowable bearing stress (for yielding conditions) on 2024-T3 alloy is 88 ksi, these stresses are acceptable. If the rivet spacing were increased to 2 in. (50 mm), then the bearing stress on the same rivets would become 55 ksi (380 MPa). Even though the static margin is high, the change in stress due to the fastener spacing is significant.

Another important factor in improving component life is hole preparation. If a hole is drilled through the skin and doubler, the resulting stress concentration factor is three. However, if the hole is cold worked by expanding the material through the use of a mandrel and split sleeve, then a residual compressive stress is placed into the material. This residual compressive stress greatly reduces the effect of the bearing stress at the edge of the hole, and crack initiation time is greatly lengthened (Ref 47). Furthermore, small cracks or discontinuities near the edge of the hole are closed, and component life is greatly enhanced.

A second method which can be used to improve component behavior through hole preparation and component attachment is fastener selection. There are several types of fasteners that are used to attach structural members (rivets, bolts, hi-loks), while hi-tigue fasteners actually deform the material adjacent to the hole and impart a residual compressive stress. The effect of the residual compressive stress is to reduce the localized stress in the vicinity of the hole thus improving component life.

**Inspection.** The inspection programs for each particular aircraft are described in its SID. The rationale for these inspections, on the many PSEs, may include both a deterministic and a stochastic approach. As the aircraft ages, the number of inspection locations based upon initial flaw assumptions using EIFSD usually grows. As a result, the aging of the aircraft causes an increase in the inspection time. The determination of when and where to inspect becomes increasingly complicated. Using a lead-the-fleet aircraft, or a full scale test article gives good indication of the growing flaw population. The continuous analysis of the data from the lead the fleet aircraft, and all other aircraft inspected can be used to tune the inspection intervals. A goal of this iterative testing and analysis procedure is to determine the economic life of the aircraft itself. It is at this juncture that the aircraft is retired, because further usage can no longer be economically justified.

The documentation that is necessary to accomplish this complex undertaking is lengthy. At McDonnell Douglas, as stated in Ref 46, three volumes of information are prepared. These are:

- VOLUME I, GENERAL INFORMATION, PSE DESCRIPTION, INSPECTION REQUIREMENTS
- VOLUME II, INSPECTION METHODS
- VOLUME III, INSPECTION PLANNING AND STATUS REPORT

McDonnell Douglas plans to annually update and republish Volume III by a computer program specifically written for this purpose (Ref 46). It will contain information on fleet status, PSE population, projected supplemental inspection start dates and intervals for each PSE, inspection planning data, and a record of past inspection, according to Ref 46.

**Inspection Procedures for Corrosion.** Inspection procedures used on aircraft cover the gamut of inspection methods used in other industries. They include visual, radiography, ultrasonic, acoustic emission, eddy current, magnetic particle, and dye penetrant (Ref 48). The type of inspection procedure is dependent upon the location of the component tested, its material, and the type of corrosion. In many instances, it is necessary to gain access to the area of interest.

The preparation of a Corrosion Prevention and Control Plan, as described above, is paramount. The user must know where to inspect, how to inspect, and how often to inspect. These inspection documents are normally quite detailed. A typical mechanism is the definition and use of PSE's. These are structural components that can be grouped together in terms of corrosion susceptibility or inspectability. For each PSE, and that may consist of many components, the user is informed of all aspects of corrosion susceptibility and inspection procedures. This plan generally will call out many other specifications (ASTM, SAE, and Military) which discuss particular methods and procedures of accomplishing the necessary inspection. In many instances, it is necessary to remove plating or painting, and after the inspection to repaint or replat the affected areas.

**Repair Limits for Corrosion Damaged Structure.** The user of the aircraft receives from the manufacturer details on maintainability or repair of the aircraft. The user is given information on methods of first identifying, and secondly removing the corrosion from the aircraft. In some instances, e.g., pitting corrosion, the removal method may be as straightforward as sanding or by using chemicals to remove the offending material. If one gets to a more severe corrosion such as exfoliation, the removal of segments of material must be accomplished. If the removal of the material is within the prescribed limits of the manufacturer, the manufacturer's repair manual is sufficient. However, if the repair falls outside of the limits set by the manufacturer, approval to exceed these limits must be obtained from the FAA.

Additionally, corrosion is generally insidious. The user does not know of the existence of corrosion until it is seen, and then the type and destruction it causes cannot be deterministically evaluated. The repair of corrosion is generally an iterative process of clean-up and evaluation. Again, depending upon the type of corrosion, the amount required to clean-up cannot be determined, and portions of the structure must be removed. Stress-corrosion cracking follows grain boundaries in aluminum alloys, and its depth and severity cannot be accurately determined in a nondestructive fashion.

After the corroded area has been identified and the corrosion product removed, the repaired area should have the same surface treatment as the unaffected area adjacent to it. This may necessitate painting, plating, or using some other surface treatment on the material. As stated above, the manufacturer's repair manual usually discusses these requirements in detail.

## Ongoing Programs

A document entitled "A Review of Research in Aeronautical Fatigue in the United States, 1993-1995" was presented at the ICAF meeting in May, 1995 (Ref 49). A summary of the programs that investigated corrosion and multiple site damage is given below.

**Analytical and Test Studies on Corrosion.** There were ten programs discussed that were in the area of corrosion and corrosion fatigue, and thirteen papers were referenced. The studies consisted of examining the formation of fatigue cracks in 2024 and 7075 aluminum. Initiating mechanisms included pits that were formed as a result of pitting corrosion, wear that may cause fretting, especially in joints and around rivets, and areas that had experienced prior corrosion such as exfoliation and crevice corrosion. Additional studies determined novel means (shot peening) to determine the extent of exfoliation corrosion. Finally, there were a number of studies that examined the crack growth behavior of aluminum alloys exposed to hostile chemical environments.

**Analytical and Test Studies of Multiple Site Damage.** The document listed nine research programs that were conducted in the U.S. in this time period on MSD, and they reference fourteen papers. The research consisted of analytical studies encompassing the loss of residual strength as a result of MSD, the study of crack opening displacement (COD) and the critical crack tip opening angle (CTOA) to determine the onset of MSD. Another study was centered upon the development of a finite element program that contained techniques that allow the investigator to quickly and easily conduct analysis at the crack tip with many different structural geometries which included stringers, lap joints, tear straps, frames, etc. Additions to this program include the use of elastic-plastic FEA to better define the effect of growing cracks on residual strength.

Experimental studies that were accomplished included the teardown inspection of fuselage structure that has experienced 60,000 pressurization cycles. The locations and the size of the cracks, and whether they could be identified using nondestructive techniques are goals of the study. Other studies included the effect of crack arrest straps in fuselage structure, and large scale testing of actual fuselage structure. Finally, a study on multiple site damage in fuselage lap splices was conducted.

The conclusions from many of these efforts could be formulated on a statistical basis, i.e., a risk analysis. The results of the risk analysis would give the user information regarding the ultimate safety of the aging aircraft fleet. It may be seen that the study of MSD is a fertile area, and that Aloha Flight 243 initiated several well-needed studies.

### Damage Tolerance Certification of Commercial Aircraft

T. Swift, Federal Aviation Administration

---

### Introduction

DAMAGE TOLERANCE is the current philosophy used for maintaining the structural safety of commercial transport aircraft. The requirements for damage tolerance certification of these structures are contained in the Federal Airworthiness Requirements (FAR) 25.571 (Ref 1). Guidance for complying with FAR 25.571 is given in Advisory Circular 25.571-1A from the Federal Aviation Administration (FAA) (Ref 2). This article describes the structural evaluations necessary to comply with the regulation.

For a complete explanation of damage tolerance certification of commercial transport aircraft, it is appropriate to review the historical evolution of the damage tolerance philosophy. This is followed by discussion of design philosophies and a summary of evaluation tasks for damage tolerance certification.

## Damage Tolerance Certification of Commercial Aircraft

T. Swift, Federal Aviation Administration

---

## Historical Background

After many major fatigue failures in the 1950s on both military and commercial aircraft, the most notable of which were the DeHavilland Comet failures in early 1954, the U.S. Air Force (USAF) initiated the Aircraft Structural Integrity Program (ASIP) in 1958. The fatigue methodology adopted in the ASIP was the reliability approach, which became known as the "Safe-Life" method. (See the section "Structural Design Philosophies" in this article.) This approach, used in the development of USAF aircraft in the 1960s, involved analysis and testing to four times the anticipated service life. On the commercial scene, another philosophy, "Fail Safety," was introduced in the early 1960s, and a choice between Safe-Life and Fail-Safe methods was allowed by commercial airworthiness requirements. However, it was found that the Safe-Life method did not prevent fatigue cracking within the service life, even though the aircraft were tested to four lifetimes to support one service life (i.e., scatter factor of 4). Some notable examples were:

- *KC-135 SAFE-LIFE 13,000 H: 14 CASES OF UNSTABLE CRACKING IN LOWER WING SKINS BETWEEN 1800 AND 5000 H. LOWER WING SURFACES WERE RE-SKINNED AT 8500 H.*
- *F5 SAFE-LIFE 4000 H: FATIGUE FAILURE OF THE LOWER WING SKIN ROOT REGION AT 1900 H CAUSED LOSS OF AIRCRAFT.*
- *F-111 SAFE-LIFE 4000 H: FATIGUE FAILURE OF THE CENTER WING BOX AT 105 H CAUSED LOSS OF AIRCRAFT.*

Almost without exception, initial manufacturing or in-service accidental damage is the cause of fatigue cracking that occurs within one service lifetime on aircraft that has been substantiated both analytically and by test to four lifetimes. In fact, studies performed by the Air Force Flight Dynamics Laboratory in the late 1960s (reported in AFFDL TR-70-149) indicated that more than 56% of all in-service fatigue problems were caused by pre-existing material and fabrication quality deficiencies (i.e., initial manufacturing damage not simulated in the fatigue test or accounted for analytically).

The fatigue failure of the F-111 aircraft cited above was caused by a defect in the D6AC steel center wing box fitting, which propagated over 105 h of service to a critical size at tension stresses induced by a 4.0 g maneuver. The aircraft was designed for a load factor of 11.0 g. Of course the fatigue test was free of this defect. The failure resulted in the largest single investigation of a structural alloy ever undertaken and precipitated investigations into the history of USAF accidents related to fatigue. These investigations culminated in a complete change in design criteria for USAF aircraft. Many of the design specifications were changed and others were introduced. The most important document to come out of the investigations was MIL-A-83444, "Airplane Damage Tolerance Requirements," issued in July 1974. This document specified the fracture mechanics principles to be used in the design of all future military aircraft. Since the release of MIL-A-83444, all USAF aircraft previously designed to the Safe-Life philosophy have been assessed using damage tolerance principles.

While the USAF was developing its change in design philosophy, the commercial large transport industry was also considering changes in design philosophy. After the first generation of fail-safe aircraft had been in service for some time, the Civil Aviation Authority (CAA) in the United Kingdom became concerned about the loss of fail safety with time due to widespread fatigue damage. The CAA considered it risky that on U.S. designs, the fatigue testing of large components

and full-scale structures was not continued for as long as on equivalent structures in Europe. Most of the full-scale testing was done to two lifetimes or less, compared to five lifetimes in Europe. In addition, the CAA believed that U.S. inspection programs were not based on a sound engineering evaluation. In the early 1970s, with these concerns in mind, the CAA limited the service life of the Boeing 707 aircraft on their registry to 60,000 h.

At about the same time, the FAA became concerned about the fact that old first-generation fail-safe aircraft were being sold to new operators. It believed that new operators of old aircraft might not be familiar with the scope of required maintenance and the means that had been used to keep the aircraft in a safe and airworthy condition. The FAA held a series of meetings with the industry about aging aircraft issues, and as a result it issued a number of Advisory Circulars containing Maintenance Inspection Notes for several of these aircraft.

In late 1976, as the life limit of 60,000 h approached, U.K. operators of Boeing 707 aircraft became concerned about the economic impact of their aircraft's being grounded. However, the CAA was convinced that its policy was well founded, and it decided to seek confirmation of its policy from the Airworthiness Requirements Board (ARB). The ARB asked its technical committee to consider the matter, and a number of meetings took place starting in March 1977. These meetings included manufacturers from the United States and the United Kingdom as well as representatives from the FAA.

The life-limiting policy of the CAA had been substantiated by the loss of a Hawker Siddeley 748 in Argentina, one of the first aircraft designed by Hawker Siddeley Manchester Division on fail-safe principles. Wing bending material, instead of being concentrated in front and rear spar caps (as had been the case with the Manchester and Lancaster bombers, Shackletons, Tudors, and the Argosy), was distributed to form a multiplicity of stiffening elements on a multiple-load-path fail-safe principle. Even so, on 14 April 1976, separation of the right wing occurred due to undetected fatigue. The crack had originated at rivet holes of a reinforcing plate near the external rib of an engine, and it had propagated undetected because of the lack of adequate inspections based on engineering evaluation (i.e., damage tolerance). The aircraft had accumulated 25,760 h.

Another important incident that took place during the discussion period about aging aircraft was the loss of a Boeing 707 at Lusaka, Zambia in May 1977. This aircraft suffered the loss of pitch control following the in-flight separation of the right-hand horizontal stabilizer and elevator, which resulted from fatigue failure of the rear spar upper cap. This incident was important because the structure had been designed on fail-safe multiple-load-path principles similar to those used for the 748. The spar had an upper and lower cap plus a fail-safe center member. These members extended to three sets of lugs for fail safety. The propagation life of the upper cap from initiation to failure was approximately 7,200 flights. A further 100 flights took place with the upper spar cap failed, but the failure was undetected prior to separation of the stabilizer. The fail-safe multiple-load-path philosophy did not prevent catastrophic failure, again because of the lack of proper inspections based on engineering evaluation. At the time of failure the aircraft had accumulated 47,621 h and 16,723 flights. This accident reinforced the CAA position, and it was probably the most important incident during the discussions because it happened only two months after the start of the meetings.

After considerable discussion among authorities and manufacturers, a policy was adopted in January 1978. This policy is set out in CAA Airworthiness Notice 89, issued on 23 August 1978 with Information Leaflet AD/IL/0067/I-5. As an alternative to "life-ing" the aircraft, these documents require a structural review that results in a supplemental inspection program. As an example, the 707 limits enforced by the CAA could be eliminated pending the completion of a structural audit (damage tolerance assessment) that resulted in inspections in addition to the existing inspection program. Such supplemental inspections were made mandatory by the CAA.

The activity in Europe in the late 1970s was paralleled in the United States. In November 1976, the FAA gave notice of a Fatigue Regulatory Review Program for commercial transport aircraft and invited interested persons to submit proposals to amend the requirements of FAR 25.571 and 25.573. These proposed amendments were precipitated by significant developments in the state of the art and in industry practice regarding fatigue and damage tolerance evaluation of commercial transport aircraft. The FAA subsequently held a Fatigue Regulatory Review Conference in March 1977 to obtain the views of all concerned. (Approximately 13 meetings had been held with industry and other organizations prior to this time.) This joint effort by industry and government led to the deletion of FAR 25.573 and a revision and expansion of FAR 25.571. Amendment 45 was issued in December 1978, slightly preceded by FAA Advisory Circular 25.571-1A, which outlines an acceptable means of compliance. Thus, all commercial transport aircraft designed after December 1978 are required to meet the damage tolerance requirements of FAR 25.571.

The issue of Airworthiness Notice 89 for the aging commercial fleet in Europe was equaled in the United States. A number of meetings with the Aircraft Industries Association had taken place by the late 1970s, and a rough draft Advisory Circular was formulated as a result of committee action. Eventually, in May 1981, FAA Advisory Circular 91-56 was

released. It contains advisory material related to the aging aircraft problem, and it requires evaluation of the structure using modern fracture technology and a Supplemental Inspection Document. The philosophy incorporated into the Advisory Circular is identical to that of Airworthiness Notice 89: continued safe operation of aircraft beyond the intended life can be ensured by a continuing inspection program that is supplemental to the basic maintenance program.

### Structural Design Philosophies

#### Definitions

**Damage tolerance** is the attribute of the structure that permits it to retain its required residual strength for a period of use after the structure has sustained specific levels of fatigue, corrosion, or accidental or discrete source damage. The term "specific levels of damage" refers to damage between the levels of in-service detectability and critical at-limit load. This damage will vary, depending on the inspection method and the limit load capability for each principal structural element (PSE). A PSE is an element that contributes significantly to carrying flight, ground, and pressurization loads and whose failure, if remained undetected, could eventually lead to loss of the aircraft. FAA Advisory Circular 25.571-1A lists examples of PSEs.

**Fail-safe** is the attribute of the structure that permits it to retain its required residual strength for a period of use after the failure or partial failure of a PSE, prior to repair.

**The safe life** of a structure is the number of events (e.g., flights, landings, or flight hours) during which there is a low probability that the strength will degrade below its designed ultimate value due to fatigue cracking.

#### General Requirements

In general, an evaluation of the structure under typical load and environmental spectra must show that catastrophic failure due to fatigue, corrosion, or accidental damage will be avoided throughout the operational life of the aircraft. This can be ensured only with an adequate inspection program, and therefore the evaluation must result in inspection and maintenance procedures for each PSE. The evaluation must show that the structure is damage tolerant for fatigue, corrosion, or accidental or discrete source damage unless the manufacturer can show, to the satisfaction of the FAA, that damage tolerance is impractical. In the latter case a safe-life evaluation must be made using appropriate scatter factors. Impracticality should be related to geometrical constraints such as in-service non-inspectability rather than to manufacturing cost differences between safe-life and damage-tolerant elements.

**Philosophy of the Damage Tolerance Evaluation.** Because of the large number of areas to be considered in the damage tolerance evaluation, a high degree of reliance must be placed on analysis. It is recognized that to test every PSE for damage tolerance characteristics would generally be economically unfeasible. Thus, the evaluation is considered to be an analytical evaluation. However, sufficient testing must be performed to ensure that analysis methods are not unconservative. This is particularly true in the field of fracture mechanics, the primary tool used in damage tolerance evaluation. Each manufacturer must provide a separate report describing the analytical methodology used in the evaluation. The report must contain sufficient analysis/test correlation to assure the FAA, with a high degree of confidence, that methods are not unconservative.

The FAA does not dictate how many locations should be evaluated. A plan is normally submitted to the FAA Certification Office for approval. Some manufacturers have evaluated as many as 500 elements, while others have considered less than 100. This variability is primarily due to differences in how each manufacturer interprets the extent of each PSE.

**Flyable Crack Philosophy.** Damage tolerance evaluation has been interpreted in the past as a means to allow continued safe operation in the presence of known cracking. This interpretation is incorrect. No regulations allow the strength of the structure to be *knowingly* degraded below ultimate strength (1.5 times limit). The damage tolerance evaluation is merely a means of providing an inspection program for an aircraft that is not expected to crack under normal circumstances but

may crack in service due to inadvertent circumstances. If cracks are found in primary structure, they must be repaired before further flight. The only allowable exception is through an engineering evaluation, which must show that the strength of the structure will never be degraded below ultimate strength during flight with known cracking. This evaluation must take into account slow, stable tearing during an ultimate load application.

### Damage Tolerance Evaluation Tasks

The objective of damage tolerance evaluation is to provide a crack growth and residual strength analysis, based on the expected use of the aircraft, so that an inspection program can be developed to maintain safety during service. The primary tasks to be accomplished by the damage tolerance evaluation are:

- DEFINE AIRCRAFT UTILIZATION
- DEVELOP LOAD FACTOR SPECTRA AT THE AIRCRAFT CENTER OF GRAVITY
- SELECT CRITICAL LOCATIONS FOR EVALUATION
- DEVELOP STRESS SPECTRA FOR EACH LOCATION
- ESTABLISH THE ENVIRONMENT FOR EACH LOCATION
- DEVELOP CRACK GROWTH RATE ( $DA/DN$ ) DATA FOR EACH LOCATION
- VALIDATE BASIC CRACK GROWTH ANALYSIS METHODS
- OBTAIN FRACTURE TOUGHNESS DATA FOR EACH MATERIAL AND GEOMETRY
- DETERMINE THE EXTENT OF DAMAGE FOR EACH LOCATION AT LIMIT LOAD
- VALIDATE RESIDUAL STRENGTH ANALYSIS METHODS
- DETERMINE THE STRUCTURAL CATEGORY FOR EACH LOCATION
- PRODUCE A CRACK GROWTH CURVE FOR EACH LOCATION
- CONVENE MEETINGS BETWEEN AIRLINE OPERATORS, MANUFACTURERS, AND AUTHORITIES
- COLLECTIVELY DECIDE ON INSPECTION METHODS, THRESHOLDS, AND FREQUENCIES CONSISTENT WITH OPERATIONAL ECONOMICS

A flowchart of the first 12 tasks, which involve an engineering evaluation, appears in Fig. 1. Details about the tasks are provided below.

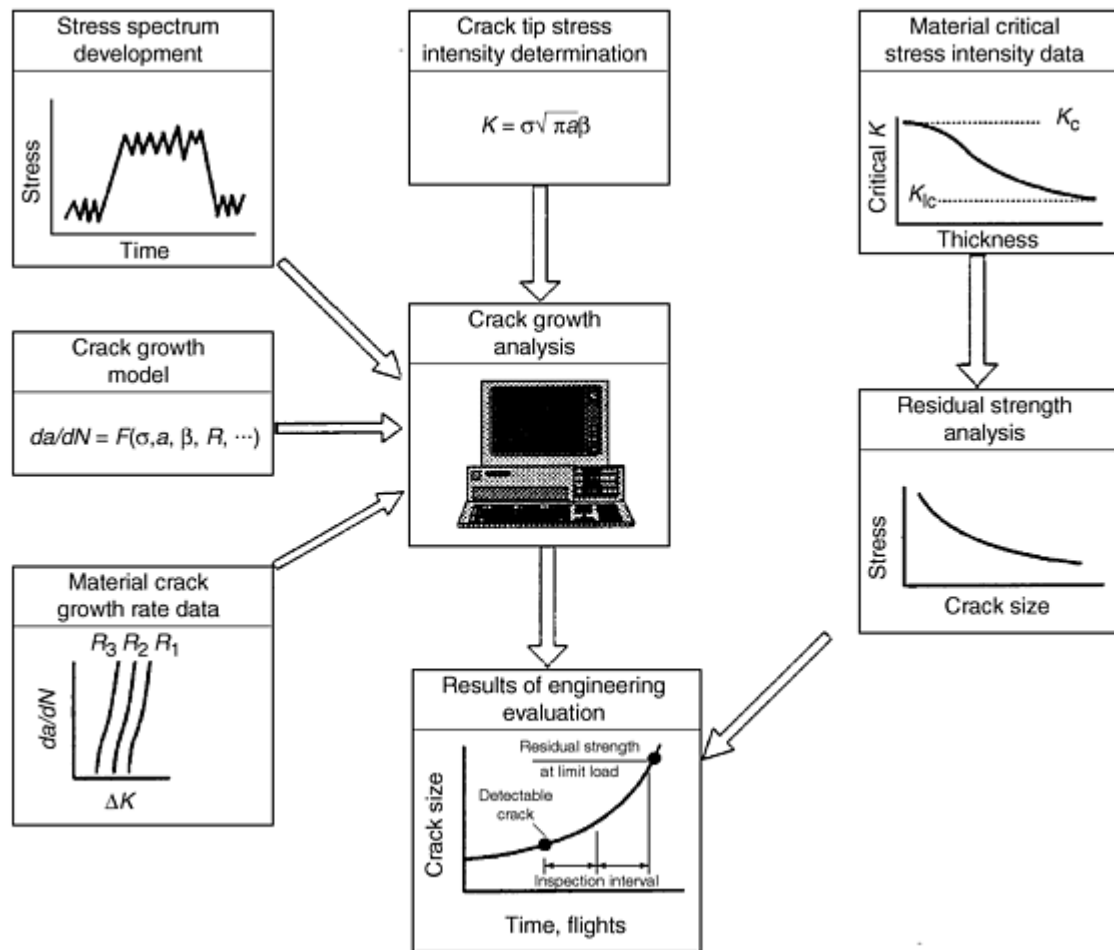

FIG. 1 CRACK GROWTH AND RESIDUAL STRENGTH EVALUATION FOR EACH PRINCIPAL STRUCTURAL ELEMENT

**Aircraft utilization** specifications should account for the different flight types expected in service, the flight lengths in terms of hours, and the percentage of time spent flying each flight type. Flight types may include long versus short flights, cargo versus passenger flights, low-altitude versus high-altitude flights, and the percentage of time spent in training. For each flight type it is important to consider the distribution of time spent at each gross weight, speed, and altitude.

Consideration also needs to be given to the structural elements involved in the damage tolerance evaluation. For example, low-level flying is extremely severe on lower wing surface crack growth life. However, for the majority, but not all, of fuselage critical elements, this effect may be secondary to the cabin pressure. In the case of longitudinal cracking in the fuselage, the internal cabin pressure is the most important loading condition. For circumferential cracking on the crown of the fuselage skin, the primary loading would most likely be fuselage downbending due to inertial loads.

Flight profiles for each flight type should be compiled that reflect each segment of the flight, such as taxi, climb, cruise, descent, landing impact, and landing roll. The number of different flight types considered may vary from about 25 for a complex military aircraft to as low as five or six for a commercial transport aircraft.

**Load factor spectra at the aircraft center of gravity** are usually developed in the form of data about cumulative frequency of occurrence of incremental load factor. These data, obtained from recorded flight histories for similar aircraft, are developed for taxi, maneuver, gust, and landing impact. All loads in the spectra must be initially considered. The spectra may be simplified in some cases by eliminating loads that are not damaging. This must be done with extreme care when considering crack growth. In the past, nondamaging loads have been eliminated by ensuring that they produce stresses below the endurance limit for crack initiation. For spectra to be used in crack growth analysis and testing, considerable care must be exercised when eliminating cycles; otherwise, the crack growth life will be unconservatively affected.

The load exceedance data referred to above is available from various sources, such as Engineering Sciences Data Unit Ltd. (ESDU) (Ref 3). Both gust and maneuver exceedances are included in ESDU data sheets. Manufacturers obtain in-flight recorded history from many other references, such as Ref 4, 5, and 6. One of the more recent programs to obtain in-flight data was the Digital VGH Program of the National Aeronautics and Space Administration (NASA), which used data from existing flight data recorders on L-1011, B-727, B-747, and DC-10 aircraft. This program, originally terminated by NASA before completion, was later completed under a NASA-FAA interagency agreement. This work is summarized in Ref 7.

**Critical Locations for Evaluation.** Following are some considerations for choosing the location where damage is to be simulated in the PSE.

**The static stress analysis** should be reviewed to determine areas where static margins are at a minimum (primarily areas subjected to tension and shear loading).

**Locations of high stress concentration** should be reviewed, particularly those at which a number of surfaces intersect each other, creating a feather edge that is prone to accidental damage. These areas usually occur in forgings and are often not easy to detect on drawings.

**Locations of high spectrum severity** should be reviewed not only for areas of high stress (1 g), but also for areas where a large number of cycles may occur during every flight. One such area, not usually given enough attention, is flap support structure. On most aircraft this structure is subjected to aerodynamic buffeting loads that may occur thousands of times per flight. The stresses induced by these loads, although often low in range, are usually at high stress ratios and can contribute significantly to crack growth damage.

**Locations where stresses would be high in secondary members after failure of a primary member** should be carefully reviewed. This is particularly necessary for each area that is not inspectable for less than primary member failure. In such a case the inspection interval will depend on the life of the secondary member under redistributed loads after primary member failure.

**Locations where crack propagation rates are high and fracture toughness values are low** should be reviewed.

**The results of full-scale fatigue testing** can be valuable for locating critical fatigue areas of the structure. This testing is normally conducted too late in the design development of the aircraft structure to be useful in the initial selection of critical locations. However, maintenance programs can easily be modified to include these areas. In fact, it is expected that the results of the damage tolerance evaluation submitted prior to certification will be updated as service and full-scale test experience is gathered.

**Locations of likely fatigue damage and crack propagation paths**, particularly when the crack path might be affected by multiple-site damage, may be most accurately determined by component fatigue testing to complete failure.

The number of areas considered should ensure that adequate coverage exists to maintain safety. This is a general statement, of course, that means little when a manufacturer is trying to judge the scope of the damage tolerance evaluation task. Generally speaking, the initial number of areas considered is approximately 150 for the complete airframe. During the course of the evaluation, this may be reduced to about 90 PSEs for which crack growth and residual strength results are documented. The number varies with aircraft type, of course, but is not necessarily a function of aircraft size because all aircraft have the same major features.

**PSE Stress Spectra Development.** Stress spectra must be developed for each PSE. This is done by converting the load factor spectra at the aircraft center of gravity (discussed above) using stress transfer functions. These transfer functions are required for each segment of the flight profile. In certain parts of the structure, such as the outer wing, dynamic magnification factors are often necessary. Load factor exceedance data are converted to stress exceedance data for each PSE, then into flight-by-flight stress spectra for use in a crack growth computer program. Most of the major manufacturers use proprietary computer programs to perform this conversion, but one commercially available program is LICAFF (Ref 8).

Because the damage tolerance evaluation of the structure is essentially analytical, it is important to develop spectra that minimize crack growth life consistent with aircraft use. From an economic standpoint, not all cycles that may be applied

to a structure in service need to be considered, but all cycles that contribute to crack propagation damage must be considered.

In the past, stress spectra were developed in the form of blocks of cycles at various stress levels, to be used in either crack initiation analysis or testing. The analysis was based on linear cumulative damage laws. The spectra were simplified by eliminating nondamaging cycles with stresses below the endurance limit. This was possible because crack initiation damage is not as sensitive to low-level cycles as crack propagation damage. However, for crack propagation analysis that satisfies the requirements of FAR 25.571, it is better to arrange the spectra in flight-by-flight order. Spectrum simplification by elimination of cycles should be performed with extreme caution, because low-level cycles that may be nondamaging during the crack initiation phase may be quite damaging during the crack propagation phase. In order to ensure inclusion of all cycles that contribute to crack growth damage, a stress range truncation study must be performed for each aircraft type. An element most sensitive to the gust environment, such as the lower wing surface, is normally chosen. The results of such studies have been quite unexpected to some manufacturers.

Figure 2 shows minimum stress range truncation data for damage tolerance evaluation of the Dash 8 aircraft. The data presented are for 2024-T3 (lower wing surface skin material) and 7050-T73651 (lower wing surface stiffener material). Stress spectra were generated at four stress range truncation levels for the 2024-T3 material: 3.56, 5.18, 6.4, and 7.66 ksi (24.5, 35.7, 44.1, and 52.8 MPa). For the 7050-T73651 material, an additional stress range of 2.35 ksi (16.2 MPa) was considered. Figure 2 also defines the stress range truncation level. Taking the first stress range of 3.56 ksi (24.5 MPa) as an example, all cycles with a stress range less than 3.56 ksi were eliminated from the spectrum. In the second case, all cycles with a stress range less than 5.18 ksi (35.7 MPa) were eliminated, and so on. Each data point in Fig. 2 is an average of three specimen tests.

**FIG. 2 EFFECT OF STRESS RANGE TRUNCATION ON CRACK GROWTH LIFE. SOURCE: REF 9. THESE DATA WERE INCLUDED IN REF 9 BY PERMISSION OF THE DEHAVILLAND AIRCRAFT CO. OF CANADA.**

In the case of the 2024-T3 material, the initial crack length ( $a_0$ ), an average of two through cracks at a fastener hole, was 6 mm (0.24 in.). Three final crack lengths were chosen: 14, 22, and 30 mm (0.55, 0.87, and 1.18 in.). For the 7050-T73651 material, the average  $a_0$  was 2 mm (0.08 in.), and the three final crack lengths considered were 10, 20, and 30 mm (0.4, 0.8, and 1.2 in.). Figure 2 represents the life to grow the cracks from initial to final size, but it is plotted against a life ratio equal to the life at the particular stress range truncation level divided by the life at a stress range truncation level of 3.56 ksi (24.5 MPa). The objective is to fix the stress range truncation level that results in the lowest crack growth life. For the Dash 8 wing spectra, this value was 5.18 ksi (35.7 MPa) for the 2024-T3 skin material and 2.35 ksi (16.2 MPa) for the 7050-T73651 stiffener material. A weighted mean stress range truncation level of 3.56 ksi (24.5 MPa) was chosen for the Dash 8 spectrum.

It can be seen that there is considerable variation in crack growth life, depending on the lower stress range truncation level used. The question of which level to use is often difficult, because one needs to balance safety with economics. Figure 2 illustrates the importance of this decision from a safety standpoint. The case for economics is illustrated by Fig. 5 of Ref 9 (which is identical to Fig. 5-4 of Ref 10), which shows that for a short-takeoff-and-landing transport aircraft spectrum, there are six times more cycles in a spectrum at a stress range truncation level of 2.0 ksi (14 MPa) than at 4.0 ksi (28 MPa). The economic issue is most important when developing spectra to be used for full-scale fatigue testing.

The highest loads in the spectrum should be those that occur once in one-tenth the projected life of the aircraft. Including higher loads can increase the projected life due to retardation effects, which may not be realistic for all aircraft in a fleet. Reference 10 provides details of the effect of including high loads that occur less frequently than once in one-tenth the projected life of the aircraft.

**PSE Environment.** FAR 25.571(a)(1)(i) states that "The typical loading spectra, temperatures, and humidities expected in service" apply. This should be interpreted to mean that any environment that can affect the crack growth life or residual strength should be accounted for.

**Low temperatures** can considerably reduce the residual strength of cracked structures. This is true particularly for 7000-series aluminum alloys and some 2000-series alloys. Crack growth life for these alloys generally improves with decreasing temperature, but care should be exercised in taking full advantage of this, because the majority of crack growth damage for some elements is experienced at low altitudes and during landing and takeoff.

**Increased humidity and moisture** usually increase crack growth. Salt content in the atmosphere can also increase crack growth rates, particularly for aircraft taking off and landing over the ocean through mist or fog.

**Sump tank water containing chlorides** can subject lower wing surface elements to increased crack growth rates.

**Increased temperatures:** Components subjected to increased temperatures, such as those surrounding engine installations, should receive careful attention. Crack growth rates are usually much higher in materials subjected to temperatures higher than room temperature.

**Corrosive environments:** Care should be exercised when developing crack growth rate data in a corrosive environment. This is true particularly in the very low  $\Delta K$  region at low stress ratios such as zero. Crack tip blunting due to corrosion can reduce crack growth rates and create misleading results. The effect of a corrosive atmosphere is more pronounced at high stress ratios, and care should be taken to account for this effect.

Every effort should be made to specify the environment that each PSE will be subjected to in service, so that the crack growth and residual strength data will not be unconservative.

**Crack Growth Rate Data.** The primary material property required for crack growth analysis is the crack growth rate ( $da/dN$ ) versus the crack-tip stress-intensity factor range ( $\Delta K$ ). Paris et al. (Ref 11) were the first to observe that  $da/dN$  plotted against  $\Delta K$  is a straight line on log-log paper. The stress-intensity factor range on a cycle is defined as  $\Delta K = K_{\max} - K_{\min}$ , where  $K_{\max}$  and  $K_{\min}$  are the maximum and minimum applied stress-intensity factors, respectively. Crack-tip stress intensity is defined as:

$$K = \sigma ( A )^{\frac{1}{2}} \beta \quad \text{(EQ 1)}$$

where  $\sigma$ ,  $a$ , and  $\beta$  are the applied gross stress, crack size, and effect of geometry, respectively.

It is essential to develop data for  $da/dN$  versus  $\Delta K$  by testing for each material, product form, and heat treatment considered in the damage tolerance evaluation. This data should be generated for the specific environment that the PSE will be subjected to in service. The loading direction and crack orientation, relative to the material grain direction, should also be considered.

Developing  $da/dN$  data is probably the most important task in the damage tolerance evaluation. The data collected in the past have produced a wide variety of results, largely because there has been no standard procedures for collecting and reporting them. The American Society for Testing and Materials (ASTM) has developed a standard test method (Ref 12) that may reduce some of the scatter that apparently exists in the literature. It is still acceptable to use data from the

literature, provided that the origin of the data and the means of collection are known, and provided that assurance can be given that the data are reliable and applicable to the element in question. The data generation standards should be compared to current standards to ensure reliability. Reference 12 contains code for a FORTRAN computer program that generates a polynomial fit to the crack growth data. The polynomial is mathematically differentiated to provide  $da/dN$  data. Use of this program will also help reduce apparent scatter in the data.

There are a number of ways to represent  $da/dN$  versus  $\Delta K$ , and each manufacturer has its own method. The simplest form is through the Paris equation (Ref 11):

$$DA/DN = C(\Delta K)^N \quad (\text{EQ 2})$$

where  $C$  is the intercept of the vertical axis at  $\Delta K = 1.0$  and  $n$  is the slope of the line. This equation gives a constant slope on log-log paper, as shown in Fig. 3(a).

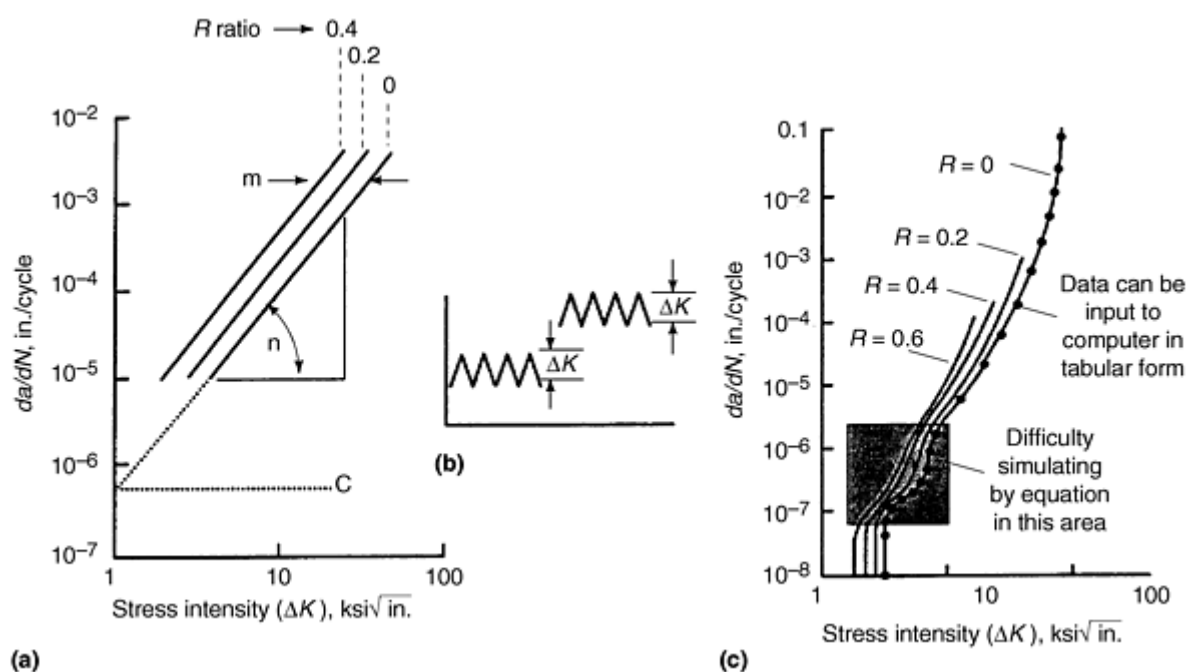

FIG. 3 CRACK GROWTH RATE DATA SIMULATION

The Paris equation was modified by Walker (Ref 13) to account for the stress ratio ( $R$ ), as indicated in Fig. 3(b)

$$DA/DN = C[\Delta K/(1 - R)^{1-M}]^N \quad (\text{EQ 3})$$

The Walker equation enables lines to be plotted at each  $R$ -ratio, as shown in Fig. 3(a). The value  $m$  adjusts the width of the line spread, as shown in this figure.

The Walker equation is widely used throughout the world, but many other equations are also in constant use. These include the Forman equation (Ref 14), the Collipriest equation (Ref 15), and the modified Collipriest equation (Ref 16). The latter is probably the most sophisticated, but none of these equations can be considered exact, and they were developed to fit test data. This can be done for most materials over the range of  $da/dN$  data shown in Fig. 3(a), but difficulty is experienced with some materials at lower  $da/dN$  levels, as shown in Fig. 3(c).

Many manufacturers now represent  $da/dN$  data in tabular form and input the data for each  $R$ -ratio into a computer, which performs logarithmic interpolation between each data point and each  $R$ -ratio. This procedure has been proven to give the most accurate results. Irrespective of the method used to represent  $da/dN$  data, it should be considered a requirement to validate the approach using a small element test program.

**Crack Growth Analysis Model Validation.** As mentioned above, each manufacturer has developed its own methodology for crack propagation analysis. These methods vary from extremely simplistic to extremely sophisticated. The simplistic methods are usually inexpensive for the manufacturers but tend to produce conservative results, which may be burdensome to the airline operator. The more sophisticated methods are more expensive to the manufacturer in terms of computer time, but the results are usually more accurate and the inspection frequencies specified may not be as burdensome to the operator.

There are many elements to the basic crack propagation computer program:

- METHOD OF REPRESENTING  $da/dN$
- BASIC  $da/dN$  INTEGRATING ROUTINE ( $N = DA/F(\Delta K, M, R, \text{ETC.})$ )
- METHOD OF CYCLE REPRESENTATION
- RETARDATION MODEL
- ACCELERATION MODEL
- METHOD OF CALCULATING  $K$

Each of these elements interacts with the others, and the combination of the elements must be validated by testing.

The method of representing  $da/dN$  varies, as discussed above. In the opinion of this author, a tabular input of the data yields the most accurate results.

**Basic  $da/dN$  Integration Scheme.** Some programs incorporate complex integration routines that tend to be costly in terms of computer time. Attempts are often made to reduce the cost of cycle-by-cycle integration by assuming constant growth rates over groups of similar cycles within a flight. This reduces the effective number of cycles required in cycle-by-cycle integration.

The method of cycle representation in the crack growth program has presented problems in the past. Some manufacturers consider each cycle and assume that crack growth occurs on increasing load, so that the inputs are the maximum stress and the  $R$ -ratio for each cycle. Other manufacturers "rain flow count" the cycles. The two representations give different crack growth lives using the same  $da/dN$  data. This problem is briefly discussed in Ref 9.

**Retardation Model.** There are a number of crack growth retardation models in use today. Some of the more common ones are the Wheeler model, the Willenborg model, the generalized Willenborg model, and the closure model. The Wheeler model depends on test data to establish an exponent term in the model, whereas the other three models are analytical. This author has had considerable success using the generalized Willenborg model. Some manufacturers have not incorporated retardation models into their crack growth programs and are therefore providing conservative crack growth curves.

**Acceleration Model.** Very few programs currently make use of acceleration models. Unless aircraft use will include extremely high sink rates on landing (which cause high compressive stresses in the lower wing surface), an acceleration model may not be necessary.

The method of calculating  $K$  is of course extremely important for accurate analysis. A number of classical solutions are usually incorporated into the computer program in analytical form. However, to account for the complex effects of geometry, such as in stiffened structure, it is essential to include a tabular routine to input  $\beta$  in the stress-intensity factor equation, Eq 1.

**Validation.** There is significant variability between different manufacturers' programs for obtaining data about crack length versus time. Therefore it is essential to validate the basic elements of the program by performing crack growth tests on simple unstiffened panels under flight-by-flight spectrum loading. For the spectrum cycle elimination discussed above, the specimens used to determine the maximum stress range truncation level are ideal for such a study.

**Fracture toughness data** should be obtained for the full range of material thickness used. This is necessary because the critical stress-intensity factor varies with material thickness, from the higher plane-stress values ( $K_{Ic}$ ) in thin materials through a mixed-mode region to the lower plane-strain values ( $K_{IIc}$ ) in thicker parts. Critical stress-intensity factors in the

mixed-mode region are influenced by the percentage of plane-strain fracture, which is a function of material thickness. As the material thickness is reduced, a greater portion of the fracture surface will be plane-stress (45°) fracture.

Standard testing methods are available for plane-strain fracture toughness to obtain  $K_{Ic}$  values (Ref 17). However, the determination of  $K_c$  is difficult because many phenomena influence plane-stress fracture, including panel width effects, crack buckling, and slow stable tearing.

**Panel Width Effects.** If the plane-stress critical stress-intensity factor is plotted against panel width for ductile materials, it becomes apparent that critical  $K$  is affected by panel width, even though fracture toughness is supposed to be a material parameter. For example,  $K_c$  values cannot be fully developed for 2024-T3 sheet unless the test panel is at least about 60 in. wide, whereas full  $K_c$  values can be developed for 7075-T6 sheet using a panel width of 16 in. This is due to gross net section yielding of the uncracked ligament. This effect can mislead designers who conduct parametric studies during candidate material selection.

**Crack buckling**, which is caused by induced compressive stress parallel to and along the edge of the crack, reduces the effective critical stress-intensity factor at failure. This is due to either local bending at the crack tip or induced Mode III fracture. Antibuckling guides are commonly used to stabilize the crack edge during center crack panel testing.

**Slow stable tearing** is another effect that needs careful consideration in thin sheet ductile materials. Crack extension can occur during application of a single load cycle. This phenomenon is usually represented by an  $R$ -curve of applied  $K$  plotted against slow stable crack extension,  $\Delta a$ .

The fracture toughness of many aluminum alloys is affected by temperature. For example, at -65 °F (-55 °C), considered to be the soaked-out temperature at altitude, the fracture toughness of most 7000-series alloys is approximately 28% lower than at room temperature. This is also true of some 2000-series alloys, particularly 2014-T6. The effects of temperature should be given careful consideration in residual strength calculations, particularly in candidate material selection for tension critical structure.

Fracture toughness in either plane-stress or plane-strain regions is affected by grain direction for a number of alloys, so data appropriate for the correct grain orientation should be used.

**PSE Limiting Residual Strength.** It is important to determine the maximum extent of damage that each PSE can tolerate at the limit load conditions specified in FAR 25.571(b). This damage extent is considered the limit for crack growth calculations, and an inspection program must be established to detect damage before these proportions are reached. Two-bay skin damage with central broken stiffening elements is usually inspectable by walk-around if it is easily observable from the ground.

**Discrete Source Damage.** FAR 25.571(e) requires a discrete source damage evaluation. The aircraft must be capable of successfully completing a flight during which structural damage is likely to occur as a result of:

- IMPACT WITH A 4 LB BIRD AT CRUISE VELOCITY ( $V_C$ ) AT SEA LEVEL OR AT  $0.85 V_C$  AT 8000 FT, WHICHEVER IS GREATER
- UNCONTAINED FAN BLADE IMPACT
- UNCONTAINED ENGINE FAILURE
- UNCONTAINED HIGH-ENERGY ROTATING MACHINERY FAILURE

Immediately obvious damage from discrete sources should be determined, and the remaining structure should be shown to have static strength for the maximum loads (considered ultimate loads) expected during completion of the flight. According to FAA Advisory Circular 25.571-1A, the load conditions during and subsequent to the incident should be as follows:

- **AT THE TIME OF THE INCIDENT:** THE MAXIMUM NORMAL OPERATING DIFFERENTIAL PRESSURE MULTIPLIED BY A FACTOR OF 1.1 (VALVE TOLERANCE), PLUS THE EXPECTED EXTERNAL AERODYNAMIC PRESSURES DURING 1 G LEVEL FLIGHT COMBINED WITH 1 G FLIGHT LOADS. THE AIRCRAFT, ASSUMED TO BE IN 1 G LEVEL

FLIGHT, SHOULD BE SHOWN TO BE ABLE TO SURVIVE ANY MANEUVER OR ANY FLIGHT PATH DEVIATION CAUSED BY CERTAIN INCIDENTS LISTED IN FAA ADVISORY CIRCULAR 25.571-1A, TAKING INTO ACCOUNT ANY LIKELY DAMAGE TO THE FLIGHT CONTROLS AND NORMAL CORRECTIVE ACTION BY THE PILOT.

- *FOLLOWING THE INCIDENT*: 70% LIMIT MANEUVER LOADS AND, SEPARATELY, 40% OF THE LIMIT GUST VELOCITY (VERTICAL OR LATERAL) AT THE SPECIFIED SPEEDS, EACH COMBINED WITH THE MAXIMUM APPROPRIATE CABIN DIFFERENTIAL PRESSURE (INCLUDING THE EXPECTED EXTERNAL AERODYNAMIC PRESSURE). THE AIRCRAFT MUST BE SHOWN BY ANALYSIS TO BE FREE FROM FLUTTER UP TO THE MAXIMUM DIVE SPEED (DEFINED BY THE DIVE SPEED/MACH NUMBER ENVELOPE), WITH ANY CHANGE IN STRUCTURAL STIFFNESS RESULTING FROM THE INCIDENT.

The federal regulations do not specify damage sizes or acceptable risk levels in the event of uncontained engine failure. In the recent past, manufacturers have conducted a quantitative risk assessment using the interpretive material in European Joint Airworthiness Regulation (ACJ) 25.903(d)(1) to show compliance with FAR 25.571(e). Briefly, for the more critical case this assessment involves showing that there is not more than a 1 in 20 chance of catastrophe resulting from the release of a single one-third piece of disc plus  $\frac{1}{3}$  height of a blade. Trajectories for this engine debris are outlined in FAA Advisory Circular 20-128 (Ref 18).

In the case of the fuselage, considered to be the most critical element for discrete source damage, the risk assessment described in ACJ 25.903(d)(1) involves an evaluation of fuselage bending capability in the presence of the discrete source damage. However, what is most important is to prevent explosive decompression failure due to longitudinal damage. Many of the larger manufacturers have a history of wedge penetration testing: a pressurized fuselage section, subjected to downbending loads, is pierced with a sharp wedge blade to simulate engine disc damage. Such testing is described in Ref 19.

It is the opinion of this author that, although not required by regulations, wise manufacturers will design the pressure cabin to sustain a full two-bay skin crack with a broken frame if there is a tendency for skin fast fracture within two bays at the applied principal stress resulting from skin hoop tension and fuselage downbending shear stresses. This is usually easy to achieve in a fuselage with crack stopper straps, as shown in Fig. 4. Assuming that the applied principal stress is given by line AD and that the damage size is as shown, skin fast fracture will occur at B, and the damage will be arrested at C. If the fuselage design does not include crack stopper straps and the peak of the residual strength curve is at point E, fast fracture at B will not be arrested, and there will be fuselage explosive decompression failure. However, if the combination of skin fracture toughness and applied stress level is such that fast fracture will not occur within two bays, as indicated by line FG, then it is not normally necessary to require capability for full two-bay damage.

FIG. 4 DISCRETE SOURCE DAMAGE RESIDUAL STRENGTH FOR LONGITUDINAL DAMAGE

**Residual Strength Analysis Validation.** Although nonlinear analysis is necessary for some configurations, linear elastic fracture mechanics has been used with a high degree of success to calculate residual strength in the presence of fatigue damage for complex structures. A wide variety of methods are available:

- LUMPED PARAMETER FINITE ELEMENT ANALYSIS
- ENERGY RELEASE RATE FINITE ELEMENT ANALYSIS
- CRACKED ELEMENT FINITE ELEMENT ANALYSIS
- DISPLACEMENT COMPATIBILITY ANALYSIS

It is generally understood that the maximum extent of damage at limit load cannot be determined for every PSE by test. Thus, this task is considered primarily analytical. However, a background of enough testing must be performed on complex structures to provide assurance that the methods used are reliable. As a minimum, the types of structures to be considered are:

- LOWER WING SURFACE STIFFENED COMPONENTS
- HORIZONTAL STABILIZER UPPER SURFACE STIFFENED COMPONENTS
- FUSELAGE STIFFENED COMPONENTS SUBJECTED TO PRESSURE FOR LONGITUDINAL CRACKS
- FUSELAGE STIFFENED COMPONENTS (MAY BE FLAT PANELS) FOR CIRCUMFERENTIAL CRACKS
- ANY OTHER PRINCIPAL STRUCTURE FOR WHICH ANALYSIS IS CONSIDERED UNRELIABLE

The **two-bay skin crack criterion** was introduced with wide-body aircraft. Although not specifically required by regulation, it is wise to design the vast expanse of basic structure in the fuselage, lower wing surface, horizontal stabilizer upper surface, and so on to sustain a two-bay skin crack with a broken central stiffener at limit load. This damage scenario

is consistent with expected cracking scenarios, and in many cases it relieves airline operators of the need for considerable sophisticated nondestructive inspection (NDI).

Figure 5(a) illustrates a fatigue-critical location in a fuselage skin at the first fastener in a circumferential frame shear clip cutout. The cutout, which allows continuous axial stiffeners to pass through the frame, creates a stress concentration in the skin, which is aggravated by increased skin stress due to frame bending at some locations. Fatigue cracks at this location will propagate into both adjacent skin bays, creating the two-bay skin crack scenario. In addition, discrete source damage, discussed below, can create the potential for stiffening element failure in addition to two-bay skin damage.

FIG. 5 CRACKING SCENARIOS LEADING TO THE TWO-BAY SKIN CRACK CRITERIA

Figure 5(b) illustrates a fatigue-critical location in the fuselage in the axial stiffeners at a circumferential frame connection. Radial loading due to internal cabin pressure causes stiffener bending ( $M$ ) and concentrated load transfer ( $P$ ) from the stiffener into the frame. A combination of these loads creates high local stresses in the stiffener, creating a potential for stiffener fatigue cracking. After failure of the stiffener, the skin becomes overloaded at the skin-to-stiffener rivets on each side of the stiffener crack. This creates the potential for skin cracks that would propagate into two adjacent bays, creating the potential for a two-bay skin crack with a broken central stiffener. Figure 5(c) summarizes these damage scenarios.

Figure 5(d), another example of basic structure, shows potential cracking of a lower wing surface stiffener at fuel transfer holes or at rib attachment fastener holes. After stiffener failure, the first fastener holes on each side of the stiffener crack become highly loaded, causing skin stress concentration and potential skin cracking. This skin cracking can propagate into both adjacent bays, creating the potential for a two-bay skin crack with a broken central stiffener.

In many areas of the airframe basic structure (e.g., in the lower wing surface and for the fuselage skin circumferential cracking case), it is essential to design for the two-bay skin crack with a broken central stiffener at limit load to relieve the inspection burden created for the airline operator. Figure 6, a typical example, shows a residual strength curve for a two-bay skin crack with a central broken stiffener in a lower wing surface. Assume that the wing has been designed such that

the limit gross stress is 33.5 ksi (241 MPa). The allowable stress for the two-bay condition is given by point A on the skin fracture curve. Any skin fast fracture below this point will be arrested. Fast fracture at stress levels above this point will cause failure. If limit load is applied during a particular flight (regulatory level), a skin fast fracture at point B will be arrested at point C. This damage would be considered detectable by walk-around visual inspection, and it would most likely be found.

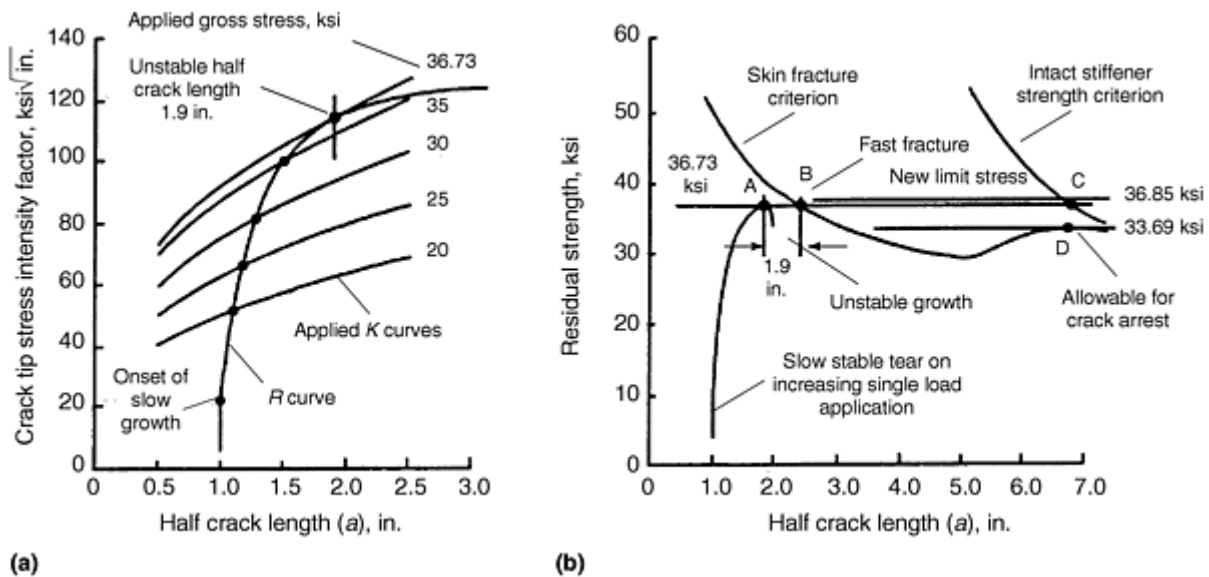

FIG. 6 TYPICAL LOWER WING SURFACE RESIDUAL STRENGTH DIAGRAM

Suppose then that a decision was made to make the limit stress level 10% higher, or 36.85 ksi (254 MPa), to save weight. This requires abandonment of the two-bay skin crack criterion if the same structural geometry is to be used. Figure 7(a) illustrates a resistance curve analysis for the typical lower wing surface element considered. This figure shows that if a skin half crack length of 1.0 in. exists at a broken stiffener, then slow stable growth will occur on a limit load application and the crack will start to become unstable at a stress of 36.73 ksi (253 MPa), which is below the limit stress level. Figure 7(b) indicates that fast fracture will occur and that the structure will fail before the limit stress is reached.

**FIG. 7 TYPICAL R-CURVE WITH APPLIED K-CURVES FOR LOWER WING SURFACE RESIDUAL STRENGTH CRACK RESISTANCE**

The implication is that the critical half crack size in the skin is less than 1.0 in. (25 mm). In order to establish a reasonable inspection interval, the detectable crack size has to be very small. In addition, when the skin crack is very small, the crack-tip stress intensity is high, because load transfer out of the broken stiffener causes rapid crack growth rates. Sophisticated NDI is then required over a wide expanse of structure, which creates a considerable burden on the airline operator. The alternative is to use an inspection method capable of finding the broken stiffener on the inside (either internal inspection of the wing tank or external inspection with low-frequency eddy current), which again is a burden on the operator. A more detailed discussion of this topic can be found in Ref 20.

**Structural Category Description.** Aircraft structures can be divided into five major categories.

**Safe-Life.** In this type of structure, flaws can become critical at limit load before they are readily detectable in-service. Under FAR 25.571, a structure cannot be qualified in the safe-life category unless it is established that damage tolerance is impractical. Currently, only landing gear are considered safe-life structures, and these must generally be qualified by testing that incorporates appropriate scatter factors.

**Single-Load-Path, Damage-Tolerant.** This type of structure is allowed by regulations, provided that a reasonable inspection threshold and frequency can be established that are economically feasible for the airline operator.

**Multiple-Load-Path, Externally Inspectable.** This category is recommended for the vast expanse of basic structure. If the structure is designed such that a reasonable safe period for inspection is feasible (considering skin crack growth after failure of an internal member), the component will be externally inspectable.

**Multiple-Load-Path, Not Inspectable for Less Than Load Path Failure.** In this type of structure, a crack in the primary member may not be readily inspectable without disassembly. However, the structure may be easily inspectable for complete failure of the primary member. In this case, inspection frequency is based on the remaining life of the secondary structure. Further explanation can be found in Ref 9.

**Multiple-Load-Path, Inspectable for Less Than Load Path Failure.** In this type of structure, the primary member is inspectable, so crack growth in the primary member followed by growth in the secondary member can be considered in establishing inspection frequency.

These categories are described in more detail in Ref 9.

A crack growth curve must be provided for each PSE. The curve should be plotted for *detectable* crack growth, as shown in Fig. 8. The most critical crack position and orientation should be assumed.

FIG. 8 TRADEOFF BETWEEN DETECTABLE CRACK SIZE AND SAFE INSPECTION

**Inspection Threshold Philosophy.** None of the regulatory material for the design of new aircraft discusses a means of establishing the threshold for detailed inspection of fatigue-critical areas. When the damage tolerance philosophy was conceived, it was intended that the threshold be equal to the interval. This was objected to by airline operators because it meant introducing detailed inspections much earlier than before. Consequently, each manufacturer established its own methods, some of them based on the growth of 0.05 in. corner cracks at fastener holes (as indicated by Fig. 44 of Ref 9). Other manufacturers based the threshold on fatigue analysis methods using an appropriate scatter factor. However, the latter approach does not account for possible initial manufacturing damage, and for some structural configurations, fatigue cracks could become critical prior to the threshold. This problem is discussed in detail, along with a typical example, in Ref 20 in a section entitled "Threshold for Detailed Inspection."

Industry and regulatory authorities have agreed to include threshold criteria in a revised version of FAA Advisory Circular 25.571-1B. As of October 1995 the document has not been officially released, but the draft form reads as follows: "(1) Where it can be shown by observation, analysis, and/or test that a load path failure in multiple load path 'fail-safe' structure, or partial failure in crack arrest 'fail-safe' structure, will be detected and repaired prior to failure of the remaining structure, the thresholds can be established using either: (i) fatigue analysis and tests with appropriate scatter factor, or (ii) slow crack growth analysis and tests, based on appropriate initial manufacturing damage and an appropriate scatter factor. (2) For single load path structure and for multiple load path and crack arrest 'fail-safe' structure, where it cannot be demonstrated that load path failure, partial failure, or crack arrest will be detected and repaired prior to failure of the remaining structure, the thresholds shall be established based on crack growth analyses and tests, assuming the structure contains an initial flaw of maximum probable size that could exist as a result of manufacturing or service induced damage."

As mentioned above, a number of manufacturers are already using this philosophy in establishing inspection thresholds.

**Inspection Frequency Philosophy.** The frequency of inspection is based on crack growth life, starting with a crack size that has a high probability of being detected using the specified inspection methodology and ending with the extent of damage at limit load. The regulation does not specify probability of detection, but 90% probability with 95% confidence appears to be a generally accepted value in a deterministic approach. The crack growth life is generally divided by a factor to provide an inspection interval. The minimum value of this factor has been 2.0 for multiple-load-path structure and 3.0 for single-load-path structure. Because the probability of finding a crack increases with crack length, some

manufacturers have used a joint probability calculation that determines the number of inspections required to provide a constant probability of survival. One such calculation is based on the computer program IPOCRE (Ref 21).

Inspection cost is influenced by the inspection interval as well as by the choice of method. Looking for small cracks using NDI may be expensive, but the interval is long, as illustrated in Fig. 8. However, it is the opinion of this author that frequent visual inspection is safer than NDI at extended intervals. Care should be exercised not to make the interval too long under the assumption that extremely small cracks will be found, because the probability of detecting them might be low.

If NDI will be used, it is usual for the fracture mechanics analyst to mark up a drawing, during development of the aircraft, with the most critical crack locations for each PSE. The NDI specialist then determines the inspection method and specifies any NDI instrumentation calibration specimens needed. These data are presented in an NDI manual for the aircraft.

**Full-Scale Fatigue Testing.** It is well known in the industry that FAA requirements do not include a mandate to perform full-scale fatigue testing for aircraft previously designated "fail-safe" and currently designated "damage tolerant." However, most manufacturers in recent years have completed a minimum of two lifetimes of simulated fatigue loading on full-scale aircraft. The two primary reasons for full-scale fatigue testing are to determine the locations of "hot spots" where early fatigue cracking might occur and to determine the point in the life at which widespread, multiple-site fatigue cracking may occur.

With industry agreement, FAR 25.571 is being modified to include the following terminology: "The evaluation must include repeated loads and static analyses supported by full-scale fatigue test evidence. It must be demonstrated with sufficient full-scale fatigue test evidence that widespread multiple-site damage will not normally occur within the design service goal of the airplane."

It has become customary with some manufacturers to perform residual strength testing at the termination of the full-scale fatigue test by introducing saw cuts in critical locations. In this case it is advisable to conduct a small element test program to validate that the same residual strength will result from saw cuts relative to fatigue cracks. This subject is discussed in more detail in Ref 9.

**Teardown Inspection Philosophy.** At the conclusion of full-scale fatigue testing, it is advisable to conduct teardown inspection of selected areas of the structure that may be susceptible to multiple-site damage (MSD). This inspection is not considered merely a visual check for cracks. It involves cutting out sections of the structure, breaking open the sections through fastener holes, and fractographically examining the fracture surfaces to determine if any sign of MSD has occurred. Extremely small cracks, even of less than detectable size, can substantially reduce the residual strength capability for which the aircraft was designed and certified. Information about MSD is needed to help determine the onset of widespread fatigue damage.

**Widespread fatigue damage** is the point in the aircraft life when MSD and multiple-element damage (MED) have degraded the originally certified residual strength capability below the regulatory level of limit load. The critical damage size can be influenced by the condition of the surrounding structure. If the structure is young, it is unlikely that MSD is present to the extent it would affect the lead crack residual strength. However, if the structure is operating beyond the life substantiated by fatigue testing, there is a strong possibility that MSD may affect lead crack residual strength. This condition is particularly important in the event of discrete source damage, as in the case of engine burst.

MSD and MED have become the most important issues in discussions of aging aircraft, and many references deal with this subject (Ref 9, 19, 20, 22, and 23). References 9 and 19 were published in 1983 and 1987, respectively, and Ref 20, 22, and 23 were published after the Aloha 737 accident in 1988. Detailed discussion of MSD and MED is beyond the scope of this article, but some guidance can be offered:

- THE BEST WAY TO HANDLE MSD IS TO MAKE SURE THAT IT NEVER OCCURS WITHIN THE OPERATIONAL LIFE OF THE AIRCRAFT. SUFFICIENT FULL-SCALE FATIGUE DATA SHOULD BE GATHERED, FOLLOWED BY A DETAILED TEARDOWN INSPECTION AS DESCRIBED ABOVE. AS MENTIONED, FOR NEW AIRCRAFT THIS WILL EVENTUALLY BE A REQUIREMENT.
- FOR EXISTING AIRCRAFT THAT MAY NOT HAVE HAD THE BENEFIT OF FULL-SCALE

FATIGUE TESTING AND TEARDOWN INSPECTION, IT IS ESSENTIAL TO PREDICT THE ONSET OF WIDESPREAD FATIGUE DAMAGE SO THAT AIRCRAFT CAN BE MODIFIED IN AREAS SUSCEPTIBLE TO MSD AND MED.

Loss in lead crack residual strength appears to be a function of structural geometry. Figure 9 shows the result of finite element analysis for the case of a two-bay longitudinal skin crack with a broken central frame. The frame cross section includes a titanium crack stopper strap. Figure 10 shows residual strength for the same cracking scenario, but in this case the frame does not include a crack stopper strap. In both figures, the residual strength is given by point A. The effects of MSD have been determined based on an intuitive failure criterion that is described in Ref 23.

FIG. 9 EFFECT OF MULTIPLE-SITE DAMAGE ON LEAD CRACK RESIDUAL STRENGTH FRAMES WITH CRACK STOPPERS. RIVET SPACING 1.0 IN. (25 MM)

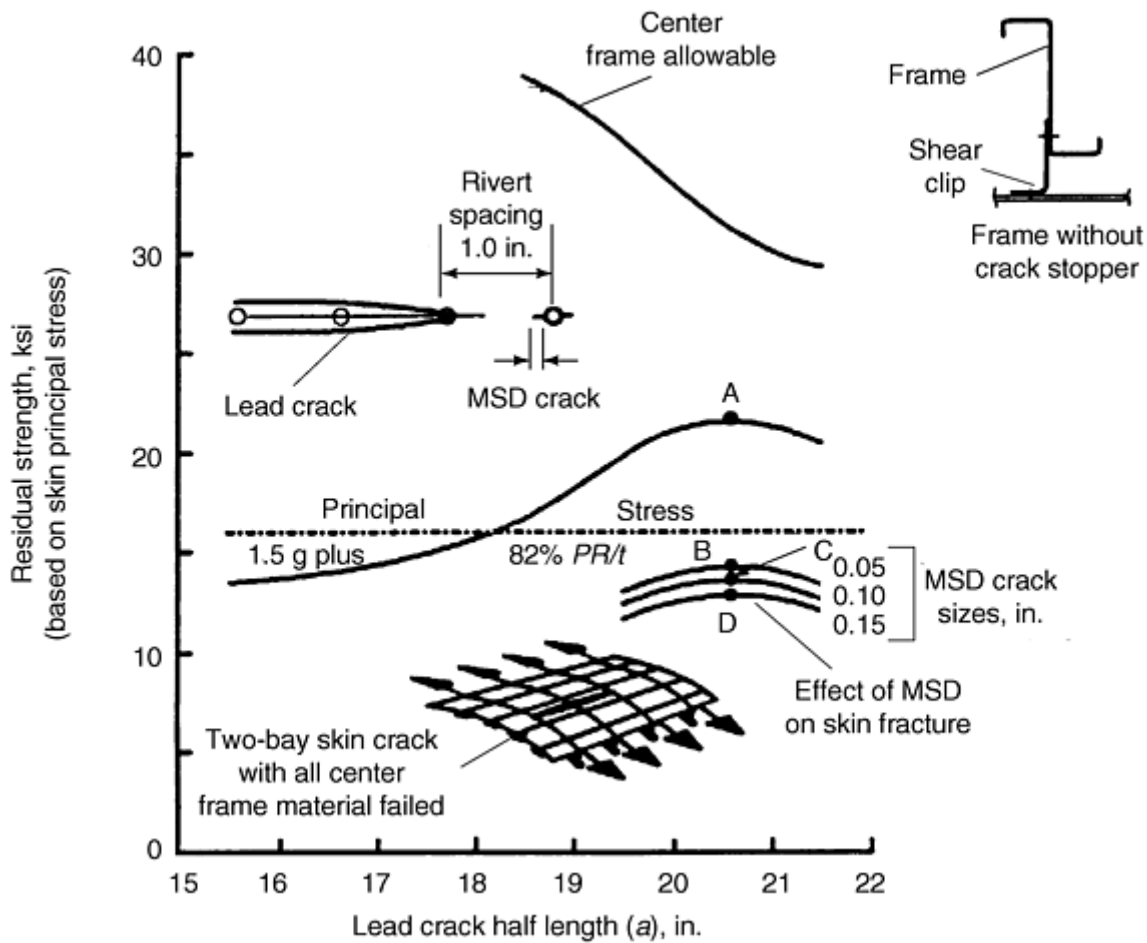

FIG. 10 EFFECT OF MULTIPLE-SITE DAMAGE ON LEAD CRACK RESIDUAL STRENGTH FRAMES WITHOUT CRACK STOPPERS. RIVET SPACING 1.0 IN. (25 MM)

In the case where titanium crack stopper straps are present, considerable MSD is tolerable and the residual strength capability is still above the required stress. However, in the case where no crack stoppers are present, even undetectable MSD can degrade the residual strength below the required value. Thus, aircraft needs to be evaluated in all areas susceptible to MSD in order to determine the extent of MSD that will degrade the residual strength below limit.

**Steering Committee Activity.** When the crack growth and residual strength have been determined for each PSE, manufacturers should convene a series of meetings, known as steering committee meetings, with airline operators and government authorities. Because the operators are responsible for performing the inspections, they should be involved in considering the tradeoff between inspection method and frequency, based on the engineering data provided by the manufacturers. Some operators prefer frequent inspections with less sophistication in the method, while others prefer a more sophisticated and usually more expensive NDI method but with reduced frequency. Not involving operators at an early stage has created problems with extended service life programs, resulting in the need for Supplemental Inspection Documents (SIDs) for mature fleets of commercial aircraft.

**Airworthiness Limitations.** The inspection program developed from the damage tolerance evaluation to prevent catastrophic failure must be included in the Airworthiness Limitation Section of the Instruction for Continuous Airworthiness required by FAR 25.1529.

**Repairs and Modifications.** Any repair or modification to an airframe structure has the potential to degrade the fatigue life and damage tolerance capability. Inspection thresholds and frequencies can be drastically affected by changes in structural geometry due to repairs or modifications. In view of this, each repair or modification should be evaluated for damage tolerance, and new inspection thresholds and frequencies should be established. This applies to aircraft initially certified as damage tolerant as well as to older aircraft operating under SIDs.

## The U.S. Air Force Approach to Aircraft Damage Tolerant Design

Mitchell P. Kaplan, Willis & Kaplan, Inc.; John W. Lincoln, Aeronautical Systems Center, Wright Patterson Air Force Base

---

## Introduction

DAMAGE TOLERANT DESIGN in U.S. Air Force aircraft has evolved over the last twenty-five years since fracture mechanics was first used in the 1970s as a tool for analyzing structural problems of aircraft. Fracture mechanics originated in the 1920s, and as a tool became viable in the 1950s. It was then a reasonably short time before fracture mechanics became the methodology used by the U.S. Air Force to ensure safe design of their aircraft. In the 1970s, the B-1A airframe was designed using damage tolerance techniques. Prior to this time, fracture mechanics was used to determine the rationale causing the failure of the TFX (F-111) aircraft and to determine a method for ensuring that the problem underlying the crash did not occur again.

It was also during the 1970s that it became apparent that significant structural problems existed in the airframe of the C-5A aircraft, which was designed using stress analysis and fatigue as the primary design tools. Fracture mechanics was used as a tool to determine the extent of these problems and to define "a fix" for them. During the 1970s and 1980s, the

U.S. Air Force established and evaluated a set of standards that would change the method of design for their aircraft and structurally reassessed their existing fleet of aircraft. Finally, the U.S. Air Force expanded the use of fracture mechanics technology to encompass not only airframes, but engines and mechanical components as well.

The chronology and rationale underlying this change is discussed in detail in this article. It is important to understand the historical bases for the change as well as the technological advances that underlie them. During this same time period, the 1970s and 1980s, the U.S. Air Force expended significant effort in a number of areas to include fracture mechanics in design. These included, as stated above, a series of standards that required contractors to use damage tolerance procedures as the primary design tool to ensure safety for new aircraft, a structural reassessment of in-service aircraft, and laboratory support from the Wright Laboratory. Funding by several areas of the U.S. Air Force in fundamental research was also provided. Additional funding included expenditures by several system programs to design new materials, obtain material data, and further examine analysis procedures that would be useful in determining component life. Finally, this data was published in a fashion that would hasten its application.

The use of fracture mechanics thus has evolved into the U.S. Air Force design program for aircraft that are damage tolerant, that is, aircraft designed to operate with manufacturing and in-service induced defects. This change in ensuring aircraft structural integrity has manifested itself in a number of ways, including:

- FEWER STRUCTURAL PROBLEMS (SURPRISES) OCCUR.
- LIFE-CYCLE COST OF A SYSTEM CAN BE DETERMINED.
- ECONOMIC LIFE OF A SYSTEM CAN BE DETERMINED.
- FLEET UTILIZATION IS ENHANCED.
- INSPECTIONS PROCEDURES ARE KNOWN.
- INSPECTION CONFIDENCE IS IMPROVED.
- INSPECTION INTERVALS CAN BE SCHEDULED.
- CHANGE IN USAGE CAN BE DETERMINED IN TERMS OF COMPONENT AND AIRCRAFT LIFE.
- ADVANCES IN INSTRUMENTATION ALLOW (1) MEASUREMENT OF ADDITIONAL RELEVANT PARAMETERS, (2) ENHANCED (REAL TIME) MEASUREMENT OF PARAMETERS, AND (3) EMBEDDING OF CRACK GAGES INTO STRUCTURE (SMART STRUCTURE).
- ADVANCES IN SOFTWARE ALLOW (1) CALCULATIONS OF SEVERITY CHANGE ON A PER FLIGHT BASIS, (2) IMPROVED INSPECTION SCHEDULE, AND (3) AN IMPROVED MAINTENANCE SCHEDULE.

In short, the inclusion of damage tolerance design and a systematic review of design procedures allows the U.S. Air Force to design, manufacture, and maintain systems that are structurally safe and economically prudent. After a brief introduction of fracture mechanics, this article describes those particular aspects that relate to aircraft design.

## **Fracture Mechanics**

Fracture mechanics provides the framework for the interrelationship among the toughness of the material, the applied stress, and the presence of a defect or crack within the material itself. It should be noted that the primary difference between fracture mechanics analysis and the type of analyses conducted previously is the a priori assumption that a crack is present. Stress analysis, fatigue analysis, corrosion, creep, and so forth do not assume the immediate presence of a crack. Many of these analyses do not consider the presence of a crack until failure occurs. Fracture mechanics analysis procedures assume that a crack exists immediately subsequent to manufacture of the component.

The study of fracture mechanics may be subdivided in a number of ways. For the purpose of this section, the subdivision consists of critical crack growth and subcritical crack growth. Critical crack growth entails those situations where the combination of a particular flaw size and applied stress lead instantly to catastrophic failure. The stress may be tensile, shear, or torsional and is not applied in a cyclical manner. As this discussion considers fracture mechanics as the primary method of material failure, the flaw is assumed to be an infinitely sharp crack. Subcritical crack growth may occur as a result of cyclic loading, corrosion, or creep. The crack grows until the combination of applied stress and crack size causes catastrophic failure. Generally, in the case of airframes, the temperature is insufficiently high for creep to become a meaningful problem and is usually ignored. This is not true in engines. Cyclic loading will be discussed, and corrosion will be addressed in conjunction with both cyclic or sustained loading.

**Critical Crack Growth.** Fracture mechanics as understood today began in 1920 with A.A. Griffith (Ref 1). At that time, Griffith was working with brittle materials such as glass and the conditions that caused them to fracture. By using basic thermodynamic principles, he was able to derive an equation that led to the energy required to create new surfaces. Through quantification of thermodynamics and the introduction of solid mechanics, he was able to derive an equation that was based on measurable invariant properties of the materials involved. These measurable properties included the surface energy of the material and Young's modulus, and additionally, the geometry of the initiation site was required. Griffith was able to show that additional new surface would be created when the elastic energy available to form a new surface was equal to or greater than the reduction of elastic energy due to the cohesive strength of the material.

The method used by Griffith to express the relationship between the cohesive strength of the material and the elastic energy was based on work done previously by C.E. Inglis (Ref 2). Inglis showed, using mathematical techniques for ellipses with many different aspect ratios, the variation of the stress in a flat, infinite plate. It is apparent that an ellipse was chosen because of its ability to mirror several different flaws that occur in nature. If we consider an elliptical hole that has equal major and minor axes (aspect ratio equal to one), then the ellipse degenerates to a circle. If the major and minor axis differ by a thousand (a very high aspect ratio), the shape of the ellipse approaches a crack.

By using Inglis's methods, Griffith was able to show

$$\sigma \sqrt{\pi a} = \sqrt{2E\gamma_e} \quad (\text{EQ 1})$$

where  $\sigma$  is the applied stress,  $a$  is the crack length,  $E$  is Young's modulus, and  $\gamma_e$  is the elastic surface energy of the material.

It was noted that the left side of Eq 1 contains measured parameters (applied stress and crack length), while the right side of the equation contains material constants (Young's modulus and the elastic surface energy). In 1948, Irwin (Ref 3) and Orowan in 1949 (Ref 4), suggested that the elastic surface energy can be rewritten to include both the elastic and plastic surface energy. In a material that is completely brittle, the plastic portion of the surface energy would be quite small. The material constants (surface energy and Young's modulus) are grouped on the right side of the equation, and they can be replaced with a new material constant, the stress-intensity factor. Rewriting the equation in this form yields

$$\sigma \sqrt{\pi a} = \sqrt{2E(\gamma_e + \gamma_p)} = K_I \quad (\text{EQ 2})$$

where  $\gamma_p$  is the plastic strain energy, and  $K_I$  is the stress-intensity parameter (mode I, tension).

As a result of Eq 2, a method came into existence that allowed the determination of the material behavior as a function of the applied stress and the crack length. In contrast to the method proposed by Griffith in Eq 1, this method does not require the independent knowledge of the surface energy. The energy required to create new surface (elastic and plastic) is combined within the equation with Young's modulus to give a new parameter. This is the stress-intensity factor. What is required is a careful determination of the stress at the tip of the crack and of the relationship between the crack-tip stress and the applied stress of the material being tested. This was accomplished in the paper written by Irwin in 1957 (Ref 5).

The results obtained for mode I loading (tension) by Irwin are:

$$\begin{aligned}\sigma_x &= \frac{K_I}{(2\pi r)^{1/2}} \cos \frac{\theta}{2} \left( 1 - \sin \frac{\theta}{2} \sin \frac{3\theta}{2} \right) \\ \sigma_y &= \frac{K_I}{(2\pi r)^{1/2}} \cos \frac{\theta}{2} \left( 1 + \sin \frac{\theta}{2} \sin \frac{3\theta}{2} \right) \\ \tau_{xy} &= \frac{K_I}{(2\pi r)^{1/2}} \sin \frac{\theta}{2} \cos \frac{\theta}{2} \cos \frac{3\theta}{2} \\ \sigma_z &= \nu(\sigma_x + \sigma_y) \quad \tau_{xy} = \tau_{yz} = 0\end{aligned}\tag{EQ 3}$$

In this instance,  $\sigma$  is the normal stress, with the subscript showing the direction,  $\tau$  is the shear stress, and  $\nu$  is Poisson's ratio.

These equations, and the similarly derived equations for mode II (shear) and mode III (torsion), show that the stress level and the geometry surrounding the crack (both the shape of the crack and the component in which the crack is situated) have a role in the quantitative value of the stress-intensity factor, but do not affect the nature of the distribution of the stress field. As Irwin stated (Ref 5):

...in situations such that a generalized plane stress or a plane stress analysis is appropriate, the influence of the test configuration, loads, and crack length upon the stresses near an end of the crack may be expressed in terms of two parameters. One of these is an adjustable uniform stress parallel to the direction of a crack extension. It is shown that the other parameter, called the stress intensity factor, is proportional to the square root of the force tending to cause crack extension.

There now exists the necessary mathematical relationships supported by Newtonian mechanics that allow the investigator to relate the applied stress and the crack length in a fashion that demonstrates the onset of fracture. The material parameter,  $K_{Ic}$ , may be experimentally obtained. The stress at the crack tip is related to the gross stress by the equations derived by Irwin, and the crack length is measured.

**Subcritical Crack Growth.** The primary area of subcritical crack growth discussed in this section is the extension of cracks due to cyclic loading. Cyclic loading (fatigue) as a failure mechanism has been studied for more than 130 years (Ref 6). The life of components experiencing fatigue loading has been analyzed using Miner's Rule (Ref 7), which does not account for stress sequence, and the Neuber method (Ref 8), which considers the effect of the stress sequence. In both cases, it is assumed that no crack exists until final failure occurs.

In 1961, a paper by Paris et al. (Ref 9) investigated the effect of crack growth using fracture mechanics criteria. These criteria included the initiation of a crack into the component prior to the start of the test, and the study of the crack as it was exposed to cyclic loading.

They found that

$$\frac{da}{dN} = f(K_{max}, R)\tag{EQ 4}$$

where  $da/dN$  is the crack growth per cycle,  $K_{max}$  is the maximum stress-intensity factor, and  $R$  is the ratio of minimum to maximum stress-intensity factor.

As the crack-growth behavior was affected by a number of different test and environmental conditions, the analysts had to go to more complicated equations that would best represent the data. These investigators developed a number of equations that could represent the crack-growth rate as a function of stress-intensity factor (Ref 10, 11, 12, 13, 14, 15, 16, 17).

One of the more important parameters that affected the crack-growth rate was the stress ratio, or  $R$  ratio. This was the ratio obtained, during cyclic loading, when the minimum stress was divided by the maximum stress. Other material behavior characteristics that had to be included in the crack-growth equation to best represent the data were the existence of a stress-intensity threshold below which cracking would not occur, followed by a straight-line portion of the crack-growth curve, and finally a portion of the curve that would be increasing at an increasing rate. The curve representing this data is shown in Fig. 1. The crack-growth-rate data itself were found to be affected by environment, microstructure, heat treatment, texture, material form (sheet, plate, casting, forging, etc.) cyclic rate, waveform,  $R$  ratio, stress history, and so forth (Ref 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24).

FIG. 1 TYPICAL CRACK GROWTH CURVE

Another set of equations was used in tandem with the crack-growth-rate equations. These dealt with retardation of crack growth. As stated above, Neuber had found that fatigue life is affected by the previous stress history that the particular component has experienced. Several investigators developed equations that account for crack-growth retardation behavior (Ref 25, 26, 27, 28, 29). These equations calculate the residual compressive stress that exists after plastic deformation occurs at the crack tip due to a high tensile load. This residual compressive stress decreases as the distance from the applied high stress increases. This varying compressive stress field is calculated, and the residual compressive stress is subtracted from the next set of minimum and maximum stresses. As the minimum and maximum stresses are now changed as a result of the compressive loading, change also occurs with both the stress ratio and the difference between the maximum and minimum stress-intensity factor ( $\Delta K$ ).

These parameters are the primary driving forces that cause the crack to grow, thereby affecting the crack-growth rate of the particular component. There are, as previously stated, a number of mathematical approximations to determine the crack-growth-rate behavior of the material. All of these formulas use crack-growth data derived from constant amplitude cyclic applied stresses as the basis for their approximations. However, in many instances the stress-time history of a

particular component does not behave as if the stresses were applied in this fashion. An exception to that statement may be the skin of a fuselage that is subjected primarily to pressurization stresses. When the aircraft is on the ground, the stresses due to pressurization of the fuselage skin is zero. At maximum altitude, the pressure differential may be 8 to 10 psi (55 to 70 kPa). Upon landing, the pressurization differential is again zero. For other areas on the aircraft, this is not true. The lower surface of the wing on a fighter aircraft sees an almost random stress-time history for each segment of the flight. Much work has been accomplished relating the life of a component to whether the stresses are applied from the lowest stress to the highest stress, the highest stress to the lowest stress, or low stress to high stress to low stress. Results indicate that randomly ordering the stresses gives the lowest component life (Ref 30, 31).

There is yet another dilemma that exists between the analysis and the testing of a particular component. The component can be tested by placing the stresses in a random fashion, but the component cannot be analyzed in the same manner. Because the analysis is based on constant amplitude data, the stress cycle goes from minimum to maximum to minimum, and this is not true for the test spectrum. To account for this effect, stress-counting methods such as rain flow or range pair (Ref 32) must be used. These methods examine the stresses and combine the maximum half cycle with the minimum half cycle, the second maximum half cycle with the second minimum half cycle, and so forth. There is now a collection of full cycles that can be analytically examined. The order of the stresses is not identical; however, the results obtained more accurately represent the test results (Ref 30, 31).

The user can determine component life once the following information is obtained:

- MATERIAL PROPERTIES, STATIC AND DYNAMIC
- COMPONENT GEOMETRY
- LOADINGS
- LOAD-TIME HISTORY
- STRESS-TO-LOAD RATIOS
- STRESS-INTENSITY FACTORS
- STRESS COUNTING COMPUTER ROUTINES
- CRACK GROWTH EQUATIONS

By selecting an initial flaw size, the component life can be determined based on that initial flaw size. An inspection interval of one-half that life is usually specified as the inspection interval. It is at this time in the service history that the particular component is inspected.

### Application of Fracture Mechanics

In the 1960s, a transition occurred in fracture mechanics. It was taken from the laboratory and the research journals and placed in the daily venue of design engineering. This transition was hastened as a result of the space program (in particular, for its widespread use of pressure vessels) and the F-111 aircraft accident.

**Fracture Mechanics as a Design Tool in the Space Program.** In 1965, Tiffany and Masters wrote an article (Ref 33) that was instrumental in promoting the use of fracture mechanics as a technique that would be useful in aircraft design. This article discusses the use of fracture mechanics as a method of predicting failure, understanding failure mechanisms, and suggesting inspection methods to protect against failure in pressure vessels. The materials from which the pressure vessels were manufactured included steel, titanium, and aluminum.

At the time, Tiffany and Masters worked at a major aircraft company, and the article was an outgrowth of a portion of their ongoing tasks. The importance of the article, however, supersedes this. It was the first time that representatives of a major manufacturer formally addressed the notion that the onset of cracking may occur as a result of manufacturing defects and worked toward a design philosophy that accounted for this occurrence in a quantitative manner.

Tiffany and Masters examined pressure vessels and the cracks that may occur as a result of their manufacturing processes, especially welding, and stated:

Clearly, it must be recognized that fabricated structures and, indeed, even the raw materials contain defects and flaws of various kinds. The lives of these structures are controlled by the flaw sizes required to cause fracture at the operating stress levels, *the initial flaw size*, and the subcritical flaw growth characteristics of the materials.

This was a vast departure in design philosophy. Never before had industry discussed the existence of flaws (cracks) in new structure. Because fracture mechanics is based on the existence of cracks, the need for fracture mechanics in design not only became viable, but necessary. The previous methods used to validate structural integrity was through either strength (static failure), or fail-safe and safe-life design (fatigue). Both of these methods assumed that no cracks exist, and more importantly, had no method to deal with cracks. Only fracture mechanics had that capability.

The article written by Tiffany and Masters dealt with the application of fracture mechanics. Because a rocket motor case is basically a pressure vessel, it was necessary to get information (materials data) regarding the critical stress-intensity factor ( $K_{Ic}$ ), and the crack-growth behavior ( $da/dN$  versus  $\Delta K$ ). In addition, the mathematical relationships for a part-through flaw (a semielliptical embedded crack) and inspection criteria were needed. The inspection criteria that were needed included the area(s) to be inspected, how to inspect the particular location, and how often the inspection should be accomplished. Here is yet another significant difference between fracture mechanics design and strength design. In the previous design systems, the structure would be retired (taken from service) after the appropriate amount of time. In

damage tolerant design, the component may be used to the point of onset of widespread fatigue damage if proper inspection procedures are utilized.

An inspection method suggested in the paper is that of proof testing. If the maximum stress the component experiences is assumed to be  $X \text{ lb/in.}^2$ , then the component is tested at some higher level, for example,  $1.5X \text{ lb/in.}^2$ . If failure does not occur, then the analyst knows that the maximum crack size existing in the component is 0.44 times the crack size that causes failure. By performing a crack-growth analysis, the investigator determines the number of cycles (flights) for the crack to grow to a size where failure occurs during normal operations. After that number of cycles is reached, the component can be proof tested yet again. In this manner, the life can be extended indefinitely. It should be noted that crack growth can occur as a result of the proof test, and that must be taken into account.

**Fracture Mechanics as an Engineering Tool in Failure Investigation.** During the late 1960s, the U.S. Air Force and Navy were jointly funding the development of the F-111 aircraft. This aircraft had a swing wing and was designated as a fighter bomber. The wing box of the aircraft was manufactured from D6ac steel. During a test flight that occurred in December 1969, the wing failed in the steel wing pivot fitting and the aircraft crashed, killing the pilots. An investigation was undertaken to determine the cause of failure. Recovered from the wreckage was a portion of the wing box containing the flaw that initiated the crash sequence. The semicircular flaw was caused by a forging lap. The flaw was 1 in. long and 0.25 in. deep. The area where the flaw was located had been inspected several times, and the inspectors had not noticed it (Ref 34).

During the investigation, it was found that D6ac steel is susceptible to cooling rate. Tests indicated the toughness of the D6ac steel was significantly high, but tests of the failed material indicated a substantially lower toughness. This quench sensitivity of the D6ac steel resulted in a difference in fracture toughness by a factor of two. It was found that the testing conducted during the development program was on thin specimens, and the cooling rate was dissimilar to the cooling rate of the material in "as-forged" condition. This difference in the cooling rate led to the difference in material toughness. The combination of these factors lowered toughness, and the existence of the manufacturing defect led to catastrophic results.

The U.S. Air Force was faced with a problem of significant proportions. They had an aircraft that was an integral part of their fleet, yet had the potential to contain a flaw that would render the aircraft unable to perform its mission. It was decided that periodic proof testing of the aircraft would allow the aircraft to become a viable member of the U.S. Air Force contingency. It is well known that steel, when subjected to lower temperatures, becomes brittle. If a steel alloy is tested below its nil-ductility transition (NDT) temperature, the toughness of the steel drops considerably. It was decided that the aircraft should be proof tested below the NDT temperature of the D6ac steel in the wing box. To allow this test to occur, it was necessary to build rooms (hangars) of sufficient size and with the appropriate thermal characteristics to allow the temperature of the room to stay below the NDT temperature. The wing box structure would be tested. If failure did not occur during testing, the aircraft could be flown safely until the next inspection. After the next inspection, the proof test would be repeated. This inspection method increases the life of the aircraft until failure occurs during test. If no crack is present, the aircraft may be flown indefinitely.

An important aspect of this approach to inspection and aircraft utilization was that retirement of the aircraft would now be done for cause. Previously, when aircraft components arrived at particular life, the component would be retired. No inspections looking for cracks were required, and none were conducted. When the life of an aircraft (component) was reached, the aircraft (component) was removed from service. With this new methodology, for a particular part of the aircraft to be retired, a tangible reason such as a crack would be required. Safety would be based on the results of inspections and not on the results of analyses and component tests. As a result of the success using fracture mechanics to uncover the reason for the failure of the F-111 and to allow the implementation of a periodic inspection technique that would ensure flight safety, the U.S. Air Force decided to incorporate fracture mechanics as a design procedure.

### Damage Tolerance in Aircraft Design

With the success of fracture mechanics both in design and in failure analysis, the U.S. Air Force presented the idea to industry to use this discipline as the design methodology that would protect the safety of aircraft. A damage tolerance design approach that would incorporate fracture mechanics, periodic inspections, and a maintenance policy based on these inspections was initiated in the B-1A program, and a structural assessment of the C-5A was initiated using this procedure.

**The B-1A Aircraft.** In the early 1970s, the U.S. Air Force began procurement of the B-1A aircraft. That aircraft was the first design that used damage tolerance as a primary method for material selection, detail design, and inspection methodology. Using damage tolerance as the design technology for the B-1A required a significant increase in analysis methods and materials data. Fracture mechanics had previously been a tool to aid the researcher in understanding the failure mechanism. Its use as a design methodology required the unleashing of significant resources to obtain the methodologies that could be used to apply it to normal design procedures on future aircraft systems.

Development was required to both obtain and develop crack-growth programs, retardation models, standard crack solutions, nonstandard crack solutions unique to specific B-1A geometries, materials data, inspection methods, and so forth. The gathering and classification of the methods and materials was in itself significant. The need to gather the necessary information changed in a nontrivial fashion. The cascade of questions seemed unending. How was the aircraft to be used? What would be the stress-time history of the aircraft? How would all the parts of the aircraft react to these loadings? What inspection intervals would be used? What initial flaw size should be used? What should be the initial flaw geometry? How would inspections occur during fabrication to ensure that no flaw greater than that assumed existed? Maintenance actions became an increasingly important topic. How should the inspections be accomplished? How does the user know the flight profiles, the severity of the flights, and the damage done during the flights? How do the inspection intervals change over time? What is the dependency of the inspection intervals on the inspection technique? The B-1A program became both a development program for an advanced bomber and a testing and proving ground for an exercise in solid mechanics.

**The C-5A Aircraft.** Also during the early 1970s, the U.S. Air Force was experiencing structural problems with the C-5A aircraft. As a result of these structural problems, a team of engineers and scientists was assigned to work on the C-5A. These individuals were selected from the U.S. Air Force, Lockheed (the designer and manufacturer of the aircraft), and selected experts from other aircraft manufacturers. The C-5A aircraft had been designed using fatigue criteria. The function of the assembled team was to structurally reassess the aircraft using damage tolerance criteria. One year was allocated for this project. During this time, material tests were initiated and completed, analyses were done, and the project was completed. Critical areas were identified, and the anticipated usage was determined. The analyses consisted of determining the external loads, the stresses, and the crack-growth life of the critical components. The results of this program illustrated to the U.S. Air Force that the structural integrity of the C-5A wing was questionable, and actions were required if a life of 30,000 h was needed for the airframe.

The B-1A and the C-5A programs, combined with the success of the F-111 accident investigation, led the U.S. Air Force to initiate a new method of structural design. The issuance of two new specifications, MIL-STD 1530 (Ref 35) and MIL-A-83444 (Ref 36) was the beginning for this new approach. The documents led to the utilization of the damage tolerance procedure as the desired method for designing U.S. Air Force aircraft. A new standard, MIL-A-87221, has been issued (Ref 37). This standard incorporates many of the requirements of the previous standards.

### Damage Tolerance Design

At the time of the B-1A development and the C-5A investigation, specifications were also being prepared to apply damage tolerance criteria more in airframe design. MIL-A-83444 was written after a series of meetings between the U.S. Air Force and representatives from all the major airframe manufacturers. Prior to the publication of the document, drafts were written and comments solicited from all present. The purpose of the specification is to present to airframe manufacturers a document that would contain the requirements for protecting the flight safety of aircraft. The specification discusses:

- INITIAL FLAW SIZE REQUIREMENTS
- IN-SERVICE FLAW SIZE REQUIREMENTS
- RESIDUAL STRENGTH
- DESIGN DEFINITIONS

It is not the purpose of the document to present a method of analysis, but to levy requirements that would result in structural aircraft safety. Because of this, the U.S. Air Force is careful not to describe a desired design methodology.

**Initial Flaw Size.** The initial flaw requirements were based on both structural design philosophies and component geometries. It is stated in Section 3.12.1 of the Appendix to MIL-A-87221 (Ref 37) that "Initial flaws shall be assumed to exist as a result of material and structural manufacturing and processing operations." This sentence in the requirement precludes the use of other design methods, for example, static strength and fatigue analysis. As stated earlier, neither of these analysis techniques has the capability to deal with the existence of flaws. The same paragraph further states, "Small imperfections equivalent to a 0.005 in. radius corner flaw resulting from these operations shall be assumed to exist in each hole of each element of the structure. . ." The contractor is now on notice that this cracking is widespread. The use of fracture mechanics to ensure safe design is now mandatory in U.S. Air Force airframes.

The U.S. Air Force, however, does not categorically select the initial flaw size. The manufacturer has the opportunity to select a flaw size compatible with his inspection methodology. But in order to choose a flaw size smaller than that discussed in the specification, it is essential that the airframe manufacturer have a nondestructive inspection (NDI) program that can reliably *not miss* flaws of the selected size. The inspection methodology that is then selected, tested, and approved is used during the manufacturing process. The significant difference between *finding* flaws and *not missing* flaws should be noted.

The third aspect of the initial flaw size is the location of the initial flaw. The specification requires that the initial flaw be present and located in the most critical location on each "separate element of the structure." However, all remaining holes (and other critical locations) must be assumed to contain a smaller flaw. This is to ensure the continuing damage portion of the requirement.

If the assumed initial flaw is smaller than that stated in the specification, then 100% inspection of these flaw locations subsequent to manufacturing is required. If the initial flaw sizes chosen are that suggested in the specification, 100% inspection of the assumed flaws is unnecessary. The sizes of the flaws prescribed in MIL-A-87221 are shown in Table 1. The definition of "slow crack" and "fail safe" are:

- "SLOW CRACK GROWTH STRUCTURE CONSISTS OF THOSE DESIGN CONCEPTS WHERE FLAWS OR DEFECTS ARE NOT ALLOWED TO ATTAIN THE CRITICAL SIZE REQUIRED FOR UNSTABLE CRACK PROPAGATION. SAFETY IS ASSURED THROUGH SLOW CRACK GROWTH FOR SPECIFIED PERIODS OF USAGE DEPENDING UPON THE DEGREE OF INSPECTABILITY."
- "FAIL-SAFE STRUCTURE IS A STRUCTURE DESIGNED AND FABRICATED SUCH THAT

UNSTABLE CRACK PROPAGATION WILL BE STOPPED WITHIN A CONFINED AREA OF STRUCTURE PRIOR TO COMPLETE FAILURE (CRACK-ARREST FAIL-SAFE STRUCTURE), OR STRUCTURE DESIGNED AND FABRICATED IN SEGMENTS WHERE EACH SEGMENT CONTAINS LOCALIZED DAMAGE AND THUS PREVENTS COMPLETE LOSS OF THE STRUCTURE (MULTIPLE-LOAD-PATH FAIL-SAFE STRUCTURE)."

Regardless of the type of fail-safe structure, "the strength and safety will not degrade below a specified level for a specified period of unrepaired service usage."

**TABLE 1 FLAW SIZES PRESCRIBED IN MIL-A-87221 FOR SLOW CRACK AND FAIL-SAFE DESIGN**

Structural design	Flaw location	Material thickness	Flaw geometry	Initial flaw size
Slow crack and fail safe	Holes	>0.05 in.	Semicircular	0.05 in. (radius)
	Holes	≤0.05 in.	Through crack	0.05 in. long
	No holes	≤0.125 in.	Through crack	0.25 in. long
	No holes	>0.125 in.	Semicircular	0.25 in. (length)

There is a benefit for using either interference fit fasteners or cold expanded holes that would reduce the maximum tensile stress at the hole/fastener interface. The benefits of the desired fastener system need to be demonstrated through laboratory testing using joint design similar to that found in the aircraft. If the desired fastener system shows beneficial results, the assumed initial flaw size may be as low as 0.005 in. (0.125 mm). This reduction in initial flaw size significantly increases the safety limit (twice the inspection interval) of the component.

The advent of widespread cracking, and a means of preventing it, is an important part of this specification. It should be noted that each hole (located in the noncritical location) also has an initial flaw requirement of 0.005 in. (0.125 mm), and that flaw will grow during normal aircraft usage. As that flaw increases in length, a time will occur when inspection of those flaws becomes necessary. If, for example, the flaw for a particular critical location (initial size of 0.05 in., or 1.25 mm) were growing from its location, and grew into another hole, then the new flaw size would be the distance between the holes, the two hole diameters, and the length the crack grew from the second hole assuming the initial flaw size for that hole was 0.005 in. (0.125 mm). One begins to see both the complexity of the analysis procedure and the implicit safety in the continuing damage philosophy.

**In-Service Flaw Size.** It is appreciated that the personnel maintaining the aircraft may not have either the same tools available to them or the same means of inspection capability (or both) as the manufacturer of the aircraft. As a result, the flaw size subsequent to initial inspection depends on field methods. In the event that the methods and access to the components are identical to those used during manufacture, then MIL-A-87221 requires that the in-service flaw size be the same as the initial flaw size. If the component (or fastener) cannot be removed, and dye penetrant, magnetic particle (ferrous alloys only), eddy current, or ultrasonic techniques are used, then the initial flaw size at fasteners would be 0.25 in. (6.35 mm) of uncovered length. For critical location other than fasteners, the flaw size would be 0.50 in. (12.5 mm). If visual inspection techniques are required, the assumed flaw size (uncovered length) would be 2 in. (50 mm).

**Residual Strength Requirements.** The residual strength of a member is "the minimum load an aircraft must sustain with damage present and without endangering safety of flight or degrading performance of the aircraft for the specified minimum period of unrepaired service usage." This definition contains a number of terms that must be explained. *Damage present* is the length of the crack in the critical structural component. A *critical structural component* is an aircraft structure whose failure will either cause the plane to crash or not successfully complete its mission. If the aircraft is a fighter aircraft on an air-to-ground mission, it may need to perform flight sequences that are extremely severe. If the aircraft cannot fly these sequences without component failure, then aircraft performance has been degraded. *Unrepaired service usage* is a time period dependent on the categorization of the inspectability of the particular structure. If an aircraft has a wet wing (fuel is stored in the wing) and a spar fails, the wing will leak fuel. This condition is observable to either the flight crew or the maintenance crew prior to the next flight. The unrepaired service usage would be one flight. If a failure occurred in a frame member, and that frame was inspected on a periodic basis, then the uninspected service usage would be that time period.

When calculating the residual strength, the particular time period regarding the inspection of the component must be defined (see the article "Residual Strength of Metal Structures" in this Volume). It is this time period that determines the maximum assumed flaw size. This is accomplished, in part, by finding the maximum expected load during this time frame. With this maximum assumed flaw size and the material properties, the minimum failure load can be determined. If that load is higher than the expected maximum load for that level of inspectability (time period), then the residual strength of the structure has been defined. If that load is less than the expected maximum load, then either the level of inspectability or inspection procedure must be redefined for the structure to meet this particular requirement.

As stated above, one part of the information that must be obtained is the maximum expected load. The loads the aircraft experiences are generally obtained through an exceedance function (see Fig. 2). The data that define the exceedances may be obtained from specifications (Ref 38) or directly from instrumented aircraft. It is well known that the load will increase as a function of time as exceedance curves are generally plotted in number of load exceedances per 1000 h. The higher loads have a lower number of occurrences. For example, there may be a load occurrence of 0.1 per thousand hours, or once every 10,000 h. To increase conservatism, the load required to determine the residual strength of a particular component is analyzed to a higher load. If the cracks for a particular component can be seen (or become evident, i.e., fuel leakage) when the aircraft is parked on the ground or during flight, one would expect that the load to determine the residual strength for that component would need to occur every flight. However, a multiplication factor of 100 is present. This means that the maximum load that occurs once every 100 flights is the actual load used, and that load is higher than the maximum load that occurs every flight. If walk-around visual inspection is necessary to see the damage, then the residual strength load would be 1000 h. If disassembly is required to visually observe the crack, then 50 years of flight (about 12,000 h of flight time) is assumed to determine the appropriate load. The remaining two-component design categories, depot level inspection and uninspectable structure, have significantly longer time periods and therefore higher loads. The base-level inspection period is five lifetimes of the aircraft, and the load required for uninspectable structure would be equal to 20 design lifetimes. To perform the crack-growth analysis, the data obtained must be placed into a stress-time history. References 39, 40, 41, 42, 43, 44 discuss various methods of accomplishing this transformation.

FIG. 2 TYPICAL STRESS EXCEEDANCE CURVE

**Design Definitions.** Included in the specification are several definitions, which are discussed in detail in Ref 37. Other than those already discussed, they will not be presented here.

## Airframe Structural Integrity Programs (ASIP)

The Airframe Structural Integrity Program (ASIP) began in 1958 as a result of fatigue failures in the B-47 aircraft. These failures were important in the issuance of a directive from the Chief of Staff of the U.S. Air Force (Ref 45). The objectives of the structural integrity program were to control structural failure of operational aircraft, to determine methods of accurately predicting aircraft service life, and to provide a design and test approach that would avoid structural fatigue problems in future weapon systems.

The original ASIP used a reliability-based method to establish the operational life. This was commonly called the "safe-life approach." The safe-life approach relied on the results of the laboratory fatigue test of a full-scale aircraft. The time-load history of the test aircraft was carefully selected to emulate the actual loadings that aircraft would experience during its anticipated lifetime. The "safe life" of the aircraft was established by dividing the number of successful test-simulated flight hours by a factor (four was commonly used by the U.S. Air Force). The purpose of the factor was to account for the many uncertainties that exist in materials and manufacturing quality. This concept was the basis for all new U.S. Air Force aircraft designed during the 1960s.

There was success in using this approach. The C-141 had an excellent safety record and good overall service history. There were, however, problems that could not be solved using this method, for example, those with the F-111 and the C-5A, which have already been discussed. Other problems began to occur as well. Losses of aircraft such as the F-5, B-52, and T-38, and the widespread cracking found on the KC-135 pointed to a deficiency in the criterion. Additionally, the ability to inspect these aircraft was impacted by the design of the aircraft itself. Because inspectability was not required as a part of the safe life approach, many details were found to be outside the inspection capability of the 1960s. Relatively small cracks and defects could escape detection with dramatic consequences.

The shortcoming of the safe life process, illustrated by several service incidents, demanded that a fundamental change be made in the approach to design, qualification, and inspection of aircraft. An improved reliability method based on a damage tolerance approach emerged as the candidate for this change. This approach assumed the aircraft was subject to a wide range of initial quality from both the manufacturing process and service-induced damage, and the aircraft had to be inspectable. To ensure the design could be safely operated in the presence of these initial flaws, it was necessary to design the structure to be tolerant of these defects for a selected period of service usage prior to inspection. The damage tolerance approach is used to determine the period of safe operation, the safety limit (the time for the crack to grow from its assumed initial size to failure), and the requisite inspection intervals. These inspection intervals are usually taken as half the safety limit.

In 1975, the damage tolerance approach was formally made a part of ASIP. During the 1970s and 1980s, the U.S. Air Force performed an assessment on every major aircraft weapon system using a damage tolerance approach to develop the appropriate inspection and modifications that were deemed necessary to ensure flight safety.

ASIP now includes five separate tasks that cover all aspects of development and support of an aircraft structure. These tasks, described in detail in Table 2, are:

- *TASK I: DESIGN INFORMATION*
- *TASK II: DESIGN ANALYSES AND DEVELOPMENT TESTS*
- *TASK III: FULL-SCALE TESTING*
- *TASK IV: FORCE MANAGEMENT DATA PACKAGE*
- *TASK V: FORCE MANAGEMENT*

**TABLE 2 USAF AIRCRAFT STRUCTURAL INTEGRITY PROGRAM TASKS**

<p><b>TASK I DESIGN INFORMATION</b></p> <ul style="list-style-type: none"> <li>• ASIP MASTER PLAN</li> <li>• STRUCTURAL DESIGN CRITERIA</li> <li>• DAMAGE TOLERANCE DURABILITY CONTROL PLANS</li> <li>• SELECTION OF MATERIALS PROCESSES AND JOINING METHODS</li> <li>• DESIGN SERVICE LIFE AND DESIGN USAGE</li> </ul>
<p><b>TASK II DESIGN ANALYSES AND DEVELOPMENT TESTS</b></p> <ul style="list-style-type: none"> <li>• MATERIALS AND JOINT ALLOWABLES</li> <li>• LOAD ANALYSIS</li> <li>• DESIGN SERVICE LOAD SPECTRA</li> <li>• DESIGN CHEMICAL/THERMAL ENVIRONMENT SPECTRA</li> <li>• STRESS ANALYSIS</li> <li>• DAMAGE TOLERANCE ANALYSIS</li> <li>• DURABILITY ANALYSIS</li> <li>• SONIC ANALYSIS</li> <li>• VIBRATION ANALYSIS</li> <li>• FLUTTER ANALYSIS</li> <li>• NUCLEAR WEAPONS EFFECTS ANALYSIS</li> <li>• NON-NUCLEAR WEAPONS EFFECTS ANALYSIS</li> <li>• DESIGN DEVELOPMENT TESTS</li> </ul>
<p><b>TASK III FULL-SCALE TESTING</b></p> <ul style="list-style-type: none"> <li>• STATIC TESTS</li> <li>• DURABILITY TESTS</li> </ul>

- DAMAGE TOLERANCE TESTS
- FLIGHT AND GROUND OPERATIONS TESTS
- SONIC TESTS
- FLIGHT VIBRATION TESTS
- FLUTTER TESTS
- INTERPRETATION AND EVALUATION OF TEST RESULTS

#### TASK IV FORCE MANAGEMENT DATA PACKAGE

- FINAL ANALYSES
- STRENGTH SUMMARY
- FORCE STRUCTURAL MAINTENANCE PLAN
- LOADS/ENVIRONMENT SPECTRA SURVEY
- INDIVIDUAL AIRPLANE TRACKING PROGRAM

#### TASK V FORCE MANAGEMENT

- LOAD/ENVIRONMENT SPECTRA SURVEY
- INDIVIDUAL AIRPLANE TRACKING DATA
- INDIVIDUAL AIRPLANE MAINTENANCE TIMES
- STRUCTURAL MAINTENANCE RECORDS

**Design Information.** The first ASIP task consists of obtaining the information that allows the contractor to perform a preliminary design. For completion of this task to become a reality, it is necessary for the contractor and the contracting agency to work closely to define the critical parameters. The performance criteria of the aircraft must be rigorously defined by the contracting agency. The desired life of the structure, its operating envelope, the missions, desired aircraft configuration(s), and so forth must be so stated.
